THEOREM A.1. *There exists an absolute constant $c_0 > 0$ such that for every field $\mathbb{F}$ and $\delta > 0$ such that $|\mathbb{F}|^{1/k}$ is* not *an integer for every integer $2 \le k \le (2/\delta)$, and every set $\mathcal{A} \subseteq \mathbb{F}$ with $|\mathbb{F}|^\delta < |\mathcal{A}| < |\mathbb{F}|^{1-\delta}$, it holds that*

$$\max\{|\mathcal{A}+\mathcal{A}|, |\mathcal{A}\cdot\mathcal{A}|\} \ge |\mathcal{A}|^{1+c_0\delta}.$$

Note that Theorem A.1 indeed implies Theorem 1.4 since a finite field $\mathbb{F}$ has a subfield of size M if and only if $M = |\mathbb{F}|^{1/k}$ for some integer k.

We prove Theorem A.1 by proving the following two claims.

CLAIM A.2. *There exists a fixed-size uniform rational expression $r(\cdot)$ such that for every δ, every field $\mathbb{F}$ satisfying the conditions of Theorem* A.1*, and every set $\mathcal{B} \subseteq \mathbb{F}$ with $|\mathcal{B}| \ge |\mathbb{F}|^\delta$,*

$$|r(\mathcal{B}, \ldots, \mathcal{B})| \ge \min\{|\mathcal{B}|^{1+\delta}, |\mathbb{F}|\}.$$

By a *rational expression* we mean an expression involving only the operations $+, -, \cdot, /$, and variable names, but no coefficients (for example, $(x_1 - x_2)/(x_2 \cdot x_3 + x_4)$).[19] By *fixed-size* we mean that the number of operations and variables in the expression does not depend on δ, $\mathbb{F}$, or $\mathcal{A}$. A rational function is obviously a division of two polynomials. We say that a polynomial is *uniform* if all its monomials have the same degree. We say that a rational function is *uniform* if it is a division of two uniform polynomials. In fact, the expression r obtained from the proof of Claim A.2 will be very simple: it will be a uniform 16-variable rational expression with both the nominator and the denominator of degree 2.

CLAIM A.3. *For every uniform rational expression $r(\cdot)$ there is a constant c (depending on $r(\cdot)$) such that if $\mathcal{A} \subseteq \mathbb{F}$ satisfies $|\mathcal{A}+\mathcal{A}|, |\mathcal{A}\cdot\mathcal{A}| \le |\mathcal{A}|^{1+\rho}$ (for sufficiently small $\rho > 0$), then there exists a set $\mathcal{B} \subseteq \mathcal{A}$ with $|\mathcal{B}| \ge |\mathcal{A}|^{1-c\rho}$, but $|r(\mathcal{B}, \ldots, \mathcal{B})| \le |\mathcal{A}|^{1+c\rho}$.*

[19] Throughout this section we define $x/0$ as 0 (it will not matter much since we will always have that the event that the denominator is zero in the expression has negligible probability).

We note that this actually holds for nonuniform rational expressions as well, but the proof is slightly easier for uniform expressions.

Proof of Theorem A.1 *using Claims* A.2 *and* A.3. Claims A.2 and A.3 together imply Theorem A.1. Indeed, let $r(\cdot)$ be the rational expression obtained from Claim A.2 and let c be the constant (depending on r) obtained from Claim A.3. If for $\delta, \mathbb{F}$ and $\mathcal{A}$, as in the conditions of the theorem, both $|\mathcal{A}+\mathcal{A}|$ and $|\mathcal{A}\cdot\mathcal{A}|$ are less than $|\mathcal{A}|^{1+\delta/(10c)}$, then there is a subset $\mathcal{B}$ of size at least $|\mathcal{A}|^{1-c\delta/(10c)} \geq |\mathbb{F}|^{\delta/2}$ such that $|r(\mathcal{B},\ldots,\mathcal{B})| \leq |\mathcal{A}|^{1+\delta/10} < |\mathcal{B}|^{1+\delta/2}$, and thus we obtain a contradiction.

We note that Claim A.3 follows almost immediately from Lemmas 2.4 and 3.1 in [9]. Nevertheless, for the sake of completeness, we do provide a proof of Claim A.3 (following lines similar to the proofs of [9]) in section A.2. We now move to the proof of Claim A.2.

A.1. Proof of Claim A.2. To prove Claim A.2 we will prove the following even simpler claim.

CLAIM A.4. *Let $\mathbb{F}$ be any field and let $\mathcal{B} \subseteq \mathbb{F}$ and $k \in \mathbb{N}$ (with $k \geq 2$) be such that $|\mathbb{F}|^{1/k} < |\mathcal{B}| \leq |\mathbb{F}|^{1/(k-1)}$. Then $|\frac{\mathcal{B}-\mathcal{B}}{\mathcal{B}-\mathcal{B}}| \geq |\mathbb{F}|^{1/(k-1)}$.*

Proof. Suppose otherwise that $|\frac{\mathcal{B}-\mathcal{B}}{\mathcal{B}-\mathcal{B}}| < |\mathbb{F}|^{1/(k-1)}$. Thus, we can find $s_1 \notin \frac{\mathcal{B}-\mathcal{B}}{\mathcal{B}-\mathcal{B}}$. Similarly, if $k > 2$, then we can find $s_2 \notin \frac{\mathcal{B}-\mathcal{B}}{\mathcal{B}-\mathcal{B}} + s_1\frac{\mathcal{B}-\mathcal{B}}{\mathcal{B}-\mathcal{B}}$ (since this set is of size at most $|\frac{\mathcal{B}-\mathcal{B}}{\mathcal{B}-\mathcal{B}}|^2 < |\mathbb{F}|$). In this way we define inductively $s_1,\ldots,s_{k-1}$ such that for $1 < i \leq k-1$,

$$s_i \notin \tfrac{\mathcal{B}-\mathcal{B}}{\mathcal{B}-\mathcal{B}} + s_1\tfrac{\mathcal{B}-\mathcal{B}}{\mathcal{B}-\mathcal{B}} + \cdots + s_{i-1}\tfrac{\mathcal{B}-\mathcal{B}}{\mathcal{B}-\mathcal{B}}.$$

Consider the function $f(x_0,\ldots,x_{k-1}) = x_0 + s_1x_1 + \cdots + s_{k-1}x_{k-1}$. This is a function from $\mathcal{B}^k$ to $\mathbb{F}$, where $|\mathcal{B}|^k > |\mathbb{F}|$, and hence it has a *collision*. That is, there are two vectors $\vec{x} = (x_0,\ldots,x_{k-1})$ and $\vec{x}\,' = (x'_0,\ldots,x'_{k-1})$ such that $\vec{x} \neq \vec{x}\,'$, but $f(\vec{x}) = f(\vec{x}\,')$. If we let i be the maximum index such that $x_i \neq x'_i$, we see that

$$(x_0 - x'_0) + s_1(x_1 - x'_1) + \ldots + s_{i-1}(x_{i-1} - x'_{i-1}) = s_i(x'_i - x_i).$$

Dividing by $(x'_i - x_i)$, we get that $s_i = y_0 + s_1y_1 + \cdots + s_{i-1}y_{i-1}$, where all the y_i's are members of $\frac{\mathcal{B}-\mathcal{B}}{\mathcal{B}-\mathcal{B}}$, contradicting our choice of s_i. □

To prove Claim A.2 we let $\mathbb{F}$,δ, $\mathcal{B}$ be as stated in the theorem and choose k such that $|\mathbb{F}|^{1/k} < |\mathcal{B}| \leq |\mathbb{F}|^{1/(k-1)}$. By one invocation of $\frac{\mathcal{B}-\mathcal{B}}{\mathcal{B}-\mathcal{B}}$, we get to a set of size at least $|\mathbb{F}|^{1/(k-1)}$, but since that is not an integer, this set is of size *larger* than $|\mathbb{F}|^{1/(k-1)}$ (this is for $k > 2$; for $k = 2$ we get to the entire field $\mathbb{F}$). Thus, if we compose this expression two times (i.e., let $r(x_1,\ldots,x_{16}) = \frac{r'(x_1,\ldots,x_4)-r'(x_5,\ldots,x_8)}{r'(x_9,\ldots,x_{12})-r'(x_{13},\ldots,x_{16})}$, where $r'(a,b,c,d) = \frac{a-b}{c-d}$), then we get that for $k > 2$,

$$|r(\mathcal{B},\ldots,\mathcal{B})| \geq |\mathbb{F}|^{\frac{1}{k-2}} = |\mathbb{F}|^{\frac{1}{k-1}(1+\frac{1}{k-2})} \geq |\mathcal{B}|^{1+\delta},$$

where for $k = 2$, $r(\mathcal{B},\ldots,\mathcal{B}) = \mathbb{F}$.

A.2. Proof of Claim A.3. We now prove Claim A.3. Before turning to the actual proof, we state two number-theoretic lemmas which we will use. These lemmas are variants of the lemmas presented in section 3.2.

A.2.1. More number-theoretic lemmas.

Stronger form of Gowers's lemma. We will use the following generalized and stronger form of Lemma 3.8 (see [21, 9] and [43, Claim 4.4]). Because it is such a useful

lemma, we state it below in the most general (and, unfortunately, also cumbersome) form.

LEMMA A.5. *Let $\mathcal{A}_1, \ldots, \mathcal{A}_k$ be subsets of some group G with $|\mathcal{A}_i| = M$ for all $i \in [k]$. Then there exists $C = C(k)$ such that for every $\rho > 0$, if $\mathsf{cp}(\sum_{i=1}^k \mathcal{A}_i) \geq \frac{1}{M^{1+\rho}}$, then there are k subsets $\mathcal{A}'_1, \ldots, \mathcal{A}'_k$ with $\mathcal{A}'_i \subseteq \mathcal{A}_i$ and $|\mathcal{A}'_i| \geq M^{1-C\rho}$ for every $i \in [k]$ satisfying*

$$\left|\sum_{i=1}^k \mathcal{A}'_i\right| \leq M^{1+C\rho}. \tag{A.1}$$

Moreover, (A.1) *is demonstrated by the fact that every element $z \in \sum_{i=1}^k \mathcal{A}'_i$ can be represented in $M^{\ell-1-C'\rho}$ different ways as a sum $z = y_1 + \cdots + y_\ell$ (for $C' = C'(k)$ and $\ell = 2k^2 - k$), where each of the y_j's is a member of A_i or $-A_i$ for some $i = i(j)$ (with the choice of a sign also being a function of j).*

Furthermore, if for all $i \in [k]$, $\mathcal{A}_i = \mathcal{A}$ or $\mathcal{A}_i = -\mathcal{A}$ for some set $\mathcal{A}$, then all the subsets $\mathcal{A}'_i$ are of the form $\mathcal{A}'_i = \mathcal{A}'$ or $\mathcal{A}'_i = -\mathcal{A}'$ for some subset $\mathcal{A}' \subseteq \mathcal{A}$.

It is easy to see that by applying Lemma A.5 for $k = 2$ we get Lemma 3.8 (perhaps with 10 replaced by a different constant). Lemma A.5 can be proven by a generalization of the proof of Lemma 3.8; see [43].[20] When using Lemma A.5, we will always be in the case that we have an upper bound on the *set size* of $\sum_{i=1}^k \mathcal{A}_i$ (i.e., $|\sum_{i=1}^k \mathcal{A}_i| \leq M^{1+\rho}$) and not just a lower bound on its collision probability.

We note that in the proofs below we will use several times this technique of showing that some set $\mathcal{B}$ is not much larger than M by showing that every $b \in \mathcal{B}$ can be represented in roughly $M^{\ell-1}$ ways as a sum of ℓ elements, each from some set $\mathcal{D}$ of size M.

Sumset estimates. We will also use the following lemma, which is a variant of Lemma 3.7.

LEMMA A.6 (see [33, 40]). *Let $\mathcal{A}, \mathcal{B}$ be subsets of some Abelian group G with $|\mathcal{A}| = |\mathcal{B}| = M$ and let $\rho > 0$ be some number. If $|\mathcal{A} + \mathcal{B}| \leq M^{1+\rho}$, then*

$$|\mathcal{A} \pm \underbrace{\mathcal{B} \pm \cdots \pm \mathcal{B}}_{h \text{ times}}| \leq M^{1+2h\rho}.$$

We note that this lemma immediately implies a similar result for sets that are of slightly different sizes. That is, if $|\mathcal{A}| = M$ and $|\mathcal{B}| = M^{1-\epsilon}$, then we can break up $\mathcal{A}$ to $\mathcal{A}_1, \ldots, \mathcal{A}_{M^\epsilon}$ that are of the same size as $\mathcal{B}$. We then have that $|\mathcal{A}_i + \mathcal{B}| \leq |\mathcal{A} + \mathcal{B}| \leq M^{1+\rho}$. and hence the lemma implies that for every i,

$$\mathcal{A}_i \pm \underbrace{\mathcal{B} \pm \cdots \pm \mathcal{B}}_{h \text{ times}}| \leq M^{1+2h\rho}.$$

However, $\mathcal{A} \pm \mathcal{B} \pm \cdots \pm \mathcal{B}$ is just the union of $\mathcal{A}_i \pm \mathcal{B} \pm \cdots \pm \mathcal{B}$ for all i, and hence we get that

$$|\mathcal{A} \pm \underbrace{\mathcal{B} \pm \cdots \pm \mathcal{B}}_{h \text{ times}}| \leq M^{1+2h\rho+\epsilon}.$$

[20] We note that this lemma is not stated exactly in this form in [43]. Rather, Claim 4.4 there states that under these conditions every such z can be represented in roughly M^{2k-2} ways as a sum of $2k-1$ elements w_l, where each of these elements can be represented in roughly M^{k-1} ways as a sum of k elements in the A_i's. It is also stated in [43] in terms of distance from having high min-entropy rather than high collision probability; see footnote 16.

Similarly if $|\mathcal{B}| = M$ and $|\mathcal{A}| = M^{1-\epsilon}$, then

$$|\mathcal{A} \pm \underbrace{\mathcal{B} \pm \cdots \pm \mathcal{B}}_{h \text{ times}}| \leq M^{1+2h\rho+h\epsilon}$$

since if we split sB into $\mathcal{B}_1, \ldots, \mathcal{B}_{M^\epsilon}$, then we have that $\mathcal{A} \pm \mathcal{B} \pm \cdots \pm \mathcal{B}$ is the union of sets of the form $\mathcal{A} \pm \mathcal{B}_{i_1} \pm \cdots \pm \mathcal{B}_{i_h}$ for all $i_1, \ldots, i_h \in [M^\epsilon]$.

A.2.2. The actual proof. In fact, to prove Claim A.3 it is enough to prove the following claim.

CLAIM A.7. *For every integer $k > 0$, there exists a constant $C = C(k) > 0$ such that for every $\rho > 0$, if $\mathcal{A} \subseteq \mathbb{F}$ satisfies $|\mathcal{A} + \mathcal{A}|, |\mathcal{A} \cdot \mathcal{A}| \leq |\mathcal{A}|^{1+\rho}$, then there is a set $\mathcal{B} \subseteq \mathcal{A}$ such that $|\mathcal{B}| \geq |\mathcal{A}|^{1-C\rho}$, but $|\mathcal{B}^k - \mathcal{B}^k| \leq |\mathcal{A}|^{1+C\rho}$.*

Obtaining Claim A.3 *from Claim* A.7. Claim A.7 implies Claim A.3 by applying Lemma A.6. Indeed, suppose that r is a rational expression, where both the numerator and denominator have at most k' monomials, each of degree k' (if one of them has monomials of smaller degree than k', we can multiply with a uniform polynomial to make the degree k'). Let $k = 4k'^2$ and let $\mathcal{B}$ be the subset of $\mathcal{A}$ obtained from Claim A.7 such that $|\mathcal{B}^k - \mathcal{B}^k|$ is at most $|\mathcal{A}|^{1+C\rho}$ for some constant $C = C(k)$. Since $|\mathcal{B}| \geq |\mathcal{A}|^{1-C\rho}$, this means that $|\mathcal{B}^k - \mathcal{B}^k| \leq |\mathcal{B}|^{1+C'\rho}$ for some different constant C'. This implies by Lemma A.6 that $|k\mathcal{B}^k| \leq |\mathcal{B}|^{1+2C'k\rho}$. Now, $k\mathcal{B}^k \supseteq \mathcal{C} \stackrel{def}{=} (k'\mathcal{B}^{k'})(k'\mathcal{B}^{k'})$, and hence the size of $\mathcal{C}$ is also at most $|\mathcal{B}|^{1+2C'k\rho}$. Applying Lemma A.6 again we get that $\left|\frac{k'\mathcal{B}^{k'}}{k'\mathcal{B}^{k'}}\right| \leq |\mathcal{A}|^{1+4C'k\rho}$. However, $r(\mathcal{B}, \ldots, \mathcal{B}) \subseteq \frac{k'\mathcal{B}^{k'}}{k'\mathcal{B}^{k'}}$ and hence we are done.

Proof of Claim A.7. We now turn to proving Claim A.7. Let $\mathcal{A}$ be a set satisfying the conditions of the claim, and denote $M = |\mathcal{A}|$. We will prove that for some constant $C = C(k) > 0$, there is a subset $\mathcal{B} \subseteq \mathcal{A}$ of size at least $M^{1-C\rho}$ such that any member of the set $\mathcal{B}^k - \mathcal{B}^k$ can be represented in at least $M^{\ell-1-C\rho}$ different ways as a sum $d_1 + \cdots + d_\ell$, where all the elements d_i come from a set $\mathcal{D}$ of size at most $M^{1+C\rho}$ for some $\ell = \ell(k)$. This clearly implies that $|\mathcal{B}^k - \mathcal{B}^k| \leq M^{1+C'\rho}$ for some constant C', thus proving the claim.

Proof idea: The case $k = 2$. To illustrate the proof idea, we now sketch the proof for the case $k = 2$. The proof for general k follows in exactly the same way, although with more cumbersome notation. Under the conditions of the claim, $|\mathcal{A}+\mathcal{A}| \leq |\mathcal{A}|^{1+\rho}$, and hence $\mathsf{cp}(\mathcal{A} - \mathcal{A}) = \mathsf{cp}(\mathcal{A} + \mathcal{A}) \geq |\mathcal{A}|^{1-\rho}$. Hence, by Lemma A.5, there exists a set $\mathcal{A}' \subseteq \mathcal{A}$ with $|\mathcal{A}'| \geq M^{1-C\rho}$ (where C is some absolute constant independent of ρ) such that not only $|\mathcal{A}' - \mathcal{A}'| \leq M^{1+C\rho}$ but actually this fact can be demonstrated by the fact that every element of $\mathcal{A}' - \mathcal{A}'$ can be represented in at least $M^{5-C\rho}$ different ways in the form $a_1 - a_2 + a_3 - a_4 + a_5 - a_6$, where for $i = 1, \ldots, 6$, $a_i \in \mathcal{A}$.[21]

We know that every member of $\mathcal{A}' - \mathcal{A}'$ can be represented in roughly M^5 different ways as $a_1 - a_2 + a_3 - a_4 + a_5 - a_6$ with the a_i's in $\mathcal{A}$. Now, if we multiply this by an arbitrary element of $\mathcal{A}$, we get that every member of $(\mathcal{A}' - \mathcal{A}')\mathcal{A}$ can be represented in roughly M^5 different ways as $b_1 - b_2 + b_3 - b_4 + b_5 - b_6$ with the b_i's in $\mathcal{A} \cdot \mathcal{A}$. Since by the conditions of the claim, $\mathcal{A} \cdot \mathcal{A}$ is also of roughly size M, we get that the set $(\mathcal{A}' - \mathcal{A}')\mathcal{A}$ is also "not large" (i.e., of size $M^{1+C'\rho}$ for some absolute constant C'). Now consider an element $y - z$ of the set $\mathcal{A}'^2 - \mathcal{A}'^2$. For the sake of simplicity, we assume for a moment (*with* loss of generality) that any y in $\mathcal{A}' \cdot \mathcal{A}'$ can be represented in roughly

[21] For simplicity of exposition we assumed that the pattern of $+$ and $-$ signs that is obtained from Lemma A.5 is as written above. The proof clearly follows through regardless of the fixed pattern we use.

M different ways as $y = y_1 y_2$ with $y_1, y_2 \in \mathcal{A}'$.[22] Since $z \in \mathcal{A}' \cdot \mathcal{A}'$, it is equal to $z_1 z_2$ for some $z_1, z_2 \in \mathcal{A}'$. Every representation $y_1 y_2$ of y induces a representation of $y - z = y_1 y_2 - z_1 z_2$ as $(y_1 - z_1)y_2 + z_1(y_2 - z_2)$, and so we get that every element of $\mathcal{A}'^2 - \mathcal{A}'^2$ can be represented as $d_1 - d_2$, with $d_1, d_2 \in \mathcal{D} \stackrel{def}{=} (\mathcal{A}' - \mathcal{A}')\mathcal{A}$ in roughly M different ways. However, since we already showed that the size of $\mathcal{D}$ is roughly M, this proves that $\mathcal{A}'^2 - \mathcal{A}'^2$ is also of size roughly M, and hence we are done (for the case $k = 2$).

Proving for general k. We now turn to proving the claim rigorously and for any k. Recall that our goal is to find a not-too-small subset $\mathcal{B}$ of $\mathcal{A}$ such that $\mathcal{B}^k - \mathcal{B}^k$ can be represented in roughly $M^{\ell-1}$ ways as a sum of ℓ elements from a set $\mathcal{D}$ that is not too large. We will start by defining the set $\mathcal{D}$.

Let ℓ be some number, and let $a, b \in \mathcal{A}'$ (where $\mathcal{A}'$ is obtained from Lemma A.5 as above) and $c \in \mathcal{A}'^{\ell}$. By the same reasoning as above, we get that the element $(a-b)c$ can be represented in at least $M^{5-C\rho}$ different ways as $a_1c - a_2c + a_3c - a_4c + a_5c - a_6c$, or in other words, it can be represented in at least $M^{5-C'\rho}$ different ways as $b_1 - b_2 + b_3 - b_4 + b_5 - b_6$ for $b_i \in \mathcal{A}^{\ell+1}$ for $i = 1, \ldots, 6$. By the multiplicative version of Lemma A.6, $|\mathcal{A}^{\ell+1}| \leq M^{1+3\ell\rho}$, and hence the set $(\mathcal{A}' - \mathcal{A}')\mathcal{A}'^{\ell}$ is "small" (i.e., of size at most $M^{6(1+3\ell\rho)} M^{-(5-C'\rho)} \leq M^{1+20C'\ell\rho}$). Using again the multiplicative version of Lemma A.6 (setting $\mathcal{A} = (\mathcal{A}' - \mathcal{A}')\mathcal{A}'^{\ell-1}$, $\mathcal{B} = \mathcal{A}'$), we get that the set $(\mathcal{A}' - \mathcal{A}')\mathcal{A}'^{\ell}\mathcal{A}'^{-\ell'}$ is also "small" (i.e., of size at most $M^{1+C''\rho}$ for some constant $C'' = C''(\ell, \ell')$).[23] Using the fact that $(\mathcal{A}'^{-1} - \mathcal{A}'^{-1}) \subseteq (\mathcal{A}' - \mathcal{A}')\mathcal{A}'^{-2}$, we get that for any ℓ_1, ℓ_2, the set $\mathcal{D}_{\ell_1,\ell_2}$ defined as

$$\mathcal{D}_{\ell_1,\ell_2} = (\mathcal{A}'^{-1} - \mathcal{A}'^{-1})\mathcal{A}'^{\ell_1}\mathcal{A}'^{-\ell_2} \cup (\mathcal{A}' - \mathcal{A}')\mathcal{A}'^{\ell_1}\mathcal{A}'^{-\ell_2}$$

is of size at most $M^{1+C'''\rho}$ for some constant C''' depending on ℓ_1, ℓ_2. We define $\mathcal{D} \stackrel{def}{=} \cup_{\ell_1+\ell_2=\ell s} D_{\ell_1,\ell_2}$ for ℓ as obtained by Lemma A.5 (i.e., $\ell = 2k^2 - k$). As desired, we have that $|\mathcal{D}| \leq M^{1+C\rho}$, where C is a constant depending on ℓ.

Defining the set $\mathcal{B}$. We now turn to defining the required set $\mathcal{B}$. Utilizing Lemma A.5 again, we obtain that for some absolute constant $D = D(k)$, there is a set $\mathcal{B} \subseteq \mathcal{A}'$ with $|\mathcal{B}| \geq M^{1-D\rho}$, and every element in $\mathcal{B}^k$ can be represented in $M^{\ell-1-D\rho}$ ways as $a_1 \cdots a_\ell$, where a_i is in $\mathcal{A}'$ or in $\mathcal{A}'^{-1}$ for $i = 1, \ldots, \ell$ (for $\ell = 2k^2 - k$). Let $y - z$ be a member of $\mathcal{B}^k - \mathcal{B}^k$. Fix one representation $z = z_1 \cdots z_\ell$ of z as a multiplication of elements of $\mathcal{A}'$ or $\mathcal{A}'^{-1}$. The element y can be represented $M^{\ell-1-D\rho}$ times as $y = y_1 \cdots y_\ell$ with $y_i \in \mathcal{A}'$ for $i = 1, \ldots, \ell$. For each such representation we define $d_i = y_1 \cdot \ldots \cdot y_{i-1}(y_i - z_i)z_{i+1} \cdots z_\ell$. Note that $\sum_{i=1}^{\ell} d_i = \prod_{i=1}^{\ell} y_i - \prod_{i=1}^{\ell} z_j = y - z$. Also note that for every i, $d_i \in \mathcal{D}$, where $\mathcal{D}$ is the set defined above. The map $(y_1, \ldots, y_\ell) \mapsto (d_1, \ldots, d_\ell)$ is one-to-one (indeed, given $z_1, \ldots, z_\ell$ we can recover $y_1, \ldots, y_\ell$ from $d_1, \ldots, d_\ell$). Hence, we get that each member of $\mathcal{B}^k - \mathcal{B}^k$ can be represented in $M^{\ell-1-D\rho}$ different ways as $\sum_{i=1}^{\ell} d_i$ with $d_i \in \mathcal{D}$, implying that $|\mathcal{B}^k - \mathcal{B}^k| \leq M^{1+D'\rho}$ for $D' = D'(k)$. ∎

Acknowledgments. We thank Amir Shpilka for many valuable discussions during the early stages of this research. We also thank the anonymous referee for many useful comments and corrections on an earlier version of this manuscript.

[22] We will not be able to get to that situation in the actual proof that follows, but we will approximate it using the multiplicative version of Lemma A.5.

[23] Again, the case of division by zero does not matter, but for simplicity, we can just remove 0 from the set $\mathcal{A}'$ if it is there.

ON WORST-CASE TO AVERAGE-CASE REDUCTIONS FOR NP PROBLEMS*

ANDREJ BOGDANOV† AND LUCA TREVISAN‡

Abstract. We show that if an NP-complete problem has a nonadaptive self-corrector with respect to any samplable distribution, then coNP is contained in NP/poly and the polynomial hierarchy collapses to the third level. Feigenbaum and Fortnow [*SIAM J. Comput.*, 22 (1993), pp. 994–1005] show the same conclusion under the stronger assumption that an NP-complete problem has a nonadaptive random self-reduction. A self-corrector for a language L with respect to a distribution $\mathcal{D}$ is a *worst-case to average-case reduction* that transforms any given algorithm that correctly decides L on *most* inputs (with respect to $\mathcal{D}$) into an algorithm of comparable efficiency that decides L correctly on *every* input. A random self-reduction is a special case of a self-corrector, where the reduction, given an input x, is restricted to only making oracle queries that are distributed according to $\mathcal{D}$. The result of Feigenbaum and Fortnow depends essentially on the property that the distribution of each query in a random self-reduction is independent of the input of the reduction. Our result implies that the average-case hardness of a problem in NP or the security of a one-way function cannot be based on the worst-case complexity of an NP-complete problem via nonadaptive reductions (unless the polynomial hierarchy collapses).

Key words. average-case complexity, worst-case to average-case reduction, one-way function

1. Introduction.

The fundamental question in the study of average-case complexity is whether there exist distributional problems in NP that are intractable on average. A distributional problem in NP is a pair $(L, \mathcal{D})$, where L is a decision problem in NP, and $\mathcal{D}$ is a samplable distribution on instances. We will say that such a problem is tractable on average if for every polynomial p there exists a polynomial-time algorithm A such that for all sufficiently large n, when given a random instance of length n from distribution $\mathcal{D}$, algorithm A determines membership in L correctly with probability at least $1 - 1/p(n)$.

This notion of average-case tractability is essentially equivalent to Impagliazzo's definition of *heuristic* polynomial-time algorithms [28]. Impagliazzo observes that if every problem in distributional NP is tractable on average, then there are no one-way functions, and thus cryptography is impossible. It is therefore generally believed that distributional NP does contain problems that are intractable on average.

The question we consider in this paper concerns the minimal complexity assumption one needs to make in order to guarantee that distributional NP does indeed contain a problem that is intractable on average. Ideally, one would like to base the existence of hard on average problems (and one-way functions) on a worst-case assumption, namely NP $\not\subseteq$ BPP. Equivalently, the question can be formulated as

follows: Is the existence of worst-case hard problems in NP sufficient to show the existence of problems in NP that are hard on average?

In the cryptographic setting, the question of whether there are cryptosystems that are NP-hard to break, that is, whose security can be based on the assumption that NP $\not\subseteq$ BPP, is as old as modern cryptography itself, and it was asked by Diffie and Hellman [14, section 6]. As we review below, there is conflicting evidence about whether the answer to this question exists.

Previous work.

Worst-case versus average-case in NP. Impagliazzo [28] observes that we know oracles relative to which NP $\not\subseteq$ P/poly, but there is no intractable problem in distributional NP (and consequently, one-way functions do not exist). Therefore, any proof that NP $\not\subseteq$ BPP implies the existence of an intractable problem in distributional NP must use a nonrelativizing argument. However, nonrelativizing arguments are commonly used in lattice-based cryptography to establish connections between the worst-case and average-case hardness of certain NP problems that are believed to be intractable (but not NP-complete).

Feigenbaum and Fortnow [17] consider the notion of a *random self-reduction*, which is a natural, and possibly nonrelativizing, way to prove that the average-case complexity of a given problem relates to its worst-case complexity. We begin by discussing the slightly more general notion of *locally random reduction*, introduced in [6] (see also the earlier works [1, 5, 18]). A locally random reduction from a language L to a distributional problem $(L', \mathcal{D})$ is a polynomial-time oracle procedure R such that $R^{L'}$ solves L and, furthermore, each oracle query of $R^{L'}(x)$ is distributed according to $\mathcal{D}$.[1] Clearly, such a reduction converts a heuristic polynomial-time algorithm for $(L', \mathcal{D})$ (with sufficiently small error probability) into a BPP algorithm for L. Observe that the reduction may depend on the choice of distributional problem $(L', \mathcal{D})$, so in general this approach does not relativize. If we had a locally random reduction from, say, satisfiability to some problem $(L', \mathcal{D})$ in distributional NP, then we would have proved that if NP $\not\subseteq$ BPP, then distributional NP contains intractable problems. A locally random reduction from L to $(L', \mathcal{D})$ is called a *random self-reduction* if $L = L'$.

Feigenbaum and Fortnow show that if for an NP-complete language L and a samplable ensemble $\mathcal{D}$ there is a *nonadaptive* random self-reduction from L to $(L, \mathcal{D})$, then NP $\subseteq$ coNP/poly and the polynomial hierarchy collapses to the third level. Their proof also establishes the slightly more general result that if there is a nonadaptive locally random reduction from a problem L to a problem $(L', \mathcal{D})$ in distributional NP, then L is in coNP/poly.

Random self-reductions and locally random reductions are natural notions, and they have been used to establish the worst-case to average-case equivalence of certain PSPACE-complete and EXP-complete problems [39]. Therefore, the result of Feigenbaum and Fortnow rules out a natural and general approach to proving a statement of the following form: "If NP $\not\subseteq$ BPP, then distributional NP contains intractable problems."

Cryptography versus NP*-hardness.* The seminal work of Diffie and Hellman [14] introducing public key cryptography asked if there exists a public key encryption scheme whose hardness can be based on an NP-complete problem. This question was seemingly answered in the affirmative by Even and Yacobi [16], who devised a public

[1] More precisely, according to the restriction of $\mathcal{D}$ to inputs of length polynomially related to x (see section 2).

key cryptosystem that is "NP-hard to break." Namely, they showed a reduction that transforms any adversary that "breaks" the cryptosystem into an algorithm that solves SAT. However, the notion of "breaking the cryptosystem" in [16] is a worst-case one: Specifically, it is assumed that the adversary can break the encryption for *every* key. Lempel [31] later showed that the same cryptosystem can in fact be broken on *most* keys. Therefore, the NP-hardness of breaking a cryptosystem in the worst case does not in general have any implications for cryptographic security.

The gap between worst-case and average-case hardness is even more transparent in the case of symmetric key cryptography, or one-way functions. It is well known that there exist "one-way functions" that are NP-hard to invert in the worst case, but easy to invert on average. (For instance, consider the function that maps a formula ϕ and an assignment a to $(1, \phi)$ if a satisfies ϕ and to $(0, \phi)$ otherwise.)

As these examples show, the notion of hardness in breaking a public key cryptosystem, or inverting a one-way function that one needs in cryptography, is fundamentally an average-case notion.

Brassard [12] addresses the question of the existence of public key cryptosystems that are hard to break from a different perspective. He argues that, under some assumptions on the key-generation algorithm and the encryption procedure, the problem of breaking the encryption is in $\mathrm{NP} \cap \mathrm{coNP}$. Specifically, he shows that if there is a reduction that transforms an oracle that breaks encryptions into an algorithm for a language L, then the reduction can be used to provide NP certificates for membership in both L and $\overline{L}$, proving that $L \in \mathrm{NP} \cap \mathrm{coNP}$. More recent work by Goldreich and Goldwasser [23] reaches the same conclusion under weaker assumptions.

In the setting of symmetric key cryptography, a similar conclusion can be reached about the hardness of inverting a one-way function if one makes additional assumptions about the function in question. For instance, if the function f is a permutation, then the existence of a reduction from any language L to an inverter for f establishes that $L \in \mathrm{NP} \cap \mathrm{coNP}$. A proof for membership in L or $\overline{L}$ consists of the transcript of all the queries made by the reduction, together with unique preimages of the queries under f. The fact that f is a permutation guarantees that this transcript perfectly simulates the reduction when given access to an inverting oracle for f.

These arguments explain why the hardness of breaking a large class of cryptosystems cannot be based on the worst-case complexity of an NP complete problem (assuming $\mathrm{NP} \neq \mathrm{coNP}$). However, neither of them uses the fact that the reduction that transforms the adversary into an algorithm for L is correct even if the adversary only performs its task well on average. In fact, the arguments merely assume that the reduction behaves correctly when given oracle access to an adversary that violates a *worst-case* assumption. Given the existence of public key cryptosystems and one-way functions that are hard to break in the worst case, one cannot expect these arguments to explain why breaking a general one-way function or a general public key encryption scheme should be an $\mathrm{NP} \cap \mathrm{coNP}$ problem, as experience seems to indicate, if this is indeed the case.

If we were to ever hope for such an explanation, we need a stronger notion of "NP hard to break" which allows for the fact that the adversary may err on some fraction of inputs. Again, what we mean by a cryptosystem being "NP-hard to break" is that there exists a reduction that transforms an adversary for the cryptosystem into an algorithm for SAT, but now the reduction is required to solve SAT correctly even if the adversary sometimes outputs an incorrect answer.

This motivates the following definition of a reduction from an NP-complete problem to the problem of inverting well on average a one-way function f: A reduction is

an oracle probabilistic polynomial-time procedure R such that for some polynomial p and for every oracle A that inverts f on a $1 - 1/p(n)$ fraction of inputs of length n, it holds that R^A is a BPP algorithm for SAT. The techniques of Feigenbaum and Fortnow imply that if R is nonadaptive, and if all of its oracle queries are done according to the same distribution (that depends only on the length of the input), then the existence of such a reduction implies that the polynomial hierarchy collapses to the third level.

As we explain below, we reach the same conclusion (see Theorem 4.1 in section 4) without any assumption on the distribution of the queries made by R^A, but also assuming as in [17] that the queries are made nonadaptively.

Worst-case to average-case reductions within NP. The most compelling evidence that the average-case hardness of certain problems in NP *can* be based on worst-case intractability assumptions comes from lattice-based cryptography.

Ajtai [3] shows that an algorithm that solves well on average the shortest vector problem (which is in NP) under a certain samplable distribution of instances implies an algorithm that solves, in the worst case, an approximate version of the shortest vector problem. The latter can be seen as an NP promise problem. If the latter problem were NP-complete, then we would have a reduction relating the average-case hardness of a distributional problem in NP to the worst-case hardness of an NP-complete problem. Unfortunately, the latter problem is known to be in $\mathrm{NP} \cap \mathrm{coNP}$, and therefore it is unlikely to be NP-hard. However, it is conceivable that improved versions of Ajtai's argument could show the equivalence between the average-case complexity of a distributional NP problem and the worst-case complexity of an NP problem. Micciancio [34] and Micciancio and Regev [35] improve Ajtai's reduction by showing that a good-on-average algorithm for the generalized subset sum problem implies better worst-case approximation algorithms for a variety of problems on lattices. Such approximations, however, still correspond to promise problems known to be in $\mathrm{NP} \cap \mathrm{coNP}$.

Average-case complexity in NP. The theory of average-case complexity was pioneered by Levin [32], who defined the notion of "efficient-on-average" algorithms and gave a distributional problem that is complete for a large subclass of distributional NP. Levin's notion of efficient-on-average algorithms is stronger than Impagliazzo's notion of polynomial-time heuristic algorithms that we consider here. Namely, every problem in distributional NP that admits an efficient-on-average algorithm also admits an efficient heuristic algorithm.

The subclass of distributional NP problems considered by Levin imposes a severe restriction on the distribution according to which instances of the problem are sampled. In particular, it does not include the problem of inverting arbitrary one-way functions. In the case of a one-way function f, the notion of "inverting f well on average" amounts to solving the search problem "Given u, find x s.t. $f(x) = u$," where u is chosen according to the distribution obtained by applying f to the uniform distribution. In general, f may be an arbitrary polynomial-time algorithm, so it makes sense to relax the definition so as to allow instances of L to be generated by arbitrary polynomial-time samplers. This yields the class distributional NP (introduced by Ben-David and others [7]) of all pairs $(L, \mathcal{D})$, where L is an NP language and $\mathcal{D}$ is an arbitrary samplable distribution according to which inputs for L are generated.

The class distributional NP turns out to be surprisingly robust for (randomized) heuristic algorithms. In particular, there exists an NP language L such that if L is tractable on average with respect to the uniform distribution, then every problem in NP is tractable on average with respect to any samplable distribution. Moreover, the average-case algorithms for distributional NP are "search algorithms" in the sense

that they provide witnesses of membership for most of the "yes" instances. In particular, average-case tractability of L implies the ability to efficiently invert one-way functions on most inputs $f(x)$, where x is chosen uniformly at random. These results on distributional NP were established by Ben-David and others [7] and Impagliazzo and Levin [29].

For an overview of these and other notions in average-case complexity, their interrelations, and explanations of the various choices made in definitions, the reader is referred to the expository papers by Impagliazzo [28], Goldreich [20], and the authors [11].

Our result. A worst-case to average-case reduction with parameter δ from a language L to a distributional problem $(L', \mathcal{D})$ is a probabilistic polynomial-time oracle procedure R such that, for every oracle A that agrees with L' on inputs of probability mass $1 - \delta$ according to $\mathcal{D}$ on each input length, R^A solves L on every input.

If L and L' are the same language, then the reduction is called a self-corrector, a notion independently introduced by Blum, Luby, and Rubinfeld [10], and by Lipton [33] in the context of program checking [8, 9]. As argued below, a locally random reduction is also a worst-case to average-case reduction and a random self-reduction is also a self-corrector, but the reverse need not be true.

In this paper we show that if there is a worst-case to average-case reduction with parameter $1/\text{poly}(n)$ from an NP-complete problem L to a distributional NP problem $(L, \mathcal{D})$, then NP $\subseteq$ coNP/poly and the polynomial hierarchy collapses to the third level. In particular, if an NP-complete problem has a self-corrector with respect to a samplable distribution, then the polynomial hierarchy collapses to the third level.

We first prove the result for the special case in which the distribution $\mathcal{D}$ is uniform (Theorem 4.1). Then, using reductions by Impagliazzo and Levin [29] and by Ben-David and others [7], we show that the same is true even if the reduction assumes a good-on-average algorithm for the *search* version of L', even if we measure average-case complexity for L' with respect to an arbitrary samplable distribution $\mathcal{D}$ (Theorem 5.3).

The generalization to arbitrary samplable distributions and to search problems also implies that there cannot be any nonadaptive reduction from an NP-complete problem to the problem of inverting a one-way function.

Our result also rules out nonadaptive reductions from an NP-complete problem to the problem of breaking a public key cryptosystem. The constraint of nonadaptivity of the reduction is incomparable to the constraints in the results of Goldreich and Goldwasser [23].

It should be noted that some of the worst-case to average-case reductions of Ajtai [3], Ajtai and Dwork [4], Micciancio [34], Regev [38], and Micciancio and Regev [35] are *adaptive*. Micciancio and Regev [35] observe that their reductions can be made nonadaptive with a slight loss in worst-case approximation factors.

Comparison with Feigenbaum and Fortnow [17]. It is easy to see that a locally random reduction R from L to L' that makes q queries, each of which is generated by the reduction according to a distribution $\mathcal{D}$, is also a worst-case to average-case reduction with parameter $\Omega(1/q)$ from L to $(L', \mathcal{D})$. Indeed, if A is an oracle that has agreement, say, $1 - 1/4q$ with L' (as measured by $\mathcal{D}$), and we access the oracle via q queries, each distributed according to $\mathcal{D}$, queries made to A and queries made to L' are answered in the same way with probability at least $3/4$.

For the result of Feigenbaum and Fortnow, it is not necessary that the distribution of each query made by the reduction be exactly $\mathcal{D}$, but it is essential that the marginal distribution of queries made by the reduction be independent of the reduction's input.

This restriction is quite strong, and in this sense, the result of [17] is extremely sensitive: If one modifies the distribution of queries even by an exponentially small amount that depends on the input, all statistical properties of the reduction are preserved, but one can no longer draw the conclusion of [17]. Our result reaches the same conclusion as [17], yet allows the queries made by the reduction to depend arbitrarily on the input.

One natural setting, where the queries made by the reduction seem to essentially depend on the input, is Levin's theory of average-case complexity. One tool for relating the average-case hardness of two distributional problems is the "average-case to average-case reduction." Such a reduction from $(L, \mathcal{D})$ and $(L', \mathcal{D}')$ uses an oracle that solves L' on most inputs chosen from $\mathcal{D}'$ to solve L on most inputs according to $\mathcal{D}$. Some important reductions, most notably those in [7, 29], choose their queries to the oracle from a distribution that depends on the input in an essential way, making the results of [17] useless for their study.

The relation between locally random reductions and our notion of worst-case to average-case reduction is similar to the relation between one-round private information retrieval and locally decodable codes [13, 40]. In one-round private information retrieval, a "decoder" is given oracle access to the encoding of a certain string, and wants to retrieve one bit of the string by making a bounded number of queries; the restriction is that the ith query must have a distribution independent of the bit that the decoder is interested in. In a locally decodable code, a decoder is given oracle access to the encoding of a certain string, and the encoding has been corrupted in a δ fraction of places; the decoder wants to retrieve a bit of the original string by making a bounded number of queries (with no restriction on the distribution on queries). An intermediate notion that is useful in the study of the relation between private information retrieval and locally decodable codes is that of a smooth decoder: Such a decoder satisfies the additional requirement that the distribution of each query should be dominated by the uniform distribution. Similarly, in the setting of worst-case to average-case reductions one can restrict attention to smooth reductions, where the distribution of queries made by the reduction is dominated by the uniform distribution.

For computationally unbounded decoders, it has been shown (see [30, 24]) that uniform, smooth, and general decoders are equivalent, but the same methods do not work in the computationally bounded setting studied in this paper. One step in our proof is, however, inspired by the techniques used to show this equivalence.

Our proof. As in the work of Feigenbaum and Fortnow, we use the fact that problems in coNP/poly cannot be NP-complete unless the polynomial hierarchy collapses to the third level. Our goal is to show that if L has a $1/\mathrm{poly}(n)$ worst-case to average-case reduction to a language $(L', \mathcal{D})$ in distributional NP, then L is in $\mathrm{NP/poly} \cap \mathrm{coNP/poly}$. In particular, if L were NP-complete, then NP would be contained inside coNP/poly, which in particular implies the collapse of the polynomial hierarchy to the third level. (However, the conclusion $\mathrm{NP} \subseteq \mathrm{coNP/poly}$ appears weaker than the more standard statement $\mathrm{NP} = \mathrm{coNP}$.)

Feigenbaum and Fortnow observe that NP/poly is exactly the class of languages which admit AM protocols with polynomial length advice. Then they show $L \in \mathrm{NP/poly} \cap \mathrm{coNP/poly}$ by giving AM protocols with advice for both L and its complement. The protocols for L and its complement are completely analogous, so we focus on describing the protocol for L.

We begin by discussing the case of a reduction from L to $(L', \mathcal{D})$ when $\mathcal{D}$ is the

uniform distribution.

The Feigenbaum–Fortnow protocol. Let us first briefly review the proof of Feigenbaum and Fortnow [17]. Given x, a prover wants to prove that $R^{L'}(x)$ accepts with high probability (implying $x \in L$), where R makes q nonadaptive queries, each uniformly distributed. The (nonuniform) verifier generates k independent computations of $R^{L'}(x)$ and sends to the prover all the kq queries generated in all the k runs. The prover has to provide all the answers, and certificates for all the "yes" answers. The verifier, nonuniformly, knows the overall fraction p of queries of $R^{L'}(x)$ whose answer is "yes" (recall that we assumed that the queries of R, and thus p, are independent of x). If k is large enough, the verifier expects the number of "yes" answers from the prover to be concentrated around kqp, and in fact this is within $kqp \pm O(q\sqrt{k})$ with high probability. If the prover gives fewer than $kqp - O(q\sqrt{k})$ "yes" answers, this provides strong evidence of cheating, and the verifier rejects. Since a cheating prover must provide certificates for all its "yes" claims, such a prover can cheat only by saying "no" on a "yes" query, and cannot do so on more than $O(q\sqrt{k})$ instances. If k is sufficiently larger than q, then with high probability either the verifier rejects, or a majority of the k computations of $R^{L'}(x)$ yields the correct answer, making the reduction output "yes" and the verifier accept.

Handling smooth reductions: The hiding protocol. The Feigenbaum–Fortnow protocol can be used with *every* oracle procedure R, provided that given x we can get a good estimate of the average fraction p_x of oracle queries made by R on input x that are answered "yes" by an oracle for L'. In general, this fraction will depend on x, so it cannot be provided as advice to the AM circuit certifying membership in L.

For starters, let us allow the distribution of R's queries to depend on x, but restrict it to being "α-smooth": We assume that every query y of R is generated with probability at most $\alpha 2^{-|y|}$. (It is useful to think of α as constant, or at most polynomial in $|y|$, so that a query made by R is not much more likely to hit any specific string than in the uniform distribution.) We devise an AM protocol with advice in which the verifier either rejects or gets a good estimate of p_x. This estimate is then fed into the Feigenbaum–Fortnow protocol to obtain an AM circuit for L.

Suppose that, given a *random* query y made by $R(x)$, we could force the prover to reveal whether or not $y \in L'$. Then by sampling enough such queries y, we can estimate p_x as the fraction of "yes" queries made by the reduction. But how do we force the prover to reveal if $y \in L'$? The idea is to hide the query y among a sequence of queries $z_1, \ldots, z_k$, for which we *do* know whether $z_i \in L'$, in such a way that the prover cannot tell where in the sequence we hid our query y. In such a case, the prover is forced to give a correct answer for y, for if he were to cheat he wouldn't know where in the sequence to cheat, and thus would likely be caught.

The problem is that we do not know a specific set of queries z_i with the desired property. We do, however, know that if we choose z_i independently from the uniform distribution on $\{0,1\}^{|y|}$, then with high probability $pk \pm O(\sqrt{k})$ of these queries will end up in L', where p is the probability that a *uniformly random* query in $\{0,1\}^{|y|}$ is in L'. Since p depends only on the length of x but not on x itself, it can be given to the verifier nonuniformly.

This suggests the following verifier strategy: Set $k = \omega(\alpha^2)$, generate k uniformly random queries $z_1, \ldots, z_k$ of length n, hide y among $z_1, \ldots, z_k$ by inserting it at a random position in the sequence, send all the queries to the prover, and ask for membership in L', together with NP-witnesses that at least $pk - O(\sqrt{k})$ queries belong to L'.

We claim that, with high probability, either the verifier rejects or the answer about

membership of y in L' must be correct. Intuitively, a cheating prover can give at most $O(\sqrt{k})$ wrong answers. The prover wants to use this power wisely and assign one of these wrong answers to the query y. However, smoothness ensures that no matter how the prover chooses the set of $O(\sqrt{k})$ queries to cheat on, it is very unlikely that the query y falls into that set.

For ease of analysis, the actual proof presented in section 3.2 combines into a single step the step of sampling enough ys to estimate p_x with the step of hiding y among a sequence of uniform queries.

This argument already provides an interesting generalization to [17]. Notice that we have not yet used the fact that the reduction is allowed access to any oracle that computes L' well on average.

Handling general reductions. We now consider the case of general reductions, allowing the distribution of a random query on input x to depend arbitrarily on x. Observe that the hiding protocol will, in general, fail to estimate p_x for this type of reduction. If a particular query y made by the reduction is very likely (that is, it occurs with probability much greater than $\alpha 2^{-|y|}$), then it cannot be hidden in a reasonably long sequence of uniform queries.

However, suppose that the verifier had the ability to identify queries y that occur with probability $\geq \alpha 2^{-|y|}$; let us call such queries "heavy" and the other ones "light." The fraction of heavy queries in the uniform distribution is at most $1/\alpha$. Suppose also that the prover answers all light queries correctly. We can then use R to certify membership in L as follows: If the query made by R is heavy, pretend that the oracle for R answered "no"; otherwise use the answer provided by the prover. This process simulates exactly a run of the reduction R^A, where A is an oracle that agrees with L' on all the light queries, and answers "no" on all the heavy queries. In particular, A agrees with L' on a $1 - 1/\alpha$ fraction of inputs, so the reduction is guaranteed to return the correct answer.

In general, the verifier cannot identify which queries made by the reduction are heavy and which are light. However, suppose the verifier knew the probability q_x that a random query, on input x, is heavy. Then, among any set of k independent queries, the verifier expects to see, with high probability, $q_x k \pm O(\sqrt{k})$ heavy queries. Using a protocol of Goldwasser and Sipser [26], the verifier can now obtain approximate AM certificates of heaviness for at least $q_x k - O(\sqrt{k})$ queries from the prover. This leaves at most $O(\sqrt{k})$ queries about whose heaviness the verifier may be misinformed.

A verifier with access to q_x can run a variant of the hiding protocol to calculate the fraction p_x of "yes" instances of L' among the light queries (treating the $O(\sqrt{k})$ heavy queries that "slip in the sample" as a statistical error to this estimate), followed by a variant of the Feigenbaum–Fortnow protocol, simulating "no" answers on all the heavy queries.

Finally, we need a protocol that helps the verifier estimate the probability q_x of heavy queries. The verifier can obtain an approximate lower bound on q_x by sampling random queries and asking for proof that each query is heavy. To obtain an approximate upper bound on q_x, the verifier uses an "upper bound" protocol for the size of certain NP sets due to Fortnow [19]. The explanation of the exact roles of these protocols in estimating q_x is deferred to section 3.1.

We observe that the generalization of the Feigenbaum–Fortnow result about locally random reductions to smooth, and then arbitrary, nonadaptive reductions parallels an analogous sequence of steps establishing the equivalence of uniform, smooth, and arbitrary decoders for locally decodable codes.

General distributions, search problems, and one-way functions. So far we have described our results for the case in which the distribution on inputs $\mathcal{D}$ is the uniform distribution. We now consider the case where $\mathcal{D}$ is an arbitrary samplable distribution. Impagliazzo and Levin [29] show that for every distributional NP problem $(L, \mathcal{D})$ and bound $\delta = n^{-O(1)}$ there is a nonadaptive probabilistic polynomial-time oracle algorithm R, an NP language L', and a bound $\delta' = \delta^{O(1)}$ such that for every oracle A that agrees with L' on a $1 - \delta'$ fraction of inputs, R^A solves L on a subset of inputs of density $1 - \delta$ under the distribution $\mathcal{D}$.

This means that if there were a nonadaptive worst-case to average-case reduction with parameter $1/\text{poly}(n)$ from a problem L to a distributional problem $(L', \mathcal{D})$, there would also be such a reduction from L to $(L'', \mathcal{U})$, where $\mathcal{U}$ is the uniform distribution and L'' is in NP. By the previously described results, this would imply the collapse of the polynomial hierarchy.

A reduction by Ben-David and others [7] implies that for every distributional NP problem $(L, \mathcal{U})$ there is a problem L' in NP such that an algorithm that solves the decision version of $(L', \mathcal{U})$ on a $1 - \delta$ fraction of inputs can be modified (via a nonadaptive reduction) into an algorithm that solves the search version of $(L, \mathcal{U})$ on a $1 - \delta \cdot \text{poly}(n)$ fraction of input. This implies that even if we modify the definition of worst-case to average-case reduction so that the oracle A is supposed to solve the *search* version of the problem, our results still apply. In particular, for every polynomial-time computable function f, the problem of inverting f well on average is precisely the problem of solving well on average a distributional NP search problem. Therefore our results also rule out the possibility of basing one-way functions on NP-hardness using nonadaptive reductions.

Organization. Section 2 provides the relevant definitions of notions in average-case complexity and interactive proof systems. In section 3 we present the protocols for estimating the fraction of heavy queries of a reduction, the fraction of light "yes" queries of a reduction, and for simulating the reduction, respectively. Section 4 contains the proof of our main result (Theorem 4.1) concerning the average-case complexity of languages with respect to the uniform distribution. In section 5 we prove our result for the average-case complexity of distributional search problems (Theorem 5.3).

2. Preliminaries. In this section we formalize the notions from average-case complexity and interactive proof systems needed to state and prove our result on the impossibility of worst-case to average-case reductions in NP.

For a distribution $\mathcal{D}$, we use $x \sim \mathcal{D}$ to denote a sample x chosen according to $\mathcal{D}$. For a finite set S, we use $x \sim S$ to denote a sample x chosen uniformly at random from S. For a sample x, we use $\mathcal{D}(x)$ to denote the probability of x in the distribution $\mathcal{D}$. For a set S, we use $\mathcal{D}(S)$ to denote the probability that a random sample chosen according to $\mathcal{D}$ falls inside the set S.

2.1. Distributional problems and heuristic algorithms. Intuitively, we think of an algorithm A as a "good heuristic algorithm" for distributional problem $(L, \mathcal{D})$ if the set of "yes" instances of A (which we also denote by A) and the set L are close according to $\mathcal{D}$. Formalizing this definition requires one to make choices regarding how $\mathcal{D}$ measures closeness and what the threshold for closeness is.

Roughly, Levin [32] considers two sets A and L to be close according to $\mathcal{D}$ if on a *random* input length n, the measure of the symmetric difference $A \triangle L$ according to the restriction of $\mathcal{D}$ on $\{0,1\}^n$ is small. We will make the stronger requirement that this quantity be small for *all* n. Notice that every heuristic algorithm satisfying the stronger requirement also satisfies the weaker requirement (and therefore reductions

that work for algorithms satisfying the weaker requirement also work for algorithms satisfying the stronger requirement), so the stronger requirement makes our impossibility result more general. This requirement simplifies some of the definitions, as we can now restrict our attention to ensembles of distributions over various input lengths rather than a single distribution over $\{0,1\}^*$.

We now turn to the actual definitions.

DEFINITION 2.1 (samplable ensemble). *An* efficiently samplable ensemble of distributions *is a collection $\mathcal{D} = \{\mathcal{D}_1, \mathcal{D}_2, \dots\}$, where $\mathcal{D}_n$ is a distribution on $\{0,1\}^n$ for which there exists a probabilistic polynomial-time sampling algorithm S that, on input 1^n, outputs a sample from $\mathcal{D}_n$.*[2]

The *uniform ensemble* is the ensemble $\mathcal{U} = \{\mathcal{U}_1, \mathcal{U}_2, \dots\}$, where $\mathcal{U}_n$ is the uniform distribution on $\{0,1\}^n$.

A *distributional problem* is a pair $(L, \mathcal{D})$, where L is a language and $\mathcal{D}$ is an ensemble of distributions. A distributional problem $(L, \mathcal{D})$ is in the class *distributional* NP, denoted DistNP, if L is in NP and $\mathcal{D}$ is efficiently samplable.

In this paper we study hypothetical reductions that might be used to establish average-case intractability of distributional NP problems based on a worst-case assumption, such as NP $\not\subseteq$ BPP. The notion of average-case intractability that we have in mind is the absence of good-on-average algorithms of the following type. (The definition is in the spirit of the treatment by Impagliazzo [28].)

DEFINITION 2.2 (heuristic polynomial time). *We say that a probabilistic polynomial-time algorithm A is a* heuristic algorithm with success probability $s(n)$ *for a distributional problem $(L, \mathcal{D})$ if, for every n, $\Pr_{x \sim \mathcal{D}_n}[A(x) = L(x)] \geq s(n)$, where the probability is taken over the sampling of x from $\mathcal{D}_n$ and over the internal coin tosses of A. The class of distributional problems for which such algorithms exist is denoted by* $\mathrm{Heur}_{s(n)}\mathrm{BPP}$.

We consider a distributional problem $(L, \mathcal{D})$ to be "hard on average" if there is a polynomial p such that $(L, \mathcal{D}) \notin \mathrm{Heur}_{1-1/p(n)}\mathrm{BPP}$. This is a fairly robust notion with respect to the choice of p: Trevisan [40] proves that there is a constant $c > 0$ such that for every polynomial p,

$$\text{DistNP} \not\subseteq \mathrm{Heur}_{1-1/p(n)}\mathrm{BPP} \text{ iff } \text{DistNP} \not\subseteq \mathrm{Heur}_{1/2+(\log n)^{-c}}\mathrm{BPP}.$$

Stronger collapses are known for nonuniform heuristic classes [37, 27].

Levin's alternative notion of an "efficient-on-average" algorithm [32] imposes the additional requirement that the average-case algorithm A be errorless: For every x for which $A(x) \neq L(x)$, $A(x)$ must output "fail" (with high probability over its internal coin tosses).[3] Hence every efficient-on-average algorithm for $(L, \mathcal{D})$ is also a heuristic algorithm for $(L, \mathcal{D})$, so the class of problems (in distributional NP) that are "hard for efficient-on-average algorithms" is possibly larger than the class of problems that are "hard for heuristic algorithms." Therefore opting for "hard for heuristic algorithms" as our notion of average-case hardness makes our impossibility result weaker, but in fact our result holds even with respect to the notion of "hard for efficient-on-average algorithms" (as explained in section 4).

[2] This definition restricts the strings in the support of $\mathcal{D}_n$ to having length exactly n. It is possible to use a more relaxed definition in which the length of strings in the support of $\mathcal{D}_n$ is variable, as long as S is nonshrinking: Namely, the length of every string in the support of $\mathcal{D}_n$ must be at least n^ϵ for some constant $\epsilon > 0$.

[3] Levin's original definition [32] is formulated differently from the one we give here, but Impagliazzo [28] shows that the two are essentially equivalent.

For a function $\delta(n)$, two languages L and L', and an ensemble of distributions $\mathcal{D}$ on inputs, we say that L and L' are δ-close with respect to $\mathcal{D}$ if for sufficiently large n, the measure of the set $L_n \triangle L'_n$ according to $\mathcal{D}_n$ is at most $\delta(n)$. The definition of "heuristic polynomial time with success probability $s(n)$" requires that A and L be $(1 - s(n))$-close.

2.2. Worst-case to average-case reductions. A worst-case to average-case reduction is a procedure that transforms any average-case algorithm for one problem into an algorithm that works on all inputs for another problem. The reduction is called *nonadaptive* if the reduction decides on all its queries before it makes any of them. The following definition formalizes this notion.

DEFINITION 2.3. *A* nonadaptive worst-case to average-case randomized reduction *from L to $(L', \mathcal{D})$ with* average hardness δ *(in short, a δ* worst-to-average reduction*) is a family of polynomial size circuits $R = \{R_n\}$ such that on input $x \in \{0,1\}^n$ and randomness r, $R_n(x; r)$ outputs strings $y_1, \ldots, y_k$ (called* queries*) and a circuit C (called a* decider*) such that for any L^* that is δ-close to L' with respect to $\mathcal{D}$, it holds that*

$$\Pr_r[C(L^*(y_1), \ldots, L^*(y_k)) = L(x)] \geq 2/3.$$

We can also think of R as a nonadaptive oracle procedure that, when provided any L^* that is δ-close to L' as an oracle, agrees with L on every input (with probability at least $2/3$ over its internal coin tosses).

Notice that if there is a δ worst-to-average reduction from L to $(L', \mathcal{D})$, and $L \notin \text{BPP}$, then $(L', \mathcal{D}) \notin \text{Heur}_{1-\delta}\text{BPP}$. When the distribution $\mathcal{D}$ is uniform, we may denote the distributional problem $(L', \mathcal{D})$ just by L'.

Remarks on the definition.

(i) The choice of constant $2/3$ for the success probability of the reduction in the definition is rather arbitrary. If there exists a worst-to-average reduction R_n from L to $(L', \mathcal{D})$ that succeeds with probability $1/2 + n^{-c}$, there also exists one that succeeds with probability $1 - 2^{-n^{c'}}$ for arbitrary constants c, c'.

(ii) Without loss of generality, we may also assume that the strings $y_1, \ldots, y_k$ are identically distributed. Suppose R is an arbitrary reduction R that makes k queries. We define a new reduction R' that randomly permutes the queries of R. Then each query of R' is distributed as a random query of R.

(iii) Without loss of generality, we can fix two polynomials $k(n)$ and $m(n)$ such that for every n, when given an input x of length n, the reduction makes exactly $k(n)/m(n)$ queries of length i for every i between 1 and $m(n)$ (so that the total number of queries made is $k(n)$). This condition guarantees that for every i between 1 and $m(n)$, and every string y of length i, the probability that a random query made by the reduction equals y is exactly $1/m(n)$ times the probability that a random query made by the reduction equals y, with the condition that the length of this query is i. When working with distributions over queries, it is convenient to fix the query length; this restriction will allow us to relate statistics over queries of fixed length to statistics over queries of arbitrary length produced by the reduction.

(iv) We used a nonuniform definition of reductions, as it gives us a more general impossibility result. In particular, our result holds for uniform reductions.

2.3. Constant-round interactive protocols. We now discuss the types of protocols used in our proof, as well as certain extensions that will be used as building blocks.

Constant-round interactive protocols with advice. All the protocols in this paper are constant-round interactive protocols with polynomially long advice. An interactive protocol with advice consists of a pair of interactive machines (P, V), where P is a computationally unbounded prover and V is a randomized polynomial-time verifier which receive a common input x and advice string a. Feigenbaum and Fortnow [17] define the class $\mathrm{AM}^{\mathrm{poly}}$ as the class of languages L for which there exists a constant c, a polynomial p, and an interactive protocol (P, V) with advice such that for every n, there exists an advice string a of length $p(n)$ such that for every x of length n, on input x and advice a, (P, V) produces an output after c rounds of interaction and

(i) if $x \in L$, then $\Pr[(P, V) \text{ accepts } x \text{ with advice } a] \geq 2/3$;

(ii) if $x \notin L$, then for every prover P^*, $\Pr[(P^*, V) \text{ accepts } x \text{ with advice } a] \leq 1/3$.

We observe that this definition is weaker than the definition of the class AM/poly following the Karp–Lipton notion of classes with advice, which requires that the (P, V) be a valid constant-round interactive protocol (possibly for some language other than L) for all possible settings of the advice. (We note that in both cases, the advice is accessible to both the prover and the verifier.) Even though $\mathrm{AM}^{\mathrm{poly}}$ appears to be larger than AM/poly, they are in fact both equal to NP/poly (cf. [17]). Owing to this, in our description of protocols we will not be concerned with the behavior of the protocol when the advice is bad.

The protocol of Feigenbaum and Fortnow uses public coins. In contrast, our protocol will use private coins. In the case of constant-round interactive protocols without advice, it is known that private coin protocols can be simulated by public coin protocols [26]. The argument extends to protocols with advice, and therefore we may drop the public coin requirement in the definition of $\mathrm{AM}^{\mathrm{poly}}$.

The existence of $\mathrm{AM}^{\mathrm{poly}}$ protocols for all of coNP implies a partial collapse of the polynomial hierarchy, as was also observed in [17]: By the above observations, the assumption $\mathrm{coNP} \subseteq \mathrm{AM}^{\mathrm{poly}}$ implies $\mathrm{coNP} \subseteq \mathrm{NP/poly}$, and by a result of Yap [42], this gives $\Sigma_3 = \Pi_3$.

Protocols with shared auxiliary input. When applying two protocols in sequence, the second protocol has access to the transcript of the interaction from the first protocol. To allow access to this transcript, we extend our definition of interactive protocol to include a shared auxiliary input. This shared auxiliary input comes with a promise Υ, which may depend on the actual input. The completeness and soundness conditions are required to hold for all auxiliary inputs satisfying the promise. In the case of sequential composition of two protocols, the promise of the second protocol includes the set of all transcripts that are not rejecting for the first protocol. The running time of the verifier in a protocol with shared auxiliary input is measured with respect to the length of the concatenation of the actual input and the shared auxiliary input.

Protocols with private verifier input. In a protocol with private verifier input, the verifier is given, in addition to the input x, a private input r not known to the prover. The input r will be a "secret" of the verifier—a random string, uniformly distributed among a range of secrets that may depend on the input x. We represent the range of secrets by an NP relation H: A secret r for input x is chosen uniformly among all r such that $(x; r)$ satisfies H.

In our application, the protocol will be applied to instances of promise problems (see [15, 22]) instead of languages. For this reason, we state a definition of constant-round protocols with private verifier input for promise problems.

DEFINITION 2.4. *An* interactive protocol with private verifier input *consists of a polynomial-time verifier V, an unbounded prover P, and an* NP *relation H. A promise problem $\Pi = (\Pi_Y, \Pi_N)$ admits such a protocol with completeness c and soundness s if*

(i) *for all $x \in \Pi_Y$, $\Pr[(P, V(r))$ accepts $x] \geq c$.*

(ii) *for all $x \in \Pi_N$ and every prover P^*, $\Pr[(P^*, V(r))$ accepts $x] \leq s$.*

In both cases, the randomness is taken over V and over r chosen uniformly from all strings that satisfy $(x; r) \in H$.

Notice that this definition extends the standard notion of proof system without a private input, as we can specialize the definition to an NP relation H that mandates a unique choice of r for every x. The definition can be naturally extended in the case of protocols with shared auxiliary input. For such protocols to be sequentially composable, we must require that the private input of the verifier be independent of the shared auxiliary input, conditioned on the actual input.

Parallel repetition of two-round protocols. Suppose, given n instances $x_1, \ldots, x_n$ of a promise problem Π in $\mathrm{AM}^{\mathrm{poly}}$, we want a $\mathrm{AM}^{\mathrm{poly}}$ protocol that distinguishes between the case when all $x_i \in \Pi_Y$ and the case when at least one $x_i \in \Pi_N$. A natural approach is to run n independent instantiations of the protocol for Π in parallel, and accept if all of them accept. Intuitively, if the protocol for Π has completeness $1 - \epsilon$ and soundness δ, we expect the parallel protocol to have completeness $1 - n\epsilon$ and soundness δ. This worsens the completeness of the original protocol, while leaving the soundness essentially unchanged.

One way to improve the soundness is the following. Suppose that we could settle for distinguishing between the case when all $x_i \in \Pi_Y$ and the case when $x_i \in \Pi_N$ *for at least t of the x_is*. Intuitively, this relaxation makes the work required of a cheating prover much more demanding: Such a prover is now trying to convince the verifier to accept an instance in which at least t of the x_i's are "no" instances of Π. We expect such a prover to have success probability at most δ^t.

We prove that this is indeed the case for public coin two-round protocols (which is sufficient for our application), even for proof systems with private verifier input. We begin by describing the promise problem intended to be solved by parallel composition. We then define parallel composition for two-round protocols with private verifier input, and prove that parallel composition solves the intended problem.[4]

Given a promise problem $\Pi = (\Pi_Y, \Pi_N)$, we define the *n-wise repetition of* Π *with threshold t* to be the promise problem $\Pi^{n,t} = (\Pi_Y^{n,t}, \Pi_N^{n,t})$ as follows:

$$\Pi_Y^{n,t} = \{(x_1, \ldots, x_n) : x_i \in \Pi_Y \text{ for all } i\},$$
$$\Pi_N^{n,t} = \{(x_1, \ldots, x_n) : x_i \in \Pi_N \text{ for at least } t \text{ values of } i\}.$$

Suppose (P, V, H) is a k round protocol with private verifier input and with advice. We define its n-fold parallel composition as the k round protocol (P^n, V^n, H^n) with private verifier input, where

(i) V^n is the machine that, on input $(x_1, \ldots, x_n)$ and private verifier input $(r_1, \ldots, r_n)$, simulates n independent runs of V, where the ith run takes input x_i, private verifier input r_i, uses randomness independent of all other runs, and responds according to the next message function of V given the transcript of messages generated

[4] Goldreich [21, Appendix C.1] proves that parallel composition has the desired completeness and soundness errors for private coin protocols with arbitrary round complexity, but without private verifier input. His proof easily extends to our setting, but for simplicity we present a self-contained proof here.

by the ith run of (P, V) so far. At the end of the interaction, V^n accepts if the transcripts produced by *all* the runs are accepting.

(ii) P^n is the machine, that, on input $(x_1, \ldots, x_n)$, simulates n runs of P, where the ith run takes input x_i and responds according to the next message function of P given the transcript of messages generated by the ith run of (P, V) so far.

(iii) H^n is defined as follows: $((x_1, \ldots, x_n); (r_1, \ldots, r_n)) \in H^n$ iff $(x_i; r_i) \in H$ for all $1 \leq i \leq n$.

LEMMA 2.5. *Suppose (P, V, H) is a two-round protocol (where the first message is sent by the verifier) with private verifier input for promise problem Π with completeness $1 - \epsilon$ and soundness δ. Moreover, suppose that the message sent by V contains all of V's coin tosses. Then (P^n, V^n, H^n) is a protocol for $\Pi^{n,t}$ with completeness $1 - n\epsilon$ and soundness δ^t.*

Proof. The completeness of (P^n, V^n, H^n) follows by taking a union bound over the n runs of (P, V, H). To argue soundness, suppose that $\mathbf{x} = (x_1, \ldots, x_n) \in \Pi_N^{n,t}$. Without loss of generality, assume that specifically $x_1, \ldots, x_t \in \Pi_N$. For an input x and private verifier input r, define $B_{x,r}$ as the set of all messages μ sent by V on input (x, r) for which there exists a response ν that makes V accept.

Consider an arbitrary prover P^* that interacts with V^n. Suppose that V^n receives private verifier input $\mathbf{r} = (r_1, \ldots, r_n)$, and sends the message $\mu = (\mu_1, \ldots, \mu_n)$. In the second round, P^* responds with the message $\nu = (\nu_1, \ldots, \nu_n)$. Note that

$$\Pr_{\mathbf{r},\mu}[V^n(\mathbf{x}, \mathbf{r}, \mu, \nu) \text{ accepts}] \leq \Pr_{\mathbf{r},\mu}[\mu_i \in B_{x_i,r_i} \text{ for all } 1 \leq i \leq t].$$

The independence of the verifier strategies on different runs implies that for every i, the event $\mu_i \in B_{x_i,r_i}$ is independent of any function of μ_j, r_j for $j \neq i$. Therefore

$$\Pr_{\mathbf{r},\mu}[\mu_i \in B_{x_i,r_i} \text{ for all } 1 \leq i \leq t] = \prod_{i=1}^{t} \Pr_{r_i,\mu_i}[\mu_i \in B_{x_i,r_i}] \leq \delta^t$$

by the soundness of (P, V, H) for promise problem Π. ∎

The lemma and the proof also extend to protocols with shared auxiliary input (in addition to the private verifier input).

2.4. Lower and upper bound protocols. We now outline two protocols, used for proving approximate bounds on the number of accepting inputs of a circuit, that will be used as components in our constructions. The lower bound protocol of Goldwasser and Sipser [26] is used to prove an approximate lower bound on the number of accepting inputs of a circuit C. The upper bound protocol of Fortnow [19] (also used by Aiello and Håstad [2]) is used to prove an approximate upper bound on the same quantity, when the verifier is given private access to a random accepting input of the circuit. We stress that our version of the upper bound protocol is somewhat different from the protocols in [19, 2], as for our application we need a better approximation than in the original protocols, but we can allow for a much larger soundness error. The lower and upper bound protocols will allow the verifier to check whether queries made by the reduction are light or heavy.

We state the completeness and soundness conditions of the protocols, and provide proof sketches in section A.2 of the appendix.

The lower bound protocol. The lower bound protocol solves the following problem, which we denote $\Pi_{LB,\epsilon}$ (where $\epsilon > 0$):

Inputs. (C, s), where $C : \{0,1\}^m \to \{0,1\}$ is a circuit, $0 \le s \le 2^m$.

Shared auxiliary input. $\delta, \epsilon > 0$ (represented in unary), where δ is a parameter that controls the completeness and soundness errors, and ϵ controls the precision of the lower bound.

Yes instances. (C, s) such that $|C^{-1}(1)| \ge s$.

No instances. (C, s) such that $|C^{-1}(1)| \le (1-\epsilon)s$.

The protocol. On input (C, s) and shared auxiliary input (δ, ϵ):

1 Verifier: Set $k = \lceil 9/\delta\epsilon^2 \rceil$. Choose a pairwise independent hash function $h : \{0,1\}^m \to \Gamma$ at random, where $|\Gamma| = \lfloor s/k \rfloor$, and send h to the prover.

2 Prover: Send a list $r_1, \ldots, r_l \in \{0,1\}^m$, where $l \le (1+\epsilon/3)k$. An honest prover sends all r_i such that $C(r_i) = 1$ and $h(r_i) = 0$.

3 Verifier: If $C(r_i) \ne 1$ for any i, reject. If $|l - k| > \epsilon k/3$, reject. If $h(r_i) \ne 0$ for any i, reject. Otherwise, accept.

An alternative version of this protocol that achieves somewhat better parameters appears in work by Goldreich, Vadhan, and Wigderson [25]. The protocol presented here parallels the upper bound protocol, described below, more closely.

