

SOME 3CNF PROPERTIES ARE HARD TO TEST*

ELI BEN-SASSON[†], PRAHLADH HARSHA[‡], AND SOFYA RASKHODNIKOVA[§]

Abstract. For a Boolean formula φ on n variables, the associated property P_φ is the collection of n -bit strings that satisfy φ . We study the query complexity of tests that distinguish (with high probability) between strings in P_φ and strings that are far from P_φ in Hamming distance. We prove that there are 3CNF formulae (with $O(n)$ clauses) such that testing for the associated property requires $\Omega(n)$ queries, even with adaptive tests. This contrasts with 2CNF formulae, whose associated properties are always testable with $O(\sqrt{n})$ queries [E. Fischer et al., *Monotonicity testing over general poset domains*, in Proceedings of the 34th Annual ACM Symposium on Theory of Computing, ACM, New York, 2002, pp. 474–483]. Notice that for every negative instance (i.e., an assignment that does not satisfy φ) there are three bit queries that witness this fact. Nevertheless, finding such a short witness requires reading a constant fraction of the input, even when the input is very far from satisfying the formula that is associated with the property.

A property is *linear* if its elements form a linear space. We provide sufficient conditions for linear properties to be hard to test, and in the course of the proof include the following observations which are of independent interest:

1. In the context of testing for linear properties, adaptive two-sided error tests have no more power than nonadaptive one-sided error tests. Moreover, without loss of generality, any test for a linear property is a linear test. A linear test verifies that a portion of the input satisfies a set of linear constraints, which define the property, and rejects if and only if it finds a falsified constraint. A linear test is by definition nonadaptive and, when applied to linear properties, has a one-sided error.
2. Random low density parity check codes (which are known to have linear distance and constant rate) are not locally testable. In fact, testing such a code of length n requires $\Omega(n)$ queries.

Key words. sublinear algorithms, lower bounds, property testing, CNF formulae, locally testable codes

1. Introduction. Property testing deals with a relaxation of decision problems, where one must determine whether an input belongs to a particular set, called a *property*, or is far from it. “Far” usually means that many characters of the input have to be modified to obtain an element in the set. Property testing was first formulated by Rubinfeld and Sudan [RS96] in the context of linear functions and was

applied to combinatorial objects, especially graphs, by Goldreich, Goldwasser, and Ron [GGR98]. Property testing has recently become quite an active research area; see [Ron01, Fis01] for surveys on the topic.

One of the important problems in property testing is characterizing properties that can be tested with a sublinear¹ number of queries to the input (cf. [GGR98, AKNS01, New02, FN04, AFKS00, Fis01, GT03]; see also section 1.1 for more information). Our paper continues this line of research by trying to relate the testability of properties over the binary alphabet with their formula complexity. We prove a linear lower bound for testing some properties with very small formula complexity, thus showing that the formula complexity of the property does not always help to assess the testability of the property. In section 1.1 several strong lower bounds on the query complexity [GGR98, GT03, BOT02, GR02] are discussed and compared to our lower bound.

Testing k CNFs. A *property* is a collection of strings of a fixed size n . Every property over the binary alphabet can be represented by a conjunctive normal form (CNF) formula, whose set of satisfying assignments equals the set of strings in the property. Testing this property can be viewed as testing whether a given assignment to Boolean variables of the corresponding CNF is close to one that satisfies the formula.² Goldreich, Goldwasser, and Ron [GGR98] prove that there exist properties over the binary alphabet that require testing algorithms to read a linear portion of the input. This implies that testing assignments to general CNF formulae is hard. A natural question is whether restricting CNF formulae to a constant number of variables, k , per clause allows for faster testers. Observe that the standard reduction from satisfiability (SAT) to 3SAT does not apply because it introduces auxiliary variables and thus changes the testing problem.

At first glance, there seems to be hope of obtaining good testers for every fixed k because, for any assignment that does not satisfy the formula, there exists a set of k queries that witnesses this fact. Indeed, Fischer et al. [FLN⁺02] prove that properties expressible as sets of satisfying assignments to 2CNF formulae are testable with $O(\sqrt{n})$ queries, where n is the length of the input. However, we will show that, already for $k = 3$, testing whether an input assignment is close to satisfying a fixed k CNF formula might require a linear number of queries.

Results and techniques. We show the existence of families of 3CNF formulae over n variables (for arbitrarily large n) of size $O(n)$ such that the corresponding properties are not testable with $o(n)$ queries. Thus, we present a gap between 2CNFs and 3CNFs. Our lower bound applies to *adaptive* tests, i.e., tests in which queries might depend on the answers to previous queries. This gives a class of properties which are easy to decide in the standard sense³ but are hard to test.

Each hard 3CNF property we use is a linear⁴ space $V \subseteq \{0, 1\}^n$ that can be expressed as the set of solutions to a set of homogeneous linear constraints of weight 3 (i.e., a 3LIN formula). While proving the lower bound, we show that every adaptive

¹We measure the query complexity as a function of the input length. Thus, linear (sublinear, respectively) query complexity means query complexity that is linear (sublinear) in the input length.

²Our problem should not be confused with the problem of testing whether a CNF formula is “close” to being satisfiable (under a proper definition of closeness). In our problem the CNF formula is fixed and known to the tester. See section 1.1 for a discussion of the seemingly related problem.

³A property is easy to decide in the following standard sense: given the entire assignment, it can be checked in time linear in the number of variables and size of the formula, whether or not the assignment is a satisfying one.

⁴We work over the field with two elements and our linear space is defined over this field.

two-sided error test for checking membership in a vector space can be converted to a nonadaptive one-sided error test with the same query complexity and essentially identical parameters. This allows us to consider only one-sided error nonadaptive tests. In order to prove that a particular linear space V is hard, we need to find, for every such test T , a *bad* vector $b \in \{0, 1\}^n$ (that is, far from V) such that T accepts b with significant probability (i.e., T fails to reject b , as it should). Yao's minimax principle allows us to switch the quantifiers. In other words, in order to prove our lower bound, it suffices to present a distribution \mathcal{B} over bad vectors such that any deterministic test (making few queries) fails to reject a random b (selected according to the distribution \mathcal{B}) with significant probability.

We now give a rough picture of how to get a vector space V that is hard to test and a distribution \mathcal{B} that shows this hardness (per Yao's minimax principle). Fix $0 < \kappa < 1$ and let V be the set of solutions to a system \mathcal{A} of $m = \kappa n$ random linear constraints over n Boolean variables, where each constraint is the sum of a *constant* number of randomly selected variables, and each variable appears in a *constant* number of constraints. Such linear spaces are called random low density parity check (LDPC) codes.⁵ These codes were introduced by Gallager [Gal63], who showed that they have constant rate and (with high probability) large minimal distance. It is possible to show that with high probability the random constraints are linearly independent. Our bad distribution \mathcal{B} is the uniform distribution over vectors that satisfy all but one random constraint of \mathcal{A} . Since the constraints are linearly independent, this distribution is well defined. By definition, each input chosen according to \mathcal{B} is not in the property. It is less obvious, but still true, that each such input is *far* from the property. The tricky part is to show that every deterministic test making $o(n)$ queries will fail to reject a random input chosen according to \mathcal{B} .

A natural way to test if an input belongs to V is to select a few random constraints in \mathcal{A} , query all entries lying in their supports, and accept if and only if all constraints are satisfied. This test always accepts inputs in V . It correctly rejects an input distributed according to \mathcal{B} when the unique random constraint falsified by the input is queried. This method is costly in query complexity because there are $O(n)$ constraints, and only one randomly chosen constraint is not satisfied. A more efficient way to attack the distribution \mathcal{B} would be to use linearity, as follows. If an input satisfies a set of constraints, it must satisfy their sum; if it falsifies exactly one of the constraints in the sum, it must falsify the sum. Thus, one might choose a set of constraints in \mathcal{A} , take their sum, and query the entries in the support of the sum. The summation might cancel out some entries (namely, those that appear in an even number of summands) and reduce the query complexity. This suggests the following general test for testing membership in V : query the input in a small subset of entries and accept if and only if these entries satisfy all possible sums (of constraints in \mathcal{A}), whose support lies entirely within the small subset. In fact, it can be easily observed that any nonadaptive one-sided error test for membership in V is of the above form. Furthermore, we prove that, without loss of generality, the only possible tests (for membership in a linear space) are of the above mentioned form (see Theorem 3.3). The crux of our proof consists of showing that this general method does not significantly reduce the query complexity. Namely, we show that the sum of *any* large subset of the constraints of \mathcal{A} has large support, and thus results in large query complexity. The reason for this phenomenon is the underlying *expansion* of the random set of constraints. Thus, any deterministic

⁵LDPC codes are linear codes defined as solutions to a system of linear constraints with small support.

testing algorithm making $o(n)$ queries essentially checks only $o(m)$ constraints of \mathcal{A} , and thus will reject a random input from \mathcal{B} with subconstant probability.

Connections to coding theory. Our results shed some light on the question of optimal locally testable codes. An infinite family of codes $\{\mathcal{C}\}_n$ is called *locally testable* if the property \mathcal{C}_n is testable with constant query complexity. These codes play a vital role in probabilistically checkable proof (PCP) constructions and are of fundamental importance in theoretical computer science. Recently, Ben-Sasson et al. [BSVW03, BGH⁺04], following the work of Goldreich and Sudan [GS02], proved the existence of such codes, which achieve linear distance and near constant rate, resulting in better PCP constructions.

As mentioned earlier, the vector spaces we use (which are hard to test) are built upon random LDPC codes, which are heavily studied in coding theory (cf. [Gal63] and [Spi95, Chap. 2] and references therein). It follows from an intermediate step in our proof that this important class of codes is not locally testable. Moreover, the property that makes random codes so good in terms of minimal distance, namely expansion, is also behind the poor testability of these codes. In his thesis, Spielman informally discusses why expander codes might not be locally testable and states that a high level of redundancy among the constraints of the code might be required to make it testable ([Spi95, Chap. 5]). In our proof, we make this argument formal and prove that random (c, d) -regular LDPC codes are not locally testable (see Theorem 3.7). This sheds some light on the question of optimal locally testable codes. The existence of such optimal codes that (i) achieve constant rate, (ii) achieve linear distance, and (iii) are locally testable (or even testable with a sublinear number of queries) remains an interesting open problem.

1.1. Connection to previous results.

Classes of testable properties. One of the important problems in property testing is characterizing properties that can be tested with a sublinear number of queries to the input. A series of works identified classes of properties testable with constant query complexity. Goldreich, Goldwasser, and Ron [GGR98] found many such properties. Alon et al. [AKNS01] proved that all regular languages are testable with constant complexity. Newman [New02] extended their result to properties that can be computed by oblivious read-once constant-width branching programs. Fischer and Newman [FN04] demonstrated a property that requires superconstant query complexity and is computable by a read-twice constant-width branching program, thus showing that Newman’s result does not generalize to read-twice branching programs. Several papers [AFKS00, Fis05] worked on the logical characterization of graph properties testable with a constant number of queries. Goldreich and Trevisan [GT03] provide a characterization of properties testable with a constant number of queries and one-sided error in the framework of graph partition properties.

Linear lower bounds. The published linear lower bounds are the aforementioned generic bound due to Goldreich, Goldwasser, and Ron [GGR98], later extended by Goldreich and Trevisan [GT03] to monotone graph properties in NP, and the bound for testing 3-coloring in bounded degree graphs due to Bogdanov, Obata, and Trevisan [BOT02]. In addition, there is a simple and elegant unpublished linear lower bound, observed by Madhu Sudan in a personal communication to the authors. His property consists of polynomials of degree at most $n/2$ over a finite field \mathbb{F}_n of size n , where each polynomial is given by its evaluation on all elements of the field. It is not hard to see that every nonadaptive one-sided error test for this property requires linear query complexity. Since the property of low-degree polynomials is linear, our

reduction from general to nonadaptive one-sided error tests implies a linear lower bound for adaptive two-sided tests for this property. A related property, suggested by Oded Goldreich in a personal communication to the authors, consists of a random linear code. It is not hard to show, using similar reasoning, that with high probability testing this property requires linear query complexity. Observe that both of these properties (low degree polynomials and random codes) are easy to decide once all the input is read, but both cannot be represented by a family of 3CNF formulae.⁶

The aforementioned linear lower bounds of Sudan and Goldreich and of Bogdanov, Obata, and Trevisan capitalize on the existence of inputs that are far from having the property, yet *any* local view of a constant fraction of them can be extended to an element having the property.⁷ But if the property is defined by a k CNF φ , this cannot happen. Clearly, any string that does not have the property must falsify at least one clause of φ . Thus, there is some view of the input of size k that proves that the input does not have the property. Our result shows that, in certain cases, finding such a falsified clause requires reading a constant fraction of the input, even if the assignment is far from any satisfying one. A similar phenomenon is exhibited by Goldreich and Ron for testing bipartiteness in 3-regular, n -vertex graphs [GR02]. They showed a lower bound of $\Omega(\sqrt{n})$ on the query complexity; despite this, short witnesses of nonbipartiteness do exist in the form of odd cycles of length $\text{poly}(\log n)$. Our result strengthens this finding, since in our case the query complexity is linear, whereas the witness size is constant.

Testing an input k CNF. A related problem, but very different from ours, is that of testing whether an *input* k CNF formula is satisfiable. (Recall that in our setting the input is an assignment to a fixed k CNF formula.) The exact version of this problem is a classical NP-complete problem. The property testing version was studied by Alon and Shapira [AS03]. They showed that satisfiability of k CNF formulae is testable with complexity independent of the input size.⁸ In contrast, our problem is very easy in its exact version but hard in its property testing version for $k \geq 3$.

2. Definitions.

Property testing. A *property* is a collection of strings of a fixed size n . A property is *linear* if it forms a vector space (over some underlying field). In this paper, strings are over a binary alphabet unless mentioned otherwise. The distance $\text{dist}(x, \mathcal{P})$ of a string x to a property \mathcal{P} is $\min_{x' \in \mathcal{P}} \text{dist}(x, x')$, where $\text{dist}(x, x')$ denotes the Hamming distance between the two strings x and x' . The *relative distance* of x to \mathcal{P} is its distance to \mathcal{P} divided by n . A string is ε -far from \mathcal{P} if its relative distance to \mathcal{P} is at least ε .

A *test for property \mathcal{P} with distance parameter ε , positive error η_+ , negative error η_- and query complexity q* is a probabilistic algorithm that queries at most q bits of the input, accepts strings in \mathcal{P} with probability at least $1 - \eta_+$, and accepts strings that are ε -far from \mathcal{P} with probability at most η_- , for some $0 \leq \eta_- < 1 - \eta_+ \leq 1$.

⁶In other words, these properties cannot be decided by a family of circuits of depth 2, where the output gate of the circuit is an AND-gate, the next level of gates are all OR-gates of fan-in 3, and the inputs to the OR-gates are either the input bits or their negations.

⁷For example, in Sudan's construction any evaluation of a polynomial on d points can be extended to an evaluation of a polynomial of degree $d' > d$. Thus, $n/2$ values of the polynomial cannot prove or disprove that the polynomial has degree at most $n/2$.

⁸Complexity of a testing problem depends on the definition of distance; in Alon and Shapira's work the distance from the input to a satisfiable formula is defined as the number of clauses that have to be removed to make the input formula satisfiable.

Note that the positive error η_+ is the maximum error made by the test on the YES-instances (i.e., strings in \mathcal{P}), and the negative error η_- is the maximum error made on NO-instances (i.e., strings ε -far from \mathcal{P}). Sometimes we refer to $\eta_+ + \eta_-$ as the sum of errors made by the test T . A test is said to have *error* η if $\eta_+, \eta_- \leq \eta$ (for $\eta < \frac{1}{2}$). If a test T accepts input x , we say $T(x) = 1$. Otherwise, we say $T(x) = 0$. A test with distance parameter ε and error η is referred to as an (ε, η) -test (analogously, $(\varepsilon, \eta_+, \eta_-)$ -test). An ε -test denotes a test with distance parameter ε . A property is (ε, η, q) -testable if it has an (ε, η) -test that makes at most q queries on every input; $(\varepsilon, \eta_+, \eta_-, q)$ -testable is defined analogously.

Two special classes of tests are of interest. An algorithm is *nonadaptive* if it makes all queries in advance before getting the answers. Namely, a query may not depend on the answers to previous queries. An algorithm has a *one-sided error* if it always accepts an input that has the property. In other words, an algorithm has a one-sided error if the positive error η_+ is 0.

CNF and linear formulae. Recall that a Boolean formula is in CNF if it is a conjunction of clauses, where every clause is a disjunction of literals. (A literal is a Boolean variable or a negated Boolean variable.) If all clauses contain at most three literals, the formula is a 3CNF.

A *linear* (LIN) Boolean formula is a conjunction of constraints, where every constraint is satisfied if and only if the variables in the constraint add up to 0 mod 2. If all constraints contain at most d literals, the formula is a d LIN.

Let φ be a formula on n variables. An n -bit string *satisfies* φ if it satisfies all clauses (constraints) of the formula. An n -bit string is ε -far from satisfying φ if at least an ε fraction of the bits needs to be changed to make the string satisfy φ . Each formula φ defines a property $\{x \mid x \text{ satisfies } \varphi\}$. For brevity, we refer to a test for this property as a test for φ .

Random regular bipartite graphs and LDPC codes. Let $G = \langle L, R, E \rangle$ be a bipartite multigraph, with $|L| = n, |R| = m$, and let $d(v)$ be the degree of a vertex v . G is called (c, d) -regular if for all $v \in L$, $d(v) = c$, and if for all $v \in R$, $d(v) = d$. A random (c, d) -regular graph with n left vertices and $m = \frac{c}{d}n$ right vertices⁹ is obtained by selecting a random matching between cn “left” nodes labeled $\{v_1^1, \dots, v_1^c, v_2^1, \dots, v_n^c\}$ and $dm = cn$ “right” nodes labeled $\{u_1^1, \dots, u_m^d\}$, collapsing every c consecutive nodes on the left to obtain n c -regular vertices, and collapsing every d consecutive nodes on the right to obtain m d -regular vertices. Formally, let $L = \{v_1, \dots, v_n\}$, $R = \{u_1, \dots, u_m\}$, and connect vertex v_i to u_j if and only if there exist $\alpha \in [c], \beta \in [d]$ such that (v_i^α, u_j^β) is an edge of the random matching. Notice that the resulting graph may be a multigraph (i.e., have multiple edges between two vertices). The code associated with G , called an LDPC code, was first described and analyzed by Gallager [Gal63].

DEFINITION 2.1 (LDPC Code). *Let $G = \langle L, R, E \rangle$ be a bipartite multigraph with $|L| = n, |R| = m$. Associate a distinct Boolean variable x_i with any $i \in L$. For each $j \in R$, let $N(j) \subseteq L$ be the set of neighbors of j . The j th constraint is $A_j(x_1, \dots, x_n) = \sum_{i \in N(j)} x_i \pmod{2}$. (Notice that a variable may appear several times in a constraint because G is a multigraph.) Let $\mathcal{A}(G)$ be the d LIN formula*

⁹Typically, one fixes c, d to be constants, whereas n, m are unbounded.

$\mathcal{A}(G) = \bigwedge_{j=1}^m (A_j(x) = 0)$. The code defined by G is the property defined by $\mathcal{A}(G)$, namely,

$$\mathcal{C}(G) = \{x \in \{0, 1\}^n \mid \forall j \in [m] \ A_j(x) = 0\}.$$

A random (c, d) -regular LDPC code of length n is obtained by taking $\mathcal{C}(G)$ for a random (c, d) -regular graph G with n left vertices.

3. Main theorem. In this section we state and prove the main theorem and show that some 3CNF properties are hard to test.

THEOREM 3.1 (main). *There exist $0 < \delta^*, \varepsilon^*, \eta^* < 1$ such that, for every sufficiently large n , there is a 3CNF formula φ on $n^* = \Theta(n)$ variables with $\Theta(n)$ clauses such that every adaptive $(\varepsilon^*, \eta_+, \eta_-, q)$ -test for φ with the sum of errors $\eta_+ + \eta_- \leq \eta^*$ makes at least $q = \delta^* n^*$ queries.*

To prove Theorem 3.1, we need to find 3CNF formulae that define hard properties. Our main idea is to work with linear properties (i.e., vector spaces). We prove that, for linear properties, tests of a very simple kind, which we call *linear*, are as powerful as general tests. In particular, linear tests are nonadaptive and have a one-sided error. Working with linear properties allows us to focus on proving a lower bound for this simple kind of tests—bypassing often insurmountable issues of adaptivity and two-sided error.

To explain how we find 3CNF formulae that define hard *linear* properties, we need some linear algebra terminology. Let \mathbb{F} be a field. We say that two vectors $u, v \in \mathbb{F}^n$ are orthogonal to each other (denoted $u \perp v$) if $\sum_{i=1}^n u_i \cdot v_i = 0$. Furthermore, we say that a vector u is orthogonal to a subset $S \subseteq \mathbb{F}^n$ (denoted $u \perp S$) if $u \perp v$ for all vectors $v \in S$. For a linear space $V \subseteq \mathbb{F}^n$ over the field \mathbb{F} , the *dual space* V^\perp is defined as the set of all vectors orthogonal to V (i.e., $V^\perp \triangleq \{u \in \mathbb{F}^n : u \perp V\}$). For $I \subseteq [n]$, let V_I^\perp be the subset of V^\perp composed of all vectors with support in I (i.e., $u \in V_I^\perp$ if and only if $u \in V^\perp$ and the indices of nonzero entries of u lie in I).

DEFINITION 3.2 (linear test). *A test for a linear property $V \subseteq \mathbb{F}^n$ is called a linear test if it is performed by selecting $I = \{i_1, \dots, i_q\} \subseteq [n]$ (according to some distribution), querying w at coordinates I , and accepting if and only if $w \perp V_I^\perp$.*

Linear tests are by definition nonadaptive and have only a one-sided error (members of V are always accepted). Since the inception of property testing, linear properties have been invariably tested by linear tests (starting with [BLR93]). The following theorem shows this is not a coincidence.

THEOREM 3.3 (linear properties have linear tests). *If a linear property $V \subseteq \mathbb{F}^n$ over a finite field \mathbb{F} has a two-sided error adaptive $(\varepsilon, \eta_+, \eta_-, q)$ -test, then it has a linear $(\varepsilon, 0, \eta_+ + \eta_-, q)$ -test.*

The proof of Theorem 3.3 appears in section 5. The reduction to linear tests does not increase the overall error but rather shifts it from the YES-instances to the NO-instances, maintaining the sum of errors $\eta_+ + \eta_-$. Although stated for general finite fields, this theorem is used in our paper only for linear properties over the binary alphabet, namely, with $\mathbb{F} = GF(2)$.

Consider a vector space $V \subseteq GF(2)^n$ and let $\mathcal{A} = (A_1, \dots, A_m)$ be a basis for the dual space V^\perp . Denote the i th coordinate of $x \in GF(2)^n$ by x_i . For two vectors $x, y \in GF(2)^n$, let $\langle x, y \rangle = \sum_{i=1}^n x_i y_i \pmod{2}$. We can view each vector $A_i \in \mathcal{A}$ as a linear constraint on Boolean variables x_1, \dots, x_n of the form $\langle x, A_i \rangle = 0$. This gives us a way to see a vector space as a set of vectors satisfying all constraints in the dual

space, or, equivalently, in the basis of the dual space: $V = \{x \mid \langle x, A_i \rangle = 0 \text{ for all } A_i \in \mathcal{A}\}$. Linear constraints can be thought of as linear formulae.

Let $|x|$ denote the size of the support of vector $x \in GF(2)^n$. Viewing each A_i as a *constraint*, we can represent V as a d LIN formula, where $d = \max_{A_i \in \mathcal{A}} |A_i|$. We work with an arbitrary constant d and later show how to reduce it to 3. Since each 3LIN formula has an equivalent 3CNF, to prove Theorem 3.1 it is enough to find hard 3LINS.

We now present sufficient conditions for a vector space to be hard to test. To understand the conditions, keep in mind that later we employ Yao's minimax principle to show that all vector spaces satisfying these conditions are hard for linear tests. Yao's principle implies that to prove that each low-query *probabilistic* linear test fails on some input, it is enough to give a distribution on the inputs on which each low-query *deterministic* linear test fails. Therefore, we need to exhibit a distribution on vectors that are far from the vector space but are orthogonal with high probability to any fixed set of linear constraints that have support $\leq q$.

DEFINITION 3.4 (hard linear properties). *Let $V \subseteq GF(2)^n$ be a vector space and let \mathcal{A} be a basis for V^\perp . Fix $0 < \varepsilon, \mu < 1$.*

- \mathcal{A} is ε -separating if every $x \in GF(2)^n$ that falsifies exactly one constraint in \mathcal{A} has $|x| \geq \varepsilon n$.
- \mathcal{A} is (q, μ) -local if every $\alpha \in GF(2)^n$ that is a sum of at least μm vectors in \mathcal{A} has $|\alpha| \geq q$.

For the proof that every vector space satisfying the above conditions is hard to test, our bad distribution that foils low-query tests is over strings that falsify exactly one constraint. The falsified constraint is chosen uniformly at random. The first condition ensures that the distribution is over vectors which are ε -far from the vector space. (To see this, notice that if the distance of x from $y \in V$ is less than εn , then $|x + y| < \varepsilon n$ and $x + y$ falsifies exactly one constraint, contradicting the first condition.)

The second condition ensures that the distribution is hard to test. Assume that each deterministic linear test corresponds to some vector $u \in V^\perp, |u| \leq q$. (This is oversimplified because a deterministic linear test may read several dual vectors, whose combined support size is at most q . However, this simple case clarifies our approach and is not far from the formal proof given in section 4.) Vector u can be expressed as a linear combination of vectors in the basis: $u = \sum_{j \in J} A_j$ for some $J \subset [m]$. Let A_k be the (random) constraint falsified by a vector w in our hard distribution. Clearly, u will reject w if and only if $k \in J$. The second condition implies that this will occur with probability at most μ . This intuitive discussion is formalized by the following theorem, proved in section 4.

THEOREM 3.5. *Let $V \subseteq GF(2)^n$ be a linear space. If V^\perp has an ε -separating (q, μ) -local basis $\mathcal{A} = (A_1, \dots, A_m)$ and $0 < \mu < 1/2$, then every linear ε -test for it with error $\leq 1 - 2\mu$ requires q queries.*

We now turn to constructing linear spaces that are hard to test. In particular, we show that for sufficiently large constants c, d , with high probability a random (c, d) -regular LDPC code (per Definition 2.1) is hard according to Definition 3.4. The proof of this lemma, which uses the probabilistic method, appears in section 6. (We do not attempt to optimize constants.)

LEMMA 3.6 (hard linear properties exist). *Fix odd integer $c \geq 7$ and constants*

$\mu, \varepsilon, \delta, d > 0$ satisfying

$$\mu \leq \frac{1}{100} \cdot c^{-2}; \quad \delta < \mu^c; \quad d > \frac{2\mu c^2}{(\mu^c - \delta)^2}; \quad \varepsilon \leq \frac{1}{100} \cdot d^{-2}.$$

Then, for all sufficiently large n , with high probability for a random (c, d) -regular graph G with n left vertices, the dLIN formula $\mathcal{A}(G)$ (as in Definition 2.1) is linearly independent, ε -separating, and $(\delta n, \mu)$ -local.

We now have an abundance of dLIN formulae that are hard to test for sufficiently large d . As an immediate corollary, we conclude that random LDPC codes are hard to test.

THEOREM 3.7 (random (c, d) -regular LDPC codes are hard to test). *Let $c, d, \mu, \varepsilon, \delta$ satisfy the conditions of Lemma 3.6. For sufficiently large n , with high probability a random (c, d) -regular LDPC code $\mathcal{C}(G)$ of length n satisfies the following: Every adaptive $(\varepsilon, \eta_+, \eta_-, q)$ -test for $\mathcal{C}(G)$ with the sum of errors $\eta_+ + \eta_- \leq 1 - 2\mu$ makes at least $q = \delta n$ queries.*

Proof. The proof follows directly from Lemma 3.6 and Theorems 3.3 and 3.5. \square

The following reduction brings d down to 3 while preserving the conditions of Definition 3.4 (with smaller constants).

LEMMA 3.8 (reduction to 3CNFs). *Suppose $\mathcal{A} \subseteq \{0, 1\}^n$ is a set of $m = \frac{c}{d}n$ vectors, each vector of weight at most d . Suppose furthermore \mathcal{A} is (i) linearly independent, (ii) ε -separating, and (iii) $(\delta n, \mu)$ -local. Then there exists a set $\mathcal{A}^* \subset \{0, 1\}^{n^*}$ of m^* vectors, each vector of weight at most 3, such that \mathcal{A}^* is (i) linearly independent, (ii) ε^* -separating, and (iii) $(\delta^* n^*, \mu^*)$ -local, for*

$$\begin{aligned} m^* &\leq 2dm; & n &\leq n^* \leq (2c+1) \cdot n; & \varepsilon &\geq \varepsilon^* \geq \frac{\varepsilon}{(2c+1)}; \\ \delta &\geq \delta^* \geq \frac{\delta}{d^{\log d+1} \cdot (2c+1)}; & \mu^* &\leq \mu + \frac{\delta(\log d+1)}{c}. \end{aligned}$$

Lemma 3.8 is proved in section 7. We now complete the proof of our main theorem.

Proof of Theorem 3.1 (main). We start by fixing the following parameters:

$$c = 7; \quad \mu = \frac{1}{100} \cdot c^{-2}; \quad \delta = \frac{\mu^c}{2}; \quad d = \left\lceil \frac{4\mu c^2}{(\mu^c - \delta)^2} \right\rceil = \lceil 16c^2 \mu^{1-2c} \rceil; \quad \varepsilon = \frac{1}{100} \cdot d^{-2}.$$

We pick $\mathcal{A}_n \subset \{0, 1\}^n$ to be a linearly independent, $(\delta n, \mu)$ -local, ε -separating collection of vectors, of weight $\leq d$. By Lemma 3.6, such a set \mathcal{A}_n exists for our setting of $\mu, \varepsilon, \delta, d$ and sufficiently large n .

Next, let $\mathcal{A}_{n^*}^* \subset \{0, 1\}^{n^*}$ be a linearly independent, $(\delta^* n^*, \mu^*)$ -local, ε^* -separating set of vectors of weight at most 3, ensured by Lemma 3.8 (where $\delta^*, \mu^*, \varepsilon^*, n^*$ are as stated in this lemma). Recall that for every 3LIN formula there is an equivalent 3CNF and let φ be the 3CNF formula equivalent to $\mathcal{A}_{n^*}^*$. Moreover, because $m^*, n^* = \Theta(n)$ and each 3LIN constraint translates into a constant number of 3CNF constraints, we conclude that the number of clauses in φ is linear in n^* .

Notice $\delta^*, \varepsilon^*, \mu^* > 0$ because $\delta, \varepsilon, \mu, d > 0$, and $\delta^*, \varepsilon^* < 1$ because $\delta, \varepsilon < 1$. Furthermore, for our setting of constants,

$$\mu^* \leq \mu + \frac{\delta(\log d+1)}{c} = \mu + \frac{\mu^c(\log(16c^2 \mu^{-(2c-1)}) + 1)}{2c} < \frac{1}{2}.$$

Therefore, $0 < 1 - 2\mu^* < 1$. Set $\eta^* = 1 - 2\mu^*$. By Theorem 3.5, every linear ε^* -test for $\mathcal{A}_{n^*}^*$ with error $\leq \eta^*$ requires $\delta^* n^*$ queries. Theorem 3.3 implies that every

adaptive $(\varepsilon^*, \eta_+, \eta_-, q)$ -test for $\mathcal{A}_{n^*}^*$ with $\eta_+ + \eta_- \leq \eta^*$ makes at least $\delta^* n^*$ queries. This completes the proof of our main theorem. \square

4. Lower bounds for linear tests: Proof of Theorem 3.5. We employ Yao's minimax principle. It states that to prove that every q -query randomized linear test fails with probability more than η , it is enough to exhibit a distribution \mathcal{B} on the inputs for which every q -query deterministic linear test fails with probability more than η . For $i = 1, \dots, m$ let \mathcal{B}_i be the uniform distribution over n -bit strings that falsify constraint A_i and satisfy the rest. The distribution \mathcal{B} is the uniform distribution over the \mathcal{B}_i 's. The comment after Definition 3.4 shows that the distribution \mathcal{B} is over strings which are ε -far from V .

A deterministic linear test T is identified by a subset $I \subseteq [n]$, $|I| = q$ and rejects the input w only if w is not orthogonal to V_I^\perp (see Definition 3.2). Write each vector $u \in V^\perp$ in the basis \mathcal{A} as $u = \mathcal{A} \cdot b_u$, where \mathcal{A} is interpreted as the $m \times n$ matrix whose i th row is A_i and $b_u \in GF(2)^m$. Let $J_T = \cup_{V_I^\perp} \text{supp}(b_u)$. We claim T rejects w distributed according to \mathcal{B} if and only if the index of the unique constraint falsified by w belongs to J_T . This is because w is orthogonal to all but one $A_i \in \mathcal{A}$, so the subspace of V^\perp that is orthogonal to w is precisely the span of $\mathcal{A} \setminus \{A_i\}$. Summing up, the probability that T rejects w is precisely $|J_T|/m$. We now give an upper bound on $|J_T|$. Notice that V_I^\perp is a vector space, so the set $V' \triangleq \{b_u : u \in V_I^\perp\}$ is also a vector space (it is the image of the vector space V_I^\perp under the linear map \mathcal{A}^{-1}). Since \mathcal{A} is (q, μ) -local, we know $|b_u| \leq \mu m$ for every $u \in V_I^\perp$. Thus, V' is a vector space over $GF(2)$ in which each element has support size $\leq \mu m$. We claim that $|J_T| = |\cup_{v' \in V'} \text{supp}(v')| \leq 2\mu m$. To see this, pick a uniformly random vector of $v \in V'$. We claim that

$$\mathbb{E}_{v' \in V'} |v| = |\cup_{v'' \in V'} \text{supp}(v'')|/2.$$

This follows from the linearity of expectation and the fact that the projection of V' onto any $j \in \cup_{V'} \text{supp}(v')$ is a linear function, so the expected value of v'_j is $1/2$. Since \mathcal{A} is (q, μ) -local, we know $\mathbb{E}_{v' \in V'} |v'| \leq \mu m$, which means that $|J_T| \leq 2\mu m$. This implies that our deterministic test (reading q entries of w) will detect a violation with probability at most $|J_T|/m \leq 2\mu$. The proof of Theorem 3.5 is complete. \square

5. Reducing general tests to linear ones. In this section we prove Theorem 3.3 by presenting a generic reduction that converts any adaptive two-sided error test for a linear property to a linear test, as in Definition 3.2. We perform this reduction in two stages: we first reduce an adaptive test with two-sided error to an adaptive linear test (Theorem 5.3), maintaining the sum of the positive and negative errors $(\eta_+ + \eta_-)$, and then remove the adaptivity and maintain all other parameters (Theorem 5.6). The second reduction was suggested by Madhu Sudan. We state and prove these reductions for the general case when the linear spaces V considered are over any finite field \mathbb{F} , though we require them only for the case $\mathbb{F} = GF(2)$.

Preliminaries. Any probabilistic test can be viewed as a distribution over deterministic tests, and each deterministic test can be represented by a decision tree. Thus, any test T can be represented by an ordered pair $(\Upsilon_T, \mathcal{D}_T)$, where $\Upsilon_T = \{\Gamma_1, \Gamma_2, \dots\}$ is a set of decision trees and \mathcal{D}_T is a distribution on this set such that on input x , T chooses a decision tree Γ with probability $\mathcal{D}_T(\Gamma)$ and then answers according to $\Gamma(x)$.

We say that a test *detects a violation* if no string in V is consistent with the answers to the queries. By linearity, it is equivalent to having a constraint α in V^\perp

such that $\langle x, \alpha \rangle \neq 0$ for all $x \in \mathbb{F}^n$, which are consistent with the answers to the queries.

Let V be a vector space. For any leaf l of decision tree Γ , let V_l be the set of all vectors in V that are consistent with the answers along the path leading to l . Similarly, for any string $x \in \mathbb{F}^n$, let V_l^x be the set of all vectors in $x + V$ that are consistent with the answers along the path leading to l .

CLAIM 5.1. *Let \mathbb{F} be a finite field and $V \subseteq \mathbb{F}^n$ be a vector space. Let $x \in \mathbb{F}^n$. For any decision tree Γ and a leaf l in Γ , if both V_l and V_l^x are nonempty, then $|V_l| = |V_l^x|$.*

Proof. Let U be the set of all strings in V which have the element 0 in all the positions queried along the path leading to l . Since $0^n \in U$, we have that U is nonempty. Observe that if $u \in U$ and $v \in V_l$, then $u + v \in V_l$. In fact, if $V_l \neq \emptyset$, $V_l = v + U$ for any $v \in V_l$. Hence, $|V_l| = |U|$. Similarly, if $V_l^x \neq \emptyset$, we have that $V_l^x = y + U$ for any $y \in V_l^x$. Hence, $|V_l^x| = |U|$ and the lemma follows. \square

5.1. Reduction from adaptive two-sided to adaptive linear.

DEFINITION 5.2 (adaptive linear test). *A test for a linear property $V \subseteq \mathbb{F}^n$ is called adaptive linear if it is performed by making adaptive queries $I = \{i_1, \dots, i_q\}$ (according to some distribution) to w and accepting if and only if $w \perp V_I^\perp$.*

Notice that adaptive linear tests have a one-sided error: every $w \in V$ is always accepted.

THEOREM 5.3. *Let \mathbb{F} be a finite field and $V \subseteq \mathbb{F}^n$ a vector space. If V has an adaptive $(\varepsilon, \eta_+, \eta_-, q)$ -test T , then it has a (one-sided error) adaptive linear $(\varepsilon, 0, \eta_+ + \eta_-, q)$ -test T' .*

Proof. Let $T = (\Upsilon_T, \mathcal{D}_T)$ be a two-sided error (adaptive) (ε, η, q) -test for V . To convert T to an adaptive linear one, we modify the test so that it rejects if and only if it observes that a constraint in V^\perp has been violated. We say that a leaf l is labeled *optimally* if its label is 0 when the query answers on the path to l falsify some constraint in V^\perp , and its label is 1 otherwise. We relabel the leaves of each tree Γ in Υ_T *optimally* to obtain the tree Γ_{opt} .

Relabeling produces a one-sided error test with unchanged query complexity. However, the new test performs well only on “average.” To get good performance on every string, we randomize the input x by adding a random vector v from V to it and perform the test on $x + v$ instead of x . Now we formally define T' .

DEFINITION 5.4. *Given a two-sided error (adaptive) test T for V , define the test T' as follows: On input x , choose a decision tree Γ according to the distribution \mathcal{D}_T as T does, choose a random $v \in V$, and answer according to $\Gamma_{\text{opt}}(x + v)$.*

Clearly, T' is adaptive linear and has the same query complexity as T . It remains to check that T' has error $\eta_+ + \eta_-$ on negative instances.

For any $x \in \mathbb{F}^n$ and any test T , let ρ_x^T be the average acceptance probability of test T over all strings in $x + V$, i.e., $\rho_x^T = \text{average}_{y \in x+V} (\Pr[T(y) = 1])$. For notational brevity, we denote $\rho_{0^n}^T$, the average acceptance probability of strings in V , by ρ^T . Observe that, for the new test T' , for each input x , $\Pr[T'(x) = 1] = \rho_x^{T'}$.

Claim 5.5 below shows that the transformation to a one-sided error test given by Definition 5.4 increases the acceptance probability of any string not in V by at most $\rho^{T'} - \rho^T$. Notice that all vectors in $x + V$ have the same distance to V . Therefore if x is ε -far from V , then $\rho_x^T \leq \eta_-$. Together with Claim 5.5, it implies that for all vectors x that are ε -far from V , the error is low:

$$\Pr[T'(x) = 1] = \rho_x^{T'} \leq \rho^{T'} - \rho^T + \rho_x^T \leq 1 - (1 - \eta_+) + \eta_- = \eta_+ + \eta_-.$$

This completes the proof of Theorem 5.3 \square

CLAIM 5.5. $\rho^T - \rho_x^T \leq \rho^{T'} - \rho_x^{T'}$ for any vector $x \in \mathbb{F}^n$.

Proof. Let $x \in \mathbb{F}^n$. It is enough to prove that relabeling one leaf l of a decision tree Γ in Υ_T optimally does not decrease $\rho^T - \rho_x^T$. Then we obtain the claim by relabeling one leaf at a time to get T' from T . There are two cases to consider.

Case (i) The path to l falsifies some constraint in V^\perp . Then l is relabeled from 1 to 0. This change preserves ρ^T because it only affects strings that falsify some constraint. Moreover, it can only decrease the acceptance probability for such strings. Therefore, ρ_x^T does not increase. Hence, $\rho^T - \rho_x^T$ does not decrease.

Case (ii) The path to l does not falsify any constraint in V^\perp . Then l is relabeled from 0 to 1. Let V_l and V_l^x , respectively, be the set of vectors in V and $x+V$ that are consistent with the answers observed along the path to l . Thus, every string in $V_l \cup V_l^x$ was rejected before relabeling but is accepted now. The behavior of the algorithm on the remaining strings in V and $x+V$ is unaltered. Hence, the probability ρ^T increases by the quantity $\mathcal{D}_T(\Gamma) \cdot \frac{|V_l|}{|V|}$. Similarly, ρ_x^T increases by $\mathcal{D}_T(\Gamma) \cdot \frac{|V_l^x|}{|V|}$.

It suffices to show that $|V_l| \geq |V_l^x|$. Since the path leading to l does not falsify any constraint, V_l is nonempty. If V_l^x is empty, we are done. Otherwise, both V_l and V_l^x are nonempty, and by Claim 5.1, $|V_l| = |V_l^x|$. \square

5.2. Reduction to linear tests. In this section, we remove the adaptivity from the linear tests. The intuition behind this is as follows: To check if a linear constraint is satisfied, a test needs to query all the variables that participate in that constraint. Based on any partial view involving some of the variables, the test cannot guess if the constraint is going to be satisfied or not until it reads the final variable. Hence, any adaptive decision based on such a partial view does not help.

THEOREM 5.6. *If $V \subseteq \mathbb{F}^n$ is a vector space over a finite field \mathbb{F} that has an adaptive linear $(\varepsilon, 0, \eta, q)$ -test, then it has a (nonadaptive) linear $(\varepsilon, 0, \eta, q)$ -test.*

Proof. Let T be an adaptive linear $(\varepsilon, 0, \eta, q)$ -test for V . Let Υ_T and \mathcal{D}_T be the associated set of decision trees and the corresponding distribution, respectively.

DEFINITION 5.7. *Given an adaptive linear test T for V , define the test T' as follows: On input x , choose a random $v \in V$, query x on all variables that T queries on input v , and reject if a violation is detected; otherwise accept.*

T' makes the same number of queries as T . Moreover, the queries depend only on the random $v \in V$ and not on the input x . Hence, the test T' is nonadaptive. The following claim relates the acceptance probability of T' to the average acceptance probability of T .

CLAIM 5.8. *Let T be an adaptive linear test and T' the nonadaptive version of T (as in Definition 5.7). Then, for any string $x \in \mathbb{F}^n$,*

$$\Pr[T'(x) = 1] = \text{average}_{v \in V} (\Pr[T(x+v) = 1]).$$

Proof. For any decision tree Γ , let $l_1(\Gamma)$ denote the set of leaves in Γ that are labeled 1. For any leaf l in a decision tree Γ , let $\text{var}(l)$ denote the set of variables queried along the path leading to l in the tree Γ . Following the notation of Claim 5.1, let V_l and V_l^x be the set of all vectors in V and $x+V$, respectively, that are consistent with the answers along the path leading to l . Also let I_l^x be a binary variable which is set to 1 if and only if x does not violate any constraint in V^\perp involving only the variables $\text{var}(l)$. Observe that if test T' chooses the decision tree $\Gamma \in \Upsilon_T$ and the vector $v \in V$ such that $v \in V_l$ for some leaf l labeled 1 in the tree Γ , then $I_l^x = 1$ if and only if $T'(x) = 1$.

The quantity “average $_{v \in V} (\Pr[T(x+v) = 1])$ ” can be obtained as follows: First,

choose a decision tree $\Gamma \in \Upsilon_T$ according to the distribution \mathcal{D}_T . Then for each leaf l labeled 1 in Γ , find the fraction of vectors in $x + V$ that follow the path leading to l . The weighted sum of these fractions is $\text{average}_{v \in V} (\Pr[T(x + v) = 1])$. Thus,

$$(5.1) \quad \text{average}_{v \in V} (\Pr[T(x + v) = 1]) = \sum_{\Gamma \in \Upsilon_T} \mathcal{D}_T(\Gamma) \left(\sum_{l \in l_1(\Gamma)} \frac{|V_l^x|}{|V|} \right).$$

Now consider the quantity $\Pr[T'(x) = 1]$. Test T' can be viewed in the following fashion: On input x , T' chooses a random decision tree $\Gamma \in \Upsilon_T$ according to the distribution \mathcal{D}_T . It then chooses a leaf l labeled 1 in Γ with probability proportional to the fraction of vectors $v \in V$ that are accepted along the path leading to l (i.e., $|V_l|/|V|$), queries x on all variables in $\text{var}(l)$, accepts if $I_l^x = 1$, and rejects otherwise. This gives us the following expression for $\Pr[T'(x) = 1]$:

$$(5.2) \quad \Pr[T'(x) = 1] = \sum_{\Gamma \in \Upsilon_T} \mathcal{D}_T(\Gamma) \left(\sum_{l \in l_1(\Gamma)} \frac{|V_l|}{|V|} \cdot I_l^x \right).$$

From (5.1) and (5.2), it suffices to prove that $|V_l^x| = I_l^x \cdot |V_l|$ for all leaves l labeled 1 in order to prove the claim.

Observe that $|V_l|$ is nonempty since l is labeled 1. Hence, by Claim 5.1, $|V_l| = |V_l^x|$ if V_l^x is also nonempty. It now suffices to show that V_l^x is nonempty if and only if $I_l^x = 1$.

Suppose V_l^x is nonempty. Then there exists $y \in x + V$ that does not violate any constraint involving only the variables $\text{var}(l)$. But y and x satisfy the same set of constraints. Hence, x also does not violate any constraint involving only the variables $\text{var}(l)$. Thus, $I_l^x = 1$.

Now, for the other direction, suppose $I_l^x = 1$. Then the values of the variables $\text{var}(l)$ of x do not violate any constraint in V^\perp . Hence, there exists $u \in V$ that has the same values as x for the variables $\text{var}(l)$. Let $v \in V_l$. Then, the vector $x - u + v \in x + V$ has the same values for the variables $\text{var}(l)$ as v . Hence, V_l^x is nonempty. This concludes the proof of the claim. \square

The above claim proves that T' inherits its acceptance probability from T . As mentioned earlier, T' inherits its query complexity from T . Hence T' is a linear $(\varepsilon, 0, \eta, q)$ -test for V . \square

6. Random codes require a linear number of queries. In this section we prove Lemma 3.6. We start by analyzing the expansion properties of random regular graphs.

6.1. Some expansion properties of random regular graphs. To prove that a random $\mathcal{C}(G)$ obeys Definition 3.4 with high probability, we use standard arguments about expansion of the random graph G . We reduce each requirement on $\mathcal{A}(G)$ to a requirement on G and then show that the expansion of a random graph G implies that it satisfies the requirements. We need the following notions of neighborhood and expansion.

DEFINITION 6.1 (neighborhood). *Let $G = \langle V, E \rangle$ be a graph. For $S \subset V$, let*

- (i) $N(S)$ be the set of neighbors of S .
- (ii) $N^1(S)$ be the set of unique neighbors of S , i.e., vertices with exactly one neighbor in S .
- (iii) $N^{\text{odd}}(S)$ be the set of neighbors of S with an odd number of neighbors in S .

Notice that $N^1(S) \subseteq N^{odd}(S)$.

DEFINITION 6.2 (expansion). *Let $G = \langle L, R, E \rangle$ be a bipartite graph with $|L| = n$, $|R| = m$.*

(i) *G is called a (λ, γ) -right expander if*

$$\forall S \subset R, |S| \leq \gamma n, |N(S)| > \lambda \cdot |S|.$$

(ii) *G is called a (λ, γ) -right unique neighbor expander if*

$$\forall S \subset R, |S| \leq \gamma n, |N^1(S)| > \lambda \cdot |S|.$$

(iii) *G is called a (λ, γ) -right odd expander if*

$$\forall S \subset R, |S| \geq \gamma n, |N^{odd}(S)| > \lambda \cdot |S|.$$

Notice that the definitions of an expander and a unique neighbor expander deal with subsets of size *at most* γn , whereas the definition of an odd expander deals with subsets of size *at least* γn . Left expanders (all three of them) are defined analogously by taking $S \subset L$ in Definition 6.2.

Lemmas 6.3 and 6.6 are proved using standard techniques for analysis of expansion of random graphs, such as those appearing in, for example, [CS88, Spi95].

LEMMA 6.3. *For any integers $c \geq 7, d \geq 2$ and sufficiently large n , a random (c, d) -regular graph with n left vertices is with high probability a $(1, \frac{1}{100} \cdot d^{-2})$ -left unique neighbor expander.*

Proof. We need the following claims, the proofs of which will follow.

CLAIM 6.4. *For any integers $c \geq 2, d$, any constant $\alpha < c - 1$, and sufficiently large n , a random (c, d) -regular bipartite graph with n left vertices is with high probability a (α, ε) -left expander for any ε satisfying*

$$(6.1) \quad \varepsilon \leq \left(2e^{(1+\alpha)} \cdot \left(\frac{\alpha d}{c} \right)^{(c-\alpha)} \right)^{-\frac{1}{c-\alpha-1}}.$$

CLAIM 6.5. *Let G be a (c, d) -regular bipartite graph with n left vertices. If G is a (α, ε) -left expander, then G is a $(2\alpha - c, \varepsilon)$ -left unique neighbor expander.*

Set $\alpha = \frac{c+1}{2}$. Then $\frac{c}{2} < \alpha < c - 1$ for $c \geq 7$. Let G be a random (c, d) -regular bipartite graph. By Claim 6.4, with high probability G is an (α, ε) -right expander for any ε satisfying (6.1).

The following inequalities hold for our selection of α and any $c \geq 7$:

$$\frac{(1 + \alpha)}{(c - \alpha - 1)} \leq 3,$$

$$\frac{\alpha}{c} > \frac{1}{2},$$

$$\frac{(c - \alpha)}{(c - \alpha - 1)} \leq 2.$$

Hence, $\varepsilon = \frac{1}{100} \cdot d^{-2}$ satisfies (6.1). Claim 6.5 completes the proof of Lemma 6.3. \square

Proof of Claim 6.4. Let BAD be the event in which the random graph is *not* an expander. This means there is some $S \subset L, |S| \leq \varepsilon n$ such that $|N(S)| \leq \alpha \cdot |S|$.

Fix sets $S \subset L, T \subset R$, $|S| = s \leq \varepsilon n$, $|T| = \alpha s$, and let B_s be the event in which all edges leaving S land inside T . We upper-bound the probability of this bad event:

$$\Pr[B_s] = \prod_{i=0}^{c \cdot s - 1} \frac{\alpha ds - i}{cn - i} \leq \left(\frac{\alpha ds}{cn} \right)^{cs}.$$

The inequality above holds as long as $\alpha ds < cn$. In the following, we now use a union bound over all sets $S \subset L$, $|S| = s \leq \varepsilon n$ and all sets $T \subset R$, $|T| = \alpha s$. Let κ be the constant $\kappa = e^{1+\alpha} \cdot \left(\frac{\alpha d}{c} \right)^{c-\alpha}$.

$$\begin{aligned} \Pr[BAD] &\leq \sum_{s=1}^{\varepsilon n} \binom{n}{s} \cdot \binom{m}{\alpha s} \cdot \Pr[B_s] \\ &\leq \sum_{s=1}^{\varepsilon n} \left(\frac{en}{s} \right)^s \cdot \left(\frac{em}{\alpha s} \right)^{\alpha s} \cdot \left(\frac{\alpha ds}{cn} \right)^{cs} \\ &= \sum_{s=1}^{\varepsilon n} \left[e^{1+\alpha} \cdot \left(\frac{\alpha d}{c} \right)^{c-\alpha} \cdot \left(\frac{s}{n} \right)^{c-\alpha-1} \right]^s \\ (6.2) \quad &= \sum_{s=1}^{\varepsilon n} \left[\kappa \cdot \left(\frac{s}{n} \right)^{c-\alpha-1} \right]^s. \end{aligned}$$

By definition of α , $c - \alpha - 1 > 0$. Hence $\left(\frac{s}{n} \right)^{c-\alpha-1} \leq 1$. Set

$$(6.3) \quad \varepsilon \leq (2\kappa)^{\frac{-1}{c-\alpha-1}} = \left(2e^{(1+\alpha)} \cdot \left(\frac{\alpha d}{c} \right)^{(c-\alpha)} \right)^{-\frac{1}{c-\alpha-1}}.$$

For this value of ε , each term of the sum (6.2) is at most $\frac{1}{2}$. Set $\lambda = \min\{\frac{1}{3}, \frac{c-\alpha-1}{2}\}$ and split the sum (6.2) into two subsums:

$$\begin{aligned} \Pr[BAD] &\leq \sum_{s=1}^{\varepsilon n} \left[\kappa \cdot \left(\frac{s}{n} \right)^{c-\alpha-1} \right]^s \\ &\leq \sum_{s=1}^{n^\lambda} \left[\kappa \cdot \left(\frac{s}{n} \right)^{c-\alpha-1} \right]^s + \sum_{s=n^\lambda}^{\varepsilon n} \left[\kappa \cdot \left(\frac{s}{n} \right)^{c-\alpha-1} \right]^s \\ &\leq n^\lambda \cdot \kappa \cdot n^{(\lambda-1)2\lambda} + n \cdot 2^{-n^\lambda} \\ &= \kappa \cdot n^{-\lambda+2\lambda^2} + n \cdot 2^{-n^\lambda} \\ &\leq \kappa \cdot n^{-\frac{1}{9}} + n \cdot 2^{-n^\lambda} = o(1). \end{aligned}$$

We conclude that, with high probability, G is an (α, ε) -left expander. \square

Proof of Claim 6.5. Let $S \subset L, |S| \leq \varepsilon|L|$. Then by expansion,

$$\alpha \cdot |S| < |N(S)|.$$

Any neighbor of S that is not a unique neighbor must be touched by at least two edges leaving S . Since the left degree of G is c ,

$$|N(S)| \leq |N^1(S)| + \frac{c \cdot |S| - |N^1(S)|}{2} = \frac{c \cdot |S| + |N^1(S)|}{2}.$$

Combining the two equations, we get our claim. \square

LEMMA 6.6. *For any odd integer c , any constants $\mu > 0, \delta < \mu^c$, and any integer $d > \frac{2\mu c^2}{(\mu^c - \delta)^2}$, a random (c, d) -regular graph is with high probability a (δ, μ) -right odd expander.*

Proof. In the proof, we make use of the following theorem (see [MR95]).

THEOREM 6.7 (Azuma's inequality). *If X_0, \dots, X_t is a martingale sequence such that $|X_i - X_{i+1}| \leq 1$ for all i , then*

$$\Pr[|X_t - X_0| \geq \lambda\sqrt{t}] \leq 2e^{-\lambda^2/2}.$$

Fix $T \subseteq R$ $|T| = t \geq \mu m$. Let $X = |N^{\text{odd}}(T)|$. We start by computing $E[X]$. For $i = 1, \dots, n$, let X_i be the random variable indicating whether vertex $i \in L$ is in $N^{\text{odd}}(T)$. Clearly, $X = \sum_{i=1}^n X_i$, so by the linearity of expectation, we need only compute $E[X_i]$. Recall that $cn = dm$. Let $\text{odd}(c) = \{1, 3, 5, \dots, c\}$ be the set of positive odd integers $\leq c$, and notice that $c \in \text{odd}(c)$ because c is odd:

$$\begin{aligned} E[X_i] &= \frac{\sum_{i \in \text{odd}(c)} \binom{\mu dm}{i} \cdot \binom{(1-\mu)dm}{c-i}}{\binom{cn}{c}} \\ &\geq \frac{\binom{\mu cn}{c}}{\binom{cn}{c}} = \mu^c - O\left(\frac{1}{n}\right). \end{aligned}$$

We conclude by linearity of expectation:

$$E[X] \geq \mu^c \cdot n - O(1).$$

We now use the following edge-exposure martingale to show concentration of X around its expectation. Fix an ordering on the μdm edges leaving T and define a sequence of random variables $Y_0, \dots, Y_{\mu dm}$ as follows: Y_i is the random variable that is equal to the expected size of $N^{\text{odd}}(T)$ after the first i edges leaving T have been revealed. By definition, $Y_{\mu dm} = X$, $Y_0 = E[X]$, and the sequence is a martingale, where $|Y_i - Y_{i+1}| \leq 1$ for all $i \leq \mu dm$. Since $d > \frac{2\mu c^2}{(\mu^c - \delta)^2}$, Azuma's inequality (Theorem 6.7) gives us

$$\begin{aligned} \Pr[X \leq \delta n] &\leq \Pr[|Y_{\mu dm} - Y_0| \geq (\mu^c - \delta)n] \\ &= \Pr\left[|Y_{\mu dm} - Y_0| \geq (\mu^c - \delta)\frac{d}{c}m\right] \\ &\leq 2e^{-\frac{d(\mu^c - \delta)^2}{2\mu c^2} \cdot m} \leq 2e^{-(1+\varepsilon)m}, \end{aligned}$$

where $\varepsilon = \frac{d(\mu^c - \delta)^2}{2\mu c^2} - 1 > 0$. Since there are at most 2^m possible sets $T \subseteq R$, by the union bound,

$$\begin{aligned} \Pr\left[\exists T \subset R \ |T| \geq \mu m, \left|\sum_{j \in T} A_j\right| \leq \delta n\right] &\leq 2^m \cdot 2e^{-(1+\varepsilon)m} \\ &= o(1). \end{aligned}$$

We conclude that with high probability $\mathcal{A}(G)$ is a (δ, μ) -right odd expander. \square

6.2. Proof of Lemma 3.6. Let G be a random (c, d) -regular graph G with n left vertices. We prove that $\mathcal{A}(G)$ is with high probability (i) linearly independent, (ii) $(\delta n, \mu)$ -local, and (iii) ε -separating.

- (i) We need to show that adding up any subset of $\mathcal{A}(G)$ cannot yield $\vec{0}$. Since we are working modulo 2, this is equivalent to proving

$$\forall T \subseteq R, \quad N^{\text{odd}}(T) \neq \emptyset.$$

For small T we use unique neighbor expansion, and for large T we use odd neighbor expansion.

Fix c , and reverse the roles of left and right in Lemma 6.3. We conclude that, for any $d \geq 7$ and for our setting of μ , G is with high probability a $(1, \mu)$ -right unique neighbor expander. This implies that if $|T| \leq \mu|R|$, then $N^{\text{odd}}(T) \neq \emptyset$ because $N^{\text{odd}}(T) \supseteq N^1(T)$ and $N^1(T) \neq \emptyset$.

Lemma 6.6 says that for any $\mu > 0$, and for our selection of d , all sets of size at least μm have a nonempty odd neighborhood. (Actually, the lemma shows that the odd neighborhood is of linear size, which is more than we need here.)

This completes the proof of the first claim.

- (ii) Notice that if $T \subseteq R$, then $N^{\text{odd}}(T)$ is exactly the support of $\sum_{j \in T} A_j$. Thus, it suffices to show that $N^{\text{odd}}(T)$ is large for large subsets T .

By definition of d, μ, δ and by Lemma 6.6, with high probability G is a $(\delta n, \mu)$ -right odd expander. This means $\mathcal{A}(G)$ is $(\delta n, \mu)$ -local. Part (ii) is proved.

- (iii) Let G_{-j} be the graph obtained from G by removing vertex $j \in R$ and all edges touching it. Since $\mathcal{A}(G)$ is linearly independent, it is sufficient to show that $\mathcal{C}(G_{-j})$ has no nonzero element of Hamming weight $< \varepsilon n$.

Let x be a nonzero element of $\mathcal{C}(G_{-j})$, and let $S_x \subseteq L$ be the set of coordinates at which x is 1. Consider the graph G_{-j} . In this graph, the set of unique neighbors of S_x is empty because $x \in \mathcal{C}(G_{-j})$ (otherwise, some $j' \in N^1(S_x)$, so $\langle A_{j'}, x \rangle = 1$, a contradiction). Thus,

$$(6.4) \quad N^1(S_x) \subseteq \{j\},$$

where $N^1(S_x)$ is the set of unique neighbors of S_x in G . Clearly, $|S_x| > 1$ because the left degree of G is $c > 1$. But if $|S_x| \leq \frac{1}{100} \cdot d^{-2} \cdot n$, then by Lemma 6.3 $|N^1(S_x)| \geq |S_x| > 1$, in contradiction to (6.4). We conclude that for any $x \in \mathcal{C}(G_{-j})$, $|x| \geq \frac{1}{100} \cdot d^{-2}$, so $\mathcal{A}(G)$ is ε -separating for our selection of ε . Part (iii) is complete.

This completes the proof of Lemma 3.6. \square

7. Reducing d LIN to 3LIN. This section proves Lemma 3.8. The randomized construction from section 6 produces d -linear formulae, which are hard to test for some constant d . We would like to make d as small as possible. This section obtains 3-linear, hard-to-test formulae. First, we give a reduction from d -linear to $\lceil \frac{d}{2} \rceil + 1$ -linear formulae and then apply it d times to get 3-linear formulae.

Let φ be a d -linear formula on variables in $X = \{x_1, \dots, x_n\}$. The reduction maps φ to a $(\lceil \frac{d}{2} \rceil + 1)$ -linear formula on variables $X \cup Z$, where Z is a collection of new variables $\{z_1, \dots, z_m\}$. For each constraint A_i , say $x_1 \oplus \dots \oplus x_d = 0$, in φ , two constraints, A_i^1 and A_i^2 , are formed: $x_1 \oplus \dots \oplus x_{\lceil \frac{d}{2} \rceil} \oplus z_i = 0$ and $x_{\lceil \frac{d}{2} \rceil + 1} \oplus \dots \oplus x_d \oplus z_i = 0$. Let $V \subseteq \{0, 1\}^n$ be the vector space of vectors satisfying φ , and let \mathcal{A} be an m -dimensional basis for the vector space V^\perp of constraints. Define $\mathcal{R}(\mathcal{A})$ to be the collection of $2m$ vectors in $\{0, 1\}^{n+m}$ formed by splitting every constraint in \mathcal{A} in two, as described above.

The following three claims show that the reduction preserves the properties which make the formula hard to test. A parameter followed by a prime denotes the value of the parameter after one application of the reduction: for example, $m' = 2m$, $n' = m + n$, and $d' = \lceil \frac{d}{2} \rceil + 1$.

CLAIM 7.1. $\mathcal{R}(\mathcal{A})$ is independent.

Proof. It is enough to prove that no set of constraints in $\mathcal{R}(\mathcal{A})$ sums up to 0. Let C be a subset of constraints in $\mathcal{R}(\mathcal{A})$. If only one of the two constraints involving a new variable z appears in C , then the sum of vectors in C has 1 in z 's position. If, on the other hand, all constraints appear in pairs, then the sum of vectors in C is equal to the sum of the constraints in \mathcal{A} from which C 's constraints were formed. By independence of old constraints, this sum is not 0. \square

CLAIM 7.2. If \mathcal{A} is ε -separating, then $\mathcal{R}(\mathcal{A})$ is ε' -separating, where $\varepsilon' = \frac{\varepsilon}{1 + (m/n)}$.

Proof. Let x' be a vector in $\{0, 1\}^{n+m}$ that falsifies exactly one constraint, say A_i^1 , in $\mathcal{R}(\mathcal{A})$. Namely, $\langle x', A_i^1 \rangle = 1$ and $\langle x', A' \rangle = 0$ for all $A' \in \mathcal{R}(\mathcal{A})$, $A' \neq A_i^1$. Let $x = x'_1 \dots x'_n$. Then $\langle x, A_i \rangle = \langle x', A_i^1 + A_i^2 \rangle = \langle x', A_i^1 \rangle + \langle x', A_i^2 \rangle = 1$, and similarly, $\langle x, A \rangle = 0$ for all $A \in \mathcal{A}$, $A \neq A_i$. Thus, x falsifies exactly one constraint in \mathcal{A} . Since \mathcal{A} is ε -separating, $|x| \geq \varepsilon n$. It follows that $|x'| \geq \varepsilon n$, implying that $\mathcal{R}(\mathcal{A})$ is $(\frac{\varepsilon n}{n+m})$ -separating. \square

CLAIM 7.3. If \mathcal{A} is (q, μ) -local, then $\mathcal{R}(\mathcal{A})$ is (q', μ') -local, where $q' = \frac{q}{d'}$ and $\mu' = \mu + \frac{q'}{m'}$.

Proof. Let $\alpha' \in \{0, 1\}^{m+n}$ be the sum of a subset T of $\mu' \cdot m'$ constraints in $\mathcal{R}(\mathcal{A})$. Let T_2 be the subset of constraints in T which appear in pairs. Namely, for every new variable z , both constraints with z are either in T_2 or not in T_2 . Let $T_1 = T \setminus T_2$.

Case 1. $|T_1| \geq q'$. For every constraint in T_1 , the new variable z from that constraint does not appear in any other constraint in T . Therefore, α' is 1 on z 's coordinate. Hence, $|\alpha'| \geq |T_1| \geq q'$.

Case 2. $|T_1| < q'$. Then $|T_2| = |T| - |T_1| \geq \mu' \cdot m' - q' = \mu \cdot m' = 2\mu m$. Let S be the set of constraints in \mathcal{A} that gave rise to constraints in T_2 . Then $|S| = |T_2|/2 \geq \mu m$. Old variables appear in the same number of constraints in S and in T_2 . Thus,

$$\left| \sum_{A' \in T_2} A' \right| \geq \left| \sum_{A \in S} A \right| \geq q.$$

The last inequality follows from the fact that \mathcal{A} is (q, μ) -local. When constraints from T_1 are added to $\sum_{A' \in T_2} A'$, each T_1 constraint zeros out at most $\lceil \frac{d}{2} \rceil = d' - 1$ coordinates:

$$|\alpha'| \geq \left| \sum_{A' \in T_2} A' \right| - \frac{d}{2} \left| \sum_{A' \in T_1} A' \right| \geq q - (d' - 1)q' = q'. \quad \square$$

If the reduction is applied $\lceil \log(d-2) \rceil$ times, the number of terms in a constraint drops to 3. To see this, think of applying the reduction i times to a formula with $d \leq 2^i + 2$ terms per constraint. Successive iterations will decrease the clause size to $\leq 2^{i-1} + 2, \leq 2^{i-2} + 2$, etc. We apply the reduction $\lceil \log d \rceil$ times to obtain hard 3LIN formulae from hard dLIN formulae, as shown in Lemma 3.8.

Proof of Lemma 3.8. For $\mathcal{A} \subset \{0, 1\}^n$ as in the statement of our lemma, let $\mathcal{R}^{(0)}(\mathcal{A}) = \mathcal{A}$, and for $i \geq 1$ let $\mathcal{R}^{(i)}(\mathcal{A}) = \mathcal{R}(\mathcal{R}^{(i-1)}(\mathcal{A}))$. Let $\mathcal{A}^* = \mathcal{R}^{(\lceil \log d \rceil)}(\mathcal{A})$. As explained above, each constraint in \mathcal{A}^* has weight at most 3. We now calculate the remaining parameters of \mathcal{A}^* . In doing so, we denote the value of a parameter in

$\mathcal{R}^{(i)}(\mathcal{A})$ by the superscript $^{(i)}$, and the superscript * signifies the final value of the parameter in \mathcal{A}^* .

Since each application of the reduction doubles the dimension, $m^* = 2^{\lceil \log d \rceil} m \leq 2dm$. To calculate n^* , observe that the reduction does not change $m - n$ and recall that $dm = cn$. Therefore,

$$n^* = n + m^* - m \leq n + 2dm = (2c + 1) \cdot n.$$

Claim 7.1 guarantees that \mathcal{A}^* is independent. By Claim 7.2, $\varepsilon' = \frac{\varepsilon}{1+(m/n)} = \varepsilon \frac{n}{n^*}$. Thus,

$$\varepsilon \geq \varepsilon^* = \varepsilon \cdot \frac{n}{n^{(1)}} \cdot \frac{n^{(1)}}{n^{(2)}} \cdots \frac{n^{(\lceil \log d \rceil - 1)}}{n^*} = \varepsilon \frac{n}{n^*} \geq \frac{\varepsilon}{2c + 1}.$$

Let $q = \delta n$. Applying Claim 7.3 $\lceil \log d \rceil$ times, we obtain

$$\begin{aligned} q \geq q^* &= \frac{q}{d^{(1)} \times d^{(2)} \times \dots \times d^*} \geq \frac{q}{d^{\lceil \log d \rceil}} \geq \frac{q}{d^{\log d + 1}}; \\ \delta \geq \delta^* &= \frac{q^*}{n^*} \geq \frac{q}{d^{\log d + 1} \cdot (2c + 1)n} = \frac{\delta}{d^{\log d + 1} \cdot (2c + 1)}; \\ \mu^* &= \mu + \frac{q^{(1)}}{m^{(1)}} + \frac{q^{(2)}}{m^{(2)}} + \dots + \frac{q^*}{m^*} \\ &< \mu + \frac{q}{m} \left(\frac{1}{2d^{(1)}} + \frac{1}{4d^{(1)}d^{(2)}} + \dots + \frac{1}{d \cdot d^{(1)}d^{(2)} \dots d^*} \right) \\ &\leq \mu + \frac{q}{m} \frac{\lceil \log d \rceil}{d} \leq \mu + \frac{d\delta n}{cn} \cdot \frac{\log d + 1}{d} = \mu + \frac{\delta(\log d + 1)}{c}. \end{aligned}$$

This completes the proof of Lemma 3.8. \square

Acknowledgments. We thank Madhu Sudan for (i) many helpful conversations, (ii) suggesting the reductions of section 5, and (iii) allowing us to include the “hard to test” properties based on Reed–Muller codes. We thank Piotr Indyk for referring us to Azuma’s inequality to simplify the analysis and thank Michael Sipser for helpful discussions. We are grateful to Oded Goldreich for allowing us to include the “hard to test” properties based on random linear codes. We thank Oded Goldreich and the anonymous referees for several useful suggestions which improved the presentation of the paper.

A PROBABILISTIC ANALYSIS OF TRIE-BASED SORTING OF LARGE COLLECTIONS OF LINE SEGMENTS IN SPATIAL DATABASES*

MICHAEL LINDENBAUM[†], HANAN SAMET[‡], AND GISLI R. HJALTASON[§]

Abstract. The size of five trie-based methods of sorting large collections of line segments in a spatial database is investigated analytically using a random lines image model and geometric probability techniques. The methods are based on sorting the line segments with respect to the space that they occupy. Since the space is two-dimensional, the trie is formed by interleaving the bits corresponding to the binary representation of the x and y coordinates of the underlying space and then testing two bits at each iteration. The result of this formulation yields a class of representations that are referred to as *quadtrie* variants, although they have been traditionally referred to as *quadtree* variants. The analysis differs from prior work in that it uses a detailed explicit model of the image instead of relying on modeling the branching process represented by the tree and leaving the underlying image unspecified. The analysis provides analytic expressions and bounds on the expected size of these quadtree variants. This enables the prediction of storage required by the representations and of the associated performance of algorithms that rely on them. The results are useful in the following two ways:

1. They reveal the properties of the various representations and permit their comparison using analytic, nonexperimental criteria. Some of the results confirm previous analyses (e.g., that the storage requirement of the MX quadtree is proportional to the total lengths of the line segments). An important new result is that for a PMR and Bucket PMR quadtree with sufficiently high values of the splitting threshold (i.e., ≥ 4) the number of nodes is proportional to the number of line segments and is independent of the maximum depth of the tree. This provides a theoretical justification for the good behavior and use of the PMR quadtree, which so far has been only of an empirical nature.
2. The random lines model was found to be general enough to approximate real data in the sense that the properties of the trie representations, when used to store real data (e.g., maps), are similar to their properties when storing random lines data. Therefore, by specifying an equivalent random lines model for a real map, the proposed analytical expressions can be applied to predict the storage required for real data. Specifying the equivalent random lines model requires only an estimate of the effective number of random lines in it. Several such estimates are derived for real images, and the accuracy of the implied predictions is demonstrated on a real collection of maps. The agreement between the predictions and real data suggests that they could serve as the basis of a cost model that can be used by a query optimizer to generate an appropriate query evaluation plan.

1. Introduction.

1.1. Background. The efficient management of data in large database systems depends on grouping the data in such a way that similar data are aggregated and also stored in proximity so that they can be operated upon at the same time or at approximately the same time (see, e.g., [17]). This grouping is usually achieved by sorting the data. The rationale for sorting the data is to facilitate the presentation of the data to the user (e.g., in reports) and also to speed up query processing using sort-based algorithms such as merge-join.

Although sorting has traditionally been applied to one-dimensional data, it is also applicable to data of higher dimensions. This data can consist of points in a higher dimensional space or of spatial objects that span the higher dimensional space (e.g., lines, regions, surfaces, volumes, etc.). In the case of spatial data in more than one dimension, which is the focus of this paper, the result of applying conventional sorting techniques does not always lead to simpler algorithms. For example, suppose that the data are sorted with respect to a particular reference point (e.g., all U.S. cities, represented as points, are sorted with respect to their distance from Chicago). In this case, if we wish to obtain the points in the order of their distance from another point (e.g., with respect to their distance from Omaha), then the sorting process will, in general, have to be reapplied to the entire set of data. The problem is that the data were sorted in an explicit manner. Instead, we need methods that provide an implicit ordering. Examples of such techniques are called *bucketing methods* (see, e.g., [43, 45]). In this case, the data are sorted on the basis of the space that they occupy and are grouped into cells (i.e., buckets) of a finite capacity.

There are two principal methods for sorting spatial data. The first makes use of an object hierarchy. It is based on propagating the space occupied by groups of the data objects up through the hierarchy (e.g., members of the R-tree family [3, 18]). We do not deal with this method in this paper. The second is based on a decomposition of the space occupied by the data into disjoint cells which are aggregated into larger cells (e.g., members of the quadtree family [44, 43, 45]). The decomposition can be either tree-based or trie-based. The distinction is that the former is applied to the values of the data (e.g., a binary search tree), while the latter makes use of the digits (termed a *trie* [5, 16, 28]) that comprise the domain of the values of the data. Data structures that make use of the latter in one dimension are also known as *digital trees* [28].

Our data consists mainly of line segments in two-dimensional space. Our focus is on using tries to sort the line segments with respect to the space that they occupy. We use tries because they result in partitioning different data sets at the same positions, thereby making it very easy and efficient to use merge-join query processing algorithms. Since the space is two-dimensional, the trie is formed by interleaving the bits corresponding to the binary representation of the x and y coordinates of the underlying space. Two similar, yet still different, trie-based data structures may be created depending on whether we test one bit at each iteration (a k - d *trie* [15]) or two bits at each iteration (a *quadtrie* [21, 43, 45]). In this paper, we focus on *quadtries* for collections of line segments. Unfortunately, the representations that make use of *quadtries* have been traditionally referred to as *quadtree* variants (see, e.g., [26, 44, 43, 45]). In our discussion, all *quadtrees* are based on tries and we precede the term *quadtree* with an appropriate qualifier whenever there is a potential for confusion. Thus the *quadtrees* that we discuss are distinct from those based on multidimensional binary search trees that are used for points (see, e.g., [13, 14]).

Variants of *quadtree* structures have been used for many different spatial objects

including points, regions, lines, rectangles, surfaces, volumes, etc. Algorithms using them generally have good average execution times while maintaining a relatively compact representation [44, 43, 45]. To use these data structures in a database application, we must be able to predict their size. The most obvious advantage of such a capability is that it enables us to determine how much space will be required to store different data sets and to choose between different data structures from an efficiency standpoint. It may also be of use at query evaluation time to aid the estimation of the cost of a particular query execution plan (i.e., processing strategy) to be used by a query optimizer. For example, suppose that we are using a filter-and-refine strategy [6] for processing a window query. In particular, suppose further that we have a method of estimating the number of data structure blocks that intersect the window based on the window's size (see, e.g., [40]). Our results could be used in a reverse sense to estimate the number of objects (i.e., line segments in our case) that intersect these blocks. This could serve as a measure of the cost of the refinement step, which must subsequently determine which of the lines actually intersect the query window. Continuing the filter-and-refine query processing strategy, suppose that we are using the histogram method (see, e.g., [29, 31, 34]) for estimating the number of objects that intersect the query window. We can now plug this information into our results to estimate the number of data structure blocks that intersect the window. This is a good measure of the cost of the filter step, i.e., the I/O (Input/Output) cost for the spatial data structure. An alternative factor in measuring performance when data is disk-based is to examine how the various data structure blocks are declustered on various disks (see, e.g., [33]), but this is beyond the scope of this paper and is not discussed further here.

1.2. Related work. Traditional worst-case analysis is often inappropriate because the worst case tends to be both very bad and highly improbable. Thus most approaches to the analysis of hierarchical data structures have been statistical in nature.

A number of statistical approaches have been tried. The most common uses a uniform distribution in the underlying space (see, e.g., [2, 11]). An alternative is to use a nonuniform distribution. Some techniques that have been used include the Gaussian distribution [36] as well as the clustering of uniformly distributed points [38] or even predetermined shapes [3]. Another approach uses a fractal distribution [9] that has the advantage of exhibiting self-similarity, which means that portions of a part of the data set are statistically similar to the entire data set. The key to this approach is to compute a fractal dimension for a particular point data set and then use it in a query optimizer.

The methods described above are for point data sets.¹ In this paper, we are interested in data where every object has nonzero size (e.g., collections of lines, regions, and so on, instead of being restricted to collections of points). Tamminen [54] considers the performance of quadtrees and bintrees under the assumption that the image consists of a single random line treated as a region, and he analyzes the number of nodes in them using geometric probability. Shaffer, Juvvadi, and Heath [52] follow Tamminen's approach and use a local straight line model to perform an analysis that yields the relative (rather than absolute) storage requirements of the region quadtree and bintree data structures. Other works on region data include Dyer [8], Shaffer [51], and

¹The fractal model has been applied to points derived from a collection of line segments in the sense that the points corresponded to intersections of line segments [9]. This was used to predict the effective occupancy of nodes in an R-tree that stores point data.

Faloutsos, Jagadish, and Manolopoulos [10], Mathieu, Puech, and Yahia [30], Puech and Yahia [42], and Vassilakopoulos and Manolopoulos [56], and these investigate the size of quadtree representations of region data and study some other related questions using some assumptions on the branching probabilities of nodes in the tree. Nelson and Samet [35, 36, 37] consider the distributions of node occupancies in hierarchical geometric data structures that store a variable number of geometric data items per node, which include points and lines. However, the methods of Nelson and Samet have much wider applicability. This approach is similar to hashing [28], where each node acts like a bucket.

Although these approaches sometimes lead to remarkable agreement between theory and simulation (see, e.g., [1, 36]), they have a common drawback. The explicit model of the image on which the statistical analysis is performed is either exceedingly simple or is not given at all. When the model is not given, the model must be implied from other assumptions. In particular, an assumption is made on the splitting probability in the data structure (see, e.g., [1, 30, 36, 42]), which implies the existence of some *implicit* model on the data. However, when we ask what kind of data (real or contrived) fit this model, the only possible answer is a circular one that says that the data give rise to these probabilities. Unfortunately, there is no explicit indication of whether there exists some image model associated with these splitting probabilities. Thus the connection between the analysis and the performance with real image data is not clear. In contrast, our approach, as described below, is to use an *explicit* nontrivial random image model and to then show that data can be generated corresponding to this model, which also fits the analysis. Note that we are not claiming that the data we generate correspond exactly to typical images, although we deal with this issue as well. In this sense our approach is complementary to the work of Flajolet and Puech [15], who analyzed the partial match query time for hierarchical data structures, while we analyze their storage requirements. Unlike their data, which consist of random points in a high-dimensional space whose coordinate values are drawn from a uniform distribution, our data consist of randomly drawn lines. It is important to note that a line is a qualitatively different data type than a point, as the action of every line on the structure is not local.

An alternative nonstatistical approach was applied by Hunter [22] and Steiglitz [23] to show that, for a polygon of perimeter l , the size (i.e., the number of nodes) of the corresponding MX quadtree (a variant of the region quadtree described in more detail in section 2) is $O(l)$. This classic result, although derived for simple polygons, has been observed to be sufficiently general to be useful for predicting the performance of a number of algorithms for different images represented by a region quadtree [48].

As we pointed out above, in this paper we investigate the use of a random image model consisting of M randomly drawn lines. Unlike Tamminen’s approach [54], which considers a single random line, here we treat the much more general and complicated situation of an arbitrary number of lines. We use geometric probability to analyze four variants of the quadtree that can be built for data that obey this model by determining the expected number of nodes in each variant. These variants are the MX quadtree [23, 43, 45], the PM quadtree [49], the PMR quadtree [35, 36, 37], and a new variant of the PMR quadtree representation, which we call a Bucket PMR quadtree (see also [19, 20]).

1.3. Contributions. The analysis that we provide is important for two reasons. First, it allows for a meaningful, quantitative, and analytic comparison of a number of

different options for representing linear spatial data, and it provides tools for choosing between these options in a way which is neither experimental nor domain dependent. The second reason is even more practical: we found that we could actually predict the storage requirements of these representation options by specifying an equivalent random lines data set, with some equivalent number of lines, and use the proposed analytic expressions for predicting its size.

In particular, our analysis shows that for images of the same complexity, the PMR quadtree and the Bucket PMR quadtree for sufficiently high values of the splitting threshold (i.e., ≥ 4) are the most efficient in the sense that they require the least storage. The PM quadtree follows, and the MX quadtree requires the largest amount of storage. This qualitative ordering verifies experimental results obtained in the past [22, 23, 35, 49] and agrees with the extensive experimentation that we have carried out. This verification, along with its accompanying theoretical justification, is one of the contributions of our research.

The agreement between the results of our analysis and the data was not surprising in the case of the MX quadtree because it confirmed previous results (i.e., [22, 23]). However, in the case of the PMR and Bucket PMR quadtrees for sufficiently high values of the splitting threshold (i.e., ≥ 4) our analysis breaks new ground because we are able to derive theoretically and verify experimentally for both random data and real map data that the number of nodes is asymptotically proportional to the number of line segments. This is quite significant, as it enables us to predict the number of nodes required by this representation, and, most importantly, to show that it is independent of the maximum depth of the tree.

It is important to note that we do not claim that our proposed random image model yields data instances which are visually similar to what appears in realistic geometric applications, such as road networks. Nevertheless, we do show that the analysis can be interpreted in terms of the geometric properties of the image, such as line length and the number of intersections between lines. With this interpretation, the predictions, derived for random images, may be applied to real data by measuring the relevant geometric property and using it to specify equivalent random images. Testing the predictions on a real set of maps yielded relatively accurate predictions of the storage required for the maps.

Although our analysis is for a particular data type (i.e., collections of line segments) and data structures, we believe that it has wider applicability. In particular, the geometric probability approach could be extended for data types other than line segments (e.g., points, polygons, surfaces, solids, etc.). Furthermore, the random image model can be used in a statistical analysis of other trie-based spatial data structures.

The rest of this paper is organized as follows. Section 2 gives a brief overview of the quadtree representations of collections of line segments, including the definitions of the four variants that we analyze. Section 3 presents the random image model and reviews some necessary results from geometric probability. Section 4 contains a statistical analysis using the model and the results of its application to each of the aforementioned quadtree variants. It also contains the results of some experiments with instances of the random image model. Section 5 describes the application of the analysis to predict the storage requirements for real data and presents results of extensive experiments that support its validity. Section 6 contains concluding remarks and gives some directions for future research.

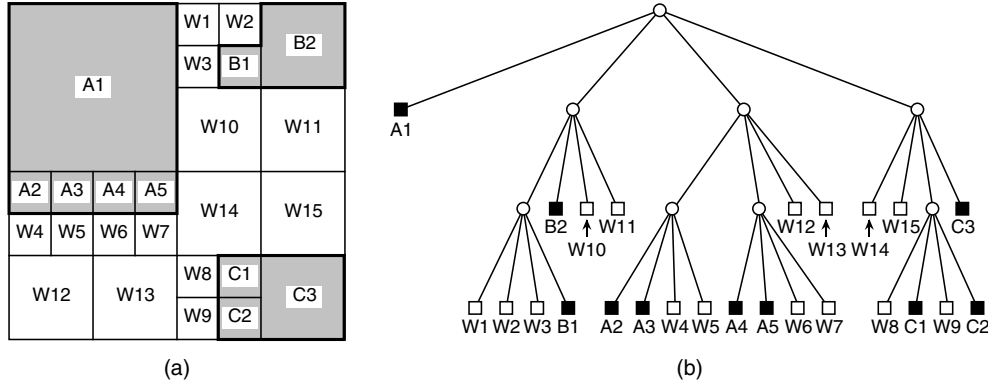

FIG. 1. (a) *Block decomposition* and (b) *its tree representation for the region quadtree corresponding to a collection of three regions A, B, and C.*

2. Overview of quadtree representations of collections of line segments.

A quadtree is a hierarchical variable resolution data structure based on the recursive partitioning of the two-dimensional plane into quadrants. It can be viewed as a 4-ary tree, where each node represents a region in the plane called a block, and the children of each node represent a partition of that region into four parts. This scheme is useful for representing geometric data at a variable resolution. The most commonly known version of the quadtree is the *region quadtree* [26]. It is used for the representation of planar regions. In this case, for two-dimensional data, the environment containing the regions is recursively decomposed into four rectangular congruent blocks until each block either is completely occupied by a region or is empty (such a decomposition process is termed *regular*). For example, Figure 1(a) is the block decomposition for the region quadtree corresponding to three regions A, B, and C. Notice that, in this case, all the blocks are square, have sides whose size is a power of 2, and are located at specific positions.

The traditional, and most natural, access structure for a region quadtree corresponding to a two-dimensional image is a tree with a fanout of 4 (see, e.g., Figure 1(b)). Each leaf node in the tree corresponds to a different block b and contains the identity of the region associated with b . Each nonleaf node f corresponds to a block whose volume is the union of the blocks corresponding to the four children of f . In this case, the tree is a containment hierarchy and closely parallels the decomposition in that they are both recursive processes and the blocks corresponding to nodes at different depths of the tree are similar in shape.

Quadtree variants exist for representing other spatial data types than just planar regions. For example, they are used to represent collections of points [12, 46], collections of line segments [35, 36, 37, 49], as well as more complicated objects (e.g., rectangles [25]). Generalizations of the quadtree to three and higher dimensions (e.g., octrees [22, 24, 32] and bintrees [27, 48, 55]) have also been investigated. These generalizations have many of the same basic properties.

The different variants of the quadtree data structure can be subdivided into two categories: those based on a regular decomposition of space using predefined positions for the partition lines (i.e., trie-based), and those in which the positions of the partition lines are determined explicitly by the data as they are inserted into the data structure (i.e., tree-based or data-based). In most cases, use of regular decomposition indicates

FIG. 2. (a) Collection of line segments in a 4×4 grid, (b) its MX quadtree, (c) its PM quadtree, and (d) its Bucket PMR quadtree with a bucket capacity of 2. Only the resulting decomposition of the underlying space into blocks is shown. The corresponding tree structure that acts as an access structure to ensure logarithmic access times is not shown.

that the shape of the resulting data structure is independent of the order in which the data are inserted into the structure when building it. This is not the case for data-based decompositions. Interestingly, for most applications, regular decomposition works at least as well as data-based decomposition. Moreover, regular decomposition is easier to implement and analyze. At times, a distinction between different variants of the quadtree data structure is also made on the basis of whether or not there is a predefined maximum depth (denoted by N).

In this paper we only consider quadtree representations of collections of line segments. We restrict ourselves to quadtrees based on a regular decomposition. In the rest of this section we review the different quadtree variants that we study. They differ in the condition that is used to determine when a quadtree block should be decomposed—this condition is termed a *splitting rule*.

The simplest quadtree representation is the *MX quadtree*, which assumes that the underlying domain of the data is a $2^N \times 2^N$ grid. The MX quadtree is built by digitizing the line segments and labeling each unit-sized cell (i.e., pixel) through which it passes as being of type **boundary**. The remaining pixels are marked **WHITE** and are merged, if possible, into larger and larger quadtree blocks, as done in the region quadtree. Figure 2(b) is the MX quadtree for the collection of line segment objects in Figure 2(a). A drawback of the MX quadtree is that it associates a thickness with a line. Also, it is difficult to detect the presence of a vertex whenever five or more line segments meet. The above definition of the MX quadtree is given in a bottom-up manner. We can also define it in a top-down manner. In particular, we start with one block corresponding to the entire $2^N \times 2^N$ space and recursively decompose it into four blocks, halting the decomposition when a block is empty or is of size 1×1 (i.e., the block corresponds to a pixel).

The PM quadtree is a refinement of the MX quadtree that is motivated by the observation that the number of blocks in the decomposition can be reduced by terminating the subdivision whenever a line segment passes through a block completely (i.e., it enters and exits the block rather than starting or terminating in the block). Nevertheless, even when this observation is used, the resulting structure still has full decomposition at each vertex or endpoint of a line segment. To avoid this situation, we further modify the above top-down MX quadtree definition so that decomposition takes place as long as more than one line segment passes through the block, unless all of the line segments that pass through the block are incident at the same vertex, which is also required to be in the same block. In addition, the decomposition is also halted whenever a 1×1 block is encountered. The PM quadtree is the structure that results when these additional halting conditions are imposed on the top-down definition of

the MX quadtree. The fact that the PM quadtree is defined in a top-down manner means that each block is maximal. It should be clear that each block at a depth less than the maximum depth contains at most one vertex. For example, Figure 2(c) is the PM quadtree corresponding to the collection of line segment objects in Figure 2(a).

The PM quadtree is vertex-based in the sense that the vertices play a role in determining when the decomposition process stops. In particular, the decomposition process halts when there is more than one line segment in a block, provided that all of the line segments are incident at the same vertex in the block. An alternative is to use an edge-based representation, where a block is split whenever there are more than q line segments passing through it. Thus the blocks serve as buckets with a capacity q . This is known as a *Bucket PMR quadtree*. The drawback of this method is that, whenever more than q line segments are incident at a vertex v , the block containing v will be decomposed until reaching the maximum depth N , which corresponds to a 1×1 block. For example, Figure 2(d) is the Bucket PMR quadtree corresponding to the collection of line segment objects in Figure 2(a) when using a bucket capacity of $q = 2$ and a maximum depth $N = 4$.

As pointed out above, the drawback of the Bucket PMR quadtree is that if the number of line segments incident at a vertex exceeds the bucket capacity, then the decomposition in the neighborhood of the vertex will not halt unless we reach the maximum allowable depth N . This problem is resolved by the *PMR quadtree*, which is similar to a Bucket PMR quadtree with the difference that, in the PMR quadtree, a block is decomposed once, and only once, if the insertion causes it to have more than q line segments. Therefore, in the PMR quadtree, q serves as a *splitting threshold*, which is quite different than a bucket capacity, which is its role in the Bucket PMR quadtree. There is no maximum depth in the PMR quadtree.

The PMR quadtree is constructed by inserting the line segments one by one into an initially empty structure consisting of one block. Each line segment is inserted into all the blocks that it intersects or occupies in its entirety. During this process, the occupancy of each block that is intersected by the line segment is checked to see if the insertion causes it to exceed the splitting threshold. If the splitting threshold is exceeded, the block is split *once*, and only once, into four blocks of equal size.

Figure 3(e) is the PMR quadtree for the collection of line segment objects in Figure 2(a) with a splitting threshold of $q = 2$. The nine line segments, labeled a–i, are inserted in alphabetic order. It should be clear that the shape of the PMR quadtree for a given collection of line segments is not unique; instead, it depends on the order in which the line segments are inserted into it. In contrast, the shapes of the MX, PM, and Bucket PMR quadtrees are unique. Figure 3(a)–(e) shows some of the steps in the process of building the PMR quadtree of Figure 3(e) with a splitting threshold of 2. In each part of Figure 3(a)–(e), the line segment that caused the subdivision is denoted by a thick line, while the gray regions indicate the blocks where a subdivision has taken place.

The insertion of line segments c, e, g, h, and i causes the subdivisions in parts (a), (b), (c), (d), and (e), respectively, of Figure 3. The insertion of line segment i causes three blocks to be subdivided (i.e., the SE block in the SW quadrant, the SE quadrant, and the SW block in the NE quadrant). The final result is shown in Figure 3(e). Note the difference from the PM quadtree in Figure 2(c)—that is, the NE block of the SW quadrant is decomposed in the PM quadtree, while the SE block of the SW quadrant is not decomposed in the PM quadtree. We also observe that, unlike the Bucket PMR quadtree in Figure 2(d), we did not have to split to the maximum

FIG. 3. *PMR quadtree with a splitting threshold of 2 for the collection of line segments of Figure 2(a). (a)–(e) illustrate snapshots of the construction process with the final PMR quadtree given in (e).*

depth in the neighborhood of the vertices, where line segments c , d , i , as well as b , e , i , meet.

It should be clear that the number of line segments in a PMR quadtree block can exceed the value of the splitting threshold q . A value of four for q is usually sufficient to store collections of line segments efficiently, as it implies that junctions of two, three, and four line segments (which are common in maps of roads and rivers, etc.) do not cause a split. Of course, there are situations in which more than four line segments will meet at a vertex. However, we assume that such situations are rare. Note that, at times, we want to express the dependence of the Bucket PMR quadtree and the PMR quadtree on q explicitly, in which case we use the term *bucket PMR_q quadtree* and *PMR_q quadtree*, respectively, to describe the structure.

Note that, in the general case, we may have a collection of line segments that intersect, while the intersection point is not a vertex. Such a situation can result when we are representing a nonplanar graph. As we shall see later, this is not an issue for the line segment arrangements that are generated by our random image model (described in section 3).

3. Random image models. In the first part of this paper (sections 3 and 4) we assumed that the quadtree variants that are discussed represent geometric structures, which are instances of a random process described as follows. Observe that the line $L(\rho, \theta)$ consists of the points (x, y) satisfying the relation

$$L(\rho, \theta) = \{(x, y) \mid x \cos \theta + y \sin \theta = \rho\}.$$

The line $L(\rho, \theta)$ is perpendicular to the vector $(\cos \theta, \sin \theta)$ (see Figure 4(a)). Although the position of every particular line, $L(\rho, \theta)$, naturally depends on the origin and orientation of the coordinate system, we shall soon see that the probability of every random line, drawn according to our model, does not. Therefore, the origin and orientation of the coordinate system relative to the image does not make a difference. The arbitrarily chosen location of the coordinate system in Figure 4(a) illustrates this invariance property. For the rectangular region R ,

$$R = \{(x, y) \mid |x|, |y| < 2^{N-1}\},$$

FIG. 4. *The random image model: (a) The process of generating a random line (note that the coordinate system is arbitrary with respect to the image). (b) A typical instance of the random image constructed for $M = 5$ independently drawn lines labeled 1–5.*

let T be the parameter set

$$T = \{(\rho, \theta) | L(\rho, \theta) \cap R \neq \emptyset\},$$

which includes all the parameter pairs (ρ, θ) that represent lines intersecting with R . Let

$$(1) \quad p(\rho, \theta) = \begin{cases} \frac{1}{|T|} & (\rho, \theta) \in T, \\ 0 & \text{otherwise} \end{cases}$$

be a probability density function, where

$$|T| = \int_T d\rho d\theta.$$

This distribution, called the *uniform density distribution*, is the only one which ensures that the probability of choosing a particular random line is independent of the coordinate system in which ρ and θ are defined (i.e., it is independent of the translation or rotation of the coordinate system [50]). Therefore, it is the natural density function to specify when modeling collections of random lines. As an illustration, see Figure 4(b), where an instance of the random image containing five lines labeled 1–5 is described.

Every instance of our random image model is a $2^N \times 2^N$ image with M random lines that intersect it and which are chosen independently according to the density function (1). The continuous uniform density distribution implies that three lines intersect at the same point with probability zero. This follows from the observation that two intersecting lines define a point, say (x_0, y_0) , which can be regarded as prespecified for the third line. The parameters of every line which intersects this point must be in the set $\{(\rho, \theta) | x_0 \cos \theta + y_0 \sin \theta = \rho\}$, the measure of which is zero (i.e., a one-dimensional quantity) with respect to the measure of T (i.e., a two-dimensional quantity). Therefore, after drawing a finite number of random lines, the probability that any three of them will intersect (x_0, y_0) is zero. This property is usually satisfied for real spatial data such as road maps, as intersections of four or more line segments are rare (i.e., junctions of four or more roads).

Each of the line segments clipped from a random infinite line by the boundary of the image is subdivided further into smaller line segments by its intersection with other infinite lines so that, eventually, no line segment crosses another line segment except at the endpoints of the line segments.

Thus the data represented by the various quadtrees (in the first, analytical, part of the paper) are a collection of random line segments specified as a set of M random infinite lines. Note that the infinite lines are not of interest by themselves but are useful for creating the distribution of line segments which we analyze.

We do not claim that our proposed random image model will enable us to generate data that correlate with what appears in realistic geometric applications, such as road networks. Finding such a correlation is unlikely, as realistic geometric data do not consist of lines whose endpoints lie on the image boundary. Nevertheless, the analysis can be interpreted, as we shall see later, in terms of the geometric properties of the image, such as line length and the number of intersections between lines. This allows us to apply its results to real data with similar geometric properties. Most important, the analysis provides us a means to justify claims about the relative qualitative behavior of the different data structures.

Before starting the analysis, we first present three results from geometric probability which form the basis of our results [50].

Geometric probability theorem 1 (Theorem GP1). Let C_1 be a convex planar set included in the convex planar set $C \subset R$. Let L_1 and L be the perimeters of C_1 and C , respectively. Let l be a random line chosen using the uniform density distribution given by (1). Therefore, the probability that a line l passing through C also passes through C_1 is

$$p\{l \cap C_1 \neq \emptyset | l \cap C \neq \emptyset\} = \frac{L_1}{L}.$$

Geometric probability theorem 2 (Theorem GP2). Let $C \subset R$ be a convex planar set with area A and perimeter L . Let l be a random line chosen using the uniform density distribution given by (1). Suppose that l intersects with C and creates a chord H with length $|H|$. Then the expected length of H is

$$E[|H|] = \frac{\pi A}{L}.$$

Geometric probability theorem 3 (Theorem GP3). Let $C \subset R$ be a convex planar set with area A and perimeter L . Let l_1 and l_2 be two random lines, independently chosen using the uniform density distribution (1). If both lines l_1 and l_2 intersect with C , then the probability that l_1 intersects with l_2 inside C is

$$p\{(l_1 \cap l_2) \cap C \neq \emptyset | l_1 \cap C \neq \emptyset, l_2 \cap C \neq \emptyset\} = \frac{2\pi A}{L^2}.$$

4. Statistical analysis of quadtree representations of collections of line segments. An image as defined in section 3 is an instance of a random event. It follows that its hierarchical representation, using one of the quadtree variants, is also a random event. Moreover, the existence of a node in the tree, or its being a leaf, is a random event. Let v be a node of the tree, at depth d , corresponding to some particular cell. Both the existence of v in the tree and its potential split are random events corresponding to the particular arrangement of random lines. Let P_d be the probability that both of these events happen. Recall that the distribution of the

random lines is independent of the coordinate system translation, thereby implying that P_d depends only on the depth.

Let v_e denote the event that the node v exists. Let v_s denote the event that the splitting condition holds for the block corresponding to node v . Letting $\text{Prob}(v_e, v_s)$ be the probability of the joint event that both node v at depth d exists (v_e) and that the splitting condition is satisfied for the square region corresponding to node v (v_s), we have that

$$(2) \quad P_d = \text{Prob}(v_e, v_s) = \text{Prob}(v_s)\text{Prob}(v_e|v_s).$$

$\text{Prob}(v_s)$ is the probability that the splitting condition is satisfied for a particular square region corresponding to a node v (at depth d), while $\text{Prob}(v_e|v_s)$ is the conditional probability that node v at depth d exists, given that the splitting condition holds for the square region corresponding to v . Note that both v_s and v_e depend on the depth d as well.² For example, in the MX quadtree, $\text{Prob}(v_s)$ is the probability that at least one line passes through this region. The node v exists if every member in the sequence of its recursive parents splits as well. For the MX quadtree, this always happens (if v_s is true) because there is at least one line passing through all of them: the line which passes through v and satisfies its splitting condition. Therefore, for the MX quadtree, $\text{Prob}(v_e|v_s) = 1$ and $P_d = \text{Prob}(v_s)$. We shall see later that this relation is not necessarily satisfied for every tree structure (e.g., the PM quadtree as discussed in subsection 4.2.1).

Let S be the total number of nodes in the tree. Every nonleaf node at depth $d-1$ contributes 4 nodes at depth d . The maximal number of nodes at depth $d-1$ is 4^{d-1} , implying that the expected size of the tree is

$$(3) \quad E[S] = 1 + \sum_{d=1}^N 4^d \cdot P_{d-1}.$$

Note that while the splitting events associated with, say, neighboring nodes, are definitely dependent events, this does not effect the calculation of the expected value [41].

Equation (3), which gives the expected number of nodes in the tree, serves as the basis for our analysis. In the following subsections we focus on splitting rules for each of the quadtree variants discussed in section 2. For each rule, we derive the corresponding splitting probabilities P_d and then use (3) to calculate the expected size of the data structure.

4.1. MX quadtree. An MX quadtree represents a collection of line segments on the plane by partitioning the plane into square blocks using the splitting rule that says a block is split if both the depth of its corresponding node is less than N and if the block contains at least one line segment. If the block does not contain a line segment, then it is not subdivided further and its corresponding node is a leaf. Otherwise, it is subdivided and its corresponding node has four children (see Figure 2(b)).

²This “backward” decomposition was preferred over the “more natural” $\text{Prob}(v_e)\text{Prob}(v_s|v_e)$ because it isolates the event v_s , which is “local” and depends only on the configuration of the lines intersecting the block corresponding to v . In contrast, v_e is a more complex event, depending on the existence of all of the ancestors of v .

4.1.1. Analysis. In order to compute the probabilities P_d , we use the following argument. A node (denoted v) at depth d corresponds to a $2^{N-d} \times 2^{N-d}$ square (denoted v as well). Theorem GP1 implies that a particular random line passes through this region with probability

$$p_d = \frac{4 \cdot 2^{N-d}}{4 \cdot 2^N} = \left(\frac{1}{2}\right)^d.$$

The probability that exactly k out of M lines pass through this region is

$$(4) \quad p_{d,k} = \binom{M}{k} \left(\frac{1}{2}\right)^{dk} \left[1 - \left(\frac{1}{2}\right)^d\right]^{M-k}.$$

The probability that this region corresponds to a nonleaf node is

$$(5) \quad P_d = \text{Prob}(v_s)\text{Prob}(v_e|v_s) = \text{Prob}(v_s) = 1 - p_{d,0} = 1 - \left[1 - \left(\frac{1}{2}\right)^d\right]^M,$$

where $\text{Prob}(v_s)$ is the probability that one or more lines pass through this region, thereby satisfying the splitting condition. As mentioned above, for the MX quadtree, $\text{Prob}(v_e|v_s)$ is always 1 because there is at least one line passing through all the regions corresponding to the recursive parents of this region: the line which passes through v and satisfies its splitting condition.

Inserting (5) into (3), we get

$$(6) \quad E[S] = 1 + \sum_{d=1}^N 4^d \cdot P_{d-1} = \sum_{d=1}^N 4^d \left[1 - \left[1 - \left(\frac{1}{2}\right)^{d-1}\right]^M\right].$$

It is difficult to derive closed forms of sums of this nature. To our knowledge, no relevant solutions exist in the literature. Furthermore, we tried, without success, to evaluate it using various symbolic equation solvers, and consulted their developers as well. Therefore, as we are primarily interested in comparing the asymptotic behavior of the storage requirements of the various data structures, we resort to closed form upper and lower bounds for $E[S]$ —that is, the expected number of nodes in the tree. However, for practical use of this estimate, we suggest inserting the known parameters (i.e., M and N) into the sum (6) and evaluating it numerically. These comments are also applicable in the analyses of the rest of the data structures (see subsections 4.2.1 and 4.3).³

Our technique is based on decomposing (6) into two sums \sum_1 and \sum_2 corresponding to the number of nodes at depth less than or equal to d_0 and all the nodes at a depth greater than d_0 , respectively. In essence, our analysis focuses on evaluating the second sum, while the first sum is bounded by the number of nodes in the complete tree (when calculating the upper bound) or by zero (when calculating the lower bound). We find it convenient to formulate our analysis of $E[S]$ in terms of an

³Note that, although the form of the sum (6) intuitively calls for the use of the commonly known $1 + x \leq e^x$ inequality, it does not help here. The problem is that, in the case at hand, we want to bound (6) from above, which means that the term $\left[1 - \left(\frac{1}{2}\right)^{d-1}\right]^M$ should be bound from below, but this is not possible with this inequality.

additional parameter β (as well as M and N), which is defined as

$$(7) \quad \beta = M \left(\frac{1}{2} \right)^{d_0}.$$

The depth d_0 is chosen so that β is less than 1. This enables us to make some assumptions leading to crucial simplifications (i.e., that certain sums converge as the index of summation gets infinitely large). The result (i.e., $E[S]$) is in terms of M , N , and β . Once the result has been obtained, the value of d_0 is adjusted so that the bounds on $E[S]$ are as tight as possible under the constraints that d_0 is an integer bounded by N and that $\beta < 1$.

Decomposing $E[S]$ into two sums \sum_1 and \sum_2 yields

$$(8) \quad E[S] = 1 + \sum_{d=1}^{d_0} 4^d \left[1 - \left[1 - \left(\frac{1}{2} \right)^{d-1} \right]^M \right] + \sum_{d=d_0+1}^N 4^d \left[1 - \left[1 - \left(\frac{1}{2} \right)^{d-1} \right]^M \right] \\ = \sum_1 + \sum_2.$$

$$(9) \quad \sum_1 = 1 + \sum_{d=1}^{d_0} 4^d \left[1 - \left[1 - \left(\frac{1}{2} \right)^{d-1} \right]^M \right] \leq \sum_{d=0}^{d_0} 4^d \cdot 1 \approx \frac{4^{d_0}}{1 - \frac{1}{4}} \approx \frac{4}{3} \frac{M^2}{\beta^2}.$$

Note that what we have done is decompose $E[S]$ into two parts, \sum_1 and \sum_2 , where \sum_1 corresponds to a complete tree at a depth less than or equal to d_0 . Taking the binomial expansion of \sum_2 , we get

$$(10) \quad \sum_2 = \sum_{d=d_0+1}^N 4^d \left[1 - \sum_{k=0}^M \left(\frac{1}{2} \right)^{kd-k} \binom{M}{k} (-1)^k \right] \\ = \sum_{d=d_0+1}^N \sum_{k=1}^M 2^{2d} \left(\frac{1}{2} \right)^{kd-k} \binom{M}{k} (-1)^{k-1}.$$

Changing the order of summation and separating the $k = 1$ (\sum_3), $k = 2$ (\sum_4), and $k > 2$ (\sum_5) cases, we get

$$(11) \quad \sum_2 = \sum_3 + \sum_4 + \sum_5,$$

$$(12) \quad \sum_3 = \sum_{d=d_0+1}^N 2^{2d} \left(\frac{1}{2} \right)^{d-1} \binom{M}{1} \\ = \sum_{d=d_0+1}^N 2^d \cdot 2 \cdot M = 4M(2^N - 2^{d_0}) = 4M \cdot 2^N - \frac{4M^2}{\beta},$$

$$(13) \quad \sum_4 = - \sum_{d=d_0+1}^N 2^{2d} \left(\frac{1}{2} \right)^{2d-2} \binom{M}{2} = - \sum_{d=d_0+1}^N 4 \binom{M}{2} = -2M(M-1)(N-d_0),$$

(14)

$$\begin{aligned}
\sum_5 &= \sum_{d=d_0+1}^N \sum_{k=3}^M 2^k \binom{M}{k} \left(\frac{1}{2}\right)^{(k-2)d} (-1)^{k-1} \\
&\leq \sum_{k=3}^M \sum_{d=d_0+1}^N 2^k \binom{M}{k} \left(\frac{1}{2}\right)^{(k-2)d} \\
&\approx \sum_{k=3}^M 2^k \binom{M}{k} \frac{\left(\frac{1}{2}\right)^{d_0(k-2)} \left(\frac{1}{2}\right)^{k-2}}{1 - \left(\frac{1}{2}\right)^{k-2}} \\
&= \sum_{k=3}^M 4 \binom{M}{k} \left[\frac{\beta}{M}\right]^{k-2} \frac{1}{1 - \left(\frac{1}{2}\right)^{k-2}} \\
&= \sum_{k=3}^M 4 \cdot \frac{M \cdot (M-1) \cdot (M-2) \cdots (M-k+1)}{k!} \frac{\beta^{k-2}}{M^{k-2}} \frac{1}{1 - \left(\frac{1}{2}\right)^{k-2}} \leq \frac{4}{3} M^2 \frac{\beta}{1-\beta}.
\end{aligned}$$

Note that all approximations performed while calculating \sum_1 and \sum_5 are also upper bounds. We continue by summing all contributions, which are partly expected values and partly upper bounds for expected values, to get

(15)

$$\begin{aligned}
E[S] &= \sum_1 + \sum_3 + \sum_4 + \sum_5 \\
&\leq 4 \cdot M \cdot 2^N - 2 \cdot M(M-1) \cdot N + M^2 \left[-\frac{4}{\beta} + \frac{4}{3} \frac{1}{\beta^2} + \frac{4}{3} \frac{\beta}{1-\beta} + 2 \log_2 \frac{M}{\beta} \right].
\end{aligned}$$

Figure 5 shows the value of the sum estimate given by (6) (second curve from the top) as well as the upper bound (upper curve) given by (15) as a function of M at a maximal depth of $N = 10$. Recall that the upper bounds in the figure are minimal in the sense that, for each value of M , upper bounds were calculated for every possible value of d_0 (subject to the constraint $\beta < 1$) and the minimal (tightest) upper bound was taken.

4.1.2. Interpretation. Asymptotically, the dominant contribution to the number of nodes comes from the first term in (15), which may be transformed into a more familiar form using the GP2. Letting L_i be the length of the i th line in our geometric structure, the expected total length L of all lines is

$$(16) \quad E[L] = \sum_{i=1}^M E[L_i] = M \cdot \pi \frac{(2^N)^2}{4 \cdot 2^N} = \frac{\pi}{4} \cdot M \cdot 2^N.$$

Substituting (16) into the first term of (15), we get

$$(17) \quad E[S] \approx \frac{16}{\pi} E[L].$$

In other words, the expected number of nodes in an MX quadtree is proportional to the total expected length of the lines, which agrees with results derived previously under different (nonprobabilistic) models [22, 23].

4.1.3. A lower bound. The derivation of $E[S]$ given by (9)–(15) may be used to set a lower bound on the expected number of nodes. $E[S]$ consists of the contributions

FIG. 5. The upper bound (UB), the model prediction (Sum Estimate), the empirical estimate (Empirical), and the lower bound (LB) on the number of nodes necessary to store an MX quadtree. The empirical estimate almost coincides with the model prediction. These are the two middle curves, which actually look like one curve. The x and y axes correspond to the number of lines and nodes, respectively, for a tree of depth $N = 10$.

of \sum_1 , \sum_3 , \sum_4 , and \sum_5 . \sum_3 and \sum_4 are exact values, \sum_1 is positive, thereby having a lower bound of 0, while \sum_5 can be easily bounded from below by $-\frac{4}{3}M^2\frac{\beta}{1-\beta}$. Thus,

$$(18) \quad E[S] \geq \sum_3 + \sum_4 - \frac{4}{3}M^2\frac{\beta}{1-\beta}.$$

Furthermore, for large N satisfying $2^N \geq M \cdot N$, we have that \sum_1 , \sum_4 , and \sum_5 are small with respect to \sum_3 . Thus the difference between the upper bound and the lower bound is small, and each of the bounds is a good approximation of $E[S]$ (see the lowest curve in Figure 5).

4.2. PM quadtree. Our variant of a PM quadtree represents a collection of line segments in the plane. It partitions the plane into square blocks using the splitting rule that says a block is split unless the depth of the corresponding node is N , or only one line passes through the block, or there is just one vertex in the block and all the lines that pass through the block meet at that vertex. Thus if the block contains a single line, or all the lines pass through a common point in the block and there is no other endpoint in the block, then the block is not subdivided further and its corresponding node is a leaf. Otherwise, it is subdivided and its corresponding node has four children (see Figure 2(c)).

4.2.1. Analysis. Recall from the opening remarks in section 4 that the probability that a region corresponds to a nonleaf node is $P_d = \text{Prob}(v_s)\text{Prob}(v_e|v_s)$. Consider first $\text{Prob}(v_s)$, the probability that the splitting condition is satisfied. Let α be the probability that two lines intersect inside a square region Q given that each of these lines passes through Q . For a square $2^{N-d} \times 2^{N-d}$ region ($0 \leq d \leq N$), the probability that the splitting conditions of a PM quadtree are satisfied for a node v in depth d may be written as

$$(19) \quad \text{Prob}(v_s) = 1 - p_{d,0} - p_{d,1} - \alpha \cdot p_{d,2},$$

where $p_{d,k}$ is the probability that exactly k of M lines pass through a square region of side 2^{N-d} . The random image model implies that three lines intersect with zero probability at a common point. Therefore, this event may be ignored, leading to the conclusion that a region is always split if three or more lines pass through it. If only two lines pass through the region, then the region is split only if the two lines do not intersect within the region. The intersection probability α may be inferred from Theorem GP3, which implies that

$$\alpha = \frac{2\pi A}{L^2} = \frac{2\pi(2^{N-d})^2}{(4 \cdot 2^{N-d})^2} = \frac{\pi}{8}.$$

Hence,

$$(20) \quad \begin{aligned} \text{Prob}(v_s) = & 1 - \binom{M}{0} \left[1 - \left(\frac{1}{2}\right)^d \right]^M \\ & - \binom{M}{1} \left(\frac{1}{2}\right)^d \left[1 - \left(\frac{1}{2}\right)^d \right]^{M-1} \\ & - \frac{\pi}{8} \binom{M}{2} \left(\frac{1}{2}\right)^{2d} \left[1 - \left(\frac{1}{2}\right)^d \right]^{M-2}. \end{aligned}$$

In contrast to the other quadtree variants considered in this paper, the probability $\text{Prob}(v_e|v_s)$ is not 1 here. In particular, for a PM quadtree, it is possible that the splitting condition is satisfied for some node (region) at depth d but not for its parent node. For the random image model, this arises only in one case, which is when exactly two lines pass through both the node v and its parent node, with their intersection point lying inside the region corresponding to the parent node and outside the region corresponding to the node v . In this case, we have the anomalous situation that, although the node v does not exist, its corresponding region would be split (if it did exist).

Note that $P_d \leq \text{Prob}(v_s)$. We start our analysis by treating this bound, denoted by P'_d , as the splitting probability itself. The difference between the following analysis and the one carried out for the MX quadtree is that here the sum itself is an upper bound as well. Later, we also derive a tighter bound, based on an asymptotic approximation.

To obtain a bounded expression in a simpler way, let us once again, as in the MX quadtree, formulate our analysis of $E[S]$ in terms of an additional parameter β (as well as M and N), which is defined in (7). Here we shall not try to find a lower bound on the sum, as the sum itself is an upper bound.

The result of inserting (20) into (3) (i.e., a bound on $E[S]$) is decomposed into two sums \sum_1 and \sum_2 corresponding to the number of nodes at depth less than or equal to d_0 , and all the nodes at a depth greater than d_0 , respectively. In essence, we assume that the part of the tree at depth less than or equal to d_0 is complete. The value of d_0 is adjusted later so that the bounds on $E[S]$ are as tight as possible under the constraints that d_0 is an integer bounded by N and that $\beta < 1$.

Thus, we have

$$(21) \quad E[S] \leq 1 + \sum_1^N 4^d P'_{d-1} = 1 + \sum_{d=1}^{d_0} 4^d P'_{d-1} + \sum_{d=d_0+1}^N 4^d P'_{d-1} = \sum_1 + \sum_2.$$

A bound on \sum_1 is obtained as in the case of the MX quadtree:

$$(22) \quad \sum_1 = 1 + \sum_{d=1}^{d_0} P'_{d-1} 4^d \leq \sum_{d=0}^{d_0} 4^d \approx \frac{4}{3} 4^{d_0} = \frac{4}{3} \frac{M^2}{\beta^2}.$$

\sum_2 is evaluated by taking its binomial expansion to get a sum of the powers of $(\frac{1}{2})^d$ (i.e., $(\frac{1}{2})^0, (\frac{1}{2})^d, (\frac{1}{2})^{2d}, \dots$). After some algebraic manipulation, the $(\frac{1}{2})^0$ and $(\frac{1}{2})^d$ terms cancel out, and we get

$$(23) \quad \sum_2 = \sum_{d=d_0+1}^N \sum_{k=2}^M C_k \left(\frac{1}{2}\right)^{kd-k} \cdot 4^d,$$

where

$$C_k = (-1)^{k-1} \left[\binom{M}{k} - \binom{M}{1} \cdot \binom{M-1}{k-1} + \binom{M}{2} \cdot \binom{M-2}{k-2} \frac{\pi}{8} \right].$$

Changing the order of summation and separating the $k = 2$ (\sum_3) and $k > 2$ (\sum_4) cases yield

$$(24) \quad \sum_2 = \sum_3 + \sum_4,$$

$$(25) \quad \begin{aligned} \sum_3 &= \sum_{d=d_0+1}^N C_2 \left(\frac{1}{2}\right)^{2d-2} 4^d \\ &= 2 \left(1 - \frac{\pi}{8}\right) M(M-1)(N-d_0) \approx 1.215M(M-1)(N-d_0), \end{aligned}$$

$$(26) \quad \begin{aligned} \sum_4 &= \sum_{k=3}^M C_k 2^k \sum_{d=d_0+1}^N \left(\frac{1}{2}\right)^{d(k-2)} \approx \sum_{k=3}^M C_k 2^k \frac{(\frac{1}{2})^{(k-2)(d_0+1)}}{1 - (\frac{1}{2})^{k-2}} \\ &= 4 \sum_{k=3}^M \frac{C_k}{1 - (\frac{1}{2})^{k-2}} \left[\frac{\beta}{M}\right]^{k-2}. \end{aligned}$$

Now, let us examine the coefficients C_k :

$$(27) \quad \begin{aligned} C_k &= (-1)^{k-1} \left[\binom{M}{k} - \binom{M}{1} \cdot \binom{M-1}{k-1} + \binom{M}{2} \cdot \binom{M-2}{k-2} \frac{\pi}{8} \right] \\ &= (-1)^{k-1} \left[\binom{M}{k} - M \cdot \frac{k}{M} \cdot \binom{M}{k} + \binom{M}{2} \frac{k(k-1)}{M(M-1)} \cdot \binom{M}{k} \frac{\pi}{8} \right] \\ &= (-1)^{k-1} \binom{M}{k} \left[1 - k + \frac{k(k-1)\pi}{2 \cdot 8} \right]. \end{aligned}$$

By checking a few values of k , it can be shown that, for $k \geq 3$,

$$(28) \quad -0.137M^k \leq C_k \leq 0.027M^k.$$

Inserting (28) into (27) and accounting for the worst cases lead to

$$(29) \quad -1.1M^2 \frac{\beta}{1-\beta} \leq \sum_4 \leq 0.22M^2 \frac{\beta}{1-\beta}.$$

FIG. 6. The upper bound (UB), the sum estimate (Sum Estimate), which is also an upper bound, the empirical estimate (Empirical), and the asymptotic approximation (Asymptotic) on the number of nodes in a PM quadtree. The x and y axes correspond to the number of lines and nodes, respectively, for a tree of depth $N = 10$. Note the “rounded staircase-like” behavior of the upper bound resulting from our method of analysis, which calculates several bounds (each for different integer values of the d_0 parameter) retaining the tightest one.

Therefore, the contribution of \sum_4 to $E[S]$ is $O(M^2)$. Collecting the contributions of \sum_1 , \sum_3 , and \sum_4 , we have

$$(30) \quad E[S] = \sum_1 + \sum_3 + \sum_4 \leq 1.215M(M-1)N + M^2 \left[\frac{4}{3} \frac{1}{\beta^2} + 0.22 \frac{\beta}{1-\beta} - 1.215 \log_2 \frac{M}{\beta} \right].$$

Once again, d_0 is chosen to minimize (30), subject to the conditions that d_0 is an integer less than N and that β (as defined in (7)) is less than 1. Figure 6 shows the value of the upper bounds given by (30) (the uppermost curve) as a function of M at a maximal depth of $N = 10$, as well as the value of the sum (21) from which it is derived (second curve from the top). Recall that, here, the sum is also an upper bound itself. In addition, we also recall that the upper bounds in the figure are minimal in the sense that, for each value of M , upper bounds were calculated for every possible value of d_0 (subject to the constraint $\beta < 1$) and the minimal (tightest) upper bound was taken.

4.2.2. An asymptotic approximation. The bound developed above is valid but may not be tight. We now propose an asymptotic approximation which is expected to be more accurate when N is large. Denoting the parent node of v (as well as the corresponding region) by fv , we have

$$(31) \quad \begin{aligned} \text{Prob}(v_e|v_s) &= \text{Prob}((fv_e \text{ and } fv_s)|v_s) = \text{Prob}(fv_s|v_s)\text{Prob}(fv_e|(v_s \text{ and } fv_s)) \\ &= \gamma_d \text{Prob}(fv_e|(v_s \text{ and } fv_s)) \leq \gamma_d, \end{aligned}$$

where γ_d is the conditional probability $\text{Prob}(fv_s|v_s)$. As discussed above, the only possibility of this conditional event not happening is when exactly two lines cross both the region v and its parent region fv , and when these lines are arranged so that they do not intersect within v but do intersect within fv .

This probability does not have a simple expression, though, as it depends on the number of lines intersecting the region, which is distributed differently for different

depths. Note that, as the depth is increased, the probability that more than two lines intersect the region (i.e., $\sum_{k=3}^M p_{d,k}$ (see (4)) gets smaller and eventually becomes negligible. Quantitatively, the ratio of the probability that three or more lines intersect the region and the probability that exactly two lines intersect the region (i.e., $(\sum_{k=3}^M p_{d,k})/p_{d,2}$) tends to zero as d increases. As a result, the probability γ_d correspondingly decreases and reaches a constant asymptotic value $\gamma_\infty \approx 0.405$, which corresponds to the assumption that exactly two lines intersect the parent region f_v . (The value of γ_∞ was estimated by probabilistic simulation.)

Thus, with the asymptotic approximation, and relying on (31), we get a tighter bound on P_d :

$$(32) \quad P_d = \text{Prob}(v_s)\text{Prob}(v_e|v_s) \leq \text{Prob}(v_s)\gamma_\infty = P_d^\infty.$$

Using the bound P_d^∞ as P'_d in the sum (21) we get an asymptotic approximation, which is expected to better model the splitting process when the depth is high. Note that this approximation is not an upper bound, as the asymptotic approximation of the splitting probability holds only for large depths. Naturally, the asymptotic approximation is good when the majority of the nodes satisfies the above assumption but is expected to fail otherwise (i.e., when the maximal depth of the tree is small and the number of lines is large). In our experiments, we show that this is indeed the case (see Table 1). Note that technically the approximation is equal to the upper bound we obtained above (when we used $P'_d = \text{Prob}(v_s)$ in the sum) multiplied by a factor of γ_∞ . Figure 6 shows the value of the resulting asymptotic approximation as a function of M at a maximal depth of $N = 10$ (lowest curve).

4.2.3. Interpretation. The number of possible line pairs in the image is $\binom{M}{2}$. Multiplying this number by α yields the expected number of intersections. Approximating $\binom{M}{2}$ by $M^2/2$, we have that the expected number of vertices (line intersections) in the whole image is approximately $\frac{\pi}{16}M^2$. Considering only the dominant first term in (30), which is roughly proportional to $N \cdot M^2$, we see that the results of the analysis may be interpreted as confirming that both the number of vertices and the maximum depth of the tree impact the number of nodes necessary. The dependence of $E[S]$ on the number of vertices (i.e., the factor M^2) is intuitively clear, as each vertex will be stored in a separate node in the tree.

The dependence of $E[S]$ on the maximum depth of the tree (i.e., N) is less obvious. On the one hand, it could be said that, since our result is only an upper bound, it may be that the actual PM quadtree node count does not increase with the depth. However, it actually confirms a known result that, when the vertices of the line segments are constrained to lie on the grid points of a $2^n \times 2^n$ grid, the PM quadtree can be as deep as $4n$ [47]. In fact, for an image generated by the random line model, there is no constraint on the positions of the vertices (i.e., the intersection points), and thus the maximum decomposition depth can be even higher than $4 \cdot n$, as this depth depends on the locations of the vertices. Thus we see that this dependence is in agreement with the fact that, in the worst case, some of the vertices created by a random configuration of lines could appear in nodes at the maximum level. The linear dependence predicts that the probability of the occurrence of such “bad” line sets is not zero. This behavior was confirmed by our experiments, which found that the expected number of nodes in the PM quadtree increases linearly, but very slowly, with depth (see subsection 4.6). A related result is that, in most cases, the randomly generated PM quadtree is small, but in some rare cases it can be very large.

4.3. Bucket PMR_q quadtree. A bucket PMR_q quadtree represents a collection of line segments in the plane. It partitions the plane into square blocks using the splitting rule that stipulates that a block is split if both the depth of its corresponding node is less than N and more than q line segments pass through the block. Thus if the block contains q or less line segments, then it is not subdivided further and its corresponding node is a leaf. Otherwise, it is subdivided and its corresponding node has four children (see Figure 2(d)).

Note that if the expected degree of a vertex v is k , then choosing $q < k$ results in splitting the node containing v to the maximal depth. Observe that for the random image model, the degree of every vertex is 4. Thus, using a Bucket PMR_q quadtree, with $q < 4$ is not recommended. Nevertheless, for the sake of completeness, we briefly comment on these special cases below.

The Bucket PMR_0 quadtree is an MX quadtree. For the Bucket PMR_1 quadtree,

$$(33) \quad P_d < \text{Prob}(v_s) = 1 - p_{d,0} - p_{d,1}.$$

Observe that $\text{Prob}(v_e|v_s) = 1$ for all Bucket PMR quadtrees. For the Bucket PMR_2 quadtree,

$$(34) \quad P_d < \text{Prob}(v_s) = 1 - p_{d,0} - p_{d,1} - (1 - \alpha) \cdot p_{d,2}.$$

For the Bucket PMR_3 quadtree, the splitting probability is the same as in (34) with the subtraction of a term corresponding to the small probability that three line segments intersect the region, but not each other. Thus, the splitting probabilities for $q = 3$ satisfy

$$(35) \quad P_d < \text{Prob}(v_s) < 1 - p_{d,0} - p_{d,1} - (1 - \alpha) \cdot p_{d,2}$$

and are assumed to be very close to its bound.

For a Bucket PMR_2 quadtree, it is clear that the splitting probability is identical to that of the PM quadtree, apart from changing a multiplicative constant from α to $1 - \alpha$. Therefore, the expected number of nodes is given by an expression similar to (30). The same considerations hold for the Bucket PMR_3 quadtree.

While it is less obvious, the Bucket PMR_1 quadtree behaves very similarly to the PM quadtree as well. This is apparent by observing that the term $\sum 3$ (25), which dominates the number of nodes in the PM quadtree, grows by a factor of $1/(1 - \pi/8)$ if the split probability (33) is used.

The situation, however, changes dramatically when considering bucket PMR_q quadtrees with values of q equal to 4 and higher. For $q = 4$, the splitting probability satisfies

$$(36) \quad P_d < \text{Prob}(v_s) = 1 - p_{d,0} - p_{d,1} - p_{d,2}.$$

The probability P_d is smaller than the right side of the above inequality because the probabilities of some additional events that imply the absence of splitting are not included. For example, if three or four lines intersect the region, but not each other, then the region is not split. The inclusion of these contributions is complicated and is not needed for computing an upper bound. Using the upper bound $P'_d = \text{Prob}(v_s)$ in (36) as the probability P_d , and the same techniques as in subsection 4.2, we define β and d_0 as in (7) and decompose the sum corresponding to $E[S]$ into two sums, \sum_1

from (22) and \sum_2 from (23). Here, however,

$$\begin{aligned}
(37) \quad C_k &= (-1)^{k-1} \left[\binom{M}{k} - \binom{M}{1} \cdot \binom{M-1}{k-1} + \binom{M}{2} \cdot \binom{M-2}{k-2} \right] \\
&= (-1)^{k-1} \left[\binom{M}{k} - \binom{M}{1} \cdot \frac{k}{M} \cdot \binom{M}{k} + \binom{M}{2} \cdot \frac{k(k-1)}{M(M-1)} \cdot \binom{M}{k} \right] \\
&= (-1)^{k-1} \binom{M}{k} \left[\frac{(k-1)(k-2)}{2} \right],
\end{aligned}$$

implying that $C_2 = 0$ and that

$$(38) \quad -\frac{1}{8}M^k \leq C_k \leq \frac{1}{6}M^k.$$

The bounds (38) are derived by evaluating C_k for several values of k and by observing that $|C_k|$ decreases with k . The fact that $C_2 = 0$ is important, as it means that \sum_3 is 0, and thus once we bound the finite geometric series in $\frac{1}{2}$ by the infinite geometric series, the expected number of nodes will no longer depend on N . Now,

$$(39) \quad \sum_4 = \sum_{k=3}^M C_k 2^k \sum_{d=d_0+1}^N \left(\frac{1}{2}\right)^{d(k-2)} \approx \sum_{k=3}^M C_k 2^k \frac{\left(\frac{1}{2}\right)^{(k-2)(d_0+1)}}{1 - \left(\frac{1}{2}\right)^{k-2}}$$

$$(40) \quad = 4 \sum_{k=3}^M \frac{C_k}{1 - \left(\frac{1}{2}\right)^{k-2}} \left[\frac{\beta}{M}\right]^{k-2} \leq \frac{4}{3}M^2 \frac{\beta}{1 - \beta}.$$

This derivation is based on bounding the finite geometric progression with the corresponding infinite progression, expressing d_0 in terms of β and M , and performing some additional arithmetic manipulations. Therefore,

$$(41) \quad E[S] \leq \frac{4}{3}M^2 \left[\frac{1}{\beta^2} + \frac{\beta}{1 - \beta} \right].$$

Figure 7 shows the value of the upper bound given by (41) (uppermost curve) as a function of M at a maximal depth of $N = 10$ as well as the value given by the corresponding sum (middle curve). Again, we recall that the upper bounds in the figure are minimal in the sense that, for each value of M , upper bounds were calculated for every possible value of d_0 (subject to the constraint $\beta < 1$) and the minimal (tightest) upper bound was chosen. To get a clearer interpretation of the bound, select a specific value for β , say, 0.75 (which corresponds to sets of 6, 12, 24, ... lines and to d_0 values of 3, 4, 5, ..., respectively). Then, we get

$$(42) \quad E[S] \leq 6.37M^2 \quad (q = 4).$$

The bound (42) means that for a bucket PMR_q quadtrees (with $q = 4$) the expected number of nodes is proportional to the expected number of intersection points (approximately $\frac{\pi M^2}{16}$ as derived in subsection 4.2.2), henceforth referred to as *vertices*, and does not depend on the maximal depth N . Therefore, if the maximal depth is large enough, the subdivision stops before reaching the maximal depth almost everywhere. Alternatively, the $O(M^2)$ intersection points result in $O(M^2)$ line segments. Thus, an equally powerful characterization of this result is that the number of nodes is proportional to the number of line segments and does not depend on the maximal

FIG. 7. The upper bound (UB), the sum estimate (Sum Estimate), and the empirical estimate (Empirical) on the number of nodes necessary to store a PMR_4 quadtree. The x and y axes correspond to the number of lines and nodes, respectively, for a tree of depth $N = 10$. Note the “rounded staircase-like” behavior of the upper bound resulting from our method of analysis, which calculates several bounds (each for different integer values of the d_0 parameter) retaining the tightest one.

depth of the tree. Higher values of q require a more complicated analysis, as the number of line segments created by the intersection of more than two lines is a random variable of more complicated statistics. In particular, we have more possibilities to consider than just the two events corresponding to the intersection or nonintersection of two lines. It is clear, however, that the splitting probability decreases as q increases, and therefore, for $q \geq 4$ the bound (41) still holds. Note that it is not possible to reduce this bound by much (even for higher values of q) since the bound on the first term, \sum_1 , remains $\frac{4}{3} \frac{M^2}{\beta^2} < \frac{4}{3} M^2$.

Regions that contain a vertex (resulting from the intersection of lines) are split if the number of line segments that are incident at this vertex is higher than q . This explains the significant change in the quadtree size when $q \geq 4$. For our random image model, all vertices have four line segments incident at them, and therefore the regions in a Bucket PMR_2 quadtree must split until the maximal depth is achieved. On the other hand, in the Bucket PMR_4 quadtree (and for values of $q \geq 4$), regions that contain a single vertex are not split, which leads to a tree whose size is independent of the maximal depth N .

4.4. PMR_q quadtree. A PMR_q quadtree represents a collection of line segments in the plane. It depends on a parameter q and is created as a dynamic result of a sequence of insertion of line segments using the splitting rule that says a block b is split once, and only once, if b is intersected by the new line segment and if b already contains q or more line segments. Thus the block is subdivided at most once when a new line segment, which intersects it, enters the structure. Clearly, this may not be enough to ensure that the number of line segments stored in each leaf node is q or less.

Note that since the PMR_q quadtree depends on the order in which the line segments are inserted into it, we must specify some order. We assume that the M infinite lines are generated in one step, followed by the insertion of the $O(M^2)$ line segments in an arbitrary order. For the case that $q \geq 4$, we may use the upper bound (41) that we obtained on the number of nodes in a bucket PMR_q quadtree to also bound the number of nodes in a PMR_q quadtree. First, note that the node set associated

with the Bucket PMR_q quadtree is a superset of the node set associated with the PMR_q quadtree, provided that the maximal depth of the tree is high enough, since the number of times a node in the Bucket PMR_q quadtree is split upon insertion is at least as large as the number of times it is split in the PMR_q quadtree. Second, observe that the maximal depth of the PMR_q quadtree for i line segments is $i - q$, as the first split happens when the $q + 1$ st line segment is inserted. Therefore, the PMR_q quadtree representation of the $O(M^2)$ line segments created by the M infinite random lines is of a maximal finite depth $O(M^2) - q$. Thus, we can construct a bucket PMR_q quadtree with a maximal depth $N = M^2$ so that, regardless of the order in which the $O(M^2)$ line segments are inserted into the PMR_q quadtree t , the nodes in t will always be a subset of the nodes in the bucket PMR_q quadtree v for the $O(M^2)$ line segments. Recall that the bound on the number of nodes in a bucket PMR_q quadtree that we obtained was independent of the depth N of the bucket PMR_q quadtree as we let N go to infinity when we computed \sum_4 in (40). Thus the bound that we obtained in (41) is also good for bucket PMR_q quadtrees of any depth. Therefore, it is also applicable to PMR_q quadtrees subject to $q \geq 4$.

Unfortunately, we cannot get a reasonable bound using this method for $q < 4$. For $q = 2$, for example, recall that the number of nodes in the Bucket PMR_2 quadtree is similar to this number in the PM quadtree, which is given by (30). Therefore, the upper bound on the number of nodes in the Bucket PMR_2 quadtree is linear in the maximum depth. The guarantee that the Bucket PMR_2 quadtree is a superset of the PMR_2 quadtree requires setting the maximal depth of the Bucket PMR_2 quadtree higher than the maximal of the PMR_2 quadtree. The latter, however, may be as high as $O(M^2)$, where M is the number of infinite random lines, thus giving an unrealistically high upper bound. Therefore, obtaining an upper bound on the number of nodes in a PMR_2 quadtree is an issue left for future research, although, as mentioned before, the case of $q \geq 4$ is more relevant from a practical standpoint, as we do not want the common situation of a road junction (i.e., when four line segments meet at a point) to cause an arbitrarily large amount of splitting. The same considerations apply for $q = 1$ and $q = 3$.

4.5. A general discussion of the bounds. The bounds developed here lead to the following asymptotic results on the expected number of nodes as a function of the number of random lines M and the level of permitted subdivision N :

$$(43) \quad \begin{aligned} \text{MX quadtree } E[S] &= O(M \cdot 2^N), \\ \text{PM quadtree } E[S] &= O(M^2 \cdot N), \\ \text{PMR}_q \text{ quadtree } E[S] &= O(M^2) \quad (q \geq 4), \\ \text{bucket PMR}_q \text{ quadtree } E[S] &= O(M^2 \cdot N) \quad (q = 2), \\ \text{bucket PMR}_q \text{ quadtree } E[S] &= O(M^2) \quad (q \geq 4). \end{aligned}$$

These results were obtained by summing the expected number of nodes at each level of the hierarchical structures. The differences are due to the different rates at which the splitting probabilities decrease as the depth increases. For example, for the MX quadtree, the probability that a node splits decreases with the depth, but does not decrease fast enough, resulting in a tree of exponential size. On the other hand, for the PM quadtree, the splitting probability decreases at a fast enough rate to offset the exponential growth of the tree, thereby resulting in a tree whose size is proportional to its depth. The same holds for the Bucket PMR_2 quadtree. For $q \geq 4$, for both the PMR_q quadtree and the bucket PMR_q quadtree, the splitting probability

decreases at an even faster rate, thereby implying that the expected number of nodes at each level decreases exponentially with the depth and that the sum converges (i.e., is independent of the depth of the tree).

The main conclusions that can be drawn from these results are as follows. For the MX quadtree, the number of nodes is proportional to the total length of the line segments. This conclusion confirms a similar result obtained by Hunter [22] and Hunter and Steiglitz [23]. For both the PM and Bucket PMR_2 quadtrees, the number of nodes can be interpreted as being proportional to the product of the number of intersections among the lines (i.e., the original lines in the random image model or, alternatively, the vertices of the resulting line segments) and the maximal depth of the tree. For both the PMR_q quadtree and the Bucket PMR_q quadtree with node capacities $q \geq 4$, the number of nodes is proportional to the number of line segments (recall that there are $O(M^2)$ intersection points for the M lines, resulting in $O(M^2)$ line segments). It also appears that, for the PMR_q ($q \geq 4$) quadtree, almost everywhere, the subdivision stops before the maximal depth, provided, of course, that the density of the lines (i.e., the M random lines) does not make the tree almost full.

To get the actual values of the bounds (in contrast to the orders of magnitude summarized above) we use the exact upper bounds as given in (15), (30), and (41), which depend on a parameter β . It is worth re-emphasizing that the values d_0 and β are not a part of the random image model. They are just parameters used to simplify the expression of the bounds. In order to apply these bounds, it is required to choose a value of β which minimizes them while satisfying relation (7) (with d_0 being an integer bounded by N). Fixing the value of β at some constant (e.g., 0.75) gives a bound, which may not be the tightest but is still useful for understanding the behavior of the size of the data structure. From a strict theoretical standpoint, such an arbitrary choice of a value for β is not justified because it usually implies a noninteger value for d_0 . Note also that the upper bounds contain negative terms which reduce the bounds and make them tighter. These negative terms compensate for nodes which are counted twice in other (positive) terms. For example, nodes in the PM quadtree at a depth less than d_0 are accounted for both by the $\sum_1 = \frac{4}{3} \frac{M^2}{\beta^2}$ term and also by the $M^2 \cdot N$ term. The negative term $-M^2 \log_2 \frac{M}{\beta} \approx -M^2 d_0$ compensates for this situation. Note also that these bounds hold for all values of M and N . However, they become trivial when $M \geq 2^N$.

The bounds in this paper were computed under the assumption of a particular image model. We conjecture that the results apply also to more general images. In section 5 we examine several methods for inferring the size of quadtrees that represent real maps and test them experimentally. In essence, we characterize the map by some property, which may be the total length of its constituent line segments, the number of vertices, etc., and use this property to specify a class of random images which share the same property (in an expected value sense). Next, we conjecture that the number of quadtree nodes required to represent the real map is equal to the expected number of nodes required to represent a random map from that class.

4.6. Some experimental results for instances of the random model. We conducted several experiments with synthetic and real data. In this section we describe the tests that were made with synthetic data. They were aimed at determining how close the upper and lower bounds on the expected storage costs come to the actual storage costs when using random data. Section 5 describes the results of tests with real data.

In these experiments, we built the MX, PM, and Bucket PMR_4 quadtrees of

several depths N , using random synthetic data created by the random image model described in section 3. For each case, several instances of each random image were created and the average quadtree size was calculated. The results are summarized in Table 1 (see also Figure 5). They usually agree with the analytical predictions, and, in particular, the nonasymptotic bounds for all of the quadtree variants always hold.

We also evaluated the expression (3) for the values of the number of lines M and the maximum depth N of the quadtrees. We found that while this sum closely approximates the actual expected number of nodes for the MX quadtree, it only bounds the number of nodes for the PM and the Bucket PMR_4 quadtrees. This is expected because, for these trees, the P'_d expressions, which we used, are bounds of the probabilities and not the probabilities themselves. The PM quadtree asymptotic approximation, which corrects every bound by the γ_∞ factor (see subsection 4.2.2), yields a more accurate estimate for trees with a high depth and a low number of lines (as expected). For the Bucket PMR_4 quadtree, the sum is a more accurate estimate (as it errs only by about 25%).

The upper bounds obtained for the MX quadtree were consistently very close to the observed node counts. In contrast, the upper bounds for the PM and Bucket PMR_4 quadtrees consistently exceed the observed node counts by factors as high as 3 and 7, respectively. This difference can be attributed to the simplifications made in the bound derivation process. As mentioned above, we did not attach much significance to obtaining tighter bounds, as they are not used for predictions but, instead, only for performing a qualitative comparison between the different quadtree representations.

We also conducted some experiments to test the performance of the PM quadtree under “asymptotic” conditions—that is, when N is relatively large and M is not too high. These experiments were undertaken to determine whether or not the PM quadtree grows linearly with the maximal depth N (like the upper bound that we found). The results were still inconclusive; when examining the number of nodes, we found that the average number (over 1000 random trials) increases slowly but steadily with maximal depth, but the high variance still does not allow us to conduct a decisive statistical test. We also examined histograms of the actual maximal depth

TABLE 2

as a function of the allowed maximal depth. Here we found that even for depths as large as 30 we still had trials (and corresponding random collections of 25 lines), where the PM quadtree had nodes at this maximal depth. In contrast, this never happened for the PMR quadtree.

5. Predicting storage requirements for real data. In this section we show that the expected storage predictions, derived for the random image model, are also useful when real data is considered.

We conducted our tests using real data corresponding to U.S. city and county road maps that are part of the TIGER files used by the U.S. Census Bureau (see Figure 8). We used maps ranging from a small map having only 585 road segments (Falls Church, Virginia) to the largest map having 39,719 segments (Montgomery County, Maryland). The actual data for the maps, such as the depth (N), number of vertices, segments, nonshape vertices (abbreviated *NSV* and described below), the normalized length (abbreviated *NormL* and equal to the total length of the line segments divided by 2^N), and the number of nodes in the MX, PM, and Bucket PMR₄ quadtrees, are given in Table 2.

Our approach to applying the expected node count predictions to a real map r depends on finding, for each map r , a class c of a random line image which shares some property with r . The expected number of nodes required to represent a random image from class c is taken to be the estimate for the number of nodes required to represent the map r .

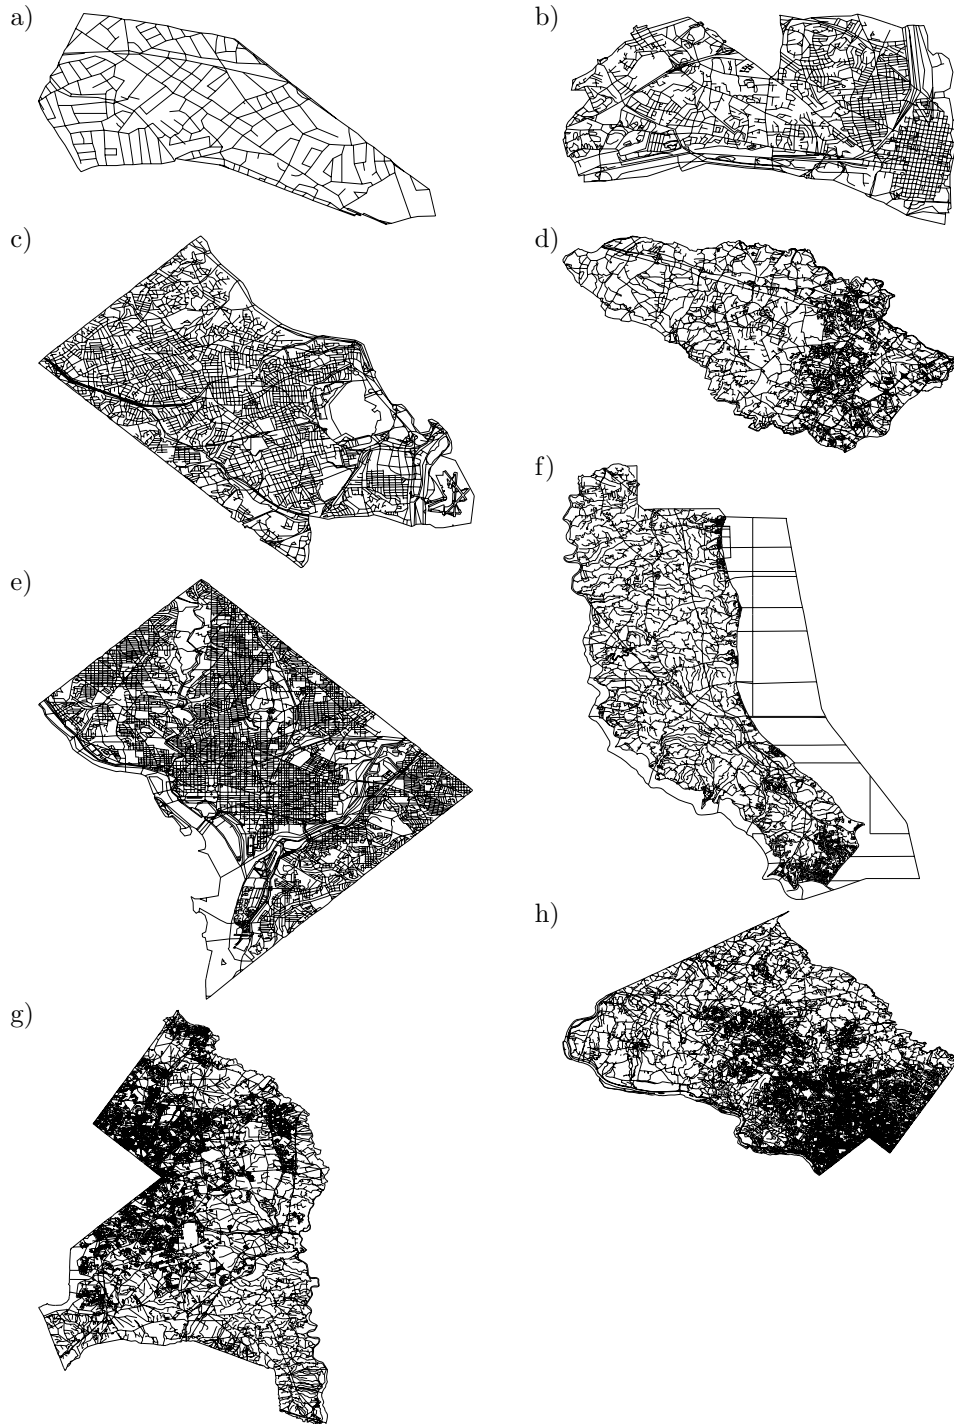

FIG. 8. Eight maps used to test the estimates on the number of nodes in the representing quadtrees.

In most cases, the equivalent random image to a given map r is specified, as in section 3, by the effective number of lines \hat{M} , which is inferred, in a number of alternative ways (termed *estimators* and described below), from r . Another degree of freedom in the specification of the equivalent random image is gained if we account for sparse or empty image parts. Therefore, the equivalent random image is specified in two stages. First, a random image is specified by \hat{M} . Second, only a fraction of this image is retained, while the rest is considered to be empty. A normalization factor is inferred from the image r and specifies the fraction that is retained. Thus, we assume that the number of nodes is directly proportional to the portion of the area that is nonempty, and we use this normalization factor to obtain the number of nodes in the equivalent class. For most of the estimators, no normalization is done and the images of the equivalent class are just random images resulting from the random image model defined in section 3. The parameters specifying the class of random images are estimated from other parameter values of the real map r such as the total length L_{map} , the total number of vertices V_{map} , and the total number of segments S_{map} .

The first estimator that we consider is termed an *L-based estimator*. This estimator is based on measuring the total length L_{map} of the line segments. Recall that, for the random images created by the random image model, the expected total line length $E[L]$ is $\pi/4 \cdot M \cdot 2^N$. This is the result of (16), which follows directly from Theorem GP2. Therefore, the number of lines in every one of the random images which share the “expected line length” property with the given map is estimated by $\hat{M} = (L_{map}/2^N) \cdot (4/\pi)$. For this estimator, there is no area normalization (that is, the equivalent random image is assumed not to contain empty regions). For example, the total length of the line segments in the smallest map (i.e., Falls Church, Virginia shown in Figure 8(a)) that we used is $16.77 \cdot 2^N$, which yields $\hat{M} \approx 21$ (the length is normalized relative to the side of the map). Note that this has the effect of converting the line segments of the test image to a different number of infinite lines, the intersection of which, with the space in which they are embedded, has the same total length (in an expected value sense).

The second estimator that we consider is termed a *V-based estimator*. It uses the number of vertices V_{map} in the map to estimate the effective number of lines \hat{M} by treating all vertices as intersection points between random lines. Recalling that the expected number of intersection points between the lines of the random image model is $E[V] = \pi M^2/16$, we have $\hat{M} = \sqrt{16V_{map}/\pi}$. Here, again as in the case of the L-based estimator, no area normalization is performed. Note, however, that most vertices (termed *shape points* [7]) in a typical map image are the results of a piecewise polygonal approximation of a curve, thereby implying that only two line segments meet at them. This is in contrast to the intersection points in a random image, which are true intersections (i.e., they correspond to the intersections of pairs of random lines). A simple heuristic, which we use here, deletes these degree-2 vertices from the total vertex count and yields the *NSV estimator*. Clearly, there are many cases for which this heuristic is nonapplicable. For example, we could not apply it to a non-self-intersecting curve (e.g., a spiral), as vertex deletion would predict that the representation requires just a single node (which is clearly erroneous).

The third estimator that we consider is termed an *S-based estimator*. Like the L-based and V-based estimators, it is based on replacing the given map with a random line image of the same size, and no area normalization is performed. Again, we calculate an effective number of random lines \hat{M} , but this time it is based on the

number of line segments. We assume that each vertex corresponds to the intersection of two random lines, and hence results in four line segments (also termed *edges* or *segments*). Therefore, each vertex has degree 4. Each line segment is incident at two vertices. This is approximately true, as only a small fraction of the line segments (i.e., $2M$) are incident at just one vertex, as the other endpoint of the line is on the boundary of the image. Therefore, set the number of incidences (i.e., the sum of the degrees of the vertices), which is four times the expected number of vertices (i.e., $4 \cdot \pi M^2/16$), to two times the number of edges (i.e., $2 \cdot S_{map}$) and solve for \hat{M} , which is equal to $\sqrt{8S_{map}/\pi}$.

The fourth estimator that we consider is termed a *d-based estimator*. This estimator is based on replacing the given map with a (usually smaller) random line image having the same number of vertices and average line segment length (termed *density* here). The expected segment length in the random line image is crudely approximated as the ratio between the expected length of the part of a random line included in the image and the expected number of vertices on the line. Using Theorem GP2 from geometric probability, we know that the expected length of the part of a random line included in the image is $\pi \cdot 2^N/4$, while the expected number of vertices in the map is $\pi M^2/16$. Since each vertex corresponds to the intersection of two lines and hence lies on two lines, the expected number of vertices per line is $(\pi M^2/16)/(2M) = \pi M/8$. Therefore, the expected segment length is $(\pi \cdot 2^N/4)/(\pi M/8) = 2 \cdot 2^N/M$. Equating this expected segment length to the average segment length of the given map, calculated simply as the ratio between the total length L_{map} and the number of segments S_{map} (i.e., L_{map}/S_{map}), and solving for M yield an estimate \hat{M} on the effective number of lines, which is equal to $2 \cdot S_{map} \cdot 2^N/L_{map}$.

Unlike instances of the random image model, real maps tend to be highly nonuniform, and, in particular, to have a large proportion of short segments and large empty “white” regions. This implies that the value of the effective number of lines \hat{M} calculated for the d-based estimator above leads to node number estimates which are much higher than the actual ones. Therefore, we have chosen to compensate for this deviation by imposing the additional natural constraint that the total number of NSVs in the actual map is equal to the expected number of vertices in the random line images. This constraint, which was also used to obtain the effective number of lines for the V-based estimator, is now used as an area normalization factor to specify the nonuniform class of random images. In particular, every one of these images is equal to the random lines image in one region and is empty in the rest of it. The area of the “busy” part is specified to be $\frac{NSV_{map}}{(\pi \cdot M^2/16)}$ and is usually smaller than 1. Note that the expected density remains the same. Since the random image model defined in section 3 is uniform, we can assume that the expected number of nodes representing every region is proportional to its area, and thus the node count is reduced by the aforementioned factor.

In order to estimate the number of nodes in the quadtrees representing the actual maps, we round the different values of the estimate \hat{M} and insert this estimate into the basic sum (3) for the expected number of nodes together with the appropriate node splitting probability (which depends only on the quadtree type). These results are tabulated in Table 3. Notice that we do not tabulate the S-based estimator, as it is very similar to the V-based estimator, and the data bears this out. In particular, the S-based estimator relies on the number of line segments. This number is related to the number of vertices, which is the basis of the V-based estimator. Upper bounds, which have a more compact form and do not require the evaluation of a sum, may be

TABLE 3

Predicted storage requirements for the MX, PM, and bucket PMR₄ quadtrees using the three estimators. The numbers given in the table are the ratios between the predicted requirements using the estimator and the actual ones given in Table 2.

obtained by inserting the rounded estimate \hat{M} directly into the upper bounds (15), (30), and (41), although we do not tabulate them here.

The particular estimators described have a number of inherent limitations. For example, suppose that the scale of the line segments (roads) of the map is lowered by a factor of 2 so that all the roads are totally embedded in the NW quadrant of the original map image, while the rest of the scaled map image is empty. In this case, if the depth is high enough, it is likely that the number of leaf nodes in PM and Bucket PMR₄ quadtrees will stay the same, while that in the MX quadtree will decrease significantly. However, the total length of the lines in the quadtree of the scaled-down map will be off by a factor of 2, thereby implying that the L-based estimator is likely to be inaccurate for the PM and bucket PMR₄ quadtrees. This is most relevant for maps containing many line segments in a small area and appears to dampen the suitability of the L-based estimator for arbitrary images, although it does seem to work for images that span most of the space in which they are embedded.

From our experiments, the L-based estimator seems to perform best for the MX quadtrees, while the V-based estimator seems to work best for the PM and PMR₄ quadtrees. We constructed the d-based estimator to try to improve further on the estimates for the PM and PMR₄ quadtrees but found that it does not improve on the V-based estimator, and sometimes even does worse. The good performance of the L-based estimator for the MX quadtree was not surprising, as it confirms the original result of the analysis of Hunter [22] and Hunter and Steiglitz [23], who found a propor-

tionality to the perimeter of the image. The correlation between the estimated and actual values that we observed is noteworthy, considering that the number of nodes in the maps ranged between 77,000 and 38 million (i.e., a factor of 500). Nevertheless, we believe that a more detailed examination of the differences between the actual and predicted storage requirements, as well as other properties, of hierarchical spatial data structures is an extremely interesting open problem.

We were also interested in testing the validity of the asymptotic results given in (43) on the expected number of nodes as a function of the number of line segments in real images and the level of permitted subdivision. To do that, we interpret these results in terms of an actual map parameter—for example, by replacing the number of infinite lines M with its estimate, as done above. For example, using the S-based estimator indicates that the size of the PMR quadtree should be proportional to the number of map segments and independent of the maximal depth (as long as both are large). Note that this expectation is verified (or refuted) only on the basis of the real map data and not on the basis of any modeling assumptions, although we were indeed led to it by the random line model analysis.

We first examine the MX quadtree. Figure 9 shows the ratios of the node count to the length of a side of the image (i.e., 2^N) as a function of the depth (i.e., N) for the different maps, which are close to being constant (i.e., horizontal lines) as expected. Figure 10 shows the ratios of the node count to the square root of the number of line segments as a function of the number of line segments (i.e., M^2) for the different depths. These curves are close to being constant (i.e., horizontal lines) when the number of line segments is large enough. This is expected when the S-estimator (which stipulates that the number of nodes is proportional to the square root of the number of segments) is used for M and implies that the asymptotic estimate is useful for predicting the quadtree size for a wide range of maps. We used a logarithmic scale in Figure 10 to illustrate a similar relative deviation in the ratios for the different depths as the size of the data increases.

Next, we examine the PM quadtree. Figures 11 and 12 show the ratio of the node count to the NSVs and to the number of line segments (i.e., M^2), respectively, as a function of the depth for the different maps, which are close to being constant (i.e., horizontal lines). This means that the node count is independent of the depth. This is contrary to the prediction of the asymptotic analysis and to the existing worst cases that arise when the vertices of the line segments are constrained to lie on grid points [47]. This difference may be explained by observing that, for images generated using the random image model, factors that lead to the maximum depth (e.g., two vertices or nonintersecting lines being very close to each other, or a vertex and a line being very close [49]) are more likely to arise. For road networks, on the other hand, it is unlikely that a pair of intersections 10 cm from each other will be specified. In such a case, these intersections will be merged to a higher degree vertex, which is not split for the PM quadtree. Thus, it seems that there is room for a better model for road networks (and maybe for other types of real data), which takes such merging processes into account. This subject is left for future research.

Finally, we examine the PMR₄ quadtree. Figures 13 and 14 show the ratio of the node count to the NSVs and to the number of line segments (i.e., M^2), respectively, as a function of the depth for the different maps, which we expect to be constant (i.e., horizontal lines), especially for the larger maps. At lower depths, the ratios increase with depth for a particular map since the segment counts are constant and the number of nodes does increase with depth until converging once the decomposition rule can

FIG. 9. Ratio of MX quadtree nodes to side length.

no longer be applied. It is interesting to observe that the lines in Figures 13 and 14 are not quite horizontal (i.e., representing a constant function) in the sense that they have a small positive slope. This is because the line segments in the maps are not really formed by random infinite lines. Thus, it is not true that the probability that more than two infinite lines intersect at a point is zero. In particular, we find that in our maps there are instances when more than four line segments meet at a point, and hence the number of nodes really grows linearly with depth (since the decomposition rule is still applicable, and, in fact, will always be applicable in this case), although this growth is not substantial in our graphs at higher depths. Experiments with larger values of q verified that the number of nodes does in fact converge as the depth increases. This can be seen in Figure 15 for $q = 12$. Figure 5 shows the ratio of the node count to the segment count (i.e., M^2) versus the segment count at depth 16 for $q = 4$ and $q = 12$. The ratios are all within 6% of their average value. Figure 5 also reveals a general trend in which the ratios decrease as the maps get larger. We used a logarithmic scale to illustrate a similar relative deviation in the ratios for the different values of q as the size of the maps increases.

To more clearly see the effect of the existence of points, where more than four line segments intersect, consider the map of Washington, D.C. (Figure 8). From Figure 11, we can see that the number of nodes increases by a ratio of about 7:4 when the depth is changed from 10 to 40. From Table 2, we can see that this amounts to an increase of about $(7/4 - 1) \cdot 35,000 = 26,250$ vertices. Now, let W be the number of

FIG. 13. Ratio of PMR quadtree nodes to NSV, $q = 4$.

FIG. 14. Ratio of PMR quadtree nodes to segment count, $q = 4$.

FIG. 15. Ratio of PMR quadtree nodes to segment count, $q = 12$.

FIG. 16. Ratio of PMR quadtree nodes to segment count versus segment count at a depth of 16.

vertices associated with the intersection of more than four roads. Each such vertex leads to a split of its corresponding region until the maximal depth is reached. At every depth, four nodes are added. Therefore, when the depth is changed from 10 to 40, the number of nodes that are added is $W \cdot (40 - 10) \cdot 4 = 26,250$, implying that the number of such high degree vertices is about 220. Given that the Washington, D.C. map has 8805 NSVs (i.e., vertices of degree greater than 20), the fraction of such high degree vertices is about $220/8805 = 0.025$. While this number is larger than 0 (the value predicted by our model), it does not appear to change the predictions by much, as is apparent from the relatively modest increase in the node count as the depth increases. Note that for the other maps considered the relative increase in the node count, as well as the fraction of high degree vertices, is much lower. Observe also that the range of maximum tree depths considered in these graphs is much larger than in any reasonable application. In particular, if the original map is embedded in a 100×100 km square area, then a maximum depth of 40 amounts to a resolution of 0.1 micron. Therefore, for a more reasonable maximum depth, the variation in the predicted node count will be much lower even if, say, 0.025 of the vertices have high degree.

6. Concluding remarks. The analysis of the space requirements of a number of trie-based hierarchical geometric data structures for storing large collections of line segments was investigated using a random image model. An appropriate model was developed for each of these structures and estimates of $E[S]$, the expected number of nodes, were found for them. Future work includes the investigation of the use of these estimates in a cost model by a query optimizer to generate an appropriate query evaluation plan in a spatial database application. The analysis presented here is also of interest because it uses a detailed explicit model of the image, instead of relying on modeling the branching process represented by the tree and leaving the underlying image unspecified. The behavior of these expected values is intuitively and concisely expressed by analytic upper and lower bounds. Other directions for future research include the application of the geometric probability approach to additional data types besides line segments (e.g., points, polygons, surfaces, solids, etc.), as well as alternative trie-based spatial data structures.

We have demonstrated that these estimates, derived for a particular random image model, are applicable to real data. Specifically, in the case of line map images, we provided estimators which are based on simple characterizations of the map data, and which enabled us to successfully apply the results of the analytic model to real data and to obtain reasonably accurate and useful results. This was verified, however, only for map data, and characterizing collections of other types of line segments, or even more general types of spatial information, is still an open problem, and thus a subject for further research.

Our results can be used to justify claims on the qualitative differences between the different alternative spatial data structures. For example, we showed that the bucket (and conventional) PMR_q quadtree for $q \geq 4$ is superior to the PM quadtree in terms of the number of nodes that are required. The problem with the PM quadtree is that, although its behavior is usually acceptable, there are cases in which it requires much space due to certain point and line configurations. This follows from our analysis and simulations, as well as from confirming earlier observations on the possible worst-case behavior of the PM quadtree [47].

Perhaps our most important result is showing that the space requirements of the Bucket PMR_q and PMR_q ($q \geq 4$) quadtrees are asymptotically proportional to the number of line segments. This was shown theoretically for a random image model and was also found to hold for random data and real map data. This is quite significant as it enables us to predict the number of nodes required by this representation, and, most important, to show that it is independent of the maximum depth of the tree. It is thus not surprising that the PMR_q quadtree is useful in experimental systems (e.g., QUILT [53]) as well as commercial systems (e.g., United Parcel Service (UPS) [4]).

Acknowledgments. We thank S. K. Bhaskar and Gary D. Knott for suggestions about the evaluation of the sums.

HOLOGRAPHIC PROOFS AND DERANDOMIZATION*

DIETER VAN MELKEBEEK[†] AND RAHUL SANTHANAM[‡]

Abstract. We derive a stronger consequence of EXP (deterministic exponential time) having polynomial-size circuits than was known previously, namely that for each language $L \in \mathcal{P}$ (polynomial time), and for each efficiently decidable error-correcting code E having nontrivial relative distance, there is a simulation of L in Merlin-Arthur polylogarithmic time that fools all deterministic polynomial-time adversaries for inputs that are codewords of E . Using the connection between circuit lower bounds and derandomization, we obtain uniform assumptions for derandomizing BPP (probabilistic polynomial time). Our results strengthen the space-randomness tradeoffs of Sipser [*J. Comput. System Sci.*, 36 (1988), pp. 379–383], Nisan and Wigderson [*J. Comput. System Sci.*, 49 (1994), pp. 149–167], and Lu [*Comput. Complexity*, 10 (2001), pp. 247–259].

We also consider a more quantitative notion of simulation, where the measure of success of the simulation is the fraction of inputs of a given length on which the simulation works. Among other results, we show that if there is no polynomial-time bound t such that \mathcal{P} can be simulated well by Merlin-Arthur machines operating in time t , then for any $\epsilon > 0$ there is a simulation of BPP in \mathcal{P} that works for all but 2^{n^ϵ} inputs of length n . This is a uniform strengthening of a recent result of Goldreich and Wigderson [*Proceedings of the 6th International Workshop on Randomization and Approximation Techniques in Computer Science*, 2002, pp. 209–223].

Finally, we give an unconditional simulation of multitape Turing machines operating in probabilistic time t by Turing machines operating in deterministic time $o(2^t)$. We show similar results for randomized NC^1 circuits.

Our proofs are based on a combination of techniques in the theory of derandomization with results on holographic proofs.

1. Introduction. The power of randomness is a central issue in the theory of computing. Although the use of random bits seems to simplify a lot of computational tasks, their actual computational power remains open. We have techniques that allow us to eliminate the randomness from many important randomized algorithms at a small cost. Just recently, a deterministic polynomial-time algorithm was discovered for the “prime” example of a computational problem where randomness seemed to provide a superpolynomial speed-up [AKS02]. For arbitrary (bounded-error) randomized computations running in time t , we have strong indications that they can be simulated deterministically in time $t^{O(1)}$. However, we have not even been able to prove the existence of a deterministic simulation that runs in time $o(2^t)$.

The standard approach for deterministic simulations uses the notion of a pseudorandom generator: an efficient deterministic procedure that expands short random seeds into longer strings such that no small circuit can distinguish the outputs of

the generator from truly random strings. Given a pseudorandom generator G that “fools” circuits of size t , and a bounded-error randomized algorithm A that can be implemented by circuits of size t , when A is run with $G(\sigma)$ on its random tape for seed σ chosen uniformly at random, the acceptance probability of A is approximately the same as when it is run with truly random bits. Thus, we obtain a deterministic simulation of A on a given input x by cycling through all short seeds σ , running A on x using $G(\sigma)$ as the random bit sequence, and outputting the majority result of these runs.

As a result of a long line of research (e.g., [Yao82, BM84, NW94, BFNW93, IW97]), we know that pseudorandom generators exist iff exponential time requires large circuits. Thus, efficient deterministic simulations of arbitrary randomized computations exist unless exponential time has small circuits. Recent work [IKW02, KI03] indicates that circuit lower bounds are also necessary for the existence of such simulations.

The connections between deterministic simulations and circuit lower bounds are a double-edged sword. On the one hand, the connections between deterministic simulations and circuit lower bounds provide strong evidence that the randomness in probabilistic polynomial-time algorithms can be eliminated, since exponential time is widely believed to require large circuits. On the other hand, proving circuit lower bounds for exponential time has been one of the most elusive pursuits in the theory of computing. A justified attempt to circumvent that problem is to relax the notion of simulation. Instead of requiring that the simulation be correct on *every* input, we may content ourselves with simulations that err on few inputs, or for which it is computationally hard to pinpoint an error [Kab01]. For example, we may be happy if no probabilistic polynomial-time machine succeeds with significant probability in generating, on input 0^n , for infinitely many n , an input of length n on which the simulation fails.¹ Borrowing terminology from cryptography, we then say that the simulation “fools” probabilistic polynomial-time adversaries. By allowing machines other than probabilistic polynomial-time ones, we obtain other notions of simulations against uniform adversaries; see section 2 for the precise definitions. The standard notion of simulation coincides with the relaxed one for nonuniform adversaries, i.e., polynomial-size circuits instead of polynomial-time probabilistic machines.

We apply these relaxed notions of simulations to inclusions of deterministic and nondeterministic time in small Merlin-Arthur classes [BM88]. In fact, we consider four types of simulations of various types of computations: (i) the traditional one against nonuniform adversaries, (ii) the recent one against uniform adversaries, (iii) a slightly stronger type of simulation than (ii) in which the adversary only needs to output a list of inputs (instead of a single input) such that the simulation fails on at least one of these inputs, and (iv) a more quantitative notion. The last notion uses the fraction of inputs on which the simulation works as the measure of success [GW02]. Whereas a simulation against a uniform adversary may err on a substantial fraction of the inputs, but these inputs are hard to generate, the quantitative type of simulation is guaranteed to work on a large fraction of the inputs, but inputs on which it errs may be easy to generate.

We establish new tradeoffs between deterministic simulations of randomized computations and very efficient Merlin-Arthur simulations of deterministic and nondeterministic time. We also prove an unconditional deterministic time $o(2^t)$ simulation of randomized computations running in time t in the multitape Turing machine model. Our results make use of the known pseudorandom generator constructions based on

¹This has been proposed as an interesting formalization of the notion of a “heuristic” [IW01].

hard functions, and of the results on holographic proofs (also known as probabilistically checkable proofs).

1.1. Simulations against uniform adversaries. Recall that efficient deterministic simulations of arbitrary randomized computations against nonuniform adversaries exist unless exponential time has small circuits. We investigate simulations of deterministic and nondeterministic time against uniform adversaries that follow from the assumption that exponential time has small circuits. Thus, we obtain tradeoffs between simulations of randomized computations against nonuniform adversaries, and simulations of deterministic and nondeterministic computations against uniform adversaries.

Following earlier work [KL82], Nisan (credited in [BFL91]) showed that if exponential time has small circuits, then it collapses to MA (Merlin-Arthur polynomial time). We show a stronger consequence by considering simulations of problems in P (deterministic polynomial time). We need to settle for simulations of promise problems in P, where the promise is that the input is a codeword of a “nice” code E , namely a polynomial-time decidable error-correcting code with relative distance at least an inverse polylogarithmic fraction of the length of the codeword.

We first give the precise statement of our result and then explain our notation.

THEOREM 1. *If $\text{EXP} \subseteq \text{SIZE}(\text{poly})$ (where EXP refers to deterministic exponential time), then for each language $L \in \text{P}$ and each nice code E , $(E, L) \in \text{quasi}_{\text{P}}\text{-MAPOLYLOG}$.*

The consequent in the statement of Theorem 1 requires some explanation. (E, L) is the promise problem consisting of the decision problem L restricted to inputs in E . MAPOLYLOG is the “scaled-down” version of MA, where the verifier has random access to the input and runs in polylogarithmic time. The “*quasi*” refers to the stronger type of simulation against an adversary that runs in P (type (iii) above). More precisely, “ $(E, L) \in \text{quasi}_{\text{P}}\text{-MAPOLYLOG}$ ” means that there exists a machine M for which no deterministic polynomial-time adversary can generate a list of inputs such that M does not behave like a Merlin-Arthur polylogarithmic time machine for L on all inputs in the list which belong to E . The inclusion $\text{EXP} \subseteq \text{MA}$ follows from the consequent of Theorem 1 and the existence of a polynomial-time computable linear nice code E by a translation argument. Thus, Theorem 1 gives a stronger consequence of the assumption that EXP has polynomial-size circuits than was known before. Similar theorems hold for PSPACE and $\text{P}^{\#\text{P}}$.

In order to prove Theorem 1, we cast Nisan’s argument as an application of the “easy witness” method [Kab01, IKW02] to holographic proofs, i.e., as a search for holographic proofs that can be described by small circuits.

Given Theorem 1, the known connections between circuit lower bounds and derandomization imply tradeoffs between efficient simulations of P that fool uniform adversaries and deterministic simulations of BPP (probabilistic polynomial time) for a range of parameters. In a seminal paper, Sipser [Sip88] showed tradeoffs between efficient simulations of P in deterministic space and derandomizations of RP (randomized polynomial time with one-sided error)—indeed, the easy witness method is implicit in [Sip88]. These results were extended by Nisan and Wigderson [NW94] and by Lu [Lu01]. Using Theorem 1, we further strengthen these tradeoffs. For example, we obtain the following corollary to Theorem 1.

COROLLARY 2. *For each language $L \in \text{P}$ and nice code E , $(E, L) \in \text{quasi}_{\text{P}}\text{-MAPOLYLOG}$, or $\text{BPP} \subseteq \text{infinitely often (i.o.) SUBEXP}$.*

Theorem 1 provides an interesting perspective on proving circuit lower bounds

for EXP. We observe that PARITY is not contained in MAPOLYLOG unconditionally. Thus P is not contained in MAPOLYLOG. Theorem 1 says that a stronger separation of P and MAPOLYLOG implies circuit lower bounds for EXP.² This opens the possibility that methods from low-level circuit complexity may be useful in this area. In fact, we apply the circuit lower bounds of Hastad for PARITY [Hås86] in a novel way to obtain a partial converse to one of our results. See section 3 for more details.

We also show tradeoffs between simulations of NP in MAPOLYLOG that fool nondeterministic adversaries, and nondeterministic simulations of MA. For technical reasons explained in section 4, we cannot use our stronger notion of simulation against uniform adversaries here but need to switch back to the weaker notion, where the adversary outputs a single output of a given length on which the simulation is supposed to fail. Among other results, we also give a different proof of the gap theorem due to Impagliazzo, Kabanets, and Wigderson [IKW02] that either $\text{NEXP} = \text{MA}$ or else $\text{MA} \subseteq i.o. [\text{NTIME}[2^{n^\epsilon}]/n^\epsilon]$ for every $\epsilon > 0$.

1.2. Quantitative simulations. A second family of results in our paper concerns a different, more quantitative notion of simulation, where the measure of success is the fraction of inputs of a given length on which the simulation works. This relates to recent work of Goldreich and Wigderson [GW02], who obtained efficient deterministic simulations of BPP that work on almost all inputs under a certain nonuniform assumption (see section 5 for the precise assumption). Their idea, in a nutshell, is to extract randomness from the *input*—most inputs are “random” enough that this can be done. By combining the easy witness method and results on holographic proofs with the idea of Goldreich and Wigderson, we derive a stronger and uniform version of their result, as follows.

THEOREM 3. *If there is no polynomially bounded t such that $\text{P} \subseteq [\text{io} - \text{corr}_{2/3}]\text{-MATIME}(t)$, then for every $\epsilon > 0$, $\text{BPP} \subseteq \text{corr}_{1-2^{n^\epsilon}/2^n}\text{P}$.*

This theorem states that if there is no fixed polynomial t such that for every language L in P there is a machine M which is a Merlin-Arthur machine for L operating in time t on at least a fraction $2/3$ of the inputs for infinitely many input lengths, then for every $\epsilon > 0$ and every language L in BPP there is a simulation of L in P which succeeds on all but 2^{n^ϵ} inputs for all input lengths.

1.3. Unconditional simulations. The standard approach to derandomization in the time-bounded setting is the construction of an efficient pseudorandom generator that fools all computations that run within time t on the model of computation under consideration. It is well known that the existence of such a pseudorandom generator $g_n : \{0, 1\}^\sigma \rightarrow \{0, 1\}^n$ (where $\sigma < n$) implies the existence of an explicit problem outside a nonuniform version of the class \mathcal{C} being derandomized, namely the problem of deciding whether a string of length $\sigma+1$ is the initial segment of a string in the range of g_n . If that problem were in the class \mathcal{C}/n , running the decision procedure with the correct advice on a random input of length $\sigma+1$ would accept with probability at most $1/2$, whereas the simulated process using the pseudorandom generator would accept with probability 1. Thus, short of establishing new lower bounds for explicit functions, one can only hope to construct pseudorandom generators that are unconditionally secure for settings where such bounds are known.

In general models of computation, only very weak lower bounds of the above type are known. On one-tape Turing machines, the strongest known is a quadratic lower

²[AG91] also considers the consequences of strong separations of P from lower-level classes. The notion of a “strong separation” there is different from ours.

bound for deciding the palindromes. Almost matching that lower bound, [INW94] managed to construct a pseudorandom generator with seed length $\sigma = \tilde{O}(\sqrt{t})$ for probabilistic one-tape Turing machine computations that run in time t . The approach of [INW94] does not yield any nontrivial results for multitape Turing machines with more than one tape. For a fixed number $k > 1$ of tapes and a fixed alphabet, the best lower bounds known are of the form cn for some constant $c > 1$, so one may hope to obtain a pseudorandom generator with seed length $\sigma = (1 - \delta)t$, where δ is a positive constant depending on the number of tapes and the alphabet size. We manage to do so. The straightforward deterministic simulation using our pseudorandom generator yields the following result.

THEOREM 4. *For any integers $k > 0$ and $\beta > 0$, there is a constant $\delta > 0$ such that for each language L accepted by a bounded-error probabilistic k -tape Turing machine with alphabet size β running in time t , $L \in \text{DTIME}(2^{(1-\delta)t})$.*

To the best of our knowledge, the fact that time t probabilistic multitape Turing machine computations can be simulated deterministically in time $o(2^t)$ is new. We also demonstrate our technique for randomized NC^1 computations.

Note that the typical constructions of pseudorandom generators [NW94, SU01] are unable to establish Theorem 4 because these constructions lose a superlinear factor in the transformation of a hard function into a pseudorandom generator, and we only have linear lower bounds to start from. Thus, we need a different angle. Our approach is inspired by the idea of Impagliazzo and Zuckerman [IZ89] to recycle random bits, and specifically by an application of this idea due to Nisan and Zuckerman [NZ96]. The latter authors considered randomized space s computations, and argued as follows. Consider the configuration C reached after processing the first $\Theta(s)$ random bits r . Since there are only $2^{O(s)}$ possible configurations C in total, we can ignore the contributions of those C 's that have probability less than $2^{-\Omega(s)}$ of occurring. For every other C , the distribution of r conditioned on reaching C has $\Omega(s)$ bits of randomness, which we can extract and feed to the randomized algorithm as the next $\Omega(s)$ (pseudo-)random bits. This way, we save a number of random bits equal to $\Omega(s)$ minus the seed length of the extractor.

The small number of reachable configurations plays a crucial role in the correctness argument. Reaching the same configuration C guarantees that the future behavior of the original machine will be the same, irrespective of the actual value of r . In our setting, we do not have strong bounds on the number of reachable configurations. However, we can bound the number of different future behaviors of a Turing machine during the next s steps. Since a Turing machine can move each of its k tape heads over at most one position per step, only $2ks$ tape cells can affect the next s steps. Thus, the number of different behaviors is bounded by $O(\alpha^{2ks})$, where α is the alphabet size of the machine. Using this bound in the argument of [NZ96] and an appropriate extractor, we obtain a simulation that runs in time polynomial in t and uses only $(1 - \delta)t$ random bits for some positive constant δ .

1.4. Organization. The rest of this paper is organized as follows. We define our main concepts in section 2. We discuss our simulations against uniform adversaries for deterministic time in section 3, and then for nondeterministic time in section 4. Next we consider the quantitative simulations in section 5, and we end with our unconditional simulation results in section 6.

2. Preliminaries. In this section, we describe the complexity classes we consider, and formally define the various types of simulation between them. We review results on pseudorandom generators and extractors, as well as on holographic proofs,

and explain how the latter will be used in combination with “nice” codes in the rest of the paper.

We will use numbered definitions for notions that originate in this paper or are not widely known, and unnumbered definitions for more conventional notions.

2.1. Complexity classes. The definitions of standard deterministic, nondeterministic, and probabilistic resource-bounded classes can be found in [BDG88] and [BDG90]. We will also need definitions of sublinear time complexity classes. These classes are defined by Turing machines with a separate index tape on which the address of an input bit can be written. Given this address, the machine can access the bit in constant time. Analogous to classes defined by polynomial-time machines, we can define DPOLYLOG, NPOLYLOG, BPPOLYLOG, and MAPOLYLOG. All of our results hold for both the one-sided and two-sided error version of MAPOLYLOG. In proofs, we always choose the model that makes our results stronger. We can also define versions of the classes above where the machine takes advice of a given length—we assume that the advice is written on a separate tape and that the machine has random access to the advice. If \mathcal{C} is a complexity class defined by machines of a certain kind, $\mathcal{C}/poly$ denotes the complexity class defined by machines of the right kind taking polynomial length advice strings, and $\mathcal{C}/qpoly$ denotes the complexity class defined by machines of the right kind taking quasi-polynomial (i.e., $2^{O(polylog(n))}$) length advice strings (where the complexity is measured in terms of the original input size).

We use standard definitions of nonuniform classes. The class of languages with circuits of size t is denoted by $\text{SIZE}(t)$, and the class of languages that have \mathcal{A} -oracle circuits of size t for some complexity class \mathcal{A} is denoted $\text{SIZE}^{\mathcal{A}}(t)$.

If L is a language and \mathcal{C} is a class, we say $L \in i.o.\mathcal{C}$ if there is a language $L' \in \mathcal{C}$ such that $\{n : L \cap \{0, 1\}^n = L' \cap \{0, 1\}^n\}$ is infinite.

In general, complexity classes are defined by acceptance and rejection criteria on the behavior of a specific kind of computation device on an input. The acceptance and rejection criteria are always exclusive but need not be exhaustive. Classes for which they are not exhaustive, such as BPP and MA, are referred to as *promise classes*. We introduce some notation to capture the general case in which the criteria may or may not be exhaustive.

DEFINITION 5. *Given a complexity class \mathcal{C} , a computation device M of the right kind, and an input x , we say that M conforms to \mathcal{C} on input x if the disjunction of the acceptance and rejection criteria for \mathcal{C} holds for the computation of M on input x .*

A *promise problem* is a formalization of the notion of a partially defined decision problem. Formally, a promise problem is a pair (X, L) , where $X, L \subseteq \{0, 1\}^*$. X denotes the domain of the problem (the set of inputs that satisfy the “promise” of the problem), and L denotes an underlying (fully defined) decision problem. We now define what it means for a promise problem to belong to a complexity class.

DEFINITION 6. *Given a complexity class \mathcal{C} , we write $(X, L) \in \mathcal{C}$ if there exists a computation device M of the right kind such that for all $x \in X$, M conforms to \mathcal{C} on input x , and M accepts iff $x \in L$.*

Note that the behavior of M on inputs $x \notin X$ may be arbitrary.

2.2. Simulations. In this paper, we are concerned with various simulations of one type of computation by another type of computation. According to the conventional notion, a simulation is successful if it fools all nonuniform adversaries, i.e., the languages accepted by the two machines coincide on all but finitely many inputs. Kabanets [Kab01] formalized a notion of what it means for a simulation to fool uniform

adversaries (which is weaker than the conventional notion of a simulation). He considered a simulation of a language L in a class \mathcal{C} against adversaries in a class \mathcal{A} to correspond to a language $L' \in \mathcal{C}$ such that no adversary in \mathcal{A} can efficiently find an input on which the simulation makes an error, i.e., an input on which L and L' differ, for infinitely many input lengths. We need to refine the notion of simulation against uniform adversaries for the case of simulation by promise classes. In general, we consider a simulation to correspond to a specific *machine* rather than to a *language*, and say that the simulation makes an error on an input if either the simulating machine does not conform to the simulating class on the input, or the simulating machine and the simulated language do not agree on the input. Arguably, our notion of simulation against uniform adversaries is more natural (though weaker) than the earlier notion in the case of simulations by promise classes. We point out that this is the first paper that considers the issues involved in such simulations, and that our notion coincides with the earlier one in the case of simulations by nonpromise classes.

DEFINITION 7. *Given a complexity class \mathcal{C} , a machine M of the right kind, a language L , and an input x , M makes a simulation error on input x for the simulation of L in \mathcal{C} if one of the following two conditions holds:*

1. M does not conform to \mathcal{C} on input x , or
2. M accepts x iff $x \notin L$.

Next, we formally define a notion of “uniform adversary.”

DEFINITION 8. *A refuter is a deterministic Turing machine that, on input 0^n , outputs a string of length n .*

P and SUBEXP are the classes of refuters operating in polynomial time and subexponential time, respectively, and Tally is the singleton class consisting of the refuter that outputs 0^n on input 0^n . LOGSPACE is the class of refuters equipped with a two-way read-only input tape, a one-way write-only output tape, and a logarithmic amount of work space.

Next, we define what it means for a refuter to succeed against a simulation.

DEFINITION 9. *A refuter N succeeds at length n against a simulation M of a language L in a complexity class \mathcal{C} if M makes a simulation error on input $N(0^n)$ for the simulation of L in \mathcal{C} .*

DEFINITION 10. *A refuter N succeeds against a simulation M of L in \mathcal{C} if N succeeds at length n against M for infinitely many n .*

We say that a simulation M of L fools a refuter N if N does not succeed against M . We define what it means to have simulations in a complexity class that fool refuters from a given class.

DEFINITION 11. *Given a complexity class \mathcal{C} and a class \mathcal{A} of refuters, $\text{pseudo}_{\mathcal{A}}\text{-}\mathcal{C}$ is the class of languages L such that there is a simulation M of L in \mathcal{C} that fools every refuter in \mathcal{A} .*

We reiterate that a successful simulation is a *single* machine that fools *every* refuter in a class.

We introduce a weaker concept of refutation.

DEFINITION 12. *A weak refuter is a deterministic Turing machine that, on input 0^n , outputs a set of strings, each of which is of length n .*

Note that the resource bounds of the weak refuter implicitly define a limit on the cardinality of the set of strings.

DEFINITION 13. *A weak refuter N succeeds at length n against a simulation M of a language L in a complexity class \mathcal{C} if there is at least one $x \in N(0^n)$ such that M makes a simulation error on input x for the simulation of L in \mathcal{C} .*

The notion of success of a weak refuter and the notion of a simulation fooling a weak refuter are defined analogously to the corresponding notions for refuters.

DEFINITION 14. *Given a complexity class \mathcal{C} and a class \mathcal{A} of weak refuters, $quasi_{\mathcal{A}}\text{-}\mathcal{C}$ is the class of languages L such that there is a simulation M of L in \mathcal{C} that fools every weak refuter in \mathcal{A} .*

Clearly, for each \mathcal{A} and \mathcal{C} , $\mathcal{C} \subseteq quasi_{\mathcal{A}}\text{-}\mathcal{C} \subseteq pseudo_{\mathcal{A}}\text{-}\mathcal{C}$.

We can modify and extend the notions of “refuter” and “weak refuter” in various ways. We can redefine the notion of success of a refuter to mean that a refuter succeeds at length n for almost every n rather than for infinitely many n .

DEFINITION 15. *A refuter (resp., a weak refuter) N succeeds almost everywhere against a simulation M of L in \mathcal{C} if N succeeds at length n against M for all but finitely many n .*

DEFINITION 16. *$[io\text{-}pseudo_{\mathcal{A}}]\text{-}\mathcal{C}$ (resp., $[io\text{-}quasi_{\mathcal{A}}]\text{-}\mathcal{C}$) is the class of languages L such that there is a simulation M of L in class \mathcal{C} for which no refuter (resp., weak refuter) in \mathcal{A} succeeds almost everywhere against the simulation.*

We can also consider probabilistic and nondeterministic refuters, which can output different strings on different computation paths.

DEFINITION 17. *A probabilistic refuter is a probabilistic Turing machine, which, on input 0^n , for each computation path outputs a string of length n .*

DEFINITION 18. *A probabilistic refuter succeeds at length n against a simulation M of L in \mathcal{C} if, with probability at least $2/3$ over the random bits of the refuter, M makes a simulation error on the string output by the refuter for the simulation of L in \mathcal{C} .*

DEFINITION 19. *A nondeterministic refuter is a nondeterministic Turing machine, which, on input 0^n , outputs a string of length n on each computation path and accepts on at least one computation path.*

DEFINITION 20. *A nondeterministic refuter succeeds at length n against a simulation M of L in \mathcal{C} if, for all strings x produced by the refuter on accepting paths on input 0^n , M makes a simulation error on x for the simulation of L in \mathcal{C} .*

Probabilistic weak refuters have the same relation to probabilistic refuters as deterministic weak refuters have to deterministic refuters.

Space-bounded refuters and weak refuters are equipped with a separate output tape on which a string or list of strings is written. The output tape does not contribute to the space usage.

The above notions generalize naturally to simulations of promise problems against uniform adversaries.

DEFINITION 21. *A machine M makes a simulation error on input x for the simulation of the promise problem (X, L) in complexity class \mathcal{C} if $x \in X$ and either M does not conform to \mathcal{C} on x or M does not agree with L on x .*

The definitions of “ $(X, L) \in quasi_{\mathcal{A}}\text{-}\mathcal{C}$ ” and “ $(X, L) \in pseudo_{\mathcal{A}}\text{-}\mathcal{C}$ ” are the same as for the underlying decision problem modulo the modified notion of simulation error.

We also define a quantitative notion of simulation, where the measure of success is the fraction of inputs of a given length on which the simulation works.

DEFINITION 22. *Given a language L and a complexity class \mathcal{C} , $L \in corr_s\text{-}\mathcal{C}$ if there is a machine M such that for each input length n , for at least an s fraction of inputs x of length n , M conforms to \mathcal{C} on x and agrees with L on x .*

DEFINITION 23. *Given a language L and a complexity class \mathcal{C} , $L \in [io\text{-}corr]_s\text{-}\mathcal{C}$ if there is a machine M such that for infinitely many input lengths n , for at least an s fraction of inputs x of length n , M conforms to \mathcal{C} on x and agrees with L on x .*

2.3. Pseudorandom generators and extractors. A pseudorandom generator G is a sequence of functions g_n , $n \geq 1$, where g_n maps $\{0, 1\}^{\sigma(n)}$ to $\{0, 1\}^n$ for some $\sigma(n) < n$, such that for all circuits C of size less than n ,

$$\left| \Pr_x[C(x) = 1] - \Pr_y[C(g_n(y)) = 1] \right| < \frac{1}{n},$$

where x is uniformly distributed over $\{0, 1\}^n$ and y is uniformly distributed over $\{0, 1\}^{\sigma(n)}$. The pseudorandom generators we consider will be computable in time $2^{O(\sigma(n))}$. We will sometimes abuse notation and call g_n a pseudorandom generator for some output length n if g_n fools all circuits of size less than n . We refer the reader to the survey paper by Goldreich [Gol00] for more background on pseudorandom generators.

The following theorem of Impagliazzo and Wigderson shows how to obtain a pseudorandom generator with logarithmic seed length from the truth table of a hard function.

THEOREM 24 (see [IW97]). *For every $\epsilon > 0$, there are constants c and d and a polynomial-time procedure, which, given as input the truth table of a Boolean function f on $\log(n)$ inputs, computes the graph of a function $g_{n^{\epsilon/c}} : \{0, 1\}^{d \log(n)} \rightarrow \{0, 1\}^{n^{\epsilon/c}}$, such that when f does not have circuits of size n^ϵ , $g_{n^{\epsilon/c}}$ is a pseudorandom generator.*

Note that the truth table of a language in \mathbf{E} (linear exponential time) can be generated in time polynomial in the size of the truth table (just by enumerating inputs of a given length and checking, for each input, whether the input is in the language or not). Thus the generator g corresponding to $f \in \mathbf{E}$ in Theorem 24 is computable in time $\text{poly}(n)$.

Impagliazzo and Wigderson also showed a tradeoff between uniform simulations of \mathbf{EXP} and efficient simulations of \mathbf{BPP} , which can be expressed in our notation as follows.

THEOREM 25 (see [IW01]). *If $\mathbf{EXP} \neq \mathbf{BPP}$, then $\mathbf{BPP} \subseteq [\text{io} - \text{pseudo}_{\mathbf{BPP}}]\text{-SUBEXP}$.*

Indeed, their argument actually gives the stronger consequence that $\mathbf{BPP} \subseteq [\text{io} - \text{quasi}_{\mathbf{BPP}}]\text{-SUBEXP}$.

For our results in section 6, we need to define the notion of an extractor. First we give some notation and definitions concerning probability distributions. Let D be a probability distribution on a finite set S . We write $r \leftarrow D$ if r is a random variable distributed according to D . Given $x \in S$ and $A \subseteq S$, $D(x)$ is the probability weight assigned to element x of S by the distribution D , and $D(A)$ is the probability that the event A occurs. The *min-entropy* $H_\infty(D)$ of the distribution D is defined to be $\min_{x \in S} \log(1/D(x))$. Given two distributions D_1 and D_2 over the same set S , the *statistical difference* between D_1 and D_2 is defined to be $\max_{A \subseteq S} |D_1(A) - D_2(A)|$. D_1 and D_2 are said to be ϵ -close for $\epsilon \geq 0$ if the statistical difference between D_1 and $D_2 \leq \epsilon$. If D_1 and D_2 are ϵ -close distributions on a set S , and f is a deterministic function with domain S , the distributions $f(D_1)$ and $f(D_2)$ are also ϵ -close. We let U_n denote the uniform distribution on the set $\{0, 1\}^n$.

An extractor is a function that transforms a distribution with high min-entropy to one that is close to uniform, given a short random seed. More formally, a (k, ϵ) extractor is a function $\text{Ext} : \{0, 1\}^n \times \{0, 1\}^d \rightarrow \{0, 1\}^m$ such that for every distribution D on $\{0, 1\}^n$ with $H_\infty(D) \geq k$, the distribution $\text{Ext}(D, U_d)$ is ϵ -close to U_m . There has been a lot of work done on explicit constructions of “good” extractors, where a good extractor is one with small seed length (ideally $d = \log(n - k) + 2 \log 1/\epsilon + O(1)$)

such that almost all the min-entropy in the original distribution is converted to near-uniform random bits (ideally $m = k + d - 2 \log 1/\epsilon - O(1)$). We refer to the excellent paper by Shaltiel [Sha02] for a survey of recent extractor constructions. We will use the following extractor family, which has suboptimal seed length but extracts all the min-entropy of the source and is very efficiently computable.

THEOREM 26 (see [HR00]). *For each constant $\epsilon > 0$ and all functions $k(n)$ such that $0 \leq k(n) \leq n$, there is a family of $(k(n), \epsilon)$ extractors $Ext_k : \{0, 1\}^n \times \{0, 1\}^{O((\log(n))^3)} \rightarrow \{0, 1\}^{k(n)}$ that is uniformly computable in NC^1 .*

2.4. Proofs. We need to define what it means for a promise problem to have efficiently verifiable proofs.

DEFINITION 27. *Given a promise problem (X, L) and a complexity class \mathcal{C} , (X, L) is said to have proofs of size $p(n)$ verifiable in \mathcal{C} if there is a machine V (the verifier for L) such that the following conditions hold for all $x \in X$ (considering resource bounds for V as functions of $|x|$ rather than $|x| + p(|x|)$):*

1. *Completeness: If $x \in L$, there is a string $P(x)$ (the proof for x) of length $p(|x|)$ such that V conforms to \mathcal{C} on input $\langle x, P(x) \rangle$ and accepts $\langle x, P(x) \rangle$.*
2. *Soundness: If $x \notin L$, then for all strings y of length $p(|x|)$, V conforms to \mathcal{C} on input $\langle x, y \rangle$ and rejects $\langle x, y \rangle$.*

DEFINITION 28. *A complexity class \mathcal{B} is said to have proofs of size $p(n)$ verifiable in \mathcal{C} if for every language $L \in \mathcal{B}$, $(\{0, 1\}^*, L)$ has proofs of size $p(n)$ verifiable in \mathcal{C} .*

Holographic proofs are proofs for which there is a very efficient probabilistic verifier. Babai, Fortnow, and Lund [BFL91] showed that EXP has holographic proofs. More precisely, every language L in EXP has proofs of exponential size verifiable in coRP such that for $x \in L$ a proof for x can be computed from x in exponential time. In our applications, we require a “scaled-down” version of this result due to Babai et al. [BFLS91]. The natural way to scale down the result in [BFL91] would be to show that every language L in P has proofs of polynomial size verifiable in coRPOLYLOG such that for $x \in L$ a proof for x can be computed from x in polynomial time. However, such proofs cannot exist since a coRPOLYLOG verifier cannot read the entire input and determine that the purported proof is indeed a proof for that input. What we *can* do in randomized polylogarithmic time is verify a purported proof and, if it passes the verification, extract each bit of the input for which it is a proof with high probability.

The following theorem states that for each language decidable in deterministic time t , where t is polynomially bounded, there are proofs of size nearly linear in t with corresponding randomized polylogarithmic time proof verification and input extraction procedures. We note that for our main results we actually need only the existence of efficiently verifiable polynomial-sized proofs.

THEOREM 29 (see [BFLS91]). *For each language $L \in \text{DTIME}(t)$, where $t = \text{poly}(n)$, and all $\epsilon > 0$, there exist randomized $\text{polylog}(n)$ time procedures V and I and a deterministic $\text{poly}(n)$ time procedure P with the following properties:*

1. *For each $x \in L$ of length n , $y = P(x)$ is a string of length $t^{1+\epsilon}$ such that*
 - (a) $\Pr[V(y) \text{ accepts}] = 1$,
 - (b) $\Pr[I(y, i) = x_i] = 1$ for all $1 \leq i \leq n$.
2. *For each y of length $t^{1+\epsilon}$, if*

$$\Pr[V(y) \text{ accepts}] \geq \frac{1}{2},$$

then there exists a unique $x' \in L$ of length n such that

$$\Pr[I(y, i) = x'_i] \geq \frac{2}{3} \quad \text{for all } 1 \leq i \leq n.$$

The procedure V in the statement of the theorem corresponds to the verifier in the usual definition of a proof system, except that it has access only to the purported proof and not to the input x . The correspondence between the proof and the input is made via the auxiliary procedure I , which, given a proof y accepted with high probability, computes with high probability each bit of an input x' in the language. Note that it is not possible for a **coRPOLYLOG** procedure to check whether x' is the same as the actual input x , since x' and x may differ in very few bit positions, and there is not enough time for the procedure to check all bit positions. However, if x and x' were guaranteed to be codewords in a good error-correcting code, then a **coRPOLYLOG** procedure could just compare x and x' at a few randomly chosen bit positions to determine whether they were the same.

We define “nice codes” as codes with strong enough properties that the argument above can be made precise.

DEFINITION 30. *A nice code is an error-correcting code E such that*

1. *it is decidable in deterministic polynomial time whether a string is a codeword of E ;*
2. *E has relative distance bounded below by an inverse polylogarithmic function of the size of the codeword.*

Using Theorem 29, we can show the existence of efficient proof systems for promise problems in **P** where the promise is that the input is a codeword in a nice code.

THEOREM 31. *For each language $L \in \mathbf{P}$ and each nice code E , (E, L) has proofs of size $\text{poly}(n)$ verifiable in **coRPOLYLOG**. Furthermore, given $x \in L \cap E$, a proof that $x \in L$ is computable in time $\text{poly}(n)$.*

Proof. Let $L \in \mathbf{P}$. Define the language $L' = L \cap E$. (E, L) has proofs of size $\text{poly}(n)$ verifiable in **coRPOLYLOG** iff (E, L') has proofs of size $\text{poly}(n)$ verifiable in **coRPOLYLOG**; hence it suffices to make the argument for L' rather than L . Since E is a nice code, membership in E can be decided in polynomial time; hence $L' \in \mathbf{DTIME}(t)$ for some $t = \text{poly}(n)$. Fix an $\epsilon > 0$ and let V , I , and P be procedures as in the statement of Theorem 29 corresponding to L' . Let k be a constant such that any two different codewords of E of length m have relative distance at least $1/(\log(n))^k$. We define a verifier V' in **coRPOLYLOG** for (L', E) .

Given input $\langle x, y \rangle$ with $|x| = n$, V' runs in two phases. In the first phase, V' runs V on y . If V rejects, V' rejects. Otherwise, V' begins the second phase. It picks $O((\log(n))^{k+1})$ positions $i_1, \dots, i_{O((\log(n))^{k+1})}$ between 1 and n independently at random. For each position i_j , $1 \leq j \leq n$, V' runs $I(y, i_j)$ and checks whether the returned value is equal to x_{i_j} . If all the checks succeed, V' accepts; otherwise it rejects.

Clearly, V' runs in polylogarithmic time in the size of its input. We need to show that when $x \in L'$, there is some y of length $t^{1+\epsilon} = \text{poly}(n)$ such that V' accepts with probability 1 on $\langle x, y \rangle$, and for $x \in E \setminus L'$, V' rejects with probability at least $1/2$ on $\langle x, y \rangle$ for all y of length $t^{1+\epsilon}$.

The first case is easy. When $x \in L'$, condition 1 in the statement of Theorem 29 holds. Thus, V accepts on $P(x)$ with probability 1. Also, $I(P(x), i) = x_i$ with probability 1, and hence all the checks made by V' succeed with probability 1. It follows that V' accepts with probability 1 on input $\langle x, P(x) \rangle$.

For the second case, let $x \in E \setminus L'$. We assume there is a y of length $t^{1+\epsilon}$ such that V' accepts with probability at least $1/2$ on $\langle x, y \rangle$, and we derive a contradiction. Since $\langle x, y \rangle$ passes the first phase of V' , V accepts with probability at least $1/2$ on input y . This implies that there is a unique $x' \in L'$ such that I extracts each bit of x' from y independently with probability $\geq 2/3$. Since $L' \subseteq E$, $x' \in E$. Since $x \notin L'$ and $x' \in L'$, x and x' are different codewords of E , and hence they have relative distance at least $1/((\log(n))^k)$. V' rejects $\langle x, y \rangle$ in the second phase if at least one of the positions i on which x and x' differ is selected, and for that i the call $I(y, i)$ returns x'_i . The first condition occurs with probability close to 1 (by the lower bound on the relative distance of the codeword), and the second happens with probability at least $2/3$, which implies that V' rejects with probability greater than $1/2$. This is a contradiction. \square

It is well known that nice codes exist. In fact, the Justesen code [vL98] satisfies much stronger properties, which we will need for some of our results.

THEOREM 32. *There are positive constants r and δ such that there is a linear code $E : \{0, 1\}^{rn} \rightarrow \{0, 1\}^n$ that has relative distance at least δ and is computable and invertible in quasi-linear time as well as in logarithmic space.*

The existence of nice codes implies that Theorem 31 and the consequent of Theorem 1 are not vacuously true.

3. Simulations of deterministic time against uniform adversaries. In section 3.1, we prove our main result and show how it implies Nisan’s result. We also explore the question of whether the restriction to nice codes in the consequent of our main result can be eliminated. In section 3.2, we show variants of our main result in different ranges of the parameters, and prove a partial converse to one of our results using the idea of derandomizing probabilistic weak refuters. In section 3.3, we give tradeoffs between simulations of P in small Merlin-Arthur classes and deterministic simulations of BPP, which follow from our results and the connections between circuit lower bounds and derandomization given in [BFNW93] and [IW97]. Finally, in section 3.4, we state an analogue of our main result in the space-bounded setting.

3.1. Main result.

3.1.1. Proof of main result. In this subsection, we show that the hypothesis $\text{EXP} \subseteq \text{SIZE}(\text{poly})$ implies there exists a simulation of P in MAPOLYLOG that fools uniform polynomial-time adversaries that output codewords from a nice code. In order to do so, we cast Nisan’s argument that $\text{EXP} \subseteq \text{SIZE}(\text{poly})$ implies $\text{EXP} \subseteq \text{MA}$ as an application of the easy witness method to holographic proofs for exponential time.

Recall that a language L has holographic proofs if it has an efficient probabilistic verification system that needs to read only a small part of the proof for every sequence of random bits. EXP can be characterized as the class of languages with holographic proofs of exponential size that can be verified in probabilistic polynomial time and computed in exponential time [BFL91]. The easy witness method suggests trying proofs that are described by small circuits, i.e., proofs for which there exists a small circuit that outputs the i th bit of the proof on input i . We will refer to such proofs as “compressible.” This leads to the following Merlin-Arthur-type protocol for a language L in EXP : Given an input x , Merlin sends Arthur a small circuit describing a purported proof that $x \in L$. Arthur then runs the probabilistic verification procedure; each time that procedure needs a bit of the proof, Arthur evaluates the circuit on the corresponding input. By the properties of the holographic proof system, the only way

the protocol can fail if an input $x \in L$ does not have a compressible proof. If that happens only finitely often for every language L in EXP , we have that $\text{EXP} \subseteq \text{MA}$. If it happens infinitely often for some L in EXP , consider the concatenation of the holographic proofs for all inputs of a given length, and look upon that concatenation as the truth table of a Boolean function f . Since each proof can be computed in exponential time, we can generate the truth table of f for inputs of length n in time exponential in n . Since infinitely many proofs cannot be described by small circuits, f does not have small circuits. Thus, the function f is computable in exponential time but does not have small circuits, and thus $\text{EXP} \not\subseteq \text{SIZE}(\text{poly})$.

In order to scale down, we apply the easy witness method to holographic proofs for P . There are two issues in scaling down the above arguments. First, as explained in section 2.4 (see Theorem 31), the verifier is guaranteed to work correctly only on inputs that are codewords of a nice code E , not on all inputs of length n . This is why we consider simulations of *promise* problems corresponding to languages in P , where the promise is that the input belongs to E . Second, we cannot concatenate holographic proofs of *all* inputs of length n which are codewords of E , because the resulting string could be of exponential length, whereas we need one of polynomial length. This is where the weak refuter comes in: a polynomial-time algorithm that produces, on input 0^n , a list of strings of length n such that the Merlin-Arthur protocol fails on at least one of them. Concatenating the holographic proofs of the polynomially many inputs on the list yields the truth table we need. If, for every L in P , every refuter succeeds only finitely often, we have that $(E, L) \in \text{quasi}_{\text{P}}\text{-MAPOLYLOG}$ for all $L \in \text{P}$ by definition. Otherwise, we can generate in time $n^{O(1)}$ the truth table of a function on $O(\log n)$ inputs that does not have circuits of size $\log^{O(1)} n$. Thus $\text{E} \not\subseteq \text{SIZE}(\text{poly})$.

We now fill in the details.

Proof of Theorem 1. Let L be a language in P and E a nice code. By Theorem 31, (E, L) has proofs of polynomial size that can be computed in polynomial time and verified by a coRPOLYLOG machine V_L .

Given an input $x \in E$ of length n and an integer k , we look for k -compressible proofs of membership of x in L , where a k -compressible proof is the truth table of a Boolean circuit of size at most $(\log(n))^k$. If $x \notin L$, no such proofs exist, i.e., any such purported proof is rejected by V_L with high probability. If $x \in L$, a k -compressible proof may or may not exist. And if there are inputs in $L \cap E$ without k -compressible proofs, such inputs may or may not be easy to generate. We consider two cases:

1. For each language $L \in \text{P}$, there exists a positive integer k such that large inputs in $L \cap E$ without k -compressible proofs are hard to generate. More precisely, no polynomial-time weak refuter can produce an input in $L \cap E$ without a k -compressible proof for infinitely many input lengths. In this case, we will argue that $(E, L) \in \text{quasi}_{\text{P}}\text{-MAPOLYLOG}$ for all $L \in \text{P}$.
2. There exists a language $L \in \text{P}$ such that for each positive integer k there exists a refuter N_k operating in polynomial time which for infinitely many n produces at least one input of length n in $L \cap E$ without a k -compressible proof. In this case, we will argue that $\text{EXP} \not\subseteq \text{SIZE}(\text{poly})$.

Case 1. Consider the following machine M_k that tries to decide L on input x : M_k first guesses a circuit C_k of size less than $(\log(n))^k$, which takes inputs of length $O(\log(n))$. The circuit C_k is to be interpreted as a “ k -compressed” representation of a purported proof for x ; i.e., the output of the circuit on input i is the i th bit of the proof. Since the size of proofs can be polynomially bounded, the input to C_k need only be of length $O(\log(n))$. M_k then simulates V_L as follows: When V_L accesses a bit

of the input x , M_k accesses the same bit; when V_L accesses a bit of the (purported) proof, M_k gives the address of the bit to C_k as input, runs C_k , and continues its simulation of V_L , assuming the value of the bit to be the answer given by C_k .

We now argue that under the Case 1 hypothesis, when we view M_k as a Merlin-Arthur simulation of (E, L) , no polynomial-time weak refuter succeeds against M_k . Since machine M_k runs in polylogarithmic time,³ we can conclude that $(E, L) \in \text{quasi}_P\text{-MAPOLYLOG}$.

Consider an arbitrary polynomial-time weak refuter N . We need to show that, for large enough n , M_k does not make a simulation error on any $x \in N(0^n)$ for the simulation of (E, L) in MAPOLYLOG. By assumption, for large enough n , all $x \in N(0^n)$ which belong to $L \cap E$ have k -compressible proofs, and M_k accepts with probability 1 for such inputs by guessing the correct circuit corresponding to the proof and simulating the verifier V_L . Hence, for such inputs x , M_k conforms to MAPOLYLOG on x and agrees with L on x , which implies that it does not make a simulation error. For $x \in N(0^n)$ that belong to $E \setminus L$, any circuit guessed by M_k corresponds to an invalid proof, which is rejected with high probability. Hence again, M_k conforms to MAPOLYLOG on x and agrees with L on x , which means that M_k does not make a simulation error. Thus, for large enough n , M_k does not make a simulation error on any $x \in N(0^n) \cap E$. In other words, the simulation M_k of (E, L) in MAPOLYLOG fools N .

Case 2. For each positive integer k , we will define a polynomial-time procedure Q_k which, given 0^n as input, outputs in time $\text{poly}(n)$ the truth table of a Boolean function on inputs of length $O(\log(n))$, which does not have circuits of size $(\log(n))^{k-1}$, for infinitely many n . Suppose for a moment that we have such a procedure Q_k . We then define a language $L_k \in \mathbf{E}$ such that, for infinitely many n , L_k does not have circuits of size $O(n^{k-2})$ on inputs of length n . Let the size of the truth table output by Q_k on input 0^n be n^c for some constant $c > 1$. We define the truth table of L_k on input length n to be the concatenation of the outputs of Q_k on inputs $0^i, i = 2^{n/2^c}, \dots, 2^{(n+1)/2^c}$, padded with 0's to size 2^n . Then $L_k \in \mathbf{E}$, and L_k infinitely often does not have circuits of size $(n/3c)^{k-1}$, and hence infinitely often does not have circuits of size $O(n^{k-2})$. Note that the language L_k depends on Q_k . We obtain a fixed language L that does not have circuits of size $O(n^{k-2})$ for any k by considering any linear-time complete language for \mathbf{E} : If such a language L had circuits of size n^{k-2} , then L_k would have circuits of size $O(n^{k-2})$, which is a contradiction.

We finish the proof by constructing the procedure Q_k with the required properties. Let (E, L) have proofs of length $p(n)$, and let $f : \{0, 1\}^* \rightarrow \{0, 1\}^*$ be a polynomial-time computable function that for each $x \in L \cap E$ outputs a proof for x of length $p(n)$. Let N_k be the refuter from the Case 2 hypothesis, which is supposed to output for infinitely many n a list of inputs of length n , at least one of which is in $L \cap E$ and has no k -compressible proof. Let $q_k(n)$ denote the running time of N_k . On input 0^n , Q_k first simulates N_k on 0^n to get a list of strings x_1, x_2, \dots , where each string is of length n and the size of the list is less than $q_k(n)$. Q_k concatenates the strings $f(x_1), f(x_2), \dots$ into a single string that is of size at most $p(n)q_k(n)$ and outputs this string. Since f is polynomial-time computable, Q_k works in polynomial time. It remains to show that the string output by Q_k is the truth table of a function that does not have circuits of size $(\log(n))^{k-1}$ for infinitely many n . Suppose this were false. Since each $f(x_i)$ is an easily identifiable part of the truth table output by Q_k on input 0^n , a circuit for $f(x_i)$ (interpreted as a truth table) of size $(\log(n))^k$ can be

³Note that a polylogarithmic-time Turing machine can determine the length of its input and verify that the length of the guessed string C_k is correct.

derived from the circuit of size $(\log(n))^{k-1}$ for the truth table output by Q_k . Thus, each output x_i of N_k that lies in $L \cap E$ has a k -compressible proof. This contradicts the Case 2 hypothesis. \square

3.1.2. Comparison of main result with Nisan's result. We now compare the consequent of Theorem 1 and the statement $\text{EXP} = \text{MA}$, which was the strongest previously known consequence, shown by Nisan, of the hypothesis that EXP has polynomial-size circuits. Standard translation techniques show that the statement $\text{EXP} = \text{MA}$ is equivalent to the existence of simulations of P in MAPOLYLOG that fool the tally refuter. We include the proof for completeness.

LEMMA 33. $\text{EXP} = \text{MA}$ iff $\text{P} \subseteq \text{pseudo}_{\text{Tally}}\text{-MAPOLYLOG}$.

Proof. By padding, $\text{EXP} = \text{MA}$ iff $\text{E} \subseteq \text{MA}$. We show that $\text{E} \subseteq \text{MA}$ iff $\text{P} \subseteq \text{pseudo}_{\text{Tally}}\text{-MAPOLYLOG}$.

For the forward direction, let L be a language in P . Let $L' = \{n \mid 0^n \in L\}$. L' is in E , and by hypothesis, there is a Merlin-Arthur machine M' running in polynomial time accepting L' . Now we define a Merlin-Arthur machine M running in polylogarithmic time as follows: M finds the length n of its input (which can be done in deterministic polylogarithmic time) and runs M' on input n . By construction, M accepts a string of the form 0^n iff such a string is in L . Thus the simulation of L by M fools the tally refuter.

For the converse, let $L \in \text{E}$. Consider the language $L' = \{0^n \mid n \in L\}$. L' is in P , and hence, by the hypothesis, there is a machine M' which runs in Merlin-Arthur polylogarithmic time on all inputs of the form 0^n and accepts exactly those inputs of the form 0^n which are in L' . We define a Merlin-Arthur machine M , which, given n , runs M' on the input 0^n . Whenever M' requests the i th bit of its input, M checks whether $i \leq n$. If so, M continues the simulation of M' , assuming that the input bit is 0; otherwise it continues the simulation of M' by notifying M' that the requested input bit does not exist. M is a Merlin-Arthur machine running in polynomial time accepting L , and thus $L \in \text{MA}$. \square

We next argue that the existence of a polynomial-time computable linear code E such that $(E, L) \in \text{quasi}_{\text{P}}\text{-MAPOLYLOG}$ for each $L \in \text{P}$ implies that $\text{EXP} = \text{MA}$, or equivalently that $\text{P} \subseteq \text{pseudo}_{\text{Tally}}\text{-MAPOLYLOG}$. The reason is that the tally refuter essentially is a special case of a weak refuter restricted to such a code E .

THEOREM 34. *If there is a polynomial-time computable linear code E such that for each language $L \in \text{P}$, $(E, L) \in \text{quasi}_{\text{P}}\text{-MAPOLYLOG}$, then $\text{EXP} = \text{MA}$.*

Proof. The proof is again via a translation argument. Let E be a polynomial-time computable linear nice code mapping $\{0, 1\}^n$ to $\{0, 1\}^{p(n)}$ for some polynomial $p(n)$. By linearity of E , $0^{p(n)}$ is a codeword of E for each integer n .

We show $\text{E} \subseteq \text{MA}$ under the hypothesis, which implies $\text{EXP} = \text{MA}$ by padding. Let $L \in \text{E}$. Consider the language $L' = \{0^{p(n)} \mid n \in L\}$. Since $p(n)$ is polynomial-time computable (by the polynomial-time computability of E), $L' \in \text{P}$. Hence there is a machine M' which for each weak refuter N runs in Merlin-Arthur polylogarithmic time on strings produced by N , which are codewords of E , and agrees with L' on such strings. In particular, M' is a successful simulation of (E, L') in MAPOLYLOG against the tally refuter. As in the proof of Lemma 33, we define a Merlin-Arthur polynomial-time machine M accepting L . Hence, $L \in \text{MA}$. \square

Since there exists a polynomial-time computable linear nice code (Theorem 32), Theorem 34 shows that the consequent of Theorem 1 implies that $\text{EXP} = \text{MA}$. Thus, Theorem 1 is at least as strong as Nisan's result. Since weak refuters restricted to a polynomial-time computable linear nice code E are more powerful than the tally

refuter (which is the weakest possible refuter), Theorem 1 seems stronger than Nisan's result.

3.1.3. Nonuniform simulations against weak refuters. We should point out that very efficient simulations against polynomial-time weak refuters restricted to a nice code E exist unconditionally in the *nonuniform* setting. The following result states that for each language L and each nice code E there is a simulation of (E, L) by decision trees of depth $O(\text{polylog}(n))$ that fools every polynomial-time weak refuter. Recall that *qpoly* refers to advice of quasi-polynomial length, i.e., length $2^{O(\text{polylog}(n))}$.

THEOREM 35. *For each language L and nice code E , $(E, L) \in \text{quasiP-DPOLYLOG/qpoly}$.*

Proof. The idea of the proof is that the only codewords of E that a weak refuter can produce are of low time-bounded Kolmogorov complexity and also, because E is an error-correcting code, elements from E can be distinguished from each other by looking at only a few selected bit positions. Since there are only few strings of low time-bounded Kolmogorov complexity, membership information about them can be determined from a table which is given as a quasi-polynomial length advice string.

We briefly describe the notion of time-bounded Kolmogorov complexity that we need. Fix a standard deterministic universal Turing machine U , which takes an argument p , runs the program p on the empty string, and outputs the result. We consider Levin's measure $Kt(x) = \min\{|p| + \log(t) \mid p \text{ outputs } x \text{ in } t \text{ steps}\}$. We need two observations:

1. Each string output by a polynomial-time weak refuter has $O(\log(n)) Kt$ -complexity. This is because the position of the string in the list of strings output by the refuter serves as a description of the string. Since the refuter can be described by $O(1)$ bits and the position by $O(\log(n))$ bits, this description is $O(\log(n))$ bits long.
2. There are at most 2^l strings x with $Kt(x) < l$ for any l .

The second item holds irrespective of which notion of Kolmogorov complexity we use, but Levin's measure is convenient if we require the first item to hold as well.

Let L be any language and E be a nice code. Let k be a positive constant such that any two distinct codewords of length m in E have relative distance at least $1/(\log(m))^k$. Let $\epsilon < 1$ be a positive constant. For each n , we define $EZ(n) = \{x \in E \mid |x| = n, Kt(x) \leq (\log(n))^{1+\epsilon}\}$. Given any polynomial-time weak refuter, each codeword of E of length n output by the weak refuter is in $EZ(n)$ for all but finitely many n , by observation 1 above. Also, $|EZ(n)| \leq 2^{(\log(n))^{1+\epsilon}}$, by observation 2.

For any n , we consider the following experiment: pick positions $i_1, \dots, i_{(\log(n))^{k+2}}$ uniformly and independently at random between 1 and n . We claim that with probability at least $1/2$, any distinct u and v in $EZ(n)$ differ in at least one of these positions. To see this, let u and v be a specific pair of distinct codewords in E . E has relative distance bounded below by $1/(\log(n))^k$; hence with probability at least $1 - (1 - 1/(\log(n))^k)^{(\log(n))^{k+2}}$, u and v differ in at least one of the positions $i_1, \dots, i_{(\log(n))^{k+2}}$. By a union bound, since $|EZ(n)| \leq 2^{(\log(n))^{1+\epsilon}}$, the probability that there are distinct u and v in $EZ(n)$ which do not differ in any of the positions is at most $1/2$. Thus the claim is proved.

The probabilistic argument above shows that there is some sequence of positions $i_1, \dots, i_{(\log(n))^{k+2}}$ between 1 and n such that every two distinct codewords in $EZ(n)$ differ in at least one of these positions. Fix such a sequence. For each n , we code this sequence into the advice string for a DPOLYLOG machine simulating (E, L) . We also code into the advice string a table which contains, for each possible assignment

of (0,1)-values to these positions, the value 1 if there is $u \in E \cap L$ of length n such that u is consistent with that assignment of (0,1)-values to positions, and the value 0 otherwise. The length of the advice string is $O(2^{(\log(n))^{k+2}})$.

We now describe how a DPOLYLOG machine M simulating (E, L) behaves, given an advice string as above. M , on input x of length n , first determines $i_1, \dots, i_{(\log(n))^{k+2}}$ from its advice string. It then reads these positions $x_{i_1}, \dots, x_{i_{(\log(n))^{k+2}}}$ and looks up the corresponding entry in the table coded into the advice string. If the entry is 1, it accepts; otherwise it rejects.

We need to show that this simulation succeeds against all polynomial-time weak refuters. Let N be a polynomial-time weak refuter. Without loss of generality, we can assume that N produces only codewords of E , since E is a nice code, and N cannot fool the simulation by producing a noncodeword. Let x be a string of length n produced by N . $x \in EZ(n)$, and by the choice of positions $i_j, 1 \leq j \leq (\log(n))^{k+2}$, the bits of x in these positions determine x uniquely among all strings in $EZ(n)$. Thus the entry in the table coded in the advice string of M corresponding to the assignment $x_{i_1}, \dots, x_{i_{(\log(n))^{k+2}}}$ of (0,1)-values to bit positions tells correctly whether $x \in L$ or not, and hence the simulation succeeds on input x . This argument works for any large enough n , and hence the theorem follows. \square

Arguably, Theorem 35 points to a weakness in the kind of simulations of promise problems we consider. Note, though, that nonuniformity of the simulating class plays a crucial role. In fact, a diagonalization argument as in the proof of the time hierarchy theorem yields a language $L \in \mathsf{P}$ such that $(E, L) \notin \text{quasi-P-DPOLYLOG}$ for each nice code E . Thus, we view Theorem 35 as an indication of the crucial role nonuniformity plays in Theorem 1 and in Nisan's argument.

Nevertheless, it would be more pleasing if we could lift the restriction to a nice code E in Theorem 1. However, we can prove unconditionally that $\mathsf{P} \not\subseteq \text{quasi-P-MAPOLYLOG}$.

THEOREM 36. $\mathsf{P} \not\subseteq [\text{io} - \text{quasi-P}]\text{-MAPOLYLOG}$.

Proof. Consider the language $L = \{x \mid x \text{ has an even number of 1's}\}$. We show that $L \notin [\text{io} - \text{quasi-P}]\text{-MAPOLYLOG}$. The basic idea of the proof is that the behavior of a polylogarithmic-time Merlin-Arthur machine cannot change very much if one bit of the input is changed. On the other hand, changing a bit of the input makes the difference between membership in L and nonmembership in L . Thus, given a set comprising an input $x \notin L$ and all inputs at Hamming distance 1 from x (all of which are in L), every polylogarithmic-time Merlin-Arthur machine must fail to behave correctly on at least one input in the set. We observe that there is such a set that can be generated in polynomial time.

For any purported simulation of L in MAPOLYLOG, we use the same weak refuter, which outputs the string of all 0's and all strings with exactly one 1. Clearly, the weak refuter can do this in polynomial time. We show that for every machine M , either there is an input of length n produced by the weak refuter such that M does not conform to (bounded two-sided error) Merlin-Arthur polylogarithmic time on the input, or there is an input of length n such that M does not agree with L on the input, for almost all input lengths n . If M rejects the all 0's input or if the computation of M does not conform to Merlin-Arthur polylog time on the all 0's input, then we are done. Otherwise, fix an accepting nondeterministic path p of M on the all 0's input. At most a polylogarithmic number of different input bits can be queried by this path—assume without loss of generality that each of these is one of $x_1, x_2, \dots, x_{\text{polylog}(n)}$. Now consider the associated subtree of randomized nodes,

namely the subtree of configurations accessible by M , given that it has made the nondeterministic choices corresponding to the path p . At least a fraction $2/3$ of the paths in this subtree end in an accepting node. Since only a polylogarithmic number of input bits can be queried on any one path, there is some $i, i > \text{polylog}(n)$, for which x_i is queried on less than a fraction $\text{polylog}(n)/n$ of the paths. Now, if x_i is flipped, p is still a valid path for M to take, since x_i is not queried on this path. Moreover, in the subtree of randomized nodes associated with p , at least a $2/3\text{-polylog}(n)/n$ fraction of the paths still end in accepting nodes since they do not query x_i , and all the other bits are unchanged. Thus either the computation of M does not conform to Merlin-Arthur polylog time on the input with all 0's except a 1 in the i th position, or at least $2/3$ of the paths of this subtree end in accepting nodes, which means that M accepts the input. In this case, M does not agree with L on the string with all 0's except a 1 in the i th position. \square

The result above holds even if we consider nonuniform MAPOLYLOG, i.e., the machine is also allowed a quasi-polynomial amount of advice (to which random access is available).

3.1.4. Simulations without restriction to a nice code. If we allow a slightly larger simulating class than MAPOLYLOG in the statement of Theorem 1, we *can* lift the restriction to a nice code, as follows.

THEOREM 37. *If $\text{EXP} \subseteq \text{SIZE}(\text{poly}(n))$, then $\text{P} \subseteq \text{quasi}_{\text{P}}\text{-}\Sigma_2\text{-POLYLOG}$.*

Proof sketch. The proof follows the same techniques as the proof of Theorem 1, except that instead of Theorem 31, we use the fact that P has proofs of polynomial size verifiable in coNPOLYLOG . This holds because the tableau of the computation of a deterministic Turing machine on an input is a valid proof if the input is in the language, and local consistency of the tableau can be checked in coNPOLYLOG . Since, for each $L \in \text{P}$, proofs verifiable in coNPOLYLOG exist for *all* inputs in L , not just inputs that are codewords of a nice code, we do not require the restriction to a nice code in the statement of the theorem. \square

Note that while $\text{P} \not\subseteq \text{quasi}_{\text{P}}\text{-MAPOLYLOG}$, as shown in Theorem 36, showing nonexistence of simulations in a slightly larger class or against somewhat weaker adversaries would imply that EXP does not have polynomial-size circuits.

Analogously to Theorem 35, we can show that the consequent of Theorem 37 holds unconditionally if the simulating class is nonuniform $\Sigma_2\text{-POLYLOG}$ rather than uniform $\Sigma_2\text{-POLYLOG}$.

THEOREM 38. *$\text{P} \subseteq \text{quasi}_{\text{P}}\text{-}\Sigma_2\text{-POLYLOG}/\text{qpoly}$.*

Proof sketch. As in the proof of Theorem 35, we use the fact that polynomial-time weak refuters can only produce strings of low time-bounded Kolmogorov complexity. Let L be a language in P . We define a nonuniform $\Sigma_2\text{-POLYLOG}$ machine which simulates L . The advice string for M at input length n is an enumeration of all $x \in L$ of length n with $Kt(x) \leq (\log(n))^{1+\epsilon}$, for some constant ϵ . The length of the advice string is thus $O(2^{(\log(n))^{1+\epsilon}})$. The machine M operates as follows: given an input x of length n , it tests whether x is the same as some string for which membership in L is coded into the advice string. This is done in $\Sigma_2\text{-POLYLOG}$ by existentially guessing a segment of the advice string and universally verifying that the segment matches x bit-by-bit.

Note that all strings of length n produced by a weak refuter have time-bounded Kolmogorov complexity $O(\log(n))$ and hence are accounted for by the advice string for large enough n . Thus the simulation succeeds against all polynomial-time weak refuters. \square

3.2. Variants. We can modify the parameters in Theorem 1 in several ways. First, under the same hypothesis that $\text{EXP} \subseteq \text{SIZE}(\text{poly}(n))$, we can trade off the simulation time and the running time of the adversary.

THEOREM 39. *If $\text{EXP} \subseteq \text{SIZE}(\text{poly}(n))$, then for each $L \in \text{P}$, each nice code E and each $\epsilon > 0$, $(E, L) \in \text{quasi}_{\text{SUBEXP}}\text{-MATIME}(n^\epsilon)$.*

Proof. The proof is analogous to the proof of Theorem 1. For each ϵ and each language $L \in \text{P}$, we define a simulation of (E, L) in $\text{MATIME}(n^\epsilon)$ as before. If there is a language L and an $\epsilon > 0$ such that there is some subexponential-time weak refuter not fooled almost everywhere by the simulation, the concatenation of the proofs of the strings output by the refuter is the truth table of a function that does not have polynomial-size circuits. \square

Similarly, we can prove the following result.

THEOREM 40. *If $\text{EXP} \subseteq \text{SIZE}(\text{poly}(n))$, then for each $\epsilon > 0$, $\text{P} \subseteq \text{quasi}_{\text{SUBEXP}}\text{-}\Sigma_2\text{-TIME}(n^\epsilon)$.*

We can also use weaker hypotheses than $\text{EXP} \subseteq \text{SIZE}(\text{poly}(n))$, and obtain weaker simulations.

THEOREM 41. *If $\text{E} \subseteq \text{SIZE}(2^{\epsilon n})$ for each constant $\epsilon > 0$, then for each time bound $t = n^{\Omega(1)}$, each language $L \in \text{DTIME}(t)$, each nice code E decidable in time $O(t \text{ polylog}(t))$, and each $\delta > 0$, $(E, L) \in \text{quasi}_{\text{P}}\text{-MATIME}(t^\delta)$.*

Note that by Theorem 32, quasi-linear time decidable nice codes exist.

If the assumptions in Theorems 1 and 41 hold only for infinitely many input lengths (instead of almost all), the simulation is correct on infinitely many input lengths.

It is not clear whether the consequent of Theorem 40, that for all $\epsilon > 0$, $\text{P} \subseteq \text{quasi}_{\text{SUBEXP}}\text{-}\Sigma_2\text{-TIME}(n^\epsilon)$, is unlikely to hold. We show below that the negation of this statement holds under a reasonable circuit lower bound assumption. Thus, we obtain a partial converse to Theorem 40. Interestingly, the nonuniform methods used to show circuit lower bounds for AC^0 circuits [Ajt83, FSS84, Hås86] come in useful here.

LEMMA 42. *There is a constant $\epsilon > 0$ such that $\text{P} \not\subseteq [\text{io-corr}_{2/3}]\text{-}\Sigma_2\text{-TIME}(n^\epsilon)$.*

This result immediately follows from the inapproximability of PARITY by subexponential-size constant-depth circuits [Hås86]. Note that $\Sigma_2\text{-TIME}(n^\epsilon)$ can be simulated by depth- d circuits of size 2^{n^ϵ} for some fixed constant d .

The average case hardness result of Lemma 42 has the following consequence for simulations against probabilistic weak refuters.

THEOREM 43. *There is a constant $\epsilon > 0$ such that $\text{P} \not\subseteq [\text{io-quasi}]_{\text{BPP}}\text{-}\Sigma_2\text{-TIME}(n^\epsilon)$.*

Proof. Let L be a language in P such that there is an $\epsilon > 0$ for which $L \notin [\text{io-corr}]_{2/3}\text{-}\Sigma_2\text{-TIME}(n^\epsilon)$. By Lemma 42, such a language L exists. Given a purported $\Sigma_2\text{-TIME}(n^\epsilon)$ simulation L' of L , the strategy of the probabilistic weak refuter is simple and, in fact, independent of L' : it just picks $c = O(1)$ strings of input length at random and outputs them. There is a large enough c so that, for at least $2/3$ of the random choices of the probabilistic adversary, at least one of the strings it outputs on this random choice is in $L \triangle L'$. \square

Our strategy now is to show that under appropriate circuit lower bound assumptions, the probabilistic weak refuter can be derandomized, i.e., replaced by a deterministic weak refuter. The proof will use the following derandomization lemma, which shows how probabilistic computations satisfying certain conditions can be derandomized under assumptions related to the complexity of testing for the conditions.

LEMMA 44 (see [KvM02]). *Let $D(x, r) : \{0, 1\}^n \times \{0, 1\}^{p(n)} \rightarrow \{0, 1\}^*$ be a polynomial-time computable function and $C(y, r)$ a predicate such that $C(D(x, r), r) = 1$ for at least $2/3$ of the random strings r . Let C be computable in $\text{SIZE}^A(\text{poly}(n))$, for some oracle A . If $\text{E} \not\subseteq \text{SIZE}^A(\text{poly}(n))$, then there is a set S of strings such that $S \cap \{0, 1\}^{p(n)}$ is enumerable in time 2^{n^ϵ} for any $\epsilon > 0$, and for infinitely many n , $C(D(x, r'), r') = 1$ for at least one of the strings r' of length $p(n)$ in S .*

THEOREM 45. *If $\text{E} \not\subseteq \text{SIZE}^{\Sigma_2\text{-POLY}}(\text{poly}(n))$, then there is a constant $\epsilon > 0$ such that $\text{P} \not\subseteq \text{quasi}_{\text{SUBEXP-}\Sigma_2\text{-TIME}}(n^\epsilon)$.*

Proof. From the proof of Theorem 43, we know that there is a language $L \in \text{P}$, a probabilistic weak refuter M , and a constant $\epsilon > 0$ such that for any language $L' \in \Sigma_2\text{-TIME}(n^\epsilon)$, M weakly distinguishes L from L' . We would like to transform M to a deterministic weak refuter M' for which the same property holds, under an appropriate assumption. Intuitively, this is a “derandomization” because we are trying to eliminate the randomness of the machine M . However, the derandomization needs to preserve the distinguishing properties of M . We apply Lemma 44 in order to do this.

In our application of Lemma 44, $p(n)$ is the number of random bits used by the probabilistic weak refuter, the function $D(0^n, r)$ specifies which string of length n is output by the refuter on a given sequence of random bits r , and the predicate C tests whether a given string output by the refuter is in the symmetric difference of L and L' . Since both L and L' are in $\Sigma_2\text{-POLY}$, C is computable in $\text{SIZE}^{\Sigma_2\text{-POLY}}(\text{poly}(n))$. Thus, by the theorem, if $\text{E} \not\subseteq \text{SIZE}^{\Sigma_2\text{-POLY}}(\text{poly}(n))$, there is a set S of strings such that $S \cap \{0, 1\}^{p(n)}$ is enumerable in time 2^{n^ϵ} for each $\epsilon > 0$ and $D(0^n, r')$ is in the symmetric difference of L and L' for at least one of the strings $r' \in S \cap \{0, 1\}^{p(n)}$. We define the deterministic weak refuter M' to first generate $S \cap \{0, 1\}^{p(n)}$ on input 0^n and output the set of strings $\{D(0^n, r') \mid r' \in S \cap \{0, 1\}^{p(n)}\}$. It follows from the properties of M and Theorem 44 that M' weakly distinguishes L from L' infinitely often. Also, if $S \cap \{0, 1\}^{p(n)}$ is enumerable in time 2^{n^ϵ} for any $\epsilon > 0$, then by using an appropriate enumerator for $S \cap \{0, 1\}^{p(n)}$, M' can be defined to operate in time 2^{n^ϵ} for any $\epsilon > 0$, and hence the theorem follows. \square

Theorem 45 can be considered a partial converse to Theorem 40.

3.3. Consequences. In a straightforward way, the fact that circuit lower bounds for EXP imply derandomization translates to tradeoffs between simulations of P in low-level complexity classes that fool uniform adversaries and deterministic simulations of probabilistic classes.

THEOREM 46 (see [BFNW93]). *If $\text{EXP} \not\subseteq \text{SIZE}(\text{poly})$, then $\text{BPP} \subseteq i.o.\text{SUBEXP}$.*

Corollary 2 follows from Theorems 1 and 46.

