We now reiterate the above argument, except we use (18) to eliminate alternations more efficiently than we did with (15). This yields an even more efficient complementation for sufficiently large polynomials T:

$$\Sigma_2\mathrm{TIME}[T] \subseteq \Pi_2\mathrm{TIME}[T^{\frac{c^3}{4}+o(1)}].$$

This can in turn be used to derive another more efficient complementation, and so on. In this manner, we can derive a series of complementations, each one more efficient than the previous one. Specifically, each iteration multiplies the exponent cost of the complementation by $\frac{c}{2}$, so after k iterations we obtain

$$\Sigma_2\mathrm{TIME}[T] \subseteq \Pi_2\mathrm{TIME}[T^{c\cdot e_k+o(1)}],$$

where $e_k = (\frac{c}{2})^k$. Note that for $c < 2$, $e_k \to 0$ as $k \to \infty$. Thus, by choosing k large enough so that $c \cdot e_k < 1$, we arrive at a contradiction to Lemma 6, which proves the desired lower bound of $n^{2-o(1)}$.

The following lemma precisely derives the series of complementations of Σ_2 for larger space bounds than $n^{o(1)}$. Specifically, we consider the hypothesis (8) for polynomials t and s, namely $t = n^c$ and $s = n^d$ for some constants $c \geq 1$ and $d > 0$, and derive the running time of the resulting Π_2-simulation in terms of c, d, and k, the number of times the argument is recursively applied.

LEMMA 15. *Suppose that*

$$\Sigma_2\mathrm{TIME}[n] \subseteq \mathrm{BPTISP}[n^c, n^d] \tag{19}$$

for some constants $c \geq 1$ and $d > 0$ where $c + 2d \leq 2$. Then for any time function T and integer $k \geq 0$ such that $d \leq f_k$,

$$\Sigma_2\mathrm{TIME}[T] \subseteq \Pi_2\mathrm{TIME}\left[\left((T^{f_k}+n)^{c+d}\right)\mathrm{polylog}(T+n)\right],$$

where

$$f_k = \left(\frac{c+2d}{2}\right)^k. \tag{20}$$

Proof. We give a proof by induction on k. For $k = 0$, a padded version of the initial complementation given by (14) offers a Π_2-simulation of $\Sigma_2\mathrm{TIME}[T]$ running in the desired time.

We now show the inductive step by using the kth complementation to derive the $(k+1)$st. Padding hypothesis (19) gives a simulation of $\Sigma_2\mathrm{TIME}[T]$ in $\mathrm{BPTISP}[(T+n)^c, (T+n)^d]$. Note that the addition of the term n to T ensures the validity of this step for arbitrary T, in particular for sublinear T. Applying (13) gives a speedup of the BPTISP simulation at the cost of three alternations, yielding

$$\Sigma_2\mathrm{TIME}[T] \subseteq \forall^{(T+n)^d\log(T+n)}\underbrace{\Sigma_2\mathrm{TIME}\left[(T+n)^{\frac{c+2d}{2}}\,\mathrm{polylog}(T+n)\right]}_{(\alpha)}. \tag{21}$$

The complementation given by the inductive hypothesis switches (α) to a Π_2-computation, eliminating one alternation. Specifically, (α) represents a Σ_2-machine running in time

$$\tilde{T} \doteq O\left((T+n)^{\frac{c+2d}{2}} \operatorname{polylog}(T+n)\right)$$

on inputs comprised of the original n-bit input, in addition to the $(T+n)^d \log(T+n)$ bits guessed in the preceding universal stage, for a total input size of

$$\tilde{n} \doteq O\left(n + (T+n)^d \log(T+n)\right).$$

The inductive hypothesis allows us to simulate (α) by a Π_2-machine running in time $O\big((\tilde{T}^{f_k} + \tilde{n})^{c+d} \operatorname{polylog}(\tilde{T}+\tilde{n})\big)$. Using this Π_2-machine for (α) and accounting for the time spent in the initial universal stage of the simulation given by (21) results in a Π_2-simulation of $\Sigma_2\mathrm{TIME}[T]$ running in time big-O of

$$(T+n)^d \log(T+n) + \left((\tilde{T}^{f_k} + \tilde{n})^{c+d}\right) \operatorname{polylog}(\tilde{T}+\tilde{n}).$$

All that remains is to show that the above running time is of the desired form under the conditions on c and d. To simplify this expression, note that $\operatorname{polylog}(\tilde{T}+\tilde{n}) = \operatorname{polylog}(T+n)$. Collecting all of the other polylog terms, the running time can be written as big-O of

$$\left[(T+n)^d + \left(\left((T+n)^{\frac{c+2d}{2}}\right)^{f_k} + n + (T+n)^d\right)^{c+d}\right] \operatorname{polylog}(T+n).$$

The terms depending on T in the big-O expression have exponents d, $\frac{c+2d}{2} f_k(c+d)$, and $d(c+d)$ (putting aside the $\operatorname{polylog}(T+n)$ factor for a moment). Thus, when $d \le \frac{c+2d}{2} f_k = f_{k+1}$ and $c+d \ge 1$, the dominating term is $T^{\frac{c+2d}{2} f_k(c+d)} = T^{f_{k+1}(c+d)}$.

Similarly, the terms depending on n have exponents d, $\frac{c+2d}{2} f_k(c+d), c+d$, and $d(c+d)$. Under the same conditions on c and d, the first and last terms are subsumed by the second, which can be rewritten as $f_{k+1}(c+d)$. Additionally, when $c+2d \le 2$, $f_k \le 1$ for all $k \ge 0$, so that the n^{c+d} term dominates. Thus, we simplify the running time to big-O of

$$\left((T^{f_{k+1}} + n)^{c+d}\right) \operatorname{polylog}(T+n),$$

which is of the desired form. ∎

The series of complementations given by Lemma 15 lead to a contradiction with Lemma 6 for certain values of c and d, which proves the desired lower bound.

THEOREM 16. *For any constant $c < 2$, there exists a positive constant d such that $\Sigma_2\mathrm{TIME}[n]$ cannot be simulated by randomized random-access machines with two-sided error running in time n^c and space n^d. Moreover, d approaches $1/2$ from below as c approaches 1 from above.*

Proof. For $c < 1$, the theorem holds for any d by standard techniques. Namely, take the parity function, which is surely in $\Sigma_2\mathrm{TIME}[n]$, and consider any $\mathrm{BPTIME}[n^c]$ machine M which purportedly computes it. On input 0^n, we must have that

$$\sum_{i=1}^{n} \Pr[M \text{ looks at the } i\text{th bit on input } 0^n] \le n^c.$$

For $c < 1$, this implies that there is a bit position that M looks at very rarely. Namely, there exists an i such that

$$\Pr[M \text{ looks at the } i\text{th bit on input } 0^n] = o(1).$$

From this, we can deduce that M has approximately the same probability of accepting 0^n as it does 0^n with the ith bit flipped. Therefore, M cannot compute parity.

We prove the case for $c \geq 1$ via indirect diagonalization. Suppose, by way of contradiction, that

$$\Sigma_2\text{TIME}[n] \subseteq \text{BPTISP}[n^c, n^d] \tag{22}$$

for some constant $d > 0$ to be determined later. Then for any time function $\tau(n)$, Lemma 15 gives us the complementations

$$\Sigma_2\text{TIME}[\tau] \subseteq \Pi_2\text{TIME}\left[\left((\tau^{f_k} + n)^{c+d}\right) \text{polylog}(\tau + n)\right],$$

when $c + 2d \leq 2$ and $d \leq f_k$. Choosing τ so that $\tau(n)^{f_k} \geq n$ allows us to simplify this to

$$\Sigma_2\text{TIME}[\tau] \subseteq \Pi_2\text{TIME}[\tau^{(c+d)f_k} \text{polylog}(\tau)]. \tag{23}$$

The inclusion (23) gives a contradiction with Lemma 6 for any k with $f_k < \frac{1}{c+d}$. Note that $f_k \to 0$ as $k \to \infty$ if $c + 2d < 2$. Therefore, all that remains is to show that the latter condition is compatible with the others, i.e., that we can pick a constant $d > 0$ and an integer $k > 0$ such that

$$c + 2d < 2, \tag{24}$$

$$d \leq f_k, \tag{25}$$

and

$$f_k < \frac{1}{c+d}. \tag{26}$$

For any c and d satisfying (24), consider choosing $k \geq 1$ to be the smallest integer such that (26) is satisfied. Observe that $f_k \geq \frac{c+d}{2} f_{k-1}$, and by how we chose k, $f_{k-1} \geq \frac{1}{c+d}$. This shows that $f_k \geq 1/2$, so (25) is satisfied when $d \leq 1/2$. From (24), we have $d < \frac{2-c}{2}$, which is at most $1/2$ when $c \geq 1$. Therefore, choosing d such that $d < \frac{2-c}{2}$ and then calculating k as described above yields a d and k satisfying all of the constraints, leading to the desired contradiction. As c approaches 1 from above, $\frac{2-c}{2}$ approaches $1/2$ from below, so the largest value of d that yields a contradiction approaches $1/2$ as well. This proves that $\Sigma_2\text{TIME}[n] \not\subseteq \text{BPTISP}[n^c, n^d]$ for such c and d. □

We point out that, although we can handle the same values of c as in the deterministic setting, the dependence of d on c in Theorem 16 is worse. In particular, the proofs of the time-space lower bounds for deterministic machines show that d approaches 1 from below as c approaches 1 from above [9], while in our result d approaches $1/2$ from below as c approaches 1 from above.

The proof of Theorem 16 generalizes to $\Sigma_\ell\text{TIME}[n]$ for any $\ell \geq 3$. In this setting, the hypothesis becomes

$$\Sigma_\ell\text{TIME}[n] \subseteq \text{BPTISP}[n^c, n^d]. \tag{27}$$

Along with the Π_2-simulation of BPTISP$[T, S]$ of Theorem 12, this yields a collapse of the form $\Sigma_\ell \subseteq \Pi_2$, which allows us to eliminate more than one alternation at the same cost of removing one alternation in the setting of Theorem 16, where $\ell = 2$. Therefore, we can afford to use more alternations using (4) and achieve a greater speedup. In a manner analogous to the proof of Theorem 16, we derive a series of increasingly efficient complementations of Σ_ℓ to Π_ℓ for $c < \ell$, eventually reaching a contradiction as long as $d \leq \frac{1}{\sqrt{\ell}}$.

Alternatively, we can use extra alternations to achieve a dependence of d on c, where d approaches 1 from below as c approaches 1 from above, as in the deterministic case. For example, when $\ell = 3$, this follows by deriving a complementation of Σ_3 following the same technique that derives the complementation of Σ_2 given by (18) when $\ell = 2$, modulo the replacement of the Π_2-simulation given by Theorem 12 with the Π_3-simulation given by Theorem 14. Specifically, hypothesis (27) and Theorem 14 give a complementation of Σ_3:

$$\Sigma_3\text{TIME}[n] \subseteq \forall^{n^d \log n}\exists^{n^d \log n}\forall^{\log n}\text{DTISP}[n^c \operatorname{polylog}(n), n^d \log n]. \tag{28}$$

Consider a Σ_3TIME$[\tau]$ computation for some time function τ to be determined. Applying the speedup of (2) to the final deterministic stage of the simulation given by (28) yields

$$\Sigma_3\text{TIME}[\tau] \subseteq \forall^{\tau^d \log \tau} \underbrace{\exists^{\tau^d \log \tau}\Pi_2\text{TIME}[\tau^{\frac{c+d}{2}} \operatorname{polylog}(\tau)]}_{(\alpha)}.$$

We can now use (28) to simulate (α) by a Π_3-machine, yielding a more efficient complementation than (28) for certain values of c and d:

$$\Sigma_3\text{TIME}[\tau] \subseteq \forall^{\tau^d \log \tau}\Pi_3\text{TIME}[(\tau^{\frac{c+d}{2}} + n + \tau^d)^c \operatorname{polylog}(\tau)].$$

When $\tau(n) \geq n^{\frac{2}{c+d}}$ (and $d \leq c$), this simplifies to

$$\Sigma_3\text{TIME}[\tau] \subseteq \Pi_3\text{TIME}[\tau^{c\frac{c+d}{2}} \operatorname{polylog}(\tau)], \tag{29}$$

yielding a contradiction to Lemma 6 when $c < \sqrt{2}$ and $d < \frac{2-c^2}{c}$. Therefore, as c approaches 1 from above, the upper bound on d approaches 1 from below when $\ell = 3$. Indeed, this analysis establishes the desired behavior of d as c approaches 1 for any level $\ell \geq 3$, since if (27) holds for $\ell > 3$, it must also hold for $\ell = 3$.

We point out that we can augment the strategy leading to (28) with a bootstrapping argument similar to the one in the proof of Lemma 15 and obtain increasingly efficient complementations of Σ_3. This approach results in a contradiction for $c < 2$, whereas the analogous approach using Theorem 12 leads to a contradiction for $c < 3$. More generally, at level $\ell \geq 3$, we can modify the above approach to take full advantage of the stronger hypothesis and arrive at complementations of Σ_ℓ. However, we reach a contradiction only for $c < \ell - 1$, whereas the strategy based on Theorem 12 results in a contradiction for $c < \ell$. Therefore, we need *both* approaches to prove Theorem 1—the latter achieves the lower bound for large values of c, while the former establishes the dependence of d on c for small values of c.

Since much of the proof of Theorem 1 closely follows the outline of Theorem 16, we give only a brief sketch of it here. In fact, Theorem 1 also follows from the more

general Theorem 2, which gives time-space lower bounds for simulations of space-bounded linear-time alternating machines. A complete proof of Theorem 2 appears in the next section.

Proof of Theorem 1. The case for $c < 1$ follows by standard techniques, as in the proof of Theorem 16.

For the case $c \geq 1$, assume that $\Sigma_\ell \text{TIME}[n] \subseteq \text{BPTISP}[n^c, n^d]$ for some constant $d > 0$ to be determined later. Using the speedup given by (4) rather than (2), we can step through an argument similar to that of Lemma 15 to show

$$\Sigma_\ell \text{TIME}[T] \subseteq \Pi_\ell \text{TIME}\left[\left((T^{g_k} + n)^{c+d}\right) \text{polylog}(T + n)\right], \tag{30}$$

as long as $c + \ell d \leq \ell$ and $d \leq g_k$, where

$$g_k = \left(\frac{c + \ell d}{\ell}\right)^k. \tag{31}$$

We can now use (30) as we used Lemma 15 in the proof of Theorem 16. For a time function τ such that $\tau(n)^{g_k} \geq n$, (30) gives that

$$\Sigma_\ell \text{TIME}[\tau] \subseteq \Pi_\ell \text{TIME}\left[\tau^{(c+d)g_k}\right],$$

which is a contradiction with Lemma 6 when $g_k < \frac{1}{c+d}$. Therefore, it remains to show that it is possible to choose a positive d and integer k satisfying the latter condition as well as those on (30). More specifically, for $c < \ell$ we can choose $d < \frac{\ell - c}{\ell}$ so that there exists a smallest positive integer k such that $g_k < \frac{1}{c+d}$. Since $g_k = \frac{c+\ell d}{\ell} \cdot g_{k-1} \geq \frac{c+\ell d}{\ell} \cdot \frac{1}{c+d}$, we can guarantee that the only constraint possibly left unsatisfied, namely $d \leq g_k$, is met by restricting our choice of d to $d \leq \frac{c+\ell d}{\ell} \cdot \frac{1}{c+d}$.

When $\ell = 2$, the upper bound on d approaches $\frac{1}{2}$ as c approaches 1. For $\ell \geq 3$, the upper bound on d approaches $\frac{1}{\sqrt{\ell}}$ as c approaches 1, but we can improve it using the combination of the hypothesis and Theorem 14 that leads to the complementation of Σ_3 represented by (29). For large enough τ, this gives a contradiction for values of d approaching 1 from below as c approaches 1 from above when $\ell \geq 3$.

Theorem 8 transfers the lower bounds to QSAT_ℓ. □

6. Other results. In this section, we strengthen Theorem 1 to establish time-space lower bounds for problems decidable by alternating machines that run in linear time and use only a small amount of space. We also prove Theorem 3 regarding time-space lower bounds for tautology on randomized machines with *one-sided* error.

6.1. Sublinear space on linear-time alternating machines. By paying close attention to the space used by the simulations in the proof of Theorem 1, we actually obtain time-space lower bounds for randomized simulations of linear-time alternating machines using space n^a for $a < 1$, given by Theorem 2. The main task is to use the weaker assumption that $\Sigma_\ell \text{TISP}[n, n^a] \subseteq \text{BPTISP}[n^c, n^d]$ to eliminate the alternations introduced by the speedup of (3). This requires that the Σ_k-simulation after the speedup use an amount of space which is at most the ath power of its running time. Since the simulation guesses (and stores) $O(BS)$ bits in each alternating stage, this restricts us to choose a small value of B, which in turn grants a smaller speedup. Therefore, our bounds become weaker as a becomes smaller.

To prove Theorem 2, we first prove an analogue of Lemma 15 which gives a series of complementations of $\Sigma_\ell \text{TISP}$.

LEMMA 17. *Suppose that*

$$\Sigma_\ell \mathrm{TISP}[n, n^a] \subseteq \mathrm{BPTISP}[n^c, n^d] \tag{32}$$

for some integer $\ell \geq 2$ *and constants* $0 < a \leq 1$, $c \geq 1$, *and* $d > 0$ *with* $c + \ell d \leq 1 + (\ell - 1)a$ *and* $(1 - a)d \leq ac$. *Then for any time function* T *and integer* $k \geq 0$ *such that* $d \leq h_k$,

$$\Sigma_\ell \mathrm{TISP}[T, T^a] \subseteq \Pi_\ell \mathrm{TISP}\left[\left((T^{h_k} + n)^{c+d}\right) \mathrm{polylog}(T + n), (T + n)^d \,\mathrm{polylog}(T + n)\right], \tag{33}$$

where

$$h_k = \left(\frac{c + \ell d}{1 + (\ell - 1)a}\right)^k. \tag{34}$$

Proof. The base case $k = 0$ is given by combining hypothesis (32) and the efficient Π_2-simulation of BPTISP given by Theorem 12. We now prove the inductive step $k \to k + 1$. Consider a $\Sigma_\ell \mathrm{TISP}[T, T^a]$ computation. From hypothesis (32), Theorem 12, and the speedup of (3) (to Σ_ℓ rather than Π_ℓ), we obtain a simulation which (neglecting the $\mathrm{polylog}(T + n)$ factors) is in

$$\forall^{(T+n)^d} \underbrace{\Sigma_\ell \mathrm{TISP}\left[B(T + n)^d + \frac{(T + n)^{c+d}}{B^{\ell-1}}, B(T + n)^d\right]}_{(\alpha)}.$$

In order to apply the inductive hypothesis to complete the complementation to $\Pi_\ell \mathrm{TISP}$, the space bound of (α) must be at most the ath power of its running time. This is the case when B satisfies

$$B(T + n)^d = \left(\frac{(T + n)^{c+d}}{B^{\ell-1}}\right)^a,$$

which offers the choice

$$B = (T + n)^{\frac{ac+(a-1)d}{1+(\ell-1)a}}$$

as long as $ac + (a - 1)d \geq 0$. For such a choice, (α) is a computation in

$$\Sigma_\ell \mathrm{TISP}\left[(T + n)^{\frac{c+\ell d}{1+(\ell-1)a}}, (T + n)^{a\frac{c+\ell d}{1+(\ell-1)a}}\right],$$

which takes an input of size $O(n + (T + n)^d)$, which is in $O(n + T^d)$ when $d \leq 1$. Thus, instead of achieving an ℓth root speedup, as we do when we are not concerned about the space used by the simulation of (3), we instead achieve a $(1 + (\ell - 1)a)$th root speedup.

The inductive hypothesis gives a $\Pi_\ell \mathrm{TISP}$-simulation of (α), and hence a $\Pi_\ell \mathrm{TISP}$-simulation of $\Sigma_\ell \mathrm{TISP}[T, T^a]$ running in time big-O of (neglecting the $\mathrm{polylog}(T + n)$ terms)

$$T^* \doteq (T + n)^d + \left((T + n)^{h_k \frac{c+\ell d}{1+(\ell-1)a}} + n + T^d\right)^{c+d}$$

and using space big-O of

$$S^* \doteq (T + n)^d + \left((T + n)^{\frac{c+\ell d}{1+(\ell-1)a}} + n + T^d\right)^d.$$

When $c + \ell d \leq 1 + (\ell - 1)a$ and $d \leq 1$, S^* simplifies to $(T + n)^d$. When we have the further constraint that $d \leq h_{k+1}$, T^* has the appropriate leading terms and simplifies to $(T^{h_{k+1}} + n)^{c+d}$. Accounting for the polylog factors, we have shown that the simulation is of the desired form. □

We note that the proof of Lemma 17 also yields a version in which the Π_ℓ on the right-hand side of (33) is replaced with Π_2. However, we do not see a way to exploit that fact to strengthen our final result. For the sake of clarity and consistency, we present Lemma 17 as stated.

When $c + \ell d < 1 + (\ell - 1)a$, $h_k \to 0$ as $k \to \infty$. In such a case, we can use Lemma 17 to derive a contradiction to Lemma 7 in a fashion analogous to how we used Lemma 15 to prove Theorem 16 for values of c as large as possible. For $\ell = 2$, this gives a value of d approaching $\frac{a}{2}$ from below as c approaches 1 from above. We can do better when $\ell \geq 3$ by using Theorem 14 to derive a space-bounded complementation analogous to that given by (29) in the unrestricted case.

LEMMA 18. *Suppose that*

$$\Sigma_3\text{TISP}[n, n^a] \subseteq \text{BPTISP}[n^c, n^d] \tag{35}$$

for constants $0 < a \leq 1$, $c \geq 1$, *and* $0 < d \leq ac$ *with* $c + d \leq 1 + a$. *Then for any time function* T,

$$\Sigma_3\text{TISP}[T, T^a] \subseteq \Pi_3\text{TISP}[(T^{\frac{c+d}{1+a}} + n)^c \operatorname{polylog}(T + n), (T + n)^d \operatorname{polylog}(T + n)].$$

Proof. Hypothesis (35) and Theorem 14 yield the complementation

$$\Sigma_3\text{TISP}[n, n^a] \subseteq \forall^{n^d \log n} \exists^{n^d \log^2 n} \forall^{\log n} \text{DTISP}[n^c \operatorname{polylog}(n), n^d \log n]. \tag{36}$$

Consider a $\Sigma_3\text{TISP}[T, T^a]$ computation. Padding (36) and applying the speedup of (1) (on the Π_2-side) to the final deterministic stage gives a simulation of $\Sigma_3\text{TISP}[T, T^a]$ which (neglecting the polylog terms) is in

$$\forall^{(T+n)^d} \exists^{(T+n)^d} \underbrace{\Pi_2\text{TISP}[B(T + n)^d + (T + n)^c/B, B(T + n)^d]}_{(\beta)}.$$

Choosing $B = (T + n)^{\frac{ac-d}{1+a}}$ so that the space bound of (β) is the ath power of its running time places the simulation in

$$\forall^{(T+n)^d} \underbrace{\exists^{(T+n)^d} \Pi_2\text{TISP}[(T + n)^{\frac{c+d}{1+a}}, (T + n)^{a\frac{c+d}{1+a}}]}_{(\gamma)},$$

when $d \leq ac$. Under the same condition, (γ) is a computation in $\Sigma_3\text{TISP}[(T + n)^{\frac{c+d}{1+a}}, (T+n)^{a\frac{c+d}{1+a}}]$ taking an input of size $n+(T+n)^d$, so that (36) gives a simulation of (γ) in $\Pi_3\text{TISP}$. Overall we have derived

$$\begin{aligned}
\Sigma_3\text{TISP}[T, T^a] &\subseteq \Pi_3\text{TISP} \quad \left[\left((T + n)^{\frac{c+d}{1+a}} + n + (T + n)^d\right)^c, \right. \\
&\qquad \left. (T + n)^d + \left((T + n)^{\frac{c+d}{1+a}} + n + (T + n)^d\right)^d \right] \\
&\subseteq \Pi_3\text{TISP} \quad [(T^{\frac{c+d}{1+a}} + n)^c, (T + n)^d],
\end{aligned}$$

where the last inclusion follows as long as $d \leq ac$ and $\frac{c+d}{1+a} \leq 1$. Accounting for the polylog$(T + n)$ terms finishes the proof. □

We are now ready to prove Theorem 2.

Proof of Theorem 2. The proof for $c < 1$ follows from standard techniques, as in the proof of Theorem 16.

For the case $c \geq 1$, assume by way of contradiction that $\Sigma_\ell\text{TISP}[n, n^a] \subseteq \text{BPTISP}[n^c, n^d]$ for some constant $d > 0$ to be determined later. Then for a time function τ, where $\tau(n)^{h_k} \geq n$, Lemma 17 gives the complementation

$$\Sigma_\ell\text{TISP}[\tau, \tau^a] \subseteq \Pi_\ell\text{TISP}\left[\tau^{(c+d)h_k}\,\text{polylog}(\tau), \tau^d\,\text{polylog}(\tau)\right] \tag{37}$$

when $c + \ell d \leq 1 + (\ell - 1)a$, $(1 - a)d \leq ac$, and $d \leq h_k$. When $h_k < \frac{1}{c+d}$, the time bound of the right-hand side of (37) is $o(\tau)$. Provided that $c < 1 + (\ell - 1)a$, we can choose a positive d and an integer k such that all the above conditions are met. More specifically, for any value of $d < \frac{1+(\ell-1)a-c}{\ell}$, there exists a smallest positive integer k such that $h_k < \frac{1}{c+d}$. Since $h_k = \frac{c+\ell d}{1+(\ell-1)a} \cdot h_{k-1} \geq \frac{c+\ell d}{1+(\ell-1)a} \cdot \frac{1}{c+d}$, we can guarantee that $d \leq h_k$ by imposing the condition

$$d \leq \frac{c + \ell d}{1 + (\ell - 1)a} \cdot \frac{1}{c + d}. \tag{38}$$

It follows that we can meet all constraints mentioned so far by choosing d below some positive threshold. All that remains to reach a contradiction with Lemma 7 is to ensure that the space bound of the right-hand side of (37) is $o(\tau^a)$, which can be done with the additional constraint on d that $d < a$.

For $\ell = 2$ the upper bound on d approaches $\frac{a}{2}$ from below as c approaches 1 from above. In the case $\ell \geq 3$ the upper bound on d imposed by the conditions other than (38) approaches $\frac{\ell-1}{\ell}a$ as c approaches 1; condition (38) implies an upper bound of $1/\sqrt{\ell}$ for $a = 1$ and a somewhat weaker bound for smaller values of a. However, we can achieve a contradiction for larger d as c approaches 1 and $\ell \geq 3$ using the following argument. For $\tau(n) \geq n^{\frac{1+a}{c+d}}$, Lemma 18 gives

$$\Sigma_3\text{TISP}[\tau, \tau^a] \subseteq \Pi_3\text{TISP}[\tau^{c\frac{c+d}{1+a}}\,\text{polylog}(\tau), \tau^d\,\text{polylog}(\tau)]$$

when $c + d \leq 1 + a$ and $d \leq ac$. When $c < \sqrt{1+a}$, we can choose $d < \min(\frac{(1+a)-c^2}{c}, a)$ and arrive at a contradiction with Lemma 7. As c approaches 1 from above, the upper bound on d approaches a from below, which gives the desired dependence. ∎

6.2. Tautology on randomized machines with one-sided error. In this section, we consider problems in the first level of the polynomial-time hierarchy and establish the time-space lower bounds of Theorem 3 for tautology on randomized machines with one-sided error. To do so, we actually prove time-space lower bounds for a more powerful class of machines, namely nondeterministic machines which are restricted to guess few bits.

THEOREM 19. *There exists positive constants b and d such that tautology cannot be solved by nondeterministic random-access machines which run in time $n^{1.759}\,\text{polylog}(n)$ and space n^d and that nondeterministically guess only n^b bits.*

By way of the space-bounded derandomization of Theorem 11, a space-bounded randomized machine with one-sided error can be made to use very few random bits. Since a randomized machine with one-sided error is also a special type of nondeterministic machine, we can view the one-sided error machines obtained by Theorem 11 as nondeterministic machines which guess very few random bits. Thus, the time-space lower bounds of Theorem 3 follow as a corollary to Theorem 19.

Proof of Theorem 3. Let b^* be the value of b given by Theorem 19, and let d^* be the value of d. By the derandomization of Theorem 11, if tautology can be solved in $\mathrm{RTISP}[n^c, n^d]$, then it can also be solved in $\exists^{n^d \log n}\mathrm{DTISP}[n^c \operatorname{polylog}(n), n^d]$. Thus by Theorem 19, tautology is not in $\mathrm{RTISP}[n^{1.759}, n^d]$ for any $d < \min(b^*, d^*)$. □

We now focus on proving Theorem 19 using the ideas outlined in section 1.2. In this setting, the hypothesis of the indirect diagonalization argument becomes $\mathrm{NTIME}[n] \subseteq \forall^{n^b}\mathrm{DTISP}[n^c, n^d]$. This unlikely scenario certainly yields an efficient complementation, and it is actually strong enough to allow for something more: Under this hypothesis, we can improve the space-bounded speedups of (2) and (4) for certain values of b, c, and d.

LEMMA 20. *Suppose that*

$$\mathrm{NTIME}[n] \subseteq \forall^{n^b}\mathrm{DTISP}[n^c, n^d] \tag{39}$$

for some constants b, $c \geq 1$, and d such that $c + d \leq 2$ and $b \leq c + d - 1$. Then for any time function T, space function S, and integers $i \geq 0$ and $k \geq 2$,

$$\mathrm{DTISP}[T, S] \subseteq \Pi_k\mathrm{TIME}[(TS^{k-1})^{\frac{\gamma_i}{(k-2)\gamma_i+1}} + n + S], \tag{40}$$

where $\gamma_0 = \frac{1}{2}$ and $\gamma_{i+1} = \frac{(c+d)\gamma_i}{(c+d)\gamma_i+1}$.

We point out some facts about the sequence $(\gamma_i)_i$ in order to clearly assess the speedup represented by Lemma 20. From the definition, we can see that $\gamma_{i+1} \leq \gamma_i$ if and only if $\gamma_i \leq \gamma_{i-1}$. It follows that the sequence $(\gamma_i)_i$ is monotonic. Since the transformation $x \mapsto \frac{(c+d)x}{(c+d)x+1}$ has a unique attractive fixed point at $1 - \frac{1}{c+d}$, $(\gamma_i)_i$ converges to this value. Specifically, when $c + d < 2$, this fixed point is less than $\frac{1}{2} = \gamma_0$, so in this case $(\gamma_i)_i$ decreases monotonically to $1 - \frac{1}{c+d}$.

When S is small, Lemma 20 essentially offers a $((k-2) + \frac{1}{\gamma_i})$th-root speedup of a $\mathrm{DTISP}[T, S]$ machine on a Π_k-machine, provided this running time remains at least linear. From the convergence properties of $(\gamma_i)_i$, we can see that this speedup approaches the $(k - 1 + \frac{1}{c+d-1})$th-root as i increases. Recall that the unconditional speedup offered by (4) gives a similar kth-root speedup. Thus, when hypothesis (39) holds for $c + d < 2$, Lemma 20 offers a greater speedup than we had unconditionally.

To prove Lemma 20, we start with the case $k = 2$ by inductively deriving better and better speedups of $\mathrm{DTISP}[T, S]$ into Π_2. For the case $k > 2$, we use $k - 2$ alternations for a speedup as in (3) and then one more alternation to speed up the final deterministic phase in (3) by applying (40) for $k = 2$. An optimal choice of the number of blocks B yields the result.

Proof of Lemma 20. We prove the case $k = 2$ by induction on i. In particular, we need to prove

$$\mathrm{DTISP}[T, S] \subseteq \Pi_2\mathrm{TIME}[(TS)^{\gamma_i} + n + S]. \tag{41}$$

For the base case, (41) holds unconditionally for $i = 0$ by the standard square root speedup of (2). For the inductive step $i \to i+1$, consider a $\mathrm{DTISP}[T, S]$ computation. Using the Π_2-version of the inclusion (1), we speed up this computation in Π_2:

$$\mathrm{DTISP}[T, S] \subseteq \forall^{BS}\underbrace{\exists^{\log B}\mathrm{DTISP}[T/B, S]}_{\text{(i)}}.$$

We can see that (i) represents a computation in nondeterministic time $O(T/B)$ taking an input of length $O(n + BS)$. Thus, hypothesis (39) gives a simulation of (i)

which yields

$$\mathrm{DTISP}[T,S] \subseteq \underbrace{\forall^{BS}\forall^{(T/B+n+BS)^b}}_{\text{(ii)}}\underbrace{\mathrm{DTISP}[(T/B+n+BS)^c,(T/B+n+BS)^d]}_{\text{(iii)}}.$$

Notice that the final space-bounded deterministic stage (iii) takes an input of size $O(n+BS+(T/B)^b)$ provided $b \leq 1$, so that the inductive hypothesis yields a simulation of this stage in

$$\Pi_2\mathrm{TIME}[((T/B+n+BS)^{c+d})^{\gamma_i}+n+BS+(T/B)^b+(T/B+n+BS)^d].$$

Merging the initial universal phase of this simulation with that represented by (ii) and noting that $B \geq 1$, we see that we have arrived at a simulation of $\mathrm{DTISP}[T,S]$ on a Π_2-machine running in time big-O of

$$BS+(T/B+n+BS)^{\max(b,d)}+((T/B+n+BS)^{c+d})^{\gamma_i}+n.$$

To simplify this, notice that when $c+d \leq 2$, we have that $(c+d)\gamma_i \leq 1$ (since $\gamma_i \leq \frac{1}{2}$). If $c \geq 1$, we have $d \leq (c+d)\gamma_i$ (since $\gamma_i \geq 1-\frac{1}{c+d}$). Furthermore, if $b \leq c+d-1$, we have $b \leq (c+d)\gamma_i$ (since $\gamma_i \geq 1-\frac{1}{c+d}$). Under these conditions, the above running time simplifies to big-O of

$$BS+(T/B)^{(c+d)\gamma_i}+n.$$

To minimize this running time up to a constant factor, we choose a value for B such that $BS=(T/B)^{(c+d)\gamma_i}$, namely $B^* \doteq (\frac{T^{(c+d)\gamma_i}}{S})^{1/((c+d)\gamma_i+1)}$. If $B^* \geq 1$, this choice results in a running time in big-O of

$$(TS)^{\frac{(c+d)\gamma_i}{(c+d)\gamma_i+1}}+n=(TS)^{\gamma_{i+1}}+n.$$

On the other hand, if $B^* < 1$, then $B=1$ is the best we can do. This yields a running time of $O(S+n)$. In either case, $O((TS)^{\gamma_{i+1}}+n+S)$ is an upper bound on the running time. By induction, (41) holds for all $i \geq 0$ and b, c, and d as above.

Now that we have established (41), we use it to establish (40) for $k > 2$. The first step is to use (3) to speed up a $\mathrm{DTISP}[T,S]$-machine on a Π_{k-1}-machine. This yields

$$\mathrm{DTISP}[T,S] \subseteq \underbrace{\forall^{BS}\exists^{BS}\cdots Q^{\log B}}_{k-1}\underbrace{\mathrm{DTISP}[T/B^{k-2},S]}_{(\alpha)}, \tag{42}$$

where Q is $\forall$ if k is even, and $\exists$ if k is odd.

We can see that (α) represents a computation taking an input of size $O(n+BS)$ and running in time T/B^{k-2} and space S. Provided b, c, and d satisfy the constraints of the lemma, (41) gives simulations of (α) on Π_2-machines running in time

$$O\left((TS/B^{k-2})^{\gamma_i}+n+BS\right),$$

for $B \geq 1$. Since deterministic classes are closed under complement, we also get simulations on Σ_2-machines running in the same amount of time. Choosing the former if $Q=\forall$ in (42), and the latter otherwise, the alternating stages align properly so that replacing (α) in this manner adds only one alternation. Overall, we arrive at a simulation of $\mathrm{DTISP}[T,S]$ by a Π_k-machine running in the above time bound. To

minimize this running time up to a constant factor, we choose B so that the two terms depending on B are equal. This occurs at the value

$$B^\dagger \doteq (T^{\gamma_i} S^{\gamma_i - 1})^{\frac{1}{(k-2)\gamma_i + 1}}.$$

When $B^\dagger \geq 1$, such a choice yields the running time $O\left((TS^{k-1})^{\frac{\gamma_i}{(k-2)\gamma_i+1}} + n\right)$. If $B^\dagger < 1$, then $B = 1$ is the best we can do and the running time becomes $O(S + n)$. In both cases, we obtain an upper bound of

$$O\left((TS^{k-1})^{\frac{\gamma_i}{(k-2)\gamma_i+1}} + n + S\right)$$

on the running time, which proves the claim. □

We now use a bootstrapping argument to derive a series of increasingly efficient complementations of the linear-time hierarchy at higher and higher levels. At each level, the improved speedup granted by Lemma 20 for sufficiently small b and d allows a more efficient complementation than the unconditional speedup of (4), which is key to obtaining quantitatively stronger lower bounds.

LEMMA 21. *For any constants $1 \leq c < 2$, $\epsilon > 0$, and integer $\ell \geq 2$, there exist positive constants b and d such that if*

$$\text{NTIME}[n] \subseteq \forall^{n^b}\text{DTISP}[n^c, n^d], \tag{43}$$

then

$$\Sigma_\ell\text{TIME}[n] \subseteq \Pi_\ell\text{TIME}[n^{c_\ell + \epsilon}], \tag{44}$$

where

$$c_\ell = \begin{cases} c(c-1) & \text{for } \ell = 2, \\ \frac{c^2(c-1)\prod_{j=2}^{\ell-1} c_j}{(\ell-1)(c-1)+1} & \text{otherwise.} \end{cases} \tag{45}$$

Closed forms for the exponent c_ℓ defined by (45) become rather complex. One can show by induction that

$$c_\ell = \frac{c^{3\cdot 2^{\ell-3}}(c-1)^{2^{\ell-2}}}{((\ell-1)(c-1)+1)\cdot\prod_{k=3}^{\ell-1}((k-1)(c-1)+1)^{2^{\ell-k-1}}}$$

for $\ell > 2$.

Proof of Lemma 21. Let c and ϵ be given. We argue by induction that we can choose b and d appropriately so that (43) yields the desired inclusion. For $\ell = 2$, we use the hypothesis to obtain a DTISP simulation of $\Sigma_2\text{TIME}[n]$ when $b \leq c$:

$$\begin{aligned}\Sigma_2\text{TIME}[n] = \exists^n\forall^n\text{DTIME}[n] &\subseteq \exists^n\exists^{n^b}\text{DTISP}[n^c, n^d] \subseteq \text{NTIME}[n^c] \\ &\subseteq \forall^{n^{bc}}\text{DTISP}[n^{c^2}, n^{cd}].\end{aligned}$$

The input to the final deterministic stage is of size $n + n^{bc}$, so applying Lemma 20 to simulate this stage yields

$$\Sigma_2\text{TIME}[n] \subseteq \forall^{n^{bc}}\text{DTISP}[n^{c^2}, n^{cd}] \subseteq \Pi_2\text{TIME}[(n^{c(c+d)})^{\gamma_i} + n + n^{bc} + n^{cd}].$$

As $i \to \infty$, the exponent $c(c+d)\gamma_i \to c(c+d-1)$. For d such that this limit is at most $c(c-1)+\frac{\epsilon}{2}$, we can choose i large enough so that the exponent is at most $c(c-1)+\epsilon$. Under the additional constraints $b, d \leq c-1$, the running time becomes $O(n^{c(c-1)+\epsilon}+n)$. Therefore, when $c(c-1)+\epsilon \geq 1$, we have the desired inclusion. In fact, this is the only case we need to consider, for if $c(c-1)+\epsilon < 1$, we can find $a > 1$ such that $ac(c-1)+\epsilon = 1$ and apply the above argument to $\Sigma_2\text{TIME}[n^a]$. This yields the inclusion $\Sigma_2\text{TIME}[n^a] \subseteq \Pi_2\text{TIME}[n]$, which contradicts Lemma 6. Therefore, the claim holds for $\ell = 2$.

Now suppose that for $2 \leq k < \ell$, $\Sigma_k\text{TIME}[n] \subseteq \Pi_k\text{TIME}[n^{c_k+\epsilon'}]$ for an ϵ' to be determined later. Let $b_{k,\epsilon'}$ and $d_{k,\epsilon'}$ denote the appropriate values of b and d given by the inductive hypothesis for the complementation at Σ_k to hold. To show that the desired complementation holds for Σ_ℓ, we first derive a simulation of such a computation in $\forall^n\text{DTISP}[n^{O(1)}, n^d]$ and then use Lemma 20 to achieve a faster simulation in Π_ℓ.

We accomplish the former by iteratively deriving simulations one level lower in the polynomial-time hierarchy. At step $j = 0, \ldots, \ell-3$, we start with a $\Sigma_{\ell-j}$-machine and use a complementation given by the inductive hypothesis to obtain a simulation by a $\Sigma_{\ell-j-1}$-machine. This follows by complementing the computation following the initial existential stage of the $\Sigma_{\ell-j}$-machine, which is a $\Pi_{\ell-j-1}$-computation. Thus, when the hypothesis holds for $b \leq b_{\ell-j-1,\epsilon'}$ and $d \leq d_{\ell-j-1,\epsilon'}$, we derive a simulation with one less alternation while raising the running time to the power of $c_{\ell-j-1}+\epsilon'$. This lets us write

$$\begin{aligned}\Sigma_\ell\text{TIME}[n] &\subseteq \Sigma_{\ell-1}\text{TIME}[n^{c_{\ell-1}+\epsilon'}]\\ &\subseteq \Sigma_{\ell-2}\text{TIME}[n^{(c_{\ell-1}+\epsilon')(c_{\ell-2}+\epsilon')}]\\ &\cdots\\ &\subseteq \Sigma_2\text{TIME}[n^{(c_{\ell-1}+\epsilon')(c_{\ell-2}+\epsilon')\cdots(c_2+\epsilon')}].\end{aligned}$$

Defining $C_{\ell,\epsilon'} \doteq (c_{\ell-1}+\epsilon')(c_{\ell-2}+\epsilon')\cdots(c_2+\epsilon')$ and applying hypothesis (43) twice to the latter simulation (as in the base case), we obtain the desired simulation:

$$\Sigma_\ell\text{TIME}[n] \subseteq \underbrace{\forall^{n^{bcC_{\ell,\epsilon'}}}}_{(\alpha)}\underbrace{\text{DTISP}[n^{c^2C_{\ell,\epsilon'}}, n^{cdC_{\ell,\epsilon'}}]}_{(\beta)}.$$

The input to (β) is of size $O(n+n^{bcC_{\ell,\epsilon'}})$, so applying Lemma 20 to this stage and absorbing the universal stage (α) gives

$$\Sigma_\ell\text{TIME}[n] \subseteq \Pi_\ell\text{TIME}[\underbrace{(n^{c(c+(\ell-1)d)C_{\ell,\epsilon'}})^{\frac{\gamma_i}{(\ell-2)\gamma_i+1}}}_{(*)} + n + \underbrace{n^{bcC_{\ell,\epsilon'}}+n^{cdC_{\ell,\epsilon'}}}_{(**)}], \tag{46}$$

for small enough b and d and any integer $i \geq 0$. When d is yet further restricted, the exponent of the term $(*)$ approaches $\frac{c^2(c-1)C_{\ell,\epsilon'}}{(\ell-1)(c-1)+1}+\frac{\epsilon}{4}$ as i grows. This allows the choice of i large enough, so this exponent is at most $\frac{\epsilon}{4}$ away from its limit point, namely at most $\frac{c^2(c-1)C_{\ell,\epsilon'}}{(\ell-1)(c-1)+1}+\frac{\epsilon}{2}$. We next choose ϵ' small enough so that all of the terms in the exponent of $(*)$ involving ϵ' sum to at most $\frac{\epsilon}{2}$. Under these circumstances, an upper bound for the exponent of $(*)$ is

$$\frac{c^2(c-1)C_{\ell,\epsilon'}}{(\ell-1)(c-1)+1}+\frac{\epsilon}{2} \leq \frac{c^2(c-1)\prod_{i=2}^{\ell-1}c_i}{(\ell-1)(c-1)+1}+\epsilon = c_\ell+\epsilon.$$

When we also have $b, d \leq \frac{c(c-1)}{(\ell-1)(c-1)+1}$, the term $(*)$ dominates $(**)$, so the Π_ℓ-simulation represented by (46) runs in time $O(n^{c_\ell+\epsilon} + n)$. When $c_\ell + \epsilon \geq 1$, this shows that (44) holds for b and d small enough to meet all of the above constraints. This is the only case we need to consider, since $c_\ell + \epsilon < 1$ results in a contradiction to Lemma 6 by applying the above argument to $\Sigma_\ell \mathrm{TIME}[n^a]$ for an appropriate $a > 1$ (as in the step for $\ell = 2$). □

Lemma 21 gives a series of complementations which are increasingly unlikely and eventually contradict Lemma 6 for certain values of c. We obtain Theorem 19 by analyzing the behavior of the sequence of exponents c_ℓ defined by (45).

Proof of Theorem 19. (See page 22 for the statement.) For any integer $\ell \geq 2$, consider c_ℓ defined by (45) as a function of c. One can show by induction on ℓ that c_ℓ monotonically grows from $c_\ell = 0$ at $c = 1$ to infinity. By continuity, there exists a unique value c_ℓ^* at which c_ℓ equals 1. For values $c < c_\ell^*$, Lemma 21 gives a contradiction to Lemma 6 for a choice of ϵ small enough such that $c_\ell + \epsilon < 1$. Thus, we can rule out simulations of NTIME$[n]$ in $\forall^{n^b}\mathrm{DTISP}[n^c, n^d]$ for all $c < c_\ell^*$ and b, d given by Lemma 21.

By (45), we have that at $c = c_\ell^*$,

$$c_{\ell+1} = \frac{c_{\ell+1}}{c_\ell} = \left(1 - \frac{1}{\ell + \frac{1}{c-1}}\right) \cdot c_\ell < 1.$$

The monotonicity of $c_{\ell+1}$ then implies that $c_{\ell+1}^* > c_\ell^*$; i.e., the sequence $(c_\ell^*)_\ell$ increases. Numerical calculations show that $c_{14}^* \approx 1.759708$ and $c_{15}^* \approx 1.759719$, which is enough to prove the claimed lower bound of $n^{1.759}\,\mathrm{polylog}(n)$. □

7. Further research. The techniques discussed in this work allow us to establish time-space lower bounds for QSAT_ℓ on two-sided error randomized machines for $\ell \geq 2$. They do not seem to extend to the first-level problems of satisfiability or tautology in a straightforward way. This is due only to our inability to exploit the assumption NTIME$[n] \subseteq \mathrm{BPTISP}[t, s]$ to obtain an efficient complementation at some level of the polynomial-time hierarchy. Thus, establishing time-space lower bounds for satisfiability on randomized machines with two-sided error remains open.

We employed and further developed a technique from [24] to improve the known lower bounds for satisfiability on deterministic machines. The original technique also leads to improved lower bounds for QSAT_ℓ with $\ell \geq 2$ on deterministic machines. For example, it allows the boosting of the time lower bound for QSAT_2 on deterministic subpolynomial-space machines from n^2 [9] to $n^{2.761}$ [24]. Although we were able to find purchase in adopting these techniques to establish better lower bounds for randomized machines with one-sided error, we have been unable to adopt them to improve our results for machines with two-sided error. As a next step, we suggest finding a way to extend the improved lower bounds for QSAT_ℓ with $\ell \geq 2$ on deterministic machines to randomized machines with two-sided error.

Appendices. We now prove some results on the complexity of Nisan's generator (Theorem 11) and on deterministic amplification by random walks on a Gabber–Galil expander graph (Lemma 13).

Appendix A. Nisan's generator. Theorem 11 follows from an analysis of a time- and space-efficient implementation of Nisan's pseudorandom generator using fast Fourier transform (FFT) multiplication methods to quickly evaluate and invert linear hash functions. In fact, we prove a somewhat stronger version of Theorem 11.

THEOREM 22. *Any randomized machine M running in time T and space S with error ϵ can be simulated by another randomized machine that runs in time $O(T \log^2 S \log\log S)$ and space $O(S \log T)$ and that uses only $O(S \log T)$ random bits. If two-way access to the random bits is allowed, the space requirement is reduced to $O(S)$. The error of the simulation is $\epsilon + 2^{-S}$ and is one-sided if M has one-sided error.*

Theorem 22 gives a tighter time bound than the bound of $O(T \operatorname{polylog}(T))$ stated in Theorem 11. Our arguments in sections 5 and 6 are not noticeably improved by using the tighter bound stated in Theorem 22, so we use the simpler bounds of Theorem 11 there for clarity. We state the tighter bound here because it may be of independent interest.

Before proving Theorem 22, we introduce Nisan's pseudorandom generator [20] and discuss some of its properties. Define

$$G_{m,k} : \{0,1\}^m \times H_m^k \to (\{0,1\}^m)^{2^k},$$

where H_m is a family of two-universal hash functions $h : \{0,1\}^m \to \{0,1\}^m$ [4]. The evaluation of $G_{m,k}$ is defined recursively as

$$G_{m,k}(y, h_1, \ldots, h_k) = \begin{cases} y & \text{if } k = 0, \text{ else,} \\ G_{m,k-1}(y, h_1, \ldots, h_{k-1}) \circ G_{m,k-1}(h_k(y), h_1, \ldots, h_{k-1}), \end{cases}$$

where "$\circ$" denotes concatenation. Given a randomized machine M running in time T and space S, we define $G \doteq G_{m,k}$ for $k = \log \frac{T}{m}$, where $m = \Theta(S)$ will be determined later. The simulation of M proceeds with the output of G as the random string, one block of length m at a time. Nisan proves that G fools M in the following sense.

THEOREM 23 (Nisan [20]). *There exists a constant ν such that if M is a randomized machine running in time T and space S on input x, then for $m \geq \nu \cdot S$ and $k = \log \frac{T}{m}$,*

$$\left| \Pr_r[M(x,r) \text{ accepts}] - \Pr_{y,h_1,\ldots,h_k}[M(x, G_{m,k}(y, h_1, \ldots, h_k)) \text{ accepts}] \right| \leq 2^{-S},$$

where $M(x,r)$ denotes the outcome of running M on input x and random string r.

This satisfies the error requirements of Theorem 22, so all that remains to prove Theorem 22 is to show how to simulate M on the random string $G(y, h_1, \ldots, h_k)$ within the correct bounds on the time, space, and randomness.

We start with the standard simulation that computes G in a blockwise fashion, where each subsequent m-bit block is computed after m simulation steps of M using the current block. One way to do this is to compute each block from scratch, namely, apply the appropriate sequence of at most k hash functions to the m-bit seed y. Although this technique is good enough to derive our main results, we can do slightly better, namely by a factor of $O(\frac{\log S}{\log(T/S)})$. This improvement follows by computing each block in a recursive manner, which avoids the calculations that the "from scratch" method does over and over again. We now work out the details of our simulation to complete the proof of Theorem 22.

Proof of Theorem 22. To accommodate the approach described above, we choose $m = \Theta(S)$ such that $m \geq \nu \cdot S$ and is of the form $2 \cdot 3^q$ for some integer $q \geq 0$. The latter guarantees a simple explicit formula for an irreducible polynomial of degree m over GF(2), namely $z^{2 \cdot 3^q} + z^{3^q} + 1$ [16, Thm. 1.1.28, p. 13]. We choose H_m to be the set of all invertible linear mappings from GF(2^m) to GF(2^m), i.e., all functions of the

form $x \mapsto ax+b$ where $a, b \in \mathrm{GF}(2^m)$ and $a \neq 0$ [4].[2] Such functions can be described by $2m$ bits, so that the input to G can be described by $(2k+1)m = O(S \log T)$ bits. This meets the requirements on the randomness.

To reach the desired time and space bounds, we must be able to evaluate the functions in H_m much faster than the naive bound of $O(m^2)$. Using FFT multiplication techniques based on those of Schönhage and Strassen and exploiting the sparseness of the above irreducible polynomial, we can evaluate $h \in H_m$ in time $O(m \log m \log\log m)$ and space $O(m)$. These fast multiplication techniques can be combined with the extended Euclidean algorithm to invert $h \in H_m$ in time $O(m \log^2 m \log\log m)$ and space $O(m)$. See [11, Cor. 11.8, p. 319] for more details. We use these algorithms to output the blocks of $G_{m,k}(y, h_1, \ldots, h_k)$ recursively with small space overhead. Specifically, we define the procedure P_m which uses global registers containing $k \geq 0$, $y \in \{0,1\}^m$, and $h_1, h_2, \ldots, h_k \in H_m$ to perform the following steps:

1. **If** $k > 0$:
2. $k \leftarrow k-1$;
3. Recursively **call** P_m;
4. $y \leftarrow h_{k+1}(y)$;
5. Recursively **call** P_m;
6. $y \leftarrow h_{k+1}^{-1}(y)$; $k \leftarrow k+1$ and **return**.
7. **Else output** y and **return**.

The output of $P_m(k, y, h_1, \ldots, h_k)$ is exactly $G_{m,k}(y, h_1, \ldots, h_k)$. Evaluating P_m takes 2^k recursive calls, each accompanied by an evaluation of h_i or h_i^{-1}. Thus, the overall time complexity to output $G_{m,k}$ is $O(2^k \cdot m \log^2 m \log\log m)$. By replacing y with $h_k(y)$ instead of writing down $h_k(y)$ separately on the worktape, only a constant amount of space overhead is required for each level. Thus, the space requirement is $O(m+k)$. For the settings of G, $m = O(S)$, and $k = \log \frac{T}{S} + O(1)$, the time becomes $O(T \log^2 S \log\log S)$, while the space is $O(S + \log \frac{T}{S})$, which is $O(S)$ since $T \leq 2^S$ without loss of generality. This assumes that the hash functions can be accessed repeatedly, so there is an additional space cost of $O(S \log T)$ to copy the hash functions from the random tape to the worktape, bringing the space bound to $O(S \log T + S) = O(S \log T)$. However, if the simulation has two-way access to the random tape, this cost is avoided.

Our simulation runs M for $O(S)$ steps every time P_m outputs a block of G, for a total of T steps while using space S. Thus, the above time and space bounds for computing G hold for the simulation as a whole. □

Appendix B. Deterministic amplification. We now prove Lemma 13, beginning with a brief discussion of some properties of the amplification given by Theorem 10. Let M be a randomized machine that runs in time T and space S and that uses R random bits. We may assume that M has an error of at most some small constant δ to be determined later, since this can be achieved with only a constant overhead from a machine with any error bounded away from $1/2$. The amplified machine M' given by Theorem 10 interprets its random string r' of length $O(R)$ as an initial vertex in a Gabber–Galil graph followed by $O(R)$ edge labels (of constant size) specifying the edges on a walk in the graph. Formally, this graph is described as follows.

DEFINITION 24 (Gabber–Galil graph [10]). *The Gabber–Galil graph* $\mathrm{GG}(m)$ *is a graph with vertices* $\mathbb{Z}_m \times \mathbb{Z}_m$ *of degree* 5 *where the vertices adjacent to* $(x, y) \in$

[2] Excluding the noninvertible functions ($a = 0$) introduces a small bias. Although our family H_m is not perfectly two universal, it is close enough for our purposes.

$\mathbb{Z}_m \times \mathbb{Z}_m$ are the five pairs (x', y') obtained from the matrix multiplication $[x', y', 1]^T = A_i[x, y, 1]^T$ (over $\mathbb{Z}_m$) for $1 \le i \le 5$, where

$$A_1 = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}, \quad A_2 = \begin{bmatrix} 1 & 0 & 0 \\ 1 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}, \quad A_3 = \begin{bmatrix} 1 & 0 & 0 \\ 1 & 1 & 1 \\ 0 & 0 & 1 \end{bmatrix},$$
$$A_4 = \begin{bmatrix} 1 & 1 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}, \quad A_5 = \begin{bmatrix} 1 & 1 & 1 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}.$$

We now state a useful lemma which says that the vertex at the end of a path of length p in $\mathrm{GG}(2^k)$ can be found in time quasilinear in p and k, an improvement on the naive bound of $O(pk)$. We leave the proof for later.

LEMMA 25. *Given a vertex (x, y) of the graph $\mathrm{GG}(2^k)$ and a path π of length p indicated by edge labels $(e_1, e_2, \ldots, e_p)$, where $1 \le e_i \le 5$ for $1 \le i \le p$, the vertex connected to (x, y) by π can be determined in time $O(m \operatorname{polylog}(m))$ and space $O(m)$ where $m = k + p$.*

For the purposes of Theorem 10, the vertices of the Gabber–Galil graph must be described by R bits corresponding to the possible random strings for M. To this end, we choose $\mathrm{GG}(2^{R/2})$. Given input x and random string r', M' proceeds by deterministically carrying out the walk of length $p = O(R)$ on $\mathrm{GG}(2^{R/2})$ indicated by r'. Every β steps, where β is some constant, M' simulates M on input x and a random string corresponding to the label of the current vertex on the walk. M' accepts if a majority of these trials accept. As each edge relation can be computed by simple arithmetic in time $O(R)$ and space $O(R)$, and running M requires time T and space S, M' runs in time $O(R^2 + RT) = O(RT)$ and space $O(R + S)$. Cohen and Wigderson [5] and Impagliazzo and Zuckerman [13] show that when β is large enough and M has error smaller than some constant δ, the trials specified by a randomly chosen r' are close enough to uniform so that M' errs only with probability 2^{-R}. This establishes Theorem 10.

We now prove Lemma 13, giving a more time-efficient manner to determine if M' accepts on x and r' at the cost of using alternations.

Proof of Lemma 13. To arrive at Lemma 13, we show how to use alternations to verify if there is a majority of trials on the walk given by the random string r' where M accepts, in such a way that the final deterministic phase need only to simulate M once. Specifically, given input x and random string r', we can express the acceptance condition of M' as

$$(\exists Z \subseteq \{1, 2, \ldots, R'\}, |Z| = \lceil R'/2 \rceil)(\forall i \in Z) M(x, r_i) \text{ accepts}, \tag{47}$$

where R' is the number of trials of M specified by r', and r_i is the random string produced for the ith trial. Observe that this describes a Σ_2-computation which accepts if and only if M' accepts. The initial existential phase guesses the characteristic string of the set Z consisting of $\lceil R'/2 \rceil$ indices of the R' trials, for a total of $R' = O(R)$ bits. The universal phase guesses $\log R' = O(\log R)$ bits to determine the index of a trial to verify. The final deterministic stage must first determine r_i and then run M on input x and random string r_i. Once the former has been computed, the latter task takes time T and space S. Since r_i corresponds to the label of the (βi)th vertex on the walk in $\mathrm{GG}(2^{R/2})$ specified by r', Lemma 25 shows that r_i can be computed in time $O(R \operatorname{polylog}(R))$. Therefore, the final deterministic stage takes

time $O(T + R\,\mathrm{polylog}(R))$ and space $O(R + S)$. All told, we have shown that (47) is a computation in

$$\exists^R \forall^{\log R} \mathrm{DTISP}[T + R\,\mathrm{polylog}(R), R + S],$$

which accepts if and only if M' accepts. This completes the proof. □

All that remains is to establish Lemma 25, which follows from a divide-and-conquer strategy to efficiently evaluate a product of p matrices A_i.

Proof of Lemma 25. Throughout this proof, we use the fact that multiplication of b-bit integers can be done in time $O(b\,\mathrm{polylog}(b))$ and space $O(b)$. This follows from the FFT techniques of Schönhage and Strassen [11, Thm. 8.24, p. 240]. Let

$$A \doteq A_{e_p} A_{e_{p-1}} \cdots A_{e_1}.$$

Then the vertex (x', y') connected to (x, y) by π satisfies $[x', y', 1]^T = A[x, y, 1]^T \bmod 2^k$. Therefore, computing (x', y') reduces to computing A and multiplying by the vector $[x, y, 1]^T$ modulo 2^k.

We accomplish the latter with a divide-and-conquer strategy. Namely, we split the product approximately in half and recursively compute the subproducts $A_{e_p} A_{e_{p-1}} \cdots A_{e_{\lfloor p/2 \rfloor + 1}} \doteq B$ and $A_{e_{\lfloor p/2 \rfloor}} A_{e_{\lfloor p/2 \rfloor - 1}} \cdots A_{e_1} \doteq C$. It can be shown by induction that any product of p matrices A_i has entries bounded by 2^{p-1}, since each column of any matrix A_i has at most two nonzero entries, which are ones. This shows that once B and C are computed, A can be computed as $A = BC$ by $O(1)$ multiplications and additions of integers of bit length $p/2$, so we require time $O(p\ \mathrm{polylog}(p))$ in addition to the recursive calls. Thus, by following this strategy, we can see that at each recursive call to compute the product of q matrices, we solve two subproblems of size $q/2$ and do an additional amount of work which is quasilinear in q and uses space $O(q)$. Thus, A can be computed in total time $O(p\,\mathrm{polylog}(p))$ and space $O(p)$.

By our observation on the size of the product matrix entries, we also know that the entries of the matrix A are at most 2^{p-1}. Therefore, computing the product $A[x, y, 1]^T$ and reducing modulo 2^k can be done in time $O(m\,\mathrm{polylog}(m))$ and space $O(m)$ as desired. □

We point out that another natural way to arrive at Theorem 14 is to use expander walks to generate the shift vectors for Lautemann's simulation in lieu of amplifying the confidence of the simulated algorithm as above. While the effect of the latter is to reduce the *number* of shift vectors needed, the former allows a large number of "good" shifts to be described by *very few bits*. Briefly, the hitting property of expanders guarantees that the shifts satisfy the needed property (i.e., the shifts of the accepting set cover the entire set of random strings) with approximately the same probability when they are chosen by a random walk on a Gabber–Galil graph as when they are chosen independently. Thus, we can generate a set of $O(R)$ good shifts in the initial stage of the simulation with only $O(R)$ bits. Furthermore, each shift can be computed efficiently by Lemma 25, so we can avoid the $O(R)$ blowup in the running time of the final deterministic stage by using an additional alternation to verify that M accepts on some shift. This approach leads to a simulation that matches the parameters of Theorem 14.

Acknowledgments. We would like to thank Bess Berg as well as the anonymous referees of ICALP 2005 and SIAM for their helpful comments. We are grateful to Emanuele Viola for pushing us to optimize the space parameter in Theorems 1 and 2.

INFINITELY-OFTEN AUTOREDUCIBLE SETS*

RICHARD BEIGEL†, LANCE FORTNOW‡, AND FRANK STEPHAN§

Abstract. A set A is autoreducible if one can compute, for all x, the value $A(x)$ by querying A only at places $y \neq x$. Furthermore, A is infinitely-often autoreducible if, for infinitely many x, the value $A(x)$ can be computed by querying A only at places $y \neq x$. For all other x, the computation outputs a special symbol to signal that the reduction is undefined. It is shown that for polynomial time Turing and truth-table autoreducibility there are A, B, C in the class EXP of all exponential-time computable sets such that A is not infinitely-often Turing autoreducible, B is Turing autoreducible but not infinitely-often truth-table autoreducible and C is truth-table autoreducible with $g(n)+1$ queries but not infinitely-often Turing autoreducible with $g(n)$ queries. Here n is the length of the input, g is nondecreasing, and there exists a polynomial p such that $p(n)$ bounds both the computation time and the value of g at input of length n. Furthermore, connections between notions of infinitely-often autoreducibility and notions of approximability are investigated. The Hausdorff-dimension of the class of sets which are not infinitely-often autoreducible is shown to be 1.

Key words. algorithmic randomness, autoreducible sets, infinitely-often autoreducible sets, computational complexity, exponential-time computable sets, Hausdorff-dimension

1. Introduction.

Consider a set where every element is chosen independently at random. Intuitively the membership of x should not depend on the membership of the other elements. Indeed, random sets are not *autoreducible*; that is, it is impossible to compute for every x the membership of x from the membership of the $y \neq x$. Ebert [12, 13] gives the surprising result that one can nevertheless compute correctly the membership of an infinite number of elements of a random set from the membership of the other ones. The present work extends the study of this notion, called *infinitely-often autoreducible*.

Trakhtenbrot [24] introduced in the recursion theoretic context the notion of autoreducibility. There are many natural examples of autoreducible sets; for example, any index set B of partial recursive functions is autoreducible: By the Padding Lemma there is a recursive strictly increasing function p such that, for all x, $\varphi_x = \varphi_{p(x)}$. It follows that one can for given x compute the value $p(x)$ which is different from x and query whether $p(x) \in B$. As $\varphi_x = \varphi_{p(x)}$, one has that $x, p(x)$ are either both

in B or both outside B and thus one knows whether $x \in B$. Other natural examples of autoreducible sets are retraceable sets, cylinders, creative sets like the halting problem, semirecursive sets, and recursive sets; see Odifreddi [20] for the definitions of these types of sets. On one hand, autoreducible sets are quite common and there are even nonrecursive Turing degrees containing only autoreducible sets [15]. On the other hand, Trakhtenbrot [24] constructed recursively enumerable sets which are not autoreducible.

The notion of autoreducibility can easily be carried over to resource-bounded reducibilities r such as polynomial time Turing reducibility.

DEFINITION 1.1. *A set is r-autoreducible iff there is an r-reduction that computes for every x the value $A(x)$ from the oracle A without querying A at x.*

For example, a many-one EXP-complete set A satisfies that A is many-one reducible to $\overline{A}$ via some function f; that is, $A(x) = \overline{A}(f(x)) = 1 - A(f(x))$. This guarantees that $f(x) \neq x$ for all x. So one has that A is autoreducible by a polynomial time Turing reduction which asks exactly one query: What is A at $f(x)$? Knowing this, the Turing reduction defines $A(x) = 1 - A(f(x))$.

In the present work, polynomial time truth-table and Turing reducibility are considered where the number of questions might also be bounded. Truth-table reducibility is different from Turing reducibility in the sense that the place of the nth query does not depend on the oracle's answers to previous queries and one can compute an explicit polynomially sized list of places queried. So the oracle is queried at many places in parallel, and afterwards its answers are used by the program of the truth-table reduction without any further interaction with the oracle.

Also in complexity theory there are many natural examples of autoreducible sets. The set SAT is truth-table autoreducible with two queries: If ϕ is any formula with the variable u built in, then the derived formulas $\phi[u \to 0]$ and $\phi[u \to 1]$, where u has been replaced by the logical constants 0 and 1, respectively, are different from ϕ, and one can compute with two queries to SAT whether these formulas are satisfiable. Then ϕ is satisfiable iff at least one of the formulas $\phi[u \to 0]$ and $\phi[u \to 1]$ is. By the way, Schnorr [23] studied this special case where the autoreduction goes to instances shorter than the original input and called a set self-reducible if it has such an autoreduction. Buhrman et al. [11] showed that the Turing complete sets for EXP are Turing autoreducible, while some of the Turing complete sets for the class EEXPSPACE of all sets which are, for some polynomial p, computable in space $2^{2^{p(n)}}$, fail to have this property. It is unknown whether all sets that are Turing complete for EEXP are autoreducible; settling this open question would separate some complexity classes which are not yet known to be different.

Random sets are not autoreducible, but Ebert [12, 13] showed that they satisfy the following surprising variant, called infinitely-often autoreducible.

DEFINITION 1.2. *A set A is infinitely-often r-autoreducible iff there is an r-reduction M which at input x queries A only at places $y \neq x$. For infinitely many x, M computes $A(x)$ correctly; for all other x, M is undefined and signals this by outputting a special symbol.*

The result that random sets are infinitely-often autoreducible has received a lot of attention. Not only because one would not expect that it is possible to make predictions about the membership of x in a random set by looking at which other y are in, but also because Ebert [12] introduced for his proof a mathematical puzzle which was easy to understand, became famous, and had some interest in its own right: the hat problem. It was the topic of several newspaper articles, for example, in the

German weekly newspaper *Die Zeit* [10] and in the *New York Times* [22].

It is already well known that there are sets which are not infinitely-often autoreducible [7], but these examples are outside EXP, the class of all exponential time computable sets. EXP is the first deterministic time class known to contain nondeterministic polynomial time NP and polynomial space PSPACE. Therefore, it is natural to study the structure of the sets inside EXP and the main result of the present work, given in section 2, says that there is a set A in EXP which is not infinitely-often Turing autoreducible. In section 3, the major autoreducibility notions are separated by showing that there are sets in EXP which are autoreducible for the first reduction but not infinitely-often autoreducible by the second reduction; this is done in particular for Turing versus truth-table and for truth-table with $g(n)+1$ queries versus Turing with $g(n)$ queries. This second result implies the separation of truth-table versus bounded truth-table. In section 4, the relations between notions of approximability and infinitely-often autoreducibility are investigated. Finally, in section 5, it is shown that there are a lot of sets in EXP which are not autoreducible: The class of these sets has Hausdorff-dimension 1 in exponential time.

NOTATION 1.3. *The notation follows standard textbooks in recursion theory such as that of Odifreddi* [20] *with some exceptions: The function* $x \mapsto \log(x)$ *denotes the logarithm of basis* 2 *with the exception that* $\log(q) = 0$ *for* $q < 1$ *in order to avoid to deal with too many exceptions in logarithmic expressions. The term* $\log^*(x)$ *denotes the number of iterations of* log *necessary to reach a number strictly below* 1. *So,* $\log^*(0) = 0$, $\log^*(1) = 1$ *and* $\log^*(2^x) = \log^*(x)+1$. *A set* D *is called* supersparse *iff, for all* x, $D \cap \{x, x+1, \ldots, 2^x\}$ *contains at most* $\log^*(x)$ *elements.* $A\Delta D$ *denotes the symmetric difference of* A *and* D*; the set* $A\Delta D$ *is called a* supersparse variant of A *if* D *is a supersparse set. Furthermore, the notation* $O(f)$ *is generalized to* $Poly(f)$ *which is the set of all* g *such that there is a polynomial* p *with (for all* n*)* $[g(n) \leq p(f(n))]$.

2. Some set in EXP is not infinitely-often autoreducible. Note that a computation is exponential in the length (= logarithm) of x iff it is quasi-polynomial in x itself. Therefore one considers in the case of functionals quasi-polynomial time bounds. More precisely, a partial functional f which assigns to inputs of the form $A(0)A(1)\ldots A(x)$ values $a_{x+1}a_{x+2}\ldots a_y$ is called a quasi-polynomial time extension functional iff there is a constant c permitting one to compute the extensions in time $x^{\log^c(x)}$. Following Lutz [17], one can introduce the following notion of resource-bounded genericity; see [1, 3, 5, 6, 7, 18, 19] for further background on notions of resource-bounded genericity, measure and dimension.

DEFINITION 2.1. *A set* A *is general generic iff, for every quasi-polynomial time computable functional* f*,*

- *either* $f(A(0)A(1)\ldots A(x))$ *is undefined for almost all* x
- *or there are* x, y *such that* $x < y$, $f(A(0)A(1)\ldots A(x)) = a_{x+1}a_{x+2}\ldots a_y$ *and* $A(z) = a_z$ *for* $z = x+1, x+2, \ldots, y$.

So, either "A *almost always avoids* f*" or "*A *meets* f*."*

General generic sets have to be distinguished from the weaker variant of generic sets as introduced by Ambos-Spies, Fleischhack and Huwig [2], which either meet or avoid every quasi-polynomial time extension functional which predicts only one bit whenever defined. Balcázar and Mayordomo [7] observed that these sets are not infinitely-often autoreducible.

FACT 2.2 (see [7]). *There are sets which are not infinitely-often autoreducible. In particular, general generic sets have this property.*

On the other hand, Ambos-Spies, Neis and Terwijn [5] showed that the notions

of generic sets and resource-bounded randomness are compatible. As random sets are infinitely-often autoreducible (even infinitely-often truth-table autoreducible) [12, 13], there are some generic sets which are infinitely-often autoreducible, and Fact 2.2 really needs the stronger version of general generic sets.

General generic sets cannot be in EXP due to the quasi-polynomial time bound. The following result shows that sets which are not infinitely-often autoreducible can be found in EXP. Note that many-one EXP-complete sets are (everywhere) autoreducible since they are many-one equivalent to their complement. Buhrman et al. [11] showed that every Turing EXP-complete set is autoreducible.

THEOREM 2.3. *There is a set in EXP which is not infinitely-often autoreducible with respect to Turing reducibility.*

Proof. Let $M_0, M_1, \ldots$ be an enumeration of all polynomial time autoreductions such that each M_e needs at most time $x + e$ at input x and queries the set A only at places $y \leq 2^x$ with $y \neq x$. Note that x is superpolynomial in $\log(x)$ and therefore, all polynomial time autoreductions are covered. The set A is constructed by a priority construction and satisfies at the end for every e one of the following two possibilities:

- There is a number x such that $M_e^A(x)$ outputs $b \in \{0, 1\}$ with $b \neq A(x)$.
- For almost every x, $M_e^A(x)$ is undefined.

The eth requirement is then the first of these two conditions. The construction will be such that it either satisfies the eth requirement explicitly or enforces the second condition implicitly.

The construction uses approximations A_x of A where $A_x(y) = A(y)$ for all x, y with $y < x$. So one has to simulate the construction only $x + 1$ stages to know the value of A at x. Together with a proof that every stage needs time exponential in the length of x, it follows that $A \in \text{EXP}$.

Construction of A. Let A_x and $r_{e,x}$ be the values of A and r_e before stage x, in particular, $A_0 = \emptyset$ and $r_{e,0} = 0$ for all x.

In stage x one searches the least e such that there is a finite set D satisfying the following requirements, where D is the set of the positions for which it is intended that A_{x+1} and A_x will differ:

Bound on e: $e \leq \log^*(x)$.

Respecting restraints: $r_{e',x} < x$ for all $e' \leq e$.

Requirement e not yet done: There is no number $x' < x$ such that $M_e^{A_x}(x')$ queries A_x only at places below x and computes a wrong prediction for $A(x')$.

Requirement e needs attention: $M_e^{A_x \Delta D}(x)$ computes a prediction different from $(A_x \Delta D)(x)$, where $A_x \Delta D$ denotes the symmetric difference of A_x and D.

Size-constraint on D met: $D \subseteq \{x, x + 1, x + 2, \ldots, 2^x\}$ and D has at most $2^{-e-2} \cdot \log^*(x) - 2e$ elements.

If the above procedure finds an e (which is the minimal one possible) and D is the corresponding set mentioned above, then

$$\begin{aligned} A_{x+1} &= A_x \Delta D; \\ r_{e,x+1} &= 2^x + 2; \\ r_{e',x+1} &= r_{e',x} \quad \text{for all } e' \neq e; \end{aligned}$$

else nothing changes; that is, $A_{x+1} = A_x$ and $r_{e',x+1} = r_{e',x}$ for all e'.

Verification. One first notes that in stage x the search considers only $\log^*(x)$ values of e and for each of these, the search runs over computations which make at most $x + e$ queries where at most $2^{-e-2} \cdot \log^*(x) - 2e$ of the answers can differ from the current values of A_x as these queries hit elements in D. Thus, for each e, there

are $O(x^{\log^*(x)})$ possible computation paths. As $\log^*(x) \leq \log(x+2)$, the running time of step x of the algorithm is quasi-polynomial in x, that is, exponential in $\log(x)$. As $A(x) = A_{x+1}(x)$, it follows that one can compute $A(x)$ by running the algorithm for the stages $0, 1, \ldots, x$ and thus the overall running time is quasi-polynomial in x; that is, $A \in \mathrm{EXP}$.

Note that for sufficiently large x the bound $2^{-e-2} \cdot \log^*(x) - 2e$ becomes positive as e is a constant and $\log^*(x)$ is unbounded. Therefore, cardinality requirements do not hinder Requirement e from being satisfied for sufficiently large x.

By usual priority arguments, one can show that every e is found only finitely often by the search algorithm and that $r_{e,x}$ converges from below to a final value $r_{e,\infty}$. More precisely, every $r_{e,x}$ changes only if the parameter e is selected in the search at stage x. One can show by induction that this happens only finitely often for all e. Assume that all $r_{e',\infty}$ with $e' < e$ exist and have maximum $\tilde{r}_e$. If e is not selected in the search at any $x > \tilde{r}_e$, then $r_{e,x}$ changes only finitely often and converges to some value $r_{e,\infty}$. If e is selected at some $x > \tilde{r}_e$, then the following happens. A_{x+1} is updated such that the autoreduction $M_e^{A_{x+1}}(x)$ returns a wrong value and queries A_{x+1} only at places smaller than $2^x + 1$. Furthermore, as at no $x' > x$ does the search select an $e' < e$, the restraint $r_{e,x+1}$ will be respected and the diagonalization of the autoreduction $M_e^{A_{x+1}}$ will not be undone by changing A at queried places; that is, $A_x(y) = A(y)$ for all values y queried by $M_e^{A_{x+1}}(x)$. Thus Requirement e will be counted as "done" at all stages $x' > x$ and therefore e will not be selected again by the search condition at those stages. Thus $r_{e,\infty} = 2^x + 2$.

Now it is shown that A is not infinitely-often autoreducible. Consider any autoreduction M_e which does not make any false prediction for A but might be undefined for some inputs. Let x be so large that $2^{-e-2} \cdot \log^*(x) - 2e > 2$ and $x > r_{e',\infty}$ for all $e' \leq e$. So the search does not return any $e' \leq e$ as otherwise the corresponding restraint would be increased again. It follows that $M_e^B(x)$ does not predict any value for input x on any set B of the form $A_x \Delta D$ with $|D| \leq 2^{-e-2} \cdot \log^*(x) - 2e - 1$ and $D \subseteq \{x, x+1, \ldots, 2^x\}$ (note that the search in the algorithm actually covers sets D with up to $2^{-e-2} \cdot \log^*(x) - 2e$ elements, but this one additional element might be needed to make the prediction be different from $(A_x \Delta D)(x)$). On the other hand, it might happen that up to $\log^*(x)$ requirements $e' > e$ act between stages x and 2^x. Due to the update rule of the restraints, each of them acts only once between these stages. Furthermore, each e' changes A at up to $2^{-e'-2} \cdot \log^*(2^x) - 2e' \leq 2^{-e'-2} \cdot \log^*(x) - 2e - 1$ positions between x and 2^x. The symmetric difference of A and A_x contains below x no element and between x and 2^x at most $2^{-e-2} \cdot \log^*(x) - 2e - 1$ elements. Thus, $M_e^A(x)$ also does not predict any value for $A(x)$ and M_e^A is undefined for almost all inputs. □

3. On truth-table autoreducibility. The topic of this section is the interrelation of autoreducibility notions with respect to truth-table reducibility, Turing reducibility and the variants of these reducibilities where the number of queries is bounded. It is shown that only the trivial implications hold and that all differences between the notions can be witnessed by sets in EXP. Theorem 3.2 in particular shows that there is a set in EXP which is $\mathrm{tt}(n+1)$-autoreducible but not infinitely-often $\mathrm{Turing}(n)$-autoreducible, where n is the logarithm (= length) of the input, $\mathrm{tt}(n+1)$ means that the truth-table reduction is permitted to make up to $n+1$ queries and $\mathrm{Turing}(n)$ means that the Turing reduction is permitted to make up to n queries. This implies that this set is tt-autoreducible but not btt-autoreducible.

The proof of the following theorem uses Kolmogorov complexity arguments to

construct a starting set A_0 which is Turing but not tt-complete for EXP. Watanabe [25] first constructed such a set; his ideas are also based on Kolmogorov complexity arguments.

THEOREM 3.1. *There is a set A in EXP which is Turing autoreducible but not infinitely-often tt-autoreducible.*

Proof. The construction is a modification of the one from Theorem 2.3 with the following two differences:

- The set A_0 is not empty but a set which is Turing complete (but not tt-complete) for EXP.
- Furthermore, $M_0, M_1, \ldots$ is a list of all polynomial time truth-table autoreductions which satisfy the same side conditions as in Theorem 2.3; that is, for any oracle X, $M_e^X(x)$ is computed in time $e+x$ and X is queried only at places $y \leq 2^x$ which are different from x.

The choice of A_0 is sensitive to the success of the construction because it must be guaranteed that one can compute all elements queried by M_e. This is done by placing the more difficult elements at positions which can be accessed by an adapted search but not by a nonadaptive truth-table reduction.

First take a sequence $b_0 b_1 \ldots$ of bits which is random for computations using computation time 2^{n^3} but can be computed in time 2^{n^6} and then let B be the set of all numbers of the form $2^n + \sum_{m<n} 2^m \cdot b_m$. B is in EXP. Furthermore, let C be a set which is many-one EXP-complete and contains 0. The set A_0 is then given by

$$A_0 = \{\langle b, c, d\rangle : b \in B, c \in C, c \leq b, d \in \mathbb{N}\}.$$

Now one uses that the eth truth-table autoreduction M_e queries at most x places and thus any query of it has at most Kolmogorov complexity $\log(e) + \log(x) + k$ for a constant k where the Kolmogorov complexity is measured with respect to time bound x^3. It follows that every $\langle b, c, d\rangle$ queried satisfies that b also has this bound (plus perhaps a constant) and that, whenever $\langle b, c, d\rangle$ is in A_0, then $b = 2^n + \sum_{m<n} 2^m \cdot b_m$ for some $n \leq 3(\log(x) + \log(e) + k')$, and $c \leq b$ where k' is a suitable constant independent of e, x. Thus the algorithm to compute all the values of A_0 at places queried by M_e at x with $e \leq \log^*(x)$ is exponential in x, and this gives that the set A is also in EXP.

The construction gives that A is not infinitely-often tt-autoreducible in the same way as the construction in Theorem 2.3 gives that the set constructed there is not infinitely-often Turing autoreducible. It remains to show that in this theorem the set A is Turing autoreducible.

Note that for fixed b, c and the two-thirds majority of the numbers $y = \langle b, c, d\rangle$ with $0 \leq d \leq 3\log^*(b+c)+6$ satisfies that $A(y) = A_0(y)$. Thus one can reduce every query whether $\langle b, c, 0\rangle \in A_0$ to polynomially many queries to A (omitting the query to x if it is among these queries) and thus it is sufficient to give in the construction below the queries to A_0.

- For input x, compute the c such that $A(x) = C(c)$. This can be done without querying an oracle as C is many-one EXP-complete.
- For every $b \in B$, there is an n such that $b = 2^n + \sum_{m<n} 2^m \cdot b_m$. Then one of the following numbers is the next element of B: $b + 2^n, b + 2^{n+1}$—the first one in case $b_n = 0$, the second one in case $b_n = 1$. Thus one can find for each member of B the next member of B by two queries to B and starting with 1, which is the minimum of B, one can find a $b \geq c$ such that $b \in B$ with $2\log(c) + 2$ queries to B. Since $b \in B$ iff $\langle b, 0, 0\rangle \in A_0$, this computation can also be done with the same number of queries to A_0.

- Having this $b \geq c$ such that $b \in B$, one can determine $A(x)$ with one query to A_0 as $x \in A$ iff $\langle b, c, 0\rangle \in A_0$.

The so constructed algorithm is a Turing autoreduction as the size $\log(c)$ of c is polynomially bounded in the size $\log(x)$ of x. Furthermore, as $3\log^*(b+c)+6 \leq 3\log(b+c)+12$, the number of queries to A is only by a factor polynomial in x greater than the number of queries to A_0 and thus the whole algorithm queries A only polynomially often. One can easily verify that the running time of the algorithm is also polynomial. □

THEOREM 3.2. *For every polynomial time computable and nondecreasing function $g \in Poly(n)$, there is a set A in EXP such that A is tt$(g(n)+1)$-autoreducible but not infinitely-often Turing$(g(n))$-autoreducible.*

Proof. Let $M_0, M_1, \ldots$ be a list of all polynomial time Turing$(g(n))$-autoreductions such that every value $M_e(x)$ can be computed in time $e+x$ and M_e queries only places below 2^x which are different from x. Furthermore, one can produce a polynomial time computable partition Π of almost all natural numbers with the following properties:

- There is an integer m such that $x \in I$ for some $I \in \Pi$ iff $x \geq 2^m$; that is, $\cup_{I\in\Pi} I = \{2^m, 2^m+1, \ldots\}$.
- For every $I \in \Pi$ there is an integer $n(I)$ such that all numbers $x \in I$ satisfy $n(I) \leq \log(x) < n(I)+1$.
- The cardinality of every $I \in \Pi$ is either $g(n(I))+2$ or $2g(n(I))+3$.

As $g \in Poly(n)$, one can find an m such that $2(g(n)+2)^2 < 2^n$ holds for all $n \geq m$. For each $n \geq m$, one can find a, b such that $2^n = a(g(n)+2)-b$ and $0 \leq b \leq g(n)+1$. Note that $a > 2b$ and thus one can partition the set $\{2^n, 2^n+1, \ldots, 2^{n+1}-1\}$ into b intervals of length $2g(n)+3$ followed by $a-2b$ intervals of length $g(n)+2$ and put these intervals into Π. The number $n(I)$ is for these intervals exactly the n with $I \subseteq \{2^n, 2^n+1, \ldots, 2^{n+1}-1\}$ and the numbers $0, 1, \ldots, 2^m-1$ do not belong to any interval.

Now given $I \in \Pi$, let $L(I)$ denote the $g(n(I))+2$ smallest and $H(I)$ the $g(n(I))+2$ largest elements in I. The overall construction of the set A will be such that for every interval $I \in \Pi$ the cardinalities of $L(I) \cap A$ and $H(I) \cap A$ are both even. Therefore one has the following tt$(g(n)+1)$-autoreduction for A.

- If $x < 2^m$, then output "$x \notin A$" and halt.
- Otherwise find the $I \in \Pi$ with $x \in I$.
- If $x \in L(I)$, then query the $g(n)+1$ elements in $L(I)-\{x\}$ and let a be the cardinality of $A \cap (L(I)-\{x\})$; else query the $g(n)+1$ elements in $H(I)-\{x\}$ and let a be the cardinality of $A \cap (H(I)-\{x\})$.
- If a is odd, then output "$x \in A$"; else output "$x \notin A$."

This reducibility is definitely a tt$(g(n)+1)$-autoreduction, can be done in time polynomial in $\log(x)$ and is correct since the cardinalities of $L(I) \cap A$ and $H(I) \cap A$ are even.

It remains to show that one can choose in exponential time the set A such that the resulting set is not infinitely-often Turing$(g(n))$-autoreducible. The construction is done in stages.

Construction. If $x < 2^m$, then let $A_{x+1} = \emptyset$ and $r_{e,x} = 0$ for all e. If $x \geq 2^m$, then determine the interval I with $x \in I$. Search for the least e such that there is a set D satisfying the following conditions:

Bound on e: $e \leq \log(x+1)$.

Respecting restraints: $r_{e',x} < \min(I)$ for all $e' \leq e$.

Requirement e not yet done: There is no $x' < x$ such that $M_e^{A_x}(x')$ is defined,

queries only places below $\min(I)$ and outputs something different from $A_x(x')$.

Requirement e needs attention: $M_e^{A_x \Delta D}(x)$ is defined and differs from $(A_x \Delta D)(x)$.

D not too large: D intersects only intervals J which contain either x or a $y > x$ queried by the $M_e^{A_x \Delta D}(x)$. Furthermore, $\min(I) \leq \min(D \cup \{x\})$, $\max(D \cup \{x\}) \leq 2^x$ and the sets $L(J) \cap D$ and $H(J) \cap D$ have an even number of elements for every interval $J \in \Pi$.

If the above procedure finds an e (which is the minimal one possible) and D is the corresponding set mentioned above, then

$$\begin{aligned} A_{x+1} &= A_x \Delta D; \\ r_{e,x+1} &= 2^x + 2; \\ r_{e',x+1} &= r_{e',x} \quad \text{for all } e' \neq e; \end{aligned}$$

else nothing changes; that is, $A_{x+1} = A_x$ and $r_{e',x+1} = r_{e',x}$ for all e'.

Verification. The set A is in EXP as the search in every stage goes through only exponentially many possibilities ($e \leq \log(x+1)$ and at most $g(\log(x)) + 2$ queries by M_e where g is polynomially bounded). Furthermore, every set D has on every interval of the form $L(I)$ and $H(I)$ an even number of elements so that the resulting set A has the same property: $A \cap L(I)$ and $A \cap H(I)$ have an even number of elements.

It follows from standard priority arguments that every e is found only finitely often by the above search conditions and that the restraints $r_{e,x}$ eventually all take a final value $r_{e,\infty}$.

Now assume that M_e^A never outputs an incorrect value. Consider any x in an interval $I \in \Pi$ such that $\min(I) > \max(\{r_{0,\infty}, r_{1,\infty}, \ldots, r_{e,\infty}\})$. Assume by way of contradiction that $M_e^A(x)$ is defined. Let E be the union of all intersections $J \cap (A_x \Delta A)$ where J contains either x or a $y > x$ which is queried by $M_e^A(x)$. Note that for all intervals J, $L(J) \cap E$ and $H(J) \cap E$ have an even number of elements. Furthermore, $A_x \Delta E$ and A coincide on all relevant elements; thus $M_e^{A_x \Delta E}(x) = A(x)$.

Let l and h be elements of I different from x and not queried by $M_e^{A_x \Delta E}(x)$ such that $l \in L(I)$, $h \in H(I)$, and both sets $\{l, h, x\} \cap L(I)$ and $\{l, h, x\} \cap H(I)$ have even cardinality; note that $L(I) = H(I) = I$ and $l = h$ in the case that I has $g(n) + 2$ elements. It follows from easy cardinality arguments that l, h exist. Now let $D = E \Delta \{l, h, x\}$. The autoreduction M_e behaves at x for the sets $A_x \Delta E$ and $A_x \Delta D$ exactly in the same way, but the output is wrong in the case that one considers $A_x \Delta D$. So, this e witnessed by this D or some $e' < e$ would qualify for the search in stage x, which contradicts the restraints $r_{0,\infty}, r_{1,\infty}, \ldots, r_{e,\infty}$ being below x in the limit. From this contradiction it follows that $M_e^A(x)$ is undefined for almost all x.

So, A is in EXP and A is $\mathrm{tt}(g(n) + 1)$-autoreducible but not infinitely-often $\mathrm{Turing}(g(n))$-autoreducible. □

An autoreduction is a bounded truth-table reduction iff there is a constant k such that the reduction makes for every input at most k queries. If a set A is $\mathrm{tt}(n+1)$-autoreducible but not infinitely-often $\mathrm{Turing}(n)$-autoreducible, then A is clearly tt-autoreducible but not infinitely-often btt-autoreducible. This gives the following corollary.

COROLLARY 3.3. *There is a set in EXP that is truth-table autoreducible but not infinitely-often bounded truth-table autoreducible.*

4. Notions of approximability. A set is called (a, b)-recursive iff there is a function f such that for all distinct $x_1, x_2, \ldots, x_b$ the function f computes a tuple $(y_1, y_2, \ldots, y_b)$ of bits such that at least a of the equations $A(x_k) = y_k$ are true. If

there are a, b such that $1 \leq a \leq b$ and if there is a polynomial time computable function f such that A is (a, b)-recursive via f, then A is called approximable [9] and if, in addition, $2a > b$, then A is called easily approximable.

In the recursion theoretic setting, every set which is $(1, b)$-recursive for some b is also autoreducible [16]. This does not carry over to complexity theory: Returning to the world of polynomial time computations, supersparse sets are $(1, 2)$-recursive but not Turing autoreducible. Supersparse sets are related to k-cheatable sets [8]. Nevertheless, approximable sets are still infinitely-often autoreducible.

PROPOSITION 4.1. *Every approximable set is infinitely-often btt-autoreducible.*

Proof. Assume that A is approximable via f and let l be the largest constant such that for infinitely many inputs of the form $x+1, x+2, \ldots, x+k$ at least l of the bits $y_1, y_2, \ldots, y_k$ are wrong. Let u be so large that it never happens for an $x > u$ that more than l of these bits are wrong. Now A is btt-autoreducible as follows.

Algorithm. Ignore inputs $x < u + k$. For $x \geq u + k$ query A at all numbers x' with $x - k < x' < x + k$ and $x' \neq x$. If there is an x' with $x - k \leq x' < x$ such that the answers $y_1, y_2, \ldots, y_k$ computed by f from input $x'+1, x'+2, \ldots, x'+k$ satisfy that $y_{k'} \neq A(x' + k')$ for l numbers $k' \in \{1, 2, \ldots, k\} - \{x - x'\}$, then predict $y_{x-x'}$ for $A(x)$; else do not make any prediction.

Verification. The correctness follows from the fact that there are at most l differences between $A(x' + k')$ and $y_{k'}$ and that these errors have been localized at places different from x. That this reduction works for infinitely many x is a consequence of the choice of l. □

Ogihara [21] also considered sets which are $(1, b(n))$-recursive, where b is a function in $Poly(n)$ and the parameter n is $\log(\max\{1, x_1, x_2, \ldots, x_b\})$, where $x_1, x_2, \ldots, x_b$ is the input to the function to compute the approximation. This generalized notion no longer enforces that A is infinitely-often autoreducible.

EXAMPLE 4.2. *The set from Theorem* 2.3 *satisfies Ogihara's generalized approximability condition but is not infinitely-often Turing autoreducible.*

Proof. It is sufficient to show that the set A constructed in Theorem 2.3 is $(1, b(n))$-recursive with $b(n) = 6\log^*(n) + 3$: On input $x_1, x_2, \ldots, x_{b(n)}$, let

$$y_k = \begin{cases} 0 & \text{if } x_k > \log\log(n), \\ A(x_k) & \text{if } x_k \leq \log\log(n), \end{cases}$$

and predict $(y_1, y_2, \ldots, y_{b(n)})$. If $x_k \leq \log\log(n)$, then $A(x_k) = y_k$ and this prediction is correct. Otherwise one knows that between $\log\log(n)$ and n the set A has at most $6\log^*(n) + 2$ elements. It follows that at least one of the predicted 0's is correct. Furthermore, the computations involved can all be done in polynomial time since $A(x_k)$ can be computed in time $2^{Poly(\log\log(n))}$ whenever $x_k \leq \log\log(n)$. □

An easily approximable set A has the property that every set B Turing reducible to A is also tt-reducible to A. This property is called *T-easy*. The next theorem shows that every T-easy set is either infinitely-often autoreducible or satisfies Ogihara's generalized approximability notion with $a = 1$ and $b = \log^2(n)$.

THEOREM 4.3. *Every set A satisfies at least one of the following properties.*

(a) *Not T-easy: There is a set B which is polynomial time Turing reducible but not polynomial time truth-table reducible to A.*
(b) *Infinitely-often truth-table autoreducible: For infinitely many z, $A(z)$ can be computed by queries to places different from z.*
(c) *Generalized approximable: A is $(1, 1 + \log^2(n))$-recursive via some function computable in polynomial time.*

Proof. Let A be any set. Furthermore, define a tuple-function which at input $x_1, x_2, \ldots, x_m$ computes the binary representations $u_0, u_1, \ldots, u_m$ of these numbers and outputs a number, denoted as $\langle x_1, x_2, \ldots, x_m \rangle$, which has the ternary representation $u_1 2 u_2 2 \ldots 2 u_m 2$. Note that $\langle x_1, x_2, \ldots, x_m \rangle > x_k$ for $k = 1, 2, \ldots, m$. Furthermore, $n = \log(\max\{1, x_1, x_2, \ldots, x_m\})$ satisfies $\langle x_1, x_2, \ldots, x_m \rangle < 3^{(n+3)m}$. Let $y(x_1, x_2, \ldots, x_m : A)$ be the number which is represented by the binary string $A(x_1)A(x_2)\ldots A(x_n)$. Depending on what type of reducibilities exists from

$$B = \{\langle x_1, x_2, \ldots, x_m \rangle : \langle x_1, x_2, \ldots, x_m, y(x_1, x_2, \ldots, x_m : A)\rangle \in A\}$$

to A, one of three properties holds:

(a) B is not truth-table reducible to A. Then A *is not T-easy*. This is verified by showing that B is Turing reducible to A as follows: One first queries whether $x_1, x_2, \ldots, x_m \in A$, then computes $y(x_1, x_2, \ldots, x_m : A)$ and at last queries whether $\langle x_1, x_2, \ldots, x_m, y(x_1, x_2, \ldots, x_m : A)\rangle$ is in A.

(b) B is truth-table reducible to A by a reduction which for infinitely many tuples $\langle x_1, x_2, \ldots, x_m \rangle$ computes $B(\langle x_1, x_2, \ldots, x_m \rangle)$ without querying A whether $\langle x_1, x_2, \ldots, x_m, y(x_1, x_2, \ldots, x_m : A)\rangle$ is in A. Then A *is infinitely-often truth-table autoreducible* by f defined as follows: Let $F(x)$ denote the set of queries which the truth-table reduction from B to A makes at input x. On input z, f checks whether there are a set E and numbers $m, x_1, x_2, \ldots, x_m$ such that

- $z = \langle x_1, x_2, \ldots, x_m, y(x_1, x_2, \ldots, x_m : E)\rangle$ and
- $z \notin F(E(x_1)E(x_2)\ldots E(x_m)) \cup \{x_1, x_2, \ldots, x_m\}$.

If so, then f queries A at the members of the set $F(\langle x_1, x_2, \ldots, x_m \rangle) \cup \{x_1, x_2, \ldots, x_m\}$ and outputs the result of the truth-table reduction from B to A computed for the value $B(\langle x_1, x_2, \ldots, x_m \rangle)$ in the case that $A(x_1) = E(x_1), \ldots, A(x_m) = E(x_m)$. If z is not of the above form or if the supposed values of E do not coincide with A or $z \in F(\langle x_1, x_2, \ldots, x_m \rangle)$, then $f(z)$ is undefined. Note that whenever $f(z)$ is defined, the value computed coincides with $A(z)$ and f does not query $A(z)$ as $x_1, x_2, \ldots, x_m < \langle x_1, x_2, \ldots, x_m, y(x_1, x_2, \ldots, x_m : E)\rangle = z$ and $z \notin F(E(x_1)E(x_2)\ldots E(x_m))$.

(c) The two previous cases do not hold. Then A *is* $(1, b(n))$*-recursive with* $b(n) = 1 + \lfloor \log^2(n) \rfloor$. As (a) does not hold, there is a tt-reduction from B to A. Let $F(x)$ be the set of queries made at input x. There is a constant c such that the cardinality of $F(x)$ is at most $\log^c(x)$ for almost all x. If n is sufficiently large and $x = \langle x_1, x_2, \ldots, x_m \rangle$ with $x_1 < x_2 < \ldots < x_m$ and $n = \lfloor \log(x_m) \rfloor$ and $m = b(n)$, then the following facts hold: $y(x_1, x_2, \ldots, x_m : A) \in F(\langle x_1, x_2, \ldots, x_m \rangle)$ as (b) does not hold, $n > m$, and $(\log(3) \cdot m \cdot (n+3))^c < n^{4c} < n^{\log(n)}$. As $2^m > n^{\log(n)}$, it follows that there is a number y with binary representation $d_1 d_2 \ldots d_m$ such that $\langle x_1, x_2, \ldots, x_m, y \rangle \notin F(\langle x_1, x_2, \ldots, x_m \rangle)$. Thus at least one of the conditions $A(x_1) \neq d_1, A(x_2) \neq d_2, \ldots, A(x_m) \neq d_m$ holds and A is $(1, b(n))$-recursive by outputting the vector $(1 - d(x_1), 1 - d(x_2), \ldots, 1 - d(x_m))$. The remaining case is where n is too small. But there are only finitely many $x_1, x_2, \ldots, x_m$ where this can happen and one can output the characteristic vector $(A(x_1), A(x_2), \ldots, A(x_m))$ in these finitely many cases. One can easily verify that the proposed algorithm runs in polynomial time and thus A is $(1, b(n))$-recursive. □

5. Hausdorff-dimension. Hausdorff [14] introduced a generalized notion of dimension for metric spaces; it also enables one to measure the size of fractal objects. Lutz [19] adapted the notion for complexity theory in order to measure the size of subclasses of the natural numbers. The following definition—one among several equivalent ones—defines the Hausdorff-dimension in terms of the growth rate of the capital

accumulated by a gambler who bets inductively on the bits of the characteristic functions of any set in the given class. Such growth rate functionals are called martingales.

DEFINITION 5.1. *A quasi-polynomial time computable functional f is called a* martingale, *iff it maps binary strings to positive numbers and the empty string to* 1 *and satisfies*

$$2f(a_0a_1\dots a_x) = f(a_0a_1\dots a_x0) + f(a_0a_1\dots a_x1)$$

for all binary strings $a_0a_1\dots a_x$. The Hausdorff-dimension *(with respect to EXP) of a class S is the infimum of all s such that there is a quasi-polynomial time computable martingale f succeeding on every set in $A \in S$ with growth rate 2^{1-s}; that is, f satisfies*

$$(\textit{for all } A \in S)\,(\exists^\infty x)\,[f(A(0)A(1)\dots A(x)) \geq 2^{(1-s)x}].$$

REMARK 5.2. *The class of all sets as well as the class EXP has Hausdorff-dimension* 1. *The upper bound is witnessed by the martingale mapping all strings to* 1, *and the lower bound is obtained by constructing for any given quasi-polynomial martingale f the set A in EXP which satisfies for $x = 0, 1, \dots$ that*

$$f(A(0)A(1)\dots A(x)A(x+1)) \leq f(A(0)A(1)\dots A(x));$$

that is, $A(x+1)$ takes just the value adversary to $A(x)$. Note that in EXP one cannot have one set doing this for all martingales due to the fact that every single set in EXP is predictable by a suitable quasi-polynomial time computable martingale. There are also sets A that are random for all quasi-polynomial time computable martingales and thus satisfy that the Hausdorff-dimension of $\{A\}$ is 1, *but no such A is in EXP.*

Ambos-Spies et al. [4, Corollary 16] considered the Hausdorff-dimension adapted to the class $E = \{A : (\exists c)\,(\exists M)\,(\text{for all } x)\,[M \text{ computes } A(x) \text{ in time } c + x^c]\}$. They showed that the class of many-one autoreducible sets in E has Hausdorff-dimension 1. This fact directly carries over to EXP.

FACT 5.3. *The class $\{A \text{ in EXP: } (\textit{for all } x)\,[A(x) = A(x^2)]\}$ consists only of many-one autoreducible sets and has Hausdorff-dimension* 1. *In particular, the classes of the many-one autoreducible, truth-table autoreducible and Turing autoreducible sets in EXP have Hausdorff-dimension* 1.

An interesting obvious question is to determine the Hausdorff-dimension of the class S of those sets in EXP which are not infinitely-often r-autoreducible. The next theorem shows that the Hausdorff-dimension is already 1 for the case of the polynomial time Turing reducibility; it then also follows for the other polynomial time reducibilities r. As every set which is x^3-random is already infinitely-often autoreducible [12, 13], the class S is a natural example of a class which has Hausdorff-dimension 1 and measure 0 with respect to quasi-polynomial time martingales.

THEOREM 5.4. *The class of all sets in EXP that are not infinitely-often autoreducible has Hausdorff-dimension* 1.

Proof. The basic idea of the proof is to use the same construction as in Theorem 2.3. But one has to make the following changes. One has to construct for every quasi-polynomial time martingale f such a set A. Furthermore, for given f, A_0 has to be chosen such that f does not have a fast growth rate either on A_0 or on any supersparse variant of A_0. In particular the supersparse variant A of A_0 will satisfy that there is no $s < 1$ with $(\exists^\infty x)\,[f(A(0)A(1)\dots A(x)) \geq 2^{(1-s)\cdot x}]$. Furthermore, A_0

has to be chosen such that not only A_0 itself but also the A constructed from A_0 is in EXP.

To meet these constraints, one chooses the polynomial time Turing reductions $M_0, M_1, \ldots$ in a bit more restrictive way than in Theorem 2.3; namely the M_e have to satisfy the following properties:

- $M_e^X(x)$ queries any given oracle X at up to $(\log(x))^{\log\log(x)}$ places; these places are below 2^x and different from x.
- $M_e^X(x)$ needs at most running time $e + (\log(x))^{\log\log(x)}$.

Note that the bound $(\log(x))^{\log\log(x)}$ is superpolynomial and thus one has, starting with a given reduction, only to modify it on finitely many inputs, where one can put the correct result into a table so that no query is necessary at all. Thus whenever A is infinitely-often autoreducible, then A is infinitely-often autoreducible by some M_e.

As f might behave very differently on A compared to on A_0, one has to define A_0 such that the growth rate of f does not only on A_0 but also on all supersparse variants of A_0 fail to reach 2^{1-s} for any $s < 1$.

So one considers the following functional f': Let r_D be the product of all $1 + 1/(1 + d \cdot d)$, where $d \in D$, $r_\emptyset = 1$. Now $f'(B(0)B(1)\ldots B(x))$ is the sum over all terms $r_D \cdot f(C(0)C(1)\ldots C(x))$, where $C \subseteq \{0, 1, \ldots, x\}$, $D = \{y \leq x : B(y) \neq C(y)\}$ and D is a supersparse set. The functional f' is no longer a martingale, but it satisfies the following condition:

$$f'(a_0a_1\ldots a_x0) + f'(a_0a_1\ldots a_x1) \leq 2 \cdot \tfrac{2+(x+1)\cdot(x+1)}{1+(x+1)\cdot(x+1)} \cdot f'(a_0a_1\ldots a_x).$$

Now one defines the set A_0 inductively as follows. $A_0(0) = 0$. $A_0(x+1) = 0$ iff one of the following two conditions holds and $A_0(x+1) = 1$ otherwise:

(a) there are a $y < x^{1/5}$, an $e \leq \log^*(x)$ and a supersparse set $D \subseteq \{0, 1, \ldots, 2^x\}$ such that $M_e^{(A_0 \cap \{0,1,\ldots,x\})\Delta D}(y)$ queries x.

(b) $f'(a_0a_1\ldots a_x0) \leq \frac{2+(x+1)\cdot(x+1)}{1+(x+1)\cdot(x+1)} \cdot f'(a_0a_1\ldots a_x)$.

Note that the search over the queried elements can be done in exponential time: Every M_e queries at most $(\log(x))^{\log\log(x)}$ elements, and at most $(\log^*(x)+1)^2$ of them can differ from the corresponding value of $A_0 \cap \{0, 1, \ldots, x\}$ as one searches over answers given by $A_0\Delta D$ and not just A_0. Thus one has to consider $((\log(x))^{\log\log(x)})^{(\log^*(x)+2)^2}$ computation paths for every $y \leq x^{1/5}$ and $e \leq \log^*(x)$; each path might need up to $\log^*(x) \cdot (\log(x))^{\log\log(x)}$ steps. As except $x^{1/5}$ all these factors grow slower than every function x^q, $q > 0$, there is a constant for c such that, for every x, the number of steps to be simulated is at most $x^{1/4} + c$. As every 0 caused by condition (a) in the construction of A_0 is due to a query of one of these simulated paths, there are at most $x^{1/4} + c$ places $y \leq x$ where $A_0(y+1) = 0$ due to condition (a).

If $A_0(x+1) = 0$ is caused by condition (a), then the value of f' can go up by the factor $2 \cdot \frac{2+(x+1)\cdot(x+1)}{1+(x+1)\cdot(x+1)}$; else $A(x+1)$ is chosen such that the value of f' goes up by only half of that, that is, by the factor $\frac{2+(x+1)\cdot(x+1)}{1+(x+1)\cdot(x+1)}$. The product over $f'(A(0))$ and all numbers $\frac{2+(x+1)\cdot(x+1)}{1+(x+1)\cdot(x+1)}$ is bounded by a constant d. So it follows that, for every x, $f'(A_0(x)A_1(x)\ldots A_x(x)) \leq 2^{x^{1/4}+c} \cdot d$. The construction of Theorem 2.3 gives that A is a supersparse variant of A_0. Let $B = A\Delta A_0$. For almost all x, $D = B \cap \{0, 1, \ldots, x\}$ has at most $(\log^*(x))^2$ elements, $1/r_D \leq x^{|D|} \leq 2^{x^{1/4}}$, and $f(A(0)A(1)\ldots A(x)) \leq f'(A(0)A(1)\ldots A(x))/r_D \leq 2^{x^{1/4}+c+1} \cdot d$. It follows that there is no $s < 1$ such that $f(A(0)A(1)\ldots A(x)) \geq 2^{(1-s)x}$ for infinitely many x.

It remains to show that A is in EXP. Note that it follows from the construction of Theorem 2.3 that at every stage x and every D considered in the search condition, the set $A_x \Delta D$ is a supersparse variant of A_0. It follows from the definition of A_0 that whenever $M_e^{A_x \Delta D}(x)$ queries an element $y > x^5$, then $A_0(y) = 0$. As A_0 is in EXP, there is a polynomial p such that one can compute in time $2^{p(\log(x))}$ the value of $A_0(y)$ for any given $y \leq x^5$. It follows that one can compute $A_0(y)$ in all queried places in time exponential in $\log(x)$. Every stage in the construction changes the approximation of A at fewer than x places, so one can bookkeep these changes and compute A in exponential time. This completes the proof. □

Acknowledgments. The authors would like to thank Klaus Ambos-Spies, Jack H. Lutz and Wolfgang Merkle for helpful discussions; furthermore, Jack H. Lutz proposed that we investigate the Hausdorff-dimension of the class of sets in EXP that are not infinitely-often autoreducible.

AN EXTENSION OF THE LOVÁSZ LOCAL LEMMA, AND ITS APPLICATIONS TO INTEGER PROGRAMMING*

ARAVIND SRINIVASAN†

Abstract. The Lovász local lemma due to Erdős and Lovász (*Infinite and Finite Sets*, Colloq. Math. Soc. J. Bolyai 11, 1975, pp. 609–627) is a powerful tool in proving the existence of rare events. We present an extension of this lemma, which works well when the event to be shown to exist is a conjunction of individual events, each of which asserts that a random variable does not deviate much from its mean. As applications, we consider two classes of NP-hard integer programs: minimax and covering integer programs. A key technique, *randomized rounding of linear relaxations*, was developed by Raghavan and Thompson (*Combinatorica*, 7 (1987), pp. 365–374) to derive good approximation algorithms for such problems. We use our extension of the local lemma to prove that randomized rounding produces, with nonzero probability, much better feasible solutions than known before, if the constraint matrices of these integer programs are *column-sparse* (e.g., routing using short paths, problems on hypergraphs with small dimension/degree). This complements certain well-known results from discrepancy theory. We also generalize the *method of pessimistic estimators* due to Raghavan (*J. Comput. System Sci.*, 37 (1988), pp. 130–143), to obtain constructive (algorithmic) versions of our results for covering integer programs.

Key words. Lovász local lemma, column-sparse integer programs, approximation algorithms, randomized rounding, discrepancy

1. Introduction.

The powerful Lovász local lemma (LLL) is often used to show the existence of *rare* combinatorial structures by showing that a random sample from a suitable sample space produces them with positive probability [14]; see Alon and Spencer [4] and Motwani and Raghavan [27] for several such applications. We present an extension of this lemma, and demonstrate applications to rounding fractional solutions for certain families of integer programs. A preliminary version of this work appeared in [35], with a sketch of the proof for minimax integer programs, and proofs omitted for our constructive results for covering integer programs. In this version, we provide all proofs, further generalize the main covering result of [35] to Theorem 5.9, and present applications thereof; in particular, the constructive approach to covering integer programs detailed in section 5.3, requires a fair amount of work.

Let e denote the base of natural logarithms. The symmetric case of the LLL shows that all of a set of "bad" events E_i can be avoided under some conditions.

LEMMA 1.1. (see [14]) *Let $E_1, E_2, \ldots, E_m$ be any events with $\Pr(E_i) \leq p\ \forall i$. If each E_i is mutually independent of all but at most d of the other events E_j and if $ep(d+1) \leq 1$, then $\Pr(\bigwedge_{i=1}^{m} \overline{E_i}) > 0$.*

Though the LLL is powerful, one problem is that the "dependency" d is high in some cases, precluding the use of the LLL if p is not small enough. We present a partial solution to this via an extension of the LLL (Theorem 3.1), which shows how to essentially reduce d for a class of events E_i; this works well when each E_i denotes some random variable deviating "much" from its mean. In a nutshell, we show that such events E_i can often be decomposed suitably into subevents; although the subevents may have a large dependency among themselves, we show that it suffices to have a small "bipartite dependency" between the set of events E_i and the set of subevents. This, in combination with some other ideas, leads to the following applications in integer programming.

It is well known that a large number of NP-hard combinatorial optimization problems can be cast as integer linear programming problems (ILPs). Due to their NP-hardness, good approximation algorithms are of much interest for such problems. Recall that a ρ-approximation algorithm for a minimization problem is a polynomial-time algorithm that delivers a solution whose objective function value is at most ρ times optimal; ρ is usually called the *approximation guarantee*, *approximation ratio*, or *performance guarantee* of the algorithm. Algorithmic work in this area typically focuses on achieving the smallest possible ρ in polynomial time. One powerful paradigm here is to start with the linear programming (LP) relaxation of the given ILP wherein the variables are allowed to be *reals* within their integer ranges; once an optimal solution is found for the LP, the main issue is how to *round* it to a good feasible solution for the ILP. Rounding results in this context often have the following strong property: they present an integral solution of value at most $y^* \cdot \rho$, where y^* will throughout denote the optimal solution value of the LP relaxation. Since the optimal solution value OPT of the ILP is easily seen to be lower-bounded by y^*, such rounding algorithms are also ρ-approximation algorithms. Furthermore, they provide an upper bound of ρ on the ratio OPT/y^*, which is usually called the *integrality gap* or *integrality ratio* of the relaxation; the smaller this value, the better the relaxation.

This work presents improved upper bounds on the integrality gap of the natural LP relaxation for two families of ILPs: minimax integer programs (MIPs) and covering integer programs (CIPs). (The precise definitions and results are presented in section 2.) For the latter, we also provide the corresponding polynomial-time rounding algorithms. Our main improvements are in the case where the coefficient matrix of the given ILP is *column-sparse*: i.e., the number of nonzero entries in every column is bounded by a given parameter a. There are classical rounding theorems for such column-sparse problems (e.g., Beck and Fiala [6], Karp, Leighton, Rivest, Thompson, Vazirani, and Vazirani [18]). Our results complement, and are incomparable with, these results. Furthermore, the notion of column-sparsity, which denotes no variable occurring in "too many" constraints, occurs naturally in combinatorial optimization: e.g., routing using "short" paths, and problems on hypergraphs with "small" degree. These issues are discussed further in section 2.

A key technique, *randomized rounding of linear relaxations*, was developed by Raghavan and Thompson [32] to get approximation algorithms for such ILPs. We use Theorem 3.1 to prove that this technique produces, with nonzero probability, much better feasible solutions than known before, if the constraint matrix of the given MIP/CIP is column-sparse. (In the case of MIPs, our algorithm iterates randomized rounding several times with different choices of parameters, in order to achieve our result.) Such results cannot be got via Lemma 1.1, as the dependency d, in the sense of Lemma 1.1, can be as high as $\Theta(m)$ for these problems. Roughly speaking, Theorem 3.1 helps show that if no column in our given ILP has more than a nonzero

entries, then the dependency can essentially be brought down to a polynomial in a; this is the key driver behind our improvements.

Theorem 3.1 works well in combination with an idea that has blossomed in the areas of derandomization and pseudorandomness in the last two decades: (approximately) decomposing a function of several variables into a sum of terms, each of which depends on only a few of these variables. Concretely, suppose Z is a sum of random variables Z_i. Many tools have been developed to upper-bound $\Pr(Z - \mathbf{E}[Z] \geq z)$ and $\Pr(|Z - \mathbf{E}[Z]| \geq z)$ even if the Z_is are only (almost) k-wise independent for some "small" k, rather than completely independent. The idea is to bound the probabilities by considering $\mathbf{E}[(Z - \mathbf{E}[Z])^k]$ or similar expectations, which look at the Z_i, *k or fewer at a time* (via linearity of expectation). The main application of this has been that the Z_i can then be sampled using "few" random bits, yielding a derandomization/pseudorandomness result (e.g., [3, 23, 8, 26, 28, 33]). Our results show that such ideas can in fact be used to show that some structures exist! This is one of our main contributions.

What about polynomial-time algorithms for our existential results? Typical applications of Lemma 1.1 are "nonconstructive" (i.e., do not directly imply (randomized) polynomial-time algorithmic versions), since the positive probability guaranteed by Lemma 1.1 can be exponentially small in the size of the input. However, certain algorithmic versions of the LLL have been developed starting with the seminal work of Beck [5]. These ideas do not seem to apply to our extension of the LLL, and hence our MIP result is nonconstructive. Following the preliminary version of this work [35], two main algorithmic versions related to our work have been obtained: (i) for a subclass of the MIPs [20], and (ii) for a somewhat different notion of approximation than the one we study, for certain families of MIPs [11].

Our main algorithmic contribution is for CIPs and multicriteria versions thereof: we show, by a generalization of the *method of pessimistic estimators* [31], that we can efficiently construct the same structure as is guaranteed by our nonconstructive argument. We view this as interesting for two reasons. First, the generalized pessimistic estimator argument requires a quite delicate analysis, which we expect to be useful in other applications of developing constructive versions of existential arguments. Second, except for some of the algorithmic versions of the LLL developed in [24, 25], most current algorithmic versions minimally require something like "$pd^3 = O(1)$" (see, e.g., [5, 1]); all the LLL needs is that $pd = O(1)$. While this issue does not matter much in many applications, it crucially does, in some others. A good example of this is the existentially-optimal integrality gap for the edge-disjoint paths problem with "short" paths, shown using the LLL in [21]. The above-seen "$pd^3 = O(1)$" requirement of currently-known algorithmic approaches to the LLL leads to algorithms that will violate the edge-disjointness condition when applied in this context: specifically, they may route up to three paths on some edges of the graph; see [9] for a different—random-walk based—approach to low-congestion routing. An algorithmic version of this edge-disjoint paths result of [21] is still lacking. It is a very interesting open question whether there is an algorithmic version of the LLL that can construct the same structures as guaranteed to exist by the LLL. In particular, can one of the most successful derandomization tools, the method of conditional probabilities or its generalization, the pessimistic estimators method, be applied, fixing the underlying random choices of the probabilistic argument one-by-one? This intriguing question is open (and seems difficult) for now; it is elaborated upon further in section 6. As a step in this direction, we are able to show how such approaches can indeed be developed, in the context of CIPs.

Thus, our main contributions are as follows. (a) The LLL extension is of independent interest: it helps in certain settings where the "dependency" among the "bad" events is too high for the LLL to be directly applicable. We expect to see further applications/extensions of such ideas. (b) This work shows that certain classes of column-sparse ILPs have much better solutions than known before; such problems abound in practice (e.g., short paths are often desired/required in routing). (c) Our generalized method of pessimistic estimators should prove fruitful in other contexts also; it is a step toward complete algorithmic versions of the LLL.

A note on reading this paper. In order to get the main ideas of this work across, we summarize the main ideas of each section and some of the subsections, at their beginning. We also have paragraphs marked "Intuition" in some of the sections, in order to spell out the main ideas informally. Furthermore, we have moved simple-but-tedious calculations to the appendix; it may help the reader to read the body of the paper first, and to then read the material in the appendix if necessary. The rest of this paper is organized as follows. Our results are first presented in section 2, along with a discussion of related work. The extended LLL, and some large-deviation methods that will be seen to work well with it, are shown in section 3. Sections 4 and 5 are devoted to our rounding applications. Section 6 concludes, and some of the routine calculations are presented in the appendix.

2. Our results and related work. Let Z_+ denote the set of nonnegative integers; for any $k \in Z_+$, $[k] \doteq \{1, \ldots, k\}$. "Random variable" is abbreviated as "r.v.," and logarithms are to the base 2 unless specified otherwise.

DEFINITION 2.1 (minimax integer programs). *An MIP has the following variables: $\{x_{i,j} : i \in [n], j \in [\ell_i]\}$, for some integers $\{\ell_i\}$, and an extra variable W. Let $N = \sum_{i \in [n]} \ell_i$ and let x denote the N-dimensional vector of the variables $x_{i,j}$ (arranged in any fixed order). An MIP seeks to minimize W, an unconstrained real, subject to*

(i) *equality constraints: $\forall i \in [n]$ $\sum_{j \in [\ell_i]} x_{i,j} = 1$,*

(ii) *a system of linear inequalities $Ax \leq \vec{W}$, where $A \in [0,1]^{m \times N}$ and $\vec{W}$ is the m-dimensional vector with the variable W in each component, and*

(iii) *integrality constraints: $x_{i,j} \in \{0,1\}$ $\forall i, j$.*

We let g denote the maximum column sum in any column of A, and a be the maximum number of nonzero entries in any column of A.

To see what problems MIPs model, note from constraints (i) and (iii) of MIPs that for all i, any feasible solution will make the set $\{x_{i,j} : j \in [\ell_i]\}$ have precisely one 1, with all other elements being 0; MIPs thus model many "choice" scenarios. Consider, e.g., global routing in VLSI gate arrays [32]. Given are an undirected graph $G = (V, E)$, a function $\rho : V \to V$, and $\forall i \in V$, a set P_i of paths in G, each connecting i to $\rho(i)$; we must connect each i with $\rho(i)$ using exactly one path from P_i, so that the maximum number of times that any edge in G is used for, is minimized–an MIP formulation is obvious, with $x_{i,j}$ being the indicator variable for picking the jth path in P_i. This problem, the vector-selection problem of [32], and the discrepancy-type problems of section 4, are all modeled by MIPs; many MIP instances, e.g., global routing, are NP-hard.

We now introduce the next family of integer programs that we will work with.

DEFINITION 2.2 (covering integer programs). *Given $A \in [0,1]^{m \times n}$, $b \in [1, \infty)^m$ and $c \in [0,1]^n$ with $\max_j c_j = 1$, CIP seeks to minimize $c^T \cdot x$ subject to $x \in Z_+^n$ and $Ax \geq b$. If $A \in \{0,1\}^{m \times n}$, each entry of b is assumed integral. We define $B = \min_i b_i$, and let a be the maximum number of nonzero entries in any column of*

A. A CIP is called unweighted if $c_j = 1\ \forall j$, and weighted otherwise.

Note the parameters g, a, and B of Definitions 2.1 and 2.2. Though there are usually no restrictions on the entries of A, b, and c in CIPs aside of nonnegativity, it is well known and easy to check that the above restrictions are without loss of generality. CIPs again model many NP-hard problems in combinatorial optimization. Recall that a hypergraph $H = (V, E)$ is a family of subsets E (edges) of a set V (vertices). The classical *set cover* problem—covering V using the smallest number of edges in E (and its natural weighted version)—is a standard example of a CIP. The parameter a here is the maximum number of vertices in any edge.

Next, there is growing interest in *multicriteria* optimization, since different participating individuals and/or organizations may have different objective functions in a given problem instance; see, e.g., [29]. Motivated by this, we study multicriteria optimization in the setting of covering problems.

DEFINITION 2.3 (multicriteria CIPs; informal). *A multicriteria CIP has a system of constraints "$Ax \geq b$" as in CIPs, and has several given nonnegative vectors $c_1, c_2, \ldots, c_\ell$; the aim is to keep all the values $c_i^T \cdot x$ "low." (For instance, we may aim to minimize $\max_i c_i^T \cdot x$ subject to $Ax \geq b$.) As in Definition 2.2, we assume that $A \in [0,1]^{m \times n}$, $b \in [1, \infty)^m$ and $\forall\ i,\ c_i \in [0,1]^n$ with $max_j\ c_{i,j} = 1$.*

We now present a lemma to quantify our approximation results; its proof is given in section 3.

LEMMA 2.4. *Given independent r.v.s $X_1, \ldots, X_n \in [0,1]$, let $X = \sum_{i=1}^n X_i$ and $\mu = \boldsymbol{E}[X]$.*

a. *For any $\delta > 0$, $\Pr(X \geq \mu(1+\delta)) \leq G(\mu, \delta)$, where $G(\mu, \delta) = \left(e^\delta/(1+\delta)^{1+\delta}\right)^\mu$.*
b. *$\forall \mu > 0\ \forall p \in (0,1), \exists \delta = H(\mu, p) > 0$ such that $\lceil \mu\delta \rceil \cdot G(\mu, \delta) \leq p$ and such that*

$$H(\mu, p) = \Theta\left(\frac{\log(p^{-1})}{\mu \log(\log(p^{-1})/\mu)}\right) \text{ if } \mu \leq \log(p^{-1})/2;$$

$$H(\mu, p) = \Theta\left(\sqrt{\frac{\log(\mu + p^{-1})}{\mu}}\right) \text{ otherwise.}$$

Given an ILP, we can find an optimal solution x^* to its LP relaxation efficiently, but need to round fractional entries in x^* to integers. The idea of randomized rounding is: given a real $v > 0$, round v to $\lfloor v \rfloor + 1$ with probability $v - \lfloor v \rfloor$, and round v to $\lfloor v \rfloor$ with probability $1 - v + \lfloor v \rfloor$. This has the nice property that the mean outcome is v. Starting with this idea, the analysis of [32] produces an integral solution of value at most $y^* + O(\min\{y^*, m\} \cdot H(\min\{y^*, m\}, 1/m))$ for MIPs (though phrased a bit differently); this is derandomized in [31]. But this does not exploit the sparsity of A; the previously-mentioned result of [18] produces an integral solution of value at most $y^* + g + 1$.

For CIPs, the idea is to solve the LP relaxation, scale *up* the components of x^* suitably, and then perform randomized rounding; see section 5 for the details. Starting with this idea, the work of [32] leads to certain approximation bounds; similar bounds are achieved through different means by Plotkin, Shmoys, and Tardos [30]. Work of this author [36] improved upon these results by observing a "correlation" property of CIPs, getting an approximation ratio of $1 + O(\max\{\ln(mB/y^*)/B, \sqrt{\ln(mB/y^*)/B}\})$. Thus, while the work of [32] gives a general approximation bound for MIPs, the result of [18] gives good results for sparse MIPs. For CIPs, the current-best results are those of [36]; however, no better results were known for sparse CIPs.

2.1. Improvements achieved. For MIPs, we use the extended LLL and an idea of Éva Tardos that leads to a bootstrapping of the LLL extension.

THEOREM 2.5. *For any given MIP, there exists an integral solution of value at most* $y^* + O(1) + O(\min\{y^*, m\} \cdot H(\min\{y^*, m\}, 1/a))$. Since $a \leq m$, this is always as good as the $y^* + O(\min\{y^*, m\} \cdot H(\min\{y^*, m\}, 1/m))$ bound of [32] and is a good improvement, if $a \ll m$. It also is an improvement over the additive g factor of [18] in cases where g is not small compared to y^*.

Consider, e.g., the global routing problem and its MIP formulation, sketched above; m here is the number of edges in G, and $g = a$ is the maximum length of any path in $\bigcup_i P_i$. To focus on a specific interesting case, suppose y^*, the fractional congestion, is at most one. Then while the previous results ([32] and [18], resp.) give bounds of $O(\log m / \log\log m)$ and $O(a)$ on an integral solution, we get the improved bound of $O(\log a / \log\log a)$. Similar improvements are easily seen for other ranges of y^* also; e.g., if $y^* = O(\log a)$, an integral solution of value $O(\log a)$ exists, improving on the previously known bounds of $O(\log m / \log(2 \log m / \log a))$ and $O(a)$. Thus, routing along *short* paths (this is the notion of sparsity for the global routing problem) is very beneficial in keeping the congestion low. Section 4 presents a scenario where we get such improvements, for discrepancy-type problems [34, 4]. In particular, we generalize a hypergraph-partitioning result of Füredi and Kahn [16].

Recall the bounds of [36] for CIPs mentioned in the paragraph preceding this subsection; our bounds for CIPs depend only on the set of constraints $Ax \geq b$, i.e., they hold for any nonnegative objective-function vector c. Our improvements over [36] get better as y^* decreases.

THEOREM 2.6. *For any given CIP, there exists a feasible solution of value at most* $y^* \cdot (1 + O(max\{\ln(a+1)/B, \sqrt{\ln(a+B)/B}\}))$.

This CIP bound is better than that of [36] if y^* is small enough. In particular, we generalize the result of Chvátal [10] on weighted set cover. Consider, e.g., a facility location problem on a directed graph $G = (V, A)$: given a cost $c_i \in [0, 1]$ for each $i \in V$, we want a min-cost assignment of facilities to the nodes such that each node sees at least B facilities in its out-neighborhood; multiple facilities at a node are allowed. If Δ_{in} is the maximum in-degree of G, Theorem 2.6 guarantees an integrality gap of $1 + O(\max\{\ln(\Delta_{in}+1)/B, \sqrt{\ln(B(\Delta_{in}+1))/B}\})$. This improves on [36] if $y^* \leq |V|B / \max\{\Delta_{in}, B\}$; it shows an $O(1)$ (resp., $1 + o(1)$) integrality gap if B grows as fast as (resp., strictly faster than) $\log \Delta_{in}$.

A key corollary of Theorem 2.6 is that for families of instances of CIPs, we get a good ($O(1)$ or $1 + o(1)$) integrality gap if B grows at least as fast as $\log a$; bounds on the result of a greedy algorithm for CIPs relative to the optimal *integral* solution are known [12, 13]. Our bound of Theorem 2.6 improves that of [12] and is incomparable with [13]; for any given A, c, and the unit vector $b/||b||_2$, our bound improves on [13] if B is more than a certain threshold. As it stands, randomized rounding produces such improved solutions for several CIPs only with a very low, sometimes exponentially small, probability. Thus, it does not imply a randomized algorithm, often. To this end, we generalize Raghavan's method of pessimistic estimators to derive an algorithmic (polynomial-time) version of Theorem 2.6, in section 5.3.

We also show via Theorem 5.9 and Corollary 5.10 that multicriteria CIPs can be approximated well. In particular, Corollary 5.10 shows some interesting cases where the approximation guarantee for multicriteria CIPs grows in a very much sublinear fashion with the number ℓ of given vectors c_i: the approximation ratio is at most $O(\log\log \ell)$ times what we show for CIPs (which correspond to the case where $\ell = 1$).

We are not aware of any such earlier work on multicriteria CIPs. The constructive version of Corollary 5.10 that we present in section 5.3 requires poly$(n^{\log \ell}, m)$ time, though. It would be interesting to be able to improve this to a polynomial-time algorithm.

2.2. Preliminary version of this work, and followup. A preliminary version of this work appeared in [35], with a sketch of the proof for minimax integer programs, and proofs omitted for our constructive results on covering integer programs. In this version, we provide all proofs, further generalize the main covering result of [35] to Theorem 5.9, and present a sample application of Theorem 5.9 in Corollary 5.10. As mentioned in section 1, two main algorithmic versions related to our work have been obtained following [35]. First, for a subclass of the MIPs where the nonzero entries of the matrix A are "reasonably large," constructive versions of our results have been obtained in [20]. Second, for a notion of approximation that is different from the one we study, algorithmic results have been developed for certain families of MIPs in [11]. Furthermore, our Theorem 2.6 for CIPs has been used in [19] to develop approximation algorithms for CIPs that have given upper bounds on the variables x_j.

3. The extended LLL and an approach to large deviations. We now present our LLL extension, Theorem 3.1. For any event E, define $\chi(E)$ to be its indicator r.v.: 1 if E holds and 0 otherwise. Suppose we have "bad" events $E_1, \ldots, E_m$ with a "dependency" d' (in the sense of Lemma 1.1) that is "large." Theorem 3.1 shows how to essentially replace d' by a possibly much-smaller d, if we are able to define appropriate nonnegative valued random variables $\{C_{i,j}\}$ for each E_i. It generalizes Lemma 1.1 (define one r.v., $C_{i,1} = \chi(E_i)$, for each i, to get Lemma 1.1), and its proof is very similar to the classical proof of Lemma 1.1. The motivation for Theorem 3.1 will be clarified by the applications; in particular, given some additional preparations, Theorems 4.2 and 2.6 follow, respectively, and with relatively less work, from Theorem 3.1 and its proof approach.

THEOREM 3.1. *Given events $E_1, \ldots, E_m$ and any $I \subseteq [m]$, let $Z(I) \doteq \bigwedge_{i \in I} \overline{E_i}$. Suppose that for some positive integer d, we can define, for each $i \in [m]$, a finite number of r.v.s $C_{i,1}, C_{i,2}, \ldots$ each taking on only nonnegative values such that*

(i) *any $C_{i,j}$ is mutually independent of all, but at most d of the events E_k, $k \neq i$, and*

(ii) $\forall I \subseteq ([m] - \{i\})$, $\Pr(E_i \mid Z(I)) \leq \sum_j \boldsymbol{E}[C_{i,j} \mid Z(I)]$.

Let p_i denote $\sum_j \boldsymbol{E}[C_{i,j}]$. Suppose that $\forall i \in [m]$ we have $ep_i(d+1) \leq 1$. Then $\Pr(\bigwedge_i \overline{E_i}) \geq (d/(d+1))^m > 0$.

Remark 3.2. Note, by setting $I = \phi$ in (ii), that $\Pr(E_i) \leq p_i \ \forall\ i$. Also, $C_{i,j}$ and $C_{i,j'}$ can "depend" on *different* subsets of $\{E_k | k \neq i\}$; the only restriction is that these subsets be of size at most d. Note that we have essentially reduced the dependency among the E_is to just d: $ep_i(d+1) \leq 1$ suffices. Another important point is that the dependency *among the r.v.s $C_{i,j}$* could be much higher than d: all we count is the number of E_k that any $C_{i,j}$ depends on.

Proof of Theorem 3.1. We prove by induction on $|I|$ that if $i \notin I$, then $\Pr(E_i \mid Z(I)) \leq ep_i$, which suffices to prove the theorem since $\Pr(\bigwedge_i \overline{E_i}) = \prod_{i \in [m]}(1 - \Pr(E_i \mid Z([i-1])))$. For the base case where $I = \emptyset$, $\Pr(E_i \mid Z(I)) = \Pr(E_i) \leq p_i$. For the inductive step, let $S_{i,j,I} \doteq \{k \in I \mid C_{i,j} \text{ depends on } E_k\}$, and $S'_{i,j,I} = I - S_{i,j,I}$; note that $|S_{i,j,I}| \leq d$. If $S_{i,j,I} = \emptyset$, then $\mathbf{E}[C_{i,j} \mid Z(I)] = \mathbf{E}[C_{i,j}]$. Otherwise, letting

$S_{i,j,I} = \{\ell_1, \ldots, \ell_r\}$, we have

$$\mathbf{E}[C_{i,j} \mid Z(I)] = \frac{\mathbf{E}[C_{i,j} \cdot \chi(Z(S_{i,j,I})) \mid Z(S'_{i,j,I})]}{\Pr(Z(S_{i,j,I}) \mid Z(S'_{i,j,I}))} \leq \frac{\mathbf{E}[C_{i,j} \mid Z(S'_{i,j,I})]}{\Pr(Z(S_{i,j,I}) \mid Z(S'_{i,j,I}))},$$

since $C_{i,j}$ is nonnegative. The numerator of the last term is $\mathbf{E}[C_{i,j}]$, by assumption. The denominator can be lower-bounded as follows:

$$\prod_{s\in[r]} (1 - \Pr(E_{\ell_s} \mid Z(\{\ell_1, \ell_2, \ldots, \ell_{s-1}\} \cup S'_{i,j,I}))) \geq \prod_{s\in[r]} (1 - ep_{\ell_s})$$
$$\geq (1 - 1/(d+1))^r \geq (d/(d+1))^d > 1/e;$$

the first inequality follows from the induction hypothesis. Hence, $\mathbf{E}[C_{i,j} \mid Z(I)] \leq e\mathbf{E}[C_{i,j}]$ and thus, $\Pr(E_i \mid Z(I)) \leq \sum_j \mathbf{E}[C_{i,j} \mid Z(I)] \leq ep_i \leq 1/(d+1)$.

The crucial point is that the events E_i could have a large dependency d', in the sense of the classical Lemma 1.1. The main utility of Theorem 3.1 is that if we can "decompose" each E_i into the r.v.s $C_{i,j}$ that satisfy the conditions of the theorem, then there is the possibility of effectively reducing the dependency noticeably (d' can be replaced by the value d). Concrete instances of this will be studied in later sections.

The tools behind our MIP application are our new LLL, and a result of [33]. Define, for $z = (z_1, \ldots, z_n) \in \Re^n$, a family of polynomials $S_j(z), j = 0, 1, \ldots, n$, where $S_0(z) \equiv 1$, and for $j \in [n]$,

$$S_j(z) \doteq \sum_{1\leq i_1<i_2\cdots<i_j\leq n} z_{i_1} z_{i_2} \cdots z_{i_j}. \tag{3.1}$$

Remark 3.3. For real x and nonnegative integral r, we define $\binom{x}{r} \doteq x(x-1)\cdots(x-r+1)/r!$ as usual; this is the sense meant in Theorem 3.4 below.

We define a nonempty event to be any event with a nonzero probability of occurrence. The relevant theorem of [33] is the following.

THEOREM 3.4 (see [33]). *Given r.v.s $X_1, \ldots, X_n \in [0,1]$, let $X = \sum_{i=1}^n X_i$ and $\mu = \boldsymbol{E}[X]$. Then,*

(a) *For any $q > 0$, any nonempty event Z, and any nonnegative integer $k \leq q$,*

$$\Pr(X \geq q \mid Z) \leq \boldsymbol{E}[Y_{k,q} \mid Z],$$

where $Y_{k,q} = S_k(X_1, \ldots, X_n)/\binom{q}{k}$.

(b) *If the X_is are independent, $\delta > 0$, and $k = \lceil \mu\delta \rceil$, then $\Pr(X \geq \mu(1+\delta)) \leq \boldsymbol{E}[Y_{k,\mu(1+\delta)}] \leq G(\mu, \delta)$, where $G(\cdot,\cdot)$ is as in Lemma 2.4.*

(c) *If the X_is are independent, then $\boldsymbol{E}[S_k(X_1, \ldots, X_n)] \leq \binom{n}{k} \cdot (\mu/n)^k \leq \mu^k/k!$.*

Proof. Suppose $r_1, r_2, \ldots r_n \in [0,1]$ satisfy $\sum_{i=1}^n r_i \geq q$. Then, a simple proof is given in [33], for the fact that for any nonnegative integer $k \leq q$, $S_k(r_1, r_2, \ldots, r_n) \geq \binom{q}{k}$. This clearly holds even given the occurrence of any nonempty event Z. Thus we get $\Pr(X \geq q \mid Z) \leq \Pr(Y_{k,q} \geq 1 \mid Z) \leq \mathbf{E}[Y_{k,q} \mid Z]$, where the second inequality follows from Markov's inequality. The proofs of (b) and (c) are given in [33]. □

We next present the proof of Lemma 2.4.

Proof of Lemma 2.4. Part (a) is the Chernoff–Hoeffding bound (see, e.g., Appendix A of [4], or [27]). For (b), we proceed as follows. For any $\mu > 0$, it is easy to check that

$$G(\mu, \delta) = e^{-\Theta(\mu\delta^2)} \text{ if } \delta \in (0,1), \tag{3.2}$$
$$G(\mu, \delta) = e^{-\Theta(\mu(1+\delta)\ln(1+\delta))} \text{ if } \delta \geq 1. \tag{3.3}$$

Now if $\mu \leq \log(p^{-1})/2$, choose

$$\delta = C \cdot \frac{\log(p^{-1})}{\mu \log(\log(p^{-1})/\mu)}$$

for a suitably large constant C. Since $\mu \leq \log(p^{-1})/2$, we can make $\delta \geq 1$ and have (3.3) hold, by choosing, e.g., $C \geq 1$. Simple algebraic manipulation now shows that if C is large enough, then $\lceil \mu\delta \rceil \cdot G(\mu, \delta) \leq p$ holds. Similarly, if $\mu > \log(p^{-1})/2$, we set $\delta = C \cdot \sqrt{\frac{\log(\mu + p^{-1})}{\mu}}$ for a large enough constant C, and use (3.2).

4. Approximating minimax integer programs. We now employ Theorem 3.1 to develop improved results on integral solutions for MIPs. We broadly proceed in two steps. First, we define a useful parameter t; a relatively direct application of Theorem 3.1 leads to Theorem 4.2. Second, we "bootstrap" Theorem 4.2 to develop the stronger Theorem 2.5. We present the intuitions behind these two theorems in the paragraph preceding Theorem 4.2 and in the paragraph preceding the proof of Theorem 2.5.

Let us first define a parameter t. This is useful as a first step in developing Theorem 4.2, but we will dispense with it when we work up to the proof of Theorem 2.5. Suppose we are given an MIP conforming to Definition 2.1. Define t to be $\max_{i \in [m]} NZ_i$, where NZ_i is the number of rows of A which have a nonzero coefficient corresponding to at least one variable among $\{x_{i,j} : j \in [\ell_i]\}$. Note that

$$g \leq a \leq t \leq \min\{m, a \cdot \max_{i \in [n]} \ell_i\}. \tag{4.1}$$

Theorem 4.2 now shows how Theorem 3.1 can help for sparse MIPs, those where $t \ll m$. We will then bootstrap Theorem 4.2 to get the further-improved Theorem 2.5. We start with a proposition, whose proof is shown in the appendix.

PROPOSITION 4.1. *If $0 < \mu_1 \leq \mu_2$, then for any $\delta > 0$, $G(\mu_1, \mu_2\delta/\mu_1) \leq G(\mu_2, \delta)$.*

Intuition for Theorem 4.2. Given an MIP, let us conduct randomized rounding in a natural way: independently for each i, randomly round exactly one $x_{i,j}$ to 1, with $x_{i,j}$ getting rounded to 1 with probability $x^*_{i,j}$. Now, we have one bad event E_i for each row i of A, corresponding to its row-sum going noticeably above its expectation. We would like to define random variables $C_{i,j}$ corresponding to each E_i, in order to employ Theorem 3.1. If we can choose a suitable integer k, then Theorem 3.4(a) suggests a natural choice for the $C_{i,j}$. Since E_i is an upper-tail event of the type captured by Theorem 3.4(a), we can try and bijectively map the $C_{i,j}$ to the $\binom{n}{k}$ r.v.s "$X_{i_1} X_{i_2} \cdots X_{i_k} / \binom{q}{k}$" that constitute the r.v. "$Y_{k,q}$" of Theorem 3.4(a). Condition (ii) of Theorem 3.1 is satisfied by Theorem 3.4(a); we will bound the parameter d in condition (i) of Theorem 3.1 by using the definition of t. These, in conjunction with some simple observations, lead to Theorem 4.2.

THEOREM 4.2. *Given an MIP conforming to Definition* 2.1*, randomized rounding produces a feasible solution of value at most $y^* + \lceil \min\{y^*, m\} \cdot H(\min\{y^*, m\}, 1/(et)) \rceil$, with nonzero probability.*

Proof. Conduct randomized rounding: independently for each i, randomly round exactly one $x_{i,j}$ to 1, guided by the "probabilities" $\{x^*_{i,j}\}$. Recall again that $x^* = \{x^*_{i,j}\}$ is the vector obtained by solving the LP relaxation. We may assume that $\{x^*_{i,j}\}$ is a *basic* feasible solution to this relaxation. Hence, at most m of the $\{x^*_{i,j}\}$ will be neither zero nor one, and only these variables will participate in the rounding. Since

all the entries of A are in $[0,1]$, we can assume without loss of generality from now on that $y^* \leq m$ (and that $\max_{i\in[n]}\ell_i \leq m$); this explains the "$\min\{y^*, m\}$" term in our stated bounds. Let $b_i = (Ax^*)_i$ denote the r.h.s. value that we get for the ith row in the optimal solution for the LP relaxation; so we have $b_i \leq y^*$. If $z \in \{0,1\}^N$ denotes the randomly rounded vector, then $\mathbf{E}[(Az)_i] = b_i \leq y^*$ by the linearity of expectation. Defining

$$k = \lceil y^* H(y^*, 1/(et)) \rceil \tag{4.2}$$

and events $E_1, E_2, \ldots, E_m$ by $E_i \equiv$ "$(Az)_i \geq b_i + k$," we now show that $\Pr(\bigwedge_{i\in[m]} \overline{E_i}) > 0$ using Theorem 3.1. Rewrite the ith constraint of the MIP as

$$\sum_{r\in[n]} X_{i,r} \leq W, \text{ where } X_{i,r} = \sum_{s\in[\ell_r]} A_{i,(r,s)} x_{r,s};$$

the notation $A_{i,(r,s)}$ assumes that the pairs $\{(r,s) : r \in [n], s \in [\ell_r]\}$ have been mapped bijectively to $[N]$, in some fixed way. Defining the r.v.

$$Z_{i,r} = \sum_{s\in[\ell_r]} A_{i,(r,s)} z_{r,s},$$

we note that for each i, the r.v.s $\{Z_{i,r} : r \in [n]\}$ lie in $[0,1]$ and are *independent*. Also, $E_i \equiv$ "$\sum_{r\in[n]} Z_{i,r} \geq b_i + k$."

Theorem 3.4 suggests a suitable choice for the crucial r.v.s $C_{i,j}$ (to apply Theorem 3.1). Let $u = \binom{n}{k}$; we now define the r.v.s $\{C_{i,j} : i \in [m], j \in [u]\}$ as follows. Fix any $i \in [m]$. Identify each $j \in [u]$ with some distinct k-element subset $S(j)$ of $[n]$, and let

$$C_{i,j} \doteq \frac{\prod_{v\in S(j)} Z_{i,v}}{\binom{b_i+k}{k}}. \tag{4.3}$$

We now need to show that the r.v.s $C_{i,j}$ satisfy the conditions of Theorem 3.1. For any $i \in [m]$, let $\delta_i = k/b_i$. Since $b_i \leq y^*$, we have, for each $i \in [m]$,

$$\begin{aligned} G(b_i, \delta_i) &\leq G(y^*, k/y^*) \text{ (by Proposition 4.1)} \\ &\leq G(y^*, H(y^*, 1/(et))) \text{ (by (4.2))} \\ &\leq 1/(ekt) \text{ (by the definition of } H). \end{aligned}$$

Now by Theorem 3.4, we get the following fact.

FACT 4.3. *For all $i \in [m]$ and for all nonempty events Z, $\Pr(E_i \mid Z) \leq \sum_{j\in[u]} \boldsymbol{E}[C_{i,j} \mid Z]$. Also, $p_i \doteq \sum_{j\in[u]} \boldsymbol{E}[C_{i,j}] < G(b_i, \delta_i) \leq 1/(ekt)$.*

Next since any $C_{i,j}$ involves (a product of) k terms, each of which "depends" on at most $(t-1)$ of the events $\{E_v : v \in ([m] - \{i\})\}$ by definition of t, we see the important

FACT 4.4. *$\forall i \in [m]$ $\forall j \in [u]$, $C_{i,j} \in [0,1]$ and $C_{i,j}$ "depends" on at most $d = k(t-1)$ of the set of events $\{E_v : v \in ([m] - \{i\})\}$.*

From Facts 4.3 and 4.4 and by noting that $ep_i(d+1) \leq e(kt - k + 1)/(ekt) \leq 1$, we invoke Theorem 3.1, to see that $\Pr(\bigwedge_{i\in[m]} \overline{E_i}) > 0$, concluding the proof of Theorem 4.2. □

We are now ready to improve Theorem 4.2, to obtain Theorem 2.5.

Intuition for Theorem 2.5. Theorem 4.2 gives good results if $t \ll m$, but can we improve it further, say by replacing t by a ($\leq t$) in it? As seen from (4.1), the key reason for $t \gg a^{\Theta(1)}$ is that $\max_{i\in[n]} \ell_i \gg a^{\Theta(1)}$. If we can essentially "bring down" $\max_{i\in[n]} \ell_i$ by forcing many $x^*_{i,j}$ to be zero for *each* i, then we effectively reduce t ($t \leq a \cdot max_i\ \ell_i$, see (4.1)); this is so since only those $x^*_{i,j}$ that are neither zero nor one take part in the rounding. A way of bootstrapping Theorem 4.2 to achieve this using a "slow rounding" technique that proceeds in $O(\log\log t)$ iterations, is shown by Theorem 2.5.

Proof of Theorem 2.5. Let $K_0 > 0$ be a sufficiently large absolute constant. Now if

$$(y^* \geq t^{1/7}) \text{ or } (t \leq \max\{K_0, 2\}) \text{ or } (t \leq a^4) \tag{4.4}$$

holds, then we will be done by Theorem 4.2. So we may assume that (4.4) is false. Also, if $y^* \leq t^{-1/7}$, Theorem 4.2 guarantees an integral solution of value $O(1)$; thus, we also suppose that $y^* > t^{-1/7}$. The basic idea now is, as sketched above, to set many $x^*_{i,j}$ to zero for each i (without losing too much on y^*), so that $\max_i \ell_i$ and hence, t, will essentially get reduced. Such an approach, whose performance will be validated by arguments similar to those of Theorem 4.2, is repeatedly applied until (4.4) holds, owing to the (continually reduced) t becoming small enough to satisfy (4.4). There are two cases.

Case I. $y^* \geq 1$. Solve the LP relaxation, and set $x'_{i,j} := (y^*)^2(\log^5 t)x^*_{i,j}$. Conduct randomized rounding on the $x'_{i,j}$ now, rounding *each* $x'_{i,j}$ independently to $z_{i,j} \in \{\lfloor x'_{i,j}\rfloor, \lceil x'_{i,j}\rceil\}$. (Note the key difference from Theorem 4.2, where for each i, we round exactly one $x^*_{i,j}$ to 1.)

Let $K_1 > 0$ be a sufficiently large absolute constant. We now use ideas similar to those used in our proof of Theorem 4.2 to show that with nonzero probability, we have both of the following:

$$\forall i \in [m], (Az)_i \leq (y^*)^3 \log^5 t \cdot (1 + K_1/((y^*)^{1.5}\log^2 t)), \quad \text{and} \tag{4.5}$$

$$\forall i \in [n], \left|\sum_j z_{i,j} - (y^*)^2 \log^5 t\right| \leq K_1 y^* \log^3 t. \tag{4.6}$$

To show this, we proceed as follows. Let $E_1, E_2, \ldots, E_m$ be the "bad" events, one for each event in (4.5) not holding; similarly, let $E_{m+1}, E_{m+2}, \ldots, E_{m+n}$ be the "bad" events, one for each event in (4.6) not holding. We want to use our extended LLL to show that with positive probability, all these bad events can be avoided; specifically, we need a way of associating each E_i with some finite number of nonnegative r.v.s $C_{i,j}$. (Loosely speaking, we will "decompose" each E_i into a finite number of such $C_{i,j}$.) We do this as follows. For each event $E_{m+\ell}$ where $\ell \geq 1$, we define just one r.v. $C_{m+\ell,1}$: this is the indicator variable for the occurrence of $E_{m+\ell}$. For the events E_i where $i \leq m$, we decompose E_i into r.v.s $C_{i,j}$ just as in (4.3): each such $C_{i,j}$ is now a scalar multiple of at most

$$O((y^*)^3 \log^5 t/((y^*)^{1.5}\log^2 t)) = O((y^*)^{1.5}\log^3 t) = O(t^{3/14}\log^3 t)$$

independent binary r.v.s that underlie our randomized rounding; the second equality (big-Oh bound) here follows since (4.4) has been assumed to not hold. Thus, it is easy to see that $\forall\ i$, $1 \leq i \leq m+n$, and for any j, the r.v. $C_{i,j}$ depends on at most

$$O(t \cdot t^{3/14}\log^3 t) \tag{4.7}$$

events E_k, where $k \neq i$. Also, as in our proof of Theorem 4.2, Theorem 3.4 gives a direct proof of requirement (ii) of Theorem 3.1; part (b) of Theorem 3.4 shows that for any desired constant K, we can choose the constant K_1 large enough so that $\forall\, i,\ \sum_j \mathbf{E}[C_{i,j}] \leq t^{-K}$. Thus, in view of (4.7), we see by Theorem 3.1 that $\Pr(\bigwedge_{i=1}^{m+n} \overline{E_i}) > 0$.

Fix a rounding z satisfying (4.5) and (4.6). For each $i \in [n]$ and $j \in [\ell_i]$, we renormalize as follows: $x''_{i,j} := z_{i,j}/\sum_u z_{i,u}$. Thus we have $\sum_u x''_{i,u} = 1$ for all i; we now see that we have two very useful properties. First, since $\sum_j z_{i,j} \geq (y^*)^2 \log^5 t \cdot \left(1 - O(\frac{1}{y^* \log^2 t})\right)$ for all i from (4.6), we have, $\forall i \in [m]$,

$$(Ax'')_i \leq \frac{y^*(1 + O(1/((y^*)^{1.5} \log^2 t)))}{1 - O(1/(y^* \log^2 t))} \leq y^*(1 + O(1/(y^* \log^2 t))). \tag{4.8}$$

Second, since the $z_{i,j}$ are nonnegative integers summing to at most $(y^*)^2 \log^5 t(1 + O(1/(y^* \log^2 t)))$, *at most* $O((y^*)^2 \log^5 t)$ *values* $x''_{i,j}$ *are nonzero*, for each $i \in [n]$. Thus, by losing a little in y^* (see (4.8)), our "scaling up-rounding-scaling down" method has given a fractional solution x'' with a much-reduced ℓ_i for each i; ℓ_i is now $O((y^*)^2 \log^5 t)$, essentially. Thus, t has been reduced to $O(a(y^*)^2 \log^5 t)$; i.e., t has been reduced to at most

$$K_2 t^{1/4+2/7} \log^5 t \tag{4.9}$$

for some constant $K_2 > 0$ that is independent of K_0, since (4.4) was assumed false. Repeating this scheme $O(\log \log t)$ times makes t small enough to satisfy (4.4). More formally, define $t_0 = t$ and $t_{i+1} = K_2 t_i^{1/4+2/7} \log^5 t_i$ for $i \geq 0$. Stop this sequence at the first point where either $t = t_i$ satisfies (4.4) or $t_{i+1} \geq t_i$ holds. Thus, we finally have t small enough to satisfy (4.4) or to be bounded by some absolute constant. How much has $\max_{i \in [m]} (Ax)_i$ increased in the process? By (4.8), we see that at the end,

$$\max_{i \in [m]} (Ax)_i \leq y^* \cdot \prod_{j \geq 0} (1 + O(1/(y^* \log^2 t_j))) \leq y^* \cdot e^{O(\sum_{j \geq 0} 1/(y^* \log^2 t_j))} \leq y^* + O(1), \tag{4.10}$$

since the values $\log t_j$ decrease geometrically and are lower-bounded by some absolute positive constant. We may now apply Theorem 4.2.

Case II. $t^{-1/7} < y^* < 1$. The idea is the same here, with the scaling up of $x^*_{i,j}$ being by $(\log^5 t)/y^*$; the same "scaling up-rounding-scaling down" method works out. Since the ideas are very similar to Case I, we only give a proof sketch here. We now scale up all the $x^*_{i,j}$ first by $(\log^5 t)/y^*$ and do a randomized rounding. The analogs of (4.5) and (4.6) that we now want are

$$\forall i \in [m], (Az)_i \leq \log^5 t \cdot (1 + K'_1/\log^2 t), \quad \text{and} \tag{4.11}$$

$$\forall i \in [n], \left| \sum_j z_{i,j} - \log^5 t/y^* \right| \leq K'_1 \log^3 t/\sqrt{y^*}. \tag{4.12}$$

Proceeding identically as in Case I, we can show that with positive probability, (4.11) and (4.12) hold simultaneously. Fix a rounding where these two properties hold and renormalize as before: $x''_{i,j} := z_{i,j}/\sum_u z_{i,u}$. Since (4.11) and (4.12) hold, we get that

the following analogs of (4.8) and (4.9) hold:

$$(Ax'')_i \le \frac{y^*(1+O(1/\log^2 t))}{1-O(\sqrt{y^*}/\log^2 t)} \le y^*(1+O(1/\log^2 t)); \quad \text{and}$$

t has been reduced to $O(a\log^5 t/y^*)$, i.e., to $O(t^{1/4+1/7}\log^5 t)$.

We thus only need $O(\log\log t)$ iterations, again. Also, the analog of (4.10) now is that

$$\max_{i\in[m]}(Ax)_i \le y^* \cdot \prod_{j\ge 0}(1+O(1/\log^2 t_j)) \le y^* \cdot e^{O(\sum_{j\ge 0} 1/\log^2 t_j)} \le y^* + O(1).$$

This completes the proof of Theorem 2.5. □

We now study our improvements for discrepancy-type problems, which are an important class of MIPs that, among other things, are useful in devising divide-and-conquer algorithms. Given is a set-system (X, F), where $X = [n]$ and $F = \{D_1, D_2, \ldots, D_M\} \subseteq 2^X$. Given a positive integer ℓ, the problem is to partition X into ℓ parts, so that *each* D_j is "split well"; we want a function $f : X \to [\ell]$ which minimizes $\max_{j\in[M],k\in[\ell]} |\{i \in D_j : f(i) = k\}|$. (The case $\ell = 2$ is the standard set-discrepancy problem.) To motivate this problem, suppose we have a (di)graph (V, A); we want a partition of V into $V_1, \ldots, V_\ell$ such that $\forall v \in V$, $\{|\{j \in N(v)\cap V_k\}| : k \in [\ell]\}$ are "roughly the same," where $N(v)$ is the (out-)neighborhood of v; see, e.g., [2, 17] for how this helps construct divide-and-conquer approaches. This problem is naturally modeled by the above set-system problem.

Let Δ be the degree of (X, F), i.e., $\max_{i\in[n]}|\{j : i \in D_j\}|$, and let $\Delta' \doteq \max_{D_j\in F} |D_j|$. Our problem is naturally written as an MIP with $m = M\ell$, $\ell_i = \ell$ for each i, and $g = a = \Delta$, in the notation of Definition 2.1; $y^* = \Delta'/\ell$ here. The analysis of [32] gives an integral solution of value at most $y^*(1+O(H(y^*, 1/(M\ell))))$, while [18] presents a solution of value at most $y^* + \Delta$. Also, since any $D_j \in F$ intersects at most $(\Delta-1)\Delta'$ other elements of F, Lemma 1.1 shows that randomized rounding produces, with positive probability, a solution of value at most $y^*(1 + O(H(y^*, 1/(e\Delta'\Delta\ell))))$. This is the approach taken by [16] for their case of interest: $\Delta = \Delta'$, $\ell = \Delta/\log\Delta$.

Theorem 2.5 shows the existence of an integral solution of value a constant plus $y^*(1 + O(H(y^*, 1/\delta)))$; i.e., *removes the dependence of the approximation factor on* Δ'. This is an improvement on all three results above. As a specific interesting case, suppose ℓ grows at most as fast as $\Delta'/\log\Delta$. Then we see that good integral solutions—those that grow at the rate of $O(y^*)$ or better—exist, which was not known before. (The approach of [16] shows such a result for $\ell = O(\Delta'/\log(\max\{\Delta, \Delta'\}))$. Our bound of $O(\Delta'/\log\Delta)$ is always better than this, and especially so if $\Delta' \gg \Delta$.)

5. Approximating covering integer programs. One of the main ideas behind Theorem 3.1 was to extend the basic inductive proof behind the LLL by decomposing the "bad" events E_i appropriately into the r.v.s $C_{i,j}$. We now use this general idea in a different context, that of (multicriteria) covering integer programs, with an additional crucial ingredient being a useful correlation inequality, the FKG inequality [15]. The reader is asked to recall the discussion of (multicriteria) CIPs from section 2. We start with a discussion of randomized rounding for CIPs, the Chernoff lower-tail bound, and the FKG inequality in section 5.1. These lead to our improved, but non-constructive, approximation bound for column-sparse (multicriteria) CIPs, in section 5.2. This is then made constructive in section 5.3; we also discuss there what we view

as novel about this constructive approach. The two paragraphs marked "Intuition" in section 5.2, as well as the first two paragraphs in section 5.3, describe some of our main ideas here at an intuitive level.

5.1. Preliminaries. Let us start with a simple and well-known approach to tail bounds. Suppose Y is a random variable and y is some value. Then, for any $0 \leq \delta < 1$, we have

$$\Pr(Y \leq y) \leq \Pr((1-\delta)^Y \geq (1-\delta)^y) \leq \frac{E[(1-\delta)^Y]}{(1-\delta)^y}, \tag{5.1}$$

where the inequality is a consequence of Markov's inequality.

We next setup some basic notions related to approximation algorithms for (multicriteria) CIPs. Recall that in such problems, we have ℓ given nonnegative vectors $c_1, c_2, \ldots, c_\ell$ such that $\forall\ i,\ c_i \in [0,1]^n$ with $\max_j c_{i,j} = 1$; $\ell = 1$ in the case of CIPs. Let $x = (x_1^*, x_2^*, \ldots, x_n^*)$ denote a given fractional solution that satisfies the system of constraints $Ax \geq b$. We are not concerned here with how x^* was found: typically, x^* would be an optimal solution to the LP relaxation of the problem. (The LP relaxation is obvious if, e.g., $\ell = 1$, or, say, if the given multicriteria aims to minimize $\max_i c_i^T \cdot x^*$, or to keep each $c_i^T \cdot x^*$ bounded by some target value v_i.) We now consider how to round x^* to some integral z so that

(P1) the constraints $Az \geq b$ hold, and

(P2) for all i, $c_i^T \cdot z$ is "not much bigger" than $c_i^T \cdot x^*$: our approximation bound will be a measure of how small a "not much bigger value" we can achieve in this sense.

Let us now discuss the "standard" randomized rounding scheme for (multicriteria) CIPs. We assume a fixed instance as well as x^*, from now on. For an $\alpha > 1$ to be chosen suitably, set $x'_j = \alpha x_j^*$, for each $j \in [n]$. We then construct a random integral solution z by setting, independently for each $j \in [n]$, $z_j = \lfloor x'_j \rfloor + 1$ with probability $x'_j - \lfloor x'_j \rfloor$, and $z_j = \lfloor x'_j \rfloor$ with probability $1 - (x'_j - \lfloor x'_j \rfloor)$. The aim then is to show that with positive (hopefully high) probability, (P1) and (P2) happen simultaneously. We now introduce some useful notation. For every $j \in [n]$, let $s_j = \lfloor x'_j \rfloor$. Let A_i denote the ith row of A, and let $X_1, X_2, \ldots, X_n \in \{0,1\}$ be *independent* r.v.s with $\Pr(X_j = 1) = x'_j - s_j\ \forall j$. The bad event E_i that the ith constraint is violated by our randomized rounding is given by $E_i \equiv$ "$A_i \cdot X < \mu_i(1-\delta_i)$," where $\mu_i = E[A_i \cdot X]$, s is the vector with entries s_j, and $\delta_i = 1 - (b_i - A_i \cdot s)/\mu_i$. We aim to bound $\Pr(E_i)$ for all i, when the standard randomized rounding is used. We assume without loss of generality that $A_i \cdot s < b_i$ for each i; otherwise, the bad event E_i cannot happen. So, we have $\delta_i \in (0,1)\ \forall i$.

We now bound $\Pr(E_i)$; the proof involves routine Chernoff bounds and calculations, and is shown in the appendix.

LEMMA 5.1. *Define* $g(B,\alpha) \doteq (\alpha \cdot e^{-(\alpha-1)})^B$. *Then* $\forall i$,

$$\Pr(E_i) \leq \frac{\mathrm{E}[(1-\delta_i)^{A_i \cdot X}]}{(1-\delta_i)^{(1-\delta_i)\mu_i}} \leq g(B,\alpha) \leq e^{-B(\alpha-1)^2/(2\alpha)}$$

under standard randomized rounding.

Next, we state a special case of the FKG inequality [15]. Given binary vectors $\vec{a} = (a_1, a_2, \ldots, a_\ell) \in \{0,1\}^\ell$ and $\vec{b} = (b_1, b_2, \ldots, b_\ell) \in \{0,1\}^\ell$, let us partially order them by coordinate-wise domination: $\vec{a} \preceq \vec{b}$ iff $a_i \leq b_i\ \forall\ i$. Now suppose $Y_1, Y_2, \ldots, Y_\ell$ are *independent* r.v.s, each taking values in $\{0,1\}$. Let $\vec{Y}$ denote the

vector $(Y_1, Y_2, \ldots, Y_\ell)$. Suppose an event $\mathcal{A}$ is completely defined by the value of $\vec{Y}$. Define $\mathcal{A}$ to be *increasing* iff: $\forall\ \vec{a} \in \{0,1\}^\ell$ such that $\mathcal{A}$ holds when $\vec{Y} = \vec{a}$, $\mathcal{A}$ also holds when $\vec{Y} = \vec{b}$, for any $\vec{b}$ such that $\vec{a} \preceq \vec{b}$. Analogously, event $\mathcal{A}$ is *decreasing* iff: for all $\vec{a} \in \{0,1\}^\ell$ such that $\mathcal{A}$ holds when $\vec{Y} = \vec{a}$, $\mathcal{A}$ also holds when $\vec{Y} = \vec{b}$, for any $\vec{b} \preceq \vec{a}$, the FKG inequality proves certain intuitively appealing bounds.

LEMMA 5.2 (FKG inequality). *Let $I_1, I_2, \ldots, I_t$ be any sequence of increasing events and $D_1, D_2, \ldots, D_t$ be any sequence of decreasing events (each I_i and D_i completely determined by $\vec{Y}$). Then for any $i \in [t]$ and any $S \subseteq [t]$,*

(i) $\Pr(I_i | \bigwedge_{j \in S} I_j) \geq \Pr(I_i)$ *and* $\Pr(D_i | \bigwedge_{j \in S} D_j) \geq \Pr(D_i)$;

(ii) $\Pr(I_i | \bigwedge_{j \in S} D_j) \leq \Pr(I_i)$ *and* $\Pr(D_i | \bigwedge_{j \in S} I_j) \leq \Pr(D_i)$.

Returning to our random variables X_j and events E_i, we get the following lemma as an easy consequence of the FKG inequality, since each event of the form "$\overline{E_i}$" or "$X_j = 1$" is an increasing event as a function of the vector $(X_1, X_2, \ldots, X_n)$.

LEMMA 5.3. *For all $B_1, B_2 \subseteq [m]$ such that $B_1 \cap B_2 = \emptyset$ and for any $B_3 \subseteq [n]$,* $\Pr(\bigwedge_{i \in B_1} \overline{E_i} \mid ((\bigwedge_{j \in B_2} \overline{E_j}) \wedge (\bigwedge_{k \in B_3} (X_k = 1)))) \geq \prod_{i \in B_1} \Pr(\overline{E_i})$.

5.2. Nonconstructive approximation bounds for (multicriteria) CIPs. We now work up to our main approximation bound for multicriteria CIPs in Theorem 5.9; this theorem is presented in an abstract manner, and one concrete corollary is shown by Corollary 5.10. We develop Theorem 5.9 by starting with the special case of CIPs (which have just one objective function) and proving Theorem 2.6; the basic ideas are then generalized to obtain Theorem 5.9. The randomized rounding approach underlying Theorem 5.9, as it stands, may only construct the solution guaranteed with very low (much less than inverse-polynomial) probability; algorithmic versions of Theorem 5.9, which in some cases involve superpolynomial time, are then developed in section 5.3.

DEFINITION 5.4 (the function $\mathcal{R}$). *For any s and any $j_1 < j_2 < \cdots < j_s$, let $\mathcal{R}(j_1, j_2, \ldots, j_s)$ be the set of indices i such that row i of the constraint system "$Ax \geq b$" has at least one of the variables j_k, $1 \leq k \leq s$, appearing with a nonzero coefficient. (Note from the definition of a in Definition 2.2 that $|\mathcal{R}(j_1, j_2, \ldots, j_s)| \leq a \cdot s$.)*

Let the vector $x^* = (x_1^*, x_2^*, \ldots, x_n^*)$, the parameter $\alpha > 1$, and the "standard" randomized rounding scheme, be as defined in section 5.1. The standard rounding scheme is sufficient for our (nonconstructive) purposes now; we generalize this scheme as follows for later use in section 5.3.

DEFINITION 5.5 (general randomized rounding). *Given a vector $p = (p_1, p_2, \ldots, p_n) \in [0,1]^n$, the general randomized rounding with parameter p generates independent random variables $X_1, X_2, \ldots, X_n \in \{0,1\}$ with $\Pr(X_j = 1) = p_j$; the rounded vector z is defined by $z_j = \lfloor \alpha x_j^* \rfloor + X_j\ \forall\ j$. (As in the standard rounding, we set each z_j to be either $\lfloor \alpha x_j^* \rfloor$ or $\lceil \alpha x_j^* \rceil$; the standard rounding is the special case in which $\boldsymbol{E}[z_j] = \alpha x_j^*\ \forall\ j$.)*

We now present an important lemma, Lemma 5.6, to get correlation inequalities which "point" in the "direction" opposite to FKG. Some ideas from the proof of Lemma 1.1 will play a crucial role in our proof this lemma.

LEMMA 5.6. *Suppose we employ general randomized rounding with some parameter p, and that $\Pr(\bigwedge_{i=1}^m \overline{E_i})$ is nonzero under this rounding. The following hold for*

any q and any $1 \leq j_1 < j_2 < \cdots < j_q \leq n$:

(i)

$$\Pr\left(X_{j_1} = X_{j_2} = \cdots = X_{j_q} = 1 \;\Big|\; \bigwedge_{i=1}^{m} \overline{E_i}\right) \leq \frac{\prod_{t=1}^{q} p_{j_t}}{\prod_{i \in \mathcal{R}(j_1, j_2, \ldots, j_q)} (1 - \Pr(E_i))}; \tag{5.2}$$

the events $E_i \equiv ((Az)_i < b_i)$ are defined here w.r.t. the general randomized rounding.

(ii) *In the special case of standard randomized rounding,*

$$\prod_{i \in \mathcal{R}(j_1, j_2, \ldots, j_q)} (1 - \Pr(E_i)) \geq (1 - g(B, \alpha))^{aq}; \tag{5.3}$$

the function g is as defined in Lemma 5.1.

Proof. (i) Note first that if we wanted a *lower* bound on the l.h.s., the FKG inequality would immediately imply that the l.h.s. is at least $p_{j_1} p_{j_2} \cdots p_{j_q}$. We get around this "correlation problem" as follows. Let $Q = \mathcal{R}(j_1, j_2, \ldots, j_q)$; let $Q' = [m] - Q$. Let

$$Z_1 \equiv \left(\bigwedge_{i \in Q} \overline{E_i}\right), \text{ and } Z_2 \equiv \left(\bigwedge_{i \in Q'} \overline{E_i}\right).$$

Letting $Y = \prod_{t=1}^{q} X_{j_t}$, note that

$$|Q| \leq aq \quad \text{and} \tag{5.4}$$

$$Y \text{ is independent of } Z_2. \tag{5.5}$$

Now,

$$\begin{aligned}
\Pr(Y = 1 \mid (Z_1 \wedge Z_2)) &= \frac{\Pr(((Y = 1) \wedge Z_1) \mid Z_2)}{\Pr(Z_1 \mid Z_2)} \\
&\leq \frac{\Pr((Y = 1) \mid Z_2)}{\Pr(Z_1 \mid Z_2)} \\
&= \frac{\Pr(Y = 1)}{\Pr(Z_1 \mid Z_2)} \quad \text{(by (5.5))} \\
&= \frac{\prod_{t=1}^{q} \Pr(X_{j_t} = 1)}{\Pr(Z_1 \mid Z_2)} \qquad (5.6) \\
&\leq \frac{\prod_{t=1}^{q} \Pr(X_{j_t} = 1)}{\prod_{i \in \mathcal{R}(j_1, j_2, \ldots, j_q)} (1 - \Pr(E_i))} \quad \text{(by Lemma 5.3).}
\end{aligned}$$

(ii) We get (5.3) from Lemma 5.1 and (5.4). ∎

Intuition. Note that in the proof of part (i) of Lemma 5.6, we broadly proceed as in the proofs of Lemma 1.1 and Theorem 3.1 up to (5.6). The key difference in the next (and final) step is that instead of applying induction to lower-bound the denominator as in the proofs of Lemma 1.1 and Theorem 3.1, we are directly able to obtain a lower bound via Lemma 5.3. In addition to giving a better lower bound, this type of explicitly-available denominator will be of considerable value in section 5.3.

We will use Lemmas 5.3 and 5.6 to prove Theorem 5.9. As a warmup, we start with Theorem 2.6, which deals with the special case of CIPs; recall that y^* denotes $c^T \cdot x^*$. We present a simple proposition, whose proof is in the appendix:

PROPOSITION 5.7. *Suppose α and β are chosen as follows, for some sufficiently large absolute constant $K > 0$:*

$$\alpha = K \cdot \ln(a+1)/B \text{ and } \beta = 2, \text{ if } \ln(a+1) \geq B, \text{ and} \tag{5.7}$$

$$\alpha = \beta = 1 + K \cdot \sqrt{\ln(a+B)/B}, \text{ if } \ln(a+1) < B. \tag{5.8}$$

Then we have $\beta(1 - g(B,\alpha))^a > 1$.

We now prove Theorem 2.6, our result for CIPs.

Proof of Theorem 2.6. Let α and β be as in (5.7) and (5.8). Conduct standard randomized rounding, and let $\mathcal{E}$ be the event that $c^T \cdot z > y^* \alpha\beta$. Setting $Z \equiv \bigwedge_{i \in [m]} \overline{E_i}$ and $\mu \doteq \mathbf{E}[c^T \cdot z] = y^*\alpha$, we see by Markov's inequality that $\Pr(\mathcal{E} \mid Z)$ is at most $R = (\sum_{j=1}^n c_j \Pr(X_j = 1 \mid Z))/(\mu\beta)$. Note that $\Pr(Z) > 0$ since $\alpha > 1$; so, we need only prove that $R < 1$. Lemma 5.6 shows that

$$R \leq \frac{\sum_j c_j p_j}{\mu\beta \cdot (1 - g(B,\alpha))^a} = \frac{1}{\beta(1 - g(B,\alpha))^a};$$

thus, the condition $\beta(1 - g(B,\alpha))^a > 1$ suffices. Proposition 5.7 completes the proof. □

Intuition. The basic approach of our proof of Theorem 2.6 is to follow the main idea of Theorem 3.1, and to decompose the event "$\mathcal{E} \mid Z$" into a nonnegative linear combination of events of the form "$X_j = 1 \mid Z$"; we then exploited the fact that each X_j depends on at most a of the events comprising Z. We now extend Theorem 2.6 and also generalize to multicriteria CIPs. Instead of employing just a "first moment method" (Markov's inequality) as in the proof of Theorem 2.6, we will work with higher moments: the functions S_k defined in (3.1) and used in Theorem 3.4.

Suppose some parameters $\lambda_i > 0$ are given, and that our goal is to round x^* to z so that the event

$$\mathcal{A} \equiv \left[(Az \geq b) \ \wedge \ (\forall i, \ c_i^T \cdot z \leq \lambda_i)\right] \tag{5.9}$$

holds. We first give a sufficient condition for this to hold, in Theorem 5.9; we then derive some concrete consequences in Corollary 5.10. We need one further definition before presenting Theorem 5.9. Recall that A_i and b_i, respectively, denote the ith row of A and the ith component of b. Also, the vector s and values δ_i will throughout be as in the definition of standard randomized rounding.

DEFINITION 5.8 (the functions ch and ch′). *Suppose we conduct general randomized rounding with some parameter p; i.e., let $X_1, X_2, \ldots, X_n$ be independent binary random variables such that $\Pr(X_j = 1) = p_j$. For each $i \in [m]$, define*

$$\mathrm{ch}_i(p) \doteq \frac{\boldsymbol{E}[(1-\delta_i)^{A_i \cdot X}]}{(1-\delta_i)^{b_i - A_i \cdot s}} = \frac{\prod_{j \in [n]} \boldsymbol{E}[(1-\delta_i)^{A_{i,j} X_j}]}{(1-\delta_i)^{b_i - A_i \cdot s}} \quad \text{and} \quad \mathrm{ch}'_i(p) \doteq \min\{\mathrm{ch}_i(p), 1\}.$$

(Note from (5.1) *that if we conduct general randomized rounding with parameter p, then $\Pr((Az)_i < b_i) \leq \mathrm{ch}'_i(p)$; also, "*ch*" stands for "Chernoff–Hoeffding.")*

THEOREM 5.9. *Suppose we are given a multicriteria CIP, as well as some parameters $\lambda_1, \lambda_2, \ldots, \lambda_\ell > 0$. Let $\mathcal{A}$ be as in* (5.9). *Then, for any sequence of positive*

integers $(k_1, k_2, \ldots, k_\ell)$ *such that* $k_i \le \lambda_i$, *the following hold:*

(i) *Suppose we employ general randomized rounding with parameter* $p = (p_1, p_2, \ldots, p_n)$. *Then,* $\Pr(\mathcal{A})$ *is at least*

$$\Phi(p) \doteq \left(\prod_{r\in[m]} (1 - \mathrm{ch}'_r(p))\right) - \sum_{i=1}^{\ell} \frac{1}{\binom{\lambda_i}{k_i}} \cdot \sum_{j_1<\cdots<j_{k_i}} \left(\prod_{t=1}^{k_i} c_{i,j_t} \cdot p_{j_t}\right) \cdot \prod_{r\notin\mathcal{R}(j_1,\ldots,j_{k_i})} (1 - \mathrm{ch}'_r(p)); \tag{5.10}$$

as in Definition 2.3, $c_{i,j} \in [0,1]$ *is the* j*th coordinate of the vector* c_i.

(ii) *Suppose we employ the standard randomized rounding to get a rounded vector* z. *Let* $\lambda_i = \nu_i(1+\gamma_i)$ *for each* $i \in [\ell]$, *where* $\nu_i = \boldsymbol{E}[c_i^T \cdot z] = \alpha \cdot (c_i^T \cdot x^*)$ *and* $\gamma_i > 0$ *is some parameter. Then,*

$$\Phi(p) \ge (1 - g(B,\alpha))^m \cdot \left(1 - \sum_{i=1}^{\ell} \frac{\binom{n}{k_i} \cdot (\nu_i/n)^{k_i}}{\binom{\nu_i(1+\gamma_i)}{k_i}} \cdot (1 - g(B,\alpha))^{-a\cdot k_i}\right). \tag{5.11}$$

In particular, if the r.h.s. of (5.11) *is positive, then* $\Pr(\mathcal{A}) > 0$ *for standard randomized rounding.*

The proof of Theorem 5.9 is a simple generalization of that of Theorem 2.6—basically, we use higher moments (the moment S_{k_i} for objective function c_i) and employ Theorem 3.4, instead of using the first moment and Markov's inequality. This proof is deferred to the appendix. Theorem 2.6 is the special case of Theorem 5.9 corresponding to $\ell = k_1 = 1$. To make the general result of Theorem 5.9 more concrete, we now present an additional special case, Corollary 5.10. We provide this as one possible "proof of concept," rather than as an optimized one; e.g., the constant "3" in the bound "$c_i^T \cdot z \le 3\nu_i$" of Corollary 5.10 can be improved. The proof of Corollary 5.10 requires routine calculations after setting $k_i = \lceil \ln(2\ell) \rceil$ and $\gamma_i = 2$ for all i in part (ii) of Theorem 5.9; its proof is given in the appendix.

COROLLARY 5.10. *There is an absolute constant* $K' > 0$ *such that the following holds. Suppose we are given a multicriteria CIP with notation as in part* (ii) *of Theorem* 5.9. *Define* $\alpha = K' \cdot \max\{\frac{\ln(a)+\ln\ln(2\ell)}{B},\ 1\}$. *Now if* $\nu_i \ge \log^2(2\ell)\ \forall\ i \in [\ell]$, *then standard randomized rounding produces a feasible solution* z *such that* $c_i^T \cdot z \le 3\nu_i\ \forall\ i$, *with positive probability.*

In particular, this can be shown by setting $k_i = \lceil \ln(2\ell) \rceil$ *and* $\gamma_i = 2\ \forall\ i$, *in part* (ii) *of Theorem* 5.9.

5.3. Constructive version. It can be shown that for many problems,randomized rounding produces the solutions shown to exist by Theorems 2.6 and 5.9, with very low probability: e.g., probability almost exponentially small in the input size. Thus we need to obtain constructive versions of these theorems. Our method will be a deterministic procedure that makes $O(n)$ calls to the function $\Phi(\cdot)$, in addition to $\mathrm{poly}(n,m)$ work. Now, if k' denotes the maximum of all the k_i, we see that Φ can be evaluated in $\mathrm{poly}(n^{k'}, m)$ time. Thus, our overall procedure runs in time $\mathrm{poly}(n^{k'}, m)$. In particular, we get constructive versions of Theorem 2.6 and Corollary 5.10 that run in time $\mathrm{poly}(n,m)$ and $\mathrm{poly}(n^{\log \ell}, m)$, respectively.

Our approach is as follows. We start with a vector p that corresponds to standard randomized rounding, for which we know (say, as argued in Corollary 5.10) that $\Phi(p) > 0$. In general, we have a vector of probabilities $p = (p_1, p_2, \ldots, p_n)$ such that

$\Phi(p) > 0$. If $p \in \{0,1\}^n$, we are done. Otherwise suppose some p_j lies in $(0,1)$; by renaming the variables, we will assume without loss of generality that $j = n$. Define $p' = (p_1, p_2, \ldots, p_{n-1}, 0)$ and $p'' = (p_1, p_2, \ldots, p_{n-1}, 1)$. The main fact we wish to show is that $\Phi(p') > 0$ or $\Phi(p'') > 0$: we can then set p_n to 0 or 1 appropriately and continue. (As mentioned in the previous paragraph, we thus have $O(n)$ calls to the function $\Phi(\cdot)$ in total.) Note that although some of the p_j will lie in $\{0,1\}$, we can crucially continue to view the X_j as *independent* random variables with $\Pr(X_j = 1) = p_j$.

So, our main goal is: assuming that $p_n \in (0,1)$ and that

$$\Phi(p) > 0, \tag{5.12}$$

to show that $\Phi(p') > 0$ or $\Phi(p'') > 0$. In order to do so, we make some observations and introduce some simplifying notation. Define, for each $i \in [m]$: $q_i = \mathrm{ch}'_i(p)$, $q'_i = \mathrm{ch}'_i(p')$, and $q''_i = \mathrm{ch}'_i(p'')$. Also define the vectors $q \doteq (q_1, q_2, \ldots, q_m)$, $q' \doteq (q'_1, q'_2, \ldots, q'_m)$, and $q'' \doteq (q''_1, q''_2, \ldots, q''_m)$. We now present a useful lemma about these vectors.

LEMMA 5.11. *For all $i \in [m]$, we have*

$$0 \le q''_i \le q'_i \le 1; \tag{5.13}$$

$$q_i \ge p_n q''_i + (1 - p_n) q'_i; \text{ and} \tag{5.14}$$

$$q'_i = q''_i = q_i \text{ if } i \notin \mathcal{R}(n). \tag{5.15}$$

Proof. It is directly seen from the definition of "ch_i" that $\mathrm{ch}_i(p'') \le \mathrm{ch}_i(p')$. Since $q''_i = \min\{\mathrm{ch}_i(p''), 1\}$ and $q'_i = \min\{\mathrm{ch}_i(p'), 1\}$, we get $q''_i \le q'_i$. The remaining inequalities of (5.13), as well as the equalities in (5.15), are straightforward. As for (5.14), we proceed as in [36]. First of all, if $q_i = 1$, then we are done, since $q''_i,\ q'_i \le 1$. So suppose $q_i < 1$; in this case, $q_i = \mathrm{ch}_i(p)$. Now, Definition 5.8 shows that

$$\mathrm{ch}_i(p) = p_n \mathrm{ch}_i(p'') + (1 - p_n)\mathrm{ch}_i(p').$$

Therefore, $q_i = \mathrm{ch}_i(p) = p_n \mathrm{ch}_i(p'') + (1-p_n)\mathrm{ch}_i(p') \ge p_n \mathrm{ch}'_i(p'') + (1-p_n)\mathrm{ch}'_i(p')$. ∎

Since we are mainly concerned with the vectors p, p', and p'' now, we will view the values $p_1, p_2, \ldots, p_{n-1}$ as arbitrary but *fixed*, subject to (5.12). The function $\Phi(\cdot)$ now has a simple form; to see this, we first define, for a vector $r = (r_1, r_2, \ldots, r_m)$ and a set $U \subseteq [m]$,

$$f(U, r) = \prod_{i \in U} (1 - r_i).$$

Recall that $p_1, p_2, \ldots, p_{n-1}$ are considered as constants now. Then, it is evident from (5.10) that there exist constants $u_1, u_2, \ldots, u_t$ and $v_1, v_2, \ldots, v_{t'}$, as well as subsets

$U_1, U_2, \ldots, U_t$ and $V_1, V_2, \ldots, V_{t'}$ of $[m]$, such that

$$\Phi(p) = f([m], q) - \left(\sum_i u_i \cdot f(U_i, q)\right) - \left(p_n \cdot \sum_j v_j \cdot f(V_j, q)\right); \tag{5.16}$$

$$\Phi(p') = f([m], q') - \left(\sum_i u_i \cdot f(U_i, q')\right) - \left(0 \cdot \sum_j v_j \cdot f(V_j, q')\right)$$

$$= f([m], q') - \sum_i u_i \cdot f(U_i, q'); \tag{5.17}$$

$$\Phi(p'') = f([m], q'') - \left(\sum_i u_i \cdot f(U_i, q'')\right) - \left(1 \cdot \sum_j v_j \cdot f(V_j, q'')\right)$$

$$= f([m], q'') - \left(\sum_i u_i \cdot f(U_i, q'')\right) - \left(\sum_j v_j \cdot f(V_j, q'')\right). \tag{5.18}$$

Importantly, we also have the following:

$$\text{the constants } u_i, v_j \text{ are nonnegative; } \quad \forall j,\ V_j \cap \mathcal{R}(n) = \emptyset. \tag{5.19}$$

Recall that our goal is to show that $\Phi(p') > 0$ or $\Phi(p'') > 0$. We will do so by proving that

$$\Phi(p) \leq p_n \Phi(p'') + (1 - p_n)\Phi(p'). \tag{5.20}$$

Let us use the equalities (5.16), (5.17), and (5.18). In view of (5.15) and (5.19), the term "$-p_n \cdot \sum_j v_j \cdot f(V_j, q)$" on both sides of the inequality (5.20) cancels; defining $\Delta(U) \doteq (1 - p_n) \cdot f(U, q') + p_n \cdot f(U, q'') - f(U, q)$, inequality (5.20) reduces to

$$\Delta([m]) - \sum_i u_i \cdot \Delta(U_i) \geq 0. \tag{5.21}$$

Before proving this, we pause to note a challenge we face. Suppose we only had to show that, say, $\Delta([m])$ is nonnegative; this is exactly the issue faced in [36]. Then, we will immediately be done by part (i) of Lemma 5.12, which states that $\Delta(U) \geq 0$ for any set U. However, (5.21) also has terms such as "$u_i \cdot \Delta(U_i)$" with a *negative* sign in front. To deal with this, we need something more than just that $\Delta(U) \geq 0$ for all U; we handle this by part (ii) of Lemma 5.12. We view this as the main novelty in our constructive version here.

LEMMA 5.12. *Suppose* $U \subseteq V \subseteq [m]$. *Then,* (i) $\Delta(U) \geq 0$, *and* (ii) $\Delta(U)/f(U, q) \leq \Delta(V)/f(V, q)$. *(Since* $\Phi(p) > 0$ *by* (5.12)*, we have that* $q_i < 1$ *for each* i. *So,* $1/f(U, q)$ *and* $1/f(V, q)$ *are well defined.)*

Assuming that Lemma 5.12 is true, we will now show (5.21); the proof of Lemma

5.12 is given below. We have

$$\begin{aligned}\Delta([m]) - \sum_i u_i \cdot \Delta(U_i) &= (\Delta([m])/f([m],q)) \cdot f([m],q) \\ &\quad - \sum_i (\Delta(U_i)/f(U_i,q)) \cdot u_i \cdot f(U_i,q) \\ &\geq (\Delta([m])/f([m],q)) \cdot \left[f([m],q) - \sum_i u_i \cdot f(U_i,q) \right] \\ &\quad \text{(by Lemma 5.12)} \\ &\geq 0 \quad \text{(by (5.12) and (5.16))}.\end{aligned}$$

Thus we have (5.21).

Proof of Lemma 5.12. It suffices to show the following. Assume $U \neq [m]$; suppose $u \in ([m] - U)$ and that $U' = U \cup \{u\}$. Assuming by induction on $|U|$ that $\Delta(U) \geq 0$, we show that $\Delta(U') \geq 0$ and that $\Delta(U)/f(U,q) \leq \Delta(U')/f(U',q)$. It is easy to check that this way we will prove both claims of the lemma.

The base case of the induction is that $|U| \in \{0,1\}$, where $\Delta(U) \geq 0$ is directly seen by using (5.14). Suppose inductively that $\Delta(U) \geq 0$. Using the definition of $\Delta(U)$ and the fact that $f(U',q) = (1-q_u)f(U,q)$, we have

$$\begin{aligned}f(U',q) &= (1-q_u) \cdot [(1-p_n)f(U,q') + p_n f(U,q'') - \Delta(U)] \\ &\leq (1 - (1-p_n)q'_u - p_n q''_u) \cdot [(1-p_n)f(U,q') + p_n f(U,q'')] - (1-q_u) \cdot \Delta(U),\end{aligned}$$

where this last inequality is a consequence of (5.14). Therefore, using the definition of $\Delta(U')$ and the facts $f(U',q') = (1-q'_u)f(U,q')$ and $f(U',q'') = (1-q''_u)f(U,q'')$,

$$\begin{aligned}\Delta(U') &= (1-p_n)(1-q'_u)f(U,q') + p_n(1-q''_u)f(U,q'') - f(U',q) \\ &\geq (1-p_n)(1-q'_u)f(U,q') + p_n(1-q''_u)f(U,q'') \\ &\quad + (1-q_u) \cdot \Delta(U) - (1 - (1-p_n)q'_u - p_n q''_u) \cdot [(1-p_n)f(U,q') + p_n f(U,q'')] \\ &= (1-q_u) \cdot \Delta(U) + p_n(1-p_n) \cdot (f(U,q'') - f(U,q')) \cdot (q'_u - q''_u) \\ &\geq (1-q_u) \cdot \Delta(U) \quad \text{(by (5.13))}.\end{aligned}$$

So, since we assumed that $\Delta(U) \geq 0$, we get $\Delta(U') \geq 0$; furthermore, we get that $\Delta(U') \geq (1-q_u) \cdot \Delta(U)$, which implies that $\Delta(U')/f(U',q) \geq \Delta(U)/f(U,q)$. □

6. Conclusion. We have presented an extension of the LLL that basically helps reduce the "dependency" much in some settings; we have seen applications to two families of integer programming problems. It would be interesting to see how far these ideas can be pushed further. Two other open problems suggested by this work are: (i) developing a constructive version of our result for MIPs, and (ii) developing a $\text{poly}(n,m)$-time constructive version of Theorem 5.9, as opposed to the $\text{poly}(n^{k'},m)$-time constructive version that we presented in section 5.3.

Finally, a very interesting question is to develop a theory of applications of the LLL (Lemma 1.1) that can be made constructive with (essentially) no loss. Suppose we have bad events $E_1, E_2, \ldots, E_m$ in the setting of the LLL, which are functions of n independent binary random variables $X_1, X_2, \ldots, X_n$, where $\Pr(X_i = 1) = p_i$. In an attempt to mimic the approach described in the second paragraph of section 5.3, suppose we proceed as follows. The standard proof of the LLL [14] presents a function Φ such that: (i) $\Pr(\bigwedge_{i=1}^m \overline{E_i}) > 0$ if $\Phi(p) > 0$, and (ii) if the conditions of the LLL

hold, then $\Phi(p) > 0$. Can we now try to set values for the X_i one-by-one, as in section 5.3? Unfortunately, there are two problems we face in this regard. First, the function Φ given by the proof of the LLL does not appear to be polynomial-time computable, basically due to the type of induction it uses; indeed, as briefly mentioned in the paragraph following the proof of Lemma 5.6, the type of "explicitly-available denominator" that we obtain in the proof of Lemma 5.6 is one crucial driver in obtaining an efficiently-computable Φ in section 5.3. Second, again appealing to the notation of the second paragraph of section 5.3, it is unclear if we can prove here that "$\Phi(p') > 0$ or $\Phi(p'') > 0$." (In fact, Joel Spencer has suggested to the author the possibility that such a disjunction may not hold for all applications of the LLL.) It would be of much interest to guarantee these for some interesting class of applications of the LLL, or to develop fresh approaches to obtain constructive versions of the LLL with (essentially) no loss.

Appendix. Proofs and calculation-details.

Proof of Proposition 4.1. Taking logarithms on both sides, we aim to show that

$$\mu_1 \cdot [\mu_2\delta/\mu_1 - (1+\mu_2\delta/\mu_1)\ln(1+\mu_2\delta/\mu_1)] \leq \mu_2 \cdot [\delta - (1+\delta)\ln(1+\delta)]\,.$$

This simplifies to showing

$$(1+\psi\delta)\ln(1+\psi\delta) \geq \psi \cdot (1+\delta)\ln(1+\delta),$$

where $\psi = \mu_2/\mu_1 \geq 1$. This inequality, in turn, follows from the fact that the function $t \mapsto (1+t)\ln(1+t)$ is convex for $t \geq 0$ (since its second derivative, $1/(1+t)$, is positive), and since this function equals 0 when $t = 0$. □

Proof of Lemma 5.1. The first inequality follows from (5.1). Next, the Chernoff–Hoeffding lower-tail approach [4, 27] shows that

$$\frac{E[(1-\delta_i)^{A_i\cdot X}]}{(1-\delta_i)^{(1-\delta_i)\mu_i}} \leq \left(\frac{e^{-\delta_i}}{(1-\delta_i)^{1-\delta_i}}\right)^{\mu_i} = \frac{{\mu_i}^{b_i - A_i\cdot s}\cdot e^{b_i-\mu_i-A_i\cdot s}}{(b_i - A_i\cdot s)^{b_i - A_i\cdot s}}. \tag{A.1}$$

Recall that

$$A_i \cdot s < b_i; \quad A_i\cdot s + \mu_i \geq \alpha b_i; \quad \alpha > 1. \tag{A.2}$$

Let us now bound the last (third) term in (A.1), denoted ψ, say.

Fix all parameters other than μ_i; subject to (A.2), let us first observe that ψ is maximized when the second inequality in (A.2) is an equality. This is easily seen by recalling the definition of ψ (from (A.1)) and noting by differentiation that ψ is a decreasing function of μ_i when $\mu_i > b_i - A_i\cdot s$. Next, since $\mu_i = \alpha b_i - A_i\cdot s$,

$$\psi = \left(\frac{\alpha b_i - A_i\cdot s}{b_i - A_i\cdot s}\right)^{b_i - A_i\cdot s}\cdot e^{(1-\alpha)b_i} = \left(1 + \frac{(\alpha-1)b_i}{b_i - A_i\cdot s}\right)^{b_i - A_i\cdot s}\cdot e^{(1-\alpha)b_i}.$$

Let $x = (\alpha-1)b_i/(b_i - A_i\cdot s)$, and note that $x \geq \alpha - 1$. We have

$$\ln\psi = (1-\alpha)b_i + (\alpha-1)b_i\ln(1+x)/x. \tag{A.3}$$

Keeping b_i fixed,

$$\begin{aligned}\frac{d(\ln\psi)}{dx} &= (\alpha-1)b_i\cdot\frac{x/(1+x)-\ln(1+x)}{x^2}\\ &= (\alpha-1)b_i\cdot\frac{x/(1+x)+\ln(1-x/(1+x))}{x^2}\\ &\le (\alpha-1)b_i\cdot\frac{x/(1+x)-x/(1+x)}{x^2}\\ &= 0.\end{aligned}$$

So, ψ is maximized when $x=\alpha-1$ (i.e., when $A_i\cdot s=0$). From (A.3), $\ln\psi = b_i\cdot(1-\alpha+\ln\alpha)$; the term multiplying b_i here is nonpositive, since $\ln\alpha=\ln(1+\alpha-1)\le\alpha-1$. Therefore, ψ is maximized when b_i equals its minimum value of B, and so, $\psi\le g(B,\alpha)$.

Finally, let us check that $g(B,\alpha)\le e^{-B(\alpha-1)^2/(2\alpha)}$. Taking logarithms on both sides, we want

$$1-\alpha+\ln\alpha\le-(\alpha-1)^2/(2\alpha) \tag{A.4}$$

for $\alpha\ge1$. The l.h.s. and r.h.s. of (A.4) are equal when $\alpha=1$; their respective derivatives are $-1+1/\alpha$ and $-1/2+1/(2\alpha^2)$, and so it suffices to prove that $1-1/\alpha\ge1/2-1/(2\alpha^2)$ for $\alpha\ge1$. That is, we need $2\alpha(\alpha-1)\ge(\alpha-1)\cdot(\alpha+1)$, which is true since $\alpha\ge1$. □

Proof of Proposition 5.7. Suppose first that $\ln(a+1)\ge B$. Then, $\alpha=K\cdot\ln(a+1)/B$ and so if K is large enough, then $\alpha/e^{\alpha-1}\le e^{-\alpha/2}$. Therefore,

$$g(B,\alpha)=(\alpha\cdot e^{-(\alpha-1)})^B\le e^{-\alpha B/2}=(a+1)^{-K/2}.$$

So, since $\beta=2$, our goal of proving that $\beta(1-g(B,\alpha))^a>1$ reduces to proving that $2\cdot(1-(a+1)^{-K/2})^a>1$, which is true since $a\ge1$ and K is chosen sufficiently large.

We next consider the case where $\ln(a+1)<B$. Recall from the statement of Lemma 5.1 that $g(B,\alpha)\le e^{-B(\alpha-1)^2/(2\alpha)}$. Since $\alpha<K+1$ in our case, we now have

$$g(B,\alpha)<e^{-B(\alpha-1)^2/(2(K+1))}=e^{-K^2\ln(a+B)/(2(K+1))}=(a+B)^{-K^2/(2(K+1))}.$$

So, our goal of showing that $\beta(1-g(B,\alpha))^a>1$ reduces to proving that

$$(1+K\cdot\sqrt{\ln(a+B)/B})\cdot(1-(a+B)^{-K^2/(2(K+1))})^a\ge1,$$

which in turn holds if $(1+K\cdot\sqrt{\ln(a+B)/B})\cdot(1-a\cdot(a+B)^{-K^2/(2(K+1))})\ge1$; this final inequality is true if we choose K to be a sufficiently large constant, since $a\cdot(a+B)^{-K^2/(2(K+1))}\ll K\cdot\sqrt{\ln(a+B)/B}$ under such a choice. □

Proof of Theorem 5.9. (i) Let $E_r\equiv((Az)_r<b_r)$ be defined w.r.t. general randomized rounding with parameter p; as observed in Definition 5.8, $\Pr(E_r)\le\mathrm{ch}'_r(p)$. Now if $\mathrm{ch}'_r(p)=1$ for some r, then part (i) is trivially true; so we assume that $\Pr(E_r)\le\mathrm{ch}'_r(p)<1\ \forall\ r\in[m]$. Defining $Z\equiv(Az\ge b)\equiv\bigwedge_{r\in[m]}\overline{E_r}$, we get by the FKG inequality that

$$\Pr(Z)\ge\prod_{r\in[m]}(1-\Pr(E_r)).$$

Define, for $i = 1, 2, \ldots, \ell$, the "bad" event $\mathcal{E}_i \equiv (c_i^T \cdot z > \lambda_i)$. Fix any i. Our plan is to show that

(A.5)
$$\Pr(\mathcal{E}_i \mid Z) \leq \frac{1}{\binom{\lambda_i}{k_i}} \cdot \sum_{j_1 < j_2 < \cdots < j_{k_i}} \left(\prod_{t=1}^{k_i} c_{i,j_t} \cdot p_{j_t} \right) \cdot \left(\prod_{r \in \mathcal{R}(j_1, j_2, \ldots, j_{k_i})} (1 - \Pr(E_r))^{-1} \right).$$

If we prove (A.5), then we will be done as follows. We have

(A.6)
$$\Pr(\mathcal{A}) \geq \Pr(Z) \cdot \left(1 - \sum_i \Pr(\mathcal{E}_i \mid Z) \right) \geq \left(\prod_{r \in [m]} (1 - \Pr(E_r)) \right) \cdot \left(1 - \sum_i \Pr(\mathcal{E}_i \mid Z) \right).$$

Now, the term "$(\prod_{r \in [m]} (1 - \Pr(E_r)))$" is a decreasing function of each of the values $\Pr(E_r)$; so is the lower bound on "$-\Pr(\mathcal{E}_i \mid Z)$" obtained from (A.5). Hence, bounds (A.5) and (A.6), along with the bound $\Pr(E_r) \leq \mathrm{ch}'_r(p)$, will complete the proof of part (i).

We now prove (A.5) using Theorem 3.4(a) and Lemma 5.6. Recall the symmetric polynomials S_k from (3.1). Define $Y = S_{k_i}(c_{i,1} X_1, c_{i,2} X_2, \ldots, c_{i,n} X_n) / \binom{\lambda_i}{k_i}$. By Theorem 3.4(a), $\Pr(\mathcal{E}_i \mid Z) \leq \mathbf{E}[Y \mid Z]$. Next, the typical term in $\mathbf{E}[Y \mid Z]$ can be upper bounded using Lemma 5.6

$$\mathbf{E}\left[\left(\prod_{t=1}^{k_i} c_{i,j_t} \cdot X_{j_t} \right) \mid \bigwedge_{i=1}^{m} \overline{E_i} \right] \leq \frac{\prod_{t=1}^{k_i} c_{i,j_t} \cdot p_{j_t}}{\prod_{r \in \mathcal{R}(j_1, j_2, \ldots, j_{k_i})} (1 - \Pr(E_r))}.$$

Thus we have (A.5), and the proof of part (i) is complete.

(ii) We have

$$\Phi(p) = \left[\prod_{r \in [m]} (1 - \mathrm{ch}'_r(p)) \right] \cdot \left(1 - \sum_{i=1}^{\ell} \frac{1}{\binom{\lambda_i}{k_i}} \cdot \sum_{j_1 < \cdots < j_{k_i}} \left[\prod_{t=1}^{k_i} c_{i,j_t} \cdot p_{j_t} \right] \cdot \left(\prod_{r \in \mathcal{R}(j_1, \ldots, j_{k_i})} \frac{1}{1 - \mathrm{ch}'_r(p)} \right) \right). \tag{A.7}$$

Lemma 5.1 shows that under standard randomized rounding, $\mathrm{ch}'_r(p) \leq g(B, \alpha) < 1 \; \forall \; r$. So, the r.h.s. κ of (A.7) gets lower-bounded as follows:

$$\begin{aligned}
\kappa &\geq (1 - g(B,\alpha))^m \cdot \left(1 - \sum_{i=1}^{\ell} \frac{1}{\binom{\nu_i(1+\gamma_i)}{k_i}} \cdot \sum_{j_1 < \cdots < j_{k_i}} \left(\prod_{t=1}^{k_i} c_{i,j_t} \cdot p_{j_t} \right) \right. \\
&\quad \left. \cdot \left[\prod_{r \in \mathcal{R}(j_1, \ldots, j_{k_i})} (1 - g(B,\alpha)) \right]^{-1} \right) \\
&\geq (1 - g(B,\alpha))^m \cdot \left(1 - \sum_{i=1}^{\ell} \frac{1}{\binom{\nu_i(1+\gamma_i)}{k_i}} \cdot \sum_{j_1 < \cdots < j_{k_i}} \left(\prod_{t=1}^{k_i} c_{i,j_t} \cdot p_{j_t} \right) \cdot (1 - g(B,\alpha))^{-a k_i} \right) \\
&\geq (1 - g(B,\alpha))^m \cdot \left(1 - \sum_{i=1}^{\ell} \frac{\binom{n}{k_i} \cdot (\nu_i / n)^{k_i}}{\binom{\nu_i(1+\gamma_i)}{k_i}} \cdot (1 - g(B,\alpha))^{-a k_i} \right),
\end{aligned}$$

where the last line follows from Theorem 3.4(c). □

Proof of Corollary 5.10. Let us employ Theorem 5.9(ii) with $k_i = \lceil \ln(2\ell) \rceil$ and $\gamma_i = 2 \; \forall \; i$. We just need to establish that the r.h.s. of (5.11) is positive. We need to show that

$$\sum_{i=1}^{\ell} \frac{\binom{n}{k_i} \cdot (\nu_i/n)^{k_i}}{\binom{3\nu_i}{k_i}} \cdot (1 - g(B,\alpha))^{-a \cdot k_i} < 1;$$

it is sufficient to prove that for all i,

$$\frac{\nu_i^{k_i}/k_i!}{\binom{3\nu_i}{k_i}} \cdot (1 - g(B,\alpha))^{-a \cdot k_i} < 1/\ell. \tag{A.8}$$

We make two observations now.

- Since $k_i \sim \ln \ell$ and $\nu_i \geq \log^2(2\ell)$,

$$\binom{3\nu_i}{k_i} = (1/k_i!) \cdot \prod_{j=0}^{k_i - 1} (3\nu_i - j) = (1/k_i!) \cdot (3\nu_i)^{k_i} \cdot e^{-\Theta(\sum_{j=0}^{k_i-1} j/\nu_i)} = \Theta((1/k_i!) \cdot (3\nu_i)^{k_i}).$$

- $(1 - g(B,\alpha))^{-a \cdot k_i}$ can be made arbitrarily close to 1 by choosing the constant K' large enough.

These two observations establish (A.8). □

Acknowledgments. This work started while visiting the Sandia National Laboratories in the summer of 1994; I thank Leslie Goldberg and Z. Sweedyk who were involved in the early stages of this work. I would like to thank Éva Tardos for suggesting the key idea that helped bootstrap Theorem 4.2 to get Theorem 2.5. I also thank Noga Alon, Alan Frieze, Tom Leighton, Chi-Jen Lu, Alessandro Panconesi, Prabhakar Raghavan, Satish Rao, Joel Spencer, the SODA 1996 referees, and journal referees for their very helpful comments and suggestions.

APPROXIMATING LONGEST CYCLES IN GRAPHS WITH BOUNDED DEGREES*

GUANTAO CHEN†, ZHICHENG GAO‡, XINGXING YU§, AND WENAN ZANG¶

Abstract. Jackson and Wormald conjecture that if G is a 3-connected n-vertex graph with maximum degree $d \geq 4$, then G has a cycle of length $\Omega(n^{\log_{d-1} 2})$. We show that this conjecture holds when $d-1$ is replaced by $\max\{64, 4d+1\}$. Our proof implies a cubic algorithm for finding such a cycle.

Key words. bounded degree, 3-connected components, long cycles, algorithm

1. Introduction. From the point of view of approximation algorithms, finding a longest cycle in a graph is one of the "harder" NP-hard problems. There is no known polynomial time algorithm which guarantees an approximation ratio better than $n/\text{polylog}(n)$. For graphs with a cycle of length k, it is shown in [1] that one can find in polynomial time a cycle of length $\Omega((\log k)^2/\log\log k)$. Gabow [6] showed how to find in polynomial time a cycle of length $\exp(\Omega(\sqrt{\log k/\log\log k}))$ through a given vertex v in a graph that contains a cycle of length k through v. Recently, Feder and Motwani [5] obtained a cubic algorithm which, given a graph with maximum degree d and containing a k-vertex 3-cyclable minor, finds a cycle of length $k^{1/(2c\log d)}$ for some $c \geq 2$. A consequence of their result improves Gabow's result in certain situations.

Karger, Motwani, and Ramkumar [10] showed that unless $\mathcal{P} = \mathcal{NP}$ it is impossible to find, in polynomial time, a path of length $n - n^{\epsilon}$ in an n-vertex Hamiltonian graph for any $\epsilon < 1$. They conjecture that it is as hard even for graphs with bounded degrees. On the other hand, Feder, Motwani, and Subi [4] showed that there is a polynomial time algorithm for finding a cycle of length at least $n^{(\log_3 2)/2}$ in any 3-connected cubic n-vertex graph. They also proposed the problem for 3-connected graphs with bounded degrees. For a graph G, let $\Delta(G)$ denote its maximum degree. Jackson and Wormald [9] proved that every 3-connected n-vertex graph G with $\Delta(G) \leq d$ has a cycle of length at least $\frac{1}{2}n^{\log_b 2} + 1$, where $b = 6d^2$. Recently, Chen, Xu, and Yu [3] gave a cubic algorithm that, given a 3-connected n-vertex graph G with $\Delta(G) \leq d$, finds a cycle of length at least $n^{\log_b 2}$, where $b = 2(d-1)^2 + 1$. It was conjectured in 1993 by Jackson and Wormald [9] that for $d \geq 4$ the right value for b should be $d-1$.

The main result of this paper shows that this conjecture holds for a linear function b of d. (This result appears in the extended abstract [2].)

THEOREM 1.1. *Let $n \geq 4$ and $d \geq 4$ be integers. Let G be a 3-connected graph with n vertices and $\Delta(G) \leq d$. Then G contains a cycle of length at least $\frac{1}{2}n^{\log_b 2}+3$, where $b = \max\{64, 4d+1\}$.*

For 3-connected graphs, this improves the above-mentioned result of Feder and Motwani [5]. Our proof of Theorem 1.1 implies a cubic algorithm for finding a cycle of length at least $\frac{1}{2}n^{\log_b 2} + 3$. The multiplicative constant $1/2$ and the additive constant 3 are for induction purpose. As in [3], we prove the following three statements simultaneously.

THEOREM 1.2. *Let $n \geq 5$ and $d \geq 4$ be integers, let $b = \max\{64, 4d+1\}$ and $r = \log_b 2$, and let G be a 3-connected graph with n vertices. Then the following statements hold.*

(a) *Let $xy \in E(G)$ and $z \in V(G)-\{x,y\}$, and let t denote the number of neighbors of z distinct from x and y. Assume $\Delta(G) \leq d+1$, and that every vertex of degree $d+1$ (if any) is incident with edge zx or zy. Then there is a cycle C through xy in $G-z$ such that $|C| \geq \frac{1}{2}(\frac{(d-1)n}{dt})^r + 2$.*

(b) *Suppose $\Delta(G) \leq d$. Then for any distinct $e, f \in E(G)$, there is a cycle C through e and f in G such that $|C| \geq \frac{1}{2}(\frac{n}{d})^r + 3$.*

(c) *Suppose $\Delta(G) \leq d$. Then for any $e \in E(G)$, there is a cycle C through e in G such that $|C| \geq \frac{1}{2}n^r + 3$.*

Note the degree condition in (a): zx and zy need not be edges of G, but if x (respectively, y) has degree $d+1$, then zx (respectively, zy) must be an edge of G, and if z has degree $d+1$, then zx or zy must be an edge of G. This condition is due to the addition of edges in order to maintain 3-connectivity.

When $n \geq 5$, Theorem 1.2(c) clearly implies Theorem 1.1. When $n = 4$, Theorem 1.1 is obvious. The next result says that Theorem 1.2 holds for graphs with bounded size, which will enable us to avoid dealing with small graphs in inductive proofs. We omit its proof, since it is rather straightforward.

LEMMA 1.3. *Let G, n, d, b, r be the same as in Theorem* 1.2. *If $n \leq 4d+1$, then Theorem* 1.2(a) *and* (b) *hold, and if $n \leq (4d+1)^2$, then Theorem* 1.2(c) *holds.*

To prove Theorem 1.2, we need to deal with graphs obtained from 3-connected graphs by deleting a vertex (such as $G-z$ in (a)); such graphs need not be 3-connected. By using a result of Tutte [11] and an algorithm of Hopcroft and Tarjan [7], we can decompose such graphs into "3-connected components." We then find long paths through certain 3-connected components and use properties of the function $x^{\log_b 2}$ to account for the unused 3-connected components. (For a brief outline of our approach, the reader is referred to the algorithm in section 6.) Our approach is similar to that in [3], but here we prove stronger properties of the function $x^{\log_b 2}$ and analyze the 3-connected components in a more sophisticated way.

We organize this paper as follows. In section 2, we recall notation of Hopcroft and Tarjan [7] concerning the decomposition result of Tutte [11] of 2-connected graphs into 3-connected components. We then define cycle chains of 3-connected components, and prove several results on paths in cycle chains. We prove in section 3 several useful properties of the function $f(x) = x^{\log_b 2}$. We also define block chains of 3-connected components, and prove lemmas concerning paths in block chains. Theorem 1.2 will be shown inductively. So in sections 4 and 5, we show how to reduce Theorem 1.2 to smaller graphs. In section 6, we complete the proof of our main result, and outline a cubic algorithm for finding a long cycle in a 3-connected graph with bounded degree.

For graphs G and H, we use $G \cong H$ (respectively, $G \ncong H$) to mean that G is isomorphic to (respectively, not isomorphic to) H. Let G be a graph, H a subgraph of G, and $S := \{v_1, \ldots, v_k, x_1y_1, \ldots, x_py_p\}$, where v_i, x_j, y_j are vertices of G and $\{x_1, y_1, \ldots, x_p, y_p\} \subseteq \{v_1, \ldots, v_k\} \cup V(H)$. Then $H + S$ denotes the simple graph with $V(H + S) := V(H) \cup \{v_1, \ldots, v_k\}$ and $E(H + S) = E(H) \cup \{x_1y_1, \ldots, x_py_p\}$.

2. Paths in cycle chains. For convenience, we recall the decomposition of a 2-connected graph into 3-connected components. A detailed description can be found in [3] and [7].

Let G be a 2-connected graph. We allow multiple edges for the description of this decomposition. Then, $E(G)$ in this section is treated as a multi-set. We say that $\{a, b\} \subseteq V(G)$ is a *separation pair* in G if there are subgraphs G_1, G_2 of G such that $G_1 \cup G_2 = G$, $V(G_1 \cap G_2) = \{a, b\}$, $E(G_1 \cap G_2) = \emptyset$, and $|E(G_i)| \geq 2$ for $i = 1, 2$. Let $G_i' := (V(G_i), E(G_i) \cup \{ab\})$ for $i = 1, 2$. Then G_1' and G_2' are called *split graphs* of G with respect to the separation pair $\{a, b\}$, and the new edge ab added to G_i is called a *virtual* edge. It is easy to see that, since G is 2-connected, G_i' is 2-connected or G_i' consists of two vertices and at least three multiple edges between them.

Suppose a multigraph is split, and the split graphs are split, and so on, until no more splits are possible. Then each remaining graph is called a *split component*. No split component contains a separation pair and, therefore, each split component must be one of the following: a triangle, a *triple bond* (two vertices and three multiple edges between them), or a 3-connected graph.

It is not hard to see that if a split component of a 2-connected graph is 3-connected, then it is uniquely determined. It is also easy to see that, for any two split components G_1, G_2 of a 2-connected graph, we have $|V(G_1 \cap G_2)| \leq 2$, and if $|V(G_1 \cap G_2)| = 2$, then either G_1 and G_2 share a virtual edge between the vertices in $V(G_1 \cap G_2)$ or there is a sequence of triple bonds such that the first shares a virtual edge with G_1, any two consecutive triple bonds in the sequence share a virtual edge, and the last triple bond shares a virtual edge with G_2.

In order to make such decomposition unique, some triple bonds and triangles need to be merged. Let $G_i' = (V_i', E_i')$, $i = 1, 2$, be two split components, both containing a virtual edge ab. Let $G' = (V_1' \cup V_2', (E_1' - \{ab\}) \cup (E_2' - \{ab\}))$. The graph G' is called the *merge graph* of G_1' and G_2'. Clearly, a merge of triple bonds gives a graph consisting of two vertices and multiple edges, which is called a *bond*. Also a merge of triangles gives a cycle, and a merge of cycles gives a cycle as well.

Let $\mathcal{D}$ denote the set of those 3-connected split components of a 2-connected graph G. We merge the split components of G not in $\mathcal{D}$ as follows: the bonds are merged as much as possible to give a set of bonds $\mathcal{B}$, and the cycles are merged as much as possible to give a set of cycles $\mathcal{C}$. Then $\mathcal{B} \cup \mathcal{C} \cup \mathcal{D}$ is the set of the 3-*connected components* of G. Note that any two 3-connected components either are edge disjoint or share exactly one virtual edge. The following theorem is a combination of a result of Tutte [11] and an algorithm of Hopcroft and Tarjan [7].

THEOREM 2.1. *The* 3*-connected components of any* 2*-connected graph are unique and can be found in* $O(E)$ *time.*

If we define a graph whose vertices are the 3-connected components of G and, where two vertices are adjacent whenever the corresponding 3-connected components share a virtual edge, then this graph is a tree, which we call the *block-bond tree* of G. For convenience, 3-connected components that are not bonds are called 3-*blocks*. An *extreme* 3-block is a 3-block that contains at most one virtual edge. That is, either it is the only 3-connected component (in which case G is 3-connected), or it corresponds

to a degree one vertex in the block-bond tree.

A *cycle chain* in a 2-connected graph G is a sequence $C_1C_2\dots C_k$ of 3-blocks of G such that each C_i is a cycle and there exist bonds (possibly empty) $B_1, B_2, \dots, B_{k-1}$ in G such that $C_1B_1C_2B_2\dots B_{k-1}C_k$ is a path in the block-bond tree of G. For convenience, we sometimes write $H := C_1\dots C_k$ for a cycle chain, and view H as the simple graph obtained from the union of C_i $(1 \le i \le k)$ by identifying virtual edges between the vertices of $C_i \cap C_{i+1}$ $(1 \le i \le k-1)$. The following is a direct consequence of the definition of a cycle chain.

PROPOSITION 2.2. *Let G be a 2-connected graph and $H := C_1\dots C_k$ be a cycle chain in G. Then deleting all edges of H with both ends in $V(C_i \cap C_{i+1})$, $1 \le i \le k-1$, results in a cycle.*

The next result finds a path linking two edges in a cycle chain.

PROPOSITION 2.3. *Let G be a 2-connected graph, let $H := C_1\dots C_k$ be a cycle chain in G, let $uv \in E(C_1)$ with $\{u,v\} \ne V(C_1 \cap C_2)$ when $k \ne 1$, and let $ab \in E(C_k)$ with $\{a,b\} \ne V(C_{k-1} \cap C_k)$ when $k \ne 1$. Then there is a path in $H - \{v, ab\}$ from u to $\{a,b\}$ and containing $V(\bigcup_{i=1}^{k-1}(C_i \cap C_{i+1})) - (\{a,b\} \cup \{u,v\})$.*

Proof. We apply induction on k. The result holds trivially for $k = 1$. So assume $k \ge 2$. Let $H' := C_2\dots C_k$ and $V(C_1 \cap C_2) = \{u_1, v_1\}$. Without loss of generality, we may assume that $C_1 - \{v, v_1\}$ contains a path P from u to u_1. Suppose $v_1 = v$. By induction, we find a path Q in $H' - \{v_1, ab\}$ from u_1 to $\{a,b\}$ and containing $V(\bigcup_{i=2}^{k-1}(C_i \cap C_{i+1})) - (\{a,b\} \cup \{u_1, v_1\})$. Then $P \cup Q$ gives the desired path. Now assume $v_1 \ne v$. By induction, we find a path Q' in $H' - \{u_1, ab\}$ from v_1 to $\{a,b\}$ and containing $V(\bigcup_{i=2}^{k-1}(C_i \cap C_{i+1})) - (\{a,b\} \cup \{u_1, v_1\})$. Now $(P \cup Q') + u_1v_1$ gives the desired path. □

Remark. The path, say R, found in Proposition 2.3 may use edges between the vertices of $C_i \cap C_{i+1}$ $(1 \le i \le k-1)$. However, either G has an edge between the vertices of $C_i \cap C_{i+1}$, or $C_i \cap C_{i+1}$ is contained in a 3-block of G not in $\mathcal{H}$. Hence, from R we can produce a path in G by replacing virtual edges in R with appropriate paths in G, and this new path is at least as long as R. This observation applies to the next three results as well, and will be frequently used.

A similar argument establishes the following result, which finds a path in a cycle chain between two vertices and avoiding a specific vertex.

PROPOSITION 2.4. *Let G be a 2-connected graph, let $H := C_1\dots C_k$ be a cycle chain in G, let $uv \in E(C_1)$ with $\{u,v\} \ne V(C_1 \cap C_2)$ when $k \ne 1$, and let $x \in V(C_k)$ with $x \ne v$ when $k = 1$ and $x \notin V(C_{k-1} \cap C_k)$ when $k \ne 1$. Then there is a path in $H - v$ from u to x and containing $V(\bigcup_{i=1}^{k-1}(C_i \cap C_{i+1})) - \{v\}$.*

It is clear that the paths and cycle in the above three propositions can be found in $O(V)$ time. The following two results are Propositions 2.7 and 2.8 in [3], which find in $O(V)$ time paths through a given edge in a cycle chain.

PROPOSITION 2.5. *Let G be a 2-connected graph, let $H := C_1\dots C_k$ be a cycle chain in G, let $uv \in E(C_1)$ with $\{u,v\} \ne V(C_1 \cap C_2)$ when $k \ne 1$, $ab \in E(C_k)$ with $\{a,b\} \ne V(C_{k-1} \cap C_k)$ when $k \ne 1$, and $cd \in E(\bigcup_{i=1}^{k} C_i) - \{ab\}$. Suppose $ab \ne uv$ when $k = 1$. Then there is a path P in $H - ab$ from $\{a,b\}$ to $\{c,d\}$ such that $uv \in E(P)$, $cd \notin E(P)$ unless $cd = uv$, and $V(\bigcup_{i=1}^{k-1}(C_i \cap C_{i+1})) \subseteq V(P)$.*

PROPOSITION 2.6. *Let G be a 2-connected graph, let $H := C_1\dots C_k$ be a cycle chain in G, let $uv \in E(C_1)$ with $\{u,v\} \ne V(C_1) \cap V(C_2)$ when $k \ne 1$, $x \in V(C_k)$ with $x \notin V(C_{k-1} \cap C_k)$ when $k \ne 1$, and $cd \in E(\bigcup_{i=1}^{k} C_i)$. Then there is a path P in H from x to $\{c,d\}$ such that $uv \in E(P)$, $cd \notin E(P)$ unless $cd = uv$, and*

$V(\bigcup_{i=1}^{k-1}(C_i \cap C_{i+1})) \subseteq V(P)$.

We conclude this section by recalling from [3] two graph operations and three lemmas. Let G be a graph and let e, f be distinct edges of G. An *H-transform* of G *at* $\{e, f\}$ is an operation that subdivides e and f by vertices x and y, respectively, and then adds the edge xy. Let $x \in V(G)$ such that x is not incident with e. A *T-transform* of G *at* $\{x, e\}$ is an operation that subdivides e with a vertex y and then adds the edge xy. If there is no need to specify e, f, x, we simply speak of an H-transform or a T-transform. The following result is Lemma 3.3 in [3].

LEMMA 2.7. *Let $d \geq 3$ be an integer and let G be a 3-connected graph with $\Delta(G) \leq d$. Let G' be a graph obtained from G by an H-transform or a T-transform. Then G' is a 3-connected graph, the vertex of G involved in the T-transform has degree at most $d+1$, and all other vertices of G' have degree at most d.*

The next two results are Lemmas 3.6 and 3.7 in [3], where it is shown that the path P can be found in $O(V)$ time.

LEMMA 2.8. *Let G be a 3-connected graph, let $f \in E(G)$, let $ab, cd, vw \in E(G) - \{f\}$, and assume that $\{c, d\} \neq \{v, w\}$. Then there exists a path P in G from $\{a, b\}$ to some $z \in \{c, d\} \cup \{v, w\}$ such that* (i) *$f \in E(P)$,* (ii) *$cd \in E(P)$ or $vw \in E(P)$,* (iii) *if $cd \in E(P)$, then $z \in \{v, w\}$ and $vw \notin E(P)$, and* (iv) *if $vw \in E(P)$, then $z \in \{c, d\}$ and $cd \notin E(P)$.*

LEMMA 2.9. *Let G be a 3-connected graph, let $f \in E(G)$, let $x \in V(G)$ such that x is not incident with f, let $cd, vw \in E(G) - \{f\}$, and assume that $\{c, d\} \neq \{v, w\}$. Then there exists a path P in G from x to some $z \in \{c, d\} \cup \{v, w\}$ such that* (i) *$f \in E(P)$,* (ii) *$cd \in E(P)$ or $vw \in E(P)$,* (iii) *if $cd \in E(P)$, then $z \in \{v, w\}$ and $vw \notin E(P)$, and* (iv) *if $vw \in E(P)$, then $z \in \{c, d\}$ and $cd \notin E(P)$.*

3. Paths in block chains. We first prove four lemmas concerning the function $x^{\log_b 2}$. These lemmas will then be used to find long paths in block chains. First, we recall Lemma 3.1 in [3].

LEMMA 3.1. *Let $b \geq 4$ be an integer, and let $m \geq n$ be positive integers. Then $m^{\log_b 2} + n^{\log_b 2} \geq (m + (b-1)n)^{\log_b 2}$.*

When m is sufficiently larger than n, we have the following result.

LEMMA 3.2. *Let $b \geq 9$ be an integer, let m and n be positive integers, and assume $m \geq \frac{b(b-1)}{4}n$. Then $m^{\log_b 2} + n^{\log_b 2} \geq (m + \frac{b(b-1)}{4}n)^{\log_b 2}$.*

Proof. By dividing $m^{\log_b 2}$ to the above inequality, we see what we need to prove is equivalent to the statement: for any $0 \leq s \leq \frac{4}{b(b-1)}$, $1 + s^{\log_b 2} \geq (1 + \frac{b(b-1)}{4}s)^{\log_b 2}$.

Let $f(s) = 1 + s^{\log_b 2} - (1 + \frac{b(b-1)}{4}s)^{\log_b 2}$. Clearly, $f(0) = 0$. Note that $b(b-1) > 4(b-1)$ when $b \geq 5$. Hence $f(1) = 2 - (1 + \frac{b(b-1)}{4})^{\log_b 2} < 2 - b^{\log_b 2} = 0$. Taking derivative about s, we have $f'(s) = (\log_b 2)(s^{(\log_b 2)-1} - \frac{b(b-1)}{4}(1 + \frac{b(b-1)}{4}s)^{(\log_b 2)-1})$. A simple calculation shows that $f'(s) = 0$ has a unique solution. Therefore, if $f(c) > 0$ for some $0 < c < 1$, then $f(s) \geq 0$ for all $0 \leq s \leq c$.

Note that $0 < \frac{4}{b(b-1)} < 1$ and $f(\frac{4}{b(b-1)}) > 1 + (\frac{1}{b^2})^{\log_b 2} - 2^{\log_b 2} \geq 1.25 - 2^{\log_9 2} = 0.005587\ldots > 0$. Therefore, we have $f(s) \geq 0$ for all $s \in [0, \frac{4}{b(b-1)}]$. ∎

When m is not sufficiently larger than n, we have the following complementary result.

LEMMA 3.3. *Let $b \geq 64$ be an integer, let $m \geq n$ be positive integers, and assume $m \leq \frac{b(b-1)}{4}n$. Then $m^{\log_b 2} + n^{\log_b 2} \geq (4m)^{\log_b 2}$.*

Proof. The statement of Lemma 3.3 is equivalent to $1 + s^{\log_b 2} \geq 4^{\log_b 2}$ for all $\frac{4}{b(b-1)} \leq s \leq 1$. Therefore, it suffices to show $1 + (\frac{4}{b(b-1)})^{\log_b 2} \geq 4^{\log_b 2}$. This is true

because $1+(\frac{4}{b(b-1)})^{\log_b 2} \geq 1+(\frac{4}{b^2})^{\log_b 2} = 1+\frac{4^{\log_b 2}}{4} > 4^{\log_b 2}$ (since $b \geq 64$). □

We shall also use the following observations in the proof of Theorem 1.2.

LEMMA 3.4. *Let m be an integer, $d \geq 3$, and $b \geq d+1$. If $m \geq 4$, then $m \geq \frac{1}{2}m^{\log_b 2}+3$. If $m \geq 3$, then $m > \frac{1}{2}(\frac{m}{d})^{\log_b 2}+2$. If $m \geq 2$, then $m > \frac{1}{2}(\frac{m}{d})^{\log_b 2}+1$.*

Proof. Let $f(x) = x - \frac{1}{2}x^{\log_b 2}$. We can show that $f'(x) > 0$ for $x \geq 1$. Hence $f(x)$ is an increasing function when $x \geq 1$. Thus, when $x \geq 4$, we have $f(x) \geq f(4) = 4 - \frac{1}{2}4^{\log_b 2} \geq 3$ (since $b \geq 4$). The first inequality holds.

Let $f(x) = x - \frac{1}{2}(\frac{x}{d})^{\log_b 2}$; then $f(x)$ is increasing when $x \geq 1$. The second inequality follows from $f(3) > 2$, and the third inequality follows from $f(2) > 1$. □

We now turn to paths in block chains. Let G be a 2-connected graph. A *block chain* in G is a sequence $H_1 \dots H_h$ for which (1) each H_i is either a cycle chain in G or a 3-connected 3-block of G, (2) for any $1 \leq s \leq h-1$, H_s or H_{s+1} is 3-connected, and (3) there exist bonds (possibly empty) $B_1, \dots, B_{h-1}$ such that $H_1B_1H_2B_2 \dots B_{h-1}H_h$ form a path in the block-bond tree of G (by also including the tree paths corresponding to H_i when H_i is a cycle chain). A detailed description with examples can be found in [3]. For convenience, we sometimes write $\mathcal{H} := H_1 \dots H_h$ for a block chain and view $\mathcal{H}$ as the simple graph obtained from $\bigcup_{i=1}^{n} H_i$ by identifying edges between the vertices in $H_i \cap H_{i+1}$ $(1 \leq i \leq n-1)$. The edges of $\mathcal{H}$ between the vertices of $H_i \cap H_{i+1}$ are called *separating edges* of $\mathcal{H}$. Such edges are to be avoided when we find paths in block chains.

Let $H_1 \dots H_h$ be a block chain and let $V(H_s \cap H_{s+1}) = \{x_s, y_s\}$, $1 \leq s \leq h-1$. For each $1 \leq s \leq h$, we define $A(H_s)$ as follows. If H_s is 3-connected, then $A(H_s) := V(H_s)$. If $H_s = C_1 \dots C_k$ is a cycle chain, then let

- $A(H_s) := V(\bigcup_{i=1}^{k-1}(C_i \cap C_{i+1})) - (\{x_{s-1}, y_{s-1}\} \cup \{x_s, y_s\})$ when $1 < s < h$,
- $A(H_s) := V(\bigcup_{i=1}^{k-1} C_i \cap C_{i+1})$ when $s = 1 = h$, $A(H_s) := V(\bigcup_{i=1}^{k-1}(C_i \cap C_{i+1})) - \{x_s, y_s\}$ when $s = 1 < h$, and
- $A(H_s) := V(\bigcup_{i=1}^{k-1}(C_i \cap C_{i+1})) - \{x_{s-1}, y_{s-1}\}$ when $1 < s = h$.

We write $\sigma(\mathcal{H}) := \sum_{s=1}^{h} |A(H_s)|$ and $|\mathcal{H}| := |V(\bigcup_{i=1}^{h} H_i)|$. For convenience, we define $B_1(\mathcal{H}) = \{H_i : H_i \text{ is 3-connected or } |A(H_i)| \leq 1\}$ and $B_2(\mathcal{H}) = \{H_i : H_i \text{ is a cycle chain and } |A(H_i)| \geq 2\}$.

In the remainder of this section, we show how to find long paths in block chains (in terms of $\sigma(\mathcal{H})$). All proofs imply $O(V)$ algorithms that reduce the problem of finding a path to Theorem 1.2 for smaller graphs.

LEMMA 3.5. *Let $n \geq 6$ be an integer and assume Theorem 1.2 holds for graphs with at most $n-1$ vertices. Let $\mathcal{H} := H_1H_2 \dots H_h$ be a block chain in a 2-connected graph such that $|\mathcal{H}| < n$ and $\Delta(H_i) \leq d$ for $1 \leq i \leq h$. Let $uv \in E(H_1)$ such that $\{u, v\}$ is not a cut of H_1, and if $h \geq 2$, then $\{u, v\} \neq V(H_1 \cap H_2)$. Then there is a path P in $\mathcal{H}$ from u to v such that $|E(P)| \geq \frac{1}{2}(\frac{(d-1)\sigma(\mathcal{H})}{d})^r + 2$ and P contains no separating edge of $\mathcal{H}$.*

Proof. When $h \geq 2$, we use a, b to denote the vertices in $V(H_1 \cap H_2)$. Suppose $|A(H_1)| \geq \frac{(d-1)\sigma(\mathcal{H})}{d}$. First assume H_1 is a cycle chain or $H_1 \cong K_4$. Then there is a Hamilton path P_1 in H_1 from u to v (by Proposition 2.2 when H_1 is a cycle chain). If $|H_1| = 3$, then $|A(H_1)| = 0$, and hence, $|E(P_1)| \geq \frac{1}{2}|A(H_1)|^r + 2$. If $|H_1| \geq 4$, then $|E(P_1)| \geq 3$, and by Lemma 3.4, $|E(P_1)| \geq \frac{1}{2}|H_1|^r + 2 \geq \frac{1}{2}|A(H_1)|^r + 2$. Now assume H_1 is 3-connected and $H_1 \ncong K_4$. Then by Theorem 1.2(c), H_1 has a cycle C_1 through uv such that $|E(C_1)| \geq \frac{1}{2}|H_1|^r + 3 = \frac{1}{2}|A(H_1)|^r + 3$. Let $P_1 := C_1 - uv$. If $h = 1$ or $ab \notin E(P_1)$, then $P := P_1$ gives the desired path. If $h \geq 2$ and $ab \in E(P_1)$, then by replacing ab with a path in $H_2 \dots H_h$ between a and b and not containing

any separating edge of $\mathcal{H}$, we obtain the desired path P.

So we may assume $|A(H_1)| < \frac{(d-1)\sigma(\mathcal{H})}{d}$. In particular, $h \geq 2$. If H_1 is a cycle chain or $H_1 \cong K_4$, then, as in the above paragraph, we find a Hamilton path P_1 from u to v in H_1 through ab such that $|E(P_1)| \geq \frac{1}{2}|A(H_1)|^r + 2$. Now assume H_1 is 3-connected and $H_1 \ncong K_4$. Then by Theorem 1.2(b), H_1 has a cycle C_1 through uv and ab such that $|E(C_1)| \geq \frac{1}{2}(\frac{|A(H_1)|}{d})^r + 3$; let $P_1 := C_1 - uv$.

By induction, we find a path P' in $\mathcal{H}' := H_2 \dots H_h$ from a to b and containing no separating edges of $\mathcal{H}'$ such that $|E(P')| \geq \frac{1}{2}(\frac{(d-1)\sigma(\mathcal{H}')}{d})^r + 2$. Let $P := (P_1 - ab) \cup P'$. Since $\sigma(\mathcal{H}) \leq A(H_1) + \sigma(\mathcal{H}')$ and $|A(H_1)| < \frac{(d-1)\sigma(\mathcal{H})}{d}$, $\frac{|A(H_1)|}{d} < \frac{(d-1)\sigma(\mathcal{H}')}{d}$. Hence by Lemma 3.2,

$$\begin{aligned} |E(P)| &> \frac{1}{2}\left(\frac{|A(H_1)|}{d}\right)^r + \frac{1}{2}\left(\frac{(d-1)\sigma(\mathcal{H}')}{d}\right)^r + 2 \\ &\geq \frac{1}{2}\left((b-1)\frac{|A(H_1)|}{d} + \frac{(d-1)\sigma(\mathcal{H}')}{d}\right)^r + 2 \\ &> \frac{1}{2}\left(\frac{(d-1)\sigma(\mathcal{H})}{d}\right)^r + 2. \end{aligned}$$

So P gives the desired path. □

For the next two lemmas, we define uv and x in a block chain $\mathcal{H} := H_0H_1 \dots H_h$ (in a 2-connected graph). Suppose $h = 0$. If H_0 is 3-connected or H_0 is a cycle, then let $uv \in E(H_0)$ and $x \in V(H_0) - \{u, v\}$, and if $H_0 = C_1 \dots C_k$ is a cycle chain with $k \geq 2$, then let $uv \in E(C_1)$ with $\{u, v\} \neq V(C_1 \cap C_2)$ and let $x \in V(C_k) - V(C_{k-1})$. Now assume $h \geq 1$. If H_0 is 3-connected or H_0 is a cycle, then let $uv \in E(H_0)$ with $\{u, v\} \neq V(H_0 \cap H_1)$; if $H_0 = C_1 \dots C_k$ is a cycle chain with $k \geq 2$ and $V(H_0 \cap H_1) = V(C_k \cap H_1)$, then let $uv \in E(C_1)$ with $\{u, v\} \neq V(C_1 \cap C_2)$; if H_h is a cycle or H_h is 3-connected, then let $x \in V(H_h) - V(H_{h-1})$; and if $H_h = C_1 \dots C_k$ is a cycle chain with $k \geq 2$ and $V(H_{h-1} \cap H_h) = V(H_{h-1} \cap C_1)$, then let $x \in V(C_k) - V(C_{k-1})$.

LEMMA 3.6. *Let $n \geq 6$ be an integer and assume Theorem 1.2 holds for graphs with at most $n-1$ vertices. Let $\mathcal{H} := H_0H_1 \dots H_h$, uv, x be defined as above, and assume $|\mathcal{H}| < n$, $\Delta(H_i) \leq d$ for $0 \leq i \leq h$, and the degree of x in H_h is at most $d-1$. Then there exists a path P in $\mathcal{H} - v$ from u to x and containing no separating edge of $\mathcal{H}$ such that*

(i) $|E(P)| \geq \frac{1}{2}(\sum_{i=0}^{h}(\frac{|A(H_i)|}{d})^r) + 1 \geq \frac{1}{2}(\frac{\sigma(\mathcal{H})}{d})^r + 1$, *and*

(ii) $|E(P)| \geq \frac{1}{2}(\sum\{(\frac{|A(H_i)|}{d})^r : H_i \in B_1(\mathcal{H})\}) + (\sum\{\max\{1, |A(H_i)| - 2\} : H_i \in B_2(\mathcal{H})\}) + 1$.

Proof. We apply induction on h. Suppose $h = 0$. If H_0 is 3-connected and $H_0 \ncong K_4$, then by assumption and because x has degree at most $d-1$, Theorem 1.2(a) holds for $H_0 + \{vx, ux\}$. Hence, $H_0 - v$ contains a path P from u to x such that $|E(P)| \geq \frac{1}{2}(\frac{|A(H_0)|}{d})^r + 1$. If $H_0 \cong K_4$, then we can find a path P from u to x in $H_0 - v$ such that $|E(P)| = 2 \geq \frac{1}{2}(\frac{|A(H_0)|}{d})^r + 1$. If H_0 is a cycle chain, then by Proposition 2.4, there is a path P from u to x in $H_0 - v$ containing $A(H_0) - \{v\}$. Note that $x \notin A(H_0)$ and if $v \in A(H_0)$, then $u \notin A(H_0)$. Thus, $|E(P)| \geq |A(H_0)|$. Because $|E(P)| \geq 1$ and since $|A(H_0)| = 0$ or $|A(H_0)| \geq 2$, we have $|E(P)| \geq \frac{1}{2}(\frac{|A(H_0)|}{d})^r + 1$ (by Lemma 3.4). Clearly, $|E(P)| \geq \max\{1, |A(H_0)| - 2\} + 1$ when $H_0 \in B_2(\mathcal{H})$.

Now assume $h \geq 1$. Let $V(H_0 \cap H_1) = \{u_0, v_0\}$, and assume the notation is chosen so that $u_0 \notin \{u, v\}$. By the above argument for $h = 0$, if H_0 is a cycle chain or $H_0 \cong K_4$, then $H_0 - v$ has a path P_0 from u to u_0 such that $|E(P_0)| \geq \frac{1}{2}(\frac{|A(H_0)|}{d})^r + 1$,

and $|E(P_0)| \geq \max\{1, |A(H_0)| - 2\} + 1$ when $H_0 \in B_2(\mathcal{H})$. (Note in the case H_0 is a cycle chain, $u_0 \notin A(H_0)$ because $h \geq 1$.) Now assume H_0 is 3-connected and $|H_0| \geq 5$. If $v = v_0$, then we apply Theorem 1.2(a) to find a path P_0 from u to u_0 in $(H_0 + uu_0) - v$ such that $|E(P_0)| \geq \frac{1}{2}(\frac{|A(H_0)|}{d})^r + 1$. If $v \neq v_0$, then let H_0' be obtained from H_0 by a T-transform at $\{v, u_0v_0\}$ and let u' denote the new vertex. By Theorem 1.2(a), we find a path P_0^* in $(H_0' + uu') - v$ from u to u' such that $|E(P_0^*)| \geq \frac{1}{2}(\frac{|A(H_0)|}{d})^r + 1$; and let $P_0 := P_0^* - u'$ (in this case $u_0v_0 \notin E(P_0)$).

Let $P_0' := P_0$ if $u_0v_0 \notin E(P_0)$; otherwise, let $P_0' := P_0 - u_0$. Then P_0' is a path in $H_0 - \{v, u_0v_0\}$ from u to $\{u_0, v_0\}$ such that $|E(P_0')| \geq \frac{1}{2}(\frac{|A(H_0)|}{d})^r$, and $|E(P_0')| \geq \max\{1, |A(H_0)| - 2\}$ when $H_0 \in B_2(\mathcal{H})$. Without loss of generality, we may assume that P_0' is from u_0 to u.

By applying induction to $\mathcal{H}' := H_1 \dots H_h$, there is a path P_1 from u_0 to x in $\mathcal{H}' - v_0$ containing no separating edge of $\mathcal{H}'$ such that $|E(P_1)| \geq \frac{1}{2}(\sum_{i=1}^{h}(\frac{|A(H_i)|}{d})^r) + 1 \geq \frac{1}{2}(\frac{\sigma(\mathcal{H}')}{d})^r + 1$ and $|E(P_1)| \geq \frac{1}{2}(\sum\{(\frac{|A(H_i)|}{d})^r : H_i \in B_1(\mathcal{H}) \text{ and } i \neq 0\}) + (\sum\{\max\{1, |A(H_i)| - 2\} : H_i \in B_2(\mathcal{H}) \text{ and } i \neq 0\}) + 1$.

Let $P := P_0' \cup P_1$. Because $h \geq 1$, H_0 or H_1 is not a cycle chain, and hence, $\sigma(\mathcal{H}) \leq |A(H_0)| + \sigma(\mathcal{H}')$. It is easy to see that P satisfies (i) and (ii). Note that the second inequality in (i) follows from the first in (i) by applying Lemma 3.1. □

LEMMA 3.7. *Assume the same hypothesis of Lemma* 3.6. *Then for any* $0 \leq t \leq h$ *and for any* $pq \in E(H_t)$ *such that* $|H_t| \leq n - 3$ *when* $h \geq 1$, *there exists a path* P *in* $\mathcal{H}$ *from* x *to* $\{p, q\}$ *and containing no separating edge of* $\mathcal{H}$ *such that*

(i) $pq \notin E(P)$, *and* $|E(P)| \geq \frac{1}{2}|A(H_0)|^r + \frac{1}{2}(\sum\{(\frac{|A(H_i)|}{d})^r : H_i \in B_1(\mathcal{H})$ *and* $i \neq 0\}) + (\sum\{\max\{1, |A(H_i)| - 2\} : H_i \in B_2(\mathcal{H})$ *and* $i \neq 0\}) + 1$, *and*

(ii) *if we require* $uv \in E(P)$, *then* $pq \notin E(P)$ *unless* $pq = uv$, *and* $|E(P)| \geq \frac{1}{2}(\sum\{(\frac{|A(H_i)|}{d})^r : H_i \in B_1(\mathcal{H})\}) + (\sum\{\max\{1, |A(H_i)| - 2\} : H_i \in B_2(\mathcal{H})\}) + 1 \geq \frac{1}{2}(\frac{\sigma(\mathcal{H})}{d})^r + 1$.

Proof. We apply induction on h. Note that the second inequality in (ii) follows from the first in (ii) by applying Lemma 3.1.

Case 1. $h = 0$.

First, assume H_0 is a cycle chain. Then by Proposition 2.6, there is a path P from x to $\{p, q\}$ in H_0 such that $uv \in E(P)$, $pq \notin E(P)$ unless $pq = uv$, and $A(H_0) \subseteq V(P)$. Because $x \notin A(H_0)$, $|E(P)| \geq |A(H_0)|$. Because $x \notin \{u, v\}$, $|E(P)| \geq 2$. So $|E(P)| \geq \max\{1, |A(H_0)| - 2\} + 1$. Moreover, if $|A(H_0)| \leq 3$, then $|E(P)| \geq 2 > \frac{1}{2}|A(H_0)|^r + 1$, and if $|A(H_0)| \geq 4$, then by Lemma 3.4 we have $|E(P)| \geq |A(H_0)| \geq \frac{1}{2}|A(H_0)|^r + 3$. Clearly (i) and (ii) hold.

Now assume $H_0 \cong K_4$. Let P denote a Hamilton path in H_0 from x to $\{p, q\}$ such that $uv \in E(P)$, and $pq \notin E(P)$ unless $pq = uv$. Then $|E(P)| = 3 > \frac{1}{2}|A(H_0)|^r + 1$ and (i) and (ii) hold.

Finally, assume H_0 is 3-connected and $H_0 \ncong K_4$. Then $5 \leq |H_0| < n$. If $x \in \{p, q\}$, then we apply Theorem 1.2(c) (respectively, Theorem 1.2(b)) to find a cycle C through pq (respectively, pq and uv) such that $|C| \geq \frac{1}{2}|A(H_0)|^r + 3$ (respectively, $|C| \geq \frac{1}{2}(\frac{|A(H_0)|}{d})^r + 3$). Now it is easy to see that (i) and (ii) hold with $P := C - pq$. So assume $x \notin \{p, q\}$. Then let H_0' be obtained from H_0 by a T-transform at $\{x, pq\}$ and let x' denote the new vertex. By Theorem 1.2(c) (respectively, Theorem 1.2(b)), we find a cycle C through xx' (respectively, xx' and uv) such that $|C| \geq \frac{1}{2}|H_0|^r + 3$ (respectively, $|C| \geq \frac{1}{2}(\frac{|H_0|}{d})^r + 3$). Now it is easy to see that (i) and (ii) hold with $P := C - x'$.

Case 2. $h \geq 1$.

Let $\{a, b\} = V(H_0 \cap H_1)$.

Suppose $pq \in \mathcal{H}' := H_1 \dots H_h$. By applying induction to $\mathcal{H}'$ (with ab playing the role of uv), we find a path P' in $\mathcal{H}'$ from x to $\{p, q\}$ and containing no separating edge of $\mathcal{H}'$ such that $ab \in E(P')$, $pq \notin E(P')$ unless $pq = ab$, and $|E(P')| \geq \frac{1}{2}(\sum\{(\frac{|A(H_i)|}{d})^r : H_i \in B_1(\mathcal{H}) \text{ and } i \neq 0\}) + (\sum\{\max\{1, |A(H_i)| - 2\} : H_i \in B_2(\mathcal{H}) \text{ and } i \neq 0\}) + 1$. If H_0 is a cycle chain or $H_0 \cong K_4$, then H_0 has a Hamilton cycle C through ab and uv. If H_0 is 3-connected and $|H_0| \geq 5$, we apply Theorem 1.2(c) (respectively, Theorem 1.2(b)) to find a cycle C through ab (respectively, ab and uv) such that $|C| \geq \frac{1}{2}|H_0|^r + 3$ (respectively, $|C| \geq \frac{1}{2}(\frac{|H_0|}{d})^r + 3$). Then $P := (C - ab) \cup (P' - ab)$ gives the desired path for (i) and (ii).

Therefore, we may assume $pq \in H_0$ and $pq \neq ab$. Let H_0' be obtained from H_0 by an H-transform at $\{pq, ab\}$, and let a', p' denote the new vertices. By Theorem 1.2(c) (respectively, Theorem 1.2(b)) we find a cycle C in H_0' through $a'p'$ (respectively, $a'p'$ and uv) such that $|C| \geq \frac{1}{2}|H_0|^r + 3$ (respectively, $|C| \geq \frac{1}{2}(\frac{|H_0|}{d})^r + 3$). Let $P_0 := C - \{a', p'\}$ and, without loss of generality, let a be the end of P_0. By Lemma 3.6, we can find a path P' in $\mathcal{H}' - b$ from x to a and containing no separating edge of $\mathcal{H}'$ such that $|E(P')| \geq \frac{1}{2}(\sum\{(\frac{|A(H_i)|}{d})^r : H_i \in B_1(\mathcal{H}) \text{ and } i \neq 0\}) + (\sum\{\max\{1, |A(H_i)| - 2\} : H_i \in B_2(\mathcal{H}) \text{ and } i \neq 0\}) + 1$. Now $P := P_0 \cup P'$ gives the desired path, except for (ii) when $pq = uv$. In the exceptional case, we may assume $v \notin \{a, b\}$. Let H_0'' be obtained from H_0 by a T-transform at $\{v, ab\}$, with new vertex a''. We apply Theorem 1.2(a) to find a cycle C in $(H_0'' + ua'') - v$ through ua'' such that $|C| \geq \frac{1}{2}(\frac{|H_0|}{d})^r + 2$. Without loss of generality, we may assume a is the end of $C - a''$. Let P' be found as above. Then $P := ((C - a'') \cup P') + \{v, uv\}$ gives the desired path for (ii). □

4. Cycles through two edges. We reduce Theorem 1.2(a) and (b) to Theorem 1.2 for smaller graphs. Note that finding a long cycle in Theorem 1.2(a) through xy avoiding z is equivalent to finding a long cycle through edges xz and yz. First, we reduce Theorem 1.2(a); our proof implies an $O(E)$ time reduction.

LEMMA 4.1. *Let $n \geq 6$ be an integer, and assume that Theorem* 1.2 *holds for graphs with at most $n - 1$ vertices. Let G be a 3-connected graph with n vertices, let $xy \in E(G)$ and $z \in V(G) - \{x, y\}$, and let t denote the number of neighbors of z distinct from x and y. Assume $\Delta(G) \leq d + 1$, and every vertex of degree $d + 1$ in G (if any) is incident with the edge zx or zy. Then there is a cycle C through xy in $G - z$ such that $|C| \geq \frac{1}{2}(\frac{(d-1)n}{dt})^r + 2$.*

Proof. By Lemma 1.3, we may assume $n \geq 4d + 2$. Since G is 3-connected, $t \geq 1$.

Assume that $G - z$ is 3-connected. By assumption, $\Delta(G - z) \leq d$. Since $n \geq 6$, $|G - z| \geq 5$. So by Theorem 1.2(c), $G - z$ contains a cycle C through xy such that $|C| \geq \frac{1}{2}(n - 1)^r + 3$. By Lemma 3.1, $|C| \geq \frac{1}{2}n^r + 2 > \frac{1}{2}(\frac{(d-1)n}{dt})^r + 2$.

Therefore, we may assume that $G - z$ is not 3-connected. By Theorem 2.1, we decompose $G - z$ into 3-connected components. Let $\mathcal{H} := H_1 \dots H_h$ be a block chain in $G - z$ such that (i) H_h contains an extreme 3-block of $G - z$, (ii) $xy \in E(H_1)$ and $\{x, y\} \neq V(H_1) \cap V(H_2)$ when $h \neq 1$, and if $H_1 = C_1 \dots C_k$ is a cycle chain with $k \geq 2$ and $V(H_1 \cap H_2) = V(C_k \cap H_2)$ (when $h \neq 1$), then $xy \in E(C_1)$ and $\{x, y\} \neq V(C_1 \cap C_2)$, and (iii) subject to (i) and (ii), $\sigma(\mathcal{H})$ is maximum.

We claim that $\sigma(\mathcal{H}) \geq \frac{n-1-2t}{t}$. Since G is 3-connected, each extreme 3-block of $G - z$ distinct from H_1 contains a neighbor of z. Therefore, there are at most $2t$ degree 2 vertices in $G - z$ and at most t extreme 3-blocks of $G - z$ different from H_1. Note that the vertices of $G - z$ with degree at least 3 are counted in $\sigma(\mathcal{K})$ for some

block chain $\mathcal{K}$ (defined as $\mathcal{H}$ above except condition (iii)). It then follows from (iii) that $\sigma(\mathcal{H}) \geq \frac{n-1-2t}{t}$.

Since $n > 4d+1$ and $t \leq d$, $\sigma(\mathcal{H}) \geq 2$. By Lemma 3.5, there is a path P from x to y in $\mathcal{H}$ such that $|E(P)| \geq \frac{1}{2}(\frac{(d-1)\sigma(\mathcal{H})}{d})^r + 2$. Let $C^* := P + xy$. Then

$$\begin{aligned}
|C^*| &= |E(P)| + 1 \\
&\geq \frac{1}{2}\left(\frac{(d-1)\sigma(\mathcal{H})}{d} + (b-1)\right)^r + 2 \quad \text{(by Lemma 3.1)} \\
&\geq \frac{1}{2}\left(\frac{(d-1)(n-1-2t) + dt(b-1)}{dt}\right)^r + 2 \\
&> \frac{1}{2}\left(\frac{(d-1)n}{dt}\right)^r + 2 \quad \text{(since } b \geq 4d+1\text{)}.
\end{aligned}$$

The desired cycle C can now be obtained from C^* by replacing virtual edges in C^* with appropriate paths in G. □

We now reduce Theorem 1.2(b); our proof implies an $O(E)$ time reduction.

LEMMA 4.2. *Let $n \geq 6$ be an integer, and assume that Theorem 1.2 holds for graphs with at most $n-1$ vertices. Suppose G is a 3-connected graph on n vertices and $\Delta(G) \leq d$. Then for any $\{e, f\} \subseteq E(G)$, there is a cycle C through e, f in G such that $|C| \geq \frac{1}{2}(\frac{n}{d})^r + 3$.*

Proof. By Lemma 1.3, we may assume $n \geq 4d+2$. First, assume that e is incident with f. Let $e = xz$ and $f = yz$, and let $G' := G + xy$. Then G' is 3-connected, $\Delta(G') \leq d+1$, and the possible vertices of degree $d+1$ in G' are x and y. By applying Lemma 4.1 to G', xy, z, there is a cycle C' through xy in $G' - z$ such that $|C'| \geq \frac{1}{2}(\frac{(d-1)n}{dt})^r + 2$, where t is the number of neighbors of z in G' distinct from x and y. Since $zx, zy \in E(G)$, $t \leq d-1$. Let $C := (C' - xy) + \{e, f\}$; then $|C| \geq \frac{1}{2}(\frac{(d-1)n}{dt})^r + 3 \geq \frac{1}{2}(\frac{n}{d})^r + 3$. So C gives the desired cycle in G.