LEMMA 2.6. *The lower bound protocol is a protocol for $\Pi_{LB,\epsilon}$ with completeness $1-\delta$ and soundness δ.*

In our applications we will need to apply the lower bound protocol on many instances in parallel and to be guaranteed that all runs of the protocol are correct with high probability. For this reason, we resort to Lemma 2.5, observing that the lower bound protocol satisfies the hypothesis of this lemma. Applying Lemma 2.5 for $t = 1$ and setting $\delta = \epsilon/n$ yields a parallel lower bound protocol for $\Pi^{n,1}_{LB,\epsilon}$ with completeness $1-\epsilon$ and soundness ϵ.[5]

COROLLARY 2.7 (parallel lower bound protocol). *For every n and $\epsilon > 0$ there exists a constant round protocol for $\Pi^{n,1}_{LB,\epsilon}$ (with shared auxiliary input ϵ, represented in unary) with completeness $1-\epsilon$ and soundness ϵ.*

The upper bound protocol. The upper bound protocol solves the following problem, which we denote $\Pi_{UB,\epsilon}$ (where $\epsilon > 0$):

Inputs. (C, s), where $C : \{0,1\}^m \to \{0,1\}$ is a circuit, $0 \le s \le 2^m$.

Shared auxiliary input. $\delta, \epsilon > 0$ (represented in unary), where δ is a parameter that controls the completeness error and the soundness error. In contrast to the lower bound protocol, ϵ controls the precision of the protocol and also affects the soundness.

Yes instances. (C, s) such that $|C^{-1}(1)| \le s$.

No instances. (C, s) such that $|C^{-1}(1)| \ge (1+\epsilon)s$. The upper bound protocol is a protocol with private verifier input: The verifier is provided a random sample r of

[5] For this setting of parameters, ϵ controls both the precision of the approximate lower bound and the completeness and soundness errors. Had we wished to do so, we could have used independent parameters for the precision and for the completeness/soundness errors, though this is not necessary for our application. In contrast, in the parallel upper bound protocol presented below, the precision of the protocol and the soundness error are intricately related.

$C^{-1}(1)$, not known to the prover.

Private verifier input. A string $r \in S$. (Notice that the relation $\{((C,s);r) : C(r) = 1\}$ is an NP relation.)

The protocol. On input (C,s), shared auxiliary input (δ,ϵ), and private verifier input r:

1 Verifier: Set $k = \lceil 9/\delta\epsilon^2 \rceil$. Choose a 3-wise independent hash function $h : \{0,1\}^m \to \Gamma$ at random, where $|\Gamma| = \lfloor (s-1)/k \rfloor$ and send the pair $(h, h(r))$ to the prover.

2 Prover: Send a list $r_1, \ldots, r_l \in \{0,1\}^m$, where $l \leq (1+\epsilon/3)k$. An honest prover sends all r_i such that $C(r_i) = 1$ and $h(r_i) = h(r)$.

3 Verifier: If $C(r_i) \neq 1$ for any i, reject. If $l > (1+\epsilon/3)k$ or $r \notin \{r_1, \ldots, r_l\}$, reject. Otherwise, accept.

LEMMA 2.8. *The upper bound protocol is a protocol with private verifier input for $\Pi_{UB,\epsilon}$, completeness $1-\delta$, and soundness $1-\epsilon/6+\delta$.*

Setting $\delta = o(\epsilon)$, this yields a protocol with completeness $1-o(\epsilon)$ and soundness $1-\Omega(\epsilon)$, giving a narrow gap. To improve the soundness of the protocol, which is necessary for our application, we apply parallel repetition. In particular, fixing $\delta = o(\epsilon/n)$ and setting $t = \omega(1/\epsilon)$ in Lemma 2.5 yields a protocol for $\Pi^{n,t}_{UB,\epsilon}$ with completeness $1-o(1)$ and soundness $(1-\epsilon/6+o(\epsilon/n))^t = o(1)$. More generally, we have a parallel upper bound protocol for $\Pi^{n,t}_{UB,\epsilon}$ with the following parameters.

COROLLARY 2.9 (parallel upper bound protocol). *For every n and $\epsilon > 0$ there exists a constant round protocol with private verifier input (and shared auxiliary input ϵ, represented in unary) such that for every $t > 0$ the protocol decides $\Pi^{n,t}_{UB,\epsilon}$ with completeness $1-\epsilon$ and soundness $(1-\epsilon/9)^t$.*

3. The protocols. In this section we describe the constant-round interactive protocols that will constitute the building blocks of our main protocol. The order in which the protocols are presented follows the order in which they will be composed sequentially, which is the opposite of the description in the introduction. Recall that we need protocols that accomplish each of the following tasks:

(i) For a fixed input x, estimate the probability that a random query of a given length produced by the worst-to-average reduction on input x is light (that is, the probability of it being produced by the reduction is smaller than a specified threshold). We consider the following more abstract version of the problem: Given a circuit C, estimate the fraction of heavy outputs of C. The heavy samples protocol, described in section 3.1, solves this problem.

(ii) For a fixed input x, estimate the probability that a random query of a given length produced by the worst-to-average reduction on input x is both light and a "yes" instance. Abstractly, we can think of this problem as follows. We model the worst-to-average reduction as a sampler circuit C and the set of "yes" instances of a given length as a nondeterministic circuit V. As auxiliary input, we are given the fraction of accepting inputs for V as well as the probability that a random output of C is heavy. The task is to construct a protocol that estimates the probability that a random output of C is both light and accepting for V. The hiding protocol, described in section 3.2, accomplishes this task.

(iii) For a fixed input x, simulate an "approximate membership oracle" for queries made by the reduction on input x. This calls for a protocol for the fol-

lowing task: We are given a "querier" Q, describing an instantiation of the reduction on x, and an NP verifier V for "yes" instances. The following promise holds: When provided an oracle for the set

$$S_{Q,V} = \{y : V \text{ accepts } y \text{ and } y \text{ is a light query of } Q\},$$

Q either outputs "yes" with very high probability, or outputs "no" with very high probability (these cases correspond to the reduction saying "$x \in L$" and "$x \notin L$", respectively). The simulation protocol, described in section 3.3, distinguishes between these two cases when given as auxiliary inputs the fraction of heavy queries of Q and the fraction of "yes" instances of $S_{Q,V}$.

A note on approximations. The protocols described in this section cannot be expected to certify the exact values of the probabilities in question, but can only obtain approximations thereof. Intuitively, we will think of a protocol as computing an approximation of p if, for arbitrary ϵ, the protocol runs in time polynomial in $1/\epsilon$ and distinguishes between instances whose probability is p and instances whose probability is outside the interval $(p - \epsilon, p + \epsilon)$. Indeed, additive approximations are sufficient in all our applications.

These protocols also take as inputs (actual and auxiliary) probabilities of various events. We make the assumption that these probabilities are specified exactly, but in fact the completeness and soundness of the protocols are unaffected even if only approximations of these quantities were provided. The quality of approximation required is, in all cases, a fixed inverse polynomial function of the input length.

Statistics. We use the following formulation of the law of large numbers to obtain sampling estimates for various probabilities. For completeness we provide a proof in section A.1 of the appendix.

LEMMA 3.1 (sampling bound). *Let Ω be a sample space, $\epsilon, \eta < 1$, $T \subseteq \Omega$, and $\mathcal{D}$ a distribution on Ω. Suppose that S is a random sample of Ω consisting of at least $3\log(2/\eta)/\epsilon^3$ elements chosen independently at random from the distribution $\mathcal{D}$. Then with probability at least $1 - \eta$,*

$$\big||T \cap S|/|S| - \mathcal{D}(T)\big| \leq \epsilon.$$

High probability means probability $1 - o(1)$, where the $o(\cdot)$ notation is in terms of the length of the input of the protocol.

The notation $A \triangle B$ is for the symmetric difference of sets A and B. We use standard set facts about symmetric difference.

3.1. The heavy samples protocol. In this section we describe the protocol used for estimating the fraction of heavy samples generated by a circuit C. Recall that a string y is *α-heavy* for distribution $\mathcal{D}$ on $\{0,1\}^m$ if $\mathcal{D}(y) \geq \alpha 2^{-m}$. Given a distribution $\mathcal{D}$, the probability that a random sample of $\mathcal{D}$ is α-heavy is given by the quantity

$$h_{\mathcal{D},\alpha} = \Pr_{y \sim \mathcal{D}}[\mathcal{D}(y) \geq \alpha 2^{-m}].$$

The problem we are considering is the following: Given a circuit $C : \{0,1\}^n \to \{0,1\}^m$, a threshold α, a heaviness estimate p, and an error parameter ϵ, we want a protocol that accepts when $p = h_{\mathcal{D}_C,\alpha}$ and rejects when $|p - h_{\mathcal{D}_C,\alpha}| > \epsilon$. Here, as throughout the section, $\mathcal{D}_C$ denotes the output distribution of the circuit C.

A natural approach is to estimate the unknown $h_{\mathcal{D}_C,\alpha}$ by sampling: Suppose that for a random sample $y \sim \mathcal{D}_C$ we could decide with good probability if the sample was

α-heavy or α-light. Then, given $k = O(1/\epsilon^3)$ samples $y_1, \ldots, y_k$ generated by running C on independent inputs, we could estimate $h_{\mathcal{D}_C,\alpha}$ as the fraction of samples that are α-heavy, and sampling bounds would guarantee that the answer is correct with good probability.

However, in general we have no way of efficiently deciding whether a sample $y \sim \mathcal{D}_C$ is heavy or light. However, we have at our disposal the upper and lower bound protocols of section 2.4. For each sample y_i, the verifier first asks the prover to say if sample y_i is α-heavy or α-light. Then the prover is asked to prove the claims for the heavy samples using the lower bound protocol, and the claims for the light samples using the upper bound protocol. In both cases, the claims concern the size of the set $C^{-1}(y_i)$, which is the restriction of an NP set on $\{0,1\}^m$.

There are several difficulties with implementing this approach. First, the upper bound protocol requires the verifier to have a secret, random preimage r_i of the set $C^{-1}(y_i)$. Fortunately, the verifier obtains this secret for free in the course of generating y_i. When generating y_i, the verifier in fact chooses a random $r_i \in \{0,1\}^n$ and sets $y_i = C(r_i)$, so this r_i (which is kept hidden from the prover) is indeed a random preimage of y_i.

Another difficulty is that the upper bound protocol guarantees an ϵ deviation from the true value of $C^{-1}(y_i)$ only with probability $1 - O(\epsilon)$. Therefore the prover has a good chance of getting away with a false upper bound claim on any particular y_i. But how many times can the prover play this trick? If the prover decides to submit t false upper bound claims, its success probability quickly falls to $(1 - O(\epsilon))^t$ (see Corollary 2.7), so for $t = \omega(1/\epsilon)$ the risk of detecting a false upper bound claim becomes quite high for the prover. On the other hand, $O(1/\epsilon)$ false upper bound claims make no real difference for the verifier. In the end, the verifier uses these claims to compute its estimate of $h_{\mathcal{D}_C,\alpha}$, so any set of $O(1/\epsilon)$ false claims among k samples will change its estimate only by $O(k/\epsilon) = O(\epsilon^2)$, much less than the tolerated deviation ϵ.

The final difficulty stems from the fact that both the upper and lower bound protocols are approximate. To illustrate this issue, consider the case of a circuit C for which the distribution $\mathcal{D}_C$ is close to α-flat: Namely, every $y \in \{0,1\}^m$ has probability either 0 or $(1 \pm \epsilon)\alpha 2^{-m}$ under $\mathcal{D}_C$. Now for *every* sample y_i of the verifier, it happens that y_i is approximately both α-heavy and α-light. Hence the verifier has no soundness guarantee about the prover's claims for any y_i.

This issue appears quite difficult to resolve. We sidestep it by weakening the requirement on the protocol. Instead of requiring soundness for all α, we settle for soundness for a *random* choice of α. This avoids the "flatness" issue, because an almost flat distribution is very unlikely to be close to α-flat for a random α. More generally, given any distribution $\mathcal{D}_C$, if α is assigned a random value among any set of $1/\epsilon$ values that are spaced apart by a factor of at least $1 + 2\epsilon$, then the expected probability mass under $\mathcal{D}_C$ of samples that are both $(1-\epsilon)\alpha$-heavy and $(1+\epsilon)\alpha$-light can be at most ϵ. Therefore, the fraction of samples for which the verifier fails to obtain a soundness guarantee cannot be much more than $O(\epsilon)$.

Choosing a heaviness threshold. We formalize the last observation in the following claim. The claim is also used in sections 3.2 and 3.3. For every integer α_0 and fraction $\delta > 0$, define the distribution

$$\mathcal{A}_{\alpha_0,\delta} = \text{uniform distribution on } \{\alpha_0(1+3\delta)^i : 0 \le i \le 1/\delta\}. \tag{1}$$

Observe that every value in $\mathcal{A}_{\alpha_0,\delta}$ is in the range $[\alpha_0, e^3 \cdot \alpha_0]$. Since the intervals $((1-\delta)\alpha, (1+\delta)\alpha)$ are pairwise disjoint over the various $\alpha \in \mathcal{A}_{\alpha_0,\delta}$, the following

result holds.

CLAIM 3.2 (choosing a random threshold). *For every $\alpha_0 > 0$ and $0 < \delta < 1/3$, and every distribution $\mathcal{D}$ on $\{0,1\}^m$,*

$$\mathrm{E}_{\alpha \sim \mathcal{A}_{\alpha_0,\delta}}\left[\Pr_{y\sim\mathcal{D}}[\mathcal{D}(y) \in ((1-\delta)\alpha 2^{-m}, (1+\delta)\alpha 2^{-m})]\right] \leq \delta.$$

3.1.1. The protocol. We formalize the notion of a "protocol that works for a random heaviness threshold α" by defining a family of problems $\{\Pi_{HEAVY,\alpha}\}$, parametrized by the threshold α, and requiring that the protocol be complete and sound for a random problem in this family.

Inputs. (C, p, ϵ), where $C : \{0,1\}^n \to \{0,1\}^m$ is a circuit, and $p \in [0,1]$ is a probability, and $\epsilon > 0$ is an error parameter represented in unary.

Shared auxiliary input. (α, δ), where α is a threshold parameter represented in unary and $0 < \delta < 1/3$ is an error parameter.

Yes instances. (C, p, ϵ) such that $h_{\mathcal{D}_C,\alpha} = p$.

No instances. (C, p, ϵ) such that $|h_{\mathcal{D}_C,\alpha} - p| > \epsilon$.

The heavy samples protocol. On input (C, p, ϵ) and shared auxiliary inputs α and δ:

1. Verifier: Set $k = \lceil 3 \cdot 16^3 \log(2/\delta)/\delta^3 \rceil$. Choose $r_1, \ldots, r_k \sim \{0,1\}^n$. Compute $y_j = C(r_j)$. Send $y_1, \ldots, y_k$ to the prover.
2. Prover: Send a partition (H, L) of $[k]$. An honest prover sets $H = \{i : \mathcal{D}_C(y_i) \geq \alpha 2^{-m}\}$ and $L = \{i : \mathcal{D}_C(y_i) < \alpha 2^{-m}\}$.
3. Verifier and prover: Run the parallel upper bound protocol (see section 2.4) with auxiliary input $(r_i : i \in L)$ with shared auxiliary input (error parameter) δ for the claim "$|C^{-1}(y_i)| < \alpha 2^{n-m}$ for all $i \in L$."

   Run the parallel lower bound protocol (see section 2.4) with shared auxiliary input (error parameter) δ for the claim "$|C^{-1}(y_i)| \geq \alpha 2^{n-m}$ for all $i \in H$." Accept iff $\left||H|/k - p\right| \leq \epsilon/2$.

3.1.2. Analysis of the protocol. The following lemma states the completeness and soundness of the heavy samples protocol.

LEMMA 3.3. *For every integer α_0 and fractions ϵ, δ, with probability $1 - O(\delta/\epsilon)$ over α chosen uniformly from $\mathcal{A}_{\alpha_0,\delta}$, the heavy samples protocol (with input (C, p, ϵ) and auxiliary input (α, δ) satisfying the promise) is a protocol for $\Pi_{HEAVY,\alpha}$ with completeness $1 - O(\delta)$ and soundness $O(\delta)$.*

Proof. We denote by H' and L' the set of α-heavy and α-light samples, respectively,

$$H' = \{i : \mathcal{D}_C(y_i) \geq \alpha 2^{-m}\} \text{ and } L' = \{i : \mathcal{D}_C(y_i) < \alpha 2^{-m}\}.$$

The honest prover always chooses $H = H'$ and $L = L'$.

By the sampling bound, for every prover strategy, with probability $1 - O(\delta)$ over the randomness of the verifier, the fraction of α-heavy samples among $y_1, \ldots, y_k$ should closely approximate $h_{\mathcal{D}_C,\alpha}$, and in particular,

$$\left||H'|/k - h_{\mathcal{D}_C,\alpha}\right| \leq \epsilon/6. \tag{2}$$

Completeness. Completeness (for arbitrary α) follows from high probability estimate (2), together with completeness of the parallel lower bound protocol for $\Pi_{LB,\delta}^{|L|,1}$ (see Corollary 2.7) and completeness of the parallel upper bound protocol for $\Pi_{UB,\delta}^{|H|,\cdot}$ (see Corollary 2.9).

Soundness. Fix an $\alpha \sim \mathcal{A}_{\alpha_0,\delta}$ such that

$$\Pr_{y\sim\mathcal{D}_C}\big[\mathcal{D}_C(y) \in ((1-\delta)\alpha 2^{-m}, (1+\delta)\alpha 2^{-m})\big] \le \epsilon/16.$$

By Claim 3.2 and Markov's inequality, this holds with probability $1 - O(\delta/\epsilon)$ for a random α in $\mathcal{A}_{\alpha_0,\delta}$. For such a choice of α, let B denote the set of samples that are both $(1-\delta)\alpha$-heavy and $(1+\delta)\alpha$-light, that is,

$$B = \{i : \mathcal{D}_C(y_i) \in ((1-\delta)\alpha 2^{-m}, (1+\delta)\alpha 2^{-m})\}.$$

By the sampling bound, the number of samples in B is not much larger than $\epsilon/16$ with high probability over the randomness of the verifier. Indeed,

$$\Pr\big[|B| > \epsilon k/8\big] = \Pr\big[|B|/k - \epsilon/16 > \epsilon/16\big] \le \delta.$$

Now fix a prover strategy for which the verifier accepts instance (C, p, ϵ) with probability $\omega(\delta)$. Then there exists a setting of the verifier's randomness for which $\big||H|/k - p\big| \le \epsilon/2$ (by the last step of the verifier), $\big||H'|/k - h_{\mathcal{D}_C,\alpha}\big| \le \epsilon/6$ (by high probability estimate (2)), and the following conditions hold:

(i) For $t = \lceil \log(1/\delta)/\delta \rceil$ all but $t + \epsilon k/8$ samples in L are α-light, that is, $|L - L'| \le t + \epsilon k/8$. Indeed, this is an event of probability $1 - O(\delta)$ over the randomness of the verifier: By soundness of the parallel upper bound protocol for $\Pi_{UB,\delta}^{|L|,t}$, fewer than t of the samples in L are $(1+\delta)\alpha$-heavy. Moreover, the number of samples in L that are α-heavy but $(1+\delta)\alpha$-light is upper bounded by the size of B. It follows that with probability $1 - O(\delta)$, $|L - L'| \le t + \epsilon k/8$.

(ii) All but $\epsilon k/8$ samples in H are α-heavy, that is, $|H - H'| \le \epsilon k/8$. This is also an event of probability $1 - O(\delta)$ over the randomness of the verifier: By soundness of the parallel lower bound protocol for $\Pi_{LB,\delta}^{|H|,1}$, none of the samples in H are $(1-\delta)\alpha$-light. Moreover, the number of samples in H that are α-light but $(1-\delta)\alpha$-heavy is upper bounded by the size of B. It follows that with probability $1 - O(\delta)$, $|H - H'| \le \epsilon k/8$.

It follows that

$$\big||H| - |H'|\big| \le |H - H'| + |H' - H| = |H - H'| + |L - L'| \le t + \epsilon k/4 < \epsilon k/3.$$

Therefore,

$$|h_{\mathcal{D}_C,\alpha} - p| \le \big|h_{\mathcal{D}_C,\alpha} - |H'|/k\big| + \big||H'|/k - |H|/k\big| + \big||H|/k - p\big| < \epsilon/6 + \epsilon/3 + \epsilon/2 = \epsilon.$$

Thus, (C, p, ϵ) is a "yes" instance of $\Pi_{HEAVY,\alpha}$. □

3.2. The hiding protocol. In this section we describe the protocol for estimating the probability that a random sample generated by a circuit $C : \{0,1\}^n \to \{0,1\}^m$ is both a light sample and a "yes" instance of some NP language V. Let us denote by $\mathcal{D}_C$ the distribution of outputs of the circuit C and by $\mathcal{U}$ the uniform distribution on $\{0,1\}^m$. We assume that we are given as advice the probability p_Y that a random sample in $\{0,1\}^m$ is a "yes" instance of V.

For starters, let us assume that we are guaranteed that the distribution $\mathcal{D}_C$ is α-smooth (for some reasonably small α); that is, no output of C is α-heavy. Let

us consider the following experiment. We choose among distributions $\mathcal{D}_C$ and $\mathcal{U}$ by flipping a coin biased towards $\mathcal{D}_C$ with probability b (the value of interest is around $b = 1/\alpha$) and then generate a sample y according to either $\mathcal{D}_C$ or $\mathcal{U}$, depending on the outcome of the coin. We then give the sample y to the prover and ask which distribution it came from.

The best strategy for the prover to guess the origin of the sample is a maximum likelihood test: Compute the ratio $\mathcal{D}_C(y)/\mathcal{U}(y)$, and declare "$\mathcal{D}_C$" if the ratio exceeds $1/b$, and "$\mathcal{U}$" otherwise. However, when $b < 1/\alpha$, the maximum likelihood test will always guess that the sample came from $\mathcal{U}$. This effectively gives the verifier the ability to hide samples from $\mathcal{D}_C$ among samples from $\mathcal{U}$.

Suppose now that the verifier wants to determine membership in $V \cap \{0,1\}^m$ for a random sample from $\mathcal{D}_C$, but it has only the ability to determine membership for random samples from $\mathcal{U}$. The verifier can then use the prover as follows: Generate $\omega(\alpha)$ samples by choosing each one independently. The sample size is large enough so that at least one of the samples, call it z, will originate from $\mathcal{D}_C$. The prover is then asked to determine membership in V for all the samples. The verifier then checks if the prover determined membership in V correctly for all the samples coming from $\mathcal{U}$. If this is the case, then chances are that the prover also determined membership in V correctly for z, since this sample was hidden among all the other ones.

In our case, the verifier has no way of determining membership in V on samples from $\mathcal{U}$. Instead, it knows only that the fraction of samples from $\mathcal{U}$ that fall in V should be roughly p_Y. Recall that the verifier is interested in determining the fraction $g_{\mathcal{D}_C,V}$ of samples from $\mathcal{D}_C$ that fall in V. It is tempting to try the following protocol: The verifier and prover run the hiding procedure on a sufficiently large sample. The verifier then checks that the fraction of samples originating from $\mathcal{U}$ claimed to be in V by the prover is within a small enough deviation δ of p_Y. If this is the case, the verifier estimates $g_{\mathcal{D}_C,V}$ as the fraction of samples originating from $\mathcal{D}_C$ that are claimed to be in V by the prover.

It is not difficult to see that this protocol is not sound: A prover can "convince" the verifier, for instance, that $g_{\mathcal{D}_C,V} = p_Y$. To do so, for each sample the prover answers independently "yes" with probability p_Y and "no" with probability $1 - p_Y$ about the membership of this sample in V.

However, since V is an NP set, the verifier can impose an additional requirement: Every time the prover makes a "yes" claim for a sample, an NP certificate for membership in V of the sample must be provided. The prover's cheating power now becomes *one-sided* as it can no longer provide a "yes" answer for a sample that is not in V; the only way the prover can now cheat is by providing "no" answers for samples in V. However, if the prover supplies such false answers on more than an $O(\delta)$ fraction of the samples (where $\delta > 0$ is an error parameter), it is likely that most of these falsely answered samples originated from $\mathcal{U}$, because the samples originating from $\mathcal{U}$ comprise an overwhelming majority of all the samples. Therefore it is likely that the fraction of samples from $\mathcal{U}$ claimed "yes" by the prover is smaller than $p_Y - \delta$. On the other hand, statistically it is very unlikely that fewer than a $p_Y - \delta$ fraction of samples from $\mathcal{U}$ are in V. This prevents the prover from providing false answers on more than an $O(\delta)$ fraction of *all* the samples. Since the number of samples from $\mathcal{D}_C$ is roughly a b fraction of the total number of samples, the prover in particular cannot provide false answers on more than an $O(\delta/b)$ fraction of samples originating from $\mathcal{D}_C$. Therefore a cheating prover is unlikely to skew the verifier's estimate of $g_{\mathcal{D}_C,V}$ by more than $O(\delta/b)$. Setting $\delta = \epsilon b$ allows the verifier to obtain an additive ϵ approximation of $g_{\mathcal{D}_C,V}$ in time polynomial in $1/\epsilon$, α, and the sizes of C and V.

Handling the heavy samples. Notice that if we drop the smoothness restriction on $\mathcal{D}_C$, this argument fails because very heavy samples cannot be effectively hidden among uniform samples. However, our goal is to merely estimate the probability that a sample from $\mathcal{D}_C$ is both in V and light. To do so, we run the protocol as for smooth distributions, initially ignoring the heavy samples. The soundness of that protocol still shows that the prover must have answered most of the light samples from $\mathcal{D}_C$ correctly. What remains to be done is to weed out the heavy samples. By the protocol from section 3.1, the verifier can estimate the fraction p_H of heavy samples. (To avoid duplication, we assume the protocol here is given p_H as auxiliary input.) At this point, the verifier reveals its sample to the prover and asks the prover to give lower bound proofs for a $p_H - \epsilon$ fraction of samples from $\mathcal{D}_C$. The prover's cheating power here is also one-sided: By soundness of the parallel lower bound protocol, the prover cannot claim any of the light samples as heavy, so it can cheat only by claiming that some heavy samples are light. However, since the prover is required to provide lower bound proofs for a $p_H - \epsilon$ fraction of samples from $\mathcal{D}_C$, and the number of truly heavy samples from $\mathcal{D}_C$ is likely to be upper bounded by $p_H + \epsilon$, the prover cannot cheat on more than an $O(\epsilon)$ fraction of the samples from $\mathcal{D}_C$. Therefore a cheating prover cannot skew the verifier's estimate of $g_{\mathcal{D}_C,V}$ by more than an additive term of $O(\epsilon)$.

We encounter the same issue regarding the choice of α as in the protocol for heavy samples: If too many samples from $\mathcal{D}_C$ have probability about α, the lower bound protocol provides no soundness guarantee. As in section 3.1, we sidestep this problem by choosing a random α and arguing soundness with high probability over α.

3.2.1. The protocol. We give a protocol for the following family of promise problems, which we denote by $\{\Pi_{HIDE,\alpha}\}$.

Inputs. (C, V, p, ϵ), where $C : \{0,1\}^n \to \{0,1\}^m$ is a circuit, $V : \{0,1\}^m \times \{0,1\}^l \to \{0,1\}$ is a nondeterministic circuit,[6] $p \in [0,1]$ is a probability, and $\epsilon > 0$ is an error parameter represented in unary.

Shared auxiliary input. $(\alpha, \delta, p_Y, p_H)$, where $\alpha > 0$ is a threshold integer represented in unary, $0 < \delta < 1/3$ is an error parameter represented in unary, and p_Y, p_H satisfy

$$p_Y = \Pr_{y \sim \mathcal{U}}[y \in V] \quad \text{and} \quad |p_H - p'_H| < \epsilon/32, \tag{3}$$

where $p'_H = \Pr_{y \sim \mathcal{D}_C}[\mathcal{D}_C(y) \geq \alpha 2^{-m}]$.

Yes instances. (C, V, p, ϵ) such that $p = g_{\mathcal{D}_C,V,\alpha}$, where

$$g_{\mathcal{D}_C,V,\alpha} = \Pr_{y \sim \mathcal{D}_C}[\mathcal{D}_C(y) < \alpha 2^{-m} \text{ and } y \in V].$$

No instances. (C, V, p, ϵ) such that $|p - g_{\mathcal{D}_C,V,\alpha}| > \epsilon$.

---

[6] A *nondeterministic circuit* V computes a relation over $\{0,1\}^m \times \{0,1\}^l$, and we say $y \in \{0,1\}^m$ is accepted by V if there exists a $w \in \{0,1\}^l$ such that $V(y; w)$ accepts. Abusing notation, we also write V for the set of all y accepted by V.

The hiding protocol. On input (C, V, p, ϵ) and auxiliary input $(\alpha, \delta, p_Y, p_H)$:

1. Verifier: Set $b = \delta/\alpha$ and $k = \lceil 6 \cdot 32^3 \log(2/\delta)/(b\epsilon)^3 \rceil$. Choose a set $T_{\mathcal{D}_C} \subseteq [k]$ by assigning each element of $[k]$ to $T_{\mathcal{D}_C}$ independently with probability b. Let $T_{\mathcal{U}} = [k] - T_{\mathcal{D}_C}$.
   Choose strings $y_1, \ldots, y_k \in \{0,1\}^m$ as follows. If $j \in T_{\mathcal{D}_C}$, choose $y_j \sim \mathcal{D}_C$. If $j \in T_{\mathcal{U}}$, choose $y_j \sim \mathcal{U}$. Send the sequence $y_1, \ldots, y_k$ to the prover.
2. Prover: Send sets $Y, H \subseteq [k]$ and strings $(w_j : j \in Y)$ to the prover. An honest prover sends
   (a) Y as the set of all j such that $y_j \in V$,
   (b) H as the set of all j such that y_j is α-heavy for $\mathcal{D}_C$, and
   (c) w_j such that $V(y_j; w_j)$ accepts for all $j \in Y$.
3. Verifier: Reject under any of the following circumstances:
   (a) (Witness checks) $V(y_j; w_j)$ does not accept for some $j \in Y$.
   (b) (Frequency of "yes" samples in $\mathcal{U}$) $\big||Y \cap T_{\mathcal{U}}|/|T_{\mathcal{U}}| - p_Y\big| \geq \epsilon b/32$.
   (c) (Frequency of heavy samples in $\mathcal{D}_C$) $\big||H \cap T_{\mathcal{D}_C}|/|T_{\mathcal{D}_C}| - p_H\big| \geq \epsilon/16$.
   (With prover) Run the parallel lower bound protocol with shared auxiliary input (error parameter) δ for the claim

$$\text{"}|C^{-1}(y_j)| \geq \alpha 2^{n-m} \text{ for all } j \in H \cap T_{\mathcal{D}_C}\text{."}$$

   Accept iff

$$\big||Y \cap \overline{H} \cap T_{\mathcal{D}_C}|/|T_{\mathcal{D}_C}| - p\big| < \epsilon/4. \tag{4}$$

Remark. The parameter b needs to satisfy two constraints. It has to ensure that the α-light queries are hidden well (as a choice of probability for membership in T) and also has to guarantee that the fraction of "yes" samples in $T_{\mathcal{U}}$ is very close to p_U—not only within $O(\epsilon)$, but within $O(b\epsilon)$. This is necessary because $T_{\mathcal{D}_C}$ is smaller than $T_{\mathcal{U}}$ by a factor of b, so to obtain an $O(\epsilon)$ deviation bound for the fraction of light "yes" queries in $T_{\mathcal{D}_C}$, a stronger $O(b\epsilon)$ deviation bound must be assumed for the fraction of "yes" queries in $T_{\mathcal{U}}$.

3.2.2. Analysis of the protocol. The following lemma states the completeness and soundness of the hiding protocol.

LEMMA 3.4. *For every integer α_0 and fractions ϵ, δ, with probability $1 - O(\delta/\epsilon)$ over α chosen uniformly from $\mathcal{A}_{\alpha_0,\delta}$, the hiding protocol (with input (C, V, p, ϵ) and auxiliary input $(\alpha, \delta, p_Y, p_H)$ satisfying the promise) is a protocol for $\Pi_{HIDE,\alpha}$ with completeness $1 - O(\delta)$ and soundness $O(\delta)$.*

Proof. We denote by Y' and H' the set of actual "yes" samples and the set of actual heavy samples, respectively,

$$Y' = \{j : y_j \in V\} \text{ and } H' = \{j : \mathcal{D}_C(y_j) \geq \alpha 2^{-m}\}.$$

An honest prover always chooses $Y = Y'$ and $H = H'$.

The sampling bound implies that, for any fixed prover strategy, all of the following events hold with probability $1 - O(\delta)$ over the randomness of the verifier:

(i) The number of samples in $T_{\mathcal{D}_C}$ is large:

$$|T_{\mathcal{D}_C}| > bk/2 \geq 3 \cdot 32^3 \log(2/\delta)/\epsilon^3. \tag{5}$$

(ii) The number of samples in $T_{\mathcal{U}}$ is large:

$$|T_{\mathcal{U}}| > (1 - b - \epsilon)k. \tag{6}$$

(iii) About a p_Y fraction of samples in $T_{\mathcal{U}}$ are "yes" samples:

$$\big||Y' \cap T_{\mathcal{U}}|/|T_{\mathcal{U}}| - p_Y\big| < \epsilon b/32. \tag{7}$$

(iv) About a p_H fraction of samples in $T_{\mathcal{D}_C}$ are heavy samples:

$$\big||H' \cap T_{\mathcal{D}_C}|/|T_{\mathcal{D}_C}| - p'_H\big| < \epsilon/32. \tag{8}$$

(v) About a $g_{\mathcal{D}_C,V,\alpha}$ fraction of samples in $T_{\mathcal{D}_C}$ are light "yes" samples:

$$\big||Y' \cap \overline{H}' \cap T_{\mathcal{D}_C}|/|T_{\mathcal{D}_C}| - g_{\mathcal{D}_C,V,\alpha}\big| < \epsilon/4. \tag{9}$$

Completeness. Completeness (for arbitrary α) follows from high probability estimates (7), (8), and (9), promise (3), and completeness of the parallel lower bound protocol for $\Pi_{LB,\delta}^{|H\cap T_{\mathcal{D}_C}|,1}$.

Soundness. Fix an $\alpha \sim \mathcal{A}_{\alpha_0,\delta}$ such that

$$\Pr_{y\sim\mathcal{D}_C}\big[\mathcal{D}_C(y) \in ((1-\delta)\alpha 2^{-m}, (1+\delta)\alpha 2^{-m})\big] \le \epsilon/32.$$

By Claim 3.2 and Markov's inequality, this holds with probability $1 - O(\delta/\epsilon)$ for a random α in $\mathcal{A}_{\alpha_0,\delta}$. For such a choice of α, with probability $1 - O(\delta)$ over the randomness of the verifier, the number of samples in $T_{\mathcal{D}_C}$ that are both $(1-\delta)\alpha$-heavy and α-light is at most $\epsilon|T_{\mathcal{D}_C}|/16$. (This follows from the sampling bound and high probability estimate (5).)

Now fix a prover strategy for which the verifier accepts instance (C, V, p, ϵ) with probability $\omega(\delta)$. The analysis will be split into the following two parts:

(i) Show that the fraction of samples in $T_{\mathcal{D}_C}$ that were claimed both "yes" and "light" by the prover is within $O(\epsilon)$ of the fraction of truly light samples that were claimed "yes" by the prover. More generally, we show that for any set of samples $I \subseteq T_{\mathcal{D}_C}$, the fraction of samples in I that are claimed heavy by the prover is within $O(\epsilon)$ of the fraction of truly heavy samples in I. This will be shown in Claim 3.5.

(ii) Show that if the fraction of false "no" claims for samples in $T_{\mathcal{U}}$ is small, then the fraction of false "no" claims for light samples in $T_{\mathcal{D}_C}$ is small. This will be shown in Claim 3.6, which formalizes the hiding property of the protocol and contains the main idea of the soundness analysis.

Observe that step 3(a) of the hiding protocol ensures $Y \subseteq Y'$ whenever the verifier accepts. Let $Y^- = Y' - Y$.

CLAIM 3.5 (heavy samples). *With probability* $1 - O(\delta)$ *over the randomness of the verifier, if the verifier accepts, then for every set* $I \subseteq T_{\mathcal{D}_C}$, $\big||I \cap \overline{H}| - |I \cap \overline{H}'|\big| \le \epsilon|T_{\mathcal{D}_C}|/4$.

CLAIM 3.6 (hiding property). *With probability* $1 - O(\delta)$ *over the randomness of the verifier,* $|Y^- \cap T_{\mathcal{U}}| > \frac{1}{2}|Y^- \cap \overline{H}'|$.

We give the proofs of both these claims at the end of the section. Let us see first how these claims imply soundness. By a union bound, there exists an accepting transcript for the verifier, where high probability estimates (5), (7), and (9) hold, and the properties in Claims 3.5 and 3.6 hold. Fix such an accepting transcript.

By the accepting condition (4) and high probability estimate (9),

$$\begin{aligned}
|p - g_{\mathcal{D}_C,V,\alpha}| &< \frac{\epsilon}{4} + \frac{\epsilon}{4} + \left| \frac{|Y \cap \overline{H} \cap T_{\mathcal{D}_C}|}{|T_{\mathcal{D}_C}|} - \frac{|Y' \cap \overline{H}' \cap T_{\mathcal{D}_C}|}{|T_{\mathcal{D}_C}|} \right| \qquad \text{(by (4) and (9))} \\
&= \frac{\epsilon}{4} + \frac{\epsilon}{4} + \left| \frac{|Y \cap \overline{H} \cap T_{\mathcal{D}_C}|}{|T_{\mathcal{D}_C}|} - \left(\frac{|Y \cap \overline{H}' \cap T_{\mathcal{D}_C}|}{|T_{\mathcal{D}_C}|} + \frac{|Y^- \cap \overline{H}' \cap T_{\mathcal{D}_C}|}{|T_{\mathcal{D}_C}|} \right) \right| \\
&\leq \frac{\epsilon}{4} + \frac{\epsilon}{4} + \left| \frac{|Y \cap \overline{H} \cap T_{\mathcal{D}_C}|}{|T_{\mathcal{D}_C}|} - \frac{|Y \cap \overline{H}' \cap T_{\mathcal{D}_C}|}{|T_{\mathcal{D}_C}|} \right| + \frac{|Y^- \cap \overline{H}' \cap T_{\mathcal{D}_C}|}{|T_{\mathcal{D}_C}|} \\
&\leq \frac{\epsilon}{4} + \frac{\epsilon}{4} + \frac{\epsilon}{4} + \frac{|Y^- \cap \overline{H}' \cap T_{\mathcal{D}_C}|}{|T_{\mathcal{D}_C}|} \qquad \text{(by Claim 3.5).}
\end{aligned}$$

We now apply the hiding property to bound the last term. First,

$$\frac{|Y^- \cap T_{\mathcal{U}}|}{|T_{\mathcal{U}}|} = \frac{|Y' \cap T_{\mathcal{U}}|}{|T_{\mathcal{U}}|} - \frac{|Y \cap T_{\mathcal{U}}|}{|T_{\mathcal{U}}|} = \left(\frac{|Y' \cap T_{\mathcal{U}}|}{|T_{\mathcal{U}}|} - p_Y \right) + \left(p_Y - \frac{|Y \cap T_{\mathcal{U}}|}{|T_{\mathcal{U}}|} \right) < \frac{\epsilon b}{16}$$

by high probability estimate (7) and step 3(b) of the verifier. Now, using the hiding property and high probability estimate (5),

$$\frac{|Y^- \cap \overline{H}' \cap T_{\mathcal{D}_C}|}{|T_{\mathcal{D}_C}|} \leq \frac{|Y^- \cap \overline{H}'|}{|T_{\mathcal{D}_C}|} < 2 \cdot \frac{|Y^- \cap T_{\mathcal{U}}|}{|T_{\mathcal{D}_C}|} < 2 \cdot \frac{\epsilon bk/16}{bk/2} = \frac{\epsilon}{4}.$$

It follows that $|p - g_{\mathcal{D}_C,V,\alpha}| < \epsilon$, so (C, V, p, ϵ) is a yes instance of $\Pi_{HIDE,\alpha}$. □

Proof of Claim 3.5. For ease of notation, let $G = H \cap T_{\mathcal{D}_C}$ and $G' = H' \cap T_{\mathcal{D}_C}$. Denote by $\overline{G}$ and $\overline{G}'$ the complements of G and G' in $T_{\mathcal{D}_C}$, respectively.

Fix a transcript of the verifier for which high probability estimate (8) holds, none of the samples in $T_{\mathcal{D}_C} \cap H$ are $(1-\delta)\alpha$-light, and the number of samples whose weight is between $(1-\delta)\alpha$ and α in G is at most $\epsilon|T_{\mathcal{D}_C}|/16$. By soundness of the parallel lower bound protocol for $\Pi^{|G|,1}_{LB,\delta}$, Claim 3.2, and the sampling bound, all these events hold with probability $1 - O(\delta)$.

Suppose the verifier accepts. Since none of the samples in G are $(1-\delta)\alpha$-light and the number of samples whose weight is between $(1-\delta)\alpha$ and α in G is at most $\epsilon|T_{\mathcal{D}_C}|/16$, it follows that

$$|G - G'|/|T_{\mathcal{D}_C}| < \epsilon/16.$$

On the other hand, step 3(c) of the verifier, promise (3), and high probability estimate (8) give

$$\big||G| - |G'|\big|/|T_{\mathcal{D}_C}| \leq \big||G|/|T_{\mathcal{D}_C}| - p_H\big| + |p_H - p'_H| + \big|p'_H - |G'|/|T_{\mathcal{D}_C}|\big| < \epsilon/8.$$

The last two equations imply that the sets G and G' cannot differ on all but a few elements. Therefore, $\overline{G}$ and $\overline{G}'$ must also be very close, and so must be $I \cap \overline{G}$ and $I \cap \overline{G}'$.

The rest are calculations formalizing these claims. First, $|G' - G|$ must also be small because

$$\big||G'| - |G|\big| = \big||G' - G| - |G - G'|\big| \geq |G' - G| - |G - G'|$$

so that $|G' - G|/|T_{\mathcal{D}_C}| < 3\epsilon/16$. It follows that

$$\begin{aligned}\big||I \cap \overline{G}| - |I \cap \overline{G}'|\big| &\le \big||I \cap \overline{G}| - |I \cap \overline{G} \cap \overline{G}'|\big| + |I \cap (\overline{G}' - \overline{G})| \\ &= |I \cap (\overline{G} - \overline{G}')| + |I \cap (\overline{G}' - \overline{G})| \\ &\le |\overline{G} - \overline{G}'| + |\overline{G}' - \overline{G}| \\ &\le \epsilon |T_{\mathcal{D}_C}|/4. \qquad \square\end{aligned}$$

Proof of Claim 3.6. We will, in fact, reach the stronger conclusion

$$|Y^- \cap \overline{H}' \cap T_{\mathcal{U}}| > \frac{1}{2}|Y^- \cap \overline{H}'|.$$

For every sample $j \in Y^- \cap \overline{H}'$, that is, every light sample for which the prover made a false "no" claim, consider the event "$j \in T_{\mathcal{D}_C}$" from the point of view of the prover. For a fixed prover strategy, the first message of the verifier completely determines the set $Y^- \cap \overline{H}'$. First, we show that for any first message $\mathbf{y} = (y_1, \ldots, y_k)$ of the verifier, the probability of each event "$j \in T_{\mathcal{D}_C}$" for $j \in Y^- \cap \overline{H}'$ (over the randomness of the verifier's first message) is less than any constant:

$$\begin{aligned}\Pr[j \in T_{\mathcal{D}_C} \mid \mathbf{y}] &= \Pr[j \in T_{\mathcal{D}_C} | y_j] \qquad \text{(by independence of samples)} \\ &= \frac{\Pr[y_j \mid j \in T_{\mathcal{D}_C}] \Pr[j \in T_{\mathcal{D}_C}]}{\Pr[y_j]} \\ &\le \frac{\Pr[y_j \mid j \in T_{\mathcal{D}_C}] \Pr[j \in T_{\mathcal{D}_C}]}{\Pr[y_j \mid j \in T_{\mathcal{U}}] \Pr[j \in T_{\mathcal{U}}]} \\ &\le \frac{(\alpha 2^{-m}) \cdot b}{2^{-m} \cdot (1-b)} \qquad \text{(by lightness)} \\ &\le 2\delta \qquad \text{(by choice of } b\text{)}.\end{aligned}$$

For fixed $\mathbf{y}$, the quantity $|Y^- \cap \overline{H}' \cap T_{\mathcal{D}_C}|$ is a sum of indicator random variables for the events "$j \in T_{\mathcal{D}_C}$" (one for each $j \in Y^- \cap \overline{H}'$), so it follows that

$$\mathrm{E}\big[|Y^- \cap \overline{H}' \cap T_{\mathcal{D}_C}| \mid \mathbf{y}\big] = \textstyle\sum_{j \in Y^- \cap \overline{H}'} \Pr[j \in T_{\mathcal{D}_C} \mid \mathbf{y}] \le 2\delta \cdot |Y^- \cap \overline{H}'|.$$

by Markov's inequality, we have that

$$\Pr\left[|Y^- \cap \overline{H}' \cap T_{\mathcal{D}_C}| > \frac{1}{2}|Y^- \cap \overline{H}'| \mid \mathbf{y}\right] < 4\delta.$$

Therefore

$$\Pr\left[|Y^- \cap \overline{H}' \cap T_{\mathcal{U}}| \le \frac{1}{2}|Y^- \cap \overline{H}'| \mid \mathbf{y}\right] < 4\delta.$$

The claim follows by taking expectation over $\mathbf{y}$. $\square$

3.3. Simulating the reduction. In this section we describe the protocol that simulates a querier circuit Q (describing an instantiation of the worst-to-average reduction on a particular input) querying an average-case membership oracle for some NP set V. Let us assume that all the queries made by Q are identically distributed,

and denote by $\mathcal{D}_Q$ the distribution of a single query. The average-case membership oracle is for the set

$$S = \{y \in \{0,1\}^* : y \in V \text{ and } \mathcal{D}_Q(y) \leq \alpha 2^{-|y|}\}.$$

Recall that if Q describes an instantiation of a worst-to-average reduction from some language L to V, then distinguishing between the cases when Q accepts most of its inputs and when Q rejects most of its inputs allows us to determine membership in L.

We assume that the protocol is given as advice the probability p_H that a random query of Q is α-heavy, and the probability p_S that a random query of Q is in S. In reality, the protocol is only given approximations of these values, but for the sake of simplicity we ignore the distinction in this discussion. Suppose that Q on input $r \in \{0,1\}^n$ generates k queries $y_1, \ldots, y_k$ and a circuit $C : \{0,1\}^k \to \{0,1\}$. Moreover, Q satisfies the promise that $C(S(y_1), \ldots, S(y_k))$ either accepts or rejects with probability $1 - \eta$ for some $\eta > 0$.

Let us first consider the case when the distribution $\mathcal{D}_Q$ is α-smooth, that is, all queries are α-light. In this case, $S = V$ and $p_H = 0$, and the protocol of Feigenbaum and Fortnow can be used directly, as the advice p_S gives the probability that a random query generated by Q is a "yes" query, which is the advice needed for the Feigenbaum–Fortnow protocol. Let us recall how this protocol works. The verifier generates $l = \lceil 24 \cdot (k/\eta)^3 \log(2k/\delta) \rceil$ (where $\delta > 0$ is an error parameter) random strings $r_1, \ldots, r_l$, sends these strings to the prover, and asks the prover to simulate the computation of $Q(r_i)$ with oracle S for every i. To certify that most of the simulations are correct, the prover provides, with every "yes" query made in the simulations, an NP witness (for V) for this query. With high probability, for all query indices $j \in [k]$, among the jth queries made by Q, $(p_S \pm \eta/k)l$ of these queries must be "yes" instances of V, so the verifier can ask to see at least $p_S lk - \eta l$ "yes" answers without affecting completeness. But no prover can now make more than ηl false "no" claims, so if the verifier outputs the outcome of a random simulation, it will be correct with probability $1 - \eta$.

For a general distribution $\mathcal{D}_Q$, the difficulty is that the prover can no longer certify membership in S as in the Feigenbaum–Fortnow protocol, as S is not an NP set.[7] Instead of certifying membership in S directly, the verifier will first approximately determine which of its queries are α-heavy. To do so, the verifier uses the fact that heaviness is a certifiable property, thus limiting the cheating power of the prover: Statistically, the fraction of heavy queries is within $p_H \pm \eta/k$ with high probability, and the verifier asks the prover to give proofs of heaviness (using the lower bound protocol) for at least $p_H kl - \eta l$ of its queries. Since the prover's cheating power is one-sided (the prover is likely to be caught cheating if it claims that a light query is heavy), it can fool the verifier about heaviness on at most $2\eta l$ queries.

Once the verifier knows approximately which queries are α-heavy, it can ask the prover to reveal which queries are in V among the ones that are α-light: For each query that the verifier thinks is α-light, the prover is asked to determine membership in V and provide a certificate in case of a "yes" answer. Statistically, the fraction of queries that are light and in V is within $p_S \pm \eta/k$ with high probability, and the verifier asks to see "yes" certificates for at least $p_S kl - \eta l$ queries that it thinks are

[7] In fact, if S were defined as the set of y such that $y \in V$ *or* y is α-heavy, then it would have been an AM set (almost, save the fact that heaviness is an approximate AM property). This provides an alternate way of proving the main theorem: Modify the hiding protocol to calculate the fraction of samples that are either "yes" or heavy, then simulate the reduction using the Feigenbaum–Fortnow protocol.

α-light. If the set of queries that the verifier thinks are α-light coincided exactly with the set of truly α-light queries, the prover would not be able to provide more than $2\eta l$ false answers about membership in V among the α-light queries. In general these two sets will not coincide exactly. However, the number of elements on which they differ is at most $2\eta l$, so that the total number of truly α-light queries on which the prover can cheat about membership in V is still $O(\eta l)$.

It follows that for a random $i \in [l]$, the verifier can correctly simulate membership in S with probability $1 - O(\delta + \eta)$.

Regarding the choice of α, we encounter the same issue as in sections 3.1 and 3.2: If too many queries have probability about α, the lower bound protocol provides no soundness guarantee. Again, we sidestep this issue by arguing completeness and soundness for a random α.

3.3.1. The protocol. We give a protocol for the following family of promise problems, which we denote by $\{\Pi_{SIM,\alpha}\}$.

Inputs. (Q, V, η), where V is a nondeterministic polynomial-time machine, $Q : \{0,1\}^n \to \{0,1\}^{\mathrm{poly}(n)}$ is a querier circuit producing k queries for the set

$$S = S_{\mathcal{D}_Q,V,\alpha} = \{y \in \{0,1\}^* : V \text{ accepts } y \text{ and } \mathcal{D}_Q(y) < \alpha 2^{-|y|}\},$$

and $\eta > 0$ is an error parameter.

Shared auxiliary input. $(\alpha, \delta, p_H, p_S)$, where α is a threshold parameter represented in unary, $0 < \delta < 1/3$ is an error parameter represented in unary, and p_S, p_H satisfy

$$|p_H - p'_H| < \eta/2k \quad \text{and} \quad |p_S - p'_S| < \eta/2k, \tag{10}$$

where $p'_H = \Pr_{y\sim\mathcal{D}_Q}[\mathcal{D}_Q(y) \geq \alpha 2^{-|y|}]$ and $p'_S = \Pr_{y\sim\mathcal{D}_Q}[y \in S]$.

Yes instances. (Q, V, η) such that $\Pr_r[Q^S(r) \text{ accepts}] > 1 - \eta/2$.

No instances. (Q, V, η) such that $\Pr_r[Q^S(r) \text{ accepts}] < \eta/2$.

The simulation protocol. On input (Q, V), and auxiliary input $(\alpha, \delta, p_H, p_S)$:

1. Verifier: Set $l = \lceil 24 \cdot (k/\eta)^3 \log(2k/\delta) \rceil$. Choose l random strings $r_1, \ldots, r_l \in \{0,1\}^n$ and send them to the prover. Denote the jth query of $Q(r_i)$ by y_{ij}.
2. Prover: Send sets $Y, H \subseteq [l] \times [k]$ and strings $(w_{ij} : (i,j) \in Y)$ to the prover. An honest prover sends:
   (a) Y as the set of all (i,j) such that $y_{ij} \in V$,
   (b) H as the set of all (i,j) such that y_{ij} is α-heavy for $\mathcal{D}_Q$, and
   (c) w_{ij} such that $V(y_{ij}; w_{ij})$ accepts for all $(i,j) \in Y$.
3. Verifier: Reject under any of the following circumstances:
   (a) (Witness checks) $V(y_{ij}; w_{ij})$ does not accept for some $(i,j) \in Y$.
   (b) (Frequency of heavy samples) $\left||H|/kl - p_H\right| > \eta/k$.
   (c) (Frequency of light "yes" samples) $\left||Y \cap \overline{H}|/kl - p_S\right| > \eta/k$.

   (With prover) Run the parallel lower bound protocol with shared auxiliary input (error parameter) δ for the claim

   $$|\{r : \text{The first query of } Q(r) \text{ is } y_{ij}\}| > \alpha 2^{n-|y_{ij}|} \text{ for all } (i,j) \in H.$$

   Choose a random $i \in [l]$. Accept if the decider of $Q(r_i)$ accepts the input $(a_1, \ldots, a_k)$, where $a_j =$ "yes" if $(i,j) \in Y \cap \overline{H}$, and $a_j =$ "no" otherwise.

3.3.2. Analysis of the protocol. The following lemma states the completeness and soundness of the simulation protocol.

LEMMA 3.7. *For every integer α_0, querier circuit Q that produces k queries, and fractions η, δ, with probability $1 - O(\delta k/\eta)$ over α chosen uniformly from $\mathcal{A}_{\alpha_0,\delta}$, the simulation protocol (with input (Q, V, η) and auxiliary input $(\alpha, \delta, p_H, p_S)$ satisfying the promise) is a protocol for $\Pi_{SIM,\alpha}$ with completeness $1 - O(\delta + \eta)$ and soundness $O(\delta + \eta)$.*

Proof. We denote by H' and Y' the set of actual heavy samples, and the set of actual "yes" samples, respectively,

$$H' = \{(i,j) : \mathcal{D}_Q(y_{ij}) \geq \alpha 2^{-|y_{ij}|}\} \text{ and } Y' = \{(i,j) : y_{ij} \in V\}.$$

The honest prover always chooses $H = H'$ and $Y = Y'$.

First, we observe the following high probability estimates over the randomness of the verifier (for any prover strategy), which follow directly from the sampling bound:

$$(Q,V,\eta) \text{ is a yes instance} \implies \Pr\big[|\{i : Q^S(r_i) \text{ accepts}\}| > (1-\eta)l\big] = 1 - O(\delta). \tag{11}$$

$$(Q,V,\eta) \text{ is a no instance} \implies \Pr\big[|\{i : Q^S(r_i) \text{ accepts}\}| < \eta l\big] = 1 - O(\delta). \tag{12}$$

Let T denote an arbitrary fixed (that is, independent of both the verifier's randomness and the prover's strategy) subset of $\{0,1\}^*$. The key observation of Feigenbaum and Fortnow is that for any T, with probability $1 - O(\delta)$ over the randomness of the verifier, the fraction of queries y_{ij} that fall inside T is $|T|/kl \pm \eta/k$, even though there are dependencies among the queries. To see this, divide the queries into k sets, where the jth set consists of queries $q_{1j}, \ldots, q_{lj}$. Within each set, the queries are independent, so by the choice of $l = \lceil 24 \cdot (k/\eta)^3 \log(2k/\delta) \rceil$ and by the sampling bound, the fraction of queries in the jth set that fall inside T is $|T|/kl \pm \eta/k$ with probability $1 - O(\delta/k)$. By a union bound over j, it follows that with probability $1 - O(\delta)$ the total fraction of queries y_{ij} that fall inside T is within η/k of $|T|/kl$.

Specifically, in the case when T is the set of α-heavy queries, we obtain that with probability $1 - O(\delta)$ over the randomness of the verifier, it holds that

$$\big||H'|/kl - p_H\big| < \eta/2k. \tag{13}$$

When T is the set of α-light queries that are in V, again with probability $1 - O(\delta)$ over the randomness of the verifier, it holds that

$$\big||Y' \cap \overline{H}'|/kl - p_S\big| < \eta/2k. \tag{14}$$

Completeness. Completeness (for arbitrary α) follows from high probability estimates (11), (13), (14), promise (10), and completeness of the parallel lower bound protocol for the promise $\Pi^{|H|,1}_{LB,\delta}$.

Soundness. Fix an $\alpha \sim \mathcal{A}_{\alpha_0,\delta}$ such that

$$\Pr_{y \sim \mathcal{D}_Q}\big[\mathcal{D}_Q(y) \in ((1-\delta)\alpha 2^{-|y|}, (1+\delta)\alpha 2^{-|y|})\big] \leq \eta/2k.$$

By Claim 3.2 and Markov's inequality, this holds with probability $1 - 2\delta k/\eta$ for a random α in $\mathcal{A}_{\alpha_0,\delta}$. For such a choice of α, it follows from the sampling bound that

with probability $1 - O(\delta)$ over the randomness of the verifier, the number of queries that are both $(1-\delta)\alpha$-heavy and α-light is at most ηl.

Fix a prover strategy for which the verifier accepts instance (Q, V, η) with probability $\omega(\delta) + 11\eta$. We will show that at least an 11η fraction of the transcripts are accepting, satisfy high probability estimate (12), and have the property that the prover is honest on all but at most $10\eta l$ answers provided in step 2 of the protocol: Namely, they satisfy the condition

$$|(Y \cap \overline{H}) \triangle (Y' \cap \overline{H}')| < 10\eta l. \tag{15}$$

Now consider all prefixes of transcripts consisting of the prover-verifier interaction before the verifier's choice of index i in step 3. There must exist at least one such prefix that satisfies estimate (12) and condition (15), and for which at least an 11η fraction of choices for i yield accepting transcripts. For this prefix, condition (15) implies that for at least an $1-10\eta$ fraction of indices i, the verifier correctly simulates the computation $Q^S(r_i)$ using the claims received from the prover in step 2. Therefore, for at least an η fraction of indices i, the transcript resulting from this choice of i is accepting. By condition (12), it follows that (Q, V, η) must be a "yes" instance.

We now show that at least an 11η fraction of transcripts are accepting, satisfy high probability estimate (12), and satisfy condition (15). For an accepting transcript, step 3(a) of the verifier guarantees that $Y \subseteq Y'$. Let $Y^- = Y' - Y$. If $\overline{H}$ were equal to $\overline{H}'$ with high probability, we would have $(Y \cap \overline{H}) \triangle (Y' \cap \overline{H}') = Y^- \cap \overline{H}'$, so the claim would follow from the verifier's step 3(c) and estimates (12) and (14). The only complication is that $\overline{H}$ and $\overline{H}'$ are not equal (and the difference between them can be two-sided), but the set difference is small: $|H \triangle H'| \le 4\eta l$ for a $1 - O(\delta)$ fraction of transcripts because with probability $1 - O(\delta)$, both of the following properties hold:

(i) By soundness of the parallel lower bound protocol for $\Pi_{LB,\delta}^{|H|,1}$, none of the samples in H are $(1-\delta)\alpha$-light. Also, the number of samples whose weight is between $(1-\delta)\alpha$ and α is at most ηl, so it follows that $|H - H'| \le \eta l$.

(ii) Step 3(b) of the verifier, promise (10), and high probability estimate (13) give

$$\big||H| - |H'|\big| \le \big||H| - p_H kl\big| + |p_H - p'_H|kl + \big|p'_H kl - |H'|\big| < 2\eta l.$$

Then $|H' - H| \le 3\eta l$ because

$$\big||H'| - |H|\big| = \big||H' - H| - |H - H'|\big| \ge |H' - H| - |H - H'|.$$

It follows that

$$|H \triangle H'| = |H - H'| + |H' - H| \le 4\eta l. \tag{16}$$

By a union bound, at least an 11η fraction of transcripts are accepting and satisfy high probability estimates (12), (14) and condition (16). For such transcripts, we have

$$\begin{aligned}
\big|(Y \cap \overline{H}) \triangle (Y' \cap \overline{H}')\big| &= \big|(Y \cap \overline{H}) \triangle ((Y \cap \overline{H}') \triangle (Y^- \cap \overline{H}'))\big| \\
&= \big|(Y \cap (\overline{H} \triangle \overline{H}')) \triangle (Y^- \cap \overline{H}')\big| \\
&\le \big|\overline{H} \triangle \overline{H}'\big| + |Y^- \cap \overline{H}'| \\
&\le 4\eta l + |Y^- \cap \overline{H}'|.
\end{aligned}$$

The last line follows from the fact that the symmetric difference stays the same if the sets are complemented. Therefore,

$$\begin{aligned}
|Y^- \cap \overline{H}'| &\le \big||Y^- \cap \overline{H}'| + (|Y \cap \overline{H}'| - |Y \cap \overline{H}|)\big| + \big||Y \cap \overline{H}'| - |Y \cap \overline{H}|\big| \\
&\le \big||Y' \cap \overline{H}'| - |Y \cap \overline{H}|\big| + \big|(Y \cap \overline{H}') \vartriangle (Y \cap \overline{H})\big| \\
&= \big||Y' \cap \overline{H}'| - |Y \cap \overline{H}|\big| + \big|Y \cap (\overline{H}' \vartriangle \overline{H})\big| \\
&\le \big(\big||Y' \cap \overline{H}'| - p'_S kl\big| + |p'_S - p_S|kl + \big|p_S kl - |Y \cap \overline{H}|\big|\big) + |H \vartriangle H'| \\
&< (\eta l/2 + \eta l/2 + \eta l) + 4\eta l \quad \text{(by (14), (10), verifier step 3(c), and (16))}
\end{aligned}$$

so that $|(Y \cap \overline{H}) \vartriangle (Y' \cap \overline{H}')| < 4\eta l + 6\eta l = 10\eta l$. ∎

4. Main theorem and proof. In this section we state and prove the main theorem.

THEOREM 4.1 (main theorem). *For any two languages L and L' such that $L' \in$ NP and every constant c, if there is an n^{-c} nonadaptive worst-to-average reduction from L to L', then $L \in \mathrm{NP/poly} \cap \mathrm{coNP/poly}$.*

In particular, if L were hard for NP, then coNP $\subseteq$ NP/poly, and therefore $\Sigma_3 = \Pi_3$.

Proof. Fix an arbitrarily small constant $\eta > 0$. We will assume that there exist polynomials $k(n)$ and $m(n)$ such that for every n and every input x of length n, the reduction makes exactly $k(n)/m(n)$ queries of every length between 1 and $m(n)$, so that the total number of queries made by the reduction is $k(n)$. We will also assume that the queries made by the reduction are identically distributed, and that (when provided access to an average-case oracle) the reduction either accepts or rejects with probability at least $1 - \eta/2$. In section 2.2 we explained why all these assumptions can be made without loss of generality.

Observe that if there is an n^{-c} worst-to-average reduction from L to L', then there is also a worst-to-average reduction from $\overline{L}$ to L', so it suffices to prove that $L \in$ NP/poly. We describe an AM protocol for L with advice (in which completeness and soundness hold only when the advice is correct) and private coins with completeness $1 - O(\eta)$ and soundness $O(\eta)$. By the remarks in section 2.3, the existence of such a protocol for L shows that $L \in$ NP/poly.

Let R_n denote the circuit computing the worst-to-average reduction from L to L' on inputs of length n. Let V be a nondeterministic machine for L'. Set $\alpha_0 = n^{-c}$.

Input. A string x of length n.

Advice. For every $1 \le i \le m(n)$, the probability $p_{Y,i} = \Pr_{y \sim \{0,1\}^i}[y \in L']$, and the circuit R_n.

Let Q be the circuit obtained by hardwiring the input x to R_n. Thus, Q takes as input a random string r and produces as output $k(n)$ queries and a decider circuit. For every $1 \le i \le m(n)$, let C_i denote the circuit that generates a random query of Q of length i: The circuit C_i simulates the circuit Q, then uses additional randomness to select uniformly one of the $m(n)$ outputs of Q of length i. Let $\mathcal{D}_{C_i}$ be the distribution of a sample of C_i, and $\mathcal{D}_Q$ be the distribution of the first query of Q. Finally, let V_i be the nondeterministic circuit describing the computation of $M_{L'}$ on an input of length i.

The protocol.

1. Verifier: Set the error parameters δ, ϵ_1 and ϵ_2 so that $\delta = \min(\epsilon_1/m(n), 1/3)$, $\epsilon_1 = \epsilon_2/32$, and $\epsilon_2 = \eta/2k(n)$. Choose a random α from the distribution $\mathcal{A}_{\alpha_0,\delta}$ (see (1)). Send α to the prover.
2. Prover: For every $1 \le i \le m(n)$, send two probabilities $h_{\mathcal{D}_{C_i},\alpha}$ and $g_{\mathcal{D}_{C_i},V,\alpha}$ to the verifier. An honest prover sends
$$h_{\mathcal{D}_{C_i},\alpha} = \Pr_{y\sim\mathcal{D}_{C_i}}[\mathcal{D}_{C_i}(y) \ge \alpha 2^{-i}] \text{ and}$$
$$g_{\mathcal{D}_{C_i},V,\alpha} = \Pr_{y\sim\mathcal{D}_{C_i}}[\mathcal{D}_{C_i}(y) < \alpha 2^{-i} \text{ and } y \in V].$$
3. Verifier and prover: For every $1 \le i \le m(n)$, run (in parallel) the heavy samples protocol (see section 3.1) on input $(C_i, h_{\mathcal{D}_{C_i},\alpha}, \epsilon_1)$ and shared auxiliary input (α, δ).
For every $1 \le i \le m(n)$, run (in parallel) the hiding protocol (see section 3.2) on input $(C_i, V_i, g_{\mathcal{D}_{C_i},V_i,\alpha}, \epsilon_2)$ and shared auxiliary input $(\alpha, \delta, p_{Y,i}, h_{\mathcal{D}_{C_i},\alpha})$.
4. Verifier: Let
$$p_H = \sum\nolimits_{i=1}^{m(n)} \frac{1}{m(n)} \cdot h_{\mathcal{D}_{C_i},\alpha} \text{ and } p_S = \sum\nolimits_{i=1}^{m(n)} \frac{1}{m(n)} \cdot g_{\mathcal{D}_{C_i},V,\alpha}.$$
5. Verifier and prover: Run the simulation protocol (see section 3.3) on input $(Q, M_{L'}, \eta)$ and shared auxiliary input $(\alpha, \delta, p_H, p_S)$.

Observe that when the prover is honest, the probability p_H is exactly the probability that a random query of Q is α-heavy regardless of its length. Conversely, if p_H deviates from the probability that a random query of Q is α-heavy by more than ϵ, it must be that at least one of the claims $h_{\mathcal{D}_{C_i},\alpha}$ deviates from the value $\Pr_{y\sim\mathcal{D}_{C_i}}[\mathcal{D}_{C_i}(y) \ge \alpha 2^{-i}]$. Similar considerations apply to the probability p_Y.

Analysis of the protocol. The protocol intends to simulate a run of the reduction R when given oracle access to the set L^*_α for some α, where

$$L^*_\alpha = \{y \in \{0,1\}^* : y \in L' \text{ and } \mathcal{D}_Q(y) < \alpha 2^{-|y|}\}.$$

Observe that for every $\alpha \in \mathcal{A}_{\alpha_0,\delta}$, the languages L' and L^*_α are $1/\alpha_0$-close: The distance between L' and L^*_α equals the measure of the set of α-heavy samples for $\mathcal{D}_Q$ under the uniform distribution. Since the number of α-heavy samples of $\mathcal{D}_Q$ of length i cannot exceed $\alpha^{-1} \cdot 2^{-i}$, the two sets are $1/\alpha \le 1/\alpha_0$-close under the uniform distribution.

Observe that our choice of parameters guarantees that for a random choice of $\alpha \sim \mathcal{A}_{\alpha_0,\delta}$, with probability $1 - O(\eta)$ over the choice of α, all runs of the heavy samples protocol, the hiding protocol, and the query simulation protocol satisfy the completeness and soundness conditions guaranteed by Lemmas 3.3, 3.4, and 3.7. For such a choice of α, completeness and soundness of the protocol follow by inspection. The completeness error is $O(\eta)$, which we obtain by adding the completeness errors of all the component protocols. The soundness error is also $O(\eta)$, which we obtain by observing that parallel composition does not increase the soundness error (see section 2.3) and by adding the soundness errors from steps 3 and 5 of the protocol. □

Remarks.

(i) If the worst-to-average reduction were uniform, the proof of Theorem 4.1 actually gives the stronger conclusion $L \in \mathrm{AM}^{\log}$. This requires small modification to the protocol: Instead of requiring that the protocol be given as advice the values $p_{Y,i}$ for all i between 1 and $m(n)$, we ask only that the advice consist of the average $p_Y = \sum_{i=1}^{m(n)} p_{Y,i}/m(n)$, which can be represented using $O(\log n)$ bits. As a preliminary step of the modified protocol, the prover sends claims for the actual values $p_{Y,i}$, and the verifier checks that p_Y is the average of these values. To check that these claims are correct (within an arbitrarily small additive term ϵ), for each i, the verifier generates $\omega(\log(m(n))/\epsilon^3)$ uniformly random samples of length i and asks the prover to provide certificates for membership in V for at least a $p_{Y,i} - \epsilon$ fraction of them. An honest prover can provide sufficiently many certificates with high probability, and the power of the cheating prover is one-sided: Such a prover cannot understate any $p_{Y,i}$ by more than 2ϵ, so to preserve the average p_Y it cannot overstate any $p_{Y,i}$ by more than $2\epsilon m(n)$. Choosing ϵ small enough provides the verifier with sufficiently good approximations of the values $p_{Y,i}$.

(ii) The condition $L' \in \mathrm{NP}$ can be weakened to $L' \in \mathrm{NP/poly}$, as the advice for the verifier of L' can be incorporated as advice to the protocol.

(iii) The conclusion of the theorem holds even under Levin's notion of hardness for efficient-on-average algorithms. This notion makes the additional requirement that L^* be an "errorless" approximation of L in the proof of Theorem 4.1; that is, L^* now takes values in $\{0, 1, \text{"fail"}\}$ and it is required that if $L^*(x) \neq L'(x)$, then $L^*(x) =$ "fail." Accommodating this change requires merely a slight modification of the simulation protocol: Instead of simulating answers to heavy queries by "no," the modified protocol simulates answers to heavy queries by "fail."

5. Search problems and samplable distributions. In this section, we generalize our results to reductions from worst-case hard languages to average-case search problems (instead of languages) whose average-case complexity is measured with respect to arbitrary samplable distributions (instead of the uniform distribution).

Observe that if a decision problem L in NP is hard on average with respect to some distribution $\mathcal{D}$, then the search version of L is also hard with respect to $\mathcal{D}$. However, the converse is not evident. Thus, even though Theorem 4.1 shows that nonadaptive worst-case to average-case reductions from an NP-hard problem to decision problems in NP are unlikely to exist, it is conceivable that reductions to search problems in NP are possible. In this section we rule out this possibility, showing that reductions to arbitrary search problems in distributional NP are no more powerful than reductions to decision problems in NP with respect to the uniform distribution.

The idea of the proof is to show that if there exists a worst-to-average reduction from some language L to a search problem in distributional NP, then this reduction can be composed with known reductions from the average-case complexity of Impagliazzo and Levin [29] and Ben-David et al. [7] to obtain a worst-to-average reduction from L to some language L' with respect to the uniform distribution, thus reducing this to the special case studied in Theorem 4.1. A crucial property for our purpose of the reductions in [7, 29], which is implicit in those works, is that both reductions are nonadaptive.

We begin by defining the type of reduction under consideration, as well as the types of reductions implicit in [7, 29] that will be used in the proof of the main theorem of this section.

5.1. Average-case reductions for search problems. The notion of a "worst-case to average-case reduction" can be generalized in several ways. Such generalizations are needed in order to extend our impossibility result for worst-case to average-case reductions to the case when the average-case problem is a distributional search problem. To obtain this result, we will need to compose worst-to-average reductions with *average-case reductions*.

We begin with the notion of a heuristic NP search algorithm that not only works well on average, but also provides witnesses for "yes" instances.

Let V be an NP relation. We denote by L_V the NP language corresponding to V; i.e., $L_V(x) = 1$ iff there exists a w such that $V(x; w) = 1$. A family of random functions $F_n : \{0,1\}^n \to \{0,1\}^m$ is a *δ-approximate witness oracle* for V with respect to the ensemble of distributions $\mathcal{D}$ if for all n,[8]

$$\Pr_{x\sim\mathcal{D},F}[V(x; F_{|x|}(x)) = L_V(x)] > 1 - \delta.$$

We will omit the subscript of F when it is implicitly determined by the input length. Note that the definition implies the existence of a set S of measure $\mathcal{D}(S) = 1 - 3\delta$ such that for all $x \in S$,

$$\Pr_F[V(x; F_{|x|}(x)) = L_V(x)] > 2/3.$$

Intuitively, S is the set of inputs for which the oracle has a good chance of producing a witness for the input, when such a witness exists. As usual, the constant $2/3$ is arbitrary, since if one has access to F, it can be queried k times independently in parallel to obtain a good witness with probability $1 - 1/3^k$.

Just as languages in NP represent decision problems, witness oracles represent search problems. For example, inverting a one-way function $f : \{0,1\}^n \to \{0,1\}^n$ on a $1-\delta$ fraction of inputs amounts to finding an algorithm $A : \{0,1\}^n \to \{0,1\}^n$ that is δ-approximate for the relation $V(y; x) \iff y = f(x)$ with respect to the distribution $f(\mathcal{U}_n)$.

Using witness oracles, we can formalize the notion of nonadaptive reductions between search problems, as well as reductions from search to decision problems. Let us focus on the case of a reduction between two search problems $(V, \mathcal{D})$ and $(V', \mathcal{D}')$. As in the case of languages, we want the property that the reduction transforms any heuristic algorithm for $(V', \mathcal{D}')$ into a heuristic algorithm for $(V, \mathcal{D})$. Moreover, if $x \in L_V$, we want the reduction, on most inputs $x \sim \mathcal{D}$, to recover a witness for x based on the answers provided by the witness oracle for V'.

DEFINITION 5.1 (reduction between search problems). *Let V, V' be* NP *relations and $\mathcal{D}, \mathcal{D}'$ be polynomial-time samplable distribution ensembles. A* δ-to-δ' search-to-search reduction *for search problems from $(V, \mathcal{D})$ to $(V', \mathcal{D}')$ is a family of polynomial size circuits $R = \{R_n\}$ such that on input $x \in \{0,1\}^n$, randomness r, $R_n(x; r)$ outputs strings $y_1, \ldots, y_k$ and a circuit C such that for any witness oracle F^* that is δ'-approximate for V' with respect to $\mathcal{D}'$, it holds that*

$$V(x, C(F^*(y_1), \ldots, F^*(y_k))) = L_V(x)$$

with probability $1 - \delta$ over the choice of $x \sim \mathcal{D}$, F^*, and the randomness used by the reduction.