THEOREM 47 (see [IW97]). *If $\text{E} \not\subseteq \text{SIZE}(2^{\epsilon n})$, for some $\epsilon > 0$, then $\text{BPP} \subseteq i.o.\text{P}$.*

COROLLARY 48. *For each $\epsilon > 0$ and time bound $t = n^{\Omega(1)}$, for each language $L \in \text{DTIME}(t)$ and each nice code E decidable in time $O(t \text{ polylog}(t))$, $(E, L) \in \text{quasi}_{\text{P-MATIME}}(t^\epsilon)$, or $\text{BPP} \subseteq i.o.\text{P}$.*

Because $\text{MATIME}(t)$ is trivially contained in $\text{DSPACE}(t)$, our results also generalize the space-randomness tradeoffs first shown by Sipser [Sip88] and later extended by Nisan and Wigderson [NW94] and Lu [Lu01]. Sipser showed that, conditioned on the explicit constructibility of a certain kind of disperser (later shown to hold in [SSZ98]), if there does not exist an $\epsilon < 1$ such that for all polynomially bounded t , $\text{DTIME}(t) \subseteq [i.o - \text{pseudo}_{\text{Tally}}]\text{-DSPACE}(t^\epsilon)$, then $\text{RP} = \text{P}$. Nisan and Wigderson [NW94] extended this tradeoff to other ranges of parameters, and Lu [Lu01] obtained derandomizations of AM under the same assumptions. We consider simu-

lations against polynomial-time adversaries producing inputs in a nice code E , while the aforementioned papers considered only tally adversaries.⁴

3.4. Extensions. We can prove an analogue of Theorem 1 for space, as follows.

THEOREM 49. *If $\text{PSPACE} \subseteq \text{SIZE}(\text{poly})$, then for each language $L \in \text{LOGSPACE}$ and each logspace-decidable nice code E , $(E, L) \subseteq \text{quasi}_{\text{LOGSPACE}}\text{-MAPOLYLOG}$.*

Proof sketch. The proof follows along the same lines as the proof of Theorem 49, except that we use the analogue of Theorem 31 for LOGSPACE, which states that for each language $L \in \text{LOGSPACE}$ and each logspace-decidable nice code E , (E, L) has proofs of size $\text{poly}(n)$ verifiable in coRPOLYLOG , and given $x \in L \cap E$, a proof that $x \in L$ can be computed in logarithmic space. \square

4. Simulations of nondeterministic time against uniform adversaries.

Using the ideas of section 3, we can show tradeoffs between simulations of nondeterministic time against uniform adversaries and simulations of probabilistic time in nondeterministic time against nonuniform adversaries. The translation is straightforward except for two issues.

The first issue is that the hypothesis $\text{NEXP} \not\subseteq \text{SIZE}(\text{poly})$ is not known to yield subexponential nondeterministic simulations of probabilistic computations. What does suffice for the latter is a way to generate in nondeterministic exponential time the truth table of a function that requires large circuits. In particular, we have the following result.

PROPOSITION 50. *If for each k there is an NP machine M_k that accepts all inputs of the form 0^{2^n} , and outputs the truth table of a function on n inputs that does not have circuits of size n^k on each accepting path, then $\text{MA} \subseteq \text{NSUBEXP}$.*

It is open whether $\text{NEXP} \not\subseteq \text{SIZE}(\text{poly})$ implies that we can generate in nondeterministic polynomial time the truth table of a function that requires large circuits.⁵ However, the proof strategy of Theorem 1 actually yields the latter, so we can obtain the derandomization results directly from it.

The other issue is that we can no longer assume that the ability to generate a list of inputs, such that at least one of them is in the language and has no easy witnesses, implies the ability to generate the truth table of a hard function. The reason is that a nondeterministic computation cannot verify that it guessed witnesses for *all* inputs on the list that are in the language, and therefore may miss the one that has no easy witnesses. In order to remedy this problem, we weaken the notion of uniform simulation by requesting that the adversary outputs a single input. In our terminology, we switch from “quasi-” simulations to the weaker “pseudo-” simulations considered in other papers.

The following result is analogous to Corollary 2, except that the i.o. quantifier is switched: It appears in the simulation against refuters rather than in the derandomization.

THEOREM 51. *For each language $L \in \text{NP}$ and each nice code E , $(E, L) \in [\text{io} - \text{pseudo}]_{\text{NP}}\text{-MAPOLYLOG}$ or $\text{MA} \subseteq \text{NSUBEXP}$.*

Proof sketch. The simulation is the same as the one in Theorem 1, and the proof uses the holographic proofs of [BFLS91]. The condition we need for generation of proofs now is that a proof for x can be generated from an NP-witness in polynomial time. If the simulation doesn’t succeed against a restricted nondeterministic strong

⁴[NW94] and [Lu01] actually considered simulations of exponential time, but this is equivalent to simulations of polynomial time against tally adversaries.

⁵The converse is known to hold [IKW02].

refuter, the strong refuter can guess correctly a codeword of E on which the simulation fails, guess an accepting computation on that input (since the simulation fails on an input only if the input is in the NP language and in E but not in the simulating language), compute a proof from this computation, and output the proof. The failure of the simulation implies that every proof output on an accepting computation of the strong refuter is hard, and these hard proofs can be used to derandomize MA. \square

A tradeoff result involving simulations against unrestricted strong refuters can be shown in a similar way to Theorem 37, as follows.

THEOREM 52. $\text{NP} \subseteq [\text{io} - \text{pseudo}]_{\text{NP}-\Sigma_2}\text{-POLYLOG}$ or $\text{MA} \subseteq \text{NSUBEXP}$.

This is a strengthening of a theorem in [Kab01], where simulations of NP in deterministic time are considered.

Analogous to Corollary 48, we have the following.

THEOREM 53. For each $\epsilon > 0$, each language $L \in \text{NP}$, and each nice code E , $(E, L) \in [\text{io} - \text{pseudo}]_{\text{NP}-\text{MATIME}(n^\epsilon)}$ or $\text{MA} \subseteq \text{NP}$.

Note that we are not able to switch the quantifiers a.e. and i.o. as we were able to in the deterministic case of Corollaries 2 and 48. The reason is the same as that for why we can only deal with strong refuters and not with weak ones. However, as in [IKW02], the simulation of MA can use a small advice string to cue it to an input on which the refuter succeeds.

THEOREM 54. For each language $L \in \text{NP}$ and each nice code E , $(E, L) \in \text{pseudo}_{\text{NP}} - \text{MAPOLYLOG}$, or else for each $\epsilon > 0$, $\text{MA} \subseteq \text{i.o.}[\text{NTIME}(2^{n^\epsilon})/n^\epsilon]$.

Using upward translation, we obtain a “gap” theorem for NEXP, as follows.

COROLLARY 55 (see [IKW02]). $\text{NEXP} = \text{MA}$, or else for each $\epsilon > 0$, $\text{MA} \subseteq \text{i.o.}[\text{NTIME}(2^{n^\epsilon})/n^\epsilon]$.

By standard diagonalization techniques, the clauses in Corollary 55 are exclusive.

Under a slightly stronger hypothesis than in Theorem 51, we can derandomize the class AM. First, we need the following result from [KvM02] showing that certain circuit lower bounds imply a derandomization of AM.

THEOREM 56. If $\text{EXP} \not\subseteq \text{i.o.}\text{SIZE}^{\text{SAT}}(\text{poly}(n))$, then $\text{AM} \subseteq \text{NSUBEXP}$.

We obtain our derandomization result for AM using a variation on the easy witness method where, for $L \in \text{NP}$, an “easy” proof that $x \in L$ is a proof that has small SAT-oracle circuits, when the proof is considered as the truth table of a function.

THEOREM 57. $\text{NP} \subseteq [\text{io} - \text{pseudo}]_{\text{NP}-\Sigma_3}\text{-POLYLOG}$ or $\text{AM} \subseteq \text{NSUBEXP}$.

Proof sketch. We make a modification to the simulation of Theorem 51. We will use proofs verified by “local checkability,” as in the proof of Theorem 37. Given a language $L \in \text{NP}$, the simulating machine guesses a SAT-oracle circuit of small size, and then verifies that this circuit is the truth table of a valid proof by using the local checkability algorithm and querying the circuit when it needs a bit of the proof. The problem is that the machine also needs to be able to answer SAT queries in order to evaluate the circuit. This can be done using one additional alternation, by guessing the queries and answers to queries at the beginning of a computation path and verifying them on a parallel computation path. Since SAT is in nondeterministic quasi-linear time and the queries are of size $O(\text{polylog}(n))$, the overhead incurred is minimal. \square

5. Quantitative simulations. In this section, we consider a quantitative version of simulation, where a simulation is guaranteed to work on a certain number of inputs of any given input length. The simulations in previous sections correspond to the following situation: A simulation may fail on many inputs, but it is infeasible to find a place where this happens. The situation here is different: A simulation

can fail on only a limited fraction of the inputs, but it may be easy to find an input on which the simulation makes a mistake. By using the easy witness method and coupling simulations together on an input-by-input basis rather than an input-length-by-input-length basis, it is possible to prove nontrivial tradeoffs for certain ranges of the parameters. More precisely, if an input x in a language $L \in \mathsf{P}$ does not have a compressible proof, we can use its proof as the truth table of a hard function for the pseudorandom generator of Theorem 24 to derandomize the computation of a BPP machine on the same input x .

Our results are based on the following lemma, which is a corollary to Theorem 31.

LEMMA 58. *For each language $L \in \mathsf{P}$ and each polynomial-time invertible nice code E , $(E, E(L))$ has proofs of size $\text{poly}(n)$ verifiable in coRPOLYLOG , where $E(L) = \{E(x) \mid x \in L\}$. Furthermore, given $x \in L$, a proof that $E(x) \in E(L)$ is computable in time $\text{poly}(n)$.*

THEOREM 59. *Fix a function $s : N \rightarrow [0, 1]$ such that $s(n)2^n$ is an integer for all $n \in N$. There exists $t = \text{poly}(n)$ such that $\mathsf{P} \subseteq \text{corr}_s\text{-MATIME}(t)$ or $\text{BPP} \subseteq [\text{io} - \text{corr}_{1-s}]\text{-P}$.*

Proof. If for each polynomial t there is a language $L \in \mathsf{P}$ such that $L \notin \text{corr}_s\text{-MATIME}(t)$, we will show how to simulate $\text{BPTIME}(t')$ in $[\text{io} - \text{corr}_{1-s}]\text{-P}$ for each polynomial-time bound t' . Given t' , let $t = \max(n^d, (t')^k)$, where n^d is the time required to compute $E(x)$, given x of length n , and k is a constant to be determined later. By assumption, there is a language $L \in \mathsf{P}$ such that $L \notin \text{corr}_s\text{-MATIME}(t)$.

Consider the following simulation for L : For each x , compute $E(x)$, guess a circuit of size \sqrt{t} , and check, using the probabilistic polylogarithmic-time verifier for $E(L)$, whether the truth table defined by the circuit is a proof that $E(x) \in E(L)$. By the properties of the proof system for $E(L)$, for any input x which is not in $E(L)$ or has proofs with circuits of size $\leq \sqrt{t}$, this simulation operates in Merlin-Arthur time t (since there are only polylogarithmically many queries made to the circuit and it takes time at most \sqrt{t} to answer a query) and does not make an error on x .

By hypothesis, the simulation makes an error on x for at least a $1 - s$ fraction of strings x of length n for infinitely many input lengths n . We show how to use the failure of the simulation to obtain a deterministic simulation of any language R accepted by a probabilistic polynomial-time machine M running in time t' . Given an input x , compute a proof $P(x)$ that x is in L (using Lemma 58). Use $P(x)$ as a hardness source in Theorem 24 to produce a polynomial-size list of pseudorandom strings. Run M on each of these strings and output the majority result as the answer.

We show that this works if we set k large enough, e.g., $k = 4c$, where c is the constant in the statement of Theorem 24. For each string x of length n , there are two possible cases. The first is that $P(x)$ has no circuits of size \sqrt{t} , in which case by our choice of k , it can be used as a hardness source for the pseudorandom generator of Theorem 24 to produce $(t')^2$ pseudorandom bits that fool circuits of size $(t')^2$, and can therefore be used for the derandomization of $\text{BPTIME}(t')$ algorithms (which can be simulated by circuits of size $(t')^2$). The second case is that $P(x)$ has circuits of size \sqrt{t} , which implies that the simulation of L in $\text{MATIME}(t)$ does not make an error on input x . Since there are infinitely many input lengths n such that the simulation of L in $\text{MATIME}(t)$ fails on at least a fraction $1 - s$ of inputs of length n , the simulation of any $\text{BPTIME}(t')$ language in P succeeds on at least a fraction $1 - s$ of inputs of these input lengths, proving the theorem. \square

Note that the i.o. and a.e. quantifiers can be interchanged in the preceding theo-

rem.

We would like to increase the advantage for the deterministic simulation of probabilistic time, given that the simulation of deterministic time does not succeed with a certain other advantage. We can show how to do this for certain values of the parameter s . Recall that we obtain our deterministic simulation of a BPP machine R on input x by running the pseudorandom generator of Theorem 24 using a proof of membership of x in a language $L \in \mathsf{P}$ as the truth table of a supposedly hard function f . Whenever x does not have a compressible proof, the function f is indeed hard, and so the pseudorandom generator succeeds in derandomizing R on input x . In order to succeed on more inputs than just those without compressible proofs, we will not just use the proof for x but also the proofs of a polynomial number of other inputs y of the same length as x . If at least one of them does not have a compressible proof, the concatenation of the polynomially many proofs will be incompressible enough and define a hard function f that we can successfully use in the pseudorandom generator of Theorem 24 to derandomize R on input x . We would like to pick the y 's such that, for many inputs x , they hit the inputs of length n without compressible proofs. In order to do so, we pick the y 's as the neighbors of x in an appropriate expander graph.

The formal proof will use the following two lemmas. The first one states the property that forms the basis for amplification using expanders, and the second one provides a family of expanders with the properties we need.

LEMMA 60 (see [KPS85]). *Let $G = (V, E)$ be a D -regular graph with $V = \{0, 1\}^n$ and second largest eigenvalue $\lambda < D^{9/10}$. Let $s < 1$ be a constant. Let $A \subseteq V$ be a set of size greater than $s2^n$, and let $N(A)$ denote the neighborhood of A , i.e., the set of vertices of G with at least one neighbor in A . Then $|N(A)| \geq (1 - D^{-1/10}/s)2^n$.*

LEMMA 61 (see [KPS85]). *There is an explicit family of graphs $\{G\}_n$ such that G_n has 2^n vertices and is $D = \text{poly}(n)$ -regular with second largest eigenvalue less than $D^{9/10}$. Given a vertex v of G_n , the neighbor set of G is computable in time $\text{poly}(n)$.*

THEOREM 62. *Let $s < 1$ and $c > 1$ be constants. There is a polynomial time bound t such that $\mathsf{P} \subseteq \text{corr}_{1-s}\text{-MATIME}(t)$ or $\mathsf{BPP} \subseteq [\text{io} - \text{corr}_{1-1/n^c}]\text{-P}$.*

Proof. We improve the simulation of $\text{BPTIME}(t')$ in the proof of Theorem 59 by using the amplification technique of [KPS85], while using the same simulation of P by $\text{MATIME}(t)$.

The idea is to interpret the set of strings of length n as the vertices of a D -regular expander G with second largest eigenvalue less than $D^{9/10}$, where D is polynomial in n . Let $\{G\}_n$ be an explicit family of graphs as in Lemma 61. Given an input string x , the set of neighbors y_i , $i = 1, \dots, D$, of x in G_n is determined in polynomial time. The concatenation of the strings $P(y_i)$ is used as hardness source for the deterministic simulation (rather than the string $P(x)$ as in the proof of Theorem 59).

Let t depend on t' in the same way as in the proof of Theorem 59. If $\mathsf{P} \not\subseteq \text{corr}_{1-s}\text{-MATIME}(t)$, there is a language L such that the simulation in the proof of Theorem 59 makes an error on at least an s fraction of the inputs for infinitely many input lengths n . Let us call a string y of length n “good” if $P(y)$ can be used as a hardness source in the deterministic simulation of a language $R \in \text{BPTIME}(t')$. It follows from our hypothesis on L that at least an s fraction of the strings of length n are good for infinitely many input lengths n . Fix an n for which at least an s fraction of the strings are good, and let A_n be the set of good strings. By Lemma 60, $|N(A_n)| \geq (1 - 1/n^c)2^n$, where c is a constant depending on D . Now note that the deterministic simulation of R succeeds on all strings in $N(A_n)$. Thus the simulation succeeds on at least an $1 - 1/n^c$ fraction of strings of length n for infinitely many n , proving the theorem.

□

Note that the quantifiers a.e. and i.o. in the statement of Theorem 62 can be interchanged.

The advantage of the simulation of BPP can be traded off against the time required for the simulation, but we do not pursue this direction here. Instead, we would like to increase the advantage of the simulation even further while maintaining a polynomial running time. We can do so, provided that we switch the a.e. and i.o. quantifiers. In that case, we are no longer restricted in our search for inputs without compressible proofs to y 's of the same length as the input x on which we want to simulate the BPP machine R , but we can use y 's of length polynomially smaller than $|x|$. That allows us to use dispersers instead of expanders, and obtain an advantage exponentially close to 1.

Let us first recall the notion of a disperser. An (N, M, T) -disperser is a bipartite multigraph $G = (V, W, E)$ with $|V| = N$ and $|W| = M$ having the property that any subset of V having at least T vertices has a neighbor set of size at least $2M/3$.

We will use the dispersers provided by the following lemma.

LEMMA 63 (see [SSZ98]). *For all $a, b, 1 \geq a > b \geq 0$, for any $T \geq 2^{\log(N)^a}$ and $M \leq 2^{\log(N)^b}$, there is an explicit (N, M, T) -disperser $G = (V, W, E)$ such that each vertex in V has degree polylogarithmic in N and, for any vertex in V , the neighbor set of the vertex can be computed in time polynomial in $\log(M + N)$ and the size of the neighbor set.*

Proof of Theorem 3. The idea of the proof is similar to the idea of the proof of Theorem 62, except that we use disperser-based amplification rather than expander-based amplification to achieve stronger parameters in this case. We simulate a BPP algorithm R on input x of length n using the fact that the simulation of some language $L \in \mathbf{P}$ by Merlin-Arthur machines operating within some fixed polynomial-time bound has failed for at least $1/3$ of the strings on every input length smaller than n , specifically for input length n^δ , $\delta < \epsilon$. By Lemma 63, there is an explicit $(2^n, 2^{n^\delta}, 2^{n^\epsilon})$ -disperser $G = (V, W, E)$ such that neighbor sets of vertices in V are efficiently computable. We can define a deterministic polynomial-time machine S which simulates R by interpreting its input x as a vertex in V , computing the neighbors $x_1, \dots, x_{\text{poly}(n)}$ of x in G , computing proofs $P(x_1), \dots, P(x_{\text{poly}(n)})$ for these strings, concatenating the proofs together, and using the resulting string as a hardness source for the derandomization of R . It follows from the properties of the disperser G that S works correctly on all but 2^{n^ϵ} inputs of length n , for each n . □

Theorem 3 is a uniform strengthening of the following result by Goldreich and Wigderson [GW02]. Recall that $\text{MATIME}(t) \subseteq \text{SIZE}^{\text{SAT}}(\text{poly}(t))$.

THEOREM 64 (see [GW02]). *There is a polynomial time bound t such that $\mathbf{P} \subseteq [\text{io} - \text{corr}_{2/3}] - \text{SIZE}^{\text{SAT}}(t)$ or, for each $\epsilon > 0$, $\mathbf{BPP} \subseteq \text{corr}_{1-2^{n^\epsilon}/2^n} - \mathbf{P}$.*

Finally, we show a consequence of the hypothesis that \mathbf{P} cannot be simulated by $\text{MATIME}(t)$, where the notion of simulation used is the conventional one. Before stating and proving our result, we state the almost-everywhere hierarchy theorem for deterministic time [GHS91], which is used in the proof.

LEMMA 65 (see [GHS91]). *Let $T(n)$ and $t(n)$ be constructible time bounds such that $t(n) \log(t(n)) = o(T(n))$. Then there is a language D in $\text{DTIME}(T(n))$ such that neither D nor \overline{D} has an infinite subset in $\text{DTIME}(t(n))$.*

THEOREM 66. *There is a polynomial time bound t such that $\mathbf{P} \subseteq \text{MATIME}(t)$ or $\text{DTIME}(T) \not\subseteq \text{ZPP}$ for any superpolynomial time bound T .*

Proof. We shall show that, under the assumption that there is no polynomial-time

bound t such that $\mathsf{P} \subseteq \mathsf{MATIME}(t)$, for every language R in ZPP , either R has an infinite subset in P or \overline{R} has an infinite subset in P . Given this, the consequence that $\mathsf{DTIME}(T) \not\subseteq \mathsf{ZPP}$ follows from Lemma 65.

We follow the proof of Theorem 59 for $s(n)2^n = 2^n - 1$. Let R be a language in ZPP accepted by a zero-error probabilistic Turing machine M running in time t' . Let L be a language in P that is not in $\mathsf{MATIME}(t)$ for t sufficiently larger than t' but still polynomial, as set in the proof of Theorem 59. Since $L \notin \mathsf{MATIME}(t)$, there is an infinite set X of strings x such that $P(x)$ is a good hardness source for the simulation of M on input x : Using $P(x)$ as a hardness source in Theorem 24 yields a polynomial length list of strings, at least one of which is a ZPP witness for M on input x . Since we can check the validity of ZPP witnesses for M on input x in polynomial time, we have an infinite set X in P for which we can decide the membership in R in polynomial time. If $R \cap X$ is infinite, it is an infinite subset of R in P ; otherwise, $\overline{R} \cap X$ is infinite and forms an infinite subset of \overline{R} in P . \square

6. Unconditional simulations. The trivial deterministic simulation of a time t probabilistic multitape Turing machine computation runs in time $\Omega(2^t)$. All previously published $o(2^t)$ deterministic simulations work only under unproven lower bound assumptions. This raises the question whether anything nontrivial can be shown unconditionally.

The oracle relative to which there is a constant c such that $\mathsf{DTIME}(2^{cn}) \subseteq \mathsf{BPTIME}(n)$ [Hel86, KV96] can be considered a negative indication in this connection. Nevertheless, we show that nontrivial deterministic simulations *do* exist for multitape Turing machines, as well as for restricted formulae and NC^1 circuits.

As explained in the introduction, our technique involves recycling random bits. Essentially, a large initial prefix of the random string used by the probabilistic algorithm can be interpreted as a randomness source for an extractor to produce additional almost-random bits and thus save on randomness later in the computation. We refer to section 1.3 for a more detailed intuitive account of our approach. We now proceed with the formal proof.

For the sake of economy of presentation, we use the single extractor family given by Theorem 26 in the proofs of our results for Turing machines and NC^1 circuits. For each of our results, there are earlier constructions that have the properties needed for the proof of that particular result, but the construction from Theorem 26 has all these properties combined.

THEOREM 67. *For any integers $k > 0$ and $\beta > 0$, there is a constant $\delta > 0$ such that for each language L accepted by a probabilistic k -tape Turing machine with alphabet size β and constant error bound $\epsilon < 1/2$ in time t , L is accepted by a probabilistic Turing machine with error bound ϵ that runs in time $\text{poly}(t)$ and uses $(1 - \delta)t$ random bits.*

Proof. Let M be a multitape probabilistic Turing machine with k tapes and alphabet size β operating in time t and accepting the language $L(M)$ with error bounded by ϵ . Let ϵ' be a small positive constant such that $\epsilon + \epsilon' < 1/2$. We construct a probabilistic Turing machine M' accepting $L(M)$ with error bound $\epsilon + \epsilon'$ and operating in time $\text{poly}(t)$ that uses only $(1 - \delta')t + O((\log(t))^3) < (1 - \delta)t$ random bits, where δ' is a constant to be determined later, and δ is any positive constant less than δ' . Given an input x , M' begins by simulating M for $(1 - \delta')t$ steps. It stores the random bits r it uses on a separate tape. Let $C_r(x)$ be the configuration that M' attains after using the random bit sequence r . By Theorem 26, there is an explicit $(\delta't, \epsilon'/2)$ extractor $\text{Ext} : \{0, 1\}^{(1 - \delta')t} \times \{0, 1\}^{c(\log(t))^3} \rightarrow \{0, 1\}^{\delta't}$ computable in NC^1

and hence in polynomial time. M' applies Ext to arguments r and l for a random seed $l \in \{0, 1\}^{c(\log(t))^3}$ and continues the simulation of M from $C_r(x)$ on the string $Ext(r, l)$ instead of using a random string of length $s = \delta't$. M' operates in $poly(t)$ time and uses $(1 - \delta')t + O((\log(t))^3)$ random bits. We show below that, when δ' is chosen appropriately, M' has error bound $\epsilon + \epsilon'$ and accepts x iff M does.

The basic observation that we need is that when M is a multitape Turing machine, only ds bits of the configuration C_r are relevant to the last s steps of the computation of M , where $d = 2(k + 1) \log(\beta)$. If we think of the random string r as inducing a function from the last s random bits used by the computation to $\{0, 1\}$, the observation above means there can be at most 2^{ds} such functions. Let us denote the function induced by random string r by f_r . More precisely, given a random string r , let $f_r : \{0, 1\}^s \rightarrow \{0, 1\}$ be the function that maps a string r' to the outcome of M on the random string $R = rr'$. Think of the function f_r as a random variable on the sample space defined by r . Now we consider two cases for any fixed function $f : \{0, 1\}^s \rightarrow \{0, 1\}$ induced by some random string r . Either $f = f_r$ with probability at least $\epsilon'/(2^{ds+1})$ over the random strings r , or it does not. Let us call an f satisfying the first case a ‘‘probable’’ f and an f satisfying the second case an ‘‘improbable’’ f .

If f is probable, the distribution D_f on $\{0, 1\}^{(1-\delta')t}$, which is uniform on all strings r such that $f = f_r$, has high min-entropy, and we can approximate the probability (over the set of all its inputs) that f is 1 by extracting almost-random bits from D_f and evaluating f on the extracted bits. When f is improbable, we can make no guarantees about approximating the probability that f is 1, but by the observation in the previous paragraph, there are at most 2^{ds} such functions f , and we can bound the total error in this case. We now work out the argument in more detail.

Let p be the probability that M accepts on input x , and p' the probability that M' accepts on input x . We wish to bound the difference $|p - p'|$.

$$\begin{aligned}
(1) \quad |p - p'| &= \left| E_{R \in \{0, 1\}^t} [M(x, R)] - E_{R \in \{0, 1\}^{(1-\delta')t + c(\log(t))^3}} [M'(x, R)] \right| \\
(2) \quad &= \left| E_r [E_{r'} [f_r(r')]] - E_r \left[E_{l \in \{0, 1\}^{c(\log(t))^3}} [f_r(Ext(r, l))] \right] \right| \\
(3) \quad &\leq \sum_{f: \{0, 1\}^s \rightarrow \{0, 1\}} \Pr_r [f = f_r] \cdot |E_{r'} [f(r')] - E_{r \leftarrow D_{f, l}} [f(Ext(r, l))]| \\
&= \sum_{f \text{ probable}} \Pr_r [f = f_r] \cdot |E_{r'} [f(r')] - E_{r \leftarrow D_{f, l}} [f(Ext(r, l))]| \\
(4) \quad &+ \sum_{f \text{ improbable}} \Pr_r [f = f_r] \cdot |E_{r'} [f(r')] - E_{r \leftarrow D_{f, l}} [f(Ext(r, l))]| \\
(5) \quad &\leq \sum_{f \text{ probable}} \Pr_r [f = f_r] \cdot \epsilon'/2 + \sum_{f \text{ improbable}} \Pr_r [f = f_r] \cdot 1 \\
(6) \quad &\leq \frac{\epsilon'}{2} + \frac{2^{ds} \epsilon'}{(2^{ds+1})} \\
&= \epsilon'.
\end{aligned}$$

Equation (2) follows from (1) by splitting up the computations of M and M' into the first $(1 - \delta')t$ steps and the rest. Then (3) follows from (2) by grouping terms differently and applying the triangle inequality. (4) follows from (3) just by considering sums for probable and improbable f 's separately.

The second summation term in (5) follows from the second summation term in (4) because the difference in expectations of two $(0, 1)$ -random variables is bounded

above by 1. We describe how to choose δ' so that the first summation term in (4) is bounded by the first summation term in (5). If f is probable, the probability over r that r induces f is at least $\epsilon'/2^{d\delta't+1}$, and since D_f is uniform over all such r , D_f has min-entropy at least $(1-\delta')t - (d\delta't + \log(1/\epsilon') + 1)$. If we set $\delta' < 1/(d+2)$, D_f has min-entropy at least $\delta't$ for large enough t , and by assumption on the extractor Ext , the distribution $Ext(r, l)$, where r is chosen from D_f and l from $U_{c(\log(t))^3}$, is $\epsilon'/2$ -close to uniform. Hence, the distribution $f(Ext(r, l))$ is $\epsilon'/2$ -close to the distribution $f(r')$, where r' is chosen from the distribution $U_{\delta't}$, and the difference in expectations is bounded above by $\epsilon'/2$.

The first term in (6) follows from the first summation term in (5) because the events $f_r = f_1$ and $f_r = f_2$ are disjoint for distinct functions f_1, f_2 . To see that the second term in (6) follows from the second summation term in (5), note that there are at most 2^{ds} bad f 's, and for each of these the probability over r that r induces f is less than $\epsilon'/2^{ds+1}$.

Thus M' accepts L with error bound $\epsilon + \epsilon'$. By using the error reduction technique of [KPS85] (as in section 5), which does not use additional random bits, we obtain a simulating machine M' with the same error bound as the simulated machine. \square

Theorem 4 follows from Theorem 67 by running over all random strings of length $(1-\delta)t$. Using the efficient error reduction of [CW89], we obtain the following.

COROLLARY 68. *For any integers $k > 0$ and $\beta > 0$, there is a constant $\gamma > 0$ such that for each language L accepted by a probabilistic k -tape Turing machine with alphabet size β in time t with a constant error bound, L is accepted by a probabilistic multitape Turing machine using t random bits and running in time $\text{poly}(t)$ with error bound $2^{-\gamma t}$.*

Theorem 67 works in rather restricted situations. For one, the argument does not work for probabilistic classes defined by RAMs. The essential condition is that the machines defining the complexity class have polynomial ‘‘vicinity’’; i.e., the cardinality of the set of positions in any given configuration which can be accessed within s time steps is bounded above by a polynomial in s . This is true, for instance, of multi-dimensional Turing machines, but not for more general machines such as RAMs or pointer machines. Secondly, the argument works only when the probabilistic algorithm uses as much randomness as time. We can handle the situation where the number of computation steps between two consecutive accesses to the random tape is bounded, but not the general case in which the computation takes time linear in the number of random bits used, with a constant factor larger than 1. A further step would be deterministic simulations of randomized computations that run in time t and use r random bits, where the simulation runs in time $o(2^r) \cdot \text{poly}(t)$. However, as explained in section 1.3, this would imply new lower bounds in case $r = o(t)$.

Our approach works for randomized formulae and NC^1 circuits but not for general randomized circuits. Recall that a randomized circuit takes two inputs—a ‘‘random input’’ corresponding to the random bits used by the circuit and the ‘‘actual input,’’ such that for each setting of the actual input, the circuit either accepts with probability at least $2/3$ or rejects with probability at least $2/3$ over the choices of the random input.

The reason why our strategy fails for general circuits is that all but a logarithmic number of random inputs may need to be set on a given actual input in order to significantly reduce the size of the circuit. Formulae do not exhibit that problem. If we set all but the r^ϵ least popular variables occurring in a formula of size t on r variables, the resulting formula is of size no more than $s = t/r^{1-\epsilon}$. Since the number of formulae of size s on r^ϵ inputs is bounded by $2^{O(\epsilon s \log r)}$, we have the kind of

bound we need on the number of different future behaviors for our earlier argument, provided $s \log r$ is sufficiently less than r , or equivalently, that t is sufficiently less than $r^{2-\epsilon}/\log r$. Thus, we can simulate randomized formulae of less than quadratic size by picking the $r - r^\epsilon$ most popular random input bits uniformly at random, and extracting the r^ϵ remaining ones using the extractor from Theorem 26. Since that extractor is computable by a formula of polynomial size, the overall simulation can be implemented by a formula of polynomial size with r^ϵ fewer random input bits than the original formula.

Moreover, finding the r^ϵ least popular variables in a formula can be done by counting the number of occurrences of each variable, and sorting the variables using that count as the key. Since all these operations run in logspace (even in TC^0) and logspace computations compose, the overall transformation preserves logspace uniformity.

A similar argument works for randomized NC^1 circuits of restricted depth because of the standard conversion between NC^1 circuits of depth d and formulae of size $2^{\Theta(d)}$. We now provide more details for that case.

THEOREM 69. *For each constant $\epsilon > 0$, for each LOGSPACE-uniform family of randomized NC^1 circuits using r random bits of depth $(2 - \epsilon) \log(r)$, there is an equivalent LOGSPACE-uniform family of randomized NC^1 circuits using $r - r^{\epsilon/2}$ random bits.*

Proof. Let $\{C_n\}$ be a family of randomized NC^1 circuits taking a random input of length r and having depth $(2 - \epsilon) \log(r)$. We first describe how to construct an equivalent circuit family $\{C'_n\}$ that uses less randomness, and then explain how the uniformity of the circuit family can be preserved.

Fix an integer n . The idea of the simulation is to set all but $r^{\epsilon/2}$ of the random input variables of C_n to random bits, and then extract values for the remaining $r^{\epsilon/2}$ random bits using the extractors from Theorem 26. To argue that this works, we consider a representation of C_n which is semantically equivalent but easier to work with, namely a formula. By standard techniques, C_n can be transformed into a formula F_n of size $2^{(2-\epsilon) \log(r)} = r^{2-\epsilon}$. This formula contains variables for both the random input bits and the actual input bits. Let m be the number of occurrences of actual input variables in the formula. Now we need to choose values for some of the random input variables of the formula so that the formula decreases in size by a polynomial fraction when those variables are set. We do this by ranking the random input variables in decreasing order of frequency of occurrence in the formula F_n and choosing the $r^{\epsilon/2}$ least frequently occurring variables to be left unset. Setting the other random input variables and the actual input variables always reduces the size of the formula to $r^{\epsilon/2}(r^{2-\epsilon} - m)/r \leq r^{1-\epsilon/2}$ or less. Thus, as explained in the sketch before the proof, the number of different residual formulae is small enough to carry through an argument similar to the one in the proof of Theorem 67—the extractor from Theorem 26 can be successfully applied to recycle the randomness of the set random input variables and estimate the probability that the residual formula is 1.

Since the extractor of Theorem 26 can be evaluated in logarithmic depth, it is clear that the new circuit C'_n has logarithmic depth. C'_n has a slightly larger error bound than C_n , but this can be reduced by a constant factor by doing expander-based amplification [BYGW99].

In order to argue the logspace uniformity of the resulting family $\{C'_n\}$, the critical step is determining the $r^{\epsilon/2}$ least popular random input variables in F_n . Note that the transformation from C_n into F_n can be performed in logspace. Once we have F_n ,

we can follow the strategy outlined before: Count the number of occurrences of each random input variable, rank the variables in increasing order of that count, and select the first $r^{\epsilon/2}$. The overall procedure runs in logspace since each of its components does. \square

Finally, we wish to draw attention to the fact that the proof of Theorem 69 is a rare example of a “non-black-box” technique; i.e., the deterministic simulation does not merely query the results of executing the probabilistic circuit on certain random strings but also takes the structure of the circuit into consideration. More sophisticated use of these techniques may even yield simulations that beat oracle constructions. But the specific technique used here does not seem capable of reducing the amount of randomness by more than a factor of $1/2$. This is because the number of future behaviors on the last s random bits is typically at least 2^s , which implies that we need to extract s bits of randomness from the first $r - s$ random bits. The latter is impossible if $s > r/2$. Iterated applications of the idea seem difficult because the bound of $2^{O(s)}$ on the number of future behaviors typically does not hold for the *next* s steps but only for the *last* s .

Acknowledgments. Thanks to Eric Allender for his comments on an earlier version of this paper. Thanks also to Janos Simon for comments on an earlier version, and for his encouragement. We are grateful to Prahlahd Harsha and Shien Jin Ong for pointing out a problem in an earlier version of this paper. We also want to thank Albert Atserias and Michal Koucky for interesting discussions, and the anonymous referees for their thorough reports and helpful suggestions.

APPROXIMATING THE WEIGHT OF THE EUCLIDEAN MINIMUM SPANNING TREE IN SUBLINEAR TIME*

ILAN NEWMAN^{||}, RONITT RUBINFELD[#], AND CHRISTIAN SOHLER^{††}

Abstract. We consider the problem of computing the weight of a Euclidean minimum spanning tree for a set of n points in \mathbb{R}^d . We focus on the setting where the input point set is supported by certain basic (and commonly used) geometric data structures that can provide efficient access to the input in a structured way. We present an algorithm that estimates with high probability the weight of a Euclidean minimum spanning tree of a set of points to within $1 + \varepsilon$ using only $\tilde{O}(\sqrt{n} \text{poly}(1/\varepsilon))$ queries for constant d . The algorithm assumes that the input is supported by a minimal bounding cube enclosing it, by orthogonal range queries, and by cone approximate nearest neighbor queries.

Key words. sublinear algorithms, minimum spanning tree

1. Introduction. As the power and the connectivity of computers increase and the cost of memory becomes cheaper, we have become inundated with large amounts of data. Although traditionally linear time algorithms were sought to solve our problems, it is no longer clear that a linear time algorithm is good enough in every setting. The question then is whether we can solve *anything* of interest in sublinear time, when the algorithm is not even given time to read all of the input data. The answer is yes; in recent years, several sublinear time algorithms have been presented that solve a wide range of property testing and approximation problems.

In this paper we consider the problem of estimating the weight of a minimum spanning tree, where the input is a set of points in the Euclidean space \mathbb{R}^d . Since the location of a single point may dramatically influence the value of the weight of the Euclidean minimum spanning tree (EMST), we cannot hope to get a reasonable

approximation in sublinear time with access only to the locations of the points. This is true even when we consider probabilistic algorithms. However, it is often the case that massive databases, particularly in a geometric context, contain sophisticated data structures on top of the raw data that support various forms of queries. Examples of such queries are the nearest neighbor of a point, or the point with the highest value in a coordinate. Consequently, in this paper, we assume that algorithms have access to certain commonly used data structures which aid the algorithm in its computation. This may be considered a motivation for maintaining such data structures, particularly if they aid in other tasks as well.

1.1. Results. In this paper we describe three algorithms for estimating the weight of an EMST over n given points in a Euclidean space \mathbb{R}^d , where the algorithms are given access to basic geometric data structures supporting the input. Throughout the paper we assume that d is a constant, though our analysis can be easily carried over for arbitrary values of d . It should be noted that our algorithms do not supply a low weight spanning tree (which takes linear space to represent) but only estimate its weight.

We first consider the case when the algorithm is given, in addition to access to the input point set, (1) a *minimal bounding cube* that contains all points in the input set and (2) access to an *orthogonal range query* data structure which, given an axis-parallel cube, answers whether there is an input point within the cube. In this model, we give a deterministic $\mathcal{O}(n^{1/2})$ -time algorithm for the two-dimensional case that outputs a value w such that $\frac{1}{\alpha} \text{EMST}(P) - \mathcal{L}n^{-c} \leq w \leq \alpha \text{EMST}(P) + \mathcal{L}n^{-c}$, where $\alpha = \Theta(n^{1/8} \log n)$, \mathcal{L} is the side length of a minimal axis parallel bounding cube of the point set, and c is an arbitrary constant. We also show that any deterministic algorithm that uses $o(n^{1/2})$ orthogonal range queries cannot significantly improve the quality of approximation.

We next consider the case where, in addition to the above data structures, we are also given (3) access to a *cone nearest neighbor* data structure, which, given a point p and a cone C , returns a nearest point to p in the cone $p + C$. Our second algorithm combines the extra power of the cone nearest neighbor data structures with ideas from the recent randomized sublinear-time algorithm for estimating the minimum spanning tree (MST) in general graphs [10]. The algorithm outputs a value which, with high probability, is within a $1 + \varepsilon$ factor of the EMST, and it runs in $\mathcal{O}(\Lambda/\varepsilon^3)$ time, where Λ is the *spread* of P (the ratio of the maximum and minimum distances between points in P); observe that Λ can be arbitrarily large.

Our main contribution is the third algorithm that does not have any dependency on Λ and requires only cone *approximate* nearest neighbor queries, which we define in the next section. For a constant d , the algorithm runs in $\tilde{\mathcal{O}}(\sqrt{n} \text{poly}(1/\varepsilon))$ time and outputs an approximation of the EMST weight to within a multiplicative factor of $1 + \varepsilon$ with high probability. The algorithm combines the ideas from our first two algorithms. It partitions the input points into components and estimates the EMST separately by considering pairs of points that lie in the same component and pairs of points that belong to different components. To estimate the EMST within components, we use an extension of our second algorithm. To estimate the weight required to connect the components we use a variant of our first algorithm. The combination of these two algorithms leads to a significant improvement in the quality of approximation (compared to the first algorithm) and in the running time (compared to the second algorithm).

We notice also that our algorithms lead to sublinear-time $(2 + \varepsilon)$ -approximation

algorithms for two other classical geometric problems: Euclidean TSP and the Euclidean Steiner tree problem. These results follow from the well-known relationship between the weight of EMST and the weight of the Euclidean TSP and of the Euclidean Steiner tree (see, e.g., [24]). Indeed, it is known that in metric spaces the weight of the Euclidean TSP is between the weight of the EMST and twice the EMST weight. Similarly, it is known that in metric spaces the EMST weight is between the weight of the Steiner tree and twice its weight. On the plane, one can improve this result by using the fact that the EMST weight is upper bounded by at most $2/\sqrt{3}$ times the weight of the Euclidean Steiner tree [13].

1.2. Relation to previous works. The EMST problem is a classical problem in computational geometry and has been extensively studied in the literature for more than two decades. It is easy to see that to find the EMST of n points, $\mathcal{O}(dn^2)$ time suffices, by reducing the problem to finding the MST in dense graphs. In the simplest case where $d = 2$ (on the plane), Shamos and Hoey [22] show that the EMST problem can be solved in $\mathcal{O}(n \log n)$ time. For $d \geq 3$, no $\tilde{\mathcal{O}}(n)$ -time algorithm is known, and it is a major open question whether an $\mathcal{O}(n \log n)$ -time algorithm exists even for $d = 3$ [16]; in fact, it is even conjectured (see, e.g., [16]) that no $o(n^{4/3})$ -time algorithm does exist. Yao [26] was the first who broke the $\mathcal{O}(n^2)$ -time barrier for $d \geq 3$ and designed an $\tilde{\mathcal{O}}(n^{1.8})$ -time algorithm for $d = 3$. This bound has since been improved, and the fastest currently known (randomized) algorithm achieves the running time of $\tilde{\mathcal{O}}(n^{4/3})$ [2] for $d = 3$ (and the running time tends to $\mathcal{O}(n^2)$ as d grows). Significantly better bounds can be achieved if one allows the output to be approximated. Callahan and Kosaraju [7] give a $\mathcal{O}(n \log n + n \log(1/\varepsilon) \varepsilon^{-d/2})$ -time algorithm that finds an approximate EMST to within a multiplicative factor of $1 + \varepsilon$.

Our algorithms rely on a recent randomized algorithm of [10] that, given a connected graph in adjacency list representation with average degree d , edge weights in the range $[1, \dots, W]$, and a parameter $0 < \varepsilon < \frac{1}{2}$, approximates, with high probability, the weight of an MST in time $\tilde{\mathcal{O}}(dW \varepsilon^{-3})$ within a factor of $1 + \varepsilon$. The time bound does not directly depend on the number of vertices or edges in the graph. We emphasize, however, that our representation is quite different, and in general would give a graph with average degree n . Therefore, a direct application of this result to the EMST problem does not lead to a sublinear-time algorithm.

We also note that very recently a similar approach which also partitions the input points on a grid similar to that used in our paper has been used by Indyk [18] in the problem of approximating the EMST in the streaming model in one pass. He showed that the EMST of n points from $\{1, \dots, \Delta\}^d$ is approximated to within an $\mathcal{O}(d \log \Delta)$ factor using $\mathcal{O}(d \log^2 \Delta)$ bits of storage for dynamic data streams through hierarchically well-separated trees defined over a set of grids over the input points. In another recent work, Czumaj and Sohler [12] designed a randomized $(1 + \varepsilon)$ -approximation algorithm for metric MST with the running time $\mathcal{O}(n \text{polylog}(n)/\varepsilon^{\mathcal{O}(1)})$, where the input graph has n vertices and $\Theta(n^2)$ edges.

1.3. Dynamic algorithms. Our model of computation is also interesting in the context of dynamic algorithms. There exist fully dynamic algorithms that maintain the EMST subject to point insertions and deletions; [15] gives an algorithm with amortized time $\tilde{\mathcal{O}}(\sqrt{n})$ and $\mathcal{O}(n^{1-\varepsilon})$ per update operation for $d \leq 4$ and $d > 4$, respectively. A disadvantage of this algorithm (and of all typical dynamic algorithms) is that it requires as much as $\tilde{\mathcal{O}}(\sqrt{n})$ time per input update, making the algorithm very costly in situations where the EMST queries are very rare. The data structures we require

in our setting are dynamically maintained by standard geometric databases anyway. Thus, if the database supports all required data structures in polylogarithmic time, the amortized time required by our algorithm is $\tilde{O}(\sqrt{n}/U)$, where U is the typical number of updates per one EMST calculation. We note again that our algorithm does not supply the MST but returns only its approximate weight.

1.4. Discussion on the model of computations. Our results assume that the data is organized using certain types of commonly used data structures. This idea has been frequently used in other areas such as databases, where one assumes that a selected set of operations on the top of the data set is provided to the user. A similar model of computations has been used recently in a related context of geometric computations in [11] (see also [23]).

The data structures used in our paper are commonly used in algorithms in general, and some (as in supporting approximate nearest neighbor queries) are used more in the context of computational geometry. Our algorithm cannot be expected to construct these data structures given its sublinear nature. Neither can it be assumed to have collected the input set. The assumption that some other source has collected the data is inherent in the model of sublinear algorithms, and in our paper we strengthen this assumption to require that during this preprocessing, some well-known and natural data structures have been built. In most of the cases, the construction time for these data structures is not much in excess of the time needed to read and store the entire data set. One can view this as having separate agents performing the data collection and computation. Alternately, one can think of the data collection and organization step as preprocessing, to be done only once. One would like to know the degree of dependence on these underlying data structures and explore the tradeoff resulting from them. We believe that this work is an important step in understanding the nature of geometric problems and the time/resource tradeoffs (resources can include the underlying data structures) involved in their solutions. We would like to learn what inherent properties of a problem and its data set lead to better sublinear algorithms. In the future we expect to solve more problems in this area and develop an understanding of the inherent structure of geometric objects and their collections that allow different time/resource tradeoffs.

Organization of the paper. We start by presenting an algorithm that needs access to only a minimal bounding cube of the point set P and to an orthogonal range query oracle in section 3. In section 5, we present a simple algorithm that uses additionally the cone nearest neighbor oracle. Finally, in section 6, we discuss the main contribution of this paper, a sublinear time algorithm that uses a minimal bounding cube oracle, the orthogonal range query oracle, and the cone *approximate* nearest neighbor oracle.

2. Preliminaries. For a given set P of points in a Euclidean space \mathbb{R}^d , a (*Euclidean*) *graph* on P can be modeled as a weighted undirected graph $G = (P, E)$, where P is a vertex set, E is a subset of the (unordered) pairs of points in P , and the *length/weight* of edge $\{p, q\}$ is equal to the Euclidean distance between points p and q , denoted $|p - q|$. The *weight of the graph* is the sum of the weights of its edges.

Throughout the paper we denote by \mathbb{K}_P the complete (undirected) graph on P where the edge weights are the Euclidean distances between the endpoints. A graph G on a set of points P is called a *Euclidean minimum spanning tree* (EMST) of P if it is a minimum-weight spanning subgraph of \mathbb{K}_P . We denote by $\text{EMST}(P)$ both the EMST of P and the weight of the EMST of P . Similarly, for a given graph G we

will denote by $\text{MST}(G)$ the minimum spanning tree of G as well as the weight of the minimum spanning tree of G .

For a given point set P , we denote by Λ the *spread* of P , that is, the ratio of the maximum and the minimum distances between points in P . We let \mathcal{BC} be a minimal bounding cube of P (which is made available via the *minimal bounding cube oracle*) and let \mathcal{L} denote its side length.

2.1. Models of computation. In this paper we use some basic geometric data structures supporting access to the input point set. Given a point set P in \mathbb{R}^d , we use data structures supporting the following types of queries:

(i) *minimal bounding cube of P* : returns the location of a minimum size axis-parallel d -dimensional cube containing P ; that is, it returns the location of a cube $C = [a_1, a_1 + \mathcal{L}] \times [a_2, a_2 + \mathcal{L}] \times \cdots \times [a_d, a_d + \mathcal{L}]$ that contains P such that no axis-parallel cube of edge length smaller than \mathcal{L} contains P ;

(ii) *(orthogonal) range query oracle*: for a given axis-parallel cube C , tests whether C contains a point from P ;

(iii) *cone $(1 + \delta)$ -approximate nearest neighbor oracle*: δ is any nonnegative real number, and it is assumed that a set of cones \mathcal{C} with apexes at the origin is given in advance. The cone $(1 + \delta)$ -approximate nearest neighbor oracle, for a given point $p \in P$ and a given cone $C \in \mathcal{C}$, returns a $(1 + \delta)$ -approximate nearest neighbor¹ of p in $(P \setminus \{p\}) \cap (p + C)$. (We denote by $p + C$ the translated cone $\{a + p : a \in C\}$.) If $(P \setminus \{p\}) \cap (p + C)$ is empty, then a special value is returned.

In the special case where $\delta = 0$, the oracle gives the true nearest neighbor and is simply called the *cone nearest neighbor oracle*.

2.1.1. Implementing supporting data structures. To make our model of computations viable, we discuss here how our supporting data structures (oracles) can be implemented efficiently using standard geometric data structures.

Minimal bounding cube. The query about the *minimal bounding cube* of a set of points $P \in \mathbb{R}^d$ can be supported by many standard geometric data structures. Indeed, the only information required to find the minimal bounding cube is to know the minimum and maximum d -dimensional coordinates of all input points. Therefore, many standard geometric data structures can support this query in time $\mathcal{O}(d)$ or $\mathcal{O}(d \log n)$.

Orthogonal range query oracle. There are many efficient data structures supporting the *orthogonal range query oracle*, and actually, orthogonal range queries are perhaps the most widely supported geometric queries (for survey expositions, see, e.g., [1, 3, 6]). One of the first data structures for orthogonal range searching is the *quad-tree*. Despite its bad worst-case behavior, the quad-tree is still used in many applications because it provides an easy-to-implement linear-space data structure that often has a very good performance. Another standard data structure for orthogonal range queries is the range tree. It can be used to report the k points in a query range in $O(\log^d n + k)$ time. Using the fractional cascading technique, the query time can be improved to $O(\log^{d-1} n + k)$ [20, 25]. The best known data structures for orthogonal range searching based on compressed range trees and some other techniques such as filtering search can be found in [8, 9]. For more details we refer to the survey [3].

Cone nearest neighbor oracle. In the seminal paper on Euclidean minimum spanning trees, Yao [26] examined algorithms for cone nearest neighbor in the cones with

¹For a point $p \in P$ and a set of points $Q \subseteq \mathbb{R}^d$, a $(1 + \delta)$ -approximate nearest neighbor of p in Q is any point $q \in Q$ such that for every $x \in Q$ it holds that $|p - q| \leq (1 + \delta) \cdot |p - x|$.

the angular diameter $\pi/4$. Cone nearest neighbor queries have also been studied extensively in follow-up papers dealing with the EMST problem (see, e.g., [2]).

Cone approximate nearest neighbor oracle. Cone *approximate* nearest neighbor queries have been widely investigated. They play an important role in the context of construction of Euclidean spanners (see, e.g., [4, 5, 14, 21]). And thus, among others, Ruppert and Seidel [21] show how to answer a query in amortized time $\mathcal{O}(n \log^{d-1} n)$ per cone in C , simultaneously for all points in P ; a similar construction is presented in [5]. Arya, Mount, and Smid [4] present a fully dynamic algorithm which, in polylogarithmic time, supports cone approximate nearest neighbor queries. Notice also that a single cone approximate nearest neighbor query can be answered using a logarithmic number of *simplex (triangular) range queries*, which is another classical geometric data structure (see, e.g., [1, 3, 6]).

3. Estimating the EMST with bounding cube and range queries. In this section we describe a natural approach to the approximation of $\text{EMST}(P)$ using minimum bounding cube oracle and orthogonal range queries. This approach by itself does not give a good enough multiplicative approximation but is used as a building block in the sublinear algorithm we present later. For simplicity, we describe in detail only the two-dimensional case ($d = 2$); the algorithm can be generalized to arbitrary d in an obvious way. The algorithm we supply is deterministic and outputs a value w such that $\frac{1}{\alpha} \text{EMST}(P) - \beta \leq w \leq \alpha \text{EMST}(P) + \beta$, where $\alpha = \mathcal{O}(n^{1/8} \log n)$, and $\beta = \mathcal{L} n^{-c}$, where \mathcal{L} is the side length of a minimal bounding cube of P and c is a constant. The algorithm has a running time of $\mathcal{O}(n^{1/2})$. We also show that any algorithm that uses the same running time (in fact, the same amount of queries and arbitrarily large running time) cannot significantly improve the quality of the approximation.

3.1. The quad-tree algorithm. We apply a standard quad-tree subdivision to the bounding cube \mathcal{BC} (see, e.g., [6, Chapter 14]). That is, we first partition \mathcal{BC} into four disjoint blocks (squares) of equal size. We can check which blocks contain points from P via orthogonal range queries. We then further subdivide the nonempty blocks and iterate this process as long as fewer than \sqrt{n} queries are made. This induces a tree structure on the blocks, where a block at level i has side length $\mathcal{L}/2^i$. Let k be the depth of this tree. We may assume that all nonempty blocks at level $k-1$ were subdivided into subblocks (of level k) and each subblock of level k was queried. Let B be the set of nonempty blocks at level k and let $b = |B|$. Clearly $b = \mathcal{O}(\sqrt{n})$. We now run any MST algorithm (as we will see later, a $(1 + \varepsilon)$ -approximation is good enough) on the centers of the blocks in B . This would result in a value L . We set $U = L + s\sqrt{bn}$, where $s = \mathcal{L} \cdot 2^{-k}$, and output the value $w = \sqrt{LU}$ as an approximation for $T^* = \text{EMST}(P)$.

CLAIM 1. *For an arbitrary constant c , $\frac{1}{\alpha} T^* - \beta \leq w \leq \alpha T^* + \beta$, where $\alpha = \mathcal{O}(n^{1/4} \log n)$ and $\beta = \mathcal{L} n^{-c}$.*

Proof. First note that the MST of any n points in a d -dimensional cube with side length h is $\mathcal{O}(h n^{\frac{d-1}{d}})$ and that this bound is tight (i.e., it is achievable for some inputs); see, e.g., [19]. Now, we let L^* be the weight of a minimum weight tree that touches every block in B . It is easy to see that $L^* \leq T^* \leq U$ (the last inequality is by the above upper bound and by using convexity).

Assume now that $b \geq \sqrt{n}/(4(c+1) \log n)$; then it can be seen that L upper bounds L^* and approximates it within an additive term of $\mathcal{O}(sb)$, and hence within a constant factor, say δ . Namely, $a \cdot b \cdot s \leq L^* \leq L \leq \delta \cdot L^*$ for some constants a and δ .

Hence, as U is an upper bound on T^* , the approximation factor turns out to be

$\alpha = \max\{U/w, w/L^*\}$. By our choice of w and the fact that L approximates L^* up to a constant, we get $\alpha = \mathcal{O}(\frac{U}{w}) = \mathcal{O}(\sqrt{\frac{U}{L^*}}) = \mathcal{O}((\frac{s\sqrt{bn}}{L})^{1/2}) = \mathcal{O}((n/b)^{1/4})$ (where the last inequality follows by plugging in the expression for U and L , and the previous follows from the fact that L approximates L^* within a constant factor). Now, by the above bound on L and on b , we obtain that $\alpha \leq \tilde{\mathcal{O}}(n^{1/8})$. Note that if we used an approximation L' guaranteed to be within a constant factor of L , we would still get the same result.

Assume now that $b < \sqrt{n}/(4(c+1)\log n)$. Then it can be seen that the depth of the quad-tree is at least $(c+1)\log n$ and hence $s \leq \mathcal{L} \cdot n^{-(c+1)}$. Therefore, the additive term is upper bounded by $U - L \leq \mathcal{O}(s \cdot \sqrt{bn}) = \mathcal{O}(n^{-(c+1)} \cdot \mathcal{L} \cdot n) = \mathcal{O}(\mathcal{L} \cdot n^{-c})$. \square

A note on the running time is due here. We use $\mathcal{O}(\sqrt{n})$ queries in the course of constructing the quad-tree. Next, we have to find the MST (or any $(1+\delta)$ approximation to it for any fixed δ). In the two-dimensional case this can be done in $\tilde{\mathcal{O}}(\sqrt{n})$ time [22], and this term dominates the total complexity.

Higher dimensions. In the case of dimension $d > 2$ the quad-tree has to be replaced with a 2^d -ary tree. The algorithm will be run similarly to the above until $\mathcal{O}(2^d \sqrt{n})$ queries have been made and all rectangles at the bottom level have been queried. Then, L is set similarly to the two-dimensional case, and $U = L + s \cdot n^{\frac{d-1}{d}} \cdot b^{1/d}$. The approximation w for T^* is taken to be the same. To have an efficient running time, a constant approximation for L can be used, rather than the exact value. This can be done in time $\mathcal{O}(n \log n)$ by the result of Callahan and Kosaraju [7].

It is easy to see that the following replaces Claim 1 with an analogous proof.

CLAIM 2. *For an arbitrary constant c , $\frac{1}{\alpha}T^* - \beta \leq w \leq \alpha T^* + \beta$, where $\alpha = \mathcal{O}(2^{d/2} \cdot n^{(d-1)/4d} \log n)$ and $\beta = \mathcal{L} n^{-c}$.*

As it turns out, the above quality of approximation is nearly optimal for the given time bound as shown by the following claim (shown only for the two-dimensional case; a similar result is true for the d -dimensional case as well).

CLAIM 3. *Any deterministic algorithm for approximating $\text{EMST}(P)$ in the two-dimensional case that uses $\mathcal{O}(\sqrt{n})$ orthogonal range queries has an approximation factor of $\Omega(n^{1/4})$.*

Proof. Consider any deterministic algorithm that uses at most \sqrt{n} range queries. Consider the following adversary for supplying the answer to the queries: The adversary will subdivide the unit square into a mesh of squares, each of side length $s = \frac{n^{-1/4}}{10}$, namely, into $100\sqrt{n}$ squares, denoted blocks. The adversary commits itself to locating $\sqrt{n}/100$ input points in each block. In what follows, the adversary will mark some blocks in which it will commit to the internal location of points. The invariant that is kept is that in unmarked blocks, any configuration of input points is still consistent with the answers so far.

At the beginning no block is marked. Now, for each queried rectangle, if the query intersects an unmarked block, then the adversary will answer “not-empty.” In addition it will choose one unmarked block that intersects the given query, mark it, and commit to having all points in that block, in an arbitrary single point in the intersection. If the query intersects only previously marked blocks, then if it contains any of the previous locations in which the adversary has already committed to having input points, then a “non-empty” answer will be given (this is forced). If the query does not include any of the previous locations in which the adversary has committed to having input points, then the adversary will answer “empty.”

Keeping up this way, it is easy to see that the adversary can supply consistent answers to all \sqrt{n} queries.

At the end, since there are $100\sqrt{n}$ blocks while the adversary has marked at most \sqrt{n} blocks, in $99\sqrt{n}$ blocks there is complete freedom as to where the input points are located within such blocks. Now notice that if the adversary chooses to locate all points within a block in one (arbitrary) point, then the MST is of cost $\mathcal{O}(n^{1/4})$, while, if it chooses to locate the points in each unmarked block spread uniformly within the block, then the cost of the tree is $\Omega(\sqrt{n})$. Hence the lower bound follows. \square

Finally, we note that our choice of using $\mathcal{O}(\sqrt{n})$ orthogonal range queries was arbitrary; one can use a different number of queries and obtain a whole range of tradeoffs between the running time and the quality of approximation. As another example in this tradeoff, assume that αn queries are made. The adversary divides the square into βn blocks and proceeds as below. In this situation, the algorithm has no way of telling whether all cells have their points concentrated in one location, resulting in an EMST of at most $\sqrt{\beta n}$, or are distributed in the unmarked blocks as above, resulting in an EMST of at least $\frac{(\beta-\alpha)\sqrt{n}}{\beta}$, giving an approximation ratio of at least $\frac{\beta-\alpha}{\beta\sqrt{\beta}}$. To exploit the tradeoff here, we set $\beta = 1/4$. To obtain an approximation ratio of ε , the number of queries must be at least $n(1/4 - \varepsilon/8)$. One can exploit this tradeoff in other ways also.

4. Two related previous results. We now describe two previous results that we utilize in our EMST algorithms: the concept of Yao graphs [26] and an algorithm for approximating the MST in bounded degree graphs due to Chazelle, Rubinfeld, and Trevisan [10].

4.1. Yao graphs. Yao graphs are Euclidean graphs that relate the EMST to the cone nearest neighbor oracle presented in section 2.1. Fix an integer $d \geq 2$. Let \mathcal{C} be a collection of d -dimensional cones with its apex at the origin such that (a) each cone has an angular diameter² at most θ , where θ is some fixed angle, and (b) $\bigcup_{C \in \mathcal{C}} C = \mathbb{R}^d$. There is always such a collection \mathcal{C} of $\mathcal{O}(d^{3/2} \cdot \sin^{-d}(\theta/2) \cdot \log(d \sin^{-1}(\theta/2)))$ cones (not necessarily disjoint); note that for constant d and θ this bound is $\mathcal{O}(1)$. Yao [26] gives one possible construction for such a collection. For a point $p \in \mathbb{R}^d$ and a cone $C \in \mathcal{C}$, let C_p be $p + C = \{a + p : a \in C\}$, that is, a translation of C so that its apex is at p . Let $N_P\langle p, C \rangle$ be the nearest neighbor of the apex p of C_p in the set $(P \setminus \{p\}) \cap C_p$. Given a point set P and a collection of cones \mathcal{C} , the *Yao graph of P (with respect to \mathcal{C})* is the Euclidean graph G with vertex set P and (undirected) edge set $E = \{(p, q) \mid \exists C \in \mathcal{C} \text{ such that } q = N_P\langle p, C \rangle\}$. That is, each $p \in P$ is connected to its nearest neighbor in each cone that has p at its apex. The following result due to Yao [26] motivates our use of these graphs.

CLAIM 4. [26] *Let P be a point set in \mathbb{R}^d . Let G be the undirected Yao graph for P with $\theta < \pi/3$. Then, the EMST of P is a subgraph of the Yao graph G .*

4.2. Chazelle, Rubinfeld, and Trevisan [10]: Approximate MST in low-degree graphs. Our algorithms make use of a recent algorithm for estimating the weight of MST in graphs due to Chazelle, Rubinfeld, and Trevisan [10]. This algorithm assumes that the input graph (i) is represented by an adjacency list, (ii) has degree at most ν (the full version of [10] allows ν to be the average degree), and (iii) has known minimum and maximum edge weights, where the ratio of the maximum edge weight

²The angular diameter of a cone C in \mathbb{R}^d having its apex at point $p \in \mathbb{R}^d$ is defined as the maximum angle between any two vectors \overrightarrow{px} and \overrightarrow{py} , $x, y \in C$.

to the minimum is Λ . Then, for $0 < \varepsilon < \frac{1}{2}$, the algorithm estimates the weight of the MST with a relative error of at most ε and with probability at least $\frac{3}{4}$, and it runs in time $\mathcal{O}(\nu \cdot \Lambda \cdot \log(\nu \Lambda / \varepsilon) / \varepsilon^3)$. (The authors also give a nearly matching lower bound of $\Omega(\nu \cdot \Lambda / \varepsilon^2)$ on the time complexity of any ε -approximation algorithm for the MST.)

Let $H = (V, E)$ be an input graph having n vertices with maximum degree ν and edge weights in the interval $[1, \Lambda]$. For any $w \in \mathbb{R}$, let $H^{(w)}$ denote the maximal subgraph of H containing edges of weight at most w , and let c_w denote the number of connected components in $H^{(w)}$. The main ingredient of the algorithm from [10] is a procedure called ‘‘approx-number-connected-components,’’ which we call *ACC* from this point on, run on $H^{(w)}$ for estimating c_w for $w = (\frac{1}{2} + i) \cdot \varepsilon$ with $i = 1, 2, \dots, \Lambda/\varepsilon$. For integer weights, the weight of the MST of H is equal to $n - \Lambda + \sum_{j=1}^{\Lambda-1} c_j$. The algorithm uses the above estimations to produce a value which, with probability at least $\frac{3}{4}$, is a $(1 \pm \varepsilon)$ -approximation of the MST of H .

Procedure *ACC* works by sampling $\mathcal{O}(1/\varepsilon^2)$ vertices in H . For each sampled vertex u , a random estimator X_u is computed by traversing $H^{(w)}$ from u (for example, using breadth-first search) with a stochastic stopping rule. X_u is a random variable whose distribution is a function of only the size of the connected component containing u (i.e., the number of vertices reached from u in the traversal) in $H^{(w)}$. The simple relation between these sizes and c_w together with the fact that the distribution of X_u is concentrated around the expected value yields the connection between X_u and c_w . Procedure *ACC* runs in expected time $\mathcal{O}(\nu \varepsilon^{-2} \log(\Lambda/\varepsilon))$. Therefore, the expected running time of the algorithm in [10] is $\mathcal{O}(\Lambda \nu \varepsilon^{-3} \log(\Lambda/\varepsilon))$.

5. A simple estimation for EMST using Yao graphs. The algorithm we present in this section is conceptually an important component of the sublinear algorithm we design later in section 6. It combines the two results described in section 4. Our algorithm uses the cone nearest neighbor oracle and achieves a query complexity of $2^{\mathcal{O}(d)} \cdot \tilde{\mathcal{O}}(\Lambda/\varepsilon^2)$.

Since by Claim 4 the undirected Yao graph G for P contains all edges of the EMST of P , it is natural to try to apply the algorithm of Chazelle, Rubinfeld, and Trevisan to G to estimate the weight of the EMST of P . To do that efficiently, instead of generating G at the beginning of the algorithm, we generate the edges of G (using the cone nearest neighbor queries) only when the edges are needed in the algorithm. That is, whenever the algorithm needs edges adjacent in G to a vertex p , we use the cone nearest neighbor query to obtain the nearest neighbor of p in each cone in $\{p + C\}_{C \in \mathcal{C}}$. Motivated by Claim 4, we set the angular diameter of the cones to $\pi/4$. This creates parts of an *implicit directed* Yao graph \overline{G} on P with edges (p, q) such that there is a $C \in \mathcal{C}$, where $q = N_P(p, C)$.

The above approach has a number of problems. First, the algorithm of Chazelle, Rubinfeld, and Trevisan requires the input graph to be undirected and represented by an adjacency list, whereas in our model, we have fast access to only the *outgoing edges* at a vertex in \overline{G} . Furthermore, the running time is linear in Λ , which can be arbitrarily large. The following lemma helps in overcoming the first difficulty, while the second is tackled in the main algorithm in section 6. The proof of Lemma 1, being a special case of Claim 6, is omitted.

LEMMA 1. *Let n_u^ℓ be the number of vertices in \mathbb{K}_P that are reachable from u using only edges of weight at most ℓ . Let m_u^ℓ be the number of vertices in a directed Yao graph \overline{G} reachable from u using only edges of weight at most ℓ . Then $m_u^\ell = n_u^\ell$.*

Equipped with this lemma, we can modify the algorithm due to Chazelle, Rubinfeld, and Trevisan to obtain its efficient implementation in our model. The only

difference is in procedure *ACC*. We still sample $\mathcal{O}(1/\varepsilon^2)$ vertices and randomly traverse $H^{(w)}$ from the sampled vertices. To implement the traversing algorithm we explore the graph in a breadth-first search fashion by going to the *outgoing* neighbors of the vertices that are closer than the current threshold weight w . Such a procedure can be easily implemented in our model by using the cone nearest neighbor queries; the running time is proportional to the number of the edges traversed. To estimate the value of c_w we use the same estimators as in [10]. Since for each vertex u in the sample, the distribution of X_u depends only on m_u^w , the number of the vertices reachable from u in $H^{(w)}$, by Lemma 1 we can conclude that X_u has the same distribution as in the algorithm of Chazelle, Rubinfeld, and Trevisan [10]. Therefore, the quality of this algorithm of the estimation of EMST of P is the same as in the algorithm of Chazelle, Rubinfeld, and Trevisan [10]. Since the maximum out-degree of the directed Yao graph is $2^{\mathcal{O}(d)}$, the modified procedure *ACC* has complexity identical to that of running the original algorithm of Chazelle, Rubinfeld, and Trevisan in an (undirected) graph with maximum degree $2^{\mathcal{O}(d)}$. Thus, we obtain the following theorem.

THEOREM 1. *Let P be a set of points in \mathbb{R}^d . Assume that the value Λ of the spread of P is known and access to a cone nearest neighbor oracle for P is given. Then, there is an algorithm that outputs a value Υ which, with probability at least $\frac{3}{4}$, approximates the values of EMST(P) to within a factor of $1 \pm \varepsilon$ with query complexity $\tilde{\mathcal{O}}(2^{\mathcal{O}(d)} \cdot \Lambda/\varepsilon^3)$.*

For constant d and ε , this complexity is $\tilde{\mathcal{O}}(\Lambda)$, which is sublinear for $\Lambda = o(n)$. However, on the plane, for example, Λ is known to be $\Omega(\sqrt{n})$, and in general, Λ may be arbitrarily large. In the next section, we discuss our main contribution, which is a truly sublinear-time approximation algorithm whose complexity is independent of Λ .

6. Sublinear-time approximation algorithm. In this section we show how the two algorithms from sections 3 and 4 can complement each other. In addition to improving the running time, our algorithm requires a weaker computational model, in which the *cone nearest neighbor query* is replaced by the *cone $(1 + \delta)$ -approximate nearest neighbor query*.

6.1. Overview of the algorithm. In section 6.2, we begin by partitioning a minimal bounding cube \mathcal{BC} of P into blocks of equal size; we then consider only blocks containing points from P . Next, we group blocks that are “close” to each other, calling the resulting clusters *connected block-components*. The algorithm then proceeds in two phases. First, in section 6.5, we show how to approximate the weight of a minimum spanning forest (MSF) of the connected block-components by using the ideas of section 5. Then, in section 6.6, we approximate the optimal way to connect different connected block-components. We prove in Lemma 2 that the MSF of the connected block-components combined with the optimal set of edges joining them approximates the EMST of P .

In our analysis, throughout the entire section we assume that $0 < \varepsilon < \frac{1}{15}$.

6.2. Partitioning the bounding cube. After the translation and scaling of the points in P we can assume that \mathcal{BC} , the bounding cube of P , is $[0, n/\varepsilon]^d$. In particular, the side length is $\mathcal{L} = n/\varepsilon$, and we have a trivial lower bound $\text{EMST}(P) \geq n/\varepsilon$.

We follow the approach from section 3 with small modifications, by extending it to higher dimensions and applying a different stopping procedure. We first partition \mathcal{BC} into 2^d disjoint cubes of equal size, then partition each nonempty cube into 2^d disjoint subcubes, then partition each nonempty subcube further into 2^d subcubes, and so on. Call a block at level i an *active block* if it contains a point from P . Let b_k

FIG. 1. *Block-partitioning and block-components.*

be the number of active blocks at level k (the number of blocks that contain points from P), and let $\Delta_k = \mathcal{L}/2^k$ be the side length of blocks in the k th level of the subdivision. Let $b^* = \max\{\varepsilon^{d/2-3} \sqrt{n}, 2^{d+1}\}$. We stop our subdivision at the first level k_0 such that either $b_{k_0} \geq b^*$ or $\Delta_{k_0} < 2\varepsilon$. Let $b = b_{k_0}$ and $\Delta = \Delta_{k_0}$. Notice that $b \leq 2^d b^*$ and $\Delta \geq \varepsilon$. By our arguments from section 3, the active blocks at level k_0 can be found by querying the range query oracle $\mathcal{O}(b2^d \log(n/(\varepsilon \Delta)))$ times.

6.3. Spanners and connected block-components. For any $t \geq 1$, a t -*spanner* (see, e.g., [7, 14, 17]) for a set S of points in a Euclidean space is any Euclidean graph G with the vertex set S such that for every pair of points $x, y \in S$ there is a path in G between x and y of total length at most $t \cdot |x - y|$.

In our analysis, we will frequently use centers of blocks as the representatives of the blocks. Let B be the set of *centers of active blocks* and let \mathcal{SPN} be a $(1 + \varepsilon/4)$ -spanner of B with $\mathcal{O}(b(4/\varepsilon)^{d-1})$ edges. Such a spanner can be found in time $\mathcal{O}(b \log b + b \log(1/\varepsilon) \varepsilon^{-d}) = \tilde{\mathcal{O}}(\sqrt{n} \varepsilon^{3-d/2})$ [7].

Call two blocks *close* if the distance between their centers in the graph \mathcal{SPN} is at most $\Gamma \cdot \Delta$, where $\Gamma = 14 \sqrt{d}/\varepsilon$. We use equivalence classes of the transitive closure of the relation *close* to define the *connected block-components*. That is, two blocks are in the same connected block-component if there is a sequence of active blocks between them, where every consecutive pair of blocks in the sequence is close. We shall abuse notation and refer also to the partition of P induced by the connected components as *connected block-components*. Notice that all connected block-components can be found in time proportional to the number of edges in \mathcal{SPN} , which is $\mathcal{O}(b(4/\varepsilon)^{d-1})$. See Figure 1 for an example of block-partitioning.

6.4. The EMST of P and connected block-components. We refer to the *spanning forest* of a graph G as a union of spanning trees of the connected components of G . A *minimum spanning forest* of G , denoted by $\text{MSF}(G)$, is a spanning forest of G of minimum weight.

Let E_{in} be the set of edges of \mathbb{K}_P whose endpoints lie within the same connected block-component. Let $W = (\Gamma + \sqrt{d}) \Delta$. We now relate block-components to the distances between points.

Observation 1. Let p and q be an arbitrary pair of points in P .

1. If $|p - q| \leq (\Gamma - 4\sqrt{d}) \Delta$, then p and q are in the same connected block-component.
2. If p and q are in the same connected block-component, then there is a path between p and q consisting of edges in E_{in} that are all of length at most $(\Gamma + \sqrt{d}) \Delta = W$.
3. If $|p - q| > (\Gamma + \sqrt{d}) \Delta = W$ and p and q are in the same connected block-component, then $\text{EMST}(P)$ does not contain the edge pq .

Proof. For any point $p \in P$, we let c_p denote the center of the block at level k_0 that contains p .

To see the first assertion, note that if $|p-q| \leq (\Gamma - 4\sqrt{d})\Delta$, then $|c_p - c_q| \leq |p-q| + \sqrt{d}\Delta \leq (\Gamma - 3\sqrt{d})\Delta$. Therefore, the distance in \mathcal{SPN} between c_p and c_q is at most $(1 + \varepsilon/4)(\Gamma - 3\sqrt{d})\Delta \leq \Gamma\Delta$, which implies the first claim. Next, this also implies the existence of a path $c_p = c^{(0)}, c^{(1)}, \dots, c^{(s)} = c_q$ in \mathcal{SPN} such that $|c^{(i)} - c^{(i+1)}| \leq \Gamma\Delta$ for all i . Clearly, the corresponding path $p = p^{(0)}, p^{(1)}, \dots, p^{(s)} = q$ with $c^{(i)} = c_{p^{(i)}}$ shows the second assertion, since $|p^{(i)} - p^{(i+1)}| \leq |c^{(i)} - c^{(i+1)}| + \sqrt{d}\Delta \leq \Gamma\Delta + \sqrt{d}\Delta$. The third assertion follows from the second and the fact that the (strictly) largest edge in a cycle in a graph cannot be part of its MST. \square

In our algorithm we use the following graphs:

(i) G_{block} is the graph containing all edges in E_{in} of weight at most W . By Observation 1, the connected components of $\text{MSF}(G_{block})$ are identical to the connected block-components, and the MSF of these components is the same as $\text{MSF}(G_{block})$.

(ii) \overline{G}_δ is the *directed* $(1 + \delta)$ -Yao graph that is obtained from \mathbb{K}_P using the cone $(1 + \delta)$ -approximate nearest neighbor oracle. We use the same definitions as in the definition of directed Yao graphs and formally define $N_P^{(1+\delta)}(p, C)$ to be the point that is returned by the cone $(1 + \delta)$ -approximate nearest neighbor oracle for p and C . If $(P \setminus \{p\}) \cap C_p = \emptyset$, then $N_P^{(1+\delta)}(p, C)$ is undefined. Then, \overline{G}_δ is a directed Euclidean graph on P with the edge set containing an edge (p, q) if there is $C \in \mathcal{C}$ such that $q = N_P^{(1+\delta)}(p, C)$.

(iii) \mathcal{M} is the minimum weight subgraph of \mathbb{K}_P that, when added to G_{block} , forms a connected graph.

(iv) G_{out} is the same as \mathbb{K}_P except that the weights of edges in E_{in} are considered to be zero. Observe that the weight of $\text{MST}(G_{out})$ is identical to the weight of \mathcal{M} .

The following lemma displays the two-level nature of the algorithm that we will present.

LEMMA 2. *The sum of the weights of $\text{MSF}(G_{block})$ and $\text{MST}(G_{out})$ is a $(1 + \varepsilon/2)$ -approximation of $\text{EMST}(P)$.*

Proof. We show that the union of $\text{MSF}(G_{block})$ and \mathcal{M} is a spanning tree of \mathbb{K}_P whose weight approximates the weight of $\text{EMST}(P)$ to within a factor of $1 + \varepsilon/2$. From that the lemma follows immediately.

Clearly, the union of $\text{MSF}(G_{block})$ and \mathcal{M} forms a spanning tree of \mathbb{K}_P . To prove the second part of the claim, let us consider an undirected graph G^* obtained from \mathbb{K}_P by decreasing to $(\Gamma - 4\sqrt{d})\Delta$ the weight of every edge in E_{in} having weight larger than $(\Gamma - 4\sqrt{d})\Delta$ and smaller than or equal to W . (Note that we change only the weights of the edges in G_{block} .) Since the weight of every edge decreases by a factor of at most $\frac{W}{(\Gamma - 4\sqrt{d})\Delta} = \frac{(\Gamma + \sqrt{d})\Delta}{(\Gamma - 4\sqrt{d})\Delta} \leq 1 + \varepsilon/2$, we have $\text{MST}(G^*) \geq \text{EMST}(P)/(1 + \varepsilon/2)$. Note further that by Observation 1, each edge in G^* that is not in G_{block} has weight larger than $(\Gamma - 4\sqrt{d})\Delta$. This means that $\text{MST}(G^*)$ must contain an MSF of G_{block} , and hence the weight of the union of $\text{MSF}(G_{block})$ and \mathcal{M} is a $(1 + \varepsilon/2)$ approximation of $\text{EMST}(P)$. \square

6.5. First level—estimating the weight of $\text{MSF}(G_{block})$. In this section we show how to estimate the weight of the MST within a single block-component. This, combined for all block-components, yields an estimate on the weight of $\text{MSF}(G_{block})$. Since our model does not allow constant-time access to the edges of G_{block} , we will use the directed Yao graph \overline{G}_δ to estimate the weight of $\text{MSF}(G_{block})$. Our analysis will explore the relationship between \overline{G}_δ and G_{block} .

FIG. 2. Illustration for the proof of Claim 6. The figure shows the reachability in $\overline{G_\delta}$. The dashed line is the path showing the connectivity of x and y in $\overline{G_\delta}^{((1+\delta)\tau)}$.

For a weighted graph H denote by $\beta \cdot H$ the graph H with edge weights multiplied by β . Recall that $H^{(r)}$ denotes the subgraph of H consisting of the edges of weight at most r , and c_r is the number of connected components in $G_{block}^{(r)}$. Let n_u^r and m_u^r be the number of vertices in $G_{block}^{(r)}$ and in $\overline{G_\delta}^{(r)}$, respectively, that are reachable from u . Note that $c_r = \sum_{u \in P} 1/n_u^r$. Analogously, define $c_r^* = \sum_{u \in P} 1/m_u^r$. Also, let \hat{c}_r be the number of connected components in $(1 + \delta) \cdot G_{block}^{(r)}$.

The following is from [10].

CLAIM 5. Let $G^{(l)}$ denote the subgraph of a graph G consisting of all the edges of weight at most l . Define $c^{(l)}$ to be the number of connected components in $G^{(l)}$. Then, for integer $w \geq 2$, $M(G) = n - w + \sum_{i=1}^{w-1} c^{(i)}$.

From the above (see also section 4) we have that

$$(1) \quad \text{MSF}(G_{block}^{(r)}) \leq n - rc_r + \sum_{i=1}^{r-1} c_i \leq \text{MSF}(G_{block}^{(r)}) + n.$$

Since we have access only to $\overline{G_\delta}$, we can deal only with the c_r^* 's rather than the c_r 's. To bound the error due to this replacement, now we relate reachability in $\overline{G_\delta}$ to reachability in G_{block} .

CLAIM 6. Let $\varepsilon \leq \frac{1}{5}$ and $\delta \leq \frac{1}{10}$. Then for every r and every $u \in P$, $n_u^{r/(1+\delta)} \leq m_u^r \leq n_u^r$. In particular, $c_{r/(1+\delta)} \geq c_r^* \geq c_r$.

Proof. Let us first note that $m_u^r \leq n_u^r$ follows directly from the definition. To show that $n_u^{r/(1+\delta)} \leq m_u^r$, it suffices to show that for every τ , if a vertex y is reachable in $G_{block}^{(\tau)}$ from a vertex x , then y is reachable from x in $\overline{G_\delta}^{((1+\delta)\tau)}$. Assume that y is reachable from x in $G_{block}^{(\tau)}$; this implies that x and y are in the same connected block-component. Assume further, without loss of generality, that $\tau \leq W$ (indeed, if $\tau > W$, then $G_{block}^{(\tau)} = G_{block}^{(W)}$).

Let z be the $(1 + \delta)$ -approximate nearest neighbor of x (returned by the cone approximate nearest neighbor oracle) in the cone C_x containing y . Clearly, if $z = y$, then the claim holds. So let us assume that $z \neq y$. Let $a = |x - z|$, $b = |x - y|$, $c = |y - z|$, and $\alpha = \angle(xyz)$, $\beta = \angle(xzy)$, and $\gamma = \angle(yxz)$; see Figure 2. Note that since y and z are contained in the cone C_x with the angular diameter $\pi/4$, we have $\gamma \leq \pi/4$.

We first show the following three inequalities: (i) $a \leq (1 + \delta)b$, (ii) $c < b$, and (iii) $\min\{a, c\} \leq b/(1 + \varepsilon)$. Inequality (i) follows directly from the definition of the cone approximate nearest neighbor oracle. To prove inequality (ii), let us suppose that $c \geq b$. Then $\beta \leq \gamma$, and since $\gamma \leq \pi/4$, we obtain that $\alpha \geq \pi/2$. This in

turn implies that $a \geq \sqrt{b^2 + c^2} \geq \sqrt{2}b$, which contradicts the first inequality that $a \leq (1 + \delta)b \leq 1.1 \cdot b$. For inequality (iii), we first use the law of cosines to get $c^2 = a^2 + b^2 - 2ab \cos \gamma \leq a^2 + b^2 - \sqrt{2}ab$, since $\gamma \leq \pi/4$. To show $\min\{a, c\} \leq b/(1 + \varepsilon)$ we assume $a > b/(1 + \varepsilon)$ and show $c \leq b/(1 + \varepsilon)$. Since $a > b/(1 + \varepsilon) \geq \frac{\sqrt{2}}{2}b$, the expression $a^2 + b^2 - \sqrt{2}ab$ increases with a . Therefore, by inequality (i) we obtain

$$\begin{aligned} c^2 &\leq a^2 + b^2 - \sqrt{2}ab \leq ((1 + \delta)b)^2 + b^2 - \sqrt{2}(1 + \delta)b^2 \\ &= b^2((2 - \sqrt{2})(1 + \delta) + \delta^2) \leq (b/(1 + \varepsilon))^2, \end{aligned}$$

where the last inequality holds for $\varepsilon \leq \frac{1}{5}$ and $\delta \leq \frac{1}{10}$.

Now, we prove the claim using inequalities (i)–(iii). Assume, without loss of generality, that $|x - y| \leq \tau$; otherwise apply the following arguments to all edges on the path between x and y in $G_{block}^{(\tau)}$ (all the edges on this path are of length at most τ). We define inductively the sequence $x = x_0, x_1, x_2, \dots, y$ such that for every i , if $x_i \neq y$, then x_{i+1} is the $(1 + \delta)$ -approximate nearest neighbor of x_i in the cone C_{x_i} containing y . By inequality (ii), the sequence $|x_i - y|$ is strictly decreasing. This immediately implies that $x_i = y$ for some i , and so the sequence is finite.

Next, we show inductively that each x_i is in the same connected block-component as y . Suppose that x_i is in the same connected block-component as y . Since the sequence $|x_i - y|$ is decreasing and since $|x - y| \leq \tau \leq W = (\Gamma + \sqrt{d}) \cdot \Delta$, we obtain

$$\frac{|x_i - y|}{1 + \varepsilon} \leq \frac{|x - y|}{1 + \varepsilon} < \frac{(\Gamma + \sqrt{d}) \cdot \Delta}{1 + \varepsilon} \leq \frac{(\Gamma + \sqrt{d}) \cdot \Delta}{1 + \varepsilon}.$$

Therefore, using inequality (iii) with $x = x_i$ and $z = x_{i+1}$, we obtain

$$\min\{|x_i - x_{i+1}|, |x_{i+1} - y|\} \leq \frac{|x_i - y|}{1 + \varepsilon} \leq (\Gamma - \sqrt{d}) \cdot \Delta.$$

Hence, by Observation 1, either x_i and x_{i+1} are in the same connected block-component or x_{i+1} and y are in the same connected block-component. In either case, the transitivity ensures that x_{i+1} and y are in the same connected block-component. We finally observe that inequality (i) implies that $|x_i - x_{i+1}| \leq (1 + \delta)|x_i - y|$, and since $|x_i - y| \leq |x - y|$, we obtain $|x_i - x_{i+1}| \leq (1 + \delta)|x - y|$. Hence, the sequence $x = x_0, x_1, x_2, \dots, y$ corresponds to a path contained in a connected block-component having all edges of length at most $(1 + \delta)\tau$. This implies that y is reachable from x in $\overline{G}_\delta^{((1 + \delta)\tau)}$. \square

Let $W' = \lceil W(1 + \delta) \rceil$. Motivated by inequality (1), let us introduce an estimator \mathcal{A} for the value of $\text{MSF}(G_{block})$:

$$\mathcal{A} = n + \sum_{i=1}^{W'-1} c_i^* - W' \cdot c_{W'}^*.$$

We now analyze the quality of this estimator.

LEMMA 3. $\text{MSF}(G_{block}) \leq \mathcal{A} \leq (1 + \delta) \cdot \text{MSF}(G_{block}) + n$.

Proof. Let us first recall that $\hat{c}_r = c_{r/(1 + \delta)}$. Next, let us observe that if $r \geq W$, then $c_r = c_W$. As a corollary, $c_{W'}^* = c_W = c_{W'}$. With this, we have the following

sequence of inequalities:

$$\begin{aligned}
\text{MSF}(G_{block}) &\leq n + \sum_{i=1}^{W-1} c_i - W \cdot c_W \leq n + \sum_{i=1}^{W'-1} c_i - W' \cdot c_{W'} \\
&= n + \sum_{i=1}^{W'-1} c_i - W' \cdot c_{W'}^* \leq n + \sum_{i=1}^{W'-1} c_i^* - W' \cdot c_{W'}^* \\
&= \mathcal{A} \leq n + \sum_{i=1}^{W'-1} c_{i/(1+\delta)} - W' \cdot c_W = n + \sum_{i=1}^{W'-1} \hat{c}_i - W' \cdot \hat{c}_{W'} \\
&\leq \text{MSF}((1+\delta) \cdot G_{block}) + n = (1+\delta) \cdot \text{MSF}(G_{block}) + n.
\end{aligned}$$

The first inequality is due to inequality (1). The second one follows from the observation mentioned at the beginning of this proof, as does the next one, combined with Claim 6. The last inequality is implied by inequality (1). \square

We now modify the algorithm of Chazelle, Rubinfeld, and Trevisan [10] to obtain a good approximation of \mathcal{A} . Let us first note that as in section 5, we can easily traverse the graph $\overline{G}_\delta^{(r)}$: each time we want to access all edges incident to a point $p \in P$, we first ask the cone approximate nearest neighbor queries to all cones C_p and then for each nearest neighbor q of p in C_p , we verify whether $|p - q| \leq r$ and whether the blocks to which p and q belong are in the same connected block-component. The first test is a simple $\mathcal{O}(1)$ -time calculation, while the second requires the computation of the connected block-components. Establishing this, we can apply the approach from sections 4.2 and 5 to estimate the value $c^* = \sum_{r=1}^{W'-1} c_r^*$, and hence to estimate the value of \mathcal{A} . For this, we run procedure *ACC* to get an estimator X_r to c_r^* for all $r = 1, 2, \dots, W'$, and we now show that $X = \sum_{r=1}^{W'-1} X_r$ is a good approximation to $c^* = \sum_{r=1}^{W'-1} c_r^*$.

We have from [10] that after using procedure *ACC*(G, ε, W), where G denotes the input graph, ε the approximation parameter, and W the stopping condition for the breadth-first search, we have $c^* - n/W \leq \text{EX} \leq c^*$ and $\text{var}X \leq 2n c^*/s$, where s is the number of initial random choices for vertices. Our algorithm yields similar properties; thus, we have the following:

$$c^* - n/2 \leq \text{EX} \leq c^*$$

and

$$\text{var}X \leq 2n c^*/s,$$

where s is the number of random choices of initial vertices in *ACC*. Next, using the bounds above, the fact that $\text{EMST}(P) \geq n/\varepsilon$, and Chebyshev's inequality, we have

$$\begin{aligned}
\Pr[|X - c^*| \geq \varepsilon/2 \cdot \text{EMST}(P)] &\leq \Pr[|X - \text{EX}| \geq \varepsilon/4 \cdot \text{EMST}(P)] \\
&\leq \frac{16 \text{var}X}{\varepsilon^2 \cdot (\text{EMST}(P))^2} \leq \frac{32 \cdot n \cdot c^*}{\varepsilon^2 \cdot s \cdot (\text{EMST}(P))^2}.
\end{aligned}$$

We argue that $32n c^*/(\varepsilon^2 s (\text{EMST}(P))^2) = \mathcal{O}(\frac{1}{\varepsilon s})$ or, alternatively, that $(\text{EMST}(P))^2 = \Omega(nc^*/\varepsilon)$. Indeed, if $c^* \leq 2n/\varepsilon$, then $(\text{EMST}(P))^2 \geq (n/\varepsilon)^2 \geq 2n c^*/\varepsilon$ by our assumption in section 6.2. Otherwise, we have to use a stronger lower bound for $\text{EMST}(P)$.

By Lemma 2, we have

$$\text{EMST}(P) = \Omega(\text{MSF}(G_{\text{block}}) + \text{MST}(G_{\text{out}})) = \Omega(\text{MSF}(G_{\text{block}}) + W' \cdot (c'_W - 1)).$$

Next, by Lemma 3, we have

$$(1 + \delta) \cdot \text{MSF}(G_{\text{block}}) \geq \mathcal{A} - n = c^* - W' \cdot c_{W'}^*.$$

$$\text{EMST}(P) = \Omega(c^* - W' \cdot c_{W'}^* + W' \cdot (c'_W - 1)) = \Omega(c^*),$$

from which it follows that for $c^* > 2n/\varepsilon$ we have $(\text{EMST}(P))^2 = (\Omega(c^*))^2 = \Omega(nc^*/\varepsilon)$, as required.

Summarizing the discussion above, we always have $(\text{EMST}(P))^2 = \Omega(nc^*/\varepsilon)$ and hence

$$\Pr[|X - c^*| \geq \varepsilon/2 \cdot \text{EMST}(P)] \leq \mathcal{O}(\frac{1}{\varepsilon s}).$$

Therefore, if we choose $s = \mathcal{O}(1/\varepsilon)$, then we obtain

$$\Pr[|X - c^*| \geq \varepsilon/2 \cdot \text{EMST}(P)] \leq 1/4.$$

Next, observe that $c_{W'}^*$ is nothing but the number of connected block-components, which is known to the algorithm that computes the connected block-components. This leads to an efficient algorithm that calculates $\mathcal{A}' = n + X - W' \cdot c_{W'}^*$, for which $\Pr[|\mathcal{A}' - \mathcal{A}| > \frac{1}{2} \varepsilon \cdot \text{EMST}(P)] \leq 1/4$. The complexity of this algorithm follows from the analysis in section 5 and from [10] (result stated in section 4.2) and is $\tilde{\mathcal{O}}(W \cdot 2^{\mathcal{O}(d)}/\varepsilon)$ cone approximate nearest neighbor queries. The algorithm approximates c^* to within an additive error of n with probability at least $\frac{3}{4}$ (see [10], presented here in section 4.2) and hence approximates $\text{EMST}(P)$ to within an additive error of $\frac{1}{2} \varepsilon \cdot \text{EMST}(P) + \delta \cdot \text{EMST}(P) + n = (\delta + \frac{1}{2} \varepsilon) \cdot \text{EMST}(P) + n$.

We note that by scaling down all weights by a factor $\lambda > 1$, applying the algorithm above, and then rescaling to the original weight, we decrease the running time by a factor of λ and increase the additive error by the same factor. In this way we obtain an algorithm that performs $\tilde{\mathcal{O}}(W \cdot 2^{\mathcal{O}(d)}/(\lambda \varepsilon))$ cone approximate nearest neighbor queries and we achieve an additive error of $(\delta + \frac{1}{2} \varepsilon) \cdot \text{EMST}(P) + \lambda \cdot n$.

Let us examine the term W/λ in the running time and the additive error term $(\delta + \frac{1}{2} \varepsilon) \cdot \text{EMST}(P) + \lambda \cdot n$. Recall that there are two possible termination states: $b \geq b^*$ or $\Delta < 2\varepsilon$.

Consider first the case $b \geq b^*$. Since P has b active blocks of size Δ we have that $\text{EMST}(P) \geq \frac{1}{2} \Delta (\lceil b/2^d \rceil - 1)$. This bound is achieved by considering a subdivision of the active block to $2^d b$ subcubes of size $\Delta/2$. Now color these subblocks with 2^d different colors, using the same arrangement of colors for each of the original active blocks. This induces a partition of the active blocks into 2^d monochromatic sets. There has to be a set of $\lceil b/2^d \rceil$ points in P from different active blocks that are colored the same. Clearly, the minimal distance between these points must be at least $\Delta/2$, and hence the bound. Once we established that $\text{EMST}(P) \geq \frac{1}{2} \Delta (\lceil b/2^d \rceil - 1)$, we use the inequalities $b \geq b^* \geq 2^{d+1}$ to get $\text{EMST}(P) \geq \frac{1}{4} \cdot \Delta \cdot b/2^d$. Setting $\lambda = \frac{\Delta b \varepsilon}{8 \cdot 2^d n}$ we upper bound the relative error by

$$\delta + \varepsilon/2 + \frac{\lambda \cdot n}{\frac{1}{4} \cdot \Delta \cdot b/2^d} = 1 + \delta + \varepsilon.$$

The running time, using the fact that $b \geq b^* \geq \varepsilon^{d/2-3} \sqrt{n}$, is bounded by

$$\tilde{\mathcal{O}}(W'/(\lambda\varepsilon)) = \tilde{\mathcal{O}}(\sqrt{d} \cdot 2^d \cdot n/(b\varepsilon^3)) \leq \tilde{\mathcal{O}}(\sqrt{n} \cdot 2^d \cdot \sqrt{d}/\varepsilon^{d/2}) = \tilde{\mathcal{O}}(\sqrt{n}/\varepsilon^{d/2}).$$

On the other hand, when $\Delta < 2\varepsilon$, we use the trivial lower bound $\text{EMST}(P) \geq n/\varepsilon$ and by setting $\lambda = 1/2$ we obtain a multiplicative error of $1 + \delta + \varepsilon$. In this case note that $W' = \lceil (1 + \delta) \cdot \Delta \cdot \sqrt{d} \cdot (1 + 14/\varepsilon) \rceil = \mathcal{O}(1)$. And so we bound the running time by

$$W/(\lambda\varepsilon^3) = \tilde{\mathcal{O}}(\varepsilon^{-3}) \leq \tilde{\mathcal{O}}(\sqrt{n}/\varepsilon^{2+d/2})$$

for $d \geq 2$. Thus we have the following lemma.

LEMMA 4. *Given the graph G_{block} , there is an algorithm that estimates with probability at least $\frac{3}{4}$ the weight of $\text{MSF}(G_{\text{block}})$ to within a multiplicative relative error of $\delta + \varepsilon$. The algorithm requires $\tilde{\mathcal{O}}(\sqrt{n}/\varepsilon^{2+d/2})$ range queries and cone $(1 + \delta)$ -approximate nearest neighbor queries (for $\delta \leq \varepsilon/6$).*

6.6. Second level—estimating the weight of $\text{MST}(G_{\text{out}})$. Let Q be the complete undirected graph with the vertex set B , the set of active blocks, and with the edge weights equal to the Euclidean distances between the corresponding block-centers if the blocks are in different connected block-components, and zero otherwise. Arguments similar in spirit to those used in Observation 1 can be used to show the following lemma.

LEMMA 5. $(1 - \varepsilon/2) \cdot \text{EMST}(Q) \leq \text{MST}(G_{\text{out}}) \leq (1 + \varepsilon/2) \cdot \text{EMST}(Q)$.

Proof. Given $\text{EMST}(Q)$, consider a subgraph \hat{G} of G_{out} defined as follows. Include in \hat{G} the MST of the subgraph in each connected block-component of G_{out} ; notice that the total weight of the MST is 0. Then, for each nonzero weight edge e in $\text{EMST}(Q)$ connecting two connected block-components, include in \hat{G} the lowest weight edge e' in G_{out} that connects the two block-components joined by e . Due to the construction of Q , the weight of e is at least $\frac{\Gamma \cdot \Delta}{1 + \varepsilon/4}$ and the weight of e' exceeds that of e by at most $\sqrt{d} \Delta$, which is less than an $\varepsilon/2$ fraction of the weight of e . Also note that any two connected block-components in Q will be connected by at most one edge in $\text{EMST}(Q)$; thus such an e' will always be found. It is easy now to see that \hat{G} is a spanning tree of $\text{MST}(G_{\text{out}})$ of weight at most $\text{EMST}(Q)(1 + \varepsilon/2)$. Thus, $\text{MST}(G_{\text{out}}) \leq (1 + \varepsilon/2) \cdot \text{EMST}(Q)$.

To see the lower bound, we follow similar arguments. We start with $\text{MST}(G_{\text{out}})$ and construct a spanning tree of Q in a similar fashion—with the exception that for an edge in $\text{MST}(G_{\text{out}})$ joining two block-components, we include an edge from Q which joins these components by linking two block-centers—again with an increase in weight of at most an $\varepsilon/2$ fraction. Using a similar argument as above, we can show that $(1 - \varepsilon/2) \cdot \text{EMST}(Q) \leq \text{MST}(G_{\text{out}})$, which concludes the proof. \square

In view of Lemma 5, to obtain a good estimation of the weight of $\text{MST}(G_{\text{out}})$ it is sufficient to estimate the weight of an MST of Q .

We could find an MST of Q by calling any algorithm that finds an MST in graphs. However, any such algorithm requires time significantly more than $\mathcal{O}(b)$ time (at least for $d \geq 3$), because Q contains $\Theta(b^2)$ edges. To improve the running time to $\tilde{\mathcal{O}}(b\varepsilon^{1-d}) = \tilde{\mathcal{O}}(\sqrt{n}/\varepsilon^{2+d/2})$ we use \mathcal{SPN} , which is the $(1 + \varepsilon/4)$ -spanner of B (having $\mathcal{O}(b(1/\varepsilon)^{d-1})$ edges) defined in section 6.2. Let \mathcal{F} be any spanning forest of the subgraph of Q induced by the edges of weight 0. It is easy to see that the weight of any MST of Q is identical to the weight of an MST of Q that uses the edges from \mathcal{F} .

We create a new graph SG with the vertex set B and the edge set which is the union of the edges in \mathcal{F} and the spanner edges. Note that the number of edges

in \mathcal{F} is less than the number of spanner edges. Then we apply, for instance, the classical Kruskal's algorithm to find in time $\mathcal{O}(b \varepsilon^{1-d} \log(b/\varepsilon^{d-1})) = \tilde{\mathcal{O}}(\sqrt{n}/\varepsilon^{2+d/2})$ a minimum weight spanning tree of SG . It is easy to see that the obtained spanning tree of B is a spanning tree of B that uses edges from \mathcal{F} , since those edges are of weight 0 and do not form a cycle, and thus are bound to be picked by Kruskal's algorithm. Also, note that the resulting spanning tree's weight is at most $(1 + \varepsilon/4)$ times the minimum, due to the properties of a spanner. This allows us to summarize the discussion in this section in the following lemma.

LEMMA 6. *There is an algorithm which, given as input the graph G_{block} , estimates the weight of \mathcal{M} to within a relative error of $\frac{3}{4}\varepsilon$ with running time $\tilde{\mathcal{O}}(\sqrt{n}/\varepsilon^{2+d/2})$.*

Our analysis in this section can be slightly improved in the case where $d = 2$. In this case, one can simplify the arguments to achieve the running time of $\mathcal{O}(b \log b) = \mathcal{O}(\sqrt{n} \varepsilon^{-2} \log(\sqrt{n}/\varepsilon^2))$. The main difference is that for $d = 2$ we can find in $\mathcal{O}(b \log b)$ time an MST of Q using a modification of the classical algorithm due to Shamos and Hoey [22] for finding an EMST in \mathbb{R}^2 . We first construct (in $\mathcal{O}(b \log b)$ time) the Delaunay triangulation of B . Next, we observe that there is an MST of Q that uses only edges of cost zero and edges from the Delaunay triangulation (for example, this follows from the proof of Lemma 1 in [14] or from [22]). Therefore, an MST of Q can be found by calling, for example, Kruskal's algorithm on the subgraph of Q containing only the edges from the Delaunay triangulation of B and the edges of the forest \mathcal{F} as defined above. Since the number of edges in the Delaunay triangulation and in \mathcal{F} is $\mathcal{O}(b)$, this algorithm finds $\text{MST}(Q)$ in $\mathcal{O}(b \log b) = \tilde{\mathcal{O}}(\sqrt{n}/\varepsilon^2)$ time.

6.7. Estimating the weight of $\text{MSF}(G_{block}) \cup \text{MST}(G_{out})$. We can now summarize our algorithm for estimating the EMST of any set of points in \mathbb{R}^d . We use the fact that $\mathcal{L} = \Theta(n/\varepsilon)$ and apply Lemmas 2, 4, and 6 to estimate the weight of the EMST. Summing up the error terms in our estimation stated in each of those lemmas, we get that the multiplicative relative error is at most $\delta + 2\frac{1}{4}\varepsilon$ with probability at least $\frac{3}{4}$. Using $\varepsilon' = \varepsilon/3$ as the input parameter for our algorithm, we can conclude with the following main theorem of the paper.

THEOREM 2. *Let P be a set of n points in \mathbb{R}^d for a constant d . Let ε be any real number, $0 < \varepsilon < \frac{1}{15}$, and let $\delta \leq \varepsilon/4$. There is an algorithm that with probability at least $\frac{3}{4}$ estimates the weight of a Euclidean minimum spanning tree of P with a relative error of at most ε . This algorithm runs in $\tilde{\mathcal{O}}(\sqrt{n}/\varepsilon^{2+d/2})$ time and requires $\tilde{\mathcal{O}}(\sqrt{n}/\varepsilon^{2+d/2})$ orthogonal range queries, $\tilde{\mathcal{O}}(\sqrt{n}/\varepsilon^{2+d/2})$ cone $(1 + \delta)$ -approximate nearest neighbor queries, and a single minimal bounding cube of P .*

Let us also mention that the remark at the end of section 6.6 can be incorporated here to improve the complexity bounds in the most basic case when $d = 2$, that is, for the EMST problem on the Euclidean plane. Then, we obtain the following theorem.

THEOREM 3. *Let P be a set of n points in \mathbb{R}^2 . Let ε be any real number, $0 < \varepsilon < \frac{1}{15}$, and let $\delta \leq \varepsilon/4$. There is an algorithm that, with probability at least $\frac{3}{4}$, estimates the weight of a Euclidean minimum spanning tree of P with a relative error of at most ε . This algorithm runs in $\tilde{\mathcal{O}}(\sqrt{n}/\varepsilon^2)$ time and requires $\tilde{\mathcal{O}}(\sqrt{n}/\varepsilon^2)$ orthogonal range queries, $\tilde{\mathcal{O}}(\sqrt{n}/\varepsilon^2)$ cone $(1+\delta)$ -approximate nearest neighbor queries, and a single minimal bounding cube of P .*

Acknowledgments. We thank Bernard Chazelle and Sarel Har-Peled for helpful discussions on geometric data structures. We also thank the anonymous referees for their helpful comments.

POLYNOMIAL TIME APPROXIMATION SCHEMES FOR MAX-BISECTION ON PLANAR AND GEOMETRIC GRAPHS*

KLAUS JANSEN[†], MAREK KARPINSKI[‡], ANDRZEJ LINGAS[§], AND EIKE SEIDEL[†]

Abstract. The max-bisection and min-bisection problems are to find a partition of the vertices of a graph into two equal size subsets that, respectively, maximizes or minimizes the number of edges with endpoints in both subsets.

We design the first polynomial time approximation scheme for the max-bisection problem on arbitrary planar graphs solving a long-standing open problem. The method of solution involves designing exact polynomial time algorithms for computing optimal partitions of bounded treewidth graphs, in particular max- and min-bisection, which could be of independent interest.

Using a similar method we design also the first polynomial time approximation scheme for max-bisection on unit disk graphs (which could also be easily extended to other geometrically defined graphs).

Key words. combinatorial optimization, NP-hardness, approximation algorithms, polynomial time approximation schemes, graph bisection, planar graphs

1. Introduction. The max-bisection and min-bisection problems, i.e., the problems of constructing a halving of the vertex set of a graph that, respectively, maximizes or minimizes the number of edges across the partition, belong to the basic combinatorial optimization problems.

The best-known approximation algorithm for max-bisection yields a solution whose size is at least 0.701 times the optimum [16] (cf. [12, 14, 23]), whereas the best-known approximation algorithm for min-bisection achieves “solely” a log-square approximation factor [11]. The former factor for max-bisection is considerably improved for regular graphs to 0.795 in [10], whereas the latter factor for min-bisection is improved for graphs excluding any fixed minor (e.g., planar graphs) to a logarithmic one in [11]. For dense graphs, Arora, Karger, and Karpinski give polynomial time approximation schemes for max- and min-bisection in [2].

In this paper, we study the max-bisection and min-bisection problems on bounded treewidth graphs and on planar graphs. Both graph families are known to admit exact polynomial time algorithms for max-cut, i.e., for finding a bipartition that maximizes the number of edges with endpoints in both sets in the partition [9, 15].

Our first main result are exact polynomial time algorithms for finding a partition of a bounded treewidth graph into two sets of a priori given cardinalities, respectively maximizing or minimizing the number of edges with endpoints in both sets. Thus, in

particular, we obtain polynomial time algorithms for max-bisection and min-bisection on bounded treewidth graphs.

The complexity and approximability status of max-bisection on planar graphs have been long-standing open problems. Contrary to the status of planar max-cut, planar max-bisection has been proven only recently to be NP-hard in exact setting by Jerrum [18]. (For the sake of completeness of our paper, we provide this proof with his agreement in section 3.) The technique used in his proof is similar to the method used by Barahona [4] to prove NP-hardness of the planar spin glass problem within a magnetic field. Karpinski, Kowaluk, and Lingas observed in [19] that the max-bisection problem for planar graphs does not fall directly into the Khanna–Motwani syntactic framework for planar optimization problems [20]. On the other hand, they provided a polynomial time approximation scheme (PTAS) for max-bisection in planar graphs of sublinear maximum degree. (In fact, their method implies that the size of max-bisection is very close to that of max-cut in planar graphs of sublinear maximum degree.)

Our second main result is the first PTAS for the max-bisection problem for arbitrary planar graphs. It is obtained by combining (via tree-typed dynamic programming) the original Baker’s method of dividing the input planar graph into families of k -outerplanar graphs [3] with our method of finding maximum partitions of bounded treewidth graphs.

Note that the NP-hardness of exact planar max-bisection makes our PTAS result best possible under usual assumptions.

Interestingly, our PTAS for planar max-bisection can be easily modified to a PTAS for the problem of min-bisection on planar graphs in the very special case where the min-bisection is relatively large, i.e., cuts $\Omega(n \log \log n / \log n)$ edges.

Unit disk graphs are another important class of graphs defined by the geometric conditions on a plane. An undirected graph is a unit disk graph if its vertices can be put in one-to-one correspondence with disks of equal radius in the plane in such a way that two vertices are joined by an edge if and only if the corresponding disks intersect. Tangent disks are considered to intersect.

Our third main result is the first PTAS for the max-bisection problem on unit disk graphs. The scheme can be easily generalized to include other geometric intersection graphs. It is obtained by combining (again via tree-typed dynamic programming) the idea of Hunt et al. of dividing the input graph defined by plane conditions into families of subgraphs [17] with the aforementioned known methods of finding maximum partitions of dense graphs [2].

The structure of our paper is as follows. The next section complements the introduction with basic definitions and facts. In section 3, we provide the proof of NP-hardness of planar max-bisection communicated by Jerrum [18]. In section 4, the algorithms for optimal partitions of bounded treewidth graphs are given. Section 5 presents the PTAS for planar max-bisections. In section 6, we make several observations on the approximability of planar min-bisection. Finally, section 7 describes the PTAS for max-bisection on unit disk graphs. In conclusion we notice that the same technique can be applied also for other geometric intersection graphs.

2. Preliminaries. We start with formulating the underlying optimal graph partition problems.

DEFINITION 2.1. *A partition of a set of vertices of an undirected graph G into two sets X, Y is called an $(|X|, |Y|)$ -partition of G . The edges of G with one endpoint in X and the other in Y are said to be cut by the partition. The size of an (l, k) -partition*

is the number of edges which are cut by it. An (l, k) -partition of G is said to be a maximum (l, k) -partition of G if it has the largest size among all (l, k) -partitions of G . An (l, k) -partition of G is a bisection if $l = k$. A bisection of G is a max-bisection or a min-bisection of G if it, respectively, maximizes or minimizes the number of cut edges. An (l, k) -partition of G is a max-cut of G if it has the largest size among all (l', k') -partitions of G . The max-cut problem is to find a max-cut of a graph. Analogously, the max-bisection problem is to find a max-bisection of a graph. The min-cut problem and the min-bisection problem are defined analogously.

The notion of treewidth of a graph was originally introduced by Robertson and Seymour [22]. It has turned out to be equivalent to several other interesting graph theoretic notions, e.g., the notion of partial k -trees [1, 5].

DEFINITION 2.2. A tree-decomposition of a graph $G = (V, E)$ is a pair $(\{X_i \mid i \in I\}, T = (I, F))$, where $\{X_i \mid i \in I\}$ is a collection of subsets of V , and $T = (I, F)$ is a tree, such that the following conditions hold:

1. $\bigcup_{i \in I} X_i = V$.
2. For all edges $(v, w) \in E$, there exists a node $i \in I$, with $v, w \in X_i$.
3. For every vertex $v \in V$, the subgraph of T , induced by the nodes $\{i \in I \mid v \in X_i\}$, is connected.

The treewidth of a tree-decomposition $(\{X_i \mid i \in I\}, T = (I, F))$ is $\max_{i \in I} |X_i| - 1$. The treewidth of a graph is the minimum treewidth over all possible tree-decompositions of the graph. A graph which has a tree-decomposition of treewidth $O(1)$ is called a bounded treewidth graph.

FACT 1 (see [6]). For a bounded treewidth graph, a tree-decomposition of minimum treewidth can be found in linear time.

To state our approximation results on max-bisection we need the following definition.

DEFINITION 2.3. A real number α is said to be an approximation ratio for a maximization problem, or equivalently the problem is said to be approximable within a ratio α , if there is a polynomial time algorithm for the problem which always produces a solution of size at least α times the optimum. If a problem is approximable for arbitrary $\alpha < 1$, then it is said to admit a polynomial time approximation scheme (a PTAS for short).

An approximation ratio and a PTAS for a minimization problem are defined analogously.

3. Planar max-bisection is NP-hard. It is not difficult to observe that the known result of Garey, Johnson, and Stockmeyer asserting the NP-hardness of the maximum independent in planar cubic graphs [13] can be restated as follows:

Given a planar cubic graph G and an integer k , is there a $(k, n - k)$ -partition of G cutting at least $3k$ edges?

The only difference from max-bisection is that we have a $(k, n - k)$ -partition instead of a bisection. Jerrum has recently combined this observation with the idea of shifting the cut point in order to overcome the difference. The method of his proof follows a similar construction from the proof of NP-hardness of the problem of planar spin glass within a magnetic field (Problem P5) [4]. As a result, he obtained the following fact [18].

LEMMA 3.1. Let G be a planar cubic graph on n vertices, and let G' be the disjoint union of G with the complete bipartite graph $K_{2, n-2k+2}$, where $k \leq n/2$. G has an independent set of size k if and only if G' has a bisection of size at least $2n - k + 4$.

Proof. Suppose G has an independent set of size k . Form a $(k, n-k)$ -partition of G , where the set of cardinality k is an independent set in G , and the natural $(2, n-2k+2)$ -partition of $K_{2, n-2k+2}$. These two partitions yield a $(k+n-2k+2, n-k+2)$ -partition, i.e., a bisection of G' , cutting $3k+2(n-2k+2)$, i.e., $2n-k+4$ edges.

Suppose that G' has a bisection cutting at least $2n-k+4$ edges. The bisection yields an $(j, n-2k+2+2-j)$ -partition of the $K_{2, n-2k+2}$ subgraph and consequently an $(n-k-j+2, k+j-2)$ -partition of G . We may assume without loss of generality (w.l.o.g.) $j \leq n-2k+2+2-j$, which in turn implies $n-k-j+2 \geq k+j-2$. How many edges of $K_{2, n-2k+2}$ are cut by the bisection?

Clearly, the maximum $2(n-2k+2)$ can be achieved when $j=2$ and the $(j, n-2k+2+2-j)$ -partition of $K_{2, n-2k+2}$ is that bipartite one. If $j > 2$, then at least $j-2$ vertices out of the j vertices have to be on the larger side of $K_{2, n-2k+2}$, decreasing the maximum by at least $2(j-2)$. We conclude that if $j \geq 2$, at most $2(n-2k+2+2-j)$ edges can be cut. If $j=0, 1$, the number of edges that can be cut is clearly at most $j(n-2k+2)$.

Let U be the smaller set in the $(n-k-j+2, k+j-2)$ -partition of G , i.e., the one with $k+j-2$ vertices.

Consider the general case $j \geq 2$. By our assumptions, at least $2n-k+4-2(n-2k+4-j) = 3k+2j-4$ edges leave U . Suppose U has i internal edges (i.e., having both endpoints in U). Then by counting degrees, $3|U|-2i \geq 3k+2j-4$, i.e., $3(k+j-2)-2i \geq 3k+2j-4$, which yields $2i \leq j-2$. Thus, although U may not be an independent set itself, it has very few internal edges and must therefore contain a large independent set. Precisely, it must contain an independent set of size $|U|-2i \geq |U|-(j-2) = k$.

The cases $j=0, 1$ are easily seen to be infeasible: $|U|$ has size less than k but defines a partition of size at least $2n-k+4-(n-2k+2) > 2n-k+4-2(n-2k+2) = 3k$. \square

Lemma 3.1, combined with the NP-hardness of the maximum independent set for planar cubic graphs, immediately yields the NP-hardness of planar max-bisection.

THEOREM 3.2. *Planar max-bisection is NP-hard.*

4. Optimal partitions for graphs of bounded treewidth. Let G be a graph admitting a tree-decomposition $T = (I, F)$ of treewidth at most k for some constant k . By [9], one can easily modify T , without increasing its treewidth, such that one can see T as a rooted tree, with root $r \in I$, fulfilling the following conditions:

1. T is a binary tree.
2. If a node $i \in I$ has two children j_1 and j_2 , then $X_i = X_{j_1} = X_{j_2}$.
3. If a node $i \in I$ has one child j , then either $X_j \subset X_i$ and $|X_i \setminus X_j| = 1$, or $X_i \subset X_j$ and $|X_j \setminus X_i| = 1$.

We will assume in the remainder that such a modified tree-decomposition T of G is given.

For each node $i \in I$, let Y_i denote the set of all vertices in a set X_j with $j = i$ or j being a descendant of i in the rooted tree T . Our algorithm computes for each $i \in I$ an array $maxp_i$ with $O(2^k|Y_i|)$ entries. For each $l \in \{0, 1, \dots, |Y_i|\}$ and each subset S of X_i , the entry $maxp_i(l, S)$ is set to $\max_{S' \subseteq Y_i, |S'|=l, S' \cap X_i=S} |\{(v, w) \in E | v \in S' \text{ \& } w \in Y_i \setminus S'\}|$. In other words, $maxp_i(l, S)$ is set to the maximum number of cut edges in an $(l, |Y_i| - l)$ -partition of Y_i , where S and $X_i \setminus S$ are in the different sets of the partition and the set including S is of cardinality l . For convention, if such a partition is impossible, $maxp_i(l, S)$ will be set to $-\infty$.

The entries of the array are computed following the levels of the tree-decomposition T in a bottom-up manner. The following lemma shows how the array can be determined efficiently.

LEMMA 4.1.

- Let i be a leaf in T . Then for all $l \in \{0, 1, \dots, |X_i|\}$ and $S \subseteq X_i$, where $|S| = l$, $\max p_i(l, S) = |\{(v, w) \in E \mid v \in S, w \in X_i \setminus S\}|$. The remaining entries of $\max p_i$ are set to $-\infty$.
- Let i be a node with one child j in T . If $X_i \subseteq X_j$, then for all $l \in \{0, 1, \dots, |Y_i|\}$ and $S \subseteq X_i$, $\max p_i(l, S) = \max_{S' \subseteq X_j, S' \cap X_i = S} \max p_j(l, S')$.
- Let i be a node with one child j in T . If $X_j \cup \{v\} = X_i$, where $v \notin X_j$, then for all $l \in \{0, 1, \dots, |Y_i|\}$ and $S \subseteq X_i$, if $v \in S$, then $\max p_i(l, S) = \max p_j(l-1, S \setminus \{v\}) + |\{(v, s) \mid s \in X_i \setminus S\}|$; else $\max p_i(l, S) = \max p_j(l, S) + |\{(v, s) \mid s \in S\}|$.
- Let i be a node with two children j_1, j_2 in T , with $X_i = X_{j_1} = X_{j_2}$. For all $l \in \{0, 1, \dots, |Y_i|\}$ and $S \subseteq X_i$, $\max p_i(l, S) = \max_{l_1+l_2-|S|=l \& l_1 \geq |S| \& l_2 \geq |S|} (\max p_{j_1}(l_1, S) + \max p_{j_2}(l_2, S) - |\{(v, w) \in E \mid v \in S, w \in X_i \setminus S\}|)$.

It follows that computing an array $\max p_i$ on the basis of the arrays computed for the preceding level of T can be done in time $O(2^k |Y_i|^2)$. Consequently, one can compute the array $\max p_r$ for the root r of T in cubic time.

THEOREM 4.2. All maximum $(l, n-l)$ -partitions of a graph on n nodes given with a tree-decomposition of treewidth k can be computed in time $O(2^k n^3)$.

By substituting *min* for *max*, we can analogously compute all minimum $(l, n-l)$ -partitions of a graph with constant treewidth.

THEOREM 4.3. All minimum $(l, n-l)$ -partitions of a graph on n nodes given with a tree-decomposition of treewidth k can be computed in time $O(2^k n^3)$.

By Fact 1 we obtain the following corollary.

COROLLARY 4.4. All maximum and minimum $(l, n-l)$ -partitions of a bounded treewidth graph on n vertices can be computed in time $O(n^3)$.

Since a tree-decomposition of a planar graph on n vertices with treewidth $O(\sqrt{n})$ can be found in polynomial time by the planar separator theorem [7], we obtain also the following corollary.

COROLLARY 4.5. All maximum and minimum $(l, n-l)$ -partitions of a planar graph on n vertices can be computed in time $2^{O(\sqrt{n})}$.

5. A PTAS for max-bisection of an arbitrary planar graph. The authors of [19] observed that the requirements of the equal size of the vertex subsets in a two partition yielding a max-bisection makes the max-bisection problem hardly expressible as a maximum planar satisfiability formula. For this reason we cannot directly apply Khanna and Motwani's syntactic framework [20], yielding PTASs for several basic graph problems on planar graphs (e.g., max-cut). Instead, we combine the original Baker's method [3] with our algorithm for optimal maximum partitions on graphs of bounded treewidth via tree-type dynamic programming in order to derive the first PTAS for max-bisection of an arbitrary planar graph.

ALGORITHM 1.

input: a planar graph $G = (V, E)$ on n vertices and a positive integer k ;

output: $(1 - \frac{1}{k+1})$ -approximations of all maximum $(l, n-l)$ -partitions of G

1. Construct a plane embedding of G .
2. Set the level of a vertex in the embedding as follows: the vertices on the outer boundary have level 1, and the vertices on the outer boundary of the subgraph

obtained by deleting the vertices of level $i - 1$ have level i ; for convention extend the levels by k empty ones numbered $-k + 1, -k + 2, \dots, 0$.

3. For each level j in the embedding, construct the subgraph H_j of G induced by the vertices on levels $j, j + 1, \dots, j + k$.
4. For each level j in the embedding, set n_j to the number of vertices in H_j and compute all maximum $(l, n_j - l)$ -partitions of H_j .
5. For each i , $0 \leq i \leq k$, set G_i to the union of the subgraphs H_j , where $j \pmod{k + 1} = i$.
6. For each i , $0 \leq i \leq k$, compute all maximum $(l, n - l)$ -partitions of G_i by dynamic programming in a tree fashion; i.e., first compute all maximum partitions for pairs of “consecutive” H_j , where $j \pmod{k + 1} = i$, then for quadruples of such H_j , etc.
7. For each l , $1 \leq l < n$, output the largest among the maximum $(l, n - l)$ -partitions of G_i , $0 \leq i \leq k$.

LEMMA 5.1. *For each l , $1 \leq l < n$, Algorithm 1 outputs an $(l, n - l)$ -partition of G within $k/(k + 1)$ of the maximum.*

Proof. Let P be a maximum $(l, n - l)$ -partition of G .

We claim that for each edge e in P , there is at most one i , $0 \leq i \leq k$, such that e is not an edge of G_i . Let j be the maximum level of an endpoint of e . It follows that the other endpoint of e has level $j - 1$ and the endpoints of e belong to the subgraphs H_{j-k-1} and H_j , respectively. These are the only H subgraphs containing a single endpoint of e , and they both are part of the G_i subgraph where $j \pmod{k + 1} = i$.

By our claim, there is i' , $0 \leq i' \leq k$, such that $G_{i'}$ does not include at most $|P|/(k + 1)$ edges of P . It follows that a maximum $(l, n - l)$ -partition of such a $G_{i'}$ cuts at least $k|P|/(k + 1)$ edges. Algorithm 1 outputs an $(l, n - l)$ -partition of G cutting at least as many edges as a maximum $(l, n - l)$ -partition of $G_{i'}$. \square

LEMMA 5.2. *Algorithm 1 runs in $O(k2^{3k+2}n^3)$ time.*

Proof. The time complexity of the algorithm is dominated by that of steps 4 and 6.

The subgraphs H_j of G are so-called $(k + 1)$ -outerplanar graphs and have bounded treewidth $3k + 2$ [7]. Hence, for a given i , $0 \leq i \leq k$, all maximum $(l, n_j - l)$ -partitions of H_j , where $j \pmod{k + 1} = i$, can be computed in time $O(2^{3k+2}n^3)$ by Theorem 4.2, the pairwise disjointness of the subgraphs, and $j \leq n$. It follows that the whole step 4 can be implemented in time $O(k2^{3k+2}n^3)$.

In step 6, a maximum $(l, n' - l)$ -partition of the union of 2^{q+1} “consecutive” H_j ’s satisfying $j \pmod{k + 1} = i$ on n' vertices can be determined on the basis of appropriate maximum partitions of its two halves, each being the union of 2^q of the H_j ’s, in time $O(n)$. Hence, since $l \leq n'$ and the number of nodes in the dynamic programming tree is $O(n)$, the whole step 6 takes $O(kn^3)$ time. \square

THEOREM 5.3. *Algorithm 1 yields a PTAS for all maximum $(l, n - l)$ -partitions of a planar graph.*

COROLLARY 5.4. *The problem of max-bisection on planar graphs admits a PTAS.*

6. Observations on min-bisection for planar graphs. We can easily obtain an analogous PTAS for min-bisection of planar graphs in the very special case when the size of min-bisection is $\Omega(n)$. Simply, at least one of the subgraphs G_i of G misses at most $|E|/(k + 1)$ edges of G . Therefore, the number of edges cut by a min-bisection of such a G_i can increase at most by $|E|/(k + 1)$ in G . By picking k sufficiently large we can guarantee an arbitrarily close approximation of min-bisection in G .

In fact, we can obtain even a slightly stronger result on min-bisection for planar graphs by observing that our method runs in polynomial time even for nonconstant k (up to $O(\log n)$), provided that a tree-decomposition of graphs with treewidth equal to such a k can be determined in polynomial time. At present, the best tree-decomposition algorithms have the leading term k^k [8], so we can set k to $O(\log n / \log \log n)$, keeping the polynomial time performance of our method. In this way, we obtain the following theorem.

THEOREM 6.1. *The min-bisection problem on planar graphs in which the size of min-bisection is $\Omega(n \log \log n / \log n)$ admits a PTAS.*

Observe that the presence of large degree vertices in a planar graph can cause the large size of min-bisection, e.g., in a star graph. For bounded-degree planar graphs, the size of min-bisection is $O(\sqrt{n})$ by the following argument.

The planar separator theorem yields a linear-time method of disconnecting a planar graph into two subgraphs, each having at least one third of its vertices, by removing $O(\sqrt{n})$ vertices [21]. For a planar graph of maximum degree d , construct a separator tree by applying the planar separator theorem recursively. Next, find a path in the tree from the root down to the median leaf. By deleting the edges incident to the vertex separators along the path and additionally $O(1)$ edges, we can easily halve the set of vertices of the graph such that none of the remaining edges connects a pair of vertices from the opposite halves. The number of deleted edges at the i th level of the tree is $O(d\sqrt{n}(\frac{2}{3})^{i/2})$. Thus, the total number of deleted edges is $O(d\sqrt{n})$. In fact, we do not have to construct the whole separator tree, but just the path, and this can be easily done in time $O(n \log n)$ [21].

THEOREM 6.2. *For a planar graph on n vertices and maximum degree d , a bisection of size $O(d\sqrt{n})$ can be found in time $O(n \log n)$.*

Clearly, if a graph has an $O(1)$ -size bisection, it can be found by exhaustive search in polynomial time. We conclude that at present we have efficient methods for at least $O(1)$ -approximation of min-bisection in planar graphs if its size is either $\Omega(n \log \log n / \log n)$ or $O(1)$, or it is $O(\sqrt{n})$ and the maximum degree is constantly bounded. These observations suggest that a substantial improvement of the logarithmic approximation factor for min-bisection on planar graphs given in [11] might be possible.

7. PTAS for max-bisection of a unit disk graph. In this section we design a PTAS for max-bisection of unit disk graphs, another important class of graphs defined by the geometric conditions on a plane.

Recall that an undirected graph G is a unit disk graph if its vertices can be put in one-to-one correspondence with disks of equal radius in the plane in such a way that two vertices are joined by an edge if and only if the corresponding disks intersect. Tangent disks are considered to intersect. We may assume w.l.o.g. that the radius of each disk is one. Since the recognition problem for the unit disk graph is NP-hard, we shall also assume that a geometric representation of the graph is given as input.

Our technique works in a similar way as in the case for planar graphs. The input graph G is divided into families of subgraphs $H_{i,j}$ using the ideas of Hunt et al. given in [17]. Next, either an optimal or approximative solution to all $(l, n_{i,j} - l)$ -partitions of every subgraph $H_{i,j}$, where $n_{i,j}$ denotes the number of vertices in $H_{i,j}$, can be computed. If the number of vertices $n_{i,j}$ is smaller than a constant c , then we can compute an optimal solution in constant time. If the number $n_{i,j}$ is larger than a constant c , then we use the methods given in [2]. We show below that in such a case the underlying graph is dense; i.e., it has at least $an_{i,j}^2$ edges for a constant $a > 0$. Via

tree-type dynamic programming these solutions are used to obtain an overall solution for G .

In order to divide the graph G , we impose a grid of horizontal and vertical lines on the plane that are 2 apart of each other. The v th vertical line, $-\infty < v < \infty$, is at $x = 2v$. The h th horizontal line, $-\infty < h < \infty$, is at $y = 2h$. We say that the v th vertical line has index v and that the h horizontal line has index h . Further, we denote the vertical strip between the v th and the $(v + 1)$ th vertical line as the strip with index v and as the analogue for the horizontal strip between the h th and the $(h + 1)$ th horizontal line.

Each vertical strip is left-closed and right-open, and each horizontal strip is closed at the top and open at the bottom. A disk is said to lie in a given strip if its center lies in that strip. Note that every disk lies in exactly one horizontal and vertical strip.

For a fixed k , consider the subgraph $H_{i,j}$ of G , $-\infty < i, j < \infty$, induced by the disks that lie in the intersection of the horizontal strips $i, i + 1, \dots, i + k$ and the vertical strips $j, j + 1, \dots, j + k$. Let $n_{i,j}$ be the number of vertices of $H_{i,j}$. By a packing argument it can be shown that for fixed $k > 0$, the size of a maximum independent set of such a subgraph is at most $4(k + 3)^2/\pi$. The area of the square (given by the intersection of the $(k + 1)$ horizontal and $(k + 1)$ vertical strips) is $4(k + 1)^2$. Since a disk can lie close to or at the border of a horizontal strip i and $i + k$ and at the border of a vertical strip j and $j + k$, the total area that an independent set of disks (of subgraph $H_{i,j}$) can cover is at most $4(k + 3)^2$. Since the area of each disk is π , the size of an independent set is at most $4(k + 3)^2/\pi$.

LEMMA 7.1. *If $n_{i,j} > 8(k + 3)^2/\pi$, then the subgraph $H_{i,j}$ of G is dense.*

Proof. Partition the vertex set of $H_{i,j}$ successively into maximal independent sets by determining a maximal independent set I_1 , remove its vertices, and again determine a maximal independent set I_2 , and so on. As described above, the number of independent sets is at least $\pi n_{i,j}/4(k + 3)^2$. Since each I_j is maximal, there is at least one edge from a vertex of I_j to every $I_{j'}$, $j < j'$. If we understand the set of independent sets as a complete graph on $\pi n_{i,j}/4(k + 3)^2$ vertices, it follows that $H_{i,j}$ has at least $n_{i,j}^2 \pi^2/64(k + 3)^4$ edges for $n_{i,j} \geq 8(k + 3)^2/\pi$. This implies that $H_{i,j}$ is dense. \square

COROLLARY 7.2. *If $n_{i,j} > 8(k + 3)^2/\pi$, then the size of a maximum bisection of $H_{i,j}$ is $\Omega(n_{i,j}^2)$.*

Proof. Partition the vertex set of $H_{i,j}$ as before and use the maximum independent sets to build up the sets of the bisection. Since all independent sets are maximal, there are at least $n_{i,j}^2 \pi^2/16^2(k + 3)^4$ edges between the sets of bisection. \square

The main idea of our algorithm is that each subgraph $H_{i,j}$ (corresponding to the $(k + 1) \times (k + 1)$ square) either has at most a constant number of vertices (case $n_{i,j} \leq 8(k + 3)^2/\pi$) or is dense and has a large bisection (case $n_{i,j} > 8(k + 3)^2/\pi$; see Lemma 7.1 and Corollary 7.2 above). In the former case, the problem can be solved optimally, while in the later case, we use a PTAS of [2] to obtain an approximately optimal solution. Let $c = 8(k + 3)^2/\pi$.

ALGORITHM 2.

input: a unit disk graph $G = (V, E)$ specified by a set V of disks in the plane and the coordinates of their centers and a positive integer k ;

output: $(1 - \frac{1}{k+1})^2(1 - \delta)$ -approximations of maximum bisection of G

1. Divide the plane by imposing a grid of width two.
2. Construct the subgraphs $H_{i,j}$ of G as described above.
3. For each i and each j , set $n'_{i,j}$ to the number of vertices in $H_{i,j}$ and compute all

$(l, n'_{i,j} - l)$ -partitions of $H_{i,j}$ either approximatively (for $n'_{i,j} > c$) or optimally (for $n'_{i,j} \leq c$).

4. For each r and s , $0 \leq r, s \leq k$, set $G_{r,s}$ to the union of the subgraphs $H_{i,j}$, where $i \pmod{k+1} = r$ and $j \pmod{k+1} = s$.
5. For each r and s , $0 \leq r, s \leq k$, set $n_{r,s}$ to the number of vertices in $G_{r,s}$ and compute a bisection of $G_{r,s}$ within $(1 - \delta)$ of its maximum by dynamic programming in a tree fashion. Therefore, enumerate the subgraphs in increasing order of the sum $i + j$ and compute all partitions of pairs of “consecutive” $H_{i,j}$, respectively, to this ordering on the basis of the computed partitions, then for quadruples of such $H_{i,j}$, etc.
6. Output the largest bisection of $G_{r,s}$, $0 \leq r, s \leq k$.

If $n_{i,j} \leq c = 8(k+3)^2/\pi$, we can find all the maximum $(l, n_{i,j} - l)$ -partitions of the subgraph $H_{i,j}$ in constant time by enumerating all possibilities. Otherwise (for $n_{i,j} > c = 8(k+3)^2/\pi$) the problem is solvable approximatively in polynomial time by solving the following polynomial integer program:

$$(7.1) \quad \text{maximize} \quad \sum_{\{i,j\} \in E(H_{i,j})} x_i(1-x_j) + x_j(1-x_i)$$

$$(7.2) \quad \text{subject to} \quad \sum x_i = l,$$

$$(7.3) \quad x_i \in \{0, 1\}, \quad i = (1, \dots, n_{i,j}).$$

This program can be solved by the use of Theorem 1.10 in [2] within an error of at most $\epsilon n_{i,j}^2$, which also satisfies the linear constraint (7.2) of the program within an additive error of $O(\epsilon \sqrt{n_{i,j} \log n_{i,j}})$. In order to get a subset of size l , we move at most $\epsilon \sqrt{n_{i,j} \log n_{i,j}}$ in or out. This affects the number of edges included in the partition by at most $\epsilon n_{i,j} \sqrt{n_{i,j} \log n_{i,j}} \leq \epsilon n_{i,j}^2$. Hence we can compute a maximum $(l, n_{i,j} - l)$ -partition of a subgraph $H_{i,j}$ that has more than c vertices within an additive error of $2\epsilon n_{i,j}^2$ of the maximum.

LEMMA 7.3. *Algorithm 2 outputs a bisection of G within $(1 - \frac{1}{k+1})^2(1 - \delta)$ of the maximum.*

Proof. Let P be a maximum bisection of G . For each edge $e \in P$ and a fixed r , $0 \leq r \leq k$, there is at most one s , $0 \leq s \leq k$, such that e crosses a vertical line whose index modulo $k+1$ is s . Analogously, there is for each $e \in P$ and a fixed s , $0 \leq s \leq k$, at most one r , $0 \leq r \leq k$, such that e crosses a horizontal line whose index modulo $k+1$ is r . Consequently, there is a pair (r, s) , $0 \leq r, s \leq k$, such that a maximum $(l, n - l)$ -partition of $G_{r,s}$ cuts at least $(1 - \frac{1}{k+1})^2 |P|$ edges.

By Corollary 7.2, the size of maximum bisection of the subgraph $G'_{r,s}$ of $G_{r,s}$ that consists of all $H_{i,j}$ with more than $c = 8(k+3)^2/\pi$ vertices is at least $\sum_{n_{i,j} > c} dn_{i,j}^2$, where $d = \pi^2/16^2(k+3)^4$. Choosing $\epsilon = \delta d/2$, the error $2\epsilon n_{i,j}^2 = \delta dn_{i,j}^2$ caused by the solutions of the polynomial integer programs for the subgraphs $H_{i,j}$ of $G'_{r,s}$ is at most a δ fraction of an optimum solution of maximum bisection for $G'_{r,s}$. Since the partitions for each $H_{i,j}$ with at most c vertices are computed optimally, we obtain a bisection of $G_{r,s}$ within $(1 - \delta)$ of the maximum.

Thus Algorithm 2 outputs a bisection of G within $(1 - \frac{1}{k+1})^2(1 - \delta)$ of the maximum. \square

THEOREM 7.4. *The problem of max-bisection on unit disk graphs admits a PTAS.*

The same approach can be used to obtain a PTAS for the maximum bisection problem in geometric intersection graphs, both of other regular polygons and also of regular geometric objects in higher dimensions.

Acknowledgments. We are grateful to Mark Jerrum for providing the proof of NP-hardness of planar max-bisection in exact setting and agreeing on presenting it in this paper. We thank also Andreas Björklund, Hans Bodlaender, Uri Feige, Miroslaw Kowaluk, Mike Langberg, and Monique Laurent for many stimulating remarks and discussions.

MINIMUM-WEIGHT SPANNING TREE CONSTRUCTION IN $O(\log \log n)$ COMMUNICATION ROUNDS*

ZVI LOTKER[†], BOAZ PATT-SHAMIR[†], ELAN PAVLOV[‡], AND DAVID PELEG[§]

Abstract. We consider a simple model for overlay networks, where all n processes are connected to all other processes, and each message contains at most $O(\log n)$ bits. For this model, we present a distributed algorithm which constructs a minimum-weight spanning tree in $O(\log \log n)$ communication rounds, where in each round any process can send a message to every other process. If message size is $\Theta(n^\epsilon)$ for some $\epsilon > 0$, then the number of communication rounds is $O(\log \frac{1}{\epsilon})$.

Key words. minimum-weight spanning tree, distributed algorithms

1. Introduction. A minimum-weight spanning tree (MST) is one of the most useful distributed constructs, as it minimizes the cost associated with global operations such as broadcasts and convergecasts. This paper presents an MST construction algorithm that works in $O(\log \log n)$ communication rounds, where in each round each process can send $O(\log n)$ bits to every other process (intuitively allowing each message to contain the identity and weight of only a constant number of edges). Our result shows that an MST can be constructed with little communication: throughout the execution of the algorithm, each pair of processes exchanges at most $O(\log n \log \log n)$ bits; the overall number of bits sent is $\Theta(n^2 \log n)$, which is optimal. The algorithm extends to larger message sizes, in the sense that the number of communication rounds is $O(\log \frac{1}{\epsilon})$ if each message can contain n^ϵ bits for some $\epsilon > 0$. Note that if messages are not restricted in size, then the MST can be trivially constructed in a single round of communication: each process sends all its information to all its neighbors, allowing each node to locally compute the MST.

The number of communication rounds dominates the time complexity in situations where latency is high and bandwidth is scarce. This may be the situation in some *overlay networks*. Briefly, the idea in overlay networks is to think of the underlying communication network (e.g., the Internet) as a “black box” that provides reliable point-to-point communication. On top of that network run distributed applications. This approach (whose precursor is the Internet’s “end-to-end argument” [13]) is different from classical distributed models, where processes reside in networks nodes (i.e., switches or routers), and thus their implementation would require using low-level communication. Rather, the pragmatic view now is that distributed applica-

tions create their own overlay network by choosing which pairs of local processes will communicate directly according to various criteria. The concept of overlay networks is central to areas such as multicast or content distribution networks (see, e.g., [8] and the references therein), peer-to-peer systems (for example, Chord [14]), and others.

1.1. Related work. Spanning tree construction is well studied as a sequential optimization problem (see, e.g., [15, 9]). Distributed MST constructions are presented in [6, 3] (and see the references in [11]). These classical distributed algorithms are oriented towards minimizing the total number of messages in general networks, and their time complexity is inherently $\Omega(\log n)$, even when run on fully connected graphs. The model we use in this paper is a special case of the model studied in [7, 12, 10]: in these papers, each message has $O(\log n)$ bits, but the fully connected graph is not directly considered. The best previously known upper bound for fully connected graphs in this model is $O(\log n)$ communication rounds. This bound holds also for graphs of diameter 2 [10]. (It is known that the number of rounds jumps at least to $\Omega(n^{1/4})$ when the diameter of the network is 3 or more [10, 12].)

The parallel time complexity of MST construction depends on the particular architecture considered, but we are not aware of any sublogarithmic time algorithm that uses small messages. For the PRAM model, there are quite a few $O(\log n)$ algorithms, including a deterministic one for the CRCW model [4] and a randomized one for the EREW model [5]. Adler et al. [1] study the total number of bits that must be communicated in the course of an MST construction problem under various parallel architectures. For our model, their results imply that the worst-case number of bits that need to be communicated throughout the execution of the algorithm is $\Omega(n^2 \log n)$.

1.2. System model. In the underlying formal model, the system is represented by a complete n -node weighted undirected graph $G = (V, E, \omega)$, where $\omega(e)$ denotes the weight of edge $e \in E$. Each node has a distinct ID of $O(\log n)$ bits. Each node knows all the edges incident to it (and hence, since the graph is a clique, each node knows about all other nodes in the system). An execution of the system proceeds in asynchronous steps: in a “receive” step, a node receives some of the messages sent to it in previous steps. In a “send” step, a node makes a local computation and sends messages to the other nodes in the system. Each message may be different, and we require that each message contains at most $O(\log n)$ bits. (The results are extended to larger message sizes in section 4.) We assume that messages may be delayed arbitrarily but are never lost or corrupted. The time complexity of an algorithm in the asynchronous model is measured by normalizing the scale so that the longest message delivery time is one unit.

Simplification: The synchronous model. In the synchronous model, computation advances in global rounds, where in each round processes send messages, receive them, and do some local computation. This model is much more convenient as a programming mode. Fortunately, since we assume that the system is reliable, we may apply a *synchronizer* that allows us to present the algorithm in the synchronous model. Specifically, we use the α synchronizer of Awerbuch [2]. Let us outline the idea briefly. Assume that we have an algorithm SA for the synchronous model. The execution in the asynchronous model is done as follows. A process starts the next round only after receiving a special “proceed” message from a distinguished node v^* (say, the node with the lowest ID in the system). It then sends messages according to SA . For each SA message received, the receiver node sends an “ack” message back to the sender; when a sender has received acknowledgements to all the messages it

sent, the sender forwards a “safe” message to v^* ; when v^* receives “safe” messages from all nodes in the system, it sends a “proceed” message to all other nodes, which may then send their SA messages of the next round. Note that since we assume that the graph is fully connected, this transformation incurs only a constant blowup in the message complexity and in time complexity. We shall henceforth use the synchronous model, but we emphasize that the algorithm works in the asynchronous model using the simple synchronizer described above.

1.3. The MST construction problem. We assume that in the initial state, the input to each node $v \in V$ consists of the weights of all its incident edges $\omega(v, u)$ for all $u \in V \setminus \{v\}$. Edge weights are assumed to be integers that can be represented using $O(\log n)$ bits. Without loss of generality, we assume that all the edge weights are distinct (otherwise we can break ties by node IDs), and hence the MST is unique. When our algorithm halts, all nodes know the full list of all $n - 1$ edges in the MST of G .

2. Algorithm description. In this section we describe the algorithm. In section 2.1 we give an overview of the main ideas. In section 2.2 we specify the main algorithm, and in sections 2.3 and 2.4 we specify local subroutines used by the main algorithm.

2.1. Overview. The algorithm operates in phases: Each phase takes $O(1)$ rounds, and there are at most $O(\log \log n)$ phases. At the end of each phase $k \geq 0$, the nodes of G are partitioned into disjoint clusters $\mathcal{F}^k = \{F_1^k, \dots, F_{m_k}^k\}$, $\bigcup_i F_i^k = V$. For each cluster $F \in \mathcal{F}^k$, the algorithm selects also a spanning subtree $T(F)$. The partition \mathcal{F}^k and the corresponding subtree collection $\mathcal{T}^k = \{T(F) \mid F \in \mathcal{F}^k\}$, including the weights of the edges in those subtrees, are known to every vertex in the graph. (For notational consistency, we think of the initial situation at the beginning of phase 1 as the end of an “imaginary” phase 0, with each node forming a singleton cluster, i.e., $\mathcal{F}^0 = \{F_1^0, \dots, F_n^0\}$, where $F_i^0 = \{v_i\}$ for every $1 \leq i \leq n$.)

Define a *fragment* to be a connected subtree of the MST. For a set of nodes $F \subseteq V$, denote by $\mathcal{T}(F)$ the subgraph of the MST induced by F . With these notations, we can state the following invariant, satisfied by the algorithm at the end of each phase $k \geq 0$:

$\mathcal{T}(F) = T(F)$ for every cluster F ; namely, the spanning subtree selected for F is a fragment.

In our model, it is easy for the nodes of each cluster to learn, in constant time, the lightest edge to every other cluster. Hence, intuitively, it is possible to “contract” each cluster C into a vertex v_C , thus creating a smaller logical graph \hat{G} , and continue working on this logical graph. (In practice, each real vertex belonging to some cluster C knows the weight of the edge connecting its vertex v_C to every other vertex in \hat{G} . The operations of each vertex v_C of the logical graph \hat{G} are carried out by the real vertices belonging to the cluster C , or by a single representative called the *leader* of C , denoted $\ell(C)$.) This enables us to simulate the usual “fragment growing” MST construction process for \hat{G} , based on examining the edges one by one in increasing order of weight and including in the MST each inspected edge that is the *minimum-weight outgoing edge (MWOE)* of its fragment. This can be done in $O(\log n)$ time.

To reduce the time complexity to $O(\log \log n)$, it is necessary to speed up the process by making the cluster sizes grow quadratically in each phase. The main idea used for achieving this growth rate is the following. Essentially, we would like to provide every vertex v_C in the logical graph \hat{G} with information about additional

edges in \hat{G} , beyond its own. In particular, if we were somehow able to let every vertex v_C learn the *entire* topology of \hat{G} , then we could finish the MST construction for \hat{G} in a single step by asking each vertex in the graph to compute the MST locally. Unfortunately, such information exchange seems to require too much time. On the positive side, denoting the minimum cluster size by N , it is possible for the (N or more) members of each cluster to inform a distinguished vertex v^* of the graph, in constant time, of the N lightest edges connecting their cluster to other clusters, by appropriately sharing the workload of this task among them. (For concreteness, we assume that v^* is the node with the smallest ID in the system.)

Subsequently, we now face a special subtask of the MST construction problem to solve in v^* . This node now has a partial picture of the logical graph \hat{G} , consisting of all the vertices v_C but only some of the edges connecting them, particularly the N lightest edges emanating from each vertex of \hat{G} (to N other vertices). It is now necessary to perform (locally) as many *legal* “fragment merging” steps as possible on the basis of this information. That is, we would like to sort the edges known to us by increasing order of weight, examine them one by one, and add edges that are the MWOE of one of the two fragments they connect, so long as we can be sure of that fact. So the question becomes: When is it “dangerous” to continue the merging steps in the absence of information about the weights of the edges unknown to us?

The answer to this question is that it is perfectly safe to continue merging a fragment F (in the logical graph \hat{G}), so long as for each vertex v_C in F we have still not inspected *at least one* of its N lightest edges (which is known to us by assumption). However, once we have already inspected all the edges of some vertex v_C in the fragment F , it becomes dangerous to continue attempting to merge the fragment over edges known to us, as it is possible that the true MWOE of F is the $(N + 1)$ st lightest edge emanating from v_C , which is not known to us (yet is lighter than any edge emanating from C that we do know of at this moment).

The crucial observation is that this “safety rule” still allows us to grow each of the fragments to contain at least $N + 1$ vertices of \hat{G} . This means that the clusters of the next phase will be of minimum size $\Omega(N^2)$.

An interesting observation is that even when we can no longer identify the MWOE of some fragment F , we may still be able to safely merge F with some other fragment F' . This may still be legitimate if we can ascertain that the edge connecting F and F' is the MWOE of F' .

Finally, after constructing locally the new fragments, v^* sends out the identity of the edges added to the chosen set. This can be done in constant time by letting v^* send each edge to a different intermediate node, which will broadcast that edge to all other nodes.

2.2. The main algorithm. In the algorithm, whenever a node is instructed to send a message containing the edge $e = (u, v)$, this should be interpreted as a message including the IDs of its two endpoints, $ID(u)$ and $ID(v)$, as well as the edge weight $\omega(e)$.

We now describe the steps taken in phase k for all $1 \leq k \leq \log \log n$. Let v^* denote the node whose ID is minimal among all nodes in the graph.

Throughout, the algorithm is illustrated on the 16-vertex complete graph K_{16} with weights as depicted in Figure 1. Note that in this case there are only two phases. The flow of the algorithm is illustrated in Figure 2. In the first column, the fragment leaders are marked by horizontal stripes. Note that in the first phase all the nodes are leaders, whereas in the second phase only half of the nodes are leaders. The

FIG. 1. The example graph K_{16} : (a) The edge weights (weight 1 is a solid line, 2 is a dashed line, and 3 is a double-dashed line). Edges not shown in the figure have weight 4; hence they do not participate in the MST. (b) The resulting MST.

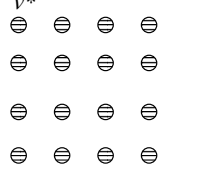

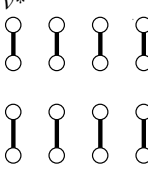

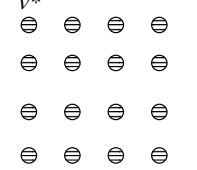

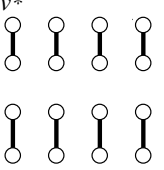

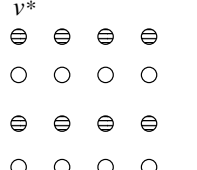

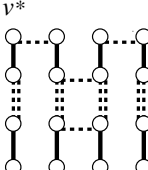

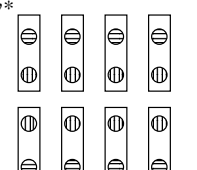

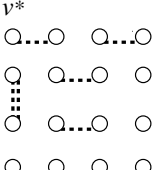

Phase	Fragment leaders	Selected edges	Edge guardians	Information sent by v^*
1	v^* 	v^* 	v^* 	v^* 
2	v^* 	v^* 	v^* 	v^* 

FIG. 2. An illustration of the execution of the algorithm on the example graph K_{16} .

second column shows the selected edges. In the first phase each fragment chooses one edge, while in the second phase each fragment chooses two edges, with the cheapest edge of each fragment denoted by a single-dashed line and the second cheapest edge denoted by a double-dashed line. The third column shows the guardian of each of the selected edges: the horizontally striped nodes are the guardians of cheapest edges and the vertically striped nodes are the guardians of the second cheapest edges. The last column shows the new edges that node v^* adds to the MST.

Phase k : Code for node v in cluster F of size $N = |F|$

Input: A set of chosen edges. The set of connected components defined by this set is the set of clusters \mathcal{F}^{k-1} . For each cluster $F' \in \mathcal{F}^{k-1}$, $\ell(F')$ is the node with the minimal ID in F' .

1. (a) Compute the minimum-weight edge $e(v, F')$ that connects v to (any node of) F' for all clusters $F' \neq F$.
 (b) Send $e(v, F')$ to $\ell(F')$ for all clusters $F' \neq F$.
 2. **If $v = \ell(F)$ then**
 - (a) Using the messages received from step 1, compute the lightest edge between F' and F for every other cluster F' .
 - (b) Perform (locally) Procedure **Cheap_Out** (described below), which does the following:
 - It selects a set $\mathcal{A}(F)$ containing the N cheapest MWOEs that go out of F to $N = |F|$ distinct clusters.
 - It appoints for each such edge e a *guardian* node $g(e)$ in F , ensuring that each node in F is appointed as guardian to at most one edge.
 3. Let $e' \in \mathcal{A}(F)$ be the edge for which v was appointed as guardian, i.e., such that $g(e') = v$. Send e' to v^* , the node with the minimal ID in the graph.
 (At the end of this step, v^* knows all the edges in the set $\mathcal{A} = \bigcup_{F' \in \mathcal{F}^{k-1}} \mathcal{A}(F')$.)
 4. **If $v = v^*$ then**
 - (a) Perform (locally) Procedure **Const_Frags**. This procedure (described below) computes E^k , the new set of edges to add.
 - (b) For each edge $e \in E^k$, send a message to $g(e)$.
 5. **If v receives a message from v^* that $e \in E^k$** , then v sends e to all nodes in the graph.
 6. Each node adds all edges in E^k and computes \mathcal{F}^k .
-

2.3. Procedure Cheap_Out. The local procedure **Cheap_Out** is invoked by cluster leaders in each phase, and it operates as follows at the leader of cluster F with $|F| = N$ at phase k .

Input: Cheapest edge $e(F, F')$ for every $F' \in \mathcal{F}^{k-1}$.

1. Sort the input edges in increasing order of weight.
 2. Let $\mu = \min\{N, |\mathcal{F}^{k-1}| - 1\}$.
 3. Define $\mathcal{A}(F)$ to be the first μ edges in the sorted list.
 4. Sort the nodes of F by increasing order of ID.
 5. Appoint the i th node of F as the guardian of the i th edge added to $\mathcal{A}(F)$.
 6. For each node $u \in F$: send the edge to which u is appointed.
-

2.4. Procedure Const_Frags. The local procedure **Const_Frags** is invoked only by the distinguished node v^* , and it operates as follows. It receives as input the initial partition \mathcal{F}^{k-1} , the spanning subtree collection \mathcal{T}^{k-1} , and the set of edges for inspection, \mathcal{A} . Its output is a set of edges E^k , which defines a new partition \mathcal{F}^k and its spanning subtree \mathcal{T}^k : the edge set of \mathcal{T}^k is the union of the set of edges in \mathcal{T}^{k-1} with the set E^k , and \mathcal{F}^k is the set of connected components of \mathcal{T}^k .

The procedure operates in two stages. In the first stage, it contracts the input clusters into vertices, thus creating a *logical graph* \hat{G} , partitions this logical graph into “superclusters,” and constructs a spanning subtree for each such supercluster. In the second stage, the procedure transforms the superclusters and spanning subtrees constructed for \hat{G} into clusters and spanning subtrees for the original graph G .

We now continue with a more detailed description of the two stages. The first stage operates as follows. The procedure starts by creating the logical graph $\hat{G} = (\hat{V}, \hat{E})$, where each input cluster is viewed as a vertex, namely, $\hat{V} = \mathcal{F}^{k-1}$. The edge set \hat{E} consists of the logical edges corresponding to the edges of the set \mathcal{A} . Set the logical edge corresponding to $e = (u, w)$ to be $X(e) = (F, F')$, where $u \in F$ and $w \in F'$. Then $\hat{E} = \{X(e) \mid e \in \mathcal{A}\}$. Each logical edge $X(e)$ is assigned the same weight as e .

Then the procedure constructs a collection $\hat{\mathcal{F}}$ of superclusters and a corresponding collection $\hat{\mathcal{T}}$ of spanning subtrees on this logical graph. The construction operates as follows. The procedure first initializes the output partition as $\mathcal{F} = \{\{F\} \mid F \in \mathcal{F}^{k-1}\}$; i.e., each vertex of $\hat{V} = \mathcal{F}^{k-1}$ is a separate supercluster. The output collection of spanning subtrees is initialized to $\hat{\mathcal{T}} = \emptyset$. The procedure then inspects the edges of \hat{E} sequentially in increasing order of weight. An inspected logical edge $X(e)$ is added to $\hat{\mathcal{T}}$ if it does not close a cycle with edges already in $\hat{\mathcal{T}}$. Whenever an edge $X(e) = (F_1, F_2)$ is added to $\hat{\mathcal{T}}$, the superclusters \hat{F}_1 and \hat{F}_2 containing F_1 and F_2 , respectively, are merged into one supercluster \hat{F} , setting $\hat{F} = \hat{F}_1 \cup \hat{F}_2$ and eliminating \hat{F}_1 and \hat{F}_2 , and the corresponding spanning subtrees are fused together into a spanning subtree for the new supercluster \hat{F} , setting $\hat{T}(\hat{F}) = \hat{T}(\hat{F}_1) \cup \hat{T}(\hat{F}_2) \cup \{X(e)\}$.

In each step during this process, whenever a logical edge $X(e) = (F_1, F_2)$ between two superclusters \hat{F}_1 and \hat{F}_2 such that $F_1 \in \hat{F}_1$ and $F_2 \in \hat{F}_2$ is inspected, the procedure also considers declaring one or two superclusters *finished* as follows:

- If the step resulted in a merge operation creating a new supercluster $\hat{F} = \hat{F}_1 \cup \hat{F}_2$, then the newly constructed supercluster \hat{F} is declared finished if one of the following conditions hold:
 - e is the heaviest edge in $\mathcal{A}(F_1)$ or in $\mathcal{A}(F_2)$, or
 - either \hat{F}_1 or \hat{F}_2 is finished.
- If the step did not result in a merge between \hat{F}_1 and \hat{F}_2 , then
 - the supercluster \hat{F}_1 is declared finished if e is the heaviest edge in $\mathcal{A}(F_1)$;
 - the supercluster \hat{F}_2 is declared finished if e is the heaviest edge in $\mathcal{A}(F_2)$.

Also, after every edge inspection step, some of the remaining edges become “dangerous” and are removed from the set \mathcal{A} . A remaining logical edge $X(e) = (F_1, F_2)$, $F_1 \in \hat{F}_1$, $F_2 \in \hat{F}_2$, is still “safe” (i.e., not dangerous) if $e \in \mathcal{A}(F_1)$ and the supercluster \hat{F}_1 is still unfinished, or if $e \in \mathcal{A}(F_2)$ and the supercluster \hat{F}_2 is still unfinished. Thus after every edge inspection step, the procedure examines every edge and removes each dangerous edge e from the set \mathcal{A} . The procedure also removes the corresponding logical edge $X(e)$ from \hat{E} . The process terminates once all superclusters are declared finished (which, as can easily be verified, happens concurrently with the set \mathcal{A} becoming empty).

In the second stage, the procedure transforms the superclusters and spanning subtrees constructed for \hat{G} into ones for the original graph G . Specifically, for every supercluster $\hat{F} \in \hat{\mathcal{F}}$ of the logical graph \hat{G} , with spanning subtree $\hat{T}(\hat{F})$, the procedure merges the original clusters included in the supercluster \hat{F} into a cluster F' of G and creates the corresponding spanning subtree $T(F')$ for this cluster by merging $\hat{T}(\hat{F})$ together with all the spanning subtrees from the collection \mathcal{T}^{k-1} spanning the original

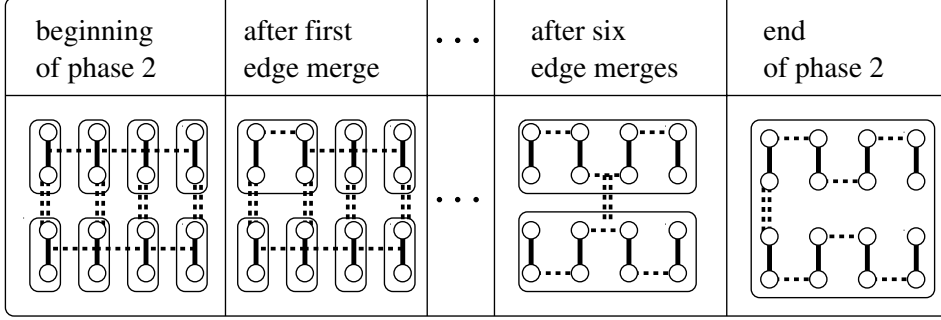

FIG. 3. The operation of Procedure `Const_Frags` during phase 2 on K_{16} and the logical graph structure after various stages of its execution.

clusters included in the supercluster \hat{F} , i.e., setting

$$T(F') = \{e \mid X(e) \in \hat{T}(\hat{F})\} \cup \bigcup_{F \in \hat{F}} T(F).$$

It then adds the cluster F' to the output cluster collection \mathcal{F}^k and the spanning subtree $T(F')$ for it into \mathcal{T}^k .

The operation of Procedure `Const_Frags` during the second phase of the algorithm's execution on our example graph K_{16} is illustrated in Figure 3.

3. Analysis. In this section we prove that the algorithm described in section 2 is correct and analyze its complexity. It is more convenient to start with the complexity analysis.

3.1. Complexity. The following lemma is the key to the complexity analysis. It bounds from below the growth rate of fragments.

Consider phase k of the algorithm. Let \hat{G} be the logical graph constructed by Procedure `Const_Frags`. Let $\hat{\mathcal{F}}$ be the collection of clusters constructed by Procedure `Const_Frags` for \hat{G} . Define μ to be the minimum between the smallest cluster size and number of clusters minus one (cf. line 2 in Procedure `Cheap_Out`).

LEMMA 3.1. *Every supercluster in $\hat{\mathcal{F}}$ consists of at least $\mu + 1$ logical vertices of \hat{G} .*

Proof. To establish the lemma, we prove the following stronger claim: whenever the procedure declares a supercluster \hat{F} finished, it contains at least $\mu + 1$ logical vertices of \hat{G} . This claim is proved by structural induction on the superclusters.

There are three base cases. The first is when \hat{F} is declared finished following a merge step $\hat{F} = \hat{F}_1 \cup \hat{F}_2$ where the two merged superclusters were unfinished. This merge step was based on the inspection of some logical edge $X(e) = (F_1, F_2)$ such that $F_1 \in \hat{F}_1$ and $F_2 \in \hat{F}_2$. By the specification of Procedure `Const_Frags`, without loss of generality we may assume that e is the heaviest edge in $\mathcal{A}(F_1)$. As the edges are inspected in increasing weight order, all other edges in $\mathcal{A}(F_1)$ have already been inspected. There are μ such edges, $e_{i_1}, \dots, e_{i_\mu}$, leading to *distinct* original clusters $F_{j_1}, \dots, F_{j_\mu}$. Whenever an edge e_{i_l} was inspected, either the superclusters containing F_1 and F_{j_l} were merged, or e_{i_l} was found to close a cycle, indicating that F_1 and F_{j_l} already belonged to the same supercluster. Hence the finished supercluster \hat{F} contains (at least) the $\mu + 1$ original clusters $F_1, F_{j_1}, \dots, F_{j_\mu}$.

The second base case is when \hat{F} is declared finished following the inspection of some logical edge $X(e) = (F, F_2)$ such that $F \in \hat{F}$ and $F_2 \in \hat{F}_2$, which did not result in a merge. This happens since e is the heaviest edge in $\mathcal{A}(F)$. Again, all $\mu - 1$ other edges in $\mathcal{A}(F)$ have already been inspected, and by a similar reasoning as above, the finished supercluster \hat{F} contains (at least) $\mu + 1$ original clusters. The third base case is the dual case where \hat{F} is declared finished following the inspection of some logical edge $X(e) = (F_1, F)$ such that $F_1 \in \hat{F}_1$ and $F \in \hat{F}$, which did not result in a merge. Again this happens since e is the heaviest edge in $\mathcal{A}(F)$, and the claim follows in the same way.

The inductive claim concerns the case where \hat{F} is declared finished following a merge step $\hat{F} = \hat{F}_1 \cup \hat{F}_2$ where one or both of the two merged superclusters were finished. In this case, the claim follows directly from the inductive hypothesis. \square

LEMMA 3.2. *For any cluster $F \in \mathcal{F}^k$, $|F| \geq 2^{2^{k-1}}$.*

Proof. Denote by μ_k the minimum size of a cluster $F \in \mathcal{F}^k$. First, note that for all $k \geq 0$,

$$(3.1) \quad \mu_{k+1} \geq \mu_k(\mu_k + 1).$$

Equation (3.1) is true by Lemma 3.1, which implies that clusters generated in phase $k+1$ consist of the union of at least $\mu_k + 1$ clusters of phase k , each containing at least μ_k nodes. Now, since $\mu_0 = 1$, we have $\mu_1 \geq 2$. Since (3.1) implies that $\mu_{k+1} > \mu_k^2$, we conclude that $\mu_k > \mu_1^{2^{k-1}} = 2^{2^{k-1}}$. \square

COROLLARY 3.3. *The algorithm terminates after at most $\log \log n + 1$ phases.*

Proof. The proof follows from Lemma 3.2, since the algorithm terminates at phase k in which $|F| \geq n$ for any $F \in \mathcal{F}^k$. \square

The following statement is immediate from the code of the algorithm.

LEMMA 3.4. *Each phase requires $O(1)$ rounds.*

We now conclude with the following result.

THEOREM 3.5. *The time complexity of the algorithm is $O(\log \log n)$ rounds, and the overall number of bits communicated is $O(n^2 \log n)$.*

Proof. The time complexity bound follows directly from Corollary 3.3 and Lemma 3.4. For the total number of bits communicated, we account for each step separately as follows. In step 1 of the main algorithm, each node in a cluster F sends messages to all other clusters; i.e., each node sends $|\mathcal{F}^{k-1}| - 1$ messages. Since each cluster is of size at least $2^{2^{k-1}}$ by Lemma 3.2, it follows that $|\mathcal{F}^{k-1}| \leq n/2^{2^{k-1}}$. Therefore, the number of messages sent by a node at step 1 of phase k is less than $n/2^{2^{k-1}}$. Since each message contains at most $c \log n$ bits for some constant c , the number of bits sent over all phases in step 1 is less than

$$\sum_{k=0}^{\log \log n + 1} n \cdot c \log n \cdot \frac{n}{2^{2^{k-1}}} = n^2 c \log n \sum_{k=0}^{\log \log n + 1} 2^{-2^{k-1}} = O(n^2 \log n).$$

No messages are sent in step 2. The number of messages sent in step 3 of the algorithm in each phase is $O(n)$ over all nodes (since each node receives at most one message), for a total of $O(n \log n \log \log n)$ bits throughout the execution. To account for the number of messages sent in steps 4 and 5, we bound the total number of messages sent in that step over all nodes and over all phases: note that each edge added to the MST contributes $O(n \log n)$ bits sent at steps 4 and 5, and since exactly $n - 1$ edges are added to the MST overall, the total number of bits sent in these steps throughout the execution of the algorithm is $O(n^2 \log n)$. The result follows. \square

We note that by the results of Adler et al. [1] applied to our model, the minimal number of bits required to solve the MST problem is $\Omega(n^2 \log n)$ in the worst case.

3.2. Correctness. The correctness of the algorithm is proved by the following invariant.

LEMMA 3.6. *In each phase k , for every cluster $F \in \mathcal{F}^k$ constructed by Procedure Const.Frags, the corresponding spanning tree is a fragment, namely, $T(F) = \mathcal{T}(F)$.*

Proof. The proof is by induction on k . The initial partition, \mathcal{F}^0 , trivially satisfies the claim. Now suppose that the collection \mathcal{T}^{k-1} consists of only MST edges, and consider the collection \mathcal{T}^k constructed in phase k . The spanning subtrees in this collection are composed of spanning subtrees from \mathcal{T}^{k-1} fused together by new edges added by Procedure Const.Frags. It suffices to show that every edge added to the trees of \mathcal{T}^k in phase k is indeed an MST edge. For this, we rely on the standard MST construction rule which says that if e is the lightest outgoing edge incident on a fragment, then it belongs to the MST. Consequently, we have to show that whenever Procedure Const.Frags selects a logical edge $X(e) = (F_1, F_2)$, $F_1 \in \hat{F}_1$, $F_2 \in \hat{F}_2$, and uses it to merge the two superclusters \hat{F}_1 and \hat{F}_2 in G , then e is the lightest edge outgoing from one of the two corresponding clusters $H_1 = \bigcup_{F \in \hat{F}_1} F$ and $H_2 = \bigcup_{F \in \hat{F}_2} F$ in G .

As the edge e has not been erased prior to this step, necessarily either $e \in \mathcal{A}(F_1)$ and \hat{F}_1 is unfinished, or $e \in \mathcal{A}(F_2)$ and \hat{F}_2 is unfinished. Without loss of generality suppose the former. We claim that in this case, e is the lightest outgoing edge incident on H_1 .

Consider some other outgoing edge e' incident on H_1 ; i.e., e' is incident on some fragment $F' \in \hat{F}_1$. Suppose, towards contradiction, that $\omega(e') < \omega(e)$. If $e' \in \mathcal{A}(F')$, then e' should have been considered by Const.Frags before e , and subsequently either added to the spanning subtree $\hat{T}(\hat{F}_1)$ or discarded as an internal edge, in either case contradicting our assumption that e' is an outgoing edge of H_1 (hence $X(e')$ is an outgoing edge of \hat{F}_1). It follows that $e' \notin \mathcal{A}(F')$. Let $X(e') = (F', F'')$. There may be two reasons why e' was not added to $\mathcal{A}(F')$. The first is that some other edge e'' with $X(e'') = (F', F'')$ was already included in $\mathcal{A}(F')$ before e' . In that case, $\omega(e'') < \omega(e')$, and hence also $\omega(e'') < \omega(e)$. This implies that e'' has already been inspected by the procedure at some earlier step. But then the clusters F' and F'' must already belong to the supercluster \hat{F}_1 ; and hence in \hat{F}_1 , the edge e' is internal, a contradiction. The other possible reason why e' was not added to $\mathcal{A}(F')$ is that there are μ lighter edges incident on F' , which were added to $\mathcal{A}(F')$. Letting e'' be the heaviest edge in $\mathcal{A}(F')$ in this case, it follows that $\omega(e'') < \omega(e')$, and hence $\omega(e'') < \omega(e)$. This means that e'' has already been inspected by the procedure at some earlier step. But then the supercluster \hat{F}_0 that contained F' at the end of that step should have been declared finished upon inspection of its heaviest edge. This would necessitate that \hat{F}_1 is finished now, a contradiction.

THEOREM 3.7. *The tree produced by the algorithm is an MST of the graph.*

Proof. The proof follows from Lemma 3.6 and the fact that by Lemma 3.2, \mathcal{F}^k contains exactly one cluster for $k > \log \log n$. \square

4. Extension to larger messages. In this section we extend the algorithm to a model in which each message can contain any number of bits (so long as it is at least $\log n$). Specifically, we assume that each message may contain $\ell \log n$ bits. The extension of the algorithm to this case is straightforward. It turns out that the asymptotic worst-case number of rounds drops to a constant when the message size

is n^ϵ for $\epsilon > 0$, but $\Theta(\log \log n)$ rounds are required by our algorithm for any polylog message size.

First, we explain how to modify the algorithm to use messages that can contain ℓ edges. The idea is to change steps 2(b) (which is the invocation of Procedure `Cheap_Out`) and 3 in the main algorithm so that each node can be the guardian of ℓ edges. Specifically, the modified algorithm is identical to the algorithm of section 2, except for the following steps.

2b*. Perform (locally) Procedure `Cheap_Out*`. This procedure (described below) does the following:

- It selects a set $\mathcal{A}(F)$ containing the $\ell \cdot N$ cheapest edges that go out of F to $\ell \cdot N$ distinct clusters.
- It appoints for each such edge e a *guardian* node $g(e)$ in F , ensuring that each node in F is appointed as guardian to at most ℓ edges.

3*. Let $\{e'_1, \dots, e'_\ell\} \subseteq \mathcal{A}(F)$ be the edges for which v was appointed as guardian, i.e., all edges e'_i such that $g(e'_i) = v$. Send $\{e'_1, \dots, e'_\ell\}$ to v^* , the node with the minimal ID in the graph.

(At the end of this step, v^* knows all the edges in the set $\mathcal{A} = \bigcup_{F' \in \mathcal{F}^{k-1}} \mathcal{A}(F')$.)

The modified `Cheap_Out*` procedure is identical to Procedure `Cheap_Out`, except for the following two steps:

2*. Let $\mu = \min\{\ell \cdot N, |\mathcal{F}^{k-1}| - 1\}$.

5*. Appoint the i th node of F as the guardian of the j th edge added to $\mathcal{A}(F)$ if $j \bmod (\ell \cdot N) = i$.

The correctness of the modification is obvious, as Lemma 3.6 is stated in terms of a general μ , and it relies only on the assumption that $\mathcal{A}(F)$ contains the μ lightest edges connecting F to μ distinct clusters.

The complexity analysis of the generalized algorithm requires a little work. First, we observe that Lemma 3.1 holds without change: it is also stated in terms of a general μ . Lemma 3.4 also holds by the assumption that each message can contain ℓ edges, and since each node is the guardian of at most ℓ messages by the modified procedure `Cheap_Out*`. However, Lemma 3.2 holds only for $\ell = \Theta(1)$. Below we generalize Theorem 3.5 to different values of ℓ .

THEOREM 4.1. *The extended algorithm terminates in $O(\log(\frac{\log n}{\log \ell}))$ rounds, and the total number of bits communicated is $\Theta(n^2 \log n)$.*

Proof. Let μ_k be the smallest possible cluster size after the k th round. By definition, $\mu_0 = 1$. If each guardian node sends ℓ edges, then each cluster merges with at least $\ell \mu_k$ other clusters in the k th phase. It follows that $\mu_{k+1} \geq (\ell \mu_k + 1) \mu_k > \ell \mu_k^2$. Since $\mu_0 = 1$, we have $\mu_1 > \ell$, and therefore $\mu_k > \ell^{2^{k-1}}$. The bound on the number of rounds follows, since the algorithm terminates when $\mu_k \geq n$, and each phase takes only $O(1)$ rounds by Lemma 3.4. For the total number of bits communicated by the algorithm, we observe that the only difference is the number of messages sent in step 3*. Let B_3 denote the total number of bits sent in step 3* throughout the execution of the algorithm. We claim that $B_3 = O(n^2 \log n)$. To see this, note that the total number of edge identifiers sent in step 3 in a single phase, over all nodes, is $O(n\ell)$. It follows that $B_3 = O(Tn\ell \log n)$, where T is the number of phases. As shown

above, $T = O(\log(\frac{\log n}{\log \ell}))$. This means that $B_3 = O(n^2 \log n)$: If $1 < \ell < n/\log \log n$, then T is bounded by $O(\log \log n)$; and if $\ell \geq n/\log \log n$, then $T = O(1)$. \square

Let us interpret the result of Theorem 4.1 in two typical cases. First, if ℓ is polynomial in n , i.e., $\ell = n^\epsilon$ for some $\epsilon > 0$, then the total running time of the algorithm is $O(\log(1/\epsilon))$. However, the number of rounds remains $\Theta(\log \log n)$ if ℓ is only polylogarithmic in n . (In fact, it remains $O(\log \log n)$ even if ℓ is as large as $(\log n)^{(\log n)^{1-\epsilon}}$ for some constant $\epsilon > 0$.)

5. Conclusion. This paper shows that an MST can be constructed in sublogarithmic time, even if each message can contain only a constant number of edges. We believe that the algorithm may be useful in some overlay networks. Theoretically, important gaps remain. While there are nontrivial lower bounds on the running time of MST construction in graphs of diameter 3 or more, currently no superconstant lower bound is known even for graphs of diameter 2. We do not know whether there exist lower bounds or better algorithms for graphs of diameter 1 and 2 (recall that the fastest known algorithm for diameter 2 runs in $O(\log n)$ rounds).

Acknowledgment. We thank the anonymous reviewers, whose comments helped improve the presentation of the paper.

THE COMPLEXITY OF APPROXIMATING THE ENTROPY*

TUĞKAN BATU[†], SANJOY DASGUPTA[‡], RAVI KUMAR[§], AND RONITT RUBINFELD[¶]

Abstract. We consider the problem of approximating the entropy of a discrete distribution under several different models of oracle access to the distribution. In the evaluation oracle model, the algorithm is given access to the explicit array of probabilities specifying the distribution. In this model, linear time in the size of the domain is both necessary and sufficient for approximating the entropy.

In the generation oracle model, the algorithm has access only to independent samples from the distribution. In this case, we show that a γ -multiplicative approximation to the entropy can be obtained in $O(n^{(1+\eta)/\gamma^2} \log n)$ time for distributions with entropy $\Omega(\gamma/\eta)$, where n is the size of the domain of the distribution and η is an arbitrarily small positive constant. We show that this model does not permit a multiplicative approximation to the entropy in general. For the class of distributions to which our upper bound applies, we obtain a lower bound of $\Omega(n^{1/(2\gamma^2)})$.

We next consider a combined oracle model in which the algorithm has access to both the generation and the evaluation oracles of the distribution. In this model, significantly greater efficiency can be achieved: we present an algorithm for γ -multiplicative approximation to the entropy that runs in $O((\gamma^2 \log^2 n)/(h^2(\gamma - 1)^2))$ time for distributions with entropy $\Omega(h)$; for such distributions, we also show a lower bound of $\Omega((\log n)/(h(\gamma^2 - 1) + \gamma^2))$.

Finally, we consider two special families of distributions: those in which the probabilities of the elements decrease monotonically with respect to a known ordering of the domain, and those that are uniform over a subset of the domain. In each case, we give more efficient algorithms for approximating the entropy.

1. Introduction. The Shannon entropy is a measure of the randomness of a distribution and plays a central role in statistics, information theory, and coding theory. The entropy of a random source sheds light on the inherent compressibility of data produced by such a source. In this paper we consider the complexity of approximating the entropy under various assumptions on the way the input is presented.

Suppose the algorithm has access to an *evaluation oracle*¹ in which the distribution \mathbf{p} is given as an array whose i th location contains the probability p_i assigned to the i th element of the domain. It is clear that an algorithm that reads the entire representation can calculate the exact entropy. However, it is also easy to see that in this model, time linear in the size of the domain is required even to approximate the entropy: consider two distributions, one with a singleton support set (zero entropy) and the other with a two-element support set (positive entropy). Any algorithm that

¹We use the terminology from [9].

approximates the entropy to within a multiplicative factor must distinguish between these two distributions, and a randomized algorithm for distinguishing two such distributions requires linear time in general.

Next suppose the distribution $\mathbf{p} = \langle p_1, \dots, p_n \rangle$ is given as a *generation oracle* that draws samples from it. This model has been considered in the statistics, physics, and information theory communities (cf. [1, 4, 7, 8, 10, 11, 12, 14, 15, 16]). None of these previous works, however, provides a rigorous analysis of computational efficiency and sample complexity in terms of the approximation quality and the domain size. To the best of our knowledge, the only previously known algorithms that do not require superlinear (in the domain size) sample complexity are those presented in [10, 14, 12], which give good estimates in some cases, such as when the infinity norm of the distribution is small. Some of these algorithms use an estimate of the collision probability, $\|\mathbf{p}\|^2$, to give a lower bound estimate of the entropy: using Jensen's inequality, it is shown [14] that

$$\log \|\mathbf{p}\|^2 = \log \sum_i p_i^2 \geq \sum_i p_i \log p_i = -H(\mathbf{p}).$$

In fact, when the infinity norm $\|\mathbf{p}\|_\infty$ of \mathbf{p} is at most $n^{-\alpha}$ (in other words, when the min-entropy of \mathbf{p} is large), the collision probability can be used to give an upper bound on the entropy of the distribution: using the relationship between norms,

$$\log \|\mathbf{p}\|^2 \leq \log(\|\mathbf{p}\|_\infty) \leq \log n^{-\alpha} = -\alpha \log n \leq -\alpha \cdot H(\mathbf{p}).$$

It is, however, unclear how to use the collision probability to obtain an arbitrary multiplicative approximation with a better sample complexity than our results (stated below), since approximating the collision probability itself will require $\Omega(\sqrt{n})$ samples. However, the collision probability can be used to understand much more about certain types of distributions; for instance, it exactly determines the entropy in the special case of distributions that are known to be uniform over an unknown subset of arbitrary size (see section 7).

1.1. Our results. In this section, we summarize the results in this paper. Table 1 also presents some of the upper and lower bounds proved in the paper.

(1) THE GENERATION ORACLE MODEL. When the distribution is given as a generation oracle, we show that the entropy can be approximated well in sublinear time for a large class of distributions. Informally, a γ -multiplicative approximation to the entropy can be obtained in time $O(n^{(1+\eta)/\gamma^2} \log n)$, where n is the size of the domain of the distribution and η is an arbitrarily small positive constant, provided that the distribution has $\Omega(\gamma/\eta)$ entropy. Our algorithm is simple—we partition the elements in the domain into big or small elements based on their probability masses and approximate the entropy of the big and small elements separately by different methods. On the other hand, we show that one cannot obtain a multiplicative approximation to the entropy in general. Furthermore, even for the class of distributions to which our upper bound applies, we obtain a lower bound of $\Omega(n^{1/(2\gamma^2)})$. In the conference version of this paper, we also claimed another lower bound of $\Omega(n^{2/(5\gamma^2-2)})$ for this problem. We retract this bound, as there was a gap in our proof.

It is interesting to consider what these bounds imply for the complexity of achieving a 2-approximation for distributions with nonconstant entropy. Our upper bound yields an algorithm that runs in $\tilde{O}(n^{(1+o(1))/4})$ time, while our lower bound demonstrates that a running time of at least $\Omega(n^{1/8})$ is necessary.

(2) **THE EVALUATION ORACLE MODEL.** When the distribution is given as an evaluation oracle, we show a lower bound of $\Omega(n2^{-\gamma^2(h+1)})$ on the number of oracle accesses needed to γ -approximate the entropy for the class of distributions with entropy at least h .

(3) **THE COMBINED ORACLE MODEL.** We then consider a *combined oracle* model, in which the algorithm has access to both the generation and the evaluation oracles of the distribution. We assume that the two oracles are consistent, which is a natural assumption for such a model. In the combined oracle model, we give a γ -approximation algorithm that runs in time $O((\gamma^2 \log^2 n)/(h^2(\gamma-1)^2))$ for distributions with entropy $\Omega(h)$; we also show a lower bound of $\Omega((\log n)/(h(\gamma^2-1)+\gamma^2))$ for this class of distributions. For example, to achieve a constant approximation for distributions with entropy $\Omega(h)$, our algorithm runs in time $O((1/h^2) \log^2 n)$, while our lower bound is $\Omega((1/h) \log n)$, that is, quadratically smaller than the upper bound.

(4) **SPECIAL FAMILIES OF DISTRIBUTIONS.** Finally, we consider two families of distributions for which we show more efficient upper bounds. The first family is that of *monotone distributions*, in which the probabilities decrease monotonically over some known ordering of the elements (i.e., $p_i \geq p_{i+1}$). We give an $O((1 + \log^{-1} \gamma) \log n)$ -time (resp., $O((\log n)^6 \text{poly}(\gamma))$ -time) algorithm for γ -approximating the entropy in the evaluation oracle model (resp., generation oracle model). The second family is that of *subset-uniform distributions*, in which the distribution is uniform over some subset of the domain. In this case we give $O(\sqrt{k})$ -time algorithms for approximating the entropy, where k is the size of the support set.

TABLE 1
Our results for γ -approximation, where $\gamma > 1$.

Model		Lower bound	Upper bound
Evaluation oracle:	General	$\Omega(n)$	$O(n)$
	$H(\mathbf{p}) \geq h$	$\Omega(n2^{-\gamma^2(h+1)})$, Thm. 8	?
Generation oracle:	General	∞ , Thm. 6	—
	High enough entropy	$\Omega(n^{1/(2\gamma^2)})$, Thm. 7, $H(\mathbf{p}) > \Omega((\log n)/\gamma^2)$	$\tilde{O}(n^{1/\gamma^2})$, Thm. 2, $H(\mathbf{p}) > \Omega(\gamma)$
Combined oracle:	General	$\Omega(n^{(1-o(1))/\gamma^2})$, Thm. 12	?
	$H(\mathbf{p}) \geq h$	$\Omega\left(\frac{\log n}{h(\gamma^2-1)+\gamma^2}\right)$, Thm. 13	$O\left(\frac{\gamma^2 \log^2 n}{h^2(\gamma-1)^2}\right)$, Thm. 9

1.2. Related work. The work of Goldreich and Vadhan [6] considers the complexity of approximating the entropy in a different model in which a distribution Y is encoded as a circuit $Y = C(X)$ whose input X is uniformly distributed; in this model, they show that a version of the problem is complete for statistical zero-knowledge. Their version of the problem could be viewed as an additive approximation to the entropy.

The work of [3] and [2] considers algorithms for testing other properties of distributions in the generation oracle model. The properties considered are whether two input distributions are close or far, and whether a joint distribution is independent, respectively. Both papers give algorithms whose sample complexity is sublinear in the domain size, along with lower bounds showing the algorithms to be nearly optimal.

1.3. Organization. In section 2, we introduce the basic definitions used in this paper. In section 3, we give algorithms and lower bounds for the generation oracle model. Section 4 describes a lower bound for the evaluation oracle model, and section 5 gives algorithms and lower bounds for the combined oracle case. Finally, in sections 6 and 7, we give more efficient algorithms for two families of distributions.

2. Preliminaries. We consider discrete distributions over a domain of size n , which we denote by $[n] \stackrel{\text{def}}{=} \{1, \dots, n\}$. Let $\mathbf{p} = \langle p_1, \dots, p_n \rangle$ be such a distribution, where $p_i \geq 0$, $\sum_{i=1}^n p_i = 1$. An algorithm is said to have *evaluation oracle* access to the distribution \mathbf{p} if oracle query i is answered by p_i . An algorithm is said to have *generation oracle* access to \mathbf{p} if it is given a source that draws samples independently from \mathbf{p} . An algorithm has *combined oracle* access to \mathbf{p} if it has both evaluation and generation oracle access to \mathbf{p} . We say the algorithm is in model \mathcal{O} if it has oracle access of type \mathcal{O} to the distribution.

The entropy of distribution \mathbf{p} is defined as

$$H(\mathbf{p}) \stackrel{\text{def}}{=} - \sum_{i=1}^n p_i \log p_i,$$

where all the logarithms are to the base 2. For a set $S \subseteq [n]$, we define $w_{\mathbf{p}}(S) \stackrel{\text{def}}{=} \sum_{i \in S} p_i$, and we define the contribution of S to the entropy as

$$H_S(\mathbf{p}) \stackrel{\text{def}}{=} - \sum_{i \in S} p_i \log p_i.$$

Notice that $H_S(\mathbf{p}) + H_{[n] \setminus S}(\mathbf{p}) = H(\mathbf{p})$.

The L_2 -norm of distribution \mathbf{p} is $\|\mathbf{p}\| \stackrel{\text{def}}{=} \sqrt{\sum_{i=1}^n p_i^2}$ and the L_∞ -norm of \mathbf{p} is $\|\mathbf{p}\|_\infty \stackrel{\text{def}}{=} \max_{i=1}^n p_i$. We denote the L_1 -distance between two distributions \mathbf{p}, \mathbf{q} by $|\mathbf{p} - \mathbf{q}| \stackrel{\text{def}}{=} \sum_{i=1}^n |p_i - q_i|$.

The following lemma summarizes some upper and lower bounds on entropy that will turn out to be useful at many points in the paper.

LEMMA 1. *Pick any $S \subseteq [n]$.*

(a) *The partial entropy $H_S(\mathbf{p})$ is maximized when $w_{\mathbf{p}}(S)$ is spread uniformly over the set $|S|$:*

$$H_S(\mathbf{p}) \leq w_{\mathbf{p}}(S) \cdot \log(|S|/w_{\mathbf{p}}(S)) \leq w_{\mathbf{p}}(S) \cdot \log |S| + (\log e)/e.$$

(b) *Suppose there is some $\beta \leq 1/e$ such that $p_i \leq \beta$ for all $i \in S$. Then $H_S(\mathbf{p}) \leq \beta |S| \log(1/\beta)$.*

(c) *Suppose there is some β such $\beta \leq p_i \leq 1/e$ for all $i \in S$. Then $H_S(\mathbf{p}) \geq \beta |S| \log(1/\beta)$.*

(d) *Suppose there is some β such that $p_i \leq \beta$ for all $i \in S$. Then $H_S(\mathbf{p}) \geq w_{\mathbf{p}}(S) \log(1/\beta)$.*

Proof. Statement (a) follows from the concavity of the logarithm function. By Jensen's inequality,

$$\frac{1}{w_{\mathbf{p}}(S)} \cdot H_S(\mathbf{p}) = \sum_{i \in S} \frac{p_i}{w_{\mathbf{p}}(S)} \log \frac{1}{p_i} \leq \log \left(\sum_{i \in S} \frac{p_i}{w_{\mathbf{p}}(S)} \cdot \frac{1}{p_i} \right) = \log \frac{|S|}{w_{\mathbf{p}}(S)}.$$

Therefore,

$$H_S(\mathbf{p}) \leq w_{\mathbf{p}}(S) \cdot \log \frac{|S|}{w_{\mathbf{p}}(S)} \leq w_{\mathbf{p}}(S) \cdot \log |S| + \frac{\log e}{e}.$$

The last inequality comes from observing that the function $x \log(1/x)$ is zero at $x = 0, 1$ and has a single local maximum in the interval $[0, 1]$ at $x = 1/e$.

Statement (b) follows immediately from the previous observation about $x \log(1/x)$, which implies that, under the given constraint, $H_S(\mathbf{p})$ is maximized by setting all the p_i to β .

The proof of statement (c) also follows from the concavity of $x \log(1/x)$; under the given constraints, $p_i \log(1/p_i)$ is minimized when $p_i = \beta$.

For statement (d), we notice that $H_S(\mathbf{p})$ is strictly concave; therefore, over any closed domain, it is minimized at a boundary point. In particular, when the domain is $[0, \beta]^{|S|}$, the minimum point must have some coordinate with $p_i = 0$ or $p_i = \beta$. We can now restrict our attention to the remaining coordinates and apply the same argument again. In this way, we find that the minimum is realized when $w_{\mathbf{p}}(S)/\beta$ of the p_i are β , and the rest are zero. \square

Let $\gamma > 1$ and let \mathcal{D} be a family of distributions. We say that \mathcal{A} is an algorithm in model \mathcal{O} for γ -approximating the entropy of a distribution in \mathcal{D} if, for every $\mathbf{p} \in \mathcal{D}$, given oracle access of type \mathcal{O} to \mathbf{p} , algorithm \mathcal{A} outputs a value $\mathcal{A}(\mathbf{p})$ such that $H(\mathbf{p})/\gamma \leq \mathcal{A}(\mathbf{p}) \leq \gamma \cdot H(\mathbf{p})$ with probability at least $3/4$. (This probability of success can generically be increased to $1 - \delta$ by running the algorithm $\log(1/\delta)$ times and returning the median of the values.) The time complexity of \mathcal{A} is specified as a function of γ and n . We will use the notation \mathcal{D}_h to denote the family of distributions with entropy at least h .

3. The generation oracle model.

3.1. Upper bounds. In this section we obtain an algorithm for estimating the entropy of a large class of distributions in the generation oracle model. We prove the following theorem.

THEOREM 2. *For every $\gamma > 1$ and every ϵ_o such that $0 < \epsilon_o \leq 1/2$, there exists an algorithm in the generation oracle model that runs in time $O((n^{1/\gamma^2}/\epsilon_o^2) \cdot \log n)$ and, with success probability at least $3/4$, returns a $(1 + 2\epsilon_o)\gamma$ -approximation to the entropy of any distribution on $[n]$ in $\mathcal{D}_{4\gamma/(\epsilon_o(1-2\epsilon_o))}$.*

Given any $\eta > 0$ and $\gamma' > 1$, one can set $\gamma = \gamma'/(1+2\epsilon_o)$ above and choose ϵ_o small enough to yield a γ' -approximation algorithm with running time $O(n^{(1+\eta)/\gamma'^2} \log n)$ for distributions of entropy $\Omega(\gamma/\eta)$. Note that choosing η to be small affects both the running time and the family of distributions to which the algorithm can be applied.

The main idea behind the algorithm is the following. We classify elements in $[n]$ as either big or small, depending on their probability mass. For a fixed $\alpha > 0$ and a distribution \mathbf{p} , the set of indices with high probabilities (the *big* elements) is defined as

$$B_\alpha(\mathbf{p}) \stackrel{\text{def}}{=} \{i \in [n] \mid p_i \geq n^{-\alpha}\}.$$

We then approximate the contributions of the big and small elements to the entropy separately. Section 3.1.1 shows how to approximate the entropy of the big elements, section 3.1.2 shows how to approximate the entropy of the small elements, and section 3.1.3 combines these approximations to yield Theorem 2.

3.1.1. Approximating the entropy of the big elements. To estimate the amount by which the big elements contribute to the entropy, we approximate each of their probabilities by drawing samples from the generation oracle.

LEMMA 3. *For every α such that $0 < \alpha \leq 1$, every ϵ_o such that $0 < \epsilon_o \leq 1/2$, and sufficiently large n , there is an algorithm that uses $O((n^\alpha/\epsilon_o^2) \cdot \log n)$ samples from \mathbf{p} and outputs a distribution \mathbf{q} over $[n]$ such that with probability at least $1 - n^{-1}$, the following hold for all i :*

1. *If $p_i \geq \frac{1-\epsilon_o}{1+\epsilon_o}n^{-\alpha}$ (in particular, if $i \in B_\alpha(\mathbf{p})$), then $|p_i - q_i| \leq \epsilon_o p_i$, and*
2. *if $p_i \leq \frac{1-\epsilon_o}{1+\epsilon_o}n^{-\alpha}$, then $q_i \leq (1 - \epsilon_o)n^{-\alpha}$.*

Proof. Let $m = (18n^\alpha/\epsilon_o^2) \cdot \log 2n$. Fix any $i \in [n]$ and define X_j to be the indicator variable that the j th sample is i . Let $q_i = \sum X_j/m$, the average of independent, identically distributed Boolean random variables. If $p_i \geq \frac{1-\epsilon_o}{1+\epsilon_o}n^{-\alpha}$, then by Chernoff bounds,

$$\Pr[|p_i - q_i| > \epsilon_o p_i] \leq 2 \exp\left(-\frac{\epsilon_o^2 p_i m}{3}\right) \leq \frac{1}{2n^2}.$$

Moving onto smaller elements, we again can use Chernoff bounds to show that if $p_i < \frac{1-\epsilon_o}{1+\epsilon_o}n^{-\alpha}$, then

$$\begin{aligned} \Pr[q_i > (1 - \epsilon_o)n^{-\alpha}] &= \Pr[q_i - p_i > (1 - \epsilon_o)n^{-\alpha} - p_i] \\ &\leq \Pr\left[q_i - p_i > \frac{\epsilon_o(1 - \epsilon_o)}{1 + \epsilon_o}n^{-\alpha}\right] \\ &\leq \exp\left(-\left(\frac{\epsilon_o(1 - \epsilon_o)n^{-\alpha}}{(1 + \epsilon_o)p_i}\right)^2 \cdot \frac{p_i m}{3}\right) \\ &\leq \exp\left(-\left(\frac{1 - \epsilon_o}{1 + \epsilon_o}\right)^2 \cdot \frac{6n^{-\alpha}}{p_i} \cdot \log 2n\right) \\ &\leq \exp(-2 \log 2n) \leq \frac{1}{2n^2}. \end{aligned}$$

Statements (1) and (2) of the lemma follow from a union bound over all i . \square

The following lemma shows that the contribution of the big elements $B_\alpha(\mathbf{p})$ to the entropy can be approximated well using \mathbf{q} instead of \mathbf{p} .

LEMMA 4. *Pick any $B \subseteq [n]$. Let $\epsilon_o \in (0, 1)$ be chosen so that each $i \in B$ satisfies $|p_i - q_i| \leq \epsilon_o p_i$. Then,*

$$|H_B(\mathbf{q}) - H_B(\mathbf{p})| \leq \epsilon_o \cdot H_B(\mathbf{p}) + 2\epsilon_o \cdot w_{\mathbf{p}}(B).$$

Proof. For $i \in B$, write $q_i = (1 + \varepsilon_i)p_i$. We know that $|\varepsilon_i| \leq \epsilon_o$.

$$\begin{aligned} H_B(\mathbf{q}) - H_B(\mathbf{p}) &= -\sum_{i \in B} (1 + \varepsilon_i)p_i \log((1 + \varepsilon_i)p_i) + \sum_{i \in B} p_i \log p_i \\ &= -\sum_{i \in B} (1 + \varepsilon_i)p_i \log p_i - \sum_{i \in B} (1 + \varepsilon_i)p_i \log(1 + \varepsilon_i) + \sum_{i \in B} p_i \log p_i \\ &= -\sum_{i \in B} \varepsilon_i p_i \log p_i - \sum_{i \in B} (1 + \varepsilon_i)p_i \log(1 + \varepsilon_i). \end{aligned}$$

By the triangle inequality,

$$\begin{aligned} |H_B(\mathbf{q}) - H_B(\mathbf{p})| &\leq \left| -\sum_{i \in B} \varepsilon_i p_i \log p_i \right| + \left| \sum_{i \in B} (1 + \varepsilon_i) p_i \log(1 + \varepsilon_i) \right| \\ &\leq \sum_{i \in B} -|\varepsilon_i| p_i \log p_i + \sum_{i \in B} p_i |(1 + \varepsilon_i) \log(1 + \varepsilon_i)| \\ &\leq \epsilon_o \cdot H_B(\mathbf{p}) + 2\epsilon_o \cdot w_{\mathbf{p}}(B). \end{aligned}$$

The last step above uses that for $|\varepsilon| \leq \epsilon_o \leq 1$, $|(1 + \varepsilon) \log(1 + \varepsilon)| \leq 2|\varepsilon| \leq 2\epsilon_o$. \square

3.1.2. Approximating the entropy of the small elements. We now estimate the entropy contribution of the small elements. Let S be any subset of small elements, that is, $S \subseteq [n] \setminus B_\alpha(\mathbf{p})$.

If $w_{\mathbf{p}}(S) \leq n^{-\alpha}$, then the contribution of S to the entropy is below any constant and can be ignored for approximation purposes. So, we may assume without loss of generality that $w_{\mathbf{p}}(S) \geq n^{-\alpha}$. Let $\hat{w}(S)$ be the empirical estimate of the probability mass of S , in other words, the number of samples from S divided by the total number of samples. The following lemma bounds the accuracy of this estimate.

LEMMA 5. *If $S \subseteq [n]$ satisfies $w_{\mathbf{p}}(S) \geq n^{-\alpha}$ and if $m = O((n^\alpha/\epsilon_o^2) \log n)$ samples are drawn from \mathbf{p} , then with probability at least $1 - n^{-1}$, the empirical estimate $\hat{w}(S)$ satisfies $(1 - \epsilon_o) \cdot w_{\mathbf{p}}(S) \leq \hat{w}(S) \leq (1 + \epsilon_o) \cdot w_{\mathbf{p}}(S)$. Moreover, if $w_{\mathbf{p}}(S) < n^{-\alpha}$, then $\hat{w}(S) < (1 + \epsilon_o)n^{-\alpha}$.*

Proof. Let X_j be the indicator random variable that takes value 1 when the j th sample lies in S , and let $X = \sum X_j$. Then X is $m\hat{w}(S)$ and it has expected value $E[X] = m \cdot w_{\mathbf{p}}(S)$. The lemma follows by Chernoff bounds and the fact that $w_{\mathbf{p}}(S) \geq n^{-\alpha}$. Similar to the proof of Lemma 3, we can show that if $w_{\mathbf{p}}(S) < n^{-\alpha}$, then $\hat{w}(S) < (1 + \epsilon_o)n^{-\alpha}$. \square

Since $p_i < n^{-\alpha}$ for $i \in S$, by Lemma 1(a),(d), we have that

$$\alpha w_{\mathbf{p}}(S) \log n \leq H_S(\mathbf{p}) \leq w_{\mathbf{p}}(S) \log n + (\log e)/e.$$

Hence, using estimate $\hat{w}(S)$ for $w_{\mathbf{p}}(S)$, we get an approximation to $H_S(\mathbf{p})$.

3.1.3. Putting it together. In this section we describe our approximation algorithm for $H(\mathbf{p})$ and prove Theorem 2. The following is our algorithm for obtaining a γ -approximation to the entropy:

ALGORITHM APPROXIMATEENTROPY (γ, ϵ_o) .

1. Set $\alpha = 1/\gamma^2$.
2. Get $m = O((n^\alpha/\epsilon_o^2) \cdot \log n)$ samples from \mathbf{p} .
3. Let \mathbf{q} be the empirical probabilities of the n elements; that is, q_i is the frequency of i in the sample divided by m . Let $B = \{i \mid q_i > (1 - \epsilon_o)n^{-\alpha}\}$.
4. Output $H_B(\mathbf{q}) + \frac{w_{\mathbf{q}}([n] \setminus B) \log n}{\gamma}$.

Notice that the set B is an empirically determined substitute for $B_\alpha(\mathbf{p})$. We now prove that this algorithm satisfies Theorem 2.

Proof of Theorem 2. First of all, Lemma 3 assures us that with probability at least $1 - 1/n$, two conditions hold: (1) $B_\alpha(\mathbf{p}) \subseteq B$, and (2) every element $i \in B$ satisfies $|p_i - q_i| \leq \epsilon_o p_i$. For the rest of the proof, we will assume that these conditions hold.

Let $S = [n] \setminus B$. Assume for the moment that $w_{\mathbf{p}}(S) \geq n^{-\alpha}$. In this case, we know from Lemma 5 that, with high probability, $|w_{\mathbf{q}}(S) - w_{\mathbf{p}}(S)| \leq \epsilon_o w_{\mathbf{p}}(S)$. Lemma 1(a),(d) tells us that

$$\alpha w_{\mathbf{p}}(S) \log n \leq H_S(\mathbf{p}) \leq w_{\mathbf{p}}(S) \log n + (\log e)/e.$$

Then by Lemma 4,

$$\begin{aligned}
H_B(\mathbf{q}) + \frac{w_{\mathbf{q}}(S) \log n}{\gamma} &\leq (1 + \epsilon_o) \cdot H_B(\mathbf{p}) + 2\epsilon_o + \frac{1 + \epsilon_o}{\gamma} \cdot w_{\mathbf{p}}(S) \log n \\
&\leq (1 + \epsilon_o)(H_B(\mathbf{p}) + \gamma \cdot H_S(\mathbf{p})) + 2\epsilon_o \\
&\leq (1 + \epsilon_o)\gamma \cdot H(\mathbf{p}) + 2\epsilon_o \\
&\leq (1 + 2\epsilon_o)\gamma \cdot H(\mathbf{p})
\end{aligned}$$

if $H(\mathbf{p}) \geq 2/\gamma$. Similarly,

$$\begin{aligned}
H_B(\mathbf{q}) + \frac{w_{\mathbf{q}}(S) \log n}{\gamma} &\geq (1 - \epsilon_o) \cdot H_B(\mathbf{p}) - 2\epsilon_o + \frac{1 - \epsilon_o}{\gamma} \cdot w_{\mathbf{p}}(S) \log n \\
&\geq (1 - \epsilon_o) \left(H_B(\mathbf{p}) + \frac{(H_S(\mathbf{p}) - e^{-1} \log e)}{\gamma} \right) - 2\epsilon_o \\
&= (1 - \epsilon_o) \left(H_B(\mathbf{p}) + \frac{H_S(\mathbf{p})}{\gamma} \right) - \frac{1 - \epsilon_o}{\gamma} e^{-1} \log e - 2\epsilon_o \\
&\geq \frac{H(\mathbf{p})}{(1 + 2\epsilon_o)\gamma}
\end{aligned}$$

if $H(\mathbf{p}) \geq \frac{4\gamma}{\epsilon_o(1-2\epsilon_o)} \geq 2/\gamma$.

It remains to handle the case when $w_{\mathbf{p}}(S)$ is less than $n^{-\alpha}$. Lemma 5 tells us that $w_{\mathbf{q}}(S)$ is with high probability at most $(1 + \epsilon_o)n^{-\alpha}$. Therefore, our estimate of the entropy from small elements, $(w_{\mathbf{q}}(S) \log n)/\gamma$, lies somewhere between zero and $((1 + \epsilon_o)n^{-\alpha} \log n)/\gamma$. For any γ bounded away from one, this is only a negligible contribution to $H(\mathbf{p})$, well within the approximation bound. \square

3.2. Lower bounds. In this section we prove lower bounds on the number of samples needed to approximate the entropy of a distribution to within a multiplicative factor of $\gamma > 1$. All of our lower bounds are shown by exhibiting pairs of distributions that have very different entropies, with ratio at least γ^2 , and yet are hard to distinguish given only a few samples.

3.2.1. Impossibility of approximating entropy in general. First we show that there is no algorithm for computing entropy that can guarantee a bounded approximation factor for all input distributions. The basic problem is that no amount of sampling can conclusively establish that a distribution has zero entropy.

THEOREM 6. *For every $\gamma > 1$, there is no algorithm that γ -approximates the entropy of every distribution in the generation oracle model.*

Proof. Let \mathcal{A} be any algorithm for computing entropy, and let $t(n)$ be an upper bound on its running time on distributions over $[n]$. Consider the two distributions $\mathbf{p} = \langle 1, 0, \dots, 0 \rangle$ and $\mathbf{q} = \langle 1 - 1/(100t(n)), 1/(100t(n)), 0, \dots, 0 \rangle$. Notice that \mathbf{p} has zero entropy while \mathbf{q} has positive entropy.

Suppose we run \mathcal{A} on either \mathbf{p} or \mathbf{q} . Since it uses at most $t(n)$ samples, its oracle calls will almost always (99% of the time) produce a succession of identical elements regardless of whether the underlying distribution is \mathbf{p} or \mathbf{q} . In such cases, if \mathcal{A} guesses that the entropy is zero, its approximation factor on \mathbf{q} will be unbounded, whereas if it guesses a positive number, its approximation factor on \mathbf{p} will be unbounded. \square

3.2.2. A lower bound on approximating the entropy of high-entropy distributions. The following theorem shows a lower bound on the number of samples required to approximate the entropy of distributions with high entropy.

THEOREM 7. *For every $\gamma > 1$ and sufficiently large n , any algorithm in the generation oracle model that γ -approximates the entropy of a distribution in $\mathcal{D}_{(\log n)/\gamma^2}$ requires $\Omega(n^{1/2\gamma^2})$ samples.*

Proof. Consider two distributions \mathbf{p} and \mathbf{q} on n elements, where \mathbf{p} is uniform on the set $[n]$ and \mathbf{q} is uniform on a randomly chosen subset $S \subseteq [n]$ of size n^{1/γ^2} . It is easy to see that $H(\mathbf{p})/H(\mathbf{q}) = \gamma^2$. By the birthday paradox, with probability $1/2$, we will not see any repetitions if we take $n^{1/2\gamma^2}$ samples from either distribution. In such cases, the samples from \mathbf{p} and \mathbf{q} appear identical. Thus at least $\Omega(n^{1/2\gamma^2})$ samples are needed to distinguish these distributions. \square

As we mentioned before, in the conference version of this paper, we claimed another lower bound of $\Omega(n^{2/(5\gamma^2-2)})$ for approximating the entropy, but retract this bound as there is a gap in our proof. Recently, however, Ron [13] showed a lower bound of $\tilde{\Omega}(n^{2/(6\gamma^2-3)})$ for approximating the entropy. This is better than the lower bound (in Theorem 7) of $\Omega(n^{1/2\gamma^2})$ when $\gamma < \sqrt{3}/2$. Her proof also exhibits two distributions with entropy ratio γ^2 and shows that the two distributions are indistinguishable unless $\tilde{\Omega}(n^{2/(6\gamma^2-3)})$ samples are taken.

4. The evaluation oracle model: A lower bound. In the introduction, we mentioned that, for general distributions over $[n]$, a linear number of queries is necessary to approximate the entropy in the evaluation oracle model. Since there are only n possible queries, the complexity of entropy approximation in this model is settled. Next, we study the number of queries needed when a lower bound on the entropy of the distribution can be assumed.

THEOREM 8. *Let $\gamma > 1, h > 0$, and n be sufficiently large. If an algorithm \mathcal{A} that operates in the evaluation oracle model achieves a γ -approximation to the entropy of distributions over $[n]$ in \mathcal{D}_h , then it must make $\Omega(n2^{-\gamma^2(h+1)})$ queries.*

Proof. We will define two distributions \mathbf{p} and \mathbf{q} in \mathcal{D}_h that have entropy ratio at least γ^2 and yet require $\Omega(n2^{-\gamma^2(h+1)})$ queries to distinguish.

Let R be a subset of $[n]$ of size $2^{\gamma^2(h+1)}$, chosen uniformly at random. Distribution \mathbf{p} is defined to be uniform over R . Let S also be a uniform-random subset of $[n]$, but of smaller size $\beta \cdot 2^{\gamma^2(h+1)}$, where $\beta = 1/(\gamma^2(h+1)/h)$. In addition, pick s randomly from $[n] \setminus S$. Distribution \mathbf{q} assigns probability $2^{-\gamma^2(h+1)}$ to each element in S and assigns the rest of the probability mass, namely, $1 - \beta$, to s .

Both these distributions belong to \mathcal{D}_h : $H(\mathbf{p}) = \gamma^2(h+1)$, and $H(\mathbf{q})$ is between h and $h+1$ (to see this, notice $H_S(\mathbf{q}) = h$). The ratio between their entropies is $H(\mathbf{p})/H(\mathbf{q}) \geq \gamma^2$.

In the evaluation oracle, any algorithm that distinguishes between \mathbf{p} and \mathbf{q} must (on at least one of these two inputs) discover some location $i \in [n]$ with nonzero probability. The number of queries required is therefore at least the reciprocal of the fraction of the elements with nonzero probabilities, which is $\Omega(n/2^{\gamma^2(h+1)})$. \square

5. The combined oracle model. In this section we consider the combined oracle model in which an algorithm is given both evaluation and generation oracle access to the same distribution.

5.1. Upper bound. The entropy of a distribution \mathbf{p} can be viewed as the expected value of $-\log p_i$, where i is distributed according to \mathbf{p} . This suggests an algorithm as follows:

1. Draw m samples from the generation oracle (m to be defined later). Call these i_1, \dots, i_m .

2. For each i_j , ask the evaluation oracle for p_{i_j} .
3. Return $-\frac{1}{m} \sum_{j=1}^m \log p_{i_j}$.

As we will now see, if $H(\mathbf{p})$ is not too small, this algorithm needs only a polylogarithmic number of queries in order to return a good approximation.

THEOREM 9. *Pick any $\gamma > 1$ and any $h > 0$. If the above algorithm is run with $m = O\left(\frac{\gamma^2 \log^2 n}{h^2(\gamma-1)^2}\right)$, then it returns a γ -approximation to the entropy of any distribution over $[n]$ in \mathcal{D}_h , with success probability at least $3/4$.*

Proof. Let $m \stackrel{\text{def}}{=} \frac{3\gamma^2 \log^2 n}{h^2(\gamma-1)^2}$. Define the random variable $X_j \stackrel{\text{def}}{=} -\log p_{i_j}$ for $j = 1, \dots, m$, and let $X = (1/m) \sum_j X_j$ be the final answer returned. Clearly, $E[X] = E[X_j] = H(\mathbf{p})$. All that needs to be shown is that the variance of X is not too large. Since the X_j 's are independent, it will suffice to bound the variance of an individual X_j .

LEMMA 10. $\text{Var}[X_j] \leq \log^2 n$.

Proof. For $n = 2$, maximizing $\text{Var}[X_j] = p \log^2 p + (1-p) \log^2(1-p) - (p \log p + (1-p) \log(1-p))^2$ subject to $0 \leq p \leq 1$ yields $\text{Var}[X_j] < 1 = \log^2 n$. Therefore, let $n \geq 3$. Since $\text{Var}[X_j] \leq E[X_j^2]$, it suffices to show an upper bound on $E[X_j^2] = \sum_i p_i \log^2 p_i$.

Note that the function $f(x) = x \log^2 x$ is concave for $0 < x < e^{-1}$. Hence, $\sum_i f(p_i)$ is a symmetric concave function when its domain is limited to $\mathbf{p} \in (0, 1/e)^n$ and, as in Lemma 1, is maximized (on this domain) when \mathbf{p} is uniform. This maximum value is $\log^2 n$.

To finish the proof, we need to show that we cannot attain higher values of $\sum_i f(p_i)$ by looking at $\mathbf{p} \notin (0, 1/e)^n$. To this end, suppose $p_j \geq e^{-1}$ for some j . Then there exists k such that $p_k \leq (1 - p_j)/(n - 1)$. Consider the derivative $f'(x) = \log^2 x + 2 \log(e) \log x$ at points p_j and p_k . Using simple calculus and the fact that $n \geq 3$, it is easy to check that $f'(p_k) > f'(p_j)$. Hence, we can increase the sum by simultaneously decreasing p_j and increasing p_k . By combining this result with the argument above, we conclude that $\sum_i f(p_i) \leq \log^2 n$. \square

Since the X_j 's are identical and independent, $\text{Var}[X] = \text{Var}[X_j]/m \leq (\log^2 n)/m$. To bound the error probability of our algorithm, we now use Chebyshev's inequality, which states that, for any $\rho > 0$,

$$\Pr[|X - E[X]| \geq \rho] \leq \text{Var}[X]/\rho^2.$$

Hence, we get

$$\begin{aligned} \Pr[\text{A does not } \gamma\text{-approximate } H(\mathbf{p})] &= \Pr\left[X \leq \frac{H(\mathbf{p})}{\gamma} \text{ or } X \geq \gamma \cdot H(\mathbf{p})\right] \\ &\leq \Pr\left[|X - H(\mathbf{p})| \geq \frac{(\gamma - 1) \cdot H(\mathbf{p})}{\gamma}\right] \\ &\leq \frac{\gamma^2 \log^2 n}{m \cdot H(\mathbf{p})^2 (\gamma - 1)^2} \leq \frac{1}{3}, \end{aligned}$$

where the last inequality follows from the choice of m . \square

COROLLARY 11. *There exists an algorithm \mathcal{A} in the combined oracle model that γ -approximates $H(\mathbf{p})$ in $O\left(\frac{\gamma}{\gamma-1}\right)^2$ time for distributions with $H(\mathbf{p}) = \Omega(\log n)$.*

5.2. Lower bounds. This next theorem gives a lower bound for the combined oracle model when the entropy of the distribution is allowed to be very small—so small that, for instance, the previous upper bound does not apply.

THEOREM 12. *Pick any $\gamma > 1$ and any sufficiently large n . Then any algorithm in the combined oracle model that γ -approximates the entropy of distributions over $[n]$ (with nonzero entropy) must make $\Omega(n^{1/\gamma^2})$ oracle calls.*

Proof. Let $\alpha = \frac{1}{\gamma^2} - \frac{\log e}{\log n} < 1$. Consider distributions \mathbf{p} and \mathbf{q} defined as follows:

$$p_i \stackrel{\text{def}}{=} \begin{cases} 1 - n^{-\alpha} & i = 1, \\ n^{-\alpha} & i = 2, \\ 0 & \text{otherwise,} \end{cases}$$

$$q_i \stackrel{\text{def}}{=} \begin{cases} 1 - n^{-\alpha} & i = 1, \\ n^{-1} & 2 \leq i \leq n^{1-\alpha} + 1, \\ 0 & \text{otherwise.} \end{cases}$$

Note that, by the concavity of $f(x) = -x \log x$ for $0 \leq \delta < 1$, and that $f'(1) = -\log e$, we have that $-(1 - \delta) \log(1 - \delta) \leq \delta \log e$. Hence, a quick calculation shows that $H(\mathbf{p}) = -(1 - n^{-\alpha}) \log(1 - n^{-\alpha}) + n^{-\alpha} \log n^\alpha \leq n^{-\alpha} (\log e + \alpha \log n)$ and $H(\mathbf{q}) > n^{-\alpha} \log n$. By the choice of α , $H(\mathbf{q})/H(\mathbf{p}) > \gamma^2$.

Let \mathcal{P} be the family of distributions obtained from \mathbf{p} by permuting the labels of the elements. Define \mathcal{Q} similarly for \mathbf{q} . It is simple to verify that any algorithm taking $o(n^\alpha)$ samples and making $o(n^\alpha)$ probes will fail to distinguish between a randomly chosen member of \mathcal{P} and a randomly chosen member of \mathcal{Q} with high probability. To finish, notice that $n^\alpha = e^{-1} n^{1/\gamma^2}$. \square

The next theorem gives a lower bound on the complexity of approximating the entropy in the combined oracle model for distributions with entropy above some specific threshold. The proof generalizes the counterexample in Theorem 12.

THEOREM 13. *Pick any $\gamma > 1$, any $h > 0$, and any sufficiently large n . Then any algorithm in the combined oracle model that γ -approximates the entropy of distributions over $[n]$ in \mathcal{D}_h must make $\Omega(\log n / (h(\gamma^2 - 1) + 2\gamma^2))$ oracle calls.*

Proof. Let $w = (h(\gamma^2 - 1) + 2\gamma^2) / \log n$ and $k \stackrel{\text{def}}{=} \lceil 2^{h/(1-w)} \rceil$. Consider the following distributions \mathbf{p} and \mathbf{q} :

$$p_i \stackrel{\text{def}}{=} \begin{cases} (1 - w)/k & 1 \leq i \leq k, \\ w & i = k + 1, \\ 0 & \text{otherwise,} \end{cases}$$

$$q_i \stackrel{\text{def}}{=} \begin{cases} (1 - w)/k & 1 \leq i \leq k, \\ n^{-1} & k + 1 \leq i \leq k + wn, \\ 0 & \text{otherwise.} \end{cases}$$

Note that $H(\mathbf{p}) = (1 - w) \log \frac{k}{1-w} - w \log w = (1 - w) \log k - (1 - w) \log(1 - w) - w \log w$. Hence, $h \leq H(\mathbf{p}) \leq h + 2$. Similarly, $H(\mathbf{q}) > h + w \log n$.

Let \mathcal{P} be the family of distributions obtained from \mathbf{p} by permuting the labels of the elements. Define \mathcal{Q} similarly for \mathbf{q} . It is simple to verify that any algorithm taking $o(1/w)$ samples and making $o(1/w)$ probes will fail to distinguish between a randomly chosen member of \mathcal{P} and a randomly chosen member of \mathcal{Q} with high probability.

Meanwhile, by the choice of w , the entropy ratio is

$$\frac{H(\mathbf{q})}{H(\mathbf{p})} > \frac{h + w \log n}{h + 2} = \frac{h\gamma^2 + 2\gamma^2}{h + 2} = \gamma^2.$$

This concludes the proof. \square

6. Monotone distributions. A *monotone distribution* $\mathbf{p} = \langle p_1, \dots, p_n \rangle$ is one for which $p_i \geq p_{i+1}$ for all i . The structure of a monotone distribution makes it much easier to approximate the entropy.

6.1. The evaluation oracle model. We show that given evaluation oracle access to a monotone distribution, we can approximate the entropy in polylogarithmic time.

THEOREM 14. *For any $\gamma > 1$, there is an algorithm in the evaluation oracle model that γ -approximates the entropy of monotone distributions on $[n]$ in the family $\mathcal{D}_{\Omega(\gamma^2/(\sqrt{\gamma}-1))}$ and runs in $O(\lceil 1/\log \gamma \rceil \log n)$ time.*

Proof. Algorithm \mathcal{A} partitions the domain $[n]$ into intervals and only queries the endpoints of each interval. The remaining probability values are interpolated from these queries.

The partition of $[n]$ is constructed recursively, starting with a single *active* interval $[1, n]$ as follows:

While there is some active interval $[\ell, u]$:

- Make it inactive.
- If $p_\ell > n^{-2}$ and $p_\ell/p_u > \gamma$, then split $[\ell, u]$ into two equal-sized active subintervals.

Any required probability values (i.e., p_ℓ, p_u at each iteration) are obtained from the oracle. At the end of the procedure, the algorithm has probabilities for a particular sequence of elements $1 = i_0 \leq i_1 \leq \dots \leq i_k = n$, such that for each $j < k$, either $p_{i_j} \leq n^{-2}$ or $p_{i_j}/p_{i_{j+1}} \leq \gamma$. The splitting criteria ensure that the total number of queries $k + 1$ is roughly logarithmic in the number of elements; more precisely, $k \leq 1 + (1 + 4/\log \gamma) \log n$.

The algorithm then approximates \mathbf{p} by a distribution \mathbf{q} that is interpolated from the handful of p_i values that it queries as follows:

- For each i_j , set $q_{i_j} = p_{i_j}$.
- For any $i \in (i_j, i_{j+1})$: if $p_{i_j} \leq n^{-2}$, then set $q_i = 0$; otherwise set $q_i = \sqrt{p_{i_j} p_{i_{j+1}}}$.

Let B_0 denote the elements whose probabilities get set to zero, and let $B = [n] \setminus B_0$ be the remaining elements. We know that for $i \in B_0$, $p_i \leq n^{-2}$. Thus, $w_{\mathbf{p}}(B_0) \leq n^{-1}$ and, by Lemma 1(b), B_0 doesn't contribute much to the entropy: $H_{B_0}(\mathbf{p}) \leq 2n^{-1} \log n$. We therefore need to focus on B .

For each $i \in B$, define $c_i \stackrel{\text{def}}{=} q_i/p_i$. Since the endpoints of the interval containing i have probabilities that are within a multiplicative factor γ of each other, it follows that $\frac{1}{\sqrt{\gamma}} \leq c_i \leq \sqrt{\gamma}$. This means that $H_B(\mathbf{q})$ is not too different from $H_B(\mathbf{p})$:

$$\begin{aligned} H_B(\mathbf{q}) &= - \sum_{i \in B} q_i \log q_i = - \sum_{i \in B} c_i p_i \log(c_i p_i) = - \sum_{i \in B} c_i p_i \log p_i - \sum_{i \in B} c_i p_i \log c_i \\ &\leq \sqrt{\gamma} \cdot H_B(\mathbf{p}) + \frac{w_{\mathbf{p}}(B) \log e}{e} \leq \gamma \cdot H(\mathbf{p}) \end{aligned}$$

when $H(p) \geq \log e/(e(\gamma - \sqrt{\gamma}))$. The first inequality follows from the fact (see Lemma 1) that $-x \log x \leq (\log e)/e$ for all $x \in (0, 1)$. Similarly,

$$\begin{aligned} H_B(\mathbf{q}) &= - \sum_{i \in B} q_i \log q_i = - \sum_{i \in B} c_i p_i \log(c_i p_i) = - \sum_{i \in B} c_i p_i \log p_i - \sum_{i \in B} c_i p_i \log c_i \\ &\geq \frac{1}{\sqrt{\gamma}} \cdot H_B(\mathbf{p}) - w_{\mathbf{p}}(B) \sqrt{\gamma} \log \sqrt{\gamma} \geq \frac{1}{\sqrt{\gamma}} \left(H(\mathbf{p}) - \frac{2 \log n}{n} \right) - w_{\mathbf{p}}(B) \sqrt{\gamma} \log \sqrt{\gamma} \\ &\geq H(\mathbf{p})/\gamma \end{aligned}$$

when $H(\mathbf{p}) \geq (\gamma^2 + (2n^{-1}\sqrt{\gamma} \log n))/(\sqrt{\gamma} - 1)$. The second-to-last inequality uses $H_{B_0}(\mathbf{p}) \leq 2n^{-1} \log n$.

The algorithm outputs $H(\mathbf{q}) = H_B(\mathbf{q})$, which we've shown is a γ -approximation to $H(\mathbf{p})$. \square

6.2. The generation oracle model. We show that the entropy of a monotone distribution can also be approximated in polylogarithmic time in the generation oracle model. Our algorithm rests upon the following observation that is formally stated in Lemma 15: if a monotone distribution \mathbf{p} over $[n]$ is such that $w_{\mathbf{p}}([n/2])$ and $w_{\mathbf{p}}([n] \setminus [n/2])$ are very close, then the distribution must be close to uniform. In such a case, we can approximate the entropy of the distribution by the entropy of the uniform distribution.

The main idea behind our algorithm is to recursively partition the domain into halves, stopping the recursion when either (1) the probability masses of two halves are very close or (2) they are both too small to contribute much to the total entropy. Our algorithm can be viewed as forming a tree based on the set of samples S , where the root is labeled by the range $[1, n]$, and if the node labeled by the range $[i, j]$ is partitioned, its children are labeled by the ranges $[i, (i+j)/2]$ and $[(i+j)/2 + 1, j]$, respectively. Once the partition tree is determined, the algorithm estimates the entropy by summing the contributions from each leaf, assuming that the conditional distribution within a leaf (that is, the distribution restricted to the leaf's range) is uniform. By the choice of our splitting and stopping criteria, we show that the number of leaves in the tree is at most polylogarithmic in n . This in turn allows us to bound both the running time and the probability of error.

More specifically, the procedure **BuildTree** (S, β) takes as input a parameter $\beta > 1$ and a multiset S of m samples from \mathbf{p} and outputs a rooted binary tree T_S as follows: Let v be a node in the tree that is currently a leaf corresponding to the interval $[i, j]$ for some $i < j$. For an interval I , let S_I denote the set of samples that fall in I , and let $|I|$ denote the length of the interval. We determine that v will remain a leaf if either of the following two conditions is satisfied:

- $|S_{[i,j]}| < m\beta/\log^3 n$ (call v *light*), or
- $|S_{[i, \lfloor (i+j)/2 \rfloor]}| \leq \beta |S_{[\lfloor (i+j)/2 \rfloor + 1, j]}|$ (call v *balanced*).

Otherwise, we split v 's interval by attaching two children to v , corresponding to the intervals $[i, \lfloor (i+j)/2 \rfloor]$ (the left child) and $[\lfloor (i+j)/2 \rfloor + 1, j]$ (the right child). Let $\mathcal{I}(T_S)$ denote the set of intervals corresponding to the balanced leaves of T_S .

For each balanced interval $I \in \mathcal{I}(T_S)$, we estimate the contribution of the interval to the total entropy of the distribution. Note that if the interval I had uniform conditional distribution, then

$$\begin{aligned} H_I(\mathbf{p}) &= \sum_{i \in I} \frac{w_{\mathbf{p}}(I)}{|I|} \log \frac{|I|}{w_{\mathbf{p}}(I)} \\ &= w_{\mathbf{p}}(I) (\log |I| - \log w_{\mathbf{p}}(I)) \\ &= w_{\mathbf{p}}(I) \left(\log \left(\frac{|I|}{2} \right) - \log \left(\frac{w_{\mathbf{p}}(I)}{2} \right) \right). \end{aligned}$$

Motivated by this, we define a function $\alpha(I, \beta)$ that approximates the entropy in the balanced interval I :

$$\alpha(I, \beta) \stackrel{\text{def}}{=} \frac{|S_I|}{m} \left(\log \frac{|I|}{2} + \log \frac{m}{\beta |S_I|} \right).$$

We now give the top level description of our algorithm.

ALGORITHM MONOTONEAPPROXIMATEENTROPY (γ).

1. $\beta = \sqrt{\gamma}$.
2. Get a multiset S of $m = O((\beta^5 \log^4 n)/(\beta - 1)^2)$ samples from \mathbf{p} .
3. $T_S = \mathbf{BuildTree}(S, \beta)$.
4. Output $\sum_{I \in \mathcal{I}(T_S)} \alpha(I, \beta)$.

Overview of the proof. The main steps in the proof are the following. First, we give a key lemma on which the whole algorithm is based; this lemma implies that for an interval corresponding to a balanced leaf, the upper and lower bounds on the possible entropy values are fairly close (Lemma 15). The rest of the proof is devoted to showing that the domain can be split into intervals that are either balanced or small enough that they do not contribute much (in total) to the entropy of the distribution. In Lemma 16, we show that sampling can be reliably used to decide whether or not to split an interval. We then quantify the relationship between $\alpha(I, \beta)$ and $H_I(\mathbf{p})$ for each interval I corresponding to a balanced leaf, taking the sampling error into account (Lemma 18). Note that if it were possible to partition the whole domain into balanced intervals of large enough size, then it would be a simple matter to bound the number of intervals and thus the error probability and running time of the algorithm. The most challenging part of the proof is to deal with the light intervals, in particular to show the following two properties: (1) the number of such intervals is approximately logarithmic in the size of the domain (Lemma 19), and (2) their total entropy contribution is negligible and thus can be ignored. To show these properties, we prove an interesting and nontrivial property of the tree T_S : at any level, it contains at most $O(\log \log n)$ nodes. Thereafter, (1) and (2) follow easily.

First, we show upper and lower bounds on the entropy contribution of an interval in terms of the total weight and the weight distribution between two halves of the interval.

LEMMA 15. *Let I be an interval of length $2k$ in $[n]$, let I_1 and I_2 be the bisection of I , and let \mathbf{p} be a monotone distribution over $[n]$. Then,*

$$H_I(\mathbf{p}) \leq w_{\mathbf{p}}(I) \log k - w_{\mathbf{p}}(I_1) \log w_{\mathbf{p}}(I_1) - w_{\mathbf{p}}(I_2) \log w_{\mathbf{p}}(I_2)$$

and

$$H_I(\mathbf{p}) \geq 2w_{\mathbf{p}}(I_2) \log k - w_{\mathbf{p}}(I_2) \left(\log w_{\mathbf{p}}(I_1) + \log w_{\mathbf{p}}(I_2) \right).$$

Notice in particular that the ratio of the upper bound to the lower bound is at most $w_{\mathbf{p}}(I)/2w_{\mathbf{p}}(I_2)$.

Proof. The upper bound follows from Lemma 1(a): the partial entropies $H_{I_1}(\mathbf{p})$ and $H_{I_2}(\mathbf{p})$ are maximized when their weights are spread uniformly over their constituent elements.

Let $w_1 \stackrel{\text{def}}{=} w_{\mathbf{p}}(I_1)$ and $w_2 \stackrel{\text{def}}{=} w_{\mathbf{p}}(I_2)$. We will prove the lower bound even for functions that satisfy a relaxation of the monotonicity property: namely, the condition that for $i \leq k$, $p_i \geq w_2/k$, and for $i > k$, $p_i \leq w_1/k$. It is easy to verify that any monotone distribution will satisfy this new constraint. A lower bound on $H_{I_1}(\mathbf{p})$ is given by Lemma 1(c) (plug in w_2/k for as many elements as possible), and for $H_{I_2}(\mathbf{p})$ it follows immediately from $p_i \leq w_1/k$ for $i \in I_2$. Combining, we get

$$H_I(\mathbf{p}) \geq w_2 \log \frac{k}{w_2} + w_2 \log \frac{k}{w_1}. \quad \square$$

For a balanced leaf corresponding to an interval I with bisection I_1, I_2 , the error in the entropy estimate depends upon the ratio $w_{\mathbf{p}}(I)/2w_{\mathbf{p}}(I_2)$. This can be made small by choosing the parameter β appropriately.

The following lemma shows that the samples can be used to decide if an interval should be split.

LEMMA 16. *Let I be an interval in $[1, n]$ such that $w_{\mathbf{p}}(I) \geq \log^{-3} n$, and let I_1, I_2 be a bisection of I . Let S be a sample set of size $m = O((\beta^5 \log^4 n)/(\beta - 1)^2)$ drawn from \mathbf{p} . For $\beta > 1$,*

1. *with probability at least $1 - n^{-2}$, $(1/\beta) \cdot m \cdot w_{\mathbf{p}}(I) \leq |S_I| \leq \beta \cdot m \cdot w_{\mathbf{p}}(I)$;*
2. *if $w_{\mathbf{p}}(I_1)/w_{\mathbf{p}}(I_2) \geq 2\beta - 1$, then with probability at least $1 - 2n^{-2}$, $|S_{I_1}| \geq \beta \cdot |S_{I_2}|$;*
3. *if $w_{\mathbf{p}}(I_1)/w_{\mathbf{p}}(I_2) \leq (1 + \beta)/2$, then with probability at least $1 - 2n^{-2}$, $|S_{I_1}| \leq \beta \cdot |S_{I_2}|$.*

Proof. Part 1 follows from a straightforward application of multiplicative Chernoff bounds. The random variable $|S_I|$ is the sum of m independent Bernoulli trials, each with success probability $w_{\mathbf{p}}(I)$. Therefore $\mathbb{E}[|S_I|] = mw_{\mathbf{p}}(I)$, and by the choice of m in the algorithm, the probability that $|S_I|$ deviates from its expectation by more than a multiplicative factor of β is at most $1/n^2$.

From part 1, we know that with probability at least $1 - n^{-2}$, $|S_I| \geq mw_{\mathbf{p}}(I)/\beta$. Fix any $t \geq mw_{\mathbf{p}}(I)/\beta$. To prove part 2, consider the ratio of the number of samples from I_1 and I_2 conditioned on the event that there are exactly t samples from I . Let Y_i , for $i = 1, \dots, t$, be an indicator random variable that takes the value 1 if the i th of these t samples is in I_2 , and $Y = \sum_i Y_i$. Therefore, we want to show that the probability that $(t - Y)/Y < \beta$ is at most $2/n^2$.

The rest of the proof is an application of Chernoff bounds. Note that $(t - Y)/Y < \beta$ implies $Y > t/(\beta + 1)$. Since $\mathbb{E}[Y] \leq t/(2\beta)$, we get

$$\Pr \left[Y > \frac{t}{\beta + 1} \right] \leq \Pr \left[Y > \mathbb{E}[Y] + \frac{t(\beta - 1)}{2\beta(\beta + 1)} \right] \leq \exp \left(\frac{-t(\beta - 1)^2}{\beta^2(\beta + 1)^2} \right).$$

Conditioned on the event that $t \geq mw_{\mathbf{p}}(I)/\beta$, this probability is less than $1/n^2$. Combining this with part 1, we can conclude that, with probability at least $1 - 2n^{-2}$, we have $|S_{I_1}| \geq \beta \cdot |S_{I_2}|$.

Similarly, the third part of the lemma can be proved. \square

There are various events that we would like to count on, for instance, that for balanced intervals I the ratio of the weights of the two halves is at most $2\beta - 1$, and that intervals associated with two sibling nodes have weight ratio at least $(1 + \beta)/2$. Lemma 16 tells us that these events hold with high probability. We now package all of them into a single assumption.