Therefore, we may assume that e and f are not incident. Let $e = xy$; then $f \in E(G-y)$. Since G is 3-connected, $G-y$ is 2-connected.

Suppose $G-y$ is 3-connected. Let $y' \neq x$ be a neighbor of y. Then $G' := (G-y)+xy'$ is a 3-connected graph, $\Delta(G') \leq d$, and $5 \leq |G'| < n$. By Theorem 1.2(b), there is a cycle C' through xy' and f in G' such that $|C'| \geq \frac{1}{2}(\frac{n-1}{d})^r + 3$. Let $C := (C' - xy') + \{y, xy, yy'\}$. Then $|C| = |C'| + 1 \geq \frac{1}{2}(\frac{n-1}{d})^r + 4$. By Lemma 3.1, $|C| \geq \frac{1}{2}(\frac{n}{d})^r + 3$. So C gives the desired cycle in G.

Hence, we may assume that $G-y$ is not 3-connected. By Theorem 2.1, we decompose $G-y$ into 3-connected components. Let $\mathcal{H} := H_1 \dots H_h$ be a block chain in $G-y$ such that (a) $f \in E(H_1)$ and $x \in V(H_h)$, (b) if $h = 1$ and $H_1 = C_1 \dots C_k$ is a cycle chain with $k \geq 2$, then $x \in V(C_k) - V(C_{k-1})$, $f \in E(C_1)$, and f is not incident with both vertices in $V(C_1 \cap C_2)$, and (c) if $h \geq 2$, then $x \in V(H_h) - V(H_{h-1})$, if $H_h = C_1 \dots C_k$ is a cycle chain with $k \geq 2$ and $V(H_{h-1} \cap H_h) = V(C_1 \cap H_{h-1})$, then $x \in V(C_k) - V(C_{k-1})$, $f \in E(H_1)$, f is not incident with both vertices in $V(H_1 \cap H_2)$, and if $H_1 = C_1 \dots C_k$ is a cycle chain with $k \geq 2$ and $V(H_1 \cap H_2) = V(C_k \cap H_2)$, then $f \in E(C_1)$ and f is not incident with both vertices in $V(C_1 \cap C_2)$. Define $V(H_s \cap H_{s+1}) = \{a_s, b_s\}$ for $1 \leq s \leq h-1$.

Suppose $V(\mathcal{H}) = V(G-y)$. If $h = 1$, then $G-y$ is a cycle chain, and it is easy to see that G has a Hamilton cycle through e and f, and hence, Theorem 1.2(b) holds. So assume $h \geq 2$. Let $x' \in V(H_1) - V(H_2)$ so that $yx' \in E(G)$, and in addition, if f has an end with degree 2 in $\mathcal{H}$, then choose x' to be that end (in this case, $yx' \in E(G)$).

Let G' be obtained from $G-y$ by adding xx' and then suppressing all degree 2 vertices and deleting separating edges of $\mathcal{H}$. Now G' is 3-connected, $|G'| \geq n-1-(d-2)$ (because degree of y in G is at most d), and $\Delta(G') \leq d$. Therefore, by Theorem 1.2(b), G' has a cycle C' through f and xx' such that $|C'| \geq \frac{1}{2}(\frac{|G'|}{d})^r + 3$. By replacing edges in $(C' - xx') + \{y, yx, yx'\}$ but not in G with appropriate paths in G, we obtain a cycle C in G through e and f such that $|C| \geq |C'| + 1 \geq \frac{1}{2}(\frac{n-d+1}{d})^r + 4 \geq \frac{1}{2}(\frac{n}{d})^r + 3$, where the final inequality follows from Lemma 3.1. So C is the desired cycle.

We thus may assume that $\mathcal{H} \neq G - y$. Then there is a 2-cut $\{p, q\}$ of $G - y$ such that pq is a virtual edge in H_t for some $1 \leq t \leq h$. Define G_1 as the graph obtained from G by deleting those components of $(G - y) - \{p, q\}$ containing a vertex of $\mathcal{H}$. Note that $G_1 - \{p, q, y\}$ contains a neighbor of y. We choose $\{p, q\}$ so that $|G_1|$ is maximum. Because y has degree at most d in G and $yx \in E(G)$, and since all degree 2 vertices of $G - y$ are neighbors of y, we have (from the choice of G_1) the following observation.

Observation 1. $|G_1| \geq \frac{n-\sigma(\mathcal{H})}{d-1}$.

If there is a 2-cut $\{v, w\}$ of $G-y$ such that $\{v, w\} \subseteq V(\mathcal{H} \cup G_1)$ and $(G-y)-\{v, w\}$ has a component not containing any vertex of $\mathcal{H} \cup G_1$, then let G_2 denote the graph obtained from G by deleting those components of $(G-y)-\{v, w\}$ containing a vertex of $\mathcal{H} \cup G_1$. If such a 2-cut does not exist, then let $G_2 = \emptyset$. From the definition of G_1, we see that $\{v, w\} \subseteq V(\mathcal{H})$, $\{v, w\} \neq \{p, q\}$, and $V(G_1 \cap G_2) \subseteq \{p, q, y\} \cap \{v, w, y\}$. Choose $\{v, w\}$ so that $|G_2|$ is maximum. By the same reason for Observation 1, we have the following two observations.

Observation 2. If $\sigma(\mathcal{H}) \geq |G_2|$, then $\sigma(\mathcal{H}) \geq \frac{n-|G_1|}{d-1}$.

Observation 3. If $|G_2| \geq \sigma(\mathcal{H})$, then $|G_2| \geq \frac{n-|G_1|}{d-1}$.

We consider three cases.

Case 1. $\sigma(\mathcal{H}) \geq |G_2|$.

We use $\mathcal{H}$ and G_1 to find the desired cycle. Choose t so that $\{p, q\} \neq \{a_t, b_t\}$. (Note that a_t, b_t are not defined when $t = h$.) Clearly, $|H_t| \leq n - 3$ when $h \geq 2$. By Lemma 3.7(ii), there is a path P from x to $\{p, q\}$ in $\mathcal{H}$ such that $f \in E(P)$, $pq \notin E(P)$ unless $pq = f$, and $|E(P)| \geq \frac{1}{2}(\frac{\sigma(\mathcal{H})}{d})^r + 1$. Assume the notation of $\{p, q\}$ is chosen so that P is from x to p.

Since G is 3-connected, $G_1' := G_1 + \{yp, yq, pq\}$ is 3-connected. If $G_1' \cong K_4$, then we can find a path Q in $G_1' - q$ from p to y such that $|E(Q)| = 2 \geq \frac{1}{2}(\frac{|G_1|}{d})^r + 1$. Now assume that $G_1' \ncong K_4$. Note that $\Delta(G_1') \leq d + 1$, and y, p, q are the only possible vertices with degree $d+1$. By Theorem 1.2(a), there is a cycle C_1 through py in $G_1' - q$ such that $|C_1| \geq \frac{1}{2}(\frac{(d-1)|G_1|}{dt_1})^r + 2$, where $t_1 \leq d - 1$ is the number of neighbors of q in G_1' distinct from p and y. Hence, $|C_1| \geq \frac{1}{2}(\frac{|G_1|}{d})^r + 2$.

Let $C^* := (P \cup (C_1 - py)) + xy$. Then C^* is a cycle through e and f and $|C^*| \geq \frac{1}{2}[(\frac{\sigma(\mathcal{H})}{d})^r + (\frac{|G_1|}{d})^r] + 3$. If $\sigma(\mathcal{H}) \leq |G_1|$, then

$$\begin{aligned}
|C^*| &\geq \frac{1}{2}\left(\frac{(b-1)\sigma(\mathcal{H})}{d} + \frac{|G_1|}{d}\right)^r + 3 \quad \text{(by Lemma 3.1)} \\
&> \frac{1}{2}\left(\frac{n-|G_1|}{d} + \frac{|G_1|}{d}\right)^r + 3 \quad \text{(by Observation 2)} \\
&= \frac{1}{2}\left(\frac{n}{d}\right)^r + 3.
\end{aligned}$$

So we may assume $\sigma(\mathcal{H}) \geq |G_1|$. Then

$$\begin{aligned}|C^*| &\geq \frac{1}{2}\left(\frac{\sigma(\mathcal{H})}{d} + \frac{(b-1)|G_1|}{d}\right)^r + 3 \quad \text{(by Lemma 3.1)}\\ &> \frac{1}{2}\left(\frac{\sigma(\mathcal{H})}{d} + \frac{n-\sigma(\mathcal{H})}{d}\right)^r + 3 \quad \text{(by Observation 1)}\\ &= \frac{1}{2}\left(\frac{n}{d}\right)^r + 3.\end{aligned}$$

The desired cycle C can be obtained from C^* by replacing virtual edges in C^* with appropriate paths in G.

Case 2. $\sigma(\mathcal{H}) < |G_2|$.

Then G_2 is nonempty. We use G_1 and G_2 to find the desired cycle. There exists some $1 \leq u \leq h$ such that $\{v, w\} \subseteq V(H_u)$, and we may choose u so that $\{v, w\} \neq \{a_{u-1}, b_{u-1}\}$. (Note that a_{u-1}, b_{u-1} are not defined when $u = 1$.) We may choose t so that $\{p, q\} \neq \{a_{t-1}, b_{t-1}\}$. Again, a_{t-1}, b_{t-1} are not defined when $t = 1$.

(1) We claim that there is a path P in $\mathcal{H}$ from x to some $z \in \{p, q\} \cup \{v, w\}$ and containing no separating edge of $\mathcal{H}$ such that (i) $f \in E(P)$, (ii) $pq \in E(P)$ or $vw \in E(P)$, (iii) if $pq \in E(P)$, then $z \in \{v, w\}$, and $vw \notin E(P)$ unless $vw = f$, and (iv) if $vw \in E(P)$, then $z \in \{p, q\}$, and $pq \notin E(P)$ unless $pq = f$.

We prove (1) for $t \leq u$; the case $t \geq u$ can be treated in the same way.

First, we define Q. When $t \neq 1$, we find a cycle Q' in $\bigcup_{s=1}^{t-1} H_s$ through $a_{t-1}b_{t-1}$ and f and containing no separating edge of $\mathcal{H}$ (except $a_{t-1}b_{t-1}$). Let $Q := Q' - a_{t-1}b_{t-1}$, which is a path from a_{t-1} to b_{t-1} through f. Let $Q = \emptyset$ when $t = 1$.

Suppose $t < u$. Since removing separating edges of $H_{t+1} \dots H_h$ that are different from vw results in a 2-connected graph, we may choose the notation of $\{a_t, b_t\}$ so that $(\bigcup_{s=t+1}^{h} H_s) - b_t$ contains a path X from a_t to x through vw and containing no separating edge of $\mathcal{H}$ (except possibly vw).

We claim that there is a path C_t in $H_t - a_tb_t$ from a_t to $\{p, q\}$ through $a_{t-1}b_{t-1}$ (or f when $t = 1$), or a path C'_t in H_t from a_t to b_t through $a_{t-1}b_{t-1}$ (or f when $t = 1$) and pq. If $\{p, q\} = \{a_t, b_t\}$, then the existence of C_t follows from 2-connectivity of H_t. So we may assume that $\{p, q\} \neq \{a_t, b_t\}$. Again by 2-connectivity of H_t there is a cycle D in H_t through pq and $a_{t-1}b_{t-1}$ (or f when $t = 1$). If $a_tb_t \in E(D)$, then $C'_t := D - a_tb_t$ is as desired. So we may assume $a_tb_t \notin E(D)$. By 2-connectivity of H_t, there is a path A in H_t from a_t to D and internally disjoint from D. One can easily check that C_t exists in $A \cup D$.

If we find C_t, then let $P_t := C_t - a_{t-1}b_{t-1}$ when $t \neq 1$ and $P_t := C_t$ when $t = 1$. In this case, $P := Q \cup P_t \cup X$ gives the desired path for (1). So assume that we find C'_t. Let $P_t := C'_t$ if $t = 1$, and otherwise let $P_t := C'_t - a_{t-1}b_{t-1}$. Let $H := H_{t+1} \dots H_h$. If $x \in \{v, w\}$, then we find a cycle C' in H through a_tb_t and vw and containing no separating edge of $\mathcal{H}$ (except a_tb_t and vw), and $P := Q \cup P_t \cup (C' - \{a_tb_t, vw\})$ gives the desired path for (1). Therefore, we may assume $x \notin \{v, w\}$. Let H' be obtained from H by a T-transform at $\{x, vw\}$, let x' denote the new vertex, and let H'' be obtained from H' by deleting all separating edges of H different from a_tb_t. Then H'' is a 2-connected graph. So there is a cycle C'' in H'' through a_tb_t and xx'. Now $P := Q \cup P_t \cup (C'' - \{x', a_tb_t\})$ gives the desired path for (1).

Therefore, we may assume $t = u$. We claim that there is a path Q_t in H_t from $\{a_t, b_t\}$ when $t \neq h$, or from x when $t = h$, to some $z \in \{p, q\} \cup \{v, w\}$ such that (i) $a_{t-1}b_{t-1} \in E(Q_t)$ (or $f \in E(Q_t)$ when $t = 1$), (ii) $pq \in E(Q_t)$ or $vw \in E(Q_t)$, (iii) if $pq \in E(Q_t)$, then $z \in \{v, w\}$, and $vw \notin E(Q_t)$ unless $vw = f$, and (iv) if $vw \in E(Q_t)$,

then $z \in \{p, q\}$, and $pq \notin E(Q_t)$ unless $pq = f$. This is easy to see if H_t is a cycle chain (because $pq \neq vw$). Otherwise, it follows from Lemma 2.8 or Lemma 2.9 when $f \notin \{pq, vw\}$, and follows from 3-connectivity of H_t when $f \in \{pq, vw\}$.

Assume without loss of generality that a_t is an end of Q_t. When $t \neq h$, we find a path R from a_t to x in $(H_{t+1} \dots H_h) - b_t$ containing no separating edge of $\mathcal{H}$. When $t = h$, let $R = \emptyset$. Let $P_t := Q_t$ when $t = 1$, and otherwise let $P_t := Q_t - a_{t-1}b_{t-1}$. Then $P := Q \cup P_t \cup R$ gives the desired path for (1).

We may assume that $vw \in E(P)$ and p is an end of P, since the case $pq \in E(P)$ is similar.

(2) Note that $G_1' := G_1 + \{yp, yq, pq\}$ is 3-connected, $\Delta(G_1') \leq d + 1$, and y, p, q are the possible vertices of degree $d + 1$ in G_1'. If $G_1' \cong K_4$, then we can find a path P_1 from p to y in $G_1' - q$ such that $|E(P_1)| = 2 \geq \frac{1}{2}(\frac{|G_1|}{d})^r + 1$. If $G_1' \ncong K_4$, then by Theorem 1.2(a), there is a cycle C_1 through py in $G_1' - q$ such that $|C_1| \geq \frac{1}{2}(\frac{(d-1)|G_1|}{dt_1})^r + 2$, where $t_1 \leq d-1$ is the number of neighbors of q in G_1' distinct from p and y. Let $P_1 := C_1 - py$; then $|E(P_1)| \geq \frac{1}{2}(\frac{|G_1|}{d})^r + 1$.

(3) Note that $G_2' := G_2 + \{yv, yw, vw\}$ is 3-connected, $\Delta(G_2') \leq d + 1$, and y, v, w are the possible vertices of degree $d + 1$ in G_2'. If $G_2' \cong K_4$, then we can find a path P_2 from v to w in $G_2' - y$ such that $|E(P_2)| = 2 \geq \frac{1}{2}(\frac{|G_2|}{d})^r + 1$. If $G_2' \ncong K_4$, then by Theorem 1.2(a), there is a cycle C_2 through vw in $G_2' - y$ such that $|C_2| \geq \frac{1}{2}(\frac{(d-1)|G_2'|}{dt_2})^r + 2$, where $t_2 \leq d-1$ is the number of neighbors of y in G_2' distinct from v and w. Let $P_2 := C_2 - vw$; then $|E(P_2)| \geq \frac{1}{2}(\frac{|G_2|}{d})^r + 1$.

Let $C^* := ((P - vw) \cup P_1 \cup P_2) + e$. Then C^* is a cycle through e and f and

$$\begin{aligned}
|C^*| &\geq |E(P_1)| + |E(P_2)| + 1 \\
&\geq \frac{1}{2}\left(\frac{|G_1|}{d}\right)^r + \frac{1}{2}\left(\frac{|G_2|}{d}\right)^r + 3 \quad \text{(by (2) and (3))} \\
&\geq \frac{1}{2}\left(\frac{|G_1|}{d} + \frac{(b-1)|G_2|}{d}\right)^r + 3 \quad \text{(by Lemma 3.1 and since } |G_1| \geq |G_2|) \\
&> \frac{1}{2}\left(\frac{|G_1|}{d} + \frac{n - |G_1|}{d}\right)^r + 3 \quad \text{(by Observation 3 and since } |G_2| \geq \sigma(\mathcal{H})) \\
&= \frac{1}{2}\left(\frac{n}{d}\right)^r + 3.
\end{aligned}$$

As before, the desired cycle C can be obtained by modifying C^*. □

5. Cycles through one edge. We now reduce Theorem 1.2(c); our proof implies an $O(E)$ time reduction. Here we use Lemmas 3.2 and 3.3, and need $b = \max\{64, 4d + 1\}$.

LEMMA 5.1. *Let $n \geq 6$ be an integer, and assume that Theorem 1.2 holds for graphs with at most $n - 1$ vertices. Let G be a 3-connected graph with n vertices and $\Delta(G) \leq d$. Then for any $e \in E(G)$, there is a cycle C through e in G such that $|C| \geq \frac{1}{2}n^r + 3$.*

Proof. By Lemma 1.3, we may assume $n > (4d+1)^2$. Let $e = xy \in E(G)$. If $G - y$ is 3-connected, then let y' be a neighbor of y other than x. Clearly, $G' := (G - y) + xy'$ is 3-connected, $\Delta(G') \leq d$, and $5 \leq |G'| < n$. By Theorem 1.2(c), there is a cycle C' through xy' in G' such that $|C'| \geq \frac{1}{2}(n-1)^r + 3$. Now let $C := (C' - xy') + \{y, xy, yy'\}$. Then C is a cycle through xy in G and, by Lemma 3.1,

$$|C| = |C'| + 1 \geq \frac{1}{2}(n-1)^r + 1 + 3 \geq \frac{1}{2}n^r + 3.$$

Therefore, we may assume that $G-y$ is not 3-connected. Since $G-y$ is 2-connected, we use Theorem 2.1 to decompose $G-y$ into 3-connected components.

Suppose all 3-blocks of $G-y$ are cycles. Let $\mathcal{L}=L_1\dots L_\ell$ be a cycle chain in $G-y$ such that (i) $x\in V(L_1)$, (ii) L_ℓ is an extreme 3-block of $G-y$, and (iii) subject to (i) and (ii), $|\mathcal{L}|$ is maximum. Because G is 3-connected, each degree 2 vertex in $\mathcal{L}$ is a neighbor of y or is contained in a 3-block of $G-y$ not in $\mathcal{L}$. Hence, it is easy to see that there is some $y'\in V(\mathcal{L})-\{x\}$ such that $\mathcal{L}$ contains a Hamilton path P from x to y' and G has a path Q from y' to y disjoint from $V(\mathcal{L})-\{y'\}$. Let $C:=(P\cup Q)+\{y,xy,yy'\}$, which is a cycle in G. Then $|C|\geq|\mathcal{L}|+1$. If $V(G-y)=V(\mathcal{L})$, then $|C|=n\geq\frac{1}{2}n^r+3$ (since $n\geq 5$ and by Lemma 3.4). So we may assume $V(G-y)\neq V(\mathcal{L})$. Write $B:=L_1$. Because $x\in V(L_1)$ and $xy\in E(G)$, it follows from (iii) that $|\mathcal{L}|\geq\frac{(n-1)-|B|}{t}+|B|=\frac{n+(t-1)|B|-1}{t}$, where t is the number of extreme 3-blocks of $G-y$ distinct from L_1. So $2\leq t\leq d-1$ (because $V(G-y)\neq V(\mathcal{L})$). Then $|C|\geq|\mathcal{L}|+1\geq\frac{n+(t-1)|B|-1}{t}+1$. Note that $|C|-3\geq\frac{n+(t-1)|B|-1}{t}-2\geq\frac{n+t-4}{t}$ (since $|B|\geq 3$). Using elementary calculus, we can show that the function $\frac{x+t-4}{t}-\frac{1}{2}x^r$ is increasing when $x\geq(4d+1)^2$. Hence $\frac{n+t-4}{t}\geq\frac{1}{2}n^r$ (because $t\leq d-1$ and $n\geq(4d+1)^2$). Therefore, $|C|\geq\frac{1}{2}n^r+3$ and C gives the desired cycle in G.

Hence, we may assume that not all 3-blocks of $G-y$ are cycles. We choose a 3-connected 3-block H_0 of $G-y$ with $|H_0|$ maximum. Let $\mathcal{H}=H_0H_1H_2\dots H_h$ be a block chain in $G-y$ such that either $h=0$ and $x\in V(H_0)$, or $h\geq 1$ and $x\in V(H_h)-V(H_{h-1})$, and if $H_h=C_1\dots C_k$ is a cycle chain with $k\geq 2$ and $V(H_{h-1}\cap H_h)=V(C_1\cap C_2)$, then $x\in V(C_k)-V(C_{k-1})$. For $0\leq i\leq h-1$, let $V(H_i\cap H_{i+1})=\{a_i,b_i\}$.

If $V(G-y)\neq V(\mathcal{H})$, there is a block chain $\mathcal{L}:=L_1L_2\dots L_\ell$ in $G-y$ such that $V(\mathcal{H}\cap\mathcal{L})=V(\mathcal{H}\cap L_1)$ consists of two vertices c_0 and d_0, L_ℓ is (or contains) an extreme 3-block of $G-y$, and if $L_1=C_1\dots C_k$ is a cycle chain with $k\geq 2$ and $V(L_1\cap L_2)=V(C_k\cap H_2)$ when $\ell\geq 2$, then $c_0d_0\in E(C_1)$ and $\{c_0,d_0\}\neq V(C_1\cap C_2)$. For $1\leq i\leq\ell-1$, let $V(L_i\cap L_{i+1})=\{c_i,d_i\}$. If $\mathcal{L}$ exists, we choose $\mathcal{L}$ so that $\sigma(\mathcal{L})$ is maximum.

(1) We may assume $V(G-y)\neq V(\mathcal{H})$, and $\sigma(\mathcal{L})+2\geq\frac{n-\sigma(\mathcal{H})-1}{d-1}$.

Suppose $V(G-y)=V(\mathcal{H})$. When $h=0$, let x' be a neighbor of y in H_0-x, otherwise, let x' be a neighbor of y in $H_0-V(H_1)$. Let G' be obtained from $H+xx'$ by suppressing all degree 2 vertices and deleting separating edges of $\mathcal{H}$. Then G' is 3-connected. By Theorem 1.2(c), there is a cycle C' in G' through xx' such that $|C'|\geq\frac{1}{2}|G'|^r+3$. Let $C^*:=(C'-xx')+\{y,yx,yx'\}$. Since $\Delta(G)\leq d$, $|G'|\geq(n-1)-(d-2)$. Hence, $|C^*|=|C'|+1\geq\frac{1}{2}(n-d+1)^r+1+3>\frac{1}{2}n^r+3$ (by Lemma 3.1). Clearly, the desired cycle C can be obtained by modifying C^*.

So we may assume $V(G-y)\neq V(\mathcal{H})$. Note that any vertex of G not contained in any $A(H_i)$, $1\leq i\leq h$, either is counted in $\sigma(\mathcal{L}')+2$ for some block chain $\mathcal{L}'$ defined as $\mathcal{L}$ except the maximum requirement (the constant 2 counts the vertices in $V(\mathcal{H}\cap\mathcal{L}')$), or is a degree 2 vertex in $G-y$ (and hence a neighbor of y). Therefore, since $xy\in E(G)$ and $\Delta(G)\leq d$, $\sigma(\mathcal{L})+2\geq\frac{n-\sigma(\mathcal{H})-1}{d-1}$.

(2) There exists a path P in $\mathcal{H}$ from x to $\{c_0,d_0\}$ such that $c_0d_0\notin E(P)$ and $|E(P)|\geq\frac{1}{2}|H_0|^r+\frac{1}{2}(\sum\{(\frac{|H_i|}{d})^r:i\neq 0\text{ and }H_i\in B_1(\mathcal{H})\})+(\sum\{\max\{1,|A(H_i)|-2\}:i\neq 0\text{ and }H_i\in B_1(\mathcal{H})\})+1$. In particular, $|E(P)|\geq\frac{1}{2}(\sigma(\mathcal{H}))^r+1$.

The first part of (2) follows from Lemma 3.7(i). The second part of (2) follows from Lemma 3.1. When applying Lemma 3.1, we express $\max\{1,|A(H_i)|-2\}$ as the sum of 1, and we use $b\geq 4d+1$, $(b-1)(|A(H_i)|-2)\geq|A(H_i)|$ when $|A(H_i)|\geq 3$,

and the fact that $|H_0| \geq |H_i|$ for all 3-connected H_i.

(3) We may assume $\sigma(\mathcal{H}) < \frac{n-1}{4}$.

Suppose $\sigma(\mathcal{H}) \geq \frac{n-1}{4}$. Without loss of generality, assume c_0 is an end of the path P in (2). By Lemma 3.6(i), there is a path Q in $\mathcal{L} - d_0$ from c_0 to some $y' \in N(y) \cap V(L_\ell)$ such that $|E(Q)| \geq \frac{1}{2}(\frac{\sigma(\mathcal{L})}{d})^r + 1$. Let $C^* := (P \cup Q) + \{y, yy', yx\}$. Then

$$|C^*| = |E(P)| + |E(Q)| + 2 \geq \frac{1}{2}(\sigma(\mathcal{H}))^r + 1 + \frac{1}{2}\left(\frac{\sigma(\mathcal{L})}{d}\right)^r + 3.$$

If $\sigma(\mathcal{H}) \leq \frac{b(b-1)}{4}\frac{\sigma(\mathcal{L})}{d}$, then by Lemmas 3.3 and 3.1,

$$|C^*| \geq \frac{1}{2}(4\sigma(\mathcal{H}) + 1)^r + 3 \geq \frac{1}{2}n^r + 3.$$

If $\sigma(\mathcal{H}) \geq \frac{b(b-1)}{4}\frac{\sigma(\mathcal{L})}{d}$, then by Lemma 3.2 and since $b \geq 4d + 1$,

$$\begin{aligned} |C^*| &> \frac{1}{2}\left(\sigma(\mathcal{H}) + \frac{b(b-1)}{4}\frac{\sigma(\mathcal{L})}{d} + 2(b-1)\right)^r + 3 \\ &\geq \frac{1}{2}(\sigma(\mathcal{H}) + (4d+1)\sigma(\mathcal{L}) + 8d)^r + 3 \\ &> \frac{1}{2}n^r + 3. \end{aligned}$$

The final inequality holds by (1) and $\sigma(\mathcal{H}) < n - 1$. Now the desired cycle C can be obtained from C^* by replacing virtual edges in C^* with appropriate paths in G.

(4) We may assume $|H_0| + 4(\sigma(\mathcal{H}) - |H_0| + \sigma(\mathcal{L})) < n$. In particular, $\sigma(\mathcal{L}) \leq \frac{n-1-|H_0|}{4}$.

Suppose $|H_0| + 4(\sigma(\mathcal{H}) - |H_0| + \sigma(\mathcal{L})) \geq n$. Without loss of generality, assume that the path P in (2) is from x to c_0. By Lemma 3.6(ii), there is a path Q in $\mathcal{L} - d_0$ from c_0 to some $y' \in N(y) \cap V(L_\ell)$ such that $|E(Q)| \geq \frac{1}{2}(\sum\{(\frac{|A(L_i)|}{d})^r : L_i \in B_1(\mathcal{L})\}) + (\sum\{\max\{1, |A(L_i)| - 2\} : L_i \in B_2(\mathcal{L})\}) + 1$.

Let $C^* = (P \cup Q) + \{y, yy', yx\}$. Then by (2) and above, $|C^*| = |E(P)| + |E(Q)| + 2 \geq \frac{1}{2}|H_0|^r + \frac{1}{2}(\sum\{(\frac{|A(H_i)|}{d})^r : i \neq 0 \text{ and } H_i \in B_1(\mathcal{H})\}) + (\sum\{\max\{1, |A(H_i)| - 2\} : i \neq 0 \text{ and } H_i \in B_2(\mathcal{H})\}) + \frac{1}{2}(\sum\{(\frac{|A(L_i)|}{d})^r : L_i \in B_1(\mathcal{L})\}) + (\sum\{\max\{1, |A(L_i)| - 2\} : L_i \in B_2(\mathcal{L})\}) + 4$. Because $|H_0|$ is maximum among all 3-connected 3-blocks of $G - y$, it follows from Lemma 3.1 and the fact that $b \geq 4d + 1$ that

$$\begin{aligned} |C^*| &\geq \frac{1}{2}\left[|H_0| + 4\left(\sum_{i=1}^{h}|A(H_i)| + \sum_{j=1}^{\ell}|A(L_j)|\right)\right]^r + 4 \\ &= \frac{1}{2}[|H_0| + 4(\sigma(\mathcal{H}) - |H_0| + \sigma(\mathcal{L}))]^r + 4 \\ &> \frac{1}{2}n^r + 3. \end{aligned}$$

As before, the desired cycle C can be obtained by modifying C^*. This proves (4).

We need to consider block chains other than $\mathcal{H}$ and $\mathcal{L}$. A block chain $\mathcal{M} := M_1M_2 \dots M_m$ is called an *$\mathcal{HL}$-leg* if M_m contains an extreme 3-block of $G - y$ and $V(\mathcal{M} \cap (\mathcal{H} \cup \mathcal{L}))$ consists of two vertices x_0 and y_0 such that $\{x_0, y_0\} \subseteq V(M_1)$ and $\{x_0, y_0\} \neq V(M_1 \cap M_2)$ when $m \geq 2$, and if $M_1 = C_1 \dots C_k$ is a cycle chain with

$k \geq 2$ and $V(C_k \cap M_2) = V(M_1 \cap M_2)$ when $m \geq 2$, then $\{x_0, y_0\} \subseteq V(C_1)$ and $\{x_0, y_0\} \neq V(C_1 \cap C_2)$. We view degree 2 vertices of $G - y$ (which are neighbors of y) as trivial $\mathcal{HL}$-legs.

(5) We may assume that there is an $\mathcal{HL}$-leg $\mathcal{M}$ such that $\sigma(\mathcal{M}) > \frac{n}{4(d-2)} > 4d+2$.

Note that each extreme 3-block of $G-y$ contains a neighbor of y. Since $\Delta(G) \leq d$, there are at most $d-2$ $\mathcal{HL}$-legs in $G-y$ (including those trivial ones). Choose an $\mathcal{HL}$-leg $\mathcal{M}$ such that $\sigma(\mathcal{M})$ is maximum. Note that every vertex of $G-y$ is either a degree 2 vertex (hence covered in a trivial $\mathcal{HL}$-leg), or is counted in $\sigma(\mathcal{H})$, or in $\sigma(\mathcal{L})+2$, or in $\sigma(\mathcal{M})+2$ for some $\mathcal{HL}$-leg $\mathcal{M}$. Hence, because $\sigma(\mathcal{H}) < \frac{n-1}{4}$ (by (3)) and $\sigma(\mathcal{L}) \leq \frac{n-1-|H_0|}{4} \leq \frac{n-5}{4}$ (by (4) and $|H_0| \geq 4$), $\sigma(\mathcal{M})+2 \geq \frac{n-1-\sigma(\mathcal{H})-\sigma(\mathcal{L})-2}{d-2} > \frac{n-3}{2(d-2)}$. Since we assume $n > (4d+1)^2$, $\sigma(\mathcal{M}) > \frac{n}{4(d-2)} > 4d+2$.

Let $\mathcal{M}$ be an $\mathcal{HL}$-leg in $G-y$ with $\sigma(\mathcal{M}) \geq \frac{n}{4(d-2)}$. By (5), $\mathcal{M}$ is nontrivial. Let x_0 and y_0 be the vertices in $V(\mathcal{M} \cap (\mathcal{H} \cup \mathcal{L}))$. We consider three cases.

Case 1. $\mathcal{M}$ may be chosen so that $x \notin \{x_0, y_0\} \cap \{c_0, d_0\}$ and $\{x_0, y_0\} \not\subseteq V(\mathcal{H})$.

Then we may assume $\{x_0, y_0\} \subseteq V(L_t)$ with $\{x_0, y_0\} \neq \{c_{t-1}, d_{t-1}\}$.

We claim that there is a path P' in $\mathcal{H}$ from x to $z \in \{c_0, d_0\}$ such that (i) $|E(P')| \geq \frac{1}{2}(\frac{|H_0|}{d})^r + 1$, (ii) $c_0d_0 \notin E(P')$, and (iii) if $z \notin \{c_0, d_0\} \cap \{x_0, y_0\}$, then $\{c_0, d_0\} \cap \{x_0, y_0\} = \emptyset$ or $\{c_0, d_0\} \cap \{x_0, y_0\} \not\subseteq V(P')$. Choose $z' \in \{c_0, d_0\}$ such that, if possible, $z' \in \{c_0, d_0\} \cap \{x_0, y_0\}$. Suppose $c_0d_0 \in E(H_1 \dots H_h)$. Deleting separating edges of $H_1 \dots H_h$ results in a 2-connected graph, which contains disjoint paths Q_1, Q_2 from x, z' to a_0, b_0, respectively. In H_0 we use Theorem 1.2(c) to find a cycle C_0 through a_0b_0 such that $|C_0| \geq \frac{1}{2}|H_0|^r + 3$. If $c_0d_0 \in E(Q_2)$, then $P' := (C_0 - a_0b_0) \cup Q_1 \cup (Q_2 - z')$ gives the desired path; otherwise, $P' := (C_0 - a_0b_0) \cup Q_1 \cup Q_2$ gives the desired path. So we may assume $c_0d_0 \notin E(H_1 \dots H_h)$. Suppose $h = 0$. We apply Theorem 1.2(a) to find a cycle C_0 in $(H_0 + \{xc_0, xd_0\}) - (\{c_0, d_0\} - \{z'\})$ through xz' such that $|C_0| \geq \frac{1}{2}(\frac{|H_0|}{d})^r + 2$; then $P' := C_0 - xz'$ gives the desired path. So let $h \geq 1$. Then $c_0d_0 \in E(H_0)$ and $\{c_0, d_0\} \neq \{a_0, b_0\}$. Without loss of generality, we may assume $a_0 \notin \{c_0, d_0\}$. Let Q' be a path in $(H_1 \dots H_h) - b_0$ from x to a_0 and not containing any separating edge of $\mathcal{H}$. If $z' = b_0$ we use Theorem 1.2(c) to find a cycle C_0 through a_0b_0 in H_0 such that $|C_0| \geq \frac{1}{2}|H_0|^r + 3$, and $P' := (C_0 - a_0b_0) \cup Q'$ (when $c_0d_0 \notin E(C_0)$) or $P' := (C_0 - b_0) \cup Q'$ (when $c_0d_0 \in E(C_0)$) gives the desired path. So assume $z' \neq b_0$. If $z' \in \{c_0, d_0\} \cap \{x_0, y_0\}$, then z' has at most $d-1$ neighbors in H_0 (since $\{x_0, y_0\} \neq \{c_0, d_0\}$), and in $(H_0 + \{a_0z', z'b_0\}) - b_0$ we apply Theorem 1.2(a) to find a cycle C_0 through a_0z' such that $|C_0| \geq \frac{1}{2}(\frac{|H_0|}{d})^r + 2$; then $P' := (C_0 - a_0z') \cup Q'$ gives the desired path. So we may assume $z' \notin \{c_0, d_0\} \cap \{x_0, y_0\}$. By the choice of z', $\{c_0, d_0\} \cap \{x_0, y_0\} = \emptyset$ (so (iii) is automatic). Let H_0' be obtained from H_0 by an H-transform at $\{a_0b_0, c_0d_0\}$, and let a', x' denote the new vertices. By applying Theorem 1.2(c) we find a cycle C_0 through $a'x'$ in H_0' such that $|C_0| \geq \frac{1}{2}|H_0|^r + 3$. Now $C_0 - \{a', x'\}$ is a path from some $z \in \{c_0, d_0\}$ to some $b' \in \{a_0, b_0\}$. Then $C_0 - \{a', x'\}$ and a path in $(H_1 \dots H_h) - (\{a_0, b_0\} - \{b'\})$ from x to b' (not containing any separating edge of $\mathcal{H}$) gives the desired path P'.

Without loss of generality, we may assume that P' is from x to c_0. Then $d_0 \notin V(P')$ or $d_0 \notin \{x_0, y_0\}$. Therefore, since each L_i is 3-connected or is a cycle chain, there exists a path Q in $\bigcup_{i=0}^{t} L_i$ from c_0 to some $z \in \{c_t, d_t\} \cup \{x_0, y_0\}$ such that (i) $c_0d_0 \in E(Q)$ Q contains no separating edge of $\mathcal{L}$ except possibly c_td_t and x_0y_0, (ii) Q avoids d_0 if $d_0 \in V(P')$ (since in that case $\{x_0, y_0\} \cap \{c_0, d_0\} = \emptyset$), (iii) if $z \in \{c_t, d_t\}$, then $x_0y_0 \in E(Q)$, and $c_td_t \notin E(Q)$ unless $x_0y_0 = c_td_t$, and (iv) if $z \in \{x_0, y_0\}$, then $c_td_t \in E(Q)$, and $x_0y_0 \notin E(Q)$ unless $x_0y_0 = c_td_t$.

Suppose $z \in \{c_t, d_t\}$, and assume the notation is chosen so that $z = c_t$. By Lemma 3.6(ii) there is a path P_1 in $(L_{t+1} \dots L_\ell) - d_t$ from z to some $y' \in N(y) \cap V(L_\ell)$ and containing no separating edge of $\mathcal{L}$ such that $|E(P_1)| \geq \frac{1}{2}(\sum\{(\frac{|A(L_i)|}{d})^r : t+1 \leq i \leq \ell$ and $L_i \in B_1(\mathcal{L})\}) + (\sum\{\max\{1, |A(L_i)| - 2\} : t+1 \leq i \leq \ell$ and $L_i \in B_2(\mathcal{L})\}) + 1$. By Lemma 3.5, let P_2 be a path from x_0 to y_0 in $\mathcal{M}$ such that $|E(P_2)| \geq \frac{1}{2}(\frac{(d-1)\sigma(\mathcal{M})}{d})^r + 1$. Let $n^* := \sum_{i=t+1}^{\ell} |A(L_i)|$; then by the choice of $\mathcal{L}$, $n^* \geq \sigma(\mathcal{M}) - 2$. Let $C^* := (P' \cup (Q - x_0y_0) \cup P_1 \cup P_2) + \{y, yy', yx\}$. As in the proof of (4),

$$\begin{aligned}
|C^*| &\geq |E(P')| + |E(P_1)| + |E(P_2)| + 2 \\
&\geq \frac{1}{2}\left[\left(\frac{|H_0|}{d}\right)^r + 2 + \sum\left(\frac{|A(L_i)|}{d}\right)^r + \sum \max\{1, |A(L_i)| - 2\}\right. \\
&\quad \left. + \left(\frac{(d-1)\sigma(\mathcal{M})}{d}\right)^r\right] + 4 \\
&> \frac{1}{2}[(2 + (b-1)n^*/d)^r + ((d-1)\sigma(\mathcal{M})/d)^r] + 4 \quad \text{(by Lemma 3.1)} \\
&> \frac{1}{2}[2 + n^* + (b-1)(d-1)\sigma(\mathcal{M})/d]^r + 4 \quad \text{(by Lemma 3.1)} \\
&> \frac{1}{2}(4(d-1)\sigma(\mathcal{M}))^r + 3 \quad \text{(since } b \geq 4d+1\text{)} \\
&> \frac{1}{2}n^r + 3 \quad \text{(by (5))}.
\end{aligned}$$

As before, the desired cycle C may be obtained by modifying C^*.

Now assume $z \in \{x_0, y_0\}$, and that the notation is chosen so that $z = x_0$. By Lemma 3.6(ii), there is a path P_2 in $\mathcal{M} - y_0$ from x_0 to some $y'' \in N(y) \cap V(M_m)$ and containing no separating edge of $\mathcal{M}$ such that $|E(P_2)| \geq \frac{1}{2}(\sum\{(\frac{|A(M_i)|}{d})^r : M_i \in B_1(\mathcal{M})\}) + (\sum\{\max\{1, |A(M_i)| - 2\} : M_i \in B_2(\mathcal{M})\}) + 1$. By Lemma 3.5 there is a path P_1 in $L_{t+1} \dots L_\ell$ from c_t to d_t such that $|E(P_1)| \geq \frac{1}{2}((d-1)n^*/d)^r$. Let $C^* := (P' \cup (Q - c_td_t) \cup P_1 \cup P_2) + \{y, yx, yy''\}$. Then by applying Lemma 3.1 as in the above paragraph (by swapping the roles of L_i and M_i), we have

$$|C^*| \geq \frac{1}{2}[(2 + \sigma(\mathcal{M}))^r + ((d-1)n^*/d)^r] + 4.$$

If $(d-1)n^*/d \leq 2 + \sigma(\mathcal{M})$, then by Lemma 3.1 and because $n^* \geq \sigma(\mathcal{M}) - 2$,

$$\begin{aligned}
|C^*| &\geq \frac{1}{2}(2 + \sigma(\mathcal{M}) + (b-1)(d-1)n^*/d + 2(b-1))^r + 3 \\
&> \frac{1}{2}(4(d-1)\sigma(\mathcal{M}))^r + 3 \quad \text{(since } b \geq 4d+1\text{)} \\
&> \frac{1}{2}n^r + 3 \quad \text{(by (5))}.
\end{aligned}$$

So assume $(d-1)n^*/d \geq 2 + \sigma(\mathcal{M})$. Applying Lemma 3.1 and (5) again, we have

$$|C^*| \geq \frac{1}{2}((d-1)n^*/d + (b-1)(2 + \sigma(\mathcal{M})))^r + 4 > \frac{1}{2}(4d\sigma(\mathcal{M}))^r + 3 > \frac{1}{2}n^r + 3.$$

As before, the desired cycle C can be obtained by modifying C^*.

Case 2. $\mathcal{M}$ may be chosen so that $x \notin \{x_0, y_0\} \cap \{c_0, d_0\}$, $\{c_0, d_0\} \neq \{x_0, y_0\}$, and $\{x_0, y_0\} \subseteq V(\mathcal{H})$.

We may assume that $\{c_0, d_0\} \subseteq V(H_s)$ and $\{c_0, d_0\} \neq \{a_{s-1}, b_{s-1}\}$, and $\{x_0, y_0\} \subseteq V(H_t)$ and $\{x_0, y_0\} \neq \{a_{t-1}, b_{t-1}\}$. Note that a_{-1} and b_{-1} are not defined. We consider only the case $s \leq t$, since the case $s \geq t$ is similar. By the choice of $\mathcal{L}$ and by (5), $\sigma(\mathcal{L}) \geq \sigma(\mathcal{M}) \geq \frac{n}{4(d-2)}$.

We claim that there is a path P_0 in $\mathcal{H}$ from x to some $z \in \{c_0, d_0\} \cup \{x_0, y_0\}$ and containing no separating edge of $\mathcal{H}$ (except possibly c_0d_0 or x_0y_0) such that (a) $|E(P_0)| \geq \frac{1}{2}(|H_0|/d)^r + 1$, (b) $c_0d_0 \in E(P_0)$ or $x_0y_0 \in E(P_0)$, (c) if $c_0d_0 \in E(P_0)$, then $z \in \{x_0, y_0\}$ and $x_0y_0 \notin E(P_0)$, and (d) if $x_0y_0 \in E(P_0)$, then $z \in \{c_0, d_0\}$ and $c_0d_0 \notin E(P_0)$.

Suppose $h = 0$. We may assume $x \notin \{x_0, y_0\}$ (the case $x \notin \{c_0, d_0\}$ is symmetric). Let H_0' be obtained from H_0 by a T-transform at $\{x, x_0y_0\}$, and let x' denote the new vertex. By Theorem 1.2(b) we find a cycle C_0 in H_0' through c_0d_0 and xx' such that $|C_0| \geq \frac{1}{2}(|H_0|/d)^r + 3$. Now $P_0 := C_0 - x'$ gives the desired path.

So we may assume $h \geq 1$. Let H' be obtained from $H_1 \dots H_h$ by deleting all separating edges of $\mathcal{H}$ different from a_0b_0, c_0d_0, and x_0y_0. Note that H' is 2-connected.

Assume $s = t = 0$. Since $c_0d_0 \neq x_0y_0$, we may assume $x_0y_0 \neq a_0b_0$ (the case $c_0d_0 \neq a_0b_0$ is the same). Suppose $c_0d_0 = a_0b_0$. By Theorem 1.2(b) we find a cycle C_0 in H_0 through a_0b_0 and x_0y_0 such that $|C_0| \geq \frac{1}{2}(|H_0|/d)^r + 3$. In $H' - b_0$ we find a path P' from x to a_0. Then $P_0 := (C_0 - a_0b_0) \cup P'$ gives the desired path. So assume $c_0d_0 \neq a_0b_0$. Let H_0' be obtained from H_0 by an H-transform at $\{x_0y_0, a_0b_0\}$, and let x', a' denote the new vertices with a' subdividing a_0b_0. By Theorem 1.2(b), there is a cycle C_0 in H_0' through c_0d_0 and $a'x'$ such that $|C_0| \geq \frac{1}{2}(|H_0|/d)^r + 3$. Let P' be a path in $H' - a_0b_0$ from x to the end, say v, of $C_0 - \{a', x'\}$ adjacent to a' and avoiding $\{a_0, b_0\} - \{v\}$. Then $P_0 := (C_0 - \{a', x'\}) \cup P'$ gives the desired path.

Now assume $s = 0 < t$. Then $x_0y_0 \neq a_0b_0$. By 2-connectivity of H', let P' be a path in $H' - a_0b_0$ from x to $z \in \{a_0, b_0\}$ through x_0y_0. By choosing appropriate notation, we may let $z = a_0$. Suppose $a_0b_0 = c_0d_0$. By Theorem 1.2(c), we find a cycle C_0 in H_0 through a_0b_0 such that $|C_0| \geq \frac{1}{2}|H_0|^r + 3$. Now $P_0 := (C_0 - a_0b_0) \cup P'$ gives the desired path. So we may assume $a_0b_0 \neq c_0d_0$, and let $c_0 \notin \{a_0, b_0\}$ (by choosing appropriate notation). If $d_0 \in \{a_0, b_0\}$, then let $z' \in \{a_0, b_0\} - \{d_0\}$, and apply Theorem 1.2(a) to find cycle C_0 in $(H_0 + z'c_0) - b_0$ through a_0c_0 such that $|C_0| \geq \frac{1}{2}(|H_0|/d)^r + 2$; then $P_0 := (C_0 - a_0c_0) \cup P'$ gives the desired path. Now assume $d_0 \notin \{a_0, b_0\}$. Let H_0' be obtained from H_0 by a T-transform at $\{a_0, c_0d_0\}$, and let c' denote the new vertex. We apply Theorem 1.2(a) to find a cycle C_0 in $(H_0' + b_0c') - b_0$ through a_0c' such that $|C_0| \geq \frac{1}{2}(|H_0|/d)^r + 2$. Now $P_0 := (C_0 - c') \cup P'$ gives the desired path.

Finally, we may assume $s \geq 1$. By exactly the same argument as for (1) of Case 2 in the proof of Lemma 4.2, with a_0b_0, c_0d_0, x_0y_0 playing the roles of f, pq, vw, respectively, we find a path P' through a_0b_0 in H' from x to $z \in \{c_0, d_0\} \cup \{x_0, y_0\}$ such that P' satisfies (b), (c), and (d). By Theorem 1.2(c), we find a cycle C_0 in H_0 through a_0b_0 such that $|C_0| \geq \frac{1}{2}|H_0|^r + 3$. Now $P_0 := (C_0 - a_0b_0) \cup (P' - a_0b_0)$ gives the desired path.

Suppose $x_0y_0 \in E(P_0)$. Without loss of generality, assume $z = c_0$. By Lemma 3.6(ii) there is a path P_1 in $\mathcal{L} - d_0$ from c_0 to some $y' \in N(y) \cap V(L_\ell)$ and containing no separating edge of $\mathcal{L}$ such that $|E(P_1)| \geq \frac{1}{2}(\sum\{(|A(L_i)|/d)^r : L_i \in B_1(\mathcal{L})\}) + (\sum\{\max\{1, |A(L_i)| - 2\} : L_i \in B_2(\mathcal{L})\}) + 1$. By Lemma 3.5, there is a path P_2 from x_0 to y_0 in $\mathcal{M}$ such that $|E(P_2)| \geq \frac{1}{2}((d-1)\sigma(\mathcal{M})/d)^r + 2$. Let C^* be the cycle obtained from $(P_0 \cup P_1) + \{y, yy', yx\}$ by replacing x_0y_0 with P_2. Then, as in Case 1 (with $\sigma(\mathcal{L})$ playing the role of n^*), by Lemma 3.1, and since $\sigma(\mathcal{L}) \geq \sigma(\mathcal{M})$,

we have

$$\begin{aligned}|C^*| &\geq |E(P_0)| + |E(P_1)| + |E(P_2)| + 1\\ &> \frac{1}{2}[(2+\sigma(\mathcal{L}))^r + ((d-1)\sigma(\mathcal{M})/d)^r] + 4\\ &> \frac{1}{2}[(b-1)(d-1)\sigma(\mathcal{M})/d]^r + 3\\ &> \frac{1}{2}n^r + 3 \quad \text{(by (5))}.\end{aligned}$$

Now assume $c_0d_0 \in E(P_0)$. Without loss of generality, assume $z = x_0$. By Lemma 3.6(ii), there is a path P_1 from x_0 to some $y' \in N(y) \cap V(M_m)$ in $\mathcal{M} - y_0$ such that $|E(P_1)| \geq \frac{1}{2}(\sum\{(|A(M_i)|/d)^r : M_i \in B_1(\mathcal{M})\}) + (\sum\{\max\{1, |A(M_i)| - 2\} : M_i \in B_2(\mathcal{M})\}) + 1$. By Lemma 3.5, there is a path P_2 from c_0 to d_0 in $\mathcal{L}$ such that $|E(P_2)| \geq \frac{1}{2}(\frac{(d-1)\sigma(\mathcal{L})}{d})^r + 2$. Let C^* be the cycle obtained from $(P_0 \cup P_1) + \{y, yy', yx\}$ by replacing c_0d_0 with P_2. Then as in Case 1 and by Lemma 3.1,

$$\begin{aligned}|C^*| &\geq |E(P_0)| + |E(P_1)| + |E(P_2)| + 1\\ &\geq \frac{1}{2}[(2+\sigma(\mathcal{M}))^r + ((d-1)\sigma(\mathcal{L})/d)^r] + 4.\end{aligned}$$

If $(d-1)\sigma(\mathcal{L})/d \geq 2 + \sigma(\mathcal{M})$, then by Lemma 3.1 and by (5),

$$|C^*| > \frac{1}{2}((b-1)\sigma(\mathcal{M}))^r + 4 > \frac{1}{2}(4d\sigma(\mathcal{M}))^r + 3 > \frac{1}{2}n^r + 3.$$

Now assume $(d-1)\sigma(\mathcal{L})/d \leq 2 + \sigma(\mathcal{M})$. Then by Lemma 3.1 and (5) and because $\sigma(\mathcal{L}) \geq \sigma(\mathcal{M})$,

$$|C^*| > \frac{1}{2}((b-1)(d-1)\sigma(\mathcal{L})/d)^r + 4 > \frac{1}{2}(4(d-1)\sigma(\mathcal{M}))^r + 3 > \frac{1}{2}n^r + 3.$$

As before, the desired cycle C can be obtained by modifying C^*.

Case 3. For every choice of $\mathcal{M}$ with $\sigma(\mathcal{M}) \geq \frac{n}{4(d-2)}$, we have $x \in \{c_0, d_0\} \cap \{x_0, y_0\}$ or $\{c_0, d_0\} = \{x_0, y_0\}$.

Let $\mathcal{M}_i$, $1 \leq i \leq k$, denote the $\mathcal{HL}$-legs with $\sigma(\mathcal{M}_i) \geq \frac{n}{4(d-2)}$. Since $\sum\{\sigma(\mathcal{M}) : \mathcal{M}$ is an $\mathcal{HL}$-leg as in Case 1 or Case 2$\} \leq \frac{(d-2-k)n}{4(d-2)}$ and because $n > (4d+1)^2$, it follows from (3) and (4) that

$$\sum_{i=1}^{k} \sigma(\mathcal{M}_i) \geq (n-1) - \frac{n-1}{4} - \frac{n-1}{4} - \frac{(d-2-k)n}{4(d-2)} - 2d > \frac{n}{4}.$$

Let G_i denote the graph obtained from G by deleting all components of $(G-y) - V(\mathcal{M}_i \cap (\mathcal{H} \cup \mathcal{L}))$ not containing any vertex of $\mathcal{M}_i$. Let $z \in \{c_0, d_0\}$ such that $z = x$ if $x \in \{c_0, d_0\}$. Since we are in Case 3, $z \in V(\mathcal{M}_i)$ for $1 \leq i \leq k$. Let t_i be the number of neighbors of z in G_i different from y and not in $V(\mathcal{M}_i \cap (\mathcal{H} \cup \mathcal{L}))$. Then $t_i \geq 1$. We claim that $\sum_{i=1} t_i \leq d-1$. This is clear when $z = x$ because yx is an edge of G. Now suppose $z \neq x$. Then $\{c_0, d_0\} \subseteq V(\mathcal{M}_i)$ for all $1 \leq i \leq k$. Since z is incident with edges in both $\mathcal{H} - c_0d_0$ and $\mathcal{L} - c_0d_0$, we have $\sum_{i=1}^{k} t_i \leq d-1$.

Let $1 \leq s \leq k$ such that $\frac{|G_s|}{t_s}$ is maximum. Then $\frac{|G_s|}{t_s} \geq \frac{n}{4(d-1)}$. This follows from the following result (which can be proved by induction on k): If $\alpha_1 + \cdots + \alpha_k \geq \alpha$ and $t_1 + \cdots + t_k = m$, then $\max\{\frac{\alpha_i}{t_i} : 1 \leq i \leq k\} \geq \frac{\alpha}{m}$.

For convenience, let $\{x_s, y_s\} = V(\mathcal{M}_s \cap (\mathcal{H} \cup \mathcal{L}))$, and assume, without loss of generality, $z = x_s = c_0$. Note that $G_s^* := G_s + \{yx_s, yy_s, x_sy_s\}$ is 3-connected, $\Delta(G_s^*) \le d+1$, and any vertex of degree $d+1$ must be incident with x_sy or x_sy_s. By Theorem 1.2(a), there is a path Q_2 from y_s to y in $G_s^* - x_s$ such that

$$|E(Q_2)| \ge \frac{1}{2}\left(\frac{(d-1)|G_s|}{dt_s}\right)^r + 1 \ge \frac{1}{2}\left(\frac{n}{4d}\right)^r + 1.$$

Suppose $y_s \in V(\mathcal{H})$. By 2-connectivity of $\mathcal{H}$, there is a path Q_0 from x to y_s in $\mathcal{H}$ through c_0d_0. By Lemma 3.5, there is a path Q_1 from c_0 to d_0 in $\mathcal{L}$ such that $|E(Q_1)| \ge \frac{1}{2}(\frac{(d-1)\sigma(\mathcal{L})}{d})^r + 2$. Let $C^* := ((Q_0 - c_0d_0) \cup Q_1 \cup Q_2) + yx$. Then

$$|C^*| \ge |E(Q_1)| + |E(Q_2)| \ge \frac{1}{2}\left[\left(\frac{(d-1)\sigma(\mathcal{L})}{d}\right)^r + \left(\frac{n}{4d}\right)^r\right] + 3.$$

If $\frac{(d-1)\sigma(\mathcal{L})}{d} \ge \frac{n}{4d}$, then by Lemma 3.1 and since $b \ge 4d+1$,

$$|C^*| \ge \frac{1}{2}\left(\frac{(b-1)n}{4d}\right)^r + 3 \ge \frac{1}{2}n^r + 3.$$

Now assume $\frac{(d-1)\sigma(\mathcal{L})}{d} \le \frac{n}{4d}$. By Lemma 3.1 and since $\sigma(\mathcal{L}) \ge \sigma(\mathcal{M}) > \frac{n}{4(d-2)}$ (by (5)),

$$|C^*| \ge \frac{1}{2}\left[\frac{(b-1)(d-1)\sigma(\mathcal{L})}{d}\right]^r + 3 > \frac{1}{2}n^r + 3.$$

As before, the desired cycle C can be obtained by modifying C^*.

Thus, we may assume $y_s \notin V(\mathcal{H})$. Then $z = x$ and $y_s \in V(L_t)$ for some $1 \le t < \ell$ ($t \ne \ell$ by the choice of $\mathcal{L}$). Let $n^* := \sum_{i=t+1}^{\ell} |A(L_i)|$. Note that $n^* \le \sigma(L_{t+1} \dots L_\ell)$. By our choice of $\mathcal{L}$, $n^* \ge \sigma(\mathcal{M}) - 2$. By 2-connectivity, let Q_0 be a path from x to y_s through c_td_t in $L_1 \dots L_t$. Note that $|E(Q_0)| \ge 2$. By Lemma 3.5 there is a path Q_1 from c_t to d_t in $L_{t+1} \dots L_\ell$ such that $|E(Q_1)| \ge \frac{1}{2}(\frac{(d-1)n^*}{d})^r + 1$. Let $C^* := ((Q_0 - c_td_t) \cup Q_1 \cup Q_2) + yx$. Then

$$|C^*| \ge |E(Q_1)| + |E(Q_2)| + 2 \ge \frac{1}{2}\left[\left(\frac{(d-1)n^*}{d}\right)^r + 2 + \left(\frac{n}{4d}\right)^r\right] + 3.$$

If $\frac{(d-1)n^*}{d} \ge \frac{n}{4d}$, then by Lemma 3.1 and since $b \ge 4d+1$,

$$|C^*| \ge \frac{1}{2}\left(\frac{(b-1)n}{4d}\right)^r + 3 \ge \frac{1}{2}n^r + 3.$$

Now assume $\frac{(d-1)n^*}{d} \le \frac{n}{4d}$. Then by Lemma 3.1 and since $n^* \ge \sigma(\mathcal{M}) - 2 > \frac{n}{4(d-1)} - 2$ (by (5)),

$$|C^*| > \frac{1}{2}\left(\frac{(b-1)(d-1)n^*}{d} + 2(b-1)\right)^r + 3 > \frac{1}{2}[4(d-1)n^* + 2(b-1)]^r + 3 > \frac{1}{2}n^r + 3.$$

Again, the desired cycle C can be obtained by modifying C^*. □

6. Conclusions. We now complete the proof of Theorem 1.2.

Proof of Theorem 1.2. Let n, d, r, G be given as in Theorem 1.2. We apply induction on n. When $n = 5$, G is isomorphic to one of the following three graphs: K_5, K_5 minus an edge, or the wheel on five vertices. In each case, we can verify that Theorem 1.2 holds. So assume that $n \geq 6$ and Theorem 1.2 holds for all 3-connected graphs with at most $n - 1$ vertices. Then Theorem 1.2(a) holds by Lemma 4.1, Theorem 1.2(b) holds by Lemma 4.2, and Theorem 1.2(c) holds by Lemma 5.1. This completes the proof of Theorem 1.2. □

Our proof of Theorem 1.2 implies a polynomial time algorithm which, given a 3-connected n-vertex graph, finds a cycle of length $\frac{1}{2}n^r + 3$. When combined with the next two results [8], our proof implies a cubic algorithm.

LEMMA 6.1. *Let G be a k-connected graph where k is a positive integer. Then G contains a k-connected spanning subgraph with $O(V)$ edges; such a subgraph can be found in $O(E)$ time.*

LEMMA 6.2. *Let G be a 2-connected graph and let $e, f \in E(G)$. Then there is a cycle through e and f in G, and such a cycle can be found in $O(V)$ time.*

Lemma 6.2 is actually an easy consequence of a result in [8] which states that, in a 2-connected graph G, one can find, in $O(V)$ time, two disjoint paths linking two given vertices. Our algorithm is similar to that in [3]. Therefore, we give only an outline and omit complexity analysis.

ALGORITHM. Let G be a 3-connected graph with $\Delta(G) \leq d$, and assume $|G| \geq 5$. The following procedure finds a cycle C in G with $|C| \geq \frac{1}{2}|G|^r + 3$.

1. **Preprocessing.** Replace G with a 3-connected spanning subgraph of G with $O(|G|)$ edges.
2. We either find the desired cycle C, or we reduce the problem to Theorem 1.2 for some 3-connected graphs G_i, for which $|G_i| < |G|$ and each G_i contains a vertex which does not belong to any other G_i.
3. Replace each G_i with a 3-connected spanning subgraph of G_i with $O(|G_i|)$ edges.
4. Apply Lemma 4.1 to those G_i for which Theorem 1.2(a) needs to be applied. Apply Lemma 4.2 to those G_i for which Theorem 1.2(b) needs to be applied. Apply Lemma 5.1 to those G_i for which Theorem 1.2(c) needs to be applied.
5. Repeat steps 3 and 4 for new 3-connected graphs.
6. In the final output, replace all virtual edges by appropriate paths in G to complete the desired cycle C.

FAIRNESS MEASURES FOR RESOURCE ALLOCATION*

AMIT KUMAR† AND JON KLEINBERG‡

Abstract. In many optimization problems, one seeks to allocate a limited set of resources to a set of individuals with demands. Thus, such allocations can naturally be viewed as vectors, with one coordinate representing each individual. Motivated by work in network routing and bandwidth assignment, we consider the problem of producing solutions that simultaneously approximate *all* feasible allocations in a coordinate-wise sense. This is a very strong type of "global" approximation guarantee, and we explore its consequences in a wide range of discrete optimization problems, including facility location, scheduling, and bandwidth assignment in networks. A fundamental issue—one not encountered in the traditional design of approximation algorithms—is that good approximations in this global sense need not exist for every problem instance; there is no a priori reason why there should be an allocation that simultaneously approximates all others. As a result, the existential questions concerning such good allocations lead to a new perspective on a number of fundamental problems in resource allocation, and on the structure of their feasible solutions.

Key words. fairness, approximation algorithms, scheduling, facility location, bandwidth allocation

DOI. 10.1137/S0097539703434966

1. Introduction.

Fair allocations. In many optimization problems, one seeks to allocate a limited set of resources to a set of individuals with demands. For example, given n users of a network, each seeking to transmit data between some pair of nodes, we must decide how to route these connection requests and allocate a portion of the available bandwidth to each. Much work on exact and approximate algorithms for such resource allocation problems has sought allocations that optimize a particular aggregate figure of merit. In the case of routing connections, for example, we could seek a solution that maximizes the minimum amount of bandwidth allocated to any request, or the total bandwidth allocated to all requests.

But these types of problems genuinely involve n distinct objectives—the demands of each individual—and a rich set of issues emerges when we adopt this perspective, treating the feasible solutions as vectors with a separate coordinate to represent the allocation to each individual. In the networking literature, this approach underlies the notion of *max-min fairness* [1, 15, 16], a widely used mechanism which produces an allocation for a fixed set of routes that is *lexicographically maximum*: the minimum bandwidth assigned to any connection is maximized; subject to this, the minimum bandwidth assigned to any of the remaining connections is maximized; and so forth.

Such a vector is often called the *max-min fair vector*. The same notion was formulated in the context of network flow problems by Megiddo [21].

There are cases in which it is computationally intractable to determine the max-min fair vector of allocations. In such settings, Kleinberg, Rabani, and Tardos [17] proposed the notion of a *coordinate-wise approximation*: We say that a vector X is a coordinate-wise c-approximation to a vector X' if for each j, the jth largest coordinate of X is at least $1/c$ times the values of the jth largest coordinate of X'. One can then look for efficiently computable vectors X that form good approximations in this sense to the max-min fair vector.

Recently, Goel, Meyerson, and Plotkin [9] developed algorithms for on-line path selection and bandwidth allocation satisfying a stronger notion of fairness. They were motivated by the following problem: Given a set of requests in a network, we would like to allocate bandwidth to them so that the allocation vector is max-min fair and the total throughput (i.e., the sum of the values in the vector) is maximized. But it is easy to construct examples showing that a max-min fair solution can have low total throughput and, conversely, that a solution maximizing the total throughput can be quite far from any max-min fair solution.

One way to get around this problem is to take the average of the max-min fair allocation and the maximum total throughput allocation. But examples in [9] show that even such an allocation vector may not be good in terms of fairness. This led them to define a stronger notion of fairness: Compute an allocation vector X that is a coordinate-wise c-approximation to *every* allocation vector. Such a vector satisfies the following natural and strong type of guarantee: For any value of m, if there is any allocation in which m users each get bandwidth at least b, then at least m users get bandwidth at least b/c under allocation X. We will therefore refer to X as a *global c-approximation* for this instance.

A simple example from [9] shows that the max-min fair vector does not perform well under this measure of quality. Suppose our network is a single path P; for an arbitrary number k, we have k "long" requests that need to use all the links of P, and we have k^2 "short" requests, each of which needs to use only a distinct edge of P. We wish to assign a bandwidth value to each connection in such a way that the sum of the values assigned to any set of connections passing through a common edge is at most 1. Then the max-min fair vector X^* assigns bandwidth $1/(k+1)$ to each request, while the vector X_0 that maximizes the sum of all values assigns 1 unit to each short connection and 0 units to each long connection. Note that X^* is only a coordinate-wise $(k+1)$-approximation to X_0, while there is no c for which X_0 is a coordinate-wise c-approximation to X^*. However, as we will see later, there is a vector X for this instance which is a coordinate-wise $O(\log k)$-approximation to *every* feasible vector of bandwidths; in other words, it exhibits the following natural and strong type of guarantee: For any value of m, if there is any allocation in which m users each get bandwidth at least b, then at least m users get bandwidth at least $b/O(\log k)$ under allocation X. We will therefore refer to X as a *global $O(\log k)$-approximation* for this instance.

The present work. In this work, we develop algorithms that produce allocations with this stronger type of guarantee: global approximation to all possible allocations. We consider a wide range of problems that can be cast in the framework of resource allocation, with an emphasis on three particular domains.

(i) *Bandwidth allocation.* We consider a version of the setting discussed above, in which there are n given paths in a network, and we must assign bandwidth to each one in a way that respects capacity constraints. Such an assignment

induces an *allocation vector* of length n, whose ith coordinate is the amount of bandwidth assigned to path i.

(ii) *Scheduling.* Given a set of n jobs that need to be processed, a schedule for these jobs induces a *completion time vector*, whose ith coordinate is the completion time of job i. Using the above notions, we can compare different completion time vectors in a coordinate-wise sense.

(iii) *Facility location.* Given a set of n demand points in a metric space, opening k facilities to serve these points induces a *distance vector* of length n: The ith coordinate is the distance from the ith demand point to its nearest facility. Again, we can compare the distance vectors induced by different sets of k facilities, so as to find the "fairest" solution.

What we find particularly interesting is that the notion of approximation actually plays a fundamentally different role in this type of allocation problem than it does in standard approximation algorithms for NP-complete problems. In the traditional design of approximation algorithms, the existence of an optimum (or of optima) is not in question; rather, we lack the computational power to find these optima. The definition of global approximation, on the other hand, comes with the following crucial point: There is no a priori guarantee that a good global approximation exists for a particular instance of a problem. Indeed, global 1-approximations—allocations that are as good as every allocation in every coordinate of a sorted order—turn out to be quite rare and often indicate something striking in the structure of the instance.

Thus, our study of this notion has two related components: an existential aspect, in which we try to determine whether good global approximations exist for all instances of a particular problem, and an algorithmic aspect, in which we look for efficient ways to compute global approximations. Each is important for our understanding of this issue, existential results illustrating the kinds of fair allocations that are achievable, even when we do not yet know of corresponding efficient algorithms that produce them.

Formulating the problem. We now introduce some precise notation for expressing the basic questions and results. All three types of problems above have the property that a solution to the problem induces a vector of length n; thus, for each instance $\mathcal{I}$ of such a problem, we have a set $V(\mathcal{I})$ consisting of all vectors that are induced by some feasible solution to the instance. Now, for a vector $X \in V(\mathcal{I})$, we define $\overrightarrow{X}$ to be the vector in which the coordinates of X have been reordered so that they are in nondecreasing order, and we define $\overleftarrow{X}$ to be the vector in which the coordinates of X have been reordered so that they are in nonincreasing order. For example, if $X = \{4, 1, 5, 10, 3\}$, then $\overrightarrow{X} = \{1, 3, 4, 5, 10\}$, $\overleftarrow{X} = \{10, 5, 4, 3, 1\}$. For two vectors $X, Y \in V(\mathcal{I})$, we write $X \prec_c Y$ if $X_i \leq Y_i$ for all i. Note that for purposes of coordinate-wise comparison, we have $\overrightarrow{X} \prec_c \overrightarrow{Y}$ if and only if $\overleftarrow{X} \prec_c \overleftarrow{Y}$—it clearly does not matter for the comparison whether we write the small values at the left or the right. Note an important fact: Often the coordinates of vectors in $V(\mathcal{I})$ correspond to individual users in the problem instance (e.g., in the bandwidth allocation problem, each coordinate may correspond to a request); when we compare vectors $\overrightarrow{X}$ and $\overrightarrow{Y}$ (or $\overleftarrow{X}$ and $\overleftarrow{Y}$), we are not comparing the allocations in the two solutions to the same user. But such a comparison makes sense because according to our notion of fairness we would like to compare, for example, the allocation to the kth least favored users in the two solutions, respectively.

As is common in discussing approximation, our terminology will be slightly different depending on whether we are discussing a minimization problem or a maximization problem (note that both arise in our list of problems above). For an allocation vec-

tor X in a minimization problem, we define $c(X)$ to be the infimum of α such that $\overrightarrow{X} \prec_c \alpha \overrightarrow{Y}$ for all $Y \in V(\mathcal{I})$. For an allocation vector X in a maximization problem, we define $c(X)$ to be the infimum of α such that $\overrightarrow{Y} \prec_c \alpha \overrightarrow{X}$ for all $Y \in V(\mathcal{I})$. In both cases, this can be informally viewed as the *global approximation ratio of* X: It is the smallest α for which $\overrightarrow{X}$ is an α-approximation, in the natural coordinate-wise sense, to every vector $Y \in V(\mathcal{I})$. The best global approximation ratio achievable on the instance $\mathcal{I}$ is then defined as

$$c^*(\mathcal{I}) = \inf_{X \in V(\mathcal{I})} c(X).$$

For several types of problems, we will find that good global approximations do not necessarily exist, but in many of these cases there will always exist solutions satisfying a weaker global guarantee, in which we compare the *prefix sums* of one allocation to the prefix sums of other allocations [17]. Thus, for a vector $X \in V(\mathcal{I})$, we define $\sigma(X)$ to be the vector whose ith coordinate is $\sum_{j \le i} X_j$. We say that $X \prec_s Y$ if $\sigma(X) \prec_c \sigma(Y)$. Now for a minimization (resp., maximization) problem, we define $s(X)$ to be the infimum of α such that $\overleftarrow{X} \prec_s \alpha \overleftarrow{Y}$ (resp., $\overrightarrow{Y} \prec_s \alpha \overrightarrow{X}$) for all $Y \in V(\mathcal{I})$. In this case, we say that X is a *global* α*-approximation under prefix sums*. In a bandwidth allocation problem, for example, we can view such a vector X as conveying the following guarantee: For any m, if at least m users receive an *average bandwidth* of b in X, then at least m users receive an average allocation of at most αb in any allocation. Note, crucially, that in a minimization (resp., maximization) problem, we begin computing prefix sums with the largest (resp., smallest) coordinates. Finally, for an instance $\mathcal{I}$, we define the best possible global approximation ratio under prefix sums as

$$s^*(\mathcal{I}) = \inf_{X \in V(\mathcal{I})} s(X).$$

Note that since $s(X) \le c(X)$ for any vector X, we have $s^*(\mathcal{I}) \le c^*(\mathcal{I})$ for any instance $\mathcal{I}$. The notion of s^* as an approximation ratio has also been used by Bhargava, Goel, and Meyerson [2] and Goel, Meyerson, and Plotkin [10], where they denote this by *approximate majorization*.

Sometimes we will have an instance $\mathcal{I}$ and want to evaluate the quality of an allocation $X \notin V(\mathcal{I})$. Thus, we allow the definitions of $c(X)$ and $s(X)$, exactly as written above, to apply to vectors $X \notin V(\mathcal{I})$; there is no difficulty in doing this, and the meaning will be clear from the context.

An illustrative example. Before discussing our results, we consider a very simple example to illustrate how the optimal allocations can differ qualitatively under the c^* and s^* measures. Suppose we have n users of a network, each trying to transmit data across a single shared link of unit capacity. (Thus the underlying network consists of two nodes joined by a single edge.)

First, we claim that the bandwidth allocation vector X in which each coordinate is equal to $1/n$ satisfies $s(X) = 1$. Indeed, in any other vector Y, and for any $j \le n$, the j smallest coordinates of Y must add up to at most j/n, while in X they add up to exactly j/n.

However, the uniform allocation vector X has a very large global approximation ratio under coordinate-wise comparison; specifically, $c(X) = n$. To see this, consider the vector Y_1 in which the first coordinate is 1 and all others are 0. A much better global approximation ratio is achieved by the vector X', whose jth coordinate is equal

to $1/jH_n$, where $H_n = \sum_{i=1}^{n} 1/i$. We claim that $c(X') = H_n$; for in any other vector Y, the jth largest coordinate is at most $1/j$. In fact, $c^*(\mathcal{I}) = H_n$ for this simple instance $\mathcal{I}$: Any vector Y must have some coordinate, say the jth largest, that is at most the value of corresponding coordinate in X', and hence this coordinate is H_n times smaller than the jth largest coordinate of the vector assigning $1/j$ to j of the coordinates, and 0 to all others.

In some sense, of course, the optimal allocation X under the s^* measure has a more intuitive meaning—equal division of resources among all individuals—than the optimal allocation X' under the c^* measure. However, it is interesting that the allocation X' also corresponds to a well-studied distribution of wealth: It is an instance of the *Pareto distribution* [22], one of the simplest types of allocations to follow an inverse power law. This connection can also be justified at an intuitive level. Pareto distribution basically states that a larger portion of the wealth in a society is owned by a smaller percentage of people in the same society. The allocation X' must also follow a similar principle—there are allocations which allocate all the resources to a few coordinates, but X' has to be close to such solutions under the c^* measure.

2. Overview of results.

Bandwidth allocation. We consider the problem that underlies the Hayden–Jaffe model of *max-min fairness* [1, 15, 16]. We are given a graph $G = (V, E)$ and paths $P_1, \ldots, P_n$ in this graph, representing users transmitting data. We must assign a *rate* x_i to each path P_i so that the following *capacity condition* is satisfied: If $P_{i_1}, \ldots, P_{i_t}$ all pass through a common edge, then $\sum_{j=1}^{t} x_{i_t} \leq 1$. Thus, a solution to an instance of this problem is a vector X of rates. We will refer to this problem as the *bandwidth allocation problem.* Note that our capacity condition implies that all links have the same capacity (set to 1); we can obtain bounds for the more general case where edges have different capacities but do not go into the details here.

For an instance $\mathcal{I}$, let U denote the *congestion* of the set of paths: the maximum number of paths that pass through any single edge. Note that $U \leq n$. Although Goel, Meyerson, and Plotkin [9] considered a problem in which both the paths and the rates had to be chosen, their on-line algorithm can be applied to this setting with fixed paths as well; it shows that $c^*(\mathcal{I}) = (\log^2 |V| \log U)$ for every instance $\mathcal{I}$.

Here, we are not restricted to using on-line algorithms. Nevertheless, there are instances where a constant-factor global approximation does not exist, even in the sense of prefix sums. We can show the following (we omit the details in this version):

- For arbitrarily large U, there exist instances $\mathcal{I}$ of the bandwidth allocation problem with congestion U for which $s^*(\mathcal{I}) = \Omega(\frac{\log U}{\log \log U})$.

Since $c^*(\mathcal{I}) \geq s^*(\mathcal{I})$ for every instance, this is a lower bound for c^* as well.

However, we can produce upper bounds that nearly match this lower bound. Specifically,

- $s^*(\mathcal{I}) \leq 2\lceil \log U \rceil + 2$ for every instance $\mathcal{I}$ of the bandwidth allocation problem.

We can produce a vector of rates X achieving this bound via a polynomial-time algorithm. More strongly, we can show that the same bound holds for the c^* measure:

- $c^*(\mathcal{I}) \leq 2\lceil \log U \rceil + 2$ for every instance $\mathcal{I}$ of the bandwidth allocation problem.

Here, however, we do not have an accompanying polynomial-time algorithm.

One can obtain strong bounds on s^* for certain related problems. For the problem of single-source fractional flow to each of n sinks—where we consider the vector of flow values to each sink—Megiddo showed that there is a maximum flow that induces the max-min fair vector of flows to the sinks [21]. By adapting some of the analysis from his proof of this, one can in fact show that $s^*(\mathcal{I}) = 1$ for all instances of this problem.

For the uniform load balancing problem considered by Kleinberg, Rabani, and Tardos, one can extend the analysis of [17] to show that $s^*(\mathcal{I}) = 1$ for all instances $\mathcal{I}$.

Scheduling problems. There are a large number of possible scheduling problems, but we can begin with some general ideas. First, in all the scheduling problems we will consider, a solution S induces a vector X_S of completion times. Two traditional objective functions are the *makespan*—the first coordinate in $\overleftarrow{X_S}$—and the sum of all completion times. A sequence of papers beginning with Stein and Wein [25] have shown that there always exist solutions to many types of scheduling problems that are good approximations to both objectives simultaneously. The algorithm of [25] does not provide a simultaneous approximation to all prefix sums of $\overleftarrow{X_S}$, however.

We follow the standard notation for scheduling problems proposed by Graham et al. [13]. Under this notation, a scheduling problem is usually denoted by three parameters $\alpha|\beta|\gamma$, where α designates the number of machines (and whether they are identical or different); β generally designates special conditions such as precedence constraints, release dates, or fixed processing times; and γ denotes an objective function such as the makespan or the sum of completion times. In our formulations, γ will be set equal to the symbol *all*, to denote the fact that we are considering the full vector of completion times, rather than an aggregate objective function.

There are approximation algorithms for scheduling that perform coordinate-by-coordinate comparison with respect to the completion time vector of the optimal schedule. If this analysis implicitly holds with respect to *any* schedule, rather than just the optimal one, then one is, in fact, giving a bound for c^*. The most basic example of this is Smith's rule for 1-processor scheduling, in which jobs are scheduled in nondecreasing order of processing time [24] $(1||all)$. The optimality proof for this schedule in fact shows that $c(X_S) = 1$. Also, for 1-processor scheduling with release dates $(1|r_j|all)$, the analysis of Phillips, Stein, and Wein [23] shows that their schedule S achieves $c(X_S) \leq 2$; for the case of $m > 1$ identical parallel machines with release dates $(P|r_j|all)$, their schedule achieves $c(X_S) \leq 3$.

Here we focus on problems with precedence constraints: We have a set J of n jobs, with a partial order $<_J$ representing dependencies, and must produce a schedule in which each job must end before the jobs that depend on it can begin. For many types of precedence-constrained scheduling problems, Hall et al. [14] produced a coordinate-wise $O(1)$-approximation to an optimal vector of *fractional completion times*, corresponding to a linear programming relaxation. However, their analysis does not, in fact, yield a global $O(1)$-approximation, for we show the following:

- For every number α, there exists an instance $\mathcal{I}$ of precedence-constrained 1-processor scheduling $(1|prec|all)$ in which the optimal vector of fractional completion times X in the linear programming formulation of Hall et al. does not satisfy $c(X) \leq \alpha$.

Thus, it is natural to ask whether there is a constant upper bound on $c^*(\mathcal{I})$ for all instances of this problem or its more general variants.

We show the following general result:

- $c^*(\mathcal{I}) \leq 4$ for all instances $\mathcal{I}$ of precedence-constrained scheduling with release dates on m identical parallel machines $(P|prec, r_j|all)$ for any $m \geq 1$.

Interestingly, our construction of the schedule S that achieves $c(X_S) \leq 4$ does not yield a polynomial-time algorithm even in the 1-processor case; in fact we show that it may be a difficult problem to obtain such a polynomial-time algorithm. Specifically, we show that any polynomial-time algorithm producing a schedule S that satisfies $c(X_S) = O(1)$ for instances of precedence-constrained 1-processor scheduling

$(1|prec|all)$ implies a polynomial-time constant-factor approximation algorithm for the *densest subgraph problem*: Given a graph G and a number k, find an induced k-node subgraph with the maximum possible number of edges. For this problem, the current best approximation ratios have the form $O(k^c)$ for a constant $0 < c < 1$ [18].

Interestingly enough, we show that there is a polynomial-time algorithm which produces a schedule S such that $s(X_S) = O(1)$ for any instance of $P|prec, r_j|all$.

We consider the special case of precedence-constrained scheduling in which there are no release dates and all jobs have unit processing times $(P|p_j = 1, prec|all)$. We show that

- $c^*(\mathcal{I}) = 1$ for every instance $\mathcal{I}$ of precedence-constrained 2-processor scheduling with unit-size jobs.

It is not difficult to show that there are instances with $m \geq 3$ machines for which $c^*(\mathcal{I}) > 1$, and a simple greedy algorithm can be used to establish the following:

- $c^*(\mathcal{I}) \leq 2$ for every instance $\mathcal{I}$ of precedence-constrained m-processor scheduling with unit jobs, for every m.

This dichotomy between $m = 2$ and $m \geq 3$ forms an interesting parallel to the fact that the 2-processor case is known to be polynomially solvable [5, 7], while the complexity of the m-processor case for fixed $m \geq 3$ is an open question.

As a final note, one can view traveling salesman problems within this perspective on scheduling, since tours yield vectors of *arrival times* at each city. In this context, the approximation of the minimum latency problem by k-trees [3, 11] shows that there is a constant upper bound on $c^*(\mathcal{I})$ for all instances of the traveling salesman problem.

Facility location problems. Finally, we consider facility location problems. Suppose we have a metric space M, a set $P = \{p_1, \ldots, p_n\}$ of *demand points* in M, and a set F of n' *candidate facility points*. The *k-center problem* and the *k-median problem* are two classical facility location problems. The first asks, Choose k facilities so that the maximum distance from any point to its nearest facility is minimized; the second asks, Choose k facilities so that the total distance from all points to their nearest facility is minimized.

Guided by the present framework, we say that opening facilities at locations $F' \subseteq F$ induces a *distance vector* $X_{F'}$ whose ith coordinate is $d(p_i, F')$, the distance from p_i to its nearest facility in F'. Thus, when we speak of a *k-facility instance* $\mathcal{I}$, we mean a metric space M, with sets P and F, and we will compare solutions to the set $V(\mathcal{I})$ of all vectors $X_{F'}$ such that $|F'| = k$. Now, the k-center problem seeks to minimize the first coordinate of $\overleftarrow{X_{F'}}$, while the k-median problem seeks to minimize the sum of all coordinates in $X_{F'}$. What can be said about global approximations for arbitrary k-facility instances?

First we consider the case $k = 1$. We show that

- $s^*(\mathcal{I}) \leq 4$ for every instance $\mathcal{I}$ of the 1-facility location problem.

The c^* measure is trickier. Consider an instance with a set P of five points in the plane—two at the ends of a very short line segment, and three at the corners of a moderately sized equilateral triangle, arbitrarily far away. If $F = P$, it is easy to see that such an instance can be constructed in which c^* is arbitrarily large. By extending this idea, we can show the following:

- For any number α, there are 1-facility instances $\mathcal{I}$ for which no set F' of fewer than $\log n$ facilities achieves $c(X_{F'}) \leq \alpha$.

At the same time, this lower bound is essentially tight:

- For every 1-facility instance $\mathcal{I}$, there is a set F' of at most $1 + \log n$ facilities for which $c(X_{F'}) \leq 3$.

Note that here we are comparing the distance vector $X_{F'}$, for a set F' of $\leq 1 + \log n$ facilities, to all possible distance vectors obtained by opening a *single* facility. Also, we note that our two upper bounds here are achieved by polynomial-time algorithms.

Now consider a larger value of k. If there were a constant bound on $s^*(\mathcal{I})$ for every k-facility instance $\mathcal{I}$, it would imply that in every instance there is a set of k facilities that provides a simultaneous constant-factor approximation for the k-center and k-median objective functions. But this is not true. Consider an instance with a set P of $2m + 1$ points in the plane: m are clustered in a small circle, m more are clustered in a nearby small circle, and one is very far away from all others. If $F = P$ and $k = 2$, then we see that any good solution for the k-median problem must put one facility in each circle, while any good solution for the k-center problem must put one facility near the far-away point.

However, we can prove the following upper bound:

- For every k-facility instance $\mathcal{I}$, there is a set F' of $O(k \log n + \varepsilon^{-1})$ facilities for which $s(X_{F'}) \leq 3 + \varepsilon$. Moreover, we can compute an F'' of this size in polynomial time for which $s(X_{F''})) \leq 9 + \varepsilon$.

We have a lower bound showing this is almost tight:

- For every α, there are k-facility instances where no set F' of fewer than $\Omega(k \frac{\log(n/k)}{\log \alpha})$ facilities can achieve $s(F') \leq \alpha$.

For the c^* measure, we can show that there are essentially no nontrivial upper bounds when $k > 1$:

- For every α, there are 2-facility instances for which no proper subset $F' \subseteq F$ can achieve $c(F') \leq \alpha$.

There has been work in discrete location theory on defining notions of "fairness" in facility location problems [6, 20]. Most of the measures to arise from this previous work are concerned with making the distance vector approximately uniform in some cases relative to a priori weights on the points, rather than optimizing the types of approximation measures we are considering here.

3. Bandwidth allocation. Recall that in our bandwidth allocation problem from section 1, we have a graph $G = (V, E)$ and a set $\mathcal{P}$ of paths $P_1, \ldots, P_n$ in this graph. We wish to assign a vector X of rates to these paths, respecting the (unit) capacities in the graph. For a set of paths $\mathcal{P}' \subseteq \mathcal{P}$, we use $\nu(\mathcal{P}')$ to denote their congestion; we write $U = \nu(\mathcal{P})$.

We first show the following theorem.

THEOREM 3.1. *$s^*(\mathcal{I}) \leq 2\lceil \log U \rceil + 2$ for every instance $\mathcal{I}$ of the bandwidth allocation problem. Further, given an instance $\mathcal{I}$, a solution X satisfying $s(X) \leq 2\lceil \log U \rceil + 2$ can be found in polynomial time.*

Proof. We describe an algorithm that constructs a vector X of rates so that $s(X) \leq 2\lceil \log U \rceil + 2$.

We call a set of paths $\mathcal{P}'$ a *block* if they all contain a common edge e; we call e a *blocking edge* of $\mathcal{P}'$. We divide our algorithm into $1 + \lceil \log U \rceil$ phases. We say that two blocks are *disjoint* if they do not contain a common path. In phase $i = 0, 1, \ldots, \lceil \log U \rceil$, we find a maximal collection of disjoint blocks, each of which has size greater than $\frac{U}{2^{i+1}}$. This can be easily done in a greedy manner—first find a block of size greater than $\frac{U}{2^{i+1}}$, delete all the paths in this block, and iterate this procedure as long as possible. For every path P in one of these blocks $\mathcal{P}'$ we allocate it a rate of $\frac{1}{|\mathcal{P}'|}$. We then delete all these paths but—at this point in the construction—do not reduce the capacity of any edges.

We observe that the following invariant is maintained by this algorithm: At the end of phase $i \leq \lceil \log U \rceil$, the overall congestion of the remaining paths is at most $\frac{U}{2^{i+1}}$. Thus after phase $1 + \lceil \log U \rceil$, all paths have been assigned a rate.

Let X_0 denote the resulting vector of rates. Although X_0 does not respect the capacities, it is useful to compare it to feasible rate vectors. Let $\mathcal{P}_1, \ldots, \mathcal{P}_r$ be the set of blocks found by the above algorithm in descending order of size. Consider any feasible rate vector Y. For any i, let $X_0|\mathcal{P}_i$ and $Y|\mathcal{P}_i$ denote the vectors X_0 and Y restricted to coordinates corresponding to paths in $\mathcal{P}_i$. We claim that $\overrightarrow{Y|\mathcal{P}_i} \prec_s \overrightarrow{X_0|\mathcal{P}_i}$. Indeed, the rates assigned by Y to paths in $\mathcal{P}_i$ must sum to at most one—since they all pass through the blocking edge e—and so the j smallest coordinates in $\overrightarrow{Y|\mathcal{P}_i}$ must sum to at most $j/|\mathcal{P}_i|$. X_0 assigns rates to the paths in $\mathcal{P}_i$ so that the sum of the j smallest coordinates is exactly $j/|\mathcal{P}_i|$.

Now, $\overrightarrow{X_0}$ consists of vectors $\overrightarrow{X_0|\mathcal{P}_1}, \overrightarrow{X_0|\mathcal{P}_2}, \ldots, \overrightarrow{X_0|\mathcal{P}_r}$ concatenated in this order. Consider the vector Y with its coordinates arranged in this same order. Each prefix sum of $\overrightarrow{X_0}$ is at least as large as the corresponding prefix sum of Y in this order, and if we now rearrange the coordinates of Y so that they are in ascending order, the prefix sums of Y cannot increase. Thus $\overrightarrow{Y} \prec_s \overrightarrow{X_0}$.

Now we claim that the rate vector X obtained by dividing each coordinate of X_0 by $2\lceil \log U \rceil + 2$ respects all the capacity conditions; this will complete the proof. Indeed, to prove this, we need only show that the total of all rates assigned to paths using edge e in a given phase i is at most 2. At the start of phase i, the congestion is at most $\frac{U}{2^i}$. Each set of paths $\mathcal{P}'$ which is selected in this phase has congestion at least $\frac{U}{2^{i+1}}$; thus, all paths that get assigned a rate in this phase get rate at most $\frac{2^{i+1}}{U}$. Hence at most 2 extra units of rate are assigned in this phase to all paths using e. □

Note that the procedure in the theorem above does not give an allocation X for which $c(X)$ is logarithmic. Indeed consider an instance consisting of a single edge and n paths using it. The procedure in Theorem 3.1 will allocate $1/n$ units of rate to each of the n paths—call this allocation X. Clearly, $c(X) = n$.

We now prove the following stronger statement. It, too, is based on a construction in which we allocate bandwidth according to an exponentially decaying sequence; however, for this construction, we do not know how to run each iteration efficiently, since it involves the solution of an independent set problem.

THEOREM 3.2. *$c^*(\mathcal{I}) \leq 2\lceil \log U \rceil + 2$ for every instance $\mathcal{I}$ of the bandwidth allocation problem.*

Proof. We give a procedure for assigning rates to paths. Initially, let $\mathcal{P}_0 = \mathcal{P}$. Let $\mathcal{Q}_0 \subseteq \mathcal{P}_0$ be a maximum cardinality subset of paths of congestion 1. Each path in $\mathcal{Q}_0$ is assigned a rate of 1, and we define $\mathcal{P}_1 = \mathcal{P}_0 \setminus \mathcal{Q}_0$. Now suppose we have a set of paths $\mathcal{P}_i$, $i \geq 1$. Define $\mathcal{Q}_i \subseteq \mathcal{P}_i$ to be a maximum cardinality subset of congestion at most 2^i. Each path in $\mathcal{Q}_i$ is assigned a rate of $\frac{1}{2^i}$, and we define $\mathcal{P}_{i+1} = \mathcal{P}_i \setminus \mathcal{Q}_i$. We define these sets of paths for all i, $0 \leq i \leq \lceil \log U \rceil$; it is clear that after the end of this process, every path gets assigned a rate. Let X^* denote the rate vector produced (note that it does not necessarily satisfy the capacity constraints) and let n_i denote $|\mathcal{Q}_i|$.

Let Y be any vector of rates that satisfies the capacity constraints. We claim that (1) $\overleftarrow{Y} \prec_c 2\overleftarrow{X^*}$.

To prove this, we fix an i, $0 \leq i \leq \log U$. Let $\mathcal{Q}'$ denote the set of paths which get rate at least $\frac{1}{2^i}$ in Y. Define $n' = |\mathcal{Q}'|$. Clearly, the congestion of $\mathcal{Q}'$ is at most 2^i. We claim that $n_0 + \cdots + n_i \geq n'$. Indeed, while selecting $\mathcal{Q}_i$, we must have considered the paths in $\mathcal{Q}' - (\mathcal{Q}_1 \cup \cdots \cup \mathcal{Q}_{i-1})$.

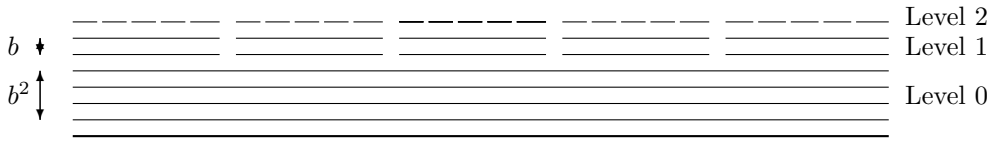

FIG. 1. *The instance when* $k = 2$.

Since the $(n_0 + \cdots + n_i)$th coordinate of $\overleftarrow{X^*}$ is 2^{-i}, it is at least as large as the $(n_0 + \cdots + n_i + 1)$st coordinate of $\overleftarrow{Y}$. Now consider a coordinate j. If $j \leq n_0$, then $\overleftarrow{X^*}_j \geq \overleftarrow{Y}_j$. Otherwise, there is some i so that $n_0 + n_1 + \cdots + n_i + 1 \leq j \leq n_0 + n_1 + \cdots + n_{i+1}$, and $\overleftarrow{X^*}_j = \frac{1}{2^{i+1}}$. But $\overleftarrow{Y}_j \leq \overleftarrow{Y}_{n_0+\cdots+n_i+1} \leq \overleftarrow{X^*}_{n_0+\cdots+n_i} = \frac{1}{2^i}$. Thus, $\overleftarrow{Y}_j \leq 2\overleftarrow{X^*}_j$; since this applies to an arbitrary coordinate j, we have $\overleftarrow{Y} \prec_c 2\overleftarrow{X^*}$.

We also claim the following:

(2) Given an edge e, the total rate assigned in X_0 to paths containing e is at most $1 + \lceil \log U \rceil$.

To see this, note that in each phase at most one additional unit of rate can be assigned to paths passing through a single edge e, and thus (2) follows.

Thus, if we define the rate vector X by dividing each coordinate of X_0 by $1 + \lceil \log U \rceil$, we obtain the theorem. □

We now show that the above result is almost optimal.

THEOREM 3.3. *For arbitrarily large U, there exist instances $\mathcal{I}$ of the bandwidth allocation problem with congestion U for which $s^*(\mathcal{I}) = \Omega(\frac{\log U}{\log \log U})$.*

Proof. The construction involves a number of parameters defined in terms of U; the relationships among these parameters will be specified as needed. We define an instance $\mathcal{I}$ as follows. Let k be a constant to be specified later in terms of U. We define constants $b = k + 1$, $d = (k + 1)^2$, and $a_i = d^{2i}$ for $i = 0, 1, \ldots, k$. The underlying graph G is a simple path on $n = a_k$ vertices. The set of paths $\mathcal{P}$ is partitioned into $k+1$ sets of paths, which we refer to as *level* 0 through *level* k. For each r, the paths in level r are grouped into a_r edge-disjoint *bundles* of b^{k-r} identical paths, each having length n/a_r; the union of these bundles covers the entire graph G. Each path in level $r + 1$ is entirely contained in some path in level r. Note that

$$U = b^k + b^{k-1} + \cdots + b + 1 = \frac{(k+1)^{k+1} - 1}{k},$$

and hence $k = \Theta(\frac{\log U}{\log \log U})$. For a schematic example of the construction (with smaller constants), see Figure 1.

Let X be an assignment of rates to paths. We define $\tilde{X}$ to be the vector obtained from X by arranging the coordinates as follows. The coordinates for paths in the same bundle occur contiguously in $\tilde{X}$, beginning with level 0, then all the bundles in level 1, then all the bundles in level 2, and so on. Moreover, the bundles in a fixed level r are arranged so that if bundle β occurs before bundle β', then the sum of the rates of paths in β is at most the sum of the rates of paths in β'.

We set $c = k/3$ and suppose that $s(X) \leq c$. First observe that $\sigma(\overrightarrow{X}) \prec_c \sigma(\overrightarrow{\tilde{X}})$. Indeed, the ith coordinate in $\overrightarrow{X}$ is the sum of the i lowest values in X, and so it must be smaller than the corresponding coordinate in $\overrightarrow{\tilde{X}}$. It follows that for any assignment Y of rates to paths in $\mathcal{P}$, $\sigma(\overrightarrow{Y}) \prec_c c\sigma(\tilde{X})$. Now consider $k + 1$ different assignments of rates to the paths. Y_0 assigns $(b^k + b^{k-1} + \cdots + 1)^{-1}$ to all paths. Similarly, Y_r,

for $0 < r \leq k$, assigns rate $(b^{k-r} + \cdots + 1)^{-1}$ to all paths in levels $r, r+1, \ldots, k$ and 0 to paths in levels $0, \ldots, r-1$.

The fact that $\sigma(\overrightarrow{Y}) \prec_c c\sigma(\tilde{X})$ for all vectors Y implies that the vector $\tilde{X}$ assigns each path in level 0 a rate of at least $c^{-1}(b^{k-r} + \cdots + 1)^{-1}$. Now consider the vector Y_r; let p_r denote the total number of paths in levels 0 through $r-1$, and define a constant $\ell_r = d^{2r-1}$. The coordinates of Y_r for the bundles in levels 0 to $r-1$ are 0. The sum of the next $\ell_r b^{k-r}$ coordinates in $\overrightarrow{Y_r}$ is equal to $\ell_r b^{k-r}(b^{k-r} + \cdots + 1)^{-1}$. Thus the sum of the first $p_r + \ell_r b^{k-r}$ coordinates in $\overrightarrow{Y_r}$ is $\ell_r b^{k-r}(b^{k-r} + \cdots + 1)^{-1}$. In $\tilde{X}$, the sum of the coordinates for paths at level j can be at most a_j, because the sum of the rates in any one bundle can be at most 1. So the sum of the first p_r coordinates in $\tilde{X}$ is at most $a_0 + a_1 + \cdots + a_{r-1}$. Therefore, the sum of the next ℓ_r bundles—each of which is from level r—must be at least

$$\frac{\ell_r b^{k-r}}{c(b^{k-r} + \cdots + 1)} - (a_0 + \cdots + a_{r-1}).$$

Hence one of these ℓ_r bundles must have the property that the sum of the rates assigned to paths in it in $\tilde{X}$ is at least

$$\frac{b^{k-r}}{c(b^{k-r} + \cdots + 1)} - \frac{a_0 + \cdots + a_{r-1}}{\ell_r}.$$

Now, the bundles in $\tilde{X}$ are arranged in ascending order of their total sums, and so we have the following fact: For at least $a_r - \ell_r$ bundles β in level r, the sum of the rates assigned to β in $\tilde{X}$ is at least

$$\frac{b^{k-r}}{c(b^{k-r} + \cdots + 1)} - \frac{a_0 + \cdots + a_{r-1}}{\ell_r}. \tag{1}$$

Call a bundle in level $r > 0$ *bad* if it does not satisfy the bound in (1); hence there are at most ℓ_r bad bundles in level r. The total number of edges covered by bad bundles of all levels is at most

$$\sum_{r=1}^{k} \frac{\ell_r a_k}{a_r} = \sum_{r=1}^{k} d^{2k-1} < d^{2k} = n,$$

and so there is at least one edge e of G that is not contained in any bad bundle.

Applying the capacity constraint to this edge e, we have

$$\begin{aligned}
1 &\geq \sum_{r=0}^{k} \left(\frac{b^{k-r}}{c(b^{k-r} + \cdots + 1)} - \frac{a_0 + \cdots + a_{r-1}}{\ell_r} \right) \\
&\geq \sum_{r=0}^{k} \left(\frac{b-1}{cb} - \frac{r a_{r-1}}{\ell_r} \right) = \sum_{r=0}^{k} \left(\frac{b-1}{cb} - \frac{r}{d} \right) \\
&\geq \frac{(k+1)(b-1)}{cb} - \frac{(k+1)^2}{d} \\
&\geq \frac{(k+1)k}{\frac{k}{3}(k+1)} - \frac{(k+1)^2}{(k+1)^2} = 3 - 1 = 2.
\end{aligned}$$

This contradiction completes the proof. □

We also consider global approximations for the problem of single-source fractional flow to n sinks, for which Megiddo showed that there is a maximum flow that is also lexicographically optimal. In fact, by adapting some of the analysis from his proof of this fact, one can show that $s^*(\mathcal{I}) = 1$ for all instances $\mathcal{I}$ of this problem. (We can also show that $c^*(\mathcal{I}) = O(\log n)$ for all instances of this problem, using an adaptation of the proof of Theorem 3.2.)

4. Scheduling. We first consider the problem of precedence-constrained scheduling, with release dates, on m identical parallel machines ($P|prec, r_j|all$). Thus, we are given a set of jobs $J = \{j_1, \ldots, j_n\}$ and a partial order $<_J$ on the jobs indicating precedence constraints. Job j_i has processing time p_i and release date r_i. We say that j_i "precedes" j_ℓ if $j_i <_J j_\ell$, and we say j_i is *minimal* if no job precedes it. For any subset $J' \subseteq J$, we can restrict the partial order to just the jobs in J'; we denote this by $<_{J'}$. We say that a set of jobs $K \subseteq J'$ is *independent* under $<_{J'}$ if there is no element in $J' \setminus K$ that precedes an element in K in the ordering $<_{J'}$.

As mentioned in the introduction, Hall et al. [14] considered many types of precedence-constrained scheduling problems. They produced a coordinate-wise $O(1)$-approximation to an optimal vector of *fractional completion times*, corresponding to a linear programming relaxation for these problems. However, we show that the linear programming formulation of Hall et al. [14] does not yield a global $O(1)$-approximation.

THEOREM 4.1. *For every number α, there exists an instance $\mathcal{I}$ of precedence-constrained 1-processor scheduling in which the optimal vector of fractional completion times X in the linear programming formulation of Hall et al. does not satisfy $c(X) \leq \alpha$.*

Proof. We choose a number β so that $\beta > \alpha^2$. We define an instance $\mathcal{I}$ with a set of $n = \beta + 2$ jobs $\{j_1, j_2, \ldots, j_n\}$. Job j_1 has processing requirement $p_1 = 1$, job j_2 has processing requirement $p_2 = \alpha$, and jobs $j_3, \ldots j_n$ each have processing requirement 0. The precedence constraints are simply the following: j_2 precedes j_i for every $i \geq 3$.

For any schedule S, let $X(S)$ denote its vector of completion times. Consider the schedule S that chooses the jobs in the order of their indices. We have $X(S) = (1, \alpha + 1, \alpha + 1, \ldots, \alpha + 1)$.

Now consider the linear programming formulation given by [14] for $\mathcal{I}$. It seeks a vector of completion times $(C_1, \ldots, C_n)$ so that $C_k \geq C_i + p_i$ when p_i precedes p_k, and

$$\sum_{j \in S} p_j C_j \geq \frac{1}{2}\left(p^2(S) + p(S)^2\right) \tag{2}$$

for every subset S of jobs. The objective is to minimize $\sum_i C_i$.

In our instance $\mathcal{I}$, the integer optimum for the objective value is $(\beta+1)\alpha+(\alpha+1)$; this is obtained by scheduling in the order $j_2, j_3, \ldots, j_n, j_1$. Thus, the optimum value of the linear program is at most this quantity.

Let $\tilde{C}$ denote an optimal solution to the linear program, represented as a vector of completion times. Note that the inequalities concerned with precedence constraints enforce $\tilde{C}_1 \geq 1$ and $\tilde{C}_i \geq \alpha$ for $i > 1$.

First we claim that $\tilde{C}_2 \leq \alpha + \frac{\alpha}{\beta}$. To see why this is so, suppose $\tilde{C}_2 > \alpha + \frac{\alpha}{\beta}$. We would then have $\tilde{C}_i > \alpha + \frac{\alpha}{\beta}$ for all $i > 2$, so the optimum value of the linear program would be greater than $(\beta+1)\alpha+\alpha+\frac{\alpha}{\beta}+1$, which is larger than the integer optimum.

(1) Initialize $J_0 \leftarrow J$ (J_0 denotes the jobs that haven't been processed yet and t denotes the current time).
(2) For $T = 1, 2, 4, \ldots$ do
  (i) Find a subset $J' \subseteq J_0$ such that all jobs in J' can be completely processed in the interval $[T, 2T)$, and $|J'|$ is maximum.
  (ii) Starting from time T schedule the jobs in J' such that they finish by time $2T$.
  (iii) $J_0 \leftarrow J_0 - J'$.

FIG. 2. *Algorithm that shows $c^* \leq 4$ for $P|prec, r_j$.*

Next we claim that $\tilde{C}_1 \geq \alpha$. We prove this by considering inequality (2) applied to the set $S = \{j_1, j_2\}$. We have $p(S) = 1 + \alpha$ and $p^2(S) = 1 + \alpha^2$. By our claim in the previous paragraph, we know that $\tilde{C}_2 \leq \alpha + \frac{\alpha}{\beta}$. Now suppose $\tilde{C}_1 < \alpha$. Then the left-hand side of (2) is at most $\alpha + \alpha^2 + \frac{\alpha^2}{\beta}$, but we have

$$\begin{aligned}\alpha + \alpha^2 + \frac{\alpha^2}{\beta} &< \alpha + \alpha^2 + 1 \\ &= \frac{1}{2}(1+\alpha)^2 + \frac{1}{2}(1+\alpha^2),\end{aligned}$$

which is a contradiction.

So in the solution $\tilde{C}$, the fractional completion time of each job is at least α. In the schedule S, on the other hand, there is a job with completion time 1. Thus $c(\tilde{C}) \geq \alpha$. □

THEOREM 4.2. *$c^*(\mathcal{I}) \leq 4$ for all instances $\mathcal{I}$ of precedence-constrained scheduling with release dates on m identical parallel machines for any $m \geq 1$.*

Proof. The scheduling algorithm is given in Figure 2. The For loop runs till J_0 becomes empty. The algorithm divides the time into exponentially growing intervals and tries to finish as many jobs as possible in each such interval. Let S denote the schedule it produces, and let X denote the vector of completion times of jobs under S. We write $\overrightarrow{X} = (C_1, C_2, \ldots, C_n)$. Let A_T denote the set J' chosen in iteration T of step (2)(ii). Let D_T denote the set J_0 at the beginning of this iteration.

Now consider some other schedule S' for this instance, let X' denote the vector of completion times of jobs under S', and write $\overrightarrow{X'} = (C'_1, C'_2, \ldots, C'_n)$. We focus on a particular coordinate k and let B' denote the first k jobs to finish under the schedule S'.

We wish to show that $C_k \leq 4C'_k$. Suppose $2^i \leq C'_k < 2^{i+1}$. Consider the iteration $T = 2^{i+1}$ of the For loop in Figure 2. At time T, all jobs in B' have been released. Further, all jobs in $B' - D_T$ can be completely processed in $[T, 2T)$ (because B' can be processed completely in $[0, T)$ in S'). So at least $|B'|$ jobs must finish by time $2T$ in S. But then $C_k \leq 2T \leq 4C'_k$, which is what we wanted to prove. □

We note that there exist instances $\mathcal{I}$ for which $c^*(\mathcal{I}) \geq 2$; finding the tightest upper bound is an open question. The construction in the proof of Theorem 4.2 does not yield a polynomial-time algorithm, since computing the set J' in step (2)(i) is an NP-hard problem. In fact, we can show that efficiently producing a schedule S satisfying $c(X_S) = O(1)$ for this problem would yield a greatly improved approximation algorithm for the *densest subgraph problem* described in the introduction: Given

a graph G and a number k, find an induced k-node subgraph with the maximum possible number of edges.

THEOREM 4.3. *Suppose there exists a polynomial-time algorithm $\mathcal{A}$ that, for any instance of precedence-constrained 1-processor scheduling $(1|prec|all)$, produces a schedule S satisfying $c(X_S) \leq \alpha$. Then there exists a randomized polynomial-time $8\alpha^2$-approximation algorithm for the densest subgraph problem.*

Proof. Suppose we are given an instance of the densest subgraph problem, specified by a graph $G = (V, E)$, with $|V| = n$, and a number $k \leq n$. We assume that $k \geq 2$ and that G contains at least $k/2$ edges; otherwise the instance is simple. We also assume for simplicity that α is an integer.

We construct the following instance $\mathcal{I}$ of $1|prec|all$. The set of jobs J will be partitioned into sets $J_V = \{j_v : v \in V\}$ and $J_E = \{j_e : e \in E\}$. Each job $j_v \in J_V$ has processing time 1, and each job $j_e \in J_E$ has processing time 0. The precedence constraints are as follows: If $e = (u, v)$, then j_u and j_v must precede j_e.

Using the algorithm $\mathcal{A}$, we construct a schedule S for the instance $\mathcal{I}$. Let X denote the set of jobs that finish by time αk. Let V' and E' denote the vertices and edges corresponding to jobs in X; note that since the endpoints of any edge in E' must belong to V', (V', E') is a subgraph of G. If $|V'| > k$, then, using a simple randomized algorithm, we can produce a set of vertices $V'' \subseteq V'$ so that $|V''| = k$ and the number of edges in the subgraph induced by V'' is at least

$$|E'| \cdot \frac{k(k-1)}{\alpha k(\alpha k - 1)} \geq \frac{|E'|}{4\alpha^2}.$$

Indeed, V'' is formed by picking k random vertices independently (and without replacement) from V. The probability that an edge $e \in E'$ has both endpoints in V'' is $\frac{k(k-1)}{|V'|(|V'|-1)}$. Using the fact $|V'| \leq \alpha k$ and linearity of expaction implies the bound mentioned above.

If the number of edges induced by V'' is less than $k/2$, then we replace V'' by a set of vertices inducing at least $k/2$ edges. We return V'' as the approximate solution to the instance of densest subgraph.

Now, consider an optimal solution to the densest subgraph instance; it consists of an induced subgraph (V^*, E^*) where $|V^*| = k$. We write $q = |E^*|$. Now, consider a schedule S' which first orders the jobs corresponding to V^* arbitrarily, followed by the jobs corresponding to E^*. In S', all $k + q$ of these jobs finish by time k; hence in our schedule S, at least $k + q$ jobs must finish by time αk. Since $|V'| \leq \alpha k$, it follows that $|E'| \geq q + k - \alpha k$.

If $q \leq 2\alpha k$, then our solution is a 4α-approximation, since it induces at least $k/2$ edges. Otherwise, $|E'| \geq q/2$; since our solution induces at least $|E'|/(4\alpha^2)$, it is an $8\alpha^2$-approximation. ∎

Surprisingly enough, we show that it is indeed possible to produce a schedule S in polynomial time such that $s(X_S) = O(1)$ for any instance of $P|prec, r_j|all$. We begin with an observation of Goel and Meyerson [8], which we prove for sake of completeness.

LEMMA 4.4. *Let $\mathcal{Y}$ be the set of feasible solutions to a linear program $\mathcal{P} = \{A \cdot Y \leq b\}$, where $Y \in \mathbf{R}^n$. We can find a vector $Y^* \in \mathcal{Y}$ in polynomial time such that $s(Y^*) = s^*(\mathcal{Y})$.*

Proof. We use the definition of s^* for minimization problems. We construct a vector $Z = (Z_1, \ldots, Z_n)$ such that Z_i will be the smallest value of $\sigma(\overleftarrow{Y})_i$ for any i.

Let us now show how to find Z_i. We add a variable z_i to the linear program $\mathcal{P}$. Further, for every subset $S \subseteq \{1, \ldots, n\}$, $|S| = i$, we add a constraint $z_i \geq \sum_{j \in S} Y_j$.

It is easy to see that minimizing z_i subject to these constraints gives us Z_i.

Now, suppose $\alpha = s^*(\mathcal{Y})$. Then, the vector Y^* can be found by adding the following constraints to $\mathcal{P}$: for every i, $1 \le i \le n$, and $S \subseteq \{1, \ldots, n\}$, where $|S| = i$, $\sum_j Y_j \le \alpha Z_i$. Now, treating α as a variable and minimizing its value gives us the vector Y^*. □

Hall et al. [14] gave a linear programming relaxation for $P|prec, r_j|\sum_j C_j$ for minimizing the sum of completion times. This linear program $\mathcal{P}$ had the completion time C_j of the jobs as variables. Note that here C_j denotes the completion time of job j. They showed the following nice fact about this linear program.

THEOREM 4.5 (see [14]). *Let $(C_1, \ldots, C_n)$ be a fractional solution to $\mathcal{P}$. Then, there exists a schedule S such that the completion time C'_j of job j in S is at most $2C_j$.*

We are now ready to prove the following theorem.

THEOREM 4.6. *Given any instance $\mathcal{I}$ of precedence-constrained scheduling with release dates on m identical parallel machines $(P|prec, r_j|all)$, we can find in polynomial time a schedule S such that $s(X_S) \le 16$.*

Proof. Consider the set of all solutions $C = (C_1, \ldots, C_n)$ to the linear program $\mathcal{P}$ given by Hall et al. [14]. We claim that there exists a solution C' such that $s(C') \le 8$.

Indeed, consider a schedule S' such that $c(X_{S'}) \le 4$. Now, given any solution C to $\mathcal{P}$, Theorem 4.5 states that there is a schedule S such that $X_S \prec_c 2\overleftarrow{C}$. But then, $X_{S'} \prec_c 4X_S \prec_c 8\overleftarrow{C}$. Thus, C' is a sequence of completion times in the schedule S'.

It follows from Lemma 4.4 that we can find such a solution C' in polynomial time. Now, one more application of Theorem 4.5 gives a schedule S with the desired properties. □

We now consider the special case in which there are two identical machines and all jobs have unit size $(2|p_j = 1, prec|all)$.

THEOREM 4.7. *$c^*(\mathcal{I}) = 1$ for every instance $\mathcal{I}$ of precedence-constrained two-processor scheduling with unit jobs.*

Proof. For a schedule S, define $X(S)$ to be its vector of completion times. We will consider only schedules that place at least one job in each time slot until all jobs are completed. Define $Z(S)$ to be the vector whose ith coordinate is the time at which the ith gap occurs. In other words, $Z(S)$ is the sorted (in increasing order) sequence of time slots in which only one job is scheduled.

Here is a basic property of the vectors of gaps.

LEMMA 4.8. *Let S and S' be two schedules. $\overrightarrow{X(S)} \not\prec_c \overrightarrow{X(S')}$ if and only if at least one of the following two conditions holds:* (i) *$Z(S')$ has fewer coordinates than $Z(S)$; or* (ii) *there is an index i so that $Z(S')_i > Z(S)_i$.*

We define the following two orderings on vectors.

DEFINITION 4.9. *Suppose $A = (a_1, \ldots, a_n)$ and $B = (b_1, \ldots, b_m)$ are two vectors. We say that A is lexicographically greater than B if either of the following holds:*

- *$n < m$ and $a_1 = b_1, \ldots, a_n = b_n$.*
- *There is an index i such that $a_1 = b_1, \ldots, a_{i-1} = b_{i-1}$ and $a_i > b_i$.*

DEFINITION 4.10. *Let A and B be vectors defined as above. We say that A is greater than B in the colex ordering if either of the following holds:*

- *$n < m$.*
- *$n = m$ and there is an index i such that $a_m = b_m, \ldots, a_{i+1} = b_{i+1}, a_i > b_i$.*

Let S be a solution to $\mathcal{I}$ with lexicographically maximum vector $Z(S)$ (i.e., the first gap occurs as late as possible as possible; subject to this, the second gap occurs as late as possible; and so on). We show that $\overrightarrow{X(S)} \prec_c \overrightarrow{X(S')}$ for every schedule S'.

Suppose this is not true, and let Ω denote the set of S' for which $\overrightarrow{X(S)} \not\prec_c \overrightarrow{X(S')}$. Thus, every schedule $S' \in \Omega$ satisfies one of conditions (i) or (ii) in Lemma 4.8.

Let S' be the schedule in Ω whose vector $Z(S')$ is maximum in the colex ordering. Note that S' schedules at least one job in each time slot before its completion. We write $Z(S) = (g_1, \ldots, g_m)$ and $Z(S') = (g'_1, \ldots, g_{m'})$. We know that $Z(S)$ is greater than $Z(S')$ in lexicographic order, but if the first condition in Definition 4.9 were to hold, this would contradict Lemma 4.8. Thus there is an index i so that $g_1 = g'_1, \ldots, g_{i-1} = g'_{i-1}$ and $g_i > g'_i$.

From our precedence relation, we define the following undirected graph G_f on the set of jobs: (j, j') is an edge if and only if neither j nor j' precedes the other. The following result is due to Fujii, Kasami, and Ninomiya [7].

LEMMA 4.11 (see [7]). *Suppose G_f has a perfect matching. Then all jobs can be scheduled with no gaps.*

For our analysis, we create $i-1$ fictitious jobs $k_1, \ldots, k_{i-1}$, which are involved in no precedence relations. We consider the schedules that result from augmenting S and S' with the jobs $k_1, \ldots, k_{i-1}$ placed in gap positions $g_1 = g'_1, \ldots, g_{i-1} = g'_{i-1}$, respectively.

Define A to be the set of jobs which start before time g_i in S. Define B to be the set of jobs which start at time g'_i or before in S'. Let x denote the job in B which is run at time g'_i. In both cases, we include the fictitious jobs; thus A and $B \setminus \{x\}$ are each scheduled with no gaps. Note that $|A| > |B|$.

Now, there exists a matching M in G_f covering the set A, and there exists a matching M' in G_f covering the set $B \setminus \{x\}$. Let G'_f denote the subgraph of G_f on nodes $A \cup B$ and edges $M \cup M'$. All vertices of G'_f have degree at most 2, and x has degree 0 or 1 depending on whether it belongs to A. Thus, the component of G'_f containing x is a path P; note that P may be a single-node path if $x \notin A$. Let P consist of nodes $x = v_0, \ldots, v_r$ in order, with $e_i = (v_i, v_{i+1})$.

We now consider two possible cases.

(1) Suppose that P has an even number of nodes so that v_r is not matched in M. Hence $v_r \in B \setminus A$. Consider the set of jobs in $A \setminus B$, and let y be a minimal element of this set. We claim that (v_r, y) is an edge of G_f. Indeed, y occurs before v_r in the schedule S, and v_r occurs before y in the schedule S'. We define the matching M'' to consist of $M' \setminus E(P)$, together with the edges $(v_0, v_1), (v_2, v_3), \ldots, (v_r, y)$. Note that M'' covers $B \cup \{y\}$. Also, there cannot be a pair of jobs j, j' so that $j \notin B \cup \{y\}$, $j' \in B \cup \{y\}$, and j precedes j'. For if there were, then $j' = y$—since B was an initial set of jobs in S'—and this contradicts the minimality of y among the set of jobs in $A \setminus B$.

(2) Suppose that P has an odd number of nodes, so that v_r is matched in M but not in M'; thus, $v_r \in A \setminus B$. Among all jobs in $A \setminus B$ that precede v_r, including v_r, choose a minimal job y. (Thus we may have $y = v_r$.) We claim that (v_{r-1}, y) is an edge of G_f. For if v_{r-1} preceded y, then it would precede v_r, which is not the case, and we know that y cannot precede v_{r-1} since v_{r-1} precedes y in S'. We define the matching M'' to consist of $M' \setminus E(P)$, together with the edges $(v_0, v_1), (v_2, v_3), \ldots, (v_{r-1}, y)$. M'' covers $B \cup \{y\}$, and as in (a) there cannot be a pair of jobs j, j' so that $j \notin B \cup \{y\}$, $j' \in B \cup \{y\}$, and j precedes j'.

Thus in both cases, we have a job $y \in A \setminus B$ so that no job outside $B \cup \{y\}$ precedes any job in $B \cup \{y\}$, and there is a matching in G_f that covers $B \cup \{y\}$. We construct a new schedule S'' as follows: Using Lemma 4.11, we schedule all the jobs in $B \cup \{y\}$ initially with no gaps. We then schedule the rest of the jobs as in S',

replacing fictitious jobs by gaps and introducing a gap where y was in S'. (If this results in a time slot having two gaps, we slide all later jobs forward.)

We write $Z(S'') = (g''_1, \ldots, g''_{m''})$. We can view S'' as having been constructed from S' as follows: We first rearrange the order of jobs in B, within the first g'_i time slots; we then move y forward; we then eliminate any resulting time slots with two gaps. The first of these steps affects only the first i gaps, the second step pushes the ith gap later, and the third step does not push any gap earlier (and may lead to fewer gaps). Thus we have the following lemma.

LEMMA 4.12. *$m'' \leq m'$, $g''_i > g'_i$, $g''_j \geq g'_j$ for $i+1 \leq j \leq m''$, and hence $Z(S'')$ is greater than $Z(S')$ in the colex ordering.*

Now, since $S' \in \Omega$, we know that $Z(S')$ is shorter than $Z(S)$, or there is a j so that $g'_j > g_j$. In the former case, we see that $Z(S'')$ is also shorter than $Z(S)$. In the latter case, we know that $j > i$, since $g_1 = g'_1, \ldots, g_{i-1} = g'_{i-1}$ and $g_i > g'_i$. Now, either $j > m''$, in which case $Z(S'')$ is again shorter than $Z(S)$, or else by Lemma 4.12 it follows that $g''_j \geq g'_j > g_j$. Thus $Z(S'')$ satisfies condition (i) or (ii) in Lemma 4.8, and thus we have the following lemma.

LEMMA 4.13. *$S'' \in \Omega$.*

But Lemmas 4.12 and 4.13 contradict our choice of S', which establishes that Ω must be empty. We have therefore proved the theorem. □

The situation changes for precedence-constrained scheduling with unit jobs ($P|p_j = 1, prec|all$) when we have $m \geq 3$ machines. First, let $m = 3$ and consider an instance $\mathcal{I}$ with eight jobs and the following precedence relations: $j_1 < j_2 < j_3$ and $j_a < j_b$ for $a \in \{4,5,6\}$ and $b \in \{7,8\}$. Then the only schedule with makespan 3 leaves a machine idle in the second time slot, while there is a schedule with makespan 4 that completes six jobs in the first two time slots. Thus $c^*(\mathcal{I}) = 4/3$ for this instance. Similar examples can be constructed for larger numbers of machines.

However, it is easy to show that the greedy algorithm presented in the following theorem and its proof, based on the ideas of Graham [12], provides a global 2-approximation for every instance.

THEOREM 4.14. *$c^*(\mathcal{I}) \leq 2$ for every instance $\mathcal{I}$ of precedence-constrained m-processor scheduling with unit jobs.*

Proof. We produce a greedy schedule. Define the *depth* of a job j as the length of a longest chain in $<_J$ which ends at j (this can be easily computed in linear time). Order the jobs in a list L such that if job j comes before j', then the depth of j is at most that of j'. List schedule the jobs in L in a greedy manner while respecting the precedence constraints. Assume without loss of generality that the jobs are scheduled in the order $j_1, \ldots, j_n$. The completion time of job j_r in this schedule is at most $depth(j_r) + \frac{r}{m}$. It is not difficult to show that in any other schedule, the rth smallest completion time is at least $depth(j_r)$ and $\frac{r}{m}$. This proves the theorem. □

Finally, recall Smith's algorithm for 1-processor scheduling, which simply sequences jobs in nondecreasing order of processing time [24]. The standard proof of optimality in fact shows that $c^*(\mathcal{I}) = 1$ for all instances of this problem. To better understand where this strong global approximation result comes from, we can consider the following problem. We say that a precedence relation P (represented as a partially ordered set) is *universally fair* if, for any choice of processing times for the underlying jobs, we obtain an instance for which $c^*(\mathcal{I}) = 1$. Thus, Smith's algorithm shows that empty precedence relations are universally fair. For trivial reasons, precedence relations that are equal to chains are universally fair, since there is only one feasible schedule. We now state a result that completely characterizes all universally fair precedence relations.

THEOREM 4.15. *P is universally fair if and only if it can be partitioned into antichains $A_1, A_2, \ldots, A_k$ so that for every i from 1 to $k-1$, every $x \in A_i$, and every $y \in A_{i+1}$, we have $x \leq y$.*

Proof. To see the "if" direction, note that every valid schedule must do all of A_1, then all of A_2, and so forth up through A_k. Applying Smith's algorithm to each A_i separately, we see that $c^* = 1$.

Conversely, suppose that P does not have this "layered antichain" property, and assume by way of contradiction that $c^* = 1$ for every set of lengths assigned to the jobs of P. Let $n = |P|$. We first decompose P into a sequence of antichains by defining B_1 to be all minimal elements, B_2 to be all minimal elements of $P - B_1$, and so forth up to an antichain B_k. Since P does not have the layered property above, we can find the smallest index i for which there is an $x \in B_i$ and a $y \in B_{i+1}$ for which $x \not\leq y$. Note that there is some $x' \in B_i$ for which $x' \leq y$; otherwise, our decomposition procedure would have placed $y \in B_i$. Also, $y \not\leq x$, since x was minimal in $P - (B_1 \cup \cdots \cup B_{i-1})$, and $y \in P - (B_1 \cup \cdots \cup B_{i-1})$. Now consider assigning the following lengths to the jobs in P: We give each job other than $\{x, x', y\}$ a weight of $6n$ and we give x a length of 2, x' a length of 3, and y a length of 1. Note that because i was the minimum index for which $\{x, x', y\}$ could be found, any schedule must complete the jobs in $B_1 \cup \cdots \cup B_{i-1}$ before choosing any job in $B_i \cup \cdots \cup B_k$. Let $m = |B_1 \cup \cdots \cup B_{i-1}|$. Then there is a schedule which chooses x as job $m+1$ in sequence, and it has an $(m+1)$st coordinate of $6nm + 2$. There is another schedule which chooses x' as job $m+1$ and y as job $m+2$; this schedule has an $(m+2)$nd coordinate equal to $6nm + 4$. But there is no schedule whose $(m+1)$st coordinate is at most $6nm + 2$ and whose $(m+2)$nd coordinate is at most $6nm + 4$, and this contradicts our assumption that $c^* = 1$ for this set of weights. ∎

5. Facility location.

One facility. Recall that in the facility location problems we consider, we have a metric space M, a set $P = \{p_1, \ldots, p_n\}$ of *demand points* in M, and a set F of n' *candidate facility points*. First, we consider the case of 1-facility instances. For each point $f \in F$, let X_f denote the distance vector that arises when the facility is placed at f.

THEOREM 5.1. *For every 1-facility instance, there is a point $f^* \in F$ such that $s(X_{f^*}) \leq 4$.*

Proof. For simplicity, we assume n is even. We define the radius of $P' \subseteq P$ to be $\text{rad}(P') = \min_{f \in F} \max_{p' \in P} d(f, p')$. We choose a set $P' \subseteq P$ of $n/2$ points of minimum radius r, and define $f^* \in F$ to be a point for which $\max_{p' \in P} d(f^*, p') = \text{rad}(P')$.

Let $\overleftarrow{X_{f^*}} = (d_1, d_2, \ldots, d_n)$. Now, consider any facility $f' \in F$; let $\overleftarrow{X_{f'}} = (d'_1, d'_2, \ldots, d'_n)$. We must show that for each i, we have $d_1 + \cdots + d_i \leq 4(d'_1 + \cdots + d'_i)$. We observe that $d'_{n/2} \geq r$ since P' has the minimum radius r of any set of $n/2$ points, and f^* achieves this radius. Also, consider the set Q' consisting of the $i-1$ points at maximum distance from f' and the set Q^* consisting of the i points at maximum distance from f^*. There is at least one point $q \in Q^* \setminus Q'$, and we have

$$d_i \leq d(f^*, q) \leq d(f^*, f') + d(f', q) \leq d(f^*, f') + d'_i,$$

where the first inequality follows from the fact that $q \in Q^*$, and the third inequality follows since $q \notin Q'$.

If $p' \in P'$, then

$$r + d(p', f') \geq d(f^*, p') + d(p', f') \geq d(f^*, f'),$$

and so $d(p, f') \geq d(f^*, f') - r$. Since there are at least $n/2$ such points, it follows that for any index $i \leq n/2$, we have $d'_i \geq d(f^*, f') - r$. Hence $d(f^*, f') \leq d'_i + r \leq 2d'_i$, and so $d_i \leq d'_i + d(f', f^*) \leq 3d'_i$. For an index $i > n/2$, we have

$$\begin{aligned} d_1 + \cdots + d_i &\leq d_1 + \cdots + d_{n/2} + (i - n/2)r \\ &\leq 3(d'_1 + \cdots + d'_{n/2}) + (d'_1 + \cdots + d'_{n/2}) \\ &\leq 4(d'_1 + \cdots + d'_i). \qquad \square \end{aligned}$$

For the measure c^*, we have the following complementary pair of results for 1-facility instances. For the first, we construct a set of at most $1 + \log n$ facilities by iteratively identifying sets of size $1, 2, 4, 8, \ldots$ of minimum radius and including one facility for each of these sets that achieves this radius.

THEOREM 5.2. *Let $\mathcal{I}$ be an arbitrary 1-facility instance. There exists a set $F^* \subseteq F$ of size at most $1 + \log n$ so that $c(X_{F^*}) \leq 3$.*

Proof. We construct the set F^* as follows. Initialize the set S_0 to the set of all demand points P. We inductively define sets S_i, $i > 0$, and sets A_i, $i \geq 0$, as follows: A_i is a set of 2^i points from S_i of minimum radius. Let f_i be the facility which achieves the radius of A_i. Define S_i as $S_{i-1} \setminus A_{i-1}$.

We stop this process when some set $S_i = \phi$. This defines $m = O(\log n)$ sets A_i total. Define $F^* = \{f_0, f_1, \ldots, f_m\}$. Note that the last set A_m may have fewer than 2^m points. Also, note that in the distance vector X_{F^*}, points in A_i are not necessarily assigned to f_i but to the closest facility in F^*; this observation is important in the proof.

Now, consider any facility point $f \in F$, and let us label the points in P so that $d(f, p_1) \leq d(f, p_2) \leq \cdots \leq d(f, p_n)$. We fix an index t and consider the distance $d = d(f, p_t)$; we must show that at least t coordinates of X_{F^*} are each at most $3d$.

Let $P' = \{p_1, \ldots, p_t\}$; note that since $d(f, p_i) \leq d$ for all $p_i \in P'$, the radius of P' is at most d. We define s so that $2^s \leq t < 2^{s+1}$ and consider the following two cases.

First, suppose $P' \cap A_i = \phi$ for each i, $0 \leq i \leq s$. Now, A_i has minimum radius of all subsets of size 2^i in S_i; since we have $P' \subseteq S_i$ and $2^i \leq t$, it follows that A_i has radius at most d. Thus, all the coordinates in X_{F^*} corresponding to points in A_i have value at most d. Hence at least $|A_0| + \cdots + |A_s| = 2^{s+1} - 1 \geq t$ coordinates of X_{F^*} have value at most d.

Now, suppose instead that there is an index $i \leq s$ for which $P' \cap A_i \neq \phi$; in this case, choose the smallest such i. Let p' be a point in $P' \cap A_i$. Since P' does not intersect $A_0 \cup \cdots \cup A_{i-1}$, it is a subset of S_i; thus the radius of A_i is at most the radius of P' and hence at most d. Now, consider the vector X_{f_i}; since $f_i \in F^*$, we have $X_{F^*} \prec_c X_{f_i}$, and so it is enough to show that X_{f_i} contains t coordinates of value at most $3d$. But for any $p'' \in P'$, we have

$$d(p'', f_i) \leq d(p'', f) + d(f, p') + d(p', f_i) \leq 3d. \qquad \square$$

We have an essentially matching lower bound, which has a structure paralleling the construction that proves the previous theorem; essentially we build an instance consisting of widely separated clusters of size $1, 2, 4, 8, \ldots$; by defining distances appropriately in each, we can argue that each cluster must contain a facility.

THEOREM 5.3. *For any number α, there are 1-facility instances $\mathcal{I}$ for which no set F' of fewer than $\log n$ facilities achieves $c(X_{F'}) \leq \alpha$.*

Proof. The point set is divided into m "clusters." Cluster C_i (for $0 \leq i \leq m$) has 2^i demand points and one facility point. The distance between any two points in C_i

(including the facility point) is a number d_i, and we choose these distances so that $d_i < \alpha d_{i+1}$. The distance between any two points in different clusters is defined to be a number $d > \alpha d_1$. It is not difficult to show that this defines a metric. Note that there are $n = 2^{m+1} - 1$ demand points.

Suppose F' is a set of facility points such that $|F'| < m+1$. Then there is a cluster C_i such that $F' \cap C_i = \phi$. Let f be the facility point in C_i, and define $j = n - 2^i + 1$. The jth coordinate of $\overleftarrow{X_f}$ is d_i. On the other hand, all the points in $C_i \cup \cdots \cup C_m$ have coordinates in $X_{F'}$ that are at least $d_{i+1} > \alpha d_i$. As the number of such points is $n - 2^i + 1 = j$, the result follows. □

Multiple facilities. Now we consider a k-facility instance $\mathcal{I}$, where $k > 1$ is arbitrary.

THEOREM 5.4. *Fix numbers k and ε such that $\varepsilon \leq 1$. There exists a set $F^* \subseteq F$ of size $O(k \log n + \varepsilon^{-1})$ so that $\overleftarrow{X_{F^*}} \prec_c (3+\varepsilon)\overleftarrow{X_{F'}}$ for every set F' of at most k facilities.*

Proof. We first describe the construction of the set F^* that achieves this bound. For a point p and a set of points Q, we define $d(p, Q) = \min_{q \in Q} d(p, q)$. We define the *$k$-radius* of a set of demand points P' as follows:

$$\mathrm{rad}_k(P') = \min_{|F'|=k} \max_{p \in P'} d(p, F').$$

We choose a sufficiently large constant $\alpha = \Theta(\varepsilon^{-1})$, and perform the following construction. Define $x_0 = n$. Let $P_1 = P$ be the initial set of demand points, let $n_1 = |P_1|$, let $x_1 = \lceil n_1/2 \rceil$, and let C_1 be a subset of x_1 points of P_1 of minimum k-radius. In general, having defined P_i, n_i, x_i, C_i, we set $P_{i+1} = P_i \setminus C_i$, $n_{i+1} = |P_{i+1}|$, and $x_{i+1} = \lceil n_{i+1}/2 \rceil$, and let C_{i+1} be a subset of x_{i+1} points of P_{i+1} of minimum k-radius. Let r_{i+1} denote the k-radius of C_{i+1}.

We stop this process at the first s for which $x_s \leq \alpha$. Let $R \subseteq P$ denote the set of demand points not contained in $C_1 \cup \cdots \cup C_s$; note that $|R| \leq \alpha$. We define our set F^* of facilities as follows. For each set C_i, we include a set of k facilities that achieves the k-radius of C_i. For each point $p \in R$, we include a facility that is closest to p.

Note that $s = O(\log n)$, and hence $|F^*| = O(k \log n + \alpha)$. Now, consider any set F' of k facilities. We write $\overleftarrow{X_{F^*}} = (d_1, d_2, \ldots, d_n)$ and $\overleftarrow{X_{F'}} = (d'_1, d'_2, \ldots, d'_n)$.

The following lemma now directly implies Theorem 5.4.

LEMMA 5.5. *For each j, we have $d_1 + \cdots + d_j \leq (3+\varepsilon)(d'_1 + \cdots + d'_j)$.*

Proof. We claim first that

(1) for each i, $1 \leq i \leq s$, we have $d'_{x_i} \geq r_i$.

Now suppose this is not true for some i. Then there exists a set Q of at least $n - x_i + 1$ demand points of k-radius less than r_i. Since

$$|Q \setminus (C_1 \cup \cdots \cup C_{i-1})| \geq (n - x_i + 1) - (x_1 + \cdots + x_{i-1}) = n_i - x_i + 1 \geq x_i,$$

P_i contains a set Q' of at least x_i points from Q. But the k-radius of Q' is less than r_i, which contradicts our choice of C_i. This proves (1).

Now, consider an index i. For any $j < i$, we have $x_j \geq x_i$, and thus $d'_{x_i} \geq d'_{x_j} \geq r_j$. Thus we have

(2) $d'_{x_i} \geq \max(r_1, \ldots, r_i)$.

Using this, we show that

(3) for each $j \leq x_s$, we have $d_j \leq d'_j$.

We consider two cases in proving (3). First, if $d_j \leq \max(r_1, \ldots, r_s)$, then $d_j \leq d'_j$, since (2) implies that $d'_j \geq d'_{x_s} \geq \max(r_1, \ldots, r_s)$. On the other hand,

if $d_j > \max(r_1, \ldots, r_s)$, then each of $d_1, \ldots, d_j > \max(r_1, \ldots, r_s)$, and hence the points achieving these distances must belong to R. For each of these points, its coordinate in $X_{F'}$ is at least as large as its coordinate in X_{F^*}. It follows that the vector $\overleftarrow{X_{F'}}$ contains at least j coordinates of value at least d_j, and hence $d_j \leq d'_j$.

To handle boundary cases, we define $x_0 = n$, $x_{s+1} = 0$, $C_{s+1} = \phi$, and $n_{s+1} = n_s - x_s$. We now claim the following:

(4) Suppose j is an integer satisfying $x_i < j \leq x_{i-1}$, where $1 \leq i \leq s$. Then $d_j \leq d'_{x_i}$.

To prove this, we observe that

$$|C_{i+1}| + |C_{i+2}| + \cdots + |C_s| + |R| = x_{i+1} + \cdots + x_s + \alpha = n_{i+1} = n_i - x_i \leq x_i.$$

Now, $j > x_i$, so among the points with the j largest coordinates in X_{F^*}, there is at least one point that does not belong to $C_{i+1} \cup \cdots \cup C_s \cup R$. Thus, $d_j \leq \max(r_1, \ldots, r_i)$. But by (2), $d'_{x_i} \geq \max(r_1, \ldots, r_i)$, and so $d_j \leq d'_{x_i}$, as desired.

We now complete the proof of the lemma. First, if α is a sufficiently large multiple of ε^{-1}, then

$$x_{i-1} - x_i \leq (2 + \varepsilon)(x_i - x_{i+1})$$

for each i, $1 \leq i \leq s$. Now, for each such i, we have

$$\sum_{x_i < \ell \leq x_{i-1}} d_\ell \leq (x_{i-1} - x_i) d'_{x_i} \leq (2 + \varepsilon)(x_i - x_{i+1}) d'_{x_i} \leq (2 + \varepsilon) \sum_{x_{i+1} < \ell \leq x_i} d'_\ell.$$

Now, let j be any index between 1 and n. For $j \leq x_s$, we have $d_1 + \cdots + d_j \leq d'_1 + \cdots + d'_j$ by (3). Otherwise, there is an i so that $x_i < j \leq x_{i-1}$.

$$\begin{aligned} d_1 + \cdots + d_j &= \sum_{1 \leq \ell \leq x_s} d_\ell + \sum_{x_s < \ell \leq x_{s-1}} d_\ell + \cdots + \sum_{x_{i+1} < \ell \leq x_i} d_\ell + \sum_{x_i < \ell \leq j} d_\ell \\ &\leq \sum_{1 \leq \ell \leq x_s} d'_\ell + (2 + \varepsilon) \left(\sum_{1 \leq \ell \leq x_s} d'_\ell + \cdots + \sum_{x_{i+1} < \ell \leq x_i} d'_\ell \right) \\ &\leq (3 + \varepsilon)(d'_1 + \cdots + d'_{x_i}) \\ &\leq (3 + \varepsilon)(d'_1 + \cdots + d'_j). \end{aligned}$$

This proves the theorem. □

Note that the construction described in the proof does not yield a polynomial-time algorithm since it involves computing the k-radius of subsets of points. However, a recent result of Charikar et al. [4] provides a polynomial-time 3-approximation algorithm for the following problem: Given a set P and a parameter x, find a subset C of size x of minimum k-radius. We can use this algorithm to construct the sets C_i in the proof; as a result we lose a factor of 3 in each of the claims (1)–(4) above, and hence obtain a set F^* of size $O(k \log n + \varepsilon^{-1})$ for which $s(F^*) \leq 9 + \varepsilon$.

As mentioned in section 1, we have a lower bound that nearly matches the result of Theorem 5.4.

THEOREM 5.6. *For any number α, there are k-facility instances $\mathcal{I}$ for which no set F' of fewer than $\Omega(k \frac{\log(n/k)}{\log \alpha})$ facilities achieves $s(X_{F'}) \leq \alpha$.*

Proof. For simplicity we will consider values of k that are even, and write $k = 2k'$. We choose a constant $a > 12\alpha$. For a number m, we define $n_1, n_2, \ldots, n_m$ via $n_i = a^{4(m-i)}$ and $n_0 = n_1$.

Our instance $\mathcal{I}$ consists of a set of $n = n_0 + n_1 + \cdots + n_m$ points P, partitioned into *clusters* $C_0, \ldots, C_m$, where C_i has n_i points. We call a cluster *large* if it has at least k points; we divide each large cluster C_i into k' *subclusters* $C_{i,1}, \ldots, C_{i,k'}$ such that the difference in the size of any two subclusters of C_i is at most one. Note that each such subcluster has size at least $\frac{n_i}{k'} - 1$. For the clusters that are not large, we will say that they consist of a single subcluster. We define $F = P$, so that the set of candidate facility points is the same as the set of demand points.

We define the interpoint distances as follows. The distance between any two points in the same subcluster is 0 (or a very small number). The distance from a point in $C_{i,s}$ to a point in $C_{i,s'}$, with $s \neq s'$, is $y_i = a^{2(i-1)}$ for $i > 0$ and $y_0 = 1$ for $i = 0$. The distance from a point in C_i to a point in any cluster C_j for $j < i$ is equal to a number $x_i = a^{2i-1}$. For simplicity of notation, we will define $x_0 = 0$.

Note that $n \leq 3a^{4(m-1)} \leq a^{4m}$, and hence $m \geq \frac{\log n}{4 \log a}$. Since C_j is large whenever $a^{4(m-j)} \geq k$, and hence whenever $m - j \geq \frac{\log k}{4 \log a}$, there are at least

$$m' = m - \frac{\log k}{4 \log a} \geq \frac{\log n}{4 \log a} - \frac{\log k}{4 \log a} = \frac{\log(n/k)}{\log \alpha}$$

large sets.

Let F' be a set of facility points such that $|F'| \leq m' \lfloor \frac{k'}{2} \rfloor$. Then there is some large C_i such that $|F' \cap C_i| \leq \lfloor \frac{k'}{2} \rfloor$. Since there are k' subclusters in C_i and at most $\lfloor \frac{k'}{2} \rfloor$ contain a facility, the distance of at least

$$\frac{k'}{2} \left(\frac{n_i}{k'} - 1 \right) = \frac{n_i}{2} - \frac{k'}{2}$$

points in C_i from the nearest facility in F' is at least y_i. So, if ℓ denotes $\frac{n_i}{2} - \frac{k'}{2}$, then the ℓth coordinate of $\sigma(\overleftarrow{X_{F'}})$ is at least

$$\sigma(\overleftarrow{X_{F'}})_\ell = y_i \left(\frac{n_i}{2} - \frac{k'}{2} \right).$$

Consider the following set F'' of k facility points: If $i > 0$, we place k facilities in clusters C_i and C_{i-1}, one in each subcluster. If $i = 0$, we place k facilities in C_0 and C_1, again one in each subcluster. Since the cases $i = 0$ and $i = 1$ are similar, we will assume in what follows that $i > 0$.

Now, observe that if C_j is large, then

$$n_{j+1} + \cdots + n_m \leq 2n_{j+1} \;\leq\; \frac{n_j}{4} \;\leq\; \frac{n_j - k'}{2} \;=\; \ell,$$

and thus the ℓth coordinate of $\sigma(\overleftarrow{X_{F''}})$ is equal to

$$\sigma(\overleftarrow{X_{F''}})_\ell = \sum_{j>i} n_j x_j + \left(\frac{n_i}{2} - \frac{k'}{2} - \sum_{j>i} n_j \right) x_{i-1}.$$

Now we can compare these two quantities as follows:

$$\begin{aligned}
\sigma(\overleftarrow{X_{F''}})_\ell &= \sum_{j>i} n_j x_j + \left(\frac{n_i}{2} - \frac{k'}{2} - \sum_{j>i} n_j\right) x_{i-1} \\
&\le \sum_{j>i} a^{4m-2j-1} + \frac{n_i x_{i-1}}{2} \\
&\le 3a^{4m-2i-3} \\
&< \frac{1}{12\alpha} \cdot 3a^{4m-2i-2} \\
&= \frac{1}{\alpha} \cdot \frac{a^{4m-2i-2}}{4} \\
&= \frac{1}{\alpha} \cdot \frac{y_i n_i}{4} \\
&\le \frac{1}{\alpha} \cdot y_i \left(\frac{n_i}{2} - \frac{k'}{2}\right) \\
&\le \frac{1}{\alpha} \cdot \sigma(\overleftarrow{X_{F'}})_\ell. \qquad \square
\end{aligned}$$

For the c^* measure, we show that in general the lower bound is essentially as bad as possible when $k > 1$.

THEOREM 5.7. *For any number α, there are 2-facility instances $\mathcal{I}$ for which no proper subset $F' \subseteq F$ achieves $c(X_{F'}) \le \alpha$.*

Proof. Consider the following instance $\mathcal{I}$. The n demand points $P = \{p_1, \ldots, p_n\}$ and $n' = n$ candidate facilities $F = \{f_1, \ldots, f_n\}$ are partitioned into n *clusters* $C_1, \ldots, C_n$ so that $C_i = \{p_i, f_i\}$. The distance between p_i and f_i is equal to a number y_i, and the distance from a point in C_i to a point in any cluster C_j for $j < i$ is equal to a number x_i. We choose these distances so that $\alpha x_i < y_{i+1}$ and $\alpha y_i < x_i$ for each i.

Now consider any set $F' \subseteq F$ of fewer than n facilities, and suppose it does not contain the facility in C_i. Define $F'' = \{f_{i-1}, f_i\}$. Then the ith coordinate of the distance vector $\overrightarrow{X_{F''}}$ is equal to $d(p_i, f_i) = y_i$. On the other hand, among the first i coordinates of the distance vector $\overrightarrow{X_{F'}}$, there is at least one corresponding to the distance to some point in $C_i \cup \cdots \cup C_n$. But all these distance are at least $x_i > \alpha y_i$, and thus the theorem follows. $\square$

DYNAMIC SUBGRAPH CONNECTIVITY WITH GEOMETRIC APPLICATIONS*

TIMOTHY M. CHAN†

Abstract. Inspired by dynamic connectivity applications in computational geometry, we consider a problem we call *dynamic subgraph connectivity*: design a data structure for an undirected graph $G = (V, E)$ and a subset of vertices $S \subseteq V$ to support insertions/deletions in S and connectivity queries (are two vertices connected?) in the subgraph induced by S. We develop the first sublinear, fully dynamic method for this problem for general sparse graphs, using a combination of several simple ideas. Our method requires $\widetilde{O}(|E|^{4\omega/(3\omega+3)}) = O(|E|^{0.94})$ amortized update time, and $\widetilde{O}(|E|^{1/3})$ query time, after $\widetilde{O}(|E|^{(5\omega+1)/(3\omega+3)})$ preprocessing time, where ω is the matrix multiplication exponent and $\widetilde{O}$ hides polylogarithmic factors.

1. Introduction.

1.1. Geometric motivation. *Dynamic graph connectivity*—maintaining an undirected graph under edge insertions and deletions to answer queries of the form, "Are two vertices connected?"—is a basic problem in the area of graph data structures. In the same way, connectivity problems concerning a dynamic collection of geometric objects are fundamental in computational geometry. However, unlike dynamic graph connectivity, which has been extensively studied and has enjoyed much recent success with the discovery of near-logarithmic algorithms [17, 21, 32], progress in *dynamic geometric connectivity* has been scarce. For this reason, we decide to start our investigation with a simple version of the problem:

> Maintain a set of n axis-parallel rectangles in the plane, under insertions and deletions, to answer queries of the form, "Given two points a and b, is there a path from a to b that lies inside the union of these rectangles?"

Rectangular connectivity queries have numerous applications, for example, in VLSI design, communication networks, and geographic information systems. (See Figure 1.1.) Solving this problem might pave the way for the study of dynamic connectivity of other objects and, perhaps, tougher questions such as dynamic shortest paths and motion planning.

No fully dynamic solution for rectangular connectivity has been reported even for the special case of orthogonal line segments. Existing geometric data structuring techniques (notably, range searching) [2, 29] seem insufficient, because connectivity queries are more global in nature. On the other hand, although our problem is equivalent to dynamic connectivity in the intersection graph (where we place an edge between

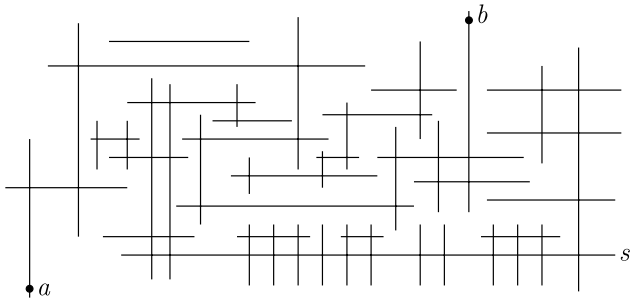

FIG. 1.1. *A collection of "roads." Is b reachable from a?*

every pair of intersecting rectangles), a straightforward application of dynamic graph connectivity results would not lead to an efficient solution either, because the intersection graph can have quadratic size, and an insertion/deletion of a rectangle can cause a linear number of edge updates in the worst case. (Imagine deleting and reinserting a segment such as s into Figure 1.1.) Thus, work on dynamic graph connectivity [13, 15, 18, 17, 21, 31, 32] is only the beginning if we want to tackle the more challenging dynamic connectivity problems from geometry.

In this paper, we show that a sublinear time bound is indeed theoretically possible for dynamic connectivity of rectangles and, in fact, axis-parallel boxes in any fixed dimension d. Specifically, we achieve $\widetilde{O}(n^{4\omega/(3\omega+3)})$ amortized time for insertions and deletions, and $\widetilde{O}(n^{1/3})$ time for queries, using $\widetilde{O}(n)$ space. Here and throughout the paper, the $\widetilde{O}$ notation hides polylogarithmic factors in n, and ω denotes the matrix multiplication exponent. The current best matrix multiplication result with $\omega < 2.376$ by Coppersmith and Winograd [7] implies an $O(n^{0.94})$ upper bound for updates, but any subcubic method with $\omega < 3$ (such as Strassen's) would already imply a sublinear upper bound.

This result is striking in two respects: (i) the independence of the exponent of our time bounds on the dimension d and (ii) the usage of fast matrix multiplication, which is rare among algorithms in computational geometry. (Applications of fast matrix multiplication are more common in dynamic graph algorithms (see, e.g., [9, 24]), but the sublinearity of our update bound is still unusual.) In section 7, we partially explain why a polylogarithmic solution is unlikely given the current state of the art and why points (i) and (ii) might be inherent to the problem itself, at least for $d \geq 3$.

1.2. Previous geometric work. Statically, connectivity for n rectangles in the plane can be decided in $O(n \log n)$ time [23]. Agarwal and van Kreveld [3] gave an approach for the *incremental* (insertion-only) case that, in particular, yielded an $O(\log^2 n)$ amortized time bound for orthogonal segments.

For unit squares and unit hypercubes (and thus for near-equal-size boxes of bounded aspect ratios), a fully dynamic, polylogarithmic method can be obtained by an easy reduction to the maintenance of the L_∞-minimum spanning tree of a point set, which was solved by Eppstein [12] in any fixed dimension (using known dynamic minimum spanning tree results for graphs [21]). For arbitrary rectangles and arbitrary hypercubes, Hershberger and Suri [19, 20] considered the *kinetic* problem of maintaining connectivity as objects move continuously according to given flight plans: allowing a quadratic number of events, we can easily reduce the kinetic problem to dynamic graph connectivity using the intersection graph; Hershberger and Suri showed that

the space complexity can be decreased from quadratic to linear while still supporting efficient updating.

1.3. The dynamic subgraph connectivity problem. As we have pointed out, the intersection graph cannot directly be used for dynamic rectangular connectivity. However, existing geometric range searching results allow us to compress the intersection graph, using so-called biclique covers [1, 14]. Although this technique is familiar, it has not been used in connectivity applications and, in our opinion, leads to a conceptually cleaner description of geometric connectivity algorithms because of the separation of geometric and nongeometric elements.

As it turns out (see section 2), the problem on the compressed intersection graph leads to an interesting generalization of dynamic graph connectivity, which is not as well studied but that we believe is equally fundamental:

> Maintain an undirected graph $G = (V, E)$ with n vertices and m edges, and a subset $S \subseteq V$ of vertices, under the following operations: insert an edge into E, delete an edge from E, insert a vertex into S, and delete a vertex from S. Queries to be answered are of the form, "Given two vertices $u, v \in S$, is there a path from u to v that uses only vertices from S?"

We call this problem *dynamic subgraph connectivity*. The difficulty lies not in edge updates to E but in vertex updates to the subset S. If each vertex is inserted and deleted only once, then we can directly apply data structures for dynamic graph connectivity to maintain the subgraph induced by S; the amortized cost would be near-logarithmic per edge, since each edge is inserted and deleted $O(1)$ times. In particular, we can therefore handle the *incremental* (insertion-only) or *decremental* (deletion-only) case. However, in general, vertices may be deleted and reinserted into S as often as we like; this naive approach would have cost proportional to the degree of the vertex, which can be linear in n for every update in the worst case. We give a nontrivial sublinear solution for arbitrary update sequences in general sparse graphs with $\widetilde{O}(m^{4\omega/(3\omega+3)})$ amortized update time, $\widetilde{O}(m^{1/3})$ query time, $\widetilde{O}(m^{(5\omega+1)/(3\omega+3)})$ preprocessing time, and $\widetilde{O}(m)$ space.

To appreciate the result, note that existing polylogarithmic dynamic graph techniques [17, 21, 32] do not work, because the usual "certificate" [13, 24], a spanning forest, can change drastically in a single vertex update. Alternatively, it is possible to reduce the problem to reachability in a dynamic *directed* graph, so that a vertex update can be simulated by a single edge change (by creating two copies of each vertex joined by a directed edge). However, dynamic directed graph reachability [16, 30] is computationally more demanding (a main goal there was to obtain an $o(n^2)$ update bound).

1.4. Previous graph work. The dynamic subgraph connectivity problem has indeed been proposed before, in a paper by Frigioni and Italiano [16]. The motivation there was on the connectivity of communication networks, where processors can become faulty and can later go back up; viewed alternatively, vertices can be "switched" on and off. Frigioni and Italiano used the term *complete dynamic graph model* to describe the setting where both edge and vertex updates are supported. They described polylogarithmic connectivity results for the special case of planar graphs (relying on separators) but left the general case (which is necessary in our geometric application) open.

1.5. How to solve it. Our solution to dynamic subgraph connectivity involves several techniques. Each in itself is not difficult, and when put together in the right way, they yield the winning combination. Our recipe includes the following:

- Processing the update sequence in blocks. Khanna, Motwani, and Wilson [24] have used this trick to design various dynamic graph algorithms for *offline* updates (when the update sequence is given in advance), while the author [5, 6] has applied essentially the same idea to several dynamic geometric problems under *semi-online* updates (when only the deletion times are given in advance) as well as general updates.
- The "high-low" trick of Alon, Yuster, and Zwick [4]. This was originally developed for the problem of finding triangles in sparse graphs. We observe how the idea can yield faster multiplication algorithms for sparse rectangular matrices (see section 3).
- Precomputing information for high-degree vertices, so that their repeated deletions and reinsertions would not be as costly.
- Finally, amortizing deletion cost via a standard "weighted split" idea, which is analogous to the standard "weighted union" heuristic (e.g., see [8, Chapter 21]).

To illustrate the effects of these ideas progressively, we present the algorithm in stages (in the actual order of discovery), starting with an $O(m^{0.82})$ offline update method (section 4), extending it to an $O(m^{0.91})$ semi-online update method (section 5), and ending with the $O(m^{0.94})$ fully dynamic update method (section 6).

2. From geometry to graphs. We first describe how to reduce dynamic geometric connectivity problems to dynamic subgraph connectivity. This section is the only place where computational geometry techniques are used; afterwards, we can devote all our attention to the graph problem.

The reduction is a simple consequence of known compact representations of geometric intersection graphs. Specifically, any intersection graph of boxes can be represented as a union of bicliques (complete bipartite subgraphs $A_i \times B_i$ over some vertex subsets A_i and B_i) so that the size of the representation (the total number of vertices in the bicliques) is near-linear.

LEMMA 2.1. *Fix any constant d. Given a set of n (axis-parallel) boxes in $\mathbb{R}^d$, we can form subsets A_i and B_i of total size $\widetilde{O}(n)$ in $\widetilde{O}(n)$ time, such that two boxes a and b intersect iff (a, b) or (b, a) is in $A_i \times B_i$ for some index i. This property can be maintained dynamically: each insertion/deletion of a box causes an amortized $\widetilde{O}(1)$ number of insertions/deletions in the A_i's and B_i's.*

Proof. We first consider the static case. The following *orthogonal range (or intersection) searching* problem [2, 11, 26, 27, 28, 29] is well studied in computational geometry: preprocess a given set of n boxes in a data structure so that given a query box b, we can quickly report all boxes intersecting b. A standard solution to this problem is the *range tree* (or a multilevel *segment tree*). The precise details behind the data structure are not important here (see the above references for more information). The main properties to note are that the data structure consists of $O(n \log^{d-1} n)$ "nodes," each of which stores a subset of boxes which we refer to as a *canonical subset*, and that given a query box b, the set of boxes intersecting b can be returned as the union of the canonical subsets at $O(\log^d n)$ nodes of the data structure. The total size of the canonical subsets is $O(n \log^d n)$; the preprocessing time is $O(n \log^d n)$ and the query time is $O(\log^d n)$.

To form the subsets A_i and B_i, we build the data structure for the given input boxes and perform queries for all the boxes. For each node i, we let A_i be the canonical subset at i and B_i be all boxes whose query returns the canonical subset at i. The total size of the A_i's and B_i's is $O(n \log^d n)$, and correctness is obvious.

For the dynamic case, we need a version of the orthogonal range searching problem that supports insertion. A weight-balanced range tree, for instance, can be used [26, 28]. Again the precise details behind the data structure are not important. The main additional properties are that although each canonical subset does not change, new nodes and canonical subsets may be created, and the total size of all canonical subsets created by a sequence of n insertions is bounded by $O(n \log^{d+1} n)$. (With more care, a log factor can probably be saved.)

To update the subsets A_i and B_i under the insertion of a new box b, we perform a query for b and insert b into every set B_i such that the query returns the canonical subset at node i. We then insert b into the data structure itself, and for every new node i created, we insert all elements of the new canonical subset into A_i and initialize $B_i = \emptyset$. (We do not delete canonical subsets of old nodes destroyed.) The amortized number of insertions into the A_i's and B_i's is $O(\log^{d+1} n)$.

To update the subsets A_i and B_i under the deletion of a box b, we simply remove b from each subset that contains b. The cost of deletion can be "charged" to the insertion cost by amortization. (If n is to denote the number of current boxes instead of the number of insertions, we need another standard amortization trick: rebuilding the whole data structure whenever the value of n is halved [26, 28].) □

THEOREM 2.2. *Fix any constant d. The dynamic connectivity problem for boxes in $\mathbb{R}^d$ can be reduced to the dynamic subgraph connectivity problem on a graph with $m = \widetilde{O}(n)$ edges. Each box update causes an amortized $\widetilde{O}(1)$ number of graph updates.*

Proof. Given a set of boxes, we apply Lemma 2.1 and define the following graph G: for each box, we create a vertex; in addition, for each subset pair (A_i, B_i), we create a new vertex v_i and place edges from v_i to all members of $A_i \cup B_i$. (See Figure 2.1 for an idealized example.) Initially, all vertices are put in the subset S. Whenever A_i or B_i becomes empty, we delete the vertex v_i from S. When both A_i and B_i are nonempty, we reinsert v_i into S.

Each insertion/deletion of a box causes the subsets A_i and B_i to undergo $\widetilde{O}(1)$ amortized number of insertions/deletions, which in turn causes the above graph G and subset S to undergo $\widetilde{O}(1)$ amortized number of edge and vertex insertions/deletions.

To test whether two query boxes are connected in the intersection graph, we just test whether the two boxes are connected in the subgraph of G induced by S.

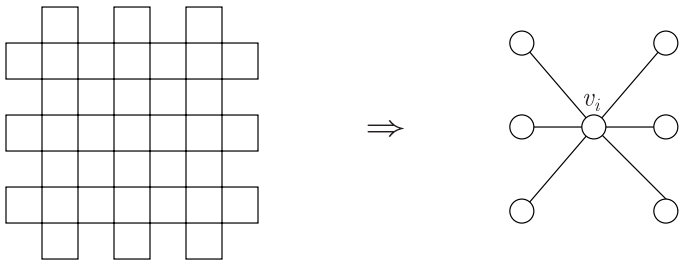

FIG. 2.1. *From dynamic box connectivity to dynamic subgraph connectivity.*

Correctness is evident (if A_i and B_i are nonempty, the members of $A_i \cup B_i$ are indeed all connected to each other in the intersection graph). To test whether two query points are connected, we first find a box containing each point (which takes polylogarithmic time by known data structures for orthogonal range searching) and then test whether these two boxes are connected. □

Remarks. The above reduction also works in the static, incremental (insertion-only), decremental (deletion-only), offline, and semi-online settings.

In the static case, graph and subgraph connectivity can be solved in linear time by depth-first search, so we automatically get an $O(n \operatorname{polylog} n)$ algorithm for the box connectivity problem. This result was known before, as noted in section 1.

In the incremental/decremental case, subgraph connectivity reduces to graph connectivity, as we have observed in section 1 (by explicitly maintaining the induced subgraph). Incremental graph connectivity is equivalent to the union-find problem [8], and decremental graph connectivity can be solved in near-logarithmic time [31, 32], so we automatically get $O(\operatorname{polylog} n)$ incremental/decremental box connectivity algorithms. (We do not state the precise polylogarithmic bounds, because slight improvements are likely possible by a more direct approach.) The incremental box connectivity result was already known [3], but the decremental box connectivity has not been addressed before.

In the offline, semi-online, and fully dynamic cases, the subgraph connectivity results in sections 4–6 will imply corresponding box connectivity results, up to polylogarithmic factors.

Other classes of objects can be considered. For example, we can obtain the same results for line segments that have a fixed number of slopes, by using variants of orthogonal range searching in the proof of Lemma 2.1.

For arbitrary line segments in the plane, we need to use known nonorthogonal range searching data structures [2] in the proof of Lemma 2.1, but these data structures require canonical subsets of total size $\widetilde{O}(n^{4/3})$ instead of $O(n \operatorname{polylog} n)$; as a result, the graph in Theorem 2.2 now has $m = \widetilde{O}(n^{4/3})$ edges, and each segment update causes an amortized $\widetilde{O}(n^{1/3})$ number of graph updates. Unfortunately, our dynamic subgraph connectivity results are too weak to yield meaningful bounds in this case. Still, we can obtain an $\widetilde{O}(n^{4/3})$ result for static connectivity and an $\widetilde{O}(n^{1/3})$ result for incremental and decremental connectivity for arbitrary line segments. This static result was known [25], so was the incremental result [3], but the decremental result appears new.

3. Fast sparse matrix multiplication. Our sublinear results for dynamic subgraph connectivity will require a time bound for matrix multiplication that is sensitive to the sparseness of the given matrices. Although obtaining such an input-sensitive bound is in general an outstanding problem for the standard square-matrix case (see [34] for an independent, recent development), in this section we note a simple input-sensitive bound for a rectangular-matrix case that is sufficient for our application.

Specifically, we consider the complexity $M(n, q \,|\, m)$ of multiplying a $q \times n$ 0-1 matrix A with an $n \times q$ 0-1 matrix B, where m is the number of nonzero entries per matrix, with $m = \Omega(n)$. This is asymptotically equivalent to the complexity of the following graph problem: given an m-edge bipartite graph with a set P of n vertices on one side and a set Q of q vertices on the other, count the number $C[u, v]$ of vertices adjacent to both u and v for every vertex pair $u, v \in Q$. (To reduce the graph problem to matrix multiplication, let $a_{vw} = 1$ iff $b_{wv} = 1$ iff $w \in P$ and $v \in Q$ are adjacent;

then $C[u,v] = \sum_{w \in P} a_{uw} b_{wv}$. Conversely, to reduce matrix multiplication to the graph problem, let $P = \{1, \ldots, n\}$ and $Q = \{1, \ldots, q\} \times \{1, 2\}$ (of size $2q$), and place an edge between k and $(j,1)$ if $a_{jk} = 1$ and an edge between k and $(j,2)$ if $b_{jk} = 1$; then $C[(i,1),(j,2)] = \sum_{k=1}^{n} a_{ik} b_{kj}$.)

We are primarily interested in the case when q is small. For dense matrices, we have the upper bound $M(n, q \,|\, m) = O(nq^{\omega-1} + q^{\omega})$, since we can solve the problem by multiplying $\lceil n/q \rceil$ pairs of $q \times q$ square submatrices. To take the sparseness m into account, we adapt a simple trick by Alon, Yuster, and Zwick [4].

LEMMA 3.1. $M(n, q \,|\, m) = O(mq^{(\omega-1)/2} + q^{\omega})$.

Proof. Consider the graph formulation. Divide P into two groups: P_H, vertices of degree $> r$, and P_L, vertices of degree $\leq r$. Then $|P_H| = O(m/r)$. We first set $C[u,v]$ to be the number of vertices in P_H adjacent to both u and v for every pair $u, v \in Q$; this takes time $O(M(m/r, q \,|\, m)) = O(mq^{\omega-1}/r + q^{\omega})$ by the dense-matrix bound. To complete the overall count, we can examine each edge uw incident to a vertex $w \in P_L$, go through all adjacent edges wv, and increment $C[u,v]$; this takes $O(mr)$ time. Setting $r = q^{(\omega-1)/2}$ yields the desired bound. □

Remark. There are improved rectangular matrix multiplication methods [22] for dense matrices, which may lead to slight improvements to Lemma 3.1 for certain ranges of parameters. However, these improvements do not seem to matter here, since we will eventually select parameters to equalize the contribution of the terms $mq^{(\omega-1)/2}$ and q^{ω}, and the critical case will occur when the dense submatrices are essentially square matrices.

4. An offline solution. In the next three sections, we present our algorithms for dynamic subgraph connectivity. We begin by considering the offline case, where we are given the update sequence in advance (or the ability to look sufficiently far ahead in the update sequence). The approach is simple: we divide a dynamic set into two subsets, P and Q, where P is static and Q is dynamic but small; to keep Q small, we rebuild the data structure from scratch periodically, after a certain number of updates. Khanna, Motwani, and Wilson [24] have adopted this very approach for strongly connected components and reachability in directed graphs. We obtain a sublinear result in m by, in addition, employing Lemma 3.1.

In what follows, let $G = (V, E)$ be the input graph with n vertices and m edges. Without loss of generality, assume that $m = \Omega(n)$. For clarity's sake, we focus only on the more difficult update operations, i.e., vertex insertions/deletions in S; edge insertions/deletions in G will be treated later in the remarks after Theorem 6.2.

LEMMA 4.1. *Given a static subset $P \subseteq V$ and a static subset $Q_0 \subseteq V$ of size q_0, we can design a data structure to maintain a subset $Q \subseteq Q_0$, where preprocessing takes $\widetilde{O}(mq_0^{(\omega-1)/2} + q_0^{\omega})$ time, updates to Q take $\widetilde{O}(q_0)$ amortized time, and connectivity queries on the subgraph induced by $P \cup Q$ take $\widetilde{O}(q_0)$ time.*

Proof. We first compute the connected components of the subgraph induced by P in linear time by depth-first search [8]. Our data structure consists of three parts:

- We form a bipartite multigraph Γ with the connected components as vertices on one side and V as vertices on the other side: for each edge $uv \in E$ with $u \in P$, we place a corresponding edge γv in Γ for the component γ containing u. The $O(m)$ edges of Γ are stored in a dictionary [8]. (For example, a balanced search tree can support updates and lookups in $O(\log n)$ time; alternatively, hashing can support these operations in $O(1)$ randomized time.)

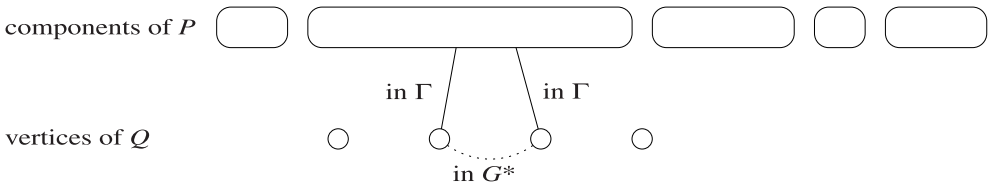

FIG. 4.1. *Overview of the data structure.*

- We precompute and store the following values:

$$C[u,v] \;=\; \text{number of components adjacent to both } u \text{ and } v \text{ in } \Gamma \tag{4.1}$$

  over all $u, v \in Q_0$. This preprocessing step takes $O(mq_0^{(\omega-1)/2} + q_0^\omega)$ time by applying Lemma 3.1 to a bipartite subgraph of Γ (with Q_0 on one side and edge multiplicities ignored).
- Finally, we maintain a small dynamic graph G^* over the vertex set Q, where for every $u, v \in Q$,

$$uv \text{ is in } G^* \text{ iff } C[u,v] > 0 \text{ or } uv \in E. \tag{4.2}$$

  (See Figure 4.1.) This graph is stored in a polylogarithmic data structure for dynamic graph connectivity. (For example, the method of Holm, de Lichtenberg, and Thorup [21] can support updates in $O(\log^2 n)$ amortized time and queries in $O(\log n / \log\log n)$ time; alternatively, Thorup's improved method [32] can support updates in $O(\log n \log^3 \log n)$ randomized amortized time and queries in $O(\log n / \log\log\log n)$ time.)

INSERTIONS/DELETIONS IN Q: To insert a vertex u to Q, we simply insert edges uv to G^* for all $v \in Q$ with $C[u,v] > 0$ or $uv \in E$. To delete u from Q, we delete all edges incident to u from G^*. For $|Q| = q$, this requires at most q edge updates to the dynamic graph connectivity structure for G^* and costs $\widetilde{O}(q)$ amortized time.

QUERIES ON $P \cup Q$: Given vertices $u, v \in P \cup Q$, we want to test whether u and v are connected in the subgraph induced by $P \cup Q$.

- EASIEST CASE: $u, v \in Q$. We can simply test whether u and v are connected in G^* in $\widetilde{O}(1)$ time by the dynamic graph connectivity structure for G^*. Correctness is evident (if there is a path connecting u and v in the subgraph induced by $P \cup Q$, then the path must alternate between some vertices of Q and some component of P, so there must be a corresponding path in G^*).
- HARDEST CASE: $u, v \in P$. Here we first find the components γ_u and γ_v containing u and v. We then find any $u' \in Q$ with $\gamma_u u' \in \Gamma$ and any $v' \in Q$ with $\gamma_v v' \in \Gamma$ by performing $O(q)$ dictionary lookups in $\widetilde{O}(q)$ time. If u' or v' does not exist, the answer is no, unless $\gamma_u = \gamma_v$. Otherwise, we can just test whether u' and v' are connected by the previous case.

The remaining cases are similar. ∎

THEOREM 4.2. *We can design a data structure to maintain a subset $S \subseteq V$ under any* offline *update sequence, where preprocessing takes $\widetilde{O}(m^{2\omega/(\omega+1)}) = O(m^{1.41})$ time, updates to S take $\widetilde{O}(m^{2(\omega-1)/(\omega+1)}) = O(m^{0.82})$ amortized time, and connectivity queries on the subgraph induced by S take $\widetilde{O}(m^{2/(\omega+1)}) = O(m^{0.60})$ time.*

Proof. At the beginning of each block of q_0 updates, we set Q_0 to be the vertices involved in the coming q_0 updates, set $P = S \setminus Q_0$, set $Q = S \cap Q_0$, and rebuild the data structure from Lemma 4.1. Updates to S are applied to Q, with amortized cost

$$\widetilde{O}\left(\frac{mq_0^{(\omega-1)/2} + q_0^{\omega}}{q_0} + q_0\right),$$

which is asymptotically minimized by setting $q_0 = m^{2/(\omega+1)}$. Queries can be answered in $\widetilde{O}(q_0)$ time, since $S = P \cup Q$ at all times. ∎

5. A semi-online solution. It is perhaps not surprising that an offline problem can be solved more quickly by batching and performing fast matrix multiplication. It is interesting, however, that with more effort a similar strategy can lead to a fully dynamic solution to our problem. Although we cannot predict which vertices are about to be inserted in advance, we can concentrate preprocessing on vertices of high degrees, since these vertices are the costly ones. To obtain a sublinear bound, we now have to rebuild the data structure more frequently, as the setting of parameters becomes more delicate.

Before describing the fully dynamic algorithm, we consider the semi-online case [10], where we are told when a vertex will next be deleted at the time it is inserted. Because of the extra information, we can force all deletions to occur in the small subset Q, thereby ensuring that P is static (see [6] for more examples of this kind of dynamization).

LEMMA 5.1. *Given a subset $P \subseteq V$ and a parameter $q_0 \leq m$, we can design a data structure to maintain a subset $Q \subseteq V$ of size $q \leq q_0$, where preprocessing takes $\widetilde{O}(mq_0^{(\omega-1)/2} + q_0^{\omega})$ time, updates to Q take $\widetilde{O}(mq/q_0)$ amortized time, and connectivity queries on the subgraph induced by $P \cup Q$ take $\widetilde{O}(q)$ time.*

Proof. Set Q_0 to contain all vertices in V of degree $> m/q_0$ in Γ. Then $|Q_0| = O(q_0)$. As in the proof of Lemma 4.1, we form the same bipartite multigraph Γ and precompute the same values $C[u, v]$ (as defined by (4.1)) for all $u, v \in Q_0$. In addition, we now maintain $C[u, v]$ for all $u, v \in Q$ as well, in order to keep track of the graph G^* over the vertex set Q (as defined by (4.2)). Preprocessing time is still $O(mq_0^{(\omega-1)/2} + q_0^{\omega})$, and queries can be answered in the same way in $\widetilde{O}(q)$ time.

INSERTIONS/DELETIONS IN Q: Deletions are as before. Insertions are more involved, because Q is not necessarily a subset of Q_0, so new entries of $C[\cdot, \cdot]$ need to be computed. To insert a vertex u into Q, consider two cases.

- CASE 1: $u \notin Q_0$; i.e., u has degree $\leq m/q_0$ in Γ. For each $v \in Q$, we can compute $C[u, v]$ by going through each of the $O(m/q_0)$ different components γ adjacent to u in Γ and testing whether $\gamma v \in \Gamma$ in $\widetilde{O}(1)$ time via a dictionary lookup. The total time of this step is $\widetilde{O}(qm/q_0)$.
- CASE 2: $u \in Q_0$. For each $v \in Q_0$, $C[u, v]$ has already been precomputed. For each $v \in Q \setminus Q_0$, since v has degree $\leq m/q_0$ in Γ, we can compute $C[u, v]$ by going through each of the $O(m/q_0)$ different components γ adjacent to v in Γ and testing whether $\gamma u \in \Gamma$ in $\widetilde{O}(1)$ time via a dictionary lookup. The total time in this case is also $\widetilde{O}(qm/q_0)$.

We can now maintain the graph G^*, as in the proof of Lemma 4.1, by at most q edge updates to the dynamic graph connectivity structure, in additional $\widetilde{O}(q)$ time. ∎

THEOREM 5.2. *We can design a data structure to maintain a subset $S \subseteq V$ under any* semi-online *update sequence, where preprocessing takes $\widetilde{O}(m^{2\omega/(\omega+1)}) = O(m^{1.41})$ time, updates to S take $\widetilde{O}(m^{(3\omega-1)/(2\omega+2)}) = O(m^{0.91})$ amortized time, and connectivity queries on the subgraph induced by S take $\widetilde{O}(m^{1/2})$ time.*

Proof. At the beginning of each block of q updates, we set Q to contain the vertices in S with the q smallest deletion times, set $P = S \setminus Q$, and rebuild the data structure from Lemma 5.1. Each insertion in S is applied to Q with $|Q| \le 2q$ at all times, and deletions in S can occur to Q only. The amortized update cost is

$$\widetilde{O}\left(\frac{mq_0^{(\omega-1)/2} + q_0^{\omega}}{q} + \frac{mq}{q_0}\right),$$

which is asymptotically minimized by setting $q_0 = m^{2/(\omega+1)}$ and $q = m^{1/2}$. ∎

6. A fully dynamic solution. In the fully dynamic problem, we have no control on future deletions, so the subset P can no longer remain static. However, since P undergoes deletions only, we can bring in amortization techniques (see [5] for a similar, geometric example). Deletions cause splitting of components, and a standard idea is to always split the smaller set from the larger set. Remarkably, the matrix-multiplication output can be updated efficiently during this process, due to the linear dependence on m in Lemma 3.1.

LEMMA 6.1. *We can make the data structure in Lemma* 5.1 *support an additional operation: deletion in P. The total cost of ℓ such deletions is bounded by $\widetilde{O}(mq_0^{(\omega-1)/2} + \ell q_0^{\omega})$.*

Proof. The data structure is the same as in the proof of Lemma 5.1 but with one additional ingredient: To maintain the connected components of P, we store the subgraph induced by P in a decremental graph connectivity data structure [17, 31, 32]; the total maintenance cost over a sequence of deletions is $\widetilde{O}(m)$. Note that such a structure can handle auxiliary operations, such as reporting the size of a component or enumerating the vertices of a component. Insertions and deletions in Q are done exactly as in the proof of Lemma 5.1; it remains to describe how to perform deletions in P.

DELETIONS IN P: To delete a vertex w from P, we find the component γ containing w and observe how γ is split into several components $\gamma_1, \ldots, \gamma_k$ from the decremental graph connectivity structure. Without loss of generality, suppose that γ_1 has the largest size. Note that each γ_i $(i = 2, \ldots, k)$ has at most half the size of γ. Let m' be the sum of the degrees over all vertices of $\{w\} \cup \gamma_2 \cup \cdots \cup \gamma_k$ in G. (See Figure 6.1.)

Both Γ and $C[\cdot, \cdot]$ change as a result of the split.

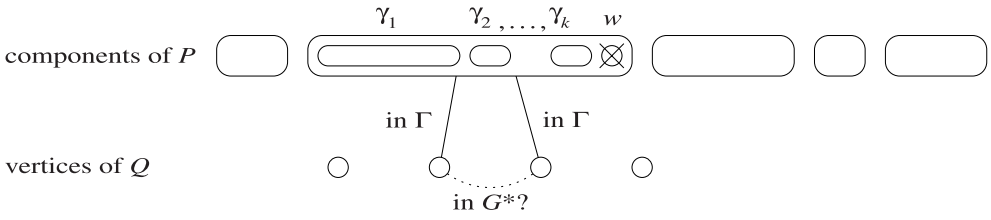

FIG. 6.1. *Making the data structure fully dynamic.*

- To update the multigraph Γ, we perform the following steps: For each edge $uv \in E$ with $u \in \gamma_i$ $(i = 2, \ldots, k)$, we insert a copy of $\gamma_i v$ and remove a copy of γv. For each $wv \in E$, we remove a copy of γv. Finally, we remove $\{w\} \cup \gamma_2 \cup \cdots \cup \gamma_k$ from γ so that γ becomes γ_1. These steps require $O(m')$ dictionary updates and take $\widetilde{O}(m')$ time.
- To update the $C[\cdot, \cdot]$ values, we perform the following steps: For each $(u, v) \in (Q_0 \times Q_0) \cup (Q \times Q)$, if $\gamma u, \gamma v \in \Gamma$ before, we decrement $C[u, v]$. For each $(u, v) \in (Q_0 \times Q_0) \cup (Q \times Q)$, if $\gamma_1 u, \gamma_1 v \in \Gamma$, we increment $C[u, v]$. These steps require $O(q^2)$ dictionary lookups and take $\widetilde{O}(q_0^2)$ time. Finally, for each $(u, v) \in (Q_0 \times Q_0) \cup (Q \times Q)$, we add to $C[u, v]$ the number of components from $\{\gamma_2, \ldots, \gamma_k\}$ adjacent to both u and v in Γ. These numbers can be computed in $O(m' q_0^{(\omega-1)/2} + q_0^\omega)$ total time by applying Lemma 3.1 to a bipartite subgraph of Γ with $O(m')$ edges (with $\gamma_2, \ldots, \gamma_k$ on one side and Q_0 or Q on the other).

We can now rebuild the graph G^* from scratch (according to the definition (4.2)) in time $O(q^2)$, which is absorbed by the other cost.

We can account for the $O(m' q_0^{(\omega-1)/2} + q_0^\omega)$ cost by charging $O(\deg(v) q_0^{(\omega-1)/2})$ units to each vertex $v \in \{w\} \cup \gamma_2 \cup \cdots \cup \gamma_k$ and charging $O(q_0^\omega)$ units to the deletion operation itself. Here $\deg(v)$ denotes the degree of v in G. Each vertex v is charged at most $O(\log n)$ times overall, since each time v is charged, the component containing v shrinks at least by a factor of two in size (and components never expand, as P undergoes only deletions). Therefore, the total cost charged to vertices is bounded by $O(\sum_{v \in V} \deg(v) q_0^{(\omega-1)/2} \log n) = \widetilde{O}(m q_0^{(\omega-1)/2})$. The total cost charged to the deletion operations is $O(\ell q_0^\omega)$. ∎

THEOREM 6.2. *We can design a data structure to maintain a subset $S \subseteq V$ under any* online *update sequence, where preprocessing takes $\widetilde{O}(m^{(5\omega+1)/(3\omega+3)}) = O(m^{1.28})$ amortized time, updates to S take $\widetilde{O}(m^{4\omega/(3\omega+3)}) = O(m^{0.94})$ amortized time, and connectivity queries on the subgraph induced by S take $\widetilde{O}(m^{1/3})$ time.*

Proof. At the beginning of each block of q updates, we set $P = S$, set $Q = \emptyset$, and rebuild the data structure from Lemma 6.1. Insertions into S are applied to Q, with $|Q| \le q$ at all times, but deletions can occur to both P and Q. The amortized update cost is

$$\widetilde{O}\left(\frac{m q_0^{(\omega-1)/2} + q q_0^\omega}{q} + \frac{mq}{q_0}\right),$$

which is asymptotically minimized by setting $q_0 = q^{4/(\omega+1)}$ and $q = m^{1/3}$. ∎

Remarks. The space requirement of the data structure is indeed $\widetilde{O}(m)$: The dynamic graph connectivity structures take $\widetilde{O}(m)$ space, the dictionary for Γ takes $O(m)$ space, and the $C[\cdot, \cdot]$ entries take $O(q_0^2)$ space, which is sublinear for the parameters chosen in the proof of Theorem 6.2.

We can obtain a query-update trade-off version of Theorem 6.2: With $\widetilde{O}(q)$ query time for any given parameter $q \le m^{1/3}$, the amortized update time is $\widetilde{O}(m/q^{(3-\omega)/(\omega+1)}) = \widetilde{O}(m/q^{0.18})$.

Edge updates are indeed less difficult than vertex updates: For example, to insert a new edge vw into E, we can create a new dummy vertex u joined to v and w and then insert u into S (i.e., Q). In the proof of Lemma 5.1, since u has degree 2 only, we can update Γ in $\widetilde{O}(1)$ time and follow Case 1 to update $C[\cdot, \cdot]$ in less than $\widetilde{O}(q_0 m/q)$ time (note that Q_0 does not change). Later, to delete the edge vw, we can simply

delete the dummy vertex u from S. Therefore, the cost of an edge insertion/deletion is at most the cost of a vertex insertion/deletion.

7. Discussions.

7.1. Is fast matrix multiplication necessary? Our algorithms have limited practical appeal because of the use of fast matrix multiplication (FMM). One may wonder whether FMM is essential to solve our problem. We suspect that the answer might be yes, in view of the following observations.

OBSERVATION 7.1.

1. *The problem of multiplying a $\sqrt{n} \times n$ Boolean matrix with an $n \times \sqrt{n}$ Boolean matrix with m nonzero entries can be reduced to offline dynamic subgraph connectivity on a graph with n vertices and m edges using $O(n)$ updates and queries.*

2. *The problem of detecting a triangle (a 3-cycle) in a directed graph with m edges can be reduced to offline dynamic subgraph connectivity using $O(m)$ updates and queries.*

3. *The problem of detecting a quadrilateral (a 4-cycle) in a directed graph with m edges can be reduced to offline dynamic subgraph connectivity using $O(m)$ updates and queries.*

Proof.

1. As noted essentially in section 3, an equivalent problem is the following: given a bipartite graph G with a set P of n vertices on one side and a set Q of $O(\sqrt{n})$ vertices on the other side, decide whether u and v are adjacent to a common vertex for every pair $u, v \in Q$. To solve this problem, we first put all vertices of P in the subset S. For each pair $u, v \in Q$, we insert u and v into S, test whether u and v are connected in the subgraph induced by S, and then delete u and v from S. The number of queries and vertex updates to S is $O(|Q|^2) = O(n)$.

2. Let $H = (V, E)$ be the given graph. Define an undirected graph G with vertex set $V \times \{(1, 2, 3)\}$, where we create edges $(u, 1)(v, 2)$ and $(u, 2)(v, 3)$ whenever $uv \in E$. Initially, we put all vertices of the form $(w, 2)$ in S. To detect a triangle in H, we go through each edge $(v, u) \in E$, insert $(u, 1)$ and $(v, 3)$ into S, test whether $(u, 1)$ and $(v, 3)$ are connected, and then delete $(u, 1)$ and $(v, 3)$ from S. The answer is yes iff one of the tests returns true.

3. Define G as before, but with the addition of a vertex s adjacent to all vertices of the form $(u, 1)$, and another vertex t adjacent to all vertices of the form $(v, 3)$. Initially, we put s and t in S, along with all vertices of the form $(w, 2)$. To detect a quadrilateral in H, we go through each vertex $z \in V$, insert all vertices into the subsets $A = \{(u, 1) \mid (z, u) \in E\}$ and $B = \{(v, 3) \mid (v, z) \in E\}$ to S, test whether s and t are connected, and then delete all vertices in A and B from S. The answer is yes iff one of the tests returns true (if s and t are connected, there is a length-2 path from A to B, yielding a quadrilateral through z). The number of vertex updates to S is $O(\sum_{z \in V} \deg(z)) = O(m)$. ∎

For the first problem, the best bound we know that does not use FMM is $O(m\sqrt{n})$ (by Lemma 3.1 with $\omega = 3$). So, it is unlikely that offline dynamic subgraph connectivity can be solved in $o(n^{1/2})$ time without some kind of FMM (though this does not rule out the possibility of a sublinear bound without FMM). For the second and third problem, the best algorithms known for sparse graphs, due to Alon, Yuster, and Zwick [4] and Yuster and Zwick [33], both require FMM and run in time $O(m^{2\omega/(\omega+1)}) = O(m^{1.41})$ and (a little less than) $O(m^{(4\omega-1)/(2\omega+1)}) = O(m^{1.48})$, respectively.

7.2. Is the graph problem necessary? The problem we start with is geometric, but the solution we give is mostly graph-theoretic. One may wonder whether this is the right approach. For $d = 3$, the answer is yes, as shown below.

OBSERVATION 7.2. *The dynamic subgraph connectivity problem can be reduced to the dynamic box connectivity problem in* $\mathbb{R}^3$.

Proof. We use only orthogonal segments (degenerate boxes) in $\mathbb{R}^3$: For each vertex i of the given graph, construct a line ℓ_i from $(i, -\infty, 0)$ to $(i, \infty, 0)$. For the kth edge ij, create a path π_k of three segments through the points $(i, k, 0), (i, k, 1), (j, k, 1), (j, k, 0)$. Then i and j are connected iff ℓ_i and ℓ_j are connected. Inserting/deleting a vertex i in S corresponds to inserting/deleting ℓ_i. Inserting/deleting an edge in E corresponds to inserting/deleting a π_k. □

Thus, by Theorem 2.2, subgraph connectivity is *equivalent* to box connectivity in three dimensions, up to polylogarithmic factors. In particular, box connectivity in any fixed dimension ≥ 3 is equally difficult, up to polylogarithmic factors. It is intriguing to contemplate whether one can exploit the geometry of the rectangular connectivity problem to get a faster algorithm for $d = 2$ (perhaps without FMM).

7.3. Global connectivity? On a final note, we have purposely defined connectivity queries as just deciding whether two points, or two vertices, are connected. One may wonder about other kinds of connectivity queries; for example, "Is the union of the boxes connected?", or "Is the subgraph induced by S connected?"

Obtaining nontrivial results for such queries appears difficult, even in the offline setting. A major obstacle appears to be the following dynamic set union problem: Given a collection $\mathcal{C}$ of n subsets of U, of total size m, maintain a subcollection $\mathcal{S} \subseteq \mathcal{C}$ under insertions and deletions of subsets to answer the following query: "Is the union of $\mathcal{S}$ equal to U?"

ON THE NUMBER OF CROSSING-FREE MATCHINGS, CYCLES, AND PARTITIONS*

MICHA SHARIR† AND EMO WELZL‡

Abstract. We show that a set of n points in the plane has at most $O(10.05^n)$ perfect matchings with crossing-free straight-line embedding. The expected number of perfect crossing-free matchings of a set of n points drawn independently and identically distributed from an arbitrary distribution in the plane is at most $O(9.24^n)$. Several related bounds are derived: (a) The number of all (not necessarily perfect) crossing-free matchings is at most $O(10.43^n)$. (b) The number of *red-blue* perfect crossing-free matchings (where the points are colored red or blue and each edge of the matching must connect a red point with a blue point) is at most $O(7.61^n)$. (c) The number of *left-right* perfect crossing-free matchings (where the points are designated as left or right endpoints of the matching edges) is at most $O(5.38^n)$. (d) The number of perfect crossing-free matchings across a line (where all the matching edges must cross a fixed halving line of the set) is at most 4^n. These bounds are employed to infer that a set of n points in the plane has at most $O(86.81^n)$ crossing-free spanning cycles (simple polygonizations) and at most $O(12.24^n)$ crossing-free partitions (these are partitions of the point set so that the convex hulls of the individual parts are pairwise disjoint). We also derive lower bounds for some of these quantities.

Key words. crossing-free geometric graphs, counting, simple polygonizations, crossing-free matchings, crossing-free partitions

1. Introduction.

Let P be a set of n points in the plane. A *geometric graph* on P is a graph that has P as its vertex set and whose edges are drawn as straight segments connecting the corresponding pairs of points. The graph is *crossing-free* if no pair of its edges cross each other; i.e., any two edges are not allowed to share any points other than common endpoints. Therefore, these are planar graphs with a plane embedding given by this specific drawing. We are interested in the number of crossing-free geometric graphs on P of several special types; see, e.g., Figure 1. Specifically, we consider the numbers $\mathsf{tr}(P)$ of *triangulations* (i.e., maximal crossing-free graphs), $\mathsf{pm}(P)$ of crossing-free *perfect matchings*, $\mathsf{sc}(P)$ of crossing-free *spanning cycles*, and $\mathsf{cfp}(P)$ of *crossing-free partitions*[1] (these are partitions of P so that the convex hulls of the individual parts are pairwise disjoint). We are primarily concerned with upper bounds for the numbers listed above in terms of n.

[1]Our research was triggered by Marc van Kreveld asking about the number of crossing-free partitions (see [10] for a motivation from geographic information systems) and, in the same week, by Michael Hoffmann and Yoshio Okamoto asking about the number of crossing-free spanning paths of a point set (motivated by their quest for good fixed parameter algorithms for the planar Euclidean traveling salesman problem in the presence of a fixed number of inner points [14]); see also [23].

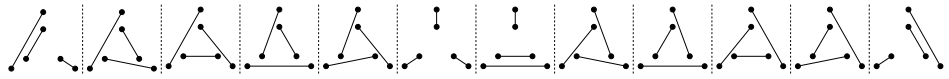

FIG. 1. 6 *points with* 12 *crossing-free perfect matchings, the maximum possible number. See* [3] *for the maximum numbers for up to* 10 *points:* 3 *for* 4 *points,* 12 *for* 6, 56 *for* 8, *and* 311 *for* 10.

History. This problem goes back to Newborn and Moser [32] in 1980 who asked for the maximal possible number of crossing-free spanning cycles in a set of n points[2]—they provide an upper bound of $2 \cdot 6^{n-2} \left\lfloor \frac{n}{2} \right\rfloor !$ but conjectured that the right bound should be of the form c^n for some constant c. This fact was established in 1982 by Ajtai et al. [4], who showed[3] that there are at most 10^{13n} crossing-free graphs on n points. For motivation they mentioned—besides [32]—a question of Avis about the maximum number of triangulations a set of n points can have.

Further developments were mainly concerned with deriving progressively better upper bounds for the number of triangulations[4] [38, 17, 35], thus far culminating in a 59^n upper bound by Santos and Seidel [34] in 2003.[5] This compares to $\Omega(8.48^n)$, the largest known number of triangulations for a set of n points, recently derived by Aichholzer et al. [1]; this improves an earlier lower bound of $8^n/\mathrm{poly}(n)$ given by García, Noy, and Tejel [21]. (We let "poly(n)" denote a polynomial factor in n.)

Since every crossing-free graph is contained in some triangulation, and a triangulation has at most $3n-6$ edges, an upper bound of c^n for the number of triangulations immediately yields an upper bound of $2^{3n-6}c^n < (8c)^n$ for the number of all crossing-free graphs on a set of n points. Thus, with $c \leq 59$, this number is at most 472^n. To the best of our knowledge, *all* upper bounds derived so far on the number of crossing-free graphs of various types are derived via a bound on the number of triangulations, albeit in more refined ways.

One such approach is to exploit the fact that graphs of certain specific types have a fixed number of edges. For example, since a perfect matching has $\frac{n}{2}$ edges, we readily obtain $\mathsf{pm}(P) \leq \binom{3n-6}{n/2} \mathsf{tr}(P) < 227.98^n$ [18]. A short historical account of bounds on $\mathsf{sc}(P)$, with references including [6, 16, 21, 22, 24, 32, 33], can be found at the web site [15] (see also [12, section 8.4, Problem 8]). The best bound published so far is $3.37^n \cdot \mathsf{tr}(P) \leq 198.83^n$, which relies on a bound of 3.37^n on the number of cycles in a planar graph [7]. (In the course of our investigations, we showed that a graph with m edges and n vertices can have at most $\left(\frac{m}{n}\right)^n$ cycles; hence, a planar graph can have at most 3^n cycles. Then Seidel provided us with an argument, based on linear algebra, that a planar graph can have at most $\sqrt{6}^n < 2.45^n$ spanning cycles.)

Crossing-free partitions fit into the picture, since every such partition can be uniquely identified with the graph of edges of the convex hulls of the individual parts—these edges form a crossing-free geometric graph of at most n edges; see Figure 2.

[2]In fact, Akl's work [6] appeared earlier, but it already referred to the manuscript by Newborn and Moser, and improved a lower bound (on the maximal number of crossing-free spanning cycles) of theirs.

[3]This paper is famous for its *crossing lemma*, proved in preparation of the singly exponential bound. The lemma gives an upper bound on the number of edges a geometric graph with a given number of crossings can have.

[4]Interest was also motivated by the obviously related question (from geometric modeling [38]) of how many bits it takes to encode a triangulation of a point set.

[5]Recently, this bound was improved to 43^n in [37]. However, the bounds on spanning cycles and crossing-free partitions we derive here via matchings are still better than the bounds obtained via this new triangulation bound.

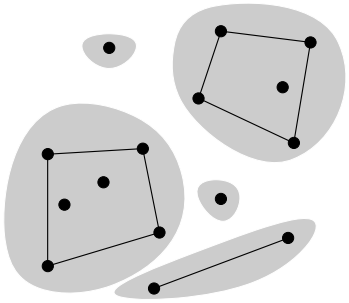

FIG. 2. *A crossing-free partition and its graph.*

The situation is better understood for special configurations, for example, for P a set of n points in convex position[6] (namely, the vertex set of a convex n-gon), where the *Catalan numbers* $C_m := \frac{1}{m+1}\binom{2m}{m} = \Theta(m^{-3/2}4^m)$, $m \in \mathbb{N}_0$, play a prominent role. In convex position $\mathsf{tr}(P) = C_{n-2}$ (the Euler–Segner problem; cf. [39, p. 212] for a discussion of its history), $\mathsf{pm}(P) = C_{n/2}$ for n even (due to [20]; cf. [39]; e.g., see Figure 3), $\mathsf{sc}(P) = 1$, and $\mathsf{cfp}(P) = C_n$ (see [9]).

Crossing-free partitions for points in convex position constitute a well-established notion because of many connections to other problems, probably starting with "planar rhyme schemes" in Becker's note [9]; cf. [39, Solution to 6.19pp]. The general case was considered by [13] (under the name of pairwise linearly separable partitions) for clustering algorithms. They show that the number of partitions into k parts is $O(n^{6k-12})$ for k constant.

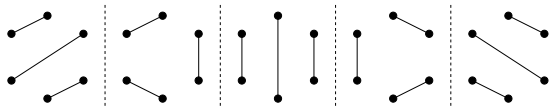

FIG. 3. *6 points in convex position with $C_3 = 5$ crossing-free perfect matchings.*

Under the assumption of *general position* (no three points on a common line) it is known [21] that the number of crossing-free perfect matchings on a set of fixed size is minimized when the set is in convex position.[7] With little surprise, the same holds for spanning cycles, but it does not hold for triangulations [2, 25, 30]. For crossing-free partitions, this is an open question.

New results. The main results of this paper are the following upper bounds for a set P of n points in the plane: $\mathsf{pm}(P) = O(10.05^n)$, $\mathsf{sc}(P) = O(86.81^n)$, and $\mathsf{cfp}(P) = O(12.24^n)$. Also, the expected number of perfect crossing-free matchings of a set of n points drawn independently and identically distributed (i.i.d.) from *any* distribution in the plane (as long as two random points coincide with probability 0) is at most $O(9.24^n)$.

The new bound on the number of crossing-free perfect matchings is derived by an inductive technique that we have adapted from the method that Santos and Seidel [34] used for triangulations (the adaption is, however, far from obvious). We then

[6] For another example, it can be shown that the number of triangulations is at most $2^{3mn-m-n}$ for an $m \times n$ grid (with $(m+1)(n+1)$ points) [5] (cf. also [26]).

[7] Recently, Aichholzer et al. [1] showed that any family of acyclic graphs has the minimal number of crossing-free embeddings on a fixed point set when the set is in convex position.

go on to derive several improved bounds on the number of crossing-free matchings of various special types. Specifically, we show the following:

(a) The number of all (not necessarily perfect) crossing-free matchings is at most $O(10.43^n)$.

(b) The number of *red-blue* perfect crossing-free matchings (where half of the points are colored red and half blue, and each edge of the matching must connect a red point with a blue point) is at most $O(7.61^n)$.

(c) The number of *left-right* perfect crossing-free matchings (where the points are designated as left or right endpoints of the matching edges) is at most $O(5.38^n)$.

(d) The number of perfect crossing-free matchings across a line (where all the matching edges must cross a fixed halving line of the set) is at most 4^n.

Finally, we derive upper bounds for the numbers of crossing-free spanning cycles and crossing-free partitions of P in terms of the number of certain types of matchings of certain point sets P' that are constructed from P. This yields the bounds $O(86.81^n)$ for the number of crossing-free cycles and $O(12.24^n)$ for the number of crossing-free partitions.

We summarize the state of affairs in Table 1, including lower bounds which we will derive in section 6, many of which use the *double-chain* configuration from [21].

TABLE 1

*Entries c in the upper bound row should be read as $O(c^n)$, and entries c in the lower bound row should be read as $\Omega(c^n/\mathrm{poly}(n))$, where $n := |P|$. "*ma*" stands for all (not necessarily perfect) crossing-free matchings, "*rbpm*" for perfect red-blue crossing-free matchings, "*lrpm*" for perfect left-right crossing-free matchings, "*alpm*" for perfect crossing-free matchings across a line, and "*rdpm*" for the expected number of perfect crossing-free matchings of a set of i.i.d. points.*

	tr	pm	sc	cfp	ma	rbpm	lrpm	alpm	rdpm
$\forall P :\leq$	59 [34]	10.05	86.81	12.24	10.43	7.61	5.38	4	9.24
$\exists P :\geq$	8.48 [1]	3 [21]	4.64 [21]	5.23	4	2.23	2	2	3

This paper shows that significantly better bounds can be derived for matchings than those known earlier for other types of graphs and, moreover, that matchings are a good basis for deriving bounds for crossing-free partitions and spanning cycles—as opposed to the situation before, where such bounds have always relied on triangulations.

2. Matchings: The setup and a recurrence. Let P be a set of n points in the plane in general position, no three on a line, no two on a vertical line. It is easy to see that this is no constraint when it comes to upper bounds on $\mathsf{pm}(P)$. A *crossing-free matching* is a collection of pairwise disjoint segments whose endpoints belong to P. Given such a matching M, each point of P is either *matched* if it is an endpoint of a segment of M, or *isolated* otherwise. The number of matched points is clearly always even. If $2m$ points are matched and s points are isolated, we call M a *crossing-free m-matching* or *(m, s)-matching*. We have $n = 2m + s$.

We denote by $\mathsf{ma}_m(P)$ the number of crossing-free matchings of P with m segments (for $m \in \mathbb{R}$—this number is clearly 0 unless $m \in \{0, 1, \ldots, \lfloor \frac{n}{2} \rfloor\}$), and by $\mathsf{ma}(P)$ the number of all crossing-free matchings of P (i.e., $\mathsf{ma}(P) = \sum_m \mathsf{ma}_m(P)$). Recall that $\mathsf{pm}(P) = \mathsf{ma}_{n/2}(P)$.

Let M be a crossing-free (m, s)-matching on a set P of $n = 2m + s$ points, as above. The *degree* $d(p)$ of a point $p \in P$ in M is defined as follows. It is 0 if p is isolated in M. Otherwise, if p is a left (resp., right) endpoint of a segment of M, $d(p)$ is equal to the number of visible left (resp., right) endpoints of other segments of M,

plus the number of visible isolated points; "*visible*" means *vertically* visible from the *relative interior* of the segment of M that has p as an endpoint. Thus p and the other endpoint of the segment are not counted in $d(p)$. See Figure 4 for an illustration.

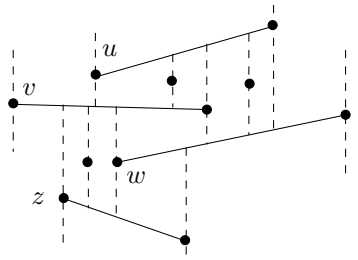

FIG. 4. *Degrees in a matching:* $d(u) = 2$, $d(v) = 5$, $d(w) = 1$, $d(z) = 2$.

Each left (resp., right) endpoint u in M can contribute at most 2 to the degrees of other points: 1 to each of the left (resp., right) endpoints of the segments lying vertically above and below u if there exist such segments. Similarly, each isolated point u can contribute at most 4 to the degrees of other points: 1 to each of the endpoints of the segments lying vertically above and below u. It follows that

$$\sum_{p\in P} d(p) \le 4m + 4s.$$

There are many segments ready for removal. The idea is to remove segments incident to points of low degree in an (m, s)-matching (points of degree at most 3 or at most 4, to be specific). We will show that there are many such points at our disposal. Then, in the next step, we will show that segments with an endpoint of low degree can be reinserted in not very many ways. These two facts will be combined to derive a recurrence for the matching count.

For each integer $i \in \mathbb{N}_0$, let $v_i = v_i(M)$ denote the number of *matched* points of P with degree i in M. Hence, $\sum_{i\ge 0} v_i = 2m$.

LEMMA 2.1. *Let $n, m, s \in \mathbb{N}_0$, with $n = 2m + s$. In every (m, s)-matching of any set of n points, we have*

$$2n \le 4v_0 + 3v_1 + 2v_2 + v_3 + 6s, \tag{1}$$

$$3n \le 5v_0 + 4v_1 + 3v_2 + 2v_3 + v_4 + 7s. \tag{2}$$

Proof. Let P be the underlying point set. We have

$$\sum_{i\ge 0} i\, v_i = \sum_{p\in P} d(p) \le 4s + 4m = 4s + \sum_{i\ge 0} 2v_i.$$

Therefore, $0 \le 4s + \sum_{i\ge 0}(2 - i)v_i$. For $\kappa \in \mathbb{R}^+$, we add κ times $n = s + \sum_{i\ge 0} v_i$ to both sides to get

$$\kappa n \le (4 + \kappa)s + \sum_{i\ge 0}(2 + \kappa - i)v_i \le (4 + \kappa)s + \sum_{0\le i<2+\kappa} (2 + \kappa - i)v_i. \tag{3}$$

We specialize[8] to $\kappa = 2$ for assertion (1) and $\kappa = 3$ for (2). □

[8] We list here explicitly the two values that lead to the best results in the further derivations, although at this point it clearly looks rather arbitrary.

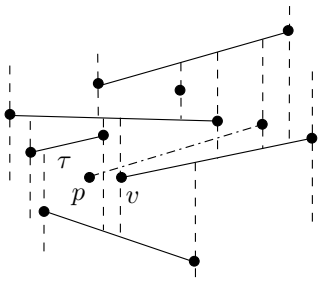

FIG. 5. *Inserting a segment at p; $d(p) = 1$ after insertion.*

There are not very many ways of inserting a segment. Fix some $p \in P$ and let M be a crossing-free matching which leaves p isolated. Now we match p with some other isolated point such that the overall matching continues to be crossing-free. For $i \in \mathbb{N}_0$, let $h_i = h_i(p, P, M)$ be the number of ways this can be done so that p has degree i after its insertion.

LEMMA 2.2.

$$4h_0 + 3h_1 + 2h_2 + h_3 \leq 24, \tag{4}$$

$$5h_0 + 4h_1 + 3h_2 + 2h_3 + h_4 \leq 48. \tag{5}$$

Proof. Let $\ell_i = \ell_i(p, P, M)$ be the number of ways we can match the point p as a left endpoint of degree i. First, we claim that $\ell_0 \in \{0, 1\}$.

To show this, form the *vertical decomposition* of M by drawing a vertical segment up and down from each (matched or isolated) point of $P \setminus \{p\}$ and extend these segments until they meet an edge of M or else, all the way to infinity; see Figure 5 for an illustration of such a decomposition. We call these vertical segments *walls* in order to distinguish them from the segments in the matching.

We obtain a decomposition of the plane into vertical trapezoids. Let τ be the trapezoid containing p (assuming general position, p lies in the interior of τ). See Figure 5.

We move from τ to the right through vertical walls to adjacent trapezoids until we reach a vertical wall that is determined by a point v that is either a left endpoint or an isolated point (if at all—we may make our way to infinity when p cannot be matched as a left endpoint to any point, in which case $\ell_i = 0$ for all i).

Note that up to that point there was always a unique choice for the next trapezoid to enter. Every crossing-free segment with p as its left endpoint will have to go through all of these trapezoids. It connects either to v (which *can* happen only if v is isolated) or crosses the vertical wall up or down from v. The former case yields a segment that gives p degree 0. In the latter case, v will contribute 1 to the degree of p. So pv, if an option, is the only possible segment that lets p have degree 0 as a left endpoint. (pv will not be an option when it crosses some segment or when v is a left endpoint.)

We will return to this setup when we consider degrees ≥ 1, in which case v acts as a *bifurcation point*. Before doing so, we first introduce a function f. It maps every nonnegative real vector $(\lambda_0, \lambda_1, \ldots, \lambda_k)$ of arbitrary length $k+1 \in \mathbb{N}$ to the maximum possible value[9] the expression

$$\lambda_0\ell_0 + \lambda_1\ell_1 + \cdots + \lambda_k\ell_k \tag{6}$$

[9] A priori, this value could be infinite.

can attain (for any isolated point in any matching of any finite point set *of any size*). We have already shown that $f(\lambda) \leq \lambda$ for $\lambda \in \mathbb{R}_0^+$. We claim that for all $(\lambda_0, \lambda_1, \ldots, \lambda_k) \in (\mathbb{R}_0^+)^{k+1}$, with $k \geq 1$, we have

$$f(\lambda_0, \lambda_1, \ldots, \lambda_k) \;\leq\; \max\{\lambda_0 + f(\lambda_1, \ldots, \lambda_k),\; 2f(\lambda_1, \ldots, \lambda_k)\}. \tag{7}$$

Assuming (7) has been established, we can conclude that $f(1) \leq 1$, $f(2,1) \leq 3$, $f(3,2,1) \leq 6$, and $f(4,3,2,1) \leq 12$; that is,[10] $4\ell_0 + 3\ell_1 + 2\ell_2 + \ell_3 \leq 12$ and the first inequality of the lemma follows, since the same bound clearly holds for the case when p is a right endpoint. The second inequality follows similarly from $f(5,4,3,2,1) \leq 24$.

So it remains to prove (7). Consider a constellation with a point p that realizes the value of $f(\lambda_0, \lambda_1, \ldots, \lambda_k)$. We return to the setup considered above, where we have traced a unique sequence of trapezoids from p to the right, till we encountered the first bifurcation point v (if v does not exist, then all ℓ_i vanish).

Case 1. *v is isolated.* We know that $\lambda_0\ell_0 \leq \lambda_0$. If we remove v from the point set, then every possible crossing-free segment emanating from p to its right has its degree decreased by 1. Therefore, $\lambda_1\ell_1 + \cdots + \lambda_k\ell_k \;\leq\; f(\lambda_1, \ldots, \lambda_k)$, so the expression (6) cannot exceed $\lambda_0 + f(\lambda_1, \ldots, \lambda_k)$ in this case.

Case 2. *v is a matched left endpoint.* Then $\lambda_0\ell_0 = 0$ (that is, we cannot connect p to v). Possible crossing-free segments with p as a left endpoint are discriminated according to whether they pass above or below v. We first concentrate on the segments that pass above v; we call them *relevant segments* (emanating from p). Let ℓ_i' be the number of relevant segments that give p degree i. We carefully remove isolated points from $P \setminus \{p\}$ and segments with their endpoints from the matching M (eventually also the segment of which v is a left endpoint), so that in the end all relevant segments are still available and each one, if inserted, makes the degree of p exactly 1 unit smaller than its original value (this deletion process may create new possibilities for segments from p). That will show $\lambda_1\ell_1' + \cdots + \lambda_k\ell_k' \;\leq\; f(\lambda_1, \ldots, \lambda_k)$. The same will apply to segments that pass below v, using a symmetric argument, which gives the bound of $2f(\lambda_1, \ldots, \lambda_k)$ for (6) in this second case.

The removal process is performed as follows. We define a relation $\prec$ on the set whose elements are the edges of M and the singleton sets formed by the isolated points of $P \setminus \{p\}$: $a \prec b$ if a point $a' \in a$ is vertically visible from a point $b' \in b$, with a' below b'. As is well known (cf. [19, Lemma 11.4]), $\prec$ is acyclic. Let $\prec^+$ denote the transitive closure of $\prec$, and let $\prec^*$ denote the transitive reflexive closure of $\prec$.

Let e be the segment with v as its left endpoint, and consider a minimal element a with $a \prec^+ e$. Such an element exists, unless e itself is a minimal element with respect to $\prec$.

a is a singleton: Thus it consists of an isolated point; with abuse of notation we also denote by a the isolated point itself. a cannot be a point to which p can connect with a relevant edge. Indeed, if this were the case, we add that edge $e' = pa$ and modify $\prec$ to include e' too; more precisely, any pair in $\prec$ that involves a is replaced by a corresponding pair involving e', and new pairs involving e' are added (clearly, the relation remains acyclic and all pairs related under $\prec^+$ continue to be so related after e' is included and replaces a). See Figure 6(a). We have $e \prec e'$ (since, by assumption, the left endpoint v of e is vertically visible below e') and $e' \prec^+ e$ (since

[10] Note that $\ell_i \leq 2^i$ for each $i \geq 0$ (which can be shown to be tight); this only yields a bound of 26 for the linear combination in question. Moreover, $\sum_{i=0}^{k} \ell_i \leq 2^k$ (which again is tight), but this only improves the bound to 15, still short of what we need.

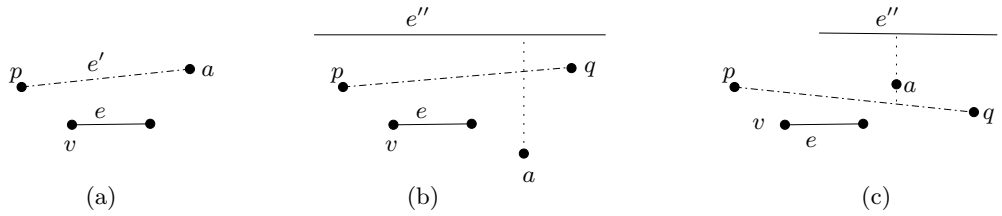

FIG. 6. (a) *The point a cannot be connected to p via a relevant edge.* (b), (c) *a cannot contribute from below (in* (b)*) or from above (in* (c)*) to the degree of p when a relevant edge pq is inserted.*

the right endpoint a of e' satisfies $a \prec^+ e$)—a contradiction. With a similar reasoning we can rule out the possibility that a contributes to the degree of p when matched via a relevant edge pq. Indeed, if this is the case, let e'' be the segment directly above a, which is the first link in the chain that gives $a \prec^+ e$; i.e., $a \prec e'' \prec^* e$ (e'' must exist since $a \prec^+ e$). After adding pq with a contributing to its degree, we have either $a \prec pq$ and $pq \prec e''$ (see Figure 6(b)) or we have $pq \prec a$ (see Figure 6(c)). In the former case, we have $a \prec pq \prec e'' \prec^* e \prec pq$, contradicting the acyclicity of $\prec$. In the latter case, we have $pq \prec a \prec^+ e \prec pq$, again a contradiction. So if we remove a, then all relevant edges from p remain in the game and the degree of each of them (i.e., the degree of p that the edge induces when inserted) does not change.

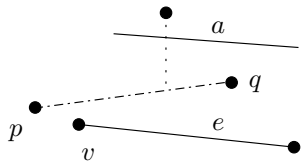

FIG. 7. *Edge a cannot obstruct a point from contributing from above to the degree of p when a relevant edge pq is inserted.*

a is an edge: It cannot obstruct any isolated point or left endpoint below it from contributing to the degree of a relevant edge pq above v (because a is minimal with respect to $\prec$). If a obstructs a contribution to a relevant edge pq from above, then we add pq; thus $pq \prec a$, which, together with $a \prec^+ e$ and $e \prec pq$, contradicts the acyclicity of $\prec$. See Figure 7. Again, we can remove a without any changes to relevant possible edges from p.

We keep successively removing elements until e is minimal with respect to $\prec$. Note that so far all the relevant edges from p are still possible, and the degree of p that any of them induces when inserted has not changed.

Now we remove e with its endpoints. This cannot clear the way for any new contribution to the degree of a relevant edge. In fact, any such degree decreases by exactly 1 because v disappears. The claim is shown, and the proof of the lemma is completed. ∎

Deriving a recurrence.

LEMMA 2.3. *Let $n, m \in \mathbb{N}_0$, such that $m \le \frac{n}{2}$ and $s := n - 2m$. For every set P of n points, we have*

$$\mathsf{ma}_m(P) \le \begin{cases} \frac{12(s+2)}{n-3s}\,\mathsf{ma}_{m-1}(P) & \text{if } s < \frac{n}{3}, \\ \frac{16(s+2)}{n-7s/3}\,\mathsf{ma}_{m-1}(P) & \text{if } s < \frac{3n}{7}. \end{cases}$$

Let us note right away that the first inequality supersedes the second for $s < \frac{n}{5}$ (i.e., $m > \frac{2n}{5}$), while the second one is superior for $s > \frac{n}{5}$.

Proof. Fix the set P, and let $\mathcal{X}$ and $\mathcal{Y}$ be the sets of all crossing-free m-matchings and $(m-1)$-matchings, respectively, in P.

Let us concentrate on the first inequality. We define an edge-labeled bipartite graph $\mathcal{G}$ on $\mathcal{X} \dot\cup \mathcal{Y}$ as follows: Given an m-matching M, if p is an endpoint of a segment $e \in M$ and $d(p) \le 3$, then we connect $M \in \mathcal{X}$ to the $(m-1)$-matching $M \setminus \{e\} \in \mathcal{Y}$ with an edge labeled $(p, d(p))$; $d(p)$ is the *degree label* of the edge. Note that M and $M \setminus \{e\}$ can be connected by two (differently labeled) edges if both endpoints of e have degree at most 3.

For $0 \le i \le 3$, let x_i denote the number of edges in $\mathcal{G}$ with degree label i. We have

$$(2n-6s)\ \underbrace{|\mathcal{X}|}_{\mathsf{ma}_m(P)}\ \le\ 4x_0+3x_1+2x_2+x_3\ \le\ 24(s+2)\ \underbrace{|\mathcal{Y}|}_{\mathsf{ma}_{m-1}(P)}\ .$$

The first inequality is a consequence of inequality (1) of Lemma 2.1. The second inequality is implied by inequality (4) in Lemma 2.2, as follows. For a fixed $(m-1)$-matching M' in P, consider an edge of $\mathcal{G}$ that is incident to M' and is labeled by (p, i) (if there is such an edge). Then p must be one of the $s+2$ isolated points of P (with respect to M'), and there is a way to connect p to another isolated point in a crossing-free manner so that p has degree i in the new matching. Hence, the contribution by p and M' to the sum $4x_0+3x_1+2x_2+x_3$ is at most 24 by inequality (4) in Lemma 2.2, and the right inequality follows. The combination of both inequalities yields the second inequality in (8).

By considering endpoints up to degree 4 (instead of 3), we get the second inequality in an analogous fashion (with the help of inequality (2) in Lemma 2.1 and inequality (5) in Lemma 2.2). ∎

For $m, n \in \mathbb{N}_0$, let $\mathsf{ma}_m(n)$ denote the maximum number of crossing-free m-matchings a set of n points can have.

LEMMA 2.4. *Let $s, m, n \in \mathbb{N}_0$, with $n = 2m + s$. We have*

$$\mathsf{ma}_0(0) = 1,$$
$$\mathsf{ma}_m(n) \le \begin{cases} \frac{n}{s}\,\mathsf{ma}_m(n-1) & \text{for } s \ge 1, \\ \frac{12(s+2)}{n-3s}\,\mathsf{ma}_{m-1}(n) & \text{for } s < \frac{n}{3}, \\ \frac{16(s+2)}{n-7s/3}\,\mathsf{ma}_{m-1}(n) & \text{for } s < \frac{3n}{7}. \end{cases} \tag{8}$$

Proof. $\mathsf{ma}_0(0) = 1$ is trivial.

The first of the three inequalities in (8) is implied by

$$s \cdot \mathsf{ma}_m(P) = \sum_{p \in P} \mathsf{ma}_m(P \setminus \{p\}) \le n \cdot \mathsf{ma}_m(n-1)$$

for any set P of n points. The second and third inequalities follow from Lemma 2.3. ∎

3. Solving a recurrence. We derive an upper bound for a function

$$G \equiv G_{\lambda,\mu} :\ \mathbb{N}_0^2 \to \mathbb{R}^+$$

for a pair of parameters $\lambda, \mu \in \mathbb{R}^+$, $\mu \geq 1$, which satisfies

$$G(0,0) = 1,$$
$$G(m,n) \leq \begin{cases} \frac{n}{s}\, G(m, n-1) & \text{for } s \geq 1, \\ \frac{\lambda(s+2)}{n-\mu s}\, G(m-1, n) & \text{for } s < \frac{n}{\mu}, \end{cases} \tag{9}$$

with the convention $s := n - 2m$.

The recurrence in (8) implies that an upper bound on $G_{12,3}(m,n)$ also serves as an upper bound for $\mathsf{ma}_m(n)$, and the same holds for $G_{16,7/3}(m,n)$. We will see how to best combine the two parameter pairs to obtain even better bounds for $\mathsf{ma}_m(n)$. Later, we will encounter other instances of this recurrence, with other values of λ and μ.

We normalize by dividing by $\lambda^m \mu^{n-m}$. Then (9) becomes

$$\frac{G(m,n)}{\lambda^m \mu^{n-m}} \leq \begin{cases} \frac{n}{\mu s}, \frac{G(m,n-1)}{\lambda^m \mu^{n-1-m}} & \text{for } s \geq 1, \\ \frac{\mu(s+2)}{n-\mu s}\, \frac{G(m-1,n)}{\lambda^{m-1} \mu^{n-m+1}} & \text{for } s < \frac{n}{\mu}. \end{cases}$$

We set $H(m,n) = H_\mu(m,n) := \frac{G(m,n)}{\lambda^m \mu^{n-m}}$. Therefore, still with the convention $s := n - 2m$ and the assumption $\mu \geq 1$, we have

$$H(0,0) = 1,$$
$$H(m,n) \leq \begin{cases} \frac{n}{\mu s}\, H(m, n-1) & \text{for } s \geq 1, \\ \frac{\mu(s+2)}{n-\mu s}\, H(m-1, n) & \text{for } s < \frac{n}{\mu}. \end{cases} \tag{10}$$

We note that this recurrence depends only on μ.

LEMMA 3.1. *Let $m, n \in \mathbb{N}_0$, with $m \leq \frac{n}{2}$. Then $H(m,n) \leq \binom{n}{m}$.*

Proof. $H(0,0) = 1 \leq \binom{0}{0}$ forms the basis of a proof by induction on n and m. For all $n \in \mathbb{N}_0$, $H(0,n) \leq \mu^{-n} \leq 1 = \binom{n}{0}$ follows, since $\mu \geq 1$.

Let $1 \leq m \leq \frac{n}{2}$. If $m \leq n - \mu s$, then $s \leq \frac{n-m}{\mu} < \frac{n}{\mu}$. Hence, the second inequality in (10) can be applied, after which the first inequality can be applied. Hence,

$$\begin{aligned} H(m,n) &\leq \frac{\mu(s+2)}{n-\mu s}\, H(m-1,n) \\ &\leq \frac{\mu(s+2)}{n-\mu s}\, \frac{n}{\mu(s+2)}\, H(m-1,n-1) \\ &\leq \frac{n}{m} \binom{n-1}{m-1} = \binom{n}{m}. \end{aligned}$$

Otherwise, $m > n - \mu s$ holds, which ensures that $\mu s > n - m \geq 0$, i.e., $s \geq 1$. We can therefore employ the first inequality of (10) and obtain

$$H(m,n) \leq \frac{n}{\mu s}\, H(m,n-1) < \frac{n}{n-m} \binom{n-1}{m} = \binom{n}{m}. \qquad \square$$

By expanding along the first inequality for a while before employing Lemma 3.1,

we get

$$\begin{aligned} H(m,n) &\le \frac{n}{\mu s}\cdots\frac{n-k+1}{\mu(s-k+1)}\,H(m,n-k) \\ &\le \frac{1}{\mu^k}\left(\prod_{i=0}^{k-1}\frac{n-i}{s-i}\right)\binom{n-k}{m} \\ &= \frac{1}{\mu^k}\frac{\binom{n}{k}}{\binom{s}{k}}\binom{n-k}{m} \qquad (11) \\ &= \frac{1}{\mu^k}\frac{\binom{2m}{m}}{\binom{n-m-k}{m}}\binom{n}{2m} \quad \text{for } \mathbb{N}_0 \ni k \le s. \qquad (12) \end{aligned}$$

When we stop this unwinding of the recurrence, we could have alternatively proceeded one more step, and upper bound $H(m,n-k)$ by $\frac{n-k}{\mu(s-k)}\binom{n-k-1}{m}$, provided that $k<s$. As long as this expression is smaller than $\binom{n-k}{m}$, we should indeed have expanded further. That is, we expand as long as

$$\begin{aligned} &\frac{n-k}{\mu(s-k)}\binom{n-k-1}{m} < \binom{n-k}{m} \\ \Leftrightarrow\ &\frac{n-k}{\mu(s-k)}(n-k-m) < n-k \\ \Leftrightarrow\ &k < \frac{\mu s+m-n}{\mu-1} = n - m\left(\frac{2\mu-1}{\mu-1}\right) = n-\frac{m}{\rho} \end{aligned}$$

for $\rho := \frac{\mu-1}{2\mu-1}$. In other words, the best choice of k in (11) is

$$k = \left\lceil n - \frac{m}{\rho}\right\rceil = n - \left\lfloor \frac{m}{\rho}\right\rfloor. \qquad (13)$$

In fact, if this suggested value of k is negative (or if $\rho = 0$), we should not expand at all. Instead, we can try to expand along the second inequality of (10), to get (note that here reducing m by 1 increases s by 2)

$$\begin{aligned} H(m,n) &\le \frac{\mu(s+2)}{n-\mu s}\cdots\frac{\mu(s+2+2(k-1))}{n-\mu(s+2(k-1))}H(m-k,n) \\ &\le \left(\prod_{i=0}^{k-1}\frac{\frac{s}{2}+1+i}{\frac{n}{2\mu}-\frac{s}{2}-i}\right)\binom{n}{m-k} \\ &= \frac{\binom{\frac{s}{2}+k}{k}}{\binom{\frac{n}{2\mu}-\frac{s}{2}}{k}}\binom{n}{m-k} \qquad (14) \end{aligned}$$

for $\mathbb{N}_0 \ni k < \frac{n}{2\mu}-\frac{s}{2}+1 = m - \frac{\mu-1}{2\mu}n + 1$; here we employ the usual generalization of binomial coefficients $\binom{a}{k}$ to $a\in\mathbb{R}$, namely, $\binom{a}{k} := \frac{a(a-1)\cdots(a-k+1)}{k!}$.

Rather than optimizing the value of k at which we stop the unwinding of the second recurrence inequality of (10), we approximate it by

$$k = \left\lceil m - \frac{\mu-1}{2\mu-1}\,n\right\rceil = m - \lfloor \rho n\rfloor \qquad (15)$$

and note that it lies in the allowed range, provided that it is positive. (With some tedious calculations, one can show that the optimal stopping value is $k = m - \lfloor \rho(n+1) \rfloor$, which is either equal to the k in (15) or is smaller than it by 1.)

When $\frac{m}{n} = \rho$, both values suggested for k in (13) and (15) are 0, which indicates that we have to content ourselves with the bound $\binom{n}{m}$ from Lemma 3.1. Otherwise, it is clear which way to expand, since

$$\frac{m}{n} < \rho \;\Rightarrow\; n - \left\lfloor \tfrac{m}{\rho} \right\rfloor \geq 0,$$
$$\frac{m}{n} > \rho \;\Rightarrow\; m - \lfloor \rho n \rfloor \geq 0.$$

We are now ready for an improved bound. For that we substitute k in (11) according to (13), and in (14) according to (15).

LEMMA 3.2. *Let $m, n \in \mathbb{N}_0$, where $2m \leq n$, and set $\rho := \frac{\mu-1}{2\mu-1}$. If $\frac{m}{n} \leq \rho$, then*

$$H_\mu(m,n) \leq \frac{1}{\mu^{n-\lfloor m/\rho \rfloor}} \frac{\binom{n}{n-\lfloor m/\rho \rfloor}}{\binom{n-2m}{n-\lfloor m/\rho \rfloor}} \binom{\lfloor m/\rho \rfloor}{m},$$

and for $\frac{m}{n} > \rho$, we have

$$H_\mu(m,n) \leq \frac{\binom{\frac{n}{2} - \lfloor \rho n \rfloor}{m - \lfloor \rho n \rfloor}}{\binom{m - \frac{n}{2}(1-\frac{1}{\mu})}{m - \lfloor \rho n \rfloor}} \binom{n}{\lfloor \rho n \rfloor}.$$

Thus, $G_{\lambda,\mu}(m,n) \leq \overline{G}_{\lambda,\mu}(m,n)$ with

$$\overline{G}_{\lambda,\mu}(m,n) := \begin{cases} \lambda^m \mu^{\lfloor m/\rho \rfloor - m} \dfrac{\binom{n}{n-\lfloor m/\rho \rfloor}}{\binom{n-2m}{n-\lfloor m/\rho \rfloor}} \binom{\lfloor m/\rho \rfloor}{m} & \text{for } \frac{m}{n} \leq \rho, \\ \lambda^m \mu^{n-m} \dfrac{\binom{\frac{n}{2} - \lfloor \rho n \rfloor}{m - \lfloor \rho n \rfloor}}{\binom{m - \frac{n}{2}(1-\frac{1}{\mu})}{m - \lfloor \rho n \rfloor}} \binom{n}{\lfloor \rho n \rfloor} & \text{for } \frac{m}{n} > \rho. \end{cases}$$

Next we work out a number of properties of the upper bound $\overline{G}_{\lambda,\mu}$.

Estimates up to a polynomial factor. In the following derivations, we sometimes use "$\approx_n$" to denote equality up to a polynomial factor in n.

We will frequently use the following estimate (implied by Stirling's formula; cf. [29, Chapter 10, Corollary 9]):

$$\binom{\alpha n}{\lceil \beta n \rceil} \approx_n \binom{\alpha n}{\lfloor \beta n \rfloor} \approx_n \left(\frac{\alpha^\alpha}{\beta^\beta (\alpha-\beta)^{\alpha-\beta}} \right)^n \qquad \text{for } \alpha, \beta \in \mathbb{R},\ \alpha \geq \beta \geq 0.$$

Big m. We note that for $\frac{m-1}{n} \geq \rho$

$$\overline{G}_{\lambda,\mu}(m,n) = \frac{\lambda(s+2)}{n - \mu s}\, \overline{G}_{\lambda,\mu}(m-1,n) \quad \text{with } s := n - 2m.$$

Since $\frac{\lambda(s+2)}{n-\mu s} < 1 \Leftrightarrow s < \frac{n-2\lambda}{\lambda+\mu} \Leftrightarrow m > \frac{(\lambda+\mu-1)n+2\lambda}{2(\lambda+\mu)}$, the function $\overline{G}_{\lambda,\mu}(m,n)$ maximizes for integers m in the range $\rho n \leq m \leq \frac{n}{2}$ at

$$m^* := \left\lfloor \frac{(\lambda+\mu-1)n + 2\lambda}{2(\lambda+\mu)} \right\rfloor = \left\lfloor \frac{n}{2} - \frac{n-2\lambda}{2(\lambda+\mu)} \right\rfloor \tag{16}$$

unless this value is not in the provided range. However, $m^* \leq \frac{n}{2}$ unless n is very small ($n < 2\lambda$). And $m^* \geq \rho n$ unless $\lambda < \mu - 1$.

Small m. With the identity indicated in (12) we have, for $\frac{m}{n} \le \rho$, that $\overline{G}$ can also be written as

$$\overline{G}_{\lambda,\mu}(m,n) \;=\; \lambda^m \mu^{\lfloor m/\rho \rfloor - m} \frac{\binom{2m}{m}}{\binom{\lfloor m/\rho \rfloor - m}{m}} \binom{n}{2m} \;\approx_m\; (4\lambda(\mu-1))^m \binom{n}{2m}. \tag{17}$$

This bound peaks (up to an additive constant) at

$$m^{**} := \left\lfloor \frac{\sqrt{\lambda(\mu-1)}}{1+2\sqrt{\lambda(\mu-1)}}\, n \right\rfloor.$$

We observe that $m^{**} \le \rho n$ for $\lambda \le \mu - 1$.

We can summarize that the function $\overline{G}_{\lambda,\mu}(m,n)$ attains its maximum—up to a poly(n)-factor—over m at

$$m = \begin{cases} m^{**} & \text{if } \lambda \le \mu - 1, \\ m^{*} & \text{otherwise.} \end{cases} \tag{18}$$

In all applications in this paper we have $\lambda > \mu - 1$; thus the peak occurs at m^*.

4. Bounds for matchings.

4.1. Perfect matchings. For perfect matchings we consider the case where n is even, $m = \frac{n}{2}$, and $s = 0$. We note that in this case $m/n = 1/2 > \rho$ for any value of μ. Hence, the second bound of Lemma 3.2 applies. We first calculate $\frac{n}{2} - \frac{n}{2}(1-\frac{1}{\mu}) = \frac{1}{2\mu}\, n$ and $\frac{n}{2} - \lfloor \rho n \rfloor = \lceil \frac{n}{2} - \frac{\mu-1}{2\mu-1}\, n \rceil = \lceil \frac{1}{2(2\mu-1)}\, n \rceil$. Hence,

$$\begin{aligned}
\overline{G}_{\lambda,\mu}\left(\frac{n}{2}, n\right) \;&=\; (\lambda\mu)^{n/2} \binom{\frac{1}{2\mu}\, n}{\left\lceil \frac{1}{2(2\mu-1)}\, n \right\rceil}^{-1} \binom{n}{\left\lfloor \frac{\mu-1}{2\mu-1}\, n \right\rfloor} \\
&\approx_n\; (\lambda\mu)^{n/2} \left(\frac{\left(\frac{1}{2(2\mu-1)}\right)^{\frac{1}{2(2\mu-1)}} \left(\frac{\mu-1}{2\mu(2\mu-1)}\right)^{\frac{\mu-1}{2\mu(2\mu-1)}}}{\left(\frac{1}{2\mu}\right)^{\frac{1}{2\mu}} \left(\frac{\mu-1}{2\mu-1}\right)^{\frac{\mu-1}{2\mu-1}} \left(\frac{\mu}{2\mu-1}\right)^{\frac{\mu}{2\mu-1}}} \right)^n \\
&=\; (\lambda\mu)^{n/2} \left(\mu^{\frac{1}{2(2\mu-1)} - \frac{\mu}{2\mu-1}} (\mu-1)^{\frac{\mu-1}{2\mu(2\mu-1)} - \frac{\mu-1}{2\mu-1}} (2\mu-1)^{-\frac{1}{2\mu}+1} \right)^n \\
&=\; (\lambda\mu)^{n/2} \left((\mu-1)^{-\frac{\mu-1}{2\mu}} \mu^{-\frac{1}{2}} (2\mu-1)^{\frac{2\mu-1}{2\mu}} \right)^n \\
&=\; \left(\lambda^{\frac{1}{2}} (\mu-1)^{-\frac{\mu-1}{2\mu}} (2\mu-1)^{\frac{2\mu-1}{2\mu}} \right)^n.
\end{aligned}$$

Substituting $(\lambda,\mu) = (12,3)$ and $(16, \frac{7}{3})$, as suggested by Lemma 2.4, we obtain the following upper bounds for the number of crossing-free perfect matchings:

$$\begin{aligned}
\overline{G}_{12,3}\left(\frac{n}{2}, n\right) &\approx_n \left(2^{\frac{2}{3}} \cdot 3^{\frac{1}{2}} \cdot 5^{\frac{5}{6}}\right)^n = O(10.5129^n) \quad \text{and} \\
\overline{G}_{16,\frac{7}{3}}\left(\frac{n}{2}, n\right) &\approx_n \left(2^{\frac{10}{7}} \cdot 3^{-\frac{1}{2}} \cdot 11^{\frac{11}{14}}\right)^n = O(10.2264^n).
\end{aligned}$$

While the second bound is obviously superior, we remember that the recurrence with $(\lambda,\mu) = (12,3)$ is better for $m > \frac{2n}{5}$ (or $s < \frac{n}{5}$). This observation leads to the

following better bound for P a set of n points and for $k = \lfloor \frac{n}{2} - \frac{2n}{5} \rfloor = \lfloor \frac{n}{10} \rfloor$, where we expand as in the first inequality of Lemma 2.3:

$$\begin{aligned}\mathsf{pm}(P) \;&\le\; \left(\prod_{i=0}^{k-1} \frac{12(2i+2)}{n-6i}\right) \mathsf{ma}_{n/2-k}(P) \le 4^k \binom{\frac{n}{6}}{k}^{-1} \overline{G}_{16,7/3}(n/2-k,n) \\ &\approx_n \left(2^{20/21}\, 3^{-2/7}\, 5^{1/21}\, 11^{11/14}\right)^n = O(10.0438^n).\end{aligned}$$

Perfect versus all matchings. Recall from Lemma 2.3 that

$$\mathsf{ma}_m(P) \le \frac{12(s+2)}{n-3s} \mathsf{ma}_{m-1}(P).$$

Note that $\frac{12(s+2)}{n-3s} < 1$ for $m > \frac{7n}{15} + \frac{4}{5}$ (and in this range the factor $\frac{12(s+2)}{n-3s}$ is smaller than the alternative offered in Lemma 2.3). That is, there are always fewer perfect matchings than there are $\lfloor \frac{7n}{15} + \frac{4}{5} \rfloor$-matchings. More specifically, for sets P with $n := |P|$ even and for $k = \frac{n}{2} - \lfloor \frac{7n}{15} + \frac{4}{5} \rfloor = \lceil \frac{n}{30} - \frac{4}{5} \rceil$, we have

$$\begin{aligned}\mathsf{pm}(P) = \mathsf{ma}_{n/2}(P) \;&\le\; \prod_{i=0}^{k-1} \frac{12(2i+2)}{n-6i}\; \mathsf{ma}_{n/2-k}(P) \\ &=\; \left(\frac{12\cdot 2}{6}\right)^k \binom{\frac{n}{6}}{k}^{-1} \mathsf{ma}_{n/2-k}(P) \\ &\approx_n\; 4^{n/30} \left(\left(\frac{1}{5}\right)^{1/5} \left(\frac{4}{5}\right)^{4/5}\right)^{n/6} \mathsf{ma}_{\lfloor 7n/15+4/5 \rfloor}(P) \\ &=\; \left(2^{1/3}\, 5^{-1/6}\right)^n \mathsf{ma}_{\lfloor 7n/15+4/5 \rfloor}(P)\,.\end{aligned}$$

This implies that $\mathsf{pm}(P) \le \left(2^{1/3}\, 5^{-1/6}\right)^n \mathsf{ma}(P)\, \mathrm{poly}(n) = O(0.9635^n)\, \mathsf{ma}(P)$. In every point set there are exponentially (in the size of the set) more crossing-free matchings than there are crossing-free perfect matchings.

4.2. All matchings. Our considerations in the derivation of the bound for perfect matchings imply the following upper bound for matchings with m segments:

$$\mathsf{ma}_m(P) \le \begin{cases} \overline{G}_{16,7/3}(m,n), & m \le \frac{2n}{5}, \\ \overline{G}_{12,3}(m,n)\; \frac{\overline{G}_{16,7/3}(\frac{2n}{5},n)}{\overline{G}_{12,3}(\frac{2n}{5},n)}, & \text{otherwise.} \end{cases} \tag{19}$$

To determine where the expression (19) maximizes, we note that $\overline{G}_{16,7/3}$ does not peak in its "small m"-range ($m \le \frac{4}{11}$) since $16 > \frac{7}{3} - 1$ (recall (18)). In the "big m"-range, it peaks at roughly $\frac{26n}{55}$ (see (16)), which exceeds $\frac{2}{5}$. Therefore, the maximum occurs when $\overline{G}_{12,3}$ comes into play, which peaks at roughly $\frac{7n}{15}$. For that value the upper bound evaluates to $\approx_n (2^{13/21}\, 3^{-2/7}\, 5^{3/14}\, 11^{11/14})^n = O(10.4244^n)$.

We summarize in the following main theorem.

THEOREM 4.1. *Let P be a set of n points in the plane. Then the following hold:*

(1) $\mathsf{pm}(P) \le \left(2^{20/21}\, 3^{-2/7}\, 5^{1/21}\, 11^{11/14}\right)^n \mathrm{poly}(n) = O(10.0438^n)$.

(2) $\mathsf{pm}(P) \le \left(2^{1/3}\, 5^{-1/6}\right)^n \mathsf{ma}(P)\, \mathrm{poly}(n) = O(0.9635^n)\, \mathsf{ma}(P)$.

(3) $\mathsf{ma}(P) \le \left(2^{13/21}\, 3^{-2/7}\, 5^{3/14}\, 11^{11/14}\right)^n \mathrm{poly}(n) = O(10.4244^n)$.

We note, by the way, that the first inequality in the theorem is a direct consequence of the other two inequalities.

4.3. Random point sets. Let P be any set of $N \in \mathbb{N}$ points in the plane, no three on a line, and let $r \in \mathbb{N}$ with $r \leq N$. If R is a subset of P chosen uniformly at random from $\binom{P}{r}$, then for $\lambda = 16$, $\mu = \frac{7}{3}$, and provided that $m \leq \frac{\mu-1}{2\mu-1}N = \frac{4}{11}N$, and that $r \geq 2m$, we have, using (17),[11]

$$\begin{aligned}
\mathbf{E}[\mathsf{ma}_m(R)] &= \left(\sum_{R\in\binom{P}{r}} \mathsf{ma}_m(R)\right) \Big/ \binom{N}{r} = \mathsf{ma}_m(P)\binom{N-2m}{r-2m}\Big/\binom{N}{r} \\
&\leq (4\lambda(\mu-1))^m \binom{N}{2m}\left(\binom{N-2m}{r-2m}\Big/\binom{N}{r}\right)\mathrm{poly}(m) \\
&\approx_m (4\lambda(\mu-1))^m \binom{r}{2m} = \left(2^8\,3^{-1}\right)^m \binom{r}{2m}.
\end{aligned}$$

We see that if we sample r points from a large enough set, then the expected number of crossing-free matchings observes for all m the upper bound derived for the range of small m.

Suppose now that, for n even, we sample n i.i.d. points from an arbitrary distribution, for which we require only that two sampled points coincide with probability 0. Then we can first sample a set P of $N > \frac{11}{8}n$ points and then choose a subset of size n uniformly at random from the family of all subsets of this size. We obtain a set R of n i.i.d. points from the given distribution. If P is in general position, by the argument above the expected number of perfect crossing-free matchings is at most $\approx_n (2^8\,3^{-1})^{n/2}$. If P exhibits collinearities, we perform a small perturbation yielding a set $\tilde{P}$ and the subset $\tilde{R}$. Now the bound applies to $\tilde{R}$ and also to R since a sufficiently small perturbation cannot decrease the number of crossing-free perfect matchings.

THEOREM 4.2. *For any distribution in the plane for which two sampled points coincide with probability* 0*, the expected number of crossing-free perfect matchings of* n *i.i.d. points is at most*

$$\left(2^4\,3^{-1/2}\right)^n \mathrm{poly}(n) = O(9.2377^n).$$

We next consider several variants of crossing-free *bipartite* matchings for which better upper bounds can be derived.

4.4. Red-blue perfect matchings. We assume that the given set P of n points is the disjoint union $R \dot\cup B$ of two subsets, and that each edge in the matching has to connect a point of R with a point of B. We refer to the points of R as red points and to those of B as blue.

We repeat the preceding analysis but modify the definition of the degree $d(p)$ of a point: If p is a matched point in R, say the left endpoint of its edge e, then $d(p)$ is equal to the number of left endpoints plus the number of *blue* isolated points that are vertically visible from (the relative interior of) e. A symmetric definition holds for right endpoints and for points $p \in B$. (Intuitively, a blue isolated point q has to contribute only to the degrees of red points because, when we insert an edge emanating from a blue point p, it cannot connect to q, and it does not matter whether

[11] There is a small subtlety in that the second identity in the derivation relies on the fact that P is in general position. For that consider 3 points on a line.

it passes above or below q; that is, q does not cause any bifurcation in the ways in which p can be connected.)

In this case we have

$$\sum_{p\in P} d(p) \le 4m + 2s$$

because each isolated point contributes to the degree of only 2 matched points. This changes the bounds in Lemma 2.1 to

$$2n \le 4v_0 + 3v_1 + 2v_2 + v_3 + 4s, \quad \text{and}$$
$$3n \le 5v_0 + 4v_1 + 3v_2 + 2v_3 + v_4 + 5s.$$

The rest of the analysis continues verbatim, except that now the recurrence (8) involves the factors $\frac{12(s+2)}{n-2s}$ and $\frac{16(s+2)}{n-5s/3}$ or, in other words, $(\lambda,\mu) = (12,2)$ (with $\rho = 1/3$) and $(16,\frac{5}{3})$ (with $\rho = 2/7$), respectively. The first factor is superior for $s < \frac{n}{3}$, i.e., $m > \frac{n}{3}$.

We thus obtain, with $k = \lfloor \frac{n}{6} \rfloor$, a bound of

$$\left(\prod_{i=0}^{k-1} \frac{12(2i+2)}{n-4i}\right) \overline{G}_{16,5/3}(n/2-k,n)$$

for the number of perfect red-blue matchings. Manipulating it, as above, yields the following theorem.

THEOREM 4.3. *Let P be a set of n points in the plane with each one colored red or blue. Then the number of red-blue perfect crossing-free matchings in P is at most*

$$\left(2^{6/5}\, 3^{-3/20}\, 7^{7/10}\right)^n \operatorname{poly}(n) = O(7.6075^n)\,.$$

4.5. Left-right perfect matchings. Here we assume that P is partitioned into two disjoint subsets L, R and consider bipartite matchings in $L \times R$ such that, for each edge of the matching, its left endpoint belongs to L and its right endpoint to R.

We modify the definition of the degrees of the points, as in the red-blue case, and have, as above,

$$\sum_{p\in P} d(p) \le 4m + 2s.$$

The analysis further improves because when we insert an edge emanating from a point $p \in L$, say, the corresponding numbers h_i must be equal to ℓ_i, since p can only be the left endpoint of the edge. A similar improvement holds for points $q \in R$. Hence, we can bound the sum $4h_0 + 3h_1 + 2h_2 + h_3$ by 12, rather than 24; similarly, we have $5h_0 + 4h_1 + 3h_2 + 2h_3 + h_4 \le 24$. That is, we have the two options $(\lambda,\mu) = (6,2)$ and $(8,\frac{5}{3})$. We thus obtain the bound

$$\left(\prod_{i=0}^{k-1} \frac{6(2i+2)}{n-4i}\right) \overline{G}_{8,5/3}(n/2-k,n) \quad \text{for } k = \lfloor \tfrac{n}{6} \rfloor,$$

which leads to the following result.

THEOREM 4.4. *Let P be a set of n points in the plane and assume that the points are classified as left endpoints or right endpoints. Then the number of left-right perfect crossing-free matchings in P that obey this classification is at most*

$$\left(2^{7/10}\, 3^{-3/20}\, 7^{7/10}\right)^n \operatorname{poly}(n) = O(5.3793^n).$$

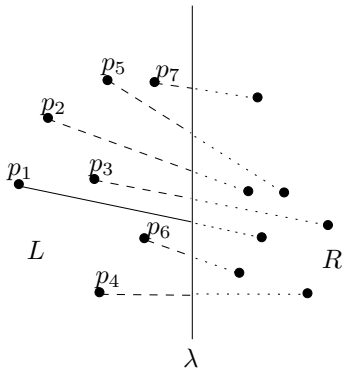

FIG. 8. *Recursively counting permutations induced on λ by left half-edges.*

4.6. Matchings across a line. Consider next the special case of crossing-free bipartite perfect matchings between two sets of $\frac{n}{2}$ points each that are separated by a line. Here we can obtain an upper bound that is smaller than the one in Theorem 4.4.

THEOREM 4.5. *Let n be an even integer. The number of crossing-free perfect bipartite matchings between two separated sets of $\frac{n}{2}$ points each in the plane is at most ${C_{n/2}}^2 < 4^n$ (recall that C_m is the mth Catalan number).*

Proof. Let L and R be the given separated sets. Without loss of generality, take the separating line λ to be the y-axis and assume that the points of L lie to the left of λ and the points of R lie to its right. Let M be a crossing-free perfect bipartite matching in $L \times R$. For each edge e of M, let e_L (resp., e_R) denote the portion of e to the left (resp., right) of λ, and refer to them as the *left half-edge* and the *right half-edge* of e, respectively. We will obtain an upper bound for the number of combinatorially different ways to draw the left half-edges of a crossing-free perfect matching in $L \times R$. The same bound will apply symmetrically to the right half-edges, and the final bound will be the square of this bound.

In more detail, we ignore R and consider collections S of $\frac{n}{2}$ pairwise disjoint segments, each connecting a point of L to some point on λ, so that each point of L is incident to exactly one segment. For each segment in S, we label its λ-endpoint by the point of L to which it is connected. The increasing y-order of the λ-endpoints of the segments thus defines a permutation of L, and our goal is to bound the number of different permutations that can be generated in this way. (In general, this is a *strict* upper bound on the quantity we seek; see below.)

We obtain this bound in the following recursive manner. Write $m := |L| = \frac{n}{2}$. Sort the points of L from left to right (we may assume that there are no ties—they can be eliminated by a slight rotation of λ), and let $p_1, p_2, \ldots, p_m$ denote the points in this order. Consider the half-edge e_1 emanating from the leftmost point p_1. Any other point p_j lies either above or below e_1. By rotating e_1 about p_1, we see that there are at most m (exactly m, if we assume general position) ways to split $\{p_2, \ldots, p_m\}$ into a subset L_1^+ of points that lie above e_1 and a complementary subset L_1^- of points that lie below e_1, where in the ith split, $|L_1^+| = i - 1$ and $|L_1^-| = m - i$. Note that, in any crossing-free perfect bipartite matching that has e_1 as a left half-edge incident to p_1, all the points of L_1^+ (resp., of L_1^-) must be incident to half-edges that terminate on λ *above* (resp., *below*) the λ-endpoint of e_1; see Figure 8.

Hence, after having fixed i, we can proceed to bound recursively and separately

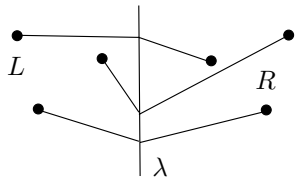

FIG. 9. *A left and a right permutation which are not compatible.*

the number of permutations induced by L_1^+ and the number of those induced by L_1^-. In other words, denoting by $\Pi(m)$ the maximum possible number of different permutations induced in this way by a set L of m points (in general position), we get the following recurrence:

$$\Pi(m) \leq \sum_{i=1}^{m} \Pi(i-1)\Pi(m-i)$$

for $m \geq 1$, where $\Pi(0) = 1$. However, this is the recurrence that (with equality) defines the Catalan numbers, so we conclude that $\Pi(m) \leq C_m$.

A (probably weak) upper bound for the number of crossing-free perfect bipartite matchings in $L \times R$ is thus ${C_m}^2$. Indeed, for any permutation π_L of L and any permutation π_R of R, there is at most one crossing-free perfect bipartite matching in $L \times R$ that induces both permutations. Namely, it is the matching that connects the jth point in π_L to the jth point in π_R for each $j = 1, \ldots, m$. See Figure 9 for an example of two such permutations that do not yield a (straight-edge) crossing-free matching.

We thus obtain the asserted upper bound ${C_m}^2 = {C_{n/2}}^2 < 4^n$. □

5. Two implications. We show how bounds for matchings can be used to infer bounds for other problems, in particular spanning cycles and crossing-free partitions.

5.1. Spanning cycles. Apart from triangulations, crossing-free spanning cycles (simple polygonizations) have received the most attention in this context (see the original question in [32], the web site [15], or the book [12, section 8.4, Problem 8]). It is easy to see the relation $\mathsf{sc}(P) \leq \mathsf{pm}(P)^2$ for sets P with an even number of points. A better bound on $\mathsf{sc}(P)$ can be obtained via left-right matchings as follows.

THEOREM 5.1. *Let P be a set of n points in the plane. Then the number of crossing-free spanning cycles satisfies*

$$\mathsf{sc}(P) \leq (2^{7/5}\, 3^{7/10}\, 7^{7/5})^n \mathrm{poly}(n) = O(86.8089^n).$$

Proof. Let P be a given set of n points. We construct a new set P' of $2n$ points by creating two copies p^+, p^- of each point $p \in P$, and by placing these copies covertically very close to the original location of p, with p^+ lying above p^-.

Let π be a cycle in P. We map π to a perfect matching in P' as follows. For each $p \in P$, let q, r be its neighbors in π. (i) If both q, r lie to the left of p, with the edge qp lying above rp, we connect p^+ to either q^+ or q^-, and connect p^- to either r^+ or r^- (the actual choices will be determined at q and r by similar rules). (ii) The same rule applies in the case where both q, r lies to the right of p. (iii) If q lies to the left of p and r lies to the right of p, then we connect p^+ to either q^+ or q^-, and connect p^- to either r^+ or r^-. It is clear that the resulting graph π^* is a crossing-free perfect

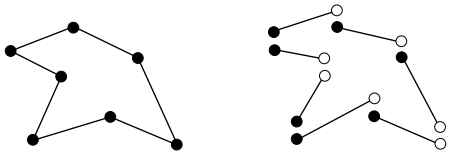

FIG. 10. *A cycle in P induces a left-right perfect matching in P'.*

matching in P', assuming general position of the points of P, if we draw each pair of points p^+, p^- sufficiently close to each other. See Figure 10 for an illustration.