[8] Technically, a witness oracle is an ensemble of distributions over function families $\{F_n\}$, but to simplify notation we will identify samples from this ensemble with the ensemble itself.

This definition subsumes the case of a worst-to-average reduction: A δ' worst-to-average reduction is simply a 0-to-δ' average-to-average reduction. The other type of reduction used in the analysis—the search-to-decision reduction—is formalized in a similar way as follows.

DEFINITION 5.2 (search-to-decision reduction). *Let V be an* NP *relation, L' be an* NP *language, and $\mathcal{D}, \mathcal{D}'$ be polynomial-time samplable distribution ensembles. A* δ-to-δ' search-to-decision reduction *for search problems from $(V, \mathcal{D})$ to $(L', \mathcal{D}')$ is a family of polynomial size circuits $R = \{R_n\}$ such that on input $x \in \{0,1\}^n$, randomness r, $R_n(x; r)$ outputs strings $y_1, \ldots, y_k$, and a circuit C such that for any L^* that is δ'-close to L' with respect to $\mathcal{D}'$, it holds that*

$$V(x, C(L^*(y_1), \ldots, L^*(y_k))) = L_V(x)$$

with probability $1 - \delta$ over the choice of $x \sim \mathcal{D}$ and the randomness used by the reduction.

5.2. Reductions to distributional search problems. We now state the main result of this section.

THEOREM 5.3. *Let L be a language, V' be an* NP *relation, $\mathcal{D}'$ be an arbitrary polynomial-time samplable ensemble of distributions, and c be a constant. If there is a nonadaptive n^{-c} worst-to-average reduction from L to $(V', \mathcal{D}')$, then $L \in$ NP/poly $\cap$* coNP/poly.

To understand the meaning of Theorem 5.3, consider a polynomial-time computable function f and a samplable ensemble of inputs $\mathcal{D} = \{\mathcal{D}_n\}$, and suppose that we want to prove that f is a one-way function with respect to the distribution $\mathcal{D}$. (That is, for a random $x \sim \mathcal{D}_n$, it is hard on average to find a preimage of $f(x)$.) We may set our aim low and try only to prove that f is just infinitely often a weak one-way function. This means that there is a polynomial p such that, for every polynomial-time inverter A, the computation $A(f(x))$ fails with probability at least $1/p(n)$ to output a preimage of $f(x)$, where the probability is over the coin tosses of A and the sampling of x from $\mathcal{D}_n$, and the statement is true for infinitely many n. We could try to provide evidence for the hardness of f by giving a reduction showing that an adversary that inverts A with probability better than $1 - 1/p(n)$ on all input lengths would imply a BPP algorithm for a presumably hard language L. Theorem 5.3 implies that if such a reduction is nonadaptive, then $L \in$ coNP/poly, and if L were NP-hard we would have a collapse of the polynomial hierarchy. Specifically, in order to apply Theorem 5.3 to our setting, consider the NP relation V' made of pairs $(f(x), x)$, and define the distribution $\mathcal{D}'$ as the ensemble $\{f(x)\}$ when x is sampled from $\mathcal{D}$. Then solving the search problem of V' on a random instance of $\mathcal{D}'$ is the same as inverting $f(x)$ on a random x taken from $\mathcal{D}$. A nonadaptive reduction of a decision problem L to such a problem implies that $L \in$ coNP/poly.

Theorem 5.3 is an immediate consequence of Theorem 4.1 and the following two lemmas.

LEMMA 5.4. *For every $\delta = \delta(n)$ and* NP *relation $V \subseteq \cup_n \{0,1\}^n \times \{0,1\}^{m(n)}$ there exists an* NP *language L' for which there is an $O(\delta(m(n))^2)$-to-δ average-to-average reduction from $(V, \mathcal{U})$ to $(L', \mathcal{U})$.*

LEMMA 5.5. *For every $\delta = \delta(n)$,* NP *relation V, and polynomial-time samplable ensemble of distributions $\mathcal{D}$ there exists a constant c and an* NP *relation V' for which there is an $O(\delta n^c)$-to-δ average-to-average reduction from $(V, \mathcal{D})$ to $(V', \mathcal{U})$.*

Analogues of Lemmas 5.4 and 5.5 are known in the context of the distributional hardness of NP-problems. A variant of Lemma 5.4 appears in Ben-David et al. [7],

while a variant of Lemma 5.5 was proved by Impagliazzo and Levin [29]. Our proofs are in essence a recasting of these arguments in the formalism of nonadaptive average-to-average reductions. These proofs are presented in sections A.3 and A.4, respectively.

Appendix A.

A.1. Additive bounds for sampling. We provide the proof of Lemma 3.1 below.

Proof of Lemma 3.1. Let $N = |S|$ and $p = \mathcal{D}(T)$. We use the following form of the Chernoff bound (see [36, section 4.1]):

$$\Pr[|T \cap S| < (1-\xi)Np] < \exp(-\xi^2 Np/2) \text{ for } \xi < 1$$

and

$$\Pr[|T \cap S| > (1+\xi)Np] < \begin{cases} (4/e)^{-(1+\xi)Np} \text{ for } \xi > 1, \\ \exp(-\xi^2 Np/3) \text{ for } \xi \le 1. \end{cases}$$

If $p < \epsilon$, the lower bound holds trivially, and for the upper bound we set $\xi = \epsilon/p > 1$ to obtain

$$\Pr[|T \cap S| > (p+\epsilon)N] < (4/e)^{-(p+\epsilon)N} < \eta.$$

If $p \ge \epsilon$, we set $\xi = \epsilon$ to obtain

$$\Pr[|T \cap S| \notin (1 \pm \epsilon)Np] < 2\exp(-\epsilon^2 Np/3) \le 2\exp(-\epsilon^3 N/3) < \eta. \qquad \square$$

A.2. Proof sketches for the lower and upper bound protocols. We provide proof sketches for Lemmas 2.6 and 2.8 below.

Proof sketch for Lemma 2.6. Let $S = C^{-1}(1)$. For $r \in S$, let I_r be an indicator for the event $h(r) = 0$, and let $R = h^{-1}(0)$, so that $|R| = \sum_{r \in S} I_r$. By the pairwise independence of h, we have $\mathrm{E}[|R|] = |S|k/s$, $\mathrm{Var}[|R|] \le |S|k/s$, so by Chebyshev's inequality,

$$\Pr\left[|R| \notin \left(1 \pm \frac{\epsilon}{3}\right)\frac{|S|k}{s}\right] \le \frac{9}{\epsilon^2} \cdot \frac{s}{|S|k}.$$

The bounds now follow by direct calculation. $\square$

Proof sketch for Lemma 2.8. Let $S = C^{-1}(1)$. Fix r and let $S' = S - \{r\}$, $k' = |S'|/|\Gamma|$, $R = h^{-1}(h(r))$, $R' = R - \{r\}$. For every $r' \in S'$, let $I_{r'}$ be an indicator for the event $r' \in R'$, so that $|R'| = \sum_{r' \in S'} I_{r'}$. By the 3-wise independence of h, the $I_{r'}$ are pairwise independent conditioned on $h(r)$, so that $\mathrm{E}[|R'|] = k'$, $\mathrm{Var}[|R'|] = k'(1 - 1/|\Gamma|) < k'$, and by Chebyshev's inequality, for every $\xi > 0$,

$$\Pr[|R'| \notin (1 \pm \xi)k'] < 1/\xi^2 k'.$$

Suppose $|S| \le s$. Without loss of generality we may assume $|S| = s$, since for larger values of s the acceptance probability may only increase. In this case $k' = k$, so that

$$\Pr[|R| > (1+\epsilon/3)k] = \Pr[|R'| \ge (1+\epsilon/3)k] < 9/\epsilon^2 k.$$

Given that $|R| \le (1+\epsilon/3)k$, the prover can list all elements of R, so that $R = \{r_1, \ldots, r_l\}$ and $l \le (1+\epsilon/3)k$. In particular, this ensures that $r \in R$ and the verifier accepts.

Now suppose $|S| \ge (1+\epsilon)s$, so that $k' > (1+\epsilon)k$. Then

$$\Pr\left[|R'| < \left(1+\frac{\epsilon}{2}\right)k\right] < \Pr\left[|R'| < \frac{1+\epsilon/2}{1+\epsilon}k'\right] < \Pr\left[|R'| < \left(1-\frac{\epsilon}{3}\right)k'\right] < \frac{9}{\epsilon^2 k}.$$

Given that $|R| > (1+\epsilon/2)k$, what is the best strategy for a prover to make the verifier accept? Conditioned on $(h, h(r))$, r is uniformly distributed in R, so the best the prover can do is set $l = (1+\epsilon/3)k$ and pick $\{r_1, \ldots, r_l\}$ to be an *arbitrary* subset of R. In this case,

$$\Pr[r \in \{r_1, \ldots, r_l\}] = \frac{l}{|R|} < \frac{(1+\epsilon/3)k}{(1+\epsilon/2)k} < 1 - \frac{\epsilon}{6}. \qquad \square$$

A.3. Reductions from decision to search problems. We provide the proof of Lemma 5.4 below.

Proof of Lemma 5.4. As in [7], we first reduce the search problem V to a search problem with a unique witness, then encode the bits of the witness in the language L'. The first step is based on the hashing argument of Valiant and Vazirani [41]. The reduction, as described below, succeeds only with probability 1/16, but this can be amplified to 2/3 by applying the reduction three times.

The inputs of the language L' are of the form (x, k, j, h), where x is an instance of L_V, k and j are integers between 0 and $m(|x|)$, and h is a pairwise independent hash function mapping $|x|$ bits to k bits (padded appropriately so the length of (x, k, j, h) is a fixed polynomial of $|x|$ only). Let w_i denote the ith bit of a string w. We define

> $(x, k, j, h) \in L'$ if there exists a w of length $m(|x|)$ for which $h(w) = 0$ and $w_i = 1$.

It is immediate that $L' \in$ NP.

The reduction works as follows: On input $x \in \{0,1\}^n$, choose a random h uniformly at random and generate the queries $q_{kj} = (x, k, j, h)$ for all $1 \le k \le m$ and $1 \le j \le m$. Let $a_{kj} \in \{0,1\}$ denote the claimed answer to query q_{kj} and w_k be the concatenation $a_{k1} \ldots a_{km}$. The decider looks for an index k such that w_k is a witness for x for all $1 \le j \le m$ and outputs w_k; if no such k is found, the decider returns an arbitrary answer.

Let L^* be an arbitrary decision oracle that is δ-close to L'. Say an input x is *good* in L^* if for all $1 \le k \le m$, $1 \le j \le m$,

$$\Pr_{h, L^*}[L^*(x, k, j, h) = L(x, k, j, h)] > 15/16.$$

By a pigeonhole argument, $x \sim \mathcal{U}_n$ is good with probability at least $1 - O(\delta(m(n))^2)$. We show that the reduction succeeds on a good input with probability 1/16. By the Valiant–Vazirani argument, for $k = \lfloor \log_2 |\{w : V \text{ accepts } (x; w)\}| \rfloor$, with probability 1/8 there exists a unique w such that $h(w) = 0$. It follows that whenever x is good and $x \in L_V$, with probability at least 1/16, $L^*(x, k, j, h) = w_k$ for all $1 \le j \le m$, so the decider encounters the witness w_k. $\square$

Remark. The argument can be strengthened to obtain an $O(\delta m(n))$-to-δ average-to-average reduction from (V, U) to (L', U) by applying a Hadamard code to the witness w in L' instead of revealing its bits.

A.4. Reductions for arbitrary samplable distributions. We provide the proof of Lemma 5.5 below.

Proof of Lemma 5.5. Let S denote the sampler that yields the distribution ensemble $\mathcal{D}$: S is a polynomial-time computable function $\{0,1\}^n \times \{0,1\}^{s(n)} \to \{0,1\}^n$, such that $S(1^n, \mathcal{U}_{s(n)}) = \mathcal{D}_n$.

We want to be able to map instances of V into instances of V' in such a way that witnesses for V can be recovered from witnesses for V', and so that for most x, the probability of an image of x in the uniform distribution is polynomially related to the probability of x in distribution $\mathcal{D}$.

Let V' be an NP relation for language L', which we define next. The inputs of L are of the form (n, k, h_1, z, h_2), where

(i) the integer n will denote the length of the input to the reduction coming from $\mathcal{D}$;

(ii) the integer $k \in [s]$ $(s = s(n))$ will encode the approximate likelihood of the input to the reduction according to $\mathcal{D}$;

(iii) $h_1 : \{0,1\}^n \to \{0,1\}^{k+6}$ is a pairwise independent hash function, and $z \in \{0,1\}^{k+6}$ is an element in the range of h_1;

(iv) $h_2 : \{0,1\}^s \to \{0,1\}^{s-k-3}$ is another pairwise independent hash function.

Suppose that the inputs (n, k, h_1, z, h_2) are padded appropriately so that their length depends on n only.

A pair (w, r) is an NP-witness for input (n, k, h_1, z, h_2) in V' if the following three conditions are satisfied: (1) $V(S(1^n, r); w) = 1$; (2) $h_1(S(1^n, r)) = z$; (3) $h_2(r) = 0$.

On input x, where $|x| = n$, the reduction produces queries $(n, k, h_1, h_1(x), h_2)$ for all possible values of k by choosing h_1 and h_2 uniformly at random. The decider looks at all answers (w_k, r_k) and returns w_k if $V(S(1^n, r_k); w_k) = 1$ for some k. If no such k is found, the decider returns the string 0^m.

Suppose F^* is a δ-approximate oracle for V' with respect to the uniform ensemble. Given $x \in \{0,1\}^n$, we call an instance (n, k, h_1, z, h_2) *good* for x if the following three conditions are satisfied:

(i) $|x| = n$, $\lfloor -\log_2 \mathcal{D}(x) \rfloor = k$, and $h_1(x) = z$.

(ii) There exists an r such that $h_1(S(1^n, r)) = z$ and $h_2(r) = 0$.

(iii) If, for some r, $h_1(S(1^n, r)) = z$ and $h_2(r) = 0$, then $S(1^n, r) = x$.

Let $G(x)$ denote the set of all queries in L' that are good for x. It is immediate that the sets $G(x)$ are pairwise disjoint over all $x \in \{0,1\}^n$. On the one hand, we will show that, on input x, the reduction has a constant probability of producing a query that lands in $G(x)$. Moreover, conditioned on k, this query is uniformly distributed in $G(x)$. If $x \in L$ and F^* and V' agree on the query that falls within $G(x)$, then $F^*(x) = (w, r)$ with $S(1^n, r) = x$, so $V(x; w) = 1$. In addition, we will show that when $x \sim \mathcal{D}$, with probability at least $1 - \delta s$, F^* and V' do agree on a constant fraction of $G(x)$ for every k, so that the reduction has a constant probability of producing a query on which F^* and V' agree.

Claim A.1. *Suppose $|x| = n$ and $\lfloor -\log_2 \mathcal{D}(x) \rfloor = k$. With probability 3/4 over the choice of h_1 and h_2, the instance (n, k, h_1, z, h_2) is in $G(x)$.*

Proof. We first show that, with probability 7/8, the instance satisfies the second condition for goodness; i.e., there exists an r such that $S(1^n, r) = x$ and $h_2(r) = 0$. If $S(1^n, r) = x$, let I_r be an indicator for the event $h_2(r) = 0$. By our choice of k, $|\{r : S(1^n, r) = x\}| \geq 2^{s-k}$, so that

$$\mathrm{E}\left[\textstyle\sum_{r:S(1^n,r)=x} I_r\right] \geq 2^{s-k}\mathrm{E}[I_r] = 8.$$

As the I_r are pairwise independent, the variance of this sum is at most the expectation,

so by Chebyshev's inequality at least one $I_r = 1$ with probability 7/8.

Now we look at the probability of satisfying the third condition for goodness. Fix r such that $S(1^n, r) \neq x$. By pairwise independence, $\Pr_{h_1}[h_1(S(1^n, r)) = h_1(x)] = 2^{-k-6}$, and independently, $\Pr_{h_2}[h_2(r) = 0] = 2^{-s+k+3}$. It follows that

$$\begin{aligned}\Pr[\exists r : S(1^n, r) \neq x \text{ and } h_1(S(1^n, r)) = h_1(x) \text{ and } h_2(r) = 0] \\ \leq \sum\nolimits_{r:S(1^n,r)\neq x} \Pr[h_1(S(1^n, r)) = h_1(x)] \Pr[h_2(r) = 0] \\ \leq \sum\nolimits_{r\in\{0,1\}^s} 2^{-k-6}2^{-s+k+3} = 1/8.\end{aligned}$$

It follows that both conditions for goodness are satisfied with probability at least 3/4. ∎

Claim A.2. *For every x, $\mathcal{U}(G(x)) \geq (3/64)(\mathcal{D}(x)/ns)$.*

Proof. Consider a random string (n, k, h_1, z, h_2). With probability $1/ns$, $n = |x|$ and $k = \lfloor -\log_2 \mathcal{D}(x) \rfloor$. Conditioned on this, $z = h_1(x)$ with probability 2^{-k-3}. By the last claim, with probability 3/4 over h_1 and h_2, $(n, k, h_1, h_1(x), h_2)$ is in $G(x)$. Putting this together,

$$\Pr[(n, k, h_1, z, h_2) \in G(x)] \geq \frac{1}{ns} \cdot \frac{3}{4} \cdot 2^{-k-3} \geq \frac{3}{64} \cdot \frac{\mathcal{D}(x)}{ns}. \qquad \blacksquare$$

Let Z denote the set of all $x \in L_V$ for which

$$\Pr_{y\sim\mathcal{U},F^*}[V'(y, F^*(y)) = 1 \mid y \in G(x)] > 8/9,$$

so that if the kth query q_k lands in $G(x)$, the answer (w_k, r_k) has an 8/9 probability of being a good witness for the query. It follows that, unconditionally, $V(q_k, F^*(q_k)) = 1$ with probability at least $8/9 \cdot 3/4 = 2/3$, and the decider is successful on the queries that come from S.

On the other hand, by the disjointness of the sets $G(x)$,

$$\begin{aligned}\delta &\geq \sum\nolimits_{x\in L_V} \mathcal{U}(G(x)) \Pr_{y\sim\mathcal{U}}[V'(y, F^*(y)) = 0 \mid y \in G(x)] \\ &> \sum\nolimits_{x\in\overline{Z}} \mathcal{U}(G(x)) \cdot \frac{1}{9} \\ &\geq \sum\nolimits_{x\in\overline{Z}} \frac{1}{9} \cdot \frac{3}{64} \cdot \frac{\mathcal{D}(x)}{ns} \text{ (by Claim A.2)} \\ &= \Omega(\mathcal{D}(\overline{Z})/ns),\end{aligned}$$

so that $\mathcal{D}(\overline{Z}) = O(\delta ns)$. ∎

Acknowledgments. We thank Madhu Sudan for suggesting the relevance of [29], Oded Goldreich for stressing the relevance of our result to the question of basing cryptography on NP-hardness, and Amit Sahai for helpful discussions. We also thank Oded Goldreich and an anonymous reviewer for many useful comments on the presentation. The hiding protocol was suggested by Manikandan Narayanan.

AN UNCONDITIONAL STUDY OF COMPUTATIONAL ZERO KNOWLEDGE*

SALIL P. VADHAN†

Abstract. We prove a number of general theorems about **ZK**, the class of problems possessing (computational) zero-knowledge proofs. Our results are *unconditional*, in contrast to most previous works on **ZK**, which rely on the assumption that one-way functions exist. We establish several new characterizations of **ZK** and use these characterizations to prove results such as the following:

1. Honest-verifier **ZK** equals general **ZK**.
2. Public-coin **ZK** equals private-coin **ZK**.
3. **ZK** is closed under union.
4. **ZK** with imperfect completeness equals **ZK** with perfect completeness.
5. Any problem in $\mathbf{ZK} \cap \mathbf{NP}$ can be proven in computational zero knowledge by a $\mathbf{BPP}^{\mathbf{NP}}$ prover.
6. **ZK** with black-box simulators equals **ZK** with general, non–black-box simulators.

The above equalities refer to the resulting *class* of problems (and do not necessarily preserve other efficiency measures such as round complexity). Our approach is to combine the conditional techniques previously used in the study of **ZK** with the unconditional techniques developed in the study of **SZK**, the class of problems possessing statistical zero-knowledge proofs. To enable this combination, we prove that every problem in **ZK** can be decomposed into a problem in **SZK** together with a set of instances from which a one-way function can be constructed.

Key words. cryptography, computational complexity, zero-knowledge proofs, pseudoentropy, language-dependent commitment schemes, auxiliary-input one-way functions

1. Introduction.

Since their introduction by Goldwasser, Micali, and Rackoff [35], zero-knowledge interactive proofs have become a central tool in cryptographic protocol design, and have also provided fertile grounds for complexity-theoretic investigations into the interplay between fundamental notions such as proofs, randomness, interaction, and secrecy.

The notion of zero-knowledge proofs raised a number of intriguing basic questions, such as the following:

- Can we characterize the class **ZK** of problems possessing zero-knowledge proofs?[1]
- Can we transform proof systems that are zero knowledge for the "honest verifier" (i.e., the verifier that follows the specified protocol) into ones that are zero knowledge in general (i.e., for all polynomial-time verifier strategies)?

*Received by the editors March 18, 2005; accepted for publication (in revised form) April 4, 2006; published electronically December 15, 2006. [1] In this paper, we focus on the original notion of *computational* zero-knowledge *proof* systems, as introduced in [35]. That is, the zero-knowledge condition is defined with respect to computationally bounded verifiers (and distinguishers), and the soundness is defined with respect to computationally unbounded prover strategies. In particular, we do not consider *argument* systems [10], which are only computationally sound.

That is, does **HVZK** = **ZK**, where **HVZK** denotes the class of problems possessing honest-verifier zero-knowledge proofs?

- Is it always possible to modify zero-knowledge proofs to have additional useful properties—such as having a small number of rounds, perfect completeness, or public coins? Or do the latter properties restrict the class of problems possessing zero-knowledge proofs?
- What closure properties does **ZK** have? Is it closed under complement? Under union?

Almost all of these questions were seemingly resolved by a series of exciting works that appeared within a few years after zero-knowledge proofs were defined. Specifically, under the assumption that one-way functions (OWF) exist, it was shown that **ZK** "hits the roof," namely, **ZK** = **IP**, where **IP** is the class of problems possessing interactive proofs [29, 39, 7, 45, 37]. Thus, **ZK** is completely characterized and, moreover, has natural complete problems (namely, any complete problem for **IP** = **PSPACE** [42, 54]). This also implies that **HVZK** equals **ZK**, since **ZK** $\subseteq$ **HVZK** $\subseteq$ **IP** is immediate from the definitions. In addition, the equality **ZK** = **IP** is proven by a generic transformation from interactive proofs into zero-knowledge proofs, and this transformation preserves many properties, such as those mentioned above, i.e., the round complexity,[2] public coins, and perfect completeness. Since we already know how to transform interactive proofs into interactive proofs with public coins [36] and perfect completeness [19], it follows that we can also transform zero-knowledge proofs into zero-knowledge proofs with the same properties. **ZK** also inherits all the closure properties of **IP** = **PSPACE**, in particular closure under complement and union. However, *all of these results are based on the assumption that one-way functions exist*, and without this assumption, all the questions listed above are open.

In this paper, we answer most of these questions *unconditionally* (i.e., without any unproven complexity assumption). In particular, we do the following:

- Give several characterizations of **ZK** that make no reference to interaction or zero knowledge. (These characterizations are not quite complete problems, but turn out to have similar utility.)
- Prove that **HVZK** = **ZK**.
- Show how to transform any computational zero-knowledge proof into one with public coins and perfect completeness.
- Establish closure properties of **ZK**, such as closure under union.

This paper is inspired by the work of Ostrovsky and Wigderson [50], who gave the first hint that it might be possible to prove unconditional results about zero knowledge. They showed that if computational zero knowledge is nontrivial (i.e., **ZK** $\neq$ **BPP**), then "some form of one-way functions" exists. Then they made the appealing suggestion that one might prove unconditional results about computational zero knowledge by a case analysis as follows: If **ZK** = **BPP**, then many results about **ZK** hold trivially (because every problem in **BPP** has a trivial zero-knowledge proof, where the prover sends nothing and the verifier decides membership on its own, using the **BPP** algorithm). On the other hand, if **ZK** $\neq$ **BPP**, then we can try to use their "one-way functions" in the known conditional results about **ZK**. Unfortunately, as they point out, this approach does not work because the form of one-way functions they construct (in this case, **ZK** $\neq$ **BPP**) is too weak

[2] The round complexity is preserved up to an additive constant for achieving a polynomially small soundness error. For a negligible error, any superconstant multiplicative factor suffices (by sequential repetition).

for the conditional constructions mentioned above.[3] (See section 7.1 for more details.)

Our approach is to replace **BPP** with **SZK**, the class of problems possessing *statistical* zero-knowledge proofs (to be described in more detail shortly). In particular, in the case when $\mathbf{ZK} \neq \mathbf{SZK}$, we are able to construct a form of one-way functions that is much closer to the standard notion than that in the Ostrovsky–Wigderson result. However, now the case that $\mathbf{ZK} = \mathbf{SZK}$ is not as trivial as before; instead we rely on a large body of previous work giving unconditional results about **SZK** (as described below). To make this approach work, we actually carry out the case analysis on an input-by-input basis. That is, we show that for every problem in **ZK**, we can partition its instances into "**SZK** instances" and "one-way function instances." This characterization is described in more detail below.

1.1. The SZK/OWF characterization.

Statistical zero knowledge. The distinction between general (computational) zero knowledge and statistical zero knowledge involves the formulation of the "zero-knowledge" property, i.e., the requirement that the verifier "learns nothing" from the interaction other than the fact that the assertion being proven is true. The original (and most general) notion discussed above, called *computational zero knowledge*, informally says that a *polynomial-time* verifier learns nothing. *Statistical zero knowledge* guarantees that even a computationally unbounded verifier learns nothing from the interaction.[4] Naturally, the stronger security guarantee of statistical zero knowledge is preferable, but unfortunately it seems to severely constrain the class of statements that can be proven in zero knowledge. Specifically, it is known that the class **SZK** of problems possessing statistical zero-knowledge proofs is contained in $\mathbf{AM} \cap \mathbf{co\text{-}AM}$ [18, 1], and thus **NP**-complete problems are unlikely to have statistical zero-knowledge proofs. Thus statistical zero-knowledge proofs do not seem to have the wide applicability of computational zero-knowledge proofs (which stems from the existence of computational zero-knowledge proofs for all of **NP** [29]).

Nevertheless, the class **SZK** of problems possessing statistical zero-knowledge proofs has turned out to be a rich object of study, and in recent years, there have been a number of results substantially improving our understanding of it. These results include the identification of natural complete problems for class **SZK** [52, 34], showing that **SZK** is closed under complement [48]; that honest-verifier **SZK** equals general **SZK** [32]; and that private-coin **SZK** equals public-coin **SZK** [48]. (See [57] for a unified presentation of all these results.) In contrast to what was known for computational zero knowledge, all these results are unconditional. That is, they do not rely on any unproven complexity assumptions (such as the existence of one-way functions).

It was suggested in [34, 57] that the study of **SZK** could provide a useful testbed for understanding zero knowledge before moving on to more complex models that

[3] A similar approach was used in an attempt to prove $\mathbf{HVSZK} = \mathbf{SZK}$ [15], but subsequently a more direct approach that avoids these difficulties was found [32].

[4] Recall that the zero-knowledge property is formalized by requiring that there be a probabilistic polynomial-time algorithm S that "simulates" the verifier's view of the interaction (when the assertion being proven is true). In computational zero knowledge, the output distribution of the simulator is required only to be computationally indistinguishable from the verifier's view of the interaction, whereas in statistical zero knowledge, it must be statistically close. We note that there is a similar choice in the soundness condition. We, like the authors of [35], focus on interactive *proof* systems, where even a *computationally unbounded* prover cannot convince the verifier to accept a false statement, except with negligible probability. In interactive *argument* systems [10], this soundness condition is required only for *polynomial-time* provers.

incorporate computational intractability (such as **ZK**). In this paper, we make extensive use of that methodology—not just proving results about **ZK** by analogy to **SZK**, but actually making direct use of known results about **SZK** (e.g., in establishing and using the characterization below).

The characterization. In this paper, we provide a new characterization of **ZK** in terms of **SZK** and one-way functions as follows.

DEFINITION 1.1. *A promise problem*[5] $\Pi = (\Pi_Y, \Pi_N)$ *satisfies the* SZK/OWF CONDITION *if there exists a set* $I \subseteq \Pi_Y$ *of* YES *instances, a polynomial-time computable function* f*, and a polynomial* $p(n)$ *such that the following hold:*

- *Ignoring the inputs in* I*, the problem* Π *has a statistical zero-knowledge proof. Formally, we have* $\Pi' \in \mathbf{SZK}$*, where* $\Pi' = (\Pi_Y \setminus I, \Pi_N)$.
- *When* $x \in I$*, the function* $f_x(\cdot) \stackrel{\text{def}}{=} f(x, \cdot)$ *is hard to invert. That is, for every nonuniform polynomial-time algorithm* A*, there exists a negligible function* ϵ *such that for every* $x \in I$*,*

$$\Pr\left[A(f_x(U_{p(|x|)})) \in f_x^{-1}(f_x(U_{p(|x|)}))\right] \leq \epsilon(|x|).$$

Intuitively, this characterization says that for every YES instance x, either one can prove the membership of x in Π_Y in statistical zero knowledge ("x is an **SZK** instance") or one can use x to construct a one-way function that is given x as an auxiliary input ("x is an OWF instance"). Note that if one-way functions exist (in the standard sense, i.e., without auxiliary input), then *all* promise problems satisfy the SZK/OWF CONDITION (by setting $I = \Pi_Y$, and $f_x(y) = g(y)$ where g is the one-way function assumed to exist).

On the other hand, the above condition (regarding Π) alone *cannot* characterize **ZK**, since if one-way functions do exist, Π will satisfy Definition 1.1 even if $\Pi \notin \mathbf{IP}$. We prove that if we simply add the condition $\Pi \in \mathbf{IP}$, then we do indeed obtain an exact characterization.

THEOREM 1.2 (SZK/OWF characterization of ZK). $\Pi \in \mathbf{ZK}$ *if and only if* $\Pi \in \mathbf{IP}$ *and* Π *satisfies the* SZK/OWF CONDITION.

As noted above, the usefulness of this characterization is that it essentially reduces the unconditional study of **ZK** to its conditional study plus the study of **SZK**. Theorem 1.2 is in some sense the central theorem of this paper; all other results are deduced as consequences of it or its proof. When proving each direction of Theorem 1.2, we actually prove stronger statements than required. In the forward ("only if") direction, we actually show that every problem in **HVZK**, not just **ZK**, satisfies the SZK/OWF CONDITION. In the reverse ("if") direction, we show that every problem in **IP** satisfying the SZK/OWF CONDITION is not only in **ZK**, but has a computational zero-knowledge proof with many nice properties, such as public coins, perfect completeness, universal black-box simulation, etc. Combining the two directions, we deduce that **HVZK** = **ZK**, and that every problem in **ZK** has a computational zero-knowledge proof with the aforementioned properties.

1.2. Proof outline. Figure 1 illustrates our main steps in establishing both directions of Theorem 1.2. In proving the forward direction, we first prove that every problem in **HVZK** satisfies a "CONDITIONAL PSEUDOENTROPY CONDITION" and an "INDISTINGUISHABILITY CONDITION." These are computational analogues

[5] A promise problem Π consists of a pair (Π_Y, Π_N) of disjoint sets of strings, corresponding to the YES instances and NO instances of Π, respectively [17]. All complexity classes we consider in this paper, e.g., **ZK**, **SZK**, and **IP**, are taken to be classes of promise problems. See section 2.3.

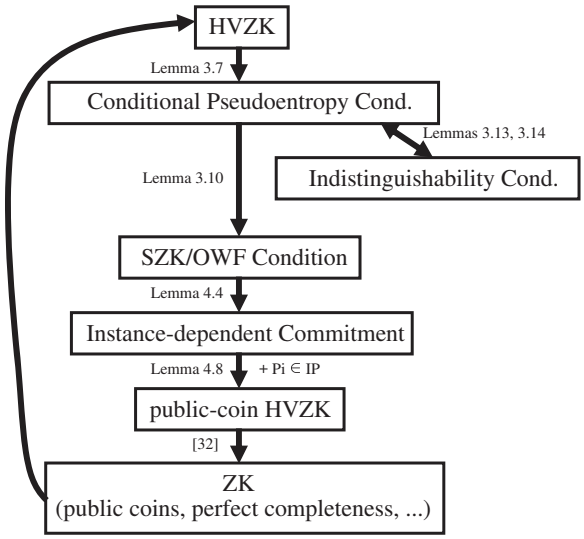

FIG. 1. *Steps of our proof.*

of the known complete problems for **SZK** [52, 34] and are described in more detail below. The reductions from **HVZK** to these characterizations are natural adaptations of the reductions from **HVSZK** = **SZK** to the **SZK**-complete problems (which in turn are based on the simulator analyses of [18, 1, 51]). We then show that every problem satisfying the CONDITIONAL PSEUDOENTROPY CONDITION also satisfies the SZK/OWF CONDITION. This step utilizes the techniques of Håstad et al. [37] to construct the needed one-way functions f_x.

In proving the reverse direction of Theorem 1.2, we first show that every problem satisfying the SZK/OWF CONDITION has a certain kind of "instance-dependent commitment scheme" [40] as discussed in more detail below. We then use the techniques of [29, 39, 7, 40] to show that every problem in **IP** with such a commitment scheme has a public-coin honest-verifier zero-knowledge proof. The honest-verifier zero-knowledge proof is then converted into one that is zero knowledge even for cheating verifiers using the compiler of [32]. The resulting proof system remains public coin, and also has additional nice properties such as perfect completeness and black-box simulation.

Putting these steps together, we deduce that membership in **HVZK**, membership in **ZK** (even with additional nice properties), the SZK/OWF CONDITION, the CONDITIONAL PSEUDOENTROPY CONDITION, the INDISTINGUISHABILITY CONDITION, and having an instance-dependent commitment scheme are all equivalent (for problems in **IP**). The latter three characterizations of **ZK** are of interest beyond their role in establishing Theorem 1.2, so we describe them in more detail below.

1.3. Additional characterizations of ZK.

Computational analogues of the **SZK***-complete problems.* Recall that in [52, 34], it was demonstrated that **SZK** has two natural complete problems, STATISTICAL DIFFERENCE and ENTROPY DIFFERENCE. These problems proved to be very useful tools in the study of **SZK** (cf. [52, 57]) because they reduced the study of the entire class to the study of these specific problems.

In this work, we provide characterizations of **ZK** that are natural computational analogues of these two problems. For example, recall that instances of the STATIS-

TICAL DIFFERENCE problem consist of pairs (X, Y) of probability distributions on strings, specified by circuits that sample from them. The YES instances are pairs that are statistically close and the NO instances are pairs that are statistically far apart. We show that if "statistically close" is replaced with "computationally indistinguishable," the resulting condition characterizes **ZK**. This condition, which we refer to as the INDISTINGUISHABILITY CONDITION, cannot be cast as a complete problem because there can be distributions that are both computationally indistinguishable and statistically far apart. Rather, we say that a promise problem satisfies the INDISTINGUISHABILITY CONDITION if its instances can be efficiently mapped to pairs (X, Y) that are computationally indistinguishable or statistically far apart, according to whether the instance is a YES or NO instance. We show that this characterizes **ZK** in the sense that a promise problem is in **ZK** if and only if it is in **IP** and satisfies the INDISTINGUISHABILITY CONDITION.

The computational analogue of ENTROPY DIFFERENCE is less immediate, and in fact a crucial step towards our establishment of the SZK/OWF characterization theorem was the realization that the "right" problem to generalize is a variant of ENTROPY DIFFERENCE, which we call CONDITIONAL ENTROPY APPROXIMATION rather than ENTROPY DIFFERENCE itself. (See section 3 for more details.)

Instance-dependent commitments. A fundamental tool in the construction of many zero-knowledge proofs is that of a *commitment scheme*. This is a protocol whereby a *sender* can "commit" to a bit b in such a way that the *receiver* learns nothing about b (the scheme is *hiding*), but nevertheless the sender cannot "open" the commitment to a value other than b (the scheme is *binding*). Commitment schemes, which can be constructed from any one-way function [45, 37], play an essential role in the construction of zero-knowledge proofs for all of NP and **IP** [29, 39, 7]. Some evidence that commitments are necessary for zero knowledge came from the work of Damgård [12, 13], who focused on 3-round public-coin zero-knowledge proofs, and Ostrovsky [49] and Ostrovsky and Wigderson [50], who showed that zero-knowledge proofs for *hard-on-average* languages imply one-way functions (and hence standard commitment schemes [45, 37]).

In this work, we show an *equivalence* between zero-knowledge proofs and certain types of commitment schemes, which we now describe. In an *instance-dependent* commitment scheme [6, 40, 44] for a promise problem Π, both the sender and receiver get a common auxiliary input x, which is an instance of Π. It is required that if x is a YES instance of Π, then the scheme is hiding, and if x is a NO instance, then the scheme is binding. Thus, instance-dependent commitment schemes are a relaxation of commitment schemes because the hiding and binding properties are not required to hold at the same time. Nevertheless, this relaxation is still useful in constructing zero-knowledge proofs. The reason is that zero-knowledge proofs based on commitments (see, e.g., [29, 39, 7]) typically use only the hiding property in proving zero knowledge (which is required only when x is a YES instance) and use only the binding property in proving soundness (which is required only when x is a NO instance).

We show that a promise problem is in **ZK** (resp., **SZK**) if and only if it has an instance-dependent commitment scheme that is computationally (resp., statistically) hiding on YES instances (and statistically binding on NO instances). Indeed, the most technical part of this paper is the construction of instance-dependent commitment schemes for all of **SZK**, which utilizes much of the machinery previously developed in the study of **SZK** [48, 52, 34]. The construction of instance-dependent commitments for **ZK** then follows using the SZK/OWF characterization theorem and the known construction of commitment schemes from one-way functions [45, 37].

Two deficiencies in our instance-dependent commitments are that the hiding property holds only against an honest receiver (i.e., one that follows the specified protocol) and that the sender of the commitment scheme is not polynomial time, but rather $\mathbf{BPP}^{\mathbf{NP}}$. The effect of these are that the direct constructions of zero-knowledge proofs that we obtain using the commitments are only honest-verifier zero knowledge and have provers that require an **NP** oracle (rather than just an **NP** witness, as would be preferable for problems in **NP**). The honest-verifier constraint is removed using the compiler of [32], which converts *public-coin* honest-verifier zero-knowledge proofs into general zero-knowledge proofs. The **NP** oracle has been removed in subsequent work [46] by using a new, more relaxed, type of instance-dependent commitment scheme; see section 8.

1.4. Organization. We begin in section 2 with the definitions, notation, and basic results that we will use throughout the paper, in particular covering probability and information theory, promise problems, and zero-knowledge proofs. Section 3 contains the proof of the forward direction of Theorem 1.2, including establishing the computational analogues of the **SZK**-complete problems. Section 4 contains the proof of the reverse direction of Theorem 1.2, except for the construction of instance-dependent commitments for all of **SZK**, which is deferred to section 5. Section 6 ties together the results of sections 3–5, in particular establishing Theorem 1.2. Section 7 contains several applications and extensions of our results, including monotone closure properties of **ZK**, new proofs of the Ostrovsky–Wigderson theorems [50], and an equivalence between strict and expected polynomial-time simulators. In section 8, we conclude with some open problems and directions for further work.

2. Preliminaries.

2.1. Basic notation. If X is a random variable taking values in a finite set $\mathcal{U}$, then we write $x \leftarrow X$ to indicate that x is selected according to X. If S is a subset of $\mathcal{U}$, then $x \leftarrow S$ means that x is selected according to the uniform distribution on S. We adopt the convention that when the same random variable occurs several times in an expression, all occurrences refer to a single sample. For example, $\Pr[f(X) = X]$ is defined to be the probability that when $x \leftarrow X$, we have $f(x) = x$. We write U_n to denote the random variable distributed uniformly over $\{0,1\}^n$. The *support* of a random variable X is $\mathrm{Supp}(X) = \{x : \Pr[X = x] > 0\}$. A random variable is *flat* if it is uniform over its support. If X and Y are random variables, then $X \otimes Y$ denotes the random variable obtained by taking independent random samples $x \leftarrow X$ and $y \leftarrow Y$ and outputting the pair (x, y). We write $\otimes^k X$ to denote the random variable consisting of k independent copies of X. For an event E, $X|_E$ denotes the random variable X conditioned on E.

A function $\mu : \mathbb{N} \to [0,1]$ is called *negligible* if $\mu(n) = n^{-\omega(1)}$. We let $\mathrm{neg}(n)$ denote an arbitrary negligible function (i.e., when we say that $f(n) < \mathrm{neg}(n)$ we mean that *there exists* a negligible function $\mu(n)$ such that for every n, $f(n) < \mu(n)$). Likewise, $\mathrm{poly}(n)$ denotes an arbitrary function $f(n) = n^{O(1)}$.

For a probabilistic algorithm A, we write $A(x; r)$ to denote the output of A on input x and coin tosses r. In this case, $A(x)$ is a random variable representing the output of A for uniformly selected coin tosses. *PPT* refers to probabilistic algorithms (i.e., Turing machines) that run in *strict* polynomial time. A *nonuniform* PPT algorithm is a pair $(A, \bar{z})$, where $\bar{z} = z_1, z_2, \ldots$ is an infinite sequence of strings in which $|z_n| = \mathrm{poly}(n)$, and A is a PPT algorithm that receives pairs of inputs of the form $(x, z_{|x|})$. (The string z_n is called the *advice string* for A for inputs of length n.) Non-

uniform PPT algorithms are equivalent to (nonuniform) families of polynomial-sized Boolean circuits.

A Boolean circuit $C : \{0,1\}^m \to \{0,1\}^n$ defines a probability distribution on $\{0,1\}^n$ by evaluating C on a uniformly chosen input in $\{0,1\}^m$. That is, we view C as specifying a sampling algorithm for the distribution, with C's input gates being the coin tosses; thus we will often refer to distributions specified by circuits as *samplable distributions*. This is a "nonuniform" notion of samplability, because the sampling algorithm C can be tailored to a particular output length n. Later, in Definition 2.11, we will consider a uniform notion of samplability, which refers to ensembles (i.e., sequences) of probability distributions that are generated by a uniform PPT algorithm. Samplable distributions will play a central role in the paper.

2.2. Statistical measures.

Statistical difference. The *statistical difference* (also known as the *variation distance*) between random variables X and Y taking values in $\mathcal{U}$ is defined to be

$$\begin{aligned}\Delta(X,Y) &\stackrel{\text{def}}{=} \max_{S\subset\mathcal{U}} |\Pr[X\in S] - \Pr[Y\in S]| \\ &= \frac{1}{2}\sum_{x\in\mathcal{U}} |\Pr[X=x] - \Pr[Y=x]| \\ &= 1 - \sum_{x\in\mathcal{U}} \min\{\Pr[X=x], \Pr[Y=x]\}.\end{aligned}$$

We say that X and Y are *ε-close* if $\Delta(X,Y)\le\varepsilon$. For basic facts about this metric, see [52, sect. 2.3].

Entropy. The *entropy* of a random variable X is $\mathrm{H}(X) = \mathrm{E}_{x\leftarrow X}[\log(1/\Pr[X=x])]$, where here and throughout the paper all logarithms are to base 2. Intuitively, $\mathrm{H}(X)$ measures the amount of randomness in X *on average* (in bits). The *min-entropy* of X is $\mathrm{H}_\infty(X) = \min_x[\log(1/\Pr[X=x])]$; this is a "worst-case" measure of randomness. In general $\mathrm{H}_\infty(X)\le\mathrm{H}(X)$, but if X is flat, then $\mathrm{H}(X) = \mathrm{H}_\infty(X) = \log|\mathrm{Supp}(X)|$. For $p\in[0,1]$, we define the *binary entropy function* $\mathrm{H}_2(p)$ to be the entropy of a binary random variable that is 1 with probability p and 0 with probability $1-p$, i.e., $\mathrm{H}_2(p) = p\cdot\log(1/p) + (1-p)\cdot\log(1/(1-p))$. For jointly distributed random variables X and Y, we define the *conditional entropy of X given Y* to be

$$\mathrm{H}(X|Y) \stackrel{\text{def}}{=} \mathop{\mathrm{E}}_{y\leftarrow Y}[\mathrm{H}(X|_{Y=y})] = \mathop{\mathrm{E}}_{(x,y)\leftarrow(X,Y)}\left[\log\frac{1}{\Pr[X=x|Y=y]}\right] = \mathrm{H}(X,Y) - \mathrm{H}(Y).$$

A useful fact is that if two random variables are statistically close, then their entropies must also be close, as follows.

LEMMA 2.1 (cf. [34, Fact B.1]). *For any two random variables, X and Y, ranging over a universe $\mathcal{U}$, if $\delta = \Delta(X,Y)$, then*

$$|\mathrm{H}(X) - \mathrm{H}(Y)| \le \log(|\mathcal{U}|-1)\cdot\delta \;+\; \mathrm{H}_2(\delta).$$

Another useful fact is that random variables taking values in a universe $\mathcal{U}$ can be modified so that they do not assign any elements in their support of a probability mass much smaller than $1/|\mathcal{U}|$ without incurring a significant statistical difference or change in entropy.

LEMMA 2.2. *Let (X,Y) be a random variable taking values in $\mathcal{U}\times\mathcal{V}$. Then for any $\delta>0$, there is a random variable (X',Y') that is δ-close to (X,Y) and satisfies*

$\Pr[X' = x | Y' = y] \geq \delta/|\mathcal{U}|$ *for all* $(x, y) \in \mathrm{Supp}(X', Y')$. *Moreover,*

$$|\mathrm{H}(X'|Y') - \mathrm{H}(X|Y)| \leq \log(|\mathcal{U}| - 1) \cdot \delta + \mathrm{H}_2(\delta).$$

Proof. For each $y \in \mathrm{Supp}(Y)$, the set

$$S_y = \{x \in \mathcal{U} : \Pr[X = x | Y = y] < \delta/|\mathcal{U}|\}$$

has total probability mass less than δ under the conditional distribution $X|_{Y=y}$. Thus shifting the probability mass of the points in S_y to other points in $\mathcal{U}$ yields a random variable Z_y that is δ-close to $X|_{Y=y}$. By Lemma 2.1, for every y, the entropy of Z_y differs from that of $X|_{Y=y}$ by at most $\delta' = \log(|\mathcal{U}| - 1) \cdot \delta + \mathrm{H}_2(\delta)$. Thus taking $(X', Y') = (Z_Y, Y)$ satisfies the conclusion of the lemma. ∎

For more background on entropy, see [11].

Direct products. We will often refer to the behavior of the above measures under direct products, i.e., when we take k independent copies of a random variable. For statistical difference, we have the following bounds.

LEMMA 2.3 (cf. [52, Lemma 3.4]). *For random variables X and Y, if $\delta = \Delta(X, Y)$, then for every $k \in \mathbb{N}$, we have*

$$1 - 2\exp(-k\delta^2/2) \leq \Delta(\otimes^k X, \otimes^k Y) \leq k\delta.$$

For entropy, it holds that for every X, Y, $\mathrm{H}(X \otimes Y) = \mathrm{H}(X) + \mathrm{H}(Y)$, and thus $\mathrm{H}(\otimes^k X) = k \cdot \mathrm{H}(X)$. Similarly, for conditional entropy, if we write $\otimes^k(X, Y) = ((X_1, Y_1), \ldots, (X_k, Y_k))$, then $\mathrm{H}((X_1, \ldots, X_k)|(Y_1, \ldots, Y_k)) = k \cdot \mathrm{H}(X|Y)$.

Another well-known and useful feature of taking direct products is that it "flattens" random variables so that probability masses become concentrated around $2^{-\mathrm{H}(X)}$. (This is known as the asymptotic equipartition property in information theory; see [11].) Our formalization of it follows [34], with an extension to conditional distributions.

DEFINITION 2.4 (heavy, light, and typical elements). *Let X be a random variable taking values in a universe $\mathcal{U}$, and let x be an element of $\mathcal{U}$. For a positive real number Φ, we say that x is* Φ-heavy *(resp.,* Φ-light*) if* $\Pr[X = x] \geq 2^{\Phi} \cdot 2^{-\mathrm{H}(X)}$ *(resp.,* $\Pr[X = x] \leq 2^{-\Phi} \cdot 2^{-\mathrm{H}(X)}$*). Otherwise, we say that x is* Φ-typical.

If Y is a random variable jointly distributed with X, and $y \in \mathrm{Supp}(Y)$, we say that x is Φ-heavy given y *(resp.,* Φ-light given y*) if* $\Pr[X = x | Y = y] \geq 2^{\Phi} \cdot 2^{-\mathrm{H}(X|Y)}$ *(resp., if* $\Pr[X = x | Y = y] \leq 2^{-\Phi} \cdot 2^{-\mathrm{H}(X|Y)}$*). Otherwise, we say that x is* Φ-typical given y.

A natural relaxed definition of flatness follows. The definition links the amount of slackness allowed in "typical" elements with the probability mass assigned to non-typical elements.

DEFINITION 2.5 (nearly flat distributions).[6] *A distribution X is called* Φ-flat *if for every $t \geq 1$ the probability that an element chosen from X is $t \cdot \Phi$-typical is at least* $1 - 2^{-t^2}$.

If Y is jointly distributed with X, then we say that X is Φ-flat given Y *if for every $t \geq 1$, when $(x, y) \leftarrow (X, Y)$, the probability that x is $t \cdot \Phi$-typical given y is at least* $1 - 2^{-t^2}$.

[6] The definition in [34] allows any $t > 0$, but requires only that the probability of being $t \cdot \Phi$-typical be $1 - 2^{-t^2+1}$. We find it more convenient to restrict to $t \geq 1$, a setting that is satisfied in all our applications.

A consequence of this definition is that if X is Φ-flat, then for every $t \geq 1$, the random variable X is (2^{-t^2})-close to a random variable X' with min-*entropy* at least $\mathrm{H}(X) - t\Phi$.

LEMMA 2.6 (flattening lemma). *Let X be a distribution, k be a positive integer, and $\otimes^k X$ denote the distribution composed of k independent copies of X. Suppose that for all x in the support of X it holds that $\Pr[X = x] \geq 2^{-m}$. Then $\otimes^k X$ is $\sqrt{k}\cdot m$-flat.*

Suppose Y is jointly distributed with X, and for all (x, y) in the support of (X, Y) it holds that $\Pr[X = x|Y = y] \geq 2^{-m}$. Then, defining the random variable $((X_1, Y_1), \ldots, (X_k, Y_k)) = \otimes^k(X, Y)$, the random variable $(X_1, \ldots, X_k)$ is $\sqrt{k} \cdot m$-flat given $(Y_1, \ldots, Y_k)$.

The key point is that deviation from flatness grows sublinearly with k, while the entropy grows linearly with k. We prove the flattening lemma in Appendix A for completeness.

Hashing. The topic of *randomness extraction* is concerned with efficiently extracting as many almost-uniform random bits as possible from random variables that are not uniformly distributed. The entropy of a random variable does not provide a good measure of how many almost-uniform bits can be extracted, but its min-entropy does, as long as we are willing to let the extraction procedure itself be probabilistic. Surveys of the large body of work on this topic can be found in [47, 53]. Much of that work focuses on minimizing the number of extra random bits used by the extractor; this is not a major concern for us, so we can use relatively simple randomness extractors. In particular, the leftover hash lemma of [8, 37] shows that universal (or pairwise-independent) hash functions can be used for this purpose.

LEMMA 2.7 (leftover hash lemma). *Let H be randomly selected from a family of universal hash functions mapping $\{0,1\}^n$ to $\{0,1\}^m$. Then, for every $\varepsilon > 0$ and every distribution X on $\{0,1\}^n$ of min-entropy at least $m + 2\log(1/\varepsilon)$, the random variable $(H, H(X))$ is ε-close to (H, U_m).*

Recall that for every n, m, there is an explicit family of universal hash functions mapping $\{0,1\}^n$ to $\{0,1\}^m$, where a random hash function in the family can be described by $O(n+m)$ random bits and can be evaluated in time $\mathrm{poly}(n, m)$ (cf. [22, sect. 3.6.1]).

2.3. Promise problems. Roughly speaking, a *promise problem* [17] is a decision problem in which some inputs are excluded. Formally, a promise problem is specified by two disjoint sets of strings $\Pi = (\Pi_Y, \Pi_N)$, where we call Π_Y the set of YES *instances* and Π_N the set of NO *instances*. Such a promise problem is associated with the following computational problem: Given an input that is "promised" to lie in $\Pi_Y \cup \Pi_N$, decide whether it is in Π_Y or in Π_N. Note that languages are special cases of promise problems (namely, a language L over an alphabet Σ corresponds to the promise problem $(L, \Sigma^* \setminus L)$). Thus, working with promise problems makes our results more general. Moreover, even for proving our results just for languages, it turns out to be extremely useful to work with promise problems along the way.

The *complement* of a promise problem $\Pi = (\Pi_Y, \Pi_N)$ is the promise problem $\overline{\Pi} = (\Pi_N, \Pi_Y)$. The *union* of two promise problems Π and Γ is the promise problem $\Pi \cup \Gamma = (\Pi_Y \cup \Gamma_Y,\ \Pi_N \cap \Gamma_N)$. The *intersection* of two promise problems Π and Γ is the promise problem $\Pi \cap \Gamma = (\Pi_Y \cap \Gamma_Y,\ \Pi_N \cup \Gamma_N)$.

Most complexity classes, typically defined as classes of languages, can be extended to promise problems in a natural way by translating conditions on inputs in the language into conditions on YES instances, and conditions on inputs not in the language into conditions on NO instances. For example, a promise problem Π is in

BPP if there is a PPT algorithm A such that $x \in \Pi_Y \Rightarrow \Pr[A(x) = 1] \geq 2/3$ and $x \in \Pi_N \Rightarrow \Pr[A(x) = 0] \leq 1/3$. All complexity classes in this paper denote classes of promise problems.

A promise problem Π *reduces* to promise problem Γ if there is a polynomial-time computable function f such that

$$x \in \Pi_Y \Rightarrow f(x) \in \Gamma_Y,$$
$$x \in \Pi_N \Rightarrow f(x) \in \Gamma_N.$$

That is, we work with polynomial-time mapping reductions (i.e., Karp reductions) unless otherwise specified. If $\mathbf{C}$ is a class of promise problems, then Π is *complete for* $\mathbf{C}$ (or $\mathbf{C}$-*complete*) if $\Pi \in \mathbf{C}$ and every promise problem in $\mathbf{C}$ reduces to Π. Sometimes we will restrict our attention to reductions f that are *nonshrinking*, in the sense that there is a constant $\delta > 0$ such that $|f(x)| \geq |x|^\delta$ for all strings x.

We refer the reader to the recent survey of Goldreich [24] for more on the utility and subtleties of promise problems.

2.4. Auxiliary-input cryptographic primitives. It will be very useful for us to work with cryptographic primitives that are parameterized by an additional "auxiliary" input x, and where the security condition will hold only if x is in some particular set I. Indeed, recall that the SZK/OWF Condition refers to such a variant of the notion of one-way functions (as captured in the definitions below). Auxiliary-input primitives have been considered in the past, such as in the instance-dependent commitments of [40] (which we consider in section 4.1) and the auxiliary-input one-way functions of [50] (which are weaker than our formulation below). In this section, we provide a general framework for discussing and relating such primitives.

Definition 2.8. *An* auxiliary-input function ensemble *is a collection of functions* $\mathcal{F} = \{f_x : \{0,1\}^{p(|x|)} \to \{0,1\}^{q(|x|)}\}_{x \in \{0,1\}^*}$, *where* p *and* q *are polynomials. We call* $\mathcal{F}$ polynomial-time computable *(or just* poly-time*) if there is a (deterministic) polynomial-time algorithm* F *such that for every* $x \in \{0,1\}^*$ *and* $y \in \{0,1\}^{p(|x|)}$, *we have* $F(x,y) = f_x(y)$.

Definition 2.9. *An* auxiliary-input one-way function on I *is a poly-time auxiliary-input function ensemble* $\mathcal{F} = \{f_x : \{0,1\}^{p(|x|)} \to \{0,1\}^{q(|x|)}\}$ *such that for every nonuniform PPT* A, *there exists a negligible function* μ *such that for all* $x \in I$,

$$\Pr\left[A(x, f_x(U_{p(|x|)})) \in f_x^{-1}(f_x(U_{p(|x|)}))\right] \leq \mu(|x|).$$

(We note that since A is nonuniform, it is not essential that we give it the input x, because x can be hardwired in as advice, but the definition seems more natural, as above.) The standard definition of a one-way function is obtained by considering $I = \{1^n : n \geq 0\}$ and $p(n) = n$. The above is a stronger notion of an auxiliary-input one-way function than the notion considered by Ostrovsky and Wigderson [50]. In their formulation (which they denote by $\exists 1WF$), the set I is not fixed for all A, but rather can depend on A. That is, they require that for every PPT A, there must exist an infinite set I_A such that A has small probability of inverting f_x for all $x \in I_A$. (See our Theorem 7.1 for a precise formulation of this notion and the result of [50].)

Given the above definition, we can restate the SZK/OWF Condition as follows.

Definition 2.10. *A promise problem* $\Pi = (\Pi_Y, \Pi_N)$ *satisfies the* SZK/OWF Condition *if there is* $I \subseteq \Pi_Y$ *such that*

- *the promise problem* $\Pi' = (\Pi_Y \setminus I, \Pi_N)$ *is in* **SZK**.
- *there exists an auxiliary-input one-way function on* I.

Similarly, the notion of computational indistinguishability has an auxiliary-input analogue (which is widely used in the definition of zero knowledge; see section 2.5).

DEFINITION 2.11. *An* auxiliary-input probability ensemble *is a collection of random variables* $\{X_x\}_{x\in\{0,1\}^*}$*, where* X_x *takes values in* $\{0,1\}^{p(|x|)}$ *for some polynomial* p*. We call such an ensemble* samplable *if there is a PPT algorithm* M *such that for every* x*, the output* $M(x)$ *is distributed according to* X_x*.*

DEFINITION 2.12. *Two auxiliary-input probability ensembles* $\{X_x\}$ *and* $\{Y_x\}$ *are* computationally indistinguishable *on* $I \subseteq \{0,1\}^*$ *if for every nonuniform PPT* D*, there exists a negligible function* μ *such that for all* $x \in I$*,*

$$|\Pr[D(x, X_x) = 1] - \Pr[D(x, Y_x) = 1]| \leq \mu(|x|).$$

Similarly, we say that $\{X_x\}$ *and* $\{Y_x\}$ *are* statistically indistinguishable *on* $I \subseteq \{0,1\}^*$ *if the above is required for all functions* D *(instead of only nonuniform PPT* D*'s). Equivalently,* $\{X_x\}$ *and* $\{Y_x\}$ *are statistically indistinguishable on* I *if and only if* X_x *and* Y_x *are* $\mu(|x|)$*-close for some negligible function* μ *and all* $x \in I$*. If* X_x *are* Y_x *are identically distributed for all* $x \in I$ *(i.e.,* $\mu = 0$*), we say that they are* perfectly indistinguishable.

Often, we will informally say "X_x and Y_x are computationally indistinguishable when $x \in I$" to mean that the ensembles $\{X_x\}$ and $\{Y_x\}$ are computationally indistinguishable on I. It is well known that indistinguishability is preserved when we take polynomially many direct products. See the following lemma.

LEMMA 2.13 (cf. [23, Chap. 3, Ex. 9]). *If* $\{X_x\}$ *and* $\{Y_x\}$ *are computationally indistinguishable on* I*, then for every polynomial* p*,* $\{\otimes^{p(|x|)}X_x\}$ *and* $\{\otimes^{p(|x|)}Y_x\}$ *are computationally indistinguishable on* I*.*

Now we can naturally define auxiliary-input pseudorandom generators.

DEFINITION 2.14. *An* auxiliary-input pseudorandom generator on I *is a polytime auxiliary-input function ensemble* $\mathcal{G} = \{G_x : \{0,1\}^{p(|x|)} \to \{0,1\}^{q(|x|)}\}$ *such that* $q(n) > p(n)$*, and the probability ensembles* $\{G_x(U_{p(|x|)})\}_x$ *and* $\{U_{q(|x|)}\}_x$ *are computationally indistinguishable on* I*.*

Almost all reductions between cryptographic primitives immediately extend to their auxiliary-input analogues (using the same proof). One example is the equivalence between the existence of pseudorandom generators and the existence of one-way functions.

THEOREM 2.15 (see [37]). *For every set* $I \subseteq \{0,1\}^*$*, there exists a pseudorandom generator on* I *if and only if there exists a one-way function on* I*.*

2.5. Zero-knowledge proofs. An *interactive protocol* (A, B) consists of two algorithms that compute the *next-message function* of the (honest) parties in the protocol. Specifically, $A(x, a, \alpha_1, \ldots, \alpha_k; r)$ denotes the next message α_{k+1} sent by party A when the common input is x, A's auxiliary input is a, A's coin tosses are r, and the messages exchanged so far are $\alpha_1, \ldots, \alpha_k$. There are two special messages, `accept` and `reject`, which immediately halt the interaction. We say that party A (resp., B) is *probabilistic polynomial time (PPT)* if its next-message function can be computed in polynomial time (in $|x| + |a| + |\alpha_1| + \cdots + |\alpha_k|$). Sometimes (though not in this section) we will refer to protocols with a joint output; such an output is specified by a deterministic, polynomial-time computable function of the messages exchanged.

For an interactive protocol (A, B), we write $(A(a), B(b))(x)$ to denote the random process obtained by having A and B interact on common input x, with (private) auxiliary inputs a and b to A and B, respectively (if any), and with independent

random coin tosses for A and B. We call (A, B) *polynomially bounded* if there is a polynomial p such that for all x, a, b, the total length of all messages exchanged in $(A(a), B(b))(x)$ is at most $p(|x|)$ with probability 1. Moreover, if B^* is any interactive algorithm, then A will immediately halt and reject in $(A(a), B^*(b))(x)$ if the total length of the messages ever exceeds $p(|x|)$; we have the analogous requirement for B interacting with any A^*.

The number of *rounds* in an execution of the protocol is the *total* number of messages exchanged between A and B, not including the final `accept`/`reject` message. We call the protocol (A, B) *public coin* if all the messages sent by B are simply the output of its coin tosses (independent of the history), except for the final `accept`/`reject` message, which is computed as a deterministic function of the transcript. (Such protocols are also sometimes known as *Arthur–Merlin games* [2].)

DEFINITION 2.16. *An interactive protocol (P, V) is an* interactive proof system *for a promise problem Π if there are functions $c, s : \mathbb{N} \to [0, 1]$ such that $1 - c(n) > s(n) + 1/\mathrm{poly}(n)$ and the following hold:*

- *(Efficiency) (P, V) is polynomially bounded, and V is computable in PPT.*
- *(Completeness) If $x \in \Pi_Y$, then V accepts in $(P, V)(x)$ with probability at least $1 - c(|x|)$.*
- *(Soundness) If $x \in \Pi_N$, then for every P^*, V accepts in $(P^*, V)(x)$ with probability at most $s(|x|)$.*

We call $c(\cdot)$ the completeness error *and $s(\cdot)$ the* soundness error. *We say that (P, V) has* negligible error *if both c and s are negligible. We say that it has* perfect completeness *if $c = 0$. We denote by* **IP** *the class of promise problems possessing interactive proof systems. We denote by* **AM** *the class of promise problems possessing two-round, public-coin interactive proof systems.*

AM is known to equal the class of promise problems possessing constant-round (possibly private-coin) interactive proof systems [36, 2].

We write $\langle A(a), B(b)\rangle(x)$ to denote B's view of the interaction, i.e., a transcript $(\gamma_1, \gamma_2, \ldots, \gamma_t; r)$, where the γ_i's are all the messages exchanged and r is B's coin tosses.

There are various notions of zero knowledge arising from different choices for the class of verifiers to be considered. The weakest is to consider only the "honest verifier," the one that follows the specified protocol.[7]

DEFINITION 2.17 (honest-verifier zero knowledge). *An interactive proof system (P, V) for a promise problem Π is* (perfect/statistical/computational) honest-verifier zero knowledge *if there exists a PPT* simulator S *such that the ensembles $\{\langle P, V\rangle(x)\}$ and $\{S(x)\}$ are (perfectly/statistically/computationally) indistinguishable on Π_Y.*[8] *We will often omit the word "computational" in reference to computational zero knowledge.*

HVPZK, **HVSZK**, *and* **HVZK** *denote the classes of promise problems that have honest-verifier perfect, statistical, and computational zero-knowledge proofs, respectively.*

While honest-verifier zero knowledge is already a nontrivial and interesting notion, cryptographic applications usually require that the zero-knowledge condition

[7] This is an instantiation of what is called an "honest-but-curious adversary" or "passive adversary" in the literature on cryptographic protocols.

[8] Actually, in the case of perfect zero knowledge, it is common to allow the simulator to output a failure symbol $\perp$ with some small probability (say, at most 1/2) and require that the output of $S(x)$ conditioned on nonfailure be identical to $\langle P, V\rangle(x)$ (cf. [23, Def. 4.3.1]). However, we define perfect zero knowledge only for the sake of context and will not use it anywhere else in the paper.

hold even if the verifier deviates arbitrarily from the specified protocol. This idea is captured by the following definition.

DEFINITION 2.18 (auxiliary-input zero knowledge).[9] *An interactive proof system* (P, V) *for a promise problem* Π *is (perfect/statistical/computational)* (auxiliary-input) zero knowledge *if for every PPT* V^* *and polynomial* p*, there exists a PPT* S *such that the ensembles*

$$\{\langle P, V^*(z)\rangle(x)\} \qquad \text{and} \qquad \{S(x,z)\} \tag{1}$$

are (perfectly/statistically/computationally) indistinguishable on the set

$$\{(x,z) : x \in \Pi_Y,\ |z| = p(|x|)\}.$$

PZK, **SZK**, *and* **ZK** *are the classes of promise problems possessing perfect, statistical, and computational (auxiliary-input) zero-knowledge proofs, respectively.*

The auxiliary input z in the above definition allows one to model a priori information that the verifier may possess before the interaction begins, such as from earlier steps in a larger protocol in which the zero-knowledge proof is being used or from prior executions of the same zero-knowledge proof. As a result, auxiliary-input zero knowledge is closed under sequential composition. That is, if an auxiliary-input zero-knowledge proof is repeated sequentially polynomially many times, then it remains auxiliary-input zero knowledge [30]. Plain zero knowledge (i.e., without auxiliary inputs) is not closed under sequential composition [27], and thus auxiliary-input zero knowledge is the definition typically used in the literature.

Typically, a protocol is proven to be zero knowledge by actually exhibiting a single, universal simulator that simulates an arbitrary verifier strategy V^* by using V^* as a subroutine. That is, the simulator does not depend on or use the code of V^* (or its auxiliary input) and instead requires only black-box access to V^*. This type of simulation is formalized as follows.

DEFINITION 2.19 (black-box zero knowledge). *An interactive proof system* (P, V) *for a promise problem* Π *is (perfect/statistical/computational)* black-box zero knowledge *if there exists an oracle PPT* S *such that for every nonuniform PPT* V^**, the ensembles*

$$\{\langle P, V^*\rangle(x)\}_{x\in\Pi_Y} \qquad \text{and} \qquad \{S^{V^*(x,\cdot,\cdot)}(x)\}_{x\in\Pi_Y}$$

are (perfectly/statistically/computationally) indistinguishable.

Even though the above definition does not explicitly refer to an auxiliary input, the definition encompasses auxiliary-input zero knowledge because we allow V^* to be nonuniform (and thus the auxiliary input can be hardwired in V^* as advice). The recent work of Barak [3] demonstrated that non–black-box zero-knowledge proofs can achieve properties (such as simultaneously being public coin, having a constant number of rounds, and having negligible error) that were known to be impossible for black-box zero knowledge [27]. Nevertheless, our results will show that, when ignoring

[9] Our formulation of auxiliary-input zero knowledge is slightly different than, but equivalent to, the definition in the textbook [23]. We allow V^* to run in polynomial time in the lengths of both its input x and its auxiliary input z, but put a polynomial bound on the length of the auxiliary input. In [23, sect. 4.3.3], V^* is restricted to run in time that is polynomial in just the length of the input x, and no bound is imposed on the length of the auxiliary input z (so V^* may only be able to read a prefix of z). The purpose of allowing the auxiliary input to be longer than the running time of z is to provide additional nonuniformity to the distinguisher (beyond that which the verifier has); we do this directly by allowing the distinguisher to be nonuniform in Definition 2.12.

efficiency considerations, black-box zero knowledge is as rich as standard, auxiliary-input zero knowledge; that is, every problem in **ZK** has a black-box zero-knowledge proof system.

Remarks on the definitions. Our definitions mostly follow the now standard definitions of zero-knowledge proofs as presented in [23], but we highlight the following points:

1. (Promise problems) As has been done numerous times before (see, e.g., [28, 52]), we extended all of the definitions to promise problems $\Pi = (\Pi_Y, \Pi_N)$ in the natural way; i.e., conditions previously required for inputs in the language (e.g., completeness and zero knowledge) are now required for all YES instances, and conditions previously required for inputs not in the language (e.g., soundness) are now required for all NO instances. Similarly, all our complexity classes (e.g., **ZK**, **SZK**, **HVZK**, **HVSZK**, **BPP**) are classes of promise problems. These extensions to promise problems are essential for formalizing our arguments, but all the final characterizations and results we derive about **ZK** automatically hold for the corresponding class of languages, simply because languages are special cases of promise problems.
2. (Nonuniform formulation) As has become standard, we have adopted a nonuniform formulation of zero knowledge, where the computational indistinguishability has to hold even with respect to nonuniform distinguishers and is universally quantified over all YES instances. Uniform treatments of zero knowledge are possible (see [21] and [4, Apdx. A]), but the definitions are much more cumbersome. We do not know whether analogues of our results hold for uniform zero knowledge, and thus we leave that as a problem for future work.
3. (Strict polynomial-time simulators) Following [23], we initially restrict our attention to zero knowledge with respect to simulators that run in *strict* polynomial time. The original definition of zero knowledge [35] allows for simulators that run in *expected* polynomial time. In section 7.3, we extend our techniques to zero knowledge with respect to expected polynomial-time simulators (in fact, an even weaker notion) and ultimately prove that the class of problems having zero-knowledge proofs with expected polynomial-time simulators and the class of problems having zero-knowledge proofs with strict polynomial-time simulators are equal.
4. (Proof systems versus arguments) We restrict our attention to the original notion of interactive *proof* systems [35, 2], where the soundness condition holds even for computationally unbounded prover strategies. A direction for future work is to consider the more relaxed notion of interactive *argument* systems [10], where the soundness condition is required only for polynomial-time prover strategies.
5. (Security parameterization) In the definition of computational indistinguishability (Definition 2.12), and consequently in the formulation of zero knowledge, computational indistinguishability is measured in terms of the input length, $|x|$. That is, only "long" statements can be proven with "high" security. An alternative, and perhaps more natural, formulation of zero knowledge (see [57, sect. 2.3]) measures indistinguishability in terms of a separate security parameter k, given to the prover, verifier, and simulator, and such that the protocol is allowed running time $\mathrm{poly}(|x|, k)$. We stick with the formulation in terms of the input length $|x|$ because it is the original and more commonly used definition. However, all of our results can be

extended to the security-parameterized definition via the observation that a security-parameterized zero-knowledge proof for a promise problem Π is equivalent to a (standard, non–security-parameterized) zero-knowledge proof for its "padded" version Π' defined by $\Pi'_Y = \{(x, 1^k) : x \in \Pi_Y,\ k \in \mathbb{N}\}$ and $\Pi'_N = \{(x, 1^k) : x \in \Pi_N,\ k \in \mathbb{N}\}$. For example, our result that $\mathbf{HVZK} = \mathbf{ZK}$ implies that the security-parameterized versions of these classes are also equal: for any promise problem Π having a security-parameterized honest-verifier zero-knowledge proof, we have $\Pi' \in \mathbf{HVZK} = \mathbf{ZK}$, which implies that Π has a security-parameterized (cheating-verifier) zero-knowledge proof. Note that we are not claiming that every problem in **ZK** has a security-parameterized zero-knowledge proof. (In contrast, it was shown in [52] that every problem in **SZK** has a security-parameterized statistical zero-knowledge proof.)

6. (Closure under reductions) All of the zero-knowledge classes defined above, in particular **HVZK** and **ZK**, are easily seen to be closed under *nonshrinking* reductions f (i.e., ones where $|f(x)| \geq |x|^{\Omega(1)}$): If f reduces Π to $\Gamma \in \mathbf{ZK}$, we can obtain a zero-knowledge proof for Π by having the prover and verifier on input x execute the zero-knowledge proof for Γ on $f(x)$. The nonshrinking condition is needed because the security of the zero-knowledge proof for Γ is measured as a function of $|f(x)|$, and we need to relate it to security in terms of $|x|$. The nonshrinking condition is unnecessary if one works with a security-parameterized definition of zero-knowledge proofs, as in item 5 above (cf. [57, Prop. 2.4.1]).

3. From HVZK to the SZK/OWF Condition. In this section, we prove that every problem in **HVZK** satisfies the SZK/OWF Condition.

A first attempt. To show that every $\Pi \in \mathbf{HVZK}$ satisfies the SZK/OWF Condition, it is tempting to take the following approach. Consider the (honest-verifier) simulator for Π's computational zero-knowledge proof system. Let I be the set of inputs $x \in \Pi_Y$ for which the simulator's output is statistically far from the verifier's view. When we ignore the inputs in I, we have an (honest-verifier) statistical zero-knowledge proof system. On inputs in I, the output of the simulator and the verifier's view are statistically far apart but computationally indistinguishable. Goldreich [20] has shown that from any two samplable distributions that are statistically far apart but computationally indistinguishable, we can construct a one-way function.

This approach has two difficulties:

- What threshold of statistical difference should we use to partition the inputs in Π_Y? The result of Goldreich requires a statistical difference of at least $1/p(n)$ for any fixed polynomial $p(n)$, but the definition of statistical zero knowledge requires negligible statistical difference $1/n^{\omega(1)}$.
- The result of Goldreich [20] requires that both distributions be (polynomial-time) *samplable*, but the verifier's view of the real interaction with the prover will typically not be samplable. Moreover, if we require only one of the two distributions in Goldreich's hypothesis to be samplable, then it is unlikely to imply one-way functions. Indeed, it has been proven unconditionally that the uniform distribution on $\{0,1\}^n$ (which is trivially samplable) is computationally indistinguishable from some (nonsamplable) distributions that are statistically very far from uniform (indeed have entropy polylog(n)) [26].