ASSUMPTION 17. (1) *For each interval I corresponding to a balanced node of the tree, $|S_I|$ lies in the range $[(1/\beta) \cdot m \cdot w_{\mathbf{p}}(I), \beta \cdot m \cdot w_{\mathbf{p}}(I)]$; (2) for each interval I we decide to split, $w_{\mathbf{p}}(I_1)/w_{\mathbf{p}}(I_2) \geq (1 + \beta)/2$; (3) for each balanced interval I , we have $w_{\mathbf{p}}(I_1)/w_{\mathbf{p}}(I_2) \leq 2\beta - 1$; and (4) each light leaf has weight at most $\beta^2/\log^3 n$.*

Now we can show that under the assumption above, the entropy contribution of each balanced interval is approximated well. Recall that $\mathcal{I}(T_S)$ is the set of all balanced intervals in T_S .

LEMMA 18. *Under Assumption 17, for every $I \in \mathcal{I}(T_S)$, if $w_{\mathbf{p}}(I) \geq \log^{-3} n$, then*

$$\frac{H_I(\mathbf{p})}{\beta} - 2\beta \cdot w_{\mathbf{p}}(I) \leq \alpha(I, \beta) \leq \beta^2 \cdot H_I(\mathbf{p}).$$

Proof. Let I_1, I_2 be the bisection of I . Under Assumption 17, $|S_I|/(m\beta) \leq w_{\mathbf{p}}(I) \leq |S_I|/\beta/m$ and $w_{\mathbf{p}}(I_1)/w_{\mathbf{p}}(I_2) \leq 2\beta - 1$. These imply that the upper and

lower bounds for $H_I(\mathbf{p})$ given in Lemma 15 are within a multiplicative factor β of each other. Therefore our entropy estimate $\alpha(I, \beta)$ is not too far from $H_I(\mathbf{p})$:

$$\begin{aligned} \alpha(I, \beta) &= \frac{|S_I|}{m} \left(\log \frac{|I|}{2} + \log \frac{m}{\beta |S_I|} \right) \\ &\leq \beta w_{\mathbf{p}}(I) \log \left(\frac{|I|}{2} \right) - \beta w_{\mathbf{p}}(I) \log w_{\mathbf{p}}(I) \\ &\leq \beta \cdot \left(w_{\mathbf{p}}(I) \log \left(\frac{|I|}{2} \right) - w_{\mathbf{p}}(I_1) \log w_{\mathbf{p}}(I_1) - w_{\mathbf{p}}(I_2) \log w_{\mathbf{p}}(I_2) \right) \\ &\leq \beta^2 \cdot H_I(\mathbf{p}). \end{aligned}$$

The second inequality above is a simple consequence of $w_{\mathbf{p}}(I) = w_{\mathbf{p}}(I_1) + w_{\mathbf{p}}(I_2)$, and the expression on that line is exactly (β times) the upper bound of Lemma 15. Similarly, for the other direction,

$$\begin{aligned} \alpha(I, \beta) &= \frac{|S_I|}{m} \left(\log \frac{|I|}{2} + \log \frac{m}{\beta |S_I|} \right) \\ &\geq \frac{w_{\mathbf{p}}(I)}{\beta} \log \frac{|I|}{2} - \frac{w_{\mathbf{p}}(I)}{\beta} \log \frac{w_{\mathbf{p}}(I)}{2} - \frac{w_{\mathbf{p}}(I)}{\beta} \log 2\beta^2 \\ &\geq \frac{1}{\beta} \left(w_{\mathbf{p}}(I) \log \frac{|I|}{2} - w_{\mathbf{p}}(I_1) \log w_{\mathbf{p}}(I_1) - w_{\mathbf{p}}(I_2) \log w_{\mathbf{p}}(I_2) \right) - 2\beta \cdot w_{\mathbf{p}}(I) \\ &\geq \frac{H_I(\mathbf{p})}{\beta} - 2\beta \cdot w_{\mathbf{p}}(I). \end{aligned}$$

The second inequality follows from the concavity of $\log x$. \square

Next, we show a bound on the number of nodes in the tree.

LEMMA 19. *Under Assumption 17, given $\beta > 1$, the number of nodes in T_S is at most*

$$\frac{12 \log n \log \log n}{\log(\beta + 1) - 1}.$$

Proof. For any given level of the tree, let v_1, \dots, v_{2k} denote the internal (that is, nonleaf) nodes at that level, ordered by the intervals they define. There is an even number of these nodes because each has a sibling at the same level. If v_i, v_{i+1} are siblings, we know from Assumption 17 that $w(v_i) \geq w(v_{i+1}) \cdot (1 + \beta)/2$. In general, by monotonicity, $w(v_i) \geq w(v_{i+1})$. Therefore, as one moves from v_1 to v_{2k} , the weight $w(v_i)$ drops by a factor of at least $(1 + \beta)/2$ for every two nodes. Moreover, these weights never drop below $1/\log^3 n$, by the split criterion and Assumption 17. It follows that

$$k \leq \frac{3 \log \log n}{\log(1 + \beta) - 1}.$$

We now have a bound on the number of internal nodes at any level. To finish the lemma, we observe that there are at most $\log n$ levels, that the total number of nodes (internal and leaf) is twice the number of internal nodes plus one, and that we have overcounted by at least one at the root level. \square

Now, we are ready to complete our proof.

THEOREM 20. *For every $\gamma > 1$, there is an algorithm that approximates the entropy of a monotone distribution on $[n]$ in $\mathcal{D}_{(6\gamma^{3/2}/(\log(\sqrt{\gamma}+1)-1)(\sqrt{\gamma}-1))}$ to within a multiplicative factor of γ with probability at least $3/4$ in*

$$O\left(\frac{\gamma^{5/2} \log^6 n}{(\sqrt{\gamma}-1)^2(\log(\sqrt{\gamma}+1)-1)}\right) \text{ time.}$$

Proof. Suppose Assumption 17 holds; we will come back and address this later. Let's start by handling the leaves. By Assumption 17, each light leaf has weight at most $\beta^2/\log^3 n$, and so by Lemma 19, the total weight of the intervals associated with light leaves is at most

$$\frac{6\beta^2 \log \log n}{(\log(\beta+1)-1) \log^2 n}.$$

Therefore, their combined entropy contribution is at most $\log n$ times this,

$$\frac{6\gamma \log \log n}{(\log(\sqrt{\gamma}+1)-1) \log n}$$

(recall $\beta^2 = \gamma$), which will turn out to be negligible for our purposes.

Now we move on to the internal nodes. By Lemma 18,

$$\frac{H_I(\mathbf{p})}{\beta} - 2\beta \cdot w_{\mathbf{p}}(I) \leq \alpha(I, \beta) \leq \beta^2 \cdot H_I(\mathbf{p})$$

for each interval I associated with a balanced leaf. Let $B = \cup_{I \in \mathcal{I}(T_S)} I$. The algorithm's output is

$$\sum_{I \in \mathcal{I}(T_S)} \alpha(I, \beta) \leq \sum_{I \in \mathcal{I}(T_S)} \beta^2 \cdot H_I(\mathbf{p}) = \gamma \cdot H_B(\mathbf{p}) \leq \gamma \cdot H(\mathbf{p}).$$

We can show the other direction as follows:

$$\sum_{I \in \mathcal{I}(T_S)} \alpha(I, \beta) \geq \frac{H_B(\mathbf{p})}{\beta} - 2\beta \geq \frac{H(\mathbf{p}) - \frac{6\gamma \log \log n}{(\log(\sqrt{\gamma}+1)-1) \log n}}{\beta} - 2\beta \geq \frac{H(\mathbf{p})}{\beta^2}$$

when $H(\mathbf{p}) \geq (6\gamma^{3/2}/(\log(\sqrt{\gamma}+1)-1)(\sqrt{\gamma}-1))$.

We now proceed to justify Assumption 17. Consider the $2n$ intervals that correspond to the nodes of a complete tree T . By Lemma 16, Assumption 17 fails to hold for a particular interval of T with probability $O(1/n^2)$. Hence, Assumption 17 fails to hold for T_S with probability $O(1/n)$ by the union bound over all the intervals. Therefore, the error probability of the algorithm is $o(1)$. The running time of the algorithm is the sample size times the size of T_S . \square

Note that the lower bound shown in Theorem 6 applies to monotone distributions. Therefore, a restriction on the entropy such as the one in the statement of Theorem 20 is necessary.

7. Subset-uniform distributions. Consider the family of distributions \mathcal{E}_k that are uniform over some subset $K \subseteq [n]$ with $|K| = k$. The entropy of this class of distributions is $\log k$. If we approximate k to within a multiplicative factor of γ , then we get a very strong additive approximation to $\log k$. Now, given a generation

oracle access to a distribution that is promised to be from \mathcal{E}_k for some k , the entropy estimation problem reduces to approximating k .

THEOREM 21. *For every $\gamma > 1$, there exists an algorithm in the generation oracle model that, for every k and for any distribution $\mathbf{p} \in \mathcal{E}_k$, outputs ℓ such that $k/\gamma \leq \ell \leq \gamma k$ with probability at least $3/4$ in $O(\gamma\sqrt{k}/(\gamma - 1))$ time.*

Proof. Our algorithm, inspired by [5], is as follows.

1. Let $c = 16\gamma/(\gamma - 1)^2$.
2. Draw samples until at least c pairwise collisions are observed.
3. If M is the number of samples seen, output $\binom{M}{2}/c$.

Note that M is a random variable.

To analyze this algorithm, pick any integer m and suppose that m samples are drawn from the distribution. For $i < j$, let X_{ij} be an indicator random variable denoting a collision between the i th and j th samples seen. Let $S_m = \sum_{i < j} X_{ij}$ be the total number of collisions.

For any $i < j$, $E[X_{ij}] = 1/k$; therefore $E[S_m] = \binom{m}{2} \cdot 1/k$. This motivates the algorithm above. To bound the chance of failure, we also need the variance of S_m . Notice that

$$E[S_m^2] = E\left[\left(\sum_{i < j} X_{ij}\right)\left(\sum_{a < b} X_{ab}\right)\right] = \sum_{i < j, a < b} E[X_{ij}X_{ab}].$$

In the final summation, the various terms can be segregated according to the cardinality of the set $\{i, j, a, b\}$. If this set has cardinality 3 or 4, then $E[X_{ij}X_{ab}] = 1/k^2$. If the set has cardinality 2, then $E[X_{ij}X_{ab}] = 1/k$. This last possibility occurs for exactly $\binom{m}{2}$ of the $\binom{m}{2}^2$ terms in the summation. Therefore

$$E[S_m^2] = \left(\binom{m}{2}^2 - \binom{m}{2}\right) \frac{1}{k^2} + \binom{m}{2} \frac{1}{k},$$

whereupon $\text{Var}[S_m] = E[S_m^2] - E[S_m]^2 = \binom{m}{2}(1/k - 1/k^2) \leq E[S_m]$.

What is the chance that the algorithm outputs a number less than k/γ ? Let m_0 be the largest integer m such that $\binom{m}{2} < ck/\gamma$:

$$\begin{aligned} \Pr[\text{Output is } < k/\gamma] &= \Pr[M \leq m_0] = \Pr[S_{m_0} \geq c] \\ &\leq \Pr[|S_{m_0} - E[S_{m_0}]| \geq (c - E[S_{m_0}])]. \end{aligned}$$

This last probability can be bounded by Chebyshev's inequality, giving

$$\Pr[\text{Output is } < k/\gamma] \leq \frac{\text{Var}[S_{m_0}]}{(c - E[S_{m_0}])^2} \leq \frac{E[S_{m_0}]}{(c - E[S_{m_0}])^2} \leq \frac{\gamma}{c(\gamma - 1)^2} \leq \frac{1}{16},$$

where the last two inequalities follow from $E[S_{m_0}] < c/\gamma$ and from the particular choice of c .

To bound that chance that the output is more than $k\gamma$, we proceed similarly, letting m_0 denote the smallest integer m for which $\binom{m+1}{2} > c\gamma k$. Then,

$$\begin{aligned} \Pr[\text{Output is } > k\gamma] &= \Pr[M > m_0] = \Pr[S_{m_0} < c] \\ &\leq \Pr[|S_{m_0} - E[S_{m_0}]| \geq (E[S_{m_0}] - c)]. \end{aligned}$$

Again using Chebyshev's inequality, we get

$$\Pr[\text{Output is } > k\gamma] \leq \frac{\text{Var}[S_{m_0}]}{(\mathbb{E}[S_{m_0}] - c)^2} \leq \frac{\mathbb{E}[S_{m_0}]}{(\mathbb{E}[S_{m_0}] - c)^2} \leq \frac{3\gamma}{c(\gamma - 1)^2} \leq \frac{3}{16}.$$

The total probability of error is therefore at most $1/4$. When the algorithm succeeds, $\binom{M}{2}/c \leq k\gamma$, and so the number of samples (and the running time) is $O(\sqrt{ck\gamma})$. \square

WELL-SEPARATED PAIR DECOMPOSITION FOR THE UNIT-DISK GRAPH METRIC AND ITS APPLICATIONS*

JIE GAO[†] AND LI ZHANG[‡]

Abstract. We extend the classic notion of well-separated pair decomposition [P. B. Callahan and S. R. Kosaraju, *J. ACM*, 42 (1975), pp. 67–90] to the unit-disk graph metric: the shortest path distance metric induced by the intersection graph of unit disks. We show that for the unit-disk graph metric of n points in the plane and for any constant $c \geq 1$, there exists a c -well-separated pair decomposition with $O(n \log n)$ pairs, and the decomposition can be computed in $O(n \log n)$ time. We also show that for the unit-ball graph metric in k dimensions where $k \geq 3$, there exists a c -well-separated pair decomposition with $O(n^{2-2/k})$ pairs, and the bound is tight in the worst case. We present the application of the well-separated pair decomposition in obtaining efficient algorithms for approximating the diameter, closest pair, nearest neighbor, center, median, and stretch factor, all under the unit-disk graph metric.

1. Introduction. Well-separated pair decomposition, introduced by Callahan and Kosaraju [10], has found numerous applications in solving proximity problems for points in the Euclidean space [8, 10, 9, 5, 4, 29, 25, 19, 14]. A pair of point sets (A, B) is *c-well-separated* if the distance between A, B is at least c times the diameters of both A and B . A well-separated pair decomposition of a point set consists of a set of well-separated pairs that cover all the pairs of distinct points, i.e., any two distinct points belong to the different sets of some pair. In [10], Callahan and Kosaraju showed that for any point set in an Euclidean space and for any constant $c \geq 1$, there always exists a c -well-separated pair decomposition with linearly many pairs. This fact has been very useful in obtaining nearly linear time algorithms for many problems, such as computing k -nearest neighbors, N -body potential fields, geometric spanners, and approximate minimum spanning trees. Well-separated pair decomposition is also shown to be very useful in obtaining efficient dynamic, parallel, and external memory algorithms [8, 9, 10, 7, 18].

The definition of well-separated pair decomposition can be naturally extended to any metric space. Curiously enough, however, there has been no work for such an extension. A possible reason is that a general metric space may not admit a well-separated pair decomposition with a subquadratic size. Indeed, even for the metric induced by a star tree with unit weight on each edge,¹ any well-separated pair decomposition requires quadratically many pairs. This makes the well-separated pair decomposition useless for such a metric. In this paper, we will show that for a certain metric, there do exist well-separated pair decompositions with almost linear size, and

¹A metric induced by a graph (with positive edge weights) is the shortest path distance metric of the graph.

therefore many proximity problems under that metric can be solved efficiently. The metric we investigate is the so-called unit-disk graph metric. At the same time we call the well-separated pair decomposition in the Euclidean space the *geometric well-separated pair decomposition*, to be distinguished from the decomposition in graph metrics.

For a point set S in the plane, its unit-disk graph [12] is formed by connecting two points p, q in S if the Euclidean distance $d(p, q)$ is at most 1. A unit-disk graph can also be viewed as the intersection graph of a set of unit disks centered at the points in S . We consider the weighted unit-disk graphs where each edge (p, q) receives the weight $d(p, q)$. Similarly, unit-ball graphs can be defined for points in high dimensions. Such graphs have been used extensively to model the communication or influence between objects [27, 21] and studied in many different contexts [12, 6, 22, 15]. For example, wireless ad hoc networks can be modeled by unit-disk graphs [23, 30, 31], as two wireless nodes can directly communicate with each other only if they are within a certain distance. In unsupervised learning, for a dense sampling of points from some unknown manifold, the length of the shortest path on the unit-ball graph is a good approximation of the geodesic distance on the underlying (unknown) manifold if the radius is chosen appropriately [34, 16]. In this paper, we show that the all-pairs shortest path lengths of nodes in unit-disk graphs (or unit-ball graphs) can be compactly encoded and efficiently estimated by a subquadratic size well-separated pair decomposition.

2. Overview. In this paper, we show that for the metric induced by the unit-disk graph on n points and for any constant $c \geq 1$, there does exist a c -well-separated pair decomposition with $O(n \log n)$ pairs, and such a decomposition can be computed in $O(n \log n)$ time. We also show that the bounds can be extended to higher dimensions: for $k \geq 3$, there always exists a c -well-separated pair decomposition with size $O(n^{2-2/k})$ for the unit-ball graph metric on n points, and the bound is tight in the worst case. The construction time is $O(n^{4/3} \text{polylog } n)$ for $k = 3$ and $O(n^{2-2/k})$ for $k \geq 4$.

The difficulty in obtaining a well-separated pair decomposition for unit-disk graph metric is that two points that are close in the space are not necessarily close under the graph metric. We first prove the bound for the point set with constant-bounded density, i.e., a point set where any unit disk covers only a constant number of points in the set, by using a packing argument similar to the one in [20]. For a point set with unbounded density, we apply the clustering technique similar to the one used in [17] to the point set and obtain a set of clusterheads with a bounded density. We then apply the result for bounded density point set on those clusterheads. Then, by combining the well-separated pair decomposition for the bounded density point sets and for the Euclidean metric, we are able to show that the bound holds for any point sets.

For a pair of well-separated sets, the distance between two points from different sets can be approximated by the distance between the two sets or the distance between any pair of points in different sets. In other words, a well-separated pair decomposition can be thought of as a compressed representation to approximate the $\Theta(n^2)$ pairwise distances. Many problems that require checking of the pairwise distances can therefore be approximately solved by examining those distances between the well-separated pairs of sets. When the size of the well-separated pair decomposition is subquadratic, it often gives us more efficient algorithms than examining all the pairwise distances. Indeed, this is the intuition behind many applications of the geometric well-separated

pair decomposition. By using the same intuition, we show the application of well-separated pair decomposition in several proximity problems under the unit-disk graph metric.

Specifically, we consider the following natural proximity problems. Assume that $S_1 \subseteq S$.

- *Furthest neighbor, diameter, center.* The furthest neighbor of $p \in S_1$ is the point in S_1 that maximizes the distance to p . Related problems include computing the *diameter*, the maximum pairwise shortest distance for points in S_1 , and the *center*, the point that minimizes the maximum distance to all the other points.
- *Nearest neighbor, closest pair.* The nearest neighbor of $p \in S_1$ is the point in S_1 with the minimum distance to p . Related problems include computing the *closest pair*, the pair with minimum shortest distance, and the *bichromatic closest pair*, the pair that minimizes distance between points from two different sets.
- *Median.* The median of S is the point in S that minimizes the average (or total) distance to all the other points.
- *Stretch factor.* For a graph G defined on S , its stretch factor with respect to the unit-disk graph metric is defined to be the maximum ratio $\pi_G(p, q)/\pi(p, q)$, where π_G, π are the distances induced by G and by the unit-disk graph, respectively.

All the above problems can be solved or approximated efficiently for points in the Euclidean space. However, for the metric induced by a graph, even for planar graphs, very little is known other than solving the expensive all-pairs shortest path problem. For computing diameter, there is a simple linear time method that achieves a 2-approximation² and a 4/3-approximate algorithm with running time $O(m\sqrt{n \log n} + n^2 \log n)$ for a graph with n vertices and m edges [2]. By using the powerful tool of the well-separated pair decomposition, we are able to obtain, for all the above problems, nearly linear time algorithms for computing 2.42-approximation³ and $O(n\sqrt{n \log n}/\varepsilon^3)$ time algorithms for computing $(1 + \varepsilon)$ -approximation for any $\varepsilon > 0$. In addition, the well-separated pair decomposition can be used to obtain an $O(n \log n/\varepsilon^4)$ space distance oracle so that any $(1 + \varepsilon)$ distance query in the unit-disk graph can be answered in $O(1)$ time.

While the existence of almost linear size well-separated pair decomposition has reduced the number of pairs needed to examine when solving many proximity problems, we still need good approximation of the distances between those pairs. Our construction algorithm only produces well-separated pair decompositions without knowing an accurate approximation of the distances. For approximation algorithms, we need accurate estimation of shortest distances between $O(n \log n)$ pairs of points in the unit-disk graph. Indeed, the approximation ratio and the running time of our algorithms are dominated by the efficiency of such algorithms. Once the distance estimation has been made, the remaining computation only takes almost linear time.

For a general graph, it is unknown whether $O(n \log n)$ -pairs shortest path dis-

²Select an arbitrary node v and compute the shortest path tree rooted at v . Suppose that the furthest node from v is of distance D away. Then the diameter of the graph is no longer than $2D$, by triangular inequality.

³For a minimization problem, a quantity $\hat{\ell}$ is a c -approximation of ℓ if $\ell \leq \hat{\ell} \leq c\ell$. An object \hat{O} is a c -approximation of O with respect to a cost function f if $f(O) \leq f(\hat{O}) \leq cf(O)$. For a maximization problem, $\hat{\ell}$ is a c -approximation of ℓ if $\ell/c \leq \hat{\ell} \leq \ell$, and \hat{O} is a c -approximation of O if $f(O)/c \leq f(\hat{O}) \leq f(O)$.

tances can be computed significantly faster than all-pairs shortest path distances. For the planar graph, one can compute $O(n \log n)$ -pairs shortest path distance in $O(n\sqrt{n \log n})$ time by using separators with $O(\sqrt{n})$ size [3]. This method extends to the unit-disk graph with constant bounded density since such graphs enjoy similar separator property as the planar graphs [28, 32]. As for approximation, Thorup [35] recently discovered an algorithm for planar graphs that can answer any $(1+\varepsilon)$ -shortest distance query in $O(1/\varepsilon)$ time after almost linear time preprocessing. Unfortunately, Thorup's algorithm uses balanced shortest path separators in planar graphs which do not obviously extend to the unit-disk graphs. On the other hand, it is known that there does exist planar 2.42-spanner for a unit-disk graph [26]. By applying Thorup's algorithm to that planar spanner, we can compute 2.42-approximate shortest path distance for $O(n \log n)$ pairs in almost linear time.

Another application of well-separated pair decomposition is that we are able to obtain an almost linear size data structure to answer $(1 + \varepsilon)$ -approximate shortest path query in $O(1)$ time. Approximate distance oracles have been studied where the emphasis is often on the size of the oracles (for a survey, see [38]). For general graphs, it has been shown that it is possible to construct a $(2k - 1)$ -approximate distance oracle with size $O(kn^{1+1/k})$ [36]. It is also shown in [36] that this bound is tight for some small k 's and is conjectured to be tight for all the k 's. For planar graphs, Thorup [35] and Klein [24] have shown that there exists $(1 + \varepsilon)$ -approximate distance oracle by using almost linear space for any $\varepsilon > 0$. As mentioned, their results do not extend to the unit-disk graph. In addition, the query time of their algorithm is $O(1/\varepsilon)$. Recently, Gudmundsson et al. showed that when a geometric graph is a Euclidean spanner, there does exist an almost linear time (and therefore almost linear space) method to construct $(1 + \varepsilon)$ -approximate and $O(1)$ query time distance oracles [19]. Again, a unit-disk graph is not necessarily a Euclidean spanner with bounded stretch factor, and their technique does not extend.

3. Definitions. *Unit-disk graphs.* Denote by $d(\cdot, \cdot)$ the Euclidean metric. For a set of points S in the plane, the unit-disk graph $I(S) = (S, E)$ is defined to be the weighted graph where an edge $e = (p, q)$ is in the graph if $d(p, q) \leq 1$, and the weight of e is $d(p, q)$. Likewise, we can define the unit-ball graph for points in higher dimensions.

Metric space. Suppose that (S, π) is a metric space where S is a set of elements and π the distance function defined on $S \times S$. For any subset $S_1 \subseteq S$, the *diameter* $D_\pi(S_1)$ (or $D(S_1)$ when π is clear from the context) of S is defined to be $\max_{s_1, s_2 \in S_1} \pi(s_1, s_2)$. The *distance* $\pi(S_1, S_2)$ between two sets $S_1, S_2 \subseteq S$ is defined to be $\min_{s_1 \in S_1, s_2 \in S_2} \pi(s_1, s_2)$.

In this paper, we are interested in the *unit-disk graph metric* $\pi = \pi_{I(S)}$ induced by the unit-disk graph of a set of points S in the plane, where the distance between any two nodes is defined to be the length of the shortest path between them.

Well-separated pair decomposition. For a metric space (S, π) , two nonempty subsets $S_1, S_2 \subseteq S$ are called *c-well-separated* if $\pi(S_1, S_2) \geq c \cdot \max(D_\pi(S_1), D_\pi(S_2))$.

Following the definition in [10], for any two sets A and B , a set of pairs $\mathcal{P} = \{P_1, P_2, \dots, P_m\}$, where $P_i = (A_i, B_i)$, is called a *pair decomposition* of (A, B) (or of A if $A = B$) if

- for all the i 's, $A_i \subseteq A$ and $B_i \subseteq B$;
- $A_i \cap B_i = \emptyset$;
- for any two elements $a \in A$ and $b \in B$, there exists a unique i such that $a \in A_i$ and $b \in B_i$. We call (a, b) is *covered* by the pair (A_i, B_i) .

FIG. 4.1. An example of the decomposition tree.

If in addition, every pair in \mathcal{P} is c -well-separated, \mathcal{P} is called a c -well-separated pair decomposition (c -WSPD). Clearly, any metric space admits a c -WSPD with quadratic size by using the trivial family that contains all the pairwise elements.

4. Well-separated pair decomposition for unit-disk graph metric. We start with the point set with constant bounded density. Then, by combining with geometric well-separated pair decomposition, we show the extension of the result to arbitrary point sets. We will focus our discussion on points in the plane, but most results extend to higher dimensions, resulting in subquadratic size well-separated pair decomposition. We also show that our bounds in \mathbb{R}^k for $k \geq 3$ are tight.

4.1. Point sets with constant bounded density. The density α of a point set S is defined to be the maximum number of points in S covered by a unit disk. S has constant bounded density if its density is $O(1)$. We assume that the unit-disk graph on S is connected; otherwise, we can consider each connected component separately.

To construct a well-separated pair decomposition, we first compute the unit-disk graph $I(S)$ of S and then a spanning tree T of $I(S)$, where the maximum degree of T is 6. This can be done by computing the relative neighborhood graph of S [37] and keeping those edges with length at most 1. Let G be the resulting graph. It is well known that G is connected, and the degree of G is at most 6. We then compute a spanning tree of G . This step takes $O(n \log n)$ time [33]. It is also known that any n -vertex tree with maximum degree $\beta - 1$ can be divided into two parts by removing a single edge so that each subtree contain at least n/β vertices. We now recursively apply the balanced partitioning to obtain a balanced hierarchical decomposition of T (see Figure 4.1). The decomposition can be represented as a rooted binary tree T' where each node $v \in T'$ corresponds to a (connected) subtree $T(v)$ of T . The root of T' corresponds to T , and for a node $v \in T'$, v 's two children v_1, v_2 represent the two connected subtrees $T(v_1)$ and $T(v_2)$ obtained by removing an edge from $T(v)$. We denote by $S(v)$ the set of points in the subtree in $T(v)$. For a node $v \in T'$, denote by $P(v)$ the parent node of v in T' . We also use $P(S(u))$ to denote $S(P(u))$. The height of the tree T' is obviously $O(\log n)$.

Now, we describe a procedure to produce a c -WSPD of S .

For each node $v \in T'$, we pick an arbitrary point from $S(v)$ as a representative of $S(v)$ and denote it by $\sigma(S(v))$ (or $\sigma(v)$). We place in a queue the pair $(S(r), S(r))$, where r is the root of T' . We run the following process until the queue becomes empty: repeatedly remove the first element $(S(v_1), S(v_2))$ from the queue. There are two cases:

- $d(\sigma(v_1), \sigma(v_2)) \geq (c+2) \cdot \max(|S(v_1)|-1, |S(v_2)|-1)$. In this case, we include the pair to \mathcal{P} .
- $d(\sigma(v_1), \sigma(v_2)) < (c+2) \cdot \max(|S(v_1)|-1, |S(v_2)|-1)$. If $|S(v_1)| = |S(v_2)| = 1$, then it must be the case that $S(v_1)$ and $S(v_2)$ contain the same point. In this case, we simply discard the pair. Otherwise, suppose that $|S(v_1)| \geq |S(v_2)|$ and that u_1, u_2 are two children of v_1 . We add to the queue two pairs $(S(u_1), S(v_2))$ and $(S(u_2), S(v_2))$.

The above process is very similar to the collision detection algorithm in [20] except that here a pair is produced when they are c -well-separated. We now make the following claims.

LEMMA 4.1. *\mathcal{P} is a c -WSPD of S . Furthermore, each ordered pair of distinct points (p, q) is covered by exactly one pair in \mathcal{P} .*

Proof. By the construction, a pair $(S(v_1), S(v_2))$ is included in \mathcal{P} if and only if $d(\sigma(v_1), \sigma(v_2)) \geq (c+2) \cdot \max(|S(v_1)|-1, |S(v_2)|-1)$. Since for any $v \in T'$, $S(v)$ is connected, $D_\pi(S(v)) \leq |S(v)|-1$. In addition, $\pi(p, q) \geq d(p, q)$. Thus, we have that

$$\begin{aligned}
& \pi(S(v_1), S(v_2)) \\
& \geq \pi(\sigma(v_1), \sigma(v_2)) - (D_\pi(S(v_1)) + D_\pi(S(v_2))) \\
& \geq d(\sigma(v_1), \sigma(v_2)) - 2 \max(|S(v_1)|-1, |S(v_2)|-1) \\
& \geq c \cdot \max(|S(v_1)|-1, |S(v_2)|-1) \\
& \geq c \cdot \max(D_\pi(S(v_1)), D_\pi(S(v_2))).
\end{aligned}$$

That is, every pair in \mathcal{P} is a c -well-separated pair. The process clearly ends. To argue that \mathcal{P} covers all the pairs of distinct points, we observe that we begin with the pair $(S(r), S(r))$ that covers all the pairs, and each time when we split a node, the union of the pairs covered remain the same. The pairs we discard are of the form $(\{p\}, \{p\})$. Thus, all the ordered pairs of distinct points are covered by \mathcal{P} . Since the splitting produces two disjoint sets, each ordered pair is covered exactly once. \square

The following lemma shows that the sizes of two sets in the same pair do not differ too much.

LEMMA 4.2. *Each pair (A, B) that ever appears in the queue satisfies $1/\beta \leq |A|/|B| \leq \beta$.*

Proof. The proof is done by induction. Clearly, it is true for the pair $(S(r), S(r))$. Now, consider the splitting that generates the pair (A, B) . Without loss of generality, assume that we split $P(B)$, the parent node of B . By the splitting rule, we have that $|A| \leq |P(B)|$. By induction hypothesis, $|A| \geq |P(B)|/\beta \geq |B|/\beta$. Since the splitting is balanced, $|B| \geq |P(B)|/\beta \geq |A|/\beta$. Therefore $1/\beta \leq |A|/|B| \leq \beta$. \square

Now, we bound the size of \mathcal{P} .

LEMMA 4.3. *If $(A, B_i) \in \mathcal{P}$, $i = 1, \dots, m(A)$, then $B_i \cap B_j = \emptyset$, and $m(A) = O(c^2|A|)$.*

Proof. By Lemma 4.1, each pair of points can be covered only once; thus $B_i \cap B_j = \emptyset$ if both (A, B_i) and (A, B_j) are in \mathcal{P} .

If $(A, B_i) \in \mathcal{P}$, then $(P(A), P(B_i))$ is not in \mathcal{P} . So $d(\sigma(P(A)), \sigma(P(B_i))) < (c+2) \cdot \max(|P(A)|-1, |P(B_i)|-1)$. Set $R = \beta|P(A)| \leq \beta^2|A|$. If we split $P(B_i)$ to get the pair (A, B_i) , then $(A, P(B_i))$ appeared in the queue, by Lemma 4.2, we have $|P(B_i)| \leq \beta|A| \leq \beta|P(A)| = R$. If we split $P(A)$ to get the pair (A, B_i) , then $|B_i| \leq |P(A)|$, so $|P(B_i)| \leq \beta|B_i| \leq \beta|P(A)| = R$. Then,

$$d(\sigma(P(A)), \sigma(P(B_i))) < (c+2)R, D_\pi(P(B_i)) \leq R.$$

Then all the points in B_i must be inside a disk of radius $(c+3)R$ centered at $\sigma(P(A))$. Therefore we have that $|\cup_{i=1}^{m(A)} B_i| = O((c+3)^2 R^2)$ because S has constant

bounded density. By Lemma 4.2, we know that $|B_i| \geq |A|/\beta \geq |P(A)|/\beta^2$. Thus, $|B_i| \geq R/\beta^3$. Then, we have that $m(A) = O((c+3)^2 R^2/(R/\beta^3)) = O(c^2 R) = O(c^2 |A|)$. \square

LEMMA 4.4. $|\mathcal{P}| = O(c^2 n \log n)$.

Proof. Define $V_i = \{v \in T' \mid |S(v)| \in [2^i, 2^{i+1})\}$ for $0 \leq i \leq \log n$. Clearly, $|V_i| = O(n/2^i)$. Define $\Sigma_i = \{(S(v), B) \in \mathcal{P} \mid v \in V_i\}$. Denote by $m(S(v))$ the total number of pairs in which $S(v)$ is involved. By Lemma 4.3, we have that

$$\begin{aligned} |\Sigma_i| &= \sum_{v \in V_i} m(S(v)) = \sum_{v \in V_i} O(c^2 |S(v)|) \\ &= O(c^2 2^{i+1} \cdot n/2^i) = O(c^2 n). \end{aligned}$$

Thus, $|\mathcal{P}| = \sum_{i=0}^{\log n} |\Sigma_i| = O(c^2 n \log n)$. \square

Combining the above result, we now have the following theorem.

THEOREM 4.5. *For any n points with constant-bounded density in the plane and any $c \geq 1$, there exists a c -WSPD with $O(c^2 n \log n)$ pairs, which can be computed in $O(c^2 n \log n)$ time.*

Proof. Clearly, the time needed is proportional to the number of pairs that ever appear in the queue. We can represent the construction as a tree: each pair corresponds to a node in the tree, and when a pair is split, we treat those two resulting pairs as the children of the pair. Clearly, the leaves of the tree correspond to those pairs included in \mathcal{P} and the pairs discarded. All the discarded pairs have the form $(\{p\}, \{p\})$, and there are $O(n)$ such pairs. Thus, the total number of nodes in the tree is bounded by $O(|\mathcal{P}|) = O(c^2 n \log n)$. Each split costs $O(1)$. Therefore, the total computation cost is $O(c^2 n \log n)$. \square

The result can be easily extended to the point set with maximum density α .

COROLLARY 4.6. *For a point set with maximum density α , for any $c \geq 1$, a c -WSPD with $O(\alpha c^2 n \log n)$ pairs can be constructed in $O(\alpha c^2 n \log n)$ time.*

Proof. If the point set has maximum density α , Lemma 4.3 still holds if we change $m(A)$ to $O(\alpha c^2 |A|)$. Substituting the value in Lemma 4.4, we have that $|\mathcal{P}| = O(\alpha c^2 n \log n)$. The claim then follows from Theorem 4.5. \square

By a similar argument, we can extend the result to higher dimensions.

THEOREM 4.7. *Given a point set in \mathbb{R}^k , where $k \geq 3$, with constant bounded density and any constant $c \geq 1$, there exist a c -WSPD with $O(n^{2-2/k})$ pairs for the unit-ball graph metric. This bound is tight in the worst case. And the decomposition can be computed in $O(n^{2-2/k})$ time.*

Proof. We first compute a spanning tree of S with constant maximum degree β_k , a constant dependent on k only. This can be done by using the technique in [4]. We then follow the same process as described above. The upper bound follows from the same packing argument as in Lemma 4.4. Lemma 4.3 can be changed so that the number of pairs associated with a node A is $m(A) = O(|A|^{k-1})$. In addition, by Lemma 4.2, for any pair $(A, B) \in P$, $1/\beta_k \leq |A|/|B| \leq \beta_k$. Thus, $m(A) = O(n/|A|)$. Define V_i as in Lemma 4.4, $|V_i| = O(n/2^i)$. When $0 \leq i \leq \frac{1}{k} \log n$, $|\Sigma_i| = \sum_{v \in V_i} m(S(v)) = O(\sum_{v \in V_i} |S(v)|^{k-1}) = O(2^{i(k-1)} \cdot n/2^i) = O(n2^{i(k-2)})$. When $i > \frac{1}{k} \log n$, $|\Sigma_i| = \sum_{v \in V_i} m(S(v)) = O(\sum_{v \in V_i} n/|S(v)|) = O((n/2^i)^2)$. Therefore,

$$\begin{aligned} |\mathcal{P}| &= \sum_{0 \leq i \leq \frac{1}{k} \log n} n2^{i(k-2)} + \sum_{\frac{1}{k} \log n < i \leq \log n} O(n^2/2^{2i}) \\ &= O(n^{2-2/k}). \end{aligned}$$

FIG. 4.2. A lower bound example of the well-separated pair decomposition for points in $k = 3$ dimensions. The shaded dots are tip points.

As for the lower bound, consider the points on the k -dimensional grid $[0, n^{1/k}) \times \dots \times [0, n^{1/k})$. Define a graph G with edges between pairs of points $(x_1, \dots, x_i, \dots, x_k)$ and $(x_1, \dots, x_i + 1, \dots, x_k)$ for $i = 1$, or $x_1 = 0$ and $i \geq 2$. A point $(n^{1/k} - 1, x_2, \dots, x_k)$ for $0 \leq x_i < n^{1/k}$ is called a *tip point*. Intuitively, G can be thought as a graph where the tip points dangle down from a $(k - 1)$ -dimensional mesh. See Figure 4.2. Clearly, we can perturb the point set so that its unit-ball graph equals G . The metric defined by G has the following property: (i) the diameter of G is $kn^{1/k}$; (ii) the distance between any two tip points is at least $2n^{1/k}$. Therefore, when $c > k/2$, a c -WSPD cannot have two tip points in the same set of a pair. Since there are $\Theta(n^{1-1/k})$ tip points, $\Omega(n^{2-2/k})$ pairs are needed, just to separate those tip points.

By the same argument as in Theorem 4.5, it is easily seen that the c -WSPD can be computed in $O(n^{2-2/k})$ time. \square

4.2. Arbitrary point sets. The packing argument fails for the unit-disk graph of point sets with unbounded density. However, we can reduce the problem to the constant density case by first clustering the points and then considering those crowded points separately by using geometric well-separated pair decompositions.

For $0 \leq \delta \leq 1$, a point p is δ -covered (or simply covered) by a point s if $d(s, p) \leq \delta$. Denote by $U(s)$ the set of points δ -covered by s . A subset $X \subseteq S$ is called a δ -cover of S if any point in S is δ -covered by some point in X . We call the points in a δ -cover X *clusterheads*. For each point in S , we assign it to the nearest clusterhead. Thus X induces a partitioning of S into sets $C(s) = S \cap \text{Vor}(s)$, where $\text{Vor}(s)$ denotes the Voronoi cell of s in X . Clearly, for any $p \in C(s)$, $d(s, p) \leq \delta$, i.e., $C(s) \subseteq U(s)$. A δ -cover is called *minimal* if no two points in X are within distance δ to each other. For any set $A \subseteq X$, denote by \hat{A} the set $\hat{A} = \cup_{s \in A} C(s)$.

To deal with an arbitrary point set S , we first compute a minimal cover X of S with an appropriately chosen δ . We then apply our results on constant-bounded density point sets to X . Note that we cannot use the unit-disk graph on X because it may not have the same connectivity as the unit-disk graph on S . Denote any two points s_1, s_2 in X *neighbors* if $d(s_1, s_2) > 1$, and there exist two points $p_1 \in C(s_1)$ and $p_2 \in C(s_2)$ such that $d(p_1, p_2) \leq 1$. We call the pair (p_1, p_2) a *bridge* between s_1 and s_2 . For each neighboring pair, we only pick one bridge arbitrarily. Let Y denote the set of all bridge points. Consider the point set $Z = X \cup Y$. Let π' denote the unit-disk graph metric on the set Z . Now, we make the claim in the next lemma.

LEMMA 4.8. X has $O(1/\delta^2)$ -density. Z can be computed in $O(n \log n/\delta^2)$ time.

Proof. Any two points s_1, s_2 in a minimal cover X are of at least distance δ away from each other. Therefore, there are $O(1/\delta^2)$ points of X inside any unit disk. So X has $O(1/\delta^2)$ density.

To compute X , we can use a greedy algorithm with the assistance of a dynamic point location data structure of unit disks [11]. The algorithm runs in $O(n \log n)$ time. To compute all the neighboring pairs, we can enumerate all the pairs (s_1, s_2) , where s_2 is inside the square centered at s_1 and with side-length $2(1 + 2\delta)$. There are $O(n/\delta^2)$ such pairs according to Lemma 4.8, and they can be computed in $O(n \log n/\delta^2)$ time by using a standard rectangular range searching data structure. Call such pairs *candidate pairs*. Clearly, only a candidate pair can possibly be a neighboring pair. To find a bridge between two clusterheads s_1, s_2 of a candidate pair, we can compute the bichromatic closest pair between two sets $C(s_1), C(s_2)$. In the plane, this can be done in $O(|U(s_1) \cup U(s_2)| \log n)$ time. Since we need only to examine each clusterhead against $O(1/\delta^2)$ clusterheads, the total computation time is bounded by $O(n \log n/\delta^2)$ [1]. \square

Now we show that π' approximates π well on the set X .

LEMMA 4.9. For any two points $p, q \in X$,

$$\pi(p, q) \leq \pi'(p, q) \leq (1 + 12\delta)\pi(p, q) + 12\delta.$$

Proof. Since $Z \subseteq S$, $\pi(p, q) \leq \pi'(p, q)$. On the other hand, assume that $p_0 p_1 \cdots p_m$, where $p_0 = p$ and $p_m = q$ is a shortest path between p and q in the unit-disk graph of S . For $0 \leq i \leq m$, suppose that s_i is the clusterhead that covers p_i . Note that $s_0 = p$ and $s_m = q$ as $p, q \in X$.

Consider two consecutive points p_i, p_{i+1} . If $s_i = s_{i+1}$, then $d(p_i, p_{i+1}) \leq 2\delta$. Otherwise, suppose that $s_i \neq s_{i+1}$. If $d(s_i, s_{i+1}) \leq 1$, then $\pi'(s_i, s_{i+1}) = d(s_i, s_{i+1}) \leq d(p_i, p_{i+1}) + 2\delta$. If $d(s_i, s_{i+1}) > 1$, then s_i, s_{i+1} must be a neighboring pair since $d(p_i, p_{i+1}) \leq 1$. In this case, it is easy to verify that $\pi'(s_i, s_{i+1}) \leq d(p_i, p_{i+1}) + 6\delta$. Thus,

$$\begin{aligned} \pi'(p, q) &\leq \sum_{i=0}^{m-1} \pi'(s_i, s_{i+1}) \\ &\leq \sum_{i=0}^{m-1} d(p_i, p_{i+1}) + 6m\delta \leq \pi(p, q) + 6m\delta. \end{aligned}$$

Since $p_0 p_1 \cdots p_m$ is a shortest path, $d(p_i, p_{i+2}) \geq 1$ for any $0 \leq i \leq m - 2$ because otherwise the path could be shortened due to triangular inequality. That is, $\pi(p, q) \geq \lfloor m/2 \rfloor > m/2 - 1$, i.e., $m < 2(\pi(p, q) + 1)$. Thus we have that $\pi'(p, q) \leq (1 + 12\delta)\pi(p, q) + 12\delta$. \square

Before we describe the construction of c -WSPD for S , we need a straightforward extension of geometric well-separated pair decomposition in [10] to two separable point sets.

LEMMA 4.10. Suppose that A and B are two point sets that can be separated by a line and have n points in total. For any constant $c \geq 1$, there exists a geometric c -well-separated pair decomposition of (A, B) with $O(n)$ pairs.

Proof. This can be done by modifying the algorithm in [10] so that the first split of the point set of $A \cup B$ is by the line that separates A and B . \square

Now, we describe a process that produces a c -WSPD of S for any $c \geq 1$. Set $\delta = 1/(2c + 4)$ and $c' = 9(c + 14)$. We first construct a minimal δ -cover X and the

set Z as described above. Next we compute a c' -well-separated pair decomposition of the clusterheads X in the unit-disk graph metric of point set Z . Specifically, we give weight 1 to points in X and 0 to bridge points. We find the spanning tree T of the unit-disk graph $I(Z)$. T has total weight $|X|$. We then recursively find balanced weighted decomposition of T : by removing an edge, each subtree has weight at least $1/\beta$ times the weight of the parent. Since X has a bounded density $O(1/\delta^2)$, the packing argument is still valid and we can compute a c' -well-separated pair decomposition for X . Suppose the decomposition obtained is $\mathcal{P} = \{P_1, P_2, \dots, P_m\}$, where $P_i = (A_i, B_i)$, $A_i \subseteq X$, $B_i \subseteq X$. We now create a set of pairs $\mathcal{P}' = \mathcal{P}'_1 \cup \mathcal{P}'_2 \cup \mathcal{P}'_3$ as follows:

1. For each $P_i \in \mathcal{P}$, if $|A_i| > 1$ or $|B_i| > 1$, we include in \mathcal{P}'_1 the pair $P'_i = (\hat{A}_i, \hat{B}_i)$. Recall that $\hat{A} = \cup_{s \in A} C(s)$.
2. If $|A_i| = |B_i| = 1$, suppose that $A_i = \{a\}$ and $B_i = \{b\}$. If $d(a, b) \geq (2c+2)\delta$, we then include in \mathcal{P}'_1 the pair $P'_i = (\hat{A}_i, \hat{B}_i)$. Otherwise, any pair of points in $\hat{A}_i \cup \hat{B}_i$ is within distance $(2c+2)\delta + 2\delta = 1$. Since $\hat{A}_i \subset \text{Vor}(a)$, and $\hat{B}_i \subset \text{Vor}(b)$, \hat{A}_i and \hat{B}_i are separable by a line. Per Lemma 4.10, we compute a geometric c -WSPD of (\hat{A}_i, \hat{B}_i) and include in \mathcal{P}'_2 all the pairs produced this way.
3. For every $s \in X$, we compute a geometric c -WSPD of $C(s)$ and include into \mathcal{P}'_3 all the pairs produced.

Now, we make the next claim.

LEMMA 4.11. \mathcal{P}' is a c -WSPD of S .

Proof. We first argue that \mathcal{P}' is a pair decomposition of S . For any pair of points $s_1, s_2 \in S$, suppose that the clusterheads covering them are s'_1 and s'_2 , respectively. If $s'_1 \neq s'_2$, then (s_1, s_2) is covered by a pair in $\mathcal{P}'_1 \cup \mathcal{P}'_2$. Otherwise, it is covered by a pair in \mathcal{P}'_3 . It is also easily verified that each ordered pair is covered exactly once.

Now, we show that all the pairs in \mathcal{P}' are c -well-separated with respect to the unit-disk graph metric. Since $\delta = 1/(2c+4)$, for all the pairs in \mathcal{P}'_2 , the Euclidean distance between any two points in $\hat{A}_i \cup \hat{B}_i$ is at most $(2c+4)\delta = 1$. Therefore, the unit-disk graph on the subset $\hat{A}_i \cup \hat{B}_i$ is a complete graph, i.e., every pair in \mathcal{P}'_2 is c -well-separated under the unit-disk graph metric. The same argument applies to \mathcal{P}'_3 as the distance between two points in $C(s)$ is at most $2\delta \leq 1$.

Now, consider a pair $(\hat{A}_i, \hat{B}_i) \in \mathcal{P}'_1$. We distinguish two cases:

1. When $|A_i| = |B_i| = 1$. Then we must have $\pi(A_i, B_i) \geq (2c+2)\delta$ according to the construction rule, and thus

$$\pi(\hat{A}_i, \hat{B}_i) \geq \pi(A_i, B_i) - 2\delta \geq 2c\delta = c/(c+2).$$

On the other hand, $D(\hat{A}_i), D(\hat{B}_i) \leq 2\delta = 1/(c+2)$. Therefore, (\hat{A}_i, \hat{B}_i) is c -well-separated.

2. When $|A_i| > 1$ or $|B_i| > 1$. In what follows, we use D and D' to denote $D_\pi, D_{\pi'}$, respectively. Clearly,

$$\pi(\hat{A}_i, \hat{B}_i) \geq \pi(A_i, B_i) - 2\delta, \text{ and } D(\hat{A}) \leq D(A) + 2\delta.$$

Since either A_i or B_i contains at least two clusterheads, it must be true that $\max(D(A_i), D(B_i)) \geq \delta$, as the distance between two clusterheads is at least δ . So, $\max(D(\hat{A}_i), D(\hat{B}_i)) \geq \delta$, and $\max(D(\hat{A}_i), D(\hat{B}_i)) \leq \max(D(A_i), D(B_i)) + 2\delta \leq 3 \max(D(A_i), D(B_i))$.

As A_i, B_i are c' -well-separated under π' , $\pi'(A_i, B_i) \geq c' \cdot \max(D'(A_i), D'(B_i))$.

Therefore,

$$\begin{aligned}
\pi(\hat{A}_i, \hat{B}_i) &\geq \pi(A_i, B_i) - 2\delta \\
&\geq (\pi'(A_i, B_i) - 12\delta)/(1 + 12\delta) - 2\delta \\
&\quad \text{by Lemma 4.9} \\
&\geq c'/(1 + 12\delta) \cdot \max(D'(A_i), D'(B_i)) - 14\delta \\
&\geq c'/(1 + 12\delta) \cdot \max(D(A_i), D(B_i)) - 14\delta \\
&\geq (c'/(3(1 + 12\delta)) - 14) \cdot \max(\hat{D}(A_i), \hat{D}(B_i)) \\
&\geq c \max(D(\hat{A}_i), D(\hat{B}_i)). \\
&\quad \text{by } c \geq 1, \delta = 1/(2c + 4), \text{ and } c' = 9(c + 14).
\end{aligned}$$

In both cases, \hat{A}_i, \hat{B}_i are c -well-separated, i.e., all the pairs in \mathcal{P}'_1 are c -well-separated. \square

Now, we make the claim in the next theorem.

THEOREM 4.12. *For any set S of n points in the plane and any $c \geq 1$, there exists a c -WSPD \mathcal{P} of S under the unit-disk graph metric where \mathcal{P} contains $O(c^4 n \log n)$ pairs and can be computed in $O(c^4 n \log n)$ time.*

Proof. By combining Corollary 4.6 and Lemma 4.8, we have that $|\mathcal{P}'_1| \leq |\mathcal{P}| = O(c^2 n \log n / \delta^2) = O(c^4 n \log n)$. If $|A_i| = 1$, then the number of pairs $(A_i, B_i) \in \mathcal{P}'_2$ where $|B_i| = 1$ is bounded by $O(1/\delta^2) = O(c^2)$. Since the size of the geometric well-separated pair decomposition is linear in terms of the number of points [10], $|\mathcal{P}'_2| = O(c^2 n)$. Clearly, $|\mathcal{P}'_3| = O(n)$. When we sum the sizes, we have that $|\mathcal{P}'| = O(c^4 n \log n)$.

By Theorem 4.5 and Lemma 4.8, it is easy to see that the total time needed is $O(c^4 n \log n)$. \square

Similarly, in higher dimensions, we have the next corollary.

COROLLARY 4.13. *For any set S of n points in \mathbb{R}^k , for $k \geq 3$, and for any constant $c \geq 1$, there exists a c -WSPD \mathcal{P} of S under the unit-ball graph metric where \mathcal{P} contains $O(n^{2-2/k})$ pairs and can be constructed in $O(n^{4/3} \text{polylog } n)$ time for $k = 3$ and in $O(n^{2-2/k})$ time for $k \geq 4$.*

Proof. For simplicity of computation, we use boxes instead of balls to find clusterheads with constant bounded density. A point p is covered by a point s if p is inside the box with size 2δ centered at s . Finding the minimal cover can be done by using a dynamic rectilinear range search tree in k -dimensions [11]. The running time is $O(n \text{polylog } n)$. Notice that every point can be covered by at most a constant number of clusterheads; thus we can find the nearest clusterhead for every point in linear time in total. To find a bridge between two clusterheads s_1, s_2 , we compute the bichromatic closest pair between two sets $C(s_1), C(s_2)$. Let $m_1 = |C(s_1)|$ and $m_2 = |C(s_2)|$. According to [1], when $k = 3$, it takes $O((m_1 m_2)^{2/3} \text{polylog } n)$ time, and when $k = 4$, it is

$$\begin{aligned}
&O((m_1 m_2)^{1-1/(\lceil k/2 \rceil + 1)+\epsilon} + m_1 \log m_2 + m_2 \log m_1) \\
&= O((m_1 m_2)^{1-1/k} + m_1 \log m_2 + m_2 \log m_1).
\end{aligned}$$

Since each set is involved only in $O(1)$ bichromatic closest pair computation, the total time is $O(n^{4/3} \text{polylog } n)$ when $k = 3$ and $O(n^{2-2/k})$ for $k \geq 4$. Computing the WSPD on the clusterheads takes $O(n^{2-2/k})$ time, according to Theorem 4.5. \square

4.3. Estimating distance between pairs. In the above, we showed how to construct well-separated pair decomposition for unit-disk and unit-ball graphs. As mentioned in the introduction, to apply WSPD in solving proximity problems in

the unit-disk graphs, we first need to estimate the shortest path distances between $O(n \log n)$ pairs of the WSPD. Note that in our construction for the point sets with constant bounded density, we use Euclidean distance as a lower bound for the unit-disk graph distance and the size of the point set as an upper bound for the diameter. While these approximations are sufficient for bounding the size of WSPDs, they are too coarse for obtaining good approximation. Recall that $\sigma(A)$ is an (arbitrary) point picked from a set A . For a c -well-separated pair (A, B) , we can use the estimated distance $\hat{\pi}(\sigma(A), \sigma(B))$ to approximate all the pairwise distances between points in A and points in B . In this section, we show several trade-offs for measuring the distance between m pairs of points in the unit-disk graph.

Denote by $\tau(n, c, m)$ the time needed to compute m -pairs c -approximate distance in a unit disk graph. In what follows, we set $c_0 = 2.42 > \frac{4\sqrt{3}}{9}\pi$ and c_1 a number slightly smaller than c_0 but greater than $\frac{4\sqrt{3}}{9}\pi$.

LEMMA 4.14.

1. $\tau(n, c_1, m) = O(n \log^3 n + m)$.
2. $\tau(n, 1 + \varepsilon, m) = O(n^2/(\varepsilon r) + mr/\varepsilon)$, for any $1 \leq r \leq n$.

Proof. 1. We first construct a planar $\frac{4\sqrt{3}}{9}\pi$ -spanner of the unit disk graph. Such spanner exists and can be computed in $O(n \log n)$ time [26]. Now, we apply Thorup's construction of $(1 + \varepsilon)$ -approximate distance oracle [35] to that planar spanner, for a sufficiently small constant $\varepsilon > 0$. The bound follows immediately from the preprocessing and query time bounds of Thorup's algorithm.

2. We again cluster the points and consider the set of clusterheads, X . Suppose that we have constructed a $(1 + \varepsilon/2)$ -approximate shortest distance oracle for X . For two query points q_1, q_2 , if $d(q_1, q_2) \leq 1$, we return $d(q_1, q_2)$. Otherwise, we find the clusterheads s_1, s_2 that cover q_1 and q_2 , respectively, and return $\hat{\pi}(q_1, q_2) = \pi'(s_1, s_2) + 2\delta$ as an approximation of $\pi(q_1, q_2)$. It is easily verified that $\hat{\pi}(q_1, q_2)$ is a $(1 + \varepsilon)$ -approximation for $\delta = O(\varepsilon)$. The density of X is $O(1/\delta^2) = O(1/\varepsilon^2)$. The graph formed by connecting neighboring pairs in X is an $O(1/\varepsilon^2)$ -overlap graph as defined by Miller, Teng, and Vavasis [28] and therefore admits a balanced separator with size $O(\sqrt{n}/\varepsilon)$. Furthermore, it can be computed in deterministic linear time by the method of Eppstein, Miller, and Teng [13].

Now, it is easy to extend the shortest distance algorithm for planar graphs by Arikati et al. [3] to the above geometric graph on X . By using the same technique, we can obtain a trade-off with $O(n^2/(\varepsilon r))$ preprocessing time and $O(r/\varepsilon)$ query time for any $1 \leq r \leq \sqrt{n}$. \square

5. Applications. In this section, we show the application of the well-separated pair decomposition in obtaining efficient algorithms for approximating the furthest neighbor (diameter, center), nearest neighbor (closest pair), median, and stretch factor, all under the unit-disk graph metric. Since the running time of the algorithms for computing c_0 -approximate and $(1 + \varepsilon)$ -approximate distance are different, we will be describing the bounds for both approximations (recall that $c_0 = 2.42$). Roughly speaking, our algorithms for computing c_0 -approximation is about linear and for computing $(1 + \varepsilon)$ -approximation is about $O(n\sqrt{n})$, dominated by the distance estimation.

We should note that for the problems of computing diameter and center, there is a simple linear time method to achieve 2-approximation. It is therefore not interesting to present algorithms to obtain c_0 -approximation for those problems, with $c_0 = 2.42$. For the other problems, it is still interesting, as we are not aware of any algorithms that achieve comparable approximation ratio in subquadratic time, even for planar graphs.

We need first to describe the well-separated pair decomposition we will be using. In what follows, we also include the time for measuring the distances between pairs into the construction time. For c_0 -approximation, $c_0 = 2.42$, we construct a c -well-separated pair decomposition \mathcal{P}_1 for sufficiently large constant c and, for each pair (A, B) in the WSPD, compute c_1 -approximate distance $\hat{\pi}_1(A, B)$ between $\sigma(A)$ and $\sigma(B)$ according to Lemma 4.14.1. For $(1 + \varepsilon)$ -approximation, we compute a c -well-separated pair decomposition \mathcal{P}_2 for $c = O(1/\varepsilon)$ and, for each pair (A, B) , compute the $(1 + \varepsilon/2)$ -approximate distance $\hat{\pi}_2(A, B)$ between $(\sigma(A), \sigma(B))$ by Lemma 4.14.2 and by setting $r = \varepsilon^2 \sqrt{n/\log n}$. The following is immediate.

LEMMA 5.1. *\mathcal{P}_1 contains $O(n \log n)$ pairs and can be computed in $O(n \log^3 n)$ time. \mathcal{P}_2 contains $O(n \log n/\varepsilon^4)$ pairs and can be computed in $O(n\sqrt{n \log n}/\varepsilon^3)$ time. For any pair of points (p, q) , suppose that its covering pair in \mathcal{P}_1 (\mathcal{P}_2) is (A, B) ; then $\hat{\pi}_1(A, B)$ ($\hat{\pi}_2(A, B)$) is a c_0 -approximation ($(1 + \varepsilon)$ -approximation) of $\pi(p, q)$, $c_0 = 2.42$.*

In the process of producing a well-separated pair decomposition, we constructed several trees, the balanced hierarchical decomposition tree for constant bounded density points and the fair split trees for geometric well-separated pair decomposition [10]. For simplicity of presentation, we treat them as a single tree T'_1 and T'_2 , for \mathcal{P}_1 and \mathcal{P}_2 , respectively, by joining the trees created in the geometric well-separated pair decomposition to the clusterheads appropriately. In what follows, $\mathcal{P}, T', \hat{\pi}$ mean that they could be either case.

5.1. $(1 + \varepsilon)$ -distance oracle. Although \mathcal{P}_2 takes time $O(n\sqrt{n \log n}/\varepsilon^3)$, the space needed is only $O(n \log n/\varepsilon^4)$. We can use \mathcal{P}_2 to answer $(1 + \varepsilon)$ -approximate distance query between any two points (p_1, p_2) by first locating the pair (A, B) that covers (p, q) and returning $\hat{\pi}(A, B)$. The query time is the time needed to discover a pair in \mathcal{P}_2 that covers the query pair. We show that this can be done in $O(1)$ time by using the properties of WSPD.

COROLLARY 5.2. *For a unit-disk graph on n points and for any $\varepsilon > 0$, we can preprocess it into a data structure with $O(n \log n/\varepsilon^4)$ size so that for any query pair, a $(1 + \varepsilon)$ -approximate distance can be answered in $O(1)$ time.*

Proof. It suffices to prove for constant-bounded density point sets. We store all the pairs in \mathcal{P} in a hash table indexed by the pairs. We will show that for each query pair (p, q) , we can find $O(1)$ candidate pairs that are guaranteed to contain the pair in \mathcal{P} that covers (p, q) . Then, we simply query the hash table using those candidate pairs and discover the one that does cover (p, q) .

We modify our construction in section 4.1 so that we are more careful on deciding when to include a pair in \mathcal{P} . We use a c_1 -approximate distance oracle as constructed in Lemma 4.14.1. When producing \mathcal{P} , we include a pair in \mathcal{P} if $\hat{\pi}(A, B) > (cc_1 + 2) \max(|A| - 1, |B| - 1)$. Then there is a constant $c_2 > 0$ such that for any $c \geq 2$ and any pair $(A, B) \in \mathcal{P}$, $cc_1 s \leq \pi(A, B) \leq cc_2 s$, where $s = \max(|A| - 1, |B| - 1)$.

Now, to answer a query (p, q) , we first use the c_1 -approximate distance oracle to compute an approximation ℓ of $\pi(p, q)$, i.e., $\pi(p, q) \leq \ell \leq c_1 \pi(p, q)$. Suppose that $(A, B) \in \mathcal{P}$ is the pair that covers (p, q) . Without loss of generality, let us assume that $|A| \geq |B|$, i.e., $s = |A| - 1$. Then we have

$$s \leq \pi(A, B)/(cc_1) \leq \pi(p, q)/(cc_1) \leq \ell/(cc_1).$$

On the other hand, $s \geq \pi(A, B)/(cc_2) \geq (\pi(p, q) - 2s)/(cc_2)$. That is, $s \geq \pi(p, q)/(cc_2 + 2) \geq \ell/(c_1(cc_2 + 2))$.

Set $\hat{\ell} = \ell/(cc_1)$. Then, for (A, B) to cover (p, q) , A has to be an ancestor of p in T' , and the size of A is sandwiched by $\hat{\ell}/(c_2 + 1)$ and $\hat{\ell}$. Notice that c_1, c_2 are constants independent of c . There are only $O(1)$ such nodes in T' . Similarly, there are only $O(1)$ such B 's. We now form $O(1)$ candidate pairs by joining every pair. Clearly, this can be done in $O(1)$ time. \square

5.2. Furthest neighbor. Suppose that $S_1 \subseteq S$. For any p , define the (relative) furthest neighbor of p to be $\xi(p) = \arg \max_{q \in S_1} \pi(p, q)$ in S_1 . Then the diameter of S_1 is $D(S_1) = \max_{p \in S_1} \pi(p, \xi(p))$. The center of S_1 is the point that minimizes the maximum distance to the other points, i.e., $\arg \min_{p \in S_1} \pi(p, \xi(p))$. Therefore, once we compute approximate furthest neighbors for all the p , we also obtain approximate diameter and center.

Consider any WSPD. To compute the furthest neighbor of S_1 , we traverse the balanced hierarchical decomposition tree T' and mark all the nodes $v \in T'$, where $S(v) \cap S_1 \neq \emptyset$. This can be done in $O(n)$ time in a postorder visit of the tree. A pair $P = (S(u), S(v))$ is called *marked* if both u and v are marked. Let

$$R_1(u) = \max\{\hat{\pi}(S(u), B) \mid (S(u), B) \text{ is marked}\}$$

and 0 if there is no such pair. With each node u , we also record $\ell(u)$, the node that achieves $R_1(u)$.

For any $p \in S_1$, consider the path P in T' from p to the root. Suppose that u is the node that maximizes $R_1(u)$ among all the nodes on P . Now, we pick any point, say, q , from $S(\ell(u)) \cap S_1$ (since $\ell(u)$ is marked, $S(\ell(u)) \cap S_1 \neq \emptyset$) and claim that it is an approximate furthest neighbor with the approximation ratio 2.42, if the above process is applied to \mathcal{P}_1 , or $1 + \varepsilon$, if applied to \mathcal{P}_2 . For correctness, consider the (marked) pair in \mathcal{P} that covers $(p, \xi(p))$. Suppose it is $(S(u), S(v))$. Then $R_1(u) \geq \hat{\pi}(S(u), S(v))$. Since the pairs are well-separated, it is easy to see that q is an approximate furthest neighbor of p with the approximation ratio determined by the WSPD we use. After we have computed the approximate furthest neighbor, it is simple to compute the diameter and the center. Therefore, we have the next corollary.

COROLLARY 5.3. *For any set S of n points in the plane and any $S_1 \subseteq S$, we can compute*

- c_0 -approximate furthest neighbor for all the points in S_1 in $O(n \log^3 n)$ time, $c_0 = 2.42$; and
- $(1 + \varepsilon)$ -approximation, for any $\varepsilon > 0$, of the furthest neighbor, the diameter of S_1 , and the center of S_1 in $O(n\sqrt{n} \log n / \varepsilon^3)$ time.

Remark. We did not list c_0 -approximation ($c_0 = 2.42$) for the diameter and the center because there is a simple linear time 2-approximate algorithm.

5.3. Nearest neighbor, closest pair. Computing the nearest neighbor or closest pair in S under the unit-disk graph metric is trivial—it is the same as under the Euclidean metric as long as the graph is connected. However, the problem becomes harder if we restrict our attention to a subset $S_1 \subseteq S$, i.e., computing the nearest neighbor in S_1 for each point in S_1 or computing the closest pair between points in S_1 . For any two sets S_1, S_2 , we can also define the bichromatic closest pair to be $\arg \min_{p \in S_1, q \in S_2} \pi(S_1, S_2)$.

By using the same technique as in the previous section, we are able to show the next corollary.

COROLLARY 5.4. *For any set S of n points in the plane, and any $S_1, S_2 \subseteq S$, we can compute*

- c_0 -approximation ($c_0 = 2.42$) for the nearest neighbor for all the points in S_1 , the closest pair in S_1 , the bichromatic closest pair of S_1, S_2 , in time $O(n \log^3 n)$; and
- $(1 + \varepsilon)$ -approximation for the same problems in time $O(n\sqrt{n \log n}/\varepsilon^3)$.

Remark. We should note that by applying the technique in [10], we can actually enumerate a set of $O(n)$ pairs of points that is guaranteed to include the closest pair. However, since our distance oracle is approximate, we can compute only the approximate closest pair, unlike in the geometric case.

5.4. Median. Similar to the definition of center, median is defined to be the point that minimizes the average (or total) distance to all the other points. Let $\rho(p) = \sum_{q \in S_1} \pi(p, q)$. Then the median of S_1 is the point that minimizes $\rho(p)$.

By using a similar technique, we can show the following.

COROLLARY 5.5. *For any planar point set S with n points and $S_1 \subseteq S$, a c_0 -approximate median ($c_0 = 2.42$) of S_1 can be computed in $O(n \log^3 n)$ time, and for any $\varepsilon > 0$, a $(1 + \varepsilon)$ -approximation can be computed in $O(n\sqrt{n \log n}/\varepsilon^3)$ time.*

Proof. Computing approximate median is similar to computing the furthest neighbor. The only difference is that instead of computing $R_1(u)$, we compute

$$R_2(u) = \sum_{(S(u), B) \in \mathcal{P}} \hat{\pi}(S(u), B) \cdot |B|,$$

and then for each point p and the path P from p to the root, compute $\hat{\rho}(p) = \sum_{u \in P} R_2(u)/(n - 1)$, as an approximation of $\rho(p)$. The correctness is guaranteed by the property of pair decomposition that every pair of points is covered by a unique pair in the decomposition. Again, we pick the point with the minimum $\hat{\rho}(p)$ to be the approximate median. The approximation ratio and running time bounds follow immediately. \square

5.5. Stretch factor. For a graph G defined on S , the *stretch factor* of G with respect to π is defined as $\max_{p, q \in S} \pi_G(p, q)/\pi(p, q)$. Narasimhan and Smid [29] gave an algorithm to approximate the stretch factor of a geometric graph to the Euclidean metric using the geometric well-separated pair decomposition. By following the same argument we can approximate the stretch factor of an arbitrary graph G with respect to the unit-disk graph metric. Again, we consider the well-separated pair decomposition \mathcal{P} . For each pair $(A, B) \in \mathcal{P}$, we pick any pair of points (p, q) , where $p \in A$ and $q \in B$, and compute the approximate shortest path $\hat{\pi}_G(p, q)$ in G and $\hat{\pi}(p, q)$ in I . The maximum ratio of $\hat{\pi}_G(p, q)/\hat{\pi}(p, q)$ over all pairs in \mathcal{P} is an approximation to the stretch factor by the same argument in [29].

COROLLARY 5.6. *For any graph G on S , we can compute an $O(1)$ -approximate stretch factor of G in time $O(\tau'_1(n \log n))$, where $\tau'_1(m)$ is the time to compute m $O(1)$ -approximate shortest path queries in G . In particular, if G is a subgraph of I , an $O(1)$ -approximate can be computed in time $O(n \log^3 n)$. Similarly, we can compute for any $\varepsilon > 0$, a $(1 + \varepsilon)$ -approximate stretch factor of G in time $O(\tau'_2(n \log n/\varepsilon^4) + n\sqrt{n \log n}/\varepsilon^3)$, where $\tau'_2(m)$ is the time to compute m $(1 + \varepsilon)$ -approximate shortest path queries in G . When G is a subgraph of I , this can be done in $O(n\sqrt{n \log n}/\varepsilon^3)$ time.*

6. Extensions. There are several direct extensions of our techniques. Here, we outline the extension to the intersection graph of disks with bounded radii ratio and to the unweighted unit-disk graph.

6.1. Intersection graphs of disks with bounded radii ratio. When the sizes of the disks are not uniform, it is generally not possible to obtain subquadratic well-separated pair decomposition of the metric induced by the intersection graph. This can be shown by the example where there is a big disk and $n - 1$ pairwise disjoint small disks intersecting it. Indeed, the intersection graph of this example is a tree with one internal node and $n - 1$ leaves.

However, if the ratio between the radii of any two disks (or balls) is upper bounded by a constant, then the packing property (Lemma 4.3) still holds. We can obtain similar results for the intersection graph of disks (or balls in high dimensions) with bounded radii ratio.

6.2. Unweighted unit-disk graphs. In the previous part, we considered only weighted unit-disk graphs. There are applications in which we need the unweighted unit-disk graph. The results for point set with constant bounded density can be directly extended to unweighted unit-disk graphs. If the density is unbounded, then it is impossible to obtain a subquadratic size well-separated pair decomposition as shown by the example of the unweighted complete graph. But again for the applications, we can apply the clustering technique to reduce it to the problem for point sets with constant unbounded density. The clustering increases the approximation ratio by a multiplicative factor of 3 [17]. Thus in near linear time we can compute $3c_0$ -approximation ($c_0 = 2.42$) for the following problems: the furthest neighbor, nearest neighbor, closest pair, bichromatic closest pair, median, and stretch factor, all with respect to the unweighted unit-disk graph metric. Again we didn't list the problems of computing diameter and center because there are trivial 2-approximate algorithms.

Furthermore, we can get a better multiplicative approximation factor by permitting an additive error as shown in the following. For the unweighted unit-disk graph $I(S)$ on point set S , we cluster the points by finding a minimal 1-cover X of S ; i.e., any two clusterheads $c_1, c_2 \in X$ must be distance at least 1 away, and any point is covered by at least one clusterhead. We also assign a unique clusterhead $c(p)$ to every node p in S , as before. For any two clusterheads in X within distance 3, if there exists a path with no more than three hops to connect them, we select such two nodes as a bridge. Define Z to be the union of centers X and bridge nodes Y . Again, the shortest path metric in the unweighted unit-disk graph $I(Z)$ is denoted by π' , to be distinguished by the metric π in $I(S)$. It is easy to see that Z has constant bounded density. So we build the c -well-separated pair decomposition \mathcal{P}' on Z . For each pair $(A', B') \in \mathcal{P}'$, we build a pair (A, B) , where $A = \bigcup_{c(p) \in A'} p$, $B = \bigcup_{c(q) \in B'} q$. The collection of the pairs is denoted by \mathcal{P} .

LEMMA 6.1. For $p, q \in S$,

1. $\pi(p, q) \leq \pi'(p, q)$;
2. $\pi'(p, q) \leq 3\pi(p, q) + 2$, if p, q are clusterheads, then $\pi'(p, q) \leq 3\pi(p, q)$.

Proof. The first claim is because $I(Z)$ is a subgraph of $I(S)$. The second one is proved in [17]. \square

Set $c = 6/\varepsilon$; we have the next lemma.

LEMMA 6.2. For any two pairs of points $(p_1, q_1), (p_2, q_2) \in (A, B)$, where $(A, B) \in \mathcal{P}$, $\pi(p_1, q_1) \leq (1 + \varepsilon)\pi(p_2, q_2) + (4 + 2\varepsilon)$.

Proof. Take the centers of p_2, q_2 , $c(p_2) \in A'$, $c(q_2) \in B'$. We can see that $\pi(p_1, c(p_2)) \leq 1 + \pi(c(p_1), c(p_2)) \leq 1 + \pi'(c(p_1), c(p_2)) \leq 1 + D'(A')$, where D' denote the diameter in metric π' . Since (A', B') is c -well-separated, we have $\pi'(A', B') \geq c \cdot \max(D'(A'), D'(B'))$. So $\pi'(c(p_2), c(q_2)) \geq c \cdot \max(D'(A'), D'(B'))$. $\pi(c(p_2), c(q_2)) \leq$

$\pi(p_2, q_2) + 2$. Combining Lemma 6.1 and all these, we have

$$\begin{aligned}
\pi(p_1, q_1) &\leq \pi(p_1, c(p_2)) + \pi(c(p_2), c(q_2)) + \pi(c(q_2), q_1) \\
&\leq 1 + D'(A') + \pi(c(p_2), c(q_2)) + 1 + D'(B') \\
&\leq \pi(c(p_2), c(q_2)) + 2 + (2/c)\pi'(c(p_2), c(q_2)) \\
&\leq \pi(c(p_2), c(q_2)) + 2 + (2/c)(3\pi(c(p_2), c(q_2))) \\
&\leq (1 + 6/c)\pi(c(p_2), c(q_2)) + 2 \\
&\leq (1 + 6/c)\pi(p_2, q_2) + (4 + 12/c) \\
&= (1 + \varepsilon)\pi(p_2, q_2) + (4 + 2\varepsilon). \quad \square
\end{aligned}$$

THEOREM 6.3. *For an unweighted unit-disk graph $I(S)$ on a point set S and any $1 > \varepsilon > 0$, we can find in time $O(n\sqrt{n \log n}/\varepsilon^3)$ a data structure of size $O(n \log n/\varepsilon^4)$ such that for any pair of points p, q with distance $\pi(p, q) > 2$, we can return a value x in $O(1)$ time such that*

$$\frac{1}{1 + \varepsilon}(x - 4 - 2\varepsilon) \leq \pi(p, q) \leq (1 + \varepsilon)x + 4 + 2\varepsilon.$$

Proof. For each pair (A', B') , we take an arbitrary pair of points a_0, b_0 from A', B' , respectively, and compute the distance $\pi(a_0, b_0)$. By using the same idea as in Lemma 4.14, we can show that the total amount of time is $O(n\sqrt{n \log n}/\varepsilon^3)$. Note that any pair of points p, q with distance $\pi(p, q) > 2$ must be in different clusters. We find the pair (A', B') that includes the pair of points $(c(p), c(q))$ in $O(1)$ time. (Notice that there exists a constant-spanner for the unweighted unit-disk graph on point set with constant density [17].) Therefore we take $x = \pi(a_0, b_0)$, where (a_0, b_0) is the representative pair of (A', B') . The theorem then follows from Lemma 6.2. \square

Similarly, this gives us $O(n\sqrt{n \log n}/\varepsilon^3)$ -time algorithms for finding approximate solutions to the following problems: the furthest neighbor, nearest neighbor, closest pair, bichromatic closest pair, median, diameter, center, and stretch factor, all with respect to the unweighted unit-disk graph metric.

7. Conclusion. In this paper, we extend the well-separated pair decomposition, originally developed in the Euclidean metric, to the unit-disk and unit-ball graph metrics. This allows us to obtain almost linear time 2.42-approximate and subquadratic time $(1 + \varepsilon)$ -approximate algorithms for several proximity problems where no efficient methods were previously known. The combinatorial bounds in \mathbb{R}^k for $k \geq 3$ are also tight.

The most notable open problem is the gap between $\Omega(n)$ and $O(n \log n)$ on the number of pairs needed in the plane. Also, the time bound for $(1 + \varepsilon)$ -approximation is still about $\tilde{O}(n\sqrt{n})$ because of the lack of efficient method for computing $(1 + \varepsilon)$ -approximate shortest distance between $O(n)$ pairs of points. Any improvement to the algorithm for that problem will immediately lead to improvement to all the $(1 + \varepsilon)$ -approximate algorithms presented in this paper.

A SUBEXPONENTIAL-TIME QUANTUM ALGORITHM FOR THE DIHEDRAL HIDDEN SUBGROUP PROBLEM*

GREG KUPERBERG[†]

Abstract. We present a quantum algorithm for the dihedral hidden subgroup problem (DHSP) with time and query complexity $2^{O(\sqrt{\log N})}$. In this problem an oracle computes a function f on the dihedral group D_N which is invariant under a hidden reflection in D_N . By contrast, the classical query complexity of DHSP is $O(\sqrt{N})$. The algorithm also applies to the hidden shift problem for an arbitrary finitely generated abelian group.

The algorithm begins as usual with a quantum character transform, which in the case of D_N is essentially the abelian quantum Fourier transform. This yields the name of a group representation of D_N , which is not by itself useful, and a state in the representation, which is a valuable but indecipherable qubit. The algorithm proceeds by repeatedly pairing two unfavorable qubits to make a new qubit in a more favorable representation of D_N . Once the algorithm obtains certain target representations, direct measurements reveal the hidden subgroup.

Key words. quantum algorithm, dihedral hidden subgroup

1. Introduction. The hidden subgroup problem (HSP) in quantum computation takes as input a group G , a finite set S , and a black-box function (or oracle) $f : G \rightarrow S$. By promise there is a subgroup $H \subseteq G$ such that $f(a) = f(b)$ if and only if a and b are in the same (right) coset of H . The problem is to identify the subgroup H . We assume that G is given explicitly; black-box groups are a separate topic [13].

Shor's algorithm [22] solves HSP when $G = \mathbb{Z}$ in polynomial time in the length of the output. An important predecessor is Simon's algorithm [23] for the case $G = (\mathbb{Z}/2)^n$. Shor's algorithm extends to the general abelian case [14], to the case when H is normal [10], and to the case when H has few conjugates [9]. Since the main step in the generalized algorithm is the quantum character transform on the group algebra $\mathbb{C}[G]$, we will call it the *character algorithm*.

In the dihedral hidden subgroup problem (DHSP), G is the dihedral group D_N and H is generated by a reflection. (Other subgroups of D_N are only easier to find; see Proposition 2.1.) In this case H has many conjugates and the character algorithm works poorly. This hidden subgroup problem was first considered by Ettinger and Høyer [7]. They presented an algorithm that finds H with a linear number of queries (in the length of the output) but an exponential amount of computation. Ettinger, Høyer, and Knill generalized this result to the general finite hidden subgroup problem [8].

In this paper we will describe a new quantum algorithm for the dihedral group D_N with a favorable compromise between query complexity and computation time per query.

FIG. 1. Some elements of D_8 .

THEOREM 1.1. *There is a quantum algorithm that finds a hidden reflection in the dihedral group $G = D_N$ (of order $2N$) with time and query complexity $2^{O(\sqrt{\log N})}$.*

The time complexity $2^{O(\sqrt{\log N})}$ is not polynomial, but it is subexponential. By contrast any classical algorithm requires at least $2N^{1/2}$ queries on average. Unfortunately, our algorithm also requires $2^{O(\sqrt{\log N})}$ quantum space.

We will prove Theorem 1.1 in a convenient case, $N = 2^n$, in section 3. In section 5, we will provide another algorithm that works for all N , and we will obtain the sharper time and query complexity bound $\tilde{O}(3\sqrt{2^{\log_3 N}})$ when $N = r^n$ for some fixed radix r . The algorithm for this last case generalizes to many other smooth values of N .

2. Group conventions. The dihedral group D_N with $2N$ elements has the conventional presentation

$$D_N = \langle x, y \mid x^N = y^2 = yxyx = 1 \rangle.$$

(See Artin [2, section 5.3].) An element of the form x^s is a *rotation* and an element of the form yx^s is a *reflection*. The parameter s is the *slope* of the reflection yx^s . This terminology is motivated by realizing D_N as the symmetry group of a regular N -gon in the plane (Figure 1). In this model yx^s is a reflection through a line which makes an angle of $\frac{\pi s}{N}$ with the reflection line of y .

In this paper we will describe algorithms for the hidden subgroup problem with $G = D_N$ and $H = \langle yx^s \rangle$. If we know that the hidden subgroup is a reflection, then the hidden subgroup problem amounts to finding its slope s .

PROPOSITION 2.1. *Finding an arbitrary hidden subgroup H of D_N reduces to finding the slope of a hidden reflection.*

Proof. If H is not a reflection, then either it is the trivial group or it has a non-trivial intersection with the cyclic subgroup $C_N = \langle x \rangle$. Finding the hidden subgroup $H' = H \cap C_N$ in C_N is easy if we know the factors of N , and we can factor N using Shor’s algorithm. Then the quotient group H/H' is either trivial or a reflection in the quotient group G/H' .

If H is trivial, then this will be revealed by the fact that an algorithm to find the slope of a hidden reflection must fail. \square

3. A basic algorithm. In this section we will describe an algorithm to find the slope s of a hidden reflection in D_N when the period $N = 2^n$ is a power of 2. The main part of the algorithm actually finds only the parity of s . Once this parity is known, the main part can be repeated with a subgroup of D_N isomorphic to $D_{N/2}$. The group D_N has two such subgroups:

$$F_0 = \langle x^2, y \rangle, \quad F_1 = \langle x^2, yx \rangle.$$

The subgroup $F_{s \bmod 2}$ contains H and the other does not, so we can pass to one of these subgroups if and only if we know $s \bmod 2$.

For any finite set S , the notation $\mathbb{C}[S]$ denotes a Hilbert space with S as an orthogonal basis. (This is the quantum analogue of a classical data type that takes values in S .) Define the *constant pure state* $|S\rangle$ in $\mathbb{C}[S]$, or more generally in $\mathbb{C}[T]$ for any $T \supseteq S$, as the superposition

$$|S\rangle = \frac{1}{\sqrt{|S|}} \sum_{s \in S} |s\rangle.$$

For the moment let us assume an arbitrary finite hidden subgroup problem $f : G \rightarrow S$ with hidden subgroup H . Assuming that there is a classical circuit to compute f , we can dilate it to a unitary embedding

$$U_f : \mathbb{C}[G] \rightarrow \mathbb{C}[G] \otimes \mathbb{C}[S] = \mathbb{C}[G \times S]$$

which evaluates f in the standard basis:

$$U_f |g\rangle = |g, f(g)\rangle.$$

All finite hidden subgroup algorithms, including ours, begin by computing

$$U_f |G\rangle$$

and then discarding the output register $\mathbb{C}[S]$, leaving the input register for further computation. The result is the mixed state

$$\rho_{G/H} = \frac{1}{|G|} \sum |Ha\rangle \langle Ha|$$

on the input register $\mathbb{C}[G]$.

Many works on hidden subgroup algorithms describe these steps differently [22, 18, 7, 8, 9, 10]. Instead of defining U_f as an embedding that creates $f(g)$, they define it as a unitary operator that adds $f(g)$ to an ancilla. They describe its output as measured rather than discarded, and they describe the mixed state $\rho_{G/H}$ as a randomly chosen coset state $|Ha\rangle$. We have presented an equivalent description in the formalism of mixed states and quantum operations [18, Chapter 8].

Now let $G = D_N$ with $N = 2^n$. The general element of D_N is $g = y^t x^s$ with $s \in \mathbb{Z}/N$ and $t \in \mathbb{Z}/2$. Thus the input register $\mathbb{C}[D_N]$ consists of n qubits to describe s and 1 qubit to describe t . The second step of our algorithm is to apply a unitary operator to $\rho_{D_N/H}$ which is almost the character transform (section 8.2). Explicitly, we apply the quantum Fourier transform (QFT) to $|s\rangle$,

$$F_N : |s\rangle \mapsto \frac{1}{\sqrt{N}} \sum_k e^{2\pi i ks/N} |k\rangle,$$

and then measure $k \in \mathbb{Z}/N$. The measured value is uniformly random, while the state on the remaining qubit is

$$|\psi_k\rangle \propto |0\rangle + e^{2\pi i k s/N} |1\rangle.$$

(The symbol \propto means “proportional to,” so that we can omit normalization and global phase.) We will always create the same state $\rho_{D_N/H}$ and perform the same measurement, so we can suppose that we have a supply of $2^{O(\sqrt{n})}$ states $|\psi_k\rangle$, each with its own known but random value of k .

Note that $|\psi_{-k}\rangle$ and $|\psi_k\rangle$ carry equivalent information about s , because

$$(1) \quad |\psi_{-k}\rangle = X|\psi_k\rangle,$$

where X is the bit flip operator. They will be equivalent in our algorithms as well.

We would like to create the state

$$|\psi_{2^{n-1}}\rangle \propto |0\rangle + (-1)^s |1\rangle$$

because its measurement in the $|\pm\rangle$ basis reveals the parity of s . To this end we create a sieve which creates new $|\psi_k\rangle$'s from pairs of old ones. The sieve increases the number of trailing zeroes $\alpha(k)$ in the binary expansion of k . Given $|\psi_k\rangle$ and $|\psi_\ell\rangle$, their joint state is

$$|\psi_k\rangle \otimes |\psi_\ell\rangle \propto |0,0\rangle + e^{2\pi i k s/N} |1,0\rangle + e^{2\pi i \ell s/N} |0,1\rangle + e^{2\pi i (k+\ell)s/N} |1,1\rangle.$$

We now apply a CNOT gate

$$|a, b\rangle \mapsto |a, a + b\rangle$$

and measure the right qubit. The left qubit has the residual state

$$|\psi_{k\pm\ell}\rangle \propto |0\rangle + e^{2\pi i (k\pm\ell)s/N} |1\rangle$$

and the label $k \pm \ell$, which is inferred from the measurement of $a + b$. Thus we have a procedure to extract a new qubit $|\psi_{k\pm\ell}\rangle$ from the old qubits $|\psi_k\rangle$ and $|\psi_\ell\rangle$. The extraction makes an unbiased random choice between $k + \ell$ and $k - \ell$. We may well like the extracted qubit better than either of the old ones.

By iterating qubit extraction, we can eventually create the state that we like best, $|\psi_{2^{n-1}}\rangle$. We will construct a sieve that begins with $2^{\Theta(\sqrt{n})}$ qubits. Each stage of the sieve will repeatedly find two qubits $|\psi_k\rangle$ and $|\psi_\ell\rangle$ such that k and ℓ agree in $\Theta(\sqrt{n})$ low bits in addition to their trailing zeroes. With probability $\frac{1}{2}$, the label $k \pm \ell$ of the extracted qubit has \sqrt{n} more trailing zeroes than k or ℓ . If the sieve has depth $\Theta(\sqrt{n})$, we can expect it to produce copies of $|\psi_{2^{n-1}}\rangle$.

In conclusion, here is a complete description of the algorithm to find a hidden reflection in D_N with $N = 2^n$. Also let $m = \lceil \sqrt{n-1} \rceil$.

ALGORITHM 3.1. *Input:* An oracle $f : D_N \rightarrow S$ with a hidden subgroup $H = \langle yx^s \rangle$ and $N = 2^n$.

1. Make a list L_0 of copies of the state $\rho_{D_N/H}$ by applying the dilation D_f to the constant pure state $|D_N\rangle$ and discarding the input. Extract $|\psi_k\rangle$ from each $\rho_{D_N/H}$ with a QFT-based measurement.
2. For each $0 \leq j < m$, we assume a list L_j of qubit states $|\psi_k\rangle$ such that k has at least mj trailing zeroes. Divide L_j into pairs of qubits $|\psi_k\rangle$ and $|\psi_\ell\rangle$ that share at least m low bits (in addition to trailing zeroes), or $n - 1 - mj$ bits if $m = j - 1$. Extract the state $|\psi_{k\pm\ell}\rangle$ from each pair. Let the new list L_{j+1} consist of those qubit states of the form $|\psi_{k-\ell}\rangle$.

3. The final list L_m consists of states $|\psi_0\rangle$ and $|\psi_{2^{n-1}}\rangle$. Measure a state $|\psi_{2^{n-1}}\rangle$ in the $|\pm\rangle$ basis to determine the parity of the slope s .
4. Repeat steps 1–3 with the subgroup of D_N which is isomorphic to $D_{N/2}$ and which contains H .

3.1. Proof of the complexity.

THEOREM 3.2. Algorithm 3.1 requires $O(8^{\sqrt{n}})$ queries and $\tilde{O}(8^{\sqrt{n}})$ computation time.

Proof. In outline, if $|L_j| \gg 2^m$, then we can pair almost all the elements of L_j so that k and ℓ share m low bits for each pair $|\psi_k\rangle$ and $|\psi_\ell\rangle$. Then about half the pairs will form L_{j+1} , so that

$$\frac{|L_{j+1}|}{|L_j|} \approx \frac{1}{4}.$$

We can set $|L_m| = \Theta(2^m)$. Working backward, we can set $|L_0| = \Theta(8^m)$. The computation time consists of tasks with only logarithmic overhead.

In detail, we will assume that

$$|L_j| \geq C_{m-j} 2^{3m-2j}$$

for a certain constant $9 > C_k \geq 3$. We will bound the probability that this assumption survives as j increases. The constants are defined by letting $C_0 = 3$ and letting

$$C_k = \frac{C_{k-1}}{1 - 2^{-k-\frac{m}{3}}} + 2^{-2k}$$

by induction on k . It is not hard to check that

$$C_k > C_{k-1}, \quad \lim_{k \rightarrow \infty} C_k < 9.$$

(A calculator may help for the first few terms of the limit, the worst case being $m = 1$.)

Since we create L_0 directly from oracle calls, we can set

$$|L_0| = C_0 2^{3m}.$$

Given L_j , let P_j be a maximal set of pairs $|\psi_k\rangle$ and $|\psi_\ell\rangle$ with m low matching bits. Then

$$|P_j| \geq \frac{|L_j| - 2^m}{2} \geq \frac{2^{3m-2j} C_j (1 - 2^{2j-2m})}{2},$$

because there are at most 2^m unmatched pairs. The list L_{j+1} is then formed from P_j by summand extraction, so $|L_{j+1}|$ can be understood as the sum of N independent, unbiased Bernoulli random variables. In general, if B_N is a sum of N unbiased Bernoulli random variables, then

$$P[B_N \leq \frac{(1-b)N}{2}] \leq (\cosh b)^N e^{-Nb^2} \leq e^{-Nb^2/2}.$$

(The first inequality is the Chernoff bound on large deviations.) Setting

$$b = 2^{j-\frac{4m}{3}},$$

we learn that

$$|L_{j+1}| \geq \frac{2^{3m-2j}(C_j - 2^{2j-2m})(1 - 2^{j-\frac{4m}{3}})}{4} = C_{j+1}2^{3m-2j-2}$$

with probability at least

$$1 - e^{-2^{\frac{m}{3}-1}}.$$

Finally by induction on j ,

$$P[|P_j| \geq C_{m-j}2^{3m-2j} \forall j] \geq (1 - e^{-2^{\frac{m}{3}-1}})^m \rightarrow 1$$

as $m \rightarrow \infty$.

Thus the final list L_m is very likely to be large. Since the highest bit of k in $|\psi_k\rangle$ was never used for any decisions in the algorithm, it is unbiased Bernoulli for each entry of L_m . Therefore L_m is very likely to contain copies of $|\psi_{2^{n-1}}\rangle$. \square

4. Some motivation. Algorithm 3.1 can be motivated by related ideas in representation theory and the theory of classical algorithms.

On the representation theory side, the input space $\mathbb{C}[D_N]$ has an orthogonal decomposition into two-dimensional representations V_k of D_N ,

$$(2) \quad \mathbb{C}[D_N] \cong \bigoplus_{k \in \mathbb{Z}/N} V_k.$$

This means that each element of D_N is represented by a unitary operator on $\mathbb{C}[D_N]$ (given by left multiplication) and each V_k is an invariant subspace, so that each element of D_N is also represented by a unitary operator on each V_k [2, section 9.2]. Every orthogonal decomposition of a Hilbert space corresponds to a projective measurement [18, section 2.2.5]; this particular measurement can be computed using a QFT.

In the representation V_k , the generators x and y are represented as follows:

$$x \mapsto \begin{pmatrix} e^{2\pi/N} & 0 \\ 0 & e^{-2\pi/N} \end{pmatrix}, \quad y \mapsto \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}.$$

Since the state $|Ha\rangle$ is invariant under the represented action of H , the residual state $|\psi_k\rangle$ is too. Thus abstract representation theory motivates the use of this state to find H . Note also that $V_k \cong V_{-k}$ as representations, as if reflected in the equivalence between $|\psi_k\rangle$ and $|\psi_{-k}\rangle$ in (1).

The representation V_k is irreducible except when $k = 0$ or $k = N/2$. Thus (2) is not far from the Burnside decomposition of $\mathbb{C}[G]$ into irreducible representations in the special case $G = D_N$. When expressed as a unitary operator, the Burnside decomposition is called the *character transform* or the noncommutative Fourier transform. (Measuring the character name solves the hidden subgroup problem for normal subgroups [10] and almost normal subgroups [9].) Use of $V_{N/2}$ as the target of Algorithm 3.1 is motivated by its reducibility; the measurement corresponding to its irreducible decomposition is the one that reveals the slope of s .

On the algorithm side, the sieve in Algorithm 3.1 is similar to a sieve algorithm for a learning problem due to Blum, Kalai, and Wasserman [5] and to a sieve to find shortest vector in a lattice due to Ajtai, Kumar, and Sivakumar [1].

Ettinger and Høyer [7] observed that if the state $|\psi_k\rangle$ for the hidden subgroup $H = \langle x^s y \rangle$ will be found in the state $|\psi'_k\rangle$ for a reference subgroup $H' = \langle x^t y \rangle$ with probability

$$\cos(\pi i(s-t)k/N)^2.$$

Thus the state $|\psi_k\rangle$ can provide a coin flip with this bias. We call such a coin flip a *cosine observation* of the slope s . Ettinger and Høyer showed that s is revealed by a maximum likelihood test with respect to $O(\log N)$ cosine observations with random values of k . They suggested a brute-force search to solve this maximum likelihood problem. Our first version of Algorithm 3.1 was a slightly subexponential, classical sieve on cosine observations that even more closely resembles the Blum–Kalai–Wasserman algorithm. Replacing the cosine observations by the qubit states $|\psi_k\rangle$ themselves significantly accelerates the algorithm.

5. Other algorithms. Algorithm 3.1 presents a simplified sieve which is close to the author’s original thinking. But it is neither optimal nor fully general. In this section we present several variations which are faster or more general.

The first task is to prove Theorem 1.1 when N is not a power of 2. Given any qubit state $|\psi_k\rangle$, we can assume that $0 \leq k \leq \frac{N}{2}$, since $|\psi_k\rangle$ and $|\psi_{-k}\rangle$ are equivalent. The list L_j will consist of qubits $|\psi_k\rangle$ with

$$0 \leq k < 2^{m^2-mj+1},$$

where

$$m = \lceil \sqrt{(\log_2 N) - 2} \rceil.$$

Another difference when N is not a power of 2 is that the quantum Fourier transform on \mathbb{Z}/N is more complicated. An efficient approximate algorithm was given by Kitaev [14]; another algorithm which is exact (in a sense) is due to Mosca and Zalka [17].

ALGORITHM 5.1. *Input: An oracle $f : D_N \rightarrow S$ with a hidden subgroup $H = \langle yx^s \rangle$.*

1. *Make a list L_0 of copies of $\rho_{D_N/H}$. Extract a qubit state $|\psi_k\rangle$ from each $\rho_{D_N/H}$ using a QFT on \mathbb{Z}/N and a measurement.*
2. *For each $0 \leq j < m$, we assume a list L_j of qubit states $|\psi_k\rangle$ such that $0 \leq k \leq 2^{m^2-mj+1}$. Randomly divide L_j into pairs of qubits $|\psi_k\rangle$ and $|\psi_\ell\rangle$ that such that*

$$|k - \ell| \leq 2^{m^2-m(j+1)+1}.$$

Let the new list L_{j+1} consist of those qubit states of the form $|\psi_{|k-\ell|}\rangle$.

3. *The final list L_m consists of states $|\psi_0\rangle$ and $|\psi_1\rangle$. Perform the Ettinger–Høyer measurement on the copies of $|\psi_1\rangle$ with different values of t to learn $s \in \mathbb{Z}/N$ to within $N/4$.*
4. *Write $N = 2^a M$ with M odd. By the Chinese remainder theorem,*

$$C_N \cong C_{2^a} \times C_M.$$

For each $1 \leq j \leq \lceil \log_2 N \rceil$, apply Algorithm 3.1 to produce many $|\psi_k\rangle$ with $2^{\min(a,j)}|k|$. Then repeat steps 1–4 after applying the group automorphism $x \mapsto x^{2^{-j}}$ to the C_M factor of D_N . This produces copies of $|\psi_{2^j}\rangle$, and hence cosine observations $\cos(\pi i 2^j(s-t)/N)^2$. These observations determine s .

TABLE 1
Average canceled bits in a simulation (100 trials).

Queries	3	3 ²	3 ³	3 ⁴	3 ⁵	3 ⁶	3 ⁷	3 ⁸
Zeroed bits	3.62	6.75	12.53	19.07	27.14	36.44	47.51	59.76
$\sqrt{2 \log_3 2^n}$	2.14	2.92	3.98	4.91	5.85	6.78	7.74	8.68

The proof of Theorem 3.2 carries-over to show that Algorithm 5.1 also requires only $O(8\sqrt{\log_2 N})$ queries and quasi-linear time in its data. The only new step is to check that in the final list L_m , the qubit states $|\psi_0\rangle$ and $|\psi_1\rangle$ are almost equally likely. This is a bit tricky but inevitable, given that the lowest bit of k can be almost uncorrelated with the way that $|\psi_k\rangle$ is paired.

Remark 5.2. Høyer described a simplification of Algorithm 5.1 [11]. Given only one copy each of

$$|\psi_1\rangle, |\psi_2\rangle, \dots, |\psi_{2^k}\rangle,$$

with $2^k \geq N$, the slope s can be recovered directly by a quantum Fourier transform. More precisely, the measured Fourier number t of these qubits reveals s by the relation

$$\frac{t}{2^k} \sim \frac{s}{N}.$$

This simplification saves a factor of $O(\log N)$ computation time.

Now suppose that $N = r^n$ for some small radix r ; Algorithm 3.1 generalizes to this case with only slight changes. It is natural to accelerate it by recasting it as a greedy algorithm. To this end, we define an objective function $\alpha(k)$ that expresses how much we like a given state $|\psi_k\rangle$. Namely, let αk be the number of factors of r in k with the exception that $\alpha(0) = 0$. Within the list L of qubit states available at any given time, we will greedily pick $|\psi_k\rangle$ and $|\psi_\ell\rangle$ to maximize $\alpha(k \pm \ell)$. It is also natural to restrict our greed to the qubits that minimize α , because there is no advantage to postponing their use in the sieve.

ALGORITHM 5.3. *Input: An oracle $f : D_N \rightarrow S$ with a hidden subgroup $H = \langle yx^s \rangle$ and $N = r^n$.*

1. *Make a list L of qubit states $|\psi_k\rangle$ extracted from copies of $\rho_{D_N/H}$.*
2. *Within the sublist L' of L that minimizes α , repeatedly extract $|\psi_\ell\rangle$ from a pair of qubits $|\psi_k\rangle$ and $|\psi_\ell\rangle$ that maximize $\alpha(k \pm \ell)$.*
3. *After enough qubits $|\psi_k\rangle$ appear with $\frac{N}{r}|k$, measure $s \pmod r$ using state tomography. Then repeat the algorithm with a subgroup of D_N isomorphic to $D_{N/r}$.*

The behavior of Algorithm 5.3 (but not its quantum state) can be simulated by a classical randomized algorithm. We include the source code of a simulator written in Python with this article [15] with $r = 2$. Our experiments with this simulator led to a false conjecture for algorithm’s precise query complexity. Nonetheless we present some of its results in Table 1. The last line of the table is roughly consistent with Theorem 5.4. Note that the sieve is a bit more efficient when $r = 2$ because then $k \pm \ell$ increases by 1 in the unfavorable case and at least 2 in the favorable case.

THEOREM 5.4. *Algorithm 5.3 requires $\tilde{O}(3\sqrt{2 \log_3 N})$ queries and quasi-linear time in the number of queries.*

Here is a heuristic justification of the query bound in Theorem 5.4. We assume, as the proof will, that $r = 3$ and $N = 3^n$. Then with $3\sqrt{2^n}$ queries, we can expect

qubit extraction to initially cancel about $\sqrt{2n}$ ternary digits (trits) with probability $\frac{1}{2}$. If we believe the query estimate for $n' < n$, then we can expect the new qubit to be about 3 times as valuable as the old one, since

$$\sqrt{2n} - \sqrt{2n - \sqrt{2n}} \approx 1.$$

Such a qubit extraction trades 2 qubits for 1 qubit, which is half the time equivalent to the original 2 and half the time 3 times as valuable. Thus each step of the sieve breaks even; it is like a gamble with \$2 that is equally likely to return \$1 or \$3.

Sketch of proof. We will show that the sieve produces states $|\psi_{a_{N/r}}\rangle$ (which we will call *final states*) with adequate probability when provided with at least $Cn3^{\sqrt{2\log_3 N}}$ queries. The work per query is quasi-linear in $|L|$ (initially the number of queries) if the list L is dynamically sorted. To simplify the formulas, we assume that $r = 3$, although the proof works for all r .

We can think of a qubit state $|\psi_k\rangle$ as a monetary asset, valued by the function

$$V(k) = 3^{-\sqrt{2(n-1-\alpha(k))}}.$$

Thus the total value $V(L)$ of the initial list L is at least

$$V(L) \geq Cn.$$

We claim that over a period of the sieve that increases $\min \alpha$ by 1, the expected change in $V(L)$ is at worst $-C$. Since $\min \alpha$ can only increase $n - 1$ times, $V(L) \geq C$ when $\min \alpha = n - 1$. Thus the sieve produces at least C final states on average. Along the way, the changes to $V(L)$ are independent (but not identically distributed) Bernoulli trials. One can show using a version of the Chernoff bound (as in the proof of Theorem 3.2) that the number of final states is not maldistributed. We will omit this refinement of the estimates and spell out the expected behavior of $V(L)$.

Given k , let

$$\beta = \beta(k) = n - 1 - \alpha(k)$$

for short, so that β can be thought of as the number of uncanceled trits in the label k of $|\psi_k\rangle$. Suppose that two labels k and ℓ or $-\ell$ share m trits in addition to $\alpha(k)$ cancelled trits. Then

$$(3) \quad V(k) = V(\ell) = 3^{-\sqrt{2\beta}}.$$

The state $|\psi_{k\pm\ell}\rangle$ extracted from $|\psi_k\rangle$ and $|\psi_\ell\rangle$ has the expected value

$$(4) \quad \begin{aligned} E[V(k \pm \ell)] &= \frac{3^{-\sqrt{2\beta}} + 3^{-\sqrt{2(\beta-m)}}}{2} \\ &> 2V(k) \frac{1 + 3^{m/\sqrt{2\beta}}}{4}, \end{aligned}$$

using the elementary relation

$$\sqrt{2\beta} - \sqrt{2(\beta-m)} = \frac{2m}{\sqrt{2\beta} + \sqrt{2(\beta-m)}} > \frac{m}{\sqrt{2\beta}}.$$

The most important feature of (4) is that if $m > \sqrt{2\beta}$, the expected change in $V(L)$ is positive. Thus in bounding the attrition of $V(L)$, we can assume that $m \leq \sqrt{2\beta}$ for the best-matching qubits $|\psi_k\rangle$ and $|\psi_\ell\rangle$ in the sublist L' that minimizes α . By the pigeonhole principle, this can happen only when

$$|L'| \leq 3\sqrt{2\beta}.$$

(To apply the pigeonhole principle properly, use the equivalence between $|\psi_k\rangle$ and $|\psi_{-k}\rangle$ to assume that the first nonzero digit is 1. There are then 3^m choices for the next m digits.)

When qubit extraction decreases $V(L)$, it decreases by at worst the value of one parent, given by the right side of (3). Likewise, if $|L'| = 1$ and its unique element $|\psi_k\rangle$ must be discarded, the loss to $V(L)$ is again the right side of (3). Thus the total expected loss as L' is exhausted is at most

$$3^{-\sqrt{2\beta}} 3^{\sqrt{2\beta}} < 1.$$

We can therefore take $C = 1$, although a larger C may be convenient to facilitate the Chernoff bound. \square

Remark 5.5. A close examination of Algorithm 5.3 and Theorem 5.4 reveals that the sieve works with the same complexity bound if N factors as

$$N = N_1 N_2 \dots N_m$$

and N_k is within a bounded factor of 3^k . In this case the sieve will determine $s \pmod{N_1}$. This is enough values of N to extend to an algorithm for all N by the method of spliced approximation section 7.

6. Generalized dihedral groups and hidden shifts. In this section we consider several other problems that are equivalent or closely related to the hidden dihedral subgroup problem.

In general if A is an abelian group, let $\exp(A)$ denote the multiplicative form of the same group. Let $C_n = \exp(\mathbb{Z}/n)$ be the multiplicative cyclic group of order n . If A is any abelian group, define the *generalized dihedral group* to be the semidirect product

$$D_A \cong C_2 \ltimes \exp(A)$$

with the conjugation relation

$$x^{-1} = yxy$$

for all $x \in \exp(A)$ and for the nontrivial $y \in C_2$. Any element of the form yx is a *reflection* in D_A .

Suppose that A is an abelian group and $f, g : A \rightarrow S$ are two injective functions that differ by a shift:

$$f(a) = g(a + s).$$

Then the task of finding s from f and g is the *abelian hidden shift problem*. Another problem is the hidden reflection problem in A (as opposed to in D_A). In this problem, $f : A \rightarrow S$ is a function which is injective except that

$$f(a) = f(s - a)$$

TABLE 2
An oracle that hides $\langle yx^3 \rangle$ in D_8 and its hidden shift.

a	1	x	x^2	x^3	x^4	x^5	x^6	x^7
$f(a)$	A	B	C	D	E	F	G	H
a	y	yx	yx^2	yx^3	yx^4	yx^5	yx^6	yx^7
$f(a)$	F	G	H	A	B	C	D	E

for some hidden s .

PROPOSITION 6.1. *If A is an abelian group, the hidden shift and hidden reflection problems in A are equivalent to the hidden reflection problem in D_A .*

See Table 2 for an example.

Proof. If $a \in A$, let x^a denote the corresponding element in $\exp(A)$. Given $f, g : A \rightarrow S$, define

$$h(x^a) = f(a), \quad h(yx^a) = g(a).$$

Then evidently

$$h(x^a) = h(yx^{s+a})$$

if and only if

$$f(a) = g(a + s).$$

We can also reduce the pair f and g to a function with a hidden reflection. Namely, let $S^{(2)}$ be the set of unordered pairs of elements of S and define $h : A \rightarrow S^{(2)}$ by

$$h(a) = \{f(-a), g(a)\}.$$

Then h is injective save for the relation

$$h(a) = h(s - a).$$

Conversely, suppose that $h : A \rightarrow S$ is injective save for the relation

$$h(a) = h(s - a).$$

If there is a $v \in A$ such that $2v \neq 0$, define

$$f : A \rightarrow S^{\times 2}, \quad g : A \rightarrow S^{\times 2}$$

by

$$f(a) = (h(-a), h(v - a)), \quad g(a) = (h(a), h(a - v)).$$

(If A is cyclic, we can just take $v = 1$.) Then f and g are injective and

$$f(a) = g(a + s).$$

If all $v \in A$ satisfy $2v = 0$, then h hides a subgroup of A generated by s , so we can find s by Simon's algorithm. \square

Note also that Proposition 2.1 generalizes readily to generalized dihedral subgroups: finding a hidden reflection in D_A is as difficult as finding any hidden subgroup.

A final variation of DHSP is the hidden substring problem. In the $N \hookrightarrow M$ hidden substring problem,

$$\begin{aligned} f &: \{0, 1, 2, \dots, N - 1\} \rightarrow S, \\ g &: \{0, 1, 2, \dots, M - 1\} \rightarrow S \end{aligned}$$

are two injective functions such that f is a shifted restriction of g , i.e.,

$$f(x) = g(x + s)$$

for all $0 \leq x < N$ and for some fixed $0 \leq s < M - N$.

7. More algorithms. In this section we will establish a generalization of Theorem 1.1 and a corollary.

THEOREM 7.1. *The abelian hidden shift problem has an algorithm with time and query complexity $2^{O(\sqrt{n})}$, where n is the length of the output, uniformly for all finitely generated abelian groups.*

COROLLARY 7.2. *The $N \hookrightarrow 2N$ hidden substring problem has an algorithm with time and query complexity $2^{O(\sqrt{\log N})}$.*

The proof of Corollary 7.2 serves as a warm-up to the proof of Theorem 7.1. It introduces a technique for converting hidden shift algorithms that we call *spliced approximation*.

Proof of Corollary 7.2. Identify the domain of f with \mathbb{Z}/N (no matter that this identification is artificial). Make a random estimate t for the value of s , and define $h : D_N \rightarrow S$ by

$$g'(n) = g(n + t).$$

If t is a good estimate for s , then f and g' approximately hide the hidden shift $s - t$. If we convert f and g to a function $h : D_N \rightarrow S$, then apply its dilation U_h with input $|D_N\rangle$ and discard the output, the result is a state $\rho_h = \rho_{f,g'}$ which is close to the state $\rho_{D_N/H}$ used in Algorithm 5.1.

We need to quantify how close. The relevant metric on states for us is the trace distance [18, section 9.2]. In general if ρ and ρ' are two states on a Hilbert space \mathcal{H} , the trace distance $\|\rho - \rho'\|$ is the maximum probability that any measurement, indeed any use in a quantum algorithm, will distinguish them. In our case,

$$\|\rho_h - \rho_{D_N/H}\| = \frac{|s - t|}{N}.$$

If

$$\frac{|s - t|}{N} = 2^{-O(\sqrt{\log N})},$$

then with bounded probability, Algorithm 5.1 will never see the difference between ρ_h and $\rho_{D_N/H}$. Thus $2^{O(\sqrt{\log N})}$ guesses for s suffice. \square

A second warm-up to the general case of Theorem 7.1 is the special case $A = \mathbb{Z}$. Recall that more computation is allowed for longer output. Suppose that the output

has n bits, i.e., the shift s is at most 2^n . In the language of deterministic hiding, we restrict the domain of $f, g : \mathbb{Z} \rightarrow S$ to the set $\{0, 1, 2, \dots, 2^m\}$, where $m = n + \Theta(\sqrt{n})$, and interpret this set as $\mathbb{Z}/2^m$. Then f and g approximately differ by the shift s . If we form the state $\rho_{f,g}$ as in the proof of Corollary 7.2, then its trace distance from the state $\rho_{D_N/H}$, with $N = 2^m$, is $2^{-O(\sqrt{n})}$. Thus Algorithm 5.1 will never see the states differ.

Sketch of proof of Theorem 7.1. In the general case, the classification of finitely generated abelian groups says that

$$A \cong \mathbb{Z}^b \oplus \mathbb{Z}/N_1 \oplus \mathbb{Z}/N_2 \oplus \dots \oplus \mathbb{Z}/N_a.$$

Assuming a bound on the length of the output, we can truncate each \mathbb{Z} summand of A , as in the case $A = \mathbb{Z}$. (We suppose that we know how many bits of output are allocated to each free summand of A .) Thus we can assume that

$$A = \mathbb{Z}/N_1 \oplus \mathbb{Z}/N_2 \oplus \dots \oplus \mathbb{Z}/N_a,$$

and the problem is to find s in time $2^{O(\sqrt{\log |A|})}$. In other words, the problem is to solve HSP for a finite group D_A .

The general element of D_A can be written $y^t x^a$ with $t \in \mathbb{Z}/2$ and $a \in A$. Following the usual first step, we can first prepare the state $\rho_{D_A/H}$. Then we can perform a quantum Fourier transform on each factor of A , then measure the answer, to obtain a label

$$k = (k_1, k_2, \dots, k_a) \in A$$

and a qubit state

$$|\psi_k\rangle \propto |0\rangle + e^{2\pi i \sum_j s_j k_j / N_j} |1\rangle.$$

(As in section 4, this state is H -invariant in a two-dimensional representation V_k of D_A .) We will outline a sieve algorithm to compute any one coordinate of the slope, without loss of generality s_a .

As in Algorithm 5.3, we will guide the behavior of the sieve by an objective function α on A . Given k , let $b(k)$ be the first j such that $k_j \neq 0$. If $b < a$, then let

$$\alpha(k) = \sum_{j=1}^b [1 + \log_2(N_j + 1)] - \lceil \log_2(k_b + 1) \rceil.$$

If $b = a$, then let

$$\alpha(k) = \sum_{j=1}^a [1 + \log_2(N_j + 1)].$$

As in Algorithm 5.3, we produce a list L of $2^{O(\sqrt{\log |A|})}$ qubits with states $|\psi_k\rangle$. Within the minimum of α on L , we repeatedly find pairs $|\psi_k\rangle$ and $|\psi_\ell\rangle$ that maximize $\alpha(k + \ell)$ or $\alpha(k - \ell)$, then we extract $|\psi_{k+\ell}\rangle$ from each such pair. The end result is a list of qubit states $|\psi_k\rangle$ with

$$k = (0, 0, \dots, 0, k_a).$$

The set of k of this form is closed under sums and differences, so we can switch to Algorithm 5.1 to eventually determine the slope s_a . \square

Note that many abelian groups A are not very different from cyclic groups, so that the generalized dihedral group D_A can be approximated for our purposes by a standard dihedral group. For example, if $A \cong \mathbb{Z}^a$ is free abelian with many bits of output allocated to each coordinate, then we can pass to a truncation

$$\mathbb{Z}/N_1 \oplus \mathbb{Z}/N_2 \oplus \cdots \oplus \mathbb{Z}/N_a$$

with relatively prime N_j 's. In this case the truncation is cyclic.

8. Hidden subgroup generalities. In this section we will make some general observations about quantum algorithms for hidden subgroup problems. Our comments are related to work by Hallgren, Russell, and Ta-Shma [10] and by Grigni et al. [9].

8.1. Quantum oracles. The first step of all quantum algorithms for the hidden subgroup problem is to form the state $\rho_{G/H}$, or an approximation when G is infinite, except when the oracle $f : G \rightarrow S$ has special properties.

Suppose that a function $f : G \rightarrow S$ that hides the subgroup H . We can say that f *deterministically* hides H because it is a deterministic function. Some problems in quantum computation might reduce to a nondeterministic oracle $f : G \rightarrow \mathcal{H}$, where \mathcal{H} is a Hilbert space. We say that such an f *orthogonally* hides H if f is constant on each right coset Ha of H and orthogonal on distinct cosets. If a quantum algorithm invokes the dilation D_f of f and then discards the output, then it solves the orthogonal hidden subgroup problem as well as the deterministic one.

Computing D_f and discarding its output can also be viewed as a quantum oracle. A general quantum computation involving both unitary and nonunitary actions can be expressed as a quantum operation [18, Chapter 8]. In this case the operation is a map $\mathcal{E}_{G/H}$ on $\mathcal{M}(\mathbb{C}[G])$, where in general $\mathcal{M}(\mathcal{H})$ denotes the algebra of operators on a Hilbert space \mathcal{H} . It is defined by

$$\mathcal{E}_{G/H}(|a\rangle\langle b|) = \begin{cases} |a\rangle\langle b| & \text{if } Ha = Hb, \\ 0 & \text{if } Ha \neq Hb. \end{cases}$$

We say that the quantum oracle $\mathcal{E}_{G/H}$ *projectively* hides the subgroup H . Unlike deterministic and orthogonal oracles, the projective oracle is uniquely determined by H . Again, all quantum algorithms for hidden subgroup problems work with this more difficult oracle.

Finally, if G is finite, the projective oracle $\mathcal{E}_{G/H}$ can be applied to the constant pure state $|G\rangle$ to produce the state

$$\rho_{G/H} = \frac{|H|}{|G|} \sum |Ha\rangle\langle Ha|.$$

So an algorithm could use a no-input oracle that simply broadcasts copies of $\rho_{G/H}$. Such an oracle *coherently* hides H . This oracle has been also been called the random coset oracle [20] because the state $\rho_{G/H}$ is equivalent to the constant pure state $|Ha\rangle$ on a uniformly randomly chosen coset. Almost all existing quantum algorithms for finite hidden subgroup problems need only copies of the state $\rho_{G/H}$. Algorithms 3.1 and 5.3 are exceptions: They use $\rho_{D_N/H}$ to find the parity of the slope s and then rely on $\mathcal{E}_{D_N/H}$ with other inputs (constant pure states on subgroups) for later stages.

The possibly slower algorithm, Algorithm 5.1, works with the coherent oracle; it uses only $\rho_{D_N/H}$.

The distinctions between deterministic, orthogonal, and projective hiding apply to any hidden partition problem. In one special case, called the hidden stabilizer problem [14], a group G acts transitively on a set S and a function $f : S \rightarrow T$ is invariant under a subgroup $H \subseteq G$. The hidden stabilizer problem has enough symmetry to justify consideration of coherent hiding. It would be interesting to determine when one kind of hiding is harder than another. For example, if f is injective save for a single repeated value, then there is a sublinear algorithm for deterministic hiding [6]. But projective hiding requires at least linear time and we do not know an algorithm for coherent hiding which is faster than quadratic time.

In a variant of coherent HSP, the oracle outputs nonuniform mixtures of coset states $|Ha\rangle$. The mixtures may even be chosen adversarially. This can make the subgroup H less hidden, for example, in the trivial extreme in which the state is $|H\rangle$ with certainty. At the other extreme, we can always uniformize the state by translating by a random group element. Thus uniform coherent HSP is the hardest representative of this class of problems.

8.2. The character measurement. The second step of all quantum algorithms for the generic hidden subgroup problem is to perform the character measurement. (The measurement in our algorithms is only trivially different.) The result is the name or character of an irreducible unitary representation (or irrep) V and a state in V . Mathematically the character measurement is expressed by the Burnside decomposition of the group algebra $\mathbb{C}[G]$ as a direct sum of matrix algebras [21]:

$$\mathbb{C}[G] \cong \bigoplus_V \mathcal{M}(V).$$

Here $\mathcal{M}(V)$ is the algebra of operators on the irrep V ; the direct sum runs over one representative of each isomorphism type of unitary irreps. The group algebra $\mathbb{C}[G]$ has two commuting actions of G , given by left and right multiplication, and with respect to these two actions,

$$\mathcal{M}(V) \cong V \otimes V^*,$$

so that the Burnside decomposition can also be written

$$(5) \quad \mathbb{C}[G] \cong \bigoplus_V V \otimes V^*.$$

In light of the identification with matrices, the factor of V^* is called the *row space*, while the factor of V is the *column space*.

The Burnside decomposition is also an orthogonal decomposition of Hilbert spaces and so corresponds to a projective measurement on $\mathbb{C}[G]$. This is the character measurement. A character transform is an orthonormal change of basis that refines equation (5). Its precise structure as a unitary operator depends on choosing a basis for each V .

The state $\rho_{G/H}$ has an interesting structure with respect to the Burnside decomposition. In general if \mathcal{H} is a finite-dimensional Hilbert space, let $\rho_{\mathcal{H}}$ denote the uniform mixed state on \mathcal{H} ; if V is a representation of a group G , let V^G denote its invariant space. It is easy to check that

$$\rho_{G/H} = \rho_{\mathbb{C}[G]^H},$$

where G (and therefore H) acts on $\mathbb{C}[G]$ by left multiplication. In the Burnside decomposition, the left multiplication action on each $V \otimes V^*$ is trivial on the right factor V^* and is just the defining action of G on V . Since $\rho_{G/H}$ is the uniform state on all H -invariant vectors in $\mathbb{C}[G]$, this property descends through the Burnside decomposition:

$$\rho_{G/H} = \bigoplus_V \rho_{V^H} \otimes \rho_{V^*}.$$

This relation has two consequences. First, as has been noted previously [9], the state on the row space V^* has no useful information. Second, since $\rho_{G/H}$ decomposes as a direct sum with respect to the Burnside decomposition, the character measurement sacrifices no coherence to the environment; it only measures something that the environment already knows. Our reasoning here establishes the following proposition.

PROPOSITION 8.1. *Let G be a finite group and assume an algorithm or oracle to compute the character transform on $\mathbb{C}[G]$. Then a process provides the state $\rho_{G/H}$ is equivalent to a process that provides the name of an irrep V and the state ρ_{V^H} with probability*

$$P[V] = \frac{(\dim V)(\dim V^H)|H|}{|G|}.$$

Proposition 8.1 sharpens the motivation to work with irreps in the hidden subgroup problem. If you obtain the state $\rho_{G/H}$, and if you can efficiently perform the character measurement on states, then you might as well apply it to $\rho_{G/H}$.

Proposition 8.1 and the definition of coherent HSP in section 8.1 suggest another class of oracles related to the hidden subgroup problem. In general an oracle might provide the name of a representation V and a state ρ which is some mixture of H -invariant pure states in V . It is tempting to describe such a ρ as H -invariant, but technically that is a weaker condition that also applies to other states. For example, the uniform state on V is H -invariant. So we say that ρ is *purely H -invariant* if it is supported on the H -invariant space V^H . For example, the uniform state $\rho_{G/H}$ is purely H -invariant. More generally the purely H -invariant states on $\mathbb{C}[G]$ are exactly the mixtures of constant pure states of right cosets $|Ha\rangle$.

PROPOSITION 8.2. *Let G be a finite group. Then any purely H -invariant state ρ on $\mathbb{C}[G]$ can be converted to $\rho_{G/H}$. In the presence of an algorithm or oracle to perform the character transform on $\mathbb{C}[G]$, any purely H -invariant state ρ on any irrep V can be converted to $\rho_{G/H}$.*

Proof. If we right-multiply ρ by a uniformly random element of G , it becomes $\rho_{G/H}$. If we perform the reverse character transform to a purely H -invariant state ρ on V , it becomes a purely H -invariant state on $\rho_{G/H}$ itself. \square

The message of Proposition 8.2 is that the uniform mixture $\rho_{G/H}$ reveals the least information about H among all mixtures of coset states $|Ha\rangle$. The distribution on irreps V described in Proposition 8.1, together with the uniform state on V^H , also reveals the least information about H among all such distributions.

9. A general algorithm. In this section we will discuss a general algorithm for coherent HSP for an arbitrary finite group G and an arbitrary subgroup H . It is an interesting abstract presentation of all the algorithms for dihedral groups in this paper. Unfortunately, it might not be directly useful for any groups other than dihedral groups.

The algorithm uses the definitions and methods of section 8.2, together with a generalized notion of summand extraction. In general if V and W are two unitary representations of G , their tensor product decomposes as an orthogonal direct sum of irreps with respect to the diagonal action of G :

$$(6) \quad V \otimes W \cong \bigoplus_X \mathcal{H}_X^{W,V} \otimes X.$$

Here again the direct sum runs over one representative of each isomorphism class of irreps. The Hilbert space $\mathcal{H}_X^{W,V}$ is the *multiplicity factor* of the decomposition; its dimension is the number of times that X arises as a summand of $V \otimes W$. The decomposition defines a partial measurement of the joint Hilbert space $V \otimes W$, which extracts X (and $\mathcal{H}_X^{W,V}$). If V and W carry purely H -invariant states, then the state on X is also purely H -invariant.

ALGORITHM 9.1. *Input: An oracle that produces $\rho_{G/H}$.*

1. *Make a list L of copies of $\rho_{G/H}$. Extract an irrep V with a purely H -invariant state from each copy.*
2. *Choose an objective function α on $\text{Irrep}(G)$, the set of irreps of G .*
3. *Find a pair of irreps V and W in L such that $\alpha(V)$ and $\alpha(W)$ are both low, but such that α is significantly higher for at least one summand of $V \otimes W$. Extract an irreducible summand X from $V \otimes W$ and replace V and W in L with X . Discard the multiplicity factor.*
4. *Repeat step 3 until α is maximized on some irrep V . Perform tomography on V to reveal useful information about H .*
5. *Repeat steps 2–4 to fully identify H .*

For any given group G , Algorithm 9.1 requires subalgorithms to compute the character measurement (5) and the tensor decomposition measurement (6). Efficient algorithms for character measurements and character transforms are a topic of active research [4, 16] and are unknown for many groups. We observe that tensor decomposition measurement at least reduces to the character measurement.

PROPOSITION 9.2. *Let V and W be irreducible representations of a finite group G . If group operations in G and summand extraction from $\mathbb{C}[G]$ are both efficient, then summand extraction from $V \otimes W$ is also efficient.*

Proof. Embed V and W into separate copies of $\mathbb{C}[G]$ in a G -equivariant way. Then apply the unitary operator

$$U(|a\rangle \otimes |b\rangle) = |b^{-1}a\rangle \otimes |b\rangle$$

to $\mathbb{C}[G] \otimes \mathbb{C}[G]$. The operator U transports left multiplication by the diagonal subgroup $G_\Delta \subset G \times G$ to left multiplication by G on the right factor. Then summand extraction from the right factor of $\mathbb{C}[G] \otimes \mathbb{C}[G]$ is equivalent to summand extraction from $V \otimes W$, since, after U is applied, the group action on the right factor of $\mathbb{C}[G] \otimes \mathbb{C}[G]$ coincides with the diagonal action on $V \otimes W$. \square

In light of Beals's algorithm to compute a character transform on the symmetric group [4] and Proposition 9.2, Algorithm 9.1 may look promising when $G = S_n$ is the symmetric group. But the algorithm seems to work poorly for this group, because the typical irrep V of S_n is very large. Consequently the decomposition (6) typically involves many irreps of S_n . This offers very little control for a sieve.

Note that if Algorithm 9.1 were useful for the symmetric group, its time complexity would be $2^{O(\sqrt{\log |G|})}$ at best. This is the same complexity class as a known classical algorithm for the graph isomorphism or automorphism problem [3], which

is the original motivation for the symmetric hidden subgroup problem (SHSP). We believe that general SHSP is actually much harder than graph isomorphism. If graph isomorphism does admit a special quantum algorithm, it could be analogous to a quantum polynomial time algorithm found by van Dam, Hallgren, and Ip [24] for certain special abelian hidden shift problems. (In particular their algorithm applies to the Legendre symbol with a hidden shift.) All these problems have special oracles f that allow faster algorithms.

One reason that SHSP looks hard is that symmetric groups have many different kinds of large subgroups. For example, if p_1, p_2, \dots, p_n is a set of distinct primes, then

$$D_{p_1 p_2 \dots p_n} \hookrightarrow S_{p_1 + p_2 + \dots + p_n}$$

(exercise). Thus DHSP reduces to SHSP. Hidden shift in the symmetric group also reduces to SHSP (exercise).

The sieve of Algorithm 9.1 looks the most promising when the group G is large but $V \otimes W$ always has few terms. This is similar to demanding that most or all irreps of G are low-dimensional. So suppose that all irreps have dimension at most k and consider the limit $|G| \rightarrow \infty$ for fixed k . Isaacs and Passman [12] showed that there is a function $f(k)$ such that if all irreps have dimension at most k , then G has an abelian subgroup $\exp(A)$ of index at most $f(k)$. By the reasoning of Proposition 2.1, the hardest hidden subgroup H for a such a G is one which is disjoint from $\exp(A)$ (except for the identity). But by the reasoning of section 6, any such hidden subgroup problem reduces to the hidden shift problem on A . The generalized sieve of Algorithm 9.1 is not as fast as the dihedral sieve on D_A .

Acknowledgments. Some elements of the algorithms in this article are due to Ettinger and Høyer [7]. Regev has presented some related ideas related to lattice problems [20] and more recently has found a space-efficient variation of the algorithms in this article [19]. (We have also borrowed some aspects of his exposition of our algorithm.) The author would like to thank Robert Beals, Robert Guralnick, Peter Høyer, and Eric Rains for useful discussions. The author would also like to thank the referees for useful comments.

A BETTER-THAN-GREEDY APPROXIMATION ALGORITHM FOR THE MINIMUM SET COVER PROBLEM*

REFAEL HASSIN[†] AND ASAF LEVIN[‡]

Abstract. In the weighted set-cover problem we are given a set of elements $E = \{e_1, e_2, \dots, e_n\}$ and a collection \mathcal{F} of subsets of E , where each $S \in \mathcal{F}$ has a positive cost c_S . The problem is to compute a subcollection SOL such that $\bigcup_{S \in SOL} S_j = E$ and its cost $\sum_{S \in SOL} c_S$ is minimized. When $|S| \leq k \forall S \in \mathcal{F}$ we obtain the weighted k -set cover problem. It is well known that the greedy algorithm is an H_k -approximation algorithm for the weighted k set cover, where $H_k = \sum_{i=1}^k \frac{1}{i}$ is the k th harmonic number, and that this bound is exact for the greedy algorithm for all constant values of k . In this paper we give the first improvement on this approximation ratio for all constant values of k . This result shows that the greedy algorithm is not the best possible for approximating the weighted set cover problem. Our method is a modification of the greedy algorithm that allows the algorithm to regret.

Key words. greedy algorithm, approximation algorithms, set cover problem

1. Introduction. In the weighted set-cover problem we are given a set of elements $E = \{e_1, e_2, \dots, e_n\}$ and a collection \mathcal{F} of subsets of E , where $\bigcup_{S \in \mathcal{F}} S = E$ and each $S \in \mathcal{F}$ has a positive cost c_S . The goal is to compute a subcollection $SOL \subseteq \mathcal{F}$ such that $\bigcup_{S \in SOL} S = E$ and its cost $\sum_{S \in SOL} c_S$ is minimized. Such a subcollection of subsets is called a *cover*. When we consider instances of the weighted set-cover such that each S_j has at most k elements ($|S| \leq k \forall S \in \mathcal{F}$), we obtain the weighted k -set cover problem. The unweighted set cover problem and the unweighted k -set cover problem are the special cases of the weighted set cover and of weighted k -set cover, respectively, where $c_S = 1 \forall S \in \mathcal{F}$.

It is well known (see [2]) that a greedy algorithm is an H_k -approximation algorithm for the weighted k -set cover, where $H_k = \sum_{i=1}^k \frac{1}{i}$ is the k th harmonic number, and that this bound is tight even for the unweighted version of the problem (see [10, 13]). For unbounded values of k , Slavík [17] showed that the approximation ratio of the greedy algorithm for the unweighted set cover problem is $\ln n - \ln \ln n + \Theta(1)$. Feige [5] proved that unless $NP \subseteq DTIME(n^{\text{polylog } n})$ the unweighted set cover problem cannot be approximated within a factor $(1 - \epsilon) \ln n$ for any $\epsilon > 0$. Raz and Safra [16] proved that if $P \neq NP$, then for some constant c , the unweighted set cover problem cannot be approximated within a factor $c \log n$. This result shows that the greedy algorithm is an asymptotically best possible approximation algorithm for the weighted set cover problem (unless $NP \subseteq DTIME(n^{\text{polylog } n})$). The unweighted k -set cover problem is known to be NP-complete [11] and MAX SNP-hard for all $k \geq 3$ [3, 12, 14]. The hardness results obtained for the unweighted k -set cover problem do not exclude the possibility of obtaining a cH_k -approximation algorithm for some

constant $c < 1$ for constant values of k ; however, such positive results are unknown. Another algorithm for the weighted set cover problem by Hochbaum [9] has an approximation ratio that depends on the maximum number of subsets that contain any given item. (The local-ratio algorithm of Bar-Yehuda and Even [1] has the same performance guarantee.) See Paschos [15] for a survey on these results.

Despite this bad news, which also holds for the unweighted set cover, Goldschmidt, Hochbaum, and Yu [7] modified the greedy algorithm for the unweighted set cover and showed that the resulting algorithm has a performance guarantee of $H_k - \frac{1}{6}$. Halldórsson [8] presented an algorithm based on local search that has an approximation ratio of $H_k - \frac{1}{3}$ for the unweighted k -set cover and a $(1.4 + \epsilon)$ -approximation algorithm for the unweighted 3-set cover. Duh and Fürer [4] further improved this result and presented an $(H_k - \frac{1}{2})$ -approximation algorithm for the unweighted k -set cover.

This important progress in the approximability of the unweighted k -set cover does not help to approximate the weighted k -set cover problem within a factor better than H_k . The question whether there are similar results for the weighted problems was left unanswered. A first answer was given by Fujito and Okumura [6], who presented an $H_k - \frac{1}{12}$ -approximation algorithm for the k -set cover problem where the cost of each subset is either 1 or 2. Their method is based on extending the algorithm of [7] for this case, but this approach does not extend further to the general case. In this paper we give the first positive answer for a general cost function by developing an approximation algorithm for the weighted k -set cover problem whose performance guarantee is bounded by $H_k - \frac{k-1}{8k^9}$. This bound is not tight, but it is sufficient to show that the greedy algorithm does not give the best possible performance guarantee for approximating the weighted set cover problem. Our method is based on a modification of the greedy algorithm that allows the algorithm to regret throughout its execution.

In section 2 we review the greedy algorithm for the weighted minimum k -set cover problem and review its analysis. In section 3 we present the greedy algorithm with withdrawals. We analyze its performance in section 4. We conclude the paper in section 5 by a short discussion on possible extensions and improvements of our results.

2. The greedy algorithm. In this section we review the greedy algorithm and the proof of its performance guarantee for the weighted k -set cover problem.

The greedy algorithm starts with an empty collection of subsets in the solution and no item is covered. Then, it iterates the following procedure until all items are covered.

Let w_S be the number of uncovered items in S , and the current *ratio* of S is $r_S = \frac{c_S}{w_S}$. Let S^* be a set such that r_{S^*} is minimized. The algorithm adds S^* to the collection of subsets of the solution, it defines the items of S^* as covered, and it assigns a *price* of r_{S^*} to all the items that are now covered but were uncovered before this iteration (i.e., the items that were first covered by S^*).

Chvátal [2], extending previous results of Johnson [10] and Lovász [13] for the unweighted set cover, showed that this is an H_k -approximation algorithm for the weighted k -set cover.

Chvátal's proof is the following. First, note that the cost of the greedy solution equals the sum of prices assigned to the items. Second, consider a set S that belongs to an optimal solution OPT . Then, OPT pays c_S for S . When the i th item of S was covered by the greedy algorithm, the algorithm could choose S as a feasible solution with current ratio of $\frac{c_S}{|S|-i+1}$. (This is an upper bound on the current ratio because

S has at least $|S| - i + 1$ uncovered elements at this point.) Therefore, the price assigned to the this item is at most $\frac{c_S}{|S|-i+1}$. It follows that the total price assigned to the items of S is at most $c_S \sum_{i=1}^{|S|} \frac{1}{|S|-i+1} = c_S \sum_{i'=1}^{|S|} \frac{1}{i'} \leq c_S H_k$, and therefore, the approximation ratio of the greedy algorithm is at most H_k .

3. The greedy algorithm with withdrawals. In this section we present our modification of the greedy algorithm where in each iteration we are allowed to withdraw a subset S from the solution. However, if we decide to do so, we must pick new subsets that cover all the items that were covered by S (i.e., an item that is covered in some iteration remains covered in any future iteration). Such a *withdrawal step* allows the algorithm to overcome some choices that are essential in the known bad examples for the greedy algorithm. Incorporating the withdrawal steps, we will prove an improved performance guarantee. The first step of the algorithm adds to \mathcal{F} all the subsets of every given set $S \in \mathcal{F}$. These subsets are given the same cost as S . If $S' \subseteq S_1, S_2$, where $S_1, S_2 \in \mathcal{F}$, then $c_{S'} = \min\{c_{S_1}, c_{S_2}\}$. It is clear that this addition does not change the value of a minimum cover and optimal solutions remain optimal. Moreover, given a solution to the new instance, it is easy to compute a feasible solution to the original instance with the same cost (by mapping each new subset to the original set that contains it). However, it will make the analysis of the algorithm easier, as reflected by Lemma 2. Formally, the algorithm is defined as follows.

ALGORITHM GAWW.

Let $\alpha_k = 1 - \frac{1}{k^3}$.

1. **Initialization:** $SOL := \emptyset$ [the solution collection of subsets], $U := E$ [the set of uncovered items].
 For every subset $S \in \mathcal{F}$ and every $S' \subseteq S$, add S' to \mathcal{F} with cost $c_{S'} = c_S$. If $S' \subseteq S_1, S_2$, where $S_1, S_2 \in \mathcal{F}$, then $c_{S'} = \min\{c_{S_1}, c_{S_2}\}$. Let $\mathcal{F} := \{S_1, \dots, S_n\}$ be the resulting extended collection, and denote by c_j the cost of S_j .
2. **Iteration:** While $U \neq \emptyset$ do:
 - (a) For every j , let $w_j := |S_j \cap U|$. If $w_j \neq 0$, let $r_j := \frac{c_j}{w_j}$.
 - (b) For every $S_j \in SOL$ and every subcollection $C \subseteq \mathcal{F}$ of at most k subsets such that $S_j \subseteq \bigcup_{S \in C} S$, let $w(C) := |\bigcup_{S \in C} S \cap U|$ be the number of still uncovered items that belong to the subsets in C . If $w(C) \neq 0$, let
$$r(S_j, C) := \frac{\sum_{i: S_i \in C} c_i - c_j}{w(C)}.$$
 - (c) Let j^* be an index such that r_{j^*} is minimized (in case of a tie we prefer a minimal subset), and let \tilde{j}, \tilde{C} be such that $r(S_{\tilde{j}}, \tilde{C})$ is minimized (again, in case of a tie we prefer minimal subsets).
 - (d) **Greedy step:** If $r_{j^*} \leq \frac{1}{\alpha_k} r(S_{\tilde{j}}, \tilde{C})$, then add S_{j^*} to the solution and define the price of the newly covered items as r_{j^*} . Formally, do the following:
 - i. For every $e \in S_{j^*} \cap U$, let $price(e) := r_{j^*}$.
 - ii. $U := U \setminus S_{j^*}$.
 - iii. $SOL := SOL \cup \{S_{j^*}\}$.
 - (e) **Withdrawal step:** Otherwise (i.e., $r(S_{\tilde{j}}, \tilde{C}) < \alpha_k r_{j^*}^1$), replace $S_{\tilde{j}}$ by the subsets in \tilde{C} and define the price of the newly covered items as $r(S_{\tilde{j}}, \tilde{C})$. Formally, do the following:

¹We note that in this case each $C \in \tilde{C}$ satisfies $C \cap S_{\tilde{j}} \neq \emptyset$; however, we do not use this property and therefore do not prove it.

- i. For every $e \in \bigcup_{S \in \tilde{C}} S \cap U$, let $price(e) := r(S_j, \tilde{C})$.
- ii. $U := U \setminus \bigcup_{S \in \tilde{C}} S$.
- iii. $SOL := (SOL \setminus \{S_j\}) \cup \tilde{C}$.

3. Return SOL .

In each iteration the size of U decreases until $U = \emptyset$, and therefore the number of iterations throughout the algorithm is at most n . Since each iteration takes at most $|\mathcal{F}| + |\mathcal{F}|^k$ and because k is a constant, each iteration takes polynomial time. Therefore, the greedy algorithm with withdrawals is a polynomial time algorithm that returns a feasible solution. Therefore, we establish the following lemma.

LEMMA 1. *The greedy algorithm with withdrawals is a polynomial time algorithm for every constant value of k .*

In the next section we analyze its performance.

4. The analysis of algorithm GAWW. In this section we prove the main theorem of this paper, that for all constant values of k , GAWW guarantees a better approximation ratio than the greedy algorithm.

LEMMA 2. *We can assume without loss of generality (w.l.o.g.) that the sets in OPT are disjoint.*

Proof. The claim follows from the initialization step of GAWW in which it adds to \mathcal{F} for each subset $S \in \mathcal{F}$ with cost c_S all the subsets of S , with the same cost c_S . \square

LEMMA 3. *When analyzing the worst-case performance of GAWW, we can assume w.l.o.g. that each set of OPT has exactly k elements.*

Proof. Assume that OPT contains sets with less than k elements. We construct a new instance by extending E with a set of *dummy elements*. We extend each subset of OPT with less than k elements using some dummy elements to create a new subset with the same cost. We also add to \mathcal{F} the set $\{e\}$ for any dummy element e . All these new singleton subsets have zero cost. GAWW will first choose a full cover of the dummy elements and then continue like it acts on the original instance. However, the new instance has an optimal solution with disjoint k -sets. \square

LEMMA 4. *In each step of GAWW the sets in SOL are disjoint.*

Proof. We prove the claim by induction. The claim clearly holds when SOL is empty. It is sufficient to prove that in each step GAWW adds subsets that are disjoint to the other subsets in SOL .

- Assume that the current step is a greedy step that adds a subset X . \mathcal{F} contains all the subsets of X with costs of at most c_X . Let $X' = X \setminus \bigcup_{S \in SOL, S \neq X} S$. If $X' \neq X$, then because X' has at most the ratio of X , and GAWW prefers to use a minimal subset, we obtain a contradiction. Therefore, X is disjoint to all the prior subsets in SOL .

- Assume that the current step is a withdrawal step that withdraws a subset X and inserts $C = \{X_1, X_2, \dots, X_l\}$. Let SOL be the family of subsets in the solution before the withdrawal step took place. Recall that for all i , \mathcal{F} contains all the subsets of X_i with a cost at most c_{X_i} . Let $X'_i = (X_i \setminus (\bigcup_{S \in SOL, S \neq X} S)) \setminus \bigcup_{j \neq i} X_j$. If there exists i such that $X'_i \neq X_i$, then let C' be as C but with X'_i replacing X_i . Because the withdrawal step that withdraws X and inserts C' has at most the same ratio as the withdrawal step that withdraws X and inserts C , and GAWW prefers to use minimal subsets, we obtain a contradiction. Therefore, every X_i , $i = 1, \dots, l$, is disjoint to all the other subsets in SOL and to X_j $j \neq i$. \square

LEMMA 5. *When analyzing the performance of the greedy algorithm with withdrawals, we can assume w.l.o.g. that every X that entered the solution in some step*

of the algorithm (X may be in the final solution or it might have been withdrawn by a withdrawal step) and every $O \in OPT$, satisfy $|X \cap O| \leq 1$.

Proof. Consider an instance of the problem, and assume that the claimed property does not hold. Then we construct a new instance that satisfies the claimed property and with the same approximation ratio as the original instance. The new instance is composed of k copies of the original instance. We also add, for each $O \in OPT$, k subsets, each having exactly one element of O from each copy, and the k subsets cover the elements of the k copies of O . Then the new instance has an optimal solution that contains all these added subsets (k subsets for each original subset in OPT). GAWW applies a series of k copies of steps for each step in the original instance. Therefore, it never adds one of the new subsets but it adds only subsets that belong to a single copy of the original instance. The cost of the obtained solution is k times the cost of the resulting solution in the original instance. Therefore, the ratio in this new instance is the same as the old instance. However, the claimed property holds in the new instance. \square

LEMMA 6. *The cost of SOL is equal to $\sum_{e \in E} price(e)$, the sum of prices assigned to the elements.*

Proof. The claim clearly holds during initialization phase. Throughout an iteration we partition the increase in the cost of SOL among the new covered elements. The claim follows because the price of each element is set exactly once. \square

LEMMA 7. *Assume that $X \in SOL$ in some step of GAWW and that $x_1 \in X$ is the last element of X that was covered by GAWW. Then $price(x_1) \geq price(x_i)$ for all $x_i \in X$.*

Proof. We show a stronger claim: let x_l, x_{l-1}, \dots, x_1 be the elements of X according to the order that GAWW covers the elements, then $price(x_1) \geq price(x_2) \geq \dots \geq price(x_l)$. Suppose that X entered SOL in a greedy step. Since GAWW prefers to use a minimal subset, we conclude that all the elements of X were covered for the first time by X and all of them have the same price.

Suppose that X entered SOL in a withdrawal step that withdraws Y and inserts $C = \{X = X_1, \dots, X_l\}$. If $X \subseteq Y$, then the claim can be assumed to hold by an inductive argument. Therefore, w.l.o.g. we assume that $X \setminus Y \neq \emptyset$. Note that the elements of $X \setminus Y$ were given a common price. Then using an inductive argument it is sufficient to show that $price(x_1) \geq price(x)$ for every $x \in X \cap Y$.

We now argue that $r(Y, C)$, the ratio associated with the withdrawal step that withdraws Y and inserts C , is larger than the ratio at the step in which the algorithm inserted Y .

- Suppose that Y entered in a greedy step. Using Lemma 4,

$$\begin{aligned} r(Y, C) &= \frac{\sum_{i=1}^l c_{X_i} - c_Y}{\sum_{i=1}^l |X_i \setminus Y|} = \frac{\sum_{i=1}^l \left(c_{X_i} \frac{|X_i \setminus Y| + |X_i \cap Y|}{|X_i|} - c_Y \frac{|X_i \cap Y|}{|Y|} \right)}{\sum_{i=1}^l |X_i \setminus Y|} \\ &\geq \frac{\sum_{i=1}^l \frac{c_{X_i}}{|X_i|} |X_i \setminus Y|}{\sum_{i=1}^l |X_i \setminus Y|} \geq \min \left\{ \frac{c_{X_i}}{|X_i|} : i = 1, \dots, l \right\} \geq \frac{c_Y}{|Y|}. \end{aligned}$$

The first and third inequalities follow from $\frac{c_{X_i}}{|X_i|} \geq \frac{c_Y}{|Y|}$, which holds since Y was chosen instead of X_i and both Y and X_i were legal at the step in which GAWW inserts Y . The second inequality follows because the average is at least the minimum value.

- Suppose that Y entered SOL in a withdrawal step that withdraws a subset Z and inserts $C' = \{Y = Y_1, \dots, Y_{l'}\}$. We first prove that $r(Y, C) \geq r(Z, C')$. The proof

will assume the opposite, that $r(Y, C) < r(Z, C')$, and lead to a contradiction. Note that both ratios $r(Y, C)$ and $r(Z, C')$ refer to the time of the withdrawal that replaced Z by C' .

Consider the step in which C' replaced Z , and consider the “withdrawal step” that withdraws Z and inserts $C \cup C' \setminus \{Y\}$. (This step may be illegal because it may insert more than k subsets.) By Lemma 4, the subsets in $C' \setminus \{Y\}$ and C are pairwise disjoint. We use this last fact to show that the number of uncovered elements in $C \cup C' \setminus \{Y\}$ is $\sum_{S \in C \cup C'} |S| - |Y| - |Z|$. To see this, note that each element of $Y \cap Z$ is counted twice in $\sum_{S \in C \cup C'} |S|$ (once in C and once in C') and therefore zero times in total, each element of $Z \setminus Y$ is counted once in C' in $\sum_{S \in C \cup C'} |S|$ and therefore zero times in total, and the other elements are counted exactly once. Therefore,

$$\begin{aligned} r(Z, C \cup C' \setminus \{Y\}) &= \frac{\sum_{S \in C \cup C'} c_S - c_Y - c_Z}{\sum_{S \in C \cup C'} |S| - |Y| - |Z|} \\ &= \frac{\sum_{S \in C} c_S - c_Y}{\sum_{S \in C} |S| - |Y|} \left(\sum_{S \in C} |S| - |Y| \right) + \frac{\sum_{S \in C'} c_S - c_Z}{\sum_{S \in C'} |S| - |Z|} \left(\sum_{S \in C'} |S| - |Z| \right)}{\sum_{S \in C \cup C'} |S| - |Y| - |Z|} \\ &= \frac{r(Y, C) \left(\sum_{S \in C} |S| - |Y| \right) + r(Z, C') \left(\sum_{S \in C'} |S| - |Z| \right)}{\left(\sum_{S \in C} |S| - |Y| \right) + \left(\sum_{S \in C'} |S| - |Z| \right)} \\ &< r(Z, C'). \end{aligned}$$

The inequality follows by the assumption $r(Y, C) < r(Z, C')$. We now argue that there is a legal withdrawal step (that is, one that inserts at most k subsets) that withdraws Z with a ratio of at most $r(Z, C \cup C' \setminus \{Y\})$. By Lemma 4, because $|Z| \leq k$, there are at most k subsets in $C \cup C' \setminus \{Y\}$ that intersect Z . Let $A \in C \cup C' \setminus \{Y\}$ satisfy $A \cap Z = \emptyset$.² Then

$$\begin{aligned} r(Z, C \cup C' \setminus \{Y\}) &= \frac{\sum_{S \in C \cup C'} c_S - c_Y - c_Z}{\sum_{S \in C \cup C'} |S| - |Y| - |Z|} \\ &= \frac{\frac{c_A}{|A|} |A| + \sum_{S \in C \cup C' \setminus \{A\}} c_S - c_Y - c_Z}{\sum_{S \in C \cup C' \setminus \{A\}} |S| - |Y| - |Z|} \left(\sum_{S \in C \cup C' \setminus \{A\}} |S| - |Y| - |Z| \right)}{\sum_{S \in C \cup C'} |S| - |Y| - |Z|} \\ &= \frac{r_A |A| + r(Z, C \cup C' \setminus \{Y, A\}) \left(\sum_{S \in C \cup C' \setminus \{A\}} |S| - |Y| - |Z| \right)}{|A| + \left(\sum_{S \in C \cup C' \setminus \{A\}} |S| - |Y| - |Z| \right)} \\ &\geq \min\{r_A, r(Z, C \cup C' \setminus \{Y, A\})\}. \end{aligned}$$

Since GAWW could choose to add A greedily, $r_A > r(Z, C') > r(Z, C \cup C' \setminus \{Y\})$, and we conclude that $r(Z, C' \cup C \setminus \{Y, A\}) < r(Z, C')$. Repeating this argument we reach a legal withdrawal step (that inserts at most k subsets) with ratio that is better than $r(Z, C')$, and this is a contradiction.

We have shown that $r(Y, C) \geq r(Z, C')$, where each of these ratios is defined for the step that implemented the respective withdrawal. To complete the proof, we note that after Y is added to SOL and the withdrawal step that withdraws Y and inserts C becomes feasible, $r(Y, C)$ may increase only because the number of uncovered elements

²It is possible to show that in this case $A \in C$. However, we do not use this property and therefore we do not prove it.

of Y is nonincreasing. Thus, for every $x \in X \cap Y$, $price(x_1) = r'(Y, C) > r(Y, C) = price(x)$, where r' refers to the step that inserted X and r refers to the step that inserted Y . \square

We picture OPT as a matrix, where each column contains a subset $S_j \in OPT$. By Lemma 2 each element appears exactly once in this matrix, and by Lemma 3 each column has exactly k elements. We sort the elements of S_j according to the order they were covered by GAWW, so that the i th element of S_j that is covered by the greedy algorithm with withdrawals is in the i th row of the matrix. We break ties arbitrarily. By Lemmas 2 and 3, this representation is well defined.

For a set $X \in SOL$, denote by $COL(X)$ the submatrix defined by the set of columns where the elements of X appear.

Given $X \in SOL$, the elements of X might have been covered during different steps of GAWW (if X entered SOL in a withdrawal step and X has previously uncovered elements). Given $X \in SOL$ such that X is not contained in the last row of the matrix, we will show that the total price paid by the algorithm for all the elements in $COL(X)$ is at most $\sum_{i:S_i \in COL(X)} c_i(H_k - \frac{1}{8k^8})$. Our proof distinguishes between a set X whose elements were covered in a single step and a set X whose elements were covered in at least two steps.

LEMMA 8. *If the elements of X were covered in at least two steps, then the total price paid by GAWW for the elements in $COL(X)$ is at most $(H_k - \frac{1}{k^5+k}) \sum_{S_i \in COL(X)} c_i$.*

Proof. Assume that the element $x_1 \in X$ was covered last among the elements of X (other elements of X might have been covered during the same step). Assume that the elements of X are in columns S_1, S_2, \dots, S_l , where $X \cap S_i = \{x_i\}$, and x_i is in row $k - n_i$ of its column. (Recall that by Lemma 5, $|X \cap S_i| \leq 1$.)

Since x_1 was covered last among the elements of X , by Lemma 7 $price(x_1) \geq price(x_i) \forall i$. Since GAWW prefers minimal subsets, the step in which X was inserted to SOL is a withdrawal step. When applying the withdrawal step that inserts X into SOL , GAWW could apply a greedy step that inserts S_1 with a ratio of $\frac{c_1}{n_1+1}$. Therefore, $price(x_1) \leq \alpha_k \cdot \frac{c_1}{n_1+1} = \frac{k^3-1}{k^3} \cdot \frac{c_1}{n_1+1}$. Thus, $price(x_1) + \frac{price(x_1)}{k^3-1} \leq \frac{c_1}{n_1+1}$, and

$$\begin{aligned} price(x_1) &\leq \frac{c_1}{n_1+1} - \frac{price(x_1)}{k^3-1} \\ &\leq \frac{c_1}{n_1+1} - \frac{1}{k^3-1} \frac{1}{l} \sum_{i=1}^l price(x_i), \end{aligned}$$

where the second inequality holds because $price(x_1) \geq price(x_i) \forall i$. Therefore,

$$\begin{aligned} \sum_{i=1}^l price(x_i) &\leq \sum_{i=1}^l \frac{c_i}{n_i+1} - \frac{1}{k^3-1} \frac{1}{l} \sum_{i=1}^l price(x_i) \\ &\leq \sum_{i=1}^l \frac{c_i}{n_i+1} - \frac{1}{k^4} \sum_{i=1}^l price(x_i). \end{aligned}$$

It follows that

$$\sum_{i=1}^l price(x_i) \leq \left(1 - \frac{1}{k^4+1}\right) \sum_{i=1}^l \frac{c_i}{n_i+1}.$$

For elements $a \in S_i \setminus X$ in the $k - n_a$ row, the price of a is bounded by $\text{price}(a) \leq \frac{c_i}{n_a + 1}$. Therefore,

$$\begin{aligned} \sum_{e \in \text{COL}(X)} \text{price}(e) &= \sum_{e \in \text{COL}(X) \setminus X} \text{price}(e) + \sum_{i=1}^l \text{price}(x_i) \\ &\leq \sum_{i=1}^l \left(H_k - \frac{1}{n_i + 1} \right) c_i + \sum_{i=1}^l \left(1 - \frac{1}{k^4 + 1} \right) \frac{c_i}{n_i + 1} \\ &\leq \sum_{i=1}^l \left(H_k - \frac{1}{k^5 + k} \right) c_i, \end{aligned}$$

where the last inequality holds because $n_i + 1 \leq k$. \square

LEMMA 9. *Assume that X is not contained in the last row. If the elements of X were covered in a single step, then the total price paid by the algorithm for all the elements in $\text{COL}(X)$ is at most $(H_k - \frac{1}{8k^8}) \sum_{S_i \in \text{COL}(X)} c_i$.*

Proof. Assume that the elements of X are in columns S_1, S_2, \dots, S_l , where $X \cap S_i = \{x_i\}$, and x_i is in row $k - n_i$ of its column. By assumption, $\text{price}(x_i) = \frac{c_i}{l} \forall i$.

• Assume that $\text{price}(x_1) = \frac{c_X}{l} \leq c_1 \left(\frac{1}{n_1 + 1} - \frac{1}{4k^5} \right)$. Partition $\{2, 3, \dots, l\}$ into A and B such that $j \in A$ iff $c_j \left(\frac{1}{n_j + 1} - \frac{1}{8k^7} \right) \geq \frac{c_X}{l}$. Since $\frac{1}{n_j + 1} - \frac{1}{8k^7} \geq \frac{1}{k} - \frac{1}{8k^7} \geq \frac{1}{2k}$, it follows that $\frac{c_j}{2k} \leq \frac{c_X}{l}$ for $j \in B$. Therefore,

$$\sum_{j \in B} \frac{c_j}{8k^8} \leq \frac{1}{4k^7} \sum_{j \in B} \frac{c_X}{l} \leq \frac{c_X}{4lk^6} \leq \frac{c_1}{4k^6} \left(\frac{1}{n_1 + 1} - \frac{1}{4k^5} \right) \leq \frac{c_1}{4k^6},$$

where the second inequality follows since $|B| \leq |X| \leq k$, the third inequality follows by the assumption on x_1 , and the last inequality follows because $n_1 + 1 \geq 1$. We conclude that

$$\begin{aligned} &\sum_{e \in \text{COL}(X)} \text{price}(e) \\ &= \sum_{e \in \text{COL}(X) \setminus X} \text{price}(e) + \sum_{i=1}^l \text{price}(x_i) \\ &\leq \sum_{i=1}^l \left(H_k - \frac{1}{n_i + 1} \right) c_i + \sum_{i \in A} \left(\frac{1}{n_i + 1} - \frac{1}{8k^7} \right) c_i + \sum_{i \in B} \frac{c_i}{n_i + 1} + \left(\frac{1}{n_1 + 1} - \frac{1}{4k^5} \right) c_1 \\ &\leq \sum_{i=1}^l \left(H_k - \frac{1}{n_i + 1} \right) c_i + \sum_{i \in A} \left(\frac{1}{n_i + 1} - \frac{1}{8k^7} \right) c_i + \sum_{i \in B} \left(\frac{1}{n_i + 1} - \frac{1}{8k^8} \right) c_i + \left(\frac{1}{n_1 + 1} - \frac{1}{4k^5} + \frac{1}{4k^6} \right) c_1 \\ &\leq \left(H_k - \frac{1}{8k^8} \right) \sum_{i=1}^l c_i. \end{aligned}$$

• Assume that for every i $\text{price}(x_i) = \frac{c_X}{l} \geq c_i \left(\frac{1}{n_i + 1} - \frac{1}{4k^5} \right)$. Recall that the elements of X were covered in a single step, and not all of them are in the last row. Therefore, there exists an element $y \in \text{COL}(X)$ that was covered after X . Let y be the first element to be covered after X , and w.l.o.g. assume that $y \in S_1$.

When GAWW inserted X , it could also choose S_1 with a ratio of $\frac{c_1}{n_1 + 1}$. Therefore, $\frac{c_X}{l} \leq \frac{c_1}{n_1 + 1}$. Hence, by assumption, $c_i \left(\frac{1}{n_i + 1} - \frac{1}{4k^5} \right) \leq \frac{c_1}{n_1 + 1}$, $i = 1, \dots, l$, so that

$c_i \left(1 - \frac{1}{4k^4}\right) \leq c_i \left(1 - \frac{n_i+1}{4k^5}\right) \leq c_1 \frac{n_i+1}{n_1+1}$. Therefore, for $i = 1, \dots, l$,

$$\begin{aligned} c_i &\leq c_1 \frac{n_i + 1}{n_1 + 1} \left(1 + \frac{1}{4k^4 - 1}\right) \\ &\leq c_1 \left(\frac{n_i + 1}{n_1 + 1} + \frac{k}{4k^4 - 1}\right) \\ &\leq c_1 \left(\frac{n_i + 1}{n_1 + 1} + \frac{1}{3k^3}\right). \end{aligned}$$

When GAWW covered y it could use a withdrawal step that withdraws X and inserts S_1, S_2, \dots, S_l . Therefore,

$$\begin{aligned} price(y) &\leq \frac{1}{\alpha_k} \frac{\sum_{i=1}^l c_i - c_X}{\sum_{i=1}^l n_i} \\ &\leq \frac{1}{\alpha_k} \left(\frac{c_1 \sum_{i=1}^l \frac{n_i+1}{n_1+1} - c_X}{\sum_{i=1}^l n_i} + \frac{c_1}{3k^2}\right) \\ &= \frac{1}{\alpha_k} \left(\frac{c_1}{n_1+1} \left(1 + \frac{l}{\sum_{i=1}^l n_i}\right) - \frac{c_X}{\sum_{i=1}^l n_i} + \frac{c_1}{3k^2}\right) \\ &\leq \frac{c_1}{\alpha_k} \left(\frac{1}{n_1+1} + \frac{l}{4k^5 \sum_{i=1}^l n_i} + \frac{1}{3k^2}\right) \\ &\leq \frac{c_1}{\alpha_k} \left(\frac{1}{n_1+1} + \frac{1}{2k^2}\right) \\ &= \frac{c_1}{n_1+1} + \frac{c_1}{(k^3-1)(n_1+1)} + \frac{c_1 k^3}{2k^2(k^3-1)} \\ &\leq c_1 \left(\frac{1}{n_1+1} + \frac{9}{13k^2}\right) \\ &\leq c_1 \left(\frac{1}{n_1} - \frac{1}{4k^2}\right), \end{aligned}$$

where the first inequality follows because we could use the above withdrawal step to cover y , the second inequality follows because $c_i \leq c_1 \left(\frac{n_i+1}{n_1+1} + \frac{1}{3k^3}\right)$ for all i and $l \leq k$ (note that $\sum_{i=1}^l n_i$ can be as small as 1), the equation follows by simple algebra, the third inequality follows because by assumption $\frac{c_1}{n_1+1} - \frac{c_1}{4k^5} \leq \frac{c_X}{l}$ and therefore $\frac{c_1}{n_1+1} \frac{l}{\sum_{i=1}^l n_i} - \frac{c_X}{\sum_{i=1}^l n_i} \leq \frac{lc_1}{4k^5 \sum_{i=1}^l n_i}$, the fourth inequality follows because $\frac{1}{4k^4} + \frac{1}{3k^2} \leq \frac{1}{2k^2}$ for $k \geq 3$, the second equation follows by substituting $\alpha_k = 1 - \frac{1}{k^3}$, the fifth inequality follows because $n_1+1 \geq 2$ and for all values of $k \geq 3$ $\frac{1}{2(k^3-1)} + \frac{k}{2(k^3-1)} \leq \frac{9}{13k^2}$, and the last inequality follows because $n_1 \leq k - 1$. We conclude that

$$\begin{aligned} &\sum_{e \in COL(X)} price(e) \\ &= \sum_{e \in COL(X) \setminus (X \cup \{y\})} price(e) + \sum_{i=1}^l price(x_i) + price(y) \end{aligned}$$

$$\begin{aligned}
&\leq \left(H_k - \frac{1}{n_1+1} - \frac{1}{n_1}\right) c_1 + \sum_{i=2}^l \left(H_k - \frac{1}{n_i+1}\right) c_i + \sum_{i=1}^l \text{price}(x_i) + \left(\frac{1}{n_1} - \frac{1}{4k^2}\right) c_1 \\
&\leq \sum_{i=1}^l \left(H_k - \frac{1}{n_i+1}\right) c_i + \sum_{i=1}^l \text{price}(x_i) - \frac{1}{4k^2} \frac{c_1}{n_1+1} \\
&\leq \sum_{i=1}^l \left(H_k - \frac{1}{n_i+1}\right) c_i + \sum_{i=1}^l \text{price}(x_i) - \frac{1}{4k^2} \frac{1}{l} \sum_{i=1}^l \text{price}(x_i) \\
&\leq \sum_{i=1}^l \left(H_k - \frac{1}{n_i+1}\right) c_i + \left(1 - \frac{1}{4k^3}\right) \sum_{i=1}^l \text{price}(x_i) \\
&\leq \sum_{i=1}^l \left(H_k - \frac{1}{4k^4}\right) c_i,
\end{aligned}$$

where the first inequality follows because $\text{price}(y) \leq c_1 \left(\frac{1}{n_1} - \frac{1}{4k^2}\right)$, the second inequality follows because $n_1 + 1 \geq 1$, the third inequality follows because $\text{price}(x_i) = \text{price}(x_1) \leq \frac{c_1}{n_1+1} \forall i$, the fourth inequality follows because $l \leq k$, and the last inequality follows because $\text{price}(x_i) \leq \frac{c_i}{n_i+1}$ and therefore $(1 - \frac{1}{4k^3}) \text{price}(x_i) \leq (1 - \frac{1}{4k^3}) \frac{c_i}{n_i+1} \leq c_i \left(\frac{1}{n_i+1} - \frac{1}{4k^4}\right)$. \square

The following lemma follows from the fact that when we cover an element we pay a price that is at most the price paid for this element by the greedy algorithm.

LEMMA 10. *For every subset $S \in OPT$, the total price of the elements that belong to S is at most $H_k c_S$.*

THEOREM 11. *The approximation ratio of the greedy algorithm with withdrawals is at most $H_k - \frac{k-1}{8k^9}$. The time complexity of the algorithm is polynomial for every constant value of k .*

Proof. The claim on the time complexity of GAWW follows by Lemma 1. It remains to show the approximation ratio of GAWW. We consider the solution SOL returned by GAWW. Denote by Y the elements of the last row, and consider the following column multiset $MS = \{S \in COL(X) : X \in SOL, X \not\subseteq Y\}$. For a copy of a column S that appears in MS as part of $COL(X)$, we associate a cost of $c_S(H_k - \frac{1}{8k^8})$. By Lemmas 8 and 9, the total price of the elements in MS , where each element is counted the number of times its column appears in MS , is at most the total associated cost of the columns in MS . By Lemma 5, the number of copies of each column in this collection is at least $k - 1$ and at most k . For each column S that appears in MS $k - 1$ times, we add an additional copy of it associated with a cost of $H_k c_S$. By Lemma 10, the total price of the elements in MS , where each element is counted the number of times its column appears in MS , is at most the total associated cost of the columns in MS . Since MS has exactly k copies of each column, by Lemma 6, it suffices to show that the average associated cost of each column S is at most $(H_k - \frac{k-1}{8k^9}) c_S$. The average cost of the copies in the resulting multiset is at most $c_S \left(\frac{1}{k} H_k + \frac{k-1}{k} (H_k - \frac{1}{8k^8})\right) = c_S \left(H_k - \frac{k-1}{8k^9}\right)$, and therefore $H_k - \frac{k-1}{8k^9}$ is an upper bound on the approximation ratio of GAWW. \square

Remark 12. The following is a bad instance for the greedy algorithm with withdrawals: Assume that

$$OPT = \begin{pmatrix} X & X & X \\ Y & Y & Y \\ a & b & c \end{pmatrix},$$

where the costs of the sets in OPT (the columns of the matrix) are $c_1 = 936$, $c_2 = 1161$, and $c_3 = 1543$. Therefore $OPT = 3640$. Assume that $c_X = 936$, $c_Y = 1404$, $c_a = 774$, $c_b = 1161$, $c_c = 1543$. GAWW could pick the sets X, Y, a, b, c in this order, with a total cost of 5818. Therefore, the approximation ratio of GAWW is at least $\frac{5818}{3640} \sim 1.5984$. We note that the cost values in this example were chosen to give the worst possible ratio for any instance with the same OPT and sequence of operations chosen by the algorithm.

5. Discussion. In this paper we addressed the weighted k -set cover problem and introduced the first improvement over the greedy algorithm for any constant k . Although we are able to prove only a small improvement over the greedy algorithm, the worst example we found for $k = 3$ is with ratio of $\frac{5818}{3640}$, and the gap between these numbers is relatively large. Tightening this gap is left for future research.

In this paper we were mainly interested in proving an improvement over the greedy algorithm, and we did not try to optimize the constant and the exponent of the term $\frac{k-1}{8k^9}$.

We defined the greedy algorithm with withdrawals requiring that in each withdrawal step a single set in the current solution is withdrawn (and its elements must be covered by the new added subsets). We can generalize this algorithm and consider in each step the possibility of withdrawing at most l subsets from the current solution. This version of the algorithm is clearly polynomial for any constant l . It is natural to conjecture that the approximation ratio of the resulting algorithm is a decreasing function of l . In this paper we proved that $l = 1$ strictly improves the bound of $l = 0$ which corresponds to the greedy algorithm of Chvátal [2].

We conclude this discussion by noting that the withdrawal operation was crucial to obtain better approximation ratio. We mean that allowing the greedy algorithm to insert p subsets at each step (where p is some constant) does not improve the approximation ratio of the algorithm. To see this, note that we can take p copies of an original instance, and the new algorithm will have the same performance guarantee on the new instance as the greedy algorithm has on the original instance.

A SUPERPOLYNOMIAL LOWER BOUND FOR A CIRCUIT COMPUTING THE CLIQUE FUNCTION WITH AT MOST (1/6) log log N NEGATION GATES*

KAZUYUKI AMANO[†] AND AKIRA MARUOKA[†]

Abstract. In this paper, we investigate the lower bound on the number of gates in a Boolean circuit that computes the clique function with a limited number of negation gates. To derive strong lower bounds on the size of such a circuit we develop a new approach by combining three approaches: the restriction applied to constant depth circuits due to Håstad, the approximation method applied to monotone circuits due to Razborov, and the boundary covering developed in the present paper. We prove that if a circuit C with at most $\lfloor (1/6) \log \log m \rfloor$ negation gates detects cliques of size $(\log m)^{3(\log m)^{1/2}}$ in a graph with m vertices, then C contains at least $2^{(1/5)(\log m)^{1/2}}$ gates. No nontrivial lower bounds on the size of such circuits were previously known, even if we restrict the number of negation gates to be a constant. Moreover, it follows from a result of Fischer [*Lect. Notes Comput. Sci.*, 33 (1974), pp. 71–82] that if one can improve the number of negation gates from $\lfloor (1/6) \log \log m \rfloor$ to $\lfloor 2 \log m \rfloor$ in the statement, then we have $P \neq NP$. We also show that the problem of lower bounding the negation-limited circuit complexity can be reduced to the one of lower bounding the maximum of the monotone circuit complexity of the functions in a certain class of monotone functions.

Key words. circuit complexity, monotone circuit, negation-limited circuit, approximation method, lower bound, clique function

1. Introduction. There has been substantial progress in obtaining strong lower bounds on the size of restricted Boolean circuits, such as constant depth circuits or monotone circuits that compute certain functions. For example, exponential lower bounds were derived for the size of constant depth circuits computing the parity function [7] and for the size of monotone circuits computing the clique function and other functions (see [1, 2, 5, 8, 9, 10, 13]). It is natural to ask if we could use the approaches developed so far to derive strong lower bounds for a more general model. In such a generalized model, we consider circuits with a limited number of negation gates. In fact, it so far remains open to derive nontrivial lower bounds on the size of a circuit computing a certain monotone function with, say, a constant number of negation gates [14]. Fischer [6] showed that for any function f on n variables, the size of the smallest circuit computing f with an arbitrary number of NOT gates and the one with, at most, $\lceil \log(n+1) \rceil$ NOT gates are polynomially related (see also [4]). So if one can prove superpolynomial lower bounds on the size of circuits with at most $\lceil \log(n+1) \rceil$ NOT gates computing an explicit function in NP, then we have $P \neq NP$.

In this paper, we try to obtain superpolynomial lower bounds on the size of circuits computing an explicit function in NP with $O(\log \log n)$ NOT gates rather than $O(\log n)$ NOT gates. More precisely we prove the following: If a circuit C

with at most $\lfloor (1/6) \log \log m \rfloor$ NOT gates detects cliques of size $(\log m)^{3(\log m)^{1/2}}$ in a graph with m vertices, then C contains at least $2^{(1/5)(\log m)^{(\log m)^{1/2}}}$ gates (Theorem 5.1). Note that the problem of detecting a clique in a graph with m vertices will be written as a Boolean function of $n = \binom{m}{2}$ variables. We also show that the problem of lower bounding the negation-limited circuit complexity can be reduced to the one of lower bounding the maximum of the monotone circuit complexity of the functions in a certain class of monotone functions. (Theorem 3.2).

To achieve the main results, we develop a new approach by combining three approaches: the restriction applied to constant depth circuits [7], the approximation method applied to monotone circuits [10, 11], and the boundary covering developed in the present paper. A Boolean function f partitions the Boolean cube into two regions, $f^{-1}(0)$ and $f^{-1}(1)$. We can think of the boundary between the two regions, defined as the collection of pairs of vectors (w, w') such that $f(w) \neq f(w')$, and the Hamming distance between w and w' is 1. The idea of the proof of the main theorem is as follows. First, we prove in section 3 a theorem showing that the problem of proving a lower bound on the size of the negation-limited circuit computing a monotone function f can be reduced to that of proving a lower bound on the maximum over sizes of monotone circuits such that the union of boundaries of the functions computed by the monotone circuits covers the boundary of the monotone function f (Theorem 3.2). Second, we analyze carefully in section 4 the proof of Amano and Maruoka [2] that gives an exponential lower bound on the monotone circuit size of the clique function, and prove a statement saying that we still need a superpolynomial number of gates in a monotone circuit that implements even a certain small fraction of the boundary of the clique function (Theorem 4.1). Finally, we prove in section 5 a statement (Theorem 5.1) that no matter what collection of monotone functions we take to cover the boundary of the clique function, the largest fraction of the boundary covered by a monotone function in the collection is more than what is needed to apply the result (Theorem 4.1) in section 4. This is the most difficult part of the proof.

2. Preliminaries. For w in $\{0, 1\}^n$, let w_i denote the value of the i th bit of w . Let w and w' be in $\{0, 1\}^n$. We denote $w \leq w'$ if $w_i \leq w'_i$ for all $1 \leq i \leq n$, and $w < w'$ if $w \leq w'$ and $w \neq w'$. Let $\text{Ham}(w, w')$ denote the Hamming distance between w and w' , i.e., $\text{Ham}(w, w') = |\{i \in \{1, \dots, n\} \mid w_i \neq w'_i\}|$, where $|S|$ denotes the number of elements in a set S . For two Boolean functions f and g of n variables, we write $f \leq g$ if $f(w) \leq g(w)$ for all $w \in \{0, 1\}^n$.

A *Boolean circuit* is a directed acyclic graph with gate nodes (or, simply gates) and input nodes. The operation AND or OR is associated with each gate whose indegree is 2, whereas NOT is associated with each gate whose indegree is 1. A Boolean variable or a constant, namely, 0 or 1, is associated with each input node whose indegree is 0. There is one designated node in a Boolean circuit with outdegree 0, which is called the output gate. Each gate of the circuit computes a Boolean function in the obvious way and the function computed by the circuit is the function computed by the output gate. In particular, a circuit with no NOT gates is called a *monotone circuit*.

A Boolean function of n variables is *monotone* if $f(w) \leq f(w')$ holds for any $w, w' \in \{0, 1\}^n$ such that $w \leq w'$. Let \mathcal{M}^n denote the set of all monotone functions on n variables. It is well known that f is monotone if and only if f can be computed by a monotone circuit. The *size* of a circuit C , denoted $\text{size}(C)$, is the number of gates in the circuit C . The *circuit complexity* (respectively, *monotone circuit complexity*) of a function f , denoted $\text{size}(f)$ (respectively, $\text{size}_{\text{mon}}(f)$), is the size of the smallest circuit (respectively, the smallest monotone circuit) computing f . For a function f and

a positive integer t , the *circuit complexity with t limited negation* (negation limited complexity, for short) of a function f , denoted $\text{size}_t(f)$, is the size of the smallest circuit C that computes f and includes at most t NOT gates. If a function f cannot be computed with only t NOT gates, then $\text{size}_t(f)$ is undefined. For a circuit C and a gate g in C , let $C_g(w)$ denote the output of the gate g in the circuit C that has the input w . We sometimes assume that a gate g of circuit C is specified as an output gate of the circuit C . In such a case, we say the circuit computes the function $C_g(w)$, which will simply be denoted by $C(w)$. We say a gate g in a circuit C separates a pair of vectors (w, w') (or simply, a gate g separates (w, w') when no confusion arises) if $C_g(w) = 0$, $C_g(w') = 1$ and $\text{Ham}(w, w') = 1$. In particular, when g is taken to be the output gate in C , we simply say that the circuit C separates such a pair (w, w') . Similarly, when a circuit separates a pair we say the function computed by the circuit separates the pair.

Throughout this paper, the function $\log x$ denotes the logarithm base 2 of x .

3. Relationship between negation-limited and monotone circuit complexity. In this section, we explore a relationship between negation-limited circuit complexity and monotone circuit complexity for a monotone Boolean function.

DEFINITION 3.1. *Let f be a Boolean function of n variables. A boundary graph of f , denoted $G(f)$, is defined as follows: $G(f) = (V, E)$ is a directed graph with $V = \{0, 1\}^n$ and $E = \{(w, w') \mid \text{Ham}(w, w') = 1, f(w) = 0 \text{ and } f(w') = 1\}$.*

So a boundary graph of f is a graph whose edge set consists of pairs that are separated by the function f . Let $G_1 = (V, E_1)$ and $G_2 = (V, E_2)$ be two graphs on the same set V of vertices. Then the *union* $G_1 \cup G_2$ is defined to be the graph $(V, E_1 \cup E_2)$. Furthermore, we say G_1 contains G_2 , denoted by $G_1 \supseteq G_2$, if $E_1 \supseteq E_2$ holds.

THEOREM 3.2. *Let f be a monotone function of n variables. For any positive integer t ,*

$$\text{size}_t(f) \geq \min_{F' = \{f_1, \dots, f_\alpha\} \subseteq \mathcal{M}^n} \left\{ \max_{f' \in F'} \{ \text{size}_{\text{mon}}(f') \} \mid \bigcup_{f' \in F'} G(f') \supseteq G(f) \right\},$$

where $\alpha = 2^{t+1} - 1$. Here the functions f_i are not necessarily distinct, so F' could be a multiset.

This theorem shows that the problem of deriving lower bounds on the negation-limited circuit complexity of a monotone function can be reduced to the one of deriving the maximum monotone circuit complexity over the monotone functions such that the corresponding boundary graphs of the functions cover that of the original function. Intuitively, this is because any pair of vectors (w, w') separated by a function f , which is supposed to be computed by a negation-limited circuit C , belongs to the boundary of a monotone circuit obtained by restricting outputs of some NOT gates (possibly, all of the NOT gates) in C , to constants 0 or 1 appropriately and throwing away the remaining NOT gates in C . So lines where we place restriction to constants are outputs of some NOT gates inside of the circuit rather than inputs to the entire circuit as in the case of the lower bound proof for constant depth circuits.

It is worthwhile to note that the set of all variables $F' = \{x_1, \dots, x_n\}$ satisfies the condition $\bigcup_{f' \in F'} G(f') \supseteq G(f)$ for any monotone function f . Hence, if $\alpha \geq n$, that is, $t \geq \log(n + 1) - 1$, the right-hand side of the inequality in Theorem 3.2 does not give a nontrivial lower bound.

Proof of Theorem 3.2. Let f be a monotone function of n variables. Let C be the smallest circuit that computes f using no more than t NOT gates, that is, $\text{size}(C) = \text{size}_t(f)$. Without loss of generality, we assume the number of NOT gates in C is given by t . Furthermore, without loss of generality we assume that the output gate of C is not a NOT gate. Let g_1, \dots, g_t be a list of NOT gates of C arranged in the topological ordering and g_{t+1} be the output gate of the entire circuit C . For $0 \leq i \leq t$ and $u = (u_1, \dots, u_i) \in \{0, 1\}^i$, let C_u denote the subcircuit of C obtained by fixing the output of the NOT gates g_j to constant u_j for $1 \leq j \leq i$ and making the input to g_{i+1} in C the output of the circuit C_u . In particular, for the empty sequence λ , C_λ denotes the circuit obtained by making the input to g_1 in C the output of entire circuit C_λ .

Clearly, for any u of length at most t , the function computed by the circuit C_u is monotone, and the size of the circuit C_u is not greater than the size of the circuit C . Then it is easy to see that, for any $(w, w') \in \{0, 1\}^n \times \{0, 1\}^n$ separated by the circuit C , there exists $0 \leq i \leq t$ and $u \in \{0, 1\}^i$ such that the circuit C_u separates the (w, w') . This is because as such an i we can simply take i such that g_{i+1} is the first gate in the sequence (g_1, \dots, g_{t+1}) such that $C_{g_{i+1}}(w) \neq C_{g_{i+1}}(w')$, and put $u_j = g_j(w) (= g_j(w'))$ for $1 \leq j \leq i$. The number of the circuits represented as C_u for $u \in \{0, 1\}^*$ such that $|u| \leq t$ is given by $\sum_{j=0}^t 2^j = 2^{t+1} - 1 = \alpha$. Hence, denoting by f_j 's functions computed by circuit C_u 's, we have $\bigcup_{f' \in F'} G(f') \supseteq G(f)$ for $F' = \{f_1, \dots, f_\alpha\}$. Thus, since $\text{size}_t(f) (= \text{size}(C)) \geq \text{size}_{\text{mon}}(f')$ for any $f' \in F'$, the proof is completed. \square

4. Hardness of approximating clique function. The clique function, denoted $\text{CLIQUE}(m, s)$, of $m(m-1)/2$ variables is defined to take the value 1 if and only if the undirected graph on m vertices represented in the obvious way by the input contains a clique of size s . For a positive integer s_2 , a graph on m vertices is called *good* if it consists of a clique on some set of s_2 vertices and contains no other edges. Let $I(m, s_2)$ denote the set of such good graphs. For a positive integer s_1 , a graph on m vertices is called *bad* if there is a partition of the vertices into $m \bmod (s_1 - 1)$ sets of size $\lceil m/(s_1 - 1) \rceil$ and $s_1 - 1 - (m \bmod (s_1 - 1))$ sets of size $\lfloor m/(s_1 - 1) \rfloor$ such that any two vertices chosen from different sets have an edge between them, and no other edges exist. Let $O(m, s_1)$ denote the set of such bad graphs.

For $1 \leq s_1 \leq s_2 \leq m$, let $F(m, s_1, s_2)$ denote the set of all the monotone functions f of $\binom{m}{2}$ variables representing a graph G on m vertices such that the function f outputs 0 if G contains no clique of size s_1 , outputs 1 if G contains a clique of size s_2 , and outputs an arbitrary value otherwise. We remark that $F(m, s, s) = \{\text{CLIQUE}(m, s)\}$ and that if $s_1 < s_2$, then $F(m, s_1, s_2)$ consists of more than one function. For any function f in $F(m, s_1, s_2)$, the value of f is 1 for any good graph, and is 0 for any bad graph. Moreover, a good graph is minimal in the sense that removing any edge from the graph destroys the clique of size s_2 . On the other hand, a bad graph is maximal in the sense that adding any edge to the graph makes the graph contain a clique of size s_1 .

In this section, we prove the following theorem, which will be needed in the next section to prove the main theorem. This theorem says that, if $64 \leq s_1 \leq s_2$ and $s_1^{1/3} s_2 \leq m/200$, then no function in $F(m, s_1, s_2)$ can be approximated by a feasible monotone circuit.

THEOREM 4.1. *Let s_1 and s_2 be positive integers such that $64 \leq s_1 \leq s_2$ and $s_1^{1/3} s_2 \leq m/200$. Suppose that C is a monotone circuit and that the fraction of good graphs in $I(m, s_2)$ such that C outputs 1 is at least $h = h(s_2)$. Then at least one of*

the following holds:

- (i) The number of gates in C is at least $(h/2)2^{s_1^{1/3}/4}$.
- (ii) The fraction of bad graphs in $O(m, s_1)$ such that C outputs 0 is at most $2/s_1^{1/3}$.

Let $\Pr_{v \in I(m, s_2)}[E(v)]$ denote the probability of event $E(v)$ provided that the uniform distribution over $I(m, s_2)$ is assumed, and similarly for $\Pr_{u \in O(m, s_1)}[E(u)]$. Theorem 4.1 is restated as follows: Assume that the conditions on the parameters described in the theorem are satisfied. If monotone circuit C is such that

$$\Pr_{v \in I(m, s_2)}[C(v) = 1] \geq h,$$

and

$$\Pr_{u \in O(m, s_1)}[C(u) = 0] > \frac{2}{s_1^{1/3}},$$

then

$$\text{size}(C) \geq \left(\frac{h}{2}\right) 2^{s_1^{1/3}/4}.$$

The proof of Theorem 4.1 is done by employing the symmetric version of the method of approximation [2, 5, 8, 9, 13]. In particular, we use arguments similar to the proof of an exponential lower bound on the monotone circuit complexity of the clique function (Theorem 3.1 in [2]). The key to the proof is to define the approximate operations $\bar{\vee}$ (which approximates an OR gate) and $\bar{\wedge}$ (which approximates an AND gate) in terms of disjunctive normal form (DNF) and conjunctive normal form (CNF) formulas such that the size of terms and clauses in the formulas is limited appropriately. For the purpose of the arguments of the current paper, we adopt the same definition for the approximate operations as in [2] except for the values of the parameters l and r in their definitions, and follow their arguments to obtain Theorem 4.1.

In what follows we present a rough sketch of a proof of Theorem 4.1. As in [2], a monotone circuit is assumed to be converted to satisfy the following conditions: Any input of an OR gate (respectively, an AND gate) is connected to either an output of an AND gate (respectively, an OR gate) or an input node; and the output gate of the circuit is an AND gate. It is easy to see that in order to convert a monotone circuit to satisfy these conditions, we need to at most double the size of the circuit.

A DNF formula is a disjunction of conjunctions of input variables and each conjunction of a DNF formula is called a *term*. A CNF formula is a conjunction of disjunctions of input variables and each disjunction of a CNF formula is called a *clause*. Let t be a term or a clause. The *endpoint set* of t is a set of all endpoints of the edges corresponding to variables in t . The *size* of t is defined to be the cardinality of the endpoint set of t . The approximate operations $\bar{\vee}$ and $\bar{\wedge}$ are defined as follows:

$\bar{\vee}$: Let f_1^D and f_2^D be two functions, represented by monotone DNF formulas, feeding into an $\bar{\vee}$ gate. $f_1^D \bar{\vee} f_2^D$ is the CNF formula obtained by transforming the monotone DNF formula $f_1^D \vee f_2^D$ into the monotone CNF formula and then taking away all the clauses whose size exceeds r .

$\bar{\wedge}$: Let f_1^C and f_2^C be two functions, represented by monotone CNF formulas, feeding into an $\bar{\wedge}$ gate. $f_1^C \bar{\wedge} f_2^C$ is the DNF formula obtained by transforming the monotone CNF formula $f_1^C \wedge f_2^C$ into the monotone DNF formula and then taking away all the terms whose size exceeds l .

In what follows, AND and OR gates are also written as \wedge and \vee gates, respectively. Given a monotone circuit C , the circuit obtained by replacing all \vee and \wedge gates in C by $\bar{\vee}$ and $\bar{\wedge}$ gates, respectively, is denoted by \bar{C} , which will be called the approximator circuit corresponding to C . The approximate operations and the approximator circuits are introduced to derive good lower bounds on the size of circuits computing a certain function. Theorem 4.1 derives a lower bound on the size of monotone circuits approximately computing the clique function. Its proof, based on the approximation method, is as follows. First, we show that the number of good and bad graphs that are classified incorrectly by an approximator circuit is large (Lemma 4.3). More precisely, for an approximator circuit \bar{C} arbitrarily given, \bar{C} outputs 0 for a large number of good graphs or yields 1 for a large number of bad graphs. Second, we show that the number of good and bad graphs for which a usual gate and the corresponding approximate gate behave differently is small. More precisely, it is only for a small number of bad graphs that \vee gate outputs 0 and $\bar{\vee}$ gate yields 1 (Lemma 4.4), whereas it is only for a small number of good graphs that \wedge gate outputs 1 and $\bar{\wedge}$ gate yields 0 (Lemma 4.5). Recall that, in general, the usual gates and the corresponding approximate gates behave differently because long clauses or long terms are taken away when defining the approximate operations based on the formulas. Finally, since for each good or bad graph classified incorrectly by an approximator circuit there exist an approximate gate in \bar{C} that behaves differently from the corresponding usual gate on that graph, the number of approximate gates that compensate for a large number of good or bad graphs misclassified by the entire circuit must be large (Theorem 4.1).

Choose $l = \lfloor s_1^{1/3}/4 \rfloor$ and $r = \lfloor 30s_1^{1/3} \rfloor$. Put $w = m \bmod (s_1 - 1)$. A simple calculation shows the following.

FACT 4.2. $|I(m, s_2)| = (m!)/(s_2!(m - s_2)!) \text{ and}$

$$|O(m, s_1)| = \frac{m!}{(\lceil m/(s_1 - 1) \rceil!)^w (\lfloor m/(s_1 - 1) \rfloor!)^{s_1 - 1 - w} w! (s_1 - 1 - w)!}.$$

We proceed to the technical parts of the proof. Although the arguments are analogous to that presented in [2], we give proofs here to make this paper self-contained.

LEMMA 4.3. *Let C be a monotone circuit. An approximator circuit \bar{C} outputs identically 0 or the fraction of bad graphs in $O(m, s_1)$ such that \bar{C} outputs 1 is at least $1 - s_1^{-1/3}$.*

Proof. Let \bar{f} be the output of an approximator circuit \bar{C} . Because of the assumption that the output gate of the approximator circuit is an AND gate, \bar{f} can be represented by a monotone DNF formula consisting of terms of size at most l . If \bar{f} is identically 0, then the first conclusion holds. If not, then there is a term t whose size is at most l such that $\bar{f} \geq t$ holds. In what follows, bad graphs are represented as one-to-one mapping from the vertex set to $\{(1, 1), \dots, (1, \lceil m/(s_1 - 1) \rceil), \dots, (s_1 - 1, 1), \dots, (s_1 - 1, \lfloor m/(s_1 - 1) \rfloor)\}$, so there are many mappings corresponding to one bad graph. Such a mapping specifies a bad graph in the obvious way: Two vertices in the graph have an edge between them if and only if the mapping assigns pairs to the vertices with different first components. The function in question will be estimated in terms of the ratio of the corresponding mappings. It is easy to see that the ratio of mappings that satisfy the condition that there is a variable x in the term t such that the two vertices incident to x are assigned a pair with the same first component, i.e.,

the term t outputs 0 on the bad graphs specified by such mappings, is at most

$$\frac{l(l-1)}{2} \frac{\lceil m/(s_1-1) \rceil}{m} < \frac{s_1^{2/3}}{32} \frac{2}{s_1} < s_1^{-1/3}.$$

This completes the proof. \square

LEMMA 4.4. *Suppose \vee gate and ∇ gate are given as inputs the same monotone formulas such that the size of any term in the formulas is at most l . The number of bad graphs in $O(m, s_1)$ for which the OR and ∇ gates produce different outputs (the OR gate produces 0, whereas the ∇ gate produces 1) is at most*

$$(4.1) \quad \frac{(m/s_1^{1/6})^{r+1}(m-r-1)!}{(\lceil m/(s_1-1) \rceil!)^w (\lfloor m/(s_1-1) \rfloor!)^{s_1-1-w} w!(s_1-1-w)!},$$

where $w = m \bmod (s_1 - 1)$.

Proof. Let f_1^D and f_2^D denote monotone formulas, such that the size of any term in the formulas is at most l . Let $f_1^D \vee f_2^D$ and $f_1^D \nabla f_2^D$ be denoted by f^D and f^C , respectively. Let t_1, \dots, t_q be the complete list of the terms in f^D . We shall count the number of bad graphs u such that both $f^D(u) = 0$ and $f^C(u) = 1$ hold. As in the proof of Lemma 4.3, bad graphs are represented as the mappings described there. Since each bad graph in $O(m, s_1)$ is represented exactly as $(\lceil m/(s_1-1) \rceil!)^w (\lfloor m/(s_1-1) \rfloor!)^{s_1-1-w} w!(s_1-1-w)!$ mappings as in the proof of Lemma 4.3, it suffices to show that the number of mappings corresponding to the bad graphs described in the lemma is at most $(m/s_1^{1/6})^{r+1}(m-r-1)!$. In order to count such mappings we will count the number of ways of choosing one or two vertices in a certain manner repeatedly from the variables in t_1, \dots, t_q so that the corresponding bad graph u satisfies the conditions $f^D(u) = 0$ and $f^C(u) = 1$.

Suppose that we somehow already assigned distinct pairs of integers to endpoints of variables from terms t_1, \dots, t_{i-1} so as to make all these terms take the value 0 and that we proceed to the term t_i . We now typically choose one or two vertices from the endpoints of variables from t_i in the way described below and then proceed to the next term t_{i+1} .

We first consider two extreme cases. If there is a variable in t_i already assigned 0 by the partial assignment, we skip to the next term t_{i+1} . The other extreme case occurs when all the variables in t_i are, so far, assigned 1. In this case the term t_i will never take value 0, hence we do not need to consider the case.

If neither of these extreme cases happens, choose a variable from the term t_i such that at least one of the vertices associated with the variable is not assigned a pair of integers. There are two cases to consider: If exactly one of the vertices has been assigned, then assign a pair to the remaining vertex whose first component is identical to the first component of the pair of integers associated with the variable so that the variable takes the value 0. In this case, there are at most $\lfloor m/(s_1-1) \rfloor \leq m/(s_1-1)$ ways of assigning the pairs of integers to the vertex. On the other hand, if both of the vertices have not been chosen, assign to these vertices pairs of integers with their first components being the same so that the variable associated with two vertices takes the value 0. So, for the two vertices, there are at most $(s_1-1)(\lceil m/(s_1-1) \rceil)(\lfloor m/(s_1-1) \rfloor - 1) \leq 2m^2(s_1-1)$ ways of assigning the pairs of integers.

Let k be the number of variables in term t_i such that exactly one of the vertices corresponding to the variables is assigned a pair of integers so far. Then there exist at most $l(l-1)/2 - k$ variables in term t_i such that none of the vertices associated

with the variables has been assigned a pair of integers so far. So the number of ways of choosing an unassigned vertex in the endpoints of variables in t_i and assigning a pair of integers to the chosen vertex is at most

$$(4.2) \quad \begin{aligned} & \max_{0 \leq k \leq l(l-1)/2} \{k(m/(s_1 - 1)) + \sqrt{(l(l-1)/2 - k)(2m^2/(s_1 - 1))}\} \\ & \leq (l(l-1)/2)(m/(s_1 - 1)) + \sqrt{(l(l-1)/2)(2m^2/(s_1 - 1))}. \end{aligned}$$

This is because doing something to two vertices in i ways can be regarded as doing something to a vertex appropriately in \sqrt{i} ways twice successively. Recall that $l = \lfloor s_1^{1/3}/4 \rfloor$. We have that

$$(4.2) \leq \frac{s_1^{2/3}}{32} \frac{2m}{s_1} + \sqrt{\frac{s_1^{2/3}}{32} \frac{4m^2}{s_1}} < \frac{m}{32s_1^{1/3}} + \frac{m}{2s_1^{1/6}} < \frac{m}{s_1^{1/6}}.$$

By the definition of ∇ gate, a bad graph u corresponding to a mapping specified in this way satisfies $f^D(u) = 0$ and $f^C(u) = 1$ only if there exist more than r vertices assigned to pairs of integers in the above procedure. Thus the number of mappings corresponding to such bad graphs is at most the number of the ways of assigning the $r + 1$ vertices to the pairs of integers in the manner described above multiplied by the number of ways of assigning the remaining $m - r - 1$ vertices arbitrarily to the remaining distinct pairs of integers, which is given by $(m/s_1^{1/6})^{r+1}(m - r - 1)!$. This completes the proof. \square

LEMMA 4.5. *The number of good graphs in $I(m, s_2)$ for which the AND and $\bar{\wedge}$ gates produce different outputs (the AND gate produces 1, whereas the $\bar{\wedge}$ gate produces 0) is at most*

$$\frac{(2rs_2)^{l+1}(m - l - 1)!}{s_2!(m - s_2)!}.$$

Proof. The proof is similar to that of Lemma 4.4. Suppose an AND gate and an $\bar{\wedge}$ gate are given as input for the same monotone CNF formulas, denoted f_1^C and f_2^C . Let $f^C = f_1^C \wedge f_2^C$ and $f^D = f_1^C \bar{\wedge} f_2^C$. Let c_1, \dots, c_q be the complete list of clauses in f^C . Note that, for each clause c_i , the size of c_i is at most r and so the clause c_i contains at most $r(r-1)/2$ variables. The number in question is equal to the number of good graphs v such that $f^C(v) = 1$ and $f^D(v) = 0$.

Instead of the mappings from vertices to pairs of integers in the case of Lemma 4.4, we consider one-to-one mappings from the vertex set to the set of integers $\{1, \dots, m\}$. Such a mapping is thought to specify a good graph such that the set of vertices assigned with integers from 1 to s_2 forms a clique. Since each good graph in $I(m, s_2)$ is represented as exactly $s_2!(m - s_2)!$ mappings, it suffices to show that the number of mappings corresponding to good graphs v such that $f^C(v) = 1$ and $f^D(v) = 0$ is at most $(2rs_2)^{l+1}(m - l - 1)!$.

As in the proof of Lemma 4.4 we proceed from c_1 up to c_q repeatedly by assigning one or two vertices to integers from $\{1, \dots, m\}$ so that the resulting good graph v satisfies the condition that $f^C(v) = 1$ and $f^D(v) = 0$. Suppose that we somehow already assigned distinct integers to the endpoints of variables from clauses c_1, \dots, c_{i-1} so as to make all these clauses take the value 1 and we proceed to clauses c_i . We now choose one or two vertices from the endpoints of variables from c_i in a way similar to that in the proof of Lemma 4.4 and then proceed to the next clause c_{i+1} . As in

the case of the proof of Lemma 4.4, we need only to consider the case where there remain variables in c_i such that assigning one or two endpoints, not chosen so far, of these variables makes the clause c_i take the value 1. Since the number of endpoints of vertices in c_i is at most r , the number of ways of choosing a vertex and assigning an integer in the manner described above is at most $r(s_2 - 1)$, while the number of ways of choosing two adjacent vertices and assigning integers is at most $(r(r - 1)/2)s_2(s_2 - 1)$. Thus the number of ways per a vertex is at most

$$r(s_2 - 1) + \sqrt{(r(r - 1)/2)s_2(s_2 - 1)} < 2rs_2.$$

Thus, in a way similar to the proof of Lemma 4.4, it is easily seen that the number of mappings corresponding to good graphs v such that $f^C(v) = 1$ and $f^D(v) = 0$ is at most $(2rs_2)^{l+1}(m - l - 1)!$ because clauses of length more than l are taken away when CNF formula $f_1^C \wedge f_2^C$ is transformed into DNF formulas $f_1^C \bar{\wedge} f_2^C$. This completes the proof of the lemma. \square

Proof of Theorem 4.1. Assume that a monotone circuit C is such that $\Pr_{v \in I(m, s_2)}[C(v) = 1] \geq h(s_2)$ and $\Pr_{u \in O(m, s_1)}[C(u) = 0] > 2/s_1^{1/3}$ hold. To prove the theorem, it suffices to show $\text{size}(C) \geq (h/2)2^{s_1^{3/4}}$. From Lemma 4.3, the approximator circuit \bar{C} satisfies $\Pr_{v \in I(m, s_2)}[C(v) \neq \bar{C}(v)] \geq h(s_2)$ or $\Pr_{u \in O(m, s_1)}[C(u) \neq \bar{C}(u)] > 1/s_1^{1/3}$. Thus, in view of Fact 4.2 and Lemmas 4.3, 4.4, and 4.5, the size of C is at least

$$(4.3) \quad \frac{1}{2} \min \left(\frac{h(s_2)m!}{(2rs_2)^{l+1}(m - l - 1)!}, \frac{m!}{s_1^{1/3}(m/s_1^{1/6})^{r+1}(m - r - 1)!} \right).$$

The coefficient $\frac{1}{2}$ here is needed to take into account the fact that circuit C is assumed to be modified so the AND and OR gates alternate along any path from an input to the output in the circuit. An elementary calculation completes the proof. \square

5. Proof of the main theorem. The goal of this section is to prove Theorem 5.1, which says that $\lfloor (1/6) \log \log m \rfloor$ NOT gates are not enough to compute the clique function feasibly. We do not intend here to optimize the constant $1/6$ in the number of NOT gates.

THEOREM 5.1. *For any sufficiently large integer m ,*

$$\text{size}_{\lfloor (1/6) \log \log m \rfloor}(\text{CLIQUE}(m, (\log m)^{3(\log m)^{1/2}})) > 2^{(1/5)(\log m)^{(\log m)^{1/2}}}.$$

Before proceeding to the proof, we describe the idea behind the proof.

Let f be $\text{CLIQUE}(m, s)$. Suppose to the contrary that a small circuit C with t NOT gates computes f . By Theorem 3.2, there are $2^{t+1} - 1 (= \alpha)$ monotone functions f_1, \dots, f_α such that each of them can be computed by a monotone circuit and that $\cup_{i \in \{1, \dots, \alpha\}} G(f_i) \supseteq G(f)$.

All proofs of lower bounds on the size of a monotone circuit computing a certain function are based on the observation that the circuit separates the minterms and maxterms of the target function [2, 5, 8, 9, 10, 13] (see Figure 5.1). Instead of focusing on the separation of the minterms and maxterms of the target function f , we consider separating pairs of vectors (w, w') in $G(f)$, that is, pairs (w, w') such that $f(w) = 0$, $f(w') = 1$ and $\text{Ham}(w, w') = 1$. Theorem 3.2 says that, if f can be computed by a small circuit C with t NOT gates, then it follows that there exists a collection of

FIG. 5.1. A figure showing the minterms and maxterms of *CLIQUE* in the Boolean cube.

monotone functions f_1, \dots, f_α such that they separate $G(f)$ (i.e., $\cup_{i \in \{1, \dots, \alpha\}} G(f_i) \supseteq G(f)$) and that each of functions f_1, \dots, f_α can be computed by a small monotone circuit, where $\alpha = 2^{t+1} - 1$. In what follows we shall show that the circuit C is not small by showing that it is not the case that all of the function f_i 's satisfying the above condition can be computed by small monotone circuits. In fact we only pay attention to a subset of $G(f)$ which contains pairs that seem to be hard to separate. As the following example shows, it is crucial to decide which subset of $G(f)$ we pay attention to. As an example of a bad choice for a subset, take the subset $G'(f)$ defined as

$$G'(f) = \{(u, u^+) \mid u \in O(m, s) \text{ and } (u, u^+) \in G(f)\} \\ \cup \{(v^-, v) \mid v \in I(m, s) \text{ and } (v^-, v) \in G(f)\}.$$

Clearly, the number of 1's in u is the same for all $u \in O(m, s)$, and similarly for $v \in I(m, s)$. So if we set f_1 and f_2 to be the two threshold functions whose threshold values are the number of 1's in v and that in u^+ , then we have $G(f_1) \cup G(f_2) \supseteq G'(f)$. On the other hand, it is known that a monotone circuit of size $O(n \log n)$ can compute a threshold function on n variables for any given threshold value. So we cannot derive a contradiction by the usual approximation method argument. We will give a subset which we use as the subset of $G(f)$ consisting of edges illustrated in Figure 5.2.

Let $l_0 < l_1 < \dots < l_\alpha$ be a monotone increasing sequence of integers, where $l_0 = s$, $l_\alpha = m$, and others are chosen appropriately later. For $1 \leq i \leq \alpha$, a graph v is called *good in the i th layer* if v consists of a clique of size l_{i-1} , and contains no other edges. For $1 \leq i \leq \alpha$, a graph u is called *bad in the i th layer* if there exist l_i vertices and a partition of these l_i vertices into $s - 1$ blocks with nearly equal size such that u has an edge between any two vertices chosen from different blocks and no other edges. In other words, a bad graph in the i th layer is a $(s - 1)$ -partite complete graph on some subset of vertices of size l_i . Note that, for any good graph v in the first layer, there is an edge in $G(f)$ whose head is v because deleting an edge from v breaks the clique in v . (Recall that each vertex of the boundary graph $G(f)$ corresponds to an input graph of the clique function.) Similarly, for any bad graph u in any layer, there is an edge in $G(f)$ whose tail is u because adding an appropriate edge (between

FIG. 5.2. Layered structure of the good and bad graphs: The good graphs and bad graphs are described as solid circles and open circles, respectively. A small monotone circuit cannot separate its good graphs and bad graphs in any one layer. When a bad graph u in the i th layer is connected by an arrow to a good graph v in the $(i + 1)$ th layer, they satisfy the condition $v \geq u$.

vertices in a block) to u ends up with having a clique of size s . In what follows we will prove that if monotone functions f_1, \dots, f_α separate $G(f)$ and each f_1, \dots, f_α can be computed by a small monotone circuit, then a contradiction follows. In order to prove it, because we must consider α functions which are supposed to separate $G(f)$, we must fully exploit the computational complexity of the function CLIQUE, considering α layers and focusing on the separation between good and bad graphs in each layer.

Since $\cup_{i \in \{1, \dots, \alpha\}} G(f_i) \supseteq G(f)$, there exists a function, say f_1 , in $\{f_1, \dots, f_\alpha\}$ such that $G(f_1)$ contains at least $1/\alpha$ fraction of edges of $G(f)$ ending at good graphs in the first layer, and hence f_1 outputs 1 on at least $1/\alpha$ fraction of good graphs in the first layer. Since we can use Theorem 4.1 to show that every small monotone circuit that outputs 1 for a certain fraction of good graphs in the first layer must output 1 for a large number of bad graphs in the same layer, the function f_1 takes the value 1 for a large number of bad graphs u in the first layer. By adding an edge appropriately to such a u we get a graph u^+ which contains a clique of size s . Hence there are many edges, denoted (u, u^+) , which are not included in the edges in $G(f_1)$. Since $\cup_{i \in \{1, \dots, \alpha\}} G(f_i) \supseteq G(f)$, there exists a function, say f_2 , in $\{f_2, \dots, f_\alpha\}$ such that $G(f_2)$ contains at least $1/\alpha$ fraction of such edges (u, u^+) . On the other hand, because f_2 is monotone and $f_2(u^+) = 1$, f_2 takes the value 1 on the good graph v in the second layer such that $u^+ \leq v$. Applying Theorem 4.1 again, we can conclude that f_2 outputs 1 for a large number of bad graphs in the second layer. It can be shown that f_1 also outputs 1 for such bad graphs.

By continuing the above argument, we can conclude that every function f_1, \dots, f_α outputs 1 on some bad graph u in the last layer, contradicting the fact that $\cup_{i \in \{1, \dots, \alpha\}} G(f_i) \supseteq G(f)$. This is the outline of the proof.

Proof of Theorem 5.1. Let m be a sufficiently large integer. Put $t = \lfloor (1/6) \log \log m \rfloor$, $s = (\log m)^{3(\log m)^{1/2}}$, $M = 2^{(1/5)(\log m)(\log m)^{1/2}}$, and $\alpha = 2^{t+1} - 1$. We suppose to the contrary that a circuit C with at most t NOT gates computes CLIQUE(m, s) and that

$\text{size}(C) \leq M$. From Theorem 3.2, there are monotone functions $f_1, \dots, f_\alpha \in \mathcal{M}^n$ such that $\text{size}_{\text{mon}}(f_i) \leq M$ for any $1 \leq i \leq \alpha$, and $\bigcup_{i \in \{1, \dots, \alpha\}} G(f_i) \supseteq G(\text{CLIQUE}(m, s))$.

Let $l_0 = s, l_\alpha = m$, and for every $j = 1, \dots, \alpha-1$, let $l_j = m^{1/10+(1/3)(j-1)/(\log m)^{1/6}}$. Since $l_{\alpha-1} \leq m^{1/10+(1/3)(2^{(1/6)\log \log m+1})/(\log m)^{1/6}} = m^{1/10+2/3} < m^{9/10}$, we have $l_0 < l_1 < \dots < l_\alpha$. Let V be the set of m vertices of the graph associated with CLIQUE . For $j \in \{0, \dots, \alpha\}$, let \mathcal{L}_j denote $\{L \subseteq V \mid |L| = l_j\}$ and let $\mathcal{L}_j(L)$ denote $\{L' \subseteq L \mid L' \in \mathcal{L}_j\}$. For $i \in \{1, \dots, \alpha\}$ and $L_i \in \mathcal{L}_i$, a graph v is called *good on the set L_i in the i th layer* if it consists of a clique of size l_{i-1} on some $L_{i-1} \in \mathcal{L}_{i-1}(L_i)$ (i.e., $|L_{i-1}| = l_{i-1}$ and $L_{i-1} \subseteq L_i$), and contains no other edges. For $i \in \{1, \dots, \alpha\}$ and $L_i \in \mathcal{L}_i$, a graph u is called *bad on the set L_i in the i th layer* if there is a partition of L_i into V_1, \dots, V_{s-1} such that

- (i) $|V_i| \in \{[\lfloor L_i/(s-1) \rfloor], \lceil \lceil L_i/(s-1) \rceil \rceil\}$ for $i = 1, \dots, s-1$,
- (ii) u has an edge (w, w') if and only if $w \in V_i$ and $w' \in V_j$ such that $i \neq j$, i.e., u is a complete $(s-1)$ -partite complete graph on the vertex set L_i .

Let I_{L_i} (respectively, O_{L_i}) denote the set of all good (respectively, bad) graphs on the set L_i in the i th layer. Note that a good graph in the first layer (respectively, a bad graph in the last layer) is a minterm (respectively, a maxterm) of $\text{CLIQUE}(m, s)$. We also note that there is a one-to-one correspondence between I_{L_i} and $I(l_i, l_{i-1})$, and between O_{L_i} and $O(l_i, s)$, where $I(l_i, l_{i-1})$ and $O(l_i, s)$ are defined in section 4. Hence a function in $F(l_i, s, l_{i-1})$ can be viewed as separating the graphs into two groups, I_{L_i} and O_{L_i} . Since $s^{1/3}l_{i-1} \leq l_i/200$ holds, the following corollary is straightforward from Theorem 4.1. This corollary says that a small monotone circuit cannot separate O_{L_i} and I_{L_i} for any i and for any vertex set $L_i \in \mathcal{L}_i$.

COROLLARY 5.2. *Let $i \in \{1, \dots, \alpha\}$ and $L_i \in \mathcal{L}_i$. Suppose that C is a monotone circuit and the fraction of good graphs in I_{L_i} (i.e., the set of good graphs on L_i in the i th layer) such that C outputs 1 is at least h . Then at least one of the following holds:*

- (i) *The number of gates in C is at least $(h/2)2^{s^{1/3}/4}$.*
- (ii) *The fraction of bad graphs in O_{L_i} (i.e., the set of bad graphs on L_i in the i th layer) such that C outputs 0 is at most $2/s^{1/3}$.*

Proof of Theorem 5.1 (continued). For $L \subseteq V$, let v_L denote a graph corresponding to a clique on the set L and having no other edges. Recall that $\mathcal{L}_0 = \{L \subseteq V \mid |L| = s\}$. Thus for any $L_0 \in \mathcal{L}_0$, there exists $u < v_{L_0}$ such that the edge (u, v_{L_0}) is in $G(\text{CLIQUE}(m, s))$. Hence there exists i_1 in $\{1, \dots, \alpha\}$ such that $\Pr_{L_0 \in \mathcal{L}_0}[\exists u < v_{L_0} \ (u, v_{L_0}) \in G(f_{i_1})] \geq 1/\alpha > 1/2^{t+1}$ holds, and this implies

$$(5.1) \quad \Pr_{L_0 \in \mathcal{L}_0} [f_{i_1}(v_{L_0}) = 1] \geq \frac{1}{2^{t+1}}.$$

Then we can obtain

$$(5.2) \quad \Pr_{L_1 \in \mathcal{L}_1} \left[\Pr_{v \in I_{L_1}} [f_{i_1}(v) = 1] \geq \frac{1}{2^{t+2}} \right] \geq \frac{1}{2^{t+2}}.$$

This is because from (5.1), we have

$$(5.3) \quad \begin{aligned} \sum_{L_1 \in \mathcal{L}_1} |\{v \in I_{L_1} \mid f_{i_1}(v) = 1\}| &\geq \frac{1}{2^{t+1}} \binom{m}{l_0} \binom{m-l_0}{l_1-l_0} \\ &= \frac{1}{2^{t+1}} \binom{m}{l_1} \binom{l_1}{l_0}. \end{aligned}$$

But if (5.2) does not hold, then

$$\begin{aligned} \sum_{L_1 \in \mathcal{L}_1} |\{v \in I_{L_1} \mid f_{i_1}(v) = 1\}| &< \binom{m}{l_1} \frac{1}{2^{t+2}} \binom{l_1}{l_0} + \binom{m}{l_1} \left(1 - \frac{1}{2^{t+2}}\right) \binom{l_1}{l_0} \frac{1}{2^{t+2}} \\ &< \frac{2}{2^{t+2}} \binom{m}{l_1} \binom{l_1}{l_0} = \frac{1}{2^{t+1}} \binom{m}{l_1} \binom{l_1}{l_0}, \end{aligned}$$

contradicting (5.3).

Now we call $L_1 \in \mathcal{L}_1$ *dense* if $\Pr_{v \in I_{L_1}} [f_{i_1}(v) = 1] \geq 1/2^{t+2}$ holds. Put $h = 1/2^{t+2}$. An easy calculation shows that $h \geq 1/m$. Thus by applying Claim 5.2 to every dense L_1 , we have $\text{size}_{\text{mon}}(f_{i_1}) \geq (1/2m)2^{s^{1/3}/4} = 2^{(1/4)(\log m)(\log m)^{1/2} - \log m - 1} > M$ or $\Pr_{u \in O_{L_1}} [f_{i_1}(u) = 1] \geq 1 - 2/s^{1/3} \geq 1/2$ for any dense L_1 . Since the former contradicts the assumption that $\text{size}_{\text{mon}}(f_{i_1}) \leq M$, we have $\Pr_{u \in O_{L_1}} [f_{i_1}(u) = 1] \geq 1/2$ for any dense L_1 . By (5.2), we have

$$(5.4) \quad \Pr_{L_1 \in \mathcal{L}_1} \left[\Pr_{u \in O_{L_1}} [f_{i_1}(u) = 1] \geq \frac{1}{2} \right] \geq \frac{1}{2^{t+2}}.$$

The proof will be by induction on a level of the layers. We use (5.4) as the basis of the induction, and the induction steps are as follows.

CLAIM 5.3. *Suppose $c_1 > 1$ and $c_2 > 1$. Put $c_3 = \alpha$. Let f_1, \dots, f_{c_3} be the monotone functions such that $\cup_{i \in \{1, \dots, c_3\}} G(f_i) \supseteq G(\text{CLIQUE}(m, s))$ and $\text{size}_{\text{mon}}(f_i) \leq M$ for any $1 \leq i \leq c_3$. Suppose that, for distinct indices $i_1, \dots, i_k \in \{1, \dots, c_3\}$,*

$$\Pr_{L_k \in \mathcal{L}_k} \left[\Pr_{u \in O_{L_k}} [f_{i_1}(u) = \dots = f_{i_k}(u) = 1] \geq 1/c_1 \right] \geq 1/c_2$$

holds. If $c_1 c_2 c_3 \leq s^{1/3}/8$, then there exists $i_{k+1} \in \{1, \dots, c_3\} \setminus \{i_1, \dots, i_k\}$ such that

$$\Pr_{L_{k+1} \in \mathcal{L}_{k+1}} \left[\Pr_{u \in O_{L_{k+1}}} [f_{i_1}(u) = \dots = f_{i_k}(u) = f_{i_{k+1}}(u) = 1] \geq \frac{1}{4c_1 c_2 c_3} \right] \geq \frac{1}{2c_2 c_3}.$$

For a proof of this claim, see the appendix.

Proof of Theorem 5.1 (continued). First we claim that for any $k \in \{1, \dots, \alpha\}$, there are k distinct indices $i_1, \dots, i_k \in \{1, \dots, \alpha\}$ such that

$$(5.5) \quad \Pr_{L_k \in \mathcal{L}_k} \left[\Pr_{u \in O_{L_k}} [f_{i_1}(u) = \dots = f_{i_k}(u) = 1] \geq \frac{1}{2k^2(t+2)} \right] \geq \frac{1}{2k(t+2)}$$

holds. The claim is proved by induction on k . The basis, $k = 1$, is trivial from (5.4). Now we suppose the claim holds for any $k \leq l$ and let $k = l + 1$. By the induction hypothesis, we have

$$\Pr_{L_l \in \mathcal{L}_l} \left[\Pr_{u \in O_{L_l}} [f_{i_1}(u) = \dots = f_{i_l}(u) = 1] \geq \frac{1}{2^{l^2(t+2)}} \right] \geq \frac{1}{2^{l(t+2)}}.$$

Putting $c_1 = 2^{l^2(t+2)}$, $c_2 = 2^{l(t+2)}$, and $c_3 = \alpha$, we have $4c_1 c_2 c_3 \leq 2^{2+l^2(t+2)+l(t+2)+(t+1)} \leq 2^{(l+1)^2(t+2)}$, $2c_2 c_3 \leq 2^{l+l(t+2)+t+1} = 2^{(l+1)(t+2)}$, and $c_1 c_2 c_3 \leq$

$2^{(l+1)^2(t+2)}/4 \leq 2^{(2^{t+1})^2(t+2)}/4 \leq 2^{2^{3t}}/8 \leq 2^{2^{(1/2)\log\log m}}/8 = 2^{\sqrt{\log m}}/8 < (\log m)\sqrt{\log m}/8 = s^{1/3}/8$. Thus by Claim 5.3,

$$\Pr_{L_{l+1} \in \mathcal{L}_{l+1}} \left[\Pr_{u \in O_{L_{l+1}}} [f_{i_1}(u) = \cdots = f_{i_{l+1}}(u) = 1] \geq \frac{1}{4c_1c_2c_3} \right] \geq \frac{1}{2c_2c_3}$$

holds. Therefore

$$\begin{aligned} \Pr_{L_{l+1} \in \mathcal{L}_{l+1}} \left[\Pr_{u \in O_{L_{l+1}}} [f_{i_1}(u) = \cdots = f_{i_{l+1}}(u) = 1] \geq \frac{1}{2^{(l+1)^2(t+2)}} \right] &\geq \frac{1}{2c_2c_3} \\ &\geq \frac{1}{2^{(l+1)(t+2)}}. \end{aligned}$$

This completes the induction step and hence the proof of the claim.

Recalling $\mathcal{L}_\alpha = \{V\}$ and setting k in (5.5) to α , we have $\Pr_{u \in O_V} [\forall i \in \{1, \dots, \alpha\} f_i(u) = 1] > 0$. Thus there exist $u \in O_V$ and $u^+ \in \text{CLIQUE}(m, s)^{-1}(1)$ such that $(u, u^+) \in G(\text{CLIQUE}(m, s))$ and $(u, u^+) \notin G(f_i)$ for any $i \in \{1, \dots, \alpha\}$. This implies that $\bigcup_{i \in \{1, \dots, \alpha\}} G(f_i) \not\supseteq G(\text{CLIQUE}(m, s))$, completing the proof. \square

6. Concluding remarks. There are still many interesting questions yet to be answered in the line of research pursued in the present paper. An obvious challenge is to improve the number of negation gates in the main theorem to $\omega(\log \log n)$. Another interesting problem is to show a tradeoff between the circuit size and the number of negation gates in a circuit to compute a certain monotone function. Analyzing the size complexity more carefully along the line suggested in this paper might help to explore such a tradeoff. Note that we have recently proved that such a tradeoff exists for the merging function $\text{MERGE}(n, n)$, which is a collection of monotone functions that merges two presorted binary sequence each of length n into a sorted sequence of length $2n$, by showing $\text{size}_t(\text{MERGE}(n, n)) = \Theta(n \log n / 2^t)$ for every $t = 0, \dots, \log \log n$ [3].

Finally, it should be noted that there is a large obstacle in generalizing our techniques to obtain a good lower bound for a circuit without restricting the number of negation gates. This comes from the notion of “natural proofs” introduced by Razborov and Rudich [12]. They proved that almost all known combinatorial lower bound proof techniques are “natural,” and such proofs cannot yield a good lower bound for general circuit complexity under some commonly believed cryptographic assumption. Our techniques seem to fall under the category of natural proofs although we have not tried to give a formal proof. Some radically different techniques would be needed to improve the number of negation gates in our main theorem to, say, $\log n$.

Appendix. *Proof of Claim 5.3.* Let $\mathcal{L}_k^{\text{bad}}$ denote the collection of sets $L_k \in \mathcal{L}_k$ with $\Pr_{u \in O_{L_k}} [f_{i_1}(u) = \cdots = f_{i_k}(u) = 1] \geq 1/c_1$. By the assumption of Claim 5.3, we have

$$(A.1) \quad \Pr_{L_k \in \mathcal{L}_k} [L_k \in \mathcal{L}_k^{\text{bad}}] \geq \frac{1}{c_2}.$$

Let $u \in O_{L_k}$ be such that $f_{i_1}(u) = \cdots = f_{i_k}(u) = 1$. By the definition of boundary graphs, none of $G(f_{i_1}), \dots, G(f_{i_k})$ contains an edge from u . Note that $\text{CLIQUE}(m, s)(u) = 0$. Let u^+ be a graph obtained from u by adding an arbitrary edge whose both endpoints are in L_k . Clearly, $\text{Ham}(u, u^+) = 1$, $\text{CLIQUE}(m, s)(u^+) = 1$ and $(u, u^+) \in G(\text{CLIQUE}(m, s))$. Since $u^+ \leq v_{L_k}$, we have

$$\forall L_k \in \mathcal{L}_k^{\text{bad}} \exists u \in O_{L_k} \exists u^+ \leq v_{L_k} \quad (u, u^+) \in \bigcup_{j \in \{1, \dots, c_3\} \setminus \{i_1, \dots, i_k\}} G(f_j).$$

Therefore there exists $l \in \{1, \dots, c_3\} \setminus \{i_1, \dots, i_k\}$ such that

$$\Pr_{L_k \in \mathcal{L}_k^{bad}} [\exists u \in O_{L_k} \exists u^+ \leq v_{L_k} \quad (u, u^+) \in G(f_l)] \geq \frac{1}{c_3}$$

holds. If $(u, u^+) \in G(f_l)$ for $u \in O_{L_k}$, then $f_l(u^+) = 1$, which together with $u^+ \leq v_{L_k}$ implies $f_l(v_{L_k}) = 1$ by the monotonicity of f_l . Thus we can conclude that $\Pr_{L_k \in \mathcal{L}_k} [f_l(v_{L_k}) = 1 \mid L_k \in \mathcal{L}_k^{bad}] \geq 1/c_3$. From this and (A.1), there exists $l \in \{1, \dots, c_3\} \setminus \{i_1, \dots, i_k\}$ such that

$$(A.2) \quad \Pr_{L_k \in \mathcal{L}_k} [L_k \in \mathcal{L}_k^{bad} \text{ and } f_l(v_{L_k}) = 1] \geq \frac{1}{c_2 c_3}.$$

Now we choose an index l arbitrarily that satisfies the above inequality and let $i_{k+1} = l$. Letting \mathcal{L}_k^{target} denote a collection of sets $L_k \in \mathcal{L}_k$ such that $L_k \in \mathcal{L}_k^{bad}$ and $f_{i_{k+1}}(v_{L_k}) = 1$, we have $\Pr_{L_k \in \mathcal{L}_k} [L_k \in \mathcal{L}_k^{target}] \geq 1/(c_2 c_3)$. By a similar argument to the derivation of (5.2), we have

$$(A.3) \quad \Pr_{L_{k+1} \in \mathcal{L}_{k+1}} \left[\Pr_{L_k \in \mathcal{L}_k(L_{k+1})} [L_k \in \mathcal{L}_k^{target}] \geq \frac{1}{2c_2 c_3} \right] \geq \frac{1}{2c_2 c_3}.$$

Now we call a $L_{k+1} \in \mathcal{L}_{k+1}$ *dense* if

$$(A.4) \quad \Pr_{L_k \in \mathcal{L}_k(L_{k+1})} [L_k \in \mathcal{L}_k^{target}] \geq \frac{1}{2c_2 c_3}$$

holds, and let $\mathcal{L}_{k+1}^{dense}$ denote a collection of all dense sets in \mathcal{L}_{k+1} . Note that

$$\Pr_{v \in I_{L_{k+1}}} [f_{i_{k+1}}(v) = 1] \geq 1/(2c_2 c_3)$$

for any dense $L_{k+1} \in \mathcal{L}_{k+1}^{dense}$. Put $h = 1/(2c_2 c_3) > 1/m$. Thus by applying Claim 5.2 to every dense L_{k+1} , we have $\text{size}_{mon}(f_{i_{k+1}}) > (1/2m)2^{s^{1/3}/4} > M$ or $\Pr_{u \in O_{L_{k+1}}} [f_{i_{k+1}}(u) = 0] \leq 2/s^{1/3} \leq 1/(4c_1 c_2 c_3)$ for any dense L_{k+1} . (We use the assumption $c_1 c_2 c_3 \leq s^{1/3}/8$ in Claim 5.3 here.) Since the former contradicts the assumption $\text{size}_{mon}(f_{i_{k+1}}) \leq M$, we have

$$(A.5) \quad \Pr_{u \in O_{L_{k+1}}} [f_{i_{k+1}}(u) = 0] \leq \frac{1}{4c_1 c_2 c_3},$$

for any $L_{k+1} \in \mathcal{L}_{k+1}^{dense}$. By (A.4), for any dense \mathcal{L}_{k+1} , we have

$$(A.6) \quad \Pr_{L_k \in \mathcal{L}_k(L_{k+1})} \left[\Pr_{u \in O_{L_k}} [f_{i_1}(u) = \dots = f_{i_k}(u) = 1] \geq \frac{1}{c_1} \right] \geq \frac{1}{2c_2 c_3}.$$

From the above inequality, we can get

$$(A.7) \quad \Pr_{u \in O_{L_{k+1}}} [f_{i_1}(u) = \dots = f_{i_k}(u) = 1] \geq \frac{1}{2c_1 c_2 c_3}.$$

To derive this, we consider the bipartite graph $G = (U_1, U_2, E)$ with vertex sets $U_1 = O_{L_{k+1}}$ and $U_2 = \cup_{L_k \in \mathcal{L}_k(L_{k+1})} O_{L_k}$ and the edge set

$$E = \{(u_1, u_2) \in U_1 \times U_2 \mid u_1 \geq u_2\}.$$

Let U_2^{mark} be the set of $u_2 \in U_2$ such that $f_{i_1}(u_2) = \cdots = f_{i_k}(u_2) = 1$ and let $N(U_2^{mark}) \subseteq U_1$ be the set of vertices adjacent to vertices in U_2^{mark} . By the monotonicity of f_i 's, for every $u_1 \in N(U_2^{mark})$, $f_{i_1}(u_1) = \cdots = f_{i_k}(u_1) = 1$ holds. From (A.6), we have $|U_2^{mark}| \geq |U_2|/(2c_1c_2c_3)$. Clearly every vertex in U_1 has the same degree, and similarly for U_2 . Hence we can prove that $|N(U_2^{mark})| \geq |U_1|/(2c_1c_2c_3)$, which implies (A.7).

By (A.5) and (A.7), we have

$$\Pr_{u \in O_{L_{k+1}}} [f_{i_1}(u) = \cdots = f_{i_{k+1}}(u) = 1] \geq \frac{1}{2c_1c_2c_3} - \frac{1}{4c_1c_2c_3} = \frac{1}{4c_1c_2c_3}$$

for any $L_{k+1} \in \mathcal{L}_{k+1}^{dense}$. Claim 5.3 is straightforward from this and (A.3). \square

BOUNDS ON THE EFFICIENCY OF GENERIC CRYPTOGRAPHIC CONSTRUCTIONS*

ROSARIO GENNARO[†], Yael GERTNER[‡], JONATHAN KATZ[§], AND LUCA TREVISAN[¶]

Abstract. A central focus of modern cryptography is the construction of efficient, high-level cryptographic tools (e.g., encryption schemes) from weaker, low-level cryptographic primitives (e.g., one-way functions). Of interest are both the *existence* of such constructions and their *efficiency*.

Here, we show essentially tight lower bounds on the best possible efficiency of any black-box construction of some fundamental cryptographic tools from the most basic and widely used cryptographic primitives. Our results hold in an extension of the model introduced by Impagliazzo and Rudich and improve and extend earlier results of Kim, Simon, and Tetali. We focus on constructions of pseudorandom generators, universal one-way hash functions, and digital signatures based on one-way permutations, as well as constructions of public- and private-key encryption schemes based on trapdoor permutations. In each case, we show that any black-box construction beating our efficiency bound would yield the unconditional existence of a one-way function and thus, in particular, prove $P \neq NP$.

Key words. lower bounds, pseudorandom generators, hash functions, digital signatures, encryption

1. Introduction. A central focus of modern cryptography is the construction of high-level cryptographic protocols and tools that are both provably secure and efficient. Generally speaking, work proceeds along two lines: (1) demonstrating the *feasibility* of a particular construction, based on the weakest possible primitive; and (2) improving the *efficiency* of such constructions, either based on the weakest primitive for which a construction is known or perhaps by assuming the existence of a stronger primitive. The first of these approaches has been immensely successful; for example, the existence of one-way functions is known to be sufficient for constructing pseudorandom generators [8, 22, 27, 42], pseudorandom functions [21], universal one-way hash functions and digital signature schemes [36, 38], private-key encryption schemes and message-authentication codes [20], and commitment schemes [35]. In each of these cases one-way functions are also known to be necessary [30, 38], thus exactly characterizing the feasibility of these constructs.

Unfortunately, progress on the second approach—i.e., improving the efficiency of these constructions—has been much less successful. Indeed, while the constructions referred to above are all important from a theoretical point of view, their practical impact has been limited by their inefficiency. In practice, more efficient constructions based on stronger assumptions (or, even worse, heuristic solutions with no proofs of security) tend to be used. Furthermore, relying on stronger assumptions (or resorting to heuristic solutions) seems necessary to obtain improved efficiency; for each of the examples listed above, no provably secure constructions based on general assumptions are known that improve on the efficiency of the initial solutions.

This trade-off between the efficiency of a cryptographic construction and the strength of the complexity assumption on which it relies motivates the question, *How efficient can cryptographic constructions be when based on general assumptions?* We show in this paper that, in fact, the efficiency of many of the known constructions based on general assumptions *cannot be improved* without using non-black-box techniques or without finding an unconditional proof that one-way functions exist (and hence proving $P \neq NP$).

Our results hold in a generalization of the Impagliazzo–Rudich model [31], introduced by those authors in the context of proving impossibility results for the existence of certain black-box cryptographic constructions. (See section 1.3 for further discussion.) Following their work, a number of additional black-box impossibility results have appeared [13, 16, 17, 32, 40, 41]. Kim, Simon, and Tetali [33] initiated work focused on bounding the *efficiency* of black-box cryptographic constructions (rather than their *existence*), and their work provided the original inspiration for our research. We compare our results with those of Kim et al. in the following section.

1.1. Our results. Informally, we say a permutation $\pi : \{0, 1\}^n \rightarrow \{0, 1\}^n$ is *one-way with security S* if any circuit of size¹ at most S inverts π with probability less than $1/S$ (one can think of S as a slightly superpolynomial function of n but our results hold for any choice of S). In this work, we consider two types of black-box constructions, described informally now and discussed in more detail in section 1.3. Following the terminology introduced in [37], a *semi-black-box construction* (based on a one-way permutation) is an oracle procedure $P^{(\cdot)}$ such that, for any one-way permutation f given as an oracle, (1) P^f has the desired functionality and (2) P^f is “secure” (in some appropriate sense) against every efficient (oracle) adversary \mathcal{A}^f even when considering adversaries given oracle access to f . In contrast, a *weak black-box construction* is an oracle procedure $P^{(\cdot)}$ satisfying (1) as before but for which, for any one-way permutation f given as an oracle, the only guarantee is that (2) P^f is secure against efficient adversaries \mathcal{A} that are *not* given oracle access to f . Both notions preclude using the code (or circuit) of the one-way permutation f in the construction; roughly speaking (see [37] for further elaboration), semi-black-box constructions also rule out the use of the *adversary’s* code in the *security reduction* (whereas weak black-box constructions do not). Clearly, any semi-black-box construction is also a weak black-box construction and so impossibility results for the latter are stronger than impossibility results for the former.

Given these definitions, our results may be summarized informally as follows.

Pseudorandom generators (PRGs). Let U_ℓ denote the uniform distribution over ℓ -bit strings. A PRG is a deterministic, length-increasing function $G : \{0, 1\}^\ell \rightarrow \{0, 1\}^{\ell+k}$ such that $G(U_\ell)$ is computationally indistinguishable (by poly-time algo-

¹We let the *size* of a circuit refer to the number of gates the circuit has.

arithms) from $U_{\ell+k}$. The notion of a PRG was introduced by Blum and Micali [8] and Yao [42], who showed that PRGs can be constructed from any one-way permutation. This was subsequently improved by Håstad et al. [27], who show that a PRG can be constructed from any one-way function. The Blum–Micali–Yao construction, using a later improvement of Goldreich and Levin [22] (see also [18, section 2.5.3]), requires $\Theta(k/\log S)$ invocations of a one-way permutation with security S to construct a PRG stretching its input by k bits. This is the best-known efficiency for constructions based on arbitrary one-way permutations.

We show that this is essentially the best efficiency that can be obtained using black-box constructions. More formally, we show that any *weak* black-box construction of a PRG that stretches its input by k bits while making $o(k/\log S)$ invocations of a one-way permutation with security S implies the *unconditional* existence of a PRG (i.e., without any invocations of the one-way permutation). Put another way, the only way to design a more efficient construction of a PRG is to design a PRG from scratch! This would in particular imply the unconditional existence of a one-way function, as well as a proof that $P \neq NP$.

(Families of) universal one-way hash functions (UOWHFs). A UOWHF $\mathcal{H} = \{h_s\}$ is a family of length-decreasing functions (all defined over the same domain and range) such that for any input x and random choice of $h_i \in \mathcal{H}$ it is hard to find a *collision* (i.e., an $x' \neq x$ such that $h_i(x') = h_i(x)$). UOWHFs were introduced by Naor and Yung [36], who show that UOWHFs suffice to construct secure signature schemes and furthermore show how to construct the former from any one-way permutation. Rompel [38] later gave a construction of UOWHFs, and hence signature schemes, based on any one-way function. The Naor–Yung construction requires one invocation of the one-way permutation per bit of compression; that is, if $h_i : \{0, 1\}^{\ell+k} \rightarrow \{0, 1\}^\ell$ (for all $h_i \in \mathcal{H}$), then evaluating h_i requires k invocations of the one-way permutation. This can be improved easily to obtain a construction making $\Theta(k/\log S)$ invocations to compress by k bits.

We show that this, too, is essentially optimal. In particular, any *semi*-black-box construction of a UOWHF whose hash functions compress their input by k bits yet can be evaluated using $o(k/\log S)$ invocations of a one-way permutation (with security S) implies the *unconditional* existence of a UOWHF. Since the existence of UOWHFs implies the existence of one-way functions, this consequence would again imply a proof of $P \neq NP$. This improves on the work of Kim, Simon, and Tetali [33], who show a similar result but only for the case of constructions making $o(\sqrt{k}/\log S)$ invocations of a one-way permutation.

Encryption schemes. PRGs and UOWHFs may be viewed as one-party, or stand-alone, cryptographic primitives for which there is no inherent notion of interaction. We also explore the efficiency of two-party protocols, including those used in a public-key setting.