We assign to each point $p \in P$ a label that depends on π. A point whose two neighbors in π lie to its left is labeled as a *right point*, a point whose two neighbors in π lie to its right is labeled as a *left point*, and a point having one neighbor in π to its right and one to its left is labeled as a *middle point*.

We assign the cycle π to the pair (π^*, λ), where π^* is the resulting perfect matching on P' and λ is the labeling of P, as just defined.

Each pair (π^*, λ) can be realized by at most one cycle π in P, by simply merging each pair p^+, p^- back into the original point p. (The resulting graph need not be a cycle; in general it is a collection of pairwise disjoint cycles.) It therefore suffices to bound the number of such pairs (π^*, λ).

A given labeling λ of P uniquely classifies each point of P' as being either a left point of an edge of the matching or a right endpoint of such an edge. Hence, the number of crossing-free perfect matchings π' on P' that respect this left-right assignment is at most $(2^{7/10}\, 3^{-3/20}\, 7^{7/10})^{2n}\mathrm{poly}(n)$. The number of labelings of P is 3^n. Hence, the number of crossing-free cycles in P is at most $(2^{7/5}\, 3^{7/10}\, 7^{7/5})^n\mathrm{poly}(n)$, as asserted. □

Clearly, it follows from the proof that the bound holds for the number of crossing-free spanning paths as well, and also for the number of cycle covers (or path covers) of P.[12]

5.2. Crossing-free partitions. We now relate crossing-free partitions of a point set P to matchings, thereby establishing an upper bound on $\mathsf{cfp}(P)$.

To this end, every crossing-free partition of P is mapped to a tuple (M, S, I^+, I^-) where (see Figure 11)

(i) M is the matching in P, whose edges connect the leftmost point to the rightmost point of each set in the partition with at least two elements (we refer to each such segment as the *spine* of its set);

(ii) S is the set of all points that form singleton sets in the partition; and

(iii) I^+ (resp., I^-) is the set of points in $P \setminus S$ that are neither the leftmost nor the rightmost in their set, and which lie *above* (resp., *below*) the spine of their set.

We observe that M is crossing-free and that the partition is uniquely determined by (M, S, I^+, I^-). Therefore, any upper bound on the number of such tuples will establish an upper bound on the number of crossing-free partitions. For every crossing-free matching M on P there are $3^{n-2|M|}$ triples (S, I^+, I^-) which form a 4-tuple with M (clearly, not all of them have to come from a crossing-free partition, so we overcount). Therefore $\sum_m 3^{n-2m}\mathsf{ma}_m(P)$ is an upper bound on the number of crossing-free partitions.

[12] A slight improvement can be obtained by noting that when a cycle has j middle points, we can derive from it 2^j distinct matchings in P', by flipping the connections to some of the pairs of P' that represent middle points.

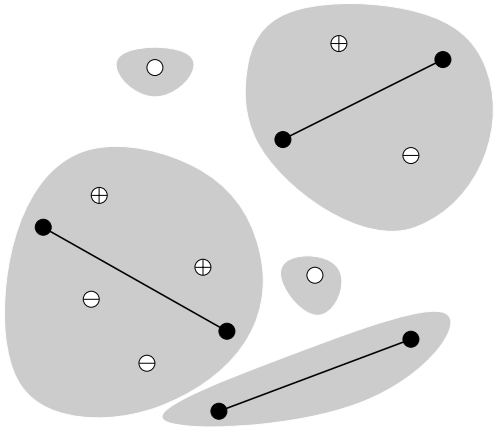

FIG. 11. *Encoding a crossing-free partition: Spines, isolated (◯), top (⊕), and bottom (⊖) points.*

Ignoring the 3^n-factor for the time being, we have to determine an upper bound on $3^{-2m}\mathsf{ma}_m(P)$, for which we employ the bound from inequality (19). We observe that $3^{-2m}\overline{G}_{\lambda,\mu}(m,n) = \overline{G}_{\lambda/9,\mu}(m,n)$, and therefore

$$3^{-2m}\mathsf{ma}_m(P) \le \begin{cases} \overline{G}_{16/9,7/3}(m,n), & m \le \frac{2n}{5}, \\ \overline{G}_{4/3,3}(m,n)\ \frac{\overline{G}_{16,7/3}(\frac{2n}{5},n)}{\overline{G}_{12,3}(\frac{2n}{5},n)}, & \text{otherwise.} \end{cases} \tag{20}$$

Since $\frac{16}{9} \ge \frac{7}{3} - 1$ (see (18)), the peak will not occur in the "small m"-range of $\overline{G}_{16/9,7/3}$. In its "big m"-range, the maximum occurs at m roughly $\frac{14n}{37}$ (see (16)) which lies in the interval $[\frac{4}{11}, \frac{2}{5}]$. Also, $G_{4/3,3}$ peaks for $m \le \frac{2n}{5}$ since $\frac{4}{3} \le 3 - 1$ (consult (18)). Therefore, the bound peaks at m roughly $\frac{14n}{37}$ with the value

$$3^n\,\overline{G}_{16/9,7/3}(\lfloor\tfrac{14n}{37}\rfloor, n) \approx_n (2^{4/7}\,3^{-1/2}\,11^{11/14}\,37^{3/14})^n\ .$$

Note that we could have estimated the number of 4-tuples by first choosing a subset Q, which is the union of S and the endpoints of M, then choosing a matching in Q, and then partitioning $P \setminus Q$ into $I^+ \cup I^-$. This leads to a bound of $\approx_n \sum_k \binom{n}{k} c^k 2^{n-k} = (c+2)^n$, where c is the constant in the bound for all matchings. This yields a bound of $O(12.43^n)$, which falls short of our bound obtained above.

THEOREM 5.2. *Let P be a set of n points in the plane. Then the number of crossing-free partitions satisfies*

$$\mathsf{cfp}(P) \le \left(2^{4/7}\,3^{-1/2}\,11^{11/14}\,37^{3/14}\right)^n \mathrm{poly}(n) = O(12.2388^n).$$

6. Lower bounds. In this section we briefly derive the lower bounds mentioned in Table 1. Most of them rely on an analysis of the so-called *double chain*, as it was first considered by García, Noy, and Tejel [21] in the context of crossing-free graphs. For matchings across a line (and left-right matchings) we use a different configuration.

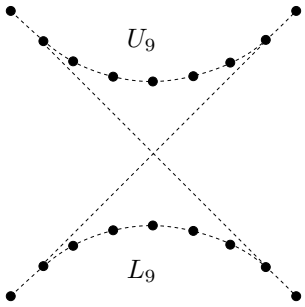

FIG. 12. *The double chain* D_{18}.

6.1. The double chain. Given $m \in \mathbb{N}$, the double chain D_{2m} consists of $n := 2m$ points; see Figure 12. There is an upper half U_m of m points on the parabola $y = \frac{x^2+1}{2}$ with their x-coordinates in $[-1, +1]$, and there is a lower half L_m of m points on the parabola $y = -\frac{x^2+1}{2}$ in the same x-range. The important property is that U_m and L_m are in convex position, and the relative interior of each segment connecting a point from U_m with a point from L_m is disjoint from the convex hulls of U_m and of L_m and thus cannot cross any segment connecting points within these sets.

García, Noy, and Tejel [21] show, among other things, that $\mathsf{sc}(D_{2m}) = \Omega(4.64^n)$ and that

$$\mathsf{pm}(D_{2m}) = \sum_{k=0}^{\lfloor m/2 \rfloor} \binom{m}{2k}^2 {C_k}^2 \approx_n 3^n. \tag{21}$$

We wish to recapitulate the argument for the latter bound. A crossing-free perfect matching with k inner edges within U_m leaves $m - 2k$ points in U_m to be matched to the same number of points in L_m. So within L_m, we also have k inner edges. If we choose the $2k$ endpoints in U_m for the inner edges ($\binom{m}{2k}$ choices), then we have C_k possibilities to connect them in a perfect crossing-free matching; the same bound applies to L_m. The remaining points from U_m and L_m allow exactly one crossing-free perfect matching from the upper set to the lower set. This gives the bound in (21). (The estimate for the sum builds on the observation that $\sum_{i=0}^{N} {a_i}^2 \approx_N \left(\sum_{i=0}^{N} a_i\right)^2$ for nonnegative real numbers a_i.)

In a similar fashion we can argue now for

$$\mathsf{ma}(D_{2m}) = \sum_{k=0}^{m} \binom{m}{k}^2 {M_k}^2 \approx_n 4^n,$$

where $M_k = \sum_i \binom{k}{2i} C_i = \Theta(k^{-3/2} 3^k)$ is the kth Motzkin number that counts the number of all matchings of k points in convex position [31].

Crossing-free partitions. Along similar lines we easily get a lower bound of

$$\mathsf{cfp}(D_{2m}) \geq \sum_{k=0}^{m} \binom{m}{k}^2 {C_k}^2 \approx_n 5^n.$$

This bound for crossing-free partitions counts only a restricted class of such partitions, namely, those composed of a matching between $m - k$ points in U_m and $m - k$ points

in L_m, together with crossing-free partitions among the remaining k points in U_m and among the remaining k points in L_m.

Let us perform an exhaustive counting of crossing-free partitions of the double chain. Here are the ingredients.

Recall first that for $N \in \mathbb{N}_0$, $i \in \mathbb{N}$, the number N can be written as an ordered sum of i nonnegative integers in $\binom{N+i-1}{i-1}$ ways, and as an ordered sum of i positive integers in $\binom{N-1}{i-1}$ ways.

Now we "prepare" the upper half U_m for a crossing-free partition as follows. We specify the number k of parts that extend to the lower half, and we also specify which k contiguous nonempty subsequences of points of U_m form the upper portions of these extended parts; we refer to these sequences as *docking places*. If the overall size of these docking places is $k+\ell$, we have to specify numbers $a_i \in \mathbb{N}_0$, $0 \le i \le k$, which are the sizes of intermediate nondocking parts, and numbers $b_i \in \mathbb{N}$, $1 \le i \le k$, which are the sizes of docking parts, so that $m = a_0+b_1+a_1+\cdots b_k+a_k$, with $\sum a_i = m-k-\ell$ (and so $\sum b_i = k+\ell$).

There are $\binom{m-k-\ell+(k+1)-1}{(k+1)-1} = \binom{m-\ell}{k}$ ways to choose the a_i's, and $\binom{k+\ell-1}{k-1}$ ways to choose the b_i's. That is, the number of configurations with k docking places (with the nondocking points already forming a crossing-free partition within U_m) is exactly

$$\sum_{\ell=0}^{m-k} \binom{m-\ell}{k}\binom{k+\ell-1}{k-1} C_{m-k-\ell}.$$

Hence, repeating the same analysis for the lower half L_m and observing that, as in the case of matchings, there is a unique way to connect the upper and lower docking places in a noncrossing manner, we obtain

$$\mathsf{cfp}(D_{2m}) = {C_m}^2 + \sum_{k=1}^{m} \left(\sum_{\ell=0}^{m-k} \binom{m-\ell}{k}\binom{k+\ell-1}{k-1} C_{m-k-\ell} \right)^2.$$

So for an estimate up to a polynomial factor in m, it remains to find k and ℓ so that $f(m,\ell,k) := \binom{m-\ell}{k}\binom{k+\ell-1}{k-1}C_{m-k-\ell}$ is large. We have

$$f(m, \lfloor 0.05m \rfloor, \lfloor 0.22m \rfloor) > 5.23^m \mathrm{poly}(m),$$

which gives $\mathsf{cfp}(D_{2m}) > (5.23^m \mathrm{poly}(m))^2 = 5.23^n \mathrm{poly}(n)$. (The coefficients 0.05 and 0.22 were chosen via a numerical experimentation.)

Red-blue matchings. It is worthwhile to notice that if we color n points in convex position, with n even, alternately red and blue along the boundary of their convex hull, then all perfect matchings on this set are compatible with this coloring. That is, we have a colored set of n points with $C_{n/2} \approx_n 2^n$ crossing-free perfect red-blue matchings. Again, we will employ the double chain for a better lower bound.

Assume m to be even, consider D_{2m}, and color the points in U_m alternately red and blue, starting with red at the leftmost point. Then color L_m alternately blue and red, starting with blue at the leftmost point. Given that coloring, we generate perfect red-blue matchings as follows:

(i) Choose some k, $0 \le k \le \frac{m}{2}$.

(ii) Select k red points in U_m ($\binom{m/2}{k}$ possibilities).

(iii) Select k blue points in L_m ($\binom{m/2}{k}$ possibilities).

(iv) Match the selected red points and their next (to the right) blue neighbors in U_m with the selected blue points and their next (to the right) red neighbors in L_m. This can be done in a *unique* crossing-free manner, which is also red-blue compatible.

(v) Match the remaining $m-2k$ points in U_m. By the way points were selected, the remaining points are still alternately red and blue and thus allow $C_{m/2-k}$ red-blue matchings, and the same holds for the lower chain L_m.

This gives

$$\sum_{k=0}^{m/2} \binom{m/2}{k}^2 {C_{m/2-k}}^2 \approx_m \sum_{k=0}^{m/2} \binom{m/2}{k}^2 \left(4^{m/2-k}\right)^2 \approx_m 5^m = \sqrt{5}^{\,n} = \Omega(2.23^n)$$

perfect crossing-free red-blue matchings as claimed in Table 1. The above procedure does not catch all possible perfect crossing-free red-blue matchings—a more accurate analysis might lead to a better bound.

Perfect matchings in random sets. Finally, let us describe a distribution in the plane such that the expected number of crossing-free perfect matchings of n i.i.d. points, for n even, is at least $3^n/\mathrm{poly}(n)$. We draw a random point p by first choosing an x uniformly at random in $[-1,+1]$ and then letting $p = (x, \frac{x^2+1}{2})$ or $p = (x, -\frac{x^2+1}{2})$, each of the two possibilities with probability $\frac{1}{2}$. A set P of n i.i.d. points from this distribution is of the form $U_k \cup L_{n-k}$ with probability $\frac{1}{2^n}\binom{n}{k}$. Therefore,

$$\mathbf{E}[\mathsf{pm}(P)] = \frac{1}{2^n}\sum_{k=0}^{n}\binom{n}{k}\mathsf{pm}(U_k \cup L_{n-k}) \geq \frac{1}{2^n}\binom{n}{n/2}\mathsf{pm}(\underbrace{U_{n/2} \cup L_{n/2}}_{D_n}) \approx_n 3^n.$$

6.2. Matchings across a line. We present a simple construction with about 2^n different crossing-free perfect bipartite matchings across a line.

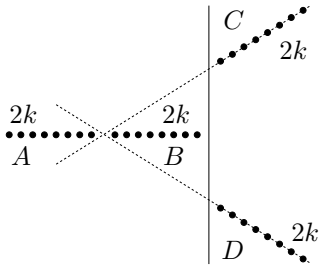

FIG. 13. *The lower bound construction for crossing-free perfect matchings across a line.*

Assume that $n = 8k$, and refer to Figure 13. Take two disjoint horizontal segments that lie on the x-axis to the left of the y-axis, and place on each of them $2k$ points. Denote by A (resp., B) the set of points on the left (resp., right) segment. The set L is $A \cup B$. To form R, draw two lines that separate A and B, one with positive slope and one with negative slope. Place $2k$ points on each of these lines to the right of the y-axis, and denote the set on the line with positive (resp., negative) slope by C (resp., D). The set R is $C \cup D$.

In order to specify a crossing-free perfect bipartite matching, we proceed as follows: Split A into two sets A_C and A_D of size k each, split B into two sets B_C and B_D of size k each, split C into two sets C_A and C_B of size k each, and split D into two sets D_A and D_B of size k each. The total number of choices is $\binom{2k}{k}^4 \approx_k 2^{8k} = 2^n$.

Now we match A_C with C_A, A_D with D_A, B_C with C_B, and B_D with D_B, which can always be done in a unique way that is noncrossing; see Figure 13.

We have thus shown that the following theorem holds.

THEOREM 6.1. *The maximum number of crossing-free perfect bipartite matchings between two separated sets, each of $\frac{n}{2}$ points, is at least $\binom{2\lfloor n/8\rfloor}{\lfloor n/8\rfloor}^4 \approx_n 2^n$.*

Clearly, this also serves as a lower bound for the more general case of perfect left-right matchings, for which we were not able to improve over the 2^n bound.

7. Discussion, open problems.

Relating the basis-constants. For $n \in \mathbb{N}$, let $\mathsf{pm}(n) := \max_{|P|=n} \mathsf{pm}(P)$ and $c_{\mathsf{pm}} := \limsup_{n\to\infty} \sqrt[n]{\mathsf{pm}(n)}$. (In fact, there is a unique limit for n over the even integers.) In an analogous fashion, define the constants c_{ma}, c_{sc}, c_{cfp}, and c_{lrpm} for the corresponding matching bounds. Also, define

$$\mathsf{rdpm}(n) := \sup_{\mu} \mathbf{E}_{\mu,n}[\mathsf{pm}(P)] \quad \text{and} \quad c_{\mathsf{rdpm}} := \limsup_{n\to\infty} \sqrt[n]{\mathsf{rdpm}(n)},$$

where μ ranges over all distributions of the plane which let two points coincide with probability 0, and $\mathbf{E}_{\mu,n}$ denotes the expectation for P a set of n i.i.d. points from distribution μ.

Apart from the absolute bounds that we derived for these constants, we have shown a number of relations among them, e.g.,

$$\begin{aligned}
&c_{\mathsf{pm}} \le 2^{1/3}\,5^{-1/6}\,c_{\mathsf{ma}} \qquad \text{(note also that } c_{\mathsf{ma}} \le c_{\mathsf{pm}} + 1\text{)},\\
&c_{\mathsf{sc}} \le 3\,{c_{\mathsf{lrpm}}}^2 \qquad \text{(also } c_{\mathsf{sc}} \le {c_{\mathsf{pm}}}^2\text{), and}\\
&c_{\mathsf{cfp}} \le c_{\mathsf{ma}} + 2 \qquad \text{(see remark preceding Theorem 5.2; note } c_{\mathsf{ma}} \le c_{\mathsf{cfp}}\text{)}.
\end{aligned}$$

We also derived a better upper bound on c_{rdpm} than on c_{pm} (while these constants still share the same lower bound of 3). It would be interesting to know whether that is an artifact of our proof. We believe not, supported by the following observation: If we consider four points, then in nonconvex position they have three crossing-free perfect matchings. If, however, we choose four i.i.d. points from any distribution, then they are in nonconvex position with probability less than $\frac{5}{8}$ [28], and therefore the expected number of crossing-free perfect matchings has to be less than $\frac{5}{8}\cdot 3 + \frac{3}{8}\cdot 2 = 2.625$.

Conjecture 1. $c_{\mathsf{rdpm}} < c_{\mathsf{pm}}$.

Also, can the bound for i.i.d. points be improved for specific distributions, uniform distribution in a disk, say?

Counting and enumeration. As far as we know, the algorithmic complexity of computing the number $\mathsf{pm}(P)$ of crossing-free perfect matchings for a set P of points is open—neither a polynomial algorithm is known, nor any lower bounds, $\#\mathcal{P}$-complete, say. The same is true for the numbers $\mathsf{tr}(P)$, $\mathsf{sc}(P)$, or $\mathsf{cfp}(P)$.

The situation looks somewhat more promising for enumeration. For triangulations and crossing-free spanning trees of a point set, Avis and Fukuda [8] show how to enumerate these objects in time poly(n) times the size of the output (see [27] for an application for enumeration of crossing-free graphs on a point set).

Nothing of the kind is known for perfect crossing-free matchings and spanning cycles. We mention on the side that *maximal* crossing-free matchings can be enumerated efficiently, due to a general result of that kind for maximal cliques in graphs [11]. To see this, define a graph for an n point set as follows. Let the vertices be the $\binom{n}{2}$ segments connecting pairs of points. Two such segments are connected by an edge if

they are disjoint, i.e., they neither cross nor share an endpoint. Now cliques in this graphs correspond to crossing-free matchings of the point set.

For perfect crossing-free matchings, we would need maximum cliques in the constructed graph. For these, no efficient enumeration algorithms exist (and are unlikely to exist at all), but it is still feasible that the special geometric structure allows such an algorithm for our problem.

Acknowledgment. We thank Andreas Razen for reading a draft of the paper and for several helpful comments.

COUNTING AND ENUMERATING POINTED PSEUDOTRIANGULATIONS WITH THE GREEDY FLIP ALGORITHM*

HERVÉ BRÖNNIMANN†, LUTZ KETTNER‡, MICHEL POCCHIOLA§, AND JACK SNOEYINK¶

Abstract. We present an algorithm to enumerate the pointed pseudotriangulations of a given point set, based on the greedy flip algorithm of Pocchiola and Vegter [*Discrete Comput. Geom.* 16 (1996), pp. 419–453]. Our two independent implementations agree and allow us to experimentally verify or disprove conjectures on the numbers of pointed pseudotriangulations and triangulations of a given point set. (For example, we establish that the number of triangulations is bounded by the number of pointed pseudotriangulations for all sets of up to 10 points.)

1. Introduction.

Algorithms that perform computations on sets of points in the plane frequently benefit from using the points to decompose the plane into simpler regions: triangulations, Voronoi diagrams, visibility maps, and Delaunay tessellations are good examples [18]. Decompositions called pseudotriangulations or geodesic triangulations have been studied for convex sets and for simple polygons in the plane because of their applications to visibility [39, 40], ray shooting [17, 22], covering and separation [42], and stretchability of pseudolines arrangements [44]. They have been used in a number of kinetic data structures (KDSs) for collision detection among moving objects in the plane [1, 30, 31] because they can be maintained by edge flips and can form a partition of the free space, whose size is related to minimum link separators of the objects. Streinu used them in an elegant proof, where it is possible to unfold any chain in the plane without self-intersection [50].

Pseudotriangulations possess versatility and uniformity properties that make them worthy of study. For instance, there is an edge-flip operation that applies to any internal edge in a pointed pseudotriangulation, unlike the edge-flip operation in triangulations. In section 2 we recall the definition of the edge-flip operation on pointed pseudotriangulations and some results on the graph of pointed pseudotriangulations, in which two pseudotriangulations are adjacent if they differ by a single edge flip.

The main result of this paper is an algorithm that uses edge flips to enumerate all pointed pseudotriangulations of a given point set. There have been many interesting results on counting and enumerating triangulations for a given set of points in the

plane. In a series of upper bounds on the number of triangulations of a given n-point set, a bound of $59^{n+o(n)}$ by Santos and Seidel [48] recently replaced the previous best result of $2^{8.12n+O(\log n)}$ by Denny and Sohler [20]. There are examples of point sets with as many as $72^{0.5n-\Theta(\log n)} = \Omega(8.48^n)$ triangulations [8], and it is even known that for *any* n-point set in general position in the plane, its number of triangulations is $\Omega(2.33^n)$ [9]. Aichholzer [3] has a counting algorithm (that can be executed from his Web page for small point sets [2]) and Bespamyatnikh [14] and Ray and Seidel [46] present enumeration algorithms. There remain elementary open questions, such as what point sets have the most and the fewest triangulations. (Aichholzer [2] maintains a list of the leading examples for up to 20 points.)

Less is known about the number of pointed pseudotriangulations of a given point set. Even the following conjecture is open.

CONJECTURE 1 (see [19]). *For any finite set of points in general position in the plane, its number of triangulations is bounded by its number of pointed pseudotriangulations with equality iff the points are in convex position.*

Randall et al. [45] have established that the number of pointed pseudotriangulations of any point set with i points inside the convex hull is upper bounded by 3^i times its number of triangulations. When combined with the best known upper bound on the number of triangulations, this gives that the number of pointed pseudotriangulations of an n-point set is bounded by $177.3^{n+o(n)}$. Bespamyatnikh has extended his enumeration algorithm [14] to pointed pseudotriangulations, but has yet to implement it. Also, his algorithm cannot efficiently enumerate only the pointed pseudotriangulations containing a given set of edges, which our algorithm can do. This in turn implies a strong connectivity property that is useful when studying the graph of pointed pseudotriangulations (see section 2.2, see also [47]).

Our algorithm, presented in section 3, is based on the greedy flip algorithm of Pocchiola and Vegter for computing the visibility complex of a scene of n convex objects in the plane [40], and on its extension developed in [11]. In section 4, we provide some implementation details; we have produced two independent implementations, which may be obtained from http://geometry.poly.edu/pstoolkit/ and www.cs.unc.edu/Research/compgeom/pseudoT/. In section 5, we present the results of experiments that explore basic conjectures on the number of pointed pseudotriangulations and triangulations. Both implementations agree in these experiments.

Note that Tutte [51] and others have studied the number of topological embeddings of triangulations and rooted triangulations when the locations of vertices are not specified. Li and Nakano [35] enumerate topologically distinct triangulations with a prescribed number of points on their boundaries. We focus strictly on the geometric question of when the vertex set must be a given set of points in the plane.

2. Minimum, or pointed, pseudotriangulations.

In this section, we recall the definition and basic properties of *pointed* pseudotriangulations. These are also called *minimum* by Streinu [50] because pointed pseudotriangulations are precisely the pseudotriangulations with the minimum number of edges. Since these are the only kind of pseudotriangulations we will consider in this paper, we will omit the words "pointed" and "minimum" and simply refer to pseudotriangulations.

2.1. Definitions.

Pseudotriangulations were defined by Pocchiola and Vegter [41] for the case of two-dimensional convex sets. In this paper, we are solely concerned with pseudotriangulations of point sets. One could replace each point p by a disk with center p and radius ϵ, for some small $\epsilon > 0$, and work within this framework. There are many subtleties involved, however, which warrant a study of pseudotriangulations

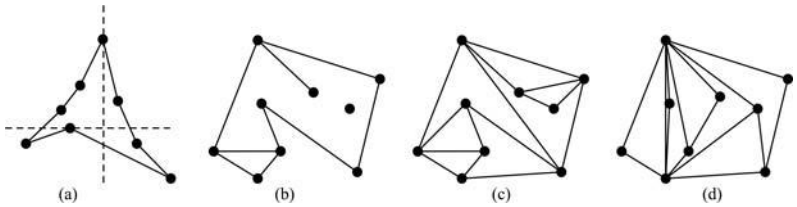

FIG. 1. (a) *A pseudotriangle and its horizontal and vertical tangents.* (b) *An acyclic planar set of edges.* (c) *A maximal acyclic planar set of edges or, put differently, a pseudotriangulation.* (d) *The canonical sorted pseudotriangulation.*

of point sets in their own right. For instance, two disks have four bitangents, only three of which can be nonintersecting; if we collapse the disks to points, all bitangents collapse to a single edge. To ease the reader's task and prevent circular dependencies, we do not make reference to the case of convex sets except in the proof of the flip property (Theorem 3).

Pseudotriangles. A *pseudotriangle* is a simple polygon in the plane that has exactly three vertices, called *corners*, with internal angle less than π. The three corners of a pseudotriangle decompose its boundary into three concave chains. The notions of *pseudoquadrangle* and *pseudo-n-gon* are defined similarly by allowing four or n corners.

Let T be a pseudotriangle. A *tangent* to T is a line l in the plane that goes either through a corner p of T and separates the two edges of T incident upon p, or through a noncorner p of T and does not separate the two edges of T incident upon p. A pseudotriangle has exactly one tangent line parallel to any given line. (See Figure 1(a).)

Pseudotriangulations. Let P be a set of n points in general position (i.e., no three collinear points) and let E be the set of $n(n-1)/2$ undirected line segments with endpoints in P (edges for short). For the purpose of this paper, we assume that there are no two parallel edges and no edge parallel to the x-axis.[1]

A subset H of E is called *planar* if its edges are pairwise interior disjoint, and it is called *acyclic* if for any endpoint p of an edge of H there is a line through p that leaves the edges of H incident upon p all on the same side. (See Figure 1(b).)

Following Streinu [50] we define a *pseudotriangulation* of P to be a maximal (for the inclusion relation), acyclic, and planar subset of E; note that the set of edges of the convex hull of P is included in every pseudotriangulation. (See Figures 1(c) and (d) for an illustration.) The following lemma recalls the connection between the acyclicity and the number of edges. It is stated and proved in [50, Theorem 3.1], and an easy proof can be adapted from [41, Lemma 2].

LEMMA 2. *The bounded faces of the subdivision of the plane induced by a pseudotriangulation of P are pseudotriangles. Furthermore the number of pseudotriangles of the subdivision is $n-2$ and its number of edges is $2n-3$.*

For points in convex position, the set of pseudotriangulations is exactly the set of triangulations; the external angle of each vertex on the convex hull is greater than π, so triangulations are acyclic. We define a canonical *sorted pseudotriangulation*, as in Figure 1(d), for any set of n points in general position by the following construction: Sort the points lexicographically by (x, y) coordinates and form a triangle with the first three points; then for each subsequent point in order, add one pseudotriangle by

[1] These two restrictions can be lifted, and indeed should be, in a good implementation. In section 5, we apply the algorithm to the point sets from the database of Aichholzer, Aurenhammer, and Krasser [5] which obey these restrictions.

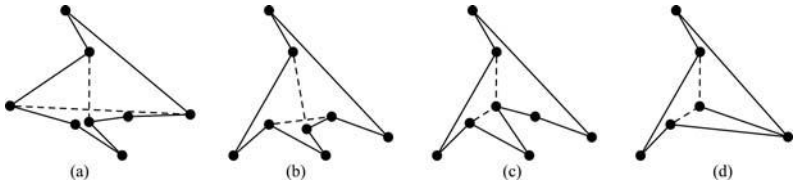

FIG. 2. *Four pseudoquadrangles. The last one,* (d)*, uses both sides of one segment. Each pseudoquadrangle has two diagonals (dashed segments), one on each shortest path that joins opposite corners. Each diagonal forms a pair of pseudotriangles, and an edge flip replaces one diagonal with the other.*

creating two tangents to the convex hull. This pseudotriangulation, called incremental in [1], has links to rigidity (where it is called a Henneberg construction) and has been used in collision detection.

Edge flips in pseudotriangulations. In a triangulation, an *edge flip* replaces any edge whose adjacent triangles form a convex quadrilateral by the opposite diagonal of that quadrilateral. Edge flips, sometimes known as Lawson flips, are useful tools for studying the properties of triangulations and for generating triangulations algorithmically [25, 33, 37].

The situation is even nicer in pseudotriangulations of point sets, since any edge that is inside the convex hull can be flipped, as described below. An almost identical flip operation is defined for pseudotriangulations of disks by Pocchiola and Vegter [40]. For completeness, we give the definition below. In section 3.2, we consider algorithms for computing flips.

Consider an edge e that is adjacent to two neighboring pseudotriangles. Each endpoint of e is a corner in at least one of the neighboring pseudotriangles, since each vertex has at most one angle that is greater than π; see Figure 2 for examples. Removing edge e merges the two neighboring pseudotriangles into a pseudoquadrangle. Indeed, at each endpoint of e either two corners merge into one corner or one corner merges with an angle greater than π. Thus, the six corners of the original two pseudotriangles become the four corners of a pseudoquadrangle.

A *diagonal* for a pseudoquadrangle is defined by connecting opposite corners with a shortest path through the interior. Such a shortest path cannot go through one of the other two corners, so it must separate the pseudoquadrangle into exactly two regions, each of which contains one of the other two corners. Hence, both regions must be pseudotriangles sharing exactly one edge e, which is the sought-after diagonal. Since there are two pairs of opposite corners, a pseudoquadrangle has two diagonals.

Now, any nonhull edge e is one diagonal of the pseudoquadrangle formed by removing e. We define the *edge flip* for e as the operation that removes e and replaces it with the other diagonal e'. Figure 2 shows four examples. It should be clear that flipping the new edge e' restores the original pseudotriangulation.

2.2. Graph and polytopes of pseudotriangulations. Formally, the *graph of pseudotriangulations* for a given set of points contains a node for each possible pseudotriangulation. An arc connects two nodes if the two corresponding pseudotriangulations differ by a single edge flip. The graph is undirected since flips are reversible.

In a previous version, we had shown, using the canonical sorted pseudotriangulation, that the graph of pseudotriangulations is connected and given a bound of $O(n^2)$ on its diameter. In 2003, Aichholzer et al. [7] improved the diameter bound to

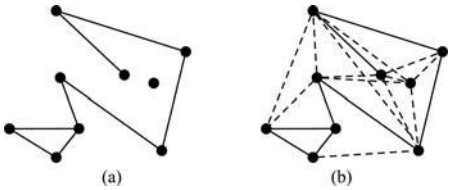

FIG. 3. (a) *An acyclic and planar subset K of E.* (b) *The set $E_K = \{e \mid K \cup \{e\}$ is acyclic and planar$\}$.*

$O(n \log^2 n)$, Bereg [13] to $O(n \log n)$, and more recently, Aichholzer et al. [4] improved it to $O(n \log k)$, where k is the number of convex layers of the point set.

The graph of pseudotriangulations has an even stronger connectivity property. If we consider only the pseudotriangulations that contain a chosen (acyclic and planar) set of edges, then we get a subgraph induced by the nodes corresponding to those pseudotriangulations, whose arcs join nodes that correspond to flips of the edges not in the chosen set of edges. This subgraph is connected. As we will see, this is a simple consequence of our enumeration algorithm. To put it in a different terminology [36], one can say that the poset, ordered by reverse inclusion, of planar acyclic sets of edges that contain the edges of the convex hull is an abstract polytope whose 1-skeleton is the graph of pseudotriangulations. Rote, Streinu, and Santos have shown that this abstract polytope is actually geometrically realizable, using a beautiful relation to minimally rigid graphs [47].

3. Enumerating pseudotriangulations. Our goal is to enumerate the set of pseudotriangulations over a given set of points. To this end we are going to define a total order $\prec$ on the set of edges and a binary tree of pseudotriangulations whose leaves considered as increasing sequences of edges are the pseudotriangulations ordered lexicographically; furthermore two adjacent pseudotriangulations in the tree are either identical or related by a flip operation. Our enumeration algorithm is a traversal of this tree guided by the aforementioned total order $\prec$. Our technique can also be applied to enumerate the pseudotriangulations that contain a given set of edges.

3.1. The flip property. We introduce some definitions and prove a flip property that is essential to proving the correctness of the enumeration algorithm. For each edge $e \in E$, define $\Theta(e)$ as the angle in $[0, \pi)$ that the edge e directed upward makes with the positive horizontal direction Ox.

Given an acyclic planar subset of edges $K \subseteq E$, we denote by E_K the set of edges $e \in E$ that can be used to complete K to a pseudotriangulation, i.e., such that $K \cup \{e\}$ is acyclic and planar. See Figure 3 for an illustration.

We define a partial order $\prec_K$ on E_K as follows: $e \prec_K e'$ if there exists a sequence of edges $e_1 = e, e_2, \ldots, e_k = e'$ such that e_i and e_{i+1} share a common endpoint and angles $\Theta(e_i) < \Theta(e_{i+1})$. According to the general position assumption, two edges sharing an endpoint have different angles and therefore are comparable. It follows that the edges of a pseudotriangle are pairwise comparable and are encountered in increasing order when traversing the boundary of the pseudotriangle counterclockwise, starting from its point of horizontal tangency. Following [40, Lemma 7] we observe that two crossing edges in E_K are the diagonals of some pseudoquadrangle (with edges in E_K) and consequently are comparable with respect to $\prec_K$.

A *filter* for a poset $(X, \prec)$ is a subset I of elements such that for any $x \prec y$, if $x \in I$ then $y \in I$. In particular, to each angle θ corresponds a filter $I_{K,\theta}$ of the poset

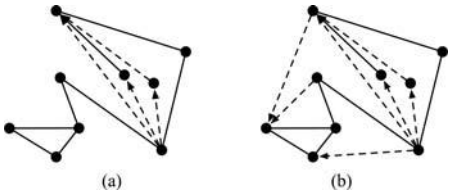

FIG. 4. *The set $G(I_{\pi/2})$ is constructed by adding edges from the filter $I_{\pi/2}$, i.e., edges with increasing angles greater than $\pi/2$, until a pseudotriangulation is formed.* (a) *illustrates that it is not sufficient to consider angles in $[\pi/2, \pi)$ only, but by "wrapping around"* (b) *we complete a pseudotriangulation.*

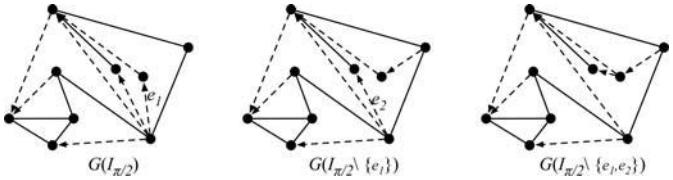

FIG. 5. *Illustration of the flip property for points.*

$(E_K, \prec_K)$ whose elements are the edges e' of E_K whose angle $\Theta(e')$ is greater than θ. Note that $I_{K,0} = E_K$, and $I_{\emptyset,0} = E$.

For any filter I of the poset $(E_K, \prec_K)$, we define a maximal planar acyclic set of edges $G(I) = \{e_1, e_2, \ldots, e_k\}$ recursively: edge e_1 is minimal in I, and, for $i \geq 1$, edge e_{i+1} is minimal in the set of edges $e \in I \setminus \{e_1, \ldots, e_i\}$ such that $K \cup \{e_1, \ldots, e_i, e\}$ is acyclic and planar. Since two edges that cross or that share an endpoint are comparable, $e_1, e_2, \ldots, e_k$ is independent on the choice of the minimal element at each step, or in other words, the set $G(I)$ is well defined.

We would like for $G(I)$ to be a pseudotriangulation, and for this it suffices to make sure that $G(I)$ has $2n - 3$ edges. This is not always possible, however, due to the fact that we chose the principal determination of Θ in $[0, \pi)$, therefore introducing a discontinuity in the comparisons, and forcing the algorithm to stop perhaps too early. (See Figure 4.) To circumvent this, we replace, in the previous definitions, the set of edges E_K with its infinite cover $\mathbb{E}_K = E_K \times \mathbb{Z}$: elements of $\mathbb{E}_K$ are still called edges, and the angle $\Theta(v)$ of an edge $v = (e, k)$ of $\mathbb{E}_K$ is defined to be the real $\Theta(e) + k\pi$. The operator on $\mathbb{E}_K$ that increases the angle of an edge by π is denoted ι. It is not hard to see that if I is a filter of $(\mathbb{E}_K, \prec_K)$, then its projection on the first factor E_K is onto, from which we deduce that $G(I)$ is a pseudotriangulation. In this context we redefine the flip operation as follows: To flip e in $G(I)$ means to replace e with $\iota(e)$ if $e \in \mathbb{K} := K \times \mathbb{Z}$ or if e is a hull-edge, otherwise to perform an edge flip on e and assign the angle of the diagonal by adding a multiple of π to fall into the range $(\Theta(e), \Theta(e) + \pi)$.

The pseudotriangulation $G(I_{\emptyset,0})$ is called the *horizontal greedy pseudotriangulation* and plays a particular role in our enumeration algorithm. Below we explain how to efficiently compute this pseudotriangulation.

We are now in a position to state the *flip property*. This property states that flipping a minimal edge in a pseudotriangulation of the form $G(I)$ results in a pseudotriangulation of the form $G(J)$, and this will be crucial in our enumeration algorithm. See Figure 5 for an illustration.

THEOREM 3 (flip property for points). *Let I be a filter of the poset $(\mathbb{E}_K, \prec_K)$ and let e be minimal in I. Then $G(I \setminus e)$ is obtained from $G(I)$ by flipping e.*

The proof relies on the theory of pseudotriangulations developed for bounded two-dimensional convex sets in [11, 40]. The heart of the proof is to replace each point $p \in P$ by the disk with center p and radius ϵ, for some small $\epsilon > 0$, and to derive the flip property for points from the "flip property for disks" (cf. [40, Theorem 12] and [11, Theorem 5]). There are many subtleties involved, however. For one thing, disks have four bitangents, only three of which can be nonintersecting, and they all map to a single edge of the point set. Nevertheless, with a bit of care, it is possible to carry the flip property from the case of disks to the case of points.

We briefly recall the terminology and the results of [11, 40] needed for our purpose. Let $O_1, O_2, \ldots, O_n$ be a collection of n pairwise disjoint bounded closed convex subsets of the plane with nonempty interiors and regular boundaries (obstacles or disks for short). We assume that there is no line tangent to three disks. A *bitangent* is a closed undirected line segment whose supporting line is tangent to two disks at its endpoints. A *free* bitangent is a bitangent whose interior lies in free space, defined as the complement of the disks. In the following considerations all bitangents are free. A set of (free) bitangents is called *planar* if its elements are pairwise disjoint. A *pseudotriangulation* (of the O_i's) is a planar set of bitangents that is maximal for the inclusion relation. It is known that a pseudotriangulation contains $3n-3$ bitangents that decompose the convex hull of the disks into $2n-2$ *pseudotriangles* where, in this context, a pseudotriangle is a simply connected region of the plane whose boundary consists of three convex curves that share a tangent at their common endpoint and which is included in the triangle formed by the three endpoints of these convex curves.

We denote by B the set of (free) bitangents and we introduce its infinite cover $\mathbb{B} = B \times \mathbb{Z}$: elements of $\mathbb{B}$ are still called bitangents; the angle $\Theta(v)$ of the bitangent $v = (b, k) \in \mathbb{B}$ is defined to be the real $\Theta(b) + k\pi$, where $\Theta(b)$ is the angle in $[0, \pi)$ that b, oriented upward, makes with the horizontal positive direction Ox, and the direction of $v \in \mathbb{B}$ is the unit vector $(\cos\Theta(v), \sin\Theta(v)) \in \mathbb{S}^1$; the operator that increases the angle of a bitangent by π is denoted ι.

Given a planar subset H of B, we introduce the set B_H of bitangents of B that cross no bitangent of H properly (thus $H \subseteq B_H$). The set $\mathbb{B}_H$ is endowed with a partial order $\prec_H$ defined as follows: $b \prec_H b'$ if there exists a sequence of bitangents $b_1 = b, b_2, \ldots, b_k = b'$ in $\mathbb{B}_H$ such that b_i and b_{i+1} touch the same oriented disk[2] and such that $\Theta(b_i) < \Theta(b_{i+1})$. Each (proper) filter I of $(\mathbb{B}_H, \prec_H)$ is associated with its so-called greedy pseudotriangulation

$$G(I) = \{b_1, b_2, \ldots, b_{3n-3}\} \subset I$$

defined as follows: (1) b_1 is minimal in I, and (2) b_{i+1} is minimal in the subset of bitangents of I crossing none of the bitangents $b_1, b_2, \ldots, b_i$. Since crossing bitangents are comparable (cf. Lemma [40, Lemma 7]), $G(I)$ is well defined and is a superset of the set of minimal elements of I. To flip b in $G(I)$ means to replace b with $\iota(b)$ if $b \in \mathbb{H} := H \times \mathbb{Z}$ or if b is a hull bitangent, otherwise to replace b with the second diagonal (with the appropriated angle) of the pseudoquadrangle obtained by merging the two pseudotriangles incident upon b in $G(I)$.

[2] An oriented disk is a disk with a "direction," "sense," or "orientation" assigned to its boundary. An oriented disk and a bitangent touch each other, or are tangent to each other, if their directions at the point of touching are the same.

THEOREM 4 (flip property for disks [11, 40]). *Let b be minimal in the filter I of the poset $(\mathbb{B}_H, \prec_H)$. Then $G(I \setminus b)$ is obtained from $G(I)$ by flipping b.*

According to the flip property, the mapping that associates with the bitangent $b \in \mathbb{B}_H$ the bitangent $b' \in \mathbb{B}_H$ defined by $\{b'\} = G(I \setminus b) \setminus G(I)$, where b is minimal in I, is well defined (because it is independent of I), one-to-one, and onto; the bitangent b' is denoted $\phi(b; H)$.

We turn now to the proof of the flip property for points. We split the proof into several lemmas. The key idea of the proof is to define an epimorphism of posets to carry the flip property from the case of disks to the case of points. Before defining this epimorphism, we reformulate the greedy procedure in terms more suitable for our subsequent analysis.

LEMMA 5. *Let I be a filter of $\mathbb{B}_H$ and let F be* initial *in I; i.e., $I \setminus F$ is a filter. Then $G(I) = G(I(F))$, where $I(F)$ is the filter of the poset $\mathbb{B}_{H \cup G(F)}$ defined by $I(F) = I \cap \mathbb{B}_{H \cup G(F)}$. A similar result holds when taking K and $\mathbb{E}_K$ for H and $\mathbb{B}_H$, respectively.*

Proof. Since F is initial, $G(F)$ is a subset of $G(I)$. The lemma follows easily. □

Now we turn to the construction of the epimorphism. For $\epsilon > 0$ let $O_i(\epsilon)$ be the disk with center p_i and radius ϵ. Since the points are in general position, there exists a real $\epsilon_0 > 0$ such that for all $\epsilon < \epsilon_0$ no line pierces three of the disks $O_i(\epsilon)$ and no horizontal line pierces two disks. (Remember that we assumed that no two points have the same ordinate.) We choose such an ϵ, introduce the set B of $2n(n-1)$ (free) bitangents of the $O_i(\epsilon)$s, and denote by η the four-to-one mapping that associates with a bitangent b in B tangent to the disks O_i and O_j the edge $\eta(b)$ of E with endpoints p_i and p_j. Our first lemma provides a characterization of acyclicity in terms of the crossing predicate.

LEMMA 6. *Let K be a planar subset of E. Then K is acyclic iff for all maximal (for the inclusion relation) planar subsets H of $\eta^{-1}(K)$ one has $\eta(H) = K$.*

Proof. The "if part" is easy. To prove the "only if part" we show that if there exists an edge $e \in K$ and a maximal planar subset H of $\eta^{-1}(K)$ such that $e \notin \eta(H)$, then K is not acyclic. Let p and q be the endpoints of e and let p^+ (resp., p^-) be the set of edges $e' \in K$ such that (i) p is the endpoint of e', i.e., $e' = [p, r]$ for some point r, and (ii) the triplet of points (p, r, q) is oriented counterclockwise (resp., clockwise).

The assumption that $e \notin \eta(H)$ is equivalent to saying that for all $b \in \eta^{-1}(e)$ there exists a bitangent b' of H such that b and b' are crossing. A simple case analysis shows that this is equivalent to saying that the sets $p^+ \cup q^+$, $p^+ \cup q^-$, $p^- \cup q^+$, and $p^- \cup q^-$ are nonempty; from this, we deduce that p^+ and p^- (or q^+ and q^-) are nonempty and consequently that K is not acyclic. □

Our next lemma is the key to the construction of an epimorphism from some $B_H \subseteq \eta^{-1}(E_K)$ onto E_K.

LEMMA 7. *Let K be an acyclic and planar subset of E and let H be a maximal (for the inclusion relation) planar subset of $\eta^{-1}(K)$. Then*

1. *$\eta(\mathbb{B}_H) = \mathbb{E}_K$, and*
2. *if $b \prec_H b'$, then $\eta(b) \preceq_K \eta(b')$.*

Proof. Claim (1) is a consequence of Lemma 6. Indeed, let $K' = K \cup \{e\}$ be planar and acyclic and let $H' \supseteq H$ be a maximal planar subset of $\eta^{-1}(K')$ that contains H. According to Lemma 6 applied to the pair K', H', one has $\eta(H') = K'$ and consequently some bitangent of $\eta^{-1}(e) \in B_H$. Claim (2) is a simple consequence of Claim (1) and the observation that if b and b' touch the same oriented disk with

$\Theta(b) < \Theta(b')$, then $\eta(b)$ and $\eta(b')$ share a common endpoint and $\Theta(\eta(b)) \leq \Theta(\eta(b'))$ with equality iff $\eta(b) = \eta(b')$. □

In other words, the restriction η_H of η to $\mathbb{B}_H$ is a mapping onto $\mathbb{E}_K$ that preserves the orderings. We show that η_H preserves also the greedy pseudotriangulations.

LEMMA 8. *Let K be an acyclic and planar subset of E, let H be a maximal planar subset of $\eta^{-1}(K)$, and let I be a filter of $(\mathbb{E}_K, \prec_K)$. Then*

1. *$\eta_H^{-1}(I)$ is a filter of $(\mathbb{B}_H, \prec_H)$, and*
2. *$\eta(G(\eta_H^{-1}(I))) = G(I)$.*

Proof. Claim (1) is a simple consequence of Lemma 7. Claim (2) is proved by induction on the set of planar acyclic subsets K of E ordered by reverse inclusion. Let $J = \eta_H^{-1}(I)$. This is clearly valid if K is maximal since in that case $\mathbb{E}_K = \mathbb{K}$, $\mathbb{B}_H = \mathbb{H}$, and consequently $G(I) = I \setminus \iota(I)$ and $G(J) = J \setminus \iota(J)$ from which we deduce that $\eta(G(J)) = G(I)$. Assume now that K is not maximal and let e be minimal in I. If $e \notin K$, we set $K' = K \cup \{e\}$ and $H' = H \cup G(\eta_H^{-1}(\{e\})$. According to Lemma 5, $G(I) = G(I')$ and $G(J) = G(J')$, where $I' = I(\eta_H^{-1}\{e\})$ and $J' = J(\{e\})$. One can check that $I' = \eta_{H'}^{-1}(J')$, from which the result follows by induction since $K \subset K'$. If $e \in K$, we replace e with an initial segment of J that contains exactly one element not in K and proceed similarly. □

We are now ready to carry the flip property from the case of disks to the case of points.

Proof of Theorem 3. Let $J = \eta_H^{-1}(I)$ and let $F = \eta_H^{-1}(e)$. Note that F is initial in J since $J \setminus F = \eta_H^{-1}(I \setminus e)$ (cf. Lemma 8, claim 1). Thanks to the flip property for disks, the set $G(J \setminus F)$ is obtained from $G(I)$ by successively flipping the bitangents of F. Therefore one has

$$G(J \setminus F) = (G(J) \setminus G(F)) \cup \phi(F; H) \setminus F$$

and consequently, according to Lemma 8,

$$G(I \setminus e) = (G(I) \setminus e) \cup \eta(\phi(F, H) \setminus F).$$

Since $G(I \setminus e)$ and $G(I)$ have the same cardinality, namely $2n - 3$, it follows that $G(I \setminus e) \setminus G(I)$ is reduced to a single edge, which is one of the edges of $\eta(\phi(F; H) \setminus F)$. □

3.2. Algorithms for edge flip. In this section we sketch two implementations of the edge-flip operation, assuming that the pseudotriangulation is stored in a data structure that allows us to access its edges in order around a given face. Standard structures for planar subdivisions, such as doubly connected edge lists or quadedge [18, 23], provide this.

Rotational sweep for edge flip. We can determine the new diagonal obtained by flipping edge e using a rotational sweep somewhat similar to the rotating caliper [18]. The algorithm proceeds by rotating parallel tangents simultaneously along the interiors of the two pseudotriangles adjacent to e. Starting from the edge e that we want to flip, the two tangents initially coincide but have opposite orientations. If we sweep through the angles, the two tangents immediately separate and meet again only when they reach the new diagonal. We can discretize this sweep because the tangents rotate around vertices until they are collinear with the next edge of a pseudotriangle. Then they advance to the next vertex. At corners, the tangent changes its orientation with respect to the edge orientation. The sweep terminates when the tangents again coincide. See Figure 8 for an implementation.

A matroidal flip algorithm. The predicate in the rotational sweep is a test ordering two vectors. One can also give an implementation that only uses the orientation predicate `left_turn`(p, q, r), which returns true iff the point sequence p, q, r forms a left turn. We can call such an algorithm "matroidal," in that it uses only information about the order type of the points [15, 32]. Such algorithms are usually better in that they have fewer degenerate configurations, lower arithmetic complexity, and generalize to other matroids.

The idea behind the algorithm is to identify the flip as the only diagonal edge on the shortest path connecting the opposite corners. The funnel algorithm of Lee and Preparata [34] can be modified [24] to compute shortest paths in linear time and to return the unique edge not on the boundary of the pseudoquadrangle. Alternatively, one can compute common tangents for the pairs of chains in a pseudoquadrangle to identify the diagonals. Tangents for two separated chains can be found in $O(\log n)$ time [29, 38]. When computing the visibility graph of a set of convex obstacles, Angelier and Pocchiola [11] use a clever amortization scheme to compute tangents in $O(1)$ time apiece.

3.3. The enumeration algorithm. In this section, we consider the total order $<$ on E and $\mathbb{E}$ induced by Θ. This order is compatible with, and linearly extends, $(E, \prec)$. Although we assume general position, the case of parallel edges could be handled by considering a linear extension of $(E, \prec)$.

In the algorithm, we speak of edges in E as colored red or blue. The red edges are fixed and will not be flipped; the blue edges can be flipped. We now describe the following binary tree $\mathcal{T} = \mathcal{T}(P)$ of {red,blue}-colored pseudotriangulations of P. Each node of the tree corresponds to a colored pseudotriangulation G, and we identify the node of the tree with its pseudotriangulation G. The tree is defined as follows:

1. The root of $\mathcal{T}$ is the horizontal greedy pseudotriangulation $G(I_{\emptyset,0})$; all its edges are blue.
2. Let G be a node of $\mathcal{T}$: If either (i) a blue edge of G has an angle $\geq \pi$, or (ii) all the edges of G are red, then G is a leaf of the tree. Otherwise, let e be a minimal blue edge, e.g., the blue edge with minimum angle $\Theta(e)$. The right child of G is obtained from G by flipping e, and its left child is obtained by changing the color of e to red.

A leaf G satisfying 2(i) is called a blue leaf, and a leaf satisfying 2(ii) is called a red leaf. Blue leaves stop the algorithm from enumerating a pseudotriangulation G several times; without stopping for blue leaves, the tree would be infinite, and each pseudotriangulation would be reported for every value of Θ with the same remainder modulo π.

The algorithm simply explores the tree $\mathcal{T}$ by a depth-first traversal, visiting the left child before the right child, and reporting the red leaves in the order in which they are discovered.

The algorithm is fully described once we explain how to find the minimal blue edge e. In the most direct implementation, the blue edges are stored in a priority queue, ordered by Θ. The edge e at the top of the queue is removed upon descending to either child, and edge e' is enqueued when descending to a right child iff its angle $\Theta(e') < \pi$ (otherwise the right child is a blue leaf and the recursion stops).

It is not necessary to store the priority queue in the recursion stack if we simply add edge e back to the queue when returning to the parent after visiting the right subtree. Thus, the stack grows by $O(1)$ at each recursive call.

THEOREM 9. *The set of red leaves of $\mathcal{T}(P)$ ordered from left to right (in the order they are reported by the algorithm) is the set of pseudotriangulations of P ordered lexicographically by Θ.*

Proof. Let G be a pseudotriangulation with edges in E and let $G_0, G_1, \dots G_i, \dots G_k$ be the path in the tree defined inductively: G_0 is the root of the tree and G_{i+1} is the left child of G_i if the minimal blue edge of G_i belongs to G; otherwise G_{i+1} is its right child. Let K_i be the set of red edges of G_i, edge e_i be the minimal blue edge of G_i, and filter $I_i = I_{K_i,\Theta(e_i)}$ of E_{K_i}. We claim that

1. $K_i \subseteq G$,
2. $G \setminus K_i \subset I_i$,
3. $G(I_i) = (G_i \setminus K_i) \cup \iota(K_i)$,

from which we deduce that G_k is a red leaf and $G = G_k$.

Claims (1), (2) and (3) are easily proven by induction on i using the flip property of the previous section. The proof is finished by noting that the red leaves of the tree are pseudotriangulations with edges in E. □

Note that the theorem is also valid for any total order $<$ that is a linear extension of $\prec$, yielding a well-defined tree $\mathcal{T}_<(P)$. Since Θ induces such a total order and is easy to compute, thanks to the geometry, it is convenient to use it. See remark 1 below.

THEOREM 10. *The height of the tree $\mathcal{T}(P)$ is at most $n(n-1)/2$.*

Remarks. 1. In this formulation, the algorithm depends on the order Θ of the edges, which is not implied by the orientation of all triplets of points. For this reason, the algorithm as described here is not matroidal. It is, however, possible to give a matroidal algorithm, by selecting for e *any* blue edge that is minimal for the partial order $\prec$. In this case the tree $\mathcal{T}(P)$ isn't uniquely defined, and finding such an edge is more difficult, necessitating the maintenance of the antichain ($\hat{I}$ in the notation of [11]) associated with the current filter I while traversing the tree.

2. Maintaining the *dual* pseudotriangulation of G (in the terminology of [11]) while traversing the tree, where an edge and its dual have the same color, allows us to retrieve e when coming back from the right subtree. Hence instead of storing a recursive stack to remember e on the way up the tree, the algorithm can maintain only G and its dual. This changes the space complexity of the algorithm from quadratic to linear.

3. If K is an acyclic and planar set of edges, then by coloring the edges of K red, and replacing the root of the tree with the horizontal greedy pseudotriangulation $G(I_{K,0}) \subseteq E_K$, the algorithm enumerates the set of pseudotriangulations that contain K. Observe that this proves that the subgraph of pseudotriangulations that contain K is connected.

3.4. The horizontal greedy triangulation. We now explain how to compute $G(I_{\emptyset,0})$. In fact, the algorithm can be adapted by a simple rotation to compute $G(I_\theta)$ for any $\theta \in [0, \pi)$. It is convenient for the exposition (and for the algorithm) to order the points of P by lexicographical order, i.e., $p_1 <_{yx} p_2 <_{yx} \cdots p_n$.

The construction uses *lower* and *upper horizon trees*, defined here as follows. For all point p_i with $1 \le i < n$, denote by $\ell(p)$ the point p_j, for $j > i$, which minimizes the angle $\Theta(p\vec{p}_j) \in [0, \pi)$. Define $\ell(p_n) = p_n$. Since $\ell^n(p) = p_n$, the set of edges of the form $p\ell(p)$ is a tree whose root is p_n (it is connected because every p_i has a path to p_n, and it has n vertices and $n-1$ edges). We call that tree the *lower horizon tree* and denote it by $T_\ell(P)$.

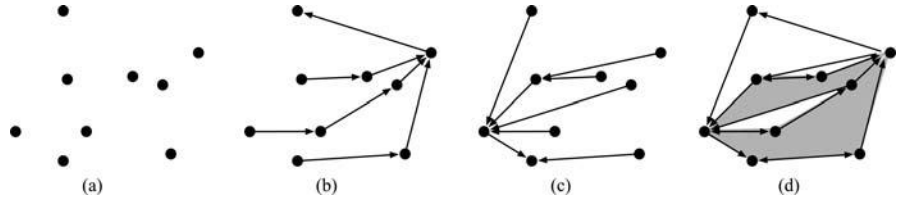

FIG. 6. (a) *shows point set,* (b) *its lower horizon tree and* (c) *its upper horizon tree;* (d) *shows that the superimposition of the horizon trees yields pseudoquadrangles (shaded areas) and pseudotriangles.*

COMPUTELOWERHORIZONTREE(P)	COMPUTEUPPERHORIZONTREE(P)
Effects: computes $\ell(p_i)$ for every $p_i \in P$	**Effects:** computes $u(p_i)$ for every $p_i \in P$
1: $\ell(p_n) \leftarrow p_n$	1: $u(p_1) \leftarrow p_1$
2: **for** $i \leftarrow n-1$ **downto** 1 **do**	2: **for** $i \leftarrow 2$ **to** n **do**
3: $j \leftarrow i+1$	3: $j \leftarrow i-1$
4: **while** `right_turn`$(p_i, p_j, \ell(p_j))$ **do**	4: **while** `right_turn`$(p_i, p_j, u(p_j))$ **do**

6: $\ell(p_i) \leftarrow p_j$	6: $u(p_i) \leftarrow p_j$

FIG. 7. *Computing the lower and upper horizon trees.*

Likewise, for point p_i with $1 < i \leq n$, denote by $u(p)$ the point p_j, $j < i$, which minimizes the angle $\Theta(\vec{pp}_j) \in [\pi, 2\pi)$ (define $u(p_1) = p_1$). The set of edges of the form $pu(p)$ is also a tree, of root p_1, which we call the *upper horizon tree* and denote by $T_u(P)$.

The following lemma, first observed in [43], forms the basis of the algorithm. See Figure 6 for an illustration.

LEMMA 11. *Let $K = T_\ell(P) \cup T_u(P)$ be the set of edges belonging to the horizon trees.*

1. *K contains all the edges of the convex hull of P.*

2. *K decomposes the convex hull of P into regions, each of which is either a pseudotriangle or a pseudoquadrangle.*

3. *$K \subseteq G(I_{\emptyset,0})$.*

With this lemma, the algorithm is straightforward. The pseudocode is given in Figure 7. It computes $\ell(p)$ for each $p \in P$ by Andrew's variant of Graham's convex hull algorithm [10]. We need the predicate `right_turn`(p, q, r) which returns true if the point sequence p, q, r forms a right turn. (In particular, the inner **while** loop will stop at $j = n$ since `right_turn`(p_i, p_n, p_n) is always false.)

Note that the algorithm still produces the correct tree if two edges are parallel, or even if two points have the same ordinate (thanks to the lexicographical order).

Computing $u(p)$ is performed by a similar algorithm. The initial sorting takes $O(n \log n)$ time. Once the horizon trees have been computed in $O(n)$ time, the subdivision they induce can be constructed in linear time, and each region can be visited to determine if it is a pseudotriangle or pseudoquadrangle. A pseudoquadrangle can be split in time linearly proportional to its number of edges by computing its two diagonals and inserting the one with smaller Θ. Thus, once the points are sorted lexicographically, the algorithm computes $G(I_{\emptyset,0})$ in linear time.

3.5. Complexity analysis. The algorithm spends $O(n)$ time for a flip or a priority queue operation in the worst case, and hence time $O(n)$ per edge of the tree.

Since the number of edges is the same as the number of internal nodes, which is also the number of leaves minus one, the algorithm spends amortized time $O(n)$ per pseudotriangulation.

Using a heap for the priority queue reduces the cost of the priority queue operations to $O(\log n)$. Moreover, using binary search can reduce the complexity of the flip algorithm to $O(\log n)$ as well, at the cost of maintaining the corners of pseudotriangles (which can be done in $O(1)$ time after a flip) and maintaining the boundary of the pseudotriangles as splittable queues as in [40].

Unfortunately, this is the time spent per leaf, counting both the n_r red *and* the n_b blue leaves. The following ratio is therefore important for analyzing the complexity of the algorithm: $\rho = (n_b + n_r)/n_r$. We initially conjectured a bound of 2 on this ratio, which was disproved by experiments (see next section). Currently, the best upper bound we have is the number of edges of a pseudotriangulation not on the convex hull, i.e., $2n - 3 - h$.

To conclude, the algorithm is set up in time $O(n \log n)$ to compute the horizontal greedy triangulation $G(I_{\emptyset,0})$ and insert its edges into the priority queue. The running time of the algorithm per red leaf of the tree (i.e., pseudotriangulation of P) is upper bounded by $O(\rho n) = O(n^2)$ and can be lowered with more complicated algorithmic machinery to $O(\rho \log n) = O(n \log n)$. All of this is in the worst case.

Note that the average complexity of a pseudotriangle is $O(1)$; thus on the average the flip will be performed in constant time. We expect that ρ is much smaller than n, although not constant ($\rho = O(\log n)$ seems a tempting conjecture, but we do not have a shred of evidence to support it). Thus, in practice we expect that the amortized cost per pseudotriangulation is much lower than $O(n \log n)$, perhaps $O(\rho)$. In order to state such a result, however, we lack what is needed, namely, an amortized bound for the flip (in the spirit of the analysis developed in [11]) and an upper bound for ρ.

Note finally that the number of pseudotriangulations grows exponentially fast (it is at least the Catalan number C_{n-2} for convex configurations [6]), thus limiting the domain of practicality of our algorithm in the low tens (resp., twenties). Thus, all the asymptotic complexities should be taken with a grain of salt. A good implementation will settle for low-complexity algorithms as well as simplicity of the code.

4. Implementation issues. Two independent implementations based on the above algorithm have been developed in order to ensure the correctness of the experimental validation of the conjecture.

4.1. Half-edge data structure. In both implementations, we chose to represent pseudotriangulation by a half-edge data structure (HDS), a.k.a. a doubly connected edge list (DCEL). One implementation is based on CGAL and described in [26, 21], and the other is based on an independent half-edge data structure described in [16].

An HDS is an edge-based data structure capable of storing a pseudotriangulation, or more generally, any connected planar set of edges. Each edge is split into two half-edges with opposite orientations. By convention, the half-edges incident to a face are oriented counterclockwise around the face. An `opposite` pointer links a half-edge to its opposite half-edge, and `next` and `prev` pointers links it to the next half-edge in counterclockwise orientation along the incident face. The incident vertices of a half-edge are named the `source` and `target`, as in [16].

4.2. Flip algorithm. Since the algorithm needs to examine the flip edge and decide whether to actually perform the flip or not, it is advantageous to implement

```
FindPseudoFlip(h)
Returns: a pair (h', g') such that the edge joining source(h') and source(g') is
the flip of the edge supporting h.
 1: g ← opposite(h)
 2: reverse_h←is_corner(h), reverse_g←is_corner(g)
 3: while true do
 4:   {decide which of g or h is the next tangent to jump to the next vertex}
 5:   if rotate_ccw_less(source(h), target(h), source(g), target(g))
                  is the same as (reverse_h≠reverse_g) then
 6:     {test if advancing g crosses over h and thus is the solution}
 7:     if left_turn(source(h), source(g), target(g))≠reverse_g then
 8:       return (h, g)
 9:     {not a solution yet, advance g}
10:     g ← next(g)
11:     if is_corner(g) then
12:       reverse_g←negate(reverse_g)
13:   else
14:     {test if advancing h crosses over g and thus is the solution}
15:     if left_turn(source(h), source(g), target(g))≠reverse_h then
16:       return (h, g)
17:     {not a solution yet, advance h}
18:     g ← next(h)
19:     if is_corner(h) then
20:       reverse_h←negate(reverse_h)
```

FIG. 8. *An implementation of the rotational flip method.*

the rotational sweep method. Moreover, in this case, neither the flip algorithm nor the enumeration algorithm needs the reverse `prev` pointers, thus saving space and execution time. For simplicity, we present below an implementation that uses `prev` pointers, namely, in the `is_corner` function. Eliminating `prev` pointers is possible (see the implementation in http://geometry.poly.edu/pstoolkit/) but complicates the pseudocode.

The function FindPseudoFlip returns two half-edge handles whose source vertices form the endpoints of the flipped diagonal rotated counterclockwise from the old diagonal. The function does not actually flip the diagonal. Note that the result could include the old diagonal, which needs to be considered before removing the old diagonal. In the function, h and g are the half-edges whose source vertices are in contact with the two rotating tangents. The two flags `reverse_h` and `reverse_g` indicate the relative orientation of the tangents to the half-edge h and g, respectively.

The pseudocode is presented in Figure 8. This function needs two geometric predicates: `left_turn`(p, q, r) returns true if the point sequence p, q, r forms a left turn, while `rotate_ccw_less`(p, q, r, s) returns true if the angle from the oriented segment pq to the oriented segment rs is less than π, which is equivalent to `left_turn`$(p, q, p + (s - r))$. As a convenience, `is_corner`(h) returns `left_turn(source(prev(`h`)), source(`h`), target(`h`))`.

We note that it is possible for two pseudotriangles to share more than the original edge h (but then it is easy to see that they cannot share more than two). In this

case, the reader can check that the algorithm does not miss the flip due to such (unavoidable) singularities.

An optimization we could have tried for the flip is to see if the two adjacent regions are triangles, which gives the diagonal without any geometric tests. (Note that because of the minimality of pseudotriangulations, the union of these two triangles must be a convex quadrilateral.) There is no guarantee, however, that even a single edge is adjacent to two triangles (consider, for instance, $p_1 = (0, -1)$, $p_2 = (0, 1)$, $p_k = (k, 0)$ for $k = 3, \ldots, n$). Nevertheless, if the point set has h edges on the boundary of its convex hull, there are at least $h - 2$ triangles in the pseudotriangulation (with equality iff all the pseudotriangles are at most quadrangular).

4.3. Enumeration algorithm. Using the FindPseudoFlip function, it is easy to implement the recursive variant of the enumeration algorithm. As noted, the only variable that we need to store in the recursion stack is the minimal edge e at the current node.

Since the number of pseudotriangulations of n points grows exponentially with n, we will not be able to run the algorithm for values of n larger than, say, 20. In fact, $n = 10$, with up to 234,160 pseudotriangulations, is already a challenge and takes on the order of a second. This dictates a few implementation choices.

First, the priority queue can be a simple vector of edges, sorted by Θ values, although using a binary heap is not a penalty and improves the performance slightly. Second, finding the flip without performing it saves a constant time. Third, a nonrecursive version of the algorithm eliminates the function call overhead, which contributes a (small) constant factor overall. Fourth, storing the old diagonal e on the stack when a diagonal is flipped avoids searching for this edge by reverse flipping the edge e' in order to restore the original pseudotriangulation. The second and fourth optimizations combined save 36% in runtime.

5. Experimental results. We started this investigation to support or find a counterexample to Conjecture 1 in section 1. The conjecture is not known to be true even for small values of n. We ran our enumeration algorithm on Aichholzer, Aurenhammer, and Krasser's comprehensive database of point sets with cardinality $n \leq 10$ [5] to obtain the number of pointed pseudotriangulations for every point set. The corresponding numbers triangulations are available on Aichholzer's Web page [2]. Our result is that for the over 14 million point sets S in the database up to $n \leq 10$, the number of triangulations of S is bounded by its number of pointed pseudotriangulations. Moreover, we also have computed the maximum number of pseudotriangulations (Table 5.1), which enriches Aichholzer's compendium. Finally, we have packaged our software into a pseudotriangulation workbench with which we can interactively examine pseudotriangulations, flip edges, and perform various algorithms (Figure 9). This was extremely useful in exploring other conjectures, including those concerning bounded-degree pseudotriangulations.

In order to elicit confidence in our implementations, we have independently devised two implementations of the enumeration algorithm and have checked that they agree on every point set in the database. The case $n = 10$ took about a month to compute on a cluster of 26 Sun workstations, and on another eight Pentium processors at 1 Ghz, and the independent computation by a coauthor took about 200 days. Luckily, both results agreed!

Interestingly, it was observed by Aichholzer that, for $n = 8$, the maximum number of pointed pseudotriangulations was achieved for the *same two* point sets as for the maximum number of triangulations, and he conjectured that the same would be true

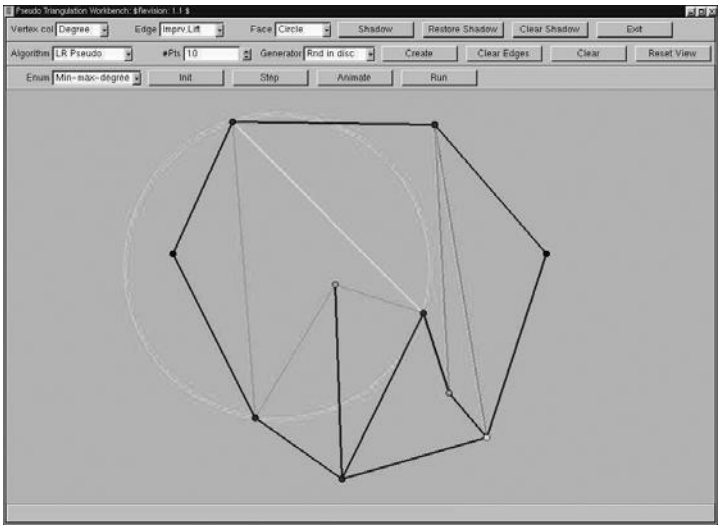

FIG. 9. *Screen shot of using the pseudotriangulation workbench to test a conjecture.*

TABLE 5.1

Number of pointed pseudotriangulations found among all the order types. In parentheses is the number of triangulations for the order type S maximizing its number of pointed pseudotriangulations, followed by the index of S in the database.

10	14 309 547	1430	234 160	(4550, #13 413 894 and #13 812 360)	About 200 days

for $n = 10$. Indeed, this is now verified. But this is not true for $n < 8$ or for $n = 9$. At this time, it seems far-fetched to conjecture that, for all even $n \geq 8$, the number of pointed pseudotriangulations attains its maximum exactly for the point sets which also maximize the number of triangulations. Nevertheless, we can state the following.

EXPERIMENTALLY PROVEN FACT 12. *For any n-point set with $n \leq 10$, its number of triangulations is less than its number of pointed pseudotriangulations, with equality iff the point set is in convex position. In that case, the number of pointed pseudotriangulations is minimal.*

Table 5.1 shows the minimum and maximum values of the number of pointed pseudotriangulations for every value of n and indicates the running time of our algorithms (both implementations were comparable). The point set with minimum number of pseudotriangulations is the point set in convex position for $n \leq 10$. This contrasts sharply with the situation on triangulations [2]. In a previous version of this paper, we conjectured that the number of pseudotriangulations is minimized for point sets in convex position for any value of n. In fact, this has been proven recently [6].

For $n = 11$, the point set database has recently been assembled by Aichholzer, Aurenhammer, and Krasser [5] and consists of 2,334,512,907 point sets. It is thus

TABLE 5.2

Maximum ratio ρ of (blue and red) leaves to red leaves during the enumeration. The second column is (a 5-digit approximation of) the exact number when available. The third column is a lower bound, obtained by trying random point sets with various distributions, while the fourth column is the best known upper bound.

# points	Exact	Lower bound	Upper bound

infeasible to compute the exact lower and upper bounds using this algorithm. Nevertheless, we can still compute the number of pseudotriangulations for particular configurations (this is a further test of correctness of our algorithm when the result is know mathematically) and on random point sets.

We conjectured that the ratio ρ of (blue and red) leaves to red leaves was bounded by 2. Experiments showed that this is simply not true. In Table 5.2, we display some lower bounds on ρ, as well as the best known upper bound.

6. Conclusion. We have presented and implemented a new algorithm to enumerate all the pseudotriangulations of a point set. This algorithm uses the theory of pseudotriangulations that was developed for convex obstacles; in particular, it makes use of the greedy flip algorithm.

Using the polytopal construction of [47], one could obtain another algorithm via the reverse-search paradigm [12]. Our algorithm is more general, however, since with the proper flip algorithm it also applies to matroids (in the dual, it applies to arrangements of pseudolines).

The running time per pseudotriangulation is $O(n^2)$, although it should be possible not only to lower that upper bound by using amortization of the flip algorithm but also to obtain better upper bounds on the ratio of leaves over red leaves. Also, the algorithm can be improved in theory using fancier data structures, but since it is unlikely to be applied to point sets larger than 20, this is more of a theoretical exercise.

We independently developed two implementations of the algorithm, which agree on all point sets for $n \leq 10$. Using these implementations, we verified that Conjecture 1 is true for $n \leq 10$. The mathematical proof (even for such small values of n) is still waiting to be discovered.

Acknowledgments. This work was begun at a Bellairs workshop on pseudotriangulations organized by Ileana Streinu and partially supported by the NSF. The published results by the participants include the numbers of pseudotriangulations of special point configurations [45], the existence of pseudotriangulations with bounded degree [28, 27], and an analysis of the graph of pointed pseudotriangulations [47]. This latter work, especially quotes some of the results on flipping contained in this paper. We thank Ileana Streinu and the other participants of the NSF-supported Bellairs workshop on pseudotriangulations for many enjoyable discussions.

RANDOM k-SAT: TWO MOMENTS SUFFICE TO CROSS A SHARP THRESHOLD*

DIMITRIS ACHLIOPTAS† AND CRISTOPHER MOORE‡

Abstract. Many NP-complete constraint satisfaction problems appear to undergo a "phase transition" from solubility to insolubility when the constraint density passes through a critical threshold. In all such cases it is easy to derive upper bounds on the location of the threshold by showing that above a certain density the first moment (expectation) of the number of solutions tends to zero. We show that in the case of certain symmetric constraints, considering the second moment of the number of solutions yields nearly matching lower bounds for the location of the threshold. Specifically, we prove that the threshold for both random hypergraph 2-colorability (Property B) and random Not-All-Equal k-SAT is $2^{k-1}\ln 2 - O(1)$. As a corollary, we establish that the threshold for random k-SAT is of order $\Theta(2^k)$, resolving a long-standing open problem.

Key words. satisfiability, random formulas, phase transitions

1. Introduction.

In the early 1900s, Bernstein [15] asked the following question: Given a collection of subsets of a set V, is there a partition of V into V_1, V_2 such that no subset is contained in either V_1 or V_2? If we think of the elements of V as vertices and of each subset as a hyperedge, the question can be rephrased as whether a given hypergraph can be 2-colored so that no hyperedge is monochromatic. Of particular interest is the setting where all hyperedges contain k vertices, i.e., k-uniform hypergraphs. This question was popularized by Erdős—who dubbed it "Property B" in honor of Bernstein—and has motivated some of the deepest advances in probabilistic combinatorics. Indeed, determining the smallest number of hyperedges in a non–2-colorable k-uniform hypergraph remains one of the most important problems in extremal graph theory, perhaps second only to the Ramsey problem [13].

A more modern problem, with a somewhat similar flavor, is Boolean Satisfiability: Given a Conjunctive Normal Form (CNF) formula F, is it possible to assign truth values to the variables of F so that it evaluates to true? Satisfiability has been the central problem of computational complexity since Cook [22] proved that it is complete for the class NP. The case where all clauses have the same size k is known as k-SAT and is NP-complete for all $k \geq 3$.

Random formulas and random hypergraphs have been studied extensively in probabilistic combinatorics in the last three decades. While there are a number of slightly different models for generating such structures "uniformly at random," we will see that results transfer readily between them. For the sake of concreteness, let $F_k(n,m)$ denote a formula chosen uniformly from among all $\binom{2^k\binom{n}{k}}{m}$ k-CNF formulas on n variables

with m clauses. Similarly, let $H_k(n,m)$ denote a hypergraph chosen uniformly from among all $\binom{\binom{n}{k}}{m}$ k-uniform hypergraphs with n vertices and m hyperedges. We will say that a sequence of events $\mathcal{E}_n$ occurs *with high probability* (w.h.p.) if $\lim_{n\to\infty} \Pr[\mathcal{E}_n] = 1$ and *with uniformly positive probability* (w.u.p.p.) if $\liminf_{n\to\infty} \Pr[\mathcal{E}_n] > 0$. Throughout the paper, k will be arbitrarily large but fixed.

In recent years, random instances of both problems have been understood to undergo a "phase transition" as the ratio of constraints to variables passes through a critical threshold. That is, for a given number of vertices (variables), the probability that a random instance has a solution drops rapidly from 1 to 0 around a critical number of hyperedges (clauses). This sharp threshold phenomenon was discovered in the early 1990s, when several researchers [19, 49] performed computational experiments on $F_3(n, m = rn)$ and found that while for $r < 4.1$ almost all formulas are satisfiable, for $r > 4.3$ almost all are unsatisfiable. Moreover, as n increases, this transition narrows around $r \approx 4.2$. Along with similar results for other fixed $k \geq 3$ this has led to the following popular conjecture.

Satisfiability threshold conjecture. For each $k \geq 3$, there exists a constant r_k such that

$$\lim_{n\to\infty} \Pr[F_k(n, rn) \text{ is satisfiable}] = \begin{cases} 1 & \text{if } r < r_k, \\ 0 & \text{if } r > r_k. \end{cases}$$

In the last ten years, this conjecture has become an active area of interdisciplinary research, receiving attention in theoretical computer science, artificial intelligence, combinatorics, and, more recently, statistical physics. Much of the work on random k-SAT has focused on proving upper and lower bounds for r_k, both for the smallest computationally hard case $k = 3$ and for general k. At this point the existence of r_k has not been established for any $k \geq 3$. Nevertheless, we will take the liberty of writing $r_k \geq r^*$ to denote that for all $r < r^*$, $F_k(n, rn)$ is w.h.p. satisfiable; analogously, we will write $r_k \leq r^*$ to denote that for all $r > r^*$, $F_k(n, rn)$ is w.h.p. unsatisfiable.

As we will see, an elementary counting argument yields $r_k \leq 2^k \ln 2$ for all k. Lower bounds, on the other hand, have been exclusively algorithmic: To establish $r_k \geq r^*$ one shows that for $r < r^*$ some specific algorithm finds a satisfying assignment with probability that tends to 1. We will see that an extremely simple algorithm [20] already yields $r_k = \Omega(2^k/k)$. We will also see that while more sophisticated algorithms improve this bound slightly, to date no algorithm is known to find a satisfying truth assignment (even w.u.p.p.) when $r = \omega(k) \times 2^k/k$ for any $\omega(k) \to \infty$.

The threshold picture for hypergraph 2-colorability is completely analogous: For each $k \geq 3$, it is conjectured that there exists a constant c_k such that

$$\lim_{n\to\infty} \Pr[H_k(n, cn) \text{ is 2-colorable}] = \begin{cases} 1 & \text{if } c < c_k, \\ 0 & \text{if } c > c_k. \end{cases}$$

The same counting argument here implies $c_k < 2^{k-1} \ln 2$, while another simple algorithm yields $c_k = \Omega(2^k/k)$. Again, no algorithm is known to improve this bound asymptotically, leaving a multiplicative gap of order $\Theta(k)$ between the upper and lower bounds for this problem as well.

In this paper, we use the *second moment method* to show that random k-CNF formulas are satisfiable and random k-uniform hypergraphs are 2-colorable for density up to $2^{k-1} \ln 2 - O(1)$. Thus, we determine the threshold for random k-SAT within a factor of two and the threshold for Property B within a small additive constant.

Recall that $F_k(n, rn)$ is w.h.p. unsatisfiable if $r > 2^k \ln 2$. Our first main result is the following theorem.

THEOREM 1. *For all $k \geq 3$, $F_k(n, m = rn)$ is w.h.p. satisfiable if*

$$r \leq 2^{k-1} \ln 2 - 2.$$

Our second main result determines the Property B threshold within an additive $1/2 + o(1)$.

THEOREM 2. *For all $k \geq 3$, $H_k(n, m = cn)$ is w.h.p. non–2-colorable if*

$$c > 2^{k-1} \ln 2 - \frac{\ln 2}{2}. \tag{1}$$

There exists a sequence $t_k \to 0$ such that for all $k \geq 3$, $H_k(n, m = cn)$ is w.h.p. 2-colorable if

$$c < 2^{k-1} \ln 2 - \frac{\ln 2}{2} - \frac{1 + t_k}{2}. \tag{2}$$

The bound in (1) corresponds to the density for which the expected number of 2-colorings of $H_k(n, cn)$ is $o(1)$. Our main contribution is inequality (2), which we prove using the second moment method. In fact, our approach yields explicit lower bounds for the hypergraph 2-colorability threshold for each value of k (although these bounds lack an attractive closed form). We give the first few of these bounds in Table 1. We see that the gap between our upper and lower bounds converges to its limiting value of $1/2$ rather rapidly.

TABLE 1
Bounds for the 2-colorability threshold of random k-uniform hypergraphs.

k	3	4	5	6	7	8	9	10
Upper bound	2.410	5.191	10.741	21.833	44.014	88.376	177.099	354.545
Lower bound	1.5	4.083	9.973	21.190	43.432	87.827	176.570	354.027

Unlike the bounds for random k-SAT and hypergraph 2-colorability provided by analyzing algorithms, our arguments are nonconstructive: We establish that w.h.p. solutions exist for certain densities but do not offer any hint on how to find them. We believe that abandoning the algorithmic approach for proving such lower bounds is natural and, perhaps, necessary. At a minimum, the algorithmic approach is limited to the small set of rather naive algorithms whose analysis is tractable using current techniques. Perhaps more gravely, it could be that *no* polynomial-time algorithm can overcome the $\Theta(2^k/k)$ barrier. Determining whether this is true even for certain limited classes of algorithms, e.g., random walk algorithms, is a very interesting open problem.

In addition, by not seeking out some specific truth assignment, as algorithms do, the second moment method gives some first glimpses of the "geometry" of the set of solutions. Deciphering these first glimpses, getting clearer ones, and exploring potential interactions between the geometry of the set of solutions and computational hardness are great challenges that lie ahead.

We note that recently, and independently, Frieze and Wormald [34] applied the second moment method to random k-SAT in the case where k is a moderately growing

function of n. Specifically, they proved that when $k - \log_2 n \to \infty$, $F_k(n, m)$ is w.h.p. satisfiable if $m < (1 - \epsilon)m^*$ but is w.h.p. unsatisfiable if $m > (1 + \epsilon)m^*$, where $m^* = (2^k \ln 2 - O(1))\, n$ and $\epsilon = \epsilon(n) > 0$ is such that $\epsilon n \to \infty$. Their result follows by a direct application of the second moment method to the number of satisfying assignments of $F_k(n, m)$. As we will see shortly, while this approach gives a very sharp bound when $k - \log_2 n \to \infty$, it fails for any fixed k and indeed for any $k = o(\log n)$.

We also note that since this work first appeared [4, 5], the line of attack we put forward has had several other successful applications. Specifically, in [7], the lower bound for the random k-SAT threshold was improved to $2^k \ln 2 - O(k)$ by building on the insights presented here. In [8], the method was successfully extended to random Max k-SAT, while in [9, 10] it was applied to random graph coloring. We discuss these subsequent developments in the conclusions.

1.1. The second moment method and the role of symmetry. The version of the second moment method we will use is given by Lemma 1 and follows from a direct application of the Cauchy–Schwarz inequality (see Remark 3.1 in [38]).

LEMMA 1. *For any nonnegative random variable X,*

$$\Pr[X > 0] \geq \frac{\mathbf{E}[X]^2}{\mathbf{E}[X^2]}. \tag{3}$$

It is natural to try to apply Lemma 1 to random k-SAT by letting X be the number of satisfying truth assignments of $F_k(n, m)$. Unfortunately, as we will see, this "naive" application of the second moment method fails rather dramatically: For all $k \geq 1$ and every $r > 0$, $\mathbf{E}[X^2] > (1 + \beta)^n\, \mathbf{E}[X]^2$ for some $\beta = \beta(k, r) > 0$. As a result, the second moment method gives only an exponentially small lower bound on the probability of satisfiability.

The key step in overcoming this failure lies in realizing that we are free to apply the second moment method to any random variable X such that $X > 0$ implies that the formula is satisfiable. In particular, we can let X be the size of any *subset* of the set of satisfying assignments. By choosing this subset carefully, we can hope to significantly reduce the variance of X relative to its expectation and use Lemma 1 to prove that the subset is frequently nonempty. Indeed, we will establish the satisfiability of random k-CNF by focusing on those satisfying truth assignments *whose complement is also satisfying*. In section 3 we will give some intuition for why the number of such assignments has much smaller variance than the number of all satisfying assignments. For now, we observe that considering only such satisfying assignments is equivalent to interpreting the random k-CNF formula $F_k(n, m)$ as an instance of Not-All-Equal (NAE) k-SAT, where a truth assignment σ is a solution if and only if under σ every clause contains at least one satisfied literal *and* at least one unsatisfied literal. In other words, our lower bound for the k-SAT threshold in Theorem 1 is, in fact, a lower bound for the NAE k-SAT threshold.

Indeed, for both random NAE k-SAT and random hypergraph 2-colorability we will apply Lemma 1 naively, i.e., by letting X be the number of solutions. This will give Theorem 2 and the values in Table 1 for hypergraph 2-colorability and, as we will see, exactly the same bounds for random NAE k-SAT. (The proof of Theorem 2 is a slight generalization of the proof for random NAE k-SAT.) We will see that this success of the naive second moment is due to the symmetry inherent in both problems, i.e., to the fact that the complement of a solution is also a solution. We feel that highlighting this role of symmetry—and showing how it can be exploited even in asymmetric problems like k-SAT—is our main conceptual contribution. Exploiting

these ideas in other constraint satisfaction problems that have a permutation group acting on the variables' domain is an interesting area for further research.

1.2. Organization of the paper. In section 2 we give some background on random k-SAT and random hypergraph 2-colorability. In section 3 we explain why the second moment method fails when applied to k-SAT directly, and give some intuition for why counting only the NAE-satisfying assignments rectifies the problem. We also point out some connections to methods of statistical physics. In section 4 we lay the groundwork for bounding the second moment for both NAE k-SAT and hypergraph 2-colorability by dealing with some probabilistic preliminaries, introducing a "Laplace method" lemma for bounding certain sums, and outlining our strategy. The actual bounding occurs in sections 5 to 7. Specifically, in sections 5 and 6 we use the Laplace lemma to reduce the second moment calculations for both random NAE k-SAT and random hypergraph 2-colorability to the maximization of a certain function g on the unit interval, where g is independent of n. We maximize g in section 7 and prove the Laplace lemma in section 8. We conclude in section 9 by discussing some recent extensions of this work and proposing several open questions.

2.1. Random k-SAT. The mathematical investigation of random k-SAT began with the work of Franco and Paull [31], who, among other results, observed that $F_k(n, m = rn)$ is w.h.p. unsatisfiable if $r \geq 2^k \ln 2$. To see this, let $C_k = 2^k \binom{n}{k}$ be the number of all possible k-clauses and let $S_k = (2^k - 1)\binom{n}{k}$ be the number of k-clauses consistent with a given truth assignment. Since any fixed truth assignment is satisfying with probability $\binom{S_k}{m}/\binom{C_k}{m} < (1-2^{-k})^m$, the expected number of satisfying truth assignments of $F_k(n, m = rn)$ is at most $[2(1-2^{-k})^r]^n = o(1)$ for $r \geq 2^k \ln 2$.

Shortly afterwards, Chao and Franco [18] complemented this result by proving that for all $k \geq 3$, if $r < 2^k/k$, then the following linear-time algorithm, called Unit Clause (uc), finds a satisfying truth assignment w.u.p.p.: If there exist unit clauses, pick one randomly and satisfy it; else pick a random unset variable and give it a random value. Note that since uc succeeds only w.u.p.p. (rather than w.h.p.) this does not imply a lower bound for r_k.

The satisfiability threshold conjecture gained a great deal of popularity in the early 1990s and has received an increasing amount of attention since then. The polynomial-time solvable case $k = 2$ was settled early on: Independently, Chvátal and Reed [20], Fernandez de la Vega [29], and Goerdt [35] proved that $r_2 = 1$. Chvátal and Reed [20], in addition to proving $r_2 = 1$, gave the first lower bound for r_k, strengthening the positive probability result of Chao and Franco [18] by analyzing the following refinement of uc, called Short Clause (sc): If there exist unit clauses, pick one randomly and satisfy it; else if there exist binary clauses, pick one randomly and satisfy a random literal in it; else pick a random unset variable and give it a random value. In [20], the authors showed that for all $k \geq 3$, sc finds a satisfying truth assignment w.h.p. for $r < (3/8)\, 2^k/k$ and raised the question of whether this lower bound for r_k can be improved asymptotically.

A large portion of the work on the satisfiability threshold conjecture since then has been devoted to the first computationally hard case, $k = 3$, and a long series of results [16, 17, 33, 1, 11, 36, 41, 25, 42, 39, 24, 44, 40, 26, 31] has narrowed the potential range of r_3. Currently this is pinned between 3.52 by Kaporis, Kirousis, and Lalas [41] and Hajiaghayi and Sorkin [36] and 4.506 by Dubois, Boufkhad, and Mandler [25]. Upper bounds for r_3 come from probabilistic counting arguments, refining the above

calculation of the expected number of satisfying assignments. Lower bounds, on the other hand, have come from analyzing progressively more sophisticated algorithms. Unfortunately, neither of these approaches helps narrow the asymptotic gap between the upper and lower bounds for r_k. The upper bounds improve $r_k \le 2^k \ln 2$ by only a small additive constant; the best algorithmic lower bound, due to Frieze and Suen [33], is $r_k \ge a_k 2^k/k$, where $\lim_{k\to\infty} a_k = 1.817\ldots$.

Two more results stand out in the study of random k-CNF formulas. In a breakthrough paper, Friedgut [32] proved the existence of a *nonuniform* satisfiability threshold, i.e., of a sequence $r_k(n)$ around which the probability of satisfiability goes from 1 to 0.

THEOREM 3 ([32]). *For each $k \ge 2$, there exists a sequence $r_k(n)$ such that for every $\epsilon > 0$,*

$$\lim_{n\to\infty} \Pr[F_k(n, rn) \text{ is satisfiable}] = \begin{cases} 1 & \text{if } r = (1-\epsilon)\, r_k(n), \\ 0 & \text{if } r = (1+\epsilon)\, r_k(n). \end{cases}$$

In [21], Chvátal and Szemerédi established a seminal result in proof complexity, by extending the work of Haken [37] and Urquhart [53] to random formulas. Specifically, they proved that for all $k \ge 3$, if $r \ge 2^k \ln 2$, then w.h.p. $f_k rn$ is unsatisfiable, but every resolution proof of its unsatisfiability contains at least $(1+\epsilon)^n$ clauses for some $\epsilon = \epsilon(k, r) > 0$. In [2], Achlioptas, Beame, and Molloy extended the main result of [21] to random CNF formulas that also contain 2-clauses, as this is relevant for the behavior of Davis–Putnam–Logemann–Loveland (DPLL) algorithms on random k-CNF. (DPLL algorithms proceed by setting variables sequentially, according to some heuristic, and backtracking whenever a contradiction is reached.) By combining the results in the present paper with the results in [2], it was recently shown [3] that a number of DPLL algorithms require exponential time *significantly below* the satisfiability threshold, i.e., for provably satisfiable random k-CNF formulas.

Finally, we note that if one chooses to live unencumbered by the burden of mathematical proof, powerful nonrigorous techniques of statistical physics, such as the "replica method," become available. Indeed, several claims based on the replica method have been subsequently established rigorously; thus it is frequently (but definitely not always) correct. Using this technique, Monasson and Zecchina [50] predicted $r_k \simeq 2^k \ln 2$. Like most arguments based on the replica method, their argument is mathematically sophisticated but far from rigorous. In particular, they argue that as k grows large, the so-called *annealed approximation* should apply. This creates an analogy with the second moment method which we discuss in section 3.4.

2.2. Random hypergraph 2-colorability. While Bernstein originally raised the 2-colorability question for certain classes of infinite set families [15], Erdős popularized the finite version of the problem [14, 27, 28, 43, 45, 51, 52] and the hypergraph representation. Recall that a 2-uniform hypergraph, i.e., a graph, is 2-colorable if and only if it has no odd cycle. In a random graph with cn edges this occurs with constant probability if and only if $c < 1/2$ (see [30] for more on the evolution of cycles in random graphs).

For all $k \ge 3$, on the other hand, hypergraph 2-colorability is NP-complete [46], and determining the 2-colorability threshold c_k for k-uniform hypergraphs $H_k(n, cn)$ remains open. Analogously to random k-SAT, we will take the liberty of writing $c_k \ge c^*$ if $H_k(n, cn)$ is w.h.p. 2-colorable for all $c < c^*$, and $c_k \le c^*$ if $H_k(n, cn)$ is w.h.p. non–2-colorable for all $c > c^*$.

Alon and Spencer [12] were the first to give bounds on the potential value of c_k. Specifically, they observed that, analogously to random k-SAT, the expected number of 2-colorings of $H_k(n, cn)$ is at most $[2(1-2^{1-k})^c]^n$ and concluded that $H_k(n, cn)$ is w.h.p. non–k-colorable if $c \geq 2^{k-1} \ln 2$. More importantly, by employing the Lovász local lemma, they proved that $H_k(n, cn)$ is w.h.p. 2-colorable if $c = O(2^k/k^2)$. Regarding the upper bound, it is easy to see that, in fact, $2(1-2^{1-k})^c < 1$ if $c = 2^{k-1} \ln 2 - (\ln 2)/2$, and this yields the upper bound of Theorem 2. Moreover, the techniques of [44, 24] can be used to improve this bound further to $2^{k-1} \ln 2 - (\ln 2)/2 - 1/4 + t_k$, where $t_k \to 0$.

The lower bound of [12] was improved by Achlioptas et al. [6] motivated by the analogies drawn in [12] between hypergraph 2-colorability and earlier work [18, 20] for random k-SAT. Specifically, it was shown in [6] that a simple, linear-time algorithm w.h.p. finds a 2-coloring of $H_k(n, cn)$ for $c = O(2^k/k)$, implying $c_k = \Omega(2^k/k)$. These were the best bounds for c_k prior to Theorem 2 of the present paper.

Finally, we note that Friedgut's result [32] applies to hypergraph 2-colorability as well, as presented in the following theorem.

THEOREM 4 ([32]). *For each $k \geq 3$, there exists a sequence $c_k(n)$ such that for every $\epsilon > 0$,*

$$\lim_{n\to\infty} \Pr[H_k(n, cn) \text{ is 2-colorable}] = \begin{cases} 1 & \text{if } c = (1-\epsilon)\, c_k(n), \\ 0 & \text{if } c = (1+\epsilon)\, c_k(n). \end{cases}$$

3. The second moment method: First look. In the rest of the paper it will be convenient to work with a model of random formulas that differs slightly from $F_k(n, m)$. Specifically, to generate a random k-CNF formula on n variables with m clauses we simply generate a string of km independent random literals, each such literal being drawn uniformly from among all $2n$ possible ones. Note that this is equivalent to selecting, with replacement, m clauses from among all possible $2^k n^k$ ordered k-clauses. This choice of distribution for k-CNF formulas will simplify our calculations significantly. As we will see in section 4.1, the derived results can be easily transferred to all other standard models for random k-CNF formulas.

3.1. Random *k*-SAT. For any formula F, given truth assignments $\sigma_1, \sigma_2, \ldots \in \{0,1\}^n$, we will write $\sigma_1, \sigma_2, \ldots \models F$ to denote that *all* of $\sigma_1, \sigma_2, \ldots$ satisfy F. Let $X = X(F)$ denote the number of satisfying assignments of a formula F. Then, for a k-CNF formula with random clauses $c_1, c_2, \ldots, c_m$ we have

(4)
$$\mathbf{E}[X] = \mathbf{E}\left[\sum_{\sigma} \mathbf{1}_{\sigma\models F}\right] = \sum_{\sigma} \mathbf{E}\left[\prod_{c_i} \mathbf{1}_{\sigma\models c_i}\right] = \sum_{\sigma}\prod_{c_i} \mathbf{E}[\mathbf{1}_{\sigma\models c_i}] = 2^n(1-2^{-k})^m,$$

since clauses are drawn independently and the probability that σ satisfies the ith random clause, i.e., $\mathbf{E}[\mathbf{1}_{\sigma\models c_i}]$, is $1-2^{-k}$ for every σ and i. Similarly, for $\mathbf{E}[X^2]$ we have

$$\mathbf{E}[X^2] = \mathbf{E}\left[\left(\sum_{\sigma} \mathbf{1}_{\sigma\models F}\right)^2\right] = \mathbf{E}\left[\sum_{\sigma,\tau} \mathbf{1}_{\sigma,\tau\models F}\right] = \sum_{\sigma,\tau}\prod_{c_i} \mathbf{E}[\mathbf{1}_{\sigma,\tau\models c_i}]. \tag{5}$$

We claim that $\mathbf{E}[\mathbf{1}_{\sigma,\tau\models c_i}]$, i.e., the probability that a fixed pair of truth assignments σ, τ satisfy the ith random clause, depends only on the number of variables z to which

σ and τ assign the same value. Specifically, if the overlap is $z = \alpha n$, we claim that this probability is

$$f_S(\alpha) = 1 - 2^{1-k} + 2^{-k}\alpha^k. \tag{6}$$

Our claim follows by inclusion-exclusion and observing that if c_i is not satisfied by σ, the only way for it to also not be satisfied by τ is for all k variables in c_i to lie in the overlap of σ and τ. Thus, f_S quantifies the correlation between the events that σ and τ are satisfying as a function of their overlap. In particular, observe that truth assignments with overlap $n/2$ are uncorrelated since $f_S(1/2) = (1 - 2^{-k})^2 = \Pr[\sigma \text{ is satisfying}]^2$.

Since the number of ordered pairs of assignments with overlap z is $2^n \binom{n}{z}$, we thus have

$$\mathbf{E}[X^2] = 2^n \sum_{z=0}^{n} \binom{n}{z} f_S(z/n)^m. \tag{7}$$

Writing $z = \alpha n$ and using the approximation $\binom{n}{z} = (\alpha^\alpha (1-\alpha)^{1-\alpha})^{-n} \times \text{poly}(n)$, we see that

$$\begin{aligned}\mathbf{E}[X^2] &= 2^n \left(\max_{0 \le \alpha \le 1} \left[\frac{f_S(\alpha)^r}{\alpha^\alpha (1-\alpha)^{1-\alpha}} \right] \right)^n \times \text{poly}(n) \\ &\equiv \left(\max_{0 \le \alpha \le 1} \Lambda_S(\alpha) \right)^n \times \text{poly}(n).\end{aligned}$$

At the same time observe that $\mathbf{E}[X]^2 = \left(2^n (1 - 2^{-k})^{rn}\right)^2 = (4 f_S(1/2)^r)^n = \Lambda_S(1/2)^n$. Therefore, if there exists some $\alpha \in [0,1]$ such that $\Lambda_S(\alpha) > \Lambda_S(1/2)$, then the second moment is exponentially greater than the square of the expectation and we get only an exponentially small lower bound for $\Pr[X > 0]$. Put differently, unless the dominant contribution to $\mathbf{E}[X^2]$ comes from "uncorrelated" pairs of satisfying assignments, i.e., pairs with overlap $n/2$, the second moment method fails.

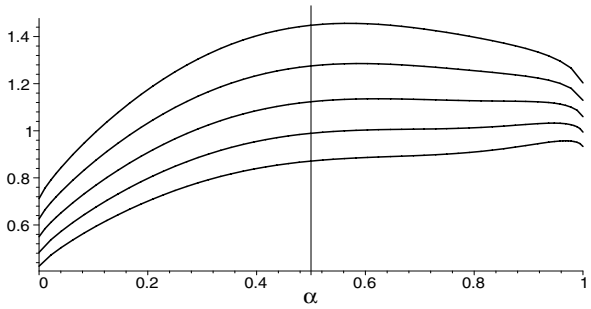
With these observations in mind, in Figure 1 we plot $\Lambda_S(\alpha)$ for $k = 5$ and different values of r. We see that, unfortunately, for all values of r shown, Λ_S is maximized at some $\alpha > 1/2$. If we look closely into the two factors comprising Λ_S, the reason for the failure of the second moment method becomes apparent: While the entropic factor $\left(\alpha^\alpha (1-\alpha)^{1-\alpha}\right)^{-1}$ is symmetric around $1/2$, the correlation function f_S is strictly increasing in $[0,1]$. Therefore, the derivative of Λ_S is never 0 at $1/2$, instead becoming 0 at some $\alpha > 1/2$ where the benefit of positive correlation balances with the cost of decreased entropy. (Indeed, this is true for all $k = o(\log n)$ and constant $r > 0$.)

3.2. Random NAE k-SAT. Let us now repeat the above analysis but with $X = X(F)$ being the number of NAE-satisfying truth assignments of a formula F. Recall that σ is an NAE-satisfying assignment if and only if under σ every clause has at least one satisfied literal *and* at least one unsatisfied literal. Thus, for a k-CNF formula with random clauses $c_1, c_2, \ldots, c_m$, proceeding as in (4), we get

$$\mathbf{E}[X] = 2^n (1 - 2^{1-k})^m, \tag{8}$$

since the probability that σ NAE-satisfies the ith random clause is $1 - 2^{1-k}$ for every σ and i.

Regarding the second moment, proceeding exactly as in (5), we write $\mathbf{E}[X^2]$ as a sum over the 4^n ordered pairs of assignments of the probability that both assignments



$k = 5$, $r = 16, 18, 20, 22, 24$ (top to bottom)

FIG. 1. *The nth root of the expected number of pairs of satisfying assignments at distance αn.*

are NAE-satisfying. As for k-SAT, for any fixed pair this probability depends only on the overlap. The only change is that if σ, τ agree on $z = \alpha n$ variables, then the probability that they both NAE-satisfy a random clause c_i is

$$\begin{aligned} \Pr[\sigma \text{ and } \tau \text{ NAE-satisfy } c_i] &= 1 - 2^{2-k} + 2^{1-k}\left(\alpha^k + (1-\alpha)^k\right) \\ &\equiv f_N(\alpha). \end{aligned} \tag{9}$$

Again, this claim follows from inclusion-exclusion and observing that for both σ, τ to NAE-violate c_i, the variables of c_i must either all be in the overlap of σ and τ or all be in their nonoverlap.

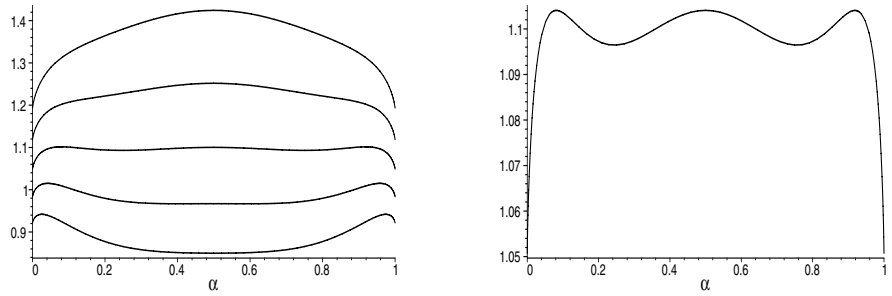
Applying Stirling's approximation for the factorial again and observing that the sum defining $\mathbf{E}[X^2]$ has only a polynomial number of terms, we now get (analogously to Λ_S in random k-SAT)

$$\begin{aligned} \mathbf{E}[X^2] &= 2^n \left(\max_{0 \le \alpha \le 1} \left[\frac{f_N(\alpha)^r}{\alpha^\alpha (1-\alpha)^{1-\alpha}} \right] \right)^n \times \text{poly}(n) \\ &\equiv \left(\max_{0 \le \alpha \le 1} \Lambda_N(\alpha) \right)^n \times \text{poly}(n). \end{aligned} \tag{10}$$

As before, it is easy to see that $\mathbf{E}[X]^2 = \Lambda_N(1/2)^n$. Therefore, if $\Lambda_N(1/2) > \Lambda_N(\alpha)$ for every $\alpha \neq 1/2$, then (10) implies that the ratio between $\mathbf{E}[X^2]$ and $\mathbf{E}[X]^2$ is at most polynomial in n. Indeed, with a more careful analysis of the interplay between the summation and Stirling's approximation, we will later show that whenever $\Lambda_N(1/2)$ is a global maximum, the ratio $\mathbf{E}[X^2]/\mathbf{E}[X]^2$ is bounded by a constant, implying that NAE-satisfiability holds w.u.p.p. So, all in all, again we hope that the dominant contribution to $\mathbf{E}[X^2]$ comes from pairs of assignments with overlap $n/2$.

The crucial difference is that now the correlation function f_N is *symmetric* around $1/2$ and, hence, so is Λ_N. As a result, the entropy-correlation product Λ_N always has a local extremum at $1/2$. Moreover, since the entropic term is always maximized at $\alpha = 1/2$ and is independent of r, for sufficiently small r this extremum is a global maximum. With these considerations in mind, in Figure 2 we plot $\Lambda_N(\alpha)$ for $k = 5$ and various values of r.

Let us start with the picture on the left, where r increases from 8 to 12 as we go from top to bottom. For $r = 8, 9$ we see that indeed Λ_N has a global maximum at $1/2$ and the second moment method succeeds. For the cases $r = 11, 12$, on the other hand, we see that $\Lambda_N(1/2)$ is actually a global minimum. In fact, we see that $\Lambda_N(1/2) < 1$,



$k = 5$, $r = 8, 9, 10, 11, 12$ (top to bottom) $k = 5$, $r = 9.973$

FIG. 2. *The nth root of the expected number of pairs of NAE-assignments at distance αn.*

implying that $\mathbf{E}[X]^2 = \Lambda_N(1/2)^n = o(1)$ and so w.h.p. there are no NAE-satisfying assignments for such r. It is worth noting that for $r = 11$, even though $X = 0$ w.h.p., the second moment is exponentially large (since $\Lambda_N > 1$ near 0 and 1).

The most interesting case is $r = 10$. Here $\Lambda(1/2) = 1.0023\ldots$ is a local maximum and greater than 1, but the two global maxima occur at $\alpha = 0.08\ldots$ and $\alpha = 0.92\ldots$, where the function equals $1.0145\ldots$. As a result, again, the second moment method gives only an exponentially small lower bound on $\Pr[X > 0]$. Note that this is in spite of the fact that $\mathbf{E}[X]$ is now exponentially large. Indeed, the largest value for which the second moment succeeds for $k = 5$ is $r = 9.973\ldots$ when the two side peaks reach the same height as the peak at $1/2$ (see the plot on the right in Figure 2).

So, the situation can be summarized as follows. By requiring that we count only NAE-satisfying truth assignments, we make it roughly twice as hard to satisfy each clause. This manifests itself in the additional factor of 2 in the middle term of f_N compared to f_S. On the other hand, now, the third term of f, capturing "joint" behavior, is symmetric around $1/2$, making Λ itself symmetric around $1/2$. This enables the second moment method which, indeed, breaks down only when the density gets within an additive constant of the upper bound for the NAE k-SAT threshold.

3.3. How symmetry reduces variance. Given a truth assignment σ and an arbitrary CNF formula F, let $Q = Q(\sigma, F)$ denote the total number of literal *occurrences* in F satisfied by σ. With this definition at hand, a potential explanation of how symmetry reduces the variance is suggested by considering the following trivial refinement of our generative model: First (i) draw km literals uniformly and independently just as before and then (ii) partition the drawn literals randomly into k-clauses (rather than assuming that the first k literals form the first clause, the next k the second, etc.).

In particular, imagine that we have just finished performing the first generative step above and we are about to perform the second. Observe that at this point the value of Q has already been determined for every $\sigma \in \{0,1\}^n$. Moreover, for each fixed σ the conditional probability of yielding a satisfying assignment corresponds to a balls-in-bins experiment: Distribute $Q(\sigma)$ balls in m bins, each with capacity k, so that every bin receives at least one ball. It is clear that those truth assignments for which Q is large at the end of the first step have a big advantage in the second.

To get an idea of what Q typically looks like on $\{0,1\}^n$ we begin by observing that the number of occurrences of a fixed literal ℓ, B_ℓ, is distributed as $\mathrm{Bin}(km, 1/(2n))$.

Thus, $\mathbf{E}[B_\ell] = O(1)$ and, moreover, the random variables B_ℓ are very weakly correlated. In particular, Q takes its maximum value on the subcube of truth assignments where every variable is assigned its majority value and, typically, decreases gradually away from there. Thus, at the end of the first step the "more promising" truth assignments are highly correlated: In satisfying many literal occurrences (thus increasing their odds for the second step), they tend to overlap with each other (and the majority assignment) at more than half the variables.

In contrast, if we focus on NAE-satisfying assignments, at the end of the first step the most promising assignments σ are those for which $Q(\sigma)$ is very close to its average value $km/2$. So, when the problem is symmetric, the typical case becomes the most favorable case and the clustering around truth assignments that satisfy many literal occurrences disappears.

If indeed "populism," i.e., the tendency of each variable to assume its majority value in the formula, is the main source of correlations in random k-SAT, then the second moment method is a good candidate for k-CNF models which do not encourage this tendency.[1] For example, one such model is *regular* random k-SAT, in which every literal occurs exactly the same number of times. Such formulas can be analyzed using a model analogous to the configuration model of random graphs, i.e., by taking precisely d copies of each literal and partitioning the resulting $2dn$ copies into clauses randomly (exactly as in the second step of our two-step model for random k-SAT).

3.4. Geometry and connections to statistical physics. A key quantity in statistical physics is the *overlap distribution* between configurations of minimum energy, known as ground states. When a constraint satisfaction problem is satisfiable, ground states correspond to solutions, such as satisfying assignments, valid colorings, and so on. In the case of random k-SAT, the overlap distribution is the probability $P(\alpha)$ that a random pair of satisfying assignments have overlap αn. Our calculation of the expected number of pairs of solutions at each possible distance is thus a weighted average of $P(\alpha)$ over all formulas, whereby formulas with more solutions contribute more heavily. Physicists call this weighted average the "annealed approximation" of $P(\alpha)$ and denote it $P_{\mathrm{ann}}(\alpha)$. It is worth pointing out that, while the annealed approximation clearly overemphasizes formulas with more satisfying assignments, Monasson and Zecchina conjectured in [50], based on the replica method, that it becomes asymptotically tight as $k \to \infty$.

On a more rigorous footing, it is easy to see that as long as Λ has a global maximum at $1/2$, $P_{\mathrm{ann}}(\alpha)$ is tightly concentrated around $1/2$, since $\Lambda(\alpha)^n$ is exponentially smaller than $\Lambda(1/2)^n$ for all other α. Our results establish that Λ is maximized at $1/2$ for densities up to $2^{k-1}\ln 2 - O(1)$. In other words, for densities almost all the way to the threshold, in the annealed approximation, almost all pairs of solutions have distance $n/2 + \Theta(\sqrt{n})$, just as if solutions were scattered uniformly at random throughout the hypercube.

Note that even if $P(\alpha)$ is concentrated around $1/2$ (rather than just $P_{\mathrm{ann}}(\alpha)$) this still allows for a typical geometry where there are exponentially many exponentially large clusters, each centered at a random assignment. Indeed, this is precisely the picture suggested by some very recent groundbreaking work of Mézard, Parisi, and Zecchina [47] and Meźard and Zecchina [48], based on nonrigorous techniques of statistical physics. If this is indeed the true picture, establishing it rigorously would require considerations much more refined than the second moment of the number of

[1] We describe recent developments on this point in the conclusions.

solutions. More generally, getting a better understanding of the typical geometry and its potential implications for algorithms appears to us a very challenging and very important open problem.

4. Groundwork.

4.1. Generative models. Given a set V of n Boolean variables, let $C_k = C_k(V)$ denote the set of all proper k-*clauses* on V, i.e., the set of all $2^k\binom{n}{k}$ disjunctions of k literals involving distinct variables. Similarly, given a set V of n vertices, let $E_k = E_k(V)$ be the set of all $\binom{n}{k}$ k-subsets of V. As we saw, a random k-CNF formula $F_k(n,m)$ is formed by selecting uniformly a random m-subset of C_k, while a random k-uniform hypergraph $H_k(n,m)$ is formed by selecting uniformly a random m-subset of E_k.

While $F_k(n,m)$ and $H_k(n,m)$ are perhaps the most natural models for generating random k-CNF formulas and random k-uniform hypergraphs, respectively, there are a number of slight variations of each model. Those are largely motivated by amenability to certain calculations. To simplify the discussion we focus on models for random formulas in the rest of this subsection. All our comments transfer readily to models for random hypergraphs.

For example, it is fairly common to consider the clauses as ordered k-tuples (rather than as k-sets) and/or to allow replacement in sampling the set C_k. Clearly, for properties such as satisfiability the issue of ordering is irrelevant. Moreover, as long as $m = O(n)$, essentially the same is true for the issue of replacement. To see that, observe that w.h.p. the number of repeated clauses is $q = o(n)$ and the subset of $m-q$ distinct clauses is uniformly random. Thus, if a monotone decreasing property (such as satisfiability) holds with probability p for a given $m = r^*n$ when replacement is allowed, it holds with probability $p - o(1)$ for all $r < r^*$ when replacement is not allowed.

The issue of selecting the literals of each clause with replacement (which might result in some "improper" clauses) is completely analogous. That is, the probability that a variable appears more than once in a given clause is at most $k^2/n = O(1/n)$ and hence w.h.p. there are $o(n)$ improper clauses. Finally, we note that by standard techniques our results also transfer to the $F_k(n,p)$ model where every clause appears independently of all others with probability p, for any p such that the expected number of k-clauses is $r^*n - n^\beta$ for some $\beta > 1/2$ (see [33]).

4.2. Strategy and tools. Our plan is to consider random k-CNF formulas formed by generating km independently and identically distributed random literals, where $m = rn$, and proving that if $X = X(F)$ is the number of NAE-satisfying assignments, then the following lemma holds.

LEMMA 2. *For all $\epsilon > 0$, $k \geq k_0(\epsilon)$, and $r < 2^{k-1}\ln 2 - (1+\ln 2)/2 - \epsilon$, there exists some constant $C = C(k,r) > 0$ such that for all sufficiently large n,*

$$\mathbf{E}[X^2] < C \times \mathbf{E}[X]^2.$$

By Lemma 1 and our discussion in section 4.1, this implies that $F_k(n, rn - o(n))$ is NAE-satisfiable, and thus satisfiable, w.u.p.p. Therefore, for all r as in Lemma 2, $F_k(n,rn)$ is satisfiable w.u.p.p. To boost this to a high probability result, thus establishing Theorem 1, we employ the following immediate corollary of Theorem 3.

COROLLARY 1. *If $F_k(n, r^*n)$ is satisfiable w.u.p.p., then for all $r < r^*$, $F_k(n,rn)$ is satisfiable w.h.p.*

Friedgut's arguments [32] also apply to NAE k-SAT, implying that $F_k(n, rn)$ is w.h.p. NAE-satisfiable for r as in Lemma 2. Thus, Lemma 2 readily yields (12) below, while (11) comes from noting that the expected number of NAE-satisfying assignments is $[2(1-2^{1-k})^r]^n$. (Similarly to hypergraphs, the techniques of [44, 24] can be used to improve the bound in (11) to $2^{k-1}\ln 2 - (\ln 2)/2 - 1/4 + t_k$, where $t_k \to 0$.) Indeed, we will see that the proof of Theorem 5 will yield Theorem 2 for random hypergraphs with little additional effort.

THEOREM 5. *For all $k \geq 3$, $F_k(n, m = rn)$ is w.h.p. non–NAE-satisfiable if*

$$r > 2^{k-1}\ln 2 - \frac{\ln 2}{2}. \tag{11}$$

There exists a sequence $t_k \to 0$ such that for all $k \geq 3$, $F_k(n, m = rn)$ is w.h.p. NAE-satisfiable if

$$r < 2^{k-1}\ln 2 - \frac{\ln 2}{2} - \frac{1+t_k}{2}. \tag{12}$$

As we saw in section 3.2, the second moment of the number of NAE-satisfying assignments is

$$2^n \sum_{z=0}^{n} \binom{n}{z} f_N (z/n)^{rn}.$$

A slightly more complicated sum will occur when we bound the second moment of the number of 2-colorings. To bound both sums we will use the following lemma which we prove in section 8.

LEMMA 3 (Laplace lemma). *Let ϕ be a positive, twice-differentiable function on $[0,1]$ and let $q \geq 1$ be a fixed integer. Let $t = n/q$ and let*

$$S_n = \sum_{z=0}^{t} \binom{t}{z}^q \phi(z/t)^n.$$

Letting $0^0 \equiv 1$, define g on $[0,1]$ as

$$g(\alpha) = \frac{\phi(\alpha)}{\alpha^\alpha (1-\alpha)^{1-\alpha}}.$$

If there exists $\alpha_{\max} \in (0,1)$ such that $g(\alpha_{\max}) \equiv g_{\max} > g(\alpha)$ for all $\alpha \neq \alpha_{\max}$ and $g''(\alpha_{\max}) < 0$, then there exists a constant $C = C(q, g_{\max}, g''(\alpha_{\max}), \alpha_{\max}) > 0$ such that for all sufficiently large n,

$$S_n < C\, n^{-(q-1)/2}\, g_{\max}^n.$$

5. Bounding the second moment for NAE k-SAT. Recall that if X is the number of NAE-assignments, then

$$\mathbf{E}[X] = 2^n (1-2^{1-k})^{rn}$$

and

$$\mathbf{E}[X^2] = 2^n \sum_{z=0}^{n} \binom{n}{z} f_N (z/n)^{rn}, \tag{13}$$

where

$$f_N(\alpha) = 1 - 2^{2-k} + 2^{1-k}\left(\alpha^k + (1-\alpha)^k\right).$$

To bound the sum in (13) we apply Lemma 3 with $q = 1$ and $\phi(\alpha) = f_N(\alpha)^r$. Thus, $g = g_r$, where

$$g_r(\alpha) = \frac{f_N(\alpha)^r}{\alpha^\alpha (1-\alpha)^{1-\alpha}}. \tag{14}$$

To show that Lemma 3 applies, we will prove in section 7 that the following lemma holds.

LEMMA 4. *For every $\epsilon > 0$, there exists $k_0 = k_0(\epsilon)$ such that for all $k \geq k_0$, if*

$$r < 2^{k-1}\ln 2 - \frac{\ln 2}{2} - \frac{1}{2} - \epsilon,$$

then $g_r(\alpha) < g_r(1/2)$ for all $\alpha \neq 1/2$, and $g_r''(1/2) < 0$.

Therefore, for all r, k, and ϵ as in Lemma 4, there exists a constant $C = C(k,r) > 0$ such that

$$\mathbf{E}[X^2] < C \times 2^n g_r(1/2)^n.$$

Since $\mathbf{E}[X]^2 = 2^n g_r(1/2)^n$, we get that for all r, k, ϵ as in Lemma 4

$$\mathbf{E}[X^2] < C \times \mathbf{E}[X]^2.$$

6. Bounding the second moment for hypergraph 2-colorability. Just as for NAE k-SAT, it will be easier to work with the model in which generating a random hypergraph corresponds to choosing km vertices uniformly at random with replacement and letting the first k vertices form the first hyperedge, the second k vertices form the second hyperedge, etc.

In [5] we proved (2) of Theorem 2 by letting X be the set of all 2-colorings and using a convexity argument to show that $\mathbf{E}[X^2]$ is dominated by the contribution of *balanced* colorings, i.e., colorings with an equal number of black and white vertices. Here we follow a simpler approach suggested by Karger; namely, we *define* X to be the number of balanced 2-colorings. We emphasize that, while technically convenient, the restriction to balanced 2-colorings is not essential for the second moment method to succeed on hypergraph 2-colorability; i.e., one has $\mathbf{E}[X^2] = O(\mathbf{E}[X]^2)$ even if X is the number of all 2-colorings.

Of course, in order for balanced colorings to exist n must be even and we will assume that in our calculations below. To get Theorem 2 for all sufficiently large n, we observe that if for a given c^*, $H_k(2n, m = 2c^*n)$ is w.h.p. 2-colorable, then for all $c < c^*$, $H_k(n, cn)$ is w.h.p. 2-colorable since deleting a random vertex of $H_k(2n, 2c^*n)$ w.h.p. removes $o(n)$ edges. With this in mind, in the following we let X be the number of balanced 2-colorings and assume that n is even.

Since the vertices in each hyperedge are chosen uniformly with replacement, the probability that a random hyperedge is bichromatic in a fixed balanced partition is $1 - 2^{1-k}$. Since there are $\binom{n}{n/2}$ such partitions and the m hyperedges are drawn independently, we have

$$\mathbf{E}[X] = \binom{n}{n/2}\left(1 - 2^{1-k}\right)^m. \tag{15}$$

To calculate the second moment, as we did for [NAE] k-SAT, we write $\mathbf{E}[X^2]$ as a sum over all pairs of balanced partitions. In order to estimate this sum we first observe that if two balanced partitions σ and τ have exactly z black vertices in common, then they must also have exactly z white vertices in common. Thus σ and τ define four groups of vertices: z that are black in both, z that are white in both, $n/2-z$ that are black in σ and white in τ, and $n/2-z$ that are white in σ and black in τ. Clearly, a random hyperedge is monochromatic in both σ and τ if and only if all its vertices fall into the same group. Since the vertices of each hyperedge are chosen uniformly with replacement, this probability is

$$2\left(\frac{z}{n}\right)^k + 2\left(\frac{n/2-z}{n}\right)^k = 2^{1-k}\left[\left(\frac{2z}{n}\right)^k + \left(1-\frac{2z}{n}\right)^k\right].$$

Thus, by inclusion-exclusion, the probability that a random hyperedge is bichromatic in both σ and τ is

$$1 - 2^{2-k} + 2^{1-k}\left[\left(\frac{2z}{n}\right)^k + \left(1-\frac{2z}{n}\right)^k\right] = f_N(2z/n),$$

where $f_N(\alpha) = 1 - 2^{2-k} + 2^{1-k}(\alpha^k + (1-\alpha)^k)$ is the function we defined for NAE k-SAT in (9).

Moreover, observe that the number of pairs of partitions with such overlap is

$$\binom{n}{z,\, z,\, n/2-z,\, n/2-z} = \binom{n}{n/2}\binom{n/2}{z}^2.$$

Since hyperedges are drawn independently and with replacement, by summing over z we thus get

$$\mathbf{E}[X^2] = \binom{n}{n/2}\sum_{z=0}^{n/2}\binom{n/2}{z}^2 f_N(2z/n)^{cn}.$$

To bound this sum we apply Lemma 3 with $q=2$ and $\phi(\alpha) = f_N(\alpha)^c$. Felicitously, we find ourselves maximizing a function g_c which, if we replace c with r, is exactly the same function g_r we defined in (14) for NAE k-SAT. Thus, setting $c=r$ where k, r and ϵ are as in Lemma 4, g_c is maximized at $\alpha = 1/2$ with $g''(1/2) < 0$, and Lemma 3 implies that there exists a constant $C = C(r,k) > 0$ such that

$$\mathbf{E}[X^2] < C\, n^{-1/2}\binom{n}{n/2} g_c(1/2)^n.$$

We now bound $\mathbf{E}[X]$ from below using Stirling's approximation (29) and get

$$\frac{\mathbf{E}[X^2]}{\mathbf{E}[X]^2} < C \times \frac{n^{-1/2}\binom{n}{n/2} g_c(1/2)^n}{\binom{n}{n/2}^2 (1-2^{1-k})^{2cn}} = C \times \frac{n^{-1/2}\, 2^n}{\binom{n}{n/2}} \to C \times \sqrt{\frac{\pi}{2}}.$$

To complete the proof, analogously to [NAE] k-SAT, we use the following "boosting" corollary of Theorem 4.

COROLLARY 2. *If $H_k(n, c^* n)$ is w.u.p.p. 2-colorable, then for all $c < c^*$, $H_k(n, cn)$ is w.h.p. 2-colorable.*

7. Proof of Lemma 4. We need to prove $g_r''(1/2) < 0$ and $g_r(\alpha) < g_r(1/2)$ for all $\alpha \neq 1/2$. As g_r is symmetric around $1/2$, we can restrict to $\alpha \in (1/2, 1]$. We divide $(1/2, 1]$ into two parts and handle them with two separate lemmata. The first lemma deals with $\alpha \in (1/2, 0.9]$ and also establishes that $g_r''(1/2) < 0$.

LEMMA 5. *Let $\alpha \in (1/2, 0.9]$. For all $k \geq 74$, if $r \leq 2^{k-1} \ln 2$, then $g_r(\alpha) < g_r(1/2)$ and $g_r''(1/2) < 0$.*

The second lemma deals with $\alpha \in (0.9, 1]$.

LEMMA 6. *Let $\alpha \in (0.9, 1]$. For every $\epsilon > 0$ and all $k \geq k_0(\epsilon)$, if $r \leq 2^{k-1} \ln 2 - \frac{\ln 2}{2} - \frac{1}{2} - \epsilon$, then $g_r(\alpha) < g_r(1/2)$.*

Combining Lemmata 5 and 6 we see that for every $\epsilon > 0$ and $k \geq k_0 = k_0(\epsilon)$, if

$$r \leq 2^{k-1} \ln 2 - \frac{\ln 2}{2} - \frac{1}{2} - \epsilon,$$

then $g_r(\alpha) < g_r(1/2)$ for all $\alpha \neq 1/2$ and $g_r''(1/2) < 0$, establishing Lemma 4.

We prove Lemmata 5 and 6 below. The reader should keep in mind that we have made no attempt to optimize the value of k_0 in Lemma 6, aiming instead for proof simplicity. For the lower bounds presented in Table 1 we computed numerically, for each k, the largest value of r for which the conclusions of Lemma 4 hold. In each case, the condition $g''(1/2) < 0$ was satisfied with room to spare, while establishing $g(1/2) > g(\alpha)$ for all $\alpha \neq 1/2$ was greatly simplified by the fact that g never has more than three local extrema in $[0, 1]$.

Proof of Lemma 5. We will first prove that for $k \geq 74$, g_r is strictly decreasing in $\alpha = (1/2, 0.9]$, thus establishing $g_r(\alpha) < g_r(1/2)$. Since g_r is positive, to do this it suffices to prove that $(\ln g_r)' = g_r'/g_r < 0$ in this interval. In fact, since $g_r'(\alpha) = (\ln g_r)' = 0$ at $\alpha = 1/2$, it will suffice to prove that for $\alpha \in [1/2, 0.9]$ we have $(\ln g_r)'' < 0$. Now,

$$\begin{aligned}(\ln g_r(\alpha))'' &= r\left(\frac{f''(\alpha)}{f(\alpha)} - \frac{f'(\alpha)^2}{f(\alpha)^2}\right) - \frac{1}{\alpha(1-\alpha)} \\ &\leq r\,\frac{f''(\alpha)}{f(\alpha)} - \frac{1}{\alpha(1-\alpha)}. \qquad (16)\end{aligned}$$

To show that the right-hand side (R.H.S.) of (16) is negative we first note that for $\alpha \geq 1/2$ and $k > 3$,

$$f''(\alpha) = 2^{1-k}k(k-1)(\alpha^{k-2} + (1-\alpha)^{k-2}) < 2^{2-k}\alpha^{k-2}k^2$$

is monotonically increasing. Therefore, $f''(\alpha) \leq f''(0.9) < 2^{2-k}\,0.9^{k-2}\,k^2$.

Moreover, for all α, $f(\alpha) \geq f(1/2) = (1-2^{-k})^2$. Therefore, since $1/(\alpha(1-\alpha)) \geq 4$ and $r \leq 2^{k-1}\ln 2$, it suffices to observe that for all $k \geq 74$,

$$(2^{k-1}\ln 2) \times \frac{2^{2-k}\,0.9^{k-2}\,k^2}{(1-2^{-74})^2} - 4 < 0.$$

Finally, recalling that $g'(1/2) = 0$ and using

$$(\ln g_r)'' = \frac{g_r''(\alpha)}{g_r(\alpha)} - \frac{g_r'(\alpha)^2}{g_r(\alpha)^2},$$

we see that $g_r''(1/2) < 0$ since $(\ln g_r)''(1/2) < 0$. □

Proof of Lemma 6. We let $h(\alpha) = -\alpha \ln \alpha - (1-\alpha)\ln(1-\alpha)$ denote the entropy function and for all $\alpha > 1/2$ we define

$$w(\alpha) \equiv \frac{f(\alpha) - f(1/2)}{f(1/2)} = \frac{2^{1-k}(\alpha^k + (1-\alpha)^k - 2^{1-k})}{(1-2^{1-k})^2} > 0.$$

By the definition of g_r, we thus see that $g_r(\alpha) < g_r(1/2)$ if and only if

$$\frac{r}{\ln 2 - h(\alpha)} < \frac{1}{\ln(1+w(\alpha))}. \tag{17}$$

Moreover, we observe that for any $x > 0$,

$$\frac{1}{\ln(1+x)} \geq \frac{1}{x} + \frac{1}{2} - \frac{x}{12}.$$

Since $f(\alpha) - f(1/2) < 2^{1-k}$ and $f(1/2) > 1 - 2^{2-k}$, we thus see that (17) holds as long as

$$\frac{r}{\ln 2 - h(\alpha)} < \frac{2^{k-1}-2}{\alpha^k + (1-\alpha)^k - 2^{1-k}} + \frac{1}{2} - \frac{2^{1-k}}{12(1-2^{2-k})}. \tag{18}$$

Now observe that for any $0 < \alpha < 1$ and $0 \leq q < \alpha^k$,

$$\frac{1}{\alpha^k - q} \geq 1 + k(1-\alpha) + q.$$

Since $\alpha > 1/2$ we can set $q = 2^{1-k} - (1-\alpha)^k$, yielding

$$\frac{1}{\alpha^k + (1-\alpha)^k - 2^{1-k}} \geq 1 + k(1-\alpha) + 2^{1-k} - (1-\alpha)^k.$$

Since $2^k(1-\alpha)^k < 5^{-k}$, we find that (18) holds as long as $r \leq \phi(y) - 2^{3-k}$, where

$$\phi(\alpha) \equiv \big(\ln 2 - h(\alpha)\big)\left(2^{k-1} + (2^{k-1}-2)k(1-\alpha) - \frac{1}{2}\right).$$

We are thus left to minimize ϕ in $(0.9, 1]$. Since ϕ is differentiable, its minima can only occur at 0.9 or 1, or where $\phi' = 0$. The derivative of ϕ is

$$\phi'(\alpha) = (2^{k-1}-2) \times \left[-k\left(\ln 2 - h(\alpha)\right) + \left(\ln \alpha - \ln(1-\alpha)\right)\left(1 + k(1-\alpha) + \frac{3}{2^k - 4}\right)\right]. \tag{19}$$

Note now that for all $k > 1$

$$\lim_{\alpha \to 1} \frac{\phi'(\alpha)}{\ln(1-\alpha)} = -\frac{2^k - 1}{2};$$

i.e., the derivative of ϕ as $\alpha \to 1$ becomes positively infinite. At the same time,

$$\phi'(0.9) < -0.07 \times 2^k k + 1.1\,(2^k - 1) + 0.3\,k$$

is negative for $k \geq 16$. Therefore, ϕ is minimized in the interior of $(0.9, 1]$ for all $k \geq 16$. Setting ϕ' to zero gives

$$-\ln(1-\alpha) = \frac{k\,(\ln 2 - h(\alpha))}{1 + k(1-\alpha) + 3/(2^k - 4)} - \ln \alpha. \tag{20}$$

By "bootstrapping" we derive a tightening series of lower bounds on the solution for the left-hand side (L.H.S.) of (20) for $\alpha \in (0.9, 1)$. Note first that we have an easy upper bound,

$$-\ln(1-\alpha) < k \ln 2 - \ln \alpha. \tag{21}$$

At the same time, if $k > 2$, then $3/(2^k - 4) < 1$, implying

$$-\ln(1-\alpha) > \frac{k\,(\ln 2 - h(\alpha))}{2 + k(1-\alpha)} - \ln \alpha. \tag{22}$$

If we write $k(1-\alpha) = B$, then (22) becomes

$$-\ln(1-\alpha) > \frac{\ln 2 - h(\alpha)}{1-\alpha} \left(\frac{B}{B+2} \right) - \ln \alpha. \tag{23}$$

By inspection, if $B \geq 3$, the R.H.S. of (23) is greater than the L.H.S. for all $\alpha > 0.9$, yielding a contradiction. Therefore, $k(1-\alpha) < 3$ for all $k > 2$. Since $\ln 2 - h(\alpha) > 0.36$ for $\alpha > 0.9$, we see that for $k > 2$, (22) implies

$$-\ln(1-\alpha) > 0.07\,k. \tag{24}$$

Finally, observe that (24) implies that as k increases, the denominator of (20) approaches 1.

To bootstrap, we note that since $\alpha > 1/2$ we have

$$h(\alpha) \leq -2(1-\alpha)\ln(1-\alpha) \tag{25}$$

$$\begin{aligned} &< 2\,\mathrm{e}^{-0.07\,k}(k \ln 2 - \ln 0.9) \\ &< 2\,k\,\mathrm{e}^{-0.07\,k}, \end{aligned} \tag{26}$$

where (26) relies on (21) and (24). Moreover, $\alpha > 1/2$ implies $-\ln \alpha \leq 2(1-\alpha) < 2\,\mathrm{e}^{-0.07\,k}$. Thus, by using (24) and the fact $1/(1+x) > 1 - x$ for all $x > 0$, (20) gives for $k \geq 3$

$$\begin{aligned} -\ln(1-\alpha) &> \frac{k\,(\ln 2 - h(\alpha))}{1 + k(1-\alpha) + 3/(2^k - 4)} \\ &> \frac{k\,(\ln 2 - 2\,k\,\mathrm{e}^{-0.07\,k})}{1 + 2\,k\,\mathrm{e}^{-0.07\,k}} \\ &> k\,(\ln 2 - 2\,k\,\mathrm{e}^{-0.07\,k})(1 - 2\,k\,\mathrm{e}^{-0.07\,k}) \\ &> k \ln 2 - 4\,k^2\,\mathrm{e}^{-0.07\,k}. \end{aligned} \tag{27}$$

For $k \geq 166$, $4\,k^2\,\mathrm{e}^{-0.07\,k} < 1$. Thus, by (27), we have $1 - \alpha < 3 \times 2^{-k}$. This, in turn, implies $-\ln \alpha \leq 2(1-\alpha) < 6 \times 2^{-k}$ and thus, by (25) and (21), we have for $\alpha > 0.9$

$$h(\alpha) < 6 \times 2^{-k}(k \ln 2 - \ln \alpha) < 5\,k\,2^{-k}. \tag{28}$$

Plugging (28) into (20) to bootstrap again, we get that for $k \geq 166$

$$\begin{aligned} -\ln(1-\alpha) &> \frac{k\,(\ln 2 - 5\,k\,2^{-k})}{1 + 3\,k\,2^{-k} + 3/(2^k-4)} \\ &> \frac{k\,(\ln 2 - 5\,k\,2^{-k})}{1 + 6\,k\,2^{-k}} \\ &> k\,(\ln 2 - 5\,k\,2^{-k})(1 - 6\,k\,2^{-k}) \\ &> k \ln 2 - 11\,k^2\,2^{-k}. \end{aligned}$$

Since $e^x < 1 + 2x$ for $x < 1$ and $11\,k^2\,2^{-k} < 1$ for $k > 10$, we see that for $k \geq 166$,

$$1 - \alpha < 2^{-k} + 22\,k^2\,2^{-2k}.$$

Plugging into (21) the fact $-\ln\alpha < 6 \times 2^{-k}$, we get $-\ln(1-\alpha) < k \ln 2 + 6 \times 2^{-k}$. Using that $\mathrm{e}^{-x} \geq 1 - x$ for $x \geq 0$, we get the closely matching upper bound,

$$1 - \alpha > 2^{-k} - 6 \times 2^{-2k}.$$

Thus, we see that for $k \geq 166$, ϕ is minimized at an $\alpha_{\min}$ which is within δ of $1 - 2^{-k}$, where $\delta = 22\,k^2\,2^{-2k}$. Let T be the interval $[1 - 2^{-k} - \delta, 1 - 2^{-k} + \delta]$. Clearly the minimum of ϕ is at least $\phi(1-2^{-k}) - \delta \times \max_{\alpha \in T} |\phi'(\alpha)|$. It is easy to see from (19) that if $\alpha \in T$, then $|\phi'(\alpha)| \leq 2\,k\,2^k$.

Now, a simple calculation using that $\ln(1 - 2^{-k}) > -2^{-k} - 2^{-2k}$ for $k \geq 1$ gives

$$\begin{aligned} \phi(1-2^{-k}) &= \frac{1}{2}\big((2^k - k)\ln 2 + (2^k - 1)\ln(1-2^{-k})\big) \times \big(1 + (k-1)\,2^{-k} - k\,2^{2-2k}\big) \\ &> 2^{k-1}\ln 2 - \frac{\ln 2}{2} - \frac{1}{2} - k^2\,2^{-k}. \end{aligned}$$

Therefore,

$$\phi_{\min} \geq 2^{k-1}\ln 2 - \frac{\ln 2}{2} - \frac{1}{2} - 45\,k^3\,2^{-k}.$$

Finally, recall that (17) holds as long as $r < \phi_{\min} - 2^{3-k}$, for example, if

$$r < 2^{k-1}\ln 2 - \frac{\ln 2}{2} - \frac{1}{2} - 46\,k^3\,2^{-k}.$$

Clearly, we can take $k_0 = O(\ln \epsilon^{-1})$ so that for all $k \geq k_0$ the error term $46\,k^3\,2^{-k}$ is smaller than any $\epsilon > 0$. □

8. Proof of Lemma 3. The idea behind Lemma 3 is that sums of this type are dominated by the contribution of $\Theta(n^{1/2})$ terms around the maximum term. The proof amounts to replacing the sum by an integral and using the Laplace method for asymptotic integrals [23].

We start by establishing two upper bounds for the terms of S_n, a crude one and one which is sharper when $\alpha = z/t$ is bounded away from both 0 and 1. For the sharper bound we will use the following form of Stirling's approximation, valid for all $n > 0$:

$$\sqrt{2\pi n} < \frac{n!}{(n/\mathrm{e})^n} < \sqrt{2\pi n}\,(1 + 1/n)\,. \tag{29}$$

The zth term of S_n is $\binom{t}{z}^q \phi(z/t)^n$, where $n = qt$ and $\phi(\alpha) = g(\alpha)\,\alpha^\alpha(1-\alpha)^{1-\alpha}$. Fix any $\delta > 0$ and suppose that $z = \alpha t$, where $\alpha \in [\delta, 1-\delta]$. Then (29) yields

$$\binom{t}{z}^q \phi(z/t)^n < s(\alpha)\, g(\alpha)^n \left(1 + \frac{q}{n}\right)^q, \tag{30}$$

where $s(\alpha) = (2\pi\alpha(1-\alpha)t)^{-q/2}$. In addition to (30), valid for $z \in [t\delta, t(1-\delta)]$, we will also use a cruder bound, valid for all $0 \le z \le t$. Namely, by induction on $t - z$ it is easy to show that $\binom{t}{z} \le t^t/[z^z(t-z)^{t-z}]$, implying

$$\binom{t}{z}^q \phi(z/t)^n \;<\; g(\alpha)^n. \tag{31}$$

Recall now that $g(\alpha_{\max}) > g(\alpha)$ for all $\alpha \ne \alpha_{\max}$. If I_ϵ denotes the interval $[\alpha_{\max} - \epsilon, \alpha_{\max} + \epsilon]$, then for every $\epsilon > 0$, there exists a constant $g_\epsilon < g(\alpha_{\max}) = g_{\max}$ such that $g(\alpha) < g_\epsilon$ for all $\alpha \notin I_\epsilon$. Let $z_\epsilon^- = \lfloor(\alpha_{\max} - \epsilon)t\rfloor$ and $z_\epsilon^+ = \lceil(\alpha_{\max} + \epsilon)t\rceil$, and let

$$S_n^{(\epsilon)} = \sum_{z=z_\epsilon^-}^{z_\epsilon^+} \binom{t}{z}^q \phi(z/t)^n. \tag{32}$$

We use (30) to bound the terms in $S_n^{(\epsilon)}$ and (31) to bound the remaining terms of S_n. Since $\lim_{n\to\infty}(1 + q/n)^q = 1$, and since $\lim_{n\to\infty} n^s\, g_\epsilon^n / g_{\max}^n = 0$ for any s, we see that for every $\epsilon > 0$

$$S_n < (C_\epsilon t)^{-q/2} \times \sum_{z=z_\epsilon^-}^{z_\epsilon^+} g(z/t)^n \tag{33}$$

for any constant $C_\epsilon > 2\pi \times \min\{(\alpha_{\max} - \epsilon)(1 - \alpha_{\max} + \epsilon), (\alpha_{\max} + \epsilon)(1 - \alpha_{\max} - \epsilon)\}$.

Say that a twice-differentiable function $\psi(x)$ is *unimodal* on an interval $[a, b]$ if ψ' has a unique zero $c \in [a, b]$ with $a < c < b$ and, furthermore, $\psi''(c) < 0$. Since $g_{\max} > g(\alpha)$ for all $\alpha \ne \alpha_{\max}$ and $g''(\alpha_{\max}) < 0$, we can take ϵ small enough so that g is unimodal on I_ϵ. This implies that $\ln g$ is also unimodal on I_ϵ and, for $n \ge 1$, that g^n is unimodal also. For any function $\gamma(x)$ which is nonnegative and unimodal on an interval $[a, b]$ with maximum $\gamma_{\max}$, no matter how tightly peaked, we have

$$\sum_{z=\lfloor at\rfloor}^{\lceil bt\rceil} \gamma(z/t) \le t \int_a^b \gamma(x)\,\mathrm{d}x \;+ \gamma_{\max},$$

and thus

$$\sum_{z=z_\epsilon^-}^{z_\epsilon^+} g(z/t)^n \le \frac{n}{q} \int_{I_\epsilon} g(x)^n\,\mathrm{d}x \;+ g_{\max}^n. \tag{34}$$

We evaluate this last integral using Lemma 7, i.e., the Laplace method for asymptotic integrals.

LEMMA 7 (see [23, section 4.2]). *Let $h(x)$ be unimodal on $[a, b]$, where c is the unique zero of h' in $[a, b]$. Then*

$$\lim_{n\to\infty} \int_a^b \mathrm{e}^{nh(x)}\,\mathrm{d}x \;\sim\; \sqrt{\frac{2\pi}{n\,|h''(c)|}}\,\mathrm{e}^{nh(c)}.$$

Applying Lemma 7 to (34) with $h = \ln g$ and $c = \alpha_{\max}$, we see that

$$S_n < C\, n^{-(q-1)/2}\, g_{\max}^n,$$

where $C = (2\pi)^{-(q-1)/2} \times q^{q/2} \times \sqrt{g_{\max}/|g''(\alpha_{\max})|}$. □

9. Conclusions. Before this work, lower bounds on the thresholds of random constraint satisfaction problems were largely derived by analyzing very simple heuristics. Here, instead, we derive such bounds by applying the second moment method to the number of solutions. In particular, for random NAE k-SAT and random hypergraph 2-colorability we determine the location of the threshold within a small additive constant for all k. As a corollary, we establish that the asymptotic order of the random k-SAT threshold is $\Theta(2^k)$, answering a long-standing open question.

Since this work first appeared [4, 5], our methods have been extended and applied to other problems. For random k-SAT, Achlioptas and Peres [7] confirmed our suspicion (see section 3.3) that the main source of correlations in random k-SAT is the "populist" tendency of satisfying assignments toward the majority vote assignment. By considering a carefully constructed random variable which focuses on balanced solutions, i.e., on satisfying assignments that satisfy roughly half of all literal occurrences, they showed $r_k \geq 2^k \ln 2 - k/2 - O(1)$, establishing $r_k \sim 2^k \ln 2$.

In [8], Achlioptas, Naor, and Peres extended the approach of balanced solutions to Max k-SAT. Let us say that a k-CNF formula is p-satisfiable if there exists a truth assignment which satisfies at least $(1 - 2^{-k} + p2^{-k})$ of all clauses; note that every k-CNF is 0-satisfiable. For $p \in (0, 1]$ let $r_k(p)$ denote the threshold for $F_k(n, m = rn)$ to be p-satisfiable (so that $r_k(1) = r_k$). In [8], the result $r_k = r_k(1) \sim 2^k \ln 2$ of [7] was extended to all $p \in (0, 1]$, showing that

$$r_k(p) \sim \frac{2^k \ln 2}{p + (1-p)\ln(1-p)}.$$

In both [7] and [8], controlling the variance crucially depends on focusing on an appropriate subset of solutions (akin to our NAE-assignments but less heavy-handed). In [9], Achlioptas and Naor applied the naive second moment method to the canonical symmetric constraint satisfaction problem, i.e., to the number of k-colorings of a random graph. Bearing out our belief that the naive approach should work for symmetric problems, they obtained asymptotically tight bounds for the k-colorability threshold, and in [10] Achlioptas and Moore extended this analysis to random d-regular graphs. The difficulty here is that the "overlap parameter" is a $k \times k$ matrix rather than a single real $\alpha \in [0, 1]$. Since $k \to \infty$, this makes the asymptotic analysis dramatically harder and much closer to the realm of statistical mechanics calculations.

We propose several questions for further work.

1. Does the second moment method give tight lower bounds on the threshold of all constraint satisfaction problem with a permutation symmetry?
2. Does it perform well for problems that are symmetric "on average"? For example, does it perform well for *regular* random k-SAT where every literal appears an equal number of times?
3. What rigorous connections can be made between the success of the second moment method and the notion of "replica symmetry" in statistical physics?
4. Is there a polynomial-time algorithm that succeeds with uniformly positive probability close to the threshold, or at least for $r = \omega(k) \times 2^k/k$ where $\omega(k) \to \infty$?

Acknowledgments. We are grateful to Paul Beame, Ehud Friedgut, Michael Molloy, Assaf Naor, Yuval Peres, Alistair Sinclair, and Chris Umans for reading earlier versions and making many helpful suggestions, and to Remi Monasson for discussions on the replica method. We would like to thank Henry Cohn for bringing [23] to our attention. Finally, we would like to thank the anonymous referees for a number of excellent suggestions.

QUANTUM ALGORITHMS FOR SOME HIDDEN SHIFT PROBLEMS*

WIM VAN DAM†, SEAN HALLGREN‡, AND LAWRENCE IP§

Abstract. Almost all of the most successful quantum algorithms discovered to date exploit the ability of the Fourier transform to recover subgroup structures of functions, especially periodicity. The fact that Fourier transforms can also be used to capture shift structure has received far less attention in the context of quantum computation. In this paper, we present three examples of "unknown shift" problems that can be solved efficiently on a quantum computer using the quantum Fourier transform. For one of these problems, *the shifted Legendre symbol problem*, we give evidence that the problem is hard to solve classically, by showing a reduction from breaking algebraically homomorphic cryptosystems. We also define the *hidden coset problem,* which generalizes the hidden shift problem and the hidden subgroup problem. This framework provides a unified way of viewing the ability of the Fourier transform to capture subgroup and shift structure.

Key words. quantum computing, efficient algorithms, Legendre symbol

1. Introduction.

The first problem to demonstrate a superpolynomial separation between random and quantum polynomial time was the recursive Fourier sampling problem [6]. Exponential separations were subsequently discovered by Simon [35], who defined a problem with respect to an oracle, and by Shor [34], who found polynomial-time quantum algorithms for factoring and discrete logarithms. We now understand that the natural generalization of Simon's problem and the factoring and discrete log problems is the hidden subgroup problem (HSP), and that when the underlying group is abelian and finitely generated, we can solve the HSP efficiently on a quantum computer. While recent results have continued to study important generalizations of the HSP (for example, [19, 21, 24, 25, 27, 37]), only the recursive Fourier sampling problem remains outside the abelian HSP framework.

In this paper, we give quantum algorithms for several hidden shift problems where we are given two functions f, g such that there is a shift s for which $f(x) = g(x + s)$ for all x. The problem is then to find s. We show how to solve this problem for several classes of functions, but perhaps the most interesting example is the shifted Legendre symbol problem, where g is the *Legendre symbol* with respect to a prime

size finite field, and the problem is the following: "Given the function $f(x) = \left(\frac{x+s}{p}\right)$ as an oracle, find s."

The oracle problem that our algorithms solve can be viewed as the problem of predicting a pseudorandom function f. Such tasks play an important role in cryptography and have been studied extensively under various assumptions about how one is allowed to query the function (nonadaptive versus adaptive, deterministic versus randomized, etc.) [7, 31]. In this paper we consider the case where the function is queried in a quantum mechanical superposition of different values x. We show that if $f(x)$ is an s-shifted multiplicative character $\chi(x+s)$—like the Legendre symbol—then a polynomial-time quantum algorithm making such queries can determine the hidden shift s, breaking the pseudorandomness of f.

We conjecture that classically the shifted Legendre symbol is a pseudorandom function; that is, it is impossible to efficiently predict the value of the function after a polynomial number of queries if one is allowed only a classical algorithm with oracle access to f. Damgård gave partial evidence for this conjecture, proposing the related task: "Given a part of the Legendre sequence $\left(\frac{s}{p}\right), \left(\frac{s+1}{p}\right), \ldots, \left(\frac{s+\ell}{p}\right)$, where ℓ is $O(\log p)$, predict the next value $\left(\frac{s+\ell+1}{p}\right)$" as a hard problem with applications in cryptography [17].

As further evidence of our conjecture, we show that breaking certain algebraically homomorphic cryptosystems can be reduced to the shifted Legendre symbol problem. The reduction, together with our quantum algorithm for the shifted Legendre symbol problem, yields a polynomial-time quantum algorithm for breaking such cryptosystems. The best known classical algorithm [9] for breaking these cryptosystems is subexponential and is based on a smoothness assumption. Thus the shifted Legendre symbol problem is a problem for which there is an exponential separation between a quantum algorithm and the fastest known classical algorithm. These cryptosystems can also be broken by Shor's algorithm for period finding, but the two attacks on the cryptosystems appear to use completely different ideas.

While current quantum algorithms solve problems based on an underlying group and the Fourier transform over that group, we initiate the study of problems where there is an underlying ring or field. The Fourier transform over the additive group of the ring is defined using the characters of the additive group, the additive characters of the ring. Similarly, the multiplicative group of units induces multiplicative characters of the ring. The interplay between additive and multiplicative characters is well understood [30, 36], and we show that this connection can be exploited in quantum algorithms. In particular, we put a multiplicative character into the phase of the registers and compute the Fourier transform over the additive group. The resulting phases are the inner products between the multiplicative character and each of the additive characters, a Gauss sum. We hope the new tools presented here will lead to other quantum algorithms.

We give algorithms for three types of hidden shift problems. In the first problem, g is a multiplicative character of a finite field. Given f, a shifted version of g, the shift is uniquely determined from f and g. An example of a multiplicative character of $\mathbb{Z}/p\mathbb{Z}$ is the Legendre symbol. Our algorithm uses the Fourier transform over the additive group of a finite field. In the second problem, g is a multiplicative character of the ring $\mathbb{Z}/n\mathbb{Z}$. This problem has the feature that the shift is not uniquely determined by f and g, and our algorithm identifies all possible shifts. An example of a multiplicative character of $\mathbb{Z}/n\mathbb{Z}$ is the *Jacobi symbol*. In the third problem we have the same setup as in the second problem with the additional twist that n is unknown.

We also define the *hidden coset problem*, which is a generalization of the hidden shift problem and the hidden subgroup problem. This definition provides a unified way of viewing the quantum Fourier transform's ability to capture subgroup and shift structure.

Some of our hidden shift problems can be reduced to the nonabelian HSP, although efficient algorithms for these HSP instances are not known. The shifted Legendre symbol problem over $\mathbb{Z}/p\mathbb{Z}$ can be reduced to an instance of the HSP over the dihedral group $D_p = \mathbb{Z}/p\mathbb{Z} \rtimes \mathbb{Z}/2\mathbb{Z}$ if we assume a conjecture about subsequences of the Legendre symbol. Let $f(x,0) = \left(\left(\frac{x}{p}\right), \left(\frac{x+1}{p}\right), \ldots, \left(\frac{x+\ell}{p}\right)\right)$ and $f(x,1) = \left(\left(\frac{x+s}{p}\right), \left(\frac{x+s+1}{p}\right), \ldots, \left(\frac{x+s+\ell}{p}\right)\right)$, where s is unknown and $\ell = \text{polylog}(p)$. Then the hidden subgroup is $H = \{(0,0),(s,1)\}$. The conjecture that is necessary to ensure that f will be distinct on distinct cosets of H is thus the statement that the subsequence $\left(\left(\frac{x+s}{p}\right), \left(\frac{x+s+1}{p}\right), \ldots, \left(\frac{x+s+\ell}{p}\right)\right)$ is unique for every x (cf. Conjecture 2.1 in [9]). For the general shifted multiplicative character problem, the analogous reduction to the HSP may fail because f may not be distinct on distinct cosets. However, we can efficiently generate random coset states, that is, superpositions of the form $|x,0\rangle + |x+s,1\rangle$, although it is unknown how to use these to efficiently find s [18]. The issue of nondistinctness on cosets in the HSP has been studied for some groups [8, 20, 23, 22].

The existence of a time-efficient quantum algorithm for the shifted Legendre symbol problem was posed as an open question in [13]. The Fourier transform over the additive group of a finite field was independently proposed for the solution of a different problem in [4]. The current paper subsumes [14, 15, 26]. Building on the ideas in this paper, a quantum algorithm for estimating Gauss sums is described in [16].

This paper is organized as follows. Section 2 contains some definitions and facts. In section 3, we give some intuition for the ideas behind the algorithms. In section 4, we present an algorithm for the shifted multiplicative problem over finite fields, of which the shifted Legendre symbol problem is a special case, and show how we can use this algorithm to break certain algebraically homomorphic cryptosystems. In section 5, we extend our algorithm to the shifted multiplicative problem over rings $\mathbb{Z}/n\mathbb{Z}$. This has the feature that, unlike in the case of the finite field, the possible shifts may not be unique. We then show that this algorithm can be extended to the situation where n is unknown. In section 6, we show that all these problems lie within the general framework of the hidden coset problem. We give an efficient algorithm for the hidden coset problem provided g satisfies certain conditions. We also show how our algorithm can be interpreted as solving a deconvolution problem using Fourier transforms.

2. Background.

2.1. Notation and conventions. We use the following notation: ω_n is the nth root of unity $\exp(2\pi\mathrm{i}/n)$, and $\hat{f}$ denotes the Fourier transform of the function f. An algorithm computing in $\mathbb{F}_q$, $\mathbb{Z}/n\mathbb{Z}$, or G runs in polynomial time if it runs in time polynomial in $\log q$, $\log n$, or $\log |G|$.

In a ring $\mathbb{Z}/n\mathbb{Z}$ or a field $\mathbb{F}_q$, additive characters $\psi : \mathbb{Z}/n\mathbb{Z} \to \mathbb{C}^*$ or $\psi : \mathbb{F}_q \to \mathbb{C}^*$ are characters of the additive group, that is, $\psi(x+y) = \psi(x)\psi(y)$, and multiplicative characters $\chi : (\mathbb{Z}/n\mathbb{Z})^* \to \mathbb{C}^*$ or $\chi : \mathbb{F}_q^* \to \mathbb{C}^*$ are characters of the multiplicative group of units, that is, $\chi(xy) = \chi(x)\chi(y)$ for all x and y. We extend the definition of a multiplicative character to the entire ring or field by assigning the value zero to elements outside the unit group. All nonzero $\chi(x)$ values have unit norm and thus $\chi(x^{-1}) = \overline{\chi(x)}$.

We ignore the normalization term in front of a superposition unless we need to explicitly calculate the probability of measuring a particular value.

2.2. Computing superpositions. We will need to be able to compute the superposition $\sum_x f(x)|x\rangle$, where the function $f : G \to \mathbb{C}$ describes the *amplitudes* of the state in an efficient way. The specific functions f that we deal with in this article have the property that for each x either $f(x) = 0$ or $f(x)$ is an mth root of unity. Hence there is a function $f' : G \to \mathbb{Z}$ such that if $f(x) \neq 0$, then $f(x) = \exp(2\pi \mathrm{i} f'(x)/m)$. This additional function helps us in the following lemma, which describes how to construct the superpositions in an efficient way.

LEMMA 2.1 (computing superpositions). *Let $f : G \to \mathbb{C}$ be a complex-valued function with a finite domain G that is characterized by a function $f' : G \to \mathbb{Z}/m\mathbb{Z} \cup \{\mathrm{i}\infty\}$ such that $f(x) = \omega_m^{f'(x)}$ for all x with $f'(x) \in \mathbb{Z}/m\mathbb{Z}$ and $f(x) = 0$ if $f'(x) = \mathrm{i}\infty$. Then there is an efficient algorithm for creating the superposition $\sum_x f(x)|x\rangle$ with success probability equal to the fraction of $x \in G$ with $f(x)$ nonzero and that uses two queries to the function f'.*

Proof. Start with the superposition over all $x \in G$: $\sum_x |x, 0\rangle$. Compute $f'(x)$ into the second register and measure to see whether $f'(x) \neq \mathrm{i}\infty$. This succeeds with probability equal to the fraction of x such that $f(x)$ is nonzero. If successful, we are left with a superposition over all x such that $f(x)$ is nonzero. Next, compute the phase shift $\omega_m^{f'(x)}$ by adding $\bmod m$ the value $f'(x)$ to the superposition $\sum_j \omega_m^{-j}|j\rangle$ (which by itself is the Fourier transform over $\mathbb{Z}/m\mathbb{Z}$ of the state $|-1\rangle$), such that

$$\begin{aligned}\sum_{x\in G, f(x)\neq 0} |x\rangle \otimes \frac{1}{\sqrt{m}} \sum_{j\in\mathbb{Z}/m\mathbb{Z}} \omega_m^{-j}|j\rangle &\mapsto \sum_{x\in G, f(x)\neq 0} |x\rangle \otimes \frac{1}{\sqrt{m}} \sum_{j\in\mathbb{Z}/m\mathbb{Z}} \omega_m^{-j}|j + f'(x)\rangle \\ &= \sum_{x\in G, f(x)\neq 0} \omega_m^{f'(x)}|x\rangle \otimes \frac{1}{\sqrt{m}} \sum_{j\in\mathbb{Z}/m\mathbb{Z}} \omega_m^{-j}|j\rangle \\ &= \sum_{x\in G} f(x)|x\rangle \otimes \frac{1}{\sqrt{m}} \sum_{j\in\mathbb{Z}/m\mathbb{Z}} \omega_m^{-j}|j\rangle.\end{aligned}$$

If necessary, the state $\sum_j \omega_m^{-j}|j\rangle = \mathcal{F}|-1\rangle$ can be approximated arbitrarily closely (see [33, section 5.1]). □

2.3. The Fourier transform and approximate Fourier sampling. Although it is not known how to efficiently compute the quantum Fourier transform over $\mathbb{Z}/n\mathbb{Z}$ exactly, it is known how to efficiently approximate such transformations [12, 23, 28, 29]. The current section deals with the problem of approximating the right probability distribution induced by the Fourier transform if the size of the group is not known. This result will be used in section 5.2.

Fourier sampling a quantum state is the process of computing the Fourier transform and measuring the resulting state. The best-known example is Shor's factoring algorithm which finds the period of a function f defined on $\mathbb{Z}$. In that case the function f is periodic with period r and is injective in $\{0, \ldots, r-1\}$. By evaluating the function in superposition up to some chosen value q and measuring the function value, the state $|\phi\rangle = \sqrt{\frac{r}{q}} \sum_{i=0}^{q/r-1} |k + ir\rangle$ is created, where k depends on which function value was measured. If q were a multiple of r, then Fourier sampling $|\phi\rangle$ would result in a random integer multiple of q/r.

When a multiple of r is not known, we must understand the distribution induced by Fourier sampling $|\phi\rangle$ for values of q that we choose. This understanding was at the

heart of Shor's factoring algorithm when he showed that it is possible to still compute multiples of q/r using continued fractions. This principle has been generalized for arbitrary states $|\phi\rangle$ and is known as *approximate* Fourier sampling [23]. This process, described below, allows one to sample from a distribution which is close to the one that could be generated if a multiple of r were known. This will be required in section 5.2 for finding the period of the shifted character problem. In that case the shifted character problem will have a property very different from that of Shor's periodic function. In particular, the periodic function f in Shor's case takes r different values, whereas there are nontrivial cases of the shifted character problem when the function only takes *two* values (ignoring zero amplitudes, which appear in an exponentially small fraction of the amplitudes and thus are insignificant).

Approximate Fourier sampling works as follows: Let $|\phi\rangle = \sum_{x=0}^{n-1} \phi_x |x\rangle$ be an arbitrary superposition, and let $\hat{\mathcal{D}}_{|\phi\rangle}$ be the distribution induced by Fourier sampling $|\phi\rangle$ over $\mathbb{Z}/n\mathbb{Z}$. Let the superposition $|\tilde{\phi}\rangle = \sum_{x=0}^{q'-1} \phi_{x \bmod n} |x\rangle$ be $|\phi\rangle$ repeated until some arbitrary integer q', not necessarily a multiple of n. Let $\hat{\mathcal{D}}_{|\tilde{\phi}\rangle}$ be the distribution induced by Fourier sampling $|\tilde{\phi}\rangle$ over $\mathbb{Z}/q\mathbb{Z}$, where $q > q'$ and $\phi_x = 0$ if $x \geq q'$.

Since $\hat{\mathcal{D}}_{|\phi\rangle}$ is a distribution on $\mathbb{Z}/n\mathbb{Z}$ and $\hat{\mathcal{D}}_{|\tilde{\phi}\rangle}$ is a distribution on $\mathbb{Z}/q\mathbb{Z}$, we define new distributions over fractions which can be compared. Define $\hat{\mathcal{D}}^{\mathrm{RF}}_{|\phi\rangle}(j,k) = \hat{\mathcal{D}}_{|\phi\rangle}(jm)$ if $mk = n$. The distribution $\hat{\mathcal{D}}^{\mathrm{RF}}_{|\phi\rangle}$ is the distribution on the reduced fractions of $\hat{\mathcal{D}}_{|\phi\rangle}$ since it describes the process of sampling x from $\hat{\mathcal{D}}_{|\phi\rangle}$ and returning the fraction x/n in lowest terms.

Let $\hat{\mathcal{D}}^{\mathrm{CF}}_{|\tilde{\phi}\rangle}$ be the distribution induced on fractions from sampling $\hat{\mathcal{D}}_{|\tilde{\phi}\rangle}$ to obtain x, and then using continued fractions to compute the closest approximation to x/q with denominator at most n. It is a theorem that if $q' = \Omega(\frac{n^2}{\epsilon^2})$ and $q = \Omega(\frac{q'}{\epsilon})$, then $|\hat{\mathcal{D}}^{\mathrm{RF}}_{|\phi\rangle} - \hat{\mathcal{D}}^{\mathrm{CF}}_{|\tilde{\phi}\rangle}|_1 < \epsilon$ [23].

It is easy to apply this to the periodic function with period r that is injective on $\{0, \ldots, r-1\}$. Let $n = r$ and consider the state $|\phi\rangle = \sum_{i=1}^{r} |k\rangle$. The distribution $\hat{\mathcal{D}}^{\mathrm{RF}}_{|\phi\rangle}$ is uniform over $\{0, 1/r, 2/r, \ldots, (r-1)/r\}$. By the theorem, if a large enough value q is chosen, then $\hat{\mathcal{D}}^{\mathrm{CF}}_{|\tilde{\phi}\rangle}$ will be ϵ-close to this and efficiently computable.

2.4. Legendre symbol and Jacobi symbol. The Legendre symbol $\left(\frac{\cdot}{p}\right) : \mathbb{F}_p \to \{0, \pm 1\}$ is a quadratic multiplicative character of $\mathbb{F}_p$ defined by

$$\left(\frac{x}{p}\right) = \begin{cases} 0 & \text{if } x = 0, \\ +1 & \text{if } x \text{ is a nonzero square in } \mathbb{F}_p, \\ -1 & \text{if } x \text{ is not a square in } \mathbb{F}_p. \end{cases}$$

The Legendre symbol satisfies $\left(\frac{x}{p}\right) = x^{(p-1)/2} \bmod p$, which shows that we can efficiently compute the Legendre symbol using repeated squaring mod$p$.

The Jacobi symbol $\left(\frac{\cdot}{n}\right) : \mathbb{Z}/n\mathbb{Z} \to \{0, \pm 1\}$ is a quadratic multiplicative character of $\mathbb{Z}/n\mathbb{Z}$ with n an odd integer. It is defined so that it satisfies the relation $\left(\frac{a}{bc}\right) = \left(\frac{a}{b}\right)\left(\frac{a}{c}\right)$ and reduces to the Legendre symbol when the lower parameter is prime. With $n = p_1^{r_1} \cdots p_k^{r_k}$ and all p_i odd primes, this gives the definition $\left(\frac{x}{n}\right) = \left(\frac{x}{p_1}\right)^{r_1} \cdots \left(\frac{x}{p_k}\right)^{r_k}$ such that $\left(\frac{x}{n}\right) \neq 0$ if and only if $x \in \mathbb{Z}/n\mathbb{Z}^*$. The value of the Jacobi symbol can be calculated efficiently without factoring n using the *quadratic reciprocity theorem,* which states that $\left(\frac{m}{n}\right) = (-1)^{(m-1)(n-1)/4}\left(\frac{n}{m}\right)$ in combination with the rule that $\left(\frac{m}{n}\right) = \left(\frac{m'}{n}\right)$ if $m = m' \bmod n$.

2.5. Finite fields. The elements of a finite field $\mathbb{F}_q$ (where $q = p^r$ for some prime p) can be represented as polynomials in $\mathbb{F}_p[X]$ modulo a degree r irreducible polynomial in $\mathbb{F}_p[X]$. In this representation, addition, subtraction, multiplication, and division can all be performed in $O((\log q)^2)$ time [2].

We will need to compute the Fourier transform over the additive group of a finite field, which is isomorphic to $(\mathbb{Z}/p\mathbb{Z})^r$. The additive characters are of the form $\psi_y(x) = \omega_p^{\mathrm{Tr}(xy)}$, where $\mathrm{Tr} : \mathbb{F}_q \to \mathbb{F}_p$ is the trace of the finite field $\mathrm{Tr}(x) = \sum_{j=0}^{r-1} x^{p^j}$ and $y \in \mathbb{F}_q$ [30]. We can efficiently compute the Fourier transform over the additive group of a finite field. (The efficiency of this transform was independently shown in [4].)

An operation U approximates U' to within ϵ if for any unit vector $|\psi\rangle$, $||U|\psi\rangle - U'|\psi\rangle||_2 \leq \epsilon$.

LEMMA 2.2 (Fourier transform over $\mathbb{F}_q$). *The Fourier transform*

$$|x\rangle \mapsto \frac{1}{\sqrt{q}} \sum_{y \in \mathbb{F}_q} \omega_p^{\mathrm{Tr}(xy)} |y\rangle$$

for all $x \in \mathbb{F}_q$ can be approximated to within error ϵ in time polynomial in $\log q$ and $\log 1/\epsilon$.

Proof. Let $q = p^r$, where p is the prime number that denotes the base field: $\mathbb{F}_q = \mathbb{F}_p[X]/f(X)$, with $f(X)$ an irreducible polynomial of degree r. Assume that the mapping $|x\rangle \mapsto \bigotimes_{j=0}^{r-1} |\mathrm{Tr}(xX^j)\rangle$ can be computed in polynomial time. First apply this map and then compute the Fourier transform over $(\mathbb{Z}/p\mathbb{Z})^r$. This gives us the final state

$$\bigotimes_{j=0}^{r-1} \frac{1}{\sqrt{p}} \sum_{y_j \in \mathbb{F}_p} \omega_p^{\mathrm{Tr}(xX^j)y_j} |y_j\rangle = \frac{1}{\sqrt{q}} \sum_{y \in \mathbb{F}_q} \omega_p^{\mathrm{Tr}(xy)} |y\rangle.$$

We first show that the map $|x\rangle \mapsto |\mathrm{Tr}(x), \mathrm{Tr}(xX), \ldots, \mathrm{Tr}(xX^{r-1})\rangle$ is reversible and then that it can be computed in polynomial time. Let $T(x) = (\mathrm{Tr}(x), \mathrm{Tr}(xX), \ldots, \mathrm{Tr}(xX^{r-1}))$. T is additive since Tr is; thus if $T(a) = T(b)$, then $T(a-b)$ is the zero vector. If T is not one-to-one, there is a nonzero x with $T(x)$ equal to the zero vector. Since Tr is not the zero map, choose $a \in \mathbb{F}_q$ such that $\mathrm{Tr}(a) \neq 0$. Choose elements of the base field $z_0, \ldots, z_{r-1}$ such that $x \cdot \sum_j z_j X^j = a$ (these must exist because x is nonzero). Then $\mathrm{Tr}(a) = \mathrm{Tr}(\sum_j z_j x X^j) = \sum_j z_j \mathrm{Tr}(xX^j) = 0$, since $\mathrm{Tr}(xX^j) = 0$ for all j. But this contradicts $\mathrm{Tr}(a) \neq 0$. Thus T is one-to-one.

We now show that the map is computable in polynomial time. Write $x = \sum_{j=0}^{r-1} x_j X^j$, where the x_j are from the base field of $\mathbb{F}_q$. Then for the trace $\mathrm{Tr}(xX^k) = \sum_{j=0}^{r-1} x_j \mathrm{Tr}(X^{j+k})$; hence the components of $T(x)$ are linear combinations of the x_js and thus can be computed in polynomial time.

So far we have assumed that all operations are performed exactly. As we observed earlier in Lemma 2.1 we can approximate the powers of ω_p to within ϵ in time polynomial in $\log p$ and $\log 1/\epsilon$. The Fourier transform over $(\mathbb{Z}/p\mathbb{Z})^r$ can also be approximated to within ϵ in time polynomial in $\log p^r$ and $\log 1/\epsilon$. ∎

For clarity of exposition we assume throughout the rest of the paper that the Fourier transform over $\mathbb{F}_q$ can be performed exactly, as we can make the errors due to the approximation exponentially small with only polynomial overhead.

2.6. Multiplicative characters and their Fourier transforms. The multiplicative group $\mathbb{F}_q^*$ of a finite field $\mathbb{F}_q$ is cyclic. Let g be a generator of $\mathbb{F}_q^*$. Then the

multiplicative characters of $\mathbb{F}_q$ are of the form $\chi(g^\ell) = \omega_{q-1}^{k\ell}$ for all $\ell \in \{0, \ldots, q-2\}$, where the $q-1$ different multiplicative characters are indexed by $k \in \{0, \ldots, q-2\}$. The trivial character is the character with $k = 0$. We can extend the definition of χ to $\mathbb{F}_q$ by defining $\chi(0) = 0$. On a quantum computer we can efficiently compute $\chi(x)$ because the value is determined by the discrete logarithm $\log_g(x)$, which can be computed efficiently using Shor's algorithm [34]. The Fourier transform of a multiplicative character χ of the finite field $\mathbb{F}_q$ is given by $\hat{\chi}(0) = 0$, and $\hat{\chi}(y) = \overline{\chi(y)}\hat{\chi}(1) = \omega_{q-1}^{-k\ell} \sum_j \omega_{q-1}^{kj} \omega_p^{\mathrm{Tr}(g^j)}$, where $y = g^\ell$ [30, 36].

Let $n = p_1^{m_1} \cdots p_k^{m_k}$ be the prime factorization of n. Then by the Chinese remainder theorem, $(\mathbb{Z}/n\mathbb{Z})^* \cong (\mathbb{Z}/p_1^{m_1}\mathbb{Z})^* \times \cdots \times (\mathbb{Z}/p_k^{m_k}\mathbb{Z})^*$. Every multiplicative character χ of $\mathbb{Z}/n\mathbb{Z}$ can be written as the product $\chi(x) = \chi_1(x_1) \cdots \chi_k(x_k)$, where χ_i is a multiplicative character of $\mathbb{Z}/p_i^{m_i}\mathbb{Z}$ and $x_i \equiv x \bmod p_i^{m_i}$. We say χ is *completely nontrivial* if each of the χ_i is nontrivial. We extend the definition of χ to all of $\mathbb{Z}/n\mathbb{Z}$ by defining $\chi(y) = 0$ if $\gcd(y, n) \neq 1$. The character χ is aperiodic on $\{0, \ldots, n-1\}$ if and only if all its χ_i factors are aperiodic over their respective domains $\{0, \ldots, p_i^{m_i} - 1\}$. We call χ a *primitive character* if it is completely nontrivial and aperiodic. Hence, χ is primitive if and only if all its χ_i terms are primitive.

If χ is primitive, the Fourier transform of χ is the product of the Fourier transform of its components and has an expression analogous to the Fourier transform of a multiplicative transform of a finite field. That is,

$$\begin{aligned}\hat{\chi}(y) &= \hat{\chi}_1(y_1) \cdots \hat{\chi}_k(y_k) \\ &= \overline{\chi_1(y_1)}\hat{\chi}_1(1) \cdots \overline{\chi_k(y_k)}\hat{\chi}_k(1) \\ &= \overline{\chi_1(y_1) \cdots \chi_k(y_k)}\hat{\chi}_1(1) \cdots \hat{\chi}_k(1) \\ &= \overline{\chi}(y)\hat{\chi}(1).\end{aligned}$$

If χ is completely nontrivial but periodic with period ℓ, let χ' be the primitive character of $\mathbb{Z}/\ell\mathbb{Z}$ given by $\chi'(x) = \chi(x)$ for $x \in \{0, \ldots, \ell - 1\}$. The Fourier transform of χ is then given by

$$\hat{\chi}(y) = \begin{cases} 0 & \text{if } n/\ell \nmid y, \\ \hat{\chi}'(y\ell/n) = \overline{\chi'(y\ell/n)}\hat{\chi}'(1) & \text{if } n/\ell \mid y. \end{cases}$$

See the book by Tolimieri, An, and Lu [36] for details.

3. The intuition behind the algorithms for the hidden shift problem. We give some intuition for the ideas behind our algorithms for the hidden shift problem. We use the shifted Legendre symbol problem as our running example, but the approach works more generally. In the shifted Legendre symbol problem we are given a function $f_s : \mathbb{Z}/p\mathbb{Z} \to \{0, \pm 1\}$ such that $f_s(x) = \left(\frac{x+s}{p}\right)$, and are asked to find s.

The algorithm starts by putting the function value in the phase to get $|f_s\rangle = \sum_x f_s(x)|x\rangle = \sum_x \left(\frac{x+s}{p}\right)|x\rangle$. For random f we can expect the functions f_z to be mutually (near) orthogonal, so that the inner product squared $|\langle f_z|f_s\rangle|^2$ approximates the delta function $\delta_s(z)$. The Legendre sequence $\left(\frac{0}{p}\right), \left(\frac{1}{p}\right), \ldots, \left(\frac{p-1}{p}\right)$ has many pseudo-random properties, and for its autocorrelation we have, in fact, $|\langle f_z|f_s\rangle|^2 = \delta_s(z) - \frac{1}{p}$. With this, we define the (near) unitary matrix C, where the zth row is $|f_{-z}\rangle$. The state $|f_s\rangle$ is one of the rows; hence $C|f_s\rangle = |-s\rangle$. The problem then reduces to the following: How do we efficiently implement C? By definition, C is a circulant

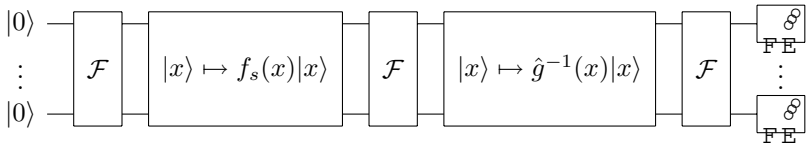

FIG. 3.1. *Circuit for hidden shift problem for a known function g and an unknown shift s of the black-box $f_s(x) = g(x+s)$. Notice that the function values of f_s and $\hat{g}^{-1}$ are computed into the phase.*

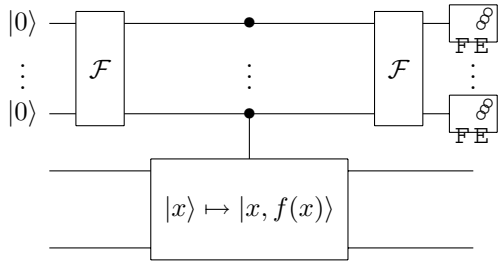

FIG. 3.2. *Circuit for hidden subgroup problem. Here f is computed into a register.*

matrix ($c_{x,y} = f_{-x}(y) = f_0(y-x) = f_{-(x+1)}(y+1) = c_{x+1,y+1}$). Since the Fourier transform matrix diagonalizes a circulant matrix, we can write $C = \mathcal{F}(\mathcal{F}^{-1}C\mathcal{F})\mathcal{F}^{-1} = \mathcal{F}D\mathcal{F}^{-1}$, where D is diagonal. Thus we can implement C if we can implement D. The vector on the diagonal of D is the vector $\mathcal{F}^{-1}|f_0\rangle = \mathcal{F}^{-1}\sum_x \left(\frac{x}{p}\right)|x\rangle$, the inverse Fourier transform of the Legendre symbol. The Legendre symbol is an eigenvector of the Fourier transform, so the diagonal matrix contains the values of the Legendre symbol times a global constant that can be ignored. Because the Legendre symbol can be computed efficiently classically, it can be computed into the phase, so C can be implemented efficiently.

In summary, to implement C for the hidden shift problem for the Legendre symbol, compute the Fourier transform, compute $\left(\frac{x}{p}\right)$ into the phase at $|x\rangle$, and then compute the Fourier transform again (it is not important whether we use $\mathcal{F}$ or $\mathcal{F}^{-1}$). Figure 3.1 shows a circuit diagram outlining the algorithm for the hidden shift problem for a general function g. Contrast this with the circuit for the hidden subgroup problem shown in Figure 3.2.

4. Shifted multiplicative characters of finite fields. In this section we show how to solve the hidden shift problem for any nontrivial multiplicative character of a finite field. The Fourier transform we use is the Fourier transform over the additive group of the finite field.

DEFINITION 4.1 (shifted multiplicative character problem over $\mathbb{F}_q$). *Given a nontrivial multiplicative character $\chi : \mathbb{F}_q \to \mathbb{C}$ (where $q = p^r$ for some prime p) and a black-box function f for which there is an s such that $f(x) = \chi(x+s)$ for all x, find s.*

ALGORITHM 1 (shifted multiplicative character problem over finite field $\mathbb{F}_q$).

1. Create $\sum_{x\in\mathbb{F}_q} \chi(x+s)|x\rangle$, using Lemma 2.1.

2. Compute the Fourier transform to obtain the state $\sum_{y\in\mathbb{F}_q}\omega_p^{\mathrm{Tr}(-sy)}\hat{\chi}(y)|y\rangle$, using Lemma 2.2.
3. For all $y\neq 0$, compute $\chi(y)$ into the phase to obtain $\hat{\chi}(1)\sum_{y\in\mathbb{F}_q^*}\omega_p^{\mathrm{Tr}(-sy)}|y\rangle$.
4. Compute the inverse Fourier transform and measure the outcome $-s$.

THEOREM 4.2. *For any finite field $\mathbb{F}_q$ and any nontrivial multiplicative character, Algorithm* 1 *solves the shifted multiplicative character problem over finite fields with probability* $(1-1/q)^2$.

Proof.

1. Since $\chi(x)=0$ only at $x=0$, by Lemma 2.1 we can create the superposition with probability $1-1/q$.
2. By Lemma 2.2 we can compute the Fourier transform efficiently. The Fourier transform moves the shift s into the phase as described.
3. Because $\hat{\chi}(y)=\overline{\chi(y)}\hat{\chi}(1)$ for every nonzero y, the phase change $|y\rangle\mapsto\chi(y)|y\rangle$ establishes the required transformation.
4. The amplitude of $|-s\rangle$ is

$$\frac{1}{\sqrt{q}}\frac{1}{\sqrt{q-1}}\sum_{y\in\mathbb{F}_q^*}\omega_p^{\mathrm{Tr}(-sy)}\omega_p^{\mathrm{Tr}(sy)}=\frac{1}{\sqrt{q}}\frac{1}{\sqrt{q-1}}\sum_{y\in\mathbb{F}_q^*}1$$
$$=\sqrt{\frac{q-1}{q}},$$

and thus the probability of measuring $-s$ is $1-1/q$. ∎

4.1. The Legendre symbol and homomorphic encryption. The quantum algorithm of the previous section showed us how we can determine the shift $s\in\mathbb{F}_p$ given the function $f_s(x)=\left(\frac{x+s}{p}\right)$. We now show how this algorithm enables us to break schemes for "algebraically homomorphic encryption."

A cryptosystem is *algebraically homomorphic* [9] if given the encryption of two plaintexts $E(x)$, $E(y)$ with $x,y\in\mathbb{F}_p$, an untrusted party can construct the encryption of the plaintexts $E(x+y)$ and $E(xy)$ in polynomial time. More formally, we have the secret encryption and decryption functions $E:\mathbb{F}_p\to S$ and $D:S\to\mathbb{F}_p$, in combination with the public add and multiplication transformations $A:S^2\to S$ and $M:S^2\to S$ such that $D(A(E(x),E(y)))=x+y$ and $D(M(E(x),E(y)))=xy$ for all $x,y\in\mathbb{F}_p$. We assume that the functions E, D, A, and M are deterministic. This definition is slightly more general than the definition in [9, Definition 4.1] because we require equality between texts after unencryption rather than equality between encrypted texts. In other words, the decryption function may be many-to-one. As a result the encryption of a given number can vary depending on how the number is constructed. For example, $A(E(4),E(2))$ may not be equal to $M(E(2),E(3))$. In addition to the public A and M functions, we also assume the existence of a public zero tester $Z:S\to\{0,1\}$, with $Z(E(x))=0$ if $x=0$, and $Z(E(x))=1$ otherwise. In [9] the existence of a zero tester is trivial because the decryption function is injective.

An algebraically homomorphic cryptosystem is a cryptographic primitive that enables two players to perform noninteractive secure function evaluation. It is an open problem whether or not such a cryptosystem can be constructed. We say we can break such a cryptosystem if, given $E(s)$, we can recover s in time polylog(p) with the help of the public functions A, M, and Z. The best known classical attack, due to Boneh and Lipton [9], has expected running time $O\left(\exp\left(c\sqrt{\log p\log\log p}\right)\right)$ for the field $\mathbb{F}_p$ and is based on a smoothness assumption.

Suppose we are given the ciphertext $E(s)$. Test $E(s)$ using the Z function. If s is not zero, create the encryption $E(1)$ via the identity $x^{p-1} \equiv 1 \bmod p$, which holds for all nonzero x. In particular, using $E(s)$ and the M function, we can use repeated squaring and compute $E(s)^{p-1} = E(1)$ in $\log p$ steps.

Clearly, from $E(1)$ and the A function we can construct $E(x)$ for every $x \in \mathbb{F}_p$. Then, given such an $E(x)$, we can compute $f(x) = \left(\frac{x+s}{p}\right)$ in the following way. Add $E(s)$ and $E(x)$, yielding $E(x+s)$, and then compute the encrypted $(p-1)/2$th power of $x+s$, giving $E(\left(\frac{x+s}{p}\right))$. Next, add $E(0)$, $E(-1)$, or $E(1)$ and test if it is an encryption of zero, and return 0, 1, or -1 accordingly. Applying this method on a superposition of $|x\rangle$ states, we can create (after reversibly uncomputing the garbage of the algorithm) the state $\frac{1}{\sqrt{p-1}} \sum_x f_s(x)|x\rangle$. We can then recover s by using Algorithm 1.

COROLLARY 4.3. *Given an efficient test to decide if a value is an encryption of zero, Algorithm* 1 *can be used to break any algebraically homomorphic encryption system.*

We can also break algebraically homomorphic cryptosystems using Shor's discrete log algorithm as follows. Suppose g is a generator for $\mathbb{F}_p^*$ and that we are given the unknown ciphertext $E(g^s)$. Create the superposition $\sum_{i,j} |i, j, E(g^{si+j})\rangle$ and then append the state $|\psi_{si+j}\rangle = \sum_t \left(\frac{g^{si+j}+t}{p}\right)|t\rangle$ to the superposition in i, j by the procedure described above. Next, uncompute the value $E(g^{si+j})$, which gives $\sum_{i,j} |i, j\rangle|\psi_{si+j}\rangle$. Rewriting this as $\sum_{i,r} |i, r - si\rangle|\psi_r\rangle$ and observing that the ψ_r are almost orthogonal, we see that we can apply the methods used in Shor's discrete log algorithm to recover s and thus g^s.

5. Shifted multiplicative characters of finite rings. In this section we show how to solve the shifted multiplicative character problem for $\mathbb{Z}/n\mathbb{Z}$ for any completely nontrivial multiplicative character of the ring $\mathbb{Z}/n\mathbb{Z}$ and extend this to the case when n is unknown. Unlike in the case for finite fields, the characters may be periodic. Thus the shift may not be unique. The Fourier transform is now the familiar Fourier transform over the additive group $\mathbb{Z}/n\mathbb{Z}$.

5.1. Shifted multiplicative characters of $\mathbb{Z}/n\mathbb{Z}$ for known n. We start with the following definition.

DEFINITION 5.1 (shifted multiplicative character problem over $\mathbb{Z}/n\mathbb{Z}$). *Given χ, a completely nontrivial multiplicative character of $\mathbb{Z}/n\mathbb{Z}$, and a function f for which there is an s such that $f(x) = \chi(x + s)$ for all x, find all t satisfying $f(x) = \chi(x + t)$ for all x.*

Multiplicative characters of $\mathbb{Z}/n\mathbb{Z}$ may be periodic, so to solve the shifted multiplicative character problem we first find the period and then we find the shift. If the period is ℓ, then the possible shifts will be $\{s, s + \ell, s + 2\ell, \dots\}$. Note that step 1 of Algorithm 2, which computes the period of χ, uses different properties of a periodic function than Shor's algorithm. In particular, when χ is the Legendre symbol, the function takes only three values, whereas Shor's algorithm assumes functions are injective in $\{0, \dots, r - 1\}$ when the period is r.

ALGORITHM 2 (shifted multiplicative character problem over $\mathbb{Z}/n\mathbb{Z}$).

1. Find the period ℓ of χ. Let χ' be χ restricted to $\{0, \dots, \ell - 1\}$.
   (a) Create $\sum_{x=0}^{n-1} \chi(x + s)|x\rangle$ using f.
   (b) Compute the Fourier transform over $\mathbb{Z}/n\mathbb{Z}$ to obtain the superposition $\sum_{y=0}^{\ell-1} \omega_\ell^{-sy} \hat{\chi}'(y)|yn/\ell\rangle$.
   (c) Measure $|yn/\ell\rangle$. Compute $n/\ell = \gcd(n, yn/\ell)$.

2. Find s using the period ℓ and χ'.
   (a) Create $\sum_{x=0}^{\ell-1} \chi'(x+s)|x\rangle$.
   (b) Compute the Fourier transform over $\mathbb{Z}/\ell\mathbb{Z}$ to obtain $\sum_y \omega_\ell^{-sy}\hat{\chi}'(y)|y\rangle$.
   (c) For all y coprime to ℓ, compute $\hat{\chi}'(y)^{-1}$ into the phase to obtain $\sum_{y:\hat{\chi}'(y)\neq 0} \omega_\ell^{-sy}|y\rangle$.
   (d) Compute the inverse Fourier transform and measure.

THEOREM 5.2. *Algorithm 2 solves the shifted multiplicative character problem over $\mathbb{Z}/n\mathbb{Z}$ for completely nontrivial multiplicative characters of $\mathbb{Z}/n\mathbb{Z}$ in polynomial time with probability at least $(\phi(n)/n)^3 = \Omega((\frac{1}{\log\log n})^3)$, where ϕ is Euler's totient function; $\phi(n)$ is the number of positive integers less than n that are coprime to n.*

Proof. Note that because χ is completely nontrivial, χ' is a primitive character of $\mathbb{Z}/\ell\mathbb{Z}$.

1. (a) $\chi(x+s)$ is nonzero exactly when $\gcd(x+s,n)=1$; thus by Lemma 2.1 we can create the superposition with probability $\phi(n)/n$.
   (b) Since χ has period ℓ, the Fourier transform is nonzero only on multiples of n/ℓ.
   (c) Since $\hat{\chi}'(y) = \overline{\chi'(y)}\hat{\chi}'(1)$, and $\chi'(y)$ is nonzero precisely when $\gcd(y,n) = 1$, when we measure yn/ℓ we have $n/\ell = \gcd(n, yn/\ell)$.
2. (a) Similar to the argument above, we can create the superposition with probability $\phi(\ell)/\ell$.
   (b) The Fourier transform moves the shift s into the phase.
   (c) As in the case for the finite field, this can be done by computing the phase of $\chi'(y)$ into the phase of $|y\rangle$.
   (d) Let $A = \{y \in \mathbb{Z}/\ell\mathbb{Z} : \hat{\chi}'(y) \neq 0\}$. $A = (\mathbb{Z}/\ell\mathbb{Z})^*$ and thus $|A| = \phi(\ell)$. Then the amplitude of $|-s\rangle$ after the Fourier transform is

$$\frac{1}{\sqrt{\phi(\ell)}}\frac{1}{\sqrt{\ell}}\left(\sum_{y\in A}\omega_\ell^{-ys}\,\omega_\ell^{ys}\right) = \frac{1}{\sqrt{\phi(\ell)}}\frac{1}{\sqrt{\ell}}\left(\sum_{y\in A}1\right) = \sqrt{\frac{\phi(\ell)}{\ell}}.$$

   Hence the probability of measuring $|-s\rangle$ is $\phi(\ell)/\ell$.

Thus the algorithm succeeds with probability $(\phi(n)/n)(\phi(\ell)/\ell)^2$, which is lower bounded by $\Omega((\frac{1}{\log\log n})^3)$ (because of the bound $\phi(n) = \Omega(n/\log\log n)$). ∎

5.2. Shifted multiplicative characters of $\mathbb{Z}/n\mathbb{Z}$ for unknown n. We now consider the case when n is unknown.

DEFINITION 5.3 (shifted multiplicative character problem over $\mathbb{Z}/n\mathbb{Z}$ with unknown n). *Given a completely nontrivial multiplicative character $\chi : \mathbb{Z}/n\mathbb{Z} \to \mathbb{C}$ for some unknown n, and a function f for which there is an s such that $f(x) = \chi(x+s)$ for all x, find all t satisfying $f(x) = \chi(x+t)$ for all x.*

THEOREM 5.4. *Given an upper bound on the size of the period of f, we can efficiently solve the shifted multiplicative character problem over $\mathbb{Z}/n\mathbb{Z}$ for unknown n on a quantum computer.*

Proof. Let ℓ be the period of f and χ' be χ restricted to $\mathbb{Z}/\ell\mathbb{Z}$. Using the Fourier sampling algorithm described in section 2.3, we can approximately Fourier sample f over $\mathbb{Z}/\ell\mathbb{Z}$. Because $\chi'(y)$ is nonzero precisely when $\gcd(y,\ell) = 1$, this Fourier sampling algorithm returns y/ℓ with high probability, where y is coprime to ℓ. Thus we can find ℓ with high probability. Next, apply Algorithm 2 to find $s \bmod \ell$. ∎

6. The hidden coset problem. In this section we define the hidden coset problem and give an algorithm for solving the problem for abelian groups under certain conditions on the functions. As we will show, this problem abstracts out two properties that appeared in the hidden shift problems in earlier sections. We will also show how finding the coset representative can be interpreted as solving a deconvolution problem.

DEFINITION 6.1 (hidden coset problem). *Given functions f and g defined on a group G such that for some $s \in G$, $f(x) = g(x+s)$ for all x in G, find the set of all t satisfying $f(x) = g(x+t)$ for all x in G. The function f is given as an oracle, and g is known but not necessarily efficiently computable.*

LEMMA 6.2. *The answer to the hidden coset problem is a coset of some subgroup H of G, and g is constant on cosets of H.*

Note that g is not necessarily a hidden subgroup problem instance because while it is constant on cosets, it does not have to be distinct on different cosets.

Proof. Let $S = \{t \in G : f(x) = g(x+t) \text{ for all } x \in G\}$ be the set of all solutions and let H be the largest subgroup of G such that g is constant on cosets of H. Clearly this is well defined (note that H may be the trivial subgroup as in the shifted Legendre symbol problem). Suppose t_1, t_2 are in S. Then we have $g(x+(-t_2+t_1)) = g((x-t_2)+t_1) = f(x-t_2) = g((x-t_2)+t_2) = g(x)$ for all x in G; thus $-t_2+t_1$ is in H. This shows that S is contained in a coset of H. Since s is in S we must have that S is contained in $s+H$. Conversely, suppose $s+h$ is in $s+H$ (where h is in H). Then $g(x+s+h) = g(x+s) = f(x)$ for all x in G; hence $s+h$ is in S. It follows that $S = s+H$. While this proof was written with additive notation, it carries through if the group is nonabelian. ∎

A familiar example of a nonabelian case of the hidden coset problem is given by the graph isomorphism problem. For each n vertex graph X we let $M(X) \in \{0,1\}^{n\times n}$ denote the adjacency matrix of X, and given X we define the function $g : S_n \to \{0,1\}^{n\times n}$ by $g : \sigma \mapsto M(\sigma(X))$ for all permutations $\sigma \in S_n$ in the symmetric group. Now, the shifted function $f : S_n \to \{0,1\}^{n\times n}$ coincides with a description of the permuted adjacency matrix $M(\pi(X))$ and has $f(\sigma) = M(\sigma \cdot \pi(X))$ for all σ. This shows how the search for an element $\sigma' \in S_n$ such that $f(\sigma) = g(\sigma \cdot \sigma')$ is identical to the search for a permutation that transforms X to $\pi(X)$: the GRAPH ISOMORPHISM problem. Moreover, the determination of the constant subgroup of g of all the permutations σ that have $M(X) = M(\sigma(X))$ solves the GRAPH AUTOMORPHISM problem of the graph X.

Unlike for the hidden subgroup problem, we can prove that there are cases of the hidden coset problem that cannot be solved efficiently on a quantum computer. Let $g : \mathbb{Z}/n\mathbb{Z} \to \{0,1\}$ be the delta function δ_0 with $g(0) = 1$, and $g(x) = 0$ otherwise. Consequently, f_s will be the unknown delta function δ_{-s}, which determines the hidden coset $\{s\}$. However, given f_s and g, finding s amounts to searching a list of n items, which requires $\Omega(\sqrt{n})$ queries to f_s [5].

The algorithm for the hidden coset problem instances that we can solve consists of two parts: identifying the subgroup on which g is constant and finding a coset representative, where computing a coset representative corresponds to computing one hidden shift. The algorithms in this article that compute the subgroup and a coset representative exploit different facets of the power of the quantum Fourier transform. After computing a Fourier transform, the subgroup structure is captured in the magnitude, whereas the shift structure is captured in the phase. In the hidden subgroup problem we measure after computing the Fourier transform and so discard information about shifts. Our algorithms for hidden shift problems do additional processing

to take advantage of the information encoded in the phase. Thus the solution to the hidden coset problem requires fully utilizing the abilities of the Fourier transform.

6.1. Identifying the unknown subgroup. The first step of the hidden coset problem algorithm is to compute the unknown subgroup of g. As the examples in the previous section show, computing the subgroup may be difficult for at two least reasons. First, g may be an HSP instance over a nonabelian group, for which no efficient algorithm is known. Second, while g is constant on cosets, it may not be distinct on different cosets; that is, it may not be an HSP instance.

We start by finding the subgroup H. We need two different algorithms for determining H: the "standard" algorithm for the hidden subgroup problem and the algorithm we used in section 5.

In the standard algorithm for the hidden subgroup problem we form a superposition over all inputs, compute $g(x)$ into a register, measure the function value, compute the Fourier transform, and then sample. The standard algorithm may fail when g is not distinct on different cosets of H. In such cases, we need other restrictions on g to be able to find the hidden subgroup H using the standard algorithm. Boneh and Lipton [8], Mosca and Ekert [32], and Hales and Hallgren [23] have all given criteria under which the standard hidden subgroup algorithm outputs H even when g is not distinct on different cosets of H.

In section 5 we used a different algorithm to determine H because the function we were considering did not satisfy the conditions mentioned above. In this algorithm we compute the value of g into the amplitude, Fourier transform, and then sample, whereas in the standard hidden subgroup algorithm we compute the value of g into a register. In general, this algorithm works when the fraction of values for which $\hat{g}$ is zero is sufficiently small and the nonzero values of $\hat{g}$ have constant magnitude.

6.2. Finding a coset representative as a deconvolution problem. Once we have identified H, we can find a coset representative by solving the associated hidden coset problem for f' and g', where f' and g' are defined on the quotient group G/H and are consistent in the natural way with f and g. For notational convenience we assume that f and g are defined on G and that H is trivial, that is, the shift is uniquely defined.

The hidden shift problem may be interpreted as a *deconvolution* problem. In a deconvolution problem, we are given functions g and $f = g \star h$ (the convolution of g with some unknown function h) and asked to find this h. Let $\delta_y(x) = \delta(x - y)$ be the delta function centered at y. In the hidden shift problem, f is the convolution of δ_{-s} and g, that is, $f = g \star \delta_{-s}$. Finding s or, equivalently, finding δ_{-s}, given f and g, is therefore a deconvolution problem.

Recall that under the Fourier transform convolution becomes pointwise multiplication. Thus, taking Fourier transforms, we have $\hat{f} = \hat{g} \cdot \hat{\delta}_{-s}$ and hence $\hat{\delta}_{-s} = \hat{g}^{-1} \cdot \hat{f}$, provided that $\hat{g}$ is everywhere nonzero. For the multiplication by $\hat{g}^{-1}$ to be performed efficiently on a quantum computer would require $\hat{g}$ to have constant magnitude and be everywhere nonzero. However, even if only a fraction of the values of $\hat{g}$ are zero we can still approximate division of $\hat{g}$ by only dividing when $\hat{g}$ is nonzero and doing nothing otherwise. The zeros of $\hat{g}$ correspond to loss of information about δ_{-s}.

ALGORITHM 3.

1. Create $\sum_{x \in G} g(x + s)|x\rangle$.
2. Compute the Fourier transform to obtain $\sum_{y \in G} \overline{\psi_y(s)} \hat{g}(\psi_y)|y\rangle$, where ψ_y are the characters of the group G.

3. For all y for which $\hat{g}(\psi_y)$ is nonzero compute $\hat{g}(\psi_y)^{-1}$ into the phase of $|y\rangle$ to obtain $\sum_{y,\hat{g}(\psi_y)\neq 0} \overline{\psi_y(s)}|y\rangle$.
4. Compute the inverse Fourier transform and measure to obtain $-s$.

THEOREM 6.3. *Suppose f and $\hat{g}$ are efficiently computable, the magnitude of $f(x)$ is constant for all values of x in G for which $f(x)$ is nonzero, and the magnitude of $\hat{g}(\psi_y)$ is constant for all values of ψ_y in $\hat{G}$ for which $\hat{g}(\psi_y)$ is nonzero. Let α be the fraction of x in G for which $f(x)$ is nonzero and let β be the fraction of ψ_y in $\hat{G}$ for which $\hat{g}(\psi_y)$ is nonzero. Then Algorithm 3 outputs $-s$ with probability $\alpha\beta$.*

Proof.

1. By Lemma 2.1 we can create the superposition with probability α.
2. The Fourier transform moves the shift s into the phase.
3. Because $\hat{g}$ has constant magnitude, for values where $\hat{g}$ is nonzero, $\hat{g}(\psi_y)^{-1} = C\overline{\hat{g}(\psi_y)}$ for some constant C. So we can perform this step by computing the phase of $\overline{\hat{g}}$ into the phase. For the values where $\hat{g}$ is zero we can just leave the phase unchanged as those terms are not present in the superposition.
4. Let $A = \{y \in G : \hat{g}(\psi_y) \neq 0\}$. Then the amplitude of $|-s\rangle$ is

$$\begin{aligned}\frac{1}{\sqrt{|A|}}\frac{1}{\sqrt{|G|}}\left(\sum_{y\in A}\overline{\psi_y(s)}\,\overline{\psi_y(-s)}\right) &= \frac{1}{\sqrt{|A|}}\frac{1}{\sqrt{|G|}}\left(\sum_{y\in A}1\right)\\ &= \sqrt{\frac{|A|}{|G|}}\\ &= \sqrt{\beta}.\end{aligned}$$

Hence we measure $|-s\rangle$ with probability β.

Thus the algorithm succeeds in identifying s with probability $\alpha\beta$ and requires only one query of f and one query of $\hat{g}$. ∎

6.3. Examples. We show how the hidden shift problems we considered earlier fit into the framework of the hidden coset problem. In the shifted multiplicative character problem over finite fields, G is the additive group of $\mathbb{F}_q$, $g = \chi$, and H is trivial since the shift is unique for nontrivial χ. In the shifted multiplicative character problem over $\mathbb{Z}/n\mathbb{Z}$, G is the additive group of $\mathbb{Z}/n\mathbb{Z}$, $g = \chi$, and H is the subgroup $\{0, \ell, \ldots, n/\ell\}$, where ℓ (which is a factor of n) is the period of χ. In the shifted period multiplicative character problem over $\mathbb{Z}/n\mathbb{Z}$ for unknown n, G is the additive group of $\mathbb{Z}$, $g = \chi$, and H is the infinite subgroup $\ell\mathbb{Z}$.

Acknowledgments. We would like to thank the anonymous referee who pointed out the application of the shifted Legendre symbol problem to algebraically homomorphic cryptosystems, and Umesh Vazirani, whose many suggestions greatly improved this paper. We also thank Dylan Thurston and an anonymous referee for pointing out that algebraically homomorphic cryptosystems can be broken using Shor's algorithm for discrete log. Thanks to Lisa Hales for helpful suggestions.

TESTING POLYNOMIALS OVER GENERAL FIELDS*

TALI KAUFMAN† AND DANA RON‡

In memory of Bilha Segev (1963–2005)*, a true scientist*

Abstract. In this work we fill the knowledge gap concerning testing polynomials over finite fields. As previous works show, when the cardinality of the field, q, is sufficiently larger than the degree bound, d, then the number of queries sufficient for testing is polynomial or even linear in d. On the other hand, when $q = 2$ then the number of queries, both sufficient and necessary, grows exponentially with d. Here we study the intermediate case where $2 < q = O(d)$ and show a smooth transition between the two extremes. Specifically, let p be the characteristic of the field (so that p is prime and $q = p^s$ for some integer $s \geq 1$). Then the number of queries performed by the test grows like $\ell \cdot q^{2\ell+1}$, where $\ell = \lceil \frac{d+1}{q-q/p} \rceil$. Furthermore, $q^{\Omega(\ell)}$ queries are necessary when $q = O(d)$. The test itself provides a unifying view of the tests for these two extremes: it considers random affine subspaces of dimension ℓ and verifies that the function restricted to the selected subspaces is a polynomial of degree at most d. Viewed in the context of coding theory, our result shows that Reed–Muller codes over general fields (usually referred to as *generalized Reed–Muller (GRM)* codes) are locally testable. In the course of our analysis we provide a characterization of small-weight words that span the code. Such a characterization was previously known only when the field size is a prime or is sufficiently large, in which case the minimum-weight words span the code.

1. Introduction.

In this paper we consider the problem of testing, for a given finite field F and degree-bound d, whether a function $f : F^n \to F$ is a multivariate polynomial of total degree at most d over F. Specifically, the testing algorithm is given query access to f and a parameter $\epsilon > 0$. If f is a polynomial of degree at most d then the testing algorithm must accept. On the other hand, if f differs from every such polynomial on more than an ϵ-fraction of the domain elements, then the test should reject with probability at least 2/3. Our aim is to design algorithms that perform this task using as few queries as possible.

The problem of testing multivariate low-degree polynomials over finite fields has been studied extensively, mainly due to its applications to probabilistically checkable proofs systems (see, for example, [32, 3]). This is true both for the special case of linear functions (degree-1 polynomials) [15, 7, 18, 10, 11, 9, 31] and for the more general case of degree-d polynomials [7, 6, 20, 18, 30, 19, 4]. However, all these results apply only to testing polynomials over fields that are *larger than the degree-bound, d*. In particular, when the field size $|F|$ is at least $c \cdot d$, for some sufficiently large

constant c, then a number of queries that is linear in d is sufficient [29, 19], and when $d+2 \leq |F| < c \cdot d$ then the dependence on d is known to be polynomial [19, 30]. In recent work, Alon et al. [1] studied the same property for the case $|F| = 2$ and for $d \geq 2$. Namely, they considered the case in which the degree-bound may be (much) larger than the field size, but their result holds only for $F = \mathrm{GF}(2)$. They showed that the number of queries both necessary and sufficient in this case is *exponential* in d. Hence we encounter a very large gap in terms of the dependence on d between the query complexity when $|F| > d$ and the query complexity when $|F| = 2$.

Our main result. In this work we bridge the gap between the two cases mentioned above and show a smooth transition between them. In particular, we prove the following theorem.

THEOREM 1. *There exists a testing algorithm for polynomials of degree at most d over finite fields of cardinality q where $2 \leq q = O(d)$. The algorithm performs $O\left(\ell \cdot q^{2\ell+1} + 1/\epsilon\right)$ queries, where for prime q, $\ell = \left\lceil \frac{d+1}{q-1} \right\rceil$, and, more generally, when q is a power of a prime p, then $\ell = \left\lceil \frac{d+1}{q-q/p} \right\rceil$.*

Observe that as the field size q increases, the dependence on d decreases from being exponential to being polynomial. We note that this query complexity (when $q = O(d)$) is almost tight: for prime fields (and constant ϵ) $\Omega(q^{\ell-1})$ queries are necessary, and for nonprime fields $\Omega\left(q^{\lceil \ell/2 \rceil - 1}\right)$ queries are necessary. As we discuss in more detail subsequently, the "gap phenomenon" that we observe is not unique to testing polynomials: analogous gaps arise in other property testing problems.

Characterization of degree-d polynomials over $\mathrm{GF}(q)$. One of the building blocks of our analysis is a characterization of (total) degree-d multivariate polynomials over finite fields. In particular, we prove the following theorem.

THEOREM 2. *Let $F = \mathrm{GF}(q)$ where $q = p^s$ and p is prime. Let d be an integer, and let $f : F^n \to F$. Then f is a polynomial of degree at most d if and only if its restriction to every affine subspace of dimension $\ell = \left\lceil \frac{d+1}{q-q/p} \right\rceil$ is a polynomial of degree at most d.*

Theorem 2 generalizes the characterization result of Friedl and Sudan [19] that refers to the case $q - q/p \geq d+1$ (that is, $\ell = 1$). We also note that this value, ℓ, of the dimension of the considered subspaces, is tight. Namely, there exist polynomials of degree greater than d whose restrictions to affine subspaces of dimension less than ℓ are all degree-d polynomials.

A unifying approach to testing low-degree polynomials over $\mathrm{GF}(q)^n$. The testing algorithm presented in this work utilizes the characterization in Theorem 2 (which is shown to be *robust* in the sense defined in [30]). Specifically, the algorithm selects random affine subspaces (of dimension ℓ as defined in Theorem 2) and checks that the restriction of the input function f to each of the selected subspaces is indeed a polynomial of degree at most d. Such a check is implemented by verifying that various linear combinations of the values of f on the subspace sum to 0. Observe that when the size of the field F is sufficiently larger than the degree-bound d, then $\ell = 1$. That is, when the field is sufficiently large, then the algorithm checks whether the univariate polynomials that correspond to restrictions of the function f to random *lines* in F^n all have degree at most d. This is essentially the original low-degree test of Rubinfeld and Sudan [30]. The reason we say "essentially" is that when $|F| > d$ then it is not necessary to query f on all points on a selected line, but rather it suffices to interpolate using $d+1$ points and check that the resulting degree-d polynomial agrees with a random point on the line.

On the other hand, when $q = 2$ then the test in [1] works by uniformly selecting

$\frac{d+1}{q-1} = d+1$ points in $\mathrm{GF}(2)^n$ and verifying that the sum of the values of f taken over all sums of subsets of these points is 0. This too can be shown to amount to checking whether the restriction of f to the $(d+1)$-dimensional subspace spanned by the selected points is a polynomial of degree at most d. Thus our test suggests a uniform view of the aforementioned tests for low-degree polynomials.

Relation to coding. The *generalized Reed–Muller (GRM)* code of rank d and length q^n over $\mathrm{GF}(q)$, which we denote by $\mathcal{GRM}_q(d,n)$,[1] consists of all words of length q^n that correspond to the evaluations of degree-d polynomials over $\mathrm{GF}(q)^n$. (When $q=2$ then the code is simply referred to as *Reed–Muller (RM).*) The *weight* of a codeword is the number of its nonzero symbols. An equivalent view of our main result, from a coding theory perspective, is that GRM codes are locally testable. Furthermore, our characterization of low-degree polynomials translates into a characterization of a set of small-weight words that span the dual code, where the dual code of $\mathcal{GRM}_q(d,n)$ is the GRM code $\mathcal{GRM}_q(n(q-1)-(d+1),n)$ (see [5, Theorem 5.4.2]). The question concerning when GRM codes are spanned by their *minimum-weight* words has been studied in the coding theory literature.[2] Specifically, Ding and Key [16] have shown that if q is prime or q is sufficiently larger than d, then the minimum-weight words of a GRM code indeed span the code, but this is not true in general. In particular, this is not true when q is not prime and $q-q/p < d+1$. To be precise, there are two special cases in which the minimum-weight words *do* span the code though q is not prime and $q-q/p<d+1$: the special case of $n=1$ (Reed–Salomon codes) and the special case that d is almost the maximum possible degree $n\cdot(q-1)$.

We complement the result of Ding and Key by deducing the following corollary from Theorem 2.

COROLLARY 3. *Every GRM code is spanned by words of weight that is at most quadratic in the weight of its minimum-weight words.*

We note that our interest in small-weight words that span a GRM code is due to the way our test works. Similarly to other low-degree tests, our test can be viewed as randomly selecting small-weight words from the dual code (which is a GRM code itself) and checking that each is indeed orthogonal to the tested word. Thus the weight of the selected words is an important factor in the query complexity of our algorithm.

The paper of Jutla et al. [25]. Independently from our work, Jutla et al. [25] studied the problem of testing low-degree polynomials and described a testing algorithm that has the same query complexity as our algorithm. However, their algorithm works only for prime fields. We further discuss the relation between our approaches in section 6.

A broader perspective: The gap phenomenon in property testing. Property testing [30, 21] in general deals with distinguishing between objects that have a particular predetermined property and objects that are far from having the property. Low-degree testing clearly falls under this framework. As discussed above, for this property we encounter a huge gap in a different setting of the problem. Interestingly, a similar gap phenomenon is encountered for the property of graph bipartiteness. Specifically, dense graphs can be tested for bipartiteness with complexity $\Theta(1)$ [21], while the complexity

[1] We note that in the coding theory literature, the code is usually denoted by $\mathcal{GRM}_q(r,m)$ (or $\mathcal{R}_q(r,m)$), and n is used to denote the codeword length q^m.

[2] The minimum-weight words of $\mathcal{GRM}_q(d,n)$ have weight $(q-t)q^{n-r-1}$, where $r(q-1)+t=d$ and $0\le t<q-1$, and the points in the support of each such word belong to an affine subspace of dimension $(n-r)$.

of testing bipartiteness in constant-degree graphs is $\Theta(\sqrt{n})$ [23, 22], where n is the number of vertices in the graph. It has been shown [26] that for this property too there is an algorithm that gives a smooth transition between the two extremes, and there is an almost matching lower bound. Additional properties that exhibit similar gaps are k-colorability and subgraph-freeness, where there has been recent progress on the latter problem [2].

Other related results on locally testing codes. The problem of designing good codes that are locally testable was explicitly defined, e.g., in [19, 30, 3]. By *good* we mean that they have high rate and large distance. This question has regained attention recently. Goldreich and Sudan [24] initiated a systematic study of the problem and showed (by probabilistic arguments) that there exist locally testable (linear) codes over binary alphabets, with almost constant rate, and linear minimum distance. Their construction was derandomized in [14] and further improved in [12]. The best locally testable codes known to date are given by Dinur [17]. In [13] it was shown that local testing of random low-density parity-check codes, which have linear minimum distance and constant rate, requires $\Omega(n)$ queries. In [8] it was proved that there are no locally testable cyclic codes that have constant rate and linear minimum distance.

Subsequent work. In recent work, Kaufman and Litsyn [27] provided a sufficient condition for local testability of linear codes. The sufficient condition is related to the weight distribution (spectra) of the code and of its dual. They use the condition to show that every linear code of length n and minimum distance $\frac{n}{2} - \Theta(\sqrt{n})$ is locally testable. Such codes contain polynomially many codewords, and hence they are called sparse codes. Moreover, in [27] it is shown that in such a case the dual code is spanned by small-weight codewords. Their results imply that dual-BCH codes and some subcodes of algebraic-geometric codes are locally testable.

2. Preliminaries. Let F be a field of cardinality q and characteristic p (that is, $q = p^s$ where p is prime). Let $\omega \in F$ be a generator of the field F, so that $F = \{0, \omega^1 = \omega, \omega^2, \ldots, \omega^{q-2}, \omega^{q-1} = 1\}$. We note that this order of the elements in F in which 1 is represented by ω^{q-1} rather than ω^0 will serve us better than the more standard order $F = \{0, \omega^0 = 1, \omega^1 = \omega, \omega^2, \ldots, \omega^{q-2}\}$. In particular, using this order, for any $n \geq 1$ we consider a one-to-one mapping between $[q-1]^n$ and F^n (where $[q-1] \stackrel{\text{def}}{=} \{0, 1, \ldots, q-1\}$). Specifically, for each $\beta \in [q-1]^n$, the point $x \in F^n$ that *corresponds* to β is defined as follows: $x_i = 0$ if $\beta_i = 0$, and otherwise $x_i = \omega^{\beta_i}$.

Consider the standard (and unique) representation of the function f as a polynomial over F with degree at most $q-1$ in each variable:

$$f(x) = \sum_{\alpha \in [q-1]^n} C^f_\alpha \cdot x^\alpha, \qquad \text{where} \qquad x^\alpha = \prod_{i=1}^{n} x_i^{\alpha_i}. \tag{2.1}$$

Here $\vec{C^f}$ is the *coefficients vector* (indexed by points $\alpha \in [q-1]^n$). If we view the function f as a q^n-dimensional vector $\vec{f}$ (where for $\beta \in [q-1]^n$, f_β is the evaluation of f on the point $x \in F^n$ that corresponds to β), then we can write (2.1) in the following equivalent form:

$$\vec{f} = \mathcal{H}_n \cdot \vec{C^f}.$$

Here $\mathcal{H}_n$ is the $q^n \times q^n$ matrix whose entries are indexed by pairs $\beta, \alpha \in [q-1]^n$ where $\mathcal{H}_n(\beta, \alpha)$ is the evaluation of the term x^α at the point $x \in F^n$ that corresponds to β.

By inverting $\mathcal{H}_n$ (which is nonsingular) we can represent the coefficients vector $\vec{C}^f$ in terms of $\vec{f}$ as follows:

$$\vec{C}^f = \mathcal{A}_n \cdot \vec{f}. \tag{2.2}$$

Both $\mathcal{H}_n$ and $\mathcal{A}_n$ can be defined recursively using tensor products:

$$\mathcal{H}_n = \mathcal{H}_1 \otimes \mathcal{H}_{n-1} \quad \text{and} \quad \mathcal{A}_n = \mathcal{A}_1 \otimes \mathcal{A}_{n-1}, \tag{2.3}$$

where

$$\mathcal{H}_1 = \begin{pmatrix} 1 & 0 & 0 & \dots & 0 \\ 1 & \omega & \omega^2 & \dots & 1 \\ 1 & \omega^2 & \omega^4 & \dots & 1 \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ 1 & \omega^{q-2} & \omega^{2(q-2)} & \dots & 1 \\ 1 & 1 & 1 & \dots & 1 \end{pmatrix} \tag{2.4}$$

and

$$\mathcal{A}_1 = (-1) \cdot \begin{pmatrix} -1 & 0 & 0 & \dots & 0 \\ 0 & \omega^{-1} & \omega^{-2} & \dots & 1 \\ 0 & \omega^{-2} & \omega^{-4} & \dots & 1 \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & \omega^{-(q-2)} & \omega^{-2(q-2)} & \dots & 1 \\ 1 & 1 & 1 & \dots & 1 \end{pmatrix}. \tag{2.5}$$

For our purposes, the important thing that should be noted is that every coefficient C^f_α of the polynomial representation of f is some (easy to compute) linear combination of the values of f on different domain elements $x \in F^n$. In particular, for $\alpha = \langle q-1, \dots, q-1 \rangle$, $C^f_\alpha = (-1)^n \cdot \sum_{x \in F^n} f(x)$.

DEFINITION 1. *Let* $\mathrm{POLY}_{n,d}$ *denote the class of all functions* $f : F^n \to F$ *that are polynomials of total degree at most* d *(where the degree in each variable is at most* $q-1$*). Namely, if we consider the representation of* f *as defined in* (2.1)*, then* $C^f_\alpha = 0$ *for every* $\alpha \in [q-1]^n$ *such that* $\sum_{i=1}^n \alpha_i > d$.

DEFINITION 2. *For* $m \geq 1$ *and any choice of a point* $y \in F^n$ *and* m *linearly independent points* $y_1, \dots, y_m \in F^n$*, let* $S(y_0, y_1, \dots, y_m)$ *denote the affine subspace of dimension* m *that contains all points of the form* $y_0 + \sum_{i=1}^m a_i y_i$*, where* $a_1, \dots, a_m \in F$*. Note that* y_0 *has a different role from all other* y_i*'s.*

Observe that in the special case that y_0 is a linear combination of $y_1, \dots, y_m$, then $S(y_0, y_1, \dots, y_m)$ is a linear subspace of dimension m.

DEFINITION 3. *For a function* $f : F^n \to F$*, a point* $y_0 \in F^n$*, and* m *linearly independent points* $y_1, \dots, y_m \in F^n$*, we denote by* $f_{|(y_0, y_1, \dots, y_m)}$ *the restriction of* f *to the affine subspace* $S(y_0, y_1, \dots, y_m)$*. Namely,* $f_{|(y_0, y_1, \dots, y_m)} : F^m \to F$ *is defined as follows: for every* $v \in F^m$*,* $f_{|(y_0, y_1, \dots, y_m)}(v) = f(y_0 + \sum_{i=1}^m v_i y_i)$*. With slight abuse of notation (and for the sake of succinctness), we shall sometimes use the notation* $f_{|S}$ *instead, where* $S = S(y_0, y_1, \dots, y_m)$ *is the subspace spanned by the points. In case the set of points spanning the subspace* S *is not explicitly stated, then* $f_{|S}$ *is determined by some canonical choice of a basis.*[3]

[3]Our interest lies in the *degree* of these functions (represented as polynomials). Since for any given subspace this degree is invariant with respect to the choice of the basis, the particular choice of the basis is only a matter of convenience.

DEFINITION 4. *For any two functions $f, g : F^n \to F$, let* $\mathrm{dist}(f,g) = \Pr_{y \in F^n}[f(y) \neq g(y)]$ *(where y is selected uniformly).*

3. The characterization. In this section we prove Theorem 2, which was stated in the introduction and provides a characterization of polynomials of total degree at most d over finite fields. Using the notation introduced in section 2, Theorem 2 states that a function $f : F^n \to F$ belongs to $\mathrm{POLY}_{n,d}$ if and only if for every affine subspace S of F^n having dimension $\ell = \lceil \frac{d+1}{q-q/p} \rceil$, we have that $f_{|S} \in \mathrm{POLY}_{\ell,d}$.

In particular, when q is prime, that is, $q = p$, we get that $\ell = \lceil \frac{d+1}{q-1} \rceil$ and we obtain a set of words having weight at most $q^{\lceil \frac{d+1}{q-1} \rceil}$ that span the code $\mathcal{GRM}_q(n(q-1)-(d+1), n)$ (which is dual to $\mathcal{GRM}_q(d,n)$). If we further have that $d+1$ is divisible by $q-1$, then these are exactly the minimum-weight words of $\mathcal{GRM}_q(n(q-1)-(d+1), n)$ (i.e., the characteristic vectors of affine subspaces of dimension ℓ). Otherwise, they have weight that is at most a factor of q larger than the minimum weight words (which correspond to weighted sums of characteristic vectors of affine subspaces of dimension $\ell - 1$). As noted in the introduction, in the case of GRM codes over prime fields, it is known that the minimum-weight words span the code [16]. However, when q is not prime then this is not the case (unless $n = 1$ or d is very large) [16]. Thus, as stated in Corollary 3 in the introduction, we obtain a new result concerning small-weight words that span GRM codes: Since $p \geq 2$, we have that $q - q/p > (q-1)/2$, and so the words that span the code have weight that is at most quadratic in the weight of the minimum weight words.

The following theorem shows that Theorem 2 is tight.

THEOREM 4. *For any given d and $q = p^s$, let ℓ be as defined in Theorem 2. Then there exists a function $f : F^n \to F$ such that for every affine subspace S of F^n having dimension less than ℓ, the function f restricted to S is a degree-d polynomial,* but *f is not a degree-d polynomial.*

Proof. Let $f = x_1^{(p-1)p^{s-1}} \cdot x_2^{(p-1)p^{s-1}} \cdots x_\ell^{(p-1)p^{s-1}}$, so that the degree of f is $\ell \cdot (p-1)p^{s-1}$, which is at least $d+1$. On the other hand, consider any choice of ℓ points $y_0, y_1, \ldots, y_{\ell-1}$ (where $y_1, \ldots, y_{\ell-1}$ are linearly independent). Then

$$\begin{aligned} f_{|(y_0,y_1,\ldots,y_{\ell-1})}(z_1,\ldots,z_{\ell-1}) &= \prod_{j=1}^{\ell} \left(y_{0,j} + \sum_{i=1}^{\ell-1} z_i \cdot y_{i,j} \right)^{(p-1)p^{s-1}} \\ &= \prod_{j=1}^{\ell} \left(y_{0,j}^{p^{s-1}} + \sum_{i=1}^{\ell-1} \left(y_{i,j}^{p^{s-1}} \cdot z_i^{p^{s-1}} \right) \right)^{p-1} \end{aligned} \tag{3.1}$$

(where we have used the fact that $(a+b)^p = a^p + b^p$). If we group together all terms that correspond to the same monomial in the z_i's, then we get a sum of terms of the following form:

$$C \cdot \prod_{i=1}^{\ell-1} z_i^{p^{s-1} \cdot A_i}, \tag{3.2}$$

where $\sum_{i=1}^{\ell-1} A_i \leq \ell(p-1)$ and C is a coefficient that is a function of the $y_{i,j}$'s. Recall that $z_i^q = z_i$ for every $z_i \in F$. We claim that this implies that the total degree of each of the monomials in (3.2) is at most $(\ell-1) \cdot (p-1)p^{s-1}$.

To verify this, consider any choice of $A = A_1, \ldots, A_{\ell-1}$ such that $\sum_{i=1}^{\ell-1} A_i \leq \ell(p-1)$, and let D_A denote the degree of the corresponding monomial. That is,

$$D_A = \sum_{i=1}^{\ell-1} \left((p^{s-1} \cdot A_i) \bmod (q-1) \right). \tag{3.3}$$

Note that each summand on the right-hand side of (3.3) is computed modulo $q-1$, but the sum is then taken over the integers. Let us fix any choice of $A = A_1, \ldots, A_{\ell-1}$ and show that $D_A \leq (\ell-1)(p-1)p^{s-1}$. Assume, without loss of generality, that $A_1 = \max_{1 \leq i \leq \ell-1}\{A_i\}$. If $A_1 \leq p-1$ then clearly $D_A \leq (\ell-1)(p-1)p^{s-1}$. Otherwise, $A_1 = (p-1)+a$ where $0 < a \leq (\ell-1)(p-1)$ and $\sum_{i=2}^{\ell-1} A_i \leq (\ell-1)(p-1)-a$. Now

$$\begin{aligned}
D_A &\leq (p^{s-1} \cdot A_1) \bmod (q-1) \quad + \sum_{i=2}^{\ell-1} p^{s-1} \cdot A_i \\
&\leq (p^{s-1} \cdot (p-1+a)) \bmod (q-1) \quad + p^{s-1} \cdot \Big((\ell-1)(p-1) - a \Big) \\
&= (\ell-1)(p-1)p^{s-1} - ap^{s-1} + ((p-1+a)p^{s-1}) \bmod (q-1) \\
&< (\ell-1)(p-1)p^{s-1} \,.
\end{aligned}$$

We have thus established that the monomial with the highest degree has degree at most $(\ell-1) \cdot (p-1)p^{s-1}$. But now,

$$(\ell-1) \cdot (p-1)p^{s-1} \;=\; \left(\left\lceil \frac{d+1}{(p-1)p^{s-1}} \right\rceil - 1 \right) \cdot (p-1)p^{s-1} \;<\; d+1$$

and since $(\ell-1) \cdot (p-1)p^{s-1}$ is an integer, we are done. □

Proof of Theorem 2. As noted in the introduction, our proof of Theorem 2 generalizes the proof of the special case of $\ell = 1$, which is presented in [19]. If $f \in \mathrm{POLY}_{n,d}$, then clearly $f_{|S} \in \mathrm{POLY}_{\ell,d}$ for every affine subspace S of dimension ℓ. We prove the other direction by induction. Namely, we prove that for every $m \geq \ell$ and every affine subspace S of F^n having dimension m, if for every affine subspace S' of S that has dimension ℓ, we have $f_{|S'} \in \mathrm{POLY}_{\ell,d}$, then $f_{|S} \in \mathrm{POLY}_{m,d}$. Theorem 2 follows by setting $m = n$. The base case $m = \ell$ clearly holds, and so we turn to the induction step.

Assume the induction claim holds for every $m \geq \ell$; we prove it for $m+1$. Namely, we take any $(m+1)$-dimensional affine subspace T of F^n and consider the function $h = f_{|T} : F^{m+1} \to F$. We then use the induction hypothesis by which for every affine subspaces S of F^{m+1} having dimension m (which is isomorphic to an affine subspace of T having dimension m), the restriction of $h = f_{|T}$ to S is a degree-d polynomial.

Let the coefficients of the polynomial representation of h be denoted by $\{C^h_\alpha\}_{\alpha \in [q-1]^{m+1}}$. Our goal is to show that for each $\alpha \in [q-1]^{m+1}$ such that $\sum_{i=1}^{m+1} \alpha_i > d$, we have that $C^h_\alpha = 0$. Let us fix any such α, denote it by α^*, and prove that $C^h_{\alpha^*} = 0$. We break the proof into three cases.

Case 1. *There exists a subset $R \subset \{1, \ldots, m+1\}$, where $|R| = m$, such that $\sum_{i \in R} \alpha^*_i > d$.*

Assume, without loss of generality (since the variables of h, and the corresponding α^*_i's can be reordered), that $R = \{1, \ldots, m\}$, and assume, contrary to the claim, that $C^h_{\alpha^*} \neq 0$. We will show that this implies that there exist $y_0, y_1, \ldots, y_m \in F^{m+1}$ and $\gamma = \gamma_1, \ldots, \gamma_m$, where $\gamma_i \in [q-1]$, and $\sum_{i=1}^m \gamma_i > d$, such that for the affine

subspace of $S = S(y_0, y_2, \ldots, y_m)$ of dimension m we have $C_\gamma^{h_{|S}} \neq 0$, contradicting the induction hypothesis.

Specifically, for $i = 1, \ldots, m+1$ we denote by e_i the ith unit vector of dimension $m+1$. Let $y_i = e_i$ for $i = 1, \ldots, m$, and for each $b \in F$, let $y_0(b) = b \cdot e_{m+1}$. Let $g_b = h_{|(y_0(b), y_1, \ldots, y_m)}$ (so that $g_b : F^m \to F$). Then for each choice of $b \in F$ we have

$$\begin{aligned} g_b(z_1, \ldots, z_m) &= h(z_1, \ldots, z_m, b) \\ &= \sum_{\alpha \in [q-1]^{m+1}} C_\alpha^h \cdot \prod_{i=1}^{m} z_i^{\alpha_i} \cdot b^{\alpha_{m+1}}. \end{aligned}$$

Consider the coefficient of the term $z_1^{\alpha_1^*} \cdot z_2^{\alpha_2^*} \cdots z_m^{\alpha_m^*}$ in g_b, that is, $C^{g_b}_{\alpha_1^*, \ldots, \alpha_m^*}$ (where recall that α^* satisfies $\sum_{i=1}^{m+1} \alpha_i^* > d$, as well as the premise of this case). This coefficient has the following form:

$$C^{g_b}_{\alpha_1^*, \ldots, \alpha_m^*} = \sum_{j=0}^{q-1} C^h_{\alpha_1^*, \ldots, \alpha_m^*, j} \cdot b^j.$$

Namely, it is the evaluation, at b, of the univariate polynomial: $\sum_{j=0}^{q-1} C^h_{\alpha_1^*, \ldots, \alpha_m^*, j} \cdot x^j$. Note that for $j = \alpha_{m+1}^*$, the coefficient of x^j in this polynomial is $C^h_{\alpha^*}$, which is nonzero by our counterassumption. Hence, this polynomial is a nonzero polynomial of degree at most $q-1$ over F. This implies that for at least one value of b, this polynomial attains a nonzero value. But this means that for some choice of b, $C^{g_b}_{\alpha_1^*, \ldots, \alpha_m^*} \neq 0$. Since $\sum_{i=1}^{m} \alpha_i^* > d$, we have reached a contradiction and hence completed the proof for this case.

Case 2. *There exists a pair of indices $i, j \in \{1, \ldots, m+1\}$ such that $\alpha_i^*, \alpha_j^* \neq 0$, and $\alpha_i^* + \alpha_j^* < q$.*

Assume, without loss of generality, that $i = m$ and $j = m+1$. Here too we assume, contrary to the claim, that $C^h_{\alpha^*} \neq 0$, and we reach a contradiction to the induction hypothesis.

Let y_0 be the all-0 vector, let $y_i = e_i$ for $i = 1, \ldots, m-1$, and for each $b \in F$, let $y_m(b) = \langle 0, \ldots, 0, 1, b \rangle$ (recall that $y_0, \ldots, y_m \in F^{m+1}$). Here too we denote $g_b = h_{|(y_0, \ldots, y_m(b))}$. Then for each choice of $b \in F$ we have

$$\begin{aligned} g_b(z_1, \ldots, z_m) &= h(z_1, \ldots, z_m, b \cdot z_m) \\ &= \sum_{\alpha \in [q-1]^{m+1}} C_\alpha^h \cdot \prod_{i=1}^{m-1} z_i^{\alpha_i} \cdot z_m^{\alpha_m} \cdot (z_m \cdot b)^{\alpha_{m+1}} \\ &= \sum_{\alpha \in [q-1]^{m+1}} C_\alpha^h \cdot \prod_{i=1}^{m-1} z_i^{\alpha_i} \cdot z_m^{\alpha_m + \alpha_{m+1}} \cdot b^{\alpha_{m+1}}. \end{aligned}$$

Consider the coefficient of the term $z_1^{\alpha_1^*} \cdots z_{m-1}^{\alpha_{m-1}^*} \cdot z_m^{\alpha_m^* + \alpha_{m+1}^*}$ in g_b (recall that $\alpha_m^* + \alpha_{m+1}^* < q$). This coefficient has the following form:

$$C^{g_b}_{\alpha_1^*, \ldots, \alpha_{m-1}^*, \alpha_m^* + \alpha_{m+1}^*} = \sum_{\substack{j,k \in [q-1]^2 \\ j+k = \alpha_m^* + \alpha_{m+1}^*}} C^h_{\alpha_1^*, \ldots, \alpha_{m-1}^*, j, k} \cdot b^k.$$

That is, it is the evaluation, at b, of the univariate polynomial

$$\sum_{k=0}^{q-1} C^h_{\alpha^*_1,\ldots,\alpha^*_{m-1},\alpha^*_m+\alpha^*_{m+1}-k,k} \cdot x^k.$$

Note that for $k = \alpha^*_{m+1}$, the coefficient of x^k in this polynomial is $C^h_{\alpha^*}$, which is nonzero by our counterassumption. Hence, this polynomial is a nonzero polynomial of degree at most $q-1$ over F, which implies that for at least one value of b it attains a nonzero value. But this means that for some choice of b, $C^{g_b}_{\alpha^*_1,\ldots,\alpha^*_{m-1},\alpha^*_m+\alpha^*_{m+1}} \neq 0$ and the proof of this case follows.

Remark. We observe that if $\ell = \lceil \frac{2(d+1)}{q} \rceil$ then either Case 1 or Case 2 must hold. This implies that Theorem 2 is established for q that is a power of 2 (since in this case $q - q/p = q/2$). It also follows that for any value of q, a variant of Theorem 2 which takes ℓ to be at most a factor of 2 larger than that stated in the theorem, is established as well.

In order to get the tighter result which holds for $\ell = \lceil \frac{d+1}{q-(q/p)} \rceil$ and any q, we need to analyze the third and final case.

Case 3 (neither Case 1 nor Case 2 holds). *For every subset $R \subset \{1,\ldots,m+1\}$, $|R| = m$, we have that $\sum_{i\in R} \alpha^*_i \leq d$, and for every pair of indices $i, j \in \{1,\ldots,m+1\}$ we have that $\alpha^*_i + \alpha^*_j \geq q$.*

Our proof of this case is similar in its general structure to the proofs of Cases 1 and 2, but is somewhat more involved since we take into account a larger set of m-dimensional affine subspaces. In what follows, when we write $t \cdot a$, where $a \in F$ and t is an integer, we mean the sum $\underbrace{a + a + \ldots + a}_{t}$ in the field F. For every choice of $a_1,\ldots,a_m,b$ each in F, let $y_0 = b \cdot e_{m+1}$, and for $i = 1,\ldots,m$, let $y_i = a_i \cdot e_i + e_{m+1}$. Consider the function $g_{a_1,\ldots,a_m,b} = h_{|(y_0(b),y_1(a_1),\ldots,y_m(a_m))} : F^m \to F$. By definition,

$$\begin{aligned}
&g_{a_1,\ldots,a_m,b}(z_1,\ldots,z_m)\\
&= h\Big(a_1 \cdot z_1,\ldots,a_m \cdot z_m, \sum_{i=1}^m z_i + b\Big)\\
&= \sum_{\alpha\in[q-1]^{m+1}} C^h_\alpha \cdot \prod_{i=1}^m (a_i \cdot z_i)^{\alpha_i} \cdot \left(\sum_{i=1}^m z_i + b\right)^{\alpha_{m+1}}\\
&= \sum_{\alpha\in[q-1]^{m+1}} \sum_{\substack{\delta\in[q-1]^m\\ \sum_{i=1}^m \delta_i \leq \alpha_{m+1}}} \binom{\alpha_{m+1}}{\delta_1,\ldots,\delta_m} \cdot C^h_\alpha\\
&\qquad\qquad \cdot \prod_{i=1}^m a_i^{\alpha_i} \cdot b^{\alpha_{m+1}-\sum\delta_i} \cdot \prod_{i=1}^m z_i^{\alpha_i+\delta_i}. \qquad (3.4)
\end{aligned}$$

Roughly speaking, for each $\alpha \in [q-1]^{m+1}$, the exponent α_{m+1} "gets distributed" among the different z_i's ($i = 1,\ldots,m$) and b. Note that if $\alpha_i + \delta_i = q$ then $z_i^{\alpha_i+\delta_i} = z_i$, and, more generally, if $\alpha_i + \delta_i \geq q$ then $z_i^{\alpha_i+\delta_i} = z_i^{(\alpha_i+\delta_i) \bmod (q-1)}$. In what follows we use the shorthand $(j)_q$ to denote $(j \bmod (q-1))$.

For any choice of $\gamma = \gamma_1,\ldots,\gamma_m$, $\gamma_i \in [q-1]$, we consider the coefficient of the term $\prod_{i=1}^m z_i^{\gamma_i}$ in the representation of $g_{a_1,\ldots,a_m,b}(z_1,\ldots,z_m)$ as a polynomial of degree at most $q-1$ in each variable (that is, $C_\gamma^{g_{a_1,\ldots,a_m,b}}$). It follows from (3.4) that this

coefficient is the evaluation of the *multivariate* polynomial

$$H_\gamma(x_1,\ldots,x_{m+1}) = \sum_{\substack{\alpha\in[q-1]^{m+1}\\ \alpha_{m+1}\geq\sum_{i=1}^m(\gamma_i-\alpha_i)_q}} \binom{\alpha_{m+1}}{(\gamma_1-\alpha_1)_q,\ldots,(\gamma_m-\alpha_m)_q} \cdot C_\alpha^h \cdot \prod_{i=1}^m x_i^{\alpha_i} \cdot x_{m+1}^{\alpha_{m+1}-\sum_{i=1}^m(\gamma_i-\alpha_i)_q} \tag{3.5}$$

at the point $x_1=a_1,\ldots,x_m=a_m,x_{m+1}=b$.

As in Cases 1 and 2, we would like to show that under the assumption that $C^h_{\alpha^*}\neq 0$ for α^* such that $\sum_{i=1}^{m+1}\alpha_i^*>d$, we can get the following. There exist $a_1,\ldots,a_m$ and b in F and $\gamma_1,\ldots,\gamma_m\in[q-1]$ such that $\sum_{i=1}^m\gamma_i>d$ and the coefficient of the term $\prod_{i=1}^m z_i^{\gamma_i}$ in the representation of $g_{a_1,\ldots,a_m,b}$ as a polynomial of degree at most $q-1$ (in each variable) is nonzero. Since we want to exploit the existence of $\alpha^*\in[q-1]^{m+1}$ as stated above, we shall consider $\gamma_1,\ldots,\gamma_m$ of the form $\gamma_i=\alpha_i^*+\delta_i$, where $\delta_1,\ldots,\delta_m$ ($\delta_i\in[q-1]$) obey the following conditions:

C1. $\sum_{i=1}^m\delta_i\leq\alpha^*_{m+1}$;
C2. $\alpha_i^*+\delta_i\ (=\gamma_i)\ \leq q-1$ for every i, $1\leq i\leq m$;
C3. $\sum_{i=1}^m(\alpha_i^*+\delta_i)>d$ (that is, $\sum_{i=1}^m\gamma_i>d$);
C4. $\binom{\alpha^*_{m+1}}{\delta_1,\ldots,\delta_m}$ is not divisible by p. (If q is prime, that is, $q=p$, then this condition follows from condition C1, but this is not true in general.)

Suppose we have a setting of the δ_i's that satisfies conditions C1–C4 (where we later show how to obtain such a setting). Let $\gamma=\gamma_1,\ldots,\gamma_m$ be such that $\gamma_i=\alpha_i^*+\delta_i$. By condition C3, $\sum_{i=1}^m\gamma_i>d$, and by condition C2 we have that $\gamma_i\leq q-1$ and $\delta_i=(\gamma_i-\alpha_i^*)_q$. We claim that H_γ (which is defined in (3.5)) includes at least one nonzero coefficient. To verify this first note that by condition C1 (and since $\delta_i=(\gamma_i-\alpha_i^*)_q$), the sum in (3.5) includes $\alpha=\alpha^*$. By our counterassumption, $C^h_{\alpha^*}\neq 0$. Combining this with condition C4 we get that $\binom{\alpha^*_{m+1}}{\delta_1,\ldots,\delta_m}\cdot C^h_{\alpha^*}$ is a nonzero coefficient of the term $\prod_{i=1}^m x_i^{\alpha_i^*}\cdot x_{m+1}^{\alpha^*_{m+1}-\sum_{i=1}^m\delta_i}$ in the polynomial H_γ, so that H_γ is a nonzero polynomial. That is, there exists a choice of $a_1,\ldots,a_m$ and b on which the value of H_γ is nonzero. But by definition of H_γ this means that $C_\gamma^{g_{a_1,\ldots,a_m,b}}\neq 0$ for γ that satisfies $\sum_{i=1}^m\gamma_i>d$, in contradiction to the induction hypothesis.

It remains to show how we find a setting of the δ_i's that satisfies conditions C1–C4.

Subcase 1: *q is prime.* Consider first the case that q is prime. That is, $q=p$. In this case $m\geq\ell=\lceil\frac{d+1}{q-1}\rceil$. Let $\delta_1=q-1-\alpha_1^*$, and recall that, by the premise of this case, for every i,j we have $\alpha_i^*+\alpha_j^*\geq q$, so that necessarily $\delta_1<\alpha^*_{m+1}$. Next let $\delta_2=\min\{q-1-\alpha_2^*,\alpha^*_{m+1}-\delta_1\}$, and in general, $\delta_i=\min\{q-1-\alpha_i^*,\alpha^*_{m+1}-\sum_{j<i}\delta_j\}$. Conditions C1 and C2 directly follow from the definition of the δ_i's, and condition C4 is implied by C1 (since q is prime). It remains to verify that condition C3 holds. If there exists an index i such that $\delta_i=\alpha^*_{m+1}-\sum_{j<i}\delta_j$, then

$$\sum_{i=1}^m(\alpha_i^*+\delta_i)=\sum_{i=1}^{m+1}\alpha_i^*>d.$$

Otherwise, $\delta_i=q-1-\alpha_i^*$ for every $1\leq i\leq m$ and so

$$\sum_{i=1}^m(\alpha_i^*+\delta_i)=m\cdot(q-1)\geq\ell\cdot(q-1)\geq d+1.$$

Subcase 2: *q is not prime.* When q is not a prime number, so that $q = p^s$ for $s > 1$, then the setting of the δ_i's is a bit more involved because condition C4 does not follow from any of the other conditions, and we have to attend to it separately. Since

$$\binom{\alpha^*_{m+1}}{\delta_1, \ldots, \delta_m} = \binom{\alpha^*_{m+1}}{\delta_1} \cdot \binom{\alpha^*_{m+1} - \delta_1}{\delta_2} \cdots \binom{\alpha^*_{m+1} - \sum_{j<i} \delta_j}{\delta_i} \cdots \binom{\alpha^*_{m+1} - \sum_{j<m} \delta_j}{\delta_m}$$

it suffices to show that each term in the above product is not divisible by p. Let us hence rewrite condition C4.

C4. For every $1 \le i \le m$, $\binom{\alpha^*_{m+1} - \sum_{j<i} \delta_j}{\delta_i}$ is not divisible by p.

We shall use the following notation: For each α^*_i, let $k_{i,j}$ for $j \in [p-1]$ be such that $\alpha^*_i = \sum_{j=0}^{s-1} k_{i,j} p^j$. That is, in the representation of α^*_i in basis p, $k_{i,j}$ is the coefficient of p^j. Let us assume without loss of generality that α^*_{m+1} is the smallest α^*_i and that $\alpha^*_1 \le \alpha^*_2 \le \cdots \le \alpha^*_m$ (we may reorder the variables to get that). We know that $\alpha^*_1 < (p-1)p^{s-1}$ (or else $\sum_{i=1}^m \alpha^*_i \ge (p-1)p^{s-1} \cdot \ell \ge d+1$). Since, by the premise of this case, $\alpha^*_i + \alpha^*_1 \ge q = p^s$ for every $i > 1$, necessarily $\alpha^*_i > p^{s-1}$ for $i > 1$. Similarly, $\alpha^*_1 > p^{s-1}$ (since $\alpha^*_1 + \alpha^*_{m+1} \ge q$). Hence for each α^*_i we have that $1 \le k_{i,s-1} \le p-1$.

For $1 \le i \le m$, let $t_i \stackrel{\text{def}}{=} p - 1 - k_{i,s-1}$ (for technical purposes $t_0 \stackrel{\text{def}}{=} 0$). That is, t_i indicates the maximum number that can be added to the coefficient $k_{i,s-1}$ of p^{s-1} without "going over" $p-1$. Recall that $\alpha^*_1, \ldots, \alpha^*_m$ are in nondecreasing order, and so the t_i's are in nonincreasing order. In particular, if $t_i = 0$ then $t_{i'} = 0$ for every $i' > i > 0$. We shall use the following technical claim that was given in [19] and whose proof is provided for the sake of completeness in the appendix.

CLAIM 1. *Let $q = p^s$ for a prime number p and an integer s, and let r and t be integers that satisfy $0 < r \le t \le q-1$. If $r = kp^{s-1}$ for some integer k then $\binom{t}{r}$ is not divisible by p.*

The setting of the δ_i's. We now show how to set the δ_i's so that conditions C1–C4 hold. We start with an informal description of how to "distribute" the weight of α^*_{m+1} between the δ_i's. Consider the representation of α^*_{m+1} in basis p as described above. The highest coefficient in the representation is $k_{m+1,s-1}$. That is,

$$\alpha^*_{m+1} = \sum_{j=0}^{s-1} k_{m+1,j} p^j = k_{m+1,s-1} p^{s-1} + \sum_{j=0}^{s-2} k_{m+1,j} p^j.$$

We view α^*_{m+1} as having $k_{m+1,s-1}$ "units of p^{s-1}" to be distributed, and some "left over." Note that this left-over, $\sum_{j=0}^{s-2} k_{m+1,j} p^j$, is strictly smaller than p^{s-1}.

Starting from δ_1, each δ_i in its turn will be assigned the maximum possible integer multiple of p^{s-1}. Namely, as long as the number of remaining "p^{s-1} units" is more than the number of such units that can still be added to α^*_i (i.e., t_i) and $t_i > 0$, then δ_i is assigned t_i units of p^{s-1}. For these i's we get that $k_{i,s-1}p^{s-1} + \delta_i = (p-1)p^{s-1}$. If we reach an index i such that $t_i = 0$, then we stop distributing what is left of α^*_{m+1}. Alternatively, if we reach an index i for which the number of p^{s-1} units that can be added to it (i.e., t_i) is bigger than the amount of p^{s-1} units that remain to be distributed, then we assign δ_i the rest of the weight of α^*_{m+1} that was not distributed yet.

We now turn to a more formal definition. We initialize i to 1 and do the following:

1. While $i \leq m$ and $0 < t_i \leq k_{m+1,s-1} - \sum_{j<i} t_j$:
   Set $\delta_i = t_i p^{s-1}$, and increase i by 1.
2. If $i \leq m$:
   (a) If $t_i = 0$ then for every i', $i \leq i' \leq m$, set $\delta_i = 0$. (Recall that the t_i's are nonincreasing so that if $t_i = 0$ then for every $i' > i$ we also have $t_{i'} = 0$.)
   (b) Else ($t_i > k_{m+1,s-1} - \sum_{j<i} t_j$), set $\delta_i = \alpha^*_{m+1} - \sum_{j<i} \delta_j$, and for every $i' > i$ set $\delta_{i'} = 0$. Note that

$$\delta_i = \Big(k_{m+1,s-1} - \sum_{j<i} t_j\Big)p^{s-1} + \sum_{j=0}^{s-2} k_{m+1,j}p^j \;<\; t_i p^{s-1}.$$

We next verify that conditions C1–C4 hold for this setting of the δ_i's. Condition C1 ($\sum_{i=1}^m \delta_i \leq \alpha^*_{m+1}$) directly follows from the above process. By the definition of the δ_i's, for every $1 \leq i \leq m$, $\delta_i \leq t_i \cdot p^{s-1}$. Since $t_i = p - 1 - k_{i,s-1}$, we get that

$$\alpha^*_i + \delta_i \;\leq\; (p-1)\cdot p^{s-1} + \sum_{\ell=2}^{s} k_{i,s-\ell}p^{s-\ell} \;<\; q,$$

and so condition C2 holds.

We next verify that condition C3 holds, that is, $\sum_{i=1}^m (\alpha^*_i + \delta_i) > d$. Let i_0 be the index reached at the end of step 1 in the process. Observe that for every $i < i_0$, $\delta_i = t_i \cdot p^{s-1}$. By definition of t_i this implies that $\alpha^*_i + \delta_i \geq (p-1)p^{s-1}$. If $i_0 > m$ then, since $m \geq \ell = \lceil \frac{d+1}{(p-1)p^{s-1}} \rceil$, we get that $\sum_{i=1}^m (\alpha^*_i + \delta_i) \geq d+1$, as required. If $i_0 \leq m$, then there are two cases. In case $t_{i_0} = 0$ (so that for every $i' \geq i_0$ we have $t_{i'} = 0$), then $\alpha^*_i \geq (p-1)p^{s-1}$ for every $i \geq i_0$, so again we get that $\sum_{i=1}^m (\alpha^*_i + \delta_i) \geq d+1$. In case $t_{i_0} > k_{m+1,s-1} - \sum_{j<i} t_j$, then we set $\delta_{i_0} = \alpha^*_{m+1} - \sum_{j<i_0} \delta_j$, so that

$$\sum_{i=1}^{m} (\alpha^*_i + \delta_i) = \sum_{i=1}^{m+1} \alpha^*_i > d.$$

Finally, we verify that condition C4 holds. That is, for every $1 \leq i \leq m$, $\binom{\alpha^*_{m+1} - \sum_{j<i} \delta_j}{\delta_i}$ is not divisible by p. Let i_0 be as defined above in our verification of condition C3. Since for every $i < i_0$ we have that $\delta_i = t_i p^{s-1}$, by Claim 1, $\binom{\alpha^*_{m+1} - \sum_{j<i} \delta_j}{\delta_i}$ is not divisible by p. If $i_0 > m$ then we are done. Otherwise there are two cases. In the first case $\delta_i = 0$ for every $i \geq i_0$, so clearly the condition holds. In the second case, $\delta_{i_0} = \alpha^*_{m+1} - \sum_{j<i_0} \delta_j$ and $\delta_i = 0$ for every $i > i_0$. Thus condition C4 holds in this case too. We have thus completed the proof of Case 3 (Subcase 2), and hence of Theorem 2. □

4. The test. In this section we present and analyze our testing algorithm for degree-d polynomials over fields of cardinality $q = O(d)$.

ALGORITHM 1. Testing Algorithm for Degree-d Polynomials

1. *Let* $\ell = \ell(q,d) = \lceil \frac{d+1}{q - q/p} \rceil$ *and repeat the following* $t = \Theta\big(\ell \cdot q^{\ell+1} + \frac{1}{\epsilon \cdot q^\ell}\big)$ *times:*
   (a) *Uniformly at random select* ℓ *linearly independent points* $y_1, \ldots, y_\ell \in F^n$, *and a point* $y_0 \in F^n$.
   (b) *If* $f_{|(y_0,y_1,\ldots,y_\ell)} \notin \mathrm{POLY}_{\ell,d}$ *then output* reject.
2. *If no step caused rejection then output* accept.

Recall that checking whether $f_{|S} \notin \mathrm{POLY}_{\ell,d}$ (where $S = S(y_0, y_1, \ldots, y_\ell)$) can

be done by querying f on all points in the subspace S and verifying that all linear constraints corresponding to the coefficients $C_\alpha^{f|_S}$ such that $\sum_{i=1}^{\ell} \alpha_i > d$ hold. Hence the total number of queries performed by the algorithm is $O(t \cdot q^\ell) = O(\ell \cdot q^{2\ell+1} + \frac{1}{\epsilon})$ (where the q^ℓ term is due to the number of points in each affine subspace).

As noted in the introduction, when q is sufficiently larger than d so that $\ell = 1$ (the subspaces are lines), then it is not necessary to query f on all points on the line, but rather $d+2$ points suffice. We note that these checks involving $d+2$ points on a line can be interpreted as selecting minimum-weight words from the dual GRM code and checking that they are orthogonal to the word defined by f.

Given Algorithm 1, Theorem 1, as stated in the introduction, follows from the next lemma.

LEMMA 2. *If $f \in \mathrm{POLY}_{n,d}$ then Algorithm 1 accepts with probability 1, and if $\mathrm{dist}(f, \mathrm{POLY}_{n,d}) > \epsilon$ then Algorithm 1 rejects with probability at least $2/3$.*

Lemma 2 shall be proved using the "self-correcting approach," which has been applied in the analysis of many previous low-degree tests. Namely, given the function f we define another function g based on certain "majority votes" of f. We then show that if f passes the test with sufficiently high probability, then g is close to f and g is a polynomial of degree at most d. Bounding the distance between f and g follows easily from the definition of g, and hence the analysis is focused on showing that g is a polynomial of degree at most d. The analysis can be viewed as generalizing both the analysis in [30] (where the subspaces considered by the test are lines) and the analysis in [1] (where the subspaces are larger but the field is $GF(2)$, and the analysis relies on the fact that the field is $GF(2)$).