The first difficulty can be overcome using known results about **SZK**. Specifically, in [34] it is shown that if a problem Π has an interactive proof system that can be simulated to within a statistical difference of $1/p(n)$ for a sufficiently large (but fixed)

polynomial p (e.g., the cube of the communication complexity), then $\Pi \in \mathbf{SZK}$.

For the second difficulty, we use the fact that a samplable distribution that is computationally indistinguishable from an arbitrary (possibly nonsamplable) distribution of noticeably *higher entropy* does imply one-way functions [37]. This leads us to look for "high-entropy" distributions in the real prover-verifier interaction. We find such distributions using the techniques of [1, 51, 34]. This approach leads us to establish two other characterizations of **ZK** en route to the SZK/OWF Condition. These characterizations are computational analogues of the complete problems for **SZK**, and may be of independent interest.

3.1. Analogues of the SZK-complete problems. We establish two characterizations of **ZK** that are related to the complete problems for **SZK**, so we begin by recalling those.

The complete problems for **SZK**. The first problem is Statistical Difference, the promise problem $\mathrm{SD} = (\mathrm{SD}_Y, \mathrm{SD}_N)$ defined by

$$\mathrm{SD}_Y = \{(X,Y) : \Delta(X,Y) \leq 1/3\},$$
$$\mathrm{SD}_N = \{(X,Y) : \Delta(X,Y) \geq 2/3\},$$

where X and Y are samplable distributions specified by circuits that sample from them, and $\Delta(X,Y)$ denotes statistical difference. (See sections 2.1 and 2.2.)

The second problem is Entropy Difference, the promise problem $\mathrm{ED} = (\mathrm{ED}_Y, \mathrm{ED}_N)$ defined by

$$\mathrm{ED}_Y = \{(X,Y) : \mathrm{H}(X) \geq \mathrm{H}(Y) + 1\},$$
$$\mathrm{ED}_N = \{(X,Y) : \mathrm{H}(X) \leq \mathrm{H}(Y) - 1\},$$

where $\mathrm{H}(\cdot)$ denotes the entropy function (see section 2.2).

The completeness theorems of [52, 34] can be stated as follows.

Theorem 3.1 (see [52, 34]). Statistical Difference *and* Entropy Difference *are complete for* **SZK**. *That is, they are both in* **SZK**, *and for every problem* $\Pi \in \mathbf{SZK}$, *there is a polynomial-time computable function mapping strings* x *to pairs of samplable distributions* (X,Y) *such that*

- *if* $x \in \Pi_Y$, *then* $\Delta(X,Y) \leq 1/3$;
- *if* $x \in \Pi_N$, *then* $\Delta(X,Y) \geq 2/3$,

Analogous points hold for Entropy Difference.

Note that the result that **SZK** is closed under complement [48] follows from the fact that Entropy Difference trivially reduces to its complement (via the reduction $(X,Y) \mapsto (Y,X)$).

It turns out that, for obtaining **ZK** analogues of this completeness theorem, it is crucial that we do not work with Entropy Difference, but with a variant, Conditional Entropy Approximation (CEA), defined as follows:

$$\mathrm{CEA}_Y = \{((X,Y),r) : \mathrm{H}(X|Y) \geq r\},$$
$$\mathrm{CEA}_N = \{((X,Y),r) : \mathrm{H}(X|Y) \leq r - 1\}.$$

Here (X,Y) is a *samplable joint distribution* specified by two circuits that use the same coin tosses.

Proposition 3.2. Conditional Entropy Approximation *is complete for* **SZK**.

Proof. To show that CONDITIONAL ENTROPY APPROXIMATION is in **SZK**, we reduce it to ENTROPY DIFFERENCE. Given an instance $((X,Y),r)$ of CEA, we define $X' = \otimes^2(X,Y)$, $Y' = (\otimes^2 Y) \otimes U_{2r-1}$. Then

$$\mathrm{H}(X') - \mathrm{H}(Y') = 2 \cdot \mathrm{H}(X,Y) - (2 \cdot \mathrm{H}(Y) + (2r-1)) = 2 \cdot (\mathrm{H}(X|Y) - r) + 1.$$

It follows that $((X,Y),r) \in \mathrm{CEA}_Y \Rightarrow (X',Y') \in \mathrm{ED}_Y$ and $((X,Y),r) \in \mathrm{CEA}_N \Rightarrow (X',Y') \in \mathrm{ED}_N$.

To show that CEA is **SZK**-hard, we provide a reduction from SD to CEA, based on the reduction from SD to ED given in [57, sect. 4.4]. Given an instance (X_0, X_1) of SD, we construct the following samplable joint distribution:

$$(B,Y)\text{: Select } b \leftarrow \{0,1\}. \text{ Sample } x \leftarrow X_b. \text{ Output } (b,x).$$

Intuitively, both $\mathrm{H}(B|Y)$ and $\Delta(X_0,X_1)$ measure how well B can be predicted from $Y = X_B$. Indeed, it is shown in [57, Claim 4.4.2] that $1-\delta \le \mathrm{H}(B|Y) \le \mathrm{H}_2((1-\delta)/2)$, where $\delta = \Delta(X_0,X_1)$. Plugging in $\delta = 1/3$ and $\delta = 2/3$, we see that

$$\begin{aligned}(X_0,X_1) \in \mathrm{SD}_Y &\Rightarrow \mathrm{H}(B|Y) \ge 1 - 1/3 = 2/3,\\ (X_0,X_1) \in \mathrm{SD}_N &\Rightarrow \mathrm{H}(B|Y) \le \mathrm{H}_2((1-2/3)/2) < .651.\end{aligned}$$

Now we amplify the gap to more than one bit by taking direct products. Specifically, let $(B',Y') = ((B_1,\ldots,B_{66}),(Y_1,\ldots,Y_{66}))$, where the (B_i,Y_i)'s are independent copies of (B,Y). Then

$$\begin{aligned}(X_0,X_1) \in \mathrm{SD}_Y &\Rightarrow \mathrm{H}(B'|Y') \ge 66 \cdot (2/3) = 44,\\ (X_0,X_1) \in \mathrm{SD}_N &\Rightarrow \mathrm{H}(B'|Y') < 66 \cdot .651 < 43.\end{aligned}$$

So $(X_0,X_1) \mapsto ((B',Y'),44)$ is a valid reduction from SD to CEA. ∎

We note that the unconditional version of CEA (where Y is not present and we consider only $\mathrm{H}(X)$), called ENTROPY APPROXIMATION, is known to be complete for *noninteractive* statistical zero knowledge [33].

Analogous characterizations of **ZK**. We present analogous characterizations of **ZK**, albeit not in terms of complete problems.

DEFINITION 3.3. *A promise problem* Π *satisfies the* INDISTINGUISHABILITY CONDITION *if there is a polynomial-time computable function mapping strings* x *to pairs of samplable distributions* (X,Y) *such that*

- *if* $x \in \Pi_Y$*, then* X *and* Y *are computationally indistinguishable (in the sense of Definition* 2.12*);*
- *if* $x \in \Pi_N$*, then* $\Delta(X,Y) \ge 2/3$.

We note that the constant $2/3$ in the second bullet is arbitrary. By taking direct products and applying Lemmas 2.3 and 2.13, we can boost a threshold as low as $1/\mathrm{poly}(n)$ to as high as $1 - 2^{-\mathrm{poly}(n)}$, while preserving the computational indistinguishability in the first bullet.

Like the SZK/OWF CONDITION, if one-way functions exist, then every promise problem satisfies the INDISTINGUISHABILITY CONDITION: On an input x of length n, we can define $X = G(U_n)$ and $Y = U_{2n}$, where G is a length-doubling pseudorandom generator, and then X and Y are both computationally indistinguishable and have large statistical difference. Thus, as before, to obtain a characterization of **ZK**, we need to add the condition $\Pi \in \mathbf{IP}$.

THEOREM 3.4 (indistinguishability characterization of **ZK**). $\Pi \in \mathbf{ZK}$ *if and only if* $\Pi \in \mathbf{IP}$ *and* Π *satisfies the* INDISTINGUISHABILITY CONDITION.

The preceding example, showing that every promise problem satisfies the Indistinguishability Condition if one-way functions exist, also illustrates why Π satisfying the Indistinguishability Condition cannot be cast as a reduction from Π to some promise problem—the conditions for YES instances and NO instances may hold at the same time. Nevertheless, we expect that the indistinguishability characterization of **ZK** will have much the same utility as a complete problem (such as Statistical Difference). Indeed, several of the results about **ZK** presented in section 7 can be established simply by taking the corresponding proof for **SZK** and replacing Statistical Difference with the Indistinguishability Condition. However, we instead choose to use the results for **SZK** as a "black box," and reduce the **ZK** case to the **SZK** case via the SZK/OWF characterization.

In [52], it was already proven that every problem that has a *public-coin* computational zero-knowledge proof satisfies the Indistinguishability Condition. Thus, what is new here is showing that the characterization *holds even for private-coin proofs* and *establishing a converse* (for $\Pi \in \mathbf{IP}$).

A characterization analogous to Conditional Entropy Approximation follows.

Definition 3.5. *A promise problem* Π *satisfies the* Conditional Pseudoentropy Condition *if there is a polynomial-time computable function mapping strings* x *to a* samplable joint distribution (X, Y) *(i.e., two circuits that use the same coin tosses) and a parameter* r *such that*

- *if* $x \in \Pi_Y$*, then there exists a (not necessarily samplable) joint distribution* (X', Y') *such that* (X', Y') *is computationally indistinguishable from* (X, Y) *and* $\mathrm{H}(X'|Y') \geq r$*, and*
- *if* $x \in \Pi_N$*, then* $\mathrm{H}(X|Y) \leq r - 1$*,*

where $\mathrm{H}(\cdot|\cdot)$ *denotes conditional entropy. (See section* 2.2*.)*

As before, this definition is satisfied by all promise problems if one-way functions exist. It is crucial that we generalize Conditional Entropy Approximation instead of Entropy Difference. Indeed, in [57] we pointed out that the condition analogous to Entropy Difference, using $\mathrm{H}(X) - \mathrm{H}(Y)$ instead of $\mathrm{H}(X|Y)$, is satisfied by *all* promise problems (regardless of whether or not one-way functions exist) and thus is useless.[10] (At the time, we saw this as an obstacle to finding **ZK** analogues of the complete problems for **SZK**.) Our use of conditional entropy was inspired in part by its role in the conjectures of [4, sect. 9].

Theorem 3.6 (conditional pseudoentropy characterization of **ZK**). $\Pi \in \mathbf{ZK}$ *if and only if* $\Pi \in \mathbf{IP}$ *and* Π *satisfies the* Conditional Pseudoentropy Condition.

Note that, in contrast to the **SZK**-completeness of Entropy Difference, this theorem does not seem to imply that **ZK** is closed under complement. The reason is that the Conditional Pseudoentropy Condition is not symmetric with respect to YES and NO instances.

Overview of the proofs of Theorems 1.2*,* 3.6*, and* 3.4. In the remainder of this section, we show that every promise problem in **HVZK** satisfies the Conditional Pseudoentropy Condition, that the Conditional Pseudoentropy Condition is equivalent to the Indistinguishability Condition, and that every promise problem

[10] The reason comes from the fact that we do not require X' and Y' above to be samplable. It is known (via the probabilistic method) that there exists a (nonsamplable) distribution D of low entropy (e.g., $n/2$) that is indistinguishable from the uniform distribution U_n [26]. Thus, if the above characterization referred to $\mathrm{H}(X) - \mathrm{H}(Y)$, then it would hold for all promise problems by setting $X = Y = X' = U_n$, $Y' = D$, and $r = 1$ so that $\mathrm{H}(X') - \mathrm{H}(Y') \geq n/2 \geq r$ and $\mathrm{H}(X) - \mathrm{H}(Y) = 0 = r - 1$.

satisfying the CONDITIONAL PSEUDOENTROPY CONDITION satisfies the SZK/OWF CONDITION. This establishes the forward ("only if") directions of Theorems 1.2, 3.6, and 3.4. The reverse directions, showing that problems in **IP** satisfying the characterizations are in **ZK**, follow from our results in sections 4 and 5. Section 6 puts everything together and formally deduces the theorems.

3.2. The CONDITIONAL PSEUDOENTROPY CONDITION.

LEMMA 3.7. *If a promise problem* Π *is in* **HVZK**, *then* Π *satisfies the* CONDITIONAL PSEUDOENTROPY CONDITION.

Proof. The proof is an adaptation of the reduction from **HVZK** to ENTROPY DIFFERENCE in [34]. Let (P, V) be an honest-verifier computational zero-knowledge proof for Π, with simulator S. We modify the proof system to satisfy the following (standard) additional properties:

- The completeness error $c(|x|)$ and soundness error $s(|x|)$ are both negligible. This can be achieved by standard error reduction via (sequential) repetition.
- On every input x, the two parties exchange $2\ell(|x|)$ messages for some polynomial ℓ, with the verifier sending even-numbered messages and sending all its $r(|x|) \geq |x|$ random coin tosses in the last message. Having the verifier send its coin tosses at the end does not affect soundness because it is after the prover's last message and does not affect honest-verifier zero knowledge because the simulator is required to simulate the verifier's coin tosses.
- On every input x, the simulator always outputs *accepting transcripts*, where we call a sequence γ of 2ℓ messages an accepting transcript on x if all the verifier's messages are consistent with its coin tosses (as specified in the last message) and the verifier accepts in such an interaction. To achieve this, we first modify the proof system so that the verifier always accepts if its coin tosses are $0^{r(|x|)}$; this increases the soundness error only negligibly. Then we modify the simulator so that any time it is about to output a nonaccepting transcript, it instead outputs the accepting transcript where all of the prover messages are the empty string and the verifier's coin tosses are $0^{r(|x|)}$. This has a negligible effect on the quality of the simulation because when $x \in \Pi_Y$, the original simulator can only output nonaccepting transcripts with negligible probability (otherwise its output could easily be distinguished from the real interaction, which has nonaccepting transcripts with probability at most $c(|x|) = \mathrm{neg}(|x|)$).

For a transcript γ, we denote by γ_i the *prefix* of γ consisting of the first i messages. For readability, we often drop the input x from the notation, e.g., using $\ell = \ell(|x|)$, $\langle P, V\rangle = \langle P, V\rangle(x)$, etc. Thus, in what follows, $\langle P, V\rangle_i$ and S_i are random variables representing prefixes of transcripts generated by the real interaction and simulator, respectively, on a specified input x.

The following two claims are shown in [1, 51, 34].

CLAIM 3.8. *For every* x,

$$\sum_{i=1}^{\ell} [\mathrm{H}(\langle P, V\rangle_{2i}) - \mathrm{H}(\langle P, V\rangle_{2i-1})] = r.$$

Since $\langle P, V\rangle_{2i-1}$ is a prefix of $\langle P, V\rangle_{2i}$, the term $\mathrm{H}(\langle P, V\rangle_{2i}) - \mathrm{H}(\langle P, V\rangle_{2i-1})$ in the sum equals the conditional entropy $\mathrm{H}(\langle P, V\rangle_{2i} | \langle P, V\rangle_{2i-1})$. Thus, the sum measures the total entropy contributed by the verifier's messages, and it is natural that this should equal the number of coin tosses of the verifier. (Recall that the verifier reveals its coin tosses at the end.)

What is less obvious is that the sum should be significantly smaller when we consider the simulated transcripts for $x \in \Pi_N$ (rather than for $x \in \Pi_Y$).

CLAIM 3.9. *For every $x \in \Pi_N$,*

$$\sum_{i=1}^{\ell} [\mathrm{H}(S_{2i}) - \mathrm{H}(S_{2i-1})] \leq r - \log \frac{1}{s(|x|)} < r - 1.$$

It may seem strange to consider the simulator's output distribution on NO instances, since the zero-knowledge condition does not provide any guarantees about the quality of simulation on NO instances. Indeed, Claim 3.9 is not derived from the zero-knowledge property of the proof system. Rather, it is based on the *soundness* of the proof system and the fact that the simulator always produces accepting transcripts (by our modification above). Intuitively, it says that the simulation captures at most an $s(|x|)$ fraction of the probability space of the verifier's messages. Indeed, it is shown in [1, 51, 34] that if this were not the case, then the simulator could be used to construct a prover strategy that convinces the verifier to accept with probability greater than $s(|x|)$, contradicting the soundness of the proof system. Now, given input x, we construct circuits that sample from the following (joint) random variables:

(X, Y): Select $i \leftarrow \{1, \ldots, \ell(|x|)\}$, choose random coin tosses R for the simulator, and output $(S_{2i}(x; R), S_{2i-1}(x; R))$.

When $x \in \Pi_Y$, then S is computationally indistinguishable from $\langle P, V\rangle$. So (X, Y) is indistinguishable from $(X', Y') = (\langle P, V\rangle_{2I}, \langle P, V\rangle_{2I-1})$, where I denotes a uniform random element of $\{1, \ldots, \ell\}$. By Claim 3.8, we have

$$\mathrm{H}(X'|Y') = \frac{1}{\ell} \sum_{i=1}^{\ell} \mathrm{H}(\langle P, V\rangle_{2i} | \langle P, V\rangle_{2i-1}) = \frac{r}{\ell}.$$

When $x \in \Pi_N$, then by Claim 3.9, we have

$$\mathrm{H}(X|Y) = \frac{1}{\ell} \sum_{i=1}^{\ell} \mathrm{H}(S_{2i}|S_{2i-1}) \leq \frac{r-1}{\ell}.$$

This is what we need to prove, except the entropy gap is only $1/\ell$. This can be increased to 1 by taking ℓ independent samples from the joint distribution. That is, we define $(\overline{X}, \overline{Y}) = ((X_1, \ldots, X_\ell), (Y_1, \ldots, Y_\ell))$, where the (X_i, Y_i)'s are independent copies of (X, Y). When $x \in \Pi_Y$, then $(\overline{X}, \overline{Y})$ is computationally indistinguishable from the analogously defined $(\overline{X'}, \overline{Y'})$, and $\mathrm{H}(\overline{X'}|\overline{Y'}) = \ell \cdot \mathrm{H}(X'|Y') = r$. Also, when $x \in \Pi_N$, then $\mathrm{H}(\overline{X}|\overline{Y}) = \ell \cdot \mathrm{H}(X|Y) \leq r - 1$.

Therefore the mapping $x \mapsto ((\overline{X}, \overline{Y}), r)$ satisfies Definition 3.5. ∎

3.3. The SZK/OWF CONDITION. In this section, we show that the CONDITIONAL PSEUDOENTROPY CONDITION implies the SZK/OWF CONDITION.

LEMMA 3.10. *If a promise problem satisfies the* CONDITIONAL PSEUDOENTROPY CONDITION*, then it also satisfies the* SZK/OWF CONDITION.

The idea behind the proof is the following. If Π satisfies the CONDITIONAL PSEUDOENTROPY CONDITION, then on every YES instance, we obtain a samplable distribution (X, Y) that is computationally indistinguishable from (X', Y'), where $\mathrm{H}(X'|Y')$ is large. We consider two cases. If, for the original distributions X and Y, we have

that $\mathrm{H}(X|Y)$ is large, then the instance is information-theoretically distinguishable from a NO instance (where $\mathrm{H}(X|Y)$ is small), and such instances can be reduced to CONDITIONAL ENTROPY APPROXIMATION, which is complete for **SZK** by Proposition 3.2. If instead $\mathrm{H}(X|Y)$ is small, then (X, Y) is computationally indistinguishable from a joint distribution with higher conditional entropy (namely, (X', Y')). From such a pair, we can construct a one-way function using the techniques of Håstad et al. [37]. This case analysis provides the partition of YES instances into **SZK** instances and OWF instances.

Before proceeding with the actual proof, we state the result we need from [37], adapted to our auxiliary-input setting.

DEFINITION 3.11. *An* auxiliary-input false entropy generator on I *is a samplable auxiliary-input probability ensemble* $\mathcal{D} = \{D_x\}$ *for which there exists a samplable auxiliary-input probability ensemble* $\mathcal{F} = \{F_x\}$ *that is computationally indistinguishable from* $\mathcal{D}$ *on* I *and satisfies* $\mathrm{H}(F_x) \geq \mathrm{H}(D_x) + 1$ *for all* $x \in I$.

Note that the above definition refers to entropy, rather than conditional entropy as in the intuition above. We will need to cope with this in the proof. Also note that the definition requires that $\mathcal{F} = \{F_x\}$ is also samplable. This is actually not necessary (i.e., Lemma 3.12 below holds regardless), but we will achieve samplability of $\mathcal{F}$ in passing from conditional entropy to entropy, so we include the samplability condition for consistency with [37].[11]

LEMMA 3.12 (see [37]; cf. our Appendix B). *If there exists an auxiliary-input false entropy generator on* I*, then there exists an auxiliary-input one-way function on* I.

Håstad et al. [37] actually show how to construct pseudorandom generators, rather than just one-way functions, but we need only a one-way function to establish the SZK/OWF CONDITION. This allows some steps in the construction to be omitted; see Appendix B for a proof of Lemma 3.12 (and a generalization, which we use to handle expected polynomial-time simulators in section 7.3).

Proof of Lemma 3.10. Given an instance x of the promise problem Π, we can efficiently construct two samplable distributions (X, Y) and parameter r such that if $x \in \Pi_Y$, then $\mathrm{H}(X'|Y') \geq r + 1$ for some (X', Y') indistinguishable from (X, Y), and if $x \in \Pi_N$, then $\mathrm{H}(X|Y) \leq r - 1$. (We may assume a gap of 2 rather than 1 by taking multiple independent samples from the joint distribution.)

Let I be the set of instances $x \in \Pi_Y$ such that $\mathrm{H}(X|Y) < r$. First, we show that $\Pi' = (\Pi_Y \setminus I, \Pi_N)$ is in **SZK**. We prove this by reducing Π' to CONDITIONAL ENTROPY APPROXIMATION. Indeed, the reduction is simply $x \mapsto ((X, Y), r + 1)$. Then $\mathrm{H}(X|Y) \geq r$ when $x \in \Pi_Y \setminus I$, and $\mathrm{H}(X|Y) \leq r - 1$ when $x \in \Pi_N$, as needed.

Now we show that we can construct a one-way function from instances $x \in I$. Intuitively, the facts that $\mathrm{H}(X'|Y') \geq r + 1$ and that (X', Y') is indistinguishable from (X, Y) mean we should be able to extract $r+1$ *pseudorandom* bits from X given Y. That is, if we let H be a random hash function mapping to $r + 1$ bits, then the distribution $(H, Y, H(X))$ is computationally indistinguishable from $(H, Y', H(X'))$, which we might hope to be statistically close to (H, Y', U_{r+1}) (because $\mathrm{H}(X'|Y') \geq r+1$), which in turn is computationally indistinguishable from (H, Y, U_{r+1}). However, the entropy of $(H, Y, H(X))$ equals $\mathrm{H}(H)+\mathrm{H}(Y)+\mathrm{H}(X|Y) < \mathrm{H}(H)+\mathrm{H}(Y)+r$, which is one bit less than the entropy of (H, Y, U_{r+1}). So, if this argument worked, then

[11] The samplability of $\mathcal{F}$ is needed only in [37] for proving results with respect to *uniform* adversaries. Indeed, the condition was not included in the conference version [38], which dealt only with nonuniform adversaries.

$(H, Y, H(X))$ would be a false entropy generator.

However, there are two (standard) difficulties in implementing this intuition. First, entropy (much less conditional entropy) is not a strong enough measure of randomness to allow extracting almost-uniform bits. (That is, it is not guaranteed that $(H, Y', H(X'))$ is statistically close to (H, Y', U_{r+1}).) Instead, we need a lower bound on (conditional) *min-entropy*, as required in the leftover hash lemma (Lemma 2.7). Second, randomness extraction (e.g., as provided by the leftover hash lemma) does not extract all the bits of min-entropy, but rather suffers an entropy loss related to the distance ε desired from uniform in the extracted bits. So we need a larger gap than one bit of entropy to tolerate this loss and still obtain a false entropy generator. Both of these difficulties are solved by taking direct products, i.e., many independent samples of (X, Y). Taking a direct product has the effect of both (linearly) growing the entropy gap and converting entropy to min-entropy (with a sublinearly loss in entropy, as shown by the flattening lemma, Lemma 2.6).

We now proceed with the formal details. Let $n = |x|$, let m be the number of bits output by X, set $k = 4n \cdot (m+n)^2$, and let $\mathcal{H}$ be an explicit family of universal hash functions mapping $\{0,1\}^{km}$ to $\{0,1\}^{kr+1}$. Let $s = O(km)$ be the number of random bits to choose a random hash function from $\mathcal{H}$. Consider the samplable distribution

$$D = (H, Y_1, \ldots, Y_k, H(X_1, \ldots, X_k)),$$

where H is a random hash function from $\mathcal{H}$, and the (X_i, Y_i)'s are independent copies of (X, Y). When $x \in I$, we have $\mathrm{H}(D) \leq s + k \cdot \mathrm{H}(Y) + k \cdot r$. On the other hand, we will show below that D is computationally indistinguishable from the samplable distribution

$$F = (H, Y_1, \ldots, Y_k, U_{kr+1}),$$

which has entropy $s + k \cdot \mathrm{H}(Y) + (kr+1)$, which in turn is one bit larger than the entropy of D. Thus, we have constructed an auxiliary-input false entropy generator on I, and thus by Lemma 3.12 there exists a one-way function on I, as desired.

We now proceed to show that when $x \in \Pi_Y$, D is computationally indistinguishable from F. We know that there exist (X', Y') indistinguishable from (X, Y) such that $\mathrm{H}(X'|Y') \geq r+1$. By Lemma 2.2, we can modify (X', Y') to obtain (X^*, Y^*) indistinguishable from (X, Y) such that $\mathrm{H}(X^*|Y^*) \geq r+1$ and $\Pr[X^* = x | Y^* = y] \geq 2^{-n} \cdot 2^{-m}$ for all $(x, y) \in \mathrm{Supp}(X^*, Y^*)$.

By a hybrid argument (Lemma 2.13), D and F are computationally indistinguishable from

$$D^* = (H, Y_1^*, \ldots, Y_k^*, H(X_1^*, \ldots, X_k^*))$$

and

$$F^* = (H, Y_1^*, \ldots, Y_k^*, U_{kr+1}),$$

respectively, where the (X_i^*, Y_i^*)'s are independent copies of (X^*, Y^*).

Now we proceed to show that D^* is statistically indistinguishable from F^*, which will complete the proof. By Lemma 2.6, $\overline{X^*} = (X_1^*, \ldots, X_k^*)$ is Φ-flat given $\overline{Y^*} = (Y_1^*, \ldots, Y_k^*)$ for $\Phi = \sqrt{k} \cdot (m+n)$. This implies that $(\overline{X^*}, \overline{Y^*})$ is (2^{-n})-close to some $(W, \overline{Y^*})$ such that for every $\overline{y} \in \mathrm{Supp}(\overline{Y^*})$, the min-entropy of W conditioned on $\overline{Y^*} = \overline{y}$ is at least

$$\begin{aligned} k \cdot \mathrm{H}(X^*|Y^*) - \sqrt{n} \cdot \Phi &\geq k \cdot (r+1) - \sqrt{n} \cdot \Phi \\ &> kr + 2n + 1, \end{aligned}$$

where in the last inequality we use $\sqrt{n}\Phi \leq k/2$ and $2n+1 \leq k/2$.

Thus, D^* is statistically close to the distribution $(H, \overline{Y^*}, H(W))$, which is (2^{-n})-close to $(H, \overline{Y^*}, U_{kr+1}) = F^*$ by the leftover hash lemma (Lemma 2.7). This completes the proof. □

3.4. The Indistinguishability Condition. In this section, we show that the Indistinguishability Condition is equivalent to the Conditional Pseudoentropy Condition, and is thus satisfied by every problem in **HVZK**. This equivalence is proven using computational analogues of the reductions given in [57, sects. 3.4 and 4.4] between the complete problems for **SZK**. We note that the results of this section are not used later in the paper, except of course to establish the indistinguishability characterization of **ZK** (Theorem 3.4); they are included because this characterization may be of independent interest and may be of use in further studies of **ZK**.

Lemma 3.13. *If a promise problem satisfies the* Conditional Pseudoentropy Condition*, then it satisfies the* Indistinguishability Condition.

Proof. The reduction is identical to the one used in the proof of Lemma 3.10 to construct a pseudoentropy generator on the instances in I. Let Π be a promise problem satisfying the Conditional Pseudoentropy Condition. As in the proof of Lemma 3.10, given an instance x of the promise problem Π, we can efficiently construct two samplable distributions (X, Y) and parameter r such that if $x \in \Pi_Y$, then $\mathrm{H}(X'|Y') \geq r+1$ for some (X', Y') indistinguishable from (X, Y), and if $x \in \Pi_N$, then $\mathrm{H}(X|Y) \leq r-1$. From X and Y, we can construct the samplable distributions D and F as in the proof of Lemma 3.10. In that proof, it is shown that when $x \in \Pi_Y$, then D and F are computationally indistinguishable. It is also shown that when $\mathrm{H}(X|Y) < r$ (in particular if $x \in \Pi_N$), then $\mathrm{H}(F) \geq \mathrm{H}(D) + 1$. By Lemma 2.1, this implies that $\Delta(D, F) \geq 1/2\ell$, where $\ell = \mathrm{poly}(n)$ is the number of bits output by D and F. Applying Lemmas 2.3 and 2.13, we can increase the statistical difference to $2/3$ on NO instances while maintaining computationally indistinguishability on YES instances. Thus, we conclude that Π satisfies the Indistinguishability Condition. □

Lemma 3.14. *If a promise problem satisfies the* Indistinguishability Condition*, then it satisfies the* Conditional Pseudoentropy Condition.

Proof. This is proved in the same way that we reduced Statistical Difference to Conditional Entropy Approximation in the proof of Proposition 3.2. Let Π be a promise problem satisfying the Indistinguishability Condition. This means that given an instance x of Π, we can efficiently construct two samplable distributions (X_0, X_1) such that X_0 and X_1 are computationally indistinguishable if $x \in \Pi_Y$ and such that $\Delta(X_0, X_1) \geq 2/3$ if $x \in \Pi_N$. Consider the following pair of jointly distributed random variables:

$$(B, Y): \quad \text{Select } b \leftarrow \{0,1\}. \ \text{Sample } x \leftarrow X_b. \ \text{Output } (b, x).$$

When $x \in \Pi_Y$, the distributions X_0 and X_1 are computationally indistinguishable. This implies that (B, Y) is computationally indistinguishable from (B', Y), where B' is a random bit independent of Y. Note that $\mathrm{H}(B'|Y) = 1$.

When $x \in \Pi_N$, it holds that $\Delta(X_0, X_1) \geq 2/3$. Then, as in the proof of Proposition 3.2, we have $\mathrm{H}(B|Y) < .651 < 2/3$.

Thus, the mapping $x \mapsto (B, Y), r = 1$ meets the requirements of the Conditional Pseudoentropy Condition, except that the gap in conditional entropies between the two cases is only $1 - 2/3 = 1/3$ bits. The gap can be amplified to one bit by taking direct products in the usual manner. □

4. From the SZK/OWF Condition to ZK. In this section, we construct a computational zero-knowledge proof system for every problem Π in **IP** that satisfies the SZK/OWF Condition. A first approach is for the prover to use the **SZK** proof system, when the input is in $\Pi_Y \setminus I$, and to use the proof system obtained by the generic, one-way-function-based compiler from **IP** to **ZK** [39, 7] when the input is in I. The difficulty with this is that the set I may not be efficiently recognizable, so this approach leaks information to the verifier (namely, whether or not the input is in I). Because of this difficulty, we take a more indirect approach. Instead of trying to construct separate zero-knowledge proofs for the "**SZK** instances" and the "OWF instances" and then combining them, we construct a certain type of bit-commitment scheme in each of the two cases. The advantage is that the commitment schemes are easy to combine (via simple secret sharing). We then use the combined commitment scheme in the generic compiler from **IP** to **ZK** [39, 7].

4.1. Instance-dependent commitments. Recall that a *commitment scheme* is a two-phase protocol between a sender and a receiver. In the first phase, called the *commit phase*, the sender "commits" to a private bit b. In the second phase, called the *reveal phase*, the sender reveals b and "proves" that it was the bit to which she committed in the first phase. We require two properties of commitment schemes. The *hiding* property says that the receiver learns nothing about m in the first phase. The *binding* property says that after the commit phase, the sender is bound to a particular value of m; that is, she cannot successfully open the commitment to two different messages in the reveal phase. It is impossible to have commitment schemes that are both statistically hiding and statistically binding, but it is known how to construct commitment schemes that are computationally hiding and statistically binding, assuming one-way functions exist [45, 37]. In fact, this is the only way that one-way functions are used in the construction of computational zero-knowledge proofs for all of **IP** [29, 39, 7] and all the resulting theorems about **ZK** that rely on the assumption that one-way functions exist.

In this section, we will show how to use the fact that a promise problem Π satisfies the SZK/OWF Condition to construct a relaxed form of commitment scheme, tailored to Π, that still suffices for obtaining a zero-knowledge proof for Π. Specifically, we will construct an *instance-dependent commitment scheme* for Π. This is an auxiliary-input version of a commitment protocol, where the auxiliary input x (given to both the sender and receiver) is viewed as an instance of the promise problem Π. It is required that the scheme is hiding when $x \in \Pi_Y$ and is binding when $x \in \Pi_N$. Thus, they are a relaxation of standard commitment schemes, since we do not require that the hiding and binding properties hold at the same time. Nevertheless, this relaxation is still useful in constructing zero-knowledge proofs. The reason is that zero-knowledge proofs based on commitments (in, e.g., [29, 39, 7]) typically use only the hiding property in proving zero knowledge (which is required only when x is a YES instance) and use only the binding property in proving soundness (which is required only when x is a NO instance).

An example, used in Bellare, Micali, and Ostrovsky [6], is based on the Graph Isomorphism problem: Given graphs (G_0, G_1), a commitment to bit $b \in \{0,1\}$ is a random isomorphic copy of G_b. When $G_0 \cong G_1$, the commitment is perfectly hiding, and when $G_0 \ncong G_1$, then the commitment is perfectly binding. This idea was abstracted by Itoh, Ohta, and Shizuya [40], who studied the general utility of instance-dependent commitment schemes for constructing zero-knowledge proofs. Specifically, they showed that every language possessing a noninteractive instance-dependent

commitment scheme that is perfectly binding and perfectly hiding is in **PZK**, as is the complement of every such language. Recently, in [44], the notion was further generalized to allow interactive commitments, statistical security, and promise problems, and was suggested as a possible tool for proving that every problem in $\mathbf{SZK} \cap \mathbf{NP}$ has a statistical zero-knowledge proof system with an efficient prover.

Here we consider further relaxations of the definition. First, we allow the hiding property to be computational, since we will use them to construct computational zero-knowledge proofs. Second, we require security only for an honest receiver (i.e., one that follows the specified protocol); this means that the zero-knowledge proofs we construct with them will only be *honest-verifier* zero knowledge. However, since our honest-verifier zero-knowledge proofs will also be public coin (due to the instance-dependent commitments being public coin), we will be able to make them robust against cheating verifiers using the compiler of [32]. Third, and most significantly, we allow the sender's algorithm to be computationally unbounded. This is okay when we use the instance-dependent commitments to construct zero-knowledge proofs, because the sender's role is played by the prover, who is allowed to be computationally unbounded. (Though this naturally renders the commitments useless for the application in [44], which focused on prover efficiency.)

The fact that the sender is not polynomial time, however, complicates the definition substantially, because many commonly used properties of commitment schemes implicitly use the fact that the sender algorithm is polynomial time. For example, with a standard commitment scheme, one can assume without loss of generality that we have a "canonical reveal phase," whereby the sender gives the message m and her coin tosses r to the receiver and the receiver checks that the transcript of the commit phase is consistent with m and r. (See [23, sect. 4.4.1].) This is not possible when the sender is computationally unbounded, because the receiver cannot run the sender's algorithm to check the transcript. Another example is the fact that commitments are automatically "zero knowledge" in the sense that the receiver learns nothing (from both phases) other than the bit b to which the sender commits; this is the case because the receiver can simulate a commitment to bit b by simply running the sender's algorithm. Instead, we will need to explicitly include such properties in the following definition.

DEFINITION 4.1. *An (unbounded-sender, honest-receiver)* instance-dependent commitment scheme *for a promise problem* Π *consists of two interactive protocols* (S_1, R_1) *(the* commitment phase*) and* (S_2, R_2) *(the* reveal phase*) and a promise problem* $\textsc{Val} = (\textsc{Val}_Y, \textsc{Val}_N)$ *(capturing the "valid" commitments). In the commitment phase, both* S_1 *and* R_1 *receive a common input* $x \in \{0,1\}^*$*,* S_1 *receives a private input* $b \in \{0,1\}$*, and the protocol produces as output a* commitment z*. In the reveal phase, both* S_2 *and* R_2 *receive the common input* $x \in \{0,1\}^*$*, a commitment* z*, and a bit* $b \in \{0,1\}$*, and at the end of the protocol,* R_2 *accepts or rejects. We allow* S_1 *and* S_2 *(resp.,* R_1 *and* R_2*) to share the same coin tosses (as a way to maintain private state beyond the public commitment value* z*). We write* $(S_1(b), R_1)(x)$*,* $(S_2, R_2)(x, z, b)$*, and* $(S, R)(x, b)$ *to denote the interaction between* S *and* R *in the commit phase, reveal phase, and the two phases combined, respectively.*

We require the following conditions:

1. *(Efficiency)* $R = (R_1, R_2)$ *is computable in PPT (in the length of the common input* x*). (In contrast,* S *is allowed to be computationally unbounded.)*
2. *(Completeness) For all* $x \in \{0,1\}^n$ *and all* $b \in \{0,1\}$*, if we let* z *be the output of* $(S_1(b), R_1)(x)$*, then* $(x, z, b) \in \textsc{Val}_Y$ *with probability* $1 - \mathrm{neg}(n)$*.*

3. *(Validity tests)* (S_2, R_2) *is an interactive proof system (with negligible error probabilities) for* VAL. *Moreover, the promise problem* VAL *is in* **AM**.
4. *(Statistical zero knowledge) There is a PPT algorithm* M *such that for every* $x \in \{0,1\}^*$ *and* $b \in \{0,1\}$, *the distribution* $M(x,b)$ *has statistical difference* $\mathrm{neg}(n)$ *from* R*'s view of* $(S,R)(x,b)$.
5. *(Computationally hiding on* YES *instances) If* $x \in \Pi_Y$, *then* R*'s views in* $(S_1(0), R_1)(x)$ *and* $(S_1(1), R_1)(x)$ *are computationally indistinguishable. In case these views are statistically indistinguishable, we will refer to the scheme as* statistically hiding.
6. *(Statistically binding on* NO *instances) If* $x \in \Pi_N$, *then for every* S^*, *if we let* z *be the output of* $(S_1^*, R_1)(x)$, *then with probability at least* $1 - \mathrm{neg}(n)$, *either* $(x,z,0)$ *or* $(x,z,1)$ *is in* VAL_N.

The commitment scheme is called public coin *if it is public coin for the receiver* R.

We make a few remarks on the above conditions, as follows:

- As mentioned earlier, the fact that we allow S to be computationally unbounded results in several differences between the above definition and standard definitions of commitment schemes. When S is restricted to be polynomial time, the zero-knowledge condition is trivial to satisfy (because $M(x,b)$ could carry out an execution of $(S,R)(x,b)$) and thus is typically omitted, and the reveal phase can, without loss of generality, consist of S just sending its coin tosses to R.
- The completeness and zero-knowledge conditions (and the validity tests) are required for all inputs $x \in \{0,1\}^*$, not just those that satisfy the promise of Π. This will be useful in combining two instance-dependent commitment schemes to obtain one for the union of the corresponding promise problems.
- The definition provides for two different kinds of validity tests. One is the specified protocol (S_2, R_2) (which may have many rounds, but is "zero knowledge" according to item 4). The other is the (unspecified) **AM** protocol for VAL (which has only two rounds). Both will be useful for us.
- Both the zero-knowledge and hiding conditions are required only for honest receivers. The result is that the proof systems we construct using such commitments will be only honest-verifier zero knowledge. We will then obtain zero knowledge against cheating-verifier strategies using the compiler of [32] and the fact that our commitment schemes are public coin.

As shown in section 6, our results yield characterizations of **ZK** and **SZK** in terms of instance-dependent commitment schemes, as follows.

THEOREM 4.2 (commitment characterization of **ZK**). $\Pi \in$ **ZK** *if and only if* $\Pi \in$ **IP** *and* Π *has a public-coin,* computationally *hiding instance-dependent commitment scheme in the sense of Definition* 4.1.

THEOREM 4.3 (commitment characterization of **SZK**). $\Pi \in$ **SZK** *if and only if* $\Pi \in$ **IP** *and* Π *has a* statistically *hiding instance-dependent commitment scheme in the sense of Definition* 4.1.

These theorems demonstrate that commitment schemes are at the heart of all zero-knowledge proofs. This intuition has been held by researchers for a number of years, based first on the construction of zero-knowledge proofs for all of NP and **IP** from commitment schemes [29, 39, 7]. Partial converses were given by Damgård [12, 13], who showed that every problem having a 3-*round, public-coin* zero-knowledge proof has an instance-dependent commitment scheme[12] (as above, the commitment is

[12] Damgård's result is not stated in the language of instance-dependent commitments, but this formulation seems to follow from his technique.

statistically hiding if the proof system is statistical zero knowledge), and by Ostrovsky [49] and Ostrovsky and Wigderson [50], who showed that zero-knowledge proofs for *hard-on-average* languages imply one-way functions (and hence standard commitment schemes [45, 37]). As far as we know, the above theorems are the first to establish a genuine *equivalence* between zero-knowledge proofs and some form of commitment schemes.

In this section, we focus on proving the forward direction of Theorem 4.2.

LEMMA 4.4. *If a promise problem* Π *satisfies the* SZK/OWF CONDITION*, then* Π *has an instance-dependent commitment scheme (in the sense of Definition* 4.1*). Moreover, the scheme is public coin and the sender is PPT given an* **NP** *oracle.*

We will prove this lemma by dealing separately with the **SZK** instances and OWF instances. This is done by combining two instance-dependent commitment schemes, one that is hiding on the "OWF instances" and the other that is hiding on the "**SZK** (YES) instances." For the OWF instances, we use a straightforward application of the known construction of commitment schemes from one-way functions [45, 37].

LEMMA 4.5. *If there exists an auxiliary-input one-way function on set* I*, then there is an instance-dependent commitment scheme for the promise problem* $\Pi = (I, \overline{I})$*. Moreover, this commitment scheme is public coin and the sender is PPT.*

Proof. By Theorem 2.15, we can construct an auxiliary-input pseudorandom generator $\{G_x : \{0,1\}^{p(|x|)} \to \{0,1\}^{3p(|x|)}\}$ on I. Now we adapt Naor's commitment scheme from pseudorandom generators [45] as follows:

Commit phase. $(S_1(b), R_1)(x)$, where $|x| = n$.

1. R_1 chooses $v \leftarrow \{0,1\}^{3p(n)}$ and sends v to S_1. Both parties set $v_1 = v$ and $v_0 = 0^{3p(n)}$.
2. S_1 chooses $r \leftarrow \{0,1\}^{p(n)}$ and sends $w = G_x(r) \oplus v_b$ to R_1.
3. The commitment z is defined to be the pair (v, w).

We define the promise problem $\text{VAL} = (\text{VAL}_Y, \text{VAL}_N)$ by

$$\text{VAL}_Y = \{(x,(v,w),b) : \exists r \in \{0,1\}^{p(|x|)}\ w = G_x(r) \oplus v_b\},$$
$$\text{VAL}_N = \overline{\text{VAL}_Y},$$

where again we define $v_1 = v$ and $v_0 = 0^{3p(|x|)}$. Clearly $\text{VAL} \in \mathbf{NP}$, and in fact the reveal phase (S_2, R_2) simply consists of the sender S_2 providing the standard **NP** proof that $(x,(v,w),b) \in \text{VAL}_Y$ (namely, r such that $w = G_x(r) \oplus v_b$). Thus we have the required validity tests.

The completeness and public coin properties hold by inspection. The zero-knowledge condition holds because the sender is polynomial time. Following [45], the (computational) hiding property on $x \in I$ follows from the pseudorandomness of G_x on such instances. Specifically, we know that $G_x(U_{p(n)})$ is indistinguishable from $U_{3p(n)}$. Thus, if we let the random variable V denote the message of R_1, we see that R_1's view of a commitment to 1, $(V, G_x(U_{p(n)}) \oplus V)$, is indistinguishable from $(V, U_{3p(n)} \oplus V) \equiv (V, U_{3p(n)})$, which in turn is indistinguishable from R_1's view of a commitment to 0, $(V, G_x(U_{p(n)}))$. Following [45], the (statistical) binding property on $x \notin I$ (in fact on all $x \in \{0,1\}^*$) follows from the fact that G_x is length-tripling. Specifically, with probability at least $1 - 2^{-p(n)}$ over $v \leftarrow \{0,1\}^{3p(n)}$, the image of G_x will be disjoint from the image of $G_x \oplus v$, in which case there is no w such that (v, w) is a valid commitment of both 0 and 1. ∎

For the **SZK** instances, we prove the following (which is the forward direction of Theorem 4.3) in section 5.

LEMMA 4.6. *Every problem* Π *in* **SZK** *has an instance-dependent commitment*

scheme. Moreover, the scheme is public coin and statistically hiding, and the sender is PPT given an **NP** *oracle.*

We now show how to combine these two commitment schemes to prove Lemma 4.4.

LEMMA 4.7. *If promise problems* $\Pi = (\Pi_Y, \Pi_N)$ *and* $\Gamma = (\Gamma_Y, \Gamma_N)$ *each have instance-dependent commitment schemes, then the promise problem* $\Pi \cup \Gamma \stackrel{\text{def}}{=} (\Pi_Y \cup \Gamma_Y, \Pi_N \cap \Gamma_N)$ *has an instance-dependent commitment scheme. If the commitment schemes for* Π *and* Γ *are both public coin, then so is the commitment scheme for* $\Pi \cup \Gamma$*. Moreover, the strategy of the sender in the commitment scheme for* $\Pi \cup \Gamma$ *on auxiliary input* x *is PPT given oracle access to the strategies of the senders in the commitment schemes for* Π *and* Γ *on auxiliary input* x*.*

Proof. Let (S', R') be the instance-dependent commitment scheme for Π, and (S'', R'') the one for Γ, with valid commitments defined by promise problems VAL' and VAL''. Intuitively, on an input x, we would like to use (S', R') if $x \in \Pi_Y$ and use (S'', R'') if $x \in \Gamma_Y$. Unfortunately, we do not know which is the case. So we will use *both*, and do so in such a way that the resulting scheme is hiding even when only one of the two is hiding. The natural thing to do is for the sender to commit to two "shares" of its bit b, one with each scheme, and this is indeed what we do.

Specifically the new scheme $(S, R) = ((S_1, S_2), (R_1, R_2))$ is constructed as follows:

Commit phase $(S_1(b), R_1)(x)$:
1. S_1 chooses random $b', b'' \leftarrow \{0,1\}$ such that $b' \oplus b'' = b$.
2. S_1 and R_1 execute $(S_1'(b'), R_1')(x)$ and $(S_1''(b''), R_1'')(x)$ to obtain commitments z' and z'', respectively.
3. The output commitment is $z = (z', z'')$.

Valid commitments: The promise problem of valid commitments is defined to be $\text{VAL} = (\text{VAL}_Y, \text{VAL}_N)$, where

$$\text{VAL}_Y = \{(x, (z', z''), b) : \exists\, b', b'' \in \{0,1\} \quad [b' \oplus b'' = b] \wedge [(x, z', b') \in \text{VAL}_Y'] \wedge [(x, z'', b'') \in \text{VAL}_Y'']\},$$

$$\text{VAL}_N = \{(x, (z', z''), b) : \forall\, b', b'' \in \{0,1\} \quad [b' \oplus b'' \neq b] \vee [(x, z', b') \in \text{VAL}_N'] \vee [(x, z'', b'') \in \text{VAL}_N'']\}.$$

Reveal phase $(S_2, R_2)(x, (z', z''), b)$:
1. S_2 sends b', b''.
2. R_2 checks that $b' \oplus b'' = b$ and rejects immediately if not.
3. S_2 and R_2 execute $(S_2', R_2')(x, z', b')$ and $(S_2'', R_2'')(x, z'', b'')$, and R_2 accepts if both R' and R'' accept.

The completeness property of (S, R) on all x follows from the completeness properties of (S', R') and (S'', R''), which guarantee that with high probability $(x, z', b') \in \text{VAL}_Y'$ and $(x, z'', b'') \in \text{VAL}_Y''$, and hence $(x, (z', z''), b) \in \text{VAL}_Y$. (Here it is important that we require completeness to hold on all instances, rather than just on YES instances, since Π_Y and Γ_Y need not be the same.) The fact that (S_2, R_2) is an interactive proof for VAL follows by inspection, and the fact that $\text{VAL} \in \mathbf{AM}$ follows from the fact that both VAL' and VAL'' are in **AM** (combining the **AM** proof systems in the same way that we combined (S_2', R_2') and (S_2'', R_2'') to get (S_2, R_2)). For the zero-knowledge property, we have the new simulator $M(x, b)$ choose $b', b'' \leftarrow \{0,1\}$ such that $b' \oplus b'' = b$, run the original simulators $M'(x, b')$ and $M''(x, b'')$, and combine their outputs to simulate the view of R.

For the hiding property on $\Pi_Y \cup \Gamma_Y$, suppose w.l.o.g. that $x \in \Gamma_Y$. Note that the view of R_1 in $(S_1(b), R_1)(x)$ consists of the view of R_1' in $(S_1'(b'), R_1')(x)$ concatenated

with the view of R_1'' in $(S_1''(b''), R_1'')(x)$, where b' and b'' are chosen randomly such that $b' \oplus b'' = b$. The first part of the view (namely, the R_1'-view) has the same distribution regardless of the value b, because b' is a random bit. Thus, it suffices to show that for every fixed value of b' and the R_1'-view, the R_1''-view in case $b'' = b'$ (i.e., $b = 0$) is indistinguishable from the R_1''-view in case $b'' \neq b'$ (i.e., $b = 1$). But this follows from the hiding property of (S'', R'') on $x \in \Gamma_Y$.

The binding property on $x \in \Pi_N \cap \Gamma_N$ follows from the binding properties of the two commitment schemes: For every strategy S^*, we know that with high probability, the output (z', z'') of (S^*, R) satisfies the following. There is at most one $b' \in \{0,1\}$ such that $(x, z', b') \notin \text{VAL}_N'$, and there exists at most one $b'' \in \{0,1\}$ such that $(x, z'', b'') \notin \text{VAL}_N''$. Thus there is at most one b (namely, $b = b' \oplus b''$) such that $(x, (z', z''), b) \notin \text{VAL}_N$, as desired.

By inspection, the above transformation maintains public coins and the sender's complexity. □

Putting the above together, we can prove Lemma 4.4, stating that every language satisfying the SZK/OWF CONDITION has an instance-dependent commitment scheme.

Proof of Lemma 4.4. Let Π be any promise problem satisfying the SZK/OWF CONDITION, and let $I \subseteq \Pi_Y$ be the set of "OWF instances." Since $\Pi' = (\Pi_Y \setminus I, \Pi_N)$ is in **SZK**, Lemma 4.6 gives us an instance-dependent commitment scheme for Π', with public coins and a sender that is PPT given an **NP** oracle. Since we have an auxiliary-input one-way function on I, Lemma 4.5 gives us an instance-dependent commitment scheme for $\Gamma = (I, \overline{I})$, with public coins and a PPT sender. Combining these via Lemma 4.7, we get an instance-dependent commitment scheme for $\Pi' \cup \Gamma = \Pi$, with public coins and a sender that is PPT given an **NP** oracle. □

4.2. The zero-knowledge proof. We now show that to obtain a zero-knowledge proof for a problem $\Pi \in$ **IP**, it suffices for Π to have an instance-dependent commitment scheme in the sense of the previous section. This is done by simply using the instance-dependent commitment scheme to implement the **IP**-to-**ZK** compiler of [29, 39, 7].

LEMMA 4.8. *If a promise problem* Π *is in* **IP** *and has a computationally hiding (resp., statistically hiding) instance-dependent commitment scheme (in the sense of Definition* 4.1*), then* $\Pi \in$ **HVZK** *(resp.,* $\Pi \in$ **HVSZK***). Moreover, if the instance-dependent commitment scheme is public coin, then so is the honest-verifier zero-knowledge proof for* Π*. Also, the prover's strategy* P_x' *in the honest-verifier zero-knowledge proof is PPT given with oracles for* S_x *and* P_x*, where* S *is the sender algorithm in the instance-dependent commitment scheme and* P *is a prover in any public-coin interactive proof system for* Π*.*

Proof. We begin with the special case that $\Pi \in$ **NP**, where we follow the approach of Itoh, Ohta, and Shizuya [40] using our more general notion of instance-dependent commitments. The idea is to use the zero-knowledge proofs of Goldreich, Micali, and Wigderson [29] for all of **NP**, replacing the commitment scheme used there with the instance-dependent commitment for Π. An outline of the steps of the resulting protocol follows.

Zero-knowledge proof $(P, V)(x)$:

1. Both parties reduce x to an instance G of 3-COLORING.
2. P selects an arbitrary 3-coloring C_0 of G and lets C be the coloring obtained by permuting the three colors in C_0 uniformly at random.
3. P commits to the color of each vertex under C by engaging with V in (polynomially many executions of) the commitment phase of instance-dependent

commitment scheme for Π on common input x.

4. V selects a random edge e in G and sends e to P.
5. P reveals the colors of the endpoints of e and proves their validity to V via the reveal phase of the instance-dependent commitment scheme.
6. V accepts if the colors of the endpoints are different and accepts in both executions of the reveal phase.

Completeness follows from completeness of the instance-dependent commitment scheme. Soundness follows from the binding property of the instance-dependent commitment scheme when $x \in \Pi_N$. (Honest-verifier) zero knowledge follows from the hiding and zero-knowledge properties of the commitment scheme when $x \in \Pi_Y$. Specifically, the simulator chooses a random edge e in the graph (to be the verifier's challenge), chooses two random distinct colors for its endpoints, and assigns arbitrary colors for the rest of the graph. It uses the simulator for the commitment scheme to simulate all the commitments, using the simulated commitment phase for all the commitments, but the simulated reveal phase only for the edge e. (Note that here, unlike in [29], we deal with an honest verifier, and thus the verifier's challenge e is equivalent to its coin tosses and is indeed chosen uniformly at random.) The computational (resp., statistical) hiding property of the commitment scheme implies that this simulation is computationally (resp., statistically) indistinguishable from the (honest) verifier's view.

For the general case that $\Pi \in \mathbf{IP}$, we follow [39, 7] and transform an interactive proof (P, V) for Π into a zero-knowledge proof. By [36], we may assume that (P, V) is public coin. An outline of the zero-knowledge proof follows.

Zero-knowledge proof $(P', V')(x)$:

1. (P', V') simulate the public-coin interactive proof $(P, V)(x)$, but instead of sending P's messages explicitly, P' commits to P's messages using the commit phase of the instance-dependent commitment scheme on common input x. (The public-coin nature of (P, V) ensures that V can compute its messages without seeing P's messages explicitly.) Let $(z_1, \ldots, z_m)$ be all the commitments obtained in this way.
2. V chooses and sends a random strings $r_1, \ldots, r_m$ for the **AM** proof system for VAL.
3. Now P proves the following **NP** statement to V using the zero knowledge protocol described above (i.e., that of Goldreich, Micali, and Wigderson implemented with instance-dependent commitments): There exist values $b_1, \ldots, b_m$ such that (a) V would have accepted in the interactive proof if the prover responses were given by $b_1, \ldots, b_m$, and (b) there are prover responses $s_1, \ldots, s_m$ such that the **AM** verifier for VAL would accept on transcript $((x, z_i, b_i), r_i, s_i)$ for $i = 1, \ldots, m$.

The analysis of this proof system is similar to the previous one. The claim about the prover complexity follows by inspection. □

The above gives honest-verifier zero-knowledge proofs. These can be converted into zero-knowledge proofs that tolerate cheating verifiers using the following compiler of Goldreich, Sahai, and Vadhan [32].

THEOREM 4.9 (see [32]). *Any honest-verifier public-coin zero-knowledge proof system can be transformed into a (cheating-verifier) public-coin zero-knowledge proof system. Furthermore,*

1. *the resulting proof system has twice as many rounds as the original one.*
2. *the resulting prover strategy on any input x is PPT given oracle access to the original prover strategy on the same input x.*

3. *the resulting proof system has completeness error* $2^{-\Omega(n)}$ *and soundness error* $1/n$ *on input length* n*. In case the original proof system has perfect completeness, so does the resulting one.*
4. *if the original proof system is statistical zero knowledge, then so is the resulting proof system.*
5. *the resulting proof system has a black-box simulator.*

Note that the above theorem provides a zero-knowledge proof with a nonnegligible soundness error (namely $1/n$). This can be reduced to a negligible error by performing $\omega(1)$ sequential repetitions.

5. Instance-dependent commitments for SZK. In this section, we construct our instance-dependent commitment schemes for **SZK**, thereby proving Lemma 4.6. This is technically the most involved part of our work.

5.1. Overview. We will construct an instance-dependent commitment scheme for the **SZK**-complete problem STATISTICAL DIFFERENCE [52]. This means that we will design a commitment protocol in which both the sender and receiver get as auxiliary input a pair (X_0, X_1) of samplable distributions. The commitment scheme should be statistically hiding when X_0 and X_1 are statistically close and should be statistically binding when X_0 and X_1 are statistically far apart. By the polarization lemma of [52], we may assume, w.l.o.g., that the statistical difference between X_0 and X_1 is either exponentially small (for YES instances) or exponentially close to 1 (for NO instances).

A natural idea, suggested in [44], is the following. To commit to a bit b, the sender sends a random sample $x \leftarrow X_b$. To decommit, the sender reveals b and the coin tosses r used to generate x, and the receiver verifies that $x = X_b(r)$.

When X_0 and X_1 are statistically close, this scheme is indeed hiding. On the other hand, when $\Delta(X_0, X_1) = 1$ (i.e., X_0 and X_1 have disjoint supports), then the scheme is perfectly binding. But we are guaranteed only that $\Delta(X_0, X_1)$ is exponentially close to 1, and this does not suffice for any sort of binding. Indeed, two distributions can have statistical difference exponentially close to 1 and yet have identical supports (which means that every commitment can be opened in two ways).

To get around this difficulty, we notice that the intersection of the supports can consist of two kinds of elements. First, there can be samples that are atypically light for at least one of the distributions (i.e., have probability mass much smaller than 2^{-h}, if we assume (w.l.o.g.) that $\mathrm{H}(X_0) = \mathrm{H}(X_1) = h$). Note that there can be many ($\gg 2^h$) such elements. Second, there can be samples that are not atypically light for either distribution. However, it can be shown that there can be only a relatively few ($\ll 2^h$) elements of this second type, provided the distributions have statistical difference exponentially close to 1. Still, we need to cope with both kinds of samples.

To deal with these problems, we replace both the commit phase and reveal phase with interactive protocols. The commit phase protocol constrains the sender's choice of the sample/commitment x. Even if the sender deviates from the protocol, with high probability the commit phase will produce a sample that is atypically light for at least one of the two distributions, in which case we will regard it as a commitment to the bit corresponding to the *other* distribution. The fact that this is feasible relies on the fact that there are relatively few samples that are not atypically light for both distributions. The reveal phase protocol, then, is simply an interactive proof that the sample is not atypically light for X_b.

Needless to say, the challenge is to design both of these protocols so that the

hiding property is maintained in the case of YES instances. Fortunately, there are two protocols due to Okamoto [48] (see also [34, 57]) that turn out to be well-suited for these tasks. Specifically, we use an adaptation of Okamoto's "sample generation protocol" for the commitment phase, and his "sample test protocol" for the reveal phase. The price we pay for using these protocols is that the sender is no longer PPT (but rather in $\mathbf{BPP}^{\mathbf{NP}}$), and also that the round complexity becomes polynomial rather than being a constant.

5.2. Preprocessing the distributions. We will not apply Okamoto's protocols directly to instances of STATISTICAL DIFFERENCE itself, but rather do some preprocessing on the distributions. The first drives the thresholds from 1/3 and 2/3 to be exponentially close to 0 and 1, respectively.

LEMMA 5.1 (polarization lemma [52]). *There is a polynomial-time computable function mapping pairs of distributions (X_0, X_1) (specified by circuits which sample from them) and a unary parameter 1^k to pairs of distributions (Y_0, Y_1) such that*

$$\Delta(X_0, X_1) \leq 1/3 \Rightarrow \Delta(Y_0, Y_1) \leq 2^{-k},$$
$$\Delta(X_0, X_1) \geq 2/3 \Rightarrow \Delta(Y_0, Y_1) \geq 1 - 2^{-k}.$$

The second transformation we will use is simply taking direct products, as analyzed in section 2.2. Combining these two transformations, we prove the following.

LEMMA 5.2. *For every promise problem $\Pi \in \mathbf{SZK}$, there is a polynomial-time computable function mapping instances x of length n and unary parameters $1^k, 1^\ell$ to pairs of distributions (Z_0, Z_1) such that*

- *if $x \in \Pi_Y$, then $\Delta(Z_0, Z_1) \leq \ell \cdot 2^{-k}$.*
- *if $x \in \Pi_N$, then $\Delta(Z_0, Z_1) \geq 1 - 2^{-\ell}$.*
- *for all x, $\mathrm{H}(Z_0) = \mathrm{H}(Z_1)$ and both Z_0 and Z_1 are $\sqrt{\ell} \cdot \mathrm{poly}(n, k)$-flat.*

The key point for us is that the statistical difference in the case of NO instances goes to 1 exponentially fast with ℓ, whereas the deviation from flatness grows sublinearly with ℓ. Specifically, we can take k to be linear in n and take ℓ to be a large polynomial in n and have the deviation from flatness $\sqrt{\ell} \cdot \mathrm{poly}(n, k)$ remain sublinear in ℓ. We will show (in Lemma 5.3 below) that this implies that the intersection of the supports of the two distributions is due only to (a) atypically light elements and (b) a *small* number of other elements (i.e., much fewer than $2^{\mathrm{H}(Z_b)}$).

Proof. Let an instance x of $\Pi \in \mathbf{SZK}$ and the parameters 1^k and 1^ℓ be given. By the completeness of STATISTICAL DIFFERENCE and the polarization lemma (Lemma 5.1), we can produce in polynomial time distributions (Y_0, Y_1) such that

$$x \in \Pi_Y \Rightarrow \Delta(Y_0, Y_1) \leq 2^{-2k},$$
$$x \in \Pi_N \Rightarrow \Delta(Y_0, Y_1) \geq 1 - 2^{-2k} \geq 1/2.$$

Now, let $W_0 = Y_0 \otimes Y_1$ (i.e., a sample of Y_0 followed by an independent sample of Y_1) and $W_1 = Y_1 \otimes Y_0$. This ensures $\mathrm{H}(W_0) = \mathrm{H}(W_1)$, and we have

$$x \in \Pi_Y \Rightarrow \Delta(W_0, W_1) \leq 2 \cdot 2^{-2k},$$
$$x \in \Pi_N \Rightarrow \Delta(W_0, W_1) \geq 1/2.$$

Now we let $Z_0 = \otimes^{c \cdot \ell} W_0$ and $Z_1 = \otimes^{c \cdot \ell} W_1$, for a sufficiently large constant c. Then, by Lemma 2.3,

$$x \in \Pi_Y \Rightarrow \Delta(Z_0, Z_1) \leq c\ell \cdot 2 \cdot 2^{-2k} \leq \ell \cdot 2^{-k},$$
$$x \in \Pi_N \Rightarrow \Delta(Z_0, Z_1) \geq 1 - \exp(-\Omega(c\ell)) \geq 1 - 2^{-\ell},$$

for an appropriate constant c and sufficiently large k. Also, $\mathrm{H}(Z_0) = c\ell \cdot \mathrm{H}(W_0) = \mathrm{H}(Z_1)$. Finally, if $m = \mathrm{poly}(n,k)$ is the number of input gates to W_0 and W_1, then $\Pr[W_b = w] \geq 2^{-m}$ for all $b \in \{0,1\}$ and all w in the support of W_b, so the flattening lemma (Lemma 2.6) tells us that Z_0 and Z_1 are both $\sqrt{\ell} \cdot m$-flat. □

The following lemma shows that for two nearly flat distributions with statistical difference very close to 1, there can be only a relatively small number of strings that are nonlight for both distributions.

LEMMA 5.3. *Suppose Z_0 and Z_1 are random variables such that $\mathrm{H}(Z_0) = \mathrm{H}(Z_1)$ and $\Delta(\mathrm{H}(Z_0), \mathrm{H}(Z_1)) \geq 1 - 2^{-\ell}$. Then for any $\Phi > 0$,*

$$\#\{z : z \text{ is not } \Phi\text{-light for } Z_0 \text{ and } z \text{ is not } \Phi\text{-light for } Z_1\} \leq \frac{2^{\mathrm{H}(Z_0)}}{2^{\ell-\Phi}}.$$

Proof. Let S be the set of z that are neither Φ-light for Z_0 nor for Z_1. Then

$$\begin{aligned} 2^{-\ell} &\geq 1 - \Delta(Z_0, Z_1) \\ &= \sum_z \min\{\Pr[Z_0 = z], \Pr[Z_1 = z]\} \\ &> \sum_{z \in S} \min\left\{2^{-\Phi} \cdot 2^{-\mathrm{H}(Z_0)}, 2^{-\Phi} \cdot 2^{-\mathrm{H}(Z_1)}\right\} \\ &= |S| \cdot 2^{-\Phi} \cdot 2^{-\mathrm{H}(Z_0)}. \end{aligned}$$

Thus, $|S| < 2^{\mathrm{H}(Z_0)}/2^{\ell-\Phi}$, as desired. □

Note that the above lemma gives us a useful bound ($\ll 2^{\mathrm{H}(Z_b)}$) when the slackness parameter of Φ is smaller than ℓ. Fortunately, Lemma 5.2 allows us to obtain $\Phi = o(\ell)$ while still having a statistical difference of $1 - 2^{-\ell}$ on NO instances.

5.3. Okamoto's protocols. We now describe the two protocols of Okamoto [48] that we will use in our commitment scheme. The first is used for generating a random sample from a nearly flat distribution so that even if one party cheats, the output will be unlikely to fall in any sufficiently small set. The second is used to test that a sample from a nearly flat distribution is not too light. Our presentation of these protocols follows [34, 57].

Below, all distributions are given in the form of circuits that generate them. The input to these protocols will include a distribution, denoted X. We will denote by m (resp., n) the length of the input to (resp., output of) the circuit generating the distribution X.

DEFINITION 5.4 (sample generation protocol). *A protocol (S, R) is called a* sample generation protocol *if on common input a distribution X, specified by a circuit with m input gates and n output gates, and parameters Φ and t, such that X is Φ-flat and $1 \leq t \leq \Phi$, the protocol yields a common output in $\{0,1\}^n$ such that the following holds:*

1. *(Efficiency) R is PPT.*
2. *("Completeness") If both parties are honest, then the output of the protocol has a statistical difference of at most $m \cdot 2^{-\Omega(t^2)}$ from X.*
3. *("Soundness I") If R is honest, then no matter how S plays, the output will be $2\sqrt{t\Phi} \cdot \Phi$-heavy with probability at most $m \cdot 2^{-\Omega(t^2)}$.*
4. *("Soundness II") If R is honest, then for every set $T \subseteq \{0,1\}^n$ of size at most $2^{-6\sqrt{t\Phi}\cdot\Phi} \cdot 2^{\mathrm{H}(X)}$, no matter how S plays, the output will be in T with probability at most $m \cdot 2^{-\Omega(t^2)}$.*

5. *(Strong "zero knowledge") There exists a PPT* simulator M *so that for every* (X, Φ, t) *as above, the following two distributions have statistical difference at most* $m \cdot 2^{-\Omega(t^2)}$*:*
   (A) *Execute* (S, R) *on common input* (X, Φ, t) *and output the view of* R*, appended by the output.*
   (B) *Choose* $x \leftarrow X$ *and output* $(M(X, \Phi, t, x), x)$.

A sample generation protocol is said to be public coin *if it is public coin for* R.

In [48, 34, 57], only the first soundness condition is given, but we will actually use the second. (Our proof that the protocol satisfies the second soundness condition will make use of the first.) The above zero-knowledge property is referred to as *strong* since the simulator cannot produce a view-output pair by first generating the view and then computing the corresponding output. Instead, the simulator is forced (by the explicit inclusion of x in distribution (B)) to generate a random view consistent with a given random output (of the protocol). We comment that the trivial protocol in which R uniformly selects an input r to the circuit X and reveals both r and the output $x = X(r)$ cannot be used since the simulator is given only x, and it may be difficult to find an r yielding x in general. Still, a sample generation protocol is implicit in Okamoto's work [48] (where it is called a "pretest"). Note also that the zero-knowledge condition implies the completeness condition; still, conceptually it is convenient to state them separately.

THEOREM 5.5 (implicit in [48]; explicit in [34]). *There exists a sample generation protocol. Furthermore, the protocol is public coin, the sender strategy is PPT given an* **NP** *oracle, and the number of messages exchanged in the protocol is linear in* m*, the input length of the sampling circuit for the input distribution* X.

Actually, in [48, 34], the sample generation protocol is not shown to satisfy either the Soundness II condition of Definition 5.4 or the bound on sender complexity specified in Theorem 5.5. Thus we repeat the description of the protocol here.

Sample generation protocol (S, R):
Input: (X, Φ, t), where X has m input gates and n output gates and $t \leq \Phi$.

1. S: Select $x_0 \in \{0,1\}^n$ according to X and send x_0 to R.
2. S, R: Repeat for i from 1 to m:
   (a) R: Choose h_i uniformly from a family of pairwise independent hash functions mapping $\{0,1\}^{m+n}$ to $\{0,1\}^{m-3t\Phi}$ and send h_i to S.
   (b) S: Choose (r_{i-1}, x_i) from the distribution $\{r : X(r) = x_{i-1}\} \otimes X$, conditioned on $h(r_{i-1}, x_i) = 0$, and send (r_{i-1}, x_i) to R. (If there is no such pair (r, x'), then S sends `fail` to R.)
   (c) R: Check that $X(r_{i-1}) = x_{i-1}$ and $h(r_{i-1}, x_i) = 0$. If either condition fails, reject.

Output: x_m, unless R rejects in some iteration of the above loop, in which case output any canonical string outside $\{0,1\}^n$, e.g., 0^{n+1}.

The sender complexity claimed in Theorem 5.5 follows from the observation that the sender need only sample strings uniformly from efficiently decidable sets (i.e., satisfying assignments to a known, polynomial-sized circuit), and it is known how to do such sampling given an **NP** oracle [41, 5].

LEMMA 5.6. *The above protocol satisfies the Soundness* II *condition of Definition* 5.4.

Proof. Fix a set T of size at most $2^{-6\sqrt{t\Phi}\cdot\Phi} \cdot 2^{\mathrm{H}(X)}$. We need to show that the output x_m is in T with probability at most $m \cdot 2^{-\Omega(t^2)}$, even under a cheating strategy for S. The Soundness I condition says that x_m is $2\sqrt{t\Phi} \cdot \Phi$-heavy with probability

at most $m \cdot 2^{-\Omega(t^2)}$. In fact, the proof of this condition in [34] also shows that x_{m-1} is $2\sqrt{t\Phi} \cdot \Phi$-heavy with probability at most $m \cdot 2^{-\Omega(t^2)}$. (Indeed, the protocol could have been terminated after $m-1$ or even slightly fewer stages, but m was chosen as a clean upper bound on the number of stages needed.) We will show that if x_{m-1} is not $2\sqrt{t\Phi} \cdot \Phi$-heavy, then the probability (over h_m) that S can select x_m to be in T (without R rejecting) is at most $2^{-\Omega(t^2)}$.

The number N of strings r_{m-1} such that $X(r_{m-1}) = x_{m-1}$ is

$$N = 2^m \cdot \Pr[X = x_{m-1}] < 2^m \cdot 2^{2\sqrt{t\Phi}\cdot\Phi} \cdot 2^{-\mathrm{H}(X)},$$

where the inequality is due to x_{m-1} not being $2\sqrt{t\Phi} \cdot \Phi$-heavy. Thus, the number of pairs (r_{m-1}, x_m) such that $X(r_{m-1}) = x_{m-1}$ and $x_m \in T$ equals

$$N \cdot |T| = \left(2^m \cdot 2^{2\sqrt{t\Phi}\cdot\Phi} \cdot 2^{-\mathrm{H}(X)}\right) \cdot \left(2^{-6\sqrt{t\Phi}\cdot\Phi} \cdot 2^{\mathrm{H}(X)}\right) \leq 2^{-t^2} \cdot 2^{m-3t\Phi},$$

where the last inequality uses $t \leq \Phi$. Since $h_m(z)$ is uniformly distributed in its range $\{0,1\}^{m-3t\Phi}$ for every z, the probability that there exists a pair (r_{m-1}, x_{m-1}) such that $h_m(r_{m-1}, x_{m-1}) = 0$ is at most 2^{-t^2}. □

The second protocol tests whether a sample is too light; here we do not need any modifications from the definition in [34].

DEFINITION 5.7 (sample test protocol). *A protocol (S, R) is called a* sample test protocol *if on common input a distribution X, specified by a circuit with m input gates and n output gates, a string $x \in \{0,1\}^n$, and parameters Φ, t, such that X is Φ-flat and $t \leq \Phi$, the following hold:*

1. *(Efficiency) R is PPT.*
2. *("Completeness") If both parties are honest and x is $t \cdot \Phi$-typical, then R accepts with probability at least $1 - m \cdot 2^{-\Omega(t^2)}$.*
3. *("Soundness") If x is $6\sqrt{t\Phi} \cdot \Phi$-light and R is honest, then no matter how S plays, R accepts with probability at most $m \cdot 2^{-\Omega(t^2)}$.*
4. *(Weak "zero knowledge") There exists a PPT* simulator *M so that for every (X, Φ, t) as above and for every $t \cdot \Phi$-typical x, the following two distributions have statistical difference at most $m \cdot 2^{-\Omega(t^2)}$:*
   (A) *Execute (S, R) on common input (X, x, Φ, t), and output the view of R.*
   (B) *Choose r uniformly in $\{r' : X(r') = x\}$, and output $M(X, x, \Phi, t, r)$.*

A sample test protocol is said to be public coin *if it is public coin for R.*

The above zero-knowledge property is referred to as *weak* since the simulator gets a random r giving rise to x (i.e., $x = X(r)$) as an auxiliary input (whereas R is given only x). A sample test protocol is implicit in Okamoto's work [48] (where it is called a "posttest").