A public-key encryption scheme for m -bit messages is semantically secure [25] if for any two messages $M_0, M_1 \in \{0, 1\}^m$ the distribution over encryptions of M_0 is computationally indistinguishable from the distribution over encryptions of M_1 , even when given the public key as input. A similar definition (but with no public key) holds for the case of private-key encryption. Public-key encryption schemes constructed using the hard-core bit paradigm [8, 7, 22, 42] require $\Theta(m/\log S)$ invocations of a trapdoor permutation to encrypt an m -bit message. Similarly, private-key encryption schemes constructed using this paradigm require $\Theta(\frac{m-k}{\log S})$ invocations of a one-way permutation, where k is the length of the shared key. The same bound holds in the

private-key case even if one is willing to use the stronger assumption of a trapdoor permutation.

We show that the above constructions are essentially the best possible (at least, for the notions of security considered above). For the case of public-key encryption, we show that any *weak* black-box construction supporting encryption of m -bit messages requires $\Omega(m/\log S)$ invocations of the trapdoor permutation for the encryption algorithm alone (i.e., in addition to any invocations made during the key-generation phase). Using related techniques, we also show that any *weak* black-box construction of a private-key encryption scheme—even when based on trapdoor permutations—which securely encrypts m -bit messages using a k -bit key must query its permutation oracle $\Omega(\frac{m-k}{\log S})$ times. In each case, we show that any weak black-box construction beating our bound would imply the unconditional existence of a one-way function (from which a secure private-key encryption scheme, with no reliance on an oracle, can be derived) and hence a proof that $P \neq NP$.

Signature schemes. We say a one-time signature scheme is secure if no efficient adversary can forge a valid signature on a new message after seeing a signature on a single, random message. (We remark that it is easy to covert any such scheme to one that is secure when an adversary sees a signature on a single, *chosen* message: run two of the basic schemes in parallel to obtain keys (PK_1, SK_1) , (PK_2, SK_2) and set $PK = (PK_1, PK_2)$; to sign a message $M \in \{0, 1\}^m$ choose random $r \in \{0, 1\}^m$, sign r using SK_1 , sign $r \oplus M$ using SK_2 , and output both signatures.) Of course, lower bounds on one-time schemes immediately extend to schemes satisfying stronger definitions of security [26]. We show that in any *semi*-black-box construction of a one-time signature scheme for messages of length m based on a one-way permutation, the verification algorithm must evaluate the one-way permutation $\Omega(m/\log S)$ times. As before, any semi-black-box construction beating our bound implies the unconditional existence of a one-way function (from which a secure signature scheme requiring no oracle access can be constructed).

We observe that there exist one-time signature schemes essentially meeting our lower bound; see section 4.5 for further discussion.

1.2. Overview of our techniques. We prove our results in an extension of the model of Impagliazzo and Rudich [31, 39]. Among other things, Impagliazzo and Rudich prove that a semi-black-box construction of a secure key-exchange protocol based on a one-way permutation would inherently yield a proof that $P \neq NP$, and hence it is presumably hard to come up with such a construction. (This was later strengthened by Reingold, Trevisan, and Vadhan [37], who proved *unconditionally* that there exists no semi-black-box construction of a key-exchange protocol based on one-way permutations.) Our results are in the same vein but are in many respects even stronger. First, some of our impossibility results concern the larger class of *weak* black-box constructions. Furthermore, in all cases we show that constructions beating our bounds would imply the unconditional existence of a one-way function; this is stronger than the results of Impagliazzo–Rudich both because the existence of a one-way function is not known to be implied by $P \neq NP$ and because (in all but one case) a one-way function suffices to give an *unconditional* construction of the object under consideration. Finally, we stress that Impagliazzo and Rudich were concerned with the question of *feasibility*, while we are concerned with questions of *efficiency*.

Each of our proofs hinges on a technical result that has not been stated or proved previously: a random permutation on t -bit strings is, with high probability, one-way with security $2^{\Omega(t)}$ even against nonuniform adversaries. For the related case of

random functions, a similar result has been proved by Impagliazzo and Rudich [31] in the (much simpler) uniform case and by Impagliazzo [29] in the nonuniform case.² We also show a similar result for the case of trapdoor permutations.

Using this result, we now describe the intuition behind our lower bound using the case of PRGs as an example. Given a secure construction G of a PRG having oracle access to a one-way permutation over n -bit strings, we run G with a permutation oracle that randomly permutes its first $t = \Theta(\log S)$ bits while leaving the remaining $n - t$ bits unchanged. It follows from the technical result above that with high probability such a permutation is one-way with security S , and hence G is secure when run with a permutation chosen from this distribution. Let q be the number of queries made by G to its oracle. The key point of our proof is to notice that the answers to these q oracle queries can be simulated by a deterministic function G' *itself* (i.e., without access to any oracle) if $q \cdot t$ random bits, representing the t -prefixes of the q answers to G 's oracles queries, are included as part of the seed of G' . The distribution on the output of G' (over random choice of seed) is essentially identical to that of the output of G (over random seed, and random choice of oracle as above) and is thus indistinguishable from uniform. Finally, if q is small, then the seed-length does not grow too much and the input of G' remains shorter than its output. But this means that G' is an *unconditional* PRG which does not require any oracle access (a corollary of which is a proof that $P \neq NP$).

Additional technical work is needed to prove our bounds on UOWHFs, public-key encryption schemes, and digital signature schemes. In the latter two cases in particular, which are in a public-key setting, there is no seed as part of which to include the necessary randomness for answering oracle queries, and thus no immediate way to apply the above technique. The proofs of our lower bounds in these cases follow a slightly different approach. In the case of public-key encryption, for example, we show that a scheme making fewer than the prescribed number of queries can be used to construct (unconditionally) a secure *private-key* encryption scheme in which the key is shorter than the message. Moving from the public-key to the private-key setting circumvents the issues above and enables the necessary randomness to be included as part of the shared key without compromising the functionality or the security of the scheme. Unfortunately, our result in this case is somewhat weaker than what we obtain in all other cases; namely, we show that a *public-key* encryption scheme making few black-box oracle queries exists only if a secure *private-key* encryption scheme (or, equivalently, a one-way function) exists unconditionally. This is, of course, weaker than showing the unconditional existence of a secure public-key encryption scheme. We stress that for the case of PRGs, UOWHFs, private-key encryption schemes, and signature schemes, constructions beating our bounds imply the existence of an unconditional construction for each of these tasks.

1.3. Black-box lower bounds and impossibility results. We provide here a brief discussion regarding the notion of black-box constructions. Our presentation adapts the recent definitional work of Reingold, Trevisan, and Vadhan [37], simplifying their definitions when appropriate for the present context. The discussion here is relatively informal, and we have chosen to provide definitions specific to each primitive in the relevant subsections of section 4 rather than providing a single, generic definition as in [37].

²Although one could derive our result from Impagliazzo's result and the fact that a random function is indistinguishable from a random permutation, our proof is quite different and a bit simpler.

At a high level, a construction P of a primitive based on, say, a one-way permutation is a procedure which takes as input a permutation f and outputs a (description of a) circuit³ having some desired functionality. Informally, a construction P *uses f as a black-box* if P relies only on the input/output characteristics of the provided function f and not on any internal structure of the circuit computing f ; formally, this means the construction can be described as an oracle procedure $P^{(\cdot)}$ such that P^f itself realizes the desired functionality.

In addition to correctness (i.e., the requirement that P^f has the desired functionality for any permutation f), a construction also provides some guarantee with regard to the security of the resulting implementation P^f . We say P is a *semi-black-box construction* if the following holds:

For any hard-to-invert permutation f , the implementation P^f is secure (in some sense appropriate for the primitive being constructed) against all efficient adversaries, *even those given oracle access to f* .

In contrast, P is a *weak black-box construction* if the following relaxed definition holds:

For any hard-to-invert permutation f , the implementation P^f is secure against all efficient adversaries (who are *not* given oracle access to f).

The distinction between whether an adversary is given oracle access to f is important since the above are required to hold *even when f is not efficiently computable* (and so the only way for an efficient adversary to evaluate f , in general, may be via oracle access to f). We hasten to point out, however, that even weak black-box constructions suffice to give implementations with meaningful security guarantees in the real world: in this case, f *will* be efficiently computable, and furthermore an explicit circuit for f will be known; hence, it is irrelevant whether an adversary is given oracle access to f .

Clearly, any semi-black-box construction is also a weak black-box construction, and hence impossibility results for the latter are stronger. Indeed, Reingold, Trevisan, and Vadhan [37] show that (1) a semi-black-box construction of key exchange from one-way functions is unconditionally impossible, yet (2) (informally) if the statement “one-way functions imply key exchange” is true, then there does exist a weak black-box construction of key exchange (for a single-bit key) from one-way functions. Roughly speaking, a difference between semi-black-box and weak black-box constructions is with regard to whether the circuits of *adversaries* attacking P^f can be used in the security *reduction* (i.e., the proof that P is secure). In more detail, typical security proofs for a construction P proceed by showing via *reduction* how any efficient adversary \mathcal{A}_P breaking the security of P^f can be used to construct an efficient adversary \mathcal{A}_f inverting f . Since the latter is impossible by assumption on f , this implies that no \mathcal{A}_P with the claimed properties exists. If the reduction relies only on the input/output characteristics of \mathcal{A}_P , we refer to this as a reduction which *uses the adversary as a black-box*. In contrast, a reduction which relies on knowledge of the circuit for \mathcal{A}_P is said to *make non-black-box use of the adversary*. A security reduction for a *weak* black-box construction may potentially make non-black-box use of the adversary. As argued in [37], however, security reductions for *semi*-black-box constructions are essentially restricted to using the adversary as a black-box (see [37] for further discussion).

Non-black-box constructions. Black-box constructions form an important

³For simplicity, the present discussion is phrased in terms of circuits rather than Turing machines, although similar definitions could be made in the latter case as well.

subclass, since most cryptographic constructions are black-box (indeed, most known constructions are *fully black-box* [37], a notion which is even more restrictive than semi-black-box). We stress, however, that a number of non-black-box cryptographic constructions are known.⁴ The examples of which we are aware occur in two ways: due to the use of generic zero-knowledge proofs (of knowledge) [23, 12, 4] or due to the use of generic protocols for secure computation [43, 24]. As an illustrative example, let L_f denote the image of a function f ; i.e., $L_f \stackrel{\text{def}}{=} \{y | y = f(x)\}$. A cryptographic protocol which utilizes a zero-knowledge proof that $y \in L_f$ (for f a one-way function, say) requires the parties to agree on a circuit computing f and is thus inherently non-black-box.⁵ Examples of non-black-box constructions where zero-knowledge proofs of this sort are used include a construction of an identification protocol based on one-way functions [12], a signature scheme based on noninteractive zero-knowledge [5], and *all* known constructions of chosen-ciphertext-secure encryption schemes from trapdoor permutations (e.g., [11]). Furthermore, protocols for distributed computation (without honest majority) tolerating computationally bounded, malicious adversaries [24, 43] are *themselves* non-black-box.⁶ (This is in contrast to the case of zero-knowledge proofs; cf. footnote 5.)

Knowledge of the circuit computing f is also necessary if one wants to evaluate f in a secure, distributed fashion (e.g., if two parties with respective inputs x_1, x_2 want to evaluate $y = f(x_1 \oplus x_2)$ without revealing any more information about their inputs than what is revealed by y itself). Thus, a generic construction of a threshold cryptosystem [10] based on a family F of trapdoor permutations (in which the parties share the trapdoor for inverting a single member of this family) would inherently make non-black-box use of the underlying circuit(s) for F . Another example is a result of Beaver [3], which makes non-black-box use of a one-way function f to extend “few” oblivious transfers into “many.”

Given the above, a black-box impossibility result cannot be said to rule out the feasibility of a particular construction. Yet, it is unclear how non-black-box techniques can help outside the domains mentioned above (i.e., generic use of zero-knowledge proofs or secure computation). Furthermore, a black-box impossibility result is useful insofar as it indicates the type of techniques that will be necessary to achieve a desired result or, conversely, the type of techniques that are ruled out. Finally, it is fair to say that non-black-box constructions are much less efficient than black-box ones (this is certainly the case for all the examples given above, and we are aware of no exceptions), and thus a black-box impossibility result does seem to rule out constructions likely to be *practical*.

1.4. Future work and open problems. This work suggests a number of intriguing research directions. The results given here suggest that assuming only the existence of one-way permutations (or, in some cases, even trapdoor permutations) may be too weak of a computational hypothesis to obtain *efficient* cryptographic con-

⁴We focus here on constructions making non-black-box use of an underlying function f , rather than on constructions whose security analysis makes non-black-box use of the adversary (as in [1, 2]).

⁵Note that constructions of zero-knowledge proofs for NP (e.g., [23]) are *themselves* black-box in their usage of primitives such as one-way functions. The issue is that a proof for the language of interest—e.g., L_f in the example in the text—cannot be given unless a (poly-size) circuit computing f is available.

⁶For example, although the well-known protocol for oblivious transfer secure against *semi-honest* adversaries [19, section 7.3.2] makes black-box use of trapdoor permutations, adapting the protocol (using zero-knowledge proofs) to ensure security against *malicious* adversaries involves *non-black-box* use of the circuit for the trapdoor permutation.

structions. Thus, stronger assumptions may be needed to build practical schemes. It is important to explore the minimal such assumptions necessary to achieve greater efficiency, as well as to bound the maximum achievable efficiency even when such stronger assumptions are made. For example, what additional efficiency is possible if *homomorphic* one-way permutations (i.e., permutations over a group G satisfying $f(ab) = f(a)f(b)$ for all $a, b \in G$) are assumed?

In a related vein, it will be interesting to explore more efficient constructions based on specific number-theoretic assumptions. As will be evident from our proof techniques, the efficiency limitations of constructions based on arbitrary (trapdoor) one-way permutations stem from the fact that a one-way permutation may have security S even if it has only $\Theta(\log S)$ hard-core bits. (Actually, we use pathological functions of this form to prove our lower bounds.) But specific one-way permutations and trapdoor permutations with $\Theta(n)$ hard-core bits are known under suitable number-theoretic assumptions (e.g., [28, 9]). Given such functions, we know how to construct PRGs and semantically secure private- and public-key encryption schemes with improved efficiency. It remains open, however, whether such functions can also be used to improve the efficiency of digital signature schemes or (say) public-key encryption schemes achieving chosen-ciphertext security.

The present work also leaves some more concrete open questions. First, can bounds on the efficiency of other cryptographic constructions (e.g., commitment schemes) also be given? Additionally, our lower bounds essentially match known upper bounds only for schemes achieving relatively weak notions of security, namely, semantic security for encryption of a *single* message in the case of encryption and one-time security for the case of signatures. What can be said about schemes achieving stronger notions of security? Examples of interest include private-key encryption schemes secure when polynomially many messages are encrypted (this seems related to the efficiency of pseudorandom *functions*, for which a gap remains between known upper and lower bounds), public-key encryption schemes satisfying various flavors of nonmalleability/security against chosen-ciphertext attacks, and signature schemes secure when polynomially many messages are signed.

Finally, our bound for signatures pertains to the efficiency of signature verification. It would be nice to have corresponding bounds for the efficiency of key-generation/signing.

2. Definitions and preliminaries. In this section, we review some notation and definitions for the various standard cryptographic primitives considered in this work. Appropriate definitions of black-box constructions are deferred to the relevant sections containing our lower bounds.

In what follows, we consider a number of definitions of (S, ε) -security having the form “no circuit of size S can have advantage better than ε ,” where advantage is defined in some appropriate way. In each of the cases considered here, the existence of an (S, ε) -secure scheme for any $\varepsilon < 1$ implies the existence of an (S', ε') -secure scheme for an arbitrarily small $\varepsilon' > 0$. For this reason, in all our lower bounds we content ourselves with showing the existence of an (S, ε) -secure construction for an arbitrary $\varepsilon < 1$.

All our results are stated and proved in the nonuniform setting for simplicity only; we stress that they extend immediately to the uniform setting as well. Indeed, it is for this reason that we claim that constructions beating our efficiency bounds imply the existence of one-way functions and $P \neq NP$. For example, Theorem 4.2 states only that the existence of a certain PRG construction $G^{(\cdot)} : \{0, 1\}^\ell \rightarrow \{0, 1\}^{\ell+k}$

based on a permutation $\pi : \{0, 1\}^n \rightarrow \{0, 1\}^n$ implies the unconditional existence of a PRG $G' : \{0, 1\}^{\ell'} \rightarrow \{0, 1\}^{\ell'+k}$. Essentially the same proof, however, also shows that a certain construction of a PRG family $\{G_i^{(\cdot)} : \{0, 1\}^{\ell(i)} \rightarrow \{0, 1\}^{\ell(i)+k(i)}\}$ based on a one-way permutation family $\{\pi_i : \{0, 1\}^{n(i)} \rightarrow \{0, 1\}^{n(i)}\}$, where $G_i^{(\cdot)}$ can be evaluated by a uniform algorithm in polynomial time (in i), implies the unconditional existence of a PRG family $\{G'_i : \{0, 1\}^{\ell'(i)} \rightarrow \{0, 1\}^{\ell'(i)+k(i)}\}$, where again each G'_i can be evaluated by a uniform algorithm in polynomial time.

2.1. One-way permutations and trapdoor permutations. We say that a function $\pi : \{0, 1\}^n \rightarrow \{0, 1\}^n$ is (S, ε) -one way if for every circuit A of size $\leq S$ we have $\Pr_x[A(f(x)) \in f^{-1}(f(x))] \leq \varepsilon$. When f is given as an oracle, we provide A with access to f and write this as A^f . To reduce the number of parameters, we will call a function S -hard if it is $(S, 1/S)$ -one way.

Let Π_t denote the set of all permutations over $\{0, 1\}^t$. In section 3.1 we prove the following theorem.

THEOREM 2.1. *For all sufficiently large t , a random $\pi \in \Pi_t$ is $2^{t/5}$ -hard with probability at least $1 - 2^{-2^{t/2}}$.*

For $t \leq n$, let $\Pi_{t,n}$ denote the subset of Π_n such that $\pi \in \Pi_{t,n}$ iff $\pi(a, b) = (\hat{\pi}(a), b)$ for some $\hat{\pi} \in \Pi_t$ (that is, π permutes the first t bits of its input, while leaving the remaining $n - t$ bits fixed). An immediate corollary of the above theorem is that if $t = 5 \log S$, then for any $n \geq t$ a random $\pi \in \Pi_{t,n}$ is S -hard with very high probability.

COROLLARY 2.2. *For all sufficiently large t and any $n \geq t$, a random $\pi \in \Pi_{t,n}$ is $2^{t/5}$ -hard with probability greater than $1 - 2^{-2^{t/2}}$.*

Our model for (one-way) trapdoor permutations is somewhat more involved. We represent a family of trapdoor permutations as a tripartite oracle $\tau = (G, F, F^{-1})$. Informally, G corresponds to the key generation oracle which when queried on a string td (intended as a trapdoor) produces the corresponding public key k . The oracle F is the actual trapdoor permutation, which will be queried on key k and an input x . The oracle F^{-1} allows inversion of F ; i.e., if $G(td) = k$ and $F(k, x) = y$, then $F^{-1}(td, y) = x$.

More formally, consider the class $T_n = \{\tau \mid \tau = (G, F, F^{-1})\}$ where

- $G \in \Pi_n$ is a permutation over $\{0, 1\}^n$ (having G map trapdoors to keys rather than having G map seeds to a (trapdoor, key) pair does not affect our results);
- $F : \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}^n$ is an oracle such that, for each $k \in \{0, 1\}^n$, $F(k, \cdot)$ is a permutation on $\{0, 1\}^n$;
- $F^{-1} : \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}^n$ is an oracle defined as follows: $F^{-1}(td, y)$ returns the unique x such that $G(td) = k$ and $F(k, x) = y$.

A uniformly random $\tau = (G, F, F^{-1}) \in T_n$ is chosen in the natural way: G is chosen at random from Π_n and, for each $k \in \{0, 1\}^n$, the permutation $F(k, \cdot)$ is chosen independently at random from Π_n . We say that trapdoor permutation family $\tau = (G, F, F^{-1})$ is (S, ε) -trapdoor one way if for every circuit A of size $\leq S$ we have

$$\Pr_{x, td}[k := G(td) : A^\tau(k, F(k, x)) = x] \leq \varepsilon.$$

We say that τ is S -trapdoor one way if it is $(S, 1/S)$ -trapdoor one way. When clear from the context, we will also say that τ is S -hard. Although technically one must always speak of families of trapdoor permutations, we will often abuse terminology and simply refer to a $\tau \in T_n$ as a trapdoor permutation.

In section 3.2, we prove the following analogue of Theorem 2.1 for trapdoor permutations.

THEOREM 2.3. *For all sufficiently large t , a random $\tau \in T_t$ is $2^{t/5}$ -hard with probability greater than $1 - 2^{-2^{t/2}}$.*

For $t \leq n$, we let $T_{t,n} \subseteq T_n$ be defined as follows: $\tau = (G, F, F^{-1}) \in T_{t,n}$ iff the following hold:

- $G \in \Pi_{t,n}$, and thus $G(td_a, td_b) = (\hat{G}(td_a), td_b)$ for some $\hat{G} \in \Pi_t$.
- $F((k_a, k_b), (x_a, x_b)) = (\hat{F}(k_a, x_a), x_b)$, where $\hat{F}(k_a, \cdot) \in \Pi_t$. Equivalently, $F(k, \cdot) \in \Pi_{t,n}$ and furthermore this permutation is determined by the first t bits of k .
- As before, $F^{-1}(td, y)$ returns the unique x s.t. $G(td) = k$ and $F(k, x) = y$.

An immediate corollary of Theorem 2.3 is that if $t = 5 \log S$, then for any $n \geq t$ a random $\tau \in T_{t,n}$ is S -hard with very high probability.

COROLLARY 2.4. *For all sufficiently large t and any $n \geq t$, a random $\tau \in T_{t,n}$ is $2^{t/5}$ -hard with probability greater than $1 - 2^{-2^{t/2}}$.*

2.2. Pseudorandom generators. We say that two distributions X, Y are (S, ε) -indistinguishable if for every distinguishing circuit Dist of size at most S we have

$$\left| \Pr_{x \in X} [\text{Dist}(x) = 1] - \Pr_{y \in Y} [\text{Dist}(y) = 1] \right| \leq \varepsilon.$$

We also write this as $X \stackrel{(S, \varepsilon)}{\approx} Y$. We say that a function $G : \{0, 1\}^\ell \rightarrow \{0, 1\}^{\ell+k}$ is an (S_g, ε) -secure PRG if $G(U_\ell)$ is (S_g, ε) -indistinguishable from $U_{\ell+k}$, where U_n denotes the uniform distribution over $\{0, 1\}^n$.

2.3. Universal one-way hash functions. As discussed in the introduction, a family of UOWHFs is a family \mathcal{H} of length-decreasing functions such that, for a random function $h \in \mathcal{H}$ and a random point x in the domain, it is hard (given h, x) to find $x' \neq x$ such that $h(x') = h(x)$. More formally, a family $\mathcal{H} = \{h_s : \{0, 1\}^{\ell+k} \rightarrow \{0, 1\}^\ell\}_{s \in \{0, 1\}^r}$ of functions is an (S, ε) -UOWHF if for every circuit A of size at most S we have

$$\Pr_{s,x} [A(s, x, h_s(x)) = x' : x' \neq x \wedge h_s(x') = h_s(x)] \leq \varepsilon.$$

We will represent such a family as a single function $H : \{0, 1\}^r \times \{0, 1\}^{\ell+k} \rightarrow \{0, 1\}^\ell$, where $H(s, x) = h_s(x)$.

2.4. Public- and private-key encryption.

2.4.1. Public-key encryption. A public-key encryption scheme for m -bit messages is a tuple of algorithms $\mathcal{PKC} = (\text{Gen}, \text{Enc}, \text{Dec})$ having the following functionality:

- The *key generation algorithm* Gen is a probabilistic algorithm which generates a key pair (pk, sk) . We say pk is the public key and sk is the secret key.
- The *encryption algorithm* Enc is a probabilistic algorithm which, on input a public key pk and a message $M \in \{0, 1\}^m$, outputs a ciphertext C .
- The *decryption algorithm* Dec is a deterministic algorithm which, on input a secret key sk and a ciphertext C , outputs a message $M \in \{0, 1\}^m$ or \perp .

We also require perfect correctness; that is, for all (pk, sk) output by Gen , all $M \in \{0, 1\}^m$, and all C output by $\text{Enc}(pk, M)$, we have $\text{Dec}(sk, C) = M$. (Our results can be modified appropriately for the case of decryption schemes with error; see the remark following Lemma 4.6.)

For $M \in \{0, 1\}^m$, let $\mathcal{PK}\mathcal{E}(M)$ denote the distribution on the view of an adversary eavesdropping on the encryption of message M ; i.e.,

$$\mathcal{PK}\mathcal{E}(M) \stackrel{\text{def}}{=} \{(pk, sk) \leftarrow \text{Gen}; C \leftarrow \text{Enc}(pk, M) : (pk, C)\}.$$

We say that $\mathcal{PK}\mathcal{E}$ is (S_e, ε) -secure if for all $M_0, M_1 \in \{0, 1\}^m$ we have

$$\mathcal{PK}\mathcal{E}(M_0) \stackrel{(S_e, \varepsilon)}{\approx} \mathcal{PK}\mathcal{E}(M_1).$$

This corresponds to a definition of indistinguishability, or semantic security [25].

The above can be extended in the natural way to allow for interactive encryption schemes. However, since we do not explicitly consider interactive public-key encryption in this work and since a formal definition of interactive encryption in the private-key setting is given below, we omit the details.

2.4.2. Private-key encryption. The model for private-key encryption is an appropriate modification of the above. A private-key encryption scheme for m -bit messages using k -bit keys is a pair of algorithms $\mathcal{SK}\mathcal{E} = (\text{Enc}, \text{Dec})$, where

- the encryption algorithm Enc is a probabilistic algorithm which, on input a key $sk \in \{0, 1\}^k$ and a message $M \in \{0, 1\}^m$, outputs a ciphertext C ;
- the decryption algorithm Dec is a deterministic algorithm which, on input a key $sk \in \{0, 1\}^k$ and a ciphertext C , outputs either a message $M \in \{0, 1\}^m$ or \perp .

As in the public-key case, we require perfect correctness: i.e., for all $sk \in \{0, 1\}^k$, all $M \in \{0, 1\}^m$, and all C output by $\text{Enc}(sk, M)$, we have $\text{Dec}(sk, C) = M$. (Our results can be modified appropriately for the case of decryption schemes with error; see the remark following Lemma 4.6.)

For $M \in \{0, 1\}^m$, denote by $\mathcal{SK}\mathcal{E}(M)$ the probability distribution over the view of an adversary eavesdropping on the encryption of message M (where the shared key sk is chosen uniformly at random); i.e.,

$$\mathcal{SK}\mathcal{E}(M) \stackrel{\text{def}}{=} \{sk \leftarrow \{0, 1\}^k; C \leftarrow \text{Enc}(sk, M) : C\}.$$

We say that $\mathcal{SK}\mathcal{E}$ is (S_e, ε) -secure if for all $M_0, M_1 \in \{0, 1\}^m$ we have

$$\mathcal{SK}\mathcal{E}(M_0) \stackrel{(S_e, \varepsilon)}{\approx} \mathcal{SK}\mathcal{E}(M_1).$$

The above can be extended to allow for interactive encryption in the natural way. In this case, Enc and Dec represent interactive Turing machines operating in a sequence of rounds. For notational convenience, we let $T \leftarrow \widehat{\text{Enc}}(sk, M)$ denote the experiment in which random coins ω_1, ω_2 are chosen for Enc and Dec , respectively, and T is the transcript resulting from the interaction of $\text{Enc}(sk, M; \omega_1)$ with $\text{Dec}(sk; \omega_2)$. We also let $M' \leftarrow \widehat{\text{Dec}}(sk, M)$ denote the final output of Dec at the conclusion of the above experiment. Perfect correctness requires that $\widehat{\text{Dec}}(sk, M) = M$ with probability 1. In the interactive setting, $\mathcal{SK}\mathcal{E}(M)$ denotes the distribution

$$\mathcal{SK}\mathcal{E}(M) \stackrel{\text{def}}{=} \left\{ sk \leftarrow \{0, 1\}^k; T \leftarrow \widehat{\text{Enc}}(sk, M) : T \right\};$$

definitions for (S_e, ε) -security follow in the obvious way.

2.5. Signature schemes. A signature scheme for m -bit messages is a tuple of algorithms $\text{SIG} = (\text{Gen}, \text{Sign}, \text{Vrfy})$ having the following functionality:

- The *key generation algorithm* Gen is a probabilistic algorithm which generates a key pair (PK, SK) , where PK is the *public key* and SK is the *secret key*.
- The *signing algorithm* Sign is a probabilistic algorithm which, on input SK and a message $M \in \{0, 1\}^m$, outputs a signature σ .
- The *verification algorithm* Vrfy is a deterministic algorithm which, on input PK , a message M , and a signature σ , outputs a single bit.

We also require that for all (PK, SK) output by Gen , all $M \in \{0, 1\}^m$, and all σ output by $\text{Sign}(SK, M)$ we have $\text{Vrfy}(PK, M, \sigma) = 1$.

Our definition of security for signature schemes is extremely weak: we require security against existential forgery only for an adversary who gets a signature on a single, random message (i.e., we consider a *one-time signature scheme* secure under *random-message attack*). Our lower bounds apply even to weakly secure schemes of this type. Since any signature scheme secure against adaptive chosen-message attack (cf. [26]) trivially achieves this “weak” level of security, our results immediately imply a bound for the more general case. Formally, signature scheme SIG is (S_Σ, ε) -secure if for all circuits A of size at most S_Σ we have

$$\Pr \left[\begin{array}{l} (PK, SK) \leftarrow \text{Gen}; M \leftarrow \{0, 1\}^m; \\ \sigma \leftarrow \text{Sign}(SK, M); (M', \sigma') := A(PK, M, \sigma); \\ \text{Vrfy}(PK, M', \sigma') = 1 \wedge M' \neq M \end{array} \right] \leq \varepsilon.$$

3. Hardness of random (trapdoor) permutations. In this section, we state and prove two key technical theorems which show that a random permutation $\pi \in \Pi_t$ and a random trapdoor permutation $\tau \in T_t$ are exponentially hard with all but negligible probability for t large enough. Before doing so, we first state the following bound on the number of oracle circuits of a given size S .

LEMMA 3.1. *The number of circuits of size S having input/output length n and oracle access to a function $f : \{0, 1\}^n \rightarrow \{0, 1\}^n$ is at most $2^{2S+(S+1)n(\log(Sn+n)+1)}$.*

Proof. A circuit of the form considered here consists of three types of gates: and gates, or gates, and oracle gates; the first two have in-degree 2 and out-degree 1, while oracle gates have in-degree and out-degree n . A circuit may be specified by listing for each gate its type and, for each of this gate’s at most n input wires, the source of the wire (which may be the output wire of another gate or one of the input wires of the circuit) and whether its value is complemented. Finally, for each of the n output wires of the circuit one must also specify the source of this wire and whether its value is complemented. The information associated with each gate can be specified using at most $2 + n(\log(Sn + n) + 1)$ bits (per gate), while the information associated with each output wire can be specified using at most an additional $\log(Sn + n) + 1$ bits. The lemma follows. \square

3.1. Hardness of random permutations. We now prove Theorem 2.1, restated for convenience.

THEOREM 3.2. *For all sufficiently large t , a random $\pi \in \Pi_t$ is $2^{t/5}$ -hard with probability at least $1 - 2^{-2^{t/2}}$.*

Proof. We begin by showing that given any (π, A) such that A inverts π with high probability, the permutation π has a short description (given A).

CLAIM. *Let A be a circuit that makes q queries to a permutation $\pi : \{0, 1\}^t \rightarrow \{0, 1\}^t$ and for which $\Pr_y[A^\pi(y) = \pi^{-1}(y)] \geq \varepsilon$. Then π can be described using at*

most

$$2 \log \binom{2^t}{a} + \log ((2^t - a)!)$$

bits (given A), where $a = \varepsilon 2^t / (q + 1)$.

Proof of claim. Let $N = 2^t$. Consider the set I of at least εN points on which A is able to invert π , after making q queries to π . We argue that there exists a set $Y \subseteq I$ such that $|Y| \geq a$ and such that the value of π^{-1} is completely determined by the circuit A , the sets Y and $X \stackrel{\text{def}}{=} \pi^{-1}(Y)$, and the value of π^{-1} on all points in $\{0, 1\}^t \setminus Y$.

Define Y via the following process. Initially Y is empty, and all elements in I are candidates for inclusion in Y . Take the lexicographically first element y from I , and place it in Y . Next, simulate the computation of $A^\pi(y)$ and let x_1, \dots, x_q be the queries made by A to π (we assume without loss of generality that they are different), and let y_1, \dots, y_q be the corresponding answers (i.e., $y_i = \pi(x_i)$). If $y \notin \{y_i\}_{i=1}^q$, then remove y_1, \dots, y_q from I . If $y = y_i$ for some i , then remove y_1, \dots, y_{i-1} from I . Then take the lexicographically smallest of the remaining elements of I , put it into Y , etc. At any step of the construction, one element is added to Y and at most q are removed from I . Since I initially contains at least εN elements, in the end we have $|Y| \geq \lceil \varepsilon N / q \rceil > \varepsilon N / (q + 1)$.

We claim that given descriptions of the sets Y and $X = \pi^{-1}(Y)$, the values of π on $\{0, 1\}^t \setminus X$, and the circuit A , it is possible to invert (or, equivalently, compute) π everywhere. For $y \notin Y$, the value of $\pi^{-1}(y)$ is explicitly given. The values of π^{-1} on Y can be reconstructed sequentially for all $y \in Y$, taken in lexicographic order, as follows. Simulate the computation of $A^\pi(y)$. By construction of Y , during its computation $A^\pi(y)$ will query π either on points not in X , on points $x \in X$ for which $\pi(x) <_{lex} y$, or on the point $x \in X$ for which $\pi(x) = y$. In the first two cases, we have enough information to continue the simulation. In the last case, the query itself gives the desired answer $\pi^{-1}(y)$. In all possible cases, we have enough information to reconstruct $\pi^{-1}(y)$.

Describing Y , X , and the values of π on $\{0, 1\}^t \setminus X$ requires

$$2 \log \binom{N}{|Y|} + \log ((N - |Y|)!)$$

bits, which is at most the number of bits claimed.

Given the above claim, we may now easily prove the theorem. Let A be an oracle circuit of size at most $S = 2^{t/5}$. Note that A will make at most $q = 2^{t/5}$ queries to π . Let $N = 2^t$. From the claim, we see that the fraction of permutations $\pi \in \Pi_t$ such that

$$(1) \quad \Pr_x [A^\pi(\pi(x)) = x] \geq 2^{-t/5}$$

is at most

$$\frac{\binom{N}{a}^2 (N - a)!}{N!} = \frac{\binom{N}{a}}{a!},$$

where $a = 2^{-t/5} 2^t / (2^{t/5} + 1) \geq N^{3/5} / 2$. Using the inequalities $a! \geq (a/e)^a$ and $\binom{N}{a} \leq (eN/a)^a$, we may derive the following upper bound on the above expression:

$$\frac{\binom{N}{a}}{a!} \leq \left(\frac{e^2 N}{a^2} \right)^a < \left(\frac{4e^2}{N^{1/5}} \right)^a < 2^{-a} < 2^{-N^{3/5}/2}$$

for all sufficiently large N .

By Lemma 3.1 there are at most $2^{2S+(S+1)t(\log(S+t)+1)} = 2^{\tilde{O}(N^{1/5})}$ circuits of size S (where the \tilde{O} -notation suppresses polylogarithmic factors). A union bound thus shows that the probability over a random choice of $\pi \in \Pi_t$ that there *exists* a circuit of size S for which (1) holds is at most

$$2^{\tilde{O}(N^{1/5})} \cdot 2^{-N^{3/5}/2} < 2^{-N^{1/2}}$$

for all sufficiently large N . \square

3.2. Hardness of random trapdoor permutations. We now prove an analogue of the above theorem for trapdoor permutations. (This is Theorem 2.3, restated for convenience.)

THEOREM 3.3. *For all sufficiently large t , a random $\tau \in T_t$ is $2^{t/5}$ -hard with probability greater than $1 - 2^{-2^{t/2}}$.*

Proof. The proof is substantially similar to the proof of Theorem 2.1. We first prove the following claim.

CLAIM. *Let A be a circuit making q queries to a trapdoor permutation $\tau \in T_t$ and for which $\Pr_{k,y}[A^\tau(k,y) = x \wedge F(k,x) = y] \geq \varepsilon$. Then τ can be described using at most*

$$1 + 2^t \log(2^t!) + t + 2 \log \binom{2^t}{a} + \log((2^t - a)!)$$

bits (given A), where $a = \varepsilon 2^t / (2q + 1)$.

Proof of claim. Let $N = 2^t$, and let $Q(k, y)$ denote the event that $A^\tau(k, y)$ queries either $G(td)$ or $F^{-1}(td, y')$, where y' is arbitrary and $G(td) = k$. Also, we say A^τ inverts (k, y) if $A^\tau(k, y) = x$ such that $F(k, x) = y$. There are two possibilities: either

$$(2) \quad \Pr_{k,y}[A^\tau \text{ inverts } (k, y) \wedge Q(k, y)] \geq \varepsilon/2$$

or

$$(3) \quad \Pr_{k,y}[A^\tau \text{ inverts } (k, y) \wedge \overline{Q(k, y)}] \geq \varepsilon/2.$$

Consider the first case. Here, there certainly exists a \hat{y} for which it is the case that $\Pr_k[A^\tau \text{ inverts } (k, \hat{y}) \wedge Q(k, \hat{y})] \geq \varepsilon/2$. Proceeding as in the proof of Theorem 2.1, we will specify G using a small number of bits. Let I be the set of at least $\varepsilon N/2$ points (k, \hat{y}) on which A^τ inverts (k, \hat{y}) and $Q(k, \hat{y})$ occurs. Define a set $K \subseteq I$ via the following process. Initially K is empty, and all elements in I are candidates for inclusion in K . Take the lexicographically first element (k, \hat{y}) from I and place it in K . Next, simulate the computation of $A^\tau(k, \hat{y})$. Since $Q(k, \hat{y})$ occurs, we know that there is a query i of the form $G(td)$ or $F^{-1}(td, y')$, where $G(td) = k$. Looking at each of the preceding $i - 1$ queries, for each query of the form $G(td')$ with answer k' remove (k', \hat{y}) from I . For each query of the form $F^{-1}(td', y')$ let $G(td') = k'$ and remove (k', \hat{y}) from I . Then take the lexicographically smallest of the remaining elements of I , put it into K , etc. At any step of the construction, one element is added to K and at most q are removed from I . Since I initially contains at least $\varepsilon N/2$ elements, in the end we have $|K| \geq \lceil \varepsilon N/2q \rceil > \varepsilon N/(2q + 1)$.

Exactly as in the proof of Theorem 2.1 (and so we omit the details), the permutation G is completely specified given A , \hat{y} , descriptions of K and $G^{-1}(K)$, the

values of G^{-1} on $\{0, 1\}^t \setminus K$, and the values of F on all points. This requires $2 \log \binom{N}{|K|} + \log((N - |K|)!)$ bits plus an additional $2^t \log(2^t!)$ bits to specify F . Using an additional bit to specify that we are in the first case, we can completely specify τ in at most the number of bits claimed.

Consider next the second case (i.e., when (3) holds). Here, there must exist a \hat{k} for which $\Pr_y[A^\tau \text{ inverts } (\hat{k}, y) \wedge Q(\hat{k}, y)] \geq \varepsilon/2$. Now, we specify $F(\hat{k}, \cdot)$ using a small number of bits. Let I be the set of at least $\varepsilon N/2$ points (\hat{k}, y) on which A^τ inverts (\hat{k}, y) and $Q(\hat{k}, y)$ does not occur. Define a set $Y \subseteq I$ via the following process. Initially Y is empty, and all elements in I are candidates for inclusion in Y . Take the lexicographically first element (\hat{k}, y) from I and place it in Y . Next, simulate the computation of $A^\tau(\hat{k}, y)$. Consider the $\ell \leq q$ queries made by A of the form $\{F(\hat{k}, x_i)\}$ with corresponding answers $\{y_i\}$. If $y \notin \{y_i\}_{i=1}^\ell$, then remove $\{(\hat{k}, y_i)\}_{i=1}^\ell$ from Y . If $y = y_j$ for some j , then remove $\{(\hat{k}, y_i)\}_{i=1}^{j-1}$ from Y . Then take the lexicographically smallest of the remaining elements of I , put it into Y , etc. At any step of the construction, one element is added to Y and at most q are removed from I . Since I initially contains at least $\varepsilon N/2$ elements, in the end we have $|Y| \geq \lceil \varepsilon N/2q \rceil > \varepsilon N/(2q + 1)$.

Following the proof of Theorem 2.1, the permutation $F(\hat{k}, \cdot)$ is completely specified given A , descriptions of Y and the set X such that $F(\hat{k}, X) = Y$, the value of $F(\hat{k}, \cdot)$ on $\{0, 1\}^t \setminus X$, the values of G at all points, and the values of $F(k, \cdot)$ at all points for all $k \neq \hat{k}$. (We omit the details, but remark that we crucially use the fact that in the computation of $A^\tau(\hat{k}, y)$ with $y \in Y$ we are guaranteed that $Q(\hat{k}, y)$ does not occur and, in particular, A does not make a query of the form $F^{-1}(td, y')$ with $G(td) = \hat{k}$.) This requires $2 \log \binom{N}{|Y|} + \log((N - |Y|)!)$ bits plus $\log(2^t!)$ bits to specify G and $(2^t - 1) \log(2^t!)$ bits to specify $F(k, \cdot)$ for $k \neq \hat{k}$. Using an additional t bits to specify \hat{k} , as well as a bit to specify that we are in the second case, we have that τ is specified in at most the number of bits claimed.

Proceeding as in Theorem 2.1, let A be an oracle circuit of size at most $S = 2^{t/5}$ and note that A makes at most $q = 2^{t/5}$ queries to τ . Let $N = 2^t$. From the claim, we see that the fraction of $\tau \in T_t$ such that $\Pr_{k,y}[A^\tau \text{ inverts } (k, y)] \geq 2^{-t/5}$ is at most

$$\frac{2^{t+1} \binom{N}{a}}{a!} \leq 2^{-N^{3/5}/4}$$

for sufficiently large N , where $a = 2^{-t/5} 2^t / (2^{t/5+1} + 1)$ and using the fact that $a \geq N^{3/5}/4$.

Applying Lemma 3.1 (and taking into account that A here has input length $2t$, output length t , and access to three oracles some of which are functions from $\{0, 1\}^{2t}$ to $\{0, 1\}^t$), there are at most $2^{\tilde{O}(N^{1/5})}$ circuits of size S . A union bound thus shows that the probability over a random choice of $\pi \in \Pi_t$ that there *exists* a circuit of size S for which (1) holds is at most

$$2^{\tilde{O}(N^{1/5})} \cdot 2^{-N^{3/5}/4} < 2^{-N^{1/2}}$$

for all sufficiently large N . □

4. Lower bounds. In this section we prove our lower bounds.

4.1. Pseudorandom generators. We first show a lower bound for PRG constructions, defined formally as follows.

DEFINITION 4.1. *A PRG construction from a one-way permutation is an oracle procedure $G^{(\cdot)} : \{0, 1\}^\ell \rightarrow \{0, 1\}^{\ell+k}$ that expects as an oracle a permutation $\pi \in \Pi_n$. We refer to k as the stretch of G .*

We say $G^{(\cdot)}$ is an (S_p, S_g, ε) -OWP-to-PRG weak black-box construction if for every permutation π that is S_p -hard, G^π is an (S_g, ε) -secure PRG.

For any (S_p, S_g, ε) -OWP-to-PRG weak black-box construction with stretch k , we prove that unless G queries π on at least $\Omega(k/\log S_p)$ points, it is possible to derive an *unconditional* construction of a pseudorandom generator. Before giving the proof, we provide some intuition.

The basic idea of the proof is as follows. Let $t = \Theta(\log S_p)$. First, note that if G uses as an oracle $\pi \in \Pi_{t,n}$ chosen uniformly at random, then G is an (S_g, ε) -secure PRG with all but negligible probability (since a random permutation from $\Pi_{t,n}$ is S_p -hard with all but negligible probability). Now, if G queries the oracle at only a few (say, q) points, we can encode the answers to these queries in the seed of the PRG itself. Furthermore, this encoding is short since only t bits are needed to answer a query to $\pi \in \Pi_{t,n}$. We thus obtain a PRG $G' : \{0, 1\}^{\ell'} \rightarrow \{0, 1\}^{\ell+k}$ which uses no oracle at all, but which is able to simulate the computation of G when using a random permutation oracle. The desired bound comes from the fact that G' still stretches its input provided that ℓ' is smaller than $\ell + k$. But $\ell' = \ell + qt$ since qt bounds the number of bits needed to encode the t -bit answers to G 's q queries.

THEOREM 4.2. *Let $G^{(\cdot)} : \{0, 1\}^\ell \rightarrow \{0, 1\}^{\ell+k}$ be an (S_p, S_g, ε) -OWP-to-PRG weak black-box construction that makes q queries to an oracle $\pi \in \Pi_n$. If $q < k/(5 \log S_p)$, then there exists an $(S_g, \varepsilon + 2^{-S_p^2} + q^2/S_p^5)$ -secure PRG $G' : \{0, 1\}^{\ell'} \rightarrow \{0, 1\}^{\ell+k}$ with $\ell' < \ell + k$.*

Proof. Since $G^{(\cdot)}$ is an (S_p, S_g, ε) -OWP-to-PRG construction, this means that if $\pi : \{0, 1\}^n \rightarrow \{0, 1\}^n$ is S_p -hard, then for any distinguisher T of size at most S_g we have

$$\left| \Pr_{x \in U_{\ell+k}} [T(x) = 1] - \Pr_{s \in U_\ell} [T(G^\pi(s)) = 1] \right| \leq \varepsilon.$$

Let $t = 5 \log S_p$. From Corollary 2.2 we know that a random permutation $\pi \in \Pi_{t,n}$ is S_p -hard with probability greater than $1 - 2^{-2^{t/2}}$. An averaging argument thus shows that for any circuit T of size at most S_g we have

$$(4) \quad \left| \Pr_{x \in U_{\ell+k}} [T(x) = 1] - \Pr_{\substack{\pi \in \Pi_{t,n} \\ s \in U_\ell}} [T(G^\pi(s)) = 1] \right| < \varepsilon + 2^{-2^{t/2}}.$$

Recall that any $\pi \in \Pi_{t,n}$ operates only on its first t input bits; i.e., any such π satisfies $\pi(a, b) = (\hat{\pi}(a), b)$, where $\hat{\pi}$ is a permutation over $\{0, 1\}^t$. Without loss of generality, we now assume that G always queries π with strings having distinct t -prefixes. Indeed, for any G asking arbitrary queries, one can construct a \widehat{G} with essentially the same running time, such that if G asks (a, b) with a equal to the t -prefix of a previous query, \widehat{G} simulates the answer without querying π using the previously obtained value of $\hat{\pi}(a)$. In general the behavior of \widehat{G} is different from that of G , but when we restrict to $\pi \in \Pi_{t,n}$ they are equivalent.

By assumption, G queries π at most $q < k/t$ times. We now construct G' , which takes as input a seed s' of length $\ell' \stackrel{\text{def}}{=} \ell + qt < \ell + k$. Let s denote the first ℓ bits of s' , and let $y_1, \dots, y_q \in \{0, 1\}^t$ denote the remaining qt bits. We then define

$$G'(s') = G'(s, y_1, \dots, y_q) \stackrel{\text{def}}{=} G^{y_1, \dots, y_q}(s),$$

where the notation $G^{y_1, \dots, y_q}(s)$ denotes the computation of $G^{(\cdot)}(s)$ when its i th oracle query $x_i = (a_i, b_i)$ (with $|a_i| = t$) is answered with (y_i, b) . (Here we use the fact that the t -prefixes of G 's queries are distinct.)

G' stretches its input by at least one bit and requires no oracle access. Furthermore,

$$\left| \Pr_{\substack{\pi \in \Pi_{t,n} \\ s \in U_\ell}} [T(G^\pi(s)) = 1] - \Pr_{s' \in U_{\ell'}} [T(G'(s')) = 1] \right| \leq 2 \cdot \Pr_{\vec{y} \in \{0,1\}^{qt}} [\text{Coll}],$$

where we let $\vec{y} = y_1, \dots, y_q$ and Coll denotes the event that these q values are not distinct. An easy birthday problem calculation shows that $\Pr_{\vec{y} \in \{0,1\}^{qt}} [\text{Coll}] \leq q^2/2^{t+1}$, which together with (4) implies the statement of the theorem. \square

4.2. Universal one-way hash functions. In this section we prove lower bounds for constructions of universal one-way hash functions based on one-way permutations. The formal definition of such constructions follows.

DEFINITION 4.3. *A construction of a UOWHF from a one-way permutation is an oracle procedure $H^{(\cdot)}(\cdot, \cdot)$ that expects as an oracle a permutation $\pi \in \Pi_n$ and is given inputs $s \in \{0, 1\}^r$ and $x \in \{0, 1\}^{\ell+k}$. The output is $H^\pi(s, x) \in \{0, 1\}^\ell$. We refer to k as the compression of H .*

We say H is an (S_p, S_h, ε) -OWP-to-UOWHF semi-black-box construction if for every π that is S_p -hard, H^π is an (S_h, ε) -UOWHF even for circuits given oracle access to π .

We show that if there exists an (S_p, S_h, ε) -OWP-to-UOWHF semi-black-box construction with compression k making $q < k/(5 \log S_p)$ queries to its oracle π , then it is possible to derive an unconditionally secure construction of a UOWHF (i.e., without any access to π).

As in the case of PRGs, we first observe that H^π is secure when π is chosen uniformly at random from $\Pi_{t,n}$, for $t = 5 \log S$. We then show that the computation of H^π for random $\pi \in \Pi_{t,n}$ can be simulated by an H' (without any oracle access) by including as part of the key for H' the t -prefixes of the answers for the q queries H makes to π . Furthermore, we include in the output of H' the t -prefixes of the q queries themselves. The crux of the proof is to show that H' is a UOWHF. As some intuition toward this, note that since the t -prefixes of the queries (resp., answers) are included with the output (resp., key), an adversary finding a collision in H' is bound to these particular values. Hence, any collision in H' is also a collision in H^π . Since $\ell + qt < \ell + k$ (and hence H' is length-decreasing) whenever $q < k/(5 \log S_p)$, this yields the desired bound.

THEOREM 4.4. *Let $H^{(\cdot)} : \{0, 1\}^r \times \{0, 1\}^{\ell+k} \rightarrow \{0, 1\}^\ell$ be an (S_p, S_h, ε) -OWP-to-UOWHF semi-black-box construction that makes q queries to an oracle $\pi \in \Pi_n$. If $q < k/(5 \log S_p)$, then there exists an $(S_h - S_H, \varepsilon + 2^{-S_p^2} + q^2/2S_p^5)$ -secure UOWHF $H' : \{0, 1\}^{r'} \times \{0, 1\}^{\ell+k} \rightarrow \{0, 1\}^\ell$ with $\ell' < \ell + k$, where S_H is the size of the circuit computing H .*

Proof. Since $H^{(\cdot)}$ is an (S_p, S_h, ε) -OWP-to-UOWHF construction, this means that if $\pi \in \Pi_n$ is S_p -hard, then any circuit A of size $\leq S_h$ finds a collision with probability at most ε ; that is,

$$\Pr_{\substack{s \in U_r \\ z \in U_{\ell+k}}} \left[A^\pi(s, z, H^\pi(s, z)) = z' : z' \neq z \wedge H^\pi(s, z') = H^\pi(s, z) \right] \leq \varepsilon.$$

We say that z' as above is a *collision* exactly when $z' \neq z$ but $H^\pi(s, z') = H^\pi(s, z)$.

We now restrict the class of adversaries A under consideration. We consider adversaries that do not access π arbitrarily but are instead simply given the t -prefixes of the queries and answers made during the computation of $H^\pi(s, z)$. Since such restricted adversaries can be simulated by general adversaries with overhead S_H (recall that this is the size of the circuit computing H), we have that if π is S_p -hard and A is a circuit of size $\leq S_h - S_H$, then

$$\Pr_{\substack{s \in U_r \\ z \in U_{\ell+k}}} [A(s, y_1, \dots, y_q, z, H^\pi(s, z), x_1, \dots, x_q) = z' : z' \text{ is a collision}] \leq \varepsilon,$$

where x_1, \dots, x_q are the t -prefixes of the q queries made to π during computation of $H^\pi(s, z)$, and y_1, \dots, y_q are the t -prefixes of the corresponding answers.

Let $t = 5 \log S_p$. From Corollary 2.2 we know that a random permutation $\pi \in \Pi_{t,n}$ is S_p -hard with probability greater than $1 - 2^{-2^{t/2}}$. An averaging argument thus shows that for any circuit A of size $\leq S_h - S_H$ we have

$$(5) \quad \Pr_{\substack{\pi \in \Pi_{t,n} \\ s \in U_r, z \in U_{\ell+k}}} [A(s, y_1, \dots, y_q, z, H^\pi(s, z), x_1, \dots, x_q) = z' : z' \text{ is a collision}] < \varepsilon + 2^{-2^{t/2}}.$$

As in the proof of Theorem 4.2, we may assume without loss of generality that H queries π on points with distinct t -prefixes. Consider the function $H' : \{0, 1\}^{r'} \times \{0, 1\}^{\ell+k} \rightarrow \{0, 1\}^{\ell'}$ defined as follows, where $r' = r + qt$ and $\ell' = \ell + qt$:

$$H'(s', z) = H'((s, y_1, \dots, y_q), z) \stackrel{\text{def}}{=} H^{y_1, \dots, y_q}(s, z), x_1, \dots, x_q,$$

where by $H^{y_1, \dots, y_q}(s, z)$ we mean the computation of $H^{(\cdot)}(s, z)$ when its i th oracle query (a_i, b_i) (with $|a_i| = t$) is answered with (y_i, b_i) , and where x_1, \dots, x_q denote the t -prefixes of the q oracle queries made (i.e., $x_i = a_i$). Note that if $q < k/t$, then $\ell' < \ell + k$, so $H'(s', \cdot)$ is a length-decreasing function.

By definition of H' , if $H'((s, y_1, \dots, y_q), z) = H'((s, y_1, \dots, y_q), z')$, then $H^\pi(s, z) = H^\pi(s, z')$ for any π satisfying $\pi(x_1) = y_1, \dots, \pi(x_q) = y_q$. Thus,

$$\begin{aligned} & \Pr_{\substack{s' \in U_{r'} \\ z \in U_{\ell+k}}} \left[A(s', z, H'(s', z)) = z' : z' \neq z \wedge H'(s', z') = H'(s', z) \right] \\ & \leq \Pr_{\substack{\pi \in \Pi_{t,n} \\ s \in U_r, z \in U_{\ell+k}}} [A(s, y_1, \dots, y_q, z, H^\pi(s, z), x_1, \dots, x_q) = z' : z' \text{ is a collision}] \\ & \quad + \Pr_{\bar{y} \in \{0,1\}^{qt}} [\text{Coll}], \end{aligned}$$

where Coll denotes the event that the q values y_1, \dots, y_q are not distinct.⁷ Equation (5) and a simple birthday problem calculation give the result stated in the theorem. \square

⁷In fact—in contrast to the seemingly similar situation arising in the proof of Theorem 4.2—there is no need to conserve random bits here since the values y_1, \dots, y_q are included as part of the *key* and not the *output* (and the length of the key is irrelevant for our purposes). A tighter security reduction is possible by lowering $\Pr[\text{Coll}]$, for example, by including random values y_1, \dots, y_{2q} in the key and using the first q distinct values (when they exist) to answer the queries of H .

4.3. Public-key encryption. We begin with a definition of constructions of public-key encryption schemes.

DEFINITION 4.5. *A construction of a public-key encryption scheme based on trapdoor permutations is a tuple of oracle procedures $\mathcal{PK}\mathcal{E}^{(\cdot)} = (\text{Gen}^{(\cdot)}, \text{Enc}^{(\cdot)}, \text{Dec}^{(\cdot)})$ such that, for all $\tau \in T_n$, the resulting $\mathcal{PK}\mathcal{E}^\tau$ satisfies the functional definition of a public-key encryption scheme. (The construction may be for either an interactive or a noninteractive encryption scheme, as it does not affect our results.)*

We say $\mathcal{PK}\mathcal{E}^{(\cdot)}$ is an (S_p, S_e, ε) -TDP-to-PKE weak black-box construction if for every oracle $\tau \in T_n$ that is S_p -trapdoor one way, $\mathcal{PK}\mathcal{E}^\tau$ is (S_e, ε) -secure.

We prove that for any such construction which encrypts messages of length m , unless Enc^τ queries τ at least $\Omega(m/\log S_p)$ times, there exists a one-way function which does not require any oracle access. Our proof proceeds by showing that unless Enc^τ makes at least $\Omega(m/\log S_p)$ queries to τ , we can explicitly construct an interactive, private-key encryption scheme $(\text{Enc}', \text{Dec}')$ requiring no access to the oracle and in which the encrypted message is longer than the shared key. Using a previous result of Impagliazzo and Luby [30] (see also Lemma 4.6), this implies the existence of a one-way function.

As in the previous proofs, we first observe that a random $\tau \in T_{t,n}$ is S_p -hard with all but negligible probability when $t = 5 \log S_p$ (cf. Corollary 2.4). To construct an interactive, private-key encryption scheme without access to an oracle, we have the parties simulate a random τ by appropriately choosing random t -prefixes for the answers to their queries, as needed. The bits to simulate τ cannot be included in the private key, since the encryption and decryption algorithms may make their queries in different order and, indeed, may make different queries altogether. However, we must somehow ensure consistency between the oracle answers of the sender and the receiver. A possibility that comes to mind is to have each party include, along with each protocol message it sends to the other party, a list of t -prefixes for the queries and answers generated thus far in accessing τ . In this case, however, privacy is no longer guaranteed as the queries may reveal information about the plaintext message. But this is easily remedied in the private-key setting: the parties simply share a sufficiently long one-time pad in advance and then encrypt their queries and answers using this pad.

Let q_g be the number of queries made to τ by Gen , and let q_e be the number of queries made by Enc . The private-key encryption scheme outlined above requires a shared key of size roughly $O(t) \cdot (q_g + q_e)$ to encrypt an m -bit message. Recalling the result of Impagliazzo and Luby [30], if $O(t) \cdot (q_g + q_e) < m$, then the key is shorter than the message and a one-way function exists. This already gives a weak lower bound. To obtain the better lower bound $q_e < m/O(t)$ (so that we bound the efficiency of encryption alone), additional work is needed; details are given in the proof of Theorem 4.7.

We begin by showing that the existence of a private-key encryption scheme (Enc, Dec) which securely encrypts messages longer than the shared key implies the existence of a one-way function. Although this result is already known [30] (without the concrete bounds given below), we give a much simpler and more direct proof. We stress that the result applies even in the case of interactive encryption.

LEMMA 4.6. *Let (Enc, Dec) be an (S, ε) -secure private-key encryption scheme for messages of length m using a shared key of length $k < m$. Let S_{Enc} be the size of the circuit needed to run the encryption protocol (i.e., the size of the circuit for Enc in the noninteractive case, or the combined sizes of the circuits for Enc and Dec*

in the interactive setting). Then for any $\ell \in \mathbb{N}$ there exists a function f which is $(S - \ell S_{\text{Enc}}, \ell\varepsilon + 2^{-\ell(m-k)})$ -one way.

Proof. We prove the lemma for the case of interactive encryption, which implies the same result for the degenerate, noninteractive case as well. First note that via standard hybrid argument, running ℓ parallel copies of (Enc, Dec) using ℓ independent keys yields an $(S, \ell\varepsilon)$ -secure private-key encryption scheme for messages of length ℓm in which the shared key has length ℓk . Let $\mathcal{SK}\mathcal{E}_\ell = (\text{Enc}_\ell, \text{Dec}_\ell)$ denote this modified scheme.

Define f by $f(sk, M, \omega_1, \omega_2) = \widehat{\text{Enc}}_\ell(sk, M; \omega_1, \omega_2) \| M$, where ω_1, ω_2 represent the random coins used by Enc_ℓ and Dec_ℓ , respectively. We claim that this function is (S', ε') -one way, where $S' = S - \ell S_{\text{Enc}}$ and $\varepsilon' = \ell\varepsilon + 2^{-\ell(m-k)}$. If not, then there is an algorithm B of size at most S' for which $\text{Succ}_{B,f} > \varepsilon'$, where

$$\text{Succ}_{B,f} \stackrel{\text{def}}{=} \Pr \left[sk \leftarrow \{0, 1\}^{\ell k}; M \leftarrow \{0, 1\}^{\ell m}; T \leftarrow \widehat{\text{Enc}}_\ell(sk, M) : B(T \| M) \in f^{-1}(T \| M) \right].$$

We show how such a B can be used to construct an algorithm A of size at most S for which $\text{Succ}_{A, \mathcal{SK}\mathcal{E}_\ell} > \ell\varepsilon$, where

$$\text{Succ}_{A, \mathcal{SK}\mathcal{E}_\ell} \stackrel{\text{def}}{=} \left| \Pr_{\substack{M_0, M_1 \in \{0, 1\}^{\ell m} \\ T \in \mathcal{SK}\mathcal{E}_\ell(M_0)}} [A(M_0, M_1, T) = 1] - \Pr_{\substack{M_0, M_1 \in \{0, 1\}^{\ell m} \\ T \in \mathcal{SK}\mathcal{E}_\ell(M_1)}} [A(M_0, M_1, T) = 1] \right|.$$

This implies that there exist two messages M_0, M_1 for which A can distinguish encryptions of M_0 from encryptions of M_1 with probability better than $\ell\varepsilon$, contradicting the assumed security of $(\text{Enc}_\ell, \text{Dec}_\ell)$. Thus, we are done once we have demonstrated such an A .

Define A as follows. On input (M_0, M_1, T) , algorithm A runs $B(T \| M_0)$ to obtain the result $sk' \| M' \| \omega'_1 \| \omega'_2$. It then checks whether $f(sk', M', \omega'_1, \omega'_2) \stackrel{?}{=} T \| M_0$. If so (i.e., B has succeeded in inverting f), then A outputs 0. Otherwise, A outputs 1. Note that $|A| = |B| + \ell S_{\text{Enc}} \leq S$, as required.

First, note that

$$\Pr_{\substack{M_0, M_1 \in \{0, 1\}^{\ell m} \\ T \in \mathcal{SK}\mathcal{E}_\ell(M_0)}} [A(M_0, M_1, T) = 0] = \text{Succ}_{B,f} > \varepsilon'.$$

For a transcript T , we say (sk, M) is *consistent with* T if there exist ω_1, ω_2 such that $T = \widehat{\text{Enc}}_\ell(sk, M; \omega_1, \omega_2)$. We have

$$\begin{aligned} & \Pr_{\substack{M_0, M_1 \in \{0, 1\}^{\ell m} \\ T \in \mathcal{SK}\mathcal{E}_\ell(M_1)}} [A(M_0, M_1, T) = 1] \\ & \leq \Pr[sk \leftarrow \{0, 1\}^{\ell k}; M_0, M_1 \leftarrow \{0, 1\}^{\ell m}; \\ & \quad T \leftarrow \widehat{\text{Enc}}_\ell(sk, M_1) : \exists sk' \text{ s.t. } (sk', M_0) \text{ is consistent with } T] \\ & \leq \sum_{sk' \in \{0, 1\}^{\ell k}} \Pr[sk \leftarrow \{0, 1\}^{\ell k}; M_0, M_1 \leftarrow \{0, 1\}^{\ell m}; \\ & \quad T \leftarrow \widehat{\text{Enc}}_\ell(sk, M_1) : (sk', M_0) \text{ is consistent with } T]. \end{aligned}$$

Perfect correctness of the encryption scheme implies that for any sk, T there is at most one value of $M \in \{0, 1\}^{\ell m}$ such that (sk, M) is consistent with T . Using this and the fact that M_0 is chosen at random independent of anything else gives

$$\begin{aligned} \Pr_{\substack{M_0, M_1 \in \{0, 1\}^{\ell m} \\ T \in \mathcal{SK}\mathcal{E}_\ell(M_1)}} [A(M_0, M_1, T) = 1] &\leq \sum_{sk' \in \{0, 1\}^{\ell k}} 2^{-\ell m} \\ &= 2^{\ell(k-m)}. \end{aligned}$$

Putting everything together shows that $\text{Succ}_{A, \mathcal{SK}\mathcal{E}_\ell} > \varepsilon' - 2^{\ell(k-m)} \geq \ell\varepsilon$, giving the desired contradiction. \square

We remark that an analogue of the above lemma is known to hold also for the case of (interactive) private-key encryption schemes *with error* [30]. This, in turn, implies results analogous to those of Theorems 4.7 and 4.9 for black-box constructions of encryption schemes with error. However, as we were unable to simplify the proof of [30] in this setting (and as the concrete bounds on the resulting one-way function are rather unwieldy), we do not explicitly focus on the case of encryption schemes with error here.

Our main result of this section follows. The theorem is stated for the case of noninteractive public-key encryption, but the proof immediately extends to the case of *interactive* public-key encryption as well (where q_e will in this case refer to the total number of queries made by sender and receiver during the encryption protocol, and S_{Enc} will refer to the sizes of Enc and Dec jointly).

THEOREM 4.7. *Let $\mathcal{PK}\mathcal{E}^{(\cdot)} = (\text{Gen}^{(\cdot)}, \text{Enc}^{(\cdot)}, \text{Dec}^{(\cdot)})$ be an (S_p, S_e, ε) -TDP-to-PKE weak black-box construction for messages of length m , and let $t = 5 \log S_p$. Assume Gen makes q_g queries to an oracle $\tau \in T_n$ and Enc makes q_e queries to τ ; set $\ell = 2 \cdot \lceil 5tq_g / (m - 5tq_e) \rceil$. Assume further that $\varepsilon < (1/4 - 2^{-S_p^2})/\ell$. If $q_e < m/5t$, then there exists an $(S_e - 3\ell S_{\text{Enc}}, 3/4)$ -one-way function (without access to any oracle), where S_{Enc} is the size of the circuit for Enc.*

Proof. Note that we did not try to optimize the constants in the proof or the required bound on ε . In applications of cryptographic interest, S_p and S_e are typically superpolynomial, S_{Enc} , q_g , q_e , and m are (small) polynomials, and ε is negligible; thus, $\varepsilon \ll (1/4 - 2^{-S_p^2})/\ell$ and $S_e \gg 3\ell S_{\text{Enc}}$ anyway.

Let $\mathcal{PK}\mathcal{E}^{(\cdot)} = (\text{Gen}^{(\cdot)}, \text{Enc}^{(\cdot)}, \text{Dec}^{(\cdot)})$. As in the proof of Lemma 4.6, for any $\ell \in \mathbb{N}$ we may construct a public-key encryption scheme $\mathcal{PK}\mathcal{E}_\ell^{(\cdot)} = (\text{Gen}_\ell^{(\cdot)}, \text{Enc}_\ell^{(\cdot)}, \text{Dec}_\ell^{(\cdot)})$ for ℓm -bit messages in the natural way; furthermore, we may set $\text{Gen}_\ell = \text{Gen}$ since we are now in the public-key setting and so key generation need be done only once. It is easy to see (via hybrid argument) that $\mathcal{PK}\mathcal{E}_\ell^{(\cdot)}$ is an $(S_p, S_e - \ell S_{\text{Enc}}, \ell\varepsilon)$ -TDP-to-PKE construction, where the number of queries made by Gen_ℓ is q_g and the number of queries made by Enc_ℓ is at most ℓq_e .

Set $\ell = 2 \cdot \lceil 5tq_g / (m - 5tq_e) \rceil$ as in the statement of the theorem, and let $S' = S_e - \ell S_{\text{Enc}}$ and $\varepsilon' = \ell\varepsilon + 2^{-S_p^2}$. We use $\mathcal{PK}\mathcal{E}_\ell^{(\cdot)}$ to construct an (S', ε') -secure interactive, private-key encryption scheme $\mathcal{SK}\mathcal{E} = (\text{Enc}', \text{Dec}')$ for ℓm -bit messages in which the shared key will have length $5t \cdot (q_g + \ell q_e)$. Furthermore, $\mathcal{SK}\mathcal{E}$ will require no access to the trapdoor permutation oracle. Finally, we have $5t \cdot (q_g + \ell q_e) < \ell m$ (in fact, $\ell m - 5t \cdot (q_g + \ell q_e) \geq 1$) and $\varepsilon' < 1/4$; thus, application of Lemma 4.6 (with $\ell = 1$ there) yields the desired result.

Security of $\mathcal{PK}\mathcal{E}_\ell^{(\cdot)}$ implies that if τ is S_p -hard, then for any circuit B of size $\leq S'$

and for any messages $M_0, M_1 \in \{0, 1\}^{\ell m}$ we have

$$\left| \Pr_{v \in \mathcal{PK}\mathcal{E}_\ell^\tau(M_0)} [B(v) = 1] - \Pr_{v \in \mathcal{PK}\mathcal{E}_\ell^\tau(M_1)} [B(v) = 1] \right| \leq \ell\varepsilon.$$

Corollary 2.4 shows that a random $\tau \in T_{t,n}$ is S_p -hard except with probability less than $2^{-S_p^2}$. A straightforward averaging argument thus shows that for any circuit B of size $\leq S'$ and for any messages $M_0, M_1 \in \{0, 1\}^{\ell m}$ we have

$$(6) \quad \left| \Pr_{\substack{\tau \in T_{t,n} \\ v \in \mathcal{PK}\mathcal{E}_\ell^\tau(M_0)}} [B(v) = 1] - \Pr_{\substack{\tau \in T_{t,n} \\ v \in \mathcal{PK}\mathcal{E}_\ell^\tau(M_1)}} [B(v) = 1] \right| < \ell\varepsilon + 2^{-S_p^2} = \varepsilon'.$$

As mentioned in the discussion at the beginning of this section, our private-key encryption scheme $\mathcal{SK}\mathcal{E}$ will simulate a random $\tau \in T_{t,n}$ for algorithms Gen , Enc_ℓ , and Dec_ℓ . We achieve this simulation using a simulation procedure \mathcal{SIM} which ensures consistency of the answers to all oracle queries. This procedure takes as input a list L of (appropriate prefixes of) previous oracle queries and answers; before answering any query, \mathcal{SIM} examines L and ensures that the answer it gives will not generate any inconsistencies. After answering a query, L is updated accordingly. As an example, if query $td\|b$ to G was answered by $k\|b$ (where $|td| = |k| = t$), then subsequent query $td'\|b'$ to G must be answered by $k'\|b'$ where $k' = k$ iff $td' = td$. A more involved procedure is needed to answer queries to F and F^{-1} . We now describe the details of this simulation.

$\mathcal{SIM}(L)$.

- On query $G(td\|b)$ (where $|td| = t$): if $\exists k$ s.t. $(td, k) \in L$, return $k\|b$. Otherwise pick random $k \in \{0, 1\}^t$ such that $\forall td' : (td', k) \notin L$, return $k\|b$, and store (td, k) in L .
- On query $F(k\|b, x\|b')$ (where $|k| = |x| = t$):
 1. if $\exists y$ s.t. $(k, x, y) \in L$, return $y\|b'$.
 2. Otherwise, if $\exists td$ s.t. $(td, k) \in L$, choose random $y \in \{0, 1\}^t$ such that $\forall x' : (k, x', y) \notin L$, return $y\|b'$, and store (k, x, y) in L .
 3. Otherwise, choose random $td \in \{0, 1\}^t$ such that $\forall k' : (td, k') \notin L$, choose random $y \in \{0, 1\}^t$, return $y\|b'$, and store $(k, td), (k, x, y)$ in L .
- On query $F^{-1}(td\|b, y\|b')$ (where $|tk| = |y| = t$):
 1. if $\exists k, x$ s.t. $(td, k), (k, x, y) \in L$, return $x\|b'$
 2. Otherwise, if $\exists k$ s.t. $(td, k) \in L$, choose random $x \in \{0, 1\}^t$ such that $\forall y' : (k, x, y') \notin L$, return $x\|b'$, and store (k, x, y) in L
 3. Otherwise, choose random $k \in \{0, 1\}^t$ such that $\forall td' : (td', k) \notin L$, choose random $x \in \{0, 1\}^t$, return $x\|b'$, and store $(td, k), (k, x, y)$ in L

Note that each time a query is answered, at most $5t$ bits are stored in L .

Construct $\mathcal{SK}\mathcal{E}$ as follows. Parse the shared key s as (s_1, s_2) , where $|s_1| = 5tq_g$ and $|s_2| = 5tq_e$. To encrypt message M , the receiver Dec' begins by initializing list $L := \emptyset$. The receiver then computes $(pk, sk) \leftarrow \text{Gen}^{\mathcal{SIM}(L)}$ (updating L in the process) and sends $pk, s_1 \oplus L$ to the sender. The receiver stores sk, L for later use. On receiving the first message pk, \hat{s}_1 , the sender computes $L_1 := s_1 \oplus \hat{s}_1$ and sets $L := L_1$. The sender then computes $C \leftarrow \text{Enc}_\ell^{\mathcal{SIM}(L)}(pk, M)$ and sets $L_2 := L \setminus L_1$. Finally, Enc' sends $C, s_2 \oplus L_2$ to the receiver. On receiving message C, \hat{s}_2 , the receiver decrypts by setting $L_2 := s_2 \oplus \hat{s}_2$ and $L := L_0 \cup L_2$ (here, L_0 is the list stored by the receiver from the first stage). The receiver can then compute $M := \text{Dec}_\ell^{\mathcal{SIM}(L)}(sk, C)$.

It is clear that $\mathcal{SK}\mathcal{E}$ has correct decryption. We now show that the scheme is (S', ε') -secure. Assume toward a contradiction that there exists a circuit A of size $\leq S'$ and messages $M_0, M_1 \in \{0, 1\}^{\ell m}$ such that

$$\left| \Pr_{v \in \mathcal{SK}\mathcal{E}(M_0)} [A(v) = 1] - \Pr_{v \in \mathcal{SK}\mathcal{E}(M_1)} [A(v) = 1] \right| > \varepsilon'.$$

We construct circuit B attacking $\mathcal{PK}\mathcal{E}_\ell$ as follows. On input pk, C , circuit B picks random strings \hat{s}_1, \hat{s}_2 , where $|\hat{s}_1| = 5tq_g$ and $|\hat{s}_2| = 5t\ell q_e$. Then, B outputs $A(pk, \hat{s}_1, C, \hat{s}_2)$. Because the keys s_1, s_2 of $\mathcal{SK}\mathcal{E}$ are used as a one-time pad, it is easy to see that, for $b \in \{0, 1\}$,

$$\Pr_{\substack{\tau \in T_{t,n} \\ (pk, C) \in \mathcal{PK}\mathcal{E}_\ell^\tau(M_b)}} [B(pk, C) = 1] = \Pr_{v \in \mathcal{SK}\mathcal{E}(M_b)} [A(v) = 1].$$

Thus, the advantage of B is equal to the advantage of A (which is greater than ε'), contradicting (6). \square

4.4. Private-key encryption. The techniques of the previous section can be adapted to show a similar lower bound for private-key encryption schemes based on trapdoor permutations; note that trapdoor permutations generalize one-way permutations (which are sufficient for private-key encryption), and therefore our result shows that improved efficiency cannot be obtained in this case even by assuming a stronger primitive.

DEFINITION 4.8. *A construction of a private-key encryption scheme based on trapdoor permutations is a pair of oracle procedures $\mathcal{SK}\mathcal{E}^{(\cdot)} = (\text{Enc}^{(\cdot)}, \text{Dec}^{(\cdot)})$ such that for all $\tau \in T_n$, the resulting $\mathcal{SK}\mathcal{E}^\tau$ satisfies the functional definition of a private-key encryption scheme given earlier. (Again, the construction may yield either an interactive or a noninteractive scheme.)*

We say $\mathcal{SK}\mathcal{E}^{(\cdot)}$ is an (S_p, S_e, ε) -TDP-to-SKE weak black-box construction if for every $\tau \in T_n$ that is S_p -hard, $\mathcal{SK}\mathcal{E}^\tau$ is (S_e, ε) -secure.

Suppose a construction of the above type exists which encrypts m -bit messages using a shared key of length k . We show that unless Enc^τ queries τ at least $q = \Omega(\frac{m-k}{\log S_p})$ times, then an unconditional one-way function exists. This matches the known upper bound, even for schemes constructed using one-way permutations.

The proof is similar to that of Theorem 4.7 in that we convert $\mathcal{SK}\mathcal{E}^{(\cdot)}$ to a private-key encryption scheme $\mathcal{SK}\mathcal{E}'$ that does not access an oracle at all. The only difference between the proof here and the proof of Theorem 4.7 is that here the parties need to share a k -bit key in addition to the one-time pad used to encrypt their simulated queries and answers to the oracle. Set $t = 5 \log S_p$. The resulting $\mathcal{SK}\mathcal{E}'$ requires a shared key of length $k + 5tq$ and encrypts an m -bit message. As before, then, if $k + 5tq < m$ we obtain a private-key encryption scheme (making no oracle queries) in which the message is longer than the key. By Lemma 4.6, this implies the existence of a one-way function.

The following theorem is stated for the case of noninteractive private-key encryption, but the proof immediately extends to the case of interactive private-key encryption as well.

THEOREM 4.9. *Let $\mathcal{SK}\mathcal{E}^{(\cdot)} = (\text{Enc}^{(\cdot)}, \text{Dec}^{(\cdot)})$ be an (S_p, S_e, ε) -TDP-to-SKE weak black-box construction for messages of length m using a key of length k in which Enc makes q queries to an oracle $\tau \in T_n$. Let $t = 5 \log S_p$. If $q < \frac{m-k}{5t}$, then there exists*

an $(S_e, \varepsilon + 2^{-S_p^2})$ -secure private-key encryption scheme in which the message is longer than the key, without access to any oracle.

Proof. The proof is substantially similar to the proof of Theorem 4.7, so the discussion here will be somewhat terse. Let $t = 5 \log S_p$. As in the previous proof, security of the given construction and a straightforward averaging argument imply that for any circuit B of size $\leq S_e$ and for any messages $M_0, M_1 \in \{0, 1\}^m$ we have

$$\left| \Pr_{\substack{\tau \in T_{t,n} \\ v \in \text{SK}\mathcal{E}^\tau(M_0)}} [B(v) = 1] - \Pr_{\substack{\tau \in T_{t,n} \\ v \in \text{SK}\mathcal{E}^\tau(M_1)}} [B(v) = 1] \right| < \varepsilon + 2^{-S_p^2}.$$

We now construct an $(S_e, \varepsilon + 2^{-S_p^2})$ -secure private-key encryption scheme $\text{SK}\mathcal{E}' = (\text{Enc}', \text{Dec}')$ for m -bit messages in which the shared key has length $k' \stackrel{\text{def}}{=} k + 5t \cdot q$. Furthermore, $\text{SK}\mathcal{E}'$ requires no oracle access. If $q < (m - k)/5t$, then $k' < m$ and we obtain the desired result.

The approach for constructing $\text{SK}\mathcal{E}'$ is exactly as in Theorem 4.7 (and as discussed earlier in this section), and in particular we use the same simulation procedure SIM as there. $\text{SK}\mathcal{E}'$ is constructed as follows. The shared key s of length k' is parsed as (s_1, s_2) , where $|s_1| = k$ and $|s_2| = 5t \cdot q$. To encrypt message M , the sender initializes $L := \emptyset$, computes $C \leftarrow \text{Enc}^{\text{SIM}(L)}(s_1, M)$ (updating L in the process), and then sends $C, s_2 \oplus L$ to the receiver. The receiver obtains ciphertext C, \hat{L} , recovers $L = \hat{L} \oplus s_2$, and then computes $M = \text{Dec}^{\text{SIM}(L)}(s_1, C)$.

It is not hard to see that $\text{SK}\mathcal{E}'$ has correct decryption. Arguing exactly as in Theorem 4.7 we see that $\text{SK}\mathcal{E}'$ is $(S_e, \varepsilon + 2^{-S_p^2})$ -secure, completing the proof of the theorem. \square

4.5. Signature schemes. We now demonstrate a lower bound on the efficiency of signature verification for any signature scheme based on one-way permutations.

DEFINITION 4.10. *A construction of a digital signature scheme based on one-way permutations is a tuple of procedures $\text{SIG}^{(\cdot)} = (\text{Gen}^{(\cdot)}, \text{Sign}^{(\cdot)}, \text{Vrfy}^{(\cdot)})$ such that for all $\pi \in \Pi_n$, the resulting SIG^π satisfies the functional definition of a signature scheme given earlier. We say $\text{SIG}^{(\cdot)}$ is an $(S_p, S_\Sigma, \varepsilon)$ -OWP-to-signature semi-black-box construction if for every oracle $\pi \in \Pi_n$ that is S_p -hard, SIG^π is (S_Σ, ε) -secure, where this must hold even for circuits given access to π .*

Given a construction of this sort, we prove that unless Vrfy queries π at least $\Omega(m/\log S_p)$ times, then it is possible to construct from SIG a one-way function which does not access any oracle. Note that this one-way function could then be used to construct a secure signature scheme (which requires no oracle access) [38].

We start with an informal overview of our proof technique. As a first attempt to construct a one-way function from the verification algorithm, one might define

$$F_1(PK, M, \sigma) = PK \parallel \text{Vrfy}^{(\cdot)}(PK, M, \sigma).$$

Intuitively, this function is difficult to invert on elements of the form $PK \parallel 1$ if PK is a valid and randomly generated public key, since inverting the function on points of this form is equivalent to signature forgery. As presently defined, however, evaluating F_1 requires calls to π ; however, our goal is to construct a function which does not require access to any oracle. As in the previous section, however, one may observe that π is S_p -hard (and thus SIG is secure) when π is uniformly chosen from $\Pi_{t,n}$ for $t = 5 \log S_p$ (cf. Corollary 2.2). So, if Vrfy makes q queries to π , then specifying qt

bits as the answers to these queries removes any need to query the oracle. Based on this, one might consider the function

$$(7) F_2(PK, y_1, \dots, y_q, M, \sigma) = PK \|y_1\| \cdots \|y_q\| x_1 \| \cdots \|x_q\| \text{Vrfy}^{y_1, \dots, y_q}(PK, M, \sigma),$$

where $|y_1| = \cdots = |y_q| = |x_1| = \cdots = |x_q| = t$ and the i th query $x_i \|b_i$ of Vrfy is answered with $y_i \|b_i$. (We assume without loss of generality that Vrfy queries π with strings having distinct t -prefixes.) The intuition, as before, is that F_2 is difficult to invert on elements of the form $PK \|y\| \vec{x} \|1$ if PK, \vec{y} , and \vec{x} are chosen appropriately.

Now, however, another problem arises. For F_2 to qualify as a one-way function, it must be hard to invert $F_2(PK, \vec{y}, M, \sigma)$ when PK, \vec{y}, M, σ are sampled from an *efficiently sampleable* distribution (cf. Lemma 4.12). More specifically, a proof of one-wayness will need to show how to efficiently sample PK, \vec{y}, M, σ such that inverting the value $F_2(PK, \vec{y}, M, \sigma)$ results in a signature forgery and hence a contradiction. A necessary condition for inversion to result in signature forgery is that $\text{Vrfy}^{\vec{y}}(PK, M, \sigma) = 1$. Generating PK, \vec{y}, M, σ such that this holds is easy if we have the secret key SK , but then inverting F_2 and forging a signature does not yield the desired contradiction!

Instead, in the proof we will obtain M, σ from the signer. In this case, however, inverting $F_2(PK, \vec{y}, M, \sigma)$ does not result in a forgery if it results in the same message/signature pair M, σ . We come now to the crux of our proof. If the number of queries is small, we show that inversion of F_2 yields a different message M' (and thus a successful forgery) with noticeable probability. More precisely, for randomly generated $PK, \vec{y}, \vec{x}, \sigma$, let

$$Y = PK \|y\| \vec{x} \|1 = F_2(PK, \vec{y}, M, \sigma).$$

If $|\vec{x}| = \sum_{i=1}^q |x_i| < |M|$, then (on average) there exists an element $PK \|y\| M' \| \sigma' \in F_2^{-1}(Y)$ with $M' \neq M$; hence inverting Y results in a forgery with noticeable probability. This idea is formalized in the proof of the following theorem.

THEOREM 4.11. *Let $STG^{(\cdot)}$ be an $(S_p, S_\Sigma, \varepsilon)$ -OWP-to-signature semi-black-box construction for messages of length m in which Vrfy makes q queries to an oracle $\pi \in \Pi_n$, algorithms Gen , Sign , and Vrfy jointly make \hat{q} queries to π , and $\varepsilon < 1/4 - 2^{-S_p^2}$. If $q < m/(5 \log S_p)$, then there exists an $(S_\Sigma - S_{\text{Gen}} - S_{\text{Sign}} - 2S_{\text{Vrfy}}, 3/4 + \hat{q}^2/2S_p^5)$ -one-way function (without access to a permutation oracle), where $S_{\text{Gen}}, S_{\text{Sign}},$ and S_{Vrfy} are the sizes of the circuits for $\text{Gen}, \text{Sign},$ and Vrfy , respectively.*

Proof. As in Theorem 4.7, we did not try to optimize the constants in the proof or the required bound on ε . In applications of cryptographic interest, one will anyway have $S_\Sigma \gg S_{\text{Gen}} + S_{\text{Sign}} + 2S_{\text{Vrfy}}$ and $\varepsilon \ll 1/4 - 2^{-S_p^2}$.

We first present a technical lemma showing that the existence of a function which is one-way over an efficiently sampleable domain implies the existence of a function which is one-way under the definition of section 2.1.

LEMMA 4.12. *Let \mathcal{D} be a distribution sampleable by a circuit of size $S_{\mathcal{D}}$ and let f be a function such that for every circuit A of size $\leq S$ we have*

$$\Pr[x \leftarrow \mathcal{D} : A(f(x)) \in f^{-1}(f(x))] \leq \delta.$$

Then there exists a function \hat{f} that is $(S - S_{\mathcal{D}}, \delta)$ -one way.

Proof of Lemma 4.12. We equate the distribution \mathcal{D} with the circuit of size $S_{\mathcal{D}}$ which samples it; i.e., $\{\mathcal{D}(r)\} \equiv \mathcal{D}$ (where r is a string of the appropriate length chosen uniformly at random). Define $\hat{f}(r) \stackrel{\text{def}}{=} f(\mathcal{D}(r))$. We claim that \hat{f} is $(S - S_{\mathcal{D}}, \delta)$ -one

way. Assume the contrary. Then there exists a circuit \hat{A} of size at most $S - S_{\mathcal{D}}$ for which

$$\Pr_r[\hat{A}(\hat{f}(r)) \in \hat{f}^{-1}(\hat{f}(r))] > \delta.$$

Toward a contradiction, define a circuit A as follows: $A(y) \stackrel{\text{def}}{=} \mathcal{D}(\hat{A}(y))$. Notice that $|A| \leq S$. Furthermore,

$$\begin{aligned} \Pr[x \leftarrow \mathcal{D} : A(f(x)) \in f^{-1}(f(x))] \\ &= \Pr_r[x := \mathcal{D}(r) : f(A(f(x))) = f(x)] \\ &= \Pr_r[f(A(\hat{f}(r))) = \hat{f}(r)] \\ &= \Pr_r[\hat{f}(\hat{A}(\hat{f}(r))) = \hat{f}(r)] \\ &= \Pr_r[\hat{A}(\hat{f}(r)) \in \hat{f}^{-1}(\hat{f}(r))] > \delta. \end{aligned}$$

The proof of the theorem proceeds by using \mathcal{SIG} to construct a function F along with a distribution \mathcal{D} such that for every circuit A of size $\leq S_{\Sigma} - S_{\text{Vrfy}}$ we have

$$(8) \quad \begin{aligned} \Pr[X \leftarrow \mathcal{D} : A(F(X)) \in F^{-1}(F(X))] &\leq \varepsilon + 2^{-S_p} + 1/2 + \hat{q}^2/2S_p^5 \\ &< 3/4 + \hat{q}^2/2S_p^5. \end{aligned}$$

Furthermore, \mathcal{D} will be computable by a circuit of size $S_{\text{Gen}} + S_{\text{Sign}} + S_{\text{Vrfy}}$. Applying Lemma 4.12 then yields the desired result.

Since $\mathcal{SIG}^{(\cdot)}$ is an $(S_p, S_{\Sigma}, \varepsilon)$ -OWP-to-signature construction, if π is S_p -hard, then for any circuit B of size $\leq S_{\Sigma}$ we have $\text{Succ}_{\pi, B} \leq \varepsilon$ where

$$\begin{aligned} \text{Succ}_{\pi, B} &\stackrel{\text{def}}{=} \\ \Pr[(PK, SK) \leftarrow \text{Gen}^{\pi}; M \leftarrow \{0, 1\}^m; \sigma \leftarrow \text{Sign}^{\pi}(SK, M); (M', \sigma') := B^{\pi}(PK, M, \sigma) : \\ &\quad \text{Vrfy}^{\pi}(PK, M', \sigma') = 1 \wedge M' \neq M]. \end{aligned}$$

Let $t = 5 \log S_p$. Corollary 2.2 shows that a random $\pi \in \Pi_{t, n}$ is S_p -hard except with probability less than $2^{-S_p^2}$. An averaging argument then implies that for any circuit B of size $\leq S_{\Sigma}$ we have $\text{Succ}_B^* < \varepsilon + 2^{-S_p^2}$ where Succ_B^* is defined analogously to $\text{Succ}_{\pi, B}$ except that the probability is now taken over random choice of $\pi \in \Pi_{t, n}$ as well.

Define a function F as in (7), repeated here for convenience:

$$F(PK, \vec{y}, M, \sigma) = PK \parallel \vec{y} \parallel \vec{x} \parallel \text{Vrfy}^{\vec{y}}(PK, M, \sigma),$$

where $\vec{y} = (y_1, \dots, y_q)$, $\vec{x} = (x_1, \dots, x_q)$, $|y_1| = \dots = |y_q| = |x_1| = \dots = |x_q| = t$, and the i th query $x_i \parallel b_i$ of Vrfy is answered with $y_i \parallel b_i$. (As in the proof of Theorem 4.2, we assume Vrfy queries its oracle on points having distinct t -prefixes.) We also define distribution \mathcal{D} by the following experiment, which depends on uniformly distributed coins r_g, r_s (of some appropriate length), $r_y \in \{0, 1\}^{\hat{q}t}$ (parsed as a sequence of t -bit strings $\hat{y}_1, \dots, \hat{y}_{\hat{q}} \in \{0, 1\}^t$), and $M \in \{0, 1\}^m$:

$$\left\{ \begin{array}{l} (PK, SK) := \text{Gen}(r_g); \\ \sigma := \text{Sign}(SK, M; r_s); \text{Vrfy}(PK, M, \sigma) \end{array} : PK \parallel \vec{y} \parallel M \parallel \sigma \right\}.$$

In the above experiment, the coins $r_y = \hat{y}_1, \dots, \hat{y}_{\hat{q}}$ are used to give a simulation⁸ of a random $\pi \in \Pi_{t,n}$ which is consistent across the executions of **Gen**, **Sign**, and **Vrfy**. The component y_i of \vec{y} is the t -prefix of the answer given in response to the i th query of **Vrfy**. Note that \mathcal{D} is computable by a circuit of size essentially $S_{\text{Gen}} + S_{\text{Sign}} + S_{\text{Vrfy}}$.

We claim that F satisfies the requirement expressed in (8). Assume toward a contradiction that there exists a circuit A of size $\leq S_{\Sigma} - S_{\text{Vrfy}}$ for which (8) does not hold. We use A to construct an algorithm B which—given PK , a random message M , and a signature σ on M —forges a valid signature on a new message M' with high probability. $B^{\pi}(PK, M, \sigma)$ first runs **Vrfy**(PK, M, σ), answering the queries of **Vrfy** by forwarding them to π . Let \vec{x} be the t -prefixes of the queries made by **Vrfy**, and let \vec{y} be the t -prefixes of the corresponding answers. Define $X = PK \parallel \vec{y} \parallel M \parallel \sigma$ and $Y = PK \parallel \vec{y} \parallel \vec{x} \parallel 1$; note that $Y = F(X)$. Finally, algorithm B computes $PK' \parallel \vec{y}' \parallel M' \parallel \sigma' = A(Y)$ and outputs (M', σ') . We clearly have $|B| \leq S_{\Sigma}$.

B outputs a successful forgery if both $F(PK' \parallel \vec{y}' \parallel M' \parallel \sigma') = Y$ and $M' \neq M$ hold. To see this, note that the first condition implies $\vec{y} = \vec{y}'$, and hence $\text{Vrfy}^{\vec{y}}(PK, M', \sigma') = 1$, and furthermore **Vrfy** makes queries with t -prefixes \vec{x} . Thus, $\text{Vrfy}^{\pi}(PK, M', \sigma') = 1$. If furthermore $M' \neq M$, then (M', σ') is a successful forgery. Finally, the distribution on X —over random choice of $\pi \in \Pi_{t,n}$ —is statistically close to distribution \mathcal{D} , where the difference is due to the fact that the $\hat{y}_1, \dots, \hat{y}_{\hat{q}}$ used in the experiment defining \mathcal{D} may not be distinct. This accounts for the term $\hat{q}^2/2S_p^2$ in the analysis below (obtained using a simple birthday problem calculation), but see footnote 7.

Let Eq be the event that $M' = M$. Then

$$\begin{aligned}
 \text{Succ}_B^* &\geq \Pr_{X \leftarrow \mathcal{D}}[Y = F(X); X' = A(Y) : X' \in F^{-1}(Y) \wedge \overline{\text{Eq}}] - \hat{q}^2/2S_p^5 \\
 &= \Pr_{X \leftarrow \mathcal{D}}[Y = F(X); X' = A(Y) : X' \in F^{-1}(Y)] \\
 &\quad - \Pr_{X \leftarrow \mathcal{D}}[Y = F(X); X' = A(Y) : X' \in F^{-1}(Y) \wedge \text{Eq}] - \hat{q}^2/2S_p^5 \\
 &> \varepsilon + 2^{-S_p} + 1/2 \\
 &\quad - \Pr[X \leftarrow \mathcal{D}; PK \parallel \vec{y} \parallel \vec{x} \parallel 1 = F(X); \\
 &\quad \quad PK' \parallel \vec{y}' \parallel M' \parallel \sigma' = A(PK \parallel \vec{y} \parallel \vec{x} \parallel 1) : M' = M] \\
 &= \varepsilon + 2^{-S_p} + 1/2 \\
 &\quad - \sum_{\vec{z}} \Pr[X \leftarrow \mathcal{D}; PK \parallel \vec{y} \parallel \vec{x} \parallel 1 = F(X); \\
 &\quad \quad PK' \parallel \vec{y}' \parallel M' \parallel \sigma' = A(PK \parallel \vec{y} \parallel \vec{x} \parallel 1) : M' = M \wedge \vec{x} = \vec{z}],
 \end{aligned}$$

where the sum is over \vec{z} consisting of \hat{q} distinct t -bit strings. Substituting \vec{z} for \vec{x} in part of the final equation above gives

$$\begin{aligned}
 \text{Succ}_B^* &\geq \varepsilon + 2^{-S_p} + 1/2 \\
 &\quad - \sum_{\vec{z}} \Pr[X \leftarrow \mathcal{D}; PK \parallel \vec{y} \parallel \vec{x} \parallel 1 = F(X); \\
 &\quad \quad PK' \parallel \vec{y}' \parallel M' \parallel \sigma' = A(PK \parallel \vec{y} \parallel \vec{z} \parallel 1) : M' = M \wedge \vec{x} = \vec{z}] \\
 &\geq \varepsilon + 2^{-S_p} + 1/2
 \end{aligned}$$

⁸Simulating a random $\pi \in \Pi_{t,n}$ is done as expected: the oracle query $x_j \parallel b$ with the j th distinct t -prefix across the executions of **Gen**, **Sign**, and **Vrfy** is answered with $\hat{y}_j \parallel b$, and an oracle query $x \parallel b$ with a previously used t -prefix is answered in a consistent manner in the obvious way.

$$- \sum_{\vec{z}} \Pr[X \leftarrow \mathcal{D}; PK \|\vec{y}\|\vec{x}\|1 = F(X);$$

$$PK' \|\vec{y}'\|M'\|\sigma' = A(PK \|\vec{y}\|\vec{z}\|1) : M' = M].$$

In this last equation we may note that A has no information about M , which is chosen at random from $\{0, 1\}^m$ independently of PK , \vec{y} , and \vec{z} . Therefore,

$$(9) \quad \text{Succ}_B^* \geq \varepsilon + 2^{-S_p} + 1/2 - \sum_{\vec{z}} 2^{-m}.$$

Noting that there are $\binom{2^t}{q} < 2^{qt} \leq 2^{m-1}$ terms in the sum of (9), we derive the contradiction $\text{Succ}_B^* > \varepsilon + 2^{-S_p}$. \square

Upper bounds on the efficiency of signature schemes. As mentioned in the introduction, our lower bounds focus on the efficiency of signature verification. We briefly observe some upper bounds on the efficiency of verification for one-time signatures (satisfying the notion of security considered here) on m -bit messages. The Lamport scheme [34] requires m invocations of a one-way permutation to verify a signature. Instead of signing bit by bit, the scheme can be modified to sign block by block. When basing the construction on an S -hard one-way permutation, it is possible to obtain provable security using blocks of length $\Theta(\log(S/m))$; this gives a signature scheme requiring only $\Theta(m/\log(S/m))$ invocations for verification. When S is polynomial, this is essentially optimal as far as verification is concerned (although the key-generation time and public-key size are prohibitive); however, the resulting scheme does not even run in polynomial time when S is super-polynomial. An alternate approach is to include a universal one-way hash function h_s as part of the public key and to use the (basic) Lamport scheme to sign $h_s(M)$. Verification now requires evaluation of h_s followed by a verification in the underlying Lamport scheme. Since h_s can be used to compress an arbitrary-length message to an n -bit string (when using an S -hard permutation on n bits) [36], we obtain a verification complexity of $\Theta(n + (m - n)/\log S)$ when $m \geq n$.

Acknowledgments. We thank the anonymous referee and Oded Goldreich for corrections and numerous comments which greatly improved the presentation.

APPROXIMATING k -NODE CONNECTED SUBGRAPHS VIA CRITICAL GRAPHS*

GUY KORTSARZ[†] AND ZEEV NUTOV[‡]

Abstract. We present two new approximation algorithms for the problem of finding a k -node connected spanning subgraph (directed or undirected) of minimum cost. The best known approximation guarantees for this problem were $O(\min\{k, \frac{n}{\sqrt{n-k}}\})$ for both directed and undirected graphs, and $O(\ln k)$ for undirected graphs with $n \geq 6k^2$, where n is the number of nodes in the input graph. Our first algorithm has approximation ratio $O(\frac{n}{n-k} \ln^2 k)$, which is $O(\ln^2 k)$ except for very large values of k , namely, $k = n - o(n)$. This algorithm is based on a new result on ℓ -connected p -critical graphs, which is of independent interest in the context of graph theory. Our second algorithm uses the primal-dual method and has approximation ratio $O(\sqrt{n} \ln k)$ for all values of n, k . Combining these two gives an algorithm with approximation ratio $O(\ln k \cdot \min\{\sqrt{k}, \frac{n}{n-k} \ln k\})$, which asymptotically improves the best known approximation guarantee for directed graphs for all values of n, k , and for undirected graphs for $k > \sqrt{n}/6$. Moreover, this is the first algorithm that has an approximation guarantee better than $\Theta(k)$ for all values of n, k . Our approximation ratio also provides an upper bound on the integrality gap of the standard LP-relaxation.

1. Introduction and preliminaries. A basic problem in network design is, given a graph, to find its minimum cost k -connected spanning subgraph; a graph is k -(*node*) *connected* if it is simple and there are at least k internally disjoint paths from every node to any other node. This problem is NP-hard for undirected graphs with $k = 2$ and for directed graphs with $k = 1$. The best known approximation guarantees for this problem were $O(\min\{k, \frac{n}{\sqrt{n-k}}\})$ for both directed and undirected graphs [16, 4], and $O(\ln k)$ for undirected graphs with $n \geq 6k^2$ [4], where n is the number of nodes in the input graph.¹ Better approximation guarantees are known for restricted edge costs, as follows. For metric costs, they are $2 + 2(k-1)/n$ for undirected graphs [17] (for a slight improvement to $2 + (k-1)/n$; see [16]) and $2 + k/n$ for directed graphs [16]. For uniform costs there is a $(1 + 1/k)$ -approximation algorithm for both directed and undirected graphs [3]. The case when the input graph is complete and the cost of every edge is in $\{0, 1\}$ (the so-called “vertex-connectivity augmentation problem”) is polynomially solvable for directed graphs [7]; polynomial algorithms that compute a near optimal solution for undirected graphs are given in [11, 13]. But in this paper we consider only the case of general costs.

The main result of this paper is the following theorem.

THEOREM 1.1. *There exists an algorithm for the minimum cost k -connected subgraph problem with approximation ratio $O(\ln k \cdot \min\{\sqrt{k}, \frac{n}{n-k} \ln k\})$ and running time $O(k^2 nm^2)$.*

¹For undirected graphs, Ravi and Williamson [28] claimed an $O(\ln k)$ -approximation algorithm, but the proof was found to contain an error; see [29].

This gives the first algorithm that has an approximation guarantee better than $\Theta(k)$ for all values of n, k and that improves the previously best known approximation guarantees for directed graphs for all values of n, k and for undirected graphs for $k > \sqrt{n/6}$. Note that our approximation ratio is $O(\ln^2 k)$ except for very large values of k (namely, $k = n - o(n)$). In particular, for instances with $n > kc$, where $c > 1$ is a fixed constant, the approximation ratio is $O(\ln^2 k)$. For example, the previously best known approximation ratios for $k = \sqrt{n}$ and $k = n/2$ were $O(k)$ and $O(\sqrt{k})$, respectively; our approximation ratio for both these cases is $O(\ln^2 k)$. For $k = n - o(n)$ the improvement is from $O(k)$ to $O(\sqrt{k} \ln k)$. Our algorithm is combinatorial and runs significantly faster than the $O(\frac{n}{\sqrt{n-k}})$ -approximation algorithm of [4], which solves linear programs.

Remark. A generalization of the minimum cost k -connected subgraph problem is the *survivable network design problem (SNDP)*, which is to find a cheapest spanning subgraph such that, for every pair (u, v) of nodes, there are at least k_{uv} pairwise internally disjoint paths from u to v . It is interesting to compare Theorem 1.1 with results in [15, 27], which show that the SNDP with $k_{uv} \in \{0, k\}$, $k = \Theta(n)$, and costs in $0, 1$, is unlikely to have a polylogarithmic approximation guarantee. On the other hand, Jain [14] showed that the version of the SNDP in which the paths are only required to be pairwise *edge* disjoint admits a 2-approximation algorithm.

Our $O(\frac{n}{n-k} \ln^2 k)$ -approximation algorithm is based on a new result on ℓ -connected p -critical graphs, which is of independent interest in graph theory. Namely, we will prove that any ℓ -connected graph (directed or not) on n nodes has a subset U of nodes with $|U| = O(\frac{n}{n-\ell} \ln \ell)$ such that no node-cut of cardinality ℓ contains U ; we call such a U an ℓ -cover (since U covers the complements of node-cuts of cardinality ℓ) and denote by $\tau_\ell(G)$ the minimum cardinality of an ℓ -cover in G . An ℓ -connected graph G is p -critical if $p < \tau_\ell(G)$ (this definition is shown to be equivalent to the one used in the papers on the topic; see section 1.2). For undirected graphs, our result partly bridges the gap between two main bounds: the obvious fact that $\tau_\ell(G) \leq \ell + 1$ and a result of Mader [21], which states that $\tau_\ell(G) \leq 3$ for $n \geq 6\ell^2$. Other previous bounds were for undirected graphs only, and of the type $\tau_\ell(G) = \Theta(\ell)$ (see, e.g., [18]), or of the type $\tau_\ell(G) = \Theta(1)$ for $n = \Omega(\ell^2)$ (see, e.g., [22]). Our result gives the first nontrivial bound in the intermediate range for undirected graphs and, overall, the first nontrivial bound for directed graphs. Moreover, our proof provides a polynomial algorithm that computes an ℓ -cover within the stated bound.

Throughout the paper, let $\mathcal{G} = (V, \mathcal{E})$ denote the input graph with nonnegative costs on the edges; n denotes the number of nodes in \mathcal{G} , and m denotes the number of edges in \mathcal{G} . Unless stated otherwise, “graph” stands for both a directed and an undirected graph.

This paper is organized as follows. In the rest of this section, we introduce a standard LP-relaxation to the minimum cost k -connected subgraph problem and state some simple facts about ℓ -outconnected graphs and p -critical graphs. In sections 2 and 3 we give our algorithm for the minimum cost k -connected subgraph problem: in section 2 we establish existence of an ℓ -cover of size $O(\frac{n}{n-\ell} \ln \ell)$ and show how to compute it, which implies an $O(\frac{n}{n-k} \ln^2 k)$ -approximation algorithm, and in section 3 we present our primal-dual $O(\sqrt{n} \ln k)$ -approximation algorithm.

1.1. LP-relaxation and ℓ -outconnected graphs. For an edge set or a graph J on a node set V and $S, T \subseteq V$ let $\delta_J(S, T)$ denote the set of edges in J going from S to T . By Menger’s theorem, there are k internally disjoint paths from a node s to a node t in a graph $G = (V, E)$ if and only if $|\delta_E(S, T)| \geq k - (n - |S \cup T|)$ for all disjoint

$S, T \subset V$ with $s \in S$ and $t \in T$. We will compare the cost of our solutions to the optima opt_k of the following LP-relaxation for the minimum cost k -node connected spanning subgraph introduced in [7] and used in [4]:

$$\begin{aligned}
 opt_k = \min \quad & \sum_{e \in \mathcal{E}} c_e x_e \\
 \text{s.t.} \quad & \sum_{e \in \delta_{\mathcal{E}}(S, T)} x_e \geq k - (n - |S \cup T|) \quad \forall \emptyset \neq S, T \subset V, S \cap T = \emptyset, \\
 & 0 \leq x_e \leq 1 \quad \forall e \in \mathcal{E}.
 \end{aligned}$$

A graph is ℓ -outconnected from a node r if it contains ℓ internally disjoint paths from r to any other node; a graph is ℓ -inconnected to r if its reverse graph is ℓ -outconnected from r (for undirected graphs these two concepts have the same meaning). Frank and Tardos [8] showed that for directed graphs, the problem of finding an ℓ -outconnected spanning subgraph of minimum cost is solvable in polynomial time; a faster algorithm with time complexity $O(\ell^2 n^2 m) = O(m^3)$ is due to Gabow [9] (observe that $n\ell = O(m)$ in an ℓ -outconnected graph).

Let $G = (V, E)$ be an ℓ -connected spanning subgraph of cost zero of a directed graph \mathcal{G} , and suppose that G has a subset U of nodes such that no node-cut of cardinality ℓ contains all of them. Then using the algorithm of [8] it is easy to get a $2|U|$ -approximation algorithm for the problem of augmenting G to be $(\ell+1)$ -connected by adding an edge set of minimum cost as follows: for each node $r \in U$ we compute an $(\ell+1)$ -outconnected spanning subgraph from r and an $(\ell+1)$ -inconnected spanning subgraph to r and take the union of these $2|U|$ subgraphs. In fact, the following lemma, which can be easily deduced from [5, Theorem 7] (see, e.g., [4]) implies that the augmenting edge set produced has cost at most $\frac{2|U|}{k-\ell} opt_k$.

LEMMA 1.2. *Let G be an ℓ -outconnected from r subgraph of cost zero of a directed graph \mathcal{G} , and for an integer p let α^p be the minimum cost of an $(\ell+p)$ -outconnected spanning subgraph of \mathcal{G} . Then $\alpha^1 \leq \alpha^p/p$. In particular, for $\ell < k$ the minimum cost of an $(\ell+1)$ -outconnected spanning subgraph of \mathcal{G} is at most $\frac{1}{k-\ell} opt_k$.*

Khuller and Raghavachari [17] observed that the algorithm of [8] implies a 2-approximation algorithm for the problem of finding an optimal ℓ -outconnected subgraph of an undirected graph, as follows. First, replace every undirected edge e of \mathcal{G} with the two antiparallel directed edges having the same ends and being of the same cost as e . Then compute an optimal ℓ -outconnected subdigraph from r and output its underlying (undirected) simple graph. Several papers used this observation for designing approximation algorithms for node connectivity problems; see, e.g., [1, 2, 4, 16].

1.2. p -critical graphs and k -connected subgraphs. Let $\kappa(G)$ denote the connectivity of G , that is, the maximum integer ℓ for which G is ℓ -connected. A (directed or undirected) graph $G = (V, E)$ is p -critical if $\kappa(G - U) = \kappa(G) - |U|$ for any $U \subset V$ with $|U| \leq p$. One can characterize p -critical graphs in terms of covers of set families, as follows. Let $G = (V, E)$ be an ℓ -connected graph. Let $X^* = X_G^* = \{v \in V - X : \delta_G(X, v) = \emptyset\}$ denote the “node complement” of X in G . We say that $X \subset V$ is an ℓ -fragment if $X^* \neq \emptyset$ and $|V - (X \cup X^*)| = \ell$. It is well known that if G is ℓ -connected, then $|V| \geq \ell + 1$, and if $|V| = \ell + 1$, then G must be a complete graph. Note that Menger’s theorem implies the following well-known statement.

PROPOSITION 1.3. *An ℓ -connected graph G (on at least $\ell + 2$ nodes) is $(\ell + 1)$ -connected if and only if G has no ℓ -fragments.*

Given a family \mathcal{F} of subsets of a groundset V we say that $U \subseteq V$ covers \mathcal{F} if U intersects every set in \mathcal{F} . Let $\mathcal{F}_\ell(G)$ be the family of all ℓ -fragments of G . We say that $U \subseteq V$ is an ℓ -cover of G if U covers $\{X \cup X^* : X \in \mathcal{F}_\ell(G)\}$; let $\tau_\ell(G)$ denote the minimum cardinality of an ℓ -cover of G . From Proposition 1.3 we have the following.

PROPOSITION 1.4. *Let $G = (V, E)$ be a graph with $\kappa(G) = \ell$ and $|V| \geq \ell + 2$. Then*

- (i) *G is p -critical if and only if for any $U \subseteq V$ with $|U| \leq p$ there exists an ℓ -fragment X with $U \cap (X \cup X^*) = \emptyset$. Thus if G is p -critical, then G is p' -critical for any $p' \leq p$, and $\tau_\ell(G) - 1$ is the maximum p for which G is p -critical.*
- (ii) *U is an ℓ -cover of G if and only if there exists an edge set F incident to U (that is, every edge in F has at least one endpoint in U) such that $G + F$ is $(\ell + 1)$ -connected.*

Combining Proposition 1.4(ii) with Lemma 1.2 and the discussion before it, we get the following statement, which was implicitly proved in [4] for undirected graphs.

PROPOSITION 1.5 (see [4]). *Suppose there is a polynomial algorithm that finds in any ℓ -connected graph G on n nodes an ℓ -cover of G of size at most $t(\ell, n)$. Then there exists a polynomial algorithm that, for instances of the minimum k -connected subgraph problem on n nodes, finds a feasible solution of cost at most $opt_k \cdot 2 \sum_{\ell=0}^{k-1} \frac{t(\ell, n)}{k-\ell} = opt_k \cdot O(\ln k \cdot \max_{0 \leq \ell \leq k-1} t(\ell, n))$.*

For undirected graphs with $n \geq 6k^2$, Cheriyan, Vempala, and Vetta [4] gave a $6H(k)$ -approximation algorithm for the undirected minimum cost k -connected subgraph problem combining Proposition 1.5 with the following theorem due to Mader.

THEOREM 1.6 (see [21]). *Any undirected 3-critical graph G has less than $6\kappa(G)^2$ nodes.*

In a recent paper, Mader [22] improved his bound for 3-critical graphs to $n \leq \kappa(G)(2\kappa(G) - 1)$; hence via Proposition 1.5 the $6H(k)$ -approximation algorithm of [4] is valid for $n \geq k(2k - 1)$ as well.

On the other hand, it is easy to see that there are no $\kappa(G)$ -critical noncomplete graphs. But for undirected graphs, a stronger result was conjectured in [26] and answered by Su as follows.

THEOREM 1.7 (see [30]). *If a noncomplete graph G is p -critical, then $p \leq \lfloor \kappa(G)/2 \rfloor$.*

For a survey on p -critical graphs see [24, 25]; for some recent results see [22, 23] and [18].

2. Computing logarithmic covers. Note that in terms of covers of set families Theorem 1.6 states that $\tau_\ell(G) \leq 3$ for any undirected graph G with $\kappa(G) = \ell$ and $n \geq 6\ell^2$, and Theorem 1.7 states that $\tau_\ell(G) \leq \lfloor \ell/2 \rfloor + 1$ (if $n \geq \ell + 2$). Our result on p -critical graphs partly bridges the gap between these two bounds, and also gives the first nontrivial bound on $\tau_\ell(G)$ for directed graphs. Let $\theta = \theta(\ell, n) = \frac{2n}{n+\ell}$.

THEOREM 2.1. *There exists a polynomial algorithm that, given an ℓ -connected graph G on $n \geq \ell + 2$ nodes, finds an ℓ -cover of G of size at most*

$$t(\ell, n) = 2 + \frac{3n}{n-\ell} + \frac{1}{\ln \theta} \ln \frac{1}{2} \left(\ell - 1 - \frac{\ell^2}{n} \right) = O \left(\frac{n}{n-\ell} \ln \ell \right)$$

if G is undirected and of size at most $2t(\ell, n)$ if G is directed.

Combining with Proposition 1.5 we get the following.

THEOREM 2.2. *For the minimum cost k -connected subgraph problem there exists a polynomial algorithm that finds a feasible solution of cost at most $opt_k \cdot O(\frac{n}{n-k} \ln^2 k)$.*

Remark. Note that $\tau_\ell(G)$ is the minimum cardinality of a cover (transversal) of the $(n - \ell)$ -uniform hypergraph $\{X \cup X^* : X \in \mathcal{F}_\ell(G)\}$. Several general bounds on covers of uniform hypergraphs are known; see, e.g., [10]. But, as far as we can see, none of them implies the bound given in Theorem 2.1.

We need several definitions and simple facts to prove Theorem 2.1. In the rest of this section, let ℓ be a fixed integer, and let G be a graph with $\kappa(G) \geq \ell$. An ℓ -fragment X of G is *small* if $|X| \leq |X^*|$, that is, if $|X| \leq \lfloor (n - \ell)/2 \rfloor$. Note that by Proposition 1.3, G is $(\ell + 1)$ -connected if and only if G (and the reverse graph of G , if G is directed) has no small ℓ -fragments. Let $\mathcal{S}_\ell(G)$ denote the family of all small ℓ -fragments of G . The following lemma is well known; see, e.g., [11, Lemma 1.2], where it was stated for undirected graphs.

LEMMA 2.3. *Let X, Y be two intersecting ℓ -fragments in an ℓ -connected (directed or undirected) graph G on n nodes. If $n - |X \cup Y| \geq \ell$, then $X \cap Y$ is an ℓ -fragment, and if a strict inequality holds, then $X \cup Y$ also is an ℓ -fragment. In particular, the intersection of two intersecting small ℓ -fragments is also a small ℓ -fragment.*

A *core* of G is an inclusion minimal small ℓ -fragment. By Lemma 2.3 the cores of G are pairwise disjoint and $\nu(G) = \nu_\ell(G)$ denote their number; note that if $\kappa(G) > \ell$, then $\nu_\ell(G) = 0$. For a core C_i of G , let A_i be the union of all small ℓ -fragments that contain a unique core, which is C_i . Let $\mathcal{A}_\ell(G) = \{A_1, \dots, A_{\nu(G)}\}$. The properties of the sets in $\mathcal{A}_\ell(G)$ that we use are summarized in the following statement.

COROLLARY 2.4. *The sets in $\mathcal{A}_\ell(G)$ are pairwise disjoint. Moreover, for every $A \in \mathcal{A}_\ell(G)$ it holds that either A is an ℓ -fragment or $|A| \geq n - \ell$ (and $A^* = \emptyset$); thus $|A \cup A^*| \geq n - \ell$.*

Proof. Suppose to the contrary that A_i and A_j intersect for some $1 \leq i \neq j \leq \nu(G)$. Then, by the definition of A_i, A_j , there are two small ℓ -fragments D_i, D_j such that D_i contains a unique core which is C_i , D_j contains a unique core which is C_j , and D_i, D_j intersect. By Lemma 2.3 $D_i \cap D_j$ is a small ℓ -fragment, and thus contains a core C . This implies that D_i contains the two cores C_i and C , which gives a contradiction.

To prove the second statement, let us fix some set $A \in \mathcal{A}_\ell(G)$. Since the sets in $\mathcal{A}_\ell(G)$ are disjoint, A contains a unique core, say C . Consider the family \mathcal{D} of all small ℓ -fragments that contain a unique core, which is C , so A is the union of the sets in \mathcal{D} . If $n - |A| \leq \ell$, then clearly $|A \cup A^*| \geq |A| \geq n - \ell$ (in fact, in this case $A^* = \emptyset$, and thus $|A \cup A^*| = |A|$). Otherwise, $n - |A| \geq \ell + 1$; then by Lemma 2.3, the union of the sets in \mathcal{D} is an ℓ -fragment, and thus $|A \cup A^*| = n - \ell$. In both cases, the statement is valid. \square

Note that Corollary 2.4 does *not* imply that the sets in $\mathcal{A}_\ell(G)$ are small or that they are ℓ -fragments; it might be that A is large and that $A^* = \emptyset$ for some $A \in \mathcal{A}_\ell(G)$, but in any case, $|A \cup A^*| \geq n - \ell$ holds.

LEMMA 2.5. *Let \mathcal{A} be a family of sets on a groundset V such that $|A| \geq n - \ell$ holds for every $A \in \mathcal{A}$, where $n = |V|$ and ℓ is an integer. Then there exists an element $r \in V$ that covers (that is, intersects) at least $(1 - \frac{\ell}{n})|\mathcal{A}|$ sets in \mathcal{A} .*

Proof. For $r \in V$, let $\mathcal{A}_r = \{A \in \mathcal{A} : r \in A\}$ be the sets in \mathcal{A} covered by r . The claim follows since we have

$$\sum_{r \in V} |\mathcal{A}_r| = \sum_{A \in \mathcal{A}} |A| \geq |\mathcal{A}|(n - \ell). \quad \square$$

For $r \in V$ let $F_r = \{vr : v \in V - r\}$, and let $G + F_r$ be the graph obtained by

adding an edge from every node $v \in V$ to r if such does not exist in G . We say that $r \in V$ *outercovers* $A \in \mathcal{A}_\ell(G)$ if $r \in A^*$.

LEMMA 2.6. *Let C_i be a core of an ℓ -connected graph G . If r outercovers A_i , then any small ℓ -fragment X of $G + F_r$ that contains C_i must contain a core of G distinct from C_i .*

Proof. Let X be a small ℓ -fragment of $G + F_r$ that contains C_i . Assume by contradiction that this is the unique core of G that X contains. Note that X is a small ℓ -fragment of G . Since A_i is defined as the union of all small ℓ -fragments of G containing C_i as their unique core, we obtain that $X \subseteq A_i$. This gives a contradiction, since then $r \in A_i^* \subseteq X^*$, which implies that X cannot be an ℓ -fragment of $G + F_r$. \square

LEMMA 2.7. *Let r be a node that outercovers q sets in $\mathcal{A}_\ell(G)$. Then $\nu_\ell(G + F_r) \leq \nu_\ell(G) - q/2$.*

Proof. If $\kappa(G + F_r) > \ell$, then $\nu_\ell(G + F_r) = 0$ and the statement is obvious, so assume that $\kappa(G + F_r) = \ell$. By Lemma 2.3, the cores of $G + F_r$ are pairwise disjoint. Clearly, every core of $G + F_r$ is a small ℓ -fragment of G , and thus contains at least one core of G . Let t be the number of cores of $G + F_r$ containing exactly one core of G . By Lemma 2.6, any core C of $G + F_r$ that contains some core C_i of G with $r \in A_i^*$ must contain another core of G distinct from C_i , so such C contains at least two cores of G . Thus $t \leq \nu_\ell(G) - q$. From this we get that $\nu_\ell(G + F_r) \leq t + (\nu_\ell(G) - t)/2 \leq \nu_\ell(G) - q/2$, as required. \square

Since the sets in $\mathcal{A}_\ell(G)$ are pairwise disjoint, a node can belong to at most one of them. Thus, if $\mathcal{A}' \subseteq \mathcal{A}_\ell(G)$ and r covers $\{A \cup A^* : A \in \mathcal{A}'\}$, then there is at most one set $A' \in \mathcal{A}'$ such that $r \in A'$; for any other $A \in \mathcal{A} - A'$ we must have $r \in A^*$; hence r outercovers at least $|\mathcal{A}'| - 1$ sets in \mathcal{A}' . Combining this with Corollary 2.4 and Lemmas 2.5 and 2.7 we get the following.

COROLLARY 2.8. *Any ℓ -connected graph G has a node r that outercovers at least $\nu_\ell(G)(1 - \ell/n) - 1$ sets in $\mathcal{A}_\ell(G)$, and $\nu_\ell(G + F_r) \leq \frac{n+\ell}{2n}\nu_\ell(G) + 1/2$.*

Let us apply the following algorithm on an ℓ -connected graph G starting with $U = \emptyset$.

While $\nu_\ell(G) > 0$ do:

1. Find a node r for which $\nu_\ell(G + F_r)$ is minimal;
2. $U \leftarrow U + r, G \leftarrow G + F_r$;

End While

Output U .

By Proposition 1.4(ii), at the end of the algorithm U is an ℓ -cover; let us estimate its size. Let t_j be the number of cores in G after j iterations of the main loop, and set $\theta = \frac{2n}{n+\ell}$ and $\alpha = 1/\theta$. Corollary 2.8 gives the recursive bound

$$t_{j+1} \leq \alpha t_j + 1/2.$$

We will prove later that $t_1 \leq \ell$ (see Corollary 2.11 below) which implies

$$\begin{aligned} t_j &\leq \alpha^{j-1}\ell + \frac{1}{2}(1 + \alpha + \dots + \alpha^{j-2}) = \alpha^{j-1}\ell + \frac{1 - \alpha^{j-1}}{2(1 - \alpha)} \\ &= \alpha^{j-1} \left(\ell - \frac{1}{2(1 - \alpha)} \right) + \frac{1}{2(1 - \alpha)} = \frac{1}{\theta^{j-1}} \left(\ell - \frac{n}{n - \ell} \right) + \frac{n}{n - \ell}. \end{aligned}$$

The inequality can be easily proved by induction on j . Let $\beta = 3n/(n - \ell)$.

CLAIM 2.9.

$$t_j \leq \beta \quad \text{for} \quad j \geq j(\beta) \equiv \frac{1}{\ln \theta} \ln \frac{1}{2} \left(\ell - 1 - \frac{\ell^2}{n} \right) + 1.$$

Proof. We solve for j the inequality

$$\frac{1}{\theta^{j-1}} \left(\ell - \frac{n}{n-\ell} \right) + \frac{n}{n-\ell} \leq \frac{3n}{n-\ell} = \beta.$$

That is,

$$\theta^{j-1} \geq \frac{\ell(n-\ell) - n}{2n} = \frac{1}{2} \left(\ell - 1 - \frac{\ell^2}{n} \right).$$

The claim follows by taking logarithm base θ from both sides and then changing the logarithm base as follows:

$$j - 1 \geq \log_{\theta} \frac{1}{2} \left(\ell - 1 - \frac{\ell^2}{n} \right) = \frac{1}{\ln \theta} \ln \frac{1}{2} \left(\ell - 1 - \frac{\ell^2}{n} \right). \quad \square$$

On the other hand, if $t_j > 0$, then $t_{j+1} \leq t_j - 1$ since $\nu_{\ell}(G + F_r) \leq \nu_{\ell}(G) - 1$ for any node r belonging to a core C_i of G (indeed, every core of $G + F_r$ must contain some core of G , but cannot contain C_i). Thus the number of iterations in the algorithm (which is equal to the size of the cover found) is bounded by $\lceil j(\beta) \rceil + \lfloor \beta \rfloor \leq t(\ell, n)$. This proves Theorem 2.1 for undirected graphs. In the case of a directed graph G , at the end of the algorithm, G has no small ℓ -fragments, but G may not be $(\ell + 1)$ -connected since the reverse graph of G might have small ℓ -fragments. Thus we apply the above procedure twice, that is, on G and on the reverse graph of G , and take the union of the resulting two node sets.

Let us now show that $t_1 \leq \ell$ and discuss some consequences of our approach. The following statement is obvious.

LEMMA 2.10. *Let r be a node of a (directed or undirected) noncomplete graph $G = (V, E)$ with $\kappa(G) = \ell$, and let $N_r = \{v \in V : vr \in E\}$ be the nodes in G having r as their neighbor. Then N_r covers all ℓ -fragments of $G + F_r$.*

An ℓ -connected graph J is *minimally ℓ -connected* if $J - e$ is not ℓ -connected for every edge e of J . Mader [19, 20] showed that any minimally ℓ -connected graph J on n nodes has at least $\frac{(\ell-1)n+2}{2^{\ell-1}}$ nodes of degree (indegree, if J is directed) ℓ . Since $\mathcal{F}_{\ell}(G) \subseteq \mathcal{F}_{\ell}(J)$ for any ℓ -connected spanning subgraph J of an ℓ -connected graph G , Lemma 2.10 implies the following corollary, which also proves that $t_1 \leq \ell$.

COROLLARY 2.11. *Let $G = (V, E)$ be an ℓ -connected graph. Then there is $R \subseteq V$ with $|R| \geq \frac{(\ell-1)n+2}{2^{\ell-1}}$ such that for any $r \in R$ the following holds: r and at most ℓ nodes having r as their neighbor cover all ℓ -fragments of G and, in particular, $\nu_{\ell}(G + F_r) \leq \ell$.*

We note that for a directed graph G , Corollary 2.11 implies only the trivial bound $\tau_{\ell}(G) \leq \ell + 1$; however, for undirected G the following theorem provides an easy proof of Theorem 1.7 and is similar to the proof given by Jordán in [12]; recall that in terms of covers, Theorem 1.7 states that $\tau_{\ell}(G) \leq \lfloor \ell/2 \rfloor + 1$.

THEOREM 2.12. *Let G be an undirected ℓ -connected graph and let W be a cover of $\mathcal{F}_{\ell}(G)$. Then there exists an ℓ -cover $U \subseteq W$ of size at most $\lfloor |W|/2 \rfloor$.*

Proof. In [19], Mader implicitly proved (see, e.g., [11] and [16, Corollary 2.2]) that if W covers all the ℓ -fragments of an undirected ℓ -connected graph G , then there

exists a forest F on W such that $G + F$ is $(\ell + 1)$ -connected. Since F is a forest, there exists $U \subseteq W$ such that $|U| \leq \lfloor |W|/2 \rfloor$ and every edge in F is incident to a node in U . Thus, by Proposition 1.4(ii), U is a cover of $\mathcal{F}_\ell(G)$ as required. \square

Let us now analyze the time complexity of our approximation algorithm for k -connected spanning subgraphs. Using max-flow techniques, we find that an ℓ -cover as in Theorem 2.1 can be found in $O(\ell m^2)$ time, as follows. For the first iteration, we find a minimally ℓ -connected spanning subgraph J of G and choose a node s of degree (indegree, if G is directed) ℓ in J ; such J can be found in $O(\ell m^2)$ time by repeatedly checking every edge for deletion. By Lemma 2.10 the set $N = N_s$ of nodes having s as their neighbor in J covers all ℓ -fragments of $J + F_s$, and thus also of $G + F_s$. Now we set $G \leftarrow G + F_s$. We compute for every $u \in N_s$ and $v \in V$ a set of ℓ internally disjoint paths. This can be done in $O(\ell m)$ time per pair, and thus in $O(\ell^2 nm)$ total time, using the Ford–Fulkerson algorithm (the node-capacitated version) and flow decomposition. For each pair uv we check whether v is reachable from u in the corresponding residual network. If so, then the pair uv is discarded; otherwise, a minimal ℓ -fragment containing v is found, and if its size is $\leq (n - \ell)/2$, it is the minimal core containing v . At each iteration, for every $r \in V$, we can recompute the cores of $G + F_r$ in $O(\ell m)$ time. Thus each iteration can be implemented in $O(\ell nm)$ time, and since the number of iterations is at most ℓ , an ℓ -cover as in Theorem 2.1 can be found in $O(\ell^2 nm) = O(\ell m^2)$ time, as claimed.

We also need to find a minimum cost edge set to increase the outconnectivity from ℓ to $\ell + 1$ from each node in the cover found. Frank [6] showed that a generalization of this problem can be solved in $O(n^2 m)$ time, but with some care Frank’s algorithm can be implemented in $O(m^2)$ time. As the size of the cover found is $O(\ell)$, we get that the overall time complexity for increasing connectivity from ℓ to $\ell + 1$ is $O(\ell m^2)$, where $m \geq n\ell$ is the number of edges in \mathcal{G} . Consequently, the overall running time of the algorithm is $O(k^2 m^2)$.

3. A primal-dual algorithm. In this section we prove the following theorem.

THEOREM 3.1. *For the problem of making a k_0 -connected graph (directed or undirected) k -connected by adding a minimum cost edge set, there exists an approximation algorithm with approximation ratio $O(\sqrt{n}H(k - k_0)) = O(\sqrt{n} \ln k)$ and time complexity $O(km(k^2 n^2 + \sqrt{nm})) = O(n^5 m)$, where $H(j)$ denotes the j th Harmonic number.*

We start by giving an algorithm for increasing the connectivity of a *directed graph* by one. We use as a subroutine the primal-dual algorithm of Ravi and Williamson [28], which we adapt to directed graphs. Given an ℓ -connected graph G , the algorithm of [28] uses the primal-dual method to find an edge set F so that $G + F$ is $(\ell + 1)$ -connected. We use the same approach, but unlike the algorithm in [28], the primal-dual procedure terminates when we find an edge set F^+ so that $\nu_\ell(G + F^+) = \sqrt{2n}$; we will show that $c(F^+) = O(\frac{\sqrt{n}}{k-\ell})opt_k$. We then find in $G + F^+$ a node set U of size $O(\sqrt{n})$ by picking one node from every core; for every $r \in U$ we find an $(\ell + 1)$ -inconnected subgraph to r subgraph. The cost of each subgraph found is $O(\frac{1}{k-\ell})opt_k$ and its number is $|U| = O(\sqrt{n})$. Thus the cost of the edge set found during this step is also $O(\frac{\sqrt{n}}{k-\ell})opt_k$. We apply this procedure twice, that is, on G and on the reversed graph of G . Consequently, the total cost of the edge set found is $O(\frac{\sqrt{n}}{k-\ell})opt_k$.

Let $G = (V, E)$ be an ℓ -connected spanning subgraph of a directed graph $\mathcal{G} = (V, \mathcal{E})$ such that all the edges in E have cost zero, and let $I = \mathcal{E} - E$. Let $\mathcal{S} = \mathcal{S}_\ell(G)$ denote the set of small ℓ -fragments of G . For an edge set F and $S \in \mathcal{S}$, let $d_F(S) =$

$|\delta_F(S, S^*)|$ be the number of edges in F going from S to S^* . Recall that $G + F$ is $(\ell + 1)$ -connected if and only if the graph $G + F$ and its reverse graph have no small ℓ -fragments. Note that for $F \subseteq I = \mathcal{E} - E$, $G + F$ has no small ℓ -fragments if and only if $d_F(S, S^*) \geq 1$ for any $S \in \mathcal{S}$. Consider the following linear program (P) and its dual program (D), where (P) is a linear relaxation for the problem of finding a minimum cost augmenting edge set F such that $G + F$ contains no small ℓ -fragments:

$$\begin{aligned}
 \text{(P)} \quad & \min \quad \sum_{e \in I} c_e x_e \\
 \text{s.t.} \quad & \sum_{e \in \delta_I(S, S^*)} x_e \geq 1 \quad \forall S \in \mathcal{S}, \\
 & x_e \geq 0 \quad \forall e \in I.
 \end{aligned}$$

$$\begin{aligned}
 \text{(D)} \quad & \max \quad \sum_{S \in \mathcal{S}} y_S \\
 \text{s.t.} \quad & \sum_{S \in \mathcal{S}: e \in \delta_I(S, S^*)} y_S \leq c_e \quad \forall e \in I, \\
 & y_S \geq 0 \quad \forall S \in \mathcal{S}.
 \end{aligned}$$

LEMMA 3.2. *Let x be an optimal solution to (P). Then $\sum_{e \in I} c_e x_e \leq \frac{1}{k-\ell} \text{opt}_k$.*

Proof. Let x be an optimal solution to the LP-relaxation for the minimum cost k -connected spanning subgraph problem (given in section 1.1). Define $x'_e = 1$ if $e \in E$ and $x'_e = \frac{1}{k-\ell} x_e$ otherwise. Then x' is a feasible solution to (P). Since all the edges in E have zero cost, the claim follows. \square

Given a feasible solution y to (D), an edge $e \in I$ is *tight* if the corresponding inequality in the dual program (D) holds with equality. If $F^+ \subseteq I$ is a set of tight edges, then

$$(1) \quad c(F^+) = \sum_{e \in F^+} c_e = \sum_{e \in F^+} \sum_{S \in \mathcal{S}: e \in \delta(S, S^*)} y_S = \sum_{S \in \mathcal{S}} d_{F^+}(S) y_S.$$

Recall that by Lemma 2.3 the cores of G are disjoint. Let us fix the threshold $\beta = \sqrt{2n}$ and apply the following procedure.

Procedure 1. While $\nu_\ell(G) \geq \beta$, raise dual variables corresponding to cores of G uniformly until some edge $e \in I$ becomes tight, and add this edge to G .

Let \tilde{F}^+ be the set of edges added to the input graph G by Procedure 1.

LEMMA 3.3. *Let $F^+ \subseteq \tilde{F}^+$. Then*

$$c(F^+) \leq \frac{|F^+|}{\beta} \frac{\text{opt}_k}{k-\ell}.$$

Proof. Let y be the dual solution produced by Procedure 1. Since the edges in F^+ are tight, we have $c(F^+) = \sum_{S \in \mathcal{S}} d_{F^+}(S) y_S$ by (1). Let \mathcal{C}_i be the family of cores of G at iteration i , and let ε_i be the amount at which they were raised at iteration i , $i = 1, \dots, q$. Note that $y_S = \sum_{\{i: S \in \mathcal{C}_i\}} \varepsilon_i$ for any set $S \in \mathcal{S}$. Using this, together with the fact that the sets in \mathcal{C}_i are disjoint and that $|\mathcal{C}_i| \geq \beta$, we get

$$\begin{aligned}
 \sum_{S \in \mathcal{S}} d_{F^+}(S) y_S &= \sum_{i=1}^q \varepsilon_i \sum_{S \in \mathcal{C}_i} d_{F^+}(S) \leq \sum_{i=1}^q \varepsilon_i |F^+| \frac{|\mathcal{C}_i|}{\beta} = \frac{|F^+|}{\beta} \sum_{i=1}^q \varepsilon_i |\mathcal{C}_i| \\
 &= \frac{|F^+|}{\beta} \sum_{S \in \mathcal{S}} y_S \leq \frac{|F^+|}{\beta} \frac{\text{opt}_k}{k-\ell}.
 \end{aligned}$$

The first inequality follows by upper bounding 1 by $|\mathcal{C}_i|/\beta$ and noting that in $\sum_{S \in \mathcal{C}_i} d_{F^+}(S)$ every edge is counted exactly once (since the graphs we consider are directed). The last inequality follows from Lemma 3.2 and the weak duality theorem. \square

After executing Procedure 1, let C_1, \dots, C_{ν^+} be the cores of $G + \tilde{F}^+$.

Procedure 2. For $j = 1, \dots, \nu^+$, choose $r_j \in C_j$, and compute an optimal edge set \tilde{F}_j^+ such that $G + \tilde{F}_j^+$ is $(\ell + 1)$ -outconnected from r_j .

Note that by Lemma 1.2, $c(\tilde{F}_j^+) \leq \frac{1}{k-\ell} \text{opt}_k$, $j = 1, \dots, \nu^+$.

We then apply Procedures 1 and 2 on the reverse graph of $G + I$ to find appropriate edge sets \tilde{F}^- and $\tilde{F}_1^-, \dots, \tilde{F}_{\nu^-}^-$. Let \tilde{F} be the union of all the edge sets found. Then $G + \tilde{F}$ is $(\ell + 1)$ -connected. The last step in our algorithm is finding an inclusion minimal edge set $F \subseteq \tilde{F}$ such that $G + F$ is $(\ell + 1)$ -connected. Note that $|\tilde{F}|$ might be large, but the following statement shows that $|F| = O(n)$.

THEOREM 3.4 (see [20]). *Let G be an ℓ -connected directed graph, and let F be an inclusion minimal augmenting edge set such that $G + F$ is $(\ell + 1)$ -connected. Then $|F| \leq 2n - 1$.*

LEMMA 3.5. *The algorithm produces a feasible solution of cost at most $\frac{4\sqrt{2n}}{k-\ell} \text{opt}_k$.*

Proof. By Theorem 3.4, $|F| \leq 2n$. Set $F^+ = \tilde{F}^+ \cap F$, $F^- = \tilde{F}^- \cap F$, $F_j^+ = \tilde{F}_j^+ \cap F$ for $j = 1, \dots, \nu^+$, and $F_j^- = \tilde{F}_j^- \cap F$ for $j = 1, \dots, \nu^-$. Applying Lemmas 3.3 and 1.2, Theorem 3.4, and recalling that $\nu^+, \nu^- \leq \beta \leq \sqrt{2n}$, we get

$$c(F) \leq c(F^+) + c(F^-) + \sum_{j=1}^{\nu^+} c(F_j^+) + \sum_{j=1}^{\nu^-} c(F_j^-) \leq \frac{2\text{opt}_k}{k-\ell} \left(\frac{2n}{\beta} + \beta \right) \leq \frac{4\sqrt{2n}}{k-\ell} \text{opt}_k. \quad \square$$

Suppose now that the input graph \mathcal{G} contains a k_0 -connected spanning subgraph of cost zero. We can repeatedly apply the above algorithm starting with $\ell = k_0$ until $\ell = k - 1$ to compute a k -connected spanning subgraph of \mathcal{G} ; the overall cost of the subgraph found will be at most $4\sqrt{2n}H(k - k_0)\text{opt}_k = O(\sqrt{n} \ln k)\text{opt}_k$.

For undirected graphs, an $8\sqrt{2n}H(k - k_0)$ -approximation algorithm easily follows using the reduction due to Khuller and Raghavachari [17] described at the end of section 1.1.

To finish the proof of Theorem 3.1, let us discuss the implementation and the time complexity of the algorithm. As was mentioned, Procedure 1 in our algorithm is similar to the procedure used in [28], and we can adapt the implementation of [28] as well. We omit the details but note that for implementing all Procedures 1 in the algorithm, as well as finding minimal edge sets $F \subseteq \tilde{F}$ such that $G + F$ is $(\ell + 1)$ -connected, $\ell = 0, \dots, k - 1$, can be done in $O(k^3mn^2) = O(k^2nm^2)$ total time; see section 5 in [28]. Using the algorithm of [9], the overall time required for Procedure 2 implementations is $O(k^3mn^2\sqrt{n})$. Note however, that Procedure 2 requires finding a minimum cost edge set to increase the outconnectivity from ℓ to $\ell + 1$. As was mentioned, this problem can be solved in $O(m^2)$ time using Frank's algorithm [6]. Thus the total time required for Procedure 2 executions is $O(k\sqrt{nm}^2)$.

A PARAMETRIZED ALGORITHM FOR MATROID BRANCH-WIDTH*

PETR HLINĚNÝ†

Abstract. Branch-width is a structural parameter very closely related to tree-width, but branch-width has an immediate generalization from graphs to matroids. We present an algorithm that, for a given matroid M of bounded branch-width t which is represented over a finite field, finds a branch decomposition of M of width at most $3t$ in cubic time. Then we show that the branch-width of M is a uniformly fixed-parameter tractable problem. Other applications include recognition of matroid properties definable in the monadic second-order logic for bounded branch-width, and [S.-I. Oum, *Approximating rank-width and clique-width quickly*, in Proceedings of the 31st International Workshop on Graph-Theoretic Concepts in Computer Science, Springer-Verlag, Heidelberg, to appear] a cubic time approximation algorithm for graph rank-width and clique-width.

Key words. representable matroid, parametrized algorithm, branch-width, rank-width

1. Introduction. We assume that the reader is familiar with basic concepts of graph theory; see, for example, [8]. In the past decade, the notion of a *tree-width* of graphs [22] attracted plenty of attention from both graph-theoretical and computational points of view. This attention followed the pioneering work of Robertson and Seymour on the graph minor project [21], and results of various researchers using tree-width in dynamic programming and parametrized complexity; see [3] for a brief introduction. We postpone formal definitions until later sections.

The theory of *parametrized complexity* provides a background for analysis of difficult algorithmic problems and is finer than classical complexity theory. For an overview, we suggest [9]. Briefly, a problem is called “fixed-parameter tractable” if there is an algorithm having running time with the (possible) super-polynomial part separated in terms of some natural “parameter,” which is supposed to be small even for large inputs in practice. Successful practical applications of this concept are known, for example, in computational biology and database theory: Imagine a query of a small size k to a large database of size $n \gg k$; then an $O(2^k \cdot n)$ parametrized algorithm may be better in practice than, say, an $O(n^k)$ algorithm, or even an $O((kn)^c)$ polynomial algorithm.

Generally speaking, we are interested in algorithmic problems that are parametrized by a tree-like structure of the input objects or the tree-width parameter. However, for matroid theorists, it is the (very similar, but less known) parameter called branch-width [22] that has proved to be the more useful tool. This is because, unlike tree-width, branch-width does not refer to vertices, and thus extends directly from graphs to matroids, and hence also to matrices and vector configurations. We refer to [16] for a more detailed discussion on matroid tree-width.

†Department of Computer Science, FEI, VŠB—Technical University of Ostrava, 17. listopadu 15, 708 33 Ostrava, Czech Republic (hlineny@member.ams.org, petr.hlineny@vsb.cz).

The tree-width of a graph is hard to compute in general. It has been shown by Bodlaender [4] that graph tree-width is a uniformly fixed-parameter tractable property, and, moreover, an optimal tree-decomposition of a graph can be found in parametrized linear time. That algorithm is used in [5] to find an optimal branch-decomposition of a graph in parametrized linear time. However, these algorithms are so closely tied to graphs that it seems impossible to generalize them to matroids. Recent advances concerning matroid connectivity, on the other hand, lead to a simple and practical polynomial algorithm [12] for deciding whether a given matroid has branch-width at most 3. Unfortunately, there seems to be no generalization of that algorithm to higher values of branch-width.

In this paper we show (Algorithm 4.1, Theorem 4.14) how to construct a near-optimal branch-decomposition of a matroid represented over any finite field in parametrized (with respect to branch-width) cubic time. We also prove (Theorem 5.5) that matroid branch-width and tree-width are fixed-parameter tractable properties for matroids represented over finite fields.

These algorithms and their consequences are formulated in the language of matroid theory since it is natural and convenient, and since it shows the close relations of this research to well-known graph structural and computational concepts. Our work could be, as well, viewed in terms of matrices, point configurations, or linear codes over a finite field \mathbb{F} . The key to the subject is the notion of parse trees for bounded-width \mathbb{F} -represented matroids, defined in section 3 as an analogue of parse trees for graphs of bounded tree-width.

In [14] we prove a result analogous to the so-called “ MS_2 -theorem” of Courcelle [6, 7] for matroids represented by matrices over a finite field \mathbb{F} : If \mathcal{M} is a family of matroids described by a sentence in the monadic second-order logic of matroids, then the “parse trees” of bounded-branch-width \mathbb{F} -represented members of \mathcal{M} are recognizable by a finite tree automaton. So by relating [14] to Algorithm 4.1, we prove that all matroid properties expressible in the monadic second-order logic are uniformly fixed-parameter tractable for \mathbb{F} -represented matroids of bounded branch-width. Another application [13] gives an efficient algorithm for computing the Tutte polynomial of a matroid, the critical index, and the Hamming weight or the weight enumerator of a linear code, when the branch-width is bounded. Moreover, a recent algorithm of Oum [19] uses Algorithm 4.1 to approximate the clique-width of a graph in parametrized cubic time via a new parameter related to matroid branch-width called the rank-width [18].

In order to make the paper accessible to a wide audience of computer scientists, we provide sufficient introductory definitions for relevant concepts of structural matroid theory.

2. Basics of matroids. We refer to Oxley [20] for our matroid terminology. A *matroid* is a pair $M = (E, \mathcal{B})$, where $E = E(M)$ is the ground set of M (elements of M), and $\mathcal{B} \subseteq 2^E$ is a nonempty collection of *bases* of M , no two of which are in an inclusion. Moreover, matroid bases satisfy the “exchange axiom”; if $B_1, B_2 \in \mathcal{B}$ and $x \in B_1 - B_2$, then there is $y \in B_2 - B_1$ such that $(B_1 - \{x\}) \cup \{y\} \in \mathcal{B}$. Subsets of bases are called *independent sets*, and the remaining sets are *dependent*. Minimal dependent sets are called *circuits*. The *rank function* $r_M(X)$ in M is the maximal cardinality of an independent subset of a set $X \subseteq E(M)$.

If G is a graph, then its *cycle matroid* on the ground set $E(G)$ is denoted by $M(G)$. The independent sets of $M(G)$ are the forests of G , and the circuits of $M(G)$ are the cycles of G . In fact, much of matroid terminology is inherited from graphs. Another typical example of a matroid is a finite set of vectors with usual linear dependency.

Both examples are illustrated in Figure 1.

FIG. 1. An example of a vector representation of the cycle matroid $M(K_4)$. The matroid elements are depicted by dots, and their (linear) dependency is shown using lines.

The dual matroid M^* of M is defined on the same ground set E , and the bases of M^* are the set-complements of the bases of M . An element e of M is called a loop (a coloop) if $\{e\}$ is dependent in M (in M^*). The matroid $M \setminus e$ obtained by deleting a nonloop element e is defined as $(E - \{e\}, \mathcal{B}^-)$, where $\mathcal{B}^- = \{B : B \in \mathcal{B}, e \notin B\}$. The matroid M/e obtained by contracting a nonloop element e is defined using duality $M/e = (M^* \setminus e)^*$. (This corresponds to contracting an edge in a graph.) A minor of a matroid is obtained by a sequence of deletions and contractions of elements.

The connectivity function λ_M of a matroid M is defined for all $A \subseteq E$ by

$$\lambda_M(A) = r_M(A) + r_M(E - A) - r(M) + 1.$$

Here $r(M) = r_M(E)$. Notice that $\lambda_M(A) = \lambda_M(E - A)$. A subset $A \subseteq E$ is k -separating if $\lambda_M(A) \leq k$. When equality holds here, A is said to be exactly k -separating. An arbitrary partition $(A, E - A)$ of M is called a separation in M . A partition $(A, E - A)$ is called a k -separation if A is k -separating and both $|A|, |E - A| \geq k$. Geometrically, the affine closures of the two sides of an exact k -separation intersect in a subspace of rank $k - 1$ (such as in a line if $k = 3$).

2.1. Branch-decomposition. A subcubic tree is a tree in which all nodes have degree at most 3. (We do not use the word ternary because such trees are actually subbinary in the sense of the next section.) Let $\ell(T)$ denote the set of leaves of a tree T . The next definition of branch-width for matroids directly extends branch-width of graphs.

Let M be a matroid on the ground set $E = E(M)$. A branch-decomposition of M is a pair (T, τ) , where T is a subcubic tree, and τ is an injection of E into $\ell(T)$, called labeling. Let e be an edge of T , and let T_1, T_2 be the connected components of $T - e$. We say the e displays the partition (A, B) of E , where $A = \tau^{-1}(\ell(T_1))$, $B = \tau^{-1}(\ell(T_2))$. The width of an edge e in T is $\omega_T(e) = \lambda_M(A) = \lambda_M(B)$. The width of the branch-decomposition (T, τ) is the maximum of the widths of all edges of T , and the branch-width of M is the minimal width over all branch-decompositions of M . If T has no edge, then we take its width as 0.

Examples of branch-decompositions are presented in Figure 2. We remark that the branch-width of a graph is defined analogously, using the connectivity function λ_G , where $\lambda_G(F)$ is the number of vertices incident with both F and $E(G) - F$. Clearly, the branch-width of a graph G is never smaller than the branch-width of its

FIG. 2. Two examples of width-3 branch decompositions of the Pappus matroid (top left, in rank 3) and of the binary affine cube (bottom left, in rank 4). The lines in the matroids show dependencies among elements.

cycle matroid $M(G)$. It is still an open conjecture whether these numbers are actually equal. On the other hand, branch-width is within a constant factor of tree-width on graphs [22] and also on matroids [16].

2.2. Represented matroids. We now turn our attention to matroids represented over a fixed finite field \mathbb{F} . This is a crucial part of our introductory definitions. A *representation* of a matroid M is a matrix \mathbf{A} whose column vectors correspond to the elements of M , and maximal linearly independent subsets of columns form the bases of M . We denote by $M(\mathbf{A})$ the matroid represented by a matrix \mathbf{A} .

We denote by $PG(n, \mathbb{F})$ the *projective geometry (space)* obtained from the vector space \mathbb{F}^{n+1} . See [20, sections 6.1, 6.3] for an overview of projective spaces and of (in)equivalence of matroid representations. For a set $X \subseteq PG(n, \mathbb{F})$, we denote by $\langle X \rangle$ the span (affine closure) of X in the space. The (projective) rank $r(X)$ of X is the maximal cardinality of a linearly independent subset of X . A projective transformation is a mapping between two projective spaces over \mathbb{F} that is induced by a linear transformation between the underlying vector spaces. Clearly, the matroid $M(\mathbf{A})$ represented by a matrix \mathbf{A} is unchanged when column vectors are scaled by nonzero elements of \mathbb{F} . Hence we may view a loopless matroid representation $M(\mathbf{A})$ as a multiset of points in the finite projective space $PG(n, \mathbb{F})$, where n is the rank of $M(\mathbf{A})$.

DEFINITION 2.1. We call a finite multiset of points in a projective space over \mathbb{F} a point configuration, and we represent a loop in a point configuration by the empty subspace \emptyset . Two point configurations P_1, P_2 in projective spaces over \mathbb{F} are equivalent if there is a nonsingular projective transformation between the projective spaces that maps P_1 onto P_2 bijectively. (Loops are mapped only to loops.) We define an \mathbb{F} -represented matroid to be such an equivalence class of point configurations over \mathbb{F} .

One may think that we do not have to include the word “bijectively” in the previous definition since nonsingular projective transformations are always injective on the points, but, in fact, we have to do this to handle multiple elements in multisets. Two labeled point configurations over \mathbb{F} are equivalent in our sense if and only if, in the language of [20, Chapter 6], the matrix representations are equivalent without use

of \mathbb{F} -automorphisms, otherwise called *strongly equivalent* in matroid theory. However, notice that our represented matroids are unlabeled in general.

Standard matroidal terms are inherited from matroids to represented matroids. Obviously, all point configurations in one equivalence class belong to the same isomorphism class of matroids, but the converse is not true in general since matroids often have inequivalent representations. When we want to deal with an \mathbb{F} -represented matroid, we actually pick an arbitrary point configuration from the equivalence class.

3. Parse trees for matroids. In this section we introduce our basic formal tool—the parse trees for represented matroids of bounded branch-width. Loosely speaking, a parse tree shows how to “build up” a matroid along the tree using only a fixed amount of information at each tree node, and so it forms a suitable background for dynamic programming.

We are inspired by analogous boundaried graphs and parse trees known for handling graphs of bounded tree-width (see for example [1] or [9, section 6.4]): A boundaried graph is a graph with a distinguished subset of labeled vertices. (The purpose of distinguishing the boundary is that only the boundary vertices can be “accessed from outside”). Then, simply speaking, a graph has tree-width at most $t - 1$ if and only if it can be composed from small pieces by gluing them onto boundaries of size at most t . We similarly define boundaried represented matroids, in which the boundary is a distinguished subspace of the representation, and composition operators that are used to glue representations together. (The role of composition operators, however, differs between tree-width and branch-width.)

A *rooted ordered subbinary tree* is such that each of its nodes has at most two sons that are ordered as “left” and “right.” (If there is one son, then it may be either left or right.) A *rooted subtree* T_0 of a rooted tree T is a subgraph of T such that T_0 is the connected component of $T - e$ not containing the root for some $e \in E(T)$. Let Σ be a finite alphabet. We denote by Σ^{**} the class of rooted ordered subbinary trees with nodes labeled by symbols from Σ .

3.1. Boundaried matroids. All matroids throughout this section are \mathbb{F} -represented for some fixed finite field \mathbb{F} . Hence, for simplicity, if we say “(represented) matroid,” then we mean an \mathbb{F} -represented matroid. If we speak about a projective space, we mean a projective geometry over the field \mathbb{F} . Let $[s, t]$ denote the set $\{s, s + 1, \dots, t\}$.

The following definition presents a possible way of formalizing the notion of a “matroid with a boundary.” (Since matroids have no vertices, unlike graphs, we have to introduce some special elements that define the matroid boundary.)

DEFINITION 3.1. A pair $\bar{N} = (N, \delta)$ is a t -boundaried (represented) matroid if the following holds: $t \geq 0$ is an integer, N is a represented matroid, and $\delta : [1, t] \rightarrow E(N)$ is an injective mapping such that $\delta([1, t])$ is an independent set in N .

We call $J(\bar{N}) = E(N) - \delta([1, t])$ the *internal elements* of \bar{N} , elements of $\delta([1, t])$ the *boundary points* of \bar{N} , and t the *boundary rank* of \bar{N} . The represented matroid $N \setminus \delta([1, t])$, which is the restriction of N to $J(\bar{N})$, is called the *internal matroid* of \bar{N} . We denote by $\partial(\bar{N})$ the boundary subspace spanned by $\delta([1, t])$. In particular, the boundary points are not loops. The basic operation we use is the *boundary sum* \oplus of the next definition, illustrated in Figure 3.

DEFINITION 3.2. Let $\bar{N}_1 = (N_1, \delta_1)$, $\bar{N}_2 = (N_2, \delta_2)$ be two t -boundaried represented matroids. We denote by $\bar{N}_1 \oplus \bar{N}_2 = N$ the represented matroid defined as follows: Let Ψ_1, Ψ_2 be projective spaces such that the intersection $\Psi_1 \cap \Psi_2$ has rank exactly t . Suppose that, for $i = 1, 2$, $P_i \subset \Psi_i$ is a point configuration representing N_i

FIG. 3. An example of a boundary sum of two 2-boundaried matroids. The internal matroid elements are drawn as solid dots; the boundary points and the boundary subspace of rank 2 are drawn in gray. Solid lines show matroid dependencies. The resulting sum is a matroid represented on two intersecting planes in rank 4 (three-dimensional picture on the right).

such that $P_1 \cap P_2 = \delta_1([1, t]) = \delta_2([1, t])$, and $\delta_2(j) = \delta_1(j)$ for $j \in [1, t]$. Then N is the matroid represented by $(P_1 \cup P_2) - \delta_1([1, t])$.

Informally, the boundary sum $\bar{N}_1 \oplus \bar{N}_2 = N$ on the ground set $E(N) = J(\bar{N}_1) \dot{\cup} J(\bar{N}_2)$ is obtained by gluing the representations of N_1 and N_2 onto a common subspace (the boundary) of rank t so that the boundary points of both are identified in order and then deleted. Keep in mind that a point configuration is a multiset. It is a matter of elementary linear algebra to verify that the boundary sum is well defined with respect to equivalence of point configurations.

We write “ $\leq t$ -boundaried” to mean t' -boundaried for some $0 \leq t' \leq t$. We now define a composition operator (over the field \mathbb{F}) which will be used to generate large boundaried matroids from smaller pieces (Figure 4).

DEFINITION 3.3. A $\leq t$ -boundaried composition operator is defined as a quadruple $\odot = (R, \gamma_1, \gamma_2, \gamma_3)$, where R is a represented matroid, $\gamma_i : [1, t_i] \rightarrow E(R)$ is an injective mapping for $i = 1, 2, 3$ and some fixed $0 \leq t_i \leq t$, each $\gamma_i([1, t_i])$ is an independent set in R , and $(\gamma_i([1, t_i]) : i = 1, 2, 3)$ is a partition of $E(R)$.

The $\leq t$ -boundaried composition operator \odot is a binary operator applied to a t_1 -boundaried represented matroid $\bar{N}_1 = (N_1, \delta_1)$ and to a t_2 -boundaried represented matroid $\bar{N}_2 = (N_2, \delta_2)$. The result of the composition is a t_3 -boundaried represented matroid $\bar{N} = (N, \gamma_3)$, written as $\bar{N} = \bar{N}_1 \odot \bar{N}_2$, where a matroid N is defined using boundaried sums: $N' = \bar{N}_1 \oplus (R, \gamma_1)$, $N = (N', \gamma_2) \oplus \bar{N}_2$.

Speaking informally, a boundaried composition operator is a bounded-rank configuration with three boundaries distinguished by $\gamma_1, \gamma_2, \gamma_3$ and with no other internal points. For reference we denote $t_i(\odot) = t_i$, $R(\odot) = R$, and $\gamma_i(\odot) = \gamma_i$. The meaning of a composition $\bar{N} = \bar{N}_1 \odot \bar{N}_2$ is that, for $i = 1, 2$, we glue the represented matroid N_i onto R , matching $\delta_i([1, t_i])$ with $\gamma_i([1, t_i])$ in order. The result is a t_3 -boundaried matroid \bar{N} with boundary $\gamma_3([1, t_3])$. One may abbreviate the composition as $\bar{N} = ((\bar{N}_1 \oplus (R, \gamma_1), \gamma_2) \oplus \bar{N}_2, \gamma_3)$.

3.2. Parse trees. The main purpose of introducing parse trees is in that they allow us to formally define how to construct a represented matroid of branch-width at most $t + 1$ using $\leq t$ -boundaried composition operators.

Let $\bar{\Omega}_t$ denote the empty t -boundaried matroid (Ω, δ_0) , where $t \geq 0$ and $\delta_0([1, t]) = E(\Omega)$ (t will often be implicit in the context). If $\bar{N} = (N, \delta)$ is an arbitrary t -boundaried matroid, then $\bar{N} \oplus \bar{\Omega}_t$ is actually the internal matroid of \bar{N} . Let $\bar{\Upsilon}$ denote the single-element 1-boundaried matroid (Υ, δ_1) , where $E(\Upsilon) = \{x, x'\}$ are two parallel elements and $\delta_1(1) = x'$. Let $\bar{\Upsilon}_0$ denote the loop 0-boundaried matroid (Υ_0, δ_0) ,

FIG. 4. An example of a bounded parse tree. The ovals represent composition operators, with shaded parts for the boundaries and edge-numbers for the boundary ranks (e.g., $\odot^4 = (R^4, \gamma_1^4, \gamma_2^4, \gamma_3^4)$, where $\gamma_1^4, \gamma_2^4 : [1, 2] \rightarrow E(R^4)$, $\gamma_3^4 : [1, 3] \rightarrow E(R^4)$).

where $E(\Upsilon_0) = \{z\}$ is a loop and δ_0 is an empty mapping. Let $\mathcal{R}_t^{\mathbb{F}}$ denote the finite set of all $\leq t$ -bounded composition operators over the field \mathbb{F} . We set $\Pi_t = \mathcal{R}_t^{\mathbb{F}} \cup \{\tilde{\Upsilon}, \tilde{\Upsilon}_0\}$.

Let $T \in \Pi_t^{**}$ be a rooted ordered subbinary tree with nodes labeled by the alphabet Π_t . Considering a node v of T , we set $\varrho(v) = 1$ if v is labeled by $\tilde{\Upsilon}$, $\varrho(v) = 0$ if v is labeled by $\tilde{\Upsilon}_0$, and $\varrho(v) = t_3(\odot)$ if v is labeled by \odot . We call T a $\leq t$ -bounded parse tree if the following are true:

- Only leaves of T are labeled by $\tilde{\Upsilon}$ or $\tilde{\Upsilon}_0$.
- If a node v of T labeled by a composition operator \odot has no left (no right) son, then $t_1(\odot) = 0$ ($t_2(\odot) = 0$).
- If a node v of T labeled by \odot has left son u_1 (right son u_2), then $t_1(\odot) = \varrho(u_1)$ ($t_2(\odot) = \varrho(u_2)$).

Informally, the boundary ranks of composition operators and/or single-element terminals must “agree” across each edge. Notice that $\tilde{\Upsilon}$ or $\tilde{\Upsilon}_0$ are the only labels from Π_t that “create” elements of the resulting represented matroid $P(T)$ in the next definition. See an illustrative example in Figure 4.

DEFINITION 3.4. Let T be a $\leq t$ -bounded parse tree. The $\leq t$ -bounded represented matroid $\bar{P}(T)$ parsed by T is recursively defined as follows:

- If T is an empty tree, then $\bar{P}(T) = \bar{\Omega}_0$.
- If T has one node labeled by $\tilde{\Upsilon}$ (by $\tilde{\Upsilon}_0$), then $\bar{P}(T) = \tilde{\Upsilon}$ ($= \tilde{\Upsilon}_0$).
- If the root r of T is labeled \odot^r , and r has a left rooted subtree T_1 and a right rooted subtree T_2 (possibly empty), then $\bar{P}(T) = \bar{P}(T_1) \odot^r \bar{P}(T_2)$.

The composition is well defined according to the parse-tree description in the previous paragraph. The represented matroid parsed by T is $P(T) = \bar{P}(T) \oplus \bar{\Omega}$.

We say that a t -bounded represented matroid \bar{M} is spanning if the boundary subspace $\partial(\bar{M})$ is contained in the span $\langle J(\bar{M}) \rangle$ of the internal points of \bar{M} . We say that a $\leq t$ -bounded parse tree T is spanning if, for each nonempty rooted subtree T_1 of T , the bounded matroid $\bar{P}(T_1)$ is spanning and nonempty. The following natural result about parse trees of matroids is proved in [14].

THEOREM 3.5 (Hliněný [14]). An \mathbb{F} -represented matroid M has branch-width at most $t + 1$ if and only if M is parsed by some spanning $\leq t$ -bounded parse tree.

It is easy to turn a bounded parse tree into a branch-decomposition. Conversely, the proof of Theorem 3.5 shows how to construct a bounded parse tree from a given branch-decomposition. It is, however, more efficient to construct a bounded parse tree directly from scratch and that is what we are going to do in this paper.

4. Constructing a parse tree. We start with an overview of our algorithm for construction of a matroid parse tree. We assume that a matroid M is given by a matrix $\mathbf{A} \in \mathbb{F}^{r \times n}$ of rank r over a finite field \mathbb{F} . The size of M is expressed in terms of the number n of elements, i.e., the number of columns of \mathbf{A} . Clearly, $r \leq n$. Additionally, there are two *parameters*—a finite field \mathbb{F} and an integer $t > 0$. These parameters form a separate part of the input in our algorithm, but they are considered constants for the purpose of complexity analysis of the algorithm. A more formal description in the scope of parametrized complexity can be found in section 5.2.

We call a labeled tree T a *partial $\leq t$ -boundaried parse-tree* if T satisfies all properties of the parse-tree definition (section 3.2) except that some leaves of T may be labeled by arbitrary t' -boundaried represented matroids for $t' \leq t$. The matroid $\bar{P}(T)$ parsed by T is defined analogously to ordinary parse trees.

Notice that a 0-boundaried represented matroid is essentially an ordinary represented matroid, and that the boundary sum of 0-boundaried represented matroids is the ordinary direct sum of matroids. Let $M \upharpoonright X$ denote the restriction of a represented matroid M to a subset of elements $X \subseteq E(M)$. Let \mathbf{I}_r denote the $r \times r$ identity submatrix.

ALGORITHM 4.1. *Computing a spanning boundaried parse tree of a matroid:*

Parameters: A given finite field \mathbb{F} , and an integer $t \geq 1$.

Input: A matrix $\mathbf{A} = [\mathbf{I}_r \mid \mathbf{A}'] \in \mathbb{F}^{r \times n}$ given in the standard form over \mathbb{F} , such that the matroid $M(\mathbf{A})$ represented by \mathbf{A} has branch-width at most $t + 1$.

1. Let $M = M(\mathbf{A})$, and let $E(M) = B \cup F$, where a basis B marks the columns of \mathbf{I}_r and F the columns of \mathbf{A}' . We initially set $X = B$, and set T to be an arbitrary 0-boundaried parse tree for the independent matroid $M \upharpoonright B$.
2. For an arbitrary element $f \in F - X$, we set $X = X \cup \{f\}$, and we add a new single-element leaf representing f in $M \upharpoonright X$ to the parse tree T .
3. If the width of the parse tree T exceeds, say, $10t$, or if $X \supseteq F$, then we compute a new spanning $\leq 3t$ -boundaried parse tree T' for $M \upharpoonright X$ using T :
 - (a) We start with T' equal to the trivial 0-boundaried partial parse tree having one node labeled by $M \upharpoonright X$.
 - (b) Let ℓ be a leaf of T' labeled by a boundaried matroid \bar{N} with more than one internal element. If the boundary rank of \bar{N} is less than $3t$, then we choose an arbitrary internal element e in \bar{N} . We add to T' a new leaf ℓ_1 representing a single-element e , another new leaf ℓ_2 labeled by $\bar{N} \setminus e$, and we relabel ℓ with the corresponding composition operator.
 - (c) If the boundary rank of \bar{N} equals $3t$, then there are two $\leq 3t$ -boundaried matroids \bar{N}_1, \bar{N}_2 such that $\bar{N} = \bar{N}_1 \odot \bar{N}_2$ for some $\leq 3t$ -boundaried composition operator \odot . Using the decomposition T , we can find \bar{N}_1, \bar{N}_2 and \odot efficiently. Then we add two new leaves ℓ_1, ℓ_2 to T' labeled by \bar{N}_1, \bar{N}_2 , respectively, and we relabel ℓ with \odot .
 - (d) We repeat steps 3(b)–(c) until T' is an ordinary parse tree.

Finally, we set $T = T'$.

4. We repeat steps 2–3 until $X \supseteq F$.

Output: A spanning $\leq 3t$ -boundaried parse tree $T \in \Pi_{3t}^{**}$ such that the represented matroid $P(T)$ parsed by T is equal to $M(\mathbf{A})$.

Remark 4.2. If the above promise that the matroid $M(\mathbf{A})$ has branch-width at most $t + 1$ is false, then step 3(c) may fail to find \bar{N}_1 and \bar{N}_2 . In such a case, Algorithm 4.1 ends up with an error. The algorithm may be formulated so that it always finds a spanning $\leq 3t$ -boundaried parse tree T for $M(\mathbf{A})$ if branch-width of

$M(\mathbf{A})$ is at most $t + 1$, but the output is (possibly) empty if branch-width of $M(\mathbf{A})$ exceeds $t + 1$.

Remark 4.3. Another point concerns the given finite field \mathbb{F} : A finite field is uniquely determined by the number of its elements $q = |\mathbb{F}|$. Moreover, it is easy to construct addition and multiplication tables for \mathbb{F} algorithmically from given q .

We claim that Algorithm 4.1 finds the $\leq 3t$ -boundaried parse tree T for $M(\mathbf{A})$ in time $O(n^3)$, where n is the number of columns of \mathbf{A} . If the matrix \mathbf{A} is not in the standard form, we can easily get the standard form in time $O(n^3)$. Step (4.1) can be implemented in time $O(nr) \leq O(n^2)$. Each iteration of the cycle in step (4.1) can be implemented in time $O(n)$, and there are at most $n - 1$ iterations. Altogether, the main cycle in the algorithm is repeated $n - r$ times.

We also note that the running time $O(n^3)$ of our algorithm refers to the number n of columns of \mathbf{A} , not to the real size of the input. The real input size of the matrix \mathbf{A} is $O(n \cdot r)$, which is typically of order up to n^2 . We do not attempt to determine how the running time of Algorithm 4.1 depends on the parameters \mathbb{F} and t (which is at least an exponential function). However, we do care that the algorithm is recursive in \mathbb{F} and t —there is one algorithm, *not* a sequence of algorithms, running for all values of the parameters (cf. section 5.2).

4.1. Step 4.1: Adding an element to a parse tree. Step 4.1 in Algorithm 4.1 is easy to implement. We are going to describe the implementation of step 4.1 of Algorithm 4.1. This is a surprisingly nontrivial task despite our adding the element f to the parse tree T arbitrarily. The main complication comes from the necessity of recomputing all boundary subspaces of the separations in T —a straightforward implementation of which would require us to solve systems of linear equations. All of our succeeding algorithms are parametrized by a finite field \mathbb{F} and integers t and $t' \leq 10t$, where \mathbb{F} , t are as in Algorithm 4.1.

Let $M = M(\mathbf{D})$ be a matroid represented by a matrix $\mathbf{D} \in \mathbb{F}^{r \times n}$, and consider a separation (E_1, E_2) in M (i.e., a partition of $E(M)$). The projective subspace $\langle E_1 \rangle \cap \langle E_2 \rangle$ spanned by both sides of the separation is called the *guts of the separation* (E_1, E_2) . The rank of the guts equals $\lambda_M(E_1) - 1$ by modularity. Naturally, one may compute a spanning set of *generator vectors* (with respect to \mathbf{D}) for the guts of (E_1, E_2) from the vectors in \mathbf{D} . If the rank of the guts is less than t' , which is a constant, then the combined size of its independent generator vectors is $O(r)$.

ALGORITHM 4.4 (adding a vector to separation guts in a represented matroid).

Input: A matrix $\mathbf{D} = [\mathbf{I}_r \mid \mathbf{D}'] \in \mathbb{F}^{r \times n}$ representing the matroid $M = M(\mathbf{D})$; a separation (F_1, F_2) of the matroid $M \setminus f$, where f is the element represented by the last column of \mathbf{D} and where $\lambda_{M \setminus f}(F_1) \leq t' + 1$; and independent generator vectors for the guts of the separation (F_1, F_2) with respect to $\mathbf{D} \setminus f$.

Output: Independent generator vectors for the guts of the separation $(F_1 \cup \{f\}, F_2)$ of M with respect to \mathbf{D} , computed in time $O(r)$.

Proof. Notice that we cannot even read the whole matrix \mathbf{D} in time $O(r)$. This is, however, not a big problem since we are going to use only the unit vectors of \mathbf{I}_r and the generator vectors of the guts in the algorithm. Let $\Psi = \langle F_1 \rangle \cap \langle F_2 \rangle$ be the given guts, and let $\Psi' = \langle F_1 \cup \{f\} \rangle \cap \langle F_2 \rangle$ be the guts we have to generate. Let \mathbf{f} denote the last column of \mathbf{D} representing the element f , and let \mathbf{f}_1 denote the vector obtained from \mathbf{f} by setting to 0 the coordinates corresponding to the unit vectors of \mathbf{I}_r appearing in F_1 . Then \mathbf{f}_1 belongs to the span $\langle F_2 \rangle$ by definition.

We may easily compute \mathbf{f}_1 in time $O(r)$. Moreover, we may decide whether $\mathbf{f}_1 \in \Psi$ in time $O(r)$ since there is a bounded number of generator vectors for Ψ . If

$\mathbf{f}_1 \in \Psi$, then \mathbf{f} belongs to the span $\langle F_1 \rangle$ and so $\Psi' = \Psi$. Otherwise, since \mathbf{f}_1 belongs to the span $\langle F_1 \cup \{f\} \rangle$, we get $\Psi' = \langle \Psi \cup \mathbf{f}_1 \rangle$. \square

Let $M = M(\mathbf{D})$ be a matroid represented by a matrix $\mathbf{D} \in \mathbb{F}^{r \times n}$, and let T be a spanning $\leq t'$ -boundaried parse tree for M . A *coordinatization* (with respect to \mathbf{D}) of the parse tree T is the assignment of the appropriate vectors to the boundary points of the matroids $\bar{P}(T_1)$ for all rooted subtrees T_1 of T , as computed from the vectors of \mathbf{D} . Similarly as above, the combined size of the vectors for each boundary subspace is $O(r)$.

ALGORITHM 4.5 (computing the coordinatization of a spanning $\leq t'$ -boundaried parse tree T for the represented matroid $M(\mathbf{D})$ over \mathbb{F}).

Input: A matrix $\mathbf{D} \in \mathbb{F}^{r \times n}$, and a spanning $\leq t'$ -boundaried parse tree T for the represented matroid $M(\mathbf{D})$.

Output: The coordinatization of T with respect to \mathbf{D} , computed in time $O(nr)$.

Proof. If T_0 is a rooted subtree of T with one node, then the coordinatization of T_0 is trivial. So assume that the root r_0 of T_0 has the left and right rooted subtrees T_1 and T_2 , and that r_0 is labeled by a composition operator \odot . (Hence $\bar{P}(T_0) = \bar{P}(T_1) \odot \bar{P}(T_2)$. One of the subtrees may be empty.) Since T is a spanning parse tree, the boundary of $\bar{P}(T_0)$ is spanned by the boundaries of $\bar{P}(T_1)$ and $\bar{P}(T_2)$. Thus the vectors assigned to the boundary points of $\bar{P}(T_0)$ with respect to \mathbf{D} are linear combinations of the vectors of the boundary points of $\bar{P}(T_1)$ and $\bar{P}(T_2)$. There are finitely many $\leq t'$ -boundaried composition operators for a fixed t' , and so the scalars of these linear combinations can be precomputed for the parameter t' and each \odot . Then, at each node of T , we have to compute a bounded number of linear combinations from a bounded number of vectors of length r , which can be accomplished in time $O(r)$. There are $O(n)$ nodes in T . \square

Consider three sequences $U_1, U_2, U_3 \subset \mathbb{F}^s$ of vectors, where each $U_i, i = 1, 2, 3$, is formed by independent vectors. Then these sequences represent the composition operator $(U, \gamma_1, \gamma_2, \gamma_3)$, where $U = U_1 \cup U_2 \cup U_3$ is the point configuration, and γ_i maps the elements of the sequence in order $U_i = \{\gamma_i(1), \gamma_i(2), \dots, \gamma_i(t_i)\}$ for $i = 1, 2, 3$.

ALGORITHM 4.6 (computing the composition operator from given vectors).

Input: Three independent sequences $U_1, U_2, U_3 \subset \mathbb{F}^s$ of vectors where each sequence has at most t' members.

Output: The $\leq t'$ -boundaried composition operator represented by the vectors of U_1, U_2, U_3 , computed in time $O(s)$.

Proof. There is a bounded number of $\leq t'$ -boundaried composition operators for each t' , and since each one is nothing else than a labeled point configuration, it may be identified by a bounded number of homogeneous linear vector equations and inequations. (The equations are invariant under nonsingular linear transformations.) Hence we find the composition operator represented by (U_1, U_2, U_3) in parametrized time $O(s)$ even by brute force. \square

LEMMA 4.7. Step 4.1 in Algorithm 4.1 is implemented in time $O(n \cdot r)$ for fixed parameters t' and \mathbb{F} .

Proof. Let $N = M \upharpoonright X$ in step 4.1 of Algorithm 4.1 (before adding f to X). We first compute the coordinatization of the parse tree T for N using Algorithm 4.5. Let T_1 be a rooted subtree of T , and let $F_1 = J(\bar{P}(T_1))$, $F_2 = E(N) - F_1$. Then, since the parse tree T is spanning, the boundary subspace of $\bar{P}(T_1)$ make up the guts of the separation (F_1, F_2) . We denote by T' the rooted subbinary tree obtained from T by arbitrarily adding a new leaf ℓ representing the element f . To turn T' into a parse tree for $N' = M \upharpoonright X \cup \{f\}$, we have to recompute all composition operators in T' .

Let T'_1 be the rooted subtree of T' corresponding to T_1 above, and let $F'_1 = J(\bar{P}(T'_1))$, $F'_2 = E(N') - F'_1$. Then $F'_1 = F_1 \cup \{f\}$ and $F'_2 = F_2$ for $\ell \in V(T'_1)$, or $F'_2 = F_2 \cup \{f\}$ and $F'_1 = F_1$ otherwise. We denote by $\mathbf{D} = [\mathbf{I}_r \mid \mathbf{D}']$ the submatrix of the matrix \mathbf{A} from Algorithm 4.1 representing the matroid N' . We apply Algorithm 4.4 to \mathbf{D} , the separation (F_1, F_2) and f , and to the generator vectors of the boundary points of $\bar{P}(T_1)$ computed above, obtaining generator vectors of the boundary of $\bar{P}(T'_1)$. We repeat the same procedure for all $O(n)$ rooted subtrees of T' . Finally, we use Algorithm 4.6 to determine the new composition operators to label all internal nodes of T' . \square

4.2. Step 4.1: Getting a better parse tree. The heart of the implementation of step 4.1 in Algorithm 4.1 is the next claim. (We remark that the proof of this claim implicitly uses a so-called “tangle” [22]—a notion dual to a branch-decomposition.)

LEMMA 4.8. *Let $t \geq 1$ and \bar{N} be a spanning $3t$ -boundaried represented matroid such that the branch-width of the internal matroid $\bar{N} \oplus \bar{\Omega}$ is at most $t + 1$. Then there are two $\leq 3t$ -boundaried matroids \bar{N}_1, \bar{N}_2 such that $\bar{N} = \bar{N}_1 \odot \bar{N}_2$ for some $\leq 3t$ -boundaried composition operator \odot .*

Proof. Recall that the internal matroid $N' = \bar{N} \oplus \bar{\Omega}$ is the restriction of \bar{N} to the internal elements $J(\bar{N}) = E(N')$. We define a function $g : 2^{E(N')} \rightarrow \mathbb{Z}$, for a subset $F \subseteq E(N')$, as $g(F) = r(\partial(\bar{N}) \cap \langle F \rangle)$, i.e., as the projective rank of the intersection of the span of F with the boundary of \bar{N} . Clearly, $g(E(N')) = 3t$ since \bar{N} is spanning.

Let (U, τ) be a width- $(t + 1)$ branch-decomposition of N' . For an edge $e \in E(U)$, we define $F_i(e) = \tau^{-1}(V(U_i))$ for $i = 1, 2$, where U_1 and U_2 are the connected components of $U - e$. Note that $g(F_1(e)) + g(F_2(e)) \geq g(E(N')) = 3t$.

CLAIM. *There is an edge $e \in E(U)$ such that both $g(F_1(e)), g(F_2(e)) \geq t$.*

For a contradiction, we assume that no such edge e exists in U . Let (arbitrary) $e = w_1 w_2$, where $w_i \in U_i$, $i = 1, 2$, as above, and $a = \min \{g(F_1(e)), g(F_2(e))\}$. If $a < t$, then, say, $a = g(F_1(e)) < g(F_2(e))$. In such a case we direct the edge e from w_1 to w_2 . Since U is a cubic tree, there is a node w_0 of U such that all three edges incident with w_0 are directed toward it. Then, denoting by U'_1, U'_2, U'_3 the connected components of $U - w_0$ and denoting by $F'_i = \tau^{-1}(V(U'_i))$, we get $g(F'_1) + g(F'_2) + g(F'_3) < t + t + t$, which is a contradiction to $g(E(N')) = 3t$.

We consider further the edge e from the claim. The rank of $\langle F_1(e) \rangle \cap \langle F_2(e) \rangle$ is at most t since (U, τ) is a width- $(t + 1)$ branch-decomposition. Together for $i = 1, 2$ we get, by modularity of the rank in projective spaces,

$$\begin{aligned} & r[\langle F_i(e) \rangle \cap \langle F_{3-i}(e) \cup \partial(\bar{N}) \rangle] \\ &= r[\langle F_i(e) \rangle \cap \langle F_{3-i}(e) \rangle] + r[\langle F_i(e) \rangle \cap \partial(\bar{N})] - r[\langle F_i(e) \rangle \cap \langle F_{3-i}(e) \rangle \cap \partial(\bar{N})] \\ &\leq t + 2t - 0 = 3t. \end{aligned}$$

Hence the partition $(F_1(e), F_2(e))$ decomposes the internal elements into two $\leq 3t$ -boundaried matroids \bar{N}_1, \bar{N}_2 , which are glued together by a suitable $\leq 3t$ -boundaried composition operator \odot . \square

The task now is to find the partition (F_1, F_2) of $J(\bar{N})$ inducing the boundaried matroids \bar{N}_1, \bar{N}_2 and to find the composition operator \odot from Lemma 4.8 efficiently. We use the $\leq t'$ -boundaried parse tree T previously constructed in Algorithm 4.1. Unlike in the implementation of step 4.1, we do not work with the vectors representing $M(\mathbf{A})$ —instead, we obtain all necessary information from the parse tree T . This results in a more complicated but faster implementation. Again, all algorithms in this section are parametrized by a finite field \mathbb{F} and integers t and $t' \leq 10t$. We first

present the following two simple algorithms.

ALGORITHM 4.9 (computing the connectivity function of a separation).

Input: A $\leq t'$ -boundaried parse tree T parsing the matroid $N = P(T)$, and a partition (F_1, F_2) of $E(N)$.

Output: The connectivity value $\lambda_N(F_1) - 1$ of the separation (F_1, F_2) , computed in time $O(|V(T)|)$.

Proof. In other words, we are computing the projective rank of the guts of separation (F_1, F_2) in N . This is a straightforward application of dynamic programming over T . Let x be a node of T , and let T_x be the rooted subtree of T with the root x . Denote by $\bar{M}_x = \bar{P}(T_x)$ and by T'_x, T''_x the left and right rooted subtrees of x in T .

For \bar{M}_x as above, and for $E_i = F_i \cap J(\bar{M}_x)$, we call *boundary data* the triple (Σ_1, Σ_2, g) , where $\Sigma_i = \partial(\bar{M}_x) \cap \langle E_i \rangle$ for $i = 1, 2$ is the intersection of the span $\langle E_i \rangle$ with the boundary of \bar{M}_x , and where g is the projective rank of the guts $\langle E_1 \rangle \cap \langle E_2 \rangle$ of the subseparation (E_1, E_2) . Clearly, one may compute boundary data of $\bar{M}_x = \bar{P}(T_x)$ from boundary data of $\bar{P}(T'_x)$ and $\bar{P}(T''_x)$, and from the composition operator labeling x in (parametrized) constant time. Hence the whole algorithm is implemented in linear time. \square

ALGORITHM 4.10 (computing a good partition (F_1, F_2) for Lemma 4.8).

Input: A $\leq t'$ -boundaried parse tree T parsing the represented matroid $N = P(T)$, and a subset $F_0 \subseteq E(N)$ such that $\lambda_N(F_0) = 3t$.

Output: A partition (F_1, F_2) of the set $E(N) - F_0$ such that $\lambda_N(F_1), \lambda_N(F_2) \leq 3t$ (or an answer NO if no such partition exists) computed in time $O(|V(T)|)$.

Proof. This is a straightforward extension of the dynamic program implemented in Algorithm 4.9. Moreover, for each instance of boundary data in this case, we record one representative of the partition we compute. Since the ground set of N can be easily implemented so that the operation of a set union (of the representatives) takes constant time, the overall computing time is still linear in T . We leave details to the reader. \square

Now we come to the hard part—computing a valid composition operator for the new node of the parse tree T' in step 3(b) or 3(c). We (implicitly) know the three boundaries of the composition operator from a defining tripartition of the matroid elements. However, we have to choose independent spanning sets of generator points for the boundaries in such a way that the two matching boundaries of adjacent composition operators in the parse tree T' get the same generator points. For a parse tree U , we call a *virtual point* of U any point which is contained in the span of some composition operator in the tree U . The concept of virtual points of the parse tree U allows us to determine relative positions of certain points with respect to the elements of the matroid $P(U)$, without the necessity of using absolute vectors in a particular matroid representation.

If (F_1, F_2) is a separation in the represented matroid $P(U)$ parsed by U , then we express spanning generator points for the guts of (F_1, F_2) as a sequence of virtual points of the parse tree U . We naturally say that a set Z of virtual points in U is independent if Z is linearly independent in the point configuration parsed by U . Next follows the corresponding extension of Algorithm 4.9: The fact that the guts are always spanned by some virtual points of U is implicitly proved in the algorithm.

ALGORITHM 4.11 (computing virtual points spanning the guts of a given separation over a parse tree).

Input: An $\leq t'$ -boundaried parse tree T parsing the matroid $N = P(T)$, and a partition (F_1, F_2) of $E(N)$ such that $\lambda_N(F_1) \leq 3t$. (The partition is symmetric, i.e.,

(F_1, F_2) is considered the same as (F_2, F_1) .)

Output: A uniquely determined sequence $\{x_1, x_2, \dots, x_k\}$, $k = \lambda_N(F_1) - 1$, of independent virtual points of the parse tree T which span the guts of the separation (F_1, F_2) . This is computed in time $O(|V(T)|)$.

Proof. Let x be a node of T labeled by \odot , and let T_x be the rooted subtree of T with the root x . Denote by $\bar{M}_x = \bar{P}(T_x)$ and by T'_x, T''_x the left and right rooted subtrees of x in T . Analogously to Algorithm 4.9, we call *boundary data* of \bar{M}_x the quadruple $(\Sigma_1, \Sigma_2, g, Z)$, where $E_i = F_i \cap J(\bar{M}_x)$ and $\Sigma_i = \partial(\bar{M}_x) \cap \langle E_i \rangle$ for $i = 1, 2$, where $g = r(\langle E_1 \rangle \cap \langle E_2 \rangle)$, and where $Z = \{z_1, \dots, z_g\}$ is a sequence of independent virtual points of T which span the guts of (E_1, E_2) in \bar{M}_x . Moreover, we require that the points of $Z \cap \partial(\bar{M}_x)$ contained in the boundary span the set $\Sigma_1 \cap \Sigma_2$ (boundary-span condition).

We denote $\bar{M}'_x = \bar{P}(T'_x)$, $\bar{M}''_x = \bar{P}(T''_x)$ and $E'_i = F_i \cap J(\bar{M}'_x)$, $E''_i = F_i \cap J(\bar{M}''_x)$. The guts $\langle E_1 \rangle \cap \langle E_2 \rangle$ are clearly spanned by the four sets $\langle E'_1 \rangle \cap \langle E'_2 \rangle$, $\langle E''_1 \rangle \cap \langle E''_2 \rangle$, $\langle E'_1 \rangle \cap \langle E''_2 \rangle$, $\langle E''_1 \rangle \cap \langle E'_2 \rangle$. The latter two sets $\langle E'_1 \rangle \cap \langle E''_2 \rangle$ and $\langle E''_1 \rangle \cap \langle E'_2 \rangle$ are contained in the span of the composition operator \odot labeling x in the parse tree T by definition. Hence, using the boundary-span condition above, we can compute boundary data \bar{M}_x from boundary data of \bar{M}'_x and \bar{M}''_x , and from the composition operator \odot in a canonical way.

Since the guts of (E_1, E_2) have bounded rank $g \leq 3t$ in \bar{M}_x , boundary data carry only a limited amount of information. One node x of the parse tree T is processed in time depending on \mathbb{F} and t , but not depending on the size of T . So the whole algorithm is implemented in (parametrized) linear time. \square

Lastly, we present an analogue of Algorithm 4.6 computing the composition operator from sequences of virtual points. Consider three sequences Z_1, Z_2, Z_3 of virtual points in a common parse tree T , each Z_i , $i = 1, 2, 3$, formed by g_i independent points. Then these sequences represent the composition operator $(Z, \gamma_1, \gamma_2, \gamma_3)$, where $Z = Z_1 \cup Z_2 \cup Z_3$ is the ground point configuration as parsed by T , and γ_i maps the elements of the sequence in order $Z_i = \{\gamma_i(1), \gamma_i(2), \dots, \gamma_i(g_i)\}$ for $i = 1, 2, 3$.

ALGORITHM 4.12 (computing the composition operator from the given virtual points in a parse tree).

Input: Three independent sequences Z_1, Z_2, Z_3 of virtual points in a common $\leq t'$ -boundaried parse tree T , where each sequence has at most $3t$ members.

Output: The $\leq 3t$ -boundaried composition operator represented by the virtual points of Z_1, Z_2, Z_3 , computed in time $O(|V(T)|)$.

Proof. We argue similarly as in Algorithm 4.6. There is a bounded number of $\leq t'$ -boundaried composition operators, and each one of them may be identified by a bounded number of linear vector equations and inequations. Moreover, these equations are homogeneous, and thus invariant under nonsingular vector transformations by the definition of a composition operator. Thus we can decide their validity for the input from information given in the parse tree T .

Let x be a node of T labeled by \odot^x , and let T_x be the rooted subtree of T with the root x . Denote by T'_x, T''_x the left and right rooted subtrees of x in T by $\bar{M}_x = \bar{P}(T_x)$ and by $Z_x \subseteq Z_1 \cup Z_2 \cup Z_3$ those of given virtual points of T which are contained in the composition operators in the subtree T_x . We use the following dynamic program: We call *boundary-combination data* of \bar{M}_x the list of all linear combinations of the virtual points Z_x which result in a point in the boundary $\partial(\bar{M}_x)$. This is a well-defined notion according to the definition of a parse tree and to elementary linear algebra, and one can determine boundary-combination data of $\bar{M}_x = \bar{P}(T_x)$ from boundary-

combination data of $\bar{P}(T'_x)$ and of $\bar{P}(T''_x)$, and from the composition operator \odot^x labeling x . Since boundary-combination data carry a limited amount of information at each tree node, the whole parse tree T can be processed in linear parametrized time.

Consider a homogeneous linear (in)equation EQ over the points $Z_1 \cup Z_2 \cup Z_3$. Then, obviously, we can decide validity of EQ from boundary-combination data at the node y of T in which the last point involved in EQ is encountered in the set Z_y . This takes constant time. Therefore, for any $\leq 3t$ -boundaried composition operator \odot , we can decide whether the virtual points of Z_1, Z_2, Z_3 represent \odot . In this way we find the $\leq 3t$ -boundaried composition operator represented by Z_1, Z_2, Z_3 in total linear (parametrized) time $O(|V(T)|)$. \square

LEMMA 4.13. *Step 4.1 in Algorithm 4.1 is correctly implemented in time $O(n^2)$ for fixed parameters $t, t' \leq 10t$, and \mathbb{F} .*

Proof. Let $M = M(\mathbf{A})$ be the given matroid on n elements, and let the set X and the $\leq t'$ -boundaried parse tree T be as in Algorithm 4.1. (So $P(T) = M \upharpoonright X$.) Notice that the size of the partial parse trees considered in the algorithm is at most linear in $|X| \leq n$. The important point of the implementation of step 4.1 in Algorithm 4.1 is that the boundaried matroids labeling the partial spanning tree T' are not explicitly described: Instead of a boundaried matroid \bar{N} , we record only the set $J(\bar{N})$ of its internal elements. The boundary subspace of \bar{N} is then implicitly given by the guts of the separation $(J(\bar{N}), X - J(\bar{N}))$, and the boundary points are handled as virtual points in the parse tree T .

Part 3(a) of Algorithm 4.1 is trivial to implement. Let us look at part 3(b): The boundary rank of the boundaried matroid \bar{N} labeling a chosen leaf ℓ of T' is computed in time $O(n)$ by Algorithm 4.9. Suppose that the computed rank is less than $3t$. Let $e \in J(\bar{N})$ be an arbitrary element. Then the new composition operator being added to the parse tree T' corresponds to a tripartition $X_1 = J(\bar{N}) - \{e\}$, $X_2 = \{e\}$, and $X_3 = X - J(\bar{N})$. Rest is described below.

Suppose that the above computed boundary rank of \bar{N} equals $3t$. Then we are in part 3(c): We call Algorithm 4.10 for $F_0 = X_3 = X - J(\bar{N})$ over the parse tree T . The result is a partition (X_1, X_2) of the set $X - X_3 = J(\bar{N})$, which does exist by Lemma 4.8 if branch-width of M is at most $t + 1$. The whole tripartition of X to X_1, X_2, X_3 then determines the new composition operator and the new leaf labels which will be added to T' . On the other hand, if branch-width of M exceeds $t + 1$, then this part may possibly fail, and then Algorithm 4.1 ends without a parse tree and with an error message. Computing time is $O(n)$ here.

So far, we have constructed a tripartition (X_1, X_2, X_3) of the set X such that $\lambda_{M \upharpoonright X}(X_i) \leq 3t$ for $i = 1, 2, 3$, and we are going to find the composition operator that would “glue” these three parts together in an enlarged parse tree T'_1 : We call Algorithm 4.11 for the separation $(X_i, X - X_i)$ over the parse tree T , for each $i = 1, 2, 3$. Then we call Algorithm 4.12 for the resulting three sequences $Z_i, i = 1, 2, 3$, of virtual points over the parse tree T to construct a composition operator \odot' . We construct the new tree T'_1 from T' by adding two new leaves ℓ_1, ℓ_2 as sons of ℓ . We label $\ell_i, i = 1, 2$, by the boundaried matroid \bar{N}_i induced on the elements X_i and the boundary Z_i , and we relabel ℓ with \odot' . (Rest of T'_1 is unchanged.) This is all done in time $O(n)$ again.

It remains to prove correctness of the above construction by induction on $|V(T')|$. At the beginning, when T' has one node, the matroid \bar{N} has boundary rank 0, and $X_3 = \emptyset$, so Z_3 is an empty sequence. Otherwise, the sequence Z_3 coincides with the set

of boundary points of \bar{N} since they were both determined uniquely by Algorithm 4.11 for the same separation $(X_3, J(\bar{N}))$. Therefore, $\bar{N}_1 \odot' \bar{N}_2 = \bar{N}$, and so $\bar{P}(T'_1) = \bar{P}(T')$ and $P(T'_1) = P(T) = M \upharpoonright X$.

Since each iteration of step 4.1 adds a new leaf to the constructed parse tree T' , there are at most $|X| - 1 = O(n)$ iterations. Thus step 4.1 is finished in time $O(n^2)$. We remark that our implementation works for an arbitrary finite field \mathbb{F} and an integer $t \geq 1$ given as parameters. \square

4.3. Conclusion: Implementation of Algorithm 4.1. Using Lemmas 4.7 and 4.13, and the preceding description, we immediately conclude as follows.

THEOREM 4.14. *Let us fix an integer $t \geq 1$ and a finite field \mathbb{F} , and consider a given n -element \mathbb{F} -represented matroid $M = M(\mathbf{A})$.*

(a) *If branch-width of M is at most $t+1$, then Algorithm 4.1 computes a spanning $\leq 3t$ -boundaried parse tree T for M in time $O(n^3)$.*

(b) *If branch-width of M exceeds $t+1$, then Algorithm 4.1 (possibly) ends with no output parse tree, but the computation is also finished in time $O(n^3)$.* \square

5. Parametrized complexity of branch-width. There are many connections between tree-width of graphs and parametrized complexity of hard graph problems [9, Chapter 6]. A large class of natural graph problems, including the notoriously hard like Hamiltonicity or 3-coloring problems, can be expressed in monadic second-order logic. By the results of Courcelle [6, 7], and Arnborg, Lagergren, and Seese[2], all such monadic second-order (MSO)-definable problems can be solved quickly for (incidence) graphs with a tree-decomposition of bounded width. A similar phenomenon occurs for represented matroids, and we can use that to determine the exact value of branch-width of a represented matroid, in addition to an approximation following from Algorithm 4.1.

5.1. MSO logic of matroids. The *monadic second-order logic (MSOL) of matroids* is defined as follows: The syntax includes variables for matroid elements and element sets, the quantifiers \forall, \exists applicable to these variables, the logical connectives \wedge, \vee, \neg , and the following predicates:

1. $=$, the equality for elements and their sets;
2. $e \in F$, where e is an element and F is an element set variable;
3. $\text{indep}(F)$, where F is an element set variable, and the predicate tells whether F is independent in the matroid.

In our paper, we follow a tree-automata formalization of Courcelle’s result, as in [1].

THEOREM 5.1 (Hliněný [14]). *Let $t \geq 1$, and let \mathbb{F} be a finite field. Assume \mathcal{M} is a set of represented matroids over \mathbb{F} described by a sentence in the MSOL of matroids. Then there is a finite tree automaton accepting exactly the $\leq (t - 1)$ -boundaried parse trees of members of \mathcal{M} (of branch-width bounded by t).*

We remark that the proof [14] of Theorem 5.1 is constructive—there is an algorithm that computes the accepting tree automaton for the given field \mathbb{F} , the formula ϕ describing \mathcal{M} , and t .

5.2. Parametrized complexity. When speaking about parametrized complexity, we closely follow [9]. Here we present only the basic definition of parametrized tractability. For simplicity, we restrict the definition to decision problems, although an extension to computation problems is straightforward. Let Σ be the input alphabet. A *parametrized problem* is an arbitrary subset $A^p \subseteq \Sigma^* \times \mathbb{N}$. For an instance $(x, k) \in A^p$, we call k the *parameter* and x the input for the problem. (The parameter

is sometimes implicit in the context.)

DEFINITION 5.2. We say that a parametrized problem A^p is (nonuniformly) fixed-parameter tractable if there is a sequence of algorithms $\{\mathcal{A}_i : i \in \mathbb{N}\}$, and a constant c , such that $(x, k) \in A^p$ if and only if the algorithm \mathcal{A}_k accepts (x, k) , and if the running time of \mathcal{A}_k on (x, k) is $O(|x|^c)$ for each k .

We say that a parametrized problem A^p is uniformly fixed-parameter tractable if there is an algorithm \mathcal{A} , a constant c , and an arbitrary function $f : \mathbb{N} \rightarrow \mathbb{N}$ such that $(x, k) \in A^p$ if and only if the algorithm \mathcal{A} accepts (x, k) , and if the running time of \mathcal{A} on (x, k) is $O(f(k) \cdot |x|^c)$.

In our context, the input X is an \mathbb{F} -represented matroid, and the parameter k is an upper bound on the branch-width of X . (Notice that correctness of the assumed branch-width bound is implicitly checked in Algorithm 4.1.) In a more general setting, we may even consider the parameter as a pair (\mathbb{F}, k) encoded as an integer.

5.3. Computing branch-width exactly. We use Theorem 5.1 to determine branch-width in the following way. We remark that, unlike for graph minors, it is not known how to test for a fixed matroid minor in polynomial time.

LEMMA 5.3. For every matroid N there is an MSOL formula ψ_N such that $\psi_N \models M$ (i.e., ψ_N is true on a matroid M) if and only if N is a minor of M .

Proof. We include a short proof here; more details can be found in [15]. Matroid N is a minor of M if there are two sets C, D such that $N = M \setminus D/C$. Suppose that $N = M \setminus D/C$ holds. Then a set $X \subseteq E(N)$ is dependent in N if and only if there is a dependent set $Y \subseteq E(M)$ in M such that $Y - X \subseteq C$.

Since N is fixed, we may identify the elements of an N -minor in M by variables x_1, \dots, x_n in order, where $n = |E(N)|$. For each $J \subseteq [1, n]$, we write

$$\text{mdep}(x_j : j \in J; C) \equiv \exists Y \left[\neg \text{indep}(Y) \wedge \forall y \left(y \notin Y \vee y \in C \vee \bigvee_{j \in J} y = x_j \right) \right].$$

Now, $M \setminus D/C$ is isomorphic to N if and only if the dependent subsets of $\{x_1, \dots, x_n\}$ exactly match the dependent sets of N . Hence we express ψ_N as

$$\psi_N \equiv \exists C \exists x_1, \dots, x_n \left[\bigwedge_{1 \leq i < j \leq n} x_i \neq x_j \wedge \bigwedge_{J \in \mathcal{J}_+} \neg \text{mdep}(x_j : j \in J; C) \wedge \bigwedge_{J \in \mathcal{J}_-} \text{mdep}(x_j : j \in J; C) \right],$$

where \mathcal{J}_+ is the set of all $J \subseteq [1, n]$ such that $\{x_j : j \in J\}$ actually is independent in N , and where \mathcal{J}_- is the complement of \mathcal{J}_+ . \square

The class \mathcal{B}_k of matroids of branch-width at most k is closed under taking minors, and so membership in \mathcal{B}_k can be tested by looking for the excluded (or forbidden) minors for \mathcal{B}_k . By the result of [11], the excluded minors for the class \mathcal{B}_k have size at most $(6^{k+1} - 1)/5$, and hence their number is finite and they can all be found by a brute force algorithmic search.

COROLLARY 5.4. For every $k \geq 1$, there is a computable MSOL formula ϕ_k such that $\phi_k \models M$ if and only if M has branch-width at most k (i.e., shortly $\phi_k(M) \equiv M \in \mathcal{B}_k$). \square

THEOREM 5.5. Let \mathbb{F} be a finite field, and let $t \geq 1$ be a constant. There is an algorithm that, given a rank r matrix $\mathbf{A} \in \mathbb{F}^{r \times n}$ such that the branch-width of the matroid $M(\mathbf{A})$ is at most $t + 1$, finds the exact branch-width of $M(\mathbf{A})$ in time $O(n^3)$.

Proof. For $k = 2, 3, \dots, t + 1$, the algorithm first precomputes all the excluded minors for the class \mathcal{B}_k , and the formulas ϕ_k from Corollary 5.4. Then the algorithm

computes the finite tree automaton \mathcal{A}_k from Theorem 5.1, which accepts the parse trees for represented matroids described by ϕ_k . (This precomputation is done in time not depending on M .)

Given an n -element matroid $M(\mathbf{A})$ represented over \mathbb{F} , the algorithm calls Algorithm 4.1 to produce an $\leq 3t$ -boundaried parse tree T of $M(\mathbf{A})$ in time $O(n^3)$. Then it finds the smallest $k_0 \leq t + 1$ such that the parse tree T is accepted by \mathcal{A}_{k_0} , where each automaton \mathcal{A}_k is emulated in time $O(n)$. The branch-width of $M(\mathbf{A})$ is k_0 . \square

COROLLARY 5.6. *For a finite field \mathbb{F} , the branch-width of an \mathbb{F} -represented matroid is a uniformly fixed-parameter tractable problem.* \square

Remark 5.7. We may analogously argue in the case of matroid tree-width, which has been defined in [16]: The tree-width of a matroid represented over a finite field is nonuniformly fixed-parameter tractable. However, we do not have a size-bound analogous to [11] at hand, and so we have to use a nonconstructive well-quasi-ordering argument of [10] to establish existence of a finite list of excluded minors for represented matroids of tree-width at most k . Since the definition of matroid tree-width is not easy, we include no formal statements here.

6. Concluding remarks. Using Theorem 4.14, one may easily derive the following corollary of Theorem 5.1.

COROLLARY 6.1. *Let $t \geq 1$, let \mathbb{F} be a finite field, and let ϕ be a sentence in the MSOL of matroids. Consider a given n -element \mathbb{F} -represented matroid $M = M(\mathbf{A})$ of branch-width at most t . The question of whether ϕ is true for the matroid $M(\mathbf{A})$ is uniformly fixed-parameter tractable with respect to the combined parameter (\mathbb{F}, t, ϕ) . If \mathbb{F} , t , and ϕ are fixed, then the answer can be computed from the matrix \mathbf{A} in time $O(n^3)$.*

More similar algorithmic applications, including recognition of any minor-closed matroid family, can be found in [15]. Besides applications based directly on Theorem 5.1, we may use the machinery of matroid parse trees from sections 3 and 4 for solving other problems. For example, we provide a straightforward recursive formula and an algorithm for computing the Tutte polynomial of a represented matroid in [13].

THEOREM 6.2 (Hliněný [13]). *Let $t \geq 1$, and let \mathbb{F} be a finite field. Consider a given n -element \mathbb{F} -represented matroid $M = M(\mathbf{A})$ of branch-width at most t . Then the Tutte polynomial $T(M(\mathbf{A}); x, y)$ of $M(\mathbf{A})$ can be computed in time $O(n^6 \log n \log \log n)$.*

Moreover, a recent research of Oum shows that our matroid results are of interest also in graph theory—he uses Algorithm 4.1 to approximate the clique-width of a graph in parametrized cubic time [19]. That application uses important notion of rank-width [18], defined by the matrix rank function on adjacency matrices of graphs. (No efficient approximation algorithms for graph clique-width were known before the introduction of rank-width.) In particular, the clique-width of a graph of rank-width r is between r and $2^{r+1} - 1$, and the rank-width of a bipartite graph G equals the branch-width minus one of the matroids represented over $GF(2)$ by the bipartite adjacency matrix of G . Oum’s result is briefly stated as follows.

THEOREM 6.3 (Oum [19]). *For every fixed $r > 0$, there is an algorithm checking whether the rank-width of a given graph G is at most r in time $O(n^3)$. Moreover, the algorithm outputs a rank-decomposition of width at most $24r$ in the “yes” case.*

It is interesting to watch the radical structural change when we move from represented matroids over finite fields to general abstract matroids, or even to matroids over infinite fields. For example, Theorem 5.1 [14] is provably false even for matroids that are represented over the integers by matrices with entries from $\{-1, 1, 3\}$.

Also, the problems of Corollary 6.1 and Theorem 6.2 become NP-hard for matroids of branch-width 3 over the integers. The computational borderline is even more clear when considering decidability of matroid theories [17]: While MSO theories of the matroids of bounded branch-width are decidable over finite fields (and, conversely, decidability of such a theory implies a bound on branch-width), the MSO theory of all matroids of branch-width 3 is undecidable.

The situation seems to be slightly different for the problem of branch-width itself, at least when branch-width is 3. We present in [12] an easy algorithm that decides whether a matroid has branch-width at most 3 in polynomial time. (The algorithm also has a fast practical implementation.) This algorithm is not restricted to represented matroids—it works for all matroids for which the rank function can be efficiently determined. Unfortunately, there seems to be no straightforward way to extend the algorithm to higher values of branch-width.

PROBLEM 6.4. *What is the parametrized complexity of the problem to determine the branch-width of a matroid M ?*

- (a) *If $M = M(\mathbf{A})$ is given by a matrix representation over an infinite field?*
- (b) *If M is given by a rank oracle?*

ON THE PERFORMANCE OF GREEDY ALGORITHMS IN PACKET BUFFERING*

SUSANNE ALBERS[†] AND MARKUS SCHMIDT[†]

Abstract. We study a basic buffer management problem that arises in network switches. Consider m input ports, each of which is equipped with a buffer (queue) of limited capacity. Data packets arrive online and can be stored in the buffers if space permits; otherwise packet loss occurs. In each time step the switch can transmit one packet from one of the buffers to the output port. The goal is to maximize the number of transmitted packets. Simple arguments show that any work-conserving algorithm, which serves any nonempty buffer, is 2-competitive. Azar and Richter recently presented a randomized online algorithm and gave lower bounds for deterministic and randomized strategies.

In practice, greedy algorithms are very important because they are fast, use little extra memory, and reduce packet loss by always serving a longest queue. In this paper we first settle the competitive performance of the entire family of greedy strategies. We prove that greedy algorithms are not better than 2-competitive no matter how ties are broken. Our lower bound proof uses a new recursive construction for building adversarial buffer configurations that may be of independent interest. We also give improved lower bounds for deterministic and randomized online algorithms.

In this paper we present the first deterministic online algorithm that is better than 2-competitive. We develop a modified greedy algorithm, called *semigreedy*, and prove that it achieves a competitive ratio of $17/9 \approx 1.89$. The new algorithm is simple, fast, and uses little extra memory. Only when the risk of packet loss is low does it not serve the longest queue. Additionally we study scenarios when an online algorithm is granted additional resources. We consider resource augmentation with respect to memory and speed; i.e., an online algorithm may be given larger buffers or higher transmission rates. We analyze greedy and other online strategies.

Key words. buffer, competitive, greedy, network switch, online, packet, throughput

1. Introduction. The performance of high-speed networks critically depends on switches that route data packets arriving at the input ports to the appropriate output ports so that the packets can reach their correct destinations in the network. To reduce packet loss when the traffic is bursty, ports are equipped with buffers in which packets can be stored temporarily. However, the buffers are of limited capacity so that effective buffer management strategies are important for maximizing the throughput at a switch. As a result there has recently been considerable research interest in the design and analysis of various buffer management policies [1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16].

We study a very basic problem in this context. Consider m input ports which serve a given output port. Each input port has a buffer that can simultaneously store up to B packets and is organized as a queue. In any time step new packets may arrive at the input ports and can be appended to the corresponding buffers if space permits. More specifically, suppose that the buffer at port i currently stores b_i packets and

that a_i new packets arrive there. If $b_i + a_i \leq B$, then all new packets can be accepted; otherwise $a_i + b_i - B$ packets must be dropped. In any time step the switch can select one nonempty buffer and transmit the packet at the head through the output port. We assume w.l.o.g. that the packet arrival step precedes the transmission step. The goal is to maximize the *throughput*, i.e., the total number of transmitted packets. The scenario we study here arises, for instance, in input-queued (IQ) switches, which represent the dominant switch architecture today. In an IQ switch with m input and m output ports, packets that arrive at input i and have to be routed to output j are buffered in a virtual output queue Q_{ij} . In each time step, for any output j , one data packet from queues Q_{ij} , $1 \leq i \leq m$, can be sent to that output. The buffer size B is large—typically several hundreds or thousands. We emphasize that we consider all packets to be equally important, i.e., they all have the same value. Most current networks, in particular IP networks, treat packets from different data streams equally in intermediate switches.

Information on future packet arrivals usually is very limited or not available at all. We make no probabilistic assumptions about the input and investigate an online setting, where at any time future packet arrivals are unknown. We are interested in online buffer management strategies that have a provably good performance. Following [17] we call a deterministic online algorithm ALG c -competitive if $c \cdot T_{ALG}(\sigma) \geq T_{OPT}(\sigma)$ for all packet arrival sequences σ . Here $T_{ALG}(\sigma)$ and $T_{OPT}(\sigma)$ denote the throughputs achieved by ALG and by an optimal offline algorithm OPT that knows the entire input σ in advance. If ALG is a randomized algorithm, then $T_{ALG}(\sigma)$ has to be replaced by the expected throughput $E[T_{ALG}(\sigma)]$.

In practice, greedy algorithms are most important. At any time, a greedy algorithm serves a queue that currently buffers the largest number of packets. Serving the longest queue is a very reasonable strategy to avoid packet loss if future arrival patterns are unknown. Moreover, greedy strategies are interesting because they are fast and use little extra memory. A switch cannot afford complex computations to decide which queue to serve, nor has it sufficient memory to maintain detailed information on past or current configurations. In this paper we present a thorough study of greedy algorithms and their variants.

Previous work. The following simple observation shows that any work-conserving algorithm ALG , which serves any nonempty queue, is 2-competitive: Partition σ into subsequences σ_l such that ALG 's buffers are empty at the end of each σ_l . W.l.o.g. we postpone the beginning of σ_{l+1} until OPT has emptied its buffers, too. If OPT buffers b_i packets in queue i at the end of subsequence σ_l , then at least b_i packets must have arrived there in σ_l . ALG has transmitted at least $\sum_{i=1}^m b_i$ packets because it has accepted at least $\sum_{i=1}^m b_i$ packets and all its buffers are empty again. Since both ALG and OPT transmit exactly one packet during each time step and OPT still buffers $\sum_{i=1}^m b_i$ packets when ALG 's buffers become empty, OPT delivers $\sum_{i=1}^m b_i$ more than ALG does.

Prior to our work, no deterministic online algorithm with a competitive ratio smaller than 2 was known. Azar and Richter [4] showed that if $B = 1$, no deterministic strategy can be better than $(2 - \frac{1}{m})$ -competitive. For arbitrary B , they gave a lower bound of 1.366. Azar and Richter also considered randomized algorithms and presented a strategy that achieves a competitiveness of $e/(e-1) \approx 1.58$. For $B = 1$, they showed a lower bound of 1.46 on the performance of any randomized online algorithm.

Bar-Noy et al. [9] and Fleischer and Koga [10] studied buffer management policies when buffers have unlimited capacity and one wishes to minimize the maximum queue

length. They presented $\Theta(\log m)$ -competitive online algorithms. Additional results are known when packets have values and the goal is to maximize the total value of the transmitted packets. Almost all of the previous work has focused on the single queue problem; i.e., we have to maintain only one buffer. Kesselman et al. [12] gave 2-competitive algorithms for various models where preemption is allowed; i.e., packets admitted to the queue may be discarded in the event of buffer overflow. Recently, Kesselman, Mansour, and van Stee [14] developed a 1.983-competitive algorithm when packets must be transmitted in the order they arrive. The bound was improved to 1.75 by Bansal et al. [8]. Aiello et al. [1] investigated single queue problems assuming that preemption is not allowed. For this scenario Andelman, Mansour, and Zhu [2] showed tight bounds of $\Theta(\log \alpha)$, where α is the ratio of the maximum to the minimum packet value.

Azar and Richter [4] presented a technique that transforms any c -competitive algorithm for a single queue into a $2c$ -competitive algorithm for m queues. Using results from [2, 12] they derived 4-competitive preemptive and $2e\lceil \ln \alpha \rceil$ -competitive nonpreemptive algorithms. An improved 3-competitive preemptive algorithm was given in [5].

Our contribution. In the first part of the paper we settle the competitive performance of the entire family of greedy algorithms. We prove that a greedy algorithm cannot be better than 2-competitive, no matter how ties are broken. Since any work-conserving algorithm is 2-competitive, the competitiveness of any greedy policy is indeed 2. Our lower bound construction is involved and relies on a new recursive construction for building dynamic adversarial buffer configurations. We believe that our technique may be useful for proving lower bounds in other multiqueue buffering problems. In fact, we use a variant of our technique to develop a lower bound for any deterministic online algorithm. We show that, for any buffer size B , no deterministic online strategy ALG can achieve a competitiveness smaller than $e/(e-1) \approx 1.58$. Interestingly, we establish this bound by comparing the throughput of ALG to that of any greedy algorithm. Using an approach different from [4], we show that for any B , a randomized online algorithm cannot be better than 1.46-competitive, which is exactly the same bound as the one shown in [4] for $B = 1$. Since the techniques used in [4] cannot be generalized to $B > 1$, our method is independent of previous work.

Although in terms of competitiveness greedy algorithms are not better than arbitrary work-conserving algorithms, greedy strategies are important from a practical point of view. Therefore it is interesting to consider variants of greedy policies and to analyze greedy approaches in extended problem settings. In the second part of the paper we develop a slightly modified deterministic greedy strategy, called *semigreedy* (SGR), and prove that it achieves a competitive ratio of $17/9 \approx 1.89$. We conjecture that SGR is actually an optimal deterministic algorithm because, for $B = 2$, we give a proof that it achieves an optimal competitiveness of $13/7 \approx 1.86$. These results show, in particular, that deterministic algorithms can beat the factor of 2 and perform better than arbitrary work-conserving strategies.

The new SGR algorithm is simple. If there is a queue buffering more than $\lfloor B/2 \rfloor$ packets, SGR serves a longest queue. If all queues store at most $\lfloor B/2 \rfloor$ packets, SGR serves a longest queue that has never buffered B packets, provided there is one; otherwise SGR serves a longest queue. The idea of this rule is to establish some fairness among the queues. SGR is essentially as fast as greedy. It can be implemented such that at most one extra comparison is needed in each time step. The extra memory requirements are also low. For each queue, we have only to maintain one

bit indicating whether or not the queue has ever buffered B packets. SGR does not follow the standard greedy strategy only if each queue buffers at most $\lfloor B/2 \rfloor$ packets and, hence, the risk of packet loss is low. Thus we consider SGR to be a very practical algorithm. We analyze SGR by defining a new potential function that measures the number of packets that SGR has already lost or could lose if an adversary replenishes corresponding queues. In contrast to standard amortized analysis, we do not bound the potential change in each time step. Rather, we show that if the potential increased at T_1 time steps and $T_1 > C_1$ for some constant C_1 , then the potential must have decreased at T_2 steps with $T_2 > C_2$.

In the second part of the paper we also study the case when an online algorithm is granted more resources than an optimal offline algorithm and show that we can beat the competitiveness of 2. We consider resource augmentation with respect to *memory* and *speed*; i.e., we study settings in which an online algorithm has (a) larger buffers in each queue or (b) a higher transmission rate. For scenario (a) we prove that any work-conserving algorithm, and in particular any greedy algorithm, achieves a competitive ratio of $(c+2)/(c+1)$ if it has an additional buffer of $A = cB$ in each queue. We show that this bound is tight for greedy strategies. Hence, by doubling the buffer capacities we obtain a performance ratio of 1.5. For scenario (b) we show an upper bound of $1 + 1/k$ if in each time step an online algorithm can transmit k times as many packets as an adversary. Again, by doubling the transmission rate we obtain a competitiveness of 1.5. Finally, we give a linear time offline algorithm for computing an optimal service schedule maximizing the throughput.

This paper is organized as follows. In section 2 we develop our lower bounds. In section 3 we present the new SGR algorithm and investigate scenarios with resource augmentation. The optimal offline algorithm is given in section 4.

2. Lower bounds. We first analyze greedy algorithms and then develop lower bounds for arbitrary deterministic and randomized online strategies.

2.1. Greedy algorithms. Formally, we call an online algorithm GR *greedy* if GR always serves a longest queue. Greedy algorithms may differ in the way ties are broken in case several queues currently store a maximum number of packets. The tie-breaking rule may also be randomized.

THEOREM 1. *For any B , the competitive ratio of any randomized greedy algorithm GR is not smaller than $2 - 1/B$ if $m \gg B$.*

Proof. Fix a buffer size $B > 0$. We show that there exist infinitely many m and associated packet arrival sequences for m queues such that the throughput achieved by an adversary ADV is at least $2 - 1/B - \Theta(m^{-1/2^{B-2}})$ times that achieved by GR . This proves the theorem. We use arrival sequences, where whenever there are several queues of maximum lengths, all these queues are served once before the next packets arrive. Thus, the tie-breaking criteria need not be considered.

Let $\mu \geq 2$ be an integer and $b = 2^{B-2}$. Set $m = \mu^b$. We construct a recursive partitioning of the m queues. For any i with $1 \leq i \leq B-2$, let $m_i = m^{1/2^i}$. The m queues are divided into m_1 blocks, each consisting of m_1 subsequent queues. These blocks are labeled $1, \dots, m_1$ in ascending order. Block n_1 with $1 \leq n_1 \leq m_1$ is subdivided into m_2 blocks, each consisting of m_2 subsequent queues labeled $(n_1, 1), \dots, (n_1, m_2)$. This partitioning is repeated up to level $B-2$. In general, any block (n_1, \dots, n_i) at level i consisting of m_i queues is subdivided into m_{i+1} blocks each, containing m_{i+1} queues. These blocks are labeled $(n_1, \dots, n_i, 1), \dots, (n_1, \dots, n_i, m_{i+1})$. Note that a block (n_1, \dots, n_{B-2}) at level $B-2$ consists of exactly μ queues. We define a lexicographic

ordering on the $(B-2)$ -tuples (n_1, \dots, n_{B-2}) in the standard way. Given (n_1, \dots, n_{B-2}) and (n'_1, \dots, n'_{B-2}) we have $(n_1, \dots, n_{B-2}) < (n'_1, \dots, n'_{B-2})$ if $n_i < n'_i$, for some i and $n_j = n'_j$ for all $1 \leq j < i$. Furthermore, $(n_1, \dots, n_{B-2}) \leq (n'_1, \dots, n'_{B-2})$ if $(n_1, \dots, n_{B-2}) < (n'_1, \dots, n'_{B-2})$ or $n_i = n'_i$ for all $1 \leq i \leq B-2$.

The basic idea of the lower bound construction is to maintain a *staircase of packets* in GR 's queues, where we call a buffer configuration a staircase *centered at block* (n_1, \dots, n_{B-2}) if GR 's queues in any block (n'_1, \dots, n'_{B-2}) buffer i packets if $n_j = n'_j$, for $1 \leq j \leq i$, but $n_{i+1} \neq n'_{i+1}$. During our construction, the staircase center moves through the blocks in increasing lexicographic order. Note that at each such center move from (n_1, \dots, n_{B-2}) to its successor (n'_1, \dots, n'_{B-2}) , where $(n_1, \dots, n_i) = (n'_1, \dots, n'_i)$ is the greatest common label prefix of the two blocks, only the queues in blocks whose labels also have this prefix are affected.

When the center is located at (n_1, \dots, n_{B-2}) we force a packet loss of B at each of GR 's queues in that block. ADV will be able to accept all packets and essentially has full queues in all blocks (n'_1, \dots, n'_{B-2}) that are lexicographically smaller than (n_1, \dots, n_{B-2}) . When the construction ends, almost all of ADV 's queues are fully populated while GR 's queues are empty. Since a total of nearly mB packets are transmitted by ADV and GR during the construction, this gives the desired lower bound.

Formally, we process blocks (n_1, \dots, n_{B-2}) with $n_i \geq 2$ for all i in increasing lexicographic order. Blocks (n_1, \dots, n_{B-2}) with $n_i = 1$ for some i are special in that less than B packets will arrive there. When we start processing a block (n_1, \dots, n_{B-2}) with $n_i \geq 2$ for all i , certain invariants, given below, hold. We show how to process it such that the invariants are also true when we start processing the next block.

- (G1) Let (n'_1, \dots, n'_{B-2}) be a block with $(n'_1, \dots, n'_{B-2}) < (n_1, \dots, n_{B-2})$ and $n'_i \geq 2$ for all i . GR buffers exactly $j+1$ packets in each of the queues if j is the largest index with $n'_1 = n_1, \dots, n'_j = n_j$.
- (G2) Let (n'_1, \dots, n'_{B-2}) be a block with $(n'_1, \dots, n'_{B-2}) < (n_1, \dots, n_{B-2})$ such that $n'_i = 1$ and $n'_j \geq 2$ for all $j \leq i-1$. GR has $j+1$ packets in each of the queues if $n'_j = n_j$ for all $1 \leq j \leq i-1$.
- (G3) Let (n'_1, \dots, n'_{B-2}) be a block with $(n'_1, \dots, n'_{B-2}) \geq (n_1, \dots, n_{B-2})$. GR buffers exactly j packets in each of the queues if j is the largest index with $n'_1 = n_1, \dots, n'_j = n_j$.
- (A1) Let (n'_1, \dots, n'_{B-2}) be a block with $(n'_1, \dots, n'_{B-2}) < (n_1, \dots, n_{B-2})$ and $n'_i \geq 2$ for all i . ADV has B packets in each of the first $m_{B-2} - 1 = \mu - 1$ queues and $B-1$ packets in the last queue of this block.
- (A2) Let (n'_1, \dots, n'_{B-2}) be a block with $(n'_1, \dots, n'_{B-2}) < (n_1, \dots, n_{B-2})$ such that $n'_i = 1$ and $n'_j \geq 2$ for all $1 \leq j \leq i-1$. ADV has two packets in each of the queues if $n'_j = n_j$ for all $1 \leq j \leq i-1$ and one packet in those queues otherwise.
- (A3) Let (n'_1, \dots, n'_{B-2}) be a block with $(n'_1, \dots, n'_{B-2}) \geq (n_1, \dots, n_{B-2})$. ADV has 0 packets in each of those queues.

Initialization. We show how to establish the six invariants for the block $(2, \dots, 2)$, for which we illustrate in Figure 1 the initial configurations to be described next. Initially there arrive $2m_1$ packets in the queues of block (1) at level 1, with two packets in each queue, and m_1 packets in the queues of block (2) at level 1, with one packet in each queue. GR starts transmission from block 1 while ADV does so from block 2. After both GR and ADV have transmitted m_1 packets, we jump to level 2, where the arrival pattern is adopted in gauge: there arrive $2m_2$ packets in block $(2, 1)$, with two in each queue, and m_2 packets in block $(2, 2)$, with one in each

FIG. 1. Queue configurations when we start processing block $(2, 2, 2)$.

queue. We continue to copy and scale down this pattern until blocks $(2, \dots, 2, 1)$ and $(2, \dots, 2, 2)$ at level $B - 2$ are reached. At level i , GR always clears m_i packets in block $(2, \dots, 2, 1)$ while ADV does so in $(2, \dots, 2, 2)$.

Invariants (A1) and (G1) trivially hold because there is no block $N' < (2, \dots, 2)$ with $n'_i \geq 2$ for all $1 \leq i \leq B - 2$. If $N' < (2, \dots, 2)$ and i is the smallest index with $n'_i = 1$, then $n'_1 = \dots = n'_{i-1} = 2$. Queues in N' received $i + 1$ packets, $i - 1$ of which have been transmitted by ADV , while only one of them has been transmitted by GR . Hence, invariants (A2) and (G2) hold. If $N' \geq (2, \dots, 2)$ and j is the largest index with $n'_1 = n_1, \dots, n'_j = n_j$, then queues in N' received j packets, all of which have been transmitted by ADV , while none of them have been transmitted by GR , giving that invariants (A3) and (G3) hold.

Processing of a block. We next describe how to process block $N = (n_1, \dots, n_{B-2})$. Figure 2 shows the buffer configurations when the processing starts. Let $q_1, \dots, q_{m_{B-2}}$ be the m_{B-2} queues in that block. By (G3), GR has $B - 2$ packets in each of these queues. By (A3), ADV stores no packets there. We subsequently apply the following arrival pattern to all but the last of the q_j 's: There arrive B packets at queue q_j and one packet at queue q_{j+1} . First, GR accepts two packets in q_1 and one packet in q_2 . Then q_1 is completely populated while q_2 still has one free buffer cell left. Afterward, GR transmits a packet from q_1 . At the arrival of B packets at q_2 , GR must reject all but one of them and can accept the additional packet at q_3 as well. This behavior is repeated until the last queue in N is reached. In contrast, ADV always processes the single packet in q_{j+1} to be able to accept B packets in the next step. When B packets arrive at $q_{m_{B-2}}$, we omit the additional packet because we would cross the boundary to the next block of level $B - 2$. We assume that both ADV and GR then transmit one packet from $q_{m_{B-2}}$. Hence GR stores $B - 1$ packets in each queue of N , whereas ADV buffers B packets in all but the last queue and $B - 1$ packets in the last one. Next, we show how to establish the six invariants for the next block $\bar{N} = (\bar{n}_1, \dots, \bar{n}_{B-2})$ in lexicographic order satisfying $\bar{n}_i \geq 2$ for all i . We distinguish cases depending on whether or not $\bar{n}_{B-2} = n_{B-2} + 1$.

FIG. 2. Queue configurations when we start processing block (n_1, n_2, n_3) .

Case 1. If $\bar{n}_{B-2} = n_{B-2} + 1$, then N and \bar{N} belong to the same block of level $B - 3$. By (G3), GR buffers $B - 3$ packets in each queue of \bar{N} . Now there arrive m_{B-2} packets at \bar{N} , one at each of the queues. Thus, each queue in N buffers $B - 1$ packets, and each queue in \bar{N} buffers $B - 2$ packets. In the following m_{B-2} time steps, GR transmits one packet from each queue in N while ADV serves the queues in \bar{N} , which are then empty again in ADV 's configuration. Since only N and \bar{N} have been affected, the invariants (G1), (G2), and (G3) hold for \bar{N} as well. The same is true for (A1) because the statement holds for block N , as argued in the previous paragraph. (A2) was not affected during the processing of N because $\bar{n}_i \geq 2$ for all $1 \leq i \leq B - 2$. Since no new packets arrived at blocks that are lexicographically larger than \bar{N} , (A3) is also satisfied.

Case 2. If $\bar{n}_{B-2} \neq n_{B-2} + 1$, then N and \bar{N} do not belong to the same block at level $B - 3$. Let i be the largest index such that $n_i < m_i$; i.e., there is another block at level i . Hence $\bar{N} = (n_1, \dots, n_{i-1}, n_i + 1, 2, \dots, 2)$. In the following $\sum_{j=i+1}^{B-2} m_j$ time steps, no new packets arrive, and since (G1) and (G2) hold, GR transmits m_j packets from the queues of block $(n_1, \dots, n_i, m_{i+1}, \dots, m_j)$, for $j = B - 2, \dots, i + 1$. During each iteration, one packet is transmitted from each of these queues. In these time steps, for $j = B - 2, \dots, i + 1$, ADV transmits one packet from each of the queues in $(n_1, \dots, n_i, m_{i+1}, \dots, m_{j-1}, 1)$. By invariant (A2), these queues hold exactly two packets in ADV 's configuration and store precisely one packet after the transmission. In the next time step m_i packets arrive at the queues of $(n_1, \dots, n_i + 1)$, one packet at each of these queues. At that time in GR 's configuration, the queues in (n_1, \dots, n_i) buffer exactly $i + 1$ packets while all other queues buffer less. GR then transmits one packet from each of the queues in (n_1, \dots, n_i) while ADV serves the queues in $(n_1, \dots, n_i + 1)$ so that they are empty again. In the following $\sum_{j=i+1}^{B-2} m_j$ time steps, we restore in GR 's configuration the full staircase on top of the i packets in the queues of $(n_1, \dots, n_i + 1)$. More precisely, there arrive $2m_{i+1}$ packets at the queues of $(n_1, \dots, n_i + 1, 1)$, two at each of these queues, and m_{i+1} packets at the

queues of $(n_1, \dots, n_i + 1, 2)$, one packet at each of these queues. GR transmits one packet from each queue in $(n_1, \dots, n_i + 1, 1)$ while ADV clears block $(n_1, \dots, n_i + 1, 2)$. Then there arrive $2m_{i+2}$ packets in $(n_1, \dots, n_i + 1, 2, 1)$ and m_{i+2} packets in $(n_1, \dots, n_i + 1, 2, 2)$. Again GR serves the queues in the first of these blocks while ADV clears the second. This process continues up to blocks $(n_1, \dots, n_i + 1, 2, \dots, 2, 1)$ and $(n_1, \dots, n_i + 1, 2, \dots, 2)$ at level $B - 2$.

LEMMA 1. *Invariants (G1–3) and (A1–3) hold when we start processing $\bar{N} = (n_1, \dots, n_i + 1, 2, \dots, 2)$.*

Proof. Consider block $\bar{N} = (n_1, \dots, n_i + 1, 2, \dots, 2) =: (\bar{n}_1, \dots, \bar{n}_{B-2})$. Let $N' = (n'_1, \dots, n'_{B-2})$ be an arbitrary block. We first study (G1). Let $N' < N$, $n'_j \geq 2$ for all j , and let k be the largest index such that $n'_1 = n_1, \dots, n'_k = n_k$. If $k < i$, then there is nothing to show because the queues in N' have not been touched by GR since the processing of N started. If $k \geq i$, we have $N' = (n_1, \dots, n_i, m_{i+1}, \dots, m_k, n'_{k+1}, \dots, n'_{B-2})$. Thus N' is affected at the iteration steps for $j = k, \dots, i$, and hence $k - i + 1$ times, where iteration i corresponds to the subsequent transmission of one packet from each queue in (n_1, \dots, n_i) . Since N' buffered $k + 1$ packets before the processing of N started, there are $k + 1 - (k - i + 1) = i$ packets after the iteration steps. On the other hand, $i - 1 = \max\{j : n'_1 = \bar{n}_1, \dots, n'_j = \bar{n}_j\}$. For $N' = N$ the statement of (G1) also holds because exactly i packets are buffered at these queues. If $N' < N$, statement (G2) holds because of the same arguments, starting with k packets before the processing and eventually getting i packets.

If $N < N' < \bar{N}$, then let j be the largest index with $n'_1 = \bar{n}_1, \dots, n'_j = \bar{n}_j$. We have $i \leq j < B - 2$ and $n'_{j+1} = 1$. Since $n'_{i+1} = \dots = n'_j = 2$, GR buffers exactly $j + 1$ packets in the queues of N' . Hence (G2) holds here as well. Moreover, since GR has $B - 2$ packets in the queues of \bar{N} , (G3) holds for $N' = \bar{N}$. If $N' > \bar{N}$, then we distinguish two cases. If $n'_l > \bar{n}_l$ for some $1 \leq l \leq i$, there is nothing to show because GR 's configuration in these queues has not changed and the largest index j with $n_1 = n'_1, \dots, n_j = n'_j$ is equal to the largest index j with $\bar{n}_1 = n'_1, \dots, \bar{n}_j = n'_j$. If $n'_1 = \bar{n}_1, \dots, n'_i = \bar{n}_i = n_i + 1$, then let j be the largest index with $n'_1 = \bar{n}_1, \dots, n'_j = \bar{n}_j$. We have $n'_{i+1} = 2, \dots, n'_j = 2$ and $n'_{j+1} > 2$. Hence the queues in N' store exactly j packets and (G3) holds.

Invariant (A1) obviously holds because it held when we started processing N and the desired property was established for block N . There exist no blocks N' with $N < N' < \bar{N}$ and $n'_i \geq 2$ for all i . Invariant (A2) is satisfied for blocks N' with $N' \leq N$ because, during the processing of N , ADV served the queues in $(n_1, \dots, n_i, m_{i+1}, \dots, m_{j-1}, 1)$ for $j = B - 1, \dots, i + 1$ exactly once, thus reducing the number of packets stored there from 2 to 1. If $N' > N$, then the queues store exactly two packets, as desired. Finally, (A3) holds because ADV has transmitted all packets that have arrived at blocks $N' \geq \bar{N}$. \square

After processing the last block (m_1, \dots, m_{B-2}) , no further packets arrive, but the iteration steps are executed as if there were another block. Then, we have the following configurations: From invariants (G1), (G2), and (G3), we derive that GR buffers one packet in each queue. Due to (A1), (A2), and (A3), ADV buffers $B - 1$ or B packets in the queues in blocks (n_1, \dots, n_{B-2}) with $n_i \geq 2$ for all i while the others buffer exactly one packet like GR does.