We start by introducing several notations.

DEFINITION 5. *Let*

$$\eta = \eta(f,d) \stackrel{\mathrm{def}}{=} \Pr_{y_0,y_1,\ldots,y_\ell}\Big[f_{|(y_0,y_1,\ldots,y_\ell)} \notin \mathrm{POLY}_{\ell,d}\Big], \tag{4.1}$$

where the probability is taken over $y_0, y_1, \ldots, y_\ell$ such that $y_1, \ldots, y_\ell$ are linearly independent.

By definition of Algorithm 1, η is the probability that a single step of the algorithm causes f to be rejected. That is, it is the probability that the restriction of f to a random affine subspace of dimension ℓ is *not* a polynomial of degree at most d.

DEFINITION 6. *For each $\alpha \in [q-1]^\ell$, $y \in F^n$, and linearly independent points $y_1, \ldots, y_\ell \in F^n$, let $C_\alpha^f(y_0, y_1, \ldots, y_\ell)$ denote the coefficient C_α of the polynomial representation of $f_{|(y_0,y_1,\ldots,y_\ell)}$. We shall use the notation $B^f(y_0, y_1, \ldots, y_\ell)$ as a shorthand for the coefficient $C^f_{\langle q-1,\ldots,q-1\rangle}(y_0, y_1, \ldots, y_\ell)$. That is, $B^f(y_0, y_1, \ldots, y_\ell)$ denotes the coefficient of the highest-degree monomial $x_1^{q-1} \cdot x_2^{q-1} \cdots x_\ell^{q-1}$ in the polynomial representation of $f_{|(y_0,y_1,\ldots,y_\ell)}$. Recall that this coefficient equals $(-1)^\ell$ times the sum of the values of f taken over all points in the subspace.*

We denote by $V^f(y; y_1, \ldots, y_\ell)$ the value that $f(y)$ "should have" so that $B^f(y, y_1, \ldots, y_\ell) = 0$. That is,

$$V^f(y; y_1, \ldots, y_\ell) = \quad - \sum_{\substack{b_1,\ldots,b_\ell \in F \\ \exists i \text{ s.t. } b_i \neq 0}} f\Big(y + \sum_{i=1}^{\ell} b_i \cdot y_i\Big)\,. \tag{4.2}$$

We refer to $V^f(y; y_1, \ldots, y_\ell)$ as the vote *of $(y_1, \ldots, y_\ell)$ on the value assigned to y.*

For succinctness of the notation, we shall remove f from the last two notations (i.e., $B(\cdot) = B^f(\cdot)$ and $V(\cdot) = V^f(\cdot)$).

Note that for η as in Definition 5,

$$\eta \geq \Pr_{y,y_1,\ldots,y_\ell}[V(y;y_1,\ldots,y_\ell) \neq f(y)],$$

where the probability is taken over $y_1,\ldots,y_\ell$ that are linearly independent. This is true since the test checks that *all* coefficients $C^f_\alpha(y,y_1,\ldots,y_\ell)$ for which $\sum_{i=1}^{\ell}\alpha_i > d$ are 0.

In our analysis, we shall sometimes have to address the case that $y_1,\ldots,y_\ell$ are linearly dependent and we shall use the notation $V(y;y_1,\ldots,y_\ell)$ (as defined in (4.2)), in this case as well. This is despite the fact that it no longer has the same meaning of a "vote" on the value of $f(y)$ (or at least not an "objective vote"). We show the following.

LEMMA 3. *For every $y \in F^n$ and for $y_1,\ldots,y_\ell \in F^n$ that are linearly dependent, $V(y;y_1,\ldots,y_\ell) = f(y)$.*

Proof. Since $y_1,\ldots,y_\ell$ are linearly dependent, we can write y_ℓ as a linear combination of the other points. That is, $y_\ell = \sum_{i=1}^{\ell-1} a_i y_i$, where $a_1,\ldots,a_{\ell-1} \in F$. By definition of $V(\cdot)$,

$$V(y;y_1,\ldots,y_\ell) = -\sum_{b_1,\ldots,b_\ell \in F} f\Big(y + \sum_{i=1}^{\ell} b_i \cdot y_i\Big) + f(y)\,. \tag{4.3}$$

Since $y_\ell = \sum_{i=1}^{\ell-1} a_i y_i$,

$$\sum_{b_1,\ldots,b_\ell \in F} f\Big(y + \sum_{i=1}^{\ell} b_i \cdot y_i\Big) = \sum_{b_1,\ldots,b_\ell \in F} f\Big(y + \sum_{i=1}^{\ell-1} b_i \cdot y_i + b_\ell \sum_{i=1}^{\ell-1} a_i y_i\Big) \tag{4.4}$$

$$= \sum_{b_\ell \in F} \sum_{b_1,\ldots,b_{\ell-1} \in F} f\Big(y + \sum_{i=1}^{\ell} (b_i + b_\ell \cdot a_i) y_i\Big) \tag{4.5}$$

$$= |F| \cdot \sum_{c_1,\ldots,c_{\ell-1} \in F} f\Big(y + \sum_{i=1}^{\ell} c_i y_i\Big) \tag{4.6}$$

$$= 0\,. \tag{4.7}$$

In the above sequence of equalities, (4.6) follows from the fact that for each $b_\ell \in F$, and for every choice of $c_1,\ldots,c_{\ell-1} \in F$, there exists a choice of $b_1,\ldots,b_{\ell-1} \in F$ such that $c_i = b_i + b_\ell \cdot a_i$ (i.e., $b_i = c_i - b_\ell \cdot a$). ∎

We are now ready to define the *self-corrected* version of f, denoted by g.

DEFINITION 7. *Let g be a* plurality *function that is defined as follows. For each $y \in F^n$,*

$$g(y) = \mathrm{argmax}_{a \in F}\Big\{\Pr_{y_1,\ldots,y_\ell \in F^n}[V(y;y_1,\ldots,y_\ell) = a]\Big\}\,. \tag{4.8}$$

The next lemma readily follows from the definition of g.

LEMMA 4. *For any function f and for η and g as defined in* (4.1) *and* (4.8)*, respectively,* $\mathrm{dist}(f,g) \leq 2\eta$.

Proof. First observe that if the test selects points $y_0,y_1,\ldots,y_\ell \in F^n$ such that $f(y_0) \neq V(y_0;y_1,\ldots,y_\ell)$, then this means that $B(y_0;y_1,\ldots,y_\ell) \neq 0$ (where $B(\cdot)$ is as defined in Definition 6), which causes the test to reject. Recall that the test selects $y_1,\ldots,y_\ell$ that are linearly independent. If $y_1,\ldots,y_\ell$ are linearly dependent

then by Lemma 3, $V(y_0; y_1, \ldots, y_\ell) = f(y_0)$. Let $U \subseteq F^n$ consist of all ("bad") points $y \in F^n$ such that $\Pr_{y_1,\ldots,y_\ell \in F^n}[f(y) \neq V(y; y_1, \ldots, y_\ell)] > 1/2$. By definition of η (and Lemma 3) we know that $|U|/q^n < 2\eta$. But for every $x \in F^n \setminus U$, by definition of g we have that $f(x) = g(x)$, and the lemma follows. □

In the next series of lemmas we prove that if η is sufficiently small then g is a polynomial of total degree at most d. In the first, and central lemma, we show that for every y, the value of $g(y)$, which by Definition 7 is the "plurality vote" of $V(y; y_1, \ldots, y_\ell)$, taken over all $y_1, \ldots, y_\ell$, equals the vote of a large fraction of the ℓ-tuples $y_1, \ldots, y_\ell$ (assuming η is sufficiently small).

LEMMA 5. *For any fixed $y \in F^n$, let*

$$\gamma(y) \stackrel{\text{def}}{=} \Pr_{y_1,\ldots,y_\ell}\Big[V(y; y_1, \ldots, y_\ell) = g(y)\Big]. \tag{4.9}$$

Then $\gamma(y) \geq 1 - 2q\ell\eta$.

In order to prove Lemma 5 it will actually be more convenient to work with another measure of "correctness" (or "consistency") of a point y.

LEMMA 6. *For any fixed $y \in F^n$, let*

$$\delta(y) = \Pr_{y_1,\ldots,y_\ell,z_1,\ldots,z_\ell}\Big[V(y; y_1, \ldots, y_\ell) = V(y; z_1, \ldots, z_\ell)\Big] \tag{4.10}$$

and let $\gamma(y)$ be as defined in (4.9). *Then $\gamma(y) \geq \delta(y)$.*

Proof. Let $\beta_a(y) = \Pr_{y_1,\ldots,y_\ell}[V(y; y_1, \ldots, y_\ell) = a]$ (so that in particular, $\sum_{a \in F} \beta_a(y) = 1$). By definition of $\gamma(y)$ we have that $\gamma(y) = \max_a \beta_a(y)$, and by definition of $\delta(y)$ we have that $\delta(y) = \sum_{a \in F}(\beta_a(y))^2$. By convexity, $\max_a \beta_a(y) \geq \sum_{a \in F}(\beta_a(y))^2$, and the claim follows. □

An auxiliary "voting graph." In order to show that $\delta(y)$ is large (and hence $\gamma(y)$ is large), it will be useful to consider the following auxiliary graph. The definition of this graph was inspired by the way Shpilka and Wigderson used Cayley graphs in their work [31] and can also be viewed as formalizing and generalizing part of the analysis in [1]. Each vertex in this graph is labeled by a subset (multiset) of ℓ points, $\{y_1, \ldots, y_\ell\}$, $y_i \in F^n$. The neighbors of $\{y_1, \ldots, y_\ell\}$ are of the form $\{y_2, \ldots, y_{\ell+1}\}$. Each vertex corresponds to ℓ points that can "vote" on the value of $f(y)$ for any given y and hence we refer to it as the *voting graph*.

For a fixed point $y \in F^n$, we say that an edge between $\{y_1, \ldots, y_\ell\}$ and $\{y_2, \ldots, y_{\ell+1}\}$ is *good with respect to y* if $V(y; y_1, \ldots, y_\ell) = V(y; y_2, \ldots, y_{\ell+1})$.

Recall that for linearly independent $y_1, \ldots, y_\ell$, $B(y_0, y_1, \ldots, y_\ell)$ denotes the coefficient $C_{\langle q-1,\ldots,q-1\rangle}(y_0, y_1, \ldots, y_\ell)$, of the restriction of f to the ℓ-dimensional affine subspace determined by $y_0, y_1, \ldots, y_\ell$. That is,

$$B(y_0, y_1, \ldots, y_\ell) = (-1)^\ell \cdot \sum_{b_1,\ldots,b_\ell \in F} f\Big(y + \sum_{i=1}^{\ell} y_i\Big).$$

LEMMA 7. *For any choice of $y, y_1, \ldots, y_{\ell+1} \in F^n$ such that $y_1, \ldots, y_{\ell+1}$ are linearly independent,*

$$\begin{aligned} &V(y; y_1, \ldots, y_\ell) - V(y; y_2, \ldots, y_{\ell+1}) \\ &= (-1)^\ell \left(\sum_{a \in F,\ a \neq 0} B(y + a \cdot y_{\ell+1}, y_1, \ldots, y_\ell) - \sum_{a \in F,\ a \neq 0} B(y + a \cdot y_1, y_2, \ldots, y_{\ell+1}) \right). \end{aligned}$$

Proof. By definition of $V(y;\cdot)$ we have

$$
\begin{aligned}
&V(y;y_1,\ldots,y_\ell)-V(y;y_2,\ldots,y_{\ell+1})\\
&=-\sum_{\substack{b_1,\ldots,b_\ell\in F\\ b_1\neq 0}} f\Big(y+\sum_{i=1}^{\ell} b_i\cdot y_i\Big)+\sum_{\substack{b_2,\ldots,b_{\ell+1}\in F\\ b_{\ell+1}\neq 0}} f\Big(y+\sum_{i=2}^{\ell+1} b_i\cdot y_i\Big)\\
&=-\sum_{\substack{b_1,\ldots,b_\ell\in F\\ b_1\neq 0}} f\Big(y+\sum_{i=1}^{\ell} b_i\cdot y_i\Big)-\sum_{\substack{b_1,\ldots,b_{\ell+1}\in F\\ b_1,b_{\ell+1}\neq 0}} f\Big(y+\sum_{i=1}^{\ell+1} b_i\cdot y_i\Big)\\
&\quad+\sum_{\substack{b_2,\ldots,b_{\ell+1}\in F\\ b_{\ell+1}\neq 0}} f\Big(y+\sum_{i=2}^{\ell+1} b_i\cdot y_i\Big)+\sum_{\substack{b_1,\ldots,b_{\ell+1}\in F\\ b_1,b_{\ell+1}\neq 0}} f\Big(y+\sum_{i=1}^{\ell+1} b_i\cdot y_i\Big)\\
&=-\sum_{\substack{b_1,\ldots,b_{\ell+1}\in F\\ b_1\neq 0}} f\Big(y+b_1\cdot y_1+\sum_{i=2}^{\ell+1} b_i\cdot y_i\Big)+\sum_{\substack{b_1,\ldots,b_{\ell+1}\in F\\ b_{\ell+1}\neq 0}} f\Big(y+b_{\ell+1}\cdot y_{\ell+1}+\sum_{i=1}^{\ell} b_i\cdot y_i\Big)\\
&=(-1)^{\ell}\Bigg(\sum_{a\in F,\ a\neq 0} B(y+a\cdot y_{\ell+1},y_1,\ldots,y_\ell)\\
&\qquad\qquad-\sum_{a\in F,\ a\neq 0} B(y+a\cdot y_1,y_2,\ldots,y_{\ell+1})\Bigg).
\end{aligned}
$$

□

Proof of Lemma 5. Given Lemma 6, it suffices to show that for every $y\in F^n$, $\delta(y)\geq 1-2q\ell\eta$. For any (random) choice of $y_1,\ldots,y_\ell$ and $z_1,\ldots,z_\ell$, and for each $0\leq i\leq \ell$ let $v_i=\{y_1,\ldots,y_i,z_{i+1},\ldots,z_\ell\}$, where we view v_i as a vertex in the voting graph. In particular, $v_\ell=\{y_1,\ldots,y_\ell\}$ and $v_0=\{z_1,\ldots,z_\ell\}$. Since $y_1,\ldots,y_\ell,z_1,\ldots,z_\ell$ are selected uniformly and at random, each v_i is a random variable. Consider the path $v_\ell,\ldots,v_0$ between v_ℓ and v_0. In what follows we shall use the shorthand $V(y;v_i)$ for the vote $V(y;y_1,\ldots,y_i,z_{i+1},\ldots,z_\ell)$. Recall that an edge (v_i,v_{i-1}) is good if $V(y;v_i)=V(y;v_{i-1})$.

We next show that the probability (taken over the choice of $y_1,\ldots,y_\ell,z_1,\ldots,z_\ell$) that an edge (v_i,v_{i-1}) on the path is not good is at most $2q\eta$. By taking a union bound it follows that the probability that all the edges on the path are good is at least $1-2q\ell\eta$. That is, with probability at least $1-2q\ell\eta$, $V(y;y_1,\ldots,y_\ell)=V(y;y_1,\ldots,y_{\ell-1},z_\ell)=\cdots=V(y;z_1,\ldots,z_\ell)$, and the lemma follows.

Consider any edge (v_i,v_{i-1}). We say that $V(y;v_i)$ is an *independent vote* for y if $y_1,\ldots,y_i,z_{i+1},\ldots,z_\ell$ are linearly independent points; otherwise we say that $V(y;v_i)$ is a *dependent vote* for y. If both votes for y are dependent, then by Lemma 3, $V(y;v_i)=f(y)$ and $V(y;v_{i-1})=f(y)$ so that $V(y;v_i)=V(y;v_{i-1})$ and the edge is good. If one of the votes is a dependent vote and the other is an independent vote, then the probability that the edge is not good is the probability that an independent vote for y differs from $f(y)$, which is η.

We next show that if both $V(y;v_i)$ and $V(y;v_{i-1})$ are independent votes for y then the edge (v_i,v_{i-1}) is not good with probability at most $2q\eta$. Indeed, by Lemma 7

such an edge is good if

$$\sum_{a\in F,a\neq 0} B(y+a\cdot y_i, y_1,\ldots,y_{i-1},z_i,\ldots,z_\ell) - \sum_{a\in F,a\neq 0} B(y+a\cdot z_i, y_1,\ldots,y_i,z_{i+1},\ldots,z_\ell) = 0. \tag{4.11}$$

Since $y_1,\ldots,y_i,z_{i+1},\ldots,z_\ell$ and $y_1,\ldots,y_{i-1},z_i,\ldots,z_\ell$. are two sets of linearly independent vectors selected uniformly at random, each of the $B(\cdot)$'s in the above summation is nonzero with probability at most η. Hence, by applying a union bound, the probability that (v_i,v_{i-1}) is not good is at most $2q\eta$ as claimed. □

We next show that if η is sufficiently small then $g\in \mathrm{POLY}_{n,d}$. This is obtained by showing that the restriction of g to every affine subspace of dimension ℓ results in a polynomial of degree at most d. By applying Theorem 2 we conclude that in such a case g is indeed in $\mathrm{POLY}_{n,d}$. In order to show that the restriction of g to every affine subspace of dimension ℓ is a polynomial of degree at most d, we generalize the proof technique applied in [1] for the case of $F=GF(2)$. Roughly speaking, we show that the high degree coefficients in the polynomial representation of the restriction of g to any *fixed* subspace, can be expressed as linear combinations of these coefficients in the restriction of f to *random* subspaces.

LEMMA 8. *If* $\eta < \frac{1}{2(\ell+1)q^{\ell+1}}$, *then* $g\in \mathrm{POLY}_{n,d}$.

Proof. Consider any fixed set of points $y_0,y_1,\ldots,y_\ell\in F^n$ such that $y_1,\ldots,y_\ell$ are linearly independent. We shall show that $g_{|(y_0,y_1,\ldots,y_\ell)}\in \mathrm{POLY}_{\ell,d}$. Lemma 8 follows by applying Theorem 2. We start by describing the high-level idea of the proof. By using a probabilistic argument we shall show that there exists a choice of a subset of elements, denoted $\{z_{i,j}\}$, for which the following conditions hold. First, the value of g on every point w in the subspace $S(y_0,y_1,\ldots,y_\ell)$ equals the vote on w of a set, T_w, of ℓ points that are linear combinations of the $z_{i,j}$'s. Next, for each of these sets of points T_w, the restriction of f to the affine subspace defined by w and T_w is a polynomial of degree at most d. That is, all high degree coefficients in each of these restrictions are 0. We then show that each high degree coefficient in the restriction of g to the subspace $S(y_0,y_1,\ldots,y_\ell)$ is a linear combinations of the high degree coefficients in the abovementioned restrictions of f, and is hence 0. A formal proof follows.

Each point w in the affine subspace $S(y_0,y_1,\ldots,y_\ell)$ is of the form $y_0+\sum_{i=1}^{\ell} b_i y_i$, where $b_i\in F$. Now consider $(\ell+1)\cdot\ell$ elements in F^n, denoted $\{z_{i,j}\}_{i=0,\ldots,\ell}^{j=1,\ldots,\ell}$. Suppose that for every choice of $b_1,\ldots,b_\ell\in F$,

$$g\Big(y_0+\sum_{i=1}^{\ell} b_i\cdot y_i\Big) = V\Big(y_0+\sum_{i=1}^{\ell} b_i\cdot y_i\ ;\ z_{0,1}+\sum_{i=1}^{\ell} b_i\cdot z_{i,1},\ldots,z_{0,\ell}+\sum_{i=1}^{\ell} b_i\cdot z_{i,\ell}\Big). \tag{4.12}$$

If we select the elements $\{z_{i,j}\}$ uniformly and at random, then by Lemma 5 and the union bound, this event occurs with probability at least $1-2q\ell\eta\cdot q^{\ell}$. We assume from this point on that (4.12) holds for every choice of $b_1,\ldots,b_\ell\in F$.

In order to show that $g_{|(y_0,y_1,\ldots,y_\ell)}\in \mathrm{POLY}_{\ell,d}$ we need to show that for every $\alpha\in[q-1]^\ell$ such that $\sum_{i=1}^{\ell}\alpha_i > d$, we have that $C_\alpha^g(y_0,y_1,\ldots,y_\ell)=0$. Let us fix any such α, and let R_α denote the row vector $\mathcal{A}_\ell(\alpha,\cdot)$ (where the matrix $\mathcal{A}_\ell$ is as

defined by (2.3) and (2.5)). Recall that the coordinates of R_α are indexed by strings $\beta \in [q-1]^\ell$ (where we denote the corresponding coordinate by $R_\alpha^\beta \in F$). In what follows we use the notation $ex(\beta_i) = \omega^{\beta_i}$ if $\beta_i \neq 0$ and $ex(\beta_i) = 0$ if $\beta_i = 0$. Consider the structure of $\mathcal{A}_\ell$ presented in section 2. We need to show that

$$\sum_{\beta \in [q-1]^\ell} R_\alpha^\beta \cdot g\Big(y_0 + \sum_{i=1}^{\ell} ex(\beta_i) \cdot y_i\Big) = 0. \tag{4.13}$$

For any fixed $\beta \in [q-1]^\ell$, by our assumption that (4.12) holds, and by definition of $V(\cdot)$, we have

$$\begin{aligned}
&g\Big(y_0 + \sum_{i=1}^{\ell} ex(\beta_i) \cdot y_i\Big) \\
&= \; - \sum_{\substack{\gamma \in [q-1]^\ell \\ \gamma \neq (0,0,\ldots,0)}} f\left(y_0 + \sum_{i=1}^{\ell} ex(\beta_i) \cdot y_i \;\; + \sum_{j=1}^{\ell} ex(\gamma_j) \cdot \Big(z_{0,j} + \sum_{i=1}^{\ell} ex(\beta_i) \cdot z_{i,j}\Big)\right) \\
&= \; - \sum_{\substack{\gamma \in [q-1]^\ell \\ \gamma \neq (0,0,\ldots,0)}} f\left(y_0 + \sum_{j=1}^{\ell} ex(\gamma_j) \cdot z_{0,j} \;\; + \sum_{i=1}^{\ell} ex(\beta_i) \cdot \Big(y_i + \sum_{j=1}^{\ell} ex(\gamma_j) \cdot z_{i,j}\Big)\right).
\end{aligned}$$

This implies (by switching the order of summations) that $\sum_{\beta \in [q-1]^\ell} R_\alpha^\beta \cdot g(y_0 + \sum_{i=1}^{\ell} ex(\beta_i) \cdot y_i)$, which we would like to show is 0, is the sum over all nonzero $\gamma \in [q-1]^\ell$ and all $\beta \in [q-1]^\ell$ of R_α^β times the evaluation of f at

$$y_0 + \sum_{j=1}^{\ell} ex(\gamma_j) \cdot z_{0,j} + \sum_{i=1}^{\ell} ex(\beta_i) \cdot \Big(y_i + \sum_{j=1}^{\ell} ex(\gamma_j) \cdot z_{i,j}\Big).$$

But for any given choice of $\gamma = \gamma_1, \ldots, \gamma_\ell$,

$$\begin{aligned}
&\sum_{\beta \in [q-1]^\ell} R_\alpha^\beta \cdot f\left(y_0 + \sum_{j=1}^{\ell} ex(\gamma_j) \cdot z_{0,j} \;\; + \sum_{i=1}^{\ell} ex(\beta_i) \cdot \Big(y_i + \sum_{j=1}^{\ell} ex(\gamma_j) \cdot z_{i,j}\Big)\right) \\
&= C_\alpha^f\Big(y_0 + \sum_{j=1}^{\ell} ex(\gamma_j) \cdot z_{0,j},\; y_1 + \sum_{j=1}^{\ell} ex(\gamma_j) \cdot z_{1,j},\; \ldots,\; y_\ell + \sum_{j=1}^{\ell} ex(\gamma_j) \cdot z_{\ell,j}\Big).
\end{aligned}$$

Consider the event that for every choice of $\gamma_1, \ldots, \gamma_\ell$ that are not all 0,

$$y_1 + \sum_{j=1}^{\ell} ex(\gamma_j) \cdot z_{1,j},\; \ldots,\; y_\ell + \sum_{j=1}^{\ell} ex(\gamma_j) \cdot z_{\ell,j}$$

are linearly independent. This event occurs with probability at least $1 - q^\ell \cdot q^{\ell-n}$. In what follows we shall assume that this is indeed the case. Since $\gamma_1, \ldots, \gamma_\ell$ are not all 0, then we know that for each setting of $\gamma_1, \ldots, \gamma_\ell$, with probability at most η over the choice of the $z_{i,j}$'s, for every α such that $\sum_{i=1}^{\ell} \alpha_i > d$,

$$C_\alpha^f\Big(y_0 + \sum_{j=1}^{\ell} ex(\gamma_j) \cdot z_{0,j},\; y_1 + \sum_{j=1}^{\ell} ex(\gamma_j) \cdot z_{1,j},\; \ldots,\; y_\ell + \sum_{j=1}^{\ell} ex(\gamma_j) \cdot z_{\ell,j}\Big) \neq 0.$$

By taking a union bound over all $\gamma_1, \ldots, \gamma_\ell$, adding the probability that we have at least one linearly dependent combination, and adding the probability that (4.12) does not hold for some $\beta \in [q-1]^\ell$, we get that with probability at least

$$1 - q^\ell \eta - 2q\ell\eta q^\ell - q^{2\ell - n} \tag{4.14}$$

there exist $z_{i,j}$'s that satisfy all required constraints. Hence (4.13) holds as desired. Note that our algorithm performs $\Theta(\ell q^{2\ell+1} + 1/\epsilon)$ queries, so that we may assume that $\ell q^{2\ell+1} < q^n$ (or else the algorithm would simply query all q^n points). Therefore, the expression in (4.14) is greater than 0 and the lemma follows. □

By combining Lemmas 4 and 8 we obtain that if f is $\Omega(\frac{1}{\ell q^\ell})$-far from $\mathrm{POLY}_{n,d}$, then $\eta = \Omega(\frac{1}{\ell q^\ell})$, and so the algorithm rejects f with sufficiently high constant probability.

The next lemma, which will help us deal with the case in which η is small, is a variant of a very similar lemma that was proved in [1]. For the sake of completeness we provide its proof in the appendix.

LEMMA 9. *Let* $\zeta \stackrel{\text{def}}{=} \frac{1-q^\ell \cdot \mathrm{dist}(f,g)}{1+q^\ell \cdot \mathrm{dist}(f,g)} \cdot q^\ell \cdot \mathrm{dist}(f,g)$. *If we uniformly and independently select* $y_0, y_1, \ldots, y_\ell \in F^n$ *where* $y_1, \ldots, y_\ell$ *are linearly independent, then the probability that for* exactly *one choice of* $b_1, \ldots, b_\ell \in F$, *we have that* $f(y_0 + \sum_{i=1}^{\ell} b_i \cdot y_i) \neq g(y_0 + \sum_{i=1}^{\ell} b_i \cdot y_i)$ *is at least* ζ.

We are now ready to wrap up the proof of Lemma 2 (and hence Theorem 1).

Proof of Lemma 2. If $f \in \mathrm{POLY}_{n,d}$, then, as stated in Theorem 2, $f_{|S} \in \mathrm{POLY}_{\ell,d}$ for every affine subspace S of dimension ℓ, and so the tester accepts with probability 1. We next show that if f is ϵ-far from $\mathrm{POLY}_{n,d}$, then the tester rejects with probability at least $\frac{2}{3}$.

Suppose that $\mathrm{dist}(f, \mathrm{POLY}_{n,d}) > \epsilon$. We shall show that $\eta \geq \min\{\frac{1}{2}q^\ell\epsilon, \frac{1}{2(\ell+1)q^{\ell+1}}\}$. Since η is the probability that a single iteration of the algorithm causes f to be rejected, and the algorithm performs $\Theta(1/\eta)$ iterations, the lemma follows. If $\eta \geq \frac{1}{2(\ell+1)q^{\ell+1}}$ then we are done. Hence, assume that $\eta < \frac{1}{2(\ell+1)q^{\ell+1}}$. We shall show that in such a case $\eta \geq \frac{1}{2} \cdot q^\ell \cdot \mathrm{dist}(f,g) > \frac{1}{2} \cdot q^\ell \cdot \epsilon$. To verify this, first note that by Lemma 8 we have that $g \in \mathrm{POLY}_{n,d}$ (since $\eta < \frac{1}{2(\ell+1)q^{\ell+1}}$). Next observe that if f and g disagree on exactly one point in a subspace S of dimension ℓ, then $f_{|S} \notin \mathrm{POLY}_{\ell,d}$. It follows from Lemma 9 and the definition of η that $\eta \geq \zeta$ (where ζ is as defined in Lemma 9). In particular, since by Lemma 4 $\mathrm{dist}(f,g) \leq 2\eta \leq \frac{1}{(\ell+1)q^{\ell+1}}$ where $\ell \geq 1$ and $q \geq 2$, we get that

$$\begin{aligned}
\eta &\geq \frac{1 - q^\ell \cdot \mathrm{dist}(f,g)}{1 + q^\ell \cdot \mathrm{dist}(f,g)} \cdot q^\ell \cdot \mathrm{dist}(f,g) \\
&\geq \frac{1 - \frac{1}{q(\ell+1)}}{1 + \frac{1}{q(\ell+1)}} \cdot q^\ell \cdot \mathrm{dist}(f,g) \\
&\geq \frac{1 - 1/4}{1 + 1/4} \cdot q^\ell \cdot \mathrm{dist}(f,g) \\
&> \frac{1}{2} \cdot q^\ell \cdot \mathrm{dist}(f,g)
\end{aligned}$$

as claimed. □

5. A lower bound.

THEOREM 5. *Every algorithm for testing* $\mathrm{POLY}_{n,d}$ *with distance parameter* ϵ *must perform* $\Omega\left(\max\{\frac{1}{\epsilon}, q^{\ell-1}\}\right)$ *queries when* q *is prime, and* $\Omega\left(\max\{\frac{1}{\epsilon}, q^{\lceil \ell/2 \rceil - 1}\}\right)$ *queries otherwise.*

In order to establish Theorem 5, we consider the relation between polynomials and codes. Specifically, recall that the family $\mathrm{POLY}_{n,d}$ over a field $F = \mathrm{GF}(q) = \mathrm{GF}(p^s)$ corresponds to the GRM code $\mathcal{GRM}_q(d,n)$. Namely, each codeword (having length q^n) is determined by the evaluation of a polynomial in $\mathrm{POLY}_{n,d}$ on all points in the domain F^n. The minimum distance, $\Delta(\mathcal{GRM}_q(d,n))$, of the code is the following (cf. [16]): If $d = r(q-1)+t$, where $0 \le t < q-1$, and r is an integer, then $\Delta(\mathcal{GRM}_q(d,n)) = (q-t)q^{n-r-1}$. The dual code of $\Delta(\mathcal{GRM}(d,n))$ is the GRM code $\mathcal{GRM}_q(n(q-1)-(d+1),n)$, so that it has distance $\Omega(q^{\lceil \frac{d+1}{q-1} \rceil - 1})$. Let us denote the distance of the dual code by $\overline{\Delta}(\mathcal{GRM}_q(d,n)$, and let $\ell = \lceil \frac{d+1}{q-q/p} \rceil$ be as in our previous notation. Hence, if q is prime then $\overline{\Delta}(\mathcal{GRM}_q(d,n)) = \Omega(q^{\ell-1})$, and for nonprime q we can say that $\overline{\Delta}(\mathcal{GRM}_q(d,n)) = \Omega(q^{\lceil \ell/2 \rceil - 1})$.

Theorem 5 follows by applying the theorem below, which is a straightforward generalization of a similar theorem proved in [1] for binary codes. For the sake of completeness we include the proof in the appendix.

THEOREM 6. *Let* $\mathcal{F}$ *be any family of functions* $f : F^n \to F$ *that corresponds to a linear code* $\mathcal{C}$*. Let* $\Delta(\mathcal{C})$ *denote the minimum distance of the code* $\mathcal{C}$ *and let* $\overline{\Delta}(\mathcal{C})$ *denote the minimum distance of the dual code of* $\mathcal{C}$*.*

Every testing algorithm for the family $\mathcal{F}$ *must perform* $\Omega(\overline{\Delta}(\mathcal{C}))$ *queries, and if the distance parameter* ϵ *is at most* $\Delta(\mathcal{C})/(2q^n)$*, then* $\Omega(1/\epsilon)$ *is also a lower bound for the necessary number of queries.*

6. The paper of Jutla et al. [25]. As noted in the introduction, independently from our work, Jutla et al. [25] give a testing algorithm for low-degree polynomials over prime fields. They too provide a characterization of low-degree polynomials (over prime fields) and define their test based on this characterization. As we discuss below, our characterization (in the case of prime fields) is related to the one in [25]. However, our approach, and hence the proofs for the characterizations, are different, and in particular our characterization holds for all fields. Our testing algorithms and their analysis have a similar structure (which follows that of previous low-degree tests), but there are several technical and expositional differences (partly due to our unifying view of low-degree testing). We next discuss how the characterization in [25] relates to ours.

Recall that we show that for $F = \mathrm{GF}(q)$ (where $q = p^s$ and p is prime), a function $f : F^n \to F$ is a polynomial of degree at most d if and only if its restriction to every affine subspace of dimension $\ell = \lceil \frac{d+1}{q-q/p} \rceil$ is a polynomial of degree at most d. In other words, if we consider the unique representation of each such restriction of f as a polynomial over ℓ variables, then all coefficients that correspond to monomials having degree greater than d must be 0. Each such coefficient can be shown to equal a certain linear combination of the values of f in the subspace (see section 2).

The characterization of Jutla et al. for prime fields ($q = p$) is that one particular linear constraint over each subspace must hold. They do not approach the problem as we do (that is, by characterizing low-degree polynomials as functions whose restrictions to lower-dimensional spaces are low-degree polynomials). However, translating their result using our terminology, it can be shown that the linear constraint they consider corresponds to the coefficient of exactly one monomial of degree $d+1$. This

monomial has the following form: $x_1^{q-1} \cdot x_2^{q-1} \cdots x_{\ell-1}^{q-1} \cdot x_\ell^t$, where $1 \le t \le q-1$ and $d+1 = (\ell-1)(q-1)+t$.

In retrospect we observe that our analysis can be slightly extended so as to show that in the case that q is prime then the characterization can be restricted to a single polynomial coefficient. When q is not prime then it is not clear whether the characterization can be restricted in a similar manner.

Appendix. Proofs of Claim 1, Lemma 9, and Theorem 6.

CLAIM 1. *Let $q = p^s$ for a prime number p and an integer s, and let r and t be integers that satisfy $0 < r \le t \le q-1$. If $r = kp^{s-1}$ for some integer k then $\binom{t}{r}$ is not divisible by p.*

Proof. For any positive integer j, the largest power of p that divides $j!$ is

$$\lfloor j/p \rfloor + \lfloor j/p^2 \rfloor + \lfloor j/p^3 \rfloor + \cdots \ .$$

But for $r = kp^{s-1}$, the identity $\lfloor t/p^i \rfloor = \lfloor r/p^i \rfloor + \lfloor (t-r)/p^i \rfloor$ holds. Thus the largest power of p that divides $t!$ is

$$\sum_{i=1}^{\infty} \lfloor t/p^i \rfloor = \sum_{i=1}^{\infty} \left(\lfloor r/p^i \rfloor + \lfloor (t-r)/p^i \rfloor \right) \ .$$

Therefore $t!$ and $r!(t-r)!$ are divisible by exactly the same power of p. ∎

LEMMA 9. *Let $\zeta \stackrel{\text{def}}{=} \frac{1-q^\ell \mathrm{dist}(f,g)}{1+q^\ell \mathrm{dist}(f,g)} \cdot q^\ell \mathrm{dist}(f,g)$. If we uniformly and independently select $y_0, y_1, \ldots, y_\ell \in F^n$ where $y_1, \ldots, y_\ell$ are linearly independent, then the probability that for* exactly *one choice of $b_1, \ldots, b_\ell \in F$, we have that $f(y_0 + \sum_{i=1}^{\ell} b_i \cdot y_i) \neq g(y_0 + \sum_{i=1}^{\ell} b_i \cdot y_i)$ is at least ζ.*

Proof. For each $\beta = \beta_1, \ldots, \beta_\ell, \beta_i \in [q-1]$ let X_β be the indicator random variable whose value is 1 if and only if $f(y_0 + \sum_{i=1}^{\ell} ex(\beta_i) y_i) \neq g(y_0 + \sum_{i=1}^{\ell} ex(\beta_i) y_i)$. Thus $\Pr[X_\beta = 1] = \mathrm{dist}(f,g)$ for every β. It is not difficult to verify that the random variables X_β are pairwise independent. This is true since for any two distinct β^1, β^2, the points $(y_0 + \sum_{i=1}^{\ell} ex(\beta_i^1) y_i)$ and $(y_0 + \sum_{i=1}^{\ell} ex(\beta_i^2) y_i)$ attain each pair of distinct values in F^n with equal probability. It follows that the random variable $X = \sum_\beta X_\beta$, which counts the number of points $v = (y_0 + \sum_{i=1}^{\ell} ex(\beta_i) y_i)$ in which $f(v) \neq g(v)$, has expectation $\mathrm{E}[X] = q^\ell \cdot \mathrm{dist}(f,g)$ and variance $\mathrm{Var}[X] = q^\ell \cdot \mathrm{dist}(f,g) \cdot (1 - \mathrm{dist}(f,g)) \le \mathrm{E}[X]$. Our objective is to lower bound the probability that $X = 1$. We need the well-known fact that for a random variable X that attains nonnegative, integer values,

$$\Pr[X > 0] \ge \frac{\left(\mathrm{E}[X]\right)^2}{\mathrm{E}[X^2]} \ .$$

Indeed, if X attains the value i with probability ν_i for $i > 0$, then, by Cauchy–Schwarz,

$$\begin{aligned} \left(\mathrm{E}[X]\right)^2 = \left(\sum_{i>0} i\nu_i\right)^2 &= \left(\sum_{i>0} i\sqrt{\nu_i}\sqrt{\nu_i}\right)^2 \\ &\le \left(\sum_{i>0} i^2\nu_i\right) \cdot \left(\sum_{i>0} \nu_i\right) \\ &= \mathrm{E}[X^2] \cdot \Pr[X > 0] \ . \end{aligned}$$

In our case, this implies

$$\Pr[X > 0] \geq \frac{\Big(\mathrm{E}[X]\Big)^2}{\mathrm{E}[X^2]} \geq \frac{\Big(\mathrm{E}[X]\Big)^2}{\mathrm{E}[X] + \Big(\mathrm{E}[X]\Big)^2} = \frac{\mathrm{E}[X]}{1 + \mathrm{E}[X]} \ .$$

Therefore

$$\mathrm{E}[X] \geq \Pr[X = 1] + \Big(\frac{\mathrm{E}[X]}{1 + \mathrm{E}[X]} - \Pr[X = 1]\Big) \cdot 2 = \frac{2\mathrm{E}[X]}{1 + \mathrm{E}[X]} - \Pr[X = 1] \ ,$$

implying that

$$\Pr[X = 1] \geq \frac{\mathrm{E}[X] - (\mathrm{E}[X])^2}{1 + \mathrm{E}[X]} \ .$$

Substituting the value of $\mathrm{E}[X]$, the desired result follows. □

THEOREM 6. *Let $\mathcal{F}$ be any family of functions $f : F^n \to F$ that corresponds to a linear code $\mathcal{C}$. Let $\Delta(\mathcal{C})$ denote the minimum distance of the code $\mathcal{C}$ and let $\overline{\Delta}(\mathcal{C})$ denote the minimum distance of the dual code of $\mathcal{C}$.*

Every testing algorithm for the family $\mathcal{F}$ must perform $\Omega(\overline{\Delta}(\mathcal{C}))$ queries, and if the distance parameter ϵ is smaller than $\Delta(\mathcal{C})/(2q^n)$, then $\Omega(1/\epsilon)$ is also a lower bound for the necessary number of queries.

Proof. We start by showing that $\Omega(\overline{\Delta}(\mathcal{C}))$ queries are necessary. A well-known fact from coding theory (see [28, Chap. 1, Thm. 10]) states the following: for every linear code $\mathcal{C}$ whose dual code has distance $\overline{\Delta}(\mathcal{C})$, if we examine a subword having length Δ', where $\Delta' < \overline{\Delta}(\mathcal{C})$, of a uniformly selected codeword in $\mathcal{C}$, then the resulting subword is uniformly distributed in $F^{\Delta'}$. Hence it is not possible to distinguish between a random codeword in $\mathcal{C}$ and a random word in F^n (which with high probability is far from any codeword) using less than $\overline{\Delta}(\mathcal{C})$ queries.

We now turn to the case $\epsilon < \Delta(\mathcal{C})/2q^n$. To prove the lower bound here, we apply, as usual, the Yao principle by defining two distributions, one of positive instances, and the other of negative ones, and then showing that in order to distinguish between those distributions any algorithm must perform $\Omega(1/\epsilon)$ queries. The positive distribution has all its mass at the zero vector $\bar{0} = (0, \ldots, 0)$. To define the negative distribution, partition the set of all coordinates randomly into $t = 1/\epsilon$ nearly equal parts $I_1, \ldots, I_t$ and give weight $1/t$ to each of the characteristic vectors w_i of I_i, $i = 1, \ldots, t$. (Observe that indeed $\bar{0} \in \mathcal{C}$ due to linearity, and $\mathrm{dist}(w_i, \mathcal{C}) = \epsilon$ due to the assumption on the minimum distance of $\mathcal{C}$.) Finally, a random instance is generated by first choosing one of the distributions with probability $1/2$ and then generating a vector according to the chosen distribution.

Consider the two distributions that were defined. Let A be a deterministic testing algorithm with query complexity s (where s is a function of ϵ). We need to show that if A gives an incorrect answer with probability at most $1/3$, it must be that $s > 1/(3\epsilon)$. If A is incorrect on $\bar{0}$ (that is, it does not accept it), then it is already incorrect with probability at least $1/2$. Otherwise A should accept the input if all the s queried bits are 0. Therefore it accepts as well at least $t - s$ (where $t = 1/\epsilon$ is as defined above) of the inputs w_i. This shows that A gives an incorrect answer with probability at least $(t - s)/2t$. For this to be smaller than $1/3$ it must be the case that $s > 1/(3\epsilon)$. □

Acknowledgments. We are greatly indebted to Madhu Sudan who suggested the unifying view for testing polynomials over finite fields that we apply in this work. We would also like to thank Simon Litsyn, Alex Samorodnitsky, and Adam Smith for helpful discussions. Finally, we would like to thank two anonymous reviewers for helpful comments.

EXPONENTIAL DETERMINIZATION FOR ω-AUTOMATA WITH A STRONG FAIRNESS ACCEPTANCE CONDITION*

SHMUEL SAFRA†

Abstract. In [S. Safra, *Proceedings of the 29th IEEE Symposium on Foundations of Computer Science*, 1988, pp. 319–327] an exponential determinization procedure for Büchi automata was shown, yielding tight bounds for decision procedures of some logics (see [A. E. Emerson and C. Jutla, *Proceedings of the 29th IEEE Symposium on Foundations of Computer Science*, 1988, pp. 328–337; Safra (1988); S. Safra and M. Y. Vardi, *Proceedings of the 21st ACM Symposium on Theory of Computing*, 1989, pp. 127–137; and D. Kozen and J. Tiuryn, *Logics of program*, in Handbook of Theoretical Computer Science, Elsevier, Amsterdam, 1990, pp. 789–840]). In Safra and Vardi (1989) the complexity of determinization and complementation of ω-automata was further investigated, leaving as an open question the complexity of the determinization of a single class of ω-automata. For this class of ω-automata with strong fairness as an acceptance condition (*Streett automata*), Safra and Vardi (1989) managed to show an exponential complementation procedure; however, the blow-up of translating these automata—to any of the classes known to admit exponential determinization—is inherently exponential. This might suggest that the blow-up of the determinization of Streett automata is inherently doubly exponential. This paper shows an exponential determinization construction for Streett automata. In fact, the complexity of our construction is roughly the same as the complexity achieved in Safra (1988) for Büchi automata. Moreover, a simple observation extends this upper bound to the complementation problem. Since any ω-automaton that admits exponential determinization can be easily converted into a Streett automaton, we have obtained a single procedure that can be used for all of these conversions. Furthermore, this construction is optimal (up to a constant factor in the exponent) for all of these conversions. Our results imply that Streett automata (with strong fairness as an acceptance condition) can be used instead of Büchi automata (with the weaker acceptance condition) without any loss of efficiency.

Key words. ω-automata, verification, reactive systems

AMS subject classification. 68Q45

DOI. 10.1137/S0097539798332518

1. Introduction.

Finite automata on infinite words (ω-automata), despite their seemingly fantastic definition, have quite an earthly role in the formal analysis of ongoing (reactive) systems. A *reactive system* is one whose goal is to continuously interact with its environment, as opposed to computing a function on an input and terminating. Take, for example, a file editor; it is not computing a function of a preset input, and its execution should not terminate, unless the environment so insists. (Other examples of such systems are control programs of a robot or an unmanned spacecraft.) Suppose one would like to make sure that a reactive system functions properly. For systems that compute functions, we need to verify that the system always terminates and computes the correct value of the function; what would be the reactive system's equivalent?

First, one needs to make sure that every reaction produced by the system is proper (safety), and second, that every anticipated reaction is eventually produced (liveness). In our file editor example, once an editor command is given, it must eventually be

carried out. This demonstrates the notion usually referred to as *weak fairness*:

- Weak fairness: Any continuously enabled action is eventually carried out.

Now suppose we are working on a paper[1] on an operating system that can run several file editors concurrently, but there is only one display on which we can see how the paper will look once printed. So, every now and then, while we continue to work on the paper, we try to display it, but each time there is someone else's paper already on display. The system might be "weakly fair" and yet not display the paper, since this action is not continuously enabled. Still, some might find it unfair if they try again and again to display their file but never get the chance. This demonstrates the stronger notion of fairness usually referred to as *strong fairness*:

- Strong fairness: Any action that is repeatedly enabled is eventually carried out.

Notice a problem here; suppose some action is enabled every now and then, and the computation ends without the action having been carried out. Just by observing a finite computation, how can one distinguish between the two cases (a) the system is not strongly fair, and (b) the system is slow and whoever wanted the action taken eventually gave up. (Decided to print the paper?)

Our solution is to interpret reactive systems over infinite computations; it does not mean we actually run infinite computations,[2] rather that we *analyze the fairness* of the system on infinite computations. On such computations we can distinguish between the case of a slow system and an unfair one, using algorithms that run in *finite* time. The two fairness conditions above look as follows:

- Weak fairness: A computation is unfair if there is an action that is enabled continuously from some point on but is carried out only finitely many times.
- Strong fairness: A computation is unfair if there is an action that is enabled infinitely often but is carried out only finitely many times.

Therefore, our computations are infinite objects (an infinite sequence for linear time, and an infinite tree for branching time), and the formal meaning (semantics) of a system is the set of computations it may produce. The specification of the system is given in some specification language (logic) over these infinite objects. In order to verify that the system functions properly, we check that the set of computations produced by the system is a subset of the computations that meet the specification.

For a complete exposition of the above subjects and related ones, the reader is referred to [HP85, Fra86, MP91].

Finite memory systems. We now restrict our attention to systems that can be described as finite-state machines (at least for the purpose of the formal analysis). It turns out that any reasonable logic for specification in the finite-state case describes a set of computations acceptable by a finite automaton over infinite objects (described below). Moreover, the most efficient decision procedures for these logics are usually obtained by translating a formula in the logic to an automaton and checking emptiness of the language this automaton accepts [VW86]. The most efficient procedures for the problem of model checking (checking that a program meets some specification) are also usually obtained using automata. A finite-state program can be viewed as a finite-state machine, and in order to check that it meets some specification, it is enough to check the *containment* of the language accepted by this finite-state machine in the language accepted by the specification automaton [VW86a].

[1] at the latest possible time to meet the deadline, quite naturally.

[2] if anyone has doubts.

There are two basic automata conversions that come up in these procedures: *complementation* and *determinization*.

This type of procedure was first suggested by Büchi [Büc62] in his original paper introducing ω-automata, in order to show that the validity of S1S (the monadic second order theory of one successor) is decidable. Büchi showed that ω-automata are closed under complementation; however, the blow-up of the complementation procedure he suggested is doubly exponential. McNaughton [McN66] showed that ω-automata can be determinized (into a deterministic automaton with a stronger acceptance condition than the one Büchi suggested). The blow-up of his determinization construction, however, is also doubly exponential. Rabin introduced tree automata and used McNaughton's result to show that these automata are closed under complementation. He could then give a decision procedure for a stronger logic—S2S (the monadic second order theory of many successors).

The decision of these logics is known to be nonelementary [Mey75], and thus there is no hope of achieving a reasonable complexity. However, when considering simpler logics and attempting to obtain more efficient procedures, the blow-up of the above constructions was prohibitive.

Sistla, Vardi, and Wolper [SVW87] showed an exponential complementation procedure for Büchi automata and utilized this result to obtain tight bounds for various logics. The exponential determinization of Büchi automata [Saf88], which also improves on [SVW87], was used [EJ88] to show a tight bound for the complexity of the decision procedure of various logics, which allow quantification over time-paths and thus require translation to tree automata (e.g., CTL*, Δ-PDL, μ-calculus, etc.). An exponential complementation for Streett automata was shown [SV89] and was utilized so as to improve the upper bound for the decision of linear-time logics that are translatable more efficiently to automata with strong fairness as an acceptance condition.

Finite automata over infinite objects. Automata on infinite words (ω-automata) are the same as automata on finite words except that, since a run over a word does not have a final state, the acceptance condition is on the set of states visited infinitely often in the run. The simplest acceptance condition was suggested by Büchi [Büc62], in which some of the states are designated as accepting, and a run is accepting if it visits infinitely many times the accepting set of states.

Muller [Mul63] suggested deterministic ω-automata, with a different acceptance condition, as a means of describing the behavior of nonstabilizing circuits. The acceptance condition he suggested is to specify explicitly all the "good" infinity sets (the *infinity set* of a run ξ is the set of states that occur infinitely many times in ξ). A run is accepting if its infinity set is one of the designated accepting sets. When we consider acceptance conditions based on the infinity set, this is obviously the most expressive condition.

A Rabin acceptance condition is, syntactically, a set of pairs of subsets of the states, $\{(L_i, U_i)\}_i$. A run ξ is accepting if, for one of the pairs i, ξ visits infinitely many times some states in L_i (the "good" states), and only finitely often the states in U_i (the "bad" states).

Streett [Str82] suggested the complementary condition to Rabin's condition, which is syntactically the same: a set of pairs of subsets of the states. A run ξ is accepting according to Streett's condition if, for all pairs i, if the run visits infinitely many times L_i it also visits infinitely many times U_i.

We may write Rabin's condition as $\bigvee_i L_i \wedge \neg U_i$ and Streett's condition as $\bigwedge_i L_i \rightarrow U_i$. Streett's condition corresponds to strong fairness (as defined above) since for each

event e the acceptance condition could contain a pair $\langle L_i, U_i \rangle$, in which L_i is the set of states in which e is enabled and U_i is the set of states in which e is taken (weak fairness can be expressed by Büchi automata).

Previous best results on determinization and complementation. In [Saf88, SV89, Kla91] the complexities of determinization and complementation of different classes of ω-automata were studied, and they were solved in full except for the complexity of determinization of Streett automata. An exponential complementation procedure was shown for Streett automata in [SV89] and with a better exponent in [Kla91]. It was shown [SV89] that the blow-up of the translation of Streett automata to any of the classes of ω-automata that were known to admit exponential determinization is inherently exponential.

Our results. Our main result (Theorem 1) is a new determinization construction for Streett automata. Given a Streett automaton with n state and h accepting pairs, we construct a deterministic Rabin automaton with $2^{\mathrm{O}(nh \log nh)}$ states and nh accepting pairs. Using the small number of accepting pairs in the determinized Rabin automaton, and a simple complementation construction for deterministic Rabin automata, which is exponential only in the number of accepting pairs (Lemma 3), we show that nondeterministic Streett automata can be converted into deterministic Streett automata with the same (exponential) blow-up (Corollary 4). Since the same deterministic automaton interpreted as a Streett or Rabin automaton accepts two complementary languages, this implies that Streett automata can be simultaneously complemented and determinized (codeterminized) into both Streett or Rabin automata with only an exponential blow-up.

The exact complexity of the complementation procedures obtained in this way matches the complexity of the complementation procedure of [Kla91].

The results reported herein were first published as an extended abstract [Saf92]. It is worthwhile noting that an independent work reported in [Wa93] may share some of these methods in a somewhat different setting.

2. Basic definitions. An *ω-automaton* over an *alphabet* Σ, $\mathcal{A} = \langle \Sigma, Q, q_0, \delta, C \rangle$, consists of a finite set of *states* Q, an *initial state* $q_0 \in Q$, a *transition relation* $\delta \colon Q \times \Sigma \to 2^Q$, and an *acceptance condition* C. We extend δ to sets of states and sequences of letters in the usual way.

A sequence of states, $\xi \in Q^\omega$, is an *$\mathcal{A}$-run* over a word $\sigma \in \Sigma^\omega$ if $\xi_0 = q_0$ and, for every i, ξ_{i+1} is a σ_i successor of ξ_i, i.e., $\xi_{i+1} \in \delta(\xi_i, \sigma_i)$.

The *infinity set* of a sequence of letters (or states) σ, $\inf(\sigma)$, is the set of letters that appear infinitely many times in σ (i.e., $\inf(\sigma) = \{a \text{ s.t. } |\{i \text{ s.t. } \sigma_i = a\}| = \infty\}$).

An infinite word $\sigma \in \Sigma^\omega$ is *accepted* by an automaton $\mathcal{A}$ if there exists an accepting $\mathcal{A}$-run over σ. The *language* accepted by an automaton is the set of all words accepted by it.

An automaton is *deterministic* if for all $a \in \Sigma$, $q \in Q$, $|\delta(q, a)| = 1$, i.e., δ is a function into Q. Obviously, any word has exactly one run in a deterministic automaton.

We define classes of automata corresponding to the different acceptance conditions. We write N for nondeterministic and D for deterministic, and B, M, R, S for Büchi, Muller, Rabin, and Streett, respectively.

The acceptance conditions are summarized in the following table:

	Syntax	Semantics
B	$F \subseteq Q$	$\inf(\xi) \cap F \neq \phi$
M	$\mathbf{F} \subseteq 2^Q$	$\inf(\xi) \in \mathbf{F}$
R	$\bigvee_i L_i \wedge \neg U_i$	$\exists i\colon \ \inf(\xi) \cap L_i \neq \phi \ \wedge$ $\inf(\xi) \cap U_i = \phi$
S	$\bigwedge_i L_i \rightarrow U_i$	$\forall i\colon \ \inf(\xi) \cap L_i \neq \phi \ \rightarrow$ $\inf(\xi) \cap U_i \neq \phi$

Concerning the *size* of an automaton, we denote both the number of states and the size of the acceptance condition (except for Büchi automata, where the acceptance condition may be neglected). For example, our main result can be written as $\mathrm{NS}(n,h) \rightarrow \mathrm{DR}(2^{\mathrm{O}(nh\log(nh))}, nh)$.

3. Determinization of NS.

THEOREM 1. $\mathrm{NS}(n,h) \rightarrow \mathrm{DR}(2^{O(nh\log nh)}, nh)$*; i.e., for any* NS *automaton* $\mathcal{A} = \langle \Sigma, Q, q_0, \delta, \bigwedge_{0<i\leq h} L_i \rightarrow U_i\rangle$ *with* n *states and* h *acceptance pairs, there exists an equivalent* DR *automaton* $\mathcal{D} = \langle \Sigma, \widetilde{Q}, \widetilde{q}_0, \widetilde{\delta}, \bigvee_{0<i\leq nh} G_i \wedge \neg B_i\rangle$*, with* $2^{\mathrm{O}(nh\log(nh))}$ *states and* nh *acceptance pairs.*

Proof of Theorem 1. Throughout this proof we denote by H the set of indexes $[1..h]$.

Intuition. It is easier to look at the deterministic Rabin automaton $\mathcal{D}$ as a program with bounded memory and some infinitary acceptance condition. This program reads the input one letter at a time and changes its memory accordingly. The corresponding finite ω-automaton has a different state for each of the possible states of the program's memory. The infinite string is accepted if the set of memory states visited infinitely often satisfies the acceptance condition. We now describe $\mathcal{D}$ informally.

An accepting $\mathcal{A}$-run ξ has a *witness set* $J \subseteq H$ for which ξ visits infinitely many times each U_j for $j \in J$ and only finitely many time any L_j for $j \notin J$.

Given a witness set J, one can construct a small nondeterministic Büchi automaton that accepts all strings for which there is an accepting run ξ with witness set J. This automaton consists of two parts; the first one is a copy of $\mathcal{A}$ (without the acceptance condition). Each run at each point can nondeterministically guess that no state in any of the sets L_j, for $j \notin J$, will be visited from now on, and choose to move to the second part. The second part consists of $|J|+1$ copies of $\mathcal{A}$, in which the run can move to the next copy only after visiting the set U_j corresponding to the current copy. A run is accepting if it cycles infinitely through all the copies. All states $q \in L_j$ for $j \notin J$ are removed from all the copies of $\mathcal{A}$ in the second part. Hence an accepting run visits only finitely many times copies of $q \in L_j$ for $j \notin J$, and infinitely many times copies of $q \in U_j$ for each $j \in J$.

This automaton can be determinized with only an exponential blow-up [Saf88]. However, since the number of possible witness sets is exponential, a construction of an automaton that deterministically considers all the witness sets results in a doubly exponential blow-up.

The determinization construction suggested here may be viewed as a deterministic dynamic process that at each point in time considers only a polynomial number of witness sets.

The deterministic automaton $\mathcal{D}$, while maintaining the subset of $\mathcal{A}$-states reached by reading the prefix of the input, starts by assuming that the witness set of the accepting run (if one exists) is H, i.e., $\mathcal{D}$ tries, during each run, to cycle through all the U_j's. Whenever a run is waiting to visit some U_{j_1}, $\mathcal{D}$, assuming (the worst) that the run will never again visit U_{j_1}, spawns off a parallel construction, with possibly a

smaller subset of the $\mathcal{A}$-states, and with the witness set $J' = J \setminus \{j_1\}$ (disallowing any state $q \in L_{j_1}$ in the subprocess). Any run that eventually visits U_{j_1} is advanced to the next index. In the subprocess, if again a run is waiting for U_{j_2}, $\mathcal{D}$ branches off recursively with a smaller witness set. An important observation is that, for each such parallel process and for each state that appears in the subset maintained by the process, one needs to consider only one index—the most advanced one; hence the subset of the $\mathcal{A}$-states maintained by the process is partitioned among the different indexes. In the good case, in which eventually all $\mathcal{A}$-states have runs that completed a cycle, all the subprocesses are killed and the process is restarted. If any of these processes is restarted infinitely many times, $\mathcal{D}$ accepts.

However, suppose that some runs completed a cycle, but some other runs are stuck waiting for some U_{j_1}. The latter runs prevent the former runs from restarting the process. Therefore, for all runs that completed a cycle through U_j for every $j \in J$, $\mathcal{D}$ spawns off a parallel process with a smaller set of $\mathcal{A}$-states (this is similar to the determinization construction of [Saf88]). In addition (again following [Saf88]) $\mathcal{D}$ maintains an order among the subprocesses according to which subprocess was spawned first. Whenever a state appears in more than one subprocess (with the same index; otherwise, as mentioned above, the more advanced index takes priority) it is removed from all but the one spawned first.

Since for each state in each process one needs to consider only one U_j it is waiting for, the number of witness sets we need to try in parallel at any given time is polynomial.

We now return to the formal proof of Theorem 1. We start with some definitions we need for the construction of the set $\widetilde{Q}$ of states of $\mathcal{D}$.

Let $V = [1..2nh]$ be the set of *names* (these are used by $\mathcal{D}$ to preserve the identity of different parallel applications of some basic construction).

For $S \subseteq Q$, let an *S-atom* be $\langle v, S\rangle$, where $v \in V$.

For $S \subseteq Q$ and $J \subseteq H$, we give a recursive definition of an *(S, J)-decomposition*:

1. An S-atom is an (S, J)-decomposition.
2. Let $v \in V$.
   Let $S_1, \ldots, S_l$ be a partition of S (i.e., $\bigcup_i S_i = S$ and for any $i \neq j \in [1..l]$, $S_i \cap S_j = \phi$).
   Let $j_1, \ldots, j_l \in J \cup \{0\}$, where at least one of the j's is nonzero. Denote by J_i, for each $i \in [1..l]$, the set $J \setminus \{j_i\}$.
   Let $\Pi_1, \ldots, \Pi_l$ be such that for each $i \in [1..l]$, Π_i is an (S_i, J_i)-decomposition.
   Then $\langle v, (\Pi_1, j_1), \ldots, (\Pi_l, j_l)\rangle$ is an (S, J)-decomposition.

For an (S, J)-decomposition we refer to the decompositions used in the recursion of this definition as *subdecompositions*.

An (S, J)-decomposition has a *good name* if the names assigned to each of the subdecompositions are all different. We consider, from now on, only decompositions with a good name.

Note that the recursion in the definition of an (S, J)-decomposition is finite, since not all the indexes j can be 0, and thus either the set of states S or the set of indexes J decreases each level down the recursion.

We can even give a more specific bound on the size and number of decompositions, as follows.

LEMMA 2. *The number of subdecompositions in an (S, H)-decomposition ($S \subseteq Q$) is at most nh, and the total number of (S, H)-decompositions ($S \subseteq Q$) is at most $2^{O(nh \log(nh))}$.*

Proof. For an (S, J)-decomposition Π we say that a pair (q, j), for $q \in Q$, $j \in H$, is

special for a (S', J')-subdecomposition Π' of Π if the following three conditions hold:

- $q \in S'$;
- the index set of the immediate subdecomposition of Π' that contains q is a strict subset of J' (i.e., this subdecomposition is not indexed by 0);
- if a subdecomposition has index set $J'' \neq J'$ such that $J' \subseteq J''$, then $j \in J''$.

Now, each pair (q, j) is special for a subdecomposition, and each subdecomposition Π' has a pair (q, j) which is special for it. Therefore, Π can be represented as a partial function from the set of pairs (q, j) to the set of names V. □

The construction of $\mathcal{D}$.

The set of states. $\widetilde{Q}$ is the set of all (S, H)-decompositions for a subset of the states $S \subseteq Q$.

The initial state. $\widetilde{q}_0 = \langle 1, \{q_0\}\rangle$, i.e., the $\{q_0\}$-atom with 1 (arbitrarily) as its name.

The transition function. For each $\mathcal{D}$-state $\widetilde{q} \in \widetilde{Q}$ and a letter $a \in \Sigma$, $\widetilde{\delta}(\widetilde{q}, a)$ is the result of applying the following sequence of operations to $\widetilde{q}$:

1. Replace each atom $\langle v, S\rangle$ in $\widetilde{q}$ by $\langle v, \delta(S, a)\rangle$.
   This results in some structure that may violate the requirement, in the definition of an (S, J)-decomposition above, that the sets $S_1, \ldots, S_l$ be disjoint. At the end of the following several steps, this requirement is restored.
2. For any nonatomic (S, J)-subdecomposition in $\widetilde{q}$, let $j_1, \ldots, j_l$ be the indexes as in the definition of a decomposition above, and let $S'_1, \ldots, S'_l$ be its sets of $\mathcal{A}$-states after step 1. For each $\mathcal{A}$-state q and i such that $q \in S'_i$,
   - if $q \in L_{j_i}$, then remove q from S'_i and append to the list of subdecompositions an atom $\langle v, \{q\}\rangle$ with index $j = \max\{J\}$;
   - otherwise, if $q \in U_{j_i}$, then append an atom $\langle v, \{q\}\rangle$ with index $j = \max\{(J \cup \{0\}) \cap \{0, \ldots, j_i - 1\}\}$.

   In both cases $v \in V$ is an unused name in $\widetilde{q}$, and each new atom is assigned a different name. This is possible since, by Lemma 2, only nh out of $2nh$ names in V are used in $\widetilde{q}$.
   For atomic (S, J)-subdecompositions, we follow the same procedure, assuming S is a one-item list with the maximal index in J as its index.
3. For a nonatomic subdecomposition in $\widetilde{q}$ for which, after the previous steps, an $\mathcal{A}$-state q appears in a set S'_i with index j and a set $S'_{i'}$ with index $j' > j$, remove q from $S'_{i'}$.
4. For a nonatomic subdecomposition in $\widetilde{q}$ for which, after the previous steps, an $\mathcal{A}$-state q appears in a set S'_i and a set $S'_{i'}$, where $i' > i$, remove q from $S'_{i'}$.
5. Remove any empty set from any list.
6. Replace any nonatomic (S, J)-subdecomposition whose name is v, in which after the previous steps all indexes are 0, by an atom $\langle v, S\rangle$.

The acceptance condition. For each name $v \in V$, let G_v be the set of states $\widetilde{q}$ in which v is the name of an atom, and let B_v be the set of states $\widetilde{q}$ in which v is not used in the decomposition.

Correctness. $L(\mathcal{D}) \subseteq L(\mathcal{A})$: Given that there is a name v, which in the $\mathcal{D}$-run ξ over a word σ is used (in the decompositions ξ_i) continuously from some point on, and is the name of an atom infinitely many times, we prove that there is an accepting $\mathcal{A}$-run over σ.

For two positions $0 \leq l < k$, we denote by $\sigma[l, k)$ the finite word $\sigma_l, \ldots, \sigma_{k-1}$.

Let l be the largest such that v is not used in the decomposition ξ_l, and let S_i, for $i > l$, be the set such that v is the name of an (S_i, J)-subdecomposition of ξ_i. Let

$l_1 < l_2 < \cdots$ (where $l_1 > l$) be the positions at which v is the name of an atom in ξ_{l_k}. By the construction, $S_{l_1} \subseteq \delta(q_0, \sigma[1, l_1))$. The condition to make a subdecomposition become an atom (step 6) and the conditions to create new subdecompositions and maintain them (steps 2 and 1) ensure that for each $q \in S_{l_{k+1}}$, for $k > 0$, there exists some $q' \in S_{l_k}$, as well as an $\mathcal{A}$-run over $\sigma[l_k, l_{k+1})$ which leads from q' to q while visiting all U_j for $j \in J$ and no L_j for $j \notin J$.

Intending to use König's lemma, we construct a tree whose nodes are all the pairs of the form (q, k) for $q \in S_{l_k}$. As the parent of a node $(q, k+1)$ we pick one of the pairs (q', k) such that $q' \in S_{l_k}$ and there exists an $\mathcal{A}$-run from q' to q, as described above. The root of the tree is $(q_0, 0)$.

By König's lemma, since there are infinitely many pairs, and the number of pairs at each level of the tree is bounded, there is an infinite path, $(q_0, 0), (q_1, 1), \ldots$, in the tree. By the construction of this tree, for each $k > 0$ there is an $\mathcal{A}$-run, as described above, from q_k to q_{k+1}, over $\sigma[l_k, l_{k+1})$. The infinite concatenation of these segments gives an $\mathcal{A}$-run over σ which visits each $\mathcal{A}$-state in U_j for $j \in J$ infinitely many times, and visits any state in L_j for $j \notin J$ only at the first segment. This $\mathcal{A}$-run is accepting.

$L(\mathcal{A}) \subseteq L(\mathcal{D})$: Given that, for a string σ, there is an accepting $\mathcal{A}$-run, ξ, we prove that there is a name v which in the $\mathcal{D}$-run over σ is used continuously from some point on and is the name of an atom infinitely many times.

Let l be the length of the finitary prefix of ξ; i.e., every state ξ_k for $k > l$ appears infinitely many times in ξ. Let the ith state $\widetilde{q}_i$ of the $\widetilde{\mathcal{D}}$-run over σ be an (S_i, H)-decomposition; then it must be that $\xi_i \in S_i$. Therefore, S_i is never empty and its name v_1 remains fixed in all $\widetilde{q}_i$. If $\widetilde{q}_i$ becomes an atom infinitely many times, we are done. Otherwise, let i_1 be the largest such that $\widetilde{q}_i$ is an atom. For $i > i_1$, as i increases, the $\mathcal{A}$-state ξ_i appears in subdecompositions with monotonically nonincreasing index, and thus its index is eventually fixed. Thereafter, ξ_i can move only closer to the beginning of the sequence of immediate subdecompositions. Hence, there is an i'_1 such that for all $i > i'_1$, ξ_i appears in a subdecomposition with a fixed name v_2. We can now repeat the argument and show that if v_2 is not a name of an atom infinitely many times, then eventually the state of ξ appears one level down in the decomposition. Since the depth of the decomposition is finite, there must be a subdecomposition which becomes an atom infinitely many times.

This completes the proof of our main theorem. □

4. Complementation of DR. In order to see how to codeterminize (construct a deterministic automaton that accepts the complement) Streett automata, we need the following lemma.[3]

LEMMA 3. $\mathrm{DS}(n, h) \to \mathrm{DR}(n \cdot 2^{h \log h}, h + 1)$*; i.e., for any deterministic Streett automaton with* n *states and* h *accepting pairs, there exists an equivalent deterministic Rabin automaton with* $n \cdot 2^{h \log h}$ *states and* $h + 1$ *accepting pairs.*

One should comment here that one can quite easily complement such automata while leaving the set of states fixed, translating the acceptance condition from Rabin's to Streett's. Such a translation, however, would incur an exponential blow-up in the size of the acceptance condition. The above lemma is useful when applying it to the main theorem, as the size of the acceptance condition remains polynomial in the size of the original automaton, while the number of states becomes exponential.

Proof. We show an explicit construction, given a DS automaton, $\mathcal{D} = \langle \Sigma, Q, q_0, \delta,$

[3]This lemma appears in [Saf88] but only in the journal version and is repeated here for the 21st century reader.

$\bigwedge_{1\le i\le h} L_i \to U_i\rangle$, of a DR automaton, $\widetilde{\mathcal{D}} = \langle \Sigma, \widetilde{Q}, \widetilde{q}_0, \widetilde{\delta}, \bigvee_{1\le i\le h+1} \neg\widetilde{L}_i \wedge \widetilde{U}_i\rangle$.

Intuition. Again let us think of the automaton $\widetilde{\mathcal{D}}$ as a program with bounded memory; the states of $\widetilde{\mathcal{D}}$ will be all possible data states that this program's memory can be in.

$\widetilde{\mathcal{D}}$ maintains, aside from the state $\mathcal{D}$ reaches after reading the prefix of the input, a permutation of the set of indexes $[1..h]$. Whenever a state in some U_j is visited, the index j is moved to the end of the permutation (if several are visited, all of their indexes are moved to the end with no particular order). Hence, for every accepting run, let J be its witness set and let $i = h - |J|$; then eventually the first i elements of the permutation are fixed, and for each index j in the suffix of the permutation, U_j is visited infinitely many times. The Rabin acceptance condition contains, for each $i \in [0..h]$, a pair in which the "bad" set contains all states in which some L_j for j in the first i elements in the permutation is visited, and the "good" set contains all states in which U_j is visited for j being the $(i+1)$th element in the permutation.

We now give the formal proof of the lemma.

The construction. The states of $\widetilde{\mathcal{D}}, \widetilde{Q}$ have the form of a tuple, (q, π, r, g), where $q \in Q$, π is a permutation of $[1..h]$, and $r, g \in [1..h+1]$. The initial state $\widetilde{q}_0 = (q_0, \langle 1, \ldots, h\rangle, h+1, h+1)$.

Consider a state $\widetilde{q} = (q, \pi, r, g)$, where $\pi = \langle i_1, \ldots, i_h\rangle$. For a letter $a \in \Sigma$ define $\widetilde{\delta}(\widetilde{q}, a)$ to be the state $\widetilde{q}' = (q', \pi', r', g')$ as follows:

- $q' = \delta(q, a)$.
- g' is the minimal index i such that $q' \in U_{j_i}$, if it exists, and otherwise $g' = h+1$.
- r' is the minimal index i such that $q' \in L_{j_i}$, if it exists, and otherwise $r' = h+1$.
- $\pi' = \langle j_1, \ldots, j_{g'-1}, j_{g'+1}, \ldots, j_h, j_{g'}\rangle$ if $g' \le h$; otherwise, $\pi' = \pi$.

For i, $1 \le i \le h+1$, $\widetilde{L}_i$ consists of all the states $\widetilde{q}$ in which $r < i$, and $\widetilde{U}_i$ consists of all the states $\widetilde{q}$ in which $g = i$.

Note that after reading a finite prefix of the input, there is a part to the left of π which is fixed from then on, and that contains all the indexes j such that U_j is visited only finitely many times. If that prefix is of length i, then from then on $g > i$.

$L(\widetilde{\mathcal{D}}) \subseteq L(\mathcal{D})$: Assume that for some i, $r \ge i$ from some point on, and $g = i$ infinitely many times. Since $g = i$ infinitely many times, for every j, if U_j is visited only finitely many times, eventually j is placed in π with an index smaller than i ($j = j_k$ for $k < i$), and by the construction, from then on, L_j is never visited.

$L(\mathcal{D}) \subseteq L(\widetilde{\mathcal{D}})$: Assume there is an accepting $\mathcal{D}$-run; then there exists a maximal set $J \subseteq [1..h]$ such that for $k \in J$, U_{j_k} is visited infinitely many times, and for $k \notin J$, neither L_{j_k} nor U_{j_k} is visited from some point on. There exists a further point, after which $[1..h] \setminus J$ occupies the leftmost positions in π, and none of its indexes changes its place. Let $i = h - |J|$. Obviously, $r \ge j$ beyond this point. We claim that $g = i$ infinitely many times. At any point, let $j_i = k$. Since the run visits U_k infinitely many times, on the next visit to U_k, g will be i.

Complexity. The number of states is $n \cdot h! \cdot (h+1)^2 < n \cdot 2^{h \log h}$ (for $h > 5$). ∎

Since in their deterministic versions the same automaton interpreted as a Rabin automaton and as a Streett automaton accept two complementary languages, we can conclude the following.

COROLLARY 4. $\overline{\mathrm{NS}(n,h)} \to \mathrm{DR}(2^{\mathrm{O}(nh\log(nh))}, nh+1)$. ∎

Hence, NS can be translated to DS with this complexity.

5. Complementation of Streett tree automata. Rabin [Rab69, Rab70] introduced automata on infinite trees. The input of such an automaton is an infinite binary tree, whose nodes are labeled by letters from some finite alphabet Σ, $T\colon \{0,1\}^* \to \Sigma$. A Σ-tree automaton, $\mathcal{T} = \langle \Sigma, Q, q_0, \delta, C\rangle$, is similar to an ω-automaton except that the transition function specifies, for a state $q \in Q$ and a letter $a \in \Sigma$, a set of pairs of states containing both a left successor state q_l and a right successor state q_r (i.e., $\delta\colon Q \times \Sigma \to 2^{Q\times Q}$). A $\mathcal{T}$-run is a Q-tree, $\Gamma\colon \{0,1\}^* \to Q$, in which the root node is q_0, and all the nodes satisfy δ, i.e., for each node $p \in \{0,1\}^*$, $(\Gamma(p0), \Gamma(p1)) \in \delta(\Gamma(p), T(p))$. The acceptance condition C is any ω-condition, such as those of Büchi, Rabin, Muller, or Streett. A $\mathcal{T}$-run Γ is defined to be accepting if the infinity set of *every* infinite path in Γ satisfies C.

Given a tree automaton $\mathcal{A}$, the complementary tree automaton $\bar{\mathcal{A}}$ may be viewed as supplying a proof, given some input tree, that every nondeterministic $\mathcal{A}$-run has a path that does not satisfy $\mathcal{A}$'s acceptance condition. Following the procedure of Gurevich and Harrington [GH82] the proof is supplied by a finite memory strategy. A finite memory strategy is one that can be represented by a set of finite tables, for each node in the tree, giving for each state and some finite information about the history of the run so far either a left direction or a right direction. Such a strategy serves as a proof that the input tree is not accepted by $\mathcal{A}$ if, for any choice of nondeterministic moves, and following the direction the strategy supplies for each move, the resulting infinite sequence of states is not accepted according to $\mathcal{A}$'s acceptance condition.

Using the techniques of [EJ91] it can be shown [Jutla] that the complement of a Streett tree automaton has a memoryless strategy; i.e., $\bar{\mathcal{A}}$, for each node in the input tree, needs to guess a table showing for each *state* (i.e., no information at all on the history of the run) the direction to go for a nonaccepting path. Using the exponential determinization for Streett automata shown here this implies an exponential complementation procedure for Streett tree automata. A different proof for this theorem appeared first in [Kla92].

Discussion. This paper showed that ω-automata with a strong fairness acceptance condition can replace Büchi automata in all applications without loss of efficiency. This should have further applications than those shown here, in the formal analysis of finite-state systems, and, in general, for a better understanding of the notion of fairness.

The main result of this paper has applications with regards to the complementation of tree automata: Streett tree automata were shown to have exponential complementation construction [Kla92]; the results reported herein imply a simple such exponential complementation procedure for these automata. The main open problem left in this area is the complexity of complementation of Rabin tree automata; is it doubly exponential, or can one show an upper bound similar to the one for Streett tree automata?

Acknowledgments. I would like to thank Moshe Vardi and Amir Pnueli for many most insightful discussions on this problem, and the unnamed referees for most constructive comments.

COMPUTING MAXIMALLY SEPARATED SETS IN THE PLANE*

PANKAJ K. AGARWAL†, MARK OVERMARS‡, AND MICHA SHARIR§

Abstract. Let S be a set of n points in $\mathbb{R}^2$. Given an integer $1 \le k \le n$, we wish to find a *maximally separated subset* $I \subseteq S$ of size k; this is a subset for which the minimum among the $\binom{k}{2}$ pairwise distances between its points is as large as possible. The decision problem associated with this problem is to determine whether there exists $I \subseteq S$, $|I| = k$, so that all $\binom{k}{2}$ pairwise distances in I are at least 2. This problem can also be formulated in terms of disk-intersection graphs: Let D be the set of unit disks centered at the points of S. The *disk-intersection* graph G of D has as edges all pairs of disks with nonempty intersection. Any set I with the above properties is then the set of centers of disks that form an independent set in the graph G. This problem is known to be NP-complete if k is part of the input. In this paper we first present a linear-time ε-approximation algorithm for any constant k. Next we give exact algorithms for the cases $k = 3$ and $k = 4$ that run in time $O(n^{4/3}\text{polylog}(n))$. We also present a simpler $n^{O(\sqrt{k})}$-time exact algorithm (as compared with the recent algorithm in [J. Alber and J. Fiala, *J. Algorithms*, 52 (2004), pp. 134–151]) for arbitrary values of k.

1. Introduction.

Let S be a set of n points in the plane. We are interested in finding a small subset I of S such that all the pairwise distances between points in I are large. To be more precise, let I be a subset of S of cardinality k, for $1 \le k \le n$. We define the *separation distance* $d_{\text{sep}}(I)$ to be the minimum among the $\binom{k}{2}$ pairwise distances between its k points. We call I *δ-separated* if $d_{\text{sep}}(I) \ge \delta$. We call I a *maximally separated* subset of S if $d_{\text{sep}}(I) \ge d_{\text{sep}}(I')$ for all subsets $I' \subseteq S$ of size k. Let $d^k_{\text{sep}}(S) = \max_{I \subseteq S,\ |I|=k} d_{\text{sep}}(I)$.

In this paper we study algorithms for computing such maximally separated subsets. We consider small (constant) values of k, but we also address the general case. For the case $k = 2$ the problem is equivalent to finding a diametral pair of S and thus can be solved (exactly) in $O(n \log n)$ time [10], and can be ε-approximated in linear time (see, e.g., [1]). For larger k, the problem becomes considerably more complicated, and is known to be NP-complete if k is part of the input [9].

Finding small well-separated subsets is important in certain pattern-matching problems, where the points in the subset form a representation of the total set of points. For example, Vleugels and Veltkamp [23] describe a method for fast indexing of multimedia databases using so-called *vantage objects*. These vantage objects are points in the feature space for the matching problem. It has been observed that, for the application at hand, the chosen vantage objects best be well-separated.

The decision problem associated with the problem of computing a maximally separated subset of size k calls for determining whether a δ-separated subset I of size k exists for a given $\delta > 0$. This problem can also be formulated in terms of disk-intersection graphs: Let D be the set of disks of radius $\delta/2$ centered at the points of S. The *disk-intersection* graph G of D has the disks as nodes and two disks are connected by an edge if they intersect. Clearly, a δ-separated subset I is the set of centers of an independent set in G (and vice versa). So the decision problem is equivalent to the problem of finding an independent set of size k in the disk-intersection graph G. Recently, the problem of computing the maximum independent set in intersection graphs has attracted considerable attention because of its application in geographic information systems (GIS); see [2, 11, 12] and references therein.

Related work. The problem of computing an independent set in a graph is one of the earliest problems known to be NP-complete [13]. In fact, for a general graph with n vertices, there cannot be a polynomial-time algorithm with approximation ratio better than $n^{1-\varepsilon}$, for any $\varepsilon > 0$, unless $NP = ZPP$ [15]. The best known polynomial-time algorithm finds an independent set of size $\Omega((\kappa \log^2 n)/n)$, where κ is the size of the maximum independent set in the graph [6]. However, better approximation algorithms are known for intersection graphs of geometric objects. The maximum independent set in the intersection graph of intervals on a line can be computed in polynomial time, but the problem remains NP-complete for intersection graphs of orthogonal segments, unit disks, and unit squares [9]. Still, ε-approximation algorithms have been proposed for intersection graphs of unit disks, unit squares, arbitrary disks, and fat objects [7, 9, 11, 17, 19, 20, 22], and an $O(\log n)$-approximation algorithm is known for intersection graphs of rectangles [2].

Little is known about computing maximally separated sets. Formann and Wagner [12] developed a 2-approximation algorithm under the L_∞-metric. Alber and Fiala [5] present an algorithm that computes, in time $n^{O(\sqrt{k})}$, an independent set of cardinality k in the intersection graph of a set of disks. Their algorithm, however, is rather complicated, and they do not consider cases involving small values of k. Moreover, since they compute all pairwise distances between input points, their algorithm takes $\Omega(n^2)$ time even for small values of k.

Our results. In this paper we consider both the general problem and special instances of it that involve small values of k, and develop exact and approximation algorithms for these problems. The paper contains four main results:

(i) For any constant k, we present in Section 2 a simple, linear-time algorithm that returns a subset I of size k such that $d_{\text{sep}}(I) \geq (1-\varepsilon)d^k_{\text{sep}}(S)$. Such an approximation algorithm is suitable for the pattern-matching application mentioned above.

(ii, iii) We present in Sections 3 and 4 $O(n^{4/3}\text{polylog}(n))$-time algorithms for computing (exactly) maximally separated subsets of size 3 and 4, respectively.

(iv) We also present, in Section 5, a simpler $n^{O(\sqrt{k})}$-time exact algorithm (as compared with the algorithm in [5]) for arbitrary values of k.

2. An ε-approximation algorithm. In this section we show that, for any constant k and for any constant $0 < \varepsilon < 1$, we can find in linear time a subset I of S of cardinality k such that $d_{\text{sep}}(I) \geq (1-\varepsilon)d^k_{\text{sep}}(S)$. The running time is exponential in k. We refer to such an I as an *ε-approximation* of the optimal solution.

As a warm-up exercise let us consider the case $k = 2$. We want to find an ε-approximation of the diameter of the set S in linear time. This is an already solved problem (see, e.g., [1]), but we sketch a solution (a) for the sake of completeness, and (b) to prepare for tackling the general case $k \geq 3$.

Let B be the axis-parallel bounding box of S. Let w be the width of B and h its height, and let us assume, without loss of generality, that $w \geq h$. Clearly, the diameter d lies between w and $\sqrt{2}w$. Choose $\delta = \varepsilon w/2\sqrt{2}$ and divide the box B into $O\left(1/\varepsilon^2\right)$ squares of size $\delta \times \delta$. In each nonempty square τ we pick a single point from $\tau \cap S$ and retain only the highest and lowest point in each row or column of the grid. So we end up with a subset S' of S with $O(1/\varepsilon)$ points. We compute the diameter d' of S' exactly, which takes $O((1/\varepsilon)\log(1/\varepsilon)) = O(1)$ time. Now it is easy to see that the actual diameter d satisfies

$$d \leq d' + 2\sqrt{2}\delta.$$

So

$$d' \geq d - 2\sqrt{2}\delta \geq d - \varepsilon w \geq (1-\varepsilon)d,$$

since $d \geq w$. Hence the diameter of the set S' is an ε-approximation for the diameter of S. As computing the bounding box and the set S' takes $O(n)$ time, this procedure computes an ε-approximate diameter of S in $O(n + (1/\varepsilon)\log(1/\varepsilon))$ time.

Let us next assume that $k \geq 3$. Our algorithm uses recursion on k. As above, we compute the smallest axis-parallel bounding box B of S, denote its width and height as w and h, respectively, and assume that $w \geq h$.

We first consider the case in which $d^k_{\text{sep}}(S) \leq w/(k+1)$. (Note that this case cannot arise for $k = 2$.) We subdivide the box B into $k+1$ vertical strips $s_0, \ldots, s_k$, each of width $w/(k+1)$, and set $S_i := S \cap s_i$, for $i = 0, \ldots, k$. Any solution will use points from at most k of these $k+1$ strips. Therefore, for each strip s_i, we compute an ε-approximation of a maximally separated set in $S \setminus S_i$. The best among those $k+1$ solutions is the answer we are looking for.

For each $i = 0, \ldots, k$, we process $S \setminus S_i$ as follows. A crucial observation is that, for $1 \leq i \leq k-1$, we may assume that the optimal solution uses points that *lie on both sides* of s_i. Indeed, if an optimal solution I consists only of points that lie, say, to the right of s_i, replace I by $I' \cup \{p_L\}$, where p_L is the leftmost point of P (which lies on the left edge of B), and I' is an optimal solution with $k-1$ points for the subset S_R of S that lies to the right of s_i. Since $d^k_{\text{sep}}(S) \leq w/(k+1)$, it follows that the separation of the new solution, which does have points on both sides of s_i, is at least as large as that of $d_{\text{sep}}(I)$. The same argument works for $i = 0$ and for $i = k$ (in the latter case we use the rightmost point p_R of S instead of p_L). As is easily seen, these observations also carry over to ε-approximations of the optimal solution.

Hence, for $i = 0$ and $i = k$, we invoke the procedure recursively for finding an ε-approximate solution with $k-1$ points for the set $S \setminus S_i$, and then add to the solution the leftmost point of S (for $i = 0$) or the rightmost point (for $i = k$).

Consider then the case $1 \leq i \leq k-1$. Put $S_L := \bigcup_{j<i} S_j$ and $S_R := \bigcup_{j>i} S_j$. We need to guess the number t of points of the optimal solution that lie in S_L (so that $k-t$ points lie in S_R). As argued above, we may assume that $1 \leq t \leq k-1$. For

each value of t in this range, we compute recursively an ε-approximation I_L (resp., I_R) of a maximally separated set of size t in S_L (resp., of size $k-t$ in S_R). Then $I_L \cup I_R$ form an ε-approximation of the optimal solution to the whole problem. Thus, for each strip we solve $2(k-1)$ problems with size smaller than k. In total, we need to solve $O(k^2)$ subproblems. Denoting by $T_k(n,\varepsilon)$ the maximum time needed to ε-approximate $d^k_{\text{sep}}(S)$, over sets S of n points, we thus obtain a procedure that handles the case $d^k_{\text{sep}}(S) \le w/(k+1)$, with total cost of $O(n + k^2 T_{k-1}(n,\varepsilon))$.

So we are left with the case in which the maximal separation distance $d^k_{\text{sep}}(S)$ is larger than $w/(k+1)$. We proceed in a manner similar to that for the case $k=2$. Let

$$\delta = \frac{\varepsilon w}{2\sqrt{2}(k+1)}.$$

We partition the bounding box B of the set S into $O(k^2/\varepsilon^2)$ grid cells of size at most $\delta \times \delta$, choose an arbitrary single point of S from each nonempty cell of the grid, obtain a set A of $O(k^2/\varepsilon^2)$ representative points, and compute an exact maximally separated set I of size k for A, using any, potentially brute-force, method. (One possibility is to use the algorithm presented in Section 5.)

We claim that $d_{\text{sep}}(I) \ge (1-\varepsilon) d^k_{\text{sep}}(S)$. Indeed, let $\{p_1, \ldots, p_k\} \subseteq S$ be a maximally separated set of S of size k. Since $\varepsilon < 1$, these points must lie in different cells. Let $p'_i \in A$ be the representative point from the cell in which p_i lies, and let $I' = \{p'_1, \ldots, p'_k\}$. As in the case $k=2$, it is easily seen that

$$d_{\text{sep}}(I') \ge d^k_{\text{sep}}(S) - 2\sqrt{2}\delta = d^k_{\text{sep}}(S) - \frac{\varepsilon w}{k+1} > (1-\varepsilon) d^k_{\text{sep}}(S),$$

because $d^k_{\text{sep}}(S) > w/(k+1)$. Since we solve the problem exactly for A, $d_{\text{sep}}(I) \ge d_{\text{sep}}(I') > (1-\varepsilon) d^k_{\text{sep}}(S)$, as asserted. The running time bound $T_k(n,\varepsilon)$ thus satisfies the recurrence

$$T_k(n,\varepsilon) = O(n + k^2 T_{k-1}(n,\varepsilon) + C_k(O(k^2/\varepsilon^2))),$$

where $C_k(m)$ is the time needed to compute exactly a maximally separated subset of size k in a set of m points. Clearly, the solution of this recurrence is $O(n)$, for any constant k. More precisely, it is upper bounded by $c^k (k!)^2 n + b(k)/\varepsilon^{a(k)}$, for some constant $c > 0$, where $b(k)$ is exponential in k, and $a(k)$ is at most linear in k. (For example, using a brute-force solution for the case of large separation, for which $C_k(m) = O(m^k)$, we obtain $b(k) \le (c'k)^{2k}$, for some constant $c' > 0$, and $a(k) = 2k$.) Thus, we have the following theorem.

THEOREM 2.1. *For a set S of n points in $\mathbb{R}^2$ and any constants k and $0 < \varepsilon < 1$, we can compute in $k^{O(k)} n + (k/\varepsilon)^{O(k)}$ time a subset $I \subseteq S$ of size k such that $d_{\text{sep}}(I) \ge (1-\varepsilon) d^k_{\text{sep}}(S)$.*

3. Computing a maximally separated triple. Let S be a set of n points in $\mathbb{R}^2$. We wish to compute a maximally separated triple in S. Our overall approach consists of three steps. First, we perform a binary search on the pairwise distances of S, and for each distance δ that the search encounters, we determine whether S contains a δ-separated triple. Next, in order to determine the existence of a δ-separated triple, we draw a sufficiently small grid within the bounding box of S so that each point of a δ-separated triple of S lies in a distinct grid cell. We thus reduce the problem of computing a δ-separated triple to a trichromatic variant of this problem. Finally, we determine the existence of a trichomatic δ-separated triple in $O(n^{4/3} \log^2 n)$ time.

For simplicity, we describe these steps in the reverse order. That is, we first describe the decision algorithm for the trichromatic version, then we show how to reduce the original decision problem to the trichromatic problem, and finally we sketch the binary-search procedure.

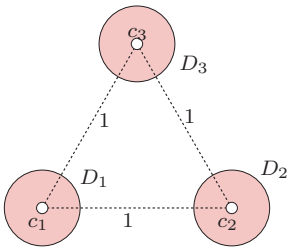

FIG. 1. *An instance of three point sets* (*contained in the shaded disks*) *with property* ($\triangle$).

We need a few notations. First, we may assume for the decision problem that $\delta = 1$. For a point $p \in \mathbb{R}^2$, let $\mathbb{D}(p)$ denote the disk of unit radius centered at p. For a set A of points in $\mathbb{R}^2$, let $K(A) = \bigcap_{p\in A} \mathbb{D}(p)$. $K(A)$ is a convex region bounded by circular arcs that lie on the boundaries of the disks $\mathbb{D}(p)$, and each disk contributes at most one such arc to $\partial K(A)$; $K(A)$ can be constructed in time $O(|A| \log |A|)$ [10].

3.1. Computing a trichromatic 1-separated triple. Let S_1, S_2, and S_3 be three sets of n points each in $\mathbb{R}^2$ that satisfy the following property.

($\triangle$) There is a constant $\delta \leq 1/6$ so that, for $i = 1, 2, 3$, S_i is contained in a disk D_i of radius δ centered at a point c_i, and $|c_1c_2| = |c_2c_3| = |c_3c_1| = 1$.

Without loss of generality, we assume that $c_1 = (0, 0), c_2 = (1, 0)$, and $c_3 = (1/2, \sqrt{3}/2)$; see Figure 1. We wish to compute a 1-separated triple in $S_1 \times S_2 \times S_3$, or to determine that no such triple exists. Clearly, no other triple of points in $S_1 \cup S_2 \cup S_3$ can be 1-separated.

Before continuing, we remark that, informally, property ($\triangle$) captures the hard case for finding a 1-separated trichromatic triple. If two of the sets S_i are too close to each other, then no trichromatic 1-separated triple exists, and if some pairs of sets are too far apart, the problem reduces to finding a diametral pair. This will be discussed in detail in section 3.2.

Let $G \subseteq S_1 \times S_2$ denote the bipartite graph

$$G = \{(p, q) \mid p \in S_1, q \in S_2;\ |pq| \geq 1\}.$$

Using the algorithm of Katz and Sharir [18], we compute, in $O(n^{4/3} \log n)$ time, a family $\mathcal{F} = \{A_1 \times B_1, \ldots, A_u \times B_u\}$, which is a partition of G into complete bipartite graphs, satisfying

$$\sum_i (|A_i| + |B_i|) = O(n^{4/3} \log n).$$

For each $1 \leq i \leq u$, let $R_i = K(A_i) \cup K(B_i)$. Set $\mathcal{R} := \bigcap_{i=1}^{u} R_i$. The following lemma is a straightforward reformulation of the original problem.

LEMMA 3.1. *There exists a* 1*-separated* (*trichromatic*) *triple in* $S_1 \times S_2 \times S_3$ *if and only if* $S_3 \not\subseteq \mathcal{R}$.

Proof. Let $p \in S_3$ be a point that does not lie in $\mathcal{R}$. Then there exists an $i \leq u$ so that $p \notin R_i = K(A_i) \cup K(B_i)$. Since $p \notin K(A_i)$, there is a point $q \in A_i$ so that

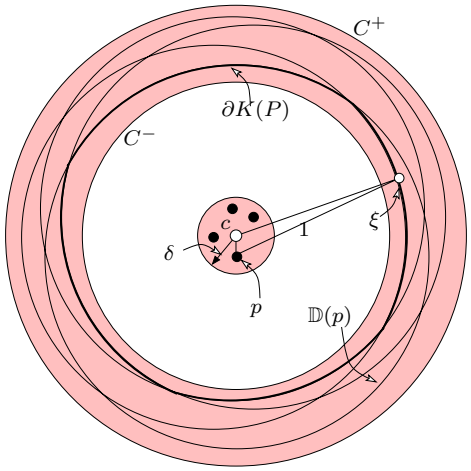

FIG. 2. *The annulus that contains* $\partial K(P)$ (*drawn as a thick curve*).

$p \notin \mathbb{D}(q)$. Similarly there is a point $r \in B_i$ so that $p \notin \mathbb{D}(r)$. Hence, $|pq|, |pr| \geq 1$. Moreover, $|qr| \geq 1$ because $(q, r) \in A_i \times B_i$, thereby implying that (q, r, p) is a 1-separated triple. The converse implication is established in a similar manner: Suppose that $q \in S_1$, $r \in S_2$, and $p \in S_3$ form a 1-separated triple. Since $|qr| \geq 1$, there exists an i such that $(q, r) \in A_i \times B_i$. Since $|pq|, |pr| \geq 1$, it follows that $p \notin K(A_i)$ and $p \notin K(B_i)$, and therefore $p \notin \mathcal{R}$. □

The following simple technical observation is important for our algorithm.

LEMMA 3.2. *Let P be a set of points in $\mathbb{R}^2$ lying in a disk of radius δ centered at a point c. Then $\partial K(P)$ lies between two concentric circles of radius $1 + \delta$ and $1 - \delta$ centered at c.*

Proof. Let C^+ (resp., C^-) denote the circle of radius $1 + \delta$ (resp., $1 - \delta$) centered at c. Fix a point $p \in P$. For any point $\xi \in \partial\mathbb{D}(p)$,

$$1 - \delta \leq |\xi p| - |pc| \leq |\xi c| \leq |\xi p| + |pc| \leq 1 + \delta.$$

Hence, $\partial\mathbb{D}(p)$ lies between C^- and C^+. Since this is true for every point $p \in P$, $\partial K(P)$ lies between C^- and C^+; see Figure 2. □

LEMMA 3.3. *For each $1 \leq i \leq u$, the upper (resp., lower) boundaries of $K(A_i)$ and $K(B_i)$ cross at exactly one point.*

Proof. Let W_1 (resp., W_2) denote the annulus bounded by the concentric circles of radii $1+\delta$ and $1-\delta$ centered at c_1 (resp., c_2). By Lemma 3.2, $\partial K(A_i)$ (resp., $\partial K(B_i)$) is contained in W_1 (resp., W_2). Therefore $\partial K(A_i) \cap \partial K(B_i) \subseteq W_1 \cap W_2$. Since $\delta < 1/6$ and $|c_1 c_2| = 1$, the inner circles of W_1 and W_2 intersect, and thus $W_1 \cap W_2$ consists of two connected components Σ^+, Σ^-, where Σ^+ lies above the x-axis and Σ^- below the x-axis; see Figure 3. An easy calculation shows that the x-coordinate of the leftmost (resp., rightmost) point of Σ^+ is $1/2 - 2\delta$ (resp., $1/2 + 2\delta$), and that the y-coordinate of the bottommost point is $\sqrt{(1-\delta)^2 - 1/4}$. Since $\delta \leq 1/6$, Σ^+ lies fully to the right of D_1, to the left of D_2, and above both these disks. This implies that, within Σ^+, the boundary of each $\mathbb{D}(p)$, for $p \in A_i$, is the graph of a strictly decreasing function, and thus $\partial K(A_i)$ is also the graph of a strictly decreasing function within Σ^+. By a fully symmetric argument, $\partial K(B_i)$ is the graph of a strictly increasing function within Σ^+. Moreover, $\partial K(A_i) \cap \Sigma^+$ is contained in the upper boundary of $K(A_i)$,

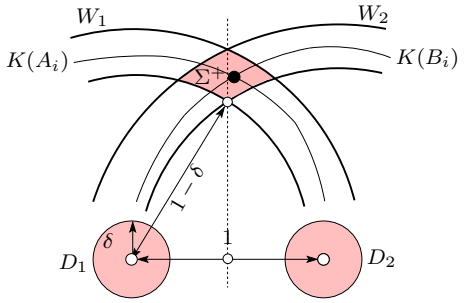

FIG. 3. *The annuli W_1, W_2 and their top intersection Σ^+. For $\delta \le 1/6$, the lowest point of Σ^+ lies above the line $y = \delta$, and its leftmost point has x-coordinate $\ge \delta$.*

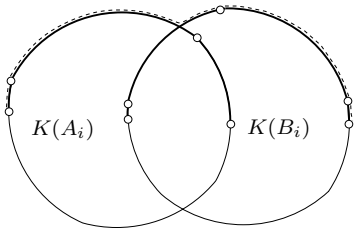

FIG. 4. *$K(A_i)$, $K(B_i)$ (whose top boundaries are drawn as thick curves), and the edges of Γ_i (drawn as dashed arcs).*

and similarly for $K(B_i)$, because Σ^+ lies above D_1 and D_2. This is easily seen to imply the assertion of the lemma. □

Lemma 3.3 implies that ∂R_i consists of a connected portion of $\partial K(A_i)$ and a connected portion of $\partial K(B_i)$. The leftmost and rightmost points of R_i partition ∂R_i into two parts, which we refer to as the upper and lower boundaries of R_i. Let Γ_i be the set of circular arcs forming the upper boundary of R_i; we have $|\Gamma_i| \le |A_i| + |B_i|$. See Figure 4. Set $\Gamma := \bigcup_{i=1}^{u} \Gamma_i$; then $|\Gamma| \le \sum_{i=1}^{u} (|A_i| + |B_i|)$. Let $\mathcal{L}_\Gamma$ denote the lower envelope of Γ.

LEMMA 3.4. *A point $p \in S_3$ lies inside $\mathcal{R}$ if and only if p lies below the lower envelope $\mathcal{L}_\Gamma$.*

Proof. If $p \in \mathcal{R}$, then it lies below the upper boundary of each R_i, thereby implying that p lies below $\mathcal{L}_\Gamma$. Conversely, suppose that p lies below $\mathcal{L}_\Gamma$. Then p lies below the upper boundary of every R_i. Let Σ^+ be the same region as in the proof of Lemma 3.3. Since $|c_1c_2| = |c_1c_3| = |c_2c_3| = 1$, and $\delta \le 1/6$, a simple calculation shows that $D_3 \subset \Sigma^+$, and thus S_3 is also contained in Σ^+. The argument in the proof of Lemma 3.3 implies that Σ^+ lies above the lower boundaries of every $K(A_i)$ and of every $K(B_i)$. Hence, if p lies below the boundary of each R_i, it lies in each R_i and thus also in $\mathcal{R}$. □

In view of Lemma 3.4, we may proceed as follows. For each i, we compute $K(A_i)$, $K(B_i)$, R_i, and Γ_i. The total time spent in this step is

$$O\left(\sum_{i=1}^{u} (|A_i| + |B_i|) \log n\right) = O\big(n^{4/3} \log^2 n\big).$$

Since each arc in Γ is a portion of the upper boundary of a unit-radius disk, two arcs of Γ intersect in at most one point. Hence, we can compute the lower envelope

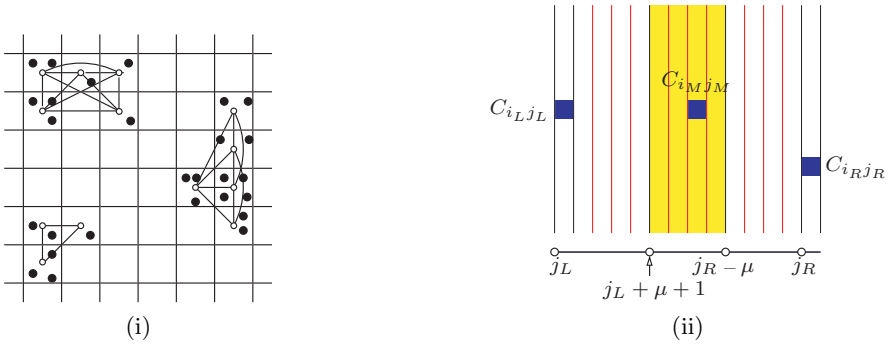

FIG. 5. (i) *Drawing a grid and the graph* $\mathcal{G}$. (ii) *The case where* $\mathcal{C}$ *spans more than* $3\mu + 1$ *columns.*

$\mathcal{L}_\Gamma$ of Γ in $O(|\Gamma| \log n)$ time, using the algorithm of Hershberger [16] (see also [21]). For each edge ξ of $\mathcal{L}_\Gamma$ we store the index j such that ξ is (a portion of) an arc in Γ_j. Finally, for each point $p \in S_3$ we determine whether p lies below or above $\mathcal{L}_\Gamma$, using a simple binary search over the arcs of $\mathcal{L}_\Gamma$. If p lies above $\mathcal{L}_\Gamma$, then the test yields an arc of $\mathcal{L}_\Gamma$ that lies below p. This arc is contained in an arc of some Γ_i, and we can thus deduce that $p \notin R_i$ (by Lemma 3.4). Then, scanning the points of $A_i \cup B_i$ in additional $O(|A_i| + |B_i|)$ time, we are certain to find a 1-separated triple $(a, b, p) \in A_i \times B_i \times S_3$. The total running time of the algorithm is $O(n^{4/3} \log^2 n)$. Hence, we obtain the following result.

THEOREM 3.5. *Let* S_1, S_2, *and* S_3 *be three finite point sets in* $\mathbb{R}^2$ *that satisfy property* $(\triangle)$, *and put* $n_i = |S_i|$, *for* $i = 1, 2, 3$. *Then one can construct, in time* $O(n^{4/3} \log^2 n)$, *a* 1*-separated triple in* $S_1 \times S_2 \times S_3$, *if one exists, or determine that no such triple exists.*

3.2. Reduction to the trichromatic case. Let S be a set of n points in $\mathbb{R}^2$. We wish to compute a 1-separated triple in S if one exists, or else to determine that no such triple exists. We fix a small constant $\varepsilon \ll 1/16$, and set $\mu = \lceil 1/\varepsilon \rceil$. We draw a square grid of size ε in the plane. For $i, j \in \mathbb{Z}$, let C_{ij} denote the grid cell $[i\varepsilon, (i+1)\varepsilon) \times [j\varepsilon, (j+1)\varepsilon)$, and let $S_{ij} = S \cap C_{ij}$. Let $\mathcal{C}$ denote the set of nonempty grid cells (i.e., those with $S_{ij} \neq \emptyset$). We construct a graph $\mathcal{G} = (\mathcal{C}, \mathcal{E})$ where $(C, C') \in \mathcal{E}$ if $\min\{|pp'| \mid p \in C, p \in C'\} < 1$; see Figure 5 (i).

LEMMA 3.6. *If* $\mathcal{G}$ *is not connected, then we can compute a* 1*-separated triple in* S (*or determine that no such triple exists*) *in* $O(n \log n)$ *time.*

Proof. First, note that if two nonempty grid cells $C_{ij}, C_{kl} \in \mathcal{C}$ lie in different connected components of $\mathcal{G}$, then for any pair $(p, q) \in S_{ij} \times S_{kl}$, $|pq| \geq 1$. If $\mathcal{G}$ has three (or more) connected components $\mathcal{C}_1, \mathcal{C}_2, \mathcal{C}_3$, then a 1-separated triple is obtained by choosing one point of S lying in a single grid cell of each of $\mathcal{C}_1, \mathcal{C}_2, \mathcal{C}_3$. If $\mathcal{G}$ has at least two connected components, then let $S_1 \subseteq S$ be the subset of points lying in the grid cells of one connected component, and put $S_2 := S \setminus S_1$. We test, in $O(n \log n)$ time, whether $\max\{\mathrm{diam}(S_1), \mathrm{diam}(S_2)\} \geq 1$. Suppose that p, q is a diametral pair of, say, S_1 and that $|pq| \geq 1$; then we choose an arbitrary point $r \in S_2$ and return (p, q, r). By construction, this is a 1-separated triple. If $\mathrm{diam}(S_1), \mathrm{diam}(S_2)$ are both smaller than 1, then clearly no 1-separated triple exists. Hence, if $\mathcal{G}$ is not connected, then we can construct in time $O(n \log n)$ a 1-separated triple in S if one exists, or determine that no such triple exists. ∎

LEMMA 3.7. *If $\mathcal{G}$ is connected and $\mathcal{C}$ spans more than $3\mu+1$ columns or rows of the grid, i.e., it has cells in two columns (or rows) whose indices j_L, j_R satisfy $j_R - j_L \geq 3\mu+1$, then a 1-separated triple in S exists, and can be constructed in $O(n)$ time.*

Proof. Without loss of generality, it suffices to consider the case where $\mathcal{C}$ spans more than $3\mu+1$ columns. Let $C_{i_L j_L}$ (resp., $C_{i_R j_R}$) be a grid cell of $\mathcal{C}$ in the leftmost (resp., rightmost) column, let $p_L \in S_{i_L j_L}$, and let $p_R \in S_{i_R j_R}$. By assumption, $j_R - j_L \geq 3\mu+1$; see Figure 5 (ii). We group the columns between the j_Lth and j_Rth columns (exclusive) into three pairwise-disjoint vertical strips V_1, V_2, V_3, appearing in this left-to-right order, each of width at least $\mu\varepsilon \geq 1$. It is easily seen that V_2 must contain a point of S, or else $\mathcal{G}$ would not be connected. Then p_L, p_R, and any point in $V_2 \cap S$ form a 1-separated triple. Clearly, finding these points takes linear time. ∎

By Lemmas 3.6 and 3.7, it remains to consider the case in which $\mathcal{G}$ is connected and $\mathcal{C}$ spans at most $3\mu+1$ rows and at most $3\mu+1$ columns. Clearly, in this case $|\mathcal{C}| \leq (3\mu+1)^2$. We consider all triples $C_1, C_2, C_3 \in \mathcal{C}$ and determine whether $S_1 \times S_2 \times S_3$ contains a 1-separated triple, where $S_i = C_i \cap S$, for $i = 1, 2, 3$. If the maximum distance between two of these three cells, say, C_1 and C_2, is less than 1, then no 1-separated triple in $S_1 \times S_2 \times S_3$ exists. Hence, we can assume that the maximum distance between every pair of C_1, C_2, C_3 is at least 1. There are four cases to consider, depending on the number k of edges of $\mathcal{G}$ between these three cells:

(i) $k = 0$; that is, C_1, C_2, C_3 is an independent set in $\mathcal{G}$. Then any triple in $S_1 \times S_2 \times S_3$ is 1-separated, and we return one of these triples.

(ii) $k = 1$; suppose, without loss of generality, that $(C_1, C_2) \in \mathcal{E}$ and $(C_1, C_3), (C_2, C_3) \notin \mathcal{E}$. We compute a diametral pair (p, q) of $S_1 \cup S_2$. If $|pq| \geq 1$, then we return (p, q, r), where r is any point of S_3. If $|pq| < 1$, no triple in $S_1 \times S_2 \times S_3$ is 1-separated. This step takes $O(n \log n)$ time.

(iii) $k = 2$; suppose, without loss of generality, that $(C_1, C_2), (C_1, C_3) \in \mathcal{E}$ and $(C_2, C_3) \notin \mathcal{E}$. We compute $K(S_2)$ and $K(S_3)$. If a point $p \in S_1$ lies neither in $K(S_2)$ nor in $K(S_3)$, then there exists a pair $(q, r) \in S_2 \times S_3$ so that $p \notin \mathbb{D}(q) \cup \mathbb{D}(r)$ and thus (p, q, r) is 1-separated. If $S_1 \subseteq K(S_2) \cup K(S_3)$, then, arguing as in the proof of Lemma 3.1, no triple in $S_1 \times S_2 \times S_3$ is 1-separated. This step too takes $O(n \log n)$ time.

(iv) $k = 3$; that is, $(C_1, C_2), (C_1, C_3), (C_2, C_3) \in \mathcal{E}$. In other words, for any pair $i \neq j \in \{1, 2, 3\}$ we have

$$\min\{|xy| \mid x \in C_i, y \in C_j\} < 1 \leq \max\{|xy| \mid x \in C_i, y \in C_j\}.$$

By the triangle inequality, this implies that any $x \in C_i$, $y \in C_j$ satisfy $1 - 2\sqrt{2}\varepsilon \leq |xy| \leq 1 + 2\sqrt{2}\varepsilon$. We claim that our choice of ε implies that there exist points $c_1, c_2, c_3 \in \mathbb{R}^2$ so that $|c_i c_j| = 1$ for each pair of distinct points c_i, c_j, and S_i is contained in the disk D_i of radius $\delta \leq 1/6$ centered at c_i, for $i = 1, 2, 3$. To see this, pick any pair of points $c_1 \in C_1$, $c_2 \in C_2$, such that $|c_1 c_2| = 1$. Let $c_3 \in \mathbb{R}^2$ be a point such that $\Delta c_1 c_2 c_3$ is equilateral and c_3 lies on the same side of the line through c_1 and c_2 as C_3 (our choice of ε is easily seen to imply that C_3 does not intersect such a line). By what we have just argued, C_3 is fully contained in the intersection of the two annuli

$$1 - 2\sqrt{2}\varepsilon \leq |c_1 x| \leq 1 + 2\sqrt{2}\varepsilon,$$
$$1 - 2\sqrt{2}\varepsilon \leq |c_2 x| \leq 1 + 2\sqrt{2}\varepsilon.$$

A simple calculation then shows that C_3 is fully contained in the disk of radius $1/6$ centered at c_3. In other words, in this case S_1, S_2, and S_3 satisfy property ($\triangle$), and we can therefore use Theorem 3.5 to compute a 1-separated triple in $S_1 \times S_2 \times S_3$, if one exists, or to determine that no such triple exists.

The total running time of the algorithm is dominated by the overall cost of handling case (iv), and is thus, by Theorem 3.5, $O(n^{4/3}\log^2 n)$ since $\mu = O(1)$. We thus obtain the following main result of this section.

THEOREM 3.8. *Let S be a set of n points in $\mathbb{R}^2$. We can compute, in $O(n^{4/3}\log^2 n)$ time, a 1-separated triple in S, if one exists, or determine that no such triple exists.*

Finally, we run a binary search on the $\binom{n}{2}$ pairwise distances in S. The kth smallest pairwise distance δ_k in S, for any $1 \le k \le \binom{n}{2}$, can be computed in time $O(n^{4/3}\log^2 n)$ [18], and by Theorem 3.8, we can determine whether a δ_k-separated triple exists in S within the same time bound. Hence, we obtain the following theorem.

THEOREM 3.9. *Let S be a set of n points in $\mathbb{R}^2$. We can compute, in $O(n^{4/3}\log^3 n)$ time, a maximally separated triple in S.*

4. Computing a maximally separated quadruple. Our overall approach to this problem is similar to the one in Section 3. We first consider a multicolored version of this problem, in which we are given four sets, S_1, S_2, S_3, and S_4, of points, placed "reasonably far" from each other, and we wish to determine whether there exists a 1-separated quadruple in $S_1 \times S_2 \times S_3 \times S_4$. The easy cases are when some pairs of subsets S_i, S_j are either too far from each other or too near each other. The difficult case is when these sets are arranged in a so-called *diamond* configuration, and we present in Section 4.1 below an algorithm for handling this case. We then present the overall algorithm, which, as in the previous section, runs a binary search through the pairwise distances in S, and, for each fixed distance, reduces the general problem to a constant number of multicolored instances.

4.1. The diamond configuration. Let S_1, S_2, S_3, and S_4 be sets of n points each in $\mathbb{R}^2$ that satisfy the following property:

($\diamond$) There is a constant $\delta \le 1/8$ so that each S_i, for $i = 1, \ldots, 4$, is contained in a disk D_i of radius δ centered at a point c_i, so that $|c_1c_3|, |c_2c_3|, |c_1c_4|, |c_2c_4| = 1$, and $1 \le |c_1c_2| \le 1 + 2\delta < |c_3c_4|$.

Without loss of generality assume that $c_3 = (0,0)$, c_4 lies on the x-axis to the right of c_3, and c_1 (resp., c_2) lies below (resp., above) the x-axis (in symmetric positions). The conditions on the c_i's imply that

$$1 \le |c_1c_2| \le 1 + 2\delta < \sqrt{2} \le |c_3c_4| \le \sqrt{3}.$$

See Figure 6.

Note that one helpful property of the diamond configuration is that any pair of points in $S_3 \times S_4$ is 1-separated, so only five of the six pairwise distances in a quadruple in $S_1 \times S_2 \times S_3 \times S_4$ need to be considered.

For a point $p \in S_1$, let $S_p^{(3)} = \{q \in S_3 \mid |pq| \ge 1\}$ and $S_p^{(4)} = \{q \in S_4 \mid |pq| \ge 1\}$. (We ignore for the time being the issue of efficient construction of these sets; this will be addressed later on.) We remove from S_1 any point p for which one of these sets is empty, because such a p cannot be part of a 1-separated quadruple in $S_1 \times S_2 \times S_3 \times S_4$.

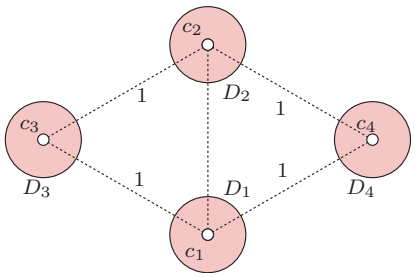

FIG. 6. *A diamond configuration. The missing edge between D_3 and D_4 indicates that every pair of points in $S_3 \times S_4$ is 1-separated.*

Set, for each remaining $p \in S_1$,

$$K_p^{(3)} := \bigcap_{q \in S_p^{(3)}} \mathbb{D}(q), \qquad K_p^{(4)} := \bigcap_{q \in S_p^{(4)}} \mathbb{D}(q),$$

$$R_p := K_p^{(3)} \cup K_p^{(4)} \cup \mathbb{D}(p), \qquad \mathcal{R} := \bigcap_{p \in S_1} R_p.$$

The following lemma is fairly straightforward (cf. Lemma 3.1).

LEMMA 4.1. *There exists a 1-separated quadruple in $S_1 \times S_2 \times S_3 \times S_4$ if and only if $S_2 \not\subseteq \mathcal{R}$.*

Proof. If there exists a point $q \in S_2 \setminus \mathcal{R}$, then there exists a point $p \in S_1$ so that $q \notin R_p = K_p^{(3)} \cup K_p^{(4)} \cup \mathbb{D}(p)$, which implies that there is a pair $(u, v) \in S_p^{(3)} \times S_p^{(4)}$ so that $q \notin \mathbb{D}(u) \cup \mathbb{D}(v) \cup \mathbb{D}(p)$. Therefore, $|pu|, |qu|, |pv|, |qv|, |pq| \geq 1$. By property $(\diamond)$, $|uv| \geq 1$ too. Hence, (p, q, u, v) is 1-separated. The converse implication is argued in the same manner. ∎

The following is a variant of Lemma 3.3, proved in a similar manner.

LEMMA 4.2.

(i) *For any $p \in S_1$, $\partial K_p^{(3)}$ and $\partial K_p^{(4)}$ intersect above the x-axis at exactly one point σ_p, which lies on the upper boundaries of both regions.*

(ii) *For any $p \in S_1$, $\partial K_p^{(3)}$ and $\partial \mathbb{D}(p)$ intersect above the x-axis exactly once, and similarly for $\partial K_p^{(4)}$ and $\partial \mathbb{D}(p)$.*

Proof. (i) Let W_3 (resp., W_4) denote the annulus bounded by the concentric circles of radii $1 + \delta$ and $1 - \delta$ centered at c_3 (resp., c_4). By Lemma 3.2, $\partial K_p^{(3)}$ (resp., $\partial K_p^{(4)}$) is contained in W_3 (resp., W_4). Therefore $\partial K_p^{(3)} \cap \partial K_p^{(4)} \subseteq W_3 \cap W_4$. Since $\delta < 1 - \sqrt{3}/2$ and $|c_3 c_4| \leq \sqrt{3}$, the inner circles of W_3 and W_4 intersect and thus $W_3 \cap W_4$ consists of two connected components Σ^+, Σ^-, where Σ^+ lies above the x-axis and Σ^- below the x-axis (as in Figure 3(i)). Moreover, by the choice of δ, Σ^+ lies fully to the right of D_3, to the left of D_4, and above both these disks, as is easily verified. This implies that, within Σ^+, the boundary of each $\mathbb{D}(q)$, for $q \in S_p^{(3)}$, is the graph of a decreasing function, and thus $\partial K_p^{(3)}$ is also the graph of a decreasing function within Σ^+. By a fully symmetric argument, $\partial K_p^{(4)}$ is the graph of an increasing function within Σ^+. Moreover, $\partial K_p^{(3)} \cap \Sigma^+$ is contained in the upper boundary of $K_p^{(3)}$, and similarly for $K_p^{(4)}$, because Σ^+ lies above D_3 and D_4. This is easily seen to imply the assertion in (i).

(ii) The center p of $\mathbb{D}(p)$ lies to the right of the center of the circle of any arc that appears on $\partial K_p^{(3)}$, and only the upper semicircle of $\mathbb{D}(p)$ can be above the x-axis.

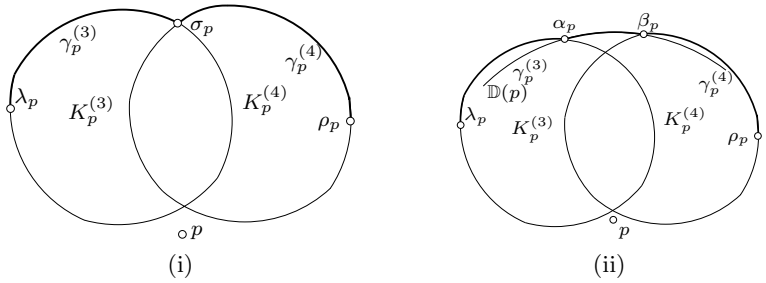

FIG. 7. (i) *Implicit representation of the upper boundary of R_p when $\mathbb{D}(p)$ does not appear on this boundary.* (ii) *Implicit representation of the upper boundary of R_p when $\mathbb{D}(p)$ appears on it. In both cases, the boundary is drawn as a thick curve.*

Hence, above the x-axis, $\partial\mathbb{D}(p)$ intersects any arc γ that bounds $\partial K_p^{(3)}$ in at most one point, and lies above γ to the right of that point. Hence $\partial\mathbb{D}(p)$ lies above $\partial K_p^{(3)}$ to the right of any intersection point between the two curves, which readily implies (ii). □

DEFINITION 4.3. *For a point $p \in S_1$, let σ_p denote, as in Lemma* 4.2*, the unique intersection point of the upper boundaries of $K_p^{(3)}$ and $K_p^{(4)}$, and let α_p (resp., β_p) denote the intersection point of the upper boundary of $K_p^{(3)}$ (resp., $K_p^{(4)}$) with $\mathbb{D}(p)$ if such a point exists.*

Consider the upper envelope of the upper boundaries of $K_p^{(3)}$, $K_p^{(4)}$, and $\mathbb{D}(p)$. The preceding analysis implies that the envelope has one of the following two structures: (a) Either $\mathbb{D}(p)$ does not appear on the envelope, and then the envelope consists of a connected portion $\gamma_p^{(3)}$ of the upper boundary of $K_p^{(3)}$ and a connected portion $\gamma_p^{(4)}$ of the upper boundary of $K_p^{(4)}$, meeting at the point σ_p (see Figure 7 (i)); or (b) $\mathbb{D}(p)$ appears on the envelope, and then the envelope consists of a connected portion $\gamma_p^{(3)}$ of the upper boundary of $K_p^{(3)}$, a connected portion δ_p of the upper boundary of $\mathbb{D}(p)$, and a connected portion $\gamma_p^{(4)}$ of the upper boundary of $K_p^{(4)}$, so that the first and second portions meet at α_p and the second and third portions meet at β_p (see Figure 7 (ii)).

Let $\Gamma^{(3)} = \{\gamma_p^{(3)} \mid p \in S_1\}$, $\Gamma^{(4)} = \{\gamma_p^{(4)} \mid p \in S_1\}$, and $\Delta = \{\delta_p \mid p \in S_1\}$. Note the difference between this notation and the one in section 3. There Γ_i was a family of circular arcs, whereas here each arc in $\Gamma^{(3)}$ or $\Gamma^{(4)}$ is a sequence of circular arcs. Let $\mathcal{L}^{(3)}$ (resp., $\mathcal{L}^{(4)}$, $\mathcal{L}^{(1)}$) denote the lower envelope of $\Gamma^{(3)}$ (resp., $\Gamma^{(4)}$, Δ).

The following corollary follows from Lemmas 3.4 and 4.2. Its proof uses the obvious observation that the lower envelope of $\mathcal{L}^{(3)}$, $\mathcal{L}^{(4)}$, and $\mathcal{L}^{(1)}$ is the same as the lower envelope of the upper boundaries of the regions R_p, for $p \in S_1$. (We follow here the convention that if a curve is undefined at some x, it is assumed to be $+\infty$ there.) Arguing in much the same way as in Section 3 and exploiting the fact that $\delta < 1/8$, one can show that a point of S_2 does not lie below the lower boundary of any $K_p^{(3)}, K_p^{(4)}$, or $\mathbb{D}(p)$. Hence, we obtain the following corollary.

COROLLARY 4.4. *A point $q \in S_2$ lies in $\mathcal{R}$ if and only if q lies below each of $\mathcal{L}^{(3)}$, $\mathcal{L}^{(4)}$, and $\mathcal{L}^{(1)}$.*

We thus compute each of the envelopes $\mathcal{L}^{(3)}$, $\mathcal{L}^{(4)}$, and $\mathcal{L}^{(1)}$ separately, and determine whether any point of S_2 lies above any of them. If the answer is yes, we can conclude that a 1-separated quadruple in $S_1 \times S_2 \times S_3 \times S_4$ exists, and we can compute

it in additional linear time. Otherwise no such quadruple exists.

However, unlike the situation in Section 3, computing these envelopes explicitly is expensive, because they consist of too many arcs, so we represent them implicitly. We first describe the implicit representation of the envelopes and of their arcs, following a similar representation used by Agarwal, Sharir, and Welzl [4], and then present the algorithm for computing and searching in the envelopes.

Implicit representation of $K_p^{(3)}, K_p^{(4)}$, and of the lower envelopes. For a subset $Q \subseteq S_1$, let $\mathcal{L}_Q^{(3)}$ denote the lower envelope of arcs in the set $\{\gamma_p^{(3)} \mid p \in Q\}$. We represent $\mathcal{L}_Q^{(3)}$ by the sequence of its *breakpoints* in increasing order of their x-coordinates. The breakpoints are defined so that each portion ξ of $\mathcal{L}_Q^{(3)}$ between two consecutive breakpoints is contained in a single $\gamma_p^{(3)}$ (such a ξ may overlap with many $\gamma_p^{(3)}$'s, but there is (at least) one point $p \in S_1$ such that ξ is fully contained in $\gamma_p^{(3)}$). We maintain ξ implicitly, by recording a point $p \in Q$ that satisfies $\xi \subseteq \gamma_p^{(3)}$. Recall that each $\gamma_p^{(3)}$ may consist of many circular arcs, bounding different disks centered at points of $S_p^{(3)}$; our implicit representation avoids the costly explicit enumeration of these arcs.

Let $\mathcal{D}_3 = \{\mathbb{D}(q) \mid q \in S_3\}$. To represent each $\gamma_p^{(3)}$ implicitly, we choose a parameter $n \le s \le n^2$, and use the result of Katz and Sharir [18], which shows that there exists a family $\mathcal{F}^{(3)} = \{\mathcal{D}^{(1)}, \ldots, \mathcal{D}^{(u)}\}$ of *canonical* subsets of $\mathcal{D}$, with a corresponding family of intersection regions $\mathcal{I}^{(i)} = \bigcap \mathcal{D}^{(i)}$, for $i = 1, \ldots, u$, such that $\sum_{i=1}^{u} |\mathcal{D}^{(i)}| = O(s \log n)$, and such that for any $p \in S_1$, $K_p^{(3)}$ can be represented as the intersection of $O((n/\sqrt{s}) \log n)$ of these canonical regions $\mathcal{I}^{(i)}$. Let $J_p^{(3)}$ denote the set of indices of these canonical regions, i.e., $K_p^{(3)} = \bigcap_{j \in J_p^{(3)}} \mathcal{I}^{(j)}$. We represent each arc $\gamma_p^{(3)}$ by its endpoints and by the set $J_p^{(3)}$. We also store the vertices of all $\mathcal{I}^{(j)}$ in a single master list Λ, sorted in increasing order of their x-coordinates.

As shown in [18], $\mathcal{F}^{(3)}$ and the sets $J_p^{(3)}$ for all $p \in S_3$ can be computed in time $O((s + n^2/\sqrt{s}) \log n)$, and we spend another $O(s \log^2 n)$ time to compute the regions $\mathcal{I}^{(j)}$. A similar representation was developed by Agarwal, Sharir, and Welzl [4], who showed that the above representation enables us to perform each of the following four operations on $\{\partial K_p^{(3)}\}_{p \in S_1}$ in $O((n/\sqrt{s}) \log^3 n)$ time.

(S1) *Leftmost and rightmost points:* Given a point $p \in S_1$, compute the leftmost and rightmost points of $K_p^{(3)}$.

(S2) *Intersection point(s) with a vertical line:* Given a vertical line ℓ and a point $p \in S_1$, determine the intersection point(s) of ℓ with $\partial K_p^{(3)}$.

(S3) *Intersection points with a unit disk:* Given a unit disk $\mathbb{D}$ and a point $p \in S_1$, determine the intersection point(s) of $\mathbb{D}$ with $\partial K_p^{(3)}$.

(S4) *Crossing point of two arcs:* Given two points $p, q \in S_1$ and an x-interval $[a, b]$ contained in the x-span of the top boundaries of $K_p^{(3)}$ and $K_q^{(3)}$, determine whether they cross in $[a, b]$. If so, return their crossing point. If they *weakly cross* in $[a, b]$, i.e., overlap over some subinterval J of $[a, b]$ and their vertical order to the right of J is the reverse of their vertical order to the left of J, then return the leftmost endpoint of their common overlap in $[a, b]$.

In a fully analogous fashion, we process S_4 in $O((s + (n^2/\sqrt{s})) \log n)$ time, to compute an implicit representation of all the arcs $\gamma_p^{(4)}$. Each of the operations (S1)–(S4) on $\{\partial K_p^{(4)}\}_{p \in S_1}$ can also be performed in $O((n/\sqrt{s}) \log^3 n)$ time. Moreover, given any $p \in S_1$, the intersection point of the top boundaries of $K_p^{(3)}$ and $K_p^{(4)}$ can also be

computed in $O((n/\sqrt{s})\log^3 n)$ time.

Computing $\mathcal{L}^{(3)}$, $\mathcal{L}^{(4)}$, and $\mathcal{L}^{(1)}$. Using the subroutine (S1), we first compute the lefmost point λ_p of $K_p^{(3)}$ and the rightmost point ρ_p of $K_p^{(4)}$, for each $p \in S_1$. Next, using (S3) and (S4), we compute the intersection point σ_p of the upper boundaries of $K_p^{(3)}$ and $K_p^{(4)}$, the intersection point α_p of the upper boundaries of $K_p^{(3)}$ and $\mathbb{D}(p)$, and the intersection point β_p of the upper boundaries of $K_p^{(4)}$ and $\mathbb{D}(p)$. By comparing the x-coordinates of these three points, we can determine whether the upper boundary of R_p is of the first kind (disjoint from $\mathbb{D}(p)$) or of the second kind (overlapping an arc of $\mathbb{D}(p)$). In the first case, $\gamma_p^{(3)}$ (resp., $\gamma_p^{(4)}$) is the portion of the upper boundary of $K_p^{(3)}$ (resp., $K_p^{(4)}$) between λ_p and σ_p (resp., σ_p and ρ_p). In the second case it is the portion of $\partial K_p^{(3)}$ (resp., $\partial K_p^{(4)}$) between λ_p and α_p (resp., β_p and ρ_p). We thus have the endpoints of γ_p and its implicit representation at our disposal.

The x-coordinate of any point $p \in S_1$ is at most $\sqrt{3}/2 + \delta$ and the x-coordinate of the rightmost point of R_p is at least $1 - \delta$. This easily implies that p lies below $K_p^{(3)}$ (i.e., the vertical ray emanating upward from p intersects $K_p^{(3)}$). Since this holds for any point $p \in S_1$, Theorem 2.8 of Agarwal, Sharir, and Welzl [4] (concerning the "pseudo-segment" property of the upper portions of $\partial K_p^{(3)}$) implies that, for any $p, q \in S_1$, $\gamma_p^{(3)}$ and $\gamma_q^{(3)}$ cross in at most one point. A similar argument proves the corresponding claim for the curves in $\Gamma^{(4)}$. Hence, each of $\Gamma^{(3)}, \Gamma^{(4)}$ is a collection of pseudo-segments. We can therefore compute the lower envelopes $\mathcal{L}^{(3)}, \mathcal{L}^{(4)}$ using the divide-and-conquer algorithm of Hershberger [16], mentioned above. In the main step of this algorithm, we have envelopes $\mathcal{L}_A^{(3)}, \mathcal{L}_B^{(3)}$ of two subsets $A, B \subseteq \Gamma^{(3)}$ at our disposal, and we need to merge these envelopes to compute $\mathcal{L}_{A\cup B}^{(3)}$. The only nontrivial part in the merge step is computing the crossing point of two arcs $\gamma_p^{(3)}$ and $\gamma_q^{(3)}$ in a given x-interval $[a, b]$ that is contained in the x-span of both $\gamma_p^{(3)}$ and $\gamma_q^{(3)}$. Using the subroutine (S4), we can compute, in $O((n/\sqrt{s})\log^3 n)$ time, the crossing point of the upper boundaries of $K_p^{(3)}$ and $K_p^{(4)}$ in the interval $[a, b]$, if it exists. If so, this is the crossing point of $\gamma_p^{(3)}$ and $\gamma_q^{(3)}$; otherwise, these arcs do not intersect over $[a, b]$. Plugging this bound into Hershberger's algorithm, we can compute an implicit representation of $\mathcal{L}^{(3)}$ in overall time $O((n^2/\sqrt{s})\log^4 n + s\log^2 n)$. Similarly, we can compute an implicit representation of $\mathcal{L}^{(4)}$ within the same time bound $O((n^2/\sqrt{s})\log^4 n + s\log^2 n)$. Computing $\mathcal{L}^{(1)}$ is easier, since no implicit representation is needed here: We simply have to compute the lower envelope of at most n upper unit circular arcs that behave as pseudo-segments, so their envelope can be computed in $O(n \log n)$ time (as in [16]). Finally, for each point $q \in S_2$, we determine in $O((n/\sqrt{s})\log^3 n)$ time, using the subroutine (S2), whether q lies above $\mathcal{L}^{(3)}$ or above $\mathcal{L}^{(4)}$. Testing whether q lies above $\mathcal{L}^{(1)}$ is easy to accomplish in $O(\log n)$ time. The total time spent is thus $O\left((n^2/\sqrt{s})\log^4 n + s\log^2 n\right)$. By choosing $s = n^{4/3}\log^{4/3} n$, we obtain the following summary result.

THEOREM 4.5. *Let S_1, S_2, S_3, and S_4 be four sets of n points each in $\mathbb{R}^2$ that satisfy property ($\diamond$). One can determine, in time $O(n^{4/3}\log^{10/3} n)$, whether $S_1 \times S_2 \times S_3 \times S_4$ contains a 1-separated quadruple, and, if so, compute such a quadruple.*

4.2. Reduction to the multicolored case. As in section 3, we construct a square grid of size ε, for a sufficiently small constant parameter $\varepsilon > 0$. Let $C_{ij}, S_{ij}, \mathcal{C}, \mathcal{G}$, and μ be as in section 3.

LEMMA 4.6. *If $\mathcal{G}$ is not connected, then we can compute a 1-separated quadruple in S (or determine that no such quadruple exists) in $O(n^{4/3}\log^2 n)$ time.*

Proof. If $\mathcal{G}$ has at least two connected components, then let $S_1 \subseteq S$ be the subset of points lying in the grid cells of one connected component, and put $S_2 := S \setminus S_1$. If a 1-separated quadruple exists, then there also exists a 1-separated quadruple that has points in both S_1 and S_2. Indeed, if (p_1, p_2, p_3, p_4) is a 1-separated quadruple that is contained in, say, S_1, then the quadruple obtained by replacing, say, p_1 by any point of S_2 is also 1-separated. Hence it suffices to look for 1-separated quadruples that have two points in each of S_1, S_2, or have three points in one of these sets and one point in the other set. Moreover, it suffices to find the two parts of such a quadruple *independently*—putting together any pair of such parts, one contained in S_1, the other in S_2, and consisting together of four points, will form a 1-separated quadruple in S. In the former case, it suffices to check that $\min\{\mathrm{diam}(S_1), \mathrm{diam}(S_2)\} \geq 1$, and then return a pair of diametral points in each of S_1, S_2. In the latter case, we apply the decision procedure of Section 3 to S_1 and to S_2. If either of these applications yields a 1-separated triple, combining it with any point in the other set yields a 1-separated quadruple in S. If none of these steps succeeds, S has no 1-separated quadruple. The overall cost of the procedure just sketched is, by Theorem 3.8, $O(n^{4/3}\log^2 n)$. □

LEMMA 4.7. *If $\mathcal{G}$ is connected and $\mathcal{C}$ spans more than $5\mu+1$ columns or rows of the grid, i.e., it has cells in two columns (or rows) whose indices j, j' satisfy $j'-j \geq 5\mu+1$, then a 1-separated quadruple in S exists, and can be constructed in $O(n)$ time.*

Proof. Consider the case where $\mathcal{C}$ spans more than $5\mu + 1$ columns. Let $C_{i_L j_L}$ (resp., $C_{i_R j_R}$) be a grid cell of $\mathcal{C}$ in the leftmost (resp., rightmost) column, and let $p_L \in S_{i_L j_L}$, and $p_R \in S_{i_R j_R}$. By assumption, $j_R - j_L \geq 5\mu + 1$. We group the columns between the j_Lth and j_Rth columns (exclusive) into five pairwise-disjoint vertical strips $V_1, \ldots, V_5$, appearing in this left-to-right order, each of width at least $\mu\varepsilon \geq 1$. We argue that each of V_2, V_4 must contain points of S, or else $\mathcal{G}$ would not be connected. Then p_L, p_R, any point in $V_2 \cap S$, and any point in $V_4 \cap S$ form a 1-separated quadruple. Clearly, finding these points takes linear time. □

By Lemmas 4.6 and 4.7, we may therefore assume that $\mathcal{G}$ is connected and that $\mathcal{C}$ spans at most $5\mu + 1$ rows and at most $5\mu + 1$ columns. In this case, we try all quadruples $C_1, C_2, C_3, C_4 \in \mathcal{C}$ and determine whether the corresponding product $S_1 \times S_2 \times S_3 \times S_4$ contains a 1-separated quadruple. We can assume that, for each pair of cells, the maximum distance between points in these two cells is at least one, and that the subgraph induced by these four cells is connected, because if the former assumption is violated, then no 1-separated quadruple exists, and if the latter is violated, then we can find a 1-separated quadruple (or determine that none exists), proceeding as in Lemma 4.6. In other words, we may assume that, for each C_i, C_j,

$$1 \leq \max_{x \in C_i,\, y \in C_j} |xy| \leq 1 + 2\sqrt{2}\varepsilon.$$

We now proceed by case analysis, according to the structure of the edges of $\mathcal{G}$ that connect the cells $C_1, \ldots, C_4$. Figure 8 shows all the possible cases, up to symmetries. It is easily checked that the complete graph on $C_1, \ldots, C_4$ is impossible, if ε is chosen sufficiently small.

In cases (i), (ii), and (iii), there is at least one node that has degree 1 in $\mathcal{G}$. It is then easy to reduce the problem to the case of finding a 1-separated triple. Consider for example case (iii), where the only edge incident to C_2 is (C_2, C_3). We then replace

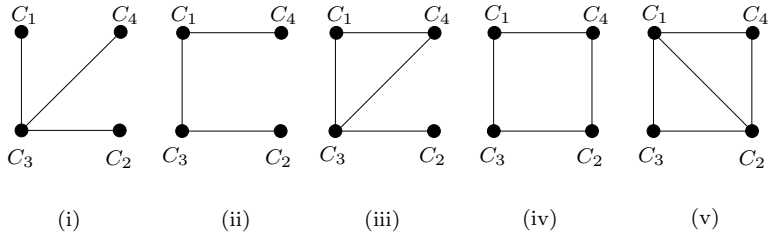

FIG. 8. *Possible graphs for $k = 4$.*

S_3 by the set

$$S_3' = \Big\{ p \in S_3 \mid \max_{q \in S_2} |pq| \geq 1 \Big\}.$$

S_3' can be computed in time $O(n \log n)$, by constructing $K(S_2)$ and choosing all points of S_3 that lie outside $K(S_2)$. We now find, in time $O(n^{4/3} \log^2 n)$, a 1-separated triple in $S_1 \times S_2 \times S_3'$, or determine that none exists. Once such a triple (p, q, r) is found, any point $s \in S_2$ for which $|rs| \geq 1$ can be added to it to form a 1-separated quadruple; s can be found in additional $O(n)$ time.

This leaves us with cases (iv) and (v). Pick points $c_i \in C_i$, for $i = 1, 2, 3, 4$, such that $|c_1c_3| = |c_2c_4| = 1$. Then

$$1 - 2\sqrt{2}\varepsilon \leq |c_2c_3|, |c_1c_4| \leq 1 + 2\sqrt{2}\varepsilon.$$

Hence, by translating c_2c_4 by distance $\leq 2\sqrt{2}\varepsilon$, we can also enforce $|c_2c_3| = 1$, and $1-4\sqrt{2}\varepsilon \leq |c_1c_4| \leq 1+4\sqrt{2}\varepsilon$. Note that $\angle c_1c_3c_2$ and $\angle c_3c_2c_4$ cannot be much smaller than $\pi/3$ each, because otherwise c_1 and c_2, or c_3 and c_4, would be too close to each other, contrary to what we are assuming. For the same reason, these angles cannot be much larger than $2\pi/3$.

This is easily seen to imply that, by slightly rotating c_4 around c_2, we can make the distance $|c_1c_4|$ also equal to 1. The new points c_i are no longer necessarily inside the respective cells C_i, for $i = 2, 3, 4$, but they remain close to these cells. If ε is chosen sufficiently small, the disk of radius $\delta = 1/8$ around c_i will fully contain C_i, for $i = 1, \ldots, 4$. Moreover, by slightly flexing the rhombus $c_1c_3c_2c_4$, we can also assume that $|c_1c_2| \geq 1$, while the containment property just mentioned continues to hold. If $|c_1c_2| \leq 1 + 2\delta = 5/4$, then S_1, S_2, S_3, S_4 satisfy property ($\diamond$). In this case, we can apply the algorithm of Theorem 4.5 to find a 1-separated quadruple in $S_1 \times S_2 \times S_3 \times S_4$, or to determine that none exists, in time $O(n^{4/3} \log^{10/3} n)$.

If $|c_1c_2| > 5/4$, any pair of points $p \in S_1$, $q \in S_2$ is 1-separated. We can then apply a simpler variant of the algorithm in section 4.1, in which we ignore any interaction between S_1 and S_2. Thus we may ignore the family Δ of disks, and only consider the intersection points σ_p and not α_p, β_p. Alternatively, we can run the algorithm as is, and the disks $\mathbb{D}(p)$, for $p \in S_1$, will never show up on the overall envelope. In either case, the running time is $O(n^{4/3} \log^{10/3} n)$.

In summary, we show the following theorem.

THEOREM 4.8. *Let S be a set of n points in $\mathbb{R}^2$. A 1-separated quadruple in S can be computed (or be determined not to exist) in time $O(n^{4/3} \log^{10/3} n)$.*

Finally, by performing a binary search on the pairwise distances in S, as in section 3, we obtain the following main result of this section.

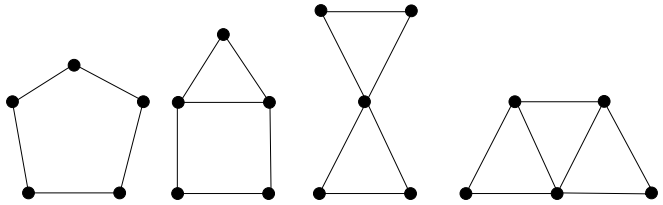

FIG. 9. *Possible graphs for* $k = 5$.

THEOREM 4.9. *Let S be a set of n points in $\mathbb{R}^2$. A maximally separated quadruple in S can be computed in $O(n^{4/3}\log^{13/3} n)$ time.*

4.3. Discussion. The technique that we have presented in sections 3 and 4 can be extended in principle to larger values of k. As above, it suffices to solve the decision problem: Determine whether a 1-separated k-tuple exists in S. Lemmas 4.6 and 4.7 can be extended in a straightforward manner, and they reduce the problem to $O(1)$ subproblems. In each subproblem we have k $\varepsilon \times \varepsilon$ square cells $C_1, \ldots, C_k$ of a grid, and subsets $S_i = S \cap C_i$, for $i = 1, \ldots, k$. Every pair of cells is such that the maximum distance between their points is at least 1, and some pairs of cells are such that the minimum distance between their points is at most 1. The collection of the pairs of the second kind constitutes the edge set of a graph $\mathcal{G}$, and the problem proceeds by case analysis, depending on the structure of $\mathcal{G}$. As above, we may assume that $\mathcal{G}$ is connected, and that the degree of each node is at least two.

For example, consider the case $k = 5$. The possible graphs $\mathcal{G}$ that need to be considered are shown in Figure 9. We leave it as an open problem to design efficient algorithms for the decision problem on each of these graphs, and thus to obtain an efficient algorithm for finding a maximally separated 5-tuple in S.

5. An exact algorithm for an arbitrary *k*. Let S be a set of n points in $\mathbb{R}^2$, and let $k \geq 2$ be an integer. We describe an $n^{O(\sqrt{k})}$-time algorithm for computing a maximally separated subset of S of size k. As in the previous sections, it suffices to focus on the decision problem: Given a set $\mathcal{D}$ of n unit disks and an integer $1 \leq k \leq n$, is there a subset $I \subseteq \mathcal{D}$ of k pairwise-disjoint disks?

Suppose that all the disks of $\mathcal{D}$ lie inside a horizontal strip W of (integer) width w. Using a sweep-line algorithm, similar to the one by Gonzalez [14] for computing a k-center of a set of points, we can compute a largest subset of pairwise-disjoint disks in $n^{O(w)}$ time, as follows.

We define the *index* of a set $A = \{D_1, \ldots, D_q\}$ of unit disks, for $q \leq n$, to be the $2n$-vector

$$\sigma(A) = (\underbrace{0, \ldots, 0, x_1, \ldots, x_q}_{n}, \underbrace{0, \ldots, 0, y_1, \ldots, y_q}_{n}),$$

where (x_i, y_i) is the center of D_i, $x_1 \leq x_2 \leq \cdots \leq x_q$, and if $x_i = x_{i+1}$, then $y_i < y_{i+1}$. We refer to the set of pairwise-disjoint disks with the maximal index in lexicographic order as the *optimal independent set*. The sweep-line algorithm computes the optimal independent set of $\mathcal{D}$, as follows.

For a subset $A \subseteq \mathcal{D}$ and a vertical line ℓ, let $\chi(A, \ell) \subseteq A$ be the set of disks in A that intersect ℓ. We sweep a vertical line ℓ from left to right, stopping at the leftmost and rightmost point of each disk in $\mathcal{D}$. At any time, the algorithm maintains a family $\mathcal{F} = \{I_1, \ldots, I_u\}$ of subsets of pairwise-disjoint disks that satisfies the following invariants:

(I.1) For every $1 \le j \le u$, no disk in $I_j \subseteq \mathcal{D}$ is contained in the (closed) halfplane lying to the right of the sweep line.

(I.2) For $a \ne b$, $\chi(I_a, \ell) \ne \chi(I_b, \ell)$.

(I.3) If there is a subset $A \subseteq \mathcal{D}$ of pairwise-disjoint disks so that no disk in A lies completely to the right of ℓ, then there is a subset $I_j \in \mathcal{F}$ so that $\chi(I_j, \ell) = \chi(A, \ell)$ ($\chi(I_j, \ell)$ may be empty) and $\sigma(A) \le_{\text{lex}} \sigma(I_j)$.

Since at most $O(w)$ pairwise-disjoint disks of $\mathcal{D}$ can intersect ℓ, invariant (I.2) implies that $|\mathcal{F}| = n^{O(w)}$ throughout the sweep. When the sweep line ℓ passes through the leftmost point of a disk $D \in \mathcal{D}$, we test, for each set $I \in \mathcal{F}$, whether D does not intersect any disk in I, and, if so, we add the set $I \cup \{D\}$ to $\mathcal{F}$ (and we also keep I in $\mathcal{F}$). When ℓ passes through the rightmost point of a disk D, we delete all the sets I_a from $\mathcal{F}$ for which there is another set $I_b \in \mathcal{F}$ with $\sigma(I_a) <_{\text{lex}} \sigma(I_b)$ and $\chi(I_a, \ell) \setminus \{D\} = \chi(I_b, \ell) \setminus \{D\}$. We spend $O(|\mathcal{F}|^2 n)$ time at each leftmost or rightmost point of a disk, so the overall running time remains $n^{O(w)}$ (with an appropriate calibration of the constant of proportionality in the exponent). The reader can easily verify that the invariants (I.1)–(I.3) ensure that the algorithm computes the optimal independent set of $\mathcal{D}$.

If $w \le 2\sqrt{k}+2$, we use the above algorithm to determine, in $n^{O(\sqrt{k})}$ time, whether $\mathcal{D}$ contains k pairwise-disjoint disks. So assume that $w > 2\sqrt{k}+2$. Let Π be the set of at most $2n$ horizontal lines tangent to disks in $\mathcal{D}$. The following packing lemma was proved by Agarwal and Procopiuc [3].

LEMMA 5.1. *Let $\mathcal{D}$ be a set of n disks in $\mathbb{R}^2$, and let $\mathcal{D}' \subseteq \mathcal{D}$ be a subset of at most k pairwise-disjoint unit disks that lie in a horizontal strip of width larger than $2\sqrt{k}+2$. Then there exists a horizontal line tangent to one of the disks in $\mathcal{D}$ that intersects at most $\sqrt{k}$ disks of $\mathcal{D}'$.*

For any $h \in \Pi$ and $I \subseteq \mathcal{D}$, we call (h, I) a *canonical pair* if $|I| \le \sqrt{k}$, the disks in I are pairwise disjoint, and all disks in I intersect h (in general, h may also intersect other disks of $\mathcal{D}$). We define a *c-strip* to be a triple $\tau = (\omega, A_1, A_2)$, where ω is a strip bounded by two lines $\ell_1, \ell_2 \in \Pi$, with ℓ_1 lying above ℓ_2, and (ℓ_1, A_1) and (ℓ_2, A_2) are canonical pairs; A_1, A_2 are not necessarily disjoint. Let $\mathcal{D}_\tau \subseteq \mathcal{D}$ be the set of disks that do not intersect ℓ_1, ℓ_2 or any disk of $A_1 \cup A_2$. We define the optimal independent set of τ, denoted by $\mathbb{I}_\tau$, to be the optimal independent set of $\mathcal{D}_\tau$, and set $\kappa_\tau := |\mathbb{I}_\tau|$. We call τ *thin* if the width of ω is at most $2\sqrt{k}+2$, and *thick* otherwise.

For a given $\tau = (\omega, A_1, A_2)$, we compute $\mathbb{I}_\tau$ as follows. If τ is thin, then we compute $\mathbb{I}_\tau$ using the sweep-line algorithm described above. So assume that τ is thick. If $\mathcal{D}_\tau \ne \emptyset$, then by Lemma 5.1, there exists a canonical pair (h, I) so that h divides ω into two strips ω^+, ω^- each of width less than that of ω. Let $\tau^+ = (\omega^+, A_1, I)$ and $\tau^- = (\omega^-, I, A_2)$. We compute $\mathbb{I}_{\tau^+}$ and $\mathbb{I}_{\tau^-}$ recursively, and output $\mathbb{I}_\tau := \mathbb{I}_{\tau^+} \cup I \cup \mathbb{I}_{\tau^-}$. Since we do not know the true canonical pair (h, I), we try all canonical pairs and choose the one for which the solution has the largest index. Moreover, instead of solving the problem recursively, we use a bottom-up approach based on dynamic programming.

In particular, we build a table, each of whose entries corresponds to a c-strip $\tau = (w, A_1, A_2)$ and stores κ_τ and $\sigma_\tau = \sigma(\mathbb{I}_\tau)$. If we ever encounter an entry with

$\kappa_\tau > k$, we can conclude that the size of the largest independent set in $\mathcal{D}$ is greater than k, and we restart the algorithm with a new larger value of k. So we assume that $\kappa_\tau \leq k$ for all entries. We fill the entries of the table as follows. If $\mathcal{D}_\tau = \emptyset$, we set $\mathbb{I}_\tau := \emptyset$, and if τ is thin, we compute $\mathbb{I}_\tau$ using the sweep-line algorithm and fill the entry. Otherwise, we compute all canonical pairs (h, I) for which h lies inside ω, and let ω^+ (resp., ω^-) be the portion of ω lying above (resp., below), and let $\tau^+ = (\omega^+, A_1, I)$ and $\tau^- = (\omega^-, I, A_2)$. Compute

$$\kappa_\tau := \max_{(h,I)} \left\{ \kappa_{\tau^+} + \kappa_{\tau^-} + |I \setminus (A_1 \cup A_2)| \right\},$$

where the maximum is taken over all canonical pairs. Let (h^*, I^*) be the canonical pair for which the maximum is attained. Then $\sigma(\tau)$ is the index of $\mathbb{I}_{\tau^*_+} \cup \mathbb{I}_{\tau^*_-} \cup I^*$, where τ^*_+, τ^*_- are the c-strips defined by the canonical pair (h^*, I^*). If the maximum value of κ_τ is attained by more than one canonical pair, we choose the one for which $\sigma(\tau)$ is maximal.

Let $(\omega_1, \ldots, \omega_M)$, for $M = O(n^2)$, be the sequence of horizontal strips determined by pairs of lines in Π, sorted in nondecreasing order of their widths. We fill out the entries of the table having ω_i as the first component of the index before filling the entries with ω_{i+1} as their first component. If $\mathcal{D}$ contains an independent set of size at most k, then the optimal solution for the c-strip $(\omega_M, \emptyset, \emptyset)$ gives the size and index of the optimal independent set of $\mathcal{D}$. Since there are $n^2 \cdot n^{O(\sqrt{k})} \cdot n^{O(\sqrt{k})}$ c-strips, and each entry can be filled in $n^{O(\sqrt{k})}$ time, the overall running time of the decision algorithm is $n^{O(\sqrt{k})}$ (again, with calibration of the constant of proportionality). We thus obtain the following theorem.

THEOREM 5.2. *Let $\mathcal{D}$ be a set of n unit disks in $\mathbb{R}^2$. The optimal independent set $\mathbb{I}$ of $\mathcal{D}$ can be computed in time $n^{O(\sqrt{k})}$, where k is the size of $\mathbb{I}$.*

Returning to the problem of computing a maximally separated subset of S of size k, we perform a binary search on the pairwise distances in S. At each step, we need to determine whether there exists a maximally separated subset $I \subseteq S$ of size k with $d_{\text{sep}}(I) \geq r$, for a given r, which reduces to determining whether there is an independent set of size k in the set $\{D(p, r) \mid p \in S\}$. Using Theorem 5.2, we thus obtain the following theorem.

THEOREM 5.3. *Let S be a set of n points in $\mathbb{R}^2$, and let $1 \leq k \leq n$ be an integer. A maximally separated subset of S of size k can be computed in $n^{O(\sqrt{k})}$ time.*

6. Conclusion. In this paper we have presented efficient exact and approximation algorithms for computing maximally separated subsets of a set of points in the plane. The approximation algorithm runs in linear time for fixed values of k, and the exact algorithm runs in time $n^{O(\sqrt{k})}$. We also presented $O(n^{4/3}\text{polylog}(n))$-time algorithms for $k = 3, 4$. As mentioned in Section 4.3, it is not clear whether our approach gives a subquadratic algorithm for $k = 5$. Another interesting open problem is whether a maximally separated subset of size k can be computed in time $n^{O(1)} + k^{O(\sqrt{k})}$.

A PROBABILISTIC APPROACH TO THE DICHOTOMY PROBLEM*

TOMASZ ŁUCZAK† AND JAROSLAV NEŠETŘIL‡

Abstract. Let $\mathcal{R}(n,k)$ denote the random k-ary relation defined on the set $[n]=\{1,2,\dots,n\}$. We show that the probability that $([n],\mathcal{R}(n,k))$ is projective tends to one, as either n or k tends to infinity. This result implies that for most relational systems $(B,\underline{R})$ the CSP$(B,\underline{R})$ problem is NP-complete (and thus that the dichotomy conjecture holds with probability 1), and confirms a conjecture of Rosenberg [I. G. Rosenberg, *Rocky Mountain J. Math.*, 3 (1973), pp. 631–639].

Key words. CSP, projectivity, random relation

1. Introduction.

Let $\Delta=(\delta_i)_{i\in I}$ be a finite sequence of positive integers. A *relational system of type* Δ is a pair $(A,\underline{R})$, where A is a finite set, $\underline{R}=(R_i)_{i\in I}$, and R_i is a δ_i-ary relation on A, i.e., $R_i\subseteq A^{\delta_i}$ for $i\in I$. A system $(A,(R_i)_{i\in I})$ is *loop-free* if for every $a\in A$ and $i\in I$ the δ_i-tuple $(a,\dots,a)$ is not in R_i. If $(A,\underline{R})$, $(A',\underline{R}')$ are relational systems of the same type $\Delta=(\delta_i)_{i\in I}$, then by a *homomorphism* from $(A',\underline{R}')$ to $(A'',\underline{R}'')$ we mean a map $f:A'\to A''$ such that for every $i\in I$, we have $(f(x_1),\dots f(x_{\delta_i}))\in R_i''$ whenever $(x_1,\dots,x_{\delta_i})\in R_i'$ (for a recent introduction to homomorphisms of graphs and structures, see [8].)

Relational structures and homomorphisms express various decision and counting combinatorial problems such as coloring, satisfiability, and linear algebra problems. Many of them can be reduced to special cases of a general constraint satisfaction problem CSP$(B,\underline{R})$ which, in the language of homomorphisms, can be stated as follows (cf. [6]): *given a relational system* $(A,\underline{R}')$ *decide if there exists a homomorphism* $f:(A,\underline{R}')\to(B,\underline{R})$. A number of such problems have been studied and have known complexity, e.g., when we deal with undirected graphs or the problem is restricted to small sets A (see [4, 7, 14]). However at this moment we are far from understanding the behavior of the CSP$(B,\underline{R})$ problem even for binary relations $(B,\underline{R})$ (i.e., for relational systems of type $\Delta=(2)$). It seems that "most" CSP$(B,\underline{R})$ are hard (NP-complete) problems while few exceptions from this seem to be polynomial. Thus, for instance, for undirected graphs (i.e., symmetric binary relations) CSP$(B,\underline{R})$ is always a hard problem with exactly three exceptions: when $(B,\underline{R})$ is a loop, or a single vertex (with no relation), or a symmetric edge [7]. Results for other solved cases are similar (see [4, 14]).

One of the basic unsolved questions in this area of constraint satisfaction problems is the following [6].

CONJECTURE 1 (dichotomy conjecture). *Every CSP$(B,\underline{R})$ problem is either NP-complete or polynomially solvable.*

This remains widely open even for $\Delta = (2)$ (in fact, the complexity of the problem is reflected by this case). In this paper we consider a "probabilistic version" of this problem showing that $\mathrm{CSP}(B, \underline{R})$ is NP-complete for most "large" loop-free relational systems $(B, \underline{R})$.

THEOREM 2. *Let $\Delta = (\delta_i)_{i\in I}$ be such that $\max_{i\in I} \delta_i \geq 2$. Then CSP$(B, \underline{R})$ is NP-complete for almost all loop-free relational systems $(B, \underline{R})$ of type Δ.*

Note that for $(B, \underline{R})$ of type $(1, 1, \ldots, 1)$ the problem $\mathrm{CSP}(B, \underline{R})$ is trivial. We also remark that our probabilistic approach is very different from those considered by Achlioptas et al. [1] who study random instances of $\mathrm{CSP}(B, \underline{R})$ for a given (i.e., nonrandom) relational system $(B, \underline{R})$.

The paper is organized as follows. In the following section we formulate the main result of the paper, Theorem 4, which states that most relational systems are strongly rigid, as conjectured by Rosenberg [13]. We also make the formulation of Theorem 2 precise by introducing a notion of a random k-ary relation and remark that Theorem 2 follows from Theorem 4. Then, we introduce "reach" relations and show that reachness implies projectivity. Finally, in section 4, we prove Theorem 4.

2. Projective and rigid relational system. Let $(A, \underline{R})$ be a relational system of type $\Delta = (\delta_i)_{i\in I}$. By (A^ℓ, R^ℓ) we denote the relational system of type Δ such that for every $i \in I$

$$\big((a_1^1, \ldots, a_\ell^1), \ldots, (a_1^k, \ldots, a_\ell^k)\big) \in R_i^\ell$$

if and only if $(a_j^1, \ldots, a_j^k) \in R_i$ for each $j = 1, \ldots, \ell$ (thus $k = \delta_i$). An *operation* (*polymorphism* in [2, 5, 9, 13]) of a relational system (A, R) is a homomorphism $f : A^\ell \to A$ from (A^ℓ, R^ℓ) to (A, R) for some $\ell \geq 1$. Such an operation is *idempotent* if $f(a, \ldots, a) = a$ for every $a \in A$, and it is a *projection* (on the jth coordinate) if there exists j, $1 \leq j \leq \ell$, such that for every $(a_1, \ldots, a_\ell) \in A^\ell$ we have $f(a_1, \ldots, a_\ell) = a_j$. We say that a system (A, R) is *projective* if for every $\ell \geq 1$ every idempotent operation $f : A^\ell \to A$ is a projection (cf., [10, 11]). The system $(A, \underline{R})$ is *rigid* if the identity mapping is the only homomorphism from A to A and *strongly rigid* if it is both projective and rigid. It is easy to see that $(A, \underline{R})$ is strongly rigid if and only if for each $\ell \geq 1$ every operation $f : A^\ell \to A$ is a projection.

The notions of projective and rigid relational systems play an important role in investigations of complexity of $\mathrm{CSP}(B, \underline{R})$ problems. In particular, it is known that these problems are hard whenever the system $(B, \underline{R})$ is strongly rigid, i.e., the following result holds (see, for instance, [2, 3, 5, 9]).

THEOREM 3. *If a relational system $(B, \underline{R})$ is strongly rigid, then the problem CSP$(B, \underline{R})$ is* NP*-complete.*

Thus, in order to show Theorem 2, it is enough to verify that most of relational systems are strongly rigid. In order to make this statement precise, let $\mathcal{R}(n, k)$ denote a random k-ary relation defined on a set $[n] = \{1, 2, \ldots, n\}$ for which the probability that $(a_1, \ldots, a_k) \in \mathcal{R}(n, k)$ is equal to $1/2$ independently for each $(a_1, \ldots, a_k)$, where $1 \leq a_r \leq n$ for $r = 1, \ldots, k$ and not all a_i's are equal; for $a \in [n]$, we put $(a, a, \ldots, a) \notin \mathcal{R}(n, k)$. Let $([n], (\mathcal{R}(\delta_i, n)_{i\in I}))$ denote the random relational system of type $\Delta = (\delta_i)_{i\in I}$. We shall show that the probability that $([n], (\mathcal{R}(\delta_i, n)_{i\in I}))$ is strongly rigid tends to one as either n or $\max_i \delta_i$ tends to infinity. Note that a relational system $(A, \underline{R})$ is strongly rigid, provided for some $i_0 \in I$ the system (A, R_{i_0}) of type (δ_{i_0}) is strongly rigid (although the converse implication, in general, does not hold). Thus, it is enough to prove our result for "simple" relational systems which consist of just one k-ary relation.

THEOREM 4. *For a fixed $k \geq 2$,*

$$\lim_{n\to\infty} \Pr\big(([n], \mathcal{R}(k,n)) \text{ is strongly rigid}\big) = 1, \tag{1}$$

while, for a given $n \geq 2$,

$$\lim_{k\to\infty} \Pr\big(([n], \mathcal{R}(k,n)) \text{ is strongly rigid}\big) = 1. \tag{2}$$

The proof of Theorem 4 we postpone until section 4. It is based on an argument which is somewhat similar to that used by the authors in [12] to show that almost every graph (i.e., almost every binary symmetric relation) is strongly rigid.

We also remark that (2) settles in the affirmative a conjecture posed by Rosenberg [13].

3. Reach relational systems. Let R be a k-ary relation on a set A. A system (A, R) is *reach* if there exist elements $z_1, \ldots, z_{k-2} \in A$ such that for any four different elements $x_1, x_2, y_1, y_2 \in A$, there is a $w \in A$ such that for $r = 1, 2$, we have

$$(z_1, \ldots, z_{k-2}, w, x_r) \in R \text{ but } (z_1, \ldots, z_{k-2}, w, y_r) \notin R. \tag{3}$$

We shall show that reachness implies projectivity.

THEOREM 5. *Each reach system (A, R) with $|A| \geq 5$ is projective.*

Before we prove Theorem 5 we introduce some more notation. Let $f : A^\ell \to A$ be an idempotent operation from A^ℓ to A. For an ℓ-tuple $(a_1, \ldots, a_\ell) \in A^\ell$, we set

$$\Xi(a_1, \ldots, a_\ell) = \{a \in A : a = a_i \text{ for some } i = 1, 2, \ldots, \ell\},$$

by $\xi(a_1, \ldots, a_\ell) = |\Xi(a_1, \ldots, a_\ell)|$ we denote the number of different coordinates of $(a_1, \ldots, a_\ell)$, and we set

$$\Lambda_f(a_1, \ldots, a_\ell) = \{i : f(a_1, \ldots, a_\ell) = a_i\}.$$

Hence, for instance, $\Xi(a, \ldots, a) = \{a\}$, $\xi(a, \ldots, a) = 1$, and, since f is idempotent, $\Lambda_f(a, \ldots, a) = \{1, 2, \ldots, \ell\}$. Our proof of Theorem 5 is based on the following two claims.

CLAIM 1. *If (A, R) is reach, then for every idempotent operation $f : A^\ell \to A$, and every $(a_1, \ldots, a_\ell) \in A^\ell$,*

$$\Lambda_f(a_1, \ldots, a_\ell) \neq \emptyset. \tag{4}$$

Proof. We shall use induction on $\xi(a_1, \ldots, a_\ell)$. As we have already observed, the fact that f is idempotent implies that $\Lambda_f(a, \ldots, a) = \{1, 2, \ldots, \ell\}$. Let us suppose that the assertion holds for every $(a_1, \ldots, a_\ell)$ with at most m, $1 \leq m \leq \ell - 1$, different coordinates, and let $(b_1, \ldots, b_\ell)$ be such that $\Xi(b_1, \ldots, b_\ell) = \{c_1, \ldots, c_{m+1}\}$. For a contradiction let us assume that

$$f(b_1, \ldots, b_\ell) = d \notin \{c_1, \ldots, c_{m+1}\}.$$

Because R is reach one can choose from A elements e_i, $i = 1, \ldots, k-2$, and $\bar{c}_j$, $j = 1, \ldots, m$, such that for each $j = 1, \ldots, m$, we have

$$(e_1, \ldots, e_{k-2}, \bar{c}_j, c_j) \in R \quad \text{but} \quad (e_1, \ldots, e_{k-2}, \bar{c}_j, d) \notin R,$$

and

$$(e_1, \ldots, e_{k-2}, \bar{c}_m, c_{m+1}) \in R.$$

For $i = 1, 2, \ldots, \ell$, define

$$\bar{b}_i = \begin{cases} \bar{c}_j & \text{if} \quad b_i = c_j \text{ for some } j = 1, \ldots, m, \\ \bar{c}_m & \text{if} \quad b_i = c_{m+1}. \end{cases}$$

Then $\xi(\bar{b}_1, \ldots, \bar{b}_\ell) = m$ and so, by the inductive assumption, for some $s_0 = 1, \ldots, m$, we have $f(\bar{b}_1, \ldots, \bar{b}_\ell) = \bar{c}_{s_0}$. Note however that the k-tuple

$$\big((e_1, \ldots, e_1), (e_2, \ldots, e_2), \ldots, (e_{k-2}, \ldots, e_{k-2}), (\bar{b}_1, \ldots, \bar{b}_\ell), (b_1, \ldots, b_\ell)\big)$$

belongs to R^ℓ but is mapped by f into $(e_1, \ldots, e_{k-2}, \bar{c}_{s_0}, d)$, which, due to the choice of $\bar{c}_{s_0}$, does not belong to R. This contradiction shows that $\Lambda_f(b_1, \ldots, b_\ell) \neq \emptyset$. □

Claim 2. *If (A, R) is reach, then for every idempotent operation $f : A^\ell \to A$, and every pair of ℓ-tuples $(a_1, \ldots, a_\ell)$, $(b_1, \ldots, b_\ell)$, there exists t, $1 \leq t \leq \ell$, such that*

$$\{a_t, b_t\} \subseteq \{f(a_1, \ldots, a_\ell), f(b_1, \ldots, b_\ell)\}. \tag{5}$$

Proof. Claim 1 implies that $f(a_1, \ldots, a_\ell) = a_{j_1}$, $f(b_1, \ldots, b_\ell) = b_{j_2}$ for some indices j_1, j_2, $1 \leq j_1, j_2 \leq \ell$. Since (A, R) is reach one can find elements e_i, $i = 1, \ldots, k-2$, and $c_1, \ldots, c_\ell$ such that for each $s = 1, \ldots, \ell$,

$$(e_1, \ldots, e_{k-2}, c_s, a_s), (e_1, \ldots, e_{k-2}, c_s, b_s) \in R \tag{6}$$

but

$$(e_1, \ldots, e_{k-2}, c_s, w) \notin R \quad \text{for} \quad w \in \{a_{j_1}, b_{j_2}\} \setminus \{a_s, b_s\}. \tag{7}$$

From Claim 1 it follows that $f(c_1, \ldots, c_\ell) = c_t$ for some t, $1 \leq t \leq \ell$. Note also that both k-tuples

$$\big((e_1, \ldots, e_1), \ldots, (e_{k-2}, \ldots, e_{k-2}), (c_1, \ldots, c_\ell), (a_1, \ldots, a_\ell)\big)$$

and

$$\big((e_1, \ldots, e_1), \ldots, (e_{k-2}, \ldots, e_{k-2}), (c_1, \ldots, c_\ell), (b_1, \ldots, b_\ell)\big)$$

belong to R^ℓ, and so we must have

$$(e_1, \ldots, e_{k-2}, c_t, a_{j_1}), (e_1, \ldots, e_{k-2}, c_t, b_{j_2}) \in R\,.$$

This fact, together with (7), implies that $\{a_t, b_t\} \subseteq \{a_{j_1}, b_{j_2}\}$. □

Proof of Theorem 5. Let

$$\hat{A}^\ell = \{(a_1, \ldots, a_\ell) \in A^\ell : \xi(a_1, \ldots, a_\ell) \leq 3\}.$$

Let us observe that for some $(a_1, \ldots, a_\ell) \in \hat{A}^\ell$ we have $|\Lambda_f(a_1, \ldots, a_\ell)| = 1$. Indeed, take $(a_1, \ldots, a_\ell) \in \hat{A}^\ell$ for which $|\Lambda_f(a_1, \ldots, a_\ell)|$ is minimal. Since, by Claim 1,

$|\Lambda_f(a_1,\dots,a_\ell)| \geq 1$, assume that $j \in \Lambda_f(a_1,\dots,a_\ell)$. Let $b, b' \in A \setminus \Xi(a_1,\dots,a_\ell)$ and let

$$c_i = \begin{cases} b & \text{if } i = j, \\ b' & \text{if } i \in \Lambda_f(a_1,\dots,a_\ell) \setminus \{j\}, \\ a_j & \text{if } i \notin \Lambda_f(a_1,\dots,a_\ell). \end{cases}$$

Then $(c_1,\dots,c_\ell) \in \hat{A}^\ell$, but Claim 2 implies that $\Lambda_f(c_1,\dots,c_\ell)$ is a proper subset of $\Lambda_f(a_1,\dots,a_\ell)$. Hence, there is an $(a_1,\dots,a_\ell) \in A^\ell$ such that $\Lambda_f(a_1,\dots,a_\ell) = \{t\}$ for some $1 \leq t \leq \ell$.

Let us fix such $(a_1,\dots,a_\ell)$ and t, pick $b \in A \setminus \Xi(a_1,\dots,a_\ell)$, and define

$$\bar{a}_i = \begin{cases} b & \text{if } i = t, \\ a_i & \text{if } i \neq t. \end{cases}$$

Then, using again Claims 1 and 2, we infer that $\Lambda_f(\bar{a}_1,\dots,\bar{a}_\ell) = \{t\}$. A similar argument shows that $\Lambda_f(d_1,\dots,d_\ell) = \{t\}$ whenever $(d_1,\dots,d_\ell)$ belongs to the set $\tilde{A}^\ell \subset \hat{A}^\ell$ which consists of all ℓ-tuples $(d_1,\dots,d_\ell)$ such that for all $i,j \neq t$ we have $d_i = d_j \neq d_t$.

Now let $(a_1,\dots,a_\ell)$ be any ℓ-tuple of A^ℓ and suppose that $f(a_1,\dots,a_\ell) = a_s \neq a_t$ for some s, $1 \leq s \leq \ell$. Consider $(d_1,\dots,d_\ell) \in \tilde{A}^\ell$ such that

$$d_i = \begin{cases} a_s & \text{if } i = t, \\ a_t & \text{if } i \neq s. \end{cases}$$

Then, the pair $(a_1,\dots,a_\ell)$, $(d_1,\dots,d_\ell)$ contradicts Claim 2. Consequently, for every $(a_1,\dots,a_\ell)$ we have $f(a_1,\dots,a_\ell) = a_t$, and the assertion follows. □

In order to deal with relational systems defined on small sets, we introduce one more definition. Let $2 \leq i \leq k-1$ and (A,R) be a relation system with k-ary relation R. We call (A,R) *i-reach* if (A,R) is reach and there exist elements $z_1,\dots,z_{k-i-1} \in A$ such that for every two different i-tuples $(x_1,\dots,x_i)$, $(y_1,\dots,y_i) \in A^i$, there is a $w \in A$ for which

$$(z_1,\dots,z_{k-i-1},w,x_1,\dots,x_i) \in R \tag{8}$$

but

$$(z_1,\dots,z_{k-i-1},w,y_1,\dots,y_i) \notin R. \tag{9}$$

It turns out that (A,R) is projective also for $|A| \geq 2$ if the assumption of Theorem 5 is slightly strengthened.

THEOREM 6. *If (A,R) is 3-reach, then (A,R) is projective.*

The following result, which is, in a way, a generalization of Claim 1, can be shown by imitating the proof of Claim 2.

CLAIM 3. *If (A,R) is i-reach for some $i \geq 2$, then for every set of i ℓ-tuples $(a_1^r,\dots,a_\ell^r)$, $r = 1,2,\dots,i$, we have*

$$\bigcap_{r=1}^{i} \Lambda_f(a_1^r,\dots,a_\ell^r) \neq \emptyset. \tag{10}$$

Proof. Let us assume that (A,R) is i-reach, and let $(a_1^r,\dots,a_\ell^r)\in A^\ell$ for $r=1,\dots,i$. From Claim 1 it follows that there exist indices j_r, $1\le j_r\le \ell$, such that $f(a_1^r,\dots,a_\ell^r)=a_{j_r}^r$ for $r=1,\dots,i$. Since (A,R) is i-reach one can find elements e_i, $i=1,\dots,k-i-1$, and $c_1,\dots,c_\ell$, such that for each $s=1,\dots,\ell$,

$$(e_1,\dots,e_{k-i-1},c_s,a_s^1,\dots,a_s^i)\in R \tag{11}$$

but

$$(e_1,\dots,e_{k-2},c_s,a_{j_1}^1,\dots,a_{j_i}^i)\notin R \quad\text{unless}\quad (a_s^1,\dots,a_s^i)=(a_{j_1}^1,\dots,a_{j_i}^i). \tag{12}$$

Claim 1 implies that $f(c_1,\dots,c_\ell)=c_t$ for some t, $1\le t\le \ell$. Note that for each $r=1,2,\dots,i$, the k-tuple

$$\big((e_1,\dots,e_1),\dots,(e_{k-i-1},\dots,e_{k-i-1}),(c_1,\dots,c_\ell),(a_1^1,\dots,a_\ell^1),\dots,(a_1^i,\dots,a_\ell^i)\big)$$

belongs to R^ℓ, and so its image under f, equal to $(e_1,\dots,e_{k-i-1},\ c_t,\ a_{j_1}^1,\dots,a_{j_i}^i)$, belongs to R. But then (12) implies that $(a_t^1,\dots,a_t^i)=(a_{j_1}^1,\dots,a_{j_i}^i)$, i.e.,

$$t\in\bigcap_{r=1}^{i}\Lambda_f(a_1^r,\dots,a_\ell^r). \qquad \square$$

Proof of Theorem 6. As in the proof of Theorem 5 we show first that for some $(a_1,\dots,a_\ell)\in A^\ell$ we have $|\Lambda_f(a_1,\dots,a_\ell)|=1$.

Indeed, suppose that $|\Lambda_f(a_1,\dots,a_\ell)|$ is minimal, $|\Lambda_f(a_1,\dots,a_\ell)|\ge 2$. Choose $j\in\Lambda_f(a_1,\dots,a_\ell)$, and $b\in A\setminus\{a_j\}$. Define

$$c_i=\begin{cases} a_j & \text{if } i\ne j,\\ b & \text{if } i=j.\end{cases}$$

Then we have the following possibilities for $\Lambda_f(c_1,\dots,c_\ell)$:

(i) $\Lambda_f(c_1,\dots,c_\ell)=\{j\}$ (in the case $f(c_1,\dots,c_\ell)=b$),

(ii) $\Lambda_f(c_1,\dots,c_\ell)\cap\Lambda_f(a_1,\dots,a_\ell)=\emptyset$ (if $f(c_1,\dots,c_\ell)\ne a_j,b$),

(iii) $\Lambda_f(c_1,\dots,c_\ell)=\Lambda_f(a_1,\dots,a_\ell)$ (in the case $f(c_1,\dots,c_\ell)=a_j$).

In the first case we are done, the second case is impossible by Claim 3, and the last case is impossible as we have chosen $(a_1,\dots,a_\ell)$ such that $|\Lambda_f(a_1,\dots,a_\ell)|$ is minimal. Thus, for some $(a_1,\dots,a_\ell)\in A^\ell$, we have $\Lambda_f(a_1,\dots,a_\ell)=\{t\}$. Now the assertion follows from Claim 3. $\square$

4. Proof of the main result. Let us start with the following result, which, in fact, gives more than we need.

LEMMA 7. *Let $i\ge 2$ be a fixed natural number.*

(i) *For a fixed $k>i$*

$$\lim_{n\to\infty}\Pr\big(([n],\mathcal{R}(n,k))\ \textit{is } i\textit{-reach}\big)=1.$$

(ii) *For a fixed $n\ge 2$*

$$\lim_{k\to\infty}\Pr\big(([n],\mathcal{R}(n,k))\ \textit{is } i\textit{-reach}\big)=1.$$

Proof. Let $k > i \geq 2$ be fixed and let $z_1, \ldots, z_{k-i-1}$ be any given elements of $[n]$, say, $z_r = r$ for $r = 1, \ldots, k-i-1$. Then, the probability that for two given i-tuples $(x_1, \ldots, x_i)$, $(y_1, \ldots, y_i)$ for all elements w either (8) or (9) does not hold is bounded from above by $(3/4)^n$. Hence the probability that one cannot find a required w, for some of at most n^{2i} possible choices for x's and y's, is smaller than $n^{2i}(3/4)^n$ and tends to 0 as $n \to \infty$. This proves the first part of the lemma.

In order to show (ii) observe first that there are at most $4n^{2i+1}$ choices for i-tuples $(x_1, \ldots, x_i)$, $(y_1, \ldots, y_i)$ and $w \in [n]$. The probability that for all these choices and for given $z_1, \ldots, z_{k-i-1}$ each of the relations (3), (8), and (9) holds is bounded from below by $\rho = 2^{-4n^{2i+1}}$. But there are $N = n^{k-i-1}$ possible choices for z's and so the number of $(k-i-1)$-tuples $(z_1, \ldots, z_{k-i-1})$ for which (3), (8), and (9) hold is bounded from below by the random variable Z with binomial distribution $Bi(N, \rho)$. Since $N \to \infty$ as $k \to \infty$ but ρ remains bounded away from 0, with probability tending to 1 as $k \to \infty$, we have $Z > 0$. Hence, with probability tending to 1 as $k \to \infty$, there exists a choice of $z_1, \ldots, z_{k-i-1}$ for which (3), (8), and (9) hold (for all $w \in A$!) and (ii) follows. □

Let us remark that in Lemma 7(i) it would be sufficient for our purposes to prove that for every fixed $k \geq 2$ we have

$$\lim_{n\to\infty} \Pr\big(([n], \mathcal{R}(n,k)) \text{ is reach}\big) = 1.$$

This can be proved similarly to (i); nevertheless Lemma 7 gives a stronger (and more symmetric) result. However there are two exceptions: for $k = 2, 3$, where (according to Theorem 6) we have to use the reach property only.

We shall also need to know that the system $([n], \mathcal{R}(n,k))$ typically has no non-trivial endomorphisms. This is a variant on the well-known result for graphs; see, e.g., [8].

LEMMA 8.

(i) *For a fixed $k \geq 2$,*

$$\lim_{n\to\infty} \Pr\big(([n], \mathcal{R}(n,k)) \textit{ is rigid}\big) = 1.$$

(ii) *For a fixed $n \geq 2$,*

$$\lim_{k\to\infty} \Pr\big(([n], \mathcal{R}(n,k)) \textit{ is rigid}\big) = 1.$$

Proof. Let us consider first the case when k is fixed. Let $f : [n] \to [n]$ be an endomorphism of $([n], \mathcal{R}(n,k))$. Note that with probability tending to 1 as $n \to \infty$ for any $S \subseteq [n]$, $|S| = m_0 = \lfloor 2 \log n \rfloor$, we have $|f(S)| \geq 2$. Indeed, if S is mapped into a single point, then, since $\mathcal{R}(n,k)$ is loop-free, for all $a_1, \ldots, a_k \in S$ we have $(a_1, \ldots, a_k) \notin \mathcal{R}(n,k)$, and the probability that such an S exists is bounded from above by

$$\binom{n}{m_0}\Big(\frac{1}{2}\Big)^{m_0^k} \leq \Big(\frac{en}{m}\Big(\frac{1}{2}\Big)^{m_0^{k-1}}\Big)^{m_0} \to 0\,.$$

Let us denote by W the number of vertices of $[n]$ which are not fixed by f. We show that with probability $1 - o(1)$ we have $|W| \leq 17 \log^2 n$. Let us assume that this is not the case. Then, using the fact we have just proved, one can greedily construct two disjoint sets $S_1 \subseteq W$, $S_2 \subseteq f(W)$, $|S_1|, |S_2| \geq \frac{17 \log^2 n}{2 \log n + 1} \geq m_1 = \lfloor 8 \log n \rfloor$, such

that $f|S_1$ is a bijective homomorphism from S_1 to S_2. However, the probability that two such sets exist is bounded from above by

$$\sum_{m_1 \geq \log^2 n} \binom{n}{m_1}\binom{n}{m_1} m_1! \left(\frac{3}{4}\right)^{m_1^k} \leq \sum_{m_1 \geq \log^2 n} \left(\frac{e^2 n^2}{m_1}\left(\frac{3}{4}\right)^{m_1^{k-1}}\right)^{m_1} \to 0\,, \tag{13}$$

since the probability that, given $f : S_1 \to S_2$, and $a_1, \ldots, a_k \in S_1$, we have $(a_1, \ldots, a_k) \in \mathcal{R}(n,k)$ but $(f(a_1), \ldots, f(a_k)) \notin \mathcal{R}(n,k)$ is equal to $1/4$.

In order to complete the proof of (i) one can argue as in the proof of Lemma 7 that with probability $1 - o(1)$, for each pair of elements $v, w \in [n]$ and each $W \subseteq [n]$, $|W| \leq 17 \log^2 n$, there are vertices $z_1, \ldots, z_{k-1} \in [n] \setminus W$ such that $(z_1, \ldots, z_{k-1}, v) \in \mathcal{R}(n,k)$ but $(z_1, \ldots, z_{k-1}, w) \notin \mathcal{R}(n,k)$ tends to one. Hence, with probability tending to one as $n \to \infty$, we have $W = \emptyset$; i.e., each endomorphism of $([n], \mathcal{R}(n,k))$ is an identity.

In order to show (ii) observe that, since with probability tending to 1 as $k \to \infty$ the relation $\mathcal{R}(n,k)$ is nonempty (see Lemma 7), the image of each homomorphism of $([n], \mathcal{R}(n,k))$ contains at least two points. Let us take any nontrivial function $f : [n] \to [n]$ with $|f([n])| \geq 2$, and let $j, j' \in [n]$, be such that $f(j) \neq j, f(j')$. For $r = 1, \ldots, k$, $s = 1, \ldots, k$, let

$$a_r^s = \begin{cases} j & \text{if} \quad r \leq s, \\ j' & \text{if} \quad r > s. \end{cases}$$

Note that all $2k$ k-tuples $(a_1^s, \ldots, a_k^s)$, $(f(a_1^s), \ldots, f(a_k^s))$, $s = 1, \ldots, k$, are different. Furthermore, the probability that for some $s = 1, \ldots, k$, it does not happen that $(a_1^s, \ldots, a_k^s) \in \mathcal{R}(n,k)$ and $(f(a_1^s), \ldots, f(a_k^s)) \notin \mathcal{R}(n,k)$, is $3/4$. Consequently, the probability that for each of at most n^n possible nontrivial mappings $f : [n] \to [n]$ none of the pairs $(a_1^s, \ldots, a_k^s)$, $(f(a_1^s), \ldots, f(a_k^s))$, $s = 1, \ldots, k$, is a "witness" that f is not a homomorphism is bounded from above by $n^n (3/4)^k$ and tends to 0 when n is fixed and $k \to \infty$. Consequently, if $n \geq 2$ is fixed and $k \to \infty$, the probability that there exists nontrivial endomorphism of $([n], \mathcal{R}(n,k))$ tends to 0. □

Proof of Theorem 4. Theorem 4 follows immediately from Theorems 5 and 6 and Lemmas 7 and 8 (and the remark following the proof of Lemma 7). □

SPECIAL ISSUE ON RANDOMNESS AND COMPLEXITY

The idea of a SICOMP special issue on randomness and complexity occurred to us when we were in residence at the Radcliffe Institute for Advanced Study at Harvard University during the academic year 2003–2004. We were part of a science cluster in theoretical computer science at the Radcliffe Institute whose other members were Eli Ben-Sasson, Dana Ron, Ronitt Rubinfeld, and Salil Vadhan. The focus of this cluster was randomness and computation. The extensive interaction within the cluster members as well as with frequent visitors (most notably Irit Dinur, Shafi Goldwasser, and Tali Kaufman) made us more aware than ever of the richness of the area, and the idea of editing a special issue on randomness and complexity emerged naturally.

The interplay of randomness and complexity is at the heart of modern cryptography and plays a fundamental role in the design of algorithms and in complexity theory at large. Specifically, this interplay is pivotal to several intriguing notions of probabilistic proof systems (e.g., interactive proofs, zero-knowledge proofs, and probabilistically checkable proofs), is the focus of the computational approach to randomness, and is essential for various types of sub–linear time algorithms. All these areas were at the focus of extensive research in the last two decades, but each research generation brings its own new perspective (and/or focus) to them. This special issue reports some of the recent progress achieved in these related areas, where recent relates to spring 2004, when papers were invited for this issue. Following are some of the issue's main themes.

Cryptography. The paper of Applebaum, Ishai, and Kushilevitz provides strong evidence that many cryptographic primitives and tasks can be implemented at very low complexity. For example, they show that the existence of one-way functions that can be evaluated in $\mathcal{NC}1$ implies the existence of one-way functions that can be evaluated in $\mathcal{NC}0$. Whereas the former are widely believed to exist (e.g., based on the standard factoring assumption), most researchers have previously believed that the latter do not exist. We stress that evaluation in $\mathcal{NC}0$ means that each output bit only depends on a constant number of input bits. The new work further shows that dependence on *four* input bits suffices (whereas dependence on at least *three* input bits is definitely necessary).

Probabilistically checkable proofs (PCPs). Current research in the area is marked by a renewed attention to aspects such as the following:

1. Achieving constructs of almost-linear length that can be tested by very few (say constant number of) queries.
2. Obtaining a combinatorial proof of the PCP theorem.
3. Exploration of the relationship between PCP and coding theory (e.g., locally testable codes).
4. Applications of PCPs to obtaining new inapproximability results regarding long-standing problems such as min-bisection.

Specifically, the paper of Ben-Sasson et al. presents significant improvements to the trade-off between proof-length and the number of queries. The paper of Dinur and Reingold makes a major step in the project of obtaining combinatorial proofs of the PCP theorem. Both papers share a reformulation of the proof-composition paradigm, where "proximity testing" and "robustness" play a central role. Finally, Khot's paper puts forward new PCP parameters and introduces new PCP constructions that are used to provide evidence that min-bisection is not approximable up to some constant.

Randomness extraction. The construction of randomness extractors has received much attention in the last two decades. Much of the past work (especially in the 1990s) has focused on extracting randomness from a single weak source while using an auxiliary short (uniformly distributed) seed. The focus was on using the weakest possible form of a source (i.e., a min-entropy source). In contrast, the current era is marked by a focus on stronger sources while disallowing the use of an auxiliary (uniformly distributed) seed. The paper of Gabizon, Raz, and Shaltiel studies bit-fixing sources, whereas the paper of Barak, Impagliazzo, and Wigderson studies extraction from a constant number of independent sources of linear min-entropy (which may be viewed as a single source consisting of a constant number of independent blocks). Indeed, each of these papers revisits problems raised in the mid 1980s, which were neglected in the 1990s (due to the focus of that era on obtaining the best results for seed-assisted extraction from a single min-entropy source). Needless to say, we believe that the renewed interest in these problems (especially the second one) is highly justified.

We wish to seize the opportunity to say a few words regarding seed-assisted versus seedless randomness extraction. Seed-assisted randomness extraction found many applications (via direct and indirect connections to other important problems), but still one may ask what they mean for the original problem of implementing a randomized procedure using a weak source of randomness. One answer is that the seed can be obtained from an expensive high-quality auxiliary source and that one wishes to minimize the use of this source (and thus uses a cheaper low-quality random source for the bulk of the randomness required). Another answer is that if the seed is short enough, then one may afford to try all possible seeds, invoke the procedure with the corresponding randomness extracted (from the same source output and varying seeds), and rule by majority. This suggestion is adequate for the implementation of standard randomized algorithms, but not in "adversarial" settings (e.g., cryptography) in which a randomized procedure is invoked in order to protect against some (adversarial) party. Thus, seedless randomness extraction is essential in many applications.

Worst-case to average-case reductions. The question of whether worst-case to average-case reductions or even merely "hardness amplification" exist for $\mathcal{NP}$ has received much interest recently. The first part of the question is studied in the paper of Bogdanov and Trevisan which provides a negative indication, restricted to nonadaptive reductions. The second part of the question is unfortunately not represented in this special issue (and the interested reader is directed to [1]).

Zero-knowledge. Vadhan's paper presents an *unconditional* study of *computational* zero-knowledge, yielding valuable transformations between various forms of zero-knowledge (e.g., from a weak form of zero-knowledge to the standard form). This work builds on studies of *statistical* zero-knowledge that were conducted in the late 1990s, thus fulfilling a prophecy made at the time.

Low-degree tests. The celebrated low-degree tests have been revisited recently with a focus on derandomization and on low-degree tests over small finite fields. The first direction is represented by the work of Shpilka and Wigderson that seems to provide a "proof from The Book" for (a derandomized version of) the linearity test. The second direction is unfortunately not represented in this special issue (and the interested reader is directed to [2, 3]).

Acknowledgments. We are grateful to the contributing authors for accepting our invitation to publish in this special issue. In some cases, they had to decline other competitive invitations in order to do so.

We are grateful to Eva Tardos for handling the refereeing process of the paper by Ben-Sasson, Goldreich, Harsha, Sudan, and Vadhan.

CRYPTOGRAPHY IN NC^0*

BENNY APPLEBAUM†, YUVAL ISHAI†, AND EYAL KUSHILEVITZ†

Abstract. We study the parallel time-complexity of basic cryptographic primitives such as one-way functions (OWFs) and pseudorandom generators (PRGs). Specifically, we study the possibility of implementing instances of these primitives by NC^0 functions, namely, by functions in which each output bit depends on a constant number of input bits. Despite previous efforts in this direction, there has been no convincing theoretical evidence supporting this possibility, which was posed as an open question in several previous works.

We essentially settle this question by providing strong positive evidence for the possibility of cryptography in NC^0. Our main result is that every "moderately easy" OWF (resp., PRG), say computable in NC^1, can be compiled into a corresponding OWF (resp., "low-stretch" PRG) in which each output bit depends on at most 4 input bits. The existence of OWFs and PRGs in NC^1 is a relatively mild assumption, implied by most number-theoretic or algebraic intractability assumptions commonly used in cryptography. A similar compiler can also be obtained for other cryptographic primitives such as one-way permutations, encryption, signatures, commitment, and collision-resistant hashing.

Our techniques can also be applied to obtain (unconditional) constructions of "noncryptographic" PRGs. In particular, we obtain ϵ-biased generators and a PRG for space-bounded computation in which each output bit depends on only 3 input bits.

Our results make use of the machinery of *randomizing polynomials* [Y. Ishai and E. Kushilevitz, *Proceedings of the* 41*st Annual IEEE Symposium on Foundations of Computer Science (FOCS)*, 2000, pp. 294–304], which was originally motivated by questions in the domain of information-theoretic secure multiparty computation.

Key words. cryptography, constant depth circuits, NC^0, cryptographic primitives, pseudorandom generator, one-way function, randomizing polynomials

1. Introduction.

The efficiency of cryptographic primitives is of both theoretical and practical interest. In this work, we consider the question of minimizing the *parallel time-complexity* of basic cryptographic primitives such as one-way functions (OWFs) and pseudorandom generators (PRGs) [11, 52]. Taking this question to an extreme, it is natural to ask if there are instances of these primitives that can be computed in *constant* parallel time. Specifically, the following fundamental question was posed in several previous works (e.g., [32, 22, 16, 41, 43]):

Are there one-way functions, or even pseudorandom generators, in NC^0?

Recall that NC^0 is the class of functions that can be computed by (a uniform family of) constant-depth circuits with bounded fan-in. In an NC^0 function each bit of the output depends on a constant number of input bits. We refer to this constant as the *output locality* of the function and denote by NC^0_c the class of NC^0 functions with locality c.

The above question is qualitatively interesting, since one might be tempted to conjecture that cryptographic hardness requires some output bits to depend on many

input bits. Indeed, this view is advocated by Cryan and Miltersen [16], whereas Goldreich [22] takes an opposite view and suggests a concrete candidate for OWFs in NC^0. However, despite previous efforts, there has been no convincing theoretical evidence supporting either a positive or a negative resolution of this question.

1.1. Previous work. Linial, Mansour, and Nisan show that pseudorandom *functions* cannot be computed even in AC^0 [42]. However, no such impossibility result is known for PRGs. The existence of PRGs in NC^0 has been recently studied in [16, 43]. Cryan and Miltersen [16] observe that there is no PRG in NC^0_2 and prove that there is no PRG in NC^0_3 achieving a superlinear stretch, namely, one that stretches n bits to $n + \omega(n)$ bits.[1] Mossel, Shpilka, and Trevisan [43] extend this impossibility to NC^0_4. Viola [50] shows that a PRG in AC^0 with superlinear stretch cannot be obtained from an OWF via nonadaptive black-box constructions. Negative results for other restricted computation models appear in [20, 54].

On the positive side, Impagliazzo and Naor [36] construct a (sublinear-stretch) PRG in AC^0, relying on an intractability assumption related to the subset-sum problem. PRG candidates in NC^1 (or even TC^0) are more abundant and can be based on a variety of standard cryptographic assumptions including ones related to the intractability of factoring [39, 44], discrete logarithms [11, 52, 44], and lattice problems [2, 33] (see Remark 6.6).[2]

Unlike the case of pseudorandom generators, the question of OWFs in NC^0 is relatively unexplored. The impossibility of OWFs in NC^0_2 follows from the easiness of 2-SAT [22, 16]. Håstad [32] constructs a family of permutations in NC^0 whose inverses are P-hard to compute. Cryan and Miltersen [16], improving on [1], present a circuit family in NC^0_3 whose range decision problem is NP-complete. This, however, gives no evidence of cryptographic strength. Since any PRG is also an OWF, all PRG candidates cited above are also OWF candidates. (In fact, the one-wayness of an NC^1 function often serves as the underlying cryptographic *assumption*.) Finally, Goldreich [22] suggests a candidate OWF in NC^0, whose conjectured security does not follow from any well-known assumption.

1.2. Our results. As indicated above, the possibility of implementing most cryptographic primitives in NC^0 was left wide open. We present a positive answer to this basic question, showing that, surprisingly, many cryptographic tasks can be performed in constant parallel time.

Since the existence of cryptographic primitives implies that $P \neq NP$, we cannot expect unconditional results and have to rely on some unproven assumptions.[3] However, we avoid relying on *specific* intractability assumptions. Instead, we assume the existence of cryptographic primitives in a relatively "high" complexity class and transform them to the seemingly degenerate complexity class NC^0 without substantial loss of their cryptographic strength. These transformations are inherently nonblack-box, thus providing further evidence for the usefulness of nonblack-box techniques in cryptography.

[1] From here on, we use a crude classification of PRGs into ones having sublinear, linear, or superlinear additive stretch. Note that a PRG stretching its seed by just one bit can be invoked *in parallel* (on seeds of length n^ϵ) to yield a PRG stretching its seed by $n^{1-\epsilon}$ bits for an arbitrary $\epsilon > 0$.

[2] In some of these constructions it seems necessary to allow a *collection* of NC^1 PRGs and use polynomial-time preprocessing to pick (once and for all) a random instance from this collection. This is similar to the more standard notion of an OWF collection (cf. [23, section 2.4.2]). See Appendix A for further discussion of this slightly relaxed notion of PRGs.

[3] This is not the case for noncryptographic PRGs such as ϵ-biased generators, for which we do obtain unconditional results.

We now give a more detailed account of our results.

A general compiler. Our main result is that any OWF (resp., PRG) in a relatively high complexity class, containing uniform NC^1 and even $\oplus L/poly$, can be efficiently "compiled" into a corresponding OWF (resp., sublinear-stretch PRG) in NC^0_4. (The class $\oplus L/poly$ contains the classes $L/poly$ and NC^1 and is contained in NC^2. In a nonuniform setting it also contains the class $NL/poly$ [51].) The existence of OWFs and PRGs in this class is a mild assumption, implied in particular by most number-theoretic or algebraic intractability assumptions commonly used in cryptography. Hence, the existence of OWFs and sublinear-stretch PRGs in NC^0 follows from a variety of standard assumptions and is not affected by the potential weakness of a particular algebraic structure. A similar compiler can also be obtained for other cryptographic primitives including one-way permutations, encryption, signatures, commitment, and collision-resistant hashing.

It is important to note that the PRG produced by our compiler will generally have a sublinear additive stretch even if the original PRG has a large stretch. However, one cannot do much better when insisting on an NC^0_4 PRG, as there is no PRG with superlinear stretch in NC^0_4 [43].

OWFs with optimal locality. The above results leave a small gap between the possibility of cryptography in NC^0_4 and the known impossibility of implementing even OWFs in NC^0_2. We partially close this gap by providing positive evidence for the existence of OWFs in NC^0_3. In particular, we construct such OWFs based on the intractability of decoding a random linear code.

Noncryptographic generators. Our techniques can also be applied to obtain unconditional constructions of noncryptographic PRGs. In particular, building on an ϵ-biased generator in NC^0_5 constructed by Mossel, Shpilka, and Trevisan [43], we obtain a linear-stretch ϵ-biased generator in NC^0_3. This generator has optimal locality, answering an open question posed in [43]. It is also essentially optimal with respect to stretch, since locality 3 does not allow for a superlinear stretch [16]. Our techniques also apply to other types of noncryptographic PRGs such as generators for space-bounded computation [6, 45], yielding such generators (with sublinear stretch) in NC^0_3.

1.3. Organization. In section 2 we provide an overview of our techniques, which evolve around the notion of "randomized encoding" introduced in this work. Following some preliminaries (section 3), in section 4 we formally define our notion of randomized encoding and discuss some of its variants, properties, and constructions. We then apply randomized encodings to obtain NC^0 implementations of different primitives: OWFs (section 5), cryptographic and noncryptographic PRGs (section 6), and other cryptographic primitives (section 7). In section 8 we construct OWFs with optimal locality based on specific intractability assumptions. We conclude in section 9 with some further research directions and open problems. We also call the reader's attention to Appendix A which discusses *collections* of cryptographic primitives and how they fit in the context of the current work.

2. Overview of techniques. Our key observation is that instead of computing a given "cryptographic" function $f(x)$, it might suffice to compute a function $\hat{f}(x,r)$ having the following relation to f:

1. For every fixed input x and a uniformly random choice of r, the output distribution $\hat{f}(x,r)$ forms a "randomized encoding" of $f(x)$, from which $f(x)$ can be decoded. That is, if $f(x) \neq f(x')$, then the random variables $\hat{f}(x,r)$ and $\hat{f}(x',r')$, induced by a uniform choice of r, r', should have disjoint supports.

2. The distribution of this randomized encoding depends only on the encoded value $f(x)$ and does not further depend on x. That is, if $f(x) = f(x')$, then the random variables $\hat{f}(x,r)$ and $\hat{f}(x',r')$ should be identically distributed. Furthermore, we require that the randomized encoding of an output value y be efficiently samplable given y. Intuitively, this means that the output distribution of $\hat{f}$ on input x reveals no information about x except what follows from $f(x)$.

Each of these requirements alone can be satisfied by a trivial function $\hat{f}$ (e.g., $\hat{f}(x,r) = x$ and $\hat{f}(x,r) = 0$, respectively). However, the combination of the two requirements can be viewed as a nontrivial natural relaxation of the usual notion of computing. In a sense, the function $\hat{f}$ defines an "information-theoretically equivalent" representation of f. In the following, we refer to $\hat{f}$ as a *randomized encoding* of f.

For this approach to be useful in our context, two conditions should be met. First, we need to argue that a randomized encoding $\hat{f}$ can be *securely* used as a substitute for f. Second, we hope that this relaxation is sufficiently *liberal*, in the sense that it allows us to efficiently encode relatively complex functions f by functions $\hat{f}$ in NC^0. These two issues are addressed in the following subsections.

2.1. Security of randomized encodings. To illustrate how a randomized encoding $\hat{f}$ can inherit the security features of f, we consider the case where f is an OWF. We argue that the hardness of inverting $\hat{f}$ reduces to the hardness of inverting f. Indeed, a successful algorithm A for inverting $\hat{f}$ can be used to successfully invert f as follows: Given an output y of f, apply the efficient sampling algorithm guaranteed by requirement 2 to obtain a random encoding $\hat{y}$ of y. Then, use A to obtain a preimage (x,r) of $\hat{y}$ under $\hat{f}$, and output x. It follows from requirement 1 that x is indeed a preimage of y under f. Moreover, if y is the image of a uniformly random x, then $\hat{y}$ is the image of a uniformly random pair (x,r). Hence, the success probability of inverting f is the same as that of inverting $\hat{f}$.

The above argument can tolerate some relaxations in the notion of randomized encoding. In particular, one can relax the second requirement to allow a small statistical variation of the output distribution. On the other hand, to maintain the security of other cryptographic primitives, it may be required to further strengthen this notion. For instance, when f is a PRG, the above requirements do not guarantee that the output of $\hat{f}$ is pseudorandom, or even that its output is longer than its input. However, by imposing suitable "regularity" requirements on the output encoding defined by $\hat{f}$, it can be guaranteed that if f is a PRG, then so is $\hat{f}$. Thus, different security requirements suggest different variations of the above notion of randomized encoding.

2.2. Complexity of randomized encodings. It remains to address the second issue: Can we encode a complex function f by an NC^0 function $\hat{f}$? Our best solutions to this problem rely on the machinery of *randomizing polynomials,* described below. But first, we outline a simple alternative approach[4] based on Barrington's theorem [7], combined with a randomization technique of Kilian [40].

Suppose f is a boolean function in NC^1. (Nonboolean functions are handled by repeating the following procedure for each bit of the output.) By Barrington's theorem, evaluating $f(x)$, for such a function f, reduces to computing an iterated product of polynomially many elements $s_1, \ldots, s_m$ from the symmetric group S_5, where each s_i is determined by a single bit of x (i.e., for every i there exists j such

[4]In fact, a modified version of this approach has been applied for constructing randomizing polynomials in [15].

that s_i is a function of x_j). Now, let $\hat{f}(x,r) = (s_1 r_1,\ r_1^{-1} s_2 r_2, \ldots,\ r_{m-2}^{-1} s_{m-1} r_{m-1},\ r_{m-1}^{-1} s_m)$, where the random inputs r_i are picked uniformly and independently from S_5. It is not hard to verify that the output $(t_1, \ldots, t_m)$ of $\hat{f}$ is random subject to the constraint that $t_1 t_2 \cdots t_m = s_1 s_2 \cdots s_m$, where the latter product is in one-to-one correspondence to $f(x)$. It follows that $\hat{f}$ is a randomized encoding of f. Moreover, $\hat{f}$ has constant locality when viewed as a function over the alphabet S_5, and thus yields the qualitative result we are after.

However, the above construction falls short of providing a randomized encoding in NC^0, since it is impossible to sample a uniform element of S_5 in NC^0 (even up to a negligible statistical distance).[5] Also, this $\hat{f}$ does not satisfy the extra "regularity" properties required by more "sensitive" primitives such as PRGs or one-way permutations. The solutions presented next avoid these disadvantages and, at the same time, apply to a higher complexity class than NC^1 and achieve a very small constant locality.

Randomizing polynomials. The concept of randomizing polynomials was introduced by Ishai and Kushilevitz [37] as a representation of functions by vectors of low-degree multivariate polynomials. (Interestingly, this concept was motivated by questions in the area of *information-theoretic* secure multiparty computation, which seems unrelated to the current context.) Randomizing polynomials capture the above encoding question within an algebraic framework. Specifically, a representation of $f(x)$ by randomizing polynomials is a randomized encoding $\hat{f}(x,r)$ as defined above, in which x and r are viewed as vectors over a finite field $\mathcal{F}$ and the outputs of $\hat{f}$ as multivariate polynomials in the variables x and r. In this work, we will always let $\mathcal{F} = \mathrm{GF}(2)$.

The most crucial parameter of a randomizing polynomial representation is its algebraic *degree*, defined as the maximal (total) degree of the outputs (i.e., the output multivariate polynomials) as a function of the input variables in x and r. (Note that both x and r count toward the degree.) Quite surprisingly, it is shown in [37, 38] that every boolean function $f : \{0,1\}^n \to \{0,1\}$ admits a representation by *degree*-3 randomizing polynomials whose number of inputs and outputs is at most *quadratic* in its branching program size.[6] (Moreover, this degree bound is tight in the sense that most boolean functions do not admit a degree-2 representation.) Note that a representation of a nonboolean function can be obtained by concatenating representations of its output bits, using independent blocks of random inputs. This concatenation leaves the degree unchanged.

The above positive result implies that functions whose output bits can be computed in the complexity class $\oplus$L/*poly* admit an efficient representation by degree-3 randomizing polynomials. This also holds if one requires the most stringent notion of representation required by our applications. We note, however, that different constructions from the literature [37, 38, 15] are incomparable in terms of their exact efficiency and the security-preserving features they satisfy. Hence, different constructions may be suitable for different applications. These issues are discussed in section 4.

Degree vs. locality. Combining our general methodology with the above results on randomizing polynomials already brings us close to our goal, as it enables "degree-3 cryptography." Proceeding from this point, we show that any function $f : \{0,1\}^n \to \{0,1\}^m$ of algebraic degree d admits an efficient randomized encoding $\hat{f}$ of (degree d and) locality $d+1$. That is, each output bit of $\hat{f}$ can be computed by a degree-d polynomial over GF(2) depending on at most $d+1$ inputs and random inputs.

[5] Barrington's theorem generalizes to apply over arbitrary nonsolvable groups. Unfortunately, there are no such groups whose order is a power of two.

[6] By default, the notion of "branching programs" refers here to mod-2 branching programs, which output the parity of the number of accepting paths. See section 3.

Combined with the previous results, this allows us to make the final step from degree 3 to locality 4.

3. Preliminaries.

Probability notation. Let U_n denote a random variable that is uniformly distributed over $\{0,1\}^n$. Different occurrences of U_n in the same statement refer to the same random variable (rather than independent ones). If X is a probability distribution, we write $x \leftarrow X$ to indicate that x is a sample taken from X. If S is a set, we write $x \in_R S$ to indicate that x is uniformly selected from S. The *statistical distance* between discrete probability distributions X and Y is defined as $\|X - Y\| \stackrel{\text{def}}{=} \frac{1}{2}\sum_z |\Pr[X = z] - \Pr[Y = z]|$. Equivalently, the statistical distance between X and Y may be defined as the maximum, over all boolean functions T, of the *distinguishing advantage* $|\Pr[T(X) = 1] - \Pr[T(Y) = 1]|$. A function $\varepsilon(\cdot)$ is said to be *negligible* if $\varepsilon(n) < n^{-c}$ for any $c > 0$ and sufficiently large n. For two distribution ensembles $X = \{X_n\}$ and $Y = \{Y_n\}$, we write $X \equiv Y$ if X_n and Y_n are identically distributed, and $X \stackrel{s}{\approx} Y$ if the two ensembles are *statistically indistinguishable*; namely, $\|X_n - Y_n\|$ is negligible in n.

We will rely on the following standard properties of statistical distance.

FACT 3.1. *For all distributions X, Y, Z we have $\|X - Z\| \le \|X - Y\| + \|Y - Z\|$.*

FACT 3.2. *For all distributions X, X', Y, Y' we have $\|(X \times X') - (Y \times Y')\| \le \|X - Y\| + \|X' - Y'\|$, where $A \times B$ denotes the product distribution of A, B, i.e., the joint distribution of independent samples from A and B.*

FACT 3.3. *For all distributions X, Y and every function f we have $\|f(X) - f(Y)\| \le \|X - Y\|$.*

FACT 3.4. *Let $\{X_z\}_{z\in\mathcal{Z}}$, $\{Y_z\}_{z\in\mathcal{Z}}$ be distribution ensembles. Then, for every distribution Z over $\mathcal{Z}$, we have $\|(Z, X_Z) - (Z, Y_Z)\| = E_{z\leftarrow Z}[\|X_z - Y_z\|]$. In particular, if $\|X_z - Y_z\| \le \varepsilon$ for every $z \in \mathcal{Z}$, then $\|(Z, X_Z) - (Z, Y_Z)\| \le \varepsilon$.*

Branching programs. A branching program (BP) is defined by a tuple $BP = (G, \phi, s, t)$, where $G = (V, E)$ is a directed acyclic graph, ϕ is a labeling function assigning each edge either a positive literal x_i, a negative literal $\bar{x}_i$, or the constant 1, and s, t are two distinguished nodes of G. The *size* of BP is the number of nodes in G. Each input assignment $w = (w_1, \ldots, w_n)$ naturally induces an unlabeled subgraph G_w, whose edges include all $e \in E$ such that $\phi(e)$ is satisfied by w (e.g., an edge labeled x_i is satisfied by w if $w_i = 1$). BPs may be assigned different semantics: In a *nondeterministic* BP, an input w is accepted if G_w contains at least one path from s to t; in a (*counting*) *mod-p* BP, the BP computes the number of paths from s to t modulo p. In this work, we will mostly be interested in mod-2 BPs. An example of a mod-2 BP is given in Figure 3.1.

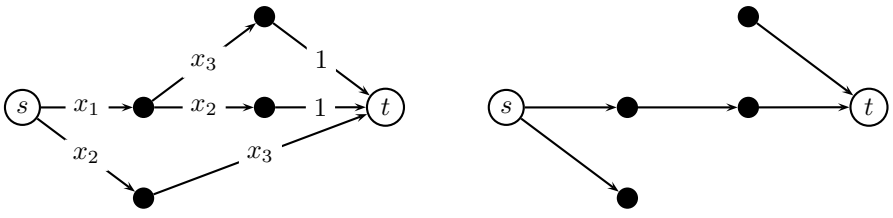

FIG. 3.1. *A mod-2 branching program computing the majority of three bits (left side), along with the graph G_{110} induced by the assignment* 110 *(right side).*

Function families and representations. We associate with a function $f : \{0,1\}^* \to \{0,1\}^*$ a function family $\{f_n\}_{n\in\mathbb{N}}$, where f_n is the restriction of f to n-bit inputs. We assume all functions to be length regular; namely, their output length depends only on their input length. Hence, we may write $f_n : \{0,1\}^n \to \{0,1\}^{l(n)}$. We will represent functions f by families of circuits, branching programs, or vectors of polynomials (where each polynomial is represented by a formal sum of monomials). Whenever f is taken from a uniform class, we assume that its representation is uniform as well. That is, the representation of f_n is generated in time poly(n) and in particular is of polynomial size. We will often abuse notation and write f instead of f_n even when referring to a function on n bits.

Locality and degree. We say that f is c-local if each of its output bits depends on at most c input bits.[7] For a constant c, the nonuniform class NC^0_c includes all c-local functions. We will sometimes view the binary alphabet as the finite field $\mathcal{F} = GF(2)$, and say that a function $f : \mathcal{F}^n \to \mathcal{F}^{l(n)}$ has degree d if each of its outputs can be expressed as a multivariate polynomial of degree (at most) d in the inputs.

Complexity classes. For brevity, we use the (somewhat nonstandard) convention that all complexity classes are polynomial-time uniform unless otherwise stated. For instance, NC^0 refers to the class of functions admitting uniform NC^0 circuits, whereas *nonuniform* NC^0 refers to the class of functions admitting nonuniform NC^0 circuits. We let NL/*poly* (resp., $\oplus$L/*poly*) denote the class of boolean functions computed by a polynomial-time uniform family of nondeterministic (resp., modulo-2) BPs. (Recall that in a uniform family of circuits or branching programs computing f, it should be possible to generate the circuit or branching program computing f_n in time poly(n).) Equivalently, the class NL/*poly* (resp., $\oplus$L/*poly*) is the class of functions computed by NL (resp., $\oplus$L) Turing machines taking a uniform advice. (The class $\oplus$L/*poly* contains the classes L/*poly* and NC^1 and is contained in NC^2. In a nonuniform setting it also contains the class NL/*poly* [51].) We extend boolean complexity classes, such as NL/*poly* and $\oplus$L/*poly*, to include nonboolean functions by letting the representation include $l(n)$ branching programs, one for each output. Uniformity requires that the $l(n)$ branching programs all be generated in time poly(n).

4. Randomized encoding of functions.

In this section we formally introduce our notion of randomized encoding. In section 4.1 we introduce several variants of randomized encoding and in section 4.2 we prove some of their useful properties. Finally, in section 4.3 we construct NC^0_4 encodings for branching programs, building on [37, 38].

4.1. Definitions.

We start by defining a randomized encoding of a finite function f. This definition will be later extended to a (uniform) family of functions.

DEFINITION 4.1 (randomized encoding). *Let $f : \{0,1\}^n \to \{0,1\}^l$ be a function. We say that a function $\hat{f} : \{0,1\}^n \times \{0,1\}^m \to \{0,1\}^s$ is a δ-correct, ε-private* randomized encoding *of f if it satisfies the following:*

- δ-correctness. *There exists a deterministic*[8] *algorithm C, called a* decoder, *such that for every input $x \in \{0,1\}^n$, $\Pr[C(\hat{f}(x, U_m)) \neq f(x)] \leq \delta$.*

[7] A boolean function depends on the ith input bit if there exists an assignment such that flipping the ith input bit changes the value of the function.

[8] We restrict the decoder to be deterministic for simplicity. This restriction does not compromise generality, in the sense that one can transform a randomized decoder to a deterministic one by incorporating the coins of the former in the encoding itself.

- ε-privacy. *There exists a randomized algorithm S, called a* simulator*, such that for every $x \in \{0,1\}^n$, $\|S(f(x)) - \hat{f}(x, U_m)\| \leq \varepsilon$.*

We refer to the second input of $\hat{f}$ as its random input *and to m and s as the* randomness complexity *and* output complexity *of $\hat{f}$, respectively.*

Note that the above definition refers only to the *information* about x revealed by $\hat{f}(x,r)$ and does not consider the complexity of the decoder and the simulator. Intuitively, the function $\hat{f}$ defines an "information-theoretically equivalent" representation of f. The correctness property guarantees that from $\hat{y} = \hat{f}(x,r)$ it is possible to reconstruct $f(x)$ (with high probability), whereas the privacy property guarantees that by seeing $\hat{y}$ one cannot learn too much about x (in addition to $f(x)$). The encoding is δ-correct (resp., ε-private) if it is correct (resp., private) up to an "error" of δ (resp., ε). This is illustrated by the next example.

Example 4.2. Consider the function $f(x_1, \ldots, x_n) = x_1 \vee x_2 \vee \cdots \vee x_n$. We define a randomized encoding $\hat{f} : \{0,1\}^n \times \{0,1\}^{ns} \to \{0,1\}^s$ by $\hat{f}(x,r) = (\sum_{i=1}^n x_i r_{i,1}, \ldots, \sum_{i=1}^n x_i r_{i,s})$, where $x = (x_1, \ldots, x_n)$, $r = (r_{i,j})$ for $1 \leq i \leq n, 1 \leq j \leq s$, and addition is over GF(2). First, observe that the distribution of $\hat{f}(x, U_{ns})$ depends only on the value of $f(x)$. Specifically, let S be a simulator that outputs an s-tuple of zeros if $f(x) = 0$, and a uniformly chosen string in $\{0,1\}^s$ if $f(x) = 1$. It is easy to verify that $S(f(x))$ is distributed the same as $\hat{f}(x, U_{ns})$ for any $x \in \{0,1\}^n$. It follows that this randomized encoding is 0-private. Also, one can obtain an efficient decoder C that, given a sample y from the distribution $\hat{f}(x, U_{ns})$, outputs 0 if $y = 0^s$ and otherwise outputs 1. Such an algorithm will err with probability 2^{-s}; thus $\hat{f}$ is 2^{-s}-correct.

On uniform randomized encodings. The above definition naturally extends to functions $f : \{0,1\}^* \to \{0,1\}^*$. In this case, the parameters $l, m, s, \delta, \varepsilon$ are all viewed as functions of the input length n, and the algorithms C, S receive 1^n as an additional input. In our default uniform setting, we require that $\hat{f}_n$, the encoding of f_n, be computable in time poly(n) (given $x \in \{0,1\}^n$ and $r \in \{0,1\}^{m(n)}$). Thus, in this setting both $m(n)$ and $s(n)$ are polynomially bounded. We also require both the decoder and the simulator to be efficient. (This is not needed by some of the applications but is a feature of our constructions.) We formalize these requirements below.

DEFINITION 4.3 (uniform randomized encoding). *Let $f : \{0,1\}^* \to \{0,1\}^*$ be a polynomial-time computable function and $l(n)$ an output length function such that $|f(x)| = l(|x|)$ for every $x \in \{0,1\}^*$. We say that $\hat{f} : \{0,1\}^* \times \{0,1\}^* \to \{0,1\}^*$ is a $\delta(n)$-correct $\epsilon(n)$-private uniform randomized encoding of f if the following hold:*

- Length regularity. *There exist polynomially bounded and efficiently computable length functions $m(n), s(n)$ such that for every $x \in \{0,1\}^n$ and $r \in \{0,1\}^{m(n)}$, we have $|\hat{f}(x,r)| = s(n)$.*
- Efficient evaluation. *There exists a polynomial-time* evaluation algorithm *that, given $x \in \{0,1\}^*$ and $r \in \{0,1\}^{m(|x|)}$, outputs $\hat{f}(x,r)$.*
- δ-correctness. *There exists a polynomial-time* decoder *C, such that for every $x \in \{0,1\}^n$ we have $\Pr[C(1^n, \hat{f}(x, U_{m(n)})) \neq f(x)] \leq \delta(n)$.*
- ε-privacy. *There exists a probabilistic polynomial-time* simulator *S, such that for every $x \in \{0,1\}^n$ we have $\|S(1^n, f(x)) - \hat{f}(x, U_{m(n)})\| \leq \varepsilon(n)$.*

When saying that a uniform encoding $\hat{f}$ is in a (uniform) circuit complexity class, we mean that its evaluation algorithm can be implemented by circuits in this class. For instance, we say that $\hat{f}$ is in NC^0_d if there exists a polynomial-time circuit generator G such that $G(1^n)$ outputs a d-local circuit computing $\hat{f}(x,r)$ on all $x \in \{0,1\}^n$ and $r \in \{0,1\}^{m(n)}$.

From here on, a randomized encoding of an efficiently computable function is assumed to be uniform by default. Moreover, we will freely extend the above definition to apply to a uniform collection of functions $\mathcal{F} = \{f_z\}_{z\in Z}$, for some index set $Z \subseteq \{0,1\}^*$. In such a case it is required that the encoded collection $\hat{\mathcal{F}} = \{\hat{f}_z\}_{z\in Z}$ is also uniform, in the sense that the same efficient evaluation algorithm, decoder, and simulator should apply to the entire collection when given z as an additional input. (See Appendix A for a more detailed discussion of *collections* of functions and cryptographic primitives.) Finally, for the sake of simplicity we will sometimes formulate our definitions, claims, and proofs using finite functions, under the implicit understanding that they naturally extend to the uniform setting.

We move on to discuss some variants of the basic definition. Correctness (resp., privacy) can be either *perfect*, when $\delta = 0$ (resp., $\varepsilon = 0$), or *statistical*, when $\delta(n)$ (resp., $\varepsilon(n)$) is negligible. In fact, we can further relax privacy to hold only against efficient algorithms, i.e., to require that for every $x \in \{0,1\}^n$, every polynomial-time algorithm A distinguishes between the distributions $S(f(x))$ and $\hat{f}(x, U_m)$ with no more than negligible advantage. Such an encoding is referred to as *computationally* private and it suffices for the purpose of many applications discussed in this paper. (Further details and additional applications appear in [4].) However, while for some of the primitives (such as OWFs) computational privacy and statistical correctness will do, others (such as PRGs or one-way permutations) require even stronger properties than perfect correctness and privacy. One such additional property is that the simulator S, when invoked on a uniformly random string from $\{0,1\}^l$ (the output domain of f), will output a uniformly random string from $\{0,1\}^s$ (the output domain of $\hat{f}$). We call this property *balance*. Note that the balance requirement does not impose any uniformity condition on the output of f, which in fact can be concentrated on a strict subset of $\{0,1\}^l$.

DEFINITION 4.4 (balanced randomized encoding). *A randomized encoding $\hat{f} : \{0,1\}^n \times \{0,1\}^m \to \{0,1\}^s$ of a function $f : \{0,1\}^n \to \{0,1\}^l$ is called* balanced *if it has a perfectly private simulator S such that $S(U_l) \equiv U_s$. We refer to S as a* balanced simulator.

A last useful property is a syntactic one: We sometimes want $\hat{f}$ to have the same additive stretch as f. Specifically, we say that $\hat{f}$ is *stretch-preserving* (with respect to f) if $s - (n + m) = l - n$ or, equivalently, $m = s - l$.

We are now ready to define our two main variants of randomized encoding.

DEFINITION 4.5 (statistical randomized encoding). *A* statistical randomized encoding *is a randomized encoding that is statistically correct and statistically private.*

DEFINITION 4.6 (perfect randomized encoding). *A* perfect randomized encoding *is a randomized encoding that is perfectly correct, perfectly private, balanced, and stretch-preserving.*

A combinatorial view of perfect encoding. To gain better understanding of the properties of perfect encoding, we take a closer look at the relation between a function and its encoding. Let $\hat{f} : \{0,1\}^{n+m} \to \{0,1\}^s$ be an encoding of $f : \{0,1\}^n \to \{0,1\}^l$. The following description addresses the simpler case where f is onto. Every $x \in \{0,1\}^n$ is mapped to some $y \in \{0,1\}^l$ by f, and to a 2^m-size multiset $\{\hat{f}(x,r) | r \in \{0,1\}^m\}$ which is contained in $\{0,1\}^s$. Perfect privacy means that this multiset is common to all the x's that share the same image under f; thus we have a mapping from $y \in \{0,1\}^l$ to multisets in $\{0,1\}^s$ of size 2^m (such a mapping is defined by the perfect simulator). Perfect correctness means that these multisets are mutually disjoint. However, even perfect privacy and perfect correctness together do not promise that this mapping

covers all of $\{0,1\}^s$. The balance property guarantees that the multisets form a perfect tiling of $\{0,1\}^s$; moreover it promises that each element in these multisets has the same multiplicity. If the encoding is also stretch-preserving, then the multiplicity of each element must be 1, so that the multisets are actually sets. Hence, a perfect randomized encoding guarantees the existence of a perfect simulator S whose 2^l output distributions form a perfect tiling of the space $\{0,1\}^s$ by sets of size 2^m.

Remark 4.7 (a padding convention). We will sometimes view $\hat{f}$ as a function of a single input of length $n+m(n)$ (e.g., when using it as an OWF or a PRG). In this case, we require $m(\cdot)$ to be monotone nondecreasing, so that $n+m(n)$ uniquely determines n. We apply a standard padding technique for defining $\hat{f}$ on inputs whose length is not of the form $n+m(n)$. Specifically, if $n+m(n)+t<(n+1)+m(n+1)$, we define $\hat{f}'$ on inputs of length $n+m(n)+t$ by applying $\hat{f}_n$ on the first $n+m(n)$ bits and then appending the t additional input bits to the output of $\hat{f}_n$. This convention respects the security of cryptographic primitives such as OWFs, PRGs, and collision-resistant hashing, provided that $m(n)$ is efficiently computable and is sufficiently dense (both of which are guaranteed by a uniform encoding). That is, if the unpadded function $\hat{f}$ is secure with respect to its partial domain, then its padded version $\hat{f}'$ is secure in the standard sense, i.e., over the domain of all strings.[9] (See a proof for the case of OWFs in [23, Proposition 2.2.3].) Note that the padded function $\hat{f}'$ has the same locality and degree as $\hat{f}$. Moreover, $\hat{f}'$ also preserves syntactic properties of $\hat{f}$; for example, it preserves the stretch of $\hat{f}$ and if $\hat{f}$ is a permutation, then so is $\hat{f}'$. Thus, it is enough to prove our results for the partially defined unpadded function $\hat{f}$ and keep the above conventions implicit.

Finally, we define two complexity classes that capture the power of randomized encodings in NC^0.

DEFINITION 4.8 (the classes $\mathcal{SRENC}$, $\mathcal{PRENC}$). *The class $\mathcal{SRENC}$ (resp., $\mathcal{PRENC}$) is the class of functions $f:\{0,1\}^*\to\{0,1\}^*$ admitting a statistical (resp., perfect) uniform randomized encoding in* NC^0.

4.2. Basic properties. We now put forward some useful properties of randomized encodings. We first argue that an encoding of a nonboolean function can be obtained by concatenating encodings of its output bits, using an independent random input for each bit. The resulting encoding inherits all the features of the concatenated encodings and, in particular, preserves their perfectness.

LEMMA 4.9 (concatenation). *Let $f_i:\{0,1\}^n\to\{0,1\}$, $1\le i\le l$, be the boolean functions computing the output bits of a function $f:\{0,1\}^n\to\{0,1\}^l$. If $\hat{f}_i:\{0,1\}^n\times\{0,1\}^{m_i}\to\{0,1\}^{s_i}$ is a δ-correct ε-private encoding of f_i, then the function $\hat{f}:\{0,1\}^n\times\{0,1\}^{m_1+\cdots+m_l}\to\{0,1\}^{s_1+\cdots+s_l}$ defined by $\hat{f}(x,(r_1,\ldots,r_l))\stackrel{\mathrm{def}}{=}(\hat{f}_1(x,r_1),\ldots,\hat{f}_l(x,r_l))$ is a (δl)-correct, (εl)-private encoding of f. Moreover, if all $\hat{f}_i$ are perfect, then so is $\hat{f}$.*

Proof. We start with correctness. Let C_i be a δ-correct decoder for $\hat{f}_i$. Define a decoder C for $\hat{f}$ by $C(\hat{y}_1,\ldots,\hat{y}_l)=(C_1(\hat{y}_1),\ldots,C_l(\hat{y}_l))$. By a union bound argument, C is a (δl)-correct decoder for $\hat{f}$ as required.

We turn to analyze privacy. Let S_i be an ε-private simulator for $\hat{f}_i$. An (εl)-private simulator S for $\hat{f}$ can be naturally defined by $S(y)=(S_1(y_1),\ldots,S_l(y_l))$,

[9] This can be generally explained by viewing each slice of the padded function $\hat{f}'$ (i.e., its restriction to inputs of some fixed length) as a *perfect* randomized encoding of a corresponding slice of $\hat{f}$.

where the invocations of the simulators S_i use independent coins. Indeed, for every $x \in \{0,1\}^n$ we have

$$\begin{aligned}\|S(f(x)) - \hat{f}(x,(U_{m_1},\ldots,U_{m_l}))\| &= \|(S_i(y_i))_{i=1}^l - (\hat{f}_i(x,U_{m_i}))_{i=1}^l\| \\ &\le \sum_{i=1}^{l} \|S_i(y_i) - \hat{f}_i(x,U_{m_i})\| \\ &\le \varepsilon l,\end{aligned}$$

where $y = f(x)$. The first inequality follows from Fact 3.2 and the independence of the randomness used for different i, and the second from the ε-privacy of each S_i.

Note that the simulator S described above is balanced if all S_i are balanced. Moreover, if all $\hat{f}_i$ are stretch-preserving, i.e., $s_i - 1 = m_i$, then we have $\sum_{i=1}^l s_i - l = \sum_{i=1}^l m_i$ and hence $\hat{f}$ is also stretch-preserving. It follows that if all $\hat{f}_i$ are perfect, then so is $\hat{f}$. □

We state the following uniform version of Lemma 4.9, whose proof is implicit in the above.

LEMMA 4.10 (concatenation: uniform version). *Let $f : \{0,1\}^* \to \{0,1\}^*$ be a polynomial-time computable function, viewed as a uniform collection of functions $\mathcal{F} = \{f_{n,i}\}_{n\in\mathbb{N},1\le i\le l(n)}$; that is, $f_{n,i}(x)$ outputs the ith bit of $f(x)$ for all $x \in \{0,1\}^n$. Suppose that $\hat{\mathcal{F}} = \{\hat{f}_{n,i}\}_{n\in\mathbb{N},1\le i\le l(n)}$ is a perfect (resp., statistical) uniform randomized encoding of $\mathcal{F}$. Then, the function $\hat{f} : \{0,1\}^* \times \{0,1\}^* \to \{0,1\}^*$ defined by $\hat{f}(x,(r_1,\ldots,r_{l(|x|)})) \stackrel{\text{def}}{=} (\hat{f}_{|x|,1}(x,r_1),\ldots,\hat{f}_{|x|,l(|x|)}(x,r_{l(|x|)}))$ is a perfect (resp., statistical) uniform randomized encoding of f.*

Another useful feature of randomized encodings is the following intuitive composition property: Suppose we encode f by g and then view g as a deterministic function and encode it again. Then, the resulting function (parsed appropriately) is a randomized encoding of f. Again, the resulting encoding inherits the perfectness of the encodings from which it is composed.

LEMMA 4.11 (composition). *Let $g(x,r_g)$ be a δ_g-correct, ε_g-private encoding of $f(x)$ and let $h((x,r_g),r_h)$ be a δ_h-correct, ε_h-private encoding of $g((x,r_g))$ (viewed as a single-argument function). Then, the function $\hat{f}(x,(r_g,r_h)) \stackrel{\text{def}}{=} h((x,r_g),r_h)$ is a $(\delta_g+\delta_h)$-correct, $(\varepsilon_g+\varepsilon_h)$-private encoding of f. Moreover, if g,h are perfect (resp., statistical) uniform randomized encodings, then so is $\hat{f}$.*

Proof. We start with correctness. Let C_g be a δ_g-correct decoder for g and C_h a δ_h-correct decoder for h. Define a decoder C for $\hat{f}$ by $C(\hat{y}) = C_g(C_h(\hat{y}))$. The decoder C errs only if either C_h or C_g errs. Thus, by the union bound we have for every x

$$\begin{aligned}\Pr_{r_g,r_h}[C(\hat{f}(x,(r_g,r_h))) \ne f(x)] &\le \Pr_{r_g,r_h}[C_h(h((x,r_g),r_h)) \ne g(x,r_g)] \\ &\quad + \Pr_{r_g}[C_g(g(x,r_g)) \ne f(x)] \\ &\le \delta_h + \delta_g,\end{aligned}$$

as required.

Privacy is argued similarly. Let S_g be an ε_g-private simulator for g and let S_h be an ε_h-private simulator for h. We define a simulator S for $\hat{f}$ by $S(y) = S_h(S_g(y))$.

Letting m_g, m_h denote the randomness complexity of g, h, respectively, we have for every x

$$\begin{aligned}\|S(f(x)) - \hat{f}(x,(U_{m_g},U_{m_h}))\| &= \|S_h(S_g(f(x))) - h((x,U_{m_g}),U_{m_h})\| \\ &\le \|S_h(S_g(f(x))) - S_h(g(x,U_{m_g}))\| \\ &\quad + \|S_h(g(x,U_{m_h})) - h((x,U_{m_g}),U_{m_h})\| \\ &\le \varepsilon_g + \varepsilon_h,\end{aligned}$$

where the first inequality follows from the triangle inequality (Fact 3.1), and the second from Facts 3.3 and 3.4.

It is easy to verify that if S_g and S_h are balanced, then so is S. Moreover, if g preserves the additive stretch of f and h preserves the additive stretch of g, then h (hence also $\hat{f}$) preserves the additive stretch of f. Thus $\hat{f}$ is perfect if both g, h are perfect. All of the above naturally carries over to the uniform setting, from which the last part of the lemma follows. □

Finally, we prove two useful features of a *perfect* encoding.

LEMMA 4.12 (unique randomness). *Suppose $\hat{f}$ is a perfect randomized encoding of f. Then,* (a) *$\hat{f}$ satisfies the following* unique randomness *property: For any input x, the function $\hat{f}(x,\cdot)$ is injective; namely, there are no distinct r, r' such that $\hat{f}(x,r) = \hat{f}(x,r')$. Moreover,* (b) *if f is a permutation, then so is $\hat{f}$.*

Proof. Let $f : \{0,1\}^n \to \{0,1\}^l$ and $\hat{f} : \{0,1\}^n \times \{0,1\}^m \to \{0,1\}^s$. To prove part (a), assume toward a contradiction that $\hat{f}$ does not satisfy the unique randomness property. Then, by perfect privacy, we have $|\mathrm{Im}(\hat{f})| < |\mathrm{Im}(f)| \cdot 2^m$. On the other hand, letting S be a balanced simulator, we have

$$\begin{aligned}|\mathrm{Im}(\hat{f})| \cdot 2^{-s} &= \Pr_{y \leftarrow U_l}[S(y) \in \mathrm{Im}(\hat{f})] \\ &\ge \Pr_{y \leftarrow U_l}[S(y) \in \mathrm{Im}(\hat{f}) | y \in \mathrm{Im}(f)] \cdot \Pr_{y \leftarrow U_l}[y \in \mathrm{Im}(f)] \\ &= 1 \cdot \frac{|\mathrm{Im}(f)|}{2^l},\end{aligned}$$

where the last equality follows from perfect privacy. Since g is stretch-preserving ($s - l = m$), we get from the above that $|\mathrm{Im}(\hat{f})| \ge |\mathrm{Im}(f)| \cdot 2^m$ and derive a contradiction.

If f is a permutation, then $n = l$ and since $\hat{f}$ is stretch-preserving, we can write $\hat{f} : \{0,1\}^s \to \{0,1\}^s$. Thus, to prove part (b), it is enough to prove that $\hat{f}$ is injective. Suppose that $\hat{f}(x,r) = \hat{f}(x',r')$. Then, since f is injective and $\hat{f}$ is perfectly correct, it follows that $x = x'$; hence, by part (a), $r = r'$ and the proof follows. □

4.3. Constructions. In this section we construct randomized encodings in NC^0. We first review a construction from [38] of degree-3 randomizing polynomials based on mod-2 branching programs and analyze some of its properties. Next, we introduce a general locality reduction technique, allowing us to transform a degree-d encoding to a $(d+1)$-local encoding. Finally, we discuss extensions to other types of BPs.

Degree-3 randomizing polynomials from mod-2 branching programs [38]. Let $BP = (G, \phi, s, t)$ be a mod-2 BP of size ℓ, computing a boolean[10] function $f : \{0,1\}^n \to \{0,1\}$; that is, $f(x) = 1$ if and only if the number of paths from s to t in G_x equals 1

[10] The following construction generalizes naturally to a (counting) mod-p BP, computing a function $f : \{0,1\}^n \to Z_p$. In this work, however, we will be interested only in the case $p = 2$.

$$\begin{pmatrix} 1 & r_1^{(1)} & r_2^{(1)} & \cdot & r_{\ell-2}^{(1)} \\ 0 & 1 & \cdot & \cdot & \cdot \\ 0 & 0 & 1 & \cdot & \cdot \\ 0 & 0 & 0 & 1 & r_{\binom{\ell-1}{2}}^{(1)} \\ 0 & 0 & 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} * & * & * & * & * \\ -1 & * & * & * & * \\ 0 & -1 & * & * & * \\ 0 & 0 & -1 & * & * \\ 0 & 0 & 0 & -1 & * \end{pmatrix} \begin{pmatrix} 1 & 0 & 0 & 0 & r_1^{(2)} \\ 0 & 1 & 0 & 0 & r_2^{(2)} \\ 0 & 0 & 1 & 0 & \cdot \\ 0 & 0 & 0 & 1 & r_{\ell-2}^{(2)} \\ 0 & 0 & 0 & 0 & 1 \end{pmatrix}$$

FIG. 4.1. *The matrices $R_1(r^{(1)}), L(x), R_2(r^{(2)})$ (from left to right). The symbol $*$ represents a degree-*1 *polynomial in an input variable.*

modulo 2. Fix some topological ordering of the vertices of G, where the source vertex s is labeled 1 and the terminal vertex t is labeled ℓ. Let $A(x)$ be the $\ell \times \ell$ adjacency matrix of G_x viewed as a formal matrix whose entries are degree-1 polynomials in the input variables x. Specifically, the (i,j) entry of $A(x)$ contains the value of $\phi(i,j)$ on x if (i,j) is an edge in G, and 0 otherwise. (Hence, $A(x)$ contains the constant 0 on and below the main diagonal and degree-1 polynomials in the input variables above the main diagonal.) Define $L(x)$ as the submatrix of $A(x) - I$ obtained by deleting column s and row t (i.e., the first column and the last row). As before, each entry of $L(x)$ is a degree-1 polynomial in a single input variable x_i; moreover, $L(x)$ contains the constant -1 in each entry of its second diagonal (the one below the main diagonal) and the constant 0 below this diagonal. (See Figure 4.1.)

FACT 4.13 (see [38]). *$f(x) = \det(L(x))$, where the determinant is computed over* GF(2).

Proof sketch. Since G is acyclic, the number of $s-t$ paths in G_x mod 2 can be written as $(I + A(x) + A(x)^2 + \cdots + A(x)^\ell)_{s,t} = (I - A(x))^{-1}_{s,t}$, where I denotes an $\ell \times \ell$ identity matrix and all arithmetic is over GF(2). Recall that $L(x)$ is the submatrix of $A(x) - I$ obtained by deleting column s and row t. Hence, expressing $(I - A(x))^{-1}_{s,t}$ using the corresponding cofactor of $I - A(x)$, we have

$$\begin{aligned} (I - A(x))^{-1}_{s,t} &= (-1)^{s+t} \frac{\det(-L(x))}{\det(I - A(x))} \\ &= \det L(x). \qquad \square \end{aligned}$$

Let $r^{(1)}$ and $r^{(2)}$ be vectors over GF(2) of length $\sum_{i=1}^{\ell-2} i = \binom{\ell-1}{2}$ and $\ell - 2$, respectively. Let $R_1(r^{(1)})$ be an $(\ell-1) \times (\ell-1)$ matrix with 1's on the main diagonal, 0's below it, and the elements of $r^{(1)}$ in the remaining $\binom{\ell-1}{2}$ entries above the diagonal (a unique element of $r^{(1)}$ is assigned to each matrix entry). Let $R_2(r^{(2)})$ be an $(\ell - 1) \times (\ell - 1)$ matrix with 1's on the main diagonal, the elements of $r^{(2)}$ in the rightmost column, and 0's in each of the remaining entries. (See Figure 4.1.)

FACT 4.14 (see [38]). *Let M, M' be $(\ell-1) \times (\ell-1)$ matrices that contain the constant -1 in each entry of their second diagonal and the constant* 0 *below this diagonal. Then,* $\det(M) = \det(M')$ *if and only if there exist $r^{(1)}$ and $r^{(2)}$ such that $R_1(r^{(1)}) M R_2(r^{(2)}) = M'$.*

Proof sketch. Suppose that $R_1(r^{(1)}) M R_2(r^{(2)}) = M'$ for some $r^{(1)}$ and $r^{(2)}$. Then, since $\det(R_1(r^{(1)})) = \det(R_2(r^{(2)})) = 1$, it follows that $\det(M) = \det(M')$.

For the second direction assume that $\det(M) = \det(M')$. We show that there exist $r^{(1)}$ and $r^{(2)}$ such that $R_1(r^{(1)}) M R_2(r^{(2)}) = M'$. Multiplying M by a matrix $R_1(r^{(1)})$ on the left is equivalent to adding to each row of M a linear combination

of the rows below it. On the other hand, multiplying M by a matrix $R_2(r^{(2)})$ on the right is equivalent to adding to the last column of M a linear combination of the other columns. Observe that a matrix M that contains the constant -1 in each entry of its second diagonal and the constant 0 below this diagonal can be transformed, using such left and right multiplications, to a canonic matrix H_y containing -1's in its second diagonal, an arbitrary value y in its top-right entry, and 0's elsewhere. Since $\det(R_1(r^{(1)})) = \det(R_2(r^{(2)})) = 1$, we have $\det(M) = \det(H_y) = y$. Thus, when $\det(M) = \det(M') = y$ we can write $H_y = R_1(r^{(1)})MR_2(r^{(2)}) = R_1(s^{(1)})M'R_2(s^{(2)})$ for some $r^{(1)}, r^{(2)}, s^{(1)}, s^{(2)}$. Multiplying both sides by $R_1(s^{(1)})^{-1}, R_2(s^{(2)})^{-1}$ and observing that each set of matrices $R_1(\cdot)$ and $R_2(\cdot)$ forms a multiplicative group finishes the proof. □

LEMMA 4.15 (implicit in [38]). *Let BP be a mod-2 branching program computing the boolean function f. Define a degree-3 function $\hat{f}(x,(r^{(1)},r^{(2)}))$ whose outputs contain the $\binom{\ell}{2}$ entries on or above the main diagonal of the matrix $R_1(r^{(1)})L(x)R_2(r^{(2)})$. Then, $\hat{f}$ is a perfect randomized encoding of f.*

Proof. We start by showing that the encoding is stretch-preserving. The length of the random input of $\hat{f}$ is $m = \binom{\ell-1}{2} + \ell - 2 = \binom{\ell}{2} - 1$ and its output length is $s = \binom{\ell}{2}$. Thus we have $s = m + 1$, and since f is a boolean function its encoding $\hat{f}$ preserves its stretch.

We now describe the decoder and the simulator. Given an output of $\hat{f}$, representing a matrix M, the decoder C simply outputs $\det(M)$. (Note that the entries below the main diagonal of this matrix are constants and therefore are not included in the output of $\hat{f}$.) By Facts 4.13 and 4.14, $\det(M) = \det(L(x)) = f(x)$; hence the decoder is perfect.

The simulator S, on input $y \in \{0,1\}$, outputs the $\binom{\ell}{2}$ entries on and above the main diagonal of the matrix $R_1(r^{(1)})H_yR_2(r^{(2)})$, where $r^{(1)}$, $r^{(2)}$ are randomly chosen and H_y is the $(\ell-1)\times(\ell-1)$ matrix that contains -1's in its second diagonal, y in its top-right entry, and 0's elsewhere.

By Facts 4.13 and 4.14, for every $x \in \{0,1\}^n$ the supports of $\hat{f}(x,U_m)$ and of $S(f(x))$ are equal. Specifically, these supports include all strings in $\{0,1\}^s$ representing matrices with determinant $f(x)$. Since the supports of $S(0)$ and $S(1)$ form a disjoint partition of the entire space $\{0,1\}^s$ (by Fact 4.14) and since S uses $m = s-1$ random bits, it follows that $|\text{support}(S(b))| = 2^m$ for $b \in \{0,1\}$. Since both the simulator and the encoding use m random bits, it follows that both distributions, $\hat{f}(x,U_m)$ and $S(f(x))$, are uniform over their support and therefore are equivalent. Finally, since the supports of $S(0)$ and $S(1)$ halve the range of $\hat{f}$ (that is, $\{0,1\}^s$), the simulator is also balanced. □

Reducing the locality. It remains to convert the degree-3 encoding into one in NC^0. To this end, we show how to construct for any degree-d function (where d is constant) a $(d+1)$-local perfect encoding. Using the composition lemma, we can obtain an NC^0 encoding of a function by first encoding it as a constant-degree function and then applying the locality construction.

The idea for the locality construction is to represent a degree-d polynomial as a sum of monomials, each having locality d, and randomize this sum using a variant of the method for randomizing group product described in section 2.2. (A direct use of the latter method over the group Z_2 gives a $(d+2)$-local encoding instead of the $(d+1)$-local one obtained here.)

CONSTRUCTION 4.16 (locality construction). *Let $f(x) = T_1(x) + \cdots + T_k(x)$, where $f, T_1, \ldots, T_k : \text{GF}(2)^n \to \text{GF}(2)$ and summation is over* GF(2). *The local*

encoding $\hat{f} : \mathrm{GF}(2)^{n+(2k-1)} \to \mathrm{GF}(2)^{2k}$ *is defined by*

$$\hat{f}(x,(r_1,\ldots,r_k,r'_1,\ldots,r'_{k-1})) \stackrel{\text{def}}{=} (T_1(x)-r_1, T_2(x)-r_2,\ldots,T_k(x)-r_k,\\ r_1-r'_1, r'_1+r_2-r'_2,\ldots,r'_{k-2}+r_{k-1}-r'_{k-1}, r'_{k-1}+r_k).$$

For example, applying the locality construction to the polynomial $x_1x_2 + x_2x_3 + x_4$ results in the encoding $(x_1x_2 - r_1, x_2x_3 - r_2, x_4 - r_3, r_1 - r'_1, r'_1 + r_2 - r'_2, r'_2 + r_3)$.

LEMMA 4.17 (locality lemma). *Let f and $\hat{f}$ be as in Construction* 4.16. *Then, $\hat{f}$ is a perfect randomized encoding of f. In particular, if f is a degree-d polynomial written as a sum of monomials, then $\hat{f}$ is a perfect encoding of f with degree d and locality* $\max(d+1,3)$.

Proof. Since $m = 2k-1$ and $s = 2k$, the encoding $\hat{f}$ is stretch-preserving. Moreover, given $\hat{y} = \hat{f}(x,r)$, we can decode the value of $f(x)$ by summing up the bits of $\hat{y}$. It is not hard to verify that such a decoder never errs. To prove perfect privacy we define a simulator as follows. Given $y \in \{0,1\}$, the simulator S uniformly chooses $2k-1$ random bits $r_1,\ldots,r_{2k-1}$ and outputs $(r_1,\ldots,r_{2k-1}, y-(r_1+\cdots+r_{2k-1}))$. Obviously, $S(y)$ is uniformly distributed over the $2k$-length strings whose bits sum up to y over GF(2). It thus suffices to show that the outputs of $\hat{f}(x,U_m)$ are uniformly distributed subject to the constraint that they add up to $f(x)$. This follows by observing that, for any x and any assignment $w \in \{0,1\}^{2k-1}$ to the first $2k-1$ outputs of $\hat{f}(x,U_m)$, there is a unique way to set the random inputs r_i, r'_i so that the output of $\hat{f}(x,(r,r'))$ is consistent with w. Indeed, for $1 \le i \le k$, the values of x, w_i uniquely determine r_i. For $1 \le i \le k-1$, the values w_{k+i}, r_i, r'_{i-1} determine r'_i (where $r'_0 \stackrel{\text{def}}{=} 0$). Therefore, $S(f(x)) \equiv \hat{f}(x,U_m)$. Moreover, S is balanced since the supports of $S(0)$ and $S(1)$ halve $\{0,1\}^s$ and $S(y)$ is uniformly distributed over its support for $y \in \{0,1\}$. ∎

In Appendix B we describe a graph-based generalization of Construction 4.16, which in some cases can give rise to a (slightly) more compact encoding $\hat{f}$.

We now present the main theorem of this section.

THEOREM 4.18. $\oplus\mathrm{L}/poly \subseteq \mathcal{PREN}$. *Moreover, any $f \in \mathcal{PREN}$ admits a perfect randomized encoding in* NC^0_4.

Proof. The first part of the theorem is derived by combining the degree-3 construction of Lemma 4.15 together with the locality lemma (Lemma 4.17), using the composition lemma (Lemma 4.11) and the concatenation lemma (Lemma 4.10).

To prove the second part, we first encode f by a perfect encoding $\hat{f}$ in NC^0 (guaranteed by the fact that f is in $\mathcal{PREN}$). Then, since $\hat{f}$ is in $\oplus\mathrm{L}/poly$, we can use our constructions (Lemmas 4.15, 4.17, 4.11, 4.10) to perfectly encode $\hat{f}$ by a function $\hat{f}'$ in NC^0_4. By the composition lemma (Lemma 4.11), $\hat{f}'$ perfectly encodes the function f. ∎

Remark 4.19. An alternative construction of perfect randomized encodings in NC^0 can be obtained using a randomizing polynomial construction from [38, section 3], which is based on an information-theoretic variant of Yao's garbled circuit technique [53]. This construction yields an encoding with a (large) constant locality, without requiring an additional "locality reduction" step (of Construction 4.16). This construction is weaker than the current one in that it only efficiently applies to functions in NC^1 rather than $\oplus\mathrm{L}/poly$. For functions in NC^1, the complexity of this alternative (in terms of randomness and output length) is incomparable to the complexity of the current construction.

There are variants of the above construction that can handle nondeterministic branching programs as well, at the expense of losing perfectness [37, 38]. For instance, it is shown in [37] that if f is represented by a nondeterministic BP of size ℓ, then the function $\hat{f}(x,(R_1,R_2)) \stackrel{\text{def}}{=} R_1 L(x) R_2$ is a perfectly private, statistically correct encoding of f provided that R_1, R_2 are uniformly random $(\ell-1)\times(\ell-1)$ matrices over $\mathrm{GF}(p)$, where p is prime and $p > \ell^\ell$. (The matrix $L(x)$ is as defined above, except that here it is interpreted as a matrix over $\mathrm{GF}(p)$.) To obtain an encoding over a binary alphabet, we rely on the facts that one can sample an almost uniform element of $\mathrm{GF}(p)$ (up to a negligible statistical distance) as well as perform multiplications in $\mathrm{GF}(p)$ using NC^1 boolean circuits. Thus, we get a statistical *binary* encoding in NC^1, which can be converted (using Theorem 4.18 and the composition lemma (Lemma 4.11)) to a statistical encoding in NC^0_4. Based on the above, we get the following theorem.

THEOREM 4.20. *$\mathrm{NL}/poly \subseteq \mathcal{SREN}$. Moreover, any $f \in \mathcal{SREN}$ admits a statistical randomized encoding in NC^0_4.*

Note that the second part of Theorem 4.20 can be proved similarly to the second part of Theorem 4.18.

5. One-way functions in $\mathbf{NC^0}$. A *one-way function* (OWF) $f : \{0,1\}^* \to \{0,1\}^*$ is a polynomial-time computable function that is hard to invert; namely, every polynomial-time algorithm that tries to invert f on input $f(x)$, where x is picked from U_n, succeeds only with a negligible probability. Formally, we have the following definition.

DEFINITION 5.1 (one-way function). *A function $f : \{0,1\}^* \to \{0,1\}^*$ is called a* one-way function *(OWF) if it satisfies the following two properties:*

- Easy to compute: *There exists a deterministic polynomial-time algorithm computing $f(x)$.*
- Hard to invert: *For every probabilistic polynomial-time algorithm, B, the probability $\Pr_{x\leftarrow U_n}[B(1^n, f(x)) \in f^{-1}(f(x))]$ is negligible in n (where the probability is taken over a uniform choice of x and the internal coin tosses of B).*

The function f is called weakly one-way *if the second requirement is replaced with the following (weaker) one:*

- Slightly hard to invert: *There exists a polynomial $p(\cdot)$, such that for every probabilistic polynomial-time algorithm, B, and all sufficiently large n's $\Pr_{x\leftarrow U_n}[B(1^n, f(x)) \notin f^{-1}(f(x))] > \frac{1}{p(n)}$ (where the probability is taken over a uniform choice of x and the internal coin tosses of B).*

The above definition naturally extends to functions whose domain is restricted to some infinite subset $I \subset \mathbb{N}$ of the possible input lengths, such as ones defined by a randomized encoding $\hat{f}$. As argued in Remark 4.7, such a partially defined OWF can be augmented into a fully defined OWF provided that the set I is polynomially dense and efficiently recognizable (which is a feature of functions $\hat{f}$ obtained via uniform encodings).

5.1. Key lemmas. In the following we show that a perfectly correct and statistically private randomized encoding $\hat{f}$ of an OWF f is also an OWF. The idea, as described in section 2.1, is to argue that the hardness of inverting $\hat{f}$ reduces to the hardness of inverting f. The case of a statistical randomized encoding that does not enjoy perfect correctness is more involved and will be dealt with later in this section.