THEOREM 5.8 (implicit in [48]; explicit in [34]). *There exists a public-coin sample test protocol. Furthermore, the protocol is public coin, the sender strategy is computable in PPT with an* **NP** *oracle, and the number of messages exchanged in the protocol is linear in m.*

5.4. The commitment scheme. Now we use the above protocols to design instance-dependent commitments for all of **SZK**, and thereby prove Lemma 4.6. Let Π be a promise problem in **SZK**, let x be any string of length n, and let $k = 2n$, and $\ell = n^{7c}$ for a sufficiently large constant c to be determined later. Applying the reduction of Lemma 5.2 to x, we obtain distributions (Z_0, Z_1) such that

- if $x \in \Pi_Y$, then $\Delta(Z_0, Z_1) \leq \ell \cdot 2^{-k} < 2^{-n}$.

- if $x \in \Pi_N$, then $\Delta(Z_0, Z_1) \geq 1 - 2^{-\ell}$.
- for all x, it holds that $\mathrm{H}(Z_0) = \mathrm{H}(Z_1)$ and both Z_0 and Z_1 are Φ-flat for $\Phi = \sqrt{\ell} \cdot \mathrm{poly}(n,k) < n^{4c}$, when c is sufficiently large.

Now we also define a new distribution Z as follows $Z(b,r) = Z_b(r)$. That is, Z outputs a random sample of Z_0 with probability 1/2 and a random sample of Z_1 with probability 1/2. Since $\mathrm{H}(Z_0) = \mathrm{H}(Z_1)$, we have $\mathrm{H}(Z_0) \leq \mathrm{H}(Z) \leq \mathrm{H}(Z_0) + 1$. We also claim that Z inherits the flatness of Z_0 and Z_1.

CLAIM 5.9. *Z is 3Φ-flat.*

The tedious proof of this claim is deferred to Appendix A. Now we construct the instance-dependent commitment scheme (S, R) as follows, setting $t = n$:

Commit phase $(S_1(b), R_1)(x)$:

1. S_1 and R_1 execute the sample generation protocol of Theorem 5.5 on input $(Z, 3\Phi, t)$ to obtain output z, where Z, Φ, and t are as defined above.
2. S_1 chooses (c,r) uniformly s.t. $Z(c,r) = z$ and sends $d = b \oplus c$ to R.
3. The commitment is defined as the pair (z,d).

(Intuitively, if Z_0 and Z_1 are statistically close, then a random sample z of Z is nearly equally likely to have come from Z_0 or Z_1, so the bit c is random and hides b.)

Valid commitments: The promise problem of valid commitments is defined to be $\mathrm{VAL} = (\mathrm{VAL}_Y, \mathrm{VAL}_N)$, where

$$\mathrm{VAL}_Y = \{(x,(z,d),b) : z \text{ is } t\Phi\text{-typical for } Z_{d \oplus b}\},$$
$$\mathrm{VAL}_N = \{(x,(z,d),b) : z \text{ is } 6\sqrt{t\Phi} \cdot \Phi\text{-light for } Z_{d \oplus b}\}.$$

Reveal phase $(S_2, R_2)(x,(z,d),b)$: S_2 and R_2 execute the sample test protocol of Theorem 5.8 on the input $(Z_{d \oplus b}, z, \Phi, t)$, and R_2 accepts or rejects according to its outcome.

CLAIM 5.10. *The above protocol is a statistically hiding instance-dependent commitment scheme in the sense of Definition* 4.1.

Proof.

1. (Receiver's efficiency) This follows from the efficiency of the sample generation and sample test protocols.
2. (Completeness) By the completeness of the sample generation protocol, the string z generated in the $(S_1(b), R_1)(x)$ has statistical difference at most $m \cdot 2^{-t^2} < 2^{-n}$ from Z, where $m = \mathrm{poly}(n)$ is the number of input gates of the circuit generating Z. Thus, (c,r) has statistical difference at most 2^{-n} from uniform. If (c,r) were uniformly distributed, then by the Φ-flatness of $Z_{c \oplus d}$, the probability (over r) that $z = Z_c(r)$ is $t\Phi$-typical for $Z_c = Z_{d \oplus b}$ is at least $1 - 2^{-t^2} > 1 - 2^{-n}$. Therefore, $(x,(z,d),b) \in \mathrm{VAL}_Y$ with probability at least $1 - 2 \cdot 2^{-n}$.
3. (Validity tests) The completeness and soundness of the sample test protocol show that (S_2, R_2) is an interactive proof system for VAL. To show that VAL is in **AM**, we design an **AM** proof system for it as follows. On input $(x,(z,d),b)$, the prover sends an approximation k to $\mathrm{H}(Z_{d \oplus b})$, and then proves that (a) $\mathrm{H}(Z_{d \oplus b}) \lesssim k$, and (b) $|\{r : Z_{d \oplus b}(r) = z\}| \gtrsim 2^m \cdot 2^{-k - t\Phi}$, where again m is the number of input gates of the circuit generating Z. Step (a) can be done because approximating entropy to within an additive constant (say ± 1)

is in **AM** $\cap$ **co-AM** [51].[13] Step (b) can be done using an **AM** protocol for proving approximate lower bounds on the sizes of efficiently recognizable sets [55, 56, 2]. Proving (a) and (b) suffices because on YES instances of VAL, we have

$$|\{r : Z_{d\oplus b}(r) = z\}| \geq 2^m \cdot 2^{-\mathrm{H}(Z_{d\oplus b})-t\Phi},$$

and on NO instances, we have

$$|\{r : Z_{d\oplus b}(r) = z\}| \leq 2^m \cdot 2^{-\mathrm{H}(Z_{d\oplus b})-6\sqrt{t\Phi}\cdot\Phi} < 2^m \cdot 2^{-\mathrm{H}(Z_{d\oplus b})-t\Phi-5}.$$

4. (Zero knowledge) This follows from the zero-knowledge conditions of the sample generation and sample test protocols. Specifically, the simulator $M(x, b)$ chooses a uniformly random (c, r), sets $z = Z(c, r)$ and $d = b \oplus c$, runs the simulator for the sample generation protocol on input $(Z, 3\Phi, t, z)$ to obtain a transcript γ_1, runs the simulator for the sample test protocol on $(Z_c, z, \Phi, t, (c, r))$ to obtain a transcript γ_2, and outputs (γ_1, d, γ_2).
5. (Statistically hiding on YES instances) The only dependence of R_1's view on the bit b is in the value $d = b \oplus c$, where c is selected according to the conditional distribution $C|_{Z_C=z}$, where C is uniform in $\{0, 1\}$. We have seen above that the sample generation protocol generates z according to a distribution that has a statistical difference of at most 2^{-n} from a random sample of $Z \equiv Z_C$. Thus, the pair (z, c) is generated according to a distribution having a statistical difference of at most 2^{-n} from (Z_C, C). In the case of a YES instance, where Z_0 and Z_1 have a statistical difference of at most 2^{-n}, (Z_C, C) has a statistical difference of at most 2^{-n} from (Z_C, C'), where C' is a random bit independent of C. Thus, R_1's view in case $b = 0$ is statistically indistinguishable from R_1's view in case $b = 1$.
6. (Statistically binding on NO instances) Let

$$T = \{z : z \text{ is not } 6\sqrt{t\Phi} \cdot \Phi\text{-light for } Z_0 \text{ or for } Z_1\}.$$

By Lemma 5.3,

$$|T| \leq \frac{2^{\mathrm{H}(Z_0)}}{2^{\ell-6\sqrt{t\Phi}\cdot\Phi}} \leq 2^{-6\sqrt{t\Phi}\cdot\Phi} \cdot 2^{\mathrm{H}(Z)},$$

where the last inequality holds because $\ell = n^{7c} > 12n^{6c+.5} > 12\sqrt{t\Phi} \cdot \Phi$. By the second soundness condition of the sample generation protocol, the probability that the output z is in T is at most $2^{-\Omega(t^2)} < 2^{-n}$. If the output is not in T, then for any d, there is at most one value of b such that z is not $6\sqrt{t\Phi} \cdot \Phi$-light for $Z_{d\oplus b}$. That is, there is at most one value of b such that $(x, (z, d), b) \notin \mathrm{VAL}_N$, as desired. □

Proof of Lemma 4.6. Using Claim 5.10, all that is left to verify is that the protocol is public coin, and the sender is PPT given an **NP** oracle. Both of these follow from the analogous properties of the sample generation and sample test protocols given in Theorems 5.5 and 5.8. □

[13] Indeed, the promise problem ENTROPY APPROXIMATION (EA), where $\mathrm{EA}_Y = \{(X, k) : \mathrm{H}(X) \geq k + 1\}$, $\mathrm{EA}_N = \{(X, k) : \mathrm{H}(X) \leq k\}$, is complete for noninteractive statistical zero knowledge (**NISZK**) [33], and **NISZK** $\subseteq$ **SZK** $\subseteq$ **AM** $\cap$ **co-AM** [18, 1].

6. Putting it together. Now we can put together the results proved in the previous three sections and establish Theorems 1.2, 3.4, 3.6, and 4.2.

THEOREM 6.1 (**ZK** characterization theorem). *For a promise problem* Π*, the following conditions are equivalent:*

1. $\Pi \in \mathbf{HVZK}$.
2. $\Pi \in \mathbf{IP}$*, and* Π *satisfies the* CONDITIONAL PSEUDOENTROPY CONDITION.
3. $\Pi \in \mathbf{IP}$*, and* Π *satisfies the* SZK/OWF CONDITION.
4. $\Pi \in \mathbf{IP}$*, and* Π *satisfies the* INDISTINGUISHABILITY CONDITION.
5. $\Pi \in \mathbf{IP}$*, and* Π *has a public-coin computationally hiding instance-dependent commitment scheme in the sense of Definition* 4.1*. Moreover, the sender is PPT given an* **NP** *oracle.*
6. $\Pi \in \mathbf{ZK}$.
7. Π *has a public-coin computational zero-knowledge proof with a black-box simulator and perfect completeness.*
8. Π *has a public-coin computational zero-knowledge proof with a black-box simulator, where on any input* x*, the prover strategy* P_x *is PPT given an* **NP** *oracle and an oracle for* $\hat{P}_x$*, where* $\hat{P}$ *is the prover in any interactive proof system for* Π*. In particular, if* $\Pi \in \mathbf{NP}$ *(or even* $\Pi \in \mathbf{AM}$*), then* P_x *is PPT given an* **NP** *oracle.*

Proof.

1 ⇒ 2 This follows from Lemma 3.7, together with the trivial inclusion $\mathbf{HVZK} \subseteq \mathbf{IP}$.

2 ⇒ 3 This is Lemma 3.10.

3 ⇒ 5 This is Lemma 4.4.

5 ⇒ 7 Suppose $\Pi \in \mathbf{IP}$, and that Π has a public-coin instance-dependent commitment scheme. By Lemma 4.8, Π has a public-coin honest-verifier zero-knowledge proof. We can convert this into a public-coin proof system with perfect completeness using the transformation of Fürer et al. [19], which preserves honest-verifier zero knowledge. Finally, by Theorem 4.9, this can be converted into a public-coin (cheating-verifier) zero-knowledge proof with a black-box simulator and perfect completeness.

5 ⇒ 8 This is proved the same way as in the previous item, except we omit the transformation of Fürer et al. [19] (which seems to increase the prover complexity beyond $\mathbf{BPP}^{\mathbf{NP}}$). For bounding the prover complexity, we first note that if $\Pi \in \mathbf{IP}$, then a (variant of) the Goldwasser–Sipser [36] transformation converts any interactive proof $(\hat{P}, \hat{V})$ for Π into a public-coin interactive proof, where the prover on input x is PPT given an **NP** oracle and oracle access to $\hat{P}_x$. Then Lemma 4.8 preserves this prover complexity because the sender in the instance-dependent commitment is PPT given with an **NP** oracle. The same holds for Theorem 4.9.

7/8 ⇒ 6 ⇒ 1 These are immediate from the definitions.

2 ⇔ 4 This is by Lemmas 3.13 and 3.14. □

We also prove Theorem 4.3, which we restate here.

THEOREM 6.2 (Theorem 4.3, restated). $\Pi \in \mathbf{SZK}$ *if and only if* $\Pi \in \mathbf{IP}$ *and* Π *has a* statistically *hiding instance-dependent commitment scheme in the sense of Definition* 4.1*.*

Proof.

⇒ This follows from Lemma 4.6, together with the trivial inclusion $\mathbf{SZK} \subseteq \mathbf{IP}$.

⇐ This follows from Lemma 4.8, together with the fact that $\mathbf{HVSZK} = \mathbf{SZK}$ [48, 32]. □

7. Applications and extensions.

7.1. The Ostrovsky–Wigderson theorems. As described in the introduction, the approach of this paper, and in particular the SZK/OWF characterization theorem, are inspired by the work of Ostrovsky and Wigderson [50], who showed that "nontriviality" of **ZK** implies "some form of one-way functions." In this section, we show how our results can be used to give new, more modular proofs of the Ostrovsky–Wigderson theorems. Specifically, we use the SZK/OWF characterization theorem to deduce the Ostrovsky–Wigderson theorems about **ZK** from the earlier (and much simpler) work of Ostrovsky [49] on **SZK**. In fact, we need only our results from section 3, showing that every problem in **HVZK** satisfies the SZK/OWF CONDITION. Our results in the converse direction, from sections 4, 5, and 6, are not needed.

The two Ostrovsky–Wigderson theorems are obtained by two different interpretations of "nontriviality" and "some form of one-way functions." In their first theorem (mentioned in the introduction), both are interpreted in a weak sense as follows.

THEOREM 7.1 (see [50, Thm. 1]). *If* $\mathbf{HVZK} \neq \mathbf{BPP}$*, then there exists a poly-time auxiliary-input family of functions* $\{f_x : \{0,1\}^{p(|x|)} \to \{0,1\}^{q(|x|)}\}$ *that is not "easy to invert." That is, for every PPT* A *and every polynomial* $r(n)$*, there exists an infinite set* $I \subseteq \{0,1\}^*$ *such that*

$$\Pr\left[A(x, f_x(U_{p(|x|)})) \in f_x^{-1}(f_x(U_{p(|x|)}))\right] \leq 1/r(|x|)$$

for all $x \in I$*.*

We point out that the theorem above refers to *uniform* PPT inverters A; to obtain functions that are not easy to invert by nonuniform algorithms, the hypothesis should be replaced with $\mathbf{HVZK} \not\subset \mathbf{P/poly}$.

In their second theorem, both conditions are interpreted in a strong sense as follows.

DEFINITION 7.2. *A promise problem* Π *is* hard on average *if there exists a PPT sampling algorithm* S*, a polynomial* r*, and a constant* $\delta > 0$ *such that for every nonuniform PPT* A*, the following holds for all but finitely many* n*:*

$$\Pr_{x \leftarrow S(1^n)}\left[(x \in \Pi_Y \cup \Pi_N) \wedge (A(x) \neq \chi_\Pi(x)) \wedge |x| \geq n^\delta\right] \geq \frac{1}{r(n)},$$

where χ_Π *is the characteristic function of* Π*, i.e.,* $\chi_\Pi(x) = 1$ *if* $x \in \Pi_Y$*,* $\chi_\Pi(x) = 0$ *if* $x \in \Pi_N$*, and* $\chi_\Pi(x) = \star$ *otherwise.*

THEOREM 7.3 (see [50, Thm. 2]). *If* **HVZK** *contains a hard-on-average promise problem, then (standard) one-way functions exist.*

We begin by observing that the SZK/OWF characterization (Theorem 1.2) immediately implies a stronger form of one-way functions than given by Theorem 7.1 under the stronger (but still worst-case) hypothesis that $\mathbf{HVZK} \neq \mathbf{HVSZK}$.

THEOREM 7.4. *If* $\mathbf{HVZK} \neq \mathbf{HVSZK}$*, then there exists an auxiliary-input one-way function on some infinite set* I*. That is, there is a poly-time auxiliary-input family of functions* $\{f_x : \{0,1\}^{p(|x|)} \to \{0,1\}^{q(|x|)}\}$ *and an infinite set* I *such that for every nonuniform PPT* A *and every polynomial* $r(n)$*, we have*

$$\Pr\left[A(x, f_x(U_{p(|x|)})) \in f_x^{-1}(f_x(U_{p(|x|)}))\right] \leq 1/r(|x|)$$

for all sufficiently long $x \in I$*.*

The key difference between the conclusions of Theorems 7.1 and 7.4 is that the order of quantifiers between the adversary A and the infinite set I is reversed. In

the former, the infinite set of indices x for which the adversary fails to invert f_x can depend on the adversary A, whereas in the latter, there is a fixed infinite set of indices such that f_x is hard for *all* polynomial-time adversaries A.

Recall that $\mathbf{HVSZK} \subseteq \mathbf{AM} \cap \mathbf{co\text{-}AM}$ [18, 1], and thus it is unlikely that $\mathbf{NP} \subseteq \mathbf{HVSZK}$. Thus Theorem 7.4 can be interpreted as further evidence, incomparable to what is given by the Ostrovsky–Wigderson theorems (Theorems 7.1 and 7.3), that one-way functions are necessary to construct zero-knowledge proofs for all of NP (not to mention all of **IP**). (Recall that it is known that one-way functions are *sufficient* to establish that $\mathbf{IP} = \mathbf{ZK}$ [29, 39, 7, 45, 37].)

Proof of Theorem 7.4. Suppose $\mathbf{HVZK} \neq \mathbf{HVSZK}$, and let Π be any promise problem in $\mathbf{HVZK} \setminus \mathbf{HVSZK}$. By Theorem 6.1, Π satisfies the SZK/OWF Condition. That is, there is a set I such that $\Pi' = (\Pi_Y \setminus I, \Pi_N)$ is in **SZK** and there exists an auxiliary-input one-way function on I. We claim that I is infinite (which suffices to complete the proof). Suppose for the sake of contradiction that I is finite. Since $\Pi' \in \mathbf{SZK}$ and Π and Π' differ on only a finite set of inputs, we conclude that $\Pi \in \mathbf{SZK} \subseteq \mathbf{HVSZK}$. (The statistical zero-knowledge proof for Π is the same as the statistical zero-knowledge proof for Π', except we hardwire the set I into the verifier and simulator, have the verifier immediately accept inputs $x \in I$, and have the prover send nothing on such inputs.) This contradicts the choice of Π. ∎

We now give alternate proofs of the Ostrovsky–Wigderson theorems themselves based on the work of Ostrovsky on **SZK**, as captured in the following theorem.

Theorem 7.5 (implicit in Ostrovsky [49]). *For every problem $\Pi \in \mathbf{HVSZK}$, there exists a poly-time auxiliary-input function ensemble $\mathcal{F} = \{f_x : \{0,1\}^{p(|x|)} \to \{0,1\}^{q(|x|)}\}_{x \in \{0,1\}^*}$, a probabilistic polynomial-time oracle machine M, and a negligible function ϵ such that for every $x \in \Pi_Y \cup \Pi_N$, every $t \in \mathbb{N}$, and every function $A : \{0,1\}^{q(|x|} \to \{0,1\}^{p(|x|)}$, we have*

$$\begin{aligned} &\Pr\left[A(f_x(U_{p(|x|)})) \in f_x^{-1}(f_x(U_{p(|x|)}))\right] > \epsilon(|x|) + \frac{1}{t} \\ &\Rightarrow \Pr\left[M^A(x, 1^t) = \chi_\Pi(x)\right] \geq 1 - 2^{-|x|}, \end{aligned}$$

where χ_Π is again the characteristic function of Π.

Note that t, which specifies A's success probability in inverting f_x (up to a negligible term), is given as an input (in unary) to the oracle machine M. Intuitively, for M to take advantage of the fact that A inverts f_x with probability $\approx 1/t$, M must be allowed running time polynomially related to t.

Proof of Theorem 7.1. Suppose that $\mathbf{HVZK} \neq \mathbf{BPP}$. Then either $\mathbf{HVZK} \neq \mathbf{HVSZK}$ or $\mathbf{HVSZK} \neq \mathbf{BPP}$. In the first case, we are done by Theorem 7.4. Thus, we need only show that $\mathbf{HVSZK} \neq \mathbf{BPP}$ implies the existence of an auxiliary-input family of functions that is not easy to invert. This follows readily from Theorem 7.5. Let Π be any promise problem in $\mathbf{HVSZK} \setminus \mathbf{BPP}$, and let $\{f_x\}$ be the family of functions provided by Theorem 7.5. If there is a uniform PPT A inverting f_x with probability at least $1/r(|x|)$, for some polynomial r and all but finitely many x, then by Theorem 7.5, $M^{A(x,\cdot)}(x, 1^{2r(|x|)})$ is a PPT algorithm that decides Π correctly for all but finitely many x.[14] This contradicts the assumption that $\Pi \notin \mathbf{BPP}$. ∎

[14] A minor technicality is that Theorem 7.5 is stated for deterministic oracles A, whereas here A may be probabilistic. However, after a standard error reduction obtained by $O(r(|x|))$ repeated trials, we can ensure that with probability .99 over A's coin tosses w, the deterministic algorithm $A(x, \cdot; w)$ inverts $f_x(U_{p(|x|)})$ with probability $(.75) \cdot (1/r(|x|))$. So we obtain a **BPP** algorithm for Π by randomly choosing w and running $M^{A(x,\cdot,w)}(x, 1^{2r(|x|)})$.

The above proof illustrates why Theorem 7.1 yields only a family of functions that is not easy to invert, rather than the stronger notion of auxiliary-input one-way functions achieved in Theorem 7.4. The reason is that the supposed inverter A for the family of functions is used to construct a **BPP** algorithm for the promise problem $\Pi \in \mathbf{SZK}$. The hypothesis that $\mathbf{SZK} \neq \mathbf{BPP}$ seems to guarantee only that for every inverter A there exists an infinite set I_A of instances on which this procedure fails, not that there exists a fixed infinite set I of "hard" instances on which the procedure fails for any A. For example, an inverter A running in time n^2 may be able to succeed on a larger set of instances than an inverter running in time n, and one running in time n^3 may succeed on an even larger set of instances, and so on. Ultimately, the set of instances which are hard for *all* polynomial-time A may be empty.

How is this difficulty avoided in Theorem 7.4, which relies on the SZK/OWF CONDITION as established in section 3? Intuitively, the reason is that the hardness of inverting the function f_x of the SZK/OWF CONDITION when x is an "OWF instance" is not derived from the intractability of the promise problem Π, which does not make sense for fixed instances x (for the reasons discussed above), but rather is based on the intractability of distinguishing the output of the simulator from the real interaction in an **HVZK** proof system (which makes sense for fixed instances x and indeed is required to hold for every $x \in \Pi_Y$).

Theorem 7.3 gets around this difficulty in a different way by requiring a stronger form of intractability for the problem Π, namely, that it is hard on average. Let us first consider the case that we have a hard-on-average problem $\Pi \in \mathbf{HVSZK}$, following Ostrovsky [49]. Instead of hoping that x's membership in Π will be hard to decide, and thus that f_x from Theorem 7.5 will be hard to invert for particular values of x, we simply can sample a random instance x and be guaranteed, by the definition of "hard on average," that for *any* polynomial-time algorithm A, the instance x will be "hard" for A with at least a fixed nonnegligible probability. Thus $f(x,y) = (x, f_x(y))$ will be hard to invert with a fixed nonnegligible probability for any polynomial-time inverter. Now to handle the more general case of $\Pi \in \mathbf{HVZK}$, we use the SZK/OWF CONDITION, combining Ostrovsky's one-way functions just described, which are hard to invert in the case that x is an "SZK instance," with the one-way functions of the SZK/OWF CONDITION, which are hard to invert in the case that x is an "OWF instance." This yields the following new proof of Theorem 7.3.

Proof of Theorem 7.3. Suppose $\Pi \in \mathbf{HVZK}$ is hard-on-average with respect to the sampling algorithm S. Theorem 6.1 tells us that Π satisfies the SZK/OWF CONDITION, so there is a set $I \subseteq \Pi_Y$ and a poly-time auxiliary-input function ensemble $\mathcal{F} = \{f_x : \{0,1\}^{p(|x|)} \to \{0,1\}^{q(|x|)}\}$ such that $\Pi' = (\Pi_Y \setminus I, \Pi_N)$ is in $\mathbf{SZK} = \mathbf{HVSZK}$ and $\mathcal{F}$ is one-way on I. We now apply Theorem 7.5 to Π' to get another poly-time auxiliary-input function ensemble $\mathcal{F}' = \{f'_x : \{0,1\}^{p'(|x|)} \to \{0,1\}^{q'(|x|)}\}$ such that any inverter for f'_x can be used to decide whether x is a YES or NO instance of Π'.

Now we construct a one-way function g_n, where n is the security parameter, as follows: The input to g_n is a triple (r, w, w'). To compute $g_n(r, w, w')$, we interpret r as coin tosses for the sampling algorithm S, obtaining an instance $x = S(1^n; r)$ of Π, and output $(x, f_x(w), f'_x(w'))$.

We will now argue that g_n is a *weak* one-way function, namely, that no nonuniform PPT algorithm can invert g_n with probability higher than $1 - 1/(4r(n))$, where r is the polynomial in the definition of hard on average. Suppose that there is a nonuniform PPT inverter A such that

$$\Pr\left[A(g_n(R,W,W')) \in g_n^{-1}(g_n(R,W,W'))\right] \geq 1 - 1/(4r(n))$$

for infinitely many n, when R, W, and W' are chosen uniformly at random from the bit-strings of appropriate length. (Since A is nonuniform, we may assume that it is deterministic w.l.o.g.)

First, we note that when $X = S(1^n; R) \in I$, then A has only a negligible probability of inverting over the choice of W, by the one-wayness of f_X. Thus, we have

$$\Pr\left[A(g_n(R, W, W')) \in g_n^{-1}(g_n(R, W, W')) \wedge S(1^n; R) \notin I\right] \geq 1 - 1/(3r(n)). \tag{2}$$

Now we use Theorem 7.5 to convert A into an algorithm B that decides Π', and hence Π, well on average (with respect to the distribution $S(1^n)$). Specifically, on input x, B chooses w uniformly at random and runs $M^{A(x, f_x(w), \cdot)_3}(x, 1^{|x|})$, where δ is the constant in the definition of hard on average and $A(x, f_x(w), \cdot)_3$ denotes the third component of the output of A.

From (2), it follows that with probability at least $1 - 2/(3r(n))$ over the choices of $r \leftarrow R$ and $w \leftarrow W$, we have $x = S(1^n; r) \notin I$ and

$$\begin{aligned} &\Pr\left[A(x, f_x(w), f'_x(W'))_3 \in (f'_x)^{-1}(f'_x(W'))\right] \\ &\geq \Pr\left[A(g_n(r, w, W')) \in g_n^{-1}(g_n(r, w, W'))\right] \geq 1/2, \end{aligned} \tag{3}$$

where the probabilities are taken only over W'. Whenever inequality (3) holds and we have $x \in \Pi'_Y \cup \Pi'_N = (\Pi_Y \cup \Pi_N) \setminus I$, Theorem 7.5 ensures that $M^{A(x, f_x(w), \cdot)_3}(x, 1^{|x|})$ correctly decides whether x is a YES or NO instance of Π' with probability at least $1 - 2^{-|x|}$. Thus, setting $X = S(1^n; R)$, we have

$$\Pr\left[(X \in \Pi_Y \cup \Pi_N) \wedge (B(X) \neq \chi_\Pi(X)) \wedge (|X| \geq n^\delta\right] \leq 2/(3r(n)) + 2^{-n^\delta} < 1/r(n).$$

This contradicts the fact that Π is hard on average with respect to the distribution $S(1^n)$. □

We note that an alternative way to prove a version of Theorem 7.3 is to combine our results with [52, Thm. 5.12], which shows that if a hard-on-average problem satisfies the INDISTINGUISHABILITY CONDITION, then one-way functions exist. However, [52, Thm. 5.12] uses a stronger definition of hard on average than Definition 7.2, requiring that any PPT algorithm has error probability negligibly close to 1/2, rather than just $1/\text{poly}(n)$. In addition, we feel that it is informative to see how the result for **ZK** follows from combining Ostrovsky's work on **SZK** (i.e., Theorem 7.5) with the SZK/OWF
CONDITION.

7.2. Monotone closure. In this section, we use our results to prove closure properties of **ZK**. We begin by noting that the fact that **ZK** is closed under intersection is immediate: To prove that $x \in \Pi_Y \cap \Gamma_Y$ for promise problems $\Pi, \Gamma \in \mathbf{ZK}$, the prover can prove that $x \in \Pi_Y$ using the zero-knowledge proof for Π and then prove that $x \in \Gamma_Y$ using the zero-knowledge proof for Γ, and the verifier accepts only if both proofs are convincing. The analogous approach for union, however, does not work. In particular, proving that $x \in \Pi_Y \cup \Gamma_Y$ seems to require the prover to reveal whether $x \in \Pi_Y$ or $x \in \Gamma_Y$, and thus the proof system may not be zero knowledge.

In this section, we show **ZK** is indeed closed under union. More generally, for every $\Pi \in \mathbf{ZK}$, we give zero-knowledge proofs for arbitrary monotone Boolean formulae over statements about membership in Π, where the formula can even be specified as part of the common input. Such closure properties were previously known for **SZK**

[14, 48, 52].[15] Indeed we prove our results by reduction to the **SZK** case via the SZK/OWF characterization theorem. (An alternative way of proving the results is to mimic the proofs for **SZK**, replacing the STATISTICAL DIFFERENCE in the construction of [52] with the INDISTINGUISHABILITY CONDITION.)

THEOREM 7.6. **ZK** *is closed under union.*

Proof. By Theorem 1.2, a promise problem is in **ZK** if and only if it is in **IP** and it satisfies the SZK/OWF CONDITION. Since **IP** is closed under union, it suffices to show that the class of problems satisfying the SZK/OWF CONDITION is closed under union.

Suppose that Π and Γ satisfy the SZK/OWF CONDITION. Then there are sets I and J and poly-time auxiliary-input families of functions $\{f_x\}, \{g_x\}$ such that $\Pi' = (\Pi_Y \setminus I, \Pi_N)$ and $\Gamma' = (\Gamma_Y \setminus J, \Gamma_N)$ are both in **SZK**, f_x is one-way when $x \in I$, and g_x is one-way when $x \in J$. We claim that the set $K = I \cup J$ of "OWF instances" and the family of functions $\{h_x\}$, where $h_x(y,z) = (f_x(y), g_x(z))$, meet the requirements for showing that $\Pi \cup \Gamma$ satisfies the SZK/OWF CONDITION. Indeed, when $x \in K$, then h_x is one-way because either f_x or g_x is one-way. The promise problem $((\Pi_Y \cup \Gamma_Y) \setminus K, \Pi_N \cap \Gamma_N)$ is in **SZK** because it is a restriction of the promise problem $\Pi' \cup \Gamma' = (\Pi'_Y \cup \Gamma'_Y, \Pi'_N \cap \Gamma'_N)$ (i.e., the YES instances of the former problem are a subset of those of the latter, and the NO instances of both problems are the same), and $\Pi' \cup \Gamma'$ in **SZK** because **SZK** is closed under union [48]. □

We now present some definitions (closely following [52]) to formalize the more general monotone closure properties we will obtain. Specifically, in order to deal with instances of promise problems that violate the promise, we will work with an extension of Boolean algebra that includes an additional "ambiguous" value $\star$.

DEFINITION 7.7. *A* partial assignment *to variables $v_1, \ldots, v_k$ is a k-tuple $\overline{a} = (a_1, \ldots, a_k) \in \{0, 1, \star\}^k$. For a propositional formula (or circuit) ϕ on variables $v_1, \ldots, v_k$, the evaluation $\phi(\overline{a})$ is recursively defined as follows:*

$$v_i(\overline{a}) = a_i, \qquad (\phi \wedge \psi)(\overline{a}) = \begin{cases} 1 & \text{if } \phi(\overline{a}) = 1 \text{ and } \psi(\overline{a}) = 1, \\ 0 & \text{if } \phi(\overline{a}) = 0 \text{ or } \psi(\overline{a}) = 0, \\ \star & \text{otherwise,} \end{cases}$$

$$(\neg\phi)(\overline{a}) = \begin{cases} 1 & \text{if } \phi(\overline{a}) = 0, \\ 0 & \text{if } \phi(\overline{a}) = 1, \\ \star & \text{if } \phi(\overline{a}) = \star, \end{cases} \qquad (\phi \vee \psi)(\overline{a}) = \begin{cases} 1 & \text{if } \phi(\overline{a}) = 1 \text{ or } \psi(\overline{a}) = 1, \\ 0 & \text{if } \phi(\overline{a}) = 0 \text{ and } \psi(\overline{a}) = 0, \\ \star & \text{otherwise.} \end{cases}$$

Note that $\phi(\overline{a})$ equals 1 (resp., 0) for some partial assignment $\overline{a}$; then $\phi(\overline{a}')$ also equals 1 (resp., 0) for every Boolean $\overline{a}'$ obtained by replacing every $\star$ in $\overline{a}$ with either a 0 or 1. The converse, however, is not true: The formula $\phi = v \vee \neg v$ evaluates to 1 on every Boolean assignment, yet is not 1 when evaluated at $\star$. Thus, the "law of excluded middle" $\phi \vee \neg\phi \equiv 1$ no longer holds in this setting. However, other identities in Boolean algebra, such as De Morgan's laws (e.g., $\neg(\phi \vee \psi) \equiv \neg\phi \wedge \neg\psi$), do remain true.

DEFINITION 7.8. *For a promise problem* Π, *the* characteristic function *of* Π *is*

[15] In fact, since **SZK** is closed under complement [48], its closure properties extend even to non-monotone formulae.

the map $\chi_\Pi : \{0,1\}^* \to \{0,1,\star\}$ *given by*

$$\chi_\Pi(x) = \begin{cases} 1 & \text{if } x \in \Pi_Y, \\ 0 & \text{if } x \in \Pi_N, \\ \star & \text{otherwise.} \end{cases}$$

DEFINITION 7.9. *For any promise problem* Π *and constant* $\delta > 0$*, we define a new promise problem* $\mathrm{Mon}_\delta(\Pi)$ *as follows:*

$$\mathrm{Mon}_\delta(\Pi)_Y = \{(\phi, x_1, \ldots, x_k) : \phi(\chi_\Pi(x_1), \ldots, \chi_\Pi(x_k)) = 1 \text{ and } \forall i\ |x_i| \geq n^\delta\},$$
$$\mathrm{Mon}_\delta(\Pi)_N = \{(\phi, x_1, \ldots, x_k) : \phi(\chi_\Pi(x_1), \ldots, \chi_\Pi(x_k)) = 0 \text{ and } \forall i\ |x_i| \geq n^\delta\},$$

where ϕ *is a* monotone *k-ary propositional formula, and* $n = |(\phi, x_1, \ldots, x_k)|$.

The condition $|x_i| \geq n^\delta$ is a technicality due to the fact that the security of zero-knowledge proofs is defined with respect to the input length. Intuitively, we will be constructing zero-knowledge proofs for instances of $\mathrm{Mon}_\delta(\Pi)$ of length $n = |(\phi, x_1, \ldots, x_k)|$, but these will be built by using zero-knowledge proofs (or the resulting SZK/OWF CONDITION) for the individual x_i's. Hence to achieve security in terms of n, we will need the x_i's to be of length polynomially related to n. Naturally, this entire issue disappears if one works with a security-parameterized definition of zero knowledge (cf. remark 5 at the end of section 2.5).

THEOREM 7.10. *For any promise problem* $\Pi \in \mathbf{SZK}$ *and any constant* $\delta > 0$*,* $\mathrm{Mon}_\delta(\Pi) \in \mathbf{SZK}$.

Proof. First, we note that **IP** is closed under $\mathrm{Mon}_\delta(\cdot)$. To prove that $(\phi, x_1, \ldots, x_k)$ is in $\mathrm{Mon}_\delta(\Pi)_Y$, it suffices to prove that a subset of the x_i's is in Π_Y, due to the monotonicity of ϕ. Thus, by Theorem 1.2 we need only show that if Π satisfies the SZK/OWF CONDITION, then $\mathrm{Mon}_\delta(\Pi)$ satisfies the SZK/OWF CONDITION.

Let Π be any promise problem satisfying the SZK/OWF CONDITION, with a corresponding set $I \subseteq \Pi_Y$ and poly-time auxiliary-input functions $\{f_x\}$ such that $\Pi' = (\Pi_Y \setminus I, \Pi_N)$ is in **SZK** and f_x is hard to invert when $x \in I$. Since **SZK** is closed under $\mathrm{Mon}_\delta(\cdot)$ (even for $\delta = 0$) [14, 52], we have that $\mathrm{Mon}_\delta(\Pi') \in \mathbf{SZK}$. Note that $\mathrm{Mon}_\delta(\Pi')$ is identical to $\mathrm{Mon}_\delta(\Pi)$ except on instances $(\phi, x_1, \ldots, x_k)$, where at least one x_i is in I, because then $\chi_\Pi(x_i) = 1$ but $\chi_{\Pi'}(x_i) = \star$. Specifically, since changing a variable's assignment from 1 to $\star$ can change the value of a monotone formula only from 1 to $\star$, we have $\mathrm{Mon}_\delta(\Pi')_N = \mathrm{Mon}_\delta(\Pi)_N$ and $\mathrm{Mon}_\delta(\Pi')_Y = \mathrm{Mon}_\delta(\Pi)_Y \setminus J$, where

$$J = \{(\phi, x_1, \ldots, x_k) \in \mathrm{Mon}_\delta(\Pi)_Y : \exists i\ x_i \in I\}.$$

Thus, to show that $\mathrm{Mon}_\delta(\Pi)$ satisfies the SZK/OWF CONDITION, it suffices to show that we can construct a one-way function from any instance in J. To do this, we simply define

$$g_{(\phi, x_1, \ldots, x_k)}(y_1, \ldots, y_k) = (f_{x_1}(y_1), \ldots, f_{x_k}(y_k)).$$

Then when $x = (\phi, x_1, \ldots, x_k) \in J$, there is at least one f_{x_i} that is hard to invert (by nonuniform PPT algorithms running in time $\mathrm{poly}(|x_i|) = \mathrm{poly}(|x|)$, since $|x| \geq |x_i| \geq |x|^\delta$), implying that g is hard to invert. ∎

Following [52], Theorem 7.10 implies that **ZK** is closed under "$\mathbf{NC}^1$ truth-table reductions" (nonadaptive Cook reductions, where the postcomputation is done by a polynomial-sized formula) and implies that the hierarchy of "computational knowledge complexity in the hint sense" [31] collapses by logarithmic additive terms. Details can be found in our technical report [59].

7.3. Expected polynomial-time simulators and weak-ZK. Recall that, following Goldreich [23], our definitions of zero knowledge (in section 2.5) refer to simulators that run in strict polynomial time. In this section, we extend our results to the original Goldwasser–Micali–Rackoff [35] definition, which allows the simulator to run in expected polynomial time. Indeed, we will prove that the two definitions yield exactly the same class **ZK**; that is, every problem having a zero-knowledge proof with an expected polynomial-time simulator also has one with a strict polynomial-time simulator. In fact, we will consider a further relaxation, captured by the following definitions.

DEFINITION 7.11. *For a function $\varepsilon : \mathbb{N} \to [0,1]$, we say that two auxiliary-input probability ensembles $\{X_x\}$ and $\{Y_x\}$ are* ε-indistinguishable *on $I \subseteq \{0,1\}^*$ if for every nonuniform PPT D, there exists a negligible function μ such that for all $x \in I$,*

$$|\Pr[D(x, X_x) = 1] - \Pr[D(x, Y_x) = 1]| \leq \varepsilon(|x|) + \mu(|x|).$$

DEFINITION 7.12 (weak zero knowledge [15]). *An interactive proof system (P, V) for a promise problem Π is* weak honest-verifier zero knowledge *if for every polynomial p there exists a probabilistic (strict) polynomial-time* simulator *S such that the ensembles $\{\langle P, V\rangle(x)\}_{x \in \Pi_Y}$ and $\{S(x)\}_{x \in \Pi_Y}$ are $(1/p(n))$ indistinguishable.*

weak-HVZK *denotes the class of promise problems having weak honest-verifier zero-knowledge proofs.*

The above definition is more relaxed than allowing expected polynomial-time simulators, because if a simulator S has expected running time $t(n)$, then running it for $p(n) \cdot t(n)$ steps yields a strict polynomial-time simulator whose output distribution is $(1/p(n))$-close to that of S. In particular, if the verifier's view is computationally indistinguishable from the output of S, then it is $(1/p(n))$-indistinguishable from the truncated version of S. (An intermediate notion is that of ε-knowledge [16], where the simulator's running time is required to be bounded by a fixed polynomial in $p(n)$ and $t(n)$.)

We remark that in the past, expected polynomial-time simulators and weak simulators have arisen mainly when considering cheating verifiers (e.g., in [35, 29, 25, 15, 16]); that is, *strict* polynomial-time simulators have always seemed to suffice for simulating the *honest* verifier's view. For such cases, an equivalence between zero knowledge with weak simulators (for cheating verifiers) and zero knowledge with strict polynomial-time simulators has already been established by our result that **HVZK** = **ZK** (Theorem 6.1). However, this does leave open the possibility that weak simulation makes a difference for honest-verifier zero knowledge. We rule out this possibility in the following theorem.

THEOREM 7.13. **weak-HVZK** = **ZK**.

Analogous results were previously known for statistical zero knowledge [34] and noninteractive statistical zero knowledge [33].

By the definitions, **ZK** $\subseteq$ **weak-HVZK**, so we need only show **weak-HVZK** $\subseteq$ **ZK**. We will do this by showing that every problem in **weak-HVZK** satisfies the SZK/OWF CONDITION, and by applying Theorem 6.1. (By definition, **weak-HVZK** $\subseteq$ **IP**.) We will do the former by extending our proof that every problem in **HVZK** satisfies the SZK/OWF CONDITION (from section 3). Intuitively, the "weak" computational indistinguishability in the definition of **weak-HVZK** will translate into obtaining a "weak" one-way function (in the sense that the inversion probability is bounded by, say, 1/2 rather than being negligible), and then we will apply Yao's conversion from weak one-way functions to standard one-way functions (see Goldreich [23, Thm. 2.3.2]).

We begin with an extension of Lemma 3.7.

LEMMA 7.14. *If a promise problem* Π *is in* **weak-HVZK**, *then* Π *satisfies the following* WEAK CONDITIONAL PSEUDOENTROPY CONDITION*: There exists a* fixed *polynomial* m *such that for* every *polynomial* p*, there is a polynomial-time computable function mapping strings* x *to a* samplable joint distribution (X, Y) *on* $\{0,1\}^{m(|x|)} \times \{0,1\}^{m(|x|)}$ *and a parameter* r *such that*

- *if* $x \in \Pi_Y$*, then there exists a (not necessarily samplable) joint distribution* (X', Y') *such that* (X', Y') *is* $(1/p(n))$*-indistinguishable from* (X, Y) *and* $\mathrm{H}(X'|Y') \geq r$*, and*
- *if* $x \in \Pi_N$*, then* $\mathrm{H}(X|Y) \leq r - 1$.

A crucial point is that the output length m of the circuits X and Y does not grow with the level of indistinguishability required (as specified by p).[16] Note, however, that we allow the sizes of the circuits and their input length (i.e., number of coin tosses) to indeed depend on p.

Proof sketch. Recall that the proof of Lemma 3.7 first constructed distributions X and Y as follows:

(X, Y): Select $i \leftarrow \{1, \ldots, \ell(|x|)\}$, choose random coin tosses R for the simulator, and output $(S_{2i}(x; R), S_{2i-1}(x; R))$,

where $\ell = \ell(|x|)$ is the number of rounds in the proof system. Here we do the same, but for any given polynomial p, we take S to be the simulator achieving ε-indistinguishability, where $\varepsilon(|x|) = 1/(\ell(|x|) \cdot p(|x|))$.

As in the proof of Lemma 3.7, when $x \in \Pi_Y$, then (X, Y) is ε-indistinguishable from $(X', Y') = (\langle P, V\rangle_{2I}, \langle P, V\rangle_{2I-1})$, where I denotes a uniform random element of $\{1, \ldots, \ell\}$, and $\mathrm{H}(X'|Y') = r/\ell$. On the other hand, when $x \in \Pi_N$, then $\mathrm{H}(X|Y) \leq (r-1)/\ell$, exactly as in Lemma 3.7.

The final distributions are taken to be $(X_1, \ldots, X_\ell)$ and $(Y_1, \ldots, Y_\ell)$, where each (X_i, Y_i) is an independent copy of (X, Y). This increases the entropy gap to 1 bit as before, and the level of indistinguishability deteriorates to $\ell \cdot \varepsilon < 1/p$. Notice that the output lengths of these distributions depend only on the communication complexity of the proof system (but the circuit sizes and number of random bits required depend on the simulator, which in turn depends on the choice of p). □

Given this lemma, we proceed to reduce the WEAK CONDITIONAL PSEUDOENTROPY CONDITION to the SZK/OWF CONDITION, analogously to Lemma 3.10. In the proof, we will need a weak analogue of the notion of a false entropy generator, as follows.

DEFINITION 7.15. *We say that there is an* auxiliary-input weak false entropy generator on I *if there exists a* fixed *polynomial* m *such that for* every *polynomial* p*, we have samplable auxiliary-input probability ensembles* $\mathcal{D} = \{D_x\}$ *and* $\mathcal{F} = \{F_x\}$ *such that* D_x *and* F_x *take values in* $\{0,1\}^{m(|x|)}$ *and when* $x \in I$*,* D_x*, and* F_x *are* $1/p(|x|)$*-indistinguishable and satisfy* $\mathrm{H}(F_x) \geq \mathrm{H}(D_x) + 1$.

The following generalization of Lemma 3.12, proved in Appendix B, states that such weak false entropy generators also imply one-way functions.

[16] Indeed, otherwise every promise problem would trivially satisfy the WEAK CONDITIONAL PSEUDOENTROPY CONDITION. Let $p = p(n)$ be an arbitrary polynomial, and let $m = p$. Given an input x of length n, let (X, Y) be the distribution that always outputs $(0^m, 0^m)$, let $r = 1$, and let (X', Y') equal $(0^m, 0^m)$ with probability $1 - 1/p$ and equal $(U_m, 0^m)$ with probability $1/p$. Then $\mathrm{H}(X|Y) = 0 \leq r - 1$, (X', Y') is $1/p$-close to (X, Y), and $\mathrm{H}(X'|Y') \geq (1/p) \cdot m = r$.

LEMMA 7.16. *If there is an auxiliary-input weak false entropy generator on I, then there exists an auxiliary-input one-way function on I.*

We now use this to establish the SZK/OWF CONDITION.

LEMMA 7.17. *If a promise problem satisfies the* WEAK CONDITIONAL PSEUDOENTROPY CONDITION*, then it satisfies the* SZK/OWF CONDITION.

Proof. Let Π be a promise problem satisfying the WEAK CONDITIONAL PSEUDOENTROPY CONDITION, with m being the associated fixed polynomial. Then for any given $\varepsilon = \varepsilon(n) = 1/\text{poly}(n)$ and any instance $x \in \{0,1\}^n$, we can efficiently construct two samplable distributions (X, Y) on $\{0,1\}^m \times \{0,1\}^m$ and a parameter r such that if $x \in \Pi_Y$, then $\mathrm{H}(X'|Y') \geq r + 1$ for some (X', Y') that is ε-indistinguishable from (X, Y), and if $x \in \Pi_N$, then $\mathrm{H}(X|Y) \leq r - 1$.

Let I be the set of instances $x \in \Pi_Y$ such that $\mathrm{H}(X|Y) < r$. The argument that $\Pi' = (\Pi_Y \setminus I, \Pi_N)$ is in **SZK** is identical to the argument in the proof of Lemma 3.10.

Thus, we focus on constructing one-way functions on I. The first step of the construction (given in the proof of Lemma 3.10) does not change. We set $k = 4n \cdot (m+n)^2$ and consider the samplable distributions

$$D = (H, Y_1, \ldots, Y_k, H(X_1, \ldots, X_k)),$$
$$F = (H, Y_1, \ldots, Y_k, U_{kr+1}).$$

As in the proof of Lemma 3.10, $\mathrm{H}(F) \geq \mathrm{H}(D) + 1$. The only change is that instead of arguing that D and F are computationally indistinguishable, we claim that they are ε'-indistinguishable from Z for $\varepsilon' = 2k \cdot \varepsilon$. The deterioration by a factor of k comes from applying the hybrid argument to k samples of (X_i, Y_i); this occurs both when relating D to D^* and when relating F to F^* in the proof of Lemma 3.10; hence the additional factor of 2. Recalling that $k = 4n \cdot (m+n)^2$ depends only on n and the output length m, we see that we can still make the level ε' of indistinguishability arbitrarily small (by a suitable choice of ε). Moreover, the output length m' of D and F remains independent of the choice of $\varepsilon' = 1/\text{poly}(n)$. Thus, we have a weak auxiliary-input false entropy generator on I. By Lemma 7.16, we have an auxiliary-input one-way function on I, as needed. ∎

8. Open problems. The following are some results that are known about **ZK** under the assumption that one-way functions exist, but for which we have not given unconditional proofs:

1. **ZK** is closed under complement. (If one-way functions exist, then **ZK** = **IP** = **PSPACE** = **co-PSPACE** [29, 39, 7, 45, 37, 42, 54].)
2. If $\Pi \in \mathbf{ZK} \cap \mathbf{NP}$, then Π has a constant-round zero-knowledge proof with soundness error $1/\text{poly}(n)$ [29, 9]. (Constant-round protocols with negligible soundness error are known under stronger assumptions [25].)
3. If $\Pi \in \mathbf{ZK} \cap \mathbf{NP}$, then Π has a computational zero-knowledge proof, where the prover runs in PPT given an **NP** witness for membership [29]. (In our Theorem 6.1, the prover needs an **NP** *oracle*.)

The only bottleneck for proving the latter two results unconditionally is our instance-dependent commitment scheme for **SZK** (Theorem 4.3), which has polynomially many rounds and a $\mathbf{BPP}^{\mathbf{NP}}$ sender, so any improvement to that commitment scheme in these respects would have an analogous impact on **ZK**. In fact, at the time of this work, the last two items (round complexity and prover efficiency) were open problems for **SZK** as well, and in [44] instance-dependent commitments were proposed as an approach to the question of prover efficiency for **SZK**. Subsequent to this work, in joint work with Nguyen [46], we resolve the prover efficiency question, proving

item 3 unconditionally, as well as its **SZK** analogue. That work does not, however, construct standard instance-dependent commitment schemes with an efficient sender for all of **SZK** and **ZK** (but rather some new variant of such commitment schemes), and this remains an interesting open problem having additional consequences, e.g., for unconditional results on concurrent zero knowledge [43].

Given that we have been able to prove unconditional results about **ZK**, which allows for computational security in the zero-knowledge condition, a natural subsequent project is to try and handle computational security in the *soundness* condition, that is, undertake a similar unconditional study of zero-knowledge *arguments*, as defined in [10, 23].

Appendix A. Lemmas about flat distributions.

LEMMA A.1 (flattening lemma restated). *Let X be a distribution, k be a positive integer, and $\otimes^k X$ denote the distribution composed of k independent copies of X. Suppose that for all x in the support of X it holds that $\Pr[X = x] \geq 2^{-m}$. Then $\otimes^k X$ is $\sqrt{k} \cdot m$-flat.*

Suppose Y is jointly distributed with X, and for all (x, y) in the support of (X, Y) it holds that $\Pr[X = x|Y = y] \geq 2^{-m}$. Then, defining $((X_1, Y_1), \ldots, (X_k, Y_k)) = \otimes^k (X, Y)$, the random variable $(X_1, \ldots, X_k)$ is $\sqrt{k} \cdot m$-flat given $(Y_1, \ldots, Y_k)$.

Proof. For every (x, y) in the support of (X, Y), we define the *weight of x given y* to be $\mathrm{wt}(x|y) = \log(1/\Pr[X = x|Y = y])$. Then $\mathrm{wt}(\cdot)$ maps the support of (X, Y) to $[0, m]$. For every $x_1, \ldots, x_k$ and $y_1, \ldots, y_k$, we have

$$\log \frac{1}{\Pr[(X_1, \ldots, X_k) = (x_1, \ldots, x_k)|(Y_1, \ldots, Y_k) = (y_1, \ldots, y_k)]} = \sum_{i=1}^{k} \mathrm{wt}(x_i|y_i).$$

Thus, if we let $\overline{X} = (X_1, \ldots, X_k)$ and $\overline{Y} = (Y_1, \ldots, Y_k)$, we have

$$\Pr\left[\overline{X} \text{ is not } t\Phi\text{-typical given } \overline{Y}\right] = \Pr\left[\left|\sum_{i=1}^{k} \mathrm{wt}(X_i|Y_i) - \mathrm{H}(\overline{X}|\overline{Y})\right| \geq t\Phi\right].$$

For every i, $\mathrm{E}[\mathrm{wt}(X_i|Y_i)] = \mathrm{H}(X|Y)$ and $\mathrm{H}(\overline{X}|\overline{Y}) = k \cdot \mathrm{H}(X|Y)$, so we are bounding the probability that the average of k independent, identically distributed random variables taking values in $[0, m]$ deviates from its expectation by $t\Phi/k$. By the Hoeffding inequality, this probability is at most

$$2 \cdot \exp\left(\frac{-2 \cdot k \cdot (t\Phi/k)^2}{m^2}\right).$$

For $\Phi = \sqrt{k} \cdot m$ and $t \geq 1$, this bound becomes $2\exp(-2t^2) \leq 2^{-t^2}$, establishing the lemma. □

LEMMA A.2 (Claim 5.9 restated). *Let Z_0 and Z_1 be Φ-flat distributions, for $\Phi \geq 1$. Let $Z = Z_C$, where C is a uniformly chosen random bit. Then Z is 3Φ-flat.*

Proof. We need to show that, for every $t \geq 1$, a random sample $z \leftarrow Z$ is not $t \cdot 3\Phi$-typical for Z with probability at most 2^{-t^2}. For this, it suffices to separately bound the probabilities that z is not $t{\cdot}3\Phi$-light and that z is not $t{\cdot}3\Phi$-heavy. Note that $t{\cdot}3\Phi \geq 2t{\cdot}\Phi{+}1$, so we can bound the probabilities with respect to a lightness/heaviness threshold of $2t \cdot \Phi + 1$ instead.

Bounding the lightness probability is relatively straightforward because z being light for Z implies that it is light for both Z_0 and Z_1. Specifically, for any z that is

$(2t \cdot \Phi + 1)$-light for Z, we have

$$\Pr[Z_0 = z] \leq 2 \cdot \Pr[Z = z] \leq 2 \cdot 2^{-(2t\Phi+1)} \cdot 2^{-\mathrm{H}(Z)} \leq 2^{-2t\Phi} \cdot 2^{-\mathrm{H}(Z_0)}.$$

The analogous bound holds for Z_1. Therefore any such z is also $2t\Phi$-light for Z_0 and Z_1. Hence, if $z \leftarrow Z$, then z is $(2t \cdot \Phi + 1)$-light for Z with probability at most $2^{-(2t)^2}$.

The heaviness probability is a bit more subtle because z being heavy for Z implies only that it is heavy for either Z_0 or Z_1; specifically, if z is $(2t \cdot \Phi + 1)$-heavy for Z, then

$$\max\{\Pr[Z_0 = z], \Pr[Z_1 = z]\} \geq \Pr[Z = z] \geq 2^{2t\Phi+1} \cdot 2^{-\mathrm{H}(Z)} \geq 2^{2t\Phi+1} \cdot 2^{-(\mathrm{H}(Z_0)+1)}.$$

Thus, any such z is $2t\Phi$-heavy for either Z_0 or Z_1. W.l.o.g. say that z is heavy for Z_0. The probability that Z_0 outputs a string that is $2t\Phi$-heavy (for Z_0) is at most $2^{-(2t)^2}$, by Φ-flatness. However we also need to bound the probability that Z_1 outputs such a string. Let H_0 be the set of strings that are $2t\Phi$-heavy for Z_0. The total probability mass of H_0 under Z_0 is at least $|H_0| \cdot 2^{-\mathrm{H}(Z_0)+2t\Phi}$ and at most $2^{-(2t)^2}$ by Φ-flatness. Thus, $|H_0| \leq 2^{-(2t)^2} \cdot 2^{\mathrm{H}(Z_0)-2t\Phi}$. Then

$$\Pr[Z_1 \in H_0] \leq \Pr[Z_1 \text{ is } 2t\Phi\text{-heavy}] + |H_0| \cdot 2^{-\mathrm{H}(Z_1)+2t\Phi} \leq 2^{-(2t)^2} + 2^{-(2t)^2}.$$

We can perform an identical analysis for the strings H_1 that are $2t\Phi$-heavy for Z_1. Then

$$\begin{aligned}\Pr[Z \in H_0 \cup H_1] &= \frac{1}{2}\left(\Pr[Z_0 \in H_0] + \Pr[Z_1 \in H_0] + \Pr[Z_0 \in H_1] + \Pr[Z_1 \in H_1]\right) \\ &\leq \frac{1}{2}\left(2^{-(2t)^2} + 2 \cdot 2^{-(2t)^2} + 2 \cdot 2^{-(2t)^2} + 2^{-(2t)^2}\right) \\ &= 3 \cdot 2^{-(2t)^2}.\end{aligned}$$

In total, we see that the probability that a random sample of Z is not $(2t\Phi+1)$-typical for Z is at most $2^{-(2t)^2} + 3 \cdot 2^{-(2t)^2} \leq 2^{-t^2}$, for $t \geq 1$. ∎

Appendix B. Weak false entropy generators imply one-way functions. We recall the definition of a weak false entropy generator.

DEFINITION B.1 (Definition 7.15 restated). *We say that there is an* auxiliary-input weak false entropy generator on I *if there exists a* fixed *polynomial m such that for* every *polynomial p, we have samplable auxiliary-input probability ensembles $\mathcal{D} = \{D_x\}$ and $\mathcal{F} = \{F_x\}$ such that D_x and F_x take values in $\{0,1\}^{m(|x|)}$ and when $x \in I$, D_x, and F_x are $1/p(|x|)$-indistinguishable and satisfy $\mathrm{H}(F_x) \geq \mathrm{H}(D_x) + 1$.*

The following generalizes Lemma 3.12 (due to [37]). Intuitively, the weakness of the false entropy generator translates to constructing only a weak one-way function (where the inversion probability is at most, say, 1/2), which is known to imply standard one-way functions [60] (cf. [23]).

LEMMA B.2 (Lemma 7.16 restated). *If there is an auxiliary-input weak false entropy generator on I, then there exists an auxiliary-input one-way function on I.*

Proof. Let $x \in I$, $n = |x|$, and let $D = D_x$ and $F = F_x$ be the samplable auxiliary-input probability ensembles on $\{0,1\}^m$ that are ε-indistinguishable. Recall that the definition of auxiliary-input weak false entropy generators gives us a fixed polynomial $m = m(n)$ such that we can take $\varepsilon = 1/p(n)$ for any desired polynomial p (which we will choose later in the proof). To construct an auxiliary-input one-way

function, we will essentially follow the construction of Håstad et al. [37] which converts a "false entropy generator" to a "pseudoentropy generator"—where the output is indistinguishable from a distribution whose min-entropy is higher than the seed-length of the generator. However, since we are starting from only a weak false entropy generator D, we need to ensure that the level of indistinguishability deteriorates only as a function of the output length m of D and the security parameter (but not with the number of random bits used to generate D).

This part of the construction depends on "guess" e for (an approximation to) the entropy of D. (At the end we will enumerate over all choices for e.) Specifically, set $k = 256n \cdot (m+n)^2$, let q be the number of random bits used to generate D, let G be a random universal hash function mapping $\{0,1\}^{kq}$ to $\{0,1\}^{kq-ke-k/8}$, and consider the following samplable distributions:

$$W_e = (D(R_1), \ldots, D(R_k), G, G(R_1, \ldots, R_k)),$$
$$W'_e = (F_1, \ldots, F_k, G, U_{kq-ke-k/8}),$$

where $R_1, \ldots, R_k$ are independent copies of U_q, and $F_1, \ldots, F_k$ are independent copies of F.

Claim B.3. *For* $\mathrm{H}(D) \le e \le \mathrm{H}(D) + 1/2$*, we have that*

1. W_e *and* W'_e *are* $k\varepsilon$*-indistinguishable.*
2. $\Pr[W'_e \in \mathrm{Supp}(W_e)] \le (k+2) \cdot 2^{-n}$.

Before proving the claim, we describe how it completes the proof of the lemma. Specifically, we argue that the circuit generating W_e defines a (weak) one-way function. Any algorithm that inverts W_e with probability at least δ can be used to distinguish between W_e and W'_e with an advantage of at least $\delta - (k+2) \cdot 2^{-n}$ (because by item 2 it is information-theoretically impossible to find a W_e-preimage of a random sample of W'_e, except with probability $(k+2) \cdot 2^{-n}$). By item 1, we conclude that W_e can be inverted with probability at most $\delta = (k+2) \cdot 2^{-n} + k\varepsilon \le 1/2$, for a sufficiently large choice of the polynomial p (recalling that $\varepsilon = 1/p$), and is thus a weak one-way function. Since we do not know the value of $\mathrm{H}(D)$, we consider the function $f_x(y_1, \ldots, y_{2m}) = (W_{1/2}(y_1), W_1(y_2), \ldots, W_{m-1/2}(y_{2m-1}), W_m(y_{2m}))$, which is a weak one-way function because one of its components is a weak one-way function (and the others are independent). Applying the standard reduction from weak one-way functions to standard one-way functions [60] (cf. [23]) completes the proof. Thus, all that remains is to establish Claim B.3.

Proof of Claim B.3. It will first be useful to remove low-probability samples from both D and F, analogously to Lemma 2.2. Let

$$L = \{z : \Pr[D = z] \le 2^{-n} \cdot 2^{-m}\}.$$

By a union bound, $\Pr[D \in L] \le 2^{-n}$. Then $\hat{D} = D|_{D \notin L}$ is 2^{-n}-close to D and, moreover, for every $z \in \mathrm{Supp}(\hat{D})$,

$$\Pr\left[\hat{D} = z\right] \ge \Pr[D = z] \ge 1/2^{m+n}.$$

By Lemma 2.1, we have $|\mathrm{H}(\hat{D}) - \mathrm{H}(D)| \le 2^{-n} \cdot m + \mathrm{H}_2(2^{-n})$, which is negligible. By the flattening lemma, $\otimes^k \hat{D}$ is Φ-flat for $\Phi = \sqrt{k} \cdot (m+n)$. Analogously, using F we can define a set L' of light samples and obtain an $\hat{F}$ satisfying the same conclusions.

The Φ-flatness of $\otimes^k \hat{D}$ implies that with probability at least $1 - 2^{-n}$ over $\overline{z} = (z_1, \ldots, z_k) \leftarrow \otimes^k \hat{D}$, we have

$$\Pr[\otimes^k \hat{D} = \overline{z}] \geq 2^{-\sqrt{n}\cdot\Phi} \cdot 2^{-k\cdot \mathrm{H}(\hat{D})}.$$

Since $\otimes^k D$ and $\otimes^k \hat{D}$ are $k\cdot 2^{-n}$-close (by Lemma 2.3), the same holds with probability at least $1 - (k+1)\cdot 2^{-n}$ over $\overline{z} \leftarrow \otimes^k D$. For any such $\overline{z}$, we have

$$\begin{aligned}
&\#\{(r_1, \ldots, r_k) : \forall i\ D(r_i) = z_i\} \\
&= 2^{kq} \cdot \Pr[\otimes^k D = \overline{z}] \\
&\geq 2^{kq} \cdot \Pr[\otimes^k D = \overline{z} | \otimes^k D \in (L^c)^k] \cdot \Pr\left[\otimes^k D \in (L^c)^k\right] \qquad (\text{where } L^c = \{z : z \notin L\}) \\
&\geq 2^{kq} \cdot \Pr[\otimes^k \hat{D} = \overline{z}] \cdot (1 - k \cdot 2^{-n}) \\
&\geq 2^{kq} \cdot 2^{-\sqrt{n}\cdot\Phi - k\cdot \mathrm{H}(\hat{D})} \cdot (1 - k \cdot 2^{-n}) \\
&\geq 2^{kq - ke - k/8 + 2n},
\end{aligned}$$

where L^c denotes the complement of L and in the last inequality we use the facts that $\mathrm{H}(\hat{D}) \leq \mathrm{H}(D) + \mathrm{neg}(n) \leq e + \mathrm{neg}(n)$ and $\sqrt{n}\cdot\Phi = k/16$, $2n + 1 \leq k/16$ for sufficiently large n. This implies that conditioned on $(D(R_1), \ldots, D(R_k)) = \overline{z}$, the min-entropy of $(R_1, \ldots, R_k)$ is at least $kq - ke - k/8 + 2n$. Thus, by the leftover hash lemma (Lemma 2.7), $(G, G(R_1, \ldots, R_k))$ is (2^{-n})-close to $(G, U_{kq-ke-k/8})$. We conclude that W_e is statistically indistinguishable from

$$V = (D_1, \ldots, D_k, G, U_{kq-ke-k/8}),$$

where $D_1, \ldots, D_k$ are independent copies of D. Since D is ε-indistinguishable from F, it follows that V is $(k\varepsilon)$-indistinguishable from W'_e. Therefore, W_e and W'_e are $(k\varepsilon)$-indistinguishable, as desired.

Now we proceed to item 2. First, we bound $|\mathrm{Supp}(W_e)|$. Let g be the number of random bits to generate G. Then the number of random bits used to generate W_e is at most $kq + g$. Hence $|\mathrm{Supp}(W_e)| \leq 2^{kq+g}$. Next, we show that W'_e is statistically indistinguishable from a distribution with min-entropy significantly higher than $kq+g$. This amounts to lower bounding the min-entropy of $(F_1, \ldots, F_k) = \otimes^k F$, since the remaining components of the W'_e are independent and have min-entropy $g + kq - ke - k/8$. As above, instead of F, we consider $\hat{F}$. Recall that $\otimes^k \hat{F}$ is $(k2^{-n})$-close to $\otimes^k F$ and is Φ-flat. By Φ-flatness, $\otimes^k \hat{F}$ is (2^{-n})-close to a distribution with min-entropy $k \cdot \mathrm{H}(\hat{F}) - \sqrt{n}\Phi \geq k \cdot (e + 1/2 - \mathrm{neg}(n)) - k/16 \geq ke + k/4$ for sufficiently large n. Therefore, W'_e is $(k+1)\cdot(2^{-n})$-close to a distribution with min-entropy at least

$$(g + kq - ke - k/8) + (ke + k/4) > kq + g + n$$

for sufficiently large n. A distribution of min-entropy at least $w = kq + g + n$ can land in $\mathrm{Supp}(W_e)$ with probability at most $2^{-w} \cdot |\mathrm{Supp}(W_e)| \leq 2^{-n}$. Therefore W'_e lands in $\mathrm{Supp}(W_e)$ with probability at most $2^{-n} + (k+1)\cdot 2^{-n}$, as desired. □

Acknowledgments. I am grateful to Emanuele Viola for an inspiring conversation about pseudoentropy and [37] that prompted me to revisit the questions addressed in the present paper. I thank Oded Goldreich, Shafi Goldwasser, and Shien Jin Ong for clarifying discussions. Their comments, as well as those of the anonymous referees, also improved the presentation significantly. Finally, I thank Danny Gutfreund, Madhu Sudan, and Luca Trevisan for some past conversations that have influenced this work.

DERANDOMIZING HOMOMORPHISM TESTING IN GENERAL GROUPS*

AMIR SHPILKA† AND AVI WIGDERSON‡

Abstract. The main result of this paper is a near-optimal derandomization of the *affine* homomorphism test of Blum, Luby, and Rubinfeld [*J. Comput. System Sci.,* 47 (1993), pp. 549–595].

We show that for any groups G and Γ, and any *expanding* generating set S of G, the natural deramdomized version of the BLR test in which we pick an element x randomly from G and y randomly from S and test whether $f(x)\cdot f(y) = f(x\cdot y)$, performs nearly as well (depending of course on the expansion) as the original test. Moreover, we show that the underlying homomorphism can be found by the natural local "belief propagation decoding."

We note that the original BLR test uses $2\log_2|G|$ random bits, whereas the derandomized test uses only $(1+o(1))\log_2|G|$ random bits. This factor of 2 savings in the randomness complexity translates to a near quadratic savings in the length of the tables in the related locally testable codes (and possibly probabilistically checkable proofs which may use them).

Our result is a significant generalization of recent results that either refer to the special case of the groups $G = Z_p^m$ and $\Gamma = Z_p$ or are nonconstructive. We use simple combinatorial arguments and the transitivity of Cayley graphs (and this analysis gives optimal results up to constant factors). Previous techniques used the Fourier transform, a method which seems unextendable to general groups (and furthermore gives suboptimal bounds).

Finally, we provide a polynomial time (in $|G|$) construction of a (somewhat) small ($|G|^\epsilon$) set of expanding generators for *every* group G, which yield efficient testers of randomness $(1+\epsilon)\log|G|$ for G. This result follows from a simple derandomization of a known probabilistic construction.

Key words. derandomization, linearity testing, homomorphism testing

1. Introduction.

1.1. Property testers and randomness complexity. Let F be the family of all functions (from a given domain to a given range), and P a subset of these functions (those with property "P"). A tester T is a probabilistic algorithm that receives as input a (black box for) function $f \in F$, evaluates f on a set of points in the domain, and uses this information to accept or reject the input function f. Roughly speaking, T is a tester for the property P if every f in P is accepted with high probability, and every f which is "far" from P (in Hamming distance) is rejected with high probability. This is the basic set up of property testing, by now a very large field dealing with many other objects than functions, such as strings, distributions, graphs, etc. (see excellent surveys by Goldreich [19] and by Ron [30]). A central theme in this field is relating $error(T)$, the probability that our tester fails to give the correct output, to its "complexity" $query(T)$, measuring the number of domain samples it used, and its "accuracy" $\mathrm{dist}(T)$, which is how far from P are the functions it rejects. The importance of this field for various applications follow numerous results giving testers

for a variety of properties P, in which both *query* and *distance* depend only on *error* (and not on the size of the domain of the functions).

Central applications of this area are (the related) locally testable codes (LTCs) and probabilistically checkable proofs (PCPs). In these, the answers to all possible sets of queries are explicitly written down, and it is a major concern to minimize their length. This length can be seen to be directly related to (indeed, an exponential of) the number of random bits $random(T)$ used by the tester T, and so this parameter and its tradeoffs with the others have been investigated as well. Related are the "derandomized" amplification of hardness results [23, 33] which lead to optimal derandomization of BPP.

A recent paper of Goldreich and Sudan [20] addresses the minimization of $random(T)$ for two important testers: the homomorphism tester of Blum, Luby, and Rubinfeld [12] (which was the first and motivating example of property testing of functions), and the "point vs. lines" low-degree tester of Rubinfeld and Sudan [31] (which was central in the proof of the PCP theorem). Both testers use randomness to name *two* random domain queries, which is related to having *quadratic* proof/code length (as a function of the length of the appropriate input). They note that in order to reduce this length to near *linear*, one must use only randomness which is sufficient for only *one* query. Moreover, [20] showed that *nonuniformly* such a saving is possible (the arguments of [20] can achieve similar savings in much more general contexts of multiprover systems, but we will restrict our discussion from this point on only to the first tester for homomorphism, which is the subject of our paper). Indeed Ben-Sasson et al. [13] were able to minimize $random(T)$ for the special case of testing homomorphism between the groups Z_p^m and Z_p.

1.2. Affine homomorphism testing. Given two finite groups G, Γ, a homomorphism is a function $f : G \to \Gamma$ such that for every $g_1, g_2 \in G$ we have that $f(g_1 \cdot g_2) = f(g_1) \cdot f(g_2)$. When the groups are abelian it is customary to use "$+$" instead of "$\cdot$," so a homomorphism is a function that for every $g_1, g_2 \in G$ satisfies $f(g_1 + g_2) = f(g_1) + f(g_2)$. This is the reason that in abelian groups homomorphisms are referred to as linear functions. In particular the famous paper of Blum et al. [12] analyze homomorphism testing (which they call linearity testing) for abelian groups. An *affine* homomorphism between G and Γ is a function f such that $f(1)^{-1} \cdot f$ is a homomorphism (in the case of abelian groups this is sometimes denoted as $f - f(0)$). The BLR linearity testing can be slightly changed to yield an affine version of their linearity test.

Let G and Γ be finite groups. Let F be all functions from G to Γ, let $P_{hom} \subseteq F$ be the set of all homomorphisms from G to Γ, and $P_{aff} \subseteq F$ be the set of all affine homomorphisms from G to Γ. For two functions $f, h \in F$ we have the normalized Hamming distance $\text{dist}(f, h) = Prob[f(x) \neq h(x)]$ for a uniform element $x \in G$.

Fix a subset E of $G \times G$ (which may be viewed as a directed graph on G), and consider the following tester T_E. It picks uniformly a random pair $(x, y) \in E$; evaluates the input function f on the three (related) elements x, y, and $x^{-1}y$; and accepts if and only if it satisfies the equation $f(x)f(x^{-1}y)f(y)^{-1} = 1$. It is easy to see that if f is a homomorphism, then T_E will accept f with probability one. The interesting direction is showing that if the error of the test is small, then f is close to a homomorphism (or an affine homomorphism). We say that T_E is a (δ, ϵ)-test if every function that passes the test with probability at least $1 - \delta$ is at most ϵ far from having the property (either P_{hom} or P_{aff}).

The well known BLR linearity tester [12] uses (in this notation) $E = G \times G$. They

proved that $T_{G\times G}$ is a $(\delta, 9\delta/2)$-test. However, their analysis wasn't tight and was later improved by [9, 8, 7]. Ben-Or et al. [10] extended the BLR result and showed that the test with $E = G \times G$ works for general groups as well. The proof of Ben-Or et al. is similar to the proof of [12].

THEOREM 1.1 (see [12, 10, 8, 9, 7]). *Let G, Γ be groups. Consider the test $T_{G\times G}$ described above. There the test picks uniformly at random two elements $x, y \in G$ and accepts if $f(x) \cdot f(y) = f(x \cdot y)$. For every $\delta > 0$, if f passes the test with probability $> 1-\delta$, then there exist a homomorphism $h \in P_{hom}$ such that $\mathrm{dist}(f, h) \leq \delta/3+O(\delta^2)$. In other words, $T_{G\times G}$ is a $\left(\delta, \delta/3 + O(\delta^2)\right)$-test for P_{hom}.*

To save on randomness, [20] suggested to use sparser graphs E. The tester T_E obviously has $random(T_E) = \log |E|$ (all logs are to base 2). The value attained by the BLR test, $random(T_{G\times G}) = 2\log |G|$. It is also easy to see that any nontrivial tester (giving any dependence between error and distance) must satisfy $random(T_E) \geq \log |G| - O(1)$. Goldreich and Sudan [20] showed that this lower bound can essentially be matched, and at negligible cost to the dependence of distance on error.