Let T_G be the throughput achieved by GR and T_A be the throughput achieved by ADV . For any block (n_1, \dots, n_{B-2}) with $n_i \geq 2$ for all i , GR transmits B packets from each of the associated queues. For any block $(n_1, \dots, n_{i-1}, 1)$ with $n_j \geq 2$, for $j = 1, \dots, i - 1$, GR transmits $i + 1$ packets from each queue. There are $\prod_{j=1}^{i-1} (m_j - 1)$

such blocks, each containing m_i queues. Thus $T_G = (m - \check{m})B + \delta_1$, where

$$\check{m} = \sum_{i=1}^{B-2} \prod_{j=1}^{i-1} (m_j - 1)m_i \quad \delta_1 = \sum_{i=1}^{B-2} \prod_{j=1}^{i-1} (m_j - 1)m_i(i + 1).$$

The throughput of *ADV* is equal to that of *GR* plus the number of packets that are in *ADV*'s final configuration when the processing of blocks ends minus the number of packets that are in *GR*'s final configuration when the processing of blocks ends. In this final configuration, queues in blocks (n_1, \dots, n_{B-2}) with $n_i \geq 2$ for all i store B packets, except for the last of these queues, which buffers only $B - 1$ packets. All other queues are empty. Hence, $T_A = T_G + (m - \check{m})B - \delta_2 - (m - \check{m})$, where $\delta_2 = (m - \check{m})/\mu$. Hence $T_A \geq T_G + (m - \check{m})(B - 1) - m\mu^{-1}$. Moreover, $\check{m} \in \Theta(\prod_{j=1}^{B-2} m_j) = \Theta(\prod_{j=1}^{B-2} m^{\frac{1}{2^j}}) = \Theta(m^{1 - \frac{1}{2^{B-2}}})$, $m\mu^{-1} \in \Theta(m^{1 - \frac{1}{2^{B-2}}})$, and $\delta_1 \in \Theta(B \prod_{j=1}^{B-2} m_j) = \Theta(Bm^{1 - \frac{1}{2^{B-2}}})$. This implies

$$\begin{aligned} \frac{T_A}{T_G} &\geq \frac{(m - \check{m})B + \delta_1 + (m - \check{m})(B - 1) - m\mu^{-1}}{(m - \check{m})B + \delta_1} = 2 - \frac{(m - \check{m}) + \delta_1 + m\mu^{-1}}{(m - \check{m})B + \delta_1} \\ &\geq 2 - \frac{1}{B} - \frac{\delta_1 + m\mu^{-1}}{(m - \check{m})B + \delta_1} = 2 - \frac{1}{B} - \Theta\left(\frac{Bm^{1 - \frac{1}{2^{B-2}}}}{mB}\right) \\ &= 2 - \frac{1}{B} - \Theta\left(m^{-\frac{1}{2^{B-2}}}\right). \quad \square \end{aligned}$$

2.2. Arbitrary algorithms. We first study deterministic online algorithms and then address randomized strategies.

THEOREM 2. *The competitive ratio of any deterministic online algorithm ALG is at least $e/(e - 1)$ if $m \gg B$.*

Proof. Let B be a positive integer representing the buffer size. For any positive integer N , let $m = (B + 1)^N$ be the number of queues. Let the B buffer columns be indexed $1, \dots, B$, where column B is the one at the head of the queues and column 1 is the one at the tails. At the beginning there arrive B packets at each of the m queues such that all buffers are fully populated. We present a scheme S for constructing request sequences σ . Our scheme has the property that the throughput achieved by an adversary is at least $e/(e - 1)$ times the throughput obtained by any greedy algorithm and that the throughput of any greedy strategy is at least as large as the throughput of any deterministic online algorithm *ALG*. This establishes the theorem. It will be sufficient to consider the standard greedy algorithm, denoted by *GR*, which serves the smallest indexed queue in case there is more than one queue of maximum length.

A request sequence σ consists of superphases P_1, \dots, P_B . Superphase P_i consists of phases $(i, N), \dots, (i, 1)$. In a phase (i, s) essentially $\lfloor (B + 1)^s (\frac{B+1}{B})^{i-2} \rfloor$ packets arrive at the $q_s = (B + 1)^{s-1}$ most populated queues in the online configuration. We first present an informal description of the superphases and phases, explaining how *GR* would serve them. Then we give a formal definition with respect to any online strategy. When superphase P_i is finished, the last i columns in *GR*'s buffers are empty while the other columns are fully populated. In particular, when σ ends, all buffers are empty. Superphase P_i is meant to empty column i . After phase (i, s) the first $m - q_s$ queues contain $B - i$ packets while the remaining queues buffer $B - i + 1$ packets. This load difference of one packet in the last q_s queues compared to the others is sufficient for *GR* to serve each of these q_s queues exactly once during the next q_s time steps.

Since GR is a deterministic algorithm, the adversary knows, for each $1 \leq k \leq q_s$, which of the q_s queues are served by GR during the first k time steps of the next phase if no new packets arrive, and uses this knowledge to serve other queues and make new packets arrive there to cause as large as possible a packet loss for GR .

We first describe superphase P_1 and start with phase $(1, N)$. Initially, all $q_{N+1} = m$ queues are fully populated. During the first $q_N B$ time steps no packets arrive and GR transmits a packet from each of the first $q_N B$ queues. Then B packets arrive at each of the remaining q_N queues, all of which must be dropped by GR because the last q_N queues already buffer B packets each. An adversary, on the other hand, could transmit all packets from the last q_N queues during the first $q_N B$ time steps so that no packet loss occurs. At the end of phase $(1, N)$ the last q_N queues are fully populated in GR 's buffer configuration. The arrival pattern now repeats for the other phases in P_1 . At the beginning of $(1, s)$ the last q_{s+1} queues in GR 's configuration store B packets each. During the first $q_s B$ time steps no packets arrive and GR transmits one packet from each of the first $q_s B$ of these q_{s+1} queues. Then B packets are sent to each of the last q_s queues, all of which are lost by GR . Again, an adversary can accept all packets by transmitting from the last q_s queues in the previous time steps. At the end of $(1, 1)$ the last queue in GR 's configuration contains B packets while all other queues buffer $B - 1$ packets. Now there is one time step without packet arrivals such that GR can transmit one packet from the last queue and has exactly $B - 1$ packets in each of its buffers.

Superphase P_2 is similar. In $(2, N)$ there are no packet arrivals during the first $q_N B$ time units. Then there arrive B packets at each of the last q_N queues. This time GR loses $B - 1$ packets at each of the last queues, which are then fully populated again. To these last q_N queues we recursively apply the packet arrival pattern used to empty column 1 in P_1 . In phase $(2, s)$ there are no packet arrivals during the first $q_s B$ time units. Then B packets are sent to the last q_s queues, causing a packet loss of $(B - 1)$ at each of these buffers. To empty the last column of these queues, we recursively apply the pattern of P_1 . In general, in any phase (i, s) of P_i there are $q_s B$ time units without packet arrivals, followed by the arrival of B packets at each of the last q_s queues. GR loses $B - i + 1$ packets at each of these buffers, which are then fully populated again. To empty the last $i - 1$ columns of these buffers we recursively apply the pattern used in P_{i-1} .

Formally, for any deterministic online algorithm ALG , $\sigma = P_1, \dots, P_B$, where $P_i = (i, N), \dots, (i, 1)$. We call the BN phases in P_1, \dots, P_B *main phases*. A main phase triggers *auxiliary phases*. Auxiliary phases are identified by their complete triggering path. If φ_1 is a main phase and φ_i triggers φ_{i+1} , then the auxiliary phase φ_n is denoted by $[\varphi_1 \varphi_2, \dots, \varphi_n]$. Let Φ be the set of phases. To identify sets of queues on which phases work, we define a predecessor mapping $\pi : \Phi \rightarrow \Phi$. For a main phase $\varphi = (i, s)$, let i be the level of φ . If φ is a main phase, then $\pi(\varphi)$ is the immediately preceding phase in σ of the same level if such exists; otherwise we define $\pi(\varphi) = (0, 0)$. If φ is an auxiliary phase, then $\pi(\varphi)$ is the triggering phase:

- $\pi((i, N)) = (0, 0)$ and $\pi((i, s)) = (i, s + 1)$ if $s < N$,
- $\pi([(i_1, s_1), \dots, (i_n, s_n)]) = [(i_1, s_1), \dots, (i_{n-1}, s_{n-1})]$ if $s_n = s_{n-1} - 1$,
- $\pi([(i_1, s_1), \dots, (i_n, s_n)]) = [(i_s, s_1), \dots, (i_n, s_n + 1)]$ if $s_n < s_{n-1} - 1$.

Furthermore, we need a recursive mapping $Q : \Phi \rightarrow \mathcal{P}(\{1, \dots, m\})$ that associates phases with sets of queues. Let $Q(0, 0)$ be the set of all m queues.

Each phase φ with suffix (i, s) consists of the following steps.

1. $q_s B$ time steps without packet arrival, i.e., only packet transmission.

2. Arrival of B packets at each of the q_s most populated queues in $Q(\pi(\varphi))$; these queues form $Q(\varphi)$.
3. If $i > 1$ and $s > 1$, triggering of the phases $[\varphi, (1, s - 1)], \dots, [\varphi, (1, 1)], \dots, [\varphi, (i - 1, s - 1)], \dots, [\varphi, (i - 1, 1)]$ on $Q(\varphi)$.
4. If $s = 1$, then i time steps without packet arrival.

LEMMA 2. *If a sequence of phases $(1, s), \dots, (1, 1), \dots, (i, s), \dots, (i, 1)$ is served by GR on a set $Q_{G,s}$ consisting of $q_{s+1} = (B + 1)^s$ consecutive queues, then after phase (j, r) the buffer configuration in $Q_{G,s}$ is as follows. If $r > 1$, then the last q_r queues buffer $B - j + 1$ packets while the other queues buffer $B - j$ packets. If $r = 1$, then all queues buffer $B - j$ packets.*

Proof. We first prove the statement of the lemma under the condition that queues not contained in $Q_{G,s}$ buffer less than $B - i$ packets. Then we show that the condition is always satisfied.

The proof is by induction on i . First consider $i = 1$. At the beginning all buffers in $Q_{G,s}$ are full because the sequence is either a sequence of main phases started with fully populated buffers or a sequence of triggered phases, which are also initiated on full buffers only. In $(1, s)$ during the first $q_s B$ time steps, GR transmits a packet from the first $q_s B$ queues in $Q_{G,s}$ because queues outside $Q_{G,s}$ contain less than B packets. In the next time step the packets arriving at the last q_s queues in $Q_{G,s}$ are rejected because the queues already buffer B packets. No further phases are triggered in $(1, s)$. Thus the last q_s queues buffer B packets while the other queues store $B - 1$ packets. If $s = 1$, then $q_s = 1$ and in the last time step in $(1, 1)$ a packet is transmitted from the last queue so that all queues buffer exactly $B - 1$ packets. The desired statement on the buffer population holds after phase $(1, s)$. Suppose inductively that it holds after $(1, r + 1)$. Then the last q_{r+1} queues in $Q_{G,s}$ store B packets while the remaining queues each have $B - 1$ packets. During the next $q_r B$ time steps in $(1, r)$ one packet is transmitted from the first $q_r B$ queues among the last q_{r+1} buffers in $Q_{G,s}$. Thus the last q_r queues in $Q_{G,s}$ still have B packets while the remaining queues buffer $B - 1$ packets. Again, if $r = 1$, one packet is transmitted from the last queue in the final time steps in $(1, r)$ so that all queues have exactly $B - 1$ packets. Thus the stated buffer population is maintained after phase $(1, r)$ and the desired statement holds for $i = 1$.

Suppose that the statement holds for every integer smaller than i ; we prove that it is also satisfied for i . As above, we can show that after phase $(1, s)$ the buffer population is as desired. Assume that the statement on the buffer population holds up to but excluding phase (j, r) . At the beginning of (j, r) the last q_{r+1} buffers in $Q_{G,s}$ store $B - j + 1$ packets while the remaining queues contain $B - j$ packets. During the next time steps, GR transmits one packet from each of the first $q_r B$ buffers among the q_{r+1} last ones in $Q_{G,s}$ because buffers outside $Q_{G,s}$ store less than $B - i < B - j + 1$ packets. Thus the last q_r queues in $Q_{G,s}$ store $B - j + 1$ packets while the remaining queues each contain $B - j$ packets. Then B packets arrive at the last q_r queues so that they are fully populated again. If $r = 1$, then no phases are triggered and, since $q_1 = 1$, only the last queue is fully populated. During the next j time steps j packets are transmitted from this last queue and all queues in $Q_{G,s}$ then buffer $B - j$ packets. The queues are populated as desired. If $r > 1$, then phases $(1, r - 1), \dots, (1, 1), \dots, (j - 1, r - 1), \dots, (j - 1, 1)$ are triggered on the last q_r fully populated queues. The other queues buffer less than $B - (j - 1)$ packets. By an induction hypothesis, when the triggered phases end, the last q_r queues again buffer $B - j + 1$ packets. Thus the buffers are populated as desired and the desired

statement holds for every integer i .

It remains to show that the condition mentioned at the beginning of the proof holds; i.e., if a sequence of phases $(1, s), \dots, (1, 1), \dots, (i, s), \dots, (i, 1)$ is served on a set $Q_{G,s}$ of queues, then all queues not contained in $Q_{G,s}$ store less than $B - i$ packets. The condition holds when the initial sequence σ of main phases is started. Suppose that the condition holds for all sequences triggered after the beginning of σ but before the start of $(1, s), \dots, (1, 1), \dots, (i, s), \dots, (i, 1)$. Assume that the latter sequence is triggered by phase $[\varphi_1, \dots, \varphi_n]$ such that $\varphi_j = (i_j, s_j)$ and phase φ_j is executed on queues in Q_{φ_j} . We have $Q_{\varphi_{j+1}} \subset Q_{\varphi_j}$ for $j = 1, \dots, n - 1$, and queues outside Q_{φ_j} contain less than $B - i_j$ packets. Thus all queues outside Q_{φ_n} buffer less than $B - i_n$ packets. The sequence is triggered on the last q_{s_n} buffers in Q_{φ_n} . Since the first $q_{s_n} B$ buffers in Q_{φ_n} store $B - i_n$ packets and $i_1 > i_2 > \dots > i_n > i$, the sequence is triggered on a set of buffers storing less than $B - i$ packets. The proof is complete. \square

LEMMA 3. *The packet loss of any deterministic online algorithm ALG is not smaller than the one of GR.*

Proof. Before presenting the details of the proof, we outline the basic idea. We construct a request sequence σ that is similar in structure to the sequence used for GR in the previous lemma. While GR gives us a hierarchical structure for the distinct phases, ALG might serve the queues in such a way that the set of the most populated queues varies over time. Therefore, we generalize the request sequence such that, upon each packet arrival, the new packets arrive at the currently most populated queues. In the sequence to be constructed, there are packet arrivals at exactly the same time steps as for GR . Moreover, the arrival pattern is not changed either; i.e., for each time step there is a match between GR 's queues and ALG 's queues such that the same number of packets arrives at each pair of matched queues. We shall show that the number of packets transmitted by ALG is at most the number of packets transmitted by GR .

To establish the claim, we use Lemma 2. We consider sequences $\sigma(i, s) = (1, s), \dots, (1, 1), \dots, (i, s), \dots, (i, 1)$ processed by ALG and GR on sets Q_A and Q_G of q_s buffers each. For any given time since the beginning of $\sigma(i, s)$, let N_G be the total number of packets in GR 's queues of Q_G and let L_G be the total packet loss of GR accumulated since the start of $\sigma(i, s)$. For algorithm ALG , N_A and L_A are defined similarly. Furthermore, let S_A be the number of time steps in $\sigma(i, s)$ where neither do packets arrive nor does ALG transmit a packet from queues in Q_A . We are interested in the following invariants:

$$(I1) \quad N_A - S_A + L_A = N_G + L_G, \quad (I2) \quad N_A - S_A \leq N_G.$$

We prove the following statement. If a sequence $\sigma(i, s)$ is processed by ALG and GR on sets Q_A and Q_G , respectively, then after each phase, invariants (I1) and (I2) hold. The lemma then follows by considering a sequence $\sigma = \sigma(B, N)$. At the end of the sequence, by (I1), $L_A = N_G + L_G - (N_A - S_A)$. By (I2) we conclude $L_A \geq L_G$.

We prove the desired statement by induction on i . First consider $i = 1$. At the beginning of $\sigma(1, s)$ all queues in Q_A and Q_G are fully populated because sequence σ as well as triggered phases are initiated on full buffers only. Therefore $N_A = N_G$. Since initially $L_A = L_G = 0$ and $S_A = 0$, both invariants hold at the beginning of $\sigma(1, s)$. While serving $\sigma(1, s)$, in each time step GR transmits a packet from queues in Q_G . Moreover, GR always serves a fully populated queue. Therefore, at any time, GR always has the smallest number of fully populated queues. By Lemma 2, at the

beginning of phase $(1, r)$ the last q_{r+1} queues in Q_G buffer B packets while all other queues store $B-1$ packets. After the next $q_r B$ time steps, the last q_r queues still buffer B packets such that all packets arriving in step 2 of $\sigma(1, r)$ are lost. Since ALG has at least q_r fully populated queues, ALG also loses all incoming packets. Therefore, at any time the packet loss of ALG and GR is the same. Since GR transmits a maximum number of packets and no incoming packets can be accepted by ALG and GR , $N_A \geq N_G$. If $N_A - N_G = \delta > 0$, then there must have been δ time units, where ALG did not transmit a packet. Therefore (I1) and (I2) hold throughout the execution of $\sigma(1, s)$.

Assume that the statement to be proven holds for integers smaller than i . We consider a sequence $\sigma(i, s)$. Again (I1) and (I2) hold initially, when $\sigma(i, s)$ is started. We show that if the invariants (I1) and (I2) hold before any phase (j, r) , then they also hold after the phase. At the beginning of (j, r) , GR buffers $B - j + 1$ packets in the last q_{r+1} queues of Q_G and $B - j$ packets in the remaining queues. During the first $q_r B$ time steps, GR always transmits one packet. Consider any time step. If ALG also transmits a packet from queues in Q_A , then both N_A and N_G decrease by 1. If ALG does not serve a queue in Q_A , then only N_G decreases by 1 but S_A increases by 1. The invariants are maintained. Immediately before step 2 of phase (j, r) let Q_A^1 be the set of the q_r most populated buffers in Q_A to which packets are sent in step 2. Set $Q_A^2 = Q_A \setminus Q_A^1$ and let N_A^i be the number of packets in $Q_A^i, i = 1, 2$. Similarly, let Q_G^1 be the set of the q_r most populated queues in $Q_G, Q_G^2 = Q_G \setminus Q_G^1$ and N_G^i be the packet number in $Q_G^i, i = 1, 2$. Each queue in Q_G^2 has exactly $B - j$ packets while each queue in Q_G^1 buffers exactly $B - j + 1$ packets. We have $N_A^2 - S_A \leq N_G^2$. Otherwise, if $N_A^2 - S_A > N_G^2$, then the most populated queues in Q_A^2 would store at least $B - j + 1$ packets. Hence $N_A^1 \geq N_G^1$ and (I1) would be violated.

Now consider the effect of step 2 of phase (j, r) in which the queues of Q_A^1 and Q_G^1 are refilled. If $L_A - L_G$ changes by δ , then $N_G - N_A$ changes by δ so that (I1) is maintained. Since $N_A^1 = N_G^1$ after the step and $N_A^2 - S_A \leq N_G^2$, invariant (I2) also holds. If $r = 1$, then no phases are triggered and there are j more time steps with packet transmission in which the invariants are maintained. If $r > 1$, then phases $(1, r - 1), \dots, (1, 1), \dots, (j - 1, r - 1), \dots, (j - 1, 1)$ are triggered in step 3 of (j, r) . The triggered phases are executed on Q_A^1 and Q_G^1 . Since $N_A^1 = N_G^1$ initially, the desired invariants hold at the beginning of the triggered sequence. By an induction hypothesis we have $N_A^1 - S_A^1 + L_A^1 = N_G^1 + L_G^1$ and $N_A^1 - S_A^1 \leq N_G^1$ when the sequence is finished. Here L_A^1 and L_G^1 denote the loss incurred during the sequence and S_A^1 is the number of time steps, ALG does not transmit packets from Q_A^1 . Let $S_A^{1,1}$ be the number of time steps in the triggered sequence where ALG works on neither Q_A^1 nor Q_A^2 , and let $S_A^{1,2}$ be the number of time steps where ALG does not work on Q_A^1 but does transmit packets from Q_A^2 . Then $S_A^1 = S_A^{1,1} + S_A^{1,2}$. Before step 3 of the phase, (I1) held and $N_A^1 = N_G^1$. Therefore $N_A^2 - S_A + L_A = N_G^2 + L_G$ and, as argued above, $N_A^2 - S_A \leq N_G^2$. Using the invariants for the triggered sequence, we obtain

$$(N_A^1 + N_A^2 - S_A^{1,2}) - (S_A + S_A^{1,1}) + (L_A + L_A^1) = (N_G^1 + N_G^2) + (L_G + L_G^1)$$

and

$$(N_A^1 + N_A^2 - S_A^{1,2}) - (S_A + S_A^{1,1}) \leq (N_G^1 + N_G^2).$$

The invariants thus hold at the end of phase (j, r) because $N_A^1 + N_A^2 - S_A^{1,2}$ is the total number of packets in queues from $Q_A; S_A + S_A^{1,1}$ is the total number of time

steps ALG does not transmit packets from Q_A ; and $N_G^1 + N_G^2$ is the number of packets in Q_G . Finally, $L_A + L_A^1$ is the total loss accumulated by ALG and $L_G + L_G^1$ is the corresponding value of GR . The inductive proof is complete. \square

LEMMA 4. *The throughput of the adversary ADV is at least $e/(e - 1)$ times that of GR .*

Proof. We analyze the competitive ratio of the GR algorithm. To this end we analyze the throughput T_{ADV} achieved by an adversary ADV and the throughput T_G of GR . At the beginning of σ , all queues are fully populated. When σ ends, by Lemma 2, all of GR 's buffers are empty. We describe how ADV serves σ . In phase (i, s) during the first $q_s B$ time steps ADV transmits all packets from the q_s queues at which packets arrive in step 2 of the phase. If $s = 1$, then in step 4 of the phase ADV is idle and does not transmit packets. Thus in each phase ADV can always accept all incoming packets and at the end of the phase all buffers are full. Let S_{ADV} be the total number of time steps where ADV is idle in σ . Since GR transmits a packet in each time step and ADV 's queues contain mB packets at the end of σ , we have $T_G = T_{ADV} - mB + S_{ADV}$.

We estimate S_{ADV} . The adversary is idle in a phase $\varphi = [\varphi_1, \dots, \varphi_n]$ with $\varphi_j = (i_j, s_j)$ if $s_n = 1$. Since $i_1 > \dots > i_n$ and $i_j > 1$ for $j < n$, there are $\sum_{n=1}^B \binom{B}{n} (N - 1)^{n-1} \leq N^B$ such phases, in each of which ADV is idle for at most B time units. Thus $S_{ADV} \leq BN^B$ and the competitive ratio of GR is at least

$$c \geq T_{ADV}/T_G \geq 1 / \left(1 - \frac{mB}{T_{ADV}} + \frac{N^B B}{T_{ADV}} \right) \geq 1 / \left(1 - \frac{mB}{T_{ADV}} + \frac{N^B}{m} \right)$$

because $T_{ADV} \geq mB$. To lower bound the last expression we have to upper bound T_{ADV} . The throughput of ADV is equal to the mB packets initially buffered in the queues plus the packets accepted by ADV during the service of σ . As argued above, ADV can always accept all packets. Let $a_{i,s}$ be the number of packets accepted by ADV in a phase (i, s) . We show by induction on i that $a_{i,s} \leq (B + 1)^s \left(\frac{B+1}{B}\right)^{i-2}$. The inequality holds for $i = 1$ because $a_{1,s} = q_s B = (B + 1)^{s-1} B$. Suppose that the inequality holds for i . We have $a_{i+1,s} = q_s B + \sum_{j=1}^i \sum_{r=1}^{s-1} a_{j,r} = a_{i,s} + a_{i,s-1} + \dots + a_{i,1} \leq \left(\frac{B+1}{B}\right)^{i-2} \sum_{r=1}^s (B + 1)^r \leq \left(\frac{B+1}{B}\right)^{i-1} (B + 1)^s$. The total number of accepted packets in σ is at most

$$\begin{aligned} \sum_{i=1}^B \sum_{s=1}^N a_{i,s} &\leq \sum_{i=1}^B \left(\frac{B+1}{B}\right)^{i-2} \frac{(B+1)^{N+1} - 1}{B} \leq (B+1)^N \sum_{i=1}^B \left(\frac{B+1}{B}\right)^{i-1} \\ &= (B+1)^N B \left(\left(1 + \frac{1}{B}\right)^B - 1 \right) = mB \left(\left(1 + \frac{1}{B}\right)^B - 1 \right). \end{aligned}$$

Since the initial buffer configuration stores mB packets, we have $T_{ADV} \leq mB(1 + \frac{1}{B})^B$ and we conclude $c \geq 1/(1 - (1 + 1/B)^{-B} + N^B/m)$ and for large B and N this expression can be arbitrarily close to $e/(e - 1)$. \square

Lemmas 3 and 4 establish the theorem. \square

Azar and Richter [4] proved a lower bound of 2 for all deterministic online algorithms if $B = 1$. In the previous theorem we presented a construction of a lower bound that converges to $e/(e - 1)$ if $B \rightarrow \infty$. This raises the question of whether the competitive ratio can be bounded away from both $e/(e - 1)$ and 2 if $B > 1$, but small. For $B = 2$ we can show such a stronger bound, which we prove to be optimal in section 3 by presenting a matching upper bound.

THEOREM 3. *For $B = 2$, no deterministic online algorithm can achieve a competitive ratio smaller than $13/7$.*

Proof. We enhance the request sequence σ presented in the proof of Theorem 2. Let there be m additional queues for both ADV and ALG . At the beginning, there arrives one packet in each of the $2m$ queues. During the first m time steps, ADV serves those queues not served by ALG during this period. Then, σ is applied to those queues already served by ADV . Let T_{ADV} and T_{ALG} denote the throughputs of ADV and ALG , respectively, for σ , again, and let T'_{ADV} and T'_{ALG} denote the respective throughputs for the composed request sequence. Since $T'_{ADV} = T_{ADV} + 2m$ and $T'_{ALG} = T_{ALG} + m$, the throughput difference for any online algorithm is the same as for GR . Hence, we can apply Lemma 3 again and adopt the proof of Lemma 4. Let T_G and T'_G denote the respective throughputs for GR . Since $T'_G = T'_{ADV} - (m + 1)B + S_{ADV}$ and $mB \leq T'_{ADV} \leq m(B(1 + \frac{1}{B})^B + 2)$, we get for the competitive ratio that

$$\begin{aligned} c \geq T'_{ADV}/T'_G &\geq 1 / \left(1 - \frac{m(B+1)}{T_{ADV}} + \frac{N^B}{m} \right) \\ &\geq 1 / \left(1 - (B+1) \left(B \left(1 + \frac{1}{B} \right)^B + 2 \right)^{-1} + \frac{N^B}{m} \right), \end{aligned}$$

taking values arbitrarily close to $1/(1 - (B+1)(B(1 + \frac{1}{B})^B + 2)^{-1})$ for large N . Putting $B = 2$ yields $c \geq 1/(1 - 3(2(1 + \frac{1}{2})^2 + 2)^{-1}) = 1/(1 - 3(\frac{13}{2})^{-1}) = 1/(1 - \frac{6}{13}) = \frac{13}{7}$. \square

We next consider randomized algorithms. The advantage of randomization consists of the online algorithm's being more powerful against the adversary than in the deterministic case because the former can use its probability distribution to fool the latter. For packet buffering, Azar and Richter [4] showed that if $B = 1$, no randomized online algorithm can achieve a competitive ratio smaller than 1.4659. We prove the same lower bound for any buffer size B . This reveals a significant difference from deterministic algorithms, where the lower bound of 2 shown for $B = 1$ does not hold for any other B .

THEOREM 4. *If ALG is a randomized online algorithm, its competitive ratio cannot be smaller than 1.4659 for any buffer size B .*

Proof. Let each queue be populated by B packets at the beginning. We call B subsequent time steps a round. At the end of each round, B packets arrive in the queue currently having the maximum expected load. Since the adversary ADV knows where the next packets will arrive, it serves this queue during the preceding B time steps. Hence, ADV can accept all packets, whereas ALG has an expected loss of l_i packets in round i . First, we show that

$$(1) \quad \sum_{i=1}^n l_i \geq \sum_{i=1}^n \left(\frac{m-1}{m} \right)^i B.$$

Then, we will derive three lemmas from which we eventually conclude our claim.

We show (1) by induction on i . Let $i = 1$. After B time steps, ALG has a population of $mB - B = (m - 1)B$ packets. Hence, the average queue length is $\frac{m-1}{m}B$. So, the maximum expected queue length is at least $\frac{m-1}{m}B$, yielding an expected loss $l_1 \geq \frac{m-1}{m}B$. Now assume $\sum_{i=1}^j l_i \geq \sum_{i=1}^j \left(\frac{m-1}{m} \right)^i B$. Until the end of round $j + 1$, ALG has transmitted $(j + 1)B$ packets while its expected number of accepted packets

is $jB - \sum_{i=1}^j l_i$. Hence, its expected buffer population is

$$mB - (j+1)B + jB - \sum_{i=1}^j l_i = (m-1)B - \sum_{i=1}^j l_i.$$

So, the expected average queue length is

$$\frac{1}{m} \left((m-1)B - \sum_{i=1}^j l_i \right) = \frac{m-1}{m}B - \frac{1}{m} \sum_{i=1}^j l_i.$$

We derive that the maximum expected queue length after round $j+1$ is at least $\frac{m-1}{m}B - \frac{1}{m} \sum_{i=1}^j l_i$, yielding an expected loss $l_{j+1} \geq \frac{m-1}{m}B - \frac{1}{m} \sum_{i=1}^j l_i$. Hence

$$\begin{aligned} \sum_{i=1}^{j+1} l_i &\geq \sum_{i=1}^j l_i + \frac{m-1}{m}B - \frac{1}{m} \sum_{i=1}^j l_i = \frac{m-1}{m} \left(B + \sum_{i=1}^j l_i \right) \\ &\geq \frac{m-1}{m} \left(B + \sum_{i=1}^j \left(\frac{m-1}{m} \right)^i B \right) = \sum_{i=1}^{j+1} \left(\frac{m-1}{m} \right)^i B. \end{aligned}$$

If there are n rounds, then the throughputs of *ADV* and *ALG* are $T_{ADV} = (m+n)B$ and $E[T_{ALG}] = T_{ADV} - \sum_{i=1}^n l_i \leq (m+n)B - \sum_{i=1}^n \left(\frac{m-1}{m} \right)^i B$, giving the ratio

$$r = \frac{T_{ADV}}{E[T_{ALG}]} \geq \frac{(m+n)B}{(m+n)B - \sum_{i=1}^n \left(\frac{m-1}{m} \right)^i B} = \frac{m+n}{m+n - \sum_{i=1}^n \left(\frac{m-1}{m} \right)^i}.$$

The number of rounds n is to be chosen such that r is maximized, which is equivalent to the minimization of its reciprocal

$$\frac{m+n - \sum_{i=1}^n \left(\frac{m-1}{m} \right)^i}{m+n} = 1 - \frac{1}{m+n} \sum_{i=1}^n \left(\frac{m-1}{m} \right)^i.$$

Hence we want to maximize $\frac{1}{m+n} \sum_{i=1}^n \left(\frac{m-1}{m} \right)^i$. In order to analyze this ratio we consider a more general term $a_n = \frac{1}{m+n} \sum_{i=1}^n q^i$, where $0 < q < 1$. In the following two lemmas, we show that the sequence (a_n) first increases and then decreases from where we deduce a useful property for the sequence item where the maximum is achieved.

LEMMA 5. *If $a_{n+1} < a_n$, then $a_{n+2} < a_{n+1}$.*

Proof. Let $a_{n+1} < a_n$. Algebraic manipulations give $(m+n) \sum_{i=1}^{n+1} q^i < (m+n+1) \sum_{i=1}^n q^i$ and $(m+n)q^{n+1} < \sum_{i=1}^n q^i$. Using the latter inequality, we obtain

$$(m+n+1)q^{n+2} < (m+n)q^{n+1} + q^{n+2} < \sum_{i=1}^n q^i + q^{n+2} < \sum_{i=1}^{n+1} q^i.$$

This implies

$$(m+n+1) \sum_{i=1}^{n+1} q^i + (m+n+1)q^{n+2} < (m+n+1) \sum_{i=1}^{n+1} q^i + \sum_{i=1}^{n+1} q^i = (m+n+2) \sum_{i=1}^{n+1} q^i.$$

We conclude

$$(m + n + 1) \sum_{i=1}^{n+2} q^i < (m + n + 2) \sum_{i=1}^{n+1} q^i$$

and finally, as desired,

$$\frac{1}{m + n + 2} \sum_{i=1}^{n+2} q^i < \frac{1}{m + n + 1} \sum_{i=1}^{n+1} q^i. \quad \square$$

COROLLARY 1. *There exists a unique $n \in \mathbf{N}$ such that $a_{n-1} \leq a_n$ and $a_n > a_{n+1}$. For this n , there holds $a_n = \max_{r \in \mathbf{N}} a_r$.*

LEMMA 6. *There is a unique $n \in \mathbf{N}$ such that $q < \frac{a_n}{q^n} \leq 1$.*

Proof. By Corollary 1, there exists a unique $n \in \mathbf{N}$ such that $a_{n-1} \leq a_n$ and $a_n > a_{n+1}$. These two inequalities are equivalent to $\sum_{i=1}^{n-1} q^i \leq (m + n - 1)q^n$ and $\sum_{i=1}^n q^i > (m + n)q^{n+1}$. This is equivalent to $(m + n)q^{n+1} < \sum_{i=1}^n q^i \leq (m + n)q^n$. Dividing by q^n and $m + n$, we obtain the inequality to be proven. \square

COROLLARY 2. *$a_n = \max_{r \in \mathbf{N}} a_r$ if and only if $q < \frac{a_n}{q^n} \leq 1$.*

LEMMA 7. *If $q = (m - 1)/m$ and $a_{n(m)} = \max_{r \in \mathbf{N}} a_r$, then $\lim_{m \rightarrow \infty} n(m)/m = x$, where x is the unique positive solution of the equation $e^x = x + 2$.*

Proof. We fix m and look for n such that $a_n/q^n = 1$. Then, by Corollary 2, $n(m) = \lfloor n \rfloor$. Define \tilde{q} by $q\tilde{q} = 1$. We have $\tilde{q} - 1 = m/(m - 1) - 1 = 1/(m - 1)$ and $m = \tilde{q}/(\tilde{q} - 1)$. The equation $a_n/q^n = 1$ is equivalent to $\sum_{i=1}^n q^i = (m + n)q^n$, which in turn is equivalent to $\sum_{i=1}^n \tilde{q}^{-i} = (m + n)\tilde{q}^{-n}$. We obtain $\sum_{i=0}^{n-1} \tilde{q}^i = m + n$, and hence $\tilde{q}^n - 1 = (m + n)/(\tilde{q} - 1)$. Thus $\tilde{q}^n = (2m + n - 1)/(\tilde{q} - 1)$. Since $m = \tilde{q}/(\tilde{q} - 1)$, we have

$$\tilde{q}^n = \left(2 \frac{\tilde{q}}{\tilde{q} - 1} + n - 1\right) / \left(\frac{\tilde{q}}{\tilde{q} - 1} - 1\right) = 2\tilde{q} + (n - 1)(\tilde{q} - 1) = (\tilde{q} - 1)n + (\tilde{q} + 1).$$

Define α by $n = \alpha m$. We conclude that the inequality $a_n/q^n = 1$ is equivalent to $\tilde{q}^n = (\tilde{q} - 1)n + (\tilde{q} + 1)$, which in turn is equivalent to

$$\left(\left(\frac{m}{m - 1}\right)^m\right)^\alpha = \left(\frac{m}{m - 1} - 1\right) \alpha m + \left(\frac{m}{m - 1} + 1\right) = \frac{m}{m - 1} \alpha + \frac{2m - 1}{m - 1}.$$

For $m \rightarrow \infty$, this equation takes the form $e^\alpha = \alpha + 2$. \square

It remains to determine the competitive ratio r . We have

$$a_{n(m)} = \frac{\sum_{i=1}^{\lfloor \alpha_m m \rfloor} \left(\frac{m-1}{m}\right)^i}{m + \lfloor \alpha_m m \rfloor} \geq \frac{m - 1}{m} \frac{1 - \left(\frac{m-1}{m}\right)^{\alpha_m m - 1}}{1 - \frac{m-1}{m}} \frac{1}{m + \lfloor \alpha_m m \rfloor} \xrightarrow{m \rightarrow \infty} \frac{1 - e^{-\alpha}}{1 + \alpha} =: p.$$

For the ratio r , there holds

$$r \geq 1/(1 - p) = 1 / \left(1 - \frac{1 - e^{-\alpha}}{1 + \alpha}\right) = \frac{1 + \alpha}{1 + \alpha - 1 + e^{-\alpha}} = \frac{1 + \alpha}{1 + \alpha e^{-\alpha}} e^\alpha.$$

Since $e^\alpha = \alpha + 2$, we get

$$r = \frac{(1 + \alpha)(\alpha + 2)}{1 + \alpha(\alpha + 2)} = \frac{(1 + \alpha)(\alpha + 2)}{\alpha^2 + 2\alpha + 1} = \frac{(\alpha + 1)(\alpha + 2)}{(\alpha + 1)^2} = \frac{\alpha + 2}{\alpha + 1} = 1 + \frac{1}{\alpha + 1}.$$

Numerically solving equation $e^\alpha = \alpha + 2$ yields $\alpha \approx 1.1462$ and $r \approx 1.4659$. \square

3. Upper bounds. We first present our new algorithm *SGR* and then study the influence of resource augmentation.

3.1. A new semigreedy algorithm. We have seen in section 2.1 that any greedy algorithm is not better than 2-competitive. Nevertheless, it is the most reasonable decision to serve a queue that is (nearly) completely populated because, otherwise, the adversary sends packets to such a queue and the online algorithm loses almost all of them. In the request sequence from which we derive the lower bound of 2 for greedy algorithms, it is a crucial point that *GR* always serves the queue with the maximum load and ignores all other queues no matter how small the load difference is and causes the packet loss at the latter queues. Thus, the number of queues in which packets are lost increases. We shall now present a new algorithm *SGR* which embodies the greedy criterion but simultaneously tries to keep small the number of queues in which packet loss occurs. At queues that have already been fully populated, the greedy rule is relaxed and queues with less load are preferred. The risk of losing packets at the ignored queues that the adversary does not lose is low because the high load indicates that a lot of packets have already arrived there and, hence, the adversary presumably has a high load there as well. We now give a precise description of our algorithm.

ALGORITHM *SGR*. In each time step the algorithm executes the first rule that applies to the current buffer configuration.

1. If there is a queue buffering more than $\lfloor B/2 \rfloor$ packets, serve the queue currently having the maximum load.
2. If there is a queue, the hitherto maximum load of which is less than B , serve among these queues the one currently having the maximum load.
3. Serve the queue currently having the maximum load.

Ties are broken by choosing the queue with the smallest index. The hitherto maximum load is reset to 0 for all queues whenever all queues are unpopulated in *SGR*'s configuration.

In the remainder of this subsection we analyze *SGR*. Let σ be any packet arrival sequence. We divide σ into several phases, where phase P_1 starts at time $t = 0$. Phase P_i ends when *SGR* has completely cleared its buffers for the i th time, and phase P_{i+1} starts when the first packet arrives after the end of phase P_i . W.l.o.g. we can assume that at the beginning of each phase *ADV*'s buffers are empty as well because we can always postpone the start of the subsequent phase until this state is reached, thus only enlarging *ADV*'s throughput and hence the throughput ratio. So, the total throughput is given by the sum of the throughputs in the distinct phases if these were served separately. We derive that the ratio of the total throughputs cannot be worse than the throughput ratio in a single phase. Hence we can restrict ourselves to arrival sequences that terminate when *SGR* has completely cleared its buffers. Furthermore it suffices to consider sequences where, at any time step, if there is packet loss at queue i , either *SGR* or *ADV* loses packets. If both lose packets, then we can reduce the number of packets arriving at i by the minimum loss of any of the two algorithms.

For the analysis of *SGR* we introduce a new potential function. Let $l_{i,t,A}$ and $l_{i,t,S}$ be the load of queue i at time t in the configurations of *ADV* and *SGR*, respectively. We define the potential of the queue as $\Phi_{it} = (l_{i,t,A} - l_{i,t,S})_+$, where $x_+ = (x + |x|)/2$. The total potential at time t is given by $\Phi_t = \sum_{i=1}^m \Phi_{it}$. Let T be the time when *SGR* has completely emptied its buffers. Since both *ADV* and *SGR* transmit one packet in each time step until T , the potential Φ_T describes their throughput difference. By

$\Delta\Phi$ we denote the potential change $\Phi_t - \Phi_{t-1}$. We assume that during each time step, the arrival step precedes the transmission step.

LEMMA 8. *The potential Φ does not increase during the arrival step, but Φ decreases by the number of packets lost by ADV.*

Proof. Let p packets arrive at queue i at time step t . If neither *ADV* nor *SGR* loses any packet, there holds $l_{it,A} = l_{i,t-1,A} + p$, $l_{it,S} = l_{i,t-1,S} + p$, where we measure the load at $t-1$ after the transmission step. Hence $\Phi_{it} = (l_{it,A} - l_{it,S})_+ = ((l_{i,t-1,A} + p) - (l_{i,t-1,S} + p))_+ = (l_{i,t-1,A} - l_{i,t-1,S})_+ = \Phi_{i,t-1}$ and the potential does not change due to the packet arrival at queue i . As mentioned above we can restrict ourselves to arrival sequences, where either *ADV* or *SGR* loses packets whenever packet loss occurs. First we assume that *SGR* loses some packets. We derive $l_{i,t-1,A} < l_{i,t-1,S}$ and, hence, $\Phi_{i,t-1} = 0$. After the arrival of the p packets, there holds $l_{it,S} = B$ yielding $l_{it,A} \leq l_{it,S}$ and, hence, $\Phi_{it} = 0 = \Phi_{i,t-1}$. Since the single potentials do not change, neither does the total potential. Now we assume that *ADV* loses p_0 of the arriving p packets. Then $\Phi_{i,t-1} = (l_{i,t-1,A} - l_{i,t-1,S})_+ \geq p_0$. After the arrival of the p packets, there hold $l_{it,A} = B = l_{i,t-1,A} + (p - p_0)$ and $l_{it,S} = l_{i,t-1,S} + p$ yielding $(l_{it,A} - l_{it,S})_+ = (l_{i,t-1,A} + (p - p_0) - l_{i,t-1,S} - p)_+ = (l_{i,t-1,A} - l_{i,t-1,S} - p_0)_+ = (l_{i,t-1,A} - l_{i,t-1,S})_+ - p_0$ and, hence, $\Phi_{it} = \Phi_{i,t-1} - p_0$. \square

LEMMA 9. *During each transmission step the potential can change by at most 1.*

Proof. If *ADV* and *SGR* serve the same queue, the potential does not change at all. Let *ADV* serve queue i while *SGR* serves queue $j \neq i$. Let t^a and t be the moments after the arrival and the transmission steps, respectively. $\Phi_{it} = (l_{it,A} - l_{it,S})_+ = (l_{it^a,A} - l_{it^a,S})_+ = (l_{it^a,A} - l_{it^a,S} - 1)_+$ and $\Phi_{jt} = (l_{jt,A} - l_{jt,S})_+ = (l_{jt^a,A} - (l_{jt^a,S} - 1))_+ = (l_{jt^a,A} - l_{jt^a,S} + 1)_+$. Since $0 \leq (x+1)_+ - x_+ \leq 1$, we derive $-1 \leq \Phi_{it} - \Phi_{it^a} \leq 0$ and $0 \leq \Phi_{jt} - \Phi_{jt^a} \leq 1$. Hence there holds $-1 \leq \Phi_t - \Phi_{t^a} \leq 1$. \square

LEMMA 10. *During transmission step t the potential increases if and only if ADV serves a queue currently having potential 0 while SGR serves a queue having positive potential afterward.*

Proof. Let the potential increase by 1. Let *ADV* serve queue i while *SGR* serves queue $j \neq i$. As shown in Lemma 9, $-1 \leq \Delta\Phi_{it} \leq 0$ and $0 \leq \Delta\Phi_{jt} \leq 1$. Hence the potential increases by 1 if and only if $\Delta\Phi_{it} = 0$ and $\Delta\Phi_{jt} = 1$. On the one hand, if $\Phi_{i,t-1} > 0$, there holds $\Phi_{it} = \Phi_{i,t-1} - 1$ and, hence, $\Delta\Phi_{it} = -1$. On the other hand, if $\Phi_{jt} = 0$, there holds $\Phi_{j,t-1} = 0$ and, hence, $\Delta\Phi_{jt} = 0$. So, the potential increases if and only if $\Phi_{i,t-1} = 0$ and $\Phi_{jt} > 0$. \square

Before stating the next lemma, in the following three paragraphs, we define some new terms and introduce some further notation that will be used throughout the remainder of this section. If the potential increases, the queue served by *SGR* is called the *causal queue*, whereas the one served by *ADV* is termed *counter queue*. Whenever the potential increases, the situation of *ADV* worsens in such a way that *ADV* buffers more packets in queue j than *SGR* does. But, the same is true, interchanging their roles, for *SGR* and queue i . The difference in the number of packets held by *ADV* and *SGR* in queue i increases whenever Φ increases and *ADV* serves i . Hence, Φ measures the number of packets that *SGR* has already lost or could lose if *ADV* replenishes the corresponding queues. These replenishments are necessary to generate a larger throughput for *ADV*.

If t is a time step where the potential does not increase during packet transmission, we call t an *additional time step* and denote their number by T_0 . Hence, Φ increases $T - T_0$ times. Let T_{-1} be the number of time steps in which the potential decreases during packet transmission. Obviously, $T_{-1} \leq T_0$. Furthermore, we derive from

Lemma 8 that Φ decreases by L_0 during the arrival steps, where L_0 is the total number of packets lost by ADV . We have $\Phi_T = T - T_0 - T_{-1} - L_0$. Let T_A and T_S denote the throughputs of ADV and SGR , respectively. From $T_A = T_S + \Phi_T$ and $T_S = T$, we derive

$$(2) \quad \frac{T_A}{T_S} = \frac{T + \Phi_T}{T} \leq \frac{T + T - T_0 - T_{-1} - L_0}{T} = 2 - \frac{T_0 + T_{-1} + L_0}{T}.$$

In the following, we shall present buffer configurations, where the potential does not increase, and hence derive that $\frac{T_0 + T_{-1} + L_0}{T} \geq \frac{1}{9}$, establishing the $(2 - \frac{1}{9})$ -competitiveness of SGR .

The queues are divided into $B + 1$ sets Q^0, \dots, Q^B , where queue q is a member of Q^k if and only if k is the maximum load of q in SGR 's configuration while processing σ . In the following analysis we can ignore Q^0 , as no packets arrive there. Furthermore, depending on SGR 's configuration at q , we call q a Q_2 -queue if SGR currently buffers at least $\lfloor \frac{B}{2} \rfloor + 1$ packets in q . In case of SGR 's buffering at most $\lfloor \frac{B}{2} \rfloor$ packets in q , we call q a Q_{12} -queue if q has already had a total load of B packets, i.e., all buffers have been populated; otherwise we call it a Q_{11} -queue. By s_{11}, s_{12} , and s_2 we denote the number of time steps in which the potential increases while SGR serves a Q_{11} -, Q_{12} -, and Q_2 -queue, respectively. We partition s_{11} into s_{111} and s_{112} , where we assign an s_{11} time step to s_{111} if the counter queue is a Q_{11} -queue in SGR 's configuration, and to s_{112} , otherwise. Finally, let $b = \lfloor \frac{B}{2} \rfloor$, $L = \{1, \dots, b\}$, $R = \{b + 1, \dots, B\}$, and $R^* = R \setminus \{B\}$.

LEMMA 11. *The following inequality holds:*

$$L_0 + T_0 \geq \left(s_2 - (B - b) \sum_{k \in R} |Q^k| \right)_+.$$

Proof. Let $k \in R$ and $j \in Q^k$ be a queue that SGR 's serving of which has already increased s_2 at least $B - b$ times. We conclude that at least B packets have arrived at j because, at each of these time steps, j buffers more than b packets and one packet is transmitted at each such time step. For each further increase of s_2 , a buffer in queue j must have been repopulated due to a further packet arrival. If ADV can accept the arriving packet, ADV must have served j , too. In these time steps, ADV serves a queue having positive potential. Hence, they are additional. If ADV cannot accept the arriving packet, ADV has a further packet loss. Thus, s_2 can increase at most $B - b$ times at SGR 's serving j without additional time steps or packet loss for ADV , and each further such increase induces either an additional time step or another packet loss for ADV and, thus, increases by 1 either T_0 or L_0 . Since we have this result for all queues $j \in Q^k, k \in R$, there can be at most $(B - b) |\bigcup_{k \in R} Q^k| = (B - b) \sum_{k \in R} |Q^k|$ time steps at which s_2 increases without an increase of $L_0 + T_0$. We derive that if s_2 exceeds $(B - b) \sum_{k \in R} |Q^k|$, the amount of exceedence is a lower bound for $L_0 + T_0$. Since $L_0 + T_0$ is nonnegative, we can strengthen our result by adding the $(\cdot)_+$ operator. \square

LEMMA 12. *The following inequality holds:*

$$T_0 \geq (s_{111} - b|Q^B|)_+ + s_{112} + s_{12} + (B - 2b)|Q^B| - T_{-1}.$$

Proof. We investigate s_{11} and s_{12} increases and focus on steps in which queue i is counter queue. We first study the case when i is a Q_{11} -queue and then consider the setting when i is a Q_{12} -queue.

We first observe that if i is a Q_{11} -queue, then by the definition of SGR the potential increase cannot be one assigned to s_{12} . Suppose that i is used n_i times as a counter queue for an s_{11} increase while i is a Q_{11} queue itself. We denote these time steps by $t_1 < \dots < t_{n_i}$. First, we assume that $i \in Q^k, k < B$. In this case, SGR has no packet loss in i . Due to Lemma 10, ADV buffers at most as many packets in i as SGR before the transmission steps at t_1, \dots, t_{n_i} . Since each packet is transmitted only once, there exist time steps $t'_1 < \dots < t'_{n_i}$, with $t'_j > t_j, 1 \leq j \leq n_i$, where SGR serves i while ADV does not and SGR buffers more packets than ADV in i . These time steps are additional. Now, assume that $i \in Q^B$ and that SGR buffers B packets in i for the first time at time t . Since i cannot be a Q_{11} -queue after t , we derive that $t_{n_i} < t$. At each $t_j, 1 \leq j \leq n_i$, SGR buffers at most b packets in i . We claim that there exist time steps $t'_1 < \dots < t'_{n_i-b} < t$, with $t'_j > t_j, 1 \leq j \leq n_i - b$, where SGR serves queue i while ADV does not and SGR buffers more packets than ADV in queue i . These time steps are additional. To see the claim, take the time steps t_j in increasing order and match each one with the next unmatched time step $t'_j > t_j$ at which SGR serves i . Clearly, the unmatched t_j form a consecutive subsequence of t_1, \dots, t_{n_i} that includes t_{n_i} . Each unmatched time step corresponds to an increase of 1 in the buffer population difference between SGR and ADV . If more than b time steps were unmatched, then SGR would buffer more than b packets in i at time t_{n_i} , contradicting the fact that i is a Q_{12} -queue at that time. Hence, at most the b time steps $t_j, n_i - b < j \leq n_i$, are not matched. Combining the arguments of this paragraph, we derive that $T_0 \geq (s_{111} - b|Q^B|)_+$.

Now, we assume that at time t' , queue i is a Q_{12} -queue and used as a counter queue for an s_{11} or s_{12} increase. Then, there holds $i \in Q^B$ and $t' \geq t$. By Lemma 10, in both ADV 's and SGR 's configurations, only the L -part is populated in queue i . If i is used as a counter queue during $n'_i > b$ increases of s_{11} or s_{12} and it is a Q_{12} -queue at all the respective time steps, then, as above, we can prove that there are at least $n'_i - b$ time steps in which SGR serves queue i while ADV does not and SGR buffers more packets than ADV in queue i . These time steps are additional. Moreover, these time steps are different from those identified in the last paragraph because they occur after t .

Next, we consider the first use of i as a counter queue for an s_{11} or s_{12} increase when i is a Q_{12} -queue. Consider the first $B - b$ time steps after t satisfying one of the following properties: (a) both SGR and ADV serve i ; (b) only the algorithm currently having the larger buffer population in i serves i . These time steps exist and all occur before the first use of i being a Q_{12} -queue because SGR serves i at least $B - b$ times during that time window. The $B - b$ time steps are additional. However, they need not be distinct for the various queues i and i' and need not be distinct from the additional time steps identified so far. If a time step is counted twice, ADV serves i having a larger population than SGR in that queue, while SGR serves i' having a larger population in there. Note that the potential drops during packet transmission in this case. In order not to count one time step twice when summing up over all queues, we diminish this amount of time steps by T_{-1} . Since $n'_i - b + B - b = n'_i + (B - 2b)$, combining the arguments of the three paragraphs, we obtain the lemma. \square

While the two lemmas above cover the case that there are many time steps in which the potential increases, the following one considers the opposite situation.

LEMMA 13. *The following inequality holds:*

$$T_0 \geq T_{0,11} + T_{0,12} + T_{0,2},$$

where

$$\begin{aligned} T_{0,11} &= \left(\sum_{k \in L} k|Q^k| + \sum_{k \in R^*} b|Q^k| - s_{11} \right)_+, \\ T_{0,12} &= (b|Q^B| - s_{12})_+, \\ T_{0,2} &= \left(\sum_{k \in R} (k - b)|Q^k| - s_2 \right)_+. \end{aligned}$$

Proof. *SGR* must serve each buffer cell that is populated at least once. If $k \in L$ and $i \in Q^k$, in *SGR*'s configuration, the populated part consists only of the k first cells and i is always a Q_{11} -queue and, hence, can only cause s_{11} increases. If $k \in R^*$ and $i \in Q^k$, in *SGR*'s configuration, i is always a Q_{11} -queue when the j th cell, $1 \leq j \leq b$, becomes unpopulated and, hence, can only cause s_{11} increases at these time steps. If $i \in Q^B$, in *SGR*'s configuration, i is always a Q_{12} -queue when the j th cell, $1 \leq j \leq b$, becomes unpopulated after the buffer has once been populated by B packets and can only cause s_{12} increases afterward. If $k \in R$ and $i \in Q^k$, in *SGR*'s configuration, the populated R -part consists of $k - b$ cells. There must be additional time steps if the potential increases less often than the number of populated buffer cells. \square

LEMMA 14. *If $B \geq 2$, the following inequalities hold:*

$$\begin{aligned} T_0 + T_{-1} &\geq s_{12}, \\ 2T_0 + T_{-1} &\geq s_{11} + (B - 2b)|Q^B|, \\ L_0 + 5T_0 + 2T_{-1} &\geq s_2 - (B - 2b) \sum_{k \in R^*} |Q^k|. \end{aligned}$$

Proof. The first inequality is an immediate result of Lemma 12. Summing up the inequalities of Lemmas 12 and 13 yields

$$\begin{aligned} 2T_0 + T_{-1} &\geq (s_{111} - b|Q^B|)_+ + s_{112} + s_{12} + (B - 2b)|Q^B| + (b|Q^B| - s_{12})_+ \\ &\geq s_{111} + s_{112} + (-b + (B - 2b) + b)|Q^B| \\ &= s_{11} + (B - 2b)|Q^B|, \end{aligned}$$

establishing the second inequality. By the summation of the inequalities of Lemmas 11, 12, and 13, we get

$$\begin{aligned} L_0 + 3T_0 + T_{-1} &\geq \left(s_2 - (B - b) \sum_{k \in R} |Q^k| \right)_+ + s_{112} + s_{12} \\ &\quad + (B - 2b)|Q^B| + (b|Q^B| - s_{12})_+ \\ &\quad + \left(\sum_{k \in L} k|Q^k| + \sum_{k \in R^*} b|Q^k| - s_{11} \right)_+ \\ &\geq s_2 - s_{111} - (B - 2b) \sum_{k \in R^*} |Q^k|. \end{aligned}$$

The addition of the second inequality of the lemma yields $L_0 + 5T_0 + 2T_{-1} \geq s_2 - (B - 2b) \sum_{k \in R^*} |Q^k|$. \square

THEOREM 5. *SGR achieves a competitive ratio of 17/9.*

Proof. Let β denote $(B - 2b) \sum_{k \in R^*} |Q^k|$. If $i \in Q^k$ and $k \in R^*$, at least $b + 1$ packets arrive at i . Hence $T \geq (b + 1)\beta$, and, thus, $\frac{\beta}{T} \leq \frac{1}{b+1}$. The summation of the three inequalities in Lemma 14 yields $L_0 + 8T_0 + 4T_{-1} \geq s_{11} + s_{12} + s_2 - \beta$. We derive

$$L_0 + 9T_0 + 4T_{-1} \geq s_{11} + s_{12} + s_2 + T_0 - \beta = T - \beta$$

and, hence, $L_0 + T_0 + T_{-1} \geq \frac{1}{9}L_0 + T_0 + \frac{4}{9}T_{-1} \geq \frac{T-\beta}{9}$, yielding

$$(L_0 + T_0 + T_{-1})/(T - \beta) \geq 1/9.$$

If B is even, then $\beta = 0$ and $(L_0 + T_0 + T_{-1})/T \geq 1/9$, and by (2) the theorem follows. If B is odd, $\frac{L_0 + T_0 + T_{-1}}{T} = \frac{L_0 + T_0 + T_{-1}}{T - \beta} (1 - \frac{\beta}{T}) \geq \frac{1}{9} (1 - \frac{1}{b+1}) = \frac{1}{9} (1 - \frac{2}{B+1})$. Let $\delta_B = \frac{2}{B+1}$. Then $\lim_{B \rightarrow \infty} \delta_B = 0$ and we derive by (2) that

$$T_A/T_S \leq 2 - (1 - \delta_B)/9 = 17/9 + \delta_B/9 \rightarrow 17/9 \text{ as } B \rightarrow \infty. \quad \square$$

We can strengthen our analysis and show that, for $B = 2$, *SGR* is optimal.

THEOREM 6. *For $B = 2$, *SGR* achieves a competitive ratio of $13/7$.*

Proof. If we put $B = 2$ into the inequalities of Lemmas 11, 12, and 13, they take the following forms: $L_0 + T_0 \geq (s_2 - |Q^2|)_+$, $T_0 \geq (s_{111} - |Q^2|)_+ + s_{112} + s_{12} - T_{-1}$, and $T_0 \geq (|Q^1| - s_{11})_+ + (|Q^2| - s_{12})_+ + (|Q^2| - s_2)_+$, from which we deduce the corresponding inequalities of Lemma 14 for $B = 2$: $T_0 + T_{-1} \geq s_{12}$ and $2T_0 + T_{-1} \geq s_{11}$. Summing up the three inequalities in Lemmas 11, 12, and 13, we can strengthen the third inequality of Lemma 14: $L_0 + 3T_0 + T_{-1} \geq (s_2 - |Q^2|)_+ + s_{12} + (|Q^2| - s_{12})_+ \geq s_2 - |Q^2| + s_{12} + |Q^2| - s_{12} = s_2$. Since $5T_0$ is replaced by $3T_0$ in the left-hand side, we get a competitive factor of $\frac{13}{7}$ instead of $\frac{17}{9}$ in Theorem 5. \square

3.2. Resource augmentation. We first study the case that an online algorithm is granted additional buffer space. Then we consider different transmission rates.

3.2.1. Additional buffer space. Let *ADV* and *ALG* have buffers of size B and $B + A$ for each queue, respectively. We denote the ratio of the additional buffer space A and the standard buffer space B by c . Recall that an algorithm is called work-conserving if in any time step it serves some nonempty queue, provided such nonempty queues exist.

THEOREM 7. *Every work-conserving online algorithm *ALG* having additional buffer space $A = cB$ per queue is $(\frac{c+2}{c+1})$ -competitive.*

Proof. Let σ be any arrival sequence. As in the analysis of *SGR*, we can restrict ourselves to arrival sequences that terminate when *ALG* has completely cleared its buffer. Furthermore, we assume that in the case of packet loss at a queue either *ADV* or *ALG* loses packets. If there is no packet loss at all or if only *ADV* loses packets, then the throughput of *ALG* is at least as large as that of *ADV* and our claim holds. Hence we may assume that *ALG* loses packets. We partition the queues into two disjoint sets Q^ℓ and Q^o , where Q^ℓ comprises exactly those in which *ALG* loses packets when serving σ . The difference in the total packet losses corresponds to *ADV*'s buffer population at the time when *ALG*'s buffers become empty. Let T_{ADV} and T_{ALG} denote the throughputs of *ADV* and *ALG*, respectively. By L_{ADV} and L_{ALG} we denote the losses of *ADV* and *ALG*, respectively. We derive

$$T_{ADV} - T_{ALG} = L_{ALG} - L_{ADV} \leq |Q^\ell|B.$$

Furthermore, the total throughput is given by the throughputs in Q^o and Q^ℓ , denoted by $T_{ADV}^o, T_{ADV}^\ell, T_{ALG}^o$, and T_{ALG}^ℓ , respectively. So $T_{ADV} = T_{ADV}^o + T_{ADV}^\ell$ and

$T_{ALG} = T_{ALG}^o + T_{ALG}^\ell$. Since there occurred packet loss in the queues in Q^ℓ , at least $A + B = (1 + c)B$ packets must have arrived there, all of which could be accepted by ALG . Hence there holds

$$T_{ALG}^\ell \geq (1 + c)|Q^\ell|B$$

yielding

$$\begin{aligned} \frac{T_{ADV}}{T_{ALG}} &= \frac{T_{ALG} + L_{ALG} - L_{ADV}}{T_{ALG}} = 1 + \frac{L_{ALG} - L_{ADV}}{T_{ALG}} = 1 + \frac{L_{ALG} - L_{ADV}}{T_{ALG}^o + T_{ALG}^\ell} \\ &\leq 1 + \frac{L_{ALG} - L_{ADV}}{T_{ALG}^\ell} \leq 1 + \frac{|Q^\ell|B}{(1 + c)|Q^\ell|B} = 1 + \frac{1}{1 + c} = \frac{c + 2}{c + 1}. \quad \square \end{aligned}$$

THEOREM 8. *For any greedy algorithm GR , the upper bound of $\frac{c+2}{c+1}$ is tight for all B and all $A = cB$.*

Proof. For all values of A and B we construct an instance with a throughput ratio arbitrarily close to $\frac{c+2}{c+1}$. First, we assume that both ADV and GR have buffers of size $B + A$. From the previous section we know that we can construct a staircase sequence such that ADV has a throughput of about $2m(B + A)$, whereas GR has a throughput of only $m(B + A)$ packets. While the staircase is built up in GR , ADV always serves the corresponding queues such that they are empty in ADV 's configuration. This results in the fact that ADV can accept additional $B + A$ packets in these queues. Although—now—the buffer of ADV is smaller than the one of GR , ADV can build up a staircase of level $B + A$ in GR 's configuration. The difference consists only of ADV 's not being able to accept $B + A$, but only B additional packets per queue, while GR cannot accept any of them. Hence, GR accepts $B + A$ packets per queue, whereas ADV accepts $B + A + B = 2B + A$ packets per queue. This results in the following throughput ratio:

$$\frac{T_{ADV}}{T_{GR}} = \frac{2B + A}{B + A} = \frac{2B + cB}{B + cB} = \frac{c + 2}{c + 1}. \quad \square$$

3.2.2. Increased transmission rate. Now we assume that ADV and ALG have the same buffer sizes, but ALG can transmit k packets per time step while ADV is still able to transmit only one packet per time step.

THEOREM 9. *Every work-conserving online algorithm ALG is $(1 + \frac{1}{k})$ -competitive if its transmission rate is the k -fold of the adversary's one.*

Proof. As usual, we restrict ourselves to sequences which terminate when ALG has completely emptied its buffers and assume that in the case of packet loss at a queue either ADV or ALG loses packets. Let $l_{it,ADV}$ and $l_{it,ALG}$ be the loads (i.e., the numbers of packets) in queue i at time t in the configurations of ADV and ALG , respectively. By $L_{it,ADV}$ and $L_{it,ALG}$ we denote the numbers of packets ADV and ALG lose at queue i at time t , respectively. Let T_{ADV} , L_{ADV} , T_{ALG} , and L_{ALG} denote the throughputs and losses of ADV and ALG , respectively. For each queue i we define a potential function $\Phi_{it} = (l_{it,ALG} - l_{it,ADV})_+$ which sums up to $\Phi_t = \sum_{i=1}^m \Phi_{it}$. At time t , ALG can lose packets in queue i only if $\Phi_{it} > 0$. Then $\Delta\Phi_{it} = -L_{it,ALG}$. During each transmission step, Φ_{it} can increase only if ADV serves a queue not served by ALG . But if so, ALG transmits k packets from other queues, hence $\frac{1}{k}\Delta T_{t,ALG} \geq \Delta\Phi_{it}$. So we derive

$$\Delta\Phi_t \leq \frac{1}{k}\Delta T_{t,ALG} - L_{t,ALG}.$$

Let τ denote the time step when ALG 's buffers become empty. Since $\Phi_0 = 0 = \Phi_\tau$, it is the case that $0 \leq \frac{T_{ALG}}{k} - L_{ALG}$, hence $L_{ALG} \leq \frac{T_{ALG}}{k}$, giving us the following throughput ratio:

$$\frac{T_{ADV}}{T_{GR}} = \frac{T_{ALG} + (L_{ALG} - L_{ADV})}{T_{ALG}} \leq \frac{T_{ALG} + L_{ALG}}{T_{ALG}} \leq 1 + \frac{1}{k}. \quad \square$$

THEOREM 10. *If $B = 1$, every work-conserving online algorithm ALG with transmission rate greater than that of the adversary by a factor of k has a competitive ratio of at least $1 + 1/k$.*

Proof. Let there be m queues, each of them populated at the beginning. While ALG serves $k \lfloor \frac{m}{k+1} \rfloor$ queues, ADV serves other $\lfloor \frac{m}{k+1} \rfloor$ ones. At time $\lfloor \frac{m}{k+1} \rfloor$, one packet arrives at each of the latter queues. ADV accepts all new packets, whereas ALG must reject of all of them. This pattern is repeated on the queues still populated by ALG , resulting in $\lfloor (\frac{1}{k+1})^2 m \rfloor$ new packets. We iterate this procedure on $\lfloor (\frac{1}{k+1})^3 m \rfloor, \lfloor (\frac{1}{k+1})^4 m \rfloor, \dots$ queues not served yet by ALG until the block size reaches 1. Since ALG accepts only the m initial packets and ADV can accept all the other packets as well, we get

$$\frac{T_{ADV}}{T_{ALG}} = \frac{\sum_{j=0}^{\infty} \lfloor (\frac{1}{k+1})^j m \rfloor}{m}$$

and this expression tends to

$$\frac{\sum_{j=0}^{\infty} (\frac{1}{k+1})^j m}{m} = 1 / \left(1 - \frac{1}{k+1} \right) = 1 + \frac{1}{k}$$

as m goes to infinity. \square

4. An optimal offline algorithm. We present an optimal offline algorithm for our problem.

ALGORITHM SFOD (SHORTEST FORWARD OVERFLOW DISTANCE). If there can no longer be any buffer overflow, serve the queues in an arbitrary order. Otherwise select in each transmission step t a queue in which the next overflow would occur if none of the queues were served. More precisely, let $l_{i,t}$ and $\sigma_{i,t}$ denote the length of queue i at time t and the number of packets arriving at queue i at time t , respectively. At time t , determine the earliest time step $t_0 > t$ such that $l_{i,t} + \sum_{\tau=t+1}^{t_0-1} \sigma_{i,\tau} \leq B$ for all i and $l_{i,t} + \sum_{\tau=t+1}^{t_0} \sigma_{i,\tau} > B$ for some queue i . If t_0 exists, select queue i ; otherwise serve any queue.

The algorithm can be implemented so that it runs in linear time.

THEOREM 11. *SFOD is an optimal offline algorithm.*

Proof. We prove the following two statements, which imply the theorem.

1. For each arrival sequence σ there exists an optimal schedule satisfying the *SFOD* rule.
2. Each schedule satisfying the *SFOD* rule is optimal.

We first prove statement 1. Let σ be any arrival sequence and let S be an optimal schedule for σ . We show that we can convert S into an *SFOD* schedule S' without decreasing the throughput. If S satisfies the *SFOD* property, then there is nothing to show. Now assume that there exists a time step t in which S does not satisfy *SFOD*. Let S serve queue i at time t and let queue j be a queue in which the next buffer overflow would occur after t . S' is a copy of S , but at time t , S' serves queue j

instead of i . Let t_0 denote the time step in which the next overflow in queue j would occur if it were no longer served. Due to the *SFOD* rule, the next overflow in queue j would occur before the next overflow in queue i . If S serves queue j at time t' with $t < t' < t_0$, S' serves queue i at time t' . Then at time t' both S and S' are again in the same configuration and their throughputs are the same. If S does not serve queue j until t_0 , the buffer will overflow, and S will lose one packet more than S' will. If there is an overflow at queue i later on, S' will lose one packet more than S will. Then, the configurations of S and S' are the same, again, and yield the same throughputs. Hence, in either case, we get $T_{S'} \geq T_S$. We can repeatedly apply this procedure until we obtain a schedule S' satisfying the *SFOD* rule. The procedure terminates because σ is finite.

We next prove statement 2. We derive from statement 1 that there is an optimal schedule \hat{S} satisfying the *SFOD* rule. Let S be any *SFOD* schedule. If there is a packet loss in S at time t , \hat{S} must lose the same number of packets because in both schedules queues have been served, where the next overflow was nearest in the future. Hence there can be a difference between S and \hat{S} only if there are several queues whose next overflows occur at the same time. If packet loss is inevitable at t , S and \hat{S} lose the same number of packets at t because they served the queues concerned as often as possible. \square

5. Conclusions and open problems. In this paper we have studied the problem of maximizing the throughput of unit-value packets at a switch with m input buffers. We have developed improved upper and lower bounds on the competitive performance of online algorithms. In particular, we have devised a strategy, called *semigreedy*, that achieves a competitiveness of $\frac{17}{9}$ and is the first deterministic algorithm that beats the trivial upper bound of 2. We remark here that after the publication of our preliminary work, improved deterministic and randomized algorithms were developed in [3, 16].

An important problem is to determine tight upper and lower bounds on the performance of deterministic and randomized algorithms. Furthermore, it is interesting to study scenarios in which data packets have values and we wish to maximize the total value of transmitted packets. As mentioned in the introduction, Azar and Richter [4] gave a general technique that transforms any c -competitive algorithm for a single queue into a $2c$ -competitive algorithm for multiqueue systems. As a result, they derived competitive algorithms for various settings such as preemptive and nonpreemptive models with both 2 values and an arbitrary number of values. It is conceivable that improved solutions are possible by investigating the respective settings directly.

Acknowledgments. We thank two anonymous referees for their helpful comments which improved the presentation of the paper.

ANALYSIS OF LINK REVERSAL ROUTING ALGORITHMS*

COSTAS BUSCH[†] AND SRIKANTA TIRTHAPURA[‡]

Abstract. Link reversal algorithms provide a simple mechanism for routing in communication networks whose topology is frequently changing, such as in mobile ad hoc networks. A link reversal algorithm routes by imposing a direction on each network link such that the resulting graph is a destination oriented DAG. Whenever a node loses routes to the destination, it reacts by reversing some (or all) of its incident links. Link reversal algorithms have been studied experimentally and have been used in practical routing algorithms, including TORA [V. D. Park and M. S. Corson, A highly adaptive distributed routing algorithm for mobile wireless networks, in *Proc. INFOCOM*, IEEE, Los Alamitos, CA, 1997, pp. 1405–1413].

This paper presents the first formal performance analysis of link reversal algorithms. We study these algorithms in terms of *work* (number of node reversals) and the *time* needed until the network stabilizes to a state in which all the routes are reestablished. We focus on the *full reversal* algorithm and the *partial reversal* algorithm, both due to Gafni and Bertsekas [*IEEE Trans. Comm.*, 29 (1981), pp. 11–18]; the first algorithm is simpler, while the latter has been found to be more efficient for typical cases. Our results are as follows:

- The full reversal algorithm requires $O(n^2)$ work and time, where n is the number of nodes that have lost routes to the destination. This bound is tight in the worst case.
- The partial reversal algorithm requires $O(n \cdot a^* + n^2)$ work and time, where a^* is a nonnegative integral function of the initial state of the network. Further, for every nonnegative integer α , there exists a network and an initial state with $a^* = \alpha$, and with n nodes that have lost their paths to the destination, such that the partial reversal algorithm requires $\Omega(n \cdot a^* + n^2)$ work and time.
- There is an inherent lower bound on the worst-case performance of link reversal algorithms. There exist networks such that for *every* deterministic link reversal algorithm, there are initial states that require $\Omega(n^2)$ work and time to stabilize. Therefore, surprisingly, the full reversal algorithm is asymptotically optimal in the worst case, while the partial reversal algorithm is not, since a^* can be arbitrarily larger than n .

1. Introduction. A mobile ad hoc network is a temporary interconnection network of mobile wireless nodes without a fixed infrastructure. The attractive feature of such a network is the ease with which one can construct it: there is no physical setup needed at all. If mobile nodes come within the wireless range of each other, then they will be able to communicate. More significant, even if two mobile nodes aren't within the wireless range of each other, they might still be able to communicate through a multihop path. However, the lack of a fixed infrastructure makes routing between nodes a hard problem. Since nodes are moving, the underlying communication graph is changing, and the nodes have to adapt quickly to such changes and reestablish their routes.

1.1. Link reversal. *Link reversal* routing algorithms [12, Chapter 8] are adaptive, self-stabilizing, distributed algorithms used for routing in mobile ad hoc networks. The first link reversal algorithms are due to Gafni and Bertsekas [7]. Link reversal is the basis of the temporally ordered routing algorithm TORA [10], and has also been used in the design of leader election algorithms for mobile ad hoc networks [9]. Link reversal routing is best suited for networks in which the rate of topological changes is high enough to rule out algorithms based on shortest paths, but not so high as to make flooding the only alternative.

Consider the graph representing the network, where the vertices are the wireless nodes, and each node has a link with each other node within its transmission radius. We assume that this underlying graph is undirected; i.e., the communication links are all bidirectional. Link reversal algorithms route on this graph by assigning directions to different links, hence converting it to a directed graph. A directed graph G is said to be connected if the underlying undirected graph of G (formed upon erasing the directions on the edges of G) is connected.

DEFINITION 1.1. *A connected directed acyclic graph with a single destination node is said to be destination oriented iff every directed path in the graph leads to the destination.*

For a given destination node, the link reversal algorithms assign directions to the links of this graph such that the resulting directed graph is a destination oriented directed acyclic graph (see Figure 1). Routing on a destination oriented network is easy: when a node receives a packet, it forwards the packet on *any* outgoing link, and the packet will eventually reach the destination.¹

The task of the link reversal algorithm is to create and maintain the routes to the destination. When two nodes move out of each other's range, the link between them is destroyed, and some nodes might lose their routes to the destination. The routing algorithm reacts by performing *link reversals* (i.e., reorienting some of the edges) so that the resulting directed graph is again destination oriented. In particular, when a node finds that it has become a *sink* (has lost all of its outgoing links), then the node reacts by reversing the directions of some or all of its incoming links. The link reversals due to one node may cause adjacent nodes to perform reversals, and in this way, the reversals propagate in the network until the routes to the destination are reestablished.

Gafni and Bertsekas [7] describe a general family of link reversal algorithms and present two particular algorithms: the *full reversal* algorithm and the *partial reversal* algorithm (referred to as the GB algorithms in the rest of this paper). In the full reversal algorithm, when a node becomes a sink, it reverses the directions of all of its incident links. In the partial reversal algorithm, the sink reverses the directions of only those incident links that have not been recently reversed by adjacent nodes (a detailed description appears in the following section). The full reversal algorithm is simpler to implement, but the partial reversal algorithm may need fewer link reversals in some cases. Gafni and Bertsekas show that when link failures occur, these algorithms *eventually* converge to a destination oriented graph. However, it was not known how many reversals the nodes performed, or how much time it would take till convergence.

1.2. Performance of link reversal. We present the first formal performance analysis of link reversal routing algorithms. We give tight upper and lower bounds

¹If there are multiple destinations in the network, then there is a separate directed graph for each destination; here, we will assume for simplicity that there is only one destination.

FIG. 1. Sample executions of the GB full and partial reversal algorithms. Each transition is labeled with the nodes that reverse.

on the performance of the full and partial reversal algorithms. We also show a lower bound on the performance of *any* deterministic link reversal algorithm. Surprisingly, from the perspective of worst-case performance, the full reversal algorithm is asymptotically optimal while the partial reversal algorithm is not.

Our setting for analysis is as follows. Suppose topological changes occur in the network, driving the system to a state in which some nodes have lost their paths to the destination. This is called the *initial state* of the network. If there are no further

topological changes, the network is said to have *stabilized* when it again becomes destination oriented. We analyze two metrics:

Work: The number of *node reversals* until stabilization; a node reversal is the action of a sink reversing some or all of its adjacent links. This is a measure of the power and computational resources consumed by the algorithm in reacting to topological changes.

Time: The number of parallel steps until stabilization, which is a measure of the speed in reacting to topological changes. We model reversals so that each reversal requires one time step, and reversals may occur simultaneously whenever possible.

Reversals are implemented using *heights*. A reversal algorithm assigns a height to every node in the network. The link between adjacent nodes is directed from the node of greater height to the node of lesser height. A sink performs a reversal by increasing its height by a suitable amount. This will reverse the direction of some or all of its incident links. We consider *deterministic* link reversal algorithms, in which a sink increases its height according to some deterministic function of its own height and the heights of the adjacent nodes. The GB link reversal algorithms are deterministic.

In the analysis, we separate the nodes into bad and good. A node is *bad* if there is no route from the node to the destination. Any other node, including the destination, is *good*. Note that a bad node is not necessarily a sink. We present results for the following algorithms.

Full reversal algorithm. For the full reversal algorithm, we show that when started from an initial state with n bad nodes, the work and time needed to stabilize is $O(n^2)$. This bound is tight. We show that there are networks with initial states which require $\Omega(n^2)$ time for stabilization.

Our result for full reversal is actually stronger. For any network, we present a decomposition of the bad nodes in the initial state into *layers*, which allows us to predict *exactly* the work performed by each node in *any* distributed execution. A node in layer j will reverse exactly j times before stabilization. Our lower and upper bounds follow easily from the exact analysis.

Partial reversal algorithm. For the partial reversal algorithm, we show that when started from an initial state with n bad nodes, the work and time needed to stabilize is $O(n \cdot a^* + n^2)$, where a^* corresponds to the difference between the maximum and minimum heights of the nodes in the initial state. This bound is tight. We show that there are networks with initial states which require $\Omega(n \cdot a^* + n^2)$ time for stabilization.

The a^* value can grow unbounded as topological changes occur in the network. Consequently, in the worst case, the full reversal algorithm outperforms the partial reversal algorithm.

Deterministic algorithms. We show a lower bound on the worst-case work and time until stabilization for *any* deterministic reversal algorithm. We show that for any deterministic reversal algorithm on a given graph, there exists an initial state such that if a bad node d hops away from its closest good node, then it has to reverse d times before stabilization. Using this, we further show that there exist networks and initial states with n bad nodes such that the algorithm needs $\Omega(n^2)$ work and time until stabilization. As a consequence, from the worst-case perspective, the full reversal algorithm is work and time optimal, while the partial reversal algorithm is not.

Equivalence of executions. We show that for any deterministic reversal algorithm, all distributed executions of the algorithm starting from the same initial state are

equivalent: (1) the resulting final state of the network upon stabilization is the same, and (2) each node performs the same number of reversals until stabilization in all executions. As a result, the work of the algorithm is independent of the execution schedule.

1.3. Related work. Link reversal algorithms were introduced by Gafni and Bertsekas in [7], where they provide a proof that shows that a general class of link reversal algorithms, including the partial and full reversal algorithms, eventually stabilize when started from any initial state. However, they do not give work and time bounds.

The TORA [10] builds on a variation of the GB partial reversal algorithm and adds a mechanism for detecting and dealing with partitions (disconnected components) in the network. The practical performance of the TORA has been studied in [11]. A variant of a link reversal routing algorithm is the lightweight mobile routing (LMR) algorithm [5, 6]. An overview of link reversal routing algorithms can be found in [12, Chapter 8]. A performance comparison of various ad hoc routing algorithms, including TORA, is presented in [1]. Further surveys can be found in [13, 14].

Malpani, Welch, and Vaida [9] build a mobility aware leader election algorithm on top of TORA and present partial correctness proofs (TORA does not have any) showing the stability of the algorithm. Although all the above work use link reversal, none of them have any formal performance analysis.

In the context of distributed sensor networks, coordination algorithms which are based on the paradigm of *directed diffusion* [8] are closely related to link reversal algorithms. For example, Intanagonwiwat et al. [8] state that their algorithm is closest to the TORA algorithm [10] in its attempt to localize the repairs due to node failures. Hence, our analysis also might lead to a better understanding of the performance of directed diffusion.

Link reversal algorithms attempt to always maintain routes to destinations in ad hoc networks. In cases when the network is sparsely populated with nodes, or when the rate of topology changes is too high, it may be infeasible to maintain such paths to the destination. In such cases, other strategies are needed for data delivery, such as those in [3, 4] which do not maintain paths to destination at all, but instead transmit data through strategies based on gossiping.

Outline of the paper. The rest of the paper is organized as follows. Section 2 contains a description of the GB partial and full reversal algorithms as well as a definition of deterministic algorithms. In section 3 we show the equivalence of executions of a given deterministic algorithm. Sections 4 and 5 contain the analyses of the full and partial reversal algorithms, respectively. In section 6, we show the general lower bound for deterministic link reversal algorithms, and we conclude with a discussion and open problems in section 7.

2. Link reversal algorithms. We assume that each node has a unique integer id and denote the node with id i by v_i . The nodes have heights which are guaranteed to be unique (ties broken by node ids) and are chosen from a totally ordered set. A link is always directed from the node of greater height to the node of the smaller height. The destination has the smallest height, and it is a special kind of sink which never reverses. Since any directed path in such a graph always proceeds in the direction of decreasing height, *the directed graph will always be a directed acyclic graph (DAG)*. This is a significant feature, since the algorithms need not make further effort to maintain acyclicity in routing, and the graph remains acyclic even if topological changes occur.

If the underlying graph is connected, the link reversal algorithms bring the directed graph from its initial state to a state in which it is destination oriented. In our analysis, we consider only connected graphs. Note that there could possibly be multiple paths from any node to the destination. We now describe the two GB algorithms, adapting the discussion from [7], and then we define the class of deterministic algorithms.

Full reversal algorithm. In the full reversal algorithm, when a node becomes a sink it simply reverses the directions of all its incoming links (see top part of Figure 1, which is adapted from [7]). The algorithm can be implemented with heights as follows. The height h_i of node v_i is the pair (a_i, i) (the second field is used to break ties). The height of the destination (say v_d) is $(0, d)$. Heights are ordered lexicographically. If v_i is a sink, then its height upon reversal is updated to be larger than the heights of all its neighbors. Let $N(v_i)$ denote the set of adjacent nodes to v_i . Formally, the height of v_i after its reversal is $(\max\{a_j \mid v_j \in N(v_i)\} + 1, i)$.

Partial reversal algorithm. In the partial reversal algorithm, the height of each node v_i is a triple (a_i, b_i, i) . As in full reversal, node v_i reverses only when it becomes a sink. The height of v_i after reversal is greater than the height of at least one neighbor, but may not be greater than the height of every neighbor. The height of the destination v_d is $(0, 0, d)$. Heights are ordered lexicographically. The second field b_i helps the sink avoid reversing links toward adjacent nodes, which have caused the node to become a sink in the first place. Thus, reversals are not immediately propagated to parts of the network which have already reversed. Formally, let $\bar{h}_i = (\bar{a}_i, \bar{b}_i, i)$ denote the height of v_i after its reversal. See the bottom part of Figure 1 (adapted from [7]) for an example execution of the partial reversal algorithm. The partial reversal algorithm updates heights as follows:

- $\bar{a}_i = \min\{a_j \mid v_j \in N(v_i)\} + 1$.
- $\bar{b}_i = \min\{b_j \mid v_j \in N(v_i) \text{ and } \bar{a}_i = a_j\} - 1$ if there exists a neighbor v_j with $\bar{a}_i = a_j$; otherwise, $\bar{b}_i = b_i$.

The basic idea behind these functions is as follows. In a network state I , where v_i is a sink, we can divide the neighbors of v_i into two categories: (i) $\{v_j \mid a_j = a_i\}$ and (ii) $\{v_j \mid a_j > a_i\}$. Node v_i must have reversed after the last reversal of every node in category (i) since, otherwise, those nodes would have $a_j \geq a_i + 1$. On the other hand, nodes of category (ii) must have reversed after the last reversal of node v_i since, otherwise, the heights of those nodes would not be higher than a_i . Therefore, node v_i is a sink in state I due only to nodes of category (ii). Thus, when v_i reverses after state I , its new height should be set so that the links point only toward nodes of category (i). This is achieved by setting $\bar{a}_i = a_i + 1$. In order to make the nodes of category (ii) to point to v_i , we need only take care of nodes with $a_j = \bar{a}_i$, for which we adjust \bar{b}_i to be lower than all the corresponding b_j 's.²

Deterministic algorithms. A deterministic reversal algorithm is defined by a ‘‘height increase’’ function g . We assume that the heights are chosen from some totally ordered universe and that the heights of different nodes are unique. If node v is a sink of degree k , whose current height is h_v , and adjacent nodes v_1, v_2, \dots, v_k have heights h_1, h_2, \dots, h_k , respectively, then v 's height after reversal is $g(h_1, h_2, \dots, h_k, h_v)$. Function g is such that the sink reverses at least one of its incoming links. The GB full and partial reversal algorithms are deterministic.

²The function for the update of \bar{a}_i is expressed in terms of the minimum value of the neighbors, since topological changes might generate a state in which no neighbor has $a_j = a_i$.

3. Equivalence of executions. In this section, we prove some properties about deterministic link reversal algorithms. The main result of this section is that for any deterministic reversal algorithm, all executions that start from the same initial state are essentially equivalent: the resulting final state of the network upon stabilization is the same. We actually show the stronger result that each node performs the same number of reversals, with the same heights, until stabilization in all executions. We first give some basic definitions for states and executions; then we define the dependency graph, which will help to show that all executions are equivalent, and finally, we give the main result.

3.1. States, executions, and dependency graphs. Here we give basic definitions for states and executions. At any configuration of the network, the *node state* of a node v is defined as the current height of v . The *network state* is defined as the collection of the individual states of all the nodes in the network. Note that the network state uniquely determines the directions of all the links in the network.

A node reversal r is defined as a tuple $r = (v, h, H)$, where v is the sink executing the reversal, h is v 's height before reversal, and H is the set of the heights of all of v 's neighbors before the reversal. Given an initial state containing bad nodes, an *execution* E is defined as a sequence of reversals $E = r_1, r_2, \dots, r_k$, where $r_i = (v_i, h_i, H_i)$, and $1 \leq i \leq k$. A *complete execution* is defined as an execution that ends in a destination oriented graph; unless otherwise stated, we will refer to complete executions from here on.

Clearly, there are many possible executions starting from the same initial state. We give the following definition for equivalent executions.

DEFINITION 3.1. *Starting from the same initial state, two executions are equivalent if they give the same final state.*

In order to show that two executions are equivalent, we will use the dependency graphs of the executions which we define next. Any execution imposes a partial order on the reversals. The partial order induced by execution $E = r_1, r_2, \dots, r_k$ is defined as a directed graph whose nodes are the reversals $r_i, i = 1, \dots, k$. There is a directed edge from $r_i = (v_i, h_i, H_i)$ to $r_j = (v_j, h_j, H_j)$ if

- v_j is a neighbor of v_i , and
- r_j is the first reversal of v_j after r_i in execution E .

We will refer to this graph as the *dependency graph* of execution E . Intuitively, if there is a directed path between reversals r_i and r_j in the dependency graph, then the order of these two reversals cannot be interchanged. Moreover, if there is no directed path from r_i to r_j , then these two reversals are independent and can be performed in parallel (in the same time step).

We define the *depth* of a reversal in the dependency graph as follows. A reversal that does not have any incoming edges has depth 1 (these are the reversals of the nodes which are sinks in the initial state). The depth of any other reversal r is one more than the maximum depth of a reversal which points to r . The depth of the dependency graph is the maximum depth d of any reversal in the graph. The dependency graph is important for the following reason.

Fact 1. The dependency graph of an execution uniquely determines

- the final state of the network,
- the number of reversals performed by each node, and
- the stabilization time when all sinks reverse simultaneously, which is the depth of the dependency graph d .

3.2. Proof of equivalence. We show that all executions of a link reversal algorithm give the same dependency graph, which implies that the executions are equivalent. Fact 1 implies that this result is actually stronger than simply showing that executions are equivalent. We first show two lemmas that will be of use in further proofs.

LEMMA 3.2. *For any reversal algorithm starting from any initial state, a good node never reverses until stabilization. Further, a good node always remains good until stabilization.*

Proof. If v is a good node, then by definition there exists a path $v = v_k, v_{k-1}, \dots, v_1, v_0 = s$, where s is the destination, and there is an edge directed from v_i to v_{i-1} for each $i = 1, \dots, k$.

For each $i = 0, \dots, k$, we prove that node v_i never reverses, using induction on i . The base case ($i = 0$) is obvious since the destination never reverses. Suppose the hypothesis is true for $i = l < k$. Then v_l never reverses, so that the edge between v_{l+1} and v_l is always directed from v_{l+1} to v_l . Thus, there is always an outgoing edge from v_{l+1} , which implies that v_{l+1} never reverses, and completes the proof by induction.

This also implies that the directed path $v = v_k, v_{k-1}, \dots, v_1, v_0 = s$ always exists in the network, showing that node v remains good. \square

LEMMA 3.3. *If a node v is a sink, then v remains a sink until it reverses. Further, v eventually reverses.*

Proof. If a node v is a sink, then clearly none of its neighbors can be sinks at the same time, and hence they cannot reverse. Thus, the only node that can change the direction of the incoming links to v is v itself. Reversals by other nodes in the network do not affect this. Thus, v remains a sink until it reverses.

Further, the reversal of v is enabled continuously until v actually reverses. Since we assume that the distributed system eventually makes progress (an action that is continuously enabled will eventually take place), v eventually reverses. \square

THEOREM 3.4 (identical dependency graphs). *All executions of a deterministic reversal algorithm starting from the same initial state give identical dependency graphs.*

Proof. Consider two executions of the algorithm starting from the same initial state, say, execution $R = r_1, r_2, \dots$ and execution $S = s_1, s_2, \dots$. Let p_R and p_S be the dependency graphs induced by R and S , respectively. We will show that p_R and p_S are identical.

We will show by induction that, for every $k = 1, 2, \dots$, the induced subgraph of p_R consisting of vertices at depths k or less is identical to the similarly induced subgraph of p_S consisting of vertices at depths of k or less.

Base case $k = 1$. Consider any reversal $r = (v, h, H)$ in p_R at depth 1. Since r does not have any incoming edges in p_R , node v must be a sink in the initial state of the network. From Lemma 3.3, v must also reverse in S . Since h and H are the heights of v and its neighbors, respectively, in the initial state, and they do not change until v reverses at least once, the first reversal of v in S is also (v, h, H) , and is at depth 1. Similarly, any other reversal at depth 1 in p_S is also a reversal at depth 1 in p_R , and this proves the base case.

Inductive case. Suppose the hypothesis is true for all $k < l$. We show that it is also true for $k = l$. Consider any reversal $r = (v, h, H)$ at depth l in p_R . We show that this reversal is also present in p_S with the same set of incoming edges. Let U be the set of reversals that are pointing into r in p_R . Once all reversals in U are executed, node v becomes a sink in execution R . From the inductive step, all reversals in U are

also present in p_S , and hence in S . We examine two cases.

Case 1. Reversal r is the first reversal of v in R . Then, the execution of all reversals in U will also cause v to be a sink in S . Thus v also will reverse in S . Its height before reversal in S is h , since the height has not changed from the initial state. Consider the heights of v 's neighbors before v 's reversal in S . These are equal to H . The reason is as follows. The neighbors of v who haven't reversed so far in S have the same height as in the initial state. The other neighbors are present in U , and hence their heights are the same as in H . Thus, there is a reversal (v, h, H) at depth l in p_S whose incoming edges are the same as in p_R .

Case 2. Reversal r is not the first reversal of v in R . Let r' denote the previous reversal of v in R . Since r' is at a lower depth in p_R than r , by the induction hypothesis, r' is also present in p_S . After reversal r' , node v will be in the same state in both R and S . After the reversals in U , v 's neighbors will be in the same state in S as in R . Thus, the reversal (v, h, H) is also present in S at depth l with the same incoming edges as in p_R .

Thus, we have shown that every node at depth l in p_R is present at depth l of p_S , with the same incoming edges. The same argument goes the other way too: every node in p_S is present in p_R . This proves the inductive case for $k = l$, and concludes the proof. \square

The following corollary follows from Fact 1 and Theorem 3.4.

COROLLARY 3.5 (equivalence of executions). *All executions of a deterministic reversal algorithm starting from the same initial state are equivalent. Moreover,*

- *the number of reversals of each node in every execution is the same, and*
- *when all sinks reverse simultaneously, the stabilization time of every execution is d , the depth of the (unique) dependency graph.*

4. Full reversal algorithm. In this section, we present the analysis of the full reversal algorithm. We present a decomposition of the bad nodes in the initial network state into *layers*, which allows us to predict *exactly* the work performed by each node in any distributed execution until stabilization: a node at layer i will reverse exactly i times. From the exact analysis, we obtain worst-case bounds for the work and time needed for stabilization.

4.1. State sequence for full reversal. In order to obtain the exact analysis, we first show that, starting from any initial state, there exists an execution which consists of consecutive execution segments such that at each execution segment, each remaining bad node reverses exactly once. We will then use this result to determine the exact number of reversals of each bad node in the layer decomposition.

In particular, consider some initial state I_1 of the graph which contains bad nodes. We will show that there is an execution $E = E_1, E_2, E_3, \dots$, and states I_1, I_2, I_3, \dots , such that execution segment E_i , $i \geq 1$, brings the network from a state I_i to a state I_{i+1} , and in E_i each bad node of I_i reverses exactly one time. In order to show that E exists, we need to prove the following two lemmas.

LEMMA 4.1. *Consider a state I in which a node v is bad. Then, node v will reverse at least one time before it becomes a good node.*

Proof. If v is a sink, then clearly node v has to reverse at least one time. Now consider the case when v is not a sink in state I . Suppose, for contradiction, that node v becomes good without performing any reversals after state I . Consider an execution which brings the graph from state I to a state I^g in which node v is good. A *nonreversed* node is any node w such that in state I node w is bad, while in state I^g node w is good, and w does not reverse between I and I^g . Since in state I^g node

v is good, there must exist in I^g a directed path $v, v_1, \dots, v_{k-1}, v_k$, $k \geq 1$, in which v_k is good in I^g and I .

We will show that nodes v_1, \dots, v_{k-1} are nonreversed. Consider node v_1 . Assume for contradiction that node v_1 has reversed between states I and I^g . Since in I^g there is a link directed from node v to node v_1 , and v_1 has reversed between states I and I^g , it must be that node v has reversed at least one time, a contradiction. Thus, node v_1 is nonreversed. Similarly, using induction, we can easily show that nodes v_2, \dots, v_{k-1} are also nonreversed. Since nodes v_1, \dots, v_{k-1} are nonreversed, it has to be that in state I there is a directed path $v, v_1, \dots, v_{k-1}, v_k$. Thus, in state I node v is a good node. This contradiction completes the proof. \square

LEMMA 4.2. *Consider some state I which contains bad nodes. There exists an execution which brings the network from state I to a state I' (not necessarily a final state) such that every bad node of state I reverses exactly one time.*

Proof. Suppose for contradiction that there is no such execution. Then, there exists an execution E^f which brings the system from state I to a state I^f such that the following conditions hold:

1. There is at least one bad node in I which hasn't reversed in E^f . Let A denote the set of such bad nodes of I .
2. Any other bad node v of I , with $v \notin A$, has reversed exactly one time. Let B denote the set of such bad nodes of I .
3. The number of nodes in set B is maximal.

First we show that all the nodes that are sinks in state I^f have to be members of set B . Suppose that a sink in state I^f is a member of set A . Then the sink hasn't reversed since state I . If the sink reverses then it could be an additional member of set B . Thus, B is not maximal as required by the third condition. Therefore, the sink has to be a member of B .

Next we show that at least one node in A is a sink in state I^f , which proves that execution E^f does not exist. Assume for contradiction that no node of A is a sink in I^f . Then, each node in A has an outgoing edge in I^f . These outgoing edges from A cannot point toward nodes in B , since the nodes in B have reversed their edges, while the nodes in A haven't. Moreover, these outgoing edges cannot point toward good nodes of state I , since this would imply that nodes in A are good in state I^f , while Lemma 4.1 implies that each node of set A remains bad in state I^f . Thus, these outgoing edges must point toward nodes in set A . Since each node in set A has an outgoing edge in set A , it must be, from the pigeonhole principle, that there is a walk in which a node in A is repeated. Thus, there is a cycle in the graph, violating the fact that the graph is acyclic. Thus, it must be that a node in A is a sink, a contradiction. \square

Lemma 4.2 implies that the execution segments E_i and the states I_i exist. The *link-state* of a node v is the vector of directions of its incident links. We show that each execution segment leaves the link-state of bad nodes unchanged for the bad nodes, which are not adjacent to good nodes.

LEMMA 4.3. *If in state I_i , $i \geq 1$, node v is bad and v is not adjacent to a good node, then v will remain in the same link-state in I_{i+1} .*

Proof. Let $A(v)$ denote the set of nodes adjacent to v in state I_i . Since all nodes in $A(v)$ are bad in state I_i , each of them reverses in execution E_i . Moreover, v also reverses in E_i . These reversals leave the directions of the links between v and $A(v)$ in state I_{i+1} the same as in state I_i . \square

4.2. Layers for full reversal. Here, we show that given some initial state I with bad nodes, it is possible to decompose the bad nodes into layers and determine the exact number of reversals for the nodes of each layer until stabilization: a node in layer i reverses exactly i times.

In particular, we decompose the bad nodes into layers $L_1^I, L_2^I, \dots, L_m^I$, defined inductively as follows (see Figure 2). A bad node v is in layer L_1^I if the following conditions hold:

- There is an incoming link to node v from a good node, or
- there is an outgoing link from node v to a node in layer L_1^I .

A node v is in layer L_k^I , $k > 1$, if k is the smallest integer for which one of the following hold:

- There is an incoming link to node v from a node in layer L_{k-1}^I , or
- there is an outgoing link from node v to a node in layer L_k^I .

From the above definition, it is easy to see that any node of layer L_k^I , where $k > 1$, can be connected only with nodes in layers L_{k-1}^I , L_k^I , and L_{k+1}^I . The nodes of layer L_1^I are the only ones that can be connected with good nodes. The links connecting two consecutive layers L_{k-1}^I and L_k^I can be directed only from L_{k-1}^I to L_k^I . Note that the number of layers m is not greater than the number of bad nodes in the network n .

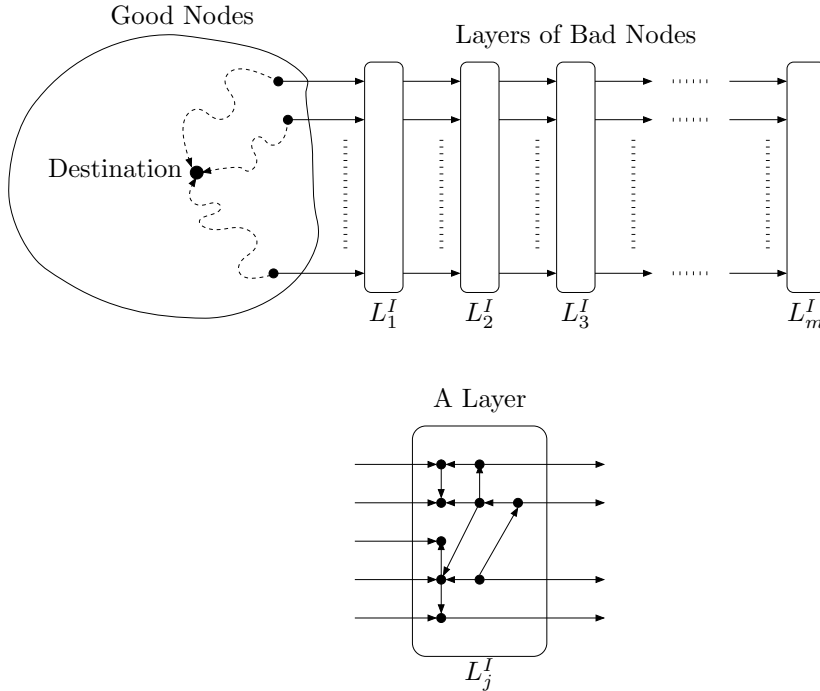

FIG. 2. Decomposition of the bad nodes into layers.

Consider now the states I_1, I_2, \dots and execution segments E_1, E_2, \dots , as described in section 4.1. For each of these states we can divide the bad nodes into layers, as described above. In the following sequence of lemmas we will show that the layers of state I_1 become good one by one at the end of each execution segment E_i , $i \geq 1$. We show now that the first layer of state I_i becomes good at the end of execution E_i .

LEMMA 4.4. *At the end of execution E_i , $i \geq 1$, all the bad nodes of layer $L_1^{I_i}$ become good, while all the bad nodes in layers $L_j^{I_i}$, $j > 1$, remain bad.*

Proof. First we show that the bad nodes of layer $L_1^{I_i}$ become good. There are two kinds of bad nodes in layer $L_1^{I_i}$ at state I_i : type α , nodes which are connected with an incoming link to a good node; and type β , nodes which are connected with an outgoing link to another node in layer $L_1^{I_i}$.

It is easy to see that there is a direct path from any β node to some α node, consisting of nodes of layer $L_1^{I_i}$. Since all bad nodes reverse exactly once in execution E_i , all α nodes become good in state I_{i+1} . Moreover, from Lemma 4.3, the paths from β nodes to α remain the same in state I_{i+1} . Thus, the β nodes also become good in state I_{i+1} . Therefore, all the bad nodes of layer $L_1^{I_i}$ become good in state I_{i+1} .

Now we show that the bad nodes in layers $L_j^{I_i}$, $j > 1$, remain bad in state I_{i+1} . From Lemma 4.3, in state I_{i+1} , the links connecting layers $L_1^{I_i}$ and $L_2^{I_i}$ are directed from $L_1^{I_i}$ to $L_2^{I_i}$. Thus, in state I_{i+1} , there is no path connecting nodes of layer $L_2^{I_i}$ to good nodes. Similarly, there is no path from the nodes of layer $L_j^{I_i}$, for any $j > 2$, to good nodes. Thus all nodes in layers $L_j^{I_i}$, $j > 1$, remain bad. \square

We now show that the basic structure of layers of the bad nodes remains the same from state I_i to state I_{i+1} , with the only difference being that the first layer of I_{i+1} is now the second layer of I_i .

LEMMA 4.5. $L_j^{I_{i+1}} = L_{j+1}^{I_i}$, $i, j \geq 1$.

Proof. From Lemma 4.4, at the end of execution E_i , all the bad nodes of layer $L_1^{I_i}$ become good, while all the bad nodes in layers $L_j^{I_i}$, $j > 1$, remain bad. From Lemma 4.3 all bad nodes in layers $L_j^{I_i}$, $j > 1$, remain in the same link-state in I_{i+1} as in I_i . Therefore, $L_j^{I_{i+1}} = L_{j+1}^{I_i}$, $j \geq 1$. \square

From Lemmas 4.4 and 4.5, we have that the number of layers is reduced by one from state I_i to state I_{i+1} . If we consider the layers of the initial state I_1 , we have that all the bad nodes in the layers become good one by one at the end of executions E_1, E_2, E_3, \dots in the order $L_1^{I_1}, L_2^{I_1}, L_3^{I_1}, \dots$. Since in each execution E_i all the bad nodes reverse exactly one time, we obtain the following.

LEMMA 4.6. *Each node in layer $L_j^{I_1}$, $j \geq 1$, reverses exactly j times before it becomes a good node.*

From Corollary 3.5, we know that all possible executions when started from the same initial state require the same number of reversals. Thus, the result of Lemma 4.6, which is specific to the particular execution E , applies to all possible executions. Therefore, we obtain the following theorem.

THEOREM 4.7 (exact number of reversals for full reversal). *For any initial state I , and any execution of the full reversal algorithm, L_1^I, L_2^I, \dots is a division of the bad nodes in I into layers such that each node in layer L_j^I , $j \geq 1$, reverses exactly j times before it becomes a good node.*

4.3. Worst-case bounds for full reversal. We now give worst-case upper and lower bounds for the work and time needed for stabilization by the full reversal algorithm. Both bounds are obtained with the use of Theorem 4.7.

From Theorem 4.7, we have that for any initial state I , each node in layer L_j^I reverses exactly j times until it becomes good. Thus, the total number of reversals of the nodes of layer j is $j \cdot |L_j^I|$. If there are m layers of bad nodes, the total number of reversals is $\sum_{j=1}^m j \cdot |L_j^I|$. If I has n bad nodes, there are at most n layers in the worst case (each layer contains one bad node). Thus, each node reverses at most n times. Since there are n bad nodes, the total number of reversals in the worst case

is $O(n^2)$. Moreover, since a node reversal takes one time step and in the worst case all reversals are executed sequentially, the total number of reversals gives an upper bound on the stabilization time. Thus, we have the following.

COROLLARY 4.8 (work and time upper bounds for full reversal). *For any graph with an initial state with n bad nodes, the full reversal algorithm requires at most $O(n^2)$ work and time until stabilization.*

FIG. 3. Worst-case work for full reversal: graph G_1 with $n = 6$ bad nodes.

Actually, the upper bound of Corollary 4.8 is tight in both work and time in the worst case. First we show that the work bound is tight. Consider a graph G_1 which is an initial state with n layers of bad nodes such that each layer has exactly one node (see Figure 3 with $n = 6$). From Theorem 4.7, each node in the i th layer will reverse exactly i times. Thus, the sum of all the reversals performed by all the bad nodes is $n(n + 1)/2$, leading to the following corollary.

COROLLARY 4.9 (work lower bound for full reversal). *There is a graph with an initial state containing n bad nodes such that the full reversal algorithm requires $\Omega(n^2)$ work until stabilization.*

FIG. 4. Worst-case stabilization time for full reversal: graph G_2 with $n = 8$ bad nodes, $m_1 = 5$ layers, and $m_2 = 4$ nodes in layer m_1 .

We will now show that the time bound of Corollary 4.8 is tight (within constant factors) in the worst case. Consider a graph G_2 (see Figure 4) with an initial state in which there are n bad nodes, such that it consists of $m_1 = \lfloor n/2 \rfloor + 1$ layers. The first $m_1 - 1$ layers contain one node each, while the last layer contains $m_2 = \lceil n/2 \rceil$ nodes. The last layer m_1 is as follows: there are m_2 nodes v_1, v_2, \dots, v_{m_2} . Node v_i has outgoing links to all nodes v_j such that $j < i$. The node of layer $m_1 - 1$ has an outgoing link to node v_1 (see Figure 4).

From Theorem 4.7, we know that each node in layer m_1 requires exactly m_1 reversals before it becomes good. Since there are m_2 nodes in layer m_1 , $m_1 \cdot m_2 = \Omega(n^2)$, reversals are required before these nodes become good. The key point is that any two nodes in layer m_1 are adjacent, so that all the reversals in that layer have to be performed sequentially. Thus, the reversals in layer m_1 alone take $\Omega(n^2)$ time, providing the following corollary.

COROLLARY 4.10 (time lower bound for full reversal). *There is a graph with an initial state containing n bad nodes such that the full reversal algorithm requires $\Omega(n^2)$ time until stabilization.*

Note that Corollary 4.10 subsumes Corollary 4.9, since a lower bound on time is also a lower bound on work.

5. Partial reversal algorithm. In this section, we present the analysis of the partial reversal algorithm. We first give an upper bound for work and stabilization time. We then present lower bounds for a class of worst-case graphs which is used to show that the upper bound is tight.

5.1. Upper bounds for partial reversal. Given an arbitrary initial state I , we give an upper bound on the work and stabilization time needed for the partial reversal algorithm. In order to obtain the bound, we decompose the bad nodes into levels and give an upper bound for the number of reversals of the nodes in each level; this then gives us an upper bound on work and time.

In particular, suppose that initial state I of the network contains n bad nodes. We say that a bad node v of state I is in *level* i if the shortest undirected path from v to a good node has length i . Note that the number of levels is no more than n .

The upper bound depends on the minimum and maximum heights of the nodes in state I . According to the partial reversal algorithm, each node v_i has a height (a_i, b_i, i) . We will refer to a_i as the *alpha value* of node v_i . Let a^{\max} and a^{\min} denote the respective maximum and minimum alpha values of any node in the network in state I . Let $a^* = a^{\max} - a^{\min}$. We first give an upper bound on the alpha value of any node upon stabilization.

LEMMA 5.1. *After a node in level i becomes good its alpha value never exceeds $a^{\max} + i$.*

Proof. We prove the claim by induction on the number of levels. For the induction basis, consider a node v in level 1. If the alpha value of v becomes at least $a^{\max} + 1$, then v must have become a good node, since its height is more than the height of at least one adjacent node v' which is good in state I (from Lemma 3.2 v' does not reverse, and thus its alpha value remains at most a^{\max}). We need only show that during its final reversal, the alpha value of v will not exceed $a^{\max} + 1$. According to the partial reversal algorithm, the alpha value of v is equal to the smallest alpha value of its neighbors plus one. Moreover, the smallest alpha value of the neighbors cannot be greater than a^{\max} , since in I node v is adjacent to good nodes which don't reverse in future states (a consequence of Lemma 3.2). Thus, the alpha value of v will not exceed $a^{\max} + 1$ when v becomes a good node. Further, from Lemma 3.2, the alpha value of node v will not change thereafter.

For the induction hypothesis, let's assume that the alpha value of any node in level i , where $1 \leq i < k$, does not exceed $a^{\max} + i$, after that node becomes good. For the induction step, consider layer L_k . Let v be a node in level k . Clearly, node v is adjacent to some node in level $k - 1$. From the induction hypothesis, the alpha value of every node in level $k - 1$ cannot exceed $a^{\max} + (k - 1)$ in any future state from I . If the alpha value of v becomes at least $a^{\max} + k$, then v must have become a good node, since its height is more than that of the adjacent nodes in level $k - 1$ when these nodes become good. We need only show that during its final reversal, the alpha value of v will not exceed $a^{\max} + k$. According to the partial reversal algorithm, the alpha value of v is not more than the smallest alpha value of its neighbors plus one. Moreover, the smallest alpha value of the neighbors cannot exceed $a^{\max} + (k - 1)$, which is the maximum alpha value of the nodes in level $k - 1$ when these nodes become good. Thus, the alpha value of v will not exceed $a^{\max} + k$ when v becomes a good node. Further, from Lemma 3.2, the alpha value of node v will not change thereafter. \square

At each reversal, the alpha value of a node increases by at least 1. Since the alpha value of a node can be as low as a^{\min} , Lemma 5.1 implies that a node in level i reverses at most $a^{\max} - a^{\min} + i$ times. Furthermore, since there are at most n levels, we obtain the following corollary.

COROLLARY 5.2. *A bad node will reverse at most $a^* + n$ times before it becomes a good node.*

Considering now all the n bad nodes together, Corollary 5.2 implies that the work needed until the network stabilizes is at most $n \cdot a^* + n^2$. Since in the worst case the reversal of the nodes may be sequential, the upper bound for work is also an upper bound for the time needed to stabilize. Thus we have the following.

THEOREM 5.3 (work and time upper bounds for partial reversal). *For any initial state with n bad nodes, the partial reversal algorithm requires at most $O(n \cdot a^* + n^2)$ work and time until the network stabilizes.*

5.2. Lower bounds for number of reversals. We will show that the upper bounds on work and time given in Theorem 5.3 are tight. We construct a class of worst-case graphs with initial states which require as much work and time as the upper bounds. In order to prove the lower bounds, we first determine how many reversals each node performs in the network.

In particular, consider a graph with an initial state I containing n bad nodes which can be decomposed into an even number m of layers $L_1, L_2, \dots, L_{m-1}, L_m$ in the following way. A node is a *source* if all the links incident to the node are outgoing. The odd layers L_1, L_3, \dots, L_{m-1} contain only nodes which are nonsources, while the even layers L_2, L_4, \dots, L_m contain only nodes which are sources. The nodes in layer L_1 are the only bad nodes adjacent to good nodes. Let G denote the set of good nodes adjacent to layer L_1 . Nodes in layer L_i may be adjacent only to nodes of the same layer and layers L_{i-1} and L_{i+1} .³ We actually require that each node of L_i is adjacent to at least one node of L_{i-1} and at least one node of L_{i+1} . In addition, state I is taken so that all good nodes in the network have alpha value a^{\max} , while all the bad nodes have alpha value a^{\min} , where $a^{\max} > a^{\min}$. Let $a^* = a^{\max} - a^{\min}$. Instances of such an initial state are shown in Figures 5 and 6; at the end of this section we describe how to obtain such configurations with arbitrary large a^{\max} in a mobile ad hoc network.

Given such an initial state I , we will give a lower bound on the number of reversals performed by each node at each layer until the network stabilizes. In order to obtain this result, we first show some necessary lemmas. A *full reversal* is a reversal in which a node reverses all of its links. Note that after a full reversal, a node becomes a source. We show that bad nodes which are sources always perform full reversals whenever they become sinks.

LEMMA 5.4. *Consider any state I_1 of the network in which a bad node v is a source with alpha value a . In a subsequent state I_2 , in which node v becomes a sink for the first time after state I_1 , the following occur: (1) v performs a full reversal, and (2) after the reversal of v , the alpha value of v becomes $a + 2$.*

Proof. In state I_1 , since v is a source, all the adjacent nodes of v have alpha value at most a . Between states I_1 and I_2 , each adjacent node of v has reversed at least once. We will show that in state I_2 , the alpha value of each adjacent node of v is $a + 1$.

Let w be any adjacent node of v . First, we show that the alpha value of w in I_2 is at least $a + 1$. If in I_2 the alpha value of w is less than a , then v must have an outgoing link toward w , and thus v cannot possibly be a sink in I_2 , a contradiction. Therefore, in I_2 the alpha value of w has to be at least a . Next, we show that this alpha value cannot be equal to a . If the alpha value of w in I_2 is a , then it must

³If $i = 1$, substitute G for L_{i-1} . If $i = m$, don't consider L_{i+1} .

be that the alpha value of w in I_1 was less than a (since w reversed between I_1 and I_2 and points toward v). When w was a sink the last time before I_2 , w must have been adjacent to another node u with height $a - 1$. When w reversed, its alpha value became a , but its incoming link from v didn't change direction since u had a smaller alpha value. Thus v cannot possibly be a sink in I_2 , a contradiction. Therefore, the alpha value of w in I_2 cannot be equal to a , and it has to be at least $a + 1$.

Next, we show that the alpha value of w cannot be greater than $a + 1$. When w reverses, its alpha value is at most the minimum alpha value of its neighbors plus one. Therefore, since v is a neighbor of w with alpha value a , when w reverses, its alpha value cannot exceed $a + 1$.

Therefore, the alpha value of w in state I_2 is exactly $a + 1$. This implies that in I_2 all the neighbors of v have alpha value $a + 1$. Thus, when v reverses, it performs a full reversal and its alpha value becomes $a + 2$. \square

Given state I described above, we give a lower bound for the alpha values of the nodes in each layer when the network stabilizes.

LEMMA 5.5. *When the network stabilizes from state I , the alpha values of all the nodes in layers L_{2i-1} and L_{2i} , $1 \leq i \leq m/2$, are at least $a^{\max} + i$.*

Proof. Let I' denote the state of the network when it stabilizes. We prove the claim by induction on i . For the basis case, where $i = 1$, we consider layers L_1 and L_2 . In state I , all the nodes of layer L_1 have only incoming links from G . In state I' , there must exist a set S , consisting of nodes from L_1 , such that the nodes in S have outgoing links pointing toward G .

Let v be a node in S . In state I' , the alpha value of v is at least a^{\max} , since the nodes in G have alpha value a^{\max} . Actually, we will show that the alpha value of v in I' is larger than a^{\max} . Assume for contradiction that this value is a^{\max} . When node v reversed and obtained the alpha value a^{\max} , it cannot possibly have reversed its links toward G since, for these links, v adjusted only its second field on its height. Thus, in state I' node v is still bad, a contradiction. Therefore, in state I' , node v has alpha value at least $a^{\max} + 1$; thus, in state I' , all nodes in set S have alpha value at least $a^{\max} + 1$.

Now, consider the rest of the nodes in layers L_j , $j \geq 1$. Let w be any such node. In state I' , w is good, and thus there exists a directed path from w to a good node in G . This path has to go through the nodes of S ; thus each node in the path must have alpha value at least $a^{\max} + 1$, which implies that w has alpha value at least $a^{\max} + 1$. Therefore, in state I' , all nodes in L_1 and L_2 (including S) have alpha value at least $a^{\max} + 1$.

Now, let's assume that the claim holds for all $1 \leq i < k$. We will show that the claim is true for $i = k$. We consider layers L_{2k-1} and L_{2k} . In state I all the nodes of layer L_{2k-1} have only incoming links from L_{2k-2} . In state I' , there must exist a set S , consisting of nodes of L_{2k-1} , such that the nodes in S have outgoing links pointing toward L_{2k-2} . The rest of the proof is similar to the induction basis, where now we show that the nodes in S in state I' , have alpha values at least $a^{\max} + k$, which implies that all nodes in L_{2k-1} and L_{2k} have alpha value at least $a^{\max} + k$. \square

We are now ready to show a central theorem for the lower bound analysis, which is a lower bound on the number of reversals for the nodes of each layer. This result will help us to obtain lower bounds for work and time needed for stabilization.

THEOREM 5.6 (lower bound on reversals for partial reversal). *Until the network stabilizes, each node in layers L_{2i-1} and L_{2i} , $1 \leq i \leq m/2$, will reverse at least $\lfloor (a^* + i)/2 \rfloor$ times.*

Proof. Consider a bad node v of L_{2i} . Node v is a source in state I . Lemma 5.4 implies that whenever v reverses in the future, it reverses all of its incident links, and therefore it remains a source. Moreover, Lemma 5.4 implies that every time that v reverses, its alpha value increases by 2. Lemma 5.5 implies that when the network stabilizes, the alpha value of v is at least $a^{\max} + i$. Since in state I the alpha value of v is a^{\min} , node v reverses at least $\lfloor (a^* + i)/2 \rfloor$ times after state I . Similarly, any other node in L_{2i} reverses at least $\lfloor (a^* + i)/2 \rfloor$ times.

Consider now a bad node w of L_{2i-1} . Node w is adjacent to at least one node u in layer L_{2i} . In state I , node u is a source, and it remains a source every time that u reverses (Lemma 5.4). Since u and w are adjacent, the reversals of u and w should alternate. This implies that node w reverses at least $\lfloor (a^* + i)/2 \rfloor$ times, since node u reverses at least $\lfloor (a^* + i)/2 \rfloor$ times. Similarly, any other node in L_{2i-1} reverses at least $\lfloor (a^* + i)/2 \rfloor$ times. \square

FIG. 5. Worst-case work for partial reversal: graph G_3 with $n = 6$ bad nodes.

Using Theorem 5.6 we now give worst-case graphs for work and stabilization time, which show that the upper bounds of Theorem 5.3 are tight. First, we give the lower bound on work. Consider a graph G_3 which is in state I , as described above, in which there are n bad nodes, where n is even, and there is exactly one bad node in each layer (see Figure 5). From Theorem 5.6, each node in the i th layer will reverse at least $\lfloor (a^* + \lceil i/2 \rceil)/2 \rfloor$ times before the network stabilizes. Thus, the sum of all the reversals performed by all the bad nodes is at least $\sum_{i=1}^n \lfloor (a^* + \lceil i/2 \rceil)/2 \rfloor$, which is $\Omega(n \cdot a^* + n^2)$. Thus, we have the following corollary.

COROLLARY 5.7 (work lower bound for partial reversal). *There is a graph with an initial state containing n bad nodes such that the partial reversal algorithm requires $\Omega(n \cdot a^* + n^2)$ work until stabilization.*

FIG. 6. Worst-case stabilization time for partial reversal: graph G_4 with $n = 8$ bad nodes, $m_1 = 6$ layers, and $m_2 = 3$ nodes in layer $m_1 - 1$.

Now we give the lower bound on time. Consider a graph G_4 in a state I as described above, in which there are n bad nodes, where $n/2$ is even. The graph consists of $m_1 = n/2 + 2$ layers. The first $m_1 - 2$ layers contain one node each, while layer $m_1 - 1$ contains $m_2 = n/2 - 1$ nodes, and layer m_1 contains 1 node. The layer $m_1 - 1$ is as follows: there are m_2 nodes v_1, v_2, \dots, v_{m_2} . Node v_i has outgoing links to all nodes v_j such that $j < i$ (see Figure 6). Note that each node in layer v_i is connected to the nodes in the adjacent layers from the specification of state I .

From Theorem 5.6, we know that each node in layer $m_1 - 1$ requires at least $k_1 = \lfloor (a^* + \lceil (m_1 - 1)/2 \rceil)/2 \rfloor$ reversals before it becomes a good node. Since layer

$m_1 - 1$ contains m_2 nodes, at least $k_1 \cdot m_2 = \Omega(n \cdot a^* + n^2)$ reversals are required before these bad nodes become good nodes. All these reversals have to be performed sequentially, since the nodes of layer $m_1 - 1$ are adjacent, and any two of these nodes cannot be sinks simultaneously. Thus, we have the following corollary.

COROLLARY 5.8 (time lower bound for partial reversal). *There is a graph with an initial state containing n bad nodes such that the partial reversal algorithm requires $\Omega(n \cdot a^* + n^2)$ time until stabilization.*

Note that Corollary 5.8 subsumes Corollary 5.7, since a lower bound on time is also a lower bound on work.

We now describe scenarios in mobile ad hoc networks which could result in the state I of graph G_4 and with arbitrary a^* value and number of nodes n . We first describe how to obtain an arbitrary a^{\max} value in a small graph. Consider a graph consisting of the destination node and two nodes w_1 and w_2 . Initially node w_1 points only to w_2 , which points to the destination; further, the alpha values of the nodes are all zero. Next, w_1 moves and gets also connected to the destination, without changing its height. Now w_2 moves and gets disconnected from the destination, but it still is connected to w_1 . However, w_2 is now a sink, and thus it performs a reversal, where its alpha value increases by one, since it has one neighbor (w_1). This scenario can be repeated an arbitrary number of times with the roles of w_1 and w_2 interchanged. This results in a state with an arbitrary value of a^{\max} .

Next, we describe how to obtain arbitrary $a^* = d$ in a state I of graph G_4 . Let $a^*(I)$ denote a^* in state I . Consider a graph H in an initial state I' in which all the nodes are good and all have alpha value equal to zero (thus, $a^*(I') = 0$). The nodes, except the destination, are divided into three components H_1 , H_2 , and H_3 . Graph H_1 consists of n nodes and is in a state isomorphic to the bad nodes in graph G_4 . Graph H_2 is a set of good nodes such that each node of H_1 is connected with an outgoing link to a good node in H_2 ; essentially, the nodes of H_1 are good because they are connected to the nodes of H_2 . Graph H_3 is a network consisting only of nodes w_1 and w_2 as described in the previous paragraph. From state I' we obtain a state I'' as follows. We let the nodes in H_3 oscillate (as described in the previous paragraph) until the alpha value of w_1 or w_2 is equal to d . Suppose that w_1 is the node that gets height d first and we stop the oscillation immediately when w_1 gets connected directly to the destination. Note that the nodes in H_1 and H_2 haven't changed their heights since I' , and therefore their alpha values remain zero in I'' (thus, $a^*(I'') = d$). Now, from state I'' we will obtain a state I as follows. The nodes in H_2 and the node w_2 disappear from the network; also, the node in the first layer of H_1 gets connected to w_1 . The resulting network configuration and state I are the same as in graph G_4 . Since the nodes in H_1 haven't changed their original alpha value (zero) and the node w_1 has the largest alpha value d , we obtain $a^*(I) = d$, as needed.⁴

6. Deterministic algorithms. In this section, we give worst-case lower bounds for the work and time needed for stabilization for any deterministic link reversal algorithm. Given an arbitrary deterministic function g , we will establish the existence of a family of graphs with initial states containing any number of $n > 2$ bad nodes which require at least $\Omega(n^2)$ work and time until stabilization. The lower bounds follow from a lower bound on the number of reversals performed by each node, which we describe next.

⁴A similar scenario could give a state I with arbitrary a^* , where a^{\min} is larger than zero. However, the state we gave with $a^{\min} = 0$ suffices for our lower bounds.

6.1. Lower bound on number of reversals. Given a graph G , we construct a state I in which we determine a lower bound on the number of reversals required by each bad node until stabilization. In particular, we decompose the bad nodes into levels and show that the node at level i reverses at least $i - 1$ times until stabilization. We then use this result to obtain lower bounds for work and time.

The construction of state I depends on a level decomposition of the network. Let s be the destination node. A node v (bad or not) is defined to be in *level* i if the (undirected graph) distance between v and s is i . Thus s is in level 0, and a node in level i is connected only with nodes in levels $i - 1$, i , and $i + 1$. Let m denote the maximum level of any node.

We now construct recursively states $I_{m+1}, I_m, I_{m-1}, \dots, I_2$ such that state $I = I_2$. The basis of the recursion is state I_{m+1} . The construction is as follows.

- In state I_{m+1} every node is good. Further, the heights of nodes in levels $1, 2, 3, \dots, m$ are in increasing order with the levels, i.e., given two vertices u, v at respective levels l_u, l_v with $l_u < l_v$, u 's height is less than v 's. An example assignment of heights in state I_{m+1} is to set a node's height to be equal to its level.
- Suppose we have constructed state I_i , where $m + 1 \geq i > 2$. We construct state I_{i-1} as follows:
 - For every node in levels $i - 1, i, \dots, m$, the height of the node in I_{i-1} is the same as its height in I_i .
 - Let \max_i denote the maximum height of a node in the destination oriented graph that is reached by an execution starting from I_i . (We note that from Corollary 3.5, \max_i does not depend on the actual execution sequence, but only on the initial state I_i .) For every node v in levels $1, 2, \dots, i - 2$, v 's height in I_{i-1} is assigned to be v 's height in I_i plus \max_i .

In the above construction, we assumed that the function g converges at a finite amount of time to a stable state starting from any initial state I_i . This assumption doesn't hurt the generality of our analysis, since if g didn't stabilize it would trivially require at least $\Omega(n^2)$ work and time, for n bad nodes, and thus our main result still holds. So, without loss of generality, we will assume that g stabilizes.

Next, we show that each state I_i , $m + 1 \geq i \geq 2$, satisfies the following properties:

- $P1_i$: The heights of nodes in levels $1, 2, 3, \dots, i - 1$ are in increasing order with the levels; i.e., given two vertices u, v at respective levels l_u, l_v with $l_u < l_v$, u 's height is less than v 's. Thus, every node in levels $1, 2, \dots, i - 1$ is a good node.
- $P2_i$: The heights of nodes in levels $i - 1, i, i + 1, \dots, m$ are in decreasing order with the levels, i.e., given two vertices u, v at respective levels l_u, l_v with $l_u < l_v$, u 's height is greater than v 's. Thus, every node in levels $i, i + 1, \dots, m$ is bad. In the case when $i = m + 1$, no node is bad.
- $P3_i$: Starting from initial state I_i , every node in level j , $j = i, i + 1, \dots, m$, reverses at least $j - i + 1$ times until stabilization. In the case when $i = m + 1$, no node reverses.

For $i = m + 1, \dots, 2$, we will now argue about the number of reversals starting from state I_i until stabilization. From Corollary 3.5, we know that all executions of a deterministic algorithm starting from the same initial state are essentially identical. In particular, the number of reversals of each node in every execution is the same.

For convenience, we consider a specific execution E_i which starts from initial

state I_i and reverses nodes in the following order: next reverse the bad node which has the smallest height in the current state. Clearly, such a node is a sink, and hence a candidate for reversal. The number of reversals of a node in any execution starting from I_i is equal to the number of reversals of the node in E_i .

LEMMA 6.1. *State I_i , $m + 1 \geq i \geq 2$, satisfies properties $P1_i$, $P2_i$, and $P3_i$.*

Proof. The proof is by induction on i . For the induction basis, state I_{m+1} clearly satisfies all the properties $P1_{m+1}$, $P2_{m+1}$, $P3_{m+1}$ from the construction of this state. Suppose now that state I_i , where $m + 1 \geq i > 2$, satisfies the respective three properties. We will show that state I_{i-1} satisfies the respective properties too. It can be easily checked that properties $P1_{i-1}$ and $P2_{i-1}$ are satisfied in I_{i-1} . We focus on property $P3_{i-1}$.

An execution is a sequence of reversals. We say that two reversals (v, h, H) and (v, h', H') of the same node in different network states are *equal* if the heights of the node and its neighbors are the same in both states, namely, $h = h'$ and $H = H'$. If two reversals are equal, then the heights of the node after the reversals are the same, since we are using a deterministic height increase function g . An execution E is said to be a prefix of an execution E' if the reversal sequence constituting E is elementwise equal to a prefix of the reversal sequence constituting E' . In Lemma 6.2, we show that E_i is a prefix of E_{i-1} .

Consider the state of the system which started in I_{i-1} , but after executing the reversals in E_i . In this state, the height of each node in levels $1, 2, \dots, i - 2$ is greater than \max_i by construction (it was greater than \max_i in I_{i-1} , and heights can never decrease). Let v be a node in level $l_v > i - 2$. After the execution segment E_i , v 's height is the same as the final height in the destination oriented graph reached from I_i , and by the definition of \max_i , this is no more than \max_i .

Thus, in the current state, the height of every node in levels $i - 1, i, \dots, m$ is less than the height of every node in levels $1, 2, \dots, i - 2$. Consider any node u in level $l_u \geq i - 1$. In the final destination oriented graph, there is a path of decreasing height from u to the destination s , and this path contains at least one node from levels $1, \dots, i - 2$. Thus, in the final state, u 's height is greater than the height of some node in levels $1, \dots, i - 2$, while it was less to begin with. This implies that u must have reversed at least once until stabilization.

In E_i , each node in level j , $j = i, i + 1, \dots, m$ has reversed at least $j - i + 1$ times. If we add an extra reversal to all nodes in levels $i - 1, i, \dots, m$, then in E_{i-1} , each node in levels $j = i - 1, i, \dots, m$ reverses at least $j - i + 2$ times, thus proving property $P3_{i-1}$. \square

LEMMA 6.2. *Execution E_i is a prefix of execution E_{i-1} .*

Proof. Executions E_i and E_{i-1} start from states I_i and I_{i-1} , respectively. Let $E_i = r_1^i, r_2^i, \dots, r_f^i$ and $E_{i-1} = r_1^{i-1}, r_2^{i-1}, \dots$. We prove by induction that $r_j^i = r_j^{i-1}$ for $j = 1, \dots, f$.

Base case. The nodes with the lowest height in I_i and I_{i-1} are the same node v , and v lies in layer m . The heights of all nodes in layer $m - 1$ are the same in I_i and I_{i-1} by construction. Thus, all of v 's neighbors have the same height in I_i and I_{i-1} , so that $r_1^i = r_1^{i-1}$.

Inductive case. Suppose that $r_1^i, r_2^i, \dots, r_l^i$ is identical to $r_1^{i-1}, r_2^{i-1}, \dots, r_l^{i-1}$ for some $l < f$. Let I_l^i and I_l^{i-1} , respectively, denote the state of the system starting from I_i after reversals $r_1^i, r_2^i, \dots, r_l^i$, and the state of the system starting from I_{i-1} after reversals $r_1^{i-1}, r_2^{i-1}, \dots, r_l^{i-1}$.

Let v be the bad node with the lowest height in I_l^i so that r_{l+1}^i reverses v . We

claim that this is also the bad node with the lowest height in I_l^{i-1} . The reason is as follows.

Node v must be at a level $l_v \geq i$, since E_i does not reverse any nodes at a lower level than i . All nodes in levels $i - 1$ or greater have the same heights in I_l^i and I_l^{i-1} , due to the induction hypothesis, and these are all less than \max_i . All nodes in levels $i - 2$ or less in I_l^{i-1} have heights greater than \max_i by construction. Thus, the bad node with the minimum height in I_l^{i-1} is also v , and its neighbors also have the same heights as in I_l^i , implying that r_{l+1}^i is the same as r_{l+1}^{i-1} . This completes the proof. \square

We are now ready to show the main result of this section.

THEOREM 6.3 (lower bound on reversals for deterministic algorithms). *Given any graph G and any height increase function g , there exists an initial state I (an assignment of heights to the nodes of G) which causes each node in level $i > 0$ to reverse at least $i - 1$ times until stabilization.*

Proof. Let m denote the maximum node level. We first construct a sequence of initial states I_{m+1}, I_m, \dots, I_2 as described above. Lemma 6.1 implies that starting from initial state I_i , each node in level $j, j \geq i$ reverses at least $j - i + 1$ times until stabilization (property $P3_i$). We take $I = I_2$. \square

6.2. Worst-case graphs. Here we give lower bounds on the work and time for any deterministic algorithm. Theorem 6.3 applies to any graph. Consider the list graph G_1 with $n + 2$ nodes, shown in Figure 3 and described in section 4.3. We construct a state I with n bad nodes as described in section 6.1. From Theorem 6.3, the lower bound for the worst-case number of reversals of any reversal algorithm on state I is the sum of the reversals of each bad node: $1 + 2 + \dots + n = \Omega(n^2)$. Thus we have the following corollary.

COROLLARY 6.4 (work lower bound for deterministic algorithms). *There is a graph with an initial state containing n bad nodes such that any deterministic reversal algorithm requires $\Omega(n^2)$ work until stabilization.*

We can derive a similar lower bound on the time needed for stabilization. We use the graph G_4 with $n + 2$ nodes, shown in Figure 4. The structure of the graph, and the parameters m_1 and m_2 , are defined as in section 5.2 with respect to $n + 1$. We construct a state I with n bad nodes as described in section 6.1. From Theorem 6.3, we know that each node in level $m_1 - 1$ of G_4 requires at least $(m_1 - 2)$ reversals before it becomes a good node. Level $m_1 - 1$ contains m_2 nodes. Therefore, at least $(m_1 - 2) \cdot m_2 = \Omega(n^2)$ reversals are required before these nodes become good nodes. All these reversals have to be performed sequentially, since the nodes of layer $m_1 - 1$ are adjacent, and no two of these nodes can be sinks simultaneously. Thus, we have the following corollary.

COROLLARY 6.5 (time lower bound for deterministic algorithms). *There is a graph with an initial state containing n bad nodes such that any deterministic reversal algorithm requires $\Omega(n^2)$ time until stabilization.*

7. Conclusions and discussion. We presented a worst-case analysis of link reversal routing algorithms in terms of work and time. We showed that for n bad nodes, the GB full reversal algorithm requires $O(n^2)$ work and time, while the partial reversal algorithm requires $O(n \cdot a^* + n^2)$ work and time. The above bounds are tight in the worst case. Our analysis for the full reversal is exact. For any network, we present a decomposition of the bad nodes in the initial state into *layers*, which allows us to predict *exactly* the work performed by each node in *any* distributed execution.

Furthermore, we show that for any deterministic reversal algorithm on a given

graph, there exists an assignment of heights to all the bad nodes in the graph such that if a bad node d hops away from its closest good node, then it has to reverse d times before stabilization. Using this, we show that there exist networks and initial states with n bad nodes such that the algorithm needs $\Omega(n^2)$ work and time until stabilization. As a consequence, from the worst-case perspective, the full reversal algorithm is work and time optimal, while the partial reversal algorithm is not. Since a^* can grow arbitrarily large, the full reversal algorithm outperforms the partial reversal algorithm in the worst case.

Since it is known that partial reversal performs better than full reversal in some cases, it would be interesting to find a variation of the partial reversal algorithm, which is as good as full reversal in the worst case. Another research problem is to analyze the average performance of link reversal algorithms. It would be also interesting to extend our analysis to nondeterministic algorithms, such as randomized algorithms, in which the new height of a sink is some randomized function of the neighbors' heights.

Acknowledgments. We thank the reviewers for their valuable comments and suggestions. We also thank Srikanth Surapaneni for helping in the preparation of an earlier version of this paper.

TWO-WAY CHAINING WITH REASSIGNMENT*

KETAN DALAL[†], LUC DEVROYE[†], EBRAHIM MALALLA[†], AND ERIN MCLEISH[†]

Abstract. We present an algorithm for hashing $\lfloor \alpha n \rfloor$ elements into a table with n separate chains that requires $O(1)$ deterministic worst-case insert time and $O(1)$ expected worst-case search time for constant α . We exploit the connection between two-way chaining and random graph theory in our techniques.

1. Introduction. In classical uniform hashing with chaining, a set of s keys is inserted into a hash table with n separate chains (or linked lists) via a uniform hash function. The insertion time is constant, and the average search time is proportional to the load factor of the hash table $\alpha := s/n$. However, even for a constant load factor, the worst-case search time (the length of the longest chain) is asymptotic to $\log n / \log \log n$ in probability [18, 27].

Azar et al. [3] suggested a novel approach called the *greedy two-way chaining* paradigm. It uses two independent uniform hash functions to insert the keys, where each key is inserted *on-line* into the shorter chain, with ties broken randomly. The insertion time is still constant, while the average search time cannot be more than twice the average search time of classical uniform hashing. However, the expected maximum search time is only $2 \log_2 \log n + 2\alpha + O(1)$ [3, 4, 24]. The two-way chaining paradigm has been effectively used to derive many efficient algorithms [5, 6, 7]. A further variant of on-line two-way chaining [28] improves the maximum search time by a constant factor.

On the other hand, one can show that the *off-line* version of two-way chaining, where all the hashing values of the keys are known in advance, yields better worst-case performance [3, 8, 25]. Czumaj and Stemann [8] proved that if $s \leq 1.67545943 \dots \times n$, one can find an assignment for the keys such that the maximum chain length is at most 2 w.h.p. (with high probability, i.e., with probability tending to one as $n \rightarrow \infty$). In general, for any integer $k \geq 2$, it is known [23] that there is a threshold $c_k \sim k$ such that if $s \leq c_k n$, one can assign the keys such that the maximum chain length is at most k w.h.p. The insertion time, however, is proportional to s . This shows that there is a large gap between the worst-case performances of the on-line and off-line versions of two-way chaining. One wonders if it is possible to design an efficient on-line two-way chaining algorithm whose worst-case search time is close enough to its off-line one, while preserving constant insertion time and $O(\alpha)$ average search time. Our goal here is to obtain constant expected maximum search and deterministic $O(1)$

insertion times when the load factor of the hash table is constant.

Many hashing schemes that achieve constant worst-case search time have been developed [11, 12, 13, 16]. However, these schemes use a large number of hash functions, sometimes employ rehashing techniques, and have insertion times that are constant only in an expected amortized sense. Closest to our work is a new hashing scheme called cuckoo hashing [26, 10], which utilizes the two-choice paradigm to improve the worst-case performance but also relies on the idea of reallocation of the inserted keys. It inserts n keys into a hash table that is partitioned into two parts, each of size $\lceil (1 + \epsilon)n \rceil$, for some constant $\epsilon > 0$. It uses two independent hash functions chosen from an $O(\log n)$ -universal class—one function only for each subtable. Each key is hashed initially by the first function to a cell in the first subtable. If the cell is full, then the new key is inserted there anyway, and the old key is kicked out to the second subtable to be hashed by the second function. The same rule is applied in the second subtable. Keys are moved back and forth until a key moves to an empty location or a limit of $O(\log n)$ moves is reached. When the limit is reached, new independent hash functions are chosen, and the whole table is rehashed. The worst-case search time is at most two, but the insertion time is constant only in an amortized expected sense. An off-line and static version of this algorithm previously appeared in [25].

In this paper, we present a two-way chaining algorithm that is close to cuckoo hashing but achieves constant worst-case insertion time, deterministically, and constant worst-case search time asymptotically almost surely, when the load factor is constant. The space consumption is also linear. The idea is based on the structure of a random multigraph, a key reassignment technique, and a deamortization method. The algorithm is divided into stages where, at each stage, the hash table is modeled by a random graph with n vertices representing the chains and m edges denoting the keys inserted during the stage. Inserting keys into chains corresponds to orienting edges toward vertices. Our goal then is to minimize the maximum out-degree. This model has been used earlier to analyze the off-line version of two-way chaining [8]. When the graph is a forest, it is easy to orient the edges such that the maximum out-degree is one. In order to keep the maximum out-degree as low as possible, some edges need to be reoriented when two trees are joined during the hashing process, and this means that the corresponding keys also need to be reassigned. Furthermore, cycles could occur in the random graph. Since the hashing process is on-line, we use a queue to control the orientation process, thereby ensuring that every insertion operation takes only a constant time of work. This leads us to the elegant deamortization method introduced by Gajewska and Tarjan [17]. In the next section we describe the algorithm precisely and ensure that an insert takes $O(1)$ deterministic worst-case time. We analyze the worst-case search time in section 3.

2. The algorithm. We start by presenting a simplified algorithm that requires $\omega(1)$ insertion time in the worst case and then use a standard deamortization trick to reduce the insertion time to $O(1)$.

Our algorithm inserts $s = \lfloor \alpha n \rfloor$ keys into a hash table \mathcal{T} with n separate chains (implemented as doubly linked lists) denoted by $\mathcal{T}[1], \dots, \mathcal{T}[n]$ by using two independent uniform hash functions f and g . We assume throughout that f and g map the space of the keys to $\{1, \dots, n\}$ such that if x_1, \dots, x_s are different keys, then $f(x_1), g(x_1), \dots, f(x_s), g(x_s)$ are independent and uniformly distributed on $\{1, \dots, n\}$. So, a key x is inserted into one of the chains $\mathcal{T}[f(x)]$ or $\mathcal{T}[g(x)]$. To search for any key, we examine only the two possible hashing chains available to it. Thus, the worst-case search time is at most twice the length of the longest chain plus the time needed to

compute the hashing values. For simplicity, we ignore the time for evaluating the hash functions.

The hashing process is described as follows (see Figure 2.1). In addition to the hash table, the algorithm maintains a directed graph $\mathcal{G}(V, A)$, where V is a set of n vertices and A is a set of arcs. Each vertex of \mathcal{G} corresponds to a chain of \mathcal{T} . An arc $\langle u, v \rangle \in A$ implies that there exists some key x whose hash values are u and v . The direction of this arc indicates that x is located in the chain corresponding to u , i.e., $\mathcal{T}[u]$. (With some abuse of notation, we will refer to an edge (u, v) of \mathcal{G} to indicate either $\langle u, v \rangle$ or $\langle v, u \rangle$.) In addition, let \mathbf{X} be a pointer to the linked-list node that contains x , and let $*\mathbf{X}$ be the node itself. An important property of the arcs is that they correspond to a *subset* of the keys contained in \mathcal{T} ; i.e., some keys are *dropped*.

FIG. 2.1. Upon arrival of key x , it is inserted into $\mathcal{T}[f(x)]$, and then a request for adding a corresponding arc is appended to the queue \mathcal{Q} . Next, κ extra units of work are performed to process the requests at the front of the queue. The figure also illustrates the **ReverseRoot** operation and the insertion of $\langle f(y), g(y) \rangle$.

To insert a key x into \mathcal{T} , see Pseudocode 1. Notice that initially any key x is always inserted into the chain $\mathcal{T}[f(x)]$. However, during the hashing process the key x may be reassigned back and forth between the two chains $\mathcal{T}[f(x)]$ and $\mathcal{T}[g(x)]$. This could happen by edge reversals as is shown, e.g., in Pseudocode 5.

Pseudocode 1 Insert(x)

- 1: $u \leftarrow f(x)$
 - 2: $v \leftarrow g(x)$
 - 3: Create new linked-list node, $*\mathbf{X}$ containing key x
 - 4: Insert $*\mathbf{X}$ into $\mathcal{T}[u]$.
 - 5: **UpdateGraph**(u, v, \mathbf{X}).
-

The **UpdateGraph** operation enforces that \mathcal{G} is acyclic and that every vertex has out-degree at most one. This means that the graph is simply a forest of parent-pointer trees. We represent the graph in an array, where the array element corresponding to

a vertex u contains a parent-pointer $P[u]$ and a pointer $X[u]$ to the linked-list node. Thus the array element for vertex u represents the arc, $\langle u, P[u] \rangle$. The `UpdateGraph` operation is described in Pseudocode 2. Note that in some cases, no edge is inserted into \mathcal{G} at all.

Pseudocode 2 `UpdateGraph(u, v, X)`

```

1:  $r_1 \leftarrow \text{FindRoot}(u)$ 
2:  $r_2 \leftarrow \text{FindRoot}(v)$ 
3: if  $r_1 \neq r_2$  then
4:   ReverseRoot(u)
5:   Link(u, v, X).
6: end if

```

The `FindRoot(u)` operation starts at u and takes parent pointers until the root is found. See Pseudocode 3.

Pseudocode 3 `FindRoot(u)`

```

1:  $r_1 \leftarrow u$ 
2: while  $P[r_1] \neq \text{nil}$  do
3:    $r_1 \leftarrow P[r_1]$ 
4: end while
5: return  $r_1$ 

```

The `Link(u, v, X)` operation creates the arc $\langle u, v \rangle$ and updates \mathcal{T} accordingly. Recall that the chains of \mathcal{T} are implemented as doubly linked lists. Thus, the updates to \mathcal{T} can be performed in $O(1)$ time. Additionally, `Link(u, v, X)` requires that u be a root. See Pseudocode 4.

Pseudocode 4 `Link(u, v, X)`

```

1:  $P[u] \leftarrow v$ 
2:  $X[u] \leftarrow X$ 
3: Move  $*X$  to  $\mathcal{T}[u]$ 

```

The `ReverseRoot(u)` function reverses the sequence of pointers from u to the root of u 's component. See Pseudocode 5. At the end of this operation, u is the new root of u 's component. Note that each reversal will update \mathcal{T} as part of the `Link` operation.

The following two facts are easy to see.

LEMMA 1. *At any point in time, the graph \mathcal{G} is a forest of parent-pointer trees with no self-loops or multiple edges.*

LEMMA 2. *The `Insert` operation requires worst-case time not exceeding $4M + O(1)$, where M is the maximum size of any tree in \mathcal{G} .*

We use two simple techniques to reduce the cost of the insertions. First, to reduce the size of the trees, after each $m = \lfloor \beta n \rfloor$ inserts, where $\beta < 1/2$ is some constant to be picked later, we destroy \mathcal{G} , which amounts to simply zeroing the array representation of \mathcal{G} .

Next, following [17], we use a queue \mathcal{Q} (implemented as a linked list) to defer some work to reduce the cost per insert. We define κ to be a (constant) parameter of the algorithm that indicates the maximum number of operations that may take place as part of each insert to process work items in \mathcal{Q} . (The dependence of κ on β will

Pseudocode 5 ReverseRoot(u)**Ensure:** $P[u] = \text{nil}$

```

1: if  $P[u] \neq \text{nil}$  then
2:   ReverseRoot( $P[u]$ )
3:   Temp  $\leftarrow P[u]$ 
4:    $P[u] \leftarrow \text{nil}$ 
5:   Link(Temp,  $u$ ,  $X[u]$ )
6: end if

```

be made clear later on.) The algorithm is modified as follows. After every hash table insert, where a new list node is created for key x and inserted into the chain $\mathcal{T}[f(x)]$, we append a *graph-insert request* to the *end* of the queue, \mathcal{Q} . This is a request for adding the edge $(f(x), g(x))$ to the graph \mathcal{G} and orienting that edge appropriately. Additionally, κ extra units of work will be performed on the request at the front of the queue, where one unit of work can be used to traverse or reverse an edge in the graph. Once the request is completed, it is deleted from the queue, and the remaining time is spent on the next element of the queue until either \mathcal{Q} is empty or the κ available time steps are depleted.

To combine both techniques, we keep an extra graph structure \mathcal{G}' that is zeroed incrementally as elements are inserted into \mathcal{G} . After $\lfloor \beta n \rfloor$ inserts, we will simply swap \mathcal{G} and \mathcal{G}' . This allows us to reduce the cost of zeroing the graph structure every $\lfloor \beta n \rfloor$ inserts. There are some minor technicalities in implementing this approach and the complete pseudocode for **ConstantInsert** is given in Pseudocode 6 in the appendix. Essentially, the approach is to break down the operation of **UpdateGraph** into constant time pieces.

We will write $\text{HASH}(n, s, m, \kappa)$ to refer to this modified process of hashing s keys into a hash table of size n , where m keys are inserted at each stage and κ is the constant parameter mentioned above. We omit the details for initializing the data structures and keeping track of an edge counter.

LEMMA 3. *Using the queue, the **ConstantInsert** operation requires time proportional to κ .*

The deferral described above creates a potential inconsistency between the state of the hash table and the state of the graph. Specifically, at the completion of a particular insertion request, the graph represents the state of the hash table at an earlier point in time, i.e., prior to the requests that are still pending in the queue. Only when the queue is empty will the graph represent the state of the hash table. Additionally, because some requests are dropped and, on occasion, the graph is destroyed, the graph may contain only a subset of the state of the hash table.

3. The worst-case search time. We shall prove the following theorem.

THEOREM 1. *There is a constant $\kappa > 0$ such that at any point in time during the hashing process $\text{HASH}(n, s, m, \kappa)$, where $n, s, m \in \mathbb{N}$, and $m = \lfloor \beta n \rfloor \leq s = O(n \log n)$, for some constant $\beta < 1/2$, the maximum search time is at most $2 \lceil s/m \rceil + 6$ w.h.p.*

The theorem confirms that if the load factor of the hash table $s/n = O(1)$, then asymptotically almost surely the maximum search time is constant. Since there is a trivial lower bound of $2s/n$, we see that we are roughly within $1/\beta$ of the best possible, recalling that β can be picked arbitrarily close to $1/2$. Before we proceed with the proof, we need some facts. We write $\text{Bin}(n, p)$ to denote a binomial random variable with parameters $n \in \mathbb{N}$ and $p \in [0, 1]$. We recall the following binomial tail inequalities.

LEMMA 4 (Angluin and Valiant [2]). For $n \in \mathbb{N}$, $p \in [0, 1]$, and constant $\epsilon \in (0, 1)$, we have

$$\mathbb{P} \{ \text{Bin}(n, p) \geq (1 + \epsilon)np \} \leq e^{-np\epsilon^2/3}$$

and

$$\mathbb{P} \{ \text{Bin}(n, p) \leq (1 - \epsilon)np \} \leq e^{-np\epsilon^2/2}.$$

Let $\mathbb{G}(n, m)$ denote a random graph with n vertices and m multiedges that may include loops, where each edge connects two vertices chosen—one after another—independently and uniformly at random, with replacement, from the set of all n vertices. This means that any loop is realized with probability $1/n^2$ and any undirected nonloop edge is realized with probability $2/n^2$. Recall that the classical model $G(n, p)$ of Erdős [14] and Erdős and Rényi [15] has no loops or multiedges, and each edge is realized with a fixed probability $p \in (0, 1)$. Throughout, we write $[n]$ to denote the set $\{1, \dots, n\}$.

LEMMA 5. Let $\mathcal{C}(u)$ be the number of vertices in the connected component containing a fixed vertex u from the random graph $\mathbb{G}(n, m)$, where $n \in \mathbb{N}$, and $m = \lfloor \beta n \rfloor$, for some constant $\beta < 1/2$. Then for any $t \in [n]$, we have $\mathbb{P} \{ \mathcal{C}(u) > t \} \leq 2e^{-\gamma t}$, where $\gamma = (1/2 - \beta)^2 / (2 + 4\beta)$. Thus, if M is the size of the largest connected component, then $\mathbb{P} \{ M > (1 + \epsilon)\gamma^{-1} \log n \} \leq 2n^{-\epsilon}$ for any fixed $\epsilon > 0$.

Proof. We first need to distinguish between the components of the classical $G(n, p)$ and those of $\mathbb{G}(n, m)$. Let $\mathcal{R}_p(u)$ denote the number of vertices in the component containing vertex u in $G(n, p)$ and use $C_k(u)$ for our model $\mathbb{G}(n, k)$. Next let $|G(n, p)|$ be the number of edges in $G(n, p)$. Notice that

$$\mathbb{P} \{ \mathcal{R}_p(u) > t \mid |G(n, p)| = k \} \geq \mathbb{P} \{ C_k(u) > t \}$$

because, conditional on having k edges, components in $G(n, p)$ are stochastically larger than those in $\mathbb{G}(n, k)$ since the latter includes multiedges and loops. This leads to the following relationship between $\mathcal{R}_p(u)$ and $C_m(t)$:

$$\begin{aligned} \mathbb{P} \{ \mathcal{R}_p(u) > t \} &= \sum_k \mathbb{P} \{ \mathcal{R}_p(u) > t \mid |G(n, p)| = k \} \mathbb{P} \{ |G(n, p)| = k \} \\ &\geq \sum_k \mathbb{P} \{ C_k(u) > t \} \mathbb{P} \{ |G(n, p)| = k \} \\ &\geq \sum_{k \geq m} \mathbb{P} \{ C_k(u) > t \} \mathbb{P} \{ |G(n, p)| = k \} \\ &\geq \sum_{k \geq m} \mathbb{P} \{ C_m(u) > t \} \mathbb{P} \{ |G(n, p)| = k \} \\ &= \mathbb{P} \{ C_m(u) > t \} \mathbb{P} \{ |G(n, p)| \geq m \} \\ &\geq \mathbb{P} \{ C_m(u) > t \} - \mathbb{P} \{ |G(n, p)| < m \}. \end{aligned}$$

Thus,

$$\mathbb{P} \{ C_m(u) > t \} \leq \mathbb{P} \{ \mathcal{R}_p(u) > t \} + \mathbb{P} \{ |G(n, p)| < m \}.$$

Bounding $\mathbb{P} \{ \mathcal{R}_p(u) > t \}$ in the classical model is done in the usual manner; see, for example, Janson [21]. Imagine that u 's component grows out from vertex u , picking

up neighbors according to a binomial distribution. This certainly overestimates the number of vertices in u 's component. Now suppose that the component containing vertex u contains more than t vertices. This implies that the sum of t binomial random variables is at least t . Denote these random variables by X_i for $i = 1, \dots, t$, and for an upper bound on $|\mathcal{R}_p(u)|$ assume that each X_i is distributed as $\text{Bin}(n, p)$ and that they are independent. The sum of t independent $\text{Bin}(n, p)$ is itself a $\text{Bin}(nt, p)$ random variable. So we have that

$$\mathbb{P}\{|\mathcal{R}_p(u)| > t\} \leq \mathbb{P}\{\text{Bin}(nt, p) \geq t\}.$$

Using Lemma 4, with $p = \frac{\beta+1/2}{n}$ and $\epsilon = \frac{1/2-\beta}{1/2+\beta} \in (0, 1)$, we get

$$\mathbb{P}\left\{\text{Bin}\left(nt, \frac{\beta+1/2}{n}\right) \geq t\right\} \leq \exp\left(\frac{-t(1/2-\beta)^2}{3(1/2+\beta)}\right).$$

Now it only remains to bound $\mathbb{P}\{|G(n, p)| < m\}$. Notice that $|G(n, p)|$ is distributed as $\text{Bin}(N, p)$, where $N = \binom{n}{2}$, and

$$\begin{aligned} m-1 &\leq \beta n - 1 = (n-1)(\beta/2 + 1/4) - (n/4 - \beta n/2 + 1 - \beta/2 - 1/4) \\ &\leq Np - x, \end{aligned}$$

where $x = (1/4 - \beta/2)n$. Using the lower tail bound of Lemma 4, we get

$$\begin{aligned} \mathbb{P}\{|G(n, p)| < m\} &= \mathbb{P}\{\text{Bin}(N, p) \leq m-1\} \\ &\leq \mathbb{P}\{\text{Bin}(N, p) \leq Np - x\} \\ &\leq \exp\left(\frac{-x^2}{2Np}\right) = \exp\left(\frac{-n^2(1/2-\beta)^2}{4(n-1)(1/2+\beta)}\right) \leq \exp\left(\frac{-n(1/2-\beta)^2}{4(1/2+\beta)}\right). \end{aligned}$$

Putting everything together, we see that the resulting bound for the component size in our model is

$$\mathbb{P}\{C(u) > t\} \leq \exp\left(\frac{-n(1/2-\beta)^2}{4(1/2+\beta)}\right) + \exp\left(\frac{-t(1/2-\beta)^2}{3(1/2+\beta)}\right).$$

Since the component size $t \leq n$,

$$\mathbb{P}\{C(u) > t\} \leq 2 \exp\left(\frac{-t(1/2-\beta)^2}{4(1/2+\beta)}\right) = 2e^{-\gamma t},$$

where $\gamma = (1/2 - \beta)^2 / (2 + 4\beta)$. □

The next lemma, which is included to make the paper self-contained, ensures that the asymptotic structure of $\mathbb{G}(n, m)$ is not complex when $m < n/2$. Further details can be found in [20]. An edge is said to *complete* a cycle if both of its vertices are chosen from the same connected component before its insertion.

LEMMA 6. *Let $n \in \mathbb{N}$, and $m = \lfloor \beta n \rfloor$, for some constant $\beta < 1/2$. In the random graph $\mathbb{G}(n, m)$, the expected number of edges that complete cycles is $O(\log n)$. Furthermore, the probability that $\mathbb{G}(n, m)$ contains a connected component with more than one cycle is $o(1 / \log n)$.*

Proof. Let Y_i be the number of edges that complete cycles in $\mathbb{G}(n, m)$ after $(i-1)$ edges have been inserted. Let D_i be the event that the i th edge completes a cycle. Let

M_i be the random variable corresponding to the size of the largest component after $(i - 1)$ edges have been inserted. Using the fact that the sequence $\{M_i\}$ is increasing,

$$\begin{aligned} \mathbf{E}[Y_{m+1}] &= \sum_{i=1}^m \mathbb{P}\{D_i\} \\ &= \mathbf{E}\left[\sum_{i=1}^m \mathbb{I}_{[D_i]}\right] = \mathbf{E}\left[\mathbf{E}\left[\sum_{i=1}^m \mathbb{I}_{[D_i]} \mid M_i\right]\right] \\ &\leq \sum_{i=1}^m \mathbf{E}[M_i/n] \leq \mathbf{E}[M_{m+1}] \\ &\leq \frac{2}{\gamma} \log n + m \mathbb{P}\left\{M_{m+1} > \frac{2}{\gamma} \log n\right\} \\ &= O(\log n), \end{aligned}$$

which follows from Lemma 5. Next, we show that it is unlikely for a component to contain more than one cycle.

Let A_i be the event that $M_i \leq a \log n$, where a is chosen such that $\mathbb{P}\{A_{m+1}^c\} = O(1/n)$. Let B_i be the event that $Y_i \leq \log^3 n$. Using $\mathbf{E}[Y_{m+1}] = O(\log n)$ and Markov’s inequality, we have $\mathbb{P}\{B_{m+1}^c\} = O(1/\log^2 n)$. Let C_i be the event that the i th edge causes the creation of a component that contains two cycles. Equivalently, C_i is the event that the i th edge connects two (not necessarily distinct) cyclic components. Treating these events as sets, we obtain

$$\begin{aligned} C_i &= (C_i \cap A_i \cap B_i) \cup (C_i \cap B_i^c \cap A_i) \cup (C_i \cap A_i^c) \\ &\subseteq (C_i \cap A_i \cap B_i) \cup B_i^c \cup A_i^c. \end{aligned}$$

Since A_i^c and B_i^c are increasing events, then $\bigcup_{i=1}^{m+1} A_i^c = A_{m+1}^c$, and similarly, $\bigcup_{i=1}^{m+1} B_i^c = B_{m+1}^c$. Consequently,

$$\begin{aligned} \mathbb{P}\left\{\bigcup_i C_i\right\} &\leq \left(\sum_{i=1}^m \mathbb{P}\{C_i, A_i, B_i\}\right) + \mathbb{P}\{B_{m+1}^c\} + \mathbb{P}\{A_{m+1}^c\} \\ &\leq \left(\sum_{i=1}^m \mathbb{P}\{C_i \mid A_i, B_i\}\right) + O\left(\frac{1}{\log^2 n}\right) + O\left(\frac{1}{n}\right) \\ &\leq m \left(\frac{(a \log n)(\log^3 n)}{n}\right)^2 + O\left(\frac{1}{\log^2 n}\right) = O\left(\frac{1}{\log^2 n}\right), \end{aligned}$$

as the maximum number of “bad” vertices that the i th edge can choose from is at most Y_i times M_i , which is not more than $a \log^4 n$. \square

Recall that the hashing process $\text{HASH}(n, s, m, \kappa)$ is divided into $N := \lceil s/m \rceil$ different stages, where at each stage $m \lfloor \beta n \rfloor$ keys are inserted into the hash table. Consider only the first stage. Recall that the graph \mathcal{G} does not fully represent the hash table because, first, the keys are inserted into the hash table without any delay, while the edges are queued in \mathcal{Q} for what might be a long time before they are actually inserted into the graph \mathcal{G} , and, second, any edge that completes a cycle is not added to the graph. For convenience, we will write $\mathcal{G}(m)$ to denote the graph \mathcal{G} at the end of the first stage, i.e., after having fully processed m edges, and write $\mathcal{G}(m)^+$ to denote the complete graph of $\mathcal{G}(m)$ plus all dropped edges that complete cycles. Observe

that the undirected version of the graph $\mathcal{G}(m)^+$ is stochastically equivalent to the random graph $\mathbb{G}(n, m)$. The following lemma shows that the dropped edges of the whole hashing process are disjoint. For any multiset of edges \mathcal{E} , and for any vertex u in the graph, let $\mathcal{V}(u, \mathcal{E})$ be the multiset of all vertices v such that $(u, v) \in \mathcal{E}$. Let $\deg(u, \mathcal{E}) = |\mathcal{V}(u, \mathcal{E})|$ be the degree of u in \mathcal{E} .

LEMMA 7. *Let \mathcal{D} be the multiset of dropped edges during all stages of the hashing process $\text{HASH}(n, s, m, \kappa)$, where n, s , and m are as defined in Theorem 1. Then $\max_u \deg(u, \mathcal{D}) = 1$ w.h.p.*

Proof. Recall that the number of stages is $N := \lceil s/m \rceil = O(\log n)$. For $i = 1, \dots, N$, let \mathcal{D}_i be the multiset of all dropped edges in stage i . Since the dropped edges are the ones that complete cycles, then Lemma 6 implies that $\mathbf{E}[|\mathcal{D}_1|] = O(\log n)$, and

$$\mathbb{P} \left\{ \max_u \deg(u, \mathcal{D}_1) > 1 \right\} = o(1 / \log n),$$

because $\deg(u, \mathcal{D}_1) > 1$ implies that the component containing u has more than one cycle. Clearly, $\sum_u \deg(u, \mathcal{D}_1) \leq 2|\mathcal{D}_1|$. Since we have n vertices in the graph, then

$$\mathbf{E}[\deg(u, \mathcal{D}_1)] = \mathbf{E}[\mathbf{E}[\deg(u, \mathcal{D}_1) \mid |\mathcal{D}_1|]] \leq 2\mathbf{E}[|\mathcal{D}_1|] / n.$$

For $i \neq j$, let $A_{i,j}$ be the event that there is a vertex u appearing in two dropped edges in \mathcal{D}_i and \mathcal{D}_j ; i.e., there are vertices v and w such that $(u, v) \in \mathcal{D}_i$ and $(u, w) \in \mathcal{D}_j$. Since $\mathcal{D}_1, \dots, \mathcal{D}_N$ are independent and identically distributed, we have

$$\begin{aligned} \mathbb{P} \left\{ \max_u \deg(u, \mathcal{D}) > 1 \right\} &\leq N \mathbb{P} \left\{ \max_u \deg(u, \mathcal{D}_1) > 1 \right\} + \binom{N}{2} \mathbb{P} \{A_{1,2}\} \\ &\leq o(1) + N^2 n (\mathbb{P} \{ \deg(u, \mathcal{D}_1) \geq 1 \})^2 \\ &\leq o(1) + N^2 n (\mathbf{E}[\deg(u, \mathcal{D}_1)])^2 \\ &\leq o(1) + N^2 n \left(\frac{2\mathbf{E}[|\mathcal{D}_1|]}{n} \right)^2 \\ &= o(1) + O \left(\frac{(\log n)^4}{n} \right) = o(1). \quad \square \end{aligned}$$

Finally, we recall the following inequality.

LEMMA 8 (Hoeffding [19]). *Let S be a set of m balls, where ball i has a value x_i . Let X_1, \dots, X_ν be the values of ν balls chosen from S independently and uniformly at random without replacement. Let Y_1, \dots, Y_ν be the values of ν balls chosen from S independently and uniformly at random with replacement. Then for any continuous convex function f , we have*

$$\mathbf{E} \left[f \left(\sum_{i=1}^{\nu} X_i \right) \right] \leq \mathbf{E} \left[f \left(\sum_{i=1}^{\nu} Y_i \right) \right].$$

Proof of Theorem 1. Recall that $\mathcal{G}(m)$ denotes the graph \mathcal{G} at the end of the first stage, and $\mathcal{G}(m)^+$ denotes the complete graph of $\mathcal{G}(m)$ plus all dropped edges that complete cycles. First of all, Lemma 7 says that the vertices of all dropped edges of the whole hashing process $\text{HASH}(n, s, m, \kappa)$ are distinct w.h.p. That is, the corresponding keys of these edges are inserted into distinct chains, or in other words, any chain harbors at most one key that corresponds to a dropped edge. Therefore, upon termination of the hashing process, the dropped edges may contribute at most one to the maximum chain length.

We shall prove that w.h.p. during any interval of time (measured with respect to the number of keys inserted) of length $\nu := \lfloor n^{1/4} \rfloor$ (at any stage), the queue \mathcal{Q} must be empty at least once, and no connected component is chosen more than twice. This means that w.h.p. any set of requests that exist in the queue at some point in time could have at most two requests for inserting edges in the same connected component; that is, we could insert at most two keys into the same chain before the final positions of the related keys are corrected. Assume this is true for the time being. Then clearly the length of any chain in the hash table during the first stage is not more than the out-degree of the corresponding vertex in \mathcal{G} plus three: one for any possible dropped edge contribution, and two for the two requests in the queue that have chosen the same component. However, the maximum out-degree of \mathcal{G} is ensured to be one all the time. Hence, the maximum chain length at any point in time during the first stage is at most four w.h.p. Since we follow the same strategy at each stage, it is not difficult to see that the chain length increases by at most one per stage. Note that over all stages, each chain has at most one dropped edge contribution, and a single component is present at most twice in the queue. Consequently, the maximum chain length at any point in time during the hashing process is at most $\lceil s/m \rceil + 3$ w.h.p., and hence the worst-case search time is at most $2 \lceil s/m \rceil + 6$ w.h.p., as we have to search two chains for each key.

Now we prove our assumption. We say “at time i ” to mean at the insertion time of the i th key. Thus, an interval of time of length ν means a period of time into which exactly ν keys are inserted. Let M be the size of the largest connected component in $\mathcal{G}(m)$. Since $\beta < 1/2$, then by Lemma 5, $\mathbb{P}\{M > 2\gamma^{-1} \log n\} = O(1/n)$.

Let A_{ij} be the event that the j th component is hit by the i th request and is hit at least twice more in the subsequent $\nu - 1$ requests. Note that when the insertion request at the front of the queue is being processed, the j th component is fixed. Let $A = \bigcup_{i,j} A_{ij}$. Let M_{ij} be the number of vertices in the j th component just before the i th insertion. Thus $\mathbb{P}\{\exists i, j, M_{ij} > 2\gamma^{-1} \log n\} \leq \mathbb{P}\{M > 2\gamma^{-1} \log n\} = O(1/n)$. Since we have fewer than m time intervals of length ν during the first stage, and at most n connected components in \mathcal{G} , then the binomial tail inequality yields that

$$\begin{aligned} \mathbb{P}\{A\} &\leq \mathbb{P}\{A \cap [M \leq 2\gamma^{-1} \log n]\} + \mathbb{P}\{M > 2\gamma^{-1} \log n\} \\ &\leq mn \max_{i,j} \mathbb{P}\{A_{ij} \cap [M \leq 2\gamma^{-1} \log n]\} + O(1/n) \\ &\leq mn \max_{i,j} \mathbb{P}\{A_{ij} \cap [M_{ij} \leq 2\gamma^{-1} \log n]\} + O(1/n) \\ &\leq mn \max_{i,j} \mathbb{P}\{A_{ij} \mid [M_{ij} \leq 2\gamma^{-1} \log n]\} + O(1/n). \end{aligned}$$

The probability that the i th request hits the j th component is at most $2M_{ij}/n$, since there are two vertices involved in the request. The number of times that the j th component is hit in the subsequent $\nu - 1$ requests is distributed as $\text{Bin}(2\nu - 2, M_{ij}/n)$. Thus, using $\mathbb{P}\{\text{Bin}(n, p) \geq 2\} \leq (np)^2/2$, we have

$$\begin{aligned} \mathbb{P}\{A\} &\leq mn \left(\frac{4 \log n}{\gamma n} \right) \mathbb{P}\left\{ \text{Bin}\left(2\nu, \frac{4\gamma^{-1} \log n}{n}\right) \geq 2 \right\} + O\left(\frac{1}{n}\right) \\ &\leq mn \left(\frac{4 \log n}{\gamma n} \right) \left(\frac{8\nu \log n}{\gamma n} \right)^2 + O\left(\frac{1}{n}\right) \\ &= O\left(\frac{\log^3 n}{n^{1/2}}\right). \end{aligned}$$

The event A refers to the first stage only. Multiplying the bound by the number of stages $N = O(\log n)$, we can see that the probability that during some stage there is a connected component which is chosen more than twice in some interval of time of length ν goes to zero as $n \rightarrow \infty$.

Next, let $[a, b] = \{a, a + 1, \dots, b\}$, where $|b - a + 1| = \nu$ is a time interval of length ν , and let B be the event that $[a, b]$ is the first interval of time of length ν in which the queue \mathcal{Q} is never empty. Observe that if B is true, then the queue was empty at time $a - 1$. Let e_a, \dots, e_b be the edges associated with the ν requests appended to \mathcal{Q} during $[a, b]$. For $i \in [a, b]$, let T_i be the computational time needed for the algorithm to fully process the edge e_i , that is, the number of edges traversed or reversed during the whole process of serving the request, plus one if the edge is inserted. Let R_i be the number of vertices in the connected component to which the edge e_i belongs. Thus, $T_i \leq 4R_i$ for all $i \in [a, b]$. Using Chernoff's bounding method (see e.g., [19]), we see that for parameter $\lambda > 0$,

$$\begin{aligned} \mathbb{P}\{B\} &\leq \mathbb{P}\{T_a > \kappa, T_a + T_{a+1} > 2\kappa, \dots, T_a + \dots + T_b > \kappa\nu\} \\ &\leq \mathbb{P}\{T_a + \dots + T_b > \kappa\nu\} \\ &\leq \mathbb{P}\{R_a + \dots + R_b > \kappa\nu/4\} \\ &\leq e^{-\lambda\kappa\nu/4} \mathbf{E} \left[\exp \left(\sum_{i=a}^b \lambda R_i \right) \right]. \end{aligned}$$

Recall that $\mathcal{G}(m)^+$ denotes the union of $\mathcal{G}(m)$ and the edges that completed cycles. Suppose that we choose ν edges from the set of all m edges in the graph $\mathcal{G}(m)^+$ independently and uniformly without replacement. Let V_1, \dots, V_ν be the sizes of the components containing these edges. Notice that V_1, \dots, V_ν stochastically dominate R_a, \dots, R_b . On the other hand, suppose that we repeat the experiment of choosing ν edges from the set of all m edges in the graphs $\mathcal{G}(m)^+$ independently and uniformly but *with* replacement. Let V_1^*, \dots, V_ν^* be the values of these edges which are plainly independent and identically distributed. Hence, by Lemma 8, we see that

$$\begin{aligned} \mathbb{P}\{B\} &\leq e^{-\lambda\kappa\nu/4} \mathbf{E} \left[\exp \left(\sum_{i=1}^{\nu} \lambda V_i \right) \right] \\ &\leq e^{-\lambda\kappa\nu/4} \mathbf{E} \left[\exp \left(\sum_{i=1}^{\nu} \lambda V_i^* \right) \right] \\ &= e^{-\lambda\kappa\nu/4} \left(\mathbf{E} \left[e^{\lambda V_1^*} \right] \right)^\nu. \end{aligned}$$

By definition, V_1^* is distributed as the size of the component containing a uniformly chosen edge of $\mathbb{G}(n, m)$. In distribution, this is the same as the size of the component containing the *last* edge inserted into $\mathbb{G}(n, m)$, which is in turn stochastically dominated by $C(u) + C(v)$, where u and v are uniformly chosen vertices and $C(u)$ is the size of the component containing u in $\mathbb{G}(n, m - 1)$. Using Lemma 5 for $t \in [m]$,

$$\mathbb{P}\{V_1^* \geq t\} \leq \mathbb{P}\{C(u) + C(v) \geq t\} \leq 2\mathbb{P}\{C(u) \geq t/2\} \leq 2 \left(2e^{-\gamma(t/2-1)} \right),$$

where $\gamma = \frac{(1/2-\beta)^2}{2+4\beta} > 0$. Therefore,

$$\mathbf{E} \left[e^{\lambda V_1^*} \right] \leq 4 \sum_{t=1}^m e^{\lambda t} e^{-\gamma(t/2-1)} \leq 4e^{\lambda+\gamma/2} \sum_{t=0}^{\infty} e^{(\lambda-\gamma/2)t} \leq \frac{4e^{\lambda+\gamma/2}}{1 - e^{\lambda-\gamma/2}},$$

provided that $\lambda < \gamma/2$. Finally, we get

$$\mathbb{P}\{B\} \leq e^{-\lambda\kappa\nu/4} \left(\mathbf{E} \left[e^{\lambda V_1^*} \right] \right)^\nu \leq e^{-p\nu},$$

where $p := \lambda\kappa/4 - \lambda - \gamma/2 + \log(1 - e^{\lambda-\gamma/2}) - \log 4$, which is positive if we choose $\kappa > 4 + 4(-\gamma/2 - \log(1 - e^{\lambda-\gamma/2}) + \log 4) / \lambda$. For example, if we put $\lambda = \gamma/4$, then $\kappa = \lceil -40 \log(1 - e^{-\gamma}) / \gamma \rceil$ will suffice. With this choice, and since there are $N = \lceil s/m \rceil$ stages, and in each stage there are at most m intervals of time of length ν , we see that the probability that at some stage there is an interval of time of length ν in which the queue is never empty is at most $Nme^{-p\nu} = o(1)$. Indeed, this is true even if the interval is as short as $2 \log_p s = O(\log n)$. The proof now is complete. \square

Remarks.

1. The last step of the proof reveals that asymptotically almost surely the space consumed by the queue is indeed $O(\log n)$ because the queue is always empty at least once during any interval of $O(\log n)$ insertions.
2. Notice that as β approaches $1/2$, γ goes to zero, and hence, the constant κ increases to infinity.
3. As β increases to $1/2$, the worst-case search time of our algorithm is close to $4\alpha + 6$ w.h.p., where $\alpha := s/n$ is the load factor of the hash table. This performance can be beaten by other hashing algorithms when α is large enough. For example, when $\alpha \geq \log n / \log \log n$, the classical hashing with chaining, where only a single uniform hash function is utilized, achieves better performance than our algorithm: the maximum search time is known [27] to be at most $\alpha + \Theta(\sqrt{\alpha \log n})$ w.h.p. Also, when $\log_2 \log n \leq \alpha \leq (1/3) \log n / \log \log n$, the worst-case search time of greedy two-way chaining, which is $2 \log_2 \log n + 2\alpha + O(1)$ w.h.p., is the best known [4]. However, for $\alpha < \log_2 \log n$, our algorithm has the best worst-case search time among all known hashing with chaining algorithms that have constant worst-case insertion time.
4. We did not try to optimize the constant insertion time κ or the total space consumed by the algorithm. We believe that some aspects of the algorithm can be modified to improve its performance by a constant factor. For example, the use of the graph \mathcal{G} is probably unnecessary, and one can implement the operations on the graph directly on the hash table. It is also necessary to generalize the algorithm for the dynamic case, where deletions are allowed.

Appendix. In this appendix, we give the detailed pseudocode for the procedure `ConstantInsert`. Each element of the queue is the 5-tuple $[X, \text{Root1}, \text{Root2}, \text{IndexFrom}, \text{IndexTo}]$ defined as follows:

- `X` The pointer to the linked-list node that is currently in some chain of \mathcal{T} .
 - `Root1` Current computation of the root of vertex $f(x)$'s tree.
 - `Root2` Current computation of the root of vertex $g(x)$'s tree.
 - `IndexFrom` If `Root1` and `Root2` are roots, then the new arc should point from `IndexFrom`.
 - `IndexTo` If `Root1` and `Root2` are roots, then the new arc should point to `IndexTo`.
- The last two fields are computable from each other, so only four elements are actually needed. Additionally, recall that `X` points to a structure that contains the key, which we will refer to as `X.key`.

Pseudocode 6 ConstantInsert($x, \mathcal{G}, \mathcal{T}$)

```

1: Create new linked-list node, *X containing key x
2: Insert *X into  $\mathcal{T}[f(x)]$ 
3: Create new request,  $R_{\text{new}} = [X, f(x), g(x), f(x), g(x)]$ 
4: Append  $R_{\text{new}}$  to  $\mathcal{Q}$ 
5: Zero  $\lceil \frac{1}{\beta} \rceil$  more elements of  $\mathcal{G}'$ 
6:  $i \leftarrow 1$ 
7: repeat
8:    $i \leftarrow i + 1, R \leftarrow \mathcal{Q}.\text{Peek}()$ 
9:   if  $P[R.\text{Root1}] \neq \text{nil}$  then
10:     $R.\text{Root1} = P[R.\text{Root1}]$ 
11:   else if  $P[R.\text{Root2}] \neq \text{nil}$  then
12:     $R.\text{Root2} = P[R.\text{Root2}]$ 
13:   else if  $R.\text{Root1} = R.\text{Root2}$  then
14:     $\mathcal{Q}.\text{Pop}()$ 
15:   else
16:     $Y \leftarrow X[R.\text{IndexFrom}]$ 
17:    Link( $R.\text{IndexFrom}, R.\text{IndexTo}, R.X$ )
18:    if  $Y = \text{nil}$  then
19:       $\mathcal{Q}.\text{Pop}()$  {This will happen once for every new arc in  $\mathcal{G}$ .}
20:      if  $|\mathcal{G}| = \lfloor \beta n \rfloor$  then swap( $\mathcal{G}, \mathcal{G}'$ )
21:      else if  $f(Y.\text{key}) = R.\text{IndexFrom}$  then
22:         $R \leftarrow [Y, R.\text{Root1}, R.\text{Root2}, g(Y.\text{key}), f(Y.\text{key})]$ 
23:      else
24:         $R \leftarrow [Y, R.\text{Root1}, R.\text{Root2}, f(Y.\text{key}), g(Y.\text{key})]$ 
25:      end if
26:    end if
27: until  $i = \kappa$  OR  $\mathcal{Q} = \emptyset$ 

```

CACHE-OBLIVIOUS B-TREES*

MICHAEL A. BENDER[†], ERIK D. DEMAINÉ[‡], AND MARTIN FARACH-COLTON[§]

Abstract. This paper presents two dynamic search trees attaining near-optimal performance on any hierarchical memory. The data structures are independent of the parameters of the memory hierarchy, e.g., the number of memory levels, the block-transfer size at each level, and the relative speeds of memory levels. The performance is analyzed in terms of the number of memory transfers between two memory levels with an arbitrary block-transfer size of B ; this analysis can then be applied to every adjacent pair of levels in a multilevel memory hierarchy. Both search trees match the optimal search bound of $\Theta(1 + \log_{B+1} N)$ memory transfers. This bound is also achieved by the classic B-tree data structure on a two-level memory hierarchy with a known block-transfer size B . The first search tree supports insertions and deletions in $\Theta(1 + \log_{B+1} N)$ amortized memory transfers, which matches the B-tree's worst-case bounds. The second search tree supports scanning S consecutive elements optimally in $\Theta(1 + S/B)$ memory transfers and supports insertions and deletions in $\Theta(1 + \log_{B+1} N + \frac{\log^2 N}{B})$ amortized memory transfers, matching the performance of the B-tree for $B = \Omega(\log N \log \log N)$.

Key words. memory hierarchy, cache efficiency, data structures, search trees

1. Introduction. The memory hierarchies of modern computers are becoming increasingly steep. Typically, an L1 cache access is two orders of magnitude faster than a main memory access and six orders of magnitude faster than a disk access [27]. Thus, it is dangerously inaccurate to design algorithms assuming a flat memory with uniform access times.

Many computational models attempt to capture the effects of the memory hierarchy on the running times of algorithms. There is a tradeoff between the accuracy of the model and its ease of use. One body of work explores multilevel memory hierarchies [2, 3, 5, 7, 43, 44, 49, 51], though the proliferation of parameters in these models makes them cumbersome for algorithm design. A second body of work concentrates on two-level memory hierarchies, either main memory and disk [4, 12, 32, 49, 50] or cache and main memory [36, 45]. With these models the programmer must anticipate which level of the memory hierarchy is the bottleneck. For example, a B-tree that has been tuned to run on disk has poor performance in memory.

1.1. Cache-oblivious algorithms. The cache-oblivious model enables us to reason about a simple two-level memory but prove results about an unknown multilevel memory. This model was introduced by Frigo et al. [31] and Prokop [40].

They show that several basic problems—namely, matrix multiplication, matrix transpose, the fast Fourier transform (FFT), and sorting—have optimal algorithms that are cache oblivious. Optimal cache-oblivious algorithms have also been found for LU decomposition [21, 46] and static binary search [40]. These algorithms perform an asymptotically optimal number of memory transfers for *any* memory hierarchy and at *all levels* of the hierarchy. More precisely, the number of memory transfers between any two levels is within a constant factor of optimal. In particular, any linear combination of the transfer counts is optimized.

The theory of cache-oblivious algorithms is based on the *ideal-cache model* of Frigo et al. [31] and Prokop [40]. In the ideal-cache model there are two levels in the memory hierarchy, called *cache* and *main memory*, although they could represent any pair of levels. Main memory is partitioned into *memory blocks*, each consisting of a fixed number B of consecutive cells. The cache has size M , and consequently has capacity to store M/B memory blocks.¹ In this paper, we require that M/B be greater than a sufficiently large constant. The cache is *fully associative*, that is, it can contain an arbitrary set of M/B memory blocks at any time.

The parameters B and M are unknown to the cache-oblivious algorithm or data structure. As a result, the algorithm cannot explicitly manage memory, and this burden is taken on by the system. When the algorithm accesses a location in memory that is not stored in cache, the system fetches the relevant memory block from main memory in what is called a *memory transfer*. If the cache is full, a memory block is elected for replacement based on an optimal offline analysis of the future memory accesses of the algorithm.

Although this model may superficially seem unrealistic, Frigo et al. show that it can be simulated by essentially any memory system with a small constant-factor overhead. Thus, if we run a cache-oblivious algorithm on a multilevel memory hierarchy, we can use the ideal-cache model to analyze the number of memory transfers between each pair of adjacent levels. See [31, 40] for details.

The concept of algorithms that are uniformly optimal across multiple memory models was considered previously by Aggarwal et al. [2]. These authors introduce the hierarchical memory model (HMM) model, in which the cost to access memory location x is $\lceil f(x) \rceil$, where $f(x)$ is monotone nondecreasing and polynomially bounded. They give algorithms for matrix multiplication and the FFT that are optimal for any cost function $f(x)$. One distinction between the HMM model and the cache-oblivious model is that, in the HMM model, memory is managed by the algorithm designer, whereas in the cache-oblivious model, memory is managed by the existing caching and paging mechanisms. Also, the HMM model does not include block transfers, though Aggarwal, Chandra, and Snir [3] later extended the HMM to the block transfer (BT) model to take into account block transfers. In the BT model the algorithm can choose and vary the block size, whereas in the cache-oblivious model the block size is fixed and unknown.

1.2. B-trees. In this paper, we initiate the study of dynamic cache-oblivious data structures by developing cache-oblivious search trees.

The classic I/O-efficient search tree is the *B-tree* [13]. The basic idea is to maintain a balanced tree of N elements with node fanout proportional to the memory block size B . Thus, one block read determines the next node out of $\Theta(B)$ nodes, so a search

¹Note that B and M are parameters, not constants. Consequently, they must be preserved in asymptotic notation in order to obtain accurate running-time estimates.

TABLE 1

Related work in cache-oblivious data structures. These results, except the static search tree of [40], appeared after the conference version [18] of this paper.

completes in $\Theta(1 + \log_{B+1} N)$ memory transfers.² A simple information-theoretic argument shows that this bound is optimal.

The B-tree is designed for a two-level hierarchy, and the situation becomes more complex with more than two levels. We need a multilevel structure, with one level per transfer block size. Suppose $B_1 > B_2 > \dots > B_L$ are the block sizes between the $L + 1$ levels of memory. At the top level we have a B_1 -tree; each node of this B_1 -tree is a B_2 -tree; etc. Even when it is possible to determine all these parameters, such a data structure is cumbersome. Also, each level of recursion incurs a constant-factor wastage in storage, in order to amortize dynamic changes, leading to suboptimal memory-transfer performance for $L = \omega(1)$.

1.3. Results. We develop two cache-oblivious search trees. These results are the first demonstration that even irregular and dynamic problems, such as data structures, can be solved efficiently in the cache-oblivious model. Since the conference version [18] of this paper appeared, many other data-structural problems have been addressed in the cache-oblivious model; see Table 1. Our results achieve the memory-transfer bounds listed below. The parameter N denotes the number of elements stored in the tree. *Updates* refer to both key insertions and deletions.

1. The first cache-oblivious search tree attains the following memory-transfer bounds:
 - Search:* $O(1 + \log_{B+1} N)$, which is optimal and matches the search bound of B-trees.
 - Update:* $O(1 + \log_{B+1} N)$ amortized, which matches the update bound of B-trees, though the B-tree bound is worst case.
2. The second cache-oblivious search tree adds the *scan* operation (also called the *range search* operation). Given a key x and a positive integer S , the scan operation accesses S elements in key order, starting after x . The memory-transfer bounds are as follows:
 - Search:* $O(1 + \log_{B+1} N)$.

²We use $B + 1$ as the base of the logarithm to correctly capture that the special case of $B = 1$ corresponds to the RAM.

Scan: $O(1 + S/B)$, which is optimal.

Update: $O(1 + \log_{B+1} N + \frac{\log^2 N}{B})$ amortized, which matches the B-tree update bound of $O(1 + \log_{B+1} N)$ when $B = \Omega(\log N \log \log N)$.

This last relation between B and N usually holds in external memory but often does not hold in internal memory.

In the development of these data structures, we build and identify tools for cache-oblivious manipulation of data. These tools have since been used in many of the cache-oblivious data structures listed in Table 1. In section 2.1, we show how to linearize a tree according to what we call the *van Emde Boas layout*, along the lines of Prokop’s static search tree [40]. In section 2.2, we describe a type of *strongly weight-balanced search tree* [11] useful for maintaining locality of reference. Following the work of Itai, Konheim, and Rodeh [33] and Willard [52, 53, 54], we develop a *packed-memory array* for maintaining an ordered collection of N items in an array of size $O(N)$ subject to insertions and deletions in $O(1 + \frac{\log^2 N}{B})$ amortized memory transfers; see section 2.3. This structure can be thought of as a cache-oblivious *linked list* that supports scanning S consecutive elements in $O(1 + S/B)$ memory transfers (instead of the naïve $O(S)$) and updates in $O(1 + \frac{\log^2 N}{B})$ amortized memory transfers.

1.4. Notation. We define the *hyperfloor* of x , denoted $\lfloor\!\lfloor x \rfloor\!\rfloor$, to be $2^{\lfloor \log x \rfloor}$, i.e., the largest power of 2 smaller than x .³ Thus, $x/2 < \lfloor\!\lfloor x \rfloor\!\rfloor \leq x$. Similarly, the *hyperceiling* $\lceil\!\lceil x \rceil\!\rceil$ is defined to be $2^{\lceil \log x \rceil}$. Analogously, we define *hyperhyperfloor* and *hyperhyperceiling* by $\lfloor\!\!\lfloor x \!\!\rfloor\!\rfloor = 2^{\lfloor \log x \rfloor}$ and $\lceil\!\!\lceil x \!\!\rceil\!\rceil = 2^{\lceil \log x \rceil}$. These operators satisfy $\sqrt{x} < \lfloor\!\!\lfloor x \!\!\rfloor\!\rfloor \leq x$ and $x \leq \lceil\!\!\lceil x \!\!\rceil\!\rceil < x^2$.

2. Tools for cache-oblivious data structures.

2.1. Static layout and searches. We first present a cache-oblivious *static* search-tree structure, which is the starting point for the dynamic structures. Consider a $O(\log N)$ -height search tree in which every node has at least two and at most a constant number of children and in which all leaves are on the same level. We describe a mapping from the nodes of the tree to positions in memory. The cost of any search in this layout is $\Theta(1 + \log_{B+1} N)$ memory transfers, which is optimal up to constant factors. Our layout is a modified version of Prokop’s layout for a complete binary tree whose height is a power of 2 [40, pp. 61–62]. We call the layout the *van Emde Boas layout* because it resembles the van Emde Boas data structure [47, 48].⁴

The van Emde Boas layout proceeds recursively. Let h be the height of the tree, or more precisely, the number of levels of nodes in the tree. Suppose first that h is a power of 2. Conceptually split the tree at the middle level of edges, between nodes of height $h/2$ and $h/2 + 1$. This breaks the tree into the *top recursive subtree* A of height $h/2$ and several *bottom recursive subtrees* B_1, B_2, \dots, B_ℓ , each of height $h/2$. If all nonleaf nodes have the same number of children, then the recursive subtrees all have size roughly \sqrt{N} , and ℓ is roughly \sqrt{N} . The layout of the tree is obtained by recursively laying out each subtree and combining these layouts in the order $A, B_1, B_2, \dots, B_\ell$; see Figure 1.

If h is not a power of 2, we assign a number of levels that is a power of 2 to the bottom recursive subtrees and assign the remaining levels to the top recursive subtree. More precisely, the bottom subtrees have height $\lceil\!\lceil h/2 \rceil\!\rceil$ ($= \lfloor\!\lfloor h - 1 \rfloor\!\rfloor$) and

³All logarithms are base 2 if not otherwise specified.

⁴We do not use a van Emde Boas tree—we use a normal tree with pointers from each node to its parent and children—but the order of the nodes in memory is reminiscent of van Emde Boas trees.

FIG. 1. The van Emde Boas layout. Left: in general; right: of a tree of height 5.

the top subtree has height $h - \lceil h/2 \rceil$. This rounding scheme is important for later dynamic structures because the heights of the cut lines in the lower trees do not vary with N . In contrast, this property is not shared by the simple rounding scheme of assigning $\lfloor h/2 \rfloor$ levels to the top recursive subtree and $\lceil h/2 \rceil$ levels to the bottom recursive subtrees.

The memory-transfer analysis views the van Emde Boas layout at a particular *level of detail*. Each level of detail is a partition of the tree into disjoint recursive subtrees. In the finest level of detail, 0, each node forms its own recursive subtree. In the coarsest level of detail, $\lceil \log_2 h \rceil$, the entire tree forms the unique recursive subtree. Level of detail k is derived by starting with the entire tree, recursively partitioning it as described above, and exiting a branch of the recursion upon reaching a recursive subtree of height $\leq 2^k$. The key property of the van Emde Boas layout is that, at any level of detail, each recursive subtree is stored in a contiguous block of memory.

One useful consequence of our rounding scheme is the following.

LEMMA 1. *At level of detail k all recursive subtrees except the one containing the root have the same height of 2^k . The recursive subtree containing the root has height between 1 and 2^k inclusive.*

Proof. The proof follows from a simple induction on the level of detail. Consider a tree T of height h . At the coarsest level of detail, $\lceil \log_2 h \rceil$, there is a single recursive subtree, which includes the root. In this case the lemma is trivial. Suppose by induction that the lemma holds for level of detail k . In this level of detail the recursive subtree containing the root of T has height h' , where $1 \leq h' \leq 2^k$, and all other recursive subtrees have height 2^k . To progress to the next finer level of detail, $k - 1$, all recursive subtrees that do not contain the root are recursively split once more so that they have height 2^{k-1} . If the height h' of the top recursive subtree is at most 2^{k-1} , then it is not split in level of detail $k - 1$. Otherwise, the root is split into bottom recursive subtrees of height 2^{k-1} and a top recursive subtree of height $h'' \leq 2^{k-1}$. The inductive step follows. \square

LEMMA 2. *Consider an N -node search tree T that is stored in a van Emde Boas layout. Suppose that each node in T has between $\delta \geq 2$ and $\Delta = O(1)$ children. Let h be the height of T . Then a search in T uses at most $4 \lceil \log_\delta \Delta \log_{B+1} N + \log_{B+1} \Delta \rceil = O(1 + \log_{B+1} N)$ memory transfers.*

Proof. Let k be the coarsest level of detail such that every recursive subtree contains at most B nodes; see Figure 2. Thus, every recursive subtree is stored in at

FIG. 2. The recursive subtrees visited by a root-to-leaf search path in level of detail k .

most two memory blocks. Because tree T has height h , $\lceil h/2^k \rceil$ recursive subtrees are traversed in each search, and thus at most $2\lceil h/2^k \rceil$ memory blocks are transferred. Because the tree has height h , $\delta^{h-1} < N < \Delta^h$, that is, $\log_\Delta N < h < \log_\delta N + 1$. Because a tree of height 2^{k+1} has more than B nodes, $\Delta^{2^{k+1}} > B$, so $\Delta^{2^{k+1}} \geq B + 1$. Thus, $2^k \geq \frac{1}{2} \log_\Delta(B + 1)$. Therefore, the maximum number of memory transfers is

$$\begin{aligned} 2 \left\lceil \frac{h}{2^k} \right\rceil &\leq 4 \left\lceil \frac{1 + \log_\delta N}{\log_\Delta(B + 1)} \right\rceil = 4 \left\lceil \left(1 + \frac{\log N}{\log \delta}\right) \left(\frac{\log \Delta}{\log(B + 1)}\right) \right\rceil \\ &= 4 \lceil \log_\delta \Delta \log_{B+1} N + \log_{B+1} \Delta \rceil. \end{aligned}$$

Because δ and Δ are constants, this bound is $O(1 + \log_{B+1} N)$. \square

2.2. Strongly weight-balanced search trees. To convert the static layout into a dynamic layout, we use a dynamic balanced search tree. We require the following two properties of the balanced search tree.

PROPERTY 1 (descendant amortization). *Suppose that whenever we rebalance a node v (i.e., modify it to keep balance) we also touch all of v 's descendants. Then the amortized number of elements touched per insertion is $O(\log N)$.*

PROPERTY 2 (strong weight balance). *For some constant d , every node v at height h has $\Theta(d^h)$ descendants.*

Property 1 is normally implied by Property 2 as well as by a weaker property called weight balance. A tree is *weight balanced* if, for every node v , its left subtree (including v) and its right subtree (including v) have sizes that differ by at most a constant factor. Weight balancedness guarantees a relative bound between subtrees with a common root, so the size difference between subtrees of the same height may be large. In contrast, strong weight balance requires an absolute constraint that relates the sizes of all subtrees at the same level. For example, $\text{BB}[\alpha]$ trees [38] are weight-balanced binary search trees based on rotations, but they are not strongly weight balanced.

Search trees that satisfy Properties 1 and 2 include weight-balanced B-trees [11], deterministic skip lists [37], and skip lists [41] in the expected sense. We choose to use weight-balanced B-trees defined as follows.

DEFINITION 3 (weight-balanced B-tree [11]). *A rooted tree T is a weight-balanced*

B-tree with branching parameter d , where $d > 4$, if the following conditions hold:⁵

1. All leaves of T have the same depth.
2. The root of T has more than one child.
3. Balance: Consider a nonroot node u at height h in the tree. (Leaves have height 1.) The weight $w(u)$ of u is the number of nodes in the subtree rooted at u . This weight is bounded by

$$\frac{d^{h-1}}{2} \leq w(u) \leq 2d^{h-1}.$$

4. Amortization: If a nonroot node u at height h is rebalanced, then $\Omega(d^h)$ updates are necessary before u is rebalanced again. That is, $w(u) - d^{h-1}/2 = \Theta(d^h)$ and $2d^{h-1} - w(u) = \Theta(d^h)$.⁶

Conditions 1–4 have the following consequence:

5. The root has between 2 and $4d$ children. All internal nodes have between $d/4$ and $4d$ children. The height of the tree is $O(1 + \log_d N)$.

From the strong weight balancedness of the subtree rooted at a node, we can conclude strong weight balancedness of the top a levels in such a subtree, as follows.

LEMMA 4. Consider the subtree A of a weight-balanced B-tree containing a node v , its children, its grandchildren, etc., for exactly a levels. Then $|A| < 4d^a$.

Proof. Let T denote the subtree rooted at a node of height h . Consider the descendants of v down precisely a levels, and let B_1, B_2, \dots, B_k be the subtrees rooted at those nodes. In other words, the B_i 's are the children subtrees of A . Let $b = h - a$ denote the height of each B_i . Because T and the B_i 's are strongly weight balanced, $|T| \leq 2d^{h-1}$ and $|B_i| \geq \frac{1}{2}d^{b-1}$ for all i . Now $|B_1| + \dots + |B_k| < |T| \leq 2d^{h-1}$, so $k \leq 4d^{h-b} = 4d^a$. But the number of nodes in A is less than the number of children subtrees B_1, B_2, \dots, B_k , so the result follows. \square

Next we show how to perform updates, making a small modification to the presentation in [11]. Specifically, [11] performs deletions using the global rebalancing technique of [39], where deleted nodes are treated as “ghost” nodes to be removed when the tree is periodically reassembled. In the cache-oblivious model, we need to service deletions immediately to avoid large holes in the structure.

Insertions. We search down the tree to find where to insert a new leaf w . After inserting w , some ancestors of w may become unbalanced. That is, some ancestor node u at height h may have weight greater than $2d^{h-1}$. We bring the ancestors of w into balance starting from the ancestors closest to the leaves. If a node u at height h is out of balance, then we split u into two nodes u_1 and u_2 , which share the node u 's children, v_1, \dots, v_k . We can divide the children fairly evenly as follows. Find the longest sequence of $v_1, \dots, v_{k'}$ such that their total weight is at most $\lceil w(u)/2 \rceil$, that is, $\sum_{i=1}^{k'} w(v_i) \leq \lceil w(u)/2 \rceil$. Thus, $\lceil w(u)/2 \rceil - 2d^{h-2} + 1 \leq w(u_1) \leq \lceil w(u)/2 \rceil$ and $\lfloor w(u)/2 \rfloor \leq w(u_2) \leq \lfloor w(u)/2 \rfloor + 2d^{h-2} - 1$. Because $d > 4$, we continue to satisfy the properties of Definition 3. In particular, at least $\Theta(d^h)$ insertions or deletions are needed before either u_1 or u_2 is split.

Deletions. Deletions are similar to insertions. As before, we search down the tree to find which leaf w to delete. After deleting w , some ancestors of w may become unbalanced. That is, some ancestor node u at height h may have weight lower than $\frac{1}{2}d^{h-1}$. We merge u with one of its neighbors. After merging u , it might now have

⁵In [11] there is also a leaf parameter $k > 0$, but we simply fix $k = 1$.

⁶This property is not included in the definition in [11], but it is an important invariant satisfied by the structure.

a weight larger than its upper bound, so we immediately split it into two nodes as described in the insertion algorithm. A slightly more subtle problem is that the newly merged node may be just below the upper threshold and may need splitting soon thereafter. We can handle this problem in several ways. Here, we split a merged node v if it has weight greater than $\frac{7}{4}d^{h-1}$, thus producing two nodes of weight at least $\frac{7}{8}d^{h-1} - d^{h-2} \geq \frac{5}{8}d^{h-1}$ and at most $\frac{9}{8}d^{h-1}$. Thus, condition 4 is guaranteed. As with insertions, we handle such out-of-bound nodes u in order of increasing height.

2.3. Packed-memory array. A *packed-memory array* maintains N elements in order in an array of size $P = cN$ subject to element deletion and element insertion between two existing elements. The remaining fraction $1 - c$ of the array is blank. The packed-memory array must achieve two seemingly contradictory goals. On the one hand, we should pack the nodes densely so that scanning is fast: S consecutive elements must occupy $O(S)$ cells in the array so that scanning those elements uses $O(1 + S/B)$ memory transfers. On the other hand, we should leave enough blank space between the nodes to permit future insertions to be handled quickly. Meeting these two goals makes packed-memory arrays useful for storing dynamic linear data cache obliviously. We achieve the following balance.

THEOREM 5. *For any desired $c > 1$, the packed-memory array maintains N elements in an array of size cN and supports insertions and deletions in $O(1 + \frac{\log^2 N}{B})$ amortized memory transfers and scanning S consecutive elements in $O(1 + S/B)$ memory transfers.*

Our data structure and analysis closely follow Itai, Konheim, and Rodeh [33]. They consider the same problem of maintaining elements in order in an array of linear size, but in a different cost model and without the scanning requirement. Their structure moves $O(\log^2 N)$ amortized elements per insertion, but has no guarantee on the number of memory transfers for inserting, deleting, or scanning. This structure has been deamortized by Willard [52, 53, 54] and subsequently simplified by Bender et al. [16].⁷

At a high level, the packed-memory array keeps every interval of the array of size $\Omega(1)$ a constant fraction full, where the constant fraction depends on the interval size. When an interval of the array becomes too full or too empty, we evenly spread out (*rebalance*) the elements within a larger interval. It remains to specify the size of the interval to rebalance and the thresholds determining when an interval is too full or too empty.

Tree structure and thresholds. We divide the array into segments, each of size $\Theta(\lg P)$, so that the number of segments is a power of 2. We then implicitly build a perfect binary tree on top of these $\Theta(P / \lg P)$ segments, making each segment a leaf. Each node in the tree represents the subarray containing the segments in the subtree rooted at this node. In particular, the root node represents the entire array, and each leaf node represents a single segment.

To define the thresholds controlling rebalance, we need additional terminology. The *capacity* of a node u in the tree, denoted $\text{capacity}(u)$, is the size of its subarray. The *density* of a node u in the tree, denoted $\text{density}(u)$, is the number of elements stored in u 's subarray divided by $\text{capacity}(u)$. Define the root node to have depth 0 and the leaf nodes to have depth $d = \lg \Theta(P / \lg P)$.

For each node, we define two *density thresholds* specifying the desired range on

⁷This problem is closely related to, but distinct from, the problem of answering linked-list order queries [28, 16].

the node's density. Let $0 < \rho_d < \rho_0 < \tau_0 < \tau_d = 1$ be arbitrary constants. For a node u at depth k , the *upper-bound density threshold* τ_k is $\tau_0 + \frac{\tau_d - \tau_0}{d}k$ and the *lower-bound density threshold* ρ_k is $\rho_0 - \frac{\rho_0 - \rho_d}{d}k$. Thus,

$$0 < \rho_d < \rho_{d-1} < \dots < \rho_0 < \tau_0 < \tau_1 < \dots < \tau_d = 1.$$

A node u at depth k is *within threshold* if $\rho_k \leq \text{density}(u) \leq \tau_k$.

The main difference between our packed-memory array and the data structure of [33] is that we add lower-bound thresholds.

Insertion and deletion. To insert an element x , we proceed as follows. First we find the leaf node w where x belongs. If leaf w has free space, then we *rebalance* w by evenly distributing x and the $\Theta(\lg P)$ elements in the leaf. Otherwise, we proceed up the tree until we find the first ancestor u of w that is within threshold. Then we *rebalance* node u by evenly distributing all elements in u 's subarray throughout that subarray. Leaf w is now within threshold and we can insert x as before.

Deleting an element is similar. To delete an element x , we remove x from the leaf node w containing x . If w is still within threshold, we are done. Otherwise, we find the lowest ancestor u of w that is within threshold and we rebalance u . Leaf w is now within threshold.

Although we describe these algorithms conceptually as visiting nodes in a tree, the tree is not actually stored. The operations are implemented by two parallel scans, one moving left and one moving right, that visit the subarrays specified implicitly by the tree nodes along a leaf-to-root path. During these scans we count the number of elements found and the capacity traversed, stopping when the density of a subarray is within threshold. The memory-transfer cost of the scans is $O(1 + K/B)$, where K is the capacity of the subarray traversed. We then rebalance this subarray using $O(1)$ additional scans, so the total cost is $O(1 + K/B)$; K is also the capacity of the subarray rebalanced.

Whenever N changes by a constant factor, we rebuild the structure by copying the data into another array with newly computed densities.

Analysis. Next we bound the amortized size of a rebalance during an insertion or deletion. Suppose that we rebalance a node u at depth k . The rebalance was triggered by an insertion or deletion in the subarray of some child v of u . Before rebalancing, u is within threshold, i.e., $\rho_k \leq \text{density}(u) \leq \tau_k$, and v is not within threshold, i.e., $\text{density}(v) > \tau_{k+1}$ or $\text{density}(v) < \rho_{k+1}$. After rebalancing, the density of v (and of v 's sibling) is not only within threshold, but also within the density thresholds of its parent u , i.e., $\rho_k \leq \text{density}(v) \leq \tau_k$. Before the density of node v (or its sibling) next exceeds its upper-bound threshold, we must have at least $(\tau_{k+1} - \tau_k)$ capacity(v) additional insertions within its subarray. Similarly, before the density of node v (or its sibling) next falls below its lower-bound threshold, we must have at least $(\rho_k - \rho_{k+1})$ capacity(v) additional deletions within its subarray.

We charge the size capacity(u) of the rebalance at u to its child v . Therefore the amortized size of a rebalance per insertion into v 's subarray is

$$\frac{\text{capacity}(u)}{\text{capacity}(v)(\tau_{k+1} - \tau_k)} = \frac{2}{\tau_{k+1} - \tau_k} = \frac{2d}{\tau_d - \tau_0} = O(\lg P),$$

and the amortized size of a rebalance per deletion in v 's subarray is

$$\frac{\text{capacity}(u)}{\text{capacity}(v)(\rho_k - \rho_{k+1})} = \frac{2}{\rho_k - \rho_{k+1}} = \frac{2d}{\rho_0 - \rho_d} = O(\lg P).$$

When we insert or delete an element x , we insert or delete within $d = O(\lg P)$ different subintervals containing x . Therefore the total amortized size of a rebalance per insertion or deletion is $O(\lg^2 P) = O(\lg^2 N)$.

Because the amortized size of a rebalance per insertion or deletion is $O(\lg^2 N)$, the amortized number of memory transfers per insertion or deletion is $O(1 + \frac{\lg^2 N}{B})$. This concludes the proof of Theorem 5.

3. Main structure. We begin by describing a simple approach to cache-oblivious B-trees that is not efficient by itself and then describe the modifications and improvements necessary to obtain our structure.

The simple approach uses the principle of indirection to support fast updates. We partition the N elements into consecutive groups of $\Theta(\log N)$ elements each, and store each group in a separate array of size $\Theta(\log N)$. We maintain a standard balanced binary search tree, such as an AVL tree, on the minimum element from each group. This *top tree* thus stores $\Theta(N / \lg N)$ elements. Each element in the top tree stores a pointer to the corresponding group array, and vice versa. Most insertions and deletions can simply rewrite one of the group arrays, which costs $O(1 + \frac{\lg N}{B})$ memory transfers. Whenever a group grows by a constant factor (e.g., to $2 \lg N$) or shrinks by a constant factor (e.g., to $\frac{1}{2} \lg N$), we merge and/or split groups at a cost of $O(1 + \frac{\lg N}{B})$ memory transfers and then perform the corresponding deletion and/or insertion in the top tree at a cost of $O(\log N)$ memory transfers. The latter cost can be charged to the $\Omega(\log N)$ updates that caused the overflow or underflow, for an amortized $O(1)$ cost. Therefore the total amortized update cost is $O(1 + \frac{\lg N}{B}) = O(\log_{B+1} N)$ memory transfers.

The problem with this structure is that searching in the balanced binary search tree costs $O(\log N)$ memory transfers. The moral is that we can afford to have relatively slow insertions and deletions in the upper tree, but we need to have fast searches.

The next layer of complexity is to keep the top tree in an (approximate) van Emde Boas layout, which brings the total search time down to $O(\log_{B+1} N)$ memory transfers. (The cost to scan a group array is $O(1 + \frac{\log N}{B})$, which is negligible.) However, it is not clear how to preserve this van Emde Boas layout of a search tree under insertions and deletions. First we show that, if we use a weight-balanced B-tree from section 2.2 for the top tree, there are few changes to the relative order of elements in the van Emde Boas layout, at least in the amortized sense. Nonetheless, when we insert into the middle of the tree, we need to have extra space for newly created nodes. If we keep the tree layout in an array, each insertion may require shifting most of the tree, even though the relative order of elements changes very little. Instead we use a packed-memory array from section 2.3 to store the van Emde Boas layout, allowing us to make room for changes in the tree.

An additional technical complication arises in maintaining pointers to nodes that move during an update. We search in the top tree by following pointers from nodes to their children, represented by indices into the packed-memory array. When we insert or delete an element in the packed-memory array, amortized $O(\log^2 N)$ elements move. Any element that is moved must let its parent know where it has gone. Thus, each node must have a pointer to its parent, and so each node must also let its children know where it has moved. The $O(\log^2 N)$ nodes that move can have $O(\log^2 N)$ children scattered throughout the packed-memory array, each in separate memory blocks. Thus an insertion or deletion can potentially induce $O(\log^2 N)$ memory transfers to update these disparately located pointers. We can afford this large

cost in an amortized sense by adding another level of $\Theta(\log N)$ indirection.

The overall structure of our cache-oblivious B-tree therefore has three levels. The top level is a weight-balanced B-tree on $\Theta(N / \log^2 N)$ elements stored according to a van Emde Boas layout in a packed-memory array. The middle level is a collection of $\Theta(N / \log^2 N)$ groups of $\Theta(\log N)$ elements each. The bottom level is a collection of $\Theta(N / \log N)$ groups of $\Theta(\log N)$ elements each.

In the next section, we turn to the details of the top tree. In section 3.2, we specify exactly how we store the collections of group arrays in the middle and bottom levels, which depends on exactly which bounds we desire. In section 3.3, we put the pieces together to obtain the final algorithms and analysis.

3.1. Splits and merges. At a high level, our algorithms for searching, inserting, and deleting in the top tree follow the corresponding algorithms for a weight-balanced B-tree from section 2.2. The search algorithm is identical, and costs $O(\log_{B+1} N)$ memory transfers because of Lemma 2 bounding the cost in a van Emde Boas layout, and because replacing an array with a packed-memory array does not increase the number of memory transfers by more than a constant factor. The insertion and deletion algorithms must pay careful attention to maintain the van Emde Boas order, which sometimes changes drastically as the result of a split or merge.

An insertion or deletion in a weight-balanced B-tree consists of splits and merges along a leaf-to-root path, starting at a leaf and ending at a node at some height. We show how to split or merge a node at height h in the top tree using $O(1 + d^h/B)$ memory transfers (which we call the *split-merge cost*), plus the memory transfers incurred by a single packed-memory insertion or deletion (including updating pointers). By the amortization property of weight-balanced B-trees (condition 4 of Definition 3), it follows that the amortized split-merge cost of rebalancing a node v is $O(1/B)$ memory transfers per insertion or deletion into the subtree rooted at v . When we insert or delete an element, this element is added or removed in $O(\log N)$ such subtrees. Hence, the split-merge cost of an update is $O(1 + \frac{\log N}{B})$ amortized memory transfers.

Next we describe the algorithm to split a node v . First, we insert a new node v' into the packed-memory array immediately after v . Then we redistribute the children pointers among v and v' according to the split algorithm of weight-balanced B-trees, using $O(1)$ memory transfers. If v is the root of the tree, we also insert a new root node at the beginning of the packed-memory array and add parent-child pointers connecting this node to v and v' . Because of the rounding scheme in the van Emde Boas layout, this change in the height of the tree does not change the layout. However, adding v' and redistributing v 's children change the van Emde Boas layout significantly.

To see how to repair the van Emde Boas layout, consider the coarsest level of detail in which v is the root of a recursive subtree S . Suppose S has height h' , which can be only smaller than the height h of node v . Let S be composed of a top recursive subtree A of height $h' - \lfloor\lfloor h'/2 \rfloor\rfloor$ and bottom recursive subtrees B_1, B_2, \dots, B_k each of height $\lfloor\lfloor h'/2 \rfloor\rfloor$; refer to Figure 3. The split algorithm recursively splits A into A' and A'' . (In the base case, A is the singleton tree $\{v\}$, which we have already split into $\{v\}$ and $\{v'\}$.)

At this point, A' and A'' are next to each other. Now we must move them to the appropriate locations in the van Emde Boas layout. Let B_1, B_2, \dots, B_i be the children recursive subtrees of A' , and let $B_{i+1}, B_{i+2}, \dots, B_k$ be the children recursive subtrees of A'' . We need to move B_1, B_2, \dots, B_i in between A' and A'' . This move is accomplished by three linear scans. Specifically, we scan to copy A'' to some tem-

FIG. 3. *Splitting a node. The top shows the modification in the recursive subtree S , and the bottom shows the modification in the van Emde Boas layout.*

porary space, then scan to copy B_1, B_2, \dots, B_i immediately after A' , overwriting A'' , and then scan to copy the temporary space containing A'' to immediately after B_i .

Now that A' and B_1, B_2, \dots, B_i have been moved, we need to update the pointers to the nodes in these blocks. First, we scan through the nodes in A' and update the children pointers of the leaves to point to the new locations of B_1, B_2, \dots, B_i . That is, we increase the pointers by $\|A'\|$, the amount of space occupied in the packed-memory array by A' , including unused nodes. Second, we update the parent pointers of $B_{i+1}, B_{i+2}, \dots, B_k$ to A'' , decreasing them by $\|B_1\| + \|B_2\| + \dots + \|B_k\|$. Finally, we scan the recursive subtrees of height h' that are children of B_1, B_2, \dots, B_i and update the parent pointers of the roots, decreasing them by $\|A''\|$. This update can be done in a single scan because the children recursive subtrees of B_1, B_2, \dots, B_i are stored contiguously.

Finally, we analyze the number of memory transfers made by moving blocks at all levels of detail. At each level h' of the recursion, we perform a scan of all the nodes at most six times (three for the move, and three for the pointer updates). By strong weight balance (Property 2 and condition 3 of Definition 3), these scans cost at most $O(1 + d^{h'}/B)$ memory transfers. The total split-merge cost is given by the cost of recursing on the top recursive subtree of at most half the height and by the cost of the six scans. This recurrence is dominated by the top level:

$$T(h') \leq T\left(\frac{h'}{2}\right) + c\left(1 + \frac{d^{h'}}{B}\right) \leq c\left(1 + \frac{d^{h'}}{B}\right) + O\left(\frac{d^{h'/2}}{B}\right).$$

Hence, the split cost is $O(1 + d^{h'}/B) \leq O(1 + d^h/B)$ memory transfers (not counting the cost of a packed-memory insertion).

A merge can be performed within the same memory-transfer bound by using the same overall algorithm. To begin, we merge two nodes v and v' and apply a packed-memory deletion. In each step of the recursion, we perform the above algorithm in reverse, i.e., the opposite transformation from Figure 3. Therefore, the split-merge cost in either case is $O(1 + d^h/B)$ worst-case memory transfers per split or merge, which amortizes to $O(1 + \frac{\log N}{B})$ memory transfers per insertion or deletion.

The remaining cost per insertion and deletion is the cost to insert or delete an element from the packed-memory array, including the cost of updating pointers. By Theorem 5, the cost to rearrange the array itself is $O(1 + \frac{\log^2 N}{B})$ amortized memory transfers. Unfortunately, as mentioned above, the cost to update the pointers to the amortized $O(\log^2 N)$ elements moved can cost $O(\log^2 N)$ memory transfers. Therefore the total cost per insertion or deletion is $O(\log^2 N)$ amortized memory transfers, proving the following intermediate result.

LEMMA 6. *The top tree maintains an ordered set subject to searches in $O(1 +$*

$\log_{B+1} N$) memory transfers and to insertions and deletions in $O(\log^2 N)$ amortized memory transfers.

3.2. Using indirection. We use two levels of indirection to reduce the cost of updating pointers in the top tree of the previous section. The resulting data structure has three layers.

The bottom layer stores all N elements, clustered into $\Theta(N / \log N)$ groups of $\Theta(\log N)$ consecutive elements each. Associated with each of these bottom groups is a *representative element*, the minimum element in the group. A representative element may in fact be a *ghost element* which has been deleted but cannot be removed from the structure because it is used in higher layers.

The middle layer stores the $\Theta(N / \log N)$ representative elements from the bottom layer (some of which may be ghost elements). The middle layer may also store ghost elements which have been deleted from the bottom layer but are still representatives in the middle layer. The middle elements are clustered into $\Theta(N / \log^2 N)$ groups of $\Theta(\log N)$ consecutive elements each. Again, we elect the minimum element of each middle group as a representative element.

The top layer stores the $\Theta(N / \log^2 N)$ representative elements from the middle layer (some of which may be ghost elements).

The layers are stored according to the following data structures. The top layer is implemented by the top tree from the previous section. The middle layer is implemented by a single packed-memory structure, where the representative elements serve as markers between groups. The bottom layer is implemented by a packed-memory array if we require optimal scan operations. Otherwise, the bottom layer is implemented by an unordered collection of groups, where the elements in each group are stored in an arbitrary order within a contiguous region of memory. These memory regions are all of the same size and are allowed to be a constant fraction empty. Elements are inserted into or deleted from a group simply by rewriting the entire group.

Elements appearing on multiple layers have “down” pointers from each instantiation to the instantiation at the next lower layer. Elements appearing on both the top and middle layers have “up” pointers from the middle instantiation to the top instantiation. However, elements appearing on both the middle and bottom layers do not have up pointers from the bottom layer to the middle layer.

To search for an element in this data structure, we search in the top layer for the query element or, failing that, its predecessor. Then we follow the pointer to the corresponding group in the middle layer and scan through this middle group to find the query element or its predecessor. If the found element is a ghost element of the middle layer that has been deleted from the bottom layer, we move to the previous element in the middle layer. Finally, we follow the pointer to the corresponding group in the bottom layer and scan through this bottom group in search of the query element.

When an element is inserted, it is added to a bottom group according to order; if the inserted element could fit in two bottom groups, we favor the smaller of the two groups. Thus, a freshly inserted element never becomes the new representative element of its group. A group in the bottom or middle layer may become too full, in which case we split the group evenly into two groups, create a new representative element for the second group, and insert this representative element into the next level up. Similarly, a group in the bottom or middle layer may become too empty (by a fixed constant fraction less than $\frac{1}{2}$), in which case we merge the group with an adjacent group and delete the larger representative element from the next level up.

A merge may cause an immediate split.

3.3. Analysis. We detail the search, insert, and delete algorithms and analyze their performance in two versions of the data structure. The *ordered B-tree* stores the bottom layer as a packed-memory structure, and therefore supports scans optimally. The *unordered B-tree* stores the bottom layer as an unordered collection of groups.

LEMMA 7. *In both B-tree structures, a search uses $O(1 + \log_{B+1} N)$ memory transfers.*

Proof. A search examines each layer once from the top down. Searching through the tree in the top layer costs $O(1 + \log_{B+1} N)$ memory transfers by Lemma 6. Scanning through a group in the middle or bottom layer costs $O(1 + \frac{\log N}{B})$ memory transfers because each group contains $O(\log N)$ elements and is stored in a contiguous array of $O(\log N)$ elements. The cost at the top layer dominates. \square

LEMMA 8. *In the ordered B-tree, an update uses $O(1 + \log_{B+1} N + \frac{\log^2 N}{B})$ memory transfers.*

Proof. An update (insertion or deletion) examines each layer once from the bottom up. At the bottom layer, we pay $O(1 + \frac{\log^2 N}{B})$ amortized memory transfers according to Theorem 5 to rebalance the packed-memory array and preserve constant-size gaps. Of the $O(\log^2 N)$ amortized nodes that move during this rebalance on the bottom layer, $O(\log N)$ amortized nodes are also present on the middle layer, and we must update the down pointers from these nodes on the middle layer to the moved nodes on the bottom layer. To update these pointers, we scan the bottom and middle layers in parallel, with the middle-layer scan advancing at a relative speed of $\Theta(1 / \log N)$. These pointer updates cost $O(1 + \frac{\log^2 N}{B})$ amortized memory transfers.

A bottom group causes a split or merge after $\Omega(\log N)$ updates to that group since the last split or merge. When such a split or merge occurs, we pay $O(1 + \frac{\log^2 N}{B})$ amortized memory transfers to rebalance the packed-memory array on the middle layer. This split-merge cost can be charged to the $\Omega(\log N)$ updates that caused it, reducing the amortized cost by a factor of $\Omega(\log N)$. Thus, we pay only $O(1 + \frac{\log N}{B})$ amortized memory transfers per update. Of the $O(\log^2 N)$ amortized nodes that move during this rebalance on the middle layer, $O(\log N)$ amortized nodes are also present on the top layer, and we must update the down pointers from these nodes on the top layer to the moved nodes on the middle layer. To update these pointers, we scan the moved nodes on the middle layer, follow each node's up pointer if it is present, and update the down pointer of each node reached. These pointer updates cost at most $O(\log N + \frac{\log^2 N}{B})$ amortized memory transfers per split or merge, or $O(1 + \frac{\log N}{B})$ per update. (At this point we could also afford to update up pointers from the bottom layer to the middle layer at an amortized cost of $\Theta(1 + \frac{\log^3 N}{B})$ per split or merge, or $\Theta(1 + \frac{\log^2 N}{B})$ per update, but we do not need these pointers and, furthermore, the unordered B-tree cannot afford to maintain them.)

A middle group causes a split or merge after $\Omega(\log N)$ updates to that group, which correspond to $\Omega(\log^2 N)$ updates to the data structure. When such a split or merge occurs, we pay $O(\log^2 N)$ amortized memory transfers to update the top layer, which is only $O(1)$ amortized memory transfers per update to the data structure. Furthermore, the number of nodes moved in the top layer is also $O(\log^2 N)$ amortized, so $O(\log^2 N)$ amortized up pointers from the middle layer to the top layer need to be updated. Thus the pointer-update cost is $O(\log^2 N)$ amortized memory transfers per split or merge, or $O(1)$ per update to the data structure.

Summing all costs, an update costs $O(1 + \frac{\log^2 N}{B})$ amortized memory transfers plus the cost of searching. \square

LEMMA 9. *In the unordered B-tree, an update uses $O(1 + \log_{B+1} N)$ amortized memory transfers.*

Proof. The analysis is nearly identical. The only difference is that we no longer rebalance a packed-memory array on the bottom layer, but instead maintain an unordered collection of contiguous groups. As a result, we do not pay $O(1 + \frac{\log^2 N}{B})$ amortized memory transfers per update, neither for the packed-memory update nor for updating down pointers from the middle layer to the bottom layer. The additional cost of rewriting a bottom group during each update is $O(1 + \frac{\log N}{B})$ memory transfers. The cost of splitting and/or merging a bottom group is the same. Therefore, the total cost of an update is $O(1 + \frac{\log N}{B})$ amortized memory transfers plus the cost of searching. \square

Combining Lemmas 7–9, we obtain the following main results.

THEOREM 10. *The ordered B-tree maintains an ordered set subject to searches in $O(1 + \log_{B+1} N)$ memory transfers, insertions and deletions in $O(1 + \log_{B+1} N + \frac{\log^2 N}{B})$ amortized memory transfers, and scanning S consecutive elements in $O(1 + S/B)$ memory transfers.*

THEOREM 11. *The unordered B-tree maintains an ordered set subject to searches in $O(1 + \log_{B+1} N)$ memory transfers and to insertions and deletions in $O(1 + \log_{B+1} N)$ amortized memory transfers.*

4. Extensions and alternative approaches. A previous version [18] of this paper presents a different cache-oblivious B-tree based on *buffer nodes*. One distinguishing aspect of this approach is that it uses no indirection, storing the tree in one packed-memory array. This B-tree achieves an update bound of $O(1 + \log_{B+1} N + \frac{\log B}{\sqrt{B}} \log^2 N)$ amortized memory transfers. With one level of indirection, the B-tree’s update bound reduces to $O(1 + \log_{B+1} N + \frac{\log^2 N}{B})$ amortized memory transfers while supporting optimal scans, or $O(1 + \log_{B+1} N)$ amortized memory transfers without optimal scans. Thus, we ultimately obtain the same bounds as the simpler B-trees presented above, though with one fewer level of indirection.

The basic idea of buffer nodes is to enable storing data of different “fluidity” in a single packed array, ranging from rapidly changing data that is cheap to update to slowly changing data that is expensive to update. In the context of trees, leaves are frequently updated but their pointers are to relatively nearby nodes, so updating these pointers is usually cheap, whereas nodes in, e.g., the middle level, are updated infrequently but their pointers are to disparate regions of memory. The buffer-node solution is to add a large number of extra (dataless) nodes in between data of different fluidity to “protect” the low-fluidity data from the frequent updates of high-fluidity data. In the context of trees, we add $O(N/\log N)$ buffer nodes in between the top recursive subtree A and bottom recursive subtrees B_1, B_2, \dots, B_ℓ . These buffers prevent the rebalance intervals in the packed-memory array from touching the nodes in A for a long time, leading to an $O(\frac{\log B}{\sqrt{B}} \log^2 N)$ term in the update bound.

For any of the cache-oblivious B-tree structures, a natural question is whether the $O(\frac{\log^2 N}{B})$ term in the update bound can be removed while still supporting scans optimally. Effectively, in addition to a search-tree structure, we need a linked-list data structure for supporting fast scans. Recently, Bender et al. [15] developed a cache-oblivious linked list that supports insertions and deletions in $O(1)$ memory transfers and scans of S consecutive elements in $O(1 + S/B)$ amortized memory transfers. Using

this linked list, they obtain the following optimal bounds for cache-oblivious B-trees.

THEOREM 12 (Bender et al. [15, Corollary 1]). *There is a cache-oblivious data structure that maintains an ordered set subject to searches in $O(\log_{B+1} N)$ memory transfers, insertions and deletions in $O(\log_{B+1} N)$ amortized memory transfers, and scanning S consecutive elements in $O(1 + S/B)$ amortized memory transfers.*

It remains open whether these bounds can be achieved in the worst case. See [15, 17] for cache-oblivious B-trees achieving some worst-case bounds.

5. Conclusion. We have presented cache-oblivious B-tree data structures that perform searches optimally. The first data structure maintains the data in sorted order in an array with gaps, and it stores an auxiliary structure for searching within this array. The second data structure attains the $O(\log_{B+1} N)$ update bounds of B-trees but breaks the sorted order of elements, thus slowing sequential scans of consecutive elements. These cache-oblivious B-trees represent the first dynamic cache-oblivious data structures. The cache-oblivious tools presented in this paper play an important role in the dynamic cache-oblivious data structures that have followed.

Acknowledgments. We gratefully acknowledge Charles Leiserson for suggesting this problem to us. We thank the anonymous referees for their many helpful comments.

A POWERFUL $LL(k)$ COVERING TRANSFORMATION*

GYUNG-OK LEE[†] AND KWANG-MOO CHOE[‡]

Abstract. k -transformable grammars have been conjectured to be the uppermost class of $LL(k)$ covering transformable grammars. $PLR(k)$ grammars have been known as a well characterized subclass of k -transformable grammars. Being contrary to those claims, this paper shows that some $PLR(k)$ grammars are not k -transformable, and so k -transformable grammars are not the true uppermost.

A powerful $LL(k)$ covering transformation is suggested in this paper. It is a generalization of the transformations of k -transformable grammars and $PLR(k)$ grammars. A remarkable aspect of the new transforming process is the deterministic property, where “deterministic” means that the transformation is obtained in a single process without requiring any heuristic, unlike k -transformable grammars’ transformation for which a heuristic is required. The transformable grammar class is shown to be larger than k -transformable grammars and $PLR(k)$ grammars.

1. Introduction. LR grammars and LL grammars are two of the most representative context-free grammars for programming languages. When we compare the parsers of those grammars, we see that LL parsers are easier and simpler to implement, understand, and error recover and have a greater flexibility in computing semantic attributes during parsing, but LL grammars are a small subclass of LR grammars. Some researchers thus suggested generalized LL parsing techniques [5, 8, 11], which are more applicable to the larger grammar class than the class of LL grammars. On the other hand, the restricted $LR(k)$ grammars, k -transformable grammars [3, 4], and $PLR(k)$ grammars [10] were suggested by Hammer and Soisalon-Soininen, respectively, as the grammars able to be transformed into $LL(k)$ covering grammars. Specially, k -transformable grammars have been conjectured as the uppermost class of such $LR(k)$ grammars [3], and $PLR(k)$ grammars have been known as a well-characterized subclass of k -transformable grammars [10].

In this paper we are interested in the covering transformation of LR grammars into LL grammars. The main idea in the transformation starts from the prediction of reduction goals during LR parsing. In LR parsing, a nonterminal, to which some prefix of the remaining input is reduced, is known at the reduction time, but we can often find a reduction goal before that time. A nonterminal B and a suffix γ of α are *predicted*, when the stack string is α , if it is certain that γ and some prefix of the remaining input will be reduced to B . (That is, the left side of Figure 1.1 is expected to be the right side.) In Hammer’s method, γ is restricted to be ϵ , and in Soisalon-Soininen’s method, γ has to be the left corner symbol of the right side of a production. Soisalon-Soininen’s γ gives more information about B than Hammer’s γ and, as a result, some predictable goals by Soisalon-Soininen’s method cannot be

predicted when Hammer's method is applied. We found that the lack of predictability causes the class of k -transformable grammars not to completely include the class of $PLR(k)$ grammars.

FIG. 1.1. Prediction in LR parsing ($\alpha = \beta\gamma$).

This paper generalizes the previous prediction technique into two viewpoints. The first key idea is to predict a reduction goal after enough information for the goal is known. The delay in predicting time obviously enlarges the range of predictable goals. In this paper, we allow γ in the right side of Figure 1.1 to be an arbitrary string. On the other hand, in both Hammer and Soisalon-Soininen's methods, the prediction of goal B at a parsing time implies that whenever a generatable string from B appears as the k -length prefix of the remaining input, a reduction to B will certainly occur. The second key idea is to allow the prediction to be performed not only over the total string but also over some partial string generatable from a predicted goal. That is, B can be a predicted goal as long as any predictive string exists, although some generatable strings from B do not guarantee a reduction to B .

This paper suggests a powerful covering transformation into $LL(k)$ form based on the generalized prediction. The applicable grammar class is defined as *extended $PLR(k)$ grammars*. They are larger than k -transformable grammars and $PLR(k)$ grammars. Hammer informally described an extension [3, pp. 289–293] of k -transformable grammars. After his argument, there has been no more research on the extension. The main reason is considered to be intricateness of the construction of multiple stack machine [3], which is required to obtain an $LL(k)$ transformation. (Actually, Hammer was worried that the extension needs numerous complications in his original machine model [3, p. 292, lines 1–3].) On the other hand, recently we suggested a grammatical characterization of k -transformable grammars in [7]. This paper develops an extension of k -transformable grammars using grammatical derivation. We believe that our extension completely includes the informal extension of Hammer.

Another contribution of this paper is the deterministic selection of the new transformation compared with the nondeterministic one of Hammer's method, where "deterministic" means that an LL covering grammar can be obtained in a single process, whereas in Hammer's method a transformer has to choose a set of predictable goals using a heuristic. As a result, whether a grammar is transformable or not can be decided in a single process. The grammatical characterization of the transformable

grammars is also given.

Section 2 contains basic notation and definitions that are used in the subsequent sections. The counterexample showing that a PLR(k) grammar is not k -transformable is presented in section 3. Section 4 defines two relations, which are used to describe the generalized prediction. The idea for the deterministic transforming is developed in section 5. Section 6 suggests a new LL(k) covering transformation and relates the transformable grammars with k -transformable grammars and PLR(k) grammars. Finally, section 7 summarizes this paper.

2. Basic notation and definitions. We use notation and definitions based on [9], and the reader is assumed to be familiar with them.

Throughout this paper, the symbol G denotes an arbitrary context-free grammar $G = (N, \Sigma, P, S)$ (let $V = N \cup \Sigma$). The symbol k represents an arbitrary positive integer. Without being explicitly stated, G is assumed to be LR(k). Let $S' \notin N$ and a terminal symbol $\$ \notin \Sigma$. Then $G' = (N \cup \{S'\}, \Sigma \cup \{\$\}, P \cup \{S' \rightarrow S\$^k\}, S')$ is the augmented grammar of G . In this paper, G is assumed to be augmented and *reduced* [9].

Lowercase Greek letters, such as $\alpha, \beta,$ and $\gamma,$ denote strings in V^* ; lowercase Roman letters near the beginning of the alphabet, such as $a, b,$ and $c,$ are in $\Sigma,$ and those near the end, such as $w, x, y,$ and $z,$ are in $\Sigma^*;$ uppercase Roman letters near the end of the alphabet, such as $W, X,$ and $Y,$ are in $V.$ The empty string is denoted by $\epsilon.$ The reverse of a string α is represented by $\alpha^R.$

Let w be a terminal string. Then $k:w$ is equal to w if $|w| \leq k,$ or the first k symbols of w otherwise. For any G and any $\alpha \in (V \cup \{\$\})^*,$ $L^G(\alpha) = \{x | \alpha \Rightarrow^* x \text{ in } G, x \in \Sigma^*\},$ $FIRST_k^G(\alpha) = \{k:x | \alpha \Rightarrow^* x \text{ in } G, x \in \Sigma^*\},$ and $FOLLOW_k^G(\alpha) = \{k:x | S' \Rightarrow^* \beta\alpha x \text{ in } G, x \in \Sigma^*\}.$ If G is obvious, then it is omitted.

A string $\alpha \in V^*$ is said to be a *viable prefix of G* if there exists a derivation $S' \Rightarrow_{rm}^* \beta Bz \Rightarrow_{rm} \beta\gamma\delta z \Rightarrow_{rm}^* \beta\gamma yz$ in $G,$ where $\beta\gamma = \alpha$ and rm stands for the rightmost derivation. For a viable prefix α of $G,$ *k -right context* is defined as: $RC_k^G(\alpha) = \{k:yz | \text{there exists } S' \Rightarrow_{rm}^* \beta Bz \Rightarrow_{rm} \beta\gamma\delta z \Rightarrow_{rm}^* \beta\gamma yz \text{ in } G \text{ where } \beta\gamma = \alpha\}.$

A restricted relation $\Rightarrow_{A,R}$ of $\Rightarrow_{rm},$ where $A \in N$ and $R \subseteq FOLLOW_k(A),$ is defined. Let $p = B \rightarrow X\delta.$ Suppose that there exists $Ar \Rightarrow_{rm}^* \gamma Bzr \Rightarrow_{rm}^p \gamma X\delta zr,$ where $r \in R$ and $z \in \Sigma^*.$ Then

$$\gamma Bzr \Rightarrow_{A,R}^p \gamma X\delta zr \begin{cases} \text{holds when } FIRST_k(\delta zr) \cap R = \emptyset & \text{if } \gamma = \epsilon \text{ and } X = A, \\ \text{always holds} & \text{otherwise.} \end{cases}$$

Every derivation using $\Rightarrow_{A,R}$ starts from A and must not derive a string containing A at the leftmost position such that the string of the A immediately following belongs to $R.$ That is, the derivation $Ar \Rightarrow_{A,R}^+ Axr,$ where $r \in R$ and $k:xr \in R$ is not allowed. The difference between $\Rightarrow_{A,R}$ and \Rightarrow_{rm} is clear when A is left recursive.