LEMMA 5.2. *Suppose that $f : \{0,1\}^* \to \{0,1\}^*$ is hard to invert and $\hat{f}(x,r)$ is a perfectly correct, statistically private uniform encoding of f. Then $\hat{f}$, viewed as a single-argument function, is also hard to invert.*

Proof. Let $s = s(n), m = m(n)$ be the lengths of the output and of the random input of $\hat{f}$, respectively. Note that $\hat{f}$ is defined on input lengths of the form $n+m(n)$; we prove that it is hard to invert on these inputs. Assume, toward a contradiction, that there is an efficient algorithm $\hat{B}$ inverting $\hat{f}(x,r)$ with success probability $\phi(n+m) > \frac{1}{q(n+m)}$ for some polynomial $q(\cdot)$ and infinitely many n's. We use $\hat{B}$ to construct an efficient algorithm B that inverts f with similar success. On input $(1^n, y)$, the algorithm B runs S, the statistical simulator of $\hat{f}$, on the input $(1^n, y)$ and gets a string $\hat{y}$ as the output of S. Next, B runs the inverter $\hat{B}$ on the input $(1^{n+m}, \hat{y})$, getting (x', r') as the output of $\hat{B}$ (i.e., $\hat{B}$ "claims" that $\hat{f}(x', r') = \hat{y}$). B terminates with output x'.

Complexity. Since S and $\hat{B}$ are both polynomial-time algorithms, and since $m(n)$ is polynomially bounded, it follows that B is also a polynomial-time algorithm.

Correctness. We analyze the success probability of B on input $(1^n, f(x))$, where $x \leftarrow U_n$. Let us assume for a moment that the simulator S is perfect. Observe that, by perfect correctness, if $f(x) \neq f(x')$, then the support sets of $\hat{f}(x, U_m)$ and $\hat{f}(x', U_m)$ are disjoint. Moreover, by perfect privacy the string $\hat{y}$, generated by $\hat{B}$, is always in the support of $\hat{f}(x, U_m)$. Hence, if $\hat{B}$ succeeds (that is, indeed $\hat{y} = \hat{f}(x', r')$), then so does B (namely, $f(x') = y$). Finally, observe that (by Fact 3.4) the input $\hat{y}$ on which B invokes $\hat{B}$ is distributed identically to $\hat{f}_n(U_n, U_{m(n)})$, and therefore B succeeds with probability $\geq \phi(n+m)$. Formally, we can write

$$\begin{aligned}
\Pr_{x \leftarrow U_n}[B(1^n, f(x)) \in f^{-1}(f(x))] &\geq \Pr_{x \leftarrow U_n, \hat{y} \leftarrow S(1^n, f(x))}[\hat{B}(1^{n+m}, \hat{y}) \in \hat{f}^{-1}(\hat{y})] \\
&= \Pr_{x \leftarrow U_n, r \leftarrow U_{m(n)}}[\hat{B}(1^{n+m}, \hat{f}_n(x,r)) \in \hat{f}^{-1}(\hat{f}(x,r))] \\
&\geq \phi(n+m).
\end{aligned}$$

When S is only statistically private, we lose negligible success probabilities in the first and second transitions. The first loss is due to the fact that the simulator invoked on $y = f(x)$ might output (with negligible probability) $\hat{y}$ which is not in the support of $\hat{f}(x, U_m)$. The second loss is due to the fact that the input $\hat{y}$ on which B invokes $\hat{B}$ is not distributed identically to $\hat{f}(U_n, U_m)$, on which $\hat{B}$ is guaranteed to succeed with probability $\phi(n+m)$. However, it follows from Fact 3.4 that the second loss is also negligible. Thus, if S is $\varepsilon(n)$-private for a negligible function $\varepsilon(\cdot)$, we have

$$\begin{aligned}
\Pr_{x \leftarrow U_n}[B(1^n, f(x)) \in f^{-1}(f(x))] &\geq \Pr_{x \leftarrow U_n, \hat{y} \leftarrow S(1^n, f(x))}[\hat{B}(1^{n+m}, \hat{y}) \in \hat{f}^{-1}(\hat{y})] - \varepsilon(n) \\
&\geq \Pr_{x \leftarrow U_n, r \leftarrow U_{m(n)}}[\hat{B}(1^{n+m}, \hat{f}_n(x,r)) \in \hat{f}^{-1}(\hat{f}(x,r))] \\
&\quad - \varepsilon(n) - \varepsilon(n) \\
&\geq \phi(n+m) - 2\varepsilon(n) > \frac{1}{q(n+m)} - 2\varepsilon(n) > \frac{1}{q'(n)}
\end{aligned}$$

for some polynomial $q'(\cdot)$ and infinitely many n's. It follows that f is not hard to invert, in contradiction to the hypothesis. ∎

The efficiency of the simulator S is essential for Lemma 5.2 to hold. Indeed, without this requirement one could encode any one-way permutation f by the identity function $\hat{f}(x) = x$, which is obviously not one-way. (Note that the output of $\hat{f}(x)$ can be simulated inefficiently based on $f(x)$ by inverting f.)

The perfect correctness requirement is also essential for Lemma 5.2 to hold. To see this, consider the following example. Suppose f is a one-way permutation. Consider the encoding $\hat{f}(x,r)$ which equals $f(x)$ except if r is the all-zero string, in which case $\hat{f}(x,r) = x$. This is a statistically correct and statistically private encoding, but $\hat{f}$ is easily invertible since on value $\hat{y}$ the inverter can always return $\hat{y}$ itself as a possible preimage. Still, we show below that such an $\hat{f}$ (which is only statistically correct) is a *distributionally* one-way function. We will later show how to turn a distributionally one-way function in NC^0 into an OWF in NC^0.

DEFINITION 5.3 (distributionally one-way function [35]). *A polynomial-time computable function $f : \{0,1\}^* \to \{0,1\}^*$ is called* distributionally one-way *if there exists a positive polynomial $p(\cdot)$ such that for every probabilistic polynomial-time algorithm, B, and all sufficiently large n's, $\|(B(1^n, f(U_n)), f(U_n)) - (U_n, f(U_n))\| > \frac{1}{p(n)}$.*

Before proving that a statistical randomized encoding of an OWF is distributionally one-way, we need the following lemma.

LEMMA 5.4. *Let $f, g : \{0,1\}^* \to \{0,1\}^*$ be two functions that differ on a negligible fraction of their domain; that is, $\Pr_{x \leftarrow U_n}[f(x) \neq g(x)]$ is negligible in n. Suppose that g is slightly hard to invert (but is not necessarily computable in polynomial time) and that f is computable in polynomial time. Then, f is distributionally one-way.*

Proof. Let f_n and g_n be the restrictions of f and g to n-bit inputs, that is $f = \{f_n\}, g = \{g_n\}$, and define $\varepsilon(n) \stackrel{\text{def}}{=} \Pr_{x \leftarrow U_n}[f(x) \neq g(x)]$. Let $p(n)$ be the polynomial guaranteed by the assumption that g is slightly hard to invert. Assume, toward a contradiction, that f is not distributionally one-way. Then, there exists a polynomial-time algorithm, B, such that for infinitely many n's, $\|(B(1^n, f_n(U_n)), f_n(U_n)) - (U_n, f_n(U_n))\| \leq \frac{1}{2p(n)}$. Since $(U_n, f_n(U_n)) \equiv (x', f_n(U_n))$ where $x' \leftarrow f_n^{-1}(f_n(U_n))$, we get that for infinitely many n's, $\|(B(1^n, f_n(U_n)), f_n(U_n)) - (x', f_n(U_n))\| \leq \frac{1}{2p(n)}$. It follows that for infinitely many n's,

$$\Pr[B(1^n, f(U_n)) \in g_n^{-1}(f_n(U_n))] \geq \Pr_{x' \leftarrow f_n^{-1}(f_n(U_n))}[x' \in g_n^{-1}(f_n(U_n))] - \frac{1}{2p(n)}. \tag{5.1}$$

We show that B inverts g with probability greater than $1 - \frac{1}{p(n)}$ and derive a contradiction. Specifically, for infinitely many n's we have

$$\begin{aligned}
\Pr[B(1^n, g_n(U_n)) \in g_n^{-1}(g_n(U_n))] &\geq \Pr[B(1^n, f_n(U_n)) \in g_n^{-1}(f_n(U_n))] - \varepsilon(n) \\
&\geq \Pr_{x' \leftarrow f_n^{-1}(f_n(U_n))}[x' \in g_n^{-1}(f(U_n))] - \frac{1}{2p(n)} - \varepsilon(n) \\
&= \Pr_{x' \leftarrow f_n^{-1}(f_n(U_n))}[g_n(x') = f_n(U_n)] - \frac{1}{2p(n)} - \ \varepsilon(n) \\
&= \Pr_{x' \leftarrow f_n^{-1}(f_n(U_n))}[g_n(x') = f_n(x')] - \frac{1}{2p(n)} - \ \varepsilon(n) \\
&= 1 - \varepsilon(n) - \frac{1}{2p(n)} - \ \varepsilon(n) \\
&\geq 1 - \frac{1}{p(n)},
\end{aligned}$$

where the first inequality is due to the fact that f and g are ε-close, the second inequality uses (5.1), the second equality follows since $f(U_n) = f(x')$, the third equality is due to $x' \equiv U_n$, and the last inequality follows since ε is negligible. ∎

We now use Lemma 5.4 to prove the distributional one-wayness of a statistically correct encoding $\hat{f}$ based on the one-wayness of a related, perfectly correct, encoding g.

LEMMA 5.5. *Suppose that $f : \{0,1\}^* \to \{0,1\}^*$ is a one-way function and $\hat{f}(x,r)$ is a statistical randomized encoding of f. Then $\hat{f}$, viewed as a single-argument function, is distributionally one-way.*

Proof. Let C and S be the decoder and the simulator of $\hat{f}$. Define the function $\hat{g}(x,r)$ in the following way: If $C(\hat{f}(x,r)) \neq f(x)$, then $\hat{g}(x,r) = \hat{f}(x,r')$ for some r' such that $C(\hat{f}(x,r')) = f(x)$ (such an r' exists by the statistical correctness); otherwise, $\hat{g}(x,r) = \hat{f}(x,r)$. Obviously, $\hat{g}$ is a perfectly correct encoding of f (as C perfectly decodes $f(x)$ from $\hat{g}(x,r)$). Moreover, by the statistical correctness of C, we have that $\hat{f}(x,\cdot)$ and $\hat{g}(x,\cdot)$ differ only on a negligible fraction of the r's. It follows that $\hat{g}$ is also a statistically private encoding of f (because $\hat{g}(x,U_m) \stackrel{s}{\approx} \hat{f}(x,U_m) \stackrel{s}{\approx} S(f(x))$). Since f is hard to invert, it follows from Lemma 5.2 that $\hat{g}$ is also hard to invert. (Note that $\hat{g}$ might not be computable in polynomial time; however, the proof of Lemma 5.2 requires only that the simulator's running time and the randomness complexity of $\hat{g}$ be polynomially bounded.) Finally, it follows from Lemma 5.4 that $\hat{f}$ is distributionally one-way as required. ∎

5.2. Main results. Based on the above, we derive the main theorem of this section.

THEOREM 5.6. *If there exists an OWF in $\mathcal{SREN}$, then there exists an OWF in NC^0_4.*

Proof. Let f be an OWF in $\mathcal{SREN}$. By Lemma 5.5, we can construct a distributional OWF $\hat{f}$ in NC^0 and then apply a standard transformation (cf. [35, Lemma 1], [23, p. 96], [52]) to convert $\hat{f}$ to an OWF $\hat{f}'$ in NC^1. This transformation consists of two steps: Impagliazzo and Luby's NC^1 construction of weak OWFs from distributional OWFs [35], and Yao's NC^0 construction of a (standard) OWF from a weak OWF [52] (see [23, section 2.3]).[11] Since $NC^1 \subseteq \mathcal{PREN}$ (Theorem 4.18), we can use Lemma 5.2 to encode $\hat{f}'$ by an OWF in NC^0, in particular, by one with locality 4. ∎

Combining Lemmas 5.2 and 4.12 and Theorem 4.18, we get a similar result for one-way permutations (OWPs).

THEOREM 5.7. *If there exists an OWP in $\mathcal{PREN}$, then there exists an OWP in NC^0_4.*

In particular, using Theorems 4.18 and 4.20, we conclude that an OWF (resp., OWP) in NL/*poly* (resp., $\oplus$L/*poly*) implies an OWF (resp., OWP) in NC^0_4.

Theorem 5.7 can be extended to trapdoor permutations (TDPs) provided that the perfect encoding satisfies the following *randomness reconstruction* property: Given x and $\hat{f}(x,r)$, the randomness r can be efficiently recovered. If this is the case, then the trapdoor of f can be used to invert $\hat{f}(x,r)$ in polynomial time (but not in NC^0). First, we compute $f(x)$ from $\hat{f}(x,r)$ using the decoder; second, we use the trapdoor-inverter to compute x from $f(x)$; and, finally, we use the randomness reconstruction algorithm to compute r from x and $\hat{f}(x,r)$. The randomness reconstruction property is satisfied by the randomized encodings described in section 4.3 and is preserved under composition and concatenation. Thus, the existence of TDPs computable in NC^0_4 follows from their existence in $\oplus$L/*poly*.

[11] We will later show a degree-preserving transformation from a distributional OWF to an OWF (Lemma 8.2); however, in the current context the standard transformation suffices.

More formally, a collection of permutations $\mathcal{F} = \{f_z : D_z \to D_z\}_{z \in Z}$ is referred to as a TDP if there exist probabilistic polynomial-time algorithms (I, D, F, F^{-1}) with the following properties. Algorithm I is an index selector algorithm that on input 1^n selects an index z from Z and a corresponding trapdoor for f_z; algorithm D is a domain sampler that on input z samples an element from the domain D_z; F is a function evaluator that given an index z and x returns $f_z(x)$; and F^{-1} is a trapdoor-inverter that given an index z, a corresponding trapdoor t, and $y \in D_z$ returns $f_z^{-1}(y)$. Additionally, the collection should be hard to invert, similar to a standard collection of OWPs. (For a formal definition see [23, Definition 2.4.4].) By the above argument we derive the following theorem.

THEOREM 5.8. *If there exists a TDP $\mathcal{F}$ whose function evaluator F is in $\oplus$L/poly, then there exists a TDP $\hat{\mathcal{F}}$ whose function evaluator $\hat{F}$ is in* NC^0_4.

Remarks on Theorems 5.6, 5.7, *and* 5.8.

1. *Constructiveness.* In section 4.3, we give a constructive way of transforming a branching program representation of a function f into an NC^0 circuit computing its encoding $\hat{f}$. It follows that Theorems 5.6 and 5.7 can be made constructive in the following sense: There exists a polynomial-time *compiler* transforming a branching program representation of an OWF (resp., OWP) f into an NC^0 representation of a corresponding OWF (resp., OWP) $\hat{f}$. A similar result holds for other cryptographic primitives considered in this paper.
2. *Preservation of security: a finer look.* Loosely speaking, the main security loss in the reduction follows from the expansion of the input. (The simulator's running time has only a minor effect on the security, since it is added to the overall running time of the adversary.) Thus, to achieve a level of security similar to that achieved by applying f on n-bit inputs, one would need to apply $\hat{f}$ on $n+m(n)$ bits (the random input part of the encoding does not contribute to the security). Going through our constructions (bit-by-bit encoding of the output based on some size-$\ell(n)$ BPs, followed by the locality construction), we get $m(n) = l(n) \cdot \ell(n)^{O(1)}$, where $l(n)$ is the output length of f. If the degree of all nodes in the BPs is bounded by a constant, the complexity is $m(n) = O(l(n) \cdot \ell(n)^2)$. It is possible to further reduce the overhead of randomized encoding for specific representation models, such as balanced formulas, using constructions of randomizing polynomials from [38, 15].
3. *Generalizations.* The proofs of the above theorems carry over to OWFs whose security holds against efficient *nonuniform* adversaries (inverters). The same is true for all cryptographic primitives considered in this work. The proofs also naturally extend to the case of *collections* of OWFs and OWPs (see Appendix A for discussion).
4. *Concrete assumptions.* The existence of an OWF in $\mathcal{SREN}$ (in fact, even in NC^1) follows from the intractability of factoring and lattice problems [2]. The existence of an OWF *collection* in $\mathcal{SREN}$ follows from the intractability of the discrete logarithm problem. Thus, we get OWFs in NC^0_4 under most standard cryptographic assumptions. In the case of OWPs, we can get a collection of OWPs in NC^0_4 based on the discrete logarithm problem [11, 52] (see also Appendix A) or RSA with a small exponent [49].[12] The latter assumption is also sufficient for the construction of TDP in NC^0_4.

[12] Rabin's factoring-based OWP collection [47] seems insufficient for our purposes, as it cannot be defined over the set of *all* strings of a given length. The standard modification (cf. [24, p. 767]) does not seem to be in $\oplus$L/*poly*.

6. Pseudorandom generators in NC^0. A *pseudorandom generator* (PRG) is an efficiently computable function $G : \{0,1\}^n \to \{0,1\}^{l(n)}$ such that (1) G has a positive stretch, namely $l(n) > n$, where we refer to the function $l(n) - n$ as the *stretch* of the generator and (2) any "computationally restricted procedure" D, called a *distinguisher*, has a negligible advantage in distinguishing $G(U_n)$ from $U_{l(n)}$. That is, $|\Pr[D(1^n, G(U_n)) = 1] - \Pr[D(1^n, U_{l(n)}) = 1]|$ is negligible in n.

Different notions of PRGs differ mainly in the computational bound imposed on D. In the default case of *cryptographic* PRGs, D can be any probabilistic polynomial-time algorithm (alternatively, polynomial-size circuit family). In the case of *ϵ-biased* generators, D can only compute a linear function of the output bits, namely the exclusive-or of some subset of the bits. Other types of PRGs, e.g., for space-bounded computation, have also been considered. The reader is referred to [21, Chapter 3] for a comprehensive and unified treatment of pseudorandomness.

We start by considering cryptographic PRGs. We show that a *perfect* randomized encoding of such a PRG is also a PRG. We then obtain a similar result for other types of PRGs.

6.1. Cryptographic generators.

DEFINITION 6.1 (pseudorandom generator). *A pseudorandom generator (PRG) is a polynomial-time computable function, $G : \{0,1\}^n \to \{0,1\}^{l(n)}$, satisfying the following two conditions:*

- Expansion: *$l(n) > n$ for all $n \in \mathbb{N}$.*
- Pseudorandomness: *For every probabilistic polynomial-time algorithm, D, the distinguishing advantage $|\Pr[D(1^n, G(U_n)) = 1] - \Pr[D(1^n, U_{l(n)}) = 1]|$ is negligible in n.*

Remark 6.2 (PRGs with sublinear stretch). An NC^0 PRG, G, that stretches its input by a single bit can be transformed into another NC^0 PRG, G', with stretch $l'(n) - n = n^c$ for an arbitrary constant $c < 1$. This can be done by applying G on n^c blocks of n^{1-c} bits and concatenating the results. Since the output of any PRG is computationally indistinguishable from the uniform distribution even by a polynomial number of samples (see [23, Theorem 3.2.6]), the block generator G' is also a PRG. This PRG gains a pseudorandom bit from every block and therefore stretches $n^c n^{1-c} = n$ input bits to $n + n^c$ output bits. Obviously, G' has the same locality as G.

Remark 6.2 also applies to other types of generators considered in this section, and therefore we only use a crude classification of the stretch as being "sublinear," "linear," or "superlinear."

LEMMA 6.3. *Suppose $G : \{0,1\}^n \to \{0,1\}^{l(n)}$ is a PRG and $\hat{G} : \{0,1\}^n \times \{0,1\}^{m(n)} \to \{0,1\}^{s(n)}$ is a uniform perfect randomized encoding of G. Then $\hat{G}$, viewed as a single-argument function, is also a PRG.*

Proof. Since $\hat{G}$ is stretch-preserving, it is guaranteed to expand its seed. To prove the pseudorandomness of its output, we again use a reducibility argument. Assume, toward a contradiction, that there exists an efficient distinguisher $\hat{D}$ that distinguishes between U_s and $\hat{G}(U_n, U_m)$ with some nonnegligible advantage ϕ, i.e., ϕ such that $\phi(n+m) > \frac{1}{q(n+m)}$ for some polynomial $q(\cdot)$ and infinitely many n's. We use $\hat{D}$ to obtain a distinguisher D between U_l and $G(U_n)$ as follows. On input $y \in \{0,1\}^l$, run the balanced simulator of $\hat{G}$ on y and invoke $\hat{D}$ on the resulting $\hat{y}$. If y is taken from U_l, then the simulator, being balanced, outputs $\hat{y}$ that is distributed as U_s. On the other hand, if y is taken from $G(U_n)$, then, by Fact 3.4, the output of the simulator is distributed as $\hat{G}(U_n, U_m)$. Thus, the distinguisher D we get for

G has the same advantage as the distinguisher $\hat{D}$ for $\hat{G}$. That is, the advantage of D is $\phi'(n) = \phi(n+m)$. Since $m(n)$ is polynomial, this advantage ϕ' is not only nonnegligible in $n+m$ but also in n, in contradiction to the hypothesis. □

Remark 6.4 (the role of balance and stretch preservation). Dropping either the balance or stretch preservation requirements, Lemma 6.3 would no longer hold. To see this, consider the following two examples. Let G be a PRG, and let $\hat{G}(x,r) = G(x)$. Then, $\hat{G}$ is a perfectly correct, perfectly private, and balanced randomized encoding of G (the balanced simulator is $S(y) = y$). However, when r is sufficiently long, $\hat{G}$ does not expand its seed. On the other hand, we can define $\hat{G}(x,r) = G(x)0$, where r is a single random bit. Then, $\hat{G}$ is perfectly correct, perfectly private, and stretch-preserving, but its output is not pseudorandom.

Using Lemma 6.3 and Theorem 4.18, we get the following theorem.

THEOREM 6.5. *If there exists a PRG in $\mathcal{PREN}$ (in particular, in $\oplus$L/poly), then there exists a PRG in* NC^0_4.

As in the case of OWFs, an adversary that breaks the transformed generator $\hat{G}$ can break, in essentially the same time, the original generator G. Therefore, again, although the new PRG uses $m(n)$ extra random input bits, it is not more secure than the original generator applied to n bits. Moreover, we stress that the PRG $\hat{G}$ one gets from our construction has a sublinear stretch even if G has a large stretch. This follows from the fact that the length $m(n)$ of the random input is typically superlinear in the input length n.

Remark 6.6 (on the existence of a PRG in $\mathcal{PREN}$). The existence of PRGs in $\mathcal{PREN}$ follows from most standard concrete intractability assumptions. In particular, using Theorem 6.5 (applied to PRG collections) one can construct a collection of PRGs in NC^0_4 based on the intractability of factoring [39, 44] and the discrete logarithm problem [11, 52]. The existence of PRGs in $\mathcal{PREN}$ also follows from the existence in $\mathcal{PREN}$ of any *regular* OWF, i.e., an OWF $f = \{f_n\}$ that maps the same (polynomial-time computable) number of elements in $\{0,1\}^n$ to every element in $\mathrm{Im}(f_n)$. (This is the case, for instance, for any one-to-one OWF.) Indeed, the PRG construction from [33] (Theorem 5.4), when applied to a regular OWF f, involves only the computation of universal hash functions and hard-core bits, which can all be implemented in NC^1.[13] Thus a regular OWF in $\mathcal{PREN}$ can be transformed first into a regular OWF in NC^0 and then, using [33], into a PRG in NC^1. Combined with Theorem 6.5, this yields a PRG in NC^0_4 based on any regular OWF in $\mathcal{PREN}$.[14] This

[13] In the general case (when the OWF f is not regular) the construction of Håstad et al. (see [33, Construction 7.1]) is not in uniform NC^1, as it requires an additional nonuniform advice of logarithmic length. This (slightly) nonuniform NC^1 construction translates into a *polynomial-time* construction by applying the following steps: (1) construct a polynomial number of PRG candidates (each using a different guess for the nonuniform advice); (2) increase the stretch of each of these candidates using the standard transformation of Goldreich and Micali (cf. [23, Theorem 3.3.3]); (3) take the exclusive-or of all PRG candidates to obtain the final PRG. The second step requires polynomially many sequential applications of the PRGs, and therefore this construction is not in NC^1. (If we skip the second step, the resulting generator will not stretch its input.)

[14] In fact, the same result can be obtained under a relaxed regularity requirement. Specifically, for each n and $y \in \mathrm{Im}(f_n)$ define the value $D_{f,n}(y) = \log |f_n^{-1}(y)|$ and the random variable $R_n = D_{f,n}(f(U_n))$. The NC^1 construction of [33, Construction 7.1] needs to approximate, in $\mathrm{poly}(n)$ time, the expectations of both R_n and R_n^2. This is trivially possible when f is regular in the strict sense defined above, since in this case R_n is concentrated on a single (efficiently computable) value. Using a recent NC^1 construction from [30], only the expectation of R_n^2 needs to be efficiently approximated. We finally note that in a nonuniform computation model one can rely on [33] (which gives a nonuniform NC^1 construction of a PRG from any OWF) and get a PRG in *nonuniform* NC^0_4 from *any* OWF in $\mathcal{SREN}$.

way, for example, one can construct a (single) PRG in NC^0_4 based on the intractability of lattice problems [33, 2].

Remark 6.7 (on unconditional NC^0 reductions from PRG to OWF). Our machinery can be used to obtain an NC^0 reduction from a PRG to any regular OWF (in particular, to any one-to-one OWF), regardless of the complexity of f.[15] Moreover, this reduction only makes a *black-box* use of the underlying regular OWF f (given its regularity parameter $|\mathrm{Im}(f_n)|$). The general idea is to encode the NC^1 construction of [33, Construction 7.1] into a corresponding NC^0 construction. Specifically, suppose $G(x) = g(x, f(q_1(x)), \ldots, f(q_m(x)))$ defines a black-box construction of a PRG G from an OWF f, where g is in $\mathcal{PREN}$ and the q_i's are in NC^0. (The functions $g, q_1, \ldots, q_m$ are fixed by the reduction and do not depend on f.) Then, letting $\hat{g}((x, y_1, \ldots, y_m), r)$ be a perfect NC^0 encoding of g, the function $\hat{G}(x, r) = \hat{g}((x, f(q_1(x)), \ldots, f(q_m(x))), r)$ perfectly encodes G, and hence defines a black-box NC^0 reduction from a PRG to an OWF. The construction of [33, Construction 7.1] is of the form of $G(x)$ above,[16] assuming that f is regular. Thus, $\hat{G}$ defines an NC^0 reduction from a PRG to a regular OWF.

Comparison with lower bounds. The results of [43] rule out the existence of a superlinear-stretch cryptographic PRG in NC^0_4. Thus our NC^0_4 cryptographic PRGs are not far from optimal despite their sublinear stretch. In addition, it is easy to see that there is no PRG with degree 1 or locality 2 (since we can easily decide whether a given string is in the range of such a function). It seems likely that a cryptographic PRG with locality 3 and degree 2 can be constructed (e.g., based on its existence in a higher complexity class), but our positive result is one step short in terms of both locality and degree. (See also Table 6.1.)

6.2. ε-biased generators. The proof of Lemma 6.3 uses the balanced simulator to transform a distinguisher for a PRG G into a distinguisher for its encoding $\hat{G}$. Therefore, if this transformation can be made linear, then the security reduction goes through also in the case of ε-biased generators.

DEFINITION 6.8 (ε-biased generator). *An* ε-biased generator *is a polynomial-time computable function,* $G : \{0,1\}^n \to \{0,1\}^{l(n)}$*, satisfying the following two conditions:*

- Expansion: $l(n) > n$ *for all* $n \in \mathbb{N}$.
- ε-bias: *For every linear function* $L : \{0,1\}^{l(n)} \to \{0,1\}$ *and all sufficiently large* n*'s,*

$$|\Pr[L(G(U_n)) = 1] - \Pr[L(U_{l(n)}) = 1]| < \varepsilon(n)$$

(where a function L *is* linear *if its degree over* GF(2) *is* 1*). By default, the function* $\varepsilon(n)$ *is required to be negligible.*

LEMMA 6.9. *Let* G *be an* ε*-biased generator and* $\hat{G}$ *a perfect randomized encoding of* G*. Assume that the balanced simulator* S *of* $\hat{G}$ *is* linear *in the sense that* $S(y)$ *outputs a randomized linear transformation of* y *(which is not necessarily a linear function of the simulator's randomness). Then,* $\hat{G}$ *is also an* ε*-biased generator.*

Proof. Let $G : \{0,1\}^n \to \{0,1\}^{l(n)}$ and let $\hat{G} : \{0,1\}^n \times \{0,1\}^{m(n)} \to \{0,1\}^{s(n)}$. Assume, toward a contradiction, that $\hat{G}$ is not ε-biased; that is, for some linear function $L : \{0,1\}^{s(n)} \to \{0,1\}$ and infinitely many n's, $|\Pr[L(\hat{G}(U_{n+m})) = 1] -$

[15] Viola, in a concurrent work [50], obtains an AC^0 reduction of this type.

[16] The functions $q_1, \ldots, q_m$ are simply projections there. Interestingly, the recent NC^1 construction from [30] is not of the above form and thus we cannot encode it into an (unconditional) NC^0 construction.

$\Pr[L(U_s) = 1]| > \frac{1}{p(n+m)} > \frac{1}{p'(n)}$, where $m = m(n)$, $s = s(n)$, and $p(\cdot), p'(\cdot)$ are polynomials. Using the balance property we get

$$|\Pr[L(S(G(U_n))) = 1] - \Pr[L(S(U_l)) = 1]| = |\Pr[L(\hat{G}(U_{n+m})) = 1] - \Pr[L(U_s) = 1]| > \frac{1}{p'(n)},$$

where S is the balanced simulator of $\hat{G}$ and the probabilities are taken over the inputs as well as the randomness of S. By an averaging argument we can fix the randomness of S to some string ρ and get $|\Pr[L(S_\rho(G(U_n))) = 1] - \Pr[L(S_\rho(U_{l(n)})) = 1]| > \frac{1}{p'(n)}$, where S_ρ is the deterministic function defined by using the constant string ρ as the simulator's random input. By the linearity of the simulator, the function $S_\rho : \{0,1\}^l \to \{0,1\}^s$ is linear; therefore the composition of L and S_ρ is also linear, and thus the last inequality implies that G is not ε-biased in contradiction to the hypothesis. □

We now argue that the balanced simulators obtained in section 4.3 are all linear in the above sense. In fact, these simulators satisfy a stronger property: For every fixed random input of the simulator, each bit of the simulator's output is determined by a single bit of its input. This simple structure is due to the fact that we encode nonboolean functions by concatenating the encodings of their output bits. We state here the stronger property as it will be needed in the next subsection.

OBSERVATION 6.10. *Let S be a simulator of a randomized encoding (of a function) that is obtained by concatenating simulators (i.e., S is defined as in the proof of Lemma 4.9). Then, fixing the randomness ρ of S, the simulator's computation has the following simple form: $S_\rho(y) = \sigma_1(y_1)\sigma_2(y_2)\cdots\sigma_l(y_l)$, where each σ_i maps y_i (i.e., the ith bit of y) to one of two fixed strings. In particular, S computes a randomized degree-1 function of its input.*

Recall that the balanced simulator of the NC^0_4 encoding for functions in $\oplus\mathrm{L}/poly$ (promised by Theorem 4.18) is obtained by concatenating the simulators of boolean functions in $\oplus\mathrm{L}/poly$. By Observation 6.10, this simulator is linear. Thus, by Lemma 6.9, we can construct a sublinear-stretch ε-biased generator in NC^0_4 from any ε-biased generator in $\oplus\mathrm{L}/poly$. In fact, one can easily obtain a nontrivial ε-biased generator even in NC^0_3 by applying the locality construction to each of the bits of the degree-2 generator defined by $G(x, x') = (x, x', \langle x, x' \rangle)$, where $\langle \cdot, \cdot \rangle$ denotes inner product modulo 2. Again, the resulting encoding is obtained by concatenation and thus, by Observation 6.10 and Lemma 6.9, is also ε-biased. (This generator actually fools a much larger class of statistical tests; see section 6.3 below.) Thus, we have the following theorem.

THEOREM 6.11. *There is a (sublinear-stretch) ε-biased generator in NC^0_3.*

Building on a construction of Mossel, Shpilka, and Trevisan [43], it is in fact possible to achieve linear stretch in NC^0_3 as stated in the following theorem.

THEOREM 6.12. *There is a linear-stretch ε-biased generator in NC^0_3.*

Proof. Mossel, Shpilka, and Trevisan present an ε-biased generator in NC^0 with degree 2 and a linear stretch [43, Theorem 13].[17] Let G be their ε-biased genera-

[17] In fact, the generator of [43, Theorem 13] is in *nonuniform* NC^0_5 (and it has a slightly superlinear stretch). However, a similar construction gives an ε-biased generator in *uniform* NC^0 with degree 2 and linear stretch. (The locality of this generator is large but constant.) This can be done by replacing the probabilistic construction given in [43, Lemma 12] with a uniform construction of constant-degree bipartite expander with some "good" expansion properties—such a construction is given in [13, Theorem 7.1].

tor. We can apply the locality construction (4.16) to G (using concatenation) and get, by Lemma 6.9 and Observation 6.10, an ε-biased generator $\hat{G}$ in NC^0_3. We now relate the stretch of $\hat{G}$ to the stretch of G. Let $n, \hat{n}$ be the input complexity of $G, \hat{G}$, respectively, let $s, \hat{s}$ be the output complexity of $G, \hat{G}$, respectively, and let $c \cdot n$ be the stretch of G, where c is a constant. The generator $\hat{G}$ is stretch preserving; hence $\hat{s} - \hat{n} = s - n = c \cdot n$. Since G is in NC^0, each of its output bits can be represented as a polynomial that has a constant number of monomials and thus the locality construction adds only a constant number of random bits for each output bit of G. Therefore, the input length of $\hat{G}$ is linear in the input length of G. Hence, $\hat{s} - \hat{n} = s - n = c \cdot n = \hat{c} \cdot \hat{n}$ for some constant $\hat{c}$ and thus $\hat{G}$ has a linear stretch. ∎

Comparison with lower bounds. It is not hard to see that there is no ε-biased generator with degree 1 or locality 2.[18] In [16] it was shown that there is no superlinear-stretch ε-biased generator in NC^0_3. Thus, our linear-stretch NC^0_3 generator (building on the one from [43]) is not only optimal with respect to locality and degree but is also essentially optimal with respect to stretch.

6.3. Generators for space-bounded computation. We turn to the case of PRGs for space-bounded computation. A standard way of modeling a randomized space-bounded Turing machine is by having a random tape on which the machine can access the random bits one by one but cannot "go back" and view previous random bits (i.e., any bit that the machine wishes to remember, it must store in its limited memory). For the purpose of derandomizing such machines, it suffices to construct PRGs that fool any space-bounded distinguisher having a similar one-way access to its input. Following Babai, Nisan, and Szegedy [6], we refer to such distinguishers as *space-bounded distinguishers*.

DEFINITION 6.13 (space-bounded distinguisher [6]). *A space-$s(n)$ distinguisher is a deterministic Turing machine M, and an infinite sequence of binary strings $a = (a_1, \ldots, a_n, \ldots)$ called the advice strings, where $|a_n| = 2^{O(s(n))}$. The machine has the following tapes: read-write work tapes, a read-only advice tape, and a read-only input tape on which the tested input string, y, is given. The input tape has a one-way mechanism to access the tested string; namely, at any point it may request the next bit of y. In addition, only $s(n)$ cells of the work tapes can be used. Given an n-bit input, y, the output of the distinguisher, $M^a(y)$, is the (binary) output of M where y is given on the input tape and a_n is given on the advice tape.*

This class of distinguishers is a proper subset of the distinguishers that can be implemented by a space-$s(n)$ Turing machine with a two-way access to the input. Nevertheless, even logspace distinguishers are quite powerful, and many distinguishers fall into this category. In particular, this is true for the class of *linear* distinguishers considered in section 6.2.

DEFINITION 6.14 (PRG for space-bounded computation). *We say that a polynomial-time computable function $G : \{0,1\}^n \to \{0,1\}^{l(n)}$ is a PRG for space $s(n)$ if $l(n) > n$ and $G(U_n)$ is indistinguishable from $U_{l(n)}$ to any space-$s(n)$ distinguisher. That is, for every space-$s(n)$ distinguisher M^a, the distinguishing advantage $|\Pr[M^a(G(U_n)) = 1] - \Pr[M^a(U_{l(n)}) = 1]|$ is negligible in n.*

Several constructions of high-stretch PRGs for space-bounded computation exist in the literature (e.g., [6, 45]). In particular, a PRG for logspace computation from [6] can be computed using logarithmic space and thus, by Theorem 4.18, admits an

[18] A degree-1 generator contains more than n linear functions over n variables, which must be linearly dependent and thus biased. The nonexistence of a 2-local generator follows from the fact that every nonlinear function of two input bits is biased.

efficient perfect encoding in NC_4^0. It can be shown (see proof of Theorem 6.15) that this NC_4^0 encoding fools logspace distinguishers as well; hence, we can reduce the security of the randomized encoding to the security of the encoded generator and get an NC_4^0 PRG that fools logspace computation. However, as in the case of ε-biased generators, constructing such PRGs with a low stretch is much easier. In fact, the same "inner product" generator we used in section 6.2 can work here as well.

THEOREM 6.15. *There exists a (sublinear-stretch) PRG for sublinear-space computation in* NC_3^0.

Proof. Consider the inner product generator $G(x, x') = (x, x', \langle x, x' \rangle)$, where $x, x' \in \{0,1\}^n$. It follows from the average-case hardness of the inner product function for two-party communication complexity [14] that G fools all sublinear-space distinguishers. (Indeed, a sublinear-space distinguisher implies a sublinear-communication protocol predicting the inner product of x and x'. Specifically, the party holding x runs the distinguisher until it finishes reading x and then sends its configuration to the party holding x'.)

Applying the locality construction to G, we obtain a perfect encoding $\hat{G}$ in NC_3^0. (In fact, we can apply the locality construction only to the last bit of G and leave the other outputs as they are.) We argue that $\hat{G}$ inherits the pseudorandomness of G. As before, we would like to argue that if $\hat{M}$ is a sublinear-space distinguisher breaking $\hat{G}$ and S is the balanced simulator of the encoding, then $\hat{M}(S(\cdot))$ is a sublinear-space distinguisher breaking G. Similarly to the proof of Lemma 6.9, the fact that $\hat{M}(S(\cdot))$ can be implemented in sublinear space will follow from the simple structure of S. However, in contrast to Lemma 6.9, here it does not suffice to require S to be linear and we need to rely on the stronger property guaranteed by Observation 6.10.[19]

We now formalize the above. As argued in Observation 6.10, fixing the randomness ρ of S, the simulator's computation can be written as $S_\rho(y) = \sigma_1(y_1)\sigma_2(y_2)\cdots\sigma_l(y_l)$, where each σ_i maps a bit of y to one of two fixed strings. We can thus use S to turn a sublinear-space distinguisher $\hat{M}^a$ breaking $\hat{G}$ into a sublinear-space distinguisher $M^{a'}$ breaking G. Specifically, let the advice a' include, in addition to a, the $2l$ strings $\sigma_i(0), \sigma_i(1)$ corresponding to a "good" ρ which maintains the distinguishing advantage. (The existence of such ρ follows from an averaging argument.) The machine $M^{a'}(y)$ can now emulate the computation of $\hat{M}^a(S_\rho(y))$ using sublinear space and a one-way access to y by applying $\hat{M}^a$ in each step to the corresponding string $\sigma_i(y_i)$. ∎

6.4. Pseudorandom generators—Conclusion. We conclude this section with Table 6.1, which summarizes some of the PRGs constructed here as well as previous ones from [43] and highlights the remaining gaps.

7. Other cryptographic primitives. In this section, we describe extensions of our results to other cryptographic primitives. Aiming at NC^0 implementations, we can use our machinery in two different ways: (1) compile a primitive in a relatively high complexity class (say NC^1) into its randomized encoding and show that the encoding inherits the security properties of this primitive; or (2) use known *reductions* between cryptographic primitives, together with NC^0 primitives we already constructed (e.g.,

[19] Indeed, in the current model of (nonuniform) space-bounded computation with *one-way* access to the input (and two-way access to the advice), there exist a boolean function $\hat{M}$ computable in sublinear space and a linear function S such that the composed function $\hat{M}(S(\cdot))$ is not computable in sublinear space. For instance, let $\hat{M}(y_1, \ldots, y_{2n}) = y_1y_2 + y_3y_4 + \cdots + y_{2n-1}y_{2n}$ and $S(x_1, \ldots, x_{2n}) = (x_1, x_{n+1}, x_2, x_{n+2}, \ldots, x_n, x_{2n})$.

TABLE 6.1

Summary of known pseudorandom generators. Results of Mossel, Shpilka, and Trevisan [43] *appear in the top part and results of this paper in the bottom part. A parameter is marked as optimal (✓) if when fixing the other parameters it cannot be improved. A stretch entry is marked with ↚ if the stretch is sublinear and cannot be improved to be superlinear (but might be improved to be linear). The symbol * indicates a conditional result.*

OWFs or PRGs), to obtain new NC^0 primitives. Of course, this approach is useful only when the reduction itself is in NC^0.[20] We mainly adopt the first approach, since most of the known reductions between primitives are not in NC^0. (An exception in the case of symmetric encryption will be discussed below.)

7.1. Collision-resistant hashing in NC^0. We start with a formal definition of collision-resistant hash-functions (CRHFs).

DEFINITION 7.1 (collision-resistant hashing). *Let $\ell, \ell' : \mathbb{N} \to \mathbb{N}$ be such that $\ell(n) > \ell'(n)$ and let $Z \subseteq \{0,1\}^*$. A collection of functions $\{h_z\}_{z \in Z}$ is said to be* collision-resistant *if the following hold:*

1. *There exists a probabilistic polynomial-time* key-generation *algorithm, G, that on input 1^n outputs an* index *$z \in Z$ (of a function h_z). The function h_z maps strings of length $\ell(n)$ to strings of length $\ell'(n)$.*
2. *There exists a polynomial-time* evaluation *algorithm that on input $z \in G(1^n)$, $x \in \{0,1\}^{\ell(n)}$ computes $h_z(x)$.*
3. *Collisions are hard to find. Formally, a pair (x, x') is called a* collision *for a function h_z if $x \neq x'$ but $h_z(x) = h_z(x')$. The collision-resistance requirement states that every probabilistic polynomial-time algorithm B that is given input $(z = G(1^n), 1^n)$ succeeds in finding a collision for h_z with a negligible probability in n (where the probability is taken over the coin tosses of both G and B).*

LEMMA 7.2. *Suppose that $\mathcal{H} = \{h_z\}_{z \in Z}$ is collision-resistant and $\hat{\mathcal{H}} = \{\hat{h}_z\}_{z \in Z}$ is a uniform perfect randomized encoding of $\mathcal{H}$. Then $\hat{\mathcal{H}}$ is also collision-resistant.*

Proof. Since $\hat{h}_z$ is stretch-preserving, it is guaranteed to shrink its input as h_z. The key-generation algorithm G of $\mathcal{H}$ is used as the key-generation algorithm of $\hat{\mathcal{H}}$. By the uniformity of the collection $\hat{\mathcal{H}}$, there exists an efficient evaluation algorithm for this collection. Finally, any collision $((x,r),(x',r'))$ under $\hat{h}_z$ (i.e., $(x,r) \neq (x',r')$ and $\hat{h}_z(x,r) = \hat{h}_z(x',r')$) defines a collision (x,x') under h_z. Indeed, perfect correctness ensures that $h_z(x) = h_z(x')$ and unique randomness (see Lemma 4.12) ensures that

[20] If the reduction is in NC^1, one can combine the two approaches: First apply the NC^1 reduction to an NC^0 primitive of type X that was already constructed (e.g., an OWF or a PRG) to obtain a new NC^1 primitive of type Y, and then use the first approach to compile the latter primitive into an NC^0 primitive (of type Y). As in the first approach, this construction requires one to prove that a randomized encoding of a primitive Y preserves its security.

$x \neq x'$. Thus, an efficient algorithm that finds collisions for $\hat{\mathcal{H}}$ with nonnegligible probability yields a similar algorithm for $\mathcal{H}$. □

By Lemma 7.2 and Theorem 4.18, we get the following theorem.

THEOREM 7.3. *If there exists a CRHF $\mathcal{H} = \{h_z\}_{z \in Z}$ such that the function $h'(z,x) \stackrel{\text{def}}{=} h_z(x)$ is in $\mathcal{PRECN}$ (in particular, in $\oplus$L/poly), then there exists a CRHF $\hat{\mathcal{H}} = \{\hat{h}_z\}_{z \in Z}$ such that the mapping $(z,y) \mapsto \hat{h}_z(y)$ is in NC^0_4.*

Using Theorem 7.3, we can construct CRHFs in NC^0 based on the intractability of factoring [17], discrete logarithm [46], or lattice problems [25, 48]. All these candidates are computable in NC^1 provided that some precomputation is done by the key-generation algorithm. Note that the key-generation algorithm of the resulting NC^0 CRHF is not in NC^0. For more details on NC^0 computation of collections of cryptographic primitives, see Appendix A.

7.2. Encryption in $\mathbf{NC^0}$. We turn to the case of encryption. Suppose that $\mathcal{E} = (G, E, D)$ is a public-key encryption scheme, where G is a key-generation algorithm, the encryption function $E(e, x, r)$ encrypts the message x using the key e and randomness r, and $D(d, y)$ decrypts the cipher y using the decryption key d. As usual, the functions G, E, D are polynomial-time computable, and the scheme provides correct decryption and satisfies indistinguishability of encryptions [29]. Let $\hat{E}$ be a randomized encoding of E, and let $\hat{D}(d, \hat{y}) \stackrel{\text{def}}{=} D(d, C(\hat{y}))$ be the composition of D with the decoder C of $\hat{E}$. We argue that the scheme $\hat{\mathcal{E}} \stackrel{\text{def}}{=} (G, \hat{E}, \hat{D})$ is also a public-key encryption scheme. The efficiency and correctness of $\hat{\mathcal{E}}$ are guaranteed by the uniformity of the encoding and its correctness. Using the efficient simulator of $\hat{E}$, we can reduce the security of $\hat{\mathcal{E}}$ to that of $\mathcal{E}$. Namely, given an efficient adversary $\hat{A}$ that distinguishes between encryptions of x and x' under $\hat{\mathcal{E}}$, we can break $\mathcal{E}$ by using the simulator to transform original ciphers into "new" ciphers, and then invoke $\hat{A}$. The same argument holds in the private-key setting. We now formalize this argument.

DEFINITION 7.4 (public-key encryption). *A* secure public-key encryption (PKE) scheme *is a triple (G, E, D) of probabilistic polynomial-time algorithms satisfying the following conditions:*

- Viability: *On input 1^n the key-generation algorithm, G, outputs a pair of keys (e, d). For every pair (e, d) such that $(e, d) \in G(1^n)$, and for every plaintext $x \in \{0,1\}^*$, the algorithms E, D satisfy*

$$\Pr[D(d, E(e, x)) \neq x] \leq \varepsilon(n),$$

  where $\varepsilon(n)$ is a negligible function and the probability is taken over the internal coin tosses of algorithms E and D.
- Security: *(Indistinguishability of encryptions of a single message.) For every (nonuniform) polynomial-time distinguisher B, every polynomial $p(\cdot)$, all sufficiently large n's, and every pair of plaintexts x, x' such that $|x| = |x'| \leq p(n)$, the distinguisher cannot distinguish between encryptions of x and x' with more than $\frac{1}{p(n)}$ advantage; namely,*

$$\left| \Pr_{(e,d) \leftarrow G(1^n)}[B(e, E(e, x)) = 1] - \Pr_{(e,d) \leftarrow G(1^n)}[B(e, E(e, x')) = 1] \right| \leq \frac{1}{p(n)},$$

  where the probabilities are taken over the coin tosses of G, E.

The definition of a *private-key* encryption scheme is similar, except that the distinguisher does not get the the encryption key e as an additional input. An extension

to multiple-message security, where the indistinguishability requirement should hold for encryptions of polynomially many messages, follows naturally (see [24, Chapter 5] for formal definitions). In the public-key case, multiple-message security is implied by single-message security as defined above, whereas in the private-key case it is a strictly stronger notion. In the following we explicitly address only the (single-message) public-key case, but the treatment easily holds for the case of private-key encryption with multiple-message security.

LEMMA 7.5. *Let $\mathcal{E} = (G, E, D)$ be a secure PKE scheme, where $E(e, x, r)$ is viewed as a polynomial-time computable function that encrypts the message x using the key e and randomness r. Let $\hat{E}((e, x), (r, s)) = \hat{E}((e, x, r), s)$ be a uniform statistical randomized encoding of E and let $\hat{D}(d, \hat{y}) \stackrel{\text{def}}{=} D(d, C(\hat{y}))$ be the composition of D with the decoder C of $\hat{E}$. Then, the scheme $\hat{\mathcal{E}} \stackrel{\text{def}}{=} (G, \hat{E}, \hat{D})$ is also a secure public-key encryption scheme.*

Proof. The uniformity of the encoding guarantees that the functions $\hat{E}$ and $\hat{D}$ can be efficiently computed. The viability of $\hat{\mathcal{E}}$ follows in a straightforward way from the correctness of the decoder C. Indeed, if (e, d) are in the support of $G(1^n)$, then for any plaintext x we have

$$\begin{aligned}\Pr_{r,s}[\hat{D}(d, \hat{E}(e, x, r, s)) \neq x] &= \Pr_{r,s}[D(d, C(\hat{E}(e, x, r, s))) \neq x] \\ &\leq \Pr_{r,s}[C(\hat{E}((e, x, r), s)) \neq E(e, x, r)] \\ &\quad + \Pr_{r}[D(d, E(e, x, r)) \neq x] \\ &\leq \varepsilon(n),\end{aligned}$$

where $\varepsilon(\cdot)$ is negligible in n and the probabilities are also taken over the coin tosses of D; the first inequality follows from the union bound and the second from the viability of $\mathcal{E}$ and the statistical correctness of $\hat{E}$.

We move on to prove the security of the construction. Assume, toward a contradiction, that $\hat{\mathcal{E}}$ is not secure. It follows that there exists an efficient (nonuniform) distinguisher $\hat{B}$ and a polynomial $p(\cdot)$, such that for infinitely many n's there exist two plaintexts x, x' such that $|x| = |x'| \leq p(n)$, and

$$\left| \Pr_{(e,d)\leftarrow G(1^n),r,s}[\hat{B}(e, \hat{E}(e, x, r, s)) = 1] - \Pr_{(e,d)\leftarrow G(1^n),r,s}[\hat{B}(e, \hat{E}(e, x', r, s)) = 1] \right| > \frac{1}{p(n)},$$

where r, s are uniformly chosen random strings of an appropriate length. We use $\hat{B}$ to construct a distinguisher B that distinguishes between encryptions of x and x' under E and derive a contradiction. Define a (nonuniform) distinguisher B by $B(e, y) \stackrel{\text{def}}{=} \hat{B}(e, S(y))$, where S is the efficient (statistical) simulator of $\hat{E}$. Then, for some negligible ε,

$$\begin{aligned}&\left| \Pr_{(e,d)\leftarrow G(1^n),r}[B(e, E(e, x, r)) = 1] - \Pr_{(e,d)\leftarrow G(1^n),r}[B(e, E(e, x', r)) = 1] \right| \\ &= \left| \Pr_{(e,d)\leftarrow G(1^n),r}[\hat{B}(e, S(E(e, x, r))) = 1] - \Pr_{(e,d)\leftarrow G(1^n),r}[B(e, S(E(e, x', r))) = 1] \right| \\ &\geq \left| \Pr_{(e,d)\leftarrow G(1^n),r,s}[\hat{B}(e, \hat{E}(e, x, r, s)) = 1] - \Pr_{(e,d)\leftarrow G(1^n),r,s}[\hat{B}(e, \hat{E}(e, x', r, s)) = 1] \right| - \varepsilon(n) \\ &> \frac{1}{p(n)} - \varepsilon(n) > \frac{1}{q(n)}\end{aligned}$$

for some polynomial $q(\cdot)$ and infinitely many n's. The first inequality is due to statistical privacy and the second follows from our hypothesis. Hence, we derive a contradiction to the security of $\mathcal{E}$, and the lemma follows. □

In particular, if the scheme $\mathcal{E} = (G, E, D)$ enables errorless decryption and the encoding $\hat{E}$ is perfectly correct, then the scheme $\hat{\mathcal{E}}$ also enables errorless decryption. Additionally, the above lemma is easily extended to the case of private-key encryption with multiple-message security. Thus we get the following theorem.

THEOREM 7.6. *If there exists a secure PKE scheme (resp., a secure private-key encryption scheme) $\mathcal{E} = (G, E, D)$, such that E is in $\mathcal{SREN}$ (in particular, in* NL*/poly), then there exists a secure PKE scheme (resp., a secure private-key encryption scheme) $\hat{\mathcal{E}} = (G, \hat{E}, \hat{D})$, such that $\hat{E}$ is in* NC^0_4.

Specifically, one can construct an NC^0 PKE based on either factoring [47, 28, 10], the Diffie–Hellman assumption [19, 28] or lattice problems [3, 48]. (These schemes enable an NC^1 encryption algorithm given a suitable representation of the key.)

On decryption in NC^0. Our construction provides an NC^0 encryption algorithm but does not promise anything regarding the parallel complexity of the decryption process. This raises the question of whether decryption can also be implemented in NC^0. In Appendix C.1, we argue that, in many settings, decryption in NC^0 is impossible regardless of the complexity of encryption. In contrast, if the scheme is restricted to a *single* message of a bounded length (even larger than the key) we can use our machinery to construct a private-key encryption scheme in which both encryption and decryption can be computed in NC^0. This can be done by using the output of an NC^0 PRG to mask the plaintext. Specifically, let $E(e, x) = G(e) \oplus x$ and $D(e, y) = y \oplus G(e)$, where e is a uniformly random key generated by the key-generation algorithm and G is a PRG. Unfortunately, the resulting scheme is severely limited by the low stretch of our PRGs. This approach can be also used to give multiple-message security, at the price of requiring the encryption and decryption algorithms to maintain a synchronized *state*. In such a stateful encryption scheme the encryption and decryption algorithms take an additional input and produce an additional output, corresponding to their state before and after the operation. The seed of the generator can be used, in this case, as the state of the scheme. In this setting, we can obtain multiple-message security by refreshing the seed of the generator in each invocation; e.g., when encrypting the current bit the encryption algorithm can randomly choose a new seed for the next session, encrypt it along with the current bit, and send this encryption to the receiver (alternatively, see [24, Construction 5.3.3]). In the resulting scheme both encryption and decryption are NC^0 functions whose inputs include the inner state of the algorithm.

Theorem 7.6 can be easily extended to stronger notions of security. In particular, randomized encoding preserves security against chosen plaintext attacks (CPA) as well as a priori chosen ciphertext attacks (CCA1). However, randomized encoding does not preserve security against a posteriori chosen ciphertext attacks (CCA2). Still, it can be shown that the encoding of a CCA2-secure scheme enjoys a relaxed security property that suffices for most applications of CCA2-security. See Appendix C.2 for further discussion.

7.3. Signatures, commitments, and zero-knowledge proofs. The construction that was used for encryption can be adapted to other cryptographic primitives including (noninteractive) commitments, signatures, message authentication schemes (MACs), and noninteractive zero-knowledge proofs (for definitions see [23, 24]). In all these cases, we can replace the sender (i.e., the encrypting party,

committing party, signer, or prover, according to the case) with its randomized encoding and let the receiver (the decrypting party or verifier) use the decoding algorithm to translate the output of the new sender to an output of the original one. The security of the resulting scheme reduces to the security of the original one by using the efficient simulator and decoder. In fact, such a construction can also be generalized to the case of interactive protocols such as zero-knowledge proofs and interactive commitments. As in the case of encryption discussed above, this transformation results in an NC^0 sender but does not promise anything regarding the parallel complexity of the receiver. An interesting feature of the case of commitment is that we can also improve the parallel complexity at the receiver's end (see below). The same holds for applications of commitment such as coin-flipping and zero-knowledge proofs. We now briefly sketch these constructions and their security proofs.

Signatures. Let $\mathcal{S} = (G, S, V)$ be a signature scheme, where G is a key-generation algorithm that generates the signing and verification keys (s, v), the signing function $S(s, \alpha, r)$ computes a signature β on the document α using the key s and randomness r, and the verification algorithm $V(v, \alpha, \beta)$ verifies that β is a valid signature on α using the verification key v. The scheme is secure (unforgeable) if it is infeasible to forge a signature in a chosen message attack. Namely, any polynomial-time adversary that gets the verification key and an oracle access to the signing process $S(s, \cdot)$ fails to produce a valid signature β on a document α (with respect to the corresponding verification key v) for which it has not requested a signature from the oracle. Let $\hat{S}$ be a statistical randomized encoding of S, and let $\hat{V}(v, \alpha, \hat{\beta}) \stackrel{\text{def}}{=} V(v, \alpha, C(\hat{\beta}))$ be the composition of V with the decoder C of the encoding $\hat{S}$. We claim that the scheme $\hat{\mathcal{S}} \stackrel{\text{def}}{=} (G, \hat{S}, \hat{V})$ is also a signature scheme. Given an adversary $\hat{A}$ that breaks $\hat{\mathcal{S}}$, we can break $\mathcal{S}$ by invoking $\hat{A}$ and emulating the oracle $\hat{S}$ using the simulator of the encoding and the signature oracle S. If the forged signature $(\alpha, \hat{\beta})$ produced by $\hat{A}$ is valid under $\hat{\mathcal{S}}$, then it is translated into a valid signature (α, β) under $\mathcal{S}$ by using the decoder, i.e., $\beta = C(\hat{\beta})$. A similar argument holds also in the private-key setting (i.e., in the case of MACs).

Commitments. A commitment scheme enables one party (a sender) to commit itself to a value while keeping it secret from another party (the receiver). Later, the sender can reveal the committed value to the receiver, and it is guaranteed that the revealed value is equal to the one determined at the commit stage. We start with the simple case of a perfectly binding, noninteractive commitment. Such a scheme can be defined by a polynomial-time computable function $\textsc{Send}(b, r)$ that outputs a commitment c to the bit b using the randomness r. We assume, without loss of generality, that the scheme has a canonical decommit stage in which the sender reveals b by sending b and r to the receiver, who verifies that $\textsc{Send}(b, r)$ is equal to the commitment c. The scheme should be both (computationally) hiding and (perfectly) binding. Hiding requires that $c = \textsc{Send}(b, r)$ keeps b computationally secret (as formalized in Definition 7.4 for the case of encryption). Binding means that it is impossible for the sender to open its commitment in two different ways; that is, there are no r_0 and r_1 such that $\textsc{Send}(0, r_0) = \textsc{Send}(1, r_1)$. Let $\hat{\textsc{Send}}(b, r, s)$ be some randomized encoding of $\textsc{Send}(b, r)$. It can be shown that if $\hat{\textsc{Send}}$ is a perfectly correct (and statistically private) encoding of $\textsc{Send}$, then $\hat{\textsc{Send}}$ defines a computationally hiding perfectly binding, noninteractive commitment: Hiding follows from the privacy of the encoding, as argued for the case of encryption in section 7.2. The binding property of $\hat{\textsc{Send}}$ follows from the perfect correctness; namely, given a cheating sender $\hat{S}^*$ for $\hat{\textsc{Send}}$ that produces ambiguous commitment $(r_0, r_0'), (r_1, r_1')$

such that $\hat{\text{SEND}}(0, r_0, s_0) = \hat{\text{SEND}}(1, r_1, s_1)$, we construct a cheating sender S^* for the original scheme that invokes $\hat{S}^*$ and outputs r_0, r_1. By perfect correctness it holds that $\text{SEND}(0, r_0) = \text{SEND}(1, r_1)$, and hence the new adversary succeeds with the same probability as the original one.[21]

Using a standard construction ([9], [23, Construction 4.4.2]), it follows that commitments in NC^0 are implied by the existence of a one-to-one OWF in $\mathcal{PREN}$. It is important to note that in contrast to the noninteractive perfectly binding primitives described so far, here we also improve the parallel complexity at the receiver's end. Indeed, on input $\hat{c}, b, r, s$ the receiver's computation consists of computing $\hat{\text{SEND}}(b, r, s)$ and comparing the result to $\hat{c}$. Assuming $\hat{\text{SEND}}$ is in NC^0, the receiver can be implemented by an NC^0 circuit augmented with a single (unbounded fan-in) AND gate. We refer to this special type of AC^0 circuit as an $\text{NC}^0[\text{AND}]$ circuit. As an immediate application, we get a 3-round protocol for flipping a coin [9] between an NC^0 circuit and an $\text{NC}^0[\text{AND}]$ circuit.

One can apply a similar transformation to other variants of commitment schemes, such as unconditionally hiding (and computationally binding) interactive commitments. Schemes of this type require some initialization phase, which typically involves a random key sent from the receiver to the sender. We can turn such a scheme into a similar scheme between an NC^0 sender and an $\text{NC}^0[\text{AND}]$ receiver, provided that it conforms to the following structure: (1) the receiver initializes the scheme by *locally* computing a random key k (say, a prime modulus and powers of two group elements for schemes based on a discrete logarithm) and sending it to the sender; (2) the sender responds with a single message computed by the commitment function $\text{SEND}(b, k, r)$ which is in $\mathcal{PREN}$ (actually, perfect correctness and statistical privacy suffice); (3) as in the previous case, the scheme has a canonical decommit stage in which the sender reveals b by sending b and r to the receiver, who verifies that $\text{SEND}(b, k, r)$ is equal to the commitment c. Using the CRHF-based commitment scheme of [18, 31], one can obtain schemes of the above type based on the intractability of factoring, discrete logarithm, and lattice problems. Given such a scheme, we replace the sender's function by its randomized encoding and get as a result an unconditionally hiding commitment scheme whose sender is in NC^0. The new scheme inherits the round complexity of the original scheme and thus consists of only two rounds of interaction. (The security proof is similar to the previous case of perfectly binding, noninteractive commitment.) If the random key k cannot be computed in $\text{NC}^0[\text{AND}]$ (as in the case of factoring- and discrete logarithm-based schemes), one can compute k once and for all during the generation of the receiver's circuit and hardwire the key to the receiver's circuit. (See Appendix A.)

Zero-knowledge proofs. We end this section by addressing the case of zero-knowledge protocols. Suppose that the prover's computations are in $\mathcal{SREN}$. Then, similarly to the case of encryption, we can compile the prover into its (statistical) randomized encoding and obtain a prover whose local computations (viewed as a function of its randomness, the common instance of the language, the private witness, and previously received messages) are in NC^0. The new verifier uses the decoder to translate the prover's encoded messages to the corresponding messages of original

[21] A modification of this scheme remains secure even if we replace SEND with a *statistical* randomized encoding. However, in this modification we cannot use the canonical decommitment stage. Instead, the receiver should verify the decommitment by applying the decoder C to $\hat{c}$ and comparing the result to the computation of the original sender; i.e., the receiver checks whether $C(\hat{c})$ equals $\text{SEND}(b, r)$. A disadvantage of this alternative decommitment is that it does not enjoy the enhanced parallelism feature discussed below.

TABLE 7.1
Sufficient properties for preserving the security of different primitives.

protocol, and then invokes the original verifier. The completeness and soundness of the new protocol follow from the correctness of the encoding, and its zero-knowledge property from the privacy of the encoding. (The verifier can produce transcripts of the new protocol by composing the simulator of the encoding with the simulator of the original protocol.) A similar transformation applies to zero-knowledge *arguments*.

As before, this general approach does not parallelize the verifier; in fact, the verifier is now required to "work harder" and decode the prover's messages. However, we can improve the verifier's complexity by relying on specific, commitment-based, zero-knowledge protocols from the literature. For instance, in the constant-round protocol for graph 3-colorability of [26], the computations of the prover and the verifier consist of invoking two commitments (of both types, perfectly binding as well as statistically hiding), in addition to some AC^0 computations. Hence, we can use the parallel commitment schemes described before to construct a constant-round protocol for 3-colorability between an AC^0 prover and an AC^0 verifier. Since 3-colorability is NP complete under AC^0 reductions, we get constant-round zero-knowledge proofs in AC^0 for every language in NP.

7.4. Summary and discussion. Table 7.1 summarizes the properties of randomized encoding that suffice for encoding different cryptographic primitives. (In the case of TDPs, efficient randomness recovery is also needed.) We note that in some cases it suffices to use a *computationally private* randomized encoding, in which the simulator's output should only be computationally indistinguishable from that of the encoding. This relaxation, recently studied in [4], allows one to construct (some) primitives in NC^0 under more general assumptions.

The case of pseudorandom functions. It is natural to ask why our machinery cannot be applied to pseudorandom functions (PRFs) (assuming there exists a PRF in $\mathcal{PRE}\mathcal{N}$), as is implied from the impossibility results of Linial, Mansour, and Nisan [42]. Suppose that a PRF family $f_k(x) = f(k,x)$ is encoded by the function $\hat{f}(k,x,r)$. There are two natural ways to interpret $\hat{f}$ as a collection: (1) to incorporate the randomness into the key, i.e., $g_{k,r}(x) \stackrel{\text{def}}{=} \hat{f}(k,x,r)$; (2) to append the randomness to the argument of the collection, i.e., $h_k(x,r) \stackrel{\text{def}}{=} \hat{f}(k,x,r)$. To rule out the security of approach (1), it suffices to note that the mapping $\hat{f}(\cdot,r)$ is of degree 1 when r is fixed; thus, to distinguish $g_{k,r}$ from a truly random function, one can check whether the given function is affine (e.g., verify that $g_{k,r}(x) + g_{k,r}(y) = g_{k,r}(x+y) + g_{k,r}(0)$). The same attack applies to the function $h_k(x,r)$ obtained by the second approach, by fixing the randomness r. More generally, the privacy of a randomized encoding is guaranteed only when the randomness is secret and is freshly picked; thus our

methodology works well for cryptographic primitives which employ fresh secret randomness in each invocation. PRFs do not fit into this category: While the key contains secret randomness, it is not freshly picked in each invocation.

We finally note that by combining the positive results regarding the existence of various primitives in NC^0 with the negative results of [42] that rule out the possibility of PRFs in AC^0, one can derive a separation between PRFs and other primitives such as PRGs. In particular, we conclude that it is unlikely that a PRF is AC^0-reducible to a PRG.

8. One-way functions with optimal locality. The results presented so far leave a small gap between the strong positive evidence for cryptography in NC^0_4 and the known impossibility of even OWFs in NC^0_2. In this section we attempt to close this gap for the case of OWFs, providing positive evidence for the existence of OWFs in NC^0_3.

A natural approach for closing the gap would be to reduce the degree of our general construction of randomized encodings from 3 to 2. (Indeed, the locality construction transforms a degree-2 encoding into one in NC^0_3.) However, the results of [37] provide some evidence against the prospects of this general approach, ruling out the existence of degree-2 perfectly private encodings for most nontrivial functions. We thus take the following two alternative approaches: (1) seek *direct* constructions of degree-2 OWFs based on specific intractability assumptions; and (2) employ degree-2 randomized encodings with a weak (but nontrivial) privacy property (called *semiprivacy*), which enables the representation of general functions.

In section 8.1, we use approach (1) to construct an OWF with optimal locality based on the presumed intractability of decoding a random linear code. In section 8.2 we briefly demonstrate the usefulness of approach (2) by sketching a construction of an OWF with optimal locality based on an OWF that enjoys a certain strong "robustness" property, which is satisfied by a variant of an OWF candidate suggested in [22]. We note that neither of the above approaches yields a general result in the spirit of the results of the previous sections. Thus, we happen to pay for optimal degree and locality with the loss of generality.

8.1. OWFs in NC^0_3 from the intractability of decoding random linear codes. Several cryptographic schemes are based on hard problems from the theory of error-correcting codes. In particular, the problem of decoding random linear codes, which is a longstanding open question in coding theory, was suggested as a basis for OWFs [27]. An (n, k, δ) *binary linear code* is a k-dimensional linear subspace of $GF(2)^n$ in which the Hamming distance between each two distinct vectors (codewords) is at least δn. We refer to the ratio k/n as the *rate* of the code and to δ as its (relative) *distance*. Such a code can be defined by a $k \times n$ *generator matrix* whose rows span the space of codewords. It follows from the Gilbert–Varshamov bound that whenever $k/n < 1 - H_2(\delta) - \varepsilon$ (where H_2 is the binary entropy function and ε is an arbitrarily small positive constant), almost all $k \times n$ generator matrices form (n, k, δ)-linear codes.

Before defining our intractability assumption, imagine the following "decoding game." Let $k/n < 1 - H_2(1/3) - \varepsilon$ for some constant $\varepsilon > 0$. Pick a random $k \times n$ matrix C representing a linear code (which is with overwhelming probability an $(n, k, \frac{1}{3} + \varepsilon)$ code) and a random information word x. Encode x with C and transmit the resulting codeword $y = xC$ over a binary symmetric channel in which every bit is flipped with probability $\frac{1}{4}$. If more than $\frac{1}{3}$ of the bits were flipped, output the zero word; otherwise, output the noisy codeword $\tilde{y}$ along with the code's description C. In the

former event the adversary always wins (however, note that the probability of this event is negligible). In the latter event, the adversary's task is to find some codeword y which is at most $(n/3)$-far from $\tilde{y}$. The fact that the noise is random (rather than adversarial) guarantees, by Shannon's coding theorem, that y will be unique with overwhelming probability.

The intractability assumption on which we rely asserts that every polynomial-time adversary loses in the above game with noticeable probability. That is, roughly speaking, we assume that it is intractable to correct $n/4$ *random* errors in a random linear code of relative distance $\frac{1}{3}$. More precisely we have the following assumption.

INTRACTABILITY ASSUMPTION 8.1 (decoding a random linear code). *There exists a constant $c < 1 - H_2(\frac{1}{3})$ such that the following function f_{code} is a weak OWF:*[22]

$$f_{\text{code}}(C, x, e) \stackrel{\text{def}}{=} \begin{cases} 0 & \textit{weight}(e_1e_2, \ldots, e_{2n-1}e_{2n}) \geq n/3, \\ (C, xC + (e_1e_2, \ldots, e_{2n-1}e_{2n})) & \textit{otherwise}, \end{cases}$$

where C is a $k \times n$ binary generator matrix with $k = \lfloor cn \rfloor$, $x \in \{0,1\}^k$, $e \in \{0,1\}^{2n}$, weight$(\cdot)$ denotes Hamming weight, and arithmetic is over GF(2).

Namely, inverting f_{code} on a uniformly chosen input corresponds to winning in the above decoding game. (Two random bits, e_i and e_{i+1}, are multiplied to emulate a noise rate of $\frac{1}{4}$.) The plausibility of Assumption 8.1 is supported by the fact that a successful inverter would imply a major breakthrough in coding theory. Similar assumptions were put forward in [27, 8, 23]. It is possible to base our construction on different variants of this assumption (e.g., one in which the number of errors is bounded by half the minimal distance, as in [27]); the above formulation is preferred for simplicity (and seems even weaker than the one in [27]).

We now construct a degree-2 OWF assuming the (weak) one-wayness of f_{code}. Consider the degree-2 function f'_{code} defined by $f'_{\text{code}}(C, x, e) \stackrel{\text{def}}{=} (C, xC + (e_1e_2, \ldots, e_{2n-1}e_{2n}))$. The function f'_{code} by itself is not one-way; indeed, as there is no restriction on the choice of e, an inverter can arbitrarily pick x and then fix e to be consistent with C, x, and $\tilde{y}$. However, f'_{code} is still distributionally one-way. This follows by noting that f'_{code} differs from f_{code} only on a negligible fraction of their domain and by using Lemma 5.4. To conclude the proof we need the following lemma.

LEMMA 8.2. *A degree-2 distributional OWF implies a degree-2 OWF in* NC^0_3.

Proof. First observe that a degree-2 weak OWF can be transformed into a degree-2 (standard) OWF (cf. [52], [23, Theorem 2.3.2]). Combined with the locality construction, we get that the existence of a degree-2 weak OWF implies the existence of a degree-2 OWF in NC^0_3. Hence it is enough to show how to transform a degree-2 distributional OWF into a degree-2 weak OWF.

Let f be a degree-2 distributional OWF. Consider the function $F(x, i, h) = (f(x), h_i(x), i, h)$, where $x \in \{0,1\}^n$, $i \in \{1, \ldots, n\}$, $h : \{0,1\}^n \to \{0,1\}^n$ is a pairwise independent hash function, and h_i denotes the i-bit-long prefix of $h(x)$. This function was defined by Impagliazzo and Luby [35], who showed that in this case F is weakly one-way (see also [23, p. 96]). Note that $h(x)$ can be computed as a degree-2 function of x and (the representation of) h by using the hash family $h_{M,v}(x) = xM + v$, where M is an $n \times n$ matrix and v is a vector of length n. However, $h_i(x)$ is not of degree 2 when considered as a function of h, x, and i, since "chopping" the last $n - i$ bits of

[22] In fact, it seems likely that the function f_{code} is even strongly one-way.

$h(x)$ raises the degree of the function when i is not fixed. We get around this problem by applying n copies of F on independent inputs, where each copy uses a different i. Namely, we define the function $F'((x^{(i)}, h^{(i)})_{i=1}^n) \stackrel{\text{def}}{=} (F(x^{(i)}, i, h^{(i)}))_{i=1}^n$. Since each of the i's is now fixed, the resulting function F' can be computed by degree-2 polynomials over GF(2). Moreover, it is not hard to verify that F' is weakly one-way if F is weakly one-way. We briefly sketch the argument. Given an efficient inverting algorithm B for F', one can invert $y = F(x, i, h) = (f(x), h_i(x), i, h)$ as follows. For every $j \neq i$, uniformly and independently choose $x^{(j)}, h^{(j)}$, set $z_j = F(x^{(j)}, j, h^{(j)})$ and $z_i = y$, and then invoke B on $(z_j)_{j=1}^n$ and output the ith block of the answer. This inversion algorithm for F has the same success probability as B on a polynomially related input. □

Applying Lemma 8.2 to f'_{code} we get the following theorem.

THEOREM 8.3. *If Assumption* 8.1 *holds, there is a degree-*2 *OWF in* NC_3^0.

8.2. OWFs in NC_3^0 using semiprivate encoding. In this section we briefly address the possibility of obtaining optimal locality for OWFs (i.e., locality 3 rather than 4) by relaxing the privacy requirement of the encoding. Further details appear in [5].

We start by sketching an alternative approach for constructing OWFs in NC_3^0 based on Assumption 8.1. The basic idea is the following. Consider the degree-2 function f'_{code} defined above. This function is not one-way. However, it is possible to augment it to a (weakly) one-way function by appending to its output a single bit, $\phi(e)$, indicating whether the error vector e exceeds the weight threshold. That is, $\phi(e) = 1$ if and only if $weight(e_1e_2, \ldots, e_{2n-1}e_{2n}) \geq n/3$. (This ensures that, with high probability, the inverter will be forced to pick a low-weight error.) While we cannot encode the predicate $\phi(e)$ using degree-2 polynomials, it turns out that we can achieve this using the following type of *semiprivate* encoding. Specifically, we relax the simulation requirement to hold only when $\phi(e) = 0$. Thus, the encoding $\hat{\phi}(e, r)$ keeps e private only when $\phi(e) = 0$, i.e., when e defines a low-weight error vector. It is possible to efficiently construct such a degree-2 semiprivate encoding from the branching program representation of ϕ. (This can be done by using a variant of the BP construction described in section 4.3.) Hence, under Assumption 8.1, the degree-2 encoding $\hat{f}_{\text{code}}((C, x, e), r) \stackrel{\text{def}}{=} (f'_{\text{code}}(C, x, e), \hat{\phi}(e, r))$ is weakly one-way.

Given any OWF f, one could attempt to apply a semiprivate encoding as described above to every output bit of f, obtaining a degree-2 function $\hat{f}$. However, $\hat{f}$ will typically not be one-way: Every output bit of f that evaluates to 1 might reveal the entire input (through the corresponding block in the output of $\hat{f}$). This motivates the following notion of a *robust* OWF. Loosely speaking, an OWF f is said to be robust if it remains (slightly) hard to invert even if a random subset of its output bits are "exposed," in the sense that all input bits leading to these outputs are revealed. Intuitively, the purpose of the robustness requirement is to guarantee that the information leaked by the semiprivate encoding leaves enough uncertainty about the input to make inversion difficult. It can be shown that (1) every robust OWF with a low locality (say, logarithmic in the number of inputs) can be turned into an OWF in NC_3^0; and (2) a variant of an OWF candidate from [22] satisfies the latter property, assuming that it is indeed one-way. Thus, an intractability assumption of the flavor of the one suggested in [22] implies the existence of OWFs in NC_3^0.

9. Conclusions and open problems. Our results provide strong evidence for the possibility of cryptography in NC^0. They are also close to optimal in terms of the

exact locality that can be achieved. Still, several questions are left for further study, in particular, the following:

- What are the minimal assumptions required for cryptography in NC^0? For instance, does the existence of an arbitrary OWF imply the existence of an OWF in NC^0? We show that an OWF in NL/*poly* implies an OWF in NC^0.
- Is there a PRG with linear stretch or even superlinear stretch in NC^0? In particular, is there a PRG with linear stretch in NC^0_4? (The possibility of a PRG with superlinear stretch in NC^0_4 is ruled out in [43].) We show that there exists a PRG with *sublinear* stretch in NC^0_4, assuming the existence of a PRG in $\oplus$L/*poly*.
- Can the existence of an OWF (or PRG) in NC^0_3 be based on more general assumptions? We construct such an OWF under the intractability of decoding a random linear code.
- Is it possible to obtain constant *input* locality, i.e., construct primitives in which each input influences only a constant number of outputs? (A candidate OWF of this type is given in [22].) Note that the results of this work only address the case of a constant *output* locality, which does not imply a constant input locality.
- Can our paradigm for achieving better parallelism be of any practical use?

The above questions motivate a closer study of the complexity of randomized encodings, which so far was only motivated by questions in the domain of secure multiparty computation. In [4] we continue this study by considering a relaxed variant of randomized encoding referred to as *computationally private* encoding. We show that, under relatively mild assumptions, one can encode every polynomial-time computable function by a computationally private encoding in NC^0. This gives new sufficient conditions for cryptography in NC^0, as well as new NC^0 reductions between different cryptographic primitives.

Appendix A. On collections of cryptographic primitives.

In most cases, we view a cryptographic primitive (e.g., an OWF or a PRG) as a single function $f : \{0,1\}^* \to \{0,1\}^*$. However, it is often useful to consider more general variants of such primitives, defined by a *collection* of functions $\{f_z\}_{z\in Z}$, where $Z \subseteq \{0,1\}^*$ and each f_z is defined over a finite domain D_z. The full specification of such a collection usually consists of a probabilistic polynomial-time key-generation algorithm that chooses an index z of a function (given a security parameter 1^n), a domain sampler algorithm that samples a random element from D_z given z, and a function evaluation algorithm that computes $f_z(x)$ given z and $x \in D_z$. The primitive should be secure with respect to the distribution defined by the key-generation and the domain sampler. (See a formal definition for the case of OWFs in [23, Definition 2.4.3].)

Collections of primitives arise naturally in the context of parallel cryptography, as they allow one to shift "nonparallelizable" operations such as prime number selection and modular exponentiations to the key-generation stage (cf. [44]). They also fit naturally into the setting of P-uniform circuits, since the key-generation algorithm can be embedded in the algorithm generating the circuit. Thus, it will be convenient to assume that z is a description of a circuit computing f_z. When referring to a collection of functions from a given complexity class (e.g., NC^1, NC^0_4, or $\mathcal{PRENC}$, cf. Definition 4.8) we assume that the key-generation algorithm outputs a description of a circuit from this class. In fact, one can view collections in our context as a natural relaxation of uniformity, allowing the circuit generator to be randomized.

(The above discussion also applies to other P-uniform representation models we use, such as branching programs.)

Our usage of collections differs from the standard one in that we insist on D_z being the set of *all* strings of a given length (i.e., the set of all possible inputs for the circuit z) and restrict the domain sampler to be a trivial one which outputs a uniformly random string of the appropriate length. This convention guarantees that the primitive can indeed be invoked with the specified parallel complexity, and does not implicitly rely on a (possibly less parallel) domain sampler.[23] In most cases, it is possible to modify standard collections of primitives to conform to the above convention. We illustrate this by outlining a construction of an NC^1 collection of OWPs based on the intractability of the discrete logarithm problem. The key-generator, on input 1^n, samples a random prime p such that $2^{n-1} \leq p < 2^n$ along with a generator g of Z_p^*, and lets z be a description of an NC^1 circuit computing the function $f_{p,g}$ defined as follows. On an n-bit input x (viewed as an integer such that $0 \leq x < 2^n$) define $f_{p,g}(x) = g^x \bmod p$ if $1 \leq x < p$ and $f_{p,g}(x) = x$ otherwise. It is easy to verify that $f_{p,g}$ indeed defines a permutation on $\{0,1\}^n$. Moreover, it can be computed by an NC^1 circuit by incorporating $p, g, g^2, g^4, \ldots, g^{2^n}$ into the circuit. Finally, assuming the intractability of the discrete logarithm problem, the above collection is *weakly* one-way. It can be augmented into a collection, of (strongly) OWPs by using the standard reduction of strong OWFs to weak OWFs (i.e., using $f'_{p,g}(x_1, \ldots, x_n) = (f_{p,g}(x_1), \ldots, f_{p,g}(x_n))$).

When defining the cryptographic security of a collection of primitives, it is assumed that the adversary (e.g., inverter or distinguisher) is given the key z, in addition to its input in the single-function variant of the primitive. Here one should make a distinction between "private-coin collections," where this is all of the information available to the adversary, and "public-coin collections" in which the adversary is additionally given the internal coin tosses of the key-generator. (A similar distinction has recently been made in the specific context of CRHFs [34]; also, see the discussion of "enhanced TDP" in [24, Appendix C.1].) The above example for an OWP collection is of the public-coin type. Any public-coin collection is also a private-coin collection, but the converse may not be true.

Summarizing, we consider cryptographic primitives in three different settings:

1. *Single function setting.* The circuit family $\{C_n\}_{n\in\mathbb{N}}$ that computes the primitive is constructed by a deterministic polynomial time circuit generator that, given an input 1^n, outputs the circuit C_n. This is the default setting for most cryptographic primitives.
2. *Public-coin collection.* The circuit generator is a probabilistic polynomial time algorithm that, on input 1^n, samples a circuit from a collection of circuits. The adversary gets as an input the circuit produced by the generator, along with the randomness used to generate it. The experiments defining the success probability of the adversary incorporate the randomness used by the generator, in addition to the other random variables. As in the single function setting, this generation step can be thought of as being done "once and for all," e.g., in a preprocessing stage. Public-coin collections are typically useful for primitives based on discrete logarithm assumptions, where a large prime group should be set up along with its generator and precomputed exponents of the generator.

[23] Note that unlike the key-generation algorithm, which can be applied "once and for all," the domain sampler should be invoked for each application of the primitive.

3. *Private-coin collection.* This is the same as (2) except that the adversary does not know the randomness that was used by the circuit generator. This relaxation is typically useful for factoring-based constructions, where the adversary should not learn the trapdoor information associated with the public modulus (see [39, 44]).

We note that our general transformations apply to all of the above settings. In particular, given an NC^1 primitive in any of these settings, we obtain a corresponding NC^0 primitive in the same setting.

Appendix B. A generalization of the locality construction. In the locality construction (Construction 4.16), we showed how to encode a degree-d function by an NC^0_{d+1} encoding. We now describe a graph-based construction that generalizes the previous one. The basic idea is to view the encoding $\hat{f}$ as a graph. The nodes of the graph are labeled by terms of f and the edges by random inputs of $\hat{f}$. With each node we associate an output of $\hat{f}$ in which we add to its term the labels of the edges incident to the node. Formally, we have the following construction.

CONSTRUCTION B.1 (general locality construction). *Let* $f(x) = T_1(x) + \cdots + T_k(x)$, *where* $f, T_1, \ldots, T_k : \mathrm{GF}(2)^n \to \mathrm{GF}(2)$ *and summation is over* $\mathrm{GF}(2)$. *Let* $G = (V, E)$ *be a directed graph with* k *nodes* $V = \{1, \ldots, k\}$ *and* m *edges. The encoding* $\hat{f}_G : \mathrm{GF}(2)^{n+m} \to \mathrm{GF}(2)^k$ *is defined by*

$$\hat{f}_G(x, (r_{i,j})_{(i,j)\in E}) \stackrel{\text{def}}{=} \left(T_i(x) + \sum_{j|(j,i)\in E} r_{j,i} - \sum_{j|(i,j)\in E} r_{i,j} \right)_{i=1}^{k}.$$

From here on, we will identify with the directed graph G its underlying undirected graph. The above construction yields a perfect encoding when G is a tree (see Lemma B.2). The locality of an output bit of $\hat{f}_G$ is the locality of the corresponding term plus the degree of the node in the graph. The locality construction described in Construction 4.16 attempts to minimize the maximal locality of a node in the graph; hence it adds k "dummy" 0 terms to f and obtains a tree in which all of the k nondummy terms of f are leaves and the degree of each dummy term is at most 3. When the terms of f vary in their locality, a more compact encoding $\hat{f}$ can be obtained by increasing the degree of nodes which represent terms with lower locality.

LEMMA B.2 (generalized locality lemma). *Let* f *and* $\hat{f}_G$ *be as in Construction* B.1. *Then, the following hold:*

(1) $\hat{f}_G$ is a perfectly correct encoding of f.
(2) If G is connected, then $\hat{f}_G$ is also a balanced encoding of f (and in particular it is perfectly private).
(3) If G is a tree, then $\hat{f}_G$ is also stretch-preserving; that is, $\hat{f}_G$ perfectly encodes f.

Proof. (1) Given $\hat{y} = \hat{f}_G(x, r)$, we decode $f(x)$ by summing up the bits of $\hat{y}$. Since each random variable $r_{i,j}$ appears only in the ith and jth output bits, it contributes 0 to the overall sum and therefore the bits of $\hat{y}$ always add up to $f(x)$.

To prove (2) we use the same simulator as in the locality construction (see proof of Lemma 4.17). Namely, given $y \in \{0, 1\}$, the simulator S chooses $k-1$ random bits $r_1, \ldots, r_{k-1}$ and outputs $(r_1, \ldots, r_{k-1}, y-(r_1+\cdots+r_{k-1}))$. This simulator is balanced since the supports of $S(0)$ and $S(1)$ halve $\{0, 1\}^k$ and $S(y)$ is uniformly distributed over its support for $y \in \{0, 1\}$. We now prove that $\hat{f}_G(x, U_m) \equiv S(f(x))$. Since the support

of $S(f(x))$ contains exactly 2^{k-1} strings (namely, all k-bit strings whose bits sum up to $f(x)$), it suffices to show that for any input x and output $w \in \text{support}(S(f(x)))$ there are $2^m/2^{k-1}$ random inputs r such that $\hat{f}_G(x,r) = w$. (Note that $m \geq k-1$ since G is connected.) Let $T \subseteq E$ be a spanning tree of G. We argue that for any assignment to the $m-(k-1)$ random variables that correspond to edges in $E \setminus T$ there exists an assignment to the other random variables that is consistent with w and x. Fix some assignment to the edges in $E \setminus T$. We now recursively assign values to the remaining edges. In each step we make sure that some leaf is consistent with w by assigning the corresponding value to the edge connecting this leaf to the graph. Then, we prune this leaf and repeat the above procedure. Formally, let i be a leaf which is connected to T by an edge $e \in T$. Assume, without loss of generality, that e is an incoming edge for i. We set r_e to $w_i - (T_i(x) + \sum_{j|(j,i)\in E\setminus T} r_{j,i} - \sum_{j|(i,j)\in E\setminus T} r_{i,j})$ and remove i from T. By this we ensure that the ith bit of $\hat{f}_G(x,r)$ is equal to w_i. (This equality will not be violated by the following steps as i is removed from T.) We continue with the above step until the tree consists of one node. Since the outputs of $\hat{f}_G(x,r)$ always sum up to $f(x)$ it follows that this last bit of $\hat{f}_G(x,r)$ is equal to the corresponding bit of w. Thus, there are at least $2^{|E\setminus T|} = 2^{m-(k-1)}$ values of r that lead to w as required.

Finally, to prove (3) note that when G is a tree we have $m = k-1$, and therefore the encoding is stretch-preserving; combined with (1) and (2), $\hat{f}_G$ is also perfect. ∎

Appendix C. More on encryption schemes in $\mathbf{NC^0}$. We consider two issues regarding encryption, briefly mentioned in section 7.2.

C.1. On the impossibility of $\mathbf{NC^0}$ decryption. In this section we show that, in many settings, decryption in NC^0 is impossible regardless of the complexity of encryption. Here we consider standard *stateless* encryption schemes in contrast to the discussion at the end of section 7.2. We begin with the case of multiple-message security (in either the private-key or public-key setting). If a decryption algorithm $D(d,y)$ is in NC^0_k, then an adversary that gets n encrypted messages can correctly guess the first bits of *all* the plaintexts (jointly) with at least 2^{-k} probability. To do so, the adversary simply guesses at random the k (or fewer) bits of the key d on which the first output bit of D depends, and then computes this first output bit (which is supposed to be the first plaintext bit) on each of the n ciphertexts using the subkey it guessed. Whenever the adversary guesses the k bits correctly, it succeeds in finding the first bits of *all* n messages. When $n > k$, this violates the semantic security of the encryption scheme. Indeed, for the encryption scheme to be secure, the adversary's success probability (when the messages are chosen at random) can only be negligibly larger than 2^{-n}. (That is, an adversary cannot do much better than simply guessing these first bits.)

Even in the case of a single-message private-key encryption, it is impossible to implement decryption in NC^0_k with an arbitrary (polynomial) message length. Indeed, when the message length exceeds $(2|d|)^k$ (where $|d|$ is the length of the decryption key), there must be more than 2^k bits of the output of D which depend on the same k bits of the key, in which case we are in the same situation as before. That is, we can guess the value of more than 2^k bits of the message with constant success probability 2^{-k}. Again, if we consider a randomly chosen message, this violates semantic security.

C.2. Security against CPA, CCA1, and CCA2 attacks. In this section we address the possibility of applying our machinery to encryption schemes that enjoy

stronger notions of security. In particular, we consider schemes that are secure against CPA, CCA1, and CCA2. In all three attacks the adversary has to win the standard indistinguishability game (i.e., given a ciphertext $c = E(e, m_b)$, find out which of the two predefined plaintexts m_0, m_1 was encrypted), and so the actual difference lies in the power of the adversary. In a CPA attack the adversary can obtain encryptions of plaintexts of his choice (under the key being attacked), i.e., the adversary gets an oracle access to the encryption function. In CCA1 attack the adversary may also obtain decryptions of his choice (under the key being attacked), but he is allowed to do so only *before* the challenge is presented to him. In both cases, the security is preserved under randomized encoding. We briefly sketch the proof idea.

Let $\hat{B}$ be an adversary that breaks the encoding $\hat{\mathcal{E}}$ via a CPA attack (resp., CCA1 attack). We use $\hat{B}$ to obtain an adversary B that breaks the original scheme $\mathcal{E}$. As in the proof of Lemma 7.5, B uses the simulator to translate the challenge c, an encryption of the message m_b under $\mathcal{E}$, into a challenge $\hat{c}$, which is an encryption of the same message under $\hat{\mathcal{E}}$. Similarly, B answers the encryption queries of $\hat{B}$ (to the oracle $\hat{E}$) by directing these queries to the oracle E and applying the simulator to the result. Also, in the case of CCA1 attack, whenever $\hat{B}$ asks the decryption oracle $\hat{D}$ to decrypt some ciphertext $\hat{c}'$, the adversary B uses the decoder (of the encoding) to translate $\hat{c}'$ into a ciphertext c' of the same message under the scheme $\mathcal{E}$, and then uses the decryption oracle D to decrypt c'. This allows B to emulate the oracles $\hat{D}$ and $\hat{E}$ and thus to translate a successful CPA attack (resp., CCA1 attack) on the new scheme into a similar attack on the original scheme.

The situation is different in the case of a CCA2 attack. As in the case of a CCA1 attack, a CCA2 attacker has an oracle access to the decryption function corresponding to the decryption key in use; however, the adversary can query the oracle *even after* the challenge has been given to him, under the restriction that he cannot ask the oracle to decrypt the challenge c itself.

We start by observing that when applying a randomized encoding to a CCA2-secure encryption scheme, CCA2 security may be lost. Indeed, in the resulting encryption one can easily modify a given ciphertext challenge $\hat{c} = \hat{E}(e, x, r)$ into a ciphertext $\hat{c}' \neq \hat{c}$ which is also an encryption of the same message under the same encryption key. This can be done by applying the decoder (of the randomized encoding $\hat{E}$) and then the simulator on $\hat{c}$, that is $\hat{c}' = S(C(\hat{c}))$. Hence, one can break the encryption by simply asking the decryption oracle to decrypt $\hat{c}'$.

It is instructive to understand why the previous arguments fail to generalize to the case of CCA2 security. In the case of CCA1 attacks we transformed an adversary $\hat{B}$ that breaks the encoding $\hat{\mathcal{E}}$ into an adversary B for the original scheme in the following way: (1) we used the simulator to convert a challenge $c = E(e, m_b)$ into a challenge $\hat{c}$ which is an encryption of the same message under $\hat{\mathcal{E}}$; (2) when $\hat{B}$ asks $\hat{D}$ to decrypt a ciphertext $\hat{c}'$, the adversary B uses the decoder (of the encoding) to translate $\hat{c}'$ into a ciphertext c' of the same message under the scheme $\mathcal{E}$, and then asks the decryption oracle D to decrypt c'. However, recall that in a CCA2 attack the adversaries are not allowed to ask the oracle to decrypt the challenge itself (after the challenge is presented). So if $c' = c$ but $\hat{c}' \neq \hat{c}$, the adversary B cannot answer the (legitimate) query of $\hat{B}$.

To complement the above, we show that when applying a randomized encoding to a CCA2-secure encryption scheme not all is lost. Specifically, the resulting scheme still satisfies *replayable CCA (RCCA) security*, a relaxed variant of CCA2 security that was suggested in [12]. Loosely speaking, RCCA security captures encryption schemes that are CCA2 secure except that they allow anyone to generate new ciphers

that decrypt to the same value as a given ciphertext. More precisely, an RCCA attack is a CCA2 attack in which the adversary cannot ask the oracle to decrypt *any* cipher c' that decrypts to either m_0 or m_1 (cf. [12, Figure 3]). This limitation prevents the problem raised in the CCA2 proof, in which a legitimate query for $\hat{D}$ translates by the decoder into an illegitimate query for D. That is, if $\hat{c}'$ does not decrypt under $\hat{\mathcal{E}}$ to either m_0 or m_1, then (by correctness) the ciphertext c' obtained by applying the decoder to $\hat{c}'$ also does not decrypt to either of these messages. Hence, randomized encoding preserves RCCA security. As argued in [12], RCCA security suffices in most applications of CCA2 security.

Acknowledgments. We are grateful to Oded Goldreich for many useful suggestions and comments that helped improve this paper and, in particular, for simplifying the proof of Lemma 5.4. We also thank Iftach Haitner and Emanuele Viola for enlightening us about old and new constructions of PRGs from OWFs and for sharing with us the results of [30] and [50]. Finally, we thank Moni Naor and Amir Shpilka for helpful comments.

ROBUST PCPS OF PROXIMITY, SHORTER PCPS, AND APPLICATIONS TO CODING*

ELI BEN-SASSON†, ODED GOLDREICH‡, PRAHLADH HARSHA§, MADHU SUDAN¶, AND SALIL VADHAN‖

Abstract. We continue the study of the trade-off between the length of probabilistically checkable proofs (PCPs) and their query complexity, establishing the following main results (which refer to proofs of satisfiability of circuits of size n):

1. We present PCPs of length $\exp(o(\log\log n)^2)\cdot n$ that can be verified by making $o(\log\log n)$ Boolean queries.
2. For every $\varepsilon > 0$, we present PCPs of length $\exp(\log^{\varepsilon} n)\cdot n$ that can be verified by making a constant number of Boolean queries.

In both cases, false assertions are rejected with constant probability (which may be set to be arbitrarily close to 1). The multiplicative overhead on the length of the proof, introduced by transforming a proof into a probabilistically checkable one, is just quasi polylogarithmic in the first case (of query complexity $o(\log\log n)$), and is $2^{(\log n)^{\varepsilon}}$, for any $\varepsilon > 0$, in the second case (of constant query complexity). Our techniques include the introduction of a new variant of PCPs that we call "robust PCPs of proximity." These new PCPs facilitate proof composition, which is a central ingredient in the construction of PCP systems. (A related notion and its composition properties were discovered independently by Dinur and Reingold.) Our main technical contribution is a construction of a "length-efficient" robust PCP of proximity. While the new construction uses many of the standard techniques used in PCP constructions, it does differ from previous constructions in fundamental ways, and in particular does not use the "parallelization" step of Arora et al. [*J. ACM,* 45 (1998), pp. 501–555]. The alternative approach may be of independent interest. We also obtain analogous quantitative results for locally testable codes. In addition, we introduce a relaxed notion of locally decodable codes and present such codes mapping k information bits to codewords of length $k^{1+\varepsilon}$ for any $\varepsilon > 0$.

Key words. probabilistically checkable proofs, PCP, locally testable codes, locally decodable codes, property testing

1. Introduction. Probabilistically checkable proofs (PCPs) [FGL+96, AS98, ALM+98] (aka holographic proofs [BFLS91]) are NP witnesses that allow efficient probabilistic verification based on probing few bits of the NP witness. The celebrated PCP theorem [AS98, ALM+98] asserts that probing a constant number of bits suffices, and it turned out that three bits suffice for rejecting false assertions with probability almost 1/2 (cf. [Hås01, GLST98]).

Optimizing the query complexity of PCPs has attracted a lot of attention, motivated in part by the significance of query complexity for nonapproximability results (see, for example, [BGLR93, BGS95, Hås01, GLST98, ST00]). However, these works guarantee only that the new NP witness (i.e., the PCP) is of a length that is upper-bounded by a polynomial in the length of the original NP witness.[1] Optimizing the length of the new NP witness was the focus of [BFLS91, PS94, HS00, GS02, BSVW03], and in this work we continue the latter research direction.

In our view, the significance of PCPs extends far beyond their applicability to deriving nonapproximability results. The mere fact that NP witnesses can be transformed into a format that supports superfast probabilistic verification is remarkable. From this perspective, the question of how much redundancy is introduced by such a transformation is fundamental. Furthermore, PCPs have been used not only to derive nonapproximability results but also for obtaining positive results (e.g., computationally sound (CS) proofs [Kil92, Mic00] and their applications [Bar01, CGH04]), and the length of the PCP affects the complexity of those applications.

In any case, the length of PCPs is also relevant to nonapproximability results; specifically, it affects their *tightness with respect to the running time* (as noted in [Sze99]). For example, suppose (exact) satisfiability (SAT) has complexity $2^{\Omega(n)}$. The original PCP theorem [AS98, ALM+98] implies only that approximating maximum satisfiability (MaxSAT) requires time $2^{n^{\alpha}}$ for some (small) $\alpha > 0$. The work of [PS94] makes α arbitrarily close to 1, whereas the results of [GS02, BSVW03] further improve the lower-bound to $2^{n^{1-o(1)}}$. Our results reduce the $o(1)$ term.[2]

1.1. PCPs with better length versus query trade-off. How short can a PCP be? The answer may depend on the number of bits we are willing to read in order to reject false assertions (say) with probability at least 1/2. It is implicit in the work of [PS94] that, for proofs of satisfiability of circuits of size n, if we are willing to read $n^{0.01}$ bits, then the length of the new NP witness may be $\widetilde{O}(n)$. That is, stretching the NP witness by only a polylogarithmic amount, allows us to dramatically reduce the number of bits read (from n to $n^{0.01}$). More precisely, see the following theorem.[3]

THEOREM 1.1 (implicit in [PS94]). *Satisfiability of circuits of size n can be probabilistically verified by probing an NP witness of length* $\mathrm{poly}(\log n) \cdot n$ *in* $n^{o(1)}$ *bit locations. In fact, for any integer value of a parameter* $m \leq \log n$*, there is a PCP having randomness complexity* $(1-m^{-1}) \cdot \log_2 n + O(\log \log n) + O(m \log m)$ *and query complexity* $\mathrm{poly}(\log n) \cdot n^{1/m}$.

Recall that the proof length of a PCP is at most $2^r \cdot q$, where r is the randomness complexity and q is the query complexity of the PCP. Thus, the first part of the above theorem follows by setting $m = \log \log n / \log \log \log n$ in the second part.

Our results show that the query complexity can be reduced dramatically if we are

[1] We stress that in all the above works, as well as in the current work, the new NP witness can be computed in polynomial time from the original NP witness.

[2] A caveat: It is currently not known whether these improved lower-bounds can be achieved simultaneously with optimal approximation ratios, but the hope is that this can eventually be done.

[3] All logarithms in this work are of base 2, but in some places we choose to emphasize this fact by using the notation $\log_2$ rather than log.

willing to increase the length of the proof slightly. First, with a quasi-polylogarithmic stretch, the query complexity can be made double-logarithmic as follows.

THEOREM 1.2. *Satisfiability of circuits of size n can be probabilistically verified by probing an NP witness of length $\exp(o(\log\log n)^2)\cdot n$ in $o(\log\log n)$ bit locations. In fact, it has a PCP having randomness complexity $\log_2 n + O\big((\log\log n)^2/\log\log\log n\big)$ and query complexity $O(\log\log n/\log\log\log n)$.*

We mention that the only prior work claiming query complexity below $\exp(\sqrt{\log n})$ (cf. [GS02, BSVW03]) required stretching the NP witness by at least an $\exp(\sqrt{\log n})$ factor. With approximately such a stretch factor, these works actually achieved constant query complexity (cf. [GS02, BSVW03]). Thus, Theorem 1.2 represents a vast improvement in the query complexity of PCPs that use very short proofs (i.e., in the range between $\exp(o(\log\log n)^2)\cdot n$ and $\exp(\sqrt{\log n})\cdot n$). On the other hand, considering NP witnesses that allow probabilistic verification by a *constant* number of queries, we reduce the best known stretch factor from $\exp(\log^{0.5+\varepsilon} n)$ (established in [GS02, BSVW03]) to $\exp(\log^{\varepsilon} n)$, for any $\varepsilon > 0$ as follows.

THEOREM 1.3. *For every constant $\varepsilon > 0$, satisfiability of circuits of size n can be probabilistically verified by probing an NP witness of length $\exp(\log^{\varepsilon} n)\cdot n$ in a constant number of bit locations. In fact, it has a PCP having randomness complexity $\log_2 n + \log^{\varepsilon} n$ and query complexity $O(1/\varepsilon)$.*

It may indeed be the case that the trade-off (between length blow-up factors and query complexity) offered by Theorems 1.1–1.3 merely reflects our (incomplete) state of knowledge. In particular, we wonder whether circuit satisfiability can be probabilistically verified by a PCP having proof length $n\cdot\mathrm{poly}(\log n)$ and constant query complexity.

1.2. New notions and main techniques. A natural approach to reducing the query complexity of the PCP provided by Theorem 1.1 is via the "proof composition" paradigm of [AS98]. However, that PCP (as constructed in [PS94]) does not seem amenable to composition when the parameter m is nonconstant.[4] The reason is that standard proof composition requires the "outer" proof system to make a constant number of multivalue oracle queries (or be converted to such), whereas this specific PCP does not have this property and we cannot afford the standard parallelization involved in a suitable conversion. Thus, we begin by giving a new PCP construction whose parameters match those in Theorem 1.1, but is suitable for composition. As we will see, we cannot afford the standard proof composition techniques, and thus also introduce a new, more efficient composition paradigm.

The initial PCP. Our new proof of Theorem 1.1 modifies the constructions of [PS94] and [HS00]. The latter construction was already improved in [GS02, BSVW03] to reduce the length of PCPs to $n\cdot 2^{\widetilde{O}(\sqrt{\log n})}$. Our results go further by re-examining the "low-degree test" (query-efficient tests that verify if a given function is close to being a low-degree polynomial) and observing that the small-biased sample sets of [BSVW03] give an even more significant savings on the randomness complexity of low-degree tests than noticed in that work. However, exploiting this advantage takes a significant effort in modifying known PCP modules and redefining the ingredients in "proof composition."

For starters, PCP constructions tend to use many (i.e., a superconstant number of) functions and need to test if each is a low-degree polynomial. In prior results,

[4] Also for constant m, we get stronger quantitative results by using our new PCP construction as a starting point.

this was performed efficiently by combining the many different functions on, say, m variables, into a single new one on $m+1$ variables, where the extra variable provides an index into the many different old functions. Testing if the new function is of low-degree implicitly tests all the old functions. Such tricks, which involve introducing a few extra variables, turn out to be too expensive in our context. Furthermore, for similar reasons, we cannot use other "parallelization" techniques [FRS94, LS97, ALM+98, GS00, Raz98], which were instrumental to the proof composition technique of [AS98]. In turn, this forces us to introduce a new variant of the proof composition method, which is much more flexible than the one of [AS98]. Going back to the PCP derived in Theorem 1.1, we adapt it for our new composition method by introducing a "bundling" technique that offers a randomness-efficient alternative to parallelization.

Our new proof composition method refers to two new notions: the notion of a *PCP of proximity* and the notion of a *robust PCP*. Our method is related to the method discovered independently by Dinur and Reingold [DR04]. (There are significant differences between the two methods, as explained in section 1.3, where we also discuss our method in relation to Szegedy's work [Sze99].)

PCPs of proximity. Recall that a standard PCP is given an explicit input (which is supposedly in some NP language) as well as access to an oracle that is supposed to encode a "probabilistically verifiable" NP witness. The PCP verifier uses oracle queries (which are counted) in order to probabilistically verify whether the input, which is explicitly given to it, is in the language. In contrast, a *PCP of proximity* is given access to two oracles, one representing an input (supposedly in the NP language) and the other being a redundant encoding of an NP witness (as in a PCP). Indeed, the verifier may query both the input oracle and the proof oracle, but *its queries to the input oracle are also counted in its query complexity.* As usual we focus on verifiers having very low query complexity, certainly smaller than the length of the input. Needless to say, such a constrained verifier cannot distinguish inputs in the language from inputs out of the language, but it is not required to do so. A verifier for a PCP of proximity is required only to accept inputs that are in the language and reject inputs that are *far* from the language (i.e., far in Hamming distance from any input in the language). Indeed, PCPs of proximity are related to holographic proofs [BFLS91] and to "PCP spot-checkers" [EKR04]; see a further discussion in section 1.3.

Robust PCPs. To discuss robust PCPs, let us review the soundness guarantee of standard (nonadaptive) PCPs. The corresponding verifier can be thought of as determining, based on its coin tosses, a sequence of oracle positions and a predicate such that evaluating this predicate on the indicated oracle bits always accepts if the input is in the language and rejects with high probability otherwise. That is, in the latter case, we require that the assignment of oracle bits to the predicate satisfies the predicate. In a *robust PCP* we strengthen the latter requirement. We require that the said assignment (of oracle bits) not only fail to satisfy the predicate but also be *far* from any assignment that satisfies the predicate.

Proof composition. The key observation is that our proof composition works very smoothly when we compose an outer robust PCP with an inner PCP of proximity. We need neither worry about how many queries the outer robust PCP makes nor care about what coding the inner PCP of proximity uses in its proof oracle (much less apply the same encoding to the outer answers). All that we should make sure of is that the lengths of the objects match and that the distance parameter in the robustness condition (of the outer verifier) is at least as big as the distance parameter

in the proximity condition (of the inner verifier).

Indeed, Theorems 1.2 and 1.3 are proved by first extending Theorem 1.1 to provide a robust PCP of proximity of similar complexities, and then applying the new "proof composition" method. We stress that our contribution is in providing a proof of Theorem 1.1 that lends itself to a modification that satisfies the robustness property, and in establishing the latter property. In particular, the aforementioned "bundling" is applied in order to establish the robustness property. Some care is required when deriving Theorem 1.2 using a nonconstant number of proof compositions. In particular, Theorem 1.2 (resp., Theorem 1.3) is derived in a way that guarantees that the query complexity is linear rather than exponential in the number of proof compositions, where the latter is $o(\log \log n)$ (resp., $1/\varepsilon$). This, in turn, requires obtaining strong bounds on the robustness property of the ("robust") extension of Theorem 1.1.

We stress that the flexibility in composing robust PCPs of proximity plays an important role in our ability to derive quantitatively stronger results regarding PCPs. We believe that robust PCPs of proximity may play a similar role in other quantitative studies of PCPs. We note that the standard PCP theorem of [AS98, ALM+98] can be easily derived using a much weaker and simpler variant of our basic robust PCP of proximity, and the said construction seems easier than the basic PCPs used in the proof composition of [AS98, ALM+98].

In addition to their role in our proof composition method, PCPs of proximity also provide a good starting point for deriving improved locally testable codes (see the discussion in section 1.4). The relation of PCPs of proximity to "property testing" is further discussed in section 1.3.

1.3. Related work. As mentioned above, the notion of a PCP of proximity is related to notions that have appeared in the literature.

Relation to holographic proofs. First, the notion of a PCP of proximity generalizes the notion of holographic proofs set forth by Babai et al. [BFLS91]. In both cases, the verifier is given oracle access to the input, and we count its probes to the input in its query complexity. The key issue is that holographic proofs refer to inputs that are presented in an error-correcting format (e.g., one aims to verify that a graph that is *represented by an error-correcting encoding of its adjacency matrix* (or incidence list) is 3-colorable). In contrast, a PCP of proximity refers to inputs that are presented in any format but makes assertions only about their proximity to acceptable inputs (e.g., one is interested in whether a graph, represented by its adjacency matrix (or incidence list), *is* 3*-colorable or is far from being* 3*-colorable*).

Relation to property testing. PCPs of proximity are implicit in the low-degree testers that utilize auxiliary oracles (e.g., an oracle that provides the polynomial representing the value of the function restricted to a queried line); cf. [AS98, ALM+98]. PCPs of proximity are a natural special case of the PCP spot-checkers defined by Ergün, Kumar, and Rubinfeld [EKR04]. On the other hand, PCPs of proximity extend property testing [RS96, GGR98]. Loosely speaking, a *property tester* is given oracle access to an input and is required to distinguish the case in which the input has the property from the case in which it is far (say, in Hamming distance) from any input having the property. Typically, the interest is in testers that query their input on few bit locations (or at the very least on a sublinear number of such locations). In a PCP of proximity such a tester (now called a verifier) is also given oracle access to an alleged proof. Thus, the relation of PCPs of proximity to property testing is analogous to the relation of NP to BPP (or RP). Put differently, while property testing provides a notion of approximation for decision procedures, a PCP of proximity

provides a notion of approximation for (probabilistic) proof-verification procedures. In both cases, approximation means that inputs in the language should be accepted (when accompanied by suitable proofs), while inputs that are far from the language should be rejected (no matter what false proof is provided).

We comment that PCPs of proximity are provably stronger than property testers; that is, there are (natural) separations between property testers and PCPs of proximity (which may be viewed as the "approximation" versions of BPP and NP). For further discussions, refer to section 2.2.

Relation to assignment testers and another proof composition method. As stated above, our proof composition method is related to the method discovered independently by Dinur and Reingold [DR04]. Both methods use the same notion of PCPs of proximity (which are called assignment testers in [DR04]). A key difference between the two methods is that, while our method refers to the new notion of robustness (i.e., to the robustness of the outer verifier), the method of Dinur and Reingold refers to the number of (non-Boolean) queries (made by the outer verifier). Indeed, the method of Dinur and Reingold uses a (new) parallelization procedure (which reduces the number of queries by a constant factor), whereas we avoid parallelization altogether (but rather use a related "bundling" of queries into a nonconstant number of "bundles" such that robustness is satisfied at the bundle level).[5] We stress that we cannot afford the cost of any known parallelization procedure because, at the very least, these procedures increase the length of the proof by a factor related to the answer length, which is far too large in the context of Theorem 1.1 (which in turn serves as the starting point for all the other results in this work). We comment that the parallelization procedure of [DR04] is combinatorial (albeit inapplicable in our context), whereas our bundling relies on the algebraic structure of our proof system.

Relation to Szegedy's work [Sze99]. Some of the ideas presented in the current work are implicit in Szegedy's work [Sze99]. In particular, notions of robustness and proximity are implicit in [Sze99], in which a robust PCP of proximity (attributed to [PS94]) is composed with itself in a way that is similar to our composition theorem. We note that Szegedy does not seek to obtain PCPs with improved parameters, but rather to suggest a framework for deriving nicer proofs of existing results such as those in [PS94]. Actually, he focuses on proving the main result of [PS94] (i.e., a PCP of nearly linear length and constant number of queries) using as a building block a robust PCP of proximity that has length $\widetilde{O}(n)$ and makes $\widetilde{O}(\sqrt{n})$ queries (plus the constant query PCP of [ALM+98]).

We note that the aforementioned robust PCP of proximity is not presented in [Sze99], but is rather attributed to [PS94]. Indeed, observe that Theorem 1.1 above (implicit in [PS94]) achieves $\widetilde{O}(n)$ length and $\widetilde{O}(\sqrt{n})$ queries when the parameter $m = 2$. Thus, Szegedy's assertion is that this PCP can be strengthened to be a robust PCP of proximity, similarly to our main construct (specifically, Theorem 3.1, specialized to $m = 2$). However, our main construct achieves stronger parameters than those claimed in [Sze99], especially with respect to robust soundness. Indeed,

[5] The main part of the bundling technique takes place at the level of analysis, without modifying the proof system at all. Specifically, we show that the answers read by the verifier can be partitioned into a nonconstant number of (a priori fixed) bundles so that on any no instance, with high probability a constant fraction of the bundles read should be modified to make the verifier accept. We stress that the fact that certain sets of queries (namely, those in each bundle) are always made together is a feature that our particular proof system happens to have (or rather it was somewhat massaged to have). Once robust soundness is established at the bundle level, we need only modify the proof system so that the bundles become queries and the answers are placed in (any) good error-correcting format, which implies robustness at the bit level.

the parameters claimed in [Sze99] allow only for the robust PCP of proximity to be composed with itself a constant number of times.[6] As mentioned above, a significant amount of our effort is aimed at ensuring that our robust PCP of proximity has sufficiently strong parameters to be composed a nonconstant number of times and, moreover, to ensure that the query complexity grows only linearly rather than exponentially with the number of compositions. (See section 3.2 for further explanation.)

1.4. Applications to coding problems. The flexibility of PCPs of proximity makes them relatively easy to use towards obtaining results regarding locally testable and decodable error-correcting codes. In particular, using a suitable PCP of proximity, we obtain an improvement in the rate of locally testable codes (improving over the results of [GS02, BSVW03]). Loosely speaking, a codeword test (for a code C) is a randomized oracle machine that is given oracle access to a string. The tester may query the oracle at a constant number of bit locations and is required to (always) accept every codeword and reject with (relatively) high probability every string that is "far" from the code. The locally testable codes of [GS02, BSVW03] used codewords of length $\exp(\log^{0.5+\varepsilon} k) \cdot k$ in order to encode k bits of information for any constant $\varepsilon > 0$. Here we reduce the length of the codewords to $\exp(\log^{\varepsilon} k) \cdot k$ as follows.

THEOREM 1.4 (loosely stated; see section 4.1 for details). *For every constant $\varepsilon > 0$, there exists locally testable codes that use codewords of length $\exp(\log^{\varepsilon} k) \cdot k$ in order to encode k bits of information.*

We also introduce a relaxed notion of locally decodable codes and show how to construct such codes using any PCP of proximity (and ours in particular). Loosely speaking, a code is said to be *locally decodable* if, whenever relatively few location are corrupted, the decoder is able to recover each information bit, with high probability, based on a constant number of queries to the (corrupted) codeword. This notion was formally defined by Katz and Trevisan [KT00] and the best known locally decodable code has codewords of a length that is subexponential in the number of information bits. We relax the definition of locally decodable codes by requiring that, whenever few locations are corrupted, the decoder be able to recover most of the individual information bits (based on few queries), and for the rest of the locations, the decoder may output a fail symbol (but not the wrong value). That is, the decoder must still avoid errors (with high probability), but is allowed to say "`don't know`" on a few bit locations. We show that this relaxed notion of local decodability can be supported by codes that have codewords of a length that is almost linear in the number of information bits as follows.

THEOREM 1.5 (loosely stated; see section 4.2 for details). *For every constant $\varepsilon > 0$, there exists relaxed locally decodable codes that use codewords of length $k^{1+\varepsilon}$ in order to encode k bits of information.*

1.5. Subsequent work. Since the presentation of our results, there has been considerable progress in the construction of short PCPs.

Ben-Sasson and Sudan [BS05] constructed "shorter" PCPs for NP at the cost of a slightly larger query complexity. More precisely, they construct PCPs of length $n \cdot \mathrm{poly}(\log n)$ (to prove satisfiability of circuits of size n) that can be verified by querying at most $\mathrm{poly}(\log n)$ bits of the proof. They achieve this improvement in

[6] In the language of section 2, his soundness and robustness parameters are unspecified functions of the proximity parameter. In retrospect, it seems that the ideas of [PS94] may lead to a robust PCP of proximity with robustness that is at best linearly related to the proximity parameter; this would make the query complexity increase exponentially with the number of compositions (as discussed in section 3.2).

length by constructing PCPs of proximity for a specific problem, verifying membership in a *Reed–Solomon* code (i.e., verifying if a given function is close to the evaluation of some univariate polynomial of specified degree). Their construction also yields locally testable codes with similar parameters.

More recently, Dinur introduced a novel gap amplification technique to yield a fully combinatorial proof of the PCP theorem [Din06]. In addition, by applying the gap-amplification technique to the PCP constructed by Ben-Sasson and Sudan [BS05], she obtained PCPs for NP of length $n \cdot \text{poly}(\log n)$ and verifiable with a constant number of probes into the proof. Thus while Ben-Sasson and Sudan [BS05] reduce the proof length while increasing the number of queries, Dinur shows how to reduce the query size back to a constant, thereby improving both our results and those of [BS05].

The PCP verifiers in the constructions of both our paper and [BS05] require time at least polynomial in the length of the proof, though the verifiers probe at most $\text{poly}(\log n)$ locations in the proof. In a subsequent paper [BGH$^+$05], we demonstrate that both these constructions can in fact be accompanied with *superefficient* verifiers, i.e., verifiers that run in time at most polylogarithmic in the length of the proof.

Finally, the question of whether there exist nearly linear-sized PCPs for NP that achieve strong query-soundness trade-offs (e.g., achieving the parameters of Håstad [Hås01]) remains open. The recent work of Moshkovitz and Raz [MR06] may be useful towards answering this.

1.6. Organization. Theorems 1.2 and 1.3, which are the work's main results, are proved by constructing and using a robust PCP of proximity that achieves a very good trade-off between randomness and query complexity. Thus, this robust PCP of proximity is the main building block that underlies our work. Unfortunately, the construction of a very efficient robust PCP of proximity is quite involved and is thus deferred to the second part of this work (which starts with an overview). In the first part of this work we show how the aforementioned robust PCP of proximity can be used to derive all the results mentioned in the introduction (and, in particular, Theorems 1.2 and 1.3). Thus, the overall structure of this work is as follows.

Part I: Using the main building block (sections 2–4). We start by providing a definitional treatment of PCPs of proximity and robust PCPs. The basic definitions as well as some observations and useful transformations are presented in section 2. Most important, we analyze the natural composition of an outer robust PCP with an inner PCP of proximity.

In section 3, we state the properties of our main building block (i.e., a highly efficient robust PCP of proximity), and show how to derive Theorems 1.2 and 1.3, by composing this robust PCP of proximity with itself multiple times. Specifically, $o(\log \log n)$ compositions are used to derive Theorem 1.2, and $1/\varepsilon$ compositions are used to derive Theorem 1.3. The coding applications stated in Theorems 1.4 and 1.5 are presented in section 4.

Part II: Constructing the main building block (sections 5–8). We start this part by providing an overview of the construction. This overview (i.e., section 5) can be read before reading Part I, provided that the reader is comfortable with the notion of a robust PCP of proximity.

The construction itself is presented in section 6–8. We start by presenting a (highly efficient) ordinary PCP (establishing Theorem 1.1), which lends itself to the subsequent modifications. In section 7, we augment this PCP with a test of proximity, deriving an analogous PCP of proximity. In section 8 we present a robust version of

the PCP of proximity derived in the previous sections.

Part III: Appendices. The construction presented in section 3 also uses a PCP of proximity of polynomial randomness complexity and constant query complexity. Such a PCP of proximity can be derived by a simple augment of the Hadamard-based PCP of [ALM+98], which we present in Appendix A.

In Appendix B, we recall results regarding randomness-efficient low-degree tests and a related sampling lemma, which are used in Part II.

1.7. Relation to previous versions of this work. The current version includes a discussion of Szegedy's work [Sze99], of which we were unaware when writing the first version [BGH+04b]. The relation of his work to ours is now discussed in section 1.3.

Section 4 has been extensively revised, adding formal definitions and providing more precise descriptions of the main constructions and proofs. In addition, we identified a weaker form of the definition of a relaxed locally decodable code, proved that it essentially implies the original form, and restructured our presentation accordingly (see section 4.2).

The parameters of Theorem 1.2 in this version are stronger (to a limited extent) than that of earlier versions of this paper [BGH+04b, BGH+04a]. More specifically, we show that satisfiability of circuits of size n can be verified by probing $o(\log\log n)$ bit locations in an NP witness of length $\exp(o(\log\log n)^2)\cdot n$ as opposed to an NP witness of length $\exp(\widetilde{O}(\log\log n)^2)\cdot n$, as was claimed in earlier versions. We achieve this strengthening by improving the robustness parameter of the ALMSS-type robust PCP of proximity (Theorem 7.2) constructed in Part II of this paper, taking advantage of the greater slackness allowed in the randomness complexity of this PCP. (ALMSS-type robust PCP of proximity is one of the PCPs of proximity constructed in Part II. It is so called as it has parameters similar to the PCP constructed in [ALM+98].)

Part I. All but the main construct.

2. PCPs and variants: Definitions, observations, and transformations.

Notation. Except when otherwise noted, all *circuits* in this paper have fan-in 2 and fan-out 2, and we allow arbitrary unary and binary Boolean operations as internal gates. The *size* of a circuit is the number of gates. We will refer to the following languages associated with circuits: the P-complete language Circuit Value, defined as CktVal $= \{(C,w) : C(w) = 1\}$; the NP-complete Circuit Satisfiability, defined as CktSAT $= \{C : \exists w C(w) = 1\}$; and the NP-complete Nondeterministic CircuitValue, defined as NCktVal $= \{(C,w) : \exists z C(w,z) = 1\}$. (In the latter, we assume that the partition of the variables of C into w-variables and z-variables is explicit in the encoding of C.)

We will extensively refer to the *relative* distance between strings/sequences over some alphabet Σ: For $u, v \in \Sigma^\ell$, we denote by $\Delta(u,v)$ the fraction of locations on which u and v differ (i.e., $\Delta(u,v) \triangleq |\{i : u_i \neq v_i\}|/\ell$, where $u = u_1 \cdots u_\ell \in \Sigma^\ell$ and $v = v_1 \cdots v_\ell \in \Sigma^\ell$). We say that u is *δ-close* to v (resp., *δ-far* from v) if $\Delta(u,v) \leq \delta$ (resp., $\Delta(u,v) > \delta$). The relative distance of a string from a set of strings is defined in the natural manner; that is, $\Delta(u,S) \triangleq \min_{v\in S}\{\Delta(u,v)\}$. Occasionally, we will refer to the absolute Hamming distance, which we will denote by $\overline{\Delta}(u,v) \triangleq |\{i : u_i \neq v_i\}|$. We will also use the t-repetition x^t of a string x to denote the string formed by concatenating t copies of x (i.e., $x^t = x \ldots t \text{ times} \ldots x$).

Organization of this section. After recalling the standard definition of PCP (in section 2.1), we present the definitions of PCPs of proximity and robust PCPs (in

section 2.2 and 2.3, respectively). We then discuss (in section 2.4) the composition of a robust PCP with a PCP of proximity. Various observations and transformations regarding the new notions are presented in section 2.5.

2.1. Standard PCPs. We begin by recalling the formalism of a PCP verifier. Throughout this work, we restrict our attention to *nonadaptive* verifiers, not only for simplicity but also because one of our variants (namely robust PCPs) only makes sense for nonadaptive verifiers.

DEFINITION 2.1 (PCP verifiers).

- *A* verifier *is a* probabilistic polynomial-time *algorithm V that, on an input x of length n, tosses $r = r(n)$ random coins R and generates a* sequence *of $q = q(n)$ queries $I = (i_1, \ldots, i_q)$ and a circuit $D : \{0,1\}^q \to \{0,1\}$ of size at most $d(n)$.*
  We think of V as representing a probabilistic oracle machine that queries its oracle π for the positions in I, receives the q answer bits $\pi|_I \triangleq (\pi_{i_1}, \ldots, \pi_{i_q})$, and accepts iff $D(\pi|_I) = 1$.
- *We write $(I, D) \overset{R}{\leftarrow} V(x)$ to denote the queries and circuit generated by V on input x and random coin tosses and write $(I, D) = V(x; R)$ if we wish to specify the coin tosses R.*
- *We call r the* randomness complexity*, q the* query complexity*, and d the* decision complexity *of V.*

For simplicity in these definitions, we treat the parameters r, q, and d above (and other parameters below) as functions of only the input length n. However, at times we may also allow them to depend on other parameters, which should be understood as being given to the verifier together with the input. We now present the standard notion of PCPs, restricted to perfect completeness for simplicity.

DEFINITION 2.2 (standard PCPs). *For a function $s : \mathbb{Z}^+ \to [0,1]$, a verifier V is a* probabilistically checkable proof system *for a language L with* soundness error *s if the following two conditions hold for every string x:*

Completeness: If $x \in L$, then there exists π such that $V(x)$ accepts oracle π with probability 1*. Formally,*

$$\exists \pi \qquad \Pr_{(I,D) \overset{R}{\leftarrow} V(x)} [D(\pi|_I) = 1] = 1.$$

Soundness: If $x \notin L$, then for every oracle π, the verifier $V(x)$ accepts π with probability strictly less than s. Formally,

$$\forall \pi \qquad \Pr_{(I,D) \overset{R}{\leftarrow} V(x)} [D(\pi|_I) = 1] < s(|x|).$$

If s is not specified, then it is assumed to be a constant in $(0, 1)$*.*

Our main goal in this work is to construct *short* PCPs that use *very few queries*. Recalling that the length of a (nonadaptive) PCP is upper-bounded by $2^{r(n)} \cdot q(n)$, we focus on optimizing the (trade-off between) randomness and query complexities.

We will focus on constructing PCPs for the NP-complete problem CIRCUIT SATISFIABILITY, defined as CKTSAT $= \{C : \exists w\ C(w) = 1\}$. Recall that every language in **NTIME**$(t(n))$ reduces to CKTSAT in time $O(t(n) \log t(n))$ (cf. [HS66, PF79, Coo88]), and so a nearly linear-sized PCP for CKTSAT implies PCPs for **NTIME**$(t(n))$ of length nearly linear in $t(n)$ for every polynomial $t(n)$.

2.2. PCPs of proximity. We now present a relaxation of PCPs that verify only that the input is *close* to an element of the language. The advantage of this relaxation is that it allows for the possibility that the verifier may read only a small number of bits from the input. Actually, for greater generality, we will divide the input into two parts (x, y), giving the verifier x explicitly and y as an oracle, and we count only the verifier's queries to the latter. Thus we consider languages consisting of pairs of strings, which we refer to as *pair languages*. One pair language to keep in mind is the CircuitValue problem CktVal $= \{(C, w) : C(w) = 1\}$. For a pair language L, we define $L(x) = \{y : (x, y) \in L\}$. For example, CktVal$(C)$ is the set of satisfying assignments to C. It will be useful below to treat the two oracles to which the verifier has access as a single oracle; thus for oracles π^0 and π^1, we define the concatenated oracle $\pi = \pi^0 \circ \pi^1$ as $\pi_{b,i} = \pi_i^b$.

Definition 2.3 (PCPs of proximity (PCPPs)). *For functions $s, \delta : \mathbb{Z}^+ \to [0, 1]$, a verifier V is a* probabilistically checkable proof of proximity *(PCPP) system for a pair language L with* proximity parameter δ *and* soundness error s *if the following two conditions hold for every pair of strings (x, y):*

Completeness: If $(x, y) \in L$, then there exists π such that $V(x)$ accepts oracle $y \circ \pi$ with probability 1*. Formally,*

$$\exists \pi \qquad \Pr_{(I,D) \overset{R}{\leftarrow} V(x)} [D((y \circ \pi)|_I) = 1] = 1.$$

Soundness: If y is $\delta(|x|)$-far from $L(x)$, then for every π, the verifier $V(x)$ accepts oracle $y \circ \pi$ with probability strictly less than $s(|x|)$. Formally,

$$\forall \pi \qquad \Pr_{(I,D) \overset{R}{\leftarrow} V(x)} [D((y \circ \pi)|_I) = 1] < s(|x|).$$

If s and δ are not specified, then both are assumed to be constants in $(0, 1)$.

Note that the parameters (soundness, randomness, etc.) of a PCPP are measured as a function of the length of x, the explicit portion of the input.

In comparing PCPPs and PCPs, one should note two differences that have conflicting effects. On one hand, the soundness criterion of PCPPs is a relaxation of the soundness of PCPs. Whereas a PCP is required to reject (with high probability) every input that is not in the language, a PCPP is only required to reject input pairs (x, y) in which the second element (i.e., y) is far from being suitable for the first element (i.e., y is far from $L(x)$). That is, in a PCPP, nothing is required in the case that y is close to $L(x)$ and yet $y \notin L(x)$. On the other hand, the query complexity of a PCPP is measured more stringently, as it accounts also for the queries to the input-part y (on top of the standard queries to the proof π). This should be contrasted with a standard PCP that has free access to all its input and is charged only for access to an auxiliary proof. To summarize, PCPPs are required to do less (i.e., their performance requirements are more relaxed), but they are charged for more things (i.e., their complexity is evaluated more stringently). Although it may not be a priori clear, the stringent complexity requirement prevails. That is, PCPPs tend to be more difficult to construct than PCPs of the same parameters. For example, while CktVal has a trivial PCP (since it is in P), a PCPP for it implies a PCP for CktSAT as follows.

Proposition 2.4. *If* CktVal *has a PCPP, then* CktSAT *has a PCP with identical parameters (randomness, query complexity, decision complexity, and soundness).*

An analogous statement holds for any pair language L and the corresponding projection on first element $L_1 \triangleq \{x : \exists y \text{ s.t. } (x,y) \in L\}$; that is, if L has a PCPP, then L_1 has a PCP with identical parameters.

Proof. A PCP π for "$C \in$ CktSAT" can be taken to be $w \circ \pi'$, where w is a satisfying assignment to C and π' is a PCPP for $(C,w) \in$ CktVal. This proof π can be verified using the PCPP verifier. The key observation is that if $C \notin$ CktSAT, then there exists no w that is 1-close to CktVal(C), because the latter set is empty. ∎

Note that we obtain only a standard PCP for CktSAT rather than a PCP of proximity. Indeed, CktSAT is not a pair language, so it does not even fit syntactically into the definition of a PCPP. However, we can give a PCPP for the closely related (and also NP-complete) pair language Nondeterministic Circuit Value. Recall that it is the language NCktVal $= \{(C,w) : \exists z C(w,z) = 1\}$ (where the variables of C are explicitly partitioned into w-variables and z-variables).

Proposition 2.5. *If* CktVal *has a PCPP with proximity parameter $\delta(n)$, soundness $s(n)$, randomness $r(n)$, query complexity $q(n)$, and decision complexity $d(n)$, then* Nondeterministic Circuit Value *has a PCPP with proximity parameter $2\delta(4n)$, soundness $s(4n)$, randomness $r(4n)$, query complexity $q(4n)$, and decision complexity $d(4n)$.*

Proof. Given a circuit $C(\cdot,\cdot)$ of size n whose variables are partitioned into one group of size k and another of size ℓ, we transform it into a new circuit $C'(\cdot,\cdot)$ of size $n' = 4n$ in which the first group has size $k' \geq \ell$ and the second group has size ℓ. Specifically, we set $t = \lceil \ell/k \rceil$ and $k' = t \cdot k$ and define $C'(x',y)$ to be a circuit that checks whether $x' = x^t$ for some x such that $C(x,y) = 1$. It can be verified that this can be done in size $n + 3tk \leq 4n$ (over the full binary basis). In addition, if w is δ-far from being extendable to a satisfying assignment of C, then w^t is δ-far from being extendable to a satisfying assignment of C'.

Now, the NCktVal-verifier, on explicit input C and input oracle $w \in \{0,1\}^k$, will construct C' as above and expect a proof oracle of the form $z \circ \pi$, where $z \in \{0,1\}^m$ and π is a PCPP for $(C', w^t \circ z) \in$ CktVal satisfies as constructed above. That is, the NCktVal-verifier will simulate the CktVal-verifier on explicit input C', input oracle $w^t \circ z$ (which can easily be simulated given oracle access to w and z), and proof oracle π. Completeness can be verified by inspection. For soundness, suppose that w is 2δ-far from being extendable to a satisfying assignment of C. Then w^t is 2δ-far from being extendable to a satisfying assignment of C', which implies that, for any z, $w^t \circ z$ is δ-far from satisfying C'. Thus, by the soundness of the CktVal-verifier, the acceptance probability is at most $s(n') = s(4n)$ for any proof oracle π. ∎

Relation to property testing. Actually, the requirements of a PCPP for a pair language L refer only to its performance on the ("gap") promise problem $\Pi = (\Pi_Y, \Pi_N)$, where $\Pi_Y = L$ and $\Pi_N = \{(x,y) : y \text{ is } \delta\text{-far from } L(x)\}$. That is, this PCPP is required only to (always) accept inputs in Π_Y and reject (with high probability) inputs in Π_N (whereas nothing is required with respect to inputs not in $\Pi_Y \cup \Pi_N$). Such a gap problem corresponds to the notion of approximation in *property testing* [RS96, GGR98].[7] Indeed, property testers are equivalent to PCPP verifiers that have no access to an auxiliary proof π. Thus, the relation between property testing and PCPPs is analogous to the relation between BPP and NP (or MA). For example, the problem of testing bipartiteness can be cast by the pair language

[7] This notion of approximation (of decision problems) should not be confused with the approximation of (search) optimization problems, which is also closely related to PCPs [FGL+96, ALM+98].

$L = \{(n, G) : \text{the } n\text{-vertex graph } G \text{ is bipartite}\}$, where the first (i.e., explicit) input is used only to specify the length of the second (i.e., nonexplicit) input G, to which the tester has oracle access (measured in its query complexity). We comment that the formulation of pair languages allows us to capture more general property testing problems, where more information about the property (to be tested) itself is specified as part of the input (e.g., by a circuit, as in CktVal).

In both property testers and PCPPs, the interest is in testers/verifiers that query their input (and proof oracle) in only a small (preferably constant, and certainly sublinear) number of bit locations. It turns out that PCPPs are provably stronger than property testers; that is, there are (natural) separations between property testers and PCPPs. (Some of the following examples were pointed out in [EKR04].) In the adjacency matrix model (cf. [GGR98]), bipartiteness has a PCPP in which the verifier makes only $O(1/\delta)$ queries and rejects any graph that is δ-far from being bipartite with probability at least 2/3. (The proof oracle consists of an assignment of vertices to the two parts, and the verifier queries the assignment of the end-points of $O(1/\delta)$ random edges. This construction also generalizes to k-colorability, and in fact to any generalized graph partition property (cf. [GGR98]) with an efficient one-sided tester.) In contrast, Bogdanov and Trevisan [BT04] showed that any tester for bipartiteness that rejects graphs that are δ-far from being bipartite must make $\Omega(\delta^{-3/2})$ queries. More drastic separations are known in the incidence-lists (bounded-degree) model (of [GR02]): testing bipartiteness (resp., 3-colorability) of n-vertex graphs has query complexity $\Omega(\sqrt{n})$ [GR02] (resp., $\Omega(n)$ [BOT02]), but again a PCPP will use only $O(1/\delta)$ queries.

Another example comes from the domain of codes. For any good code (or "even" any code of linear distance), there exists a PCPP with constant queries for checking whether a given word is a codeword.[8] This stands in contrast to the linear lower-bound on the query complexity of codeword testing for some (good) linear codes, proved by Ben-Sasson, Harsha, and Raskhodnikova [BHR05].

Needless to say, there may be interesting cases in which PCPPs do not outperform property testers.

Queries versus proximity. Intuitively, the query complexity of a PCPP should depend on the proximity parameter δ. Proposition 2.8 (in section 2.5) confirms this intuition.

The relation of PCPP to other works. As discussed in the introduction (see section 1.3), notions related to (and equivalent to) PCPPs have appeared previously in the literature [BFLS91, EKR04]. In particular, holographic proofs are a special case of PCPPs (which refer to pair languages $L = \{(n, \mathcal{C}(x)) : x \in L' \cap \{0,1\}^n\}$, where $\mathcal{C}$ is an error-correcting code and $L' \in \text{NP}$), whereas PCPPs are a special case of PCP spot-checkers (when viewing decision problems as a special case of search problems). In addition, PCPPs play an important role also in the work of Dinur and Reingold [DR04]; again, see section 1.3. Recall that both our use and their use of PCPPs is for facilitating proof composition (of PCP-type constructs). Finally, existing PCP constructions (such as [ALM+98]) can be modified to yield PCPPs.

2.3. Robust soundness. In this section, we present a *strengthening* of the standard PCP soundness condition. Instead of asking that the bits which the verifier reads from the oracle be merely rejected with high probability, we ask that the bits which

[8] Indeed, this is a special case of our extension of the result of Babai et al. [BFLS91], discussed in section 1.3. On the other hand, this result is simpler than the locally testable code mentioned in section 1.4 because here the PCPP is not part of the codeword.

the verifier reads be *far* from being accepted with high probability. The main motivation for this notion is that, in conjunction with PCPPs, it allows for a very simple composition without the usual costs of "parallelization."

DEFINITION 2.6 (robust soundness). *For functions $s, \rho : \mathbb{Z}^+ \to [0,1]$, a PCP verifier V for a language L has* robust-soundness error *s with* robustness parameter *ρ if the following holds for every $x \notin L$: For every oracle π, the bits read by the verifier V are ρ-close to being accepted with probability strictly less than s. Formally,*

$$\forall \pi \quad \Pr_{(I,D) \overset{R}{\leftarrow} V(x)} [\exists a \text{ s.t. } D(a) = 1 \text{ and } \Delta(a, \pi|_I) \leq \rho] < s(|x|).$$

If s and ρ are not specified, then they are assumed to be constants in $(0,1)$. PCPPs with robust soundness are defined analogously, with the $\pi|_I$ being replaced by $(y \circ \pi)|_I$.

Note that for PCPs with query complexity q, robust soundness with any robustness parameter $\rho < 1/q$ is equivalent to standard PCP soundness. However, there can be robust PCPs with large query complexity (e.g., $q = n^{\Omega(1)}$) yet constant robustness, and indeed such robust PCPs will be the main building block of our construction.

Various observations regarding robust PCPs are presented in section 2.5. We briefly mention here the relation of robustness to parallelization; specifically, when applied to a robust PCP, the simple query-reduction technique of Fortnow, Rompel, and Sipser [FRS94] performs less poorly than usual (i.e., the resulting soundness is determined by the robustness parameter rather than by the number of queries).

2.4. Composition. As promised, a robust "outer" PCP composes very easily with an "inner" PCPP. Loosely speaking, we can compose such schemes provided that the decision complexity of the outer verifier matches the input length of the inner verifier, and soundness holds provided that the robustness parameter of the outer verifier upper-bounds the proximity parameter of the inner verifier. Note that composition does not refer to the query complexity of the outer verifier, which is always upper-bounded by its decision complexity.

THEOREM 2.7 (composition theorem). *Suppose that for functions $r_{\text{out}}, r_{\text{in}}, d_{\text{out}}, d_{\text{in}}, q_{\text{in}} : \mathbb{N} \to \mathbb{N}$, and $\varepsilon_{\text{out}}, \varepsilon_{\text{in}}, \rho_{\text{out}}, \delta_{\text{in}} : \mathbb{N} \to [0,1]$, the following hold:*

- *Language L has a* robust PCP *verifier V_{out} with randomness complexity r_{out}, decision complexity d_{out}, robust-soundness error $1 - \varepsilon_{\text{out}}$, and robustness parameter ρ_{out}.*
- CKTVAL *has a* PCPP *verifier V_{in} with randomness complexity r_{in}, query complexity q_{in}, decision complexity d_{in}, proximity parameter δ_{in}, and soundness error $1 - \varepsilon_{\text{in}}$.*
- *$\delta_{\text{in}}(d_{\text{out}}(n)) \leq \rho_{\text{out}}(n)$ for every n.*

Then, L has a (standard) *PCP, denoted V_{comp}, with*

- *randomness complexity $r_{\text{out}}(n) + r_{\text{in}}(d_{\text{out}}(n))$,*
- *query complexity $q_{\text{in}}(d_{\text{out}}(n))$,*
- *decision complexity $d_{\text{in}}(d_{\text{out}}(n))$, and*
- *soundness error $1 - \varepsilon_{\text{out}}(n) \cdot \varepsilon_{\text{in}}(d_{\text{out}}(n))$.*

Furthermore, there exists a universal algorithm with black-box access to V_{out} and V_{in} that can perform the actions of V_{comp} (i.e., evaluating $(I, D) \leftarrow V_{\text{comp}}(x; R)$). On inputs of length n, this algorithm runs in time n^c for a universal constant c, with one call to V_{out} on an input of length n and one call to V_{in} on an input of length $d_{\text{out}}(n)$. In addition,

- *if* (instead of being a PCP) *the verifier V_{out} is a PCPP with proximity parameter $\delta_{\text{out}}(n)$, then V_{comp} is a PCPP with proximity parameter $\delta_{\text{out}}(n)$;*

- *if V_{in} has robust soundness with robustness parameter $\rho_{\text{in}}(n)$, then V_{comp} has robust soundness with robustness parameter $\rho_{\text{in}}(d_{\text{out}}(n))$.*

Proof. We will use the inner PCPP to verify that the oracle positions selected by the (robust) outer verifier are close to being accepted by the outer verifier's decision circuit. Thus, the new proof will consist of a proof for the outer verifier as well as proofs for the inner verifier, where each of the latter corresponds to a possible setting of the outer verifier's coin tosses (and is intended to prove that the bits that should have been read by the outer verifier satisfy its decision circuit). We will index the positions of the new (combined) oracle by pairs such that (out, i) denotes the ith position in the part of the oracle that represents the outer verifier's proof oracle, and (R, j) denotes the jth position in the Rth auxiliary block (which represents the Rth possible proof oracle (for the inner verifiers), which in turn is associated with the outer verifier's coins $R \in \{0,1\}^{r_{\text{out}}}$). For notational convenience, we drop the input length n from the notation below; all parameters of V_{out} are with respect to length n and all parameters of V_{in} are with respect to length $d_{\text{out}}(n)$. With these conventions, the following is the description of the composed verifier $V_{\text{comp}}(x)$:

1. Choose $R \overset{\text{R}}{\leftarrow} \{0,1\}^{r_{\text{out}}}$.
2. Run $V_{\text{out}}(x; R)$ to obtain $I_{\text{out}} = (i_1, \ldots, i_{q_{\text{out}}})$ and D_{out}.
3. Run $V_{\text{in}}(D_{\text{out}})$ (on random coin tosses) to obtain $I_{\text{in}} = ((b_1, j_1), \ldots, (b_{q_{\text{in}}}, j_{q_{\text{in}}}))$ and D_{in}.
   (Recall that V_{in}, as a PCPP verifier, expects two oracles, an input oracle and a proof oracle, and thus makes queries of the form (b, j), where $b \in \{0,1\}$ indicates which oracle it wishes to query.)
4. For each $\ell = 1, \ldots, q_{\text{in}}$, determine the queries of the composed verifier as follows:
   (a) If $b_\ell = 0$, set $k_\ell = (\text{out}, i_{j_\ell})$; that is, V_{in}'s queries to its input oracle are directed to the corresponding locations in V_{out}'s proof oracle. Recall that the jth bit in V_{in}'s input oracle is the jth bit in the input to D_{out}, which in turn is the i_jth bit in the proof oracle of V_{out}.
   (b) If $b_\ell = 1$, set $k_\ell = (R, j_\ell)$; that is, V_{in}'s queries to its Rth possible proof oracle are directed to the corresponding locations in the auxiliary proof. Recall that the jth bit in the proof oracle that V_{in} is using to verify the claim referring to the outer verifier's coins R is the jth bit in the Rth block of the auxiliary proof.
5. Output $I_{\text{comp}} = (k_1, \ldots, k_{q_{\text{in}}})$ and D_{in}.

The claims about V_{comp}'s randomness, query, decision, and computational complexities can be verified by inspection. Thus, we proceed to check completeness and soundness.

Suppose that $x \in L$. Then, by completeness of the outer verifier, there exists a proof π_{out} making V_{out} accept with probability 1. In other words, for every $R \in \{0,1\}^{r_{\text{out}}}$, if we set $(I_{\text{out}}, D_{\text{out}}) = V_{\text{out}}(x; R)$, we have $D_{\text{out}}(\pi_{\text{out}}|_{I_{\text{out}}}) = 1$. By completeness of the inner verifier, there exists a proof π_R such that $V_{\text{in}}(D_{\text{out}})$ accepts the oracle $\pi_{\text{out}}|_{I_{\text{out}}} \circ \pi_R$ with probability 1. If we set $\pi(t, \cdot) = \pi_t(\cdot)$ for all $t \in \{\text{out}\} \cup \{0,1\}^{r_{\text{out}}}$, then V_{comp} accepts π with probability 1.

Suppose that $x \notin L$, and let π be any oracle. Define oracles $\pi_t(\cdot) = \pi(t, \cdot)$. By the robust soundness (of V_{out}), with probability greater than ε_{out} over the choices of $R \in \{0,1\}^{r_{\text{out}}}$, if we set $(I_{\text{out}}, D_{\text{out}}) = V_{\text{out}}(x; R)$, then $\pi_{\text{out}}|_{I_{\text{out}}}$ is ρ_{out}-far from satisfying D_{out}. Fixing such an R, by the PCPP soundness of V_{in} (and $\delta_{\text{in}} \leq \rho_{\text{out}}$), it holds that $V_{\text{in}}(D_{\text{out}})$ rejects the oracle $\pi_{\text{out}}|_{I_{\text{out}}} \circ \pi_R$ (or, actually, any proof oracle

augmenting the input oracle $\pi_{\text{out}}|_{I_{\text{out}}}$) with probability greater than ε_{in}. Therefore, $V_{\text{comp}}(x)$ rejects oracle π with probability at least $\varepsilon_{\text{out}} \cdot \varepsilon_{\text{in}}$.

The additional items follow by similar arguments. If V_{out} is a PCPP verifier, then the input is of the form (x, y), where y is given via oracle access. In this case, throughout the proof above we should replace oracle π_{out} with oracle $y \circ \pi_{\text{out}}$, and for soundness we should consider the case that y is δ_{out}-far from $L(x)$. If V_{in} has robust soundness, then at the end of the soundness analysis, we note that not only is $\pi_{\text{out}}|_{I_{\text{out}}} \circ \pi_R$ rejected with probability greater than ε_{in} but it is also ρ_{in}-far from being accepted by V_{in} (and hence also by V_{comp}). □

The above theorem can serve as a substitute for the original composition theorem in the derivation of the original PCP theorem [ALM+98]. Specifically, one simply needs to modify the (precomposition) verifiers of [ALM+98] to both test proximity and have robust soundness. As we shall see in the next section, robust soundness can be obtained automatically from "parallelized PCPs" (as already constructed in [ALM+98]). In addition, the PCPs [ALM+98] can easily be made PCPPs by augmenting them with appropriate "proximity tests." Thus, all the technical work in Part II is not forced by the new notion of robust PCPPs, but rather is aimed at constructing PCPPs (and thus PCPs) which have *nearly linear length*.

2.5. Various observations and transformations. Most of this subsection refers to robust PCPs, but we start with an observation regarding PCPPs.

Queries versus proximity. Intuitively, the query complexity of a PCPP should depend on the proximity parameter δ. The following proposition confirms this intuition.

PROPOSITION 2.8 (queries versus proximity). *Suppose pair language L has a PCPP with proximity parameter δ, soundness error $1 - \varepsilon$, and query complexity q. Suppose further that there exists $(x, y) \in L$ such that $|x| = n$ and $|y| = m$, such that if we let $z \in \{0,1\}^m$ be a random string of relative Hamming distance $\delta' \triangleq \delta'(x)$ from y, we have*

$$\Pr_z[z \text{ is } \delta\text{-far from } L(x)] \geq \gamma \triangleq \gamma(x).$$

Then

$$q > \frac{\varepsilon \cdot \gamma}{\delta'}$$

In particular, if $L =$ CKTVAL, then $q \geq \varepsilon/(\delta + O(1/n))$.

The first part of Proposition 2.8 does not specify the relation of δ' to δ (although, surely, $\delta' > \delta$ must hold for any $\gamma > 0$ because $\Delta(z, L(x)) \leq \Delta(z, y) = \delta'$). The second part relies on the fact that, for CIRCUIT VALUE, one may set δ' as low as $\delta + O(1/n)$.

Proof. By completeness, there exists an oracle π such that the PCPP verifier $V(x)$ accepts oracle $y \circ \pi$ with probability 1. Consider $z = y \oplus \eta$, where $\eta \in \{0,1\}^m$ is a uniformly distributed string with relative Hamming weight δ'. If we invoke $V(x)$ with oracle $z \circ \pi$, then the probability (over the choice of η) that any of the positions read by V has been changed is at most $q \cdot \delta'$. Thus, $V(x)$ rejects oracle $(y \oplus \eta) \circ \pi$ with probability at most $q \cdot \delta'$.

On the other hand, by assumption z is δ-far from $L(x)$ with probability at least γ, in which case $V(x)$ should reject oracle $z \circ \pi$ with probability greater than ε by the PCPP soundness. Thus, $V(x)$ should reject with probability greater than $\gamma \cdot \varepsilon$ (over the choice of z and the coin tosses of V), and we conclude that $q \cdot \delta' > \gamma \cdot \varepsilon$, as desired.

For the application to CIRCUIT VALUE, let $C : \{0,1\}^m \to \{0,1\}$ be a circuit of size n that accepts only the all-zeroes string 0^m, for $m = \Omega(n)$. Then we have $(C, 0^m) \in \text{CKTVAL}$, but for every $\delta' > \delta$ and every string z of relative Hamming weight δ', we see that (C, z) is δ-far from satisfying C. Setting $\gamma = 1$ and δ' such that $\delta' m$ is the least integer greater than δm completes the proof. □

Expected robustness. Occasionally, we will be interested in a variant of robust soundness, which refers to distance on average rather than with high probability.

DEFINITION 2.9 (expected robustness). *For a function $\rho : \mathbb{Z}^+ \to [0,1]$, a PCP has* expected robustness ρ *if for every $x \notin L$, we have*

$$\forall \pi, \mathrm{E}_{(I,D) \overset{R}{\leftarrow} V(x)}[\Delta(\pi|_I, D^{-1}(1))] > \rho(|x|).$$

Expected robustness for PCPPs is defined analogously.

We now present several generic transformations regarding robustness and soundness. Although we state them only for PCPs, all of these results also hold for PCPPs, with no change in the proximity parameter. The following proposition relates robust soundness to expected robustness.

PROPOSITION 2.10 (robust soundness versus expected robustness). *If a PCP has robust-soundness error $1 - \varepsilon$ with robustness ρ, then it has expected robustness $\varepsilon \cdot \rho$. On the other hand, if a PCP has expected robustness ρ, then for every $\varepsilon \leq \rho$, it has robust-soundness error $1 - \varepsilon$ with robustness parameter $\rho - \varepsilon$.*

Expected robustness can easily be amplified to standard robustness *with low robust-soundness error*, using any averaging (i.e., oblivious) sampler (cf. [Gol97]). Combined with Proposition 2.10, we get a (soundness) error reduction for robust PCPs. For example, using the expander-neighborhood sampler of [GW97], we have the following.

LEMMA 2.11 (error reduction via expander neighborhoods). *If a language L has a PCP with expected robustness ρ, randomness complexity r, query complexity q, and decision complexity d, then for every two functions $s, \gamma : \mathbb{Z}^+ \to [0,1]$ then L has a PCP with*

- *robust-soundness error s with robustness parameter $\rho - \gamma$,*
- *randomness complexity $r + O(\log(1/s) + \log(1/\gamma))$,*
- *query complexity $O(1/(s\gamma^2)) \cdot q$, and*
- *decision complexity $O(1/(s\gamma^2)) \cdot d$.*

An alternative error-reduction procedure that will also be used is given by pairwise independent samples as follows.

LEMMA 2.12 (error reduction via pairwise independence). *If a language L has a PCP with expected robustness ρ, randomness complexity r, query complexity q, and decision complexity d such that $\rho \cdot 2^r \geq 2$, then L has a PCP with*

- *robust-soundness error $1/2$ with robustness parameter $\rho/2$,*
- *randomness complexity $2r$,*
- *query complexity $2q/\rho$, and*
- *decision complexity $2d/\rho$.*

Non-Boolean PCPs. The next few transformations involve non-Boolean PCPs, that is, PCPs in which the oracle returns symbols over some larger alphabet $\Sigma = \{0,1\}^a$ rather than bits; we refer to $a = a(n)$ as the *answer length* of the PCP. (Often, non-Boolean PCPs are discussed in the language of multiprover interactive proofs, but it is simpler for us to work with the PCP formulation.)

Robust soundness of a non-Boolean PCP is defined in the natural way, using Hamming distance over the alphabet Σ. (In the case of a robust non-Boolean PCPP,

we still treat the input oracle as binary.)

The first transformation provides a way of converting non-Boolean PCPs to Boolean PCPs in a way that preserves robust soundness.

LEMMA 2.13 (alphabet reduction). *If a language L has a non-Boolean PCP with answer length a, query complexity q, randomness complexity r, decision complexity d, and robust-soundness error s with robustness parameter ρ, then L has a Boolean PCP with query complexity $O(a \cdot q)$, randomness complexity r, decision complexity $d + O(a \cdot q)$, and robust soundness error s with robustness parameter $\Omega(\rho)$. If, instead of robust-soundness, the non-Boolean PCP has expected robustness ρ, then the Boolean PCP has expected robustness $\Omega(\rho)$.*

The proof uses a good error-correcting code (i.e., constant relative distance and rate). Furthermore, to obtain decision complexity $d + O(a \cdot q)$ we should use a code having linear-sized circuits for encoding (cf. [Spi96]). Using more classical codes would only give decision complexity $d + \widetilde{O}(a \cdot q)$, which is actually sufficient for our purposes.

Proof. This transformation is analogous to converting non-Boolean error-correcting codes to Boolean ones via "code concatenation." Let V be the given non-Boolean PCP verifier, with answer length a. Let $\mathrm{ECC} : \{0,1\}^a \to \{0,1\}^b$ for $b = O(a)$ a binary error-correcting code of constant relative minimum distance, which can be computed by an explicit circuit of size $O(a)$. We will augment the original oracle π having a-bit entries with an additional oracle τ having b-bit entries, where τ_i is supposed to be $\mathrm{ECC}(\pi_i)$. (We note that including the original oracle simplifies the argument as well as frees us from assuming a noiseless decoding algorithm.)

Our new verifier V'(x), on oracle access to $\pi \circ \tau$, will simulate $V(x)$, and for each query i made by V, will query the a bits in π_i and the b bits in τ_i, for a total of $q \cdot (a + b)$ binary queries. That is, if V queries positions $I = (i_1, \ldots, i_q)$, V' will query positions $I' = ((0, i_1), \ldots, (0, i_q), (1, i_1), \ldots, (1, i_q))$. If V outputs a decision circuit $D : (\{0,1\}^a)^q \to \{0,1\}$, V' will output the circuit $D' : (\{0,1\}^a)^q \times (\{0,1\}^b)^q \to \{0,1\}$ defined by

$$D'(x_1, \ldots, x_q, y_1, \ldots, y_q) = D(x_1, \ldots, x_q) \wedge C(x_1, \ldots, x_q, y_1, \ldots, y_q),$$

where

$$C(x_1, \ldots, x_q, y_1, \ldots, y_q) = \bigwedge_{i=1}^{q} (y_i = \mathrm{ECC}(x_i)).$$

Since ECC can be evaluated by a circuit of size $O(a)$, we see that $|D'| = |D| + O(a \cdot q)$, as desired.

For completeness of V', we note that any accepting oracle π for V can be augmented to be an accepting oracle for V' by setting $\tau_i = \mathrm{ECC}(\pi_i)$ for all i. For soundness of V', suppose $x \notin L$ and let (π, τ) be any pair of oracles. Define a "decoded" oracle $\hat{\pi}$ by setting $\hat{\pi}_i$ to be the string $x \in \{0,1\}^a$ which minimizes the distance between $\mathrm{ECC}(x)$ and τ_i. We will relate the robustness of V on oracle $\hat{\pi}$ to the robustness of V' on oracles π and τ. Specifically, let $\beta > 0$ be a constant such that the (absolute) minimum distance of ECC is greater than $2\beta \cdot (a + b)$. Then we will show that for every sequence R of coin tosses and for every $\alpha > 0$, if the bits read by $V'(x; R)$ from $\pi \circ \tau$ are $\alpha\beta$-close to being accepted, then the bits read by V from $\hat{\pi}$ are α-close to being accepted. Thus, both robustness parameters (standard and expected) decrease by at most a factor of β.

Consider any sequence R of coin tosses, let $(I, D) = V(x; R)$, and write $I = (i_1, \ldots, i_q)$. Suppose that $(\pi_{i_1}, \ldots, \pi_{i_q}, \tau_{i_1}, \ldots, \tau_{i_q})$ is $\alpha\beta$-close to some $(\pi'_{i_1}, \ldots, \pi'_{i_q},$

$\tau'_{i_1}, \ldots, \tau'_{i_q}$) that satisfies $D' = D \wedge C$. Then, for at least a $1 - \alpha$ fraction of $j \in [q]$, the pair (π_{i_j}, τ_{i_j}) is β-close to $(\pi'_{i_j}, \tau'_{i_j}) = (\pi'_{i_j}, \mathrm{ECC}(\pi'_{i_j}))$. For such j, the choice of β implies that $\mathrm{ECC}(\pi'_{i_j})$ is the closest codeword to τ_{i_j} and hence $\hat{\pi}_{i_j} = \pi'_{i_j}$. Since the π''s satisfy D, we conclude that the $\hat{\pi}$'s are α-close to satisfying D, as desired. ∎

The usual "parallelization" paradigm of PCPs [LS97, ALM+98] converts a Boolean PCP with many queries into a non-Boolean PCP with a constant number of queries, where this is typically the first step in PCP composition. As mentioned in the introduction, we cannot afford parallelization, and robust soundness will be our substitute. Nevertheless, there is a close (but not close enough for us) connection between parallelized PCPs and PCPs with robust soundness as follows.

PROPOSITION 2.14 (parallelization versus robustness).

1. *If a language L has a non-Boolean PCP with answer length a, query complexity q, randomness complexity r, decision complexity d, and soundness error s, then L has a* (Boolean) *PCP with query complexity $O(a \cdot q)$, randomness complexity r, decision complexity $d + O(a \cdot q)$, and robust-soundness error s with robustness parameter $\rho = \Omega(1/q)$.*

2. *If a language L has a* (Boolean) *PCP with query complexity q, randomness complexity r, decision complexity d, and expected robustness ρ, then L has a 2-query non-Boolean PCP with answer length q, randomness complexity $r + \log q$, decision complexity $d + O(1)$, and soundness error $1 - \rho$.*

Thus, for constant soundness and constant robustness parameters, q-query robust (Boolean) PCPs are essentially equivalent to constant query non-Boolean PCPs with answer length $\Theta(q)$. However, note that in passing from robust soundness to a 2-query non-Boolean PCP, the randomness complexity increases by $\log q$. It is precisely this cost that we cannot afford, and hence we work with robust soundness in the rest of the paper.

Proof. For item 1, note that any non-Boolean PCP with query complexity q and soundness error s has robust-soundness error s for any robustness parameter $\rho < 1/q$. Thus, the claim follows from Lemma 2.13.

Turning to item 2, let V be a robust PCP verifier for L with the stated parameters. We use the usual query-reduction technique for PCPs [FRS94] and observe that when applied to a robust PCP, the detection probability (i.e., one minus the soundness error) does not deteriorate by a factor of q as usual. Instead, the detection probability of the resulting 2-query (non-Boolean) PCP equals the expected robustness of V.[9] Specifically, the 2-query non-Boolean PCP verifier V' is defined as follows:

- V' expects two oracles: one Boolean oracle π corresponding to the oracle for V, and a second oracle τ with answer length q, indexed by random strings of V.
- On input x, the verifier V' selects a random string R for V and $j \stackrel{R}{\leftarrow} [q]$ and computes $(I, D) = V(x; R)$, where $I = (i_1, \ldots, i_q)$. It sets $I' = (R, i_j)$ (which means the queries for the values τ_R and π_{i_j}) and $D'(a, b) = [(D(a) = 1) \wedge (a_j = b)]$; that is, it accepts if and only if $[D(\tau_R) = 1] \wedge [(\tau_R)_j = \pi_{i_j}]$.

[9] It may be more instructive (but more cumbersome) to discuss what is happening in terms of ordinary robustness. Suppose that V has robust-soundness error $s = 1 - d$ with respect to robustness ρ. The standard analysis ignores the robustness and asserts that the 2-query (non-Boolean) PCP has soundness error $s' = 1 - d'$, where $d' = d/q$. This crude analysis implicitly assumes the trivial bound (i.e., $1/q$) of the robustness parameter. A more refined analysis takes advantage of the actual bound of the robustness parameter and asserts that the 2-query (non-Boolean) PCP has soundness error $s' = 1 - \rho \cdot d$.

It can be verified that the probability that V' rejects a false assertion is precisely the expected robustness of V. In particular, suppose that $V'(x)$ accepts the oracle pair (π, τ) with probability p. We may assume, without loss of generality, that $D(\tau_R) = 1$ for any R, where $(\cdot, D) = V(x; R)$. Then, it follows that the expected (relative) distance of $\pi|_I$ from τ_R, where $(I, D) = V(x; R)$ for a random R, equals $1-p$ (because $1-p = \Pr_{R,j}[(\tau_R)_j \neq \pi_{i_j}]$, which in turn equals $\mathrm{E}_R[\Delta(\tau_R, \pi|_I)]$). This means that on the average, π is $(1-p)$-close to assignments that satisfy the corresponding decision circuits. Thus, if $x \notin L$, then $1 - p > \rho$, and $p < 1 - \rho$ follows. ∎

Robustness versus proximity. Finally, for PCPPs, we prove that the robustness parameter is upper-bounded by the proximity parameter.

PROPOSITION 2.15 (robustness versus proximity). *Suppose a pair language L has a PCPP with proximity parameter δ and expected robustness ρ. Suppose further that there exists $(x, y) \in L$ such that $|x| = n$ and $|y| = m$, such that if we let $z \in \{0,1\}^m$ be a random string at relative Hamming distance $\delta' \triangleq \delta'(x)$ from y, we have*

$$\Pr_z[z \text{ is } \delta\text{-far to } L(x)] \geq \gamma \triangleq \gamma(x).$$

Then

$$\rho \leq \delta'/\gamma.$$

In particular, if $L = \textsc{CktVal}$, then $\rho \leq \delta + O(1/n)$.

Proof. The proof is similar to that of Proposition 2.8. By completeness, there exists an oracle π such that the PCPP verifier $V(x)$ accepts oracle $y \circ \pi$ with probability 1. If we run $V(x)$ with oracle $z \circ \pi$ instead, then bits read by V have expected distance at most δ' from being accepted, where the expectation is taken over the choices of z (even when fixing the coins of V).

On the other hand, z is δ-far from $L(x)$ with probability at least γ, and for any such fixed z the bits read by V from $z \circ \pi$ should have expected distance greater than ρ from being accepted (over the coin tosses of V). Thus, the expected distance of $z \circ \pi$ from being accepted is greater than $\gamma \cdot \rho$, where here the expectation is taken over the choice of z and the coin tosses of V. We conclude that $\delta' > \gamma \cdot \rho$, as desired.

Recall that in the proof of Proposition 2.8, we have demonstrated the existence of a pair (C, w) such that for any string z at distance $\delta' = \delta + O(1/n)$ from w it holds that w is δ-far from satisfying C. Setting $\gamma = 1$, the second part follows. ∎

3. Very short PCPs with very few queries. In this section we prove the main results of this work; that is, we establish Theorems 1.2 and 1.3. Our starting point is the following robust PCPP, which is constructed in Part II, sections 5–8.

THEOREM 3.1 (main construct). *There exists a universal constant c such for all $n, m \in \mathbb{Z}^+$, $0 < \delta, \gamma < 1/2$ satisfying $n^{1/m} \geq m^{cm}/(\gamma\delta)^3$ and $\delta \leq \gamma/c$, $\textsc{CktVal}$ has a robust PCPP (for circuits of size n) with the following parameters:*

- *randomness $\left(1 - \frac{1}{m}\right)\log n + O(m \log m) + O(\log\log n) + O(\log(1/\delta))$;*
- *decision complexity $n^{1/m} \cdot \mathrm{poly}(\log n, 1/\delta)$; which also upper-bounds the query complexity;*[10]
- *perfect completeness; and*
- *for proximity parameter δ, a verifier having robust-soundness error γ with robustness parameter $(1-\gamma)\delta$.*

[10] In fact, we will upper-bound the query complexity by $q = n^{1/m} \cdot \mathrm{poly}(\log n, 1/\delta)$ and show that the verifier's decision can be implemented by a circuit of size $\widetilde{O}(q)$, which can also be bounded by $n^{1/m} \cdot \mathrm{poly}(\log n, 1/\delta)$ with a slightly larger unspecified polynomial.

We comment that the condition $\delta < \gamma/c$ merely means that we present robust PCPPs only for the more difficult cases (when δ is small), and our robustness parameter does not improve for larger values of δ. We call the reader's attention to the typically small values of the query and randomness complexities, which yield a proof length that is upper-bounded by $\text{poly}(m^m \log n) \cdot n$ (for δ and γ as small as $1/\text{poly}(m^m, \log n)$), as well as to the small values of the soundness error and the small deterioration of robustness with respect to proximity.

Note that the main construct (of Theorem 3.1) works only when n, the size of the input circuit, is not too small (more precisely, when $n^{1/m} \geq m^{cm}/\delta^3$). While constructing our short PCPs (via proof composition), we need robust PCPPs that work for even smaller values of n. For this purpose, we also construct the following robust PCPP (of Theorem 3.2) that has parameters similar to a PCP constructed in [ALM+98]. In comparison to the main construct (of Theorem 3.1), this PCPP is not as efficient in randomness (i.e., it has randomness complexity $O(\log n)$ rather than $(1 - o(1)) \log_2 n$). However, since we plan to use the latter (robust) PCPP only towards the final stages of composition, we can afford to pay this cost in randomness. Theorem 3.2 will be proved in the second part of this work by modifying the proof of Theorem 3.1. An alternate construction of this robust PCPP can be obtained by adding a suitable proximity test to the "parallelized PCPs" of [ALM+98].

THEOREM 3.2 (ALMSS-type robust PCPP). *For all $n \in \mathbb{Z}^+$ and $\delta \in (0, 1)$,* CKTVAL *has a robust PCPP (for circuits of size n) with the following parameters:*

- *randomness $O(\log n)$;*
- *decision complexity* $\text{poly} \log n$*, which also upper-bounds the query complexity;*
- *perfect completeness; and*
- *for proximity parameter δ, a verifier having robust-soundness error $1 - \Omega(\delta)$ with robustness parameter $\Omega(1)$.*

Theorems 3.1 and 3.2 differ also in their robustness parameters. Theorem 3.2 provides a better bound on the robustness parameter (i.e., $\Omega(1)$ rather than $(1 - \gamma)\delta$ provided by Theorem 3.1), while guaranteeing only a much weaker robust-soundness error (i.e., $1 - \Omega(\delta)$ rather than γ), where $\gamma > \delta > 0$ is typically small. It is instructive to compare the expected robustness provided by the two results: The expected robustness in Theorem 3.1 is at least $(1-\gamma)^2\delta$, while that in Theorem 3.2 is $\Omega(\delta) \cdot \Omega(1) = \Omega(\delta)$. Thus, for $\gamma \ll 1$, the expected robustness in Theorem 3.1 can be very close to the proximity parameter δ (which is close to optimal; see Proposition 2.15), whereas in Theorem 3.2 the expected robustness is always a constant factor smaller than the proximity parameter. Hence, the robust PCPP of Theorem 3.1 is suitable for a large number of proof composition operations, whereas the one in Theorem 3.2 is useful when the query complexity of the outer verifier is already very small (and Theorem 3.1 can no longer be applied). Indeed, this is exactly how these two theorems are used in the construction of our short PCPs. Using Theorems 3.1 and 3.2, we derive a general trade-off between the length of PCPs and their query complexity as follows.

THEOREM 3.3 (randomness versus query complexity trade-off for PCPPs). *For every parameter $n, t \in \mathbb{N}$ such that $3 \leq t \leq \frac{2 \log \log n}{\log \log \log n}$ there exists a PCPP for* CKTVAL *(for circuits of size n) with the following parameters:*

- *randomness complexity* $\log_2 n + A_t(n)$*, where*

$$A_t(n) \triangleq O(t + (\log n)^{1/t}) \log \log n + O((\log n)^{2/t}); \tag{3.1}$$

- *query complexity $O(1)$;*
- *perfect completeness; and*

- *soundness error* $1-\Omega(1/t)$ *with respect to proximity parameter* $\Theta(1/t)$.

Alternatively, we can have query complexity $O(t)$ *and soundness error* $1/2$ *maintaining all other parameters.*

For $t \in [3, \ldots, \frac{0.99 \log\log n}{\log\log\log n}]$, we have $(\log n)^{1/t} > (\log\log n)^{1/0.99}$, and thus $A_t(n) = O((\log n)^{2/t})$. On the other hand, for $t \geq \frac{1.01 \log\log n}{\log\log\log n}$, we have $(\log n)^{1/t} \leq (\log\log n)^{1/1.01}$, and thus $A_t(n) = O\big(\frac{(\log\log n)^2}{\log\log\log n}\big) = o(\log\log n)^2$.

Theorem 3.3 actually asserts a PCPP (for CktVal), but a PCP for CktSAT and a PCPP for Nondeterministic Circuit Value (of the same complexity) follow; see Propositions 2.4 and 2.5. Theorems 1.2 and 1.3 follow by suitable settings of the parameter t. Further details as well as a corollary appear in section 3.2.

3.1. Proof of Theorem 3.3. Theorem 3.3 is proved by using the robust PCPP described in Theorem 3.1. Specifically, this robust PCPP is composed with itself several times (using the composition theorem from section 2). Each such composition drastically reduces the query complexity of the resulting PCP, while only increasing very moderately its randomness complexity. The deterioration of the soundness error and the robustness is also very moderate. After composing the robust PCPP with itself $O(t(n))$ times, we compose the resulting robust PCP with the ALMSS-type robust PCPP thrice to reduce the query complexity to $\operatorname{poly}\log\log\log n$. Finally, we compose this resultant robust PCPP with a PCPP parameter roughly $\Omega(1/t)$ that has query complexity $O(1)$ and exponential length. The latter PCPP can be obtained by a suitable modification of the Hadamard-based PCP of [ALM+98], as shown in Appendix A. We now turn to the actual proof.

Proof. We construct the PCPP of Theorem 3.3 by composing the robust PCPP described in Theorem 3.1 with itself several times. Each such composition reduces the query complexity from n to approximately $n^{1/m}$. Ideally, we would like to do the following: Set $m = (\log n)^{1/t}$ and compose the robust PCPP of Theorem 3.1 with parameter m with itself $t-1$ times. This would result in a robust PCPP of query complexity roughly $n^{1/m^t} = n^{1/\log n} = O(1)$, giving us the desired result. However, we cannot continue this repeated composition for all the $t-1$ steps, as the requirements of Theorem 3.1 (namely, $n^{1/m} \geq m^{cm}/(\delta\gamma)^3$) are violated in the last two steps of the repeated composition. So we instead do the following: In the first stage, we compose the (new and) highly efficient verifier from Theorem 3.1 with itself $t-3$ times. This yields a verifier with query complexity roughly $n^{1/m^{t-2}} = (n^{1/m^t})^{m^2} = 2^{m^2} = \exp(\log^{2/t} n) \ll n$, while the soundness error is bounded away from 1 and robustness is $\Omega(1/t)$. In the second stage, we compose the resultant robust PCPP a constant number of times with the ALMSS-type robust PCPP described in Theorem 3.2 to reduce the query complexity to $\operatorname{poly}\log\log\log n$ (and keeping the other parameters essentially the same). The ALMSS-type PCPP is (relatively) poor in terms of randomness; however, the input size to the ALMSS-type PCPP is too small to affect the randomness of the resultant PCPP. Finally, we compose with the Hadamard-based verifier of Theorem A.1 to bring the query complexity down to $O(1)$. In all stages, we invoke the composition theorem (Theorem 2.7).

Throughout the proof, n denotes the size of the circuit that is given as the explicit input to the PCPP verifier that we construct. We shall actually construct a sequence of such verifiers. Each verifier in the sequence will be obtained by composing the prior verifier (used as the outer verifier in the composition) with an adequate inner verifier. In the first stage, the inner verifier will be the verifier obtained from Theorem 3.1, whereas in the second and third stages it will be the one obtained from Theorem 3.2

and Theorem A.1, respectively. Either way, the inner verifier will operate on circuits of much smaller size (than n) and will use a proximity parameter that is upper-bounded by the robustness parameter of the corresponding outer verifier.

Stage I. Let $m = (\log n)^{\frac{1}{t}} \geq 2$ and $\gamma = \frac{1}{t}$. For this choice of m and γ, let V_0 be the verifier obtained from Theorem 3.1. We recall the parameters of this verifier: For circuits of size ℓ and any proximity parameter $\delta_0 \in (\gamma/3c, \gamma/c)$, its randomness complexity is $r_0(\ell) \triangleq (1-\frac{1}{m}) \cdot \log_2 \ell + O(\log\log\ell) + O(m \log m) + O(\log t)$, its decision (and query) complexity is $d_0(\ell) \triangleq \ell^{\frac{1}{m}} \cdot \mathrm{poly}(\log \ell, t)$, its soundness error is $s_0 \triangleq \gamma$, and its robustness is $\rho_0 \geq (1-\gamma)\delta_0$.

We compose V_0 with itself $t-3$ times for the same fixed choice of m and γ to obtain a sequence of verifiers of increasingly smaller query complexity.[11] While doing so, we will use the largest possible proximity parameter for the inner verifier (V_0) in each step; that is, in the ith composition, we set the proximity parameter of the inner verifier to equal the robustness of the outer verifier, where the latter is the result of $i-1$ compositions of V_0 with itself. We get a sequence of verifiers $V_1, \ldots, V_{t-2}$ such that $V_1 = V_0$ and the verifier V_i is obtained by composing (the outer verifier) V_{i-1} with (the inner verifier) V_0, where the proximity parameter of the latter is set to equal the robustness of the former. Unlike V_0, which is invoked on different circuit sizes and (slightly) different values of the proximity parameter, all the V_i's ($i \in [t-2]$) refer to circuit size n and proximity parameter $\delta \triangleq \gamma/c < 1/t$.

Let r_i, d_i, δ_i, s_i, and ρ_i denote the randomness complexity, decision (and query) complexity, proximity parameter, soundness error, and the robustness parameter of the verifier V_i. (Recall that V_i will be composed with the inner verifier V_0, where in this composition the input size and proximity parameter of the latter will be set to d_i and ρ_i, respectively, and so we will need to verify that $d_i^{1/m} \geq m^{cm}/(\gamma\rho_i)^3$ and $\rho_i < \gamma/c$ for $i < t-2$).[12] We first claim that the decision complexity, proximity, soundness-error, robustness, and proof length parameters satisfy the following conditions:

(1) Decision complexity: $d_i(n) \leq a(n,m)^2 \cdot n^{1/m^i}$, where $a(\ell, m) \triangleq d_0(\ell)/\ell^{1/m} = \mathrm{poly}(\log \ell, t)$. On the other hand, $d_i(n) \geq n^{1/m^i}$.
(2) Proximity: $\delta_i = \delta$.
(3) Soundness error: $s_i \leq 1 - (1-\gamma)^i$. (In particular, $s_i < i\gamma$.)
(4) Robustness: $\rho_i \geq (1-\gamma)^i \cdot \delta$. On the other hand, $\rho_i \leq \rho_0 < \gamma/c$.
(5) Proof length: $2^{r_i(n)} d_i(n) \leq b(n,m)^i \cdot n$, where $b(\ell, m) \triangleq 2^{r_0(\ell)} \cdot d_0(\ell)/\ell = \mathrm{poly}(m^m, \log \ell, t)$.

We prove this claim by induction on i. For starters, note that the base case (i.e., $i = 1$) follows from the properties of V_0; in particular, $d_1(n) \leq \mathrm{poly}(\log n, t) \cdot n^{1/m}$ and $2^{r_1(n)} d_1(n) \leq \mathrm{poly}(m^m, \log n, t) \cdot n$. Turning to the induction step, assuming that

[11] We assume, for simplicity, that $t \geq 3$. Note that it suffices to establish the claimed result for t greater than any universal constant.

[12] We also need to verify that $n^{1/m} \geq m^{cm}/(\gamma\delta_0)^3$ and $\delta_0 < \gamma/c$ for the initial verifier $V_1 = V_0$, but this is true for our choice of parameters. Furthermore, as ρ_i can only deteriorate with each composition, we have that $\delta_0 = \rho_i \leq \rho_0 \leq \gamma/c$. Thus, the only condition that needs to be verified is $d_i^{1/m} \geq m^{cm}/(\gamma\rho_i)^3$ for $i < t-2$.

these claims holds for V_i, we prove that they hold also for V_{i+1}. For (1), note that

$$\begin{aligned}
d_{i+1}(n) &= d_0(d_i(n)) && \text{[by the composition theorem]}\\
&= a(d_i(n), m) \cdot d_i(n)^{1/m} && \text{[by definition of } a(\cdot,\cdot)\text{]}\\
&\le a(n, m) \cdot d_i(n)^{1/m} && \text{[by monotonicity of } a(\cdot,\cdot) \text{ and } d_i(n) \le n\text{]}\\
&\le a(n, m) \cdot \left(a(n, m)^2 \cdot n^{1/m^i}\right)^{1/m} && \text{[by induction]}\\
&\le a(n, m)^2 \cdot n^{1/m^{i+1}} && \text{[using } m \ge 2\text{]}
\end{aligned}$$

and $d_{i+1}(n) \ge d_i(n)^{1/m} \ge n^{1/m^{i+1}}$ also holds. Clearly $\delta_i = \delta$ and the bound on s_i is straightforward from the composition theorem. Recalling that the proximity parameter for V_0 in this composition is set to ρ_i, we see that the robustness of the composed verifier V_{i+1} is $\rho_{i+1} = (1-\gamma)\rho_i = (1-\gamma)^{i+1}\delta$ as desired. Furthermore, $\rho_i = (1-\gamma)^i\delta \ge (1-\frac{1}{t})^t\delta \ge e^{-1}\delta = \gamma/O(1)$. We now move to the last condition (essentially bounding the randomness). Notice first that $r_{i+1}(n) = r_i(n) + r_0(d_i(n))$, and thus

$$\begin{aligned}
2^{r_{i+1}(n)} \cdot d_{i+1}(n) &= 2^{r_i(n)} \cdot 2^{r_0(d_i(n))} \cdot d_0(d_i(n)) && \text{[by the composition theorem]}\\
&= 2^{r_i(n)} \cdot d_i(n) \cdot b(d_i(n), m) && \text{[by definition of } b(\cdot,\cdot)\text{]}\\
&\le b(n, m)^i \cdot n \cdot b(n, m) && \text{[by induction and monotonicity of } b(\cdot,\cdot)\text{]}\\
&= n \cdot b(n, m)^{i+1}.
\end{aligned}$$

Thus, Part (5) is verified. Recall that we have to verify that $d_i^{1/m} \ge m^{cm}/(\gamma\rho_i)^3$ for $i < t-2$ as promised. We have $d_i^{1/m} \ge (n^{1/m^i})^{1/m} = n^{1/m^{i+1}} \ge n^{1/m^{t-2}}$ (since $i < t-2$). Since $m = (\log n)^{1/t}$, we have $n^{1/m^t} = 2$. Hence, $d_i^{1/m} \ge (n^{1/m^t})^{m^2} = 2^{m^2}$. On the other hand, $m^{cm}/(\gamma\rho_i)^3 \le m^{cm}/(e^{-1}\gamma\delta)^3 = m^{cm} \cdot \mathrm{poly}(t)$ because $\delta = \gamma/c$ and $\gamma = 1/t$. Thus it suffices to verify that $2^{m^2}/m^{cm} \ge \mathrm{poly}(t)$ for $2 \le t \le 2\log\log n/\log\log\log n$, which is straightforward.[13]

Lastly, we consider the running time of V_i, denoted T_i, which ought to be polynomial. A careful use of the composition theorem (Theorem 2.7) indicates that $T_i(n) = \mathrm{poly}(n) + T_{i-1}(n)$ for every $i = 2, \ldots, t-2$, where $T_1(n) = \mathrm{poly}(n)$ (since $V_1 = V_0$). Alternatively, unraveling the inductive composition, we note that V_i consists of invoking V_0 i times, where in the first invocation V_0 is invoked on V_i's input and in later invocations V_0 is invoked on an input obtained from the previous invocation. Furthermore, the output of V_i is obtained by combining the inputs obtained in these $i \le t-2 < n$ invocations.

We now conclude the first stage by showing that the final verifier $V_c = V_{t-2}$ has the desired properties. By Part (5) above (and the fact that $d_{t-2} \ge 1$), we have $r_c(n) = r_{t-2}(n) \le \log n + (t-2)\cdot\log b(n,m) \le \log n + t\log b(n,m)$. By the definition of $b(n,m)$, we have $\log b(n,m) = O(\log\log n) + O(m\log m) + O(\log t) = O(\log\log n + m\log m)$, whereas $m\log m = (\log n)^{\frac{1}{t}} \cdot \frac{1}{t}\log\log n$. Thus $r_c(n) \le \log_2 n + O(t\cdot\log\log n) + t\cdot O(m\log m) = \log_2 n + O(t + (\log n)^{\frac{1}{t}})\cdot\log\log n$. The decision complexity of V_c is $d_c(n) = d_{t-2}(n) \le a(n,m)^2 \cdot n^{1/m^{t-2}} = a(n,m)^2 \cdot 2^{m^2}$, because $n^{1/m^t} = 2$. Using

[13] Note that as t varies from 2 to $2\log\log n/\log\log\log n$, the value of m varies from $\sqrt{\log n}$ to $\sqrt{\log\log n}$. For $t \in [2, 2\log\log n/\log\log\log n]$, the maximum value of $\mathrm{poly}(t)$ is $\mathrm{poly}(\log\log n/\log\log\log n) = \mathrm{poly}(\log\log n)$. On the other hand, for $m \in [\sqrt{\log\log n}, \sqrt{\log n}]$, the minimum value of $2^{m^2}/m^{cm} > 2^{m^2/2}$ is $2^{\sqrt{\log\log n}^2/2} = \sqrt{\log n} \gg \mathrm{poly}(\log\log n)$.

$a(n,m) = \text{poly}(\log n, t)$, it follows that $d_c(n) \leq 2^{m^2} \cdot \text{poly}(\log n)$. The proximity of V_c equals δ, its soundness error is $s_c = s_{t-2} = 1-(1-\gamma)^{t-2} = 1-(1-1/t)^{t-2} < 1-\Omega(1)$, and its robustness is $\rho_c = \rho_{t-2} \geq (1-\gamma)^{t-2}\delta = \delta/e = \Omega(1/t)$.

Stage II. We now compose the verifier V_c with the ALMSS-type verifier V_a described in Theorem 3.2 thrice to obtain the verifiers V', V'', and V''', respectively; that is, V' equals V_c composed with V_a, whereas V'' equals V' composed with V_a, and V''' equals V'' composed with V_a. We apply composition as before, setting the proximity parameter of the inner verifier to equal the robustness parameter of the outer verifier. Recall from Theorem 3.2 that the ALMSS-type verifier V_a has the following parameters: randomness $r_a(\ell,\delta_a) = O(\log \ell)$, decision complexity $d_a(\ell,\delta_a) = \text{poly}\log \ell$, soundness error $s_a(\ell,\delta_a) = 1-\Omega(\delta_a)$, and robustness $\rho_a(\ell,\delta_a) = \Omega(1)$ for input size ℓ and proximity parameter δ_a. Recall that when composing V_c with V_a we set $\delta_a = \rho_c = \Omega(1/t)$, whereas when composing V' (resp., V'') with V_a we set $\delta_a = \rho' = \Omega(1)$ (resp., $\delta_a = \rho'' = \Omega(1)$). Each composition with the inner verifier V_a adds $O(\log d)$ to the randomness, while reducing the query complexity to $\text{poly}\log d$, where d is the decision complexity of the outer verifier. Furthermore, when composing any of these outer verifiers (i.e., either V_c, V', or V'') with V_a, the resulting verifier has robustness parameter $\Omega(1)$ while its robust-soundness error is $1-\Omega((1-s)\rho)$, where ρ and s are the robustness parameter and soundness error of the outer verifier. Hence, the parameters of the verifiers V', V'', and V''' are as follows:

Parameters of V' (recall that $d_c = 2^{m^2} \cdot \text{poly}(\log n)$ and $\rho_c = \Omega(\delta)$):
$r' = r_c + O(\log d_c(n)) = r_c + O(m^2 + \log\log n)$,
$d' = \text{poly}(\log d_c(n)) = \text{poly}(m, \log\log n)$,
$s' = 1-\Omega((1-s_c)\rho_c) = 1-\Omega(\delta)$,
and $\rho' = \Omega(1)$.

Parameters of V'':
$r'' = r' + O(\log d') = r' + O(\log m + \log\log\log n)$,
$d'' = \text{poly}(\log d') = \text{poly}(\log m, \log\log\log n)$,
$s'' = 1-\Omega((1-s')\rho') = 1-\Omega(\delta)$,
and $\rho'' = \Omega(1)$.

Parameters of V''':
$r''' = r'' + O(\log d'') = r'' + O(\log\log m + \log\log\log\log n)$,
$d''' = \text{poly}(\log d'') = \text{poly}(\log\log m, \log\log\log\log n)$,
$s''' = 1-\Omega((1-s'')\rho'') = 1-\Omega(\delta)$,
and $\rho''' = \Omega(1)$.

Recall that the proximity parameter for all three verifiers equals that of V_c (i.e., δ). We have that

$$\begin{aligned} r''' &= r_c + O(m^2 + \log\log n) \\ &= \log_2 n + O(t + (\log n)^{1/t}) \cdot \log\log n + O(m^2), \\ q''' < d''' &= \text{poly}(\log\log\log\log n, \log\log m), \end{aligned}$$

whereas $s''' = 1-\Omega(\delta)$ and $\rho''' = \Omega(1)$. Substituting $m = (\log n)^{1/t}$, we get $r''' = \log_2 n + O(t + (\log n)^{1/t}) \cdot \log\log n + O((\log n)^{2/t})$ and $q''' = \text{poly}(\log\log\log n)$.

Stage III. Finally, we compose V''' with the Hadamard-based inner verifier V_h of Theorem A.1 to obtain our final verifier V_f. The query complexity of V_h, and hence that of V_f, is constant. The randomness complexity of V_f is $r_f(n) \triangleq r'''(n) + r_h(q'''(n)) = r'''(n) + \text{poly}(\log\log\log n)$, because $r_h(\ell) = O(\ell^2)$. Thus, $r_f(n) = \log_2 n + O(t + (\log n)^{1/t}) \cdot \log\log n + O((\log n)^{2/t})$. On proximity parameter δ_h, the soundness error of V_h is $s_h = 1-\Omega(\delta_h)$. Setting $\delta_h = \rho''' = \Omega(1)$, we conclude that

the soundness error of V_f on proximity parameter δ is $1 - \Omega(\delta) = 1 - \Omega(1/t)$, since the soundness error of V''' is $1 - \Omega(\delta)$.

To obtain soundness error $1/2$, we perform $O(t)$ repetitions of V_f, yielding a query complexity of $O(t)$. This can be done without increasing the randomness complexity by using "recycled randomness" (specifically, the neighbors of a uniformly selected vertex in a Ramanujan expander graph; see [Gol97, Apdx. C.4]). □

Comment. We note that the tight bound on the robustness (as a function of the proximity parameter) in our main construct (Theorem 3.1) plays an important role in the proof of Theorem 3.3. The reason is that when we compose two robust PCPPs, the proximity parameter of the second must be upper-bounded by the robustness parameter of the first. Thus, when we compose many robust PCPPs, the robustness parameter deteriorates exponentially in the number of composed systems, where the base of the exponent is determined by the tightness of the robustness (of the second verifier). That is, let $\tau \triangleq \rho/\delta$, where δ and ρ are the proximity and robustness parameters of the system. Then composing this system t times with itself means that at the lowest PCP-instance we need to set the proximity parameter to be τ^{t-1} times the initial proximity. This requires the lowest PCP-instance to make at least $1/\tau^{t-1}$ queries (or be composed with a PCPP that can handle proximity parameter τ^t, which again lower-bounds the number of queries). For a constant $\tau < 1$, we get $\exp(t)$ query complexity, whereas for $\tau = 1 - \gamma = (1 - (1/t))$ we get query complexity that is linear in $1/((1-\gamma)^t \cdot \gamma) = O(t)$. Finally, we argue that in the context of such an application, setting $\gamma = 1/t$ is actually the "natural" choice. Such a choice assigns to each proof oracle encountered in the composition an almost equal weight (of $1/t$); that is, such a proof oracle is assigned weight $1/t$ when it appears as the current proof oracle and maintains its weight when it appears as part of the input oracle in subsequent compositions.

3.2. Corollary to Theorem 3.3. Recall that Theorem 3.3 asserts a PCPP (for CktVal) with randomness complexity $\log_2 n + A_t(n)$, where $A_t(n) \triangleq O(t + (\log n)^{1/t}) \log\log n + O((\log n)^{2/t})$ and query complexity $O(t)$ (for soundness error $1/2$). For constant $t \geq 3$, we have $A_t(n) = O((\log n)^{2/t})$. On the other hand, for $t \geq \frac{1.01 \log\log n}{\log\log\log n}$, we have $A_t(n) = o(\log\log n)^2$. Using Proposition 2.4, these PCPPs yield corresponding PCPs for CktSAT.

Deriving Theorems 1.2 *and* 1.3. Two extreme choices of $t(n)$ are when $t(n) = \frac{2}{\varepsilon}$ for some $\varepsilon > 0$ (which maintains a constant query complexity) and $t(n) = \frac{2 \log\log n}{\log\log\log n}$ (which minimizes the randomness complexity of the verifier). Setting $t(n) = \frac{2}{\varepsilon}$ yields Theorem 1.3 (i.e., constant query complexity $O(\frac{1}{\varepsilon})$ and randomness $\log_2 n + O(\log^{\varepsilon} n)$), whereas setting $t(n) = \frac{2 \log\log n}{\log\log\log n}$ yields Theorem 1.2 (i.e., query complexity $O\left(\frac{\log\log n}{\log\log\log n}\right)$ and randomness $\log_2 n + O\left(\frac{(\log\log n)^2}{\log\log\log n}\right)$. Thus, both Theorems 1.2 and 1.3 follow from Theorem 3.3.

Deriving a PCPP for Nondeterministic Circuit Value. By Proposition 2.5, we conclude that for every $3 \leq t(n) \leq \frac{2 \log\log n}{\log\log\log n}$, there exists a PCPP for Nondeterministic Circuit Value of the same complexities (i.e., randomness complexity $\log_2 n + A_t(n)$, query complexity $O(t(n))$, perfect completeness, and soundness error $1/2$ with respect to proximity $\delta = \Omega(1/t(n))$).

A more flexible notion of a PCPP. Our definition of a PCPP (see Definition 2.3) specifies for each system a unique proximity parameter. In many settings (see, e.g., section 4.1), it is better that the proximity parameter is given as an input to the verifier and that the latter behaves accordingly (i.e., makes an adequate number of

queries). We refrain from presenting either a formal definition of such relaxed PCPPs or a general transformation of PCPPs into their more relaxed form. Instead, we state the following corollary to Theorem 3.3.

COROLLARY 3.4. *For all parameters* $n, t_1, t_2 \in \mathbb{N}$ *such that* $3 \leq t_1 \leq t_2 \leq \frac{2 \log \log n}{\log \log \log n}$ *there exists a PCPP for* CKTVAL (*for circuits of size* n) *with proof length* $2^{A_{t_1}(n)} \cdot n$, *where* $A_t(n)$ *is as in* (3.1), *query complexity* $O(t_2)$, *perfect completeness, and soundness error* $1/2$ *with respect to proximity parameter* $1/t_2$. *Furthermore, when given* (as auxiliary input) *a proximity parameter* $\delta \geq 1/t_2$, *the verifier makes only* $O(\max\{1/\delta, t_1\})$ *queries and rejects any input oracle that is* δ*-far from satisfying the circuit with probability at least* $1/2$.

Underlying the following proof is a general transformation of PCPPs to the more relaxed form as stated in Corollary 3.4.

Proof. The proof oracle consists of a sequence of proofs for the system of Theorem 3.3, when instantiated with proximity parameter 2^{-i} for $i = \lfloor \log_2 t_1 \rfloor, \ldots, \lceil \log_2 t_2 \rceil$. When the new verifier is invoked with proximity parameter δ, it invokes the original verifier with proximity parameter 2^{-i}, where $i = \lceil \log_2 1/\delta \rceil$, and emulates the answers using the ith portion of its proof oracle. □

4. Applications to coding problems. In this section we show that, combined with any good code, any PCPP yields a locally testable code (LTC). Using our PCPPs, we obtain an improvement in the rate of LTCs (improving over the results of [GS02, BSVW03]). We also introduce a relaxed notion of locally decodable codes (LDCs) and show how to construct such codes using any PCPP (and ours in particular).

Preliminaries For a string $w \in \{0,1\}^n$ and $i \in [n] \triangleq \{1, 2, \ldots, n\}$, unless stated differently, w_i denotes the ith bit of w.

We consider codes mapping sequences of k (input) bits into sequences of $n \geq k$ (output) bits. Such a generic code is denoted by $\mathrm{C} : \{0,1\}^k \to \{0,1\}^n$, and the elements of $\{\mathrm{C}(x) : x \in \{0,1\}^k\} \subseteq \{0,1\}^n$ are called *codewords* (of C). Throughout this section, *the integers* k *and* n *are to be thought of as parameters*, and we are typically interested in the relation of n to k (i.e., how n grows as a function of k). Thus, we actually discuss infinite families of codes (which are associated with infinite sets of possible k's), and whenever we say that some quantity of the code is a constant we mean that this quantity is constant for the entire family (of codes).

The distance of a code $\mathrm{C} : \{0,1\}^k \to \{0,1\}^n$ is the minimum (Hamming) distance between its codewords; that is, $\min_{x \neq y}\{\overline{\Delta}(\mathrm{C}(x), \mathrm{C}(y))\}$, where $\overline{\Delta}(u, v)$ denotes the number of bit locations on which u and v differ. Throughout this work, we focus on codes of "linear distance," that is, codes $\mathrm{C} : \{0,1\}^k \to \{0,1\}^n$ of distance $\Omega(n)$. The *distance of* $w \in \{0,1\}^n$ *from a code* $\mathrm{C} : \{0,1\}^k \to \{0,1\}^n$, denoted $\overline{\Delta}_{\mathrm{C}}(w)$, is the minimum distance between w and the codewords, that is, $\overline{\Delta}_{\mathrm{C}}(w) \triangleq \min_x\{\overline{\Delta}(w, \mathrm{C}(x))\}$. For $\delta \in [0,1]$, the n-bit long strings u and v are said to be δ*-far* (resp., δ*-close*) if $\overline{\Delta}(u, v) > \delta \cdot n$ (resp., $\overline{\Delta}(u, v) \leq \delta \cdot n$). Similarly, w is δ*-far from* C (resp., δ*-close to* C) if $\overline{\Delta}_{\mathrm{C}}(w) > \delta \cdot n$ (resp., $\overline{\Delta}_{\mathrm{C}}(w) \leq \delta \cdot n$).

As in the case of PCPs, all oracle machines considered below are *nonadaptive*. Here these oracle machines will model highly efficient testing and decoding procedures, which probe their input $w \in \{0,1\}^n$ in relatively few places. Thus, these procedures are modeled as oracle machines having oracle access to w (which is viewed as a function $w : \{1, \ldots, n\} \to \{0,1\}$).

4.1. LTCs. Loosely speaking, by a *codeword test* (for the code $\mathrm{C} : \{0,1\}^k \to \{0,1\}^n$) we mean a randomized (nonadaptive) oracle machine, also called a *tester*,

that is given oracle access to $w \in \{0,1\}^n$. The tester may query the oracle at a constant number of bit locations and is required to (always) accept every codeword and reject with (relatively) high probability every oracle that is "far" from the code. Indeed, since our focus is on positive results, we use a strict formulation in which the tester is required to accept each codeword with probability 1. (This corresponds to "perfect completeness" in the PCP setting.) The first definition below provides a general template (in terms of several parameters) for the rejection condition. Later we will discuss the kinds of asymptotic parameters we would like to achieve.

DEFINITION 4.1 (codeword tests). *A randomized* (nonadaptive) *oracle machine M is called a (δ, s)-codeword test for $\mathrm{C} : \{0,1\}^k \to \{0,1\}^n$ if it satisfies the following two conditions:*

1. Accepting codewords (i.e., completeness)*: For every $x \in \{0,1\}^k$, given oracle access to $w = \mathrm{C}(x)$, machine M accepts with probability* 1. *That is,* $\Pr[M^{\mathrm{C}(x)}=1] = 1$ *for every $x \in \{0,1\}^k$.*

2. Rejection of noncodeword (i.e., soundness)*: Given oracle access to any $w \in \{0,1\}^n$ that is δ-far from* C*, machine M accepts with probability at most s. That is,* $\Pr[M^w=1] \leq s$ *for every $w \in \{0,1\}^n$ that is δ-far from* C.

The parameter δ is called the proximity parameter *and s is called the* soundness error. *The* query complexity *q of M is the maximum number of queries it makes (taken over all sequences of coin tosses).*

Note that *this definition requires nothing with respect to noncodewords that are relatively close to the code* (i.e., are δ-close to C). In addition to the usual goals in constructing error-correcting codes (e.g., maximizing minimum distance and minimizing the blocklength $n = n(k)$), here we are also interested in simultaneously minimizing the query complexity q, the proximity parameter δ, and the soundness error s. More generally, we are interested in the trade-off between q, δ, and s. (As usual, the soundness error can be reduced to s^k by increasing the query complexity to $k \cdot q$.) A minimalistic goal is to have a family of codes with q, δ, and s all fixed constants. However, note that this would be interesting only if δ were sufficiently small with respect to the distance parameters of the code, e.g., smaller than half the relative minimum distance. (For example, if δ is larger than the "covering radius" of the code, then there does not exist any string that is δ-far from the code, and the soundness condition becomes vacuous.) A stronger definition requires the tester to work for any *given* proximity parameter $\delta > o(1)$, but allows its query complexity to depend on δ as follows.

DEFINITION 4.2 (LTCs). *A family of codes $\{\mathrm{C}_k : \{0,1\}^k \to \{0,1\}^n\}_{k \in \mathbb{N}}$ is* locally testable *if it satisfies the following.*

1. Linear distance*: There is a constant $\rho > 0$, such that for every k, C_k has minimum distance at least $\rho \cdot n$.*

2. Local testability*: There is a randomized, nonadaptive oracle machine M such that for every constant $\delta > 0$, there is a constant $q = q(\delta)$ such that for all sufficiently large k, $M^w(1^k, \delta)$ is a $(\delta, 1/2)$-codeword test for C_k with query complexity q.*

The family is called explicit *if both C_k and $M^w(1^k, \delta)$ can be evaluated with computation time polynomial in k.*

We comment that Definition 4.2 is somewhat weaker than the definitions used in [GS02].[14]

[14] In the stronger of the definitions in [GS02], the tester is not given δ as input (and thus has query complexity that is a fixed constant independent of δ) but is required to be a $(\delta, 1 - \Omega(\delta))$-codeword test for every constant $\delta > 0$ and sufficiently large k. That is, strings that are δ-far from the code

Using an adequate PCPP, we can transform any code to a related code that has a codeword tester. This is done by appending each codeword with a PCPP proving the codeword is indeed the encoding of a message. One technical problem that arises is that the PCPP constitutes most of the length of the new encoding. Furthermore, we cannot assume much about the Hamming distance between different proofs of the same statement, and thus the distance of the new code may deteriorate. But this is easily fixed by repeating the codeword many times so that the PCPP constitutes only a small fraction of the total length.[15] Specifically, given a code $\mathrm{C}_0 : \{0,1\}^k \to \{0,1\}^m$, we consider the code $\mathrm{C}(x) \triangleq (\mathrm{C}_0(x)^t, \pi(x))$, where $t = (d(k)-1) \cdot |\pi(x)|/|\mathrm{C}_0(x)|$ such that (say) $d(k) = \log k$, and $\pi(x)$ is a PCPP that asserts that an m-bit string (given as an input oracle) is a codeword (of C_0).

CONSTRUCTION 4.3. *Let d be a free parameter to be determined later, let $\mathrm{C}_0 : \{0,1\}^k \to \{0,1\}^m$ be a code, and let V be a PCPP verifier for membership in $S_0 = \{\mathrm{C}_0(x) : x \in \{0,1\}^k\}$. Let $\pi(x)$ be the proof oracle corresponding to the claim that the input oracle equals $\mathrm{C}_0(x)$; that is, $\pi(x)$ is the canonical proof obtained by using x as an NP witness for membership of $\mathrm{C}_0(x)$ in S_0. Consider the code $\mathrm{C}(x) \triangleq (\mathrm{C}_0(x)^t, \pi(x))$, where $t = (d-1) \cdot |\pi(x)|/|\mathrm{C}_0(x)|$.*

The codeword test emulates the PCP verifier in the natural way. Specifically, given oracle access to $w = (w_1, \ldots, w_t, \pi) \in \{0,1\}^{t \cdot m + \ell}$, the codeword tester selects uniformly $i \in [t]$ and emulates the PCP verifier, providing it with oracle access to the input oracle w_i and to the proof oracle π. In addition, the tester checks that the repetitions are valid (by inspecting randomly selected positions in some q_{rep} randomly selected pairs of m-bit long blocks, where q_{rep} is a free parameter to be optimized later). Let us denote this tester by T. That is, T^w

1. uniformly selects $i \in [t]$ and invokes $V^{w_i, \pi}$.
2. repeats the following q_{rep} times: Uniformly selects $i_1, i_2 \in [t]$ and $j \in [m]$ and checks whether $(w_{i_1})_j = (w_{i_2})_j$.

PROPOSITION 4.4. *Let d and q_{rep} be the free parameters in the above construction of the code C and tester T. Suppose that the code $\mathrm{C}_0 : \{0,1\}^k \to \{0,1\}^m$ has a relative minimum distance of ρ_0, and that the PCPP has a proof length of $\ell > m$, soundness error $1/4$ for proximity parameter δ_{pcpp}, and query complexity q_{pcpp}. Then, the code C and tester T have the following properties:*

1. *The blocklength of C is $n \triangleq d \cdot \ell$ and its relative minimum distance is at least $\rho_0 - 1/d$.*
2. *The oracle machine T is a $(\delta, \frac{1}{2})$-codeword tester for the C, where $\delta = \delta_{\mathrm{pcpp}} + \frac{4}{q_{\mathrm{rep}}} + \frac{1}{d}$.*
3. *The query complexity of T is $q = q_{\mathrm{pcpp}} + 2q_{\mathrm{rep}}$.*

Proof. The parameters of the code C are obvious from the construction. In particular, C has blocklength $t \cdot m + \ell = d \cdot \ell = n$, and the PCPP $\pi(x)$ constitutes only an $\ell/n = 1/d$ fraction of the length of the codeword $\mathrm{C}(x)$. Since the remainder consists of replicated versions of $\mathrm{C}_0(x)$, it follows that the relative minimum distance of C is at least $(n-\ell)\rho_0/n > \rho_0 - 1/d$.

The query complexity of T is obvious from its construction, and so we need only show that it is a good codeword tester. Completeness follows immediately from

---

are rejected with probability $\Omega(\delta)$. Such a tester implies a tester as in Definition 4.2, with query complexity $q(\delta) = O(1/\delta)$.

[15] Throughout this section we will use repetitions to adjust the "weights" of various parts of our codes. An alternative method would be to work with weighted Hamming distance (i.e., where different coordinates of a codeword receive different weights), and indeed these two methods (weighting and repeating) are essentially equivalent. For the sake of explicitness we work only with repetitions.

the completeness of the PCPP, and so we focus on the soundness condition. We consider an arbitrary $w = (w_1, \ldots, w_t, \pi) \in \{0,1\}^{t \cdot m + \ell}$ that is δ-far from C, and observe that $w' = (w_1, \ldots, w_t)$ must be δ'-far from $\mathrm{C}' = \{\mathrm{C}_0(x)^t : x \in \{0,1\}^k\}$, where $\delta' \geq (\delta n - \ell)/n = \delta - (1/d)$. Let $u \in \{0,1\}^m$ be a string that minimizes $\Delta(w', u^t) = \sum_{i=1}^t \Delta(w_i, u)$; that is, u^t is the "repetition sequence" closest to w'. We consider two cases:

Case 1. $\Delta(w', u^t) \geq 1/q_{\mathrm{rep}}$. In this case, a single execution of the basic repetition test (comparing two locations) rejects with probability:

$$\begin{aligned} \mathrm{E}_{r,s \in [t]} \left[\Delta(w_r, w_s)\right] &\geq \mathrm{E}_{r \in [t]} \left[\Delta(w_r, u)\right] \\ &= \Delta(w', u^t) \\ &\geq 1/q_{\mathrm{rep}}, \end{aligned}$$

where the last inequality is due to the case hypothesis. It follows that q_{rep} executions of the repetition test would accept with probability at most $(1 - 1/q_{\mathrm{rep}})^{q_{\mathrm{rep}}} < 1/e < 1/2$.

Case 2. $\Delta(w', u^t) \leq 1/q_{\mathrm{rep}}$. In this case

$$\Delta_{\mathrm{C}_0}(u) = \Delta_{\mathrm{C}'}(u^t) \geq \Delta_{\mathrm{C}'}(w') - \Delta(w', u^t) \geq \delta' - \frac{1}{q_{\mathrm{rep}}},$$

where the last inequality is due to the case hypothesis. Also, recalling that on the average (i.e., average i) w_i is $1/q_{\mathrm{rep}}$-close to u, it holds that at least two-thirds of the w_i's are $3/q_{\mathrm{rep}}$-close to u. Recalling that u is $(\delta' - (1/q_{\mathrm{rep}}))$-far from C_0 and using $\delta_{\mathrm{pcpp}} = \delta' - (4/q_{\mathrm{rep}})$, it follows that at least two-thirds of the w_i's are δ_{pcpp}-far from C_0. Thus, by the soundness condition of the PCP of proximity, these w_i will be accepted with probability at most $1/4$. Thus, in the current case, the tester accepts with probability at most $\frac{1}{3} + \frac{2}{3} \cdot \frac{1}{4} = \frac{1}{2}$. The soundness condition follows. ∎

To prove Theorem 1.4, we instantiate the above construction as follows. We let $\mathrm{C}_0 : \{0,1\}^k \to \{0,1\}^m$ come from a family of codes with a constant relative minimum distance of $\rho_0 > 0$ and nearly linear blocklength $m = \widetilde{O}(k)$, where encoding can be done by circuits of nearly linear size $s_0 = s_0(k) = \widetilde{O}(k)$. We take the PCPP from Corollary 3.4, setting $t_1 = O(1/\varepsilon)$ (for an arbitrarily small constant $\varepsilon > 0$) and $t_2 = 2 \log \log s_0 / \log \log \log s_0 = \omega(1)$. Thus, we obtain proof length $\ell = s_0 \cdot \exp(\log^{\varepsilon/2} s_0)$ and query complexity $q_{\mathrm{pcpp}} = O(\max\{1/\delta_{\mathrm{pcpp}}, t_1\}) = O(1/\delta_{\mathrm{pcpp}})$ for any proximity parameter $\delta_{\mathrm{pcpp}} \geq 1/t_2 = o(1)$. We actually invoke the verifier twice to reduce its soundness error to $1/4$. Setting $d = \log k = \omega(1)$, we obtain a final blocklength of $n = d \cdot \ell < k \cdot \exp(\log^{\varepsilon} k)$ and relative distance $\rho_0 - o(1)$. We further specify the test T as follows. Given a proximity parameter $\delta \geq 6/t_2 = o(1)$, the tester T invokes the aforementioned PCPP with $\delta_{\mathrm{pcpp}} = \delta/6$ and performs the repetition test $q_{\mathrm{rep}} = 6/\delta$ times. Observing that $\delta_{\mathrm{pcpp}} + (4/q_{\mathrm{rep}}) + (1/d) < \delta$, we conclude that the resulting test (i.e., $T = T(1^k, \delta_{\mathrm{pcpp}})$) is a $(\delta, 1/2)$-codeword tester of query complexity $O(1/\delta_{\mathrm{pcpp}}) + 2q_{\mathrm{rep}} = O(1/\delta)$. Thus we conclude as follows.

Conclusion (restating Theorem 1.4). *For every constant $\varepsilon > 0$, there exists a family of LTCs $\mathrm{C}_k : \{0,1\}^k \to \{0,1\}^n$, where $n = \exp(\log^{\varepsilon} k) \cdot k$, with query complexity $q(\delta) = O(1/\delta)$ (i.e., for every $\delta > 0$, the tester rejects words that are δ-far from C with probability $1/2$ by querying at most $q(\delta) = O(1/\delta)$ queries).*

4.2. Relaxed LDCs. We first recall the definition of LDCs, as formally stated by Katz and Trevisan [KT00]. A code $\mathrm{C} : \{0,1\}^k \to \{0,1\}^n$ is *locally decodable* if for some constant $\delta > 0$ (which is independent of k) there exists an efficient oracle

machine M that, on input, any index $i \in [k]$ and access to any oracle $w \in \{0,1\}^n$ such that $\Delta(w, \mathrm{C}(x)) \leq \delta$, recovers the ith bit of x with probability at least $2/3$ while making a constant number of queries to w. That is, whenever relatively few locations are corrupted, the decoder should be able to recover each information bit, with high probability, based on a constant number of queries to the (corrupted) codeword.

Katz and Trevisan showed that if M makes q queries, then $n = \Omega(k^{1+1/(q-1)})$ must hold [KT00].[16] This lower-bound is quite far from the best known upper-bound, due to Beimal et al. [BIKR02], that asserts $n = O(\exp(k^{\varepsilon(q)}))$, where $\varepsilon(q) = O((\log\log q)/(q \log q)) = o(1/q)$, which improves (already for $q = 4$) a previous upper-bound where $\varepsilon(q) = 1/(2q+1)$. It has been conjectured that, for a constant number of queries, n should be exponential in k; that is, for every constant q there exists a constant $\varepsilon > 0$ such that $n > \exp(k^{\varepsilon})$ must hold. In view of this state of affairs, it is natural to relax the definition of LDCs, with the hope of obtaining more efficient constructions (e.g., $n = \mathrm{poly}(k)$).

We relax the definition of LDCs by requiring that, whenever few location are corrupted, the decoder should be able to recover most (or almost all) of the individual information bits (based on few queries), and for the remaining locations the decoder outputs either the right message bit or a fail symbol (but not the wrong value). That is, the decoder must still avoid errors (with high probability), but is allowed to say "`don't know`" on a few bit locations. The following definition is actually weaker, yet, the (aforementioned) stronger formulation is obtained when considering $\rho \approx 1$ (and using amplification to reduce the error from $1/3$ to any desired constant).[17] Furthermore, it is desirable to recover all bits of the information whenever the codeword is not corrupted.

DEFINITION 4.5 (relaxed LDC). *A code* $\mathrm{C} : \{0,1\}^k \to \{0,1\}^n$ *is* relaxed locally decodable *if for some constants* $\delta, \rho > 0$ *there exists an efficient probabilistic oracle machine* M *that makes a constant number of queries and satisfies the following three conditions with respect to any* $w \in \{0,1\}^n$ *and* $x \in \{0,1\}^k$ *such that* $\Delta(w, \mathrm{C}(x)) \leq \delta$*:*

1. *If* $w = \mathrm{C}(x)$ *is a codeword, then the decoder correctly recovers every bit of* x *with probability at least* $\frac{2}{3}$*. That is, for every* $x \in \{0,1\}^k$ *and* $i \in [k]$*, it holds that* $\Pr[M^{\mathrm{C}(x)}(i) = x_i] \geq \frac{2}{3}$.

2. *On input, any index* $i \in [k]$ *and given access to the oracle* w*, with probability at least* $\frac{2}{3}$ *machine* M *outputs either the* i*th bit of* x *or a special failure symbol, denoted* $\perp$*. That is, for every* i*, it holds that* $\Pr[M^w(i) \in \{x_i, \perp\}] \geq \frac{2}{3}$.

3. *For at least a* ρ *fraction of the indices* $i \in [k]$*, on input* i *and oracle access to* $w \in \{0,1\}^n$*, with probability at least* $\frac{2}{3}$*, machine* M *outputs the* i*th bit of* x*. That is, there exists a set* $I_w \subseteq [k]$ *of size at least* ρk *such that for every* $i \in I_w$ *it holds that* $\Pr[M^w(i) = x_i] \geq \frac{2}{3}$.

We call δ *the* proximity parameter.

One may strengthen the definition by requiring that ρ be greater than $1/2$ or any other favorite constant smaller than 1 (but one should probably refrain from setting $\rho > 1 - \delta$, for example). A different strengthening is for condition 1 to hold with

[16] Their lower-bound refers to nonadaptive decoders and yields a lower-bound of $n = \Omega(k^{1+1/(2^q-1)})$ for adaptive decoders. A lower-bound of $n = \Omega(k^{1+1/O(q)})$ for adaptive decoders was presented in [DJK+02], and a lower-bound of $n = \Omega(k^{1+1/(q/2-1)})$ for nonadaptive decoders was presented in [KdW04]. (We note that we use a nonadaptive (relaxed) decoder.)

[17] Here error reduction may be performed by estimating the probability that the machine outputs each of the possible bits, and outputting the more frequent bit only if it has sufficient statistical support (e.g., 50% support, which the wrong bit cannot have). Otherwise, one outputs the `don't know` symbol.

probability 1 (i.e., $\Pr[M^{\mathrm{C}(x)}(i) = x_i] = 1$). In fact, we achieve both the stronger forms.

Remark 4.6. The above definition refers only to strings w that are δ-close to the code. However, using Construction 4.3, any relaxed LDC can be augmented so that strings that are δ-far from the code are rejected with high probability (i.e., for every index i, the decoder outputs $\perp$ with high probability). This can be achieved with only a nearly linear increase in the length of the code (from length n to length $n \cdot \exp(\log^{\varepsilon} n)$).

Remark 4.7. We stress that condition 2 does not mean that, for every i, and for every w that is δ-close to $\mathrm{C}(x)$, either $\Pr[M^w(i) = x_i] \geq \frac{2}{3}$ or $\Pr[M^w(i) = \perp] \geq \frac{2}{3}$ holds. We refer to the latter condition as condition X and conjecture that the seemingly minor difference between conditions 2 and X is actually substantial. This conjecture is enforced by a recent work of Buhrman and de Wolf [BdW04] who showed that codes that satisfy condition X are actually locally decodable in the standard, nonrelaxed sense (i.e., according to the definition of [KT00]).

4.2.1. Definitional issues and transformations. Note that it is very easy to come up with constructions that satisfy each one of the three conditions of Definition 4.5. For example, condition 2 can be satisfied by (any code and) a trivial decoder that always returns $\perp$. On the other hand, the identity encoding (combined with a trivial decoder) satisfies conditions 1 and 3.[18] Our aim, however, is to obtain a construction that satisfies all conditions and beats the performance of the known LDCs.

It turns out that codes that satisfy conditions 1 and 2 can be converted into "equally good" codes that satisfy all three conditions. Let us start with a key definition, which refers to the distribution of the decoder's queries *when asked to recover a random bit position.*

DEFINITION 4.8 (average smoothness). *Let M be a randomized nonadaptive oracle machine having access to an oracle $w \in \{0,1\}^n$ and getting input $i \in [k]$. Further suppose that M always makes q queries. Let $M(i,j,r)$ denote the jth query of M on input i and coin tosses r. We say that M satisfies the* average smoothness *condition if, for every $v \in [n]$,*

$$\frac{1}{2n} < \Pr_{i,j,r}[M(i,j,r) = v] < \frac{2}{n},$$

where the probability is taken uniformly over all possible choices of $i \in [k]$, $j \in [q]$, and coin tosses r.

By having M randomly permute its queries, average smoothness implies that for every $j \in [q]$ and $v \in [n]$, it holds that $\frac{1}{2n} < \Pr_{i,r}[M(i,j,r) = v] < \frac{2}{n}$, where now the probability is taken uniformly over all possible choices of $i \in [k]$ and the coin tosses r. We stress that *average smoothness is different from the notion of smoothness as defined by Katz and Trevisan* [KT00]: They require that *for every* $i \in [k]$ (and for every $j \in [q]$ and $v \in [n]$), it holds that $\frac{1}{2n} < \Pr_r[M(i,j,r) = v] < \frac{2}{n}$. Indeed, average smoothness is a weaker requirement, and (as we will shortly see) any code and decoder pair can be easily modified to satisfy it, while preserving the decoding properties (of Definition 4.5). (In contrast, Katz and Trevisan [KT00] present a

[18] In case one wishes the code to have a linear distance this can be achieved too, consider $\mathrm{C}(x) = (x, \mathrm{C}'(x))$, where C' is any code of linear length and linear distance, and a decoder that merely retrieves the desired bit from the first part.

modification that achieves smoothness while preserving strict local decodability, but their transformation does not preserve Definition 4.5.)

LEMMA 4.9. *Let* $\mathrm{C}:\{0,1\}^k \to \{0,1\}^n$ *be a code and* M *a machine that satisfies conditions* 1 *and* 2 *of Definition* 4.5 *with respect to proximity parameter* δ*. Then, for some* $n' \in [3n, 4n]$*, there exists a code* $\mathrm{C}':\{0,1\}^k \to \{0,1\}^{n'}$ *and a machine* M' *that satisfies average smoothness as well as conditions* 1 *and* 2 *of Definition* 4.5 *with respect to proximity parameter* $\delta' = \delta/20$*. Furthermore, the query complexity of* M' *is twice the one of* M*, and if* M *satisfies also condition* 3*, with respect to a constant* ρ*, then so does* M'*.*

Jumping ahead, we mention that, for a decoder that satisfies average smoothness, conditions 1 and 2 essentially imply condition 3. Hence our interest in average smoothness and in Lemma 4.9.

Proof. As noted above, we may assume without loss of generality that each of M's queries is distributed identically. Throughout the analysis, we refer to the distribution of queries for a uniformly distributed index $i \in [k]$. Let q denote the query complexity of M.

We first modify M such that for a random $i \in [k]$, each query probes each possible location with probability $\Omega(1/n)$. This is done by adding q dummy queries, each being uniformly distributed. Thus, each location gets probed by each query with probability at least $1/2n$.

Next we modify the code and the decoder such that each location is probed with almost uniform distribution. The idea is to repeat heavily probed locations for an adequate number of times and have the decoder probe a random copy. Specifically, let p_v be the probability that location v is probed (i.e., $p_v \triangleq \Pr_{i\in[k],r}[M(i,1,r)=v]$ or equivalently $p_v = \sum_{i\in[k],j\in[2q]} \Pr_r[M(i,j,r)=v]/2kq$). By the above modification, we have $p_v \geq 1/2n$. Now, we repeat location v $r_v = \lfloor 4np_v \rfloor$ times. Note that $r_v \leq 4np_v$ and $r_v > 4np_v - 1 \geq 2 - 1$ (and so $r_v \geq 2$). We obtain a new code C' of length $n' = \sum_v r_v \leq 4n$. (Note that $n' > 3n$.) The relative distance of C' is at least one-fourth that of C, and the rate changes in the same way. The new decoder, M', when seeking to probe location v, will select and probe at random one of the r_v copies of that location. (Interestingly, there is no need to augment this decoder by a testing of the consistency of the copies of an original location.)

Each new location is probed with probability $p'_v \triangleq p_v \cdot \frac{1}{r_v}$ (by each of these queries). Recalling that $\frac{p_v}{r_v} = \frac{p_v}{\lfloor 4np_v \rfloor}$, it follows that $p'_v \geq 1/4n$ and $p'_v \leq \frac{p_v}{4np_v - 1} \leq 1/2n$ (using $p_v \geq 1/2n$). Recalling that $n' \in [3n, 4n]$, each p'_v is in $[(3/4)\cdot(1/n'), 2\cdot(1/n')]$, i.e., within a factor of 2 from uniform.

Clearly, M' satisfies condition 1 (of Definition 4.5), and we show that it (essentially) satisfies condition 2 as well. Let $w = (w_1, \ldots, w_n) \in \{0,1\}^{n'}$ be δ'-close to $\mathrm{C}'(x)$, where $|w_v| = r_v$. Let Y_v be a 0-1 random variable that represents the value of a random bit in w_v; that is, $\Pr[Y_v = 1]$ equals the fraction of 1's in w_v. Then, $\Pr[Y_v \neq \mathrm{C}(x)_v] > 0$ implies that $\overline{\Delta}(w_v, c_v) \geq 1$, where $\mathrm{C}'(x) = (c_1, \ldots, c_n)$ and $|c_v| = r_v$. For $Y = Y_1 \cdots Y_n$, it follows that $\mathrm{E}(\overline{\Delta}(Y, \mathrm{C}(x))) \leq \overline{\Delta}(w, \mathrm{C}'(x))$, and so $\mathrm{E}(\overline{\Delta}(Y, \mathrm{C}(x))) \leq \delta' n' \leq (\delta/5)\cdot n$ (since $\delta' = \delta/20$ and $n' \leq 4n$). Thus, with probability at least $4/5$, the random string Y is δ-close to $\mathrm{C}(x)$, in which case the M must succeed with probability at least $2/3$. Noting that $M'^w(i)$ merely invokes $M^Y(i)$, we conclude that

$$\begin{aligned}\Pr[M'^w(i) \in \{x_i, \perp\}] &= \Pr[M^Y(i) \in \{x_i, \perp\}] \\ &\geq \Pr[\overline{\Delta}(Y, \mathrm{C}(x)) \leq \delta n] \cdot \Pr[M^Y(i) \in \{x_i, \perp\} \mid \overline{\Delta}(Y, \mathrm{C}(x)) \leq \delta n] \\ &\geq \frac{4}{5} \cdot \frac{2}{3} = \frac{8}{15}.\end{aligned}$$

An analogous argument can be applied in the case M satisfies condition 3. In both cases, additional error reduction is needed in order to satisfy the actual conditions, which require success with probability at least 2/3. (For details see footnote 17.) □

LEMMA 4.10. *Let* $\mathrm{C} : \{0,1\}^k \to \{0,1\}^n$ *be a code and* M *be a machine that satisfies conditions* 1 *and* 2 *of Definition* 4.5 *with respect to a constant* δ. *Suppose that* M *satisfies the average smoothness condition and has query complexity* q. *Then, invoking* M *for a constant number of times (and ruling as in footnote* 17*) yields a decoder that satisfies all three conditions of Definition* 4.5. *Specifically, condition* 3 *holds with respect to a constant* $\rho = 1 - 18q\delta$. *Furthermore, for any* w *and* x, *for a* $1 - 18q\overline{\Delta}(w, \mathrm{C}(x))$ *fraction of the* i*'s, it holds that* $\Pr[M^w(i) = x_i] \geq 5/9$.

Our usage of the average smoothness condition actually amounts to using the hypothesis that, for a uniformly distributed $i \in [k]$, each query hits any fixed position with probability at most $2/n$.

Proof. By condition 1, for any $x \in \{0,1\}^k$ and every $i \in [k]$, it holds that $\Pr[M^{\mathrm{C}(x)}(i) = x_i] \geq 2/3$. Considering any w that is δ-close to $\mathrm{C}(x)$, the probability that on input a *uniformly distributed* $i \in [k]$ machine M queries a location on which w and $\mathrm{C}(x)$ disagree is at most $q \cdot (2/n) \cdot \delta n = 2q\delta$. This is due to the fact that, for a uniformly distributed i, the queries are almost uniformly distributed; specifically, no position is queried with probability greater than $2/n$ (by a single query).

Let p_i^w denote the probability that on input i machine M queries a location on which w and $\mathrm{C}(x)$ disagree. We have just established that $(1/k) \cdot \sum_{i=1}^k p_i^w \leq 2q\delta$. For $I_w \triangleq \{i \in [k] : p_i^w \leq 1/9\}$, it holds that $|I_w| \geq (1 - 18q\delta) \cdot k$. Observe that for any $i \in I_w$, it holds that $\Pr[M^w(i) = x_i] \geq (2/3) - (1/9) = 5/9$. Note that, by replacing δ with $\overline{\Delta}(w, \mathrm{C}(x))/n$, the above argument actually establishes that for a $1 - 18q \cdot \overline{\Delta}(w, \mathrm{C}(x))$ fraction of the i's, it holds that $\Pr[M^w(i) = x_i] \geq 5/9$.

Additional error reduction is needed in order to satisfy the actual definition (of condition 3), which requires success with probability at least 2/3. The error reduction should be done in a manner that preserves conditions 1 and 2 of Definition 4.5. For details see footnote 17. □

In view of the last sentence of Lemma 4.10, it makes sense to state a stronger definition of relaxed LDCs.

DEFINITION 4.11 (relaxed LDC, revisited). *A code* $\mathrm{C} : \{0,1\}^k \to \{0,1\}^n$ *is* relaxed locally decodable *if for some constants* $\delta > 0$ *there exists an efficient probabilistic oracle machine* M *that makes a constant number of queries and satisfies the following two conditions with respect to any* $w \in \{0,1\}^n$ *and* $x \in \{0,1\}^k$ *such that* $\overline{\Delta}(w, \mathrm{C}(x)) \leq \delta n$*:*

1. *For every* $i \in [k]$ *it holds that* $\Pr[M^w(i) \in \{x_i, \perp\}] \geq \frac{2}{3}$.
2. *There exists a set* $I_w \subseteq [k]$ *of density at least* $1 - O(\overline{\Delta}(w, \mathrm{C}(x))/n)$ *such that for every* $i \in I_w$ *it holds that* $\Pr[M^w(i) = x_i] \geq \frac{2}{3}$.

Note that the "everywhere good" decoding of codewords (i.e., condition 1 of Definition 4.5) is implied by condition 2 of Definition 4.11. By combining Lemmas 4.9 and 4.10, we get the following theorem.

THEOREM 4.12. *Let* $\mathrm{C} : \{0,1\}^k \to \{0,1\}^n$ *be a code and* M *be a machine that makes a constant* q *number of queries and satisfies conditions* 1 *and* 2 *of Definition* 4.5 *with respect to a constant* δ. *Then, for some* $n' \in [3n, 4n]$, *there exists a code* $\mathrm{C}' : \{0,1\}^k \to \{0,1\}^{n'}$ *that is relaxed locally decodable with respect to proximity parameter* $\delta' = \delta/20$. *Furthermore, this code satisfies Definition* 4.11.

4.2.2. Constructions. In view of Lemma 4.10, we focus on presenting codes with decoders that satisfy conditions 1 and 2 of Definition 4.5 as well as the average

smoothness property. (The latter property will save us the need to invoke Lemma 4.9.) We will start with a code that has nearly quadratic length (i.e., $n = k^{2+o(1)}$), which serves as a good warm-up towards our final construction in which $n = k^{1+\varepsilon}$ for any desired constant $\varepsilon > 0$.

Motivation to our construction. We seek a code of linear distance that has some weak "local decodability" properties. One idea is to separate the codeword into two parts, the first allowing for "local decodability" (e.g., using the identity map) and the second providing the distance property (e.g., using any code of linear distance). It is obvious that a third part that guarantees the consistency of the first two parts should be added, and it is natural to try to use a PCPP in the latter part. The natural decoder will check consistency (via the PCPP), and in case it detects no error will decode according to the first part. Indeed, the first part may not be "robust to corruption" but the second part is "robust to corruption" and consistency means that both parts encode the same information. Considering this vague idea, we encounter two problems. First, a PCPP is unlikely to detect a small change in the first part. Thus, if we use the identity map in the first part, then the decoder may output the wrong value of some (although few) bits. In other words, the "proximity relaxation" in PCPPs makes sense for the second part of the codewords but not for the first part. Our solution is to provide, *for each bit* (position) in the first part, a proof of the consistency of this bit (value) with the entire second part. The second problem is that the PCPPs (let alone all of them combined) are much longer than the first two parts, whereas the corruption rate is measured in terms of the entire codeword. This problem is easy to fix by repeating the first two parts sufficiently many times. However, it is important not to "overdo" this repetition because if the third part is too short, then corrupting it may prevent meaningful decoding (as per condition 3 of Definition 4.5) even at low corruption rates (measured in terms of the entire codeword). In other words, if the third part is too short, then we have no chance to satisfy the average smoothness condition.

The actual construction. Let $\mathrm{C}_0 : \{0,1\}^k \to \{0,1\}^m$ be a good code of relative distance δ_0; then we encode $x \in \{0,1\}^k$ by $\mathrm{C}(x) \triangleq (x^t, \mathrm{C}_0(x)^{t'}, \pi_1(x), \ldots, \pi_k(x))$, where $t = |\pi_1(x), \ldots, \pi_k(x)|/|x|$ (resp., $t' = |\pi_1(x), \ldots, \pi_k(x)|/|\mathrm{C}_0(x)|$), and $\pi_i(x)$ is a PCPP to be further discussed. We first note that the replicated versions of x (resp., $\mathrm{C}_0(x)$) take a third of the total length of $\mathrm{C}(x)$. As for $\pi_i(x)$, it is a PCPP that refers to an input of the form $(z_1, z_2) \in \{0,1\}^{m+m}$ and asserts that there exists an $x = x_1 \cdots x_k$ (indeed the one that is a parameter to π_i) such that $z_1 = x_i^m$ and $z_2 = \mathrm{C}_0(x)$.[19] We use our PCPP from Theorem 3.3, while setting its parameters such that the proximity parameter is small enough but the query complexity is a constant. Specifically, let $\delta_{\mathrm{pcpp}} > 0$ be the proximity parameter of the PCPP, which will be set to be sufficiently small, and let $q = O(1/\delta_{\mathrm{pcpp}})$ denote the number of queries the verifier makes in order to support a soundness error of 1/6 (rather than the standard 1/2). A key observation regarding this verifier is that its queries to its input-oracle are uniformly distributed. The queries to the proof oracle can be made almost uniform by a modification analogous to the one used in the proof of Lemma 4.9.

Observe that the code C maps k-bit long strings to codewords of length $n \triangleq 3 \cdot k \cdot \ell$, where $\ell = s_0(m)^{1+o(1)}$ denotes the length of the PCPP proof and $s_0(m)$ denotes the size of the circuit for encoding relative to C_0. Using a good code $\mathrm{C}_0 : \{0,1\}^k \to \{0,1\}^m$ (i.e., of constant relative distance δ_0, linear length $m = O(k)$, and $s_0(m) = \widetilde{O}(m)$), we obtain $n = k^{2+o(1)}$. The relative distance of C is at least $\delta_0/3$.

[19] Indeed, z_1 is merely the bit x_i repeated $|C_0(x)|$ times in order to give equal weight to each part in measuring proximity.

We now turn to the description of the decoder D. Recall that a valid codeword has the form $(x^t, \mathrm{C}_0(x)^{t'}, \pi_1(x), \ldots, \pi_k(x))$. The decoding of the ith information bit (i.e., x_i) will depend on a random (possibly wrong) copy of x_i located in the first part (which supposedly equals x^t), a random (possibly corrupted) copy of $\mathrm{C}_0(x)$ located in the second part, and the relevant (i.e., ith) proof located in the third part (which is also possibly corrupted). On input $i \in [k]$ and oracle access to $w = (w_1, w_2, w_3) \in \{0,1\}^n$, where $|w_1| = |w_2| = |w_3|$, the decoder invokes the PCPP verifier while providing it with access to an input oracle (z_1, z_2) and a proof oracle π that are defined and emulated as follows: The decoder selects uniformly $r \in [t]$ and $r' \in [t']$, and defines each bit of z_1 to equal the $((r-1)k+i)$th bit of w_1, the string z_2 is defined to equal the r'th (m-bit long) block of w_2, and π is defined to equal the ith block (ℓ-bit long) of w_3. That is, when the verifier asks to access the jth bit of z_1 (resp., z_2, resp., π), the decoder answers with the $((r-1)k+i)$th bit of w_1 (resp., $((r'-1)m+j)$th bit of w_2 (resp., the $((i-1)\ell+j)$th bit of w_3). If the verifier rejects, then the decoder outputs a special (failure) symbol. Otherwise, it outputs the $((r-1)k+i)$th bit of w_1.

The above construction can be performed for any sufficiently small constant proximity parameter $\delta \in (0, \delta_0/18)$. All that this entails is setting the proximity parameter of the PCPP to be sufficiently small but positive (e.g., $\delta_{\mathrm{pcpp}} = (\delta_0 - 18\delta)/2$). We actually need to augment the decoder such that it makes an equal number of queries to each of the three (equal length) parts of the codeword, which is easy to do by adding (a constant number of) dummy queries. Let us denote the resulting decoder by D.

PROPOSITION 4.13. *The above code and decoder satisfy conditions* 1 *and* 2 *of Definition* 4.5 *with respect to proximity parameter* $\delta \in (0, \delta_0/18)$. *Furthermore, this decoder satisfies the average smoothness property.*

Proof. Condition 1 (of Definition 4.5) is obvious from the construction (and the completeness property of the PCPP). In fact, the perfect completeness of the PCPP implies that bits of an uncorrupted codeword are recovered with probability 1 (rather than with probability at least 2/3). The average smoothness property of the decoder is obvious from the construction and the smoothness property of the PCPP. We thus turn to establish condition 2 (of Definition 4.5).

Fixing any $x \in \{0,1\}^k$, we consider an arbitrary oracle $w = (w_1, w_2, w_3)$ that is δ-close to $\mathrm{C}(x)$, where w_1 (resp., w_2) denotes the alleged replication of x (resp., $\mathrm{C}_0(x)$) and $w_3 = (u_1, \ldots, u_k)$ denotes the part of the PCPPs. Note that w_2 is 3δ-close to $\mathrm{C}_0(x)^{t'}$. To analyze the performance of $D^w(i)$, we define random variables Z_1 and Z_2 that correspond to the input oracles to which the PCP verifier is given access. Specifically, $Z_1 = \sigma^m$, where σ is set to equal the $((r-1)k+i)$th bit of w_1, when r is uniformly distributed in $[t]$. Likewise, Z_2 is determined to be the r'th block of w_2, where r' is uniformly distributed in $[t']$. Finally, we set the proof oracle, π, to equal the ith block of w_3 (i.e., $\pi = u_i$). We bound the probability that the decoder outputs $\neg x_i$ by considering three cases as follows.

Case 1. $\sigma = x_i$. Recall that σ is the bit read by D from w_1, and that by construction D always outputs either σ or $\perp$. Thus, in this case, Condition 2 is satisfied (because, regardless of whether D outputs σ or $\perp$, the output is always in $\{x_i, \perp\}$).

Case 2. Z_2 is 18δ-far from $\mathrm{C}_0(x)$. Recall that w_2 is 3δ-close to $\mathrm{C}_0(x)^{t'}$, which means that the expected relative distance of Z_2 and $\mathrm{C}_0(x)$ is at most 3δ. Thus, the current case occurs with probability at most 1/6.

Case 3. Z_2 is 18δ-close to $\mathrm{C}_0(x)$ and $\sigma \neq x_i$. Then, on one hand, (Z_1, Z_2) is 1/2-

far from $(x_i^m, \mathrm{C}_0(x))$, because $Z_2 = \sigma^t$. On the other hand, Z_2 is $(\delta_0 - 18\delta)$-far from any other codeword of C_0, because Z_2 is 18δ-close to $\mathrm{C}_0(x)$ and the codewords of C_0 are δ_0-far from one another. Thus, (Z_1, Z_2) is $(\delta_0 - 18\delta)/2$-far from any string of the form $(y_i^m, \mathrm{C}_0(y))$. Using $\delta_{\mathrm{pcpp}} \leq (\delta_0 - 18\delta)/2$, we conclude that the PCPP verifier accepts (Z_1, Z_2) with probability at most 1/6. It follows that, in the current case, the decoder outputs $\neg x_i$ with probability at most 1/6.

Thus, in total, the decoder outputs $\neg x_i$ with probability at most $1/6 + 1/6 = 1/3$. □

Improving the rate. The reason that our code has quadratic length codewords (i.e., $n = \Omega(k^2)$) is that we augmented a standard code with proofs regarding the relation of the standard codeword to the value of *each* information bit. Thus, we had k proofs, each relating to a statement of length $\Omega(k)$. Now, consider the following improvement: Partition the message into $\sqrt{k}$ blocks, each of length $\sqrt{k}$. Encode the original message, as well as each of the smaller blocks, via a good error-correcting code. Let w be the encoding of the entire message, and let w_i $(i = 1, \ldots, \sqrt{k})$ be the encodings of the blocks. For every $i = 1, \ldots, \sqrt{k}$, append a PCPP for the claim "w_i is the encoding of the ith block of a message encoded by w." In addition, for each message bit $x_{(i-1)\sqrt{k}+j}$ residing in block i, append a PCPP of the statement "$x_{(i-1)\sqrt{k}+j}$ is the jth bit of the $\sqrt{k}$bit long string encoded in w_i." The total encoding length has decreased, because we have $\sqrt{k}$ proofs of statements of length $O(k)$ and k proofs of statements of length $O(\sqrt{k})$, leading to a total length that is almost linear in $k^{3/2}$.

In general, for any constant ℓ, we consider ℓ successively finer partitions of the message into blocks, where the $(i+1)$st partition is obtained by breaking each block of the previous partition into $k^{1/\ell}$ equally sized pieces. Thus, the ith partition uses $k^{i/\ell}$ blocks, each of length $k^{1-(i/\ell)}$. Encoding is done by providing, for each $i = 0, 1, \ldots, \ell$, encodings of each of the blocks in the ith partition by a good error-correcting code. Thus, for $i = 0$ we provide the encoding of the entire messages, whereas for $i = \ell$ we provide an "encoding" of individual bits. Each of these $\ell + 1$ levels of encodings will be assigned equal weight (via repetitions) in the new codeword. In addition, the new codeword will contain PCPPs that assert the consistency of "directly related" blocks (i.e., blocks of consecutive levels that contain one another). That is, for every $i = 1, \ldots, \ell$ and $j \in [k^{i/\ell}]$, we place a proof that the encoding of the jth block in the ith level is consistent with the encoding of the $\lceil j/k^{1/\ell} \rceil$th block in the $(i-1)$st level. The ith such sequence of proofs contains $k^{i/\ell}$ proofs, where each such proof refers to statements of length $O(k^{1-(i/\ell)} + k^{1-((i-1)/\ell)}) = O(k^{1-((i-1)/\ell)})$, which yields a total proof length that is upper-bounded by $k^{i/\ell} \cdot (k^{1-((i-1)/\ell)})^{1+o(1)} = k^{1+(1/\ell)+o(1)}$. Each of these sequences will be assigned equal weight in the new codeword, and the total weight of all the encodings will equal the total weight of all proofs. The new decoder will just check the consistency of the ℓ relevant proofs and act accordingly. We stress that, as before, the proofs in use are PCPPs. In the current context these proofs refer to two input oracles of vastly different lengths, and so the bit positions of the shorter input oracle are given higher "weight" (by repetition) such that both input oracles are assigned the same weight.[20]

CONSTRUCTION 4.14. *Let* C_0 *be a code of minimal relative distance* δ_0*, constant rate, and nearly linear-sized encoding circuits. For simplicity, assume that a single bit is encoded by repetitions; that is,* $\mathrm{C}_0(\sigma) = \sigma^{O(1)}$ *for* $\sigma \in \{0,1\}$*. Let*

[20] Indeed, this was also done in the simpler code analyzed in Proposition 4.13.

V be a PCPP of membership in $S_0 = \{\mathrm{C}_0(x) : x \in \{0,1\}^*\}$ having almost linear proof length, query complexity $O(1/\delta_{\mathrm{pcpp}})$, and soundness error $1/9$, for proximity parameter δ_{pcpp}. Furthermore, V's queries to both its input oracle and proof oracle are distributed almost uniformly.[21] *For a fixed parameter $\ell \in \mathbb{N}$, let $b \triangleq k^{1/\ell}$. For $x \in \{0,1\}^k$, we consider ℓ different partitions of x, such that the jth partition denoted $(x_{j,1}, \ldots, x_{j,b^j})$, where $x_{j,j'} = x_{(j'-1)\cdot b^{\ell-j}+1} \cdots x_{j'\cdot b^{\ell-j}}$. We define $\mathrm{C}_j(x) \triangleq (\mathrm{C}_0(x_{j,1}), \mathrm{C}_0(x_{j,2}), \ldots, \mathrm{C}_0(x_{j,b^j}))$, and $\pi_j(x) = (\pi_{j,1}(x), \ldots, \pi_{j,b^j}(x))$, where $p_{j,j'}(x)$ is a PCPP proof oracle that asserts the consistency of j'th block of $\mathrm{C}_j(x)$ and the $\lceil j'/b \rceil$th block of $\mathrm{C}_{j-1}(x)$. That is, $p_{j,j'}(x)$ refers to an input oracle of the form (z_1, z_2), where $|z_1| = |z_2| = O(b^{\ell-j+1})$, and asserts the existence of x such that $z_1 = \mathrm{C}_0(x_{j,j'})^b$ and $z_2 = \mathrm{C}_0(x_{j-1,\lceil j'/b \rceil})$. We consider the code*

$$\mathrm{C}(x) \triangleq (\mathrm{C}_0(x)^{t_0}, \mathrm{C}_1(x)^{t_0}, \ldots, \mathrm{C}_\ell(x)^{t_0}, \pi_1^{t_1}, \ldots, \pi_\ell^{t_\ell}),$$

where the t_j's are selected such that each of the $2\ell+1$ parts of $\mathrm{C}(x)$ has the same length. The decoder, denoted D, operates as follows on input $i \in [k]$ and oracle access to $w = (w_0, w_1, \ldots, w_\ell, v_1, \ldots, v_\ell)$, where $|w_0| = |w_j| = |v_j|$ for all j:

- *D selects uniformly $r_0, r_1, \ldots, r_\ell \in [t_0]$, and $(r'_1, r'_2, \ldots, r'_\ell) \in [t_1] \times [t_2] \times \cdots \times [t_\ell]$.*
- *For $j = 1, \ldots, \ell$, D invokes the PCPP verifier, providing it with access to an input oracle (z_1, z_2) and a proof oracle π that are defined as follows:*
  - *$z_1 = u^b$, where u is the $((r_j - 1) \cdot b^j + \lceil i/b^{\ell-j} \rceil)$th block of w_j.*
  - *z_2 is the $((r_{j-1} - 1) \cdot b^{j-1} + \lceil i/b^{\ell-j+1} \rceil)$th block of w_{j-1}.*
  - *π is the $((r'_j - 1) \cdot b^j + \lceil i/b^{\ell-j} \rceil)$th block of v_j.*

  The PCPP verifier is invoked with proximity parameter $\delta_{\mathrm{pcpp}} = 13\ell\delta > 0$, where $\delta \le \delta_0/81\ell$ is the proximity parameter sought for the decoder.
- *If the PCPP verifier rejects, in any of the aforementioned ℓ invocations, then the decoder outputs a special* (failure) *symbol. Otherwise, the decoder outputs a random value in the $((r_\ell - 1) \cdot k + i)$th block of w_ℓ* (which is supposedly a repetition code of x_i).
- *D satisfies the average smoothness property when we issue some dummy queries that are uniformly distributed in adequate parts of w that are queried less by the above. (In other words, suppose that V makes q_1 (resp., q_2) queries to the first (resp., second) part of its input oracle and q' queries to its proof oracle. Then, w_0 is accessed q_2 times, w_ℓ is accessed q_1 times, each other w_j is accessed $q_1 + q_2$ times, and each v_j is accessed q' times. Thus, we may add dummy queries to make each part accessed $\max(q_1 + q_2, q')$ times, which means increasing the number of queries by a factor of at most $(2\ell+1)/(\ell-1)$ assuming $\ell \ge 2$.)*

Using an adequate PCPP, it holds that $|\mathrm{C}(x)| = \ell \cdot (|x|^{1+(1/\ell)})^{1+o(1)} < |x|^{1+\varepsilon}$ for $\varepsilon = 2/\ell$. The query complexity of D is $O(\ell) \cdot O(1/\delta_{\mathrm{pcpp}}) = O(\ell^2)$. The proof of Proposition 4.13 can be extended, obtaining the following.

PROPOSITION 4.15. *The code and decoder of Construction* 4.14 *satisfy conditions* 1 *and* 2 *of Definition* 4.5 *with respect to proximity parameter $\delta \le \delta_0/81\ell$. Furthermore, this decoder satisfies the average smoothness property.*

Using Lemma 4.10, Theorem 1.5 follows.

[21] Recall that all these conditions hold for the PCPP of Theorem 3.3, where almost uniformly distributed queries to the proof oracle are obtained by a modification analogous to the proof of Lemma 4.9.

Proof. Again, condition 1 as well as the average smoothness property are obvious from the construction, and thus we focus on establishing condition 2. Thus, we fix an arbitrary $i \in [k]$ and follow the outline of the proof of Proposition 4.13.

We consider an oracle $(w_0, w_1, \ldots, w_\ell, \pi_1, \ldots, \pi_\ell)$ that is δ-close to an encoding of $x \in \{0,1\}^k$, where each w_j is assumed to consist of encodings of the $k^{j/\ell}$ (nonoverlapping) $k^{1-(j/\ell)}$-bit long blocks of x, and π_i consists of the corresponding proofs of consistency. It follows that each w_j is $(2\ell+1)\cdot\delta$-close to $\mathrm{C}_j(x)^{t_0}$. Let Z_j denote the block of w_j that was selected and accessed by D. Thus, the expected relative distance of Z_0 from $\mathrm{C}_0(x)$ is at most $(2\ell+1)\cdot\delta$, but we do not know the same about the other Z_j's because their choice depends on i (or rather on $\lceil i/b^{\ell-j}\rceil$). Assuming, without loss of generality, that $\delta_0 < 1/3$ (and $\ell \geq 1$), we consider three cases as follows.

Case 1. Z_ℓ is 1/9-close to $\mathrm{C}_0(x_i)$. In this case, D outputs either $\perp$ or a uniformly selected bit in Z_ℓ, and so D outputs $\neg x_i$ with probability at most 1/9.

Using $\delta \leq \delta_0/81\ell$ and $\delta_0 < 1/3$, it follows that $27\ell\delta < 1/9$. Thus, if Case 1 does not hold, then Z_ℓ is $27\ell\delta$-far from $\mathrm{C}_0(x_i)$.

Case 2. Z_0 is $27\ell\delta$-far from $\mathrm{C}_0(x)$. This case may occur with probability at most 1/9, because $\mathrm{E}[\overline{\Delta}(Z_0, \mathrm{C}_0(x))] \leq 3\ell\delta \cdot |\mathrm{C}_0(x)|$.

Note that if both Cases 1 and 2 do not hold, then Z_0 is $27\ell\delta$-close to $\mathrm{C}_0(x)$ but Z_ℓ is $27\ell\delta$-far from $\mathrm{C}_0(x_i)$. Also note that $x = x_{0,1}$ and $x_i = x_{\ell,i}$.

Case 3. For some $j \in [\ell]$, it holds that Z_{j-1} is $27\ell\delta$-close to $\mathrm{C}_{j-1}(x_{j-1,\lceil i/b^{\ell-j+1}\rceil})$ but Z_j is $27\ell\delta$-far from $\mathrm{C}_j(x_{j,\lceil i/b^{\ell-j}\rceil})$. In this case, the pair (Z_j^b, Z_{j-1}) is $27\ell\delta/2$-far from the consistent pair $(\mathrm{C}_j(x_{j,\lceil i/b^{\ell-j}\rceil}), \mathrm{C}_{j-1}(x_{j-1,\lceil i/b^{\ell-j+1}\rceil}))$ and is $(\delta_0 - 27\ell\delta)/2$-far from any other consistent pair. Using $\delta_{\mathrm{pcpp}} = 13\ell\delta < \min(27\ell\delta/2, (\delta_0 - 27\ell\delta)/2)$, which holds because $\delta \leq \delta_0/81\ell$, it follows that in the current case the PCPP verifier accepts (and the decoder does not output $\perp$) with probability at most 1/9.

Thus, in total, the decoder outputs $\neg x_i$ with probability at most 1/3. □

Conclusion (restatement of Theorem 1.5). *For every constant $\varepsilon > 0$, there exists a code $\mathrm{C} : \{0,1\}^k \to \{0,1\}^n$, where $n = k^{1+\varepsilon}$, that is relaxed locally decodable under Definition* 4.11. *The query complexity of the corresponding decoder is $O(1/\varepsilon^2)$ and the proximity parameter is $\varepsilon/O(1)$.*

Open problem. We wonder whether one can obtain a relaxed LDC that can be decoded using q queries while having length $n = o(k^{1+/(q-1)})$. The existence of such a relaxed LDC will imply that our relaxation (i.e., relaxed LDC) is actually strict, because such codes will beat the lower-bound currently known for LDC (cf. [KT00]). Alternatively, it may be possible to improve the lower-bound for the (q-query) LDC to $n > k^{1+\sqrt{c/q}}$ for any constant c and every sufficiently large constant q (where, as usual, k is a parameter, whereas q is a fixed constant). In fact, some conjecture that n must be superpolynomial in k for any constant q.

4.3. Linearity of the codes. We note that the codes presented above (establishing both Theorems 1.4 and 1.5) are actually $\mathbb{F}_2$-linear codes whenever the base code C_0 is also $\mathbb{F}_2$-linear. Proving this assertion reduces to proving that the PCPPs used (in the aforementioned constructions) have proof oracles in which each bit is a linear function of the bits to which the proof refers. The main part of the latter task is undertaken in section 8.4, where we show the main construct (i.e., the PCPPs stated in Theorems 3.1 and 3.2) when applied to a linear circuit yields an $\mathbb{F}_2$-linear transformation of assignments (satisfying the circuit) to proof oracles (accepted by the verifier). In addition, we also need to show that the construction underlying the proof of Theorem 3.3 satisfies this property. This is done next, and consequently we get the following.

PROPOSITION 4.16. *If C is a linear circuit (see Definition* 8.13*), then there is a linear transformation T mapping satisfying assignments w of C to proof oracles $T(w)$ such that the PCPP verifier of Theorem* 3.3 *will, on input C, accept oracle $(w, T(w))$ with probability* 1*.*

Proof sketch. In section 8.4, we establish a corresponding result for the main construct (i.e., Proposition 8.14 refers to the linearity of the construction used in the proof of Theorem 3.1, which in turn underlies Theorems 3.1 and 3.2). Here we show that linearity is preserved in composition as well as by the most inner (i.e., bottom) verifier.

In each composition step, we append the proof oracle with new (inner) PCPPs per each test of the (outer) verifier. Since all these tests are linear, we can apply Proposition 8.14 and infer that the new appended information is a linear transformation of the input oracle and the outer proof oracle (where, by induction, the latter is a linear transformation of the input).

At the bottom level of composition we apply a Hadamard-based PCP (Appendix A). The encoding defined there is not $\mathbb{F}_2$-linear (rather it is quadratic), but this was necessary for dealing with nonlinear gates. It can be verified that for a linear circuit, one can perform all necessary tests of Appendix A with the Hadamard encoding of the input. Thus, we conclude that this final phase of the encoding is also linear, and this completes the proof of Proposition 4.16. ∎

Part II. The main construct: A short, robust PCPP.

5. Overview of our main construct. Throughout this section, n denotes the length of the explicit input given to the PCPP verifier, which in the case of CKTVAL is defined as the size of the circuit (given as explicit input). As stated in the introduction, our main results rely on the following highly efficient robust PCPP.

THEOREM 3.1 (main construct restated). *There exists a universal constant c such that for all $n, m \in \mathbb{Z}^+$, $0 < \delta, \gamma < 1/2$ satisfying $n^{1/m} \geq m^{cm}/(\gamma\delta)^3$ and $\delta \leq \gamma/c$,* CKTVAL *has a robust PCPP (for circuits of size n) with the following parameters:*

- *randomness $\left(1 - \frac{1}{m}\right) \log n + O(m \log m) + O(\log \log n) + O(\log(1/\delta))$;*
- *decision complexity $n^{1/m} \cdot \mathrm{poly}(\log n, 1/\delta)$, which also upper-bounds the query complexity;*[22]
- *perfect completeness; and*
- *for proximity parameter δ, the verifier has robust-soundness error $\Omega(\gamma)$ with robustness parameter $(1 - \gamma)\delta$.*

A (simplified) variant of Theorem 3.1 also yields the ALMSS-type robust PCPP (of Theorem 3.2). Following is an overview of the proof of Theorem 3.1; the actual proof is given in the subsequent three sections.