THEOREM 1.2 (see [20]). *For all but $exp(-|G|)$ fraction of all possible graphs E of size $C|G| \log |\Gamma|$ (with C an absolute constant) the following holds. For every $\delta > 0$, T_E is a $\left(\delta, \delta/3 + O(\delta^2) + exp(-|G|)\right)$-test for P_{hom}.*

On the one hand, notice that for this size of E, we have $random(T_E) = \log |G| + \log\log |\Gamma| + O(1)$. This gives $(1 + o(1)) \log |G|$ for all interesting cases ($|\Gamma| \leq |G|$). It gives the optimal $\log |G| + O(1)$ when Γ is of fixed size, which includes the important special case of linearity testing in which $\Gamma = Z_p$ for a fixed prime p and $G = Z_p^m$ for a large m.

On the other hand, the proof of [20] is not explicit. It uses a probabilistic argument in choosing E, which gives no clue to which graphs induce good testers. This is a major problem if one wants to use such testers in objects like PCPs. This raises a natural "derandomization" problem (which Goldreich and Sudan [20] raise in their paper), of explicitly constructing good testers E, or at least characterize good testers E.

This problem was answered for a special case of affine linear testing (i.e., for the property P_{aff}), by Ben-Sasson et al. [13] who proved the following theorem.

THEOREM 1.3 (see [13]). *Fix any $\lambda > 0$. Let S be a λ-biased set in $G = Z_p^m$, and let E denote all pairs (x, xs) for all $x \in G$ and $s \in S$. Then for every $\delta > 0$, T_E is a $\left(\delta, O\left(p^2(\delta + \lambda)\right)\right)$-test [1] for P_{aff}.*

λ-biased sets of size $\mathrm{poly}(m/\lambda)$ can be explicitly constructed for these groups [3, 4, 16, 24, 29], which gives explicit testers T_E with near optimal randomness $random(T_E) \leq \log |G| + O(\log(m/\lambda))$.[2]

Ben-Sasson et al. [13] note that the resulting graphs E are precisely Cayley graphs over G with generating set S whose second (normalized) eigenvalue is bounded by λ. In short, Cayley expanders are good tests. This fact, as well as the fact that most graphs in Theorem 1.2 are expanders, may cause one to be tempted to conjecture that *any* expander leads to a good homomorphism test for *any* group G. However, [13] caution that their proof works only due to the link between the algebra of the test and the algebraic structure of the graph, which needs to be a Cayley graph over the same group GZ_p^m.

Indeed, the insight that one needs a specific expander rather than an arbitrary

[1] Observe that this bound is useless unless both δ and λ are below $1/p^2$.

[2] Note that the second term is only $O(1)$ for the case where p is a fixed prime in the existential result of Theorem 1.2.

one comes from Goldreich [18] who designed a counter example for $m = 2$. Goldreich introduced a function which is very far from any linear function from Z_p^2 to Z_p, and yet passes with high probability the test defined by the Margulis graph [27, 17] (which is a Schrier graph of some group action on $G = Z_p^2$, but is *not* a Cayley graph).

Thus the question of which graphs are good testers for general groups G (and Γ) seem more subtle. Moreover, the techniques of [13] use Fourier transforms and seem to work only for abelian groups. We make significant progress for characterizing good testers for general groups, which we describe next.

1.3. Our results. In brief, we show that for every domain group G, *all* expanding Cayley graphs E on the group G are good testers for (affine) homomorphism. Since any group G has an expanding generating set of size $O(\log |G|)$ [6], our result immediately gives a nonuniform test with a near-optimal $randomness(T_E) = \log |G| + O(\log \log |G|)$. Moreover, we derandomize [6] to give a polynomial time algorithm (in $|G|$) to generate, for every group G, an expanding set of generators of size $|G|^\epsilon$, giving the randomness $(1+\epsilon)\log |G|$ explicitly and uniformly. We also note that we can find in quasi-polynomial time an expanding generating set of size $O(\log |G|)$, which implies a test with a near-optimal $randomness(T_E) = \log |G| + O(\log \log |G|)$.

We note that even our nonexplicit result is much stronger than [20], as one can efficiently verify whether a given Cayley graph is an expander and therefore good as a test graph, while Goldreich and Sudan cannot tell which of their random graphs are good. We note again that Goldreich gave an example showing that not every expander is good. We include this example in section 5.

Our testing result depends on two parameters: λ, which is the (normalized) second largest eigenvalue (in absolute value) of the Cayley graph of G with the generating set S, and δ, which is the error of the test ($\delta = error(T_{G\times S})$). We show that if S is expanding (i.e., $\lambda < 1$), then $\mathrm{dist}(T_{G\times S}) = O(\delta)$.

THEOREM 1.4. *For every G, Γ and a subset S of G, the tester that picks uniformly at random an edge $(x, xs) \in Cay(G; S)$ and checks whether $f(x)\cdot f(s) = f(xs)$ surely accepts any homomorphism $f : G \to \Gamma$, and rejects with probability at least δ any $f : G \to \Gamma$, which is $4\delta/(1-\lambda)$ far from being an affine homomorphism, provided that $\frac{12\delta}{1-\lambda} < 1$.*

Note that it follows that if f is at least $\frac{1}{3}$-far from any affine homomorphism, then f is rejected with probability at least $\frac{1-\lambda}{12}$. We also note that the test accepts any homomorphism, but rejects any function that is far from any *affine* homomorphism (rather than any function that is far from any homomorphism). It is still open to derandomize the homomorphism test of BLR. By a slight modification to the tester $T_{G\times S}$ we can get a tester that accepts any *affine* homomorphism and rejects any function that is far from any *affine* homomorphism.

THEOREM 1.5. *For every G, Γ and a subset S of G, the tester that picks uniformly at random an edge $(x, xs) \in Cay(G; S)$ and checks whether $f(x)\cdot f(1)^{-1}\cdot f(s) = f(xs)$ surely accepts any affine homomorphism $f : G \to \Gamma$, and rejects with probability at least δ any $f : G \to \Gamma$ which is $4\delta/(1-\lambda)$ far from being an affine homomorphism, given that $\frac{12\delta}{1-\lambda} < 1$. In other words, this tester is a $(\delta, \frac{4\delta}{1-\lambda})$-test for P_{aff}.*

Note that the tester of Theorem 1.5 makes 4 queries whereas the tester of Theorem 1.4 makes only 3 queries.

The proof of Theorem 1.4 uses a simple combinatorial argument together with the transitivity of groups (the proof of Theorem 1.5 is by a reduction to Theorem 1.4). Recent analysis of (variants of) the BLR test [7, 13] use some sort of Fourier transform on abelian groups. As we deal with nonabelian groups as well, we cannot use this

approach, and so rather study what may be a natural analog—the correlation of shifts of the given function with itself. It is interesting to note that the close homomorphism is defined globally, despite the fact that the tester makes only local (neighbor) tests. We also stress that our analysis avoids what seems to be an inherent problem in the Fourier approach, i.e., the relation between the Fourier coefficients and the distance to linearity is not tight (not even up to a constant factor), resulting in the suboptimal bounds of Theorem 1.3 of [13]. We note, however, that the Fourier approach has the advantage that it extends to the case where the error is relatively large, as in [13] (list decoding regime)—something we cannot do in general groups.

Our bounds are independent of the groups at hand, and thus are meaningful for constants δ and λ (in contrast to the bounds of [13]). As a consequence of our proof we get that the natural decoding procedure in which group elements correct their values according to the majority of their neighbors' values, converges to a homomorphism. It is interesting that this local decoding proof needs the global consistency in homomorphism testing. In contrast to derandomized "low degree" testers, Ben-Sasson et al. [13] derive the global consistency via iterated local decoding. It is interesting if their result has a different proof that goes along the lines of the current paper.

Our testers require expanding generators for the groups at hand. As mentioned, for abelian groups such small explicit sets were known. We next provide the first nontrivial explicit construction of expanding generating sets in every group. It is fairly weak; improving it to approach the existential bound of Alon and Roichman [6] is very interesting.

THEOREM 1.6. *For every $\epsilon > 0$ there is a polynomial time algorithm which, on input a group G, given by its multiplication table, produces a set S of size $|G|^{\epsilon}$ of expanding generators. More precisely,*

$$\lambda(Cay(G;S)) \leq O\left(|G|^{-\epsilon/8}\right).$$

Finally, combining the two theorems we have the following corollary.

COROLLARY 1.7. *For every $\epsilon > 0$ there is a polynomial time algorithm, which given any two groups G, Γ, produces a tester of randomness complexity $(1+\epsilon)\log|G|$. This tester accepts every affine homomorphism between G and Γ with probability one, and for every $\beta > 0$, rejects every function which is β-far from any such affine homomorphism, with probability $\geq 1 - \beta/5$.*

An alternative way to view our test is that we accept with probability 1 any homomorphism and reject with high probability any function that is far from any *affine* homomorphism.

2. Preliminaries.

DEFINITION 2.1 (affine homomorphism). *Let G, Γ be finite groups. A homomorphism $\phi : G \to \Gamma$ is a function with the property that for every $g, h \in G$ we have that $\phi(g \cdot h) = \phi(g) \cdot \phi(h)$. We say that ϕ is an affine homomorphism if there exists an element $\gamma \in \Gamma$ such that $\gamma \cdot \phi$ is an homomorphism. Note that in this case $\phi \cdot \gamma\gamma^{-1} \cdot (\gamma \cdot \phi) \cdot \gamma$ is also an homomorphism.*

For two functions $f_1, f_2 : G \to \Gamma$ we define

$$\mathrm{dist}(f_1, f_2) = \mathrm{Pr}_{g \in_R G}[f_1(g) \neq f_2(g)].$$

2.1. Expander graphs. Let $\mathcal{G} = (V, E)$ be a graph on n vertices. Let $A_{\mathcal{G}}$ be its adjacency matrix. For two sets $A, B \subset V$ denote

$$E(A, B) = \{(u, v) \mid u \in A \text{ and } v \in B\}.$$

Let $e(A,B) = |E(A,B)|$. Denote with $\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_n$ the eigenvalues of $A_{\mathcal{G}}$. In case that $\mathcal{G}$ is a d-regular graph we get that $\lambda_1 = d$. Denote

$$\lambda[\mathcal{G}] = \frac{1}{d} \cdot \max(\lambda_2, |\lambda_n|);$$

we sometimes use λ instead of $\lambda[\mathcal{G}]$ when $\mathcal{G}$ is clear from the context.

The next lemma due to [1] relates the edge expansion of $\mathcal{G}$ to λ.

LEMMA 2.2 (expander mixing lemma; see [1]). *For any two sets $A, B \subset V$ we have that*

$$\left| e(A,B) - d \cdot \frac{|A| \cdot |B|}{n} \right| \leq \lambda \cdot d \cdot \sqrt{|A| \cdot |B|};$$

in case $A = B^c$, we get a stronger result [34, 5].

LEMMA 2.3 (analog of the Cheeger constant; see [34, 5]).

$$\frac{1-\lambda}{2} \cdot d \leq \min_{|A| \leq n/2} \frac{e(A, A^c)}{|A|} \leq 2\sqrt{1-\lambda} \cdot d.$$

In particular we obtain the following corollary.

COROLLARY 2.4.

- *For any A we have that*

$$\min(|A|, n - |A|) \leq \frac{2}{1-\lambda} \cdot \frac{e(A, A^c)}{d}.$$

- *If we remove $2\delta dn < \frac{1-\lambda}{6} \cdot dn$ edges from the graph, then there is a connected component of size at least $\left(1 - \frac{4\delta}{1-\lambda}\right) \cdot n$.*

Proof. The first part follows immediately from Lemma 2.3. For the second part notice that if A and A^c are disconnected after the removal of the edges, then $e(A, A^c) \leq 2\delta dn$. Thus if $|A| \leq \frac{n}{2}$, then by the first part we get that

$$|A| \leq \frac{2}{1-\lambda} \cdot \frac{2\delta dn}{d} \frac{4\delta}{1-\lambda} \cdot n < n/3. \tag{1}$$

Therefore, after the removal of the edges, if we take the union of two components smaller than $\frac{n}{2}$, then the size of the union is smaller than $2n/3 < \left(1 - \frac{4\delta}{1-\lambda}\right) \cdot n$. Thus the complement of the union has size larger than $\frac{4\delta}{1-\lambda} \cdot n$ and therefore must be of size at least $\frac{n}{2}$ (because otherwise, by (1), its size is $\leq \frac{4\delta}{1-\lambda} \cdot n$). It follows that the size of the union is smaller than $\frac{4\delta}{1-\lambda} \cdot n$. By induction we get that the union of all components of size smaller than $\frac{n}{2}$ has size at most $\frac{4\delta}{1-\lambda} \cdot n$. Hence there is a large component of size $\left(1 - \frac{4\delta}{1-\lambda}\right) \cdot n$. ∎

Next we describe a simple dynamical process on graphs, which converges quickly in every (good enough) expander. The constants below are just some parameters which suffice for our purposes—clearly one can state a more general result along the same lines.

DEFINITION 2.5 (the infection process). *Let $\mathcal{G} = (V, E)$ be a d-regular graph on n vertices. Assume that initially an adversary "infects" a subset B_0 of the vertices V.*

At every subsequent time step t the infected set B_t is determined to be exactly those vertices which have at least $1/3$ fraction of their neighbors in B_{t-1}. A graph is healthy if for every initial subset B_0 of size at most $n/4$, after a finite number T of steps we have $B_T = \emptyset$.

The following is an easy consequence of the expander mixing Lemma 2.2.

COROLLARY 2.6. *Assume that $\lambda[\mathcal{G}] < 1/13$. Then $\mathcal{G}$ is healthy. Moreover, the convergence time T is at most $O(\log n)$.*

Proof. We will show that for every t $|B_t| \leq 0.9|B_{t-1}|$. By definition, the number of edges between B_t and B_{t-1} is lower bounded by $e(B_t, B_{t-1}) \geq d|B_t|/3$. Applying the expander mixing lemma to these two sets gives

$$d|B_t|/3 \leq e(B_t, B_{t-1}) \leq d|B_t| \cdot |B_{t-1}|/n + \lambda d\sqrt{|B_t| \cdot |B_{t-1}|}.$$

As $\lambda < 1/13$ and (by induction) $|B_{t-1}| \leq n/4$, we get that

$$|B_t| \leq \left(\frac{12}{13}\right)^2 |B_{t-1}| < 0.9|B_{t-1}|.$$

Iterating $O(\log n)$ times shrinks the infected set to a number smaller than 1, hence zero. ∎

2.2. Expanding Cayley graphs. Let G be a group. Let S be a generating set for G. That is, G is the minimal subgroup of G that contains all the elements of S. S is called symmetric if $s \in S \Leftrightarrow s^{-1} \in S$. We now define the Cayley graph of G with respect to a symmetric set of generators S.

DEFINITION 2.7. *Let G be a group and S a symmetric generating set for G. We define the graph* $\mathrm{Cay}(G; S)$ *as follows. The vertices are the elements of G. For every $g \in G$ and $s \in S$ we put an edge (labeled s) from g to gs.*

The definition describes $\mathrm{Cay}(G; S)$ as a directed graph, which will be one useful view of it, e.g., for describing the testers. However, since S is symmetric, if there is an edge from g to h labeled s, then there is an edge from h to g labeled s^{-1}, and both can be thought of as one undirected edge. Thus $\mathrm{Cay}(G; S)$ can also be viewed as an undirected graph (which is regular of degree $|S|$), which will be used for studying its spectral and connectivity properties.

A very nice property of Cayley graphs is their transitivity. That is, if (g_1, g_2) is an edge, then so does (gg_1, gg_2) for every g.

An interesting open problem is to deterministically find, for a given group G, a *small* symmetric generating set S, such that $\mathrm{Cay}(G; S)$ is a good expander, in time $\mathrm{poly}(|G|)$. For $G = \mathbb{Z}_2^n$ it is easy to verify that $\mathrm{Cay}(G; S)$ is an expander with second eigenvalue λ if and only if S is a λ-biased set (see [3]). However, except for some special groups [26, 27, 28] it is not known in general how to deterministically find such an S. The following result of Alon and Roichman [6] guarantees that if we pick a large enough S at random, then almost surely the associated Cayley graph is an expander.

THEOREM 2.8 (see [6]). *For every $\eta > 0$ there is a constant $c(\eta) > 0$ such that the following holds. Let G be a group of order n and let S be a symmetric set of $c(\eta) \log n$ random elements of G then, with probability at least $1 - \eta$,*

$$\lambda[\mathrm{Cay}(G; S)] < \eta.$$

This theorem assures us that we can always find an S of size $O(\log |G|)$ such that $\mathrm{Cay}(G;S)$ is an expander.

We will show that a simple "derandomization" of this argument leads to a deterministic construction of expanding generating sets of size $O(|G|^{\epsilon})$ for every group G and $\epsilon > 0$. For this, the following well known estimate via the trace formula will be very useful.

DEFINITION 2.9. *Fix G. For a (symmetric) set $S \subseteq G$ and integer m, let P_{2m} be the probability that a random word of length $2m$ in the elements of S evaluates to the identity in G.*

PROPOSITION 2.10. *For every m,*

$$\lambda[\mathrm{Cay}(G;S)]^{2m} \leq nP_{2m} - 1.$$

Proof. Let A be the adjacency matrix of $\mathrm{Cay}(G;S)$. Let $\lambda_1 \geq \cdots \geq \lambda_n$ be its eigenvalues. Let $\lambda = \lambda[\mathrm{Cay}(G;S)]$. Note that $\forall\ 1 \leq i \leq n$, $P_{2m} = \left((\frac{1}{d}A)^{2m}\right)_{i,i}$. Thus

$$nP_{2m} = \mathrm{trace}\left(\left(\frac{1}{d}A\right)^{2m}\right) = \sum_{i=1}^{n}\left(\frac{\lambda_i}{d}\right)^{2m} \geq 1 + \lambda^{2m}. \qquad \square$$

3. Derandomized homomorphism testers. We first prove Theorem 1.4. Then we show that the natural local decoding procedure (namely belief propagation) converges to a homomorphism. As it is easy to verify that every homomorphism passes the test with probability 1, we focus on the other direction—showing that any function that passed the test is close to an affine homomorphism.

3.1. Proof of Theorem 1.4. As it is easy to verify that every homomorphism passes the test with probability 1, we focus on the other direction—showing that any function that passed the test is close to an affine homomorphism.

Let G, Γ be groups such that $|G| = n$. Let f be a given function from G to Γ. Fix a symmetric $S \subseteq G$ of size $|S| = d$ and let $\lambda = \lambda[\mathrm{Cay}(G;S)]$. Consider the test that picks a random $g \in G$ and a random $s \in S$ and accepts if $f(g)f(s) = f(gs)$. Let δ be the rejection probability, i.e.,

$$\delta = \Pr_{y \in G,\ s \in S}[f(y)f(s) \neq f(ys)]. \tag{2}$$

Also assume that

$$\frac{12\delta}{1-\lambda} < 1.$$

Define the function

$$\phi(x) = \mathrm{Plurality}_{y \in G} f(xy)f(y)^{-1}.$$

We will prove that, for every x, almost all y agree on the value of $\phi(x)$ (i.e., satisfy $f(xy)f(y)^{-1} = \phi(x)$), then prove that ϕ is a homomorphism, and finally that it is close to an affine shift of f. The first of these tasks, proved in the next lemma, is perhaps the most surprising, as the test guarantees (near) local consistency, and we show it implies (near) global consistency. This claim is the main technical contribution of our proof and the rest of it follows the footsteps of the proof of [10].

LEMMA 3.1. *For every $x \in G$ we have that*

$$\Pr_{y \in G}[f(xy)f(y)^{-1} = \phi(x)] \geq 1 - \frac{4\delta}{1-\lambda}.$$

Proof. Fix $x \in G$. Note that some constructs in this proof will depend on x and later we will use them for all values of x. From (2) we have for random $y \in G$

$$\delta = \Pr_{y \in G,\, s \in S}[f(xy)f(s) \neq f(xys)]. \tag{3}$$

We now construct a subgraph of $\mathrm{Cay}(G;S)$. Call the edge (y, ys) bad for x if either $f(y)f(s) \neq f(ys)$ or $f(xy)f(s) \neq f(xys)$. By (2) and (3) the number of bad edges is at most $2\delta dn$. Consider the subgraph H_x obtained by removing all (undirected) edges that are bad for x. By the expansion of $\mathrm{Cay}(G;S)$, and since we remove only $2\delta dn$ edges, we get by Corollary 2.4 that H_x contains a connected component C_x of size at least $\left(1 - \frac{4\delta}{1-\lambda}\right) n$.

By connectivity and the fact that the remaining edges satisfy the test, we get that for all y in that component the value $f(xy)f(y)^{-1}$ is constant. We prove it formally as it is a bit subtle.

PROPOSITION 3.2. *For every two distinct elements $v, u \in C_x$ we have $f(xv)f(v)^{-1} = f(xu)f(u)^{-1}$.*

Proof. Let $v = v_1, v_2, \ldots, v_t = u$ be a path between v and u in C_x. Let $s_i = v_i^{-1}v_{i+1}$ be the generator labeling the ith edge (i.e., the ith edge is $(v_i, v_i s_i)$). For every i, the existence of the edge (v_i, v_{i+1}) in H_x implies by definition the existence of the edge (xv_i, xv_{i+1}) in H_x as well. Since all these edges are good for x, it follows that

$$f(v_i)^{-1}f(v_{i+1}) = f(s_i) = f(xv_i)^{-1}f(xv_{i+1})$$

for all i. Thus

$$f(v)^{-1}f(u) = f(v_1)^{-1}f(v_t) = \prod_{i=1}^{t-1} f(v_i)^{-1}f(v_{i+1}) = \prod_{i=1}^{t-1} f(s_i)$$

$$= \prod_{i=1}^{t-1} f(xv_i)^{-1}f(xv_{i+1}) = f(xv_1)^{-1}f(xv_t) = f(xv)^{-1}f(xu).$$

By changing sides we get that $f(xv)f(v)^{-1} = f(xu)f(u)^{-1}$ as required. ∎

Thus, $f(xy)f(y)^{-1}$ is the same for all $y \in C_x$. As $|C_x| > |G|/2$, and we have defined ϕ using plurality over y, we get $\phi(x) = f(xy)f(y)^{-1}$ for every $y \in C_x$. Since $|C_x| \geq (1 - \frac{4\delta}{1-\lambda})n$, Lemma 3.1 follows. ∎

LEMMA 3.3. *ϕ is a homomorphism.*

Proof. We need to show that for every $x, y \in G$ we have that $\phi(x)\phi(y) = \phi(xy)$. Consider (like [10]) arbitrary $x, y \in G$ and the probability over $h \in G$

$$\Pr_{h \in G}[\phi(x)\phi(y) = \phi(xy)] \tag{4}$$

which is independent of h, and thus is either 0 or 1. We prove that this probability is positive and therefore 1. We lower bound it by the probability of the intersection of three events over the same random variable h chosen uniformly in G

$$\Pr_{h \in G}[\phi(x)\phi(y) = \phi(xy)] \geq \Pr_{h \in G}\left[\begin{array}{c} \phi(x) = f(xh)f(h)^{-1} \quad \text{and} \\ \phi(y) = f(h)f(y^{-1}h)^{-1} \quad \text{and} \\ \phi(xy) = f(xh)f(y^{-1}h)^{-1} \end{array}\right]$$

since in this case $\phi(x)\phi(y) = f(xh)f(h)^{-1}f(h)f(y^{-1}h)^{-1} = f(xh)f(y^{-1}h)^{-1} = \phi(xy)$. Now

- By Lemma 3.1 $\Pr_{h\in G}[\phi(x) = f(xh)f(h)^{-1}] \geq 1 - \frac{4\delta}{1-\lambda}$.
- Notice that

$$\Pr_{h\in G}[\phi(y) = f(h)f(y^{-1}h)^{-1}] = \Pr_{h\in G}[\phi(y) = f(y\cdot(y^{-1}h))f(y^{-1}h)^{-1}].$$

  As h is random this probability equals

$$\Pr_{h'\in G}[\phi(y) = f(yh')f(h')^{-1}]$$

  which by Lemma 3.1 is at least $1 - \frac{4\delta}{1-\lambda}$.
- Similarly we get that

$$\Pr_{h\in G}[\phi(xy) = f(xh)f(y^{-1}h)^{-1}] = \Pr_{h\in G}[\phi(xy) = f((xy)\cdot(y^{-1}h))f(y^{-1}h)^{-1}]$$

$$\geq 1 - \frac{4\delta}{1-\lambda}.$$

Note that each of these events have probability of at least $1 - \frac{4\delta}{1-\lambda}$, and so the probability of their intersection is at least $1 - \frac{12\delta}{1-\lambda}$ which is strictly positive and so must be 1. □

Finally we show that f is close to some affine shift of ϕ.

LEMMA 3.4. *There exists $\gamma \in \Gamma$ such that*

$$\Pr_{x\in G}[\phi(x)f(x)\cdot\gamma] \geq 1 - \frac{4\delta}{1-\lambda}.$$

Proof. For every $x \in G$ denote with G_x the set of ("good") y's satisfying $\phi(x) = f(xy)f(y)^{-1}$ (note that the set G_x contains the set C_x defined in the proof of Lemma 3.1, but may in fact be even larger). By Lemma 3.1, for every x it holds that $|G_x| \geq (1 - \frac{4\delta}{1-\lambda})|G|$. It follows by averaging that there exist $y \in G$ such that

$$|\{x \,:\, y \in G_x\}| \geq \left(1 - \frac{4\delta}{1-\lambda}\right)|G|.$$

For this y we have that

$$\Pr_{x\in G}[\phi(x) = f(xy)f(y)^{-1}] \geq 1 - \frac{4\delta}{1-\lambda}.$$

Therefore

$$\Pr_{x'\in G}[\phi(x'y^{-1}) = f(x')f(y)^{-1}] \geq 1 - \frac{4\delta}{1-\lambda}.$$

As ϕ is a homomorphism we get that

$$\Pr_{x'\in G}[\phi(x') = f(x')f(y)^{-1}\phi(y)] \geq 1 - \frac{4\delta}{1-\lambda}.$$

The lemma follows by defining $\gamma = f(y)^{-1}\phi(y)$.

This completes the proof of Theorem 1.4. □

3.2. Proof of Theorem 1.5. Again it is easy to see that if f is an affine homomorphism, then f passes the test with probability 1. To prove the other direction we define a new function $f' : G \to \Gamma$ in the following way:

$$f'(x) \stackrel{\triangle}{=} f(1)^{-1} \cdot f(x).$$

It is obvious that $f'(x) \cdot f'(y) = f'(xy)$ if and only if $f(x) \cdot f(1)^{-1} \cdot f(y) = f(xy)$. In particular the probability of success of the tester of Theorem 1.5 on f equals the probability of success of the tester of Theorem 1.4 on f'. Assume that f passed the test with probability $\geq \delta$ for δ as in the statement of the theorem. Theorem 1.4 implies that f' is $\frac{4\delta}{1-\lambda}$ close to some affine homomorphism $\gamma \cdot \phi$. Hence f is $\frac{4\delta}{1-\lambda}$ close to the affine homomorphism $f(1) \cdot \gamma \cdot \phi$. □

3.3. Iterated local majority decoding. Recall that the close homomorphism in the proof above was defined according to a *global* majority: every group element x chose the value $\phi(x)$ according to the plurality of $f(xy)f(y)^{-1}$ over *all* group elements $y \in G$. We show that iterated *local* majority decoding, where (in each phase) every group element x updates its value according to the plurality of $f(xs)f(s^{-1})$ over its neighbors in the Cayley graph, converges to (the same) global homomorphism ϕ.

DEFINITION 3.5 (iterated majority decoding). *Let G, Γ be groups, S a subset of G and $f : G \to \Gamma$ any function. Set $f = f_0$ and for every integer t define f_t by*

$$f_t(x) = \text{Plurality}_{s \in S} f_{t-1}(xs) f_0(s^{-1}).^3$$

THEOREM 3.6. *Let $G, \Gamma, S, \lambda, \delta, \gamma$ be as in Theorem 1.4 and further assume that $\lambda, \delta \leq 1/17$. Let $f : G \to \Gamma$ be such that the tester $\text{Cay}(G; S)$ accepts f with probability of at least $1 - \delta$. Then the iterated decoding procedure above converges to a homomorphism $\phi : G \to \Gamma$ in $O(\log |G|)$ steps. Moreover, ϕ is a conjugate of the homomorphism defined in the proof of Theorem 1.4, and is at most $4\delta/(1-\lambda)$-far from $\gamma \cdot f$.*

Proof. By Theorem 1.4 we get that there is a homomorphism ϕ such that[4] $\text{dist}(\phi, \gamma \cdot f) \leq \frac{4\delta}{1-\lambda}$ for some $\gamma \in \Gamma$. Let f_t be the sequence of functions defined by the iterated majority decoding procedure above, and let D_t denote the set of group elements on which $\gamma \cdot f_t$ and ϕ disagree. By our choice of parameters,

$$|D_0| \leq \frac{4\delta}{1-\lambda} |G| < |G|/4.$$

We reduced the analysis of the local decoding to that of the infection process in 2.6 at the end of section 2.1.

Set $B_0 = D_0$ and apply the infection process to it, to obtain a sequence B_t. We show by induction that for every t, we have $D_t \subseteq B_t$ so the theorem follows from Corollary 2.6. Assume for the moment that for all but 1/6 fraction of the $s \in S$ we have $f(s) = \phi(s)$. Then every element x in step t which has a 2/3 of its neighbors in the complement of B_{t-1}, gets the same value from at least $\frac{2}{3} - \frac{1}{6} = \frac{1}{2}$ of them (as $D_{t-1} \subset B_{t-1}$), and this value agrees with ϕ, namely $\gamma \cdot f_t(x) = \phi(x)$.

[3] Note that we keep using the *initial* values on S in all iterations.

[4] In the proof of Theorem 1.4 we found ϕ that was close to $f \cdot \gamma$, this implies that $\phi'(x) \stackrel{\triangle}{=} \gamma \cdot \phi(x) \cdot \gamma^{-1}$ is close to $\gamma \cdot f$.

We now argue that for at most 1/6 fraction of $s \in S$ it is the case that $f(s) \neq \phi(s)$. Fix any "bad" s for which $f(s) \neq \phi(s)$. Since $|D_0| < |G|/4$, for at least 1/2 of all the elements $x \in G$ we have both $\gamma \cdot f(x) = \phi(x)$ and $\gamma \cdot f(xs) = \phi(xs)$. All these pairs x, s are rejected by the tester, and since it rejects only a δ fraction of all such pairs, the number of bad s is at most $2\delta < 1/6$. □

Note that the proof relies on the fact that f passed the test with high probability. It is not sufficient that f is close to an homomorphism: consider the constant function $f = \gamma$ for some $\gamma \neq 1$. It is clear that f is an affine homomorphism and that f does not pass the test $T_{G \times S}$. We get that $f_t = \gamma^{t+1}$, where f_t is defined by the iterative process above. Clearly f_t does not converge to 1_Γ (the identity element of Γ), which is the homomorphism close to $\gamma^{-1} \cdot f$.

4. Explicit expanding generators–Proof of Theorem 1.6. In this section we give a polynomial time algorithm to find a relatively small expanding generating set in every group. We state the main technical result, which is nearly identical to Theorem 2.8 of Alon and Roichman, except adding the condition that the choices of the generators need not be fully independent. The proof remains identical to their proof, only we'll need it with different parameters. We give the proof for completeness.

DEFINITION 4.1. *A set $\mathcal{A} \subset [n]^d$ is a k-wise independent sample space if for any subset $I \subset [d]$ of size $|I| = k$, and any sequence $(g_1, ..., g_k) \in [n]^k$, we have that*

$$\Pr_{a \in_R \mathcal{A}}[a_I = (g_1, ..., g_k)] = \frac{1}{n^k},$$

where a_I denotes the restriction of the d-tuple a to the set of coordinates I.

There are many works showing how to construct k-wise independent sample spaces efficiently [2, 14, 16].

THEOREM 4.2 (see [2, 14, 16]). *There is a deterministic algorithm, which on input n, d, k outputs a k-wise independent sample space in time $\max(n, d)^{O(k)}$ (this also implies that the size of the set is $\max(n, d)^{O(k)}$).*

For the rest of the section we fix a group G of size n.

THEOREM 4.3. *Fix any integer $m \geq 2$. Consider the following distribution on Cayley graphs on G. Let $\mathcal{A}$ be a $2m$-wise independent sample space of d-tuples from G^d. Draw a random sample $(g_1, \ldots, g_d)$ from $\mathcal{A}$ to form a (multi)set $T = \{g_1, ..., g_d\}$, and let $S = T \cup T^{-1}$. Then the expectation of $\lambda(\mathrm{Cay}(G; S))$ is*

$$E[\lambda(\mathrm{Cay}(G; S))] < (2n)^{1/2m}(16m/d)^{1/4}.$$

Proof. We repeat the essentials of the proof of [6], with the only difference being the limited independence of the generators. This turns out not to change the analysis. We skip easy proofs which can be obtained from their paper.

By Proposition 2.10 and Jensen's inequality we get that

$$E[\lambda(\mathrm{Cay}(G; S))] < \left(nE[P_{2m}] - 1\right)^{1/(2m)},$$

where P_m was defined in Definition 2.9. Thus, it suffices to prove that $E[P_{2m}] \leq 1/n + 2(16m/d)^{m/2}$. In order to bound P_{2m} we construct a random word of length $2m$ in three steps.

- Pick a random word W' of length $2m$ in the alphabet $\{a_1, a_1^{-1}, \ldots, a_d, a_d^{-1}\}$.
- Reduce the word over the free group on d generators to obtain the word W.
- Replace every a_i by the associated random g_i from T.

The upper bound on the expectation of P_{2m} will follow from the following three probability estimates.

LEMMA 4.4.

$$\Pr[|W| < m] \leq (32/d)^{m/2}.$$

LEMMA 4.5. *Call W bad if none of the d letters*[5] *appears exactly once in W. Condition on $|W| \geq m$. Then*

$$\Pr[W \text{ bad}] \leq (16m/d)^{m/2}.$$

LEMMA 4.6. *Fix any good w, and replace each a_i by g_i as above to generate the word $w(T)$ in G. Then*

$$\Pr[w(T) = 1_G] = 1/n.$$

We prove only the last lemma, since this is the only point where the limited independence of T could make a difference. The first two lemmas follow from [6] after an adjustment of the parameters.

Proof. Since w is good, there is some generator, say a_1 w.l.o.g., which occurs exactly once in w. There are at most $2m-1$ other generators a_i in w. For each of these, expose their g_i value. Now the probability in question is the probability that g_1 equals a fixed group element determined by the exposed g_i's and w. But g_1 is completely uniform given these choices, and so that probability is precisely $1/n$. ∎

The proof now follows as the expectation of P_{2m} is bounded by the sum of the probabilities of the events in the lemmas above. This concludes the proof of Theorem 4.3. ∎

COROLLARY 4.7. *Take $d = n^{4/m}$. Then*

$$E[\lambda(\mathrm{Cay}(G;S))] < 3m^{1/4}d^{-1/8}.$$

Finally we show how to choose a set of generators deterministically, establishing Theorem 1.6. Given $\epsilon > 0$, we set $m = 4/\epsilon$, and $d = n^{4/m} = n^{\epsilon}$. Apply Theorem 4.2 to construct a sample space of size at most $poly(n^m)$ of d-tuples over G which are $(2m)$-wise independent. This takes polynomial time in n^m (remember that m is a constant). For each such tuple T compute (again in polynomial time, as all we need is a reasonable approximation) the associated $\lambda(\mathrm{Cay}(G;S))$, and returns the set S for which this eigenvalue is smallest.

This concludes the proof of Theorem 1.6. ∎

5. Not every expander is good. In this section we present a construction, due to Goldreich, of an expander graph on a group (but not a Cayley graph), for which the natural tester fails miserably.

Let p be a prime and consider the (Schreier) graph H_p describing the action of the group $SL_2(p)$ on the vector space Z_p^2, with generators S being the two matrices

$$\begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix} \qquad \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix}$$

and their inverses.

[5] a_i and a_i^{-1} are considered the same letter.

More concretely, the vertices of H_p are $(x, y) \in Z_p \times Z_p$, and the four neighbors of (x, y) are $(x, y \pm x)$ and $(x \pm y, y)$. Note that H_p has two connected components—the vertex $(0, 0)$ and the rest. Thus H_p has two eigenvalues of value 1, and we denote here by $\lambda(H_p)$ the maximum absolute value of any of the other eigenvalues.

The graph H_p is a variant of the famous Margulis graph—the first explicit expander. The expansion of (the large component of) H_p follows directly from the expansion of the Cayley graph $\mathrm{Cay}(SL_2(p); S)$, which follows from Selberg's celebrated 3/16 Theorem (see Lubotzky [25] for details).

THEOREM 5.1 (see [25]). *For every p, $\lambda(H_p) \leq 13/16$.*

We will consider functions from Z_p^2 to Z_p. Since the groups are abelian, we will write them additively.

For defining the tester (and the function), it will be convenient to view each undirected edge as directed "positively." In other words every vertex $v = (x, y)$ has two directed edges emanating from it: to $u = (x, y + x)$ (labeled by $u - v = (0, x)$) and to $w = (x + y, y)$, (labeled by $w - v = (y, 0)$).

Observe that in our graph, labels of edges always have 0 in one of their components. Also note that there are roughly $2p$ distinct labels, despite the graph having degree 4—this is very different from a Cayley graph (in which the number of labels is the degree).

In this notation, the tester associated to this graph, picks uniformly at random a (directed edge) from v to u and tests if $f(u) - f(v) = f(u - v)$.

We now present the example that beats this tester. It will be very far from any affine homomorphism, but will pass the test with probability close to 1.

Consider the function $f : Z_p \times Z_p \to Z_p$ defined as follows. $f(x, y) = x^2$ if $y = 0$, $f(x, y) = y^2$ if $x = 0$, and $f(x, y) = x \cdot y$ otherwise (with all arithmetic in Z_p).

THEOREM 5.2. *For the function f defined above we have that*

- *f is $(1 - 4/p)$-far from any affine homomorphism.*
- *f passes the test with probability $1 - 4/p$.*

Proof. First we prove the first item in the theorem. Every affine homomorphism g from Z_p^2 to Z_p looks like $g(x, y) \to ax + by + c$ for some constants $a, b, c \in Z_p$. Consider only pairs $x, y \neq 0$, as only $2/p$ of the pairs (x, y) are not of this form. We want to count the number of possible solutions to the equation $xy = ax + by + c$. When $x = b$ there can be p solutions. For every other possible value of x we get a (different) nonconstant linear equation in y, which has at most one solution. So for every possible affine homomorphism g we have $\mathrm{dist}(f, g) \geq 1 - 4/p$, as required.

Now we prove the second item in the theorem. Only $8p - 4$ of the $2p^2$ directed edges have a 0 component in either of their endpoints. Thus with probability of at least $1 - 4/p$ the chosen neighboring vertices v, u have no zero component. We show that all these edges pass the test. Let $v = (x, y)$. There are 2 similar cases. First take $u = (x, y + x)$. Then

$$f(u) - f(v) = x(y + x) - xy = x^2 = f(u - v).$$

Now take $w = (x + y, y)$. Then

$$f(w) - f(v) = (x + y)y - xy = y^2 = f(w - v). \qquad \square$$

Acknowledgments. We thank Eli Ben-Sasson and Salil Vadhan for many illuminating discussions and for reading and commenting earlier versions of the manuscript. We thank Oded Goldreich for many valuable discussions and for suggestions that improved the presentation of the results. We also thank Oded for kindly allowing us

to include his counterexample here. We thank the anonymous referees for their comments.

DETERMINISTIC EXTRACTORS FOR BIT-FIXING SOURCES AND EXPOSURE-RESILIENT CRYPTOGRAPHY*

JESSE KAMP† AND DAVID ZUCKERMAN‡

Abstract. We give an efficient deterministic algorithm that extracts $\Omega(n^{2\gamma})$ almost-random bits from sources where $n^{\frac{1}{2}+\gamma}$ of the n bits are uniformly random and the rest are fixed in advance. This improves upon previous constructions, which required that at least $n/2$ of the bits be random in order to extract many bits. Our construction also has applications in exposure-resilient cryptography, giving explicit adaptive exposure-resilient functions and, in turn, adaptive all-or-nothing transforms. For sources where instead of bits the values are chosen from $[d]$, for $d > 2$, we give an algorithm that extracts a constant fraction of the randomness. We also give bounds on extracting randomness for sources where the fixed bits can depend on the random bits.

Key words. extractors, randomness, deterministic, bit-fixing sources, exposure-resilient, cryptography, resilient function, random walks

1. Introduction.

True randomness is needed for many applications, such as cryptography. However, most physical sources of randomness are not even close to being truly random, and may in fact seem quite weak in that they can have substantial biases and correlations. A natural approach to dealing with the problem of weak physical sources is to apply a *randomness extractor*—a function that transforms a weak random source into an almost uniformly random source. For certain natural notions of such random sources, it has been shown that it is impossible to devise a single function that extracts even one bit of randomness [32]. One way to combat this problem is to allow the use of a small number of uniformly random bits as a catalyst in addition to the bits from the weak random source. Objects constructed in this manner, known as seeded extractors [28], have been shown to extract almost all of the randomness from general weak random sources (see [33] for a recent survey).

However, we would like to eliminate the need for the random catalyst by restricting the class of weak random sources for which we need our function to work. Following the lead of Trevisan and Vadhan [34], we call such functions deterministic extractors for the given class of sources. More formally, we say that a function is an ϵ-extractor for a class of sources if the output of the function is ϵ-close to uniform (in variation distance) for all sources in the class.

1.1. Bit-fixing and symbol-fixing sources.

The particular class of sources that we are interested in are bit-fixing sources, in which some subset of the bits are fixed and the rest are chosen at random. There are two classes of bit-fixing sources,

depending on whether the fixed bits are chosen before or after the random bits are determined, known respectively as oblivious and nonoblivious bit-fixing sources. We will construct extractors for both classes.

Extractors for oblivious bit-fixing sources were first studied in [11], in which they considered the case of exactly uniform output. They proved that at least $n/3$ random bits are needed to extract even two bits from an input of length n. Friedman generalized this result to obtain bounds on the number of random bits needed for longer outputs [16]. The large amount of randomness needed to obtain exactly uniform resilient functions led to the consideration of relaxing this restriction to allow for almost uniform output. We note that even when we allow the extractor to have small error, the best previous constructions still required that at least half of the bits be random [23, 4].

We are able to improve on these constructions by outputting $\Omega(n^{2\gamma})$ bits when the input has at least $n^{\frac{1}{2}+\gamma}$ random bits.

THEOREM 1.1. *For any $\gamma > 0$ and any constant $c > 0$, there exists an ϵ-extractor $f : \{0,1\}^n \to \{0,1\}^m$ for the set of oblivious bit-fixing sources with $n^{\frac{1}{2}+\gamma}$ random bits, where $m = \Omega(n^{2\gamma})$ and $\epsilon = 2^{-cm}$. This extractor is computable in a linear number of arithmetic operations on m-bit strings.*

We can even extract some bits when there are fewer random bits, although we get a much shorter output.

THEOREM 1.2. *There exists an ϵ-extractor $f : \{0,1\}^n \to \{0,1\}^{\frac{1}{4}\log k}$, for the set of oblivious bit-fixing sources with k random bits, where $\epsilon = \frac{1}{2}k^{\frac{1}{4}}\exp(-\frac{\pi^2\sqrt{k}}{2})$. This extractor is computable in a linear number of arithmetic operations on $\frac{1}{4}\log k$ bits.*

In addition to studying oblivious bit-fixing sources, we introduce the related model of d-ary oblivious symbol-fixing sources (SF sources). Such a source consists of a string of symbols over a d symbol alphabet where k of the symbols are random and the rest are fixed. This model is somewhat more restricted than the bit-fixing model. For example, for $d = 2$, this model is the same as the oblivious bit-fixing model, and for $d = 4$, it corresponds to oblivious bit-fixing sources where the fixed and random bits have to come in pairs. However, it is still an extremely natural and interesting model.

For SF sources with $d > 2$, we get much better results than for oblivious bit-fixing sources. We extract a constant fraction of the randomness for sources with any number of random symbols, with the constant depending on d. In particular, as d grows large we can extract almost all of the randomness.

THEOREM 1.3. *For every $d > 2$ there exists a $c_d > 0$ such that for every n and k, there exists an ϵ-extractor $f : [d]^n \to [d]^m$ for the set of d-ary SF sources with k random symbols that outputs $m = c_d\ k - O(\log_d(1/\epsilon))$ symbols, where $c_d \to 1$ as $d \to \infty$. This extractor is computable in a linear number of arithmetic operations on m-symbol strings.*

Another interesting related class of sources for which deterministic extraction is possible are nonoblivious bit-fixing sources [3, 21]. In such sources, the fixed bits can depend on the random bits chosen. This problem was originally studied in the context of collective coin flipping [3], which can be viewed as extraction of a single bit. For the single bit case, nearly optimal lower [21] and upper [2] bounds are known, though the upper bound is not completely constructive. However, little attention has previously been given to generalizing these results to the case of multiple output bits. We give bounds for this case. If $\ell = n - k$ is the number of fixed bits in the source, we show that at most n/ℓ bits can be extracted from these sources, which is likely to be nearly optimal. We also give a construction of an ϵ-extractor for nonoblivious

bit-fixing sources which outputs $\Omega((\epsilon/\ell)^{\log_2 3} \cdot n)$ bits.

1.2. Exposure-resilient cryptography. Our work has applications in cryptography. In traditional cryptography, secret keys are required to remain secret. Most cryptographic schemes have no security guarantees even when an adversary learns only a small part of the secret key. Is it possible to achieve security even when the adversary learns most of the secret key? The class of mappings known as all-or-nothing transforms (AONT), introduced by Rivest [30], address this issue. An AONT is an efficient randomized mapping that is easy to invert given the entire output, but where an adversary would gain "no information" about the input even if it could see almost the entire output of the AONT. Various important applications of the AONT have been discovered, such as the previously mentioned application of protecting against almost complete exposure of secret keys [10], and increasing the efficiency of block ciphers [27, 20, 5].

Boyko used the random-oracle model to give the first formalizations and constructions of the AONT [9]. Canetti et al. gave the first constructions in the standard computational model [10]. For their construction, they introduced a new, related primitive known as an exposure-resilient function (ERF). An ERF is an efficiently computable deterministic function where the output looks random even if the adversary obtains almost all of the bits of a randomly chosen input. They then reduced the task of constructing an AONT to constructing an equivalent ERF. This work was extended by Dodis, Sahai, and Smith [15] to the adaptive setting, where the adversary can decide which bits to look at based on the bits he has already seen. This setting is applicable to the problem of partial key exposure, where it is likely that the adversary would be adaptive.

An important idea used in both [10] and [15] is that we can construct ERF's in the computational setting by first constructing ERF's in the statistical setting and then applying a pseudorandom generator to the output. This allows us to get longer output lengths, which is useful for applications. Because of this observation, we can restrict our attention to constructing ERF's in the statistical setting, where the output must be statistically close to the uniform distribution. However, though [15] gives a probabilistic construction of adaptive statistical ERF's, the problem of giving an explicit construction was left open (see also [14]).

We address this problem by giving an explicit construction of efficient adaptive ERF's in the statistical setting, which in turn gives an explicit construction of adaptive AONT's. Our construction actually gives a stronger function, known as an almost-perfect resilient function (APRF), introduced in [23]. An APRF is like an ERF, except it works for even the case where the adversary can fix some bits of the input instead of merely looking at them. The connection between APRF's and exposure resilient cryptography was shown in [15], where it was proved that APRF's are also adaptive ERF's. In fact, it is easy to see that APRF's are essentially the same as deterministic extractors for oblivious bit-fixing sources. So by constructing extractors for oblivious bit-fixing sources, we will also get APRF's and thus adaptive statistical ERF's and AONT's.

1.3. Overview of our constructions. We now give an overview of our various extractor constructions along with an outline of the rest of the paper.

Our extractor for d-ary SF sources involves using the input symbols to take a random walk on a d-regular expander graph, starting from an arbitrary start vertex. The extractor then outputs the label of the final vertex on the walk. We show that even though we allow some of the steps to be fixed in advance, corresponding to the

fixed bits of the source, these steps will not hurt us. Therefore the random walk behaves essentially like a random walk on the random steps only. Because of the rapid mixing properties of expanders, this output will be close to uniform, and we can extract a linear fraction of the entropy, thus proving Theorem 1.3. For $d = 2$, we cannot use an expander graph since expanders only exist for degree $d > 2$, but we show that if we take a random walk on a cycle we can still extract some bits, proving Theorem 1.2; we give these constructions in section 3.1. We also note that similar types of random walks have been used in previous pseudorandomness constructions [1, 12, 19].

For oblivious bit-fixing sources, we show that we can extract even more bits by first converting the sources into sources that are close to SF sources, which we call approximate symbol-fixing (approx-SF) sources, and then applying the expander walk extractor. This gives the extractor from Theorem 1.1. We show in section 3.2 that our extractor for SF sources also works for approx-SF sources. To convert the oblivious bit-fixing source into a d-ary approx-SF source, we partition the input into blocks. For each block, we take a random walk on the d-cycle and output the label of the final vertex. Enough of the blocks will have enough random bits so that enough of the symbols are almost random. We note that the symbols in the output source have constant error, so we can't just add the errors from the almost random steps since they are too large. Because of this conversion step, we "lose" some of the randomness, which is why we require that the number of random bits be greater than $\sqrt{n}$ in Theorem 1.1. In section 4, we show how to do the conversion and prove that the extractor works.

In section 5, we show the relation between our extractors for oblivious bit-fixing sources and exposure-resilient cryptography.

We give our results for nonoblivious bit-fixing sources in section 6. For such sources, let $\ell = n - k$ be the number of fixed bits. We show that at most n/ℓ bits can be extracted from these sources using a generalization of the edge isoperimetric inequality on the cube. This is likely to be nearly optimal, as it almost corresponds to applying known single bit functions to blocks of the input. In particular, we can use any function with low "influence" [3]. Our best explicit construction uses the iterated majority function of Ben-Or and Linial [3] and outputs $\Omega((\epsilon/\ell)^{\log_2 3} \cdot n)$ bits. However, there are nonexplicit constructions that give bounds within a polylogarithmic factor of our edge isoperimetric bound [2].

1.4. Subsequent work. Since this paper first appeared, Gabizon, Raz, and Shaltiel [18] have improved upon our constructions of extractors for oblivious bit-fixing sources. Using our extractors as building blocks, they are able to extract almost all of the randomness from oblivious bit-fixing sources. Unfortunately, however, the error they achieve is not good enough for our application of constructing adaptive ERF's.

2. Preliminaries. For ease of notation, we sometimes assign noninteger values to integer variables when we mean to round off the values. It is easy to observe that any errors introduced in this manner do not affect our results.

We frequently write our definitions in terms of a single function f, though we really mean for f to represent a family of functions over all input lengths, so asymptotic notions make sense.

2.1. Probability definitions. We need some standard definitions for probability distributions. First, we express our probability distributions as probability vectors

$p = (p_1, ..., p_n)$ with $\sum_i p_i = 1$. Unless otherwise stated, π represents the uniform probability vector (of the appropriate length). The *variation (statistical) distance* $|p - q|$ between two distributions with probability vectors p and q is half the ℓ_1 distance, so $|p - q| = \frac{1}{2}\sum_i |p_i - q_i|$. Also, we use $\|.\|$ to represent the standard ℓ_2 norm for vectors. It is well known that $|p - q| \leq \frac{1}{2}\sqrt{n}\|p - q\|$.

A *source* is a family of probability distributions (a probability ensemble). For ease of notation, we usually refer to a source as a single probability distribution.

2.2. Extractor definitions. Trevisan and Vadhan studied what would happen if you removed the random catalyst from ordinary extractors, and they called such functions deterministic extractors [34]. Deterministic extractors for general weak sources are impossible, and they're even impossible for semirandom sources [32]. However, if we restrict our attention to certain classes of weak sources, then the problem becomes tractable. The following definition of a deterministic extractor is taken from [14], which is implicit in the definitions of [34].

DEFINITION 2.1. *An efficiently computable function $f : \{0,1\}^n \to \{0,1\}^m$ is an ϵ-extractor for a set of random sources $\mathcal{X}$, if for every $X \in \mathcal{X}$, $f(X)$ is within variation distance ϵ of uniform.*

The sets of sources we use are the sets of oblivious bit-fixing [11], symbol-fixing, and nonoblivious bit-fixing sources [3]. Oblivious bit-fixing sources are the easiest to handle, since the fixed bits do not depend on the random bits.

DEFINITION 2.2 (see [11]). *An (n, k) oblivious bit-fixing source X is a source with n bits, of which all but k are fixed and the rest are then chosen uniformly at random.*

DEFINITION 2.3. *An (n, k, d) oblivious SF source X is a source with n independent symbols each taken from $[d]$, of which all but k are fixed and the rest are then chosen uniformly at random.*

Note that for $d = 2^t$, SF sources can be viewed as a special case of bit-fixing sources where the bits are divided up into blocks of size t and each block is either fixed or random.

Nonoblivious bit-fixing sources are more difficult to handle, since the fixed bits can depend on the random bits.

DEFINITION 2.4 (see [3]). *An (n, k) nonoblivious bit-fixing source X is a source with n bits, of which k are chosen uniformly at random and then the remaining $n - k$ bits are chosen, possibly depending on the random bits.*

We will need a slightly weaker notion of symbol-fixing sources when converting bit-fixing sources to symbol-fixing sources.

DEFINITION 2.5. *An (n, k, d, ϵ) approximate oblivious symbol-fixing (approx-SF) source X is a source with n symbols independently chosen from $[d]$, of which k have distributions within an ℓ_2 distance of ϵ of uniform.*

2.3. Graph definitions. We define some standard notions used when studying random walks on graphs. Transition matrices indicate the probability of following any edge in a random walk. A (general) *transition matrix* P for a graph $G = (V, E)$ with n vertices is an $n \times n$ matrix with entries $p_{ij} \geq 0$ if $(i, j) \in E$ and $p_{ij} = 0$ otherwise, and $\sum_{j=1}^{n} p_{ij} = 1$ for all rows i. The *uniform transition matrix* P of a d-regular graph $G = (V, E)$ has all nonzero entries equal to $1/d$. The way to view these definitions is that the probability of choosing edge (i, j) if we are currently at vertex i corresponds to p_{ij}. The *stationary probability vector* π for a random walk with transition matrix P is the vector such that $\pi P = \pi$, and is well defined for connected graphs. In the cases we will look at, π corresponds to the uniform distribution on the vertices.

For each random walk, the input is a string of values, each of which can take on any value in $[d]$, where d is the degree of the graph. A directed edge (u, v) is *labeled* i if (u, v) is the edge taken when the random walk is at u and receives input value i.

One property that we need in our graphs is that the error shouldn't accumulate in any of the vertices. In order for our graphs to have this property, we require that no vertex has two incoming edges with the same label. Such a graph is said to be *consistently labeled*. All of our results apply only to consistently labeled graphs.

An expander graph is a graph that has low degree, but is well connected, so that random walks on expanders converge quickly to the uniform distribution. For a given matrix P, let $\lambda(P)$ denote the second largest eigenvalue in absolute value. Here we define expanders in terms of $\lambda(P)$.

DEFINITION 2.6. *A family of expander graphs is an infinite set of regular graphs G with uniform transition matrix P that have $\lambda(P) = 1 - \epsilon$ for some constant $\epsilon > 0$.*

We will need all of our expander graphs that we use to be efficiently constructible, that is, we should find the neighbors of any vertex in polynomial time in the length of the vertex label. There are various constructions that give infinite families of constant-degree consistently labeled expander graphs that are efficiently computable; see, e.g., [17, 25, 26, 29]. Though these constructions don't work for every degree, we can always construct an expander for a given degree by adding an appropriate number of self loops to an existing expander. It is easy to see that doing so maintains the eigenvalue separation. We also should note that there are expander constructions that work for degrees as small as 3.

3. Constructing extractors for SF and approx-SF sources. In this section, we first show how to construct deterministic extractors for SF sources. We will then show how this construction can be extended to extract from approx-SF sources. We will use the construction for approx-SF sources in the next section to show how we can extract from oblivious bit-fixing sources.

3.1. Extracting from SF sources. In this section, we prove the following generalization of Theorem 1.3 to show that we can extract a constant fraction of the randomness from SF sources.

THEOREM 3.1. *For any $k = k(n)$, ϵ and $d > 2$, if there exists an efficiently computable d-regular expander with $\lambda(P) \leq d^{-\alpha}$ on d^m vertices, for $m \leq 2\alpha k - \frac{2}{\log d} \log \frac{1}{2\epsilon}$, then there exists an efficiently computable ϵ-extractor for the set of (n, k, d) SF sources which outputs m symbols.*

The extractor works by taking a walk on an expander with d^m vertices starting at a fixed vertex and using the input symbols as steps. The output is the label of the final vertex.

We get extractors with the longest output length when we use Ramanujan expanders, for which $\lambda(P) = 2\sqrt{(d-1)}/d$. For certain parameters, there exist efficiently computable Ramanujan graphs [26, 25]. Note that for Ramanujan graphs, as d grows large, α approaches $1/2$, so the output length approaches k.

For $d = 2$, we can't use an expander, but we can use the symbols to take a walk on the cycle to get an extractor for oblivious bit-fixing sources that extracts a small number of bits from any source regardless of k. Note that we're restricted to using odd size cycles here, since random walks on even cycles don't converge to uniform, as they alternate between the even and odd vertices.

THEOREM 3.2. *For odd d, there exists an ϵ-extractor $f : \{0,1\}^n \to [d]$, for the set of (n, k) oblivious bit-fixing sources, where $\epsilon = \frac{1}{2}\sqrt{d}\exp(-\frac{\pi^2 k}{2d^2})$. This extractor is*

computable in a linear number of arithmetic operations on $\log d$ *bits.*

Note that for this extractor to be useful, we must have $\log d < \frac{1}{2}\log k$, which shows that we can output only a small amount of the original randomness with this technique. In particular, if we take $d = k^{\frac{1}{4}}$, we get Theorem 1.2.

Both Theorems 3.1 and 3.2 arise from the following key lemma.

LEMMA 3.3. *Let* P *be a uniform transition matrix with stationary distribution* π *for an undirected nonbipartite* d*-regular graph* G *on* M *vertices. Consider an* n *step walk on* G*, with the steps taken according to the symbols from an* (n, k, d) *SF source* X*. For any initial probability distribution* $p = v + \pi$*, the distance from uniform at the end of the walk is bounded by*

$$\left| p \prod_{i=1}^{n} P_i - \pi \right| \leq \frac{1}{2} \| p \prod_{i=1}^{n} P_i - \pi \| \sqrt{M} \leq \frac{1}{2} \lambda(P)^k \sqrt{M}.$$

To prove this lemma, we show that the random symbols from the source bring us closer to uniform and also that the fixed symbols don't bring us any further away.

For the random steps, it is well known that the distance can be bounded in terms of $\lambda(P)$. This gives the following lemma, a proof of which can be found in [24].

LEMMA 3.4. *Let* P *be a uniform transition matrix for an undirected,* d*-regular graph* G*. Then for any probability vector* $p = v + \pi$*,*

$$\| pP - \pi \| \leq \lambda(P) \| v \|.$$

In our case, most of the steps in our random walks will be fixed. The consistent labeling property ensures that the transition matrix for these fixed steps will be a permutation matrix. Thus these steps leave the distance from uniform unchanged, and so we get the following lemma.

LEMMA 3.5. *Let* P *be a transition matrix for a fixed step on an undirected,* d*-regular graph* G*. Then for any probability vector* $p = v + \pi$*,*

$$\| pP - \pi \| = \| v \|.$$

Now, using the previous two lemmas, we can prove Lemma 3.3.

Proof of Lemma 3.3. For the random symbols we can apply Lemma 3.4. Since there are k random symbols, this gives us the $\lambda(P)^k$ factor. We also use that by Lemma 3.5 the steps corresponding to the fixed symbols don't increase the distance from uniform. Combining both the random and the fixed steps together with the relation between the variation and ℓ_2 distance and the fact that the $\|v\| \leq 1$, we get the stated bound. □

Now we can use Lemma 3.3 to prove Theorem 3.1.

Proof of Theorem 3.1. We can apply Lemma 3.3, where in this case $\lambda(P) \leq d^{-\alpha}$ and $M = d^m$. Thus the error $\epsilon \leq \frac{1}{2} d^{-\alpha k + (m/2)}$. Taking logarithms and solving for m, we get the stated bound on m. □

Now, using Lemma 3.3, we can prove Theorem 3.2. We first separate out the following lemma which will be useful later.

LEMMA 3.6. *Let* P *be a uniform transition matrix for the random walk on the* d*-cycle for* d *odd. Suppose the length of the walk is* n*, with the steps taken according to the symbols from an* (n, k) *oblivious bit fixing source* X*. For any initial probability distribution* $p = v + \pi$*, the distance from uniform at the end of the walk is bounded by*

$$\left| p \prod_{i=1}^{n} P_i - \pi \right| \leq \frac{1}{2} \| p \prod_{i=1}^{n} P_i - \pi \| \sqrt{d} \leq \frac{1}{2} (\cos(\pi/d))^k \sqrt{d}.$$

Proof. The lemma follows from Lemma 3.3 and the fact that the d-cycle has $\lambda(P) = \cos(\pi/d)$ (see [13]). □

Proof of Theorem 3.2. The extractor outputs the result of a random walk on the d-cycle. By Lemma 3.6, this will be within $\frac{1}{2}\sqrt{d}(\cos(\pi/d))^k$ of uniform. Since $\cos(\pi/d) \leq \exp(-\frac{\pi^2}{2d^2})$ (see [13, p. 26]), we get the desired error. □

There is one slight difficulty, since we may want to use a family of expander graphs (or cycles) that includes graphs that don't have exactly 2^m vertices. (In fact, in the cycle case, we can't use any even sized cycle.) This difficulty can be overcome by outputting the result of the random walk on a much larger graph modulo 2^m. The following lemma shows that doing so has little impact on the error.

LEMMA 3.7. *If a random variable X is within ϵ of uniform over $[N]$, then the random variable $Y = X \mod M$ is within $\epsilon + 1/r$ of uniform over $[M]$, where $r = \lfloor N/M \rfloor$.*

Proof. Divide the $y \in [M]$ up into two classes, those corresponding to r different $x \in [N]$ with $y = x \mod M$ and those corresponding to $r+1$ different $x \in [N]$. The probability that Y assigns to each y is then either r/N or $(r+1)/N$, plus the corresponding part of the original error ϵ. Since $r/N \leq 1/M \leq (r+1)/N$, the additional error introduced for each y when going from X to Y is at most $1/N$. So the total additional error introduced is at most $M/N \leq 1/r$. □

3.2. Extracting from approx-SF sources. We now show how the previous construction can be extended to handle the case of approx-SF sources. Our main result in this section is the following variant of Lemma 3.3 for approx-SF sources.

LEMMA 3.8. *Let P be a uniform transition matrix with stationary distribution π for an undirected nonbipartite d-regular graph G on M vertices. Suppose we take a walk on G for n steps, with the steps taken according to the symbols from an (n, k, d, ϵ) approx-SF source X. For any initial probability distribution $p = v + \pi$, the distance from uniform at the end of the walk is bounded by*

$$\left| p \prod_{i=1}^{n} P_i - \pi \right| \leq \frac{1}{2} \| p \prod_{i=1}^{n} P_i - \pi \| \sqrt{M} \leq \frac{1}{2} (\lambda(P) + \epsilon\sqrt{d})^k \sqrt{M}.$$

In the case of approx-SF sources, the random steps in our random walk will be only almost uniformly random. This introduces some small amount of error into our transition matrix. We can separate out the error terms by dividing up our new transition matrix P' into the uniform transition matrix P and an error matrix E, which is defined as follows.

DEFINITION 3.9. *An ϵ-error matrix E for a d-regular graph G is a matrix with the following properties. If $|E_{ij}| > 0$, then (i, j) is an edge in G; all of the columns of E sum to 0; and the ℓ_2 norm of each column of E is at most ϵ.*

For slightly nonuniform random steps, we can modify the bound from Lemma 3.4 slightly to get the following lemma.

LEMMA 3.10. *Let P be a uniform transition matrix for an undirected, d-regular graph G. Let E be an ϵ-error matrix for G. Now let $P' = P + E$ be our modified transition matrix. Then P' has the same stationary distribution π as P and for any probability vector $p = v + \pi$,*

$$\|pP' - \pi\| \leq (\lambda(P) + \epsilon\sqrt{d})\|v\|.$$

Proof. Because π is uniform and because each of the columns of E sum to 0 by definition, $\pi E = 0$. Thus $\pi P' = \pi P + \pi E = \pi$ by the above observation combined with the stationarity of π with respect to P. Thus P' has stationary distribution π.

Now we bound $\|pP' - \pi\|$. We first observe that $\|pP' - \pi\| = \|vP' + \pi P' - \pi\| = \|vP'\|$ since we know from above that π is stationary. Now we can focus on bounding $\|vP'\|$. By the triangle inequality $\|vP'\| \leq \|vP\| + \|vE\|$. We know that $\|vP\| \leq \lambda(P)\|v\|$. Letting e_{ij} denote the entries of E, we get

$$\begin{aligned}\|vE\| &= \left(\sum_j \left(\sum_{i;e_{ij}\neq 0} e_{ij}v_i\right)^2\right)^{\frac{1}{2}} \\ &\leq \left(\sum_j \left(\sum_{i;e_{ij}\neq 0} e_{ij}^2\right)\left(\sum_{i;e_{ij}\neq 0} v_i^2\right)\right)^{\frac{1}{2}} \\ &\leq \epsilon \left(\sum_j \sum_{i;e_{ij}\neq 0} v_i^2\right)^{\frac{1}{2}} \leq \epsilon\sqrt{d}\|v\|,\end{aligned}$$

where the first line is simply from the definition, and noting that we only need to sum over all nonzero e_{ij}. The second line follows from the Cauchy–Schwarz inequality. The third line follows from the fact that the sum of the square of the errors e_{ij}^2 over any column is at most ϵ^2. The final inequality comes from the fact that e_{ij} can only be nonzero when ij corresponds to an edge in G. Since there are d edges adjacent to i, we will have at most d v_i^2 terms in the sum for each i.

Putting everything together we get the desired bound on $\|pP' - \pi\|$. ∎

Unlike in the case of SF sources, the nonrandom steps may not be fixed, but may simply not have enough randomness in them. However, we would still like to show that these steps do not take us further from the uniform distribution. The following lemma shows that since any step chosen according to a symbol from a d-ary source is a convex combination of permutations, the nonrandom steps in our random walk don't increase the distance from uniform. Note that this result depends on our assumption that the graph G is consistently labeled.

LEMMA 3.11. *Let P be a transition matrix for a step chosen according to a symbol X_j from a d-ary source X. Then P is a convex combination of permutation matrices and for any probability vector $p = v + \pi$, $\pi P = P$, and $\|pP - \pi\| \leq \|v\|$.*

Proof. First we show that P is a convex combination of permutation matrices. Every possible value from $i \in [d]$ for x gives a permutation matrix P_i. If X_j is distributed with probabilities α_i for each $i \in [d]$, then $P = \sum_{i=0}^{d-1} \alpha_i P_i$, which is a convex combination of permutation matrices.

Then note that since any permutation of π is still uniform, we have $\pi P_i = \pi$ and thus $\pi P = P$. This gives us $\|pP - \pi\| = \|vP\|$. We bound $\|vP\|$ by the triangle inequality as $\|vP\| \leq \sum_i \alpha_i \|vP_i\| = \sum_i \alpha_i \|v\| = \|v\|$, where the second inequality follows from the fact that since P_i is a permutation, $\|vP_i\| = \|v\|$. ∎

Using the previous two lemmas, we can prove Lemma 3.8.

Proof. Let P_i be the transition matrix of the random walk at the ith step. By Lemma 3.11 P_i is a convex combination of permutation matrices and $\pi P_i = \pi$. This gives us $\pi \prod_{i=1}^n P_i = \pi$, so $p\prod_{i=1}^n P_i - \pi = v\prod_{i=1}^n P_i$.

Let $v_j = \prod_{i=1}^j P_i$. Then $v_j = v_{j-1}P_j$, and $v_0 = v$. For k of the steps, the symbols are within an ℓ_2 distance of ϵ from uniform, which implies $P_j = P + E_j$, where every column of E_j has ℓ_2 norm at most ϵ. Since G is consistently labeled, the sum of each column of E_j is equal to 0, so E_j is indeed an error matrix. So for these steps, by

Lemma 3.10, $\|v_{j-1}P_j\| \leq (\lambda(P) + \epsilon\sqrt{d})\|v_{j-1}\|$. For the other steps, we still have by Lemma 3.11 that $\|v_{j-1}P_j\| \leq \|v_{j-1}\|$. So for k steps the ℓ_2 norm is reduced while for the rest of the steps it, at worst, remains the same. Thus

$$\left\| p\prod_{i=1}^{n} P_i - \pi \right\| = \left\| v\prod_{i=1}^{n} P_i \right\| \leq (\lambda(P) + \epsilon\sqrt{d})^k \|v\|.$$

Now apply the bound relating the ℓ_2 norm and variation distance and $\|v\| \leq 1$. ∎

4. From SF sources to oblivious bit-fixing sources. In this section, we show how to extend our results for SF sources to oblivious bit-fixing sources to get the following theorem, which is basically a restatement of Theorem 1.1. Though we state the theorem for general values of δ, we have in mind the case $\delta n = n^{\frac{1}{2}+\gamma}$.

THEOREM 4.1. *For any positive $\delta = \delta(n) \leq 1$ and any constant $c > 0$, there exists an ϵ-extractor $f : \{0,1\}^n \to \{0,1\}^m$, for the set of $(n, \delta n)$ oblivious bit-fixing sources, where $m = \Omega(\delta^2 n)$ and $\epsilon = 2^{-cm}$. This extractor is computable in a linear number of arithmetic operations on m-bit strings.*

There are two main steps in the extractor construction. First, we transform the source into an approx-SF source by dividing it into blocks. For each block we take a random walk on the cycle and output the label of the final vertex on the walk. The approx-SF source is then the concatenation of these outputs. Then we use the expander walk extractor from the previous section to extract from the approx-SF source.

We start by applying Lemma 3.6 to our degree 2 walks on the d-cycle for each of the blocks. We will show that enough of the blocks mix to within ϵ' of the uniform distribution, for some ϵ'. This process gives us an approx-SF source.

LEMMA 4.2. *For any odd d, any $(n, \delta n)$ oblivious bit-fixing source can be deterministically converted into a $(\frac{\delta n}{2t}, \frac{\delta^2 n}{4t}, d, \epsilon)$ approx-SF source, where $t = \lceil \frac{\log \epsilon}{\log(\cos(\pi/d))} \rceil$.*

The almost random symbols in the approx-SF source correspond to blocks where we have "enough" random bits. Using a Markov-like argument, we can quantify how many such blocks we will have, as shown in the following lemma.

LEMMA 4.3. *Suppose we have n bits from an (n, k) oblivious bit-fixing source, where $k = \delta n$. For any partition of the n bits into $\delta n/2t$ blocks of size $2t/\delta$, the number r of blocks with at least t random bits satisfies $r > \frac{\delta^2 n}{4t}$.*

Proof. We know that in the r blocks with at least t random bits there are at most $2t/\delta$ random bits. In the remaining blocks there are less than t random bits. Combining these two facts we get that the total number of random bits $k < 2rt/\delta + t((n\delta/2t) - r)$, which after a simple calculation gives the desired result. ∎

Using this lemma, we can now prove Lemma 4.2.

Proof of Lemma 4.2. Divide the input r up into $\delta n/2t$ blocks of size $2t/\delta$. Then take a random walk on a d-cycle using the bits from each block and output the vertex label of the end vertex for each walk. These vertex labels are the symbols for our approx-SF source. We call a block good if this random walk reaches within an ℓ_2 distance of ϵ from uniform, which means the corresponding symbol is good for our source. By Lemma 3.6, if there are at least t random bits in the block the ℓ_2 distance from uniform is at most $(\cos(\pi/d))^t \leq \epsilon$, which means all such blocks are good. Then by Lemma 4.3, the number of good blocks r satisfies $r > \frac{\delta^2 n}{4t}$. Thus the output source is an approx-SF source with the appropriate parameters. ∎

The symbols from the approx-SF source then correspond to our almost random steps in the expander graph, so we can apply Lemma 3.8 to the expander walk to get

that the final distribution is close to uniform.

Proof of Theorem 4.1. If $\delta = O(1/\sqrt{n})$, we can take f to be the parity function, since in this case outputting a single bit is enough. Otherwise, let G be a d-regular expander graph on 2^m vertices with uniform transition matrix P. Choose ϵ' so that $\lambda_{\epsilon'} = \lambda(P) + \epsilon'\sqrt{d} < 1$. Then use the procedure in Lemma 4.2 to convert the $(n, \delta n)$ oblivious bit-fixing source to a $(\frac{\delta n}{2t}, \frac{\delta^2 n}{4t}, d, \epsilon')$ approx-SF source, where $t = \lceil (\log \epsilon')/(\log(\cos(\pi/d))) \rceil$.

Now we use the approx-SF source to take a random walk on G. We take the label of the final vertex of the walk on G as the output $f(r)$. Then we can apply Lemma 3.8, which states that the variation distance from uniform of $f(r)$ is at most

$$\frac{1}{2}\lambda_{\epsilon'}^r 2^{m/2} < \lambda_{\epsilon'}^{\frac{\delta^2 n}{4t}} 2^{m/2}.$$

We want this to be at most $\epsilon = 2^{-cm}$, so setting $m = b\delta^2 n$ for some constant $b > 0$ and taking the logarithm, we get $\frac{1}{4t}\log\frac{1}{\lambda_{\epsilon'}} \geq b\left(c + \frac{1}{2}\right)$. The left-hand side of this inequality is just some positive constant, so for any given value of c we can select b so that the inequality is satisfied. These constants give the desired output length and the desired error ϵ.

Since there are a linear number of expander steps and there exist expanders that take a constant number of arithmetic operations per step, f is computable in a linear number of arithmetic operations on m-bit strings. □

Note that in the last proof we only needed a bound on the ℓ_2 distance, which from the proof of Lemma 3.8 is tighter than the bound on the variation distance, but this difference only affects the constants in the theorem.

5. Exposure-resilient cryptography. We now discuss the needed background from exposure-resilient cryptography and how our extractor for oblivious bit-fixing sources can be used to get better statistical adaptive ERF's and AONT's.