The k -right context function RC_k^G is localized over derivation $\Rightarrow_{A,R}$ as follows. Let $\alpha \in V^*.$ Then $RC_k^{A,R}(\alpha) = \{k:yzr | \text{there exists } Ar \Rightarrow_{A,R}^* \beta Bzr \Rightarrow_{A,R} \beta\gamma\delta zr \Rightarrow_{A,R}^* \beta\gamma yzr \text{ in } G \text{ where } r \in R \text{ and } \beta\gamma = \alpha\}.$

The equivalence of grammars can be considered in terms of languages or syntactic structures. That is, for G_1 and $G_2,$ the former means $L(G_1) = L(G_2),$ and the latter means that the grammars satisfy a covering property. We present the definition of left-to-right cover.

DEFINITION 2.1. Let $G_1 = (N_1, \Sigma, P_1, S_1)$ and $G_2 = (N_2, \Sigma, P_2, S_2)$ be grammars such that $L(G_1) = L(G_2),$ and let h be a homomorphism from P_2 to $P_1.$

Then we say that G_2 left-to-right covers G_1 with respect to h if the following conditions are satisfied:

1. If there exists $S_2 \Rightarrow_{l_m}^\pi w$ in G_2 , then there exists $S_1 \Rightarrow_{r_m}^{h(\pi)} w$ in G_1 , and
2. if there exists $S_1 \Rightarrow_{r_m}^\pi w$ in G_1 , then there exists $S_2 \Rightarrow_{l_m}^\pi w$ in G_2 , where $h(\pi) = \pi'$.

Let G_2 be $LL(k)$ and G_1 be $LR(k)$. Then G_2 *LL-to-LR(k)* covers G_1 if G_2 left-to-right covers G_1 with respect to h for some h . At this time, G_2 is said to be an *LL-to-LR(k) covering* (or simply, *LL(k) covering*) grammar of G_1 .

We next present the definition of $PLR(k)$ grammars.

DEFINITION 2.2. (see [10]). A grammar $G = (N, \Sigma, P, S)$ is said to be *PLR(k)* if in G' , for each production $A \rightarrow X\delta$, where $X\delta \neq \epsilon$, the conditions

$$\begin{aligned} S' &\Rightarrow_{r_m}^* \beta A z_1 \Rightarrow_{r_m} \beta X \delta z_1 \Rightarrow_{r_m}^* \beta X y_1 z_1, \\ S' &\Rightarrow_{r_m}^* \beta' B z_2 \Rightarrow_{r_m} \beta' \beta'' X \zeta z_2 \Rightarrow_{r_m}^* \beta' \beta'' X y_2 z_2, \text{ and} \\ &\beta' \beta'' = \beta \text{ and } k:y_1 z_1 = k:y_2 z_2 \end{aligned}$$

always imply that $\beta A = \beta' B$.

Instead of the original definition [3] of k -transformable grammars, we use the following theorem to characterize k -transformable grammars because it does not require any understanding of the intricate multiple stack machine.

THEOREM 2.3. (see [7]). G is k -transformable iff there exists a constant n , depending on G , such that if $\alpha (\neq \epsilon)$ is a viable prefix of G and v is a string in $RC_k^G(\alpha)$, then there exist B, W , and $\gamma (\neq \epsilon)$, where $\alpha = \beta\gamma$, $|\gamma| \leq n$, and $v \in RC_k^{B,W}(\gamma)$ such that whenever there exists $S' \Rightarrow_{r_m}^* \beta\gamma z \Rightarrow_{r_m}^* \beta y z$ in G , where $k:yz \in RC_k^{B,W}(\epsilon)$, there exist $S' \Rightarrow_{r_m}^* \beta B z''$ and $Bw \Rightarrow_{B,W}^* \gamma z'w \Rightarrow_{B,W}^* yz'w$ in G , where $w = k:z'' (w \in W)$ and $z'z'' = z$. (We call the n the characteristic of k -transformableness for G .)

3. A counterexample. The following example shows a $PLR(1)$ grammar that is not k -transformable for all $k \geq 0$.

Example 3.1. Let $G1 = (\{S, C, D, X, Y\}, \{c, d, b, a\}, \{S \rightarrow C, C \rightarrow DXc, C \rightarrow DYd, D \rightarrow bD, D \rightarrow a, X \rightarrow DC, X \rightarrow DD, Y \rightarrow Dd\}, S)$. Then we can decide that $G1$ is $LR(1)$ and $PLR(1)$, but is not k -transformable for all $k (k \geq 1)$. Suppose that $G1$ is k -transformable for some fixed k and n is the characteristic of k -transformableness for $G1$. Let us set α and v to be $DD(DD)^j$ for some $j > n$ and b , respectively. Then we cannot find the B, W , and γ in Theorem 2.3. Hence, $G1$ cannot be k -transformable.

Thus, $PLR(k)$ grammars are not a subclass of k -transformable grammars. Conversely, k -transformable grammars are not a subclass of $PLR(k)$ grammars. For example, a grammar with the production set $\{S \rightarrow aAa, A \rightarrow Bb, B \rightarrow Aa, A \rightarrow b\}$ is $LR(1)$ and 1-transformable. The grammar, however, is not $PLR(1)$ because there exist two contradictory derivations $S' \Rightarrow_{r_m} S\$ \Rightarrow_{r_m} aAa\$$ and $S' \Rightarrow_{r_m} S\$ \Rightarrow_{r_m} aAa\$ \Rightarrow_{r_m} aBba\$ \Rightarrow_{r_m} aAaba\$$. Thus, there is no inclusion relationship between k -transformable grammars and $PLR(k)$ grammars. A generalized grammar class, which contains both grammars, is hence motivated, and the subsequent sections treat this subject.

4. Two relations. This section defines two relations in order to formally describe the generalized prediction.

4.1. d relation. A rightmost derivation in a grammar can be analyzed through the dependency relation of Knuth [6]. The relation, called d relation, is here refined

by attributing some terminal strings in order to represent context information in sentential forms.

Let $A \in N$, $r \in \Sigma^k$, $\alpha \in V^*$, $X \in V \cup \{\epsilon\}$, and $v \in \Sigma^k \cup \Sigma^{k-1}$. Then

$$(4.1) \quad (A, r) d^\alpha (X, v) \text{ iff } A \rightarrow \alpha X \beta \in P, r \in FOLLOW_k(A),$$

$v \in FIRST_k(\beta r)$ when $X \in N \cup \{\epsilon\}$, and $v \in FIRST_{k-1}(\beta r)$ when $X \in \Sigma$.

Let $(A, r) d^{0^\epsilon} (A, r)$ be $(A, r) d^\epsilon (A, r)$, and $(A, r) d^{n^\alpha} (X, v)$, $n > 0$, be the composition of $(A, r) d^{n-1^\beta} (B, w)$ and $(B, w) d^\gamma (X, v)$, where $\beta\gamma = \alpha$. The reflexive transitive closure of d relation, denoted by d^* , is defined by $\bigcup_{n \geq 0} d^n$.

The directed graph associated with the d relation is called the d -graph. It is constructed by representing each instance (4.1) as a pair of vertices connected by a directed edge:

A path is represented by $h = (A_0, r_0) d^{\alpha_1} (A_1, r_1) \cdots (A_{n-1}, r_{n-1}) d^{\alpha_n} (A_n, r_n)$. If $A_n \in \Sigma$ or $A_n = \epsilon$, then h is a *terminal path*. If the intercomponents $(A_1, r_1), \dots, (A_{n-1}, r_{n-1})$ are not important, then h is represented by $(A_0, r_0) d^{*\alpha_1 \cdots \alpha_n} (A_n, r_n)$.

Given a path in the d -graph, we can infer a corresponding rightmost derivation, and vice versa.

PROPERTY 4.1. *Let $A_i \in N$ and $r_i \in \Sigma^k$, $i = 0, 1, \dots, n$. Then there exists a path $h = (A_0, r_0) d^{\alpha_1} (A_1, r_1) d^{\alpha_2} (A_2, r_2) \cdots (A_{n-1}, r_{n-1}) d^{\alpha_n} (A_n, r_n)$ in the d -graph iff there exists a derivation in G such that $A_0 r_0 \Rightarrow_{rm}^* \alpha_1 A_1 \beta_1 r_0 \Rightarrow_{rm}^* \alpha_1 A_1 z_1 r_0 \Rightarrow_{rm}^* \alpha_1 \alpha_2 A_2 \beta_2 z_1 r_0 \Rightarrow_{rm}^* \alpha_1 \alpha_2 \cdots \alpha_{n-1} A_{n-1} z_{n-1} \cdots z_1 r_0 \Rightarrow_{rm}^* \alpha_1 \alpha_2 \cdots \alpha_{n-1} \alpha_n A_n \beta_n z_{n-1} \cdots z_1 r_0 \Rightarrow_{rm}^* \alpha_1 \alpha_2 \cdots \alpha_{n-1} \alpha_n A_n z_n z_{n-1} \cdots z_1 r_0$ for some $z_i \in \Sigma^*$ where $k: z_i \cdots z_1 r_0 = r_i$ ($i = 1, \dots, n$).*

Proof. The *only if* part can be proved by simple induction on n , and the *if* part can be proved by directly applying the definition of the d relation. \square

A sequence of d^ϵ -related vertices in a path is defined as a *segment*. Let $h = (A_0, r_0) d^{\alpha_1} (A_1, r_1) \cdots (A_{n-1}, r_{n-1}) d^{\alpha_n} (A_n, r_n)$ be a path in the d -graph. If $\beta = \alpha_1 \cdots \alpha_i$ and $\alpha_{i+1} \cdots \alpha_j = \epsilon$, then the $|\beta|$ -segment of h is $(A_i, r_i) d^{\alpha_{i+1}} (A_{i+1}, r_{i+1}) \cdots (A_{j-1}, r_{j-1}) d^{\alpha_j} (A_j, r_j)$, where

$$(4.2) \quad \alpha_i \neq \epsilon \text{ when } i \neq 0 \text{ and } \alpha_{j+1} \neq \epsilon \text{ when } j \neq n.$$

Condition (4.2) says that the immediate predecessor and the immediate successor of a segment, if they exist, are not d^ϵ -related.

PROPERTY 4.2. *Let $A \in N$ and $r \in \Sigma^k$. There exists $(A_l, r_l) = (A, r)$ for some l ($i \leq l \leq j$) in the $|\beta|$ -segment $(A_i, r_i) d^\epsilon (A_{i+1}, r_{i+1}) \cdots (A_{j-1}, r_{j-1}) d^\epsilon (A_j, r_j)$ of the path $(A_0, r_0) d^{*\alpha} (A_n, r_n)$ iff there exists $A_0 r_0 \Rightarrow_{rm}^* \beta A z r_0$ in G , where $k: z r_0 = r$.*

We next define a specialized path in the d -graph that is related to a derivation over $\Rightarrow_{A, R}$.

DEFINITION 4.1. *Let $A \in N, r \in \Sigma^k, \alpha \in V^*$, and $u \in \Sigma^k$. Suppose that $h = (A_0, r_0) d^{\alpha_1} (A_1, r_1) \cdots (A_{n-1}, r_{n-1}) d^{\alpha_n} (A_n, r_n)$ is a terminal path in the d -graph, where $A_0 = A, r_0 = r, \alpha_1 \cdots \alpha_n = \alpha$, and $A_n r_n = u$. Assume that there is no i ($1 \leq i \leq m$) in the 0-segment $(A_0, r_0) d^\epsilon (A_1, r_1) \cdots d^\epsilon (A_m, r_m)$ of h such that $A_i = A$ and $r_i = r$. Then h is said to be an $\langle A, r, \alpha, u \rangle$ -path.*

The following property can be obtained similarly to Property 4.1.

PROPERTY 4.3. *Let $r \in R$. If there exists an $\langle A, r, \alpha, u \rangle$ -path in the d -graph, then there exists a derivation $Ar \Rightarrow_{A,R}^* \beta Bzr \Rightarrow_{A,R} \beta \gamma \delta zr \Rightarrow_{A,R}^* \beta \gamma yzr$ in G , where $\beta \gamma = \alpha$ and $k:yzr = u$, and vice versa.*

On the other hand, $RC_k^{A,R}$ can be obtained by examining some related paths in the d -graph as follows.

PROPERTY 4.4. $RC_k^{A,R}(\alpha) = \{u \mid \text{there exists an } \langle A, r, \alpha, u \rangle\text{-path in the } d\text{-graph where } r \in R\}$.

Proof. (\supseteq) Assume that there exists an $\langle A, r, \alpha, u \rangle$ -path in the d -graph, $h = (A, r) d^{*\alpha} (a, v)$, $r \in R$, where $av = u$. Then by Property 4.3, there exists a derivation $Ar \Rightarrow_{A,R}^* \beta Bzr \Rightarrow_{A,R} \beta \gamma \delta zr \Rightarrow_{A,R}^* \beta \gamma yzr$ in G , where $\beta \gamma = \alpha$ and $k:yzr = u$. Hence, $u \in RC_k^{A,R}(\alpha)$.

(\subseteq) Let $u \in RC_k^{A,R}(\alpha)$. Then there exists a derivation $Ar \Rightarrow_{A,R}^* \beta Bzr \Rightarrow_{A,R} \beta \gamma \delta zr \Rightarrow_{A,R}^* \beta \gamma yzr$ in G , where $\beta \gamma = \alpha$ and $k:yzr = u$ for some $r \in R$. By Property 4.3, there exists an $\langle A, r, \alpha, u \rangle$ -path in the d -graph. \square

4.2. $\mathbf{\Pi}$ relation. We define a predictive relation, written by $\mathbf{\Pi}$, which represents predictable symbols based on the generalized idea.

DEFINITION 4.2. *Let $A, B \in N, R \subseteq FOLLOW_k(A), W \subseteq FOLLOW_k(B), \beta, \gamma \in V^*$, where $(A, R, \beta \gamma) \neq (B, W, \gamma)$ and $u \in RC_k^{B,W}(\gamma)$. Then $(A, R, \beta \gamma) \mathbf{\Pi}_u (B, W, \gamma)$ iff, for each $\langle A, r, \beta \gamma, u \rangle$ -path, $r \in R$, we let $(A_0, r_0) d^\epsilon (A_1, r_1) \cdots (A_{n-1}, r_{n-1}) d^\epsilon (A_n, r_n)$ be the $|\beta|$ -segment of the path, then*

(i) *there exists m ($0 \leq m \leq n$) such that*

$$(4.3) \quad A_m = B$$

and

$$(4.4) \quad \bigcup_h \{r_i \mid A_i = B, 0 \leq i \leq m\} \cap \bigcup_h \{r_i \mid A_i = B, m+1 \leq i \leq n\} = \emptyset,$$

where h in (4.4) ranges over all $\langle A, r, \beta \gamma, u \rangle$ -paths, and

(ii) *if m_s is the smallest m ($m > 0$ when $\beta = \epsilon$) satisfying both (4.3) and (4.4), then*

$$(4.5) \quad W = \bigcup_h \{r_{m_s}\},$$

where h in (4.5) ranges over all $\langle A, r, \beta \gamma, u \rangle$ -paths.

$(A, R, \beta \gamma) \mathbf{\Pi}_u (B, W, \gamma)$ means that when the suffix $\beta \gamma$ of the current stack string is already predicted to be reduced to (A, R) ,¹ it is now predicted that whenever the k -length prefix of the remaining input is u , it is certain that the suffix γ of $\beta \gamma$ will be reduced to (B, W) . Figure 4.1 depicts this prediction; the left tree is expected to be the right one. This relation expresses the generalized prediction; compared to Hammer and Soisalon-Soininen's methods, γ is not restricted, and the prediction is performed over a predictive string u rather than over predictive language [3].

The smallest condition in Definition 4.2(ii) is meaningful only when B is left recursive. If B is not left recursive, then the m in Definition 4.2(i) is unique, and so the smallest condition becomes meaningless.

¹ (A, R) represents a refinement of A with the context information R such that (A, R) 's following string belongs to R and the generated language from (A, R) is $L(A, R) = \{x \mid Ar \Rightarrow_{A,R}^* xr, r \in R\}$.

FIG. 4.1. Predictive property.

The following two lemmas delineate the meaning of $(A, R, \beta\gamma)\mathbf{II}_u(B, W, \gamma)$ in terms of grammatical derivation forms.

LEMMA 4.3. *Let $(A, R, \beta\gamma)\mathbf{II}_u(B, W, \gamma)$. Then whenever there exists $Ar \Rightarrow_{A,R}^* \beta\gamma zr$, where $r \in R$ and $k:zr=u$, there exist $Ar \Rightarrow_{A,R}^* \beta Byr$ and $Bw \Rightarrow_{B,W}^* \gamma xw$, where $w = k:yr (w \in W)$ and $xy = z$.*

Proof. Consider the derivation

$$\begin{aligned}
 (4.6) \quad & B_0 r \Rightarrow_{A,R} \beta_1 B_1 \delta_1 r \Rightarrow_{A,R}^* \beta_1 B_1 z_1 r \Rightarrow_{A,R} \beta_1 \beta_2 B_2 \delta_2 z_1 r \\
 & \Rightarrow_{A,R}^* \cdots \Rightarrow_{A,R}^* \beta_1 \beta_2 \cdots \beta_n B_n z_n \cdots z_1 r,
 \end{aligned}$$

where $B_0 = A$, $\beta_1 \cdots \beta_n = \beta\gamma$, and $k:zr = u$ with $B_n z_n \cdots z_1 = z$. Then there exists a corresponding path $h = (B_0, r_0) d^{\beta_1} (B_1, r_1) d^{\beta_2} (B_2, r_2) \cdots (B_{n-1}, r_{n-1}) d^{\beta_n} (B_n, r_n)$, where $r_0 = r$, $r_i = k:z_i \cdots z_1 r$ ($i = 1, \dots, n-1$), and $B_n r_n = u$. Here, h is an $\langle A, r, \beta\gamma, u \rangle$ -path. Let $(A_0, r_0) d^\epsilon (A_1, r_1) \cdots d^\epsilon (A_n, r_n)$ be the $|\beta|$ -segment of path h . By Definition 4.2 and (4.3), there exists A_m for some $m (0 \leq m \leq n)$ such that $A_m = B$, and by Definition 4.2 and (4.4), there is no $r_j \in W, m < j \leq n$. Thus, the derivation (4.6) can be divided into $Ar \Rightarrow_{A,R}^* \beta Byr$, where $\beta = \beta_1 \cdots \beta_m$ and $y = z_m \cdots z_1$ and $Bw \Rightarrow_{B,W}^* \gamma xw$, where $\gamma = \beta_{m+1} \cdots \beta_n$, $x = B_n z_n \cdots z_{m+1}$, and $w = k:yr = r_m (w \in W)$. \square

Similar to the proof of Lemma 4.3, we can prove the following lemma; the details are omitted.

LEMMA 4.4. *Let $A, B \in N, R \subseteq FOLLOW_k(A), W \subseteq FOLLOW_k(B), \beta, \gamma \in V^*$, and $u \in RC_k^{B,W}(\gamma)$. If, whenever there exists $Ar \Rightarrow_{A,R}^* \beta\gamma zr$ where $r \in R$ and $k:zr=u$, there exist $Ar \Rightarrow_{A,R}^* \beta Byr$ and $Bw \Rightarrow_{B,W}^* \gamma xw$ where $w = k:yr (w \in W)$ and $xy = z$, then $(A, R, \beta\gamma)\mathbf{II}_u(B, W', \gamma)$ for some W' .*

Let $(A, R, \beta\gamma)\mathbf{II}_u(B, W, \gamma)$ and $(A, R, \beta\gamma)\mathbf{II}_u(B, W', \gamma)$. Then W is equal to W' because of the smallest property in Definition 4.2 (ii).

The following example shows the computing process of \mathbf{II} relations.

Example 4.1. Let $G2 = (\{S, A, C, B, X, Y\}, \{a, b, c\}, P2, S)$, where $P2 = \{S \rightarrow A, S \rightarrow C, A \rightarrow BX, A \rightarrow BY, C \rightarrow Ba, B \rightarrow b, X \rightarrow BA, X \rightarrow c, Y \rightarrow BC\}$. Note that $G2$ is LR(1). See $\langle A, \$, BBB, b \rangle$ -paths and $\langle A, \$, BBB, c \rangle$ -paths in Figure 4.2.

(i) We can find two $\langle A, \$, BBB, b \rangle$ -paths, $p1 = (A, \$) d^B(X, \$) d^B(A, \$) d^B(X, \$) d^\epsilon(B, b) d^\epsilon(b, \epsilon)$ and $p2 = (A, \$) d^B(X, \$) d^B(A, \$) d^B(Y, \$) d^\epsilon(B, b) d^\epsilon(b, \epsilon)$. Then $p1$ and $p2$ have the same 2-segment $(A, \$)$. Hence, we have $(A, \{\$, \}, BBB) \mathbf{II}_b(A, \{\$, \}, B)$. On the other hand, $p1$ and $p2$ have the 3-segments $(X, \$) d^\epsilon(B, b) d^\epsilon(b, \epsilon)$ and $(Y, \$) d^\epsilon(B, b) d^\epsilon(b, \epsilon)$, respectively. Hence, we have $(A, \{\$, \}, BBB) \mathbf{II}_b(B, \{b\}, \epsilon)$.

(ii) We next find one $\langle A, \$, BBB, c \rangle$ -path, $p3 = (A, \$) d^B(X, \$) d^B(A, \$) d^B(X, \$) d^\epsilon(c, \epsilon)$. By examining this path, we have $(A, \{\$, \}, BBB) \mathbf{II}_c(A, \{\$, \}, B)$ and $(A, \{\$, \}, BBB) \mathbf{II}_c(X, \{\$, \}, \epsilon)$.

FIG. 4.2. A part of the d -graph.

In the computation of the \mathbf{II} relation, visiting vertices in the d -graph a bounded number of times is enough even when cycles are present in the d -graph.

5. Deterministic prediction. This section develops a deterministic procedure for choosing only one relation when there exist more than one \mathbf{II}_u relation with a fixed left side. In Hammer’s method, a heuristic is used for the selection. In this paper, the choice problem is resolved by choosing the nearer one in the derivation tree between the corresponding positions of (B, W, γ) and (C, X, ζ) to that of (A, R, α) . Let $\alpha = \beta\gamma$ and $\gamma = \delta\zeta$. The roots (A, R) , (B, W) , and (C, X) of the subtrees constructed from (A, R, α) , (B, W, γ) , and (C, X, ζ) are shown in Figure 5.1. In this situation, (B, W, γ) is selected since (A, R) is nearer to (B, W) than it is to (C, X) .

FIG. 5.1. Derivation tree.

In the remaining part of the paper, if $(A, R, \beta\gamma)\mathbf{II}_u(B, W, \gamma)$, then we assume $u \in \{k:x|Bw \Rightarrow_{B,W}^* \gamma xw, w \in W\}$ for some technical simplification.

The following lemma is used to show the orderable property of \mathbf{II} in the nearest sequence.

LEMMA 5.1.

(i) Let $(A, R, \beta\delta\zeta)\mathbf{II}_u(B, W, \delta\zeta)$ and $(A, R, \beta\delta\zeta)\mathbf{II}_u(C, X, \zeta)$. Then for each $w \in W$, there exists $x \in X$ such that $(B, w)d^{*\delta}(C, x)$.

(ii) Let $(A, R, \beta\delta\zeta)\mathbf{II}_u(B, W, \delta\zeta)$ and $(B, W, \delta\zeta)\mathbf{II}_u(C, X, \zeta)$. Then $(A, R, \beta\delta\zeta)\mathbf{II}_u(C, X, \zeta)$.

(iii) Let $(A, R, \beta\delta\zeta)\mathbf{II}_u(B, W, \delta\zeta)$ and $(A, R, \beta\delta\zeta)\mathbf{II}_u(C, X, \zeta)$, where $(B, W, \delta\zeta) \neq (C, X, \zeta)$. Then when $\delta \neq \epsilon$, $(B, W, \delta\zeta)\mathbf{II}_u(C, X, \zeta)$; when $\delta = \epsilon$, $(B, W, \zeta)\mathbf{II}_u(C, X, \zeta)$ or $(C, X, \zeta)\mathbf{II}_u(B, W, \zeta)$.

(iv) There are no $A, R, \alpha, u, B, W, \gamma$ such that $(A, R, \alpha)\mathbf{II}_u(B, W, \gamma)$ and $(B, W, \gamma)\mathbf{II}_u(A, R, \alpha)$, where $(A, R, \alpha) \neq (B, W, \gamma)$.

Proof.

(i) Let $w \in W$. Then there exists an $\langle A, r, \beta\delta\zeta, u \rangle$ -path h , where $r \in R$ which contains (B, w) on the $|\beta|$ -segment. The path h also contains (C, x) for some $x \in X$ on the $|\beta\delta|$ -segment. Hence, $(B, w)d^{*\delta}(C, x)$ holds, and Lemma 5.1(i) is true.

(ii) Let $r \in R$. Take an arbitrary $\langle A, r, \beta\delta\zeta, u \rangle$ -path h . Since $(A, R, \beta\delta\zeta)\mathbf{II}_u(B, W, \delta\zeta)$ holds, h contains (B, w) for some $w \in W$ on the $|\beta|$ -segment. Take an arbitrary $\langle B, w, \delta\zeta, u \rangle$ -path h_2 that is a suffix of h . Since $(B, W, \delta\zeta)\mathbf{II}_u(C, X, \zeta)$ holds, h_2 contains (C, x) for some $x \in X$ on the $|\delta|$ -segment. Hence, $(A, R, \beta\delta\zeta)\mathbf{II}_u(C, X', \zeta)$ holds. The next goal is to show $X' = X$. When $\delta \neq \epsilon$, it is obvious that $X' = X$. We next consider the case of $\delta = \epsilon$. Figure 5.2(a)–(c) shows the possible forms of an $\langle A, r, \beta\delta\zeta, u \rangle$ -path containing (B, w) and (C, x) on the $|\beta|$ -segment. By investigating the figure, we know that there are some paths in (a) and (c) that do not contain (B, w) or (C, x) , and so (b) is the only correct form. Hence, we can conclude that every (C, x) , $x \in X$ on the $|\beta|$ -segment of h follows (B, w) for some $w \in W$ on the same segment. As a consequence, X' has to be equal to X .

(iii) We first think about the case of $\delta \neq \epsilon$. Let $w \in W$. Take an arbitrary $\langle B, w, \delta\zeta, u \rangle$ -path h . Then according to Lemma 5.1(i), h has a $\langle C, x, \zeta, u \rangle$ -path for some $x \in X$ as a suffix. Hence, $(B, W, \delta\zeta)\mathbf{II}_u(C, X, \zeta)$ holds. Let us consider the other case of $\delta = \epsilon$. Then either one of $(B, W, \zeta)\mathbf{II}_u(C, X', \zeta)$ or $(C, X, \zeta)\mathbf{II}_u(B, W', \zeta)$ holds. Without loss of generality, we assume $(B, W, \zeta)\mathbf{II}_u(C, X', \zeta)$. At this point, by Lemma 5.1(ii), $(A, R, \beta\delta\zeta)\mathbf{II}_u(C, X', \zeta)$ holds. On the other hand, X' is uniquely determined, and thus $X' = X$. In all, $(B, W, \zeta)\mathbf{II}_u(C, X, \zeta)$ holds.

(iv) Assume that $(A, R, \alpha)\mathbf{II}_u(B, W, \gamma)$ and $(B, W, \gamma)\mathbf{II}_u(A, R, \alpha)$, where $(A, R, \alpha) \neq (B, W, \gamma)$. Then $\alpha = \gamma$, and $(A, R) \neq (B, W)$ because of $(A, R, \alpha) \neq (B, W, \gamma)$. Take an arbitrary $\langle B, w, \gamma, u \rangle$ -path h , $w \in W$. Then h is a suffix of an $\langle A, r, \alpha, u \rangle$ -path for some $r \in R$ because of $(A, R, \alpha)\mathbf{II}_u(B, W, \gamma)$. Next, take an arbitrary $\langle A, r, \alpha, u \rangle$ -path h_2 ; then, h_2 is a suffix of a $\langle B, w, \gamma, u \rangle$ -path for some $w \in W$ because of $(B, W, \gamma)\mathbf{II}_u(A, R, \alpha)$. However, the 0-segment of an $\langle A, r, \alpha, u \rangle$ -path cannot contain (A, r) in any other position but the first. As a result, both $(A, R, \alpha)\mathbf{II}_u(B, W, \gamma)$ and $(B, W, \gamma)\mathbf{II}_u(A, R, \alpha)$ cannot be true. \square

Let $(A, R, \alpha)\mathbf{II}_u(B, W, \gamma)$ and $(A, R, \alpha)\mathbf{II}_u(C, X, \zeta)$. Then by Lemma 5.1(iii), we can assume $(B, W, \gamma)\mathbf{II}_u(C, X, \zeta)$ without loss of generality, and then, by Lemma 5.1(iv), $(C, X, \zeta)\mathbf{II}_u(B, W, \gamma)$ does not hold. By generalizing this property, we have the following lemma.

LEMMA 5.2. Let $(A, R, \alpha)\mathbf{II}_u(B_0, W_0, \gamma_0)$, $(A, R, \alpha)\mathbf{II}_u(B_1, W_1, \gamma_1)$, \dots , (A, R, α)

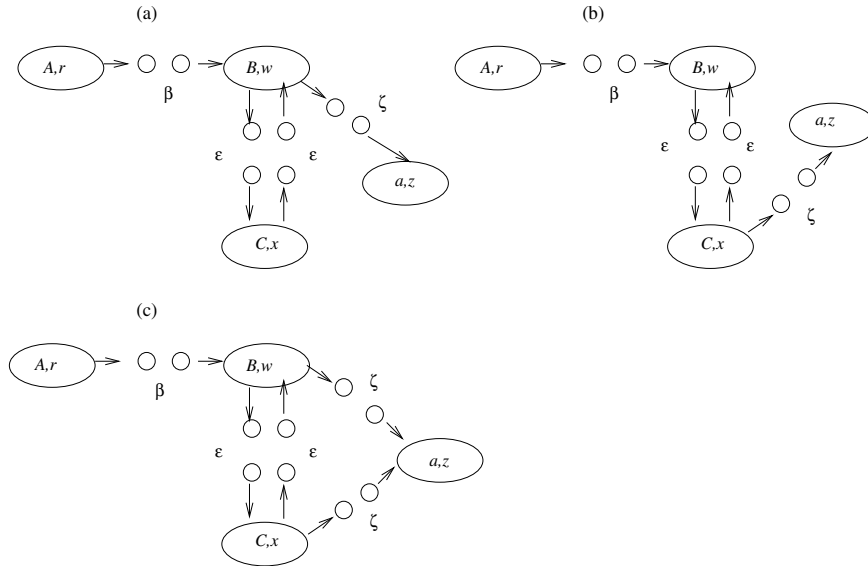

FIG. 5.2. Paths in the d -graph, where $az = u$.

$\mathbb{I}_u(B_n, W_n, \gamma_n)$ be distinct relations. For the elements $(B_0, W_0, \gamma_0), (B_1, W_1, \gamma_1), \dots, (B_n, W_n, \gamma_n)$, there exists a unique sequence $(B_{m_0}, W_{m_0}, \gamma_{m_0}), (B_{m_1}, W_{m_1}, \gamma_{m_1}), \dots, (B_{m_n}, W_{m_n}, \gamma_{m_n})$ such that $(B_{m_{i-1}}, W_{m_{i-1}}, \gamma_{m_{i-1}}) \mathbb{I}_u(B_{m_i}, W_{m_i}, \gamma_{m_i}), i = 1, \dots, n$.

The unique ordering property in Lemma 5.2 enable us to linearize \mathbb{I} relations. Consequently, we can define Φ function as follows.

DEFINITION 5.3. Let A, R, α, u be given. For all the distinct elements $(B_0, W_0, \gamma_0), (B_1, W_1, \gamma_1), \dots, (B_n, W_n, \gamma_n)$ such that $(A, R, \alpha) \mathbb{I}_u(B_i, W_i, \gamma_i), i = 0, \dots, n$, let $(B_{m_0}, W_{m_0}, \gamma_{m_0}), (B_{m_1}, W_{m_1}, \gamma_{m_1}), \dots, (B_{m_n}, W_{m_n}, \gamma_{m_n})$ be the sequence such that $(B_{m_{i-1}}, W_{m_{i-1}}, \gamma_{m_{i-1}}) \mathbb{I}_u(B_{m_i}, W_{m_i}, \gamma_{m_i}), i = 1, \dots, n$. Then $\Phi(A, R, \alpha, u)$ is defined as $(B_{m_0}, W_{m_0}, \gamma_{m_0})$; otherwise, $\Phi(A, R, \alpha, u)$ is undefined.

We have, in Example 4.1, $(A, \{\$, \}, BBB) \mathbb{I}_b(A, \{\$, \}, B)$ and $(A, \{\$, \}, BBB) \mathbb{I}_b(B, \{\$, \}, \epsilon)$. Then we have the unique sequence $(A, \{\$, \}, B), (B, \{\$, \}, \epsilon)$ satisfying the condition in Lemma 5.2; note that $(A, \{\$, \}, B) \mathbb{I}_b(B, \{\$, \}, \epsilon)$ holds. Hence, $\Phi(A, \{\$, \}, BBB, b)$ is defined as $(A, \{\$, \}, B)$. Similarly, $\Phi(A, \{\$, \}, BBB, c)$ is defined as $(A, \{\$, \}, B)$.

6. Extended PLR(k) grammars. Using the Φ function, we give a transformation into LL(k) form, and the transformable grammars are defined as extended PLR(k) grammars.

6.1. A transformation. Given G , the following algorithm is applied to obtain $T(G)$.

ALGORITHM 1 (construction of $T(G)$).

INPUT: G

OUTPUT: If this algorithm successfully terminates, $T(G) = (\mathbf{N}, \Sigma, \mathbf{P}, \mathbf{S})$ is constructed.

METHOD:

1. Initially,

$\mathbf{S} = [S, \{\$^k\}, \epsilon, \text{FIRST}_k(S\$^k)]; \mathbf{N} = \{\mathbf{S}\}; \mathbf{P} = \emptyset.$

2. **repeat**

(a) For each $[A, R, \alpha, U] \in \mathbf{N}$, let $Z = \{u \in U \mid \Phi(A, R, \alpha, u) \text{ is defined}\}$, then do the following:

Type 1. $\mathbf{P} = \mathbf{P} \cup \{[A, R, \alpha, U] \rightarrow a[A, R, \alpha a, V]\}$ if $V \neq \emptyset$, where $V = \{k:zwr \mid \text{there exists } Ar \Rightarrow_{A,R}^* \beta Bwr \Rightarrow_{A,R} \beta \gamma a \delta wr \Rightarrow_{A,R}^* \beta \gamma a zwr \text{ in } G, \text{ where } r \in R, \beta \gamma = \alpha, k:azwr \in U, \text{ and } k:azwr \notin Z\}.$

Type 2. $\mathbf{P} = \mathbf{P} \cup \{[A, R, \alpha, U] \rightarrow [A, R, \beta B, V]\}$, where $\alpha = \beta \gamma$ if $V \neq \emptyset$, where $V = \{k:wr \mid \text{there exists } Ar \Rightarrow_{A,R}^* \beta Bwr \Rightarrow_{A,R} \beta \gamma wr \text{ in } G, \text{ where } r \in R, k:wr \in U, \text{ and } k:wr \notin Z\}.$

Type 3. $\mathbf{P} = \mathbf{P} \cup \{[A, R, A, U] \rightarrow \epsilon\}$, where $R \cap U \neq \emptyset$ and $\alpha = A$.

Type 4. $\mathbf{P} = \mathbf{P} \cup \{[A, R, \alpha, U] \rightarrow [B, W, \gamma, V][A, R, \beta B, W]\}$, where $\alpha = \beta \gamma$ if $V \neq \emptyset$, where $V = \{u \mid \Phi(A, R, \alpha, u) = (B, W, \gamma), u \in U\}.$

(b) New nonterminals that appeared in \mathbf{P} are added to \mathbf{N} .

until (\mathbf{P} is not changed)

Algorithm 1 does not successfully terminate when an infinite number of nonterminals is generated. The formal characterization of the successfully transformable grammars is given in section 6.3. The remarkable observation is that our transformation depends on only G while Hammer's transformation depends on both G and a cycle-free multiple stack machine for G . As a result, given G , $\mathbf{T}(G)$ is constructed in a single process.

6.2. The LL(k) covering property. A homomorphism h is defined from \mathbf{P} to $\mathbf{P} \cup \{\epsilon\}$:

$$h(p_T) = \begin{cases} B \rightarrow \gamma & \text{if } p_T = [A, R, \beta \gamma, U] \rightarrow [A, R, \beta B, V], \\ \epsilon & \text{otherwise.} \end{cases}$$

The following two lemmas show a relationship between a rightmost derivation in G and a leftmost derivation in $\mathbf{T}(G)$.

LEMMA 6.1. Let $[A, R, \alpha, U] \in \mathbf{N}$. Assume that there exists π such that $Ar \Rightarrow_{A,R}^\pi \alpha xr$ in G , where $r \in R$ and $k:xr \in U$. Then there exists π_T such that $[A, R, \alpha, U] \Rightarrow_{lm}^{\pi_T} x$ in $\mathbf{T}(G)$, where $h(\pi_T) = \pi^R$.

Proof. We use induction on $|\pi|$. As the basis, assume that $|\pi| = 1$. Then $A \rightarrow \alpha x \in P$, and there exist an $|x|$ -length string π_T of Type 1 rules such that $[A, R, \alpha, U] \Rightarrow_{lm}^{\pi_T} x[A, R, \alpha x, T]$ and a rule string $p_T^1 p_T^2$ such that $[A, R, \alpha x, T] \Rightarrow_{lm}^{p_T^1} [A, R, A, M] \Rightarrow_{lm}^{p_T^2} \epsilon$ in $\mathbf{T}(G)$ for some M . Here, $h(\pi_T p_T^1 p_T^2) = h(\pi_T) h(p_T^1) h(p_T^2) = h(p_T^1) = A \rightarrow \alpha x$ because of $h(\pi_T) = \epsilon$ and $h(p_T^2) = \epsilon$. Hence, this lemma holds for the basis step. As an inductive hypothesis, assume that this lemma holds when $|\pi| \leq l (l > 1)$. Now suppose that $|\pi| > l$.

Case 1. There exist y, B, W , and γ such that $\Phi(A, R, \alpha y, u) = (B, W, \gamma)$, where $u = k:zr$ with $yz = x$.

In this case, we have a $|y|$ -length string π'_T of Type 1 rules such that $[A, R, \alpha, U] \Rightarrow_{lm}^{\pi'_T} y[A, R, \alpha y, X]$, where $u \in X$ and a rule p_T such that $[A, R, \alpha y, X] \Rightarrow_{lm}^{p_T} [B, W, \gamma, V][A, R, \beta B, W]$, where $u \in V$ and $\alpha y = \beta \gamma$ in $\mathbf{T}(G)$. On the other hand, π such that $Ar \Rightarrow_{A,R}^\pi \alpha yzr$ can be divided into π'' and π''' such that $Ar \Rightarrow_{A,R}^{\pi''} \beta Bz_2r$ and $Bw \Rightarrow_{B,W}^{\pi'''} \gamma z_1w$, where $w = k:z_2r (w \in W)$ and $z_1z_2 = z$ by Lemma 4.3. Note that $k:z_1w \in V$ and $k:z_2r \in W$. By applying the inductive hypothesis to π'' and π''' , we have $[A, R, \beta B, W] \Rightarrow_{lm}^{\pi''} z_2$ and $[B, W, \gamma, V] \Rightarrow_{lm}^{\pi'''} z_1$ in $\mathbf{T}(G)$, where $h(\pi''_T) = (\pi'')^R$ and $h(\pi'''_T) = (\pi''')^R$. Therefore, there exists a rule string $\pi_T (= \pi'_T p_T \pi''_T \pi'''_T)$ such

that $[A, R, \alpha, U] \Rightarrow_{lm}^{\pi_T} yz (= x)$ in $\mathbf{T}(G)$. Here, $h(\pi_T) = h(\pi'_T p_T \pi''_T \pi'''_T) = h(\pi''_T)h(\pi'''_T) = (\pi''_T)^R (\pi'''_T)^R = (\pi''_T \pi'''_T)^R = \pi^R$ because of $h(\pi'_T) = \epsilon$ and $h(p_T) = \epsilon$.

Case 2. The other cases.

(Subcase 2-1) The π is composed of π' and p such that $Ar \Rightarrow_{A,R}^{\pi'} \beta Bzr \Rightarrow_{A,R}^p \beta \gamma yzr$, where $\beta \gamma = \alpha$ and $yz = x$. Then there exist a $|y|$ -length string π''_T of Type 1 rules such that $[A, R, \alpha, U] \Rightarrow_{lm}^{\pi''_T} y[A, R, \alpha y, M]$, where $k:zr \in M$, and a Type 2 rule p_T such that $[A, R, \alpha y, M] \Rightarrow_{lm}^{p_T} [A, R, \beta B, W]$, where $k:zr \in W$ in $\mathbf{T}(G)$ according to the construction of $\mathbf{T}(G)$. On the other hand, by applying the inductive hypothesis to π' , we have $[A, R, \beta B, W] \Rightarrow_{lm}^{\pi'_T} z$ in $\mathbf{T}(G)$, where $h(\pi'_T) = (\pi')^R$. In all, there exists $\pi_T (= \pi''_T p_T \pi'_T)$ such that $[A, R, \alpha, U] \Rightarrow_{lm}^{\pi_T} yz$ in $\mathbf{T}(G)$, where $yz = x$. Here, $h(\pi_T) = h(\pi''_T p_T \pi'_T) = h(\pi''_T)h(p_T)h(\pi'_T) = h(p_T)h(\pi'_T) = ph(\pi'_T) = p\pi'^R = (\pi'p)^R = \pi^R$ because of $h(\pi''_T) = \epsilon$.

(Subcase 2-2) The π is composed of π' and p such that $Ar \Rightarrow_{A,R}^{\pi'} \alpha y_1 Bzr \Rightarrow_{A,R}^p \alpha y_1 y_2 zr$, where $y_1 y_2 z = x$. Then there exist a $|y_1 y_2|$ -length string π''_T of Type 1 rules such that $[A, R, \alpha, U] \Rightarrow_{lm}^{\pi''_T} y_1 y_2 [A, R, \alpha y_1 y_2, M]$, where $k:zr \in M$, and a Type 2 rule p_T such that $[A, R, \alpha y_1 y_2, M] \Rightarrow_{lm}^{p_T} [A, R, \alpha y_1 B, W]$, where $k:zr \in W$ in $\mathbf{T}(G)$. On the other hand, we have $[A, R, \alpha y_1 B, W] \Rightarrow_{lm}^{\pi'_T} z$ in $\mathbf{T}(G)$, where $h(\pi'_T) = (\pi')^R$ by applying the inductive hypothesis to π' . In all, there exists $\pi_T (= \pi''_T p_T \pi'_T)$ such that $[A, R, \alpha, U] \Rightarrow_{lm}^{\pi_T} y_1 y_2 z$ in $\mathbf{T}(G)$. Here, $h(\pi_T) = h(\pi''_T p_T \pi'_T) = h(\pi''_T)h(p_T)h(\pi'_T) = h(p_T)h(\pi'_T) = ph(\pi'_T) = p(\pi')^R = (\pi'p)^R = \pi^R$ because of $h(\pi''_T) = \epsilon$. \square

LEMMA 6.2. *If there exists π_T such that $[A, R, \alpha, U] \Rightarrow_{lm}^{\pi_T} x$ in $\mathbf{T}(G)$, then there exists $Ar \Rightarrow_{A,R}^{h(\pi_T)^R} \alpha xr$ in G , where $r \in R$ and $k:xr \in U$.*

Proof. If $|\pi_T| = 1$, then $x = \epsilon, \alpha = A$, and $R \cap U \neq \emptyset$. Let $r \in R \cap U$; then there exists $Ar \Rightarrow_{A,R}^\epsilon Ar$ in G . Note that $k:xr \in U$ because of $k:xr = k:r = r$ and $r \in U$; $h(\pi_T)^R = \epsilon^R = \epsilon$. We have completed the proof of the basis case. Next, as an inductive hypothesis, assume that this lemma holds when $|\pi_T| \leq l (l > 1)$. Now let $|\pi_T| > l$ and $\pi_T = p_T \pi'_T$. Then p_T is a rule of Type 1, Type 2, or Type 4. According to the type, we divide the cases as follows.

Case 1. $p_T = [A, R, \alpha, U] \rightarrow a[A, R, \alpha a, Q]$.

Let $x = az$. Then there exists π'_T such that $[A, R, \alpha a, Q] \Rightarrow_{lm}^{\pi'_T} z$ in $\mathbf{T}(G)$. By applying the inductive hypothesis to π'_T , we have $Ar \Rightarrow_{A,R}^{h(\pi'_T)^R} \alpha azr$ in G , where $r \in R$ and $k:zr \in Q$. According to the construction of the set Q , $k:azr \in U$. Note that $h(\pi_T)^R = h(p_T \pi'_T)^R = h(\pi'_T)^R$ because of $h(p_T) = \epsilon$.

Case 2. $p_T = [A, R, \alpha, U] \rightarrow [A, R, \beta B, W]$.

Let $\alpha = \beta \gamma$ and $p = B \rightarrow \gamma$. Then there exists π'_T such that $[A, R, \beta B, W] \Rightarrow_{lm}^{\pi'_T} x$ in $\mathbf{T}(G)$, and p is a rule in P . By applying the inductive hypothesis to π'_T , we have $Ar \Rightarrow_{A,R}^{h(\pi'_T)^R} \beta Bxr$ in G , where $r \in R$ and $k:xr \in W$. On the other hand, the condition of $k:xr \in U$ is true according to $\mathbf{T}(G)$'s construction. Hence, we have the derivation $Ar \Rightarrow_{A,R}^{h(\pi'_T)^R} \beta Bxr \Rightarrow_{A,R}^p \beta \gamma xr$ in G , where $r \in R$ and $k:xr \in U$. Here, $h(\pi'_T)^R p = (ph(\pi'_T))^R = (h(p_T)h(\pi'_T))^R = h(p_T \pi'_T)^R = h(\pi_T)^R$.

Case 3. $p_T = [A, R, \alpha, U] \rightarrow [B, W, \gamma, Y][A, R, \beta B, W]$.

Let $[B, W, \gamma, Y] \Rightarrow_{lm}^{\pi''_T} x_1$ and $[A, R, \beta B, W] \Rightarrow_{lm}^{\pi'''_T} x_2$ in $\mathbf{T}(G)$, where $x_1 x_2 = x$ and $p_T \pi''_T \pi'''_T = \pi_T$. Then by applying the inductive hypothesis to π''_T and π'''_T , we have $Bw \Rightarrow_{B,W}^{h(\pi''_T)^R} \gamma x_1 w$, where $w \in W$ and $k:x_1 w \in Y$, and $Ar \Rightarrow_{A,R}^{h(\pi'''_T)^R} \beta Bx_2 r$, where $r \in R$ and $k:x_2 r \in W$ in G . Here, $k:x_1 w \in U$ because of $Y \subseteq U$. Without loss of generality, we set w to be $k:x_2 r$. Then we have $Ar \Rightarrow_{A,R}^{h(\pi''_T)^R} \beta Bx_2 r \Rightarrow_{A,R}^{h(\pi'''_T)^R} \beta \gamma x_1 x_2 r$ in G . Here, $k:x_1 x_2 r = k:x_1 (k:x_2 r) = k:x_1 w$, and so $k:x_1 x_2 r \in U$. Note that

$h(\pi_T''')^R h(\pi_T'')^R = (h(\pi_T'')h(\pi_T'''))^R = (h(p_T)h(\pi_T'')h(\pi_T'''))^R = h(p_T\pi_T''\pi_T''')^R = h(\pi_T)^R$
because of $h(p_T) = \epsilon$.

In all, we have this lemma. \square

From Lemmas 6.1 and 6.2, we get the following corollaries.

COROLLARY 6.3. *If there exists π such that $S\mathbb{S}^k \Rightarrow_{rm}^\pi x\mathbb{S}^k$ in G , then there exists π_T such that $[S, \{\mathbb{S}^k\}, \epsilon, FIRST_k(S\mathbb{S}^k)] \Rightarrow_{lm}^{\pi_T} x$ in $\mathbf{T}(G)$, where $h(\pi_T) = \pi^R$.*

Proof. If there exists π such that $S\mathbb{S}^k \Rightarrow_{rm}^\pi x\mathbb{S}^k$ in G , then there exists $S\mathbb{S}^k \Rightarrow_{S, \{\mathbb{S}^k\}}^\pi x\mathbb{S}^k$ in G . On the other hand, $[S, \{\mathbb{S}^k\}, \epsilon, FIRST_k(S\mathbb{S}^k)] \in \mathbf{N}$. Then according to Lemma 6.1, there exists π_T such that $[S, \{\mathbb{S}^k\}, \epsilon, FIRST_k(S\mathbb{S}^k)] \Rightarrow_{lm}^{\pi_T} x$ in $\mathbf{T}(G)$, where $h(\pi_T) = \pi^R$. \square

COROLLARY 6.4. *If there exists π_T such that $[S, \{\mathbb{S}^k\}, \epsilon, FIRST_k(S\mathbb{S}^k)] \Rightarrow_{lm}^{\pi_T} x$ in $\mathbf{T}(G)$, then there exists $S\mathbb{S}^k \Rightarrow_{rm}^{h(\pi_T)^R} x\mathbb{S}^k$ in G .*

Proof. By Lemma 6.2, if there exists π_T such that $[S, \{\mathbb{S}^k\}, \epsilon, FIRST_k(S\mathbb{S}^k)] \Rightarrow_{lm}^{\pi_T} x$ in $\mathbf{T}(G)$, then there exists $S\mathbb{S}^k \Rightarrow_{S, \{\mathbb{S}^k\}}^{h(\pi_T)^R} x\mathbb{S}^k$ in G , and so there exists $S\mathbb{S}^k \Rightarrow_{rm}^{h(\pi_T)^R} x\mathbb{S}^k$ in G . \square

According to Corollaries 6.3 and 6.4, we conclude the following theorem.

THEOREM 6.5. *$\mathbf{T}(G)$ left-to-right covers G with respect to h .*

On the other hand, the LL property of $\mathbf{T}(G)$ can be proved as follows.

THEOREM 6.6. *$\mathbf{T}(G)$ is LL(k).*

Proof. Suppose that $\mathbf{T}(G)$ is not LL(k). Then there exist two derivations in $\mathbf{T}(G)$ such that

$$[S, \{\mathbb{S}^k\}, \epsilon, FIRST_k(S\mathbb{S}^k)] \Rightarrow_{lm}^* x[A, R, \alpha, U]_\tau \Rightarrow_{lm} x\omega_\tau \Rightarrow_{lm}^* xy_\tau \Rightarrow_{lm}^* xyz$$

and

$$[S, \{\mathbb{S}^k\}, \epsilon, FIRST_k(S\mathbb{S}^k)] \Rightarrow_{lm}^* x[A, R, \alpha, U]_{\tau'} \Rightarrow_{lm} x\rho_{\tau'} \Rightarrow_{lm}^* xy'_{\tau'} \Rightarrow_{lm}^* xy'z',$$

where $k:yz = k:y'z'$ and $\omega \neq \rho$. Here, we can observe that $k:z\mathbb{S}^k \in R$ and $k:z'\mathbb{S}^k \in R$. Let r and r' denote $k:z\mathbb{S}^k$ and $k:z'\mathbb{S}^k$, respectively. At this time, we have $k:yr = k:y'r'$. Denote $[A, R, \alpha, U] \rightarrow \omega$ and $[A, R, \alpha, U] \rightarrow \rho$ by p_T^1 and p_T^2 , respectively. The possible situations for p_T^1 and p_T^2 are divided as follows.

Case 1. $p_T^1 = [A, R, \alpha, U] \rightarrow a[A, R, \alpha a, V]$.

Then there exists $[A, R, \alpha a, V] \Rightarrow_{lm}^* y_1$ in $\mathbf{T}(G)$, where $ay_1 = y$. By applying Lemma 6.2 to this derivation, we have

$$(6.1) \quad Ar \Rightarrow_{A,R}^* \alpha ay_1 r \text{ in } G.$$

Derivation (6.1) is of the form

$$(6.2) \quad Ar \Rightarrow_{A,R}^* \beta Bwr \Rightarrow_{A,R} \beta \gamma a \delta wr \Rightarrow_{A,R}^* \beta \gamma ay_1 r,$$

where $\beta\gamma = \alpha$ according to Type 1 rule's construction.

(Subcase 1-1) $p_T^2 = [A, R, \alpha, U] \rightarrow [A, R, \beta B, V]$.

Then there exists $[A, R, \beta B, V] \Rightarrow_{lm}^* y'$ in $\mathbf{T}(G)$. By applying Lemma 6.2 to this derivation, we have $Ar' \Rightarrow_{A,R}^* \beta By'r'$ in G , and if $\alpha = \beta\gamma$, then we know that there exists

$$(6.3) \quad Ar \Rightarrow_{A,R}^* \beta By'r \Rightarrow_{A,R} \beta \gamma y'r \text{ in } G.$$

At this point, we have an LR(k) conflict with the derivations (6.2) and (6.3) because of $k:ay_1r = k:y'r'$.

(Subcase 1-2) $p_T^2 = [A, R, A, U] \rightarrow \epsilon$.

In this case, $\alpha = A$ and $y' = \epsilon$. It implies that $k:yr$ is also in R because of $k:yr = k:y'r' = r'$ and $r' \in R$. However, $k:yr (= k:ay_1r)$ cannot be in R by the definition of $\Rightarrow_{A,R}$ because we already have the derivation (6.2).

(Subcase 1-3) $p_T^2 = [A, R, \alpha, U] \rightarrow [B, W, \gamma, V][A, R, \beta B, W]$, where $\beta\gamma = \alpha$.

Let $[B, W, \gamma, V] \Rightarrow_{lm}^* y'_1$ and $[A, R, \beta B, W] \Rightarrow_{lm}^* y'_2$ in $\mathbf{T}(G)$, where $y'_1 y'_2 = y'$. By applying Lemma 6.2 to these derivations, there exist $Bw \Rightarrow_{B,W}^* \gamma y'_1 w$, where $w \in W$ and $k:y'_1 w \in V$, and $Ar' \Rightarrow_{A,R}^* \beta B y'_2 r'$, where $k:y'_2 r' = w$ in G . Then we know that $\Phi(A, R, \alpha, k:y'_1 w) = (B, W, \gamma)$. This is a contradiction to $k:ay_1r = k:y'_1 y'_2 r'$ because $k:ay_1r$ cannot be in $\{u \in U \mid \Phi(A, R, \alpha, u) \text{ is defined}\}$ according to the construction of $\mathbf{T}(G)$.

Case 2. $p_T^1 = [A, R, \alpha, U] \rightarrow [A, R, \beta B, V]$.

Then there exists $[A, R, \beta B, V] \Rightarrow_{lm}^* y$ in $\mathbf{T}(G)$. By applying Lemma 6.2 to this derivation, we have $Ar \Rightarrow_{A,R}^* \beta B yr$ in G . If $\alpha = \beta\gamma$, then $B \rightarrow \gamma \in P$ and there exists

$$(6.4) \quad Ar \Rightarrow_{A,R}^* \beta B yr \Rightarrow_{A,R} \beta \gamma yr \text{ in } G.$$

(Subcase 2-1) $p_T^2 = [A, R, \alpha, U] \rightarrow [A, R, \zeta C, Z]$.

Then there exists $[A, R, \zeta C, Z] \Rightarrow_{lm}^* y'$ in $\mathbf{T}(G)$. By applying Lemma 6.2 to this derivation, there exists $Ar' \Rightarrow_{A,R}^* \zeta C y' r'$ in G , and if $\alpha = \zeta\delta$, then there exists

$$(6.5) \quad Ar' \Rightarrow_{A,R}^* \zeta C y' r' \Rightarrow_{A,R} \zeta \delta y' r' \text{ in } G.$$

At this time, we have an LR(k) conflict with the derivations (6.4) and (6.5) because of $B \rightarrow \gamma \neq C \rightarrow \delta$, although $\beta\gamma = \zeta\delta$ and $k:yr = k:y'r'$.

(Subcase 2-2) $p_T^2 = [A, R, A, U] \rightarrow \epsilon$.

In this case, $\alpha = A$ and $y' = \epsilon$. If $\beta = \epsilon$, then $\gamma = A$, and we have a contradiction to derivation (6.4) similar to (Subcase 1-2). If $\beta \neq \epsilon$, then $\beta = A$ and $\gamma = \epsilon$. Then there exists $Ar \Rightarrow_{A,R}^* AByr \Rightarrow_{A,R} Ayr$ in G . Here, $k:yr = k:y'r'$, and so $k:yr \in R$ because of $y' = \epsilon$ and $r' \in R$. However, it is a contradiction to the definition of $\Rightarrow_{A,R}$.

(Subcase 2-3) $p_T^2 = [A, R, \alpha, U] \rightarrow [C, X, \delta, Z][A, R, \zeta C, X]$, where $\zeta\delta = \alpha$.

In this case, we have a contradiction for the construction of $\mathbf{T}(G)$ in a similar way to (Subcase 1-3).

Case 3. $p_T^1 = [A, R, A, U] \rightarrow \epsilon$.

Then $\alpha = A$, $y = \epsilon$, and the only possible form of p_T^2 is $[A, R, \alpha, U] \rightarrow [B, W, \gamma, V][A, R, \beta B, W]$, where $\beta\gamma = \alpha$. Let $[B, W, \gamma, V] \Rightarrow_{lm}^* y'_1$ and $[A, R, \beta B, W] \Rightarrow_{lm}^* y'_2$ in $\mathbf{T}(G)$, where $y'_1 y'_2 = y'$. By applying Lemma 6.2 to these derivations, we have $Bw \Rightarrow_{B,W}^* \gamma y'_1 w$, where $w \in W$, and $Ar' \Rightarrow_{A,R}^* \beta B y'_2 r'$, where $k:y'_2 r' = w$ in G . Hence, there exists $Ar' \Rightarrow_{A,R}^* \beta B y'_2 r' \Rightarrow_{A,R}^* \beta \gamma y'_1 y'_2 r'$. Note that $\beta\gamma = A$ and $k:y'_1 y'_2 r' = r$ because of $k:y'_1 y'_2 r' = k:yr$ and $y = \epsilon$. It means that $k:y'_1 y'_2 r'$ is in R , but this containment cannot occur by the definition of $\Rightarrow_{A,R}$.

Case 4. $p_T^1 = [A, R, \alpha, U] \rightarrow [B, W, \gamma, V][A, R, \beta B, W]$, where $\beta\gamma = \alpha$.

Let $[B, W, \gamma, V] \Rightarrow_{lm}^* y_1$ and $[A, R, \beta B, W] \Rightarrow_{lm}^* y_2$ in $\mathbf{T}(G)$, where $y_1 y_2 = y$. By applying Lemma 6.2 to these derivations, we have $Bw \Rightarrow_{B,W}^* \gamma y_1 w$, where $w \in W$ and $Ar \Rightarrow_{A,R}^* \beta B y_2 r$, where $k:y_2 r = w$ in G . We note that $\Phi(A, R, \alpha, k:y_1 w) = (B, W, \gamma)$. On the other hand, the only possible form of p_T^2 is $[A, R, \alpha, U] \rightarrow [C, X, \delta, Z][A, R, \zeta C, X]$, where $\zeta\delta = \alpha$. Let $[C, X, \delta, Z] \Rightarrow_{lm}^* y'_1$ and $[A, R, \zeta C, X] \Rightarrow_{lm}^* y'_2$ in $\mathbf{T}(G)$, where $y'_1 y'_2 = y'$. By applying Lemma 6.2 to these derivations, we have $Cx' \Rightarrow_{C,X}^* \delta y'_1 x'$, where $x' \in X$ and $k:y'_1 x' \in Z$, and $Ar' \Rightarrow_{A,R}^* \zeta C y'_2 r'$, where $k:y'_2 r' = x'$ in G . Here,

$\Phi(A, R, \alpha, k:y_1'x') = (C, X, \delta)$. Then we have a contradiction to the definition of Φ function because of $k:y_1w = k:y_1'x'$.

For all the possible cases of p_T^1 and p_T^2 , we showed some contradictions, and hence $T(G)$ has to be LL(k). \square

From Theorems 6.5 and 6.6, we obtain that $T(G)$ is an LL(k) covering grammar of G .

6.3. Transformable grammars. We define some special nonterminals to detect the infinite process of Algorithm 1. Let $[A, R, \alpha, U] \in \mathbf{N}$ and $\alpha = X_1 \cdots X_n$. Assume that $q_i = \{[B \rightarrow \gamma.\delta, k:zr] \mid \text{there exists } Ar \Rightarrow_{A,R}^* \beta Bzr \Rightarrow_{A,R} \beta\gamma\delta zr \Rightarrow_{A,R}^* \beta\gamma\zeta yzr \text{ in } G, \text{ where } r \in R, k:yzr \in U, \beta\gamma = X_1 \cdots X_i, \text{ and } \zeta = X_{i+1} \cdots X_n\}$ for each $i = 0, 1, \dots, n$. For q_i, q_{i+1}, \dots, q_j , if $q_i = q_j (0 \leq i < j \leq n)$ and no other pair of q_i, q_{i+1}, \dots, q_j is identical, then q_i, \dots, q_j is a *loop*. We say that $[A, R, \alpha, U]$ is *cyclic* if there exist more than two different values for $i, 0 \leq i \leq n$ for the same loop such that q_i, \dots, q_j is a loop. If $[A, R, \alpha, U]$ is cyclic and there is no $u \in U$ such that $\Phi(A, R, \alpha, u) = (B, W, \gamma)$ for some B, W , and γ , then $[A, R, \alpha, U]$ is an *indivisible cyclic*. Using this nonterminal, we can characterize the transformable grammars as follows.

LEMMA 6.7. *Algorithm 1 with G successfully terminates iff no indivisible cyclic nonterminal is generated.*

Proof. (Only if part) Assume that an indivisible cyclic nonterminal $[A, R, \alpha, U]$ is generated during the execution of Algorithm 1 with G . Then an infinite number of cyclic nonterminals that have the common loop with $[A, R, \alpha, U]$ are generated according to Algorithm 1. Hence, Algorithm 1 does not successfully terminate.

(If part) During the execution of Algorithm 1, if no indivisible cyclic nonterminal is generated, then the length of each nonterminal generated is bounded. It means that Algorithm 1 successfully terminates. \square

As a result, whenever an indivisible cyclic nonterminal is found during the working of Algorithm 1, it is desirable to stop anymore processing of the algorithm.

Next we will give another characterization of the transformable grammars using grammatical derivations.

THEOREM 6.8. *Algorithm 1 with G successfully terminates iff (Statement 1) is true:*

(Statement 1) *There exists a constant n , depending on G , such that if $\alpha (\neq \epsilon)$ is a viable prefix of G , x is a string in $L^G(\alpha)$, and v is a string in $RC_k^G(\alpha)$, then there exist B, W , and $\gamma (\neq \epsilon)$, where $\alpha = \beta\gamma$ and $|\gamma| \leq n$ such that Condition 1 holds.*

(Condition 1) *Whenever there exists π such that $S' \Rightarrow_{r_m}^\pi \beta\gamma z \Rightarrow_{r_m}^* xz$ in G , where $k:z = v$, there exist π^1 and π^2 , where $\pi^1\pi^2 = \pi$ such that $S' \Rightarrow_{r_m}^{\pi^1} \beta Bz''$ and $Bw \Rightarrow_{B,W}^{\pi^2} \gamma z'w$ in G , where $w = k:z'' (w \in W)$ and $z'z'' = z$.*

Proof. (Only if part) Assume that Algorithm 1 with G successfully terminates, but there is no n satisfying Statement 1. In other words, there exist a viable prefix α of G , a string $x, x \in L^G(\alpha)$, and a string $v, v \in RC_k^G(\alpha)$ for which there are no predicted B, W , and γ satisfying Condition 1, where $\alpha = \beta\gamma$ and $|\gamma| \leq n$ for some fixed n . Take an arbitrary rule string $\hat{\pi} (\hat{\pi} = \pi'\pi'')$ such that there exists $S\$\$^k \Rightarrow_{r_m}^{\pi'} \alpha z \Rightarrow_{r_m}^{\pi''} xz$ in G , where $k:z = v$. Corresponding to $\hat{\pi} (= \pi'\pi'')$, there exists $\hat{\pi}_T$ such that $[S, \{\$\$^k\}, \epsilon, FIRST_k(S\$\$^k)] \Rightarrow_{l_m}^{\hat{\pi}_T} xz$ in $T(G)$, where $h(\hat{\pi}_T) = \hat{\pi}^R$ according to Lemma 6.1. Furthermore, we know that $\hat{\pi}_T$ is composed of π_T'' and π_T' such that $[S, \{\$\$^k\}, \epsilon, FIRST_k(S\$\$^k)] \Rightarrow_{l_m}^{\pi_T''} \bar{x}\tau \Rightarrow_{l_m}^{\pi_T'} \bar{x}\bar{z}$ in $T(G)$, $\tau \in \mathbf{N}^*$, where $\bar{x}\bar{z} = xz, h(\pi_T'')^R = \pi''$, and $h(\pi_T')^R = \pi'$.

Let τ be $[B_n, W_n, \gamma_n, U_n][B_{n-1}, W_{n-1}, \gamma_{n-1}B_n, W_n] \cdots [B_1, W_1, \gamma_1B_2, W_2]$. Suppose that $\pi_T^i = [B_i, W_i, \gamma_iB_{i+1}, W_{i+1}] \Rightarrow_{lm}^* z_i$ for each $i = 1, \dots, n-1$ and $\pi_T^n = [B_n, W_n, \gamma_n, U_n] \Rightarrow_{lm}^* z_n$, where $\pi_T^1 \cdots \pi_T^n = \pi_T'$ and $z_n \cdots z_1 = \bar{z}$. Then by applying Lemma 6.2 to π_T^1, \dots, π_T^n , respectively, we have $B_i w_i \Rightarrow_{B_i, W_i}^{h(\pi_T^i)^R} \gamma_i B_{i+1} z_i w_i$, where $w_i \in W_i$ and $k:z_i w_i \in W_{i+1}$ for each $i = 1, \dots, n-1$, and $B_n w_n \Rightarrow_{B_n, W_n}^{h(\pi_T^n)^R} \gamma_n z_n w_n$, where $w_n \in W_n$ and $k:z_n w_n \in U_n$ in G . Because of $\pi_T^n \pi_T^{n-1} \cdots \pi_T^1 = \pi_T'$, $h(\pi_T^1)^R \cdots h(\pi_T^n)^R = (h(\pi_T^n) \cdots h(\pi_T^1))^R = h(\pi_T^n \cdots \pi_T^1)^R = h(\pi_T')^R = \pi'$. Here, we have $z = \bar{z}$, and so $x = \bar{x}$; $\gamma_1 \cdots \gamma_n = \alpha$.

On the other hand, we know that π_T'' is of the form

$$\begin{aligned} & [S, \{\mathcal{S}^k\}, \epsilon, FIRST_k(S\mathcal{S}^k)] \\ & \Rightarrow_{lm}^{\pi_T^X} x' [B_{n-1}, W_{n-1}, \gamma_{n-1}\delta_n, X_{n-1}] \cdots [B_1, W_1, \gamma_1B_1, W_2] \\ & \Rightarrow_{lm}^{r_T} x' [B_n, W_n, \delta_n, V_n][B_{n-1}, W_{n-1}, \gamma_{n-1}B_n, W_n] \cdots [B_1, W_1, \gamma_1B_1, W_2] \\ & \Rightarrow_{lm}^{\pi_T^Y} x' x'' [B_n, W_n, \gamma_n, U_n][B_{n-1}, W_{n-1}, \gamma_{n-1}B_n, W_n] \cdots [B_1, W_1, \gamma_1B_1, W_2], \end{aligned}$$

where $x'x'' = x$. Hence, we have $\Phi(B_{n-1}, W_{n-1}, \gamma_{n-1}\delta_n, u) = (B_n, W_n, \delta_n)$, where $u = k:x''z$. Consequently, we have the following statement:

(Statement 2) whenever there exists $B_{n-1}w_{n-1} \Rightarrow_{B_{n-1}, W_{n-1}}^* \gamma_{n-1}\delta_n p w_{n-1}$, where $w_{n-1} \in W_{n-1}$ and $k:p w_{n-1} = u$, there exist $B_{n-1}w_{n-1} \Rightarrow_{B_{n-1}, W_{n-1}}^* \gamma_{n-1}B_n q w_{n-1}$ and $B_n w_n \Rightarrow_{B_n, W_n}^* \delta_n r w_n$, where $w_n = k:q w_{n-1}$ and $r q = p$. Additionally, we know that when α, x , and v are fixed, $B_1, W_1, \gamma_1, \dots, B_i, W_i, \gamma_i, \dots, B_n, W_n, \gamma_n, \delta_n, U_n$ are also fixed because $T(G)$ is LL(k).

Consider the derivation $\pi_T^s = r_T \pi_T^Y \pi_T^n \pi_T^{n-1}$ such that $[B_{n-1}, W_{n-1}, \gamma_{n-1}\delta_n, X_{n-1}] \Rightarrow_{lm}^{\pi_T^s} x'' z_n z_{n-1}$. Then by applying Lemma 6.2, there exists $h(\pi_T^s)^R$ such that $B_{n-1}w_{n-1} \Rightarrow_{B_{n-1}, W_{n-1}}^* \gamma_{n-1}\delta_n x'' z_n z_{n-1} w_{n-1}$ in G , where $w_{n-1} \in W_{n-1}$ and $k:x'' z_n z_{n-1} w_{n-1} \in X_{n-1}$. Here, $h(\pi_T^s)^R = h(r_T \pi_T^Y \pi_T^n \pi_T^{n-1})^R = h(\pi_T^Y \pi_T^n \pi_T^{n-1})^R = h(\pi_T^{n-1})^R h(\pi_T^n)^R h(\pi_T^Y)^R$ because of $h(r_T) = \epsilon$. Since π_T^Y is a suffix of π_T'' , $h(\pi_T^Y)^R$ is a prefix of π_T'' . Let π^Z be the rule string such that $\pi_T'' = h(\pi_T^Y)^R \pi^Z$. Then $\hat{\pi}$ is composed of the derivations such that

$$\begin{aligned} & B_1 w_1 \\ & \Rightarrow_{rm}^{h(\pi_T^1)^R h(\pi_T^2)^R \cdots h(\pi_T^{n-2})^R} \gamma_1 \gamma_2 \gamma_3 \cdots \gamma_{n-2} B_{n-1} z_{n-2} \cdots z_2 z_1 w_1 \\ & \Rightarrow_{rm}^{h(\pi_T^{n-1})^R} \gamma_1 \gamma_2 \gamma_3 \cdots \gamma_{n-1} B_n z_{n-1} \cdots z_2 z_1 w_1 \\ & \Rightarrow_{rm}^{h(\pi_T^n)^R} \gamma_1 \gamma_2 \cdots \gamma_{n-1} \gamma_n z_n z_{n-1} \cdots z_2 z_1 w_1 \\ & \Rightarrow_{rm}^{h(\pi_T^Y)^R} \gamma_1 \gamma_2 \cdots \gamma_{n-1} \delta_n x'' z_n z_{n-1} \cdots z_2 z_1 w_1 \\ & \Rightarrow_{rm}^{\pi^Z} x' x'' z_n z_{n-1} \cdots z_2 z_1 w_1, \end{aligned}$$

where $B_1 = S$, $w_1 = \mathcal{S}^k$, $\gamma_1 \cdots \gamma_n = \alpha$, and $z_n z_{n-1} \cdots z_2 z_1 = z$. Then we have that whenever there exists π such that $S' \Rightarrow_{rm}^{\pi} \alpha z \Rightarrow_{rm}^* x z$ in G , where $k:z = v$, there exists $\tilde{\pi} (= \pi \pi'')$ such that $S' \Rightarrow_{rm}^{\pi} \alpha z \Rightarrow_{rm}^{\pi''} \gamma_1 \cdots \gamma_{n-1} \delta_n y z \Rightarrow_{rm}^* x z$ in G . The derivation $\tilde{\pi}$ is always composed of $\tilde{\pi}_1$ and $\tilde{\pi}_2$ such that $\tilde{\pi}_1 = S' \Rightarrow_{rm}^* \gamma_1 \cdots \gamma_{n-1} B_{n-1} z_2$ and $\tilde{\pi}_2 = B_{n-1} w_{n-1} \Rightarrow_{B_{n-1}, W_{n-1}}^* \gamma_n z_1 w_{n-1} \Rightarrow_{B_{n-1}, W_{n-1}}^* \delta_n y z_1 w_{n-1}$, where $w_{n-1} = k:z_2$. At this point, if we set $\beta = \gamma_1 \cdots \gamma_{n-1}$, $B = B_n$, $W = W_n$, $\gamma = \gamma_n$, and $U = U_n$, then from Statement 2, we obtain the property that whenever there exists π such that $S' \Rightarrow_{rm}^{\pi} \alpha z \Rightarrow_{rm}^* x z$ in G , where $k:z = v$, there exist π^1 and π^2 , where $\pi^1 \pi^2 = \pi$ such

that $S' \Rightarrow_{rm}^{\pi^1} \beta Bz''$ and $Bw \Rightarrow_{B,W}^{\pi^2} \gamma z'w$ in G , where $w = k:z''$ and $z'z'' = z$. Here, $|\gamma|$ is bounded since it is a component of the nonterminal $[B, W, \gamma, U]$. As a result, it is a contradiction of the assumption that α and v have no predictable B, W , and γ satisfying Condition 1.

(If part) Assume that Statement 1 is true, but Algorithm 1 with G does not successfully terminate. It means that an indivisible cyclic nonterminal is generated, while Algorithm 1 with G works. Let $[A, R, \alpha, U]$ be such a nonterminal. Suppose that n is the constant in Statement 1. Without loss of generality, we can assume $|\alpha| > n$.

Take an arbitrary derivation

$$(6.6) \quad Ar \Rightarrow_{A,R}^* \alpha yr \Rightarrow_{A,R}^* \bar{x} yr$$

in G , where $r \in R$. Let $v = k:yr$. Then there exists $S' \Rightarrow_{rm}^* \theta Az \Rightarrow_{rm}^* \theta \alpha yz \Rightarrow_{rm}^* xyz$ in G , where $k:z = r$, $k:yz = v$, and $x = \hat{x}\bar{x}$. If we consider the viable prefix $\theta\alpha$, the string $x, x \in L^G(\theta\alpha)$, and the string $u, u \in RC_k^G(\theta\alpha)$, then there exist B, W , and γ , where $\theta\alpha = \beta\gamma$ and $|\gamma| \leq n$ satisfying Condition 1 since Statement 1 is true. That is, whenever there exists π such that $S' \Rightarrow_{rm}^{\pi} \beta\gamma z \Rightarrow_{rm}^* xyz$ in G , where $k:z = v$, there exist π^1 and π^2 , where $\pi^1\pi^2 = \pi$ such that $S' \Rightarrow_{rm}^{\pi^1} \beta Bz''$ and $Bw \Rightarrow_{B,W}^{\pi^2} \gamma z'w$ in G , where $z'z'' = z$ and $w = k:z''$. Hence, we have the property that: whenever there exists a derivation (6.6), there exist $Ar \Rightarrow_{A,R}^* \delta Bz'''r$ and $Bw \Rightarrow_{B,W}^* \gamma z'w$, where $z'z''' = y$ and $\alpha = \delta\gamma$. Consequently, we have the property: whenever there exists $Ar \Rightarrow_{A,R}^* \delta\gamma yr$, where $r \in R$ and $k:yr = v$, there exist $Ar \Rightarrow_{A,R}^* \delta Bz'''r$ and $Bw \Rightarrow_{B,W}^* \gamma z'w$, where $z'z''' = y$ and $w = k:z'''r$. In accordance with Lemma 4.4, $(A, R, \delta\gamma)\mathbb{I}_v(B, W', \gamma)$ holds for some W' , and hence, there exist B', W'' , and γ' such that $\Phi(A, R, \delta\gamma, v) = (B', W'', \gamma')$ holds. Then we have a contradiction to that $[A, R, \alpha, U]$ is indivisible cyclic. \square

In other words, the transformable grammars have a fixed constant n : when the stack string is $\alpha (\neq \epsilon)$, the input string already read is x , and the k -length prefix of the remaining input is v , we always have $B, W, \gamma (\neq \epsilon)$, where $|\gamma| \leq n$ such that γ and some prefix of the remaining input will be reduced to (B, W) . Figure 6.1 describes this situation; the left side is expected to be the right.

We define the transformable grammars using Algorithm 1 as extended PLR(k) grammars.

FIG. 6.1. Derivation trees.

DEFINITION 6.9. G is an extended $PLR(k)$ grammar iff Statement 1 is true.

We next relate extended $PLR(k)$ grammars with $PLR(k)$ grammars and k -transformable grammars.

LEMMA 6.10. Let G be $PLR(k)$. Then G is extended $PLR(k)$.

Proof. Suppose that $\alpha(\neq \epsilon)$ is a viable prefix of G , x is a string in $L^G(\alpha)$, and v is a string in $RC_k^G(\alpha)$. Then there exists a derivation $S' \Rightarrow_{rm}^* \beta Bz \Rightarrow_{rm} \beta X\delta\zeta z \Rightarrow_{rm}^* \beta X\delta y_2 z \Rightarrow_{rm}^* \beta X y_1 y_2 z \Rightarrow_{rm}^* x y_2 z$ in G , where $\beta X\delta = \alpha$, $k:y_2 z = v$, and $X\delta \neq \epsilon$. On the other hand, according to the definition of $PLR(k)$ grammars,

$$\text{if there exists } S' \Rightarrow_{rm}^* \beta' Az' \Rightarrow_{rm} \beta' \beta'' X\delta' \zeta' z' \Rightarrow_{rm}^* \beta' \beta'' X\delta' y_2' z'$$

$$\Rightarrow_{rm}^* \beta' \beta'' X y_1' y_2' z' \text{ in } G, \text{ where } \beta' \beta'' = \beta \text{ and } k:y_1' y_2' z' = k:y_1 y_2 z,$$

$$(6.7) \quad \text{then } A = B \text{ and } \beta'' = \epsilon.$$

Let n be the maximum length of the right-side string of a rule of G and γ be $X\delta$. Then we know that $|\gamma| \leq n(\gamma \neq \epsilon)$. On the other hand, whenever there exists $S' \Rightarrow_{rm}^* \beta\gamma z \Rightarrow_{rm}^* xz$ in G , there exists $S' \Rightarrow_{rm}^* \beta\gamma z \Rightarrow_{rm}^* \beta Xyz \Rightarrow_{rm}^* xz$ in G and, according to (6.7), there exist $S' \Rightarrow_{rm}^* \beta Bz_2$ and $Bw \Rightarrow_{rm}^* \gamma z_1 w$ in G , where $w = k:z_2$ and $z_1 z_2 = z$. Let us set W to be $FOLLOW_k(B)$. Then we have the property that whenever there exists π such that $S' \Rightarrow_{rm}^* \beta\gamma z \Rightarrow_{rm}^* xz$ in G , there exist π^1 and π^2 such that $S' \Rightarrow_{rm}^* \beta Bz_2$ and $Bw \Rightarrow_{B,W}^{\pi^2} \gamma z_1 w$ in G , where $\pi^1 \pi^2 = \pi$, $w = k:z_2$, and $z_1 z_2 = z$. In all, G is extended $PLR(k)$. \square

LEMMA 6.11. Let G be k -transformable. Then G is extended $PLR(k)$.

Proof. Since G is k -transformable, there exists a constant n such that if $\alpha(\neq \epsilon)$ is a viable prefix of G and v is a string in $RC_k^G(\alpha)$, then there exist B, W , and $\gamma(\neq \epsilon)$, where $\alpha = \beta\gamma$, $|\gamma| \leq n$, and $v \in RC_k^{B,W}(\gamma)$ such that whenever there exists $S' \Rightarrow_{rm}^* \beta\gamma z \Rightarrow_{rm}^* \beta yz$ in G , where $k:yz \in RC_k^{B,W}(\epsilon)$, there exist $S' \Rightarrow_{rm}^* \beta Bz''$ and $Bw \Rightarrow_{B,W}^* \gamma z' w \Rightarrow_{B,W}^* yz' w$ in G , where $w = k:z''(w \in W)$ and $z' z'' = z$. Note that the condition $k:yz \in RC_k^{B,W}(\epsilon)$ implies $k:z \in RC_k^{B,W}(\gamma)$. Hence, we have the property with the above n such that if $\alpha(\neq \epsilon)$ is a viable prefix of G , $x \in L^G(\alpha)$, and $v \in RC_k^G(\alpha)$, then there exist B, W , and $\gamma(\neq \epsilon)$, where $\alpha = \beta\gamma$, $|\gamma| \leq n$, and $v \in RC_k^{B,W}(\gamma)$ such that whenever there exists π such that $S' \Rightarrow_{rm}^* \beta\gamma z \Rightarrow_{rm}^* xz$ in G , where $k:z \in RC_k^{B,W}(\gamma)$, there exist π^1 and π^2 , where $\pi^1 \pi^2 = \pi$ such that $S' \Rightarrow_{rm}^* \beta Bz''$ and $Bw \Rightarrow_{B,W}^{\pi^2} \gamma z' w$ in G , where $w = k:z''(w \in W)$ and $z' z'' = z$. Thus, G is extended $PLR(k)$. \square

We showed that extended $PLR(k)$ grammars completely contain $PLR(k)$ grammars and k -transformable grammars. Extended $PLR(k)$ grammars, moreover, are larger than k -transformable grammars and $PLR(k)$ grammars. It can be proved by the following example.

Example 6.1. Let $G3 = (\{S, A\}, \{a, d, b, c\}, \{S \rightarrow aAd, S \rightarrow aB, B \rightarrow aA, A \rightarrow ab, A \rightarrow aA, A \rightarrow bc\}, S)$. Note that $G3$ is $LR(1)$ and extended $PLR(1)$. However, $G3$ is neither k -transformable nor $PLR(k)$ for all $k \geq 1$.

THEOREM 6.12. Extended $PLR(k)$ grammars are larger than $PLR(k)$ grammars and k -transformable grammars.

7. Concluding remarks. The contribution of this paper can be summarized as follows. First, we showed the incomparable relationship between $PLR(k)$ grammars

and k -transformable grammars. Second, we presented the generalization of the reduction goal prediction in LR parsing. We believe that the proposed one is the uppermost of the reduction goal prediction, which is performed by keeping the LR stack and investigating the k -length prefix of the remaining input. Extended $PLR(k)$ grammars are thus thought of as the uppermost class of $LL(k)$ covering transformable grammars based on such a prediction. Third, we showed that $LL(k)$ covering grammars can be deterministically constructed by defining the \mathbb{III} relation and investigating the orderable property of the relation. As a result, we can decide the transformableness of a given grammar in a single process. Lastly, we characterized the transformable grammars using grammatical derivation.

COMPRESSED SUFFIX ARRAYS AND SUFFIX TREES WITH APPLICATIONS TO TEXT INDEXING AND STRING MATCHING*

ROBERTO GROSSI[†] AND JEFFREY SCOTT VITTER[‡]

Abstract. The proliferation of online text, such as found on the World Wide Web and in online databases, motivates the need for space-efficient text indexing methods that support fast string searching. We model this scenario as follows: Consider a text T consisting of n symbols drawn from a fixed alphabet Σ . The text T can be represented in $n \lg |\Sigma|$ bits by encoding each symbol with $\lg |\Sigma|$ bits. The goal is to support fast online queries for searching any string pattern P of m symbols, with T being fully scanned only once, namely, when the index is created at preprocessing time.

The text indexing schemes published in the literature are greedy in terms of space usage: they require $\Omega(n \lg n)$ additional bits of space in the worst case. For example, in the standard unit cost RAM, suffix trees and suffix arrays need $\Omega(n)$ memory words, each of $\Omega(\lg n)$ bits. These indexes are larger than the text itself by a multiplicative factor of $\Omega(\lg |\Sigma| n)$, which is significant when Σ is of constant size, such as in ASCII or UNICODE. On the other hand, these indexes support fast searching, either in $O(m \lg |\Sigma|)$ time or in $O(m + \lg n)$ time, plus an output-sensitive cost $O(occ)$ for listing the occ pattern occurrences.

We present a new text index that is based upon compressed representations of suffix arrays and suffix trees. It achieves a fast $O(m/\lg |\Sigma| n + \lg_{|\Sigma|}^{\epsilon} n)$ search time in the worst case, for any constant $0 < \epsilon \leq 1$, using at most $(\epsilon^{-1} + O(1)) n \lg |\Sigma|$ bits of storage. Our result thus presents for the first time an efficient index whose size is provably linear in the size of the text in the worst case, and for many scenarios, the space is actually sublinear in practice. As a concrete example, the compressed suffix array for a typical 100 MB ASCII file can require 30–40 MB or less, while the raw suffix array requires 500 MB. Our theoretical bounds improve *both* time and space of previous indexing schemes. Listing the pattern occurrences introduces a sublogarithmic slowdown factor in the output-sensitive cost, giving $O(occ \lg_{|\Sigma|}^{\epsilon} n)$ time as a result. When the patterns are sufficiently long, we can use auxiliary data structures in $O(n \lg |\Sigma|)$ bits to obtain a total search bound of $O(m/\lg |\Sigma| n + occ)$ time, which is optimal.

1. Introduction. A great deal of textual information is available in electronic form in online databases and on the World Wide Web, and therefore devising efficient text indexing methods to support fast string searching is an important topic for investigation. A typical search scenario involves string matching in a text string T of length n [49]: given an input pattern string P of length m , the goal is to find occurrences of P in T . Each symbol in P and T belongs to a fixed alphabet Σ of size $|\Sigma| \leq n$. An occurrence of the pattern at position i means that the substring $T[i, i + m - 1]$ is equal to P , where $T[i, j]$ denotes the concatenation of the symbols

in T at positions $i, i + 1, \dots, j$.

In this paper, we consider three types of string matching queries: existential, counting, and enumerative. An existential query returns a Boolean value that indicates whether P is contained in T . A counting query computes the number occ of occurrences of P in T , where $occ \leq n$. An enumerative query outputs the list of occ positions, where P occurs in T . Efficient offline string matching algorithms, such as that of Knuth, Morris, and Pratt [49], can answer each individual query in $O(m + n)$ time via an efficient text scan.

The large mass of existing online text documents makes it infeasible to scan through all the documents for every query, because n is typically much larger than the pattern length m and the number of occurrences occ . In this scenario, text indexes are preferable, as they are especially efficient when several string searches are to be performed on the same set of text documents. The text T needs to be entirely scanned only once, namely, at preprocessing time when the indexes are created. After that, searching is output-sensitive, that is, the time complexity of each online query is proportional to either $O(m \lg |\Sigma| + occ)$ or $O(m + \lg n + occ)$, which is much less than $\Theta(m + n)$ when n is sufficiently large.

The most popular indexes currently in use are inverted lists and signature files [48]. Inverted lists are theoretically and practically superior to signature files [72]. Their versatility allows for several kinds of queries (exact, Boolean, ranked, and so on) whose answers have a variety of output formats. They are efficient indexes for texts that are structured as long sequences of terms (or words) in which T is partitioned into nonoverlapping substrings $T[i_k, j_k]$ (the terms), where $1 \leq i_k \leq j_k < i_{k+1} \leq n$. We refer to the set of terms as the vocabulary. For each distinct term in the vocabulary, the index maintains the inverted list (or position list) $\{i_k\}$ of the occurrences of that term in T . As a result, in order to search efficiently, search queries must be limited to terms or prefixes of them; it does not allow for efficient searching of arbitrary substrings of the text as in the string matching problem. For this reason, inverted files are sometimes referred to as *term-level* or *word-level* text indexes.

Searching *unstructured* text to answer string matching queries adds a new difficulty to text indexing. This case arises with DNA sequences and in some Eastern languages (Burmese, Chinese, Taiwanese, Tibetan, etc.), which do not have a well-defined notion of terms. The set of successful search keys is possibly much larger than the set of terms in structured texts, because it consists of all feasible substrings of T ; that is, we can have as many as $\binom{n}{2} = \Theta(n^2)$ distinct substrings in the worst case, while the number of distinct terms is at most n (considered as nonoverlapping substrings). Suffix arrays [55, 35], suffix trees [57, 68], and similar tries or automata [20] are among the prominent data structures used for unstructured texts. Since they can handle all the search keys in $O(n)$ memory words, they are sometimes referred to as *full-text* indexes.

The *suffix tree* for text $T = T[1, n]$ is a compact trie whose n leaves represent the n text suffixes $T[1, n], T[2, n], \dots, T[n, n]$. By “compact” we mean that each internal node has at least two children. Each edge in the tree is labeled with one or more symbols for purposes of search navigation. The leaf with value ℓ represents the suffix $T[\ell, n]$. The leaf values in an in-order traversal of the tree represent the n suffixes of T in lexicographic order. An example suffix tree appears in Figure 1.

A *suffix array* $SA = SA[1, n]$ for text $T = T[1, n]$ consists of the values of the leaves of the suffix tree in in-order, but without the tree structure information. In other words, $SA[i] = \ell$ means that $T[\ell, n]$ is the i th smallest suffix of T in lexicographic order. The suffix array corresponding to the suffix tree of Figure 1 appears in Figure 2.

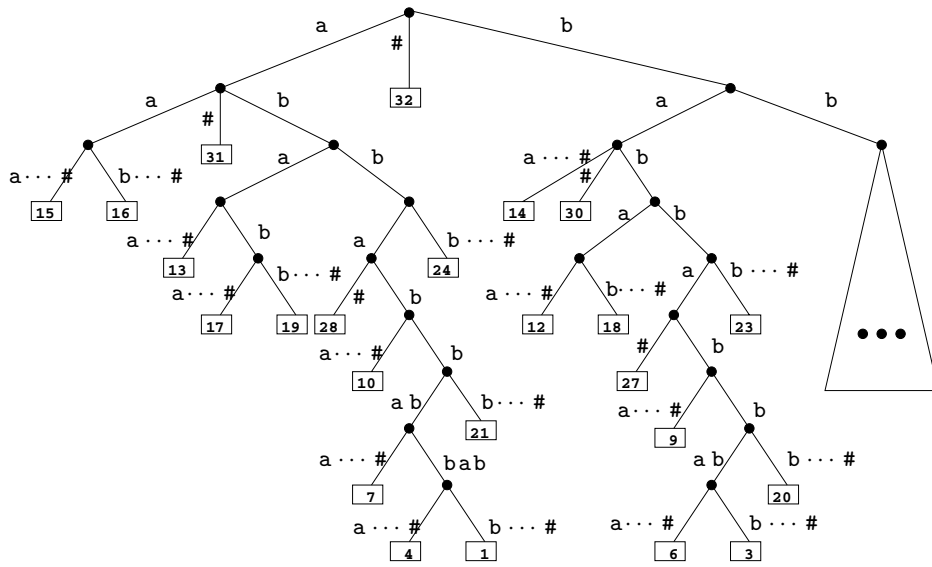

FIG. 1. Suffix tree built on text $T = \text{abbabbabbabbabaabababbabbabba}\#$ of length $n = 32$, where the last character is an end-of-string symbol $\#$. The rightmost subtree (the triangle representing the suffixes of the form $bb\cdots\#$) is not expanded in the figure. The edge label $a\cdots\#$ or $b\cdots\#$ on the edge leading to the leaf with value l denotes the remaining characters of the suffix $T[l, n]$ that have not already been traversed. For example, the first suffix in lexicographic format is the suffix $T[15, n]$, namely, $aaabababbabbabba\#$, and the last edge represents the 16-symbol substring that follows the prefix aa .

To speed up searches, a separate array is often maintained, which contains auxiliary information such as the lengths of the longest common prefixes of a subset of the suffixes [55].

Suffix trees and suffix arrays organize the suffixes so as to support the efficient search of their prefixes. Given a search pattern P , in order to find an occurrence $T[i, i + m - 1] = P$, we can exploit the property that P must be the prefix of suffix $T[i, n]$. In general, existential and counting queries take $O(m \lg |\Sigma|)$ time using automata or suffix trees and their variations, and they take $O(m + \lg n)$ time using suffix arrays along with longest common prefixes. Enumerative queries take an additive output-sensitive cost $O(occ)$. In this paper, we use the term “suffix array” to denote the array containing the permutation of positions $1, 2, \dots, n$, but without the longest common prefix information mentioned above. Full-text indexes such as suffix arrays are more powerful than term-level inverted lists, since full-text indexes can also implement inverted lists efficiently by storing the suffixes $T[i_k, n]$ that correspond to the occurrences of the terms.

1.1. Issues on space efficiency. Suffix arrays and suffix trees are data structures with increasing importance because of the growing list of their applications. Besides string searching, they also have significant use in molecular biology, data compression, data mining, and text retrieval, to name but a few applications [7, 38, 55]. However, the sizes of the data sets in these applications can become extremely large, and space occupancy is often a critical issue. A major disadvantage that limits the applicability of text indexes based upon suffix arrays and suffix trees is that they occupy significantly more space than do inverted lists.

FIG. 2. Suffix array for the text T shown in Figure 1, where $a < \# < b$. Note that the array values correspond to the leaf values in the suffix tree in Figure 1 traversed in in-order.

We can illustrate this point by a more careful accounting of the space requirements in the unit cost RAM model. We assume that each symbol in the text T is encoded by $\lg |\Sigma|$ bits, for a total of $n \lg |\Sigma|$ bits.¹ In suffix arrays, the positions of the n suffixes of T are stored as a permutation of $1, 2, \dots, n$, using $n \lg n$ bits (kept in an array consisting of n words, each of $\lg n$ bits). Suffix trees require considerably more space: between $4n \lg n$ and $5n \lg n$ bits (stored in $4n-5n$ words) [55]. In contrast, inverted lists require only approximately 10% of the text size [58], and thus suffix arrays and suffix trees require significantly more bits. From a theoretical point of view, if the alphabet is very large, namely, if $\lg |\Sigma| = \Theta(\lg n)$, then suffix arrays require roughly the same number of bits as the text. However, in practice, the alphabet size $|\Sigma|$ is typically a fixed constant, such as $|\Sigma| = 256$ in electronic documents in ASCII or larger in UNICODE format, and $\Sigma = 4$ in DNA sequences. In such cases in practice, suffix arrays and suffix trees are larger than the text by a significant multiplicative factor of $\Theta(\lg_{|\Sigma|} n) = \Theta(\lg n)$. For example, a DNA sequence of n symbols (with $|\Sigma| = 4$) can be stored with $2n$ bits in a computer. The suffix array for the sequence requires instead at least n words of 4 bytes each, or $32n$ bits, which is 16 times larger than the text itself. On the other hand, we cannot resort to inverted files since they do not support a general search on unstructured sequences.

¹In this paper, we use the notation $\lg_b^c n = (\log_b n)^c = (\log n / \log b)^c$ to denote the c th power of the base- b logarithm of n . If no base b is specified, the implied base is 2.

In [62], Munro, Raman, and Rao solve the open question raised by Muthukrishnan by showing how to represent suffix trees in $n \lg n + O(n)$ bits while allowing $O(m)$ -time search of binary pattern strings of length m . This result highlights the conceptual barrier of $n \lg n$ bits of storage needed for text indexing. In this paper, we go one step further and investigate whether it is possible to design a full-text index in $o(n \lg n)$ bits, while still supporting efficient search.

The question of space usage is important in both theory and practice. Prior to our work, the state of the art has taken for granted that at least $n \lg n$ bits are needed to represent the permutation of the text positions for any efficient full-text index. On the other hand, if we note that each text of n symbols is in one-to-one correspondence with a suffix array, then we can easily see by a simple information-theoretic argument that $\Omega(n \lg |\Sigma|)$ bits are required to represent the permutation. The argument is based upon the fact that there are $|\Sigma|^n$ different text strings of length n over the alphabet Σ ; hence, there are that many different suffix arrays, and we need $\Omega(n \lg |\Sigma|)$ bits to distinguish them from one another. It is therefore an interesting problem to close this gap in order to see if there is an efficient representation of suffix arrays that use nearly $n \lg |\Sigma| + O(n)$ bits in the worst case, even for random strings.

In order to have an idea of the computational difficulty of the question, let us follow a simple approach that saves space. Let us consider binary alphabets. We bunch every $\lg n$ bits together into a word (in effect, constructing a large alphabet) and create a text of length $n/\lg n$ and a pattern of length $m/\lg n$. The suffix array on the new text requires $O((n/\lg n) \lg n) = O(n)$ bits. Searching for a pattern of length m must also consider situations when the pattern is not aligned at the precise word boundaries. What is the searching cost? It appears that we have to handle $\lg n$ situations, with a slowdown factor of $\lg n$ in the time complexity of the search. However, this is not really so; we actually have to pay a much larger slowdown factor of $\Omega(n)$ in the search cost, which makes querying the text index more expensive than running the $O(m+n)$ -time algorithms from scratch, such as in [49]. To see why, let us examine the situation in which the pattern occurs k positions to the right of a word boundary in the text. In order to query the index, we have to align the pattern with the boundary by padding k bits to the left of the pattern. Since we do not know the correct k bits to prepend to the pattern, we must try all 2^k possible settings of the k bits. When $k \approx \lg n$, we have to query the index $2^k = \Omega(n)$ times in the worst case. (See the sparse suffix trees [47] cited in section 1.3 to partially alleviate this drawback.)

The above example shows that a small reduction in the index size can make querying the index useless in the worst case, as it can cost at least as much as performing a full scan of the text from scratch. In section 1.3, we describe previous results motivated by the need to find an efficient solution to the problem of designing a full-text index that saves space and time in the worst case. No data structures with the functionality of suffix trees and suffix arrays that have appeared in the literature to date use $\Theta(n \lg |\Sigma|) + o(n \lg n)$ bits and support fast queries in $o(m \lg |\Sigma|)$ or $o(m + \lg n)$ worst-case time. Our goal in this paper is to simultaneously reduce *both* the space bound *and* the query time bound.

1.2. Our results. In this paper, we begin the study of the compressibility of suffix arrays and related full-text indexes. We assume for simplicity that the alphabet Σ is of bounded size (i.e., ASCII or UNICODE/UTF8). We recall that the suffix array SA for text T stores the suffixes of T in lexicographic order, as shown in Figure 2. We represent SA in the form of a permutation of the starting positions, $1, 2, \dots, n$, of the

suffixes in T . For all $1 \leq i < j \leq n$, we have $T[SA[i], n] < T[SA[j], n]$ in lexicographic order. We call each entry in SA a *suffix pointer*.

Given a text T and its suffix array SA , we consider the problem of obtaining a *compressed suffix array* from both T and SA so as to support the following two basic operations:

1. *compress*(T, SA): Compress SA to obtain its succinct representation. After that, text T is retained while SA can be discarded.
2. *lookup*(i): Given the compressed representation mentioned above, return $SA[i]$, which is the suffix pointer in T of the i th suffix $T[SA[i], n]$ in lexicographic order.

(More functionalities are introduced in [64].) The primary measures of performance are the query time to do *lookup*, the amount of space occupied by the compressed suffix array, and the preprocessing time and space taken by *compress*.

In this paper, we exploit the “implicit structure” underlying the permutation of the suffix pointers stored in SA , which takes advantage of the fact that not all permutations are valid suffix arrays. For any fixed value of $0 < \epsilon \leq 1$, we show how to implement operation *compress* in $(1 + \epsilon^{-1}) n \lg |\Sigma| + o(n \lg |\Sigma|)$ bits so that each call to *lookup* takes sublogarithmic worst-case time, that is, $O(\lg_{|\Sigma|}^{\epsilon} n)$ time. We can also achieve $(1 + \frac{1}{2} \lg \lg_{|\Sigma|} n) n \lg |\Sigma| + O(n)$ bits so that calls to *lookup* can be done in $O(\lg \lg_{|\Sigma|} n)$ time. The preprocessing time is $O(n \lg |\Sigma|)$. Note that the auxiliary space during preprocessing is larger, i.e., $O(n \lg n)$ bits, since our preprocessing requires the suffix array in uncompressed form to output it in compressed form. Our findings have several implications as follows:

1. When $|\Sigma| = O(2^{o(\lg n)})$, we break the space barrier of $\Omega(n \lg n)$ bits for a suffix array while retaining $o(\lg n)$ lookup time in the worst case. We refer the reader to the literature described in section 1.3.
2. We can implement a form of compressed suffix trees in $2n \lg |\Sigma| + O(n)$ bits by using compressed suffix arrays (with $\epsilon = 1$) and the techniques for compact representation of Patricia tries presented in [62]. They occupy asymptotically up to a small constant factor the *same* space as that of the text string being indexed.
3. Our compressed suffix arrays and compressed suffix trees are provably as good as inverted lists in terms of space usage, at least theoretically. In the worst case, they require asymptotically the *same* number of bits.
4. We can build a hybrid full-text index on T in at most $(\epsilon^{-1} + O(1)) n \lg |\Sigma|$ bits by a suitable combination of our compressed suffix trees and previous techniques [17, 45, 62, 59]. We can answer existential and counting queries of any pattern string of length m in $O(m/\lg_{|\Sigma|} n + \lg_{|\Sigma|}^{\epsilon} n)$ search time in the worst case, which is $o(\min\{m \lg |\Sigma|, m + \lg n\})$, smaller than previous search bounds. For enumerative queries, we introduce a sublogarithmic slowdown factor in the output-sensitive cost, giving $O(occ \lg_{|\Sigma|}^{\epsilon} n)$ time as a result. When the patterns are sufficiently long, namely, for $m = \Omega((\lg_{|\Sigma|}^{1+\epsilon} n)(\lg_{|\Sigma|} \lg n))$, we can use auxiliary data structures in $O(n \lg |\Sigma|)$ bits to obtain a total search bound of $O(m/\lg_{|\Sigma|} n + occ)$ time, which is optimal.

The bounds claimed in point 4 need further elaboration. Specifically, searching takes $O(1)$ time for $m = o(\lg n)$, and $O(m/\lg_{|\Sigma|} n + \lg_{|\Sigma|}^{\epsilon} n) = o(m \lg |\Sigma|)$ time otherwise. That is, we achieve optimal $O(m/\lg_{|\Sigma|} n)$ search time for sufficiently large $m = \Omega(\lg_{|\Sigma|}^{1+\epsilon} n)$. For enumerative queries, retrieving all occ occurrences has cost $O(m/\lg_{|\Sigma|} n + occ \lg_{|\Sigma|}^{\epsilon} n)$ when both conditions $m \in [\epsilon \lg n, o(\lg^{1+\epsilon} n)]$ and $occ = o(n^{\epsilon})$ hold, and cost $O(m/\lg_{|\Sigma|} n + occ + (\lg^{1+\epsilon} n)(\lg |\Sigma| + \lg \lg n))$ otherwise.

The results described in this paper are theoretical, but they also have substantial practical value. The ideas described here, with the extensions described by Sadakane [64], have been tested experimentally in further work discussed in section 1.3. Central to our algorithms is the definition of function Φ and its implications described in section 2. This function is at the heart of many subsequent papers on compressed text indexing (such as suffix links in suffix trees, binary search trees in sorted dictionaries, and join operators in relational databases), thus is the major by-product of the findings presented in this paper. Ultimately Φ is related to sorting-based compression because it represents the inverse of the last-to-first mapping for the Burrows–Wheeler transform [14]. We refer the interested reader to section 1.3 for the state of the art in compressed text indexing and to section 2 for a discussion of the function Φ .

1.3. Related work. The seminal paper by Knuth, Morris, and Pratt [49] provides the first string matching solution taking $O(m+n)$ time and $O(m)$ words to scan the text. The space requirement was remarkably lowered to $O(1)$ words in [33, 19]. The new paradigm of compressed pattern matching was introduced in [2] and explored for efficiently scanning compressed texts in [3, 24]. When many queries are to be performed on the same text, it is better to resort to text indexing. A relevant paper [68] introduced a variant of the suffix tree for solving the text indexing problem in string matching. This paper pointed out the importance of text indexing as a tool to avoid a full scan of the text at each pattern search. This method takes $O(m \lg |\Sigma|)$ search time plus the output-sensitive cost $O(occ)$ to report the occurrences, where $occ \leq n$. Since then, a plethora of papers have studied the text indexing problem in several contexts, sometimes using different terminology [10, 11, 18, 28, 50, 41, 57, 55, 67]; for more references see [7, 20, 38]. Although very efficient, the resulting index data structures are greedy in terms of space, using at least n words or $\Omega(n \lg n)$ bits.

Numerous papers faced the problem of saving space in these data structures, both in practice and in theory. Many of the papers were aimed at improving the lower-order terms, as well as the constants in the higher-order terms, or at achieving tradeoff between space requirements and search time complexity. Some authors improved the multiplicative constants in the $O(n \lg n)$ -bit practical implementations. For the analysis of constants, we refer the reader to [6, 15, 34, 44, 53, 54, 55]. Other authors devised several variations of sparse suffix trees to store a subset of the suffixes [5, 35, 47, 46, 56, 59]. Some of them wanted queries to be efficient when the occurrences are aligned with the boundaries of the indexed suffixes. Sparsity saves much space but makes the search for arbitrary substrings difficult and, in the worst case, it is as expensive as scanning the whole text in $O(m+n)$ time. Another interesting index, the Lempel-Ziv index [45], occupies $O(n)$ bits and takes $O(m)$ time to search patterns shorter than $\lg n$ with an output-sensitive cost for reporting the occurrences; for longer patterns, it may occupy $\Omega(n \lg n)$ bits. An efficient and practical compressed index is discussed in [21], but its searches are at word level and are not full text (i.e., with arbitrary substrings).

An alternative line of research has been built upon succinct representation of trees in $2n$ bits, with navigational operations [42]. That representation was extended in [16] to represent a suffix tree in $n \lg n$ bits plus an extra $O(n \lg \lg n)$ expected number of bits. A solution requiring $n \lg n + O(n)$ bits and $O(m + \lg \lg n)$ search time was described in [17]. Munro, Raman, and Rao [62] used it along with an improved succinct representation of balanced parentheses [61] in order to get $O(m \lg |\Sigma|)$ search time with only $n \lg n + o(n)$ bits. They also show in [62] how to get $O(m)$ time and

$O(n \lg n / \lg \lg n)$ bits for existential queries in binary patterns.

The preliminary version of our results presented in [37] stimulated much further work; according to a search on <http://www.scholar.google.com>, as of May 2005 more than 80 interesting results have appeared citing this work. A first question raised concerns lower bounds. Assuming that the text is read-only and using a stronger version of the bit-probe model, Demaine and López-Ortiz [22] have shown in the worst case that any text index with alphabet size $|\Sigma| = 2$ that supports fast queries by probing $O(m)$ bits in the text must use $\Omega(n)$ bits of extra storage space. (See also Gál and Miltersen [32] for a general class of lower bounds.) Thus, our index is space-optimal in this sense. A second concerns compressible text. Ferragina and Manzini [29, 30] have devised the Fast Minute index (FM-index), based upon the Burrows–Wheeler transform [14], that asymptotically achieves the order- k empirical entropy of the text and allows them to obtain self-indexing texts (i.e., the compressed text and its index are the same sequence of bits). Sadakane [64] has shown that compressed suffix arrays can be used for self-indexing texts, with space bound by the order-0 entropy. (He also uses our Lemma 2 in section 3.1 to show how to store the skip values of the suffix tree in $O(n)$ bits [65].) The space of compressed suffix arrays has been further reduced to the order- k entropy (with a multiplicative constant of 1) by Grossi, Gupta, and Vitter [36] using a novel analysis based on a finite set model. Both the compressed suffix array and the FM-index require $O(n \lg n)$ auxiliary bits of space during preprocessing, so a third question arises concerning a space-efficient construction. Hon, Sadakane, and Sung [40] have shown how to build both the compressed suffix array and the FM-index with $O(n \lg |\Sigma|)$ bits of auxiliary space by using the text alone and small bookkeeping data structures. Numerous other papers have appeared as well, representing a recent new trend in text indexing, causing space efficiency to no longer be a major obstacle to the large-scale application of index data structures [71]. Ideally we’d like to find an index that uses as few as bits as possible and supports enumerative queries for each query pattern in sublinear time in the worst case (in addition to the output-sensitive cost).

1.4. Outline of the paper. In section 2 we describe the ideas behind our new data structure for compressed suffix arrays, including function Φ . Details of our compressed suffix array construction are given in section 3. In section 4 we show how to use compressed suffix arrays to construct compressed suffix trees and a general space-efficient indexing mechanism to speed up text search. We give final comments in section 5. We adopt the standard unit cost RAM for the analysis of our algorithms, as does the previous work with which we compare. We use standard arithmetic and Boolean operations on words of $O(\lg n)$ bits. Each operation takes constant time; each word is read or written in constant time.

2. Compressed suffix arrays. The compression of suffix arrays falls into the general framework presented by Jacobson [43] for the abstract optimization of data structures. We start from the specification of our data structure as an abstract data type with its supported operations. We take the time complexity of the “natural” (and less space efficient) implementation of the data structure. Then we define the class C_n of all distinct data structures storing n elements. A simple information-theoretic argument implies that each such data structure can be canonically identified by $\lg |C_n|$ bits. We try to give a succinct implementation of the same data structure in $O(\lg |C_n|)$ bits, while supporting the operations within time complexity comparable with that of the natural implementation. However, the information-theoretic argument alone does not guarantee that the operations can be supported efficiently.

We define the suffix array SA for a binary string T as an abstract data type that supports the two operations *compress* and *lookup* described in the introduction. We will adopt the convention that T is a binary string of length $n - 1$ over the alphabet $\Sigma = \{\mathbf{a}, \mathbf{b}\}$, and it is terminated in the n th position by a special end-of-string symbol $\#$, such that $\mathbf{a} < \# < \mathbf{b}$.² We will discuss the case of alphabets of size $|\Sigma| > 2$ at the end of the section.

The suffix array SA is a permutation of $\{1, 2, \dots, n\}$ that corresponds to the lexicographic ordering of the suffixes in T ; that is, $SA[i]$ is the starting position in T of the i th suffix in lexicographic order. The example below shows the suffix arrays corresponding to the 16 binary strings of length 4:

aaaa#	aaab#	aaba#	aabb#	abaa#	abab#	abba#	abbb#
12345	12354	14253	12543	34152	13524	41532	15432
baaa#	baab#	baba#	babb#	bbaa#	bbab#	bbba#	bbbb#
23451	23514	42531	25143	34521	35241	45321	54321

The natural explicit implementation of suffix arrays requires $O(n \lg n)$ bits and supports the *lookup* operation in constant time. The abstract optimization discussed above suggests that there is a canonical way to represent suffix arrays in $O(n)$ bits. This observation follows from the fact that the class C_n of suffix arrays has no more than 2^{n-1} distinct members, as there are 2^{n-1} binary strings of length $n - 1$. That is, not all the $n!$ permutations are necessarily suffix arrays.

We use the intuitive correspondence between suffix arrays of length n and binary strings of length $n - 1$. According to the correspondence, given a suffix array SA , we can infer its associated binary string T and vice versa. To see how, let x be the entry in SA corresponding to the last suffix $\#$ in lexicographic order. Then T must have the symbol \mathbf{a} in each of the positions pointed to by $SA[1], SA[2], \dots, SA[x - 1]$, and it must have the symbol \mathbf{b} in each of the positions pointed to by $SA[x + 1], SA[x + 2], \dots, SA[n]$. For example, in the suffix array $\langle 45321 \rangle$ (the 15th of the 16 examples above), the suffix $\#$ corresponds to the second entry 5. The preceding entry is 4, and thus the string T has \mathbf{a} in position 4. The subsequent entries are 3, 2, 1, and thus T must have \mathbf{b} s in positions 3, 2, 1. The resulting string T , therefore, must be **bbba#**.

The abstract optimization does not say anything regarding the efficiency of the supported operations. By the correspondence above, we can define a trivial *compress* operation that transforms SA into a sequence of $n - 1$ bits plus $\#$, namely, string T itself. The drawback, however, is the unaffordable cost of *lookup*. It takes $\Omega(n)$ time to decompress a single suffix pointer in SA , as it must build the whole suffix array on T from scratch. In other words, the trivial method proposed so far does not support efficient *lookup* operations.

In this section we describe an efficient method to represent suffix arrays in $O(n)$ bits with fast *lookup* operations. Our idea is to distinguish among the permutations of $\{1, 2, \dots, n\}$ by relating them to the suffixes of the corresponding strings, instead of studying them alone. We mimic a simple divide-and-conquer “deconstruction” of the suffix arrays to define the permutation for an arbitrary (e.g., random) string T recursively in terms of shorter permutations. For some examples of divide-and-conquer

²Usually, an end-of-symbol character is not explicitly stored in T , but rather is implicitly represented by a blank symbol \square , with the ordering $\square < \mathbf{a} < \mathbf{b}$. However, our use of $\#$ is convenient for showing the explicit correspondence between suffix arrays and binary strings.

construction of suffix arrays and suffix trees, see [8, 25, 26, 27, 55, 66]. We reverse the construction process to discover a recursive structure of the permutations that makes their compression possible. We describe the decomposition scheme in section 2.1, giving some intuition on the compression in section 2.2. We summarize the results thus obtained in section 2.3.

2.1. Decomposition scheme. Our decomposition scheme is by a simple recursion mechanism. Let SA be the suffix array for binary string T . In the base case, we denote SA by SA_0 , and let $n_0 = n$ be the number of its entries. For simplicity in exposition, we assume that n is a power of 2.

In the inductive phase $k \geq 0$, we start with suffix array SA_k , which is available by induction. It has $n_k = n/2^k$ entries and stores a permutation of $\{1, 2, \dots, n_k\}$. (Intuitively, this permutation is that resulting from sorting the suffixes of T whose suffix pointers are multiples of 2^k .) We run four main steps as follows to transform SA_k into an equivalent but more succinct representation:

Step 1. Produce a bit vector B_k of n_k bits such that $B_k[i] = \mathbf{1}$ if $SA_k[i]$ is even and $B_k[i] = \mathbf{0}$ if $SA_k[i]$ is odd.

Step 2. Map each $\mathbf{0}$ in B_k onto its companion $\mathbf{1}$. (We say that a certain $\mathbf{0}$ is the *companion* of a certain $\mathbf{1}$ if the odd entry in SA associated with the $\mathbf{0}$ is 1 less than the even entry in SA associated with the $\mathbf{1}$.) We can denote this correspondence by a partial function Ψ_k , where $\Psi_k(i) = j$ if and only if $SA_k[i]$ is odd and $SA_k[j] = SA_k[i] + 1$. When defined, $\Psi_k(i) = j$ implies that $B_k[i] = \mathbf{0}$ and $B_k[j] = \mathbf{1}$. It is convenient to make Ψ_k a total function by setting $\Psi_k(i) = i$ when $SA_k[i]$ is even (i.e., when $B_k[i] = \mathbf{1}$). In summary, for $1 \leq i \leq n_k$, we have

$$\Psi_k(i) = \begin{cases} j & \text{if } SA_k[i] \text{ is odd and } SA_k[j] = SA_k[i] + 1; \\ i & \text{otherwise.} \end{cases}$$

Step 3. Compute the number of 1's for each prefix of B_k . We use function $rank_k$ for this purpose; that is, $rank_k(j)$ counts how many 1's are in the first j bits of B_k .

Step 4. Pack together the even values from SA_k and divide each of them by 2. The resulting values form a permutation of $\{1, 2, \dots, n_{k+1}\}$, where $n_{k+1} = n_k/2 = n/2^{k+1}$. Store them in a new suffix array SA_{k+1} of n_{k+1} entries and remove the old suffix array SA_k .

The following example illustrates the effect of a single application of Steps 1–4. Here, $\Psi_0(25) = 16$ as $SA_0[25] = 29$ and $SA_0[16] = 30$. The new suffix array SA_1 explicitly stores the suffix pointers (divided by 2) for the suffixes that start at even positions in the original text T . For example, $SA_1[3] = 5$ means that the third lexicographically smallest suffix that starts at an even position in T is the one starting at position $2 \times 5 = 10$, namely, $abbabaa \dots \#$.