Theorem 3.1 is proved by modifying a construction that establishes Theorem 1.1. We follow [HS00] and modify their construction. (An alternative approach would be to start from [PS94], but that construction does not seem amenable to achieving robust soundness.) The construction of [HS00] may be abstracted as follows: To verify the satisfiability of a circuit of size n, a verifier expects oracles $\mathrm{A}_i : \mathbb{F}^m \to \mathbb{F}$, $i \in \{1 \ldots, t = \mathrm{poly} \log n\}$, where $\mathbb{F}$ is a field and m is a parameter such that $|\mathbb{F}^m| \approx m^m \cdot n$. The verifier then needs to test that (1) each of the A_i's is close to an m-variate polynomial of *low degree* and (2) the polynomials satisfy some *consistency*

[22] In fact, we will upper-bound the query complexity by $q = n^{1/m} \cdot \mathrm{poly}(\log n, 1/\delta)$ and show that the verifier's decision can be implemented by a circuit of size $\widetilde{O}(q)$, which can also be bounded by $n^{1/m} \cdot \mathrm{poly}(\log n, 1/\delta)$ with a slightly larger unspecified polynomial.

properties which verify that A_i is locally consistent with A_{i-1}.[23] (These consistency checks include tests which depend on the input circuit and verify that A_i's actually encode a satisfying assignment to the circuit.)

We work within this framework—namely, our verifier will also try to access oracles for the A_i's and test low degreeness and consistency. Our key modification to this construction is a randomness reduction in the low-degree test obtained by using the small collection of (small-biased) lines of [BSVW03], while using only the "canonical" representations of these lines (and avoiding any complication that was introduced towards proof composition). In particular, unlike in [HS00, GS02, BSVW03], we cannot afford to pack the polynomials $A_1, \ldots, A_t$ into a single polynomial (by using an auxiliary variable that blows up the proof length by a factor of the size of the field in use). Instead, we just maintain all these t polynomials separately and test them separately to obtain Theorem 1.1. (In the traditional framework of parallelized PCPs, this would give an unaffordable increase in the number of (non-Boolean) queries. However, we will later ameliorate this loss by a bundling technique that will yield robust soundness.)

The resulting PCP is converted into a PCPP by comparing the input oracle (i.e., the supposed satisfying assignment to the circuit) to the proof oracle (which is supposed to include an encoding of the said assignment). That is, we read a random location of the input and the corresponding location of the proof oracle, and test for equality. Actually, these locations of the proof oracle must be accessed via a self-correction mechanism (rather than by merely probing at the desired points of comparison), since they constitute only a small part of the proof oracle (and thus corruptions there may not be detected). This technique was already suggested in [BFLS91].

The most complex and subtle part of the proof of Theorem 3.1 is establishing the robust-soundness property. We sketch how we do this below, first dealing with the low-degree test and the consistency tests separately, and then showing how to reconcile the two "different" fixes.

Low-degree tests of $A_1, \ldots, A_t$. Selecting a random line $\ell : \mathbb{F} \to \mathbb{F}^m$ (from the aforementioned sample space), we can check that (for each i) the restriction of A_i to the line ℓ (i.e., the function $f_i(j) \triangleq A_i(\ell(j))$) is a low-degree (univariate) polynomial. Each of these tests is *individually robust*; that is, if A_i is far from being a low-degree polynomial, then with high probability the restriction of A_i to a random line ℓ (in the sample space) is far from being a low-degree polynomial. The problem is that the conjunction of the t tests is not sufficiently robust; that is, if one of the A_i's is δ-far from being a low-degree polynomial, then it is guaranteed only that the sequence of t restrictions (i.e., the sequence of the f_i's) is (δ/t)-far from being a sequence of t low-degree (univariate) polynomials. Thus, robustness decreases by a factor of t, which we cannot afford for nonconstant t.

Our solution is to observe that we can "bundle" the t functions together into a function $\overline{A} : \mathbb{F}^m \to \mathbb{F}^t$ such that if one of the A_i's is far from being a low-degree polynomial, then the restriction of $\overline{A}$ to a random line will be far from being a bundling of t low-degree univariate polynomials. Specifically, for every $x \in \mathbb{F}^m$, define $\overline{A}(x) \triangleq (A_1(x), \ldots, A_t(x))$. To test that $\overline{A}$ is a bundling of low-degree polynomials, select a

[23] Strictly speaking, the consistency checks are a little more complicated, with the functions really being indexed by two subscripts, and consistency tests being between $A_{i,j}$ and $A_{i,j-1}$, as well as between $A_{i,0}$ and $A_{i+1,0}$. However, these differences don't alter our task significantly—we ignore them in this section to simplify our notation.

random line ℓ (as above), and check that $\overline{f}_\ell(j) = \overline{\mathrm{A}}(\ell(j))$ is a bundling of low-degree univariate polynomials. Thus, we establish *robustness at the bundle level*; that is, if one of the A_i's is far from being low degree then, with high probability, one must modify $\overline{f}_\ell$ on a constant fraction of values in order to make the test accept. The point is that this robustness refers to the Hamming distance over the alphabet $\mathbb{F}^t$, rather than alphabet $\mathbb{F}$ as before. We can afford this increase in alphabet size, as we later encode the values of $\overline{\mathrm{A}}$ using an error-correcting code in order to derive *robustness at the bit level*.

We wish to highlight a key point that makes the above approach work: when we look at the values of $\overline{\mathrm{A}}$ restricted to a random line, we get the values of the individual A_i's restricted to a random line, which is exactly what a low-degree test of each A_i needs. This fact is not very surprising, given that we are subjecting all A_i's to the same test. *But what happens when we need to make two different types of tests?* This question is not academic and does come up in the consistency tests.

Consistency tests. To bundle the t consistency tests between A_i and A_{i+1} we need to look into the structure of these tests. We note that for every i, a random test essentially refers to the values of A_i and A_{i+1} on (random) ith axis-parallel lines. That is, for every i, and a random $x' = (x_1, \ldots, x_{i-1}) \in \mathbb{F}^{i-1}$ and $x'' = (x_{i+1}, \ldots, x_m) \in \mathbb{F}^{m-i}$, we need to check some relation between $\mathrm{A}_i(x', \cdot, x'')$ and $\mathrm{A}_{i+1}(x', \cdot, x'')$.[24] Clearly, querying $\overline{\mathrm{A}}$ as above on the ith axis-parallel line, we can obtain the relevant values from $\overline{\mathrm{A}}(x', \cdot, x'')$, but this works only for one specific value of i, and other values of i will require us to make other queries. The end result is that we gain nothing from the bundling (i.e., from $\overline{\mathrm{A}}$) over using the individual A_i's, which yields a factor of t loss in the robustness.[25] Fortunately, a different bundling works in this case.

Consider $\overline{\mathrm{A}}'$ such that $\overline{\mathrm{A}}'(x) \triangleq (\mathrm{A}_1(x), \mathrm{A}_2(S(x)), \ldots, \mathrm{A}_t(S^{t-1}(x)))$, for every $x \in \mathbb{F}^m$, where S denotes a (right) cyclic-shift (i.e., $S(x_1, \ldots, x_m) = (x_m, x_1, \ldots, x_{m-1})$ and $S^i(x_1, \ldots, x_m) = (x_{m-(i-1)}, \ldots, x_m, x_1, x_2, \ldots, x_{m-i})$). Now, if we ask for the value of $\overline{\mathrm{A}}'$ on the first and last axis-parallel lines (i.e., on $(\cdot, x_2, \ldots, x_m)$ and $(x_2, \ldots, x_m, \cdot) = S^{-1}(\cdot, x_2, \ldots, x_m)$), then we get all we need for all the m tests. Specifically, for every i, the ith component in the bundled function $\overline{\mathrm{A}}'(\cdot, x_2, \ldots, x_m)$ is $\mathrm{A}_i(S^{i-1}(\cdot, x_2, \ldots, x_m)) = \mathrm{A}_i(x_{m-i+2}, \ldots, x_m, \cdot, x_2, \ldots, x_{m-i+1})$, whereas the $(i+1)$st component in $\overline{\mathrm{A}}'(S^{-1}(\cdot, x_2, \ldots, x_m))$ is $\mathrm{A}_{i+1}(S^i(S^{-1}(\cdot, x_2 \ldots, x_m))) = \mathrm{A}_{i+1}(x_{m-i+2}, \ldots, x_m, \cdot, x_2, \ldots, x_{m-i+1})$. Thus, we need only query two bundles (rather than t), and robustness drops only by a constant factor.

Reconciling the two bundlings. But what happens with the low-degree tests that we need to do (which were "served" nicely by the original bundling $\overline{\mathrm{A}}$)? Note that we cannot use both $\overline{\mathrm{A}}$ and $\overline{\mathrm{A}}'$, because this will requires testing consistency between them, which will introduce new problems as well as a cost in randomness that we cannot afford. Fortunately, the new bundling (i.e., $\overline{\mathrm{A}}'$), designed to serve the axis-parallel line comparisons, can also serve the low-degree tests. Indeed, the various A_i's will not be inspected on the same lines, but this does not matter, because the property of being a low-degree polynomial is preserved when "shifted" (under S).

[24] Again, this is an oversimplification but suffices to convey the main idea of our solution.

[25] It turns out that for constant m (e.g., $m = 2$) this does not pose a problem. However, a constant m would suffice only for proving a slightly weaker version of Theorem 1.2 (where $o(\log \log n)$ is replaced by $\log \log n$) and not for proving Theorem 1.3, which requires setting and $m = \log^\varepsilon n$ for constant $\varepsilon > 0$.

Tightening the gap between robustness and proximity. The above description suffices for deriving a weaker version of Theorem 3.1 in which the robustness is only, say, $\delta/3$ rather than $(1-\gamma)\delta$ for a parameter γ that may be set as low as $1/\mathrm{poly}(\log n)$. Such a weaker result yields a weaker version of Theorem 3.3 in which the query complexity is exponentially larger (e.g., for proof length $\exp(o(\log\log n)^2)\cdot n$, we would have obtained query complexity $\exp(o(\log\log n)) = \log^{o(1)} n$ rather than $o(\log\log n)$); see the comment at the end of section 3.1. To obtain the stronger bound on the robustness parameter, we take a closer look at the conjunction of the standard PCP test and the proximity test. The PCP test can be shown to have constant robustness $c > 0$, whereas the proximity test can be shown to have robustness $\delta' \triangleq (1-\gamma)\delta$. When combining the two tests, we obtain robustness equal to $\min(\alpha c, (1-\alpha)\delta')$, where α is the relative length of queries used in the PCP test (as a fraction of the total number of queries). A natural choice, which yields the weaker result, is to weight the queries (or replicate the smaller part) so that $\alpha = 1/2$. (This yields robustness of approximately $\min(c,\delta')/2$.) In order to obtain the stronger bound, we assign weights such that $\alpha = \gamma$, and obtain robustness $\min(\gamma c, (1-\gamma)\delta') > \min(\Omega(\gamma), (1-2\gamma)\delta)$, which simplifies to $(1-2\gamma)\delta$ for $\delta < \gamma/O(1)$. (The above description avoids the fact that the PCP test has constant soundness error, but the soundness error can be decreased to γ by using sequential repetitions while paying a minor cost in randomness and *while approximately preserving the robustness*. We comment that the proximity test, as is, has soundness error γ.)

6. A randomness-efficient PCP. In this section, we present a "vanilla" version (Theorem 6.1) of Theorem 3.1. More specifically, we construct a regular PCP for CktSAT (i.e., a robust PCPP without either the robustness or proximity properties). We favor this construction over earlier PCP constructions in the fact that it is very efficient in randomness. As mentioned earlier, this theorem suffices to prove Theorem 1.1.

THEOREM 6.1. *There exists a universal constant* $0 < \varepsilon < 1$ *such that the following holds. Suppose* $m \in \mathbb{Z}^+$ *satisfies* $m \le \log n/\log\log n$. *Then there exists a PCP for* CktSAT *(for circuits of size* n*) with the following parameters:*

- *randomness* $(1-\frac{1}{m})\log n + O(m\log m) + O(\log\log n)$,
- *query complexity* $q = O(m^2 n^{1/m}\log^2 n)$ *and decision complexity* $\widetilde{O}(q)$,
- *perfect completeness,*
- *and soundness error* $1-\varepsilon$.

The construction of the PCP for CktSAT proceeds in three steps. First, we transform the input circuit φ into a well-structured circuit φ' along the lines of Polishchuk and Spielman [PS94, Spi95] (section 6.1). φ' is only slightly larger than φ, but has an algebraic structure that will be crucial to our verification process. Any legal assignment to the gates of φ (i.e., one that preserves the functionality of the gates of φ) can be transformed into a legal assignment to φ'. The important property of φ' is the following: If we encode an assignment to the gates of φ' using a specific sequence of Reed–Muller codewords (i.e., low-degree polynomials), then the legality of the assignment can be locally verified (by reading a small random portion of the encoding). The encoding via low-degree polynomials (and resulting local tests) is as in Harsha and Sudan [HS00] and is described in section 6.2. Thus, our PCP verifier will essentially test (i) that the encoding of the purported satisfying assignment to φ' is formed of low-degree polynomials (this part will be done using the randomness-efficient low-degree test of Ben Sasson et al. [BSVW03]); and (ii) that the assignment is legal. Section 6.3 describes the construction of the PCP verifier and section 6.4

analyzes its properties. Most of the above results are implicit in the literature, but carefully abstracting the results and putting them together helps us in significantly reducing the randomness of the PCP verifier.

6.1. Well-structured Boolean circuits. The main problem with designing a randomness-efficient PCP verifier directly for CktSAT is that we need to encode the assignment to all gates of the input circuit using certain Reed–Muller based codes, in such a way that will allow us to locally verify the legality of all gates of the circuit, using only the encoded assignment. In order to do this, we require the circuit to have a well-behaved structure (amenable to our specific encoding and verification demands). Of course, an arbitrary circuit does not necessarily have this structure, but we are lucky to have the technology to overcome this. More to the point, we can restructure any circuit into a well-behaved circuit that will suit our needs. The natural encoding (used, e.g., in the Hadamard-based PCP, Appendix A) incurs a quadratic blow-up in length. To get over this problem, Polishchuk and Spielman [PS94, Spi95] introduced a different, more efficient restructuring process that embeds the input circuit into well-structured graphs known as de Bruijn graphs. Indeed, the blow-up in circuit size using these circuits is merely by a logarithmic multiplicative factor, and their usefulness for the local verification of legal assignments will become evident later (in section 6.2). As in Polishchuk and Spielman [PS94, Spi95], we embed the input circuit into wrapped de Bruijn graphs (see Definition 6.2). We use a slightly different definition of de Bruijn graphs, more convenient for our purposes, than that used in [PS94, Spi95]. However, it can be easily checked that these two definitions yield isomorphic graphs. The main advantage with the de Bruijn graphs is that the neighborhood relations can be expressed very easily using simple bit-operations like cyclic-shifts and bit-flips. In [PS94, Spi95] the vertex set of these graphs is *identified* with a vector space. We instead work with a strict embedding of these graphs in a vector space, where the vertices are a *strict* subset of the vector space. The benefit of both approaches is that the neighborhood functions can be expressed as an affine functions (see section 6.2 for more details). The reason for our approach will be explained at the end of section 6.2.

Definition 6.2. *The wrapped de Bruijn graph $\mathcal{G}_{N,l}$ is a directed graph with l layers, each with 2^N nodes which are represented by N-bit strings. The layers are numbered $0, 1, \ldots, l-1$. The node represented by $v = (b_0, \ldots, b_{i^*}, \ldots, b_{N-1})$ in layer i has edges pointing to the nodes represented by $\Gamma_{i,0}(v) = (b_0, \ldots, b_{i^*}, \ldots, b_{N-1})$ and $\Gamma_{i,1}(v) = (b_0, \ldots, b_{i^*} \oplus 1, \ldots, b_{N-1})$ in layer $(i+1)$ modulo l, where i^* is i modulo N and $a \oplus b$ denotes the sum of a and b modulo 2. See Figure 1 for an example.*

We now describe how to embed a circuit into a wrapped de Bruijn graph (see Figure 2 for a simple example). Given a circuit C with n gates (including both input and output gates), we associate with it a wrapped de Bruijn graph $\mathcal{G}_{N,l}$, where $N = \log n$ and $l = 5N = 5 \log n$. We then associate the nodes in layer 0 with the gates of the circuit. Now, we wish to map each wire in the circuit to a path in $\mathcal{G}_{N,l}$ between the corresponding nodes of layer 0. Standard packet-routing techniques (see [Lei92]) can be used to show that if the number of layers l is at least $5N$, then such a routing can be done with edge-disjoint paths. (Recall that we work with circuits whose fan-in and fan-out are 2.)

Thus, we can find "switches" for each of the nodes in layers $1, \ldots, l-1$ of the graph such that the output of each gate (i.e., node in layer 0) is routed to the input of the gates that require it. Each node has two inputs and two outputs, and thus there is a constant number of switches routing incoming edges to outgoing ones (see Figure 3).

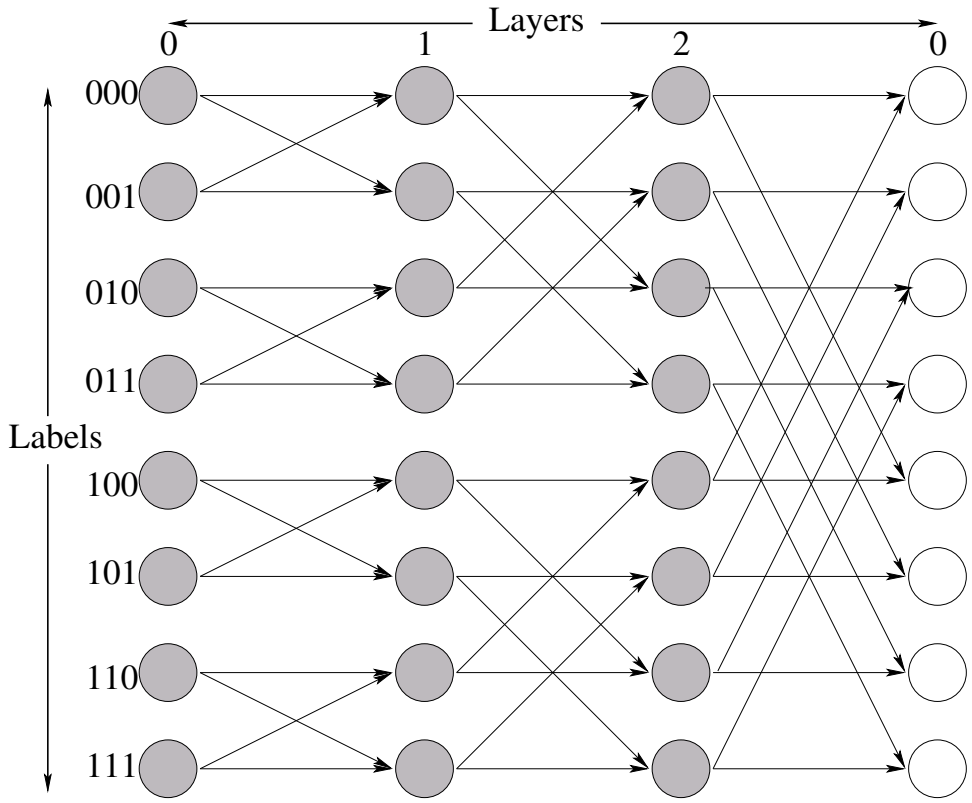

FIG. 1. *The wrapped de Bruijn graph $\mathcal{G}_{3,3}$. Notice the first and last layers are the same.*

For nodes in layer 0, instead of specifying a switch, we specify the functionality of the Boolean gate associated to that node in the circuit (e.g., AND, OR, PARITY, NOT, INPUT, OUTPUT). Actually unary gates (such as NOT and OUTPUT) have two forms (NOT, NOT′, OUTPUT, OUTPUT′) in order to specify which of the two incoming edges in the de Bruijn graph to use.

This specifies the embedding of the input circuit into a well-structured circuit (based on a de Bruijn graph). More precisely, let $\mathcal{C} = \{\text{type of switching actions}\} \cup \{\text{type of Boolean gates}\}$ be the set of allowable gates of the well-structured circuit (see Figure 3). Given a circuit on n gates, we can construct, in polynomial time, a wrapped de Bruijn graph $\mathcal{G}_{N,l}$ (where $N = \log n$ and $l = 5 \log N$) and l functions $T_0, T_1, \ldots, T_{l-1} : \{0,1\}^N \to \mathcal{C}$, where each function T_i is a specification of the gates of layer i (i.e., a specification of the switching action or Boolean functionality).

We now demonstrate how to translate a proof that a circuit is satisfiable into an assignment that satisfies the embedded circuit. A proof that a circuit is satisfiable consists of an assignment of 0's and 1's to the inputs and the gates of the circuit such that each gate's output is consistent with its inputs and the output gate evaluates to 1. The corresponding assignment to the embedded circuit consists of an assignment of 0's and 1's to the edges entering and leaving the nodes of the wrapped de Bruijn graph that is consistent with the functionality of the gates (in layer 0) and the switching actions of the nodes (in the other layers). Since we are assigning values to nodes of the embedded graph (and not their edges), the assignment actually associates a 4-tuple

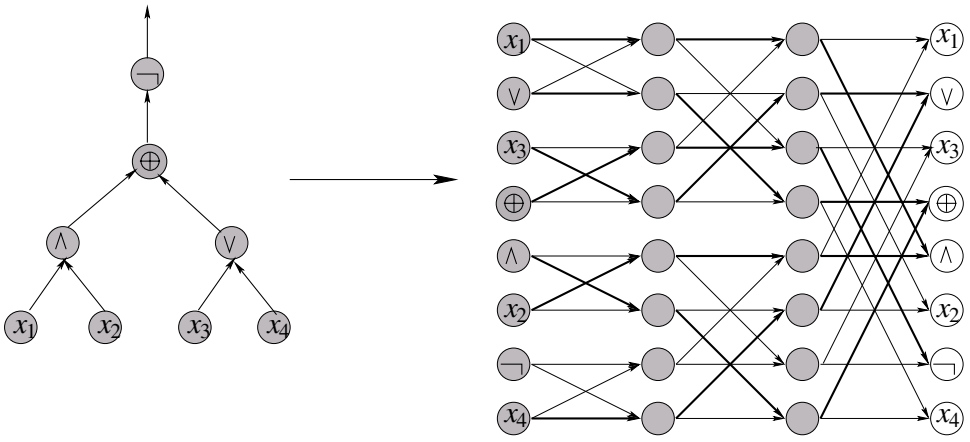

FIG. 2. *Embedding of a circuit into* $\mathcal{G}_{3,3}$. *In this example all paths between nodes at the* 0 *layer are vertex disjoint. For general circuits we merely need edge disjoint paths.*

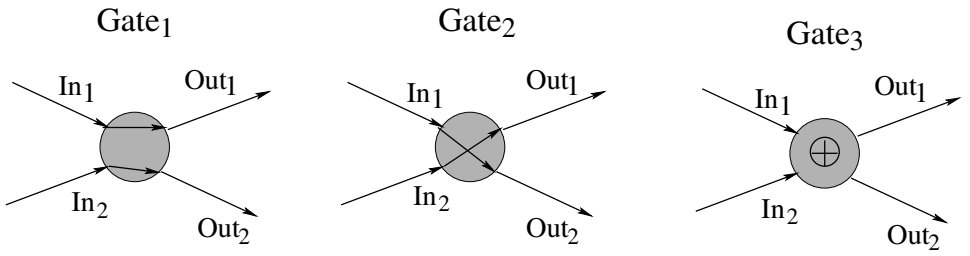

FIG. 3. *Some gates of a well-structured circuit. Gates* 1–2 *are switching gates, and gate* 3 *sits in layer* 0 *and computes the parity (xor) function.*

of 0's and 1's to each of the nodes in the graph indicating the value carried by the four edges incident at that node (two incoming and two outgoing). More formally, the embedded assignment is given by a set of l functions $A_0, A_1, \ldots, A_{l-1}$, where each function $A_i : \{0,1\}^N \to \{0,1\}^4$ specifies the values carried by the four edges incident at that vertex.

We now list the constraints on the embedded circuit that assure us that the only legal assignments are the ones that correspond to legal satisfying assignments of the original circuit, i.e., assignments that correctly propagate along the edges of the circuit, correctly compute the value of every gate, and produce a 1 at the output gate.

DEFINITION 6.3. *The* assignment constraints *for each node of the well-structured circuit require that*

- *the two outgoing values at the node are propagated correctly to the incoming values of its neighbors at the next level;*
- *for nodes at layers* $\neq 0$, *the two outgoing values have the unique values dictated by the incoming values and the switching action;*
- *for non-OUTPUT nodes in layer* 0, *both outgoing values equal the unique value dictated by the gate functionality and the incoming values (the INPUT functionality merely requires that the two outgoing values are equal to each other);*
- *for nodes in layer* 0 *with an OUTPUT functionality, the appropriate incoming*

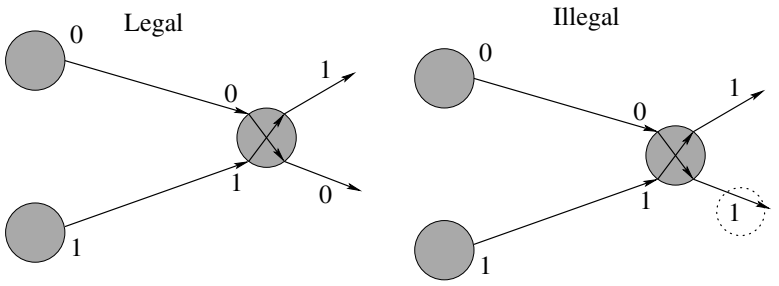

FIG. 4. *Example of legal and illegal assignments. The two vertices on the left are the inputs (at layer $i-1$) to a gate at layer i. Recall that assignments evaluate each incoming and outgoing edge of a gate.*

value equals 1.

Let $\psi : \mathcal{C} \times (\{0,1\}^4)^3 \to \{0,1\}$ be the Boolean function such that $\psi(t, a, a_0, a_1) = 0$ iff a node whose T-gate is t, A-assignment is a, and whose neighbors in the next layer have A-assignments a_0 and a_1, respectively, satisfies the aforementioned assignment constraints. See Figure 4 *for an example of legal and illegal assignments.*

Observe that the definition of ψ is independent of N, the assignments A_i, and gates T_i. By definition, the assignment $A = (A_0, \ldots, A_{l-1})$ is legal for an embedded circuit defined by $T_0, \ldots, T_{l-1}$ iff for every layer i and every node v in layer i,

$$\psi\Big(T_i(v), A_i(v), A_{i+1}\big(\Gamma_{i,0}(v)\big), A_{i+1}\big(\Gamma_{i,1}(v)\big)\Big) = 0.$$

We are now ready to formally define the well-structured circuit satisfiability problem (STRUCTURED-CKTSAT).

DEFINITION 6.4. *The problem* STRUCTURED-CKTSAT *has as its instances $\langle \mathcal{G}_{N,l}, \{T_0, T_1, \ldots, T_{l-1}\}\rangle$, where $\mathcal{G}_{N,l}$ is a wrapped de Bruijn graph with l layers and $T_i : \{0,1\}^N \to \mathcal{C}$ is a specification of the node types of layer i of the graph (T_i's are specified by a table of values).*

$\langle \mathcal{G}_{N,l}, \{T_0, \ldots, T_{l-1}\}\rangle \in$ STRUCTURED-CKTSAT *if there exists a set of assignments $A_0, A_1, \ldots, A_{l-1}$, where $A_i : \{0,1\}^N \to \{0,1\}^4$ is an assignment to the nodes of layer i of $\mathcal{G}_N$ such that for all layers i and all nodes v in layer i,*

$$\psi\Big(T_i(v), A_i(v), A_{i+1}\big(\Gamma_{i,0}(v)\big), A_{i+1}\big(\Gamma_{i,1}(v)\big)\Big) = 0.$$

The above discussion also demonstrates the existence of a reduction from CKTSAT to STRUCTURED-CKTSAT, which does not blow up the length of the target instance by more than a logarithmic multiplicative factor.

PROPOSITION 6.5. *There exists a polynomial-time reduction $\mathcal{R}$ from* CKTSAT *to* STRUCTURED-CKTSAT *such that for any circuit C, it holds that $C \in$* CKTSAT *iff $\mathcal{R}(C) \in$* STRUCTURED-CKTSAT. *Moreover, if C is a circuit of size n, then $\mathcal{R}(C) = \langle \mathcal{G}_{N,l}, \{T_0, \ldots, T_{l-1}\}\rangle$, where $N = \lceil \log n \rceil$ and $l = 5N$.*

Remark 6.6. The above reduction, though known to take polynomial time (via routing techniques), is not known to be of almost linear time.

Remark 6.7. We observe that if C is a satisfiable circuit, then any set of assignments $A_0, \ldots, A_l$ proving that the reduced instance $\mathcal{R}(C) = \langle \mathcal{G}_{N,l}, \{T_0, \ldots, T_{l-1}\}\rangle$ is a YES instance of STRUCTURED-CKTSAT contains within it a satisfying assignment

to the circuit C. Specifically, let I be the set of nodes in layer 0 that have gate functionality INPUT associated with them. Then the assignment A_0 restricted to the set of nodes I (i.e., $A_0|_I$) contains a satisfying assignment. More precisely, the satisfying assignment is obtained by concatenating the third bit (i.e., first outgoing bit) of $A_0|_i \in \{0,1\}^4$ for all $i \in I$. Conversely, every satisfying assignment w to C can be extended to $A_0, \ldots, A_{l-1}$ such that $A_0|_I$ contains w. This is done by computing the values of all gates in the computation of $C(w)$, setting the outgoing bits of A_0 according to these values, and routing them throughout $\mathcal{G}_{N,l}$ according to the switching actions to obtain $A_1, \ldots, A_{l-1}$ and the incoming bits of A_0. This observation will be vital while constructing PCPPs (see section 7).

Remark 6.8. Suppose the input circuit C is a *linear* circuit, in the sense that all gates are INPUT, OUTPUT, or PARITY gates, and the OUTPUT gates test for 0 rather 1 (see Definition 8.13). Then it can be verified that the transformation mapping satisfying assignments w of C to legal assignments $A_0, \ldots, A_{l-1}$ of $\mathcal{R}(C)$ is $\mathbb{F}_2$-linear. The reason is that each gate in the computation of $C(w)$ is an $\mathbb{F}_2$-linear function of w. These remarks will be used in the coding applications, to obtain linear codes (see section 8.4 for more information).

6.2. Arithmetization. In this section, we construct an algebraic version of Structured-CktSAT by arithmetizing it along the lines of Harsha and Sudan [HS00]. The broad overview of the arithmetization is as follows: We embed the nodes in each layer of the wrapped de Bruijn graph $\mathcal{G}_{N,l}$ into a vector space and extend the gate specifications and assignments to low-degree polynomials over this space. Finally, we express the assignment constraints (see Definition 6.3) as a pair of polynomial identities satisfied by these polynomials.

First, we have some notation. Let m be a parameter. Set h such that $h = N/m$, where 2^N is the number of nodes in each layer of the de Bruijn graph. Choose a finite extension field $\mathbb{F}$ of $\mathbb{F}_2$ of size roughly $c_F m^2 2^h = c_F m^2 2^{N/m}$, where c_F is a suitably large constant to be specified later. Specifically, take $\mathbb{F} = \mathbb{F}_2^{\mathcal{U}} = \mathbb{F}_{2^{\mathcal{U}}}$ for $\mathcal{U} = h + 2\log m + \log c_F$. Let $\{e_0, e_1, \ldots, e_{\mathcal{U}-1}\}$ be a basis of $\mathbb{F}$ over $\mathbb{F}_2$. Set H to be a subspace of $\mathbb{F}_2^{\mathcal{U}}$ (and hence a subset of $\mathbb{F}$) spanned by $\{e_0, \ldots, e_{h-1}\}$. Note that H^m is a subset of the space $\mathbb{F}^m$. Furthermore, $|H^m| = 2^N$. Hence, we can embed each layer of the graph $\mathcal{G}_{N,l}$ in $\mathbb{F}^m$ by identifying the node $v = (b_0, \ldots, b_{N-1}) \in \{0,1\}^N$ with the element $(b_0 e_0 + \cdots + b_{h-1} e_{h-1}, b_h e_0 + \cdots + b_{2h-1} e_{h-1}, \ldots, b_{(m-1)h} e_0 + \cdots + b_{mh-1} e_{h-1})$ of H^m. Henceforth, we use both representations (N-bit string and element of H^m) interchangeably. The representation will be clear from the context.

Any assignment $S : H^m \to \mathbb{F}$ can be interpolated to obtain a polynomial $\tilde{S} : \mathbb{F}^m \to \mathbb{F}$ of degree at most $|H|$ in each variable (and hence a total degree of at most $m|H|$) such that $\tilde{S}|_{H^m} = S$ (i.e., the restriction of $\tilde{S}$ to H^m coincides with the function S). Conversely, any polynomial $\tilde{S} : \mathbb{F}^m \to \mathbb{F}$ can be interpreted as an assignment from H^m to $\mathbb{F}$ by considering the function restricted to the subdomain H^m.

Recall that $\mathcal{C}$ and $\{0,1\}^4$ are the set of allowable gates and assignments given by the gate functions T_i and assignments A_i in the Structured-CktSAT problem. We identify $\mathcal{C}$ with a fixed subset of $\mathbb{F}$ and identify $\{0,1\}^4$ with the set of elements spanned by $\{e_0, e_1, e_2, e_3\}$ over $\mathbb{F}_2$. With this identification, we can view the assignments A_i and gates T_i as functions $A_i : H^m \to \mathbb{F}$ and $T_i : H^m \to \mathbb{F}$, respectively. Furthermore, we can interpolate these functions, as mentioned above, to obtain polynomials $\tilde{A}_i : \mathbb{F}^m \to \mathbb{F}$ and $\tilde{T}_i : \mathbb{F}^m \to \mathbb{F}$ of degree at most $m|H|$ over $\mathbb{F}$.

We now express the neighborhood functions of the graph in terms of affine functions over $\mathbb{F}^m$. This is where the nice structure of the wrapped de Bruijn graph will be

useful. For any positive integer i, define affine transformations $\tilde{\Gamma}_{i,0}, \tilde{\Gamma}_{i,1} : \mathbb{F}^m \to \mathbb{F}^m$ as follows: $\tilde{\Gamma}_{i,0}$ is the identity function. For $\tilde{\Gamma}_{i,1}$, first let $t = \lfloor i/h \rfloor \bmod m$ and $u = i \bmod h$. Then $\tilde{\Gamma}_{i,1}(z_0, \ldots, z_{m-1}) = (z_0, \ldots, z_{t-1}, z_t + e_u, z_{t+1}, \ldots, z_{m-1})$.[26] It can be checked from the above definition that for any layer i and node x in layer i (which we view as a point in H^m), we have $\tilde{\Gamma}_{i,j}(x) = \Gamma_{i,j}(x)$ for $j = 0, 1$. In other words, $\tilde{\Gamma}$ is an extension of the neighborhood relations of the graph $\mathcal{G}_{N,l}$ over $\mathbb{F}^m$.

Finally, we now express the assignment constraints (see Definition 6.3) as polynomial identities. The first of these identities checks that the assignments given by the assignment polynomial $\tilde{A}_i$ are actually elements of $\{0,1\}^4$ for points in H^m. For this purpose, let $\psi_0 : \mathbb{F} \to \mathbb{F}$ be the univariate polynomial of degree 2^4 given by

$$\psi_0(z) = \prod_{\alpha \in \{0,1\}^4} (z - \alpha). \tag{6.1}$$

This polynomial satisfies $\psi_0(z) = 0$ iff $z \in \{0,1\}^4$ (recall we identified $\{0,1\}^4$ with a subset of $\mathbb{F}$ spanned by $e_0, \ldots, e_3$). We check that $\psi_0(\tilde{A}_i(x)) = 0$ for all $x \in H^m$ and all layers i. We then arithmetize the rule ψ (from Definition 6.3) to obtain a polynomial $\psi_1 : \mathbb{F}^4 \to \mathbb{F}$. In other words, $\psi_1 : \mathbb{F}^4 \to \mathbb{F}$ is a polynomial such that $\psi_1(t, a, a_0, a_1) = \psi(t, a, a_0, a_1)$ for all $(t, a, a_0, a_1) \in \mathcal{C} \times (\{0,1\}^4)^3$. The degree of ψ_1 can be made constant, because $|\mathcal{C}|$ and $|\{0,1\}^4|$ are constant.[27] The two polynomial identities we would like to check are $\psi_0(\tilde{A}_i(x)) = 0$ and $\psi_1(\tilde{T}_i(x), \tilde{A}_i(x), \tilde{A}_{i+1}(\tilde{\Gamma}_{i,0}(x)), \tilde{A}_{i+1}(\tilde{\Gamma}_{i,1}(x))) = 0$ for all $x \in H^m$. For notational convenience, we express these two conditions together as a pair of polynomials $\psi' = (\psi_0, \psi_1) : \mathbb{F}^4 \to \mathbb{F}^2$ such that $\psi'(x_1, x_2, x_2, x_4) = (\psi_0(x_2), \psi_1(x_1, x_2, x_3, x_4))$.[28] Let κ be the maximum of the degree of these two polynomials. In order to make these polynomial identities sufficiently redundant, we set c_F to be a sufficiently large constant (say 100) such that $\kappa m^2 2^h / |\mathbb{F}|$ is low.

We have thus reduced Structured-CktSAT to an algebraic consistency problem, which we shall call the AS-CktSAT(Algebraic-Structured-CktSAT) problem.[29]

Definition 6.9. *The promise problem* AS-CktSAT = (AS-CktSAT$^{\text{YES}}$, AS-CktSAT$^{\text{NO}}$) *has as its instances* $\langle 1^n, 1^m, \mathbb{F}, H, \{\tilde{T}_0, \ldots, \tilde{T}_{l-1}\}\rangle$, *where* $\mathbb{F}$ *is a finite extension field of* $\mathbb{F}_2$ *(i.e.,* $\mathbb{F} = \mathbb{F}_{2^\upsilon}$ *for some* υ*),* H *an* $\mathbb{F}_2$*-linear subspace of* $\mathbb{F}$*, and* $\tilde{T}_i : \mathbb{F}^m \to \mathbb{F}$ *for* $i = 0, \ldots, l-1$ *a sequence of polynomials of degree* d*, where* $|H| = n^{1/m}$*,*

[26] An alternate description of $\tilde{\Gamma}_{i,1}$ is as follows: Since $\mathbb{F} = \mathbb{F}_2^\upsilon$, we can view $\mathbb{F}^m$ as an $m\upsilon$-dimensional space over $\mathbb{F}_2$. Hence, any vector $(z_0, \ldots, z_{m-1})$ can be written as $(b_{0,0}, \ldots, b_{0,\upsilon-1}, b_{1,0}, \ldots, b_{1,\upsilon-1}, \ldots, b_{m-1,0}, \ldots, b_{m-1,\upsilon-1})$. Furthermore, we note that for any vector $(z_0, \ldots, z_{m-1})$ in H^m, $b_{r,s} = 0$ for all $s \geq h$ and all r. It can now be checked that $\tilde{\Gamma}_{i,1}$ is the affine transformation that flips the bit $b_{t,u}$, where $t = \lfloor i/h \rfloor \bmod m$ and $u = i \bmod h$.

[27] Notice that we do not specify ψ_1 uniquely at this stage. Any choice of a constant-degree polynomial will work in this section, but to enforce linearity, we will use a somewhat nonstandard choice in section 8.4. Specifically, we argue that if C is a linear circuit, then ψ_1 can be picked to be an $\mathbb{F}_2$-linear transformation, and we point out that ψ_0 is an $\mathbb{F}_2$-linear transformation. For more details see section 8.4.

[28] An alternative approach (which we do not follow) to combine ψ_0 and ψ_1 into a single polynomial ψ was suggested to us by Sergey Yekhanin and Jaikumar Radhakrishnan. Let $p(x)$ be a monic, quadratic, irreducible polynomial over the field $\mathbb{F}$. Let $Q(x, y) = y^2 \cdot p(x, y)$. Now Q satisfies the property that $Q(a, b) = 0$ iff $a = b = 0$. (Proof: Q is homogeneous and so $Q(0, 0) = 0$; if $b = 0$, $Q(a, 0) = a^2$ (since p is monic) and so is zero only if $a = 0$. If $b \neq 0$, then $Q(a, b) = 0$ only if $p(a/b) = 0$, but p has no roots in $\mathbb{F}$.) Now define $\psi(x) = Q(\psi_0(x), \psi_1(x))$. For instance, over fields of odd characteristic, $\psi(x) = \psi_0^2(x) - \alpha \cdot \psi_1^2(x)$, where α is a nonsquare in $\mathbb{F}$ will work. ψ can be thought of as an "algebraic AND" of ψ_0 and ψ_1, since ψ' satisfies the property that $\psi(x) = 0$ iff $\psi_0(x) = 0$ and $\psi_1(x) = 0$.

[29] AS-CktSAT is actually a promise problem.

$d = m \cdot |H|$, and $|\mathbb{F}| = c_F \cdot md$. The field $\mathbb{F}$ is specified by an irreducible polynomial $p(x)$ of degree f over $\mathbb{F}_2$, H is taken to be spanned by the first $h = \log |H|$ canonical basis elements, and each of the polynomials $\tilde{T}_i$ is specified by a list of coefficients as follows:

- *$\langle 1^n, 1^m, \mathbb{F}, H, \{\tilde{T}_0, \ldots, \tilde{T}_{l-1}\}\rangle \in$ AS-CktSAT$^{\text{YES}}$ if there exists a sequence of degree d polynomials $\tilde{A}_i : \mathbb{F}^m \to \mathbb{F}, i = 0, \ldots, l-1$, such that for all $i = 0, \ldots, l-1$ and all $x \in H^m$,*

$$\psi'\left(\tilde{T}_i(x), \tilde{A}_i(x), \tilde{A}_{i+1}\big(\tilde{\Gamma}_{i,0}(x)\big), \tilde{A}_{i+1}\big(\tilde{\Gamma}_{i,1}(x)\big)\right) = (0,0).$$

- *$\langle 1^n, 1^m, \mathbb{F}, H, \{\tilde{T}_0, \ldots, \tilde{T}_{l-1}\}\rangle \in$ AS-CktSAT$^{\text{NO}}$ if for all functions $\tilde{A}_i : \mathbb{F}^m \to \mathbb{F}, i = 0, \ldots, l-1$, there exists an $i \in \{0, \ldots, l-1\}$ and $x \in H^m$ such that*

$$\psi'\left(\tilde{T}_i(x), \tilde{A}_i(x), \tilde{A}_{i+1}\big(\tilde{\Gamma}_{i,0}(x)\big), \tilde{A}_{i+1}\big(\tilde{\Gamma}_{i,1}(x)\big)\right) \neq (0,0),$$

where the $\tilde{\Gamma}_{i,j}$'s and ψ' are as defined earlier. (Recall that the $\tilde{\Gamma}$'s are linear functions while ψ' represents a pair of polynomials of degree at most κ.)

From the above discussion we have the following reduction from Structured-CktSAT to AS-CktSAT.

Proposition 6.10. *There exists a polynomial-time computable function $\mathcal{R}$ mapping any instance $\mathcal{I} = \langle \mathcal{G}_{N,l}, \{T_0, T_1, \ldots, T_{l-1}\}\rangle$ of* Structured-CktSAT *and parameter $m \leq \log n / \log\log n$ (where $n = |\mathcal{I}|$) to an instance $\mathcal{R}(\mathcal{I}, 1^m)$ of* AS-CktSAT *such that*

$$\mathcal{I} \in \text{Structured-CktSAT} \implies \mathcal{R}(\mathcal{I}, 1^m) \in \text{AS-CktSAT}^{\text{YES}},$$
$$\mathcal{I} \notin \text{Structured-CktSAT} \implies \mathcal{R}(\mathcal{I}, 1^m) \in \text{AS-CktSAT}^{\text{NO}}.$$

Moreover, if $\mathcal{R}(\mathcal{I}, 1^m) = \langle 1^{n'}, 1^{m'}, \mathbb{F}, H, \{\tilde{T}_0, \ldots, \tilde{T}_{l'-1}\}\rangle$, then $n' = 2^N$ (the number of nodes in each layer of the de Bruijn graph $\mathcal{G}_{N,l}$), $m' = m$, and $l' = l$ (the number of layers in the de Bruijn graph).

Combining Propositions 6.5 and 6.10, we have the following.

Proposition 6.11. *There exists a polynomial-time computable function $\mathcal{R}$ mapping any circuit C and parameter $m \leq \log n / \log\log n$ (where $n = |C|$) to an instance $\mathcal{R}(C, 1^m)$ of* AS-CktSAT *such that $C \in$ CktSAT $\iff \mathcal{R}(C, 1^m) \in$ AS-CktSAT.*

Moreover, if C is a circuit of size n, then $\mathcal{R}(C, 1^m) = \langle 1^{n'}, 1^{m'}, \mathbb{F}, H, \{\tilde{T}_0, \ldots, \tilde{T}_{l'-1}\}\rangle$ where $n' = \Theta(n)$, $m' = m$, and $l' \leq 5 \log n'$. Thus, $|\mathcal{R}(C, 1^m)| = O((c_F m^2)^m \log n) \cdot |C|$.

Remark 6.12. Following Remark 6.7, if C is a satisfiable circuit, then any set of polynomials $\tilde{A}_0, \ldots, \tilde{A}_{l-1}$ proving that the reduced instance $\mathcal{R}(C, 1^m) = \langle 1^n, 1^m, \mathbb{F}, H, \{\tilde{T}_0, \ldots, \tilde{T}_{l-1}\}\rangle$ is a YES instance of AS-CktSAT contains within it a satisfying assignment to the circuit C. Specifically, the set I (of layer 0 nodes with INPUT functionality in $\mathcal{G}_{N,l}$) from Remark 6.7 can now be viewed as a subset $I \subseteq H^m$. Then the polynomial $\tilde{A}_0 : \mathbb{F}^m \to \mathbb{F}$ restricted to the set I (i.e., $\tilde{A}_0|_I$) contains a satisfying assignment (again as a concatenation of third-bits). Conversely, every satisfying assignment w to C can be extended to a set of polynomials $\tilde{A}_0, \ldots, \tilde{A}_{l-1}$ such that $\tilde{A}_0|_I$ contains w. This is done by taking low-degree extensions of the functions $A_0, \ldots, A_{l-1}$ from Remark 6.7.

Remark 6.13. Following Remark 6.8, if C is a linear circuit, then the mapping of satisfying assignments w of C to polynomials $\tilde{A}_0, \ldots, \tilde{A}_{l-1}$ satisfying $\mathcal{R}(C)$ is $\mathbb{F}_2$-linear. This is due to Remark 6.8, the association of $\{0,1\}^4$ with the linear space

spanned by $\{e_0, e_1, e_2, e_3\}$ in $\mathbb{F}$, and from the fact that the interpolation from A_i to $\tilde{A}_i$ is $\mathbb{F}$-linear and hence $\mathbb{F}_2$-linear. For more information see section 8.4.

Comment. Recall that the arithmetization was obtained by considering low-degree extensions over $\mathbb{F}^m$ of functions from H^m to H. If H were a subfield of the field $\mathbb{F}$, this step would have caused a quadratic blow-up, and we avoid this problem by not insisting that H be a field. In [PS94, Spi95], H is a field and $\mathbb{F} = H^2$ is an extension of it, but the PCP system refers only to an $O(|H|)$-sized subset of $\mathbb{F}$. We cannot take this approach because we will be using a total low-degree test, which needs to refer to the entire vector space $\mathbb{F}^m$. In contrast, in [PS94, Spi95] an individual low-degree test is used, which can work with a subset of $\mathbb{F}^m$.

6.3. The PCP verifier. We design a PCP verifier for CktSAT via the reduction to AS-CktSAT based on the randomness-efficient low-degree tests of Ben-Sasson et al. [BSVW03]. Given a circuit C, the verifier reduces it to an instance of the problem AS-CktSAT (Proposition 6.11). The proof consists of a sequence of oracles $\tilde{A}_i : \mathbb{F}^m \to \mathbb{F}$ for $i = 0, \ldots, l-1$ and an auxiliary sequence of oracles $P_{i,j} : \mathbb{F}^m \to \mathbb{F}^2$ for $i = 0, \ldots, l-1$ and $j = 0, \ldots, m$. For each i and j, we view the auxiliary oracle $P_{i,j} : \mathbb{F}^m \to \mathbb{F}^2$ as a pair of functions $P_{i,j}^{(0)} : \mathbb{F}^m \to \mathbb{F}$ and $P_{i,j}^{(1)} : \mathbb{F}^m \to \mathbb{F}$ (i.e., $P_{i,j}(x) = (P_{i,j}^{(0)}(x), P_{i,j}^{(1)}(x))$). This auxiliary sequence of oracles helps the verifier to check that the functions $\tilde{A}_i$ satisfy condition ψ' (see Definition 6.9).

The verifier expects the first subsequence of auxiliary oracles $P_{i,0}(\cdot)$ for $i = 0, \ldots, l-1$, to satisfy the following relation:

$$P_{i,0}(x) = \psi'\left(\tilde{T}_i(x), \tilde{A}_i(x), \tilde{A}_{i+1}\big(\tilde{\Gamma}_{i,0}(x)\big), \tilde{A}_{i+1}\big(\tilde{\Gamma}_{i,1}(x)\big)\right) \quad \forall x \in \mathbb{F}^m. \tag{6.2}$$

Furthermore, it expects $P_{i,0}(x) = 0$ for every $x \in H^m$. Indeed, by Definition 6.9, we have the following.

Lemma 6.14.

1. *If* $\langle 1^n, 1^m, \mathbb{F}, H, \{\tilde{T}_0, \ldots, \tilde{T}_{l-1}\}\rangle$ *is a YES instance of* AS-CktSAT*, satisfied by polynomials* $\tilde{A}_0, \ldots, \tilde{A}_{l-1}$*, and* $P_{0,0}, \ldots, P_{l-1,0}$ *are defined according to* (6.2)*, then* $P_{i,0}(x) = (0,0)$ *for all* $x \in H^m$*.*

2. *If* $\langle 1^n, 1^m, \mathbb{F}, H, \{\tilde{T}_0, \ldots, \tilde{T}_{l-1}\}\rangle$ *is a NO instance of* AS-CktSAT*, then for any sequences of functions* $\tilde{A}_0, \ldots, \tilde{A}_{l-1}$*,* $P_{0,0}, \ldots, P_{l-1,0}$*, either* (6.2) *fails to hold for some* i *or* $P_{i,0}(x) \neq (0,0)$ *for some* i *and some* $x \in H^m$*.*

Recalling that the degree of the constraint ψ' (see Definition 6.9) is at most κ and that the $\tilde{A}_i$'s are of degree at most $d = m \cdot |H|$, we observe that the $P_{i,0}$'s can be taken to be of degree at most κd in item 1 above.

As mentioned above, the verifier now needs to check that the functions $P_{i,0}$ vanish on the set H^m. For this we use a "zero-propagation test" based on the sum-check protocol of Lund et al. [LFKN92]. Specifically, the verifier expects the remaining set of auxiliary oracles $P_{i,j} = (P_{i,j}^{(0)}, P_{i,j}^{(1)})$ ($i = 0, \ldots, l-1$ and $j = 1, \ldots, m$) to satisfy the following relations: Let $H = \{h_0, \ldots, h_{|H|-1}\}$ be some fixed enumeration of the elements in H. For all $b \in \{0,1\}$,

$$P_{i,j}^{(b)}\left(\underbrace{x_1, \ldots, x_{j-1}}, x_j, \underbrace{x_{j+1}, \ldots, x_m}\right) = \sum_{k=0}^{|H|-1} P_{i,j-1}^{(b)}\left(\underbrace{x_1, \ldots, x_{j-1}}, h_k, \underbrace{x_{j+1}, \ldots, x_m}\right) x_j^k \quad \forall (x_1, \ldots, x_m) \in \mathbb{F}^m. \tag{6.3}$$

These relations ensure that for all i and $j \geq 1$, $P_{i,j}(\cdot)$ vanishes on $\mathbb{F}^j \times H^{m-j}$ iff the function $P_{i,j-1}(\cdot)$ vanishes on $\mathbb{F}^{j-1} \times H^{m-j+1}$. For future reference, we (re)state this fact as a lemma.

LEMMA 6.15. $P^{(b)}_{i,j}|_{\mathbb{F}^j \times H^{m-j}} \equiv 0 \iff P^{(b)}_{i,j-1}|_{\mathbb{F}^{j-1} \times H^{m-j+1}} \equiv 0$.

Thus, for all i, $P_{i,m}$ vanishes on the entire space $\mathbb{F}^m$ iff $P_{i,0}$ vanishes on H^m. Also, as $P^{(b)}_{i,0}$ has degree at most κd in each variable, so does $P^{(b)}_{i,j}$ for each i and j. Hence, the degree of $P^{(b)}_{i,j}$ is at most κd.

Thus, the verifier needs to make the following checks:

- LOW-DEGREE TEST.
  For $i = 0, \ldots, l-1$ and $j = 0, \ldots, m$, the functions $\tilde{A}_i$ are polynomials of degree at most $d = m \cdot |H|$ and the functions $P_{i,j}$ are pairs of polynomials of degree at most κd.
- EDGE-CONSISTENCY TEST.
  For $i = 0, \ldots, l-1$, the functions $P_{i,0}$ obey (6.2).
- ZERO-PROPAGATION TEST.
  For $i = 0, \ldots, l-1$ and $j = 1, \ldots, m$, the functions $P_{i,j}$ satisfy (6.3).
- IDENTITY TEST.
  For $i = 0, \ldots, l-1$, the functions $P_{i,m}$ are identically zero on the entire domain $\mathbb{F}^m$.

The low-degree test in most earlier construction of PCP verifiers is performed using the "line-point" test. The "line-point" low degree test first chooses a random line, a random point on this line, and checks if the restriction of the function to the line (given by a univariate polynomial) agrees with the value of the function at the point. A random line l is typically chosen by choosing two random points $x, y \in \mathbb{F}^m$ and setting $l = l_{x,y} = \{x + ty | t \in \mathbb{F}\}$. However, this requires $2m \log |\mathbb{F}|$ bits of randomness, which is too expensive for our purposes. We save on randomness by using the low-degree test of Ben-Sasson et al. [BSVW03] based on small-biased spaces (see Appendix B for more details). The low-degree test of [BSVW03] uses pseudorandom lines instead of totally random lines in the following sense: The pseudorandom line $l = l_{x,y}$ is chosen by choosing the first point x at random from $\mathbb{F}^m$, while the second point y is chosen from a λ-biased subset S_λ of $\mathbb{F}^m$. This needs only $\log |S_\lambda| + \log |\mathbb{F}|^m$ bits of randomness. We further save on randomness by the use of *canonical lines*.[30] Consider any pseudorandom line $l = l_{x,y}$, where $x \in \mathbb{F}^m$ and $y \in S_\lambda$. We observe that for every $x' \in l$, we have $l_{x',y} = l_{x,y}$. In other words, $|\mathbb{F}|$ different choices of random bits lead to the same line $l_{x,y}$. We prevent this redundancy by representing each line in a canonical manner. A canonical line is chosen by first choosing a random point y from the λ-biased set S_λ. We view this y as specifying the direction (i.e., slope) of the line. This direction partitions the space $\mathbb{F}^m$ into $|\mathbb{F}|^{m-1}$ parallel lines (each with direction y). We enumerate these lines arbitrarily and select one of them uniformly at random. Thus, choosing a random canonical line costs only $\log |S_\lambda| + \log |\mathbb{F}|^{m-1}$ bits of randomness. A further point to be noted is that we perform a "line" test instead of the regular line-point test: The test queries the function for all points along the canonical line $l_{x,y}$ and verifies that the restriction of the function to this line is a low-degree polynomial.

Having performed the low-degree test (i.e., verified that the polynomials $\tilde{A}_i$'s and P_{ij}'s are close to low-degree polynomials), the verifier then performs the NODE-

[30] It is to be noted that the canonical representation of lines has been used either implicitly or explicitly in the soundness analysis of all earlier uses of the low-degree test. However, this is the first time that the canonical representation is used to save on the number of random bits.

Consistency Test, Zero-Propagation Test, and Identity Test by choosing a suitable small-sized sample in the entire space and checking if the corresponding condition is satisfied on that sample. For the Zero-Propagation Test indeed the natural sample is an axis-parallel line. For the Edge-Consistency Test and Identity Test, the sample we use is any set of $|\mathbb{F}|$ points selected from a partition of $\mathbb{F}^m$ into $|\mathbb{F}|^{m-1}$ equal sets.

We are now ready to formally describe the PCP verifier for CktSAT. We parameterize the PCP verifier in terms of m, the number of dimensions in our intermediate problem AS-CktSAT, and λ, the parameter of the λ-biased sets of $\mathbb{F}^m$ required for the low-degree tests of Ben-Sasson et al. [BSVW03]. We rely on the fact that λ-biased subsets of $\mathbb{F}^m$ of size at most $\text{poly}(\log|\mathbb{F}|^m, 1/\lambda)$ can be constructed efficiently [NN93, AGHP92].

PCP $\text{Verifier}_{m,\lambda}^{\tilde{A}_i, P_{i,j}; i=0,\ldots,l-1; j=0,\ldots,m}(C)$.

1. Use Proposition 6.11 to reduce the instance C of CktSAT, using parameter m, to an instance $\langle 1^n, 1^m, \mathbb{F}, H, \{\tilde{T}_0, \ldots, \tilde{T}_{l-1}\}\rangle$ of AS-CktSAT, and set $d = m \cdot |H|$.
   Notation. We let $S_\lambda \subset \mathbb{F}^m$ be a λ-biased set of size at most $(\frac{\log|\mathbb{F}|^m}{\lambda})^2$ [AGHP92]. Let $\mathbb{F}^m = \biguplus_{\eta=1}^{|\mathbb{F}|^{m-1}} U_\eta$ and $\mathbb{F}^m = \biguplus_{\eta=1}^{|\mathbb{F}|^{m-1}} V_\eta$ be two arbitrary partitions of the space $\mathbb{F}^m$ into $|\mathbb{F}|$-sized sets each.
2. Choose a random string R of length $\log(|S_\lambda| \cdot |\mathbb{F}|^{m-1})$. (Note: We reuse R in all tests, but only the Low-Degree Test utilizes the full length of R.)
3. Low-Degree Test.
   Use random string R to determine a random canonical line $\mathcal{L}$ in $\mathbb{F}^m$ using the λ-biased set S_λ.
   For $i = 0, \ldots, l-1$,
   query oracle $\tilde{A}_i$ on all points along the line $\mathcal{L}$ and reject if the restriction $\tilde{A}_i$ to $\mathcal{L}$ is not a (univariate) polynomial of degree at most d.
   For $i = 0, \ldots, l-1$, $j = 0, \ldots, m$, and $b \in \{0,1\}$,
   query oracle $P_{i,j}^{(b)}$ on all points along the line $\mathcal{L}$ and reject if the restriction of $P_{i,j}^{(b)}$ to $\mathcal{L}$ is not a (univariate) polynomial of degree at most κd.
4. Edge-Consistency Test.
   Use the random string R to determine a random set U_η of the partition $\mathbb{F}^m = \biguplus_{\eta=1}^{|\mathbb{F}|^{m-1}} U_\eta$.
   For $i = 0, \ldots, l-1$,
   for all $x \in U_\eta$, query $P_{i,0}(x), \tilde{A}_i(x), \tilde{A}_{i+1}(\tilde{\Gamma}_{i,0}(x))$, and $\tilde{A}_{i+1}(\tilde{\Gamma}_{i,1}(x))$ and reject if (6.2) is not satisfied.
5. Zero-Propagation Test.
   For $i = 0, \ldots, l-1$, $j = 1, \ldots, m$, and $b \in \{0,1\}$,
   use random string R to determine a random jth axis-parallel line in $\mathbb{F}^m$ of the form $\mathcal{L} = \{(a_1, \ldots, a_{j-1}, X, a_{j+1}, \ldots, a_m) : X \in \mathbb{F}\}$. Query $P_{i,j-1}^{(b)}$ and $P_{i,j}^{(b)}$ along all the points in $\mathcal{L}$. Reject if either the restriction of $P_{i,j-1}^{(b)}$ or $P_{i,j}^{(b)}$ to $\mathcal{L}$ is not a univariate polynomial of degree at most κd or if any of the points on the line $\mathcal{L}$ violate (6.3).
6. Identity Test.
   Use the random string R to determine a random set V_η of the partition

$\mathbb{F}^m = \biguplus_{\eta=1}^{|\mathbb{F}|^{m-1}} V_\eta$. For $i = 0, \ldots, l-1$,
for all $x \in V_\eta$, query $P_{i,m}(x)$. Reject if any of these $P_{i,m}(x)$ are not $(0,0)$.
Accept if none of the above tests reject.

Remark 6.16.

1. The Low-Degree Test requires $\log(|S_\lambda| \cdot |\mathbb{F}|^{m-1})$ random bits to generate a canonical line in $\mathbb{F}^m$ using the λ-biased set, while each of the other tests requires at most $\log(|\mathbb{F}|^{m-1})$ bits of randomness. Hence, the string R suffices for each of the tests. For the settings of parameters we use, $\log(|S_\lambda| \cdot |\mathbb{F}|^{m-1})$ is typically significantly smaller than $\log(|\mathbb{F}|^m)$, which we would not be able to afford.

2. The Edge-Consistency Test and Identity Test in the "standard" sense are usually performed by selecting a random point in the space $\mathbb{F}^m$ and checking whether the corresponding condition is satisfied. However, we state these tests in a "nonstandard" manner using partitions of the space $\mathbb{F}^m$ into $|\mathbb{F}|$-sized tests so that these tests can be easily adapted when we construct the robust PCP verifier (see section 8). The nonstandard tests are performed in the following manner: Choose a random set in the partition and perform the standard test for each point in the set. At present, we can work with any partition of $\mathbb{F}^m$; however, we will later need specific partitions to get "robustness."

6.4. Analysis of the PCP Verifier**.** We now analyze the PCP Verifier above. The analysis below assumes that the parameters satisfy $m \le \log n / \log\log n$ and $\lambda \le 1/c \log n$ for a sufficiently large constant c. Theorem 6.1 can be deduced by setting $\lambda = 1/c \log n$.

Complexity. The PCP Verifier makes $O(lm|\mathbb{F}|) = O(m^3 n^{1/m} \log n)$ queries, each of which expects as an answer an element of $\mathbb{F}$ or $\mathbb{F}^2$ (i.e., a string of length $O(\log|\mathbb{F}|)$). Hence, the total (bit) query complexity is $O(lm|\mathbb{F}| \log|\mathbb{F}|) = O(lm \cdot c_F m^2 n^{1/m} \log(c_F m^2 n^{1/m}))$. Recalling that $l = 5 \log n$, this quantity is at most $O(m^2 n^{1/m} \log^2 n)$ for $m \le \log n$. For the decision complexity, we note that the main computations required are (a) testing whether a function is a low-degree univariate polynomial over $\mathbb{F}$ (for Low-Degree Test and Zero-Propagation Test), (b) evaluating ψ' on $|\mathbb{F}|$ quadruples of points (for Edge-Consistency Test), and (c) univariate polynomial interpolation and evaluation (for testing (6.3) in Zero-Propagation Test). We now argue that each of these can be done with a nearly linear ($\widetilde{O}(|\mathbb{F}|)$) number of operations over $\mathbb{F}$, yielding a nearly linear ($\widetilde{O}(q)$) decision complexity overall. Each evaluation of ψ' can be done with a constant number of $\mathbb{F}$-operations because ψ' is of constant degree. Polynomial interpolation and evaluation can be done with a nearly linear number of $\mathbb{F}$-operations by [SS71, Sch77], and testing whether a function is of low degree reduces to polynomial interpolation (this is achieved by interpolating the function to represent it as a polynomial of degree $|\mathbb{F}|-1$ and checking that the high-degree coefficients are zero). Each $\mathbb{F}$-operation can be done with $\widetilde{O}(\log|\mathbb{F}|)$ bit operations, using the polynomial multiplication algorithm of [SS71, Sch77] (over $\mathbb{F}_2$).

The number of random bits used by the verifier is exactly $\log(|S_\lambda| \cdot |\mathbb{F}|^{m-1})$. Let $n' = |\mathbb{F}|^m$. Then $\log(|S_\lambda| \cdot |\mathbb{F}|^{m-1}) = \left(1 - \frac{1}{m}\right) \log n' + \log(\mathrm{poly}(\frac{\log n'}{\lambda})) = \left(1 - \frac{1}{m}\right) \log n' + O(\log\log n') + O\left(\log\left(\frac{1}{\lambda}\right)\right)$. Now, $n' = (c_F m^2)^m n$. Hence, $\log n' = \log n + 2m \log m + O(m)$ and $\log\log n' = \log\log n + O(\log m)$. Thus, the total randomness is at most $\left(1 - \frac{1}{m}\right) \log n + O(m \log m) + O(\log\log n) + O\left(\log\left(\frac{1}{\lambda}\right)\right)$.

We summarize the above observations in the following proposition for future ref-

erence.

PROPOSITION 6.17. *The randomness, query, and decision complexities of* PCP VERIFIER *are* $r = \left(1 - \frac{1}{m}\right)\log n + O(m \log m) + O(\log\log n) + O\left(\log\left(\frac{1}{\lambda}\right)\right)$, $q = O(m^2 n^{1/m} \log^2 n)$ *and* $d = \widetilde{O}(q)$, *respectively.*

Completeness. If C is satisfiable, then the reduction reduces it to a YES instance of AS-CKTSAT. Then by definition there exist polynomials $\tilde{A}_i$ that satisfy constraint ψ'. Setting $P_{i,j}$ according to (6.2) and (6.3), we notice that the verifier accepts with probability one.

Soundness. To prove the soundness, we need to prove that if C is not satisfiable then the verifier accepts with probability bounded away from 1. We will prove a stronger statement. Recall from Remark 6.12 that the function $\tilde{A}_0 : \mathbb{F}^m \to \mathbb{F}$ supposedly has the satisfying assignment embedded within it. Let $I \subset \mathbb{F}^m$ be the set of locations in $\mathbb{F}^m$ that contains the assignment (i.e., $\tilde{A}_0|_I$ is supposedly the assignment).

LEMMA 6.18. *There exists a constant c and a constant $0 < \varepsilon_0 < 1$ such that for all ε, m, λ satisfying $\varepsilon \le \varepsilon_0$, $m \le \log n / \log\log n$, and $\lambda \le 1/c \log n$, the following holds. If $\tilde{A}_0$ is 4ε-far from every polynomial $\widehat{A}_0$ of degree md such that $C(\widehat{A}_0|_I) = 1$, then for all proof oracles $\{\tilde{A}_i\}$ and $\{P_{i,j}\}$, the verifier accepts with probability at most $1 - \varepsilon$.*

Proof. Let α be the universal constant from Theorem B.4. Set $\varepsilon_0 = \min\{\alpha, \frac{1}{22}\}$. Let $d = m2^h$, and choose c_F to be a large enough constant such that $\kappa md/|\mathbb{F}| = \kappa/c_F \le \varepsilon_0$. Suppose each of the functions $\tilde{A}_i$ are 4ε-close to some polynomial of degree md and each of the functions $P_{i,j}^{(b)}$ is 4ε-close to some polynomial of κmd. If this were not the case, then by Theorem B.4, LOW-DEGREE TEST accepts with probability at most $1 - \varepsilon$ for the polynomial that is 4ε-far. It can be verified that the parameters satisfy the requirements of Theorem B.4 for sufficiently large choices of the constants c_F and c and sufficiently small ε.

For each $i = 0, \ldots, l-1$, let $\widehat{A}_i : \mathbb{F}^m \to \mathbb{F}$ be the polynomial of degree at most md that is 4ε-close to $\tilde{A}_i$. Similarly, for each $i = 0, \ldots, l-1, j = 0, \ldots, m$ and $b \in \{0,1\}$, let $\widehat{P}_{i,j}^{(b)}$ be the polynomial of degree at most κmd that is 4ε-close to $P_{i,j}^{(b)}$. Such polynomials are uniquely defined since every two polynomials of degree κmd disagree in at least a $1 - \frac{\kappa md}{|\mathbb{F}|} \ge 1 - \varepsilon_0 > 8\varepsilon$ fraction of points. As in the case of the $P_{i,j}$'s, let $\widehat{P}_{i,j} : \mathbb{F}^m \to \mathbb{F}^2$ be the function given by $\widehat{P}_{i,j}(x) = (\widehat{P}_{i,j}^{(0)}(x), \widehat{P}_{i,j}^{(1)}(x))$.

By hypothesis, $\widehat{A}_0|_I$ does not satisfy C. Then, by Lemmas 6.14 and 6.15, at least one of the following must hold.

(a) *There exists $i \in \{0, \ldots, l-1\}$ and $b \in \{0,1\}$ such that $\widehat{P}_{i,m}^{(b)} \not\equiv 0$.*
Then for this i, IDENTITY TEST fails unless a random set V_η is chosen such that for all $x \in V_\eta$, $P_{i,m}^{(b)}(x) = 0$. Hence, it must be the case that for all $x \in V_\eta$, either $P_{i,m}^{(b)}(x) \ne \widehat{P}_{i,m}^{(b)}(x)$ or $\widehat{P}_{i,m}^{(b)}(x) = 0$. Since the $V_\eta's$ form a partition of $\mathbb{F}^m$, the probability of this occurring is upper-bounded by the probability that a random $x \in \mathbb{F}^m$ satisfies either $P_{i,m}^{(b)}(x) \ne \widehat{P}_{i,m}^{(b}(x)$ or $\widehat{P}_{i,m}^{(b)}(x) = 0$. This probability is at most $4\varepsilon + \frac{\kappa md}{|\mathbb{F}|} = 4\varepsilon + \frac{\kappa}{c_F} \le 5\varepsilon_0$, where we use the fact that $\widehat{P}_{i,m}^{(b)}$ is 4ε-close to $P_{i,m}^{(b)}$ and that a nonzero polynomial of degree κmd vanishes on at most a $\kappa md/|\mathbb{F}|$ fraction of points.

(b) *There exists $i \in \{0, \ldots, l-1\}$ such that $\widehat{P}_{i,0}$, $\widehat{A}_i$, and $\widehat{A}_{i+1}$ do not obey* (6.2). In other words, $\widehat{P}_{i,0}(x) \not\equiv \psi'(\tilde{T}_i(x), \widehat{A}_i(x), \widehat{A}_{i+1}(\tilde{\Gamma}_{i,0}(x)), \widehat{A}_{i+1}(\tilde{\Gamma}_{i,1}(x)))$.
Then for this i, EDGE-CONSISTENCY TEST fails unless a random partition U_η is chosen such that for all $x \in U_\eta$, $P_{i,0}(x) = \psi'(\tilde{T}_i(x), \tilde{A}_i(x), \tilde{A}_{i+1}(\tilde{\Gamma}_{i,0}(x))$,

$\tilde{A}_{i+1}(\tilde{\Gamma}_{i,1}(x)))$. Hence, it must be the case that for every $x \in U_\eta$, one of the following (six) holds:

$$P^{(0)}_{i,0}(x) \neq \widehat{P}^{(0)}_{i,0}(x); \qquad P^{(1)}_{i,0}(x) \neq \widehat{P}^{(1)}_{i,0}(x); \qquad \tilde{A}_i(x) \neq \widehat{A}_i(x);$$
$$\tilde{A}_{i+1}(\tilde{\Gamma}_{i,0}(x)) \neq \widehat{A}_{i+1}(\tilde{\Gamma}_{i,0}(x)); \qquad \tilde{A}_{i+1}(\tilde{\Gamma}_{i,1}(x)) \neq \widehat{A}_{i+1}(\tilde{\Gamma}_{i,1}(x));$$
$$\widehat{P}_{i,0}(x) = \psi'(\tilde{T}_i(x), \widehat{A}_i(x), \widehat{A}_{i+1}(\tilde{\Gamma}_{i,0}(x)), \widehat{A}_{i+1}(\tilde{\Gamma}_{i,1}(x))).$$

The probability of this happening is at most the probability that a random $x \in \mathbb{F}^m$ satisfies these conditions, which is at most $5 \cdot 4\varepsilon + \frac{\kappa m d}{|\mathbb{F}|} \leq 21\varepsilon_0$.

(c) *For some $i = 0, \ldots, l-1$, $j = 1, \ldots, m$, and $b \in \{0,1\}$, $\widehat{P}^{(b)}_{i,j}$ does not obey* (6.3).

In other words, $\widehat{P}^{(b)}_{i,j}(\ldots, x_j, \ldots) \not\equiv \sum_{k=0}^{|H|-1} \widehat{P}^{(b)}_{i,j-1}(\ldots, h_j, \ldots) x_j^k$. Then, for this i, j, Zero-Propagation Test rejects unless a random axis-parallel line $\mathcal{L}$ is chosen such that both $P^{(b)}_{i,j}|_{\mathcal{L}}$ and $P^{(b)}_{i,j-1}|_{\mathcal{L}}$ are polynomials of degree at most κd and for every $x \in \mathcal{L}$, $P^{(b)}_{i,j}(\ldots, x, \ldots) = \sum_{k=0}^{|H|-1} P^{(b)}_{i,j-1}(\ldots, h_k, \ldots) x^k$. Suppose we have that for all $x \in \mathcal{L}$, $P^{(b)}_{i,j}(x) = \widehat{P}^{(b)}_{i,j}(x)$ and $P^{(b)}_{i,j-1}(x) = \widehat{P}^{(b)}_{i,j-1}(x)$. Then, it must be the case that for all $x \in \mathcal{L}$, $\widehat{P}^{(b)}_{i,j}(\ldots, x, \ldots) = \sum_{k=0}^{|H|-1} \widehat{P}^{(b)}_{i,j-1}(\ldots, h_k, \ldots) x^k$. Since the axis-parallel lines cover $\mathbb{F}^m$ uniformly, the probability of this occurring is at most the probability of a random $x \in \mathbb{F}^m$ satisfying this condition, which is at most $\frac{\kappa m d}{c_F} \leq \varepsilon$. The probability that both $P^{(b)}_{i,j}|_{\mathcal{L}}$ and $P^{(b)}_{i,j-1}|_{\mathcal{L}}$ are polynomials of degree κd and either $P^{(b)}_{i,j}|_{\mathcal{L}} \neq \widehat{P}^{(b)}_{i,j}|_{\mathcal{L}}$ or $P^{(b)}_{i,j-1}|_{\mathcal{L}} \neq P^{(b)}_{i,j-1}|_{\mathcal{L}}$ is at most $2 \cdot 4\varepsilon/(1-\varepsilon_0) \leq 9\varepsilon_0$, since $P^{(b)}_{i,j}$ and $P^{(b)}_{i,j-1}$ are 4ε-close to $\widehat{P}^{(b)}_{i,j}$ and $\widehat{P}^{(b)}_{i,j-1}$, respectively, and any two distinct polynomials of degree $\kappa m d$ disagree on at least a $1 - \kappa m d/|\mathbb{F}| \geq 1 - \varepsilon_0$ fraction of points. Hence, Zero-Propagation Test accepts with probability at most $10\varepsilon_0$.

We thus have that the verifier accepts with probability at most $\max\{1-\varepsilon, 5\varepsilon_0, 21\varepsilon_0, 10\varepsilon_0\} = 1 - \varepsilon$. ∎

Proof of Theorem 6.1. Theorem 6.1 is proved using PCP Verifier defined in this section setting $\lambda = 1/c \log n$. Step 1 of the verifier reduces the instance C of CktSAT to an instance $\langle 1^{n'}, 1^m, \mathbb{F}, H, \{\tilde{T}_0, \ldots, \tilde{T}_{l-1}\}\rangle$ of AS-CktSAT. We have from Proposition 6.11 that $n' = \Theta(n)$ and $l = O(\log n)$, where n is the size of the input circuit C. Setting $n = n'$ in Proposition 6.17, we have that the randomness, query and decision complexity of the verifier are as claimed in Theorem 6.1. The soundness of the verifier follows from Lemma 6.18. ∎

7. A randomness-efficient PCPP. In this section, we modify the PCP for CktSAT and construct a PCPP for CktVal while maintaining all the complexities. (Recall that, by Proposition 2.4, the latter implies the former.) We do so by adding a proximity test to PCP Verifier defined in section 6.3. This new proximity test, as the name suggests, checks the closeness of the input to the satisfying assignment that is assumed to be encoded in the proof oracle (see Remark 6.12). This check is done by locally decoding a bit (or several bits) of the input from its encoding and comparing it with the actual input oracle.

Theorem 7.1. *There exists universal constants c and $0 < \varepsilon < 1$ such that the following holds for all $n, m \in \mathbb{Z}^+$, and $0 < \delta < 1$ satisfying $n^{1/m} \geq m^{cm}/\delta^3$. There exists a PCPP for* CktVal *(for circuits of size n) with the following parameters:*

- *randomness* $\left(1 - \frac{1}{m}\right) \log n + O(m \log m) + O(\log \log n) + O(\log(1/\delta))$,

- *query complexity* $q = O(m^2 n^{1/m} \log^2 n)$ *and decision complexity* $d = \widetilde{O}(q)$,
- *perfect completeness,*
- *soundness error* $1 - \varepsilon$ *for proximity parameter* δ.

Note that the condition $n^{1/m} \geq m^{cm}/\delta^3$ (made in Theorem 7.1) implies the condition $m \leq \log n / \log\log n$ stated in Theorem 6.1. Thus, the PCPP of Theorem 7.1 works only when n, the size of the circuit, is not too small (more, precisely, when $n \geq m^{cm^2}/\delta^{3m}$). As explained in section 3, when applying multiple proof compositions, we need (at the last compositions) PCPPs that work for even smaller values of n. For this purpose, we construct the following PCPP that works for small values of n. This PCPP, however, performs relatively poorly with respect to randomness (i.e., it has randomness complexity $O(\log n)$ rather than $(1 - o(1)) \log_2 n$). This will not be a concern for us since this verifier (or rather the robust version of this verifier) is used only in the inner levels of composition.

THEOREM 7.2. *For all* $n \in \mathbb{Z}^+$ *and* $\delta \in (0, 1)$, CKTVAL *has a PCPP (for circuits of size* n*) with the following parameters:*

- *randomness* $O(\log n)$*;*
- *decision complexity* $\operatorname{poly}\log n$*, which also upper-bounds the query complexity;*
- *perfect completeness; and*
- *soundness error* $1 - \Omega(\delta)$ *for proximity parameter* δ.

Preliminaries. Recall that a PCPP verifier is supposed to work as follows: The verifier is given explicit access to a circuit C with n gates on k input bits and oracle access to the input w in the form of an input oracle $W : [k] \to \{0, 1\}$. The verifier should accept W with probability 1 if it is a satisfying assignment and accept it with probability at most $1 - \varepsilon$ if it δ-far from any satisfying assignment.

For starters, we assume that $k \geq n/5$. In other words, the size of the input w is linear in the size of the circuit C. The reason we need this assumption is that we wish to verify the proximity of w to a satisfying assignment, but our proofs encode the assignment to all n gates of the circuit, and thus it better be the case that w is a nonnegligible fraction of the circuit. This assumption is not a major restriction, because if this is not the case then we work with the modified circuit C' and input w' that are defined as follows: For $t = \lceil n/k \rceil$, the circuit C' has $n' = n + 3tk$ gates and $k' = tk$ input bits such that $C'(w') = 1$ iff $w' = w^t$ for some w such that $C(w) = 1$; that is, C' checks if its input consists of t copies of some satisfying assignment of C. (It can be verified that C' can indeed be implemented on a circuit of size $n + 3tk$.) We choose t such that $k' \geq n'/10$. However, note that the input oracle W cannot be altered. So the verifier emulates the input w' using the original input oracle $W : [k] \to \{0, 1\}$ in a straightforward manner; that is, it defines $W' : [tk] \to \{0, 1\}$ such that $W'(i) \triangleq W(((i-1) \bmod k) + 1)$. Indeed, in view of the way W' is emulated based on W, testing that W' is a repetition of some k-bit string makes no sense. This test is incorporated into C' in order to maintain the distance features of C; that is, if w is δ-far from satisfying C, then $w' = w^t$ is δ-far from satisfying C' (without having C' explicitly run C on all t copies of w, because that would make its size larger than nt and defeat our goal of increasing the length of the input relative to the circuit size). We state this fact as a proposition for future reference.

PROPOSITION 7.3. *There exists a generic transformation from* CKTVAL *to* CKTVAL *that maps the instance* (C, w)*, where* C *is a circuit with* n *gates and* k *input bits, to the instance* (C', w')*, where* C' *is a circuit on* $n' = n + 3tk$ *gates and* $k' = kt$ *input bits (where* $t = \lceil n/k \rceil$*) defined as follows:* $C'(w') = 1$ *iff* $w' = w^t$ *for some* w *such that* $C(w) = 1$ *and* $w' = w^t$*. This transformation increases the length of the input oracle*

compared to the proof oracle (here, the values of all gates in C). The transformation preserves the relative distance to the set of satisfying assignments; that is, if w is δ-far from the set of satisfying assignments of C, then $w' = w^t$ is δ-far from the satisfying assignments of C'.

We first describe PCPP Verifier which proves Theorem 7.1 and later describe ALMSS PCPP Verifier which proves Theorem 7.2.

7.1. The construction of PCPP Verifier (Theorem 7.1). As in the case of PCP Verifier described in section 6.3, PCPP Verifier is constructed by reducing the input circuit C, an instance of CktSAT, using parameter m, to an instance $\langle 1^n, 1^m, \mathbb{F}, H, \{\tilde{T}_0, \ldots, \tilde{T}_{l-1}\}\rangle$ of AS-CktSAT. The proof oracle for PCPP Verifier is the same as that of the PCP Verifier (i.e., the proof oracle consists of a sequence of functions $\tilde{A}_i : \mathbb{F}^m \to \mathbb{F}, i = 0, \ldots, l-1$, and $P_{i,j} : \mathbb{F}^m \to \mathbb{F}^2, i = 0, \ldots, l-1, j = 0, \ldots, m$, where $l = 5 \log n$).

Recall that the function $\tilde{A}_0 : \mathbb{F}^m \to \mathbb{F}$ is assumed to contain within it an assignment (see Remarks 6.7 and 6.12). Let $I \subseteq H^m \subset \mathbb{F}^m$ be the set of locations in $\mathbb{F}^m$ that contain the assignment. PCPP Verifier, in addition to the tests of PCP Verifier, performs the following Proximity Test to check if the assignment given by $\tilde{A}_0|_I$ matches the input oracle W. Specifically, we have the following.

PCPP $\text{Verifier}^{W;\ \tilde{A}_i, P_{i,j}; i=0,\ldots,l-1; j=0,\ldots,m}_{m,\lambda,\delta}(C)$.

1. Run PCP $\text{Verifier}^{W;\ \tilde{A}_i, P_{i,j}}_{m,\lambda}(C)$ and reject if it rejects.
   Let R be the random string generated during the execution of this step.
2. Proximity Test.
   Use random string R to determine a random canonical line $\mathcal{L}$ in $\mathbb{F}^m$ using the λ-biased set S_λ. Query oracle $\tilde{A}_0$ on all points along the line $\mathcal{L}$ and reject if the restriction $\tilde{A}_0$ to $\mathcal{L}$ is not a polynomial of degree at most $d = m \cdot |H|$. Query the input oracle W on all locations corresponding to those in $I \cap \mathcal{L}$ and reject if W disagrees with $\tilde{A}_0$ on any of the locations in $I \cap \mathcal{L}$.

By inspection, the proximity test increases the query and decision complexities by (even less than) a constant factor. For the randomness complexity, the randomness is used only to generate a random canonical line (as in PCP Verifier), so the randomness complexity is $\log(|\mathbb{F}|^{m-1} \cdot |S_\lambda|)$ as before. However, in order to prove soundness, we need to assume not only that $\lambda \leq 1/c \log n$ for some constant c (as before), but also that $\lambda \leq \delta^3/m^{cm}$.[31] Thus, setting $\lambda = \min\{1/c \log n, \delta^3/m^{cm}\}$, the randomness complexity increases by at most $O(m \log m) + O(\log(1/\delta))$, as claimed in Theorem 7.1. Summarizing the above observations for future reference, we have the following proposition.

Proposition 7.4. *The randomness, query, and decision complexities of* PCPP Verifier *are* $r = \left(1 - \frac{1}{m}\right) \log n + O(m \log m) + O(\log \log n) + O(\log(1/\delta))$, $q = O(m^2 n^{1/m} \log^2 n)$, *and* $d = \widetilde{O}(q)$, *respectively.*

It is straightforward to check perfect completeness of this verifier. To prove soundness, we observe that if the input W is δ-far from satisfying the circuit, then one of the following must happen: (1) The verifier detects an inconsistency in the proof oracle or (2) the input oracle does not match the encoding of the input in the proof oracle. In the case of the former, we prove soundness by invoking Lemma 6.18, while in the latter case, we prove soundness by analyzing the proximity test. These ideas are

[31] Actually, for the proximity test we need only $\lambda \leq \delta/m^{cm}$; however, to prove robustness of the proximity test (see section 8.1) we require $\lambda \leq \delta^3/m^{cm}$.

explained in detail in the following lemma which proves the soundness of the verifier.

LEMMA 7.5. *There exists a constant c and a constant $\varepsilon > 0$ such that for all m, λ, δ satisfying $n \geq 8000|\mathbb{F}|^{m-1}/\delta^3$, $\lambda \leq 1/c \log n$, and $\lambda \leq \delta/m^{cm}$, the following holds. If the input w given by the input oracle $W : [k] \to \{0,1\}$ is δ-far from satisfying the circuit, then for any proof oracle the verifier rejects W with probability at least ε.*

Proof. Set ε to be the constant ε_0 in Lemma 6.18.

Case (i). $\tilde{A}_0$ is not 4ε-close to any polynomial $\widehat{A}_0$ of degree md such that $C(\widehat{A}_0|_I) = 1$. Then by Lemma 6.18, we conclude that the verifier rejects with probability at least ε.

Case (ii). $\tilde{A}_0$ is 4ε-close to some polynomial $\widehat{A}_0$ of degree md such that $C(\widehat{A}_0|_I) = 1$. Since w is δ-far from any satisfying assignment, the assignment given by $\widehat{A}_0|_I$ must be at least δ-far from w. Let $B \subset \mathbb{F}^m$ denote the set of locations in I where the assignment given by $\widehat{A}_0$ disagrees with w (i.e., $B = \{x \in I | \widehat{A}_0(x)$ disagrees with w at $x\}$). Hence, $|B|/|I| \geq \delta$. Since $|I| = k \geq n/5$, we have $|B| \geq \delta n/5$. Consider the following two events.

Event I. $\tilde{A}_0|_{\mathcal{L}}$ is 5ε-far from $\widehat{A}_0|_{\mathcal{L}}$.

By the sampling lemma (Lemma B.3) with $\mu = 4\varepsilon$ and $\zeta = \varepsilon$, this event occurs with probability at most $\left(\frac{1}{|\mathbb{F}|} + \lambda\right) \cdot \frac{4\varepsilon}{\varepsilon^2} \leq \frac{1}{4}$ since $|\mathbb{F}|, \frac{1}{\lambda} \geq 32/\varepsilon$.

Event II. $B \cap \mathcal{L} = \emptyset$.

Again by the sampling lemma (Lemma B.3) with $\mu = \zeta = \frac{|B|}{|\mathbb{F}^m|}$, this event occurs with probability at most $\left(\frac{1}{|\mathbb{F}|} + \lambda\right) \cdot \frac{|\mathbb{F}^m|}{|B|} = \left(\frac{1}{|\mathbb{F}|} + \lambda\right) \cdot \frac{5|\mathbb{F}^m|}{\delta n} \leq \frac{1}{4}$, where the last inequality follows because $n \geq 8000|\mathbb{F}|^{m-1}/\delta^3 \geq 40|\mathbb{F}|^{m-1}/\delta$ and $\lambda \leq \delta/(40(c_F m^2)^m)$.

Suppose Event I does not occur. Then, if $\widehat{A}_0|_{\mathcal{L}} \neq \tilde{A}_0|_{\mathcal{L}}$, PROXIMITY TEST rejects since then $\tilde{A}_0|_{\mathcal{L}}$ cannot be a polynomial of degree at most d, as it is 5ε-close to the polynomial $\widehat{A}_0$ and hence cannot be closer to any other polynomial (as $5\varepsilon \leq \frac{1}{2}(1 - \frac{d}{|\mathbb{F}|}) = \frac{1}{2}(1 - \frac{1}{c_F})$). Now if $\widehat{A}_0|_{\mathcal{L}} = \tilde{A}_0|_{\mathcal{L}}$ and Event II does not occur, then PROXIMITY TEST detects a mismatch between the input oracle W and $\tilde{A}_0|_{\mathcal{L}}$. Hence, if both Event I and Event II do not occur, then the test rejects.

Thus, the probability of the test accepting in this case is at most the probability of either Event I or Event II occurring, which is at most $1/2$. Thus, the probability that the verifier accepts is at most $\max\left\{1 - \varepsilon, \frac{1}{2}\right\} = 1 - \varepsilon$. This completes the proof of the lemma. ∎

Proof of Theorem 7.1. Theorem 7.1 is proved using PCPP VERIFIER defined in this section, setting $\lambda = \min\{1/c \log n, \delta^3/m^{cm}\}$. The randomness and decision (resp., query) complexities follow from Proposition 7.4. The only fact to be verified is the soundness of the verifier. By the hypothesis of Theorem 7.1, $n^{1/m} \geq m^{cm}/\delta^3$ for a suitably large constant c. This implies that $n^{1/m} \geq 8000(c_F m^2)^{m-1}/\delta^3$ or, equivalently, $n \geq 8000|\mathbb{F}|^{m-1}/\delta^3$. Hence, Lemma 7.5 applies and we have that the verifier has soundness error $1 - \varepsilon$ for proximity parameter δ. This proves Theorem 7.1. ∎

7.2. The ALMSS-type PCPP (Theorem 7.2). We now turn to designing a PCPP that proves Theorem 7.2. We call this ALMSS PCPP VERIFIER as it has parameters similar to the "parallelized" PCPs of [ALM+98]. ALMSS PCPP VERIFIER is identical to PCPP VERIFIER of Theorem 7.1 except for the fact that it has a slightly different proximity test. All other details remain the same.

ALMSS PCPP VERIFIER$_\delta^{W;\ \tilde{A}_i, P_{i,j}; i=0,\ldots,l-1; j=0,\ldots,m}(C)$.

1. Set $m = \log n / \log\log n$ and $\lambda = 1/c \log n$.

2. Run PCP VERIFIER$_{m,\lambda}^{W;\,\tilde{A}_i,P_{i,j}}(C)$ and reject if it rejects.
3. ALMSS PROXIMITY TEST.
   Choose a random position $i \stackrel{R}{\leftarrow} \{1,\ldots,k\}$ in the input and a random direction $y \in \mathbb{F}^m$. Let $x \in I$ be the point corresponding to i in H^m. Let $\mathcal{L}$ be the line through x in the direction y. Query oracle $\tilde{A}_0$ on all points along the line $\mathcal{L}$ and reject if the restriction $\tilde{A}_0$ to $\mathcal{L}$ is not a polynomial of degree at most $d = m \cdot |H|$. Query the input oracle W at location i and reject if $W[i] \neq \tilde{A}_0(x)$.

Unlike PCPP VERIFIER, we will not calculate the randomness used by this verifier exactly. An upper bound within a constant factor suffices for our purposes. The extra randomness used by ALMSS PROXIMITY TEST is $\log k + m \log |\mathbb{F}|$ (i.e., the randomness required to choose a random index in $\{1,\ldots,k\}$ and a random direction in $\mathbb{F}^m$). For our choice of m and δ, the randomness of PCP VERIFIER is at most $O(\log n)$ (see the analysis preceding Proposition 6.17). Hence, the total randomness of ALMSS PCPP VERIFIER is at most $O(\log n)$. The query and decision complexities are at most a constant times that of PCP VERIFIER which is turn is upper-bounded by $\operatorname{poly}\log n$. Summarizing the above observations for future reference, we have the following proposition.

PROPOSITION 7.6. *The randomness and decision complexities of* ALMSS PCPP VERIFIER *are* $O(\log n)$ *and* $\operatorname{poly}\log n$*, respectively.*

The soundness of the verifier is given by the following lemma.

LEMMA 7.7. *For all* $\delta \in (0,1)$*, the following holds. If the input* w *given by the input oracle* $W : [k] \to \{0,1\}$ *is* δ*-far from satisfying the circuit, then for any proof oracle the verifier rejects* W *with probability* $\Omega(\delta)$.

Proof. Let ε_0 be the constant that appears in Lemma 6.18.

Case (i). $\tilde{A}_0$ is not $4\varepsilon_0$-close to any polynomial $\widehat{A}_0$ of degree md such that $C(\widehat{A}_0|_I) = 1$. Then by Lemma 6.18, we conclude that the verifier rejects with probability at least ε_0.

Case (ii). $\tilde{A}_0$ is $4\varepsilon_0$-close to some polynomial $\widehat{A}_0$ of degree md such that $C(\widehat{A}_0|_I) = 1$. Since w is δ-far from any satisfying assignment, the assignment given by $\widehat{A}_0|_I$ must be δ-far from w. With probability greater than δ over the choice of $i \in \{1,\ldots,k\}$ (and the corresponding point $x \in I$ in H^m), we have $W[i] \neq \widehat{A}_0(x)$. If this occurs, the only way the verifier can accept is if $\tilde{A}_0|_{\mathcal{L}}$ is a degree md polynomial other than $\widehat{A}_0|_{\mathcal{L}}$. We will show that for any fixed point x in $\mathbb{F}^m$, with probability at least $1 - 16\varepsilon_0$ over the choice of random line $\mathcal{L}$ through x, $\tilde{A}_0|_{\mathcal{L}}$ cannot be a degree md polynomial different from $\widehat{A}_0|_{\mathcal{L}}$. We can then conclude that the verifier rejects with probability at least $\delta \cdot (1 - 16\varepsilon_0) = \Omega(\delta)$. Since $\mathcal{L}$ is a random line through x, every point on $\mathcal{L}$ other than x is a uniformly random point in $\mathbb{F}^m$. Recall that $\tilde{A}_0$ and $\widehat{A}_0$ are $4\varepsilon_0$-close. By a Markov argument it follows that for every fixed value of x and a random line $\mathcal{L}$ through x, with probability at least $1 - 16\varepsilon_0$, $\tilde{A}|_{\mathcal{L}\setminus\{x\}}$ and $\widehat{A}|_{\mathcal{L}\setminus\{x\}}$ are at least 1/4-close. This implies that $\tilde{A}|_{\mathcal{L}}$ cannot be a polynomial of degree md other than $\widehat{A}|_{\mathcal{L}}$ (since two distinct polynomials agree in at most md points, and $(md-1)/|\mathbb{F}| < 1/4$).

In either case, ALMSS PCPP VERIFIER rejects with probability at least $\min\{\varepsilon_0, \Omega(\delta)\} = \Omega(\delta)$. □

Conclusion. Theorem 7.2 follows from Proposition 7.6 and Lemma 7.7.

8. A randomness-efficient robust PCPP. In this section, we modify the PCPP for CKTVAL constructed in section 7 to design a robust PCPP, while essentially maintaining all complexities. Recall the definition of robustness: If the input oracle

W is δ-far from a satisfying assignment, then a "regular" PCPP verifier rejects the input for most choices of its random coins; that is, it observes an inconsistency in the (input and) proof. In contrast, for most choices of its random coins, a *robust* PCPP verifier not only notices an inconsistency in the (input and) proof but also observes that a considerable portion of the (input and) proof read by it has to be modified to remove this inconsistency.

We construct two robust PCPPs which are robust analogues of the two PCPPs presented in section 7. The first robust PCPP is the main construct (claimed in Theorem 3.1), which is the robust analogue of PCPP Verifier. The second robust PCPP is an ALMSS-type robust PCPP (claimed in Theorem 3.2), which is the robust analogue of ALMSS PCPP Verifier. Thus, we prove Theorems 3.1 and 3.2.

Overview of the proofs of Theorem 3.1 *and* 3.2. We "robustify" the PCPP verifier in three steps. Recall that a single execution of the verifier actually involves several tests (in fact $lm+2l$ Low-Degree Tests, l Edge-Consistency Tests, lm Zero-Propagation Tests, l Identity Tests, and a single proximity test (either Proximity Test or ALMSS Proximity Test, as the case may be)). In the first step (section 8.1), we observe that each of these tests is robust individually. In the second step (section 8.2), we perform a "bundling" of the queries so that a certain set of queries can always be asked together. Indeed, bundling is analogous to "parallelization" except that it does *not* involve any increase in the randomness complexity (unlike parallelization, which introduces such an increase, which although small is too big for our purposes). We stress that bundling is tailored to the specific tests, in contrast to parallelization which is generic. The aforementioned bundling achieves robustness, albeit over a much a larger alphabet. In the final step (section 8.3), we use a good error-correcting code to transform the "bundles" into regular bit-queries such that robustness over the binary alphabet is achieved.

8.1. Robustness of individual tests. For each possible random string R, PCPP Verifier (resp., ALMSS PCPP Verifier) performs several tests. More precisely, it performs $l(m+2)$ Low-Degree Tests, l Edge-Consistency Tests, lm Zero-Propagation Tests, l Identity Tests, and a single Proximity Test (resp., ALMSS Proximity Test). In this section, we prove that each of these tests is robust individually. In other words, we show that when one of these tests fails, it fails in a "robust" manner; that is, a considerable portion of the input read by the test has to be modified for the test to pass.

First, we introduce some notation. We view functions $g, g' : \mathbb{F}^m \to \mathbb{F}$ as strings of length $|\mathbb{F}|^m$ over the alphabet $\mathbb{F}$, so their relative Hamming distance $\Delta(g, g')$ is simply $\Pr_x[g(x) \neq g'(x)]$. As before, let $I \subseteq H^m \subset \mathbb{F}^m$ be the set of locations in $\mathbb{F}^m$ that contains the assignment.

Let $0 < \varepsilon < 1$ be a small constant to be specified later. As before, for $i = 0, \ldots, l-1$, $j = 0, \ldots, m$ and $b \in \{0,1\}$, let $\widehat{A}_i$ (resp., $\widehat{P}^{(b)}_{i,j}$) be the closest polynomials of degree md (resp., κmd) to $\tilde{A}_i$ and $P_{i,j}$, respectively. (If there is more than one polynomial, choose one arbitrarily.) The proof of the soundness of the PCPP verifiers, PCPP Verifier and ALMSS PCPP Verifier (see section 6 and 7), was along the following lines: If the input oracle $W : [k] \to \{0,1\}$ is δ-far from satisfying the circuit, then one of the following must happen (changing ε by a factor of 2):

1. There exists $i \in \{0, \ldots, l-1\}$ such that $\tilde{A}_i$ is 8ε-far from every degree md polynomial or there exists $i \in \{0, \ldots, l-1\}$, $j \in \{0, \ldots, m\}$, and $b \in \{0,1\}$ such that $P^{(b)}_{i,j}$ is 8ε-far from every degree κmd polynomial. In this case,

LOW-DEGREE TEST detects the error with probability at least 2ε.

2. There exists $i \in \{0, \ldots, l-1\}$ and $b \in \{0,1\}$, such that $\Delta(P_{i,m}^{(b)}, \widehat{P}_{i,m}^{(b)}) \leq 8\varepsilon$ and $\widehat{P}_{i,m} \not\equiv 0$. In this case, IDENTITY TEST detects the error with probability at least $1 - 10\varepsilon$.
3. There exists $i \in \{0, \ldots, l-1\}$, $j \in \{1, \ldots, m\}$, and $b \in \{0,1\}$ such that
$$\Delta(P_{i,j}^{(b)}, \widehat{P}_{i,j}^{(b)}) \leq 8\varepsilon, \Delta(P_{i,j-1}^{(b)}, \widehat{P}_{i,j-1}^{(b)}) \leq 8\varepsilon,$$
$$\text{and } \widehat{P}_{i,j}^{(b)}(\ldots, x_j, \ldots) \not\equiv \sum_{k=0}^{|H|-1} \widehat{P}_{i,j-1}^{(b)}(\ldots, h_k, \ldots) x_j^k.$$
In this case, ZERO-PROPAGATION TEST detects the error with probability at least $1 - 20\varepsilon$.
4. There exists $i \in \{0, \ldots, l-1\}$ such that
$$\Delta(P_{i,0}^{(0)}, \widehat{P}_{i,0}^{(0)}) \leq 8\varepsilon, \Delta(P_{i,0}^{(1)}, \widehat{P}_{i,0}^{(1)}) \leq 8\varepsilon, \Delta(\tilde{A}_i, \widehat{A}_i) \leq 8\varepsilon, \Delta(\tilde{A}_{i+1}, \widehat{A}_{i+1}) \leq 8\varepsilon,$$
$$\text{and } \widehat{P}_{i,0}(x) \not\equiv \psi'(\tilde{T}_i(x), \widehat{A}_i(x), \widehat{A}_{i+1}(\tilde{\Gamma}_{i,0}(x)), \widehat{A}_{i+1}(\tilde{\Gamma}_{i,1}(x))).$$
In this case, EDGE-CONSISTENCY TEST detects the error with probability at least $1 - 42\varepsilon$.
5. $\Delta(\tilde{A}_0, \widehat{A}_0) \leq 8\varepsilon$, but W and $\widehat{A}_0|_I$ disagree on at least δ fraction of the points. In this case, PROXIMITY TEST (or ALMSS PROXIMITY TEST, as the case may be) detects the error with probability at least 2ε (or $\Omega(\delta)$ in the case of ALMSS PROXIMITY TEST).

Claims 8.1–8.6 below strengthen the above analysis and show that one of the tests not only detects the error, but a significant portion of the input read by that test needs to be modified in order to make the test accept. More formally, recall that each of our tests T (randomly) generates a pair (I, D), where I is a set of queries to make to its oracle and D is the predicate to apply to the answers. For such a pair $(I, D) \leftarrow T$ and an oracle π, we define the *distance of $\pi|_I$ to T* to be the relative Hamming distance between $\pi|_I$ and the nearest satisfying assignment of D. Similarly, we say that π has *expected distance ρ from satisfying T* if the expectation of the distance of $\pi|_I$ to T over $(I, D) \overset{R}{\leftarrow} T$ equals ρ.

We then have the following claims about the robustness of the individual tests.

The robustness of LOW-DEGREE TEST can be easily inferred from the analysis of the λ-biased low-degree test due to Ben-Sasson et al. [BSVW03] as shown below.

CLAIM 8.1. *The following holds for all sufficiently small $\varepsilon > 0$. If $A : \mathbb{F}^m \to \mathbb{F}$ (resp., $P : \mathbb{F}^m \to \mathbb{F}$) is 8ε-far from every polynomial of degree md (resp., degree κmd), then the expected distance of A (resp., P) from satisfying* LOW-DEGREE TEST *with degree parameter d (resp., κd) is at least 2ε.*

Proof. Recall that LOW-DEGREE TEST chooses a random canonical line $\mathcal{L}$ and checks if $A|_{\mathcal{L}}$ is a univariate polynomial of degree d. For each canonical line $\mathcal{L}$, define $A_{\text{lines}}(\mathcal{L})$ to be the degree d univariate polynomial mapping $\mathcal{L} \to \mathbb{F}$ having maximum agreement with A on $\mathcal{L}$, breaking ties arbitrarily. The distance of $A|_{\mathcal{L}}$ to satisfying LOW-DEGREE TEST is precisely $\Delta(A|_{\mathcal{L}}, A_{\text{lines}}(\mathcal{L}))$.

The low-degree test LDT of Ben-Sasson et al. [BSVW03] works as follows (see Appendix B for more details): The test LDT has oracle access to a points-oracle $f : \mathbb{F}^m \to \mathbb{F}$ and a lines-oracle g. It chooses a random canonical line $\mathcal{L}$ using the λ-biased set, queries the lines-oracle g on the line $\mathcal{L}$, and queries the points-oracle f on a random point x on $\mathcal{L}$. It accepts iff $g(\mathcal{L})$ agrees with f at x.

By inspection, the probability that $\mathrm{LDT}^{A,A_{\mathrm{lines}}}$ rejects the points-oracle A and lines-oracle A_{lines} as defined above equals $\mathrm{E}_{\mathcal{L}}[\Delta(A|_{\mathcal{L}}, A_{\mathrm{lines}}(\mathcal{L}))]$. By Theorem B.4, if A is 8ε-far from every degree md polynomial, then $\mathrm{LDT}^{A,A_{\mathrm{lines}}}$ rejects with probability at least 2ε (for sufficiently small ε). (Recall that our parameters satisfy the conditions of Theorem B.4 for sufficiently large choices of the constants c and c_F.) Thus, A has expected distance 2ε from satisfying our Low-Degree Test, as desired. □

The intuition behind the proofs of robustness of Identity Test, Zero-Propagation Test, and Edge-Consistency Test is as follows. The key point to be noted is that the checks made by each of these tests are in the form of polynomial identities. Hence, if the functions read by these tests are close to being polynomials, then it follows from the Schwartz–Zippel lemma that the inputs read by these tests either satisfy these polynomial identities or are in fact far from satisfying them. We formalize this intuition and prove the robustness of Identity Test, Edge-Consistency Test, and Zero-Propagation Test in Claims 8.2, 8.3, and 8.4, respectively.

Claim 8.2. *The following holds for all sufficiently small $\varepsilon > 0$. If for some $i = 0, \ldots, l-1$ and $b \in \{0,1\}$, $\Delta(P_{i,m}^{(b)}, \widehat{P}_{i,m}^{(b)}) \le 8\varepsilon$ and $\widehat{P}_{i,m}^{(b)}(\cdot) \not\equiv 0$, then $P_{i,m}$ has expected distance at least $1 - 9\varepsilon$ from satisfying* Identity Test.

Proof. The expected distance of $P_{i,m}$ from satisfying Identity Test equals

$$\begin{aligned}
\mathrm{E}_{V_\eta}[\Delta(P_{i,m}|_{V_\eta}, 0)] &= \Delta(P_{i,m}, 0) && \text{[since } \{V_\eta\} \text{ is a partition]} \\
&\ge \Delta(\widehat{P}_{i,m}, 0) - \Delta(P_{i,m}, \widehat{P}_{i,m}) \\
&\ge \left(1 - \tfrac{\kappa md}{|\mathbb{F}|}\right) - 8\varepsilon && \text{[by the Schwartz–Zippel lemma} \\
&&& \text{and hypothesis]} \\
&\ge 1 - 9\varepsilon. \qquad \square
\end{aligned}$$

Claim 8.3. *The following holds for all sufficiently small $\varepsilon > 0$. Suppose for some $i = 0, \ldots, l-1$, we have $\Delta(P_{i,0}^{(0)}, \widehat{P}_{i,0}^{(0)}) \le 8\varepsilon$, $\Delta(P_{i,0}^{(1)}, \widehat{P}_{i,0}^{(1)}) \le 8\varepsilon$, $\Delta(\tilde{A}_i, \widehat{A}_i) \le 8\varepsilon$, $\Delta(\tilde{A}_{i+1}, \widehat{A}_{i+1}) \le 8\varepsilon$, and $\widehat{P}_{i,0}(\cdot) \not\equiv \psi'(\tilde{T}_i(\cdot), \widehat{A}_i(\cdot), \widehat{A}_{i+1}(\tilde{\Gamma}_{i,0}(\cdot)), \widehat{A}_{i+1}(\tilde{\Gamma}_{i,1}(\cdot)))$. Then $\{P_{i,0}(\cdot), A_i(\cdot), A_{i+1}(\tilde{\Gamma}_{i,0}(\cdot))A_{i+1}(\tilde{\Gamma}_{i,1}(\cdot))\}$ has expected distance at least $(1 - 41\varepsilon)/5$ from satisfying* Edge-Consistency Test.

Proof. Note that the distance of $\{P_{i,0}(\cdot), A_i(\cdot), A_{i+1}(\tilde{\Gamma}_{i,0}(\cdot))A_{i+1}(\tilde{\Gamma}_{i,1}(\cdot))\}|_{U_\eta}$ from satisfying Edge-Consistency Test is at least $1/5$ times the distance of $P_{i,0}(\cdot)|_{U_\eta}$ to the function $\psi'(\tilde{T}_i(\cdot), A_i(\cdot), A_{i+1}(\tilde{\Gamma}_{i,0}(\cdot)), A_{i+1}(\tilde{\Gamma}_{i,1}(\cdot)))|_{U_\eta}$ (since for each point $x \in U_\eta$, where the latter two functions disagree, at least one of $P_{i,0}, A_i, A_{i+1} \circ \tilde{\Gamma}_{i,0}, A_{i+1} \circ \tilde{\Gamma}_{i,1}$ needs to be changed at x to make the test accept). As in the proof of Claim 8.2, we have

$$\begin{aligned}
&\mathrm{E}_{U_\eta}[\Delta(P_{i,0}(\cdot)|_{U_\eta}, \psi'(\tilde{T}_i(\cdot), A_i(\cdot), A_{i+1}(\tilde{\Gamma}_{i,0}(\cdot)), A_{i+1}(\tilde{\Gamma}_{i,1}(\cdot)))|_{U_\eta})] \\
&\qquad \ge \left(1 - \frac{\kappa md}{|\mathbb{F}|}\right) - 5 \cdot 8\varepsilon \ge 1 - 41\varepsilon,
\end{aligned}$$

where the $(1 - \kappa md/|\mathbb{F}|)$ term corresponds to the distance if we replace all five functions with their corrected polynomials (e.g., $\widehat{P}_{i,0}$, $\widehat{A}_i$, $\widehat{A}_{i+1} \circ \tilde{\Gamma}_{i,0}$, $\widehat{A}_{i+1} \circ \tilde{\Gamma}_{i,1}$) and the $-5 \cdot 8\varepsilon$ accounts for the distance between each of the five functions and their corrected polynomials. Thus, the overall expected distance to satisfying Edge-Consistency Test is at least $(1 - 41\varepsilon)/5$. □

Claim 8.4. *The following holds for all sufficiently small $\varepsilon > 0$. Suppose for some $i = 0, \ldots, l-1$, $j = 1, \ldots, m$, and $b \in \{0,1\}$, we have $\Delta(P_{i,j}^{(b)}, \widehat{P}_{i,j}^{(b)}) \le$*

8ε, $\Delta(P^{(b)}_{i,j-1}, \widehat{P}^{(b)}_{i,j-1}) \leq 8\varepsilon$, *and* $\widehat{P}^{(b)}_{i,j}(\dots, x_j, \dots) \not\equiv \sum_{k=0}^{|H|-1} \widehat{P}^{(b)}_{i,j-1}(\dots, h_k, \dots) x_j^k$. *Then* $(P^{(b)}_{i,j}, P^{(b)}_{i,j-1})$ *has expected distance at least* $(1-19\varepsilon)/2$ *from satisfying* Zero-Propagation Test.

Proof. Suppose that $\mathcal{L}$ is a jth axis-parallel line such that

$$\widehat{P}^{(b)}_{i,j}(\dots, x_j, \dots)|_{\mathcal{L}} \not\equiv \sum_{k=0}^{|H|-1} \widehat{P}^{(b)}_{i,j-1}(\dots, h_k, \dots) x_j^k|_{\mathcal{L}}.$$

Then in order for Zero-Propagation Test to accept, either $P^{(b)}_{i,j}|_{\mathcal{L}}$ must be modified to equal a degree κd polynomial other than $\widehat{P}^{(b)}_{i,j-1}(\dots, x_j, \dots)|_{\mathcal{L}}$, or $P^{(b)}_{i,j-1}|_{\mathcal{L}}$ must be modified to equal a degree κd polynomial other than $\widehat{P}^{(b)}_{i,j-1}(\dots, x_j, \dots)|_{\mathcal{L}}$. (Recall that Zero-Propagation Test checks that the said restrictions are in fact polynomials of degree κd.) This would require modifying $P^{(b)}_{i,j}|_{\mathcal{L}}$ (resp., $P^{(b)}_{i,j-1}|_{\mathcal{L}}$) in at least a $1 - \kappa d/|\mathbb{F}| - \Delta(P^{(b)}_{i,j}|_{\mathcal{L}}, \widehat{P}^{(b)}_{i,j}|_{\mathcal{L}})$ fraction (resp., a $1 - \kappa d/|\mathbb{F}| - \Delta(P^{(b)}_{i,j-1}|_{\mathcal{L}}, \widehat{P}^{(b)}_{i,j-1}|_{\mathcal{L}})$ fraction) of points. This implies that the pair $(P^{(b)}_{i,j}|_{\mathcal{L}}, P^{(b)}_{i,j-1}|_{\mathcal{L}})$ would have to be modified in at least a

$$\frac{1}{2} \cdot \left(1 - \frac{\kappa d}{|\mathbb{F}|} - \Delta(P^{(b)}_{i,j}|_{\mathcal{L}}, \widehat{P}^{(b)}_{i,j}|_{\mathcal{L}}) - \Delta(P^{(b)}_{i,j-1}|_{\mathcal{L}}, \widehat{P}^{(b)}_{i,j-1}|_{\mathcal{L}})\right)$$

fraction of points.

Thus the expected distance of $(P^{(b)}_{i,j}, P^{(b)}_{i,j-1})$ from satisfying Zero-Propagation Test is at least

$$\begin{aligned}
&\frac{1}{2} \cdot \mathrm{E}_{\mathcal{L}} \left[1 - \frac{\kappa d}{|\mathbb{F}|} - \Delta(P^{(b)}_{i,j}|_{\mathcal{L}}, \widehat{P}^{(b)}_{i,j}|_{\mathcal{L}}) - \Delta(P^{(b)}_{i,j-1}|_{\mathcal{L}}, \widehat{P}^{(b)}_{i,j-1}|_{\mathcal{L}})\right] \\
&\quad - \Pr_{\mathcal{L}} \left[\widehat{P}^{(b)}_{i,j}(\dots, x_j, \dots)|_{\mathcal{L}} \equiv \sum_{k=0}^{|H|-1} \widehat{P}^{(b)}_{i,j-1}(\dots, h_k, \dots) x_j^k|_{\mathcal{L}}\right] \\
&\qquad\qquad \geq \frac{1}{2}(1 - \varepsilon - 8\varepsilon - 8\varepsilon) - \frac{\kappa d}{|\mathbb{F}|} \\
&\qquad\qquad \geq \frac{1}{2}(1 - 19\varepsilon). \qquad \square
\end{aligned}$$

We are now left with analyzing the robustness of the proximity tests (Proximity Test and ALMSS Proximity Test). Note that the input for either of these proximity tests comes in two parts: (a) the restriction of A_0 to the line $\mathcal{L}$ and (b) the input W restricted to the line $\mathcal{L}$ (or to a point on $\mathcal{L}$). Thus, the robustness of these tests refers to both parts (i.e., parts of each of the two oracles), and it is beneficial to decouple the corresponding robustness properties. We note that the robustness of Proximity Test is proved by repeated applications of the sampling lemma (Lemma B.3), while the robustness of ALMSS Proximity Test follows by a simple Markov argument.

Let $B \subset \mathbb{F}^m$ denote the set of locations in I, where the assignment given by $\widehat{A}_0$ disagrees with W (i.e., $B = \{x \in I | \widehat{A}_0(x)$ disagrees with W at $x\}$). Recall that $|I| = k \geq n/5$.

Claim 8.5. *There exists a constant c and a constant $\varepsilon > 0$ such that for all $m, \lambda, \delta, \delta'$ satisfying $n \geq 8000|\mathbb{F}|^{m-1}/\delta^3$, $\lambda \leq 1/c \log n$, $\lambda \leq \delta^3/m^{cm}$, $\delta' > \delta$, the following holds. Suppose $\Delta(\tilde{A}_0, \widehat{A}_0) \leq 1/4$ and the input oracle W is δ'-far from*

$\widehat{A}_0|_I$ (i.e., $|B|/|L| \geq \delta'$); then with probability at least $1 - \delta/4$ (over the choice of the canonical line $\mathcal{L}$) either at least an ε-fraction of $A_0|_{\mathcal{L}}$ or at least a $(\delta' - \delta/4)$-fraction of $W|_{\mathcal{L}}$ needs to be changed to make PROXIMITY TEST *accept.*

This claim is the robust analogue of Lemma 7.5. Observe that the robustness of the verifier is expressed separately for the proof and input oracles. As expected, the robustness of the input oracle depends on the proximity parameter δ', while that of the proof oracle is independent of δ'.

Proof. Consider the following three events.

Event 1. $\Delta(\tilde{A}_0|_{\mathcal{L}}, \widehat{A}_0|_{\mathcal{L}}) \geq 1/3$.

By the sampling lemma (Lemma B.3) with $\mu = 1/4$ and $\zeta = 1/12$, this event occurs with probability at most $((1/|\mathbb{F}|) + \lambda) \cdot (1/4)/(1/12)^2 \leq (\delta/12)$ since $|\mathbb{F}| \geq (8000|\mathbb{F}|^m)/(\delta^3 n) > (12^3/2)/\delta$ and $\lambda < 2\delta/12^3$.

Event 2. $\frac{|I \cap \mathcal{L}|}{|\mathcal{L}|} > \left(1 + \frac{\delta}{8}\right) \cdot \frac{|I|}{|\mathbb{F}^m|}$.

Again by the sampling lemma (Lemma B.3) with $\mu = |I|/|\mathbb{F}^m| \geq \frac{n}{5|\mathbb{F}|^m}$ and $\zeta = \frac{\delta\mu}{8}$, this event occurs with probability at most

$$\left(\frac{1}{|\mathbb{F}|} + \lambda\right) \cdot \frac{8^2}{\delta^2 \mu} = \left(\frac{1}{|\mathbb{F}|} + \lambda\right) \cdot \frac{320|\mathbb{F}|^m}{\delta^2 n} \leq \frac{\delta}{12},$$

where the last inequality follows from the fact that $n \geq 24 \cdot 320 \cdot |\mathbb{F}|^{m-1}/\delta^3$ and $\lambda \leq \delta^3/(24 \cdot 320(c_F m^2)^m)$.

Event 3. $\frac{|B \cap \mathcal{L}|}{|\mathcal{L}|} < \frac{|B|}{|\mathbb{F}^m|} - \frac{\delta}{8} \cdot \frac{|I|}{|\mathbb{F}^m|}$.

Again by the sampling lemma (Lemma B.3) with $\mu = |B|/|\mathbb{F}^m| = \frac{\delta' n}{5|\mathbb{F}|^m}$ and $\zeta = \frac{\delta n}{40|\mathbb{F}|^m}$, this event occurs with probability at most

$$\left(\frac{1}{|\mathbb{F}|} + \lambda\right) \cdot \frac{\mu}{\zeta^2} \leq \left(\frac{1}{|\mathbb{F}|} + \lambda\right) \cdot \frac{320|\mathbb{F}|^m}{\delta^2 n} \leq \frac{\delta}{12}.$$

Hence, the probability that at least one of the three events occurs is at most $\delta/4$.

Now, suppose none of the three events occur. We then get that

$$\frac{|B \cap \mathcal{L}|}{|I \cap \mathcal{L}|} \geq \frac{|B| - \delta|I|/8}{(1 + \delta/8)|I|} = \frac{\delta' - \delta/8}{1 + \delta/8} \geq \delta' - \frac{\delta}{4}.$$

Now for PROXIMITY TEST to accept the pair $(\tilde{A}_0|_{\mathcal{L}}, W \cap \mathcal{L})$, either we must change $\tilde{A}_0|_{\mathcal{L}}$ to a polynomial other than $\widehat{A}_0|_{\mathcal{L}}$ or correct the input for all $x \in B \cap \mathcal{L}$. The former requires us to change at least a $(1 - (d/|\mathbb{F}|) - 1/3) \geq 1/2$-fraction of the points of $A_0|_{\mathcal{L}}$ while the latter requires us to change at least a $\delta' - \delta/4$-fraction of the input read (i.e., the input oracle W restricted to the line $\mathcal{L}$). This proves the claim. ∎

We now analyze the robustness of ALMSS PROXIMITY TEST.

CLAIM 8.6. *There exists a constant $\varepsilon_0 > 0$ such that for all $\delta \in (0, 1)$, the following holds. Suppose $\Delta(\tilde{A}_0, \widehat{A}_0) \leq 4\varepsilon_0$ and the input oracle W is δ-far from $\widehat{A}_0|_I$* (i.e., $|B|/|L| \geq \delta$)*; then with probability at least $\Omega(\delta)$ (over the choice of index i and direction y), either at least a 1/2-fraction of $A_0|_{\mathcal{L}}$ or $W[i]$ (i.e., the single symbol of the input oracle read by the verifier) needs to be changed to make* ALMSS PROXIMITY TEST *accept.*

This claim is the robust analogue of Lemma 7.7. As before, the robustness of the verifier is expressed separately for the proof and input oracles.

Proof. Since w is δ-far from any satisfying assignment, the assignment given by $\widehat{A}_0|_I$ must be δ-far from w. Thus, with probability greater than δ over the choice of

$i \in \{1, \ldots, k\}$ (and the corresponding point $x \in I$), we have $W[i] \neq \widehat{A}_0(x)$. If this occurs, the only way to make the verifier accept is to either change $W[i]$ or change $\tilde{A}_0|_{\mathcal{L}}$ to a degree md polynomial other than $\widehat{A}_0|_{\mathcal{L}}$. As in the proof of Lemma 7.7, for any fixed x, with probability at least $1 - 16\varepsilon_0$ (over the choice of the random direction y), $\tilde{A}_0|_{\mathcal{L}\setminus\{x\}}$ and $\widehat{A}_0|_{\mathcal{L}\setminus\{x\}}$ have distance at most $1/4$, and hence $\tilde{A}_0|_{\mathcal{L}}$ would have to be changed in at least $1 - ((md-1)/|\mathbb{F}|) - 1/4 \geq 1/2$ points to be a degree md polynomial other than $\widehat{A}_0|_{\mathcal{L}}$. Thus, with probability at least $\delta(1 - 16\varepsilon_0) = \Omega(\delta)$, either $W[i]$ would have to change or at least half of $\tilde{A}_0|_{\mathcal{L}}$ would have to change to make the verifier accept. ∎

8.2. Bundling. In section 8.1, we showed that each of the tests performed by the PCPP verifier is individually robust. However, we need to show that the conjunction of all these tests is also robust. This is not true for the PCPP verifier in its present form for the following reason: Suppose the input oracle W is δ-far from satisfying the circuit. We then know that one of the tests detects this fact with nonnegligible probability. Moreover, as seen in section 8.1, this test is robust. However, since this test is only one of the $O(lm)$ tests being performed by the verifier, the oracle bits read by this test comprise a small fraction of the total query complexity of the verifier. For instance, the number of bits read by a single Low-Degree Test is about $1/lm$ times the query complexity. This causes the robustness of the verifier to drop by a factor of at least lm. Note that the issue here is not the fact that the verifier performs different types of tests (i.e., Low-Degree Test, Identity Test, Zero-Propagation Test, etc.) but rather that it performs many instances of each test and that the soundness analysis guarantees only that one of these test instances rejects (robustly). This is not sufficient to make the verifier robust.

For this purpose, we bundle the various functions in the proof oracle so that the inputs required for the several test instances can be read together. This maintains the robustness of the individual tests, albeit over a larger alphabet. To understand this bundling, let us assume for the present that the only type of tests that the verifier performs is Low-Degree Test. There exists a natural bundling in this case. Instead of $l(m+2)$ different oracles $\{\tilde{A}_i\}$ and $\{P_{i,j}\}$, we have one oracle Π which bundles together the data of all these oracles. The oracle $\Pi : \mathbb{F}^m \to \mathbb{F}^{l\cdot(2m+3)}$ is assumed to satisfy $\Pi(x) = (\tilde{A}_0(x), \ldots, \tilde{A}_{l-1}(x), P_{0,0}(x), \ldots, P_{l-1,m}(x))$ for all $x \in \mathbb{F}^m$. It can now be easily checked that over this proof oracle, the conjunction of all Low-Degree Tests is robust (over alphabet $\mathbb{F}^{l\cdot(2m+3)}$) with the same soundness and robustness parameters as a single Low-Degree Test (over alphabet $\mathbb{F}$). However, this natural bundling does not lend itself to the other tests performed by the PCPP verifier—namely, Zero-Propagation Test, and Edge-Consistency Test—because the l executions of these tests each have different query patterns (i.e., we cannot execute all of these tests by querying the same set of points of Π). Next, we provide an alternate bundling and massage our verifier slightly to work with this bundling.

To find a suitable bundling, we examine the query patterns of Zero-Propagation Test and Edge-Consistency Test more closely. The (i,j)th Zero-Propagation Test queries $P_{i,j-1}$ and $P_{i,j}$ on a random jth axis-parallel line. Also the ith Edge-Consistency Test queries $P_{i,0}$, $\tilde{A}_i$ for all points $x \in U_\eta$, and $\tilde{A}_{i+1}$ for all points $x \in \tilde{\Gamma}_{i,0}(U_\eta) \cup \tilde{\Gamma}_{i,1}(U_\eta)$ for U_η being a random subset of an arbitrary partition of F^m. The key observation is that the neighborhood functions $\tilde{\Gamma}_{i,0}$ and $\tilde{\Gamma}_{i,1}$ take any ith axis-parallel line to itself. Thus, if we choose the partition U_η to consist of ith axis-parallel lines, then the ith Edge-Consistency Test is also making queries entirely along axis-parallel lines. However, for the bundling to work, we need all the tests to

be making queries along the *same* axis-parallel line. We accomplish this by shifting our functions according to appropriate cyclic permutations of the coordinates so that the query patterns of the tests "line up" (at least into a constant number of groups).

To implement this idea, we first need some notation. As mentioned earlier, we will be able to prove robustness of the verifier via bundling; however, over a larger alphabet. This large alphabet will be $\Sigma = \mathbb{F}^{l+2l\cdot(m+1)}$. Unlike before, the proof oracle for the robust PCPP verifier will consist of only one function $\Pi : \mathbb{F}^m \to \Sigma$. The robust PCPP verifier simulates the PCPP verifier as follows: To answer the queries of the PCPP verifier, the robust verifier bundles several queries together, queries the new proof oracle Π, and then unbundles the answer to obtain the answers to the queries of the original PCPP verifier. For convenience, we index the $l + 2l \cdot (m + 1)$ coordinates of $\Sigma = \mathbb{F}^{l+2l\cdot(m+1)}$ as follows: The first l coordinates are indexed by a single index i ranging from 0 to $l - 1$, while the remaining $2l \cdot (m + 1)$ are indexed by a triplet of indices (i, j, b), where i ranges over $0, \ldots, l-1$, j ranges over $0, \ldots, m$, and $b \in \{0, 1\}$. Let $S : \mathbb{F}^m \to \mathbb{F}^m$ denote the (linear) transformation that performs one cyclic-shift to the right; that is, $S(x_0, \ldots, x_{m-1}) = (x_{m-1}, x_0, \ldots, x_{m-2})$. The bundling of the proof oracles $\tilde{A}_i$ and $P_{i,j}$ by the modified proof oracle Π is as follows:

(8.1)
$$\forall x \in \mathbb{F}^m, \begin{cases} \Pi(x)_i = \tilde{A}_i\left(S^{\lfloor \frac{i}{h} \rfloor}(x)\right) & i = 0, \ldots, l-1, \\ \Pi(x)_{(i,j,b)} = P_{i,j}^{(b)}\left(S^{j+\lfloor \frac{i}{h} \rfloor}(x)\right) & i = 0, \ldots, l-1;\ j = 0, \ldots, m;\ b \in \{0,1\}, \end{cases}$$

where $h = \log |H| = \log n/m$. Note that the size of the new proof oracle Π is exactly equal to the sum of the size of the oracles $\tilde{A}_i$ and $P_{i,j}$.

We now state how the robust verifier performs the unbundling and the individual tests. We consider each step of the PCPP verifier and present its robust counterpart.

The first steps of PCPP Verifier (and ALMSS PCPP Verifier) are independent of the proof oracle and are performed as before. That is, the robust verifier, as before, reduces the CktSAT instance to an instance $\langle 1^n, 1^m, \mathbb{F}, H, \{\tilde{T}_0, \ldots, \tilde{T}_{l-1}\}\rangle$ of AS-CktSAT, sets $d = m \cdot |H|$, and generates a random string R of length $\log(|S_\lambda| \cdot |\mathbb{F}|^{m-1})$. The remaining steps are proof oracle dependent and we will discuss each of them in detail.

Proximity test. For the proximity test, the only portion of the proof oracle that we require is the portion containing $\tilde{A}_0$. For this, we observe that $\Pi(x)_0$ is $\tilde{A}_0 \circ S^{\lfloor \frac{0}{h} \rfloor}(x) = \tilde{A}_0(x)$. The two different proximity tests (Robust Proximity Test and Robust ALMSS Proximity Test) can easily be describes as follows:

Robust Proximity Test$^{W;\,\Pi}(R)$.

Use random string R to determine a random canonical line $\mathcal{L}$ in $\mathbb{F}^m$ using the λ-biased set S_λ. Query oracle Π on all points along the line $\mathcal{L}$. Unbundle $\Pi(\mathcal{L})$ to obtain the values of $\tilde{A}_0$ on all points along the line $\mathcal{L}$ and reject if the restriction $\tilde{A}_0$ to $\mathcal{L}$ is not a polynomial of degree at most d. Query the input oracle W on all locations corresponding to those in $I \cap \mathcal{L}$ and reject if W disagrees with $\tilde{A}_0$ on any of the locations in $I \cap \mathcal{L}$.

Robust ALMSS Proximity Test$^{W;\,\Pi}$.

Choose a random position $i \overset{R}{\leftarrow} \{1, \ldots, k\}$ in the input and a direction $y \leftarrow \mathbb{F}^m$. Let $x \in I$ be the point corresponding to i in H^m, and let $\mathcal{L}$ be the line through x in direction y. Query oracle Π on all points along the line $\mathcal{L}$. Unbundle $\Pi(\mathcal{L})$ to obtain the values of $\tilde{A}_0$ on all points along

the line $\mathcal{L}$ and reject if the restriction $\tilde{A}_0$ to $\mathcal{L}$ is not a polynomial of degree at most d. Query the input oracle W at location i and reject if $W[i] \neq \tilde{A}_0(x)$.

Low-degree test. We note that the distance of the polynomial $\tilde{A}_i : \mathbb{F}^m \to \mathbb{F}$ to being degree k (for any $k \in \mathbb{Z}^+$) is exactly the same as that of $\tilde{A}_i \circ S^{\lfloor \frac{i}{h} \rfloor} : \mathbb{F}^m \to \mathbb{F}$ since $S^{\lfloor \frac{i}{h} \rfloor}$ is an invertible linear transformation. Hence, it is sufficient if we check that $\tilde{A}_i \circ S^{\lfloor \frac{i}{h} \rfloor}$ is low degree. The case with the $P_{i,j}^{(b)}$'s is similar. Thus, the new Robust Low-Degree Test can be described as follows:

Robust Low-Degree Test$^{\Pi}(R)$.

Use random string R to determine a random canonical line $\mathcal{L}$ in $\mathbb{F}^m$ using the λ-biased set S_λ.

Query the oracle Π on all points along the line $\mathcal{L}$.

For $i = 0, \ldots, l-1$,

unbundle $\Pi(\mathcal{L})$ to obtain the values of $\tilde{A}_i \circ S^{\lfloor \frac{i}{h} \rfloor}$ on all points along the line $\mathcal{L}$ and reject if the restriction $\tilde{A}_i \circ S^{\lfloor \frac{i}{h} \rfloor}$ to $\mathcal{L}$ is not a polynomial of degree at most d.

For $i = 0, \ldots, l-1$, $j = 0, \ldots, m$ and $b \in \{0, 1\}$,

unbundle $\Pi(\mathcal{L})$ to obtain the values of $P_{i,j}^{(b)} \circ S^{j+\lfloor \frac{i}{h} \rfloor}$ on all points along the line $\mathcal{L}$ and reject if the restriction of $P_{i,j}^{(b)} \circ S^{j+\lfloor \frac{i}{h} \rfloor}$ to $\mathcal{L}$ is not a polynomial of degree at most κd.

Thus, effectively we are testing $\tilde{A}_i$ (respectively, $P_{i,j}$) using the line space $S^{\lfloor \frac{i}{h} \rfloor} \circ S_\lambda$ (respectively, $S^{j+\lfloor \frac{i}{h} \rfloor} \circ S_\lambda$).

Identity test. In the case of Identity Test, we observe that $P_{i,m}^{(b)}$ vanishes on $\mathbb{F}^m$ iff $P_{i,m}^{(b)} \circ S^{m+\lfloor \frac{i}{h} \rfloor}$ vanishes on $\mathbb{F}^m$. Recall that we were allowed to use arbitrary partitions of the space $\mathbb{F}^m$. The set of random 1st axis-parallel lines is one such partition and we use this partition.

- Robust Identity Test$^{\Pi}(R)$.
  - Use random string R to determine a random 1st axis-parallel line in $\mathbb{F}^m$ of the form $\mathcal{L} = (X, a_1, \ldots, a_{m-1})$. Query the oracle Π on all points along the line $\mathcal{L}$.

    For $i = 0, \ldots, l-1$ and $b \in \{0, 1\}$,

    * unbundle $\Pi(\mathcal{L})$ to obtain the values of $P_{i,m}^{(b)} \circ S^{m+\lfloor \frac{i}{h} \rfloor}$ on all points along the line $\mathcal{L}$ and reject if any of these are nonzero.

Edge-consistency test. For any $x \in \mathbb{F}^m$, we say that $P_{i,0}$ is *well formed* at x if (6.2) is satisfied for this x. Edge-Consistency Test verifies that $P_{i,0}$ is well formed for all $x \in U_\eta$ and $i = 0, \ldots, l-1$. This was done earlier by reading the values of $P_{i,0}, \tilde{A}_i, \tilde{A}_{i+1} \circ \tilde{\Gamma}_{i,0} = \tilde{A}_{i+1}$ and $\tilde{A}_{i+1} \circ \tilde{\Gamma}_{i,1}$ for all $x \in U_\eta$.

Let $\mathcal{L}$ be a random 1st axis-parallel line. The robust version of this test checks that $P_{i,0}$ is well formed for all points on $S^{\lfloor \frac{i}{h} \rfloor}(\mathcal{L})$. Consider any $x = (x_0, \ldots, x_{m-1}) \in \mathcal{L}$. To verify that $P_{i,0}$ is well formed at $S^{\lfloor \frac{i}{h} \rfloor}(x)$, the verifier needs the values $P_{i,0}(S^{\lfloor \frac{i}{h} \rfloor}(x))$, $\tilde{A}_i(S^{\lfloor \frac{i}{h} \rfloor}(x))$, $\tilde{A}_{i+1}(S^{\lfloor \frac{i}{h} \rfloor}(x))$, and $\tilde{A}_{i+1} \circ \tilde{\Gamma}_{i,1}(S^{\lfloor \frac{i}{h} \rfloor}(x))$. We will show that all these values can be obtained from unbundling the value of Π on $\mathcal{L}$ and $S^{-1}(\mathcal{L})$. Clearly, the values $P_{i,0}(S^{\lfloor \frac{i}{h} \rfloor}(x))$ and $\tilde{A}_i(S^{\lfloor \frac{i}{h} \rfloor}(x))$ can be obtained from unbundling the value of Π at x. The other two values that we require are $\tilde{A}_{i+1}(S^{\lfloor \frac{i}{h} \rfloor}(x))$ and $\tilde{A}_{i+1} \circ \tilde{\Gamma}_{i,1}(S^{\lfloor \frac{i}{h} \rfloor}(x))$. We first show that $\tilde{\Gamma}_{i,1}(S^{\lfloor \frac{i}{h} \rfloor}(x)) = S^{\lfloor \frac{i}{h} \rfloor}(x')$ for $x' = (x_0 + e_{(i \bmod h)}, x_1, \ldots, x_{m-1}) \in \mathcal{L}$ (recall that $\{e_0, \ldots, e_{f-1}\}$ are a basis for $\mathbb{F}$ over $\mathbb{F}_2$ and $\{e_0, \ldots, e_{h-1}\}$ span $H \subset \mathbb{F}$). For this purpose, we first recall the definition of $\tilde{\Gamma}_{i,1}$: $\tilde{\Gamma}_{i,1}(z_0, \ldots, z_{m-1}) =$

$(z_0, \ldots, z_{t-1}, z_t + e_u, z_{t+1}, \ldots, z_{m-1})$, where $t = \lfloor i/h \rfloor \bmod m$ and $u = i \bmod h$. Furthermore, since S^m is the identity map, we have that $S^{\lfloor \frac{i}{h} \rfloor \bmod m} = S^{\lfloor \frac{i}{h} \rfloor}$. With these observations, we have the following:

$$\begin{aligned}\tilde{\Gamma}_{i,1}\left(S^{\lfloor \frac{i}{h} \rfloor}(x)\right) &= \tilde{\Gamma}_{i,1}\left(S^{\lfloor i/h \rfloor \bmod m}(x)\right)\\ &= \tilde{\Gamma}_{i,1}\left(S^{\lfloor i/h \rfloor \bmod m}(x_0, \ldots, x_{m-1})\right)\\ &= S^{\lfloor i/h \rfloor \bmod m}\left(x_0 + e_{(i \bmod h)}, x_1, \ldots, x_{m-1}\right)\\ &= S^{\lfloor \frac{i}{h} \rfloor}(x').\end{aligned}$$

Now, $S^{\lfloor \frac{i+1}{h} \rfloor}$ is either $S^{\lfloor \frac{i}{h} \rfloor}$ or $S^{\lfloor \frac{i}{h} \rfloor + 1}$ depending on the value of i. Suppose $S^{\lfloor \frac{i+1}{h} \rfloor} = S^{\lfloor \frac{i}{h} \rfloor}$. We then have that $\tilde{A}_{i+1}(S^{\lfloor \frac{i}{h} \rfloor}(x)) = A_{i+1}(S^{\lfloor \frac{i+1}{h} \rfloor}(x))$ and $\tilde{A}_{i+1} \circ \tilde{\Gamma}_{i,1}(S^{\lfloor \frac{i}{h} \rfloor}(x)) = \tilde{A}_{i+1}(S^{\lfloor \frac{i}{h} \rfloor}(x')) = \tilde{A}_{i+1}(S^{\lfloor \frac{i+1}{h} \rfloor}(x'))$. Both these values can be obtained by unbundling the value of Π on $\mathcal{L}$ (since both x and x' lie on $\mathcal{L}$). In the other case, where $S^{\lfloor \frac{i+1}{h} \rfloor} = S^{\lfloor \frac{i}{h} \rfloor + 1}$, we have $A_{i+1}(S^{\lfloor \frac{i}{h} \rfloor}(x)) = A_{i+1}(S^{\lfloor \frac{i+1}{h} \rfloor}(S^{-1}x))$ and $A_{i+1} \circ \tilde{\Gamma}_{i,1}(S^{\lfloor \frac{i}{h} \rfloor}(x)) = A_{i+1}(S^{\lfloor \frac{i}{h} \rfloor}(x')) = A_{i+1}(S^{\lfloor \frac{i+1}{h} \rfloor}(S^{-1}x'))$. These values can be obtained by unbundling the value of Π on $S^{-1}(\mathcal{L})$. Thus, to check that $P_{i,0}$ is well formed for all points on $S^{\lfloor \frac{i}{h} \rfloor}(\mathcal{L})$, it suffices if the verifier queries Π on all points on $\mathcal{L}$ and $S^{-1}(\mathcal{L})$.

ROBUST EDGE-CONSISTENCY TEST$^{\Pi}(R)$.

Use the random string R to determine a random 1st axis-parallel line in $\mathbb{F}^m$ of the form $\mathcal{L} = (X, a_2, \ldots, a_m)$. Query the oracle Π along all points in the lines $\mathcal{L}$ and $S^{-1}(\mathcal{L})$.

For $i = 0, \ldots, l-1$,

for all $x \in S^{\lfloor \frac{i}{h} \rfloor}(\mathcal{L})$, reject if $P_{i,0}$ is not well formed at x. (Note that all the values required for this verification can be obtained by unbundling $\Pi(\mathcal{L})$ and $\Pi(S^{-1}(\mathcal{L}))$.)

Zero-propagation test. For each $i = 0, \ldots, l-1$ and $b \in \{0,1\}$, ZERO-PROPAGATION TEST checks that $P_{i,0}^{(b)}$ vanishes on H^m by verifying that (6.3) is satisfied for all $j = 1, \ldots, m-1$ (we also need to check that $P_{i,m}^{(b)} \equiv 0$; however, this is taken care of by IDENTITY TEST). Since $S(H^m) = H^m$, checking if $P_{i,0}^{(b)}$ vanishes on H^m is equivalent to checking if $P_{i,0}^{(b)} \circ S^{\lfloor \frac{i}{h} \rfloor}$ vanishes on H^m. Hence, we can perform the zero propagation on the polynomials $P_{i,0}^{(b)} \circ S^{\lfloor \frac{i}{h} \rfloor}; i = 0, \ldots, l-1, b \in \{0,1\}$, instead of the polynomials $P_{i,0}^{(b)}; i = 0, \ldots, l-1, b \in \{0,1\}$. In other words, we need to verify the following equation instead (6.3):

(8.2)

$$\begin{aligned}&P_{i,j}^{(b)} \circ S^{\lfloor \frac{i}{h} \rfloor}\left(\underbrace{x_1, \ldots, x_{j-1}}, x_j, \underbrace{x_{j+1}, \ldots, x_m}\right)\\ &= \sum_{k=0}^{|H|-1} P_{i,j-1}^{(b)} \circ S^{\lfloor \frac{i}{h} \rfloor}\left(\underbrace{x_1, \ldots, x_{j-1}}, h_k, \underbrace{x_{j+1}, \ldots, x_m}\right) x_j^k \qquad \forall (x_1, \ldots, x_m) \in \mathbb{F}^m.\end{aligned}$$

This equation can be further rewritten in terms of the cyclic-shift S as follows:

(8.3)
$$P_{i,j}^{(b)}\left(S^{\lfloor \frac{i}{h} \rfloor + j - 1}(x_1, x_2, \ldots, x_m)\right) = \sum_{k=0}^{|H|-1} P_{i,j-1}^{(b)}\left(S^{\lfloor \frac{i}{h} \rfloor + j - 1}(h_k, x_2, \ldots, x_m)\right) x_1^k \quad \forall (x_1, \ldots, x_m) \in \mathbb{F}^m.$$

This helps us to rewrite Zero-Propagation Test with bundling as follows:

Robust Zero-Propagation Test$^{\Pi(R)}$.

Use random string R to determine a random 1st axis-parallel line in $\mathbb{F}^m$ of the form $\mathcal{L} = (X, a_2, \ldots, a_m)$. Query the oracle Π along all points in the lines $\mathcal{L}$ and $S^{-1}(\mathcal{L})$.

For $i = 0, \ldots, l-1$, $j = 1, \ldots, m$, and $b \in \{0, 1\}$,

unbundle $\Pi(\mathcal{L})$ to obtain the value of $P_{i,j-1}^{(b)} \circ S^{\lfloor \frac{i}{h} \rfloor + j - 1}$ on all points along the line $\mathcal{L}$. Similarly, unbundle $\Pi(S^{-1}(\mathcal{L}))$ to obtain the value of $P_{i,j}^{(b)} \circ S^{\lfloor \frac{i}{h} \rfloor + j}$ on all points along the line $S^{-1}(\mathcal{L})$ (equivalently, this is the value of $P_{i,j}^{(b)} \circ S^{\lfloor \frac{i}{h} \rfloor + j - 1}$ on all points along the line $\mathcal{L}$). Reject either if the restriction of $P_{i,j-1}^{(b)} \circ S^{\lfloor \frac{i}{h} \rfloor + j - 1}$ or $P_{i,j}^{(b)} \circ S^{\lfloor \frac{i}{h} \rfloor + j - 1}$ to $\mathcal{L}$ is not a polynomial of degree at most κd or if any of the points on the line $\mathcal{L}$ violate (8.3).

The integrated robust verifiers. Having presented the robust version of each of the tests, the integrated robust verifiers are as follows: Robust PCPP Verifier is the robust analogue of PCPP Verifier, while ALMSS Robust PCPP Verifier is that of ALMSS PCPP Verifier. Following are full descriptions of these verifiers as well as their analyses.

8.2.1. Robust PCPP Verifier. Using the robust tests presented above, we present a robust analogue of the PCPP of section 7.1.

Robust PCPP Verifier$^{W;\,\Pi}_{m,\lambda,\delta}(C)$.

1. Using Proposition 6.11, reduce the instance C of CktSAT, using parameter m, to an instance $\langle 1^n, 1^m, \mathbb{F}, H, \{\tilde{T}_0, \ldots, \tilde{T}_{l-1}\}\rangle$ of AS-CktSAT, and set $d = m \cdot |H|$.
   We let $S_\lambda \subset \mathbb{F}^m$ be a λ-biased set of size at most $(\frac{\log |\mathbb{F}|^m}{\lambda})^2$ [AGHP92].
2. Choose a random string R of length $\log(|S_\lambda| \cdot |\mathbb{F}|^{m-1})$. (Note: We reuse R in all tests, but only Low-Degree Test utilizes the full length of R.)
3. Run Robust Low-Degree Test$^{\Pi}(R)$.
4. Run Robust Edge-Consistency Test$^{\Pi}(R)$.
5. Run Robust Zero-Propagation Test$^{\Pi}(R)$.
6. Run Robust Identity Test$^{\Pi}(R)$.
7. Run Robust Proximity Test$^{W;\Pi}(R)$.

Reject if any of the above tests reject.

The randomness of Robust PCPP Verifier is exactly the same as before, whereas the query complexity and decision complexity increase by a constant factor.[32]

[32] Though the new proof oracle returns elements of Σ and not bits, we express the query complexity as the number of bits read by the verifier rather than as the number of symbols (i.e., elements of $|\Sigma|$) to maintain consistency throughout calculation of the query complexity into the proof and input oracles.

PROPOSITION 8.7. *The randomness, query, and decision complexities of* ROBUST PCPP VERIFIER *are* $r = \left(1 - \frac{1}{m}\right)\log n + O(m \log m) + O(\log\log n) + O\left(\log\left(\frac{1}{\delta}\right)\right)$, $q = O(m^2 n^{1/m} \log^2 n)$ *and* $d = \widetilde{O}(q)$, *respectively.*

It is straightforward to check perfect completeness of this verifier.

Robustness analysis of the integrated verifier. For future use, it is beneficial (but, alas, more cumbersome) to state the robustness of the integrated verifier in a way that decouples the robustness with respect to the input oracle from the robustness with respect to the proof oracle. Let $W : [k] \to \{0,1\}$ be the input oracle and Π the proof oracle. For every sequence of coin tosses R (and a given setting of parameters), let $\Delta_{\text{inp}}^{W,\Pi}(R)$ (resp., $\Delta_{\text{pf}}^{W,\Pi}(R)$) denote the fraction of the bits read from W (resp., Π) that would need to be changed to make ROBUST PCPP VERIFIER accept on coin tosses R. The following lemma states the (expected) robustness property of our verifier.

LEMMA 8.8. *There are constants* $c \in \mathbb{Z}^+$ *and* $\rho > 0$ *such the following holds for every* $n, m \in \mathbb{Z}^+$, $\delta', \delta > 0$ *satisfying* $m \le \log n / \log\log n$, $n^{1/m} \ge m^{cm}/{\delta'}^3$, $\lambda \le \min\{1/c\log n, {\delta'}^3/m^{cm}\}$, $\delta > \delta'$. *If* W *is* δ*-far from satisfying the circuit, then for any proof oracle* $\Pi : \mathbb{F}^m \to \Sigma$, *either* $\mathrm{E}_R[\Delta_{\text{pf}}^{W,\Pi}(R)] \ge \rho$ *or* $\mathrm{E}_R[\Delta_{\text{inp}}^{W,\Pi}(R)] \ge \delta - \delta'/2$.

That is, the expected robustness with respect to the input is $\delta - \delta'/2$ (which should be compared against the proximity parameter δ), whereas the expected robustness with respect to the proof is a universal constant. Note that combining the two bounds into a single expected robustness parameter depends on the relative number of queries made to the input and proof oracles. To obtain Theorem 3.1, we will later modify ROBUST PCPP VERIFIER such that the relative number of queries is optimized to yield the best result.

Proof. Unbundle the proof oracle Π to obtain the functions $\tilde{A}_i$ and $P_{i,j}$ using (8.2). Consider the action of PCPP VERIFIER (i.e., the nonrobust verifier) on the proof oracles $\tilde{A}_i, P_{i,j}$ and input oracle W.

Let ε be a sufficiently small constant such that the Claims 8.1–8.5 hold. Suppose W is δ-far from satisfying the circuit. We then know that one of the following holds and that the corresponding test instance of PCPP VERIFIER rejects its input robustly (see Claims 8.1–8.5).

1. There exists a $i \in \{0, \ldots, l-1\}$ such that $\tilde{A}_i$ is 8ε-far from every degree md polynomial or there exists $i \in \{0, \ldots, l-1\}$, $j \in \{0, \ldots, m\}$, and $b \in \{0,1\}$ such that $P_{i,j}^{(b)}$ is 8ε-far from every degree κmd polynomial. In this case,the expected distance of $\tilde{A}_i$ (or resp., $P_{i,j}^{(b)}$) from satisfying LOW-DEGREE TEST with degree parameter d (resp., κd) is at least 2ε (Claim 8.1).
2. There exists $i \in \{0, \ldots, l-1\}$ and $b \in \{0,1\}$, such that $\Delta(P_{i,m}^{(b)}, \widehat{P}_{i,m}^{(b)}) \le 8\varepsilon$ and $\widehat{P}_{i,m} \not\equiv 0$. In this case, $P_{i,m}$ has expected distance at least $1 - 9\varepsilon$ from satisfying IDENTITY TEST (Claim 8.2).
3. There exists $i \in \{0, \ldots, l-1\}$ such that

$$\Delta(P_{i,0}^{(0)}, \widehat{P}_{i,0}^{(0)}) \le 8\varepsilon, \Delta(P_{i,0}^{(1)}, \widehat{P}_{i,0}^{(1)}) \le 8\varepsilon, \Delta(\tilde{A}_i, \widehat{A}_i) \le 8\varepsilon, \Delta(\tilde{A}_{i+1}, \widehat{A}_{i+1}) \le 8\varepsilon,$$
$$\text{and } \widehat{P}_{i,0}(x) \not\equiv \psi'(\tilde{T}_i(x), \widehat{A}_i(x), \widehat{A}_{i+1}(\tilde{\Gamma}_{i,0}(x)), \widehat{A}_{i+1}(\tilde{\Gamma}_{i,1}(x))).$$

In this case, $\{P_{i,0}(\cdot), A_i(\cdot), A_{i+1}(\tilde{\Gamma}_{i,0}(\cdot))A_{i+1}(\tilde{\Gamma}_{i,1}(\cdot))\}$ has expected distance at least $(1 - 41\varepsilon)/5$ from satisfying EDGE-CONSISTENCY TEST (Claim 8.3).

4. There exists $i \in \{0, \ldots, l-1\}$, $j \in \{1, \ldots, m\}$ and $b \in \{0,1\}$ such that

$$\Delta(P_{i,j}, \widehat{P}_{i,j}) \leq 8\varepsilon, \Delta(P_{i,j-1}, \widehat{P}_{i,j-1}) \leq 8\varepsilon,$$
$$\text{and } \widehat{P}_{i,j}(\ldots, x_j, \ldots) \not\equiv \sum_{k=0}^{|H|-1} \widehat{P}_{i,j-1}(\ldots, h_k, \ldots) x_j^k.$$

   In this case, $(P_{i,j}^{(b)}, P_{i,j-1}^{(b)})$ has expected distance at least $(1-19\varepsilon)/2$ from satisfying Zero-Propagation Test (Claim 8.4).
5. $\Delta(\tilde{A}_0, \widehat{A}_0) \leq 8\varepsilon$, but W and $\widehat{A}_0|_I$ disagree on at least δ' fraction of the points. In this case, with probability at least $1-\delta'/4$ (over the choice of the canonical line $\mathcal{L}$) either at least an ε-fraction of $A_0|_{\mathcal{L}}$ or at least a $(\delta - \delta'/4)$-fraction of $W|_{\mathcal{L}}$ needs to be changed to make Proximity Test accept (Claim 8.5). This implies that either A_0 has expected distance $(1-\delta'/4)\varepsilon \geq \varepsilon/2$ or W has expected distance $(1-\delta'/4)(\delta-\delta'/4) \geq (\delta - \delta'/2)$ from satisfying Proximity Test.

For instance, lets us assume $\tilde{A}_0$ is 8ε-far from being low degree so Low-Degree Test rejects it robustly; that is, for a random canonical line $\mathcal{L}$, the expected distance of $\tilde{A}_0|_{\mathcal{L}}$ from satisfying Low-Degree Test is at least 2ε. Recall from (8.2) that $\tilde{A}_0(x)$ is one of the coordinates in the bundled $\Pi(x)$. Hence, if $\tilde{A}_0|_{\mathcal{L}}$ is ρ-far from satisfying Low-Degree Test, so is $\Pi_{\mathcal{L}}$ from satisfying Robust Low-Degree Test. Thus, Π has expected distance at least 2ε from satisfying Robust Low-Degree Test. Now, the oracle positions read by Robust Low-Degree Test constitute a constant fraction of the oracle positions read by Robust PCPP Verifier, so Π has expected distance $\Omega(\varepsilon)$ from satisfying Robust PCPP Verifier. Thus, the robustness of the individual test instance is transferred to the combined Robust Low-Degree Test by bundling. The case with the other test types is similar. We thus have that $\mathrm{E}_R[\Delta_{\mathrm{pf}}^{W,\Pi}(R)] \geq \Omega(\varepsilon)$ or $\mathrm{E}_R[\Delta_{\mathrm{inp}}^{W,\Pi}(R)] \geq \delta - \delta'/2$. The lemma then follows by setting $\rho = \Omega(\varepsilon)$. □

8.2.2. ALMSS Robust PCPP Verifier. We now describe ALMSS Robust PCPP Verifier(which is a robust analogue of the PCPP of section 7.2) and analyze its complexity. ALMSS Robust PCPP Verifier verifier is identical to Robust PCPP Verifier except that Robust Proximity Test is replaced by Robust ALMSS Proximity Test.

ALMSS Robust PCPP Verifier$_\delta^{W;\,\Pi}(C)$.

1. Set parameters $m = \log n / \log\log n$ and $\lambda = 1/c\log n$.
   Using Proposition 6.11, reduce the instance C of CktSAT, using parameter m, to an instance $\langle 1^n, 1^m, \mathbb{F}, H, \{\tilde{T}_0, \ldots, \tilde{T}_{l-1}\}\rangle$ of AS-CktSAT, and set $d = m \cdot |H|$.
   We let $S_\lambda \subset \mathbb{F}^m$ be a λ-biased set of size at most $(\frac{\log|\mathbb{F}|^m}{\lambda})^2$ [AGHP92].
2. Choose a random string R of length $\log(|S_\lambda| \cdot |\mathbb{F}|^{m-1})$.
3. Run Robust Low-Degree Test$^\Pi(R)$.
4. Run Robust Edge-Consistency Test$^\Pi(R)$.
5. Run Robust Zero-Propagation Test$^\Pi(R)$.
6. Run Robust Identity Test$^\Pi(R)$.
7. Run Robust ALMSS Proximity Test$^{W;\Pi}$.

Reject if any of the above tests reject.

The randomness of the ALMSS Robust PCPP Verifier is exactly the same as before, whereas the query complexity and decision complexity increase by a constant

factor. Furthermore, it can easily be verified that ALMSS Robust PCPP Verifier has perfect completeness.

Proposition 8.9. *The randomness, and decision complexities of* ALMSS Robust PCPP Verifier *are* $O(\log n)$ *and* $\operatorname{poly}\log n$*, respectively.*

Robustness analysis of the integrated verifier. As in the case of Robust PCPP Verifier, it is beneficial to state the robustness of ALMSS Robust PCPP Verifier by decoupling the robustness with respect to the input oracle from the robustness with respect to the proof oracle. Here, however, we refer to the robustness and soundness parameters (rather than to expected robustness).

Lemma 8.10. *If* W *is* δ*-far from satisfying the circuit, then for any proof oracle* $\Pi : \mathbb{F}^m \to \Sigma$*, with probability at least* $\Omega(\delta)$*, either a constant fraction of the portion of the proof oracle* Π *read by the verifier or the single symbol of the input oracle* W *read by the verifier (i.e.,* $W[i]$*) needs to be changed in order to make* ALMSS Robust PCPP Verifier *accept.*

Proof. This proof proceeds in the same way as the proof of Lemma 8.8. For the sake of completeness, we present the entire proof.

Let ε be a sufficiently small constant such that Claims 8.1–8.4 hold and $\varepsilon \le \varepsilon_0/8$, where ε_0 is the constant that appears in Claim 8.6. Suppose W is δ'-far from satisfying the circuit. We then know that one of the following holds and that the corresponding test instance of ALMSS PCPP Verifier rejects its input robustly (see Claims 8.1–8.6).

1. There exists $i \in \{0, \ldots, l-1\}$ such that $\tilde{A}_i$ is 8ε-far from every degree md polynomial or there exists $i \in \{0, \ldots, l-1\}$, $j \in \{0, \ldots, m\}$, and $b \in \{0,1\}$ such that $P_{i,j}^{(b)}$ is 8ε-far from every degree κmd polynomial. In this case, the expected distance of $\tilde{A}_i$ (resp., $P_{i,j}^{(b)}$) from satisfying Low-Degree Test with degree parameter d (resp., κd) is at least 2ε (Claim 8.1).
   Translating to the bundled alphabet, we have that the expected distance of Π from satisfying Robust Low-Degree Test is at least 2ε. Since the number of oracle positions read by ALMSS Robust PCPP Verifier is at least a constant fraction of the number of oracle positions read by ALMSS Robust PCPP Verifier, the expected distance of Π from satisfying ALMSS Robust PCPP Verifier in this case is at least $\Omega(\varepsilon)$. Hence, with probability at least $\Omega(\varepsilon)$ (= constant), at least $\Omega(\varepsilon)$ (= constant)-fraction of the proof oracle Π needs to be modified to make ALMSS Robust PCPP Verifier accept.
2. There exists $i \in \{0, \ldots, l-1\}$ and $b \in \{0,1\}$ such that $\Delta(P_{i,m}^{(b)}, \widehat{P}_{i,m}^{(b)}) \le 8\varepsilon$ and $\widehat{P}_{i,m} \not\equiv 0$. In this case, $P_{i,m}$ has expected distance at least $1 - 9\varepsilon$ from satisfying Identity Test (Claim 8.2).
   Arguing as in the earlier case, we have that with probability at least $\Omega(1-9\varepsilon)$, at least $\Omega(1-9\varepsilon)$-fraction of the proof oracle Π needs to be modified in this case to make ALMSS Robust PCPP Verifier accept.
3. There exists $i \in \{0, \ldots, l-1\}$ such that

$$\Delta(P_{i,0}^{(0)}, \widehat{P}_{i,0}^{(0)}) \le 8\varepsilon, \Delta(P_{i,0}^{(1)}, \widehat{P}_{i,0}^{(1)}) \le 8\varepsilon, \Delta(\tilde{A}_i, \widehat{A}_i) \le 8\varepsilon, \Delta(\tilde{A}_{i+1}, \widehat{A}_{i+1}) \le 8\varepsilon,$$
$$\text{and } \widehat{P}_{i,0}(x) \not\equiv \psi'(\tilde{T}_i(x), \widehat{A}_i(x), \widehat{A}_{i+1}(\tilde{\Gamma}_{i,0}(x)), \widehat{A}_{i+1}(\tilde{\Gamma}_{i,1}(x))).$$

   In this case, $\{P_{i,0}(\cdot), A_i(\cdot), A_{i+1}(\tilde{\Gamma}_{i,0}(\cdot))A_{i+1}(\tilde{\Gamma}_{i,1}(\cdot))\}$ has expected distance at least $(1 - 41\varepsilon)/5$ from satisfying Edge-Consistency Test (Claim 8.3).

Again, we have that with probability at least $\Omega(1-41\varepsilon)$, at least $\Omega(1-41\varepsilon)$-fraction of the proof oracle Π needs to be modified in this case to make ALMSS Robust PCPP Verifier accept.

4. There exists $i \in \{0,\dots,l-1\}$, $j \in \{1,\dots,m\}$, and $b \in \{0,1\}$ such that

$$\Delta(P_{i,j}, \widehat{P}_{i,j}) \le 8\varepsilon, \Delta(P_{i,j-1}, \widehat{P}_{i,j-1}) \le 8\varepsilon,$$
$$\text{and } \widehat{P}_{i,j}(\dots, x_j, \dots) \not\equiv \sum_{k=0}^{|H|-1} \widehat{P}_{i,j-1}(\dots, h_k, \dots) x_j^k.$$

In this case, $(P_{i,j}^{(b)}, P_{i,j-1}^{(b)})$ has expected distance at least $(1-19\varepsilon)/2$ from satisfying Zero-Propagation Test (Claim 8.4).
We have that with probability at least $\Omega(1-19\varepsilon)$, at least $\Omega(1-19\varepsilon)$-fraction of the proof oracle Π needs to be modified in this case to make ALMSS Robust PCPP Verifier accept.

5. $\Delta(\tilde{A}_0, \widehat{A}_0) \le 8\varepsilon \le \varepsilon_0$, but W and $\widehat{A}_0|_I$ disagree on at least δ-fraction of the points. In this case, with probability at least $\Omega(\delta)$ (over the choice of index i and direction y), either at least a 1/2-fraction of $A_0|_{\mathcal{L}}$ or $W[i]$ (i.e., the entire portion of the input oracle read by the verifier) needs to be changed to make ALMSS Proximity Test accept.
This implies that with probability at least δ, either a constant fraction of the proof oracle Π or $W[i]$ (i.e., the entire portion of the input oracle read by the verifier) needs to be modified to make the verifier accept.

Since we do not know which of the five cases occur, we can guarantee only the weakest of the five claims. Hence, with probability at least $\Omega(\delta)$, either a constant fraction of the portion of the proof oracle Π read by the verifier or $W[i]$ (i.e., the entire portion of the input oracle W read by the verifier) needs to be changed in order to make ALMSS Robust PCPP Verifier accept. □

8.3. Robustness over the binary alphabet. The transformation from a robust verifier over the alphabet Σ to one over the binary alphabet is analogous to converting non-Boolean error-correcting codes to Boolean ones via "code concatenation." This transformation is exactly the same transformation as the one in the proof of Lemma 2.13. However, we cannot directly use Lemma 2.13 because we may apply the code concatenation process only to the proof oracle Π and not to the input oracle W. However, this is not a problem because the input oracle is already binary. Recall that applying the aforementioned transformation maintains the robustness of the proof oracle *up to a constant factor*, whereas the robustness of the input oracle remains unchanged (like the input oracle itself). Actually, in order to avoid decoding (by the modified decision circuit), we maintain the original proof oracle along with its encoded form. Thus, the complexity of this circuit will depend on the minimum between the complexity of encoding and decoding (rather than on the complexity of decoding). Details follow.

Let $\mathrm{ECC} : \{0,1\}^{\log|\Sigma|} \to \{0,1\}^b$ for $b = O(\log|\Sigma|)$ be a binary error-correcting code of constant relative minimum distance, which can be computed by an explicit circuit of size $O(\log|\Sigma|)$ [Spi96]. We augment the original proof oracle Π, viewed now as having $\log|\Sigma|$-bit long entries (i.e., elements of Σ) with an additional oracle Υ having b-bit long entries, where $\Upsilon(x)$ is assumed to be $\mathrm{ECC}(\Pi(x))$.

The actual transformation. We describe the transformation to the binary alphabet in the case of Robust PCPP Verifier. ALMSS Robust PCPP Verifier

can be transformed similarly. Our new verifier V, on oracle access to the input W and proof $\Pi \circ \Upsilon$, will simulate ROBUST PCPP VERIFIER. The queries to the input oracle are performed just as before. However, for each query $x \in \mathbb{F}^m$ in the proof oracle Π made by ROBUST PCPP VERIFIER, V will query the corresponding $\log|\Sigma|$ bits in $\Pi(x)$ and the b bits in $\Upsilon(x)$. Thus, the query complexity of V is at most $\log|\Sigma| + b$ times the number of queries issued by the earlier verifier. Since $b = O(\log|\Sigma|)$, the query complexity of the new verifier V is a constant times that of the previous one,[33] and the decision complexity will increase by at most the encoding time (which can even be linear). The randomness is exactly the same. The action of the new verifier V is as follows: Suppose ROBUST PCPP VERIFIER issues queries $x_1, \ldots, x_{q_1}$ to the proof oracle Π, and queries $i_1, \ldots, i_{q_2}$ to the input oracle; then V issues queries $x_1, \ldots, x_{q_1}$ to the proof oracle Π, a similar set of queries $x_1, \ldots, x_{q_1}$ to the proof oracle Υ, and $i_1, \ldots, i_{q_2}$ to the input oracle. V accepts $(\Pi(x_1), \ldots, \Pi(x_{q_1}), \Upsilon(x_1), \ldots, \Upsilon(x_{q_1}), W(i_1), \ldots, W(i_{q_2}))$ iff ROBUST PCPP VERIFIER accepts $(\Pi(x_1), \ldots, \Pi(x_{q_1}), W(i_1), \ldots, W(i_{q_2}))$ and $\Upsilon(x_i) = \mathrm{ECC}(\Pi(x_i))$ for all $i = 1, \ldots, q_1$. It is straightforward to check that V has perfect completeness if ROBUST PCPP VERIFIER has perfect completeness. For the robust soundness, we define $\Delta_{\mathrm{inp}}^{W,\Pi\circ\Upsilon}(R)$ and $\Delta_{\mathrm{pf}}^{W,\Pi\circ\Upsilon}(R)$ with respect to V analogously as in the statement immediately preceding Lemma 8.8, but referring to distance over $\{0,1\}$ (rather than Σ) for the proof oracle. The proof of the following claim regarding the robust soundness of V mimics the proof of Lemma 2.13.

LEMMA 8.11. *There are constants $c \in \mathbb{Z}^+$ and $\rho' > 0$ such that the following holds for every $n, m \in \mathbb{Z}^+$, $\delta, \delta' > 0$ satisfying $m \le \log n / \log\log n$, $n^{1/m} \ge m^{cm}/{\delta'}^3$, $\lambda \le \min\{1/c\log n, {\delta'}^3/m^{cm}\}$, $\delta > \delta'$. If W is δ-far from satisfying the circuit, then for any proof oracles $\Pi : \mathbb{F}^m \to \{0,1\}^{\log|\Sigma|}$, $\Upsilon : \mathbb{F}^m \to \{0,1\}^b$, either $\mathrm{E}_R[\Delta_{\mathrm{pf}}^{W,\Pi\circ\Upsilon}(R)] \ge \rho'$ or $\mathrm{E}_R[\Delta_{\mathrm{inp}}^{W,\Pi\circ\Upsilon}(R)] \ge \delta - \delta'/2$.*

A similar transformation for ALMSS ROBUST PCPP VERIFIER yields a verifier, the robustness of which is stated in Lemma 8.12 following. It is to be noted that the robustness of the proof oracle (i.e., ρ' in Lemma 8.11 and $\Omega(1)$ in Lemma 8.12) is a constant factor smaller than the corresponding parameter in the nonbinary verifier (i.e., the constant ρ in Lemma 8.8 and a different $\Omega(1)$ in Lemma 8.10). (Indeed, this constant factor appears also in Lemma 2.13.)

LEMMA 8.12. *If W is δ-far from satisfying the circuit, then for any proof oracles $\Pi : \mathbb{F}^m \to \{0,1\}^{\log|\Sigma|}$, $\Upsilon : \mathbb{F}^m \to \{0,1\}^b$, with probability at least $\Omega(\delta)$, either a constant (i.e., $\Omega(1)$) fraction of the portion of the proof oracle $\Pi\circ\Upsilon$ read by the verifier or $W[i]$ (i.e., the entire portion of the input oracle W read by the verifier) needs to be changed in order to make the transformed* ALMSS ROBUST PCPP VERIFIER *accept.*

We finally turn to deriving Theorem 3.1 (and Theorem 3.2).

Proof of Theorem 3.1. Theorem 3.1 is proved using ROBUST PCPP VERIFIER defined in this section, setting $\lambda = \min\{1/c\log n, \delta^3/m^{cm}\}$. The randomness, query, and decision complexity of ROBUST PCPP VERIFIER (i.e., before the transformation to the binary alphabet) are as mentioned in Proposition 8.7. As mentioned earlier in this section, the transformation from the alphabet Σ to the binary alphabet maintains the randomness complexity, while the query (and decision) complexity increases by at most a constant factor.

The manner in which the robustness of the verifier is expressed in Lemma 8.11

[33] Recall that the query complexity of the old verifier was measured in terms of "bits of information" rather than in terms of queries. That is, each query, answered by an element of Σ, contributes $\log_2|\Sigma|$ to the query complexity.

differs from that in Theorem 3.1 in two aspects. First, Lemma 8.11 expresses the robustness for the proof and input oracles separately, while Theorem 3.1 expresses them together. Second, Lemma 8.11 expresses robustness in terms of expected robustness, while Theorem 3.1 does it in terms of standard robustness. We obtain robustness as claimed in Theorem 3.1 in two steps, first by combining the proof and input oracles and then by moving from expected robustness to standard robustness.

First, we combine the robustness of the proof and input oracles, which were expressed separately in Lemma 8.11. This is done by giving adequate weights to the two oracle portions in the decision circuits (i.e., repeating queries; see Proposition 7.3). Let n, m, δ, and γ be as specified in Theorem 3.1. We give weight $(1-\gamma/3)$ to the input oracle and $\gamma/3$ to the proof oracle. Recall that these weights mean that each query to the input oracle is repeated several times such that the relative length of the input-part in the decision circuit is $1-\gamma/3$. These repeated queries may increase the query (and decision) complexity by a factor of at most $O(1/\gamma)$. Note that weighting does not affect the randomness complexity (or any other parameter, such as the proximity parameter δ).

Since $n^{1/m} \geq m^{cm}/\delta^3$, we have $n^{1/m} \geq 8000(c_F m^2)^{m-1}/\delta^3$, or equivalently $n \geq 8000|\mathbb{F}|^{m-1}/\delta^3$. Hence, Lemma 8.11 can be applied. Setting $\delta' = 2\delta\gamma/3$ in Lemma 8.11, we have that either $\mathrm{E}_R[\Delta_{\mathrm{pf}}^{W,\Pi\circ\Upsilon}(R)] \geq \rho'$ or $\mathrm{E}_R[\Delta_{\mathrm{inp}}^{W,\Pi\circ\Upsilon}(R)] \geq \delta - \delta'/2 = \delta(1-\gamma/3)$. Note that the first expression refers to the "expected robustness" of the proof-part, whereas the second expression refers to the input-part. The overall expected robustness is obtained by a weighted average of these two expressions, where the weights are with respect to the aforementioned weighting (which assigns weight $\gamma/3$ to the input-part). Hence, the expected robustness with respect to the said weighting is

$$\frac{\gamma}{3} \cdot \mathrm{E}_R[\Delta_{\mathrm{pf}}^{W,\Pi\circ\Upsilon}(R)] + \left(1-\frac{\gamma}{3}\right) \cdot \mathrm{E}_R[\Delta_{\mathrm{inp}}^{W,\Pi\circ\Upsilon}(R)] \;\geq\; \min\left\{\frac{\gamma}{3}\cdot\rho', \left(1-\frac{\gamma}{3}\right)^2 \cdot \delta\right\}.$$

This quantity is lower-bounded by $\rho \triangleq (1-\gamma/3)^2\delta$ since $\delta \leq \gamma/c$ for a suitably large c (and $\rho' > 0$ is a constant). We have thus obtained a robust PCPP for CktVal with randomness and decision complexities as claimed in Proposition 8.7, perfect completeness, and $\rho = (1-\gamma/3)^2\delta$ expected robustness for proximity parameter δ.

We now move from expected robustness to standard robustness, by using Lemma 2.11. Applying Lemma 2.11 with a slackness parameter of $\gamma' \triangleq \gamma\rho/3$ and $s = \gamma/3$ yields a robust-soundness error of $\gamma/3 \leq \gamma$ with robustness parameter of $\rho - \gamma' = (1-\gamma/3)^3 \cdot \delta \geq (1-\gamma)\delta$ for proximity parameter δ. Using $\gamma \leq 1/2$, note that the randomness increases by an additive term of $O(\log(1/\gamma')) + O(\log(1/\gamma)) = O(\log(1/\delta))$, and the decision complexity increases by a multiplicative factor of $O\left(1/(\gamma\cdot(\gamma\rho)^2)\right) = \mathrm{poly}(1/\delta)$. Hence, the randomness, query, and decision complexities of the verifier are as claimed in Theorem 3.1 □

Proof of Theorem 3.2. For this purpose we use ALMSS Robust PCPP Verifier described in this section. This verifier is then transformed to one over the binary alphabet as indicated earlier in this section. We combine the robustness of the proof and input oracles by giving equal weights to both oracles. This weighting may increase the query (and decision) complexity by at most a factor of 2 and has no affect on any other parameter. Proposition 8.9 and Lemma 8.12 then imply Theorem 3.2. □

8.4. Linearity of encoding. In this section we point out that, for linear circuits (to be defined below), the mapping from an assignment to the corresponding PCPP

is linear. Throughout this section, "linear" means $\mathbb{F}_2$-linear (yet, we will sometimes refer to $\mathbb{F}$-linearity, for an extension field $\mathbb{F}$ of $\mathbb{F}_2$). The main motivation of the current study is to derive linear codes satisfying local-testability and relaxed local-decodability (i.e., Theorems 1.4 and 1.5, respectively). Specifically, the constructions presented in section 4 yield linear codes provided that the corresponding PCPP is linear in the aforementioned sense.

We call a circuit *linear* if it is a conjunction of linear constraints. However, instead of representing this conjunction via AND gates, it is more convenient for us to work with circuits that have multiple output gates, i.e., one for each linear constraint. See the following definition.

DEFINITION 8.13. *A multi-output circuit is* linear *if all its* internal *gates are parity gates and an input is accepted by it iff all output gates evaluate to zero.*

PROPOSITION 8.14. *If C is a linear circuit, then there is a linear transformation T mapping satisfying assignments w of C to proof oracles $T(w)$ such that the PCPP verifier of Theorem* 3.1 *will, on input C, accept oracle $(w, T(w))$ with probability* 1*. Moreover, all the decision circuits produced by the verifier, on input C, can be made linear (while maintaining the claimed decision complexity). A similar result is true for the PCPP verifier of Theorem* 3.2*.*

In the rest of this section, we provide a proof of Proposition 8.14, starting with an assignment w that satisfies the linear circuit. We prove that the mapping from w to a proof oracle is linear by reviewing our construction of this mapping and ensuring that all steps in this construction are linear transformations.

Phase I: STRUCTURED-CKTSAT. In this phase (described in section 6.1) we write down the values to all gates of the circuit and route them along the wrapped de Bruijn graph. Actually, we make a few minor and straightforward modifications to Definition 6.3: we allow multiple output gates (rather than a single output gate) and require that each such gate evaluates to zero (rather than to 1).[34] Also, here we deal with gate types that are linear (e.g., XOR) rather than arbitrary (e.g., AND and OR).

Since all the circuit gates are linear functions of the input, the values on the wires leaving the zeroth layer of the well-structured circuit (i.e., the last two bits of the mapping $A_0 : \{0,1\}^N \to \{0,1\}^4$ in section 6.1) are linear in the input (i.e., in w). As to A_i, $i > 0$, (and the first two bits of A_0) notice that it is obtained by permuting the values of the previous layer A_{i-1} and setting some wires to zero (if they are not needed in the routing (e.g., gates 3 and 4 in Figure 3)). These operations are linear, and so all assignment functions are linear in the input.

Phase II: *Arithmetization.* In this phase (described in section 6.2) we extend the values given by A_i to an evaluation of a low-degree multivariate polynomial over a finite field $\mathbb{F}$ that is an extension field of $\mathbb{F}_2$ of degree $\mathfrak{v}$. Each value of A_i is four bits long (say, b_0, b_1, b_2, b_3) and identified with the element $b_0 e_0 + b_1 e_1 + b_2 e_2 + b_3 e_3$, where $e_0, \ldots, e_{\mathfrak{v}-1}$ is a basis for $\mathbb{F}$ viewed as a vector space over $\mathbb{F}_2$. We view A_i as a function $A_i : H^m \to \mathbb{F}$ and construct a low-degree extension $\tilde{A}_i : \mathbb{F}^m \to \mathbb{F}$ of A_i by interpolation on all inputs in H^m and use these values to interpolate and evaluate $\tilde{A}_i$ on all points in $\mathbb{F}^m$. Notice that interpolation is $\mathbb{F}$-linear, and hence also $\mathbb{F}_2$-linear. We conclude that the values of $\tilde{A}_i$ on all points in $\mathbb{F}^m$ are a linear transformation of the values of A_i. Since A_i is linear in the input assignment, so is $\tilde{A}_i$.

Clarification. Many parts of our encoding (starting with $\tilde{A}_i$) consist of evaluations of multivariate polynomials $P(x)$ over $\mathbb{F}^m$. The linearity we claim is not linearity in

[34] Recall that an input is accepted by the linear circuit iff all output gates evaluate to zero.

x (the free variables of the polynomial). Rather, we claim that the table of values $\{P(a) : a \in \mathbb{F}^m\}$ is linear in the initial assignment w, which may be viewed as the information encoded in this table. In contrast, throughout this section, x is merely an index to this table. For example, in Phase II we showed that the table $\{\tilde{A}_i(a) : a \in \mathbb{F}^m\}$ is obtained by a linear transformation applied to the table $\{A_i(a') : a' \in H^m\}$ (but we certainly do not claim that $\tilde{A}_i(a)$ is linear in a). That is, each $\tilde{A}_i(a)$ is a linear combination of the $A_i(a')$'s.

Phase III: *The constraint polynomials.* We now discuss the polynomials $P^{(0)}_{i,0}$ and $P^{(1)}_{i,1}$ defined in (6.2) and show that their values are a linear transformation of the values of $\tilde{A}_i$. The first polynomial (i.e., $P^{(0)}_{i,0}$) is obtained by applying the univariate polynomial ψ_0 defined in (6.1) to each value of $\tilde{A}_i$ (i.e., $P^{(0)}_{i,0}(x) = \psi_0(\tilde{A}_i(x))$). By definition, ψ_0 evaluates to zero iff its input, when represented as a vector in $\mathbb{F}_2^{\mathfrak{V}}$, belongs to the linear space spanned by $\{e_0, e_1, e_2, e_3\}$. This polynomial defines a linear transformation, as claimed by the following lemma.

LEMMA 8.15. *Let L be an $\mathbb{F}_2$-linear subspace of $\mathbb{F} = \mathbb{F}_2^{\mathfrak{V}}$ and $\psi_L(t) = \prod_{\alpha \in L}(t - \alpha)$. Then the mapping $\psi_L : \mathbb{F} \to \mathbb{F}$ is linear.*

Proof. We use the fact that for any integer i, the transformation $t \mapsto t^{2^i}$ is linear; that is, $(t + t')^{2^i} = t^{2^i} + t'^{2^i}$. Our main claim is that the polynomial $\psi_L(t)$ can be written as $\sum_i c_i t^{2^i}$ and hence is linear (being a sum of linear transformations). We prove this claim by induction on the dimension of $L \subseteq \mathbb{F}_2^{\mathfrak{V}}$. Indeed, for $\dim(L) = 0$ (i.e., $L = \{0^{\mathfrak{V}}\}$), it holds that $\psi_L(t) = t$, and our claim follows. In the induction step, write L as $L = L' \cup \{\alpha + L'\}$, where L' is a linear space of dimension $k - 1$ and $\alpha \in L \setminus L'$. Clearly, $\psi_L(t) = \psi_{L'}(t) \cdot \psi_{L'}(t + \alpha)$. Using the inductive hypothesis for L' (and the linearity of $t \mapsto t^{2^j}$), we get

$$\begin{aligned}
\psi_L(t) &= \left(\sum_i c_i \cdot t^{2^i}\right) \cdot \left(\sum_j c_j \cdot (t + \alpha)^{2^j}\right) \\
&= \left(\sum_i c_i \cdot t^{2^i}\right) \cdot \left(\sum_j c_j \cdot \left(t^{2^j} + \alpha^{2^j}\right)\right) \\
&= \sum_{i,j} c_i c_j t^{2^i} t^{2^j} + \sum_{i,j} c_i c_j t^{2^i} \alpha^{2^j} \\
&= \sum_i c_i^2 t^{2^{i+1}} + \sum_i c'_i t^{2^i},
\end{aligned}$$

where $c'_i = \sum_j c_i c_j \alpha^{2^j}$ and $\sum_{i \neq j} c_i c_j t^{2^i} t^{2^j} = 2 \sum_{i<j} c_i c_j t^{2^i} t^{2^j} = 0$ (because $\mathbb{F}$ has characteristic 2). This completes the proof of the inductive claim. ∎

We now turn to the second polynomial, $P^{(1)}_{i,0}$. Recall that $P^{(1)}_{i,0}(x) = \psi_1(s, a, a_0, a_1)$, where $s = \tilde{T}_i(x)$, $a = \tilde{A}_i(x)$, and $a_j = \tilde{A}_{i+1}(\tilde{\Gamma}_{i,j}(x))$. It can be verified that $\tilde{T}_i(x)$ (which represents the gate type) is independent of the input w to the circuit, and by our previous discussion a, a_0, a_1 are linear in the input w (to the circuit). Thus, it will suffice to show that ψ' is linear in its last three inputs. When discussing (6.2) we did not go into the specific construction of the polynomial ψ' because only its functionality mattered, and we showed that there exists a constant-degree polynomial that does the job. But for our current purposes (of showing linearity) we need to present a specific polynomial ψ' that is linear (as an operator over $\mathbb{F}_2^{\mathfrak{V}}$) and has the desired

properties needed by the verification process. To do this, we recall that $\mathcal{C}$ is the set of allowable gates in the well-structured circuit, define $\delta_{s_0}(z)$ to be the (minimal degree) univariate polynomial of degree $|\mathcal{C}|$ that is 1 if $z = s_0$ and 0 if $z \in \mathcal{C} \setminus \{s_0\}$, and write ψ' as

$$\psi'(s, a, a_0, a_1) = \sum_{s_0 \in \mathcal{C}} \delta_{s_0}(s) \cdot \psi'_{s_0}(a, a_0, a_1). \tag{8.4}$$

CLAIM 8.16. *For any $s_0 \in \mathcal{C}$ that can occur as a gate in a well-structured circuit constructed from a linear circuit C, the polynomial $\psi'_{s_0}(a, a_0, a_1)$ of (8.4) can be written as a linear transformation (of (a, a_0, a_1)).*

Proof. Recall that the value of $\psi'_{s_0}(a, a_0, a_1)$ is assumed to represent whether or not the four least significant bits of the three inputs (denoted a', a'_0, and a'_1) satisfy some specified condition. By inspecting Definition 6.3, it can be verified that (in our case) this condition is linear. That is, $\psi'_{s_0}(a, a_0, a_1) = 0$ iff the triplet (a', a'_0, a'_1), viewed as a 12-bit vector over $\mathbb{F}_2$, belongs to a specific linear space $L_{s_0} \subseteq \mathbb{F}_2^{12}$.

Recall that we may assume that $a = 0^{f-4}a'$ (and similarly for a_0 and a_1) because this condition is imposed by the constraint polynomial $P^{(0)}_{i,0}$. Thus, we seek a polynomial (over $\mathbb{F}^3$) such that if each of its three inputs belongs to $Span(e_0, \ldots, e_3)$, then it will output 0 iff the inputs reside in the linear space that is analogous to L_{s_0}; that is, the input (a, a_0, a_1) should evaluate to 0 iff $a' \circ a'_0 \circ a'_1 \in L_{s_0}$. To obtain this, we assume the existence of $\alpha \in \mathbb{F}$ such that multiplying an element by α corresponds to a left cyclic-shift by four positions (e.g., $\alpha \cdot \sigma_0 \cdots \sigma_{f-1} = \sigma_4 \cdots \sigma_{f-1}\sigma_0 \cdots \sigma_3$). Such an element exists for the standard representation of $\mathbb{F}$. Using this element we can write $\psi'_{s_0} : \mathbb{F}^3 \to \mathbb{F}$ as

$$\psi'_{s_0}(a, a_0, a_1) = \psi_{L_{s_0}}(\alpha^2 a + \alpha a_0 + a_1),$$

where $\psi_{L_{s_0}}$ is the univariate polynomial that is zero iff its input is in L_{s_0}. Note that, for inputs in $Span(e_0, \ldots, e_3)$, indeed $\psi'_{s_0}(a, a_0, a_1) = 0$ iff $a' \circ a'_0 \circ a'_1 \in L_{s_0}$. By Lemma 8.15, $\psi_{L_{s_0}}$ is linear. It follows that ψ'_{s_0} is linear because multiplication by a fixed element of $\mathbb{F}$ (i.e., α) is a linear operation. ∎

Recall $\delta_{s_0}(s)$ depends only on the circuit and not on its input (i.e., w). Thus, each summand of (8.4) is linear in w, and hence the sum is itself linear in w. We conclude that the table of evaluations of the polynomials given by (6.2) is obtained by linear transformations applied to the input to the circuit.

Phase IV: *The sum-check polynomials.* In this phase (described by (6.3)) we apply a sequence of interpolations to previously constructed polynomials $P^{(b)}_{i,j}$. Each such interpolation is an $\mathbb{F}$-linear transformation and hence also an $\mathbb{F}_2$-linear one. Thus, the sequence of polynomials $P^{(b)}_{i,j}$ is obtained by a linear transformation applied to the input.

Phase V: *Bundling and encoding.* In this phase (described in sections 8.2 and 8.3) we apply some cyclic-shifts to the (values of the) sequence of $l + 2l(m+1)$ polynomials obtained in the previous phases. Then we bundle the polynomials together, obtaining an alphabet of size $|\mathbb{F}|^{l+2l(m+1)}$. This bundling does not change the encoding (only the partitioning of the proof into symbols) and hence is also a linear transformation. Finally, we apply an error-correcting code to each symbol in order to reduce the alphabet size (from $|\mathbb{F}|^{l+2l(m+1)}$) to binary, and this is also a linear transformation as long as the error-correcting code is itself linear.

The result of this shifting, bundling, and encoding is the actual proof given to the (outer) verifier of Theorem 3.1 (the verifier of Theorem 3.2 is dealt with in a

similar fashion). Notice that this transformation from $l+2l(m+1)$ polynomials (each evaluated in $\mathbb{F}$) to one proof (over the binary alphabet) is linear because all three parts of it are linear.

Now we argue that all tests performed by the verifier are linear and the decision complexity claimed in Theorems 3.1 and 3.2 can be achieved by using small linear circuits. This can be seen by inspecting the various tests described in section 6.3, noticing that they all check either linear or $\mathbb{F}$-linear conditions, and applying the general result of Strassen [Str73], showing that any algebraic circuit that computes a linear function (as a formal polynomial) can be converted into a linear circuit with only a constant-factor increase in size. This completes the proof of Proposition 8.14.

Part III. Appendices.

Appendix A. Hadamard code–based PCPP. In this section we note that the Hadamard code–based inner verifier from Arora et al. [ALM+98] can be converted into a PCPP. Recall that the inner verifier of [ALM+98] accesses $O(1)$ input oracles, where the ith oracle is assumed to provide the Hadamard *encoding* of some string w_i, and verifies that their concatenation satisfies some given circuit C.

Here we simplify this verifier to work with a single string w, and the verifier accesses a *single input oracle* that represents this string itself (not some encoding of it) and verifies that w is close to an assignment acceptable by the circuit C given as explicit input.

THEOREM A.1. *There exists a constant $\delta_0 > 0$ such that there exists a PCPP for* CKTVAL *(for circuits of size n) with randomness complexity $O(n^2)$, query complexity $O(1)$, perfect completeness, soundness error $1-\delta$, and proximity parameter 5δ for any $\delta \le \delta_0$. That is, inputs that are δ-far from satisfying the circuit are rejected with probability at least $\min(\delta, \delta_0)/5$.*

Notice that we do not claim robustness of this PCPP. This is because we don't intend to use this verifier (or any verifier derived from it) as the outer verifier during composition. However, this verifier is robust (in a trivial sense). Indeed, any PCPP with $O(1)$ query complexity is trivially ρ-robust for some constant $\rho > 0$ (since the relative distance between two query patterns is lower-bounded by the inverse of number of bits queried).

Proof. Let V denote the claimed verifier. We first list the oracles used by V, then we describe the tests that V performs, and finally we verify that V's complexities are as claimed and analyze its performance (most notably its soundness and proximity).

Oracles. Let C be a circuit with n gates on m input bits. The verifier accesses an input oracle $W : [m] \to \{0,1\}$ (representing a string $w \in \{0,1\}^m$) and a proof oracle $\Pi = (A, B)$, with $A : \{0,1\}^n \to \{0,1\}$ and $B : \{0,1\}^{n \times n} \to \{0,1\}$.

To motivate the verifier's tests, we describe what is expected from the oracles in the "completeness" case, i.e., when $C(w) = 1$. The input oracle, by definition, gives the string w, i.e., $W[i] = w_i$. Now let $z \in \{0,1\}^n$ be the string of values of all the gates of the circuit C (including the input, the internal gates, and the output gate(s)). Without loss of generality, assume $z = w \circ y$, where y represents the values assumed for internal gates. The oracle A is expected to give the values of all linear functions at z (over $\mathbb{F}_2$), and the oracle B is supposed to give the value of all quadratic functions at z. More precisely, $A = A[x]_{x \in \{0,1\}^n}$ is expected to be $A[x] = \sum_{i=1}^{n} x_i z_i = x^T z$ (where x and z are thought of as column vectors). Similarly, $B = B[M]_{M \in \{0,1\}^{n \times n}}$ is expected to be $B[M] = \sum_{i,j} M_{ij} z_i z_j = z^T M z$ (where M is an $n \times n$ matrix). In order to verify that w satisfies C, the verifier will verify that A and B have indeed been constructed according to some string z as above, that z represents an accepting

computation of the circuit, and finally that A is the encoding of some string $w' \circ y$, where w' is close to the string w given by the input oracle W.

Tests. Given the circuit C, the verifier first constructs polynomials $P_1(z), \ldots, P_n(z)$ as follows. Viewing the variables $\{z_i\}$ as representing the values at the individual gates of the circuit C (with $z_1, \ldots, z_m$ being the input gates), the polynomial $P_i(z)$ is the quadratic polynomial (over $\mathbb{F}_2$) expressing the constraint imposed by the ith gate of the circuit on an accepting computation. For example,

$$P_i(z) = \begin{cases} z_i - z_j z_k & \text{if the } i\text{th gate is an AND gate with inputs from gates } j \text{ and } k. \\ z_i - z_j - z_k + z_j z_k & \text{if the } i\text{th gate is an OR gate with inputs from gates } j \text{ and } k. \\ z_i - (1 - z_j) & \text{if the } i\text{th gate is a NOT gate with input from gate } j. \\ z_i - (z_j + z_k) & \text{if the } i\text{th gate is a PARITY gate with inputs from gates } j \text{ and } k. \\ 1 - z_j & \text{if the } i\text{th gate is an output gate with input from gate } j. \\ 0 & \text{if the } i\text{th gate is an input gate (i.e., } i \leq m). \end{cases}$$

Note that $z = w \circ y$ reflects the computation of C on an acceptable input w iff $P_i(z) = 0$ for every $i \in [n]$. The verifier conducts the following tests.

Codeword tests. These tests refer to (A, B) being a valid encoding of some string $z \in \{0,1\}^n$. That is, these tests check that both A and B are linear functions, and that B is consistent with A. In the latter check, the verifier employs a self-correction procedure (cf. [BLR93]) to the oracle B. (There is no need to employ self-correction to A because it is queried at random locations.)

Linearity of A. Pick x_1, x_2 uniformly at random from $\{0,1\}^n$ and verify that $A[x_1 + x_2] = A[x_1] + A[x_2]$.

Linearity of B. Pick M_1, M_2 uniformly at random from $\{0,1\}^{n \times n}$ and verify that $B[M_1 + M_2] = B[M_1] + B[M_2]$.

Consistency of A and B. Pick x_1, x_2 uniformly at random from $\{0,1\}^n$ and M uniformly from $\{0,1\}^{n \times n}$ and verify that $B[M + x_1 x_2^T] - B[M] = A[x_1]A[x_2]$.

Circuit test. This test checks that the string z encoded in (A, B) represents an accepting computation of C; that is, that $P_i(z) = 0$ for every $i \in [n]$. The test checks that a random linear combination of the P_i's evaluates to 0, while employing self-correction to A and B.

Pick $\alpha_1, \ldots, \alpha_n \in \{0,1\}$ uniformly and independently and let $\sum_{k=1}^{n} \alpha_k P_k(z) = c_0 + \sum_i \ell_i z_i + \sum_{i,j} Q_{i,j} z_i z_j$. Pick $x \in \{0,1\}^n$ and $M \in \{0,1\}^{n \times n}$ uniformly at random. Verify that $c_0 + (A[x + \ell] - A[x]) + (B[M + Q] - B[M]) = 0$.

Proximity test. This test checks that the m-bit long prefix of the string z, encoded in A, matches (or is close to) the input oracle W, while employing self-correction to A.

Pick $j \in [m]$ and $x \in \{0,1\}^n$ uniformly. Let $e_j \in \{0,1\}^n$ denote the vector that is 1 in the jth coordinate and 0 everywhere else. Verify that $W[j] = A[x + e_j] - A[x]$.

The verifier *accepts* if all the tests above accept; otherwise it *rejects*.

Resources. The verifier uses $O(n^2)$ random bits and makes $O(1)$ binary queries.

Completeness. It is straightforward to see that if w, the string given by W, satisfies C, then letting z be the set of values of the gates of C and letting $A[x] = x^T z$ and $B[M] = z^T M z$ will satisfy all tests above. Thus the verifier has perfect completeness.

Soundness (with proximity). It follows directly from the analysis of [ALM+98] that there exists a $\delta_0 > 0$ such that for every $\delta \leq \delta_0$, if *Codeword tests* and *Circuit test* above accept with probability at least $1 - \delta$, then the oracle A is 2δ-close to the Hadamard encoding of some string $z = w' \circ y$ such that $C(w')$ accepts. Now we augment this soundness with a proximity condition. Suppose the verifier also accepts *Proximity test* with probability at least $1-\delta$. Then we have that $w_j \neq A[x+e_j]-A[x]$ with probability at most δ. Furthermore, the events $A[x + e_j] \neq (x + e_j)^T z$ and $A[x] \neq x^T z$ happen with probability at most 2δ each. Thus, with probability at least $1 - 5\delta$ (over the possible choices of j and x), both $w_j = A[x + e_j] - A[x]$ and $A[x + e_j] - A[x] = (x + e_j)^T z - x^T z$ hold. Since $(x + e_j)^T z - x^T z = e_j^T z = z_j = w'_j$, it follows that, with probability at least $1 - 5\delta$ (over the choices of j), $w_j = w'_j$. In other words, the string w represented by the oracle W is at distance at most 5δ away from some string w' that is accepted by the circuit C. □

Appendix B. Randomness-efficient low-degree tests and the sampling lemma. Following [BSVW03], our construction makes heavy use of small-biased spaces [NN93] to save on randomness when choosing random lines. For a field $\mathbb{F}$ and parameters $m \in \mathbb{Z}^+$ and $\lambda > 0$, we require a set $S \subseteq \mathbb{F}^m$ that is λ-*biased* (with respect to the additive group of $\mathbb{F}^m$). Rather than define small-biased spaces here, we simply state the properties we need. (See, e.g., [BSVW03] for definitions and background on small-biased spaces.)

LEMMA B.1. *For every $\mathbb{F}$ of characteristic 2, $m \in \mathbb{Z}^+$, and $\lambda > 0$, there is an explicit construction of a λ-biased set $S \subseteq \mathbb{F}^m$ of size at most* $(\log |\mathbb{F}^m|)/\lambda^2$ [AGHP92].

We now discuss the properties of such sets that we will use.

Expanding Cayley graphs. λ-biased sets are very useful pseudorandom sets in algebraic applications, and this is due in part to the expansion properties of the Cayley graphs they generate. See the following lemma.

LEMMA B.2. *If $S \subseteq \mathbb{F}^m$ is λ-biased and we let G_S be the graph with vertex set $\mathbb{F}^m$ and edge set $\{(x, x + s) : x \in \mathbb{F}^m, s \in S\}$, then all the nontrivial eigenvalues of G_S have absolute value at most $\lambda|S|$.*

Randomness-efficient line samplers. In [BSVW03], Lemma B.2 was used to prove the following sampling lemma. This lemma says that if one wants to estimate the density of a set $B \subseteq \mathbb{F}^m$ using lines in $\mathbb{F}^m$ as the sample sets, one does not need to pick a random line in $\mathbb{F}^m$ which costs $2 \log |\mathbb{F}^m|$ random bits. A pseudorandom line whose slope comes from a λ-biased set will do nearly as well, and the randomness is only $(1 + o(1)) \cdot \log |\mathbb{F}^m|$. In what follows, $l_{x,y}$ is the line passing through point x in direction y, formally; $l_{x,y} = \{x + ty : t \in \mathbb{F}\}$

LEMMA B.3 ([BSVW03, Sampling Lemma 4.3]). *Suppose $S \subseteq \mathbb{F}^m$ is λ-biased. Then, for any $B \subseteq \mathbb{F}^m$ of density $\mu = |B|/|\mathbb{F}^m|$, and any $\zeta > 0$,*

$$\Pr_{x \in \mathbb{F}^m, y \in S}\left[\left|\frac{|l_{x,y} \cap B|}{|l_{x,y}|} - \mu\right| > \zeta\right] \leq \left(\frac{1}{|\mathbb{F}|} + \lambda\right) \cdot \frac{\mu}{\zeta^2}.$$

Randomness-efficient low-degree tests. Ben-Sasson et al. [BSVW03] use the randomness-efficient sampling lemma, Lemma B.3, to obtain randomness-efficient low-degree tests by performing a "line versus point" test only for pseudorandom lines with a direction y coming from a small λ-biased set. That is, for a set $S \subseteq \mathbb{F}^m$, we consider

lines of the form $l_{x,y}(t) = x + ty$ for $x \in \mathbb{F}^m$ and $y \in S$, and let $\mathbb{L}$ be the set of all such lines, where each line is parameterized in a canonical way.

Then for functions $f : \mathbb{F}^m \to \mathbb{F}$ and $g : \mathbb{L} \to P_d$, where P_d is the set of univariate polynomials of degree at most d over $\mathbb{F}$, we let $\mathrm{LDT}_{S,d}^{f,g}$ be the test that uniformly selects $l \overset{R}{\leftarrow} \mathbb{L} \triangleq \{l_{x,y} : x \in \mathbb{F}^m, y \in S\}$ and $t \in \mathbb{F}$ and accepts iff $g(l)(t) = f(l(t))$. That is, the value of the degree d univariate polynomial $g(l)$ at point t equals the value of f at $l(t)$. We quote the main theorem of [BSVW03] and will use it in our constructions.

THEOREM B.4 ([BSVW03, Theorem 4.1]). *There exists a universal constant $\alpha > 0$ such that the following holds. Let $d \le |\mathbb{F}|/3, m \le \alpha|\mathbb{F}|/\log|\mathbb{F}|, S \subseteq \mathbb{F}^m$ be a λ-biased set for $\lambda \le \alpha/(m \log|\mathbb{F}|)$, and $\delta \le \alpha$. Then, for every $f : \mathbb{F}^m \to \mathbb{F}$ and $g : \mathbb{L} \to P_d$ such that f is at least 4δ-far from any polynomial of degree at most md, we have the following:*

$$\Pr[\mathrm{LDT}_{S,d}^{f,g} = \mathrm{rej}] > \delta.$$

Acknowledgments. We are grateful to Avi Wigderson for collaborating with us at early stages of this research and to Irit Dinur for inspiring discussions at late stages of this research. We thank Sergey Yekhanin and Jaikumar Radhakrishnan for bringing to our attention the "algebraic AND" mentioned in footnote 28. We thank the two anonymous referees for their careful reading and many comments which improved the presentation.

ASSIGNMENT TESTERS: TOWARDS A COMBINATORIAL PROOF OF THE PCP THEOREM*

IRIT DINUR† AND OMER REINGOLD‡

Abstract. In this work we look back into the proof of the PCP (probabilistically checkable proofs) theorem, with the goal of finding new proofs that are "more combinatorial" and arguably simpler. For that we introduce the notion of an assignment tester, which is a strengthening of the standard PCP verifier, in the following sense. Given a statement and an alleged proof for it, while the PCP verifier checks correctness of the *statement*, the assignment tester checks correctness of the statement *and the proof*. This notion enables composition that is truly modular; i.e., one can compose two assignment testers without any assumptions on how they are constructed. A related notion called *PCPs of proximity* was independently introduced in [E. Ben-Sasson et al., *Proceedings of the* 36*th Annual ACM Symposium on Theory of Computing*, Chicago, IL, 2004, ACM, New York, 2004, pp. 1–10]. We provide a toolkit of (nontrivial) generic transformations on assignment testers. These transformations may be interesting in their own right, and allow us to present the following two main results: 1. A new proof of the PCP theorem. This proof relies on a rather weak assignment tester given as a "black box." From this, we construct combinatorially the full PCP. An important component of this proof is a new combinatorial aggregation technique (i.e., a new transformation that allows the verifier to read fewer, though possibly longer, "pieces" of the proof). An implementation of the black-box tester can be obtained from the algebraic proof techniques that already appear in [L. Babai et al., *Proceedings of the* 23*rd ACM Symposium on Theory of Computing*, New Orleans, LA, 1991, ACM, New York, 1991, pp. 21–31; U. Feige et al., *J. ACM*, 43 (1996), pp. 268–292]. 2. Our second construction is a "standalone" combinatorial construction showing $NP \subseteq PCP[polylog, 1]$. This implies, for example, that approximating max-SAT is quasi-NP-hard. This construction relies on a transformation that makes an assignment tester "oblivious," so that the proof locations read are independent of the statement that is being proven. This eliminates, in a rather surprising manner, the need for aggregation in a crucial point in the proof.

Key words. PCP theorem, assignment tester, combinatorial proof

1. Introduction.

The PCP theorem is a characterization of the class NP which was discovered in the early 90s [2, 1] following an exhilarating sequence of results, including [20, 3, 7, 15, 22, 27, 5, 4, 13], to list just a few. It has had tremendous impact; most notably it lies at the heart of virtually all inapproximability results, starting with the seminal work of [13].

Recall that a language L is in NP if there is a polynomial-time algorithm (verifier) that can verify whether an input is in the language, with the assistance of a proof, called the NP witness. The PCP theorem says that every NP witness can be rewritten

in a "PCP" format that allows ultraefficient (probabilistic) checking. Hence the name, **P**robabilistically **C**heckable **P**roofs.

More concretely, the PCP verifier is an algorithm that is given direct access to a proof, and also a logarithmic number of random coins. The verifier reads the input, tosses the random coins, and then decides which (constant number of) bits to read from the proof. Based on the content of these bits, the verifier decides whether to accept or reject. The PCP theorem asserts the existence of a polynomial-time verifier for any $L \in NP$ such that

- (completeness) for every $x \in L$ there is a proof that causes the verifier to always accept;
- (soundness) for every $x \notin L$, every alleged proof causes the verifier to reject with probability 99% over its coin tosses.

Let us fix the NP-language L in our discussion to be (circuit) satisfiability (SAT). For every fixed outcome of the random coin tosses of the verifier, the verifier's action can be described by specifying which (constant number of) bits are read from the proof, along with the acceptance predicate over these bits. Enumerating over all possible random coin tosses, one gets a list of $\mathsf{R} = 2^{O(\log n)} = n^{O(1)}$ constant-size predicates (described, say, via circuits) over Boolean variables representing the bits in the proof. Thus, the verifier can be thought of as a deterministic polynomial-time reduction whose input is a Boolean circuit φ of size n (denoted $|\varphi| = n$), and whose output is a list of $\mathsf{R} = n^{O(1)}$ circuits $\psi_1, \ldots, \psi_{\mathsf{R}}$ over a new set of variables such that the following holds:

- (completeness) if φ is satisfiable, then there is an assignment that simultaneously satisfies all of $\psi_1, \ldots, \psi_{\mathsf{R}}$;
- (soundness) if φ is unsatisfiable, then every assignment simultaneously satisfies at most 1% of $\psi_1, \ldots, \psi_{\mathsf{R}}$.

This result is already nontrivial for $|\psi_i| = o(n)$, but in fact holds for $|\psi_i| = O(1)$. Indeed, the discovery of this theorem was extremely surprising. The proof is not an easy one and combines many beautiful and influential ideas.

1.1. Overall goals. Acknowledging the importance of the PCP theorem, we look back into its proof, with the goal of finding proofs that are substantially different and desirably also simpler. We note that while the statement of the PCP theorem is purely "combinatorial," the original proof of [2, 1] is heavily based on algebra: low degree polynomials play a crucial role. Therefore, of particular interest is coming up with proofs of "combinatorial" nature; see also [19]. In that we were also influenced by the view that such combinatorial proofs, albeit more messy, are sometimes more intuitive (or at least may shed new intuition). We also note that such new proofs and constructions have the potential to imply new results, unknown with previous techniques. A recent example is the combinatorial construction of expander graphs and the subsequent construction of the so-called lossless expanders [25, 9].

Composition and recursion. We first tackle a major ingredient in the original proof, namely the use of composition. Composition is indeed natural in this setting. A given verifier reduction may possibly be improved by applying another (inner) verifier reduction to each one of $\psi_1, \ldots, \psi_{\mathsf{R}}$, replacing each ψ_i with a system Υ_i of even smaller circuits.

Unfortunately, this simplistic composition has a "consistency flaw." It is likely that the resulting system of circuits $\bigcup_i \Upsilon_i$ will be completely satisfiable, even if the original circuit φ is unsatisfiable. Indeed each one of the ψ_i's could be individually satisfiable, as it is only impossible to satisfy more than 1% of them *by the same assignment*. Since $\Upsilon_1, \ldots, \Upsilon_{\mathsf{R}}$ are outcomes of independent runs of the second verifier

reduction, they are defined over syntactically disjoint sets of variables. This makes it easy to combine inconsistent assignments (each satisfying one ψ_i) into an assignment that satisfies all of $\cup\Upsilon_i$.

In the proof of [2, 1], this difficulty was overcome by having the second verifier utilize the concrete structural details of the circuits $\psi_1, \ldots, \psi_{\mathsf{R}}$ output by the first verifier, and relying on ingenious consistency mechanisms of algebraic nature.

In search of a simpler and more modular approach to composition, we introduce a natural strengthening of the PCP verifier, which we call an *assignment tester*. Intuitively, an assignment tester verifies not only satisfiability, but satisfiability *by a specified assignment* (given as oracle). This will provide an alternative and simple way of ensuring consistency in the context of PCP composition.

Assignment testers. An assignment tester is a polynomial-time reduction, whose input is a circuit φ over a set of variables X, and whose output is a list of polynomially many significantly smaller circuits $\Psi = \{\psi_1, \ldots, \psi_{\mathsf{R}}\}$ over *both* X and auxiliary variables Y. The guarantee of the reduction (for a complete definition, see Definition 3.1) is that for every possible assignment $a : X \to \{0,1\}$,

- (completeness) if a satisfies φ, then there is an extension of a, namely an assignment b for Y, such that all of $\psi_1, \ldots, \psi_{\mathsf{R}}$ are satisfied by $a \cup b$;
- (soundness) if a is "far" from any satisfying assignment for φ, then every extension of a to Y can satisfy at most 1% of $\psi_1, \ldots, \psi_{\mathsf{R}}$.

Thus, even if φ is satisfiable, but not by anything close to a, then 99% of $\psi_1, \ldots, \psi_{\mathsf{R}}$ must reject any extension of a. An intuitive way to understand the difference between a standard PCP verifier and an assignment tester is the following. Given a statement (a predicate φ claimed to be satisfiable) and an alleged proof for it (an assignment for X), the verifier checks that the statement is correct. In contrast, the assignment tester checks that *the proof* is correct. A related notion was independently introduced by Ben-Sasson et al. [8]; see further discussion below.

With this notion, we proceed to prove a composition theorem that is truly modular. The main idea is the following. Previously, relations between ψ_i and ψ_j (for $i \neq j$) were lost upon reduction to Υ_i and Υ_j. Now, all of the R reductions (each reducing ψ_i to the system Υ_i) are correlated through having to refer to the same assignment for X. To carry out this intuition, we give a generic transformation of any assignment tester into a "robust" one (we discuss this notion below). Once the first (outer) assignment tester is robust, the naive composition is trivially sound.

1.2. Our contributions. To be able to discuss our results, let us first briefly state the parameters of assignment testers. Let R be the number of circuits output by the assignment tester, and let s upper bound their size. There are three additional parameters: the query complexity q (how many variables are read by each output circuit), the error-probability ε (what fraction of the output circuits may erroneously accept on a "no" input; $\varepsilon = 0.01$ in the above discussion), and the distance parameter δ (what distance of the input assignment from a satisfying assignment should make the tester reject). For simplicity, we will ignore these last three parameters in most of the following discussion, with the implicit understanding that any mention of an assignment tester means constant q, ε, and δ.

New proofs of versions of the PCP theorem. As we discuss below, this paper provides a variety of transformations on assignment testers, complementing the generic composition theorem already mentioned above. Armed with this "toolkit" of transformations, we consider various ways of composing assignment testers with the goal of reproving the PCP theorem. We now elaborate on two results that we obtain

in this manner.

An assignment tester with $\mathsf{s} = n$ (recall that s is the size of the circuits produced by the assignment tester reduction) is completely trivial (letting the output equal the input). Nevertheless, we prove that, given an assignment tester with $\mathsf{s} = n^{0.99}$, we can get s all the way down to a constant.

THEOREM 1.1 (informal statement). *Given an assignment tester with* $\mathsf{R} = n^{O(1)}$ *and* $\mathsf{s} = n^{0.99}$*, we construct an assignment tester with* $\mathsf{R} = n^{O(1)}$ *and* $\mathsf{s} = O(1)$.

The idea of the construction is to use the given assignment tester as a building block and to compose it with itself. The output circuits will have size $n^{0.99}, n^{(0.99)^2}$, $n^{(0.99)^3}$, and so on, $n^{(0.99)^t}$ after t compositions. So taking $t = \log\log n$ results in a polynomially long list of constant size circuits. However, since the composition step roughly sums up the error probabilities of the two components, going beyond a constant number of composition steps requires an additional ingredient. This is where we incorporate several of the assignment tester transformations mentioned above, to achieve error reduction. Particularly, we employ a new combinatorial aggregation technique (namely, introducing new "aggregate" variables that represent ℓ-tuples of old variables).

Our building block assignment tester (i.e., the one with $\mathsf{s} = n^{0.99}$) can be constructed using *algebraic* techniques (for example, such an assignment tester can be constructed via techniques already present in [4, 13][1]). Coming up with a combinatorial construction for such an assignment tester would yield a completely combinatorial proof of the PCP theorem. Subsequent to our work, Dinur [11] *directly* (i.e., not going through this building block) gave a completely combinatorial proof of the PCP theorem.

Next, we present a combinatorial construction of an assignment tester, which is quasi-polynomial. It gives a combinatorial proof for $NP \subseteq PCP[\text{polylog}, 1]$ and implies, for example, that approximating Max-3-SAT is quasi-NP-hard.

THEOREM 1.2 (informal statement). *There exists an explicit combinatorial construction of an assignment tester with* $\mathsf{R} = n^{\text{polylog}n}$ *and* $\mathsf{s} = O(1)$.

This construction does not rely on any algebraic techniques; rather, it is based on recursive applications of our combinatorial transformations. In particular the construction relies on a transformation that makes an assignment tester "oblivious," so that the proof locations read are independent of the statement that is being proven. This eliminates, in a rather surprising manner, the need for aggregation in a crucial point in the proof.

The starting point is the previous construction, again relying on $\log\log n$ steps of composition and recursion. However, to compensate for the lack of a powerful building block, the main idea is to construct it ourselves, recursively. Thus the main step involves constructing an assignment tester with $\mathsf{s} = \mathsf{n}^{\alpha}$ (for some constant $\alpha < 1$) relying on recursion.

The resulting construction of an assignment tester is analogous to the following recursive construction of error-correcting codes based on tensor products. First, put your n-bit input in a $\sqrt{n} \times \sqrt{n}$ matrix. Now, recursively apply an error-correcting code to each row. Then, making additional recursive calls, apply an error-correcting code to each column (of the new matrix). Finally, as the relative distance has slightly deteriorated by this process, one can use simple transformations to amplify it back. Our related construction, in the context of assignment testers, is naturally more delicate and requires new ideas. However, the overall structure is very similar.

[1] Taking a low degree extension with a constant dimension, as in [23].

We note that this construction makes use of a *constant-size* assignment tester, to facilitate the composition. That is, the construction relies on an assignment tester that is required to work only on inputs of size $\leq n_0$ for some large enough constant n_0. (The only requirement from this assignment tester is that it produces small enough circuits. Say, circuits smaller than $s_0 = (n_0)^{0.99}$.) As in a similar situation in [25], such an object can be obtained via an exhaustive search over a constant range. However, the only proofs for its existence that we know of rely on previous constructions of PCP verifiers. Nevertheless, we can take the constant-size assignment tester needed by the construction to be an instantiation (for constant-size inputs) of extremely inefficient constructions, e.g., a Long-code-based assignment tester [6].

Combinatorial transformations on assignment testers. As the above description of our constructions indicates, our main technique is perhaps the most basic technique in computer science, namely recursion. This is implemented through the basic composition of a relatively weak assignment tester with a (strong) assignment tester of smaller size that is inductively constructed. In particular, the composition theorem mentioned above gives a way for reducing the circuit size (s) of an assignment tester (from s_1 or s_2 to $\mathsf{s}_1 \circ \mathsf{s}_2$).

We study several generic transformations on assignment testers that serve to improve various other parameters. We describe combinatorial methods to reduce the error probability, the query complexity, and the distance parameter. While these transformations are required for our constructions to work, we believe they are interesting in their own right. In particular, they provide tradeoffs that allow us to focus our attention on the important parameters of an assignment tester (e.g., it allows us to focus on constructing assignment testers with constant error and constant distance parameter).

Robustness. We mentioned above that for our generic composition theorem to work, the first (outer) assignment tester needs to be converted into a "robust" one. This means that in the "no" case, not only does a $1 - \varepsilon$ fraction of the circuits $\psi_1, \ldots, \psi_{\mathsf{R}}$ reject, but moreover they "strongly" reject in that their input is at least δ-far from any satisfying input. More formally, recall that each circuit reads some q variables. These are both X-variables (the original input variables of the input circuit), which are bits, and also auxiliary Y-variables that may come from a larger alphabet. We interpret here the Y-variables as bit strings (i.e., chunks of bits that are always read as a whole), and therefore the input of each ψ_i can be viewed as a longer bit string which is the concatenation of all the variables it reads. It is now well defined to say that an assignment to the input variables of ψ_i is δ-far (in Hamming distance) from any satisfying input.

We show a simple generic transformation taking every assignment tester into a robust one, where the robustness parameter is inversely related to the number of variables read, q. Loosely, the transformation goes as follows: given the output $\psi_1, \ldots, \psi_{\mathsf{R}}$ of the tester, construct a revised output $\psi'_1, \ldots, \psi'_{\mathsf{R}}$ over new variables that are supposed to be the error-corrected version of the old variables. (Here too the Y-variables are interpreted as bit strings, and each X-variable is simply encoded by repetition.) Each ψ'_i now decodes its input variables and applies ψ_i on the decoded variables. Our transformation uses an off-the-shelf error-correcting code, and its efficiency depends on standard parameters of the code (essentially on its distance, its rate, and the complexity of decoding codewords).

With this generic transformation, we can completely ignore the notion of robustness in all other transformations and refer to it only in the composition theorem. We

note in passing that [8] has the same notion of robustness. However, in that context, even the modest cost of our generic transformation is impermissible. Therefore, [8] works with assignment testers that are already robust (and indeed, they name these objects "*robust* PCP of proximity"). This difference between our definitions is further discussed in section 7.

Distance reduction. The only new parameter of assignment testers not already used by PCP verifiers is their distance parameter δ (what distance of the input assignment from a satisfying assignment should make the tester reject). We provide a generic method for strengthening assignment testers so that they identify smaller deviations from satisfying assignments. This transformation comes at a fair cost in other parameters. The main idea is the following: On input circuit φ, over Boolean variables X, encode X with "amplified" distance (so that two assignments for X that are δ' far from each other will be encoded by assignments that are $\delta > \delta'$ apart), and let φ' be the corresponding circuit (that first decodes its input and then applies φ). Now, apply the original assignment tester on φ' (instead of φ).

Error reduction with aggregation. It is easy to reduce the error probability of an assignment tester by repetition: replace $\Psi = \{\psi_1, \ldots, \psi_{\mathsf{R}}\}$ by ANDs of all possible ℓ-tuples of circuits in Ψ. This reduces the error-probability from ε to ε^ℓ but causes an ℓ-fold increase in the number of queried variables. We cannot afford such an increase, as it hurts the effective "robustness" of the assignment tester, a crucial property for composition. We avoid this increase through aggregation (or alternatively, parallelization). That is, the introduction of new variables to represent ℓ-tuples of previous ones. Our new method of aggregation is purely combinatorial.

The original proof of the PCP theorem also contains an aggregation method, based on sophisticated algebraic techniques. One disadvantage of that method is that it causes a blow-up in the size of the domain of the variables, by a factor that is roughly $\log |X|$ (more precisely, it is the degree of the low degree representation of the assignment for X), which cannot be afforded in our context. In contrast, our combinatorial aggregation increases the variables by a factor independent of $|X|$. On the other hand, our combinatorial aggregation introduces $|X|^\ell$ new variables, even if we are interested in the values of only some t possible ℓ-tuples. This is much worse than the $poly(\ell, |X|, t)$ new variables and tests introduced by the algebraic aggregation. Nevertheless, this blow-up is tolerable in our context as we care only about $\ell = O(1)$ (since we only plan on reducing error from one constant to another).

The main idea of our aggregation is the following. When reading ℓ-tuples of variables, to simulate the AND of ℓ circuits we are faced with the difficulty that the assignment to the ℓ-tuples may not be consistent with any assignment to the original variables. This problem is exactly what makes the proof of Raz's parallel repetition theorem [24] so challenging. Nevertheless, in our context, we can tolerate a more modest drop in the error probability than in [24], and can afford adding a constant (independent of ℓ) number of queries. So our main idea is the following: simply add a few queries directly aimed at testing the consistency of the ℓ-tuples of variables. This simple idea results in a significantly simpler analysis. In particular, a sufficiently good consistency test was already provided by Goldreich and Safra [19]. We give direct and simple analysis of essentially the same test.

This is somewhat similar to the situation analyzed in the parallel repetition theorem of [24]. There too, all possible ℓ-tuples are considered, and an exponential decrease in the error-probability occurs. Our situation is different in several respects. Most importantly, for the outcome system to remain an assignment tester, some sort

of "decoding" of the ℓ-tuple variables is necessary. Fortunately, we can tolerate a more modest drop in the error probability and can afford more than two (but still a constant independent of ℓ) queries, as in the case of [24]. This makes our analysis significantly simpler, as follows.

Assuming that the ℓ-tuples are assigned consistently (i.e., a variable x is assigned consistently in all ℓ-tuples containing it), the AND circuits described above can be simulated with just a few accesses to the new ℓ-tuple variables. Separately, we ensure the consistency of the ℓ-tuples through a consistency test. The consistency test that we use (see Figure 3 in section 4) simply compares two random ℓ-tuples that intersect on some $\sqrt[3]{\ell}$ elements and rejects if there is any disagreement. This test was suggested by Goldreich and Safra [19], who were interested in derandomized versions of the test and analyzed the nonderandomized version only indirectly. We provide a direct analysis by appealing to the expansion of the underlying graph. We prove that if $F : X^\ell \to \Sigma^\ell$ passes the test with high probability, then there is some $f : X \to \Sigma$, defined simply by plurality, such that F is close to $(f)^\ell$.

Related work. We have already mentioned that Ben-Sasson et al. [8] independently introduced an object called "PCP of proximity," which is essentially the same as our assignment tester, presented in a somewhat different language. The work of [8] shows connections of these objects to locally testable codes, and therefore the results of this paper seem relevant in this context as well. We further discuss this in section 7.

The notion of assignment testers is very related to the area of property testing. In fact, both assignment testers and PCPs of proximity can be viewed as special cases of more general definitions given by Ergün, Kumar, and Rubinfeld [12], in the context of proof-assisted testing. To the best of our knowledge, the connection to the construction of PCPs has not been explored in the past. The connection of assignment testers to property testing is elaborated upon in section 7.

As we discussed above, the motivation for defining assignment testers lies in the desire to obtain simple and modular composition of PCPs. This goal was already explored in the past. In particular, Szegedy [30] derived a syntactic composition theorem for abstractions of PCPs based on many valued logics.

Subsequent to our work, Dinur [11] described a combinatorial proof of the PCP theorem which also uses composition of assignment testers (and, in particular, composition with an assignment tester of constant size, just as in our second construction).

Organization. We formally define assignment testers in section 3, and then proceed to prove the composition theorem. In section 4 we provide generic transformations on assignment testers. Our two main constructions (Theorems 1.1 and 1.2) are proven in sections 5 and 6, respectively. The proof of the consistency test (required for the aggregation) can be found in Appendix A.

2. Preliminaries. In this section we define some standard combinatorial objects that our constructions rely upon. These are error-correcting codes and hitting sets. Both have a trivial random construction and can also be constructed explicitly.

2.1. Error-correcting codes. As in the original proof of the PCP theorem [2, 1], error-correcting codes are a very useful tool for our proof. However, unlike the original proof, we do not rely on algebraic properties of the codes, nor do we require the codes to be locally testable. The relevant parameters of the code in our case are rather generic: these are its rate, its distance, and the circuit complexity of verifying and decoding legitimate codewords. We call the last task "codeword decoding." In the next lemma we give the parameters of the codes that will imply the most elegant

version of our results. As we discuss below, such codes are easy to come by. We also note that much weaker codes still imply our main results.

LEMMA 2.1. *There exists a polynomial-time computable family of codes* $e = \{e_{\mathsf{w}} : \{0,1\}^{\mathsf{w}} \to \{0,1\}^{O(\mathsf{w})}\}_{\mathsf{w}\in\mathbb{N}}$ *such that* $e_{\mathsf{w}}(\cdot)$ *is a code with minimum distance* w *that satisfies the following:*

Linear circuit size for codeword decoding. *For every* w *there exists a circuit* C_{w} *of size* $O(\mathsf{w})$ *that takes as input a string* $z \in \{0,1\}^{O(\mathsf{w})}$ *and outputs* y *such that* $z = e_{\mathsf{w}}(y)$ *if such a string* y *exists and* $\perp$ *otherwise. Furthermore, the circuit* C_{w} *can be uniformly constructed in time poly*(w).

Lemma 2.1 asks for codes with constant rate and constant relative distance, which is quite standard. In addition, it requires linear circuit size for "codeword decoding," that is, for the task of verifying that a word is a legitimate codeword and then decoding it. This second part of decoding a legitimate codeword is trivial when $e_{\mathsf{w}}(y)$ contains y as a substring (such codes are sometimes called *systematic*).[2] Linear error-correcting codes can be assumed without loss of generality to be systematic. (By changing the basis of the generating matrix of the code, one can obtain a generating matrix for the *same code* that contains the identity matrix as a submatrix. Note that changing the basis doesn't change the code, so the parity check matrix is the same.) In addition, whenever a linear code is defined by a sparse parity check matrix (that contains only a linear number of nonzero entries), verifying that a word is a legitimate codeword can be performed by a circuit of linear size. In particular, Lemma 2.1 holds for the linear codes that are obtained by selecting a sparse parity check matrix, uniformly at random. In addition, it holds for the *explicit* codes best known under the name LDPC (low density parity check) codes. Note that the expander LDPC codes of [16, 31, 28, 29] have explicit combinatorial constructions based on the combinatorial construction of expander graphs in [25].

NOTATION 2.2. *We denote by* e_{w}^{-1} *the "maximum likelihood" decoding transformation that corresponds to the code* e_{w}. *That is,* $e_{\mathsf{w}}^{-1}(z') = y$ *if* $z = e_{\mathsf{w}}(y)$ *is the codeword of minimal Hamming distance to* z' (*where ties can be broken arbitrarily*). *In particular,* $e_{\mathsf{w}}^{-1}(e_{\mathsf{w}}(y)) = y$ (*assuming* $\mathsf{w} > 0$). *We do not assume anything on the computability of this mapping* (*in particular, we do not assume that it is polynomial-time computable*). *It is important to note that this maximum likelihood notion of decoding has little to do with "codeword decoding" as defined in Lemma* 2.1.

2.2. Hitting sets. We specify parameters of two families of sets with standard hitting properties. We then spell out in Corollary 2.5 the precise (standard) use of them for "error reduction." Both of these hitters can be constructed in an elementary way based on expander graphs. The hitters we give here rely on optimal expanders known as Ramanujan graphs [21]. We note that our main results can be proven using significantly weaker hitters (such as those implied by the expander graphs of [25]).

LEMMA 2.3. *Let* N *be an integer and* $0 \le \mu \le \alpha \le 1/2$ *two real values. Then there exists a family* $\mathcal{F} = \{F_1, \ldots, F_N\}$ *such that the following hold:*

[2] A natural approach for obtaining efficient codeword decoding is the following. First, slightly revise the error-correcting code such that it will be systematic (simply append y to $e_{\mathsf{w}}(y)$). Now codeword decoding is as easy as encoding: First, we can extract y from the alleged codeword, then re-encode y, and finally compare the result with the original alleged codeword. Unfortunately, error-correcting codes with linear size circuits for encoding are not known (and may very well not exist). Instead, one may use error-correcting codes with quasi-linear size circuits for encoding (these are not hard to come by). This natural approach can therefore give codes that are only slightly less efficient than those promised by Lemma 2.1 and are still good enough for obtaining the main results of this paper.

1. *Each F_i is a k-tuple of integers in $[N] = \{1, \ldots, N\}$, with $k = O(\alpha/\mu)$.*
2. *Every subset $T \subset [N]$ of size at least μN intersects at least αN of the F_i's (i.e., $|\{i : F_i \cap T \neq \phi\}| \geq \alpha N$).*
3. *Given N, i, α, and μ, each F_i can be constructed uniformly in polynomial time (in the input and output lengths).*

The set $\mathcal{F}$ in Lemma 2.3 can be constructed from a k-regular expander graph G_N on the set of vertices $[N]$. Each F_i is simply the neighbor list of vertex i. Requirement 2 asks for sets of size μN to expand by a factor α/μ, which for the expanders of [21] can be obtained with degree $k = O(\alpha/\mu)$. (For the expanders of [25] it requires $k = poly(\alpha/\mu)$.)

Next, we consider a more traditional setting of the hitting problem. For that we use the so-called combined hitter from Corollary C.5 in [17], as follows.

LEMMA 2.4. *Let N be an integer and β and μ be two positive real values. Then there exists a set $\mathcal{F} = \{F_1, \ldots, F_M\}$ of size $M = N \cdot poly(1/\beta)$ such that the following hold:*

1. *Each F_i is a k-tuple of integers in $[N]$, with $k = O(\log(1/\beta)/\mu)$.*
2. *Every subset $T \subset [N]$ of size at least μN intersects at least $(1-\beta)M$ of the F_i's (i.e., $|\{i : F_i \cap T \neq \phi\}| \geq (1-\beta)N$).*
3. *Given N, i, β, and μ, each F_i can be constructed uniformly in polynomial time (in the input and output lengths).*

The usefulness of Lemma 2.4 for this paper is in the standard application of hitters to error reduction. Particularly, we will use the following immediate corollary.

COROLLARY 2.5. *Let $\psi_1, \ldots, \psi_N$ be a sequence of N circuits over a set of variables Y. Let β and μ be two positive real values. Then there exists a sequence of $M = N \cdot poly(1/\beta)$ new circuits $\psi'_1, \ldots, \psi'_M$ such that we have the following:*

1. *Each new circuit ψ'_i is the AND of k old circuits ψ_i with $k = O(\log(1/\beta)/\mu)$. In particular, every assignment to the variables Y that satisfies all of the old circuits also satisfies all of the new circuits.*
2. *Every assignment to the variables Y that causes μN of the old circuits to reject also causes $(1-\beta)M$ of the new circuit to reject.*
3. *On input $\psi_1, \ldots, \psi_N$, β, and μ, the new sequence can be constructed uniformly in polynomial time (in the input and output lengths).*

3. Assignment testers and their composition. In this section we formally introduce the notion of an *assignment tester*, which is an enhancement of the PCP verifier. As discussed in the introduction, the motivation for assignment testers lies in the rather simple and natural way two assignment testers compose. This property is very appealing, as composition is a major ingredient in the proof of the PCP theorem.

Like the PCP verifier, an assignment tester reduces an input circuit φ over variables X into a list of output circuits $\psi_1, \ldots, \psi_{\mathsf{R}}$ over the variables (X and) Y. The main difference is that the output circuits of the PCP verifier might not depend on X at all, while the output circuits of the assignment tester certainly do. Moreover, the completeness and soundness conditions of an assignment tester are with respect to a specific assignment for X, rather than with respect to the general satisfiability of φ. Loosely, an assignment tester doesn't just check that the input is *satisfiable*, but rather that the input is *satisfied by a specified assignment*.

This simplifies composition by eliminating consistency issues altogether. Recall that the main idea of composition is to improve a given verifier reduction by applying another (inner) verifier reduction to each one of $\psi_1, \ldots, \psi_{\mathsf{R}}$, replacing each ψ_i with a system Υ_i of even smaller circuits. By feeding the same assignment to each of the

parallel runs of the inner reduction, all of the systems Υ_i directly refer to satisfiability by the same single assignment.

An important parameter, inherent to an assignment tester, is its *distance* parameter. In the soundness condition, it is unreasonable to require that in case the assignment for X is not satisfying, a sizeable fraction of $\psi_1, \ldots, \psi_{\mathsf{R}}$ reject. If we wish each ψ_i to read only a constant number of bits, most ψ_i's won't be sensitive to a single bit flip in X, turning a satisfying assignment into an unsatisfying one. Thus, we require only that if the assignment is δ-far (i.e., is at relative Hamming distance δ) from *every* satisfying assignment, then an $1-\varepsilon$ fraction of $\psi_1, \ldots, \psi_{\mathsf{R}}$ must reject. The parameter $\delta > 0$ is the distance parameter of the assignment tester, and it should be at least inversely proportional to the number of variables (unless we are willing to compromise on the detection probability $1-\varepsilon$ being subconstant).

In subsection 3.1 we give the formal definition of an assignment tester. In subsection 3.3 we define "robust" assignment testers and prove an immediate composition theorem for this object. We show a generic way to transform every assignment tester into a robust one ("robustization") in section 3.4. Finally, in subsection 3.5 we combine the above and deduce a composition theorem of assignment testers. We consider additional transformations on assignment testers in section 4. In section 7, we briefly discuss the relation between PCP testers and property testers.

3.1. Defining assignment testers. We denote Boolean circuits by φ, ψ, etc., and refer to the predicate computed by the circuit by the same name. We say that an assignment is δ-far from satisfying a circuit φ, if its relative Hamming distance from *every* satisfying assignment for φ is at least δ.

DEFINITION 3.1 (assignment tester). *An assignment tester with parameters* $(\mathsf{R}, \mathsf{s}, \mathsf{q}, \delta, \varepsilon)$ *is a reduction whose input is a Boolean circuit* φ *of size* n *over Boolean variables* X*. The reduction outputs a system of* $\mathsf{R}(\mathsf{n})$ *Boolean circuits* $\Psi = \{\psi_1, \ldots, \psi_{\mathsf{R}}\}$*, each of size at most* $\mathsf{s}(\mathsf{n})$ *over* X*, and auxiliary variables* Y *such that the following conditions hold:*

- *The running time of the algorithm is polynomial in* n *and* $\mathsf{R}(\mathsf{n})$*.*
- *Each* ψ_i *depends on* $\mathsf{q}(\mathsf{n})$ *variables from* $X \cup Y$*. The variables in* Y *take values in an alphabet* Σ *and are accessible to* ψ_i *as a tuple of* $\mathsf{w}(\mathsf{n}) = \lceil \log |\Sigma| \rceil$ *bits.*[3]
- *For every assignment* $a : X \to \{0,1\}$*,*
  1. [*completeness*] *if* a *satisfies* φ*, then there exists an assignment* $b : Y \to \Sigma$ *such that* $a \cup b$ *satisfies all of* $\psi_1, \ldots, \psi_{\mathsf{R}}$*;*
  2. [*soundness*] *if* a *is* δ*-far from every satisfying assignment for* φ*, then for every assignment* $b : Y \to \Sigma$*, at least* $1-\varepsilon$ *of* $\psi_1, \ldots, \psi_{\mathsf{R}}$ *reject* $a \cup b$*.*

Figure 1 gives a summary of the parameters.

This definition should be compared to the standard notion of a PCP verifier. The PCP verifier can also be defined as a reduction[4] precisely as above, but there are two differences. One is superficial in that the PCP verifier produces circuits that depend only on the (new) Y variables. The main difference is in the completeness and soundness conditions, which in the case of the PCP verifier reduction are defined

[3] Thus accessing all $\mathsf{w}(\mathsf{n})$ bits of a single variable in Y counts as a single "query."

[4] The PCP verifier is usually described as a probabilistic polynomial-time algorithm that verifies a (PCP) proof by tossing r random coins and then probing the proof in some q locations. By considering the action of the verifier in parallel over all possible outcomes of the random coins, the verifier corresponds to a list of 2^r circuits (each over q input variables). Thus, the verifier can also be viewed as a (deterministic) reduction that outputs a list of circuits. We call this a PCP verifier reduction.

- $\mathsf{R}(n)$ - Number of output circuits. Reminiscent of the amount of Randomness of the verifier.
- $\mathsf{s}(\mathsf{n})$ - Size of output circuits.
- $\mathsf{q}(\mathsf{n})$ - Maximal number of variables read (or queried) in one circuit.
- $\delta(\mathsf{n})$ - Distance to a satisfying assignment.
- $\varepsilon(\mathsf{n})$ - Error probability: the fraction of circuits that erroneously accept a far-from-satisfying assignment. (Sometimes we consider the detection probability $\gamma = 1 - \varepsilon$, i.e., the remaining fraction of circuits that reject.)
- $\mathsf{w}(\mathsf{n})$ - "Width" of Y variables, i.e., log of alphabet size. This parameter plays a minor role in our discussion, and so we usually omit it. We note that w is smaller than s.

FIG. 1. *The parameters* $(\mathsf{R}, \mathsf{s}, \mathsf{q}, \delta, \varepsilon)$ *of an assignment tester.*

as follows:

1. [*completeness*] *if* φ *is satisfiable, then there exists an assignment* $b : Y \to \Sigma$ *that satisfies all of* $\psi_1, \ldots, \psi_{\mathsf{R}}$*;*
2. [*soundness*] *if* φ *is unsatisfiable, then for every assignment* $b : Y \to \Sigma$*, at least* $1 - \varepsilon$ *of* $\psi_1, \ldots, \psi_{\mathsf{R}}$ *reject.*

Every assignment tester is also a PCP verifier reduction. To see, for example, that the soundness condition carries over, observe that if the input φ is unsatisfiable, then any $a : X \to \{0,1\}$ is ($\delta = 1$)-far from all (nonexistent) satisfying assignments. Thus it cannot be extended with b so as to satisfy more than ε of $\psi_1, \ldots, \psi_{\mathsf{R}}$.

The converse is not necessarily true since in an arbitrary PCP verifier reduction we have no control over the dependence of $\psi_1, \ldots, \psi_{\mathsf{R}}$ on X. In particular, the output circuits may not even depend on the variables in X. Interestingly, the original proof of the PCP theorem implicitly constructs assignment testers rather than just PCP verifiers.

THEOREM 3.2 (the PCP theorem [2, 1]). *There is a polynomial-time PCP verifier algorithm* (*alternatively, assignment tester*) *with* $\mathsf{R}(\mathsf{n}) = \mathsf{n}^{O(1)}$ *and* $\mathsf{q}(\mathsf{n}) \cdot \mathsf{w}(\mathsf{n}) \le \mathsf{s}(\mathsf{n}) = O(1)$ *and constant* $0 < \varepsilon, \delta < 1$.

3.2. On the width of variables. An assignment tester produces circuits ψ_i that are defined over two different kinds of variables. The X variables are Boolean, whereas the auxiliary Y variables take value from a possibly larger alphabet Σ. We would like to think of the assignment to a Y variable as a w-long bit string. (Recall that $\mathsf{w}(\mathsf{n}) = \lceil \log |\Sigma| \rceil$ is the width of the Y-variables.) This allows us to view each ψ_i as a Boolean circuit (just as φ is), which is particularly important for the composition theorem (where we apply the inner assignment tester to the circuits ψ_i produced by the outer assignment tester). In particular, if ψ_i reads the assignment to q_x variables from X and to q_y variables from Y, then we view its input as a $(\mathsf{q}_x + \mathsf{q}_y \cdot \mathsf{w})$-long bit string that is the concatenation of the assignment to all of the variables it reads. Note that, since the size of each ψ_i is larger than the length of its input, we have that $\mathsf{s} > \mathsf{q}_x + \mathsf{q}_y \cdot \mathsf{w}$. We can now define the restriction of a global assignment to the input variables of a particular ψ_i. This definition will allow repetitions of variables.

DEFINITION 3.3. *Each output circuit in* $\{\psi_1, \ldots, \psi_{\mathsf{R}}\}$ *is defined to be a pair* $\langle C, \tau \rangle$*, where* C *is a circuit over local inputs* $v_1, v_2, \ldots, v_q$ *and* $\tau = (x_{i_1}, \ldots, x_{i_{q_x}}, y_{i_{q_x+1}}, \ldots, y_{i_q})$ *is a tuple of variables from* $X \cup Y$ *specifying which variables are mapped to the inputs*

of the circuit. We emphasize that τ is allowed to have repetition of variables.[5]

Given an assignment σ for $X \cup Y$, its restriction to ψ_i is denoted $\sigma|_{\psi_i}$ and is defined as the appropriate string of $q_x + (q - q_x) \cdot w$ bits (that possibly reflects the repetitions in τ).

It turns out that, almost everywhere, the width parameter w plays only a very minor role. The two related parameters that will be much more crucial to our discussion are the size of the circuits s and the query complexity q. We will therefore almost always omit the reference w and be satisfied with the bound on w implied by s (as discussed above).

3.3. Robust assignment testers and their composition. A *robust* assignment tester is an assignment tester such that in the soundness case, not only do $1-\varepsilon$ of the output circuits reject, but in fact they see an assignment that is *ρ-far* from a satisfying one (i.e., at least a ρ-fraction of the bits read by each of these circuits need to be changed in order for the circuits to be satisfied). This variant is natural in the context of composition, as will be seen below.

Notation. For a circuit φ, denote by $SAT(\varphi)$ the set of all satisfying assignments for φ. Let $SAT_\delta(\varphi)$ be the set of assignments that are δ-close to some assignment in $SAT(\varphi)$ (namely, assignments that are at relative Hamming distance at most δ from some assignment in $SAT(\varphi)$).

DEFINITION 3.4. *An assignment tester is called ρ-robust if in the soundness case in Definition 3.1 above, for every assignment $b : Y \to \Sigma$, the assignment $(a \cup b)|_{\psi_i}$ is ρ-far from $SAT(\psi_i)$ for at least $1-\varepsilon$ fraction of $\psi_1, \ldots, \psi_{\mathsf{R}}$.*

It is very easy to compose robust assignment testers.

LEMMA 3.5. *Let $\mathcal{A}_1, \mathcal{A}_2$ be two assignment testers with parameters $(\mathsf{R}_1, \mathsf{s}_1, \mathsf{q}_1, \delta_1, \varepsilon_1)$ and $(\mathsf{R}_2, \mathsf{s}_2, \mathsf{q}_2, \delta_2, \varepsilon_2)$, respectively. If $\mathcal{A}_1$ is ρ-robust with $\rho = \delta_2$, then one can construct an assignment tester $\mathcal{A}_3$ with parameters $(\mathsf{R}_3, \mathsf{s}_3, \mathsf{q}_3, \delta_3, \varepsilon_3)$ such that*

$$\mathsf{R}_3(\mathsf{n}) = \mathsf{R}_1(\mathsf{n}) \cdot \mathsf{R}_2(\mathsf{s}_1(\mathsf{n})), \quad \mathsf{s}_3(\mathsf{n}) = \mathsf{s}_2(\mathsf{s}_1(\mathsf{n})), \quad \mathsf{q}_3(\mathsf{n}) = \mathsf{q}_2(\mathsf{s}_1(\mathsf{n})),$$

and

$$\varepsilon_3(\mathsf{n}) = \varepsilon_1(\mathsf{n}) + \varepsilon_2(\mathsf{s}_1(\mathsf{n})) - \varepsilon_1(\mathsf{n})\varepsilon_2(\mathsf{s}_1(\mathsf{n})), \quad \delta_3(\mathsf{n}) = \delta_1(\mathsf{n}).$$

Moreover, if $\mathcal{A}_2$ is ρ_2-robust, then so is $\mathcal{A}_3$.

Proof. Given an input φ, the tester $\mathcal{A}_3$ will simply run $\mathcal{A}_1$ on it, outputting $\psi_1, \ldots, \psi_{\mathsf{R}}$, and then run $\mathcal{A}_2$ on each ψ_i. The completeness and the parameters of $\mathcal{A}_3$ follow from the definition. The soundness of $\mathcal{A}_3$ draws on the robustness of $\mathcal{A}_1$ in the following way. Let $\{\psi_{i,j}\}$ be the list of circuits output by $\mathcal{A}_2$ on input ψ_i. The soundness of $\mathcal{A}_2$ asserts that a $1-\varepsilon_2$ of the $\{\psi_{i,j}\}$ reject if the assignment for ψ_i's variables *is far from* a satisfying one. The robustness of $\mathcal{A}_1$ guarantees that this is indeed the case for $1-\varepsilon_1$ of the ψ_i's, provided that the assignment for φ's variables is far from a satisfying one. ∎

3.4. Robustization. We next show a generic way to transform an arbitrary assignment tester into a robust one. The idea is to replace each variable in Y with a collection of bits that are supposed to be an encoding via some error-correcting code e of the value of the variable. In addition, we repeat the X variables for balance and modify the output circuits accordingly.

[5] Such repetition will be quite useful below: It implicitly affects the *distance* between the restrictions of assignments to ψ_i, turning it into a weighted Hamming distance (more weight to the repeated variable).

LEMMA 3.6. *There exists some $c_1 > 0$ such that, given an assignment tester $\mathcal{A}$ with parameters $(\mathsf{R}, \mathsf{s}, \mathsf{q}, \delta, \varepsilon)$, we can construct a ρ-robust assignment tester $\mathcal{A}'$ with parameters $\mathsf{R}' = \mathsf{R},\ s' = c_1 \cdot \mathsf{s},\ \rho = \Omega(\frac{1}{\mathsf{q}}),\ \varepsilon' = \varepsilon,\ \delta' = \delta$.*

This transformation allows us to replace the condition in Lemma 3.5 about $\mathcal{A}_1$ being ρ-robust with a condition about its query complexity; see Theorem 3.7 below. Throughout the rest of the paper Lemma 3.6 is used only in the proof of Theorem 3.7. In fact there is no further mention of robustness, as the lemma allows us to restrict our attention to the query complexity parameter.

We also mention that this transformation is useless for the setting of [8], as they cannot afford the (superlinear) increase in the number of variables that is incurred here.

Proof. $\mathcal{A}'$ will run $\mathcal{A}$ on input φ and obtain output circuits $\psi_1, \ldots, \psi_{\mathsf{R}}$ over variables X and Y. Each ψ_i will be replaced by a "robust" circuit ψ_i', whose inputs are encodings (via some error-correcting code e) of the inputs to ψ_i.

Let Σ be the alphabet of the Y variables, and let $\mathsf{w} = \lceil \log |\Sigma| \rceil$ be the number of bits needed to represent a value in Σ. Let $e_{\mathsf{w}} : \Sigma \to \{0,1\}^{\ell}$ be an error-correcting code as in Lemma 2.1 (with $\ell = c \cdot \mathsf{w}$ and c a small absolute constant). For each $y \in Y$ introduce new Boolean variables $\bar{v}(y) = v_1(y), \ldots, v_\ell(y)$ supposedly representing y's encoding $e_{\mathsf{w}}(y)$. Denote these new sets of bits by

$$Y' = \bigcup_{y \in Y} \bar{v}(y).$$

Suppose the tuple of variables accessed by ψ_i is $(x_1, \ldots, x_{\mathsf{q}_x}, y_1, \ldots, y_{\mathsf{q}_y})$, with $\mathsf{q} = \mathsf{q}_x + \mathsf{q}_y$. Define a new circuit ψ_i' whose input consists of $\ell \cdot \mathsf{q}$ variables: the first $\ell \mathsf{q}_x$ variables are ℓ copies of each variable of $x_1, \ldots, x_{\mathsf{q}_x}$. The next $\ell \mathsf{q}_y$ variables are $\bar{v}(y_1), \ldots, \bar{v}(y_{\mathsf{q}_y})$. The circuit ψ_i' accepts an input if and only if it is a correct encoding of an input that would have satisfied ψ_i. More explicitly, ψ' accepts input $z_1, \ldots, z_{\ell \mathsf{q}} \in \{0,1\}^{\ell \mathsf{q}}$ if and only if (a) $z^i = (z_{i\mathsf{q}+1}, \ldots, z_{(i+1)\mathsf{q}})$ is the all-0 or all-1 string for $1 \le i \le \mathsf{q}_x$, (b) z^i is a legal codeword of e for $i > \mathsf{q}_x$, and (c) the values encoded by the z^i's satisfy ψ_i.

This completes the description of $\mathcal{A}'$, and we now prove its properties. Completeness is clear: A satisfying assignment $a : X \to \{0,1\}$ for φ can easily be extended by $b : Y' \to \{0,1\}$ so that $a \cup b$ satisfies all of $\{\psi_i'\}$.

What is the size of ψ_i'? Since for the code e_{w} there exists a linear size circuit for codeword decoding (see Lemma 2.1), then there exists some c_1 such that the size of each ψ_i' is bounded by $\mathsf{s}(\mathsf{n}) + O(\ell \mathsf{q}) \le c_1 \cdot \mathsf{s}(\mathsf{n})$.

Next, the soundness of $\mathcal{A}'$. Assume an assignment $a : X \to \{0,1\}$ that is δ-far from satisfying φ. The soundness of $\mathcal{A}$ guarantees that every $b : Y \to \Sigma$ extending a will be rejected by at least $1 - \varepsilon$ of the ψ_i's. What does this mean for the robust version ψ_i'? Consider an arbitrary assignment $b' : Y' \to \{0,1\}$. Such an assignment defines a "decoded" assignment $b'' : Y \to \Sigma$ by relying on the "maximum likelihood" decoding mapping e_{w}^{-1} of the code e_{w} (see Notation 2.2) as follows:

$$b''(y) : Y \to \Sigma, \qquad b''(y) \stackrel{def}{=} e_{\mathsf{w}}^{-1}(b'(v_1(y)), \ldots, b'(v_\ell(y))).$$

The soundness of $\mathcal{A}$ implies that at least $1 - \varepsilon$ of $\psi_1, \ldots, \psi_{\mathsf{R}}$ will reject $a \cup b''$, regardless of the assignment b'' to Y. For each rejecting ψ_i, at least one of the q variables it queries must be reassigned in order for it to accept. Consider now the corresponding ψ_i' and its assignment $\sigma = (a \cup b')|_{\psi_i'}$. Recall that by definition

(see also Definition 3.3), σ is an $\ell\mathsf{q}$-bit string. Clearly, σ will not satisfy ψ'_i. More importantly, there must be at least one of the q (ℓ-bit) blocks that need to be changed *into a different legal ℓ-bit block* in order to turn σ into a satisfying input: If this ℓ-bit block consists of Y'-variables, then it must be changed in more than half the code distance (i.e., $\frac{\mathsf{w}}{2}$) locations. If it consists of (repetitions of) an X-variable, then it must be changed in all ℓ bits. In any case, this means that $\mathcal{A}'$ is ρ-robust with $\rho = \frac{\min(\mathsf{w}/2,\ell)}{\mathsf{q}\cdot c\mathsf{w}} = \frac{1}{2c\mathsf{q}}$. □

It is important to note that the error-correcting code e we use to obtain the robustness property is not part of the definition of an assignment tester but rather part of the robustization transformation. Furthermore, a feature of this transformation is that e, defined in Lemma 2.1, is quite a generic error-correcting code. We do not rely on algebraic properties of e nor require it to be locally testable.

3.5. Generic composition of assignment testers. Combining Lemmas 3.6 and 3.5, we get the following convenient composition theorem.

THEOREM 3.7 (composition). *There exist some constants c_1, c_2 such that $\mathcal{A}_1, \mathcal{A}_2$ are two assignment testers with parameters $(\mathsf{R}_1, \mathsf{s}_1, \mathsf{q}_1, \delta_1, \varepsilon_1)$ and $(\mathsf{R}_2, \mathsf{s}_2, \mathsf{q}_2, \delta_2, \varepsilon_2)$, respectively. If $\delta_2 \le \frac{1}{c_2\cdot\mathsf{q}_1}$, then one can construct an assignment tester $\mathcal{A}_3$ with parameters $(\mathsf{R}_3, \mathsf{s}_3, \mathsf{q}_3, \delta_3, \varepsilon_3)$ such that, for $\mathsf{n}' \stackrel{def}{=} c_1 \cdot \mathsf{s}_1(\mathsf{n})$,*

$$\mathsf{R}_3(\mathsf{n}) = \mathsf{R}_1(\mathsf{n}) \cdot \mathsf{R}_2(\mathsf{n}'), \quad \mathsf{s}_3(\mathsf{n}) = \mathsf{s}_2(\mathsf{n}'), \quad \mathsf{q}_3(\mathsf{n}) = \mathsf{q}_2(\mathsf{n}'),$$

and

$$\varepsilon_3(\mathsf{n}) = \varepsilon_1(\mathsf{n}) + \varepsilon_2(\mathsf{n}') - \varepsilon_1(\mathsf{n})\varepsilon_2(\mathsf{n}'), \quad \delta_3(\mathsf{n}) = \delta_1(\mathsf{n}).$$

Comparing this composition theorem with the robust composition of Lemma 3.5, we see that the condition about $\mathcal{A}_1$ being robust has been removed, and the condition $\delta_2 \le \rho$ has been replaced by the condition $\delta_2 \le \frac{1}{c_2\cdot\mathsf{q}_2}$. The parameters are almost the same, except here $n' = c_1 \cdot \mathsf{s}_1(\mathsf{n})$ rather than $n' = \mathsf{s}_1(\mathsf{n})$ (and this slightly affects $\mathsf{R}_3, \mathsf{s}_3, \mathsf{q}_3$, and ε_3).

We mention that the parameters of $\mathcal{A}_3$ in Theorem 3.7 are very similar to those that would follow from a naive composition of two PCP verifiers, when in the soundness argument one ignores consistency issues altogether (imagining a prover that is "honest" with respect to consistency). In that sense, these parameters are essentially the best one could hope for in this type of composition.

Proof. We first turn $\mathcal{A}_1$ into a robust assignment tester $\mathcal{A}'_1$, using the transformation of Lemma 3.6. Thus, $\mathsf{n}' = c_1 \cdot \mathsf{s}_1(\mathsf{n})$ is the size of the output circuits of $\mathcal{A}'_1$. Next, we compose $\mathcal{A}'_1$ with $\mathcal{A}_2$ according to Lemma 3.5, obtaining $\mathcal{A}_3$. See also Figure 2 for an illustration of the two transformations combined. □

4. Transformations on assignment testers. The composition of assignment testers is mainly used as a tool for reducing the size, s, of the circuits that an assignment tester outputs. In this section we give general transformations for reducing (and thus improving) three additional parameters: (i) the tested *distance*, δ, from a satisfying assignment; (ii) the *error probability*, ε, in case of a far-from-satisfying assignment; and (iii) the number, q, of variables read by each output circuit.

Our motivation is threefold. First, these transformations will come in handy in our constructions of assignment testers. Second, given these transformations, it is fair to concentrate on the construction of testers for some constant values of δ and ε.

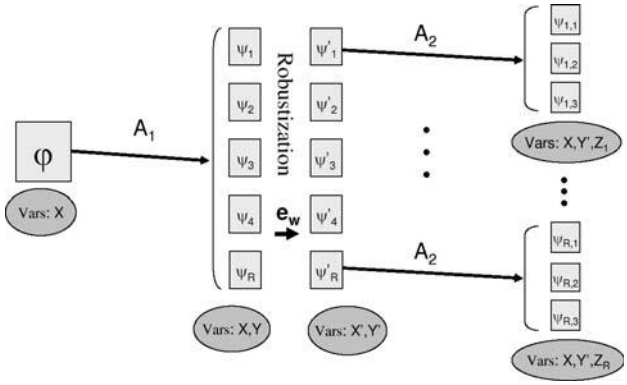

FIG. 2. *Composing* $\mathcal{A}_1$ *and* $\mathcal{A}_2$.