There are a few different types of resilient functions that we define, taken from [15], each of which involve making the output look random given an adversary with certain abilities. For all of these definitions, f is a polynomial time computable function $f : \{0,1\}^n \to \{0,1\}^m$. Also, there is a computationally unbounded adversary $\mathcal{A}$ that has to distinguish the output of f from a uniformly random string $R \in \{0,1\}^m$. A function $\epsilon(n)$ is said to be *negligible* if $\epsilon(n) = O(\frac{1}{n^c})$ for all constants c.

Adaptive k-ERFs are defined as functions that remain indistinguishable from uniform even by adversaries that can adaptively read most of the input.

DEFINITION 5.1 (see [15]). *An adaptive k-ERF is a function f where, for a random input r, when $\mathcal{A}$ can adaptively read all of r except for k bits, $|\Pr[\mathcal{A}^r(f(r)) = 1] - \Pr[\mathcal{A}^r(R) = 1]| \leq \epsilon(n)$ for some negligible function $\epsilon(n)$.*

Our goal is to construct adaptive ERF's. We might first think that any $\epsilon(n)$-extractor for oblivious bit-fixing sources would work as long as $\epsilon(n)$ is negligible. However, [15] show that there are functions that are oblivious bit-fixing extractors but not adaptive ERF's. To solve this problem, they use a stronger condition which they show is sufficient. This condition is that every single output value has to occur with almost uniform probability. Functions that satisfy this stronger condition are the APRFs (first stated in section 1.2), introduced by Kurosawa, Johansson, and Stinson [23].

DEFINITION 5.2 (see [23]). *A $k = k(n)$ APRF is a function f where, for any setting of $n - k$ bits of the input r to any fixed values, the probability vector p of the*

output $f(r)$ over the random choices for the k remaining bits satisfies $|p_i - 2^{-m}| < 2^{-m}\epsilon(n)$ for all i and for some negligible function $\epsilon(n)$.

THEOREM 5.3 (see [15]). *If f is a k-APRF, then f is an adaptive k-ERF.*

The following lemma shows that any extractor for oblivious bit-fixing sources with small enough error is also an APRF. We use this lemma to show that the extractor we constructed earlier is also an APRF, and hence an adaptive k-ERF.

LEMMA 5.4. *Any $2^{-m}\epsilon(n)$-extractor $f : \{0,1\}^n \to \{0,1\}^m$ for the set of (n,k) oblivious bit-fixing sources, where $\epsilon(n)$ is negligible, is also a k-APRF.*

Proof. Since f is an extractor, the total variation distance from uniform of the output of f when $n-k$ bits of the input are fixed is within $2^{-m}\epsilon(n)$. Thus the distance of any possible output from uniform must also be within $2^{-m}\epsilon(n)$, and the APRF property is satisfied. ∎

Now using this lemma we get the following theorem.

THEOREM 5.5. *For any positive constant $\gamma \leq 1/2$, there exists an explicit k-APRF $f : \{0,1\}^n \to \{0,1\}^m$, computable in a linear number of arithmetic operations on m-bit strings, with $m = \Omega(n^{2\gamma})$ and $k = n^{\frac{1}{2}+\gamma}$.*

Proof. Apply Lemma 5.4 to the extractor from Theorem 4.1, choosing $c > 1$. ∎

We can use adaptive ERFs to construct AONTs, which were introduced by Rivest [30] and extended to adaptive adversaries by Dodis, Sahai, and Smith [15]. We first give a formal definition of AONTs. There are two parts to the definition. First, the AONT is an efficient randomized mapping that is easily invertible given the entire output. Second, an adversary gains negligible information about the input to the AONT even when it can read almost the entire output. This is formalized by the adversary not being able to distinguish between any two distinct inputs. Note that the output of the AONT has two parts. We call the first part of the output the secret part and the second part of the output the public part.

DEFINITION 5.6 (see [15]). *A polynomial time randomized transformation $T : \{0,1\}^m \to \{0,1\}^s \times \{0,1\}^p$ is a statistical adaptive k-AONT if*

1. *T is invertible in polynomial time.*
2. *For any adversary $\mathcal{A}$ who has oracle access to string $y = (y_s, y_p)$ and is required not to read at least k bits of y_s, and for any $x_0, x_1 \in \{0,1\}^m$ and some negligible function $\epsilon(s+p)$:*

$$|\Pr[\mathcal{A}^{T(x_o)}(x_0,x_1) = 1] - \Pr[\mathcal{A}^{T(x_1)}(x_0,x_1) = 1]| \leq \epsilon(s+p).$$

The following lemma from [15] relates adaptive k-ERF's to adaptive k-AONT's, and shows that our construction gives adaptive k-AONT's.

THEOREM 5.7 (see [15]). *If $f : \{0,1\}^n \to \{0,1\}^m$ is an adaptive k-ERF, then $T(x) = \langle r, x \oplus f(r)\rangle$ is a statistical adaptive k-AONT with secret part r and public part $x \oplus f(r)$.*

By combining Theorem 5.7 with Theorem 5.5, we get the following theorem.

THEOREM 5.8. *For any positive constant $\gamma \leq 1/2$, there exists an explicit function $f : \{0,1\}^n \to \{0,1\}^m$ computable in a linear number of arithmetic operations on m-bit strings, with $m = \Omega(n^{2\gamma})$, such that $T(x) = \langle r, x \oplus f(r)\rangle$ is a statistical adaptive k-AONT with secret part r and public part $x \oplus f(r)$.*

6. Extracting from nonoblivious bit-fixing sources. In this section, we switch our focus to nonoblivious bit-fixing sources, where the fixed bits can depend on the random bits. We give upper and lower bounds for extracting from such sources.

Previous bounds on nonoblivious bit-fixing sources have been defined in terms of the "influence" of variables on a function [3]. The influence of a set of variables S on a

function f, denoted $I_f(S)$, is the probability that if the variables not in S are chosen randomly, the function remains undetermined. The following two lemmas show that the influence of a function is related to the variation distance of the function from uniform when the input comes from a nonoblivious bit-fixing source. The first lemma shows that having low influence for all sets of a given size implies that a function is an extractor, while the second lemma shows that a function that has a set with high influence cannot be an extractor.

LEMMA 6.1. *Suppose $f : \{0,1\}^n \to \{0,1\}^m$ maps the uniform distribution U_n to U_m and $I_f(S) \leq \epsilon$ for all sets S of ℓ variables. Then f is an ϵ-extractor for the set of $(n, n-\ell)$ nonoblivious bit-fixing sources.*

Proof. Let X be an $(n, n-\ell)$ nonoblivious bit-fixing source and let S denote the set of fixed variables of X. Since $I_f(S) \leq \epsilon$, for all but an ϵ fraction of the choices for the random bits in X, f has the same distribution regardless of whether the rest of the bits are chosen according to X or according to U_n. Thus the variation distance is at most ϵ. □

LEMMA 6.2. *Let S be a set of ℓ variables. If, for some $\epsilon > 0$, $I_f(S) = \epsilon$, then there exists an $(n, n-\ell)$ nonoblivious bit-fixing source X with set of fixed variables S so that*

$$|f(X) - U_m| \geq \epsilon/4.$$

Proof. View the possible outputs as vertices of a hypergraph on 2^m vertices. Look at all possible values of the $n-\ell$ bits not in S. Since $I_f(S) = \epsilon$, we know that an ϵ fraction of these values leave f undetermined. For each such value, place a hyperedge between all possible output values of f (when going over all possible values for the bits in S).

Eliminate all of the vertices with no edges. Now divide all of the remaining vertices at random into two sets of equal size, A and B. The expected number of hyperedges in the cut between A and B is at least half the total number of hyperedges, so there exists a pair of sets with at least this many hyperedges. Consider such A and B, and look at only the hyperedges in the cut. Now each of these hyperedges corresponds to a setting of the $n-\ell$ bits not in S. So we define two $(n, n-\ell)$ nonoblivious bit-fixing sources X_A and X_B based on how the values of the bits in S are set for each cut hyperedge. Define X_A (X_B) by setting the bits in S for each cut hyperedge so that the output of f lies in A (B). Since these hyperedges have total probability at least $\epsilon/2$, these sources will differ by at least $\epsilon/2$. Thus at least one of them will differ by at least $\epsilon/4$ from the uniform distribution. □

Using Lemma 6.1, we immediately see that known constructions of Boolean functions with low influence [3, 2] are extractors. To get longer output length, we show that we can construct an extractor that extracts several bits from any Boolean function with small influence. The extractor simply works by applying the low influence function to blocks of the input and concatenating the resulting output bits.

LEMMA 6.3. *Suppose there exists a function $g : \{0,1\}^s \to \{0,1\}$, with expectation $1/2$, and a value $r(s)$ such that any set S of $\ell(s,\epsilon) = \epsilon r(s)$ variables has $I_g(S) \leq \epsilon$ for all $\epsilon > 0$. Then there exists an ϵ-extractor $f : \{0,1\}^n \to \{0,1\}^m$ for the set of $(n, n-\ell(s,\epsilon))$ nonoblivious bit-fixing sources that extracts $m = n/s$ bits.*

Proof. Divide the input into $m = n/s$ blocks of size s. The jth output bit of f will be g applied to the jth block. Fix a set S. By Lemma 6.1 we need to show that f has $I_f(S) \leq \epsilon$ for all sets S of $\ell = \ell(s,\epsilon)$ variables. Let ℓ_i be the number of bits in S in block i and set $\epsilon_i = \ell_i / r(s)$. The influence for each output bit is

then at most ϵ_i. Now we note that since the random bits for each of these functions are chosen independently, the total influence is at most the sum of the influences for each of these Boolean functions. Thus, since $\sum_{i=1}^{m} \epsilon_i = (\sum_{i=1}^{m} \ell_i)/r(s) = \ell/r(s) = \epsilon$, $I_f(S) \leq \epsilon$. □

We can apply this lemma to the iterated majority function of Ben-Or and Linial [3] to get an explicit extractor for nonoblivious bit-fixing sources.

THEOREM 6.4 (see [3]). *For every s, there is an explicit construction of functions $g : \{0,1\}^s \to \{0,1\}$, with expectation $1/2$, where any set S of $\ell(s,\epsilon) = \epsilon\left(\frac{s}{3}\right)^{\alpha}$ variables has $I_g(S) \leq \epsilon$ for every $\epsilon > 0$, where $\alpha = \log_3 2$.*

THEOREM 6.5. *For every n, we can construct an ϵ-extractor $f : \{0,1\}^n \to \{0,1\}^m$ for the set of $(n, n-\ell)$ nonoblivious bit-fixing sources that extracts $m = \frac{1}{3}(\epsilon/\ell)^{1/\alpha} n$ bits, where $\alpha = \log_3 2$.*

Proof. Apply Lemma 6.3 using the function from Theorem 6.4. □

Ajtai and Linial [2] give hope for improvement since their functions allow $\Omega(s/\log^2 s)$ fixed bits. However, their construction is nonexplicit, and a bound like that in Lemma 6.3 is only known to hold for $\epsilon \geq 1/\operatorname{polylog}(s)$ [31].

In the other direction, we now show that at most n/ℓ bits can be extracted from nonoblivious bit-fixing sources. To do so, we generalize the edge-isoperimetric bound from [3].

LEMMA 6.6. *For every function $f : \{0,1\}^n \to \{0,1\}^m$ with output within ϵ of uniform on uniform input, the expected influence over all sets of variables S of size ℓ is at least*

$$1 - 2\frac{\binom{n-m+1}{l}}{\binom{n}{l}} - 2\epsilon.$$

Proof. View all 2^n possible inputs as vertices of the n dimensional cube. Color the vertices of the cube with 2^m colors, where the color of x corresponds to $f(x)$. Now for each possible set S of size ℓ and setting of the remaining $n-\ell$ random variables, there is a corresponding subcube of dimension ℓ in the cube. Note that f is undetermined over such a subcube if and only if the subcube is not monochromatic. So the average influence over all possible S is the probability that a randomly chosen ℓ dimensional subcube is not monochromatic. We divide the set of colors into two classes, those with at most 2^{n-m+1} vertices and those with more, which we call "small" and "large."

First, we handle the large colors. Let t be the number of large colors. Each of these t colors contributes at least 2^{-m} to the error ϵ of f with uniform input, so $t \leq \epsilon 2^m$. Since the distance from uniform is at most ϵ, the total number of vertices with large colors is at most $\epsilon 2^n + t2^{n-m} \leq 2\epsilon 2^n$. The probability that a subcube is monochromatic for a large color is at most the probability that the subcube lies completely within this set of vertices, which is at most the probability that any given vertex in the subcube is in this set. Thus, the probability that a subcube is monochromatic for a large color is at most 2ϵ.

Second, we handle the small colors. Each small color has at most 2^{n-m+1} vertices. By a generalization of the edge-isoperimetric inequality, the set of vertices of size 2^{n-m+1} with the most monochromatic subcubes of dimension ℓ corresponds to a subcube of dimension $n-m+1$ [7, 6]. This larger subcube contains $\binom{n-m+1}{\ell}2^{n-m+1-\ell}$ subcubes of dimension ℓ. Since there are at most 2^m small colors, the total number of monochromatic subcubes with small colors is at most $2^{n+1-\ell}\binom{n-m+1}{\ell}$. Since there are $2^{n-\ell}\binom{n}{\ell}$ subcubes total, the probability of a randomly chosen subcube being monochromatic for a small color is at most $2\frac{\binom{n-m+1}{l}}{\binom{n}{l}}$.

Thus, the probability of a randomly chosen subcube being not monochromatic is at least $1 - 2\frac{\binom{n-m+1}{l}}{\binom{n}{l}} - 2\epsilon$, which means that the average influence is at least this much. ∎

Note that due to the tightness of the isoperimetric bounds, this bound is essentially the best that can be achieved using an averaging argument. Using Lemmas 6.6 and 6.2, we're able to prove the following theorem. Note that the theorem says that if $m > n/\ell$, then we can't even extract with error a small constant.

THEOREM 6.7. *No function $f : \{0,1\}^n \to \{0,1\}^m$ is an ϵ-extractor for $(n, n-\ell)$ nonoblivious bit-fixing sources for any $\epsilon \leq \frac{1}{10}\min\{\frac{\ell\cdot(m-1)}{n}, 1\}$.*

Proof. Suppose f is an ϵ-extractor. First note that f must be within ϵ of uniform on uniform input. So by Lemma 6.6, there is a set of variables S of size ℓ with

$$\begin{aligned} I_f(S) &\geq 1 - 2\frac{\binom{n-m+1}{l}}{\binom{n}{l}} - 2\epsilon \\ &\geq 1 - 2\left(1 - \frac{m-1}{n}\right)^{\ell} - 2\epsilon \\ &\geq 1 - e^{-\ell\cdot(m-1)/n} - 2\epsilon. \end{aligned}$$

By Lemma 6.2, there is an $(n, n-\ell)$ nonoblivious bit-fixing source X so that $f(X)$ is of distance at least $I_f(S)/4$ from uniform, so $\epsilon > I_f(S)/4$. Thus $\epsilon > (1 - e^{-\ell\cdot(m-1)/n})/6$. If $\ell \cdot (m-1)/n \geq 1$, then $\epsilon > (1-e^{-1})/6 > 1/10$. If $\ell \cdot (m-1)/n < 1$, then $e^{-\ell\cdot(m-1)/n} < 1 - (1-e^{-1})\frac{\ell\cdot(m-1)}{n}$, so $\epsilon > \frac{(1-e^{-1})}{6}\frac{\ell\cdot(m-1)}{n} > \frac{1}{10}\frac{\ell\cdot(m-1)}{n}$. ∎

7. Open questions. There remains some work to be done in order to get truly optimal deterministic extractors for oblivious bit-fixing sources. Though we can get nearly optimal results for the d-ary case, for $d > 2$, we lose a factor of δ in the binary case because of the need to take the random walks on the cycle. Ideally, we would like to improve the output length from $\Omega(\delta^2 n)$ to $\Omega(\delta n)$, to match the number of random bits in the input. The extractor of [18] is able to extract almost all of the randomness; however, the error is not as good. In particular, their extractor is not useful for the application to exposure-resilient cryptography. Can we construct an extractor that extracts a linear fraction of the randomness and has small error?

For nonoblivious bit-fixing sources, there also remains more work to be done. It would be nice to eliminate some of the difference between the lower and upper bounds. For the single bit case, Kahn, Kalai, and Linial [21] give a lower bound that improves upon the edge isoperimetric bound by a factor of $\log n$ using a harmonic analysis argument. Perhaps similar techniques could be applied to the general case of many output bits. Also, we could get better extractors if we could modify the construction of Ajtai and Linial [2] to work for smaller error and make it explicit.

Another interesting future direction would be to identify additional classes of sources that have deterministic extractors. One interesting possibility is the set of affine sources, where k bits are chosen uniformly at random and the n bits of the source are affine combinations of these bits. Affine sources are a special case of nonoblivious bit-fixing sources, so our constructions apply to affine sources as well. Other methods allow us to extract when $k > n/2$, but it would be interesting to construct extractors for affine sources that work for $k \leq n/2$. Recently, Bourgain [8] has overcome this barrier by constructing extractors that work for affine sources with $k = \delta n$ for any constant δ. However, there is still room for improvement,

since probabilistic arguments show that affine source extractors exist even when k is logarithmic in n.

Another interesting model is sources generated using a small amount of space. Recently, in joint work with Rao and Vadhan [22], we have given the first explicit constructions of deterministic extractors for such sources.

8. Acknowledgments. We thank Peter Bro Miltersen for suggesting the problem of extractors for oblivious bit-fixing sources and Anindya Patthak and Vladimir Trifonov for helpful discussions.

LINEAR UPPER BOUNDS FOR RANDOM WALK ON SMALL DENSITY RANDOM 3-CNFs*

MIKHAIL ALEKHNOVICH† AND ELI BEN-SASSON‡

In memory of Mikhail (Misha) Alekhnovich—friend, colleague and brilliant mind

Abstract. We analyze the efficiency of the random walk algorithm on random 3-CNF instances and prove *linear* upper bounds on the running time of this algorithm for small clause density, less than 1.63. This is the first subexponential upper bound on the running time of a *local improvement* algorithm on random instances. Our proof introduces a simple, yet powerful tool for analyzing such algorithms, which may be of further use. This object, called a *terminator*, is a weighted satisfying assignment. We show that any CNF having a good (small weight) terminator is assured to be solved quickly by the random walk algorithm. This raises the natural question of the *terminator threshold* which is the maximal clause density for which such assignments exist (with high probability). We use the analysis of the pure literal heuristic presented by Broder, Frieze, and Upfal [*Proceedings of the Fourth Annual ACM-SIAM Symposium on Discrete Algorithms*, 1993, pp. 322–330] and Luby, Mitzenmacher, and Shokrollahi [*Proceedings of the Ninth Annual ACM-SIAM Symposium on Discrete Algorithms*, 1998, pp. 364–373] and show that for small clause densities good terminators exist. Thus we show that the pure literal threshold ($\approx$1.63) is a lower bound on the terminator threshold. (We conjecture the terminator threshold to be in fact higher.) One nice property of terminators is that they can be found efficiently via linear programming. This makes tractable the future investigation of the terminator threshold and also provides an efficiently computable certificate for short running time of the simple random walk heuristic.

Key words. SAT solving, random CNF, SAT heuristics, random walk algorithm

1. Introduction.

The phenomena we seek to explain is best described by Figure 1.

`RWalkSAT`, originally introduced by Papadimitriou [35], tries to find a satisfying assignment for a CNF $\mathcal{C}$ by the following method. We start with a random assignment, and as long as the assignment at hand does not satisfy the CNF, an unsatisfied clause $C \in \mathcal{C}$ is picked, and the assignment to a random literal in this clause is flipped. The new assignment satisfies C but may "ruin" the satisfiability of other clauses. We repeat this process (of flipping a bit in the current assignment according to some unsatisfied clause) until either a satisfying assignment is found (success) or we get tired and give up (failure).

The lower batch in Figure 1 (plus sign) was obtained by selecting 810 random 3-CNF formulas[1] with a clause density (i.e., clause/variable ratio) of 1.6 and running `RWalkSAT` on each instance. The y-axis records the number of assignments used before finding a satisfying one. In particular, the algorithm found an assignment in all

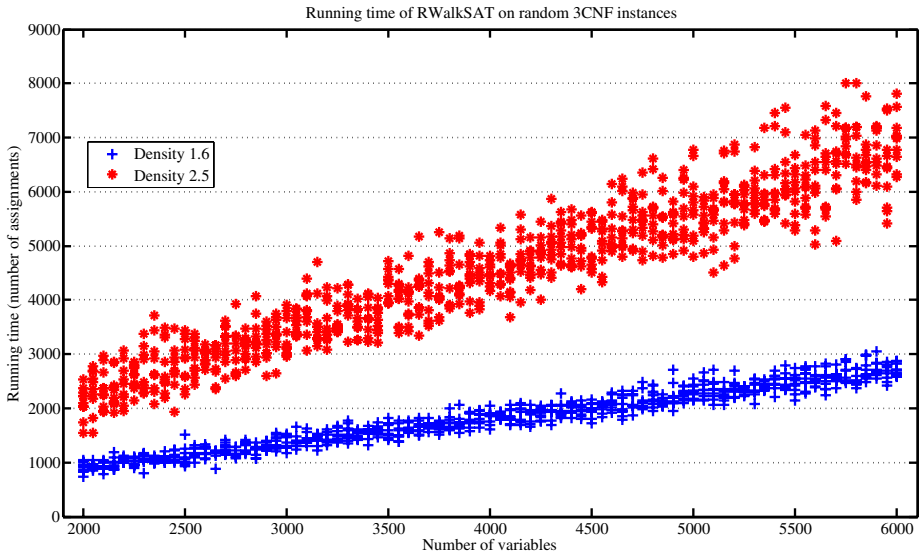

FIG. 1. *Running time of* `RWalkSAT` *on random* 3*-CNF instances with clause densities* 1.6 *and* 2.5.

instances. The upper batch (star sign) was similarly obtained by running `RWalkSAT` on 810 random 3-CNF instances with a higher clause density of 2.5.

Figure 1 raises the conjecture that for clause density 1.6 the running time is linear. Actually, it is even less than the number of variables (and clauses) and seems to have a slope of $\approx 1/2$. In this paper we offer an explanation for the seemingly linear running time of Figure 1. We prove that random 3-CNFs with clause density less than 1.63 take (with high probability) a *linear* number of `RWalkSAT` steps. (We leave the explanation of the running time displayed in the upper batch of Figure 1 as an interesting open problem.)

1.1. Techniques: Terminators. Our technique can be viewed as a generalization of the analysis of `RWalkSAT` on satisfiable 2-CNF formulas [35], so we briefly review this result. Papadimitriou showed that the Hamming distance of the assignment at time t from some fixed satisfying assignment α is a random variable that decreases at each step with probability at least $1/2$. Thus, in at most $O(n^2)$ steps this random variable will reach 0, implying we have found α. (The algorithm may succeed even earlier by finding some other satisfying assignment.)

We look at *weighted satisfying assignments*; i.e., we give nonnegative weights to the bits of α. Instead of Hamming distance, we measure the *weighted distance* between α and the current assignment α^t. We show that in some cases, one can find a satisfying assignment α and a set of weights w such that for *any* unsatisfied clause at time t, the expectation of the weighted distance (between α and α^t) decreases by at least 1. Moreover, the maximal weight given to any variable is constant. In this case the running time of `RWalkSAT` will be linear with high probability (even better than the quadratic upper bound of [35] for 2-CNFs). We call such weighted assignments *terminators*, as their existence assures us that `RWalkSAT` will terminate successfully in linear time.

Two parameters of a terminator bound the running time of `RWalkSAT`. The *total weight* (sum of weights of all variables) bounds the distance needed to be traversed by the random walk, because the weighted distance of α^0 from α can be as large as this

sum. The second parameter is the maximal weight of a variable, which bounds the variance of our random walk. Thus we define the termination weight of $\mathcal{C}$ (denoted $\mathrm{Term}(\mathcal{C})$) to be the minimal product of these two parameters, taken over all terminators for $\mathcal{C}$. As stated above, the running time of `RWalkSAT` is linear (at most) in the termination weight of $\mathcal{C}$. Not all satisfiable CNFs have these magical terminators, and if $\mathcal{C}$ has no terminator, we define its termination weight to be ∞.

1.2. Results. With the terminator concept in hand, we examine the running time of `RWalkSAT` on random 3-CNF formulas. If $\mathcal{C}$ is a random 3-CNF, then $\mathrm{Term}(\mathcal{C})$ is a random variable. Understanding this variable and bounding it from above bounds the running time of `RWalkSAT` . Our main result (Theorem 4.1) is that for clause density ≤ 1.63, a random 3-CNF has *linear* termination weight (hence `RWalkSAT` succeeds in linear time). This matches the behavior depicted in Figure 1 up to a multiplicative constant. We also present a determinisitic version of `RWalkSAT` and show it finds a satisfying assignment in linear time for the same clause density (section 3.1).

Our result relies on previous analysis done for bounding a different SAT heuristic, called the *pure literal heuristic* [10] (see also [31] for a different and shorter analysis). This heuristic is known to succeed up to a clause density threshold of 1.63 and fails above this density. We conjecture terminators should exist even beyond the pure literal threshold, as (unreported) experimental data seems to indicate. However, at clause density ≥ 2 only a negligible fraction of random CNFs has terminators (see section 5), meaning we need to develop new techniques for explaining the observed linear running time at (say) density 2.5 depicted in (the upper part of) Figure 1.

A terminator is a solution to a linear system of inequalities, and thus linear programming can be used to find it. Thus, the existence of a terminator for random $\mathcal{C}$ can be decided efficiently, and an upper bound on $\mathrm{Term}(\mathcal{C})$ can be computed efficiently. (However, obtaining the exact value of $\mathrm{Term}(\mathcal{C})$ is not known to be efficiently computable.) This may allow us to gain a better empirical understanding of the behavior of `RWalkSAT` and its connection to the termination weight parameter.

The success of the pure literal heuristic does not necessarily imply polynomial running time for `RWalkSAT`. Indeed, in section 6 we provide a counterexample that requires exponential time from `RWalkSAT`, although a solution can be found using the pure literal heuristic in linear time. Furthermore, for a random planted SAT instance with large enough clause density, `RWalkSAT` takes exponential time (section 7). This is in contrast to the efficient performance of spectral algorithms for planted SAT presented by Flaxman [18].

1.3. History and related results.

Local improvement algorithms. `RWalkSAT` was introduced by Papadimitriou, who showed it has quadratic running time on satisfiable 2-CNFs [35]. An elegant upper bound was given by Schoning, who showed that the expected running time of `RWalkSAT` on any k-CNF is at most $(1+1/k)^n$ (compared with the exhaustive search upper bound of 2^n) [38]. The (worst case) upper bound of [38] was improved in a sequence of results [15, 21, 8, 22, 37], and the best upper bound for 3-SAT is $(1.324)^n$, given by the recent paper [22].

`RWalkSAT` is one of a broad family of *local improvement* algorithms, (re)introduced in the 1990s with the work of [41]. Algorithms in this family start with an assignment to the input formula, and gradually change it one bit at a time, by trying to locally optimize a certain function. These algorithms (the most famous of which is WalkSAT) are close relatives of the simulated annealing method and were found to compete with DLL-type algorithms (also known as Davis–Putnam algorithms). Empirical

results on random 3CNFs with up to $100,000$ variables seem to indicate that `RWalkSAT` terminates successfully in linear time up to clause density ≤ 2.6 [36, 40]. More advanced algorithms such as WalkSAT (a Metropolis algorithm that is related to `RWalkSAT`) appear empirically to solve random 3CNF instances with clause density ≤ 4 in quadratic time, and there is data indicating polynomial running time up to density ≤ 4.2 (the empirical SAT threshold is ≈ 4.26) [39].

Random 3*-CNFs.* Random CNFs have received much interest in recent years, being a natural distribution on NP-complete instances that seems (empirically as well as theoretically) computationally hard for a wide range of parameters. This distribution is investigated in such diverse fields as physics [30, 32], combinatorics [24], proof complexity [13], algorithm analysis [3], and hardness of approximation [17], to mention just a few. One of the basic properties of random 3-CNFs is that for small density ($\Delta < 3.52\ldots$ (see [20, 29])) almost all formulas are satisfiable, whereas for large density ($\Delta > 4.506\ldots$ (see [16])) they are almost all unsatisfiable. Another interesting property is that the threshold between satisfiability and unsatisfiability is sharp [24]. It is conjectured that a *threshold constant* exists, and empirical experiments estimate it to be ≈ 4.26 [14]. The analysis of SAT solving algorithms on random CNFs has been extensively researched empirically, and random CNFs are commonly used as test cases for analysis and comparison of SAT solvers. From a theoretical point of view, several upper bounds were given on the running time of DPLL-type algorithms of increasing sophistication [1, 2, 3, 10, 31, 11, 12, 19, 20, 29]. The best rigorous upper bound for random 3-CNFs is given by the recent papers [20, 29]. An exponential lower bound on a wide class of DPLL algorithms for density ≈ 3.8 and above was given by [3]. Recently, Mézard et al. presented the survey propagation algorithm and showed that nonrigorous arguments based on replica symmetry and experimental results indicate it efficiently solves large random 3CNF instances very close to the empirical satisfiability [32, 33].

Upper bounds for algorithms imply lower bounds on the satisfiability threshold, and in fact, all lower bounds on the threshold (for $k = 3$) so far have come from analyzing specific SAT solving algorithms. Most of the algorithms for which average case analysis has been applied so far are DPLL algorithms (and typically, with the exception of the recent papers [20, 29], when proving upper bounds on these algorithms, myopic[2] versions are considered). Much less is known about non-DPLL algorithms, in particular local improvement ones. Our result is (to the best of our knowledge) the first rigorous theoretical analysis of a non-DPLL algorithm on random CNFs.

Paper outline. After giving the necessary formal definition in section 2, we discuss terminators in section 3. Using terminators we prove our upper bound in section 4. In section 5 we give some theoretical upper bounds on the terminator threshold. We then discuss the tightness of the terminator method (section 6). We conclude with exponential lower bounds on the running time of `RWalkSAT` on random CNFs from the "planted-SAT" distribution (section 7).

2. Preliminaries.

Random 3*-CNFs.* For x_i a Boolean variable, a *literal* ℓ_i over x_i is either x_i or $\bar{x_i}$ (the negation of x_i), where x_i is called a *positive literal* and $\bar{x_i}$ is a *negative* one. A *clause* is a disjunction of literals, and a CNF formula is a set of clauses. Throughout this paper we reserve calligraphic notation for CNF formulas. For $\mathcal{C}$ a CNF, let $Vars(\mathcal{C})$ denote the set of variable appearing in $\mathcal{C}$ (we will always assume $Vars(\mathcal{C}) =$

[2] See [3] for the definition and tightest analysis of myopic algorithms.

$\{x_1, \ldots, x_n\}$ for some n). An *assignment* to $\mathcal{C}$ is some Boolean vector $\alpha \in \{0,1\}^n$. A literal ℓ_i is satisfied by α iff $\ell_i(\alpha_i) = 1$. We study the following distribution.

DEFINITION 2.1. *Let $\mathbb{F}^n_\Delta$ be the probability distribution obtained by selecting Δn clauses uniformly at random from the set of all $8 \cdot \binom{n}{3}$ clauses of size 3 over n variables. $\mathcal{C} \sim \mathbb{F}^n_\Delta$ means that $\mathcal{C}$ is selected at random from this distribution. We call such a $\mathcal{C}$ a* random 3-CNF

The algorithm. `RWalkSAT` is described by the following pseudocode. $\mathcal{C}$ is the input CNF and T is the time bound; i.e., if no satisfying assignment is found in T steps, we give up. We use the notation $UNSAT(\mathcal{C}, \alpha)$ for the set of clauses of $\mathcal{C}$ that are unsatisfied by α.

```
RWalkSAT(C, T)
  Select α ∈ {0,1}^n (uniformly) at random
  Initialize t = 0
  While t < T  {
    If C(α) = 1 Return ("INPUT SATISFIED BY" α)
    Else {
      Select C ∈ UNSAT(C, α) at random
      Select literal ℓ ∈ C at random
      Flip assignment of α at ℓ
      t++ }
    }
  Return "FAILED TO FIND SATISFYING ASSIGNMENT IN T STEPS"
```

Martingales and Azuma's inequality. Below we state Azuma's inequality for martingales. We refer the reader to [34] for the definition of conditional expectation and for more information about martingales.

A *martingale* is a sequence $X_0, X_1, X_2, \ldots, X_m$ of random variables such that for $0 \leq i < m$ holds

$$\mathbf{E}[X_{i+1} | X_i] = X_i.$$

The following version of Azuma's inequality [7, 27] may be found in [6].

THEOREM 2.2 (Azuma's inequality). *Let $0 = X_0, \ldots, X_m$ be a martingale with $|X_{i+1} - X_i| \leq 1$ for all $0 \leq i < m$. Let $\lambda > 0$ be arbitrary. Then*

$$\Pr[X_m > \lambda\sqrt{m}] < e^{-\lambda^2/2}.$$

3. Terminators. In this section we develop the tools needed to bound the running time of `RWalkSAT` on various interesting instances.

Intuition. Suppose a k-CNF $\mathcal{C}$ over n variables has a satisfying assignment α such that each clause of $\mathcal{C}$ is satisfied by at least $k/2$ literals under α. In this case `RWalkSAT` will terminate in quadratic time (with high probability). The reason is that if a clause C is unsatisfied at time t by α^t, then α^t must disagree with α on at least half of the literals in C. So with probability $\geq 1/2$ we decrease the Hamming distance between our current assignment and α. If we let sim^t be the similarity of α^t and α, i.e., the number of bits that are identical in both assignments (notice $0 \leq \mathrm{sim}^t \leq n$), then sim^t is a submartingale, i.e., $E(\mathrm{sim}^t | \mathrm{sim}^1, \ldots, \mathrm{sim}^{t-1}) \geq \mathrm{sim}^{t-1}$. Standard techniques from the theory of martingales show that sim reaches n (so α^t reaches α) within $O(n^2)$ steps. One elegant example of this situation is when $\mathcal{C}$ is a satisfiable 2-CNF. Papadimitriou [35] proved quadratic upper bounds on the running time of `RWalkSAT` in this case, using the proof method outlined above.

For a general 3-CNF we do not expect a satisfying assignment to have two satisfying literals per clause. Yet all we need in order to prove good running time is to set up a measure of similarity between α^t and some fixed satisfying assignment α such that (i) if sim^t reaches its maximal possible value, then $\alpha^t = \alpha$; and (ii) the random variables $\mathrm{sim}^1, \mathrm{sim}^2, \ldots$ are a submartingale. We achieve both these properties by giving *nonnegative weights* $w_1, \ldots, w_n$ to the variables $x_1, \ldots, x_n$. Instead of similarity, we measure the *weighted similarity* between α and α^t, defined by $\mathrm{sim}_w(\alpha, \alpha^t) \stackrel{\mathrm{def}}{=} \sum_{\alpha_i^t = \alpha_i} w_i$. Now suppose there exists a satisfying assignment α such that for any clause C, the expected change in sim_w, conditional on C being unsatisfied, is nonnegative. Suppose, furthermore, that all w_i are bounded by a constant and every clause has a variable with nonzero weight bounded below by another constant. Then we may conclude as above that α^t will reach its maximal value $W = \sum_i w_i$ in time $O(W^2)$.

In some cases we can do even better. We set up a system of weights such that (for any clause C) the expected change in sim_w (conditional on C being unsatisfied) is *strictly positive*. In this case the running time is *linear* in $W = \sum w_i$ (instead of quadratic). As we shall later see, such a setting of weights is possible (with high probability) for random 3-CNFs. But first we formalize our intuition.

Notation. In what follows Boolean variables range over $\{-1, 1\}$. A CNF $\mathcal{C}$ with n variables and m clauses is represented by an $m \times n$ matrix $A^{\mathcal{C}}$ with $\{-1, 0, 1\}$-entries. The ith clause is represented by $A_i^{\mathcal{C}}$ (the ith row of $A^{\mathcal{C}}$) and has a -1-entry in the jth position if $\bar{x_j}$ is a literal of the ith clause of $\mathcal{C}$, a 1-entry if x_j is a literal of C_i, and is zero otherwise. Thus, if $\mathcal{C}$ is a k-CNF, then the support size of each row $A_i^{\mathcal{C}}$ is at most k. A Boolean assignment is $\alpha \in \{-1, 1\}^n$, and we say α satisfies $\mathcal{C}$ iff for all $i \in [m]$

$$\langle A_i^{\mathcal{C}}, \alpha \rangle > -\left\| A_i^{\mathcal{C}} \right\|_1, \tag{1}$$

where $\langle \alpha, \beta \rangle$ is the standard inner product over $\mathbb{R}^n$ (defined by $\sum_{i=1}^n \alpha_i \cdot \beta_i$) and $\|\cdot\|_1$ is the ℓ_1 norm (defined by $\|\beta\|_1 = \sum_{i=1}^n |\beta_i|$). It is easy to see that this definition of satisfiability coincides with the standard one.

Terminator: Definition. A terminator is a generalization of a satisfying assignment. On the one hand, we allow α to be any vector in $\mathbb{R}^n$, but we require a stronger satisfying condition than (1).

DEFINITION 3.1 (terminators). *Let $\mathcal{C}$ be a k-CNF with n variables and m clauses represented by the matrix $A^{\mathcal{C}}$. $\alpha \in \mathbb{R}^n$ is a* terminating *satisfying assignment* (*or* terminator) *if for all $i \in [m]$*

$$\langle A_i^{\mathcal{C}}, \alpha \rangle \geq 1. \tag{2}$$

The termination weight of $\mathcal{C}$ is

$$\mathrm{Term}(\mathcal{C}) \stackrel{\mathrm{def}}{=} \min\{\|\alpha\|_1 \cdot \|\alpha\|_\infty : \alpha \text{ terminator for } \mathcal{C}\}.$$

In case $\mathcal{C}$ has no terminator, we define $\mathrm{Term}(\mathcal{C})$ *to be ∞.*

One may think of $\mathrm{sign}(\alpha_i)$ as the Boolean assignment to variable x_i (where $\mathrm{sign}(\alpha_i)$ is 1 if $\alpha_i \geq 0$ and is -1 otherwise) and $|\alpha_i|$ as the weight given to x_i. Notice that if α is a terminator, then the $\{-1, 1\}$-vector $\mathrm{sign}(\alpha)$ satisfies $\mathcal{C}$. This is because by property (2) in each clause there is at least one literal that agrees in sign with α.

The decisive name given in the previous definition is justified by the following claim, which is the main theorem of this section.

THEOREM 3.2 (terminator theorem). *If a k-CNF $\mathcal{C}$ has a terminator α, then* `RWalkSAT` *succeeds on $\mathcal{C}$ in time $O(\|\alpha\|_1 \cdot \|\alpha\|_\infty)$ with probability $\geq 1 - \exp(-\Omega(\|\alpha\|_1 / \|\alpha\|_\infty))$.*

Notice that we do not claim that when `RWalkSAT` terminates, it finds the assignment $\text{sign}(\alpha)$, but rather the existence of any terminator of small weight implies short running time. We can say that `RWalkSAT` is "drawn to" α but only when using the weighted distance measure given by $|\alpha|$. If $|\alpha_i| = 1$, this means `RWalkSAT` indeed approaches α (as is the case when each clause is satisfied by two literals). But in general, being "close" according to the weighted measure $|\alpha|$ does not imply small Hamming distance.

Proof of Theorem 3.2. Let $\mathcal{C}$ be a k-CNF and α be a terminator of minimal weight for $\mathcal{C}$, i.e., $\text{Term}(\mathcal{C}) = \|\alpha\|_1 \cdot \|\alpha\|_\infty < \infty$. Let $\beta^t \in \{-1, 1\}^n$ be the sequence of assignments traversed by `RWalkSAT`$(\mathcal{C})$ starting from the random assignment β^1, where $t \leq T = c \cdot k \cdot \|\alpha\|_1 \cdot \|\alpha\|_\infty$ (c will be fixed later). For $t \geq 1$ let Y^t be the random variable $\langle \beta^t, \alpha \rangle$. If `RWalkSAT` fails to find a satisfying assignment in T steps, then the following event occurs:

$$Y^t < \|\alpha\|_1 \quad \text{for all } t < T. \tag{3}$$

This is because $\langle \beta^t, \alpha \rangle = \|\alpha\|_1$ implies $\beta^t = \text{sign}(\alpha)$ and $\text{sign}(\alpha)$ satisfies $\mathcal{C}$. Thus we need only to bound the probability of event (3). Suppose clause C_i is picked at time t (i.e., C_i is unsatisfied by β^{t-1}). We claim the expected change in Y^t (with respect to Y^{t-1}) is precisely

$$\frac{2}{k} \cdot \langle A_i^{\mathcal{C}}, \alpha \rangle. \tag{4}$$

With probability $1/k$ we flip the assignment to each literal x_j of C_i, which amounts to multiplying β_j^{t-1} by -1. Thus the expected change in Y^t is $\frac{-2}{k} \cdot \langle \beta^{t-1}|_i, \alpha \rangle$, where $\beta^{t-1}|_i$ is the restriction of β^{t-1} to support of $A_i^{\mathcal{C}}$. But C_i being unsatisfied by β^{t-1} implies $\beta^{t-1}|_i = -A_i^{\mathcal{C}}$, so (4) is proved. Thus by property (2) in Definition 3.1

$$E[Y^t | Y^1, \ldots, Y^{t-1}] = Y^{t-1} + \frac{2}{k} \langle A_i^{\mathcal{C}}, \alpha \rangle \geq Y^{t-1} + \frac{1}{k}.$$

We claim that the sequence of random variables

$$X_t \stackrel{\text{def}}{=} \sum_{\ell=1}^{t} \left(Y^\ell - \mathbf{E}[Y^\ell | Y^1, \ldots, Y^{\ell-1}] \right)$$

is a martingale satisfying $\mathbf{E}X_1 = 0$. Indeed,

$$\begin{aligned}
\mathbf{E}[X_t | X_1, \ldots, X_{t-1}] &= \mathbf{E}[X_t | Y^1, \ldots, Y^{t-1}] \\
&= \mathbf{E}\left[\sum_{\ell=1}^{t} \left(Y^\ell - \mathbf{E}[Y^\ell | Y^1, \ldots, Y^{\ell-1}] \right) | Y^1, \ldots, Y^{t-1} \right] \\
&= \mathbf{E}\left[Y^t | Y^1, \ldots, Y^{t-1} \right] - \mathbf{E}\left[\mathbf{E}[Y^t | Y^1, \ldots, Y^{t-1}] | Y^1, \ldots, Y^{t-1} \right]
\end{aligned}$$

$$+\mathbf{E}\left[\sum_{\ell=1}^{t-1}\left(Y^{\ell}-\mathbf{E}[Y^{\ell}|Y^{1},\ldots,Y^{\ell-1}]\right)|Y^{1},\ldots,Y^{t-1}\right]$$

$$=0+\mathbf{E}\left[\sum_{\ell=1}^{t-1}\left(Y^{\ell}-\mathbf{E}[Y^{\ell}|Y^{1},\ldots,Y^{\ell-1}]\right)|Y^{1},\ldots,Y^{t-1}\right]$$

$$=\sum_{\ell=1}^{t-1}\left(Y^{\ell}-\mathbf{E}[Y^{\ell}|Y^{1},\ldots,Y^{\ell-1}]\right)=X_{t-1}.$$

Also $E[X_1]=E[Y^1-E[Y^1]]=0$. For all t, $|X_{t+1}-X_t|=Y^{t+1}-\mathbf{E}[Y^{t+1}|Y^1,\ldots,Y^t]\le \|\alpha\|_\infty$. Note that

$$X_t=Y^t-\sum_{\ell=1}^{t}(\mathbf{E}[Y^{\ell}|Y^{1},\ldots,Y^{\ell-1}]-Y^{\ell})-\mathbf{E}Y^1\le Y^t-t/k+\|\alpha\|_1.$$

In order to bound the probability of event (3), it suffices to bound the probability of the event "$X_T<2\|\alpha\|_1-T/k$" (if this event does not occur, then $Y^T\ge -\|\alpha\|_1+X_T\ge\|\alpha\|_1$). Recalling $T=c\cdot k\cdot\|\alpha\|_1\cdot\|\alpha\|_\infty$ we will pick $c>\frac{4}{k}$ so that

$$2\|\alpha\|_1-\frac{T}{k}=2\|\alpha\|_1-c\cdot\|\alpha\|_1\cdot\|\alpha\|_\infty<-\frac{ck}{2}\|\alpha\|_1\cdot\|\alpha\|_\infty.$$

We now apply Azuma's inequality and get

$$\begin{aligned}(3)&\le\Pr\left[X_T<-\frac{ck}{2}\|\alpha\|_1\|\alpha\|_\infty\right]\\&=\Pr\left[\frac{X_T}{\|\alpha\|_\infty}<-\frac{ck}{2}\|\alpha\|_1\right]\\&\le\exp\left(-\frac{(\frac{ck}{2}\|\alpha\|_1)^2}{2T}\right)\\&\le\exp\left(-\frac{c^2k^2(\|\alpha\|_1)^2}{8ck\cdot\|\alpha\|_1\|\alpha\|_\infty}\right)\\&\le\exp\left(-\frac{ck\|\alpha\|_1}{8\|\alpha\|_\infty}\right)=\exp\left(-\Omega\left(\frac{\|\alpha\|_1}{\|\alpha\|_\infty}\right)\right).\end{aligned}$$

The theorem is proved. □

3.1. A deterministic variant of `RWalkSAT`. Consider the following deterministic variant of `RWalkSAT`, which we will call `DWalkSAT`. Fix an ordering on clauses in $\mathcal{C}$. Initialize α_0 to be (say) the all zero assignment. At each step t, select the smallest clause unsatisfied by α_t and flip the assignment to *all* literals in it. Repeat this process until all clauses are satisfied. Naturally, one can introduce a time bound T and declare failure if a satisfying assignment is not found within T steps. We immediately get the following result.

THEOREM 3.3. *If a CNF $\mathcal{C}$ has a terminator α, then* `DWalkSAT` *succeeds on $\mathcal{C}$ within $2\cdot\|\alpha\|_1$ steps.*

Proof. We closely follow the proof of the terminator theorem, Theorem 3.2. Let $\beta^1,\ldots$ be the (deterministic) sequence of assignments traversed by the algorithm.

Let $Y^t = \langle \beta^t, \alpha \rangle$ (noticing Y^t is no longer random). Clearly, $Y^1 \geq -\|\alpha\|_1$, and if $Y^t = \|\alpha\|_1$, then β^t (equals $\text{sign}(\alpha)$, hence) satisfies $\mathcal{C}$. So we have to only show for all t

$$Y^t \geq Y^{t-1} + 2. \tag{5}$$

This follows from the fact that the clause $\mathcal{C}_i$ flipped at time t was unsatisfied at time $t-1$. Flipping all variables in $\mathcal{C}_i$ amounts to adding to Y^{t-1} the amount $\langle A_i^{\mathcal{C}}, \alpha \rangle$, and this, by definition of terminator, is at least one. We have proved (5) and with it the theorem. □

4. Linear upper bounds on random CNFs. In this section we show that for clause densities for which the pure literal heuristic succeeds, there exist linear weight terminators. Our current analysis uses insights into the structure of such pure CNFs, but we see no reason to believe that the terminator threshold is linked to the pure literal threshold. The main theorem of this section is the following.

THEOREM 4.1. *For any $\Delta < 1.63$, there exists a constant c such that with high probability $\mathcal{C} \sim \mathbb{F}_\Delta^n$ has a terminator $\alpha \in \mathbb{R}^n$ with $\|\alpha\|_\infty \leq c$ and hence $\|\alpha\|_1 \leq c \cdot n$.*

COROLLARY 4.2. *For any $\Delta < 1.63, \epsilon > 0$, there exists a constant c such that with high probability for $\mathcal{C} \sim \mathbb{F}_\Delta^n$, `RWalkSAT` succeeds on $\mathcal{C}$ in time $c \cdot n$ with probability $\geq 1 - \epsilon$.*

COROLLARY 4.3. *For any $\Delta < 1.63, \epsilon > 0$, there exists a constant c such that with high probability for $\mathcal{C} \sim \mathbb{F}_\Delta^n$, `DWalkSAT` succeeds on $\mathcal{C}$ in time $c \cdot n$.*

To prove our main theorem, we construct small weight terminators for pure and expanding CNFs and then merge the two into one small weight terminator.

4.1. Terminators for pure CNFs. A literal ℓ in $\mathcal{C}$ is called *pure* if it appears only as a positive literal, or only as a negative literal, in $\mathcal{C}$. A clause in $\mathcal{C}$ is said to be *pure* if it contains a pure literal. When seeking a satisfying assignment, a natural strategy is to start by assigning all pure literals their satisfying assignment and thus remove all pure clauses. The removal of pure clauses may result in the emergence of new pure literals in the restricted CNF, and the process may be repeated. The *pure literal heuristic* is the heuristic that applies this removal process until no pure clauses remain. If the remaining CNF is empty, the pure literal heuristic has found a satisfying assignment, and otherwise it failed.

Let us introduce some notation. For $\mathcal{C}$ a CNF, define $\mathcal{C}_0 = \mathcal{C}$, L_0 to be the set of pure literals in $\mathcal{C}$, and P_0 to be the set of pure clauses in $\mathcal{C}$. Recursively define $\mathcal{C}_{i+1}$ to be $\mathcal{C}_i \setminus P_i$, and let L_{i+1}, P_{i+1} be, respectively, the set of pure literals and pure clauses in $\mathcal{C}_{i+1}$. Finally, let r be the minimal i such that $L_i = \emptyset$. Notice that the pure literal succeeds on $\mathcal{C}$ iff $\mathcal{C}_r = \emptyset$. If $\mathcal{C}_r = \emptyset$, we say $\mathcal{C}$ is *r-pure*.

THEOREM 4.4. *Every r-pure k-CNF over n variables has a terminator $\alpha \in \mathbb{R}^n$ with $\|\alpha\|_\infty \leq k^r$ and $\|\alpha\|_1 \leq n \cdot k^r$, so $\text{Term}(\mathcal{C}) \leq n \cdot k^{2r}$. Moreover, α is supported only on $\cup_{i=0}^{r-1} L_i$.*

Notice that invoking Theorem 3.2 we bound the running time of `RWalkSAT` on an r-pure k-CNF by $n \cdot k^{2r}$ (with high probability).

Proof. Let $L_0, \ldots, L_{r-1}$ be the pure literals in $\mathcal{C}_0, \ldots, \mathcal{C}_{r-1}$. Notice that $\cup_{j=0}^{r-1} L_j$ does not necessarily cover all variables in $\mathcal{C}$, but assigning each pure literal to 1 (i.e., if ℓ_i is pure, then set $\text{sign}(\alpha_i) = \text{sign}(\ell_i)$) and assigning the other variables arbitrarily gives a satisfying assignment α. We now deal with the weights (absolute values) of α. Fix the weight of each variable in L_j to k^{r-j}. For any variable $x_i \notin \cup_{j=0}^{r-1} L_j$ fix its weight to 0.

To see that α is a terminator (of weight nk^r), consider any clause $C_i \in P_j$. By definition of P_j there are no literals from $L_0, \ldots, L_{j-1}$ appearing in C. Thus all literals appearing in C have weight $\leq (k)^{r-j}$. There is at least one literal $\ell_s \in C$ that has weight k^{r-j} and agrees with α_s in sign, and any literal disagreeing with α must have weight $\leq (k)^{r-j-1}$. Hence

$$\langle A_i^{\mathcal{C}}, \alpha \rangle \geq k^{r-j} - (k-1) \cdot k^{r-j-1} \geq 1. \qquad \square$$

Broder, Frieze, and Upfal showed that with high probability the pure literal heuristic finds a satisfying assignment for a random 3-CNF with clause density < 1.63 [10] (for a simpler analysis of the same heuristic see [31]). In particular, the following theorem follows from the work of [10]. A proof of this theorem can be found in Appendix A.

THEOREM 4.5 (see [10]). *For every $\Delta < 1.63$, there exists a constant c such that with high probability $\mathcal{C} \sim \mathbb{F}_\Delta^n$ is $c \log n$-pure.*

By applying Theorems 3.2 and 4.4 to Theorem 4.5 we conclude that the running time of `RWalkSAT` on a random instance (with small enough clause density) is at most polynomial.

4.2. Terminators for expanding CNFs. Our next step in proving Theorem 4.1 starts with the following theorem, which is a combination of a result of Broder, Frieze, and Upfal [10] and (the now) standard analysis of random CNFs, originating in the work of Chvátal and Szemerédi [13]. Being standard and somewhat technical, we defer its proof to Appendix A.

DEFINITION 4.6. *For $\mathcal{C}$ a CNF, we say $\mathcal{C}$ is an* (r, c)-expander *if for all $\mathcal{C}' \subseteq \mathcal{C}$ $|\mathcal{C}'| \leq r$, $|Vars(\mathcal{C}')| \geq c \cdot |\mathcal{C}'|$.*

THEOREM 4.7. *For every $\Delta < 1.63$, there exists an integer d such that for $\mathcal{C} \sim \mathbb{F}_\Delta^n$, with high probability $\mathcal{C}_d$ is a $(|\mathcal{C}_d|, 7/4)$-expander, where $\mathcal{C}_d$ is the CNF remaining of $\mathcal{C}$ after removing the d outermost pure layers.*

This theorem assures us that after removing a *constant* number of the layers from a random $\mathcal{C}$ (with small clause density), we have in hand a residual CNF $\mathcal{C}_d$, such that *any* subset of it, including all of $\mathcal{C}_d$, has a very large set of neighbors. This in turn implies the existence of small weight terminators for $\mathcal{C}_d$.

THEOREM 4.8. *If $\mathcal{C}$ is an $(|\mathcal{C}|, 7/4)$-expanding 3-CNF over n variables, then $\mathcal{C}$ has a terminator $\alpha \in \mathbb{R}^n$ with $\|\alpha\|_\infty \leq 4$ (hence $\|\alpha\|_1 \leq 4n$).*

Proof. Form the following bipartite graph G. On the left-hand side, put one vertex for each clause in $\mathcal{C}$. On the right-hand side, put 4 distinct vertices for each variable appearing in $\mathcal{C}$. Connect the vertex labeled by the clause C to all 12 vertices labeled by variables appearing in C. We do not care if the appearance is as positive or negative literals.

Since $\mathcal{C}$ is an $(|\mathcal{C}|, \frac{7}{4})$-expander, G has expansion factor 7; i.e., for all subsets S on the left-hand side, $|N(S)| \geq 7 \cdot |S|$, where $N(S)$ is the set of neighbors of S. By Hall's matching theorem [26] we conclude that there is a 7-matching from the left-hand side to the right; i.e., each node C on the left-hand side can be associated with a set of seven of its neighbors on the right-hand side (denoted $N'(C)$), such that for all clauses $C \neq D$, $N'(C) \cap N'(D) = \emptyset$. We now use N' to define our terminator α. For any variable x, if there exists a clause C such that $N'(C)$ has at least three members labeled by x, then we say x is *associated* with C, and the weight of x is the number of copies of x in $N'(C)$ (notice this weight is either 3 or 4). For any variable x_i associated with a clause C, set $\text{sign}(\alpha_i)$ to the value that satisfies C and set $|\alpha_i|$ to the weight of x_i. Set all other variables to zero. α is well defined because a

variable can be associated with at most one clause. We are left with verifying that it is a terminator. This follows by a case analysis, using the fact that each clause has a dozen neighbors, and seven of them are in $N'(C_i)$. There are three cases to consider.

C_i has at least two associated variables: In this case, $\text{sign}(\alpha)$ agrees with C on at least two variables, and each variable has weight at least 3. The remaining variable has weight at most 4, so $\langle A_i^{\mathcal{C}}, \alpha \rangle \geq 6 - 4 \geq 2$.

C_i has one associated variable of weight three: The remaining four neighbors of $N'(C_i)$ must be evenly split between the two remaining variables of C (otherwise C_i would have two associated variables). So the remaining pair of variables of C_i have weight zero. Hence $\langle A_i^{\mathcal{C}}, \alpha \rangle = 3$.

C_i has one associated variable of weight four: The remaining three neighbors of $N'(C_i)$ are split between the remaining two variables. One variable has two such neighbors (and hence zero weight) and the other has one neighbor, so the weight of this literal is at most 3. Thus, $\langle A_i^{\mathcal{C}}, \alpha \rangle \geq 4 - 3 = 1$.

Theorem 4.8 follows. □

4.3. Small weight terminators for random CNFs.

Proof of Theorem 4.1. By Theorem 4.7, (with high probability) $\mathcal{C}$ can be partitioned into the d outermost pure layers $\mathcal{C}' \stackrel{\text{def}}{=} \cup_{i=0}^{d-1} P_i$ and the remaining residual inner core $\mathcal{C}'' = \mathcal{C}_d$. This inner core is a $(|\mathcal{C}''|, 7/4)$-expander. We know (by Theorems 4.4 and 4.8, respectively) how to construct terminators for each of these formulas, so all we need to do is merge them into a single terminator for $\mathcal{C}$.

Let α', α'' be the respective terminators of $\mathcal{C}', \mathcal{C}''$. By Theorem 4.4 α' has all its support on pure literals, which do not appear in $\mathcal{C}''$. Thus the supports of α' and α'' are disjoint. We merge the two assignments by defining α as the assignment that agrees with $9 \cdot \alpha'$ on the support of α' and agrees with α'' otherwise (the reason for multiplying α' by the scalar 9 will soon become clear). By our previous remark (that α' and α'' have disjoint supports) α is well defined, and we now prove it is a terminator.

Consider a clause $C_i \in \mathcal{C}$. If $C_i \in \mathcal{C}''$, then $\langle A_i^{\mathcal{C}}, \alpha \rangle = \langle A_i^{\mathcal{C}}, \alpha'' \rangle \geq 1$, because all literals appearing in $\mathcal{C}''$ are given zero weight by α'. Otherwise, $C_i \in \mathcal{C}'$ might have some of its (nonpure) literals in $Vars(\mathcal{C}'')$, but recall that the maximal weight of α'' is 4, so in the worst case C_i has two literals with weight 4 coming from α''. Thus $\langle A_i^{\mathcal{C}}, \alpha \rangle \geq 9 - 2 \cdot 4 = 1$. We have shown the existence of a terminator of linear total weight, and the proof of Theorem 4.1 is complete. □

5. Investigating the terminator threshold. When $\mathcal{C}$ is a random CNF, $\text{Term}(\mathcal{C})$ is a random variable. Since $\text{Term}(\mathcal{C})$ bounds the running time of `RWalkSAT`, investigating this random variable is an interesting question. The property of having a terminator α with $\|\alpha\|_\infty \leq w$ is monotone with respect to addition of new clauses. Thus one can define the *terminator threshold* θ_n^w as the density for which a terminator α, $\|\alpha\|_\infty \leq w$ exists with probability 1/2.

Claim 5.1. *A CNF $\mathcal{C}$ with m clauses and n variables has some terminator iff $0 \notin$ convex hull$(\{A_i^{\mathcal{C}} : i = 1, \ldots, m\})$.*

Proof. Think of a terminator α as the normal of a hyperplane in $\mathbb{R}^n$ passing through zero. This hyperplane partitions $\mathbb{R}^n$ into two parts. $\langle A_i^{\mathcal{C}}, \alpha \rangle > 0$ iff the point $A_i^{\mathcal{C}}$ lies in the positive half of $\mathbb{R}^n$. Thus $\langle A_i^{\mathcal{C}}, \alpha \rangle > 0, i = 1, \ldots, m$, iff zero is not in the convex hull of the points. □

Füredi proved the following general theorem (he gave a tighter bound than presented here, but the form we quote is sufficient for our purposes). A set of points

$P \subset \mathbb{R}^n$ is *symmetric* if $p \in P \Rightarrow (-p) \in P$.

THEOREM 5.2 (see [25]). *Let $\{P_n \subset \mathbb{R}^n\}_{n\in\mathbb{N}}$ be an infinite family of finite symmetric sets of points. Suppose $(2+\epsilon)n$ points are selected uniformly at random from P_n. Then*

$$\lim_{n\to\infty} \Pr[0 \notin \textit{ convex hull of points}] = 0.$$

In our case P_n is the symmetric set of $\{-1, 0, 1\}$-valued points with support size 3. Thus, by Füredi's theorem when the clause density is greater than 2, with high probability there is no terminator. Notice this upper bound on the terminator threshold holds for any k-CNF, even for nonconstant k (e.g., $k = n$). Combining Theorem 4.1 with Füredi's theorem gives for $k = 3$ the following bounds:

$$1.63 \le \theta_n^\infty \le 2.$$

We leave the resolution of the terminator threshold for $k = 3$ as an interesting open problem.

For the case of 2-CNFs we can bound the terminator threshold from above by 1, because this is the satisfiability threshold for random 2-CNFs (and a terminator implies satisfiability). It seems reasonable to conjecture that for $k = 2$ the satisfiability and terminator threshold coincide. This could be used to prove that for random 2-CNFs below the satisfiability threshold, `RWalkSAT` terminates in linear time (as opposed to the quadratic upper bound guaranteed for any satisfiable 2-CNF by [35]).

6. Tightness of terminator based bounds. In this section we show that the upper bound derived by the terminator method is tight, even for pure CNFs. We present pure CNFs such that the running time of `RWalkSAT` on them is exponential in the number of variables and also lower bounded by the terminator weight.

THEOREM 6.1. *For arbitrarily large n, there exist pure 3-CNFs over n variables, with total terminator weight $\ge 2^{n/2}$, and the running time of* `RWalkSAT` *on them is $2^{\epsilon n}$ for some $\epsilon > 0$.*

Proof. Use the following formula, which is a slight variation of the X-DAG contradiction used in [9].

DEFINITION 6.2. *Let $\mathcal{G}_n$ be the following CNF over variables $x_1, \ldots, x_n, y_1, \ldots, y_n, z$:*

$$\{\bar{x}_1\} \wedge \{\bar{y}_1\} \wedge \bigwedge_{i=1}^{n-1} \{x_i \vee y_i \vee \bar{x}_{i+1}\} \wedge \bigwedge_{i=1}^{n-1} \{x_i \vee y_i \vee \bar{y}_{i+1}\} \wedge \{x_n \vee y_n \vee \bar{z}\}.$$

$\mathcal{G}_n$ has a unique satisfying assignment, $\vec{0}$. Moreover, $\mathcal{G}_n$ is n-pure, because $\bar{z}$ appears only in one clause, and once z is satisfied and removed, $\bar{y}_n, \bar{x}_n$ each appear in one clause in the remaining formula. Thus, one can repeatedly remove x_{i-1}, y_{i-1} until all the formula is satisfied. This implies the existence of a terminator of weight 3^n, and it is not hard to see that any terminator must have weight 2^n at least. We claim that `RWalkSAT` requires exponential time to succeed on $\mathcal{G}_n$.

Let X_t be the number of ones assigned by α_t to the variables $x_2, \ldots, x_n, y_2, \ldots, y_n$. With high probability $X_0 > (1-\epsilon)n$, and if `RWalkSAT`$(\mathcal{G}_n, T)$ succeeds, we know $X_T = 0$. But for every step t, the probability of X_t decreasing is at most $1/3$. The theorem follows. ∎

7. Lower bounds for large density planted SAT. In this section, we state (without proofs) that RWalkSAT is not a good algorithm for random CNFs with large clause density. By definition, RWalkSAT gives the correct answer on any unsatisfiable formula. For large enough clause density ($\Delta > 4.6$), almost all formulas in $\mathbb{F}^n_\Delta$ are unsatisfiable [16]. Thus, one may argue that RWalkSAT operates very well for these densities. On second thought, on this distribution, even the constant time algorithm that fails on every input, without reading it, operates well. Thus, it makes sense to discuss the performance of RWalkSAT only on the uniform distribution over *satisfiable* formulas with Δn clauses (denoted $\mathbf{SAT}^\Delta_n$). The problem is that for small densities, $\mathbf{SAT}^\Delta_n$ is not well characterized, we do not know how to analyze it. Thus, we propose looking at the following pair of *planted SAT* distributions over satisfiable 3-CNFs.

DEFINITION 7.1 (planted SAT). *Let $\mathbb{S}^n_\Delta$ be the distribution obtained by selecting at random $\beta \in \{0,1\}^n$ and selecting at random Δn clauses out of all clauses of size 3 that are satisfied by β. Denote a random formula from this distribution by $\mathcal{C} \sim \mathbb{S}^n_\Delta$.*

Let $\mathbb{P}^n_\Delta$ be the distribution obtained by selecting at random $\beta \in \{0,1\}^n$, and for each clause C satisfied by β, select C to be in $\mathcal{C}$ with independent probability $p^\Delta_n = \frac{6\Delta}{7(n-1)(n-2)}$. Denote a random formula from this distribution by $\mathcal{C} \sim \mathbb{P}^n_\Delta$.

This distribution is highly interesting in its own right. It is the analogue of the *planted clique* and *planted bisection* distributions, studied, e.g., in [5, 23, 28]. There are efficient spectral algorithms for finding the satisfying assignment for the planted SAT distribution [18], and in this section we argue that RWalkSAT performs poorly (takes exponential running time) on this distribution. The proofs of this result are fairly straightforward, so we omit them from the paper.

THEOREM 7.2 (main lower bound). *There exists a constant $\Delta_0 > 0$, such that for all $\Delta \geq \Delta_0$ (Δ may be a function of n), with high probability for $\mathcal{C} \sim \mathbb{P}^n_\Delta$, or $\mathcal{C} \sim \mathbb{S}^n_\Delta$*

$$\mathbf{P}[\texttt{RWalkSAT}(\mathcal{C}, 2^{\epsilon n}) \text{ succeeds}] \leq 2^{-\epsilon n},$$

where $\epsilon > 0$ is some a constant, depending on Δ.

The rest of this section is devoted to a sketch of the proof of Theorem 7.2. We warm up by discussing the case of $\mathcal{C}$ being the maximal size CNF satisfying β and then apply our insights to the case of a random CNF. For the rest of this section we assume without loss of generality that β, the random planted assignment, is the all zero vector, denoted $\vec{0}$.

The full CNF of size n, denoted $\mathcal{F}_n$, has all clauses of size exactly 3 (without repetition of literals) that are satisfied by $\vec{0}$. Our starting point is the following.

LEMMA 7.3. $\mathbf{P}[\texttt{RWalkSAT}(\mathcal{F}_n, 2^{n/100}) \text{ succeeds}] \leq 2^{-n/100}$.

Intuitively, the lemma holds because for an assignment that is very close to $\vec{0}$, the fraction of falsified clauses that have two (or more) positive literals is significantly larger than the fraction of falsified clauses with only one positive literal. Thus, a random falsified clause is more likely to lead us away from $\vec{0}$ and hence the exponential running time.

To complete the proof of Theorem 7.2, notice $\mathcal{C} \sim \mathbb{P}^n_\Delta$ is a "random fraction" of $\mathcal{F}_n$. Additionally, for large Δ all satisfying assignments are close to $\vec{0}$. Thus, when the random walk algorithm reaches an assignment that is close to $\vec{0}$, the fraction of clauses with two or more positive literals is significantly larger than the fraction of falsified clauses with one positive literal. Thus, as in the case of $\mathcal{F}_n$, RWalkSAT is more likely to move away from $\vec{0}$ than to approach it, resulting in exponential running time. This completes the sketch of the proof of Theorem 7.2.

8. Open problems.

1. What is the largest Δ for which one can prove `RWalkSAT` to have polynomial running time on $\mathcal{C} \sim \mathbb{F}_{\Delta}^{n}$?
2. What are the statistics of the random variable $\mathrm{Term}(\mathcal{C})$ as a function of the clause density? Does $\mathrm{Term}(\mathcal{C}) < \infty$ have a sharp threshold? Is there a terminator threshold independent of n? How does $\mathrm{Term}(\mathcal{C})$ correspond to n (number of variables) above density 1.63 (below 1.63 it is linear)?

Appendix A. Proofs. In this section we prove Theorems 4.5 and 4.7. Our starting point is the following theorem and lemma proved implicitly in [10]. The lemma is a slight generalization of Lemma 4.4 in [10], so we provide its proof. (The original Lemma 4.4 of [10] needed only expansion factor of 3/2, whereas we need a constant fraction more than 3/2. The proof is essentially the same.)

THEOREM A.1 (see [10]). *For every $\Delta < 1.63$, there exists an integer d such that with high probability for $\mathcal{C} \sim \mathbb{F}_{\Delta}^{n}$, $|\mathcal{C}_d| \le \frac{n}{600\Delta^2}$.*

LEMMA A.2 (see [10]). *Let $\Delta_0 = 1.63$. For any constant $\Delta \le \Delta_0$ with high probability $\mathcal{C} \sim \mathbb{F}_{\Delta}^{n}$ is a $(\frac{n}{600\Delta_0^2}, 3/2 + 10^{-3})$-expander.*

Proof of Lemma A.2. Set $\epsilon = 10^{-3}$. Let A_k be the event that there exists a set of k clauses having less than $3/2 + \epsilon$ variables. Let us bound the probability of these bad events, using a union bound. Let $r = \frac{n}{600\Delta_0^2}$ and $c = 3/2 + \epsilon$. We make use of the following well-known inequality $\binom{n}{k} \le \left(\frac{en}{k}\right)^k$:

$$\begin{aligned}
\mathbf{P}[Bad] &\le \sum_{k=1}^{r} \mathbf{P}[A_k] \le \sum_{k=1}^{r} \binom{\Delta n}{k} \cdot \binom{n}{ck} \cdot \left(\frac{ck}{n}\right)^{3k} \\
&\le \sum_{k=1}^{r} \left(\frac{e\Delta_0 n}{k}\right)^{k} \cdot \left(\frac{en}{ck}\right)^{ck} \cdot \left(\frac{ck}{n}\right)^{3k} \\
&\le \sum_{k=1}^{r} \left[(e^{1+c} c^{3-c} \Delta_0) \cdot \left(\frac{k}{n}\right)^{2-c} \right]^{k} \\
&\le \sum_{k=1}^{r} \left[37 \cdot \left(\frac{k}{n}\right)^{\frac{1}{2}-\epsilon} \right]^{k} = o(1),
\end{aligned}$$

where the last inequality holds for $r \le \frac{n}{600\Delta_0^2}$. ∎

Notice that if $\mathcal{C}_d$ is a $(|\mathcal{C}_d|, \frac{3}{2} + \epsilon)$-expander, then every subset of $\mathcal{C}_d$ (including $\mathcal{C}_d$ itself) has at least ϵ *unique neighbors* (i.e., literals appearing in exactly one clause), and these unique neighbors are pure. Thus, $\mathcal{C}_d$ is $O(\log n)$-pure. Hence $\mathcal{C}$ is $O(\log n)$-pure (remember d is a constant), and this proves Theorem 4.5. In order to prove Theorem 4.7 we need the following lemma from [13].

LEMMA A.3 (see [13]). *For all constants $\Delta > 0, c < 2$, there exists some constant $\delta > 0$ such that with high probability $\mathcal{C} \sim \mathbb{F}_{\Delta}^{n}$ is a $(\delta\Delta n, c)$-expander.*

Let δ be the constant promised by Lemma A.3 for $\Delta = 1.63$ and $c = 7/4$. By Theorem 4.5, $|\mathcal{C}_d| \le n/(600\Delta_0^2)$ for some constant d. By Lemma A.2, $\mathcal{C}_d$ is a $(|\mathcal{C}_d|, \epsilon)$-boundary expander for some $\epsilon > 0$. Remove an additional d' layers from $\mathcal{C}$ (each containing at least an $\epsilon/3$ fraction of the remaining clauses) so that $|\mathcal{C}_{d+d'}| \le \delta n$, and by Lemma A.3 this remaining CNF is (with high probability) a $(|\mathcal{C}_{d+d'}|, 7/4)$-expander. This proves Theorem 4.7.

Acknowledgments. We thank Madhu Sudan for many useful discussions. We thank Bart Selman and Andrew Parkes for valuable information on the empirical results regarding `RWalkSAT` and Balint Virag for his help with the analysis of martingales. We thank Jon Feldman for providing code for running LP simulations for empirical investigation of the terminator threshold and Jeong Han Kim (via private communication) for allowing us to include the upper bound on the terminator threshold (section 5) in the paper. The second author thanks Rocco Servedio, Salil Vadhan, and Dimitris Achlioptas for helpful discussions. Finally, we thank the anonymous referees for helpful remarks.

THE COMPLEXITY OF COMPUTING THE SIZE OF AN INTERVAL*

LANE A. HEMASPAANDRA†, CHRISTOPHER M. HOMAN‡, SVEN KOSUB§, AND KLAUS W. WAGNER¶

Abstract. Given a p-order A over a universe of strings (i.e., a transitive, reflexive, antisymmetric relation such that if $(x, y) \in A$, then $|x|$ is polynomially bounded by $|y|$), an interval size function of A returns, for each string x in the universe, the number of strings in the interval between strings $b(x)$ and $t(x)$ (with respect to A), where $b(x)$ and $t(x)$ are functions that are polynomial-time computable in the length of x. By choosing sets of interval size functions based on feasibility requirements for their underlying p-orders, we obtain new characterizations of complexity classes. We prove that the set of all interval size functions whose underlying p-orders are polynomial-time decidable is exactly #P. We show that the interval size functions for orders with polynomial-time adjacency checks are closely related to the class FPSPACE(poly). Indeed, FPSPACE(poly) is exactly the class of all nonnegative functions that are an interval size function minus a polynomial-time computable function. We study two important functions in relation to interval size functions. The function #DIV maps each natural number n to the number of nontrivial divisors of n. We show that #DIV is an interval size function of a polynomial-time decidable partial p-order with polynomial-time adjacency checks. The function #MONSAT maps each monotone boolean formula F to the number of satisfying assignments of F. We show that #MONSAT is an interval size function of a polynomial-time decidable total p-order with polynomial-time adjacency checks. Finally, we explore the related notion of cluster computation.

Key words. computational complexity, interval size functions, cluster computing, counting functions

1. Introduction.

The class NP, which is widely believed to contain computationally intractable problems, captures the complexity of determining for a given problem instance whether at least one suitable affirmative solution exists within an exponentially large set of (polynomial-sized) potential solutions. It is certainly not simpler, and seemingly much harder, to count all affirmative solutions in such solution sets. The corresponding *counting functions* constitute Valiant's widely studied counting class #P [Val79]. In the theory of counting functions, which is devoted to the study of counting versions of decision problems, most classes considered try to capture the pure phenomenon of counting, and in doing so they obscure other factors, e.g., orders on solution sets.

Natural counting problems in #P, of course, sometimes exhibit strong relationships between solutions to the problems. As an example, consider the counting function #DIV, which counts for each natural number the number of its nontrivial divisors. Clearly, #DIV is in #P since division can be done in polynomial time. A suitable structure in the set of solutions is the partial order of divisibility, that is, the order defined by $n \leq_| m$ if and only if n divides m. Obviously, $\#\mathrm{DIV}(m) = \|\{k \mid 1 <_| k <_| m\}\|$, i.e., $\#\mathrm{DIV}(m)$ counts the number of elements in the open interval $(1, m)$ in the partial order "$\leq_|$" on natural numbers.