  if  $k = \ell$  then
    return  $SA_\ell[i]$ 
  else
    return  $2 \times \textit{rlookup}(\textit{rank}_k(\Psi_k(i)), k + 1) + (B_k[i] - 1)$ .

```

FIG. 3. Recursive lookup of entry $SA_k[i]$ in a compressed suffix array.

The next lemma shows that these steps preserve the information originally kept in suffix array SA_k .

LEMMA 1. *Given suffix array SA_k , let B_k , Ψ_k , \textit{rank}_k , and SA_{k+1} be the result of the transformation performed by Steps 1–4 of phase k . We can reconstruct SA_k from SA_{k+1} by the following formula for $1 \leq i \leq n_k$:*

$$SA_k[i] = 2 \cdot SA_{k+1}[\textit{rank}_k(\Psi_k(i))] + (B_k[i] - 1).$$

Proof. Suppose $B_k[i] = \mathbf{1}$. By Step 3, there are $\textit{rank}_k(i)$ 1's among $B_k[1], B_k[2], \dots, B_k[i]$. By Step 1, $SA_k[i]$ is even, and by Step 4, $SA_k[i]/2$ is stored in the $\textit{rank}_k(i)$ th entry of SA_{k+1} . In other words, $SA_k[i] = 2 \cdot SA_{k+1}[\textit{rank}_k(i)]$. As $\Psi_k(i) = i$ by Step 2, and $B_k[i] - 1 = 0$, we obtain the claimed formula.

Next, suppose that $B_k[i] = \mathbf{0}$ and let $j = \Psi_k(i)$. By Step 2, we have $SA_k[i] = SA_k[j] - 1$ and $B_k[j] = \mathbf{1}$. Consequently, we can apply the previous case of our analysis to index j , and we get $SA_k[j] = 2 \cdot SA_{k+1}[\textit{rank}_k(j)]$. The claimed formula follows by replacing j with $\Psi_k(i)$ and by noting that $B_k[i] - 1 = -1$. \square

In the previous example, $SA_0[25] = 2 \cdot SA_1[\textit{rank}_0(16)] - 1 = 2 \cdot 15 - 1 = 29$. We now give the main ideas to perform the compression of suffix array SA and support the lookup operations on its compressed representation.

Procedure compress. We represent SA succinctly by executing Steps 1–4 of phases $k = 0, 1, \dots, \ell - 1$, where the exact value of $\ell = \Theta(\lg \lg n)$ will be determined in section 3. As a result, we have $\ell + 1$ levels of information, numbered $0, 1, \dots, \ell$, which form the *compressed representation* of suffix array SA as follows:

1. Level k , for each $0 \leq k < \ell$, stores B_k , Ψ_k , and \textit{rank}_k . We do not store SA_k , but we refer to it for the sake of discussion. The arrays Ψ_k and \textit{rank}_k are not stored explicitly, but are stored in a specially compressed form described in section 3.

2. The last level $k = \ell$ stores SA_ℓ explicitly because it is sufficiently small to fit in $O(n)$ bits. The ℓ th level functionality of structures B_ℓ , Ψ_ℓ , and \textit{rank}_ℓ are not needed as a result.

Procedure lookup (i). We define $\textit{lookup}(i) = \textit{rlookup}(i, 0)$, where $\textit{rlookup}(i, k)$ is the procedure described recursively for level k in Figure 3.

If k is the last level ℓ , then it performs a direct lookup in $SA_\ell[i]$. Otherwise, it exploits Lemma 1 and the inductive hypothesis so that $\textit{rlookup}(i, k)$ returns the value of $2 \cdot SA_{k+1}[\textit{rank}_k(\Psi_k(i))] + (B_k[i] - 1)$ in $SA_k[i]$.

2.2. Compressibility. As previously mentioned, B_k , \textit{rank}_k , and Ψ_k are the key ingredients for representing a compressed suffix array. Storing B_k and \textit{rank}_k succinctly, with constant-time access, can be done using previous work (see, e.g., [42]). Hence, we focus on function Ψ_k , which is at the heart of the compressed suffix array since its compression is challenging.

Before giving some intuition on the compressibility, a few comments are in order. When $\Psi_0(i) \neq i$, we observe that Ψ_0 is the analogue of the suffix links in McCreight's

suffix tree construction [57]. (We recall that a suffix link for a node storing a nonempty string $c\alpha$, where $c \in \Sigma$, points to the node storing α .) This is clear when we consider its extension, Φ_0 , defined in section 3.2 as follows:

$$\Phi_k(i) = \begin{cases} j & \text{if } SA_k[i] \neq n_k \text{ and } SA_k[j] = SA_k[i] + 1; \\ 1 & \text{otherwise.} \end{cases}$$

Indeed, if i is the position in SA for suffix $T[SA[i], n]$, then $\Phi_0(i)$ returns j , which is the position in SA for suffix $T[SA[i] + 1, n]$ (when $\Phi_0(i)$ is seen as a suffix link, $c = T[SA[i]]$ and $\alpha = T[SA[i] + 1, n]$). Analogously, we can see Ψ_k and Φ_k as the suffix links for the positions in SA_k , for any $k \geq 0$.

Functions Ψ_k and Φ_k can be seen as by-products of the suffix array construction. Let the inverse suffix array, SA^{-1} , be the array satisfying $SA^{-1}[SA[i]] = SA[SA^{-1}[i]] = i$. Note that SA^{-1} is well defined since SA stores a permutation of $1, 2, \dots, n$. When $\Phi_0(i) \neq 1$, we have $\Phi_0(i) = SA^{-1}[SA[i] + 1]$. An analogous argument holds for any $k \geq 0$.

In order to see why Ψ_0 and Φ_0 are compressible, we focus on Ψ_0 . If we consider the values of Ψ_0 in the example of section 2.1, we do not see any particular order. However, if we restrict our focus to the positions i ($1 \leq i \leq n$) having (a) value of **0** in $B_0[i]$, and (b) the *same* leading character in the corresponding suffix, $T[SA[i], n]$, we observe that the values of Ψ_0 in those positions yield an increasing sequence. For example, choosing **a** as the leading character in condition (b), we find that the positions satisfying also condition (a) are $i = 1, 3, 4, 5, 6, 9, 11, 12$. Their corresponding values are $\Psi_0(i) = 2, 14, 15, 18, 23, 28, 30, 31$, respectively. The latter values form a sorted sequence (called **a** list) that can be implicitly represented in several ways. We clearly have to represent lists for all distinct characters that appear in the text (**a** list, **b**list, ...).

In this paper, we represent the lists by relating them to the positions of the companion **1**'s in B_0 . Let the preceding character for position i in SA be $T[SA[i] - 1]$ for $SA[i] \neq 1$; otherwise, let it be $T[n]$. We implicitly associate the preceding character for position i with each entry of B_0 containing **1**. For example, in the case of the **a** list, the positions corresponding to the **1**'s in B_0 and with preceding character **a** are $2, 14, 15, 18, 23, 28, 30, 31$, which are exactly the items in the **a** list itself! (The motivation for this nice property is that the suffixes remain sorted in relative order, even if interspersed with other suffixes, when we remove their leading character **a**.) By exploiting this relation, we can implement constant-time access to Ψ_0 's values without needing to store them explicitly. Further details on how to represent $rank_k$, Ψ_k , and Φ_k in compressed form and how to implement *compress* and *lookup(i)* will be given in section 3.

2.3. Results. Our main theorem below gives the resulting time and space complexity that we are able to achieve.

THEOREM 1 (binary alphabets). *Consider the suffix array SA built upon a binary string of length $n - 1$.*

- (i) *We can implement *compress* in $\frac{1}{2}n \lg \lg n + 6n + O(n/\lg \lg n)$ bits and $O(n)$ preprocessing time, so that each call *lookup(i)* takes $O(\lg \lg n)$ time.*
- (ii) *We can implement *compress* in $(1 + \epsilon^{-1})n + O(n/\lg \lg n)$ bits and $O(n)$ preprocessing time, so that each call *lookup(i)* takes $O(\lg^\epsilon n)$ time, for any fixed value of $0 < \epsilon \leq 1$.*

The coefficients on the second-order terms can be tweaked theoretically by a more elaborate encoding. We also state the above results in terms of alphabets with $|\Sigma| > 2$.

THEOREM 2 (general alphabets). *Consider the suffix array SA built upon a string of length $n - 1$ over the alphabet Σ with size $|\Sigma| > 2$.*

(i) *We can implement compress in $(1 + \frac{1}{2} \lg \lg_{|\Sigma|} n) n \lg |\Sigma| + 5n + O(n / \lg \lg n) = (1 + \frac{1}{2} \lg \lg_{|\Sigma|} n) n \lg |\Sigma| + O(n)$ bits and $O(n \lg |\Sigma|)$ preprocessing time, so that each call $lookup(i)$ takes $O(\lg \lg_{|\Sigma|} n)$ time.*

(ii) *We can implement compress in $(1 + \epsilon^{-1}) n \lg |\Sigma| + 2n + O(n / \lg \lg n) = (1 + \epsilon^{-1}) n \lg |\Sigma| + o(n \lg |\Sigma|)$ bits and $O(n \lg |\Sigma|)$ preprocessing time, so that each call $lookup(i)$ takes $O(\lg_{|\Sigma|}^{\epsilon} n)$ time, for any fixed value of $0 < \epsilon \leq 1$. For $|\Sigma| = O(1)$, the space bound reduces to $(1 + \epsilon^{-1}) n \lg |\Sigma| + O(n / \lg \lg n) = (1 + \epsilon^{-1}) n \lg |\Sigma| + o(n)$ bits.*

We remark that Sadakane [64] has shown that the space complexity in Theorem 1(ii) and Theorem 2(ii) can be restated in terms of the order-0 entropy $H_0 \leq \lg |\Sigma|$ of the string, giving as a result $\epsilon^{-1} H_0 n + O(n)$ bits. Grossi, Gupta, and Vitter [36] have shown how to attain order- h entropy, namely, $H_h n + O(n \lg \lg n / \lg_{|\Sigma|} n)$ bits, where $H_h \leq H_0$.

The lookup process can be sped up when we need to report several contiguous entries, as in enumerative string matching queries. Let $lcp(i, j)$ denote the length of the longest common prefix between the suffixes pointed to by $SA[i]$ and $SA[j]$, with the convention that $lcp(i, j) = -\infty$ when $i < 1$ or $j > n$. We say that a sequence $i, i + 1, \dots, j$ of indices in SA is *maximal* if both $lcp(i - 1, j)$ and $lcp(i, j + 1)$ are strictly smaller than $lcp(i, j)$, as in enumerative queries. (Intuitively, a maximal sequence in SA corresponds to all the occurrences of a pattern in T .)

THEOREM 3 (batch of lookups). *In each of the cases stated in Theorems 1 and 2, we can use the additional space of $O(n \lg |\Sigma|)$ bits and batch together $j - i + 1$ procedure calls $lookup(i), lookup(i + 1), \dots, lookup(j)$, for a maximal sequence $i, i + 1, \dots, j$, so that the total cost is*

(i) *$O(j - i + (\lg n)^{1+\epsilon} (\lg |\Sigma| + \lg \lg n))$ time when $lcp(i, j) = \Omega(\lg^{1+\epsilon} n)$, namely, the suffixes pointed to by $SA[i]$ and $SA[j]$ have the same first $\Omega(\lg^{1+\epsilon} n)$ symbols in common, or*

(ii) *$O(j - i + n^{\alpha})$ time, for any constant $0 < \alpha < 1$, when $lcp(i, j) = \Omega(\lg n)$, namely, the suffixes pointed to by $SA[i]$ and $SA[j]$ have the same first $\Omega(\lg n)$ symbols.*

3. Algorithms for compressed suffix arrays. In this section we constructively prove Theorems 1–3 by showing two ways to implement the recursive decomposition of suffix arrays discussed in section 2.1. In particular, in section 3.1 we address Theorem 1(i), and in section 3.2 we prove Theorem 1(ii). Section 3.3 shows how to extend Theorem 1 to deal with alphabets of size $|\Sigma| > 2$, thus proving Theorem 2. In section 3.4 we prove Theorem 3, showing how to batch together the lookup of several contiguous entries in suffix arrays, which arises in enumerative string matching queries.

3.1. Compressed suffix arrays in $\frac{1}{2} n \lg \lg n + O(n)$ bits and $O(\lg \lg n)$ access time. In this section we describe the method referenced in Theorem 1(i) for binary strings and show that it achieves $O(\lg \lg n)$ lookup time with a total space usage of $O(n \lg \lg n)$ bits. Before giving the algorithmic details of the method, let's continue the recursive decomposition of Steps 1–4 described in section 2.1, for $0 \leq k \leq \ell - 1$, where $\ell = \lceil \lg \lg n \rceil$. The decomposition below shows the result on the example of section 2.1:

	1 2 3 4 5 6 7 8 9 10 11 12 13 14 15 16	
SA_1 :	8 14 5 2 12 16 7 15 6 9 3 10 13 4 1 11	
B_1 :	1 1 0 1 1 1 0 0 1 0 0 1 0 1 0 0	
$rank_1$:	1 2 2 3 4 5 5 5 6 6 6 7 7 8 8 8	
Ψ_1 :	1 2 9 4 5 6 1 6 9 12 14 12 2 14 4 5	
	1 2 3 4 5 6 7 8	
SA_2 :	4 7 1 6 8 3 5 2	
B_2 :	1 0 0 1 1 0 0 1	1 2 3 4
$rank_2$:	1 1 1 2 3 3 3 4	SA_3 : 2 3 4 1
Ψ_2 :	1 5 8 4 5 1 4 9	

The resulting suffix array SA_ℓ on level ℓ contains at most $n/\lg n$ entries and can thus be stored explicitly in at most n bits. We store the bit vectors $B_0, B_1, \dots, B_{\ell-1}$ in explicit form, using less than $2n$ bits, as well as *implicit* representations of $rank_0, rank_1, \dots, rank_{\ell-1}$, and $\Psi_0, \Psi_1, \dots, \Psi_{\ell-1}$. If the implicit representations of $rank_k$ and Ψ_k can be accessed in constant time, the procedure described in Lemma 1 shows how to achieve the desired lookup in constant time per level, for a total of $O(\lg \lg n)$ time.

All that remains, for $0 \leq k \leq \ell - 1$, is to investigate how to represent $rank_k$ and Ψ_k in $O(n)$ bits and support constant-time access. Given the bit vector B_k of $n_k = n/2^k$ bits, Jacobson [42] shows how to support constant-time access to $rank_k$ using only $O(n_k(\lg \lg n_k)/\lg n_k)$ extra bits, with preprocessing time $O(n_k)$.

We show next how to represent Ψ_k implicitly. First we explain the representation by an example and then we describe it formally. In Lemma 3 we show that the space used to represent Ψ_k is $n(1/2 + 3/2^{k+1}) + O(n/2^k \lg \lg n)$ bits.

For each $1 \leq i \leq n_k/2$, let j be the index of the i th **1** in B_k . Consider the 2^k symbols in positions $2^k \cdot (SA_k[j] - 1), \dots, 2^k \cdot SA_k[j] - 1$ of T ; these 2^k symbols immediately precede the $(2^k \cdot SA_k[j])$ th suffix in T , as the suffix pointer in $SA_k[j]$ was 2^k times larger before the compression. For each bit pattern of 2^k symbols that appears, we keep an ordered list of the indices $j \in [1, n/2^k]$ that correspond to it, and we record the number of items in each list. Continuing the example above, we get the following lists for level 0:

a list:	$\langle 2, 14, 15, 18, 23, 28, 30, 31 \rangle$,	$ a \text{ list} = 8$
b list:	$\langle 7, 8, 10, 13, 16, 17, 21, 27 \rangle$,	$ b \text{ list} = 8$

Level 1:

aa list:	\emptyset ,	$ aa \text{ list} = 0$
ab list:	$\langle 9 \rangle$,	$ ab \text{ list} = 1$
ba list:	$\langle 1, 6, 12, 14 \rangle$,	$ ba \text{ list} = 4$
bb list:	$\langle 2, 4, 5 \rangle$,	$ bb \text{ list} = 3$

Level 2:

aaaa list:	\emptyset ,	$ aaaa \text{ list} = 0$	baaa list:	\emptyset ,	$ baaa \text{ list} = 0$
aaab list:	\emptyset ,	$ aaab \text{ list} = 0$	baab list:	\emptyset ,	$ baab \text{ list} = 0$
aaba list:	\emptyset ,	$ aaba \text{ list} = 0$	baba list:	$\langle 1 \rangle$,	$ baba \text{ list} = 1$
aabb list:	\emptyset ,	$ aabb \text{ list} = 0$	babb list:	$\langle 4 \rangle$,	$ babb \text{ list} = 1$
abaa list:	\emptyset ,	$ abaa \text{ list} = 0$	bbaa list:	\emptyset ,	$ bbaa \text{ list} = 0$
abab list:	\emptyset ,	$ abab \text{ list} = 0$	bbab list:	\emptyset ,	$ bbab \text{ list} = 0$
abba list:	$\langle 5, 8 \rangle$,	$ abba \text{ list} = 2$	bbba list:	\emptyset ,	$ bbba \text{ list} = 0$
abbb list:	\emptyset ,	$ abbb \text{ list} = 0$	bbbb list:	\emptyset ,	$ bbbb \text{ list} = 0$

Suppose we want to compute $\Psi_k(i)$. If $B_k[i] = \mathbf{1}$, we trivially have $\Psi_k(i) = i$; therefore, let's consider the harder case in which $B_k[i] = \mathbf{0}$, which means that $SA_k[i]$ is odd. We have to determine the index j such that $SA_k[j] = SA_k[i] + 1$. We can determine the number h of $\mathbf{0}$'s in B_k up to index i by computing $i - \text{rank}_k(i)$, i.e., by subtracting the number of $\mathbf{1}$'s in the first i bits of B_k . Consider the 2^{2^k} lists concatenated together in lexicographic order of the 2^k -bit prefixes. We denote by L_k the resulting concatenated list, which has $|L_k| = n_k/2 = n/2^{k+1}$ total items. What we need to find now is the h th entry in L_k . For example, to determine $\Psi_0(25)$ in the example above, we find that there are $h = 13$ $\mathbf{0}$'s in the first 25 slots of B_0 . There are eight entries in the **a** list and eight entries in the **b** list; hence, the 13th entry in L_0 is the fifth entry in the **b** list, namely, index 16. Hence, we have $\Psi_0(25) = 16$ as desired; note that $SA_0[25] = 29$ and $SA_0[16] = 30$ are consecutive values.

Continuing the example, consider the next level of the recursive call to *rlookup*, in which we need to determine $\Psi_1(8)$. (The previously computed value $\Psi_0(25) = 16$ has a rank_0 value of 8, i.e., $\text{rank}_0(16) = 8$, so the *rlookup* procedure needs to determine $SA_1[8]$, which it does by first calculating $\Psi_1(8)$.) There are $h = 3$ $\mathbf{0}$'s in the first eight entries of B_1 . The third entry in the concatenated list L_1 for **aa**, **ab**, **ba**, and **bb** is the second entry in the **ba** list, namely, 6. Hence, we have $\Psi_1(8) = 6$ as desired; note that $SA_1[8] = 15$ and $SA_1[6] = 16$ are consecutive values.

We now describe formally how to preprocess the input text T in order to form the concatenated list L_k on level k used for Ψ_k with the desired space and constant-time query performance. We first consider a variant of the "inventories" introduced by Elias [23] to get average bit efficiency in storing sorted multisets. We show how to get worst-case efficiency.

LEMMA 2 (constant-time access to compressed sorted integers). *Given s integers in sorted order, each containing w bits, where $s < 2^w$, we can store them with at most $s(2 + w - \lfloor \lg s \rfloor) + O(s/\lg \lg s)$ bits, so that retrieving the h th integer takes constant time.*

Proof. We take the first $z = \lfloor \lg s \rfloor$ bits of each integer in the sorted sequence. Let q_1, \dots, q_s be the integers so obtained, called *quotients*, where $0 \leq q_h \leq q_{h+1} < s$ for $1 \leq h < s$. (Note that multiple values are allowed.) Let r_1, \dots, r_s be the *remainders*, obtained by deleting the first z bits from each integer in the sorted sequence.

We store q_1, \dots, q_s in a table Q described below, requiring $2s + O(s/\lg \lg s)$ bits. We store r_1, \dots, r_s in a table R taking $s(w - z)$ bits. Table R is the simple concatenation of the bits representing r_1, \dots, r_s .

As for Q , we use the unary representation $\mathbf{0}^i \mathbf{1}$ (i.e., i copies of $\mathbf{0}$ followed by $\mathbf{1}$) to represent integer $i \geq 0$. Then we take the concatenation of the unary representation of $q_1, q_2 - q_1, \dots, q_s - q_{s-1}$. In other words, we take the first entry encoded in unary, and then the unary difference between the other consecutive entries, which are in nondecreasing order. Table Q is made up of the binary string obtained by the above concatenation S , augmented with the auxiliary data structure supporting *select* operations to locate the position of the h th $\mathbf{1}$ in constant time [15, 42, 60].

Since S requires $s + 2^z \leq 2s$ bits, the total space required by Q is $2s + O(s/\lg \lg s)$ bits; the big-oh term is due to the auxiliary data structure that implements *select*. In order to retrieve q_h , we find the position j of the h th $\mathbf{1}$ in S by calling *select*(h), and then compute the number of $\mathbf{0}$'s in the first j bits of S by returning $j - h$. As we can see, this number of $\mathbf{0}$'s gives q_h . The time complexity is constant.

In order to obtain the h th integer in the original sorted sequence, we find q_h by querying Q as described above, and we find r_i by looking up the h th entry in R .

We then output $q_h \cdot 2^{w-z} + r_h$ as the requested integer by simply returning the concatenation of the bit representations of q_h and r_h . \square

We now proceed to the implementation of Ψ_k .

LEMMA 3. *We can store the concatenated list L_k used for Ψ_k in $n(1/2+3/2^{k+1}) + O(n/2^k \lg \lg n)$ bits, so that accessing the h th entry in L_k takes constant time. Pre-processing time is $O(n/2^k + 2^{2^k})$.*

Proof. There are $d = 2^{2^k}$ lists, some of which may be empty. We number the lists composing L_k from 0 to $2^{2^k} - 1$. Each integer x in list i , where $1 \leq x \leq n_k$, is transformed into an integer x' of $w = 2^k + \lg n_k$ bits by prepending the binary representation of i to that of $x - 1$. Given any such x' , we can obtain the corresponding x in constant time. As a result, L_k contains $s = n_k/2 = n/2^{k+1}$ integers in increasing order, each integer of w bits. By Lemma 2, we can store L_k in $s(2 + w - \lg s) + O(s/\lg \lg s)$ bits, so that retrieving the h th integer takes constant time. Substituting the values for s and w , we get the space bound $(n_k/2)(2 + 2^k + \lg n_k - \lg(n_k/2)) + O(n_k/\lg \lg n_k) = (n/2^{k+1})(2^k + 3) + O(n/2^k \lg \lg n) = n(1/2 + 3/2^{k+1}) + O(n/2^k \lg \lg n)$. \square

A good way to appreciate the utility of the data structure for Ψ_k is to consider the naive alternative. Imagine that the information is stored naively in the form of an unsorted array of $s = n_k/2$ entries, where each entry specifies the particular list to which the entry belongs. Since there are $d = 2^{2^k}$ lists, the total number of bits needed to store the array in this naive manner is $s \lg d = (n_k/2)2^k = n/2$, which is efficient in terms of space. Let us define the natural ordering \prec on the array entries, in which we say that $i \prec j$ either if $i < j$ or if $i = j$ and the position of i in the array precedes the position of j . The naive representation does not allow us to efficiently look up the h th \prec -ordered entry in the array, which is equivalent to finding the h th entry in the concatenated list L_k . It also doesn't allow us to search quickly for the g th occurrence of the entry i , which is equivalent to finding the g th item in list i . In contrast, the data structure described in Lemma 3 supports both of these query operations in linear space and constant time.

COROLLARY 1. *Given an unsorted array of s entries, each in the range $[0, d - 1]$, we can represent the array in a total of $s \lg d + O(s)$ bits so that, given h , we can find the h th entry (in \prec order) in the array in constant time. We can also represent the array in $O(s \lg d)$ bits so that, given g and i , we can find the g th occurrence of i in the array in constant time. The latter operation can be viewed as a generalization of the select operation to arbitrary input patterns.*

Proof. The first type of query is identical to finding the h th item in the concatenated list L_k , and the bound on space follows from the construction in Lemma 3. The corresponding values of s and w in the proof of Lemma 3 are s and $\lg d + \lg s$, respectively.

The second type of query is identical to finding the g th entry in list i . It can be turned into the first type of query if we can compute the value of h that corresponds to g and i ; that is, we need to find the global position h (with respect to \prec) of the g th entry in list i . If $d \leq s$, then we can explicitly store a table that gives for each $0 \leq i < d$ the first location h' in the concatenated list L_k that corresponds to an entry in list i . We then set $h = h' + g - 1$ and do the first type of query. (If list i has fewer than g entries, which can be detected after the query is done, the value returned by the first query must be nullified.) The total space used is $d \lg s$, which by the assumption $d \leq s$ is at most $s \lg d$. If instead $d > s$, then we can use the same approach as above, except that we substitute a perfect hash function to compute the value h' . The space for the hash table is $O(s \lg s) = O(s \lg d)$. \square

Putting it all together. At this point, we have all the pieces needed to finish the proof of Theorem 1(i). Given text T and its suffix array, we proceed in $\ell = \lceil \lg \lg n \rceil$ levels of decomposition as discussed in procedure *compress* in section 2. The last level ℓ stores explicitly a reduced suffix array in $(n/2^\ell) \lg n \leq n$ bits. The other levels $0 \leq k \leq \ell - 1$ store three data structures each, with constant time access as follows:

1. Bit vector B_k of size $n_k = n/2^k$, with $O(n_k)$ preprocessing time.
2. Function $rank_k$ in $O(n_k(\lg \lg n_k)/\lg n_k)$ bits, with $O(n_k)$ preprocessing time.
3. Function Ψ_k in $n(1/2 + 3/2^{k+1}) + O(n/2^k \lg \lg n)$ bits, with $O(n_k + 2^{2^k})$ preprocessing time (see Lemma 3).

By summing over the levels, substituting the values $\ell = \lceil \lg \lg n \rceil$ and $n_k = n/2^k$, we get the following bound on the total space:

$$\begin{aligned}
 & \frac{n \lg n}{2^\ell} + \sum_{k=0}^{\ell-1} n \left(\frac{1}{2^k} + O\left(\frac{1}{2^k} \frac{\lg \lg(n/2^k)}{\lg(n/2^k)}\right) + \frac{1}{2} + \frac{3}{2^{k+1}} + O\left(\frac{1}{2^k \lg \lg n}\right) \right) \\
 & < \frac{n \lg n}{2^\ell} + n \left(2 + O\left(\frac{\lg \lg n}{\lg n}\right) + \frac{1}{2} \ell + 3 + O\left(\frac{1}{\lg \lg n}\right) \right) \\
 (1) \quad & = \frac{n \lg n}{2^\ell} + \frac{1}{2} \ell n + 5n + O\left(\frac{n}{\lg \lg n}\right).
 \end{aligned}$$

It's easy to show that $(n \lg n)/2^\ell + \frac{1}{2} \ell n \leq \frac{1}{2} n \lg \lg n + n$, which combined with (1) gives us the desired space bound $\frac{1}{2} n \lg \lg n + 6n + O(n/\lg \lg n)$ in Theorem 1(i).

The total preprocessing time of *compress* is $\sum_{k=0}^{\ell-1} O(n_k + 2^{2^k}) = O(n)$. A call to *lookup* goes through the $\ell + 1$ levels, in constant time per level, with a total cost of $O(\lg \lg n)$. This completes the proof of Theorem 1(i).

3.2. Compressed suffix arrays in $\epsilon^{-1}n + O(n)$ bits and $O(\lg^\epsilon n)$ access time. In this section we give the proof of Theorem 1(ii). Each of the $\lceil \lg \lg n \rceil$ levels of the data structure discussed in the previous section 3.1 uses $O(n)$ bits, so one way to reduce the space complexity is to store only a constant number of levels, at the cost of increased access time. For example, we can keep a total of three levels: level 0, level ℓ' , and level ℓ , where $\ell' = \lceil \frac{1}{2} \lg \lg n \rceil$ and, as before, $\ell = \lceil \lg \lg n \rceil$. In the previous example of $n = 32$, the three levels chosen are levels 0, 2, and 3. The trick is to determine how to reconstruct SA_0 from $SA_{\ell'}$ and how to reconstruct $SA_{\ell'}$ from SA_ℓ .

We store the $n_{\ell'}$ indices from SA_0 that correspond to the entries of $SA_{\ell'}$ in a new dictionary D_0 , and similarly we store the n_ℓ indices from $SA_{\ell'}$ that correspond to the entries of SA_ℓ in a new dictionary $D_{\ell'}$. By using the efficient static dictionary representation in [13, 63], we need less than $O(\lg \binom{n}{n_{\ell'}}) = O(n_{\ell'} \ell')$ bits for D_0 and $O(\lg \binom{n_{\ell'}}{n_\ell}) = O(n_\ell \ell)$ bits for $D_{\ell'}$. A dictionary lookup requires constant time, as does a rank query to know how many smaller or equal indices are stored in the dictionary [63].

We also have a data structure for $k = 0$ and $k = \ell'$ to support the function Ψ'_k , which is similar to Ψ_k , except that it maps $\mathbf{1}$'s to the next corresponding $\mathbf{0}$. We denote by Φ_k the resulting composition of Ψ_k and Ψ'_k , for $1 \leq i \leq n_k$:

$$\Phi_k(i) = \begin{cases} j & \text{if } SA_k[i] \neq n_k \text{ and } SA_k[j] = SA_k[i] + 1; \\ 1 & \text{otherwise.} \end{cases}$$

We implement Φ_k by merging the concatenated lists L_k of Ψ_k with the concatenated lists L'_k of Ψ'_k . For example, in level $k = 0$ shown in section 3.1, we merge the a list

of L_k with the \mathbf{a} list of L'_k , and so on (we need also the singleton list for $\#$). This is better than storing L_k and L'_k separately. Computing $\Phi_k(i)$ amounts to taking the i th entry in its concatenated list, and we no longer need the bit vector B_k .

LEMMA 4. *We can store the concatenated lists used for Φ_k in $n + O(n/\lg \lg n)$ bits for $k = 0$, and $n(1 + 1/2^{k-1}) + O(n/2^k \lg \lg n)$ bits for $k > 0$, so that accessing the h th entry takes constant time. Preprocessing time is $O(n/2^k + 2^{2^k})$.*

Proof. For $k > 0$, the proof is identical to that of Lemma 3, except that $s = n_k$ instead of $s = n_k/2$. For $k = 0$, we have only the \mathbf{a} list and the \mathbf{b} list to store, with the singleton $\#$ list handled a bit differently. Specifically, we encode \mathbf{a} and $\#$ by $\mathbf{0}$ and \mathbf{b} by $\mathbf{1}$. Then, we create a bit vector of n bits, where the bit in position f is $\mathbf{0}$ if the list for Φ_0 contains either \mathbf{a} or $\#$ in position f , and it is $\mathbf{1}$ if it contains \mathbf{b} in position f . We use auxiliary information to access the i th $\mathbf{1}$ of the bit vector in constant time by using $select(i)$ or the i th $\mathbf{0}$ by using $select_0(i)$. We also keep a counter c_0 to know the total number of $\mathbf{0}$'s in the bit vector (note that the single occurrence of $\mathbf{0}$ corresponding to $\#$ in the bit vector is the c_0 th $\mathbf{0}$ in the bit vector as we assumed $\mathbf{a} < \# < \mathbf{b}$; it is not difficult to treat the more common case $\# < \mathbf{a} < \mathbf{b}$). The additional space is $O(n/\lg \lg n)$ due to the implementation of $select$ and $select_0$. Suppose now that we want to recover the h th entry in the list for Φ_0 . If $h = c_0$, then we return the position of $\#$ by invoking $select_0(c_0)$. If $h < c_0$, then we return the h th $\mathbf{0}$ (i.e., \mathbf{a}) in the bit vector by invoking $select_0(h)$. Otherwise, we invoke $select(h - c_0)$ to get the position in the bit vector of the $(h - c_0)$ th $\mathbf{1}$ (i.e., \mathbf{b}). In this way, we simulate the concatenation of lists needed for L_0 . With $n + O(n/\lg \lg n)$ bits to implement Φ_0 , we can execute $\Phi_0(h)$ in constant time. \square

In order to determine $SA[i] = SA_0[i]$, we use function Φ_0 to walk along indices i', i'', \dots , such that $SA_0[i] + 1 = SA_0[i']$, $SA_0[i'] + 1 = SA_0[i'']$, and so on, until we reach an index stored in dictionary D_0 . Let s be the number of steps in the walk and r be the rank of the index thus found in D_0 . We switch to level ℓ' and reconstruct the r th entry at level ℓ' from the explicit representation of $SA_{\ell'}$ by a similar walk until we find an index stored in $D_{\ell'}$. Let s' be the number of steps in the latter walk and r' be the rank of the index thus found in $D_{\ell'}$. We return $(SA_{\ell'}[r'] \cdot 2^{\ell} + s' \cdot 2^{\ell'} + s \cdot 2^0)$, as this is the value of $SA_0[i]$. We defer details for reasons of brevity. The maximum length of each walk is $\max\{s, s'\} \leq 2^{\ell'} < 2\sqrt{\lg n}$, and thus the lookup procedure requires $O(\sqrt{\lg n})$ time.

To get the more general result stated in Theorem 1(ii), we need to keep a total of $\epsilon^{-1} + 1$ levels for constant $0 < \epsilon \leq 1$. More formally, let us assume that $\epsilon \ell$ is an integer. We maintain the $\epsilon^{-1} + 1$ levels $0, \epsilon \ell, 2\epsilon \ell, \dots, \ell$. The maximum length of each walk is $2^{\epsilon \ell} < 2 \lg^{\epsilon} n$, and thus the lookup procedure requires $O(\lg^{\epsilon} n)$ time.

By an analysis similar to the one we used at the end of section 3.1, the total space bound is given by $(n/2^{\ell}) \lg n \leq n$ plus a sum over the ϵ^{-1} indices $k \in \{0, \epsilon \ell, 2\epsilon \ell, 3\epsilon \ell, \dots, (1 - \epsilon)\ell\}$. We split the sum into two parts, one for $k = 0$ and the other for the remaining $\epsilon^{-1} - 1$ values of $k > 0$, and apply Lemma 4:

$$\begin{aligned}
 & \frac{n \lg n}{2^{\ell}} + n + O\left(\frac{n}{\lg \lg n}\right) + \sum_{\substack{k=i\epsilon\ell \\ 1 \leq i < \epsilon^{-1}}} n \left(1 + \frac{1}{2^{k-1}} + O\left(\frac{1}{2^k \lg \lg n}\right)\right) \\
 & \leq (1 + \epsilon^{-1})n + O\left(\frac{n}{\lg \lg n}\right) + O\left(\frac{n}{\lg^{\epsilon} n}\right) \\
 (2) \quad & = (1 + \epsilon^{-1})n + O\left(\frac{n}{\lg \lg n}\right).
 \end{aligned}$$

We have to add the contribution of the space $\sum_k |D_k| = O(n_{\epsilon\ell}) = O(n(\lg \lg n)/\lg^\epsilon n)$ taken by the dictionaries at the ϵ^{-1} levels, but this bound is hidden by the $O(n/\lg \lg n)$ term in the above formula. The final bound is $(1 + \epsilon^{-1})n + O(n/\lg \lg n)$, as stated in Theorem 1(ii).

3.3. Extension to alphabets of size $|\Sigma| > 2$. We now discuss the case of alphabets with more than two symbols. In this case, we encode each symbol by $\lg |\Sigma|$ bits, so that the text T can be seen as an array of n entries, each of $\lg |\Sigma|$ bits, or equivalently as a binary string that occupies $n \lg |\Sigma|$ bits. We describe how to extend the ideas presented in sections 3.1–3.2. We redefine ℓ to be $\lceil \lg \lg_{|\Sigma|} n \rceil$. The definitions of suffix arrays SA and SA_k , bit vector B_k , and functions $rank_k$ and Ψ_k are the same as before. Their representation does not change, with the notable exception of Ψ_k , as noted below in Lemma 5 (the analogue of Lemma 3).

LEMMA 5. *When $|\Sigma| > 2$, we can store the concatenated list L_k used for Ψ_k in $n((1/2) \lg |\Sigma| + 3/2^{k+1}) + O(n/2^k \lg \lg n)$ bits, so that accessing the h th entry in L_k takes constant time. Preprocessing time is $O(n/2^k + 2^{2^k})$.*

Proof. The extension of L_k with $|\Sigma| > 2$ is straightforward. For each of $d = |\Sigma|^{2^k} = 2^{2^k \lg |\Sigma|}$ patterns of 2^k symbols preceding the $(2^k \cdot SA_k[j])$ th suffix in T , we keep an ordered list like the **a** list and **b** list described in section 3.1. Some of these lists may be empty, and the concatenation of nonempty lists forms L_k . We number these lists from 0 to $2^{2^k \lg |\Sigma|} - 1$. Note that the number of entries in L_k remains unchanged, namely, $s = n_k/2 = n/2^{k+1}$. Each integer x in list i , where $1 \leq x \leq n_k$, is transformed into an integer x' of $w = 2^k \lg |\Sigma| + \lg n_k$ bits, by prepending the binary representation of i to that of $x - 1$. By Lemma 2, we can store L_k in $s(2 + w - \lg s) + O(s/\lg \lg s)$ bits, so that retrieving the h th integer takes constant time. Substituting the values for s and w , we get the space bound $(n_k/2)(2 + 2^k \lg |\Sigma| + \lg n_k - \lg(n_k/2)) + O(n_k/\lg \lg n_k) = n((1/2) \lg |\Sigma| + 3/2^{k+1}) + O(n/2^k \lg \lg n)$ \square

By replacing the space complexity of Ψ_k in formula (1) at the end of section 3.1, we obtain

$$\begin{aligned} & \frac{n \lg n}{2^\ell} + \sum_{k=0}^{\ell-1} n \left(\frac{1}{2^k} + O\left(\frac{1}{2^k} \frac{\lg \lg(n/2^k)}{\lg(n/2^k)}\right) + \frac{\lg |\Sigma|}{2} + \frac{3}{2^{k+1}} + O\left(\frac{1}{2^k \lg \lg n}\right) \right) \\ & < \left(1 + \frac{1}{2} \lg \lg_{|\Sigma|} n\right) n \lg |\Sigma| + 5n + O\left(\frac{n}{\lg \lg n}\right), \end{aligned}$$

as $(n \lg n)/2^\ell + \frac{1}{2} \ell n \leq (1 + \frac{1}{2} \lg \lg_{|\Sigma|} n) n \lg |\Sigma|$, thus proving Theorem 2(i).

To prove Theorem 2(ii), we follow the approach of section 3.2. We need dictionaries D_k and functions Φ_k for $k \in \{0, \epsilon\ell, 2\epsilon\ell, 3\epsilon\ell, \dots, (1 - \epsilon)\ell\}$. Their definitions and representations do not change, except for the representation of Φ_k , for which we need Lemma 6 (the analogue of Lemma 4).

LEMMA 6. *We can store the concatenated lists used for Φ_k in $n(\lg |\Sigma| + 1/2^{k-1}) + O(n/2^k \lg \lg n)$ bits, so that accessing the h th entry takes constant time. Preprocessing time is $O(n/2^k + 2^{2^k})$. When $|\Sigma| = O(1)$ and $k = 0$, we can store Φ_k in $n \lg |\Sigma| + O(|\Sigma|n/\lg \lg n) = n \lg |\Sigma| + o(n)$ bits.*

Proof. The proof is identical to that of Lemma 5, except that $s = n_k$ instead of $s = n_k/2$. When $|\Sigma| = O(1)$, we can use a better approach for $k = 0$ as in the proof of Lemma 4. We associate $\lg |\Sigma|$ bits with each character in Σ according to its lexicographic order. Then we use a bit vector of $n \lg |\Sigma|$ bits to represent Φ_0 , in which the f th chunk of $\lg |\Sigma|$ bits encoding a character $c \in \Sigma$ represents the fact that the

c list for Φ_0 contains position f . We then implement $|\Sigma| = O(1)$ versions of *select*, one version per character of Σ . The version for $c \in \Sigma$ is in charge of selecting the i th occurrence of c encoded in binary in the bit vector. To this end, it treats each occurrence of the $\lg |\Sigma|$ bits for c in the bit vector as a single $\mathbf{1}$ and the occurrences of the rest of the characters as single $\mathbf{0}$'s. It should be clear that the implementation of each version of *select* can be done in $O(n/\lg \lg n)$ bits. To execute $\Phi_0(h)$ in constant time, we proceed as in Lemma 4, generalized to more than two characters. \square

By an analysis similar to the one we used in formula (2) at the end of section 3.2, we obtain

$$\begin{aligned} \frac{n \lg n}{2^\ell} + \sum_{\substack{k=i\epsilon\ell \\ 0 \leq i < \epsilon^{-1}}} n \left(\lg |\Sigma| + \frac{1}{2^{k-1}} + O\left(\frac{1}{2^k \lg \lg n}\right) \right) \\ \leq (1 + \epsilon^{-1}) n \lg |\Sigma| + 2n + O\left(\frac{n}{\lg \lg n}\right). \end{aligned}$$

When $|\Sigma| = O(1)$, we can split the above sum for $k = 0$ and apply Lemma 6 to get $(1 + \epsilon^{-1}) n \lg |\Sigma| + O(n/\lg \lg n)$ bits, thus proving Theorem 2(ii).

3.4. Output-sensitive reporting of multiple occurrences. In this section we prove Theorem 3 by showing how to output a contiguous set $SA_0[i], \dots, SA_0[j]$ of entries from the compressed suffix array under the hypothesis that the sequence $i, i + 1, \dots, j$ is maximal (according to the definition given before Theorem 3) and the corresponding suffixes share at least a certain number of initial symbols. This requires adding further $O(n \lg |\Sigma|)$ bits of space to the compressed suffix array. One way to output the $j - i + 1$ entries is via a reduction to two-dimensional orthogonal range search [46]. Let D be a two-dimensional orthogonal range query data structure on q points in the grid space $[1 \dots U] \times [1 \dots U]$, where $1 \leq q \leq U$. Let $P(q)$ be its preprocessing time, $S(q)$ the number of occupied words of $O(\lg U)$ bits each, and $T(q) + O(k)$ the cost of searching and retrieving the k points satisfying a given range query in D .

LEMMA 7. Fix $U = n$ in the range query data structure D , and let $n' \geq 1$ be the largest integer such that $S(n') = O(n/\lg n)$. If such an n' exists, we can report $SA[i], \dots, SA[j]$ in $O(\lg_{|\Sigma|}^{1+\epsilon} n + (n/n')(T(n') + \lg |\Sigma|) + j - i)$ time when the sequence $i, i + 1, \dots, j$ is maximal and the suffixes pointed to by $SA[i], \dots, SA[j]$ have the same first $\Omega(n/n')$ symbols in common. Preprocessing time is $P(n') + O(n \lg |\Sigma|)$ and space is $O(n \lg |\Sigma|)$ bits in addition to that of the compressed version of SA .

Proof. Suppose by hypothesis that the suffixes pointed to by $SA[i], \dots, SA[j]$ have in common at least $l = \lceil n/n' \rceil$ symbols. (This requirement can be further reduced to $l = \Theta(n/n')$.) We denote these symbols by b_0, b_1, \dots, b_{l-1} , from left to right.

In order to define the two-dimensional points in D , we need to build the compressed version of the suffix array SA^R for the reversal of the text, denoted T^R . Then we obtain the points to keep in D by processing the suffix pointers in SA that are multiples of l (i.e., they refer to the suffixes in T starting at positions $l, 2l, 3l, \dots$). Specifically, the point corresponding to pointer $p = SA[s]$, where $1 \leq s \leq n$ and p is a multiple of l , has first coordinate s . Its second coordinate is given by the position r of $(T[1, p - 1])^R$ in the sorted order induced by SA^R . In other words, s is the rank of $T[p, n]$ among the suffixes of T in lexicographic order, and r is the rank of $(T[1, p - 1])^R$ among the suffixes of T^R (or, equivalently, the reversed prefixes of T). Point $\langle s, r \rangle$ corresponding to p has label p to keep track of this correspondence.

Since there are $q \leq n'$ such points stored in D and we build the compressed suffix array of T^R according to Theorem 2(ii), space is $S(n') \cdot O(\lg n) + (\epsilon^{-1} + O(1)) n \lg |\Sigma| = O(n \lg |\Sigma|)$ bits. Preprocessing time is $P(n') + O(n \lg |\Sigma|)$.

We now describe how to query D and output $SA[i], \dots, SA[j]$ in l stages, with one range query per stage. In stage 0, we perform a range query for the points in $[i \dots j] \times [1 \dots n]$. For these points, we output the suffix pointers labeling them. Then we locate the leftmost suffix and the rightmost suffix in SA^R starting with $b_{l-1} \dots b_1 b_0$. For this purpose, we run a simple binary search in the compressed version of SA^R , comparing at most $\lg n$ bits at a time. As a result, we determine two positions g and h of SA^R in $O(l \lg |\Sigma| + \lg_{|\Sigma|}^{1+\epsilon} n)$ time such that the sequence $g, g + 1, \dots, h$ is maximal for SA^R and the suffixes of T^R pointed to by $SA^R[g], \dots, SA^R[h]$ start with $b_{l-1} \dots b_1 b_0$.

Before proceeding with the next stages, we precompute some sequences of indices starting from i, j, g , and h , respectively, as done in section 3.2. We use the function Φ_0 in the compressed version of $SA = SA_0$ to walk along indices i_0, i_1, \dots, i_{l-1} , such that $i_0 = i, SA_0[i_0] + 1 = SA_0[i_1], SA_0[i_1] + 1 = SA_0[i_2]$, and so on. An analogous walk applies to $j_0 = j, j_1, \dots, j_{l-1}$. In the same way, we use the function Φ_0 in the compressed version of SA^R to obtain $g_0 = g, g_1, \dots, g_{l-1}$ and $h_0 = h, h_1, \dots, h_{l-1}$. We then run the t th stage, for $1 \leq t \leq l - 1$, in which we perform a range query for the points in $[i_t \dots j_t] \times [g_{l-t} \dots h_{l-t}]$. For each of these points, we retrieve its label p and output $p - t$.

In order to see why the above method works, let us consider an arbitrary suffix pointer in $SA[i], \dots, SA[j]$. By the definition of the points kept in D , this suffix pointer can be written as $p - t$, where p is the nearest multiple of l and $0 \leq t \leq l - 1$. We show that we output $p - t$ correctly in stage t . Let $\langle s, r \rangle$ be the point with label p in D . We have to show that $i_t \leq s \leq j_t$ and $g_{l-t} \leq r \leq h_{l-t}$ (setting border values $g_l = 1$ and $h_l = n$). Recall that the suffixes pointed to by $SA[i], p - t$ and $SA[j]$ are in lexicographic order by definition of the (compressed) suffix array and, moreover, they share the first l symbols. If we remove the first $t < l$ symbols from each of them, the lexicographic order must be preserved because these symbols are equal. Consequently, $SA[i] - t, p$, and $SA[j] - t$ are still in lexicographic order, and their ranks are i_h, s , and j_h , respectively. This implies $i_t \leq s \leq j_t$. A similar property holds for $g_{l-t} \leq r \leq h_{l-t}$, and we can conclude that p is retrieved in stage t giving $p - t$ as output. Finally, the fact that both $i, i + 1, \dots, j$ and $g, g + 1, \dots, h$ are maximal sequences in their respective suffix arrays implies that no other suffix pointers besides those in $SA[i], \dots, SA[j]$ are reported.

The cost of each stage is $T(n')$ plus the output-sensitive cost of the reported suffix pointers. Stage 0 requires an additional cost of $O((n/n') \lg |\Sigma| + \lg^{1+\epsilon} n)$ to compute g and h , and a cost of $O(n/n')$ to precompute the four sequences of indices, because the length of the walks is l . The total time complexity is therefore $O((n/n')(T(n') + \lg |\Sigma|) + \lg^{1+\epsilon} n + j - i)$, where $O(j - i + 1)$ is the sum of the output-sensitive costs for reporting all the suffix pointers. \square

We use Lemma 7 to prove Theorem 3. We employ two range query data structures for D . The first one in [1] takes $P(q) = O(q \lg q)$ preprocessing time by using the perfect hash in [39], which has constant lookup time and takes $O(q \lg q)$ construction time. Space is $S(q) = O(q \lg^\epsilon q)$ words and query time is $T(q) = O(\lg \lg q)$. Plugging these bounds into Lemma 7 gives $n' = \Theta(n / \lg^{1+\epsilon} n)$, and hence $O((\lg^{1+\epsilon} n)(\lg |\Sigma| + \lg \lg n) + j - i)$ retrieval time for suffix pointers sharing $\Omega(\lg^{1+\epsilon} n)$ symbols. Preprocessing time is $O(n \lg |\Sigma|)$ and additional space is $O(n \lg |\Sigma|)$ bits.

The second data structure in [9, 69] has preprocessing time $P(q) = O(q \lg q)$, space $S(q) = O(q)$, and query time $T(q) = O(q^\beta)$ for any fixed value of $0 < \beta < 1$. Consequently, Lemma 7 gives $n' = \Theta(n/\lg n)$ and $O(n^\beta \lg n + j - i) = O(n^\alpha + j - i)$ retrieval time for suffix pointers sharing at least $\Omega(\lg n)$ symbols (by choosing $\alpha > \beta$). Preprocessing time is $O(n \lg |\Sigma|)$ and additional space is $O(n \lg |\Sigma|)$ bits.

4. Text indexing, string searching, and compressed suffix trees. We now describe how to apply our compressed suffix array to obtain a text index, called a *compressed suffix tree*, which is very efficient in time and space complexity. We first show that, despite their extra functionality, compressed suffix trees (and compressed suffix arrays) require the same asymptotic space of $\Theta(n)$ bits as inverted lists in the worst case. Nevertheless, inverted lists are space efficient in practice [72] and can be easily maintained in a dynamic setting.

LEMMA 8. *In the worst case, inverted lists require $\Theta(n)$ bits for a binary text of length n .*

Proof. Let us take a De Bruijn sequence S of length n , in which each substring of $\lg n$ bits is different from the others. Now let the terms in the inverted lists be those obtained by partitioning S into $s = n/k$ disjoint substrings of length $k = 2 \lg n$. Any data structure that implements inverted lists must be able to solve the static dictionary problem on the s terms, and so it requires at least $\lg \binom{2^k}{s} = \Omega(n)$ bits by a simple information-theoretic argument. The upper bound $O(n)$ follows from Theorem 1, and Theorem 4 below, since we can see compressed suffix arrays and suffix trees as generalizations of inverted lists. \square

We now describe our main result on text indexing for constant size alphabets. Here, we are given a pattern string P of m symbols over the alphabet Σ , and we are interested in its occurrences (perhaps overlapping) in a text string T of n symbols (where $\#$ is the n th symbol). We assume that each symbol in Σ is encoded by $\lg |\Sigma|$ bits, which is the case with ASCII and UNICODE text files when two or more symbols are packed in each word.

THEOREM 4. *Given a text string T of length n over an alphabet Σ of constant size, we can build a full text index on T in $O(n \lg |\Sigma|)$ time such that the index occupies $(\epsilon^{-1} + O(1)) n \lg |\Sigma|$ bits, for any fixed value of $0 < \epsilon \leq 1$, and supports the following queries on any pattern string P of m symbols packed into $O(m/\lg_{|\Sigma|} n)$ words:*

(i) *Existential and counting queries can be done in $o(\min\{m \lg |\Sigma|, m + \lg n\})$ time; in particular, they take $O(1)$ time for $m = o(\lg n)$, and $O(m/\lg_{|\Sigma|} n + \lg_{|\Sigma|}^\epsilon n)$ time otherwise.*

(ii) *An enumerative query listing the occ occurrences of P in T can be done in $O(m/\lg_{|\Sigma|} n + occ \lg_{|\Sigma|} n)$ time. We can use auxiliary data structures in $O(n \lg |\Sigma|)$ bits to reduce the search bound to $O(m/\lg_{|\Sigma|} n + occ + (\lg^{1+\epsilon} n)(\lg |\Sigma| + \lg \lg n))$ time, when either $m = \Omega(\lg^{1+\epsilon} n)$ or $occ = \Omega(n^\epsilon)$.*

As a result, an enumerative query can be done in optimal $\Theta(m/\lg_{|\Sigma|} n + occ)$ time for sufficiently large patterns or number of occurrences, namely, when $m = \Omega((\lg^{2+\epsilon} n) \lg_{|\Sigma|} \lg n)$ or $occ = \Omega(n^\epsilon)$.

In order to prove Theorem 4, we first show how to speed up the search on compacted tries in section 4.1. Then we present the index construction in section 4.2. Finally, we give the description of the search algorithm in section 4.3. Let's briefly review three important data structures presented in [45, 59, 62] and that are needed later on.

The first data structure is the Lempel-Ziv (LZ) index [45]. It is a powerful tool

in searching for q -grams (substrings of length q) in T . If we fix $q = \epsilon \lg n$ for any fixed positive constant $\epsilon < 1$, we can build an LZ index on T in $O(n)$ time such that the LZ index occupies $O(n)$ bits and any pattern of length $m \leq \epsilon \lg n$ can be searched in $O(m + occ)$ time. In this special case, we can actually obtain $O(1 + occ)$ time by a suitable table lookup. (Unfortunately, for longer patterns, the LZ index may take $\Omega(n \lg n)$ bits.) The LZ index allows us to concentrate on patterns of length $m > \epsilon \lg n$.

The second data structure is the Patricia trie [59], another powerful tool in text indexing. It is a binary tree that stores a set of distinct binary strings, in which each internal node has two children and each leaf stores a string. For our purposes, we can generalize it to handle alphabets of size $|\Sigma| \geq 2$ by using a $|\Sigma|$ -way tree. Each internal node also keeps an integer (called a skip value) to locate the position of the branching character while descending toward a leaf. Each child arc is implicitly labeled with one symbol of the alphabet. For space efficiency, when there are $t > 2$ child arcs, we can represent the child arcs by a hash table of $O(t)$ entries. In particular, we use a perfect hash function (e.g., see [31, 39]) on keys from Σ , which provides constant lookup time and uses $O(t)$ words of space and $O(t \lg t)$ construction time, in the worst case.

Suffix trees are often implemented by building a Patricia trie on the suffixes of T as follows [35]: First, text T is encoded as a binary sequence of $n \lg |\Sigma|$ bits, and its n suffixes are encoded analogously. Second, a Patricia trie is built upon these suffixes; the resulting suffix tree still has n leaves (not $n \lg |\Sigma|$). Third, searching for P takes $O(m)$ time and retrieves only the suffix pointer in at most two leaves (i.e., the leaf reached by branching with the skip values, and the leaf corresponding to an occurrence). According to our terminology, it requires only $O(1)$ calls to the *lookup* operation in the worst case.

The third data structure is the space-efficient incarnation of binary Patricia tries in [62], which builds upon previous work to succinctly represent binary trees and Patricia tries [16, 42, 60, 61]. When employed to store s out of the n suffixes of T , the regular Patricia trie [59] occupies $O(s \lg n)$ bits. This amount of space usage is the result of three separate factors [15, 16], namely, the Patricia trie topology, the skip values, and the string pointers. Because of our compressed suffix arrays, the string pointers are no longer a problem. For the remaining two items, the space-efficient incarnation of Patricia tries in [62] cleverly avoids the overhead for the Patricia trie topology and the skip values. It is able to represent a Patricia trie storing s suffixes of T with only $O(s)$ bits, *provided that a suffix array is given separately* (which in our case is a compressed suffix array). Searching for query pattern P takes $O(m \lg |\Sigma|)$ time and accesses $O(\min\{m \lg |\Sigma|, s\}) = O(s)$ suffix pointers in the worst case. For each traversed node, its corresponding skip value is computed in time $O(\text{skip_value})$ by accessing the suffix pointers in its leftmost and rightmost descendant leaves. In our terminology, searching requires $O(s)$ calls to *lookup* in the worst case.

4.1. Speeding up Patricia trie search. Before we discuss how to construct the index, we first need to show that search in Patricia tries, which normally proceeds one level at a time, can be improved to sublinear time by processing $\lg n$ bits of the pattern at a time (maybe less if the pattern length is not a multiple of $\lg n$).

Let us first consider the $|\Sigma|$ -way Patricia trie PT outlined in section 4 for storing s binary strings, each of length at least $\lg n$. (For example, they could be some suffixes of the text.) To handle border situations, we assume that these strings are (implicitly) padded with $\lg_{|\Sigma|} n$ symbols $\#$. We will show how to reduce the search time for an m -symbol pattern in PT from $O(m \lg |\Sigma|)$ to $O(m / \lg_{|\Sigma|} n + \lg_{|\Sigma|}^{\epsilon} n)$. Without loss of

generality, it suffices to show how to achieve $O(m/\lg_{|\Sigma|} n + \sqrt{\lg_{|\Sigma|} n})$ time, since this bound extends from $1/2$ to any exponent $\epsilon > 0$. The point is that, in the worst case, we may have to traverse $\Theta(m)$ nodes, so we need a tool to skip most of these nodes. Ideally, we would like to branch downward, matching $\lg n$ bits (or equivalently, $\lg_{|\Sigma|} n$ symbols) in constant time, independently of the number of traversed nodes. For that purpose, we use a perfect hash function h (e.g., see [31]) on keys each of length at most $2 \lg n$ bits. In particular, we use the perfect hash function in [39], which has constant lookup time and takes $O(k)$ words of space and $O(k \lg k)$ construction time on k keys, in the worst case.

First of all, we enumerate the nodes of PT in preorder starting from the root, with number 1. Second, we build hash tables to mimic a downward traversal from a given node i , which is the starting point for searching strings x of length less than or equal to $\lg_{|\Sigma|} n$ symbols. Suppose that, in this traversal, we successfully match all the symbols in x and we reach node j (a descendent of i). In general, there can be further symbols to be added to equal the skip value in j ; let $b \geq 0$ be this number of symbols. We represent the successful traversal in a single entry of the hash table. Namely, we store pair $\langle j, b \rangle$ at position $h(i, x)$, where the two arguments i and x can be seen as a single key of at most $2 \lg n$ bits. Formally, the relation between these parameters must satisfy the following two conditions in the case of a successful search of x from node i :

1. Node j is the node identified by starting out from node i and traversing downward toward the nodes of PT according to the symbols in x ;
2. b is the unique nonnegative integer such that the string corresponding to the path from i to j has prefix x and length $|x| + b$; this condition does not hold for any proper ancestor of j .

The rationale behind conditions 1–2 is that of defining shortcut links from certain nodes i to their descendents j so that each successful branching takes constant time, matches $|x|$ symbols (with b further symbols to check), and skips no more than $|x|$ nodes downward. If the search is unsuccessful, we do not hash any pair.

The key mechanism that makes the above scheme efficient is that we adaptively follow the trie topology of Patricia so that the strings that we hash are not all possible substrings of $\lg_{|\Sigma|} n$ (or $\sqrt{\lg_{|\Sigma|} n}$) symbols, but only a subset of those that start at the distinct nodes in the Patricia trie. Using an uncompact trie would make this method inefficient. To see why, let us examine a Patricia edge corresponding to a substring of length l . We hash only its first $\lg_{|\Sigma|} n$ (or $\sqrt{\lg_{|\Sigma|} n}$) symbols because the rest of the symbols are uniquely identified (and we can skip them). Using an uncompact trie would force us to traverse further $b = l - \lg_{|\Sigma|} n$ (or $b = l - \sqrt{\lg_{|\Sigma|} n}$) nodes.

In order to keep small the number of shortcut links, we set up two hash tables H_1 and H_2 . The first table stores entries

$$H_1[h(i, x)] = \langle j, b \rangle$$

such that all strings x consist of $|x| = \lg_{|\Sigma|} n$ symbols, and the shortcut links stored in H_1 are selected adaptively by a top-down traversal of PT . Namely, we create all possible shortcut links from the root. This step links the root to a set of descendents. We recursively link each of these nodes to its descendents in the same fashion. Note that PT is partitioned into subtrees of depth at most $\lg_{|\Sigma|} n$.

We set up the second table H_2 analogously. We examine each individual subtree and start from the root of the subtree by using strings of length $|x| = \sqrt{\lg_{|\Sigma|} n}$ symbols. Note that the total number of entries in H_1 and H_2 is bounded by the number of nodes in PT , namely, $O(s)$.

In summary, the preprocessing consists of a double traversal of PT followed by the construction of H_1 and H_2 , in $O(s \lg s + n)$ worst-case time and $O(s)$ words of space. In the general case, we go on recursively and build ϵ^{-1} hash tables, whose total number of entries is still $O(s)$. The preprocessing time does not change asymptotically.

We are now ready to describe the search of a pattern (encoded in binary) in the Patricia trie PT thus augmented. It suffices to show how to match its longest prefix. We compute hash function $h(i, x)$ with i being the root of PT and x being the concatenation of the first $\lg_{|\Sigma|} n$ symbols in the pattern. Then we branch quickly from the root by using $H_1[h(i, x)]$. If the hash lookup in H_1 succeeds and gives pair $\langle j, b \rangle$, we skip the next b symbols in the pattern and recursively search in node j with the next $\lg_{|\Sigma|} n$ symbols in the pattern (read in $O(1)$ time). Instead, if the hash lookup fails (i.e., no pair is found or fewer than $\lg_{|\Sigma|} n$ symbols are left in the pattern), we switch to H_2 and take only the next $\sqrt{\lg_{|\Sigma|} n}$ symbols in the pattern to branch further in PT . Here the scheme is the same as that of H_1 , except that we compare $\sqrt{\lg_{|\Sigma|} n}$ symbols at a time. Finally, when we fail branching again, we have to match no more than $\sqrt{\lg_{|\Sigma|} n}$ symbols remaining in the pattern. We complete this task by branching in the standard way, one symbol a time. The rest of the search is identical to the standard procedure of Patricia tries. This completes the description of the search in PT .

LEMMA 9. *Given a Patricia trie PT storing s strings of at least $\lg_{|\Sigma|} n$ symbols each over the alphabet Σ , we can preprocess PT in $O(s \lg s + n)$ time so that searching a pattern of length m requires $O(m/\lg_{|\Sigma|} n + \lg_{|\Sigma|}^\epsilon n)$ time.*

Note that a better search bound in Lemma 9 does not improve the final search time obtained in Theorem 4.

Finally, let us consider a space-efficient Patricia trie [62]. The speedup we need while searching is easier to obtain. We need not skip nodes, but need only compare $\Theta(\lg n)$ bits at a time in constant time by precomputing a suitable table. The search cost is therefore $O(m/\lg_{|\Sigma|} n)$ plus a linear cost proportional to the number of traversed nodes.

A general property of our speedup of Patricia tries is that we do not increase the original number of *lookup* calls originating from the data structures.

4.2. Index construction. We blend the tools mentioned so far with our compressed suffix arrays of section 3 to design a hybrid index data structure, called the *compressed suffix tree*, which follows the multilevel scheme adopted in [17, 62]. Because of the LZ index, it suffices to describe how to support searching of patterns of length $m > \epsilon \lg n$. We assume that $0 < \epsilon \leq 1/2$, as the case $1/2 < \epsilon \leq 1$ requires minor modifications.

Given text T in input, we build its suffix array SA in a temporary area, in $O(n \lg |\Sigma|)$ time via the suffix tree of T . At this point, we start building the $O(\epsilon^{-1})$ levels of the compressed suffix tree in top-down order, after which we remove SA as follows:

1. At the first level, we build a regular Patricia trie PT^1 augmented with the shortcut links as mentioned in Lemma 9. The leaves of PT^1 store the $s_1 = n/\lg_{|\Sigma|} n$ suffixes pointed to by $SA[1]$, $SA[1 + \lg_{|\Sigma|} n]$, $SA[1 + 2\lg_{|\Sigma|} n]$, \dots . This implicitly splits SA into s_1 subarrays of size $\lg_{|\Sigma|} n$, except the last one (which can be smaller).

Complexity. The size of PT^1 is $O(s_1 \lg n) = O(n \lg |\Sigma|)$ bits. It can be built in $O(n \lg |\Sigma|)$ time by a variation of the standard suffix tree construction [51, 52] and the preprocessing described in Lemma 9.

2. At the second level, we process the s_1 subarrays from the first level, and create

s_1 space-efficient Patricia tries [62], denoted $PT_1^2, PT_2^2, \dots, PT_{s_1}^2$. We associate the i th Patricia PT_i^2 with the i th subarray. Assume without loss of generality that the subarray consists of $SA[h+1], SA[h+2], \dots, SA[h+\lg_{|\Sigma|} n]$ for a value of $0 \leq h \leq n - \lg_{|\Sigma|} n$. We build PT_i^2 upon the $s_2 = \lg_{|\Sigma|}^{\epsilon/2} n$ suffixes pointed to by $SA[h+1], SA[h+1+\lg_{|\Sigma|}^{1-\epsilon/2} n], SA[h+1+2\lg_{|\Sigma|}^{1-\epsilon/2} n], \dots$. This process splits each subarray into smaller subarrays, where each subarray is of size $\lg_{|\Sigma|}^{1-\epsilon/2} n$.

Complexity. The size of each PT_i^2 is $O(s_2)$ bits without accounting for the suffix array, and its construction takes $O(s_2)$ time [62]. Hence, the total size is $O(s_1 s_2) = O(n/\lg_{|\Sigma|}^{1-\epsilon} n)$ bits and the total processing time is $O(n \lg |\Sigma|)$.

3. In the remaining $2\epsilon^{-1} - 2$ intermediate levels, we proceed as in the second level. Each new level splits every subarray into $s_2 = \lg_{|\Sigma|}^{\epsilon/2} n$ smaller subarrays and creates a set of space-efficient Patricia tries of size $O(s_2)$ each. We stop when we are left with small subarrays of size at most s_2 . We build space-efficient Patricia tries on all the remaining entries of these small subarrays.

Complexity. For each new level thus created, the total size is $O(n/\lg_{|\Sigma|}^{\epsilon} n)$ bits and the total processing time is $O(n \lg |\Sigma|)$.

4. At the last level, we execute *compress* on the suffix array SA , store its compressed version in the level, and delete SA from the temporary area.

Complexity. By Theorem 2, the total size is $(\epsilon^{-1} + O(1))n \lg |\Sigma|$ bits; accessing a pointer through a call to *lookup* takes $O(\lg_{|\Sigma|}^{\epsilon/2} n)$ time; the cost of *compress* is $O(n \lg |\Sigma|)$ time. (Note that we can fix the value of ϵ arbitrarily when executing *compress*.)

By summing over the levels, we obtain that the compressed suffix tree of T takes $O(n \lg |\Sigma|)$ bits and $O(n \lg |\Sigma|)$ construction time. Temporary storage is $O(n \lg n)$ bits.

4.3. Search algorithm. We now have to show that searching for an arbitrary pattern P in the text T costs $O(m/\lg_{|\Sigma|} n + \lg_{|\Sigma|}^{\epsilon} n)$ time. The search locates the leftmost occurrence and the rightmost occurrence of P as a prefix of the suffixes represented in SA , without having SA stored explicitly. Consequently, a successful search determines two positions $i \leq j$ such that the sequence $i, i+1, \dots, j$ is maximal (according to the definition given before Theorem 3) and $SA[i], SA[i+1], \dots, SA[j]$ contain the pointers to the suffixes that begin with P . The counting query returns $j-i+1$, and the existence checks whether there are any matches at all. The enumerative query executes the $j-i+1$ queries $lookup(i), lookup(i+1), \dots, lookup(j)$ to list all the occurrences.

We restrict our discussion to finding the leftmost occurrence of P ; finding the rightmost is analogous. We search at each level of the compressed suffix tree in section 4.2. We examine the levels in a top-down manner. While searching in the levels, we execute $lookup(i)$ whenever we need the i th pointer of the compressed SA . We begin by searching P at the first level. We perform the search on PT^1 in the bounds stated in Lemma 9. As a result of the first search, we locate a subarray at the second level, say, the i_1 th subarray. We go on and search in $PT_{i_1}^2$ according to the method for space-efficient Patricia tries described at the end of section 4.1. We repeat the latter search for all the intermediate levels. We eventually identify a position at the last level, namely, the level which contains the compressed suffix array. This position corresponds to the leftmost occurrence of P in SA .

The complexity of the search procedure is $O(m/\lg_{|\Sigma|} n + \lg_{|\Sigma|}^{\epsilon} n)$ time at the first level by Lemma 9. The intermediate levels cost $O(m/\lg_{|\Sigma|} n + s_2)$ time each, giving a total of $O(m/\lg_{|\Sigma|} n + \lg_{|\Sigma|}^{\epsilon} n)$. We have to account for the cost of the *lookup*

operations. These calls originated from the several levels. In the first level, we call *lookup* $O(1)$ times; in the $2\epsilon^{-1} - 1$ intermediate levels we call *lookup* $O(s_2)$ times each. Multiplying these calls by the $O(\lg_{|\Sigma|}^{\epsilon/2} n)$ cost of *lookup* as given in Theorem 1 (using $\epsilon/2$ in place of ϵ), we obtain $O(\lg_{|\Sigma|}^{\epsilon} n)$ time in addition to $O(m/\lg_{|\Sigma|} n + \lg_{|\Sigma|}^{\epsilon} n)$. Finally, the cost of retrieving all the occurrences is the one stated in Theorem 3, whose hypothesis is satisfied because the suffixes pointed to by $SA[i]$ and $SA[j]$ are, respectively, the leftmost and rightmost sharing $m = \Omega(\lg n)$ symbols. Combining this cost with the $O(\lg_{|\Sigma|}^{\epsilon} n)$ cost for retrieving any single pointer in Theorem 1, we obtain $O(m/\lg_{|\Sigma|} n + occ \lg_{|\Sigma|}^{\epsilon} n)$ time when both conditions $m \in [\epsilon \lg n, o(\lg^{1+\epsilon} n)]$ and $occ = o(n^{\epsilon})$ hold, and in $O(m/\lg_{|\Sigma|} n + occ + (\lg^{1+\epsilon} n)(\lg |\Sigma| + \lg \lg n))$ time otherwise. This argument completes the proof of Theorem 4 on the complexity of our text index.

5. Conclusions. We have presented the first indexing data structure for a text T of n symbols over alphabet Σ that achieves, in the worst case, efficient lookup time and linear space. For many scenarios, the space requirement is actually sublinear in practice. Specifically, our algorithm uses $o(\min\{m \lg |\Sigma|, m + \lg n\})$ search time and $(\epsilon^{-1} + O(1)) n \lg |\Sigma|$ bits of space (where T requires $n \lg |\Sigma|$ bits). Our method is based upon notions of compressed suffix arrays and suffix trees. Given any pattern P of m symbols encoded in $m \lg |\Sigma|$ bits, we can count the number of occurrences of P in T in $o(\min\{m \lg |\Sigma|, m + \lg n\})$ time. Namely, searching takes $O(1)$ time when $m = o(\lg n)$, and $O(m/\lg_{|\Sigma|} n + \lg_{|\Sigma|}^{\epsilon} n)$ time otherwise. We achieve optimal $O(m/\lg_{|\Sigma|} n)$ search time for sufficiently large $m = \Omega(\lg_{|\Sigma|}^{1+\epsilon} n)$. For an enumerative query retrieving all occ occurrences with sufficiently long patterns, namely, $m = \Omega((\lg^{2+\epsilon} n) \lg_{|\Sigma|} \lg n)$, we obtain a total search bound of $O(m/\lg_{|\Sigma|} n + occ)$, which is optimal. Namely, searching takes $O(m/\lg_{|\Sigma|} n + occ \lg_{|\Sigma|}^{\epsilon} n)$ time when both conditions $m \in [\epsilon \lg n, o(\lg^{1+\epsilon} n)]$ and $occ = o(n^{\epsilon})$ hold, and $O(m/\lg_{|\Sigma|} n + occ + (\lg^{1+\epsilon} n)(\lg |\Sigma| + \lg \lg n))$ time otherwise. Crucial to our results are functions Ψ_k and Φ_k (see section 2), which are the building blocks of many other results in compressed text indexing.

An interesting open problem is to improve upon our $O(n)$ -bit compressed suffix array so that each call to *lookup* takes constant time. Such an improvement would decrease the output-sensitive time of the enumerative queries to $O(occ)$ also when $m \in [\epsilon \lg n, o(\lg^{1+\epsilon} n)]$ and $occ = o(n^{\epsilon})$. Another possibility for that is to devise a range query data structure that improves the data structures at the end of section 3.4. This, in turn, would improve Theorems 3 and 4. A related question is to characterize combinatorially the permutations that correspond to suffix arrays. A better understanding of the correspondence may lead to more efficient compression methods. Additional open problems are listed in [62]. The kinds of queries examined in this paper are very basic and involve exact occurrences of the pattern strings. They are often used as preliminary filters so that more sophisticated queries can be performed on a smaller amount of text. An interesting extension would be to support some sophisticated queries directly, such as those that tolerate a small number of errors in the pattern match [4, 12, 35, 70].

RECOGNIZING MORE UNSATISFIABLE RANDOM k -SAT INSTANCES EFFICIENTLY*

JOEL FRIEDMAN[†], ANDREAS GOERDT[‡], AND MICHAEL KRIVELEVICH[§]

Abstract. It is known that random k -SAT instances with at least cn clauses, where $c = c_k$ is a suitable constant, are unsatisfiable (with high probability). We consider the problem to certify efficiently the unsatisfiability of such formulas. A backtracking-based algorithm of Beame et al. [*SIAM J. Comput.*, 31 (2002), pp. 1048–1075] shows that k -SAT instances with at least $n^{k-1}/(\log n)^{k-2}$ clauses can be certified unsatisfiable in polynomial time. We employ spectral methods to improve on this bound. For even $k \geq 4$ we present a polynomial time algorithm which certifies random k -SAT instances with at least $n^{(k/2)+o(1)}$ clauses as unsatisfiable (with high probability). For odd k we focus on 3-SAT instances and obtain an efficient algorithm for formulas with at least $n^{3/2+\varepsilon}$ clauses, where $\varepsilon > 0$ is an arbitrary constant.

Key words. random structures, random satisfiability, spectral methods

Introduction. We study the complexity of certifying unsatisfiability of random k -SAT instances (or k -CNF formulas) over n propositional variables. Our discussion refers to k fixed and then letting n be sufficiently large. The probability space of random k -SAT instances has been widely studied in recent years for several good reasons. A somewhat arbitrary selection of the most recent literature is [Ac2000], [Fr99], [Be et al2002], [AcSo2000], [AcMo2002], [AcPe2004].

One of the reasons for studying random k -SAT instances is that they have the following sharp threshold behavior [Fr99]: there exists a function $c = c_k(n)$ such that for any $\varepsilon > 0$, formulas with at most $(1 - \varepsilon) \cdot c \cdot n$ clauses are satisfiable, whereas formulas with at least $(1 + \varepsilon) \cdot c \cdot n$ are unsatisfiable with high probability (that means with probability tending to 1 when n goes to infinity). In fact, it is not known if $c_k(n)$ can be taken to be a constant (i.e., if the limit of $c_k(n)$ as $n \rightarrow \infty$ exists). It might be that $c_k = c_k(n)$ satisfying the aforementioned threshold property depends on n . However, it is known that c_k is at most $2^k \cdot \ln 2$, and the general conjecture is that c_k converges to a constant. For formulas with at least $2^k \cdot (\ln 2) \cdot n$ clauses the expected number of satisfying assignments of a random formula tends to 0 and the formulas are unsatisfiable with high probability. As it is well known that the satisfiability problem for random 2-SAT instances is solvable in polynomial time, the most interesting case is that of 3-SAT. Accordingly, much work is spent to approximate the value of c_3 . Currently, the best results are that c_3 is at least 3.26 [AcSo2000] improved to the recent 3.52 [KaKiLa2002] and at most 4.601 [KiKrKr98]

improved to 4.506 [DuBoMa2000]. For $k = 2$ the threshold is known; we have $c_2 = 1$ [ChRe92], [Go96].

The algorithmic interest in this threshold is due to the empirical observation that random k -SAT instances at the threshold, i.e., with around $c_k n$ random clauses, are seemingly hard instances. The following behavior has been reported consistently in experimental studies with suitably optimized backtracking algorithms searching for a satisfying assignment (see, for example, [SeMiLe96], [CrAu96]): the average running time is quite low for instances below the threshold. For 3-SAT instances we observe that almost all formulas with at most $4n$ clauses are satisfiable and it is quite easy to find a satisfying assignment. A precipitous increase in the average running time is observed at the threshold. For 3-SAT, about half of the formulas with $4.2n$ clauses are satisfiable and it is difficult to decide whether a formula is satisfiable or not. Finally, a speedy decline to lower complexity is observed beyond the threshold. For 3-SAT, almost all formulas with $4.5n$ clauses are unsatisfiable and the running time decreases again (in spite of the fact that now the whole backtracking tree must always be searched.)

There are no general complexity theoretic results relating the threshold to hardness. The following observation is trivial: if we can efficiently certify almost all instances with dn clauses, where d above the threshold unsatisfiable, then we can certify almost all instances with $d'n$ clauses, $d' > d$, as unsatisfiable by simply chopping off the superfluous clauses. An analogous fact holds below the threshold, where we extend a given formula with some random clauses. Of course, similar remarks apply to the size of clauses.

The relationship between hardness and thresholds is not restricted to satisfiability. It has also been observed for k -colorability of random graphs with a linear number of edges. In [PeWe89] a peak in running time seemingly related to the threshold is reported. The existence of a threshold is proved in [AcFr99], but again the value and convergence to a constant are known only experimentally. For the subset sum problem, which is of a quite different nature, the threshold is known. Some discussion related to hardness is found in [ImNa96]. For the similarly looking number partitioning problem threshold results can be found in [BoChPi2001].

Abandoning the general complexity theoretic point of view and looking at concrete algorithms, we see that the following results are known for random k -SAT instances: all progress approximating the threshold from below is based on the analysis of rather simple polynomial time heuristics and is mostly restricted to clause size $k = 3$. In fact, the most advanced heuristic analyzed [AcSo2000] finds only a satisfying assignment with probability of at least ε , where $\varepsilon > 0$ is a small constant, for 3-SAT formulas with at most $3.26n$ clauses. The same applies to the recent improvement to $3.52n$ clauses in [KaKiLa2002]. The heuristic in [FrSu96] finds a satisfying assignment almost always for random 3-SAT instances with at most $3.003n$ clauses. On the other hand the progress made in approximating the threshold from above does not provide us at all with efficient algorithms certifying the unsatisfiability of the formula at hand. Only the expectation of the number of satisfying assignments is calculated and is shown to tend to 0.

In fact, beyond the threshold we have negative results: for arbitrary but fixed $d \geq 2^k \cdot \ln 2$, random k -SAT instances with dn clauses (are unsatisfiable and) have only resolution proofs with an exponential number, that is, with at least $2^{\Omega(n)}$ clauses with high probability [ChSz88]. This has been improved upon by [Fu95], [BePi96], and [Be at al2002], all of whom proved (exponential) lower bounds for somewhat larger clause/variable ratios. Note that a lower bound on the size of the resolution proofs

provides a lower bound on the number of nodes in *any* classical backtracking tree as generated by any variant of the well-known Davis–Putnam procedure.

Provably polynomial time results beyond the threshold are rather limited at present: in [Fu95] it is shown that random k -SAT formulas with at least n^{k-1} clauses allow for polynomial size resolution proofs with high probability. This is strengthened in [Be et al2002] to the best result known at present: for at least $n^{k-1}/(\log n)^{k-2}$ random clauses a backtracking-based algorithm proves unsatisfiability in polynomial time with high probability. (The result of Beame et al. is slightly stronger, as it applies to formulas with $\Omega(n^{k-1}/(\log n)^{k-2})$ random clauses.)

We extend the region, where a provably polynomial time algorithm exists. For even $k \geq 4$ we give an algorithm which works when the number of clauses is only n to a constant fraction of k (with high probability), that is, for formulas with at least $\text{POLY}(\log n) \cdot n^{k/2} = n^{(k/2)+o(1)}$ clauses, where POLY denotes a polynomial growing sufficiently fast (a degree of 7 is sufficient). A preliminary version of this result has been published in [GoKr 2001]. To obtain our result we leave the area of strictly combinatorial algorithms considered up to this point. Instead we associate a graph with a given formula and show how to certify unsatisfiability of the formula with the help of the eigenvalue spectrum of a certain matrix associated with this graph. Note that our algorithm is not wholly complete but only complete with high probability; in return for sacrificing completeness, we get small-size proofs that are efficiently computable. Note that the eigenvalue spectrum can be approximated to arbitrary accuracy in polynomial time by standard linear algebra methods. With respect to odd k we focus on the case $k = 3$ and show by extending the previous arguments that random 3-SAT instances with $n^{(3/2)+\varepsilon}$ clauses can be efficiently certified as unsatisfiable with high probability, again improving the $n^2/\log n$ bound of Beame et al. In very recent work the aforementioned results have been improved; for $k = 4$ we have an efficient certification algorithm for Cn^2 random clauses, where C is a sufficiently large constant [CoGoLaSch 2004]. And for $k = 3$, we have a bound of $\text{POLY}(\log n) \cdot n^{3/2}$ clauses [CoGoLa 2004]. It seems to be a very hard task to get a bound below $n^{k/2}$ random k -clauses; for one thing, this $n^{k/2}$ seems to be a natural barrier to the spectral techniques we use. For $k = 3$, [FeOf 2004] recently showed that formulas with $n^{3/2}$ random clauses can be efficiently certified as unsatisfiable.

Eigenvalues are used in two ways in the algorithmic theory of random structures: first, they can be used to find a solution of an NP-hard problem in a random instance generated in such a way that it has a solution (not known to the algorithm). An example for 3-colorability is shown in [AlKa97]. Second, they can be used to prove the absence of a solution of an NP-problem. However, these applications are somewhat rare at the moment. The most prominent example is the expansion property of random regular graphs [AlSp92]. Note that the expansion property is coNP-complete [Bl et al81] and the eigenvalues certify the absence of a nonexpanding subset of vertices (which is the solution in this case). Our result is an example of the second kind and it might be worthwhile to investigate more systematically the existence of efficient algorithms for coNP-complete properties of random structures. A general overview on eigenvalues as applied to random graphs is given in [Al98].

We use the following notation throughout. The probabilistic model $\text{Form}_{n,k,m}$ of k -CNF formulas with m clauses over n propositional variables is defined as follows: the probability space of clauses of size k , $\text{Clause}_{n,k}$, is the set of ordered k -tuples of literals over n propositional variables v_1, \dots, v_n . We write $l_1 \vee \dots \vee l_k$ with $l_i = x$ or $l_i = \neg x$, where x is one of our variables. To simplify the subsequent presentation, our definition of $\text{Clause}_{n,k}$ allows for clauses containing the same literal twice and

clauses containing a variable and its negation. We consider $\text{Clause}_{n,k}$ as endowed with the uniform probability distribution: the probability of a clause is given by $\text{Pr}[l_1 \vee \dots \vee l_k] = (1/(2n))^k$. $\text{Form}_{n,k,m}$ is the m -fold cartesian product space of $\text{Clause}_{n,k}$. We write $F = C_1 \wedge \dots \wedge C_m$ and $\text{Pr}[F] = (1/(2n))^{k \cdot m}$. The probability space $\text{Form}_{n,k,p}$ is obtained by the following generation procedure: throw each clause with probability p into the formula to be generated, and the probability of a given formula with m clauses is $p^m \cdot (1-p)^{(2n)^k - m}$. These two spaces $\text{Form}_{n,k,m}$ and $\text{Form}_{n,k,p}$ are essentially equivalent when $m = p \cdot (2n)^k$. There are several other ways of defining k -SAT probability spaces (for example, clauses might be sets of literals instead of sequences; tautological clauses could be forbidden). Although we have not closely checked the details, we feel confident we are in line with general usage to assume that our results can be transferred to these other spaces, too. Note that the clause size k always is fixed.

1. Even clause size.

1.1. From random formulas to random graphs. The following simple observation underlies our algorithm.

LEMMA 1. *If a propositional formula F in k -CNF over n variables is satisfiable, there exists a subset S of at least $n/2$ variables such that F has no all-positive clause $x_1 \vee \dots \vee x_k$ with $x_i \in S$ for all i or F has no all-negative clause $\neg x_1 \vee \dots \vee \neg x_k$ with $x_i \in S$ for all i .*

Proof. Let $\mathcal{A} : \{v_1, \dots, v_n\} \rightarrow \{0, 1\}$ be a satisfying assignment for F . \mathcal{A} sets at least $n/2$ variables to 0 (= false) or to 1 (= true). In the first case the set of variables set to 0 satisfies the lemma; otherwise the set of variables set to 1 does. \square

Our algorithm proves unsatisfiability by efficiently showing the nonexistence of a set S , as in the preceding lemma. To do this we translate the nonexistence of S into a graph theoretical condition. To this end we assign two graphs to a formula. Let $F \in \text{Form}_{n,k,m}$, where k is even, be given. The graph $G = G_F$ depends only on the sequence of all-positive clauses of F :

- The set of vertices of G is $V = V_F = \{x_1 \vee \dots \vee x_{k/2} \mid x_i \text{ a variable}\}$. We have $|V| = n^{k/2}$ and V is independent of F .
- The set of edges of G , $E = E_F$ is given as follows. For $x_1 \vee \dots \vee x_{k/2} \neq y_1 \vee \dots \vee y_{k/2}$ we have $\{x_1 \vee \dots \vee x_{k/2}, y_1 \vee \dots \vee y_{k/2}\} \in E$ iff $x_1 \vee \dots \vee x_{k/2} \vee y_1 \vee \dots \vee y_{k/2}$ (or $y_1 \vee \dots \vee y_{k/2} \vee x_1 \vee \dots \vee x_{k/2}$) is a clause of F . Note that it is possible that $|E| < m$ as clauses might induce no edge, or two clauses might induce the same edge. We do not allow for loops or multiple edges.

The graph H_F is defined in a totally analogous way for the all-negative clauses of F .

Recall that an *independent set* of a graph G is a subset of vertices W of G such that we have no edge $\{v, w\}$ in G , where both $v, w \in W$. The next lemma follows directly from Lemma 1, as a set S of variables induces $|S|^{k/2}$ vertices in G_F consisting only of variables from S .

LEMMA 2. *If $F \in \text{Form}_{n,k,m}$ is satisfiable, then G_F or H_F has an independent set W of vertices with*

$$|W| \geq (n/2)^{k/2} = (1/2)^{k/2} \cdot |V|.$$

Note that as k remains constant when n gets large, this is a constant fraction of all vertices of G_F . We need to show that the distribution of G_F is just the distribution of a usual random graph. To this end let $G_{n,m}$ be the probability space of random

graphs with n labeled vertices and m different edges. Each graph is equally likely; that is, the probability of G is

$$\Pr[G] = 1 / \binom{\binom{n}{2}}{m}.$$

LEMMA 3. (1) *Conditional on the event in $\text{Form}_{n,k,m}$ that $|E_F| = r$, the graph G_F is a random member of the space $G_{\nu,r}$, where $\nu = n^{k/2}$ is the number of vertices of G_F .* (2) *Let $\varepsilon > 0$; with high probability the number of edges of G_F is between $m \cdot (1/2)^k \cdot (1 - \varepsilon)$ and $m \cdot (1/2)^k \cdot (1 + \varepsilon)$.*

Proof. (1) The proof is a well-known (but sometimes forgotten) trick: let G be a graph with vertices V_F as defined above and with edge set E with $|E| = r$. The set of formulas inducing this edge set can be constructed as follows: (a) Consider m slots for clauses and pick $r' \geq r$ of these slots; fill each of these r' slots with an edge from E_F , such that each edge occurs at least once; (b) make each edge in these r' slots into an all-positive clause ($2^{r'}$ possibilities); (c) fill each of the remaining slots with a clause containing at least one negative literal or with a clause having the same first and second halves.

(2) The claim follows from the following statements, which we prove further below:

- Let $\varepsilon > 0$ be fixed. The number of all-positive clauses of $F \in \text{Form}_{n,k,m}$ is between $(1 - \varepsilon) \cdot (1/2)^k \cdot m$ and $(1 + \varepsilon) \cdot (1/2)^k \cdot m$ with high probability.
- The number of all-positive clauses, such as $x_1 \vee \dots \vee x_{k/2} \vee x_1 \vee \dots \vee x_{k/2}$, that is, with the same first and second halves, is $o(m)$.
- The unordered pairs of positions of a formula F in which we have all-positive clauses, which induce only one edge, that are pairs of clauses $x_1 \vee \dots \vee x_k$, $y_1 \vee \dots \vee y_k$, where $\{x_1 \vee \dots \vee x_{k/2}, x_{k/2+1} \vee \dots \vee x_k\} = \{y_1 \vee \dots \vee y_{k/2}, y_{k/2+1} \vee \dots \vee y_k\}$, are also $o(m)$ with high probability.

This implies the claim of the lemma, with the actual ε slightly lower than the ε from the first statement above because we have only $o(m)$ clauses, which induce no additional edge.

First statement above: This statement follows with Chernoff bounds because the probability that a clause at a fixed position is all-positive is $(1/2)^k$ and clauses at different positions are independent.

Second statement above: The probability that the clause at position i has the same first and second halves is $(1/2n)^{k/2}$. The expected number of such clauses in a random F is therefore $m \cdot (1/2n)^{k/2} = o(m)$.

Third statement above: We fix 2 slots of clauses $i \neq j$ of F . The probability that the clauses in these slots have the same set of first and second halves is bounded above by $(2/n)^k$ and the expected number of such unordered pairs is at most $m^2 \cdot (2/n)^k = O(m/n)$, provided $m = O(n^{k-1})$, which we can assume. Let X be the random variable counting the number of unordered pairs of positions with clauses with the same first and second halves and let $\varepsilon > 0$. Markov's inequality gives us

$$\Pr[X > n^\varepsilon \cdot EX] \leq EX / (n^\varepsilon \cdot EX) = 1/n^\varepsilon.$$

Therefore we get that with high probability $X \leq n^\varepsilon \cdot (m/n) = o(m)$. \square

Spectral considerations. Eigenvalues of matrices associated with general graphs are somewhat less common (at least in computer science applications) than those of regular graphs. The monograph [Ch97] is a standard reference for the general case. The easier regular case is dealt with in [AlSp92]. The necessary linear algebra details cannot all be given here. They are very well presented in the textbook [St88].

Let $G = (V, E)$ be an undirected graph (loopless and without multiple edges) with $V = \{1, \dots, n\}$ being a standard set of n vertices. For $0 < p < 1$ we consider the matrix $A = A_{G,p}$ as in [KrVu2002] and [Ju82] and define it as follows: The $(n \times n)$ -matrix $A = A_{G,p} = (a_{i,j})_{1 \leq i,j \leq n}$ has $a_{i,j} = 1$ iff $\{i, j\} \notin E$ and $a_{i,j} = -(1-p)/p = 1 - 1/p$ iff $\{i, j\} \in E$. In particular $a_{i,i} = 1$. As A is real valued and symmetric, A has n real eigenvalues when counting them with their multiplicities and allowing for 0 as an eigenvalue (necessary when the matrix is not of full rank). We denote these eigenvalues by $\lambda_1(A) \geq \lambda_2(A) \geq \dots \geq \lambda_n(A)$.

Recall that the *independence number* of G , denoted by $\alpha(G)$, is the size (= number of vertices) of a largest independent set of G . In general it is NP-hard to determine the independence number. But we have an efficiently computable bound as follows.

LEMMA 4 (Lemma 4 of [KrVu2002]). *For any p with $p > 0$ we have $\lambda_1(A_{G,p}) \geq \alpha(G)$.*

Proof. Let $l = \alpha(G)$. Let χ be the characteristic column vector of a largest independent set of G (i.e., taking the value 1 on elements from the set and 0 otherwise). The matrix $A_{G,p}$ has an $(l \times l)$ -block which contains only 1's. This block of course is indexed with the vertices from our largest independent set. From the Courant–Fisher characterization of the eigenvalues of real valued symmetric matrices we get that

$$\lambda_1(A) \geq \frac{\chi^{tr} \cdot A \cdot \chi}{\chi^{tr} \cdot \chi} = l^2/l = l. \quad \square$$

In order to bound the size of the eigenvalues of $A_{G,p}$ when G is a random graph we rely on a suitably modified version of the following theorem.

THEOREM 5 (Theorem 2 of [FuKo81]). *For $1 \leq i, j \leq n$, and $i \leq j$, let $a_{i,j}$ be independent, real valued random variables (not necessarily identically distributed) satisfying the following conditions where the values K, ν, σ are constants independent of n :*

- $|a_{i,j}| \leq K$ for all $i \leq j$,
- the expectation $Ea_{i,i} = \nu$ for all i ,
- the expectation $Ea_{i,j} = 0$ for all $i < j$,
- the variance $Va_{i,j} = E[a_{i,j}^2] - (Ea_{i,j})^2 = \sigma^2$ for all $i < j$.

For $j \geq i$ let $a_{j,i} = a_{i,j}$ and let $A = (a_{i,j})_{1 \leq i,j \leq n}$ be the random $(n \times n)$ -matrix defined by the $a_{i,j}$. Let the eigenvalues of A be $\lambda_1(A) \geq \lambda_2(A) \geq \dots \geq \lambda_n(A)$. With probability at least $1 - (1/n)^{10}$ the matrix A is such that

$$\max\{|\lambda_i(A)| \mid 1 \leq i \leq n\} = 2 \cdot \sigma \cdot \sqrt{n} + O(n^{1/3} \cdot \log n) = 2 \cdot \sigma \cdot \sqrt{n} \cdot (1 + o(1)).$$

We intend to apply this theorem to the random matrix $A = A_{G,p}$, where G is a random graph from the probability space $G_{n,m}$. However, in this case the entries of A are not strictly independent and Theorem 5 cannot be directly applied. We first consider random graphs from the space $G_{n,p}$ and proceed to $G_{n,m}$ later on. Recall that a random graph G from $G_{n,p}$ is obtained by inserting each possible edge with probability p independently of other edges.

For p constant and G a random member from $G_{n,p}$ the assumptions of Theorem 5 can easily be checked to apply to $A_{G,p}$. However, for sparser random graphs, that is, $p = p(n) = o(1)$, the situation changes. We have that $a_{i,j}$ can assume the value $-1/o(1) + 1$ and thus its absolute value is no longer bounded above by a constant. The same applies to the variance $\sigma^2 = (1-p)/p = 1/o(1) - 1$.

However, it can be checked that the proof of Theorem 5 as given in [FuKo81] holds as long as we consider matrices $A_{G,p}$, where $p = (\ln n)^7/n$. In this case we

have that $K = n/(\ln n)^7 - 1$ and $\sigma^2 = n/(\ln n)^7 - 1$. With this modification and the previous assumptions, the proof of [FuKo81] leads to the following.

COROLLARY 6. *With probability at least $1 - (1/n)^{10}$ the random matrix A satisfies*

$$\max\{|\lambda_i(A)| \mid 1 \leq i \leq n\} = 2 \cdot \sigma \cdot \sqrt{n} + O(n/(\ln n)^{22/6}) = 2 \cdot (1/(\ln n)^{7/2}) \cdot n \cdot (1 + o(1)).$$

Proof. We sketch the changes, which need to be applied to the proof of Theorem 2 in [FuKo81]. These changes refer to the final estimates of the proof on page 237 of [FuKo81]. We set

$$k := (\sigma/K)^{1/3} \cdot n^{1/6} = (\ln n)^{7/6}(1 + o(1));$$

in fact, k should be the following even number: we set the error term

$$\nu := 50 \cdot n/(\ln n)^{22/6}.$$

We have

$$2 \cdot \sigma \cdot \sqrt{n} = 2 \cdot n/(\ln n)^{7/2} = 2 \cdot n/(\ln n)^{21/6},$$

which implies that $\nu = o(2 \cdot \sigma \cdot \sqrt{n})$. Concerning the error estimate, we get

$$\frac{\nu \cdot k}{2 \cdot \sigma \cdot \sqrt{n} + \nu} = \frac{50 \cdot (\ln n)^{7/6}}{(\ln n)^{1/6}} \cdot (1 + o(1)) = 50 \cdot \ln n \cdot (1 + o(1)).$$

This implies the claim. \square

Corollary 6 together with Lemma 4 gives us an efficiently computable certificate bounding the size of independent sets in random graphs from $G_{n,m}$.

COROLLARY 7. *Let G be a random member from $G_{n,m}$, where $m = ((\ln n)^7/2) \cdot n$, and let $p = m/\binom{n}{2} = (\ln n)^7/(n-1)$. We have with high probability that*

$$\lambda_1(A_{G,p}) \leq 2 \cdot (1/(\ln n)^{7/2}) \cdot n \cdot (1 + o(1)).$$

Proof. The proof is a standard transfer from the random graph model $G_{n,p}$ to $G_{n,m}$. For G random from $G_{n,p}$ the induced random matrix $A_{G,p}$ satisfies the assumptions of the last corollary. We have that with probability at least $1 - (1/n)^{10}$ the eigenvalues of $A_{G,p}$ are bounded by $2 \cdot (1/(\ln n)^{7/2}) \cdot n \cdot (1 + o(1))$.

By the de Moivre–Laplace local limit theorem for the binomial distribution the probability that a random graph from $G_{n,p}$ has *exactly* m edges is of $\Omega(1/(n \cdot p)^{1/2}) = \Omega(1/(\ln n)^{7/2})$. This implies the claim, as the probability in $G_{n,p}$ that the eigenvalue is not bounded as claimed is $O((1/n)^{10}) = o(1/(\ln n)^{7/2})$. (We omit the formal conditioning argument.) \square

1.2. The algorithm. We fix the clause size $k \geq 4$ and assume that k is even. We consider the probability space of formulas $\text{Form} = \text{Form}_{n,k,m}$, where the number of clauses is

$$m = 2^k \cdot (\ln n^{k/2})^7 \cdot n^{k/2} = 2^k \cdot (k/2)^7 \cdot (\ln n)^7 \cdot n^{k/2}.$$

Given a random formula F from Form the algorithm first considers the all-positive clauses from F and constructs the graph G_F . From Lemma 3 we know that $G = G_F$ is a random member of $G_{\nu,\mu}$, where $\nu = n^{k/2}$ and μ is at least $m \cdot (1/2)^k \cdot (1 - \varepsilon) =$

$(\ln \nu)^7 \cdot \nu \cdot (1 - \varepsilon)$, where we fix $\varepsilon > 0$ sufficiently small—in fact, $\varepsilon = 1/2$ will do. In the case when the number of edges is smaller than this bound, the algorithm fails.

The algorithm determines the matrix $A = A_{G,p}$, where $p = \mu/\binom{\nu}{2} \geq (\ln \nu)^7/(\nu - 1)$. From Corollary 7 we get that with high probability

$$\lambda_1(A) \leq 2 \cdot (1/(\ln \nu)^{7/2}) \cdot \nu \cdot (1 + o(1)),$$

and thus $\lambda_1(A) < (1/2)^k \cdot \nu = (1/2)^k \cdot n^{k/2}$ with high probability. The algorithm approximates $\lambda_1(A)$ by a polynomial time algorithm. In the case when the preceding event does not occur, the algorithm fails. By Lemma 4 G_F is now certain (not only certain with high probability) to have no independent set comprising $(1/2)^k \cdot n^{k/2}$ vertices.

The algorithm proceeds in the same way for the all-negative clauses and the graph H_F . When it succeeds (which happens with high probability) we have that F is unsatisfiable by Lemma 2. If the algorithm fails, which happens with probability $o(1)$, we do not know whether the formula is satisfiable or not.

When the number of literals k is odd we can extend each clause by a random literal and apply the preceding algorithm. It succeeds with high probability when the number of clauses is

$$2^{k+1} \cdot ((k + 1)/2)^7 \cdot (\ln n)^7 \cdot n^{(k+1)/2}.$$

Concerning the probability space $\text{Form}_{n,k,p}$, the algorithm succeeds with high probability when p is picked such that the expected number of clauses is at least $(1 + \varepsilon) \cdot$ “the bound above” because, in this case, the number of clauses is with high probability at least as large as this bound.

2. Clause size 3. From now on we restrict our attention to the family of probability spaces $\text{Form}_{n,p} = \text{Form}_{n,3,p}$. We assume that $p = p(n) = 1/n^{1+\gamma}$, where $1/2 > \gamma > 0$ is a constant. Our formulas get sparser with increasing γ . Note that our space of formulas is analogous to the space of random graphs $G_{n,p}$. The number of clauses in a random instance from $\text{Form}_{n,p}$ follows the binomial distribution with parameters $8n^3$ and p , $\text{Bin}(8n^3, p)$, and the expected number of clauses is $8n^3 \cdot p = 8 \cdot n^{2-\gamma} = 8 \cdot n^{3/2+\varepsilon}$, where $\varepsilon = 1/2 - \gamma > 0$.

2.1. From random 3-SAT instances to random graphs. We state a graph theoretical condition which implies the unsatisfiability of a 3-SAT instance F over n propositional variables. To this end we again define the graphs G_F and H_F . $G_F = (V_F, E_F)$ is defined as follows:

- V_F is the set of ordered pairs over the n propositional variables. We have $|V_F| = n^2$.
- The edge $(a_1, b_1) \text{---} (a_2, b_2)$ (where in order to avoid loops $(a_1, b_1) \neq (a_2, b_2)$, that is, $a_1 \neq a_2$ or $b_1 \neq b_2$) is in E_F iff there exists a variable z such that F contains the two clauses $a_1 \vee a_2 \vee z$ and $b_1 \vee b_2 \vee \neg z$.

The graph H_F is defined analogously but with different clauses: Its vertices are, as before, ordered pairs of variables, and $(a_1, b_1) \text{---} (a_2, b_2)$ is an edge iff F has the clauses $\neg a_1 \vee \neg a_2 \vee z$ and $\neg b_1 \vee \neg b_2 \vee \neg z$ for a variable z . Note that in the case of G_F the clause pairs $a_1 \vee a_2 \vee z, b_1 \vee b_2 \vee \neg z$ and $a_2 \vee a_1 \vee z', b_2 \vee b_1 \vee \neg z'$ induce the same edge $(a_1, b_1) \text{---} (a_2, b_2)$. Of course analogous remarks apply to H_F .

Some remarks concerning the intuition of this definition follow from the previous case, $k = 4$. The clause $a_1 \vee a_2 \vee b_1 \vee b_2$ is obtained by resolution [Sch89] with z from the two clauses $a_1 \vee a_2 \vee z$ and $b_1 \vee b_2 \vee \neg z$, which define an edge of G_F . Similarly we

have that $\neg a_1 \vee \neg a_2 \vee \neg b_1 \vee \neg b_2$ is obtained from $\neg a_1 \vee \neg a_2 \vee z$ and $\neg b_1 \vee \neg b_2 \vee \neg z$. The correctness of resolution states that F is unsatisfiable if a set of resolvents (that is, clauses obtained by resolution) of F is unsatisfiable.

For any z the number of clauses such as $a_1 \vee a_2 \vee z$ and $b_1 \vee b_2 \vee \neg z$ is concentrated at the expectation $\approx n^2 \cdot p = n^{1-\gamma} > n^{1/2}$ as $\gamma < 1/2$. Applying resolution with z to all these clauses gives $\approx n^{(1-\gamma)^2} > n$ clauses $a_1 \vee a_2 \vee b_1 \vee b_2$. Doing this for all n variables z gives $> n^2$ all-positive clauses of size 4. In the same way we get $> n^2$ all-negative 4-clauses. Efficiently bounding the size of independent sets in these graphs, we get an efficient algorithm which demonstrates unsatisfiability of these newly obtained 4-clauses. The correctness of resolution implies that F itself is unsatisfiable.

Some detailed remarks concerning G_F follow: Only for technical reasons is the variable z , which is resolved, the *last* variable in our clauses. (Recall we consider clauses as ordered triples.) More important is the fact that the edge reflects the resolvent $a_1 \vee a_2 \vee b_1 \vee b_2$ *not* in the most natural way by the edge $(a_1, a_2) \text{---} (b_1, b_2)$ but by $(a_1, b_1) \text{---} (a_2, b_2)$. The variables of the vertices connected by the edge come from the *different* clauses taking part in the resolution step. This is important in decreasing the stochastic dependency of the edges of G_F when F is a random formula. Again we have the convention (more of a technical nature) that the variables in the first position of each vertex come from the clause which contains the positive literal z , whereas the second variables b_1, b_2 come from the clause with $\neg z$.

Recall again that $\alpha(G)$ is the *independence number* of G , that is, the maximum number of vertices of an independent set of G .

THEOREM 8. *If F is a 3-SAT instance over n variables which is satisfiable, then we have*

$$\alpha(G_F) \geq n^2/4 \quad \text{or} \quad \alpha(H_F) \geq n^2/4.$$

Proof. Let \mathcal{A} be an assignment of the n underlying propositional variables with 0, 1 (where 0 = false and 1 = true), which makes F true. We assume that \mathcal{A} assigns 1 to at least $n/2$ variables. Let S be this set of variables. We show that the set of vertices $S \times S$ is an independent set of H_F . As this set has at least $(n/2)^2 = n^2/4$ vertices, the claim holds.

Let $(a_1, b_1) \text{---} (a_2, b_2)$ be an arbitrary edge from H_F . Then F has the clauses $\neg a_1 \vee \neg a_2 \vee z$ and $\neg b_1 \vee \neg b_2 \vee \neg z$ (or $\neg a_2 \vee \neg a_1 \vee z$ and $\neg b_2 \vee \neg b_1 \vee \neg z$). As the assignment \mathcal{A} makes F true, \mathcal{A} sets at least one of the literals $\neg a_1$, $\neg a_2$, $\neg b_1$, or $\neg b_2$ to 1. (Here the correctness proof of resolution is hidden: The clause $\neg a_1 \vee \neg a_2 \vee \neg b_1 \vee \neg b_2$ is a resolvent of $\neg a_1 \vee \neg a_2 \vee z$ and $\neg b_1 \vee \neg b_2 \vee \neg z$ and we have that if \mathcal{A} satisfies F , then \mathcal{A} satisfies all resolvents of F .) So \mathcal{A} sets at least one of the variables a_1 , a_2 , b_1 , or b_2 to 0. But this means that one of these variables is not in our set S . This finishes our proof, as now $(a_1, b_1) \notin S \times S$ or $(a_2, b_2) \notin S \times S$. As the initially chosen edge is arbitrary, we get that $S \times S$ is an independent set of H_F . Finally, if \mathcal{A} sets at least half of the variables to 0, we apply the same argument to G_F . \square

Now we will proceed in an analogous way as before: Given a random F from $\text{Form}_{n,p}$ the graphs G_F and H_F are certain random graphs. With high probability our algorithm certifies that G_F has no independent set of size $\geq n^2/4$. The same applies to H_F . Therefore F is certified unsatisfiable.

The occurrence of different edges in G_F and H_F is not fully independent and techniques from the area of standard random graphs cannot be applied without further consideration. From now on we restrict our attention to G_F ; of course everything applies also to H_F . We collect some basics about G_F .

An edge $(a_1, b_1) \text{---} (a_2, b_2)$ in G_F is only possible if $a_1 \neq a_2$ or $b_1 \neq b_2$. We take a look at the structure of the clause sets which induce the fixed edge $(a_1, b_1) \text{---} (a_2, b_2)$. The edge $(a_1, b_1) \text{---} (a_2, b_2)$ is in G_F iff F contains at least one of the pairs of clauses $a_1 \vee a_2 \vee z$ and $b_1 \vee b_2 \vee \neg z$ or one of the pairs $a_2 \vee a_1 \vee z$ and $b_2 \vee b_1 \vee \neg z$ for a variable z .

Case 1. $a_1 \neq a_2$ and $b_1 \neq b_2$. In this case all z -clauses are different and all $\neg z$ -clauses are different, too. As the z and $\neg z$ clauses are clearly different for each z , we have $2n$ disjoint pairs of clauses which induce the edge $(a_1, b_1) \text{---} (a_2, b_2)$.

Case 2. $a_1 = a_2$ and $b_1 \neq b_2$. In this case the clauses $a_1 \vee a_2 \vee z$ are all different. However, $a_1 \vee a_2 \vee z = a_2 \vee a_1 \vee z$. The $\neg z$ -clauses are all different, as are the z - and $\neg z$ -clauses. We have altogether $2n$ pairs of clauses, where two pairs always have the common clause $a_1 \vee a_2 \vee z$.

The last case, $a_1 \neq a_2$ and $b_1 = b_2$, is analogous to the second case.

With these observations we can get a first impression of the probability of a fixed edge in G_F : If $a_1 \neq a_2$ and $b_1 \neq b_2$, the number of pairs of clauses which induce the edge $(a_1, b_1) \text{---} (a_2, b_2)$ is distributed as $\text{Bin}(2n, p^2)$. The probability that the edge is induced by two pairs of clauses is at most $\binom{2n}{2} \cdot p^4 = o(2np^2)$. This makes it intuitively clear that the probability of $(a_1, b_1) \text{---} (a_2, b_2)$ being in G_F is about $2n \cdot p^2$.

If $a_1 = a_2$ and $b_1 \neq b_2$, we have that the number of clauses such as $b_1 \vee b_2 \vee \neg z$ or $b_2 \vee b_1 \vee \neg z$ is distributed as $\text{Bin}(2n, p)$. The probability of having at least two of these clauses is $O(n^2 p^2) = o(2np)$. Restricting ourselves to the occurrence of at least one of these clauses, it becomes intuitively clear that the probability of the edge $(a_1, b_1) \text{---} (a_2, b_2)$ should also be about $2n \cdot p^2$.

LEMMA 9. We fix the edge $e = (a_1, b_1) \text{---} (a_2, b_2)$.

(a) For $a_1 \neq a_2$ and $b_1 \neq b_2$ we have that

$$\Pr[F; e \text{ is an edge of } G_F] = 2n \cdot p^2 \cdot \left(1 + O\left(\frac{1}{n^{1+2\gamma}}\right)\right).$$

(b) For $a_1 = a_2$ and $b_1 \neq b_2$ this probability is

$$2n \cdot p^2 \cdot \left(1 + O\left(\frac{1}{n^{1+\gamma}}\right)\right).$$

The same applies of course to $a_1 \neq a_2$ and $b_1 = b_2$.

Proof. (a) Recalling the considerations just before this lemma, we have for the probability that G_F has the edge e

$$\Pr[F; e \text{ is an edge of } G_F] = 1 - (1 - p^2)^{2n}.$$

Using the binomial formula and further simple estimates estimates such as

$$\binom{2n}{i} (-p^2)^i \leq (2np^2)^i,$$

we get

$$1 - (1 - p^2)^{2n} = 1 - 1 + 2n \cdot p^2 - \sum_{i=2}^{2n} \binom{2n}{i} (-p^2)^i \geq 2n \cdot p^2 - \frac{4}{n^{2+4\gamma}} \cdot \sum_{i \geq 0} \left(\frac{2}{n^{1+2\gamma}}\right)^i.$$

In the same way,

$$1 - (1 - p^2)^{2n} \leq 2n \cdot p^2 + \frac{4}{n^{2+4\gamma}} \cdot \sum_{i \geq 0} \left(\frac{2}{n^{1+2\gamma}}\right)^i$$

and the convergence of the geometric series and $2n \cdot p^2 = 2/n^{1+2\gamma}$ imply the claim.

(b) We have that the edge e is not in G_F iff for no z it holds that F has the clause $a_1 \vee a_2 \vee z$ and one of the clauses $b_1 \vee b_2 \vee \neg z$ or $b_2 \vee b_1 \vee \neg z$. For a given z we get that $\Pr[F; F \text{ has } a_1 \vee a_2 \vee z \text{ and one of } b_1 \vee b_2 \vee \neg z, b_2 \vee b_1 \vee \neg z] = p \cdot (2p - p^2) = 2p^2 \cdot (1 - (p/2))$. As these triples of clauses are all disjoint for different z , we get that the probability that the edge e is not in G_F is $(1 - 2p^2 \cdot (1 - (p/2)))^n$ and

$$\begin{aligned} & \Pr[e \text{ is in } G_F] \\ &= 1 - \left(1 - 2p^2 \cdot \left(1 - \frac{p}{2}\right)\right)^n \geq n \cdot 2p^2 \cdot \left(1 - \frac{p}{2}\right) - \frac{4}{n^{2+4\gamma}} \sum_{i \geq 0} \left(\frac{2}{n^{1+2\gamma}}\right)^i \\ &= 2n \cdot p^2 \cdot \left(1 + O\left(\frac{1}{n^{1+\gamma}}\right)\right). \end{aligned}$$

In the same way we get the upper bound

$$\Pr[F; e \text{ is in } G_F] \leq 2n \cdot p^2 \cdot \left(1 + O\left(\frac{1}{n^{1+\gamma}}\right)\right)$$

and the claim holds. \square

The preceding lemma implies the following expectations.

COROLLARY 10. (a) Let the random variable X denote the number of edges of G_F . For the expectation of X we get

$$EX = n^{3-2\gamma} \cdot \left(1 + O\left(\frac{1}{n}\right)\right).$$

(b) Let $X_{(a_1, b_1)}$ be the degree of the vertex (a_1, b_1) in G_F . Then

$$E[X_{(a_1, b_1)}] = 2n^{1-2\gamma} \cdot \left(1 + O\left(\frac{1}{n}\right)\right).$$

Proof. (a) The expected number of edges such as $(a_1, b_1) - (a_2, b_2)$ with $a_1 \neq a_2$ and $b_1 \neq b_2$ in G_F is with Lemma 9(a) as $2n \cdot p^2 = 2/n^{1+2\gamma}$,

$$\begin{aligned} & \frac{n^2 \cdot (n-1)^2}{2} \cdot \frac{2}{n^{1+2\gamma}} \cdot \left(1 + O\left(\frac{1}{n^{1+2\gamma}}\right)\right) \\ &= (n^{3-2\gamma} - 2n^{2-2\gamma} + n^{1-2\gamma}) \cdot \left(1 + O\left(\frac{1}{n^{1+2\gamma}}\right)\right) = n^{3-2\gamma} \cdot \left(1 + O\left(\frac{1}{n}\right)\right) \end{aligned}$$

as $\gamma > 0$. For the expected number of edges $(a_1, b_1) - (a_2, b_2)$, where $a_1 = a_2$ (and $b_1 \neq b_2$), we get by Lemma 9(b)

$$\begin{aligned} & \frac{n^2 \cdot (n-1)}{2} \cdot \frac{2}{n^{1+2\gamma}} \cdot \left(1 + O\left(\frac{1}{n^{1+\gamma}}\right)\right) = (n^{2-2\gamma} - n^{1-2\gamma}) \cdot \left(1 + O\left(\frac{1}{n^{1+\gamma}}\right)\right) \\ &= n^{2-2\gamma} \cdot \left(1 + O\left(\frac{1}{n}\right)\right). \end{aligned}$$

The same applies of course to these edges when $a_1 \neq a_2$ and $b_1 = b_2$. As $n^{2-2\gamma} = n^{3-2\gamma} \cdot 1/n$, the claim follows.

(b) Fixing the vertex (a_1, b_1) , we see the number of edges $(a_1, b_1) \text{---} (a_2, b_2)$ with $a_1 \neq a_2$ and $b_1 \neq b_2$ altogether is $(n - 1)^2$, and for the expected number of such edges we get, as $2n \cdot p^2 = 2/n^{1+2\gamma}$,

$$\begin{aligned} & (n - 1)^2 \cdot \frac{2}{n^{1+2\gamma}} \cdot \left(1 + O\left(\frac{1}{n^{1+2\gamma}}\right)\right) \\ = & \left(2n^{1-2\gamma} - \frac{4}{n^{2\gamma}} + \frac{2}{n^{1+2\gamma}}\right) \cdot \left(1 + O\left(\frac{1}{n^{1+2\gamma}}\right)\right) = 2n^{1-2\gamma} \cdot \left(1 + O\left(\frac{1}{n}\right)\right). \end{aligned}$$

The number of edges $(a_1, b_1) \text{---} (a_2, b_2)$, where $a_1 = a_2$ and $b_1 \neq b_2$ altogether, is $n - 1$, and for the expected number of these edges we get with Lemma 9(b)

$$(n - 1) \cdot \frac{2}{n^{1+2\gamma}} \cdot \left(1 + O\left(\frac{1}{n^{1+\gamma}}\right)\right) = O\left(\frac{1}{n^{2\gamma}}\right) = n^{1-2\gamma} \cdot O\left(\frac{1}{n}\right).$$

Of course the same applies to these edges, where $a_1 \neq a_2$ and $b_1 = b_2$. \square

Observe that $n^2 \cdot 2n^{1-2\gamma} = 2 \cdot n^{3-2\gamma}$, reflecting the fact that the sum of the degrees of all vertices is two times the number of edges. The number of vertices is n^2 and the probability that a given edge occurs is $\approx 2/n^{1+2\gamma}$. Disregarding edge dependencies, we see G_F is a random graph $G_{n^2, p'}$, where $p' \approx 2/n^{1+2\gamma} = 2n^{1-2\gamma}/n^2$. Note that the exponent is $1 - 2\gamma > 0$ as $0 < \gamma < 1/2$. The analogous situation in standard random graphs is the probability space $G_{n, p'}$, where $p' = n^\epsilon/n$.

For random graphs according to $G_{n, p'}$ the degree of any vertex is with high probability concentrated at its expectation. This follows easily from tail bounds for the binomial distribution. In the case of our graphs G_F and H_F there is possibly some overlap between clauses inducing edges. This entails a weak kind of stochastic dependency between the occurrence of different edges. Nevertheless the following concentration result holds.

THEOREM 11. *With high probability we have for all vertices (a_1, b_1) of G_F that the degree of (a_1, b_1) is of $2 \cdot n^{1-2\gamma}(1 + o(1))$.*

Proof. Let the variables a_1, b_1 be given. For a variable z let X_z be the indicator random variable on the probability space $\text{Form}_{n, p}$ of the event that there are (non-negated) variables a_2, b_2 such that $a_1 \vee a_2 \vee z \in F$ and $b_1 \vee b_2 \vee \neg z \in F$. Let Y_z indicate the event, $a_2 \vee a_1 \vee z \in F$, and $b_2 \vee b_1 \vee \neg z \in F$. Let $X = \sum X_z$ and Y be the same for the Y_z . We show two points: The degree of the vertex (a_1, b_1) of G_F is with probability at least $1 - o(1/n^2)$ equal to $(X + Y) \cdot (1 + o(1))$. Moreover, with probability $1 - o(1/n^2)$ the random variable $X + Y$ is $2 \cdot n^{1-2\gamma}(1 + o(1))$.

First we compute the value of $X + Y$. For a given variable z we have

$$\Pr[X_z = 1] = (1 - (1 - p)^n) \cdot (1 - (1 - p)^n) = 1 - 2 \cdot (1 - p)^n + (1 - p)^{2n},$$

as $1 - (1 - p)^n$ is the probability that at least for one a_2 the clause $a_1 \vee a_2 \vee z$ occurs in a random formula. As $0 \leq \gamma < 1/2$, we get from the binomial theorem and the formula for the geometric series that

$$(1 - p)^n = 1 - 1/n^\gamma + 1/(2 \cdot n^{2\gamma}) + O(1/n^{3\gamma})$$

and

$$(1 - p)^{2n} = 1 - 2/n^\gamma + 2/n^{2\gamma} + O(1/n^{3\gamma}).$$

Plugging these values into the formula for $Pr[X_z = 1]$, we get

$$Pr[X_z = 1] = 1/n^{2\gamma} + O(1/n^{3\gamma}) = 1/n^{2\gamma} \cdot (1 + o(1)),$$

as we can assume that $\gamma > 0$.

As distinct X_z refer to disjoint sets of clauses, the X_z are stochastically independent and X follows the binomial distribution $\text{Bin}(n, 1/n^{2\gamma} \cdot (1 + o(1)))$. Therefore the expectation of X is $n^{1-2\gamma} \cdot (1 + o(1))$. As $\gamma < 1/2$, we have $1 - 2\gamma > 0$, and exponential tail bounds for the binomial distribution imply that the random variable X is with probability at least $1 - o(1/n^2)$ of $n^{1-2\gamma} \cdot (1 + o(1))$. Of course everything holds in the same way for Y , and the required concentration result for $X + Y$ holds.

We come to the degree. The degree of (a_1, b_1) in the graph G_F is the number of distinct vertices $(a_2, b_2) \neq (a_1, b_1)$ for which there is a variable z such that $a_1 \vee a_2 \vee z \in F$ and $b_1 \vee b_2 \vee \neg z \in F$ or $a_2 \vee a_1 \vee z \in F$ and $b_2 \vee b_1 \vee \neg z \in F$. We show that there exists a constant $C = C(\gamma)$ such that with probability at most $o(1/n^2)$ the degree of (a_1, b_1) differs additively from the random variable $X + Y$ by more than this constant C . We need to analyze the cases in which a variable z with $X_z = 1$ or $Y_z = 1$ induces either no or strictly more than one additional edge incident with (a_1, b_1) .

Case 1. We have $X_z = 1$ but no additional edge is induced. This can happen only if $X_z = 1$ due to the clauses $a_1 \vee a_1 \vee z, b_1 \vee b_1 \vee \neg z \in F$ or if the edge induced by $a_1 \vee a_2 \vee z, b_1 \vee b_2 \vee \neg z \in F$ is also induced by another set of two clauses from F .

The first case occurs for at most C variables z with probability $1 - o(1/n^2)$. For constant C the expected number of sets of C variables z such that the two clauses above are in a random F is at most

$$n^C \cdot (1/n^{1+\gamma})^{2C} = 1/n^{(1+2\gamma) \cdot C}$$

and for $C = 2$, recalling $\gamma > 0$, this expectation is $o(1/n^2)$. By Markov's inequality the probability that there are at least 2 variables z accompanied by clauses as above in a random formula F is $o(1/n^2)$. The case $Y_z = 1$ proceeds in the same way.

The second case is slightly more complex but follows with the same principle. First we consider the case that no additional edge is induced by the clauses $a_1 \vee a_2 \vee z, b_1 \vee b_2 \vee \neg z \in F$ due to a *disjoint* set of two clauses, which yields the same edge. That is, there exists a $z' \neq z$ such that $a_1 \vee a_2 \vee z', b_1 \vee b_2 \vee \neg z' \in F$ or there is a z' ($z' = z$ may be possible) such that $a_2 \vee a_1 \vee z', b_2 \vee b_1 \vee \neg z' \in F$. For a suitably chosen constant C this situation occurs for C variables z with probability $o(1/n^2)$. The expected number of sets of C variables z such that for each of these z one of the preceding possibilities occurs in a random F is bounded above by

$$n^C \cdot n^C \cdot n^{2C} \cdot 2^C \cdot (1/n^{1+\gamma})^{4C} = 2^C / n^{4C\gamma}.$$

For $C \geq 1$ and $\gamma > 0$ this expectation is $o(1)$. Picking $C > 1/(2\gamma)$ makes this expectation $o(1/n^2)$ and the result follows with Markov's inequality.

It may also be the case that no additional edge is induced due to a set of two clauses which, however, now is *not disjoint* to the two clauses $a_1 \vee a_2 \vee z, b_1 \vee b_2 \vee \neg z \in F$. In this case we must have $a_1 = a_2$ (or the same for the b_i 's) and we have the clause $b_2 \vee b_1 \vee \neg z \in F$. Therefore we now have $Y_z = 1$. For the expectation as before we get

$$n^C \cdot n^{2C} \cdot 2^C \cdot (1/n^{1+\gamma})^{3C} = 1/n^{3C\gamma}$$

which is $o(1/n^2)$ for $C \geq 2/(3\gamma)$ and $\gamma > 0$.

Case 2. We consider the situation $X_z = 1$. Strictly more than one edge is induced by the clauses with $z \neg z$ in the third position. We show that the number of edges incident with (a_1, b_1) induced by clauses with the fixed $z, \neg z$ in the end can be bounded above by a constant. For the appropriate expectation we get

$$n^C \cdot n^{C'} \cdot 2^C \cdot 2^{C'} \cdot (1/n^{1+\gamma})^{C+C'} = O(1/n^{\gamma \cdot (C+C')})$$

and picking $C + C'$ large enough we get that at least $C \cdot C'$ edges are induced due the clauses with $z, \neg z$ in the end with probability $o(1/n^2)$.

We still need to bound the number of z 's altogether such that strictly more than one edge is induced due to clauses with $z, \neg z$ in the end. The appropriate expectation is

$$n^C \cdot n^{3C} \cdot 2^C \cdot (1/n^{1+\gamma})^{3C} = 1/n^{(3\gamma-1) \cdot C},$$

which is $o(1)$ if $\gamma > 1/3$, which we can safely assume, and $C \geq 1$. Picking $C > 2/(3\gamma - 1)$ we see the expectation is $o(1/n^2)$.

The claim of the theorem now follows from the preceding considerations. Picking C as the sum of all possible deviations from exactly one edge being induced by $X_z = 1$ or $Y_z = 1$ should do. \square

2.2. Spectral considerations. In this section we prove a general relationship between the size of an independent set in a graph and the eigenvalues of its adjacency matrix. Then we prove that the random graphs G_F and H_F satisfy certain eigenvalue bounds with high probability. These eigenvalue bounds certify that the graphs G_F and H_F do not have independent sets, which are necessary for F to be satisfiable by Theorem 8. Again background from spectral graph theory can be found for regular graphs in [AlSp92] and for the general case in [Ch97]. The linear algebra required is well presented in [St88].

Let $G = (V, E)$ be an undirected graph and $A = A_G$ the adjacency matrix of G . Let A 's eigenvalues be ordered as $\lambda_1(A) \geq \dots \geq \lambda_n(A)$, with $n = |V|$. We abbreviate $\lambda_i = \lambda_i(A)$. We say that G is ν -separated if $|\lambda_i| \leq \nu \lambda_1$ for $i > 1$. With $\lambda = \max_{i>1} |\lambda_i|$ this reads $\lambda \leq \nu \lambda_1$. We say that G is ϵ -balanced for some $\epsilon > 0$ if there is a real d such that the degree of each vertex is between $d(1 - \epsilon)$ and $d(1 + \epsilon)$. As opposed to Lemma 4, the subsequent theorem only uses the eigenvalues of the adjacency matrix of the graph considered.

THEOREM 12. *If G is ν -separated and ϵ -balanced, then G contains no independent set of size $> (n/5) + n \cdot f(\nu, \epsilon)$, where $f(\nu, \epsilon)$ tends to 0 as ν, ϵ tend to 0.*

We remark that this theorem can probably be greatly improved upon (see the remark in the proof). But this weak theorem does preclude independent sets of size $n/4$ for small ν, ϵ , and that is all we need here.

Proof. Let S be an independent subset of vertices of G . We will bound $|S|$. Let $T = V \setminus S$. Let χ_S, χ_T be the characteristic functions (represented as column vectors) of S, T , respectively, (i.e., taking the value 1 on the set and 0 outside of the set). As S is an independent set and G is ϵ -balanced, we have

$$(2.1) \quad d(1 - \epsilon)|S| \leq \left| \text{edges leaving } S \right| = \langle A_G \chi_S, \chi_T \rangle.$$

Note that $A_G \chi_S$ is the column vector whose i th entry is the number of edges going from vertex i into the set S . Recall that $T = V \setminus S$ and $\langle \dots, \dots \rangle$ is the standard inner product of two vectors. We show further below that

$$(2.2) \quad \langle A_G \chi_S, \chi_T \rangle \leq d(1 + \epsilon) \cdot (1/2 + \nu) \cdot \sqrt{|S||T|}.$$

Abbreviating $\theta = |S|/n$ we get from (2.1) and (2.2)

$$|S| \leq \frac{1+\varepsilon}{1-\varepsilon} \left(\frac{1}{2} + \nu \right) \cdot \sqrt{|S||T|}.$$

This implies that

$$\sqrt{\frac{|S|}{|T|}} \leq \frac{1+\varepsilon-\varepsilon+\varepsilon}{1-\varepsilon} \left(\frac{1}{2} + \nu \right) = \left(1 + \frac{2\varepsilon}{1-\varepsilon} \right) \left(\frac{1}{2} + \nu \right) = \frac{1}{2} + g(\varepsilon, \nu),$$

where $g(\varepsilon, \nu)$ goes to 0 when ε and ν do. Next we get

$$\frac{\theta}{1-\theta} \leq \left(\frac{1}{2} + g(\nu, \varepsilon) \right)^2 = \frac{1}{4} + g(\nu, \varepsilon) + g(\nu, \varepsilon)^2.$$

We set $f(\nu, \varepsilon) = (4/5)(g + g^2)$ and can easily conclude that

$$\begin{aligned} \theta &\leq (1-\theta) \cdot (1/4) + (1-\theta) \cdot g + (1-\theta) \cdot g^2 \leq (1/4) - \theta \cdot (1/4) + g + g^2 \\ &\Rightarrow \theta \leq (1/4)(4/5) + (4/5)(g + g^2) = 1/5 + f, \end{aligned}$$

which is the theorem.

We need to show inequality (2.2). Let u_1, \dots, u_n be an orthonormal basis of the n -dimensional vectorspace over the reals, where u_i is an eigenvector with eigenvalue λ_i of A_G . We can decompose the adjacency matrix as

$$A_G = \lambda_1 \cdot u_1 \cdot u_1^T + \lambda_2 \cdot u_2 \cdot u_2^T + \dots + \lambda_n \cdot u_n \cdot u_n^T,$$

where $u_i^T = (u_{i,1}, \dots, u_{i,n})$ is the transpose of the column vector u_i . Note that $\lambda_i \cdot (u_i \cdot u_i^T) \cdot v = \lambda_i \cdot v$ if $v = \alpha \cdot u_i$ and $\lambda_i \cdot (u_i \cdot u_i^T) \cdot v = 0$ for v orthogonal to u_i . Let

$$\mathcal{E} = A_G - \lambda_1 \cdot u_1 \cdot u_1^T = \sum_{i \geq 2} \lambda_i \cdot u_i \cdot u_i^T$$

and represent χ_S, χ_T over the basis of the u_i :

$$\chi_S = \sum_{i=1}^n \alpha_i \cdot u_i \quad \text{and} \quad \chi_T = \sum_{i=1}^n \beta_i \cdot u_i.$$

Recall the fact known as Parseval's equation:

$$|S| = \|\chi_S\|^2 = \sum \alpha_i^2 \quad \text{and} \quad |T| = \|\chi_T\|^2 = \sum \beta_i^2.$$

We get

$$\begin{aligned} \langle A_G \chi_S, \chi_T \rangle &= \langle \lambda_1 \cdot u_1 \cdot u_1^T \cdot \chi_S + \dots + \lambda_n \cdot u_n \cdot u_n^T \cdot \chi_S, \chi_T \rangle \\ &= \langle (\lambda_1 \cdot (u_1^T \cdot \chi_S)) \cdot u_1, \chi_T \rangle + \langle \mathcal{E} \cdot \chi_S, \chi_T \rangle \\ &= (\lambda_1 (u_1^T \cdot \chi_S)) \cdot (u_1^T \cdot \chi_T) + \langle \mathcal{E} \cdot \chi_S, \chi_T \rangle. \end{aligned}$$

We bound the two summands separately. Because of the orthornormality of the u_i we get

$$\begin{aligned} \langle \mathcal{E}\chi_S, \chi_T \rangle &= \langle \mathcal{E} \cdot (\alpha_1 u_1 + \dots + \alpha_n u_n), \chi_T \rangle \\ &= \langle \lambda_2 \alpha_2 u_2 + \dots + \lambda_n \alpha_n u_n, \beta_1 u_1 + \dots + \beta_n u_n \rangle \\ &= \langle \lambda_2 \alpha_2 u_2, \beta_2 u_2 \rangle + \langle \lambda_3 \alpha_3 u_3, \beta_3 u_3 \rangle + \dots + \langle \lambda_n \alpha_n u_n, \beta_n u_n \rangle \\ &= \lambda_2 \alpha_2 \beta_2 + \lambda_3 \alpha_3 \beta_3 + \dots + \lambda_n \alpha_n \beta_n \\ &\leq \lambda \cdot \sum_{i>1} |\alpha_i \beta_i| \leq \lambda \cdot \sqrt{\sum_{i>1} \alpha_i^2} \cdot \sqrt{\sum_{i>1} \beta_i^2} \leq \lambda \cdot \sqrt{\sum_{i \geq 1} \alpha_i^2} \cdot \sqrt{\sum_{i \geq 1} \beta_i^2} \\ &= \lambda \cdot \sqrt{|S|} \cdot \sqrt{|T|} \leq \nu \cdot d(1 + \varepsilon) \sqrt{|S||T|}, \end{aligned}$$

where the last step holds because λ_1 is bounded above by the maximal degree of a vertex, the step before the last is Parseval's equation, and the third step before the last is the Cauchy–Schwarz inequality, $\sum |\alpha_i \beta_i| \leq \sqrt{\sum \alpha_i^2} \cdot \sqrt{\sum \beta_i^2}$.

Now we come to the other summand, $(\lambda_1 (u_1^T \cdot \chi_S)) \cdot (u_1^T \cdot \chi_T)$. Let α, β be the average values of u_1 on S, T , respectively, that is, $\alpha = (\sum u_{1,j})/|S|$, where the sum goes over $j \in S$. With the Cauchy–Schwarz inequality we get

$$\alpha^2 = \frac{(\sum (u_{1,j} \cdot 1))^2}{|S|^2} \leq \frac{(\sum u_{1,j}^2) \cdot (\sum 1)}{|S|^2} = \frac{\sum u_{1,j}^2}{|S|}$$

which implies $\alpha^2 |S| \leq \sum u_{1,j}^2$. As $T = V \setminus S$ we get

$$\alpha^2 |S| + \beta^2 |T| \leq \sum_{j=1}^n u_{1,j}^2 = \|u_1\|^2 = 1.$$

Using the fact that the geometric mean is bounded by the arithmetic mean, this implies

$$\alpha \sqrt{|S|} \cdot \beta \sqrt{|T|} = \sqrt{\alpha^2 |S| \cdot \beta^2 |T|} \leq \frac{\alpha^2 |S| + \beta^2 |T|}{2} \leq \frac{1}{2}.$$

(The weakness of this theorem undoubtedly comes from the pessimistic first estimate, which is close to the truth only when $\alpha^2 |S|$ is close to $\beta^2 |T|$.) This implies, as λ_1 is bounded above by the maximum degree, that

$$\lambda_1 \cdot (u_1^T \chi_S) \cdot (u_1^T \chi_T) \leq d(1 + \varepsilon) \alpha |S| \cdot \beta |T| \leq (1/2) \cdot d(1 + \varepsilon) \sqrt{|S||T|},$$

and we get (2.2), finishing the proof. \square

We next show that the graphs G_F and H_F are ν -separated for a small ν . We do this by applying the trace method; see, for example, [Fr91]. For our purposes it is sufficient to use an elementary version of this method. We first give a general outline of this method and then apply it to the $G_{n,p}$ model of random graphs. Finally, we proceed to the technically more complex graphs G_F, H_F . For $A = A_G$, an adjacency matrix, we have from linear algebra that, for each $k \geq 0$, $\text{Trace}(A^k) = \sum_{i=1}^n \lambda_i^k$. (The trace of a matrix is the sum of the elements on the diagonal.) $\text{Trace}(A^k)$ can be calculated from the underlying graph as $\text{Trace}(A^k) = |\text{closed walks of length } k \text{ in the underlying graph}|$. A closed walk of length k in G is a walk like

$$a_0 \xrightarrow{e_1} a_1 \xrightarrow{e_2} a_2 \xrightarrow{e_3} \dots \xrightarrow{e_{k-1}} a_{k-1} \xrightarrow{e_k} a_k = a_0.$$

Note that the e_i and a_i need by no means be different, only $a_{i-1} \neq a_i$ as we assume the graph loopless. If k is even we have that all $\lambda_i^k \geq 0$ and we get $\text{Trace}(A^k) = \sum_{i=1}^n \lambda_i^k \geq \lambda_1^k + \max_{i>1} \lambda_i^k$. Abbreviating $\lambda = \max_{i>1} |\lambda_i|$ we get further

$$\lambda^k \leq \text{Trace}(A^k) - \lambda_1^k = \sum_{i=2}^n \lambda_i^k.$$

If the underlying adjacency matrix A is random, this applies in particular to the expected values:

$$(2.3) \quad E[\lambda^k] \leq E[\text{Trace}(A^k)] - E[\lambda_1^k] = E \left[\sum_{i=2}^n \lambda_i^k \right].$$

Now assume that k is an even constant, that n is a variable and sufficiently large (having a model that allows a variable n such as $G_{n,p}$), and that $E[\lambda^k] = o(\lambda_1^k)$ with high probability. Then we have that the graph underlying A is ν -separated for any fixed $\nu > 0$ with high probability, which is easy to see:

$$\Pr[\lambda > \nu \lambda_1] = \Pr[\lambda^k > (\nu \lambda_1)^k] = \Pr \left[\lambda^k > \frac{(\nu \lambda_1)^k}{E[\lambda^k]} \cdot E[\lambda^k] \right] \leq o(1),$$

where we apply Markov’s inequality, using the fact that $(\nu \lambda_1)^k / E[\lambda^k] = 1/o(1)$ with high probability, as k and ν are constant. The last estimate of course implies that for each $\nu > 0$ almost all graphs considered are ν -separated. (The idea of considering the k th power of the eigenvalues seems to be to increase the gap between the largest eigenvalue and the remaining eigenvalues.)

Now we apply this to the $G_{n,p}$ model of random graphs, where $p = n^\delta/n$ and $\delta > 0$ is a constant. We calculate the two expected values in (2.3) separately. The largest eigenvalue is always between the minimum and maximum degree of any vertex, as follows from the Courant–Fisher characterization of the eigenvalues of real symmetric matrices. From Chernoff bounds we know that for any $\varepsilon > 0$ with high probability all vertices x from a random G satisfy $(1 - \varepsilon)n^\delta \leq \text{degree of } x \leq (1 + \varepsilon)n^\delta$. Thus with high probability $(1 - \varepsilon)n^\delta \leq \lambda_1 \leq (1 + \varepsilon)n^\delta$. As the probability bounds of the degree estimate follow directly from Chernoff bounds, the probability that the estimate does not hold is exponentially low, that is, at most $n \cdot \exp(-\Omega(n^\delta))$. The same probability estimate applies to the estimate for λ_1 . (The exponentially small term is for a single fixed vertex; the factor n is necessary, as we have n vertices.) As k is even, $\lambda_1^k \geq k$ and

$$E[\lambda_1^k] \geq ((1 - \varepsilon)n^\delta)^k (1 - n \exp(-\Omega(n^\delta))) = (1 - \varepsilon)^k n^{\delta k} - o(1).$$

Next we come to the expectation of the trace in (2.3). For

$$\vec{a} = (a_0, \dots, a_{k-1}, a_k = a_0)$$

let $\text{walk}(\vec{a})$ be the indicator random variable of the event that the walk given by \vec{a} is possible in a random graph; that is, all edges $e_i = (a_{i-1}, a_i) = \{a_{i-1}, a_i\}$ for $1 \leq i \leq k$ occur. Then

$$E[\text{Trace}(A^k)] = E \left[\sum_{\vec{a}} \text{walk}(\vec{a}) \right] = \sum_{\vec{a}} P[\text{walk}(\vec{a}) = 1]$$

by linearity of expectation and as $\text{walk}(\vec{a})$ is an indicator random variable. To calculate the preceding sum we distinguish three types of possible walks \vec{a} . A walk is *distinct* iff all edges e_i are distinct. A walk is *duplicated* iff each edge among the e_i occurs at least twice. A walk is *quasi distinct* iff some edges among the e_i occur at least twice and some only once. (Notice that for quasi-distinct walks and duplicated walks, one type does not subsume the other—indeed, quasi-distinct walks must have an edge that occurs only once; furthermore the arguments given below differ essentially for the quasi-distinct and duplicated cases.) For \vec{a} distinct we have that $\text{Pr}[\text{walk}(\vec{a}) = 1] = p^k$, and the number of \vec{a} 's altogether which can induce a distinct walk is at most n^k because we can choose a_0, \dots, a_{k-1} . Hence, the expected number of distinct walks is bounded above by $n^{\delta k}$. (Compare our estimate for $E[\lambda_1]$.)

For \vec{a} duplicated we parametrize further with respect to the number j , with $1 \leq j \leq k/2$, of different edges among the e_i . Any walk which is possible at all is generated at least once by the following process: 1. Pick the j positions among k possible positions, where each of the j different edges occurs for the first time in $\vec{e} = (e_1, \dots, e_k)$: $\binom{k}{j} \leq k^k$ possibilities. 2. For each of the remaining $k - j$ positions specify which of the preceding first occurrences of an edge is to be used in this position: $\leq j^{k-j} \leq k^k$ possibilities. 3. Specify the vertices incident with the edges picked in 1. As the j edges from 1 must induce a connected graph, the number of possibilities here is at most n^{j+1} . Now we get for the expected number of duplicated walks

$$\begin{aligned} & \sum_{\vec{a} \text{ duplicated}} \text{Pr}[\text{walk}(\vec{a}) = 1] \\ & \leq \sum_{j=1}^{k/2} k^{2k} \cdot n^{j+1} \cdot (n^\delta/n)^j \leq \sum_{j=1}^{k/2} k^{2k} \cdot n \cdot n^{\delta j} \leq (k/2) \cdot k^{2k} \cdot n \cdot n^{\delta k/2}. \end{aligned}$$

Note that $1 + \delta k/2 < \delta k$ iff $2/\delta < k$. So for this estimate to be true k must increase if δ gets smaller.

For the number of quasi-distinct walks, we first assume that the last edge, e_k , is a unique edge of the walk. As our walks are quasi distinct, there are at most $1 \leq j \leq k - 2$ first occurrences of different edges in (e_1, \dots, e_{k-1}) . This implies that the expected number of quasi-distinct walks with the last edge unique is bounded by

$$\sum_{j=1}^{k-2} k^{2k} \cdot n^{j+1} \cdot \left(\frac{n^\delta}{n}\right)^j \cdot \frac{n^\delta}{n} \leq k \cdot k^{2k} \cdot n^{\delta(k-1)}.$$

We account for those quasi-distinct walks, where the last edge is not unique by shifting a unique edge to the end and counting as before. As there are k positions where a unique edge might occur, we need an additional factor of k . Note that always $\delta(k - 1) < \delta k$.

Summing the preceding estimates, we get

$$E[\text{Trace}(A^k)] \leq n^{\delta k} + k^2 \cdot k^{2k} \cdot (nn^{\delta k/2} + n^{\delta(k-1)}) = n^{\delta k} + o(n^{\delta k})$$

if $k > 2/\delta$ is an even constant, which we assume. Now (2.3) implies

$$E[\lambda^k] \leq (1 - (1 - \varepsilon)^k) \cdot n^{\delta k} + o(n^{\delta k})$$

as k even. As $\varepsilon > 0$ can be chosen arbitrarily small, k is constant and the preceding estimate holds whenever n is sufficiently large, we have that $E[\lambda^k] = o(n^{\delta k})$. Now

fix $\nu > 0$. By the general principle stated above we get that $Pr[\lambda > \nu\lambda_1] = o(1)$, meaning that almost all graphs are ν -separated. Applying Theorem 12 we can for almost all graphs from $G_{n,p}$ efficiently certify that they do not have independent sets with much more than $n/5$ vertices.

The treatment of our graphs G_F, H_F based on the method above is more technical but follows the same principles.

THEOREM 13. *For $F \in Form_{n,p,3}$ let $A = A_F$ be the adjacency matrix of G_F and let $\lambda_1 \geq \lambda_2 \geq \dots \geq \lambda_{n^2}$ be the eigenvalues of A . Then*

$$E \left[\sum_{i=1}^{n^2} \lambda_i^k \right] = E[\text{Trace}(A_F^k)]$$

$$\leq (2n^{1-2\gamma})^k + c \cdot k^4 \cdot k^{4k} \cdot 2^k \cdot (n^{(1-2\gamma)(k-1)} + n^2 \cdot n^{(1-2\gamma)k/2}),$$

where c is a constant (possibly $c = 100$ should be enough). If $k > 4/(1 - 2\gamma)$, the preceding estimate is $(2n^{1-2\gamma})^k + o((2n^{1-2\gamma})^k)$.

Proof. For any F we have that $\text{Trace}(A_F) = |\text{closed walks of length } k \text{ in } G_F|$. A typical closed walk of length k is

$$(a_0, b_0) \text{---} (a_1, b_1) \text{---} \dots \text{---} (a_{k-1}, b_{k-1}) \text{---} (a_k, b_k) = (a_0, b_0)$$

with the only constraint that adjacent vertices (= pairs of propositional variables) are different. Now consider a step $(a_{i-1}, b_{i-1}) \text{---} (a_i, b_i)$ of this walk. For this step to be possible in G_F the formula F must have one of the following $2n$ pairs of clauses: $a_{i-1} \vee a_i \vee z, b_{i-1} \vee b_i \vee \neg z$ for a propositional variable z or the other way around, that is, a_i, b_i first. We say that pairs of the first type induce the step $(a_{i-1}, b_{i-1}) \text{---} (a_i, b_i)$ with sign $+1$, whereas the second type induces this step with sign -1 . For two sequences of clauses $\vec{C} = (C_1, C_2, \dots, C_k)$, where the last literal of each C_i is a positive literal, and $\vec{D} = (D_1, D_2, \dots, D_k)$, where the last literal of each D_i is negative, and a sequence of signs $\vec{\varepsilon} = (\varepsilon_1, \dots, \varepsilon_k)$, we say that $\vec{C}, \vec{D}, \vec{\varepsilon}$ induce the walk above iff for each i the pair of clauses C_i, D_i induces the i th step of the walk with sign given by ε_i . Note that the occurrence of the clauses D_i and C_j in a random F is independent, as these clauses are always distinct. We say that F induces the walk above iff we can find sequences of clauses $\vec{C}, \vec{D} \subseteq F$ (the C_i, D_i need not necessarily be all distinct) and a sequence of signs $\vec{\varepsilon}$ such that $\vec{C}, \vec{D}, \vec{\varepsilon}$ induce the given walk. We observe that

- G_F allows for a given walk iff F induces this walk as defined above;
- three sequences $\vec{C}, \vec{D}, \vec{\varepsilon}$ induce at most one walk, but one walk can be induced by many $\vec{C}, \vec{D}, \vec{\varepsilon}$'s. (Without the $\vec{\varepsilon}$ it is possible that \vec{C}, \vec{D} induce several walks.)

Thus we get that $\text{Trace}(A_F^k)$ can be bounded above by the number of different sequences $\vec{C}, \vec{D}, \vec{\varepsilon}$ with $\vec{C}, \vec{D} \subseteq F$ inducing a closed walk of length k , and this estimate transfers to the expectation over a random formula F . The notions of distinct, quasi distinct, and duplicated are defined as for graphs: The sequence \vec{C} is *distinct* iff all component clauses C_i are different. \vec{C} is *quasi distinct* iff some C_i 's occur at least two times and some only once. \vec{C} is *duplicated* iff all C_i 's which occur in \vec{C} occur at least twice in \vec{C} . The same notions apply to \vec{D} . We decompose the expected number of $\vec{C}, \vec{D}, \vec{\varepsilon}$'s which induce a closed walk of length k according to all combinations of \vec{C}, \vec{D} being distinct, quasi distinct, or duplicated.

The expected number of $\vec{C}, \vec{D}, \vec{\varepsilon}$'s with \vec{C}, \vec{D} both distinct can be bounded as follows: The number of possible sequences \vec{C}, \vec{D} altogether can be bounded above

by n^{3k} . Note that we have unique correspondence between three sequences of variables $\vec{a} = (a_0, \dots, a_{k-1}, a_k = a_0)$, $\vec{b} = (b_0, \dots, b_{k-1}, b_k = b_0)$, and $\vec{z} = (z_1, \dots, z_k)$ and two sequences of clauses, which might induce a closed walk of length k , \vec{C}, \vec{D} : $C_i = a_{i-1} \vee a_i \vee z_i$ and $D_i = b_{i-1} \vee b_i \vee \neg z_i$. To account for the signs we get an additional factor of 2^k . The probability that $\vec{C}, \vec{D} \subseteq F$ for \vec{C}, \vec{D} distinct is $(1/n^{1+\gamma})^{2k}$ and we can bound the expectation by

$$2^k \cdot n^{3k} \left(\frac{1}{n^{1+\gamma}} \right)^{2k} = (2n^{1-2\gamma})^k.$$

Recall that $\gamma < 1/2$ and the degree of each vertex is concentrated at $2n^{1-2\gamma}$. Note also the analogous situation for $G_{n,p}$ above.

For \vec{C} distinct and \vec{D} duplicated we parameterize further with respect to the number l with $1 \leq l \leq k/2$ of different clauses D_i . Each \vec{D} possible at all is generated at least once as follows: 1. Pick l positions among the k possible positions where the different clauses D_i occur for the first time: $\binom{k}{l} \leq k^k$ possibilities. 2. For each of the $k-l$ remaining positions pick one of the preceding positions which were picked in 1: $\leq l^{k-l} \leq k^k$ possibilities. 3. Pick the clauses and the signs for the l positions from 1: $\leq n^{l+1} \cdot n^l \cdot 2^l$ possibilities. (Pick the b_i 's, pick the z_i 's, pick a sign.) 4. The remaining D_i 's are specified through 2 and 3, but perhaps we can pick a sign: 2^{k-j} possibilities. 5. Pick the sequence \vec{C} : n^k possibilities. (We can choose only the a_i 's.) For the expectation we get, observing that $l \leq k/2 < k$,

$$\begin{aligned} \sum_{l=1}^{k/2} k^{2k} \cdot 2^k \cdot n^{l+1} \cdot n^l \cdot n^k \cdot \left(\frac{1}{n^{1+\gamma}} \right)^{l+k} &\leq \sum k^{2k} \cdot 2^k \cdot n^{l+1} \cdot \left(\frac{1}{n^\gamma} \right)^{2l} \\ &= \sum_{l=1}^{k/2} k^{2k} \cdot 2^k \cdot n \cdot n^{(1-2\gamma)l} \leq k \cdot k^{2k} \cdot 2^k \cdot n \cdot n^{(1-2\gamma)k/2}, \end{aligned}$$

where we use $\gamma < 1/2$ and have omitted some of the factors $1/n^\gamma$ not necessary. Observe that $1 + (1 - 2\gamma)k/2 < (1 - 2\gamma)k$ iff $k > 2/(1 - 2\gamma)$. For this to hold k must become large when γ approaches $1/2$.

Now let \vec{C} be distinct and \vec{D} be quasi distinct. We first consider the case that the last clause from \vec{D} , D_k is unique. We parameterize further with respect to the number l with $1 \leq l \leq k - 2$ of different clauses in (D_1, \dots, D_{k-1}) . The number of possibilities for (D_1, \dots, D_{k-1}) altogether is bounded by $k^{2k} \cdot n^{l+1} \cdot n^l$. For D_1, \dots, D_{k-1}, D_k altogether we have only an additional factor of n . For the sign we get 2^k and for \vec{C} we have only at most n^k possibilities. Thus for the expectation we get, noting that always $l + 2 \leq k$,

$$\begin{aligned} \sum_{l=1}^{k-2} k^{2k} \cdot 2^k \cdot n^{l+1} \cdot n^l \cdot n \cdot n^k \cdot \left(\frac{1}{n^{1+\gamma}} \right)^{l+k} \cdot \frac{1}{n^{1+\gamma}} &\leq \sum k^{2k} \cdot 2^k \cdot n^{l+1} \cdot \left(\frac{1}{n^\gamma} \right)^{l+l+2} \\ &= \sum k^{2k} \cdot 2^k \cdot n^{(1-2\gamma)(l+1)} \leq k \cdot k^{2k} \cdot 2^k \cdot n^{(1-2\gamma)(k-1)}. \end{aligned}$$

Again we have omitted some unnecessary $1/n^\gamma$'s. To account for the fact that the unique D_i is in between we get an additional factor of k .

Now we come to the case that both \vec{C} and \vec{D} are duplicated. We parameterize further with respect to the number j ($1 \leq j \leq k/2$) of different C_i 's and l ($1 \leq l \leq k/2$)

of different D_i 's. Assume first $j \leq l$; the other case follows symmetrically. The number of different sequences $\vec{C}, \vec{D}, \vec{\varepsilon}$ altogether is bounded by $k^{4k} \cdot 2^k \cdot n^{j+1} \cdot n^j \cdot n^{l+1}$ as we choose the z_i 's with \vec{C} . Summing over j, l , this gives for the expectation a bound of

$$k^2 \cdot k^{4k} \cdot 2^k \cdot n^2 \cdot n^{(1-2\gamma)k/2}.$$

Note that $\gamma < 1/2$ and $2 + (1 - 2\gamma)k/2 < (1 - 2\gamma)k$ iff $k > 4/(1 - 2\gamma)$.

Now we look at the cases \vec{C} duplicated and \vec{D} quasi distinct. We first assume that the last clause of \vec{D} is unique. We parameterize further with respect to j , the number of distinct clauses in \vec{C} , and l , the number of distinct clauses in (D_1, \dots, D_{k-1}) . First assume that $j \leq l+1$. The number of possible sequences $\vec{C}, \vec{D}, \vec{\varepsilon}$ altogether is bounded above by $k^{4k} \cdot 2^k \cdot n^{j+1} \cdot n^j \cdot n^{l+1}$ as we choose the z_i 's with the j different C_i . For the expectation we get the sum going over $1 \leq j \leq k/2, 1 \leq l \leq k-2, j \leq l+1$

$$\begin{aligned} \sum k^{4k} \cdot 2^k \cdot n^{j+1} \cdot n^j \cdot n^{l+1} \cdot \left(\frac{1}{n^{1+\gamma}}\right)^{j+l} \cdot \frac{1}{n^{1+\gamma}} &\leq \sum k^{4k} \cdot 2^k \cdot n \cdot n^j \cdot \left(\frac{1}{n^\gamma}\right)^{2j} \\ &\leq k^2 \cdot k^{4k} \cdot 2^k \cdot n \cdot n^{(1-2\gamma)k/2}. \end{aligned}$$

Again note that $1 + (1 - 2\gamma)k/2 < (1 - 2\gamma)k$ for k a sufficiently large constant.

The case $l+1 \leq j$ yields the following in the same way, now choosing the z_i with the D_i 's:

$$\sum k^{4k} \cdot 2^k \cdot n^{l+1} \cdot n^l \cdot n \cdot n^{j+1} \cdot \left(\frac{1}{n^{1+\gamma}}\right)^{j+l} \cdot \frac{1}{n^{1+\gamma}} \leq k^2 \cdot k^{4k} \cdot 2^k \cdot n^2 \cdot n^{(1-2\gamma)k/2}.$$

For the unique clause of \vec{D} being somewhere in between we need an additional factor of k .

Now finally we look at the case that \vec{C}, \vec{D} are both quasi distinct. First assume that the two last clauses C_k, D_k are unique and let j be the number of different C_i among the first $k-1$ C_i 's and l the same for the D_i 's. First assume the $j \leq l$. We get for the expectation

$$\begin{aligned} \sum_{1 \leq j \leq l \leq k-2} k^{4k} \cdot 2^k \cdot n^{j+1} \cdot n^j \cdot n \cdot n^{l+1} \cdot \left(\frac{1}{n^{1+\gamma}}\right)^{l+j} \cdot \left(\frac{1}{n^{1+\gamma}}\right)^2 \\ \leq k^2 \cdot k^{4k} \cdot 2^k \cdot n^{(1-2\gamma)(k-1)}. \end{aligned}$$

For the unique clauses standing at different positions we get the same estimate, which altogether accounts for another factor of k^2 . For $l \leq j$ we get another factor of 2. \square

Now our algorithm is obvious: We pick ε, ν sufficiently small such that the $f(\nu, \varepsilon)$ from Theorem 12 is $< 1/20$. Given $F \in \text{Form}_{n,p}, p = 1/n^{1+\gamma}$, we construct G_F . We check if maximum degree/minimum degree $\leq (1 + \varepsilon)/(1 - \varepsilon)$. This holds with high probability; when it does not, the algorithm fails. Now we determine λ_1 and λ . With high probability we have that $\lambda \leq \nu\lambda_1$. If the last estimate does not hold, we fail. By Theorem 12 the algorithm now has certified that G_F has no independent set of size $\geq n^2/4$. We do the same for H_F . With high probability we succeed and by Theorem 8 F is certified unsatisfiable.

Conclusion. Our algorithm works with high probability with respect to the binomial space $\text{Form}_{n,p}$, where p is such that the *expected number* of clauses is the announced $n^{3/2+\varepsilon}$. When we always draw *exactly* $n^{3/2+\varepsilon}$ clauses the algorithm should

also work, as can be shown by applying very similar arguments to those given in the paper. Note that we generate formulas in $\text{Form}_{n,p}$ with exactly the expectation of many clauses with probability bounded below only $\Omega(1/\sqrt{n})$. However, after generating exactly $n^{3/2+\varepsilon}$ clauses one can formally delete some clauses with the appropriate low probability. This yields a subset having high probability on $\text{Form}_{n,p}$ with an appropriate p and the preceding consideration applies to these new formulas, thus showing the unsatisfiability of the original formula.

OPTIMAL ONLINE ALGORITHMS FOR MULTIDIMENSIONAL PACKING PROBLEMS*

LEAH EPSTEIN[†] AND ROB VAN STEE[‡]

Abstract. We solve an open problem in the literature by providing an online algorithm for multidimensional bin packing that uses only bounded space. To achieve this, we introduce a new technique for classifying the items to be packed. We show that our algorithm is optimal among bounded space algorithms for any dimension $d > 1$. Its asymptotic performance ratio is $(\Pi_\infty)^d$, where $\Pi_\infty \approx 1.691$ is the asymptotic performance ratio of the one-dimensional algorithm HARMONIC. A modified version of this algorithm for the case where all items are hypercubes is also shown to be optimal. Its asymptotic performance ratio is sublinear in d .

Furthermore, we extend the techniques used in these algorithms to give optimal algorithms for online bounded space variable-sized packing and resource augmented packing.

Key words. multidimensional bin packing, online algorithms, optimal algorithms

AMS subject classifications. 68Q25, 68W40

DOI. 10.1137/S0097539705446895

1. Introduction. Bin packing is one of the oldest and most well-studied problems in computer science [12, 6]. The study of this problem dates back to the early 1970's, when computer science was still in its formative phase—ideas which originated in the study of the bin packing problem have helped shape computer science as we know it today. The influence and importance of this problem are witnessed by the fact that it has spawned off whole areas of research, including the fields of online algorithms and approximation algorithms. In this paper, we study a natural generalization of bin packing called box packing.

Problem definition: Let $d \geq 1$ be an integer. In the d -dimensional box packing problem, we receive a sequence σ of items h_1, h_2, \dots, h_n . Each item h has a fixed size, which is $s_1(h) \times \dots \times s_d(h)$, i.e., $s_i(h)$ is the size of h in the i th dimension. We have an infinite number of bins, each of which is a d -dimensional unit hypercube. Each item must be assigned to a bin and a position $(x_1(h), \dots, x_d(h))$, where $0 \leq x_i(h)$ and $x_i(h) + s_i(h) \leq 1$ for $1 \leq i \leq d$. Further, the positions must be assigned in such a way that no two items in the same bin overlap. A bin is *empty* if no item is assigned to it, otherwise it is *used*. The goal is to minimize the number of bins used. Note that for $d = 1$, the box packing problem reduces to exactly the classic bin packing problem.

There are a number of variants of this problem which are of interest:

- In the *online* version of this problem, each item must be assigned in turn, without knowledge of the next items.

- In the *hypercube packing* problem we have the restriction that all items are hypercubes, i.e., an item has the same size in every dimension.
- In the *bounded space* variant, an algorithm has only a constant number of bins available to accept items at any point during processing. The bounded space assumption is a quite natural one, especially so in online box packing. Essentially the bounded space restriction guarantees that output of packed bins is steady, and that the packer does not accumulate an enormous backlog of bins which are only output at the end of processing.
- In *variable-sized* bin packing, bins of various sizes are available to be used for packing and the goal is to minimize the total size of all the bins used.
- In *resource-augmented* bin packing, the online algorithm has larger bins at its disposal than the offline algorithm, and the goal is to minimize the number of bins used.

The offline versions of these problems are NP-hard, while even with unlimited computational ability it is impossible in general to produce the best possible solution online. We consider online approximation algorithms.

The standard measure of algorithm quality for box packing is the *asymptotic performance ratio*, which we now define. For a given input sequence σ , let $\text{cost}_{\mathcal{A}}(\sigma)$ be the number of bins used by algorithm \mathcal{A} on σ . Let $\text{cost}(\sigma)$ be the minimum possible number of bins used to pack items in σ . The *asymptotic performance ratio* for an algorithm \mathcal{A} is defined to be

$$\mathcal{R}_{\mathcal{A}}^{\infty} = \limsup_{n \rightarrow \infty} \sup_{\sigma} \left\{ \frac{\text{cost}_{\mathcal{A}}(\sigma)}{\text{cost}(\sigma)} \mid \text{cost}(\sigma) = n \right\}.$$

Let \mathcal{O} be some class of box packing algorithms (for instance, online algorithms or bounded space online algorithms). The *optimal asymptotic performance ratio* for \mathcal{O} is defined to be $\mathcal{R}_{\mathcal{O}}^{\infty} = \inf_{\mathcal{A} \in \mathcal{O}} \mathcal{R}_{\mathcal{A}}^{\infty}$. Given \mathcal{O} , our goal is to find an algorithm with an asymptotic performance ratio close to $\mathcal{R}_{\mathcal{O}}^{\infty}$.

Previous results: The classic (one-dimensional) online bin packing problem was first investigated by Ullman [33]. He showed that the FIRST FIT algorithm has performance ratio $\frac{17}{10}$. This result was then published in [20]. Johnson [22] showed that the NEXT FIT algorithm has a performance ratio of 2. Yao showed that REVISED FIRST FIT has a performance ratio of $\frac{5}{3}$, and further showed that no online algorithm has a performance ratio of less than $\frac{3}{2}$ [38]. Brown and Liang independently improved this lower bound to 1.53635 [3, 28]. The lower bound currently stands at 1.54014, due to van Vliet [34]. Define

$$\pi_{i+1} = \pi_i(\pi_i - 1) + 1, \quad \pi_1 = 2,$$

and

$$\Pi_{\infty} = \sum_{i=1}^{\infty} \frac{1}{\pi_i - 1} \approx 1.69103.$$

Lee and Lee presented an algorithm called HARMONIC, which uses $m > 1$ classes and uses bounded space. For any $\varepsilon > 0$, there is a number m such that the HARMONIC algorithm that uses m classes has a performance ratio of at most $(1 + \varepsilon)\Pi_{\infty}$ [25]. They also showed there is no bounded space algorithm with a performance ratio below Π_{∞} . Bounded space algorithms for bin packing were also considered by Woeginger in [37]

and by Van Vliet in [36]. Currently the best known unbounded space upper bound is 1.58889 due to Seiden [31].

Offline bin packing has also received a great deal of attention, for a survey see [6]. The most prominent results are as follows: Garey, Graham, and Ullman [20] were the first to study the approximation ratios of both online and offline algorithms. Fernandez de La Vega and Lueker [15] presented the first (asymptotic) approximation scheme for bin packing. Karmarkar and Karp [23] gave an algorithm which uses at most $\text{cost}(\sigma) + \log^2(\text{cost}(\sigma))$ bins.

The online one-dimensional variable-sized bin packing problem was first investigated by Friesen and Langston [17]. Csirik [9] proposed the VARIABLE HARMONIC algorithm and showed that it has performance ratio at most Π_∞ . Seiden [30] showed that this algorithm is optimal among bounded space algorithms.

The online one-dimensional resource augmented bin packing problem was studied by Csirik and Woeginger [13]. They showed that the optimal bounded space asymptotic performance ratio is a function $\rho(b)$ of the size b of the bins of the online algorithm.

While box packing is a natural next step from bin packing, the problem seems to be more difficult, and the number of results is smaller. The offline problem was introduced by Chung, Garey, and Johnson [5]. Caprara [4] presented an algorithm with an approximation ratio of Π_∞ for $d = 2$.

The online problem was first investigated by Coppersmith and Raghavan [7], who give an algorithm based on NEXT FIT with performance ratio $\frac{13}{4} = 3.25$ for $d = 2$. Csirik, Frenk, and Labbe [10] gave an algorithm based on FIRST FIT with a performance ratio of $\frac{49}{16} = 3.0625$ for $d = 2$. Csirik and van Vliet [11] presented an algorithm with a performance ratio of $(\Pi_\infty)^d$ for all $d \geq 2$ (2.85958 for $d = 2$). Even though this algorithm is based on HARMONIC, it was not clear how to change it to bounded space. Li and Cheng [27] also gave a HARMONIC-based algorithm for $d = 2$ and $d = 3$.

Seiden and van Stee [32] improved the upper bound for $d = 2$ to 2.66013. Several lower bounds have been shown [18, 19, 35, 2]. The best lower bound for $d = 2$ is 1.907 [2], while the best lower bound for large d is less than 3. For bounded space algorithms, a lower bound of $(\Pi_\infty)^d$ is implied by [11].

For online square packing, even less is known. The following results are known for $d = 2$: Coppersmith and Raghavan [7] showed an upper bound of $43/16 = 2.6875$ and a lower bound of $4/3$ (which holds for all $d \geq 2$). The upper bound was improved to $395/162 < 2.43828$ by Seiden and van Stee [32]. For $d = 3$, Miyazawa and Wakabayashi [29] showed an upper bound of 3.954. For the offline problem, Ferreira, Miyazawa, and Wakabayashi give a 1.988-approximation algorithm [16]. A sequence of results improved this result [24, 32, 4], recently culminating in an APTAS by Bansal and Sviridenko [1] and Correa and Kenyon [8] independently.

Our results: In this paper, we present a number of results for online and offline box and square packing:

- We begin by presenting a bounded space algorithm for the packing of hypercubes. An interesting feature of the analysis is that although we show the algorithm is optimal, we do not know the exact asymptotic performance ratio; the asymptotic performance ratio is $\Omega(\log d)$ and $O(d/\log d)$.
- We then extend this algorithm to a bounded space algorithm for general hyperbox packing and show that this algorithm is also optimal, with an asymptotic performance ratio of $(\Pi_\infty)^d$. This solves the ten-year-old open problem

of how to pack hyperboxes using only bounded space.

- We present a bounded space algorithm for the variable-sized multidimensional bin packing problem. As for the first algorithm above, we do not know the exact asymptotic performance ratio.
- We then give an analogous algorithm for the problem of resource augmented online bin packing. This algorithm is also optimal, with an asymptotic performance ratio of $\prod_{i=1}^d \rho(b_i)$ where $b_1 \times \dots \times b_d$ is the size of the bins that the online algorithm uses.

For the online results, we will use the technique of weighting functions. This technique was originally introduced for one-dimensional bin packing algorithms [33, 21]. In [32], it was demonstrated how to use the analysis for one-dimensional algorithms to get results for higher dimensions. In contrast, in the current paper we will define weighting functions directly for multidimensional algorithms, without using one-dimensional algorithms as subroutines.

New technique: To construct the bounded space algorithm we adapt some of the ideas used in previous work. Specifically, the algorithm of [11] also required a scheme of partitioning bins into sub-bins, and of sub-bins into smaller and smaller sub-bins. However, in order to keep a constant number of bins active, we had to introduce a new method of classifying items. Our key improvement is that there is not one single class of “small” items like all the standard algorithms have, but instead we partition the items into an infinite number of classes that are grouped into a finite number of groups. The hypercube packing algorithm uses an easier scheme for the same purpose. This is a more direct extension of the method used in [7].

1.1. The harmonic algorithm. In this section we briefly discuss the important one-dimensional HARMONIC algorithm [25]. In the next sections we adapt it to the multidimensional cases using our novel techniques.

The fundamental idea of these algorithms is to first classify items by size, and then pack an item according to its class (as opposed to letting the exact size influence packing decisions).

For the classification of items, we need to partition the interval $(0, 1]$ into subintervals. The standard HARMONIC algorithm uses $M - 1$ subintervals of the form $(1/(i + 1), 1/i]$ for $i = 1, \dots, M - 1$ and one final subinterval $(0, 1/M]$. Each bin will contain only items from one subinterval (type). Items in subinterval i are packed i per bin for $i = 1, \dots, M - 1$ and the items in interval M are packed in bins using NEXT FIT (i.e., a greedy algorithm that opens a new active bin whenever an item does not fit into the current active bin and never uses the previous bins).

2. Packing hypercubes. In this section we define the algorithm for hypercubes denoted by ALG_ε . In the next section we extend the algorithm to deal with hyperboxes. Let the *size* of hypercube h , $s(h)$ be the length of each side of the hypercube.

The algorithm has a parameter $\varepsilon > 0$. Let $M \geq 10$ be an integer parameter such that $M \geq 1/(1 - (1 - \varepsilon)^{1/(d+1)}) - 1$. We distinguish between “small” hypercubes (of size smaller or equal to $1/M$) and “big” hypercubes (of size larger than $1/M$). The packing algorithm will treat them in different ways.

All *large* hypercubes are packed using a multidimensional version of HARMONIC [25]. The hypercubes are assigned a type according to their size: type i items have a size in the interval $(1/(i + 1), 1/i]$ for $i = 1, \dots, M - 1$. The bins that are used to pack items of these types all contain items of only one type. We use the following algorithm to pack them. A bin is called *active* if it can still receive items, otherwise it is *closed*.

Algorithm ASSIGNLARGE(i). At all times, there is at most one active bin for each type. Each bin is partitioned into i^d hypercubes (sub-bins) of size $1/i$ each (the sub-bins create a grid of i strips in each dimension). Each such sub-bin can contain exactly one item of type i . On arrival of a type i item it is assigned to a free sub-bin (and placed anywhere inside this sub-bin). If all sub-bins are taken, the previous active bin is closed, a new active bin is opened and partitioned into sub-bins.

The *small* hypercubes are also assigned types depending on their size, but in a different way. Consider an item h of size $s(h) \leq 1/M$. Let k be the largest nonnegative integer such that $2^k s(h) \leq 1/M$; clearly $2^k s(h) > 1/(2M)$. Let i be the integer such that $2^k s(h) \in (1/(i+1), 1/i]$, $i \in \{M, \dots, 2M-1\}$. The item is defined to be of type i . Each bin that is used to pack small items contains only small items with a given type i . Note that items of very different sizes may be packed together in one bin. We now describe the algorithm to pack a new small item of type i for $i = M, \dots, 2M-1$. A sub-bin which received a hypercube is said to be *used*. A sub-bin which is not used and not cut into smaller sub-bins is called *empty*.

Algorithm ASSIGNSMALL(i). The algorithm maintains a single active bin. Each bin may, during its use, be partitioned into sub-bins which are hypercubes of different sizes of the form $1/(2^j i)$. When an item h of type i arrives we perform the following. Let k be the integer such that $2^k s(h) \in (1/(i+1), 1/i]$.

1. If there is an empty sub-bin of size $1/(2^k i)$, then the item is simply assigned there and placed anywhere within the sub-bin.
2. Else, if there is no empty sub-bin of any size $1/(2^j i)$ for $j < k$ inside the current bin, the bin is closed and a new bin is opened and partitioned into sub-bins of size $1/i$. Then the procedure in step 3 is followed, or step 1 in case $k = 0$.
3. Take an empty sub-bin of size $1/(2^j i)$ for a maximum $j < k$. Partition it into 2^d identical sub-bins (by cutting into two identical pieces, in each dimension). If the resulting sub-bins are larger than $1/(2^k i)$, take *one* of them and partition it in the same way. This is done until sub-bins of size $1/(2^k i)$ are reached. The new item is assigned into one such sub-bin.

Finally, the main algorithm only determines the type of newly arriving items and assigns them to the appropriate algorithms. The total number of active bins is at most $2M-1$. In order to perform a competitive analysis, we prove the following claims.

CLAIM 1. *For a given $i \geq M$, consider an active bin of type i . At all times, the number of empty sub-bins in it of each size except $1/i$ is at most $2^d - 1$.*

Proof. Note that the number of empty sub-bins of size $1/i$ decays from i^d to zero during the usage of such a bin. Consider a certain possible size r of a sub-bin in it. When a sub-bin of some size r is created, it is due to a partition of a larger sub-bin. This means that there were no empty sub-bins of size r before the partition. Afterwards, there are at most $2^d - 1$ of them for each size that has been created during the partitioning (for the smallest size into which the sub-bin is partitioned, 2^d sub-bins created, but one is immediately used). \square

CLAIM 2. *For a given $i \geq M$, when a bin of type i is about to be closed, the total volume of empty sub-bins in the bin is at most $1/i^d$.*

Note that the above claims bound the volume of sub-bins that are not used at all. There is some waste of volume also due to the fact that each item does not fill its sub-bin totally. We compute this waste later.

Proof. For $i \geq M$, when a bin of type i is to be closed, there are no empty sub-bins of size $1/i$ in it. There are at most $2^d - 1$ empty sub-bins of each other size by Claim 1. This gives a total unused volume of at most $(2^d - 1) \sum_{k \geq 1} (2^k i)^{-d} = 1/i^d$. \square

CLAIM 3. *The occupied volume in each closed bin of type $i \geq M$ is at least $1 - \varepsilon$.*

Proof. A hypercube which was assigned into a sub-bin of size $1/(2^k i)$ always has size of at least $1/(2^k(i+1))$. Therefore the ratio of occupied space and existing space in each used sub-bin is at least $i^d/(i+1)^d$. When a bin is closed, the total volume of used sub-bins is at least $1 - 1/i^d$ by Claim 2. Therefore the occupied volume in the bin is at least $i^d/(i+1)^d(1 - 1/i^d) = (i^d - 1)/(i+1)^d$. We use $i \geq M$ and $M^d \geq M + 1$ to get $(i^d - 1)/(i+1)^d \geq (M^d - 1)/(M+1)^d \geq (\frac{M}{M+1})^{d+1} \geq 1 - \varepsilon$. \square

Now we are ready to analyze the performance. We define a weighting function for ALG_ε [33]. Each item p with type $1 \leq i \leq M - 1$ has weight $w_\varepsilon(p) = 1/i^d$. Each item p' of higher type has weight $w_\varepsilon(p') = (s(p))^d/(1 - \varepsilon)$ which is the volume of the item divided by $(1 - \varepsilon)$. We begin by showing that this weighting function is valid for our algorithm.

LEMMA 2.1. *For all input sequences σ , $\text{cost}_{\text{ALG}_\varepsilon}(\sigma) \leq \sum_{h \in \sigma} w_\varepsilon(h) + 2M - 1$.*

Proof. Each closed bin of type $1 \leq i \leq M - 1$ contains i^d items. All sub-bins are used when the bin is closed, and thus it contains a total weight of 1. Each closed bin of type $M \leq i \leq 2M - 1$ has an occupied volume of at least $1 - \varepsilon$ by Claim 3, and therefore the weights of the items in such a bin sum up to at least 1. At most $2M - 1$ bins are active. Thus the total number of bins used by ALG_ε for a given input sequence σ is upper bounded by the total weight of the items plus $2M - 1$. \square

By Lemma 2.1, for any given $\varepsilon > 0$, the asymptotic performance ratio of our algorithm can be upper bounded by the maximum amount of weight that can be packed in a single bin: for a given input sequence σ (with fixed weight w), the offline algorithm minimizes the number of bins that it needs to pack all items in σ by packing as much weight as possible in each bin. If it needs k bins, the performance ratio on this input is w/k , which is also the average weight per offline bin.

Therefore we need to find the worst case offline bin, i.e., an offline bin which is packed with a maximum amount of weight. However, for the case of cubes, we only have $M + 1$ different types of items. All large items of type i have the same weight. All small items have the same ratio of weight to volume. Therefore the exact contents of a bin are not crucial. In order to define a packed bin, we need only to know how many items there are of each type, and the volume of the small items. To maximize the weight we can assume that the large items are as small as possible (without changing their type), and the rest of the bin is filled with small items.

Formally, we define a *pattern* as a tuple $q = \langle q_1, \dots, q_{M-1} \rangle$, where there exists a feasible packing into a single bin containing q_i items of type i for all $1 \leq i \leq M - 1$. This generalizes the definition from [31]. The weight of a pattern q is at most

$$(1) \quad w_\varepsilon(q) = \sum_{i=1}^{M-1} \frac{q_i}{i^d} + \frac{1}{1 - \varepsilon} \left(1 - \sum_{i=1}^{M-1} \frac{q_i}{(i+1)^d} \right).$$

Note that for any given pattern the amounts of items of types $M, \dots, 2M - 1$ are unspecified. However, as mentioned above, the weight of such items is always their volume divided by $1 - \varepsilon$. Therefore (1) gives an upper bound for the total weight that can be packed in a single bin for a given pattern q . Summarizing, we have the following theorem.

THEOREM 2.2. *The asymptotic performance ratio of ALG_ε is upper bounded by $\max_q w_\varepsilon(q)$, where the maximum is taken over all patterns q that are valid for ALG_ε .*

In order to use Theorem 2.2, we need the following geometric claim. We immediately formulate it in a general way so that we can also apply it in the next section.

CLAIM 4. *Given a packing of hyperboxes into bins, such that component j of each hyperbox is bounded in an interval $(1/(k_j + 1), 1/k_j]$, where $k_j \geq 1$ is an integer for $j = 1, \dots, d$, then each bin has at most $\prod_{j=1}^d k_j$ hyperboxes packed in it.*

Proof. We prove the claim by induction on the dimension. Clearly for $d = 1$ the claim holds. To prove the claim for $d > 1$, the induction hypothesis means that a hyperplane of dimension $d - 1$ through the bin which is parallel to one of the sides (the side which is the projection of the bin on the first $d - 1$ dimensions) can meet at most $\prod_{j=1}^{d-1} k_j$ hyperboxes. Next, take the projection of the hyperboxes and the bin on the last axis. We get short intervals of length in $(1/(k_d + 1), 1/k_d]$ (projections of hypercubes) on a main interval of length 1 (the projection of the bin). As mentioned above, each point of the main interval can have the projection of at most $\prod_{j=1}^{d-1} k_j$ items. Consider the short intervals as an interval graph. The size of the largest clique is at most $\prod_{j=1}^{d-1} k_j$. Therefore, as interval graphs are perfect, we can color the short intervals using $\prod_{j=1}^{d-1} k_j$ colors. Note that the number of intervals of each independent set is at most k_d (due to length), and so the total number of intervals is at most $\prod_{j=1}^d k_j$. \square

LEMMA 2.3. *Let $\alpha = \liminf_{\varepsilon \rightarrow 0} \max_q w_\varepsilon(q)$, where the maximum is taken over all patterns q that are valid for ALG_ε . Then the asymptotic performance ratio of any bounded space algorithm is at least α .*

Proof. We show that there is no bounded space algorithm with an asymptotic performance ratio strictly below α . For any $\varepsilon' > 0$, there exists an $\varepsilon \in (0, \varepsilon')$ such that $\mathcal{R}^\infty(\text{ALG}_\varepsilon) \leq (1 + \varepsilon')\alpha$. Consider the pattern q for which $w_\varepsilon(q)$ is maximal. We write $w_\varepsilon(q) = (1 + \varepsilon'')\alpha$ for some $\varepsilon'' \in [0, \varepsilon']$.

Note that a pattern does not specify the precise sizes of any of the items in it. Based on q , we define a set of hypercubes that can be packed together in a single bin. For each item of type i in q , we take a hypercube of size $1/(i + 1) + \delta$ for some small $\delta > 0$. Take $V_\delta = 1 - \sum_{i=1}^{M-1} q_i(1/(i + 1) + \delta)^d$. We add a large amount of small hypercubes of total volume V_δ , where the sizes of the small hypercubes are chosen in such a way that they can all be packed in a single bin together with the large hypercubes prescribed by q . By the definition of a pattern, such a packing is feasible for δ sufficiently small.

Define the following input for a bounded space algorithm. Let N be a large constant. The sequence contains M phases. The last phase contains a volume NV_δ of small hypercubes. Phase i ($1 \leq i \leq M - 1$) contains Nq_i hypercubes of size $1/(i + 1) + \delta$. After phase i , almost all hypercubes of this phase must be packed into closed bins (except a constant number of active bins). Each such bin may contain up to i^d items, which implies that in each phase i , $Nq_i/i^d - O(1)$ bins are closed. The last phase contributes at least $V_\delta - O(1)$ extra bins. The cost of the online algorithm is $\sum_{i=1}^{M-1} Nq_i/i^d + V_\delta - O(M)$. But the optimal offline cost is simply N . Taking $\delta = 1/N$ and letting N grow without bound, N becomes much larger than M and the asymptotic performance ratio of any bounded space online algorithm is lower bounded by $\sum_{i=1}^{M-1} q_i/i^d + V_0$. Note that the weight of this set of hypercubes according to our definition of weights tends to $\sum_{i=1}^{M-1} q_i/i^d + V_0/(1 - \varepsilon) = w_\varepsilon(q) = (1 + \varepsilon'')\alpha$ as $\delta \rightarrow 0$. Therefore $\sum_{i=1}^{M-1} q_i/i^d + V_0 \geq (1 - \varepsilon)(1 + \varepsilon'')\alpha \geq (1 - \varepsilon')\alpha$. \square

Lemma 2.3 implies that our algorithm is the best possible bounded space algorithm. More precisely, for every $\varepsilon' > 0$, there exists an $\varepsilon \in (0, \varepsilon')$ such that

$\mathcal{R}^\infty(\text{ALG}_\varepsilon) \leq (1 + \varepsilon')\alpha$, and no bounded space algorithm has an asymptotic performance ratio below $(1 - \varepsilon')\alpha$. This also implies that our weighting function cannot be improved and determines the asymptotic performance ratio exactly. However, we have no general formula for this ratio. We do have the following bounds.

THEOREM 2.4. *There exists a value of M such that the asymptotic performance ratio of ALG_ε is $O(d/\log d)$. Any bounded space algorithm (in particular ALG_ε) has an asymptotic performance ratio of $\Omega(\log d)$.*

Proof. We first show the upper bound. Take $M = 2d/\log d$. The occupied area in bins of small types is at least $(\frac{M}{M+1})^{d+1}$ by the proof of Claim 3. This is greater than $(\frac{M+1}{M})^{-d} = (1 + 1/M)^{-d} = (1 + (\log d)/(2d))^{-d}$, which tends to $e^{-(\log d)/2} = (e^{\log d})^{-1/2} = 1/\sqrt{d}$ for $d \rightarrow \infty$.

Suppose the input is I . Denote by I_i the subsequence of items of type i ($i = 1, \dots, M$), where we consider all the small types as a single type. Then we have $\text{ALG}(I_i) = \text{OPT}(I_i) \leq \text{OPT}(I)$ for $i = 1, \dots, M-1$, since if items of only one type arrive, our algorithm packs them perfectly. Moreover, $\text{ALG}(I_M) = O(\sqrt{d}) \cdot \text{OPT}(I_M) = O(\sqrt{d}) \cdot \text{OPT}(I)$ for $i = M$. Thus $\text{ALG}(I) = \sum_{i=1}^M \text{ALG}(I_i) \leq (M-1)\text{OPT}(I) + O(\sqrt{d})\text{OPT}(I) = O(d/\log d)\text{OPT}(I)$.

We now prove the lower bound. Consider the following lower bound construction. (This lower bound can also be shown using the weighting function.) We use $\lceil \log d \rceil$ phases. In phase i , $N((2^i - 1)^d - (2^i - 2)^d)$ items of size $2^{-i}(1 + \delta)$ arrive, where $\delta < 2^{-\lceil \log d \rceil} \leq 1/d$. It is possible to place all these items in just N bins by using the following packing scheme. Each bin is packed identically, so we just describe the packing of a single bin. The first item is placed in a corner of the bin. We assign coordinates to the bin so that this corner is the origin and all positive axes are along edges of the bin. (The size of the bin in each dimension is 1.)

Consider any coordinate axis. We reserve the space between $(1 - 2^{1-i})(1 + \delta)$ and $(1 - 2^{-i})(1 + \delta)$ for items of phase i . Note that this is exactly the size of such an item. By doing this along every axis, we can place all $(2^i - 1)^d - (2^i - 2)^d$ items of phase i . (There would be room for $(2^i - 1)^d$ items if we used all the space until $(1 - 2^{-i})(1 + \delta)$ along each axis; we lose $(2^i - 2)^d$ items because the space until $(1 - 2^{1-i})(1 + \delta)$ is occupied.)

The minimum number of bins that any bounded space online algorithm needs to place the items of phase i is $N((2^i - 1)^d - (2^i - 2)^d)/(2^i - 1)^d = N(1 - (\frac{2^i - 2}{2^i - 1})^d)$. Note that the contribution of each phase i to the total number of bins required to pack all items is strictly decreasing in i . Consider the contribution of the last phase, which is phase $\lceil \log d \rceil$. Since $\lceil \log d \rceil \leq 1 + \log d$, it is greater than $N(1 - (\frac{2d-2}{2d-1})^d) = N(1 - (1 - \frac{1}{2d-1})^d) \geq N(1 - e^{-1/2}) > 0.39N$ for all $d \geq 2$. Thus all $\lceil \log d \rceil$ terms all contribute at least $0.39N$, and the total number of bins required is at least $0.39N(\lceil \log d \rceil)$. This implies a lower bound of $\Omega(\log d)$ on the asymptotic performance ratio of this problem. \square

In [14], we give specific upper and lower bounds for dimensions $2, \dots, 7$.

3. Packing hyperboxes. Next, we describe how to extend the algorithm for hypercubes to handle hyperboxes instead of hypercubes. This algorithm also uses the parameter ε . The value of M as a function of ε is picked so that $M \geq 1/(1 - (1 - \varepsilon)^{1/(d+2)}) - 1$. Similar to the previous algorithm, the hyperboxes are classified into types. An arriving hyperbox h of dimensions (h_1, h_2, \dots, h_d) is classified as one of $(2M - 1)^d$ types depending on its components: a type of a hyperbox is the vector of the types of its components.

There are $2M - 1$ types of components. A component larger than $1/M$ has type i if $1/(i + 1) < h_i \leq 1/i$, and is called large. A component smaller than $1/M$ has type i , where $M \leq i \leq 2M - 1$, if there exists a nonnegative integer f_i such that $1/(i + 1) < 2^{f_i} h_i \leq 1/i$. Such components are called small.

Each of the $(2M - 1)^d$ types is packed separately and independently of the others. The algorithm keeps one active bin for each type (s_1, \dots, s_d) . When such a bin is opened, it is split into $\prod_{i=1}^d s_i$ identical sub-bins of dimensions $(1/s_1, \dots, 1/s_d)$. On arrival of a hyperbox h , after classification into a type, a sub-bin has to be found for it. If there is no sub-bin in the current bin that is larger than h in every dimension, we close the bin and open a new one. Otherwise, we take an empty sub-bin that has minimum volume among all sub-bins that can contain h .

Now consider the components of h one by one. If the i th component is large, the sub-bin has the correct size in this dimension: its size is $1/s_i$ whereas the component is in $(1/(s_i + 1), 1/s_i]$.

If the i th component is small, the size of the sub-bin in the i th dimension may be too large. Suppose its size is $1/(2^{f'} s_i)$ whereas the hyperbox has size $\in (1/(2^f (s_i + 1)), 1/(2^f s_i)]$ in this dimension for some $f > f'$. In this case, we divide the sub-bin into two equal parts by cutting halfway (across the i th dimension). If the new sub-bins have the proper size, take one of the two smallest sub-bins that were created, and continue with the next component. Otherwise, take one of the new sub-bins and cut it in half again, repeating until the size of a created sub-bin is $1/(2^f s_i)$.

Thus we ensure that the sub-bin that we use to pack the item h has the proper size in every dimension. We then place this item anywhere inside the sub-bin.

We now generalize the proofs from the previous section for this algorithm.

CLAIM 5. Consider a type (s_1, \dots, s_d) , and its active bin. For every vector $(f_1, \dots, f_d) \neq 0$ of nonnegative integers such that $f_i = 0$ for each large component i , there is at most one empty sub-bin of size $(1/(2^{f_1} s_1), \dots, 1/(2^{f_d} s_d))$.

Proof. Note that the number of sub-bins of size $(1/s_1, \dots, 1/s_d)$, is initialized to be $\prod_{i=1}^d s_i$, and decays until it reaches the value zero. The cutting process does not create more than a single empty sub-bin of each size. This is true for all the sub-bins created except for the smallest size that is created in any given process. For that size we create two identical sub-bins. However, one of them is filled right away.

Furthermore, no sub-bins of existing sizes are created due to the choice of the initial sub-bin. The initial sub-bin is chosen to be of minimum volume among the ones that can contain the item, and hence all the created sub-bins (all of which can contain the item) are of smaller volume than any other existing sub-bin that can contain the item. \square

CLAIM 6. The occupied volume in each closed bin of type (s_1, \dots, s_d) is at least

$$(1 - \varepsilon) \prod_{i \in L} s_i / (s_i + 1),$$

where L is the set of large components in this type.

Proof. To bound the occupied volume in closed bins, note that a sub-bin which was assigned an item is full by a fraction of at least

$$\prod_{i=1}^d \frac{s_i}{s_i + 1} \geq \left(\frac{M}{M + 1} \right)^{d - |L|} \prod_{i \in L} \frac{s_i}{s_i + 1}.$$

Considering sub-bins that were empty when the bin was closed, by Claim 5 there may be one empty sub-bin of each size $(1/(2^{f_1} s_1), \dots, 1/(2^{f_d} s_d))$, with the restrictions

that f_i is a nonnegative integer for $i = 1, \dots, d$, $f_i = 0$ for each large component i , and there exists some $i \in \{1, \dots, d\}$ such that $f_i \neq 0$.

If there are no small components, there can be no empty sub-bins because large components never cause splits into sub-bins, so all sub-bins are used when the bin is closed. This gives a bound of $\prod_{i \in L} s_i / (s_i + 1)$.

If there is only one small component, the total volume of all empty sub-bins that can exist is $1/(s_1 \cdots s_d) \cdot (\frac{1}{2} + \frac{1}{4} + \cdots) \leq 1/(s_1 \cdots s_d) \leq 1/M$, since one of the components is small (type is at least M) and all other components have types of at least 1. The occupied volume is at least $(1 - 1/M) \cdot \frac{M}{M+1} \prod_{i \in L} (s_i / (s_i + 1)) \geq (\frac{M}{M+1})^{d+2} \prod_{i \in L} (s_i / (s_i + 1))$. This holds for any $d \geq 2$ and $M \geq 2$.

If there are $r \geq 2$ small components, the total volume of empty sub-bins is at most $(2^r - 1)/(s_1 s_2 \cdots s_d) \leq (2^r - 1)/M^r \leq 2^r/M^r$. (We get the factor $2^r - 1$ by enumerating over all possible choices of the values f_i .) We get that the fraction of each bin that is filled is at least

$$\begin{aligned} & \left(1 - \frac{2^r}{M^r}\right) \left(\frac{M}{M+1}\right)^r \prod_{i \in L} \frac{s_i}{s_i + 1} \\ &= \frac{M^r - 2^r}{(M+1)^r} \prod_{i \in L} \frac{s_i}{s_i + 1} \geq \left(\frac{M}{M+1}\right)^{r+2} \prod_{i \in L} \frac{s_i}{s_i + 1} \\ &\geq \left(\frac{M}{M+1}\right)^{d+2} \prod_{i \in L} \frac{s_i}{s_i + 1}. \end{aligned}$$

The first inequality holds for $M^r - 2^r \geq M^{r+2}/(M+1)^2$, which holds for any $r \geq 2$ and $M \geq 4$.

Using $(\frac{M}{M+1})^{d+2} \geq 1 - \varepsilon$ we get Claim 6. \square

We now define a weighting function for our algorithm. The weight of a hyperbox p with components (h_1, \dots, h_d) and type (s_1, \dots, s_d) is defined as

$$w_\varepsilon(p) = \frac{1}{1 - \varepsilon} \prod_{i \notin L} h_i \prod_{i \in L} \frac{1}{s_i},$$

where L is the set of large components in this type.

LEMMA 3.1. *For all input sequences σ , $\text{cost}_{\text{alg}}(\sigma) \leq \sum_{h \in \sigma} w_\varepsilon(h) + O(1)$.*

Proof. In order to prove the claim, it is sufficient to show that each closed bin contains items of total weight of at least 1. Consider a bin filled with hyperboxes with type (s_1, \dots, s_d) . It is sufficient to consider the subsequence σ of the input that contains only items of this type, since all types are packed independently. We build an input σ' for which both the behavior of the algorithm and the weights are the same as for σ , and show that the claim holds for σ' . Let $\delta < 1/M^3$ be a very small constant.

For a hyperbox $h \in \sigma$ with components (h_1, \dots, h_d) and type (s_1, \dots, s_d) , let $h' = (h'_1, \dots, h'_d) \in \sigma'$ be defined as follows. For $i \notin L$, $h'_i = h_i$. For $i \in L$, $h'_i = 1/(s_i + 1) + \delta < 1/s_i$. As h and h' have the same type, they require a sub-bin of the same size in all dimensions. Therefore the algorithm packs σ' in the same way as it packs σ . Moreover, according to the definition of weight above, h and h' have the same weight.

Let $v(h)$ denote the volume of an item h . For $h \in \sigma$, we compute the ratio of

weight and volume of the item h' . We have

$$\begin{aligned} \frac{w_\varepsilon(h')}{v(h')} &= \frac{1}{1-\varepsilon} \prod_{i \notin L} h'_i \prod_{i \in L} \frac{1}{s_i} \bigg/ \prod_{i=1}^d h'_i \\ &= \frac{1}{1-\varepsilon} \prod_{i \in L} \frac{1}{s_i h'_i} > \frac{1}{1-\varepsilon} \prod_{i \in L} \frac{s_i + 1}{s_i + M^2 \delta}. \end{aligned}$$

As δ tends to zero, this bound approaches the inverse of the number in Claim 6. This means that the total weight of items in a closed bin is no smaller than 1. \square

Just like in section 2, Lemma 3.1 implies that the asymptotic worst case ratio is upper bounded by the maximum amount of weight that can be packed in a single bin. After the following definition, we prove a technical lemma which implies that this weighting function is also “optimal” in that it determines the true asymptotic performance ratio of our algorithm.

DEFINITION 3.2. *The pseudovolume of a hyperbox $h = (h_1, \dots, h_d)$ is defined as $\prod_{i \notin L} h_i$, where L is the set of large components of h .*

Suppose that for a given set of hyperboxes X , we can partition the dimensions into two sets, S and T , such that for each dimension j in S , we have that the j th components of all hyperboxes in X are bounded in an interval $(1/(k_j + 1), 1/k_j]$. There are no restrictions on the dimensions in T . (Thus such a partition can always be found by taking $S = \emptyset$.)

For a hyperbox $h \in X$, define the *generalized pseudovolume* of the components in T by $\tilde{v}(h, T) = \prod_{j \in T} h_j$, where h_j is the j th component of h . Define the total generalized pseudovolume of all hyperboxes in a set X by $\tilde{v}(X, T) = \sum_{h \in X} \tilde{v}(h, T)$.

CLAIM 7. *For a given set X of hyperboxes, for sufficiently large N , any packing of X into bins requires at least $\tilde{v}(X, T)(1 - \frac{1}{N})^{|T|} / \prod_{i \in S} k_i$ bins, where S and T form a partitioning of the dimensions as described above.*

Proof. We prove the claim by induction on the number of dimensions in T . For $|T| = 0$, we find that the total generalized pseudovolume of X is simply the number of hyperboxes in X (since the empty product is 1) and thus the claim is true using Claim 4.

Assume the claim is true for $|T| = 0, \dots, r - 1$. Suppose $|S| = d - r < d$. Take any dimension $i \in T$. We replace each hyperbox h , with component h_i in dimension i , by $\lfloor N^2 h_i \rfloor$ hyperboxes that have $\frac{1}{N^2}$ as their i th component, and are identical to h in all other components. Here N is taken sufficiently large, such that $\frac{1}{N} < h_i$. Clearly, the new input X' is no harder to pack, as we split each item into parts whose sum is smaller than or equal to the original items. The total generalized pseudovolume of the hypercubes in X' is at most a factor of $1 - \frac{1}{N^2 h_i} \geq 1 - \frac{1}{N}$ smaller than that of X . So if we write $T' = T \setminus \{i\}$, we have $\tilde{v}(X', T') \cdot \frac{1}{N^2} \geq \tilde{v}(X, T)(1 - \frac{1}{N})$. By induction, it takes at least

$$\tilde{v}(X', T') \cdot \left(1 - \frac{1}{N}\right)^{r-1} / \prod_{j \in S \cup \{i\}} k_j$$

bins to pack the modified input X' . Using that $k_i = N^2$, this is $\tilde{v}(X, T) \cdot (1 - \frac{1}{N})^r / \prod_{j \in S} k_j$ bins. \square

Letting $\gamma = 1 - (1 - \frac{1}{N})^d$, we get that the required number is at least $\tilde{v}(X, T)(1 - \gamma) / \prod_{j \in S} k_j$ bins, where $\gamma \rightarrow 0$ as $N \rightarrow \infty$. In the remainder, we will take S to be the dimensions where the components of the hyperboxes in X are large, and T the

dimensions where they are small. Note that this choice of S satisfies the constraints on S above, and that this reduces the generalized pseudovolume to the (normal) pseudovolume defined before. We are ready to prove the following lemma.

LEMMA 3.3. *Let $\varepsilon > 0$. Suppose the maximum amount of weight that can be packed in a single bin is α_ε . Then our algorithm has an asymptotic performance ratio of α_ε , and the asymptotic performance ratio of any bounded space algorithm is at least $(1 - \varepsilon)\alpha_\varepsilon$.*

Proof. The first statement follows from Lemma 3.1. We show a lower bound of value which tends to α_ε on the asymptotic performance ratio of any bounded space algorithm.

Consider a packed bin for which the sum of weights is α_ε . Partition the hyperboxes of this bin into M^d types in the following way. Each component is either of a type in $\{1, \dots, M - 1\}$ or small (i.e., of a type i , $i \leq M$). Let N' be a large constant. The sequence consists of phases. Each phase consists of one item from the packed bin, repeated N' times. The optimal offline cost is therefore N' . Using Claim 7 we see that the amount of bins needed to pack a phase which consists of an item p repeated N' times is simply $N'w_\varepsilon(p)(1 - \gamma)(1 - \varepsilon)$. Therefore the cost of an online algorithm is at least $N'\alpha_\varepsilon(1 - \gamma)(1 - \varepsilon) - O(1)$, which makes the asymptotic performance ratio arbitrarily close to $(1 - \varepsilon)\alpha_\varepsilon$. \square

Furthermore, we can determine the asymptotic performance ratio of our algorithm for hyperbox packing. Comparing to the unbounded space algorithm in [11] we can see that all the weights we defined are smaller than or equal to the weights used in [11]. So the asymptotic performance ratio is not higher. However, it can also not be lower due to the general lower bound for bounded space algorithms. This means that both algorithms have the same asymptotic performance ratio, namely $(\Pi_\infty)^d$, where $\Pi_\infty \approx 1.691$ is the asymptotic performance ratio of the algorithm HARMONIC [25].

4. Variable-sized packing. In this section we consider the problem of multi-dimensional packing where the bins used can have different sizes. We assume that all bins are hypercubes, with sides $\alpha_1 < \alpha_2 < \dots < \alpha_m = 1$. In fact our algorithm is more general and works for the case where the bins are hyperboxes with dimensions α_{ij} ($i = 1, \dots, m$, $j = 1, \dots, d$). We present the special case of bins that are hypercubes in this paper in order to avoid an overburdened notation and messy technical details.

The main structure of the algorithm is identical to the one in section 3. The main problem in adapting that algorithm to the current problem is selecting the right bin size to pack the items in. In the one-dimensional variable-sized bin packing problem, it is easy to see which bin will accommodate any given item the best; here it is not so obvious how to select the right bin size, since in one dimension a bin of a certain size might seem best whereas for other dimensions, other bins seem more appropriate.

We begin by defining types for hyperboxes based on their components and the available bin sizes. Once again we use a parameter ε . The value of M as a function of ε is again picked so that $M \geq 1/(1 - (1 - \varepsilon)^{1/(d+2)}) - 1$. An arriving hyperbox h of dimensions (h_1, h_2, \dots, h_d) is classified as one of at most $(2mM/\alpha_1 - 1)^d$ types depending on its components: a type of a hyperbox is the vector of the types of its components. We define

$$T_i = \left\{ \frac{\alpha_i}{j} \mid j \in \mathbb{N}, \frac{\alpha_i}{j} \geq \frac{\alpha_1}{2M} \right\}, \quad T = \bigcup_{i=1}^m T_i.$$

Let the members of T be $1 = t_1 > t_2 > \dots > t_{q'} = \alpha_1/M > \dots > t_q = \alpha_1/(2M)$.

The interval I_j is defined to be $(t_{j+1}, t_j]$ for $j = 1, \dots, q'$. Note that these intervals are disjoint and they cover $(\alpha_1/M, 1]$.

A component larger than α_1/M has type i if $h_i \in I_i$, and is called large. A component smaller than α_1/M has type i , where $q' \leq i \leq q - 1$, if there exists a non-negative integer f_i such that $t_{i+1} < 2^{f_i} h_i \leq t_i$. Such components are called small. Thus in total there are $q - 1 \leq 2mM/\alpha_1 - 1$ component types.

Bin selection. We now describe how to select a bin for a given type. Intuitively, the size of this bin is chosen in order to maximize the number of items packed relative to the area used. This is done as follows.

For a given component type s_i and bin size α_j , write $F(s_i, \alpha_j) = \max\{k \mid \alpha_j/k \geq t_{s_i}\}$. Thus for a large component, $F(s_i, \alpha_j)$ is the number of times that a component of type s_i fits in an interval of length α_j . This number is uniquely defined due to the definition of the numbers t_i . Basically, the general classification into types is too fine for any particular bin size, and we use $F(s_i, \alpha_j)$ to get a less refined classification which only considers the points t_i of the form α_j/k .

Denote by L the set of components in type $s = (s_1, \dots, s_d)$ that are large. If $L = \emptyset$, we use a bin of size 1 for this type. Otherwise, we place this type in a bin of any size α_j which maximizes¹

$$(2) \quad \prod_{i \in L} \frac{F(s_i, \alpha_j)}{\alpha_j}.$$

Thus we do not take small components into account in this formula. Note that for a small component, $F(s_i, \alpha_j)$ is not necessarily the same as the number of times that such a component fits into any interval of length α_j . However, it is at least M for any small component.

When such a bin is opened, it is split into $\prod_{i=1}^d F(s_i, \alpha_j)$ identical sub-bins of dimensions $(\alpha_j/F(s_1, \alpha_j), \dots, \alpha_j/F(s_d, \alpha_j))$. These bins are then further sub-divided into sub-bins in order to place hyperboxes in “well-fitting” sub-bins in the manner which is described in section 3.

Similar to in section 3, the following claim can now be shown.

CLAIM 8. *The occupied volume in each closed bin of type $s = (s_1, \dots, s_d)$ is at least*

$$V_{s,j} = (1 - \varepsilon) \alpha_j^d \prod_{i \in L} \frac{F(s_i, \alpha_j)}{F(s_i, \alpha_j) + 1},$$

where L is the set of large components in this type and α_j is the bin size used to pack this type.

We now define a weighting function for our algorithm. The weight of a hyperbox h with components (h_1, \dots, h_d) and type $s = (s_1, \dots, s_d)$ is defined as

$$w_\varepsilon(h) = \frac{1}{1 - \varepsilon} \left(\prod_{i \notin L} h_i \right) \left(\prod_{i \in L} \frac{\alpha_j}{F(s_i, \alpha_j)} \right),$$

where L is the set of large components in this type and α_j is the size of bins used to pack this type.

¹For the case that the bins are hyperboxes instead of hypercubes, we get the formula $\prod_{i \in L} (F(s_i, \alpha_{ij})/\alpha_{ij})$, and similar changes throughout the text.

In order to prove that this weighting function works (gives a valid upper bound for the cost of our algorithm), we will want to modify components s_i to the smallest possible component such that $F(s_i, \alpha_j)$ does not change. (Basically, a component will be rounded to $\alpha_j/(F(s_i, \alpha_j) + 1)$ plus a small constant.) However, with variable-sized bins, when we modify components in this way, the algorithm might decide to pack the new hyperbox differently. (Remember that $F(s_i, \alpha_j)$ is a “less refined” classification which does not take other bin sizes than α_j into account.) To circumvent this technical difficulty, we will show first that as long as the algorithm keeps using the same bin size for a given item, the volume guarantee still holds.

For a given type $s = (s_1, \dots, s_d)$ and the corresponding set L and bin size α_j , define an *extended type* $\text{Ext}(s_1, \dots, s_d)$ as follows: an item h is of extended type $\text{Ext}(s_1, \dots, s_d)$ if each large component $h_i \in (\frac{\alpha_j}{F(s_i, \alpha_j)+1}, \frac{\alpha_j}{F(s_i, \alpha_j)}]$ and each small component h_i is of type s_i .

COROLLARY 4.1. *Suppose items of extended type $\text{Ext}(s_1, \dots, s_d)$ are packed into bins of size α_j . Then the occupied volume in each closed bin is at least $V_{s,j}$.*

Proof. In the proof of Claim 8, we only use that each large component h_i is contained in the interval $(\frac{\alpha_j}{F(s_i, \alpha_j)+1}, \frac{\alpha_j}{F(s_i, \alpha_j)}]$. Thus the proof also works for extended types. \square

LEMMA 4.2. *For all input sequences σ , $\text{cost}_{\text{alg}}(\sigma) \leq \sum_{h \in \sigma} w_\varepsilon(h) + O(1)$.*

Proof. In order to prove the claim, it is sufficient to show that each closed bin of size α_j contains items of total weight of at least α_j^d . Consider a bin of this size filled with hyperboxes of type $s = (s_1, \dots, s_d)$. It is sufficient to consider the subsequence σ of the input that contains only items of this type, since all types are packed independently. This subsequence only uses bins of size α_j so we may assume that *no other sizes of bins are given*. We build an input σ' for which both the behavior of the algorithm and the weights are the same as for σ and show the claim holds for σ' . Let $\delta < 1/M^3$ be a very small constant.

For a hyperbox $h \in \sigma$ with components (h_1, \dots, h_d) and type $s = (s_1, \dots, s_d)$, let $h' = (h'_1, \dots, h'_d) \in \sigma'$ be defined as follows. For $i \notin L$, $h'_i = h_i$. For $i \in L$, $h'_i = \alpha_j/(F(s_i, \alpha_j) + 1) + \delta < \alpha_j/F(s_i, \alpha_j)$.

Note that h' is of extended type $\text{Ext}(s_1, \dots, s_d)$. Since only one bin size is given, the algorithm packs σ' in the same way as it packs σ . Moreover, according to the definition of weight above, h and h' have the same weight.

Let $v(h)$ denote the volume of an item h . For $h \in \sigma$, we compute the ratio of weight and volume of the item h' . We have

$$\begin{aligned} \frac{w_\varepsilon(h')}{v(h')} &= \frac{w_\varepsilon(h)}{v(h')} = \frac{1}{1-\varepsilon} \left(\prod_{i \notin L} h'_i \right) \left(\prod_{i \in L} \frac{\alpha_j}{F(s_i, \alpha_j)} \right) \Big/ \prod_{i=1}^d h'_i \\ &= \frac{1}{1-\varepsilon} \prod_{i \in L} \frac{\alpha_j}{F(s_i, \alpha_j)h'_i} > \frac{1}{1-\varepsilon} \prod_{i \in L} \frac{F(s_i, \alpha_j) + 1}{F(s_i, \alpha_j) + M \frac{\alpha_j}{\alpha_1} \delta}. \end{aligned}$$

Here we have used in the last step that a component with a large type fits less than M times in a (one-dimensional) bin of size α_1 , and therefore less than $M \frac{\alpha_j}{\alpha_1}$ times in a bin of size $\alpha_j \geq \alpha_1$. As δ tends to zero, this bound approaches $\alpha_j^d/V_{s,j}$. We find

$$w_\varepsilon(h) \geq \alpha_j^d \frac{v(h')}{V_{s,j}} \quad \text{for all } h \in \sigma.$$

Then Corollary 4.1 implies that the total weight of items in a closed bin of size α_j is no smaller than α_j^d , which is the cost of such a bin. \square

Suppose the optimal solution for a given input sequence σ uses n_j bins of size α_j . Denote the i th bin of size α_j by $B_{i,j}$. Then

$$\frac{\sum_{h \in \sigma} w_\varepsilon(h)}{\sum_{j=1}^m \alpha_j^d n_j} = \frac{\sum_{j=1}^m \sum_{i=1}^{n_j} \sum_{h \in B_{i,j}} w_\varepsilon(h)}{\sum_{j=1}^m \alpha_j^d n_j} = \frac{\sum_{j=1}^m \sum_{i=1}^{n_j} \sum_{h \in B_{i,j}} w_\varepsilon(h)}{\sum_{j=1}^m \sum_{i=1}^{n_j} \alpha_j^d}.$$

This implies that the asymptotic worst case ratio is upper bounded by

$$(3) \quad \max_j \max_{X_j} \sum_{h \in X_j} w_\varepsilon(h) / \alpha_j^d,$$

where the second maximum is taken over all sets X_j that can be packed in a bin of size α_j . Similar to section 3, it can now be shown that this weighting function is also “optimal” in that it determines the true asymptotic performance ratio of our algorithm.

In particular, it can be shown that packing a set of hyperboxes X that have the same type vectors of large and small dimensions takes at least

$$\sum_{h \in X} \prod_{i \notin L} \frac{h_i}{\alpha_j} \bigg/ \prod_{i \in L} F(s_i, \alpha_j)$$

bins of size α_j , where h_i is the i th component of hyperbox h , s_i is the type of the i th component, and L is the set of large components (for all the hyperboxes in X). Since the cost of such a bin is α_j^d , this means that the total cost to pack N' copies of some item h is at least $N'w_\varepsilon(h)(1 - \varepsilon)$ when bins of this size are used. However, it is clear that using bins of another size α_k does not help: packing N' copies of h into such bins would give a total cost of

$$N' \left(\prod_{i \notin L} h_i \right) \left(\prod_{i \in L} \frac{\alpha_k}{F(s_i, \alpha_k)} \right).$$

Since α_j was chosen to maximize $\prod_{i \in L} (F(s_i, \alpha_j) / \alpha_j)$, this expression cannot be less than $N'w_\varepsilon(h)(1 - \varepsilon)$. More precisely, any bins that are not of size α_j can be replaced by the appropriate number of bins of size α_j without increasing the total cost by more than 1 (it can increase by 1 due to rounding).

This implies that our algorithm is optimal among online bounded space algorithms.

5. Resource augmented packing. The resource augmented problem is now relatively simple to solve. In this case, the online algorithm has bins at its disposal that are hypercubes of dimensions $b_1 \times b_2 \times \dots \times b_d$. We can use the algorithm from section 3 with the following modification: the types for dimension j are not based on intervals of the form $(1/(i + 1), 1/i]$ but rather intervals of the form $(b_j/(i + 1), b_j/i]$.

Then, to pack items of type $s = (s_1, \dots, s_d)$, a bin is split into $\prod_{i=1}^d s_i$ identical sub-bins of dimensions $(b_1/s_1, \dots, b_d/s_d)$, and then subdivided further as necessary.

We now find that each closed bin of type $s = (s_1, \dots, s_d)$ is full by at least

$$(1 - \varepsilon)B \prod_{i \in L} \frac{s_i}{s_i + 1},$$

where L is the set of large components in this type, and $B = \prod_{j=1}^d b_j$ is the volume of the bins of the online algorithm.

We now define the weight of a hyperbox h with components (h_1, \dots, h_d) and type $s = (s_1, \dots, s_d)$ as

$$w_\varepsilon(h) = \frac{1}{1 - \varepsilon} \left(\prod_{i \notin L} \frac{h_i}{b_i} \right) \left(\prod_{i \in L} \frac{1}{s_i} \right),$$

where L is the set of large components in this type.

This can be shown to be valid similarly as before, and it can also be shown that items cannot be packed better. However, in this case we are additionally able to give explicit bounds for the asymptotic performance ratio.

5.1. The asymptotic performance ratio. Csirik and Woeginger [13] showed the following for the one-dimensional case.

For a given bin size b , define an infinite sequence $T(b) = \{t_1, t_2, \dots\}$ of positive integers as follows:

$$t_1 = \lfloor 1 + b \rfloor \quad \text{and} \quad r_1 = \frac{1}{b} - \frac{1}{t_1},$$

and for $i = 1, 2, \dots$, let

$$t_{i+1} = \left\lfloor 1 + \frac{1}{r_i} \right\rfloor \quad \text{and} \quad r_{i+1} = r_i - \frac{1}{t_{i+1}}.$$

Define

$$\rho(b) = \sum_{i=1}^{\infty} \frac{1}{t_i - 1}.$$

LEMMA 5.1. *For every bin size $b \geq 1$, there exist online bounded space bin packing algorithms with worst case performance arbitrarily close to $\rho(b)$. For every bin size $b \geq 1$, the bound $\rho(b)$ cannot be beaten by any online bounded space bin packing algorithm.*

The following lemma was proved in Csirik and Van Vliet [11] for a specific weighting function which is independent of the dimension, and is similar to a result of Li and Cheng [26]. However, the proof holds for any positive one-dimensional weighting function w . We extend it for the case where the weighting function depends on the dimension. For a one-dimensional weighting function w_j and an input sequence σ , define $w_j(\sigma) = \sum_{h \in \sigma} w_j(h)$. Furthermore, define $W_j = \sup_{\sigma} w_j(\sigma)$, where the supremum is taken over all sequences that can be packed into a one-dimensional bin.

LEMMA 5.2. *Let σ be a list of d -dimensional rectangles, and let Q be a packing which packs these rectangles into a d -dimensional unit cube. Let w_j ($j = 1, \dots, d$) be arbitrary one-dimensional weighting functions. For each $h \in \sigma$, we define a new hyperbox h' as follows: $s_j(h') = w_j(s_j(h))$ for $1 \leq j \leq d$. Denote the resulting list of hyperboxes by σ' . Then, there exists a packing Q' which packs σ' into a cube of size (W_1, \dots, W_d) .*

Proof. We use a construction analogous to the one in [11]. We transform the packing $Q = Q^0$ of σ into a packing Q^d of σ' in a cube of the desired dimensions. This is done in d steps, one for each dimension. Denote the coordinates of item h in packing Q^i by $(x_1^i(h), \dots, x_d^i(h))$, and its dimensions by $(s_1^i(h), \dots, s_d^i(h))$.

In step i , the coordinates as well as the sizes in dimension i are adjusted as follows. First, we adjust the sizes and set $s_i^i(h) = w_i(s_i(h))$ for every item h , leaving other dimensions unchanged.

To adjust coordinates, for each item h in packing Q^{i-1} we find the “left-touching” items, which is the set of items g which overlap with h in $d-1$ dimensions, and for which $x_i^{i-1}(g) + s_i^{i-1}(g) = x_i^{i-1}(h)$. We may assume that for each item h , there is either a left-touching item or $x_i^{i-1}(h) = 0$.

Then, for each item h that has no left-touching items, we set $x_i^i(h) = 0$. For all other items h , starting with the ones with smallest i -coordinate, we make the i -coordinate equal to $\max(x_i^i(g) + s_i^i(g))$, where the maximum is taken over the left-touching items of h in packing S^{i-1} . Note that we use the new coordinates and sizes of left-touching items in this construction and that this creates a packing without overlap.

If in any step i the items need more than W_i room, this implies a chain of left-touching items with total size less than 1 but total weight more than W_i . From this we can find a set of one-dimensional items that fit in a bin but have total weight more than W_i (using weighting function w_i), which is a contradiction. \square

As in [11], this implies immediately that the total weight that can be packed into a unit-sized bin is upper bounded by $\prod_{i=1}^d W_i$, which in the present case is $\prod_{i=1}^d \rho(b_i)$. Moreover, by extending the lower bound from [13] to d dimensions exactly as in [11], it can be seen that the asymptotic performance ratio of any online bounded space bin packing algorithm can also not be lower than $\prod_{i=1}^d \rho(b_i)$.

6. Conclusions. An open question left by this paper is what the asymptotic performance ratio of the bounded space hypercube packing problem is. We can show that it is $\Omega(\log d)$, and we conjecture that it is $\Theta(\log d)$. Giving an explicit expression for the competitive ratio in variable-sized packing (as a function of the bin sizes) would be harder. Already in [30] where an optimal one-dimensional bounded space algorithm was given for the variable-sized problem, its ratio is unknown. It is interesting to find out whether in the multidimensional case the worst case occurs when only unit sized bins are available.

STRICTLY NONBLOCKING WDM CROSS-CONNECTS*

APRIL RASALA[†] AND GORDON WILFONG[‡]

Abstract. Using wavelength division multiplexing (WDM) technology, an optical network can route multiple signals simultaneously along a single optical fiber by encoding each signal on its own wavelength. If the network contains places where multiple fibers connect together and signals are allowed to be moved from any of the incoming fibers to any of the outgoing fibers, then the network is said to contain *cross-connects*. More precisely, a $k_1 \times k_2$ WDM *cross-connect* has k_1 input fibers and k_2 output fibers. Each of the k_1 input fibers supports the same n_1 input wavelengths and each of the k_2 output fibers supports the same n_2 output wavelengths. Since a signal on input wavelength λ can be routed from its input fiber to an output fiber such that it arrives on the output fiber using wavelength γ , where $\lambda \neq \gamma$, the cross-connect must be capable of performing wavelength conversion. Along any fiber in the cross-connect a device called a *wavelength interchanger* can be inserted to perform wavelength conversion. In other words if the path of a signal from an input fiber to an output fiber passes through a wavelength interchanger, then the wavelength of the signal can be changed to any wavelength that is not already in use along the fiber leaving the wavelength interchanger. Given the high cost of wavelength interchangers, the overall cost of a $k_1 \times k_2$ WDM cross-connect is minimized by reducing the number of wavelength interchangers in the cross-connect. However, a desirable property for a cross-connect C is for C to always be able to provide a route (and wavelength conversion) for any valid demand from any pair of input and output fibers regardless of the routes of other demands currently routed in C . If C has this capability then it is said to be *strictly nonblocking*.

For most of this paper we consider a demand to be a request for a connection from an input fiber to an output fiber such that the connection starts on a specified input wavelength and leaves the cross-connect on a second specified wavelength. Using this demand model, we consider cross-connects for which k_1 is not necessarily equal to k_2 and the number n_1 of supported input wavelengths can differ from the number n_2 of supported output wavelengths. Without loss of generality we assume that $k_1 \leq k_2$ and present a family of strictly nonblocking $k_1 \times k_2$ WDM cross-connects that use $\min(k_1 + k_2 - 1, n_1 k_1)$ wavelength interchangers. For the case when $k_1 = k_2 = k$ and $n_1 = n_2$, we prove that this is optimal. For cross-connects where n_1 is not necessarily equal to n_2 , we show that if there is at most one wavelength interchanger on any path from an input fiber to an output fiber, $\min(k_1 + k_2 - 1, n_1 k_1)$ wavelength interchangers are optimal. Finally, we consider a more flexible demand model where $k_1 = k_2$ but the input and output wavelengths are not specified as part of the demand. We show that $2k - 1$ wavelength interchangers are still necessary for any strictly nonblocking $k \times k$ WDM cross-connect.

Key words. optical networking, cross-connect, wavelength division multiplexing, strictly non-blocking

DOI. 10.1137/S0097539703434255

1. Introduction. We present designs of cross-connects for optical networks supporting wavelength division multiplexing. We prove that our designs use only the minimum number of an expensive device, known as a wavelength interchanger, and thus are optimal in terms of the cost of the cross-connect.

A fiber in an optical network supporting wavelength division multiplexing (WDM) can carry multiple signals simultaneously if each signal is encoded on a distinct wave-

length. In order to fully exploit the benefits of WDM technology, it is useful to be able to switch a signal from one wavelength to another when the signal switches to a new fiber. A $k_1 \times k_2$ WDM cross-connect has k_1 input fibers and k_2 output fibers and allows signals from the input fibers to be moved to available wavelengths on the output fibers. Specifically, a *demand* on the cross-connect specifies an input fiber, an input wavelength, an output fiber and an output wavelength. If the input wavelength is unused on the input fiber and the output wavelength is unused on the output fiber, then the cross-connect should be able to route the signal from the input fiber to the output fiber *and* change the encoding of the signal from the input wavelength to the output wavelength. A WDM cross-connect must maintain current connections (the results of previous demands placed on it) and at the same time satisfy new requests for connections between input fibers and output fibers. A *strictly nonblocking* cross-connect C is guaranteed to be able to route any new demand placed on it regardless of the set of existing connections routed through C .

A cross-connect contains various optical devices and optical fibers. A wavelength interchanger is an optical device with a single input fiber and a single output fiber. Any of the signals entering the wavelength interchanger on any of the supported wavelengths can be changed to any of the supported wavelengths on the fiber leaving the wavelength interchanger provided those wavelengths are not already in use by another connection. Given the high cost of wavelength interchangers now and in the foreseeable future [13], the cost of a strictly nonblocking WDM cross-connect is dominated by the number of wavelength interchangers required in the design. Thus we focus our attention on determining the optimal number of wavelength interchangers needed in any strictly nonblocking $k_1 \times k_2$ WDM cross-connect and on presenting a family of strictly nonblocking $k_1 \times k_2$ WDM cross-connects that use the optimal number of wavelength interchangers.

The task of optimizing strictly nonblocking WDM cross-connects is simplified by drawing from work on classical cross-connects. In classical cross-connects, signals do not share wires and therefore there is no need for wavelength conversion. Of course, one can view time slots in a time division multiplexing (TDM) network as equivalent to a WDM network but time slot interchange is an inexpensive operation as opposed to wavelength interchange in a WDM network. A vast amount of literature exists on the design of such cross-connects [4, 8, 12, 1, 7]. In particular, work has been done on the optimization of strictly nonblocking classical cross-connects that guarantee that a connection can always be made between any input line and any output line provided neither are already in use. The topology of a strictly nonblocking classical cross-connect can be used as the topology of a WDM network. In this case we assume that the WDM network supports n wavelength and does not allow any wavelength conversion. Since the WDM network has the topology of a classical network and does not support wavelength conversion, it is conceptually equivalent to n copies, one for each wavelength, of the classical network. Furthermore, since the WDM network has the topology of a strictly nonblocking classical cross-connect, any connection on any wavelength can be completed as long as the requesting input and output fibers do not already have an existing connection on that wavelength. We refer to a section of directed fiber and optical devices without wavelength conversion capability as a *fabric*.

The designs of strictly nonblocking WDM cross-connects presented in this paper use the topology of classical strictly nonblocking cross-connects as the basis for fabrics that connect the input fibers to a set of wavelength interchangers and connect those wavelength interchangers to the set of output fibers. Such a design is referred to

as a split cross-connect. For the case where the number of input fibers, k , is equal to the number of output fibers and the set of input wavelengths is the same as the set of output wavelengths, we present split cross-connects with $2k - 1$ wavelength interchangers and prove that these designs are optimal. We also consider general split cross-connects where the number of input fibers, k_1 , and the number of input wavelengths, n_1 , may differ from the number of output fibers, k_2 , and the number of output wavelengths, n_2 . In this case we present designs of strictly nonblocking split cross-connects that use $\min(k_1 + k_2 - 1, n_1 k_1)$ wavelength interchangers. We show that this is optimal for the class of split cross-connects. However, we leave as an open question whether the family of split cross-connects are optimal if the number of input fibers is not equal to the number of output fibers and the set of supported input wavelengths differs from the set of supported output wavelengths.

2. Definitions.

2.1. Wavelength division multiplexing. WDM technology allows multiple signals to be routed along an optical fiber simultaneously by encoding each signal on its own wavelength. For example, a WDM network might allow each fiber to carry up to n signals simultaneously by giving each signal its own wavelength out of a set of n supported wavelengths. Devices crucial to such networks are *optical switches*. An optical switch has an arbitrary number of input fibers and output fibers, and any signal encoded on any wavelength on any of the input fibers can be routed to the same wavelength on any of the outgoing fibers. If these are the only devices included in an optical network, then a connection that is originally routed on a particular wavelength, say λ , must stay on that wavelength for its entire route. Even in simple networks this can result in congestion of the network even when no single fiber is carrying all n signals [6, 14]. Therefore it is often desirable to allow the wavelength of a connection to be changed. A *wavelength interchanger* is a device that has a single input fiber and a single output fiber. A wavelength interchanger can change the wavelength of any subset of the signals entering it provided the wavelengths that it encodes those signals on are unused on its output fiber; see Figure 1.

FIG. 1. A wavelength interchanger W with four signals passing through it. The signals on input wavelengths λ_1 , λ_2 , λ_3 , and λ_4 are changed to output wavelengths γ_1 , γ_2 , γ_3 , and γ_4 , respectively.

2.2. WDM cross-connects. In a WDM network, fibers join at various places, and signals on the incoming fibers can be routed to the outgoing fibers. The part of the network that allows this routing of signals from some set of incoming fibers to a set of outgoing fibers is referred to as a WDM *cross-connect*. A $k_1 \times k_2$ WDM cross-connect has k_1 input fibers and k_2 output fibers. We define $I = \{I_1, \dots, I_{k_1}\}$

to be the set of input fibers and $O = \{O_1, \dots, O_{k_2}\}$ to be the set of output fibers. The set of n_1 wavelengths, $\{\lambda_1, \dots, \lambda_{n_1}\}$, supported on each of the k_1 input fibers is referred to as the set of *input wavelengths* and similarly the set of *output wavelengths* is the set of n_2 wavelengths, $\{\gamma_1, \dots, \gamma_{n_2}\}$ supported on each of the output fibers. Without loss of generality we assume that $k_1 \leq k_2$ and $n_1, n_2 \geq 2$.

In general, a demand on a WDM cross-connect could be specified in various ways. For this paper we define a *demand* $d = (I_x, \lambda_y, O_z, \gamma_w)$ to be a request for a path and an assignment of wavelengths along the path from input fiber I_x to output fiber O_z such that the connection starts on input wavelength λ_y , changes wavelength only at a wavelength interchanger, and ends on output wavelength γ_w . Such a path and wavelength assignment is called a *route*. A routing R of D is a collection of routes, one for each demand $d \in D$, such that no two demands are assigned the same wavelength along a shared section of fiber. We will show that for some classes of cross-connects, this demand and route model is equivalent to models in which a demand does not specify the input and/or the output wavelength and a route is allowed to use any wavelengths available on the specified input and output fibers. We leave as an open question whether more flexible demand models allow for improved results for other types of cross-connects.

Given an existing set of demands, D , we say demand $d = (I_x, \lambda_y, O_z, \gamma_w)$ is *valid* with respect to D if input wavelength λ_y is unused on input fiber I_x by all demands in D and output wavelength γ_w is unused on output fiber O_z by all demands in D . A route r for d is *valid* with respect to a routing R of D if the wavelength assigned to d along each fiber in r is not used by any other connection currently routed on the fiber according to R .

2.3. Nonblocking properties. Ideally a cross-connect will always be able to satisfy a valid demand with a valid route. Depending on various assumptions, a number of different levels of *nonblocking* have been defined as follows.

- **Rearrangeably nonblocking:** A cross-connect is *rearrangeably nonblocking* if any new valid demand can be assigned a valid route provided that routes for already existing demands are allowed to be rerouted.
- **Wide-sense nonblocking:** A cross-connect is *wide-sense nonblocking* if any new valid demand can be assigned a route by an algorithm A provided that all currently routed demands were routed using A .
- **Strictly nonblocking:** A cross-connect is *strictly nonblocking* if any new valid demand can be assigned a route regardless of the routes assigned to any currently routed demands.

Strictly nonblocking and wide-sense nonblocking cross-connects have many advantages over rearrangeably nonblocking cross-connects. For example, a rearrangeably nonblocking cross-connect will create a buffering problem when it must interrupt currently routed connections to reroute them. While both strictly nonblocking and wide-sense nonblocking cross-connects avoid this buffering problem, a strictly nonblocking cross-connect is perhaps more robust since it does not depend upon having taken care to route previously requested demands in order to guarantee a route for any new demands. This is particularly desirable in practice because often hardware failures necessitate that some routes are chosen without regard to a particular algorithm. A wide-sense nonblocking cross-connect might require that all routes are rerouted after such a hardware failure. In contrast, since a strictly nonblocking cross-connect does not depend on the cross-connect having routed existed demands carefully, it is capable of handling situations where the set of existing routes may have been chosen to work

around a hardware failure without regard for how they utilize the resources inside the cross-connect. We focus our attention on the design of strictly nonblocking $k_1 \times k_2$ WDM cross-connects but note that the design of optimal wide-sense nonblocking cross-connects would also be of interest.

2.4. Topologies of cross-connects.

2.4.1. Split cross-connects. A *fabric* is defined to be a subnetwork that does not contain any wavelength interchangers. A $k_1 \times k_2$ WDM cross-connect is said to be a *split cross-connect* if it has k_1 input fibers connected to a fabric, F_1 , and k_2 output fibers connected to a second fabric, F_2 . Furthermore, the output fibers of F_1 are the input fibers for a set W of wavelength interchangers and the output fibers for the set W of wavelength interchangers are the input fibers of the fabric F_2 . Another way to say this is to say that C is a split cross-connect if every path from an input fiber to an output fiber through C passes through exactly one wavelength interchanger; see Figure 2.

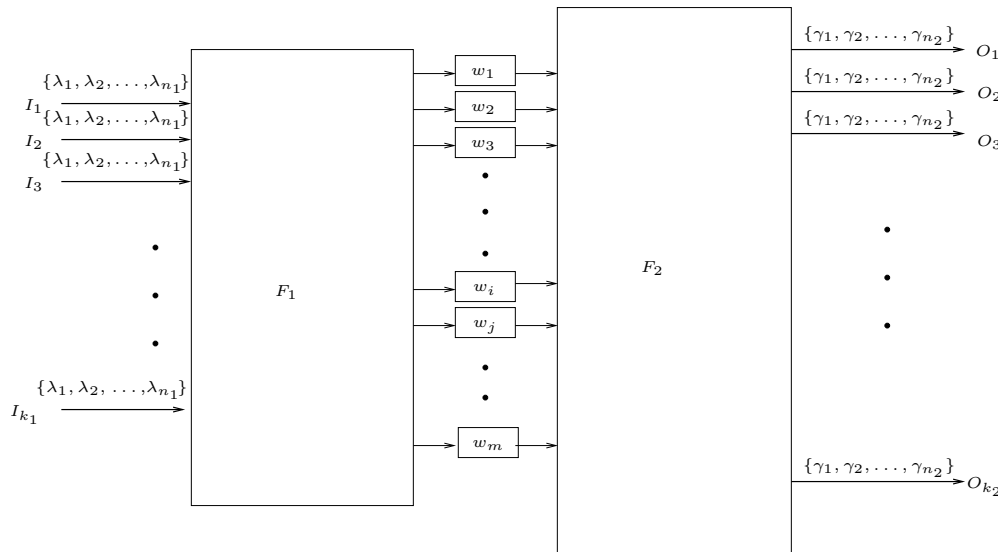

FIG. 2. A $k_1 \times k_2$ WDM split cross-connect with m wavelength interchangers. The set of k_1 input fibers is connected to the m wavelength interchangers with a fabric F_1 . The set of m wavelength interchangers is connected to the k_2 output fibers with a fabric F_2 .

The designs for strictly nonblocking cross-connects that we present are all split cross-connects. We will prove that in the case where the number of input and output fibers is the same, this is optimal. Note that without loss of generality we will overload the definition of split and allow it to also refer to any cross-connect for which every path p from any input fiber to any output fiber has *at most* one wavelength interchanger.

2.4.2. Homogeneous and heterogeneous cross-connects. We consider cross-connects for two different situations. The first situation involves cross-connects that have the same number of input fibers as output fibers. In these cross-connects the same set of input and output wavelengths are supported throughout the cross-connect. We call such cross-connects *homogeneous* cross-connects.

In the second case, the purpose of the cross-connect is to connect a set of fibers from a given network to a set of fibers from another network. In this case the set of wavelengths supported on the input fibers may differ from the set of wavelengths supported on the output fibers. Also the number of input fibers may differ from the number of output fibers. We call such a cross-connect a *heterogeneous* cross-connect.

3. Previous results. This work draws both from the literature of classical cross-connects and from more recent work on WDM cross-connects.

A classical architecture considers the case where each input and output line carries only one signal at a time. Designs for cross-connects in classical networks have been well studied [3, 12, 8, 1, 2, 7]. In a classical network the optimization criterion is the number of edges in the graph representing the topology of the cross-connect. In contrast, in wavelength interchanging WDM cross-connects the optimality criterion is the number of wavelength interchangers.

In general the cost of a design of a WDM network is dominated by the number of wavelength interchangers needed in the network. Thus the problem of optimizing WDM networks has been studied in a model that assigns a cost of one to any node in the network where wavelength conversion capability is provided [14, 6].

Other work has focused on the possibility of using less powerful (and therefore less expensive) wavelength conversion devices. One example would be a device that was capable of swapping two wavelengths while leaving the others fixed. That work has considered what effect using such less powerful wavelength interchangers has on the number of wavelength interchangers needed in total [9].

Recently some work has been done on considering the cost of providing complete wavelength conversion capability in a WDM cross-connect. For instance, various wavelength interchanging WDM homogeneous cross-connects with a variety of nonblocking capabilities have been considered and in particular one design that used $k \log k$ wavelength interchangers was shown to be strictly nonblocking [13]. We will improve upon this result by presenting a design for a strictly nonblocking cross-connect with $2k - 1$ wavelength interchangers.

4. Our contribution. We will consider homogeneous and heterogeneous cross-connects. We present the design of a strictly nonblocking $k_1 \times k_2$ WDM cross-connect that uses $k_1 + k_2 - 1$ wavelength interchangers. We also present the design of strictly nonblocking $k_1 \times k_2$ WDM cross-connects that use $n_1 k_1$ wavelength interchangers. Together these provide a family of strictly nonblocking $k_1 \times k_2$ WDM cross-connects that use at most $\min(k_1 + k_2 - 1, n_1 k_1)$ wavelength interchangers.

When considering the optimality of these designs we handle the homogeneous and heterogeneous cases separately. We start our discussion of the optimal number of wavelength interchangers in a homogeneous cross-connect by showing that if there exists a family of optimal nonsplit cross-connects, then there exists a family of split cross-connects that use the same number of wavelength interchangers. This reduces the problem to a special case of showing that a heterogeneous $k \times k$ WDM split cross-connect requires $2k - 1$ wavelength interchangers. For the heterogeneous case we consider only split cross-connects and leave as an open question whether there exist strictly nonblocking nonsplit cross-connects with strictly fewer wavelength interchangers. We present a sequence of demands that requires that any strictly nonblocking $k_1 \times k_2$ WDM heterogeneous split cross-connect use at least $\min(k_1 + k_2 - 1, n_1 k_1)$ wavelength interchangers. These results together show that the family of strictly nonblocking $k_1 \times k_2$ WDM cross-connects presented in section 5 are optimal for homogeneous cross-connects and heterogeneous split cross-connects. Finally, we consider

more relaxed demand models where the input and output wavelengths are not specified as part of the demand. We show that even under this model of demands, $2k - 1$ wavelength interchangers are necessary and sufficient for homogeneous cross-connects. Preliminary versions of much of this work were presented in [11, 10].

4.1. Overview. In section 5 we present the design of a family of $k_1 \times k_2$ WDM cross-connects. We show that these are strictly nonblocking. For the case of homogeneous cross-connects we prove, in section 6, that if there is a family of optimal nonsplit cross-connects, then there is a family of optimal split cross-connects with the same number of wavelength interchangers. We then restrict our attention to cross-connects with split designs. We present a sequence of demands that shows that any homogeneous strictly nonblocking $k \times k$ WDM cross-connect must have $2k - 1$ wavelength interchangers. We then show that the lower bounds presented hold under demand models that do not specify the input and output wavelength as part of the demand. For the heterogeneous case we show, in section 7, that any strictly nonblocking $k_1 \times k_2$ WDM split cross-connect must have $\min(k_1 + k_2 - 1, n_1 k_1)$ wavelength interchangers. Finally, in section 8, we consider future work.

5. Designs for a family of strictly nonblocking cross-connects.

5.1. Traditional cross-connects. We start our discussion with a look at traditional cross-connect designs and how they apply to the design of WDM cross-connects. In a classical network, a *line* carried only one *channel* (wavelength) and therefore no two signals shared a line. A traditional strictly nonblocking $k_1 \times k_2$ cross-connect had k_1 input lines and k_2 output lines. A demand was a request for a connection from an input line to an output line. Note that in this setting at most one demand could use any particular input or output line at a given time. A route for a demand in a classical cross-connect was a path from the input line to the output line that was edge-disjoint from any existing route in the cross-connect. Therefore we say that the topology of a strictly nonblocking classical cross-connect is pathwise strictly nonblocking.

In the WDM setting we require that no two signals on the same wavelength share a fiber. Therefore if a WDM fabric has no wavelength conversion capability, then a demand will be a request for a connection on a specified wavelength from an input fiber to an output fiber. A route for such a demand is a path from the input fiber to the output fiber that is edge-disjoint (fiber-disjoint) from all other existing demands on the same wavelength. Therefore it is natural to extend the designs of classical cross-connects to WDM fabrics as follows.

Suppose we consider the topology of a classical cross-connect C . The topology of C can be represented by a graph, G , where the edges correspond to lines in C and the nodes correspond to components in C . We create a WDM fabric F from G by putting a WDM fiber in F , supporting n wavelengths, for each edge in G and a WDM switch in F for each node in G . Notice that since we have not placed any wavelength interchangers in F , a signal passing through F must stay on the same wavelength for its entire path through F . Furthermore, since signals on different wavelengths do not interfere with each other in WDM fabrics, one can conceptually think of F as allowing us to have n copies of C , one for each of the n wavelengths. Therefore if C was pathwise strictly nonblocking, then for each wavelength λ_i we are guaranteed that we can route a demand from input fiber a to output fiber b on wavelength λ_i as long as both a and b currently do not have a demand that uses wavelength λ_i .

A WDM fabric that is pathwise strictly nonblocking greatly simplifies the design of a strictly nonblocking WDM cross-connect and therefore we will make use of this

idea when presenting our designs.

5.2. Split cross-connects. We start with the design of a strictly nonblocking $k_1 \times k_2$ WDM split cross-connect. First, we connect the input fibers to a set of $k_1 + k_2 - 1$ wavelength interchangers with a fabric F_1 . The only restriction on F_1 is that it must have the topology of a pathwise strictly nonblocking $k_1 \times (k_1 + k_2 - 1)$ classical cross-connect. We then connect the set of $k_1 + k_2 - 1$ wavelength interchangers to the input side of another fabric F_2 . The output side of F_2 is the set of k_2 output fibers of our cross-connect. The only restriction on F_2 is that it has the topology of a pathwise strictly nonblocking $(k_1 + k_2 - 1) \times k_2$ classical cross-connect. This family of strictly nonblocking $k_1 \times k_2$ WDM cross-connects is by definition a family of split cross-connects; see Figure 3.

FIG. 3. A $k_1 \times k_2$ WDM split cross-connect with $m = k_1 + k_2 - 1$ wavelength interchangers. The set of k_1 input fibers is connected to the m wavelength interchangers with a fabric F_1 . The set of m wavelength interchangers is connected to the k_2 output fibers with a fabric F_2 .

THEOREM 1. Let C be a $k_1 \times k_2$ WDM split cross-connect where the number of wavelength interchangers is $k_1 + k_2 - 1$. Suppose that the topology of F_1 is that of some pathwise strictly nonblocking $k_1 \times (k_1 + k_2 - 1)$ cross-connect. Similarly, F_2 has the topology of a pathwise strictly nonblocking $(k_1 + k_2 - 1) \times k_2$ cross-connect. Then C is a strictly nonblocking $k_1 \times k_2$ WDM cross-connect.

Proof. To show that C is strictly nonblocking it is enough to show that for any existing set of demands D that are currently routed through C and for any new valid demand $d = (a, \lambda_1, b, \gamma_2)$ where $D \cup \{d\}$ is a valid demand set, there is a valid route for d . Let R be any valid routing of D .

We will break D into three sets of demands. First, let D_1 be the set of demands in D that use λ_1 as their input wavelength and let D_2 be the set of demands in D that use γ_2 as their output wavelength. Finally, let D_3 be $D \setminus (D_1 \cup D_2)$. Notice that no demands in D_3 can possibly keep us from routing d since these demands all use a wavelength other than λ_1 as they pass through F_1 and a wavelength other than γ_2 as they pass through F_2 . Therefore we restrict our attention to showing that d cannot be blocked by demands in $D_1 \cup D_2$.

Let W be the set of wavelength interchangers without a demand in D_1 or D_2 routed through them. First, we show that W is nonempty. Since d is a valid demand, input fiber a could not have a demand in D that used input wavelength λ_1 and output fiber b could not have a demand in D that used output wavelength γ_2 . Hence, $|D_1| \leq k_1 - 1$ and $|D_2| \leq k_2 - 1$ and therefore $|D_1 \cup D_2| \leq k_1 + k_2 - 2$. Since C is a split cross-connect, each route passes through at most one wavelength interchanger. Therefore $|W| \geq k_1 + k_2 - 1 - |D_1 \cup D_2| \geq 1$.

Let $w \in W$ be a wavelength interchanger that does not currently have a demand routed through it using either λ_1 or γ_2 . If there exists a route from a to w and a route from w to b , then there exists a route for d through C . However, since F_1 has the topology of a pathwise strictly nonblocking $k_1 \times (k_1 + k_2 - 1)$ cross-connect, there must exist a path from a to w that is edge-disjoint from all other paths for demands in D_1 . Similarly, there must exist a path in F_2 from w to b that is edge-disjoint from all other paths through F_2 for demands in D_2 .

Therefore there exists a valid route through C for d and as a result C is strictly nonblocking. \square

We call this type of strictly nonblocking $k_1 \times k_2$ WDM cross-connect a *standard* strictly nonblocking $k_1 \times k_2$ WDM cross-connect.

5.3. Dedicated cross-connects. Note that the family of standard $k_1 \times k_2$ WDM cross-connects presented in the previous section uses $k_1 + k_2 - 1$ wavelength interchangers. For homogeneous cross-connects we will show in section 6 that this is optimal. However, for heterogeneous cross-connects we must also consider a limiting case.

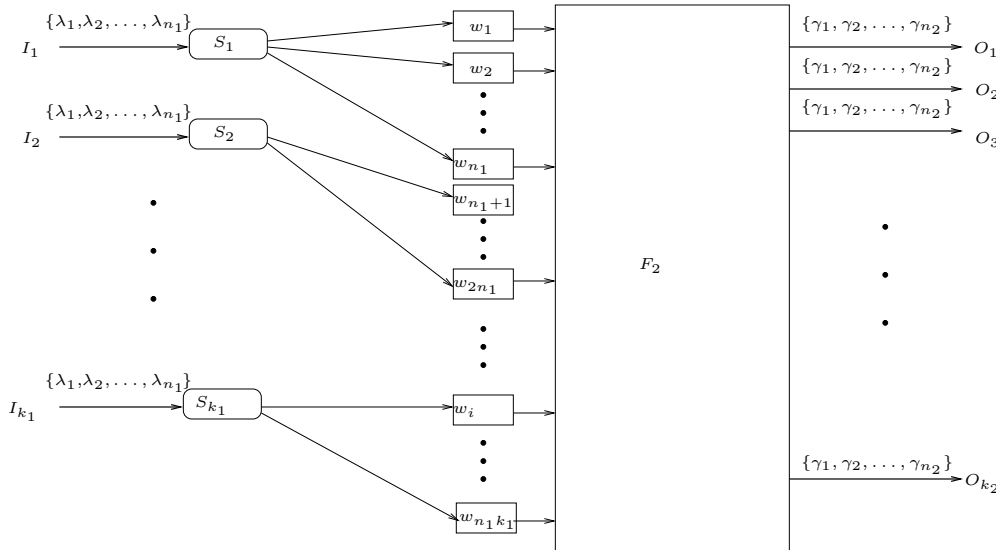

FIG. 4. A $k_1 \times k_2$ WDM dedicated cross-connect with $n_1 k_1$ wavelength interchangers. For each of the k_1 input fibers, I_i , there is a $1 \times n_1$ switch S_i . The n_1 output fibers of S_i are connected to n_1 wavelength interchangers that are used only for demands from I_i . The set of $n_1 k_1$ wavelength interchangers is connected to the k_2 output fibers with a fabric F_2 .

Notice that for a heterogeneous $k_1 \times k_2$ WDM cross-connect with n_1 supported input wavelengths on each input fiber, the maximum number of demands in any valid demand set is $n_1 k_1$. In particular, if $k_2 > (n_1 - 1)k_1$, then the maximum number of

possible demands is no more than $k_1 + k_2 - 1$. In this case we will use what we refer to as a dedicated cross-connect.

In a *dedicated* $k_1 \times k_2$ WDM cross-connect each input fiber is connected to its own $1 \times n_1$ optical switch and the n_1 output fibers of this switch are then connected to n_1 wavelength interchangers. Conceptually, each input fiber has n_1 wavelength interchangers dedicated to service demands from it. The set of $n_1 k_1$ wavelength interchangers is connected to the set of output fibers with a fabric F_2 that has the topology of a pathwise strictly nonblocking $(n_1 k_1) \times k_2$ cross-connect; see Figure 4.

THEOREM 2. *Let C be a $k_1 \times k_2$ WDM dedicated cross-connect where the number of wavelength interchangers is $n_1 k_1$. Then C is strictly nonblocking.*

Proof. Each of the k_1 input fibers can support at most n_1 demands. For each input fiber there are n_1 wavelength interchangers that are reachable from that input fiber alone. Therefore, each wavelength interchanger can be reserved for a demand using a specific input wavelength on the input fiber that can reach that wavelength interchanger. The fabric F_2 is pathwise strictly nonblocking. Therefore, after the demand has been routed through the wavelength interchanger, it can be routed through F_2 to the appropriate output fiber. \square

5.4. Minimal strictly nonblocking cross-connects. By choosing either a dedicated or standard cross-connect, this set of designs provides a family of $k_1 \times k_2$ WDM cross-connects that use $\min(k_1 + k_2 - 1, n_1 k_1)$ wavelength interchangers. In the next section we prove that this is optimal for homogeneous cross-connects and heterogeneous split cross-connects.

6. Lower bound for homogeneous cross-connects. In section 5 we presented a family of strictly nonblocking $k_1 \times k_2$ WDM cross-connects that contain $\min(k_1 + k_2 - 1, n_1 k_1)$ wavelength interchangers. If the cross-connect is a homogeneous cross-connect with k input fibers and k output fibers, these designs use $2k - 1$ wavelength interchangers. In this section we present matching lower bounds. In general, the flavor of these proofs is that we assume that we have a strictly nonblocking $k \times k$ WDM cross-connect that uses $m < 2k - 1$ wavelength interchangers and show that there is a sequence of demands and a routing of those demands such that there is a final valid demand d that cannot be routed by the cross-connect.

Although we presented our upper bounds for homogeneous and heterogeneous cases simultaneously, in this section we handle only the homogeneous case and assume that $k = k_1 = k_2$, $n = n_1 = n_2$ and the set of input wavelengths, $\{\lambda_1, \dots, \lambda_n\}$, is also the set of output wavelengths. We leave the heterogeneous case for the next section.

Initially, we prove our lower bounds using a demand model where the input and output wavelengths are specified as part of the demand. In this setting we prove that if there is some $k \geq 3$ for which there is a strictly nonblocking $k \times k$ WDM cross-connect with $m < 2k - 1$ wavelength interchangers, then there exists some $k' \geq 2$ for which there is a strictly nonblocking $k' \times k'$ WDM *split* cross-connect with $m' < 2k' - 1$ wavelength interchangers. We then show that any strictly nonblocking $k \times k$ WDM *split* cross-connect requires $2k - 1$ wavelength interchangers. Combining these results shows that any strictly nonblocking $k \times k$ WDM cross-connect requires $2k - 1$ wavelength interchangers.

We then consider a demand model in which a demand consists of only an input and output fiber and the cross-connect is allowed to choose the input and output wavelengths from the set of available input and output wavelengths. We present a simple construction that extends the proofs in this section to hold in this new demand model.

6.1. The adversarial view of a strictly nonblocking cross-connect. In this section we will prove a lower bound on the number of wavelength interchangers necessary in any strictly nonblocking $k \times k$ WDM cross-connect. To prove such a lower bound, we will present a sequence of demands and a sequence of valid routings the cross-connect could have chosen that eventually force the cross-connect to use at least $2k - 1$ wavelength interchangers.

We assume that we are given a strictly nonblocking $k \times k$ WDM cross-connect C . As an exercise, first suppose that C is such that there is an edge disjoint path from every input fiber to every wavelength interchanger and an edge disjoint path from every wavelength interchanger to every output fiber. Suppose C contains $2k - 2$ wavelength interchangers. For the purposes of this example, consider a demand set with $k - 1$ demands with input wavelength λ_1 and output wavelength λ_1 and $k - 1$ demands with input wavelength λ_2 and output wavelength λ_2 . A valid routing of these demands would use $k - 1$ wavelength interchangers to route the demands with input wavelength λ_1 and output wavelength λ_1 . Furthermore, it *could* route the $k - 1$ demands with input wavelength λ_2 and output wavelength λ_2 through a disjoint set of $k - 1$ wavelength interchangers. By the definition of strictly nonblocking, it must be possible to route another demand through C even if this is the current state of C . However, a new demand with input wavelength λ_1 and output wavelength λ_2 cannot be serviced by any of the wavelength interchangers in C . Thus C cannot be strictly nonblocking.

In general, we cannot assume that C has this structure. Therefore we will play the part of the adversary that is attempting to force C to reveal $2k - 1$ wavelength interchangers. Initially, we do not know anything about the structure of the cross-connect. Each time we place a demand d on the cross-connect, the route r that C uses to satisfy d becomes known to us. Suppose that at some point there is a set of demands D on the cross-connect and a routing R of D . Furthermore, let d be a demand that is valid with respect to D . If there is a route r that could be used to satisfy d and r is known to us at that point, then we can also insist that the cross-connect uses r to route d .

Therefore when proving our lower bounds we will sometimes insist that a demand be routed according to a particular route that is already known to exist.

6.2. Existence of minimum cost split cross-connects. In this section we prove that for the case of homogeneous $k \times k$ WDM cross-connects it is sufficient to consider only homogeneous $k \times k$ WDM *split* cross-connects. We reduce our problem to considering only strictly nonblocking $k \times k$ WDM split cross-connects through the following steps.

1. We define the set *Long* of strictly nonblocking cross-connects that contain at least one path with multiple wavelength interchangers along the path.
2. By definition, *Long* cannot contain a strictly nonblocking 1×1 WDM cross-connect with 1 wavelength interchanger. This provides a base case for our inductive proof.
3. We then consider the smallest $k > 2$ such that there exists a strictly nonblocking $k \times k$ WDM cross-connect $C \in \text{Long}$ with fewer than $2k - 1$ wavelength interchangers and show that C can be reduced to a smaller strictly nonblocking $k' \times k'$ WDM cross-connect C' with the property that C' has fewer than $2k' - 1$ wavelength interchangers.
4. Thus, 2 and 3 together imply that if there exists a strictly nonblocking $k \times k$ WDM cross-connect $C \in \text{Long}$ with fewer than $2k - 1$ wavelength inter-

changers, then we can reduce it to a strictly nonblocking $k' \times k'$ WDM cross-connect $C' \notin Long$ with fewer than $2k' - 1$ wavelength interchangers.

More precisely, we define *Long* to be the set of strictly nonblocking WDM cross-connects that contain at least one directed path P from some input node $a \in I$ through $w_P > 1$ wavelength interchangers to some output node $b \in O$. We say P is a *long* path; see Figure 5.

FIG. 5. A long path in C with three wavelength interchangers.

To reduce a cross-connect $C \in Long$ to a smaller strictly nonblocking cross-connect, we make n demands from the input fiber a to the output fiber b . By assumption, there exists a long path P from a to b . Therefore we can insist that C route these n demands along P . As long as these demands are routed along P , no other demands on C can use any part of P . Therefore all future demands will be handled by other parts of C . Thus, C is then equivalent to a smaller cross-connect that has one less input fiber and one less output fiber and at least two fewer wavelength interchangers.

Formally, for any $C \in Long$ with n wavelengths supported on each input and output fiber and any long path $P \in C$ from input fiber a to output fiber b , we define the operation $\mathbf{Fill}(C, P, n)$ that routes demands $(a, \lambda_i, b, \lambda_i)$ for all $1 \leq i \leq n$ along P with constant wavelength assignment λ_i .

LEMMA 3. *For any $C \in Long$, the result of the operation $\mathbf{Fill}(C, P, n)$ is that no new demands can be routed through any wavelength interchanger on P .*

Proof. Let D be the set of demands made by the operation $\mathbf{Fill}(C, P, n)$. Since $\mathbf{Fill}(C, P, n)$ routes one demand per wavelength, with constant wavelength assignment, along P , all wavelengths on all fibers in P are used for demands in D . Therefore there are no available supported wavelengths for any input or output fibers for any wavelength interchangers on P . \square

By definition, *Long* cannot contain a strictly nonblocking 1×1 WDM cross-connect with a 1 wavelength interchanger. Thus we now focus our attention on cross-connects in *Long* with $k \geq 2$. We show that we can reduce a strictly nonblocking $k \times k$ WDM cross-connect $C \in Long$ with $m < 2k - 1$ wavelength interchangers to a strictly nonblocking $k' \times k'$ WDM cross-connect with $m' < 2k' - 1$ wavelength interchangers.

THEOREM 4. *If for some $k \geq 2$, there exists a $k \times k$ WDM cross-connect $C \in Long$ that has fewer than $2k - 1$ wavelength interchangers, then for some k' , where $1 \leq k' < k$, there exists a strictly nonblocking $k' \times k'$ WDM cross-connect $C' \notin Long$ that has fewer than $2k' - 1$ wavelength interchangers.*

Proof. By the definition of *Long*, if $C \in Long$ then $k \geq 2$. Let $k \geq 2$ be the smallest number such that there exists some $k \times k$ WDM cross-connect $C \in Long$ with $m < 2k - 1$ wavelength interchangers. Let w_P be the number of wavelength interchangers on a long path P from input fiber a to output fiber b that must exist in C by the definition of the class *Long* of cross-connects. Let n be the number of supported wavelengths.

We will use $\mathbf{Fill}(C, P, n)$ to route n demands along P . Once these demands have been routed along P , no new demands can use any portion of P . Thus any new demand on C must be routed through other sections of C . Therefore we show that C , with these n demands routed along P , is equivalent to a strictly nonblocking $k' \times k'$ WDM cross-connect C' with one less input fiber, one less output fiber, and w_p fewer wavelength interchangers.

We start by performing $\mathbf{Fill}(C, P, n)$ and assume that the demands placed on C by $\mathbf{Fill}(C, P, n)$ are not removed. By Lemma 3 no new demands can be routed through wavelength interchangers on P . Thus consider the cross-connect C' obtained by the process $\mathbf{Modify}(C, P)$ that is defined as follows. Remove input fiber a and output fiber b from C . Remove all fibers along path P . All wavelength interchangers along P are isolated (i.e., have no incoming or outgoing fibers) and so they are also removed. This construction can easily be seen to have the property that after performing $\mathbf{Fill}(C, P, n)$ any other demand will have a routing and wavelength assignment in C if and only if it does in C' . See Figure 6 to see the change to C as a result of performing $\mathbf{Fill}(C, P, n)$ and $\mathbf{Modify}(C, P)$.

FIG. 6. The result of performing $\mathbf{Fill}(C, P, n)$ and $\mathbf{Modify}(C, P)$.

Therefore since C is strictly nonblocking, C' must also be strictly nonblocking. Notice that since we have removed one input and output fiber from C to create C' , C' is a $k' \times k'$ WDM cross-connect where $k' = k - 1$. Furthermore, we removed at least two wavelength interchangers from C in $\mathbf{Modify}(C, P)$ and therefore the number of wavelength interchangers is $m - w_P < 2k' - 1$. Therefore C' is a $k' \times k'$ WDM cross-

connect with fewer than $2k' - 1$ wavelength interchangers. Since k was assumed to be the smallest number such that there exists a $k \times k$ WDM cross-connect $C \in Long$ with fewer than $2k - 1$ wavelength interchangers and since $k' < k$ and $m' < 2k' - 1$, $C' \notin Long$. Thus $C' \notin Long$ is a strictly nonblocking $k' \times k'$ WDM cross-connect with fewer than $2k' - 1$ wavelength interchangers. \square

Theorem 4 says that if for some $k \geq 2$ there is an optimal strictly nonblocking $k \times k$ WDM cross-connect C with $m < 2k - 1$ wavelength interchangers and C is not a split cross-connect, then there is some $k' \geq 1$ for which there is a strictly nonblocking $k' \times k'$ WDM cross-connect C' with $m' < 2k' - 1$ wavelength interchangers. Furthermore, C' must be a split cross-connect. In the next section we will show that any strictly nonblocking $k \times k$ WDM split cross-connect must have at least $2k - 1$ wavelength interchangers.

6.3. Lower bound for split cross-connects. In the last section we reduced the problem of showing that the optimal number of wavelength interchangers for any strictly nonblocking $k \times k$ WDM cross-connect is $2k - 1$ to showing that this is true for any strictly nonblocking $k \times k$ WDM split cross-connect. We now show that any strictly nonblocking $k \times k$ WDM split cross-connect must have $2k - 1$ wavelength interchangers.

To do this we consider any strictly nonblocking WDM split cross-connect C with fewer than $2k - 1$ wavelength interchangers. For such a cross-connect we will create a demand set D and a routing R of D that routes D in such a way that C must use each wavelength interchanger to service a demand with either input wavelength λ_1 or output wavelength λ_2 . Given this set of demands D and routing R we will then show that one additional valid demand $d \notin D$ exists with input wavelength λ_1 and output wavelength λ_2 . Since all the wavelength interchangers in the cross-connect will already be servicing a demand that either uses this new demand's input wavelength or its output wavelength, the cross-connect will not have a wavelength interchanger to service the new demand. Thus any strictly nonblocking $k \times k$ WDM split cross-connect must have at least $2k - 1$ wavelength interchangers.

We say that a valid demand set D is *standard* if and only if

1. $|D| = 2k$ and
2. all of the demands in D use input wavelength λ_1 or λ_2 and output wavelength λ_1 or λ_2 .

Suppose we have a routing R_i for a standard set of demands D_i . Let W_i^B be the set of wavelength interchangers that service a demand with either input wavelength λ_1 or output wavelength λ_2 . These wavelength interchangers are thought of as "blocking" demands with input wavelength λ_1 and output wavelength λ_2 from being routed through them. Let W_i^F be the set of all other wavelength interchangers. The wavelength interchangers in W_i^F are thought to be "free" to service demands with input wavelength λ_1 and output wavelength λ_2 .

If a routing R_i of a standard set of demands D_i uses fewer than $2k - 1$ wavelength interchangers, then there must be at least two wavelength interchangers that are both in W_i^B and are each servicing two demands.

As an example, assume WI_u and WI_v are two such wavelength interchangers. For this example, suppose $(I_{u1}, \lambda_1, O_{u1}, \lambda_1)$ and $(I_{u2}, \lambda_2, O_{u2}, \lambda_2)$ are the two demands that WI_u services. Furthermore, suppose $(I_{v1}, \lambda_1, O_{v1}, \lambda_1)$ and $(I_{v2}, \lambda_2, O_{v2}, \lambda_2)$ are the two demands that WI_v services; see Figure 7.

Consider the following change to D_i .

- Remove $(I_{u1}, \lambda_1, O_{u1}, \lambda_1)$ and $(I_{v2}, \lambda_2, O_{v2}, \lambda_2)$ from D_i ; see Figure 8.

FIG. 7. Two wavelength interchangers that each service two demands.

FIG. 8. The effect of removing demands $(I_{u1}, \lambda_1, O_{u1}, \lambda_1)$ and $(I_{v2}, \lambda_2, O_{v2}, \lambda_2)$.

Notice that WI_u and WI_v both remain in W_i^B after we remove these two demands. However, I_{u1} now can ask for a new demand with input wavelength λ_1 and O_{v2} can now ask for a new demand with output wavelength λ_2 . Now, we do the following.

- Add demand $(I_{u1}, \lambda_1, O_{v2}, \lambda_2)$ to D_i to create D_{i+1} ; see Figure 9.

FIG. 9. The effect of adding demand $(I_{u1}, \lambda_1, O_{v2}, \lambda_2)$.

This new demand is a valid demand with respect to D_i . However, since it has input wavelength λ_1 and output wavelength λ_2 , it will not be able to be routed by any wavelength interchanger in W_i^B . Thus the route for this demand will force a new wavelength interchanger to service a demand with input wavelength λ_1 and output wavelength λ_2 . The wavelength interchanger that services this demand will thus be added to W_{i+1}^B . By repeating this process we eventually will show that either C is not strictly nonblocking or there exists a set of standard demands D_t and a routing of these demands such that $|W_t^B| \geq 2k - 1$ and thus C contains at least $2k - 1$ wavelength interchangers.

We now formalize this construction. First, we show that a standard set of demands D_0 exists and can be routed by C . Create k demands of the form $d_{i1} = (I_i, \lambda_1, O_i, \lambda_2)$ for $1 \leq i \leq k$. Clearly, since C is strictly nonblocking, C must be able to satisfy these k demands. For $1 \leq i \leq k$, create a demand $d_{i2} = (I_i, \lambda_2, O_i, \lambda_1)$ and route along the same path as d_{i1} . Notice that there are $2k$ demands and each demand uses input wavelength λ_1 or λ_2 and output wavelength λ_1 or λ_2 . Therefore this set of demands meets the definition of a standard set of demands.

Now we prove that any routing R_i of a standard set of demands D_i that uses

$2k - g$ wavelength interchangers will have g wavelength interchangers servicing two demands. Since a standard set of demands D consists of $2k$ demands each involving only wavelengths λ_1 and λ_2 , routing D will require at least k wavelength interchangers. Thus we assume that any cross-connect under consideration has at least k wavelength interchangers. Therefore in what follows, we always assume that $g \leq k$.

LEMMA 5. *If C is a strictly nonblocking $k \times k$ WDM split cross-connect, D_i is a standard set of demands and R_i is a routing of the demands in D_i that uses $2k - g$ wavelength interchangers, where $g > 0$, then g wavelength interchangers in W_i^B will each service two demands both of whose input wavelengths are λ_1 and λ_2 and whose output wavelengths are λ_1 and λ_2 .*

Proof. The $2k$ demands in D_i use only input wavelengths λ_1 and λ_2 and output wavelengths λ_1 and λ_2 . As a result no wavelength interchanger can service more than two of these demands. This implies that g wavelength interchangers in W_i^B or W_i^F must service two demands. Any such wavelength interchanger that services two of these demands must service a demand with input wavelength λ_1 and a demand with output wavelength λ_2 and therefore is by definition in W_i^B . \square

Given the standard set of demands D_0 and the routing R_0 of D_0 we now present two manipulations that together can be used to iteratively change the set of demands on C so that eventually we arrive at a standard set of demands D_t and a standard routing R_t of D_t such that every wavelength interchanger in C is servicing a demand with either input wavelength λ_1 or output wavelength λ_2 . Notice that this is equivalent to showing that if C has no more than $2k - g$ wavelength interchangers for some $g > 0$, then a standard set of demands D_i and a standard routing R_i of D_i exists such that $|W_i^B| = 2k - g$ and $|W_i^F| = 0$.

Let $WI_j \in W_i^B$ be a wavelength interchanger that services exactly two demands, d_1 and d_2 . Suppose these demands have the form $d_1 = (I_1, \lambda_1, O_2, \lambda_2)$ and $d_2 = (I_2, \lambda_2, O_1, \lambda_1)$. The operation **Uncross**(WI_j) is defined to have the effect of changing these two demands to be $(I_1, \lambda_1, O_1, \lambda_1)$ and $(I_2, \lambda_2, O_2, \lambda_2)$ and routing these new demands exactly as d_1 and d_2 were routed while keeping all other demands and routes unchanged. Recall that we can force the cross-connect to use a known route for a new demand in order to construct a particular routing. Notice that the only real change made by **Uncross**(WI_j) is to swap the output paths of the routes of d_1 and d_2 . On the other hand, if the demands have the form $d_1 = (I_1, \lambda_1, O_2, \lambda_1)$ and $d_2 = (I_2, \lambda_2, O_1, \lambda_2)$, then **Uncross**(WI_j) has no effect; see Figure 10.

FIG. 10. *In a) the wavelength interchanger is shown before the operation **Uncross** is performed. The result of **Uncross** is shown in b).*

Next, we define the operation **Block**($C, (D_i, R_i)$) where C is a strictly nonblocking $k \times k$ WDM split cross-connect, D_i is a standard set of demands, and R_i is a routing of the demands in D_i that uses fewer than $2k - 1$ wavelength interchangers. The goal of **Block**($C, (D_i, R_i)$) is to alter D_i and R_i to create a new standard set of

demands D_{i+1} and a routing R_{i+1} for D_{i+1} such that $W_{i+1}^B > W_i^B$. In order to achieve this, $\mathbf{Block}(C, (D_i, R_i))$ will use the demands serviced by two of the wavelength interchangers in W_i^B that must be servicing two demands by Lemma 5 to create a new demand with input wavelength λ_1 and output wavelength λ_2 that must be serviced by a wavelength interchanger that was not in W_i^B . Figure 11 illustrates the steps of $\mathbf{Block}(C, (D_i, R_i))$.

$\mathbf{Block}(C, (D_i, R_i))$.

1. Take two wavelength interchangers, WI_u and WI_v , in W_i^B that, by Lemma 5, each service two demands.
2. $\mathbf{Uncross}(WI_u)$ and $\mathbf{Uncross}(WI_v)$.
3. Let $(I_{u1}, \lambda_1, O_{u1}, \lambda_1)$ and $(I_{u2}, \lambda_2, O_{u2}, \lambda_2)$ be the two resulting demands that WI_u services. Let $(I_{v1}, \lambda_1, O_{v1}, \lambda_1)$ and $(I_{v2}, \lambda_2, O_{v2}, \lambda_2)$ be the two resulting demands that WI_v services.
4. Remove $(I_{u1}, \lambda_1, O_{u1}, \lambda_1)$ and $(I_{v2}, \lambda_2, O_{v2}, \lambda_2)$ from D_i and route all remaining demands according to R_i to create D_{i+1} and R_{i+1} .
5. Add $(I_{v2}, \lambda_2, O_{u1}, \lambda_1)$ to D_{i+1} and add the route chosen by C for this demand to R_{i+1} .
6. Add $(I_{u1}, \lambda_1, O_{v2}, \lambda_2)$ to D_{i+1} and add the route chosen by C for this demand to R_{i+1} .
7. Return (D_{i+1}, R_{i+1}) .

FIG. 11. The steps in $\mathbf{Block}(C, (D_i, R_i))$.

We start with D_0 and R_0 as defined above and then inductively define $(D_{i+1}, R_{i+1}) = \mathbf{Block}(C, (D_i, R_i))$ as long as R_i uses fewer than $2k - 1$ wavelength interchangers. Consider $\mathbf{Block}(C, (D_i, R_i))$. By Lemma 5 and the assumption that R_i uses fewer than $2k - 1$ wavelength interchangers, there must exist two wavelength interchangers in W_i^B that service two demands. Given these two wavelength interchangers, we then “uncross” their demands in Step 2. This does not change any of the wavelengths used along any of the fibers in C . In particular, while this alters the set of demands, the new set of demands is still a standard set of demands. In Step 4 we remove two demands and leave the remaining demands unchanged. By our choice of demands to remove we ensure that WI_v and WI_u will still each service one demand with either

input wavelength λ_1 or output wavelength λ_2 . Thus WI_v and WI_u remain in W_i^B .

Since C is strictly nonblocking, a valid route for the new demand in Step 6 must exist. A wavelength interchanger in W_i^F must be used to service this demand since all wavelength interchangers in W_i^B are servicing a demand with either input wavelength λ_1 or output wavelength λ_2 . Since the demand requested in Step 6 has both input wavelength λ_1 and output wavelength λ_2 , the wavelength interchanger that services this new demand will be in W_{i+1}^B . Notice that the demand in Step 5 ensures that there are a total of $2k$ demands on C . Hence, after Step 6, D_{i+1} is a standard set of demands and R_{i+1} is a routing for those demands such that $|W_{i+1}^B| = |W_i^B| + 1$ and $|W_{i+1}^F| = |W_i^F| - 1$. Thus we can conclude the following lemma.

LEMMA 6. *If C is a strictly nonblocking $k \times k$ WDM split cross-connect, D_i is a standard set of demands and R_i is a routing of the demands in D_i that uses fewer than $2k - 1$ wavelength interchangers, then $\mathbf{Block}(C, (D_i, R_i))$ can be executed and $(D_{i+1}, R_{i+1}) = \mathbf{Block}(C, (D_i, R_i))$, where D_{i+1} is a standard set of demands and R_{i+1} is a routing of the demands in D_{i+1} . Also, D_{i+1} and R_{i+1} are such that $|W_{i+1}^B| = |W_i^B| + 1$ and $|W_{i+1}^F| = |W_i^F| - 1$.*

We now use Lemma 6 to show that there must be $2k - 1$ wavelength interchangers in any strictly nonblocking $k \times k$ WDM split cross-connect.

THEOREM 7. *For any strictly nonblocking $k \times k$ WDM split cross-connect there must be a standard set of demands D_t and a standard routing R_t of D_t that uses at least $2k - 1$ wavelength interchangers.*

Proof. By contradiction, let C be a strictly nonblocking $k \times k$ WDM split cross-connect. As noted earlier, for such a cross-connect there exists a standard set of demands D_0 with routing R_0 . Let $M = 2k - 1$. If R_0 uses at least M wavelength interchangers, then we are done. Otherwise, by Lemma 6, we can repeatedly apply **Block** to produce a series of pairs $(D_{i+1}, R_{i+1}) = \mathbf{Block}(C, (D_i, R_i))$ where D_i is a standard set of demands and R_i is a routing of the demands in D_i as long as R_i has the property that it uses fewer than M wavelength interchangers. By Lemma 6 we know that $|W_{i+1}^F| = |W_i^F| - 1$ because the demand in Step 7 must be routed through a wavelength interchanger in W_i^F . Thus if $|W_0^F| = t$, then for some $i < t$, either R_i uses at least M wavelength interchangers and we are done or $|W_i^F| = 0$. If R_t uses fewer than M wavelength interchangers, then Lemma 6 guarantees that we can perform $\mathbf{Block}(C, (D_t, R_t))$. However, the demand in Step 7 must be serviced by a wavelength interchanger in W_t^F . Therefore Step 7 cannot be completed in $\mathbf{Block}(C, (D_t, R_t))$. Since C is strictly nonblocking it must be that R_t uses $2k - 1$ or more wavelength interchangers. \square

Theorem 7 says that any strictly nonblocking $k \times k$ WDM split cross-connect must have $2k - 1$ wavelength interchangers. Combining this with Theorem 4, we arrive at the following result for homogeneous cross-connects.

COROLLARY 8. *Any strictly nonblocking homogeneous $k \times k$ WDM cross-connect with $n > 1$ wavelengths must have at least $2k - 1$ wavelength interchangers.*

6.4. Other demand models for homogeneous cross-connects. In presenting the results of this section we have used a demand model in which the input and output wavelengths are specified as part of the demand. In this section we show that homogeneous cross-connects require $2k - 1$ wavelength interchangers even under less restrictive demand models. To prove this lower bound we must assume that $n \geq 4$. Although this is slightly weaker than our assumption in the previous sections that $n \geq 2$, it covers all cases that arise in practice.

For a fiber a and a routing R of existing demands, we define $f(a, R)$ to be the

set of wavelengths not in use on a by any route $r \in R$. We define a *general demand* $d = (I_x, O_y)$ to be a request for a connection from input fiber I_x to output fiber O_y . A *general route* r for d is a path from input fiber I_x to output fiber O_y such that the connection starts on an unused input wavelength, $\lambda_y \in f(I_x, R)$, stays on the same wavelength as long as it does not pass through a wavelength interchanger, and ends on unused output wavelength $\lambda_w \in f(O_y, R)$. We say that a cross-connect uses a *general demand model* if it supports general demands and general routes.

Note that considering a strictly nonblocking cross-connect in a general demand model actually weakens the definition of a strictly nonblocking cross-connect. Since a strictly nonblocking cross-connect must route any new demand regardless of the set of current routes in use and the wavelength assignment of those routes, one can view a demand model that specifies the input and output wavelengths as part of the demand as representing a worst-case adversary that requires not only a new connection from some input fiber to some output fiber but also chooses the *worst* wavelength assignment for the route chosen in the cross-connect. By allowing the cross-connect to choose the input and output wavelengths, the cross-connect is allowed to plan the choice of wavelengths. Therefore a cross-connect that supports only a general demand model is, to some extent, a hybrid between a strictly nonblocking cross-connect and a wide-sense nonblocking cross-connect. We consider such cross-connects and prove that by allowing the cross-connect, this added flexibility to choose the wavelength assignment of the routes does not change the number of wavelength interchangers needed in the cross-connect.

Note that although we allow the cross-connect to choose the input and output wavelengths, we still have the ability to force it to use a route that is known to satisfy a particular demand.

The outline for this section is similar to the earlier part of the section. We begin by reducing the problem to considering only split cross-connects. We then show that under certain conditions we can use a sequence of general demands to simulate a demand that specifies the input and output wavelengths as part of the demand. This allows us to prove that a strictly nonblocking $k \times k$ WDM split cross-connect supporting a general demand model requires $2k - 1$ wavelength interchangers and thus any strictly nonblocking $k \times k$ WDM cross-connect supporting a general demand model requires $2k - 1$ wavelength interchangers.

Thus, we begin this discussion showing that we can still reduce this problem to considering only split cross-connects. We assume throughout this section that $n \geq 4$. We define *LongGeneral* to be the set of strictly nonblocking WDM cross-connects using a general demand model that contain at least one directed path P from some input node $a \in I$ through $w_P > 1$ wavelength interchangers to some output node $b \in O$. We refer to P as a *long path* (see Figure 5). We define the operation **GeneralFill**(C, P, n) to route a set G of n demands from input fiber a to output fiber b along P .

LEMMA 9. *For any long path P with $w_P \leq n - 2$ and any routing chosen by the operation **GeneralFill**(C, P, n), there is a set S of demands such that*

1. $S \subset G$, and
2. S contains at most $n - 1$ demands,
3. *there is at least one wavelength λ_i such that for every section of fiber along P , there is some demand in S (possibly a different demand on each section) that is assigned λ_i along that section of fiber.*

Proof. By the assumptions of the lemma, P contains at most $n - 2$ wavelength interchangers. Therefore any route r along P can change wavelength at most $n - 2$

times. Therefore any particular demand can use at most $n - 1$ wavelengths. This implies that for any wavelength λ_i there must be at least one demand $d \in G$ that is not assigned λ_i anywhere along its route. Let $S = G \setminus \{d\}$. Since G contained n demands, each wavelength must be used by some demand on each section of P . Since d did not use λ_i on any section of P , the routes chosen for demands in S are such that for each section of fiber along P there is a route for some demand in S using λ_i . Therefore $S \subset G$ containing $n - 1$ demands and the routes for demands in S are such that for every section of fiber in P , there is some demand in S that has been assigned λ_i along that section of fiber. \square

Using Lemma 9, we can now prove that there does not exist a 2×2 WDM cross-connect with at most 2 wavelength interchangers such that those wavelength interchangers are on a long path. We will use this as a base case for a reduction that shows that we can always consider split cross-connects when showing that any $k \times k$ WDM cross-connect must have $2k - 1$ wavelength interchangers. Since a 1×1 WDM cross-connect cannot have both less than $2k - 1 = 1$ wavelength interchanger and a long path, we must use a 2×2 WDM cross-connect as our base case for the reduction.

THEOREM 10. *There does not exist a 2×2 WDM cross-connect $C \in LongGeneral$ with fewer than three wavelength interchangers.*

Proof. Assume that there exists a $C \in LongGeneral$ with two wavelength interchangers and $n \geq 4$. Let P be a long path from input fiber a to output fiber b with both wavelength interchangers in C on P . First, perform **GeneralFill**(C, P, n) to route a set G of n demands from a to b . Notice that after this has been done all wavelength interchangers along P have every wavelength in use on their input and output fibers. Since all the wavelength interchangers in C are on P , any new demands must not change wavelength. Let α be the other input fiber and β be the other output fiber. Suppose we now ask for n demands from α to β . Either the routing for these demands must use constant wavelength assignments for these demands or it contradicts the assumption that C has exactly two wavelength interchangers. Therefore assume that these new demands are routed with constant wavelength assignment.

By Lemma 9 there exists $S \subset G$ such that S contains at most $n - 1$ demands, such that for each section of fiber along P , there is some demand in S that has been assigned wavelength λ_i on that section. Remove the demand from α to β that is routed with constant wavelength assignment λ_i ; see Figure 12.

FIG. 12. A 2×2 WDM cross-connect C with $n = 4$ and a path P from input fiber a to output fiber b such that both wavelength interchangers in C are on P . There are currently three demands routed along P such that each section of P has at least one demand routed on wavelength λ_3 . There are three demands between α and β , none of which is assigned wavelength λ_3 on any fiber.

Furthermore, remove all demands along P that are not in S . At least one demand must be removed from P and that demand must have been routed such that it didn't use λ_i along any fiber in P . In particular it cannot have used λ_i on output fiber

b. Now add a demand from α to b . Since λ_i is the only wavelength available on α , any route for this demand must start with wavelength assignment λ_i . Since λ_i is not available on output fiber b this demand must change wavelength. However, each fiber along P and hence each input fiber to each wavelength interchanger along P already has a demand in S routed on it that is using wavelength λ_i . Therefore there is no wavelength interchanger that can be used to service this new demand and as a result either $C \notin \text{LongGeneral}$ or C must contain three or more wavelength interchangers which violates the assumption that C has at most two wavelength interchangers. \square

Recall that Theorem 4 considered the smallest k for which there was a $k \times k$ WDM cross-connect $C \in \text{Long}$ that had fewer than $2k - 1$ wavelength interchangers. It then used $\text{Fill}(C, P, n)$ to fill the path P with n demands. Once this path was filled with these demands, C was functionally equivalent to a $k' \times k'$ WDM cross-connect $C' \notin \text{Long}$ with fewer than $2k' - 1$ wavelength interchangers. Theorem 10 provides the base case for a similar reduction since it shows that there does not exist a cross-connect $C \in \text{LongGeneral}$ with $k = 2$ and at most two wavelength interchangers. Furthermore, the effect of $\text{GeneralFill}(C, P, n)$ when C is a cross-connect supporting a general demand model is to completely fill path P such that no new demands can use any of the fibers or any wavelength interchanger along P . Thus the following is a straightforward extension of Theorem 4.

COROLLARY 11. *If for some $k > 2$, there exists a $k \times k$ WDM cross-connect $C \in \text{LongGeneral}$ with $n \geq 4$ that has fewer than $2k - 1$ wavelength interchangers, then for some k' , where $1 < k' < k$, there exists a strictly nonblocking $k' \times k'$ WDM cross-connect $C' \notin \text{LongGeneral}$ that has fewer than $2k' - 1$ wavelength interchangers.*

Corollary 11 says that we need only consider whether there exists a strictly nonblocking $k \times k$ WDM *split* cross-connect supporting a general demand model that uses fewer than $2k - 1$ wavelength interchangers. Therefore recall the version of $\text{Block}(C, (D_i, R_i))$ that requires that demands specify the input and output wavelengths. We assume that R_i uses at most $2k - 2$ wavelength interchangers and every demand in D_i has input wavelength λ_1 or λ_2 and output wavelength λ_1 or λ_2 .

$\text{Block}(C, (D_i, R_i))$.

1. Take two wavelength interchangers, WI_u and WI_v , in W_i^B that, by Lemma 5, each service two demands.
2. $\text{Uncross}(WI_u)$ and $\text{Uncross}(WI_v)$.
3. Let $(I_{u1}, \lambda_1, O_{u1}, \lambda_1)$ and $(I_{u2}, \lambda_2, O_{u2}, \lambda_2)$ be the two resulting demands that WI_u services. Let $(I_{v1}, \lambda_1, O_{v1}, \lambda_1)$ and $(I_{v2}, \lambda_2, O_{v2}, \lambda_2)$ be the two resulting demands that WI_v services.
4. Remove $(I_{u1}, \lambda_1, O_{u1}, \lambda_1)$ and $(I_{v2}, \lambda_2, O_{v2}, \lambda_2)$ from D_i and route all remaining demands according to R_i to create D_{i+1} and R_{i+1} .
5. Add $(I_{v2}, \lambda_2, O_{u1}, \lambda_1)$ to D_{i+1} and add a valid route for this demand to R_{i+1} .
6. Add $(I_{u1}, \lambda_1, O_{v2}, \lambda_2)$ to D_{i+1} and add a valid route for this demand to R_{i+1} .
7. Return (D_{i+1}, R_{i+1}) .

Consider Step 5 which asks for a route from I_{v2} to O_{u1} such that the demand is routed on input wavelength λ_2 on input fiber I_{v2} and output wavelength λ_1 on output fiber O_{u1} . In the current model we cannot specify the input or output wavelength. Therefore we need to replace Step 5 with a sequence of general demands $\{d_1, d_2, \dots, d_j\}$ such that the final general demand, d_j , is from input fiber I_{v2} to output fiber O_{u1} and the routes for the demands $\{d_1, d_2, \dots, d_{j-1}\}$ require that demand d_j uses input wavelength λ_2 and output wavelength λ_1 . Once d_j has been routed through C , we can remove demands $\{d_1, d_2, \dots, d_{j-1}\}$ and be left with the same re-

sult as Step 5. In order to show that this is possible, we will use the fact that the set of demands D_i and routing R_i of D_i are such that all demands are routed using either input wavelength λ_1 or λ_2 and either output wavelength λ_1 or λ_2 .

More generally, for a set of demands, D , we will define a routing R of D to be **Constrained** (λ_i, λ_j) if for every demand $d \in D$, the route r for d uses either λ_i or λ_j as the input wavelength and either λ_i or λ_j as the output wavelength. Notice that the advantage of maintaining a **Constrained** (λ_i, λ_j) routing is that we are guaranteed that all other wavelengths are unused on all the fibers. Since $n \geq 4$ this implies that at most half of the wavelengths are in use on any given input or output fiber under any **Constrained** (λ_i, λ_j) routing.

Consider a cross-connect C and suppose there is a set of demands, D , where the routing R of D is **Constrained** (λ_i, λ_j) . Furthermore, assume that there is an input fiber I_a with $\lambda_i \in f(I_a, R)$ and there is an output fiber O_b with $\lambda_j \in f(O_b, R)$. We create the following operation **Force** $(C, (D, R), (I_a, \lambda_i, O_b, \lambda_j))$ that forces the route for a new general demand from I_a to O_b to use input wavelength λ_i and output wavelength λ_j . In describing **Force** $(C, (D, R), (I_a, \lambda_i, O_b, \lambda_j))$ we assume that $|f(I_a, R)| \geq |f(O_b, R)|$. The case when $|f(I_a, R)| < |f(O_b, R)|$ is analogous.

Force $(C, (D, R), (I_a, \lambda_i, O_b, \lambda_j))$.

1. Assume $|f(I_a, R)| \geq |f(O_b, R)|$.
2. Create $|f(O_b, R)|$ demands from input fiber I_a to output fiber O_b .
3. If a demand from Step 2 is routed on output wavelength λ_j , then remove it.
4. Let D' and R' be the current set of demands and current routing of these demands.
5. Create $|f(I_a, R')|$ demands from input fiber I_a to output fibers other than O_b .
6. Remove the demand that uses input wavelength λ_i on input fiber I_a and redefine D' and R' to be the current set of demands and routing of these demands.
7. Add $|f(O_b, R')|$ demands from input fibers other than I_a to output fiber O_b .
8. Remove the demand from output fiber O_b that is routed on output wavelength λ_j .
9. Add a demand from I_a to O_b to D' and add the route r for this demand to R' .
10. Remove any existing demands that were made in Steps 2, 5, and 7.
11. Return the current set of demands, D' , and the current routing R' of D' .

LEMMA 12. *Let C be a homogeneous strictly nonblocking $k \times k$ WDM split cross-connect with $n \geq 4$ available wavelengths. Let D be a set of demands and R a set of routes that are **Constrained** (λ_i, λ_j) . If $\lambda_i \in f(I_a, R)$ and $\lambda_j \in f(O_b, R)$, then*

1. $(D', R') = \mathbf{Force}(C, (D, R), (I_a, \lambda_i, O_b, \lambda_j))$ can be performed,
2. $D' = \{d\} \cup D$, where d is a demand from input fiber I_a to output fiber O_b ,
3. $R' = \{r\} \cup R$, where r is the route for d using input wavelength λ_i and output wavelength λ_j , and
4. R' is **Constrained** (λ_i, λ_j) .

Proof. Notice that the case when $|f(I_a, R)| < |f(O_b, R)|$ is analogous to the case when $|f(I_a, R)| > |f(O_b, R)|$. Therefore without loss of generality we consider $|f(I_a, R)| \geq |f(O_b, R)|$. Note that since R was **Constrained** (λ_i, λ_j) , each fiber can have at most two demands and therefore $n - 2 \leq |f(I_a, R)| \leq n$ and $n - 2 \leq |f(O_b, R)| \leq n$.

In Step 2 we make $|f(O_b, R)|$ demands. If $|f(I_a, R)| = |f(O_b, R)|$, then all free input wavelengths will be used on I_a . Otherwise, if $|f(I_a, R)| > |f(O_b, R)|$, then

one wavelength on input fiber I_a will be unused. We then remove the demand that used output wavelength λ_j . Therefore, before Step 5, $|f(I_a, R')| \leq 2$. Since R was **Constrained** (λ_i, λ_j) and since we have added only demands from output fiber O_b , all other output fibers must still have at least two wavelengths unused prior to Step 5. Therefore there are enough output wavelengths to make the requested demands in Step 5. After Step 6 there will be only one free wavelength, λ_i , on input fiber I_a and at most two free wavelengths on output fiber O_b . Therefore, by an analogous argument, there are enough free input wavelengths to make the demands requested in Step 7. Furthermore, prior to Step 7 we removed any demand from output fiber O_b that was routed on output wavelength λ_j . Therefore the demand we remove in Step 8 that is routed on output wavelength λ_j on output fiber O_b is guaranteed to use an input fiber other than I_a . Hence after Step 8, input fiber I_a has only input wavelength λ_i available and output fiber O_b has only output wavelength λ_j available. Therefore the route for the demand made in Step 9 will use input wavelength λ_i and output wavelength λ_j . Finally, since we remove all demands added in Steps 2, 5, and 7, $D' = \{d\} \cup D$, where d is a demand from input fiber I_a to output fiber O_b and R' is **Constrained** (λ_i, λ_j) . \square

Notice that Lemma 12 allows us to create a set of standard demands, D , and a set of routes R for those demands. Furthermore, Lemma 12 allows us to replace the demands made in Steps 2, 5, and 6 of $\text{Block}(C, (D_i, R_i))$ with the appropriate sequence of general demands. Therefore we arrive at the following corollary to Theorem 7.

COROLLARY 13. *For any homogeneous strictly nonblocking $k \times k$ WDM split cross-connect using a general demand model with $k \geq 2$ and $n \geq 4$, there must be a standard set of demands, D_t , and a standard routing R_t of D_t that uses at least $2k - 1$ wavelength interchangers.*

Combining the results in Corollaries 11 and 13 implies the following result for homogeneous cross-connects.

COROLLARY 14. *Any homogeneous strictly nonblocking $k \times k$ WDM cross-connect with $k \geq 2$ and $n \geq 4$ wavelengths supporting any demand model must have at least $2k - 1$ wavelength interchangers.*