These parameters can be then reduced to the desired values using the general transformations. Finally, as we believe that the concept of assignment tester is interesting in its own right, it is natural to study the behavior of its various parameters.

To illustrate the need, in our context, for transformations that improve these $(\varepsilon, \mathsf{q}, \delta)$ parameters, note that composition may indeed reduce s, but it incurs costs in other parameters. In particular, it causes the error-probability, ε, to increase, as it is the sum of the error-probabilities of the two composed component. This is easily fixable since it is easy to reduce ε by increasing q. However, if we increase q, then we will require a smaller value of δ during composition in the next phase. The transformations of this section will help us essentially enhance the basic composition theorem such that it reduces s without harming other parameters.

4.1. Reducing the distance: $\delta \to \delta'$. In this subsection we describe how the distance parameter δ of a generic assignment tester can be improved (with fair cost in terms of the other parameters). The goal here is to improve the "sensitivity" of the assignment tester, so that the behavior of its output-circuits on mildly bad assignments (i.e., whose distance from satisfying is at least δ') imitates their behavior on very bad assignments (i.e., whose distance from satisfying is at least $\delta > \delta'$).

Our transformation is of "black-box" nature: We are given an assignment tester $\mathcal{A}$, whose inner workings we do not wish to manipulate, yet we want to reduce its distance parameter. A natural approach would be to manipulate the input variables X, creating a new set of variables X' (which would be part of the auxiliary variables) that encode X with amplified distance. This encoding would guarantee that two assignments for X that are δ'-apart are encoded by two assignments for X' that are δ-apart. Naturally, manipulating the input variables is not enough, and we also need to manipulate φ such that it "recognizes" the X' variables. Specifically, instead of applying $\mathcal{A}$ to φ, we apply it to φ' that is defined over X' (rather than over X), where φ' is defined to decode the assignment to X' and to apply φ to the decoded assignment (viewed as an assignment to X). But we are not done, as the circuits that $\mathcal{A}$ produces on φ' *do not even depend on the* X *variables* (as φ' does not depend on these variables either). We therefore augment these circuits by a verification that the assignment to X' correctly encodes the assignment to X. We will need to carefully define the encoding of the X variables so that verifying consistency between the X and X' variables will be sufficiently efficient.

LEMMA 4.1 (distance reduction). *There exists a positive constant $\bar{\delta}$ such that for every $0 < \delta' \leq \delta \leq \bar{\delta}$, given an assignment tester $\mathcal{A}$ with parameters $(\mathsf{R}, \mathsf{s}, \mathsf{q}, \delta, \varepsilon)$, we can construct an assignment tester $\mathcal{A}'$ with parameters $(\mathsf{R}', \mathsf{s}', \mathsf{q}', \delta', \varepsilon)$, where for $Q = O(\frac{1}{\delta'} \log \frac{1}{\varepsilon})$ and $M = O(\frac{\delta}{\delta'}\mathsf{n})$,*

$$\mathsf{R}'(\mathsf{n}) = poly(1/\varepsilon) \cdot \mathsf{R}(M), \quad \mathsf{s}' = \mathsf{s}(M) + Q, \quad \mathsf{q}'(\mathsf{n}) = \mathsf{q}(M) + Q.$$

Remark 4.2. Note that both the size of the new circuits s' and the number of queries q' contain an additive term of $O(\frac{1}{\delta'} \log \frac{1}{\varepsilon})$. This seems acceptable, as it is not hard to show that both s' and q' must be $\Omega(\frac{1}{\delta'} \log \frac{1}{\varepsilon})$ by the definition of assignment testers and lower bounds on the query complexity of hitters [17]. Consider, for example, an input circuit φ that is only satisfied by the all-zero assignment. For each of the circuits produced by the assignment tester consider the set of variables in X that it reads. For every subset T of variable of density δ', at least a $\gamma = 1 - \varepsilon$ fraction of the sets must hit T.

Proof. We follow the basic sketch outlined above. Let the input for our tester be a circuit φ over Boolean variables X. We fix an encoding E whose properties will be formally defined below. We let X' be new variables whose assignment supposedly represents the encoding via E of some assignment for X. We define the circuit φ' over X' to be a circuit that accepts only assignments for X' that encode (via E) an assignment for X that would have caused φ to accept. In other words, $SAT(\varphi') = E(SAT(\varphi))$. We choose E so that if an assignment $a : X \to \{0,1\}$ is δ'-far from the set $SAT(\varphi)$, then its encoding $b : X' \to \{0,1\}$ is δ-far (recall $\delta > \delta'$) from the set $SAT(\varphi')$.

Now, we run $\mathcal{A}$ on φ' and obtain a list of output circuits $\psi'_1, \ldots, \psi'_{\mathsf{R}(|\varphi'|)}$ over the variables X' and new variables Y. By the soundness of $\mathcal{A}$, starting with an assignment $b \notin SAT_\delta(\varphi')$ for X', no matter how one assigns the remaining Y variables, at most ε fraction of the ψ'_is accept.

It remains to add tests comparing the assignment b for X' to the assignment a for X. In order to be able to do this via circuits that make only few queries, X' must encode X in a *"locally checkable"* manner. Thus, the heart of our proof is the encoding E, whose properties are formalized next.

LEMMA 4.3. *Let $\bar{\delta}$ be a universal constant. For every $\delta_1 < \delta_2 < \bar{\delta}$, there exists a constant $c = O(\frac{\delta_2}{\delta_1}) \geq 1$ and an encoding $E : \{0,1\}^n \to \{0,1\}^{cn}$ that is polynomial-time computable, such that*

1. *if $a_1, a_2 \in \{0,1\}^n$, $\mathsf{dist}(a_1, a_2) > \delta_1$, then $\mathsf{dist}(E(a_1), E(a_2)) > \delta_2$;*
2. *there is a linear-time circuit that computes $E^{-1}(b)$ if b is in the image of E, and otherwise rejects;*
3. *there is a polynomial-time constructible collection of n circuits each of size $O(c) = O(\frac{\delta_2}{\delta_1})$ such that, given $a \in \{0,1\}^n$ and $b \in \{0,1\}^{cn}$, the following hold:*
   - *If $b = E(a)$, all of the circuits accept.*
   - *At least a $\mathsf{dist}(b, E(a))$ fraction of the circuits reject.*

Before proving Lemma 4.3, let us complete the description of $\mathcal{A}'$ and prove its properties. Let E be as in the lemma, choosing $\delta_1 = \delta'$ and $\delta_2 = 2\delta$. As a first step, $\mathcal{A}'$ will compute φ' from φ and generate $\psi'_1, \ldots, \psi'_{\mathsf{R}(|\varphi'|)}$, which are the outcome of running $\mathcal{A}$ on φ'. Recall that φ' is a circuit over variables X' that satisfies $SAT(\varphi') = E(SAT(\varphi))$. Due to the second item in Lemma 4.3, the size of φ', denoted M, is larger than the size of φ by a multiplicative factor $O(\frac{\delta}{\delta'})$. The number of circuits output by $\mathcal{A}$ is $\mathsf{R}(M)$, their size is $\mathsf{s}(M)$, and they read $\mathsf{q}(M)$ variables.

In addition, let $\{\mathsf{compare}_r\}_r$ be the collection of at most n circuits guaranteed by the third item of Lemma 4.3. We amplify the rejection probability of $\{\mathsf{compare}_r\}_r$ by derandomized serial error-reduction. We define a set of tests by applying Corollary 2.5 on the sequence $\{\mathsf{compare}_r\}$ with parameters $\mu = \delta$ and $\beta = \varepsilon$. Denote the new tests by $\{\mathsf{compare}'_1, \ldots, \mathsf{compare}'_{M_1}\}$. By Corollary 2.5, $M_1 = poly(1/\varepsilon)n$, and each $\mathsf{compare}'_i$ is the AND of $d = O(\frac{1}{\delta}\log\frac{1}{\varepsilon})$ $\mathsf{compare}$ tests. Therefore the size, denoted by Q, of each $\mathsf{compare}'_i$ satisfies $Q = O(c \cdot d) = O(\frac{1}{\delta'}\log\frac{1}{\varepsilon})$ (which also upper bounds the number of X and X' variables these circuits read).

The final output circuits of $\mathcal{A}'$ will be $\{(\psi_i \wedge \mathsf{compare}'_i)\}_i$, where by repetition we may assume an equal number of at most $poly(1/\varepsilon) \cdot \mathsf{R}(M)$ circuits of each type.

It is easy to check that $\mathcal{A}'$ has the claimed parameters, and it remains to prove the completeness and soundness of $\mathcal{A}'$.

Completeness is immediate: Given some $a \in SAT(\varphi)$, extend it to X'-variables by letting $b : X' \to \{0,1\}$ be defined by $b \stackrel{def}{=} E(a)$. The rest follows from the completeness of $\mathcal{A}$.

For soundness, one needs to show that, given any assignment for X that is δ'-far from a satisfying assignment, no assignment for the remaining variables $(X' \cup Y)$ can cause more than ε of the output circuits to accept. So let $a \notin SAT_{\delta'}(\varphi)$. Let $b : X' \to \{0,1\}$ and $c : Y \to \Sigma$ be arbitrary. There are two cases:

- If $\mathsf{dist}(E(a), b) \geq \delta$, then by Lemma 4.3 at least δ fraction of the circuits $\{\mathsf{compare}_r\}_r$ reject, so by construction and according to Corollary 2.5, at most ε of the circuits in $\{\mathsf{compare}'_i\}$ accept.
- Otherwise, $\mathsf{dist}(E(a), b) < \delta$. Then, using $\mathsf{dist}(a, SAT(\varphi)) > \delta'$, the first item in Lemma 4.3 implies $\mathsf{dist}(E(a), SAT(\varphi')) > 2\delta$. So by the triangle inequality, $\mathsf{dist}(b, SAT(\varphi')) > \delta$. The soundness of $\mathcal{A}$ implies that no matter what the assignment for Y, at most ε of the circuits ψ'_i accept.

This completes the proof of soundness, since in both cases, $a \notin SAT_{\delta'}(\varphi)$ allows at most an ε fraction of the final circuits to accept. Thus, assuming Lemma 4.3, we have proved Lemma 4.1. □

Proof of Lemma 4.3. Clearly, item 1 can be obtained using any error-correcting code. However, this would fail to give item 3, as given strings a and b, it is not clear how to check that $\mathsf{dist}(E(a), b)$ is small with few queries.[6] Instead, we will use an encoding that is not an error-correcting code in the standard sense but does have the desired amplification property.

Let $k = O(\frac{\delta_2}{\delta_1})$. We first describe an encoding over nonbinary alphabet $\Sigma = \{0,1\}^k$, denoted $E_0 : \{0,1\}^n \to \Sigma^N$. To encode a string $a \in \{0,1\}^n$, simply write its restriction on all possible k-bit substrings (so there are $N = n^k$ possible such restrictions). It is easy to see that this encoding achieves distance amplification. Indeed, two strings $a_1, a_2 \in \{0,1\}^n$ with $\mathsf{dist}(a_1, a_2) > \delta_1$, will differ on a $1-(1-\delta_1)^k \approx k\delta_1 > \delta_2$ fraction of the symbols.

Moreover, it is unnecessary to take all $N = n^k$ restrictions. With judicious choice of k-tuples, distance amplification will hold even with $N = n$ restrictions. Let X_k be an efficiently constructible hitting set of k-tuples of $[n]$ such that every subset of X of size $\geq \delta_1 n$ intersects at least a $c_1\delta_2$ fraction of the k-tuples in X_k (the constant $c_1 > 1$ will be chosen below). Lemma 2.3 guarantees such a set X_k with $|X_k| = n$.

[6] The question of testing whether a given word is the encoding of another word slightly resembles questions regarding the local testability or local decodability of the code. However, in this context we avoid the issue altogether.

This gives an encoding $E_1 : \{0,1\}^n \to \Sigma^{|X_k|}$. The choice of X_k guarantees that if $\mathsf{dist}(a, a') > \delta_1$, then $\mathsf{dist}(E_1(a), E_1(a')) > c_1\delta_2$, because at least $c_1\delta_2$ fraction of the tuples in X_k "hit" the set $\{\, i \mid a_i \neq a'_i\}$. Note that we are assuming (when applying Lemma 2.3) $c_1\delta_2 < 1/2$, which can be ensured by setting $\bar{\delta}$ to be a small enough constant.

The encoding E_1 is almost what we want, except that it is not binary. Thus, we concatenate E_1 (in the coding-theoretical sense) with the error-correcting code $e_k : \{0,1\}^k \to \{0,1\}^{c_2 \cdot k}$, given by Lemma 2.1. We now fix $c_1 > 0$ to be a constant such that e_k has relative distance $\geq 1/c_1$. Recall that e_k also has constant rate (i.e., c_2 is a constant) and linear size "codeword decoding" as defined in Lemma 2.1. Let $E \stackrel{def}{=} E_1 \circ e_k$ encode a string $a \in \{0,1\}^n$ by first computing $E_1(a)$ and then encoding each symbol of $E_1(a)$ using e_k. The distance of e_k being at least $1/c_1$ guarantees that

$$\mathsf{dist}(a, a') > \delta_1 \Rightarrow \mathsf{dist}(E_1(a), E_1(a')) > c_1\delta_2 \Rightarrow \mathsf{dist}(E(a), E(a')) > \delta_2,$$

which establishes item 1 of the lemma. For item 2, we use the fact that codeword decoding e_k needs circuits of size $O(k)$, and the fact that verifying that a string is an output of E_1 and then inverting E_1 on it is easy to do by a linear size circuit.

For item 3, we consider the following randomized test (which translates in the natural way to the required n circuits). The input is $a \in \{0,1\}^n$ and $b \in \{0,1\}^{c_2 kn}$, and we wish to verify that $b = E(a)$.

- Select a random k-tuple in X_k, and denote it by $(i_1, \ldots, i_k)$. Read $a_{i_1}, \ldots, a_{i_k}$.
- Let $j_1, \ldots j_{c_2 k}$ be the indices such that $b|_{j_1,\ldots,j_{c_1 k}}$ supposedly equals $e_k(a|_{i_1,\ldots,i_k})$. Read $b_{j_1}, \ldots, b_{j_{c_1 k}}$.
- Accept iff $e_k(a_{i_1}, \ldots, a_{i_k}) = b_{j_1}, \ldots, b_{j_{c_1 k}}$ (this is performed by first applying the circuit for codeword decoding of e_k on $b_{j_1}, \ldots, b_{j_{c_1 k}}$ and then comparing the result with $a_{i_1}, \ldots, a_{i_k}$).

The test requires $\log |X_k| = \log n$ random bits and reads $k + c_1 k = O(\frac{\delta_1}{\delta_2})$ bits. If $b = E(a)$, the test clearly accepts. Otherwise, denote $\beta = \mathsf{dist}(b, E(a))$. By construction of E_1, for at least a β fraction of the tuples $(i_1, \ldots, i_k) \in X_k$: $e_k(a_{i_1}, \ldots, a_{i_k}) \neq (b_{j_1}, \ldots, b_{j_{c_1 k}})$, so the test rejects with probability at least β. The test for any particular fixing of the $\log n$ random bits can be implemented by a circuit of size $O(k) = O(\frac{\delta_1}{\delta_2})$. □

Remark 4.4. In the construction provided in Lemma 4.1 of the new distance-reduced assignment tester $\mathcal{A}'$ for inputs of size n, we require only that $\mathcal{A}$ be well defined on inputs of size at most $M = O(\frac{\delta}{\delta'} n)$. This will be important for our inductive constructions, where $\mathcal{A}$ has been defined only for inputs of up to a certain size.

Remark 4.5. Lemma 4.1 will be used in this work only for constant δ. However, we will ignore, for the simplicity of presentation, the requirement that δ be smaller than some fixed constant $\bar{\delta}$. It is not hard to ensure that the lemma is applied only with sufficiently small δ.

4.2. Serial error-reduction: $\varepsilon \to \varepsilon'$. Let ε be the error-probability of an assignment tester $\mathcal{A}$, i.e., the fraction of output circuits that erroneously accept a far-from-satisfying assignment. The naive way of reducing ε is by serial repetition, namely, taking ANDs of k uniformly selected output circuits of $\mathcal{A}$ (as the output circuits of the new assignment tester $\mathcal{A}'$). The set of variables for $\mathcal{A}'$ is exactly the same as for $\mathcal{A}$. (Therefore the width of variables does not change by this transformation.) However, the number of variables read by each circuit increases by a factor k. This implies the following reduction.

LEMMA 4.6 (serial error-reduction). *For any integer ℓ, given an assignment tester $\mathcal{A}$ with parameters $(\mathsf{R},\mathsf{s},\mathsf{q},\delta,\varepsilon)$, we can construct a new assignment tester $\mathcal{A}'$ whose error probability is ε^ℓ. The other parameters of $\mathcal{A}'$ are $\mathsf{R}'(\mathsf{n}) = (\mathsf{R}(\mathsf{n}))^\ell$, $\mathsf{s}' = O(\ell\mathsf{s}(\mathsf{n}))$, $\mathsf{q}' = O(\ell\mathsf{q}), \delta' = \delta$.*

The number of circuits R' that $\mathcal{A}'$ outputs can be decreased by standard derandomization techniques. Particularly, based on Corollary 2.5, we obtain the following reduction.

LEMMA 4.7 (derandomized serial error-reduction). *Given an assignment tester $\mathcal{A}$ with parameters $(\mathsf{R},\mathsf{s},\mathsf{q},\delta,\varepsilon)$, we can construct a new assignment tester $\mathcal{A}'$ whose error probability is ε'. The other parameters of $\mathcal{A}'$ are $\mathsf{R}'(\mathsf{n}) = O(poly(1/\varepsilon')\mathsf{R}(\mathsf{n}))$, $\mathsf{s}' = O(\ell\mathsf{s}(\mathsf{n}))$, $\mathsf{q}' = O(\ell\mathsf{q}), \delta' = \delta$, where $\ell = \log(1/\varepsilon')/(1-\varepsilon)$.*

The main disadvantage of the serial error reduction (in both versions) is that it reduces ε at the expense of increasing the number of variables q that the circuits read. When error reduction will be used in our constructions, increasing q will not be acceptable. Therefore, we next give a new method for decreasing q back, by aggregation (i.e., by "consistently" reading some ℓ variables at once "in parallel").

4.3. Error-reduction via parallelization/aggregation. A central ingredient in the proof of the PCP theorem is the notion of aggregation (alternatively referred to as parallelization). Namely, starting with an assignment tester that reads q variables, we want to construct a new assignment tester that reads fewer $\mathsf{q}' < \mathsf{q}$ variables and is otherwise comparable to the old assignment tester (though typically the width of the new variables will be larger to compensate for the smaller number that are being read). One motivation for aggregation in our context is error-reduction, as discussed above. (Indeed, Theorem 4.8 below reduces both q and ε.) The original proof of the PCP theorem [2, 1] gives a very powerful aggregation method based on low-degree curves. The proofs in this paper will also require an aggregation theorem. However, our setting is significantly simpler, as we only need to reduce the number of variables read by the assignment tester from one *constant* q to a smaller constant q'. A "combinatorial" aggregation method for this setting can possibly be based on parallel repetition theorems. In particular, we could rely on the work of Feige and Kilian [14], as we do not require the full exponential decrease provided by [24]. We remark that since we require the result to be an assignment tester (rather than a verifier), some more details may be involved when applying [14, 24] in this context.

In this section, we present a simple alternative to both solutions. An advantage of our aggregation compared with the one based on curves is that it can produce variables of *constant width* (rather than logarithmic width). This feature is vital for our proofs. Compared to parallel repetition theorems, our setting is easier since we can afford more than two queries (but shall make a constant number of queries).

Note that the aggregation method of Theorem 4.8 below increases the distance parameter δ. This is the reason that the constructions of this paper require a method for reducing δ, as indeed given by the transformation of Lemma 4.1.

THEOREM 4.8 (aggregation). *Let $\mathcal{A}$ be an assignment tester with parameters $(\mathsf{R},\mathsf{s},\mathsf{q},\delta,\varepsilon)$. For every $\varepsilon' > 0$, one can construct a new assignment tester with parameters $(poly(1/\varepsilon')\cdot\mathsf{R}^\ell, \ell\cdot\mathsf{s}\cdot Q, Q, 2\delta, \varepsilon')$, for $Q = O(\frac{1}{\delta}\log(\frac{1}{\varepsilon'}))$, and $\ell = poly(\frac{\mathsf{q}}{1-\varepsilon})$.*

Before turning to the actual proof, let us sketch the idea. First, it is easy to reduce q to a constant ($\mathsf{q} = 3$ in our case), at the price of increasing the error. This is done by adding auxiliary variables which encode the entire input of a circuit, and then replacing that circuit by q circuits that compare the new "big" variable to one of the q original variables. (In fact, it will be convenient for us to compare to one

X-variable and also to one Y-variable, implying query complexity three rather than two.) This (standard) transformation will be described in detail later.

Next, the error probability can easily be reduced again by serial repetition, i.e., by taking ANDs of multiple circuits. However, the resulting circuits access more variables than before (i.e., by these two steps, q just got larger). To avoid this, it is natural to use *parallel repetition*. Namely, we introduce new variables $\overline{X} \equiv X^\ell$ that are supposed to be ℓ-tuples of the original variables X. Now, the effect of serial repetition can be emulated with only *few* accesses to the new (wider) variables. The main obstacle this approach must overcome is that of consistency. Suppose that $x \in X$ occurs in two tuples, $\bar{\mathbf{x}}$ and $\bar{\mathbf{x}}'$. Given an assignment $F : \overline{X} \to \Sigma^\ell$, it is quite possible that the value that x receives in $F(\bar{\mathbf{x}})$ differs from that in $F(\bar{\mathbf{x}}')$. If we were assured that there were no (or few) inconsistencies of this sort, then the analysis of parallel repetition would be as easy as that of serial repetition. We therefore address this issue by a consistency test (described in Figure 3) such that passing it with high probability guarantees that most tuples are "mostly" consistent with the plurality function of F, defined shortly (after specifying some notation and conventions).

For the sake of generality, and in order to simplify our analyses, we will define both the plurality function and the consistency test with respect to an arbitrary distribution $\mathcal{D}$ on X. Also for simplicity, we assume that we will always encounter assignments $F : \overline{X} \to \Sigma^\ell$ that are *rotation consistent*. Namely, if $\bar{\mathbf{x}}'$ is obtained from $\bar{\mathbf{x}}$ using some cyclic shift of its ℓ components, then $F(\bar{\mathbf{x}}')$ can be obtained from $F(\bar{\mathbf{x}})$ in the same way. This assumption slightly simplifies the consistency test and is easy to achieve in our setting using a trivial folding argument (simply let F be specified by the assignment for the various *subsets* of X of at most ℓ elements rather than by assignments to *ordered ℓ-tuples of elements*). Finally, for any ℓ tuple $\bar{\mathbf{x}}$, let $\bar{\mathbf{x}}_i$ denote its ith component.

DEFINITION 4.9 (plurality). *Let X and Σ be finite sets, let $\ell \geq 1$ be an integer, and set $\overline{X} \equiv X^\ell$. Let $\mathcal{D}$ be an arbitrary probability distribution over X. Let $F : \overline{X} \to \Sigma^\ell$. Define the* plurality *function of F with respect to $\mathcal{D}$, denoted $f_{F,\mathcal{D}} : X \to \Sigma$ as follows. For every $x \in X$, let $f_{F,\mathcal{D}}(x)$ be the value that is assigned to x most frequently by F (with respect to the distribution $\mathcal{D}^\ell$ on $\overline{X}$). Formally,*

$$\forall x \in X, \quad f_{F,\mathcal{D}}(x) \stackrel{def}{=} \max_{a \in \Sigma} \arg \left\{ \Pr_{\bar{\mathbf{x}} \in \mathcal{D}^\ell, i \in [\ell]} [F(\bar{\mathbf{x}})_i = a \mid \bar{\mathbf{x}}_i = x] \right\}.$$

In case $\mathcal{D}$ is the uniform distribution over X, we denote the plurality function as f_F (i.e., we omit $\mathcal{D}$ from the notation).

In Figure 3 we describe the consistency test. Essentially the same test was first studied by Goldreich and Safra [19], who proved that (for uniform $\mathcal{D}$) the test establishes consistency with some f. Their proof used a different "two-stage" plurality function f and was established via reduction to another (derandomized) test. In Appendix A we give a direct proof for the same test, summarized by the following theorem.

THEOREM 4.10 (consistency). *Let $F : \overline{X} \to \Sigma^\ell$ and $\mathcal{D}$ be an arbitrary probability distribution over X. Let $f = f_{F,\mathcal{D}} : X \to \Sigma$ be the plurality function of F. Let T be the test described in Figure 3. Then the following hold:*

- *If for all $\bar{\mathbf{x}} = (x_1, \ldots, x_\ell) \in \overline{X}$ it holds that $F(x_1, \ldots, x_\ell) = (f(x_1), \ldots, f(x_\ell))$, then T always accepts.*
- *Call $\bar{\mathbf{x}} = (x_1, \ldots, x_\ell) \in \overline{X}$ bad if $F(\bar{\mathbf{x}})$ disagrees with $(f(x_1), \ldots, f(x_\ell))$ on*

1. Select a random $\bar{\mathbf{x}} = (x_1, \ldots, x_\ell) \in \mathcal{D}^\ell$.
2. Select a random $\bar{\mathbf{x}}' = (x'_1, \ldots, x'_\ell) \in \overline{X}$ as follows: for each $j \in [\ell]$, $x'_j = x_j$ with probability $\alpha \stackrel{def}{=} \ell^{-1/3}$; otherwise x'_j is selected independently according to $\mathcal{D}$.
3. Accept only if $F(\bar{\mathbf{x}})$ agrees with $F(\bar{\mathbf{x}}')$ on *all* common variables; otherwise reject.

FIG. 3. *Consistency test for $F : \overline{X} \to \Sigma^\ell$, any $|X|, |\Sigma| < \infty$, and any probability distribution $\mathcal{D}$ over X. In case F is not guaranteed to be rotation consistent, then the test is revised slightly: The query $\bar{\mathbf{x}}'$ is also rotated cyclicly by a random shift in $[\ell]$.*

more than $\sqrt[3]{\ell}$ entries. There exists a constant c such that for every $\gamma > 0$,

$$\Pr_{\bar{\mathbf{x}} \in \mathcal{D}^\ell}[\bar{\mathbf{x}} \text{ bad}] > \gamma \Rightarrow T \text{ rejects with probability at least } \gamma/c.$$

Proof of Theorem 4.8. Our approach will be as follows. We first transform the circuits generated by $\mathcal{A}$ to circuits that each depend on three variables. This is a simple (almost standard) transformation that replaces every circuit reading q variables by several circuits each reading three variables (over a larger domain). This causes the error-probability to increase. Next, we perform ℓ-parallel repetition: Instead of reading 3ℓ variables, as in the serial repetition, we introduce new variables that are ℓ-tuples of the previous ones and read only three of these. We ensure soundness of this step by adding a separate consistency test. The number of circuits produced by the assignment tester will be bounded by $\mathsf{R}^{O(\ell \log \ell)}$. By redefining ℓ to be a slightly larger polynomial in $\frac{\mathsf{q}}{1-\varepsilon}$, the dependence on ℓ becomes as claimed.

Let $\mathcal{A}$ be an assignment tester with parameters $(\mathsf{R}, \mathsf{s}, \mathsf{q}, \delta, \varepsilon)$. Let $\gamma = 1 - \varepsilon$ be the detection probability of $\mathcal{A}$. We first fix $\gamma' = \delta/24c$, where c is the absolute constant from Theorem 4.10, and prove that one can construct a new assignment tester with parameters $(\mathsf{R}^{O(\ell \log \ell)}, O(\ell \cdot \mathsf{s}), O(1), 2\delta, \gamma')$, for $\varepsilon' = 1 - \gamma'$ and $\ell = O((\frac{\mathsf{q}}{\gamma})^{3/2})$. The theorem will then follow for an arbitrarily small ε' as a simple corollary of Lemma 4.7 (i.e., by serial error reduction). The proof will follow the two steps mentioned above.

Step 1: Getting to three queries. Let φ be a circuit over variables X. Run $\mathcal{A}$ on input φ, generating output circuits $\psi_1, \ldots, \psi_{\mathsf{R}}$ over X, Y. Define new variables $Z = \{z_1, \ldots, z_{\mathsf{R}}\}$, one z_i per ψ_i. The variable z_i will assume values that are supposedly the complete input to ψ_i. Notation: we denote by $\Sigma_X = \{0,1\}, \Sigma_Y, \Sigma_Z$ the set of values assumed by the variables in X, Y, Z, respectively. Thus, $\Sigma_Z \subseteq (\Sigma_X \cup \Sigma_Y)^{\mathsf{q}}$. We also denote by $X(z_i)$ (resp., $Y(z_i)$) the set of X- (resp., Y-) variables accessed by the corresponding circuit, ψ_i. Assume w.l.o.g. (without loss of generality) that these sets are nonempty for all i. Clearly, $|X(z) \cup Y(z)| \leq \mathsf{q}$ for all z.

By introducing the Z variables, we can get a system of circuits each reading three (rather than q) variables, but with a lower detection probability. This is a variant on a standard "transformation to two-provers" [15], and can be done, for example, as follows. Replace each ψ_i with circuits $\psi_i^{(1)}, \ldots, \psi_i^{(\mathsf{q})}$ that each read z_i, and also one $x \in X(z_i)$ and one $y \in Y(z_i)$, and then check that the value of z_i would have satisfied ψ_i, and that it is consistent with the values of x and y. (Each one of the $x \in X(z_i)$ and $y \in Y(z_i)$ is read by at least one of these circuits $\psi_i^{(\mathsf{q})}$.) We remark that each new circuit $\psi_i^{(j)}$ could have read two variables (as is more standard) rather than three: Instead of reading both an X-variable *and* a Y-variable (in addition to

the Z-variable), it could have read either an X- *or* a Y-variable. However, looking ahead, making three queries (each into a different set of variables) will be convenient for repetition. It will allow us, more naturally, to use three separate tables for ℓ-tuples of Z-, Y-, and X-variables. This way we will avoid having to deal with tuples mixing both X- and Y-variables.

Clearly if $\sigma|_{X\cup Y}$ satisfies all ψ_i, it can be extended to Z such that all of the $\psi_i^{(j)}$ accept. Also, we find the following result.

PROPOSITION 4.11. *Let $\sigma : X \cup Y \cup Z \to \Sigma_X \cup \Sigma_Y \cup \Sigma_Z$. If $\sigma|_X$ is δ-far from satisfying φ, then*

$$\Pr_{i,j}\left[\psi_i^{(j)} \text{ rejects}\right] \geq \gamma/\mathsf{q}.$$

Proof. By the soundness of $\mathcal{A}$, at least a γ fraction of the ψ_i's reject the assignment $\sigma|_{X\cup Y}$. No matter how one assigns the Z-variables, on these ψ_i's either $\sigma(z_i) \notin SAT(\psi_i)$ or there is an inconsistency between the value of z_i and at least one of the q variables accessed by ψ_i. We detect this inconsistency with probability at least $\frac{1}{\mathsf{q}}$. □

Step 2: Parallelization. We now define new variables that are tuples of the variables X, Y, Z above. Let $\ell = O((\frac{\mathsf{q}}{\gamma})^{3/2})$. For every possible ℓ-tuple of X-variables, we have a new variable $\bar{\mathbf{x}} = (x_1, \ldots, x_\ell) \in \overline{X}$, so that $\overline{X} \equiv X^\ell$. Similarly we define $\overline{Y} \equiv Y^\ell$ and $\overline{Z} \equiv Z^\ell$.[7]

We now define three types of building-block circuits. The first will perform ℓ-parallel repetition of the circuits $\{\psi_i^{(j)}\}$ in order to reduce their error. The second will facilitate the analysis of the parallel repetition by performing a consistency test of the assignment to the ℓ-tuples (as in Figure 3). The first two types test only the new variables that supposedly represent ℓ-tuples of original variables. We therefore still need to compare the assignment for the ℓ-tuples to the assignment for the original X-variables.

Parallel-repetition circuits. For every choice of an ℓ-tuple of circuits $\psi_{i_1}^{(j_1)}, \ldots, \psi_{i_\ell}^{(j_\ell)}$ in $\{\psi_i^{(j)}\}_{i\in[R],j\in[\mathsf{q}]}$ we will have one circuit simulating their ℓ-wise AND. For every $1 \leq t \leq \ell$ let x_t (resp., y_t, z_t) be the single x- (resp., y-, z-) variable accessed by $\psi_{i_t}^{(j_t)}$. The circuit will access $\bar{\mathbf{z}} = (z_1, \ldots, z_\ell) \in \overline{Z}$, $\bar{\mathbf{x}} = (x_1, \ldots, x_\ell)$, and $\bar{\mathbf{y}} = (y_1, \ldots, y_\ell)$ and accept if on every coordinate $1 \leq t \leq \ell$, z_t satisfies ψ_{i_t} and is consistent with x_t and y_t. (Recall that the assignment for each z_t is interpreted as an assignment for all of the variables of ψ_{i_t}, and in particular it specifies values for x_t and y_t.) Denote these circuits by $C_1^1, \ldots, C_{R_1}^1$ with $R_1 = (\mathsf{q}\mathsf{R})^\ell \leq R^{O(\ell \log \ell)}$ (in this bound the $\log \ell$ could have been dropped, assuming $\mathsf{q} < R$, but this makes no difference later so we leave it as is). Let $\mathsf{C}_1 = \{C_1^1, \ldots, C_{R_1}^1\}$.

Consistency circuits. Let $\mathcal{D}_x$ be the distribution on X defined by having $\Pr_{x\in\mathcal{D}_x}[x]$ equal the probability that a uniformly random $\psi_i^{(j)}$ circuit reads x. Define $\mathcal{D}_y, \mathcal{D}_z$ similarly. For all possible random choices of $\bar{\mathbf{x}}, \bar{\mathbf{x}}'$ as described in the consistency test in Figure 3, with $\mathcal{D} = \mathcal{D}_x$, we have a consistency circuit for the corresponding test. Likewise for all choices of $\bar{\mathbf{y}}, \bar{\mathbf{y}}'$ and of $\bar{\mathbf{z}}, \bar{\mathbf{z}}'$. Let $\mathsf{C}_2 = \{C_1^2, \ldots, C_{R_2}^2\}$ be the sequence of these circuits. The number of random choices is bounded by the number of pairs

[7] As discussed above, we ensure that the assignment to these ℓ-tuples is *rotation consistent*, by a simple folding argument. Instead of requiring an assignment to ℓ-tuples we ask for an assignment to subsets of cardinality at most ℓ. This naturally defines a rotation consistent assignment to the ℓ-tuples.

of circuit $\psi_i^{(j)}$ and variable x (or y) which is $\leq \mathsf{qR}$, raised to the power ℓ, and then at most squared. So, $R_2 \leq 3\,(\mathsf{qR})^{2\ell} \leq \mathsf{R}^{O(\ell \log \ell)}$. (Note that we have exactly the same number of circuits testing the X-variables, the Y-variables, and the Z-variables.)

Comparison circuits. These ensure consistency between $\overline{X}$ and X. For each $x \in X$ and $\bar{\mathbf{x}} \in \overline{X}$ that contains it, we have a comparison circuit, comparing the value of x, with the value given to it in the tuple $\bar{\mathbf{x}}$. Denote the resulting circuits $\mathsf{C}_3 = \{C_1^3, \ldots, C_{R_3}^3\}$, then $R_3 = \ell \mathsf{R}^\ell = \mathsf{R}^{O(\ell)}$ such circuits.

Final circuits. For simplicity, we assume $R_1 = R_2 = R_3 = R^{O(\ell \log \ell)}$ (otherwise, equality can be obtained by duplication). The final circuits output by our assignment tester will be the AND of the ith C_1 circuit with the ith C_2 circuit and with the ith C_3 circuit. That is, the ith output circuit is $C_i^1 \wedge C_i^2 \wedge C_i^3$. This guarantees that if ε' of the final circuits accept, then ε' of the C_1 circuits accept, as do ε' of the C_2 circuits and ε' of the C_3 circuits. Observe that these circuits are over variables $X \cup \overline{X} \cup \overline{Y} \cup \overline{Z}$.

This completes the description of the new assignment tester. Before we prove completeness and soundness, let us examine its parameters. The number of output circuits is indeed $R^{O(\ell \log \ell)}$. Each output circuit queries $O(1)$ variables. The maximum size of an output circuit is $\leq O(\ell \cdot \mathsf{s})$.

Completeness is immediate: Given an assignment to X that satisfies φ, it can be extended (due to the completeness of $\mathcal{A}$) to the Y variables so that all ψ_i are satisfied. This naturally extends to an assignment for Z, and then for $\overline{X}, \overline{Y}, \overline{Z}$.

LEMMA 4.12 (soundness). *Given an assignment σ for $X \cup \overline{X} \cup \overline{Y} \cup \overline{Z}$, if $\sigma|_X$ is 2δ-far from satisfying φ, then at least γ' of the output circuits reject.*

Proof. Let $F_x \stackrel{def}{=} \sigma|_{\overline{X}} : \overline{X} \to \Sigma_X$ be the restriction of σ to $\overline{X}$, and similarly, $F_y \stackrel{def}{=} \sigma|_{\overline{Y}}$ and $F_z \stackrel{def}{=} \sigma|_{\overline{Z}}$. Recall that $\mathcal{D}_x$ (resp., $\mathcal{D}_y, \mathcal{D}_z$) was the distribution according to which the consistency test of $\overline{X}$ (resp., $\overline{Y}, \overline{Z}$) was performed. Let $f_x = f_{F_x, \mathcal{D}_x}$, $f_y = f_{F_y, \mathcal{D}_y}$, $f_z = f_{F_z, \mathcal{D}_z}$ be the plurality functions of F_x, F_y, F_z, respectively, as in Definition 4.9. In the following proof the reader may wish to regard $\mathcal{D}_x, \mathcal{D}_y, \mathcal{D}_z$ as being uniform, although in general this need not be the case. We will, however, require that $\mathcal{D}_x$ be uniform, so let us explain why this can be assumed with no loss of generality. The distribution $\mathcal{D}_x$ would be uniform if the sequence of $\psi_i^{(j)}$ circuits access each X-variable the same number of times. To enforce this condition, we slightly modify the ψ_i circuits. We introduce a new set of variables X' that is supposed to be the exact copy of X, and apply the ψ_i circuits on the assignment to X' (instead of the assignment to X). In addition, we add consistency checks to test that the assignments to X and to X' are δ-close, by checking equality between a random variable in X and its copy in X'. It is easy to argue that the new circuits still define an assignment tester (with a small increase in the distance parameter, but otherwise parameters almost identical to the original one, $\mathcal{A}$). In addition, since the consistency checks between X and X' access each X-variable the same number of times, we get the additional desired property.

Recall that $\sigma|_X$ is 2δ-far from satisfying φ. We prove that either γ' of the circuits in C_3 reject, or γ' of the circuits in C_2 reject, or γ' of the circuits in C_1 reject.

PROPOSITION 4.13. *If $\mathsf{dist}_X(f_x, SAT(\varphi)) \leq \delta$, then γ' of the circuits in C_3 reject.*

Proof. If $\mathsf{dist}_X(f_x, SAT(\varphi)) \leq \delta$, then since $\mathsf{dist}_X(\sigma|_X, SAT(\varphi)) > 2\delta$, the triangle inequality implies $\mathsf{dist}_X(f_x, \sigma|_X) > \delta$. Let $x \in X$ be such that $\sigma(x) \neq f_x(x)$. By definition of plurality (and since $\mathcal{D}_x$ is the uniform distribution!), $f_x = f_{F_x}(x)$ is defined to be the value that is assigned most often to x, among all tuples that contain

x. Thus, assuming $f_x \neq \sigma(x)$, the value of $\sigma(x)$ must occur in no more than half of the tuples containing x. Thus, at least half of the comparison circuits (in C_3) that access x reject; altogether, $\frac{\delta}{2} > \gamma'$ of all of the comparison circuits reject. □

Recall that an ℓ-tuple $\bar{\mathbf{x}} \in \overline{X}$ is *bad* with respect to F_x if $F_x(\bar{\mathbf{x}})$ disagrees with $(f_x(x_1), \ldots, f_x(x_\ell))$ on more than $\sqrt[3]{\ell}$ locations. A similar definition applies to bad tuples in $\overline{Y}$ and in $\overline{Z}$.

PROPOSITION 4.14. *If more than $\frac{1}{8}$ fraction of the tuples (in each of $\overline{X}, \overline{Y}$, or $\overline{Z}$) are bad, then at least γ' of the circuits in C_2 reject.*

Proof. Assume there are more than $\frac{1}{8}$ bad tuples with respect to F_x, F_y, or F_z; then Theorem 4.10 guarantees that for some absolute constant c the consistency test for the particular table will reject with probability $\geq \frac{1}{8c}$. Thus, at least $\frac{1}{24c} \geq \gamma'$ of the circuits in C_2 will reject. □

Now, assume that the conditions in both Propositions 4.13 and 4.14 fail to hold. This will enable us to argue that the circuits in C_1 are emulating the serial repetition of $\{\psi_i^{(j)}\}$, and to deduce that many of them reject. Failure of the condition of Proposition 4.13 means that $\mathsf{dist}_X(f_x, SAT(\varphi)) > \delta$. Together with Proposition 4.11, this implies that at least γ/q of the $\{\psi_i^{(j)}\}$ circuits reject the assignment $f_x \cup f_y \cup f_z$. Failure of the condition of Proposition 4.14 means that the variables $\overline{X}, \overline{Y}, \overline{Z}$ are *consistent* with the plurality assignments f_x, f_y, f_z. So, for example, reading the assignment for a tuple $(x_1, \ldots, x_\ell) \in \overline{X}$ "emulates" reading the assignment f_x in locations $x_1, \ldots, x_\ell$.

We now combine the above to deduce that at least a γ' fraction of C_1 reject.

Indeed, choose ℓ random circuits $\psi_{i_1}^{(j_1)}, \ldots, \psi_{i_\ell}^{(j_\ell)} \in \{\psi_i^{(j)}\}$, and let $\overline{\psi} = (\psi_{i_1}^{(j_1)}, \ldots, \psi_{i_\ell}^{(j_\ell)})$. Under assignment $f_x \cup f_y \cup f_z$, we expect to see at least $\ell \cdot \frac{\gamma}{\mathsf{q}}$ of $\overline{\psi}$'s components reject. Moreover, ℓ is chosen exactly so that this expectation is sufficiently above $3\sqrt[3]{\ell}$, so most tuples $\overline{\psi}$ see more than $3\sqrt[3]{\ell}$ rejecting components. Indeed the following proposition follows from a standard tail inequality.

PROPOSITION 4.15. *Assume the failure of the condition of Proposition* 4.13. *For some $\ell = O((\frac{\mathsf{q}}{\gamma})^{3/2})$,*

$$\Pr_{\overline{\psi}}\left[\overline{\psi} \text{ contains} \leq 3\sqrt[3]{\ell} \text{ circuits that reject } f_x \cup f_y \cup f_z\right] \leq 1/8.$$

We now examine which circuits in C_1 can possibly accept. A circuit $C \in \mathsf{C}_1$ corresponding to some $\overline{\psi} = (\psi_{i_1}^{(j_1)}, \ldots, \psi_{i_\ell}^{(j_\ell)})$ reads three variables $\bar{\mathbf{x}}, \bar{\mathbf{y}}, \bar{\mathbf{z}}$ and rejects unless the following hold:

1. At least one of $\bar{\mathbf{x}}, \bar{\mathbf{y}}$, or $\bar{\mathbf{z}}$ is bad, or
2. $\overline{\psi}$ has at most $3\sqrt[3]{\ell}$ components that reject $f_x \cup f_y \cup f_z$.

Indeed, otherwise there must be at least one coordinate $1 \leq t \leq \ell$ for which $\psi_{i_t}^{(j_t)}$ rejects, and also the tth coordinate of $F_x(\bar{\mathbf{x}})$ equals the plurality function $f_x(x_t)$, and similarly for $F_y(\bar{\mathbf{y}})$ and $F_z(\bar{\mathbf{z}})$; thus, by definition, C rejects.

Proposition 4.15 bounds the probability of the second item by $\frac{1}{8}$. The probability of the first item is bounded by the probability of hitting a bad tuple in any of the tables F_x, F_y, or F_z. Each of $\bar{\mathbf{x}}, \bar{\mathbf{y}}$, or $\bar{\mathbf{z}}$ is a random (according to the corresponding distribution $\mathcal{D}_x, \mathcal{D}_y, \mathcal{D}_z$) entry in the corresponding table. Therefore, by the bound on the number of bad tuples (Proposition 4.14), the probability of the first item does not exceed $3 \cdot \frac{1}{8}$. Altogether, the probability that $\overline{\psi}$ doesn't reject is bounded by $\frac{1}{8} + \frac{3}{8} = \frac{1}{2}$, which means that $\overline{\psi}$ rejects with probability at least $1/2 > \gamma'$.

In conclusion, at least γ' of the final output circuits reject, completing the proof of Lemma 4.12 (soundness). □

Now that we have established the soundness of the assignment tester, Theorem 4.8 follows. □

5. The PCP theorem—An alternate proof. In this section we give a new proof for the PCP theorem [2, 1]. Our proof involves composition, and a combination of the combinatorial transformations described in section 4, applied on a "weak" assignment tester, that is assumed to be given.

THEOREM 5.1 (weak tester). *For some constants $\beta > 0, c_1$, and q_β there exists an assignment tester $\mathcal{A}_\beta$ with the following parameters:*

- *number of output circuits,* $\mathsf{R}(\mathsf{n}) = \mathsf{n}^{c_1}$,
- *size of output circuits,* $\mathsf{s}(\mathsf{n}) = O(\mathsf{n}^{1-\beta})$,
- *number of queries,* $\mathsf{q}(\mathsf{n}) = q_\beta$,
- *error probability,* $\varepsilon(\mathsf{n}) = 0.1$,
- *distance,* $\delta(\mathsf{n}) = 0.1$.

Such an assignment tester (and even stronger) can be constructed, for example, by relying on algebraic techniques already present in [13], particularly by taking a low-degree extension with a *constant* number of dimensions (as opposed to the way it is usually invoked, with a logarithmic number of dimensions) and then performing the [22] "sum-check" procedure (while relying on a *weak* low-degree test). It is interesting to note that although an assignment tester seems stronger than just a PCP verifier, all known constructions give the stronger object.

Our main theorem in this section is the following.

THEOREM 1.1 (formal statement). *Assuming $\mathcal{A}_\beta$ as in Theorem* 5.1*, there exists an assignment tester $\mathcal{A}$ with the following parameters:*

- *number of output circuits,* $\mathsf{R}(\mathsf{n}) = poly(\mathsf{n})$,
- *size of output circuits,* $\mathsf{s}(\mathsf{n}) = O(1)$,
- *number of queries,* $\mathsf{q}(\mathsf{n}) = O(1)$,
- *error probability,* $\varepsilon(\mathsf{n}) = 0.1$,
- *distance,* $\delta(\mathsf{n}) = 0.1$.

The PCP theorem now follows as an immediate corollary, as given next.

COROLLARY 5.2 (PCP theorem). *Given a set of Boolean constraints $\psi_1, \ldots, \psi_{\mathsf{R}}$ over Boolean variables Z, such that each read a constant number of variables, it is NP-hard to distinguish between the following two cases:*

1. [*completeness*] *there is an assignment to Z satisfying all of $\psi_1, \ldots, \psi_{\mathsf{R}}$.*
2. [*soundness*] *every assignment to Z satisfies at most* 10% *of $\psi_1, \ldots, \psi_{\mathsf{R}}$.*

Proof. We reduce from SAT. On input of a SAT formula φ over variables X, feed it to the assignment tester algorithm $\mathcal{A}$ given by Theorem 1.1. The output is a list of $\mathsf{R}(|\varphi|)$ circuits $\psi_1, \ldots \psi_{\mathsf{R}}$ such that each reads a constant number of bits from $Z = X \cup Y$.

If φ is satisfiable, say by an assignment $a : X \to \{0,1\}$, then there is some b such that together $a \cup b$ satisfy all of $\psi_1, \ldots, \psi_{\mathsf{R}}$. If φ is not satisfiable, at most an $\varepsilon = 0.1$ fraction of $\{\psi_1, \ldots, \psi_{\mathsf{R}}\}$ can accept. Otherwise, the soundness condition of $\mathcal{A}$ implies that a is δ-close to a satisfying assignment for φ, and in particular it means that φ is satisfiable. □

The naive approach for proving Theorem 1.1, the main theorem of this section, is to compose $\mathcal{A}_\beta$ with itself $\log \log n$ times. Starting with an input circuit of size n, the output circuits have size $\mathsf{n}^{1-\beta}$, $(\mathsf{n}^{1-\beta})^{1-\beta} = \mathsf{n}^{(1-\beta)^2}$, and so on to $\mathsf{n}^{(1-\beta)^i}$ at step i. Therefore, the circuit size of the output circuits is constant for $i = O(\log \log n)$. While already achieving nontrivial parameters, this construction does not quite give the PCP theorem. The reason has to do with the error probability, or its complement, the

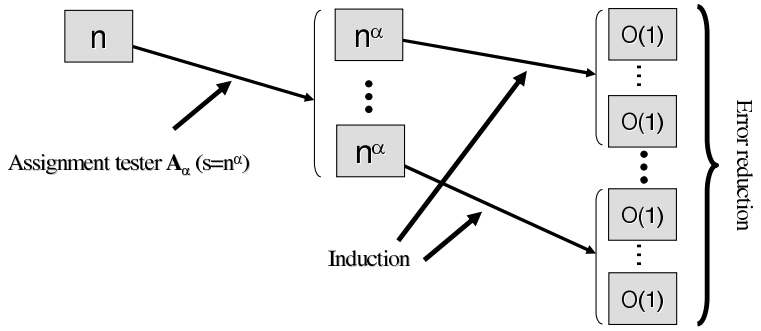

FIG. 4. *The inductive step. Error reduction encapsulates the additional parameter-fixing steps, which compensate for the error-increase of the composition step.*

detection probability ($\gamma = 1 - \varepsilon$), which will be more convenient to work with in this section. The detection probability becomes $\gamma_1\gamma_2, \ldots, \gamma_i = (\gamma_\beta)^{\log\log n} = O(1/\log n)$, rather than constant as we would like. Our proof of Theorem 1.1 will have the same general structure as in the naive approach but with a more elaborate recursive step, as follows.

It may seem at first that there is an additional more inherent problem with the naive approach. After all, to compose an assignment tester with itself we need $\delta < 1/\mathsf{q}$, which seems impossible. However, recall that the number of queries q of an assignment tester can be easily made a small fixed constant (e.g., 3) without harming the distance parameter δ (see Proposition 4.11).

Inductive step—Quick overview (*see also Figure* 4). Our construction is bottom-up. We assume having constructed an assignment tester with the desired parameters that works for inputs of size smaller than n, and show how to extend it for inputs of size n. Therefore, by induction, we obtain the desired assignment tester for all input sizes up to and including n.

Our inductive step begins with composition of the black-box assignment tester (or rather, a variant of it denoted A_α) with the one assumed by induction. This composition, as discussed above, increases the error of the assignment tester. To correct this we next perform error-reduction by "parallelization" (as in Theorem 4.8), which will take care of the error but will have two undesirable side effects: The distance parameter δ will increase, and the size of the output circuits will increase as well. The next step will be to perform a distance reduction (as in Lemma 4.1). Finally, the last step will be to reduce back the size of the output circuits, to achieve the inductive hypothesis. This is done by composition (again) but this time with a constant size assignment tester. (The inputs to this assignment tester will always be of some bounded constant size.) We note that this second assignment tester (called $\mathcal{A}_0$ below) can be obtained, e.g., by instantiation of the black-box tester (of Theorem 5.1) for a fixed input size.

Before proceeding to the formal proof, it will be convenient to strengthen somewhat the parameters of $\mathcal{A}_\beta$ given in Theorem 5.1.

COROLLARY 5.3. *Assuming $\mathcal{A}_\beta$ as in Theorem* 5.1*, there exists a constant $\bar{q}$ such that for every $\alpha > 0$ there exists c_1 and an assignment tester $\mathcal{A}_\alpha$ with the following parameters:* $\mathsf{R}(\mathsf{n}) = \mathsf{n}^{c_1}$, $\mathsf{s}(\mathsf{n}) = O(\mathsf{n}^\alpha)$, $\mathsf{q}(\mathsf{n}) = \bar{q}$, $\delta(\mathsf{n}) = 0.1$, $\varepsilon(\mathsf{n}) = 0.1$.

This strengthening follows by an appropriate sequence of transformations similar to those below. We defer the proof to Appendix B.

The rest of this section is devoted to proving Theorem 1.1 by following the outline

above. We first describe the building blocks used to construct the recursive algorithm $\mathcal{A}$, and then formally describe $\mathcal{A}$; see also the procedure in section 5.2.

5.1. Building-block testers and their parameters. As discussed above, we consider three testers in this construction. $\mathcal{A}$ itself, which is constructed recursively; $\mathcal{A}_\alpha$, which is essentially the assignment tester that we assume as a black box; and finally $\mathcal{A}_0$, the constant size assignment tester. It is important to note that there are various interdependencies between the parameters of these three testers, for example, to allow their composition (as Theorem 3.7 makes some restriction on parameters of the composed testers). The main purpose of the following definitions and discussion is to make explicit the dependencies between the various parameters, so as to make sure that we do not run into circular definitions. The reader may choose to ignore reading these subtleties initially and skip to the construction of $\mathcal{A}$ (provided in section 5.2).

First, $\mathcal{A}_\alpha$ (guaranteed by Corollary 5.3) has the parameters $(\mathsf{R}(\mathsf{n}) = \mathsf{n}^{c_1},\ \mathsf{s}(\mathsf{n}) = O(\mathsf{n}^\alpha),\ \mathsf{q}(\mathsf{n}) = \bar{q},\ \delta(\mathsf{n}) = 0.1,\ \varepsilon(\mathsf{n}) = 0.1)$. We will select α later and remember that c_1 is a constant and is the only parameter that depends on α. We stress that $\bar{q}$ is an absolute constant. Since $\mathcal{A}_\alpha$ will be applied only on input circuits of size larger than some n_0 (that can be made large enough), we can assume that $\mathsf{s}(\mathsf{n}) = \mathsf{n}^\alpha$. Denote the error probability and distance parameter by $\varepsilon_\alpha = \delta_\alpha = 0.1$, and the detection probability by $\gamma_\alpha = 1 - \varepsilon_\alpha = 0.9$.

Regarding the two additional testers $\mathcal{A}$ and $\mathcal{A}_0$, we first set their distance parameters in a way that will allow the composition needed by the construction. Set the distance parameter of $\mathcal{A}$ to be $\delta = \min(0.1, \frac{1}{c_2\bar{q}})$, where c_2 is the constant from Theorem 3.7. Recall that composition of two assignment testers is allowed (Theorem 3.7) if the distance parameter δ of the second (inner) is related to the query parameter $\bar{q}$ of the first, by $\delta \le \frac{1}{c_2\bar{q}}$. We remark that although in Theorem 1.1 the claimed distance parameter of $\mathcal{A}$ is 0.1, we constrain it here further, so that $\mathcal{A}$ can be invoked recursively. In foresight, set $\mathsf{q}_1 = O(\frac{1}{\delta}\log\frac{1}{\varepsilon_\alpha})$ (the constant in the "O" notation is an absolute constant that will be determined by the analysis below). Set $\delta_0 = \frac{1}{c_2\mathsf{q}_1}$. As we can set $\mathsf{q}_1 \ge \bar{q}$, we obtain $\delta_0 \le \delta$. We can now state the parameters of $\mathcal{A}_0$ (and prove its existence).

PROPOSITION 5.4. *For any $\alpha_0 > 0$ and any n_0 which is large enough (as a function of α_0 and δ_0), there exist $\mathsf{R}_0, \mathsf{s}_0$, and q_0 with $\mathsf{s}_0 < (n_0)^{\alpha_0}$, and there exists an assignment tester $\mathcal{A}_0$ such that for input circuits of size $\le \mathsf{n}_0$, $\mathcal{A}_0$ has parameters $(\mathsf{R}_0, \mathsf{s}_0, \mathsf{q}_0, \delta_0, \varepsilon_\alpha)$. (By definition, $q_0 \le s_0$.)*

Proof. Set $\alpha_0' = \alpha_0/3$, and let $\mathcal{A}_{\alpha_0'}$ be the assignment tester guaranteed by Corollary 5.3. $\mathcal{A}_0$ will be the result of applying the distance-reduction transformation (given by Lemma 4.1) to $\mathcal{A}_{\alpha_0'}$, reducing its distance parameter to δ_0. All we need to verify is the condition on s_0. By Corollary 5.3 and Lemma 4.1 we have that the size of the output circuits of $\mathcal{A}_0$ for input circuits of size $\le \mathsf{n}_0$ is at most $\mathsf{s}_0 = O(\mathsf{n}_0/\delta_0)^{\alpha_0'} + O(\frac{1}{\delta_0}\log\frac{1}{\varepsilon_\alpha})$. By setting n_0 to be large enough, we get that indeed $s_0 < (n_0)^{\alpha_0}$. ∎

In the proof we will need to set α_0 to be a small enough constant; this in turn will set n_0 and also R_0 to be large enough constants.

5.2. The recursive construction. The following lemma restates Theorem 1.1, giving explicit parameters for $\mathcal{A}$ that will be obtained by induction. The constants s_0 and q_0 are as in Proposition 5.4, and recall we set $\delta = \min(0.1, \frac{1}{c_2\bar{q}})$ and $\gamma_\alpha = 0.9$.

LEMMA 5.5. *There exists $C > 0$ and an assignment tester $\mathcal{A}$ with the following parameters: $\mathsf{R}(\mathsf{n}) \le \mathsf{n}^C$, $\mathsf{s}(\mathsf{n}) = \mathsf{s}_0, \mathsf{q}(\mathsf{n}) = \mathsf{q}_0, \delta(\mathsf{n}) = \delta, \varepsilon(\mathsf{n}) = 1 - (\gamma_\alpha)^2$.*

TABLE 1

Evolution of parameters during one inductive step. Recall that $\mathsf{q}_1 = O(\frac{1}{\delta}\log\frac{1}{\varepsilon_\alpha})$. *In addition,* $\mathsf{q}'_1 = O(\frac{1}{\delta_\alpha}\log\frac{1}{\varepsilon_\alpha})$ *and* $\ell = \mathrm{poly}(\frac{\mathsf{q}_0}{\gamma_\alpha})$. *The main composition step* (*step* I), *reduces the circuit size to* s_0 *at the price of reducing the detection probability from* $(\gamma_\alpha)^2$ *to* $(\gamma_\alpha)^3$. *The error-reduction step* (*step* II(a)), *increases the detection probability back* (*even above its final intended value*). *It is also crucial that the number of queries is also reduced, i.e.,* $\mathsf{q}'_1 < \mathsf{q}_0$. *However, both* s *and* δ *increase. This is corrected in steps* II(b) *and* II(c).

Name	Description	System-size (R)	Circuit-size (s)	q	Distance (δ)	Detection (γ)
$\mathcal{A}_\alpha$	Black-box	n^{c_1}	n^α	$\bar{q}$	δ_α	γ_α
$\mathcal{A}$	Induction	n^C	s_0	q_0	δ	$(\gamma_\alpha)^2$

$\mathcal{A}_I$	Reduce s	$\mathsf{n}^{c_1}\cdot O(\mathsf{n}^\alpha)^C$	s_0	q_0	δ_α	$(\gamma_\alpha)^3$
$\mathcal{A}_{IIa}$	& raise γ reduce q	$(\mathsf{n}^{c_1+\alpha C})^{O(\ell)}$	$\ell\cdot\mathsf{s}_0\cdot\mathsf{q}'_1$	q'_1	$2\delta_\alpha$	γ_α
$\mathcal{A}_{IIb}$	Reduce δ	$(\mathsf{n}^{c_1+\alpha C})^{O(\ell)}$	$\ell\cdot\mathsf{s}_0\cdot\mathsf{q}_1$	q_1	δ	γ_α
$\mathcal{A}_{IIc}$	Reduce s	$(\mathsf{n}^{c_1+\alpha C})^{O(\ell)}$	s_0	q_0	δ	$(\gamma_\alpha)^2$

Proof. We give a full description of $\mathcal{A}$ and prove (using induction) that $\mathcal{A}$ is well defined and has the desired final parameters. A brief outline of $\mathcal{A}$ is given next.

Algorithm 1. The Assignment Tester $\mathcal{A}$.

Let the input φ of $\mathcal{A}$ be a circuit of size n. If $|\varphi| \le \mathsf{n}_0$, then $\mathcal{A}$ just runs $\mathcal{A}_0$. Otherwise, we describe the algorithm $\mathcal{A}$ via several "intermediate" transformations ($\mathcal{A}_I \Rightarrow \mathcal{A}_{IIa} \Rightarrow \mathcal{A}_{IIb} \Rightarrow \mathcal{A}_{IIc} = \mathcal{A}$):

I. Initial composition (major size reduction): Let $\mathcal{A}_I = \mathcal{A}_\alpha \circ \mathcal{A}$ be the result of composing $\mathcal{A}_\alpha$ with a recursive invocation of $\mathcal{A}$ using Theorem 3.7. That is, the recursive invocation refers to circuits of size at most $\mathsf{s}(\mathsf{n}) = O(\mathsf{n}^\alpha)$.

II. Error-reduction:
   (a) (error and query reduction) Let $\mathcal{A}_{IIa}$ be the outcome of reducing the error parameter of $\mathcal{A}_I$ to ε_α using Theorem 4.8.
   (b) (distance reduction) Let $\mathcal{A}_{IIb}$ be the outcome of reducing the distance parameter of $\mathcal{A}_{IIa}$ to δ using Lemma 4.1.
   (c) (auxiliary size reduction) Let $\mathcal{A}_{IIc} = \mathcal{A}_{IIb} \circ \mathcal{A}_0$ be the composition of $\mathcal{A}_{IIb}$ with $\mathcal{A}_0$, again using Theorem 3.7, obtaining circuits of size s_0. $\mathcal{A}$ will run $\mathcal{A}_{IIc}$ on φ.

Let the input φ of $\mathcal{A}$ be a circuit of size n. If $|\varphi| \le \mathsf{n}_0$, then $\mathcal{A}$ just runs $\mathcal{A}_0$. In this case, the base of the induction is established by Proposition 5.4. As long as the constant C is chosen to be large enough so that $\mathsf{R}(\mathsf{n}_0) = \mathsf{n}_0^C \ge \mathsf{R}_0$, we have that the parameters of $\mathcal{A}_0$ (on input size at most n_0) are only better than required.

Assume by induction that Lemma 5.5 holds for all circuits of size smaller than n. (In fact, we will only use that it holds for circuits of size $\mathsf{s}(O(\mathsf{n})) = O(\mathsf{n}^\alpha)$.) We verify that each of the following steps (I, II(a), II(b), II(c) below) is well defined, and that we get the claimed parameters. Table 1 may assist the reader in following the evolving parameters.

I. $\mathcal{A}_I$ is the composition of $\mathcal{A}_\alpha$ with the recursive invocation of $\mathcal{A}$, using Theorem 3.7. This is well defined because $\mathcal{A}$ uses distance parameter $\delta \le \frac{1}{c_2\bar{q}}$ and since $\mathcal{A}$ is defined (inductively) for all inputs of size smaller than $\mathsf{s}(\mathsf{n}) < \mathsf{n}$. Based on Theorem 3.7, we have that $\mathcal{A}_I = \mathcal{A}_\alpha \circ \mathcal{A}$ produces $\mathsf{n}^{c_1}\cdot(O(\mathsf{n}^\alpha))^C$ circuits and has detection probability $\gamma_\alpha\cdot(\gamma_\alpha)^2$. As for the additional parameters, we have circuit size s_0, number of queries q_0, and error parameter δ_α.

II(a). We now apply error-reduction to $\mathcal{A}_I$ to increase the detection probability from $(\gamma_\alpha)^3$ to γ_α, using Theorem 4.8. For $\mathsf{q}'_1 = O(\frac{1}{\delta_\alpha}\log\frac{1}{\varepsilon_\alpha})$ and $\ell = \text{poly}(\frac{\mathsf{q}_0}{\gamma_\alpha})$, we have that the resulting assignment tester $\mathcal{A}_{IIa}$ produces $poly(1/\varepsilon_\alpha)\cdot(\mathsf{n}^{c_1+\alpha C})^{O(\ell)} = (\mathsf{n}^{c_1+\alpha C})^{O(\ell)}$ circuits. Its circuit size is $\ell\cdot\mathsf{s}_0\cdot\mathsf{q}'_1$, the number of queries is q'_1, the distance parameter is $2\delta_\alpha$, and the detection probability is γ_α, as desired.

II(b). Next, we get $\mathcal{A}_{IIb}$ by reducing the distance parameter of $\mathcal{A}_{IIa}$ from $2\delta_\alpha$ to δ according to Lemma 4.1. As discussed in Remark 4.4, this will require applying $\mathcal{A}_{IIa}$ on circuits of size $M = O(\frac{2\delta_\alpha}{\delta}\mathsf{n}) = O(\mathsf{n})$ (recall that $\delta = \Omega(1/\bar{q})$ is a constant). We note that as long as α is small enough, this will require invoking $\mathcal{A}$ recursively only on circuits of size smaller than $\mathsf{s}(M) < \mathsf{n}$. The number of circuits that $\mathcal{A}_{IIb}$ produces is $poly(1/\varepsilon_\alpha)(M^{c_1+\alpha C})^{O(\ell)} = (\mathsf{n}^{c_1+\alpha C})^{O(\ell)}$. The number of queries is $\mathsf{q}_1 = \mathsf{q}'_1 + O(\frac{1}{\delta}\log\frac{1}{\varepsilon_\alpha}) = O(\frac{1}{\delta}\log\frac{1}{\varepsilon_\alpha})$. Note that this is consistent with our previous definition of q_1. The circuit size is $\ell\cdot\mathsf{s}_0\cdot\mathsf{q}'_1 + O(\frac{1}{\delta}\log\frac{1}{\varepsilon_\alpha}) < \ell\cdot\mathsf{s}_0\cdot\mathsf{q}_1$ (by setting $\mathsf{q}_1 = O(\frac{1}{\delta}\log\frac{1}{\varepsilon_\alpha})$ to be large enough). The detection probability remains γ_α, and the distance parameter is δ, as desired.

II(c). Finally, for the composition $\mathcal{A}_{IIc} = \mathcal{A}_{IIb}\circ\mathcal{A}_0$ to be well defined we need to have $\mathsf{n}_0 \geq O(\ell\cdot\mathsf{s}_0\cdot\mathsf{q}_1)$. Note that $\ell\cdot\mathsf{s}_0\cdot\mathsf{q}_1 = poly(s_0)$. (There are hidden constants here which depend on $\delta_\alpha, \varepsilon_\alpha$, and $\bar{q}$.) Since $s_0 < (n_0)^{\alpha_0}$ the condition that $\mathsf{n}_0 \geq O(\ell\cdot\mathsf{s}_0\cdot\mathsf{q}_1)$ is satisfied, provided that α_0 is small enough (which translates to n_0 and R_0 being large enough). In addition, we have that δ_0 satisfies the condition of Theorem 3.7 and allows the composition of $\mathcal{A}_{IIb}$ with $\mathcal{A}_0$. The parameters obtained by $\mathcal{A}_{IIc}$ are the number of circuits $\mathsf{R}_0\cdot(\mathsf{n}^{c_1+\alpha C})^{O(\ell)} = (\mathsf{n}^{c_1+\alpha C})^{O(\ell)}$, the circuit size s_0, the number of queries q_0, the detection probability $(\gamma_\alpha)^2$, and the distance parameter δ.

It remains to verify that the parameters of $\mathcal{A}_{IIc}$ are as good as those required of $\mathcal{A}$ (and so $\mathcal{A}$ will simply simulate $\mathcal{A}_{IIc}$ on inputs with $|\varphi| > \mathsf{n}_0$, and this will complete the proof by induction). This already holds directly for all parameters apart from the number of circuits, which is supposed to be n^C. Therefore, the condition that is imposed is $(\mathsf{n}^{c_1+\alpha C})^{c'\cdot\ell} \leq \mathsf{n}^C$, for some constant c' derived from the analysis above. For that we set $\alpha < 1/(2c'\cdot\ell)$ (which causes the constant c_1 that controls the number of circuits output by $\mathcal{A}_\alpha$ to increase but still remain constant). The required condition now holds as long as $C > 2c_1\cdot c'\cdot\ell$. □

6. A combinatorial construction. In this section we describe a fully combinatorial construction of assignment testers with parameters $\mathsf{R} = n^{\text{polylog}n}$ and $\mathsf{s} = O(1)$. This implies a combinatorial proof for $NP \subseteq PCP[\text{polylog}, 1]$. Although not as strong as the PCP theorem, such a result still has quite powerful implications, for example that approximating Max-3-SAT is quasi-NP-hard.

In the construction of the assignment tester $\mathcal{A}$, we follow the recursion style of section 5. Namely, we compose an assignment tester $\mathcal{A}_\alpha$ that produces circuits of size $O(\mathsf{n}^\alpha)$, with a recursive call to $\mathcal{A}$ itself on circuits of this size. We then reduce the error of the resulting tester to maintain the induction hypothesis (as described in step II of Assignment Tester $\mathcal{A}$). The main difference is that here we can no longer assume the existence of $\mathcal{A}_\alpha$ as a black box that is given to the construction. We will therefore have to construct $\mathcal{A}_\alpha$ ourselves.

The first observation we make is the following: When defining $\mathcal{A}$ on input circuits of size n, we are allowed to assume that $\mathcal{A}$ is already well defined for inputs of size smaller than n. (In fact, we are already making this assumption in the construction of

section 5.) For this reason, we do not really have to build $\mathcal{A}_\alpha$ from scratch. Instead, in the definition of $\mathcal{A}_\alpha$ on inputs of size $\mathsf{n}' = O(\mathsf{n})$ we are allowed to invoke $\mathcal{A}$ itself, as long as we invoke it only on inputs that are smaller than n. In the presentation below we will concentrate on this task of constructing $\mathcal{A}_\alpha$ given $\mathcal{A}$ which is only defined on smaller inputs (formally stated in Lemma 6.2). This will include all of the new ideas not already described in section 5.

We note that, for the basis of the induction, we rely on a given constant-size tester, say like the one in Proposition 5.4. While in section 5 we obtained such a constant-size tester using the given black-box tester, this is no longer available. Instead we can choose any known PCP construction, even the extremely inefficient constructions of PCPs like that based on the long-code [6]. (As mentioned earlier, the constant-size assignment tester can also be found via exhaustive search, but for such an approach to work we need a proof of the *existence* of assignment testers, which is currently only known via *explicit* constructions.)

6.1. Overview–Constructing $\mathcal{A}_\alpha$ and oblivious testers. We now provide an overview of the construction of $\mathcal{A}_\alpha$. This will also allow us to introduce a new desired property of assignment testers that lies at the heart of our new construction; namely, we will discuss the notion of *oblivious* assignment testers.

Recall the task at hand: We would like to construct a tester $\mathcal{A}_\alpha$ that on input circuits of size n produces circuits of size $O(n^\alpha)$. Furthermore, we need $\mathcal{A}_\alpha$ to have constant query complexity. Namely, each of the circuits produced by $\mathcal{A}_\alpha$ should only read a constant number of variables. On the other hand, we have at our disposal a tester $\mathcal{A}$ that produces circuits of constant size (and in this respect is much better than what we need of $\mathcal{A}_\alpha$), albeit it is defined only on input circuits of size smaller than n.

Our approach is to decompose the input for $\mathcal{A}_\alpha$ into smaller pieces and apply $\mathcal{A}$ on each piece separately. If the decomposition has some nice properties, then we will be able to combine the outcomes of the different runs of $\mathcal{A}$ to obtain the desired $\mathcal{A}_\alpha$.

Ignoring various important issues (which we will soon address), the construction goes as follows: On an input circuit φ of size n, the first step will be to *decompose* φ into the disjunction of s_1 smaller circuits $\bigwedge_{\mathbf{i}} \varphi_{\mathbf{i}}$, each of size s_2. This decomposition is not necessarily syntactic, and in particular, $s_1 s_2 \gg \mathsf{n}$. The important property of this decomposition is that *there is a partition of φ's variables into blocks of size at most s_2, such that each $\varphi_{\mathbf{i}}$ accesses variables from at most $O(1)$ blocks.*

Now we apply the assignment tester $\mathcal{A}$ on each one of the $\varphi_{\mathbf{i}}$'s to obtain $\psi_{\mathbf{i},1}, \ldots, \psi_{\mathbf{i},\mathsf{R}(s_2)}$, where each $\psi_{\mathbf{i},k}$ has constant size. It may be useful to think of $\psi_{\mathbf{i},1}, \ldots, \psi_{\mathbf{i},\mathsf{R}(s_2)}$ as the $\mathbf{i}$th row of a matrix (with s_1 rows and $\mathsf{R}(s_2)$ columns). At this point, we will turn each column of this matrix into a new test. For the kth column we define the test $\psi^k = \bigwedge_{\mathbf{i}} \psi_{\mathbf{i},k}$. These new circuits have size $O(s_1)$, as they are composed of s_1 circuits of size $O(1)$. The transformation $\varphi \Rightarrow \{\psi^k\}$ defines the desired $\mathcal{A}_\alpha$. (In other words, on input φ, the tester $\mathcal{A}_\alpha$ outputs $\{\psi^k\}$.)

In the informal description above, we have ignored two major issues, to which we now draw attention.

6.1.1. Lack of robustness. This issue comes up when trying to argue soundness for $\mathcal{A}_\alpha$, say as a PCP verifier: In the case that φ is not satisfiable, then any assignment will fail to satisfy at least one of the $\varphi_{\mathbf{i}}$'s. We now want to argue that this implies that for this $\mathbf{i}$ many of the $\psi_{\mathbf{i},k}$'s will not be satisfied, which will finally imply that many of the ψ^k's will not be satisfied. Our problem is that, while the given assignment will not satisfy one of the $\varphi_{\mathbf{i}}$'s, it may be *close* to satisfying each and every one of them. In

that case, applying $\mathcal{A}$ does not guarantee anything regarding the $\psi_{\mathbf{i},k}$'s. Similarly to the proof for the composition theorem for assignment testers, we solve this difficulty by applying $\mathcal{A}$ on a "robust version" of the $\varphi_{\mathbf{i}}$'s rather than on the $\varphi_{\mathbf{i}}$'s themselves. It is possible to construct such a robust version, due to the special property of the decomposition (i.e., that each $\varphi_{\mathbf{i}}$ depends on a constant number of blocks of variables of φ). The robust circuits $\varphi'_{\mathbf{i}}$ will be defined such that when φ is not satisfiable then any assignment will be far from satisfying at least one of the $\varphi'_{\mathbf{i}}$'s. (In fact, we will need a bit more of the $\varphi'_{\mathbf{i}}$'s in order to argue soundness as an assignment tester rather than as a PCP verifier.)

We omit from this overview more specific details of how the $\varphi_{\mathbf{i}}$ and $\varphi'_{\mathbf{i}}$ circuits are defined and instead turn our attention to the second and potentially more devastating difficulty of our construction.

6.1.2. Huge query complexity. It is indeed true that the tester $\mathcal{A}_\alpha$ outlined above produces circuits ψ^k of size $O(s_1)$ as desired. However, in the general case, the query complexity of $\mathcal{A}_\alpha$ is also $O(s_1)$ rather than $O(1)$ as required. If we were able to partition the variables of $\mathcal{A}_\alpha$ into blocks of size $O(s_1)$, and ensure that the queries made by each ψ^k are contained in $O(1)$ "blocks" of variables, then this problem would be resolved by simply clustering these blocks into new larger variables (details below).

We obtain such a behavior from $\mathcal{A}_\alpha$ if the assignment tester $\mathcal{A}$ is *oblivious*. An oblivious assignment tester produces output circuits that have the property that *the names of the variables queried by each circuit are a function only of $|\varphi|$ and not of φ.* (Looking ahead, when such an $\mathcal{A}$ is applied on $\varphi_{\mathbf{i}}$ to yield $\{\varphi_{\mathbf{i},k}\}_k$, the names of the variables queried by $\varphi_{\mathbf{i},k}$ are the same for every $\mathbf{i}$.[8]) Formally, we have the following.

DEFINITION 6.1. *Let $\mathcal{A}$ be an assignment tester that, on input circuit φ over the variables $x_1, \ldots, x_{n_1}$, produces circuits $\psi_1, \ldots, \psi_{\mathsf{R}(\mathsf{n})}$ over the variables $x_1, \ldots, x_{n_1}$, $x_{n_1+1}, \ldots, x_{n_1+n_2}$. $\mathcal{A}$ is called* oblivious *if for every n there exist $\mathsf{q} = \mathsf{q}(\mathsf{n})$ functions*

$$\nu_1, \ldots, \nu_{\mathsf{q}} : \{1, \ldots, \mathsf{R}(\mathsf{n})\} \to \{1, \ldots, n_1 + n_2\}$$

such that for every $k \in [\mathsf{R}]$ the circuit ψ_k depends on the q variables indexed by $\nu_1(k), \ldots, \nu_{\mathsf{q}}(k)$.

In other words, the identity of the variables read by ψ_k depends on $|\varphi|$ but not on φ. Note that the *predicate* evaluated by each ψ_k may certainly depend on φ and not only on $|\varphi|$. Also note that we do not make any requirement on the efficiency of computing the ν_i's. (We point out, however, that their efficiency does follow from the efficiency of $\mathcal{A}$.)

Intuitively, the reason that obliviousness of $\mathcal{A}$ is useful in reducing the query complexity of $\mathcal{A}_\alpha$ is that it implies a very regular structure of the variables read by the $\psi_{\mathbf{i},k}$'s that compose the final circuit ψ^k. This implies a partition of the variables into blocks, as mentioned above, and allows us to cluster the variables read by the output circuits ψ^k into larger, $O(s_1)$-bit long, "column" variables, such that each ψ^k depends only on *a constant number* of those larger variables.

Finally it remains to address the typical case where $\mathcal{A}$ is *not oblivious*. Luckily, we show that it is not hard to turn *every assignment tester* into an oblivious one.

6.2. Constructing $\mathcal{A}_\alpha$. We now formalize the construction of $\mathcal{A}_\alpha$ for inputs of size N_α based on $\mathcal{A}$ which is only defined for input circuits whose size is smaller than N.

[8] Assuming for simplicity that $|\varphi_{\mathbf{i}}|$ is the same for all $\mathbf{i}$.

LEMMA 6.2. *For every $\alpha < \frac{1}{3}$, given an assignment tester $\mathcal{A}$ defined for inputs of size n such that $\mathsf{n} < N$, with parameters $\mathsf{R}(\mathsf{n}), \mathsf{s}(\mathsf{n}) = O(1), \mathsf{q}(\mathsf{n}) = O(1), \delta(\mathsf{n}) = O(1)$, and $\varepsilon(\mathsf{n}) = O(1)$, we can construct $\mathcal{A}_\alpha$ defined for inputs of size at most N_α, where N_α is such that $(N_\alpha)^{1-\alpha}\text{polylog}N_\alpha < N$, with circuit size $\mathsf{s}_\alpha(\mathsf{n}) = O(\mathsf{n}^{3\alpha})$, and other parameters*

$$\begin{aligned}
\mathsf{R}_\alpha(\mathsf{n}) &= \mathsf{R}(\mathsf{n}^{1-\alpha}\text{polylog}\mathsf{n}) \cdot \mathsf{n} \cdot \mathit{poly}(1/\varepsilon),\\
\mathsf{q}_\alpha(\mathsf{n}) &= O\left(\frac{1}{\delta}\log\frac{1}{\varepsilon}\right),\\
\delta_\alpha(\mathsf{n}) &= 24\delta,\\
\varepsilon_\alpha(\mathsf{n}) &= \varepsilon.
\end{aligned}$$

Note that the main advantage of $\mathcal{A}_\alpha$ over $\mathcal{A}$ is that it is defined for significantly larger inputs (i.e., we may have $N_\alpha \gg N$). In the application of Lemma 6.2, we will need it to be defined only for inputs of length at most $N_\alpha = N \cdot \text{polylog}N$. Also note that the assignment tester $\mathcal{A}_\alpha$ outputs circuits whose size is $O(\mathsf{n}^{3\alpha})$. In order to be perfectly consistent with the notation of section 5 we should have called it $\mathcal{A}_{3\alpha}$, but in order to simplify notation we call it $\mathcal{A}_\alpha$.

Proof. Let φ, $|\varphi| = \mathsf{n} \le N_\alpha$, be the input circuit over a set of variables X. First, we decompose it as the disjunction of smaller circuits $\varphi_{\mathbf{i}}$.

Decomposing φ. We begin with a standard transformation, taking our input circuit φ into a $3SAT$ formula $C_1 \wedge \cdots \wedge C_m$, where each variable appears only a constant number of times: For each internal gate of φ add a new variable. In addition, add new variables for multiple copies of X variables without degree larger than one (in the circuit φ). Some of the clauses C_i of the new $3SAT$ formula will correspond to gates in φ. These clauses verify that the assignment for any particular gate variable is consistent with the assignment for its input-variables (that may either be X-variables or other gate variables). In addition, for variables $y_{i_1}, y_{i_2}, y_{i_3}, \ldots$, that are supposed to be copies of a variable x_i, we have clauses verifying that $x_i = y_{i_1}$ and that $y_{i_j} = y_{i_{j+1}}$. Let Y denote the set of all new variables that were added. Clearly, $|X \cup Y| \le \mathsf{n} = |\varphi|$. The transformation also guarantees that an assignment to X could be extended to an assignment to $X \cup Y$ that satisfies $C_1 \wedge \cdots \wedge C_m$ if and only if the assignment to X satisfies φ.

Assume that $\mathsf{n}_1 = \mathsf{n}^{1-\alpha}$ is an integer. Arrange the variables in an n^α-by-n_1 matrix V such that the X-variables fill the first $\frac{|X|}{\mathsf{n}_1}$ rows. (For simplicity, assume that n_1 divides $|X|$.) Each row of V consists of n_1 variables. Denote the rows by V_i, $i = 1, \ldots, \mathsf{n}^\alpha$. See also Figure 5.

For every $\mathbf{i} = (i_1, i_2, i_3) \in [\mathsf{n}^\alpha]^3$, define $\varphi_{\mathbf{i}}$ to be the AND of all of the clauses C_i whose three variables are contained in $V_{i_1} \cup V_{i_2} \cup V_{i_3}$. Let us see that this is a decomposition of φ with the property mentioned in the overview. First note that

$$C_1 \wedge \cdots \wedge C_m = \bigwedge_{\mathbf{i}=(i_1,i_2,i_3)} \varphi_{\mathbf{i}}.$$

The number of circuits $\varphi_{\mathbf{i}}$ is $\mathsf{n}^{3\alpha}$. Each $\varphi_{\mathbf{i}}$ depends on (at most) three blocks (rows) of variables (i.e., the blocks V_{i_1}, V_{i_2}, and V_{i_3}), and the size of each block is at most $\mathsf{n}_1 = \mathsf{n}^{1-\alpha}$. Finally, the size of each $\varphi_{\mathbf{i}}$ is at most $O(\mathsf{n}_1)$ (since it depends on $3\mathsf{n}_1$ variables and each variable appears in a constant number of clauses C_i of the $3SAT$ formula). Going back to the overview, we have decomposed φ into $s_1 = \mathsf{n}^{3\alpha}$ circuits,

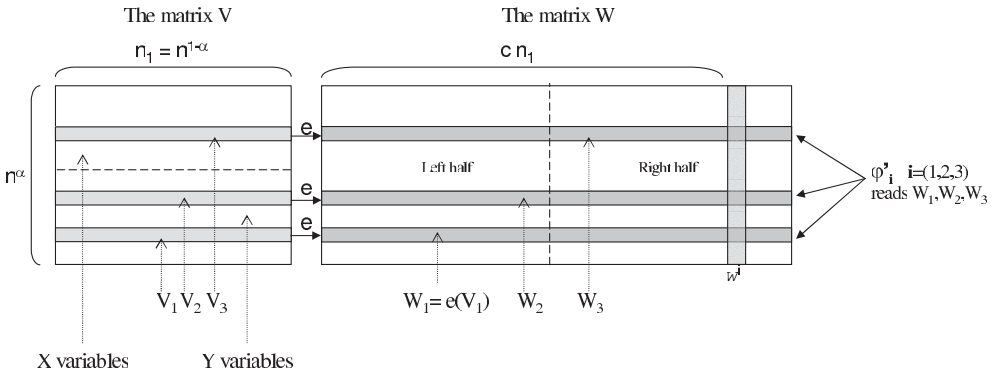

FIG. 5. *The variables $V = X \cup Y$ and W. The left half of W corresponds to encoding according to e_1, and the right half corresponds to encoding according to e_2.*

each of size at most $s_2 = O(\mathsf{n}^{1-\alpha})$, such that each circuit $\varphi_{\mathbf{i}}$ depends on three blocks of variables (and the size of each block is at most s_2).

Making the $\varphi_{\mathbf{i}}$'s robust. Next, we prepare the $\varphi_{\mathbf{i}}$'s for composition by making them robust (similarly to the proof of Lemma 3.6). Define new circuits $\varphi'_{\mathbf{i}}$ over new "encoding" variables W_i in a natural way as follows. Let $e : \{0,1\}^{\mathsf{n}_1} \to \{0,1\}^{c\mathsf{n}_1}$ be an error-correcting code, defined below. For every $i = 1, \ldots, n^\alpha$, let W_i be a set of $c\mathsf{n}_1$ new Boolean variables, supposedly representing the encoding via e of V_i. Let

$$(1) \quad \forall \mathbf{i} = (i_1, i_2, i_3) \in [\mathsf{n}^\alpha]^3, \qquad \varphi'_{\mathbf{i}} \text{ be a circuit over variables } W_{i_1} \cup W_{i_2} \cup W_{i_3}$$

that accepts only those assignments that are correct encodings (via e) of assignments that would have made $\varphi_{\mathbf{i}}$ accept.

With foresight, we choose an encoding e that, in addition to having good rate and distance, also has the following "local-checkability" property. Given an assignment a for the original X variables, and an assignment b for the encoding variables, it is easy to verify (with two queries) that either b is close to $e(a)$ or it is far from any codeword. This property will allow us to test consistency of the assignment for the new variables with the assignment to the original X-variables (which is used in the proof of Lemma 6.7 to argue that $\mathcal{A}_\alpha$ is an assignment tester, rather than just a PCP verifier). Note that this property is needed only when encoding the rows of V that are composed of X-variables, whereas for the rows containing Y-variables a more standard error-correcting code would have sufficed (for simplicity, however, we use the same code for encoding all rows of V).

We obtain the aforementioned local-checkability property by choosing e to be the string-concatenation of two error-correcting codes e_1 and e_2, where $e_1 : \{0,1\}^{\mathsf{n}_1} \to \{0,1\}^{\frac{c}{2}\mathsf{n}_1}$ is an error-correcting-code as defined in Lemma 2.1, and $e_2 : \{0,1\}^{\mathsf{n}_1} \to \{0,1\}^{\frac{c}{2}\mathsf{n}_1}$ is the trivial "repetition" encoding; i.e., it outputs $c/2$ repetitions of each bit in the input. (The choice of $c/2$ as the number of repetitions, though convenient, is somewhat arbitrary; even a single repetition would have worked, though with worse parameter.) The distance of e is at least the distance of e_1, i.e., at least n_1. By Lemma 2.1, the size of $\varphi'_{\mathbf{i}}$ is linear in that of $\varphi_{\mathbf{i}}$; i.e., it is $O(\mathsf{n}_1)$.

Let W be an $n^\alpha \times c\mathsf{n}_1$ matrix of variables whose rows are W_i. The first $\frac{c}{2}\mathsf{n}_1$ columns (the "left" half) of W correspond to encoding according to e_1, and the last $\frac{c}{2}\mathsf{n}_1$ columns (the "right" half) of W correspond to $\frac{c}{2}$ copies of V (recall that V is the matrix that contains the X-variables in its first rows). The following proposition

uses only the properties of the left-side code.

PROPOSITION 6.3. *Let $b : W \to \{0,1\}$, and define $a_b : X \to \{0,1\}$ to be the maximum-likelihood decoding*[9] *of b. If a_b doesn't satisfy φ, then there exists some $\mathbf{i}$ such that $\varphi'_{\mathbf{i}}$ is $\frac{1}{6c}$-far from being satisfied by b.*

Proof. If a_b doesn't satisfy φ, then there is some $\varphi_{\mathbf{i}}$, $\mathbf{i} = (i_1, i_2, i_3)$, that falsifies a_b. This means that at least one of $W_{i_1}, W_{i_2}, W_{i_3}$ needs to be changed *in more than half of the code's distance,* n_1 number of bits, so that together they encode a value that satisfies $\varphi'_{\mathbf{i}}$. The number of bits that need to be changed is at least $\mathsf{n}_1/2$, which is at least a $\frac{1}{6c}$ fraction of the $3 \cdot c\mathsf{n}_1$ input bits of $\varphi'_{\mathbf{i}}$. □

Applying $\mathcal{A}$. As discussed in the overview, before applying $\mathcal{A}$ on the $\varphi'_{\mathbf{i}}$ circuits we need to turn $\mathcal{A}$ into an oblivious tester. Fortunately this is can be done by the following lemma, whose proof we defer to section 6.4.

LEMMA 6.4. *There exists some constant $c_1 > 0$ such that any assignment tester $\mathcal{A}$ can be made into an oblivious assignment tester $\mathcal{A}'$, and the parameters of $\mathcal{A}'$ are equal to $\mathcal{A}$'s parameters computed on input size $\mathsf{n}' = \mathsf{n} \cdot (\log \mathsf{n})^{c_1}$. Furthermore, on an n-bit input, $\mathcal{A}'$ needs to invoke $\mathcal{A}$ only on one n'-bit input.*

Let $\mathcal{A}'$ be the oblivious version of $\mathcal{A}$ guaranteed by Lemma 6.4. Next, apply $\mathcal{A}'$ on each $\varphi'_{\mathbf{i}}$ obtained in (1), denoting the output by $\psi_{\mathbf{i},1}, \ldots, \psi_{\mathbf{i},\mathsf{R}_1}$. Note that this application of $\mathcal{A}'$ requires applying $\mathcal{A}$ only on inputs of size $\mathsf{n}_1 \mathrm{polylog} \mathsf{n}_1 < N$ (by Lemma 6.4 and the definition of N_α and n_1), so $\mathsf{R}_1 = \mathsf{R}(|\varphi'_{\mathbf{i}}| \,\mathrm{polylog}\, |\varphi'_{\mathbf{i}}|) = \mathsf{R}(\mathsf{n}_1 \mathrm{polylog} \mathsf{n}_1)$. The circuits $\psi_{\mathbf{i},1}, \ldots, \psi_{\mathbf{i},\mathsf{R}_1}$ are over variables from at most three rows in W and over new variables $Z_{\mathbf{i}}$. Each circuit has size $O(1)$.

Circuit and variable aggregation. The next step is to think of $\psi_{\mathbf{i},1}, \ldots, \psi_{\mathbf{i},\mathsf{R}_1}$ as a row in a matrix, and to define a new test (i.e., circuit) for each column:

$$\forall k = 1, \ldots, \mathsf{R}_1, \qquad \psi^k = \bigwedge_{\mathbf{i}} \psi_{\mathbf{i},k}.$$

There are $m = \mathsf{n}^{3\alpha}$ rows, and since the size of each $\psi_{\mathbf{i},k}$ is $O(1)$, these new circuits have size $m \cdot O(1) = O(\mathsf{n}^{3\alpha})$. Moreover, as long as the distance parameter of $\mathcal{A}$ is $\delta \le \frac{1}{6c}$, the next result follows immediately.

PROPOSITION 6.5. *Let b, a_b be as in Proposition 6.3 above. Let b_1 be any assignment for $\bigcup_{\mathbf{i}} Z_{\mathbf{i}}$. If a_b doesn't satisfy φ, then at most ε of $\psi^1, \ldots, \psi^{\mathsf{R}}$ are satisfied by $b \cup b_1$.*

The circuits $\psi^1, \ldots, \psi^{\mathsf{R}}$ are therefore close to being the desired output of $\mathcal{A}_\alpha$. They do, however, each depend on many (i.e., $\Theta(m)$) Boolean variables, rather than on a constant number of possibly larger-range variables. This is where the obliviousness of $\mathcal{A}'$ comes into play. We can simply cluster the variables into "columns" so that each ψ^k will depend on a constant number of clusters (and the clusters are not too large).

For any $\mathbf{i} = (i_1, i_2, i_3)$, the circuits $\psi_{\mathbf{i},1}, \ldots, \psi_{\mathbf{i},\mathsf{R}_1}$ are defined over variables in three rows of the matrix W (having n^α rows), namely $W_{i_1} \cup W_{i_2} \cup W_{i_3}$, and also over $Z_{\mathbf{i}}$, the auxiliary variables generated by running $\mathcal{A}'$ on $\varphi'_{\mathbf{i}}$. Let Z be the matrix whose rows are $Z_{\mathbf{i}}$ (i.e., Z has $\mathsf{n}^{3\alpha}$ rows). Now, for each k, the circuit $\psi'_{\mathbf{i},k}$ depends on some constant q locations in the string $W_{i_1} \cup W_{i_2} \cup W_{i_3}$, and $Z_{\mathbf{i}}$. Since $\mathcal{A}'$ is oblivious, the *positions queried in these four strings are a function only of the index k* (and are independent of $\mathbf{i}$). The punchline is therefore the following.

FACT 6.6. *For each circuit ψ^k, all of the variables read by ψ^k are contained in q columns of W and Z, where $\mathsf{q} = O(1)$ is the query complexity of $\mathcal{A}$.*

[9] As in Notation 2.2, the decoding of a word σ is $e^{-1}(\hat{\sigma})$, where $\hat{\sigma}$ is the codeword with minimal Hamming distance to σ (where ties can be broken arbitrarily).

The next step is now clear. We replace each column of variables (in both matrices W and Z) by a new (non-Boolean) variable that has width n^α or $\mathsf{n}^{3\alpha}$, respectively. Let $w^1, \ldots, w^{m_1}$ be new variables representing the columns of W, $m_1 = c\mathsf{n}_1$. Similarly let $z^1, \ldots, z^{m_2}$ be new variables representing the columns of Z, $m_2 \leq \mathsf{R}_1$. The tests simulate the previous ones as follows. For every $k \in [\mathsf{R}_1]$, recall that ψ^k was the conjunction of $\psi_{\mathbf{i},k}$ for all $\mathbf{i}$. We define $\bar{\psi}^k$ to be the test that verifies the predicate ψ^k by reading the appropriate $\leq \mathsf{q}$ column variables that, by Fact 6.6, contain all of the variables read by ψ^k.

The main point is that every variable in $W \cup Z$ appears in *exactly one* new column variable. Therefore, consistency is not an issue, as there is a one-to-one correspondence between assignments to the old variables and assignments to the new ones.

Consistency with the assignment to X. Finally, we must add tests that compare the values of $\{w^i\}_i \cup \{z^i\}_i$ to the assignment for the original X-variables. Recall that each variable x belongs to some row V_i, and that $\frac{c}{2}$ entries in the right half of W_i are supposed copies of x. For every $x \in X$ and every one of the $\frac{c}{2}$ columns in W that are supposed to contain a copy of x, we introduce a basic $\mathsf{compare}$ test that reads x and the column variable, and compare the value of x against its supposed copy.

We now amplify the detection probability of the compare tests. Let $d = O(\frac{1}{\delta}\log\frac{1}{\varepsilon})$; we then define a set of tests by applying Corollary 2.5 on the sequence of the above compare tests, with parameters $\mu = 6\delta$ and $\beta = \varepsilon$. The number of compare tests is $\frac{c}{2}|X| = O(\mathsf{n})$, and the size of each one is $O(\mathsf{n}^\alpha)$ (because it reads one bit of X, one variable w^i of width n^α, and later only compares two of its input bits). Denote the new tests by $\{\mathsf{compare}'_1, \ldots, \mathsf{compare}'_{M_1}\}$. By Corollary 2.5, $M_1 = poly(1/\varepsilon)\mathsf{n}$, and each $\mathsf{compare}'_i$ is the AND of d $\mathsf{compare}$ tests. Therefore it accesses $O(d)$ variables, and its size is $O(\mathsf{n}^{3\alpha})$.

Final circuits and their soundness. By appropriate replication, we can assume that the number (M_1) of tests in $\{\mathsf{compare}'_i\}$ is equal to the number of tests in $\{\bar{\psi}^i\}$, and both are equal to $poly(1/\varepsilon)\mathsf{nR}_1$. Let the ith final output circuit of $\mathcal{A}_\alpha$ be the AND of $\bar{\psi}^i$ and $\mathsf{compare}'_i$. We next prove the soundness condition of $\mathcal{A}_\alpha$ (completeness of $\mathcal{A}_\alpha$, its claimed parameters, and the input sizes for which it is defined are easy to verify).

LEMMA 6.7 (soundness). *Let $\delta_1 = 24\delta$, and let $a : X \to \{0,1\}$. If a is δ_1-far from satisfying φ, then for every assignment b for $\{w^1, \ldots, w^{m_1}\} \cup \{z^1, \ldots, z^{m_2}\}$, at most ε of the final circuits can be satisfied.*

Proof. The assignment b can be read as an assignment for $W \cup Z$, since w^i and z^i are variables that represent columns of W and Z, respectively. Define $a_b : X \to \{0,1\}$ to be the maximum-likelihood decoding according to e of $b|_W$:

$$\forall V_i \subset X, \qquad a_b(V_i) = e^{-1}(b(W_i)).$$

- If a_b does not satisfy φ, then we proceed just like in Proposition 6.5: There must be some $\varphi_{\mathbf{i}}$ falsified by a_b, so let us consider $\varphi'_{\mathbf{i}}$. The restriction of b to the input of $\varphi'_{\mathbf{i}}$ needs to be changed in at least $\mathsf{n}_1/2$ number of bits, in order to satisfy $\varphi'_{\mathbf{i}}$. By the definition of $\mathcal{A}$ this implies that regardless of what b assigns to the $\mathbf{i}$th row in Z, at most ε of the circuits $\{\psi_{\mathbf{i},k}\}_k$ will accept. Therefore, at most ε of the circuits in $\{\bar{\psi}^i\}$ will accept.
- Otherwise, a_b is δ_1-far from a. We must consider also the following "majority" assignment, which can be defined according to b. Recall that the right half of W is supposedly the repetition encoding of V. Let $a_{b,maj} : X \to \{0,1\}$ be the majority decoding (understood to be defined on the appropriate coordinates)

of b restricted to the right half of W (denoted W^r with rows W_i^r):

$$\forall V_i \subset X, \qquad a_{b,maj}(V_i) = majority(b(W_i^r)).$$

We have three assignments for X: $a, a_{b,maj}$, and a_b. If the first two are $\delta_1/2$-far from each other, then by definition an ε-fraction of the compare tests will reject, and we are done. We know that a and a_b are δ_1-far from each other, so the only other possibility is that the last two are $\delta_1/2$-far from each other. In this case, there must be some V_i for which $a_b(V_i)$ disagrees with $a_{b,maj}(V_i)$ on at least $\frac{\delta_1}{2} \cdot \mathsf{n}_1$ entries. This, by definition of $a_b, a_{b,maj}$, and e, implies that W_i is at least $\frac{\delta_1}{8}$-far from a legal codeword. Thus every circuit that reads W_i (say, for example, $\varphi'_{\mathbf{i}}$ with $\mathbf{i} = (i, i_2, i_3)$) sees an input that is at least $\frac{\delta_1}{24}$-far from a satisfying input. Since $\delta = \frac{\delta_1}{24}$ is the distance parameter of $\mathcal{A}$, this means that at most ε of $\psi_{\mathbf{i},1}, \ldots, \psi_{\mathbf{i},\mathsf{R}_1}$ are satisfied by b, which implies the same for $\psi^1, \ldots, \psi^{\mathsf{R}_1}$. □

This completes the proof of Lemma 6.2. □

6.3. Proof of Theorem 1.2. As discussed above, given the construction of $\mathcal{A}_\alpha$, completing the proof of Theorem 1.2 goes along the same lines as the construction of section 5. In the following, we formalize this idea.

THEOREM 1.2 (formal statement). *There exist constants* $\mathsf{s}_0, \mathsf{q}_0 > 0$ *and* $\varepsilon, \delta < 1$ *and an explicit combinatorial construction of an assignment tester* $\mathcal{A}$ *with parameters* $\mathsf{R}(\mathsf{n}) = n^{\mathrm{polylog}n}$, $\mathsf{s}(\mathsf{n}) = \mathsf{s}_0$, $\mathsf{q}(\mathsf{n}) = \mathsf{q}_0$, $\delta(\mathsf{n}) = \delta$, $\varepsilon(\mathsf{n}) = \varepsilon$.

Proof. The proof follows by induction on the input size. As discussed above, for the base of the induction, we rely on a given constant-size tester, say the one in Proposition 5.4 of section 5. Denote this tester by $\mathcal{A}_0$, and let its parameters for input circuits of size at most n_0 be $(\mathsf{R}_0, \mathsf{s}_0, \mathsf{q}_0, \delta_0, \varepsilon_0)$.[10]

Now we assume by induction that $\mathcal{A}$ has already been constructed for inputs of length smaller than N. Its parameters are $(\mathsf{R}(\mathsf{n}), \mathsf{s}(\mathsf{n}) = \mathsf{s}_0, \mathsf{q}(\mathsf{n}) = \mathsf{q}_0, \delta(\mathsf{n}) = \delta, \varepsilon(\mathsf{n}) = \varepsilon)$, with $\mathsf{s}_0, \mathsf{q}_0, \varepsilon$, and δ being fixed constants (δ will be set by the proof to a small enough constant). Applying Lemma 6.2 for some fixed $\alpha < \frac{1}{3}$, we get an assignment tester $\mathcal{A}_\alpha$ that is defined for inputs of size up to N_α (for N_α such that $(N_\alpha)^{1-\alpha}\mathrm{polylog}N_\alpha \leq \mathsf{n}$), and such that $\mathcal{A}_\alpha$'s output circuit size is $\mathsf{s}(\mathsf{n}) = O(\mathsf{n}^{3\alpha})$. The rest of $\mathcal{A}_\alpha$'s parameters are $\mathsf{R}_\alpha(\mathsf{n}) = \mathsf{R}(\mathsf{n}^{1-\alpha}\mathrm{polylog}\mathsf{n}) \cdot \mathsf{n} \cdot \mathrm{poly}(1/\varepsilon) = O(\mathsf{R}(\mathsf{n}^{1-\alpha}\mathrm{polylog}\mathsf{n}) \cdot \mathsf{n})$; $\mathsf{q}_\alpha(\mathsf{n}) = O(\frac{1}{\delta}\log\frac{1}{\varepsilon})$, $\varepsilon_\alpha(\mathsf{n}) = \varepsilon$; $\delta_\alpha(\mathsf{n}) = 24\delta$.

For simplicity, let us assume that the circuits output by $\mathcal{A}_\alpha$ each make three queries. This can be guaranteed[11] as described in the proof of Theorem 4.8; see, in particular, Proposition 4.11.

We can now use $\mathcal{A}_\alpha$ to extend $\mathcal{A}$ to n-bit inputs in exactly the same way followed in section 5. That is, we apply steps I, II(a), II(b), II(c) described in Assignment Tester $\mathcal{A}$. The analysis is as in the proof of Lemma 5.5, but a bit less delicate since we are already allowing ourselves quasi-polynomial R (and thus are less constrained in setting the relations between the various parameters). We therefore quickly go through the details.

I. $\mathcal{A}_I$ is the composition of $\mathcal{A}_\alpha$ with the recursive invocation of $\mathcal{A}$, using Theorem 3.7. This is well defined as long as we set δ (the distance parameter of

[10] Such an $\mathcal{A}_0$ can be derived from an even less efficient tester $\mathcal{A}'_0$, which produces circuits of size smaller than $(n_0)^{1-\beta_0}$ for some constant β_0 rather than circuits that are smaller than $(n_0)^{\alpha_0}$ for arbitrarily small α_0. The desired $\mathcal{A}_0$ can now be obtained as in the proof of Corollary 5.3.

[11] This replacement causes the error probability to go up, but this will be compensated for in the next steps.

$\mathcal{A}$) to be a small enough constant. $\mathcal{A}_I$ is defined for inputs of length $O(N)$. The number of circuits produced by $\mathcal{A}_I$ is $\mathsf{R}_I(\mathsf{n}) = O(\mathsf{R}(\mathsf{n}^{1-\alpha}\mathrm{polylog}\mathsf{n}) \cdot \mathsf{n} \cdot \mathsf{R}(O(\mathsf{n}^{3\alpha})))$. $\mathcal{A}_I$ has a (small) constant detection probability γ_I, circuit size s_0, number of queries q_0, and distance parameter $\delta_\alpha = 24\delta$.

II(a). We now apply error-reduction to $\mathcal{A}_I$ to increase the detection probability from γ_I to $\sqrt{\gamma}$, using Theorem 4.8, where $\gamma = 1 - \varepsilon$.
Since both γ_I and γ are constants we have that the resulting assignment tester $\mathcal{A}_{IIa}$ produces $\mathsf{R}_I(\mathsf{n})^{O(1)}$ circuits. Its circuit size is $O(\mathsf{s}_0)$, the number of queries is $O(1)$, the distance parameter has doubled to $2\delta_\alpha$, and the detection probability is $\sqrt{\gamma}$, as desired.

II(b). Next, we get $\mathcal{A}_{IIb}$ by reducing the distance parameter of $\mathcal{A}_{IIa}$ from $2\delta_\alpha$ to δ according to Lemma 4.1. As discussed in Remark 4.4, this will require applying $\mathcal{A}_{IIa}$ on circuits of size $M = O(\frac{2\delta_\alpha}{\delta}\mathsf{n}) = O(\mathsf{n})$. This is fine, as $\mathcal{A}_I$ is defined for such input lengths.
The number of circuits that $\mathcal{A}_{IIb}$ produces is $\mathsf{R}_I(M)^{O(1)} = \mathsf{R}_I(O(\mathsf{n}))^{O(1)}$. The number of queries is $O(1)$, the circuit size is $O(\mathsf{s}_0)$, the detection probability remains $\sqrt{\gamma}$, and the distance parameter is δ, as desired.

II(c). Finally, we define $\mathcal{A}_{IIc}$ as the composition $\mathcal{A}_{IIc} = \mathcal{A}_{IIb} \circ \mathcal{A}_0$. This is well defined as long as n_0 is a large enough constant with respect to s_0 (a more delicate analysis shows that here too it is enough to have $\mathsf{n}_0 = \mathrm{poly}(\mathsf{s}_0)$) and δ_0 is a small enough constant that satisfies the condition of Theorem 3.7. The parameters obtained by $\mathcal{A}_{IIc}$ are number of circuits $\mathsf{R}_0 \cdot \mathsf{R}_I(O(\mathsf{n}))^{O(1)} = \mathsf{R}_I(O(\mathsf{n}))^{O(1)}$; circuit size s_0; number of queries q_0; detection probability $\sqrt{\gamma} \cdot (1-\varepsilon_0)$, which is larger than γ in case ε_0 is small enough; distance parameter δ.

Finally, $\mathcal{A}$ is simply defined to run $\mathcal{A}_{IIc}$ on circuits of length $\mathsf{n} \leq N$. It remains to verify that the parameters obtained by $\mathcal{A}_{IIc}$ for such circuits are as good as those required of $\mathcal{A}$. Note that this holds trivially for all parameters apart from the number of circuits. The number of circuits are $\mathsf{R}_I(O(\mathsf{n}))^{O(1)}$, which opens to the following recursion formula: $\mathsf{R}(N) = (O(\mathsf{R}(\mathsf{n}^{1-\alpha}\mathrm{polylog}\mathsf{n}) \cdot \mathsf{n} \cdot \mathsf{R}(O(\mathsf{n}^{3\alpha}))))^{O(1)}$. Letting $a \geq 1$ be such that $(1-\alpha)^{a+1} + (3\alpha)^{a+1} < 1$, $\mathsf{R}(\mathsf{n}) = O(\mathsf{n}^{(\log \mathsf{n})^a})$ solves this recursive formula. □

6.4. Making testers oblivious. We now return to proving Lemma 6.4, which shows how every tester can be turned oblivious.

Proof of Lemma 6.4. We start by showing the existence of the following "universal circuit": C_U takes as input some encoding of a Boolean circuit φ, an assignment a to the input variables X of φ, and an assignment b to some additional "help variables." The following hold: (a) The encoding of φ can be computed in polynomial time; (b) if a satisfies φ, then there exists an assignment b (computed from φ and a in polynomial time) such that $C_U(\varphi, a, b) = 1$; (c) if a does not satisfy φ, then for any b, $C_U(\varphi, a, b) = 0$; (d) for input circuits φ of size n, the size of C_U is bounded by $\mathsf{n} \cdot \mathrm{polylog}\mathsf{n}$ (and this, in particular, bounds the size of the encoding of φ).

Let us first see how such a C_U can produce an oblivious tester $\mathcal{A}'$. We will then describe how to construct C_U using standard ideas.

Instead of applying $\mathcal{A}$ to φ we would like to apply it to the universal circuit C_U of the appropriate length. This will ensure obliviousness since, as $\mathcal{A}$ does not even "know" φ, the variables read by the circuits it produces cannot depend on φ. As a sanity check, we note that the input to C_U includes the description of φ, and therefore the circuits produced by $\mathcal{A}$ will read part of this description and will evaluate a predicate that does depend on φ. One (rather minor) difficulty in this approach is

that the tester $\mathcal{A}$ guarantees only that the assignment to the input of C_U is close to satisfying C_U. Unfortunately, this does not translate to saying that the assignment to the X-variables is close to satisfying φ. Instead, it is quite possible that the assignment to the X-variables will pass the test since it satisfies a circuit whose description is close to that of φ. To make sure that φ cannot be altered in our analysis, we revise C_U a bit as follows.

As a first step, $\mathcal{A}$ is applied to C'_U that takes the following inputs: an encoding of φ with the error-correcting code of Lemma 2.1, and a repetition encoding of the assignment to the X-variables, and a repetition encoding of the assignment to the Y-variables. In both cases, the number of repetitions is set so that the encoding of φ and the two assignments are of equal length. C'_U verifies that all of the encodings are legal. It then decodes the values it got and applies C_U. Now $\mathcal{A}'$ will run as follows. $\mathcal{A}'$ first applies $\mathcal{A}$ on C'_U. Then $\mathcal{A}'$ evaluates the description φ that C_U expects, and hardwires the encoding of this description to the circuits produced by $\mathcal{A}$ (i.e., whenever these circuits query a value in the encoded description of φ, this value is assigned by $\mathcal{A}'$ and the circuit is possibly simplified). Now the circuits that are obtained are just over the assignment to the X- and Y-variables. More accurately, the circuits are over the repetition encoding of these variables. However, whenever an assignment to a copy of one of the variables is required, we use the original assignment. (The purpose of the repetition encoding—here and elsewhere—is to balance the three kinds of variables on which C'_U was defined, so that $\mathcal{A}$ "notices" distance in each of the three types of input. Therefore in the output circuits we can safely replace all of the repeated copies with the original variable.)

The correctness of $\mathcal{A}'$ follows from the correctness of $\mathcal{A}$ and the properties of C_U. It essentially has the parameters of $\mathcal{A}$ (when applied to inputs of quasi-linear size). Finally, it is oblivious, as the locations accessed by the circuits produced do not depend on φ at all (as these circuits were first produced by applying $\mathcal{A}$ to the universal circuit).

We now describe how to construct the universal circuit C_U. The only subtlety comes from the requirement that $|C_U|$ be quasi-linear in its input size. This can be achieved relying on well-known ideas. Since we have not been able to find a proper reference, we include a sketch of the construction.

The circuit C_U will operate over a preprocessed φ, transformed into a $3SAT$ formula $C_1 \wedge \cdots \wedge C_m$, over variables X and Y (with $|X \cup Y| \leq \mathsf{n}$), where each variable appears only a constant number of times. This is achieved as in the proof of Lemma 6.2.

There is a very efficient (essentially linear) universal machine for such a $3SAT$ formula, if the machine is allowed *random access* to its input. Simply, read the description of the clauses C_i one-by-one and then read the three variables contained in the clause to evaluate it. When translating this universal machine naively to the setting of circuits, the universal circuit obtained is of size $O(\mathsf{n}^2)$ (as "fetching" each variable costs $O(\mathsf{n})$). To reduce the size to be quasi-linear, we use the following standard trick.

The evaluation of the formula by the smaller universal circuit will be done in three phases. First we order the m clauses by the order of their variable of smallest index (i.e., first the clauses that contain x_1 (or its negation), then those that contain x_2 and do not contain x_1, and so on). Together with the clauses we order the variable names and their assignments. Now that both are jointly ordered, we can assign values to one variable from each clause. At this point, the location of each clause in the joint

order is a constant distance away from the location of an assignment to one of its variables. Therefore, evaluating a variable from each clause can be done by a circuit of polylogarithmic size (as the input for the circuit has a logarithmic number of bits—the descriptions of a constant number of clauses and variables). Continue in the same manner to assign values to the two additional variables in each clause. Once all variable values are assigned, the value of each clause is determined by a constant size circuit which easily implies the value of the entire formula (by evaluating the AND of all clause values). It remains to argue that there are circuits of quasi-linear size for sorting. This, however, follows immediately from the existence of quasi-linear sorting networks (where any one of a number of simple sorting networks will do; see, e.g., [10, section 55]). □

7. Discussion and further research. We have introduced the notion of assignment testers and provided a simple and truly modular composition theorem for testers. We feel that it is beneficial to state even the original proof of the PCP theorem via assignment testers, as their composition seems to us simpler and more natural. In addition, we provided various generic transformations for assignment testers: (a) making assignment testers "robust" (section 3.4), (b) reducing the distance parameter (section 4.1), (c) error reduction via a new method of combinatorial aggregation (section 4.3).

Our first construction of assignment testers (given in section 5) provides a new proof of the PCP theorem. It relies on the existence of a relatively weak assignment tester, which is provided as a black box. One advantage of this construction over the original proof of the PCP theorem is that the algebraic building block requires only the algebraic techniques that are already present in [4, 13] (in particular, it only needs a weak form of the low-degree test, and it does not use aggregation via low-degree curves). More importantly, *the algebraic techniques are confined to the construction of the black box*. The way the black box was constructed can then be forgotten, and we care only about its parameters. Finally, we use a building-block PCP of only one particular kind (as opposed to the original proof, which also used Hadamard-based PCP). This is made possible through using a nonconstant number of composition steps (to which our composition theorem readily yields itself). On the other hand, one may also consider the superconstant number of recursive steps to be a disadvantage. It is indeed harder to know "what's going on" by such a construction and particularly to track how the final variables relate to the original ones.

Our second construction is fully combinatorial, and it relies only on standard objects such as error-correcting codes and hitting sets (which both follow from expander graphs). It also relies on a constant-size tester, which is easy to construct due to its allowed inefficiency. In this respect the construction is even simpler (even though the combinatorial part of the construction is somewhat more complicated). The major disadvantage is of course the quasi-polynomial size. We note, however, that such a result has applications similar to those of the PCP theorem (basing hardness of approximation on the still highly conservative assumption that NP is not contained in quasi-polynomial time).

On the robustness property. We mentioned above that a notion very related to assignment testers was independently introduced by Ben-Sasson et al. [8], where it was named "robust PCPs of proximity." Interestingly, their motivation was completely different, namely constructing length-efficient PCPs and locally testable codes, yet they came up with essentially the same object.

Just as in [8], robustness is an essential part of our composition. However, our

composition theorem (Theorem 3.7) applies directly to assignment testers that are not necessarily robust. For that we use in the proof of the composition theorem a generic transformation that turns any assignment tester into a robust one, with the robustness inversely related to the query complexity. Most of our work can therefore ignore this additional parameter of robustness. Emphasizing assignment testers rather than robust assignment testers has the advantage of staying closer to the original definition of a PCP verifier. In addition, the importance of the query complexity as the effective measure of robustness is emphasized. In particular, it seems more natural to state and prove the aggregation theorem, a central ingredient of our work, in terms of query complexity.

We note that the cost of a generic robustization transformation is too high in the context of [8]; hence they work only with assignment testers that are, by definition, robust (indeed they call these objects robust PCPs of proximity). Since [8] demonstrates the usefulness of having the robustness property as an explicit parameter, it could be interesting to study how our transformations on assignment testers behave in terms of this parameter.

On PCP testers and property testing. The notion of assignment testers is very related to the area of property testing [26, 18], and we were most likely inspired by property testing in coming up with this notion. An assignment tester can easily be converted into a test that checks whether an assignment is close to being a satisfying assignment of a circuit φ. The object being tested is the assignment (hence the name "assignment tester"), and the circuit φ is a description of the tested property. (Usually in property testing this is a fixed property such as graph connectivity.) Of course, the main difference between this and standard property testing is that assignment testers also rely on a proof (the assignment of the new variables) in order to perform the testing. This is a special case of the notion of proof-assisted testing of Ergün, Kumar, and Rubinfeld [12].

Adding proofs to property testing allows extremely efficient testing of any property computable in polynomial time. (As observed in [8], this easily extends to properties in NP.) Every such property can be tested by reading only $O(1)$ bits of an object X and a proof Y. This can loosely be interpreted as saying that every property has a highly testable representation. While being a very powerful statement, it is also a flat one, as it does not distinguish between different properties. In some sense, it reemphasizes that the richness of property testing is as a study of *specific representations*. (This was already well understood, as some properties behave very differently with respect to different representations.)

Locally testable codes. An interesting aspect of our construction, especially of the fully combinatorial one, is that we do not make any real use of locally testable codes (apart from the constant-size tester). Nevertheless, as was shown in [8], assignment testers easily imply locally testable codes (and also a relaxed form of locally decodable codes). The focus of [8] was to get *short* locally testable codes. Our Theorem 1.2 implies the first combinatorial construction of locally testable codes with subexponential (in fact, even quasi-polynomial) rate.

Further research. The most obvious problem that was left open by this work is coming up with a combinatorial proof of the PCP theorem. This has been recently obtained by Dinur [11]. Still, one may also hope to give an elementary construction for the constant-size testers used by the combinatorial constructions (constant-sized testers are used also in [11]). Nevertheless, the known constructions based on

Hadamard or Long codes are already rather simple (especially compared to other parts of the proof of the PCP theorem).

A task of a different nature is related to Raz's parallel repetition theorem [24]. Recall that our aggregation method bypasses the complexity of this theorem by adding a few additional "consistency queries." Nevertheless, we use this method only to reduce errors up to some constant probability. It seems possible that this approach could be extended to a simple, combinatorial way of reducing errors in an exponential rate. Though this will not provide a full substitute for the parallel repetition theorem, we still find it an interesting line for further research.

Appendix A. Analysis of the consistency test. As discussed in section 4, the heart of our aggregation/parallelization theorem (Theorem 4.8) is a test T for the consistency of a table $F : \overline{X} \to \Sigma^\ell$ that is supposed to contain the values of some function $f : X \to \Sigma$ on all ℓ-tuples of inputs. In other words, $F(x_1, \ldots, x_\ell)$ is supposed to equal $(f(x_1), \ldots, f(x_\ell))$, for some underlying function f. Such a "combinatorial" consistency test was given by Goldreich and Safra [19]. We described our test in Figure 3 and stated its properties in Theorem 4.10. This test is in fact a (somewhat stronger) version of Lemma 1.1 from [19], which was derived as a simple special case of a more elaborate test which is their main objective. The more sophisticated test is for tables containing a small "derandomized" subset of ℓ-tuples. Interestingly, in the context of our paper, the simple and "inefficient" version of the Goldreich–Safra test is sufficiently good. We now give a direct proof of Theorem 4.10. Our theorem proves that if the test accepts with high enough probability, then the table F is in fact consistent with the *plurality* function of F (as in Definition 4.9), which is the function f that maximizes individual agreements between F and f. This seems more natural than the two-stage plurality function obtained by the proof of [19]. We view the main contribution of this section to be the new and direct proof of the consistency test, which relies on a rather natural Markov-chain approach. Possibly, this proof can be generalized to work for a wider range of parameters (as mentioned in the open problems in section 7).

Proof of Theorem 4.10. Clearly, the completeness condition holds. We prove soundness (that is, we analyze the rejection probability when the table is sufficiently inconsistent with the plurality function).

We will concentrate on the test with respect to the uniform distribution on X (i.e., $\mathcal{D}$ in the statement of the theorem is uniform). The proof for general $\mathcal{D}$ is obtained by simple reduction to the uniform case, as follows.

PROPOSITION A.1. *Assuming a restricted version of Theorem* 4.10*, where $\mathcal{D}$ is the uniform distribution, the theorem holds for an arbitrary $\mathcal{D}$.*

Proof. We can translate any $\mathcal{D}$ over X into the uniform distribution over Z, where Z is obtained from X by duplicating elements in X according to their probability under $\mathcal{D}$. Elements that are not in support of $\mathcal{D}$ are simply dropped. It is clear that the projection of the uniform distribution on Z to the original set of variables X can be made arbitrarily close to $\mathcal{D}$ (and from now on we will simply assume that the two distributions are identical).

Let $\overline{Z} \equiv Z^\ell$. The duplication of variables naturally defines $\hat{F} : \overline{Z} \to \Sigma^\ell$, where for each $\bar{\mathbf{z}} \in \overline{Z}$ we let $\bar{\mathbf{x}}$ be the corresponding ℓ-tuple in $\overline{X}$ and define $\hat{F}(\bar{\mathbf{z}}) = F(\bar{\mathbf{x}})$. The soundness of the test of Figure 3 when applied to F with respect to $\mathcal{D}$ immediately reduces to the soundness of the same test applied to $\hat{F}$ *with respect to the uniform distribution*. (Note that, by definition, the plurality function of $\hat{F}$ agrees on any two

copies $\bar{\mathbf{z}}$ and $\bar{\mathbf{z}}'$ in $\overline{Z}$ that correspond to the same $\bar{\mathbf{x}} \in \overline{X}$.) ∎

Another simplifying convention is our assumption that F is rotation consistent. Recall that F is rotation consistent if, whenever $\bar{\mathbf{x}}'$ is obtained from $\bar{\mathbf{x}}$ using some cyclic shift of its ℓ components, F is consistent on these two entries (i.e., $F(\bar{\mathbf{x}}')$ can be obtained from $F(\bar{\mathbf{x}})$ by a similar shift). As discussed in section 4, in our setting we can indeed assume that F is rotation consistent. Moreover, it is easy to see that the general case can be reduced to the rotation consistent case.

PROPOSITION A.2. *Assuming that Theorem* 4.10 *holds for every F that is rotation consistent, the theorem holds for an arbitrary F, with the slightly revised test described in Figure* 3. ∎

Proof. The original test makes two queries into the table F for the values $F(\bar{\mathbf{x}})$ and $F(\bar{\mathbf{x}}')$. The revised test will select $\bar{\mathbf{x}}$ and $\bar{\mathbf{x}}'$ in the same manner, but instead of querying for $F(\bar{\mathbf{x}}')$, it will query for the value of F on a random cyclic rotation of $\bar{\mathbf{x}}'$. It is not hard to see that this is equivalent to performing the original test on a related *distribution* F' over rotation consistent tables. More specifically, for every set of ℓ entries $\bar{\mathbf{x}}^1, \ldots, \bar{\mathbf{x}}^\ell$ that are cyclic shifts of each other, the value of F' on *all these tuples* is defined as $F(\bar{\mathbf{x}}^i)$ for a random i. This implies that if F violates the soundness of the revised test, then at least one of those rotation consistent tables violates the soundness of the original test. ∎

Let us now recall the test T that we are analyzing and introduce some notations. Let $\bar{\mathbf{x}} = (x_1, \ldots, x_\ell)$ and suppose $F(\bar{\mathbf{x}}) = (a_1, \ldots, a_\ell)$; we write $\bar{\mathbf{x}}_i$ to mean x_i and $F(\bar{\mathbf{x}})_i$ to mean a_i.

1. Select $\bar{\mathbf{x}} \in \overline{X}$ uniformly at random.
2. Select a set of indices J_T such that each $j \in [\ell]$ is placed into J_T with probability $\alpha = 1/\sqrt[3]{\ell}$, independent of other choices.
3. Select $\bar{\mathbf{x}}' \in \overline{X}$ as follows: for each $j \in J_T$, we let $\bar{\mathbf{x}}'_j = \bar{\mathbf{x}}_j$; otherwise $\bar{\mathbf{x}}'_j$ is selected uniformly in X, independent of other choices.
4. Accept only if $F(\bar{\mathbf{x}})_j = F(\bar{\mathbf{x}}')_j$ for every $j \in J_T$; otherwise reject.

Let $f = f_F : X \to \Sigma$ be the plurality function of F. For every $\bar{\mathbf{x}} \in \overline{X}$ define the set of indices on which $F(\bar{\mathbf{x}})$ differs from f,

$$\mathsf{wrong}(\bar{\mathbf{x}}) \stackrel{def}{=} \{\, i \in [\ell] \mid F(\bar{\mathbf{x}})_i \neq f(\bar{\mathbf{x}}_i) \}\,.$$

Call a tuple $\bar{\mathbf{x}} \in \overline{X}$ bad if $|\mathsf{wrong}(\bar{\mathbf{x}})| > \frac{1}{\alpha} = \sqrt[3]{\ell}$. Let γ be the fraction of bad tuples. We will prove that the test T rejects with probability at least γ/c, where c is some absolute constant.

The general idea for our proof is the following: With probability γ a bad $\bar{\mathbf{x}}$ is selected by T. Fix some bad $\bar{\mathbf{x}}$; since $\mathsf{wrong}(\bar{\mathbf{x}}) > \frac{1}{\alpha}$ and each index is placed into J_T with probability α, we have that there exists some i in $\mathsf{wrong}(\bar{\mathbf{x}}) \cap J_T$ with constant probability. Recall that for every $i \in J_T$ the test T sets $\bar{\mathbf{x}}'_i = \bar{\mathbf{x}}_i$. Let $a_i = F(\bar{\mathbf{x}})_i$, by the definition of f, for a uniformly distributed $\bar{\mathbf{y}} \in \overline{X}$ such that $\bar{\mathbf{y}}_i = \bar{\mathbf{x}}_i$; we have that $\Pr[F(\bar{\mathbf{y}})_i = a_i \mid \bar{\mathbf{y}}_i = \bar{\mathbf{x}}_i] \leq 1/2$. Ideally, if $\bar{\mathbf{x}}'$ was distributed exactly like $\bar{\mathbf{y}}$, the test would reject with constant probability. Our argument is based on the fact that even though $\bar{\mathbf{x}}'$ has some dependency on $\bar{\mathbf{x}}$, it is still "sufficiently random," and therefore $F(\bar{\mathbf{x}}')_i \neq a_i$ (so the test rejects) with some constant probability. What do we mean by $\bar{\mathbf{x}}'$ being sufficiently random? Consider the stochastic process $G_{x,i}$ of selecting $\bar{\mathbf{x}}'$ given $\bar{\mathbf{x}}$ and conditioned on $i \in J_T$ and $\bar{\mathbf{x}}_i = x$ for some fixed i and x. We will show that this process has good expansion properties. We will later argue that these expansion properties are indeed sufficient to carry out the above intuition.

DEFINITION A.3. *For any $i \in [\ell]$ and $x \in X$ define the set $V_{x,i} \stackrel{def}{=} \{ \bar{\mathbf{x}} \in \overline{X} \mid \bar{\mathbf{x}}_i = x \}$. Note that $|V_{x,i}| = |X|^{\ell-1}$. Define $G_{x,i}$ to be the Markov process over $V_{x,i}$ where, starting at $\bar{\mathbf{x}} \in V_{x,i}$, we move to $\bar{\mathbf{x}}'$ selected as follows: $\bar{\mathbf{x}}'_i = x$, and for each $j \in [\ell] \setminus \{i\}$ with probability α we let $\bar{\mathbf{x}}'_j = \bar{\mathbf{x}}_j$; otherwise $\bar{\mathbf{x}}'_j$ is selected uniformly in X, independent of other choices. Let $A_{x,i}$ be the transition probability matrix corresponding to $G_{x,i}$.*

PROPOSITION A.4. *For every $i \in [\ell]$ and $x \in X$, the second eigenvalue of $A_{x,i}$ is $\lambda = \lambda(A_{x,i}) = \alpha$.*

Proof. Since in the space state of $G_{x,i}$ the value in the ith coordinate is fixed (to x), we can simply ignore this coordinate. On the other hand, $G_{x,i}$ acts on each one of the $\ell-1$ other coordinates independently (in an identical way). Consider the transition probability matrix A^0 corresponding to the action of $G_{x,i}$ on each one of the $\ell-1$ coordinates in $[\ell] \setminus \{i\}$. This matrix equals the convex sum $(1-\alpha)K_{|X|} + \alpha I_{|X|}$, where $K_{|X|}$ corresponds to moving to a uniformly distributed element (i.e., every entry in $K_{|X|}$ is $1/|X|$), and $I_{|X|}$ is the identity matrix. Consider any vector $P \in R^{|X|}$ which is perpendicular to the all one vector (i.e., the sum of the entries in P is zero); then $A^0 \cdot P = ((1-\alpha)K_{|X|} + \alpha I_{|X|})P = \alpha \cdot P$ (since $K_{|X|} \cdot P = \mathbf{0}$). This implies that the second eigenvalue of A^0 is α. To conclude, $G_{x,i}$ acts on $\ell-1$ coordinates independently according to a transition probability matrix A^0 that has second eigenvalue α. It is well known and not hard to show that in such a case the second eigenvalue of $A_{x,i}$ is also α.[12] □

Consider now the foregoing intuition. We know that a bad $\bar{\mathbf{x}}$ is selected by T with probability γ. Furthermore, we know that, with constant probability, some $i \in \mathsf{wrong}(\bar{\mathbf{x}})$ is selected into J_T, meaning that $\bar{\mathbf{x}}'_i = \bar{\mathbf{x}}_i$. We hope to argue that, with constant probability, this location i will reveal to T that the table F is inconsistent. Let $\bar{\mathbf{x}}_i = x$ and $a_i = F(\bar{\mathbf{x}})_i$; then we have that $\bar{\mathbf{x}} \in V_{x,i}$ (as in Definition A.3), and since $i \in \mathsf{wrong}(\bar{\mathbf{x}})$, for most $\bar{\mathbf{y}} \in V_{x,i}$ we have that $F(\bar{\mathbf{y}})_i \neq a_i$. Therefore, if $\bar{\mathbf{x}}'$ was a random element of $V_{x,i}$, the test T would reject with constant probability (conditioned on $\bar{\mathbf{x}}$ being selected and $i \in J_T$). However, the distribution of $\bar{\mathbf{x}}'$ is obtained by taking a random step from $\bar{\mathbf{x}}$ according to the process $G_{x,i}$ (again, conditioned on $\bar{\mathbf{x}}$ being selected and $i \in J_T$). With this choice of $\bar{\mathbf{x}}'$, we can no longer argue that, for any *fixed* choice of a bad $\bar{\mathbf{x}}$, with constant probability the test rejects. (It may very well be that for all the "neighboring" $\bar{\mathbf{x}}'$'s the value $F(\bar{\mathbf{x}}')$ is consistent with $F(\bar{\mathbf{x}})$.) We will therefore make an average argument that will exploit the expansion of $G_{x,i}$. We consider not one possible value of $\bar{\mathbf{x}}$ but rather a set $S_{x,i,a}$ that contains all the values of $\bar{\mathbf{x}}$ such that $\bar{\mathbf{x}}_i = x$ and $F(\bar{\mathbf{x}})_i = a$ (with $f(x) \neq a$). Conditioned on $\bar{\mathbf{x}} \in S_{x,i,a}$ and $i \in J_T$ we do have that with constant probability $\bar{\mathbf{x}}' \notin S_{x,i,a}$ (since $S_{x,i,a}$ contains at most half the tuples in $V_{x,i}$ and due to the expansion of $G_{x,i}$). Therefore, with this conditioning, the test will reject with constant probability (as with constant probability $F(\bar{\mathbf{x}}')_i \neq a$). Details follow.

Consider the process G that corresponds to T selecting $\bar{\mathbf{x}}'$ given $\bar{\mathbf{x}}$ (without further conditioning). The same transition $(\bar{\mathbf{x}}, \bar{\mathbf{x}}')$ is also an edge in various $G_{x,i}$. To complete the proof, we want to lower bound the weight of rejecting edges in each $G_{x,i}$ separately (as outlined above) and deduce a similar lower bound for G (which reflects the rejecting probability of T). However, this may not be sound, as the $G_{x,i}$'s

[12] Each eigenvector of $A_{x,i}$ corresponds to an $(\ell-1)$-tuple of eigenvectors of A^0; the corresponding eigenvalue of $A_{x,i}$ is the product of the $\ell-1$ corresponding eigenvalues of A^0. Therefore, the second eigenvalue of $A_{x,i}$ is α, and it is obtained as the product of $\ell-2$ times the eigenvalue one and the eigenvalue α once.

may not be a "uniform enough cover" of G. More specifically, consider a transition $(\bar{\mathbf{x}}, \bar{\mathbf{x}}')$, where $\bar{\mathbf{x}}$ is bad. For every $i \in \mathsf{wrong}(\bar{\mathbf{x}}) \cap J_T$, this corresponds to a transition in $G_{\bar{\mathbf{x}}_i,i}$ from some $S_{\bar{\mathbf{x}}_i,i,a}$ of density at most half in $V_{\bar{\mathbf{x}}_i,i}$. However, the cardinality of $\mathsf{wrong}(\bar{\mathbf{x}}) \cap J_T$ may vary quite a lot. Potentially, this could mean that by counting separately for each $G_{\bar{\mathbf{x}}_i,i}$, rejecting edges are counted many times, while accepting edges are counted only a few times. Indeed, if we were assured that the size of $\mathsf{wrong}(\bar{\mathbf{x}})$ would be either zero (for all of the good $\bar{\mathbf{x}}$'s) or some fixed value (for all of the bad $\bar{\mathbf{x}}$'s), then the cardinality of $\mathsf{wrong}(\bar{\mathbf{x}}) \cap J_T$ would not vary too much and the proof would become easier. Intuitively, the larger $|\mathsf{wrong}(\bar{\mathbf{x}})|$ is the better, since the test has "more opportunity" to detect an inconsistency and reject. However, the argument is much more subtle, due to the fact that we are not arguing for every value of $\bar{\mathbf{x}}$ separately but rather averaging over sets of values $S_{x,i,a}$.

To help us manipulate the conditional probabilities more elegantly, it is convenient to consider as a "mental experiment" the following revised test T':

1. Choose $\bar{\mathbf{x}} \in \overline{X}$ uniformly at random.
2. Set $k(\bar{\mathbf{x}}) = \max\{16/\alpha, |\mathsf{wrong}(\bar{\mathbf{x}})|\}$.[13] Select an index $i \in [\ell] \cup \{0\}$ such that each $i \in \mathsf{wrong}(\bar{\mathbf{x}})$ is selected with probability $1/k(\bar{\mathbf{x}})$ and with the remaining probability $i = 0$. If $i = 0$, then T' accepts and halts.
3. Let $x = \bar{\mathbf{x}}_i$. Take a random step from $\bar{\mathbf{x}}$ to $\bar{\mathbf{x}}'$ according to $G_{x,i}$.
4. If $F(\bar{\mathbf{x}}')_i \neq F(\bar{\mathbf{x}})_i$, reject; otherwise accept.

We note that T' is not efficiently implementable, and is not meant to be. T' is merely a tool of the analysis, used to bound the probability that T rejects. The main convenience of T' is that it concentrates on a single possible inconsistency between $F(\bar{\mathbf{x}})$ and $F(\bar{\mathbf{x}}')$, namely inconsistency on the ith coordinate. This way we rather naturally avoid overcounting the rejection probability associated with a particular choice of $\bar{\mathbf{x}}$ and $\bar{\mathbf{x}}'$. Such overcounting may arise by counting the same pair $(\bar{\mathbf{x}}, \bar{\mathbf{x}}')$ separately for every inconsistent coordinate. Note that if $\mathsf{wrong}(\bar{\mathbf{x}})$ is small, then $J_T \cap \mathsf{wrong}(\bar{\mathbf{x}})$ is likely to be empty, and thus T will accept. Therefore, if $\mathsf{wrong}(\bar{\mathbf{x}})$ is small, we let T' accept too with some probability (ignoring $F(\bar{\mathbf{x}}')$ altogether). We do that by allowing i to be set to zero with some probability that depends on the size of $\mathsf{wrong}(\bar{\mathbf{x}})$. We remark that if i is different than zero, it is uniformly distributed in $\mathsf{wrong}(\bar{\mathbf{x}})$.

To bound the rejection probability of T through the rejection probability of T' we would have liked to show that (a) $\Pr[T' \text{ rejects}] = O(\Pr[T \text{ rejects}])$, and (b) $\Pr[T' \text{ rejects}] = \Omega(\gamma)$. However, as we do not know how to argue that (a) holds, we first factor out a possible (but rare) bad event B, on which T' may reject with significantly higher probability than T. Taking B into account, we prove Lemmas A.8 and A.9, which are small variations on (a) and (b) above. These two lemmas immediately imply the soundness of T and therefore also Theorem 4.10.

For the definition of the bad event B, we will need a definition of a random variable $J_{T'}$ in analogy to the random variable J_T.

DEFINITION A.5. *Recall the definition of the index i selected by T'. We define the random variable $J_{T'}$ as follows: $J_{T'}$ is set to be empty if $i = 0$. Otherwise $J_{T'}$ is the set of indices $j \in [\ell]$ for which T' sets $\bar{\mathbf{x}}'_j = \bar{\mathbf{x}}_j$ (in particular $i \in J_{T'}$).*

We would like to compare the behavior of T and T', and it would be convenient to do so conditioned on the value of $\bar{\mathbf{x}}$ and on a particular value J of both J_T and $J_{T'}$. However, for sets J such that $J \cap \mathsf{wrong}(\bar{\mathbf{x}})$ is large, we have that the probability that $J_{T'} = J$ may be significantly larger than the probability that $J_T = J$. The reason is

[13] The purpose of the constant 16 is for the proof of Proposition A.11.

that as long as $i \in J \cap \mathsf{wrong}(\bar{\mathbf{x}})$, it is possible that $J_{T'} = J$. Therefore, the larger $|J \cap \mathsf{wrong}(\bar{\mathbf{x}})|$ is, the more ways there are to obtain $J_{T'} = J$. For this reason, we define the "bad event" B, where $|J_{T'} \cap \mathsf{wrong}(\bar{\mathbf{x}})|$ is too large. The exact threshold is meant to facilitate the proof of Lemma A.8 and is less important for now.

DEFINITION A.6. *Define the event B to be $|J_{T'} \cap \mathsf{wrong}(\bar{\mathbf{x}})| / k(\bar{\mathbf{x}}) > 9\alpha$.*

Recall that, by definition, $k(\bar{\mathbf{x}})$ is always positive, and hence B is well defined. We would now like to argue that B is indeed a rare event.

PROPOSITION A.7. *Conditioned on any particular value of $\bar{\mathbf{x}}$ and of i, the probability that B occurs is smaller than $2/9$.*

Proof. If $i = 0$, then $J_{T'}$ is empty, and the proposition follows trivially. Otherwise, each index in $\mathsf{wrong}(\bar{\mathbf{x}}) \setminus \{i\}$ is placed into $J_{T'}$ with probability α (and i is placed into $J_{T'}$ with probability one). Therefore, the expected size of $J_{T'} \cap \mathsf{wrong}(\bar{\mathbf{x}})$ is at most $1 + \alpha\,|\mathsf{wrong}(\bar{\mathbf{x}})| \leq 1 + \alpha \cdot k(\bar{\mathbf{x}}) < 2\alpha \cdot k(\bar{\mathbf{x}})$. (The last inequality follows from $k(\bar{\mathbf{x}}) \geq 16/\alpha > 1/\alpha$.) Now, by Markov's inequality, the event $B \equiv (|J_{T'} \cap \mathsf{wrong}(\bar{\mathbf{x}})| > 9\alpha \cdot k(\bar{\mathbf{x}}))$ has probability at most $2/9$. □

We can now relate T' to T.

LEMMA A.8. $\Pr[T' \text{ rejects} \wedge (\neg B)] = O(\Pr[T \text{ rejects}])$.

Proof. Both T and T' select $\bar{\mathbf{x}}$ uniformly at random. We prove the inequality separately for every value of $\bar{\mathbf{x}}$ (that is, conditioned on $\bar{\mathbf{x}}$ taking some arbitrary value). Therefore, fix the value of $\bar{\mathbf{x}}$ in an arbitrary way. We first argue that, for any value $J \subseteq [\ell]$,

$$\Pr[T' \text{ rejects} \mid J_{T'} = J] \leq \Pr[T \text{ rejects} \mid J_T = J]. \tag{2}$$

First note that the distribution of $\bar{\mathbf{x}}'$ is identical in both cases (i.e., $\bar{\mathbf{x}}'_j = \bar{\mathbf{x}}_j$ for $j \in J$, and $\bar{\mathbf{x}}'_j$ is uniform outside J). If $J \cap \mathsf{wrong}(\bar{\mathbf{x}}) = \phi$, then $\Pr[T' \text{ rejects} \mid J_{T'} = J] = 0$, and we are done. Otherwise, T will reject if for some $j \in J$ we have that $F(\bar{\mathbf{x}}')_j \neq F(\bar{\mathbf{x}})_j$, whereas T' will reject only if $F(\bar{\mathbf{x}}')_i \neq F(\bar{\mathbf{x}})_i$ (recall that in this case $i \neq 0$, as otherwise $J_{T'}$ is empty). This implies inequality (2).

We now want to show that $\Pr[(J_{T'} = J)] = O(\Pr[J_T = J])$. However, this may not be true in two cases, which fortunately enough we can ignore. The two cases to ignore are (a) $J \cap \mathsf{wrong}(\bar{\mathbf{x}}) = \phi$, in which case T' always accepts, and (b) $|J \cap \mathsf{wrong}(\bar{\mathbf{x}})| / k(\bar{\mathbf{x}}) > 9\alpha$, in which case the event B occurs. Let the collection of sets J satisfying either (a) or (b) be denoted $\mathcal{J}_{\mathsf{ignore}}$. For all other values of J, the event B does not occur and therefore,

$$\Pr[T' \text{ rejects} \wedge (\neg B)] = \sum_{J \notin \mathcal{J}_{\mathsf{ignore}}} \Pr[T' \text{ rejects} \mid J_{T'} = J] \cdot \Pr[J_{T'} = J].$$

In addition, for $J \notin \mathcal{J}_{\mathsf{ignore}}$ we have that

$$\begin{aligned}
\Pr[J_{T'} = J] &= \sum_{j \in J \cap \mathsf{wrong}(\bar{\mathbf{x}})} \Pr[i = j] \cdot \alpha^{|J|-1} \cdot (1-\alpha)^{\ell - |J|} \\
&= \sum_{j \in J \cap \mathsf{wrong}(\bar{\mathbf{x}})} (1/k(\bar{\mathbf{x}})) \cdot \alpha^{|J|-1} \cdot (1-\alpha)^{\ell - |J|} \\
&= (|J \cap \mathsf{wrong}(\bar{\mathbf{x}})| / k(\bar{\mathbf{x}})) \cdot \alpha^{|J|-1} \cdot (1-\alpha)^{\ell - |J|} \\
&\leq 9\alpha \cdot \alpha^{|J|-1} \cdot (1-\alpha)^{\ell - |J|} \\
&= 9 \cdot \Pr[J_T = J].
\end{aligned}$$

By inequality (2), we can now conclude that

$$\begin{aligned}\Pr[T' \text{ rejects} \wedge (\neg B)] &= \sum_{J \notin \mathcal{J}_{\mathsf{ignore}}} \Pr[T' \text{ rejects} \mid J_{T'} = J] \cdot \Pr[J_{T'} = J] \\ &\leq \sum_{J \notin \mathcal{J}_{\mathsf{ignore}}} \Pr[T \text{ rejects} \mid J_T = J] \cdot 9 \Pr[J_T = J] \\ &\leq 9 \Pr[T \text{ rejects}]. \qquad \square\end{aligned}$$

It remains to bound the probability that T' rejects (again, factoring out the bad event B), as follows.

LEMMA A.9. $\Pr[T' \text{ rejects} \wedge (\neg B)] = \Omega(\gamma)$.

Proof. Throughout this proof, $\bar{\mathbf{x}}$ will always denote the tuple selected by T' at step 1, and i the index selected at step 2. If, say, we consider the probability of this tuple being equal to a specific tuple $\bar{\mathbf{z}}$, we write $\Pr[\bar{\mathbf{x}} = \bar{\mathbf{z}}]$, etc.

If T' rejects, then in particular it selects $i \neq 0$. Recall that $\Pr[\bar{\mathbf{x}} \text{ is bad}] = \gamma$ by definition. By inspecting step 2 in the definition of T', and recalling that $\bar{\mathbf{x}}$ is bad means $|\mathsf{wrong}(\bar{\mathbf{x}})| > \frac{1}{\alpha}$, we have

$$\Pr[i \neq 0 \mid \bar{\mathbf{x}} \text{ is bad}] = \frac{|\mathsf{wrong}(\bar{\mathbf{x}})|}{k(\bar{\mathbf{x}})} = \frac{|\mathsf{wrong}(\bar{\mathbf{x}})|}{\max(|\mathsf{wrong}(\bar{\mathbf{x}})|, 16/\alpha)} \geq 1/16.$$

So we can conclude that $\Pr[i \neq 0] = \Pr[\bar{\mathbf{x}} \text{ is bad}] \cdot \Pr[i \neq 0 \mid \bar{\mathbf{x}} \text{ is bad}] \geq \gamma/16$. To complete the proof we will show that

$$\Pr[T' \text{ rejects} \wedge (\neg B) \mid i \neq 0] = \Omega(1). \tag{3}$$

We will do this by showing that for every fixed $i_0 \neq 0$ and $x_0 \in X$, conditioned on T' selecting $\bar{\mathbf{x}}$ and i such that $i = i_0$ and $\bar{\mathbf{x}}_i = x_0$, the test rejects (and B does not hold) with constant probability. Summing over all values of $i_0 \neq 0$ and $x_0 \in X$, this will complete the proof.

So let us fix an arbitrary $i = i_0 \neq 0$ and $x_0 \in X$. Denote $V_0 = V_{x_0,i_0}$, the set of tuples $\bar{\mathbf{z}}$ for which $\bar{\mathbf{z}}_{i_0} = x_0$ (as defined in Definition A.3). We will rely on the expansion of the Markov process $G_0 \stackrel{def}{=} G_{x_0,i_0}$ to show that the probability mass placed on tuples $\bar{\mathbf{z}} \in V_0$, for which $F(\bar{\mathbf{z}})_{i_0} \neq f(x_0)$, "spreads" after one step of G_0. Thus, starting from such an $\bar{\mathbf{x}}$, with high probability we arrive at an $\bar{\mathbf{x}}'$ for which $F(\bar{\mathbf{x}})_{i_0} \neq F(\bar{\mathbf{x}}')_{i_0}$. To do this, we will partition the tuples $\bar{\mathbf{z}} \in V_0$ according to the value of $F(\bar{\mathbf{z}})_{i_0} = a$, and show that each part in the partition has many outgoing transitions, each causing T' to reject.

For every $a \in \Sigma$, let us define

$$S_a = \{\, \bar{\mathbf{z}} \in V_0 \mid F(\bar{\mathbf{z}})_{i_0} = a \}\,.$$

The set S_a also depends on the specific choice of x_0 and i_0, but this is omitted from the notation.

Let $E_{x_0,i_0,a}$ denote the event that T' selects $i = i_0$, and $\bar{\mathbf{x}}$ for which $\bar{\mathbf{x}}_i = x_0$ and $F(\bar{\mathbf{x}})_{i_0} = a$. Observe that, conditioned on a specific value $i = i_0$ selected at step 2 of T', not all tuples in V_0 have positive probability of being chosen at step 1 of T'. Indeed, a tuple $\bar{\mathbf{x}} \in V_0$ for which $F(\bar{\mathbf{x}})_{i_0} = f(x_0)$ cannot be chosen, because the conditioning requires in particular that $i_0 \in \mathsf{wrong}(\bar{\mathbf{x}})$, which is equivalent to

$F(\bar{\mathbf{x}})_{i_0} \neq f(x_0)$. So $\Pr_{T'}[E_{x_0,i_0,a}] > 0$ implies $a \neq f(x_0)$. In that case let P_a denote the probability distribution over V_0, defined by

$$\forall \bar{\mathbf{z}} \in V_0, \quad P_a(\bar{\mathbf{z}}) = \Pr_{T'}[\bar{\mathbf{x}} = \bar{\mathbf{z}} \mid E_{x_0,i_0,a}].$$

Fix some value $a \in \Sigma$ such that $\Pr[E_{x_0,i_0,a}] > 0$. Note that $\Pr[T' \text{ rejects} \wedge (\neg B) \mid E_{x_0,i_0,a}] \geq \Pr[T' \text{ rejects} \mid E_{x_0,i_0,a}] - \Pr[B \mid E_{x_0,i_0,a}]$. By Proposition A.7, the probability of the bad event B is bounded by $2/9$ even if conditioned on any specific $\bar{\mathbf{x}}$ and i, so in particular: $\Pr[B \mid E_{x_0,i_0,a}] < 2/9$. It is therefore sufficient to show that

$$\Pr[T' \text{ rejects} \mid E_{x_0,i_0,a}] \geq 1/4 \tag{4}$$

(as the probability in (3) will be lower bounded by $1/4 - 2/9 > 0$).

By the definition of T', we take a random step from $\bar{\mathbf{x}}$ according to the process G_0 and arrive at $\bar{\mathbf{x}}'$. The probability distribution over $\bar{\mathbf{x}}'$ is given by $A_0 P_a$, where A_0 is the transition matrix of G_0 and $P_a \in \mathbb{R}^{V_0}$ is a vector of probabilities that corresponds to the initial choice of $\bar{\mathbf{x}}$ conditioned on $E_{x_0,i_0,a}$. Finally, T' rejects if $F(\bar{\mathbf{x}}')_{i_0} \neq a$, or in other words, if $\bar{\mathbf{x}}' \notin S_a$. In conclusion,

$$\Pr[T' \text{ rejects} \mid E_{x_0,i_0,a}] = \Pr[A_0 P_a \notin S_a]. \tag{5}$$

Following is a brief outline of how we lower bound (5). We have already established that $a \neq f(x)$. This implies that S_a cannot contain more than half of the elements in V_0 (because f is the plurality; this is formally shown in Proposition A.10). Next, observe that if $\bar{\mathbf{x}}$ had been distributed uniformly in S_a, then by expansion, one step according to G_0 leaves this set with good probability. Our situation is slightly more complicated because $\bar{\mathbf{x}}$ is not distributed uniformly over S_a but rather according to P_a. Proposition A.11 proves that P_a is "uniform enough" (or rather, that it has "enough entropy"). We deduce our bound from a (known) variant of the expander mixing lemma (Proposition A.12) that can handle slightly skewed distributions.

PROPOSITION A.10. $|S_a| / |V_0| \leq 1/2$.

Proof. Recall the definition of the plurality function (Definition 4.9). Since $f(x_0) \neq a$, we have that for less than half of $\{ (\bar{\mathbf{z}}, j) \mid j \in [\ell],\ \bar{\mathbf{z}} \in V_{x_0,j} \}$ it holds that $F(\bar{\mathbf{z}})_j = a$. Since F is rotation consistent (namely, if $\bar{\mathbf{z}}'$ is obtained from $\bar{\mathbf{z}}$ using some cyclic shift of its ℓ components, then $F(\bar{\mathbf{z}}')$ can be obtained from $F(\bar{\mathbf{z}})$ in the same way), it is easy to verify that, for any particular value of j, less than half of $V_{x_0,j}$ have $F(\bar{\mathbf{z}})_j = a$. Fixing $j = i_0$, for less than half of $V_0 = V_{x_0,i_0}$, it holds that $F(\bar{\mathbf{z}})_{i_0} = a$. The proposition follows. ∎

We first show that the distribution P_a is not too far from being uniform over S_a.

PROPOSITION A.11. *Let $\lambda(A_0)$ be the second largest eigenvalue of A_0. Then*

$$\max_{\bar{\mathbf{z}}} \{P_a(\bar{\mathbf{z}})\} \leq \frac{1}{16\,|S_a|\,\lambda(A_0)^2}.$$

Proof. Recall from Proposition A.4 that $\lambda(A_0) = \lambda(A_{x_0,i_0}) = \alpha$, and that $\alpha^3 = 1/\ell$. By definition of P_a, we may rewrite what we are trying to prove as

$$\forall \bar{\mathbf{z}}, \quad \Pr[\bar{\mathbf{x}} = \bar{\mathbf{z}} \mid E_{x_0,i_0,a}] \leq \frac{\alpha\ell}{16} \frac{1}{|S_a|}.$$

Clearly this probability is zero for all $\bar{\mathbf{z}} \notin S_a$. The point is to show that even though we have fixed i_0 and x_0 and a, this does not give too much information about $\bar{\mathbf{x}}$. We

will use Bayes' rule,

$$\Pr[\bar{\mathbf{x}} = \bar{\mathbf{z}} \,|\, E_{x_0,i_0,a}] = \Pr[E_{x_0,i_0,a} \,|\, \bar{\mathbf{x}} = \bar{\mathbf{z}}] \cdot \frac{\Pr[\bar{\mathbf{x}} = \bar{\mathbf{z}}]}{\Pr[E_{x_0,i_0,a}]}. \tag{6}$$

We now estimate each of the three factors on the right-hand side. Surely, with no conditioning, $\Pr[\bar{\mathbf{x}} = \bar{\mathbf{z}}] = 1/\left|\overline{X}\right|$. To estimate $\Pr[E_{x_0,i_0,a} \,|\, \bar{\mathbf{x}} = \bar{\mathbf{z}}]$ observe that, conditioned on $\bar{\mathbf{x}} = \bar{\mathbf{z}}$, the random choice of the index i (at step 2 of T') determines whether the event $E_{x_0,i_0,a}$ occurs or not (because $\bar{\mathbf{z}}$ and $F(\bar{\mathbf{z}})$ and therefore $\bar{\mathbf{z}}_i$ and $F(\bar{\mathbf{z}})_i$ are already fixed). The probability, for a given $\bar{\mathbf{x}} = \bar{\mathbf{z}}$, of selecting $i = i_0$ at step 2 of T' is exactly $1/k(\bar{\mathbf{z}})$. If i_0 was selected, the event occurs iff $\bar{\mathbf{z}} \in S_a$ (which means that $\bar{\mathbf{z}}_{i_0} = x_0$ and $F(\bar{\mathbf{z}})_{i_0} = a$). Thus, $\Pr[E_{x_0,i_0,a} \,|\, \bar{\mathbf{x}} = \bar{\mathbf{z}}] = 1/k(\bar{\mathbf{z}}) \leq \alpha/16$ if $\bar{\mathbf{z}} \in S_a$ and equals zero otherwise.

Finally, we estimate $\Pr[E_{x_0,i_0,a}]$. We write

$$\Pr[E_{x_0,i_0,a}] = \sum_{\bar{\mathbf{z}} \in \overline{X}} \Pr[E_{x_0,i_0,a} \,|\, \bar{\mathbf{x}} = \bar{\mathbf{z}}] \cdot \Pr[\bar{\mathbf{z}}].$$

Just as before, $\Pr[E_{x_0,i_0,a} \,|\, \bar{\mathbf{x}} = \bar{\mathbf{z}}] = 1/k(\bar{\mathbf{z}})$ if $\bar{\mathbf{z}} \in S_a$ and 0 otherwise. Plugging this into the above equation gives $\Pr[E_{x_0,i_0,a}] = \sum_{\bar{\mathbf{z}} \in S_a} \frac{1}{k(\bar{\mathbf{z}})} \cdot \Pr[\bar{\mathbf{z}}] = \sum_{\bar{\mathbf{z}} \in S_a} \frac{1}{k(\bar{\mathbf{z}})} \cdot \frac{1}{|\overline{X}|} \geq \frac{|S_a|}{|\overline{X}|} \cdot \frac{1}{\ell}$, because always $k(\bar{\mathbf{z}}) \leq \ell$. Plugging everything into (6), we find

$$\Pr[\bar{\mathbf{x}} = \bar{\mathbf{z}} \,|\, E_{x_0,i_0,a}] \leq \frac{\alpha}{16} \cdot \frac{\frac{1}{|\overline{X}|}}{\frac{|S_a|}{|\overline{X}|} \cdot \frac{1}{\ell}} = \frac{\alpha\ell}{16} \cdot \frac{1}{|S_a|}. \qquad \square$$

It remains to observe that, for every vector $\vec{p} = (p_1, \ldots, p_n)$, if $\sum_i p_i = 1$, then

$$\|\vec{p}\|_2^2 = \sum_i p_i^2 \leq \sum_i p_i \cdot \max_i p_i = \max_i p_i = \|\vec{p}\|_\infty.$$

So, in particular, the previous proposition gives $\|P_a\|_2^2 \leq \max_{\bar{\mathbf{z}}} P_a(\bar{\mathbf{z}}) \leq 1/(16\,|S_a|\,\lambda(A_0)^2)$.

We can now conclude the proof of Lemma A.9 and of the theorem by the following proposition, which is a slight generalization of the standard expander mixing lemma (for the case that the initial distribution is not uniform over some subset of the sample space).

PROPOSITION A.12. $\Pr[A_0 P_a \in S_a] \leq |S_a| / |V_0| + \lambda(A_0)\sqrt{|S_a| \cdot \|P_a\|_2^2}$.

Proof. Let $\chi_a \in \{0,1\}^{|V_0|}$ be the characteristic vector of S_a in V_0 (i.e., for every $\bar{\mathbf{z}} \in V_0$ we set $\chi_a(\bar{\mathbf{z}}) = 1$ iff $\bar{\mathbf{z}} \in S_a$). Let $U \in \{0,1\}^{|V_0|}$ be the vector corresponding to the uniform distribution, where all the entries in U equal $1/|V_0|$. As usual, we break P_a into two components, parallel to U and perpendicular to U. Let $P_a^\perp = P_a - U$. Note that $P_a^\perp$ is perpendicular to U because

$$\left\langle P_a^\perp, U \right\rangle = \langle P_a, U \rangle - \langle U, U \rangle = \sum_{\bar{\mathbf{x}} \in V_0} P_a(\bar{\mathbf{x}}) \cdot \frac{1}{|V_0|} - \sum_{\bar{\mathbf{x}} \in V_0} \frac{1}{|V_0|} \cdot \frac{1}{|V_0|} = \frac{1}{|V_0|}(1-1) = 0,$$

where $\langle \cdot, \cdot \rangle$ denotes the inner product. Now we have that

$$\begin{aligned} \Pr[A_0 P_a \in S_a] &= \langle \chi_a, A_0 P_a \rangle \\ &= \langle \chi_a, A_0 U \rangle + \left\langle \chi_a, A_0 P_a^\perp \right\rangle. \end{aligned}$$

Since $A_0 U = U$, the first summand becomes $|S_a| / |V_0|$. To bound the second summand, we use Cauchy–Schwarz inequality, and get that $\left\langle \chi_a, A_0 P_a^\perp \right\rangle \leq \|\chi_a\|_2 \cdot \|A_0 P_a^\perp\|_2$

$\leq \sqrt{|S_a|} \cdot \|A_0 P_a^{\perp}\|_2$. The proposition follows since $\lambda(A_0)$ is the second largest eigenvalue of A_0,

$$\|A_0 P_a^{\perp}\|_2 \leq \|\lambda(A_0) P_a^{\perp}\|_2 \leq \lambda(A_0)\|P_a\|_2. \qquad \square$$

Using $|S_a| / |V_0| \leq \frac{1}{2}$ and $\lambda(A_0)\sqrt{|S_a| \cdot \|P_a\|_2^2} \leq \lambda(A_0)\sqrt{(1/16) \cdot \lambda(A_0)^2} \leq \frac{1}{4}$ (as established in Propositions A.10 and A.11), we lower bound (5) by $1 - (\frac{1}{2} + \frac{1}{4}) = \frac{1}{4}$ as needed. This concludes the proof of (4) and therefore of Lemma A.9, showing that $\Pr[T' \text{ rejects} \wedge (\neg B)] = \Omega(\gamma)$. $\square$

Combining Lemma A.9 with Lemma A.8, we obtain $\Pr[T \text{ rejects}] = \Omega(\Pr[T' \text{ rejects} \wedge (\neg B)]) = \Omega(\gamma)$, and the theorem follows. $\square$

Appendix B. Strengthening the black-box assignment tester from section 5.

Proof of Corollary 5.3. We would like to compose $\mathcal{A}_\beta$ with itself a constant number of times to reduce the size of the output circuits from $O(\mathsf{n}^{1-\beta})$ to $O(\mathsf{n}^{\alpha})$. For the composition of $\mathcal{A}_\beta$ with itself to be well defined we need the distance parameter to be small enough with respect to the number of queries. To do that we first apply to $\mathcal{A}_\beta$ the distance-reduction transformation given by Lemma 4.1, reducing its distance parameter to another constant $\delta' < 1/(3c_2)$, where c_2 is the constant from the composition theorem, Theorem 3.7. We then reduce the number of queries to three, as was done in Proposition 4.11. The result of these two steps is an assignment tester $\mathcal{A}'_\beta$ with parameters $(\mathsf{R}(\mathsf{n}) = \mathsf{n}^{O(1)},\ \mathsf{s}(\mathsf{n}) = O(\mathsf{n}^{1-\beta}),\ \mathsf{q}(\mathsf{n}) = 3,\ \delta(\mathsf{n}) = \delta',\ \varepsilon(\mathsf{n}) = \bar{\varepsilon})$, with $\bar{\varepsilon}$ being some fixed constant.

It is now possible to compose $\mathcal{A}'_\beta$ with itself, and doing it a constant number of times (which depend on α, of course) will reduce the output circuit size to $O(\mathsf{n}^{\alpha})$. This almost gives us the assignment tester we are after, with the only problem being that the new error is some small constant that depends on α. Reducing the error parameter to $\varepsilon_\alpha = 0.1$ using Theorem 4.8, will complete our proof, as we now have that the circuit size is indeed $O(\mathsf{n}^{\alpha})$, and the only parameter that depends on α is the number of circuits produced (which is polynomial for every fixed α). $\square$

Acknowledgments. We sincerely thank the authors of [8]—Eli Ben-Sasson, Oded Goldreich, Prahladh Harsha, Madhu Sudan, and Salil Vadhan—for sharing with us preliminary stages of their own work, and for making excellent suggestions for ours. We thank Sanjeev Arora, Amir Shpilka, Luca Trevisan, and Avi Wigderson for many useful discussions and comments. We would like to thank William Hesse and Ilan Newman for very helpful discussions regarding the circuit size of universal circuits. Special thanks too to Oded Goldreich for his valuable contribution to the presentation of this paper.

RULING OUT PTAS FOR GRAPH MIN-BISECTION, DENSE k-SUBGRAPH, AND BIPARTITE CLIQUE*

SUBHASH KHOT†

Abstract. Assuming that NP $\not\subseteq \cap_{\epsilon>0}$ BPTIME(2^{n^ϵ}), we show that graph min-bisection, dense k-subgraph, and bipartite clique have no polynomial time approximation scheme (PTAS). We give a reduction from the minimum distance of code (MDC) problem. Starting with an instance of MDC, we build a *quasi-random probabilistically checkable proof (PCP)* that suffices to prove the desired inapproximability results. In a quasi-random PCP, the query pattern of the verifier *looks random* in a certain precise sense. Among the several new techniques we introduce, the most interesting one gives a way of certifying that a given polynomial belongs to a given linear subspace of polynomials. As is important for our purpose, the certificate itself happens to be another polynomial, and it can be checked probabilistically by reading a constant number of its values.

Key words. probabilistically checkable proofs (PCPs), hardness of approximation, approximation algorithms

1. Introduction.

Several optimization problems of theoretical and practical importance are NP-hard, meaning there is no efficient (i.e., polynomial time) algorithm to obtain exact solutions to these problems unless P = NP. However, for many of these problems, it is possible to obtain approximate solutions efficiently. An approximation algorithm with ratio C computes a solution that is guaranteed to be within a factor of C of the optimal solution (the approximation ratio for minimization and maximization problems is defined appropriately so that $C > 1$). In the best scenario, a problem may have an approximation algorithm with ratio $1+\epsilon$ for arbitrarily small constant $\epsilon > 0$. Many packing and scheduling problems have this property (e.g., the knapsack problem), and they are said to have a polynomial time approximation scheme (PTAS). For an excellent treatment of approximation algorithms, please refer to Vazirani's book [37].

Existence of a PTAS is difficult to prove in general. For example, it wasn't known till the early 1990s whether MAX-3SAT had a PTAS. The celebrated probabilistically checkable proof (PCP) theorem [4], [7] settled this question in the negative. Such results that rule out the possibility of an approximation algorithm within a certain factor (assuming of course a hypothesis like P $\neq$ NP) are known as inapproximability results or hardness results. After the discovery of the PCP theorem, there was tremendous progress in proving hardness results for various problems. A very incomplete list includes [6], [8], [16] [25], [26], [18], [15], [23], [13], [14], [28]. For some problems like MAX-3SAT [26], clique [25], and set-cover [16], optimal hardness results have been proved. A recent survey of Trevisan [36] gives a nice exposition for this area (see also [3]).

The PCP theorem has an equivalent formulation in terms of probabilistic checking of proofs. The theorem states that every NP-statement has a short proof that can be checked very efficiently by a probabilistic verifier. The verifier reads only a constant number of bits from the proof and has the following completeness and soundness properties: every correct statement has a proof that the verifier accepts with probability 1, and *every* proof of an incorrect statement is rejected with high probability. The connection between the notion of probabilistic proof checking and inapproximability results for optimization problems has been one of the most exciting developments in theoretical computer science.

In spite of great success of PCP tools towards proving inapproximability results, there are some notorious problems which so far have resisted all attempts to prove *good* inapproximability results. Examples include vertex cover, traveling salesman, and graph coloring. In this paper, we make progress on one set of notorious problems, namely, the graph min-bisection, dense k-subgraph, and bipartite clique problems. The best-known algorithms for these problems have approximation ratios $O(\log^2 n)$ (see [20]), $O(n^{1/3})$ (see [21]), and $n/(\log n)^{O(1)}$ (folklore), respectively, whereas no inapproximability results were known. Ruling out a PTAS for these problems has been considered a major open question in inapproximability theory.

Recently, Feige [17] showed that these problems have no PTAS, assuming a certain hypothesis about average-case hardness of random 3SAT (see section 1.7). The main result in this paper rules out a PTAS for these problems assuming only a (fairly) standard assumption that NP $\not\subseteq \cap_{\epsilon>0}$ BPTIME(2^{n^ϵ}) (i.e., NP does not have randomized algorithms that run in subexponential time).

Typically, inapproximability results are proved by *reducing* a known NP-hard problem to the target problem. The PCP theorem itself can be viewed as a (rather sophisticated) NP-hardness reduction. We too obtain our result via a reduction. We use a reduction from the minimum distance of linear code (MDC) problem. The inapproximability result for MDC has been obtained by Dumer, Micciancio, and Sudan [15] (see section 1.2).

1.1. Problem definitions and results.

Graph min-bisection. Given a graph $G(V, E)$ with $|V|$ even, partition V into two equal parts V' and V'' so as to minimize the number of *crossing* edges, i.e., edges with one endpoint each in V' and V''.

Dense k-subgraph. Given a graph $G(V, E)$ and a parameter k, find a subset $V' \subseteq V$ of size k so as to maximize the number of edges whose both endpoints are in V'.

Bipartite clique. Given a bipartite graph $G(V, W, E)$, maximize k such that there exist $V' \subseteq V$ and $W' \subseteq W$, each of size k, and the subgraph of G induced on the set of vertices $V' \cup W'$ is a complete bipartite graph.

Graph min-bisection is used as a subroutine by many graph algorithms based on divide-and-conquer strategy. Such algorithms partition the given graph into two equal parts, solve the desired optimization problem recursively on the two parts, and then *merge* the two solutions to obtain an overall solution (it usually suffices to partition the graph into two pieces of comparable size instead of exactly equal size). Dense k-subgraph and bipartite clique are natural graph theoretic problems which may also have algorithmic applications (e.g., the bipartite clique problem is the same as finding large monochromatic 1-squares in a 0-1 array; this may have applications to vision in processing arrays of pixels).

The main result in this paper is an inapproximability result for the above three problems. A formal statement of the result follows.

THEOREM 1.1. *Let $\epsilon > 0$ be an arbitrarily small constant. Assume that SAT does not have a probabilistic algorithm that runs in time 2^{n^ϵ} on an instance of size n. Then there is no polynomial time (possibly randomized) algorithm for graph min-bisection, dense k-subgraph, or bipartite clique that achieves an approximation ratio of $1 + \frac{1}{2^{O(1/\epsilon \log(1/\epsilon))}}$. In particular, assuming* NP $\not\subseteq \cap_{\epsilon>0}$ BPTIME (2^{n^ϵ})*, these three problems have no PTAS.*

Note that the inapproximability factor $1 + \frac{1}{2^{O(1/\epsilon \log(1/\epsilon))}}$ approaches 1 as ϵ tends to 0. Thus we have a (strange) trade-off between the quality of the inapproximability result and the complexity assumption that SAT has no 2^{n^ϵ} time algorithm. The inapproximability factor for bipartite clique can be *boosted* via randomized graph products (this is done as in [10], [11]; a proof appears in Appendix D). This gives the following theorem.[1]

THEOREM 1.2. *Let $\epsilon > 0$ be an arbitrarily small constant. Assume that SAT does not have a probabilistic algorithm that runs in time 2^{n^ϵ} on an instance of size n. Then there is no polynomial time (possibly randomized) algorithm for bipartite clique that achieves an approximation ratio of $N^{\epsilon'}$ on graphs of size N where $\epsilon' = \frac{1}{2^{O(1/\epsilon \log(1/\epsilon))}}$.*

We would like to mention that, independent of our work, Feige and Kogan [19] obtained the following (weaker) results for the bipartite clique problem.

THEOREM 1.3 (see [19]). *The bipartite clique problem is hard to approximate within factor $2^{(\log n)^\delta}$ for some $\delta > 0$ assuming that 3-SAT $\notin$ DTIME$(2^{n^{3/4+\epsilon}})$ for some $\epsilon > 0$. Also, the problem is NP-hard to approximate within some constant factor if the clique problem is NP-hard to approximate within factor $n/2^{c\sqrt{\log n}}$ for some $c > 0$.*

1.2. Minimum distance of code problem. As mentioned earlier, our hardness results are proved via a reduction from the minimum distance of (linear) code problem that we state next.

Minimum distance of code (MDC). Given a $N \times n'$ matrix $\mathbf{A}$ over a field $\mathbb{F}$, find a nonzero vector $\mathbf{z} \in \mathbb{F}^{n'}$ that minimizes the fraction of nonzero coordinates in the vector $\mathbf{Az}$. If one interprets the columns of $\mathbf{A}$ as the basis for a linear code, the problem is to find the (relative) minimum distance of the code. Let $OPT(\mathbf{A})$ denote the optimum value.

Remark 1.4. All instances of MDC in this paper are assumed to have the following properties: (1) The columns of $\mathbf{A}$ are linearly independent and $N \geq n'$; otherwise the problem becomes trivial. (2) The field $\mathbb{F}$ has characteristic 2. This enables us to concatenate the code with a binary code. (3) $N \leq |\mathbb{F}| \leq N^2$.

A result of Dumer, Micciancio, and Sudan [15] says that MDC is NP-hard to approximate within any constant factor on binary asymptotically good codes. The following result can be obtained from Dumer et al.'s result (a proof appears in Appendix B). It is the starting point for our reduction.

THEOREM 1.5. *There exists an absolute constant C such that the following holds. For every integer K, there is a reduction from SAT to MDC satisfying the following (think of K as a large constant):*

1. *The MDC instance is over a field $\mathbb{F}$ of characteristic 2 and has N rows, and $N \leq |\mathbb{F}| \leq N^2$.*
2. *(Completeness.) YES instance of SAT is mapped to an MDC instance $\mathbf{A}$ with $OPT(\mathbf{A}) \leq \frac{1}{2^K}$.*

[1] The FOCS 2004 version of this paper contains a bug. We erroneously claimed that ϵ' could be made independent of ϵ in Theorem 1.2.

3. *(Soundness.) NO instance of SAT is mapped to an MDC instance* $\mathbf{A}$ *with* $OPT(\mathbf{A}) \geq 1 - \frac{1}{2^{2^K}}$.
4. *The reduction runs in time* n^{CK} *and, in particular,* $N \leq n^{CK}$.

We would like to note that Dumer et al.'s reduction and therefore reduction in Theorem 1.5 is randomized (the completeness and soundness properties hold with high probability). The PCPs in this paper are constructed from Theorem 1.5 and their construction is randomized too, though we do not explicitly state so.

1.3. PCPs. We state the PCP theorem for future reference. The theorem was proved by Arora and Safra [4] and Arora et al. [7]. See Arora's Ph.D. thesis [2] for a comprehensive introduction to the subject. The PCP theorem states that languages in NP have short membership proofs that can be efficiently checked by a probabilistic constant-query verifier.

THEOREM 1.6 (PCP theorem). *For every language* $L \in$ NP*, there is a polynomial time probabilistic verifier* V *that has access to input* x *and a supposed proof* Π*. The size of proof* Π *is polynomial in the size of the input* $|x| = n$*. The verifier uses* $O(\log n)$ *random bits, reads* $d = O(1)$ *queries from* Π *(choice of query locations depends on verifier's random bits), performs a predetermined test on the query bits, and then accepts or rejects. The verifier has the following completeness and soundness properties:*

- *(Completeness/YES case.)* $x \in L \implies \exists\ \Pi \quad s.t. \quad \Pr[V(\Pi) = accept] = 1.$
- *(Soundness/NO case.)* $x \notin L \implies \forall\ \Pi \quad s.t. \quad \Pr[V(\Pi) = accept] \leq \frac{1}{10}.$

Here is an equivalent formulation of the PCP theorem as an inapproximability result.

THEOREM 1.7 (PCP theorem). *There exists an absolute constant* $c < 1$ *and a polynomial time reduction from* 3*SAT to MAX-*3*SAT mapping instance* ϕ *of* 3*SAT to instance* ψ *of MAX-*3*SAT with these properties:*

- *(YES case.) If* ϕ *is satisfiable, then so is* ψ*, i.e.,* $OPT(\psi) = 1$.
- *(NO case.) If* ϕ *is unsatisfiable, then* $OPT(\psi) \leq c$*, i.e., no assignment to* ψ *satisfies more than a fraction* c *of its clauses.*

*In particular, MAX-*3*SAT is hard to approximate within a factor better than* $1/c$ *unless* P = NP.

1.4. Quasi-random PCPs. In this section, we introduce the notion of quasi-random PCPs. The main contribution of the paper is a construction of a quasi-random PCP that immediately implies the inapproximability results for problems in Theorem 1.1. In section 1.5, we explain why the known PCPs are not quasi-random, and in section 1.6, we explain our new ideas for building quasi-random PCPs.

Quasi-random PCPs focus on the distribution of queries made by the verifier. We require that the distribution depends on whether the input to the PCP verifier is a YES input or a NO input. In the NO case, the queries are required to be distributed *randomly* over the proof, and in the YES case, the distribution is required to be *far from being random*. This is quite counterintuitive and mystical at first sight. The verifier does not know whether the input is YES or NO; then how can he make his query pattern depend on the YES/NO case? However, looking at some known PCPs makes this less mysterious. For example, let us look at Holmerin's [27] 4-query PCP, which has the following properties: (i) In the YES case, there exists a set of half the bits in the proof such that no PCP test accesses all 4 queries from this set. (ii) In the NO case, for any set of half the bits in the proof, at least $\frac{1}{16} - \epsilon$ fraction of the tests access all 4 queries from this set.

Thus it is conceivable (and necessary for proving inapproximability results) that the query pattern depends on the YES/NO case, without the verifier knowing which case it is. The quasi-random PCPs deal with one specific random-like property of query pattern. Here is the definition.

DEFINITION 1.8 (quasi-random PCP). *A PCP with d nonadaptive Boolean queries is called quasi-random if*[2]

- *in the YES case there exists a set of half the bits Π_0 in the proof Π such that at least $(1-o(1))\frac{1}{2^{d-1}}$ fraction of tests accesses all d queries from Π_0;*
- *in the NO case for any set Π_* of half the bits in the proof Π, the fraction of tests that accesses all d queries from Π_* is $(1\pm o(1))\frac{1}{2^d}$.*

Thus the query pattern has random-like property in the NO case, and in the YES case the property is violated.

Note that the definition of quasi-random PCPs includes conditions in both the YES and NO cases. However, by abuse of terminology, we will often refer only to the condition in the NO case. The following theorem states the main PCP construction in the paper.

THEOREM 1.9. *For every $\epsilon > 0$, there exists an integer $d = O(1/\epsilon \log(1/\epsilon))$ such that there is a PCP verifier for SAT instance of size n satisfying the following:*

1. *The proof Π for the verifier is of size 2^{n^ϵ}.*
2. *The verifier queries d bits from the proof. Let Q denote the set of query bits.*
3. *Every query is uniformly distributed over Π (two different queries are of course correlated).*
4. *(YES case/completeness.) Suppose the SAT instance is a YES instance and Π is a correct proof. Let Π_0 be the set of 0-bits in the proof (it contains half the bits from the proof). Then*

$$\Pr_Q[Q \subseteq \Pi_0] \geq (1 - O(1/d))\ \frac{1}{2^{d-1}}.$$

   The probability is taken over the random test of the verifier.
5. *(NO case/soundness.) Suppose the SAT instance is a NO instance, and let Π_* be any set of half the bits from Π. Then*

$$\frac{1}{2^d} - \frac{1}{2^{20d}} \ \leq\ \Pr_Q[Q \subseteq \Pi_*] \ \leq\ \frac{1}{2^d} + \frac{1}{2^{20d}}.$$

Note that Theorem 1.9 says nothing about the test the verifier performs on the query bits or the acceptance probability in completeness/soundness case. When we actually construct the PCP, we will use a homogeneous linear test on query bits.

The inapproximability results for graph min-bisection, dense k-subgraph, and bipartite clique follow easily from the PCP in Theorem 1.9 (see Appendix C). The reductions follow the same outline as Feige's reductions [17].

In the next two sections, we explain why the known PCPs are not quasi-random and give our new ideas for building quasi-random PCPs.

1.5. Why known PCPs are not quasi-random. Consider Håstad's 3-query PCP [26] as an illustration. The PCP can be abstracted out in the following manner:

[2]This definition is specific to the PCP that we construct in this paper. Using PCPs over alphabet $\mathbb{F}_p$ (rather than $\mathbb{F}_2$), the techniques in this paper can be extended to construct PCPs where the gap in the YES and NO cases is $\approx p$. To be precise, in the YES case, there is a set of $1/p$ fraction of positions in the proof such that $\approx 1/p^{d-1}$ fraction of tests falls into this set. In the NO case, for any set of $1/p$ fraction of positions in the proof, the fraction of tests that falls into this set is $\approx 1/p^d$.

The proof Π is partitioned into blocks:

$$\Pi = (A_1, A_2, \ldots, A_M\ ; B_1, B_2, \ldots, B_{M'}).$$

Every block A_i, B_j is of constant length and is supposed to be a long code. This is, however, irrelevant for the present discussion. The blocks B_j's are *bigger* than the blocks A_i's. The verifier picks a pair of blocks (A_i, B_j) and reads three bits from the proof: one from block A_i and two from block B_j.

It is easy to see why Håstad's PCP fails to be quasi-random (to be precise, it fails the NO case of Definition 1.8). Construct a set Π_* containing half the bits from proof Π as follows: for every block A_i or B_j, we include the entire block in Π_* with probability $\frac{1}{2}$ and exclude it from Π_* with probability $\frac{1}{2}$. Clearly, the probability that all three queries access bits from Π_* equals $\frac{1}{4}$, whereas the quasi-randomness condition requires this probability to be close to $\frac{1}{8}$.

Why does Håstad's verifier access two bits from the bigger block B_j? When one analyzes the PCP using Fourier analysis, it is necessary that the Fourier coefficient of the block B_j appears in squared form. Reading two bits from block B_j is a way to introduce redundancy and ensure that we have the Fourier coefficient $\widehat{B}_j^2$. However, as we observed, this form of redundancy leads to loss of quasi-randomness.

Though the above discussion applies only to one specific PCP (namely, Håstad's PCP) and only one specific analysis technique (namely, Fourier analysis), it turns out that all known PCPs and known techniques suffer from the same problem. On the high level, the proof is partitioned into blocks, the verifier reads q queries, and reads more than one query from at least one block. This typically happens when the verifier, instead of reading a desired bit, reads two or more related bits and infers the value of the desired bit via error correction. (PCPs, almost by definition, must use error correction in some form. See, for example, Hadamard code testing [12] and long code testing [8].) In particular, the verifier accesses less than q blocks and therefore fails to be quasi-random. Let us formulate this as an observation.

FACT 1.10. *Any q-query PCP where the proof is partitioned into blocks and the verifier accesses less than q blocks is not quasi-random.*

Thus we do need redundant bits and some form of error correction; but at the same time, we do not want to store all these bits at the same physical location (e.g., the same block B_j as in Håstad's PCP).

1.6. Basic idea behind our PCPs. Now we explain how we achieve the seemingly impossible task of constructing a quasi-random PCP. Here we present only the basic idea that has to fit in a much bigger context.

We look at the low degree test, which is an important building block of the PCP theorem (see [35], [4]). Given a function $f : \mathbb{F}^m \mapsto \mathbb{F}$, the test verifies that f is a degree $d-1$ polynomial (think of d as a constant). The verifier has access to a table of values of f, call it a *points table*. In addition, the verifier has access to a *lines table* which contains, for every line ℓ in $\mathbb{F}^m$, a degree $d-1$ univariate polynomial $f|_\ell$. The polynomial $f|_\ell$ is supposed to be the restriction of f to the line ℓ. The verifier works as follows: Pick a random line ℓ and a random point $\overline{v}$ on the line. Read $f(\overline{v})$ from the points table and read the polynomial $f|_\ell$ from the lines table. Accept if and only if $f(\overline{v})$ and $f|_\ell$ are consistent, i.e., if and only if the value produced by $f|_\ell$ at point $\overline{v}$ is the same as the value $f(\overline{v})$.

In our PCP construction, however, the verifier has no access to the additional lines table (this feature is also used independently in a recent paper of Ben-Sasson et al. [9]). Instead, the verifier proceeds as follows:

- Pick a random line ℓ and $d+1$ random points $\overline{v}_1, \overline{v}_2, \ldots, \overline{v}_{d+1}$ on the line. Read the values $f(\overline{v}_1), f(\overline{v}_2), \ldots, f(\overline{v}_{d+1})$.
- Let $f|_\ell$ be the unique degree $d-1$ univariate polynomial that takes values $f(\overline{v}_2), f(\overline{v}_3), \ldots, f(\overline{v}_{d+1})$ at points $\overline{v}_2, \overline{v}_3, \ldots, \overline{v}_{d+1}$, respectively.
- Accept if and only if $f(\overline{v}_1)$ and $f|_\ell$ are consistent.

Thus the verifier reads $f(\overline{v}_1)$ and then reads additional d random points on the line and *reconstructs* the line polynomial. This is the so-called outer verifier.

Now let us see why this PCP is quasi-random (the queries are nonboolean though). Let Π_* be any set of half the points from $\mathbb{F}^m$. What is the probability that all $d+1$ queries of the verifier fall in Π_*? It is easy to show that lines in $\mathbb{F}^m$ have excellent *mixing property*. For almost all lines ℓ, the fraction of points on ℓ that are in Π_* is very close to $\frac{1}{2}$. Once the line is chosen, the verifier picks $d+1$ random points on the line. Therefore, the probability that all the queries fall in Π_* is very close to $\frac{1}{2^{d+1}}$ and the PCP is quasi-random!

However, the queries are elements of $\mathbb{F}$, whereas we want to have boolean queries. We assume that $\mathbb{F}$ has characteristic 2 and therefore the field elements can be represented as bit strings of length $\log|\mathbb{F}|$. We use a standard technique for constructing a PCP with boolean queries. The verifier expects the proof to contain, instead of a value $f(\overline{v})$, the *Hadamard code* of the bit string $f(\overline{v})$. We can build an appropriate inner verifier that reads one bit from the (supposed) Hadamard code of $f(\overline{v}_i)$ for $i = 1, 2, \ldots, d+1$. The test of the outer verifier is replaced by a meaningful test on the $d+1$ bits read.

The inner verifier is analyzed using Fourier analysis. Recall that in Håstad's PCP, one needs to have the squared Fourier coefficient $\widehat{B}_j^2$, and this is achieved by reading two bits from block B_j. Our Fourier analysis also needs something similar. However, we cannot read more than one bit from any block (= Hadamard code); otherwise we lose the quasi-randomness property. We get around this problem by a clever trick. We modify the verifier as follows: As before, the verifier picks a random line ℓ and $d+1$ points on it $\overline{v}_1, \overline{v}_2, \ldots, \overline{v}_{d+1}$ and performs the test described. In addition, the verifier picks *another* set of $d+1$ random points on the line, say $\overline{u}_1, \overline{u}_2, \ldots, \overline{u}_{d+1}$. He verifies that the degree d polynomial reconstructed from values $f(\overline{u}_1), f(\overline{u}_2), \ldots, f(\overline{u}_{d+1})$ is identical to the polynomial reconstructed from $f(\overline{v}_1), f(\overline{v}_2), \ldots, f(\overline{v}_{d+1})$ (this polynomial actually happens to be of degree $d-1$). This is exactly the analogue of reading two bits from block B_j in Håstad's PCP. The additional queries look wasteful, but this is precisely how we introduce redundancy (= error correction) without losing quasi-randomness. Unfortunately, the exact significance of this trick will not be clear unless one looks at the actual Fourier analysis.

Remark 1.11. Definition 1.8 requires that the query pattern of the PCP verifier is different in the YES and NO cases. We would like to stress that the query pattern in the YES and NO cases is the same at the level of the (modified) outer verifier since in both the YES and NO cases, the verifier picks random points on a randomly selected line. However, quite magically, the difference in the query pattern in the YES and NO cases manifests itself at the inner verifier level.

1.7. Comparison with Feige's hypothesis. Feige [17] makes the following hypothesis about average-case hardness of 3SAT.

FEIGE'S HYPOTHESIS. *Let ϕ be a 3SAT formula with n variables and Cn clauses where every clause is picked at random from the set of all possible clauses. Then for an arbitrarily large constant C, there is no polynomial time algorithm that* (1) *says YES if ϕ is satisfiable and* (2) *says NO at least* 50% *of the times for a random formula ϕ.*

Assuming this hypothesis, Feige shows that graph min-bisection, dense k-subgraph, and bipartite clique have no PTAS (Alekhnovich [1] later shows these results assuming random instances of 3-linear-equations are hard).

Let us see how we are able to bypass Feige's hypothesis and still prove these inapproximability results. Consider the following PCP constructed from an instance ϕ of Gap-3SAT. The proof supposedly consists of a satisfying assignment to the 3SAT formula ϕ. The verifier picks one clause at random, queries the three variables in the clause, and checks if the clause is satisfied. Now what if the formula ϕ was a random instance of 3SAT? Then the query pattern of the verifier would be *truly random*. Thus Feige's hypothesis, in some sense, says that there exists a PCP whose query pattern is *truly random*.

On the other hand, quasi-randomness is only one specific property which is satisfied by a truly random query pattern. Applied to 3SAT, the quasi-randomness property says that for any set of half the variables, $(1 \pm o(1))\frac{1}{8}$ fraction of the clauses have all their three variables from this set. We make the following observation: In order to prove inapproximability results for graph theoretic problems, it suffices to have hard instances of 3SAT (or any constraint satisfaction problem (CSP) with constraints on a bounded number of variables) with a quasi-randomness property. One does not really need the 3SAT instances to be truly random, as in Feige's paper. We are able to construct such quasi-random PCPs, thereby obtaining the desired inapproximability results.

1.8. Overview of the paper. The main result in this paper is Theorem 1.9. The proof of this result is quite lengthy, involving a sequence of reductions (see Figure 1).

We introduce a new problem called the homogeneous algebraic CSP (HomAlgCSP). (Algebraic CSPs have been used before; see [24], for example. Our CSPs have the additional property that all constraints are homogeneous linear and we do not allow a trivial solution that is identically zero.) Our proof can be divided into two parts: First we reduce MDC to HomAlgCSP. This reduction appears in sections 3, 4, 5, and 6. This is perhaps the most interesting part of the paper. The modules used in this reduction, namely, the generalized sum-check protocol, the splitability certificate, and the subspace membership certificate, could be of independent interest.

Then we construct a PCP verifier from the HomAlgCSP instance. The verifier consists of an outer verifier (section 7 and 8) and an inner verifier (section 10). We actually need to modify the outer verifier before constructing the inner verifier. This modified outer verifier appears in section 9.

We recommend that in the first reading, the paper be read in the following way: (i) Browse through section 2, which gives an overview of techniques and the high level view of the reduction. Also take a look at Appendix A, which gives some of the facts/tools used. (ii) Read the beginning of section 3 and the statement of Theorem 3.4. Skip the rest of section 3 as well as sections 4, 5, and 6, which are devoted to proving Theorem 3.4. Though this is where the meat of the paper lies, it is rather lengthy and one might feel lost in the first reading. (iii) Read section 7 and Theorem 7.6. Skip section 8. (iv) Read sections 9 and 10.

2. Techniques and high level view of the reduction. In this section, we give an overview of techniques in the paper. This is a general overview that hides many subtleties involved in our reduction.

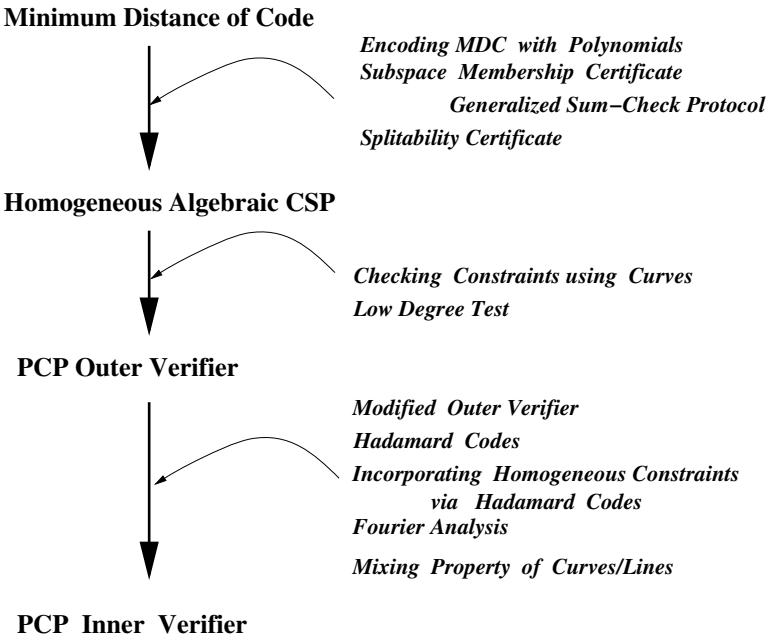

FIG. 1. *Overview of full reduction.*

2.1. MDC to homogeneous algebraic CSP. HomAlgCSP is the following problem (see Definition 3.1): Given space $\mathbb{F}^m$, the goal is to find a nonzero low degree m-variate polynomial f that satisfies a maximum number of constraints. Every constraint is a homogeneous linear constraint on $O(1)$ values of f at specific points in $\mathbb{F}^m$. As explained in Remark 3.2, HomAlgCSP is a very similar problem to MDC. A reduction from MDC to HomAlgCSP transforms (see Theorem 3.4) the *global* constraints of MDC to *local* constraints of HomAlgCSP that depend only on $O(1)$ values of f at specific points. This global-to-local transformation is a major step in our reduction (as must be the case with any PCP).

The reduction from MDC to HomAlgCSP works as follows: It is easy to encode MDC as an instance of the following problem: Given a subspace of low degree polynomials $\mathcal{B}$ and a set of points $\mathcal{P} \subseteq \mathbb{F}^m$, find a nonzero polynomial $f \in \mathcal{B}$ that vanishes at a maximum number of points in $\mathcal{P}$. Note that we now have local constraints, one for every point $\overline{p} \in \mathcal{P}$, saying that f vanishes at $\overline{p}$. However, the main trouble is, how do we enforce the condition that $f \in \mathcal{B}$?

We do this by constructing what we call a *subspace membership certificate*. It is a low degree polynomial g that supposedly certifies that $f \in \mathcal{B}$. The polynomial g needs to be of a certain type and this is certified by constructing another polynomial h which we call the *splitability certificate*. We add a collection of local constraints on values of f, g, and h that enforce the consistency between the three polynomials. The polynomials g and h are constructed as follows.

We observe that $f \in \mathcal{B}$ if and only if the value of f at any point $\mathbf{q} \in \mathbb{F}^m$ is a *weighted sum* of its values at some well-chosen points. Thus we can check whether this *sum-check* holds for a random point $\mathbf{q}$. We employ a generalization of the sum-check protocol in order to carry out the sum-check. The usual sum-check protocol sums over values of f over the boolean cube $\{0,1\}^m$, whereas our protocol sums over

an arbitrary subset of the boolean cube. We choose the subset to consist of only low Hamming-weight points of the boolean cube so that the *sum-check polynomials* remain of low degree.

The polynomial g (i.e., the subspace membership certificate) is a linear combination of all the sum-check polynomials. For the sum-check protocol to work, the sum-check polynomials need to be independent in some sense. The polynomial h (i.e., the splitability certificate) certifies that this is indeed so. The polynomials g and h together form a certificate that $f \in \mathcal{B}$. Finally, we *club together* the three polynomials f, g, and h into a single polynomial ϕ that serves as an instance of HomAlgCSP. The constraints are all homogeneous linear on $O(1)$ values of ϕ at specific points.

Let us illustrate the power of subspace membership certificate construction by an example. Let us say we have a low degree m-variate polynomial f that is given as a table of values. We want to verify that f is multilinear (i.e., f has no monomial that looks like $x_1^2 x_2 x_3$). How many queries do we need to the table of values of f (and possibly to an additional proof)?

The straightforward way is to pick a random point in $\mathbb{F}^m$ and check that on *every* axis-parallel line passing through this point, f behaves as a linear function (this is precisely what [22] does). However, this needs $O(m)$ queries. On the other hand, our construction gives a query-efficient way of certifying that f is multilinear. The certificate consists of a pair of new low degree polynomials (g, h), and we need only $O(1)$ queries to tables of values of f, g, and h! Moreover, the test is homogeneous linear. The fact that the certificate itself is a polynomial is crucial for our purpose.

2.2. HomAlgCSP to outer verifier. We construct a PCP outer verifier from the HomAlgCSP instance. Let f be the polynomial required in the HomAlgCSP instance. The outer verifier expects as a proof a table of values of f. The verifier needs to verify the following: (1) f is indeed a nonzero low degree polynomial, and (2) values of f satisfy constraints of HomAlgCSP.

It is well known how to handle the first task, namely, verifying that f is a degree d polynomial. The so-called low degree test (LDT) expects an additional proof: a table that gives for every line in $\mathbb{F}^m$ a univariate polynomial that is supposedly the restriction of f to the line. The verifier picks a random line and a point on the line, and checks consistency between the table of points and table of lines. For our purposes, however, the verifier has no access to the *lines table*. The verifier, instead, reads $d+1$ values of f on a line ℓ and reconstructs by himself the restriction of f to line ℓ. In this paper, the degree d of polynomials is a constant, and therefore the verifier still makes only a constant number of queries. We need the strong analysis of the LDT by Arora and Sudan [5].

The next task of the verifier is to verify that f satisfies certain constraints. The verifier picks one constraint at random that depends on k values of f at specific points, say $\{\overline{p}_i\}_{i=1}^k \in \mathbb{F}^m$. In principle, the verifier could just read off these values and verify the constraint. However, it is well known in PCP literature that one needs to have some form of *error correction* and infer the values of f at points $\{\overline{p}_i\}_{i=1}^k$ from the global behavior of f. We use another well-known primitive to handle this. We pick a random *curve* L that passes through the points $\{\overline{p}_i\}_{i=1}^k$. Restriction of f to the curve L is again a low degree univariate polynomial that we reconstruct by reading sufficiently many values of f on the curve. After reconstructing this *curve polynomial*, we get values of f at points $\{\overline{p}_i\}_{i=1}^k$ and verify that they indeed satisfy the constraint.

We in fact combine the two tasks of the verifier. We pick a random pair of a curve and a line that intersect at a point. The verification procedures described above are

carried out for both the line and the curve. We in addition check that the line and the curve are consistent at the intersection point. This completes the description of the outer verifier.

Now let us see what exactly the outer verifier achieves. Let us restrict ourselves to the first task (i.e., the variant of line-point LDT where the line polynomial is reconstructed by reading several values on the line). Recall that our eventual goal is to build a quasi-random PCP. The definition of the quasi-random PCP requires that if Π_* is any subset of the proof of half the size, and the number of queries is q, then the probability that all queries fall in Π_* is essentially $\frac{1}{2^q}$.

Let us illustrate that the outer verifier achieves the quasi-randomness property. Let Π_* be any set of half the points from $\mathbb{F}^m$. It is easy to show that lines in $\mathbb{F}^m$ have excellent *mixing property*, i.e., for any such set Π_*, for almost every line ℓ, the fraction of points on ℓ belonging to Π_* is very close to $\frac{1}{2}$. Now recall that the outer verifier picks a random line and q random points on the line. Thus the probability that all his queries fall into Π_* is essentially $\frac{1}{2^q}$. A similar mixing property holds for curves as well (see Appendix A.4), and therefore the outer verifier is quasi-random.

2.3. Outer verifier to modified outer verifier. The purpose of the modified outer verifier is exactly as explained in sections 1.5 and 1.6. It is the analogue of reading two bits from block B_j in Håstad's 3-query PCP. The modified outer verifier introduces redundancy (= error correction), and this enables us to bound the Fourier terms in the analysis of the inner verifier. This works in exactly the same way that the squared Fourier coefficient $\widehat{B}_j^2$ enables the analysis of Håstad's PCP.

Recall that the outer verifier reads values of f on $d+1$ points from a line and a curve and reconstructs the line and curve polynomials. The modified outer verifier reads values of f on additional $d+1$ points from the line and the curve and checks that he again gets the *same* line and curve polynomials. Thus one introduces redundancy, but without losing quasi-randomness.

2.4. Modified outer verifier to inner verifier. The final step is to build the inner verifier and prove the quasi-randomness property. Note that the proof for the modified outer verifier is a table of values of a polynomial $f : \mathbb{F}^m \mapsto \mathbb{F}$. We work only with fields of characteristic 2. Therefore denoting $|\mathbb{F}| = 2^l$, we can think of elements of $\mathbb{F}$ as l-bit strings. The inner verifier expects as a proof the Hadamard codes of these l-bit strings. Let us say the modified outer verifier makes q queries. Then the inner verifier also makes q queries, reading one bit each from the corresponding Hadamard code. As pointed out earlier, it is crucial that one reads only one bit from each code/block; otherwise the quasi-randomness property fails.

The quasi-randomness of the inner verifier is proved using Fourier analysis. We prove the desired two properties: (1) In the completeness case, let Π_0 be the set of 0-bits in the proof. This consists of half the bits in the proof. The probability that all q queries fall in Π_0 is essentially $\frac{1}{2^{q-1}}$. (2) In the soundness case, we assume on the contrary that there is a set Π_* of half the bits in the proof such that with probability $\frac{1}{2^q} \pm \delta$, all queries fall in Π_*. Then we show that one can *decode* the proof and construct a table $f : \mathbb{F}^m \mapsto \mathbb{F}$ that the outer verifier accepts with probability $\delta^{O(1)}$. This is a contradiction if the outer verifier is chosen to have sufficiently small soundness. This is ensured by choosing the MDC instance (and therefore the HomAlgCSP instance) with small soundness. The decoding is the standard probabilistic decoding in PCP literature. A supposed Hadamard code is decoded to α with probability $\widehat{A}_\alpha^2$, i.e., proportional to the square of the corresponding Fourier coefficient. We use several

nice properties of Hadamard codes that we list below (the popular long codes do not work; the Hadamard code–based inner verifier was used earlier in [29]):

1. The modified outer verifier reads q values of f and performs homogeneous linear tests. There is a natural way of accessing Hadamard codes so that only those Fourier coefficients survive which satisfy all the homogeneous linear constraints (this is where we need homogeneity). Thus, as far as the inner verifier is concerned, this testing comes for free.
2. If we have access to Hadamard codes of x and y, then we essentially have access to the Hadamard code of the concatenated string $x \circ y$. The process of accessing a bit from the Hadamard code of $x \circ y$ can be simulated by reading one bit each from codes of x and y.
3. The zero Fourier coefficient of a supposed Hadamard code equals the fraction of 1's in the supposed code.

There is a nice interpretation of the Fourier coefficients in the analysis. The zero coefficient corresponds to the term $\frac{1}{2^q}$ in the soundness probability. The nonzero coefficients are used to *decode* the proof and define a strategy for the outer verifier. This in turn gives a solution to the HomAlgCSP (and therefore the MDC) instance. Recall that the HomAlgCSP instance demands a *nonzero* polynomial f.

As mentioned in Remark 1.11, the difference in the query pattern of the verifier in the YES and NO cases is *created* at the inner verifier level. At the outer verifier level, the query pattern is the same, irrespective of the YES or NO case (in both cases, random points are chosen on a randomly selected line/curve).

Remark 2.1. Our reduction was discovered by way of *reverse engineering*. We want to use the combination of interpolation and Hadamard codes to get a boolean PCP that does not make two queries in one block (as explained in sections 1.5 and 1.6). For this, it turns out that the outer PCP test must be linear and homogeneous. This is why we start with MDC, which involves a set of homogeneous constraints, and we transform them into *local* homogeneous constraints.

Another remark on the size of the construction: we want to have a constant query PCP, and hence the polynomials must have constant degree (when restricted to a line). This forces us to work with huge numbers of dimensions (i.e., n^{ϵ}) and the size of the construction becomes subexponential.

3. MDC to HomAlgCSP: Encoding MDC with polynomials. Now we begin our construction of the quasi-random PCP. The first step is defining the HomAlgCSP problem.

DEFINITION 3.1. *Let the HomAlgCSP $\mathcal{A}(f, k, d, m, \mathbb{F}, \mathcal{C})$ be the following problem (think of k as a fixed integer like* 21*, and d as a large constant integer):*

1. *f is (supposed to be) an m-variate degree d polynomial over field $\mathbb{F}$.*
2. *$\mathcal{C}$ is a system of constraints where every constraint is on k values of the polynomial f at certain points. This constraint is a conjunction of homogeneous linear constraints. Thus a typical constraint looks like*

$$\sum_{i=1}^{k} \gamma_{ij} f(\overline{p_i}) = 0 \quad \text{for } j = 1, 2, \ldots, \qquad \text{where } \overline{p}_i \in \mathbb{F}^m \text{ and } \gamma_{ij} \in \mathbb{F}.$$

   A constraint $C \in \mathcal{C}$ will be denoted by $C(\{\overline{p}_i\}_{i=1}^{k})$, thus indicating only the points on which the constraint is defined. The actual homogeneous constraints will be implicit.
3. *$\mathcal{C}$ has $|\mathbb{F}|^{O(m)}$ constraints.*

The goal is to find a polynomial f, not identically zero, so as to maximize the fraction of constraints satisfied. Let $OPT(\mathcal{A})$ denote the optimum.

Remark 3.2. HomAlgCSP and MDC are similar problems. In MDC, we want to find a nonzero assignment to unknown variables that minimizes the number of unsatisfied homogeneous linear constraints. HomAlgCSP is essentially the same problem if we view the coefficients of the polynomial f as unknown variables (one minor difference is that HomAlgCSP is a maximization problem and we allow a constraint to be an arbitrary conjunction of homogeneous linear constraints).

However, the main difference is the following: for MDC, every constraint could depend on an arbitrary number of variables, whereas for HomAlgCSP, every constraint has a compact/local representation in terms of values of f at a constant number of points. Thus a reduction from MDC to HomAlgCSP transforms global constraints to local ones. This is what PCPs are all about!

Remark 3.3. It may help to look at the HomAlgCSP problem from a PCP viewpoint. A PCP would be the table of values of the (unknown) polynomial f. The verifier would pick a random constraint $C(\{\overline{p_i}\}_{i=1}^k) \in \mathcal{C}$, read the values $\{f(\overline{p_i})\}_{i=1}^k$, and check whether the constraint is satisfied. Thus, the HomAlgCSP problem is equivalent to finding a proof that maximizes the acceptance probability of the verifier.

The following theorem states the main result in this and the next three sections. It gives a gap-preserving reduction from MDC to HomAlgCSP.

THEOREM 3.4. *Let $\mathbf{A}$ be an instance of MDC with size $N \times n'$ over field $\mathbb{F}$. Assume that $N \le |\mathbb{F}| \le N^2$. Let $\epsilon > 0$ be an arbitrarily small constant, $m = N^\epsilon$, and let $d = \frac{100}{\epsilon}$ be an integer. There is a reduction from $\mathbf{A}$ to an instance of HomAlgCSP $\mathcal{A}(f, k = 21, d, m, \mathbb{F}, \mathcal{C})$ such that*

$$1 - OPT(\mathbf{A}) \;\le\; OPT(\mathcal{A}) \;\le\; \max\left\{1 - OPT(\mathbf{A}), O\left(\frac{d}{|\mathbb{F}|}\right)\right\}. \tag{1}$$

We begin the proof of Theorem 3.4. The first step is to encode MDC as the following problem: Given a set of points $\mathcal{P}$ in $\mathbb{F}^m$, find a nonzero degree d polynomial f that is nonzero at minimum number of points from $\mathcal{P}$. In addition, f is required to be in a certain subspace of polynomials.

The next step is to define two more polynomials g and h that are supposed to serve as a *certificate* that f indeed belongs to the required subspace of polynomials. Then we define a collection of constraints all of which are homogeneous linear constraints on k' values of f, g, and h. These constraints enforce the consistency between f, g, and h as well as the condition that f takes nonzero values at a minimum number of points from $\mathcal{P}$. In the end, we will *club together* the three polynomials f, g, and h into a single polynomial ϕ and all the constraints are homogeneous constraints on k values of ϕ. This would prove Theorem 3.4.

Remark 3.5. Actually Theorem 3.4 holds for a more general setting of parameters. For any choice of integers m and d such that $\binom{m}{d} \ge N$, the reduction produces an instance of HomAlgCSP $\mathcal{A}(f, k = 21, d' = 10d, m' = O(m^3 d), \mathbb{F}, \mathcal{C})$ such that (1) holds. However, we will stick to the setting of the parameters in Theorem 3.4 used in this paper.

3.1. Encoding MDC with polynomials. Let $\mathbf{A} = \{a_{ji}\}$ be an $N \times n'$ instance of MDC. We assume without loss of generality (w.l.o.g.) that the first n' rows of $\mathbf{A}$ form an identity matrix, i.e., $a_{ji} = 0$ if $1 \le i \ne j \le n'$ and $a_{ii} = 1$ for $1 \le i \le n'$. This can be achieved by rearranging rows so that the first n' rows are linearly

independent and then multiplying $\mathbf{A}$ by a suitable $n' \times n'$ matrix. This transformation doesn't change $OPT(\mathbf{A})$.

Remark 3.6. In the following, the polynomial f and the parameters ϵ, m, d are related to but *not* the same as those in Theorem 3.4. They keep changing somewhat over the course of the reduction.

Fix an arbitrarily small constant $\epsilon > 0$ and let $m = N^{\epsilon}$. Choose an integer d such that $N \leq \binom{m}{d}$. Thus $d = \frac{2}{\epsilon}$ suffices. Let $\mathcal{F}_0$ be a family of subsets of $[m]$ of size d such that $|\mathcal{F}_0| = N$. Let $\mathcal{F} \subseteq \mathcal{F}_0$ be a subfamily with $|\mathcal{F}| = n'$. The columns of the matrix $\mathbf{A}$ are indexed by $I \in \mathcal{F}$ and the rows are indexed by $J \in \mathcal{F}_0$, where the first n' rows are indexed by $I \in \mathcal{F}$.

For $J \in \mathcal{F}_0$, let $\overline{p}_J \in \mathbb{F}^m$ be the point with $\{0,1\}$-coordinates that is the characteristic vector of set J. Let $\mathbf{x}_J$ be the degree d monomial $\prod_{j \in J} x_j$. Let $\mathbf{x} = (x_1, x_2, \ldots, x_m)$ denote a vector of formal variables. The important property is that the monomial $\mathbf{x}_J$ evaluates to 1 at point $\overline{p}_J$ and evaluates to 0 at any point $\overline{p}_{J'}$ for $J' \neq J, |J'| = d$.

We will encode the columns of matrix $\mathbf{A}$ by polynomials in $\mathbb{F}[\mathbf{x}]$. For column I, define a degree d polynomial $f_I \in \mathbb{F}[\mathbf{x}]$ as

$$f_I := \sum_{J \in \mathcal{F}_0} a_{JI} \mathbf{x}_J \qquad (a_{JI} = a_{ji}).$$

It is clear that $f_I(\overline{p}_J) = a_{JI}$ for $J \in \mathcal{F}_0, I \in \mathcal{F}$. In other words, the coordinates of the column indexed by I are given by $f_I(\overline{p}_J)\ \forall\ J \in \mathcal{F}_0$.

Let $span\{f_I | I \in \mathcal{F}\}$ denote the linear span of polynomials f_I's. Thus the MDC problem can be reformulated as follows.

MDC (reformulation). Find a nonzero polynomial $f \in span\{f_I | I \in \mathcal{F}\}$ so as to minimize the fraction of nonzero entries in the vector

$$\{\ f(\overline{p}_J)\ | J \in \mathcal{F}_0\ \}.$$

How do we ensure that f belongs to the span of polynomials $\{f_I | I \in \mathcal{F}\}$? The next few sections are devoted to the construction of two polynomials g and h that serve as a certificate that f indeed belongs to the span.

Overview of the construction of certificate polynomials. We make a simple but important observation (Lemma 3.7): f belongs to the span of $\{f_I | I \in \mathcal{F}\}$ if and only if for all points $\mathbf{q} \in \mathbb{F}^m$, the value $f(\mathbf{q})$ is a weighted sum of the values $\{f(\overline{p}_I) | I \in \mathcal{F}\}$. So we check whether this property holds for a randomly selected point $\mathbf{q}$. The checking procedure could be carried out by reading the values $f(\mathbf{q})$ and $\{f(\overline{p}_I) | I \in \mathcal{F}\}$. This, however, would take too many queries, whereas we can afford only a constant number of queries. The idea is to use the sum-check protocol used in the proof of the PCP theorem. It turns out that the protocol needs values of linear combinations of *sum-check polynomials*. The first *certificate polynomial* g is the Hadamard code over the sum-check polynomials. However, for the sum-check protocol to work, the sum-check polynomials need to be *independent* of each other in some sense. The second *certificate polynomial* h serves as a proof of this independence. We define the notion of a *splitable polynomial*, and h is actually a certificate that the polynomial g is splitable. We call g and h the *subspace membership certificate* and *splitability certificate*, respectively.

3.2. Basic observation for constructing the subspace membership certificate. Let $f(\mathbf{x}) \in \mathbb{F}[\mathbf{x}]$ be the desired polynomial. Let $\mathbf{q}$ be a vector of formal

variables. Consider the polynomial

$$\psi(\mathbf{q}, \mathbf{x}) := \sum_{I \in \mathcal{F}} f_I(\mathbf{q}) \mathbf{x}_I. \tag{2}$$

Note that f_I's are of degree d; therefore ψ is of degree $2d$. We make the following important observation.

LEMMA 3.7. *$f \in span\{f_I | I \in \mathcal{F}\}$ if and only if this formal identity holds:*

$$f(\mathbf{q}) = \sum_{I \in \mathcal{F}} \psi(\mathbf{q}, \overline{p}_I) f(\overline{p}_I). \tag{3}$$

Proof. Assume that $f = \sum_{I' \in \mathcal{F}} \lambda_{I'} f_{I'}$, where $\lambda_{I'} \in \mathbb{F}$. Then

$$\begin{aligned}
\sum_{I \in \mathcal{F}} \psi(\mathbf{q}, \overline{p}_I) f(\overline{p}_I) &= \sum_{I \in \mathcal{F}} \psi(\mathbf{q}, \overline{p}_I) \sum_{I' \in \mathcal{F}} \lambda_{I'} f_{I'}(\overline{p}_I) \\
&= \sum_{I \in \mathcal{F}} \psi(\mathbf{q}, \overline{p}_I) \lambda_I \qquad f_{I'}(\overline{p}_I) = a_{II'} = 0 \text{ if } I \neq I' \text{ and 1 otherwise} \\
&= \sum_{I \in \mathcal{F}} \lambda_I \sum_{I'' \in \mathcal{F}} f_{I''}(\mathbf{q}) \cdot \mathbf{x}_{I''}(\overline{p}_I) \\
&= \sum_{I \in \mathcal{F}} \lambda_I f_I(\mathbf{q}) \\
&= f(\mathbf{q}),
\end{aligned}$$

as desired. For the other direction, note that if $f(\mathbf{q}) = \sum_{I \in \mathcal{F}} \psi(\mathbf{q}, \overline{p}_I) f(\overline{p}_I)$, then we have

$$\begin{aligned}
f(\mathbf{q}) &= \sum_{I \in \mathcal{F}} f(\overline{p}_I) \sum_{I' \in \mathcal{F}} f_{I'}(\mathbf{q}) \mathbf{x}_{I'}(\overline{p}_I) \\
&= \sum_{I \in \mathcal{F}} f(\overline{p}_I) f_I(\mathbf{q}),
\end{aligned}$$

as desired. ∎

Thus, one can probabilistically check whether f belongs to $span\{f_I | I \in \mathcal{F}\}$ by checking whether (3) holds for a random $\mathbf{q} \in \mathbb{F}^m$. Note that verifying (3) would require accessing all the values $f(\overline{p}_I)$. However, we want to read only a constant number of values of f. The idea is to use the sum-check protocol used in the proof of the PCP theorem. This protocol lets us verify that the sum of values of a function over $\{0,1\}^m$ equals some target value. We need a generalization of this protocol where the sum is taken over the restricted set of points $\{\overline{p}_I | I \in \mathcal{F}\}$. An important feature of this generalized protocol is that the points $\{\overline{p}_I | I \in \mathcal{F}\}$ are low Hamming-weight points (i.e., only d nonzero coordinates). This ensures that all the sum-check polynomials are of degree $O(d)$.

Before we get into the sum-check protocol, let us introduce the notion of *splitability* of polynomials and how to construct a certificate for splitability. This construction will be a useful primitive later and will introduce some of the new ideas. Admittedly, the reader would have no clue at this point how/why it is useful, but we think the construction is also of independent interest.

4. Splitability certificate. For $1 \leq j \leq M$, let $\mathbf{x}^{(j)}$ denote a vector of m_j formal variables where the sets of variables for different j are disjoint. Let $\mathbf{x} = \cup_{j=1}^{M} \mathbf{x}^{(j)}$.

DEFINITION 4.1. *A degree d polynomial $g \in \mathbb{F}[\mathbf{x}]$ is called splitable if it can be written as*

$$g(\mathbf{x}) := \sum_{j=1}^{M} g_j(\mathbf{x}^{(j)}), \tag{4}$$

where $g_j \in \mathbb{F}[\mathbf{x}^{(j)}]$ are degree d polynomials.

In other words, splitability means that the variables in different sets $\mathbf{x}^{(j)}$ do not *interfere* with each other. In this section, we show how to *certify* that a given polynomial g is splitable. The certificate consists of another polynomial h. The certificate can be verified w.h.p. with a constant number of accesses given tables of values of g and h.

THEOREM 4.2. *Let $\mathbf{x} = \cup_{j=1}^{M} \mathbf{x}^{(j)}$ be a partition of variables and let $g \in \mathbb{F}[\mathbf{x}]$ be a polynomial of degree d. Assume that every $\mathbf{x}^{(j)}$ has at most m variables. Let $h \in \mathbb{F}[\mathbf{z}]$ be a degree $2d$ polynomial that is supposed to be a certificate that g is splitable. The number of variables in $\mathbf{z}$ is bounded by $O(m^2M + dM)$. There is a verifier with the following properties:*

1. *The verifier accesses one value of g and four values of h.*
2. *If g is splitable, then there exists a unique polynomial h such that the verifier accepts with probability 1, and for any other h, the verifier accepts with probability at most $O(\frac{d}{|\mathbb{F}|})$. If $g \equiv 0$, then the corresponding $h \equiv 0$.*
3. *If g is not splitable, then no matter what h is (of degree $2d$), the verifier accepts with probability at most $O(\frac{d}{|\mathbb{F}|})$.*

4.1. Basic idea. Let us explain the basic idea behind our construction with a small example. Let us say we have a polynomial $g(x_1, x_2, \ldots, x_m; w_1, w_2, \ldots, w_m)$ and we want to certify that g is splitable, i.e., g can be written as the sum of two polynomials, one in $x_1, \ldots, x_m$ and the other in $w_1, \ldots, w_m$. Assume for the moment that g is guaranteed to be multilinear.

Here is our first attempt. We check for every pair (i_0, j_0) that g has no monomial involving the product $x_{i_0} w_{j_0}$. This can be done as follows. Substitute random values for all variables except x_{i_0}, w_{j_0} and check that the resulting (restricted) function is linear in x_{i_0} and w_{j_0}. More precisely, pick random values for variables $x_i, w_j, i \neq i_0, j \neq j_0$. Pick two sets of random values x_{i_0}, w_{j_0} and x'_{i_0}, w'_{j_0}. Pick a random value ζ and check that

$$\begin{aligned} \zeta \cdot g(\ldots, x_{i_0}, \ldots; \ldots, w_{j_0}, \ldots) + (1-\zeta) \cdot g(\ldots, x'_{i_0}, \ldots; \ldots, w'_{j_0}, \ldots) \\ = g(\ldots, \zeta x_{i_0} + (1-\zeta) x'_{i_0}, \ldots; \ldots, \zeta w_{j_0} + (1-\zeta) w'_{j_0}, \ldots), \end{aligned}$$

where the dots indicate the same set of values for $x_i, y_j, i \neq i_0, j \neq j_0$. Note that we read only 3 values of g and do not need any additional certificate. Clearly, if g is multilinear and splitable, the test always accepts. If g has a monomial involving the product $x_{i_0} w_{j_0}$, the test accepts with probability at most $O(\frac{d}{|\mathbb{F}|})$.

Now the trouble is that we have to do this for *every* pair i_0, j_0, which we cannot afford to do (we want to keep the number of queries constant). To overcome this

trouble, we use the following trick. Make the following substitution:

$$\begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_m \end{bmatrix} = \begin{bmatrix} a_{11} & \dots & a_{1m} \\ & \dots & \\ & \vdots & \\ a_{m1} & \dots & a_{mm} \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \\ \vdots \\ u_m \end{bmatrix};$$

(5)

$$\begin{bmatrix} w_1 \\ w_2 \\ \vdots \\ w_m \end{bmatrix} = \begin{bmatrix} b_{11} & \dots & b_{1m} \\ & \dots & \\ & \vdots & \\ b_{m1} & \dots & b_{mm} \end{bmatrix} \begin{bmatrix} v_1 \\ v_2 \\ \vdots \\ v_m \end{bmatrix}.$$

Here a_{ij}, b_{ij}, u_i, v_j are new formal variables. After substituting values for x_i, y_j in the polynomial g, we get a new polynomial h in a_{ij}, b_{ij}, u_i, v_j. Here is a simple observation: g is splitable if and only if h has no monomial involving the product $u_1 v_1$.

The polynomial h will be the certificate. Using the checking procedure described earlier, we can check that h has no monomial involving $u_1 v_1$. Also, we can verify that g and h are consistent by checking that they agree on points which are related via the transformation (5).

This is the basic idea behind the splitability certificate. An additional twist is that g is not necessarily multilinear, but this possibility is handled easily as well.

4.2. Defining the splitability certificate. Now we prove Theorem 4.2. For $1 \le j \le M$, let m_j be the number of variables in $\mathbf{x}^{(j)}$. Let $\mathbf{y}^{(j)}$ denote a vector of $m_j - 1$ variables and let Y_j denote a single special variable. Let $\mathbf{T}^{(j)}$ denote a matrix of m_j^2 variables. The intended meaning is that $\mathbf{x}^{(j)} = \mathbf{T}^{(j)}(\mathbf{y}^{(j)} \circ Y_j)$. To be precise, we intend that

$$\mathbf{x}_i^{(j)} = \sum_{s=1}^{m_j - 1} \mathbf{T}_{is}^{(j)} \mathbf{y}_s^{(j)} + \mathbf{T}_{im_j}^{(j)} Y_j \quad \text{for } 1 \le i \le m_j. \tag{6}$$

Let $\mathbf{T} = \cup_{j=1}^{M} \mathbf{T}^{(j)}$, $\mathbf{y} = \cup_{j=1}^{M} \mathbf{y}^{(j)}$, and $\mathbf{Y} = \cup_{j=1}^{M} \{Y_j\}$. Substituting the values of $\mathbf{x}^{(j)}$ into (4), we get

$$g = \sum_{j=1}^{M} h_j(\mathbf{T}^{(j)}, \mathbf{y}^{(j)}, Y_j),$$

where each h_j has degree $2d$. We write h_j in increasing powers of Y_j so that

$$h_j := h_{j0}(\mathbf{T}^{(j)}, \mathbf{y}^{(j)}) + \sum_{l=1}^{2d} h_{jl}(\mathbf{T}^{(j)}, \mathbf{y}^{(j)}) Y_j^l.$$

Therefore

$$g = \sum_{j=1}^{M} h_{j0}(\mathbf{T}^{(j)}, \mathbf{y}^{(j)}) + \sum_{j=1}^{M} \sum_{l=1}^{2d} h_{jl}(\mathbf{T}^{(j)}, \mathbf{y}^{(j)}) Y_j^l.$$

The *splitability certificate* is obtained by replacing powers of Y_j by new variables. To be precise, for every $1 \le j \le M$, $1 \le l \le 2d$, let U_{jl} be a single formal variable and

let $\mathbf{U}$ denote the vector of all such variables. The certificate is the polynomial

$$h(\mathbf{T},\mathbf{y},\mathbf{U}) := \sum_{j=1}^{M} h_{j0}(\mathbf{T}^{(j)},\mathbf{y}^{(j)}) + \sum_{j=1}^{M}\sum_{l=1}^{2d} h_{jl}(\mathbf{T}^{(j)},\mathbf{y}^{(j)})U_{jl}.$$

4.3. Checking the splitability certificate. The checking procedure consists of two parts: first we check that the polynomial h is a linear function of variables $\mathbf{U}$. Then we check that g and h are consistent (this automatically checks that g is indeed splitable).

Checking linearity. Pick values for $\mathbf{T}^{(j)},\mathbf{y}^{(j)}$ at random. Let $\mathbf{U}$, $\mathbf{U}'$ be two sets of values for variables in $\mathbf{U}$ picked at random. Pick a scaler/field value ζ at random. Accept if and only if

$$h(\mathbf{T},\mathbf{y},\zeta\mathbf{U}+(1-\zeta)\mathbf{U}') = \zeta\cdot h(\mathbf{T},\mathbf{y},\mathbf{U}) + (1-\zeta)\cdot h(\mathbf{T},\mathbf{y},\mathbf{U}').$$

Clearly, the test reads 3 values of h. It accepts with probability 1 if h is indeed linear in $\mathbf{U}$ and accepts with negligible probability (i.e., at most $O(\frac{d}{|\mathbb{F}|})$) otherwise.

Checking consistency. Pick values for $\mathbf{T}^{(j)},\mathbf{y}^{(j)}$ and variables Y_j at random. Define $\mathbf{x}^{(j)} = \mathbf{T}^{(j)}(\mathbf{y}^{(j)}\circ Y_j)$. Let $U_{jl} = Y_j^l$. Accept if and only if

$$g(\mathbf{x}) = h(\mathbf{T},\mathbf{y},\mathbf{U}).$$

It is clear that if g is splitable, and h is defined appropriately, then this test accepts with probability 1. So the main task is proving soundness. Assume that g is not splitable. We want to show that the test accepts with negligible probability, no matter what certificate h the adversary gives. Let $\tilde{h}$ be the polynomial given by the adversary. We can assume that it is linear in $\mathbf{U}$ and thus looks like

$$\tilde{h}(\mathbf{T},\mathbf{y},\mathbf{U}) = \tilde{h}_0(\mathbf{T},\mathbf{y}) + \sum_{j=1}^{M}\sum_{l=1}^{2d}\tilde{h}_{jl}(\mathbf{T},\mathbf{y})U_{jl}.$$

For the given polynomial $g[\mathbf{x}]$, let $\tilde{g}(\mathbf{T},\mathbf{y},\mathbf{Y})$ be the polynomial obtained by substituting $\mathbf{x}^{(j)} = \mathbf{T}^{(j)}(\mathbf{y}^{(j)}\circ Y_j)$. The test accepts with negligible probability unless we have a formal identity

$$\tilde{g}(\mathbf{T},\mathbf{y},\mathbf{Y}) = \tilde{h}_0(\mathbf{T},\mathbf{y}) + \sum_{j=1}^{M}\sum_{l=1}^{2d}\tilde{h}_{jl}(\mathbf{T},\mathbf{y})Y_j^l.$$

Now the crucial point is that on the right-hand side (RHS), the powers Y_j^l do not *interfere* with each other. In other words, there is no monomial that involves the product $Y_jY_{j'}$ where $j\neq j'$. On the other hand, if $g[\mathbf{x}]$ is not splitable, then it will have a monomial that involves the product $\mathbf{x}_i^{(j)}\mathbf{x}_{i'}^{(j')}$ for $j\neq j'$. This will give a monomial involving the product $Y_jY_{j'}$ on the left-hand side (LHS), a contradiction!

5. Generalized sum-check protocol. In this section, we describe the generalized sum-check (GSC) protocol. This protocol along with the construction of the splitability certificate (in the previous section) is used to construct the subspace membership certificate in the next section.

The protocol is much more complicated than the usual sum-check protocol that allows us to verify that the sum of values of a polynomial f over the cube $\{0,1\}^m$ equals a target value. We provide the description of the usual sum-check protocol in Appendix E. We recommend reading it before reading the generalized protocol.

Our protocol needs to work for a sum over an arbitrary set of weight-d inputs (inputs in $\{0,1\}^m$ with exactly d coordinates equal to 1). The protocol could be of independent interest.

$GSC(a, \mathbb{F}, \tilde{f}, m, D, d, \mathcal{F}, \{g_{b,r} | b \in \{0,1\}, 0 \le r \le m-1\})$ consists of the following:

1. $\mathbb{F}$ is a field and $a \in \mathbb{F}$ is a *target* value.
2. $\tilde{f} \in \mathbb{F}[\mathbf{x}]$ is a degree D polynomial where $\mathbf{x} = (x_1, x_2, \ldots, x_m)$ is a vector of m formal variables. We are given $\tilde{f}$ as a table of values.
3. $\mathcal{F} \subseteq \binom{m}{d}$, i.e., $\mathcal{F}$ is a family of size d subsets of $[m]$.
4. Every $g_{b,r}$ is a polynomial in $\mathbb{F}[\boldsymbol{\alpha}, \boldsymbol{\theta}, X]$ where $\boldsymbol{\alpha} = (\alpha_1, \ldots, \alpha_m)$, $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_m)$ are vectors of formal variables and X is a single formal variable. The degree of $g_{b,r}$ is $D + d$ and $g_{b,r}$ is guaranteed to depend only on $\alpha_1, \alpha_2, \ldots, \alpha_r$, $\theta_1, \ldots, \theta_r, X$. The polynomials $g_{b,r}$ are given as table of values.

The goal is to verify that

$$a = \sum_{I \in \mathcal{F}} \tilde{f}(\overline{p}_I) \tag{7}$$

by reading a constant number of values of $\tilde{f}$ and of each of the polynomials $g_{b,r}$. The *sum-check polynomials* $g_{b,r}$ are supposed to assist us in verifying that the summation is true. We have the following theorem.

THEOREM 5.1. *There is a protocol (verifier) for*

$$GSC(a, \mathbb{F}, \tilde{f}, m, D, d, \mathcal{F}, \{g_{b,r} | b \in \{0,1\}, 0 \le r \le m-1\})$$

satisfying these properties:

1. *The protocol picks $\boldsymbol{\alpha} \in \mathbb{F}^m$, $\boldsymbol{\theta} \in \mathbb{F}^m$ at random.*
2. *The protocol reads one value of $\tilde{f}$, namely, $\tilde{f}(\boldsymbol{\theta})$. For every $b \in \{0,1\}, 0 \le r \le m-1$, the protocol reads two values of $g_{b,r}$, namely, $g_{b,r}(\boldsymbol{\alpha}, \boldsymbol{\theta}, X = b)$ and $g_{b,r}(\boldsymbol{\alpha}, \boldsymbol{\theta}, X = \theta_{r+1})$.*
3. *The protocol performs a single homogeneous linear test on the target value a and the values read.*
4. *(Completeness.) If $a = \sum_{I \in \mathcal{F}} \tilde{f}(\overline{p}_I)$, then there exists a choice of sum-check polynomials $\{g_{b,r}\}$ such that the protocol accepts with probability 1.*
5. *If $a \neq \sum_{I \in \mathcal{F}} \tilde{f}(\overline{p}_I)$, then no matter what the sum-check polynomials $\{g_{b,r}\}$ are, the protocol accepts with probability at most $O(\frac{D+d}{|\mathbb{F}|})$.*

Before we describe the protocol, let us see what the intended meaning of $g_{b,r}$ is. For a set $I \in \mathcal{F}$, let I_i denote the ith coordinate of its characteristic vector.

For $\boldsymbol{\alpha} \in \mathbb{F}^m, I \in \mathcal{F}, 0 \le s \le m$, let

$$w(I, \boldsymbol{\alpha}, s) := \prod_{1 \le i \le s,\ I_i = 1} \alpha_i.$$

Note that in particular, for $s = 0$, $w(I, \boldsymbol{\alpha}, 0) = 1$. Also, since $|I| = d$, each $w(\cdot, \cdot, \cdot)$ is a monomial of degree at most d.

For $\boldsymbol{\theta} \in \mathbb{F}^m, I \in \mathcal{F}, 0 \le s \le m$, let $p(I, \boldsymbol{\theta}, s) \in \mathbb{F}^m$ be a point whose ith coordinate equals θ_i for $1 \le i \le s$ and equals I_i for $s < i \le m$. In particular, $p(I, \boldsymbol{\theta}, 0) = \overline{p}_I$ and $p(I, \boldsymbol{\theta}, m) = \boldsymbol{\theta}$.

Consider the following *partial sum* for $0 \le r \le m$:

$$S_r := \sum_{I \in \mathcal{F}} w(I, \boldsymbol{\alpha}, r) \tilde{f}(p(I, \boldsymbol{\theta}, r)).$$

In particular,

$$\begin{aligned} S_0 &= \sum_{I \in \mathcal{F}} w(I, \boldsymbol{\alpha}, 0) \tilde{f}(p(I, \boldsymbol{\theta}, 0)) \\ &= \sum_{I \in \mathcal{F}} \tilde{f}(\overline{p}_I). \end{aligned}$$

Thus the goal of the GSC protocol is to verify that $S_0 = a$, where a is the target value. Note that

$$S_m = \left(\sum_{I \in \mathcal{F}} w(I, \boldsymbol{\alpha}, m) \right) \tilde{f}(\boldsymbol{\theta}).$$

Here, the verifier can evaluate the quantity in the summation by himself and the value $\tilde{f}(\boldsymbol{\theta})$ can be read from the table of values of $\tilde{f}$. Thus the verifier *knows* the values S_0 and S_m and thus has to verify that the values $S_1, S_2, \ldots, S_{m-1}$ give a correct *interpolation* between S_0 and S_m.

For $b \in \{0,1\}$ and $1 \le s \le m$, let

$$\mathcal{F}_s^b := \{I \mid I \in \mathcal{F},\ I_s = b\}.$$

Thus $\mathcal{F}_s^0$ is the subfamily of $\mathcal{F}$ consisting of all sets that do not contain $s \in [m]$ and $\mathcal{F}_s^1$ consists of those sets that do contain s.

For $\boldsymbol{\theta} \in \mathbb{F}^m, I \in \mathcal{F}, 1 \le s \le m$, let $P(I, \boldsymbol{\theta}, s, X) \in \mathbb{F}^m$ be a point whose ith coordinate equals θ_i for $1 \le i < s$ and equals I_i for $s < i \le m$, and the sth coordinate is a formal variable X. Note that if $I_{s+1} = b$, then $P(I, \boldsymbol{\theta}, s+1, b) = p(I, \boldsymbol{\theta}, s)$, where $P(I, \boldsymbol{\theta}, s+1, b)$ denotes the point obtained from $P(I, \boldsymbol{\theta}, s+1, X)$ by substituting $X = b$. Also, when one substitutes $X = \theta_{s+1}$, we get $P(I, \boldsymbol{\theta}, s+1, \theta_{s+1}) = p(I, \boldsymbol{\theta}, s+1)$.

With so much notation, we are ready to see what $g_{b,r}$ are. Fix $b \in \{0,1\}$ and $0 \le r \le m-1$. Consider the sum

$$g_{b,r}(\boldsymbol{\alpha}, \boldsymbol{\theta}, X) := \sum_{I \in \mathcal{F}_{r+1}^b} w(I, \boldsymbol{\alpha}, r) \tilde{f}(P(I, \boldsymbol{\theta}, r+1, X)). \tag{8}$$

Note that $g_{b,r}$ is a polynomial in $\boldsymbol{\alpha}, \boldsymbol{\theta}$, and X. The degree in $\boldsymbol{\alpha}$ is at most d and the degree in $\boldsymbol{\theta}, X$ is at most D. Also, $g_{b,r}$ depends only on $\alpha_1, \alpha_2, \ldots, \alpha_r,\ \theta_1, \theta_2, \ldots, \theta_r$, and X.

Here is the link between the partial sums S_r and the polynomials $g_{b,r}$.

LEMMA 5.2.

$$\begin{aligned} &S_r = g_{0,r}(\boldsymbol{\alpha}, \boldsymbol{\theta}, 0) + g_{1,r}(\boldsymbol{\alpha}, \boldsymbol{\theta}, 1), \\ &g_{0,r}(\boldsymbol{\alpha}, \boldsymbol{\theta}, \theta_{r+1}) + \alpha_{r+1} g_{1,r}(\boldsymbol{\alpha}, \boldsymbol{\theta}, \theta_{r+1}) = S_{r+1}. \end{aligned}$$

Proof.

$$\begin{aligned}
S_r &= \sum_{I\in\mathcal{F}} w(I,\boldsymbol{\alpha},r)\tilde{f}(p(I,\boldsymbol{\theta},r)) \\
&= \sum_{I\in\mathcal{F}^0_{r+1}} w(I,\boldsymbol{\alpha},r)\tilde{f}(p(I,\boldsymbol{\theta},r)) + \sum_{I\in\mathcal{F}^1_{r+1}} w(I,\boldsymbol{\alpha},r)\tilde{f}(p(I,\boldsymbol{\theta},r)) \\
&= \sum_{I\in\mathcal{F}^0_{r+1}} w(I,\boldsymbol{\alpha},r)\tilde{f}(P(I,\boldsymbol{\theta},r+1,0)) + \sum_{I\in\mathcal{F}^1_{r+1}} w(I,\boldsymbol{\alpha},r)\tilde{f}(P(I,\boldsymbol{\theta},r+1,1)) \\
&= g_{0,r}(\boldsymbol{\alpha},\boldsymbol{\theta},0) + g_{1,r}(\boldsymbol{\alpha},\boldsymbol{\theta},1).
\end{aligned}$$

On the other hand,

$$\begin{aligned}
&g_{0,r}(\boldsymbol{\alpha},\boldsymbol{\theta},\theta_{r+1}) + \alpha_{r+1}g_{1,r}(\boldsymbol{\alpha},\boldsymbol{\theta},\theta_{r+1}) \\
&= \sum_{I\in\mathcal{F}^0_{r+1}} w(I,\boldsymbol{\alpha},r)\tilde{f}(P(I,\boldsymbol{\theta},r+1,\theta_{r+1})) + \sum_{I\in\mathcal{F}^1_{r+1}} (\alpha_{r+1}w(I,\boldsymbol{\alpha},r))\,\tilde{f}(P(I,\boldsymbol{\theta},r+1,\theta_{r+1})) \\
&= \sum_{I\in\mathcal{F}^0_{r+1}} w(I,\boldsymbol{\alpha},r+1)\tilde{f}(p(I,\boldsymbol{\theta},r+1)) + \sum_{I\in\mathcal{F}^1_{r+1}} w(I,\boldsymbol{\alpha},r+1)\tilde{f}(p(I,\boldsymbol{\theta},r+1)) \\
&= \sum_{I\in\mathcal{F}} w(I,\boldsymbol{\alpha},r+1)\tilde{f}(p(I,\boldsymbol{\theta},r+1)) \\
&= S_{r+1}. \qquad \square
\end{aligned}$$

COROLLARY 5.3.

$$g_{0,r}(\boldsymbol{\alpha},\boldsymbol{\theta},\theta_{r+1}) + \alpha_{r+1}g_{1,r}(\boldsymbol{\alpha},\boldsymbol{\theta},\theta_{r+1}) = g_{0,r+1}(\boldsymbol{\alpha},\boldsymbol{\theta},0) + g_{1,r+1}(\boldsymbol{\alpha},\boldsymbol{\theta},1).$$

5.1. The GSC protocol. The protocol works as follows. The protocol accepts if and only if all of the following checks are satisfied (we later combine these checks into a single homogeneous linear test):

- Pick $\boldsymbol{\alpha},\boldsymbol{\theta}\in\mathbb{F}^m$ at random.
- (Stage 0:) Check if

$$a = g_{0,0}(\boldsymbol{\alpha},\boldsymbol{\theta},0) + g_{1,0}(\boldsymbol{\alpha},\boldsymbol{\theta},1). \tag{9}$$

- (Stage $r+1$ for $r=0,1,\ldots,m-2$:) Check if

$$g_{0,r}(\boldsymbol{\alpha},\boldsymbol{\theta},\theta_{r+1}) + \alpha_{r+1}g_{1,r}(\boldsymbol{\alpha},\boldsymbol{\theta},\theta_{r+1}) = g_{0,r+1}(\boldsymbol{\alpha},\boldsymbol{\theta},0) + g_{1,r+1}(\boldsymbol{\alpha},\boldsymbol{\theta},1). \tag{10}$$

- (Stage m:) Check if

$$g_{0,m-1}(\boldsymbol{\alpha},\boldsymbol{\theta},\theta_m) + \alpha_m g_{1,m-1}(\boldsymbol{\alpha},\boldsymbol{\theta},\theta_m) = \left(\sum_{I\in\mathcal{F}} w(I,\boldsymbol{\alpha},m)\right)\tilde{f}(\boldsymbol{\theta}). \tag{11}$$

Note that the values on lines (9), (10), (11) are (supposed to be) S_0, S_{r+1}, S_m, respectively.

5.2. Completeness.

LEMMA 5.4. *If the polynomial $\tilde{f}$ satisfies* (7)*, then it is possible to define polynomials $g_{b,r}(\boldsymbol{\alpha},\boldsymbol{\theta},X)$ so that the protocol accepts with probability* 1.

Proof. The proof is obvious. Just define $g_{b,r}$ as they are supposed to be as in (8). $\square$

5.3. Soundness.

LEMMA 5.5. *If the polynomial $\tilde{f}$ does not satisfy* (7)*, then no matter what polynomials $g_{b,r}$ one takes, the protocol accepts with negligible probability, i.e., with probability at most $O(\frac{D+d}{|\mathbb{F}|})$. It is assumed that the polynomials $g_{b,r}$ have degree at most $D+d$ and $g_{b,r}$ depends only on $\alpha_1,\ldots,\alpha_r$, $\theta_1,\ldots,\theta_r$, and X.*

Proof. Let $\tilde{g}_{b,r}$ be polynomials obtained from $\tilde{f}$ using rule (8). We will argue in reverse order (i.e., $r = m-1, m-2, \ldots, 0$) that unless $g_{b,r} \equiv \tilde{g}_{b,r}$, the protocol succeeds with negligible probability. The only fact we use is that two polynomials agree with nonnegligible probability if and only if they are identical as formal polynomials.

(*Case* $r = m-1$.) Look at Stage m, equation (11). The RHS is just S_m, which, using Lemma 5.2, can be written in terms of $\tilde{g}_{0,m-1}$ and $\tilde{g}_{1,m-1}$. Thus we get

$$g_{0,m-1}(\boldsymbol{\alpha},\boldsymbol{\theta},\theta_m) + \alpha_m g_{1,m-1}(\boldsymbol{\alpha},\boldsymbol{\theta},\theta_m) = \tilde{g}_{0,m-1}(\boldsymbol{\alpha},\boldsymbol{\theta},\theta_m) + \alpha_m \tilde{g}_{1,m-1}(\boldsymbol{\alpha},\boldsymbol{\theta},\theta_m).$$

Note that $g_{0,m-1}, g_{1,m-1}, \tilde{g}_{0,m-1}, \tilde{g}_{1,m-1}$ do not depend on α_m, θ_m. Therefore, if this is a formal identity, then we must have $g_{0,m-1} = \tilde{g}_{0,m-1}$ and $g_{1,m-1} = \tilde{g}_{1,m-1}$.

(*Case* $0 \le r \le m-2$.) Assume that we have already proved that $g_{0,r+1} = \tilde{g}_{0,r+1}$ and $g_{1,r+1} = \tilde{g}_{1,r+1}$. Therefore, the RHS of (10) is

$$\begin{aligned} g_{0,r+1}(\boldsymbol{\alpha},\boldsymbol{\theta},0) + g_{1,r+1}(\boldsymbol{\alpha},\boldsymbol{\theta},1) &= \tilde{g}_{0,r+1}(\boldsymbol{\alpha},\boldsymbol{\theta},0) + \tilde{g}_{1,r+1}(\boldsymbol{\alpha},\boldsymbol{\theta},1) \\ &= \tilde{g}_{0,r}(\boldsymbol{\alpha},\boldsymbol{\theta},\theta_{r+1}) + \alpha_{r+1}\tilde{g}_{1,r}(\boldsymbol{\alpha},\boldsymbol{\theta},\theta_{r+1}), \end{aligned}$$

where we used Corollary 5.3. Now we equate this with the LHS of (10) and note that $g_{0,r}, g_{1,r}, \tilde{g}_{0,r}, \tilde{g}_{1,r}$ do not depend on $\alpha_{r+1}, \theta_{r+1}$. Hence we conclude that $g_{0,r} = \tilde{g}_{0,r}$ and $g_{1,r} = \tilde{g}_{1,r}$

Now we show that the test fails at Stage 0. This is because, $g_{0,0} = \tilde{g}_{0,0}, g_{1,0} = \tilde{g}_{1,0}$ and

$$\begin{aligned} a &\neq \sum_{I\in\mathcal{F}} \tilde{f}(\overline{p}_I) \\ &= \tilde{g}_{0,0}(\boldsymbol{\alpha},\boldsymbol{\theta},0) + \tilde{g}_{1,0}(\boldsymbol{\alpha},\boldsymbol{\theta},1) \\ &= g_{0,0}(\boldsymbol{\alpha},\boldsymbol{\theta},0) + g_{1,0}(\boldsymbol{\alpha},\boldsymbol{\theta},1). \qquad \square \end{aligned}$$

5.4. Combining all tests into a single homogeneous test. Instead of verifying (9), (10), and (11) separately, the protocol can multiply these equations with random values in $\mathbb{F}$, add them up, and verify that the single combined equation is satisfied. It is easily seen that the completeness and soundness properties are still satisfied.

6. Constructing subspace membership certificate. Now we return to the task we started with. We want polynomials g and h that certify that the polynomial f in section 3.1 satisfies (3). The equation says that $f(\mathbf{q})$ equals a sum of values of $\psi(\mathbf{q},\cdot)f(\cdot)$. We verify this by running the generalized sum-check protocol on $\psi(\mathbf{q},\cdot)f(\cdot)$. The polynomial g will be obtained by *clubbing together* all the sum-check polynomials. The polynomial h will certify that g is splitable, a property that makes sure that the sum-check protocol works (as explained below).

We want to verify (3) for a random $\mathbf{q}$. Let $\tilde{f}[\mathbf{q},\mathbf{x}] = \psi(\mathbf{q},\mathbf{x})f(\mathbf{x})$ and $a = f(\mathbf{q})$. Thus we can run the protocol

$$GSC(a = f(\mathbf{q}), \mathbb{F}, \tilde{f}, m, D = 3d, d, \mathcal{F}, \{g_{b,r} | b \in \{0,1\}, 0 \le r \le m-1\}).$$

Here, $\tilde{f}$ is a polynomial in $\mathbf{q}, \mathbf{x}$, but the sum-check protocol is run on the $\mathbf{x}$ part only. Usually, the sum-check polynomials $g_{b,r}$ are polynomials in $\boldsymbol{\alpha}, \boldsymbol{\theta}, X$. But now, examining rule (8), they are polynomials also in $\mathbf{q}$. Since $g_{b,r}$ is polynomial of degree $D+d$, we can write it in increasing powers of X as

$$g_{b,r}(\mathbf{q}, \boldsymbol{\alpha}, \boldsymbol{\theta}, X) := \sum_{t=0}^{D+d} g_{b,r,t}(\mathbf{q}, \boldsymbol{\alpha}, \boldsymbol{\theta}) X^t,$$

where $g_{b,r,t}$ are polynomials in $\mathbf{q}, \alpha_1, \ldots, \alpha_r, \theta_1, \ldots, \theta_r$.

The GSC protocol (section 5.1) needs values $a = f(\mathbf{q})$ and $\tilde{f}(\mathbf{q}, \boldsymbol{\theta})$. The protocol reads values $f(\mathbf{q})$ and $f(\boldsymbol{\theta})$ from the table of values of f. The value $\tilde{f}(\mathbf{q}, \boldsymbol{\theta}) = \psi(\mathbf{q}, \boldsymbol{\theta}) f(\boldsymbol{\theta})$ is computed from the value $f(\boldsymbol{\theta})$ and by using (2). In addition, the protocol needs the value of some homogeneous linear form on the values:

$$g_{b,r,t}(\mathbf{q}, \boldsymbol{\alpha}, \boldsymbol{\theta}) \;\; b \in \{0,1\},\; 0 \le r \le m-1,\; 0 \le t \le D+d.$$

However, we can afford only a constant number of queries. So reading all these values separately is ruled out. We do the following trick: we just *read off* the value of the linear form as a single query. This can be done if we have access to the Hadamard code over the polynomials $g_{b,r,t}$. This is exactly what the *certificate polynomial* g will do. As a first attempt (which does not work), we expect to have the following polynomial g^* as a certificate that enables us to read off the linear form. Let $R_{b,r,t}$ be formal variables and let $\mathbf{R}$ denote the vector of all these variables. The polynomial g^* is intended to be

$$g^*(\mathbf{q}, \boldsymbol{\alpha}, \boldsymbol{\theta}, \mathbf{R}) := \sum_{b,r,t} g_{b,r,t}(\mathbf{q}, \boldsymbol{\alpha}, \boldsymbol{\theta}) R_{b,r,t}. \tag{12}$$

We are not quite done yet. How do we ensure that the supposed polynomial g^* given by an adversary is of the form (12)? First of all, note that g^* is intended to be a linear function when treated as a function of $\mathbf{R}$. This can be checked by substituting random values of $\mathbf{q}, \boldsymbol{\alpha}, \boldsymbol{\theta}$ and then using a linearity test. Assuming now that g^* is indeed a linear function of $\mathbf{R}$, let $g^*_{b,r,t}$ denote the coefficient of $R_{b,r,t}$.

The problem is the following: how do we ensure that $g^*_{b,r,t}$ depends only on $\mathbf{q}, \alpha_1, \ldots, \alpha_r, \theta_1, \ldots, \theta_r$ and is independent of $\alpha_{r+1}, \ldots, \alpha_m$, $\theta_{r+1}, \ldots, \theta_m$? This property is necessary for the GSC protocol to work.

In order to fix this problem, we need to redefine the polynomial g^*. We give a *fresh copy* of variables to every polynomial $g_{b,r,t}$. To be precise, for any (b,r,t), let $\mathbf{q}^{(b,r,t)}$ denote a vector of m variables which is supposed to be a *copy* of $\mathbf{q}$. Also, let $\boldsymbol{\alpha}^{(b,r,t)}$ denote a copy of $\alpha_1, \ldots, \alpha_r$ and let $\boldsymbol{\theta}^{(b,r,t)}$ denote a copy of $\theta_1, \ldots, \theta_r$.

Let

$$\mathbf{q}' = \cup_{b,r,t} \mathbf{q}^{(b,r,t)}, \quad \boldsymbol{\alpha}' = \cup_{b,r,t} \boldsymbol{\alpha}^{(b,r,t)}, \quad \boldsymbol{\theta}' = \cup_{b,r,t} \boldsymbol{\theta}^{(b,r,t)}, \quad \mathbf{R} = \cup_{b,r,t} \{R_{b,r,t}\}. \tag{13}$$

Define

$$g(\mathbf{q}', \boldsymbol{\alpha}', \boldsymbol{\theta}', \mathbf{R}) := \sum_{b,r,t} g_{b,r,t}(\mathbf{q}^{(b,r,t)}, \boldsymbol{\alpha}^{(b,r,t)}, \boldsymbol{\theta}^{(b,r,t)}) R_{b,r,t}. \tag{14}$$

Note that g is splitable. The sets of variables on which $g_{b,r,t}$'s depend are disjoint for different (b,r,t)'s. Now we can attach a splitability certificate h to make sure that an adversary is forced to give a g that is splitable!

6.1. Proving Theorem 3.4. Now we prove Theorem 3.4. First we prove a version of the theorem where instead of a single polynomial f in the HomAlgCSP instance we have three polynomials f, g, h and the constraints are homogeneous constraints on $O(1)$ values of these polynomials.

Given tables of values of polynomials $f(\mathbf{q})$ and $g(\mathbf{q}', \boldsymbol{\alpha}', \boldsymbol{\theta}', \mathbf{R})$ and a splitability certificate h, we run the following verification procedure.

Checking that g is linear in $\mathbf{R}$. Pick random values for $\mathbf{q}', \boldsymbol{\alpha}', \boldsymbol{\theta}'$ and two sets of random values for $\mathbf{R}$ and $\mathbf{R}'$. Pick two random scalar/field values ζ, ζ' and check if

$$g(\mathbf{q}', \boldsymbol{\alpha}', \boldsymbol{\theta}', \zeta\mathbf{R} + \zeta'\mathbf{R}') = \zeta \cdot g(\mathbf{q}', \boldsymbol{\alpha}', \boldsymbol{\theta}', \mathbf{R}) + \zeta' \cdot g(\mathbf{q}', \boldsymbol{\alpha}', \boldsymbol{\theta}', \mathbf{R}').$$

Checking that h is a splitability certificate. This can be done as in section 4.3 by reading one value of g and four values of h.

Running the GSC protocol. Pick random values for $\mathbf{q}, \boldsymbol{\alpha}, \boldsymbol{\theta}$. The values $f(\mathbf{q}), f(\boldsymbol{\theta})$ needed by the protocol are read from the table of values for f. The protocol also needs a value of a linear form of type

$$\sum_{b,r,t} \zeta_{b,r,t}\ g_{b,r,t}(\mathbf{q}, \boldsymbol{\alpha}, \boldsymbol{\theta}), \qquad \zeta_{b,r,t} \in \mathbb{F}. \tag{15}$$

For all (b, r, t), we set $\mathbf{q}^{(b,r,t)} = \mathbf{q}$, $\boldsymbol{\alpha}^{(b,r,t)} = (\alpha_1, \alpha_2, \ldots, \alpha_r)$, $\boldsymbol{\theta}^{(b,r,t)} = (\theta_1, \theta_2, \ldots, \theta_r)$ (this makes sense because $\mathbf{q}^{(b,r,t)}, \boldsymbol{\alpha}^{(b,r,t)}, \boldsymbol{\theta}^{(b,r,t)}$ are supposed to be copies of the same $\mathbf{q}, \boldsymbol{\alpha}, \boldsymbol{\theta}$, respectively). Set $\mathbf{R}_{b,r,t} = \zeta_{b,rt}$. Define $\mathbf{q}', \boldsymbol{\alpha}', \boldsymbol{\theta}', \mathbf{R}$ as in (13).

Finally, take the value of the linear form in (15) needed by the protocol to be the value $g(\mathbf{q}', \boldsymbol{\alpha}', \boldsymbol{\theta}', \mathbf{R})$.

Checking that f is a solution to the MDC instance. Pick a random point from set $\{\overline{p}_J \mid J \in \mathcal{F}_0\}$ and check whether $f(\overline{p}_J) = 0$.

Number of queries. Note that the verification procedure reads three values of f (namely, $f(\overline{p}_J), f(\mathbf{q}), f(\boldsymbol{\theta})$). It reads five values of g (three for checking linearity in $\mathbf{R}$, one for checking splitability, one for reading linear form needed in sum-check). It reads four values of h (as in splitability check). Thus we have a total of 12 queries.