7. Determining the optimal number of wavelength interchangers for heterogeneous split cross-connects. In this section we focus on heterogeneous split cross-connects. Recall that a heterogeneous $k_1 \times k_2$ WDM cross-connect has k_1 input fibers that each support n_1 input wavelengths and k_2 output fibers that each support n_2 output wavelengths. Note that the set of input and output wavelengths can be completely disjoint. Therefore we now refer to the output wavelengths as $\{\gamma_1, \gamma_2, \dots, \gamma_{n_2}\}$. Without loss of generality, we assume that $k_1 \leq k_2$.

In section 5 we presented a family of strictly nonblocking $k_1 \times k_2$ WDM cross-connects that use $\min(k_1 + k_2 - 1, n_1 k_1)$ wavelength interchangers. In section 6 we showed that this is the optimal number of wavelength interchangers for any $k \times k$ WDM homogeneous cross-connect. In this section we extend the techniques of section 6 to $k_1 \times k_2$ WDM heterogeneous split cross-connects. To show that any heterogeneous $k_1 \times k_2$ WDM split cross-connect requires $\min(k_1 + k_2 - 1, n_1 k_1)$ wavelength interchangers we consider any strictly nonblocking $k_1 \times k_2$ WDM split cross-connect with $m < \min(k_1 + k_2 - 1, n_1 k_1)$ wavelength interchangers and show that there is a sequence of demands and a routing of those demands such that there is a final valid demand d that cannot be routed by the cross-connect. For the heterogeneous case we consider only split cross-connects and only a demand model where the input and output wavelengths are specified as part of the demand.

The proof that any heterogeneous strictly nonblocking $k_1 \times k_2$ WDM split cross-connect must have $\min(k_1 + k_2 - 1, n_1 k_1)$ wavelength interchangers has a flavor similar to the proof, presented in the previous section, that showed that any homogeneous $k \times k$ WDM cross-connect requires $2k - 1$ wavelength interchangers. We present the lower bound in two cases. First, we consider $k_1 \times k_2$ WDM cross-connects where $n_1 k_1 \leq k_2$. In this case we can create a set of demands that all use the same output wavelength and therefore must all use their own wavelength interchanger. Hence we arrive at a simple lower bound that says that any strictly nonblocking $k_1 \times k_2$ WDM cross-connect must have at least $n_1 k_1$ wavelength interchangers if $n_1 k_1 \leq k_2$. We then consider cross-connects where $n_1 k_1 > k_2$. Our basic idea is to mimic the proof from section 6 that showed that any $k \times k$ WDM cross-connect requires $2k - 1$ wavelength interchangers. To achieve this for heterogeneous cross-connects we use two input wavelengths, $\{\lambda_1, \lambda_2\}$, two output wavelengths $\{\gamma_1, \gamma_2\}$, and a set of input and output fibers of equal size, say z , to force $2z - 1$ wavelength interchangers to service either a demand with input wavelength λ_1 or a demand with output wavelength γ_2 . We use the remaining $k_2 - z$ output fibers and the unused wavelengths on the input fibers to “hold” $k_2 - z$ wavelength interchangers. By making z as large as possible while still having enough available input wavelengths to make the $k_2 - z$ demands, we are able to show that any strictly nonblocking $k_1 \times k_2$ WDM split cross-connect requires $\min(k_1 + k_2 - 1, n_1 k_1)$ wavelength interchangers.

7.1. Lower bound for heterogeneous split cross-connects. We approach the lower bound for the number of wavelength interchangers in a strictly nonblocking $k_1 \times k_2$ WDM cross-connect as follows.

1. We show that if $k_2 \geq n_1 k_1$, then $n_1 k_1$ wavelength interchangers are necessary.
2. We show that when $k_2 < n_1 k_1$, any strictly nonblocking $k_1 \times k_2$ WDM cross-connect must have at least $\min(k_1 + k_2 - 1, n_1 k_1 - 1)$ wavelength interchangers.
3. We then consider the case when $(n_1 - 1)k_1 < k_2 < n_1 k_1$, where the previous step only proved that $n_1 k_1 - 1$ wavelength interchangers are necessary, and show that in fact $n_1 k_1$ wavelength interchangers are necessary for any strictly nonblocking $k_1 \times k_2$ WDM cross-connect.

We begin this section by considering the case when $k_2 \geq n_1 k_1$ where we saw in section 5 that there exists a strictly nonblocking WDM cross-connect that uses $n_1 k_1$ wavelength interchangers.

THEOREM 15. *If C is a strictly nonblocking $k_1 \times k_2$ WDM cross-connect with $k_2 \geq n_1 k_1$, then C must have at least $n_1 k_1$ wavelength interchangers.*

Proof. If $k_2 \geq n_1 k_1$, then a valid demand set could include $n_1 k_1$ demands that all use the same output wavelength. Since no wavelength interchanger can service more than one of these demands, any $k_1 \times k_2$ WDM cross-connect will need at least $n_1 k_1$ wavelength interchangers if it is strictly nonblocking. \square

If $k_2 < n_1 k_1$, it is easy to see by the argument in the proof of Theorem 15 that any strictly nonblocking WDM cross-connect must have at least k_2 wavelength interchangers. In order to show that any strictly nonblocking WDM split cross-connect actually requires $\min(k_1 + k_2 - 1, n_1 k_1)$ wavelength interchangers, we first show that $\min(k_1, n_1 k_1 - k_2) + k_2 - 1 = \min(k_1 + k_2 - 1, n_1 k_1 - 1)$ wavelength interchangers are needed. To do this we consider any strictly nonblocking WDM split cross-connect C with fewer than $\min(k_1, n_1 k_1 - k_2) + k_2 - 1$ wavelength interchangers. For such a cross-connect we will create a demand set D and a routing R of D such that C must use each wavelength interchanger to service a demand with either input wavelength λ_1 or output wavelength γ_2 . Given D and R we will then show that one additional

valid demand $d \notin D$ exists with input wavelength λ_1 and output wavelength γ_2 . By construction, all the wavelength interchangers in the cross-connect will already be servicing a demand that either uses this new demand's input wavelength or its output wavelength. Therefore the cross-connect will not have a wavelength interchanger to service the new demand. This implies that if a $k_1 \times k_2$ WDM split cross-connect is strictly nonblocking, then it must have at least $\min(k_1 + k_2 - 1, n_1 k_1 - 1)$ wavelength interchangers. For cases where this construction shows that $n_1 k_1 - 1$ wavelength interchangers are necessary, we then start with the routing that uses $n_1 k_1 - 1$ wavelength interchangers and then manipulate the demands to require $n_1 k_1$ wavelength interchangers for any $k_1 \times k_2$ WDM cross-connect.

Consider a strictly nonblocking $k_1 \times k_2$ WDM cross-connect C where $k_2 < n_1 k_1$. Let $z = \min(k_1, n_1 k_1 - k_2)$, $\mathcal{I}^A = \{a_1, a_2, \dots, a_z\}$ be a subset of I consisting of z input fibers, $\mathcal{O}^A = \{b_1, b_2, \dots, b_z\}$ be a subset of z output fibers in O , and $\mathcal{O}^H = \{h_1, h_2, \dots, h_{k_2-z}\}$ be the remaining output fibers. Given this partition of the input and output fibers we say that a valid demand set D is *standard* if and only if

1. $|D| = k_2 + z$,
2. $2z$ of the demands in D are demands with an input fiber in \mathcal{I}^A , an output fiber in \mathcal{O}^A , input wavelength either λ_1 or λ_2 and output wavelength either γ_1 or γ_2 , and
3. the other $k_2 - z$ demands in D have output wavelength γ_2 and an output fiber in \mathcal{O}^H .

See Figure 13 for an example of a standard set of demands and a standard routing of those demands on a heterogeneous cross-connect C .

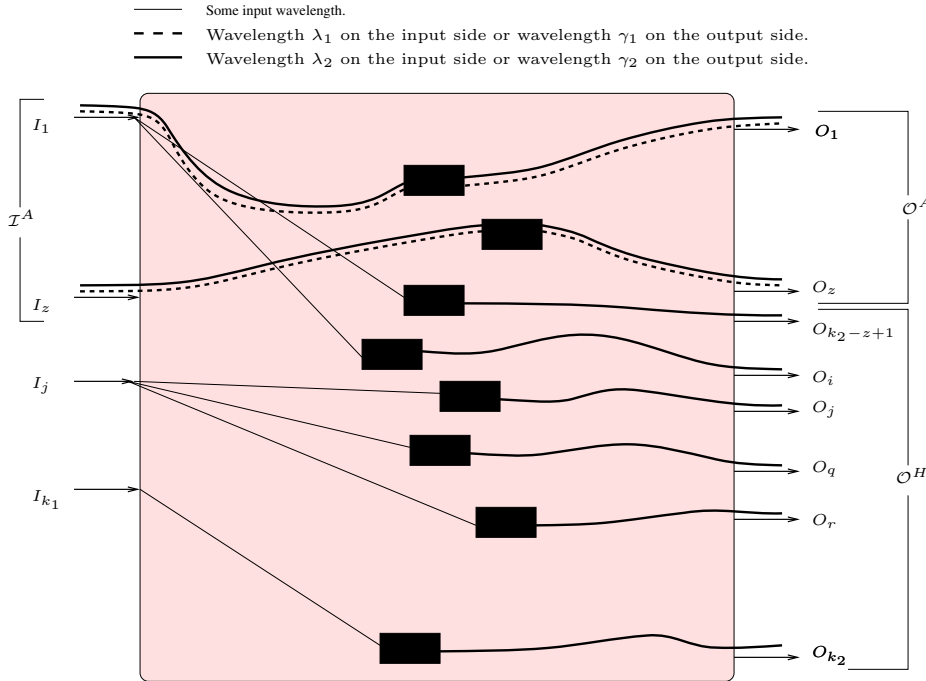

FIG. 13. A set of standard demands, D_0 , on C .

We will be constructing various standard demand sets D_i in what follows. For such a standard set of demands, D_i , define D_i^A to be the subset of demands in D_i

with an output fiber in \mathcal{O}^A . The subset of demands in D_i with an output fiber in \mathcal{O}^H will remain fixed for all i and we denote this set by D^H .

As with our construction for homogeneous cross-connects, we will assume that we have a routing R_i for a standard set of demands, D_i . We will then successively transform the standard demand sets into new standard demand sets by creating new demands with input wavelength λ_1 and output wavelength γ_2 with the goal of forcing these new demands to use wavelength interchangers that are so far unaccounted for. To do this for heterogeneous cross-connects we must partition the set of wavelength interchangers in C into three sets depending on the types of demands that they service. The routes for the fixed demands in D^H will be unchanging and the fixed set of wavelength interchangers that service these routes is denoted by W^H . The intuition is that these wavelength interchangers will always be “held” by these routes and so the cross-connect will be unable to route other demands with output wavelength γ_2 through them. We modify the definition of W_i^B from the homogeneous case to be the set of wavelength interchangers that *are not in* W^H yet service a demand with either input wavelength λ_1 and/or output wavelength γ_2 . These wavelength interchangers are thought of as “blocking” demands with input wavelength λ_1 and output wavelength γ_2 from being routed through them. Finally, let W_i^F be the set of all other wavelength interchangers. This set of wavelength interchangers is thought to be “free” to service demands with input wavelength λ_1 and output wavelength γ_2 .

We define a valid routing R_i of a standard set of demands D_i to be *standard* if

1. each wavelength interchanger in W^H services only one demand and
2. the set of output paths of the routes for demands in D^H are edge disjoint from all output paths of the routes for demands in D_i^A .

Suppose C is a strictly nonblocking $k_1 \times k_2$ WDM split cross-connect where $k_2 < n_1 k_1$. Then we show that a standard set of demands, D_0 , and a standard routing R_0 for D_0 exist within C . First, create $z = \min(k_1, n_1 k_1 - k_2)$ demands of the form $d_{i1} = (a_i, \lambda_1, b_i, \gamma_1)$ for $1 \leq i \leq z$. Since C is strictly nonblocking, C must be able to satisfy these z demands. Notice also that these demands must be routed on edge disjoint paths because they all have the same input and output wavelengths. For $1 \leq i \leq z$, create a demand $d_{i2} = (a_i, \lambda_2, b_i, \gamma_2)$ routed along the same path as d_{i1} .

Now with these $2z$ demands on the cross-connect, we would like to create $k_2 - z$ demands such that each output fiber $h_j \in \mathcal{O}^H$ has a demand with output wavelength γ_2 . First, consider the case where $k_1 \leq n_1 k_1 - k_2$ and hence $z = k_1$. In this case $(n_1 - 1)k_1 \geq k_2$. Thus, $(n_1 - 2)k_1 \geq k_2 - k_1$. Since there are $n_1 k_1 - 2k_1$ input wavelengths unused on the set of input fibers, clearly there are enough input wavelengths available to make $k_2 - k_1$ new valid demands all using output wavelength γ_2 . On the other hand, if $z = n_1 k_1 - k_2$, then $n_1 k_1 - 2z = k_2 - z$, and therefore there are again enough available wavelengths on the input side to make $k_2 - z$ demands with output wavelength γ_2 . Therefore we add $k_2 - z$ valid demands such that each fiber $h_j \in \mathcal{O}^H$ has a demand with output wavelength γ_2 .

Clearly the set of demands that use output wavelength γ_2 must all have edge disjoint output paths. Since all other demands in D_0^A are routed along a path that also has a demand in D_0^A with output wavelength γ_2 , all demands in D_0^A are routed along output paths that are edge disjoint with respect to all output paths of routes for demands in D^H . Therefore D_0 is a standard set of demands and the routing described is a standard routing R_0 for D_0 .

LEMMA 16. *If C is a strictly nonblocking $k_1 \times k_2$ WDM split cross-connect, D_i is a standard set of demands, and R_i is a standard routing of the demands in D_i that uses $\min(k_1, n_1 k_1 - k_2) + k_2 - g$ wavelength interchangers, where $g > 0$, then g wavelength interchangers in W_i^B will each service two demands both of whose input wavelengths are λ_1 and λ_2 and whose output wavelengths are γ_1 and γ_2 .*

Proof. By definition, any standard routing R_i of D_i routes at most one demand through any wavelength interchanger in W^H and therefore that demand must be a demand whose output fiber is in \mathcal{O}^H . There are $k_2 - z$ of these demands and therefore $|W^H| = k_2 - z$. Since the total number of wavelength interchangers used is $\min(k_1, n_1 k_1 - k_2) + k_2 - g = z + k_2 - g$ and $|W^H| = k_2 - z$, it must be the case that the number of wavelength interchangers in W_i^B and W_i^F is $2z - g$. The $2z$ demands of D_i^A must be routed through wavelength interchangers in W_i^B or W_i^F since R_i is a standard routing. These $2z$ demands in D_i^A use only input wavelengths λ_1 and λ_2 and output wavelengths γ_1 and γ_2 . Thus no wavelength interchanger can service more than two of these demands. This implies that g wavelength interchangers in W_i^B or W_i^F must service two demands. Any such wavelength interchanger that services two of these demands must service a demand with input wavelength λ_1 and a demand with output wavelength γ_2 and therefore is by definition in W_i^B . \square

Given the standard set of demands, D_0 , and the routing R_0 of D_0 , we now present a manipulation, similar to $\text{Block}(C, (D_i, R_i))$, that can be used to iteratively change the set of demands on C so that eventually we arrive at a standard set of demands, D_t , and a standard routing R_t of D_t such that every wavelength interchanger in C is servicing a demand with either input wavelength λ_1 or output wavelength γ_2 . Notice that this is equivalent to showing that if C has no more than $\min(k_1, n_1 k_1 - k_2) + k_2 - g$ wavelength interchangers for some $g > 0$, then a standard set of demands D_i and a standard routing R_i of D_i exist such that $|W^H| = k_2 - z$, $|W_i^B| = 2z - g$ and $|W_i^F| = 0$.

Let $WI_j \in W_i^B$ be a wavelength interchanger that services exactly two demands, d_1 and d_2 . Suppose these demands have the form $d_1 = (a_1, \lambda_1, b_2, \gamma_2)$ and $d_2 = (a_2, \lambda_2, b_1, \gamma_1)$. Recall the operation $\text{Uncross}(WI_j)$ which is defined to have the effect of changing these two demands to be $(a_1, \lambda_1, b_1, \gamma_1)$ and $(a_2, \lambda_2, b_2, \gamma_2)$ and routing these new demands exactly as d_1 and d_2 were routed while keeping all other demands and routes unchanged. Again, notice that the only real change made by $\text{Uncross}(WI_j)$ is to swap the output paths of the routes of d_1 and d_2 . On the other hand, if the demands have the form $d_1 = (a_1, \lambda_1, b_2, \gamma_1)$ and $d_2 = (a_2, \lambda_2, b_1, \gamma_2)$, then $\text{Uncross}(WI_j)$ has no effect; see Figure 10.

We define the operation $\text{HeterogeneousBlock}(C, (D_i, R_i))$, which is similar to $\text{Block}(C, (D_i, R_i))$. However, now we assume that C is a heterogeneous strictly nonblocking $k_1 \times k_2$ WDM split cross-connect, D_i is a standard set of demands, and R_i is a standard routing of the demands in D_i that uses fewer than $\min(k_1, n_1 k_1 - k_2) + k_2 - 1$ wavelength interchangers. Each time we run $\text{HeterogeneousBlock}(C, (D_i, R_i))$ we alter D_i and R_i to create a new standard set of demands D_{i+1} and a standard routing R_{i+1} for D_{i+1} such that the number of wavelength interchangers that service a demand with either input wavelength λ_1 or output wavelength γ_2 is strictly greater under D_{i+1} and R_{i+1} than it was under D_i and R_i . In section 6 we saw the operation $\text{Block}(C', (D_i, R_i))$ which performed a similar task for a homogeneous cross-connect C' . In $\text{Block}(C', (D_i, R_i))$ we did not have “extra” demands, D^H , that “held” the wavelength interchangers in W^H . For a heterogeneous cross-connect we use these demands to block the wavelength interchangers in W^H from servicing the two new demands that we create each iteration. In order to prevent either demand from being

routed through one of the wavelength interchangers in W^H , we switch the output wavelength of the demands in D^H such that the demands in D^H always use the same output wavelength as the new demand that we are creating; see Figure 14.

After we define **HeterogeneousBlock**($C, (D_i, R_i)$), we will show that it consists of a sequence of valid operations.

HeterogeneousBlock($C, (D_i, R_i)$).

1. Take two wavelength interchangers, WI_u and WI_v , in W_i^B that, by Lemma 16, each service two demands.
2. **Uncross**(WI_u) and **Uncross**(WI_v).
3. Let $(a_{u1}, \lambda_1, b_{u1}, \gamma_1)$ and $(a_{u2}, \lambda_2, b_{u2}, \gamma_2)$ be the two resulting demands that WI_u services. Let $(a_{v1}, \lambda_1, b_{v1}, \gamma_1)$ and $(a_{v2}, \lambda_2, b_{v2}, \gamma_2)$ be the two resulting demands that WI_v services.
4. Remove $(a_{u1}, \lambda_1, b_{u1}, \gamma_1)$ and $(a_{v2}, \lambda_2, b_{v2}, \gamma_2)$ from D_i and route all remaining demands according to R_i to create D_{i+1} and R_{i+1} .
5. For any demand $d_j \in D_{i+1}$ of the form $(I_e, \lambda_t, h_j, \gamma_2)$, remove d_j from D_{i+1} , replace it with the demand $d'_j = (I_e, \lambda_t, h_j, \gamma_1)$, and route d'_j along the same path that d_j was routed along.
6. Add $(a_{v2}, \lambda_2, b_{u1}, \gamma_1)$ to D_{i+1} and add a valid route for this demand to R_{i+1} .
7. For any demand $d'_j \in D_{i+1}$ of the form $(I_e, \lambda_t, h_j, \gamma_1)$, remove d'_j from D_{i+1} , replace it with demand $d_j = (I_e, \lambda_t, h_j, \gamma_2)$, and route d_j along the same path that d'_j was routed along.
8. Add $(a_{u1}, \lambda_1, b_{v2}, \gamma_2)$ to D_{i+1} and add a valid route for this demand to R_{i+1} .
9. Return (D_{i+1}, R_{i+1}) .

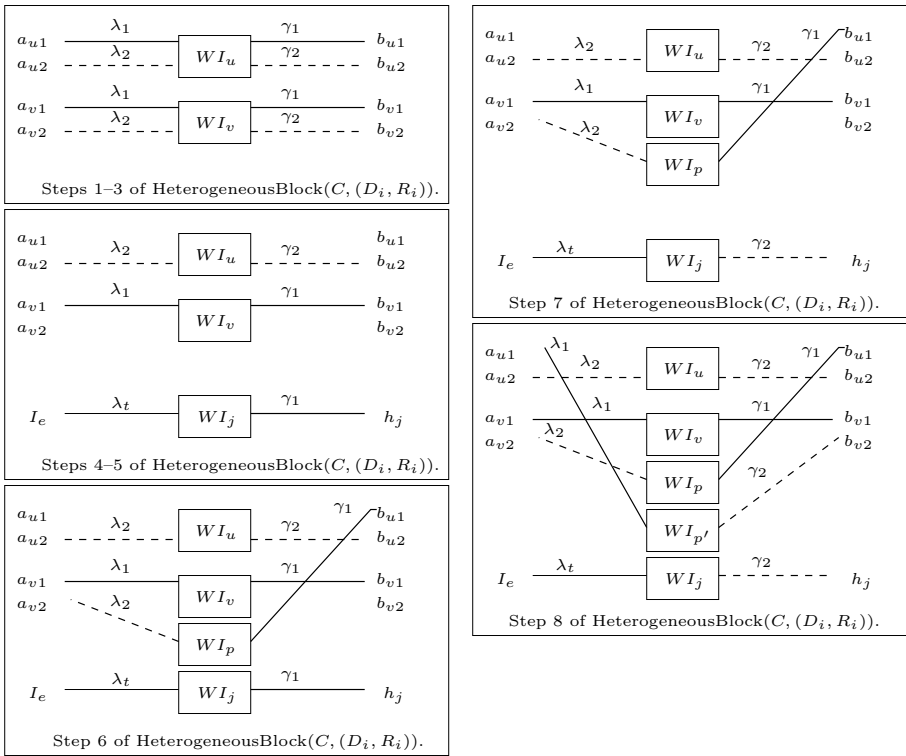

FIG. 14. The steps in *HeterogeneousBlock*($C, (D_i, R_i)$).

The initial set of demands on C is D_0 and these are routed according to R_0 as defined above. We inductively define $(D_{i+1}, R_{i+1}) = \mathbf{HeterogeneousBlock}(C, (D_i, R_i))$ as long as R_i uses fewer than $\min(k_1, n_1 k_1 - k_2) + k_2 - 1$ wavelength interchangers. Consider $\mathbf{HeterogeneousBlock}(C, (D_i, R_i))$. We now prove that each step can be performed. Consider Steps 1–3.

1. Take two wavelength interchangers, WI_u and WI_v , in W_i^B that, by Lemma 16, each service two demands.
2. $\mathbf{Uncross}(WI_u)$ and $\mathbf{Uncross}(WI_v)$.
3. Let $(a_{u1}, \lambda_1, b_{u1}, \gamma_1)$ and $(a_{u2}, \lambda_2, b_{u2}, \gamma_2)$ be the two resulting demands that WI_u services. Let $(a_{v1}, \lambda_1, b_{v1}, \gamma_1)$ and $(a_{v2}, \lambda_2, b_{v2}, \gamma_2)$ be the two resulting demands that WI_v services.

By Lemma 16 and the assumption that R_i uses fewer than $\min(k_1, n_1 k_1 - k_2) + k_2 - 1$ wavelength interchangers, there must exist two wavelength interchangers in W_i^B that service two demands. Given these two wavelength interchangers, we then “uncross” their demands. This does not change any of the wavelengths used along any of the fibers in C . In particular, while this alters the set of demands, the new set of demands is still a standard set of demands.

In Step 4, we remove two demands and leave the remaining demands unchanged. By our choice of demands to remove, we ensure that WI_v and WI_u will still each service one demand with either input wavelength λ_1 or output wavelength γ_2 . Thus WI_v and WI_u remain in W_i^B .

4. Remove $(a_{u1}, \lambda_1, b_{u1}, \gamma_1)$ and $(a_{v2}, \lambda_2, b_{v2}, \gamma_2)$ from D_i and route all remaining demands according to R_i to create D_{i+1} and R_{i+1} .

Next in Step 5, we change the output wavelength of every demand in D^H to be γ_1 . Since R_i is a standard routing, all the output paths for demands in D^H are edge disjoint from all other demands. Therefore this step does not create an invalid set of demands or routings for those demands. Changing the output wavelength of every demand in D^H means that each wavelength interchanger in W^H is servicing a demand with output γ_1 when a route for the new demand with output wavelength γ_1 in Step 6 is found.

5. For any demand $d_j \in D_{i+1}$ of the form $(I_e, \lambda_t, h_j, \gamma_2)$, remove d_j from D_{i+1} , replace it with the demand $d'_j = (I_e, \lambda_t, h_j, \gamma_1)$, and route d'_j along the same path that d_j was routed along.
6. Add $(a_{v2}, \lambda_2, b_{u1}, \gamma_1)$ to D_{i+1} and add a valid route for this demand to R_{i+1} .

As a result this demand can be serviced only by a wavelength interchanger in either W_i^B or W_i^F and any route for this demand will use an output path that is edge disjoint from the output paths for all demands in D^H . If the wavelength interchanger that does service the demand from Step 6 is in W_i^F , then it will be in W_{i+1}^F , and clearly if it is in W_i^B , then it will be in W_{i+1}^B . So after Step 6, $|W_{i+1}^B| = |W_i^B|$, $|W_{i+1}^F| = |W_i^F|$ and $|W^H|$ of course remains fixed.

Next, in Step 7, we switch all $d'_j = (I_e, \lambda_t, h_j, \gamma_1)$ back to $d_j = (I_e, \lambda_t, h_j, \gamma_2)$. Again this is possible since R_i is a standard routing and the output paths of the routes for these demands must be edge disjoint from all other output paths. Furthermore, switching the output wavelength of each of the demands serviced by a wavelength interchanger in W^H back to γ_2 means that the new demand in Step 8 must be serviced by a wavelength interchanger in either W_i^B or W_i^F and the route chosen to service the demand will have an edge disjoint output path from all output paths for demands in D^H .

7. For any demand $d'_j \in D_{i+1}$ of the form $(I_e, \lambda_t, h_j, \gamma_1)$, remove d'_j from D_{i+1} ,

replace it with demand $d_j = (I_e, \lambda_t, h_j, \gamma_2)$, and route d_j along the same path that d'_j was routed along.

8. Add $(a_{u1}, \lambda_1, b_{v2}, \gamma_2)$ to D_{i+1} and add a valid route for this demand to R_{i+1} .

A valid route for the new demand in Step 8 must exist since C is strictly non-blocking. Furthermore, a wavelength interchanger in W_i^F must be used to service this demand since all wavelength interchangers in W_i^B are servicing a demand with either input wavelength λ_1 or output wavelength γ_2 , and all wavelength interchangers in W^H are servicing a demand with output wavelength γ_2 . Since the demand requested in Step 8 has both input wavelength λ_1 and output wavelength γ_2 , the wavelength interchanger that services this new demand will be in W_{i+1}^B . Thus, after Step 8, D_{i+1} is a standard set of demands and R_{i+1} is a standard routing for those demands such that $|W^H|$ remains fixed, $|W_{i+1}^B| = |W_i^B| + 1$, and $|W_{i+1}^F| = |W_i^F| - 1$. Hence we conclude the following lemma.

LEMMA 17. *If C is a strictly nonblocking $k_1 \times k_2$ WDM split cross-connect with $k_2 < n_1 k_1$, D_i is a standard set of demands, and R_i is a standard routing of the demands in D_i that uses fewer than $\min(k_1, n_1 k_1 - k_2) + k_2 - 1$ wavelength interchangers, then*

1. **HeterogeneousBlock** $(C, (D_i, R_i))$ can be executed,
2. $(D_{i+1}, R_{i+1}) = \mathbf{HeterogeneousBlock}(C, (D_i, R_i))$,
3. D_{i+1} is a standard set of demands,
4. R_{i+1} is a standard routing of the demands in D_{i+1} ,
5. $|W^H|$ remains fixed,
6. $|W_{i+1}^B| = |W_i^B| + 1$, and
7. $|W_{i+1}^F| = |W_i^F| - 1$.

We now apply Lemma 17 to show that any strictly nonblocking $k_1 \times k_2$ WDM split cross-connect with $k_1 \leq k_2 < n_1 k_1$ must have at least $\min(k_1, n_1 k_1 - k_2) + k_2 - 1$ wavelength interchangers.

THEOREM 18. *For any strictly nonblocking $k_1 \times k_2$ WDM split cross-connect with $k_1 \leq k_2 < n_1 k_1$, there must be a standard set of demands D_t and a standard routing R_t of D_t that uses at least $\min(k_1, n_1 k_1 - k_2) + k_2 - 1 = \min(k_1 + k_2 - 1, n_1 k_1 - 1)$ wavelength interchangers.*

Proof. By contradiction, let C be a strictly nonblocking $k_1 \times k_2$ WDM split cross-connect where $k_1 \leq k_2 < n_1 k_1$. Start with the standard set of demands D_0 with standard routing R_0 , which must exist. Let $M = \min(k_1, n_1 k_1 - k_2) + k_2 - 1$. If R_0 uses at least M wavelength interchangers, then we are done. Otherwise, by Lemma 17, we can repeatedly apply **HeterogeneousBlock** to produce a series of pairs $(D_{i+1}, R_{i+1}) = \mathbf{HeterogeneousBlock}(C, (D_i, R_i))$ where each D_i is a standard set of demands and each R_i is a standard routing of the demands in D_i . This sequence continues as long as R_i has the property that it uses fewer than M wavelength interchangers. By Lemma 17 we know that $|W_{i+1}^F| = |W_i^F| - 1$ because the demand in Step 9 must be routed through a wavelength interchanger in W_i^F . Thus if $|W_0^F| = t$, then either for some $i < t$, R_i uses at least M wavelength interchangers and we are done or $|W_t^F| = 0$. If R_t uses fewer than M wavelength interchangers, then Lemma 17 guarantees that we can perform **HeterogeneousBlock** $(C, (D_t, R_t))$. However, the demand in Step 9 must be serviced by a wavelength interchanger in W_t^F . Therefore Step 9 cannot be completed in **HeterogeneousBlock** $(C, (D_t, R_t))$. Since C is strictly nonblocking it must be that R_t uses $\min(k_1, n_1 k_1 - k_2) + k_2 - 1$ or more wavelength interchangers. \square

Theorem 18 says that if $k_2 \leq (n_1 - 1)k_1$, then $k_1 + k_2 - 1$ wavelength interchangers are needed. However, if $(n_1 - 1)k_1 < k_2 < n_1k_1$, then it says only that $n_1k_1 - 1$ wavelength interchangers are needed. We now show that in this case, there must, in fact, be at least n_1k_1 wavelength interchangers.

We could easily show that n_1k_1 wavelength interchangers are necessary, if we could continue executing $(D_{i+1}, R_{i+1}) = \mathbf{HeterogeneousBlock}(C, (D_i, R_i))$ until R_{i+1} uses $n_1k_1 - 1$ wavelength interchangers and $W_{i+1}^F = 0$. However, in general, it is possible that at some point $\mathbf{HeterogeneousBlock}(C, (D_i, R_i))$ could return a standard set of demands D_{i+1} and a standard routing R_{i+1} for D_{i+1} such that $n_1k_1 - 1$ wavelength interchangers in C are used to service the demands but $W_{i+1}^F > 0$. Once this many wavelength interchangers in C are used to service a demand we can no longer run $\mathbf{HeterogeneousBlock}(C, (D_{i+1}, R_{i+1}))$. Thus we need a procedure that is similar to $\mathbf{HeterogeneousBlock}(C, (D_{i+1}, R_{i+1}))$ but instead of using the demands corresponding to two wavelength interchangers that each service two demands, it will use one such set of demands, which must exist by Lemma 16, and one single demand in D^H that uses input wavelength λ_1 and output wavelength γ_2 . Before presenting the new construction we need to prove that such a demand in D^H exists.

LEMMA 19. *Let C be a strictly nonblocking $k_1 \times k_2$ WDM split cross-connect where $(n_1 - 1)k_1 < k_2 < n_1k_1$. If D_i is a standard set of demands, then at least one demand in D^H has input wavelength λ_1 and output wavelength γ_2 .*

Proof. Since D_i is a standard set of demands, there must be one demand in D_i with output wavelength γ_2 for each output fiber in \mathcal{O}^H . The set of all such demands is by definition D^H . If $(n_1 - 1)k_1 < k_2 < n_1k_1$, then $z = n_1k_1 - k_2 < k_1$. The total number of demands is $k_2 + z = n_1k_1$. Therefore every input fiber has a demand for every input wavelength. Only z input fibers have demands with input wavelength λ_1 in D^A . Therefore at least one input fiber must have n_1 demands originating from it, all of which are in D^H . Since no two demands from the same input fiber can have the same input wavelength, this input fiber must have exactly one demand for each possible input wavelength. Therefore it has a demand in D^H with input wavelength λ_1 . Since all demands in D^H have output wavelength γ_2 , this demand is a demand in D^H with input wavelength λ_1 and output wavelength γ_2 . \square

Now assume we have a standard set of demands D_i and a standard routing R_i that routes D_i in such a way that all $n_1k_1 - 1$ wavelength interchangers in C service a demand in D_i . We can use Lemma 19 to show that in fact C must have n_1k_1 wavelength interchangers if it is strictly nonblocking.

First, we need to define the following notation. Let p_1 and p_2 be paths such that the last node v in p_1 is the first node in p_2 . We will use the notation $p_1||p_2$ to denote the path formed by following p_1 to v and then following p_2 . Consider $\mathbf{HeterogeneousBlock2}(C, (D_i, R_i))$, defined as follows.

HeterogeneousBlock2($C, (D_i, R_i)$).

1. Take one wavelength interchanger, WI_v , in W_i^B that services two demands and one wavelength interchanger, WI_u , in W^H that services a demand in D^H with input wavelength λ_1 and output wavelength γ_2 .
2. **Uncross**(WI_v).
3. Let $d_{v1} = (a_{v1}, \lambda_1, b_{v1}, \gamma_1)$ and $d_{v2} = (a_{v2}, \lambda_2, b_{v2}, \gamma_2)$ be the two resulting demands that WI_v services.
4. Let $d_u = (I_u, \lambda_1, h_2, \gamma_2)$ be the demand that WI_u services.
5. Remove d_u from D_i and replace it with demand $d'_u = (I_u, \lambda_1, h_2, \gamma_1)$ and route d'_u along the path on which d_u was routed.

6. Remove $d_{v1} = (a_{v1}, \lambda_1, b_{v1}, \gamma_1)$ and route all remaining demands according to R_i .
7. Add the demand $d'_{v1} = (a_{v1}, \lambda_1, h_2, \gamma_2)$ to D_i , add a valid route r'_{v1} for d'_{v1} to R_i , and let p'_{v1} be the input path of r'_{v1} .
8. Let WI_x be the wavelength interchanger in W_i^F that services $d'_{v1} = (a_{v1}, \lambda_1, h_2, \gamma_2)$.
9. Let $d_x = (a_{x2}, \lambda_2, b_{x1}, \gamma_1)$ be the other demand that WI_x services and let p_{x1} be the output path of the route for d_x .
10. Remove d_x and d'_{v1} from D_i .
11. Add $d_q = (a_{v1}, \lambda_1, b_{x1}, \gamma_1)$ to D_i to create D_{i+1} and add the valid route $r_q = p'_{v1} || p_{x1}$ for d_x to R_i to create R_{i+1} .
12. For any demand $d_j \in D_{i+1}$ of the form $(I_e, \lambda_t, h_j, \gamma_2)$, remove d_j from D_{i+1} , replace it with the demand $d'_j = (I_e, \lambda_t, h_j, \gamma_1)$, and route d'_j along the same path that d_j was routed on.
13. Add $(a_{x2}, \lambda_2, b_{v1}, \gamma_1)$ to D_{i+1} and add a valid route for this demand to R_{i+1} .
14. For any demand $d'_j \in D_{i+1}$ of the form $(I_e, \lambda_t, h_j, \gamma_1)$, remove d'_j from D_{i+1} , replace it with demand $d_j = (I_e, \lambda_t, h_j, \gamma_2)$, and route d_j along the same path that d'_j was routed on.
15. Return (D_{i+1}, R_{i+1}) .

Figure 15 shows the steps of **HeterogeneousBlock2** $(C, (D_i, R_i))$. In Lemma 20 we prove its correctness.

LEMMA 20. *If C is a strictly nonblocking $k_1 \times k_2$ WDM split cross-connect with $n_1 k_1 - 1$ wavelength interchangers where $(n_1 - 1)k_1 < k_2 < n_1 k_1$, D_i is a standard set of demands, and R_i is a standard routing of the demands in D_i that uses all $n_1 k_1 - 1$ wavelength interchangers, then **HeterogeneousBlock2** $(C, (D_i, R_i))$ can be executed and $(D_{i+1}, R_{i+1}) = \mathbf{HeterogeneousBlock2}(C, (D_i, R_i))$, where D_{i+1} is a standard set of demands and R_{i+1} is a standard routing of the demands in D_{i+1} such that all $n_1 k_1 - 1$ wavelength interchangers in C service a demand in D_{i+1} . Also, D_{i+1} and R_{i+1} are such that $|W^H|$ remains fixed, $|W_{i+1}^B| = |W_i^B| + 1$, and $|W_{i+1}^F| = |W_i^F| - 1$.*

Proof. We look at each step of **HeterogeneousBlock2** $(C, (D_i, R_i))$ and prove its correctness. Consider first Steps 1–4.

1. Take one wavelength interchanger, WI_v , in W_i^B that services two demands and one wavelength interchanger WI_u in W^H that services a demand in D^H with input wavelength λ_1 and output wavelength γ_2 .
2. **Uncross** (WI_v) .
3. Let $d_{v1} = (a_{v1}, \lambda_1, b_{v1}, \gamma_1)$ and $d_{v2} = (a_{v2}, \lambda_2, b_{v2}, \gamma_2)$ be the two resulting demands that WI_v services.
4. Let $d_u = (I_u, \lambda_1, h_2, \gamma_2)$ be the demand that WI_u services.

See Figure 16.

Lemmas 16 and 19 show the existence of a wavelength interchanger $WI_v \in W_i^B$ that services two demands and a wavelength interchanger $WI_u \in W^H$ that services a demand with input wavelength λ_1 and output wavelength γ_2 . After “uncrossing” the demands that WI_v services, we change the output wavelength from γ_2 to γ_1 of the demand d_u that WI_u services. The inductive assumption that R_i is a standard routing allows us to change this output wavelength without rerouting the demand.

By the definition of a standard set of demands, no other demand in D_i used the output fiber h_2 that d_u uses. Thus consider Step 5.

5. Remove d_u from D_i and replace it with demand $d'_u = (I_u, \lambda_1, h_2, \gamma_1)$ and route d'_u along the path on which d_u was routed.

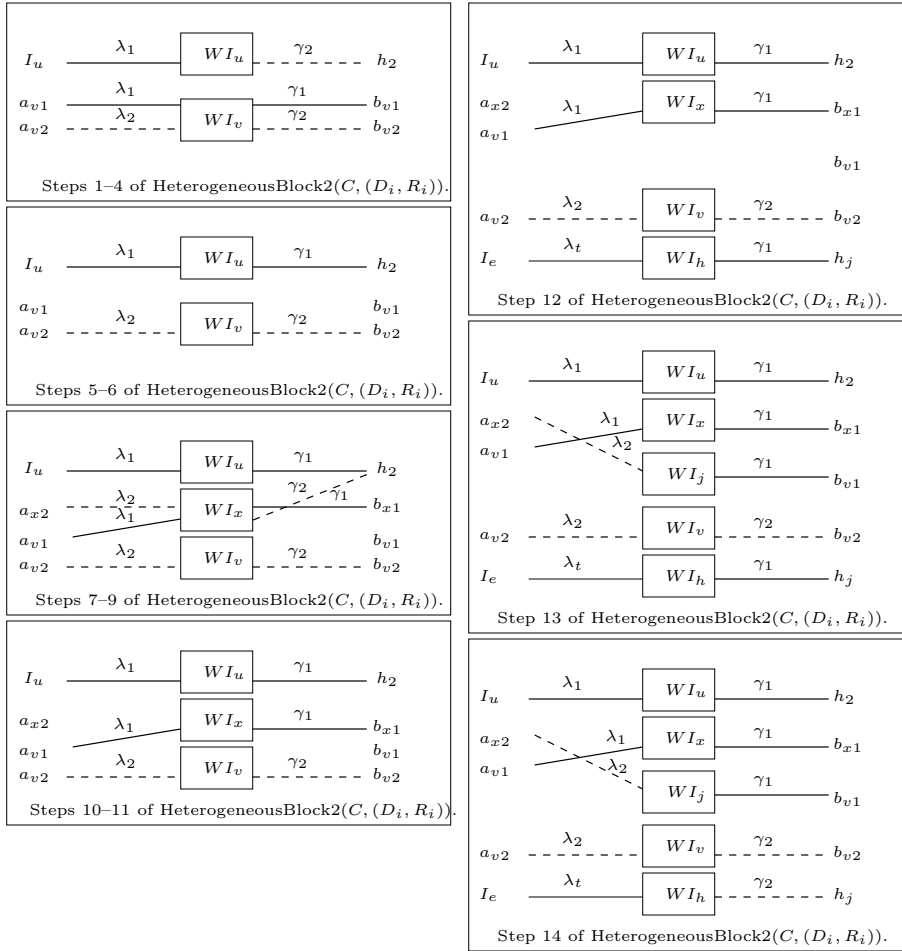

FIG. 15. The steps in $HeterogeneousBlock2(C, (D_i, R_i))$.

FIG. 16. Steps 1-4 of $HeterogeneousBlock2(C, (D_i, R_i))$.

After Step 5, when we change the only demand in D_i that uses h_2 to a demand with output wavelength γ_1 , it becomes valid to add a new demand with output wavelength γ_2 and output fiber h_2 . After Step 6, input fiber a_{v1} will have input wavelength λ_1 free.

6. Remove $d_{v1} = (a_{v1}, \lambda_1, b_{v1}, \gamma_1)$ and route all remaining demands according to R_i .

See Figure 17.

FIG. 17. Steps 5 and 6 of $HeterogeneousBlock2(C, (D_i, R_i))$.

We then add the demand, from input fiber a_{v1} to output fiber h_2 ; see Figure 18. This new demand uses input wavelength λ_1 and output wavelength γ_2 . Therefore it must be serviced by a wavelength interchanger $WI_x \in W_i^F$ since all of the wavelength interchangers in W_i^B and W^H are already servicing a demand with either input wavelength λ_1 or output wavelength γ_2 . The second demand d_x that WI_x services must exist because every wavelength interchanger in C services a demand in D_i . Thus Steps 9 and 10 are as follows.

7. Add the demand $d'_{v1} = (a_{v1}, \lambda_1, h_2, \gamma_2)$ to D_i , add a valid route r'_{v1} for d'_{v1} to R_i , and let p'_{v1} be the input path of r'_{v1} .

FIG. 18. Steps 7–9 of $HeterogeneousBlock2(C, (D_i, R_i))$.

9. Let $d_x = (a_{x2}, \lambda_2, b_{x1}, \gamma_1)$ be the other demand that WI_x services and let p_{x1} be the output path of the route for d_x .

10. Remove d_x and d'_{v1} from D_i .

Since R_i is able to route the first half of demand d'_v along p'_{v1} with wavelength λ_1 and the second half of d_x along p_{x1} with wavelength γ_1 , it must be possible to route demand d_q from Step 11 along $r_q = p'_{v1} || p_{x1}$; see Figure 19.

11. Add $d_q = (a_{v1}, \lambda_1, b_{x1}, \gamma_1)$ to D_i to create D_{i+1} and add the valid route $r_q = p'_{v1} || p_{x1}$ for d_x to R_i to create R_{i+1} .

FIG. 19. Steps 10 and 11 of $HeterogeneousBlock2(C, (D_i, R_i))$.

Notice that this adds WI_x to W_{i+1}^B .

Next in Step 12, we “switch” the output wavelength used by all demands in D^H ; see Figure 20. Since R_i is a standard routing, switching the output wavelength of

the demands in D^H does not make their routes invalid. The reason for switching the output wavelength of all demands in D^H is to ensure that the new demand in Step 13, is not serviced by a wavelength interchanger in W^H ; see Figure 21.

12. For any demand $d_j \in D_{i+1}$ of the form $(I_e, \lambda_t, h_j, \gamma_2)$, remove d_j from D_{i+1} , replace it with the demand $d'_j = (I_e, \lambda_t, h_j, \gamma_1)$, and route d'_j along the same path that d_j was routed on.

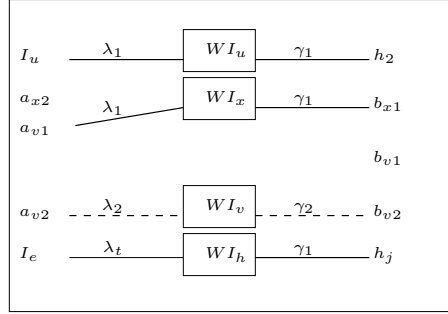

FIG. 20. Step 12 of $HeterogeneousBlock2(C, (D_i, R_i))$.

13. Add $(a_{x2}, \lambda_2, b_{v1}, \gamma_1)$ to D_{i+1} and add a valid route for this demand to R_{i+1} .

FIG. 21. Step 13 of $HeterogeneousBlock2(C, (D_i, R_i))$.

Since this new demand is a valid demand and C is strictly nonblocking, there must exist a valid route for this demand. Furthermore, the output path of the route for the new demand must be edge-disjoint from all demands that use output wavelength γ_1 . Therefore the route chosen for the new demand will maintain the inductive invariant that all demands not in D^H use edge-disjoint output paths from those used by demands in D^H . After we have found a route for the demand made in Step 13, Step 14 switches the output wavelength of all demands in D^H back to γ_2 so that D_{i+1} meets the definition of a standard set of demands; see Figure 22.

14. For any demand $d'_j \in D_{i+1}$ of the form $(I_e, \lambda_t, h_j, \gamma_1)$, remove d'_j from D_{i+1} , replace it with demand $d_j = (I_e, \lambda_t, h_j, \gamma_2)$, and route d_j along the same path that d'_j was routed on.

Notice that $|D_{i+1}| = k_2 + z$. Furthermore, $2z$ of the demands in D_{i+1} are demands with an input fiber in \mathcal{I}^A , an output fiber in \mathcal{O}^A , input wavelength either λ_1 or λ_2 , and output wavelength either γ_1 or γ_2 . The other $k_2 - z$ demands in D_{i+1} have output wavelength γ_2 and an output fiber in \mathcal{O}^H . Additionally, the routing R_{i+1} is such that each wavelength interchanger in W^H services at most one demand and

FIG. 22. Step 14 of $HeterogeneousBlock2(C, (D_i, R_i))$.

the set of output paths for demands in D^H are edge-disjoint from all output paths for demands in D_{i+1}^A . Therefore R_{i+1} is a standard routing of D_{i+1} . Furthermore, $|W^H|$ remains fixed, $|W_{i+1}^B| = |W_i^B| + 1$, and $|W_{i+1}^F| = |W_i^F| - 1$. Finally, since **HeterogeneousBlock2**($C, (D_i, R_i)$) only ever removed a demand from a wavelength interchanger that already serviced two demands, each wavelength interchanger in C must service a demand in D_{i+1} under R_{i+1} . \square

By Lemma 17 we can repeatedly perform **HeterogeneousBlock**($C, (D_i, R_i)$) until all $n_1 k_1 - 1$ wavelength interchangers are used to service a standard set of demands D_i routed according to a standard routing R_i of D_i . Using Lemma 20 we can then repeatedly augment D_i and R_i until we arrive at a standard set of demands D_t and a standard routing R_t of D_t for which $|W_t^F| = 0$. In **HeterogeneousBlock2**($C, (D_t, R_t)$), the new demand in Step 7 is a valid demand and therefore any strictly nonblocking WDM cross-connect must be able to find a route for this demand. However, since it must be serviced by a wavelength interchanger from W_t^F , C must not be strictly nonblocking. This contradiction leads to the following result.

THEOREM 21. *Any strictly nonblocking $k_1 \times k_2$ WDM split cross-connect with $(n_1 - 1)k_1 < k_2 < n_1 k_1$, where $n_1 > 1$ and $n_2 > 1$ are the number of available wavelengths in each input fiber and output fiber, respectively, will have at least $n_1 k_1$ wavelength interchangers.*

Together the results in Theorems 15, 18, and 21 imply the following.

THEOREM 22. *Any strictly nonblocking $k_1 \times k_2$ WDM split cross-connect with $n_1 > 1$ input wavelengths and $n_2 > 1$ output wavelengths must have at least $\min(k_1 + k_2 - 1, n_1 k_1)$ wavelength interchangers.*

8. Conclusions and future work. For a homogeneous $k \times k$ WDM cross-connect we have presented an optimal design using $2k - 1$ wavelength interchangers. For heterogeneous cross-connects we have considered only the case of a $k_1 \times k_2$ WDM split cross-connect and have shown that $\min(k_1 + k_2 - 1, n_1 k_1)$ wavelength interchangers are necessary and sufficient. One obvious open question is to consider whether a nonsplit design is optimal for heterogeneous cross-connects. The reason we cannot extend Theorem 4 to heterogeneous cross-connects is that we need to be able to remove $n - 1$ wavelength interchangers along a long path in some cases of heterogeneous cross-connects. However, as with the homogeneous case, we can be sure only to remove two wavelength interchangers. Therefore a new idea is required to prove that split cross-connects are optimal for heterogeneous cross-connects. Considering general demand models for heterogeneous cross-connects is also an interesting line of work.

Another open area of work is to consider wide-sense nonblocking cross-connects. In [5] it is shown that wide-sense nonblocking $k \times k$ WDM split cross-connects with $n \geq O(k^2)$ available wavelengths require at least $2k - 1$ wavelength interchangers. However, it is still open as to whether a split cross-connect is optimal for wide-sense nonblocking cross-connects. Furthermore, for wide-sense nonblocking $k \times k$ WDM cross-connects with $2 < n < O(k^2)$, the optimal number of wavelength interchangers is unknown even if only split cross-connects are considered.

Acknowledgment. We would like to thank the anonymous referee for helpful comments.

STRONG SPATIAL MIXING WITH FEWER COLORS FOR LATTICE GRAPHS*

LESLIE ANN GOLDBERG[†], RUSSELL MARTIN[‡], AND MIKE PATERSON[†]

Abstract. Recursively-constructed couplings have been used in the past for mixing on trees. We show how to extend this technique to nontree-like graphs such as lattices. Using this method, we obtain the following general result. Suppose that G is a triangle-free graph and that for some $\Delta \geq 3$, the maximum degree of G is at most Δ . We show that the spin system consisting of q -colorings of G has strong spatial mixing, provided $q > \alpha\Delta - \gamma$, where $\alpha \approx 1.76322$ is the solution to $\alpha^\alpha = e$, and $\gamma = \frac{4\alpha^3 - 6\alpha^2 - 3\alpha + 4}{2(\alpha^2 - 1)} \approx 0.47031$. Note that we have no additional lower bound on q or Δ . This is important for us because our main objective is to have results which are applicable to the lattices studied in statistical physics, such as the integer lattice \mathbb{Z}^d and the triangular lattice. For these graphs (in fact, for any graph in which the distance- k neighborhood of a vertex grows subexponentially in k), strong spatial mixing implies that there is a unique infinite-volume Gibbs measure. That is, there is one macroscopic equilibrium rather than many. Our general result gives, for example, a “hand proof” of strong spatial mixing for 7-colorings of triangle-free 4-regular graphs. (Computer-assisted proofs of this result were provided by Salas and Sokal [*J. Stat. Phys.*, 86 (1997), pp. 551–579] (for the rectangular lattice) and by Buble, Dyer, Greenhill, and Jerrum [*SIAM J. Comput.*, 29 (1999), pp. 387–400].) It also gives a hand proof of strong spatial mixing for 5-colorings of triangle-free 3-regular graphs. (A computer-assisted proof for the special case of the hexagonal lattice was provided earlier by Salas and Sokal [*J. Stat. Phys.*, 86 (1997), pp. 551–579].) Toward the end of the paper we show how to improve our general technique by considering the geometry of the lattice. The idea is to construct the recursive coupling from a system of recurrences rather than from a single recurrence. We use the geometry of the lattice to derive the system of recurrences. This gives us an analysis with a horizon of more than one level of induction, which leads to improved results. We illustrate this idea by proving strong spatial mixing for $q = 10$ on the lattice \mathbb{Z}^3 . Finally, we apply the idea to the triangular lattice, adding computational assistance. This gives us a (machine-assisted) proof of strong spatial mixing for 10-colorings of the triangular lattice. (Such a proof for 11 colors was given by Salas and Sokal [*J. Stat. Phys.*, 86 (1997), pp. 551–579].) For completeness, we also show that our strong spatial mixing proof implies rapid mixing of Glauber dynamics for sampling proper colorings of neighborhood-amenable graphs. (It is known that strong spatial mixing often implies rapid mixing, but existing proofs seem to be written for \mathbb{Z}^d .) Thus our strong spatial mixing results give rapid mixing corollaries for neighborhood-amenable graphs such as lattices.

Key words. strong spatial mixing, proper graph coloring, antiferromagnetic Potts model

AMS subject classifications. 60J20, 68W20

DOI. 10.1137/S0097539704445470

1. Introduction. This paper is concerned with (proper) colorings of an infinite graph G , such as the integer lattice \mathbb{Z}^d . A coloring is an assignment of colors from the set $\{1, \dots, q\}$ to the vertices. It is *proper* if adjacent vertices receive different colors. Proper colorings correspond to configurations in the *zero-temperature antiferromagnetic Potts model*. Two important closely-related questions which have received a lot of recent attention follow.

- Do boundary effects decay exponentially? (This notion is known as “strong spatial mixing.”)
- Is there a unique infinite-volume Gibbs measure? (The converse situation is often called a “phase transition.”)

See Weitz’s Ph.D. thesis [31] and Martinelli’s lecture notes [22] for an exposition of this material and the papers [1, 3, 13, 20, 23, 27] for some recent (and not so recent) results. For graphs like regular lattices (in fact, for any graph in which the distance- k neighborhood of a vertex grows subexponentially in k), strong spatial mixing implies that there is a unique infinite-volume Gibbs measure; see [31] and [22] for details.¹ For these graphs, the two questions above are also known to be closely related to a third question:

- Are Glauber dynamics rapidly mixing on finite pieces of the graph?

For graphs such as lattice graphs, strong spatial mixing implies rapid mixing; more details are given in section 7. A number of papers have given bounds on the number of colors that are necessary for rapid mixing, both for general graphs [9, 10, 14, 16, 17, 19, 25, 29] and for specific graphs and lattices [1, 15, 21, 24].

1.1. Definitions and background. In order to define “strong spatial mixing” and “infinite-volume Gibbs measure,” we need notation for describing colorings of finite regions of the infinite graph G . A *region* R of G is a (not necessarily connected) subset of the vertices. A *coloring* of R is a function from R to the set of *colors* $Q = \{1, \dots, q\}$. If R is nonempty and finite, then ∂R denotes the vertex boundary around R . That is, ∂R is the set of vertices that are not in R , but are adjacent to R . A coloring of ∂R is a function from ∂R to the set $\{0\} \cup Q$. The color “0” corresponds to an unconstrained boundary vertex. Given a coloring \mathcal{B} of ∂R , a coloring C of R is said to be *proper* if adjacent vertices in R receive different colors, and vertices in R receive colors different from adjacent boundary vertices. $S(\mathcal{B})$ denotes the set of proper colorings of R and $\pi_{\mathcal{B}}$ denotes the uniform distribution on $S(\mathcal{B})$. For any $\Lambda \subseteq R$, $\pi_{\mathcal{B}, \Lambda}$ denotes the distribution on colorings of Λ induced by $\pi_{\mathcal{B}}$.

A measure μ on the set of proper colorings of G is an infinite-volume *Gibbs measure* (with respect to the uniform specification) if, for any finite region R , the conditional probability distribution $\mu(\cdot \mid \sigma_{\bar{R}})$ (conditioned on the coloring $\sigma_{\bar{R}}$ of all vertices other than those in R) is the uniform distribution on proper colorings of R . Infinite-volume Gibbs measures exist for any G . The problem of determining whether there is more than one infinite-volume Gibbs measure for a given “specification” is known as the DLR problem (for Dobrushin, Lanford, and Ruelle) in statistical physics (see [3]).

An important notion in statistical physics is whether the system (as specified by the finite-volume Gibbs measures) satisfies *strong spatial mixing* [22]. Informally, this means that for any finite set of vertices R , if you consider two different colorings \mathcal{B} and \mathcal{B}' of the boundary of R which differ at a single vertex y , then the effect that this difference has on a subset $\Lambda \subseteq R$ decays exponentially with the distance from Λ to y . For the formal definition (which we take from [13]), recall that the *total variation*

¹The formal definition of “strong spatial mixing” that we use [13, 22] requires that there be exponential decay in the effect of a single discrepancy at the boundary of a region. If the graph has subexponential growth (e.g., the distance- k neighborhood of a vertex grows subexponentially in k), then this implies uniqueness.

distance between distributions θ_1 and θ_2 on Ω is

$$d_{\text{tv}}(\theta_1, \theta_2) = \frac{1}{2} \sum_{i \in \Omega} |\theta_1(i) - \theta_2(i)| = \max_{A \subseteq \Omega} |\theta_1(A) - \theta_2(A)|.$$

We can now define strong spatial mixing.

DEFINITION 1. *The spin system specified by uniform finite-volume Gibbs measures on proper q -colorings of G has strong spatial mixing if there are constants β and $\beta' > 0$ such that for any nonempty finite region R , any $\Lambda \subseteq R$, any vertex $y \in \partial R$, and any pair of colorings $(\mathcal{B}, \mathcal{B}')$ of ∂R which differ only at y ,*

$$d_{\text{tv}}(\pi_{\mathcal{B}, \Lambda}, \pi_{\mathcal{B}', \Lambda}) \leq \beta |\Lambda| \exp(-\beta' d(y, \Lambda)),$$

where $d(y, \Lambda)$ is the distance within R from the vertex y to the region Λ .

For a wide family of graphs, this notion of strong spatial mixing implies that there is a unique infinite-volume Gibbs measure with exponentially decaying correlations. For further details on this connection, see [22, 30, 31].

In order to demonstrate that there is strong spatial mixing for the systems studied in this paper, we will consider an arbitrary finite set of vertices R and two different colorings \mathcal{B} and \mathcal{B}' of the boundary of R which differ at a single vertex y . We will show inductively that there is a coupling of the two conditional distributions in which, for every vertex $v \in R$, the probability of disagreement at v is exponentially small (as a function of its distance to the boundary discrepancy).

Another issue that we address is the mixing time of Glauber dynamics for *sampling* proper graph colorings. Let R be a finite region and let \mathcal{B} be a coloring of ∂R . The (heat-bath) Glauber dynamics is a Markov chain that can be used to sample from $S(\mathcal{B})$, the set of proper colorings that are consistent with the coloring \mathcal{B} of ∂R . The transition from a coloring $\sigma \in S(\mathcal{B})$ is made by choosing a vertex v uniformly at random from R and then recoloring v from the conditional distribution induced by the colors of the neighbors of v .

A condition sufficient for the Glauber dynamics Markov chain to be *connected* (i.e., any proper coloring can be obtained from another proper coloring by a series of the transitions described) is to have $q \geq \Delta + 2$, where Δ is the maximum degree of the graph. The stationary distribution of this Markov chain is $\pi_{\mathcal{B}}$, the uniform distribution on $S(\mathcal{B})$. In this setting, the question of interest is to determine the *mixing time*, $\tau(\delta)$, of the Glauber dynamics chain defined as

$$\tau(\delta) = \min\{t : d_{\text{tv}}(P^{(t)}(\sigma, \cdot), \pi_{\mathcal{B}}) \leq \delta \quad \forall t' \geq t\}.$$

Here $P^{(t)}(\sigma, \nu)$ is the probability of moving from σ to ν in exactly t steps of the Markov chain.

Heat-bath dynamics on larger regions is defined similarly except that a “block” of K vertices is updated during each transition; see [13] for one example of heat-bath dynamics on the lattice \mathbb{Z}^2 . We discuss a general version of heat-bath dynamics later when we examine the connections between strong spatial mixing and rapid mixing more closely.

For some graphs with subexponential growth (that is, for graphs in which the volume of increasing balls around any vertex increases subexponentially with the radius), it is well known that strong spatial mixing implies rapid mixing of Glauber dynamics. For example, [13] provides a purely combinatorial proof that when G is the

d -dimensional integer lattice \mathbb{Z}^d , if the system has strong spatial mixing, then there exists a finite integer K for which the heat-bath dynamics on a “cube” of side length K mixes in $O(n \log n)$ time, where $n = |R|$. This result holds for the “permissive” case, which corresponds to the restriction $q > \Delta + 1$ in our setting. As [13] observes, it is also known for \mathbb{Z}^d that strong spatial mixing implies $O(n \log n)$ mixing for Glauber dynamics (see [6, 22]) though no purely combinatorial proof of this fact is known. Also, the proofs as written may need to be modified to apply to the “zero-temperature” (proper coloring) case. Even without using these results in the zero-temperature case, we can deduce that Glauber dynamics mix in polynomial time (in fact, in $O(n^2)$ time) for a general family of graphs. This can be shown by using the comparison method of Diaconis and Saloff-Coste [7] to turn a rapid mixing result for heat-bath dynamics (for a fixed K) into a rapid mixing result for Glauber dynamics. For an example on the integer lattice \mathbb{Z}^2 , refer to Theorem 2 of [1] which shows rapid mixing for Glauber dynamics on 6-colorings of square pieces of \mathbb{Z}^2 . (For convenience, the authors have bounded the mixing time as $O(n^2 \log n)$, but if one wanted to tighten the bound to $O(n^2)$ by tuning the parameters in the comparison, this is possible; see, for example, [11, Example 9].)

The theorems in [13] are explicitly stated for the integer lattice \mathbb{Z}^d , but the authors state that similar techniques apply to any lattice with subexponential growth. This is mentioned as a footnote in [13] and is discussed more fully in [31]. We provide a proof that strong spatial mixing implies rapid mixing of Glauber dynamics for a class of graphs that we call neighborhood-amenable, whose definition is given below.

First, for any vertex $v \in G$ and a nonnegative integer d , let $Ball_d(v)$ denote the set of vertices that are at most distance d from v . Thus we have $Ball_0(v) = \{v\}$.

DEFINITION 2. For a nonnegative integer d , let $T_d = \sup_{v \in G} \frac{|\partial Ball_d(v)|}{|Ball_d(v)|}$. G is said to be neighborhood-amenable if $\inf_d T_d = 0$.

Neighborhood-amenability is a related, yet different, notion to amenability in graphs.² From the definition we can see that for a neighborhood-amenable graph, given any real number $c > 0$, we can find $d \geq 0$ such that $\frac{|\partial Ball_d(v)|}{|Ball_d(v)|} \leq c$, uniformly in v , meaning that the “surface-area-to-volume” ratio of balls can be made arbitrarily small with a suitable choice of radius d . Most natural lattices, such as the triangular lattice and \mathbb{Z}^k , are neighborhood-amenable.

Conditions under which we can prove rapid mixing of Glauber dynamics on neighborhood-amenable graphs are given in Theorem 8 in section 1.3.

1.2. The framework. Our results rely on considering proper colorings of a finite region for a pair of boundary colorings of that region that differ on the color of a single vertex. First, we outline the general framework in which we operate.

Let G denote an infinite graph with maximum degree Δ . Let R be a *finite* subgraph of G , and as before, define ∂R to be the boundary of R , i.e., those vertices in G that are not in R but are joined by an edge to at least one vertex of R . First we give the following definition.

DEFINITION 3. A vertex-boundary pair X consists of

- a nonempty finite region R_X of the graph G ,
- a distinguished vertex v_X in ∂R_X , and

²An infinite graph G is *amenable* if

$$\inf \left\{ \frac{|\partial S|}{|S|} : S \text{ is a finite and nonempty subset of } V(G) \right\} = 0.$$

- a pair $(\mathcal{B}_X^1, \mathcal{B}_X^2)$ of colorings of ∂R_X (using the colors $Q \cup \{0\}$) which differ only on the vertex v_X . We require that the two colors $\mathcal{B}_X^1(v_X)$ and $\mathcal{B}_X^2(v_X)$ are both in the set Q . That is, the two boundary colorings differ on the color of v_X , but this vertex is not an unconstrained vertex (with color 0) in either boundary coloring.

We are interested in the effect that the difference in color at v_X has on the other vertices. Let $S(\mathcal{B}_X^1)$ be the set of proper q -colorings of R_X that are consistent with the boundary coloring \mathcal{B}_X^1 , and similarly define $S(\mathcal{B}_X^2)$. We use $\pi_{\mathcal{B}_X^1}$ (resp., $\pi_{\mathcal{B}_X^2}$) to denote the uniform distribution on $S(\mathcal{B}_X^1)$ (resp., $S(\mathcal{B}_X^2)$).

We want to construct a coupling Ψ_X of the distributions $\pi_{\mathcal{B}_X^1}$ and $\pi_{\mathcal{B}_X^2}$, i.e., a joint distribution on $S(\mathcal{B}_X^1) \times S(\mathcal{B}_X^2)$ that has $\pi_{\mathcal{B}_X^1}$ and $\pi_{\mathcal{B}_X^2}$ as its marginal distributions. For such a coupling Ψ_X and for each vertex $f \in R_X$, we define the indicator random variable $1_{\Psi_X, f}$ for the event that, when a pair of colorings is drawn according to Ψ_X , the color of f differs in these two colorings. We would like to show that $\sum_{f \in R_X} \mathbb{E}[1_{\Psi_X, f}]$ is small. If this quantity is small enough for all vertex-boundary pairs X , we can use that conclusion to infer strong spatial mixing. We can also show rapid mixing of Glauber dynamics for a general class of graphs. One way to show that the sum is small is to show that $\mathbb{E}[1_{\Psi_X, f}]$ decreases rapidly as the distance between v_X and f grows. We give a method to construct a coupling using couplings of subgraphs which may overlap. In the course of the proof we use what we call an ε -coupling cover for G , whose definition follows.

DEFINITION 4. *Let G denote an infinite graph with maximum degree Δ . Fix $\varepsilon > 0$. We say that G has an ε -coupling cover if for all vertex-boundary pairs X , there is a coupling Ψ_X of $\pi_{\mathcal{B}_X^1}$ and $\pi_{\mathcal{B}_X^2}$ such that*

$$\sum_{f \in R_X} \mathbb{E}[1_{\Psi_X, f}] \leq \frac{\Delta}{\varepsilon}.$$

Thus, if G has an ε -coupling cover, then the sum $\sum_{f \in R_X} \mathbb{E}[1_{\Psi_X, f}]$ is small. The precise manner in which this property is used to prove strong spatial mixing is described in section 4 after we lay the groundwork in sections 2 and 3.

1.3. Our results. Our first main result is the following theorem.

THEOREM 5. *Let α be the solution to $\alpha^\alpha = e$ (so $\alpha \approx 1.76322$), and $\gamma = \frac{4\alpha^3 - 6\alpha^2 - 3\alpha + 4}{2(\alpha^2 - 1)} \approx 0.47031$. Let G denote an infinite triangle-free graph, and suppose that for some $\Delta \geq 3$ the maximum degree of G is at most Δ . The spin system specified by uniform finite-volume Gibbs measures on proper q -colorings of G has strong spatial mixing if $q > \alpha\Delta - \gamma$.*

With some additional consideration of the structure of the graph we can prove two additional results about strong spatial mixing. Theorem 6, proven in section 5, uses a system of recurrence relations to show strong spatial mixing. The geometry of \mathbb{Z}^3 plays an important role in deriving this system of recurrences. This special case is not covered by our general result above since $\alpha \cdot 6 - \gamma \approx 10.10901$.

THEOREM 6. *The spin system specified by uniform finite-volume Gibbs measures on proper 10-colorings of \mathbb{Z}^3 has strong spatial mixing.*

With computational assistance, we also show another special case that is not covered by our general theorem. (This graph has lots of triangles in it!) In this case we again derive a system of recurrence relations to show strong spatial mixing; see section 6 for more details.

THEOREM 7. *The spin system specified by uniform finite-volume Gibbs measures on proper 10-colorings of the triangular lattice has strong spatial mixing.*

In addition to the results on strong spatial mixing, we prove a general result on rapid mixing of Glauber dynamics for sampling proper colorings. Provided there exists an ε -coupling cover, Glauber dynamics is rapidly mixing for neighborhood-amenable graphs.

THEOREM 8. *Let G denote an infinite neighborhood-amenable graph with maximum degree Δ . Let R be a finite subgraph of G with $|R| = n$ and $\mathcal{B}(R)$ denoting a coloring of $\partial(R)$ using the colors $Q \cup \{0\}$. (We assume that $q \geq \Delta + 2$.)*

Suppose there exists $\varepsilon > 0$ such that G has an ε -coupling cover. Then the Glauber dynamics Markov chain on $S(\mathcal{B}(R))$ is rapidly mixing and $\tau(\delta) \in O(n(n + \log \frac{1}{\delta}))$.

Path coupling is used to prove this theorem. To show Theorem 8 we first examine a heat-bath Markov chain on “windows” in the graph (more specifically, small regions of the form $Ball_d(v) \cap R$ for a suitable d) and prove this chain mixes in time $O(n \log n)$. Then using the standard technique of comparing Markov chains, we are able to conclude that the simpler Glauber dynamics (single-vertex) chain is rapidly mixing in time $O(n^2)$. It is for this reason that we require an ε -coupling cover for G , since in our analysis we examine proper colorings of R that differ at a single vertex and we need to determine what happens in a single step of the heat-bath chain.

A brief review of path coupling, the comparison method, and all the details of the proof of Theorem 8 can be found in section 7.

In the proof of Theorem 5 we construct an ε -coupling cover (see Lemmas 15 and 20). Taking these lemmas and Theorem 8 together, we obtain the following corollary regarding rapid mixing of Glauber dynamics; see section 7.5 for some remarks on the “neighborhood-amenable” condition in the hypothesis of Theorem 8 and in the corollary.

COROLLARY 9. *Let G denote an infinite triangle-free, neighborhood-amenable graph and suppose that for some $\Delta \geq 3$ the maximum degree of G is at most Δ . Suppose $q > \alpha\Delta - \gamma$. Let R be a finite subgraph of G with $|R| = n$ and $\mathcal{B}(R)$ denoting a coloring of $\partial(R)$ using the colors $Q \cup \{0\}$. (We assume that $q \geq \Delta + 2$.)*

The Glauber dynamics chain on proper colorings of R compatible with $\mathcal{B}(R)$ is rapidly mixing with $\tau(\delta) \in O(n(n + \log \frac{1}{\delta}))$.

Since \mathbb{Z}^3 and the triangular lattice are neighborhood-amenable graphs, we also obtain the following corollaries. We note that in the course of showing strong spatial mixing for 10-colorings of \mathbb{Z}^3 and the triangular lattice, we prove the existence of an ε -coupling cover in each case. These results, together with Theorem 8, give us the two corollaries below; see sections 5 and 6, respectively, for more details on the existence of an ε -coupling cover in each case.

COROLLARY 10. *Let R denote a finite subgraph of \mathbb{Z}^3 with $|R| = n$. Let $\mathcal{B}(R)$ denote a coloring of ∂R with the colors $\{1, \dots, 10\} \cup \{0\}$; Glauber dynamics is rapidly mixing on the set of 10-colorings compatible with $\mathcal{B}(R)$ and $\tau(\delta) \in O(n(n + \log \frac{1}{\delta}))$.*

COROLLARY 11. *Let R denote a finite subgraph of the triangular lattice with $|R| = n$. Let $\mathcal{B}(R)$ denote a coloring of ∂R with the colors $\{1, \dots, 10\} \cup \{0\}$; Glauber dynamics is rapidly mixing on the set of 10-colorings compatible with $\mathcal{B}(R)$ and $\tau(\delta) \in O(n(n + \log \frac{1}{\delta}))$.*

1.4. Related work. Previous papers [20, 23, 24] have used recursively-constructed couplings to show rapid mixing and exponential decay of correlations on trees. To apply this approach more generally (i.e., to graphs other than trees) we need a mechanism for constructing a coupling from couplings of subgraphs (even

though these subgraphs may overlap). Our approach (see Lemma 12) gives an upper bound on the effect of the discrepancy at a site by summing over discrepancies at adjacent edges (using the triangle inequality as in path coupling). The subgraphs corresponding to these edges overlap but the triangle inequality is used a second time to bound the quality of the resulting coupling.

The closest directly applicable result similar to ours is that of Salas and Sokal [27]. They showed that strong spatial mixing occurs whenever $q > 2\Delta$. Given that strong spatial mixing and rapid mixing are sometimes interchangeable (as we noted above), it is perhaps more appropriate to compare our result with recent (stronger) results about rapid mixing for colorings. There are lots of these results. Since our goal is to have results which apply to lattices such as those studied in statistical physics (i.e., small Δ and small q) the most relevant result is the new theorem of Dyer et al. [10]. They show that if the girth of the graph is at least 5 (i.e., there are no 4-cycles or triangles) then Glauber dynamics is rapidly mixing provided $q > \max(\alpha\Delta, C)$, where C is an absolute constant (it depends upon $q - \alpha\Delta$ but not upon the number of vertices) which is at least 200. Our result (Theorem 5) can be viewed as a companion to that one. Both results apply when $q > \alpha\Delta$. Ours gives strong spatial mixing when the girth is at least 4 (and the maximum degree $\Delta \geq 3$). The result in [10] gives rapid mixing when the girth is at least 5 and $q \geq C$. The two results are interesting for different, but overlapping, classes of graphs. Ours is interesting (since it implies uniqueness of Gibbs measure and rapid mixing) even for graphs with very small degree (all the way down to $\Delta = 3$ and $q = 6$) but the applications to uniqueness and rapid mixing apply only if the graph is neighborhood-amenable (or some similar condition). (All natural lattices satisfy this.) The result of [10] is interesting even for graphs with other neighborhood growth properties, but it applies only if $q \geq C$.

Better results for rapid mixing are known when the degree, or the girth, is guaranteed to be large. (For graphs with large degree, the distribution is concentrated, so strong results are possible.) These results include rapid mixing for $q > \alpha\Delta$ assuming $\Delta = \Omega(\log n)$ and girth of at least 4 (Hayes and Vigoda [18]), rapid mixing for $q > \alpha\Delta$ assuming $\Delta = \Omega(\log n)$ and “local sparsity” (Frieze and Vera [14]), rapid mixing for $q > (1 + \varepsilon)\Delta$ assuming $\Delta = \Omega(\log n)$ and girth of at least 9 (Hayes and Vigoda [17]), and rapid mixing for graphs with girth of at least 6 when $q > \max(\beta\Delta, C')$ for some constant C' and $\beta \approx 1.49$ (Dyer et al. [10]).

Theorem 5 provides the first hand proof of strong spatial mixing for 7-colorings of triangle-free graphs with degree of at most 4. A machine-assisted proof for the rectangular lattice was provided by Salas and Sokal [27] and a machine-assisted proof of rapid mixing for triangle-free 4-regular graphs was provided by Buble, Dyer, Greenhill, and Jerrum [5]. Our result also shows strong spatial mixing for $q = 5$ and $\Delta = 3$. This is the first hand proof of strong spatial mixing for 5-colorings of triangle-free graphs with degree of at most 3. A machine-assisted proof for the special case of the hexagonal lattice was proved by Salas and Sokal [27]. They also give a machine-assisted proof for 4-colorings of this lattice.

In section 5 we show how to improve our general technique by considering the geometry of the lattice. The idea is to construct the recursive coupling from a system of recurrences rather than from a single recurrence. We use the geometry of the lattice to derive the system of recurrences. This gives us an analysis with a horizon of more than one level of induction, which leads to improved results. We illustrate this idea by proving strong spatial mixing for $q = 10$ on the lattice \mathbb{Z}^3 .

In section 6 we further extend our results using computational assistance. An idea used to reduce the amount of computation is the notion of a “relevant” boundary pair.

In order to reduce the search space, we want to look just at “relevant” boundary pairs, and not at all of them. Boundary pairs induced by vertex boundaries are “relevant,” and we can show by induction that our method recurses from relevant boundary pairs to relevant boundary pairs of subproblems. The proof of this fact again relies on the geometry of the lattice; see section 6 for details. Using the approach we obtain a (machine-assisted) proof of strong spatial mixing (and therefore, uniqueness of the infinite-volume Gibbs measure) for $q = 10$ on the triangular lattice. This improves an earlier result of Salas and Sokal [27] which used a machine-assisted proof to show strong spatial mixing for $q = 11$. Our approach can also be used to show (with computational assistance) strong spatial mixing for $q = 6$ on the rectangular lattice. This gives an alternative proof of the result of Achlioptas, Molloy, Moore, and Van Bussel [1] (which was also proved with machine assistance).

As we have previously mentioned, by using standard techniques our results can be used to show rapid mixing for Glauber dynamics for a wide class of graphs; see section 7 for full details.

2. Exponential decay and edge discrepancies. Let R be a nonempty finite region of the graph. For most of the technical part of this paper it will be convenient to consider the edge-boundary of R rather than the boundary ∂R of vertices surrounding R . Here is the notation that we will use. The *boundary* of the region R is the collection of all edges that have exactly one endpoint in R . A *coloring* of the boundary is a function from the set of edges in the boundary to the set $\{0\} \cup Q$.

Let R be a finite region and let B be a coloring of its boundary. A coloring C of R is said to be *proper* if

- adjacent vertices in R receive different colors, and
- vertices in R receive colors different from adjacent boundary edges.

Let $S(B)$ denote the set of proper colorings of R and let π_B be the uniform distribution on $S(B)$. We will be interested in studying how much $S(B)$ varies when we change the boundary coloring B by recoloring a single edge. This small change to the boundary is formalized in the following notation.

A *boundary pair* X consists of

- a nonempty finite region R_X of the graph,
- a distinguished edge s_X on the boundary of R_X , and
- a pair (B_X, B'_X) of colorings of the boundary of R_X which differ only on the edge s_X . We require that the two colors $B_X(s_X)$ and $B'_X(s_X)$ are both in Q . That is, the two boundary colorings differ on the coloring of edge s_X , but this edge is not an unconstrained edge (with color 0) in either boundary coloring.

For any boundary pair X , we define f_X to be the endpoint of s_X that is in R_X and w_X to be the other endpoint of s_X . Let E_X be the set of edges which connect f_X to another vertex in R_X . A *coupling* Ψ of π_{B_X} and $\pi_{B'_X}$ is a distribution on $S(B_X) \times S(B'_X)$ which has marginal distributions of π_{B_X} and $\pi_{B'_X}$. For such a coupling Ψ , we define $1_{\Psi, f}$ to be the indicator random variable for the event that, when a pair of colorings is drawn from Ψ , the color of f differs in these two colorings.

For any boundary pair X we define Ψ_X to be some coupling of π_{B_X} and $\pi_{B'_X}$ minimizing $\mathbb{E}[1_{\Psi, f_X}]$. For every pair of colors c and c' , let $p_X(c, c')$ be the probability that, when a pair of colorings (C, C') is drawn from Ψ_X , f_X is colored with color c in C and with color c' in C' .

Suppose that X is a boundary pair and that f is a vertex in R_X . Let $d(f, s_X)$ denote the distance within R_X from f to s_X . Thus, $d(f_X, s_X) = 1$, and if vertex f in R_X adjoins f_X , then $d(f, s_X) = 2$ and so on.

A main objective is to prove that the effect of the discrepancy at the boundary edge s_X decays exponentially with the distance from s_X (see Lemma 19). In order to do this, we use a recursive coupling (Lemma 12). The technique in Lemma 12 does not require that the graph be triangle-free—the general technique should also be applicable to models other than colorings.

To aid our analysis, we define a labelled tree T_X associated with each boundary pair X . The tree T_X is constructed as follows. Start with a vertex r which will be the root of T_X . For every pair of colors $c \in Q$ and $c' \in Q$, add an edge labelled $(p_X(c, c'), f_X)$ from r to a new node $r_{c,c'}$. If E_X is empty, $r_{c,c'}$ is a leaf. Otherwise, let e_1, \dots, e_k be the edges in E_X . For each $i \in \{1, \dots, k\}$, let $X_i(c, c')$ be the boundary pair consisting of

- the region $R_X - f_X$;
- the distinguished edge e_i ;
- the coloring B of the boundary of $R_X - f_X$ that
 - agrees with B_X on common edges,
 - colors e_1, \dots, e_{i-1} with color c' , and
 - colors e_i, \dots, e_k with color c ; and
- the coloring B' that agrees with B except that it colors e_i with color c' .

Recursively construct $T_{X_i(c,c')}$, the tree corresponding to boundary pair $X_i(c, c')$. Add an edge with label $(1, \cdot)$ from $r_{c,c'}$ to the root of $T_{X_i(c,c')}$. That completes the construction of T_X .

We say that an edge e of T_X is *degenerate* if the second component of its label is “.”. For edges e and e' of T_X , we write $e \rightarrow e'$ to denote the fact that e is an ancestor of e' . That is, either $e = e'$ or e is a proper ancestor of e' . Define the *level* of edge e to be the number of nondegenerate edges on the path from the root down to, and including, e . Suppose that e is an edge of T_X with label (p, f) . We say that the *weight* $w(e)$ of edge e is p . Also the *name* $n(e)$ of edge e is f . The *likelihood* $\ell(e)$ of e is $\prod_{e':e' \rightarrow e} w(e')$. The *cost* $\gamma(f, T_X)$ of a vertex f in T_X is $\sum_{e:n(e)=f} \ell(e)$.

LEMMA 12. *For every boundary pair X there exists a coupling Ψ of π_{B_X} and $\pi_{B'_X}$ such that, for all $f \in R_X$, $\mathbb{E}[1_{\Psi,f}] \leq \gamma(f, T_X)$.*

Proof. The coupling Ψ is constructed recursively in the same manner as the tree T_X , where at each stage the discrepancy at a given vertex is broken into discrepancies at single edges, so at every stage of the recursion we need only consider a pair of colorings with a discrepancy at a single edge (i.e., a boundary pair).

Let (C, C') denote the random variable corresponding to a pair of colorings from Ψ . If $|R_X| = 1$, then $\Psi = \Psi_X$. Otherwise, let e_1, \dots, e_k be the edges in E_X , i.e., those that are adjacent both to f_X and to another vertex in R_X . We will use Ψ_X to couple the coloring of vertex f_X and we will recursively construct a different coupled coloring of the other vertices in R_X . We will assign $C(f_X) = c$ and $C'(f_X) = c'$ with probability $p_X(c, c')$.

Let $X(c, c')$ be an “extended boundary pair” consisting of

- the region $R_X - f_X$;
- the coloring B_c of the boundary of $R_X - f_X$ that agrees with B_X on common edges and colors edges in E_X with color c ; and
- the coloring $B_{c'}$ of the boundary of $R_X - f_X$ that agrees with B_X on common edges and colors edges in E_X with color c' .

We can complete the coupling Ψ by constructing (for each c and c') a coupling $\Psi_{c,c'}$ of π_{B_c} and $\pi_{B_{c'}}$. (The reader may verify that this ensures that the marginal dis-

tributions of Ψ are correct.) The particular choice that we make for $\Psi_{c,c'}$ is either the perfect coupling if $c = c'$ or, if $c \neq c'$, the composition³ of $\Psi_1(c, c'), \dots, \Psi_k(c, c')$, where $\Psi_i(c, c')$ is a recursively-constructed coupling for boundary pair $X_i(c, c')$.

We will now show that, for all $f \in R_X$, $\mathbb{E}[1_{\Psi,f}] \leq \gamma(f, T_X)$. The proof is by induction on $|R_X|$. If $f = f_X$, then $\mathbb{E}[1_{\Psi,f}] = \gamma(f, T_X)$ by the construction of Ψ and T_X . This handles the base case, $|R_X| = 1$. Suppose $f \neq f_X$ and $|R_X| > 1$. Then

$$\begin{aligned} \mathbb{E}[1_{\Psi,f}] &= \sum_{c,c'} p_X(c, c') \mathbb{E}[1_{\Psi_{c,c'},f}] \leq \sum_{c,c'} p_X(c, c') \sum_{i=1}^k \mathbb{E}[1_{\Psi_i(c,c'),f}] \\ &\leq \sum_{c,c'} p_X(c, c') \sum_{i=1}^k \gamma(f, T_{X_i(c,c')}) = \gamma(f, T_X), \end{aligned}$$

where the second inequality uses the inductive hypothesis. \square

Suppose that X is a boundary pair. Lemma 12 ensures that there is a coupling of π_{B_X} and $\pi_{B'_X}$ with substantial agreement as long as, for most vertices $f \in R_X$, $\gamma(f, T_X)$ is small. A key ingredient from the construction of T_X which affects $\gamma(f, T_X)$ is the quantity $\mathbb{E}[1_{\Psi_X, f_X}]$, which we denote $\nu(X)$. (Thus, $\nu(X) = \min_{\Psi} \mathbb{E}[1_{\Psi, f_X}]$, where the minimum is over all couplings Ψ of π_{B_X} and $\pi_{B'_X}$.) An important part of our method is to determine good upper bounds on $\nu(X)$.

Let $d = B_X(s_X)$ and $d' = B'_X(s_X)$. Let $Q' = Q - \{d, d'\}$. For $c \neq d$, let $n_c(X)$ denote the number of colorings in $S(B_X)$ which color f_X with color c . Let $n_d(X)$ denote the number of colorings in $S(B'_X)$ which color f_X with color d . Let $N(X) = \sum_{c \in Q'} n_c(X)$. Define $\mu(X)$ to be the maximum of the probabilities $\Pr_{\pi_{B_X}}(f_X = d')$ and $\Pr_{\pi_{B'_X}}(f_X = d)$. That is,

$$\mu(X) = \frac{\max(n_d(X), n_{d'}(X))}{N(X) + \max(n_d(X), n_{d'}(X))}.$$

We use the following straightforward lemma to derive upper bounds on $\nu(X)$. Figure 1 is an illustration of part (ii) of this lemma. The basic idea is to pick a subregion R' that contains the vertex f_X . Compute the maximum value of μ for that subregion, where we maximize over colorings of the boundary of R' that agree with $B(R)$ on the common overlap of these boundaries. This maximum value is an upper bound for $\nu(X)$.

LEMMA 13. *Suppose that X is a boundary pair. Let R' be any subset of R_X which includes f_X . Let χ be the set of boundary pairs $X' = (R_{X'}, s_{X'}, B_{X'}, B'_{X'})$ such that $R_{X'} = R'$, $s_{X'} = s_X$, $B_{X'}$ agrees with B_X on common edges, and $B'_{X'}$ agrees with B'_X on common edges. Then $\nu(X) \leq \max_{X' \in \chi} \mu(X')$.*

Proof. We will show that

- (i) $\nu(X) \leq \mu(X)$ and
- (ii) $\mu(X) \leq \max_{X' \in \chi} \mu(X')$.

Let X be a boundary pair. To shorten the notation we will use n_c to denote $n_c(X)$ and N to denote $N(X)$. Let $d = B_X(s_X)$ and $d' = B'_X(s_X)$. Let $Q' = Q - \{d, d'\}$.

³The composition that we have in mind is the natural one—to choose a pair (σ_0, σ_k) from $\Psi_{c,c'}$ first choose (σ_0, σ_1) from $\Psi_1(c, c')$. Say $\sigma_0 = x_0$ and $\sigma_1 = x_1$. Then choose (σ_1, σ_2) from the conditional distribution of $\Psi_2(c, c')$, conditioned on $\sigma_1 = x_1$. Say that $\sigma_2 = x_2$. Now choose (σ_2, σ_3) from the conditional distribution of $\Psi_3(c, c')$ conditioned on $\sigma_2 = x_2$, and so on. This is the same as the composition that occurs in path coupling [4].

FIG. 1. Fix a subregion R' containing f_X . Then maximize $\mu(X')$ over boundary colorings of R' that agree with $B(R)$ on the overlapping part of the boundary.

For (i), we can construct a coupling Ψ of π_{B_x} and $\pi_{B'_x}$ which matches N colorings, each of which occurs with probability of at least

$$\frac{1}{\max(|S(B_X)|, |S(B'_X)|)} = \frac{1}{N + \max(n_d, n_{d'})}.$$

Thus,

$$\nu(X) \leq 1 - \frac{N}{N + \max(n_d, n_{d'})} = \mu(X).$$

(In fact, $\nu(X) = \mu(X)$, but we will not need this fact.)

Part (ii) will follow from the fact that $\Pr_{\pi_{B_X}}(f_X = d')$ is a convex combination of $\Pr_{\pi_{B_{X'}}}(f_X = d')$ for $X' \in \mathcal{X}$ and that $\Pr_{\pi_{B'_X}}(f_X = d)$ can be decomposed similarly. Let $W = R_X - R_{X'}$. Let H be the set of colorings of W . For $c \neq d$ and $\rho \in H$, let $n_{c,\rho}$ denote the number of colorings in $S(B_X)$ which color f_X with color c and W with coloring ρ . For $\rho \in H$, let $n_{d,\rho}$ denote the number of colorings in $S(B'_X)$ which color f_X with color d and W with coloring ρ . Let $N_\rho = \sum_{c \in Q'} n_{c,\rho}$. Then

$$\begin{aligned} \mu(X) &= 1 - \frac{N}{N + \max(n_d, n_{d'})} \\ &= 1 - \frac{\sum_{\rho \in H} N_\rho}{\sum_{\rho \in H} N_\rho + \max(\sum_{\rho \in H} n_{d,\rho}, \sum_{\rho \in H} n_{d',\rho})} \\ &\leq 1 - \frac{\sum_{\rho \in H} N_\rho}{\sum_{\rho \in H} N_\rho + \sum_{\rho \in H} \max(n_{d,\rho}, n_{d',\rho})} \\ &= \frac{\sum_{\rho \in H} \max(n_{d,\rho}, n_{d',\rho})}{\sum_{\rho \in H} (N_\rho + \max(n_{d,\rho}, n_{d',\rho}))} \\ &\leq \max_{\rho \in H} \frac{\max(n_{d,\rho}, n_{d',\rho})}{N_\rho + \max(n_{d,\rho}, n_{d',\rho})} \\ &= \max_{\rho \in H} \mu(X'), \end{aligned}$$

where X' is the boundary pair that is induced by ρ . \square

3. Bounding $\mu(X)$. In this section we show how to bound $\mu(X)$ for triangle-free graphs with sufficiently many colors. So that we can separate the task of bounding $\mu(X)$ from the task of showing strong spatial mixing, we define the notion of “ ε -good.” Informally, the number of colors q will be ε -good for a graph G (for some $\varepsilon \in (0, 1)$) whenever we can show strong spatial mixing for q -colorings of G .

DEFINITION 14. Suppose $\varepsilon \in (0, 1)$. We will say that the number of colors, q , is ε -good for the graph G if

$$\mu(X) \leq \frac{1}{\max(1, r)} \left(\frac{1}{1 + \varepsilon} \right)$$

for every boundary pair X in which R_X consists of a node f_X plus $r \geq 0$ neighbors y_1, \dots, y_r of f_X .

The purpose of this section is to prove Lemma 15 given below, which enables us to establish strong spatial mixing whenever $q > \alpha\Delta - \gamma$. The basic idea of the lemma is as follows. Consider a triangle-free region R_X and boundary condition \mathcal{B}_X . Suppose that the region contains sufficiently many neighbors of a vertex f_X , which is adjacent to the boundary. Then we derive an upper bound on the probability, in the equilibrium distribution, that f_X is assigned a particular color (in particular, the color d' from the definition of $\mu(X)$).

LEMMA 15. Let α be the solution to $\alpha^\alpha = e$ (so $\alpha \approx 1.76322$), and $\gamma = \frac{4\alpha^3 - 6\alpha^2 - 3\alpha + 4}{2(\alpha^2 - 1)} \approx 0.47031$. Suppose that the graph G is triangle-free and that for some $\Delta \geq 3$ the maximum degree of G is at most Δ . If $q \geq \alpha\Delta - \gamma + \alpha\varepsilon(\Delta - 1)$, then q is ε -good for G .

We prove Lemma 15 by reducing to the case in which R_X contains only f_X and its neighbors. We then use the fact that the graph has no triangles to count the number of colorings as a product. This leaves us with an optimization problem, the solution of which gives the result. Before we can prove Lemma 15, it helps to prove a preliminary lemma.

LEMMA 16. Let r, q, Δ be integers satisfying $q > \Delta > r \geq 2$. Define $p = q - \Delta + 1 \geq 2$. Consider a set of $\{0, 1\}$ -variables $\{\delta_{c,j} : 1 \leq c \leq q; 1 \leq j \leq r\}$ and an integer q' , subject to the bounds

$$s_j = \sum_{c=1}^q \delta_{c,j} \geq p \text{ for } 1 \leq j \leq r, \quad q \geq q' \geq p + r.$$

Define

$$n_c = \prod_{j=1}^r (s_j - \delta_{c,j}) \text{ for } 1 \leq c \leq q', \quad \text{and} \quad Z = \sum_{c=3}^{q'} n_c / n_1.$$

Then a minimal value of Z is attained by taking $q' = p + r$ and some choice of δ 's such that $s_j = p$ for all j and $\delta_{c,j} = 0$ if $c \notin \{3, \dots, q'\}$.

Proof. The choice $q' = p + r$ is clearly optimal. Fix some j and consider the dependence of Z on $\delta_{c,j}$ for all c , $1 \leq c \leq q'$. For some positive $a_1, \dots, a_{q'}$, we can write

$$Z = \sum_{c=3}^{q'} \frac{a_c(s_j - \delta_{c,j})}{a_1(s_j - \delta_{1,j})}.$$

We now suppose that Z is minimal and derive the properties claimed. First, we can ensure that $\delta_{c,j} = 0$ for $c \notin \{3, \dots, q'\}$. If any of these values $\delta_{c,j}$ is positive, we can set it to zero without increasing Z . If s_j had been at its lower bound of p , then we can restore this value by increasing $\delta_{c,j}$ from 0 to 1 for some $c \in \{3, \dots, q'\}$. Note that such a c exists since $q' - 2 \geq p$.

Now $n_1 = a_1 s_j$ (since $\delta_{1,j} = 0$), and

$$Z = \sum_{c=3}^{q'} \frac{a_c}{a_1} \left(1 - \frac{\delta_{c,j}}{s_j} \right) = A - \frac{1}{a_1} \frac{\sum_{c=3}^{q'} a_c \delta_{c,j}}{\sum_{c=3}^{q'} \delta_{c,j}}, \text{ where } A = \sum_{c=3}^{q'} \frac{a_c}{a_1}.$$

Since $\sum_{c=3}^{q'} a_c \delta_{c,j} / \sum_{c=3}^{q'} \delta_{c,j}$ is the average of s_j of the a 's, a maximal value for this quotient can be obtained by taking $s_j = p$, i.e., as small as possible, and selecting a set of p largest a 's with the corresponding δ 's. \square

Here is the proof of Lemma 15.

Proof. We will show that q is ε -good for G , assuming that $q \geq \alpha\Delta - \gamma + \varepsilon\alpha(\Delta - 1)$. Again, let $p = q - \Delta + 1$.

Suppose that X is a boundary pair in which R_X consists of a node f_X plus $r \leq 1$ neighbors. By Part (ii) of Lemma 13, $\mu(X) \leq \max_{X'} \mu(X')$, where X' is a boundary pair containing f_X only. The numerator of $\mu(X')$ is at most 1. The denominator is at least $q - \Delta$, so $\mu(X) \leq 1/(q - \Delta)$. Now we have $q - \Delta \geq (\alpha - 1)\Delta - \gamma + \varepsilon\alpha(\Delta - 1) > 1 + \varepsilon$ for $\Delta \geq 3$, so $\mu(X) < 1/(1 + \varepsilon)$.

For a boundary pair X we will use the notation $\mu_1(X)$ to denote $n_1(X)/(N(X) + n_1(X))$; define $\mu_2(X)$ similarly. We will show that, for every boundary pair X in which R_X consists of a node f_X plus $r > 1$ neighbors y_1, \dots, y_r of f_X , we have $\mu_1(X) \leq \frac{1}{r}(\frac{1}{1+\varepsilon})$. By symmetry, every such pair has the same upper bound on $\mu_2(X)$ and therefore on $\mu(X)$.

Suppose without loss of generality that $B_X(s_X) = 1$ and $B'_X(s_X) = 2$. Let K be the set of all colors which B_X assigns to neighbors of f_X other than s_X . We can assume without loss of generality that color 1 is not in K . Otherwise, $\mu_1(X) = 0$. Let $\delta_{c,j}$ be the Boolean indicator variable which is 0 if color c is used at a neighbor of y_j in the boundary of R_X . Let $Q' = Q - K$.

Now for every $c \in Q - Q'$ we have $n_c(X) = 0$. Since the graph is triangle-free, every $c \in Q'$ satisfies $n_c(X) = \prod_{j=1}^r (s_j - \delta_{c,j})$, where $s_j = \sum_{c=1}^q \delta_{c,j}$. Thus,

$$\frac{1}{\mu_1(X)} - 1 = \frac{\sum_{c=3}^q n_c(X)}{n_1(X)} = \frac{\sum_{c \in Q' - \{1,2\}} n_c(X)}{n_1(X)}.$$

Without loss of generality, we can assume that the colors in $Q' - \{1, 2\}$ are colors $3, \dots, q'$, for some q' , so we have

$$(1) \quad \frac{1}{\mu_1(X)} - 1 = \frac{\sum_{c=3}^{q'} n_c(X)}{n_1(X)}.$$

We are now in the framework of Lemma 16. We have the constraints $s_j \geq p$ since the degree of y_j is at most Δ , and $q' \geq p + r$ since $q' - 2 = |Q' - \{1, 2\}| \geq q - 2 - (\Delta - (r + 1))$. Let Z be the right-hand side of (1). Z is minimized by taking $q' = p + r$ and some choice of δ 's such that $s_j = p$ for all j and $\delta_{c,j} = 0$ if $c \notin \{3, \dots, q'\}$. Writing $m_c = \sum_{j=1}^r \delta_{c,j}$ and plugging in $n_c(X) = \prod_{j=1}^r (s_j - \delta_{c,j})$, we have

$$(2) \quad \begin{aligned} \frac{1}{\mu_1(X)} - 1 = Z &\geq \sum_{c=3}^{q'} \prod_{j=1}^r \left(1 - \frac{\delta_{c,j}}{p} \right) \\ &= \sum_{c=3}^{q'} \left(1 - \frac{1}{p} \right)^{m_c}, \end{aligned}$$

where $\sum_{c=3}^{q'} m_c = \sum_{j=1}^r s_j = rp$, and $q' - 2 = p + r - 2 \geq p$.

Our goal is to derive a lower bound for $(Z + 1)/r$ with respect to r and the m_c 's. Let S denote the expression (2) for an arbitrary choice of m_c 's, and consider the effect of increasing r by 1. The sum of the m_c 's is increased by p and the number of them, q' , is increased by 1. One possibility is to leave the existing m_c 's unchanged and add the extra term $(1 - 1/p)^p$, corresponding to the new m_c . To show that the lower bound given by minimizing $(S + 1)/r$ with respect to the m_c 's is decreasing in r , it is sufficient to verify that

$$\frac{S + 1}{r} \geq \frac{S + 1 + \left(1 - \frac{1}{p}\right)^p}{r + 1}, \text{ i.e., } S + 1 \geq r \left(1 - \frac{1}{p}\right)^p.$$

The expression S is minimized by taking the m_c 's as equal as possible, so

$$S \geq (q' - 2) \left(1 - \frac{1}{p}\right)^{\frac{rp}{q' - 2}} \geq r \left(1 - \frac{1}{p}\right)^p,$$

since $q' - 2 \geq r$. Thus the smallest lower bound that we get is derived from the expression S with r taking its maximum value of $\Delta - 1$ (so $q' = q$) and the m_c 's being taken as nearly equal as possible subject to integrality constraints. The same bound holds for other choices of r and the m_c 's.

We therefore define

$$J(q, \Delta) = (q - 2 - v) \left(1 - \frac{1}{p}\right)^u + v \left(1 - \frac{1}{p}\right)^{u+1} = (q - 2) \left(1 - \frac{1}{p}\right)^u \left(1 - \frac{v}{(q - 2)p}\right),$$

where $u = \lfloor (\Delta - 1)p/(q - 2) \rfloor$ and $v = (\Delta - 1)p \bmod (q - 2)$, and also define

$$J'(q, \Delta) = (q - 2) \left(1 - \frac{1}{p}\right)^{\frac{p(\Delta - 1)}{q - 2}}.$$

Note that $J \geq J'$, since J and J' are minimizations with and without the constraint of integral m_c 's, respectively. We have $Z \geq J(q, \Delta) \geq J'(q, \Delta)$. To prove that q is ε -good we need to show that $Z/(\Delta - 1) \geq 1 + \varepsilon - 1/(\Delta - 1)$. For the current lemma we just use the simpler expression J' in the proof. (We observe later that by using the inequality based on J we may obtain a slight improvement for the lower bound on q for some values of Δ ; see the remark following Theorem 5 on page 18.)

Define $x = 1 - (q - 2)/(\alpha(\Delta - 1))$, so that

$$\frac{J'(q, \Delta)}{\Delta - 1} = \alpha(1 - x) \left(1 - \frac{1}{p}\right)^{\frac{p}{\alpha(1 - x)}}.$$

We use two simple inequalities.

LEMMA 17.

- (i) $-\ln(1 - x) \leq \frac{x}{1 - x}$ for $-\infty < x < 1$.
- (ii) $-p \ln\left(1 - \frac{1}{p}\right) < 1 + \frac{1}{2(p - 1)}$ for $p > 1$.

Proof. For (i), let $f(x) = x/(1 - x) + \ln(1 - x)$, so that $f(0) = 0$. Since $df/dx = x/(1 - x)^2$ has the sign of x , the inequality holds. For (ii), it is enough to compare the power series expansions in $1/p$. \square

Note that

$$(3) \quad p - 1 = q - \Delta > \alpha\Delta - \gamma - \Delta > (\alpha - 1)(\Delta - 1).$$

Applying Lemma 17, the equality $\alpha \ln \alpha = 1$, and inequality (3), we then derive

$$\begin{aligned} \ln \left(\frac{J'(q, \Delta)}{\Delta - 1} \right) &= \ln \alpha + \ln(1 - x) + \frac{p}{\alpha(1 - x)} \ln \left(1 - \frac{1}{p} \right) > \ln \alpha - \frac{x}{1 - x} - \frac{1 + \frac{1}{2(p-1)}}{\alpha(1 - x)} \\ &= \frac{\alpha \ln \alpha (1 - x) - \alpha x - 1 - \frac{1}{2(p-1)}}{\alpha(1 - x)} = \frac{-(\alpha + 1)x - \frac{1}{2(p-1)}}{\alpha(1 - x)} \\ (4) \quad &> \frac{-(\alpha + 1)x - \frac{1}{2(\alpha-1)(\Delta-1)}}{\alpha(1 - x)} = \frac{\alpha + 1}{\alpha} - \frac{\alpha + 1 + \frac{1}{2(\alpha-1)(\Delta-1)}}{\alpha(1 - x)}. \end{aligned}$$

Since

$$1 - x = \frac{q - 2}{\alpha(\Delta - 1)} = \frac{q - \alpha\Delta + \gamma}{\alpha(\Delta - 1)} + \frac{\alpha(\Delta - 1) - (2 + \gamma - \alpha)}{\alpha(\Delta - 1)} \geq \varepsilon + 1 - \frac{2 + \gamma - \alpha}{\alpha(\Delta - 1)},$$

we may write $w = 1/(\Delta - 1)$ and give the following lower bound for the right-hand side of (4):

$$\frac{\alpha + 1}{\alpha} - \frac{\frac{\alpha+1}{\alpha} + \frac{w}{2\alpha(\alpha-1)}}{1 + \varepsilon - \frac{(2+\gamma-\alpha)w}{\alpha}} = A - \frac{B(\varepsilon)}{C(\varepsilon) - Dw} = F(\varepsilon, w), \text{ say,}$$

where

$$B(\varepsilon) = \frac{\alpha + 1}{\alpha} + \frac{1 + \varepsilon}{2(\alpha - 1)(2 + \gamma - \alpha)} > 0, \quad A = B(0), \quad C(\varepsilon) = 1 + \varepsilon, \quad \text{and} \quad D = \frac{2 + \gamma - \alpha}{\alpha}.$$

Our remaining goal in proving that q is ε -good is to show that

$$(5) \quad F(\varepsilon, w) \geq \ln(1 + \varepsilon - w), \text{ for } 0 \leq \varepsilon \leq 1, \text{ and } 0 < w \leq 1/2.$$

We first show that

$$\frac{\partial(F - \ln(1 + \varepsilon - w))}{\partial w} = -\frac{DB(\varepsilon)}{(C(\varepsilon) - Dw)^2} + \frac{1}{1 + \varepsilon - w} > 0.$$

Since $1 + \varepsilon - w > 0$, this is equivalent to checking that $(C(\varepsilon) - Dw)^2 - (1 + \varepsilon - w)DB(\varepsilon) > 0$. Numerically, this polynomial in ε and w is approximately

$$0.6285\varepsilon^2 + (0.6285 - 0.4305w)\varepsilon + 0.1980w + 0.1608w^2,$$

which is clearly positive⁴ since $w \leq 0.5$. The constant term

$$C(0)^2 - DB(0) = \frac{4\alpha^3 - 6\alpha^2 - 3\alpha + 4 - 2\gamma(\alpha^2 - 1)}{2\alpha^2(\alpha - 1)}$$

is zero by the choice of γ . It is sufficient therefore to verify the inequality (5) for $w = 0$.

⁴To verify formally that the expression is positive, one can derive upper and lower bounds on the coefficients using upper and lower bounds on α .

To show that $F(\varepsilon, 0) - \ln(1 + \varepsilon) \geq 0$, we first verify that the second derivative is negative, and then merely check the inequality at the extreme values, $\varepsilon = 0, 1$.

However,

$$\begin{aligned} \frac{d^2}{d\varepsilon^2}(F(\varepsilon, 0) - \ln(1 + \varepsilon)) &= \frac{d^2}{d\varepsilon^2} \left(\frac{\alpha + 1}{\alpha} \left(1 - \frac{1}{1 + \varepsilon} \right) - \ln(1 + \varepsilon) \right) \\ &= -\frac{\alpha + 1}{\alpha} \frac{2}{(1 + \varepsilon)^3} + \frac{1}{(1 + \varepsilon)^2} = \frac{-2(\alpha + 1) + \alpha(1 + \varepsilon)}{\alpha(1 + \varepsilon)^3} < 0, \end{aligned}$$

$$F(0, 0) - \ln 1 = 0, \text{ and } F(1, 0) - \ln(1 + 1) = \frac{\alpha + 1}{2\alpha} - \ln 2 \approx 0.0904 > 0.$$

This completes the verification. \square

We now show how to use Lemma 15 to prove that the effect of a discrepancy at the boundary edge s_X decays exponentially with the distance from s_X .

Let X be a boundary pair. For any $d \geq 1$, let $E_d(X)$ denote the set of level- d edges in T_X . Let $\Gamma_d(X) = \sum_{e \in E_d(X)} \ell(e)$. In Lemma 18 below we show that $\Gamma_d(X)$ is exponentially small in d . Say that a boundary pair X is in \mathcal{N}_i (for $i \in \{0, \dots, \Delta - 1\}$) if exactly i of the neighbors of f_X are in R_X . Let Γ_d be the maximum of $\Gamma_d(X)$, maximized over all boundary pairs X .

LEMMA 18. *Suppose that q is ε -good for G . Then for every boundary pair X and any $d \geq 1$, $\Gamma_d(X) \leq (1 + \varepsilon)^{-d}$.*

Proof. The proof is by induction on d . For the base case, $d = 1$, note that for any boundary pair X , $\Gamma_1(X) \leq \nu(X)$. Now apply Lemma 13 with $R' = \{f_X\}$, and by the given upper bound on $\mu(X)$ (and the definition of ε -good), we find that $\nu(X) \leq 1/(1 + \varepsilon)$. For the inductive step, suppose that $X \in \mathcal{N}_r$. Then using the definition of ε -good again (and Lemma 13), we see that $\Gamma_d(X) \leq \nu(X) \cdot r \cdot \Gamma_{d-1}$. \square

LEMMA 19. *Suppose that q is ε -good for G . Then for every boundary pair X there exists a coupling Ψ of π_{B_X} and $\pi_{B'_X}$ such that, for all $f \in R_X$,*

$$\mathbb{E}[1_{\Psi, f}] \leq \frac{1}{\varepsilon} (1 + \varepsilon)^{-d(f, s_X) + 1}.$$

Furthermore,

$$\sum_{f \in R_X} \mathbb{E}[1_{\Psi, f}] \leq \frac{1}{\varepsilon}.$$

Proof. By Lemma 12, $\mathbb{E}[1_{\Psi, f}] \leq \gamma(f, T_X)$. Furthermore, $\gamma(f, T_X) = \sum_{e: n(e)=f} \ell(e)$, which is at most $\sum_{d \geq d(f, s_X)} \Gamma_d(X)$. By Lemma 18, this is at most

$$\sum_{d \geq d(f, s_X)} (1 + \varepsilon)^{-d} = (1 + \varepsilon)^{-d(f, s_X)} \sum_{d \geq 0} (1 + \varepsilon)^{-d} = (1 + \varepsilon)^{-d(f, s_X)} \frac{1 + \varepsilon}{\varepsilon}.$$

Similarly,

$$\sum_{f \in R_X} \mathbb{E}[1_{\Psi, f}] \leq \sum_{f \in R_X} \gamma(f, T_X) = \sum_{f \in R_X} \sum_{e: n(e)=f} \ell(e) = \sum_{e: n(e) \in R_X} \ell(e) = \sum_{d \geq 1} \Gamma_d(X). \quad \square$$

4. Exponential decay, vertex discrepancies, and strong spatial mixing.

Lemma 19 shows that the effect of a discrepancy at a boundary edge decays exponentially with the distance from that edge. In this section we show that the same holds for a discrepancy at a boundary vertex. This enables us to show that the collection of finite-volume Gibbs measures corresponding to the uniform distribution on proper colorings has strong spatial mixing.

A *vertex-boundary pair* X consists of

- a nonempty finite region R_X of the graph;
- a distinguished vertex v_X in ∂R_X ; and
- a pair $(\mathcal{B}_X, \mathcal{B}'_X)$ of colorings of ∂R which differs only on vertex v_X . We require that the two colors $\mathcal{B}_X(v_X)$ and $\mathcal{B}'_X(v_X)$ are both in Q . That is, the two boundary colorings differ on the color of vertex v_X , but this vertex is not an unconstrained vertex (with color 0) in either boundary coloring.

Let $d(f, v_X)$ be the distance within R_X from a vertex f to vertex v_X .

LEMMA 20. *Suppose that q is ε -good for a graph G with degree at most Δ . For every vertex-boundary pair X there is a coupling Ψ of $\pi_{\mathcal{B}_X}$ and $\pi_{\mathcal{B}'_X}$ such that, for all $f \in R$,*

$$\mathbb{E}[1_{\Psi, f}] \leq \Delta \frac{1}{\varepsilon} (1 + \varepsilon)^{-d(f, v_X) + 1}.$$

Furthermore,

$$\sum_{f \in R_X} \mathbb{E}[1_{\Psi, f}] \leq \frac{\Delta}{\varepsilon}.$$

Proof. This follows from Lemma 19 using a union bound by breaking the difference in a single vertex into the sum of differences in the edges that bound it. Let e_1, \dots, e_k be the boundary edges of R_X that are adjacent to v_X . Let X_i be the boundary pair consisting of the region R_X , the distinguished edge e_i , a coloring B of the boundary of R_X that agrees with \mathcal{B}_X except that edges e_1, \dots, e_{i-1} are colored with color $\mathcal{B}'_X(v_X)$ and e_i, \dots, e_k are colored with color $\mathcal{B}_X(v_X)$, and a coloring B' that is the same as B except that it colors e_i with color $\mathcal{B}'_X(v_X)$. We construct a coupling of $\pi_{\mathcal{B}_X}$ and $\pi_{\mathcal{B}'_X}$ by composing couplings Ψ_1, \dots, Ψ_k of X_1, \dots, X_k . Now

$$\mathbb{E}[1_{\Psi, f}] \leq \sum_{i=1}^k \mathbb{E}[1_{\Psi_i, f}]. \quad \square$$

COROLLARY 21. *Suppose that q is ε -good for the graph G , and that the maximum degree, Δ , of G is bounded. Then the system specified by uniform finite-volume Gibbs measures on proper q -colorings of G has strong spatial mixing.*

Proof. Using Definition 1, we wish to show that there are constants β and $\beta' > 0$ such that for any vertex-boundary pair X and any $\Lambda \subseteq R_X$,

$$d_{\text{tv}}(\pi_{\mathcal{B}_X, \Lambda}, \pi_{\mathcal{B}'_X, \Lambda}) \leq \beta |\Lambda| \exp(-\beta' d(v_X, \Lambda)).$$

The total variation distance of $\pi_{\mathcal{B}_X, \Lambda}$ and $\pi_{\mathcal{B}'_X, \Lambda}$ is at most the probability that the induced colorings differ in the coupling Ψ from Lemma 20. This is at most $\sum_{f \in \Lambda} \mathbb{E}[1_{\Psi, f}]$. As in the proof of Lemma 20, Ψ is the composition of Ψ_1, \dots, Ψ_k . Following the proof of Lemma 19,

$$\sum_{f \in \Lambda} \mathbb{E}[1_{\Psi_i, f}] \leq \sum_{e: n(e) \in \Lambda} \ell(e) \leq \sum_{d \geq d(v_X, \Lambda)} \Gamma_d(X) \leq \frac{1}{\varepsilon} (1 + \varepsilon)^{-d(v_X, \Lambda) + 1}$$

so the total variation distance is at most

$$\frac{\Delta}{\varepsilon}(1 + \varepsilon)^{-d(v_X, \Lambda)+1}.$$

Now we can take $\beta = \frac{\Delta(1+\varepsilon)}{\varepsilon}$ and $\beta' = \log(1 + \varepsilon)$. \square

Remark. Note that the $|\Lambda|$ factor is not crucial in the definition of strong spatial mixing. In particular, our upper bound on the total variation distance does not use this factor.

Combining Corollary 21 with Lemma 15 we get the following result.

THEOREM 5. *Let α be the solution to $\alpha^\alpha = e$ (so $\alpha \approx 1.76322$), and $\gamma = \frac{4\alpha^3 - 6\alpha^2 - 3\alpha + 4}{2(\alpha^2 - 1)} \approx 0.47031$. Let G denote an infinite triangle-free graph, and suppose that for some $\Delta \geq 3$ the maximum degree of G is at most Δ . The spin system specified by uniform finite-volume Gibbs measures on proper q -colorings of G has strong spatial mixing if $q > \alpha\Delta - \gamma$.*

Remark. In the proof of Lemma 15 we show that the simple bound of $q \geq \alpha\Delta - \gamma + \alpha\varepsilon(\Delta - 1)$ is sufficient to guarantee that $(J'(q, \Delta) + 1)/(\Delta - 1) \geq 1 + \varepsilon$, which yields ε -goodness since $1/\mu_1(X) - 1 = Z \geq J(q, \Delta) \geq J'(q, \Delta)$. However, for any particular value of Δ we may use the bounds $(J(q, \Delta) + 1)/(\Delta - 1) - 1 \geq (J'(q, \Delta) + 1)/(\Delta - 1) - 1 \geq \varepsilon$ directly.

For example, with $\Delta = 4$ and $q = 7$, Lemma 15 gives ε -goodness for $\varepsilon \approx 0.079$, whereas the direct use of J' or J give values of about 0.169 or 0.177, respectively.

Of a little more interest are the rather sparse cases where the direct inequalities give a reduced value of q . Strong spatial mixing can be shown for $q = \lfloor \alpha\Delta - \gamma \rfloor$ for $\Delta = 19, 36, 74, 357, 2380, 148264, 686821, \dots$. In the two cases, $\Delta = 19, 74$, the bounds of $q = 33, 130$, respectively, require the use of J (with its integral constraints) rather than just J' .

5. Using the geometry of the lattice. In this section we consider the lattice \mathbb{Z}^3 . This is a triangle-free graph with degree 6, so Theorem 5 gives strong spatial mixing for $q \geq 11$. We will exploit the geometry of the lattice to show strong spatial mixing for $q = 10$. The idea is to use the geometry to derive a system of recurrences and to use these recurrences to construct the coupling.

We start by recording some upper bounds on $\mu(X)$. Let $\mu' = 125/589$ and let $\mu'' = 625/3121$. The following corollary follows from the proof of Lemma 15.

COROLLARY 22. *Suppose X is a boundary pair in which R_X consists of a node f_X plus $r \geq 0$ neighbors y_1, \dots, y_r of f_X . If $r = 0$, then $\mu(X) \leq 1/4$. If $r = 4$, then $\mu(X) \leq \mu'$. If $r = 5$, then $\mu(X) \leq \mu''$.*

Proof. The $r = 0$ case follows from the fact that $\mu(X) \leq 1/(q - \Delta) = 1/4$. For the other cases, we use the same reasoning that we used in the proof of Lemma 15 to determine $J(q, \Delta)$. Let $q' = q - \Delta + 1 + r$, $u = \lfloor \frac{rp}{q' - 2} \rfloor$ and $v = rp \bmod (q' - 2)$. (These are the same as the definitions in the proof of Lemma 15 except that there we specialized to $r = \Delta - 1$ so we had $q' = q$.) Let $h(q, \Delta, r)$ be the sum of the $q' - 2$ terms in (2) when we minimize by making the m_c 's as equal as possible. Namely,

$$h(q, \Delta, r) = (q' - 2 - v) \left(1 - \frac{1}{p}\right)^u + v \left(1 - \frac{1}{p}\right)^{u+1}.$$

It follows from (2) and from the argument in the proof of Lemma 15 that

$$\mu(X) \leq \frac{1}{1 + h(q, \Delta, r)}.$$

FIG. 2. Configurations in U with $y \notin R_X$, or those in V with $z \notin R_X$.

The values can then be calculated directly. \square

We would like to use the bounds in Corollary 22 to prove that $\Gamma_d(X)$ is exponentially small in d . The proof in Lemma 18 uses the following simple recursive idea. If $X \in \mathcal{N}_r$, then $\Gamma_d(X) \leq \nu(X) \cdot r \cdot \Gamma_{d-1}$. This idea suffices if our upper bound on $\nu(X)$ is less than $1/r$. This is not the case for the bounds in Corollary 22. However, it is a bit pessimistic to assume that all of the r recursive subproblems correspond to the worst recursive case Γ_{d-1} . Using the geometry of the lattice, we can keep track of the recursion and do better.

We start by defining some sets of boundary pairs.

We will say that a boundary pair is in the set U if either of the following conditions hold:

- Either $X \in \mathcal{N}_1 \cup \mathcal{N}_2 \cup \mathcal{N}_3$; or
- $X \in \mathcal{N}_4$ and the following is true. Let y be the neighbor of f_X that is not in R_X and is not equal to w_X . We require that the vertices w_X and y differ in exactly two coordinates (in 3-dimensional space); see Figure 2.

We will say that a boundary pair is in the set V if the following condition holds: There is a vertex $z \notin R_X$ and a vertex $y \neq w_X$ such that $z \sim w_X$ (meaning z is adjacent to w_X) and $z \sim y \sim f_X$; see Figure 2 again for the relevant configurations. Note that the subsets U and V of boundary pairs depend only on R_X and s_X (they do not depend on B_X or B'_X). Let $U_d = \max_{X \in U} \Gamma_d(X)$ and $V_d = \max_{X \in V} \Gamma_d(X)$. The next lemma follows from the geometry of the lattice.

LEMMA 23. *Suppose that $q = 10$ and G is \mathbb{Z}^3 . Suppose $d > 1$. Then*

$$\begin{aligned} \Gamma_d &\leq \max \left(4\mu' \Gamma_{d-1}, \mu'' (\Gamma_{d-1} + 4V_{d-1}), \frac{3}{4} \Gamma_{d-1} \right), \\ U_d &\leq \max \left(\mu' (\Gamma_{d-1} + 3V_{d-1}), \frac{3}{4} \Gamma_{d-1} \right), \\ V_d &\leq \max \left(4\mu' \Gamma_{d-1}, \mu'' (U_{d-1} + 4\Gamma_{d-1}), \frac{3}{4} \Gamma_{d-1} \right). \end{aligned}$$

Proof. Consider a boundary pair X . If $X \in \mathcal{N}_1 \cup \mathcal{N}_2 \cup \mathcal{N}_3$, then $\Gamma_d(X) \leq \nu(X) \cdot 3 \cdot \Gamma_{d-1}$. By Lemma 13 and Corollary 22 (with $r = 0$), $\nu(X) \leq 1/4$, so $\Gamma_d(X) \leq \frac{3}{4} \Gamma_{d-1}$ and one of the inequalities on Γ_d is satisfied. If $X \in \mathcal{N}_4$, then applying Corollary 22 with $r = 4$ we get $\Gamma_d(X) \leq \mu' 4\Gamma_{d-1}$, and the upper bound on Γ_d is satisfied. Otherwise, X is in \mathcal{N}_5 . Using the definition of V , we can deduce that

$$(6) \quad \Gamma_d(X) \leq \nu(X) (\Gamma_{d-1} + 4V_{d-1}),$$

which gives us the other bound on Γ_d (using Corollary 22 with $r = 5$). To see that inequality (6) is satisfied, let y be any of the 4 neighbors of f_X in R_X such that y and w_X differ on two coordinates. Now consider the recursive problem in which f_X

becomes the new w_X and y becomes the new f_X . The original w_X becomes the (new) z in the definition of V . So this recursive problem is in V .

FIG. 3. The basic recursion step for a configuration.

Next, consider a boundary pair $X \in U$. We wish to show that the inequality on U_d is satisfied. This is straightforward if $X \in \mathcal{N}_1 \cup \mathcal{N}_2 \cup \mathcal{N}_3$, so suppose that X is in \mathcal{N}_4 . Let y denote the vertex in the definition of U . (So y is not in R_X and y and w_X differ in exactly two coordinates.) Using the definition of V , we can deduce that

$$\Gamma_d(X) \leq \nu(X)(\Gamma_{d-1} + 3V_{d-1}),$$

giving one of the upper bounds on U_d . (To see this, let y' be one of the three neighbors of f_X in R_X that differs from y in two coordinates. Note that the subproblem moving from f_X to y' is in V ; see Figure 4.)

FIG. 4. The recursion step for a configuration in U .

Finally, consider a boundary pair $X \in V$. The inequality for V_d is similar to that for Γ_d except when $X \in \mathcal{N}_5$. In this case, let z and y be the vertices in the definition of V . Now note that the subproblem moving from f_X to y is in U . This gives the third equation. \square

Here is the analogy of Lemma 18.

LEMMA 24. Let $\zeta = 0.0001$. Suppose that $q = 10$ and G is \mathbb{Z}^3 . For every boundary pair X and every $d \geq 1$, $\Gamma_d(X) \leq (1 - \zeta)^d$.

Proof. Let $u = 0.8294$ and $v = 0.968$. We will prove by induction on d that $\Gamma_d \leq (1 - \zeta)^d$ and $U_d \leq u(1 - \zeta)^d$ and $V_d \leq v(1 - \zeta)^d$. For the base case, $d = 1$, note that for any relevant boundary pair X , $\Gamma_1(X) \leq \nu(X)$. Now apply Lemma 13 with $R' = \{f_X\}$, and by Corollary 22 (with $r = 0$), we find that $\nu(X) \leq 1/4$. Thus, $\Gamma_1(x) \leq \min\{u, v, 1\}(1 - \zeta)$.

The inductive step follows directly from Lemma 23 since the following inequalities hold: $4\mu' \leq (1 - \zeta) \min(1, v)$, $\frac{3}{4} \leq (1 - \zeta) \min(1, v, u)$, $\mu''(1 + 4v) \leq (1 - \zeta)$, $\mu'(1 + 3v) \leq (1 - \zeta)u$, and $\mu''(u + 4) \leq (1 - \zeta)v$. \square

The proof of Theorem 6 now follows the argument in sections 3 and 4. The only difference is that instead of applying Lemma 18, we use Lemma 24 (which gives exactly the same result with $\varepsilon = \zeta/(1 - \zeta)$). The analogue of Lemma 20 provides an ε -coupling cover. Since \mathbb{Z}^3 is neighborhood-amenable, we obtain Corollary 10.

FIG. 5. *The triangular lattice.*

6. Computational assistance. In section 5 we showed strong spatial mixing for $q = 10$ and the degree-6 lattice \mathbb{Z}^3 . The same argument does not apply to the triangular lattice because we cannot apply Lemma 15 (or its proof) to a graph with triangles. Nevertheless, we can use our method with computational assistance to prove strong spatial mixing for the triangular lattice.

6.1. The lattice. A piece of the triangular lattice is depicted in Figure 5. Each vertex of the lattice is depicted as a hexagonal face in the picture. Every vertex has degree 6. Thus, the 6 neighbors of vertex f_X are w_X , y_1 , y_2 , y_3 , y_4 , and y_5 .

6.2. Relevant boundary pairs. In order to prove strong spatial mixing, we will need upper bounds on $\mu(X)$ similar to those obtained in Corollary 22. Since we will use computation, we want to restrict the search space as far as possible. We do that by defining the notion of a “relevant” boundary pair. Intuitively, the idea is that these boundary pairs are the ones that are induced by a pair of colorings of the vertex-boundary ∂R_X .

We say that a boundary pair is *relevant* if it is the case that any two *adjacent* edges on the boundary that share a vertex $f \notin R_X$ have the same color in at least one of the two colorings B_X and B'_X (and so in both of B_X and B'_X except when edge s_X is involved). For example, in Figure 5, if R_X consists of the five vertices enclosed by the thicker line (namely f_X , y_1 , y_2 , y_3 , and y_4) and X is a relevant boundary pair, then B_X and B'_X assign the same color to the edges (y_1, z_3) and (y_2, z_3) . Note that our definition of “relevant” is specific to the geometry of the lattice. The edges (y_1, z_2) and (y_1, z_3) are *adjacent* but the edges (y_1, z_3) and (y_1, z_1) are not adjacent.

It is important to observe that our recursive construction preserves “relevance.” That is, if X is a relevant boundary pair, then all of the boundary pairs in the tree T_X are also relevant. We can ensure this by refining the construction of T_X (see section 2) as follows. When the edges in E_X are given the names e_1, \dots, e_k , order these edges clockwise around the vertex f_X starting from s_X . This ordering ensures that e_i is not “adjacent” to e_j unless i and j differ by 1. Now note that if X is relevant, then so is the constructed boundary pair $X_i(c, c')$.

Next, note that Lemma 13 can be extended as follows. If the boundary pair X is relevant, then the boundary pair X' constructed in the proof is also relevant. Therefore, the set χ can be restricted to relevant boundary pairs. For convenience, we state

the extended lemma here.

LEMMA 25. *Suppose that X is a relevant boundary pair. Let R' be any subset of R_X which includes f_X . Let χ be the set of relevant boundary pairs $X' = (R_{X'}, s_{X'}, B_{X'}, B'_{X'})$ such that $R_{X'} = R'$, $s_{X'} = s_X$, $B_{X'}$ agrees with B_X on common edges, and $B'_{X'}$ agrees with B'_X on common edges. Then $\nu(X) \leq \max_{X' \in \chi} \mu(X')$.*

6.3. Bounding $\mu(X)$. By analogy to Corollary 22 we will now provide some upper bounds on $\mu(X)$ for the triangular lattice. Let $\mu' = 31/136$ and $\mu'' = 1111/4966$. We now give four lemmas bounding $\mu(X)$ for particular boundary pairs X .

LEMMA 26. *Suppose X is a boundary pair with $|R_X| = 1$. Then $\mu(X) \leq 1/4$.*

Proof. The numerator in the definition of $\mu(X)$ is at most 1. The denominator is at least $q - \Delta = 4$. \square

LEMMA 27. *Suppose X is a boundary pair in which R_X consists of f_X and one neighbor y of f_X . Then $\mu(X) \leq 5/21$.*

Proof. Let E_1 be the set of edges of f_X except for s_X and the edge between f_X and y . Let E_2 be the set of edges of y except for the edge between f_X and y . Let U be the set of colors that B_X (and so also B'_X) assigns to edges in E_1 , and similarly let V be the set of colors assigned to E_2 . Let $d = B_X(s_X)$ and $d' = B'_X(s_X)$. Let $Q' = Q - \{d, d'\}$. To shorten the notation we will use n_c to denote $n_c(X)$ and N to denote $N(X)$. Let $q_1 = |Q' \setminus U|$ and let $q_2 = |Q \setminus V|$. We see that $q_1 \geq 8 - |U| \geq 4$ and $q_2 \geq 10 - |V| \geq 5$.

For $c \in Q$ we see that

$$\begin{aligned} n_c &= 0 && \text{if } c \in U, \\ &= q_2 && \text{if } c \notin U \text{ and } c \in V, \\ &= q_2 - 1 && \text{if } c \notin U \text{ and } c \notin V. \end{aligned}$$

Thence, $\max(n_d, n_{d'}) \leq q_2$ and

$$N = \sum_{c \in Q'} n_c \geq (q_2 - 1)|Q' \setminus U| = (q_2 - 1)q_1.$$

Since $\mu(X)$ is monotone increasing in $\max(n_d, n_{d'})$ and decreasing in N , we have

$$\mu(X) \leq \frac{q_2}{q_2 + (q_2 - 1)q_1} = \frac{1}{1 + (1 - 1/q_2)q_1} \leq \frac{1}{1 + (1 - 1/5)4} = \frac{5}{21}. \quad \square$$

LEMMA 28. *Suppose X is a relevant boundary pair in which $R_X = \{f_X, y_1, y_2, y_3\}$ and f_X is adjacent to each of the y_i 's and $w_X \sim y_1 \sim y_2 \sim y_3$. Then $\mu(X) \leq \mu'$.*

Proof. By computation, we considered every such relevant boundary pair X (approximately 2×10^6 of them) and calculated $\mu(X)$. \square

LEMMA 29. *Suppose X is a relevant boundary pair in which $R_X = \{f_X, y_1, y_2, y_3, y_4\}$ and f_X is adjacent to each of the y_i 's and $w_X \sim y_1 \sim y_2 \sim y_3 \sim y_4$. Then $\mu(X) \leq \mu''$.*

Proof. By computation, we considered every such relevant boundary pair X (approximately 16×10^6 of them) and calculated $\mu(X)$. \square

6.4. Proving exponential decay. As in section 5, we will prove that $\Gamma_d(X)$ is exponentially small in d by defining a system of recursive equations. We will restrict attention to relevant boundary pairs; let Rel be the set of relevant boundary pairs. Say that a relevant boundary pair X is in \mathcal{N}_i^R (for $i \in \{0, \dots, 5\}$) if at most i of the neighbors of f_X are in R_X ; let $\Gamma_d^R = \max_{X \in \text{Rel}} \Gamma_d(X)$.

LEMMA 30. *Suppose $d > 1$. If $X \in \mathcal{N}_2^R$, then $\Gamma_d(X) \leq \Gamma_{d-1}^R/2$. If $X \in \mathcal{N}_3^R$, then $\Gamma_d(X) \leq 3\Gamma_{d-1}^R/4$. If $X \in \mathcal{N}_4^R$, then $\Gamma_d(X) \leq 20\Gamma_{d-1}^R/21$.*

Proof. If $X \in \mathcal{N}_2^R$, then by the definition of T_X , $\Gamma_d(X) \leq \nu(X) \cdot 2 \cdot \Gamma_{d-1}^R$. Then by Lemma 25 with $R' = \{f_X\}$ and Lemma 26, $\nu(X) \leq 1/4$. Similarly, if $X \in \mathcal{N}_3^R$, then $\Gamma_d(X) \leq \nu(X) \cdot 3 \cdot \Gamma_{d-1}^R \leq 3\Gamma_{d-1}^R/4$. Finally, suppose that exactly 4 neighbors of f_X are in R_X . Then $\Gamma_d(X) \leq \nu(X) \cdot 4 \cdot \Gamma_{d-1}^R$. Apply Lemma 25 where R' contains f_X and one of its neighbors in R_X . By Lemma 27, $\nu(X) \leq 5/21$. \square

Next, we define some subsets of Rel ; refer to Figure 5 to clarify these definitions. Let X be a relevant boundary pair.

- X is in U if there is a neighbor y_5 of f_X and of w_X that is not in R_X , and there is a neighbor $y_4 \neq w_X$ of f_X and of y_5 that is not in R_X .
- X is in V if there is a neighbor y_5 of f_X and of w_X that is not in R_X .
- X is in W if there is a neighbor y_5 of f_X and of w_X in R_X , and a neighbor $z_{11} \neq f_X$ of w_X and of y_5 that is not in R_X .

Let $U_d = \max_{X \in U} \Gamma_d(X)$, $V_d = \max_{X \in V} \Gamma_d(X)$, and $W_d = \max_{X \in W} \Gamma_d(X)$. The following lemma follows from the definition of T_X and the geometry of the lattice.

LEMMA 31. *Suppose that $q = 10$ and G is the triangular lattice. Suppose $d > 1$. Then*

$$\begin{aligned} \Gamma_d^R &\leq \max(\mu''(\Gamma_{d-1}^R + 2V_{d-1} + 2W_{d-1}), 20\Gamma_{d-1}^R/21), \\ U_d &\leq \max(\mu'(2V_{d-1} + W_{d-1}), \Gamma_{d-1}^R/2), \\ V_d &\leq \max(\mu''(2V_{d-1} + 2W_{d-1}), 3\Gamma_{d-1}^R/4), \text{ and} \\ W_d &\leq \max(\mu''(\Gamma_{d-1}^R + V_{d-1} + 2W_{d-1} + U_{d-1}), 20\Gamma_{d-1}^R/21). \end{aligned}$$

Proof. Suppose $X \in \text{Rel}$. If $X \in \mathcal{N}_4^R$, then $\Gamma_d(X) \leq 20\Gamma_{d-1}^R/21$ by Lemma 30. Otherwise an examination of Figure 5 reveals that

$$\Gamma_d(X) \leq \nu(X) (\Gamma_{d-1}^R + 2V_{d-1} + 2W_{d-1}).$$

The two instances of V_{d-1} correspond to y_1 and y_5 in the picture (since w_X is not in R_X), the two instances of W_{d-1} correspond to y_2 and y_4 , and the instance of Γ_{d-1}^R corresponds to y_3 . Apply Lemma 25 where R' is the set containing f_X and the vertices y_1, y_2, y_3 , and y_4 from Figure 5. By Lemma 29, $\nu(X) \leq \mu''$. This proves the upper bound on Γ_d^R .

Suppose $X \in U$. If $X \in \mathcal{N}_2^R$, then $\Gamma_d(X) \leq \Gamma_{d-1}^R/2$ by Lemma 30. Otherwise

$$\Gamma_d(X) \leq \nu(X) (2V_{d-1} + W_{d-1}).$$

As in the upper bound on Γ_d^R , one instance of V_{d-1} corresponds to y_1 and one instance of W_{d-1} corresponds to y_2 . An examination of Figure 5 reveals that, since $X \in U$, y_3 corresponds to V_{d-1} . Apply Lemma 25, where R' is the set containing f_X and the vertices y_1, y_2 , and y_3 from Figure 5; by Lemma 28, $\nu(X) \leq \mu'$. This proves the upper bound on U_d .

Suppose $X \in V$. If $X \in \mathcal{N}_3^R$, then $\Gamma_d(X) \leq 3\Gamma_{d-1}^R/4$ by Lemma 30. Otherwise

$$\Gamma_d(X) \leq \nu(X) (2V_{d-1} + 2W_{d-1}).$$

This is the same as the upper bound on Γ_d^R except that, since $X \in V$, y_3 corresponds to W_{d-1} and y_4 to V_{d-1} . Apply Lemma 25, where R' is the set containing f_X and the vertices y_1, y_2, y_3 , and y_4 from Figure 5. By Lemma 29, $\nu(X) \leq \mu''$. This proves the upper bound on V_d .

Suppose $X \in W$. If $X \in \mathcal{N}_4^R$, then $\Gamma_d(X) \leq 20\Gamma_{d-1}^R/21$ by Lemma 30. Otherwise

$$\Gamma_d(X) \leq \nu(X) (\Gamma_{d-1}^R + V_{d-1} + 2W_{d-1} + U_{d-1}).$$

This is the same as the upper bound on Γ_d^R except that, since $X \in W$, y_5 corresponds to U_{d-1} . Apply Lemma 25, where R' is the set containing f_X and the vertices y_1, y_2, y_3 , and y_4 from Figure 5; by Lemma 29, $\nu(X) \leq \mu''$. This proves the upper bound on W_d . \square

Here is the analogue of Lemma 18.

LEMMA 32. *Let $\zeta = 0.001$. Suppose that $q = 10$ and G is the triangular lattice. For every relevant boundary pair X and every $d \geq 1$, $\Gamma_d(X) \leq (1 - \zeta)^d$.*

Proof. Let $u = 15/26$, $v = 31/40$, and $w = 21/22$. We will prove by induction on d that $\Gamma_d^R \leq (1 - \zeta)^d$, $U_d \leq u(1 - \zeta)^d$, $V_d \leq v(1 - \zeta)^d$, and $W_d \leq w(1 - \zeta)^d$. For the base case, $d = 1$, note that for any relevant boundary pair X , $\Gamma_1(X) \leq \nu(X)$. Now apply Lemma 25 with $R' = \{f_X\}$ and by Lemma 26, we find that $\nu(X) \leq 1/4$. Thus, $\Gamma_1(x) \leq \min\{u, v, w, 1\}(1 - \zeta)$.

The inductive step follows directly from Lemma 31 since the following inequalities hold: $\mu''(1 + 2v + 2w) \leq 1 - \zeta$, $20/21 \leq 1 - \zeta$, $\mu'(2v + w) \leq u(1 - \zeta)$, $1/2 \leq u(1 - \zeta)$, $\mu''(2v + 2w) \leq v(1 - \zeta)$, $3/4 \leq v(1 - \zeta)$, $\mu''(1 + v + 2w + u) \leq w(1 - \zeta)$, and $20/21 \leq w(1 - \zeta)$. \square

Unlike Lemma 18, Lemma 32 applies just to relevant boundary pairs, so we have to finish up the proof of strong spatial mixing. Following the proof of Lemma 19, we obtain the following lemma.

LEMMA 33. *Let $\zeta = 0.001$. Suppose that $q = 10$ and G is the triangular lattice. Then for every relevant boundary pair X there exists a coupling Ψ of π_{B_X} and $\pi_{B'_X}$ such that, for all $f \in R_X$,*

$$\mathbb{E}[1_{\Psi, f}] \leq \frac{1}{\zeta}(1 - \zeta)^{d(f, s_X)}.$$

Furthermore,

$$\sum_{f \in R_X} \mathbb{E}[1_{\Psi, f}] \leq \frac{1 - \zeta}{\zeta}.$$

6.5. Vertex discrepancies and strong spatial mixing. The proof of strong spatial mixing (Theorem 7) is similar to the proof on section 4. The only extra problem is showing that the boundary pairs created in Lemma 20 are actually relevant boundary pairs (so that we can apply Lemma 33). This detail complicates the proof of the theorem, so we give a new version of the lemma.

LEMMA 34. *Let $\zeta = 0.001$. Suppose that $q = 10$ and G is the triangular lattice. For every vertex-boundary pair X there is a coupling Ψ of π_{B_X} and $\pi_{B'_X}$ such that, for all $f \in R$,*

$$\mathbb{E}[1_{\Psi, f}] \leq 10 \frac{1}{\zeta(1 - \zeta)}(1 - \zeta)^{d(f, v_X)}.$$

Furthermore,

$$\sum_{f \in R_X} \mathbb{E}[1_{\Psi, f}] \leq \frac{10(1 - \zeta)}{\zeta}.$$

Proof. First suppose that v_X has a neighbor $y \notin R_X$. (This case is straightforward and is like the proof of Lemma 20.) Let e_1, \dots, e_k be the boundary edges of R_X that are adjacent to v_X . Label these clockwise so that there is at least one nonboundary edge between e_k and e_1 . (The point here is that e_i and e_j are adjacent only if i and j differ by 1.) Let X_i be the relevant boundary pair consisting of the region R_X , the distinguished edge e_i , a coloring B of the boundary of R_X that agrees with \mathcal{B}_X except that edges e_1, \dots, e_{i-1} are colored with color $\mathcal{B}'_X(v_X)$ and e_i, \dots, e_k are colored with color $\mathcal{B}_X(v_X)$, and a coloring B' that is the same as B except that it colors e_i with color $\mathcal{B}'_X(v_X)$. We construct a coupling of $\pi_{\mathcal{B}_X}$ and $\pi_{\mathcal{B}'_X}$ by composing couplings Ψ_1, \dots, Ψ_k of X_1, \dots, X_k . Now

$$\mathbb{E}[1_{\Psi, f}] \leq \sum_{i=1}^k \mathbb{E}[1_{\Psi_i, f}] \leq 5 \frac{1}{\zeta} (1 - \zeta)^{d(f, v_X)}.$$

Now we must deal with the case in which all neighbors of v_X are in R_X . A technical detail arises here because the natural induced boundary pairs are not all relevant. Let y be any neighbor of v_X . Let Ψ' be any coupling of $\pi_{\mathcal{B}_X}$ and $\pi_{\mathcal{B}'_X}$. Let (C, C') be the random variable corresponding to the pair of colorings in $S(\mathcal{B}_X) \times S(\mathcal{B}'_X)$ drawn from Ψ . We will choose the color of y in C and C' according to Ψ' . To complete the construction of Ψ , for every pair (c, c') , we will let $\mathcal{B}_X(c)$ denote the vertex-boundary of $R_X - \{y\}$ which agrees with \mathcal{B}_X except that y is colored c , and we will let $\mathcal{B}'_X(c')$ denote the vertex-boundary of $R_X - \{y\}$ which agrees with \mathcal{B}'_X except that y is colored c' . We will construct a coupling of $\mathcal{B}_X(c)$ and $\mathcal{B}'_X(c')$ by composing the couplings of up-to-10 relevant boundary pairs (these boundary pairs correspond to discrepancies on the 5 boundary edges of vertex v_X and the up-to-5 boundary edges on vertex y). The $(1 - \zeta)$ in the denominator comes from the fact that the distance from a vertex f to the discrepancy edge may be one less than $d(f, v_X)$. \square

Lemma 34 provides an ε -coupling cover for $\varepsilon = \frac{\zeta}{1-\zeta} \frac{6}{10}$. Since the lattice is neighborhood-amenable, we obtain Corollary 11.

6.6. Extensions. Using techniques similar to those presented in section 6, we can give an alternative proof to the result of [1]—strong spatial mixing for 6-colorings of the rectangular lattice. The amount of computation in the alternative proof and the proof in section 6 can be reduced by applying some of the techniques from Lemma 16. Our technique can also be applied to other lattices, for example, some of the others studied by Salas and Sokal [27].

7. Rapid mixing. Now we prove Theorem 8, showing that for neighborhood-amenable graphs, our strong spatial mixing proof implies rapid mixing. It is known that strong spatial mixing implies rapid mixing in such cases (see [13, 22, 31]) but existing proofs seem to be written for \mathbb{Z}^d , so we add this section for completeness.

THEOREM 8. *Let G denote an infinite neighborhood-amenable graph with maximum degree Δ . Let R be a finite subgraph of G with $|R| = n$ and $\mathcal{B}(R)$ denote a coloring of $\partial(R)$ using the colors $Q \cup \{0\}$. (We assume that $q \geq \Delta + 2$.)*

Suppose there exists $\varepsilon > 0$ such that G has an ε -coupling cover. Then the Glauber dynamics Markov chain on $S(\mathcal{B}(R))$ is rapidly mixing and $\tau(\delta) \in O(n(n + \log \frac{1}{\delta}))$.

We use the method of path coupling to prove this theorem, approaching our result indirectly through the use of Markov chain comparison. We give a brief review of the path-coupling method in the next section, then proceed with the first step in our analysis for graphs that satisfy the hypotheses of Theorem 8. In section 7.2 we first examine an auxiliary Markov chain which allows recoloring of a slightly larger set of

vertices in a single recoloring step. We show this new chain mixes in time $O(n \log n)$. Markov chain comparison is reviewed in section 7.3, and then the second part of the proof of Theorem 8 is presented in section 7.4.

7.1. Path coupling. Coupling is a popular method for analyzing mixing times of Markov chains. A (Markovian) coupling for a Markov chain \mathcal{M} with state space Ω is a stochastic process (X_t, Y_t) on $\Omega \times \Omega$ such that each of (X_t) and (Y_t) , considered marginally, is a faithful copy of \mathcal{M} . The coupling lemma (see, for example, Aldous [2]) states that the total variation distance of \mathcal{M} at time t is bounded above by $\Pr(X_t \neq Y_t)$. The *path-coupling* method, introduced in [4], is a powerful method for finding couplings. The idea is that one can find a coupling on a subset U of $\Omega \times \Omega$ and extend this to a coupling on $\Omega \times \Omega$. The following theorem, adapted from [12], summarizes the path-coupling method.

THEOREM 35 (see [4, 12]). *Let U be a relation $U \subseteq \Omega^2$ such that U has transitive closure Ω^2 . Let $\phi : U \rightarrow \{0, 1, 2, \dots\}$ be a “proximity function” defined on pairs in U . We use ϕ to define a function Φ on Ω^2 as follows: For each pair $(\omega, \omega') \in \Omega^2$, let*

$$\Phi(\omega, \omega') = \min_{\omega_0, \dots, \omega_k} \sum_{i=0}^{k-1} \phi(\omega_i, \omega_{i+1}),$$

where the minimum is over all paths $\omega = \omega_0, \dots, \omega_k = \omega'$ such that, for all $i \in [0, k-1]$, $(\omega_i, \omega_{i+1}) \in U$. Let (X_t, Y_t) be a coupling for \mathcal{M} defined over all pairs in U . Suppose for this coupling there is $\beta < 1$ such that for all $(\sigma_1, \sigma_2) \in U$ we have

$$\mathbb{E}[\Phi(X_{t+1}, Y_{t+1}) \mid (X_t, Y_t) = (\sigma_1, \sigma_2)] \leq \beta \Phi(\sigma_1, \sigma_2).$$

Let D be the maximum value that Φ achieves on Ω^2 . Then

$$\tau(\delta) \leq \frac{\ln(D/\delta)}{1 - \beta}.$$

7.2. Proof of rapid mixing (Part I). Our goal is to sample from $S(\mathcal{B})$ the set of proper colorings of R consistent with the boundary coloring, uniformly at random, using the single-vertex Glauber dynamics Markov chain. To do this, we first define another Markov chain that corresponds to heat-bath dynamics on small subregions of R . As we defined in section 1.1, for a vertex $f \in G$ and a nonnegative integer d we let $Ball_d(f)$ denote the set of vertices that are at most distance d from f .

Now consider a problem instance of R and \mathcal{B} . For a fixed $d \geq 0$ (to be specified later) and a vertex $f \in G$, let $R_f = Ball_d(f) \cap R$. Further, let

$$R^* = \{f \in G \mid R_f \neq \emptyset\}.$$

Then \mathcal{M}_d is the heat-bath Markov chain with state space $S(\mathcal{B})$ and the following transitions: \mathcal{M}_d makes a transition from a state $\sigma \in S(\mathcal{B})$ by choosing a vertex $f \in R^*$ uniformly at random. Let \mathcal{B}_f be the coloring of ∂R_f induced by σ and \mathcal{B} . To make the transition from σ , recolor the vertices in R_f by sampling from $\pi_{\mathcal{B}_f}$, the uniform distribution of colorings on the region R_f induced by \mathcal{B}_f .

Since $Ball_0(f) = \{f\}$, Glauber dynamics is \mathcal{M}_0 . However, in order to prove rapid mixing of \mathcal{M}_0 we first demonstrate rapid mixing of the chain \mathcal{M}_d for some constant d . Then we use the comparison method (see section 7.3 below) to infer rapid mixing of \mathcal{M}_0 .

Proof of Theorem 8 (Part I). Path coupling is used to prove rapid mixing of the Markov chain \mathcal{M}_d . First, we specify the value of d that we use.

Fix an $\varepsilon > 0$ for which G has an ε -coupling cover as guaranteed in the hypothesis of Theorem 8. Recalling Definition 2, since G is neighborhood-amenable, we can find d such that

$$T_d = \sup_v \frac{|\partial Ball_d(v)|}{|Ball_d(v)|} \leq \frac{\varepsilon}{\varepsilon + \Delta}.$$

In this setting, the distance measure we use is Hamming distance. Because of this, we use the standard approach of taking the set Ω in Theorem 35 to be the set of *all* (proper and improper) q -colorings of the region R . We take U to be the set of pairs of colors that differ at a single vertex. Consider two colorings σ and θ in U with Hamming distance 1, i.e., σ and θ are two (not necessarily proper) colorings of R that disagree at a single vertex v . We describe a coupled transition from the pair (σ, θ) to a new pair of colorings (σ', θ') . In this coupling, we choose the same vertex f for the transition $\sigma \rightarrow \sigma'$ that we choose for the transition $\theta \rightarrow \theta'$. Note that while σ and θ may not be proper colorings of R , a transition $\sigma \rightarrow \sigma'$ is allowed only if σ' is “not more improper” than σ , and similarly for a transition $\theta \rightarrow \theta'$. In other words, having chosen a vertex f , we recolor the “window” R_f using a proper coloring of that window (conditioned, of course, on its induced boundary coloring).

First, note that by construction of R^* , we have $Ball_d(v) \subseteq R^*$. For each vertex $f \in Ball_d(v)$, if f is chosen in the chain \mathcal{M}_d , we can ensure that $\sigma' = \theta'$ by choosing the same coloring to recolor R_f . Thus there are $|Ball_d(v)|$ ways to decrease the Hamming distance by one.

If the chosen vertex f is far from v , in the sense that $v \notin \partial R_f$, then we will couple the transitions by again choosing the same recoloring for the region R_f . This ensures that σ' and θ' disagree only at v so they still have Hamming distance 1.

We now calculate an upper bound on how much the distance can increase in one step of the coupling. This can happen only if we choose some vertex f such that $v \in \partial R_f$. With this in mind we define $\mathcal{H}_d(v) = \{f \in R^* : v \in \partial R_f\}$; $|\mathcal{H}_d(v)|$ is an upper bound on the number of vertices whose selection can increase the distance in the new pair (σ', θ') . Let \mathcal{B}_1 be the coloring of ∂R_f induced from the coloring σ and let \mathcal{B}_2 be that induced from θ . Then \mathcal{B}_1 and \mathcal{B}_2 differ solely at the vertex v . The ε -coupling cover in the hypothesis of the theorem guarantees we can construct a coupling that allows us to choose a pair (σ', θ') of proper colorings so that the expected Hamming distance increases by at most Δ/ε .

Adding it all up, we see the expected Hamming distance between σ' and θ' after one step of the coupling is at most

$$1 - \frac{|Ball_d(v)|}{|R^*|} + \frac{|\mathcal{H}_d(v)|}{|R^*|} \frac{\Delta}{\varepsilon} = 1 - \frac{|Ball_d(v)|\varepsilon - |\mathcal{H}_d(v)|\Delta}{|R^*|\varepsilon}.$$

From the choice of d (using the neighborhood-amenable property of G), and using $\mathcal{H}_d(v) \subseteq \partial Ball_d(v)$, we have

$$|Ball_d(v)|\varepsilon - |\mathcal{H}_d(v)|\Delta \geq |\partial Ball_d(v)|(\varepsilon + \Delta) - |\partial Ball_d(v)|\Delta = |\partial Ball_d(v)|\varepsilon \geq \varepsilon.$$

Thus we have $\mathbb{E}[\Phi(\sigma', \theta')] \leq 1 - 1/|R^*|$.

So for Theorem 35, we can take $\beta = 1 - 1/|R^*|$. Since we use Hamming distance, we have that $D = n$. Using the facts that $d \in O(1)$ and that $\Delta \in O(1)$ (since Δ

is a universal bound on maximum degree for any finite subgraph of G), we see that $1/(1 - \beta) = |R^*| \in O(n)$. Using Theorem 35 we conclude that $\tau_{\mathcal{M}_d}(\delta) \in O(n \log(\frac{n}{\delta}))$.

The final step to get the desired result about \mathcal{M}_0 uses the method of comparing Markov chains. We review this method below, then continue with the proof of Theorem 8 after that.

7.3. The comparison method. In the previous section we showed rapid mixing of \mathcal{M}_d on the set of all (proper and improper) colorings. This implies that \mathcal{M}_d mixes rapidly on the set of proper colorings. In this section we will compare the mixing times of \mathcal{M}_d and \mathcal{M}_0 on the set of proper colorings. We use the method of Diaconis and Saloff-Coste [7]. We provide definitions in the context of these two coloring Markov chains. P_d (resp., P_0) will be used to denote the transition matrix for the chain \mathcal{M}_d (resp., \mathcal{M}_0).

For $i \in \{0, d\}$, let E_i be the set of pairs of distinct colorings (σ, θ) with $P_i(\sigma, \theta) > 0$. We will sometimes refer to the members of E_i as “edges” because they are edges in the transition graph of \mathcal{M}_i . For every edge $(\sigma, \theta) \in E_d$, let $\mathcal{P}_{\sigma, \theta}$ be the set of paths from σ to θ using transitions of \mathcal{M}_0 . More formally, let $\mathcal{P}_{\sigma, \theta}$ be the set of paths $\gamma = (\sigma = \sigma_0, \sigma_1, \dots, \sigma_k = \theta)$ such that

1. each (σ_i, σ_{i+1}) is in E_0 , and
2. each $(\sigma', \theta') \in E_0$ appears at most once on γ .

We write $|\gamma|$ to denote the length of path γ . So, for example, if $\gamma = (\sigma_0, \dots, \sigma_k)$ we have $|\gamma| = k$. Let $\mathcal{P} = \cup_{(\sigma, \tau) \in E_d} \mathcal{P}_{\sigma, \tau}$.

A *flow* is a function ϕ from \mathcal{P} to the interval $[0, 1]$ such that for every $(\sigma, \theta) \in E_d$,

$$(7) \quad \sum_{\gamma \in \mathcal{P}_{\sigma, \theta}} \phi(\gamma) = P_d(\sigma, \theta) \pi_{\mathcal{B}}(\sigma).$$

For every $(\sigma', \theta') \in E_0$, the *congestion* of edge (σ', θ') in the flow ϕ is the quantity

$$A_{\sigma', \theta'}(\phi) = \frac{1}{\pi_{\mathcal{B}}(\sigma') P_0(\sigma', \theta')} \sum_{\gamma \in \mathcal{P}: (\sigma', \theta') \in \gamma} |\gamma| \phi(\gamma).$$

The *congestion* of the flow is the quantity

$$A(\phi) = \max_{(\sigma', \theta') \in E_0^*} A_{\sigma', \theta'}(\phi).$$

A proof of the following theorem can be found in [11, Observation 13]. This theorem is similar to Proposition 4 of Randall and Tetali [26] except that the latter requires the eigenvalues of the transition matrices to be nonnegative. Both results are based closely on the ideas of Aldous [2], Diaconis and Stroock [8], and Sinclair [28].

THEOREM 36. *Suppose that ϕ is a flow. Let $c = \min_{\sigma} P_0(\sigma, \sigma)$ and note that $c \geq 1/q$. Then for any $0 < \delta' < \frac{1}{2}$*

$$\tau(\mathcal{M}_0, \delta) \leq \max \left\{ A(\phi) \left[\frac{\tau(\mathcal{M}_d, \delta')}{\ln \frac{1}{2\delta'}} + 1 \right], \frac{1}{2c} \right\} \ln \frac{1}{\delta \cdot \pi_{\min}},$$

where $\pi_{\min} = \min_{\sigma} \pi_{\mathcal{B}}(\sigma)$.

We continue with the proof of Theorem 8 in the next section.

7.4. Proof of rapid mixing (Part II). Suppose we take $\delta' = 1/n$ and use the upper bound from the first part of the proof of Theorem 8. We then have $\tau(\mathcal{M}_d, \delta') \in O(n \log n)$. We now construct a flow ϕ such that $A(\phi) \in O(1)$, and then Theorem 36 gives

$$\tau(\mathcal{M}_0, \delta) \leq O(1) \cdot O(n) \cdot \ln \frac{1}{\delta \cdot \pi_{\min}}.$$

This yields Theorem 8 since $\ln(1/\pi_{\min}) \in O(n)$.

Proof of Theorem 8 (Part II).

Constructing a flow.

Consider a problem instance consisting of a nonempty region R with $|R| = n$ and a coloring \mathcal{B} of ∂R . We will now construct a flow ϕ .

For every pair $(\sigma, \theta) \in E_d$, we fix some vertex f such that $Ball_d(f)$ contains all the vertices on which σ and θ differ. Then we fix a canonical ordering on these vertices where they differ, say v_1, \dots, v_m .

Let $\gamma_{\sigma, \theta} \in \mathcal{P}_{\sigma, \theta}$ be the canonical path from σ to θ , constructed as follows:

- Update the vertices v_1, \dots, v_m in order.
- In order to update a given vertex v_i :
 - If any neighbors of v_i have color $\theta(v_i)$, recolor these with the lexicographically first available color. (Note that these neighbors do not have their final color in θ .)
 - Recolor v_i with color $\theta(v_i)$.

Assign all of the flow from σ to θ to path $\gamma_{\sigma, \theta}$. That is, set $\phi(\gamma_{\sigma, \theta}) = P_d(\sigma, \theta) \pi_{\mathcal{B}}(\sigma)$.

Bounding $A(\phi)$.

We show that $A(\phi) \in O(1)$, which completes the proof of Theorem 8.

Let σ' and θ' , where $(\sigma', \theta') \in E_0$, be colorings that disagree on vertex x . Now

$$A_{\sigma', \theta'}(\phi) = \frac{1}{\pi_{\mathcal{B}}(\sigma') P_0(\sigma', \theta')} \left(\sum_{\substack{(\sigma, \theta) \in E_d \\ (\sigma', \theta') \in \gamma_{\sigma, \theta}}} |\gamma_{\sigma, \theta}| P_d(\sigma, \theta) \pi_{\mathcal{B}}(\sigma) \right).$$

Since $\pi_{\mathcal{B}}$ is uniform and all of the path lengths are $O(1)$, this simplifies to

$$A_{\sigma', \theta'}(\phi) \leq O(1) \times \left(\sum_{\substack{(\sigma, \theta) \in E_d \\ (\sigma', \theta') \in \gamma_{\sigma, \theta}}} \frac{P_d(\sigma, \theta)}{P_0(\sigma', \theta')} \right).$$

To see that this sum is $O(1)$ note that there are only $O(1)$ pairs (σ, θ) in the summation (this holds since σ and θ agree with σ' except in a constant-sized ball around x), since $\sigma \neq \theta$, $P_d(\sigma, \theta) \in O(1/n)$. Finally, $P_0(\sigma', \theta') \in \Omega(1/n)$.

7.5. Neighborhood-amenability—How restrictive is it? Theorem 8 applies to graphs that are neighborhood-amenable. This condition, while sufficient, is not necessary. The theorem could be extended to a larger class of graphs. The relevant issue is to balance the number of “good” transitions that decrease the distance between the pair with Hamming distance 1 with the number of “bad” transitions that increase the distance (of course, how much the distance increases from any bad transition also matters). There are other similar conditions that we might require from our graph to prove rapid mixing.

Instead of studying these conditions here, we show that neighborhood-amenability is applicable fairly widely. We do this by defining an alternative natural condition and showing that it implies neighborhood-amenability.

DEFINITION 37. For a vertex v of G , let $N_d(v)$ denote the set of vertices that are at distance d from v , and let $n_d(v) = |N_d(v)|$. (Note that $n_0(v) = 1$.)

We say that G is uniformly subexponential if there exists a function $\kappa(d)$ such that

1. for all $b > 1$, $\kappa(d) \in o(b^d)$, and
2. there exist $c_2 \geq c_1 > 0$ such that for all $v \in G$, $c_1\kappa(d) \leq n_d(v) \leq c_2\kappa(d)$.

As stated, the condition of being uniformly subexponential implies neighborhood-amenability as we show below. We first state a lemma that we use to prove this claim.

LEMMA 38. Let $\{a_i\}_{i \geq 0}$ be a sequence of positive numbers. Suppose that $a_d > \alpha(a_{d-1} + a_{d-2} + \dots + a_0)$ for all $d \geq 1$. Then $a_d > a_0\alpha(1 + \alpha)^{d-1}$ for $d \geq 1$.

Proof. We prove this by induction, where the base case (with $d = 1$) is obvious from the condition imposed on the sequence. Then

$$\begin{aligned} a_d &> \alpha(a_{d-1} + a_{d-2} + \dots + a_1 + a_0) \\ &> \alpha(a_0\alpha(1 + \alpha)^{d-2} + a_0\alpha(1 + \alpha)^{d-3} + \dots + a_0\alpha + a_0) \quad (\text{by inductive assumption}) \\ &= a_0\alpha \left(\alpha \left((1 + \alpha)^{d-2} + (1 + \alpha)^{d-3} + \dots + 1 \right) + 1 \right) \\ &= a_0\alpha \left(\alpha \frac{(1 + \alpha)^{d-1} - 1}{\alpha} + 1 \right) \\ &= a_0\alpha(1 + \alpha)^{d-1}. \quad \square \end{aligned}$$

LEMMA 39. Suppose that G is uniformly subexponential. Then G is neighborhood-amenable.

Proof. We apply the contrapositive of Lemma 38 to the sequence of numbers $\kappa(0), \kappa(1), \dots$. This means that given $\varepsilon > 0$, there is a d such that $\kappa(d + 1) \leq \varepsilon(\kappa(d) + \dots + \kappa(0))$. (Otherwise, if $\kappa(d + 1) > \varepsilon(\kappa(d) + \dots + \kappa(0))$ for all d , then the lemma says that $\kappa(d + 1) > \kappa(0)\varepsilon(1 + \varepsilon)^d$ for all $d \geq 0$. Clearly this would violate condition 1 in the definition of “uniformly subexponential.”)

Thus, for any vertex $v \in G$ we have, using condition 2 in Definition 37,

$$\begin{aligned} |\partial Ball_d(v)| = n_{d+1}(v) &\leq c_2\kappa(d + 1) \\ &\leq c_2 \cdot \varepsilon(\kappa(d) + \dots + \kappa(0)) \\ &\leq \frac{c_2}{c_1} \cdot \varepsilon(n_d(v) + \dots + n_0(v)) = \frac{c_2}{c_1} \cdot \varepsilon|Ball_d(v)|. \end{aligned}$$

Hence $T_d = \sup_v \frac{|\partial Ball_d(v)|}{|Ball_d(v)|} \leq \frac{c_2}{c_1} \cdot \varepsilon$. Since $\varepsilon > 0$ is arbitrary, this implies that G is neighborhood-amenable. \square

One could think of other conditions that would imply neighborhood-amenability or even different conditions for which a similar proof of rapid mixing such as the one we gave in Theorem 8 could be demonstrated. If we are dealing with a graph that is vertex-transitive, for example, checking whether it is uniformly-subexponential or not provides a relatively straightforward method to determine if it is neighborhood-amenable.

Readers should consult [30, 31] for further discussion about conditions under which one could demonstrate rapid mixing of Markov chains for sampling proper colorings.

Acknowledgments. We thank Martin Dyer and Eric Vigoda for useful discussions. We are also grateful to a very helpful anonymous referee.

GENERAL MULTIPROCESSOR TASK SCHEDULING: APPROXIMATE SOLUTIONS IN LINEAR TIME*

KLAUS JANSEN[†] AND LORANT PORKOLAB[‡]

Abstract. We study the problem of scheduling n independent tasks on a set of m parallel processors, where the execution time of a task is a function of the subset of processors assigned to the task. For any fixed m , we propose a fully polynomial approximation scheme that for any fixed $\epsilon > 0$ finds a preemptive schedule of length at most $(1 + \epsilon)$ times the optimum in $O(n)$ time. We also discuss the nonpreemptive variant of the problem, and present for any fixed m a polynomial approximation scheme that computes an approximate solution of any fixed accuracy in linear time. In terms of the running time, this linear complexity bound gives a substantial improvement of the best previously known polynomial bound [J. Chen and A. Miranda, *SIAM J. Comput.*, 31 (2001), pp. 1–17].

1. Introduction. In classical scheduling theory, each task is processed by only one processor at a time. However, recently, due to the rapid development of parallel computer systems, new theoretical approaches have emerged to model scheduling on parallel architectures. One of these is scheduling multiprocessor tasks (see, e.g., [5, 8, 9]).

In this paper we address some multiprocessor scheduling problems, where a set of n tasks has to be executed by m processors such that each processor can work on at most one task at a time and a task can be (or may need to be) processed simultaneously by several processors. In the *dedicated* variant of this model, each task requires the simultaneous use of a prespecified set of processors. In the *parallel* variant, which is also called *nonmalleable* parallel task scheduling, the multiprocessor architecture is disregarded, and there is simply a size associated with each task which indicates that the task can be processed on any subset of processors of this size. In the *malleable* variant, each task can be executed on an arbitrary (nonempty) subset of processors, and the execution time of the task depends on the number of processors assigned to it. A generalization of the dedicated variant allows tasks to have a number of *alternative modes*, where each processing mode specifies a subset of processors and the task's execution time on that particular processor set. This problem is called *general multiprocessor task scheduling*.

Depending on the model, tasks can be preempted or not. In the *nonpreemptive* model, a task once started has to be completed without interruption. In the *pre-*

emptive model, each task can be interrupted any time at no cost and restarted later, possibly on a different set of processors. The objective of the scheduling problems discussed in this paper is to minimize the makespan, i.e., the maximum completion time C_{max} . The nonpreemptive versions of malleable and nonmalleable parallel task scheduling have recently been discussed in several papers (see, e.g., [9, 15, 16]). The authors have also studied this problem [12] and proposed an approximation scheme that finds for any fixed $\epsilon > 0$ a nonpreemptive schedule of makespan at most $(1 + \epsilon)$ times the optimum (such a schedule is called an ϵ -approximate solution). The algorithm runs in linear time when the number of parallel processors is fixed. The dedicated and general variants of nonpreemptive (preemptive) scheduling for independent multiprocessor tasks on a fixed number of processors are denoted by $Pm|fix_j|C_{max}$ ($Pm|fix_j, pmtn|C_{max}$) and $Pm|set_j|C_{max}$ ($Pm|set_j, pmtn|C_{max}$), respectively.

Regarding the complexity, problems $P3|fix_j|C_{max}$ and $P3|set_j|C_{max}$ are strongly NP-hard [3, 4, 11], thus they do not have fully polynomial-time approximation schemes, unless $P=NP$. Recently, Amoura et al. [1] developed a polynomial-time approximation scheme for $Pm|fix_j|C_{max}$. For the general problem $Pm|set_j|C_{max}$, Bianco et al. [2] presented an approximation algorithm whose approximation ratio is bounded by m . Later Chen and Lee [6] improved their algorithm by achieving an approximation ratio $\frac{m}{2} + \epsilon$. Until very recently, this was the best approximation result for the problem, and it was not known whether there is a polynomial-time approximation scheme or even a polynomial-time approximation algorithm with a constant approximation guarantee. Independently from our work presented here, Chen and Miranda [7] have recently proposed a polynomial-time approximation scheme for the problem. The running time of their approximation scheme is $O(n^{\lambda_{m,\epsilon} + j_{m,\epsilon} + 1})$, where $\lambda_{m,\epsilon} = (2j_{m,\epsilon} + 1)B_m m$ and $j_{m,\epsilon} \leq (3mB_m + 1)^{\lceil m/\epsilon \rceil}$ with $B_m \leq m!$ denoting the m th Bell number. In this paper, we propose another polynomial-time approximation scheme for $Pm|set_j|C_{max}$ that computes an ϵ -approximate solution in $O(n)$ time for any fixed positive accuracy ϵ . In terms of the running time this gives a substantial improvement of the previously mentioned result [7] and also answers an open question of that paper by providing an approach that is not based on dynamic programming.

It is known that the preemptive variant $Pm|set_j, pmtn|C_{max}$ of the problem can be solved in polynomial time [2] by formulating it as a linear program with n constraints and n^m variables and computing an optimal solution by using any polynomial-time linear programming algorithm. Even though (for any fixed m), the running time in this approach is polynomial in n , the degree of this polynomial depends linearly on m . Therefore it is natural to ask whether there are more efficient algorithms for $Pm|set_j, pmtn|C_{max}$ (of running time, say, for instance, $O(n)$ or $O(n^c)$ with an absolute constant c) that compute exact or approximate solutions. In this paper we focus on approximate solutions and present a fully polynomial approximation scheme for $Pm|set_j, pmtn|C_{max}$ that finds an ϵ -approximate solution in $O(n)$ time for any fixed positive accuracy ϵ . This result also shows that as long as approximate solutions (of any fixed positive accuracy) are concerned, linear running time can be achieved for the problem, but it leaves open the question (which also partly motivated this work) of whether there exists a linear-time algorithm for computing an optimal solution of $Pm|set_j, pmtn|C_{max}$. This question was answered in an affirmative way for the dedicated variant $Pm|fix_j, pmtn|C_{max}$ of the problem by Amoura et al. [1].

2. Preemptive scheduling. In this section we consider the preemptive version $Pm|pmtn, set_j|C_{max}$ of the general multiprocessor task scheduling problem. Suppose there are a set of tasks $\mathcal{T} = \{T_0, \dots, T_{n-1}\}$ and a set of processors $M = \{1, \dots, m\}$.

Each task T_j has an associated function $t_j : 2^M \rightarrow Q^+ \cup \{+\infty\}$ that gives the execution time $t_j(S)$ of task T_j in terms of the set of processors $S \subseteq M$ that is assigned to T_j . Given a set S_j of processors assigned to task T_j , the processors in S_j are required to execute task T_j simultaneously; i.e., they all have to start processing task T_j at some starting time τ_j , and complete it at $\tau_j + t_j(S_j)$ or interrupt it before. A feasible preemptive schedule can be defined as a system of interval sequences $\{I_{j1} = [a_{j1}, b_{j1}), \dots, I_{js_j} = [a_{js_j}, b_{js_j})\}$, corresponding to the uninterrupted processing phases of task T_j , $j = 0, \dots, n - 1$, where $b_{jq} \leq a_{j,q+1}$ for every j and q . In addition there is an associated set $S_{jq} \subseteq M$ of processors for each interval I_{jq} such that $S_{jq} \neq S_{j,q+1}$ for every j and q (if $b_{jq} = a_{j,q+1}$). Moreover, for each time step τ there is no processor assigned to more than one task; i.e., $S_{jq} \cap S_{j'q'} = \emptyset$ for every τ such that $\tau \in I_{jq} \cap I_{j'q'}$, $j \neq j'$. The objective is to compute a feasible preemptive schedule that minimizes the overall makespan $C_{max} = \max\{b_{js_j} : j = 0, \dots, n - 1\}$. In section 2.1, we formulate this problem as a linear program and then, based on this linear programming formulation, we give an approximation scheme for $Pm|pmtn, set_j|C_{max}$ in section 2.2 with running time $O(n)$ for any fixed $\epsilon > 0$. Interestingly, the running time is polynomial in $\frac{1}{\epsilon}$.

2.1. Linear programming formulation. Let $\mathcal{L} \subseteq \mathcal{T}$ and $k = |\mathcal{L}|$. Later \mathcal{L} will be selected such that for any fixed m and $\epsilon > 0$, it consists of a constant number $k = \Theta(2^m(m/\epsilon))$ of “long” tasks. (For the choice of k we refer to section 2.4.) Let $P_1 = M, P_2 = M \setminus \{1\}, P_3 = M \setminus \{2\}, \dots, P_{2^m-1} = \{m\}, P_{2^m} = \emptyset$ be a fixed order of all subsets of M . Since preemptions are allowed, every feasible (and therefore also every optimal) schedule can be modified such that it remains feasible with the same makespan T and in addition has the following property: The time interval $[0, T)$ can be partitioned into 2^m consecutive subintervals $I(P_1) = [t_0 = 0, t_1), I(P_2) = [t_1, t_2), \dots, I(P_{2^m}) = [t_{2^m-1}, t_{2^m} = T)$ such that during $I(P_i), i = 1, \dots, 2^m$, tasks in \mathcal{L} are processed by *exactly* the processors in $P_i \subseteq M$. Each processor in P_i is working on one of the tasks from \mathcal{L} , and all the other processors are either idle or executing tasks from $\mathcal{S} = \mathcal{T} \setminus \mathcal{L}$. (For illustration see Figure 1, but notice that in contrast to the figure the lengths $t_{i+1} - t_i$ of the intervals are in general different and determined in the linear program below.)

FIG. 1. Schedule with processors 1, 2, 3.

For tasks from \mathcal{L} and processors in $P_i, i = 1, \dots, 2^m - 1$, we consider assignments $f_i : P_i \rightarrow \mathcal{L}$. Let A_i denote the set containing all such assignments. Let $F_i = M \setminus P_i$ be the set of free processors for executing tasks from \mathcal{S} during the interval $I(P_i)$. Notice that $F_1 = \emptyset$ and $F_{2^m} = M$. For processor sets $F_i, i = 2, \dots, 2^m$, let $P_{F_i,q}$,

$q = 1, \dots, n_i$, denote the different partitions of F_i , and let $\mathcal{P}_i = \{P_{F_i,1}, \dots, P_{F_i,n_i}\}$. Finally, to simplify the notation below, we introduce the following indicators for every $\mu \subseteq M$ and every $P_{F_i,q} \in \mathcal{P}_i$, $i = 2, \dots, 2^m$: $\xi_{F_i,q}(\mu) = 1$ if $\mu \in P_{F_i,q}$ and 0 otherwise.

The following variables will be used in the linear program:

- t_i : the starting (and finishing) time of the interval when exactly the processors in P_{i+1} , $i = 0, \dots, 2^m - 1$ (P_i , $i = 1, \dots, 2^m$) are used for processing long tasks from \mathcal{L} .
- u_f : the total processing time corresponding to the assignment $f \in A_i$, $i = 1, \dots, 2^m - 1$.
- z_{ji} : the fraction of task $T_j \in \mathcal{L}$ processed in the interval $I(P_i) = [t_{i-1}, t_i]$, $i = 1, \dots, 2^m - 1$.
- $x_{F_i,q}$: the total processing time for partition $P_{F_i,q} \in \mathcal{P}_i$, $q = 1, \dots, n_i$, $i = 2, \dots, 2^m$, where exactly processors of F_i are executing short tasks and each subset of processors $\mu \in P_{F_i,q}$ executes at most one short task at each time step in parallel.
- D^μ : the total processing time for all tasks in $\mathcal{S} = \mathcal{T} \setminus \mathcal{L}$ executed on processor set μ .
- $y_{j\mu}$: the fraction of task $T_j \in \mathcal{S}$ executed by the processor set $\mu \subseteq M$, $\mu \neq \emptyset$. (By introducing these variables we can handle the possibility of nonfixed processor assignments also for the tasks in \mathcal{S} . Later, for the nonpreemptive version of the problem, the $y_{j\mu}$'s will be 0 – 1 variables.)

We consider the following linear program (which will be explained in detail following its complete statement).

Minimize t_{2^m}

- s.t. (0) $t_0 = 0$,
- (1) $t_i \geq t_{i-1}$, $i = 1, \dots, 2^m$,
 - (2) $t_i - t_{i-1} = \sum_{f \in A_i} u_f$, $i = 1, \dots, 2^m - 1$,
 - (3) $u_f \geq 0 \forall f \in A_i$, $i = 1, \dots, 2^m - 1$,
 - (4) $\sum_{\mu \subseteq P_i} \sum_{f \in A_i: f^{-1}(j)=\mu} \frac{u_f}{t_j(\mu)} = z_{ji} \forall j \in \mathcal{L}$, $i = 1, \dots, 2^m - 1$,
 - (5) $\sum_{i=1}^{2^m-1} z_{ji} = 1 \forall j \in \mathcal{L}$,
 - (6) $z_{ji} \geq 0 \forall j \in \mathcal{L}$, $i = 1, \dots, 2^m - 1$,
 - (7) $\sum_{q=1}^{n_i} x_{F_i,q} \leq t_i - t_{i-1}$, $i = 2, \dots, 2^m$,
 - (8) $\sum_{i=2}^{2^m} \sum_{q=1}^{n_i} \xi_{F_i,q}(\mu) \cdot x_{F_i,q} \geq D^\mu \forall \mu \subseteq M$, $\mu \neq \emptyset$,
 - (9) $x_{F_i,q} \geq 0$, $i = 2, \dots, 2^m$, $q = 1, \dots, n_i$,
 - (10) $\sum_{T_j \in \mathcal{S}} t_j(\mu) \cdot y_{j\mu} = D^\mu \forall \mu \subseteq M$, $\mu \neq \emptyset$,
 - (11) $\sum_{\mu \subseteq M, \mu \neq \emptyset} y_{j\mu} = 1 \forall T_j \in \mathcal{S}$,
 - (12) $y_{j\mu} \geq 0 \forall T_j \in \mathcal{S}$, $\forall \mu \subseteq M$, $\mu \neq \emptyset$.

Constraints (0)–(1) define the endpoints of the intervals $[t_i, t_{i+1})$, $i = 0, 1, \dots, 2^m - 1$. The further subdivision of these intervals corresponding to the different assignments in A_i is described by (2)–(3). The processing time of each long job can also be partitioned according to the processor sets P_i , $i = 1, \dots, 2^m - 1$, and each of these fractions has to be covered as it is formulated by (4)–(6). The inequalities of (7) require for every set of free processors F_i , $i = 2, \dots, 2^m$, that its total processing time (which is the sum of processing times corresponding to the different partitions) be bounded by the length of the interval $[t_{i-1}, t_i)$. Furthermore, the inequalities of (8) guarantee that there is enough time for the execution of all μ -processor tasks in \mathcal{S} . In (10), the total processing times D^μ required by short tasks using processor set $\mu \subseteq M$, $\mu \neq \emptyset$, are expressed in terms of variables $y_{j\mu}$. Finally, constraints (11) and (12) formulate the possibility of nonfixed processor assignments for short tasks in \mathcal{S} . Notice that

solutions of the above linear program allow for each task from \mathcal{S} to be executed parallel on different subsets μ of processors. Thus the schedule obtained directly from a solution of this linear program might contain some incorrectly scheduled tasks, which therefore have to be corrected afterwards. (See section 2.3.)

LEMMA 2.1. *In the preemptive schedule corresponding to any feasible solution of (0)–(12), every task T_j is processed completely.*

Proof. For every task $T_j \in \mathcal{T}$, let $w_j(\mu)$ be the total time while task T_j is processed by exactly the processors in $\mu \subseteq M$. Clearly task T_j is processed completely if and only if $\sum_{\mu \subseteq M} \frac{w_j(\mu)}{t_j(\mu)} \geq 1$. Since by definition $y_{j\mu} = \frac{w_j(\mu)}{t_j(\mu)}$ for $T_j \in \mathcal{S}$, the lemma is implied by (11) for the short tasks. For a long task $T_j \in \mathcal{L}$, $w_j(\mu) = \sum_{i=1}^{2^m-1} \sum_{f \in A_i: f^{-1}(j)=\mu} u_f$. Therefore we obtain by using (4) and (5) that

$$\begin{aligned} \sum_{\mu \subseteq M} \frac{w_j(\mu)}{t_j(\mu)} &= \sum_{\mu \subseteq M} \sum_{i=1}^{2^m-1} \sum_{f \in A_i: f^{-1}(j)=\mu} \frac{u_f}{t_j(\mu)} \\ &= \sum_{i=1}^{2^m-1} \sum_{\mu \subseteq M} \sum_{f \in A_i: f^{-1}(j)=\mu} \frac{u_f}{t_j(\mu)} = \sum_{i=1}^{2^m-1} z_{ji} = 1, \end{aligned}$$

which proves the lemma also for tasks from \mathcal{L} . \square

Let $d_j = \min_{\mu \subseteq M} t_j(\mu)$ be the minimum execution time for task T_j , and let $D = \sum_{T_j \in \mathcal{T}} d_j$. Then, the minimum makespan OPT among all schedules satisfies $\frac{D}{m} \leq OPT \leq D$. By normalization (dividing all execution times by D), we may assume that $D = 1$ and that $\frac{1}{m} \leq OPT \leq 1$. This implies that for any optimal schedule, and for every $\mu \subseteq M$, $\mu \neq \emptyset$, the total execution time D^μ of tasks executed by processor set μ can be bounded by 1.

2.2. Solving the linear program. Fix the length of the schedule to a constant $s \in [\frac{1}{m}, 1]$. Let $LP(s, \lambda)$ denote the linear program obtained from (0)–(12) by setting $t_{2^m} = s$ and replacing (8) and (10) with the following constraints:

$$(8') \quad \sum_{i=2}^{2^m} \sum_{q=1}^{n_i} \xi_{F_{i,q}}(\mu) \cdot x_{F_{i,q}} \leq 1, \quad \mu \subseteq M, \mu \neq \emptyset.$$

$$(10') \quad \sum_{T_j \in \mathcal{S}} t_j(\mu) \cdot y_{j\mu} - \sum_{i=2}^{2^m} \sum_{q=1}^{n_i} \xi_{F_{i,q}}(\mu) \cdot x_{F_{i,q}} + 1 \leq \lambda, \quad \mu \subseteq M, \mu \neq \emptyset.$$

Note that we have eliminated the variables D^μ but bounded the corresponding lengths for the configurations by 1. Since $OPT \leq 1$, we have $\sum_{i=2}^{2^m} \sum_{q=1}^{n_i} x_{F_{i,q}} \leq 1$ and $\sum_{i=2}^{2^m} \sum_{q=1}^{n_i} \xi_{F_{i,q}}(\mu) \cdot x_{F_{i,q}} \leq 1$ (for any optimal solution). The problem $LP(s, \lambda)$ has a special block angular structure. The blocks $B_j = \{y_j : y_{j\mu} \geq 0, \sum_{\mu \subseteq M} y_{j\mu} = 1\}$ for $T_j \in \mathcal{S}$ are 2^m -dimensional simplices, and the block $B_{|\mathcal{S}|+1} = \{(t_i, u_f, z_{ji}, x_{F_{i,q}}) : t_{2^m} = s \text{ and conditions (0)–(7), (8'), (9)}\}$ contains only a constant number of variables and constraints (the numbers depend exponentially on m , but are polynomial in $1/\epsilon$). The coupling constraints are the replaced linear inequalities (10'). Note that for every $\mu \subseteq M$, $\mu \neq \emptyset$, the function $f^\mu = \sum_{T_j \in \mathcal{S}} t_j(\mu) \cdot y_{j\mu} - \sum_{i=2}^{2^m} \sum_{q=1}^{n_i} \xi_{F_{i,q}}(\mu) \cdot x_{F_{i,q}} + 1$ is nonnegative over the blocks.

The logarithmic potential price directive decomposition method [10] developed by Grigoriadis and Khachiyan for a large class of problems with block angular structure provides a δ -relaxed decision procedure for $LP(s, \lambda)$. This procedure either determines that $LP(s, 1)$ is infeasible or computes (a solution that is nearly feasible in the sense that it is) a feasible solution of $LP(s, (1 + \delta))$. This can be done [10, 14] in $O(2^m(m + \delta^{-2}))$ iterations, where each iteration requires $O(2^m \ln \ln(2^m \delta^{-1}))$ operations and $|\mathcal{S}| + 1 \leq n + 1$ block optimizations performed to a relative accuracy of $\Theta(\delta)$, where $\delta =$

$\Theta(\epsilon)$. In our case each block optimization over $B_1, \dots, B_{|\mathcal{S}|}$ is the minimization of a given linear function over a 2^m -dimensional simplex which can be done (not only approximately, but even) exactly in $O(2^m)$ time. Furthermore, the block optimization over $B_{|\mathcal{S}|+1}$ is the minimization of a linear function over a block with a constant number of variables and constraints, which can be done in constant time. The number M of constraints in the last block is $O(2^m k)$, and the number N of variables is $O((2k)^m)$, where $k = O(2^m(m/\epsilon))$. The execution times $t_j(\mu)$ for tasks $T_j \in \mathcal{L}$ have values between $\epsilon/(2m2^{m+1})$ and 1 (see also section 2.4). Therefore we may assume that the coefficients in the inequalities (4) have values between 1 and $2^{O(m)}/\epsilon$. A linear program with N variables and M constraints can be solved in $O((MN^2 + M^{1.5}N)L)$ time for $M \geq N$, where L is the size of instance [18]. In our case $N > M$, and the running time can be bounded by $O(N^3L)$. The size of each coefficient (either in the inequalities or the linear objective function) is at most $O(m + \log(1/\epsilon))$. The size L can be bounded by $O(NM + (k2^m)(m + \log(1/\epsilon)))$, since there are at most $O(k2^m)$ different execution times $t_j(\mu)$ for tasks $T_j \in \mathcal{L}$. Therefore the running time to solve the linear program for block $B_{|\mathcal{S}|+1}$ is at most $O(N^5(k2^m)(m + \log 1/\epsilon)) = 2^{O(m^2)}(1/\epsilon)^{O(m)}$. This implies a running time for $LP(s, \lambda)$ of at most $[2^{O(m)}n\epsilon^{-2} + 2^{O(m^2)}(1/\epsilon)^{O(m)}]$. Therefore for any fixed m and $\delta > 0$, the overall running time of this procedure for (approximately) solving $LP(s, \lambda)$ is $O(n)$. The number of strictly positive variables corresponding to block $B_{|\mathcal{S}|+1}$ is at most $O(k2^{2m}(m + \epsilon^{-2})) = [2^{O(m)}\epsilon^{-3}]$.

The next lemma summarizes a few simple observations that can be easily checked.

LEMMA 2.2. *The following assertions are true:*

1. *If $LP(s, 1)$ is feasible and $s \leq s'$, then $LP(s', 1)$ is feasible.*
2. *If $LP(s, 1)$ is infeasible, then there is no schedule with makespan at most s .*
3. *$LP(OPT, 1)$ is feasible.*

These statements imply that one can use binary search on $s \in [\frac{1}{m}, 1]$ and obtain in $O(\log \frac{m}{\epsilon})$ iterations a value $\bar{s} \leq OPT(1 + \frac{\epsilon}{4})$ such that $LP(\bar{s}, (1 + \delta))$ is feasible.

2.3. Generating a schedule. In this subsection, we show how to generate a feasible schedule using an approximate solution of the previously described linear program. Consider the solution obtained after the binary search on s . The inequalities (10') imply that for any $\mu \subseteq M$, $\mu \neq \emptyset$,

$$\sum_{T_j \in \mathcal{S}} t_j(\mu) \cdot y_{j\mu} - \sum_{i=2}^{2^m} \sum_{q=1}^{n_i} \xi_{F_i,q}(\mu) \cdot x_{F_i,q} \leq \delta.$$

Let $\bar{D}^\mu = \sum_{i=2}^{2^m} \sum_{q=1}^{n_i} \xi_{F_i,q}(\mu) \cdot x_{F_i,q}$, the free space for small tasks that use processor set μ . The idea is to shift a subset $\bar{\mathcal{S}} \subset \mathcal{S}$ of small jobs to the end of the schedule such that $\sum_{T_j \in \mathcal{S} \setminus \bar{\mathcal{S}}} t_j(\mu) \cdot y_{j\mu} \leq \bar{D}^\mu$. Then, the subset $\mathcal{S} \setminus \bar{\mathcal{S}}$ of remaining small jobs fits into the free space for the μ -processor tasks.

In the following, we show how to compute such a subset $\bar{\mathcal{S}}$ in linear time for any fixed m . First we modify the y -components of the solution obtained from the linear program. The key idea is to allow no change of processor sets $\mu \subseteq M$ (or to have fractional y -components) for small tasks. Using this assumption it is easier to compute a set $\bar{\mathcal{S}}$ and a feasible schedule for the small tasks. Furthermore, only a few small tasks will have fractional y -components. The y -components of the approximate solution of $LP(\bar{s}, (1 + \delta))$ can be considered as fractional assignments. Let the lengths of y be defined as $L^\mu = \sum_{T_j \in \mathcal{S}} t_j(\mu) \cdot y_{j\mu}$, $\mu \subseteq M$. Then for every $\mu \subseteq M$, we have $L^\mu \leq \bar{D}^\mu + \delta$. A fractional assignment y can be represented by a bipartite graph

$G = (V_1, V_2, E)$, where V_1 and V_2 correspond to row and column indices of y (tasks and subsets of processors), respectively, and $(j, \mu) \in E$ if and only if $y_{j\mu} > 0$.

Any assignment y represented by a bipartite graph G of lengths L^μ , $\mu \subseteq M$, can be converted in $O(n2^{2m})$ time into another (fractional) assignment \tilde{y} of lengths at most L^μ , $\mu \subseteq M$, represented by a forest [17] (see Lemma 5.1). For a fractional assignment y , a task T_j has a nonunique processor assignment if there are at least two processor sets μ and μ' , $\mu \neq \mu'$, such that $y_{j\mu} > 0$ and $y_{j\mu'} > 0$. Let \mathcal{U}_1 be the set of tasks with nonunique processor assignments. For an assignment y corresponding to a forest, we have $|\mathcal{U}_1| \leq 2^m - 1$.

In the next step, we compute for every $\mu \subseteq M$ a subset $S^\mu \subset S \setminus \mathcal{U}_1$ of tasks with $y_{j\mu} = 1$ for all tasks $T_j \in S^\mu$ such that the total execution length $\sum_{T_j \in S^\mu} t_j(\mu) \geq \delta$ and there is a task $T_{j_\mu} \in S^\mu$ for which $\sum_{T_j \in S^\mu \setminus \{T_{j_\mu}\}} t_j(\mu) < \delta$. Let $\mathcal{U}_2 = \{T_{j_\mu} | \mu \subseteq M\}$.

In total, we get a set $\mathcal{U}_1 \cup \mathcal{U}_2$ with at most $2^{m+1} - 1$ tasks and a subset of tasks $\mathcal{V} = (\cup_{\mu \subseteq M} S^\mu) \setminus \mathcal{U}_2$ of total execution length $2^m \delta$. By choosing $\delta = \frac{\epsilon}{4m2^m}$, the total execution length of \mathcal{V} can be bounded by $\frac{\epsilon}{4m} \leq \frac{\epsilon}{4} OPT$. Using that $\bar{s} \leq (1 + \frac{\epsilon}{4}) OPT$, this implies the following lemma.

LEMMA 2.3. *The objective function value of the computed linear programming solution restricted to $\mathcal{T}' = \mathcal{T} \setminus (\mathcal{U}_1 \cup \mathcal{U}_2)$ is at most $OPT + \frac{\epsilon}{2} OPT$, and $|\mathcal{U}_1 \cup \mathcal{U}_2| \leq 2^{m+1} - 1$.*

The next step of the algorithm computes a schedule for the tasks in $\mathcal{T}'' = \mathcal{T} \setminus (\mathcal{U}_1 \cup \mathcal{U}_2 \cup \mathcal{V})$. (The tasks in $\mathcal{U}_1 \cup \mathcal{U}_2 \cup \mathcal{V}$ will be scheduled afterwards at the end.) The makespan of the computed schedule is bounded by $(1 + \frac{\epsilon}{4}) OPT$. Furthermore, the total execution time for \mathcal{V} is bounded by $\frac{\epsilon}{4} OPT$. Note that each small task $T_j \in \mathcal{T}' \cap \mathcal{S}$ has a unique set of assigned processors.

Let \hat{D}^μ be the total processing time for all tasks in $\mathcal{T}'' \cap \mathcal{S}$ assigned to processor set μ , and let $(t^*, u^*, z^*, x^*, y^*)$ be a solution of the linear program with objective value $t_{2^m}^*$. In the first step, we compute a schedule for the long tasks $T_j \in \mathcal{L}$ according to the variables t_i^* , u_i^* , and z_i^* . As a result, during the interval $[t_{i-1}^*, t_i^*)$ only the processors in P_i are used by the long tasks for every $i = 1, \dots, 2^m$. This first step can be done in time $[2^{O(m)} \epsilon^{-3}]$.

In the second step, we schedule all μ -processor tasks in $\mathcal{S}' = \mathcal{T}'' \cap \mathcal{S}$ for every $\mu \subseteq M$. From the left to the right (starting with the second interval), we place the tasks of \mathcal{S}' on the free processors in $F_i = M \setminus P_i$ for each interval $[t_{i-1}^*, t_i^*)$ (and $2 \leq i \leq 2^m$). To do this, we consider each partition $P_{F_i, q}$ of F_i with value $x_{F_i, q}^* > 0$. For each set $\mu \in P_{F_i, q}$, we place a sequence of tasks that use processor set μ with total execution length $x_{F_i, q}^*$. If necessary, the last (and first) task assigned to μ is preempted. Since $\sum_{i=2}^{2^m} \sum_{q=1}^{n_i} \xi_{F_i, q}(\mu) \cdot x_{F_i, q}^* \geq \hat{D}^\mu$, this procedure completely schedules all small tasks (assigned to processor set μ for every $\mu \subseteq M$), and it runs in $[O(n) + 2^{O(m)} \epsilon^{-3}]$ time. Note that the computed schedule is feasible.

2.4. Selecting the cardinality of \mathcal{L} . The following lemma will be used to select the cardinality k of \mathcal{L} (a constant for any fixed m and $\epsilon > 0$), such that the total processing time of $\mathcal{U}_1 \cup \mathcal{U}_2$ can be bounded by $\frac{\epsilon}{2} OPT$. Note that a more general version of this lemma was proved in [12].

LEMMA 2.4. *Suppose $d_1 \geq d_2 \geq \dots \geq d_n > 0$ is a sequence of real numbers and $D = \sum_{j=1}^n d_j$. Let p be a nonnegative integer, $\alpha \in (0, 1)$, and assume that n is sufficiently large (i.e., all the indices of the d_i 's in the statement are smaller than n ; e.g., $n > (\lceil \frac{1}{\alpha} \rceil p + 1)$ suffices). Then, there exists an integer $k = k(p, \alpha)$ such that*

$$d_k + \dots + d_{k+p-1} \leq \alpha \cdot D$$

and

$$k \leq 1 + p \left(\left\lceil \frac{1}{\alpha} \right\rceil - 1 \right).$$

In our problem $D = \sum_{T_j \in \mathcal{T}} d_j$, where $d_j = \min_{\mu \subseteq M} t_j(\mu)$ is the minimum execution time for task T_j . The minimum makespan OPT among all schedules satisfies $\frac{D}{m} \leq OPT \leq D$. By normalization, we assumed that $D = 1$ and that $\frac{1}{m} \leq OPT \leq 1$. We select now $p = 2^{m+1} - 1$ and $\alpha = \frac{\epsilon}{2^m}$ in Lemma 2.4. Then, Lemmas 2.3 and 2.4 imply that there exists a constant $k \leq 1 + (2^{m+1} - 1)(\lceil \frac{2^m}{\epsilon} \rceil - 1)$ such that the total execution time of the tasks in $\mathcal{U}_1 \cup \mathcal{U}_2$ can be bounded by $\frac{\epsilon}{2}OPT$. Furthermore, the makespan for the partial (feasible) schedule of $\mathcal{T} \setminus (\mathcal{U}_1 \cup \mathcal{U}_2)$ is at most $(1 + \frac{\epsilon}{2})OPT$. Thus the overall makespan of the (complete) schedule is bounded by $(1 + \epsilon)OPT$. According to the arguments above all computations can be carried out in $[2^{O(m)}(1/\epsilon)^2n + 2^{O(m^2)}(1/\epsilon)^m]$ time, which implies a running time of $O(n)$ for any fixed m and $\epsilon > 0$. Thus, we have proved the following result.

THEOREM 2.5. *There is an algorithm that, given a set of n independent tasks, a constant number of processors m , a fixed positive accuracy ϵ , and execution times $t_j(\mu)$ for each task T_j and subset of processors μ , produces a preemptive schedule whose makespan is at most $(1 + \epsilon)OPT$ in $O(n)$ time.*

Clearly for any fixed m , the running time of the above algorithm depends only polynomially on $\frac{1}{\epsilon}$; hence it is a fully polynomial approximation scheme.

3. Nonpreemptive scheduling. In this section, we study the nonpreemptive variant $Pm|set_j|C_{max}$ of the general multiprocessor scheduling problem. Given a set S_j of processors assigned to task T_j , the processors in S_j are required to execute task T_j in union and without preemption; i.e., they all have to start processing task T_j at some starting time τ_j and complete it at $\tau_j + t_j(S_j)$. A feasible nonpreemptive schedule consists of a processor assignment $S_j \subseteq M$ and a starting time $\tau_j \geq 0$ for each task T_j such that for each time step τ , there is no processor assigned to more than one task. The objective is to find a feasible nonpreemptive schedule that minimizes the overall makespan $C_{max} = \max\{\tau_j + t_j(S_j) : j = 0, \dots, n - 1\}$.

3.1. Linear programming formulation. First we consider a mixed 0 – 1 integer linear program which is closely related to our scheduling problem. Similar formulations were studied in [1, 12] for restricted (dedicated and malleable) variants of the problem. Based on this linear programming formulation we will give a linear-time approximation scheme for $Pm|set_j|C_{max}$.

Let $\mathcal{L} \subset \mathcal{T}$. A processor assignment for \mathcal{L} is a mapping $f : \mathcal{L} \rightarrow 2^M$. Two tasks T_j and $T_{j'}$ are *compatible* if $f(T_j) \cap f(T_{j'}) = \emptyset$. For a given processor assignment for \mathcal{L} , a *snapshot* of \mathcal{L} is a subset of compatible tasks. A *relative schedule* of \mathcal{L} is a processor assignment $f : \mathcal{L} \rightarrow 2^M$ along with a sequence $M(1), \dots, M(g)$ of snapshots of \mathcal{L} such that

- each $T_j \in \mathcal{L}$ occurs in a subset of consecutive snapshots $M(\alpha_j), \dots, M(\omega_j)$, $1 \leq \alpha_j \leq \omega_j < g$, where $M(\alpha_j)$ is the first and $M(\omega_j)$ is the last snapshot that contains T_j ;
- consecutive snapshots are different; i.e., $M(t) \neq M(t + 1)$ for $1 \leq t \leq g - 1$;
- $M(1) \neq \emptyset$ and $M(g) = \emptyset$.

A relative schedule corresponds to an order of executing the tasks in \mathcal{L} . One can associate a relative schedule for each nonpreemptive schedule of \mathcal{L} by looking at the schedule at every time where a task of \mathcal{L} starts or ends and creating a snapshot

right after that time step. Creating snapshots this way, $M(1) \neq \emptyset$, $M(g) = \emptyset$, and g , the number of snapshots, can be bounded by $\max(2|\mathcal{L}|, 1)$. Given a relative schedule $R = (f, M(1), \dots, M(g))$, the processor set used in snapshot $M(i)$ is given by $P(i) = \cup_{T \in M(i)} f(T)$. Let \mathcal{F} denote the set containing (as elements) all the different $(M \setminus P(i))$ sets, $i = 1, \dots, g$. (Thus the sets in \mathcal{F} are the different sets of free processors corresponding to R .) For each $F \in \mathcal{F}$, let $P_{F,i}, i = 1, \dots, n_F$, denote the different partitions of F , and let $\mathcal{P}_F = \{P_{F,1}, \dots, P_{F,n_F}\}$. Furthermore, let D^μ be the total processing time for all tasks in $\mathcal{S} = \mathcal{T} \setminus \mathcal{L}$ executed on processor set $\mu \subseteq M$. Finally, we define the indicators for every $\mu \subseteq M$ and every $P_{F,i} \in \mathcal{P}_F, i = 1, \dots, n_F, F \in \mathcal{F}$, similarly as before: $\xi_{F,i}(\mu) = 1$ if $\mu \in P_{F,i}$ and 0 otherwise.

For each relative schedule $R = (f, M(1), \dots, M(g))$ of \mathcal{L} , we formulate a mixed 0–1 integer program $ILP(R)$ as follows (where again we defer a complete explanation of the linear program until after its complete statement). For every $T_j \in \mathcal{L}$, let $p_j = t_j(f(T_j))$.

Minimize t_g

- s.t. (0) $t_0 = 0$,
- (1) $t_i \geq t_{i-1}, i = 1, \dots, g$,
 - (2) $t_{\omega_j} - t_{\alpha_j-1} = p_j \forall T_j \in \mathcal{L}$,
 - (3) $\sum_{i:P(i)=M \setminus F} (t_i - t_{i-1}) = e_F \forall F \in \mathcal{F}$,
 - (4) $\sum_{i=1}^{n_F} x_{F,i} \leq e_F \forall F \in \mathcal{F}$,
 - (5) $\sum_{F \in \mathcal{F}} \sum_{i=1}^{n_F} \xi_{F,i}(\mu) \cdot x_{F,i} \geq D^\mu \forall \mu \subseteq M, \mu \neq \emptyset$,
 - (6) $x_{F,i} \geq 0 \forall F \in \mathcal{F}, i = 1, \dots, n_F$,
 - (7) $\sum_{T_j \in \mathcal{S}} t_j(\mu) \cdot y_{j\mu} = D^\mu \forall \mu \subseteq M, \mu \neq \emptyset$,
 - (8) $\sum_{\mu \subseteq M} y_{j\mu} = 1 \forall T_j \in \mathcal{S}$,
 - (9) $y_{j\mu} \in \{0, 1\} \forall T_j \in \mathcal{S}, \forall \mu \subseteq M, \mu \neq \emptyset$.

The variables of $ILP(R)$ have the following interpretation:

t_i : the time when snapshot $M(i)$ ends (and $M(i + 1)$ starts), $i = 1, \dots, g - 1$.

The starting time of the schedule and snapshot $M(1)$ is denoted by $t_0 = 0$ and the finishing time by t_g .

e_F : the total time while exactly the processors in F are free.

$x_{F,i}$: the total processing time for $P_{F,i} \in \mathcal{P}_F, i = 1, \dots, n_F, F \in \mathcal{F}$, where only processors of F are executing short tasks and each subset of processors $F_j \in P_{F,i}$ executes at most one short task at each time step in parallel.

$y_{j\mu}$: the assignment variable indicating whether task $T_j \in \mathcal{S}$ is executed on processor set μ , i.e.,

$$y_{j\mu} = \begin{cases} 1 & \text{if } T_j \text{ is executed by the processor set } \mu, \\ 0 & \text{otherwise.} \end{cases}$$

The given relative schedule R along with constraints (1) and (2) define a feasible schedule of \mathcal{L} . In (3), the total processing times e_F for all $F \in \mathcal{F}$ are determined. Clearly, these equalities can be inserted directly into (4). The inequalities in (4) require for every set of free processors $F \in \mathcal{F}$ that its total processing time (corresponding to the different partitions) be bounded by e_F . Furthermore, the inequalities (5) guarantee that there is enough time for the execution of all tasks in \mathcal{S} that use processor set μ . The constraints (8)–(9) describe the processor assignments for the tasks in \mathcal{S} . The equations of (7) express for every $\mu \subseteq M, \mu \neq \emptyset$, the total processing time D^μ of all tasks in \mathcal{S} that are executed by the processor set μ . As before, these equations can be inserted directly into the inequalities of (5).

We will use the relaxation $LP(R)$ of $ILP(R)$, where we replace the 0–1 constraints by the inequalities $y_{j\mu} \geq 0$ for every $T_j \in \mathcal{S}$ and $\mu \subseteq M$. Notice that the solutions of $LP(R)$ allow for each task from \mathcal{S} to be preempted or to be executed on different subsets μ of processors. Thus there might be incorrectly scheduled tasks in the schedule based on the solution of $LP(R)$. These have to be corrected afterwards. It is easy to check that the approach we used in section 2.2 for solving the linear program of the preemptive problem can also be applied to $LP(R)$. This way one can obtain the same approximation bounds as those in section 2.2.

3.2. Generating a schedule. Similarly to the preemptive variant, one can also compute a subset $\bar{\mathcal{S}} \subset \mathcal{S}$ of small jobs such that $\sum_{T_j \in \bar{\mathcal{S}}} t_j(\mu) \cdot y_{j\mu} \leq \bar{D}^\mu$; i.e., the set $\mathcal{S} \setminus \bar{\mathcal{S}}$ of remaining small tasks fits into the free space for the μ -processor tasks. The computation of $\bar{\mathcal{S}}$ can be done in the exact same manner as in section 2.3. Let \mathcal{U}_1 be the set of tasks with nonunique processor assignments, and let \mathcal{U}_2 be a subset of $\bar{\mathcal{S}}$ as described in section 2.3. Hence the following lemma also holds.

LEMMA 3.1. *The objective function value of the best approximate solution of $LP(R)$ (over all relative schedules R) restricted to $\mathcal{T}' = \mathcal{T} \setminus (\mathcal{U}_1 \cup \mathcal{U}_2)$ is at most $OPT + \frac{\epsilon}{2}OPT$, and $|\mathcal{U}_1 \cup \mathcal{U}_2| \leq 2^{m+1} - 1$.*

The next step of the algorithm requires the computation of a pseudoschedule $PS(\mathcal{T}'')$ for the tasks in $\mathcal{T}'' = \mathcal{T} \setminus (\mathcal{U}_1 \cup \mathcal{U}_2 \cup \mathcal{V})$, in which we allow that some tasks from \mathcal{S} are preempted. The makespan of the computed pseudoschedule is at most $OPT + \frac{\epsilon}{4}OPT$. Furthermore, the total execution time for \mathcal{V} is at most $\frac{\epsilon}{4}OPT$. We note that each task $T_j \in \mathcal{T}' \cap \mathcal{S}$ has a unique subset of assigned processors. Let \hat{D}^μ be the total processing time for all tasks in $\mathcal{T}'' \cap \mathcal{S}$ assigned to subset μ . We schedule all μ -processor tasks in $\mathcal{S}' = \mathcal{T}'' \cap \mathcal{S}$ for every subset $\mu \subseteq M$. From left to right (starting with the first snapshot $M(1)$), we place the tasks of \mathcal{S}' on the free processors in $M \setminus P(i)$ for each snapshot $M(i)$ (and $0 \leq i \leq g$). To do this, we consider each partition $P_{F(i),\ell}$ of $F(i) = M \setminus P(i)$ with value $x_{F(i),\ell}^* > 0$. For each set μ in the partition $P_{F(i),\ell}$, we place a sequence of tasks that use processor set μ with total execution length $x_{F(i),\ell}^*$. If necessary, the last (and first) task assigned to μ is preempted. Since $\sum_{F \in \mathcal{F}} \sum_{i=1}^{n_F} \xi_{F,i}(\mu) \cdot x_{F,i} \geq \hat{D}^\mu$, this procedure completely schedules all tasks (assigned to processor set μ) for every $\mu \subseteq M$, and it runs in $O(km^m + n) = [m^{O(m/\epsilon)} + O(n)]$ time (using $k = m^{O(m/\epsilon)}$; see Lemma 3.3), which leads to a running time of $O(n)$ for any fixed m and $\epsilon > 0$. Let \mathcal{W} be the set of preempted (and therefore incorrectly scheduled) tasks in $PS(\mathcal{T}'')$. The following lemma gives an upper bound on the cardinality of \mathcal{W} .

LEMMA 3.2. $|\mathcal{W}| \leq 2(m-1)k + 2m^{m+1}$.

Proof. First, we may assume that all partitions with m free processors are in the last interval $[t_{g-1}, t_g]$; otherwise we can shift all such intervals to the end of the schedule. There are two different cases of incorrectly scheduled tasks: 1. inside of an interval $[t_i, t_{i+1})$ caused by a change from a partition $P_{F,a}$ to $P_{F,a+1}$; 2. at the end of an interval $[t_i, t_{i+1})$ or inside of an interval without a change of partitions. In the second case, we have at most $(m-1)$ new incorrectly scheduled tasks (not counted before) for each interval $[t_i, t_{i+1})$. In the interval $[t_{g-1}, t_g)$, the last selected tasks are either not preempted or counted before. In total, we obtain at most $(m-1)(g-1) \leq 2(m-1)k$ incorrectly scheduled tasks in case 2. In the first case, for each change from a partition $P_{F,a}$ to $P_{F,a+1}$ we get at most m incorrectly scheduled tasks. The number of all partitions can be bounded by $m! + m^m \leq 2m^m$, which implies the bound $2m^{m+1}$ for incorrectly scheduled tasks in case 1. \square

Lemmas 3.1 and 3.2 imply the following upper bound (Corollary 3.3) on the total number of tasks that we have to shift to the end of the schedule.

COROLLARY 3.3. $|\mathcal{U}_1 \cup \mathcal{U}_2 \cup \mathcal{W}| \leq 2(m-1)k + 2m^{m+1} + 2^m \leq 2(m-1)k + 3m^{m+1}$.

The following general lemma which was proved in [13] will be used to select the cardinality k of \mathcal{L} (a constant for any fixed m and $\epsilon > 0$), such that the total processing time of $\mathcal{U}_1 \cup \mathcal{U}_2 \cup \mathcal{W}$ can be bounded. We mention in passing that this lemma (or various simplified variants and corollaries of it) can be used in designing polynomial approximation schemes for other scheduling problems as well; see [1, 7, 12, 13].

LEMMA 3.4. *Suppose $d_1 \geq d_2 \geq \dots \geq d_n > 0$ is a sequence of real numbers and $D = \sum_{j=1}^n d_j$. Let p, q be nonnegative integers, $\alpha > 0$, and assume that n is sufficiently large (i.e., all the indices of the d_i 's in the statement are smaller than n ; e.g., $n > (\lceil \frac{1}{\alpha} \rceil p + 1)(q + 1)^{\lceil \frac{1}{\alpha} \rceil}$ suffices). Then, there exists an integer $k = k(p, q, \alpha)$ such that*

$$d_k + \dots + d_{k+p+qk-1} \leq \alpha \cdot D$$

and

$$k \leq (q + 1)^{\lceil \frac{1}{\alpha} \rceil - 1} + p[1 + (q + 1) + \dots + (q + 1)^{\lceil \frac{1}{\alpha} \rceil - 2}].$$

If $q > 0$, the bound on k simplifies to $[(p + q)(q + 1)^{\lceil \frac{1}{\alpha} \rceil - 1} - p]/q$. By applying Lemma 3.4 with values $p = 3m^{m+1}$, $q = 2(m - 1)$, and $\alpha = \frac{\epsilon}{2m}$, we obtain that there exists a constant $k = k(m, \epsilon) \leq 1 + 4m^m(2m)^{2m/\epsilon} = m^{O(m/\epsilon)}$ such that the total execution time of the tasks in $\mathcal{U}_1 \cup \mathcal{U}_2 \cup \mathcal{W}$ can be bounded by $\frac{\epsilon}{2m} \leq \frac{\epsilon}{2}OPT$. Notice that $k = m^{O(m/\epsilon)}$ is exponential in $1/\epsilon$ and that the number of all relative schedules can be bounded by a constant $k^{O(k)}$. The overall running time can be bounded by $[k^{O(k)}(TIME(LP(R), \epsilon) + m^{O(m/\epsilon)} + n)]$, where $TIME(LP(R), \epsilon)$ denotes the time required to calculate an ϵ -approximate solution for the linear program $LP(R)$. Using the same arguments as in section 2.2 one can show that for any fixed m and $\epsilon > 0$, the linear program $LP(R)$ can be solved with ϵ -accuracy in $O(n)$ time. Furthermore, the makespan for the partial (feasible) schedule of $\mathcal{T} \setminus (\mathcal{U}_1 \cup \mathcal{U}_2)$ is at most $(1 + \frac{\epsilon}{2})OPT$. Thus, the overall makespan of the (complete) schedule is bounded by $(1 + \epsilon)OPT$. As stated by the arguments above, for any fixed m and $\epsilon > 0$, all computations can be carried out in $O(n)$ time. Therefore the following result holds for $Pm|set_j|C_{max}$.

THEOREM 3.5. *There is an algorithm which, given a set of n independent tasks, a constant number of processors m , a fixed positive accuracy ϵ , and execution times $t_j(\mu)$, for each task T_j and subset of processors μ , calculates in $O(n)$ time a nonpreemptive schedule whose makespan is at most $(1 + \epsilon)OPT$.*

4. Conclusions. In the present paper, we have proposed for the scheduling problem $Pm|pmtn, set_j|C_{max}$ a fully polynomial approximation scheme which for any fixed positive accuracy computes an approximate solution in $O(n)$ time. The previous approach [2] to this problem was based on a linear programming formulation with $O(n^m)$ variables, and hence it had a substantially larger time complexity in terms of n .

We have also studied the nonpreemptive version $Pm|set_j|C_{max}$ of the problem and presented a polynomial-time approximation scheme whose running time depends only linearly on n . Regarding the running time, this gives a significant improvement on the recent result obtained (independently from our work) by Chen and Miranda [7]. In addition, our approach avoids the use of dynamic programming and hence also answers an open question in [7].

OPTIMAL COVERING TOURS WITH TURN COSTS*

ESTHER M. ARKIN[†], MICHAEL A. BENDER[‡], ERIK D. DEMAINE[§],
SÁNDOR P. FEKETE[¶], JOSEPH S. B. MITCHELL[†], AND SAURABH SETHIA^{||}

Abstract. We give the first algorithmic study of a class of “covering tour” problems related to the geometric traveling salesman problem: Find a polygonal tour for a *cutter* so that it sweeps out a specified region (“pocket”) in order to minimize a cost that depends mainly on the number of *turns*. These problems arise naturally in manufacturing applications of computational geometry to automatic tool path generation and automatic inspection systems, as well as arc routing (“postman”) problems with turn penalties. We prove the NP-completeness of minimum-turn milling and give efficient approximation algorithms for several natural versions of the problem, including a polynomial-time approximation scheme based on a novel adaptation of the *m*-guillotine method.

Key words. NC machining, manufacturing, traveling salesman problem, milling, lawn mowing, covering, approximation algorithms, polynomial-time approximation scheme, *m*-guillotine subdivisions, NP-completeness, turn costs

1. Introduction. An important algorithmic problem in manufacturing is to compute effective paths and tours for covering (“milling”) a given region (“pocket”) with a cutting tool. The objective is to find a path or tour along which to move a prescribed cutter in order that the sweep of the cutter covers the region, removing all of the material from the pocket, while not “gouging” the material that lies outside of the pocket. This covering tour or “lawn mowing” problem [6] and its variants arise not only in numerically controlled (NC) machining applications but also in automatic inspection, spray painting/coating operations, robotic exploration, arc routing, and even mathematical origami.

The majority of research on these geometric covering tour problems as well as on the underlying arc routing problems in networks has focused on cost functions based on the lengths of edges. However, in many actual routing problems, this cost is dominated by the cost of switching paths or direction at a junction. A drastic example is given by

fiber-optical networks, where the time to follow an edge is negligible compared to the cost of changing to a different frequency at a router. In the context of NC machining, turns represent an important component of the objective function, as the cutter may have to be slowed in anticipation of a turn. The number of turns (“link distance”) also arises naturally as an objective function in robotic exploration (minimum-link watchman tours) and in various arc routing problems, such as snow plowing or street sweeping with turn penalties. Klein [35] has posed the question of minimizing the number of turns in polygon exploration problems.

In this paper, we address the problem of minimizing the cost of *turns* in a covering tour. This important aspect of the problem has been left unexplored so far in the algorithmic community, and the arc routing community has examined only heuristics without performance guarantee, or exact algorithms with exponential running time. Thus, our study provides important new insights and a better understanding of the problems arising from turn cost. We present several new results:

- (1) We prove that the covering tour problem with turn costs is NP-complete, even if the objective is purely to minimize the number of turns, the pocket is orthogonal (rectilinear), and the cutter must move axis-parallel. The hardness of the problem is not apparent, as our problem seemingly bears a close resemblance to the polynomially solvable Chinese postman problem; see the discussion below.
- (2) We provide a variety of constant-factor approximation algorithms that efficiently compute covering tours that are nearly optimal with respect to turn costs in various versions of the problem. While getting *some* $O(1)$ -approximation is not difficult for most problems in this class, through a careful study of the structure of the problem, we have developed tools and techniques that enable significantly stronger approximation results.

One of our main results is a 3.75-approximation for minimum-turn axis-parallel tours for a unit square cutter that covers an integral orthogonal polygon, possibly with holes. Another main result gives a $4/3$ -approximation for minimum-turn tours in a “thin” pocket, as arises in the arc routing version of our problem.

Table 1.1 summarizes our results. The term “coverage” indicates the number of times a point is visited, which is of interest in several practical applications. This parameter also provides an upper bound on the total length.

- (3) We devise a polynomial-time approximation scheme (PTAS) for the covering tour problem in which the cost is given as a weighted combination of length and number of turns, i.e., the Euclidean length plus a constant C times the number of turns. For an integral orthogonal polygon with h holes and N pixels, the running time is $2^{O(h)} \cdot N^{O(C)}$. The PTAS involves an extension of the m -guillotine method, which has previously been applied to obtain PTASs in problems involving only *length* [38].

We should stress that our paper focuses on the graph-theoretic and algorithmic aspects of the turn-cost problem; we make no claims of immediate applicability of our methods to NC machining.

Related work. In the CAD community, there is a vast literature on the subject of automatic tool-path generation; we refer the reader to Held [27] for a survey and for applications of computational geometry to the problem. The algorithmic study of the problem has focused on the problem of minimizing the length of a milling tour: Arkin, Fekete, and Mitchell [5, 6] show that the problem is NP-hard for the case

TABLE 1.1

Approximation factors achieved by our (polynomial-time) algorithms. Rows marked “APX” give approximation factors for the minimum-turn cycle cover (“Cycle cover”), the minimum-turn covering tour (“Tour”), and the simultaneous approximation of length of a covering tour (“Length”). The row marked “Max cover” indicates the maximum number of times a point is visited. The parameter δ denotes the maximum degree in the underlying graph, while the parameter ρ is the maximum number of directions in the graph. The two rows for running time refer to an “explicit” description of input pixels and output and a more compact “implicit” encoding of pixels and output. (See section 2 for more detailed definitions.)

	Discrete milling	Thin discrete		Orthogonal milling	Thin orthogonal

where the mower is a square. Constant-factor approximation algorithms are given in [5, 6, 30], with the current best factor being a 2.5-approximation for min-length milling (11/5-approximation for orthogonal simple polygons). For the closely related *lawn mowing* problem (also known as the “traveling cameraman problem” [30]), in which the covering tour is not constrained to stay within P , the best current approximation factor is $3 + \epsilon$ (utilizing PTAS results for the traveling salesman problem (TSP)). Also closely related is the watchman route problem with limited visibility (or “ d -sweeper problem”); Ntafos [42] provides a 4/3-approximation, and Arkin, Fekete, and Mitchell [6] improve this factor to 6/5. The problem is also closely related to the Hamiltonicity problem in grid graphs; the results of [44] suggest that in *simple* polygons, minimum-length milling may in fact have a polynomial-time algorithm.

Covering tour problems are related to *watchman route* problems in polygons, which have received considerable attention in terms of both exact algorithms (for the simple polygon case) and approximation algorithms (in general); see [39] for a relatively recent survey. Most relevant to our problem is the prior work on *minimum-link* watchman tours: see [2, 3, 8] for hardness and approximation results, and [14, 36] for combinatorial bounds. However, in these problems the watchman is assumed to see arbitrarily far, making them distinct from our tour cover problems.

Other algorithmic results on milling include a study of *multiple tool* milling by Arya, Cheng, and Mount [9], which gives an approximation algorithm for minimum-length tours that use different size cutters, and the paper of Arkin, Held, and Smith [7], which examines the problem of minimizing the number of retractions for “zig-zag” machining without “remilling,” showing that the problem is NP-complete and giving an $O(1)$ -approximation algorithm.

Geometric tour problems with turn costs have been studied by Aggarwal et al. [1], who study the *angular-metric TSP*. The objective is to compute a tour on a set of points, such that the sum of the direction changes at vertices is minimized: For any vertex v_i with incoming edge $v_{i-1}v_i$ and outgoing edge v_iv_{i+1} , the change of direction is given by the absolute value of the angle between $v_{i-1}v_i$ and v_iv_{i+1} . The problem turns out to be NP-hard, and an $O(\log n)$ -approximation is given. Fekete [20] and Fekete and Woeginger [21] have studied a variety of *angle-restricted tour* (ART) problems. Covering problems of a different nature have been studied by Demaine, Demaine, and Mitchell [16], who considered algorithmic issues of origami.

In the operations research literature, there has been an extensive study of arc routing problems, which arise in snow removal, street cleaning, road gritting, trash collection, meter reading, mail delivery, etc.; see the surveys of [10, 18, 19]. Arc routing with turn costs has had considerable attention, as it enables a more accurate modeling of the true routing costs in many situations. Most recently, Clossey, Laporte, and Soriano [13] presented six heuristic methods of attacking arc routing with turn penalties, without resorting to the usual transformation to a TSP problem; however, their results are purely based on experiments and provide no provable performance guarantees. The *directed* postman problem in graphs with turn penalties has been studied by Benavent and Soler [11], who prove the problem to be (strongly) NP-hard and provide heuristics (without performance guarantees) and computational results. (See also Fernández’s thesis [22] and [41] for computational experience with worst-case exponential-time exact methods.)

Our covering tour problem is related to the Chinese postman problem (CPP), which can be solved exactly in polynomial time for “purely” undirected or purely directed graphs. However, the turn-weighted CPP is readily seen to be NP-complete: Hamiltonian cycle in line graphs is NP-complete (contrary to what is reported in [25]; see page 246 of West [45]), implying that the TSP in line graphs is also NP-complete. The CPP on graph G with turn costs at nodes (and zero costs on edges) is equivalent to the TSP on the corresponding line graph, $\mathcal{L}(G)$, where the cost of an edge in $\mathcal{L}(G)$ is given by the corresponding turn cost in G . Thus, the turn-weighted CPP is also NP-complete.

2. Preliminaries. This section formally defines the problems at hand and various special cases of interest.

Problem definitions. The general *geometric milling problem* is to find a closed curve (not necessarily simple) whose Minkowski sum with a given tool (cutter) is precisely a given region P bounded by n edges. In the context of numerically controlled (NC) machines, this region is usually called a *pocket*. Subject to this constraint, we may wish to optimize a variety of objective functions, such as the length of the tour or the number of turns in the tour. We call these problems *minimum-length* and *minimum-turn* milling, respectively. While the latter problem is the main focus of this paper, we are also interested in bicriteria versions of the problem in which both length and number of turns must be small; we also consider the scenario in which the objective function is given by a linear combination of turn cost and distance traveled (see section 5.5).

In addition to choices in the objective function, the problem version depends on the constraints on the tour. The most general case arises when considering a tour that has to visit a discrete set of vertices, connected by a set of edges, with a specified turn cost at each vertex to change from one edge to the next. More precisely, at each vertex, the tour has the choice of (0) going “straight,” if there is one “collinear” edge with

the one currently used (costing no turn), (1) turning onto another, noncollinear edge (costing one turn), or (2) “U-turning” back onto the source edge (costing two turns). Which pairs of the d edges incident to a degree- d vertex are considered “collinear” are specified by a matching in the complete graph K_d : three incident edges cannot be “collinear.” We call this graph-theoretic abstraction the *discrete milling problem*, indicating the close relationship to other graph-theoretic tour optimization problems. We are able to give a number of approximation algorithms for discrete milling that depend on some graph parameters: δ denotes the maximum degree of a vertex and ρ denotes the maximum number of distinct “directions” coming together at a vertex. (For example, for graphs arising from d -dimensional grids, these values are bounded by $2d$ and d , respectively.)

A special case of discrete milling arises when dealing with “thin” structures in two- or three-dimensional space, where the task is to travel all of a given set of “channels,” which are connected at vertices. This resembles a CPP, in that it requires us to travel a given set of edges; however, in addition to the edge cost, there is a cost at the vertices when moving from one edge to the next. For this scenario, we are able to describe approximation factors that are independent of other graph parameters.

More geometric problems arise when considering the milling of a polygonal region P . In the *orthogonal milling problem*, the region P is an orthogonal polygonal domain (with holes) and the tool is an (axis-parallel) unit-square cutter constrained to axis-parallel motion, with edges of the tour alternating between horizontal and vertical. All turns are orthogonal; 90° turns incur a cost of 1, while a “U-turn” has a cost of 2. In the *integral orthogonal* case, all coordinates of boundary edges are integers, so the region can be considered to be the (connected) union of N *pixels*, i.e., axis-parallel unit squares with integer vertices. Note that in general, N may not be bounded by a polynomial in n . Instead of dealing directly with a geometric milling problem, we often find it helpful to consider a more combinatorial problem, and then adapt the solution back to the geometric problem. In particular, for integral orthogonal milling, we may assume that an optimal tour can be assumed to have its vertex coordinates of the form $k + \frac{1}{2}$ for integral k . Then, milling in an integral orthogonal polygon (with holes) is equivalent to finding a tour of all the vertices (“pixels”) of a grid graph; see Figure 2.1.

FIG. 2.1. An instance of the integral orthogonal milling problem (left) and the grid graph model (right).

An interesting special case of integral orthogonal milling is the *thin orthogonal milling problem*, in which the region does not contain a 2×2 square of pixels. This is also closely related to discrete milling, as we can think of edges embedded into the planar grid, such that vertices and channels are well separated. This problem of

finding a tour with minimum turn cost for this class of graphs is still NP-complete, even for a subclass for which the corresponding problem of minimizing total distance is trivial; this highlights the particular difficulty of dealing with turn cost. On the other hand, thin orthogonal milling allows for particularly fast and efficient approximation algorithms.

Other issues. It should be stressed that using turn cost instead of (or in addition to) edge length changes several characteristics of distances. One fundamental problem is illustrated by the example in Figure 2.2: the triangle inequality does not have to hold when using turn cost. This implies that many classical algorithmic approaches for graphs with nonnegative edge weights (such as using optimal 2-factors or the Christofides method for the TSP) cannot be applied without developing additional tools.

FIG. 2.2. *The triangle inequality may not hold when using turn cost as distance measure: $d(a, c) = 3 > 2 = d(a, b) + d(b, c)$.*

In fact, in the presence of turn costs we distinguish between the terms *2-factor*, i.e., a set of edges, such that every vertex is incident to two of them, and *cycle cover*, i.e., a set of cycles, such that every vertex is covered. While the terms are interchangeable when referring to the set of edges that they constitute, we make a distinction between their respective *costs*: a “2-factor” has a cost consisting of the sum of edge costs but does not necessarily account for the turn cost between its two incident edges, while the cost of a “cycle cover” includes also the turn costs at vertices.

It is often useful in designing approximation algorithms for optimal *tours* to begin with the problem of computing an optimal *cycle cover*, minimizing the total number of turns in a set of cycles that covers P . Specifically, we can decompose the problem of finding an optimal (minimum-turn) tour into two tasks: finding an optimal cycle cover, and merging the components. Of course, these two processes may influence each other: there may be several optimal cycle covers, some of which are easier to merge than others. (In particular, we say that a cycle cover is *connected* if the graph induced by the set of cycles and their intersections is connected.) As we will show, even the problem of optimally merging a connected cycle cover is NP-complete. This is in contrast to minimum-length milling, where an optimal connected cycle cover can trivially be converted into an optimal tour that has the same cost.

Algorithms whose running time is polynomial in the explicit encoding size (pixel count) are *pseudopolynomial*. Algorithms whose running time is polynomial in the implicit encoding size are *polynomial*. This distinction becomes an important issue when considering different ways to encode input and output; e.g., a large set of pixels forming an $a \times b$ rectangle can be described in space $O(\log a + \log b)$ by simply describing the bounding edges, instead of listing all ab individual pixels. In integral orthogonal milling, one might think that it is most natural to encode the grid graph with vertices, because the tour will be embedded on this graph and will, in general,

have complexity proportional to the number N of pixels. But the input to any geometric milling problem has a natural encoding by specifying only the n vertices of the polygon P . In particular, long edges are encoded in binary (or with one real number, depending on the model) instead of unary. It is possible to get a running time depending only on this size, but of course we need to allow for the output to be encoded *implicitly*. That is, we cannot explicitly encode each vertex of the tour because there are too many (the number can be arbitrarily large even for a succinctly encodable rectangle). Instead, we encode an abstract description of the tour that is easily decoded.

Finally, we mention that many of our results carry over from the *tour* (or cycle) version to the *path* version, in which the cutter need not return to its original position. In this paper, we omit the straightforward changes necessary to compute optimal paths. A similar adjustment can be made for the related case of *lawn mowing*, in which the sweep of the cutter is allowed to go outside P during its motion. Clearly, our techniques are also useful for scenarios of this type.

3. NP-completeness. Arkin, Fekete, and Mitchell [6] have proved that the problem of optimizing the length of a milling tour is NP-hard. Their proof is based on the well-known hardness of deciding whether a grid graph has a Hamiltonian cycle [29, 31]. This result implies that it is NP-hard to find a tour of minimum total length that visits all vertices. If, on the other hand, we are given a connected cycle cover of a graph that has minimum total length, then it is trivial to convert it into a tour of the same length by merging the cycles into one tour.

In this section we show that if the quality of a tour is measured by counting *turns*, then even this last step of turning an optimal connected cycle cover into an optimal tour is NP-complete. Thus we prove that it is NP-hard to find a milling tour that optimizes the number of turns for a polygon with holes.

THEOREM 3.1. *Minimum-turn milling is NP-complete, even when we are restricted to the orthogonal thin case, and are already provided with an optimal connected cycle cover.*

Because thin orthogonal milling is a special case of thin milling as well as orthogonal milling, and because it is easy to convert an instance of thin orthogonal milling into an instance of integral orthogonal milling, we have the following.

COROLLARY 3.2. *Discrete milling, orthogonal milling, and integral orthogonal milling are NP-complete.*

Proof of Theorem 3.1. Our reduction proceeds in two steps. First we show that the problem *Hamiltonicity of unit segment intersection graphs* (HUSIG) of deciding the Hamiltonicity of intersection graphs of axis-parallel unit segments is hard. To see this, we use the NP-hardness of deciding Hamiltonicity of grid graphs [29, 31] and argue that any grid graph can be represented in this form (see Figure 3.1).

Consider a set of integer grid points that induce a grid graph G . Note that G is bipartite, because one can 2-color the nodes by coloring a grid point (x, y) black (resp., white) if $x + y$ is odd (resp., even). After rotating the point set by $\pi/4$, the coordinate of each point is an integer multiple of $1/\sqrt{2}$. Scaling down the resulting arrangement by a factor of $3/\sqrt{2}$ results in an arrangement in which the coordinate of each point is an integer multiple of $1/3$, and the shortest distance between two points of the same color class is $2/3$. For the resulting set of points $p_i = (x_i, y_i)$, let $p'_i = p_i + (\varepsilon_i, \varepsilon_i)$ be given as the set obtained by “perturbations” ε_i that are small and all distinct. Then represent each “white” vertex by a horizontal unit segment centered at p'_i and each “black” vertex by a vertical unit segment centered at p'_i . Now

FIG. 3.1. (a) A grid graph G . (b) A representation of G as an intersection graph of axis-parallel unit segments.

it is easy to see that the resulting unit segment intersection graph is precisely the original grid graph G .

In a second step, we show that the problem HUSIG reduces to the problem of milling with turn costs. The outline of our argument is illustrated in Figure 3.2.

Consider a unit segment intersection graph G , given by a set of axis-parallel unit segments, as shown in Figure 3.2(a). Figure 3.2(b) shows the corresponding graph, with a Hamiltonian cycle indicated in bold. Without loss of generality, we may assume that G is connected. Let s be the number of nodes of G .

As shown in Figure 3.2(c), we replace each line segment by a cycle of four thin axis-parallel corridors. This results in a connected polygonal region P having $4s$ convex corners. Clearly, any cycle cover or tour cover of P must have at least $4s$ turns; by using a cycle for each set of four corridors representing a strip, we get a cycle cover \mathcal{C} with $4s$ turns. Therefore, \mathcal{C} is an optimal cycle cover, and it is connected, because G is connected.

Now assume that G has a Hamiltonian cycle. It is easy to see (Figure 3.2(f)) that this cycle can be used to construct a milling tour of P with a total of $5s$ turns: Each time the Hamiltonian cycle moves from one vertex v_i of the grid graph to the next vertex v_j , the milling tour moves from the cycle C_i representing v_i to the cycle C_j representing v_j , at an additional cost of 1 turn for each of the s edges in the Hamiltonian cycle.

Assume conversely that there is a milling tour T with at most $5s$ turns. We refer to turns at the corners of 4-cycles as *convex turns*. The other turns are called *crossing turns*.

As noted above, the convex corners of P require at least $4s$ convex turns. Consider the sequence of turns t_1, \dots, t_{5s} in T . By construction, the longest contiguous subsequence of convex turns contains at most four different convex turns. (More precisely, we can have such a subsequence with four different convex corners only if these four corners belong to the same 4-cycle representing a unit segment.) Furthermore, we need at least one additional crossing turn at an interior crossing of two corridors to get from one convex corner to another convex corner not on the same 4-cycle. (More

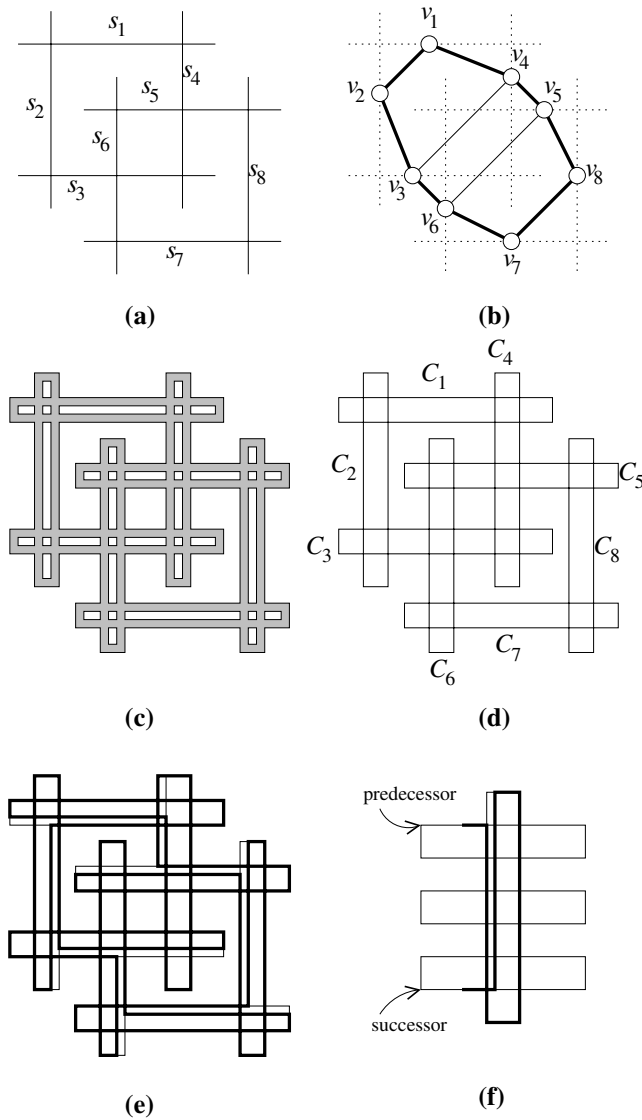

FIG. 3.2. Thin orthogonal milling with turn cost is NP-hard: (a) a set of $s = 8$ axis-parallel unit segments, denoted by s_1, \dots, s_8 ; (b) the corresponding intersection graph G , with the Hamiltonian cycle $v_1, v_2, v_3, v_6, v_7, v_8, v_5, v_4$ shown in bold; (c) representing G by a connected region consisting of $4s$ corridors; (d) a drawing of the graph induced by the instance of thin orthogonal milling, with the $s = 8$ rectangular cycles C_1, \dots, C_8 ; (e) a milling tour with $5s$ turns corresponding to the Hamiltonian cycle in G ; (f) milling the four corridors of a cycle using five turns.

precisely, one crossing turn is sufficient only if the two connected convex corners belong to 4-cycles representing intersecting unit segments.) Therefore, we need at least c crossing turns if we have at least c contiguous subsequences as described above. This means that $c \geq s$; hence, $c = s$ by the assumption on the number of turns on T . Because the c crossing turns correspond to a closed round trip in G that visits all s vertices, this implies that we have a Hamiltonian cycle, concluding the proof. \square

4. Approximation tools. There are three main tools that we use to develop approximation algorithms: computing optimal cycle covers for milling the “boundary” of P (section 4.1), converting cycle covers into tours (section 4.2), and using optimal (or nearly optimal) “strip covers” (section 4.3). In this section, our description mostly focuses on orthogonal milling; however, we will see in the following section 5.1 how some of our tools can also be applied to the general case of discrete milling.

4.1. Boundary cycle covers. Consider first the problem of finding a minimum-turn cycle cover for covering a certain subset, \bar{P} , of P that is along its boundary. This will turn out to be a useful tool for approximation algorithms. Specifically, in orthogonal milling we define the set \bar{P} of *boundary pixels* to consist of pixels that have at least one of their four edges on a boundary edge of the polygon; i.e., in the grid graph that describes adjacency of pixels, these are pixels of degree at most 3. Let $N_{\bar{P}}$ be the number of boundary pixels. A *boundary cycle cover* is a collection of cycles that visit all boundary pixels.

We define an auxiliary structure, $G_{\bar{P}} = (V_{\bar{P}}, E_{\bar{P}})$, which is a complete weighted graph on $2N_{\bar{P}}$ vertices; for ease of description, we will refer to $G_{\bar{P}}$ as a set of points and paths between them. This will allow us to map boundary cycle covers in P to matchings of corresponding turn cost in $G_{\bar{P}}$. For this purpose, map each pixel $p_i \in \bar{P}$ to two vertices in $V_{\bar{P}}$, $v_i^{(0)}$ and $v_i^{(1)}$. For each boundary pixel p_i , this pair represents an orientation that is attained by a cutter when visiting p_i . Depending on the boundary structure of p_i , there are four different cases; refer to Figure 4.1.

FIG. 4.1. Representing a boundary pixel p_i by a pair of vertices $v_i^{(0)}$ and $v_i^{(1)}$.

- (i) One edge of p_i is a boundary edge of the polygon.
- (ii) Two opposite edges of p_i are boundary edges of the polygon.
- (iii) Two adjacent edges of p_i are boundary edges of the polygon.
- (iv) Three edges of p_i are boundary edges of the polygon.

For easier description, we refer to the vertices $v_i^{(0)}$ and $v_i^{(1)}$ as points embedded

within p_i , as shown in Figure 4.1. Furthermore, we add a *mandatory path* m_i between $v_i^{(0)}$ and $v_i^{(1)}$, represented by a polygonal path with $c(m_i) = 0$ (cases (i) and (ii)), $c(m_i) = 1$ (case (iii)), or $c(m_i) = 2$ turns (case (iv)), as shown in the figure. This path maps the contour of P at p_i , and it represents orientations that a cutter has to attain when visiting pixel p_i . Note that traveling from $v_i^{(h)}$ to $v_j^{(1-h)}$ along m_i induces a heading $\delta_i^{(h,-)}$ when leaving $v_i^{(h)}$ and a heading $\delta_i^{(1-h,+)}$ when arriving at $v_i^{(1-h)}$. Note that $\delta_i^{(h,-)}$ is opposite to $\delta_i^{(h,+)}$.

Now we add a set of *optional paths*, representing the weighted edges $E_{\overline{P}}$ of the complete graph $G_{\overline{P}}$. For an example, refer to Figure 4.2. For any pair of vertices $v_i^{(h)}$ and $v_j^{(k)}$, let $d(v_i^{(h)}, v_j^{(k)})$ be the minimum number of turns necessary when traveling from $v_i^{(h)}$ with heading $\delta_i^{(h,+)}$ to $v_j^{(k)}$ with heading $\delta_j^{(k,-)}$. Note that $d(v_i^{(h)}, v_j^{(k)}) = d(v_j^{(k)}, v_i^{(h)})$, as any shortest path can be traveled in the opposite direction. Using a Dijkstra-like approach, we can compute these distances from one boundary pixel to all other boundary pixels in time $O(N_{\overline{P}} \log N_{\overline{P}})$; see the overview in [39] or the paper [37]. The overall time of $O(N_{\overline{P}}^2 \log N_{\overline{P}})$ for computing all these link distances is dominated by the following step: In time $O(N_{\overline{P}}^3)$ [24, 43], find a minimum-weight perfect matching in the complete weighted graph $G_{\overline{P}}$.

FIG. 4.2. The cost of traveling between two pixels: $d(v_i^{(1)}, v_j^{(0)}) = d(v_j^{(0)}, v_i^{(1)}) = 2$, while $d(v_i^{(0)}, v_j^{(1)}) = d(v_j^{(1)}, v_i^{(0)}) = 5$.

Now it is not hard to see the following.

LEMMA 4.1. Any boundary cycle cover in P with t turns can be mapped to a perfect matching in $G_{\overline{P}}$ of cost $t - \sum_{p_i \in \overline{P}} c(m_i)$, and vice versa.

Proof. Whenever a boundary cycle cover visits a boundary pixel p_i , it has to perform the turns corresponding to the mandatory path m_i . Moreover, moving from one pixel p_i to the next pixel p_j can be mapped to the optional path corresponding to the edges $(v_i^{(h)}, v_j^{(k)})$; clearly, the overall cost is as stated.

Conversely, it is straightforward to see that the combination of a perfect matching in $G_{\overline{P}}$ and the mandatory paths yields a boundary cycle cover of corresponding cost. \square

Using the algorithms described above, we also obtain the following.

THEOREM 4.2. *Given the set of $N_{\overline{P}}$ boundary pixels, a minimum-turn boundary cycle cover can be computed in time $O(N_{\overline{P}}^3)$, the time it takes to compute a perfect matching in $G_{\overline{P}}$.*

If the set of pixels is not given in unary, but implicitly as the pixels contained in a region with n edges, the above complexity is insufficient. However, we can use local modifications to argue the following tool for speeding up the search for an optimal perfect matching.

LEMMA 4.3. *Let p_i and p_j be neighboring boundary pixels that are adjacent to the same boundary edge, so $d(v_i^{(h)}, v_j^{(k)}) = 0$ for an appropriate choice of h and k . Then there is an optimal matching containing $(v_i^{(h)}, v_j^{(k)})$.*

Proof. This follows by a simple exchange argument. See Figure 4.3. Suppose two adjacent pixels p_i and p_j along the same boundary edge are not matched to each other, let $v_i^{(h)}$ be the vertex such that $\delta_i(h, -)$ is heading for p_j , and let $v_j^{(k)}$ be the vertex such that $\delta_j(k, -)$ is heading for p_i . Furthermore suppose that $v_{i'}^{(h')}$ is matched to $v_i^{(h)}$ and $v_{j'}^{(k')}$ is matched to $v_j^{(k)}$. Then we can match $v_{i'}^{(h')}$ to $v_{j'}^{(k')}$ and $v_i^{(h)}$ to $v_j^{(k)}$ without changing the cost of the matching. \square

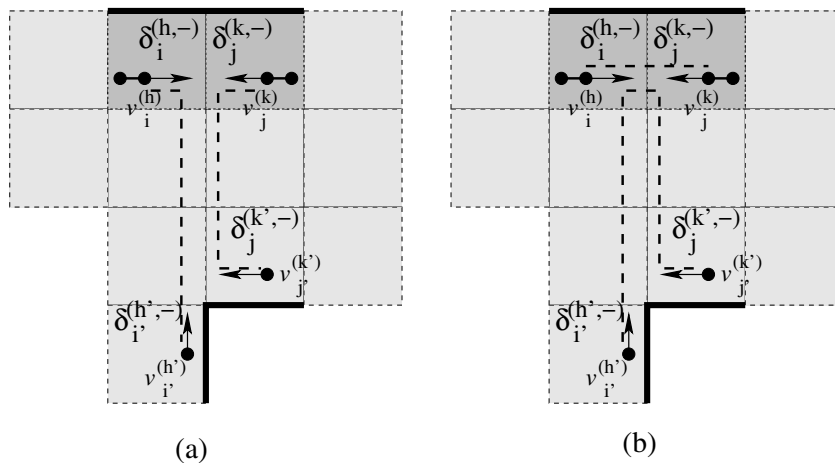

FIG. 4.3. By performing local modifications, an optimal cycle cover can be assumed to cover each collinear piece of the boundary in one connected strip.

This allows us to obtain a strongly polynomial version of the matching algorithm of Theorem 4.2.

THEOREM 4.4. *A minimum-turn boundary cycle cover can be computed in time $O(n^3)$.*

Proof. By applying Lemma 4.3 repeatedly, we get $O(n)$ connected boundary strips, consisting of sets of collinear boundary pixels. These can be determined efficiently by computing offsets of the boundary edges. This leaves only $O(n)$ endpoints of such strips to be matched, resulting in the claimed complexity. \square

Note that the validity of this argument is not restricted to the *integral* orthogonal case, but remains valid even for orthogonal regions with arbitrary boundary edges.

Remark. The definition of the “boundary” pixels \overline{P} used here does not include all pixels that touch the boundary of P in a diagonal fashion; in particular, it omits the “reflex pixels” that share a corner, but no edge, with the boundary of P . It seems

FIG. 4.4. *Optimally covering all pixels that have an edge against the boundary can leave reflex pixels uncovered.*

difficult to require that the cycle cover mill reflex pixels, because Lemma 4.3 does not extend to this case, and an optimal cycle cover of the boundary (as defined above) may have fewer turns than an optimal cycle cover that mills the boundary \bar{P} plus the reflex pixels; see Figure 4.4.

4.2. Merging cycles. It is often easier to find a minimum-turn cycle cover (or constant-factor approximation thereof) than to find a minimum-turn tour. We show that an exact or approximate minimum-turn cycle cover implies an approximation for a minimum-turn tour.

We concentrate on the integral orthogonal case. First we define a few terms precisely. Two pixels are *adjacent* if the distance between their centers is 1. Two cycles T_1, T_2 are *intersecting* if and only if $T_1 \cap T_2 \neq \emptyset$. Two cycles are called *touching* if and only if they are not intersecting and there exist pixels $p_1 \in T_1, p_2 \in T_2$ such that p_1 and p_2 are adjacent.

LEMMA 4.5. *Let P_1 and P_2 be two cycles, with t_1 and t_2 turns, respectively, and let p be a pixel that is contained in both cycles. Then there is a cycle milling the union of pixels milled by P_1 and P_2 and having at most $t_1 + t_2 + 2$ turns. This cycle can be found in time linear in the number of its turns.*

Proof. Let the neighbors of p in P_1 be a_1, a_2 and those of p in P_2 be b_1, b_2 . Connect a_1 via p to b_1 and a_2 via p to b_2 to get the required tour. The two connections may add at most a turn each. Hence the resulting tour can be of size at most $t_1 + t_2 + 2$. \square

LEMMA 4.6. *Given two touching cycles T_1, T_2 with t_1, t_2 turns, respectively, there is a tour T with at most $t_1 + t_2 + 2$ turns that mills the union of pixels milled by T_1, T_2 .*

Proof. Because T_1, T_2 are touching, $T_1 \cap T_2 = \emptyset$ and there exist adjacent pixels $p_1 \in T_1$ and $p_2 \in T_2$. Without loss of generality assume that p_2 is a leftmost such pixel, and below p_1 . Due to these constraints, T_2 can enter/exit p_2 from only two sides. Hence there are only three ways in which T_2 can visit p_2 . These are shown in Figure 4.5. For all three ways we show in Figure 4.5 how to cut and extend tour T_2 without adding any extra turns, to get a path P_2 starting and ending at pixel p_1 . Cut T_1 at p_1 to get a path P_1 . By possibly adding two turns, we can merge the two paths into one tour. \square

With the help of these lemmas, we deduce the following.

THEOREM 4.7. *A cycle cover with t turns can be converted into a tour with at*

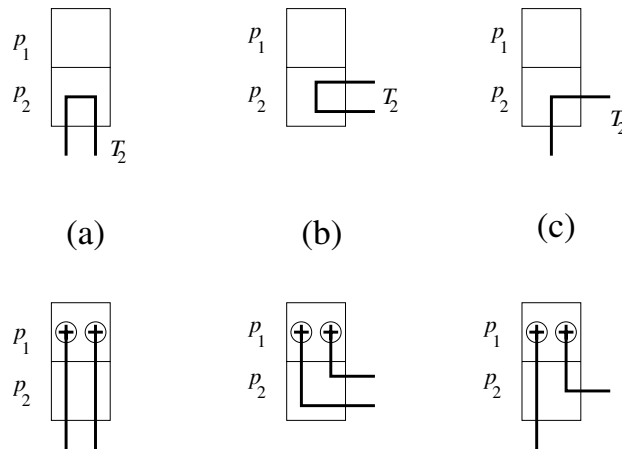

FIG. 4.5. *Merging two touching tours: There are three possible ways of tour T_2 visiting pixel p_2 (above). In each case, we can modify T_2 into a path that visits pixel p_1 (below); at a cost of possibly one extra turn at each end of the path, we can merge it with tour T_1 .*

most $t + 2(c - 1)$ turns, where c is the number of cycles.

Proof. We prove this theorem by induction on the number of tours, c , in the cycle cover. The theorem is trivially true for $c = 1$. For any other c , choose any $c - 1$ cycles with a total of t' turns and find a tour T' that covers those $c - 1$ cycles; by induction, it has $t' + 2(c - 1)$ turns. Let the remaining cycle, R , have r turns. Thus $t = t' + r$. Because the polygon is connected, the set of pixels milled by R and T' must be connected. Hence either T' and R are intersecting or touching. By Lemmas 4.5 and 4.6 we can merge R and T' into a single tour T with at most $t' + 2(c - 1) + r + 2$ turns, i.e., $t + 2c$ turns. \square

COROLLARY 4.8. *A cycle cover of a connected rectilinear polygon with t turns can be converted into a single milling tour with at most $\frac{3}{2}t$ turns.*

Proof. This follows immediately from Theorem 4.7 and the fact that each cycle has at least four turns. \square

Unfortunately, general merging is difficult (as illustrated by the NP-hardness proof of Theorem 3.1), so we cannot hope to improve these general merging results by more than a constant factor.

4.3. Strip and star covers. A key tool for approximation algorithms is a covering of the region by a collection of “strips.” A *strip* is a maximal straight segment whose Minkowski sum with the tool is contained in the region. A *strip cover* is a collection of strips whose Minkowski sums with the tool cover the entire region. A *minimum strip cover* is a strip cover with the fewest strips.

LEMMA 4.9. *The size of a minimum strip cover is a lower bound on the number of turns in a cycle cover (or tour) of the region.*

Proof. Any cycle cover induces a strip cover by extending each edge to have maximal length. The number of strips in this cover equals the number of turns in the cycle cover. \square

In the discrete milling problem, a related notion is a “rook placement.” A *rook* is a marker placed on a pixel, which can *attack* every pixel to which it is connected via a straight axis-parallel path inside the region. A *rook placement* is a collection of rooks, no two of which can attack each other. See Figure 4.6 for an illustration; this

FIG. 4.6. (Left) An orthogonal region, its subdivision into axis-parallel strips, and a resulting greedy rook cover (indicated by black pixels). (Right) An optimal strip cover, and an optimal rook cover (indicated by black pixels).

tool will be used in Theorem 5.6, based on the following lemma.

LEMMA 4.10. *The size of a maximum rook placement is a lower bound on the number of turns in a cycle cover (or tour) for discrete milling.*

Proof. Consider a rook placement and a cycle cover of the region, which must in particular cover every rook. Suppose that one of the cycles visits rooks q_1, \dots, q_k in that order. No two rooks can be connected by a single straight axis-parallel line segment, so the cycle must turn between each rook, for a total of at least k turns. Because each rook is traversed by at least one cycle, the number of turns (and hence the number of segments in a tour) is at least the number of rooks. \square

In the integral orthogonal milling problem, the notions of strip cover and rook placement are dual and efficient to compute.

LEMMA 4.11. *For integral orthogonal milling, a minimum strip cover and a maximum rook placement have equal size. For a polygonal region with n edges and N pixels they can be computed in time $O(N^{2.376})$ or $O(n^{2.5} \log N)$.*

Proof. For the case of $N \in O(n)$, the claim follows from Proposition 2.2 in [26]: We rephrase the rook-placement problem as a matching problem in a bipartite graph $G = (V_1, V_2, E)$. Let the vertices in V_1 correspond to vertical strips, and let the vertices in V_2 correspond to horizontal strips. An edge $e = (u, v) \in E$ exists if the vertical strip corresponding to u and the horizontal strip corresponding to v have a pixel in common (i.e., the strips cross). It is easy to see that a maximum-cardinality matching in this bipartite graph corresponds to a rook placement: each edge (u, v) in the matching corresponds to the unique pixel that vertical strip u and horizontal strip v have in common.

Similarly, observe that the minimum strip-cover problem is equivalent to a minimum vertex-cover problem in the bipartite graph defined above. Each strip in the strip cover defines a vertex in the vertex cover. The requirement that each pixel must be covered by at least one strip is equivalent to the requirement that each edge of the graph must be covered by at least one vertex.

By the famous König–Egerváry theorem, the maximum cardinality matching in a bipartite graph is equal in size to the minimum vertex cover, and therefore both can be solved in time polynomial in the size of the graph; more precisely, this can be achieved in time $O(N^\omega)$, the time needed for multiplying two $N \times N$ matrices, for

example, $\omega = 2.376$; see the paper [28], or the survey in chapter 16 of [43], which also lists other, more elementary methods.

To get the claimed running time even for “large” N , using implicit encoding, we decompose the region into “thick strips” by conceptually coalescing adjacent horizontal strips with the same horizontal extent, and similarly for vertical strips. In other words, thick strips are bounded by two vertices of the region, and hence there are only $O(n)$ of them. We define the same bipartite graph but add a weight to each vertex corresponding to the width of the strip (i.e., the number of strips coalesced). Instead of a matching, in which each edge of the graph is either included in the matching or not, we now have a multiplicity for each edge, which is the minimum of the weights of its two endpoints. The interpretation is that an edge corresponds to a rectangle in the region (the intersection of two thick strips), and the number of rooks that can be placed in such a rectangle is at most the minimum of its width and height.

The weighted-matching problem we consider is that each edge can be included in the matching with a multiplicity up to its weight. Furthermore, the sum of the included multiplicities of edges incident to a vertex cannot exceed the weight of the vertex. A weighted version of the König–Egerváry theorem states that the minimum-weight vertex cover is equal to the maximum-weight matching. (This weighted version can be easily proved using the max-flow min-cut theorem.) Both problems can be solved in polynomial time using a max-flow algorithm, on a modified graph in which a source vertex s is added with edges to all vertices in V_1 , of capacity equal to the weight of the vertex, and a sink vertex t is added with edges to it from all vertices in V_2 with capacity equal to the vertex capacity. Edges between V_1 and V_2 are directed from V_1 and have capacity equal to the weight of the edge. Currently, the best known running time is $O(\sqrt{nm} \log nW)$ for a bipartite graph with n vertices, m edges, and maximum weight W [23, 43]. For our purposes, this yields a complexity of $O(n^{2.5} \log N)$. \square

Note that using weights on the edges is crucial for the correctness of our objective; moreover, this has a marked effect on the complexity of the problem: Finding a minimum number of axis-parallel rectangles (regardless of their size) that covers an integral orthogonal polygon is known to be an NP-complete problem, even for the case of polygon without holes [15].

For general discrete milling, it is possible to approximate an optimal strip cover as follows. Greedily place rooks until no more can be placed (i.e., until there is no unattackable vertex). This means that every vertex is attackable by some rook, so by replacing each rook with all possible strips through that vertex, we obtain a strip cover of size ρ times the number of rooks, where ρ is the maximum degree of the underlying graph. (We call this type of strip cover a *star cover*.) But each strip in a minimum strip cover can only cover a single rook, so this is a ρ -approximation to the minimum strip cover. We have thus proved the following.

LEMMA 4.12. *In discrete milling, the number of stars in a greedy star cover is a lower bound on the number of strips, and hence serves as a ρ -approximation algorithm for minimum strip covers. Computing a greedy star cover can be done in time $O(N)$.*

Proof. Loop over the vertices of the underlying graph. Whenever an unmarked vertex is found, add it to the list of rooks, and mark it and all vertices attackable by it. Now convert each rook into a star as in the proof of Lemma 4.10. Each edge is traversed only once during this process. \square

5. Approximation algorithms. We employ four main approaches to building approximation algorithms, repeatedly in several settings:

(i) *Star cover + doubling + merging.*

The simplest but most generally applicable idea is to cover the region by a collection of stars. “Doubling” these stars results in a collection of cycles, which can then be merged into a tour using general techniques.

(ii) *Strip cover + doubling + merging.*

Tighter bounds can be achieved by covering directly with strips instead of stars. Similar doubling and merging steps follow.

(iii) *Strip cover + perfect matching of endpoints + merging.*

The covering of the region is done by the strip cover. To connect these strips into cycles, we find a minimum-weight perfect matching on their endpoints. This results in a cycle cover, which can be merged into a tour using general techniques.

(iv) *Boundary tour + strip cover + perfect matching of odd-degree vertices.*

Again coverage is by a strip cover, but the connection is done differently. We add a tour of the boundary (by merging an optimal boundary cycle cover) and attach each strip to this tour on each end. The resulting graph has several degree-3 vertices, which we fix by adding a minimum-weight matching on these vertices.

5.1. Discrete milling. As described in the preliminaries, we consider two scenarios: While general discrete milling focuses on vertices (and thus resembles the TSP), thin discrete milling requires traveling a set of edges, making it similar to the CPP.

5.1.1. General discrete milling. Our most general approximation algorithm for the discrete milling problem runs in linear time. First we take a star cover according to Lemma 4.12, which approximates an optimal strip cover to within a factor of ρ . Then we tour the stars using an efficient method described below. Finally we merge these tours using Theorem 4.7.

We tour each star emanating from a vertex v using the following method—see Figure 5.1. Consider a strip s in the star, and suppose its ends are the vertices u_i and u_j . A strip having both of its endpoints distinct from v is called a *full strip*; a strip one of whose endpoints is equal to v is called a *half strip*. Half strips are covered by three edges, (v, u_j) , (u_j, u_j) , and (u_j, v) , making a U-turn at endpoint u_j . (This covering is shown for the half strip (v, u_1) in Figure 5.1(b).) Full strips are covered by five edges, (v, u_i) , (u_i, u_i) , (u_i, u_j) , (u_j, u_j) , and (u_j, v) , with U-turns at both ends, u_i and u_j . (This covering is shown for the full strip (u_5, u_2) in Figure 5.1(b).) Now we have several paths of edges starting and ending at v . By joining their ends we can easily merge these paths into a cycle.

The number of turns in this cycle is 3 times the number of half strips, plus 5 times the number of full strips. This is equivalent to the number of distinct directions at v plus 2 times the degree of v . (The number of directions at v is equal to the number of full strips plus the number of half strips, by definition. The degree of v is equal to 2 times the number of full strips plus the number of half strips.) Lemma 4.12 implies that the number of stars is a lower bound on the number of turns in a cycle cover of the region, proving the following.

THEOREM 5.1. *There is an $O(N)$ -time $(2\delta + \rho)$ -approximation for finding a minimum-turn cycle cover in discrete milling. Furthermore, the maximum coverage of a vertex (i.e., the maximum number of times a vertex is swept) is δ , and the cycle cover is a δ -approximation on length.*

FIG. 5.1. (a) A star of degree 5 around vertex v . $(v, u_1), (v, u_3), (v, u_4)$ are half strips, and (u_2, u_5) is a full strip. (b) A covering with three edges for a half strip, and a covering with five edges for the full strip.

Proof. As the star cover, by definition, contains all vertices, the cycle cover obtained by traversing the stars also does. As stated above, the number of turns in each cycle covering a star is the number of directions at v , plus 2 times the degree of v . Summing over all stars, we get the claimed approximation bound. The running time follows directly from Lemma 4.12. Deriving the values for maximum coverage and overall length is straightforward. \square

COROLLARY 5.2. *There is a linear-time $(2\delta + \rho + 2)$ -approximation for minimum-turn discrete milling. Furthermore, the maximum coverage of a vertex is δ , and the tour is a δ -approximation on length.*

Proof. We apply Theorem 4.7. The number of cycles to be merged is the number of stars, which by Lemma 4.12 is a lower bound on the number of turns in a tour of the region. We pay at most two turns per cycle for the merge. There is no additional cost of length due to the merge, as the stars form a connected graph. \square

5.1.2. Thin discrete milling. As described in section 2, a more special structure arises if the structure to be milled consists of a connected set of “channels” that have to be milled. In this case, achieving a strip cover is trivial.

LEMMA 5.3. *In thin discrete milling a strip cover can be obtained in linear time by merging edges that are collinear at some vertex.*

Using method (ii) described at the beginning of the section, we get the following approximation results.

THEOREM 5.4. *There is a 4-approximation of complexity $O(n \log n)$ for computing a minimum-turn cycle cover for a graph with n edges, and a 6-approximation of the same complexity for computing minimum-turn tours.*

Proof. Clearly, the number of strips is a lower bound on the cost of any cycle cover or tour. Turning each strip into a cycle with two U-turns, i.e., 4 turns, yields a cycle cover within a factor 4 of the optimum. Merging these cycles at a cost of 2 turns per merge yields a tour within a factor of 6 times the optimum, as each cycle has 4 turns. \square

Clearly, all edges get covered twice (yielding a bound of 2 on the simultaneous length approximation) and no vertex gets covered more than 2ρ times.

Using the more time-consuming method (iii), we get better approximation factors for the turn cost.

THEOREM 5.5. *There is a 1.5-approximation of complexity $O(n^3)$ for computing a minimum-turn cycle cover for a graph with n edges, and a 3.5-approximation of the same complexity for computing minimum-turn tours.*

Proof. As before, we can compute an optimal strip cover S in linear time. Analogous to the approach in section 4.1, define a weight function between endpoints of strips, taking into account the direction when leaving a strip. Clearly, any feasible tour consists of two different matchings M_1 and M_2 between strip endpoints; moreover, if $d(M_1)$ and $d(M_2)$ are the total weights of the edges in the matchings, we get $d(M_1) + d(M_2) \leq d(T)$. It follows that for an optimal matching M , we have $d(M) \leq \text{OPT}/2$. By construction, the edges of M and the strips of S induce a 2-factor of the vertices that covers all edges. Thus, we get a cycle cover of cost at most 1.5 OPT.

Now consider the c cycles in a cycle cover. c is at most the number of strips in S , which is a lower bound on the cost of an optimal tour. As the cost of merging the c cycles is at most $2c - 2$, we get a total cost of not more than 3.5 OPT. \square

5.2. Integral orthogonal. As mentioned in the preliminaries, just the pixel count N may not be a satisfactory measure for the complexity of an algorithm, as the original region may be encoded more efficiently by its boundary, and a tour may be encoded by structuring it into a small number of pieces that have a short description. It is possible to use the above ideas for approximation algorithms in this extended framework. We describe how this can be done for the integral orthogonal case, where the set of pixels is bounded by n boundary edges.

THEOREM 5.6. *There is a 10-approximation of (strongly polynomial) complexity $O(n \log n)$ for computing a minimum-turn cycle cover for a region of pixels bounded by n integral axis-parallel segments, and a 12-approximation of the same complexity for computing minimum-turn tours. In both cases, the maximum coverage of a point is at most 4, so the algorithms are also 4-approximations on length.*

For the special case in which the boundary is connected (meaning that the region has no holes), the complexities drop to $O(n)$.

Proof. The basic idea is to find a greedy rook cover, then use it to build an approximate tour. Lemma 4.12 still holds, and each strip in a star (as described in the previous section) will be a full strip. The approximation ratios follow as special cases of Theorem 5.1: In this case, $\rho = 2$ and $\delta = 4$. It remains to show how we can find a greedy rook cover in the claimed time.

Refer back to Figure 4.6. Subdivide the region by the n vertical chords through its n vertices, resulting in at most n vertical strips X_1, \dots, X_n , of widths x_1, \dots, x_n . Similarly, consider a subdivision by the n horizontal chords through the n vertices into at most n horizontal strips Y_1, \dots, Y_n , of width y_1, \dots, y_n . In total, we get a subdivision into at most n^2 cells C_{ij} . Despite this quadratic number of cells, we can deal with the overall problem in near-linear time: Note that both subdivisions can be found in time $O(n \log n)$. For the case of a connected boundary, Chazelle's linear-time triangulation algorithm [12] implies a complexity of $O(n)$.

Choose any cell C_{ij} , which is a rectangle of size $x_i \times y_j$. Then $r_{ij} = \min\{x_i, y_j\}$ rooks can be placed greedily along the diagonal of C_{ij} , without causing any interference; such a set of rooks can be encoded as one "fat" rook, described by its leftmost uppermost corner (ξ_{ij}, η_{ij}) , and its width r_{ij} . Then the strip X_i can contain at most $x_i - r_{ij}$ additional rooks, and Y_j can contain at most $y_j - r_{ij}$ rooks. Therefore, replace x_i by $x_i - r_{ij}$, and y_j by $y_j - r_{ij}$. This changes the width of at least one of the strips to zero, effectively removing it from the set of strips. After at most $2n - 1$ steps of this type, all horizontal or all vertical strips have been removed, implying that we

have a maximal greedy rook cover.

It is straightforward to see that for a fat rook at position (ξ_{ij}, η_{ij}) and width r_{ij} , there is a canonical set of r_{ij} cycles with 10 edges each that covers every pixel that can be attacked from this rook. Furthermore, there is a “fat” cycle with at most $12r_{ij} - 2$ turns that is obtained by a canonical merging of the r_{ij} small cycles. Finally, it is straightforward to merge the fat cycles. \square

If we are willing to invest more time for computation, we can find an optimal rook cover (instead of a greedy one). As discussed in the proof of Lemma 4.11, this optimal rook cover yields an optimal strip cover. An optimal strip cover can be used to get a 6-approximation, and the new running time is $O(n^{2.5} \log n)$ or $O(N^{2.376})$.

THEOREM 5.7. *There is an $O(n^{2.5} \log N)$ -time or $O(N^{2.376})$ -time algorithm that computes a milling tour with number of turns within 6 times the optimal, and with length within 4 times the optimal.*

Proof. Apply Lemma 4.11 to find an optimal strip cover of the region. (See Figure 4.6.) As described in the proof of that lemma, the cardinality of an optimal strip cover is equal to the cardinality of an optimal rook cover. As stated, the number of strips is a lower bound on the number of turns in a cycle cover or tour.

Now any strip from u to w is covered by a “doubling” cycle with edges (u, w) , (w, w) , (w, u) , (u, u) . This gives a 4-approximation to minimum-turn cycle covers. Finally apply Corollary 4.8 to get a 6-approximation to minimum-turn tours.

The claim about coverage (and hence overall length) follows from the fact that an optimal strip cover has maximum coverage 2, and hence the cycle cover has maximum coverage 4. \square

By more sophisticated merging procedures, it is possible to reduce the approximation factor for tours to a figure closer to 4. Note that in the case of N being large compared to n , the above proof grossly overestimates the cost of merging, as all cycles within a fat strip allow merging at no additional cost. However, our best approximation algorithm achieves a factor less than 4 and uses a different strategy.

THEOREM 5.8. *For an integral orthogonal polygon with n edges and N pixels, there are 2.5-approximation algorithms, with running times $O(N^{2.376} + n^3)$ and $O(n^{2.5} \log N + n^3)$, for minimum-turn cycle cover, and hence there is a polynomial-time 3.75-approximation for minimum-turn tours.*

Proof. As described in Lemma 4.11, find an optimal strip cover S , in time $O(N^{2.376})$ or $O(n^{2.5} \log N)$. Let s be its cardinality and let OPT be the cost of an optimal tour; then $\text{OPT} \geq s$.

Now consider the end vertices of the strip cover. By construction, they are part of the boundary. Because any feasible tour T must encounter each pixel and cannot cross the boundary, either any endpoint of a strip is crossed orthogonally or the tour turns at the boundary segment. In any case, a tour must have an edge that crosses an end vertex orthogonally to the strip. (Note that this edge has zero length in the case of a U-turn.)

As in section 4.1 and the proof of Theorem 5.5, define a weight function between endpoints of strips, taking into account the direction when leaving a strip. Again any feasible tour consists of two different matchings M_1 and M_2 between strip endpoints, and for an optimal matching M , we have $d(M) \leq \text{OPT}/2$.

Computing such a matching can be achieved as follows. Note that for N pixels, an optimal strip cover has $O(\min\{\sqrt{N}, n\})$ strips; by matching endpoints of neighboring strips within the same fat strip, we are left with $O(n)$ endpoints. As described in the proof of Lemma 4.11, the overall cost for computing the link distance between

FIG. 5.2. A bad example for the 3.75-approximation algorithm: (a) Half the cycles constructed by the algorithm. (b) An optimal tour.

all pairs of endpoints can be achieved in $O(\min\{N \log N, n^2 \log n\})$. Computing a minimum-weight perfect matching can be achieved in time $O(\max\{N^{1.5}, n^3\})$.

The edges of M and the strips of S induce a 2-factor of the endpoints. Because any matching edges leave a strip orthogonally, we get at most 2 additional turns at each strip for turning each 2-factor into a cycle. The total number of turns is $2s + w(M) \leq 2.5 \cdot \text{OPT}$. Because the strips cover the whole region, we get a feasible cycle cover.

Finally, we can use Corollary 4.8 to turn the cycle cover into a tour. By the corollary, this tour does not have more than $3.75 \cdot \text{OPT}$ turns. \square

The class of examples in Example 5.9 shows that the cycle cover algorithm may use $2 \cdot \text{OPT}$ turns, and the tour algorithm may use $3 \cdot \text{OPT}$ turns, assuming that no special algorithms are used for matching and merging. Moreover, the same example shows that this 3.75-approximation algorithm does not give an immediate length bound on the resulting tour.

Example 5.9. The class of regions shown in Figure 5.2 may yield a heuristic cycle cover with $2 \cdot \text{OPT}$ turns, and a heuristic tour with $3 \cdot \text{OPT}$ turns.

The region consists of a “square donut” of width k . An optimal strip cover consists of $4k$ strips; an optimal matching of strip ends yields a total of $8k + 2$ turns, and we get a total of $2k$ cycles. (In Figure 5.2(a), only the vertical strips and their matching edges are shown to keep the drawing cleaner.) If the merging of these cycles is done badly (by merging cycles at crossings and not at parallel edges), it may cost another $4k - 2$ turns, for a total of $12k$ turns. As can be seen from Figure 5.2(b), there is a feasible tour that uses only $4k + 2$ turns. This shows that optimal tours may have almost all turns strictly inside of the region. Moreover, the same example shows that this 3.75-approximation algorithm does not give an immediate length bound on the resulting tour. However, we can use a local modification argument to show the following theorem.

THEOREM 5.10. *For any given feasible tour (or cycle cover) of an integral orthogonal region, there is a feasible tour (or cycle cover) of equal turn number that*

(a)

(b)

(c)

FIG. 5.3. Rearranging a tour to ensure that no pixel is covered more than three times in each direction: (a) A set of horizontal edges that covers some pixel three times. (b) A rearranged tour, if the second matching between endpoints connects two left and two right endpoints. (c) A rearranged tour, if the second matching between endpoints connects any left with a right endpoint.

covers each pixel at most four times. This implies a performance ratio of 4 on the total length.

Proof. See Figure 5.3. Suppose there is a pixel that is covered at least five times. Then there is a direction (say, horizontal) in which it is covered at least three times. Let there be three horizontal segments $(1, 1')$, $(2, 2')$, $(3, 3')$ covering the same pixel, as shown in Figure 5.3(a); we denote by 1, 2, 3 the endpoints to the left of the pixel, and by $1'$, $2'$, $3'$ the endpoints to the right of the pixel.

Now consider the connections of these points by the rest of the tour, i.e., a second matching between the points 1, 2, 3, $1'$, $2'$, $3'$ that forms a cycle when merged with

the first matching $(1, 1')$, $(2, 2')$, $(3, 3')$. This second matching is shown dashed in Figure 5.3(b,c). We consider two cases, depending on the structure of the second matching.

In the first case, there are two right endpoints that are matched, say $1'$ and $2'$. Then there must be two left endpoints that are matched; because both matchings must form one large cycle, these cannot be 1 and 2. Without loss of generality, we may assume they are 1 and 3. Thus, 2 and $3'$ must be matched, as shown in Figure 5.3(b). Then we can replace $(1, 1')$, $(2, 2')$, $(3, 3')$ by $(1, 2')$, $(2, 3)$, $(1', 3')$, respectively, which yields a feasible tour with the same number of turns, but with some pixels being covered fewer times, and no pixel being covered more times than was the case in the original tour.

In the other case, all right endpoints are matched with left endpoints. Clearly, $1'$ cannot be matched with 1; without loss of generality, we assume it is matched with 2, as shown in Figure 5.3(c). Then the cycle condition implies that the second matching is $(1, 3')$, $(2, 1')$, $(3, 2')$. This allows us to replace $(1, 1')$, $(2, 2')$, $(3, 3')$ by $(1, 3)$, $(2, 3')$, $(1', 2')$, respectively, again producing a feasible tour with the same number of turns, but with some pixels being covered fewer times, and no pixel being covered more times than was the case in the original tour.

This can be repeated until no pixel is covered more than four times. As the above procedure can be carried out as part of the merging phase (i.e., after an optimal weighted matching has been found), the overall complexity is not affected. Furthermore, it is straightforward to see that it also works for the case of “thick” strips, where N is large compared to n , by treating parallel edges in a thick strip simultaneously. \square

5.3. Nonintegral orthogonal polygons. Nonintegral orthogonal polygons present a difficulty in that no polynomial-time algorithm is known to compute a minimum strip cover for such polygons. Fortunately, however, we can use the boundary tours from section 4.1 to the approximation factor of 12 from Theorem 5.6 for the integral orthogonal case.

THEOREM 5.11. *In nonintegral orthogonal milling of a polygonal region with n edges and N pixels, there is a polynomial-time 4.5-approximation for minimum-turn cycle covers and 6.25-approximation for minimum-turn tours, with a simultaneous performance guarantee of 8 on length and cover number. The running time is $O(N^{2.376} + n^3)$, or $O(n^{2.5} \log N + n^3)$.*

Proof. Take the 2.5-approximate cycle cover of the integral pixels in the region as in Theorem 5.8; for a tour, turn it into a 3.75-approximate tour. This may leave a fractional portion along the boundary uncovered. See Figure 5.4.

Now add an optimal cycle cover of the boundary which comes from Theorem 4.4. This may leave only fractional boundary pieces uncovered that are near reflex vertices of the boundary, as shown in Figure 5.4. Whenever this happens, there must be a turn of the boundary cycle cover on both sides of the reflex vertex. The fractional patch can be covered at the cost of an extra two turns, which are charged to the two turns in the boundary cycles. Therefore, the modified boundary cover has a cost of at most $2 \cdot \text{OPT}$. Compared to an optimal cycle cover of length OPT , we get a cycle cover of length at most $4.5 \cdot \text{OPT}$, as claimed. For an optimal tour of length OPT , merging all modified boundary cycles into one cycle can be done at a cost of at most 2 turns per unmodified boundary cycle, i.e., for a total of $\frac{1}{2} \cdot \text{OPT}$.

Finally, the remaining two cycles can be merged at a cost of 2 turns. This yields an overall approximation factor of $3.75 + 2.5 = 6.25$. The claim on the cover number

FIG. 5.4. Milling a nonintegral orthogonal polygon.

(and thus length) follows from applying Theorem 5.10 to each of the two cycles.

The running times follow from Theorems 4.4 and 5.8. \square

5.4. Milling thin orthogonal polygons. In this section we consider the special case of milling *thin* polygons. Again, we focus on the integral orthogonal case. Formally, a thin polygon is one in which no axis-aligned 2×2 square fits, implying that each pixel has all four of its corners on the boundary of the polygon. Intuitively, a polygon is thin if it is composed of a network of width-1 corridors, where each pixel is adjacent to some part of the boundary of the region, making this related to discrete milling.

5.4.1. Basics of thin orthogonal polygons. Any pixel in the polygon has one, two, three, or four neighbor pixels; we denote this number of neighbors as the degree of a pixel. See Figure 5.5. Degree-1 pixels (1) are “dead ends,” where the cutter has to make a U-turn. There are two types of degree-2 pixels, without forcing a turn (2a) or with forcing a turn (2b); in either case, applying Lemma 4.3 in an appropriate manner will suggest that they should be visited in a canonical way: after one neighbor, and before the other. Neighbors of degree-3 pixels (3) form “T” intersections that force duplication of paths. Degree-4 pixels (4) are the only pixels in thin polygons that are not boundary pixels as defined in section 4; however, in the absence of 2×2 squares of pixels, all their neighbors are of degree 1 or 2.

In the following, we will use the ideas developed for boundary cycle covers in section 4.1 to obtain cycle covers for thin polygons. The following is a straightforward consequence of Theorems 4.4 and 4.7.

COROLLARY 5.12. *In thin orthogonal milling, there is an $O(n^3)$ algorithm for computing a minimum-turn cycle cover, and an $O(n^3)$ 1.5-approximation for computing a minimum-turn tour.*

Proof. Apply the strongly polynomial algorithm described in Theorem 4.4 for computing a minimum cost boundary cycle cover. By definition, this covers all pixels of degree 1, 2, and 3. Moreover, degree-4 pixels are surrounded by pixels of degree 1 or 2, implying that they are automatically covered as neighbors of those pixels, when applying Lemma 4.3. Using Theorem 4.7, we can turn this into a tour, yielding the claimed approximation factor. \square

More interesting is that we can do much better than general merging in the case

FIG. 5.5. Pixel types in a thin polygon.

of thin orthogonal milling. The idea is to decompose the induced graph into a number of cheap cycles and a number of paths.

5.4.2. Milling thin Eulerian orthogonal polygons. We first solve the special case of milling Eulerian polygons, that is, polygons that can be milled without retracing edges of the tour, so that each edge in the induced graph is traversed by the cutting tool exactly once. In an Eulerian polygon, all pixels have either two or four neighbors, meaning there are no odd-degree pixels.

Although one might expect that the optimal milling is one of the possible Eulerian tours of the graph, in fact, this is not always true, as Example 5.13 points out.

Example 5.13. *There exist thin grid graphs, such that no turn-minimal tour of the graph is an Eulerian tour.*

Proof. See Figure 5.6. Observe that an optimal milling is *not* an Eulerian tour. The best Eulerian tour for this figure requires 22 turns, as shown symbolically in the bottom left of the figure: Each cycle uses 4 turns and an additional 6 turns can be used to connect the 4 cycles together. On the other hand, the optimal milling traverses the edges in the internal pixel twice, both times in the same direction: The order of turns is 1, 2, *C*, 13, 16, 15, 14, *D*, 9, 12, 11, 10, *B*, 5, 8, 7, 6, *A*, 3, 4, 1, and the structure is shown symbolically in the bottom right. Thus, the optimal milling only requires 20 turns, where each cycle uses 4 turns and an additional 4 turns connect the cycles together. \square

By strengthening the lower bound, we can achieve the following approximation of an optimal tour of length OPT.

THEOREM 5.14. *There is an $O(n \log n)$ (or $O(N)$) algorithm that finds a tour of turn cost at most $\frac{6}{5} \cdot \text{OPT}$.*

Proof. By applying Theorem 4.4, we get an optimal boundary cycle cover. There are three observations that lead to the claimed stronger results.

(1) For a thin polygon, extracting the collinear strips can be performed in strongly polynomial time $O(n \log)$ (or weakly polynomial time $O(N)$).

(2) For an Eulerian thin polygon, no vertices in $G_{\overline{P}}$ remain unmatched after repeatedly applying Lemma 4.3. Instead, we get an optimal cycle cover right away. This cycle cover can be merged into one connecting tour by merging at pixels where two cycles cross each other: Let the optimal cycle cover be composed of c disjoint

FIG. 5.6. A thin Eulerian polygon consisting of four overlapping cycles (above). Shown symbolically below is how to obtain an overall tour by merging the four canonical cycles: A tour obtained by iteratively merging cycles incurs a total of $16 + 6 = 22$ turns (bottom left). An optimal tour has $16 + 4 = 20$ turns (bottom right).

cycles, where $c \geq 1$. Let t be the cost of the optimal cycle cover. At each phase of the cycle-merging algorithm, two cycles are merged into one. Therefore, the algorithm finds a solution having cost $t + 2 \cdot (c - 1)$.

(3) We can strengthen the lower bound on an optimal tour as follows. Consider (for $c > 1$) a lower bound on the cost of the optimal solution. Just like in the proof of Theorem 3.1, all turns in a cycle cover are forced by convex corners of the polygon, implying that any solution must contain these t turns. In addition, turning from one cycle into another incurs a crossing cost of at least one turn; thus, we get a lower bound of $t + c$. Observe that there are at least 4 turns per cycle so that $t \geq 4c$. Therefore, $\frac{t+2 \cdot (c-1)}{t+c} \leq \frac{t+2c}{t+c} \leq \frac{6}{5}$. \square

5.4.3. Milling arbitrary thin orthogonal polygons. Now we consider the case of general thin polygons. For any odd-degree vertex, and any feasible solution, some edges may have to be traversed multiple times. As in Corollary 5.12, we can apply Theorem 4.4 to achieve a minimum-cost cycle cover and merge them into a tour. Using a more refined analysis, we can use this to obtain a $4/3$ -approximation algorithm for finding a minimum-cost tour.

THEOREM 5.15. *For thin orthogonal milling, we can compute a tour of turn cost at most $\frac{4}{3} \cdot \text{OPT}$ in time $O(n^3)$, where OPT is the cost of an optimal tour.*

Proof. We start by describing how to merge the cycles into one connected tour.

1. Find an optimal cycle cover as provided by Theorem 4.4.
2. Repeat until there is only one cycle in the cycle cover:
 - If there are any two cycles that can be merged without any extra cost (by having partially overlapping collinear edges), perform the merge.

- Otherwise,
 - find a vertex at which two cycles cross each other;
 - modify the vertex to incorporate at most two additional turns, thereby connecting the two cycles.

Now we analyze the performance of our algorithm. Consider the situation after extracting the cost zero matching edges from Lemma 4.3. This already yields a set K of cycles, obtained by only turning at pixels of degree 2 that force a turn. Let k denote the number of cycles in K , and let c be the number of turns in K . Let P be the set of “dangling” paths at degree-1 or degree-3 pixels, and let p be the number of turns in P , including the mandatory turn for each endpoint. Let M be a minimum matching between odd-degree vertices, and let m be the number of turns in M . Finally, let O be the matching between odd-degree pixels that is induced by an optimal tour, and let o be the number of turns in O .

First note that P is a matching between odd-degree nodes.

P , M , and O may connect some of the cycles in K . In P a path between two odd-degree pixels connects the two cycles that the two nodes belong to. On the other hand, a path in M and O between two odd-degree nodes can encounter several cycles along the way, and thus it may be used to merge several cycles at no extra cost.

Therefore, let j be the number of cycles after using P for free merging, let i be the number of components with P and M used for free merging, and let h be the number of components with P and O used for free merging.

Note that

$$(5.1) \quad 1 \leq i \leq j \leq k$$

and

$$(5.2) \quad 1 \leq h \leq j \leq k.$$

Now consider the number of cycles encountered by a path in the matching. It is not hard to see that this number cannot exceed the number of its turns. Therefore,

$$(5.3) \quad m \geq k - i \geq j - i,$$

$$(5.4) \quad o \geq k - h \geq j - h.$$

If a particular matching results in x components, we would need at least x more turns to get a tour. Thus with O we need at least h more turns.

Thus, for an optimal tour of cost OPT , we have

$$(5.5) \quad \text{OPT} \geq c + p + o + h.$$

Our heuristic method adds the minimum matching to C and P and merges the remaining components with two turns per merge, and hence the cost HEUR of the resulting tour is

$$(5.6) \quad \text{HEUR} \geq c + p + m + 2(i - 1).$$

Thus we get the following estimate for the approximation factor $R \geq 1$:

$$(5.7) \quad R \leq \frac{c + p + m + 2i}{c + p + o + h}.$$

Because each cycle has at least four turns, we know that

$$(5.8) \quad c \geq 4k \geq 4j.$$

Using the fact that $c + p + m + 2i \geq c + p + o + h$ (because $R \geq 1$), we see that the ratio on the right in (5.7) gets *larger* if we replace c in the numerator and in the denominator by the smaller nonnegative value $4j$; thus,

$$(5.9) \quad R \leq \frac{4j + p + m + 2i}{4j + p + o + h}.$$

Because P is also a matching, we have

$$(5.10) \quad p \geq m,$$

which implies that

$$(5.11) \quad R \leq \frac{4j + 2m + 2i}{4j + m + o + h}.$$

We also know that

$$(5.12) \quad m \leq o.$$

Using this, together with the fact that R can be assumed to be less than 2, we can argue that R is maximal for maximal values of m ; hence,

$$(5.13) \quad R \leq \frac{4j + 2o + 2i}{4j + 2o + h}.$$

Using (5.4) in (5.13), we see that R is maximal for minimal o ; hence,

$$(5.14) \quad R \leq \frac{4j + 2(j - h) + 2i}{4j + 2(j - h) + h} = \frac{6j - 2h + 2i}{6j - h}.$$

Using $h > o$ in (5.14) and the facts that $R < 2$ and $i \leq j$, we get that

$$(5.15) \quad R \leq \frac{6j - 2o + 2i}{6j - o} \leq \frac{6j + 2i}{6j} \leq \frac{4}{3}. \quad \square$$

The following shows that the estimate for the performance ratio is tight.

THEOREM 5.16. *There is a class of examples for which the estimate of $4/3$ for the performance ratio of the algorithm for thin orthogonal milling is tight.*

Proof. See Figure 5.7. The region consists of $k = 2s + 4$ cycles, all with precisely 4 turns, s cycles without degree-three vertices, and $s + 4$ cycles with two degree-3 vertices each. We get $c = 4k = 8s + 16$ and $p = 2(s + 4) = 2s + 8$. Figure 5.7(b) shows a min-cost matching of cost $m = 2(s + 4) = 2s + 8$ and one of cost $o = 2s + 8$ that is induced by an optimum tour. As Figure 5.7(c) suggests, merging all cycles, odd-degree paths, and matching paths is possible without requiring any further turns, resulting in $\text{OPT} = c + p + o = 12s + 32$. On the other hand, using the min-cost matching of cost m leaves k cycles that cannot be merged for free; thus, merging two cycles at a time at a cost of 2 turns requires an additional cost of $2(k - 1) = 4s + 6$, for a total of $\text{HEUR} = c + p + m + 2(k - 1) = 16s + 38$ turns, which gets arbitrarily close to $\frac{4}{3}\text{OPT}$ for large s . \square

Note that the argument of Theorem 5.10 remains valid for this section, so the bounds on coverage and length approximation still apply.

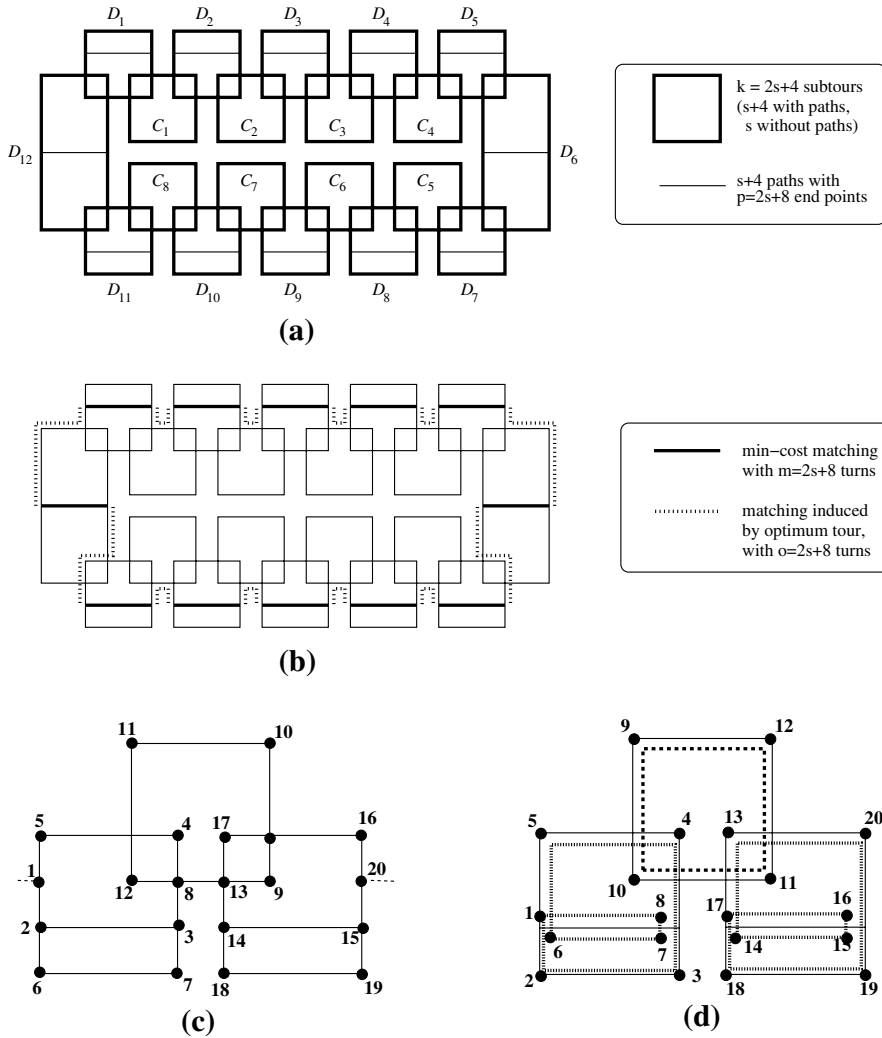

FIG. 5.7. An example with performance ratio $4/3$ for our heuristic. (a) The structure of the example for $s = 8$. (b) A min-cost matching of the odd-degree vertices, and the matching induced by an optimal tour. (c) A portion of the optimal tour: Subtours can be merged without extra cost. (d) A corresponding portion of the heuristic tour: Subtours still need to be merged, which results in an additional cost of $2(k - 1) = 4s + 6$.

5.5. PTAS. We describe a polynomial-time approximation scheme (PTAS) for the problem of minimizing a weighted average of the two cost criteria: length and number of turns. Our technique is based on using the theory of m -guillotine subdivisions [38], properly extended to handle turn costs. We prove the following result.

THEOREM 5.17. Define the cost of a tour to be its length plus C times the number of (90-degree) turns. For any fixed $\varepsilon > 0$, there is a $(1 + \varepsilon)$ -approximation algorithm, with running time $2^{O(h)} \cdot N^{O(C)}$, for minimizing the cost of a tour for an integral orthogonal polygon P with h holes and N pixels.

Proof. Let T^* be a minimum-cost tour and let m be any positive integer. Following the notation of [38], we first apply the main structure theorem of that paper to

claim that there is an m -guillotine subdivision, T_G , obtained from T^* by adding an appropriate set of bridges (m -spans, which are horizontal or vertical segments) of total length at most $\frac{1}{m}|T^*|$, with length at most $(1 + \frac{1}{m})$ times the length of T^* . (Because T^* may traverse a horizontal/vertical segment twice, we consider such segments to have multiplicities (1 or 2), as multiedges in a graph.)

We note that part of T_G may lie outside the polygon P , because the m -spans that we add to make T^* m -guillotine need not lie within P . We convert T_G into a new graph by subtracting those portions of each bridge that lie outside of P . In this way, each bridge of T_G becomes a set of segments within P ; we trim each such segment at the first and last edges of T_G that are incident on it and call the resulting trimmed segments *subbridges*. (Note that a subbridge may be a single point if the corresponding segment is incident on a single edge of T^* ; we can ignore such trivial subbridges.) As in the TSP method of [38], we *double* the (nontrivial) subbridges: We replace each subbridge by a pair of coincident segments, which we “inflate” slightly to form a degenerate loop, such that the endpoints of the subbridge become vertices of degree 4, and the endpoints of each edge incident on the interior of the subbridge become vertices of degree 3 (which occur in pairs). Refer to Figure 5.8. We let T'_G denote the resulting graph. Now $T'_G \subset P$, and, because T'_G is obtained from T^* , a tour, we know that the number of odd-degree vertices of T'_G that lie on any one subbridge is *even* (the degree-3 vertices along a subbridge come in pairs).

FIG. 5.8. Definitions of subbridges and the graph T'_G . A vertical line l is shown, which defines a cut. The slice of an optimal solution along l is shown, with thinner lines drawn along the edges of the solution (which is not intended to be an accurate instance of an optimal solution, but is drawn to illustrate some of the possible cases). Also shown is an enlargement of one portion of the cut l , showing a segment of the m -span between two portions of the boundary of P , the trimmed segment that forms the subbridge, and the portion of the resulting graph T'_G in the vicinity of the inflated subbridge.

The cost of the optimal solution T^* is its length, $|T^*|$, plus C times the number of its vertices. We consider the cost of T'_G to be also its (Euclidean) length plus C times the number of its vertices. Because the number of vertices on the subbridges is proportional to their total length, and each edge multiplicity is at most two, we see

FIG. 5.9. (a) The vertical decomposition of P (holes in dark gray). (b) The decomposition of P into junctions (light gray) and corridors, with the dual graph overlaid. The nodes of the dual graph are shown as hollow for junctions and as smaller solid disks for the corridors.

that the cost of T'_G is $O((1+C)/m) \cdot |T^*|$ greater than the optimal cost, i.e., the cost of T^* .

In order to avoid exponential dependence on n in our algorithm, we need to introduce a subdivision of P that allows us to consider the subbridges along an m -span to be grouped into a relatively small ($O(h)$) number of classes. We now describe this subdivision of P .

By standard plane sweep with a vertical line, we partition P into rectangles, using vertical chords, according to the vertical decomposition; see Figure 5.9(a). We then decompose P into a set of $O(h)$ regions, each of which is either a “junction” or a “corridor.” This decomposition is analogous to the corridor structure of polygons that has been utilized in computing shortest paths and minimum-link separators (see, e.g., [32, 33, 40]), with the primary difference being that we use the vertical decomposition into rectangles, rather than a triangulation, as the basis of the definition. Consider the (planar) dual graph, \mathcal{G} , of the vertical partition of P ; the nodes of \mathcal{G} are the rectangles, and two nodes are joined by an edge if and only if they are adjacent. We now define a process to transform the vertical decomposition into our desired decomposition. First, we take any degree-1 node of \mathcal{G} and delete it, along with its incident edge; in the vertical decomposition, we remove the corresponding vertical chord (dual to the edge of \mathcal{G} that was deleted). We repeat this process, merging a degree-1 region with its neighbor, until there are no degree-1 nodes in \mathcal{G} . At this stage, \mathcal{G} has $h+1$ faces and all nodes are of degree 2 or more. Assume that $h \geq 2$ (the case $h \leq 1$ is easy); then not all nodes are of degree 2, implying that there are at least two higher-degree nodes. Next, for each pair of adjacent degree-2 nodes, we merge the nodes, deleting the edge between them and removing the corresponding vertical chord separating them in the decomposition. The final dual graph \mathcal{G} has nodes of two types: those that are dual to regions of degree 2, which we call the *corridors*, and those that are dual to regions of degree greater than 2, which we call the *junctions*. Each corridor is bounded by exactly two vertical chords, together with two portions of

the boundary of P . (These two portions may, in fact, come from the same connected component of the boundary of P .) Each of the h bounded faces of \mathcal{G} contains exactly one of the holes of P . Refer to Figure 5.9.

Let \mathcal{V} denote the decomposition of P just described; there is an analogous horizontal partition, \mathcal{H} , of P into $O(h)$ regions. The vertical subbridges of a vertical bridge are partitioned into $O(h)$ classes according to the identity of the region, τ , that contains the subbridge in the vertical decomposition \mathcal{V} . A subbridge intersecting a region τ of \mathcal{V} is called *separating* if it separates some pair of vertical chords on the boundary of τ ; it is *trivial* otherwise. (Corridor regions have only two vertical chords on their boundary, while junctions may have several, as many as $\Theta(h)$ in degenerate cases.)

First, consider a corridor region τ in \mathcal{V} , and let a and b denote the two vertical chords that bound it. An important observation regarding subbridge classes in corridors is this: The parity of the number of times a tour crosses a must be the same as the parity of the number of times a tour crosses b . The consequence is that we can specify the parity of the number of incidences on *all* separating subbridges of a given corridor class by specifying the parity of the number of incidences on a single subbridge of the class; the trivial subbridges always have an even parity of crossing.

Now consider a junction region τ in \mathcal{V} . Because, in the merging process that defines \mathcal{V} , we never merge a degree-2 region with a higher-degree region, we know that τ consists of a single high-degree (> 2) rectangle, R_τ , from the original vertical decomposition, together with possibly many other rectangles that form a “pocket” attached to R_τ , corresponding to a tree in the dual graph (so that removal of degree-1 nodes leads to a collapse of the tree and a merging of the pocket to R_τ). The consequence of this observation is that there can be at most one separating subbridge in a junction class. (There may be several trivial subbridges.)

Our algorithm applies dynamic programming to obtain a minimum-cost m -guillotine subdivision, T_G^* , from among all those m -guillotine subdivisions that have the following additional properties:

- (1) It consists of a union of horizontal/vertical segments, having half-integral coordinates, within P .
- (2) It is connected.
- (3) It *covers* P , in that the center of every pixel of P is intersected by an edge of the subdivision.
- (4) It is a *bridge-doubled* m -guillotine subdivision, so that every (nontrivial) subbridge of an m -span appears twice (as a multiedge).
- (5) It interconnects the subbridges in each of a specified partition of the classes of subbridges.
- (6) It obeys a parity constraint on each of the $O(h)$ classes of subbridges: The number of edges of the subdivision incident on each separating subbridge of the class corresponding to a region τ is even or odd, according to the specified parity for τ .

A subproblem in the dynamic programming algorithm is specified by a rectangle, having half-integral coordinates, together with *boundary information* associated with the rectangle, which specifies how the subdivision within the rectangle interacts with the subdivision outside the rectangle. The boundary information includes (a) $O(m)$ attachment points, where edges meet the boundary at points other than along the m -span; (b) the multiplicity (1 or 2) of each attachment point, and the interconnection pattern (if any) of adjacent attachment points along the rectangle boundary; (c) the endpoints of a bridge on each side of the rectangle (from which one can deduce

the subbridges); (d) interconnection requirements among the attachment points and the classes of subbridges; and (e) a parity bit for each class of subbridge, indicating whether an even or an odd number of edges should be incident to the separating subbridges of that class. There are $N^{O(m)} \cdot 2^{O(h)}$ subproblems. At the base of the dynamic programming recursion are rectangles of constant size (e.g., unit squares).

The optimization considers each possible cut (horizontal or vertical, at half-integral coordinates) for a given subproblem, together with all possible choices for the new boundary information along the cut, and minimizes the total resulting cost, adding the costs of the two resulting subproblems to the cost of the choices made at the cut (which includes the length of edges added, plus C times the number of vertices added).

Once an optimal subdivision, T_G^* , is computed, we can recover a valid tour from it by extracting an Eulerian subgraph obtained by removing a subset of the edges on each doubled subbridge. The parity conditions imply that such an Eulerian subgraph exists. An Eulerian tour on this subgraph is a covering tour, and its cost is at most $O(C/m) \cdot |T^*|$ greater than optimal. For any fixed $\varepsilon > 0$, we set $m = \lceil C/\varepsilon \rceil$, resulting in a $(1 + \varepsilon)$ -approximation algorithm with running time $O(N^{O(C/\varepsilon)} \cdot 2^{O(h)})$. The techniques of [38], which use “grid-rounded” m -guillotine subdivisions, can be applied to reduce the exponent on N to a term, $O(C)$, independent of m . \square

Remarks. It should be possible to apply a variant of our methods to obtain a PTAS that is polynomial in n (versus N), with a careful consideration of implicit encodings of tours. We note that our result relies on effectively “charging off” turn cost to path length, because the objective function is a linear combination of the two costs (turns and length). We have not yet been able to give a PTAS for minimizing only the number of turns in a covering tour; this remains an intriguing open problem.

6. Conclusion. We have presented a variety of results for finding an optimal tour with turn cost. Many open problems remain. The most curious seems to be the following, which highlights the difference between turn cost and length, as well as the difference between a cycle cover and a 2-factor.

PROBLEM 6.1. *What is the complexity of finding a minimum-turn cycle cover in a grid graph?*

This problem has been open for several years now; in fact, it is Problem # 53 on the well-known list [17], known as “The Open Problems Project.” Finding a minimum weighted turn cycle cover is known to be NP-hard for a set of points in the plane [1]; however, the proof uses the fact that there are more than two directions for the edges in a convex cycle. While we tend to believe that Problem 6.1 may have the answer “NP-complete,” a polynomial solution would immediately lead to a 1.5-approximation for the orthogonal case, and a $(1 + \frac{2}{3})$ -approximation for the general case.