Relating the optimum of MDC with the maximum acceptance probability. It is clear that if the MDC instance $\mathbf{A}$ has a solution with value $OPT(\mathbf{A})$, then we can take this solution, encode it as a nonzero polynomial f, and construct g, h as they should be. The verification procedure accepts whenever $f(\overline{p}_J) = 0$, which happens with probability $1 - OPT(\mathbf{A})$.

On the other hand, note that the verification process accepts with negligible probability unless $f \in span\{f_I | I \in \mathcal{F}\}$. If $f \equiv 0$, then the corresponding polynomials g, h must also be identically zero (otherwise probability of acceptance is negligible). Now if f is a nonzero polynomial in the span, we can have $f(\overline{p}_J) = 0$ only for $1 - OPT(\mathbf{A})$ fraction of $J \in \mathcal{F}_0$. Hence the verification procedure can accept with probability at most $\max\{1 - OPT(\mathbf{A}), O(\frac{d}{|\mathbb{F}|})\}$.

6.2. Clubbing together f, g, h. Now we show how to combine f, g, h into a single polynomial ϕ and thus prove Theorem 3.4. Assume that $f \in \mathbb{F}[\mathbf{x}]$, $g \in \mathbb{F}[\mathbf{y}]$, $h \in \mathbb{F}[\mathbf{z}]$, where $\mathbf{x}, \mathbf{y}, \mathbf{z}$ are disjoint sets of variables. Let X, Y, Z be formal variables and let ϕ (as intended to) be

$$\phi(\mathbf{x}, \mathbf{y}, \mathbf{z}, X, Y, Z) := Xf(\mathbf{x}) + Yg(\mathbf{y}) + Zh(\mathbf{z}).$$

Again the trouble is that the adversary might give an arbitrary polynomial ϕ and not necessarily of this form. We give the following verification procedure.

Checking linearity in X, Y, Z. Pick random values for $\mathbf{x}, \mathbf{y}, \mathbf{z}$ and random values X, X', Y, Y', Z, Z'. Pick random values ζ, ζ'. Check if

$$\phi(\mathbf{x}, \mathbf{y}, \mathbf{z}, \zeta X + \zeta' X', \zeta Y + \zeta' Y', \zeta Z + \zeta' Z') = \zeta \cdot \phi(\mathbf{x}, \mathbf{y}, \mathbf{z}, X, Y, Z) + \zeta' \cdot \phi(\mathbf{x}, \mathbf{y}, \mathbf{z}, X', Y', Z').$$

Checking splitability. Thus we can assume that ϕ is linear and hence of the form $X\tilde{f} + Y\tilde{g} + Z\tilde{h}$. We need to ensure that $\tilde{f}$ depends only on $\mathbf{x}$ and not on $\mathbf{y}, \mathbf{z}$, and also that $\tilde{g}$ depends only on $\mathbf{y}$ and $\tilde{h}$ depends only on $\mathbf{z}$. This can be done by *brute force* as follows. Note that setting $X = 1, Y = 0, Z = 0$ gives us *access* to $\tilde{f}$ and similarly for $\tilde{g}, \tilde{h}$.

- Pick random values $\mathbf{x}, \mathbf{y}, \mathbf{z}$. Pick another set of random values $\mathbf{x}', \mathbf{y}', \mathbf{z}'$.
- Check that

$$\phi(\mathbf{x}, \mathbf{y}, \mathbf{z}, 1, 0, 0) = \phi(\mathbf{x}, \mathbf{y}', \mathbf{z}', 1, 0, 0),$$
$$\phi(\mathbf{x}, \mathbf{y}, \mathbf{z}, 0, 1, 0) = \phi(\mathbf{x}', \mathbf{y}, \mathbf{z}', 0, 1, 0),$$
$$\phi(\mathbf{x}, \mathbf{y}, \mathbf{z}, 0, 0, 1) = \phi(\mathbf{x}', \mathbf{y}', \mathbf{z}, 0, 0, 1).$$

Simulating the previous verification procedure. Now we can assume that ϕ is of the form $Xf(\mathbf{x}) + Yg(\mathbf{y}) + Zh(\mathbf{z})$. We run the verification procedure described in section 6.1. Values for $f[\mathbf{x}], g[\mathbf{y}], h[\mathbf{z}]$ can be accessed by reading $\phi(\mathbf{x}, \mathbf{0}, \mathbf{0}, 1, 0, 0)$, $\phi(\mathbf{0}, \mathbf{y}, \mathbf{0}, 0, 1, 0)$, and $\phi(\mathbf{0}, \mathbf{0}, \mathbf{z}, 0, 0, 1)$, respectively.

Note that the new protocol reads $3 + 6 + 12 = 21$ queries from table of values of ϕ. The maximum probability of acceptance (for any nonzero polynomial ϕ) equals $1 - OPT(\mathbf{A})$, where $\mathbf{A}$ is the MDC instance one starts with. The constraints are all homogeneous linear. This proves Theorem 3.4.

7. The LDT and outer verifier. In this section, we describe our outer verifier. Later we modify the outer verifier and build a Hadamard code–based inner verifier. This gives a quasi-random PCP.

The starting point for the outer verifier is the gap-instance of HomAlgCSP obtained by combining Theorems 1.5 and 3.4. Let $\mathcal{A}(f, k, d^*, m, \mathbb{F}, \mathcal{C})$ denote this HomAlgCSP instance. We have either

$$OPT(\mathcal{A}) \geq 1 - 1/2^K \qquad \text{or} \qquad OPT(\mathcal{A}) \leq 1/2^{2^K}.$$

Remark 7.1. It is helpful to keep in mind the quantitative parameters. If the size of the SAT instance is n, then the size of the MDC instance is $N \leq n^{CK}$, and $N \leq |\mathbb{F}| \leq N^2$, $m = N^\epsilon$, $d^* = 100/\epsilon$. In particular, the degree d^* is constant. The size of the HomAlgCSP instance is $|\mathbb{F}|^{O(m)} \leq 2^{O(N^\epsilon)}$.

The outer verifier is given the polynomial f as a table of values. He wants to pick a random constraint $C(\{\overline{p}_i\}_{i=1}^k) \in \mathcal{C}$ and check that it is satisfied. However, an adversary could cheat by giving a table which is *not* a low degree polynomial. The *LDT* allows the verifier to guard against such cheating. The LDT was first proposed by Rubinfeld and Sudan [35] and has been a crucial ingredient in the proof of the PCP theorem (see [4], [7]).

7.1. Outer verifier.

DEFINITION 7.2. *A line ℓ in $\mathbb{F}^m$ is a linear function $\ell : \mathbb{F} \mapsto \mathbb{F}^m$. In other words, for some $\overline{a}, \overline{b} \in \mathbb{F}^m$,*

$$\ell(t) = \overline{a} + \overline{b}t.$$

DEFINITION 7.3. *A curve L in $\mathbb{F}^m$ is a function $L : \mathbb{F} \mapsto \mathbb{F}^m$. In other words*

$$L(t) = \overline{a}(t) = (a_1(t), a_2(t), \ldots, a_m(t)).$$

It is a degree d curve if each of the coordinate functions $a_i(t)$ is a degree d (univariate) polynomial.

We fix a constraint $C(\{\overline{p_i}\}_{i=1}^k) \in \mathcal{C}$ for this section and the next.

Let $t_1, t_2, \ldots, t_{k+3}$ be fixed distinct field elements in $\mathbb{F}$. For $\overline{a}, \overline{b}, \overline{c} \in \mathbb{F}^m$, let $L = L_{\overline{a},\overline{b},\overline{c}}$ be the unique degree $k+2$ curve that passes through points $\{\overline{p}_i\}_{i=1}^k, \overline{a}, \overline{b}, \overline{c}$. More precisely,

$$L(t_i) = \overline{p}_i,\ 1 \le i \le k, \quad L(t_{k+1}) = \overline{a},\ L(t_{k+2}) = \overline{b},\ L(t_{k+3}) = \overline{c}. \tag{16}$$

If f is a degree d^* polynomial, then its restriction to the curve $L = L_{\overline{a},\overline{b},\overline{c}}$ is a degree $d - 1 := (k+2)d^*$ univariate polynomial. Call this polynomial $f|_L$. In particular, $f|_L$ can be *reconstructed* from *any* d values of f on the curve. The outer verifier does precisely this. He picks $d+1$ random points from the curve, say $\overline{v}_1, \overline{v}_2, \ldots, \overline{v}_d, \overline{v}$. He reconstructs $f|_L$ using values of f at first d points, and verifies that the value of $f|_L$ at point $\overline{v}$ is the same as the value $f(\overline{v})$. In addition, *knowing* $f|_L$, the verifier *calculates* the values of f at points $\{\overline{p}_i\}_{i=1}^k$ and verifies that these values indeed satisfy the constraint C.

However, we need to combine the above task with the line-point LDT. We will use the strong analysis of LDT by Arora and Safra [4]. The outer verifier becomes somewhat complicated. Note that restriction of f to a line is a degree d^* univariate polynomial. We will be generous and allow the degree to be $d - 2$.

The verifier picks a random pair of a line ℓ and a curve L intersecting at a point $\overline{v}$. The univariate polynomials $f|_L$ and $f|_\ell$ are reconstructed by reading values of f at d random points on L and $d-1$ random points on ℓ, respectively. Then the verifier checks that $f|_L$ and $f|_\ell$ both have the value $f(\overline{v})$ at point $\overline{v}$. In addition, the verifier checks that values of $f|_L$ at points $\{\overline{p}_i\}_{i=1}^k$ satisfy the constraint C.

To prove the correctness of the outer verifier, we need to be careful about how the intersecting line-curve pair is chosen. Formally, the action of the verifier is as follows (see Figure 2).

OUTER VERIFIER.

1. Pick a random line ℓ and pick random points $\overline{v}_1, \ldots, \overline{v}_{d-1}, \overline{v}_d$ on the line (assume that these points are all distinct; this happens w.h.p.). Let $\overline{v} = \overline{v_d}$.
2. Pick $t \in \mathbb{F} \setminus \{t_1, \ldots, t_{k+3}\}$ at random, pick points $\overline{a}, \overline{b}$ at random, and let L be the unique degree $k+2$ curve $L = L_{\overline{a},\overline{b},\overline{c}}$ such that

$$L(t_i) = \overline{p}_i, 1 \le i \le k, \quad L(t_{k+1}) = \overline{a}, \quad L(t_{k+2}) = \overline{b}, \quad L(t) = \overline{v}$$

   (and $\overline{c} = L(t_{k+3})$ gets defined automatically).
3. Pick random points $\overline{v}_{d+1}, \ldots, \overline{v}_{2d}$ on curve L (we assume that these points are distinct; this happens w.h.p.).
4. Read the values $f(\overline{v}_i)$ for $1 \le i \le 2d$.
5. Let $f|_\ell$ be the unique degree $d-2$ polynomial *interpolated* using the values $\{f(\overline{v}_i)\}_{i=1}^{d-1}$.
6. Let $f|_L$ be the unique degree $d-1$ polynomial *interpolated* using the values $\{f(\overline{v}_i)\}_{i=d+1}^{2d}$.
7. Check if

$$f|_L(\overline{v}) = f(\overline{v}) = f|_\ell(\overline{v}).$$

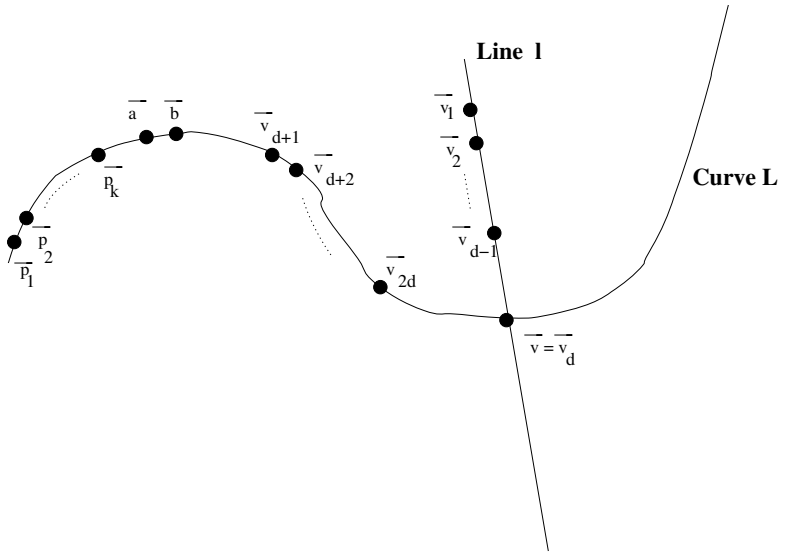

FIG. 2. *Outer verifier.*

8. Check if the values of $f|_L$ at points $\{\overline{p}_i\}_{i=1}^{k}$ satisfy the constraint C.
9. Check that not all the values read are zero, i.e., Not-All-Zero$(f(\overline{v}_i), 1 \le i \le 2d)$.

Remark 7.4. Note that the polynomials $f|_\ell$ and $f|_L$ depend on the specific choice of points $\{\overline{v}_i\}_{i=1}^{d-1}$ and $\{\overline{v}_i\}_{i=d+1}^{2d}$, respectively (i.e., these are the interpolated polynomials). We hide this fact for notational convenience. Also, a main step in the proof of Theorem 7.6 is to get rid of this dependence.

Remark 7.5. The verifier's action is straightforward except for the last step, where he checks that not all values read are zero. This is needed to make sure that the adversary does not cheat by giving a function f that is identically zero.

Given a table $f : \mathbb{F}^m \mapsto \mathbb{F}$ and an m-variate polynomial P, the *agreement* between f and P is defined to be the fraction of points $\overline{u} \in \mathbb{F}^m$ such that $f(\overline{u}) = P(\overline{u})$. Now we state the main theorem in this section. Its proof appears in the next section.

THEOREM 7.6. *There are constants c_2, c_3 such that the following holds: Let $P_1, P_2, \ldots, P_t$ be all degree d polynomials that have agreement at least $(\delta/2)^{c_2}/c_3$ with f. Then if the outer verifier accepts with probability δ, then for some $1 \le j \le t$, the polynomial P_j is a nonzero polynomial and its values at points $\{\overline{p}_i\}_{i=1}^{k}$ satisfy the constraint C. Also, $t \le 2c_3/(\delta/2)^{c_2}$.*

A crucial ingredient in the proof of Theorem 7.6 is the strong analysis of the LDT as in Arora and Sudan's paper [5] (analysis of Raz and Safra [34] could be applied as well). Let f_{lines} be a table which gives, for every line ℓ, a univariate polynomial of degree d, denoted by $f_{lines}(\ell)$.

The following theorem states the result of Arora and Sudan [5] (Theorem 3 and Proposition 2 therein). In our application, d is constant and $|\mathbb{F}|$ is a large polynomial in m (recall that $N \le |\mathbb{F}|$ and $m = N^\epsilon$, where N is the size of the MDC instance used by our reduction).

THEOREM 7.7. *There are constants c_0, c_1, c_2, c_3 such that the following holds: Let δ, d, m be parameters and let $\mathbb{F}$ be a field satisfying $|\mathbb{F}| \ge c_0(dm/\delta)^{c_1}$. Fix tables $f : \mathbb{F}^m \mapsto \mathbb{F}$ and f_{lines}. Let $\{P_1, P_2, \ldots, P_t\}$ be all degree d polynomials that have*

agreement at least δ^{c_2}/c_3 with f. Let a point $\overline{v} \in \mathbb{F}^m$ and a line ℓ passing through $\overline{v}$ be picked at random. Then

$$\Pr_{\overline{v},\ell}\left[f(\overline{v}) \notin \{P_1(\overline{v}), \ldots, P_t(\overline{v})\} \quad \textit{and} \quad f_{lines}(\ell)(\overline{v}) = f(\overline{v})\ \right] \ \leq \ \delta.$$

8. Proof of Theorem 7.6. In this section, we prove Theorem 7.6. Before applying Theorem 7.7, we need to go through a rather long sequence of arguments.

We first observe that there are two equivalent ways in which the outer verifier can make his probabilistic choices. The first way is as in steps (1)–(3). An alternate way is as follows:

- Pick $\overline{a}, \overline{b}, \overline{c}$ at random and let $L = L_{\overline{a},\overline{b},\overline{c}}$ be the curve as in (16). Pick random points $\overline{v}_{d+1}, \ldots, \overline{v}_{2d}$ on L.
- Pick a random point $\overline{v} = L(t), t \in \mathbb{F} \setminus \{t_1, \ldots, t_{k+3}\}$, on the curve. Let $\overline{v}_d = \overline{v}$.
- Pick a random line ℓ through $\overline{v}$ and pick random points $\overline{v}_1, \ldots, \overline{v}_{d-1}$ on line ℓ.

Let NZ be the event that not all values read by the verifier are zero. Let SAT^C be the event that the values of the polynomial $f|_L$ at points $\{\overline{p}_i\}_{i=1}^k$ satisfy the constraint C. The probability of acceptance of the outer verifier is

$$\Pr\left[f|_L(\overline{v}) = f(\overline{v}) = f|_\ell(\overline{v}), \quad NZ, \quad SAT^C\right]. \tag{17}$$

We will construct two new verifiers $\mathcal{V}$ and $\tilde{\mathcal{V}}$ whose acceptance probability is at least equal to the acceptance probability of the outer verifier. We finish the proof by analyzing the verifier $\tilde{\mathcal{V}}$.

8.1. Constructing verifiers $\mathcal{V}$ and $\tilde{\mathcal{V}}$. We construct a table f_{lines} that gives a single univariate polynomial of degree $d-2$ (call it $f_{lines}(\ell)$) for every line ℓ. Then we show that the probability of acceptance of the following verifier (call it $\mathcal{V}$) is at least equal to the probability of acceptance of the outer verifier: the verifier $\mathcal{V}$, instead of reconstructing $f|_\ell$ from the values $\{f(\overline{v}_i)\}_{i=1}^{d-1}$, directly uses the polynomial $f_{lines}(\ell)$. Also, instead of checking for the event NZ, it checks that not all of these are zero: the polynomial $f_{lines}(\ell)$ and the values $f(\overline{v})$, $\{f(\overline{v}_i)\}_{i=d+1}^{2d}$. Let NZ' denote this event.

It is easy to construct f_{lines}. Think of the verifier's probabilistic choices in this order: $\ell, \{\overline{v}_i\}_{i=1}^{d-1}$, $\overline{v}, L, \{\overline{v}_i\}_{i=d+1}^{2d}$. For any line ℓ, fix a choice of $\{\overline{v}_i\}_{i=1}^{d-1}$ so as to maximize the probability in (17). Define $f_{lines}(\ell)$ to be the polynomial obtained by interpolating from this *optimal* choice of $\{\overline{v}_i\}_{i=1}^{d-1}$. Thus probability of acceptance of $\mathcal{V}$ is

$$\Pr\left[f|_L(\overline{v}) = f(\overline{v}) = f_{lines}(\ell)(\overline{v}), \quad NZ', \quad SAT^C\right]. \tag{18}$$

Now we do a similar trick again. We construct a table f_{curves} that gives a single univariate polynomial of degree $d-1$ (call it $f_{curves}(L)$) for every curve L. Then we show that the probability of acceptance of the following verifier (call it $\tilde{\mathcal{V}}$) is at least equal to the probability of acceptance of $\mathcal{V}$: this verifier $\tilde{\mathcal{V}}$, instead of reconstructing $f|_L$ from the values $\{f(\overline{v}_i)\}_{i=d+1}^{2d}$, directly uses the polynomial $f_{curves}(L)$. Also, instead of checking for the event NZ', it checks that not all of these are zero: the polynomial $f_{lines}(\ell)$, the value $f(\overline{v})$, and the polynomial $f_{curves}(L)$. Let NZ'' denote this event.

It is again easy to construct f_{curves}. Think of the verifier's probabilistic choices in the alternative (but equivalent) order: $L, \{\overline{v}_i\}_{i=d+1}^{2d}, \overline{v}, \ell, \{\overline{v}_i\}_{i=1}^{d-1}$. For any curve L, fix a choice of $\{\overline{v}_i\}_{i=d+1}^{2d}$ so as to maximize the probability in (18). Define $f_{curves}(L)$

to be the polynomial obtained by interpolating from this *optimal* choice of $\{\overline{v}_i\}_{i=d+1}^{2d}$. Thus probability of acceptance of $\tilde{\mathcal{V}}$ is

$$\Pr\left[f_{curves}(L)(\overline{v}) = f(\overline{v}) = f_{lines}(\ell)(\overline{v}), \quad NZ'', \quad SAT^C\right].$$

If the outer verifier accepts with probability δ, then we have

$$\Pr\left[f_{curves}(L)(\overline{v}) = f(\overline{v}) = f_{lines}(\ell)(\overline{v}), \quad NZ'', \quad SAT^C\right] \geq \delta. \tag{19}$$

We observe that unless $f_{curves}(L) \neq 0$, the above probability is negligible. This is because if $f_{curves}(L) = 0$, one would have $0 = f(\overline{v}) = f_{lines}(\ell)(\overline{v})$ and $NZ'' \implies f_{lines}(\ell) \neq 0$. Since $\overline{v}$ is a random point on line ℓ, this can happen only with negligible probability.

Thus we can replace the condition NZ'' by the (more stringent) condition $f_{curves}(L) \neq 0$ without decreasing the above probability much. To be precise,

$$\Pr\left[f_{curves}(L)(\overline{v}) = f(\overline{v}) = f_{lines}(\ell)(\overline{v}), \quad f_{curves}(L) \neq 0, \quad SAT^C\right] \geq 3\delta/4. \tag{20}$$

8.2. Analyzing verifier $\tilde{\mathcal{V}}$. Let $P_1, P_2, \ldots, P_t$ be all degree d polynomials that agree with f at $(\delta/2)^{c_2}/c_3$ fraction of points. Let $GOOD$ be the event that $f(\overline{v}) \in \{P_1(\overline{v}), \ldots, P_t(\overline{v})\}$. Using Theorem 7.7, we see that

$$\Pr_{\overline{v},\ell}\left[\neg GOOD, \quad f_{lines}(\ell)(\overline{v}) = f(\overline{v})\ \right] \ \leq\ \delta/2. \tag{21}$$

From (20) and (21), we get

$$\Pr\left[f_{curves}(L)(\overline{v}) = f(\overline{v}) = f_{lines}(\ell)(\overline{v}),\ GOOD, \quad f_{curves}(L) \neq 0, \quad SAT^C\right] \geq \delta/4. \tag{22}$$

Now, let $GOOD_{curves}$ be the event that

$$f_{curves}(L) \in \{P_1(L), \ldots, P_t(L)\},$$

where $P_j(L)$ denotes the univariate polynomial that is the restriction of the polynomial P_j to L.

We observe that unless the event $GOOD_{curves}$ happens, the probability of acceptance in (22) is negligible. This is because $\overline{v}$ is a random point on the curve L. If it happens that $f_{curves}(L)(\overline{v}) = f(\overline{v}) \in \{P_1(\overline{v}), \ldots, P_t(\overline{v})\}$ with nonnegligible probability, then it must be the case that $f_{curves}(L)$ is identically equal to one of $P_1(L), \ldots, P_t(L)$. Hence, we conclude

$$\Pr\Big[f_{curves}(L)(\overline{v}) = f(\overline{v}) = f_{lines}(\ell)(\overline{v}), GOOD,\ GOOD_{curves}, \\ f_{curves}(L) \neq 0, \quad SAT^C\Big] \geq \delta/8.$$

Whenever the above event occurs, $f_{curves}(L) \in \{P_1(L), \ldots, P_t(L)\}$, $f_{curves}(L) \neq 0$, and the values of $f_{curves}(L)$ satisfy the constraint C. This completes the proof of Theorem 7.6.

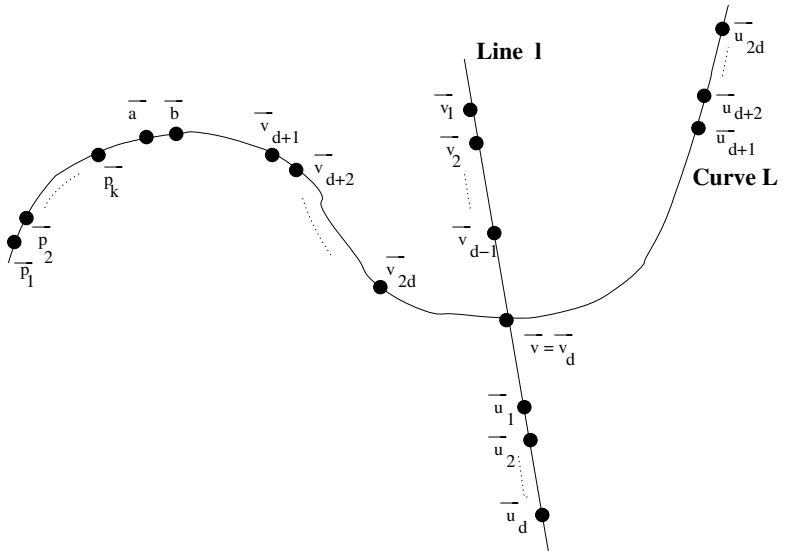

FIG. 3. *Modified outer verifier.*

9. Modified outer verifier. We use a modification of the outer verifier. This modification is necessary for the analysis of the inner verifier to go through.

Remark 9.1. Note that the outer verifier reads $2d$ values. The verifier's checks are all homogeneous linear. This is because all operations including interpolation, evaluating a polynomial at a specific value, and the constraint C are homogeneous linear.

We modify the outer verifier as follows (see Figure 3).

MODIFIED OUTER VERIFIER.

1. Follow steps (1)–(9) as in the outer verifier.
2. Pick additional random points $\overline{u}_1, \ldots, \overline{u}_d$ on line ℓ and random points $\overline{u}_{d+1}, \ldots, \overline{u}_{2d}$ on curve L.
3. Check that the degree $d-1$ univariate polynomial interpolated from values $\{f(\overline{v}_i)\}_{i=1}^{d}$ equals the polynomial interpolated from values $\{f(\overline{u}_i)\}_{i=1}^{d}$ (this actually happens to be a degree $d-2$ polynomial because of earlier steps).
4. Check that the degree $d-1$ univariate polynomial interpolated from values $\{f(\overline{v}_i)\}_{i=d+1}^{2d}$ equals the polynomial interpolated from values $\{f(\overline{u}_i)\}_{i=d+1}^{2d}$.

Remark 9.2. Note that the modified outer verifier reads $4d$ values. The verifier's checks are all homogeneous linear.

Remark 9.3. The purpose of this modification is exactly as explained in sections 1.5, 1.6, and 2.3. This modification adds *redundancy* to the outer verifier. It ensures that we get a squared Fourier coefficient when we do the Fourier analysis of the inner verifier. This is exactly the analogue of Håstad's 3-query PCP that reads 2 queries from the *larger table* so that the Fourier coefficient for the larger table appears in squared form.

10. Inner verifier.

Notation. We will let $\mathbb{F} = 2^l$ so that the field elements are represented by bit strings of length l. Note that addition over $\mathbb{F}$ and multiplication by a constant $\alpha \in \mathbb{F}$ are homogeneous linear operations on these l-bit strings. To keep the description of

the inner verifier conceptually simpler, we abstract out the modified outer verifier as follows (change of notation: redenote $2d$ by d).

ABSTRACT VIEW OF MODIFIED OUTER VERIFIER.

1. Pick an intersecting line-curve pair. Pick points $\{\overline{v}_i\}_{i=1}^{d}$ ($d/2$ of them from the line and $d/2$ from the curve, counting the intersection point as a point on the line; this is not of much relevance at the inner verifier's level).
2. Pick another set of points $\{\overline{u}_i\}_{i=1}^{d}$ (again, $d/2$ from the line and $d/2$ from the curve).
3. Let $T_{ld\times ld}$ be an invertible matrix over $\mathbb{F}_2$ chosen appropriately and let H be a subspace of $\mathbb{F}_2^{ld}$ chosen appropriately (see the remark below on how T, H are chosen).
4. Read the values $f(\overline{v}_1), \ldots, f(\overline{v}_d)$ and values $f(\overline{u}_1), \ldots, f(\overline{u}_d)$. Let
$$\begin{aligned} x &= f(\overline{v}_1) \circ f(\overline{v}_2) \circ \cdots \circ f(\overline{v}_d), \\ y &= f(\overline{u}_1) \circ f(\overline{u}_2) \circ \cdots \circ f(\overline{u}_d) \end{aligned} \tag{23}$$
($\circ$ denotes concatenation of strings).
5. Accept if and only if
$$x \neq 0, \quad x = Ty, \qquad \text{and} \qquad h \cdot x = 0 \ \forall\ h \in H \quad (\text{i.e., } x \perp H). \tag{24}$$

Remark 10.1.

1. The condition $x = Ty$ abstracts out the modified outer verifier's check that the two polynomials interpolated from values $\{f(\overline{v}_i)\}_{i=1}^{d/2}$ and $\{f(\overline{v}_i)\}_{i=d/2+1}^{d}$ are equal to the polynomials interpolated from values $\{f(\overline{u}_i)\}_{i=1}^{d/2}$ and $\{f(\overline{u}_i)\}_{i=d/2+1}^{d}$, respectively. This can be checked by multiplying one set of values by an appropriate invertible matrix and equating the result with the second set of values.
2. The condition $h \cdot x = 0\ \forall\ h \in H$ abstracts out the check that the set of values $\{f(\overline{v}_i)\}_{i=1}^{d}$ satisfy all the homogeneous constraints of the (modified) outer verifier.
3. The condition $x \neq 0$ says that Not-All-Zero$(f(\overline{v}_i), 1 \leq i \leq d)$, as in the (modified) outer verifier.

Now we are ready to describe the inner verifier. The inner verifier expects, for every point $\overline{v} \in \mathbb{F}^m$, the Hadamard code of the string $f(\overline{v}) \in \{0,1\}^l$ (see Appendix A.3 for an overview of Hadamard codes). The action of the inner verifier is as follows (remember that the following action is carried out after randomly picking a constraint $C(\{\overline{p}_i\}_{i=1}^{k})$ of the HomAlgCSP instance):

INNER VERIFIER.

1. Pick an intersecting line-curve pair, points $\{\overline{v}_i\}_{i=1}^{d}$, and points $\{\overline{u}_i\}_{i=1}^{d}$, exactly as in the modified outer verifier.
2. Let $T_{ld\times ld}$ be an invertible matrix over $\mathbb{F}_2$ chosen appropriately and let H be a subspace of $\mathbb{F}_2^{ld}$ chosen appropriately.
3. Let $A_1, A_2, \ldots, A_d$ be the (supposed) Hadamard codes of $f(\overline{v}_1), \ldots, f(\overline{v}_d)$, respectively. Let $B_1, \ldots, B_d$ be the (supposed) Hadamard codes of $f(\overline{u}_1), \ldots, f(\overline{u}_d)$, respectively.
4. Pick a random string $z \in \mathbb{F}_2^{ld}$ and a random $h \in H$. Write
$$\begin{aligned} z &= z_1 \circ z_2 \circ \cdots \circ z_d, \\ h &= h_1 \circ h_2 \circ \cdots \circ h_d, \\ zT &= w_1 \circ w_2 \circ \cdots \circ w_d. \end{aligned}$$

5. Accept if and only if

$$\oplus_{i=1}^{d} A_i(z_i \oplus h_i) = \oplus_{j=1}^{d} B_j(w_j).$$

10.1. Sanity check. Let us see why the test makes sense. Suppose each A_i is indeed a Hadamard code of $f(\overline{v}_i)$ and each B_j is indeed a Hadamard code of $f(\overline{u}_j)$. Therefore

$$A_i(z_i \oplus h_i) = (z_i \oplus h_i) \cdot f(\overline{v}_i) \quad \text{and} \quad B_j(w_j) = w_j \cdot f(\overline{u}_j).$$

Moreover assume that x and y are as in (23), and that they satisfy $x = Ty$ and $h \cdot x = 0 \ \forall \ h \in H$. Now we will show that the inner verifier's test accepts. Indeed,

$$\begin{aligned}
\oplus_{i=1}^{d} A_i(z_i \oplus h_i) &= \oplus_{i=1}^{d} (z_i \oplus h_i) \cdot f(\overline{v}_i) \\
&= (z \oplus h) \cdot (f(\overline{v}_1) \circ f(\overline{v}_2) \circ \cdots \circ f(\overline{v}_d)) \\
&= (z \oplus h) \cdot x \\
&= z \cdot x \oplus h \cdot x \\
&= z \cdot Ty \oplus 0 \\
&= (zT) \cdot y \\
&= (w_1 \circ w_2 \circ \cdots \circ w_d) \cdot (f(\overline{u}_1) \circ f(\overline{u}_2) \circ \cdots \circ f(\overline{u}_d)) \\
&= \oplus_{j=1}^{d} w_j \cdot f(\overline{u}_j) \\
&= \oplus_{j=1}^{d} B_j(w_j).
\end{aligned}$$

10.2. Proof of Theorem 1.9. Note that the inner verifier's test reads $2d$ bits in total. Let Π be the proof given to the inner verifier. Let us first prove that every query of the inner verifier is uniform over Π.

Uniformity of queries. Note that any particular query has the following distribution: pick a point $\overline{v} \in \mathbb{F}^m$ at random and then pick a random bit from the supposed Hadamard code of $f(\overline{v})$. Thus the query is uniformly distributed over proof Π.

Now the following two lemmas are sufficient to prove Theorem 1.9. These are the completeness and the soundness lemmas, respectively.

LEMMA 10.2. *Suppose that the instance $\mathcal{A}$ of HomAlgCSP has optimum $OPT(\mathcal{A})$. Let f be the polynomial that achieves this optimum and let a proof Π be constructed by taking the Hadamard code for every value of f. Let Π_0 be the set of 0-bits in the proof (this constitutes half of the bits in the whole proof). Let Q be the set of $2d$ query bits by the inner verifier. Then*

$$\Pr_Q[Q \subseteq \Pi_0] \geq OPT(\mathcal{A}) \cdot \frac{1}{2^{2d-1}}.$$

The probability is taken over the random test of the inner verifier.

LEMMA 10.3. *If Π_* is any set of half the bits from Π, and*

$$\left| \Pr_Q[Q \subseteq \Pi_*] - \frac{1}{2^{2d}} \right| \geq \delta,$$

then the instance $\mathcal{A}$ of HomAlgCSP has $OPT(\mathcal{A}) \geq \delta^{C''}$, where C'' is an absolute constant.

Let us see how these lemmas prove Theorem 1.9. Let $N = n^{CK}$ be the instance of the MDC given by Theorem 1.5. Theorem 3.4 gives an instance $\mathcal{A}$ of HomAlgCSP with parameters ϵ^*, the degree $d^* = 100/\epsilon^*$, $m = N^{\epsilon^*} = N^{100/d^*}$, and $k = 21$. We have

- $|\mathbb{F}|^m \le (N^2)^{N^{100/d^*}} \le 2^{N^{200/d^*}}$;
- $OPT(\mathcal{A}) \ge 1 - 1/2^K$ in the completeness case and $OPT(\mathcal{A}) \le 1/2^{2^K}$ in the soundness case.
- the inner verifier makes $2d$ queries, where $d = 2((k+2)d^* + 1) \le 50d^*$.

Soundness/quasi-randomness. We show that if Π_* is any set of half the bits from proof Π, then

$$\left| \Pr_Q[Q \subseteq \Pi_*] - \frac{1}{2^{2d}} \right| \le \frac{1}{2^{40d}}.$$

If on the contrary this is not true, then Lemma 10.3 implies that

$$OPT(\mathcal{A}) \ge 1/2^{40C''d} \ge 1/2^{2000C''d^*} > 1/2^{2^K},$$

where we choose $d^* = 2^K/(3000C'')$. This is a contradiction.

Now note that the size of proof Π is essentially $|\mathbb{F}|^m$ and is at most

$$|\mathbb{F}|^m \le 2^{N^{200/d^*}} \le 2^{n^{200CK \cdot 3000C''/2^K}} \le 2^{n^\epsilon}.$$

We can make ϵ arbitrarily small by choosing K large enough. Note that $\epsilon = \Omega(K/2^K)$, whereas $d = O(2^K)$. Hence $d = O(1/\epsilon \log(1/\epsilon))$.

Completeness. Completeness follows directly from Lemma 10.2 by noting that $OPT(\mathcal{A}) \ge 1 - 1/2^K = 1 - O(1/d)$.

Remark 10.4. We view the parameters $K, 1/\epsilon$, and d as constants, but "growing." The constants in the $\Omega()$ and $O()$ notation are absolute constants.

10.3. Proofs of Lemmas 10.2 and 10.3. We will prove both Lemmas 10.2 and 10.3 simultaneously. Let Π be a proof and let Π_* be a set of half the bits in the proof. Imagine setting bits in Π_* to 1 and the rest to 0. This defines the tables A_i, B_j in the proof. Let us estimate the probability that for a random test of the inner verifier, all the queries fall in Π_*, i.e.,

$$\Pr_Q[Q \subseteq \Pi_*].$$

This probability can be arithmetized as

$$E_{\substack{C,\ell,L,\overline{v_1},\ldots,\overline{v_d},\\ \overline{u_1},\ldots,\overline{u_d},z,h}} \left[\prod_{i=1}^{d} A_i(z_i \oplus h_i) \prod_{j=1}^{d} B_j(w_j) \right].$$

Here C is the choice of a random constraint of the HomAlgCSP instance. The rest of the choices are as in the inner verifier's action. Note that the bits $A_i(z_i \oplus h_i)$ and $B_j(w_j)$ are exactly the query bits. Thus we count a test only if each of the query bits falls in Π_*. We analyze this expression.

Fix everything else and consider only expectation over z, h. We drop the expectation sign for convenience. Plugging in Fourier expansions of A_i's and B_j's we get

$$\sum_{\alpha_1,\ldots,\alpha_d,\beta_1,\ldots,\beta_d} \left[\prod_{i=1}^{d} \widehat{A}_{i,\alpha_i} \prod_{j=1}^{d} \widehat{B}_{j,\beta_j} \cdot \prod_{i=1}^{d} \chi_{\alpha_i}(z_i \oplus h_i) \cdot \prod_{j=1}^{d} \chi_{\beta_j}(w_j) \right],$$

which simplifies to

$$\sum_{\substack{\alpha=\alpha_1\circ\alpha_2\ldots\circ\alpha_d,\\ \beta=\beta_1\circ\beta_2\ldots\circ\beta_d}} \left[\prod_{i=1}^{d}\widehat{A}_{i,\alpha_i}\prod_{j=1}^{d}\widehat{B}_{j,\beta_j}\cdot(-1)^{\alpha\cdot z\oplus\beta\cdot w}\cdot(-1)^{\alpha\cdot h}\right].$$

Now note that h is chosen randomly from the linear subspace H and thus the expectation over h is zero unless $\alpha\perp H$ (reason: a vector α is either orthogonal to all the vectors in H or orthogonal to exactly half the vectors in H). Moreover,

$$\begin{aligned} z\cdot\alpha\oplus w\cdot\beta &= z\cdot\alpha\oplus zT\cdot\beta\\ &= z\cdot(\alpha\oplus T\beta). \end{aligned}$$

Therefore, the expectation over z is zero unless $\alpha = T\beta$. Thus we get

$$\sum_{\substack{\alpha=\alpha_1\circ\alpha_2\ldots\circ\alpha_d,\\ \alpha\perp H,\ \beta=T^{-1}\alpha}} \left[\prod_{i=1}^{d}\widehat{A}_{i,\alpha_i}\prod_{j=1}^{d}\widehat{B}_{j,\beta_j}\right]. \tag{25}$$

10.4. Proof of Lemma 10.2. Let f be the solution for the HomAlgCSP instance with optimum $OPT(\mathcal{A})$. Thus for any $\overline{v}\in\mathbb{F}^m$, the corresponding Hadamard code $A_{\overline{v}}$ is precisely (see Fact A.7)

$$\frac{1}{2}-\frac{1}{2}\chi_{f(\overline{v})}.$$

Thus the table $A_{\overline{v}}$ has exactly two nonzero Fourier coefficients, $\widehat{A}_{\overline{v},0}=\frac{1}{2}$ and $\widehat{A}_{\overline{v},f(\overline{v})}=-\frac{1}{2}$.

Let us prove that

$$\Pr_Q[Q\subseteq\Pi_0]\geq OPT(\mathcal{A})\cdot\frac{1}{2^{2d-1}}.$$

Set $\Pi_*=\Pi_0$. As before, we imagine the bits in Π_* as set to 1 and the rest of the bits as set to 0. This corresponds to flipping the bits in the Hadamard codes. Hence the resulting tables A_i, B_j have Fourier representation (see Fact A.7)

$$A_i=\frac{1}{2}+\frac{1}{2}\chi_{f(\overline{v}_i)},\qquad B_j=\frac{1}{2}+\frac{1}{2}\chi_{f(\overline{u}_j)}.$$

Note that f satisfies $OPT(\mathcal{A})$ fraction of the constraints of the HomAlgCSP. For any satisfied constraint, we get a contribution of $\frac{1}{2^{2d}}$ in term (25) in each of these cases:

$$\begin{aligned} &\alpha_1=\alpha_2=\cdots=\alpha_d=\beta_1=\cdots=\beta_d=0,\\ &\alpha_i=f(\overline{v}_i),\ \beta_j=f(\overline{u}_j)\text{ for }i,j=1,2,\ldots,d. \end{aligned} \tag{26}$$

All other terms are nonnegative. Thus

$$\Pr_Q[Q\subseteq\Pi_0]\geq OPT(\mathcal{A})\cdot\left(\frac{1}{2^{2d}}+\frac{1}{2^{2d}}\right)=OPT(\mathcal{A})\cdot\frac{1}{2^{2d-1}}.$$

10.5. Proof of Lemma 10.3. Assume that the quantity in (25) is δ away from $\frac{1}{2^{2d}}$. First, we show that the contribution of the term with $\alpha=0$ is essentially $\frac{1}{2^{2d}}$. This implies that the contribution of terms with nonzero α is δ. Using this, we define a strategy for the outer verifier with success probability δ^2, which in turn gives a solution to the HomAlgCSP instance with value $\delta^{O(1)}$.

Contribution of the term with $\alpha = 0$. This contribution is

$$E_{\substack{\ell,L,\overline{v}_1,\ldots,\overline{v}_d,\\ \overline{u}_1,\ldots,\overline{u}_d}}\left[\prod_{i=1}^{d}\widehat{A}_{i,0}\widehat{B}_{i,0}\right],$$

where the expectation is taken over all line-curve pairs and choice of d random points each on the line and the curve.

Note that the zero Fourier coefficient equals the fraction of 1's in the table. Overall the proof contains half 1's.

We use the mixing property of curves and lines (see Appendix A.4). Therefore for a random choice of intersecting curve L and line ℓ, except with probability $O(1/|\mathbb{F}|^{1/3})$, we have

$$E_{\overline{v}\in L}[\widehat{A}_{\overline{v},0}] \approx \frac{1}{2}, \qquad E_{\overline{v}\in \ell}[\widehat{A}_{\overline{v},0}] \approx \frac{1}{2},$$

where the error in the approximation is bounded by $O(1/|\mathbb{F}|^{1/3})$. Once the curve and the line are chosen, $\overline{v}_1,\ldots,\overline{v}_d,\overline{u}_1,\ldots,\overline{u}_d$ are $2d$ random points on the curve and the line. Thus,

$$E_{\substack{\overline{v}_1,\ldots,\overline{v}_d,\\ \overline{u}_1,\ldots,\overline{u}_d}}\left[\prod_{i=1}^{d}\widehat{A}_{i,0}\widehat{B}_{i,0}\right] = \left(E_{\overline{v}\in L}[\widehat{A}_{\overline{v},0}]\right)^d \cdot \left(E_{\overline{v}\in \ell}[\widehat{A}_{\overline{v},0}]\right)^d \approx \frac{1}{2^{2d}}$$

up to error $O(1/|\mathbb{F}|^{1/3})$. This proves that the contribution of the term with $\alpha = 0$ is essentially $\frac{1}{2^{2d}}$.

Contribution of the terms with nonzero α. Using Cauchy–Schwarz, contribution of the terms with nonzero α in (25) is at most

$$\sqrt{E\left[\sum_{\alpha\neq 0,\alpha\perp H}\prod_{i=1}^{d}\widehat{A}_{i,\alpha_i}^2\right]}\sqrt{E\left[\sum_{\alpha\neq 0,\alpha\perp H,\beta=T^{-1}\alpha}\prod_{j=1}^{d}\widehat{B}_{j,\beta_j}^2\right]},$$

which is at most

$$\sqrt{E\left[\sum_{\alpha\neq 0,\alpha\perp H}\prod_{i=1}^{d}\widehat{A}_{i,\alpha_i}^2\right]}.$$

Observe that the expectation naturally gives a strategy for the outer verifier! For any point $\overline{v}\in\mathbb{F}^m$, define $f(\overline{v}) = \alpha_i$ with probability $\widehat{A}^2_{\overline{v},\alpha_i}$. This gives a (probabilistic) construction of a table of values $f:\mathbb{F}^m \mapsto \mathbb{F}$. The condition $\alpha \neq 0$ ensures that not all values read by the outer verifier are zero. The condition $\alpha\perp H$ ensures that the homogeneous linear constraint checked by the outer verifier is satisfied. These are exactly the two conditions when the outer verifier accepts. Note how the redundancy introduced by the modified outer verifier enabled us to apply Cauchy–Schwarz.

Thus, if the contribution of the terms with nonzero α is δ, then we can construct a table $f:\mathbb{F}^m \mapsto \mathbb{F}$ which the outer verifier accepts with probability δ^2. This probability is the average of the outer verifier's success probability over the choice of the HomAlgCSP constraint. Thus for at least $\delta^2/2$ fraction of the HomAlgCSP constraints, the outer verifier's success probability is $\delta^2/4$. Apply Theorem 7.6 with $\delta^2/4$ in place of δ.

Let $P_1, P_2, \ldots, P_t$ be the nonzero polynomials as in Theorem 7.6. It follows that for at least $\delta^2/4$ fraction of the HomAlgCSP constraints, at least one of the polynomials P_j satisfies this constraint. Thus there is one nonzero polynomial P_{j_0} that satisfies $(\delta^2/4)/t \geq \delta^{C''}$ fraction of the HomAlgCSP constraints. Note that $t \leq 2c_3/(\delta^2/8)^{c_2}$. This proves Lemma 10.3.

11. Conclusion. We have ruled out PTAS for three notorious problems: graph min-bisection, dense k-subgraph, and bipartite clique. Our results hold under the assumption that NP does not have subexponential time algorithms. This could be a new avenue for showing inapproximability results instead of the more common assumption that NP does not have polynomial time or quasi-polynomial time algorithms.

We have made several new contributions in terms of conceptual ideas and techniques. We introduced the notion of quasi-random PCPs that should be very useful for proving inapproximability results for graph theoretic problems, e.g., graph expansion. Some of the ideas in this paper have roots in [30]. To the best of our knowledge, it was the first paper that employed a combination of the algebraic techniques (those used to prove the PCP theorem) and more recent Fourier analysis methods. All recent results, on the other hand, use the PCP theorem as a black-box and then use parallel repetition [33] and Fourier analysis. In this paper, we make even heavier use of algebraic techniques, using generalizations and variants of the polynomial encoding method, LDT, and the sum-check protocol. This new direction in inapproximability theory looks very promising.

The connection between MDC and the graph theoretic problems is very surprising. It could be possible to prove inapproximability results assuming sufficiently strong hardness results for the shortest vector problem, the analogue of MDC for integer lattices.

Appendix A. Useful facts and tools.

A.1. Schwartz lemma. We use the following fact (called the Schwartz lemma) again and again.

FACT A.1. *Let $f(x_1, \ldots, x_m)$ be a degree d polynomial in m variables over field $\mathbb{F}$. Assume that $x_1, \ldots, x_m$ are chosen at random from $\mathbb{F}$. If*

$$\Pr[f(x_1, \ldots, x_m) = 0] \geq \frac{2d}{|\mathbb{F}|},$$

then f must identically be zero. Consequently, for two degree d polynomials f and g in m variables, if $f(x_1, \ldots, x_m) = g(x_1, \ldots, x_m)$ with probability $\frac{2d}{|\mathbb{F}|}$, then they must be identical polynomials.

A.2. Addition and multiplication over fields of characteristic 2. Here we summarize simple facts about addition and multiplication over the field $\mathbb{F} = \mathbb{F}_{2^l}$. Elements of $\mathbb{F}$ can be viewed as l-bit strings, i.e., as vectors in $\mathbb{F}_2^l$. For $x \in \mathbb{F}$, let x^* denote the corresponding vector in $\mathbb{F}_2^l$.

FACT A.2.

$$(x + y)^* = x^* \oplus y^* \ \forall\ x, y \in \mathbb{F},$$

where on the LHS we have addition in the field and on the RHS we have addition in $\mathbb{F}_2^l$.

FACT A.3. *If $\gamma \in \mathbb{F}$, then there exists an $l \times l$ matrix A_γ with entries in $\mathbb{F}_2$ such that*

$$(\gamma x)^* = A_\gamma x^* \quad \forall\ x \in \mathbb{F},$$

where on the LHS we have multiplication in the field and on the RHS we have multiplication of a matrix and a vector.

A.3. Hadamard codes and Fourier analysis.

DEFINITION A.4. *Let $x \in \mathbb{F}_2^l$ be an l-bit string. Its Hadamard code A_x is a 2^l-bit string whose coordinates are indexed by $s \in \mathbb{F}_2^l$ and*

$$A_x(s) = s \cdot x \quad \forall s \in \mathbb{F}_2^l,$$

where $s \cdot x$ denotes the inner product over $\mathbb{F}_2^l$.

DEFINITION A.5. *For $\alpha \in \mathbb{F}_2^l$, let $\chi_\alpha : \mathbb{F}_2^l \mapsto \{-1, 1\}$ be a real-valued function defined as*

$$\chi_\alpha(x) = (-1)^{\alpha \cdot x}.$$

FACT A.6. *Any real-valued function $A : \mathbb{F}_2^l \mapsto \mathbb{R}$ can be uniquely written as*

$$A = \sum_{\alpha \in \mathbb{F}_2^l} \widehat{A}_\alpha \ \chi_\alpha,$$

where $\widehat{A}_\alpha$ are real numbers called Fourier coefficients. We have Parseval's identity:

$$\sum_{\alpha \in \mathbb{F}_2^l} \widehat{A}_\alpha^2 = \|A\|_2^2 = \frac{1}{2^l} \sum_{s \in \mathbb{F}_2^l} A(s)^2.$$

FACT A.7. *Let A_x be Hadamard code of x. It can be regarded as a real-valued function $A_x : \mathbb{F}_2^l \mapsto \{0, 1\}$. Then its Fourier representation is*

$$A_x = \frac{1}{2} - \frac{1}{2}\chi_x.$$

The first term is $\frac{1}{2}\chi_0$, where $\chi_0 \equiv 1$. If A'_x is a function obtained by flipping values of A_x (i.e., 0 flipped to 1, and vice versa), then the Fourier representation of A'_x is

$$A'_x = \frac{1}{2} + \frac{1}{2}\chi_x.$$

A.4. Mixing property of lines and curves.

LEMMA A.8. *Let $\psi : \mathbb{F}^m \mapsto [0, 1]$ be any function with $E_{\overline{u} \in \mathbb{F}^m}[\psi(\overline{u})] = \frac{1}{2}$. Let ℓ be a line chosen at random. Then w.h.p. the average of ψ-values of points on ℓ is very close to $\frac{1}{2}$. To be precise,*

$$\Pr_\ell \left[\left| E_{\overline{u} \in \ell}[\psi(\overline{u})] - \frac{1}{2} \right| \geq \frac{1}{|\mathbb{F}|^{1/3}} \right] \leq \frac{1}{|\mathbb{F}|^{1/3}}.$$

Proof. A random line ℓ is chosen by picking two random points $\overline{a}, \overline{b} \in \mathbb{F}^m$ and letting

$$\ell := \{\overline{a} + t\overline{b} \mid t \in \mathbb{F}\}.$$

Note that for any $t \in \mathbb{F}$, the point $\overline{a} + t\overline{b}$ is uniformly distributed over $\mathbb{F}^m$ and, moreover, for $t_1 \neq t_2 \in \mathbb{F}$, the points $\overline{a} + t_1\overline{b}$ and $\overline{a} + t_2\overline{b}$ are pairwise independent. Hence, the random variables $\{\psi(\overline{a} + t\overline{b})| \ t \in \mathbb{F}\}$ each have expectation $\frac{1}{2}$ and are

pairwise independent. Applying Chebyshev's inequality (see below), we see that the random variable $E_t[\psi(\overline{a}+t\overline{b})]$ (which is the same as $E_{\overline{u}\in\ell}[\psi(\overline{u})]$) is sharply concentrated around $\frac{1}{2}$. □

LEMMA A.9 (Chebyshev's inequality). *Let $X_1, X_2, \ldots, X_n$ be pairwise independent random variables with range $[0,1]$, each with expectation p. Let $X = \frac{1}{n}\sum_{i=1}^{n} X_i$. Then*

$$\Pr[|X-p| \geq t] \leq \frac{var(X)}{t^2} = \frac{\frac{1}{n^2}\sum_{i=1}^{n} var(X_i)}{t^2} \leq \frac{1}{nt^2}.$$

A similar result holds for curves (the proof is similar and omitted). Let $\{\overline{p}_i\}_{i=1}^{k}$ and $\overline{v}$ be points in $\mathbb{F}^m$. Let $\{t_1, \ldots, t_{k+3}, t\}$ be distinct field elements. A random curve L passing through $\overline{v}$ is obtained as follows:

- Pick random points $\overline{a}, \overline{b} \in \mathbb{F}^m$.
- Let L be the unique degree $k+2$ curve such that

$$L(t_i) = \overline{p}_i,\ 1 \leq i \leq k, \quad L(t_{k+1}) = \overline{a},\ L(t_{k+2}) = \overline{b}, \quad L(t) = \overline{v}.$$

LEMMA A.10. *Let $\psi : \mathbb{F}^m \mapsto [0,1]$ be any function with $E_{\overline{u}\in\mathbb{F}^m}[\psi(\overline{u})] = \frac{1}{2}$. Let L be a curve chosen at random as above. Then w.h.p. the average of ψ-values of points on L is very close to $\frac{1}{2}$. To be precise,*

$$\Pr_L\left[\left|E_{\overline{u}\in L}[\psi(\overline{u})] - \frac{1}{2}\right| \geq \frac{1}{|\mathbb{F}|^{1/3}}\right] \leq \frac{1}{|\mathbb{F}|^{1/3}}.$$

Appendix B. Proof of Theorem 1.5. We start with a result of Dumer, Micciancio, and Sudan [15] that it is NP-hard to approximate the MDC within any constant factor (say 5), and the result holds on binary asymptotically good codes. Formally, we have the following.

THEOREM B.1 (see [15]). *There is an absolute constant $\zeta > 0$ and a reduction from SAT to MDC where the following hold:*

1. *The MDC instance is over $\mathbb{F}_2$, i.e., the code is binary.*
2. *(Completeness.) The YES instance of SAT is mapped to an MDC instance $\mathbf{A}$ with $OPT(\mathbf{A}) \leq \zeta$.*
3. *(Soundness.) The NO instance of SAT is mapped to an MDC instance $\mathbf{A}$ with $OPT(\mathbf{A}) \geq 5\zeta$.*
4. *The reduction runs in time n^C, where n is the size of the SAT instance and C is an absolute constant.*

The hardness of MDC can be boosted via the tensor product, giving the following theorem.

THEOREM B.2 (see [15]). *There is an absolute constant $\zeta > 0$ such that for every integer K, there is a reduction from SAT to MDC satisfying the following:*

1. *The MDC instance is over $\mathbb{F}_2$, i.e., the code is binary. It has N rows and n' columns.*
2. *(Completeness.) The YES instance of SAT is mapped to an MDC instance $\mathbf{A}$ with $OPT(\mathbf{A}) \leq \zeta^K$.*
3. *(Soundness.) The NO instance of SAT is mapped to an MDC instance $\mathbf{A}$ with $OPT(\mathbf{A}) \geq 5^K\zeta^K$.*
4. *The reduction runs in time n^{CK}, where n is the size of SAT instance and C is an absolute constant. In particular, $N \leq n^{CK}$.*

Let $\mathbf{A} = \{a_{ij}\}$ be an instance of MDC and let n, n', N, K, C, ζ be parameters as in Theorem B.2. We interpret the rows of $\mathbf{A}$ as linear forms:

$$L_i = \sum_{j=1}^{n'} a_{ij} z_j, \quad 1 \le i \le N.$$

Thus the goal of the MDC problem is to find a nonzero solution $\mathbf{z} = (z_1, z_2, \ldots, z_{n'})$ so as to minimize the number of nonzero linear forms. By taking an extension field of $\mathbb{F}_2$, we can assume that Theorem B.2 holds for codes over a field $\mathbb{F}$ of characteristic 2 with size $\approx N$.

Now the idea is the following. Create a new instance $\mathbf{A}'$ of MDC whose linear forms are linear combinations of the linear forms $\{L_i\}_{i=1}^N$. Thus a typical linear form looks like this:

$$\sum_{s=1}^{t} \alpha_s L_{i_s}, \quad \text{where } \alpha_s \in \mathbb{F},\ i_s \in [N].$$

There are $|\mathbb{F}|^t N^t$ such linear forms. However, we want to take only $O(N)$ of them, and we achieve this using walks on expanders. Choose $t = 1/(\zeta^K 2^K)$.

Let G be a degree D expander on N vertices with second largest eigenvalue λ. It is possible to explicitly (and efficiently) construct such expanders with $\lambda \le D^{9/10}$ (in fact one can get $\lambda \approx 2\sqrt{D}$ using the Ramanujan graphs [31]). Choose $D = (\frac{4}{5^K \zeta^K})^{10}$ so that $\lambda/D \le 5^K \zeta^K/4$. Let $S \subseteq \mathbb{F}$ with $|S| = 2^{2 \cdot 2^K}$.

Let the new instance $\mathbf{A}'$ of MDC consist of these linear forms:

$$\sum_{s=1}^{t} \alpha_s L_{i_s}, \quad \text{where } \alpha_s \in S, \text{ and } [i_1, i_2, \ldots, i_t] \text{ is a walk on graph } G. \tag{27}$$

The number of such linear forms is $|S|^t N \cdot D^{t-1}$, which is $O(N)$ since ζ, K are constants. Now we prove the completeness and soundness properties.

Completeness. If the SAT instance is a YES instance, we know that $OPT(\mathbf{A}) \le \zeta^K$. Thus there is a nonzero solution $\mathbf{z}$ such that at most ζ^K fraction of the linear forms $\{L_i\}_{i=1}^N$ are nonzero.

For a random walk $[i_1, i_2, \ldots, i_t]$ on G, the probability that there exists $L_{i_s} \ne 0$ is at most $t\zeta^K$. This implies that the fraction of linear forms in (27) that are nonzero is at most $t\zeta^K$. Thus $OPT(\mathbf{A}') \le t\zeta^K = \frac{1}{2^K}$.

Soundness. If the SAT instance is a NO instance, we know that $OPT(\mathbf{A}) \ge 5^K \zeta^K$. Fix any nonzero $\mathbf{z}$. We know that at least $5^K \zeta^K$ fraction of linear forms $\{L_i\}_{i=1}^N$ are nonzero. Let

$$W := \{i \mid i \in [N],\ L_i \ne 0\}$$

so that $\mu(W) = |W|/N \ge 5^K \zeta^K$. Using [32, section 15], we can bound the probability that all vertices of the random walk $[i_1, i_2, \ldots, i_t]$ fall outside W.

$$\begin{aligned}
\Pr[i_1 \in \overline{W} \wedge i_2 \in \overline{W} \ldots \wedge i_t \in \overline{W}] &\le \left(\sqrt{\mu(\overline{W})} + \frac{\lambda}{D}\right)^t \\
&\le \left(\sqrt{1 - 5^K \zeta^K} + 5^K \zeta^K/4\right)^t \\
&\le \left(1 - 5^K \zeta^K/4\right)^{1/(\zeta^K 2^K)} \\
&\le e^{-(5/2)^K/4} \le 2^{-2 \cdot 2^K}.
\end{aligned}$$

Therefore at least a fraction $1 - 2^{-2 \cdot 2^K}$ of the linear forms in (27) contain a linear form $L_{i_{s^*}} \neq 0$. For any fixed tuple $(L_{i_1}, \ldots, L_{i_t})$ that contains at least one $L_{i_{s^*}} \neq 0$, after choosing the coefficients $\alpha_1, \ldots, \alpha_t \in S$ at random, the probability that (27) is nonzero is at least $1 - \frac{1}{|S|}$. Therefore, the fraction of nonzero linear forms among (27) is at least

$$(1 - 2^{-2 \cdot 2^K}) \cdot \left(1 - \frac{1}{|S|}\right) \geq (1 - 2^{-2 \cdot 2^K}) \cdot (1 - 1/2^{2 \cdot 2^K}) \geq 1 - 1/2^{2^K}.$$

Thus $OPT(\mathbf{A}') \geq 1 - \frac{1}{2^{2^K}}$. This proves Theorem 1.5.

Appendix C. Reductions from quasi-random PCP to graph min-bisection, dense *k*-subgraph, and bipartite clique. In this section, we prove that the PCP construction given by Theorem 1.9 implies inapproximability results for graph min-bisection, dense k-subgraph, and bipartite clique. This proves Theorem 1.1. The reductions given here are similar to the reductions given by Feige [17] (correctness of his reduction, however, relies on his hypothesis about hardness of random 3SAT).

C.1. Graph min-bisection. Let N be the proof size and M the total number of tests of the PCP verifier in Theorem 1.9. Both N and M are bounded by $2^{O(n^\epsilon)}$. Let d be the integer as in that theorem.

Construct a graph G as follows: it is disjoint union of a bipartite graph and a clique. The clique has size $(1 - \frac{3}{2}\frac{1}{2^{d-1}})dM^2 - \frac{N}{2}$. The bipartite graph is constructed as follows: The LHS has N vertices corresponding to the N bits in the PCP proof. The RHS has M clusters, one for every test of the PCP verifier. Every cluster is a clique of size dM. One vertex in every cluster is designated as a *connection vertex*. The bipartite edges are only between the LHS vertices and the connection vertices on RHS. There is an edge between a vertex (= bit) on the LHS and a connection vertex (= PCP test) on the RHS if and only if the bit is accessed by the PCP test. This completes the description of the graph G. Note that every connection vertex has d neighbors on the LHS since this is a d-query PCP. Since every query is uniformly distributed, every bit in the proof appears in the same number of tests. Therefore, the LHS vertices all have the same degree, say Δ, so that $\Delta N = dM$.

Completeness. We claim that the graph G can be partitioned into two equal parts so that the number of crossing edges is at most $(\frac{1}{2} - \frac{3}{4}\frac{1}{2^{d-1}})dM$.

Theorem 1.9 gives a set Π_0 of half the bits from the proof such that at least $(1 - O(1/d))\frac{1}{2^{d-1}} \geq \frac{3}{4}\frac{1}{2^{d-1}}$ fraction of the tests access all the d queries from Π_0. Partition the graph G into two equal parts as follows: One part consists of the following:

1. $\frac{N}{2}$ vertices from the LHS corresponding to bits in Π_0. Abusing notation, denote the set of these vertices also by Π_0.
2. $\frac{3}{4}\frac{1}{2^{d-1}}M$ clusters from the RHS corresponding to the tests that access all d queries from Π_0. Call the set of these tests (or connection vertices) $\mathcal{T}_0$.
3. The clique of size $(1 - \frac{3}{2}\frac{1}{2^{d-1}})dM^2 - \frac{N}{2}$.

The second part consists of all the remaining $(1 - \frac{3}{4}\frac{1}{2^{d-1}})M$ clusters on the RHS corresponding to the tests in $\overline{\mathcal{T}}_0$. The only crossing edges are between Π_0 and $\overline{\mathcal{T}}_0$. The total number of edges incident on Π_0 is $\Delta|\Pi_0| = \Delta\frac{N}{2}$. The number of edges between Π_0 and $\mathcal{T}_0$ is $d|\mathcal{T}_0| = d(\frac{3}{4}\frac{1}{2^{d-1}}M)$ since every connection vertex in $\mathcal{T}_0$ has degree d and all its neighbors (queries) are in Π_0. Therefore, the number of crossing edges is at most

$$\Delta\frac{N}{2} - \frac{3}{4}\frac{1}{2^{d-1}}dM = \frac{dM}{2} - \frac{3}{4}\frac{1}{2^{d-1}}dM = \left(\frac{1}{2} - \frac{3}{4}\frac{1}{2^{d-1}}\right)dM.$$

Soundness. We show that for any bisection of G, the number of crossing edges is at least the expression (28). Note that the clusters and the clique have size at least dM, so any bisection that cuts either a cluster or the clique has at least $dM-1$ crossing edges. Hence we need to consider only those partitions for which every cluster and the clique are completely contained inside one of the parts.

This implies that one of the parts consists of the following:

1. $\frac{N}{2}$ vertices from the LHS. Denote the set of these vertices and the set of corresponding bits in the PCP proof by Π_*.
2. $\frac{3}{4}\frac{1}{2^{d-1}}M$ clusters from the RHS. Denote the set of corresponding connection vertices and the set of corresponding PCP tests by $\mathcal{T}_*$.
3. The clique of size $(1-\frac{3}{2}\frac{1}{2^{d-1}})dM^2-\frac{N}{2}$.

By Theorem 1.9, at most $\frac{1}{2^d}+\frac{1}{2^{20d}}$ fraction of the tests have all their queries in Π_*. Hence, the number of edges between Π_* and $\mathcal{T}_*$ is at most

$$\begin{aligned} &d\cdot\left(\frac{1}{2^d}+\frac{1}{2^{20d}}\right)M+(d-1)\cdot\left(\frac{3}{4}\frac{1}{2^{d-1}}-\left(\frac{1}{2^d}+\frac{1}{2^{20d}}\right)\right)M\\ &=dM\left(\frac{3}{4}\frac{1}{2^{d-1}}-\frac{1}{d}\left(\frac{1}{2^{d+1}}-\frac{1}{2^{20d}}\right)\right).\end{aligned}$$

The number of crossing edges is at least equal to the number of edges between Π_* and $\overline{\mathcal{T}}_*$. This is equal to the number of edges incident on Π_* (which is $\Delta\frac{N}{2}=\frac{dM}{2}$) minus the number of edges between Π_* and $\mathcal{T}_*$. Thus the number of crossing edges is at least

$$dM\left(\frac{1}{2}-\frac{3}{4}\frac{1}{2^{d-1}}+\frac{1}{d}\left(\frac{1}{2^{d+1}}-\frac{1}{2^{20d}}\right)\right). \tag{28}$$

Inapproximability factor. Clearly, the inapproximability factor is

$$\frac{\frac{1}{2}-\frac{3}{4}\frac{1}{2^{d-1}}+\frac{1}{d}(\frac{1}{2^{d+1}}-\frac{1}{2^{20d}})}{\frac{1}{2}-\frac{3}{4}\frac{1}{2^{d-1}}}.$$

This is $\approx 1+\frac{2}{d2^{d+1}}=1+\frac{1}{2^{O(1/\epsilon\log(1/\epsilon))}}$ since $d=O(1/\epsilon\log(1/\epsilon))$. Recall that the reduction runs in time $2^{O(n^\epsilon)}$ on a SAT instance of size n.

C.2. Dense *k*-subgraph. Construct a bipartite graph G as follows: The LHS consists of N vertices corresponding to the bits in the PCP proof. The RHS consists of M vertices corresponding to the tests of the PCP. Connect an LHS vertex (= bit) to an RHS vertex (= PCP test) if and only if the bit is accessed by the test. Assume that $N=\frac{M}{2^{5d}}$ (this can be achieved by duplicating vertices, since the dense subgraph must take either *all* copies of a vertex or *none*). Set the size of the subgraph to $k=\left(\frac{1}{2^{5d+1}}+\frac{3}{4}\frac{1}{2^{d-1}}\right)M$.

Completeness. By Theorem 1.9, there is a set Π_0 of $\frac{N}{2}$ bits such that at least $(1-O(1/d))\frac{1}{2^{d-1}}\geq\frac{3}{4}\frac{1}{2^{d-1}}$ fraction of the tests have all their d queries in Π_0. This gives an induced subgraph of G on

$$\frac{N}{2}+\frac{3}{4}\frac{1}{2^{d-1}}M=\left(\frac{1}{2^{5d+1}}+\frac{3}{4}\frac{1}{2^{d-1}}\right)M$$

vertices that has at least $(\frac{3}{4}\frac{1}{2^{d-1}})dM$ edges.

Soundness. Take any induced subgraph of G on $(\frac{1}{2^{5d+1}} + \frac{3}{4}\frac{1}{2^{d-1}})M$ vertices.

Case (i). If the number of LHS vertices is $\geq (\frac{1}{2} + \frac{1}{2^{5d}})N$, then the number of RHS vertices is at most

$$\left(\frac{1}{2^{5d+1}} + \frac{3}{4}\frac{1}{2^{d-1}}\right)M - \left(\frac{1}{2} + \frac{1}{2^{5d}}\right)N = \left(\frac{3}{4}\frac{1}{2^{d-1}} - \frac{1}{2^{10d}}\right)M.$$

Hence, the number of edges in the induced subgraph is at most $(\frac{3}{4}\frac{1}{2^{d-1}} - \frac{1}{2^{10d}})dM$.

Case (ii). So assume that the number of LHS vertices is $\leq (\frac{1}{2} + \frac{1}{2^{5d}})N$ (assume w.l.o.g. that the number is exactly this). Call these vertices Π'_*. The number of RHS vertices is at most $(\frac{1}{2^{5d+1}} + \frac{3}{4}\frac{1}{2^{d-1}})M$.

Now we bound the fraction of tests all of whose queries are in Π'_*. Let Π_* be any subset of Π'_* of size $\frac{N}{2}$. By Theorem 1.9, the fraction of tests with all queries in Π_* is bounded by $\frac{1}{2^d} + \frac{1}{2^{20d}}$. The fraction of tests with at least one query in $\Pi'_* \setminus \Pi_*$ is bounded by $\frac{d}{2^{5d}}$ since the queries are uniformly distributed and the probability that any single query is in $\Pi'_* \setminus \Pi_*$ equals the fractional size of this set which is at most $\frac{1}{2^{5d}}$.

Therefore, the number of tests all of whose queries are in Π'_* is at most $(\frac{1}{2^d} + \frac{1}{2^{20d}} + \frac{d}{2^{5d}})M$. Hence the number of edges in the induced subgraph is at most

$$\begin{aligned}
&d\left(\frac{1}{2^d} + \frac{1}{2^{20d}} + \frac{d}{2^{5d}}\right)M + (d-1)\left(\left(\frac{1}{2^{5d+1}} + \frac{3}{4}\frac{1}{2^{d-1}}\right) - \left(\frac{1}{2^d} + \frac{1}{2^{20d}} + \frac{d}{2^{5d}}\right)\right)M \\
&= dM\left(\left(\frac{3}{4}\frac{1}{2^{d-1}} + \frac{1}{2^{5d+1}}\right) - \frac{1}{d}\left(\frac{1}{2^{5d+1}} + \frac{3}{4}\frac{1}{2^{d-1}}\right) + \frac{1}{d}\left(\frac{1}{2^d} + \frac{1}{2^{20d}} + \frac{d}{2^{5d}}\right)\right) \\
&= dM\left(\frac{3}{4}\frac{1}{2^{d-1}} - \frac{1}{d\cdot 2^{d+1}} + (\text{low order terms})\right).
\end{aligned}$$

In either case, the number of edges in the induced subgraph is at most $(\frac{3}{4}\frac{1}{2^{d-1}} - \frac{1}{2^{10d}})dM$.

Inapproximability factor. Clearly, the inapproximability factor is

$$\frac{\frac{3}{4}\frac{1}{2^{d-1}}}{\frac{3}{4}\frac{1}{2^{d-1}} - \frac{1}{2^{10d}}},$$

which is $\approx 1 + \frac{4\cdot 2^{d-1}}{3\cdot 2^{10d}} = 1 + \frac{1}{2^{O(1/\epsilon\log(1/\epsilon))}}$ since $d = O(1/\epsilon\log(1/\epsilon))$.

C.3. Bipartite clique. Construct a bipartite graph G as follows: The LHS consists of N vertices corresponding to the bits in the PCP proof. The RHS consists of M vertices corresponding to the tests of the PCP. Connect an LHS vertex (= bit) to an RHS vertex (= PCP test) if and only if the bit is *not* accessed by the test. Assume that $\frac{N}{2} = (\frac{3}{4}\frac{1}{2^{d-1}})M$. (This can be achieved by duplicating vertices. Any maximal bipartite clique must take either *all* copies of a vertex or *none*.)

Completeness. We will show that there is a bipartite clique of size $\frac{N}{2}$. Theorem 1.9 shows that the set of 1-bits Π_1 in the proof is such that a fraction $(1 - O(1/d))\frac{1}{2^{d-1}} \geq \frac{3}{4}\frac{1}{2^{d-1}}$ of tests *does not* access any query from Π_1. Let $\mathcal{T}_1$ denote the set of all such tests with $|\mathcal{T}_1| = (\frac{3}{4}\frac{1}{2^{d-1}})M = \frac{N}{2}$. Clearly, Π_1 and $\mathcal{T}_1$ give an $\frac{N}{2}$-sized bipartite clique.

Soundness. We will show that there is no bipartite clique of size $(1 - \frac{1}{2^{5d}})\frac{N}{2}$. Assume on the contrary that there is such a clique and let Π_* be the LHS and let $\mathcal{T}_*$ be the RHS of this clique. By hypothesis,

$$|\Pi_*| = \left(1 - \frac{1}{2^{5d}}\right)\frac{N}{2} \quad \text{and} \quad |\mathcal{T}_*| = \left(1 - \frac{1}{2^{5d}}\right)\frac{N}{2} = \left(1 - \frac{1}{2^{5d}}\right)\frac{3}{4}\frac{1}{2^{d-1}}M.$$

Clearly, $|\overline{\Pi}_*| = (1 + \frac{1}{2^{5d}})\frac{N}{2}$ and $\mathcal{T}_*$ is a set of tests all of whose queries fall in $\overline{\Pi}_*$. But this is a contradiction, since by Theorem 1.9 the number of such tests is bounded by $(\frac{1}{2^d} + \frac{1}{2^{20d}} + \frac{d}{2^{5d}})M$. The calculation is exactly the same as in Case (ii) of the soundness analysis for the dense k-subgraph problem.

Inapproximability factor. Clearly, the inapproximability factor is

$$\frac{1}{1 - \frac{1}{2^{5d}}} \approx 1 + \frac{1}{2^{5d}} = 1 + \frac{1}{2^{O(1/\epsilon \log(1/\epsilon))}}.$$

Appendix D. Boosting the hardness factor for bipartite clique. In this section, we prove Theorem 1.2 showing that bipartite clique is hard to approximate within a polynomial factor. We mimic the proof of Berman and Schnitger [10], who prove a similar boosting result for the clique problem. The boosting consists of taking a random induced subgraph of a product graph.

DEFINITION D.1. *For a bipartite graph $G(V, W, E)$ with $|V| = |W| = n$, let $OPT_{BC}(G)$ denote a maximum integer t such that the complete bipartite graph $K_{t,t}$ is a subgraph of G.*

DEFINITION D.2. *For a bipartite graph $G(V, W, E)$ with $|V| = |W| = n$, and an integer k, let $G^k(V', W', E')$ denote the product graph defined as follows:*

- $V' = V^k, W' = W^k$. *Thus* $|V'| = |W'| = n^k$.
- $((v_1, v_2 \ldots, v_k), (w_1, w_2, \ldots, w_k)) \in E' \iff \forall i, j, \quad 1 \le i, j \le k, \ (v_i, w_j) \in E$.

LEMMA D.3. *Let $G(V, W, E)$ be a bipartite graph with $|V| = |W| = n$ such that $OPT_{BC}(G) \ge \alpha n$. Let $H(V_*, W_*, E_*)$ be a random induced subgraph of $G^k(V', W', E')$, where $|V_*| = |W_*| = O(n^2/\alpha^k)$. Then w.h.p. we have $OPT_{BC}(H) \ge \frac{1}{2}\alpha^k |V_*|$.*

Proof. Let $V_1 \subseteq V$, $W_1 \subseteq W$ be such that $|V_1| = |W_1| = \alpha n$ and the subgraph of G induced on V_1, W_1 is a complete bipartite graph. Clearly, the subgraph of G^k induced on V_1^k, W_1^k is a complete bipartite graph.

Now V_* is a random subset of V^k of size $O(n^2/\alpha^k)$ and $|V^k| = n^k$, $|V_1^k| = \alpha^k n^k$. We will show that w.h.p. $|V_* \cap V_1^k| \ge \frac{1}{2}\alpha^k |V_*|$. We may assume that vertices in V_* are picked randomly and independently from V^k. For every vertex in V_*, the probability that it belongs to V_1^k is α^k. Thus the expected size of $|V_* \cap V_1^k|$ is $\alpha^k |V_*|$. Using Chernoff bounds,

$$\Pr\left[|V_* \cap V_1^k| \le \frac{1}{2}\alpha^k |V_*|\right] \ \le \ 2^{-\Omega(\alpha^k |V_*|)} \le 2^{-\Omega(n^2)}.$$

Similarly w.h.p., $|W_* \cap W_1^k| \ge \frac{1}{2}\alpha^k |W_*|$. Clearly, the induced subgraph of H on $V_* \cap V_1^k, W_* \cap W_1^k$ is a complete bipartite graph and this proves the lemma. ∎

LEMMA D.4. *Let $G(V, W, E)$ be a bipartite graph with $|V| = |W| = n$ such that $OPT_{BC}(G) \le \beta n$. Let $H(V_*, W_*, E_*)$ be a random induced subgraph of $G^k(V', W', E')$, where $|V_*| = |W_*| = O(n^2/\beta^k)$. Then w.h.p. we have $OPT_{BC}(H) \le 2\beta^k |V_*|$.*

Proof. It suffices to prove that w.h.p., for *every* complete bipartite subgraph $(\tilde{V}, \tilde{W})$ of G^k, we have either $|V_* \cap \tilde{V}| \le 2\beta^k |V_*|$ or $|W_* \cap \tilde{W}| \le 2\beta^k |W_*|$.

In fact, it suffices to show this statement for every *maximal* complete bipartite subgraph of G^k. It is easily seen that a maximal complete bipartite subgraph of G^k must be of the form (V_1^k, W_1^k), where (V_1, W_1) is a complete bipartite subgraph of G. In particular, the number of maximal complete bipartite subgraphs of G^k is bounded by 2^{2n}, and for any such subgraph (V_1^k, W_1^k), either $|V_1^k| \leq \beta^k n^k$ or $|W_1^k| \leq \beta^k n^k$.

Fix any maximal complete bipartite subgraph of G^k, induced on (V_1^k, W_1^k), and assume w.l.o.g. that $|V_1^k| \leq \beta^k n^k$. We may assume that vertices in V_* are picked randomly and independently from V'. For every vertex in V_*, the probability that it belongs to V_1^k is at most β^k. Thus the expected size of $|V_* \cap V_1^k|$ is at most $\beta^k |V_*|$. Using Chernoff bounds,

$$\Pr\left[|V_* \cap V_1^k| \geq 2\beta^k |V_*|\right] \;\leq\; 2^{-\Omega(\beta^k |V_*|)} \leq 2^{-\Omega(n^2)}.$$

Taking union bound over all possible (at most 2^{2n} many) maximal complete bipartite subgraphs of G^k proves the lemma. □

D.1. Proof of Theorem 1.2. Now we prove Theorem 1.2. Fix $\epsilon > 0$ to be an arbitrarily small constant. Let $G(V, W, E)$ be the bipartite graph given by the reduction in Appendix C.3. By adding dummy vertices to the LHS, we may assume that $|V| = |W| = M$. If the size of the original SAT instance is n, then note that $M = 2^{n^\epsilon}$, and for an integer $d = O(1/\epsilon \log(1/\epsilon))$, the graph G satisfies the following:

1. If the SAT instance is a YES instance, then $OPT_{BC}(G) \geq \alpha M$, where $\alpha = \frac{3}{4}\frac{1}{2^{d-1}}$
2. If the SAT instance is a NO instance, then $OPT_{BC}(G) \leq \beta M$, where $\beta = (1 - \frac{1}{2^{5d}})\alpha$.

Let $k = 2^{5d} \log M$ and let H be a random induced subgraph of G^k of size $S = O(M^2/\beta^k)$. Applying Lemmas D.3 and D.4, we see that w.h.p.,

1. if the SAT instance is a YES instance, then $OPT_{BC}(H) \geq \frac{1}{2}\alpha^k S$;
2. if the SAT instance is a NO instance, then $OPT_{BC}(H) \leq 2\beta^k S$.

Thus the hardness factor is

$$\frac{1}{4}(\alpha/\beta)^k \geq \frac{1}{4}\left(1 + \frac{1}{2^{5d}}\right)^{2^{5d}\log M} \geq 2^{\log M} = M.$$

On the other hand,

$$S = O(M^2/\beta^k) \leq M^2 2^{dk} = M^{2+d2^{5d}} = 2^{(2+d2^{5d})n^\epsilon}.$$

Thus the hardness factor can be expressed as $S^{\frac{1}{2+d2^{5d}}}$. Hence, assuming that SAT $\notin$ BPTIME(2^{n^ϵ}), we conclude that it is hard to approximate bipartite clique on graph of size S within factor $S^{\epsilon'}$ for $\epsilon' = \frac{1}{2^{O(1/\epsilon \log(1/\epsilon))}}$.

Appendix E. The sum-check protocol. In this section, we describe the (usual) sum-check protocol. It should familiarize the reader with the ideas and techniques involved in constructing the GSC protocol.

Given a table of values of a degree D polynomial $\tilde{f} : \mathbb{F}^m \mapsto \mathbb{F}$, the goal of the protocol is to verify that the sum of values of $\tilde{f}$ over $\{0,1\}^m$ equals the given *target value*. A trivial protocol would read the values of $\tilde{f}$ on all points in $\{0,1\}^m$, whereas the sum-check protocol needs to read only $O(m)$ values. The verifier of the sum-check protocol needs access to additional auxiliary information. Specifically, he has access to polynomials $\{g_r : |\ 1 \leq r \leq m-1\}$, also given as table of values (the intended

role of these polynomials is explained below). Here is the formal description of the protocol.

$SC(a, \mathbb{F}, \tilde{f}, m, D, \{g_r | 1 \le r \le m-1\})$ consists of the following:

1. $\mathbb{F}$ is a field and $a \in \mathbb{F}$ is a *target* value.
2. $\tilde{f} \in \mathbb{F}[\mathbf{x}]$ is a degree D polynomial, where $\mathbf{x} = (x_1, x_2, \ldots, x_m)$ is a vector of m formal variables. We are given $\tilde{f}$ as a table of values.
3. Every g_r is a polynomial in $\mathbb{F}[\boldsymbol{\theta}]$, where $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_m)$ is a vector of formal variables. The degree of g_r is D and g_r is guaranteed to depend only on $\theta_1, \ldots, \theta_r$. The polynomials g_r are given as a table of values.

The goal is to (probabilistically) verify that

$$a = \sum_{x_1 \in \{0,1\}} \sum_{x_2 \in \{0,1\}} \cdots \sum_{x_m \in \{0,1\}} \tilde{f}(x_1, x_2, \ldots, x_m) \tag{29}$$

by reading a constant number of values of $\tilde{f}$ and of each of the polynomials g_r.

The values of the polynomial g_r are supposed to give sums of values of the polynomial $\tilde{f}$ over *cubes* of dimension $m - r$. To be precise, g_r is intended to be

$$g_r(\theta_1, \theta_2, \ldots, \theta_r) = \sum_{x_{r+1} \in \{0,1\}} \sum_{x_{r+2} \in \{0,1\}} \cdots \sum_{x_m \in \{0,1\}} \tilde{f}(\theta_1, \theta_2, \ldots, \theta_r, x_{r+1}, x_{r+2}, \ldots, x_m). \tag{30}$$

Here is the basic idea behind the protocol: the task of verifying a summation over the m-dimensional cube $\{0,1\}^m$ is successively reduced to the task of verifying a summation over cubes of lower dimension. In the last stage, the sum over a 0-dimensional cube, i.e., value of $\tilde{f}$ at a single point, can be read off from the table of values of $\tilde{f}$. The key observation is that

$$g_r(\theta_1, \theta_2, \ldots, \theta_r) = g_{r+1}(\theta_1, \theta_2, \ldots, \theta_r, 0) + g_{r+1}(\theta_1, \theta_2, \ldots, \theta_r, 1).$$

One can design a protocol in a natural way: just verify the above equation for $0 \le r \le m-1$. Here, g_0 would denote the sum $\sum_{x_1, x_2, \ldots, x_m \in \{0,1\}} \tilde{f}(x_1, x_2, \ldots, x_m)$, which is supposed to equal the target value a. Also, $g_m(\theta_1, \ldots, \theta_m)$ would denote the value $\tilde{f}(\theta_1, \theta_2, \ldots, \theta_m)$, which can be read from the table of values of $\tilde{f}$.

The sum-check protocol. The protocol accepts if and only if all of the following checks are satisfied:

- Pick $\theta_1, \theta_2, \ldots, \theta_m \in \mathbb{F}$ at random.
- (Stage 0:) Check if
$$a = g_1(0) + g_1(1). \tag{31}$$
- (Stage r for $r = 1, \ldots, m-2$:) Check if
$$g_r(\theta_1, \ldots, \theta_r) = g_{r+1}(\theta_1, \ldots, \theta_r, 0) + g_{r+1}(\theta_1, \ldots, \theta_r, 1). \tag{32}$$
- (Stage $m-1$:) Check if
$$g_{m-1}(\theta_1, \ldots, \theta_{m-1}) = \tilde{f}(\theta_1, \ldots, \theta_{m-1}, 0) + \tilde{f}(\theta_1, \ldots, \theta_{m-1}, 1). \tag{33}$$

E.1. Completeness.

LEMMA E.1. *If the polynomial $\tilde{f}$ satisfies* (29)*, then it is possible to define polynomials $g_r(\boldsymbol{\theta})$ so that the protocol accepts with probability* 1.

Proof. The proof is obvious. Just define g_r as they are supposed to be, as in (30). ∎

E.2. Soundness.

LEMMA E.2. *If the polynomial $\tilde{f}$ does not satisfy* (29)*, then no matter what polynomials g_r one takes, the protocol accepts with negligible probability, i.e., with probability at most $O(\frac{Dm}{|\mathbb{F}|})$. It is assumed that the polynomials g_r have degree at most D and g_r depends only on $\theta_1, \ldots, \theta_r$.*

Proof. Let $\tilde{g}_r$ be polynomials obtained from $\tilde{f}$ using rule (30). We will argue in reverse order (i.e., $r = m-1, m-2, \ldots, 1$) that unless $g_r \equiv \tilde{g}_r$, the protocol succeeds with negligible probability. The only fact we use is that two polynomials agree with nonnegligible probability if and only if they are identical as formal polynomials.

(*Case* $r = m-1$.) Look at Stage $m-1$, equation (33). The RHS is equal to $\tilde{g}_{m-1}(\theta_1, \ldots, \theta_{m-1})$. Hence, we must have $g_{m-1} = \tilde{g}_{m-1}$ if the verifier is to accept with nonnegligible probability.

(*Case* $1 \le r \le m-2$.) Assume that we have already proved that $g_{r+1} = \tilde{g}_{r+1}$. The RHS of (32) is $\tilde{g}_r(\theta_1, \ldots, \theta_r)$. Hence, we must have $g_r = \tilde{g}_r$ if the verifier is to accept with nonnegligible probability.

Now we show that the test fails in Stage 0. This is because

$$\begin{aligned} a &\neq \sum_{x_1, x_2, \ldots, x_m \in \{0,1\}} \tilde{f}(x_1, x_2, \ldots, x_m) \\ &= \tilde{g}_1(0) + \tilde{g}_1(1) \\ &= g_1(0) + g_1(1). \end{aligned}$$

DETERMINISTIC EXTRACTORS FOR BIT-FIXING SOURCES BY OBTAINING AN INDEPENDENT SEED*

ARIEL GABIZON†, RAN RAZ†, AND RONEN SHALTIEL‡

Abstract. An (n,k)-bit-fixing source is a distribution X over $\{0,1\}^n$ such that there is a subset of k variables in $X_1,\ldots,X_n$ which are uniformly distributed and independent of each other, and the remaining $n-k$ variables are fixed. A deterministic bit-fixing source extractor is a function $E:\{0,1\}^n \to \{0,1\}^m$ which on an arbitrary (n,k)-bit-fixing source outputs m bits that are statistically close to uniform. Recently, Kamp and Zuckerman [*Proceedings of the 44th Annual IEEE Symposium on Foundations of Computer Science*, 2003, pp. 92–101] gave a construction of a deterministic bit-fixing source extractor that extracts $\Omega(k^2/n)$ bits and requires $k > \sqrt{n}$.

In this paper we give constructions of deterministic bit-fixing source extractors that extract $(1-o(1))k$ bits whenever $k > (\log n)^c$ for some universal constant $c > 0$. Thus, our constructions extract almost all the randomness from bit-fixing sources and work even when k is small. For $k \gg \sqrt{n}$ the extracted bits have statistical distance $2^{-n^{\Omega(1)}}$ from uniform, and for $k \le \sqrt{n}$ the extracted bits have statistical distance $k^{-\Omega(1)}$ from uniform.

Our technique gives a general method to transform deterministic bit-fixing source extractors that extract few bits into extractors which extract almost all the bits.

Key words. bit-fixing sources, deterministic extractors, derandomization, seeded extractors, seed obtainers

1. Introduction.

1.1. Deterministic randomness extractors.

A "deterministic randomness extractor" is a function that "extracts" bits that are (statistically close to) uniform from "weak sources of randomness" which may be very far from uniform.

DEFINITION 1.1 (deterministic extractor). *Let $\mathcal{C}$ be a class of distributions on $\{0,1\}^n$. A function $E:\{0,1\}^n \to \{0,1\}^m$ is a* deterministic ϵ-extractor *for $\mathcal{C}$ if for every distribution X in $\mathcal{C}$ the distribution $E(X)$ (obtained by sampling x from X and computing $E(x)$) is ϵ-close to the uniform distribution on m-bit strings.*[1]

The distributions X in $\mathcal{C}$ are often referred to as "weak random sources," that is, distributions that "contain" some randomness. Given a class $\mathcal{C}$, the goal of this field is to design *explicit* (that is, efficiently computable) deterministic extractors that extract as many random bits as possible.

1.2. Some related work on randomness extraction.

Various classes $\mathcal{C}$ of distributions were studied in the literature. The first construction of deterministic extractors can be traced back to von Neumann [37], who showed how to use many

[1]Two distributions P and Q over $\{0,1\}^m$ are ϵ-close (denoted by $P \overset{\epsilon}{\sim} Q$) if for every event $A \subseteq \{0,1\}^m$, $|P(A)-Q(A)| \le \epsilon$.

independent tosses of a biased coin (with unknown bias) to obtain an unbiased coin. Blum [6] considered sources that are generated by a finite Markov chain. Santha and Vazirani [29], Vazirani [34, 35], Chor and Goldreich [10], Barak, Impagliazzo, and Wigderson [2], Barak et al. [3], and Raz [25] studied sources that are composed of several independent samples from various classes of distributions. Trevisan and Vadhan [31] studied sources which are "samplable" by small circuits.

A negative result was given by Santha and Vazirani that exhibits a very natural class of high-entropy sources that do not have deterministic extractors. This led to the development of a different notion of extractors called "seeded extractors." Such extractors are allowed to use a short seed of few truly random bits when extracting randomness from a source. (The notion of "seeded extractors" emerged from attempts to simulate probabilistic algorithms using weak random sources [36, 10, 12, 38, 39] and was explicitly defined by Nisan and Zuckerman [23].) Unlike deterministic extractors, seeded extractors can extract randomness from the most general class of sources: sources with high (min)-entropy. The reader is referred to [21, 22, 30, 32] for various surveys on randomness extractors.

1.3. Bit-fixing sources. In this paper we concentrate on the family of "bit-fixing sources" introduced by Chor et al. [11]. A distribution X over $\{0,1\}^n$ is a bit-fixing source if there is a subset $S \subseteq \{1,\ldots,n\}$ of "good indices" such that the bits X_i for $i \in S$ are independent fair coins and the rest of the bits are fixed.[2]

DEFINITION 1.2 (bit-fixing sources and extractors). *A distribution X over $\{0,1\}^n$ is an (n,k)-*bit-fixing source *if there exists a subset $S = \{i_1,\ldots,i_k\} \subseteq \{1,\ldots,n\}$ such that $X_{i_1}, X_{i_2}, \ldots, X_{i_k}$ is uniformly distributed over $\{0,1\}^k$ and for every $i \notin S$, X_i is constant.*

A function $E : \{0,1\}^n \to \{0,1\}^m$ is a deterministic (k,ϵ)-bit-fixing source extractor if it is a deterministic ϵ-extractor for all (n,k)-bit-fixing sources.

One of the motivations given in the literature for studying deterministic bit-fixing source extractors is that they are helpful in cryptographic scenarios in which an adversary learns (or alters) $n-k$ bits of an n-bit-long secret key [11]. Loosely speaking, one wants cryptographic protocols to remain secure even in the presence of such adversaries. Various models for such "exposure resilient cryptography" were studied [28, 7, 8, 14]. The reader is referred to [13] for a comprehensive treatment of "exposure resilient cryptography" and its relation to deterministic bit-fixing source extractors.

Every (n,k)-bit-fixing source "contains" k "bits of randomness." It follows that any deterministic (k,ϵ)-bit-fixing source extractor with $\epsilon < 1/2$ can extract at most k bits. The function $E(x) = \oplus_{1\le i\le n} x_i$ is a deterministic $(k,0)$-bit-fixing source extractor which extracts one bit for any $k \ge 1$. Chor et al. [11] concentrated on deterministic "errorless" extractors (that is, deterministic extractors in which $\epsilon = 0$). They show that such extractors cannot extract even two bits when $k < n/3$. They also give some constructions of deterministic errorless extractors for large k.

Our focus is on extractors with error $\epsilon > 0$ (which allows extracting many bits for many choices of k). A probabilistic argument shows the existence of a deterministic (k,ϵ)-bit-fixing source extractor that extracts $m = k - O(\log(n/\epsilon))$ bits for any choice of k and ϵ. Thus, it is natural to try to achieve such parameters by explicit constructions.

[2] We remark that such sources are often referred to as "oblivious bit-fixing sources" to differentiate them from other types of "nonoblivious" bit-fixing sources in which the bits outside of S may depend on the bits in S (cf. [5]). In this paper we are concerned only with the "oblivious case."

In a recent paper Kamp and Zuckerman [17] constructed explicit deterministic (k,ϵ)-bit-fixing source extractors that extract $m = \eta k^2/n$ bits for some constant $0 < \eta < 1$ with $\epsilon = 2^{-\Omega(k^2/n)}$. They pose the open problem to extract more bits from such sources. Note that the extractor of Kamp and Zuckerman is inferior to the nonexplicit extractor in two respects:

- It works only when $k > \sqrt{n}$.
- Even when $k > \sqrt{n}$ the extractor may extract only a small fraction of the randomness. For example, if $k = n^{1/2+\alpha}$ for some $0 < \alpha < 1/2$, the extractor extracts only $m = \eta n^{2\alpha}$ bits.

1.4. Our results. In this paper, we give two constructions of deterministic bit-fixing source extractors that extract $m = (1-o(1))k$ bits from (n,k)-bit-fixing sources. Our first construction is for the case of $k \gg \sqrt{n}$.

THEOREM 1.3. *For every constant $0 < \gamma < 1/2$ there exists an integer n' (depending on γ) such that for any $n > n'$ and any k, there is an explicit deterministic (k,ϵ)-bit-fixing source extractor $E : \{0,1\}^n \to \{0,1\}^m$, where $m = k - n^{1/2+\gamma}$ and $\epsilon = 2^{-\Omega(n^\gamma)}$.*

Consider $k = n^{1/2+\alpha}$ for some constant $0 < \alpha < 1/2$. We can choose any $\gamma < \alpha$ and extract $m = n^{1/2+\alpha} - n^{1/2+\gamma}$ bits whereas the construction of [17] extracts only $m = O(n^{2\alpha})$ bits. For this choice of parameters we achieve error $\epsilon = 2^{-\Omega(n^\gamma)}$ whereas [17] achieves a slightly smaller error $\epsilon = 2^{-\Omega(n^{2\alpha})}$. We remark that this comes close to the parameters achieved by the nonexplicit construction which can extract $m = n^{1/2+\alpha} - n^{1/2+\gamma}$ with error $\epsilon = 2^{-\Omega(n^{1/2+\gamma})}$.

Our second construction works for any $k > (\log n)^c$, for some universal constant c. However, the error in this construction is larger.

THEOREM 1.4. *There exist constants $c > 0$ and $0 < \mu, \nu < 1$ such that for any large enough n and any $k \geq \log^c n$, there is an explicit deterministic (k,ϵ)-bit-fixing source extractor $E : \{0,1\}^n \to \{0,1\}^m$, where $m = k - O(k^\nu)$ and $\epsilon = O(k^{-\mu})$.*

We remark that using the technique of [17] one can achieve a much smaller error ($\epsilon = 2^{-\sqrt{k}}$) at the cost of extracting very few bits ($m = \Omega(\log k)$). The precise details are given in Theorem 4.1.

1.5. Overview of techniques. We develop a general technique that transforms any deterministic bit-fixing source extractor that extracts only very few bits into one that extracts almost all of the randomness in the source. This transformation makes use of "seeded extractors."

1.5.1. Seeded randomness extractors. A seeded randomness extractor is a function which receives two inputs: In addition to a sample from a source X, a seeded extractor also receives a short "seed" Y of few uniformly distributed bits. Loosely speaking, the extractor is required to output many more random bits than the number of bits "invested" as a seed.

DEFINITION 1.5 (seeded extractors). *Let $\mathcal{C}$ be a class of distributions on $\{0,1\}^n$. A function $E : \{0,1\}^n \times \{0,1\}^d \to \{0,1\}^m$ is a* seeded ϵ-extractor *for $\mathcal{C}$ if for every source X in $\mathcal{C}$ the distribution $E(X,Y)$ (obtained by sampling x from X and a uniform $y \in \{0,1\}^d$ and computing $E(x,y)$) is ϵ-close to the uniform distribution on m-bit strings.*

A long line of research focuses on constructing such seeded extractors with as short as possible seed length that extract as many bits as possible from the most general family of sources that allow randomness extraction: the class of sources with high min-entropy.

DEFINITION 1.6 (seeded extractors for high min-entropy sources). *The min-entropy of a distribution X over $\{0,1\}^n$ is $H_\infty(X) = min_{x\in\{0,1\}^n} \log_2(1/\Pr(x))$. A function $E : \{0,1\}^n \times \{0,1\}^d \to \{0,1\}^m$ is a* (k,ϵ)-extractor *if it is a seeded ϵ-extractor for the class of all sources X with $H_\infty(X) \geq k$.*

There are explicit constructions of (k,ϵ)-extractors that use a seed of length $\text{polylog}(n/\epsilon)$ to extract k random bits. The reader is referred to [30] for a detailed survey on various constructions of seeded extractors.

Our goal is to construct *deterministic* bit-fixing source extractors. Nevertheless, in the next definition we introduce the concept of a *seeded* bit-fixing source extractor. We use such extractors as a component in our construction of deterministic bit-fixing source extractors.

DEFINITION 1.7 (seeded extractors for bit-fixing sources). *A function $E : \{0,1\}^n \times \{0,1\}^d \to \{0,1\}^m$ is a* seeded (k,ϵ)-bit-fixing source extractor *if it is a seeded ϵ-extractor for the class of all (n,k)-bit-fixing sources.*

1.5.2. Seed obtainers. There is a very natural way to try to transform a deterministic bit-fixing source extractor that extracts few (say $\text{polylog}\, n$) bits into one that extracts many bits: First run the deterministic bit-fixing source extractor to extract few bits from the source, and then use these bits as a seed to a seeded extractor that extracts all the bits from the source. The obvious difficulty with this approach is that typically the output of the first extractor is *correlated* with the imperfect random source. Seeded extractors are only guaranteed to work when their seed is *independent* from the random source. To overcome this difficulty we introduce a new object which we call a *"seed obtainer."*

Loosely speaking, a seed obtainer is a function F that, given an (n,k)-bit-fixing source X, outputs two strings X' and Y with the following properties:

- X' is an (n,k')-bit-fixing source with $k' \approx k$ good bits.
- Y is a short string that is almost uniformly distributed.
- X' and Y are almost independent.

The precise definition is slightly more technical and is given in Definition 3.1. Note that a seed obtainer reduces the task of constructing *deterministic* extractors into that of constructing *seeded* extractors: Given a bit-fixing source X, one first runs the seed obtainer to obtain X' and a short Y and then uses Y as a seed to a seeded extractor that extracts all the randomness from X'. (In fact, it is even sufficient to construct seeded extractors for bit-fixing sources.)

1.5.3. Constructing seed obtainers. Note that every seed obtainer $F(X) = (X', Y)$ "contains" a deterministic bit-fixing source extractor by setting $E(X) = Y$. We show how to transform any deterministic bit-fixing source extractor into a seed obtainer. In this transformation the length of the "generated seed" Y is roughly the length of the output of the original extractor.

It is helpful to explain the intuition behind this transformation when applied to a specific deterministic bit-fixing source extractor. Consider the "xor-extractor" $E(x) = \oplus_{1\leq i\leq n} x_i$. Let X be some (n,k)-bit-fixing source, and let $Z = E(X)$. Note that the output bit Z is indeed very correlated with the input X. Nevertheless, suppose that we somehow obtain a random small subset of the indices of X. It is expected that the set contains a small fraction of the good bits. Let X' be the string that remains after "removing" the indices in the sampled set. The important observation is that X' is a bit-fixing source that is *independent* from the output Z. It turns out that the same phenomenon happens for every deterministic bit-fixing source extractor $E(X)$. However, it is not clear how to use this idea as we don't have

additional random bits to perform the aforementioned sampling of a random set. Surprisingly, we show how to use the bits extracted by the extractor E to perform this sampling.

Following this intuition, given an extractor $E(X)$ which extracts an m-bit string Z, we partition Z into two parts Y and W. We then use W as a seed to a randomness-efficient method of "sampling" a small subset T of $\{1,\ldots,n\}$. The first output of the seed obtainer X' is given by "removing" the sampled indices from X. More formally, X' is the string X restricted to the indices outside of T. The second output is Y (the other part of the output of the extractor E).

The intuition is that if T is a size n/r uniformly distributed subset of $\{1,\ldots,n\}$, then it is expected to hit approximately k/r good bits from the source. Thus, $k-k/r$ good bits remain in X'. We will require that the extractor E extracts randomness from $(n,k/r)$-bit-fixing sources. Loosely speaking, we can hope that E will extract its output from X_T (the string obtained by restricting X to the indices of T). Thus, its output will be independent from X' (the string obtained by removing X_T).

Note that the intuition above is far from being precise. The set T is sampled using random bits W that are extracted from the source X, and thus T depends on X. Whereas, the intuition corresponds to the case where T is independent from X. The precise argument appears in section 3. We remark that the analysis requires that the extractor E has error ϵ that is smaller than $2^{-|W|}$ (where $|W|$ is the number of bits used by the sampling method).

1.5.4. A deterministic extractor for large k (i.e., $k \gg \sqrt{n}$). Our first construction builds on the deterministic bit-fixing source extractor of Kamp and Zuckerman [17] that works for $k > \sqrt{n}$ and extracts at least $\Omega(k^2/n)$ bits from the source. We first transform this extractor into a seed obtainer F. Next, we run the seed obtainer F on the input source to generate a bit-fixing source X' and a seed Y. Finally, we extract all the randomness in X' by running a seeded extractor on X' using Y as seed.

1.5.5. A deterministic extractor for small k (i.e., $k < \sqrt{n}$). In order to use our technique for $k < \sqrt{n}$ we need to start with some deterministic bit-fixing source extractor that works when $k < \sqrt{n}$ and extracts a small number of bits. Our first observation is that methods similar to the ones of Kamp and Zuckerman [17] can be applied when $k < \sqrt{n}$ but only give deterministic bit-fixing source extractors that extract very few bits (i.e., $\Omega(\log k)$ bits).[3]

Deterministic extractors that extract $\Omega(\log k)$ bits. Kamp and Zuckerman [17] consider the distribution obtained by using a bit-fixing source $X = (X_1,\ldots,X_n)$ to perform a random walk on a d-regular graph. (They consider a more general model of bit-fixing sources in which every symbol X_i ranges over an alphabet of size d.) The walk starts from some fixed vertex in the graph and at step i, one uses X_i to select a neighbor of the current vertex. They show that the distribution over the vertices converges to the uniform distribution at a rate which depends on k and the "spectral gap" of the graph. It is known that 2-regular graphs cannot have small "spectral gap." Indeed, this is why Kamp and Zuckerman consider alphabet size $d > 2$ which allows using d-regular expander graphs that have a small spectral gap. Nevertheless, using their technique while choosing the graph to be a short cycle of length $k^{1/4}$ produces an extractor construction which extracts $\log(k^{1/4}) = \Omega(\log k)$ bits.[4]

[3] This was observed independently by Lipton and Vishnoi [18].

[4] In fact, a similar idea is used in [17] in order to reduce the case of large d to the case of $d = 2$.

A seeded extractor for bit-fixing sources with seed length $O(\log\log n)$. Converting the deterministic bit-fixing source extractor above into a seed obtainer, we "obtain" an $\Omega(\log k)$-bit seed. This allows us to use a seeded extractor with seed length $d = \Omega(\log k)$. However, $d < \log n$ and by a lower bound of [23, 24] the class of high min-entropy sources does not have seeded extractors with seed $d < \log n$. To bypass this problem we construct a *seeded* extractor for *bit-fixing sources* with seed length $O(\log\log n)$. Note that the aforementioned deterministic extractor extracts this many bits as long as $k > \log^c n$ for some constant c (when $\Omega(\log k) \geq O(\log\log n)$).

The seeded extractor uses its seed to randomly partition the indices $\{1, \ldots, n\}$ into r sets $T_1, \ldots, T_r$ (for r equals, say, $\log^4 n$), with the property that with high probability each one of these sets contains at least one good bit. We elaborate on this partitioning method later. We then output r bits, where the ith bit is given by $\oplus_{j \in T_i} x_j$.

By combining the seed obtainer with the seeded bit-fixing source extractor we obtain a deterministic bit-fixing source extractor which extracts $r = \log^4 n$ bits. To extract more bits, we convert this deterministic extractor into a seed obtainer. At this point we obtain a seed of length $\log^4 n$ and can afford to use a seeded extractor which extracts all the remaining randomness.

Sampling and partitioning with only $O(\log\log n)$ random bits. We now explain how to use $O(\log\log n)$ random bits to partition the indices $\{1, \ldots, n\}$ into $r = \text{polylog} n$ sets $T_1, \ldots, T_r$ such that for any set $S \subseteq \{1, \ldots, n\}$ of size k, with high probability (probability at least $1 - O(1/\log n)$) all sets $T_1, \ldots, T_r$ contain approximately k/r indices from S.

Suppose we could afford using many random bits. A natural solution is to choose n random variables $V_1, \ldots, V_n \in \{1, \ldots, r\}$ and have T_j be the set of indices i such that $V_i = j$. We expect k/r bits to fall in each T_j, and by a union bound one can show that with high probability all sets $T_1, \ldots, T_r$ have a number of indices from S that is close to the expected value.

To reduce the number of random bits we derandomize the construction above and use random variables V_i which are ϵ-close to being pairwise independent (for $\epsilon = 1/\log^a n$ for some sufficiently large constant a). Such variables can be constructed using only $O(\log\log n)$ random bits [20, 1, 15] and suffice to guarantee the required properties.

The same technique also gives us a method for sampling a set T of indices in $\{1, \ldots, n\}$ (which we require in our construction of seed obtainers). We simply take the first set T_1. This sampling method uses only $O(\log\log n)$ random bits, and thus we can afford it when transforming our deterministic extractor into a seed obtainer. (Recall that our transformation uses part of the output of the deterministic extractor for sampling a subset of the indices.) We remark that this sampling technique was used previously by Reingold, Shaltiel, and Wigderson [27] as a component in a construction of seeded extractors.

1.6. Outline. In section 2 we define the notations used in this paper. In section 3 we introduce the concept of seed obtainers and show how to construct them from deterministic bit-fixing source extractors and "averaging samplers." In section 4 we observe that the technique of [17] can be used to extract few bits even when k is small. In section 5 we give constructions for averaging samplers. In section 6 we give a construction of a seeded bit-fixing source extractor that makes use of the sampling techniques of section 5. In section 7 we plug all the components together and prove our main theorems. Finally, in section 8 we give some open problems.

2. Preliminaries.

Notation. We use $[n]$ to denote the set $\{1, \ldots, n\}$. We use $P(S)$ to denote the set of subsets of a given set S. We use U_n to denote the uniform distribution over n bits. Given a distribution A we use $w \leftarrow A$ to denote the experiment in which w is chosen randomly according to A. Given a string $x \in \{0,1\}^n$ and a set $S \subseteq [n]$, we use x_S to denote the string obtained by restricting x to the indices in S. We denote the length of a string x by $|x|$. Logarithms will always be taken with base 2.

Asymptotic notation. As this paper has many parameters we now explain exactly what we mean when using $O(\cdot)$ and $\Omega(\cdot)$ in a statement involving many parameters. We use the Ω and O signs only to denote absolute constants (i.e., not depending on any parameters even if these parameters are considered constants). Furthermore, when writing, for example, $f(n) = O(g(n))$, we always explicitly mention the conditions on n (and maybe other parameters) for which the statement holds.

2.1. Averaging samplers.

A sampler is a procedure which, given a short seed, generates a subset $T \subseteq [n]$ such that for every set $S \subseteq [n]$, $|S \cap T|$ is with high probability "close to the expected size."

DEFINITION 2.1. *An $(n, k, k_{min}, k_{max}, \delta)$-sampler $Samp : \{0,1\}^t \to P([n])$ is a function such that for any $S \subseteq [n]$ such that $|S| = k$,*

$$\Pr_{w \leftarrow U_t}(k_{min} \leq |Samp(w) \cap S| \leq k_{max}) \geq 1 - \delta.$$

The definition above is nonstandard in several respects. In the more common definition (cf. [16]), a sampler is required to work for sets of arbitrary size. In the definition above (which is similar in spirit to the one in [33]), the sampler is only required to work against sets of size k and the bounds k_{min}, k_{max} are allowed to depend on k. Furthermore, we require that the sampler has "distinct samples" as we do not allow T to be a multiset.[5]

We will use samplers to "partition" bit-fixing sources. Note that in the case of an (n, k)-bit-fixing source, *Samp* returns a subset of indices such that, with high probability, the number of good bits in the subset is between k_{min} and k_{max}.

2.2. Probability distributions.

Some of the proofs in this paper require careful manipulations of probability distributions. We use the following notation. We use U_m to denote the uniform distribution on m-bit strings. We denote the probability of an event B under a probability distribution P by $\Pr_P[B]$. A random variable R that takes values in U is a function $R : \Omega \to U$ (where Ω is a probability space). We sometimes refer to R as a probability distribution over U (the distribution of the output of R). For example, given a random variable R and a distribution P, we sometimes write "$R = P$" and this means that the distribution of the output of R is equal to P. Given two random variables R_1, R_2 over the same probability space Ω, we use (R_1, R_2) to denote the random variable induced by the function $(R_1, R_2)(\omega) = (R_1(\omega), R_2(\omega))$. Given two probability distributions P_1, P_2 over domains Ω_1, Ω_2, we define $P_1 \otimes P_2$ to be the *product distribution* of P_1 and P_1 which is defined over the domain $\Omega_1 \times \Omega_2$.

[5] We remark that some of the "standard techniques" for constructing averaging samplers (such as taking a walk on an expander graph or using a randomness extractor) perform poorly in this setup and do not work when $k < \sqrt{n}$ (even if T is allowed to be a multiset). This happens because in order to even hit a set S of size k these techniques require sampling a (multi)set T of size larger than $(n/k)^2$ which is larger than n for $k < \sqrt{n}$. In contrast, note that a completely random set of size roughly n/k will hit a fixed set S of small size with good probability.

DEFINITION 2.2 (conditioning distributions and random variables). *Given a probability distribution P over some domain U and an event $A \subseteq U$ such that $\Pr_P[A] > 0$, we define a distribution $(P|A)$ over U as follows: Given an event $B \subseteq U$, $\Pr_{(P|A)}(B) = \Pr_P[B|A] = \frac{\Pr_P[A \cap B]}{\Pr_P[A]}$.*

We extend this definition to random variables $R : \Omega \to U$. Given an event $A \subseteq \Omega$, we define $(R|A)$ to be the probability distribution over U given by $\Pr_{(R|A)}[B] = \Pr_R[R \in B|A]$.

We also need the notion of convex combination of distributions.

DEFINITION 2.3 (convex combination of distributions). *Given distributions $P_1, \ldots, P_t$ over U and coefficients $\alpha_1, \ldots, \alpha_t \geq 0$ such that $\sum_{1 \leq i \leq t} \alpha_i = 1$, we define the distribution $P = \sum_{1 \leq i \leq t} \alpha_i P_i$ as follows: Given an event $B \subseteq U$, $\Pr_P[B] = \sum_{1 \leq i \leq t} \alpha_i \Pr_{P_i}[B]$.*

We also need the following technical lemmas.

LEMMA 2.4. *Let X, Y, and V be distributions over $\{0,1\}^n$ such that X is ϵ-close to U_n and $Y = \delta \cdot V + (1-\delta) \cdot X$. Then Y is $(2\delta + \epsilon)$-close to U_n.*

Proof. Let $B \subseteq \{0,1\}^n$ be some event such that

$$\begin{aligned} |\Pr_Y(B) - \Pr_{U_n}(B)| &= |\delta \Pr_V(B) + (1-\delta)\Pr_X(B) - \Pr_{U_n}(B)| \\ &\leq 2\delta + |\Pr_X(B) - \Pr_{U_n}(B)| \leq 2\delta + \epsilon. \qquad \square \end{aligned}$$

LEMMA 2.5. *Let (A, B) be a random variable that takes values in $\{0,1\}^u \times \{0,1\}^v$ and suppose that there exists some distribution P over $\{0,1\}^v$ such that for every $a \in \{0,1\}^u$ with $\Pr[A = a] > 0$ the distribution $(B|A = a)$ is ϵ-close to P. Then (A, B) is ϵ-close to $(A \otimes P)$.*

Proof.

$$\frac{1}{2} \cdot \sum_{a,b} |\Pr[(A,B) = (a,b)] - \Pr_{A \otimes P}[a,b]|$$

$$= \frac{1}{2} \cdot \sum_{a,b} |\Pr[A = a]\Pr[B = b|A = a] - \Pr[A = a]\Pr_P[b]|$$

$$\leq \frac{1}{2} \cdot \sum_a \Pr[A = a] \sum_b |\Pr[B = b|A = a] - \Pr_P[b]| \leq \epsilon/2. \qquad \square$$

LEMMA 2.6. *Let (A, B) be a random variable that takes values in $\{0,1\}^u \times \{0,1\}^v$ which is ϵ-close to $(A' \otimes U_v)$; then for every $b \in \{0,1\}^v$ the distribution $(A|B = b)$ is $(\epsilon \cdot 2^{v+1})$-close to A'.*

Proof. Assume for the purpose of contradiction that there exists some $b^* \in \{0,1\}^v$ such that the distribution $(A|B = b^*)$ is not α-close to A' for $\alpha = \epsilon \cdot 2^{v+1}$. Then there is an event D such that

$$|\Pr_{(A|B=b^*)}[D] - \Pr_{A'}[D]| > \alpha.$$

By complementing D if necessary we can without loss of generality (w.l.o.g.) remove the absolute value from the inequality above. We define an event D' over $\{0,1\}^u \times \{0,1\}^v$. The event $D' = \{(a,b)|b = b^*,\ a \in D\}$. We have that

$$\Pr_{(A', U_v)}[D'] = \Pr_{A'}[D] \cdot 2^{-v}.$$

And similarly,

$$\Pr_{(A,B)}[D'] = \Pr_{(A|B=b^*)}[D] \Pr_B[B = b^*].$$

We know that B is ϵ-close to U_v and therefore $\Pr_B[B = b^*] \geq 2^{-v} - \epsilon$. Thus,

$$\Pr_{(A,B)}[D'] - \Pr_{(A',U_v)}[D'] = \Pr_{(A|B=b^*)}[D] \Pr_B[B = b^*] - \Pr_{A'}[D] \cdot 2^{-v}$$

$$\geq \Pr_{(A|B=b^*)}[D](2^{-v} - \epsilon) - \Pr_{A'}[D] \cdot 2^{-v} \geq 2^{-v}[\Pr_{(A|B=b^*)}[D] - \Pr_{A'}[D]] - \epsilon.$$

By our assumption the expression in square brackets is at least α and thus

$$> 2^{-v}\alpha - \epsilon = \epsilon.$$

Thus, we get a contradiction. ∎

3. Obtaining an independent seed.

3.1. Seed obtainers and their application. One of the natural ways to try and extract *many* bits from imperfect random sources is to first run a "weak extractor" which extracts few bits from the input distribution and then use these few bits as a seed to a second extractor which extracts more bits. The obvious difficulty with this approach is that typically the output of the first extractor is *correlated* with the imperfect random source and it is not clear how to use it. (Seeded extractors are only guaranteed to work when the seed is *independent* from the random source.) In the next definition we introduce the concept of a *"seed obtainer"* that overcomes this difficulty. Loosely speaking, a seed obtainer is a deterministic function which, given a bit-fixing source X, outputs a new bit-fixing source X' (with roughly the same randomness) together with a short random seed Y which is *independent* from X'. Thus, the seed Y can later be used to extract randomness from X' using a seeded extractor.

DEFINITION 3.1 (seed obtainer). *A function $F : \{0,1\}^n \to \{0,1\}^n \times \{0,1\}^d$ is a (k, k', ρ)-seed obtainer if for every (n,k)-bit-fixing source X, the distribution $R = F(X)$ can be expressed as a convex combination of distributions $R = \eta Q + \sum_a \alpha_a R_a$ (here the coefficients η and α_a are nonnegative and $\eta + \sum_a \alpha_a = 1$) such that $\eta \leq \rho$ and for every a there exists an (n,k')-bit-fixing source Z_a such that R_a is ρ-close to $Z_a \otimes U_d$.*

It follows that given a seed obtainer one can use a *seeded extractor* for bit-fixing sources to construct a *deterministic* (i.e., seedless) extractor for bit-fixing sources.

THEOREM 3.2. *Let $F : \{0,1\}^n \to \{0,1\}^n \times \{0,1\}^d$ be a (k, k', ρ)-seed obtainer. Let $E_1 : \{0,1\}^n \times \{0,1\}^d \to \{0,1\}^m$ be a seeded (k', ϵ)-bit-fixing source extractor. Then $E : \{0,1\}^n \to \{0,1\}^m$ defined by $E(x) = E_1(F(x))$ is a deterministic $(k, \epsilon + 3\rho)$-bit-fixing source extractor*

Proof. By the definition of a seed obtainer we have that $E(X) = \eta E_1(Q) + \sum_a \alpha_a E_1(R_a)$ for some $\eta \leq \rho$. For each a we have that $E_1(R_a)$ is $(\epsilon + \rho)$-close to U_m. It follows that $E(X)$ is $(\epsilon + \rho)$-close to $\eta E_1(Q) + (1 - \eta)U_m$ and therefore by Lemma 2.4 we have that $E(X)$ is $(2\eta + \epsilon + \rho)$-close to uniform. The lemma follows because $2\eta + \epsilon + \rho \leq \epsilon + 3\rho$. ∎

3.2. Constructing seed obtainers. Note that every seed obtainer "contains" a deterministic extractor for bit-fixing sources. More precisely, given a seed obtainer $F(x) = (x', y)$, the function $E(x) = y$ is a deterministic extractor for bit-fixing sources. We now show how to convert any deterministic bit-fixing source extractor with sufficiently small error into a seed obtainer.

Ingredients:
- An $(n, k, k_{min}, k_{max}, \delta)$-sampler $Samp : \{0,1\}^t \to P([n])$.
- A deterministic (k_{min}, ϵ)-bit-fixing source extractor $E : \{0,1\}^n \to \{0,1\}^m$ with $m > t$.

Result: A (k, k', ρ)-seed obtainer $F : \{0,1\}^n \to \{0,1\}^n \times \{0,1\}^{m-t}$ with $k' = k - k_{max}$ and $\rho = \max(\epsilon + \delta, \epsilon \cdot 2^{t+1})$.

The construction of F:
- Given $x \in \{0,1\}^n$ compute $E(x)$ and let $E_1(x)$ denote the first t bits of $E(x)$ and $E_2(x)$ denote the remaining $m - t$ bits.
- Let $T = Samp(E_1(x))$.
- Let $x' = x_{[n]\setminus T}$. If $|x'| < n$, we pad it with zeros to get an n-bit long string.
- Let $y = E_2(x)$, Output x', y.

FIG. 1. *A seed obtainer for (n, k)-bit-fixing sources.*

Our construction appears in Figure 1. In words, given x, the seed obtainer first computes $E(x)$. It uses a part of $E(x)$ as the second output y and another part to sample a substring of x. It obtains the first output x' by erasing the sampled substring from x. We now state the main theorem of this section.

THEOREM 3.3 (construction of seed obtainers). *For every n and $k < n$, let Samp and E be as in Figure 1 (that is, $Samp : \{0,1\}^t \to P([n])$ is an $(n, k, k_{min}, k_{max}, \delta)$-sampler and $E : \{0,1\}^n \to \{0,1\}^m$ is a deterministic (k_{min}, ϵ)-bit-fixing source extractor). Then, $F : \{0,1\}^n \to \{0,1\}^n \times \{0,1\}^d$ defined in Figure 1 is a (k, k', ρ)-seed obtainer for $d = m - t$, $k' = k - k_{max}$ and $\rho = \max(\epsilon + \delta, \epsilon \cdot 2^{t+1})$.*

Proof of Theorem 3.3. In this section we prove Theorem 3.3. Let E be a bit-fixing source extractor and $Samp$ be a sampler which satisfy the requirements in Theorem 3.3. Let X be some (n, k)-bit-fixing source and let $S \subseteq [n]$ be the set of k good indices for X. We will use capital letters to denote the random variables which come up in the construction. We split $E(X)$ into two parts $(E_1(X), E_2(X)) \in \{0,1\}^t \times \{0,1\}^{m-t}$. For a string $a \in \{0,1\}^t$ we use T_a to denote $Samp(a)$ and T'_a to denote $[n] \setminus Samp(a)$. Given a string $x \in \{0,1\}^n$, we use x_a to denote x_{T_a} and x'_a to denote the n-bit string obtained by padding $x_{T'_a}$ to length n. Let $X' = X'_{E_1(X)}$ and $Y = E_2(X)$. Our goal is to show that the pair (X', Y) is close to a convex combination of pairs of distributions where the first component is a bit-fixing source and the second is independent and uniformly distributed.

DEFINITION 3.4. *We say that a string $a \in \{0,1\}^t$* correctly splits *X if $k_{min} \leq |S \cap T_a| \leq k_{max}$.*

Note that by the properties of the sampler, almost all strings a correctly split X. We start by showing that for every *fixed* a which correctly splits X the variables X'_a and $E(X)$ are essentially independent. Loosely speaking, this happens because we can argue that there are enough good bits in X_a and therefore the extractor can

extract randomness from X_a which is independent of the randomness in X'_a.

LEMMA 3.5. *For every fixed $a \in \{0,1\}^t$ which correctly splits X the pair of random variables $(X'_a, E(X))$ is ϵ-close to the pair $(X'_a \otimes U_m)$.*

Proof. Let $\ell = |Samp(a)|$. Given a string $\sigma \in \{0,1\}^\ell$ and a string $\sigma' \in \{0,1\}^{n-\ell}$, we define $[\sigma;\sigma']$ to be the n-bit string obtained by placing σ in the indices of T_a and σ' in the indices of T'_a. More formally, we denote the ℓ indices of T_a by $i_1 < i_2 < \cdots < i_\ell$ and the $n-\ell$ indices of T'_a by $i'_1 < i'_2 < \cdots < i'_{n-\ell}$. Given an $i \in T_a$, we define $index(i)$ to be the index j such that $i_j = i$, and equivalently, given $i \in T'_a$, we define $index'(i)$ to be the index j such that $i'_j = i$. The string $[\sigma;\sigma'] \in \{0,1\}^n$ is defined as follows:

$$[\sigma;\sigma']_i = \begin{cases} \sigma_{index(i)} & i \in T_a \\ \sigma'_{index'(i)} & i \in T'_a \end{cases}$$

Note that in this notation $X = [X_a; X'_a]$. We are interested in the distribution of the random variable $(X'_a, E(X)) = (X'_a, E([X_a; X'_a]))$. For every $b \in \{0,1\}^{n-\ell}$ we consider the event $\{X'_a = b\}$. Fix some $b \in \{0,1\}^{n-\ell}$ such that $\Pr[X'_a = b] > 0$. The distribution

$$(E(X)|X'_a = b) = (E([X_a; X'_a])|X'_a = b) = E([X_a; b]),$$

where the last equality follows because X_a and X'_a are independent and therefore X_a is not affected by fixing X'_a. Note that as a correctly splits X, the distribution $[X_a; b]$ is a bit-fixing source with at least k_{min} "good" bits. We conclude that for every $b \in \{0,1\}^{n-\ell}$ such that $\Pr[X'_a = b] > 0$ the distribution $(E(X)|X'_a = b)$ is ϵ-close to uniform. We now apply Lemma 2.5 with $A = X'_a$ and $B = E(X)$ and conclude that the pair $(X'_a, E(X))$ is ϵ-close to $(X'_a \otimes U_m)$. ∎

We now argue that if ϵ is small enough, then the pair $(X'_a, E_2(X))$ is essentially independent even when conditioning the probability space on the event $\{E_1(X) = a\}$.

LEMMA 3.6. *For every fixed $a \in \{0,1\}^t$ that correctly splits X, the distribution $((X'_a, E_2(X))|E_1(X) = a)$ is $\epsilon \cdot 2^{t+1}$-close to $(X'_a \otimes U_{m-t})$.*

Proof. First noting that the statement is meaningless unless $\epsilon < 2^{-t}$, we will assume w.l.o.g. that this is the case and then for every fixed $a \in \{0,1\}^t$ the event $\{E_1(X) = a\}$ occurs with nonzero probability as $E_1(X)$ is ϵ-close to uniform over $\{0,1\}^t$. The lemma will follow as a straightforward application of Lemma 2.6. We set $A = (X'_a, E_2(X))$, $B = E_1(X)$, and $A' = (X'_a, U_{m-t})$. We indeed have that (A, B) is ϵ-close to (A', U_t) and the lemma follows. ∎

We are now ready to prove Theorem 3.3.

Proof of Theorem 3.3. By the properties of the extractor we have that $E_1(X)$ is ϵ-close to uniform. It follows (by the properties of the sampler) that the probability that $E_1(X)$ correctly splits X is $1 - \eta$ for some η which satisfies $\eta \leq \epsilon + \delta$. We now consider the output random variable $R = (X', E_2(X))$. We need to express this random variable as a convex combination of independent distributions and a small error term. We set Q to be the distribution $(R|\text{"}E_1(X) \text{ doesn't correctly split } X\text{"})$. For every correctly splitting a we set R_a to be the distribution $(R|E_1(X) = a)$ and $\alpha_a = \Pr[E_1(X) = a]$. By our definition we have that indeed $R = \eta Q + \sum_a \alpha_a R_a$. For every a that correctly splits X we have that $R_a = ((X', E_2(X))|E_1(X) = a) = ((X'_{E_1(X)}, E_2(X))|E_1(X) = a) = ((X'_a, E_2(X))|E_1(X) = a)$. By Lemma 3.6 we have that R_a is $\epsilon \cdot 2^{t+1}$-close to $(X'_a \otimes U_{m-t})$. As a correctly splits X, we have that X'_a is an $(n, k - k_{max})$-bit-fixing source as required. Thus, we have shown that the distribution R_a is close to a convex combination of pairs of essentially independent distributions where the first is a bit-fixing source and the second is uniform. ∎

4. Extracting few bits for any k. The deterministic bit-fixing source extractor of Kamp and Zuckerman [17] works only for $k > \sqrt{n}$. However, their technique easily gives a deterministic bit-fixing source extractor that extracts very few bits ($\Omega(\log k)$ bits) from a bit-fixing source with arbitrarily small k. We will later use this extractor to construct a seed obtainer that will enable us to extract many more bits.

THEOREM 4.1. *For every $n > k \geq 100$ there is an explicit deterministic $(k, 2^{-\sqrt{k}})$-bit-fixing source extractor $E : \{0,1\}^n \to \{0,1\}^{(\log k)/4}$.*

For the proof, we need the following result, which is a very special case of Lemma 3.3 in [17].

LEMMA 4.2 (see [17, Lemma 3.3] for $\epsilon = 0$ and $d = 2$). *Let the graph G be an odd cycle with M vertices and second eigenvalue λ. Suppose we take a walk on G for n steps, starting from some fixed vertex v with the steps taken according to the symbols from an (n,k)-bit-fixing source X. Let Z be the distribution on the vertices at the end of the walk; then Z is $\left(\frac{1}{2}\lambda^k\sqrt{M}\right)$-close to the uniform distribution on $[M]$.*

To extract few bits from a bit-fixing source X, we will use the bits of X to conduct a random walk on a small cycle.

Proof of Theorem 4.1. We use the source string to take a walk on a cycle of size $\sqrt[4]{k}$ from a fixed vertex. The second eigenvalue of a d-cycle is $\cos(\frac{\pi}{d})$ [19, Ex. 11.1]. Using Lemma 4.2, we reach distance $\left(\cos\left(\frac{\pi}{\sqrt[4]{k}}\right)\right)^k k^{1/8}$ from uniform. By the Taylor expansion of cos, for $0 < x < 1$

$$\cos(x) < 1 - \frac{x^2}{2} + \frac{x^4}{24} < 1 - \frac{x^2}{4}.$$

Therefore

$$\left(\cos\left(\frac{\pi}{\sqrt[4]{k}}\right)\right)^k < \left(1 - \frac{\pi^2}{4\sqrt{k}}\right)^k$$

$$< \left(e^{-\frac{\pi^2}{4}}\right)^{\sqrt{k}} < 4^{-\sqrt{k}},$$

where the second-to-last inequality holds because $(1 - x) < e^{-x}$ for $0 < x < 1$. Therefore, we reach distance $4^{-\sqrt{k}}k^{1/8} \leq 2^{-\sqrt{k}}$. By outputting the final vertex's name we get $\frac{\log(k)}{4}$ bits with the same distance from uniform. ∎

5. Sampling and partitioning with a short seed. Let $S \subseteq [n]$ be some subset of size k. In this section we show how to use few random bits in order perform two related tasks.

Sampling: Generate a subset $T \subseteq [n]$ such that $|S \cap T|$ is in a prespecified interval $[k_{min}, k_{max}]$ (see Definition 2.1).

Partitioning: Partition $[n]$ into r distinct subsets $T_1, \ldots, T_r$ such that for every $1 \leq i \leq r$, $|S \cap T_i|$ is in a prespecified interval $[k_{min}, k_{max}]$. Needless to say, a partitioning scheme immediately implies a sampling scheme by concentrating on a single T_i.

In this section we present two constructions of such schemes. The first construction is used in our deterministic bit-fixing source extractor for $k > \sqrt{n}$. In this setup we can allow the sampler to use many random bits (say $n^{\Omega(1)}$ bits) and can have error $2^{-n^{\Omega(1)}}$.

LEMMA 5.1 (sampling with low error). *Fix any constants $0 < \gamma \leq 1/2$ and $\alpha > 0$. There exists a constant n' depending on α and γ, such that for any integers n, k satisfying $n > n'$ and $n^{1/2+\gamma} \leq k \leq n$, there exists an $(n, k, (n^{1/2+\gamma})/6, n^{1/2+\gamma}, 2^{-\Omega(\alpha \cdot n^{\gamma})})$-sampler $Samp : \{0,1\}^t \to P([n])$, where $t = \alpha \cdot n^{2\gamma}$.*

The second construction is used in our deterministic bit-fixing source extractor for small k. For that construction we require schemes that use only $\alpha \log k$ bits for some small constant $\alpha > 0$. The construction of Lemma 5.1 requires at least $\log n > \log k$ bits, which is too much. Instead, we use a different construction which has much larger error (e.g., $k^{-\Omega(1)}$).

LEMMA 5.2 (sampling with $O(\log k)$ bits). *Fix any constant $0 < \alpha < 1$. There exist constants $c > 0, 0 < b < 1$ and $1/2 < e < 1$ (all depending on α) such that for any $n \geq 16$ and $k \geq \log^c n$, we obtain an explicit $(n, k, k^e/2, 3 \cdot k^e, O(k^{-b}))$-sampler $Samp : \{0,1\}^t \to P([n])$, where $t = \alpha \cdot \log k$.*

LEMMA 5.3 (partitioning with $O(\log k)$ bits). *Fix any constant $0 < \alpha < 1$. There exist constants $c > 0, 0 < b < 1$ and $1/2 < e < 1$ (all depending on α) such that for any $n \geq 16$ and $k \geq \log^c n$, we can use $\alpha \cdot \log k$ random bits to explicitly partition $[n]$ into $m = \Omega(k^b)$ sets $T_1, \ldots, T_m$ such that for any $S \subseteq [n]$, where $|S| = k$,*

$$\Pr(\forall i, \quad k^e/2 \leq |T_i \cap S| \leq 3 \cdot k^e) \geq 1 - O(k^{-b}).$$

The first construction is based on "ℓ-wise independence," and the second is based on "almost 2-wise dependence" [20, 1, 15]. Sampling techniques based on ℓ-wise independence were first suggested by Bellare and Rompel [4]. However, this technique is not good enough in our setting and we use a different approach (which was also used in [27] with slightly different parameters). In Appendix A we explain the approach in detail, compare it to the approach of [4], and give full proofs of the lemmas above.

6. A seeded bit-fixing source extractor with a short seed. In this section we give a construction of a seeded bit-fixing source extractor that uses seed length $O(\log k)$ to extract $k^{\Omega(1)}$ bits as long as k is not too small. This seeded extractor is used as a component in our construction of deterministic extractors for bit-fixing sources.

THEOREM 6.1. *Fix any constant $0 < \alpha < 1$. There exist constants $c > 0$ and $0 < b < 1$ (both depending on α) such that for any $n \geq 16$ and $k \geq \log^c n$, there exists an explicit seeded (k, ϵ)-bit-fixing source extractor $E : \{0,1\}^n \times \{0,1\}^d \to \{0,1\}^m$ with $d = \alpha \cdot \log k$, $m = \Omega(k^b)$, and $\epsilon = O(k^{-b})$.*

Proof. Let X be an (n, k)-bit-fixing source. Let $x = x_1, \ldots, x_n$ be a string sampled by X. The extractor E works as follows: We use the extractor seed y to construct a partition of the bits of x into m sets. Then we output the xor of the bits in each set. With high probability, each set will contain a good bit and therefore, with high probability, the output will be uniformly distributed.

More formally, let b and c be the constants from Lemma 5.3 when using the lemma with the parameter α.

E(x,y):

- We use the seed y to obtain a partition of $[n]$ into $m = \Omega(k^b)$ sets $T_1, \ldots, T_m$ using Lemma 5.3 with the parameter α.
- For $1 \leq i \leq m$, compute $z_i = \oplus_{j \in T_i} x_j$.
- Output $z = z_1, \ldots, z_m$.

We give the following detailed correctness proof although it is very straightforward.

Let $S \subseteq [n]$ be the set of good indices and let Z be the distribution of the output string z. We need to prove that Z is close to uniform. Let A be the event

$\{\forall i\ T_i \cap S \neq \emptyset\}$. That is, A is the "good" event in which all sets contain a random bit (and therefore in this case the output is uniform). Let A^c be the complement event; i.e., A^c is the event $\{\exists i\ T_i \cap S = \emptyset\}$. We decompose Z according to A and A^c:

$$Z = \Pr(A^c) \cdot (Z|A^c) + \Pr(A) \cdot (Z|A).$$

$(Z|A)$ is uniformly distributed. From Lemma 5.3, when $k \geq \log^c n$, $\Pr(A) \geq 1 - O(k^{-b})$. Therefore, by Lemma 2.4

$$Z \overset{O(k^{-b})}{\sim} U_m. \qquad \square$$

7. Deterministic extractors for bit-fixing sources. In this section, we compose the ingredients from previous sections to prove Theorems 1.3 and 1.4. Namely, given choices for a deterministic bit-fixing source extractor, sampler, and seeded bit-fixing source extractor, we use Theorems 3.2 and 3.3 to get a new deterministic bit-fixing source extractor. This works as follows: We "plug in" a deterministic extractor that extracts little randomness and a sampler into Theorem 3.3 to get a seed obtainer. We then "plug in" this seed obtainer and a seeded extractor into Theorem 3.2 to get a new deterministic extractor which extracts almost all of the randomness. It is convenient to express this composition as in the following theorem.

THEOREM 7.1. *Assume we have the following ingredients:*

- *an $(n, k, k_{min}, k_{max}, \delta)$-sampler $Samp : \{0,1\}^t \to P([n])$;*
- *a deterministic (k_{min}, ϵ^*)-bit-fixing source extractor $E^* : \{0,1\}^n \to \{0,1\}^{m'}$;*
- *a seeded $(k - k_{max}, \epsilon_1)$-bit-fixing source extractor $E_1 : \{0,1\}^n \times \{0,1\}^d \to \{0,1\}^m$,*

where $m' \geq d + t$. Then we construct a deterministic (k, ϵ)-bit-fixing source extractor $E : \{0,1\}^n \to \{0,1\}^m$, where $\epsilon = \epsilon_1 + 3 \cdot \max(\epsilon^* + \delta, \epsilon^* \cdot 2^{t+1})$.

Proof. We use *Samp* and E^* in Theorem 3.3 to get a $(k, k - k_{max}, \max(\epsilon^* + \delta, \epsilon^* \cdot 2^{t+1}))$-seed obtainer $F : \{0,1\}^n \to \{0,1\}^n \times \{0,1\}^{m'-t}$. Since $m' - t \geq d$, we can use F and E_1 in Theorem 3.2 to obtain a deterministic (k, ϵ)-bit-fixing source extractor $E : \{0,1\}^n \to \{0,1\}^m$, where $\epsilon = \epsilon_1 + 3 \cdot \max(\epsilon^* + \delta, \epsilon^* \cdot 2^{t+1})$. $\square$

We also require the following construction of a seeded extractor (which is in particular a seeded bit-fixing source extractor).

THEOREM 7.2 (see [26]). *For any n, k and $\epsilon > 0$, there exists a (k, ϵ)-extractor $Ext : \{0,1\}^n \times \{0,1\}^d \to \{0,1\}^m$, where $m = k$ and $d = O(\log^2 n \cdot \log(1/\epsilon) \cdot \log k)$.*

7.1. An extractor for large k (proof of Theorem 1.3). To prove Theorem 1.3, we first state results about the required ingredients and then use the ingredients in Theorem 7.1.

We use the deterministic bit-fixing source extractor of Kamp and Zuckerman [17]. Loosely speaking, the following theorem states that when $k \gg \sqrt{n}$, we can deterministically extract a polynomial fraction of the randomness with an exponentially small error.

THEOREM 7.3 (see [17]). *Fix any integers n, k such that $k = b \cdot n^{1/2+\gamma}$ for some $b > 0$ and $0 < \gamma \leq 1/2$. There exists a constant $c > 0$ (*not *depending on any of the parameters) such that there exists an explicit deterministic (k, ϵ^*)-bit-fixing source extractor $E^* : \{0,1\}^n \to \{0,1\}^m$, where $m = cb^2 \cdot n^{2\gamma}$ and $\epsilon^* = 2^{-m}$.*

Using the theorem above we can obtain a seed of length $O(n^{2\gamma})$. This means that we can afford this many bits for our sampler and seeded bit-fixing source extractor. We use the sampler based on ℓ-wise independence from Lemma 5.1. We use the seeded extractor of [26] (Theorem 7.2) which we now restate in the following form.

COROLLARY 7.4. *Fix any constants $0 < \gamma \leq 1/2$ and $\alpha > 0$. There exists a constant n' depending on γ such that for any integers n, k satisfying $n > n'$ and $k \leq n$ there exists a (k, ϵ_1)-extractor $E_1 : \{0,1\}^n \times \{0,1\}^d \to \{0,1\}^m$, where $m = k$, $d = \alpha \cdot n^{2\gamma}$, and $\epsilon_1 = 2^{-\Omega(\alpha \cdot n^\gamma)}$.*

Proof. We use the extractor of Theorem 7.2. We need $d = c_1 \cdot (\log^3 n \cdot \log(1/\epsilon_1))$ random bits for some constant $c_1 > 0$. We want to use at most $\alpha \cdot n^{2\gamma}$ random bits. We get the inequality $\alpha \cdot n^{2\gamma} \geq c_1 \cdot \log^3 n \cdot \log(1/\epsilon_1)$. Equivalently, $\epsilon_1 \geq 2^{-\frac{\alpha \cdot n^{2\gamma}}{c_1 \cdot \log^3 n}}$. So for a large enough n (depending on γ), we can take $\epsilon_1 = 2^{-\frac{\alpha \cdot n^\gamma}{c_1}} = 2^{-\Omega(\alpha \cdot n^\gamma)}$. ∎

We now compose the ingredients from Theorem 7.3, Lemma 5.1, and Corollary 7.4 to prove Theorem 1.3. The composition is a bit cumbersome in terms of the different parameters. The main issue is that when $k = n^{1/2+\gamma}$, the deterministic extractor of Kamp and Zuckerman extracts $\Omega(n^{2\gamma})$ random bits; and this is enough to use as a seed for a sampler and seeded extractor (that extracts all the randomness) with error $2^{-\Omega(n^\gamma)}$.

Proof of Theorem 1.3. Let c be the constant in Theorem 7.3. We use Theorem 7.1 with the following ingredients:

- the $(n, k, (n^{1/2+\gamma})/6, n^{1/2+\gamma}, \delta = 2^{-\Omega(n^\gamma)})$-sampler $Samp : \{0,1\}^t \to P([n])$ from Lemma 5.1, where $t = (c/72)n^{2\gamma}$;
- the deterministic $((n^{1/2+\gamma})/6, \epsilon^* = 2^{-m'})$-bit-fixing source extractor $E^* : \{0,1\}^n \to \{0,1\}^{m'}$ from Theorem 7.3, where $m' = (c/36)n^{2\gamma}$;
- the $(k - n^{1/2+\gamma}, \epsilon_1 = 2^{-\Omega(n^\gamma)})$-extractor $E_1 : \{0,1\}^n \times \{0,1\}^d \to \{0,1\}^m$ from Corollary 7.4 with $d \leq (c/72)n^{2\gamma}$ and $m = k - n^{1/2+\gamma}$.

Note that all three objects exist for a large enough n depending only on γ (c is a universal constant). Note that $m' \geq t + d$. Therefore, applying Theorem 7.1, we get a deterministic (k, ϵ)-bit-fixing source extractor $E : \{0,1\}^n \to \{0,1\}^m$, where $m = k - n^{1/2+\gamma}$ and

$$\epsilon = \epsilon_1 + 3 \cdot \max(\epsilon^* + \delta, \epsilon^* \cdot 2^{t+1})$$

$$= 2^{-\Omega(n^\gamma)} + 3 \cdot \max\left(2^{-(c/36)n^{2\gamma}} + 2^{-\Omega(n^\gamma)}, 2^{-(c/36)n^{2\gamma}} \cdot 2^{(c/72)n^{2\gamma}+1}\right)$$

$$= 2^{-\Omega(n^\gamma)} + 3 \cdot \max\left(2^{-\Omega(n^\gamma)}, 2^{-(c/72)n^{2\gamma}+1}\right) = 2^{-\Omega(n^\gamma)}$$

(for a large enough n depending on γ). ∎

7.2. An extractor for small k (proof of Theorem 1.4). To prove Theorem 1.4 we need a deterministic bit-fixing source extractor for $k < \sqrt{n}$. We use the extractor of Theorem 4.1. We prove the theorem in two steps. First, we use Theorem 7.1 to convert the initial extractor into a deterministic bit-fixing source extractor that extracts more bits. We then apply Theorem 7.1 again to obtain a deterministic bit-fixing source extractor which extracts almost all bits.

The following lemma implements the first step and shows how to extract a polynomial fraction of the randomness with a polynomially small error, whenever $k \geq \log^c n$ for some constant c.

LEMMA 7.5. *There exist constants $c, b > 0$ such that for any $k \geq \log^c n$ and large enough n, there exists an explicit deterministic (k, k^{-b})-bit-fixing source extractor $E : \{0,1\}^n \to \{0,1\}^m$, where $m = k^{\Omega(1)}$.*

Proof. Roughly speaking, the main issue is that we can get $\Omega(\log k)$ random bits using the deterministic extractor of Theorem 4.1. We will need $c_1 \cdot \log\log n$ random bits to use the sampler of Lemma 5.2 and the seeded extractor of Theorem 6.1 (for some constant c_1). Thus, when $k \geq \log^c n$ for large enough c, we will have enough bits.

Formally, we use Theorem 7.1 with the following ingredients:

- the $(n, k, k^e/2, 3 \cdot k^e, \delta = k^{-\Omega(1)})$-sampler $Samp : \{0,1\}^t \to P([n])$ from Lemma 5.2, where $t = \log k/32$ and $e > 1/2$ is the constant from that lemma;
- the deterministic $(k^e/2, \epsilon^* = 2^{-\sqrt{k^e/2}})$-bit-fixing source extractor $E^* : \{0,1\}^n \to \{0,1\}^{m'}$ from Theorem 4.1, where $m' = \log(k^e/2)/4$;
- the seeded $(k - 3 \cdot k^e, \epsilon_1 = (k - 3 \cdot k^e)^{-\Omega(1)})$-bit-fixing source extractor $E_1 : \{0,1\}^n \times \{0,1\}^d \to \{0,1\}^m$ from Theorem 6.1 with $d = \log k/32$ and $m = (k - 3 \cdot k^e)^{\Omega(1)}$.

Note that all three objects exist for $k \geq \log^c n$ for some constant c and large enough n. Assume that n is large enough so that $k \geq \log^c n \geq 2$. To use Theorem 7.1 we need to check that $m' \geq t + d$: Indeed, $m' = \log(k^e/2)/4 \geq \log k/16 = t + d$ (where we used $e > 1/2$, as stated in Lemma 5.2). Applying Theorem 7.1, we get a deterministic (k, ϵ)-bit-fixing source extractor $E : \{0,1\}^n \to \{0,1\}^m$. Notice that for large enough n: $\epsilon_1 = k^{-\Omega(1)}$, therefore

$$\epsilon = \epsilon_1 + 3 \cdot \max(\epsilon^* + \delta, \epsilon^* \cdot 2^{t+1})$$

$$= k^{-\Omega(1)} + 3 \cdot \max\left(2^{-\sqrt{k^e/2}} + k^{-\Omega(1)}, 2^{-\sqrt{k^e/2}} \cdot 2^{\log k/32+1}\right) = k^{-\Omega(1)}$$

(for a large enough n). Also, $m = (k - 3 \cdot k^e)^{\Omega(1)} = k^{\Omega(1)}$ (for a large enough n) and thus we get the required parameters. ∎

We now compose the ingredients from Lemmas 5.2 and 7.5 and Theorem 7.2 to prove Theorem 1.4. The composition is a bit cumbersome in terms of the different parameters. The main issue is that we can extract $k^{\Omega(1)}$ random bits using the deterministic extractor of Lemma 7.5. We want $\log^5 n$ random bits to use the seeded extractor of Theorem 7.2. Thus, when $k \geq \log^c n$ for large enough c, we will have enough bits.

Proof of Theorem 1.4. Let b be the constant in Lemma 7.5. We use Theorem 7.1 with the following ingredients:

- the $(n, k, k^e/2, 3 \cdot k^e, \delta = k^{-\Omega(1)})$-sampler $Samp : \{0,1\}^t \to P([n])$ from Lemma 5.2, where $t = (b/2)\log k$ and $e > 1/2$ is the constant from that lemma;
- the deterministic $(k^e/2, \epsilon^* = (k^e/2)^{-b})$-bit-fixing source extractor $E^* : \{0,1\}^n \to \{0,1\}^{m'}$ from Lemma 7.5, where $m' = (k^e/2)^{\Omega(1)}$;
- the $(k - 3 \cdot k^e, \epsilon_1 = 1/n)$-extractor $E_1 : \{0,1\}^n \times \{0,1\}^d \to \{0,1\}^m$ from Theorem 7.2 with $d \leq \log^5 n$ and $m = (k - 3 \cdot k^e)$.

Note that all three objects exist for $k \geq \log^c n$ for some constant c and for large enough n. To use Theorem 7.1 we need to check that $m' \geq t + d$: Note that $m' = k^{\Omega(1)}$. We take c large enough so that for large enough n, $m'/2 > \log^5 n$ and $m'/2 > (b/2)/\log k$. So for such n

$$m' \geq \log^5 n + (b/2)\log k \geq d + t.$$

Applying Theorem 7.1, we get a deterministic (k, ϵ)-bit-fixing source extractor $E : \{0,1\}^n \to \{0,1\}^m$, where

$$\epsilon = \epsilon_1 + 3 \cdot \max(\epsilon^* + \delta, \epsilon^* \cdot 2^{t+1})$$

$$= 1/n + 3 \cdot \max\left((k^e/2)^{-b} + k^{-\Omega(1)}, 2 \cdot (k^e/2)^{-b} \cdot k^{b/2}\right) = k^{-\Omega(1)}$$

(for large enough n). Since $m = k - O(k^e)$, where $1/2 < e < 1$, we are done. □

8. Discussion and open problems. We give explicit constructions of deterministic bit-fixing source extractors that extract almost all the randomness. However, we achieve the rather large error $\epsilon = k^{-\Omega(1)}$ in the case that $k < \sqrt{n}$. We now explain why this happens and suggest how to reduce the error. Recall that in this case our final extractor is based on an initial extractor that extracts only $m = O(\log k)$ bits. When transforming the initial extractor into the final extractor we use the output bits of the initial extractor as a seed for an averaging sampler. The error parameter δ of an averaging sampler has to be larger than 2^{-m} and as this error is "inherited" by the final extractor we can only get an error of about $1/k$. A natural way to improve our result is to find a better construction for the initial extractor.

Some applications of deterministic bit-fixing source extractors in adaptive settings of exposure-resilient cryptography require extractors with $\epsilon \ll 2^{-m}$. We do not achieve this goal (even in our first construction that has relatively small error), unless we artificially shorten the output. Suppose one wants to extract $m = k - u$ bits (for some parameter u). It is interesting to investigate how small the error can be as a function of u. We point out that the existential nonexplicit result achieves error $\epsilon \geq 2^{-u}$ and thus cannot achieve $\epsilon < 2^{-m}$ when $m \geq k/2$. We remark that for bit-fixing sources we have examples of settings where the nonexplicit result is not optimal. For example when $m = 1$, the xor-extractor is errorless (see also [11]). Given the discussion above, we find it interesting to achieve $m = \Omega(k)$ with $\epsilon = 2^{-\Omega(k)}$ for every choice of k.

Appendix A. Sampling and partitioning. In this section we give constructions of samplers and prove Lemmas 5.1, 5.2, and 5.3.

A.1. Sampling using ℓ-wise independence. Bellare and Rompel [4] gave a sampler construction based on ℓ-wise independent variables. We use a twist on their method: Suppose we are aiming to hit k/r bits when given a subset S of size k. We generate ℓ-wise independent variables $Z_1, \ldots, Z_n \in [r]$ and define $T = \{i | Z_i = 1\}$. It follows that with high probability $S \cap T$ is of size approximately k/r. This is stated formally in the following lemma. (We explain the difference between this method and that of [4] in Remark A.3.)

LEMMA A.1. *For every integer n, k, r, t such that $r \leq k \leq n$ and $6 \log n \leq t \leq \frac{k \log n}{20r}$ there is an explicit $(n, k, \frac{1}{2} \cdot \frac{k}{r}, 3 \cdot \frac{k}{r}, 2^{-\Omega(t/\log n)})$-sampler which uses a seed of t random bits.*

Before proving this lemma we show that Lemma 5.1 is a special case.

Proof of Lemma 5.1. We use Lemma A.1 with the parameters n, k, and $r = \frac{3k}{n^{1/2+\gamma}}$, $t = \alpha \cdot n^{2\gamma}$. We need to check that $6 \log n \leq t \leq \frac{k \log n}{20r}$. Clearly, $t \geq 6 \log n$ (for a large enough n depending on α and γ). On the other hand,

$$\frac{k \log n}{20r} = \frac{n^{1/2+\gamma} \log n}{60} \geq \alpha \cdot n^{2\gamma} = t$$

(for a large enough n depending on α and γ). Thus, applying Lemma A.1, we get an $(n, k, k/2r, 3k/r, \delta)$-sampler $Samp : \{0,1\}^t \to P([n])$, where

$$\delta = 2^{-\Omega(t/\log n)} = 2^{-\Omega(\alpha \cdot n^{2\gamma}/\log n)} = 2^{-\Omega(\alpha \cdot n^{\gamma})}$$

(for a large enough n depending on α and γ). □

We need the following tail-inequality for ℓ-wise independent variables due to Bellare and Rompel [4].

THEOREM A.2 (see [4]). *Let $\ell \geq 6$ be an even integer. Suppose that $X_1, \ldots, X_n$ are ℓ-wise independent random variables taking values in $[0,1]$. Let $X = \sum_{1 \leq i \leq n} X_i$ and $\mu = E(X)$, and let $A > 0$. Then*

$$\Pr[|X - \mu| \geq A] \leq 8 \left(\frac{\ell\mu + \ell^2}{A^2} \right)^{\ell/2}.$$

We now prove Lemma A.1.

Proof of Lemma A.1. Let ℓ be the largest even integer such that $\ell \log n \leq t$, and let $q = \lfloor \log r \rfloor \leq \log n$. There are constructions which use $\ell \log n \leq t$ random bits to generate n random variables $Z_1 \ldots, Z_n \in \{0,1\}^q$ that are ℓ-wise independent [9]. The sampler generates such random variables. Let $a \in \{0,1\}^q$ be some fixed value. We define a random variable $T = \{i | Z_i = a\}$. Let $S \subseteq [n]$ be some subset of size k. For $1 \leq i \leq n$ we define a boolean random variable X_i such that $X_i = 1$ if $Z_i = a$. Let $X = |S \cap T| = \sum_{i \in S} X_i$. Note that $\mu = E(X) = k/2^q$ and that the random variables $X_1, \ldots, X_n$ are ℓ-wise independent. Applying Theorem A.2 with $A = k/2r$ we get that

$$\Pr[|X - \mu| \geq A] \leq 8 \left(\frac{\ell k/2^q + \ell^2}{A^2} \right)^{\ell/2}.$$

Note that

$$\{|X - \mu| < A\} \subseteq \left\{ \frac{k}{2^q} - A < X < \frac{k}{2^q} + A \right\} \subseteq \left\{ \frac{k}{r} - A < X < \frac{2k}{r} + A \right\}$$

$$\subseteq \{k_{min} \leq X \leq k_{max}\}$$

for $k_{min} = k/2r$ and $k_{max} = 3k/r$. Note that $\ell \leq \frac{t}{\log n} \leq \frac{k}{20r}$. We conclude that

$$\Pr[k_{min} \leq |S \cap T| \leq k_{max}] \geq 1 - 8 \left(\frac{\ell \frac{k}{2^q} + \ell^2}{(\frac{k}{2r})^2} \right)^{\ell/2} \geq 1 - 8 \left(\frac{4r^2(\frac{2\ell k}{r} + \frac{\ell k}{20r})}{k^2} \right)^{\ell/2}$$

$$\geq 1 - 8 \left(\frac{10\ell r}{k} \right)^{\ell/2} \geq 1 - 2^{-(\ell/2+3)} \geq 1 - 2^{-\Omega(t/\log n)}. \quad \square$$

Remark A.3. We remark that this construction is different from the common way of using ℓ-wise independence for sampling [4]. The more common way is to take n/r random variables $V_1, \ldots, V_{n/r} \in [n]$ which are ℓ-wise independent and sample the multiset $T = \{V_1, \ldots, V_{n/r}\}$. The expected size of the multiset $|S \cap T|$ is k/r, and one gets the same probability of success $\delta = 2^{-\Omega(\ell)}$ by the tail-inequality of [4]. The two methods require roughly the same number of random bits. Nevertheless, the method of Lemma A.1 has the following advantages:

- It can also be used for partitioning.
- The method used in Lemma A.1 guarantees that T is a set whereas the standard method may produce a multiset.

- The method used in Lemma A.1 can be derandomized and use many fewer bits (at least for small r and large δ). More precisely, suppose that $r \leq \log n$ and say $\ell = 2$. In this range of parameters, one can use $O(\log \log n)$ random bits to generate n variables $Z_1, \ldots, Z_n \in \{0,1\}^{\log r}$ which are $(1/\log n)$-close to being pairwise independent. Thus, the same technique can be used to construct more randomness-efficient samplers (at the cost of having larger error parameter δ). We use this idea in section A.2. We remark that in the case of the standard method no savings can be made as it requires variables Z_i over $\{0,1\}^{\log n}$ and even sampling one such variable requires $\log n$ random bits.

A.2. Sampling and partitioning using fewer bits. We now derandomize the construction of Lemma A.1 to give schemes which use only $O(\log k)$ bits and prove Lemmas 5.2 and 5.3. These two lemmas follow from the following more general lemma.

LEMMA A.4. *Fix any integer $n \geq 16$. Let k be an integer such that $k \leq n$. Let r satisfy $r \leq k$. Let r' be the power of 2 that satisfies $(1/2)r < r' \leq r$. Let $\epsilon > 0$ satisfy $1/kr \leq \epsilon \leq 1/8r$. We can use $7 \log r + 3(\log \log n + \log(1/\epsilon))$ random bits to explicitly partition $[n]$ into r' sets $T_1, \ldots, T_{r'}$ such that for any $S \subseteq [n]$ where $|S| = k$*

$$\Pr(\forall i, \quad k/2r \leq |T_i \cap S| \leq 3k/r) \geq 1 - O(\epsilon \cdot r^3).$$

We prove Lemma A.4 in the next section. We now explain how the two lemmas follow from Lemma A.4.

Proof of Lemma 5.3. Set $b = \alpha/38$. Use Lemma A.4 with the parameters $r = k^b$ and $\epsilon = k^{-4b}$ to obtain a partition $T_1, \ldots, T_{r'}$ of $[n]$, where $(1/2)r < r' \leq r$ is a power of 2.

To use Lemma A.4 with these parameters we need $7 \log r + 3(\log \log n + \log(1/\epsilon)) = 7 \log k^b + 3(\log \log n + \log k^{4b})$ random bits.

We want to use at most $\alpha \cdot \log k$ bits.

Set $c = 6/\alpha$. Since we assume that $k \geq \log^c n$,

$$(\alpha/2) \log k \geq (\alpha/2)(6/\alpha) \log \log n = 3 \log \log n.$$

So now we need

$$(\alpha/2) \log k \geq 7 \log k^b + 3 \log k^{4b} = b(7 + 12) \log k$$

or, equivalently,

$$b \leq \alpha/38.$$

Set $e = 1 - b$. So $k/2r = k^e/2$ and $3k/r = 3 \cdot k^e$. Note that $e > 1/2$ as required. Using Lemma A.4,

$$\Pr(\forall i, \quad k^e/2 \leq |T_i \cap S| \leq 3 \cdot k^e) \geq 1 - O(\epsilon \cdot r^3) = 1 - O(k^{-b}). \qquad \square$$

Lemma 5.2 easily follows from Lemma 5.3.

Proof of Lemma 5.2. Use Lemma 5.3 with the parameters n, k, and α to obtain a partition of $[n]$ $T_1, \ldots, T_m$ and take T_1 as the sample. It is immediate that the required parameters are achieved. $\square$

Proof of Lemma A.4. The sampler construction in Lemma A.1 relied on random variables $Z_1, \ldots, Z_n \in [r]$ which are ℓ-wise independent. We now show that we can derandomize this construction and get a (weaker) sampler by using $Z_1, \ldots, Z_n$ which are only *pairwise ϵ-dependent*. Naor and Naor [20] (and later Alon et al. [1]) gave constructions of such variables using very few random bits. This allows us to reduce the number of random bits required for sampling and partitioning.

The following definition formalizes a notion of limited independence, slightly more general than the one discussed above.

DEFINITION A.5 (ℓ-wise ϵ-dependent variables). *Let D be a distribution. We say that the random variables $Z_1, \ldots, Z_n$ are ℓ-wise ϵ-dependent according to D if for every $M \subseteq [n]$ such that $|M| \leq \ell$ the distribution Z_M (that is, the joint distribution of the Z_i's such that $i \in M$) is ϵ-close to the distribution $D^{\otimes |M|}$, i.e., the distribution of $|M|$ independent random variables chosen according to D. We sometimes omit D when it is the uniform distribution.*

Random bit variables $B_1, \ldots, B_n$ are ℓ-wise ϵ-dependent with mean p if they are ℓ-wise ϵ-dependent according to the distribution $D = (1-p, p)$ on $\{0, 1\}$.

We need two properties about ℓ-wise ϵ-dependent variables: that they can be generated using very few random bits and that their sum is concentrated around the expectation. The first property is proved in Lemma A.7 and the second in Lemma A.8.

The following theorem states that ℓ-wise ϵ-dependent bit variables can be generated by very few random bits.

THEOREM A.6 (see [1]).[6] *For any $n \geq 16$, $\ell \geq 1$, and $0 < \epsilon < 1/2$, ℓ-wise ϵ-dependent bits $B_1, \ldots, B_n$ can be generated using $3(\ell + \log\log n + \log(1/\epsilon))$ truly random bits.*

We can generate pairwise ϵ-dependent variables in larger domains using ℓ-wise ϵ-dependent bit variables.[7]

LEMMA A.7. *Let $r < n$ be a power of 2. For any $n \geq 16$ and $0 < \epsilon < 1/2$, we can generate pairwise ϵ-dependent variables $Z_1, \ldots, Z_n \in [r]$ using $7 \log r + 3(\log\log n + \log(1/\epsilon))$ truly random bits.*

Proof. Using Theorem A.6, we generate $2 \log r$-wise ϵ-dependent bit variables $B_1, \ldots, B_{n \log r}$ using $3(2 \log r + \log\log(n \log r) + \log(1/\epsilon)) \leq 7 \log r + 3(\log\log n + \log(1/\epsilon))$ bits. We partition the B_i's into n blocks of size $\log r$ and interpret the ith block as a value $Z_i \in [r]$.

The joint distribution of the bits in any block or two blocks is ϵ-close to uniform. Therefore, the Z_i's are pairwise ϵ-dependent. ∎

In the following lemma, we use Chebyshev's inequality to show that the sum of pairwise ϵ-dependent bit variables is close to its expectation with high probability.

LEMMA A.8. *Let p satisfy $0 < p < 1$. Let $\epsilon > 0$ satisfy $p/k \leq \epsilon \leq p/4$. Let $B_1, \ldots, B_k$ be pairwise ϵ-dependent bit variables with mean p. Let $B = \sum_{i=1}^{k} B_i$.*

Then

$$\Pr(|B - pk| > pk/2) = O(\epsilon/p^2).$$

Proof. Using linearity of expectation we get $|E(B) - pk| \leq \epsilon k$.

[6] The theorem is stated a bit differently and only for odd ℓ in [1], but this form is easily deduced from Theorem 3 in that paper, observing that $(\ell+1)$-wise ϵ-dependence implies ℓ-wise ϵ-dependence.

[7] Actually, a construction of such (and more general types of) variables already appears in [15].

Therefore

$$\Pr(|B - pk| > pk/2) \leq \Pr(|B - E(B)| > pk/2 - \epsilon k).$$

Thus it is enough to bound

$$\Pr(|B - E(B)| > pk/2 - \epsilon k).$$

Fix any $i, j \in [k]$ where $i \neq j$. The covariance of B_i and B_j will be small since they are almost independent:

$$\operatorname{cov}(B_i, B_j) = E(B_i \cdot B_j) - E(B_i)E(B_j)$$

$$= \Pr(B_i = 1; B_j = 1) - \Pr(B_i = 1)\Pr(B_j = 1)$$

$$\leq (p^2 + \epsilon) - (p - \epsilon)^2 = (1 + 2p - \epsilon)\epsilon \leq 3\epsilon$$

(where the second equality is because B_i and B_j are bit variables).

Therefore, the variance of B won't be too large:

$$\operatorname{Var}(B) = \sum_i \operatorname{Var}(B_i) + \sum_{i \neq j} \operatorname{cov}(B_i, B_j) \leq (p + \epsilon)k + 3\epsilon k^2 \leq pk + 4\epsilon k^2.$$

Therefore, by Chebyshev's inequality

$$\Pr(|B - E(B)| > pk/2 - \epsilon k) < \frac{pk + 4\epsilon k^2}{(pk/2 - \epsilon k)^2}$$

we required that $\epsilon \leq p/4$ and therefore

$$\leq \frac{pk + 4\epsilon k^2}{(pk/4)^2} = O(1/pk) + O(\epsilon/p^2) = O(\epsilon/p^2)$$

(where the last equality follows by the requirement that $\epsilon \geq p/k$). □

Now we can easily prove Lemma A.4.

Proof of Lemma A.4. Let r' be the power of 2 in the statement of the lemma. Using Lemma A.7, we generate pairwise ϵ-dependent $Z_1, \ldots, Z_n \in [r']$. For $1 \leq i \leq r'$, we define $T_i = \{j | Z_j = i\}$.

Assume, w.l.o.g., that $S = \{1, \ldots, k\}$.

Given $i \in [r']$, define the bit variables $B_1, \ldots, B_k$ by $B_j = 1 \Leftrightarrow Z_j = i$.

It is easy to see that the B_j's are pairwise 2ϵ-dependent with mean $1/r'$.

Define $C_i = \sum_{j=1}^{k} B_j$. Note that $C_i = |T_i \cap S|$.

Notice that $1/r'$ and 2ϵ satisfy the requirements in Lemma A.8.

Using Lemma A.8,

$$\Pr(|C_i - k/r'| > k/2r') = O(\epsilon \cdot (r')^2) = O(\epsilon \cdot r^2).$$

Using the union bound,

$$\Pr(\exists i \text{ s.t. } |C_i - k/r'| > k/2r') = O(\epsilon \cdot r^3).$$

Thus, we can obtain a partition $T_1, \ldots, T_{r'}$ of $[n]$ such that, with probability at least $1 - O(\epsilon \cdot r^3)$,

$$\forall i, \quad k/2r' \leq |T_i \cap S| \leq 3k/2r',$$

which implies that with at least the same probability,

$$\forall i, \quad k/2r \leq |T_i \cap S| \leq 3k/r. \qquad \square$$

EXTRACTING RANDOMNESS USING FEW INDEPENDENT SOURCES*

BOAZ BARAK†, RUSSELL IMPAGLIAZZO‡, AND AVI WIGDERSON§

Abstract. In this work we give the first deterministic extractors from a constant number of weak sources whose entropy rate is less than 1/2. Specifically, for every $\delta > 0$ we give an explicit construction for extracting randomness from a constant (depending polynomially on $1/\delta$) number of distributions over $\{0,1\}^n$, each having min-entropy δn. These extractors output n bits that are 2^{-n} close to uniform. This construction uses several results from additive number theory, and in particular a recent result of Bourgain et al. We also consider the related problem of constructing randomness dispersers. For any constant output length m, our dispersers use a constant number of *identical* distributions, each with min-entropy $\Omega(\log n)$, and outputs *every* possible m-bit string with positive probability. The main tool we use is a variant of the "stepping-up lemma" of Erdős and Hajnal used in establishing a lower bound on the Ramsey number for hypergraphs.

Key words. randomness extractors, Ramsey graphs, sum-product theorem

1. Introduction.

1.1. Background. Randomness is prevalent in computer science and is widely used in algorithms, distributed computing, and cryptography. Perhaps the main motivation and justification for the use of randomness in computation is that randomness exists in nature, and thus it is possible to sample natural phenomena (such as the tossing of coins) in order to make random choices in computation. However, there is a discrepancy between the type of random input that we expect when designing randomized algorithms and protocols, and the type of random data that can be found in nature. While randomized algorithms and protocols expect a stream of independent uniformly distributed random bits, this is too much to hope for from samples of natural phenomena.

Thus, a natural and widely studied problem has been that of constructing *randomness extractors.*[1] Loosely speaking, a *randomness extractor* is a (deterministic polynomial-time computable) function $\mathsf{Ext} : \{0,1\}^n \to \{0,1\}^m$ such that whenever $\mathcal{X}$ is a "good" random variable (where the definition of "good" will be discussed shortly), then $\mathsf{Ext}(\mathcal{X})$ is statistically close to the uniform distribution. The random variable $\mathcal{X}$

[1] We note that while this has been the original motivation for studying randomness extractors, such constructs have found numerous other applications in computer science and are fundamental and interesting objects in their own right.

is intended to model the natural data, while the output of the extractor will be used to make random choices in a probabilistic algorithm or protocol.

Intuitively, the "good" distributions should be the distributions that contain more than m bits of entropy. Otherwise, information-theoretic considerations show that such an extractor cannot exist, even if it is only required to extract randomness from a fixed source that is known to the designer. Actually, past works have converged to the measure of *min-entropy* [10, 49], which is a stronger notion than standard (Shannon) entropy. (The min-entropy of a random variable $\mathcal{X}$, denoted by $H^\infty(\mathcal{X})$, is equal to $\min_{x \in \mathsf{Supp}(\mathcal{X})}(-\log \Pr[\mathcal{X} = x])$.) It can be easily seen that the min-entropy of a random variable $\mathcal{X}$ is always smaller than the (Shannon) entropy of X and that if $\mathsf{Ext}(\mathcal{X})$ is statistically close to being uniform over $\{0,1\}^m$, then the distribution $\mathcal{X}$ must be statistically close to having min-entropy at least m. Thus, possessing high min-entropy is indeed a minimal requirement of the input distribution.

We note that it is known that if a random variable $\mathcal{X}$ has min-entropy k, then it is a convex combination of random variables $\mathcal{X}_1, \ldots, \mathcal{X}_t$, where each $\mathcal{X}_i$ is the uniform distribution over some subset of size 2^k. Such random variables are called *flat*. Because of this fact, when constructing randomness extractors typically we can assume without loss of generality that the input distribution is flat. This is convenient for several reasons, one of which is that the min-entropy of flat distributions is equal to their Shannon entropy.

1.2. Seeded and seedless extractors. An unfortunate and easily seen fact is that there is no *single* function Ext that will produce a (close to) uniform output on *every* input distribution having high min-entropy. Previous works have dealt with this problem in two ways: The first way is to add a short, truly random *seed* as a secondary input to the extractor, and the second way is to use no seed, but make further assumptions on the structure of the weak sources (in addition to the minimal assumption of it containing sufficient min-entropy).

Seeded extractors. As mentioned above, one approach to tackle the above problem has been to allow the extractor to be *probabilistic*. That is, in addition to its input $\mathcal{X}$, one allows the function Ext to have an additional input $\mathcal{Y}$ that is uniformly distributed. The goal is to have the input $\mathcal{Y}$ be (much) *shorter* than the output length m. We call the additional input $\mathcal{Y}$ the *seed* of the extractor, and thus we call such constructions *seeded* extractors.[2] Seeded extractors have been studied extensively in the past two decades (see the survey [42] and references therein) with a series of exciting results, techniques, and applications. The current state of the art is a construction of extractors that are nearly optimal in the sense that they use a seed $\mathcal{Y}$ of length $O(\log n)$ bits, extracting essentially all the min-entropy of the source [27]. This in particular means that by using such extractors, together with enumeration over all possible seed values, it is possible to simulate any probabilistic algorithm with polynomial overhead, using only a high min-entropy source.

Seedless extractors. There are many reasons to try constructing *seedless* extractors. One is that the polynomial overhead implied by the seed enumeration above may sometimes be too expensive. Another is that certain applications in computer science, such as in cryptography and distributed computing, intrinsically prohibit such enumeration. For example, when using a weak source of randomness to choose an encryption key via a seeded extractor, it will certainly be *insecure* to enumerate all

[2] We remark that in most of the literature, the name *randomness extractor* (without any qualifiers) refers to what we call here a *seeded* randomness extractor.

secret keys produced using all seeds and then send the encryptions of a secret message using each of these keys. More generally, it seems that typically we cannot directly use seeded extractors in cryptography (see [28, 15, 5] for different cryptographic models under weak sources of randomness).

There have been many constructions of such seedless extractors that work for specific families of high min-entropy sources. The first to consider this problem was von Neumann, who gave a seedless extractor from a stream of *biased* but independent bits [47] (see also [32]). Other works, such as [6, 41, 10, 12, 11, 29, 25, 44], constructed seedless extractors for more general families of sources.[3]

1.3. Seedless extractors from few independent sources. When seedless extraction from one source is impossible, it is natural to consider doing so from several independent sources of the same quality. After all, assuming we have one such source in nature does not seem much weaker than assuming we have several.

The first to consider this problem were Santha and Vazirani [41], who showed how to use $O(\log n)$ independent "semirandom"[4] sources of length n and min-entropy δn for every constant $\delta > 0$.

Chor and Goldreich [10] were the first to consider general min-entropy sources, and they proved that if $\delta > n/2$, then two sources suffice: indeed the Hadamard–Sylvester matrix $H : \{0,1\}^n \times \{0,1\}^n \to \{0,1\}$ defined by $H(x,y) = \langle x, y\rangle$ (with the inner product in GF(2)) is such an extractor. (We note that for this construction the $n/2$ entropy bound is tight—there are two sources of entropy exactly $n/2$ on which H is constant.) Vazirani [45] extended this to show that one can use a similar function to output from two independent sources of entropy $(\frac{1}{2} + \epsilon)n$ a linear number of bits that are exponentially close to the uniform distribution.[5]

Improving [10] seems hard. Even its disperser version, namely having a non-constant output for any two sources of entropy rate below 1/2, is the notorious "bipartite Ramsey" problem, which is still open. A slight improvement for this problem was made recently by Pudlak and Rödl [35], who lowered the min-entropy requirement for such a disperser to $n/2 - \sqrt{n}$, but getting a constant $\delta < 1/2$ remains a barrier for two sources. (Very recently, significant progress was made on this problem that builds on the results of the current work; see section 5.)

An alternative 2-source function is the Paley matrix, $P : GF(p) \times GF(p) \to \{\pm 1\}$, defined by $P(x,y) = \chi_2(x+y)$ (where p is an n-bit prime and $\chi_2 : \mathrm{GF}(p) \to \{\pm 1\}$ is the quadratic character). P too is an extractor with exponentially small error for entropy $> n/2$ and is conjectured to have the same property for entropy δn for all $\delta > 0$. While this conjecture is generally believed, proving it seems beyond current techniques.[6] Assuming even more, Zuckerman [48] showed that if this conjecture holds for *all* multiplicative characters (not just χ_2), then a constant (actually $poly(1/\delta)$) number of sources suffices for extraction of linearly many bits with exponential error.

[3] The results of Trevisan and Vadhan [44] differ from the literature, as well as from our work, in that they work in the computational setting; i.e., the restriction on the family of sources is computational, the sources are efficiently sampleable, and the extractors work while assuming an unproven computational assumption.

[4] We will not formally define these semirandom sources (also known as Santha–Vazirani sources) but will only note that they are weaker than high min-entropy sources. Nevertheless one cannot extract seedlessly from only one such source.

[5] Vazirani [45] states his result for the semirandom sources of [41] but it extends to general min-entropy sources.

[6] We note that it is known (using Weil's estimate of character sums) that P is an extractor for two sources, where one of them has entropy $> n/2$ and the other only entropy $> \log n$.

The extractor we use here is *exactly* the same as Zuckerman's (but our analysis uses no unproven assumptions).

1.4. Our results.

1.4.1. Multiple-sample extractors. In this work we will be interested in extracting randomness from a *constant* (larger than 2) number of samples from a high min-entropy source.[7] Loosely speaking, our main result is an efficient construction for extracting (almost) uniformly distributed bits from a constant number of samples from independent distributions over $\{0,1\}^n$, each sample having min-entropy at least δn, for an arbitrarily small constant $\delta > 0$. The statistical distance of our output from the uniform distribution is exponentially low (i.e., $2^{-\Omega(n)}$).[8] More formally, our main theorem is the following.

THEOREM 1.1 (multiple-sample extractor). *For every constant $\delta > 0$ there exists a constant $\ell = (1/\delta)^{O(1)}$ and a polynomial-time computable function $\mathsf{Ext} : \{0,1\}^{n \cdot \ell} \to \{0,1\}^n$ such that for every independent random variable $\mathcal{X}_1, \ldots, \mathcal{X}_\ell$ over $\{0,1\}^n$ satisfying $H^\infty(\mathcal{X}_i) \geq \delta n$ for $i = 1, \ldots, \ell$, it holds that*

$$\mathsf{dist}\Big(\mathsf{Ext}(\mathcal{X}_1, \ldots, \mathcal{X}_\ell), U_n\Big) < 2^{-n},$$

where U_n denotes the uniform distribution over the set $\{0,1\}^n$ and $\mathsf{dist}(\mathcal{X}, \mathcal{Y})$ denotes the statistical distance *of two distributions $\mathcal{X}$ and $\mathcal{Y}$. That is,*

$$\mathsf{dist}(\mathcal{X}, \mathcal{Y}) \stackrel{def}{=} \frac{1}{2} \sum_{i \in \mathsf{Supp}(\mathcal{X}) \cup \mathsf{Supp}(\mathcal{Y})} \Big| \Pr[\mathcal{X} = i] - \Pr[\mathcal{Y} = i] \Big|.$$

As mentioned in the introduction, we denote by $H^\infty(\mathcal{X})$ the min-entropy of the random variable $\mathcal{X}$ (i.e., $H^\infty(\mathcal{X}) = \min_{x \in \mathsf{Supp}(\mathcal{X})}(-\log \Pr[\mathcal{X} = x])$).

Remark 1.2. As is noted in section 3.5, we can actually reduce the statistical distance of our extractor by using more independent samples. In particular, for every $c > 1$, we can ensure that the output of our extractor will be (2^{-cn})-close to the uniform distribution by multiplying the number of samples we use by a factor of $O(c)$. Note that if a distribution $\mathcal{Y}$ over $\{0,1\}^n$ is (2^{-cn})-close to the uniform distribution, then in particular for every $y \in \{0,1\}^n$, $\Pr[\mathcal{Y} = y] \in (2^{-n} - 2^{-cn}, 2^{-n} + 2^{-cn})$ (i.e., $\mathcal{Y}$ is even close to the uniform distribution in the L_∞ norm).

1.4.2. Dispersers. We also present a construction of *dispersers* that works for much lower entropy samples of the *same* source. A *disperser* is a relaxed variant of an extractor, which does not need to output a distribution statistically close to uniform, but rather only a distribution with large support. Thus, when talking about dispersers, it is natural to consider only the support of their input, and so refer to the inputs as sets rather than random variables (where a set of size 2^k corresponds to a random variable of min-entropy k). The formal definition of dispersers is in section 2. Our main result regarding dispersers is the following theorem.

THEOREM 1.3 (multiple-sample same-source disperser). *There exist constants ℓ and d such that for every m, there is a polynomial-time computable function* Disp :

[7] We note that our results can be generalized to the case of extracting from a larger (i.e., superconstant) number of samples having sublinear entropy. However, we do not consider such extensions in this paper.

[8] Note that we get statistical distance that is much better than what is possible to obtain with seeded extractors, which cannot do better than a polynomially small distance when using a logarithmic-length seed. This low statistical distance is important for cryptographic applications.

$\{0,1\}^{n\cdot\ell} \to \{0,1\}^m$ *satisfying that for every subset* $\mathcal{X} \subseteq \{0,1\}^n$ *with* $|\mathcal{X}| \geq n^{d2^m}$,

$$\mathsf{Disp}(\mathcal{X},\ldots,\mathcal{X}) = \{0,1\}^m.$$

That is, if $|\mathcal{X}| \geq n^{d2^m}$, *then for every* $y \in \{0,1\}^m$, *there exist* $x_1,\ldots,x_\ell \in \mathcal{X}$ *such that* $\mathsf{Disp}(x_1,\ldots,x_\ell) = y$.

This is a better disperser than the multiple-source extractor of Theorem 1.1 in the sense that it works for very low min-entropy (indeed, note that if we let m be a constant, then sets of size $n^{O(1)}$ correspond to distributions of min-entropy of $O(\log n)$). However, it still has two drawbacks: one is that its output is much smaller than the input entropy (although it can still be much larger than the number of samples); another is that it requires all its input samples to come from the *same* distribution $\mathcal{X}$ (rather than from different distributions, as in our extractor). We consider the second drawback to be the more serious one. The construction of this disperser closely follows the "stepping-up" technique of Erdős and Hajnal (see Graham, Rothschild, Spencer [22, sect. 4.7]) it that it gives an (explicit) lower bound on the Ramsey number of hypergraphs. We remark that we work for worse entropy than this lower-bound[9] because we want to output a superconstant number of bits (that does not depend on the number of samples).

1.5. Techniques.

An Erdős–Szemerédi theorem for finite fields. Our main tools for Theorem 1.1 are several results from additive number theory, and in particular, a relatively recent result by Bourgain, Katz, and Tao [9]. They proved an analogue of the Erdős–Szemerédi [17] theorem for finite prime fields. Let $\mathcal{A}$ be a subset of some field $\mathbb{F}$. We define the set $\mathcal{A}+\mathcal{A}$ to equal $\{a+b \mid a,b \in \mathcal{A}\}$ and the set $\mathcal{A}\cdot\mathcal{A}$ to equal $\{a\cdot b \mid a,b \in A\}$. Note that $|\mathcal{A}| \leq |\mathcal{A}+\mathcal{A}| \leq |\mathcal{A}|^2$ (and similarly $|\mathcal{A}| \leq |\mathcal{A}\cdot\mathcal{A}| \leq |\mathcal{A}|^2$). An example for a set $\mathcal{A}$, where $\mathcal{A}+\mathcal{A}$ is small (of size about $2|\mathcal{A}|$), is an *arithmetic progression.* An example for a set $\mathcal{A}$, where $\mathcal{A}\cdot\mathcal{A}$ is small, is a *geometric progression.* The Erdős–Szemerédi theorem is that for every set $\mathcal{A} \subseteq \mathbb{N}$, either $\mathcal{A}+\mathcal{A}$ or $\mathcal{A}\cdot\mathcal{A}$ is of size at least $|\mathcal{A}|^{1+\epsilon_0}$ for some universal constant ϵ_0. In some sense, one can view this theorem as saying that a set of integers can't be simultaneously close to both an arithmetic progression and a geometric progression.

A natural question, which has many diverse applications in geometry and analysis, is whether this theorem also holds in *finite* fields. A first observation is that this theorem is *false* in a field $\mathbb{F}$ that contains a nontrivial subfield $\mathbb{F}'$. This is because if we let $\mathcal{A} = \mathbb{F}'$, then $\mathcal{A}+\mathcal{A} = \mathcal{A}\cdot\mathcal{A} = \mathcal{A}$. However, [9] showed that a variant of this theorem does hold in a finite field with no nontrivial subfields.[10] In particular it holds in the fields $\mathrm{GF}(p)$ and $\mathrm{GF}(2^p)$ for every prime p. That is, [9] proved the following.

THEOREM 1.4 (see [9]). *Let* $\delta > 0$ *be some constant and let* $\mathbb{F}$ *be a field with no subfield of size between* $|\mathbb{F}|^{\delta/2}$ *and* $|\mathbb{F}|-1$. *Let* $\mathcal{A} \subseteq \mathbb{F}$ *be a set such that* $|\mathbb{F}|^\delta < |\mathcal{A}| < |\mathbb{F}|^{1-\delta}$. *Then there exists some constant* ϵ *(depending on* δ*) such that*

$$\max\{|\mathcal{A}+\mathcal{A}|, |\mathcal{A}\cdot\mathcal{A}|\} > |\mathcal{A}|^{1+\epsilon}.$$

In [9], the dependence of the constant ϵ on δ was not specified (and examining the proof shows that it is probably of the form $\epsilon = 2^{-\Omega(1/\delta)}$). In the appendix we give

[9] Using c samples, this lower bound yields a 1-bit-output disperser for $\log^{(\Theta(c))} n$ entropy, where $\log^{(i)} n$ denotes the result of iterating $\log$ i times on n.

[10] By a *trivial* subfield in this context we mean a subfield that is either equal to the entire field or very small (e.g., of constant size).

a proof of Theorem 1.4 (using some of the lemmas of [9]) with $\epsilon = \Theta(\delta)$.[11] Konyagin [26] gave a stronger result for *prime* fields and showed that, as long as $|\mathcal{A}| < |\mathbb{F}|^{0.99}$, the value ϵ can be made a constant independent of the size of $\mathcal{A}$. That is, he proved the following theorem.

THEOREM 1.5 (see [26]). *There exists some constant ϵ_0 such that for every $\mathbb{F}$ that is a field of prime order, and every $\mathcal{A} \subseteq \mathbb{F}$ with $|\mathcal{A}| < |\mathbb{F}|^{0.99}$,*

$$\max\{|\mathcal{A}+\mathcal{A}|, |\mathcal{A}\cdot\mathcal{A}|\} > |\mathcal{A}|^{1+\epsilon_0}.$$

1.6. How is this related to extractors?

Using Theorem 1.5 *to obtain dispersers.* Theorem 1.5 actually already implies some kind of multiple-sample disperser that was not previously known. This is because it implies the following corollary.

COROLLARY 1.6. *There exists some constant ϵ_0 such that for every $\mathbb{F}$ a field of prime order, and every $\mathcal{A} \subseteq \mathbb{F}$ with $|\mathcal{A}| < |\mathbb{F}|^{0.99}$,*

$$|\mathcal{A}\cdot\mathcal{A}+\mathcal{A}| > |\mathcal{A}|^{1+\epsilon_0}.$$

Indeed, by Theorem 1.5, for every set $\mathcal{A}$ either $|\mathcal{A}\cdot\mathcal{A}|$ or $|\mathcal{A}+\mathcal{A}|$ is at least $|\mathcal{A}|^{1+\epsilon'}$ for some absolute constant ϵ'. If the former holds, then since $|\mathcal{A}\cdot\mathcal{A}+\mathcal{A}| \geq |\mathcal{A}\cdot\mathcal{A}|$ we're done. In the latter case we can use previously known number-theoretic results (see also Lemma 3.7) that imply that if $|\mathcal{A}+\mathcal{A}| \geq |\mathcal{A}|^{1+\epsilon'}$, then $|\mathcal{A}+\mathcal{B}| \geq |\mathcal{A}|^{1+\epsilon'/2}$ for every set $\mathcal{B}$ with $|\mathcal{B}| = |\mathcal{A}|$. This means that if we let s be any member of $\mathcal{A}$ and consider $\mathcal{B} = s^{-1}\mathcal{A}$, then we get that $|\mathcal{A}+\mathcal{B}| \geq |\mathcal{A}|^{1+\epsilon'/2}$ (since multiplying by a fixed element is a permutation that does not change the size of a set). For the same reason, $|\mathcal{A}+\mathcal{B}| = |\mathcal{A}+s^{-1}\mathcal{A}| = |s\mathcal{A}+\mathcal{A}|$, but the set $s\mathcal{A}+\mathcal{A}$ is a subset of $\mathcal{A}\cdot\mathcal{A}+\mathcal{A}$.

In other words, Corollary 1.6 states that there is an efficiently computable $f(\cdot)$ such that $|f(\mathcal{A},\mathcal{A},\mathcal{A})| \geq |\mathcal{A}|^{1+\epsilon_0}$ (i.e., $f(a,b,c) = a\cdot b+c$). Yet this implies that for every set $\mathcal{A}$ with $|\mathcal{A}| \geq |\mathbb{F}|^{\delta}$, if we compose f with itself $O(\log(1/\delta))$ times, we get a function $g : \mathbb{F}^{\ell} \to \mathbb{F}$ (for $\ell = 2^{O(\log(1/\delta))} = (1/\delta)^{O(1)}$) such that $g(\mathcal{A},\ldots,\mathcal{A}) = \mathbb{F}$ (where $g(\mathcal{A},\ldots,\mathcal{A})$ denotes the image of g on $\mathcal{A}^{\ell}$).[12] If we identify the field $\mathbb{F}$ with the strings $\{0,1\}^n$, then we see that this function g (which is obviously polynomial-time computable) is already some kind of a disperser.

Obtaining extractors. To obtain an *extractor* rather than a disperser, we would like to obtain a *statistical* analogue of Theorem 1.5. Consider the following notation. If $\mathcal{X}$ is a random variable, then we define $\mathcal{X}+\mathcal{X}$ to be the distribution obtained by choosing a, b independently at random from $\mathcal{X}$ and outputting $a+b$, and we define $\mathcal{X}\cdot\mathcal{X}$ in a similar way. Then, a statistical analogue of Theorem 1.5 would be that there exists some $\epsilon > 0$ such that for every random variable $\mathcal{X}$ with min-entropy at most $0.99\log|\mathbb{F}|$, either the distribution $\mathcal{X}+\mathcal{X}$ or the distribution $\mathcal{X}\cdot\mathcal{X}$ has min-entropy at least $(1+\epsilon)H^{\infty}(\mathcal{X})$. Unfortunately, this is false: For every prime field $\mathbb{F}$, there is a random variable $\mathcal{X}$ that is uniform over some set of size 2^k (for $k \ll 0.99\log|\mathbb{F}|$) and such that for both $\mathcal{X}+\mathcal{X}$ and $\mathcal{X}\cdot\mathcal{X}$, a constant fraction of the probability mass is concentrated in a set of size $O(2^k)$. Indeed, an example for such a random variable $\mathcal{X}$

[11] The proof of in our appendix also has the advantage of proving the theorem for all fields $\mathbb{F}$ simultaneously. The authors of [9] prove Theorem 1.4 for prime fields and then only mention how it can be generalized to other fields.

[12] This is because each time we apply f we grow in the set size from m to $m^{1+\epsilon_0}$. We note that one needs to analyze separately the case that $|\mathcal{A}| > |\mathbb{F}|^{0.99}$, but this can be done. This function g is described in more detail in the beginning of section 3.

is a random variable that is with probability half an arithmetic progression and with probability half a geometric progression.

Even though the statistical analogue for Theorem 1.5 does not hold, we show that a statistical analogue for Corollary 1.6 *does* hold. That is, we prove (in Lemma 3.1) that there exists some constant $\epsilon_0 > 0$ such that for every random variable $\mathcal{X}$ over a prime field $\mathbb{F}$, the distribution $\mathcal{X} \cdot \mathcal{X} + \mathcal{X}$ has (up to some negligible statistical distance) min-entropy at least $(1+\epsilon_0)H^\infty(\mathcal{X})$. (In fact, we need to (and do) prove a more general statement regarding distributions of the form $\mathcal{X} \cdot \mathcal{Y} + \mathcal{Z}$.) The proof of this lemma is the main technical step in our extractor. The proof uses Theorem 1.5, along with some other additive number-theoretic results of Ruzsa [40] and Gowers [21].

We use this lemma to show that the function g sketched above is actually not just a disperser but an *extractor*. That is, we show that for every random variable $\mathcal{X}$ of min-entropy at least $\delta \log |\mathbb{F}|$, the random variable $g(\mathcal{X}, \ldots, \mathcal{X})$ (where g is applied to ℓ independent copies of $\mathcal{X}$) not only has large support but is also in fact very close to the uniform distribution. (In fact, we need to (and do) prove a stronger version of this statement, namely, that $g(\mathcal{X}_1, \ldots, \mathcal{X}_\ell)$ is close to uniform for every independent random variable, $\mathcal{X}_1, \ldots, \mathcal{X}_\ell$ with $H^\infty(\mathcal{X}_i) \geq \delta \log |\mathbb{F}|$ for $i = 1, \ldots, \ell$.)

2. Preliminaries. In this section we establish our definitions for multiple-sample extractors and dispersers. Unfortunately, such definitions tend to have a large number of parameters.

DEFINITION 2.1 (multiple-sample extractor). *A function* $\mathsf{Ext} : \{0,1\}^{n \cdot \ell} \to \{0,1\}^m$ *is called an* ℓ-sample (k, m, ϵ)-extractor *if for every independent random variable* $\mathcal{X}_1, \ldots, \mathcal{X}_\ell$ *satisfying* $H^\infty(\mathcal{X}_i) \geq k$ *for* $i = 1, \ldots, \ell$ *it holds that*

$$\mathsf{dist}\Big(\mathsf{Ext}(\mathcal{X}_1, \ldots, \mathcal{X}_\ell), U_m\Big) < \epsilon.$$

Parameters and qualifiers:

- The parameter ℓ is called the *number of samples* of the extractor. In all our constructions we will use ℓ, which is a constant independent of the input length.
- The parameter m is called the *output length* of the extractor. Usually, we'll use $m = n$.
- The parameter k is called the min-entropy requirement by the extractor.
- The parameter ϵ is called the statistical distance of the extractor.
- One can also make a weaker definition in which the extractor is required to output a close-to-uniform value only if the variables $\mathcal{X}_1, \ldots, \mathcal{X}_\ell$ are identically distributed. We call such an extractor a *same-source* extractor. Thus, we will sometimes say that a standard (as per Definition 2.1) multiple-sample extractor is a *different-source* extractor.

We now define the weaker notion of a disperser.

DEFINITION 2.2 (multiple-sample disperser). *A function* $\mathsf{Disp} : \{0,1\}^{n \cdot \ell} \to \{0,1\}^m$ *is called an* ℓ-sample (k, m)-disperser *if for all sets* $\mathcal{X}_1, \ldots, \mathcal{X}_\ell$ *satisfying* $|\mathcal{X}_i| \geq 2^k$ *for* $i = 1, \ldots, \ell$, *it holds that*

$$\mathsf{Disp}(\mathcal{X}_1, \ldots, \mathcal{X}_\ell) = \{0,1\}^m.$$

Notes:

- We will use the same names for the parameters and qualifiers of dispersers as we used for extractors (e.g., number of samples, output length, same-source, different-source).

- In previous literature, dispersers are usually defined with a parameter ϵ analogous to the statistical distance of extractors, requiring $|\mathsf{Disp}(\mathcal{X}_1, \ldots, \mathcal{X}_\ell)| \geq (1-\epsilon)2^m$ instead of the requirement we make. Thus, one can think of our definition as setting $\epsilon = 0$. However, in our particular setting of independent samples, this is essentially without loss of generality, as we can convert a disperser satisfying the weaker definition with any constant $\epsilon < 1/2$ into a disperser satisfying the stronger definition with only a constant factor increase in the number of samples.[13]

Basic facts and observations. The following facts regarding multiple-sample extractors and dispersers are either known or easy to verify:

- There does not exist a 1-sample disperser (and hence an extractor) even with only one bit of output and even if the source is assumed to have $n-1$ bits of min-entropy.
- There is a simple construction for a 2-sample *same-source* 1-bit-output extractor whenever the source min-entropy is larger than $O(\log \frac{1}{\epsilon})$ (where ϵ is the statistical distance). This is the extractor that on input x, y outputs 1 if $x > y$.
- In contrast, by Ramsey-type arguments, a 2-sample same-source disperser (and hence an extractor) with more than one bit of output requires the input min-entropy to be at least $\log n$. The same holds for a different-source 1-bit-output disperser.

  The best known previous explicit constructions for both cases require the min-entropy to be more than $n/2$ [10, 46]. Indeed, the function $H : \{0,1\}^{2n} \to \{0,1\}$ defined as $H(x,y) = \sum x_i y_i \pmod 2$ (i.e., the adjacency function of the Hadamard graph) is known to be a 1-bit-output extractor for sources with more than $n/2$ entropy [10]. This is essentially the best known previous construction in terms of the minimum entropy requirement. There has been some improvement in obtaining variants of this extractor that have a larger output size [46, 16, 14], although these still require at least $n/2$ entropy. (Also, as mentioned above, it is known that the adjacency function of the Paley graph is a 1-bit-output extractor that works as long as one of its inputs has more than $n/2$ entropy, while the other input needs only to have more than $\log n$ entropy [23, 2]. However, in this paper we restrict ourselves to the *symmetric* case, where all sources have the same entropy requirement.)
- Using enumeration over all possible seeds, one can use a *seeded* extractor to obtain a polynomial-samples same-source extractor with the same requirement over the min-entropy. It is also possible to generalize this to work for *different sources* [38].

Explicit constructions. In the definition of extractors and dispersers we did not require these functions to be efficiently computable. However, naturally we will be interested in obtaining extractors and dispersers that are computable in polynomial time. We call such constructions *explicit*.

3. Constructing a multiple-sample extractor. In this section we prove Theorem 1.1. That is, we construct an extractor Ext (where $\mathsf{Ext} : \{0,1\}^{\ell \cdot n} \to \{0,1\}^n$)

[13] This can be done, for example, by identifying the set $\{0,1\}^n$ with elements of a prime field $\mathbb{F}$ (as we do in what follows) and using the Cauchy–Davenport theorem. This theorem says that if $\mathcal{A}$ and $\mathcal{B}$ are subsets of a prime field $\mathbb{F}$, then the set $\mathcal{A} + \mathcal{B} = \{a + b | a \in \mathcal{A}, b \in \mathcal{B}\}$ is of size at least $\min\{|\mathbb{F}|, |\mathcal{A}| + |\mathcal{B}| - 1\}$. Hence, if $\mathcal{A}_1, \ldots, \mathcal{A}_k$ are sets of size $> \epsilon|\mathbb{F}|$ with $k > 2/\epsilon$, then $\mathcal{A}_1 + \cdots + \mathcal{A}_k = \mathbb{F}$.

such that $\mathsf{Ext}(\mathcal{X}_1,\ldots,\mathcal{X}_\ell)$ is statistically close to the uniform distribution for every independent random variables $\mathcal{X}_1,\ldots,\mathcal{X}_\ell$ over $\{0,1\}^n$ with high enough min-entropy (i.e., at least δn, where $\ell = \mathrm{poly}(1/\delta)$). Our extractor will be very simple, involving only a recursive composition of the operation $(a,b,c) \mapsto a \cdot b + c$. As noted in the introduction, this is the same construction used by Zuckerman [48].

Formally, we fix a suitable field $\mathbb{F}$ (see below) and define the functions Ext^i for all $i \in \mathbb{N}$ recursively as follows:

- For every i, the function Ext^i will be a mapping from $\mathbb{F}^{3^i}$ to $\mathbb{F}$.
- $\mathsf{Ext}^0 : \mathbb{F}^{3^0} = \mathbb{F} \to \mathbb{F}$ is the identity function $\mathsf{Ext}^0(x) = x$.
- Assume Ext^i is already defined. We define $\mathsf{Ext}^{i+1} : \mathbb{F}^{3^{i+1}} = (\mathbb{F}^{3^i})^3 \to \mathbb{F}$ as follows: For every $x_1, x_2, x_3 \in \mathbb{F}^{3^i}$,

$$\mathsf{Ext}^{i+1}(x_1,x_2,x_3) \stackrel{def}{=} \mathsf{Ext}^i(x_1)\cdot\mathsf{Ext}^i(x_2) + \mathsf{Ext}^i(x_3).$$

Our extractor will be equal to Ext^i for a suitably chosen constant i. When extracting from a string in $\{0,1\}^n$, we will choose the field $\mathbb{F}$ to be of the form $\mathrm{GF}(N)$ for some prime $N \in [2^n, 2^{n+1})$ (and hence we can identify any string in $\{0,1\}^n$ with an element in the field $\mathbb{F}$). We postpone the issue of finding such a prime to section 3.4.

Theorem 1.1 will follow from the following two lemmas.

LEMMA 3.1. *There exists some constant $\epsilon > 0$ such that for every distribution $\mathcal{A},\mathcal{B},\mathcal{C}$ over a prime field $\mathbb{F}$, each with* min*-entropy at least m, the distribution $\mathcal{A}\cdot\mathcal{B}+\mathcal{C}$ is $(2^{-\epsilon m})$-close to having* min*-entropy at least $\min\{(1+\epsilon)m, 0.9\log|\mathbb{F}|\}$.*

LEMMA 3.2. *Let $\mathcal{A}_1,\ldots,\mathcal{A}_9$ be 9 independent distributions over a prime field $\mathbb{F}$ each with* min*-entropy at least $0.9\log|\mathbb{F}|$. Then, $\mathsf{Ext}^2(\mathcal{A}_1,\ldots,\mathcal{A}_9)$ is of distance at most $|\mathbb{F}|^{-0.01}$ from the uniform distribution over $\mathbb{F}$.*

Lemmas 3.1 and 3.2 imply Theorem 1.1. Indeed, Lemma 3.1 implies that for every constant $\delta > 0$, if we let $i = \log_{(1+\epsilon)}(1/\delta)$, then the output of Ext^i is close to having min-entropy $0.9\log|\mathbb{F}|$. Note that the number of samples required by Ext^i is 3^i, which is polynomial in $1/\delta$. We use Lemma 3.2 to get from min-entropy $0.9\log|\mathbb{F}|$ to a close-to-uniform output. Using the union bound, we see that the statistical distance of the extractors output from the uniform distribution on $\mathbb{F}$ will be at most $N^{-\Omega(1)}$. We defer the proof of Lemma 3.2 to section 3.6 and now turn to proving Lemma 3.1.[14]

3.1. Basic facts and notation. Before proving Lemma 3.1, we introduce some notation and some tools that will be used in the course of the proof. We identify a set $\mathcal{A}$ with the uniform distribution on elements of $\mathcal{A}$. If $\mathcal{D}$ is a distribution, then we denote by $\mathsf{cp}(\mathcal{D})$ the collision probability of $\mathcal{D}$, that is, $\mathsf{cp}(\mathcal{D}) = \Pr_{x,y\leftarrow_R\mathcal{D}}[x=y]$. Note that for a set $\mathcal{A}$, $\mathsf{cp}(\mathcal{A}) = \frac{1}{|\mathcal{A}|}$. If $\mathcal{A}$ and $\mathcal{B}$ are distributions over subsets of the field $\mathbb{F}$, then we denote by $\mathcal{A}+\mathcal{B}$ the *distribution* obtained by picking a at random from $\mathcal{A}$, picking b at random from $\mathcal{B}$, and outputting $a+b$. Note that this distribution may be far from the uniform distribution with the same support. We define the distribution $\mathcal{A}\cdot\mathcal{B}$ in a similar way. For $k \in \mathbb{Z}$ and $\mathcal{A}$ a set or a distribution, we define $k\mathcal{A}$ and $\mathcal{A}^k$ in the natural way.[15]

[14] Note that we could prove Theorem 1.1 without using Lemma 3.2 by applying the previously known 2-sample extractors, which work for entropy larger than $\frac{\log|\mathbb{F}|}{2}$. In addition, Vadhan observed that by using the fact that the function family $\{h_{b,c}\}$ (where $h_{b,c}(a) = a\cdot b+c$) is pairwise independent and the leftover hash lemma of [24], one can prove that under the conditions of Lemma 3.2 the first $0.8\log|F|$ bits of $\mathcal{A}_1\cdot\mathcal{A}_2+\mathcal{A}_3$ are within statistical distance $|F|^{-0.01}$ to the uniform distribution. This is also sufficient to prove Theorem 1.1.

[15] E.g., for $k>0$, $k\mathcal{A} = \underbrace{\mathcal{A}+\cdots+\mathcal{A}}_{k \text{ times}}$ and for $k<0$, $k\mathcal{A} = \underbrace{-\mathcal{A}-\cdots-\mathcal{A}}_{|k| \text{ times}}$.

We say that a distribution $\mathcal{X}$ is a convex combination of distributions $\mathcal{X}_1, \ldots, \mathcal{X}_m$ if there exist numbers $p_1, \ldots, p_m \in [0,1]$ such that $\sum_i p_i = 1$ and the random variable $\mathcal{X}$ (when looked at as a vector of probabilities) is equal to $\sum_i p_i \mathcal{X}_i$.

The following lemmas would be useful.

LEMMA 3.3. *Let $\mathcal{X}$ and $\mathcal{Y}$ be distributions; then* $\Pr[\mathcal{X} = \mathcal{Y}] \leq \sqrt{\mathsf{cp}(\mathcal{X})\mathsf{cp}(\mathcal{Y})} \leq \max\{\mathsf{cp}(\mathcal{X}), \mathsf{cp}(\mathcal{Y})\}$.

Proof. For every i in the union of the supports of $\mathcal{X}$ and $\mathcal{Y}$, let x_i denote the probability that $\mathcal{X} = i$ and let y_i denote the probability that $\mathcal{Y} = i$. Then

$$\Pr[\mathcal{X} = \mathcal{Y}] = \sum_i x_i y_i \leq \sqrt{\sum_i x_i^2 \sum_j y_j^2}$$

by the Cauchy-Schwarz inequality; however this is the geometric mean of $\mathsf{cp}(\mathcal{X})$ and $\mathsf{cp}(\mathcal{Y})$ (which is less than the maximum of these quantities). ∎

COROLLARY 3.4. *Let $\mathcal{A}, \mathcal{C}$ be distributions over $\mathbb{F}$. Then* $\mathsf{cp}(\mathcal{A} + \mathcal{C}) \leq \sqrt{\mathsf{cp}(\mathcal{A} - \mathcal{A})\mathsf{cp}(\mathcal{C} - \mathcal{C})}$.

Proof. Let $\mathcal{A}'$ and $\mathcal{C}'$ be two new, independent random variables distributed identically to $\mathcal{A}$ and $\mathcal{C}$, respectively. Then,

$$\mathsf{cp}(\mathcal{A} + \mathcal{C}) = Pr[\mathcal{A} + \mathcal{C} = \mathcal{A}' + \mathcal{C}'] = \Pr[\mathcal{A} - \mathcal{A}' = \mathcal{C} - \mathcal{C}'],$$

which is smaller than $\sqrt{\mathsf{cp}(\mathcal{A} - \mathcal{A})\mathsf{cp}(\mathcal{C} - \mathcal{C})}$ by Lemma 3.3. ∎

LEMMA 3.5. *Suppose that $\mathcal{X}$ is a convex combination of distributions $\mathcal{X}_1, \ldots, \mathcal{X}_m$. Then* $\mathsf{cp}(\mathcal{X}) \leq \max\{\mathsf{cp}(\mathcal{X}_1), \ldots, \mathsf{cp}(\mathcal{X}_m)\}$.

Proof. Using induction on m, this reduces to the case that $m = 2$ (since we can treat the combination of $\mathcal{X}_1, \ldots, \mathcal{X}_{m-1}$ as one distribution whose collision probability is bounded using induction). However, in this case $\mathcal{X} = \alpha\mathcal{X}_1 + (1-\alpha)\mathcal{X}_2$, and then

$$\mathsf{cp}(\mathcal{X}) = \alpha^2 \mathsf{cp}(\mathcal{X}_1) + 2\alpha(1-\alpha)\Pr[\mathcal{X}_1 = \mathcal{X}_2] + (1-\alpha)^2 \mathsf{cp}(\mathcal{X}_2).$$

However, $\Pr[\mathcal{X}_1 = \mathcal{X}_2] \leq \max\{\mathsf{cp}(\mathcal{X}_1), \mathsf{cp}(\mathcal{X}_2)\}$ by Lemma 3.3 and so we are done. ∎

LEMMA 3.6. *Let $\mathcal{X}$ be a distribution such that* $\mathsf{cp}(\mathcal{X}) \leq \frac{1}{KL}$. *Then $\mathcal{X}$ is of statistical distance* $\frac{1}{\sqrt{L}}$ *from having* min*-entropy at least* $\log K$.

Proof. We can split $\mathcal{X}$ into a convex combination $\mathcal{X} = \alpha\mathcal{X}' + (1-\alpha)\mathcal{X}''$, where $\mathcal{X}'$ contains the "heavy" elements of $\mathcal{X}$ that are obtained with probability at least $\frac{1}{K}$, and $\mathcal{X}''$ contains the rest of $\mathcal{X}$. We see that $\mathsf{cp}(\mathcal{X}) \geq \alpha^2 \mathsf{cp}(\mathcal{X}')$, and so $\frac{1}{KL} \geq \frac{\alpha^2}{K}$ and thus $\alpha \leq \frac{1}{\sqrt{L}}$. However, $H^\infty(\mathcal{X}'') \geq \log K$ and so we are done. ∎

Note that if $H^\infty(\mathcal{X}) \geq k$, then clearly $\mathsf{cp}(\mathcal{X}) \leq 2^{-k}$. Together with Lemma 3.6 this implies that, up to an arbitrarily close-to-1 multiplicative factor and an exponentially small (in the min-entropy) statistical distance, $H^\infty(X)$ is approximately equal to $\log(1/\mathsf{cp}(\mathcal{X}))$. (The quantity $\log(1/\mathsf{cp}(\mathcal{X}))$ is sometimes called the 2-*entropy* or the *Renyi entropy* of $\mathcal{X}$.)

3.2. Additive number-theoretic results. The following two lemmas hold for any Abelian group, and so their "+" operators may be replaced with "·" operators. Note that we do not state these lemmas with the most optimal choice of constants.

LEMMA 3.7 (see [40]; see also [31, 39]). *Let $\mathcal{A}, \mathcal{B}, \mathcal{C}$ be subsets of some Abelian group G. Then* $|\mathcal{A} + \mathcal{C}||\mathcal{B}| \leq |\mathcal{A} + \mathcal{B}||\mathcal{B} + \mathcal{C}|$.

In particular, $|\mathcal{A}| = |\mathcal{B}| = M$ and $\rho > 0$ is such that $|\mathcal{A} + \mathcal{B}| \leq M^{1+\rho}$. Then $|\mathcal{A} + \mathcal{A}| \leq \frac{|\mathcal{A}+\mathcal{B}|^2}{M} \leq M^{1+2\rho}$.

In other words, if $\mathcal{A}+\mathcal{B}$ is "small" for some $\mathcal{B}$, then $\mathcal{A}+\mathcal{A}$ is small. Note that Lemma 3.7 implies that we can replace $\mathcal{A}+\mathcal{A}$ and $\mathcal{A}\cdot\mathcal{A}$ in Theorem 1.4 with $\mathcal{A}+\mathcal{B}$ and $\mathcal{A}\cdot\mathcal{B}$ for every $\mathcal{B}$ satisfying $|\mathcal{B}|=|\mathcal{A}|$. Note that Lemma 3.7 also implies that if $|\mathcal{A}|=M$, $|\mathcal{B}|\geq M^{1-\epsilon}$, and $|\mathcal{A}+\mathcal{B}|\leq M^{1+\rho}$, then $|\mathcal{A}+\mathcal{A}|\leq M^{1+2\rho+\epsilon}$.

We will use the following lemma of Gowers (which is a quantitative improvement of a result by Balog and Szemerédi). We state it here using different sets $\mathcal{A}$,$\mathcal{B}$ (similarly to the way it is quoted in [9], although in [21] it is stated with $\mathcal{A}=\mathcal{B}$). See also Lemma A.5 for a generalization of this lemma obtained in [43].[16]

LEMMA 3.8 (see Proposition 12 in [21]). *Let $\mathcal{A},\mathcal{B}$ be subsets of some group G with $|\mathcal{A}|=|\mathcal{B}|=M$ and let $\rho>0$ be such that $\mathsf{cp}(\mathcal{A}+\mathcal{B})\geq\frac{1}{M^{1+\rho}}$. Then there exists $\mathcal{A}'\subseteq\mathcal{A}$ and $\mathcal{B}'\subseteq\mathcal{B}$ such that $|\mathcal{A}'|,|\mathcal{B}'|\geq M^{1-10\rho}$ and $|\mathcal{A}'+\mathcal{B}'|\leq M^{1+10\rho}$.*

We remark that it can be shown that if $\mathcal{A}=\mathcal{B}$ in the conditions of this lemma, then $\mathcal{A}'=\mathcal{B}'$ in its conclusion. We also note that we can apply the lemma even if $\mathcal{A}$ and $\mathcal{B}$ are of different sizes, as long as they are close enough. Indeed, if $|\mathcal{A}|=M$ and $|\mathcal{B}|=M^{1-\rho/10}$, then we can partition $\mathcal{A}$ to subsets $\mathcal{A}_1,\ldots,\mathcal{A}_k$ of size $|\mathcal{B}|$, and since $\mathcal{A}+\mathcal{B}$ is a convex combination of $\mathcal{A}_i+\mathcal{B}$, one of these subsets has collision probability as least as large as $\mathsf{cp}(\mathcal{A}+\mathcal{B})$, and we can apply the lemma to it.

3.3. Proof of Lemma 3.1.

Fixing ϵ. We fix ϵ small enough such that for every $M<|\mathbb{F}|^{0.99}$, Theorem 1.5 ensures us that if $\mathcal{X}$ is a set of size at least $M^{1-10^4\epsilon}$, then $\max\{|\mathcal{X}\cdot\mathcal{X}|,|\mathcal{X}+\mathcal{X}|\}$ is at least $M^{1+10^4\epsilon}$ (e.g., we can take $\epsilon=\epsilon_0/10^9$). Note that this is the only place in the proof in which we use the fact that $\mathbb{F}$ is a prime field. In particular, using Theorem 1.4 instead of Theorem 1.5, our proof yields also a variant of Lemma 3.1 for nonprime fields (see Lemma 3.14).

Statistical analogue of Theorem 1.5. Roughly speaking, Theorem 1.5 says that if $|\mathcal{A}\cdot\mathcal{A}|$ is "small," then $|\mathcal{A}+\mathcal{A}|$ is "large." By combining Theorem 1.4 with Lemma 3.7, it is possible get a "different sets" analogue of this statement and show that for every set $\mathcal{A}$ of size M, if $|\mathcal{A}\cdot\mathcal{B}|$ is small (i.e. $\leq M^{1+\epsilon}$) for some set $\mathcal{B}$ of size M, then $|\mathcal{A}+\mathcal{C}|$ is large ($\geq M^{1+\epsilon}$) for *every* set $\mathcal{C}$ of size M.

At this point we would have liked to obtain a collision probability analogue of this statement. That is, we would like to prove that if $\mathcal{A},\mathcal{B},\mathcal{C}$ are uniform distributions over sets of size M, and $\mathsf{cp}(\mathcal{A}\cdot\mathcal{B})\geq\frac{1}{M^{1+\epsilon}}$, then $\mathsf{cp}(\mathcal{A}+\mathcal{C})\leq\frac{1}{M^{1+\epsilon}}$. Unfortunately, this is false, as can be witnessed by considering the following counterexample. Let $M=N^{0.1}$, and let $\mathcal{A}=\mathcal{B}=\mathcal{C}$ be a distribution that is an arithmetic progression of size M with probability $\frac{1}{2}$ and a geometric progression of size M with probability $\frac{1}{2}$. For such a distribution, both $\mathsf{cp}(\mathcal{A}+\mathcal{A})$ and $\mathsf{cp}(\mathcal{A}\cdot\mathcal{A})$ are at least $\Omega(1/M)$.[17]

However, we are able to prove a slightly weaker statement. That is, we show that if $\mathcal{A}\cdot\mathcal{B}$ is small in *set size*, then $\mathcal{A}+\mathcal{C}$ shrinks significantly in *collision probability*. This is stated in the following lemma.

[16] We note that in some sources the lemma is stated with the condition that the distribution $\mathcal{A}+\mathcal{B}$ is of statistical distance at least $M^{-C\rho}$ from having min-entropy $(1+\rho)\log M$ (a condition that up to constant factor in the distance is equivalent to the condition that there is a subset $\mathcal{C}$ such that $|\mathcal{C}|\leq M^{1+\rho/(2C)}$ but $\Pr[\mathcal{A}+\mathcal{B}\in\mathcal{C}]\geq M^{-C\rho}$). However, this is equivalent to our statement of Lemma 3.8 by the observations above on the relation between min-entropy and collision probability. In particular, if there is such a set $\mathcal{C}$, then the collision probability of $\mathcal{A}+\mathcal{B}$ is at least $\Pr[\mathcal{A}+\mathcal{B}\in\mathcal{C}]|\mathcal{C}|^{-1}$.

[17] Let $\mathcal{A}_{\mathsf{arith}}$ denote the arithmetic progression. A random element from $\mathcal{A}+\mathcal{A}$ is in the set $\mathcal{A}_{\mathsf{arith}}+\mathcal{A}_{\mathsf{arith}}$ with probability at least $\frac{1}{4}$. However, because the set $\mathcal{A}_{\mathsf{arith}}+\mathcal{A}_{\mathsf{arith}}$ is of size at most $O(M)$, we get that $\mathsf{cp}(\mathcal{A}+\mathcal{A})\geq\frac{1}{16}\Omega(1/M)=\Omega(1/M)$. The symmetrical reasoning shows that $\mathsf{cp}(\mathcal{A}\cdot\mathcal{A})\geq\Omega(1/M)$.

LEMMA 3.9. *Let M and ϵ be as above and let $\mathcal{A} \subseteq \mathbb{F}$ be a set such that $|\mathcal{A}| \geq M^{1-20\epsilon}$, but also such that $|\mathcal{A} \cdot \mathcal{B}| \leq M^{1+20\epsilon}$, for some $\mathcal{B}$ with $|\mathcal{B}| \geq M^{1-20\epsilon}$. Then $\mathsf{cp}(\mathcal{A}+\mathcal{C})$ is smaller than $\frac{1}{M^{1+20\epsilon}}$ for* all *sets $\mathcal{C}$ of size M.*

Proof. If $\mathsf{cp}(\mathcal{A}+\mathcal{C}) \geq \frac{1}{M^{1+20\epsilon}}$, then by applying Lemma 3.8 (with $\rho = 60\epsilon$, and assuming $\epsilon < 1/10$) it holds that there exists subsets $\mathcal{A}', \mathcal{C}'$ of $\mathcal{A}$ and $\mathcal{C}$, respectively, such that $|\mathcal{A}'|, |\mathcal{C}'| \geq M^{1-600\epsilon}$, but also such that $|\mathcal{A}' + \mathcal{C}'| \leq M^{1+600\epsilon}$. This means by Lemma 3.7 that $|\mathcal{A}' + \mathcal{A}'| \leq M^{1+2000\epsilon}$. However, this means that $|\mathcal{A}' \cdot \mathcal{A}'| \geq M^{1+10^4\epsilon}$ by Theorem 1.5, which implies that $|\mathcal{A}' \cdot \mathcal{B}| \geq M^{1+10^3\epsilon}$ by Lemma 3.7. However, since $\mathcal{A}' \subseteq \mathcal{A}$ this implies that $|\mathcal{A} \cdot \mathcal{B}| \geq M^{1+10^3\epsilon}$, contradicting our initial assumption. ∎

We call a set $\mathcal{A}$ that satisfies the conclusion of Lemma 3.9 $(M, 20\epsilon)$ *plus friendly*. That is, $\mathcal{A}$ is said to be (M, ϵ') *plus friendly* if $\mathsf{cp}(\mathcal{A}+\mathcal{C}) \leq M^{-1-\epsilon'}$ for every $\mathcal{C}$ with $|\mathcal{C}| = M$. Since M and ϵ are fixed for this proof, we will sometimes drop the prefix and simply call (M, ϵ)-plus-friendly sets *plus friendly*. Reversing the roles of addition and multiplication, we obtain the following lemma.

LEMMA 3.10. *Let M and ϵ be as above and let $\mathcal{A} \subseteq \mathbb{F}$ be a set such that $|\mathcal{A}| \geq M^{1-20\epsilon}$, but also such that $|\mathcal{A} + \mathcal{B}| \leq M^{1+20\epsilon}$, for some $\mathcal{B}$ with $|\mathcal{B}| \geq M^{1-20\epsilon}$. Then $\mathsf{cp}(\mathcal{A} \cdot \mathcal{C})$ is smaller than $\frac{1}{M^{1+20\epsilon}}$ for* all *sets $\mathcal{C}$ of size M.*

Again, we call a set $\mathcal{A}$ that satisfies the conclusion of Lemma 3.10 an $(M, 20\epsilon)$-*times-friendly* set, and again in the following we will sometimes simply call such sets *times friendly*. The main step in our proof will be the following lemma.

LEMMA 3.11. *Let $\mathcal{A} \subseteq \mathbb{F}$ with $|\mathcal{A}| = M$. Then there exist two disjoint subsets $\mathcal{A}_+$ and $\mathcal{A}_\times$ such that*

- *$\mathcal{A}_+$ is either empty or (M, ϵ) plus friendly.*
- *$\mathcal{A}_\times$ is either empty or (M, ϵ) times friendly.*
- *$|\mathcal{A} \setminus (\mathcal{A}_+ \cup \mathcal{A}_\times)| < M^{1-\epsilon}$ (i.e., $\mathcal{A}_+ \cup \mathcal{A}_\times$ capture almost all of $\mathcal{A}$.)*

Note that this lemma implies that the counterexample described above (of a distribution that is an arithmetic progression with probability $\frac{1}{2}$ and a geometric progression with probability $\frac{1}{2}$) captures in some sense the worst case for the theorem.

Proof of Lemma 3.11. We prove the lemma by repeatedly applying Lemma 3.8 to construct the sets $\mathcal{A}_+, \mathcal{A}_\times$. We start with $\mathcal{A}_+ = \emptyset$ and $\mathcal{A}_\times = \mathcal{A}$. At each point, we remove some elements from $\mathcal{A}_\times$ and add them to $\mathcal{A}_+$. We always maintain the invariant that $\mathcal{A}_+$ is either empty or plus friendly.

If $|\mathcal{A}_\times| < M^{1-\epsilon}$, then we are done (since we can then let $\mathcal{A}_\times = \emptyset$ and have $|\mathcal{A}_\times \cup \mathcal{A}_+| \geq M - M^{1-\epsilon}$). If $\mathcal{A}_\times$ is (M, ϵ) times friendly, then we are done. Otherwise, there exists $\mathcal{B}''$ of size M such that $\mathsf{cp}(\mathcal{A}_\times \cdot \mathcal{B}'') \geq \frac{1}{M^{1+\epsilon}}$, and so we can apply Lemma 3.8 to obtain subsets $\mathcal{A}'$ of $\mathcal{A}_\times$ and $\mathcal{B}'$ of $\mathcal{B}''$ such that $|\mathcal{A}'|, |\mathcal{B}'| \geq M^{1-5\epsilon}$ (but also such that $|\mathcal{A}' \cdot \mathcal{B}'| \leq M^{1+5\epsilon}$). By Lemma 3.9, $\mathcal{A}'$ will be $(M, 10\epsilon)$ (and so in particular (M, ϵ)) plus friendly, and so we can remove it from $\mathcal{A}_\times$ and add it to $\mathcal{A}_1$ (i.e., let $\mathcal{A}_+ = \mathcal{A}_+ \cup \mathcal{A}'$, $\mathcal{A}_\times = \mathcal{A}_\times \setminus \mathcal{A}'$). Note that the union of disjoint-plus-friendly sets is plus friendly with the same parameters (since a convex combination of low collision-probability distributions has low collision probability by Lemma 3.5). We continue in this way until either $\mathcal{A}_\times$ is (M, ϵ) times friendly or until $|\mathcal{A}_\times| \leq M^{1-\epsilon}$. ∎

Using Lemma 3.11, we can obtain a collision-probability analogue of Corollary 1.6.

LEMMA 3.12. *Let $\mathcal{A}, \mathcal{B}, \mathcal{C} \subseteq \mathbb{F}$ with $|\mathcal{A}| = |\mathcal{B}| = |\mathcal{C}| = M$. Then $\mathcal{A} \cdot \mathcal{B} + \mathcal{C}$ is $(M^{-\epsilon})$-close to having collision probability at most $\frac{1}{M^{1+\epsilon}}$.*

Proof. We split $\mathcal{A}$ into $\mathcal{A}_+$ and $\mathcal{A}_\times$ as per Lemma 3.11. The distribution $\mathcal{A} \cdot \mathcal{B} + \mathcal{C}$ is within $M^{-\epsilon}$ statistical distance to a convex combination of the distribution $\mathcal{X}_+ =$

$\mathcal{A}_+ \cdot \mathcal{B} + \mathcal{C}$ and the distribution $\mathcal{X}_\times = \mathcal{A}_\times \cdot \mathcal{B} + \mathcal{C}$. (Unless $\mathcal{A}_+$ or $\mathcal{A}_\times$ is empty, in which case $\mathcal{A} \cdot \mathcal{B} + \mathcal{C}$ is within $M^{-\epsilon}$ statistical distance to one of these distributions.) We will finish the proof by showing that for both distributions $\mathcal{X}_+$ and $\mathcal{X}_\times$, if the corresponding set is not empty, then the collision probability is at most $\frac{1}{M^{1+\epsilon}}$.

Showing that $\mathsf{cp}(\mathcal{A}_+ \cdot \mathcal{B} + \mathcal{C}) \leq \frac{1}{M^{1+\epsilon}}$. Using Lemma 3.5, $\mathsf{cp}(\mathcal{A}_+ \cdot \mathcal{B} + \mathcal{C}) \leq \max_{b \in \mathbb{F}} \mathsf{cp}(\mathcal{A}_+ b + \mathcal{C})$. However, $\mathsf{cp}(\mathcal{A}_+ b + \mathcal{C}) = \mathsf{cp}(\mathcal{A}_+ + \mathcal{C}b^{-1})$ since the latter distribution is a permutation of the former distribution (obtained by multiplying each element by b^{-1}). Yet the fact that $\mathcal{A}_+$ is (M, ϵ) plus friendly implies that $\mathsf{cp}(\mathcal{A}_+ + \mathcal{C}b^{-1}) \leq \frac{1}{M^{1+\epsilon}}$.

Showing that $\mathsf{cp}(\mathcal{A}_\times \cdot \mathcal{B} + \mathcal{C}) \leq \frac{1}{M^{1+\epsilon}}$. This follows immediately from the fact that $\mathsf{cp}(\mathcal{A}_\times \cdot \mathcal{B}) \leq \frac{1}{M^{1+\epsilon}}$ and since $\mathsf{cp}(\mathcal{A}_\times \cdot \mathcal{B} + \mathcal{C}) \leq \mathsf{cp}(\mathcal{A}_\times \cdot \mathcal{B})$ (as $\mathcal{A}_\times \cdot \mathcal{B} + \mathcal{C}$ is a convex combination of distributions of the form $\mathcal{A}_\times \cdot \mathcal{B} + c$ for some fixed $c \in \mathcal{C}$). □

3.3.1. Finishing up. Lemma 3.12 almost directly implies Lemma 3.1. First, we use the known fact that if the distributions $\mathcal{A}, \mathcal{B}, \mathcal{C}$ have min-entropy at least m, then the joint distribution $\mathcal{A}, \mathcal{B}, \mathcal{C}$ is a convex combination on independent distributions of the form $\mathcal{A}', \mathcal{B}', \mathcal{C}'$, where each of these is a uniform distribution on a set of size at least $M = 2^m$. Thus, it is sufficient to prove Lemma 3.12 for such distributions. By Lemma 3.12, for such distributions the distribution $\mathcal{A}' \cdot \mathcal{B}' + \mathcal{C}'$ is within $M^{-\epsilon}$ distance of having collision probability at most $\frac{1}{M^{1+\epsilon}}$ for some constant $\epsilon > 0$. Now, by applying Lemma 3.6 (with $K = M^{1+\epsilon/2}$, $L = M^{\epsilon/2}$) we obtain that $\mathcal{A}' \cdot \mathcal{B}' + \mathcal{C}'$ is within statistical distance $M^{-\epsilon} + M^{-\epsilon/4}$ from having min-entropy at least $\log(M^{(1+\epsilon/2)}) = (1 + \epsilon/2)m$.

3.4. Constructing the field $\mathbb{F}$. Recall that our extractor obtains inputs in $\{0,1\}^n$ and needs to treat these inputs as elements of a field $\mathbb{F}$ of prime order. Unfortunately, there is no known deterministic polynomial-time algorithm that on input 1^n outputs an n-bit prime (without assuming a strong number-theoretic assumption about the distance between consecutive primes). Fortunately, in our setting we can still find such a prime. The reason is that we can use some of our samples from the high-entropy distribution to obtain such a prime. To do so, we will use the following result on *seeded* dispersers (which we state here with the parameters suitable for our purposes).

THEOREM 3.13 (see [49]). *For every $\delta > 0$, there exists a constant $d > 1$ and a polynomial-time computable function $\mathsf{D} : \{0,1\}^{(10/\delta)n} \times \{0,1\}^{d \log n} \to \{0,1\}^n$ such that for every set $\mathcal{A} \subseteq \{0,1\}^{(10/\delta)n}$ with $|\mathcal{A}| \geq 2^{2n}$, it holds that*

$$\left|\mathsf{D}(\mathcal{A}, \{0,1\}^{d \log n}) \cap \{0,1\}^n\right| \geq (1 - \tfrac{1}{n^2}) \cdot 2^n.$$

Let D be the function obtained from Theorem 3.13 and identify its output with a number in $[2^n]$. We say that $x \in \{0,1\}^{(10/\delta)n}$ is "bad" if $2^n + \mathsf{D}(x,y)$ is *not* a prime number for *every* $y \in \{0,1\}^{d \log n}$. Because the set of primes has more than $1/n^2$ density in the interval $[2^n, 2 \cdot 2^n]$, the set of all bad $x \in \{0,1\}^{(10/\delta)n}$ is of size at most 2^{2n}. This means that if we take $10/\delta$ samples $x_1, \ldots, x_{10/\delta}$ from $10/\delta$ independent distributions over $\{0,1\}^n$, each of min-entropy at least δn, then the probability that the concatenation x of $x_1, \ldots, x_{10/\delta}$ is bad is exponentially low (at most $2^{2n}/2^{(10/\delta)\cdot\delta n} = 2^{-8n}$). This means that with $1 - 2^{\Omega(n)}$ probability if we enumerate over all seeds $y \in \{0,1\}^{d \log n}$ (which can be done in polynomial time), then we will find some y such that $2^n + \mathsf{D}(x,y)$ is prime. Note that we can check primality in deterministic polynomial time [1].[18] Thus, we can construct the field $\mathbb{F}$

[18] It is possible to use the same idea to run also a *probabilistic* primality testing algorithm using some additional samples from the high-entropy sources.

with very high probability by using the first $(10/\delta)n$ samples and the function D to obtain a prime $P \in [2^n, 2^{n+1}]$. We then embed the set $\{0,1\}^n$ in the field $\mathbb{F} = \mathrm{GF}(P)$. Note that since $n \geq \log P - 1$, there is no significant loss in relative entropy by this embedding.

Using nonprime fields. A different approach to solving the problem of obtaining the field $\mathbb{F}$ is to use a *nonprime* field such as $\mathrm{GF}(2^p)$ (where p now is a *small* prime and hence can be easily found) and then use Theorem 1.4 (the version proved in the appendix) instead of Theorem 1.5. This would yield the following variant of Lemma 3.1.

LEMMA 3.14. *There exists an absolute constant $c > 0$ such that for every prime p, every $\delta > 0$, and every distribution $\mathcal{A}, \mathcal{B}, \mathcal{C}$ over $\mathrm{GF}(2^p)$ with $H^\infty(\mathcal{A}), H^\infty(\mathcal{B}), H^\infty(\mathcal{C}) > \delta p$, the distribution $\mathcal{A} \cdot \mathcal{B} + \mathcal{C}$ is $(2^{-\epsilon m})$-close to having* min*-entropy at least* $\min\{(1+\epsilon)m, 0.9 \log |\mathbb{F}|\}$*, where $\epsilon = c\delta$.*

3.5. Decreasing the statistical distance. We now show how we can decrease the statistical distance by repetition. We use the following variant of an XOR-lemma.

LEMMA 3.15. *Let $\mathcal{Y}_1, \ldots, \mathcal{Y}_t$ be independent distributions over $\mathbb{F}$ such that $\mathsf{dist}(\mathcal{Y}_i, U_\mathbb{F}) < \epsilon$ for every $i = 1, \ldots, t$. Then*

$$\mathsf{dist}\left(\mathcal{Y}_1 + \cdots + \mathcal{Y}_t, U_\mathbb{F}\right) \leq \epsilon^t.$$

Proof. We can represent each distribution $\mathcal{Y}_i$ as a convex combination of the following form: With probability $(1-\epsilon)$ we get U_i (where each U_i is an independent copy of the uniform distribution) and with probability ϵ an element of some distribution $\tilde{\mathcal{Y}}_i$. Thus, one can think of the distribution $\mathcal{Y}_1 + \cdots + \mathcal{Y}_t$ as a convex combination, where with probability ϵ^t we get an element of the form $\tilde{\mathcal{Y}}_1 + \cdots + \tilde{\mathcal{Y}}_t$ and with probability $1 - \epsilon^t$ get a distribution of the form $\tilde{Y} + U_\mathbb{F}$ for some distribution $\tilde{Y}$, which is independent of $U_\mathbb{F}$. In other words, with probability $1 - \epsilon^t$ we get the uniform distribution. ∎

3.6. Proof of Lemma 3.2. Before proving Lemma 3.2, we prove the following related lemma.

LEMMA 3.16. *Let $\mathbb{F}$ be any field of size N, and let $\mathcal{A}, \mathcal{B}, \mathcal{C}, \mathcal{D}$ be four independent random variables over $\mathbb{F}$, where each variable has collision probability at most $1/M$ for some $M > N^{3/4}$. Then,*

$$\mathsf{dist}\left((\mathcal{A} - \mathcal{C}) \cdot (\mathcal{B} - \mathcal{D}), U_\mathbb{F}\right) < O(N^{3/2}/M^2),$$

where $U_\mathbb{F}$ denotes the uniform distribution over $\mathbb{F}$.

We will start with a variant, where we divide rather than multiply, and where $A = C$ and $B = D$. (Throughout this section, we will always use N to denote the size of the field $\mathbb{F}$.)

LEMMA 3.17. *Let $\mathcal{A}_1, \mathcal{A}_2$ be identical independent random variables over $\mathbb{F}$ with collision probability at most $1/M$ for some $M > N^{1/2}$, and let $\mathcal{B}_1, \mathcal{B}_2$ be likewise. Then*

$$\mathsf{dist}\left((\mathcal{A}_1 - \mathcal{A}_2) \cdot (\mathcal{B}_1 - \mathcal{B}_2)^{-1}, U_\mathbb{F}\right) \leq O(N/M^2).$$

(We can ignore the event that $\mathcal{B}_1 = \mathcal{B}_2$, and we need to divide by zero since it happens with probability at most $1/M$. Thus, no matter how the value of $x/0$ is defined, it will not contribute more than $1/M$ to the statistical distance.)

Proof. Let s be an arbitrary nonzero element of $\mathbb{F}$. The distribution $\mathcal{A}_1 + s\mathcal{B}_1$ is a random variable over $\mathbb{F}$ and hence has collision probability at least $\frac{1}{N}$. Hence, we

see that

$$\Pr[(\mathcal{A}_1 + s\mathcal{B}_1) = \mathcal{A}_2 + s\mathcal{B}_2)] \geq \tfrac{1}{N}.$$

There are two ways that this equality can occur. If $\mathcal{B}_1 = \mathcal{B}_2$, then this equation can hold only if $\mathcal{A}_1 = \mathcal{A}_2$. Otherwise, it holds only if $s = (\mathcal{A}_1 - \mathcal{A}_2) \cdot (\mathcal{B}_1 - \mathcal{B}_2)^{-1}$, and hence we get that

$$\Pr[s = (\mathcal{A}_1 - \mathcal{A}_2) \cdot (\mathcal{B}_1 - \mathcal{B}_2)^{-1}] + \Pr[\mathcal{A}_{(1)} = \mathcal{A}_{(2)} \wedge \mathcal{B}_{(1)} = \mathcal{B}_{(2)}] \geq \tfrac{1}{N}.$$

Thus, $\Pr[s = (\mathcal{A}_1 - \mathcal{A}_2) \cdot (\mathcal{B}_1 - \mathcal{B}_2)^{-1}] \geq 1/N - 1/M^2$ for all $s \neq 0$, so almost all field elements are at least close to the uniform probability. The distance between two distributions D_1 and D_2 can be expressed as $2\sum_{s|D_1(s)\geq D_2(s)}(D_1(s) - D_2(s))$. Taking D_1 as the uniform distribution on $\mathbb{F}$, and D_2 as the above distribution, every s except 0 contributes at most $1/M^2$, and 0 contributes at most $1/N$ to this sum. Hence, the statistical distance is at most $2N/M^2 + 2/N = O(N/M^2)$. □

LEMMA 3.18. *Let X and Y be independent random variables on a set S of size N. Then $\mathsf{cp}(X) + \mathsf{cp}(Y) + 2\Pr[X = Y] \geq 4/N$.*

Proof. Let X be distributed according to D_0 and Y according to D_1. Then let $D_{1/2} = 1/2D_0 + 1/2D_1$. Then $D_{1/2}$ is a probability distribution on S, so $\mathsf{cp}(D_{1/2}) \geq 1/N$. On the other hand, $\mathsf{cp}(D_{1/2}) = \sum_{s\in S}(1/2D_0(s) + 1/2D_1(s))^2 = 1/4(\sum_{s\in S} D_0(s)^2 + 2\sum_{s\in S} D_0(s)D_1(s) + \sum_{s\in S} D_1(s)^2) = 1/4(\mathsf{cp}(X) + 2\Pr[X = Y] + \mathsf{cp}(Y))$. □

LEMMA 3.19. *Let $\mathcal{A}, \mathcal{B}, \mathcal{C}, \mathcal{D}$ be four independent variables over $\mathbb{F}$, each with collision probability at most $1/M$, where $M > N^{1/2}$. Let $\mathcal{A}_1, \mathcal{A}_2$ be two independent variables distributed in the same way as $\mathcal{A}$, and let $\mathcal{B}_1, \mathcal{B}_2, \mathcal{C}_1, \mathcal{C}_2, \mathcal{D}_1, \mathcal{D}_2$ be distributed likewise. Then for any $s \in \mathbb{F}$, $s \neq 0$, $\Pr[s = (\mathcal{A}_1 - \mathcal{A}_2)(\mathcal{B}_2 - \mathcal{B}_1)^{-1}] + \Pr[s = (\mathcal{C}_1 - \mathcal{C}_2)(\mathcal{D}_2 - \mathcal{D}_1)^{-1}] + 2\Pr[s = (\mathcal{A} - \mathcal{C})(\mathcal{D} - \mathcal{B})^{-1}] \geq 4/N - O(1/M^2)$.*

Proof. Let X be $\mathcal{A} + s\mathcal{B}$ and Y be $\mathcal{C} + s\mathcal{D}$. Note that, by a similar case analysis of the proof of Lemma 3.17, $\mathsf{cp}(X) \leq \Pr[s = (\mathcal{A}_1 - \mathcal{A}_2)(\mathcal{B}_2 - \mathcal{B}_1)^{-1}] + 1/M^2$, $\mathsf{cp}(Y) \leq \Pr[s = (\mathcal{C}_1 - \mathcal{C}_2)(\mathcal{D}_2 - \mathcal{D}_1)^{-1}] + 1/M^2$ and $\Pr[X = Y] \leq \Pr[s = (\mathcal{A} - \mathcal{C})(\mathcal{D} - \mathcal{B})^{-1}] + 1/M^2$ (using Lemma 3.3 to bound the probabilities that $\mathcal{A} = \mathcal{C}$ and $\mathcal{B} = \mathcal{D}$). The claim then follows from Lemma 3.18. □

LEMMA 3.20. *Let $\mathcal{A}, \mathcal{B}, \mathcal{C}, \mathcal{D}$ be four independent random variables over $\mathbb{F}$, each with collision probability at most $1/M$, where $M > N^{1/2}$. Then*

$$\mathsf{dist}\left((\mathcal{A} - \mathcal{C}) \cdot (\mathcal{B} - \mathcal{D})^{-1}, U_{\mathbb{F}}\right) < O(N/M^2),$$

where $U_{\mathbb{F}}$ denotes the uniform distribution over $\mathbb{F}$.

Proof. The statistical distance between $(\mathcal{A}-\mathcal{C})(\mathcal{D}-\mathcal{B})^{-1}$ and $U_{\mathbb{F}}$ can be computed as the sum of $\Pr[U_{\mathbb{F}} = s] - \Pr[(\mathcal{A}-\mathcal{C})(\mathcal{D}-\mathcal{B})^{-1} = s]$ for all $s \in \mathbb{F}$, where this difference is positive. Since $\Pr[U_{\mathbb{F}} = s] = 1/N$, using Lemma 3.19, we see that for all such $s \neq 0$ (the case $s = 0$ can add at most $1/M$ to the distance) it is the case that

$$\begin{aligned}
&\frac{1}{N} - \Pr[s = (\mathcal{A} - \mathcal{C})(\mathcal{D} - \mathcal{B})^{-1}] \\
&\leq \frac{1}{2}\Pr[s = (\mathcal{A}_1 - \mathcal{A}_2)(\mathcal{B}_2 - \mathcal{B}_1)^{-1}] - \frac{1}{N} - \frac{1}{2}\Pr[s = (\mathcal{C}_1 - \mathcal{C}_2)(\mathcal{D}_2 - \mathcal{D}_1)^{-1}] + O\left(\frac{1}{M^2}\right) \\
&\leq \frac{1}{2}\left|\Pr[s = (\mathcal{A}_1 - \mathcal{A}_2)(\mathcal{B}_2 - \mathcal{B}_1)^{-1}] - \frac{1}{N}\right| + \frac{1}{2}\left|\frac{1}{2}\Pr[s = (\mathcal{C}_1 - \mathcal{C}_2)(\mathcal{D}_2 - \mathcal{D}_1)^{-1}]\right| + O\left(\frac{1}{M^2}\right).
\end{aligned}$$

Summing this over all such s, we get that

$$\begin{aligned}&\mathsf{dist}\left((\mathcal{A}-\mathcal{C})\cdot(\mathcal{B}-\mathcal{D})^{-1},U_{\mathbb{F}}\right)\\&\leq\frac{1}{2}\mathsf{dist}\left((\mathcal{A}_1-\mathcal{A}_2)\cdot(\mathcal{B}_2-\mathcal{B}_1)^{-1},U_{\mathbb{F}}\right)+\frac{1}{2}\mathsf{dist}\left((\mathcal{C}_1-\mathcal{C}_2)\cdot(\mathcal{D}_2-\mathcal{D}_1)^{-1},U_{\mathbb{F}}\right)+O\left(\frac{N}{M^2}\right)\end{aligned}$$

which is at most $O(N/M^2)$ by Lemma 3.17. □

To finish the proof we also use the following simple observation about the relation between the L_2 and L_1 norms, or in our notation, between the statistical distance of a random variable from uniform and the difference between the collision probability of this random variable and $1/N$.

LEMMA 3.21. *Let $\mathcal{Z}$ be a random variable over $\mathbb{F}$. Let $\delta=\mathsf{dist}(\mathcal{Z},U_{\mathbb{F}})$. Then $1/N+\delta^2/N\leq\mathsf{cp}(\mathcal{Z})\leq 1/N+\delta^2$.*

Proof. Let $\delta_s=|\Pr[\mathcal{Z}=s]-1/N|$. Then $\sum_{s\in\mathbb{F}}\delta_s=\delta$, and $\sum_{s\in\mathbb{F}}\delta_s^2=\sum_s(\Pr[\mathcal{Z}=s])^2-2/N\sum_s[\Pr[\mathcal{Z}=s]+N/N^2=\mathsf{cp}(\mathcal{Z})-1/N$. By convexity, $\sum\delta_s^2$ is minimized when all $\delta_s=\delta/N$ and maximized when one $\delta_s=\delta$. Thus, $\delta^2/N\leq\mathsf{cp}(\mathcal{Z})-1/N\leq\delta^2$. □

To obtain Lemma 3.16, we note that for every two distributions $\mathcal{X},\mathcal{Y}$ over $\mathbb{F}\setminus\{0\}$, $\mathsf{cp}(\mathcal{X}\cdot\mathcal{Y})=\mathsf{cp}(\frac{\mathcal{X}}{\mathcal{Y}})$. Indeed, $x\cdot y=x'\cdot y'$ if and only if $\frac{x}{y'}=\frac{x'}{y}$. By Lemma 3.20, $\mathsf{dist}((\mathcal{A}-\mathcal{C})(\mathcal{D}-\mathcal{B})^{-1},U_{\mathbb{F}})=O(N/M^2)$. Thus, from the previous lemma, $\mathsf{cp}((\mathcal{A}-\mathcal{C})(\mathcal{D}-\mathcal{B}))=\mathsf{cp}((\mathcal{A}-\mathcal{C})(\mathcal{D}-\mathcal{B})^{-1})\leq 1/N+O(N^2/M^4)$. Then it follows from the lemma above that $\mathsf{dist}((\mathcal{A}-\mathcal{C})(\mathcal{D}-\mathcal{B}),\mathcal{U})^2/N\leq O(N^2/M^4)$, so $\mathsf{dist}((\mathcal{A}-\mathcal{C})(\mathcal{D}-\mathcal{B}),\mathcal{U})\leq O(N^{3/2}/M^2)$.

Proving Lemma 3.2. We can now prove Lemma 3.2. Indeed, for every nine distributions $\mathcal{X}_1,\ldots,sX_9$, $\mathsf{cp}(\mathsf{Ext}^2(\mathcal{X}_1,\ldots,\mathcal{X}_9))\leq\mathsf{cp}(\mathsf{Ext}^1(\mathcal{X}_1,\mathcal{X}_2,\mathcal{X}_3)\cdot\mathsf{Ext}^1(\mathcal{X}_4,\mathcal{X}_5,\mathcal{X}_6))$, since adding the additional independent distribution $\mathsf{Ext}^1(\mathcal{X}_7,\mathcal{X}_8,\mathcal{X}_9)$ cannot increase the collision probability. Hence, it is enough to prove that for $\mathcal{X}_1,\ldots,\mathcal{X}_6$ of min-entropy $0.9\log N$, the distribution $(\mathcal{X}_1\cdot\mathcal{X}_2+\mathcal{X}_3)\cdot(\mathcal{X}_4\cdot\mathcal{X}_5+\mathcal{X}_6)$ is $N^{-0.1}$ close to the uniform distribution over $\mathbb{F}$. Yet this distribution is a convex combination of distributions of the form $(\mathcal{X}_1\cdot x_2+\mathcal{X}_3)\cdot(\mathcal{X}_4\cdot x_5+\mathcal{X}_6)$ for fixed (and with very high probability nonzero) $x_2,x_5\in\mathbb{F}$. Any such distribution is of the form $(\mathcal{A}-\mathcal{B})(\mathcal{C}-\mathcal{D})$ (for $\mathcal{A}=\mathcal{X}_1\cdot x_2$, $\mathcal{B}=-\mathcal{X}_3$, $\mathcal{C}=\mathcal{X}_4\cdot x_5$, $\mathcal{D}=-\mathcal{X}_6$), and hence the result is implied by Lemma 3.16.

4. A constant-samples same-source disperser for low min-entropy. In this section we prove Theorem 1.3. That is, we construct a constant-samples same-source disperser for subsets of $\{0,1\}^n$ of size $n^{O(1)}$. A central tool we will use is the *deterministic coin tossing* technique. This technique was used in several contexts in computer science (e.g., the parallel algorithm of [13]), and it was also used, in a context very similar to ours, by Erdős and Hajnal (where it was called the "stepping-up lemma"; see section 4.7 of Graham, Rothschild, and Spencer [22]) and by Fiat and Naor [18]. By "deterministic coin tossing" we mean the function $\mathsf{ct}:\{0,1\}^{2n}\to[n]$ defined as follows: For every $x,y\in\{0,1\}^n$, $\mathsf{ct}(x,y)$ is equal to the first position i such that $x_i\neq y_i$ (if $x=y$, then we let $\mathsf{ct}(x,y)=n$). The following property of this function will be useful to us.

LEMMA 4.1. *For every $A\subseteq\{0,1\}^n$, $|\mathsf{ct}(A,A)|\geq\log|A|$.*

Proof. Let $S\subseteq[n]$ denote $\mathsf{ct}(A,A)$, and suppose for the sake of contradiction that $|A|>2^{|S|}$. Then, by the pigeonhole principle, there exist two distinct strings $x,y\in A$ such that x agrees with y on all the coordinates of S. However, for such x and y, clearly $\mathsf{ct}(x,y)\notin S$. □

The main idea behind our construction of a disperser is to apply the function ct in order to map our initial domain $\{0,1\}^n$ to the much smaller domain $[n]$ and then to use brute force to find an optimal disperser (or even extractor) on this smaller domain. In fact, we will need to apply the function *twice* to reduce our domain to the domain $[\log n]$ so we can apply brute force and obtain an optimal disperser for the smaller domain. That is, we use the following simple lemma.

LEMMA 4.2. *For every constant m and every n, it is possible to construct in $2^{O(n)}$ time the table for a function $E_{\mathsf{opt}} : [n] \times [n] \to [m]$ such that for every $A \subseteq [n]$ with $|A| > \log n + 10m$, it holds that $|E_{\mathsf{opt}}(A, A)| \geq \frac{m}{2}$.*

Proof. One way to do this construction is to go over all possible functions until we find a function satisfying this condition (there will exist such a function because a random function satisfies it with high probability). However, enumerating all possible functions will take m^{n^2}-time. Note that testing this condition only requires going over all such subsets A, which are at most $\min\{2^n, n^{10m+\log n}\}$ many.

Thus, if we reduce the number of functions to test to something smaller than this number, then we can reduce the overall time to $2^{O(n)}$. This can be done by considering functions from a sample space over $[m]^{n^2}$ which is (2^{-n})-close to being $(\log n + 10m)^2$-wise independent. There are explicit constructions for such sample spaces with $2^{O(n)}$ many points [30]. ∎

Proof of Theorem 1.3. To prove Theorem 1.3, we consider the following disperser Disp:

$$\mathsf{Disp}(x_1, \ldots, x_8) = E_{\mathsf{opt}}\left(\mathsf{ct}\big(\mathsf{ct}(x_1, x_2), \mathsf{ct}(x_3, x_4)\big), \mathsf{ct}\big(\mathsf{ct}(x_5, x_6), \mathsf{ct}(x_7, x_8)\big)\right).$$

It clearly runs in polynomial time. We will prove that for every set A of size at least n^{d2^m}, $|\mathsf{Disp}(A, \ldots, A)| \geq \frac{m}{2}$. Thus, Disp is a disperser with "statistical distance" equal to $\frac{1}{2}$. Such a disperser can be modified to obtain a disperser according to our standard definition. For example, this can be done by embedding $[m]$ in some prime field $[p]$ (with $m \leq p \leq 2m$) and letting $\mathsf{Disp}'(x_1, \ldots, x_{32}) = \mathsf{Disp}(x_1, \ldots, x_8) + \mathsf{Disp}(x_9, \ldots, x_{16}) + \mathsf{Disp}(x_1, \ldots, x_{24}) + \mathsf{Disp}(x_{25}, \ldots, x_{32})$. By the Cauchy–Davenport inequalities it will hold that for every set A as above, $\mathsf{Disp}'(A, \ldots, A) = [p]$.

To prove the bound on A, we note that by Lemma 4.1, if $|A| \geq n^{d2^m}$, then $\mathsf{ct}(\mathsf{ct}(A, A), \mathsf{ct}(A, A)) \geq \log\log n + m + \log d$. Since we apply E_{opt} on a domain of size $\log n$, by Lemma 4.2, this means that for d large enough, $|E_{\mathsf{opt}}(A, A)| \geq \frac{m}{2}$, thus finishing our proof. ∎

5. Subsequent and future work. In this work we have given the first extractors for a constant number of independent sources, each of linear entropy. Unfortunately the number of sources needed is a function of the (constant) entropy rate, and the most obvious subsequent challenge was to remove this dependency. Following this work, there has been a sequence of works which, using similar additive number-theoretic techniques and additional tools, obtained significant improvements on this and other fronts.

Barak et al. [3] gave the first construction of an extractor with a fixed number of sources that works for every linear entropy. Specifically, they give explicit deterministic extractors from three independent sources of any linear entropy. This was further improved by Raz [37], whose work needs only one of the sources to have linear entropy, while the others can have only a logarithmic amount of entropy. Building on both these works, Zuckerman [50] managed to obtain a new *seeded* extractor with shorter seed length for linear entropy and used this to obtain some improved inapproximability results for the clique and chromatic number problems. Rao [36] obtained multiple

source extractors that require only $O(\frac{\log k}{\log n})$ sources of k entropy, thus achieving a constant number of sources even for *polynomially small* entropy.

On the 2-*source* front, the work of Barak et al. [3] gave a 2-source disperser for sources of entropy δn for arbitrarily small δ (and in particular $\delta < 1/2$), thus improving on the previous explicit constructions for bipartite Ramsey graphs. Pudlak [34] gave a very simple construction of such a disperser for the case $\delta = \frac{1}{2} - \epsilon$ for some small $\epsilon > 0$, and Bourgain [7] gave a two source *extractor* for this case. Barak et al. [4] gave a 2-source disperser for sources of entropy n^δ for arbitrarily small δ (and in particular $\delta < 1/2$), thus beating the Frankl–Wilson [19] construction for a (nonbipartite) Ramsey graph.

In addition, Barak et al. [3] also gave a 1-*source* disperser for *affine* sources (a uniform distribution of an affine subspace) of linear entropy. Bourgain [8] gave an *extractor* with the same parameters, and Gabizon and Raz [20] gave different affine extractors with incomparable parameters.

To summarize, after nearly 20 years of no progress, there seem to be new and exciting ideas, tools, and results on deterministic extraction from independent sources, and we expect more to soon follow.

Appendix. Proof of Theorem 1.4. In this section, we prove Theorem 1.4 with a better explicit dependence between the constants ϵ and δ (namely, $\epsilon = \Theta(\delta)$). That is, we prove the following theorem.