Is #DIV an exceptional case among #P functions in that it has such an interval size characterization? Interestingly, "no" is the answer. It turns out that a function f is in #P if and only if it is an interval size function of a P-decidable partial p-order. The latter means that there exist a *partial p-order* A (i.e., A is a partial order and in addition satisfies the requirement that for some polynomial p and all x and y, it holds that $x \leq_A y$ implies $|x| \leq p(|y|)$) that is P-*decidable* (i.e., $x \leq_A y$ is decidable in polynomial time) and polynomial-time computable functions b and t such that $f(x) = \|\{z \mid b(x) <_A z <_A t(x)\}\|$, where $a <_A b$ denotes $a \leq_A b \wedge a \neq b$.

However, knowing that a partial p-order is polynomial-time decidable does not give us as much information as sometimes is needed. For example, the polynomial-time decidability of a p-order seemingly does not ensure that it has *efficient adjacency checks*, i.e., that there is a polynomial-time algorithm checking whether two elements are adjacent in this partial p-order. Indeed, if every P-decidable partial p-order has efficient adjacency checks, then P = NP (and vice versa). Hence adding efficient adjacency checks to the properties listed above seems to be a restriction. Denote by $\mathrm{IF_p}$ the class of interval size functions of P-decidable partial p-orders with efficient adjacency checks. Denote by $\mathrm{IF_t}$ the class of interval size functions of P-decidable total p-orders with efficient adjacency checks. We have $\mathrm{IF_t} \subseteq \mathrm{IF_p} \subseteq \#\mathrm{P}$. Are these containments proper? On one hand, we prove that $\mathrm{IF_t} \text{ - } \mathrm{FP} = \mathrm{IF_p} \text{ - } \mathrm{FP} = \#\mathrm{P} \text{ - } \mathrm{FP}$, where $A \text{ - } B = \{a - b \mid a \in A \wedge b \in B\}$. Thus these three classes do not seem to be very different; indeed, they are identical given the smoothing power of subtracting polynomial-time computable adjustments. On the other hand, $\mathrm{IF_p} = \#\mathrm{P}$ is equivalent to P = NP, and $\mathrm{IF_t} = \mathrm{IF_p}$ only if UP = PH. Thus it is unlikely that any two of $\mathrm{IF_t}$, $\mathrm{IF_p}$, and #P coincide. Further, we study relationships between the classes $\mathrm{IF_t}$, FP, and UPSV_t.

We already mentioned that it is unlikely that every P-decidable partial p-order has efficient adjacency checks. What about the converse? This also is not likely; if every partial p-order with efficient adjacency checks is P-decidable, then P = PSPACE (and vice versa). Hence, in the presence of efficient adjacency checks, removing the P-decidability requirement seems to be a relaxation. Denote by $\mathrm{IF_p^*}$ the class of interval size functions of partial p-orders with efficient adjacency checks. Denote by $\mathrm{IF_t^*}$ the class of interval size functions of total p-orders with efficient adjacency checks. We have $\mathrm{IF_p} \subseteq \mathrm{IF_p^*}$ and $\mathrm{IF_t} \subseteq \mathrm{IF_t^*} \subseteq \mathrm{IF_p^*} \subseteq \mathrm{FPSPACE(poly)}$. We prove that $\mathrm{IF_t^*}$ (and $\mathrm{IF_p^*}$) are remarkably powerful: $\mathrm{IF_t^*} \text{ - } \mathrm{FP} = \mathrm{FPSPACE(poly)} \text{ - } \mathrm{FP}$. Thus $\mathrm{IF_t^*}$ (and $\mathrm{IF_p^*}$) are in a certain sense close to FPSPACE(poly), the class of polynomially length-bounded, polynomial-space computable functions. Nonetheless, we show that if these classes coincide, then UP = PSPACE. We clarify further relationships among such classes and also with respect to other function classes, in order to understand the power of interval computing.

We study two important natural functions in relation to interval size functions. We prove that the counting function #DIV is in $\mathrm{IF_p}$. Also, we show that the func-

tion #MONSAT, which counts for each monotone boolean formula the number of satisfying assignments that it has, belongs to IF_{t}.

Using order-theoretic notions to approach complexity issues has a rich tradition and appears in the literature in a variety of settings (e.g., [GHJY91, GS91, VW95, HVW96, Kos99]). The approaches in the examples just cited differ in intent from our approach in that they are based on a specific ordering, namely the lexicographical ordering. In contrast, for our purposes it is essential to consider more general feasible orderings (see [MP79, Ko83]).

Among earlier studies, perhaps the notion lying nearest to our approach is that of a cluster machine, which is a nondeterministic Turing machine that satisfies the promise that, on each input, all accepting computation paths are always neighbors with respect to the lexicographical ordering, i.e., the accepting paths must form a "cluster" [Kos99]. Based on this machine type, Kosub [Kos99] defined the counting class c#P (in a manner analogous to the way that #P is based on standard, nondeterministic polynomial-time Turing machines). Kosub obtained many interesting results about c#P, e.g., c#P seems to differ dramatically from #P in its closure properties (as regards, e.g., integer division, see [OH93, Kos99]), and he showed that c#P is closely related to a relatively simple unambiguous-nondeterminism-based function class, "$\mathrm{UPSV}_{\mathrm{t}}$."

Most of the known results about c#P are proven by techniques that are exceedingly dependent on the fact that c#P is defined using adjacency clusters *with respect to lexicographic order*. In particular, the fact that in lexicographic order the function $f(a,b) = \|\{c \mid a \leq_{\mathrm{lex}} c \leq_{\mathrm{lex}} b\}\|$ is easy to compute underpins the results.

In the present paper we define the class CL#P, which studies the complexity of cluster computing in a context of relatively general (though length-respecting and having efficient adjacency checks) orders, rather than merely in the extremely special case of lexicographic order. We study CL#P and show, for example, that it does not equal c#P unless UP = PP (and thus the polynomial hierarchy collapses). On the other hand, we also prove that c#P and CL#P coincide on polynomially bounded functions, and that CL#P shows some behaviors quite reminiscent of c#P, e.g., though #P is closed under increment, we show that CL#P is closed under increment only if unexpected complexity collapses occur. More generally, we explore the relationship between CL#P and such classes as IF_{t}, IF_{p}, and #P. Though CL#P is in general flavor like an interval function (over a total order satisfying appropriate conditions but freed from the polynomial-time computability constraints of the functions defining the top and bottom of the interval), our results usually show that CL#P differs from the these classes unless unexpected complexity class collapses occur.

2. Preliminaries. Fix our finite alphabet to be $\Sigma = \{0,1\}$, and let Σ^* denote the set of all finite strings over Σ. Let ε denote the empty string. The length of a string $x \in \Sigma^*$ is denoted by $|x|$. The set of all strings of length n is denoted by Σ^n. The complement of a set $L \subseteq \Sigma^*$ is denoted by $\overline{L}$, i.e., $\overline{L} = \Sigma^* \setminus L$. For any class $\mathcal{K}$ of subsets of Σ^*, let co$\mathcal{K}$ be the class $\{L \subseteq \Sigma^* \mid \overline{L} \in \mathcal{K}\}$. The cardinality of a finite set S is denoted by $\|S\|$. The characteristic function of a set $L \subseteq \Sigma^*$ is denoted by χ_L, i.e., for all $x \in \Sigma^*$, $\chi_L(x) = 1 \Leftrightarrow x \in L$ and $\chi_L(x) = 0 \Leftrightarrow x \notin L$. Let $\mathbb{N}$ denote the set $\{0,1,2,\dots\}$. Let $\mathbb{N}^+$ denote the set $\{1,2,3,\dots\}$.

For the basic notions of complexity theory such as P, NP, PSPACE, and so on see, e.g., the handbook [HO02].

The computation model we use is the standard nondeterministic Turing machine.

We review the definitions of some complexity classes of functions, already existing

in the literature, that we will use in this paper.

- FP is the class of all (deterministic) polynomial-time computable, total functions from Σ^* to $\mathbb{N}$. We will at times use FP to mean the class of all polynomial-time computable, total functions from Σ^* to Σ^*. Via the natural, efficient bijection between $\mathbb{N}$ and Σ^*, these two notions are essentially the same.
- [Lad89] FPSPACE(poly) is the class of all polynomial-space computable, total functions from Σ^* to $\mathbb{N}$ having polynomially length-bounded outputs. We will at times use FPSPACE(poly) to mean the class of all polynomial-space computable, total functions from Σ^* to Σ^* having polynomially length-bounded outputs. Via the natural, efficient bijection between $\mathbb{N}$ and Σ^*, these two notions are essentially the same.
- [Val79] #P is the class of all total functions f for which there exists a nondeterministic polynomial-time Turing machine M such that, for each x, $f(x)$ is the number of accepting computations of $M(x)$. Equivalently, #P is the class of all total functions f for which there exist a set $B \in \mathrm{P}$ and a polynomial p such that, for all $x \in \Sigma^*$, $f(x) = \|\{z \mid |z| = p(|x|) \wedge (x, z) \in B\}\|$.
- [GS88, Kos99] $\mathrm{UPSV_t}$ is the class of all total functions f for which there exists a nondeterministic polynomial-time Turing machine M that, on each input $x \in \Sigma^*$, has exactly one accepting path, and the output of this unique accepting path is $f(x)$.

For function classes $\mathcal{F}$ and $\mathcal{G}$ where each $f \in \mathcal{F} \cup \mathcal{G}$ maps from Σ^* to $\mathbb{N}$, let $\mathcal{F} - \mathcal{G}$ denote the class of all functions $\{f - g \mid f \in \mathcal{F} \text{ and } g \in \mathcal{G}\}$. Note that the codomain of $\mathcal{F} - \mathcal{G}$ functions is $\{\ldots, -3, -2, -1, 0, 1, 2, 3, \ldots\}$. For each class $\mathcal{K}$ of sets, let $\mathrm{FP}^{\mathcal{K}}$ (respectively, $\mathrm{P}^{\mathcal{K}}$) be the class of functions (respectively, sets) that can be computed in polynomial time with an oracle from $\mathcal{K}$.

Next, we review the definitions of some complexity classes (of sets), already existing in the literature, that we will use in this paper.

- [Val76] UP is the class of all sets L such that $\chi_L \in \#\mathrm{P}$.
- [Coo71, Lev75] NP is the class of all sets L for which there exists a function $f \in \#\mathrm{P}$ such that, for all $x \in \Sigma^*$, $x \in L \Leftrightarrow f(x) > 0$.
- [Sim75, Gil77] PP is the class of all sets L for which there exist functions $f \in \#\mathrm{P}$ and $g \in \mathrm{FP}$ such that, for all $x \in \Sigma^*$, $x \in L \Leftrightarrow f(x) \geq g(x)$.
- [OH93, FFK94] SPP is the class of all sets L such that $\chi_L \in \#\mathrm{P} - \mathrm{FP}$.
- [CH90] Few is the class of all sets L for which there exist a function $f \in \#\mathrm{P}$, a set $B \in \mathrm{P}$, and a polynomial p such that, for all $x \in \Sigma^*$, $f(x) \leq p(|x|)$ and $x \in L \Leftrightarrow (x, 1^{f(x)}) \in B$. In this definition, changing from "$f(x) \leq p(|x|)$" to "$0 < f(x) \leq p(|x|)$" can easily be seen to also yield Few.
- [MS72, Sto77] $\mathrm{PH} = \mathrm{P} \cup \mathrm{NP} \cup \mathrm{NP}^{\mathrm{NP}} \cup \mathrm{NP}^{\mathrm{NP}^{\mathrm{NP}}} \cup \ldots$.

The following results are well-known or easy to see.

PROPOSITION 2.1.

1. $\mathrm{FP} \subseteq \mathrm{UPSV_t} = \mathrm{FP}^{\mathrm{UP} \cap \mathrm{coUP}} \subseteq \#\mathrm{P} \subseteq \mathrm{FPSPACE(poly)}$.
2. $\mathrm{P} \subseteq \mathrm{UP} \subseteq \mathrm{Few} \cap \mathrm{NP} \subseteq \mathrm{Few} \cup \mathrm{NP} \subseteq \mathrm{P}^{\mathrm{NP}} \subseteq \mathrm{PH} \subseteq \mathrm{PSPACE}$.
3. $\mathrm{NP} \cup \mathrm{SPP} \subseteq \mathrm{PP}$.
4. [KSTT92] $\mathrm{Few} \subseteq \mathrm{SPP}$.

In this paper, we will sometimes for conciseness refer to the jth part of Theorem i as Theorem $i.j$, e.g., we may refer to the third part of the above proposition as Proposition 2.1.3.

We will use the complexity-theoretic function-to-set operator $\exists$ of Hempel and

Wechsung [HW00], which maps function classes to set classes. For a function class $\mathcal{F}$, $\exists \cdot \mathcal{F}$ is the class of all sets L for which there exists a function $f \in \mathcal{F}$ such that, for all $x \in \Sigma^*$, $x \in L \Leftrightarrow f(x) > 0$.

The following statements are easy to see.

PROPOSITION 2.2.

1. $\exists \cdot \mathrm{FP} = \exists \cdot (\mathrm{FP} - \mathrm{FP}) = \mathrm{P}$.
2. $\exists \cdot \mathrm{UPSV_t} = \exists \cdot (\mathrm{UPSV_t} - \mathrm{FP}) = \exists \cdot (\mathrm{UPSV_t} - \mathrm{UPSV_t}) = \mathrm{UP} \cap \mathrm{coUP}$.
3. $\exists \cdot \#\mathrm{P} = \mathrm{NP}$.
4. $\exists \cdot (\#\mathrm{P} - \mathrm{FP}) = \mathrm{PP}$.
5. $\exists \cdot \mathrm{FPSPACE(poly)} = \mathrm{PSPACE}$.

3. Orders with feasibility constraints. In this section, we define the notions of ordering that we use for the remainder of this paper (see also [Ko83]).

A binary relation $A \subseteq \Sigma^* \times \Sigma^*$ is a *partial order* if it is reflexive, antisymmetric (i.e., $(\forall x, y \in \Sigma^*)[x \neq y \implies ((x,y) \notin A \vee (y,x) \notin A)]$), and transitive. A partial order A is a *total order* if, for all $x, y \in \Sigma^*$, $(x,y) \in A$ or $(y,x) \in A$. A partial order A is a *partial p-order* if there exists a polynomial q such that for all $(x,y) \in A$ it holds that $|x| \leq q(|y|)$.

For any partial p-order A, we employ the following standard notational conventions. We write $x \leq_A y$ if $(x,y) \in A$. We write $x <_A y$ if $x \leq_A y$ and $x \neq y$. We write $x \prec_A y$ if $x <_A y$ and there is no z such that $x <_A z <_A y$. If $x \prec_A y$, we say that x *precedes* y or, equivalently, y *succeeds* x. We let $A_\prec =_{\mathrm{def}} \{(x,y) \mid x \prec_A y\}$. The lexicographical order is denoted by $\leq_{\mathrm{lex}}$, and lexicographical adjacency is denoted by $\prec_{\mathrm{lex}}$.

Note that, for every partial p-order A and every string y, there exist at most exponentially (in the length of y) many strings that are less than y with respect to A. Thus, the output of an interval size function on a partial p-order is always at most exponential in the input length. Note that such exponential value bounds are typically the case with function classes, such as FP and #P, that are based on Turing machines having polynomial-time running bounds.

Feasibility constraints on orders are essential to our study. A partial p-order A is P-*decidable* if $A \in \mathrm{P}$. A partial p-order A is said to have *efficient adjacency checks* if $A_\prec \in \mathrm{P}$.

There are complexity-theoretic connections between these two feasibility requirements.

PROPOSITION 3.1. *Let A be a partial p-order.*

1. *If $A \in \mathrm{P}$, then $A_\prec \in \mathrm{coNP}$.*
2. *If $A_\prec \in \mathrm{P}$, then $A \in \mathrm{PSPACE}$.*

Proof. The proof of (1) is immediate.

For (2), let A be a partial p-order that has efficient adjacency checks. Let M be an NPSPACE machine that accepts A by, on input (x,y), accepting immediately if $x = y$ and otherwise guessing a sequence $z_1, \ldots, z_k$ such that $x \prec_A z_1 \prec_A z_2 \prec_A \cdots \prec_A z_k \prec_A y$. Since A is a partial p-order, for each $i \in \{1, \ldots, k\}$, $|z_i|$ is polynomially bounded with respect to $|y|$, so we need only guess such z_i's whose lengths are polynomially bounded in $|y|$. So $A \in \mathrm{NPSPACE}$. However, as is well-known, $\mathrm{NPSPACE} = \mathrm{PSPACE}$. □

COROLLARY 3.2.

1. *If $\mathrm{P} = \mathrm{NP}$, then all P-decidable partial p-orders have efficient adjacency checks.*

2. *If* P = PSPACE*, then all partial p-orders with efficient adjacency checks are* P*-decidable.*

In what follows we will see that the converse of each of the claims of Corollary 3.2 also holds.

4. Orders without efficient adjacency checks. We say that a function $f : \Sigma^* \to \mathbb{N}$ is an *interval size function* if there exist *boundary functions* b and t mapping from Σ^* to Σ^* and a partial order $A \subseteq \Sigma^* \times \Sigma^*$ such that, for all $x \in \Sigma^*$, $f(x) = \|\{z \mid b(x) <_A z <_A t(x)\}\|$. In this section, we characterize #P in terms of interval size functions with polynomial-time decidable p-orders and polynomial-time computable boundary functions. We also note that if we omit all feasibility restrictions on p-orders, then all polynomially length-bounded functions can be characterized in a manner analogous to the way that interval size functions of resource-bounded orders characterize #P.

THEOREM 4.1.

1. *For any function f, the following statements are equivalent.*
   (a) $f \in$ #P*.*
   (b) *There exist a partial p-order $A \in$ P and functions $b, t \in$ FP such that, for all $x \in \Sigma^*$, $f(x) = \|\{z \mid b(x) <_A z <_A t(x)\}\|$.*
   (c) *There exist a total p-order $A \in$ P and functions $b, t \in$ FP such that, for all $x \in \Sigma^*$, $b(x) \leq_A t(x)$ and $f(x) = \|\{z \mid b(x) <_A z <_A t(x)\}\|$.*
2. *For any function f the following statements are equivalent.*
   (a) *f is polynomially length-bounded.*
   (b) *There exist a partial p-order A and functions $b, t \in$ FP such that, for all $x \in \Sigma^*$, $f(x) = \|\{z \mid b(x) <_A z <_A t(x)\}\|$.*
   (c) *There exist a total p-order A and functions $b, t \in$ FP such that, for all $x \in \Sigma^*$, $b(x) \leq_A t(x)$ and $f(x) = \|\{z \mid b(x) <_A z <_A t(x)\}\|$.*

Proof. The implications (1c) ⇒ (1b), (1b)⇒ (1a), (2c) ⇒ (2b), and (2b) ⇒ (2a) are obvious. We prove that (1a) ⇒ (1c) and (2a) ⇒ (2c).

It is easy to see that, for every polynomially length-bounded function $f : \Sigma^* \to \mathbb{N}$, there exist a set $B \subseteq \Sigma^* \times \Sigma^*$ and a strictly increasing polynomial p such that $f(x) = \|\{z \mid |z| = p(|x|) \wedge (x, z) \in B\}\|$. Note that we may choose B so that, for all $x \in \Sigma^*$, $(x, 0^{p(|x|)}) \notin B$ and $(x, 1^{p(|x|)}) \notin B$. If, in addition, $f \in$ #P, then B can be chosen from P.

We construct a total p-order A on Σ^* as follows. Generally, A will coincide with the lexicographical order on Σ^* except that, for every $x \in \Sigma^*$, the interval between $x0^{p(|x|)}$ and $x1^{p(|x|)}$ (inclusively) is ordered differently in the following way.

- First comes $x1^{p(|x|)}$.
- Next come the elements of $\{xz \mid |z| = p(|x|) \wedge (x, z) \in B\}$ in lexicographical order.
- Finally come the elements of $\{xz \mid |z| = p(|x|) \wedge (x, z) \notin B \wedge z \neq 1^{p(|x|)}\}$ in lexicographical order.

Note that $f(x) = \|\{w \mid x1^{p(|x|)} <_A w <_A x0^{p(|x|)}\}\|$. If, in addition, $B \in$ P, then $A \in$ P. □

We pass on a referee's comment that if one feels that putting $x0^{p(|x|)}$ before $x1^{p(|x|)}$ results in a more natural order, one could slightly tweak the order used and still have the proof go through.

5. Polynomial-time orders with efficient adjacency checks. We know from Theorem 4.1 that counting the size of intervals with respect to P-decidable partial p-orders that have polynomial-time computable boundaries computes some

function in #P. The situation changes if in addition we require each P-decidable partial p-order to have efficient adjacency checks.

DEFINITION 5.1. $\mathrm{IF_p}$ *(respectively,* $\mathrm{IF_t}$*) is the class of all functions* $f : \Sigma^* \to \mathbb{N}$ *for which there exist a partial (respectively, total) p-order* $A \in \mathrm{P}$ *having efficient adjacency checks and functions* $b, t \in \mathrm{FP}$*, such that, for every* $x \in \Sigma^*$*,* $f(x) = \|\{z \mid b(x) <_A z <_A t(x)\}\|$.

The following theorem places the classes $\mathrm{IF_t}$ and $\mathrm{IF_p}$ between two well-known complexity classes.

THEOREM 5.2. $\mathrm{FP} \subseteq \mathrm{IF_t} \subseteq \mathrm{IF_p} \subseteq \#\mathrm{P}$.

Proof. The second inclusion follows from the definitions of $\mathrm{IF_t}$ and $\mathrm{IF_p}$, and the third inclusion follows from Theorem 4.1. Thus, it remains to prove that $\mathrm{FP} \subseteq \mathrm{IF_t}$. For each $f \in \mathrm{FP}$, there exists a strictly increasing polynomial p such that $f(x) < 2^{p(|x|)} - 1$. For $x \in \Sigma^*$ and $i < 2^{p(|x|)}$, let $\mathrm{bin}(x, i)$ be the binary description of i having exactly $p(|x|)$ bits.

We construct a total p-order A on Σ^* as follows. Generally, A coincides with the lexicographical order on Σ^* except that, for every $x \in \Sigma^*$, the interval between $x0^{p(|x|)}$ and $x1^{p(|x|)}$ (inclusively) is ordered in the following way.

- First come the elements of $\{x\mathrm{bin}(x, i) \mid 0 \le i \le f(x)\}$ in lexicographical order.
- Next comes $x1^{p(|x|)}$.
- Finally come the elements of $\{x\mathrm{bin}(x, i) \mid f(x) < i < 2^{p(|x|)} - 1\}$ in lexicographical order.

Note that A is P-decidable, has efficient adjacency checks, and satisfies $f(x) = \|\{w \mid x0^{p(|x|)} <_A w <_A x1^{p(|x|)}\}\|$. □

What else can we say about the relationships between FP, $\mathrm{IF_t}$, $\mathrm{IF_p}$, and #P? We start by providing a characterization of $\mathrm{IF_p}$ based on an important subset of #P. Let $\mathrm{supp}(f)$ denote the support of f, i.e., $\mathrm{supp}(f) = \{x \mid f(x) \neq 0\}$.

THEOREM 5.3. $\mathrm{IF_p} = \{f \in \#\mathrm{P} \mid \mathrm{supp}(f) \in \mathrm{P}\}$.

Proof. Suppose that $f \in \mathrm{IF_p}$, via p-order $A \in \mathrm{P}$ having polynomial-time adjacency checks and boundary functions $b, t \in \mathrm{FP}$. Note that $\overline{\mathrm{supp}(f)} = \{x \mid b(x) \prec_A t(x) \vee b(x) \not\preceq_A t(x)\}$. Thus, since $A \in \mathrm{P}$ and $A_\prec \in \mathrm{P}$, it follows that $\overline{\mathrm{supp}(f)} \in \mathrm{P}$ and thus that $\mathrm{supp}(f) \in \mathrm{P}$. By Theorem 5.2, $f \in \#\mathrm{P}$. Therefore $\mathrm{IF_p} \subseteq \{f \in \#\mathrm{P} \mid \mathrm{supp}(f) \in \mathrm{P}\}$.

We now show that $\{f \in \#\mathrm{P} \mid \mathrm{supp}(f) \in \mathrm{P}\} \subseteq \mathrm{IF_p}$. Suppose $f \in \#\mathrm{P}$ and $\mathrm{supp}(f) \in \mathrm{P}$. Since $f \in \#\mathrm{P}$, there exist a set $B \subseteq \Sigma^* \times \Sigma^*$ from P and a strictly increasing polynomial p such that $f(x) = \|\{z \mid |z| = p(|x|) \wedge (x, z) \in B\}\|$.

We construct a partial p-order A on Σ^* as follows. Generally, A coincides with the lexicographical order on Σ^* except that, for every $x \in \Sigma^*$, the interval between $x0^{p(|x|)}00$ and $x1^{p(|x|)}11$ (inclusively) is ordered according to the following rules.

1. $x0^{p(|x|)}00 <_A x0^{p(|x|)}01 <_A x0^{p(|x|)}11$.
2. The elements from $\{xz10 \mid |z| = p(|x|) \wedge (x, z) \in B\}$ are pairwise incomparable, and all are between $x0^{p(|x|)}01$ and $x0^{p(|x|)}11$.
3. The elements from $\{xz10 \mid |z| = p(|x|) \wedge (x, z) \notin B\} \cup \{xz\sigma \mid |z| = p(|x|) \wedge z \neq 0^{p(|x|)} \wedge \sigma \in \{00, 01, 11\}\}$ are pairwise incomparable, and all are between $x0^{p(|x|)}00$ and $x0^{p(|x|)}01$.

Note that A is P-decidable and satisfies $f(x) = \|\{w \mid x0^{p(|x|)}01 <_A w <_A x0^{p(|x|)}11\}\|$. Define $b(x) =_{\mathrm{def}} x0^{p(|x|)}01$ and $t(x) =_{\mathrm{def}} x0^{p(|x|)}11$. For each x, we have by the construction of A that $b(x) \prec_A t(x)$ if and only if $f(x) = 0$. Since by assumption $\{x \mid f(x) > 0\} \in \mathrm{P}$ the set $\{x \mid b(x) \prec_A t(x)\}$ belongs to P. By our

construction, all other adjacency questions are very easily answered by the obvious, efficient test. So $A_{\prec} \in \mathrm{P}$. □

From this it follows that $\mathrm{IF_p}$ and #P coincide on Nonzero, defined as the set $\{f \mid (\forall x \in \Sigma^*)[f(x) > 0]\}$.

COROLLARY 5.4. $\mathrm{IF_p} \cap \mathrm{Nonzero} = \#\mathrm{P} \cap \mathrm{Nonzero}$.

In what follows, we will sometimes write 1 for the function class consisting of precisely the constant function $\lambda x.1$, and we will sometimes write $\mathcal{O}(1)$ for the function class consisting of precisely the functions $\lambda x.0$, $\lambda x.1$, $\lambda x.2$, ...

COROLLARY 5.5.

1. $\#\mathrm{P} \subseteq \mathrm{IF_p} - 1$.
2. $\#\mathrm{P} - \mathcal{O}(1) = \mathrm{IF_p} - \mathcal{O}(1)$.

From Theorem 5.2 and Corollary 5.5 we can conclude that $\mathrm{IF_p} \subseteq \mathrm{IF_p} - 1$, which is equivalent to saying that $\mathrm{IF_p}$ is closed under increment, i.e., for every $f \in \mathrm{IF_p}$, the function f' is also in $\mathrm{IF_p}$, where, for all $x \in \Sigma^*$, $f'(x) =_{\mathrm{def}} f(x) + 1$.

COROLLARY 5.6. *The class* $\mathrm{IF_p}$ *is closed under increment.*

Regarding $\mathrm{IF_t}$, we have the following theorem. Note that this theorem's second part says that the three function classes $\mathrm{IF_t}$, $\mathrm{IF_p}$, and #P are so closely related that in the presence of easy-to-compute subtractive postcomputation adjustments they become the same. Though it is not concerned with interval functions, we commend to the attention of the interested reader a beautiful paper by Ogihara et al. [OTTW96] that studies whether for #P postcomputation adjustments can annihilate even the effects of various operators.

THEOREM 5.7.

1. $\#\mathrm{P} \subseteq \mathrm{IF_t} - \mathrm{FP}$.
2. $\mathrm{IF_t} - \mathrm{FP} = \mathrm{IF_p} - \mathrm{FP} = \#\mathrm{P} - \mathrm{FP}$.

Proof. (1) For $f : \Sigma^* \to \mathbb{N}$ in #P, there exist a set $B \subseteq \Sigma^* \times \Sigma^*$ from P and a strictly increasing polynomial p such that $f(x) = \|\{z \mid |z| = p(|x|) \wedge (x, z) \in B\}\|$.

We construct a total p-order A on Σ^* as follows. Generally, A coincides with the lexicographical order on Σ^* except that, for every x, the interval between $x0^{p(|x|)+2}$ and $x1^{p(|x|)+2}$ (inclusively) is ordered differently in the following way.

- First come the elements of $\{xz00 \mid |z| = p(|x|)\}$ in lexicographical order.
- Next come the elements of $\{xz11 \mid |z| = p(|x|) \wedge (x, z) \in B\} \cup \{xz01 \mid |z| = p(|x|)\}$ in lexicographical order.
- Finally come the elements of $\{xz11 \mid |z| = p(|x|) \wedge (x, z) \notin B\} \cup \{xz10 \mid |z| = p(|x|)\}$ in lexicographical order.

Note that A is in P, has efficient adjacency checks, and satisfies $\|\{w \mid x1^{p(|x|)}00 <_A w <_A x0^{p(|x|)}10\}\| = f(x) + 2^{p(|x|)}$.

(2) This follows from Theorem 5.2 and part 1 of the present theorem. □

COROLLARY 5.8. $\mathrm{FP}^{\mathrm{IF_t}} = \mathrm{FP}^{\mathrm{IF_p}} = \mathrm{FP}^{\#\mathrm{P}}$.

The previous results indicate that the computational power of $\mathrm{IF_p}$ and $\mathrm{IF_t}$ are not far from the computational power of #P. Nonetheless, Theorem 5.10 shows that these classes cannot coincide unless P = NP. In the proof of Theorem 5.10 we will draw on the following lemma regarding the application of the $\exists$ operator to $\mathrm{IF_p}$ and $\mathrm{IF_t}$. Comparing Lemma 5.9 with Corollary 5.4 and taking into account that $\exists \cdot \#\mathrm{P} = \mathrm{NP}$, it turns out that it is precisely the possibility that $f(x) = 0$ that makes the classes #P and $\mathrm{IF_p}$ potentially differ.

LEMMA 5.9. $\exists \cdot \mathrm{IF_p} = \exists \cdot \mathrm{IF_t} = \mathrm{P}$.

Proof. For $L \in \exists \cdot \mathrm{IF_p}$ there exist a p-order $A \in \mathrm{P}$ having efficient adjacency checks and $b, t \in \mathrm{FP}$ such that, for all x, it holds that $x \in L \Leftrightarrow \|\{z \mid b(x) <_A z <_A t(x)\}\| > 0$.

Thus, for all $x \in \Sigma^*$, $x \in L \Leftrightarrow [b(x) \leq_A t(x)$ and $b(x) \not\leq_A t(x)]$, so $x \in L$ can be checked in polynomial time.

Choose $L \in \mathrm{P}$. Thus $\chi_L \in \mathrm{FP}$. By Theorem 5.2, $\chi_L \in \mathrm{IF_t}$, thus $L \in \exists \cdot \mathrm{IF_t}$. □

THEOREM 5.10. *The following statements are equivalent.*

1. $\mathrm{P} = \mathrm{NP}$.
2. $\mathrm{IF_p} = \#\mathrm{P}$.
3. $\mathrm{IF_t} = \#\mathrm{P}$.
4. *Every* P*-decidable partial p-order has efficient adjacency checks.*
5. *Every* P*-decidable total p-order has efficient adjacency checks.*

Proof. (1) ⇒ (4) follows from Corollary 3.2.1. (4) ⇒ (5) is immediate from the definitions. (5) ⇒ (3) follows from Theorem 4.1.1. (3) ⇒ (2) follows from Theorem 5.2. To see that (2) ⇒ (1), if $\mathrm{IF_p} = \#\mathrm{P}$ then $\exists \cdot \mathrm{IF_p} = \exists \cdot \#\mathrm{P}$. By Lemma 5.9 and Proposition 2.2.3 we have $\mathrm{P} = \mathrm{NP}$. □

We know from Theorem 5.2 that $\mathrm{FP} \subseteq \mathrm{IF_t}$. However, if $\mathrm{IF_t} \subseteq \mathrm{FP}$ or even $\mathrm{IF_t} \subseteq \mathrm{UPSV_t}$, then severe consequences follow.

THEOREM 5.11.

1. $\mathrm{FP} = \mathrm{IF_t}$ *if and only if* $\mathrm{P} = \mathrm{PP}$.
2. $\mathrm{IF_t} \subseteq \mathrm{UPSV_t}$ *if and only if* $\mathrm{UP} = \mathrm{PP}$.
3. $\mathrm{UPSV_t} \subseteq \mathrm{IF_p}$ *if and only if* $\mathrm{P} = \mathrm{UP} \cap \mathrm{coUP}$.

Proof. For items (1) and (2) we consider the left-to-right direction first. From Theorem 5.7 and Proposition 2.2, we can conclude under the assumption $\mathrm{FP} = \mathrm{IF_t}$ that $\mathrm{PP} = \exists \cdot (\#\mathrm{P} - \mathrm{FP}) = \exists \cdot (\mathrm{IF_t} - \mathrm{FP}) = \exists \cdot (\mathrm{FP} - \mathrm{FP}) = \mathrm{P}$ and we can conclude under the assumption $\mathrm{IF_p} \subseteq \mathrm{UPSV_t}$ that $\mathrm{PP} = \exists \cdot (\#\mathrm{P} - \mathrm{FP}) = \exists \cdot (\mathrm{IF_t} - \mathrm{FP}) \subseteq \exists \cdot (\mathrm{UPSV}_t - \mathrm{FP}) = \mathrm{UP} \cap \mathrm{coUP}$. For the right-to-left directions, if $\mathrm{P} = \mathrm{PP}$, then $\mathrm{IF_t} \subseteq \#\mathrm{P} \subseteq \mathrm{FP}^{\#\mathrm{P}} = \mathrm{FP}^{\mathrm{PP}} = \mathrm{FP}$. Thus, $\mathrm{IF_t} = \mathrm{FP}$. If $\mathrm{UP} = \mathrm{PP}$, then $\mathrm{IF_t} \subseteq \#\mathrm{P} \subseteq \mathrm{FP}^{\#\mathrm{P}} = \mathrm{FP}^{\mathrm{PP}} = \mathrm{FP}^{\mathrm{UP} \cap \mathrm{coUP}} = \mathrm{UPSV_t}$.

For item (3), from $\mathrm{UPSV}_t \subseteq \mathrm{IF_p}$, Proposition 2.2, and Lemma 5.9 it follows that $\mathrm{UP} \cap \mathrm{coUP} = \exists \cdot \mathrm{UPSV}_t \subseteq \exists \cdot \mathrm{IF_p} = \mathrm{P}$. For the right-to-left direction, by Proposition 2.1.1, $\mathrm{P} = \mathrm{UP} \cap \mathrm{coUP}$ implies $\mathrm{UPSV_t} = \mathrm{FP}$. So, by Theorem 5.2, $\mathrm{P} = \mathrm{UP} \cap \mathrm{coUP}$ implies $\mathrm{UPSV_t} \subseteq \mathrm{IF_p}$ (and even $\mathrm{UPSV_t} \subseteq \mathrm{IF_t}$). □

In contrast to Theorem 5.11.3, when restricted to strictly positive functions the class $\mathrm{UPSV_t}$ is even included in $\mathrm{IF_t}$.

THEOREM 5.12. $\mathrm{UPSV_t} \cap \mathrm{Nonzero} \subseteq \mathrm{IF_t} \cap \mathrm{Nonzero}$.

A proof of Theorem 5.12 is in the technical report version [HHKW05] of this paper. Since $\mathrm{UPSV_t}$ is closed under increment, Theorem 5.12 yields the following corollary.

COROLLARY 5.13. $\mathrm{UPSV_t} \subseteq \mathrm{IF_t} - 1$.

Corollary 5.6 showed that the class $\mathrm{IF_p}$ is closed under increment. This is also true for the class $\mathrm{IF_t}$.

THEOREM 5.14. *The class* $\mathrm{IF_t}$ *is closed under increment.*

Proof. For $f \in \mathrm{IF_t}$ there exist a P-decidable p-order A on Σ^* with efficient adjacency checks and functions $b, t \in \mathrm{FP}$ such that, for all $x \in \Sigma^*$, $f(x) = \|\{w \mid b(x) <_A w <_A t(x)\}\|$. Without loss of generality we may require that $b(x) \leq_A t(x)$, since on inputs not satisfying that we may modify $t(x)$ to output $b(x)$. Let p be a strictly increasing polynomial such that, for all $y \in \Sigma^*$ satisfying $y \leq_A t(x)$, $|y| < p(|x|)$.

We construct a total p-order A' on Σ^* as follows. Generally, A' coincides with the lexicographical order on Σ^* except that, for every $x \in \Sigma^*$, the interval between $x0^{p(|x|)+2}$ and $x1^{p(|x|)+2}$ (inclusively) is ordered in the following way.

- First comes $x0^{p(|x|)+2}$.

- Next come the elements of $D_x =_{\text{def}} \{x0^{p(|x|)-|z|}1z0 \mid b(x) \leq_A z \leq_A t(x)\}$, for which we set $x0^{p(|x|)-|y|}1y0 \leq_{A'} x0^{p(|x|)-|z|}1z0$ if and only if $y \leq_A z$.
- Finally come the elements of $\{xu \mid |u| = p(|x|) + 2\} - (D_x \cup \{0^{p(|x|)+2}\})$ in lexicographical order.

Note that A' is P-decidable, that it has efficient adjacency checks, and that $f(x)+1 = \|\{w \mid x0^{p(|x|)+2} <_{A'} w <_{A'} x0^{p(|x|)-|t(x)|}1t(x)0\}\|$. □

COROLLARY 5.15. $\text{IF}_\text{t} \subseteq \text{IF}_\text{t}$ - 1.

Although the statement "$\text{UPSV}_\text{t} = \text{IF}_\text{t}$" is not likely to be true (see Theorem 5.11), for the case of strictly positive, polynomially bounded functions the analogous statement holds. We define PolyBounded $=_{\text{def}} \{f \mid (\exists \text{ polynomial } p)(\forall x)[f(x) \leq p(|x|)]\}$.

THEOREM 5.16.

1. $\text{IF}_\text{t} \cap \text{PolyBounded} \subseteq \text{UPSV}_\text{t} \cap \text{PolyBounded}$.
2. $\text{IF}_\text{t} \cap \text{PolyBounded} \cap \text{Nonzero} = \text{UPSV}_\text{t} \cap \text{PolyBounded} \cap \text{Nonzero}$.
3. $\text{UPSV}_\text{t} \cap \text{PolyBounded} \subseteq \text{IF}_\text{p} \cap \text{PolyBounded}$ *if and only if* $\text{P} = \text{UP} \cap \text{coUP}$.

A proof of Theorem 5.16 is in the technical report version [HHKW05] of this paper.

From Theorem 4.1 we know that total p-orders that are efficiently decidable and partial p-orders that are efficiently decidable describe the same class of functions in our setting (namely #P). If we consider p-orders that additionally have efficient adjacency checks, then the analogous confluence of total and partial does not hold unless an unexpected complexity class collapse occurs.

THEOREM 5.17. *If* $\text{IF}_\text{t} = \text{IF}_\text{p}$, *then* $\text{UP} = \text{PH}$.

Proof. Assume that $\text{IF}_\text{t} = \text{IF}_\text{p}$. We show that coNP $\subseteq$ UP (which is equivalent to the statement UP = PH). Let $L \in \text{coNP}$, i.e., there is a function $f \in \#\text{P}$ such that, for all $x \in \Sigma^*$, $x \in L \Leftrightarrow f(x) = 0$. Consider the function f', where $f'(x) =_{\text{def}} f(x) + 1$. Thus $x \in L \Leftrightarrow f'(x) = 1$ and, since #P is closed under increment, we conclude that $f' \in \#\text{P} \cap \text{Nonzero} = \text{IF}_\text{p} \cap \text{Nonzero} = \text{IF}_\text{t} \cap \text{Nonzero}$. Thus, there exist a total p-order $A \in \text{P}$ with efficient adjacency checks and functions $b, t \in \text{FP}$ such that $f'(x) = \|\{z \mid b(x) <_A z <_A t(x)\}\|$. Let q be a polynomial such that $(x, y) \in A$ implies $|x| \leq q(|y|)$. Define M to be a machine that, on input $x \in \Sigma^*$, nondeterministically guesses z such that $|z| \leq q(|t(x)|)$ and checks whether $b(x) \prec_A z \prec_A t(x)$. Clearly, M runs in polynomial time (since A has efficient adjacency checks) and always has at most one accepting path (since A is a total p-ordering and we are doing two adjacency checks in our test). Moreover, $x \in L$ if and only if M on x has an accepting computation path. Thus, $L \in \text{UP}$. □

6. Arbitrary orders with efficient adjacency checks. In the previous section, we studied polynomial-time-decidable p-orders having efficient adjacency checks. We showed that the classes defined by interval size functions over such orders, IF_p and IF_t, are very close to #P. In the present section, we consider what happens when we do not insist on polynomial-time decidability for the order but still require efficient adjacency checks. Section 6.1 presents our results on this. Due to its complexity and length, the proof of one key claim of that section, Lemma 6.5, is presented separately as section 6.2.

6.1. Results on arbitrary orders with efficient adjacency checks. In this section, we study p-orders that have efficient adjacency checks but that are not required to be polynomial-time decidable. We define two classes to capture this behavior.

DEFINITION 6.1. *The class* $\mathrm{IF}_{\mathrm{p}}^{*}$ *(respectively,* $\mathrm{IF}_{\mathrm{t}}^{*}$*) is the set of all functions* $f : \Sigma^* \to \mathbb{N}$ *for which there exist a partial (respectively, total) p-order* A *having efficient adjacency checks and functions* $b, t \in \mathrm{FP}$ *such that, for every* $x \in \Sigma^*$, $f(x) = \|\{z \mid b(x) <_A z <_A t(x)\}\|$.

We have the following inclusions between classes of interval size functions and other complexity classes of functions.

PROPOSITION 6.2. $\mathrm{IF}_{\mathrm{t}} \subseteq \mathrm{IF}_{\mathrm{t}}^{*} \subseteq \mathrm{IF}_{\mathrm{p}}^{*} \subseteq \mathrm{FPSPACE(poly)}$ *and* $\mathrm{IF}_{\mathrm{t}} \subseteq \mathrm{IF}_{\mathrm{p}} \subseteq \mathrm{IF}_{\mathrm{p}}^{*} \cap \#\mathrm{P} \subseteq \#\mathrm{P} \subseteq \mathrm{FPSPACE(poly)}$.

Proof. The only inclusion that is nontrivial is $\mathrm{IF}_{\mathrm{p}}^{*} \subseteq \mathrm{FPSPACE(poly)}$. Let f be in $\mathrm{IF}_{\mathrm{p}}^{*}$ via a partial p-order A having efficient adjacency checks and functions $b, t \in \mathrm{FP}$. Let p be a polynomial such that, for all $x, y \in \Sigma^*$, $(x, y) \in A$ implies $|x| \leq p(|y|)$. From Proposition 3.1 we know that A is in PSPACE. Thus, there is a polynomial-space Turing machine M that, for any input $x \in \Sigma^*$, counts by brute force how many strings z of length at most $p(|t(x)|)$ satisfy $b(x) <_A z <_A t(x)$. We may thus conclude that f is in FPSPACE(poly). □

The main results of this section show that the computational powers of $\mathrm{IF}_{\mathrm{p}}^{*}$ and $\mathrm{IF}_{\mathrm{t}}^{*}$ are close to the computational power of FPSPACE(poly). In fact, within the flexibility of the simple postcomputation adjustment of subtracting polynomial-time computable functions, these three classes become the same.

THEOREM 6.3. $\mathrm{IF}_{\mathrm{t}}^{*} \text{ - } \mathrm{FP} = \mathrm{IF}_{\mathrm{p}}^{*} \text{ - } \mathrm{FP} = \mathrm{FPSPACE(poly)} \text{ - } \mathrm{FP}$.

THEOREM 6.4. $\exists \cdot \mathrm{IF}_{\mathrm{t}}^{*} = \exists \cdot \mathrm{IF}_{\mathrm{p}}^{*} = \mathrm{PSPACE}$.

Theorem 6.4 can be interpreted to say something a bit surprising about the complexity of reachability, namely, that in a certain sense reachability checking in succinctly specified chains is PSPACE-complete. To see this, we reason as follows. There exist PSPACE-complete problems. So from that and Theorem 6.4, in light of Definition 6.1, we have that there are a total p-order A and functions $b, t \in \mathrm{FP}$ such that the set $\{x \mid f(x) > 0\}$ is PSPACE-complete, where $f(x) = \|\{z \mid b(x) <_A z <_A t(x)\}\|$. To interpret this all in terms of reachability in a succinctly specified chain, we can view A as specifying an infinite chain such that a has an edge to b precisely if b is right-adjacent to a. Testing whether $f(x) > 0$ is asking "Is it the case that both (a) $t(x)$ is not right-adjacent to $b(x)$, and (b) there is a path from $b(x)$ to $t(x)$ within the chain?" Note that the "(a)" part of this test is a polynomial-time test, so the complexity is coming from the "(b)" part. Thus, in the sense just mentioned, Theorem 6.4 shows the unexpected result that even for succinctly, simply specified chains, reachability testing where the "to" and "from" elements are indirectly polynomial-time specified by the input is PSPACE-complete. However, the problem just discussed, where the "to" and "from" elements are determined by polynomial-time computable functions of the input, can easily be seen—being careful of course about condition "(a)" from above—to polynomial-time many-one reduce to the more flexible case in which the "to" and "from" elements are the input. And so we have that there exists a set $A \subseteq \mathbb{N}^2$, $A \in \mathrm{P}$, such that the directed graph $(\mathbb{N}, A)$ is a chain and its reachability problem,

$$\{(x, y) \mid x, y \in \mathbb{N} \text{ and } y \text{ is reachable from } x \text{ in } (\mathbb{N}, A)\},$$

is PSPACE-complete. Even in light of the existing results showing that many problems about succinctly specified graphs are hard, and often PSPACE-complete (see [Wag84, Wag86, PY86, GW83], but for contrast see also [HHW05, NT05]), this result, which speaks to succinctly specified *chains*, seems surprising. (These comments all regard the "total" part of Theorem 6.4. The "partial" part of Theorem 6.4 implies the

analogous but far less surprising claim for succinctly specified graphs (as opposed to succinctly specified chains), and in fact would give one an alternate way of seeing the known (see [Wag84, Wag86, PY86, GW83]) result that the graph reachability problem in succinctly specified graphs is PSPACE-complete. By the way, PSPACE-completeness is known from those earlier works to still hold even when the graphs are restricted to outdegree one (see [Wag84, Wag86, PY86, GW83], and the discussion in [Tan01]), which brings one somewhat closer to the chains cases mentioned above.)

Theorems 6.3 and 6.4 follow immediately from Proposition 6.2 and the following lemma, whose proof is deferred to section 6.2.

LEMMA 6.5. *For each* $f \in \mathrm{FPSPACE(poly)}$*, there exist a total p-order* A *having efficient adjacency checks and polynomial-time computable functions* $s : \mathbb{N} \to \mathbb{N}$*,* $b : \Sigma^* \to \Sigma^*$*,* $b' : \Sigma^* \to \Sigma^*$*, and* $t : \Sigma^* \to \Sigma^*$ *such that, for all* $x \in \Sigma^*$*,*

1. s *is polynomially bounded,*
2. $\|\{z \mid b(x) <_A z <_A t(x)\}\| = 2^{2s(|x|)+1} + f(x) - 2$*, and*
3. $\|\{z \mid b'(x) <_A z <_A t(x)\}\| > 0$ *if and only if* $f(x) = 1$.

As a consequence of Theorems 6.3 and 6.4, we obtain characterizations for the class FPSPACE(poly) in terms of $\mathrm{IF}_{\mathrm{t}}^*$. For classes $\mathcal{F}$ and $\mathcal{G}$ of functions from Σ^* to $\mathbb{N}$, let $\mathcal{F} \ominus \mathcal{G}$ denote the class of all total, nonnegative functions in $\mathcal{F}$ - $\mathcal{G}$, i.e., the class of all total functions h for which there exist total functions $f \in \mathcal{F}$ and $g \in \mathcal{G}$ such that, for all $x \in \Sigma^*$, $f(x) \geq g(x)$ and $h(x) = f(x) - g(x)$.

COROLLARY 6.6.

1. $\mathrm{FPSPACE(poly)} = \mathrm{IF}_{\mathrm{t}}^* \ominus \mathrm{FP} = \mathrm{FP}^{\mathrm{IF}_{\mathrm{t}}^*} = \mathrm{FP}^{\exists \cdot \mathrm{IF}_{\mathrm{t}}^*}$.
2. $\mathrm{FPSPACE(poly)} = \mathrm{IF}_{\mathrm{p}}^* \ominus \mathrm{FP} = \mathrm{FP}^{\mathrm{IF}_{\mathrm{p}}^*} = \mathrm{FP}^{\exists \cdot \mathrm{IF}_{\mathrm{p}}^*}$.

Proof. Regarding part 1, by Theorem 6.3, Proposition 6.2, and Theorem 6.4 we have $\mathrm{FPSPACE(poly)} \subseteq \mathrm{IF}_{\mathrm{t}}^* \ominus \mathrm{FP} \subseteq \mathrm{FP}^{\mathrm{IF}_{\mathrm{t}}^*} \subseteq \mathrm{FP}^{\mathrm{FPSPACE(poly)}} \subseteq \mathrm{FP}^{\mathrm{PSPACE}} \subseteq \mathrm{FP}^{\exists \cdot \mathrm{IF}_{\mathrm{t}}^*} \subseteq \mathrm{FP}^{\mathrm{PSPACE}} \subseteq \mathrm{FPSPACE(poly)}$. Part 2 holds by the same inclusion chain applied to $\mathrm{IF}_{\mathrm{p}}^*$. □

Though Theorem 6.3 shows that $\mathrm{IF}_{\mathrm{t}}^*$ is almost as powerful as FPSPACE(poly), the following theorem shows that it is unlikely that $\mathrm{IF}_{\mathrm{t}}^*$ actually coincides with FPSPACE(poly).

THEOREM 6.7. *If* $\mathrm{FPSPACE(poly)} \subseteq \mathrm{IF}_{\mathrm{p}}^*$*, then* $\mathrm{UP} = \mathrm{PSPACE}$.

Proof. Suppose that $\mathrm{FPSPACE(poly)} \subseteq \mathrm{IF}_{\mathrm{p}}^*$. Let $L \in \mathrm{PSPACE}$. Then its characteristic function χ_L is in FPSPACE(poly), and by hypothesis $\chi_L \in \mathrm{IF}_{\mathrm{p}}^*$ via some partial p-order A having efficient adjacency checks, some polynomial p such that $(x, y) \in A$ implies $|x| \leq p(|y|)$, and functions $b, t \in \mathrm{FP}$ such that $\chi_L(x) = \|\{z \mid b(x) <_A z <_A t(x)\}\|$. Note that $L = \{x \mid (\exists z)[|z| \leq p(|t(x)|) \wedge b(x) \prec_A z \prec_A t(x)]\}$. Thus, keeping in mind that $(\forall x)[\chi_L(x) \leq 1]$, we have $L \in \mathrm{UP}$. □

From Theorems 6.3 and 6.4, if $\mathrm{IF}_{\mathrm{t}}^* = \mathrm{IF}_{\mathrm{t}}$ or $\mathrm{IF}_{\mathrm{t}}^* \subseteq \#\mathrm{P}$ - FP, then strong consequences follow, as the following two corollaries show.

COROLLARY 6.8. *The following statements are equivalent.*

1. $\mathrm{P} = \mathrm{PSPACE}$.
2. $\mathrm{IF}_{\mathrm{p}} = \mathrm{IF}_{\mathrm{p}}^*$.
3. $\mathrm{IF}_{\mathrm{t}} = \mathrm{IF}_{\mathrm{t}}^*$.
4. *Every partial p-order with efficient adjacency checks is* P*-decidable.*
5. *Every total p-order with efficient adjacency checks is* P*-decidable.*

Proof. (1) ⇒ (4) is just Corollary 3.2.2. (4) ⇒ (5) is trivial. (4) ⇒ (2) and (5) ⇒ (3) follow from the definitions of IF_{p}, $\mathrm{IF}_{\mathrm{p}}^*$, IF_{t}, and $\mathrm{IF}_{\mathrm{t}}^*$. By Theorem 6.4 and Lemma 5.9, (2) implies $\mathrm{PSPACE} = \exists \cdot \mathrm{IF}_{\mathrm{p}}^* = \exists \cdot \mathrm{IF}_{\mathrm{p}} = \mathrm{P}$ and so implies (1). Similarly, (3) implies $\mathrm{PSPACE} = \exists \cdot \mathrm{IF}_{\mathrm{t}}^* = \exists \cdot \mathrm{IF}_{\mathrm{t}} = \mathrm{P}$ and so implies (1). □

COROLLARY 6.9.

1. *If* $\mathrm{IF}_{\mathrm{t}}^* \subseteq \#\mathrm{P} - \mathrm{FP}$, *then* $\mathrm{SPP} = \mathrm{PSPACE}$.
2. *If* $\mathrm{IF}_{\mathrm{t}}^* \subseteq \#\mathrm{P}$, *then* $\mathrm{NP} = \mathrm{SPP} = \mathrm{PSPACE}$.

Proof. (1): For $L \in \mathrm{PSPACE}$, $\chi_L \in \mathrm{FPSPACE(poly)}$. By Proposition 6.2, Theorem 6.3, and our assumption, $\chi_L \in \#\mathrm{P} - \mathrm{FP}$. Thus, $L \in \mathrm{SPP}$.

(2): From Theorem 6.4 and our hypothesis, we obtain $\mathrm{PSPACE} \subseteq \exists \cdot \#\mathrm{P} = \mathrm{NP}$. Combining this with the first part of this theorem we have $\mathrm{SPP} = \mathrm{NP} = \mathrm{PSPACE}$. □

The next result is analogous to results regarding the potential equality of IF_{t} and IF_{p}.

THEOREM 6.10. *If* $\mathrm{IF}_{\mathrm{t}}^* = \mathrm{IF}_{\mathrm{p}}^*$, *then* $\mathrm{UP} = \mathrm{PH}$.

Proof. The proof follows the proof of Theorem 5.17, except that, for the function there called f', we now conclude that $f' \in \#\mathrm{P} \cap \mathrm{Nonzero} = \mathrm{IF}_{\mathrm{p}} \cap \mathrm{Nonzero} \subseteq \mathrm{IF}_{\mathrm{p}}^* \cap \mathrm{Nonzero} = \mathrm{IF}_{\mathrm{t}}^* \cap \mathrm{Nonzero}$. This approach works because the hypothesis $f' \in \mathrm{IF}_{\mathrm{t}}^*$ can be exploited in the same way as the hypothesis $f' \in \mathrm{IF}_{\mathrm{t}}$ was exploited in the proof of Theorem 5.17. This is because in the proof of Theorem 5.17 the P-decidability of the total p-order underlying $f' \in \mathrm{IF}_{\mathrm{t}}$ was not even used. □

Figure 1 summarizes the results we have obtained regarding the inclusion structure of our classes. Although we have not proven consequences of collapses other than those drawn in the figure, we conjecture that the inclusions in the figure are all one can prove without assuming unexpected collapses of complexity classes.

6.2. Proof of Lemma 6.5. The goal of this section is to prove Lemma 6.5. For convenience, we repeat its statement here.

Lemma 6.5. *For each* $f \in \mathrm{FPSPACE(poly)}$, *there exist a total p-order* A *having efficient adjacency checks and polynomial-time computable functions* $s : \mathbb{N} \to \mathbb{N}$, $b : \Sigma^* \to \Sigma^*$, $b' : \Sigma^* \to \Sigma^*$, *and* $t : \Sigma^* \to \Sigma^*$ *such that, for all* $x \in \Sigma^*$,

1. s *is polynomially bounded,*
2. $\|\{z \mid b(x) <_A z <_A t(x)\}\| = 2^{2s(|x|)+1} + f(x) - 2$, *and*
3. $\|\{z \mid b'(x) <_A z <_A t(x)\}\| > 0$ *if and only if* $f(x) = 1$.

Constructing the p-order A mentioned in Lemma 6.5 is, compared to the other p-orders described in this paper, more technically involved. Before we prove Lemma 6.5, we will show, for any $f \in \mathrm{FPSPACE(poly)}$, how to construct A based on the behavior of a Turing machine that computes f. We will then prove Lemma 6.5 by showing that A has all the properties claimed by the lemma.

Our approach is based on the fact that, for any deterministic Turing machine M and any halting configuration c of M, the set of all configurations of M that lead to c form a tree having c as its root and as its edges every pair of configurations where in one time step M moves from one configuration to the other. We base the order of A on a traversal of these trees. Each argument to A encodes either nonsense or an input to M, a configuration of M whose length is bounded in the space bound on $M(x)$, a direction relative to the traversal of the tree to which the given configuration belongs, a guess as to what the eventual halting configuration of M will be when run from the given configuration, and some additional information we describe later. These arguments effectively yield multiple copies of each tree. The order A organizes the arguments in such a way that, in the case of Lemma 6.5.2 (Lemma 6.5.3 uses basically the same approach) $b(x)$ and $t(x)$ delimit an interval that has two elements for every configuration within the space bound imposed by $M(x)$, and $f(x)$ additional elements.

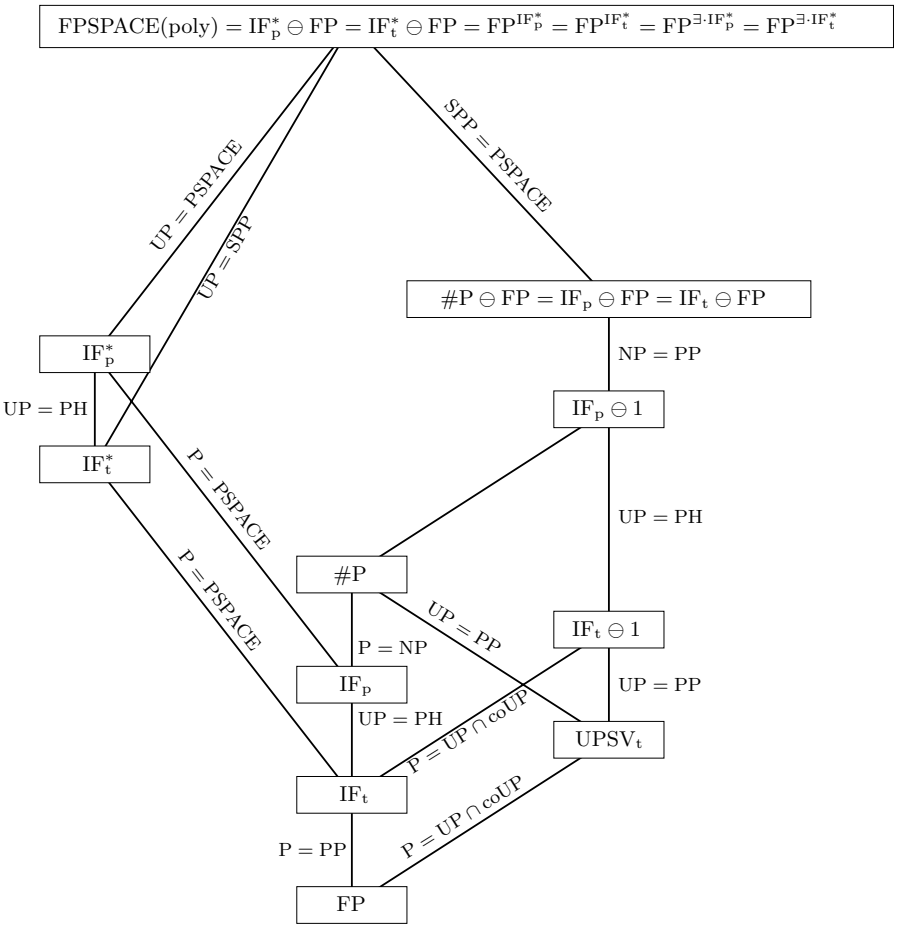

FIG. 1. *The landscape of interval size function classes and related function classes. An equation E on the edge between the function classes $\mathcal{F}_1$ and $\mathcal{F}_2$ means that $\mathcal{F}_1 = \mathcal{F}_2$ implies E. The edge equations that are not immediate consequences of the results of this paper are well-known or easy to see. Since* FP*, which forms the base of this containment tower, is of type $\Sigma^* \to \mathbb{N}$, the fact that in the above figure we use "$\ominus$" rather than "$-$" is of no consequence.*

The key "trick" in this construction is the sequence of "guess bits" each argument to A has, which allow us to send along each tree "messages" that link each configuration to its actual halting configuration. We "pad" A, near arguments containing initial configurations, with as many additional arguments as the guess bits predict. We of course do not know at this point (i.e., "near" an initial configuration) if the guess is correct. However, by the end of the computation we do know. So we simply place together in A all trees corresponding to correct guesses and set, in the case of Lemma 6.5.2, $b(x)$ and $t(x)$ to the boundaries of this interval (which "squeezes out" from the desired interval all incorrect guesses). This yields the claimed results.

We will construct A in five phases, described as follows.

1. **Fixing the computational model**. We will base A on a Turing machine M that computes f in a natural but somewhat nonstandard way. The benefit of using M rather than an arbitrary FPSPACE(poly) Turing machine for f is that it will be easier to work with binary encodings of the configurations

of M and the actions of M than with those of an arbitrary FPSPACE(poly) Turing machine for f.

2. **Fixing the encoding**. We will base A on binary encodings of the configurations of M, which we call *enhanced instantaneous descriptions*. Our encodings are like standard instantaneous descriptions (IDs) [HMU01] but differ in three crucial ways. First, our encodings are actual binary strings rather than sequences of abstract symbols. Second, we use different syntax (which we describe below). Finally, our descriptions contain more information than is actually needed to describe a configuration of M at an instant in time. This additional information is never accessed by M, so its presence in the encodings does not affect the performance of M. At the same time, its presence will greatly aid us in constructing A.
3. **Building trees**. For some appropriate polynomial s, we will, for each $x \in \Sigma^*$, define a tree whose nodes are enhanced instantaneous descriptions of M and whose edges are based on the next move function of M. This tree will have a subtree T_x having exactly $2^{2s(|x|)}$ nodes.
4. **Traversing the trees**. We will associate multiple strings with each node in the tree described above (by padding the labels of the nodes) in such a way that $f(x) + 2$ strings are associated with one of the nodes in T_x and two strings are associated with each of the remaining $2^{2s(|x|)} - 1$ nodes in T_x. We will then define a total, one-to-one, polynomial-time computable function D_M over these strings in such a way that D_M, applied repeatedly to some appropriate starting point, represents a traversal of the tree such that the traversal visits each of these strings once, i.e., from a particular one of the strings z associated with the root of the tree, for each string y associated with some node of the tree there is an integer $i \in \mathbb{N}$ such that $D_M^{(i)}(z) = y$, where $D_M^{(0)}(z) = z$, and, for each $i \in \{1, 2, 3, \dots\}$, $D_M^{(i)}(z) = D_M(D_M^{(i-1)}(z))$. Moreover, for strings w and y, $D_M(w) = y$ only if the nodes associated with w and y are related (i.e., parent/child, sibling, or identical nodes).
5. **Constructing A**. We will base A on D_M. For example, A crucially will have the property that if w and z are two of the strings described in Phase 4, then $w \prec_A z$ if and only if $z = D_M(w)$. Note there will also be many strings on which D_M is not defined that will nonetheless have to be accounted for. Through careful encoding at each phase in the construction, it will be easy to account for these strings in such a way that A has all the properties we desire.

After we handle these five phases, we will prove Lemma 6.5. We now proceed with the construction. Please note that, due to the length of this construction, we overload certain variables. For instance, the variable t denotes both a function over strings and over natural numbers, and has distinct semantics in each case. Over strings it is the function that determines the "bottom" of an interval (i.e., it is used as it typically is throughout this paper), and over the natural numbers it bounds the amount of space needed for part of the encodings we use.

Phase 1: Fixing the computational model. Let $M = (Q, \Sigma, \Gamma, \delta, B, q_0, F)$ be a Turing machine that computes f, where

- Q is the set of *state symbols*,
- $\Sigma = \{0, 1\}$ is the set of *input symbols*,
- B is the *blank symbol*,
- $\Gamma \supseteq \{0, 1, B\}$ is the set of allowable *tape symbols*,

- δ is the *next move function*, i.e., a mapping from $Q \times \Gamma$ to $Q \times \Gamma \times \{-1, 1\}$,
- q_0 is the *start state*, and
- $F \subseteq Q$ is the set of *final states*.

We assume that M has the following properties.

- For some $m \in \mathbb{N}$, $\|Q\| = \|\Gamma\| = 2^m$ (any Turing machine not having this property can be turned into one having this property by adding extra "dummy" states and symbols to its current sets of state and tape symbols, respectively). Since $\Gamma \supseteq \{0, 1, B\}$, $m \geq 2$.
- F contains a single element, q_f, and $q_0 \neq q_f$.
- M has a single, one-way infinite tape (a standard PSPACE(poly) Turing machine would have distinct input, output, and work tapes). On no input x does a true run of M move off the left end of the tape. (One way to ensure that M has this latter property is to include the symbols, 0^e, 1^e, and B^e in Γ. These symbols will be used, exactly on the leftmost cell of the tape, as replacements for 0, 1, and B. We can then construct M so that it is in its start state just once, namely at the beginning of the run, and that, from its start state, it always replaces the then-current symbol (which, in a true run, will always be located in the leftmost tape cell and will be either 0, 1, or B) not with whatever symbol it would normally write during that step but rather with the appropriate analogue among 0^e, 1^e, and B^e. Similarly, our machines can be forced to be such that they attempt to ensure that at all future times this left-marking is preserved, i.e., a $0^e/1^e/B^e$-marker square may be changed during the run but just among 0^e, 1^e, and B^e, as appropriate. A Turing machine constructed in this way can, on any true run, determine when it is about to (were it to mindlessly perform the simulation of the underlying machine) move off the left end, and can indeed handle—without itself running off the left end and in a fashion that is consistent in effect with whatever standard behavior (typically either rejection or "bouncing off" the left end) we in our notion of Turing machines associate with attempting to go off the left end—the left-end move-off that was about to happen.)
- δ on input $(q, r) \in Q \times \Gamma$ is defined if and only if $(q, r) \notin \{q_f\} \times \Gamma$.
- For all $r \in \Gamma$ and all $i \in \{-1, 1\}$, (q_0, r, i) is not in the image of δ. (That is, nothing moves *to* the start state.)
- For all $x \in \Sigma^*$, M on input x halts with $y \in \Sigma^*$ written on its $|y|$ leftmost tape cells, where y is the shortest binary representation of $f(x)$ (i.e., no leading zeros, unless $f(x) = 0$), and with every other tape cell containing the blank symbol.
- There is a strictly increasing polynomial p such that, on each input $x \in \Sigma^*$, M uses, at most, $p(|x|)$ tape cells and $p(|x|) > 0$.

Phase 2: Fixing the encoding. We now describe the binary encoding we use to describe the configurations of M. Figure 2 provides an overview of this phase of the construction. Let $\varphi : Q \to \{0, 1\}^m$ be a total bijection (recall that $\|Q\| = 2^m$ and $m \geq 2$) such that $\varphi(q_0) = 0^m$ and $\varphi(q_f) = 1^m$. The function φ^{-1} denotes the unique total bijection from $\{0, 1\}^m$ to Q that inverts φ. Let $\theta : \Gamma \to \{0, 1\}^m$ be a total bijection (recall that $\|\Gamma\| = 2^m$ and $m \geq 2$) such that $\theta(B) = 0^m$, $\theta(0) = 1^{m-1}0$, and $\theta(1) = 1^m$. Define $\hat{\theta} : \Gamma^* \to (\{0, 1\}^m)^*$ recursively as $\hat{\theta}(\epsilon) = \epsilon$, and, for all $y \in \Gamma$ and $w \in \Gamma^*$, $\hat{\theta}(wy) = \hat{\theta}(w)\theta(y)$. Since $\hat{\theta}$ is also a bijection, we use $\hat{\theta}^{-1}$ to denote the unique total bijection from $(\{0, 1\}^m)^*$ to Γ^* that inverts $\hat{\theta}$.

We define the "partially encoded" next move function $\delta' : \{0, 1\}^m \times \{0, 1\}^m \to$

FIG. 2. *A brief comparison between standard instantaneous descriptions (IDs) and the enhanced IDs we use. Before the computation step illustrated above, the tape head is at cell $b+1$ and the machine is in state q. Afterwards, the head is at cell b and the machine is in state q'. The symbol μ represents the next move function. In standard IDs, the state q appears immediately before the tape cell that the head is currently visiting (e.g., in the case illustrated above, cell $b+1$ before the move and b afterwards). Our enhanced IDs contain additional strings: x, c, and w. The string x encodes the input to the Turing machine, c encodes the number of computation steps the Turing machine has performed so far, and w is the position of the tape head. The state string remains in the same place throughout the computation, and instead w is updated with the position of the tape head. Thus, w encodes the number $b+1$ (i.e., the position of the tape head before the computation step), and w' encodes b (i.e., the position of the tape head after the computation step). The strings c and c' also represent numbers, where the number encoded by c' is one greater than the number encoded by c. For more details on* eIDs *and encodings, see the text.*

$\{0,1\}^m \times \{0,1\}^m \times \{-1,1\}$ on input $(q,r) \in \{0,1\}^m \times \{0,1\}^m$ as $\delta'(q,r) = (\varphi(q'), \theta(r'), i)$, where q', r', and i are specified by $\delta(\varphi^{-1}(q), \theta^{-1}(r)) = (q', r', i)$.

Recall that $\Sigma = \{0,1\}$. Define $\nu : \Gamma^* \to \mathbb{N}$ recursively as $\nu(\epsilon) = 0$ and, for each $y \in \Gamma$ and $w \in \Gamma^*$,

$$\nu(wy) = \begin{cases} 1 + 2\nu(w) & \text{if } y = 1 \wedge w \in \Sigma^* \\ 2\nu(w) & \text{if } y = 0 \wedge w \in \Sigma^* \\ \nu(w) & \text{if } y = B \\ 0 & \text{otherwise.} \end{cases}$$

This has the property that if $z \in \Sigma^*B^*$, then $\nu(z)$ is the natural number that z represents in binary. And if $z \in \Gamma^* - \Sigma^*B^*$, then $\nu(z) = 0$.

We also need the following notation. For any domain S, any (possibly partial)

function $h : S \to S$, any $i \in \mathbb{N}$, and any $s \in S$, we define $h^{(i)}(s)$ as

$$h^{(i)}(s) =_{\text{def}} \begin{cases} s & \text{if } i = 0 \\ h(h^{(i-1)}(s)) & \text{if } i > 0 \wedge (h^{(i-1)}(s) \text{ is defined}) \wedge \\ & \qquad (h^{(i-1)}(s) \in \text{domain}(h)) \\ \text{undefined} & \text{otherwise.} \end{cases}$$

Note that if $h(a)$ is undefined, then so, for example, will be $h^{(1)}(a)$ and $h^{(2)}(a)$.

All logarithms in this paper are base two, i.e., $\log m$ means $\log_2 m$. Define functions r, s, and t on input $n \in \mathbb{N}$ as $r(n) =_{\text{def}} \lceil \log p(n) \rceil$ (recall that, by assumption, on any input of length n, M uses at most $p(n)$ tape cells and $p(n) > 0$), $t(n) =_{\text{def}} m2^{r(n)}$, and $s(n) =_{\text{def}} m + r(n) + t(n)$.

Let $\mathtt{eID} =_{\text{def}} \bigcup_{n=0}^{\infty} \{0,1\}^{n+2s(n)}$ be the set of *enhanced instantaneous descriptions* of M. Informally speaking, for each $n \in \mathbb{N}$ and $x \in \Sigma^n$, $q \in \{0,1\}^m$, $c \in \Sigma^{s(n)}$, $w \in \Sigma^{r(n)}$, and $X_0, X_1, \ldots, X_{2^{r(n)}-1} \in \Sigma^m$, the string $xqcwX_0X_1 \cdots X_{2^{r(n)}-1} \in \mathtt{eID}$ is interpreted as follows.

- The string x represents the input to f.
- The string q represents the instantaneous state of M.
- The string c will be used as an external clock ("external" because it is not maintained by M itself but rather by an "outside observer") to count the number of computational steps M has made so far. The presence of the external clock will allow us to adapt the next move function of M to the enhanced instantaneous descriptions of M in such a way that cycles never occur, even if M from a particular configuration may cycle. Note that, since the number of tape cells M uses is polynomially bounded in the length of its input, we need only a polynomial amount of bits for the clock. Intuitively speaking, if the clock "runs out of time" by running out of bits, then (assuming we chose a large enough polynomial to control the number of clock bits) we know that a cycle has occurred.
- The string w encodes the instantaneous position of the tape head, i.e., a position of 0 or 1 or ... or $2^{r(|x|)} - 1$ is encoded (respectively) by the string $0^{r(x)}$ or $0^{r(x)-1}1$ or ... or $1^{r(x)}$.
- The strings $X_0, X_1, \ldots, X_{2^{r(n)}-1}$ represent the instantaneous contents of the leftmost $2^{r(n)}$ tape cells of M.

Note that the second, fourth, and fifth sections of the string described above (i.e., q, w, and $X_0, X_1, \ldots, X_{2^{r(n)}-1}$) are already sufficient to describe M at any instant. Note also that, because s, r, and t are all polynomial-time computable and nondecreasing, we can, in polynomial time, for each $n \in \mathbb{N}$ and each $z \in \Sigma^{n+2s(n)}$, compute from z the value n and the locations of the five above-described sections of z, and these locations are well-defined.

For each $x \in \Sigma^*$, we call $x0^m0^{s(|x|)}0^{r(|x|)}\varphi(x)0^{t(|x|)-|\varphi(x)|} = x0^{2s(|x|)-t(|x|)}\varphi(x)0^{t(|x|)-|\varphi(x)|} \in \mathtt{eID}$ the *initial configuration* of M on x, denoted $i_{M,x}$. The string $i_{M,x}$ represents a configuration on which M would be started under "normal usage." Note that eID contains strings that represent configurations of M that are never reached under "normal usage." From these "unreachable" configurations, M may run forever or attempt to move off the left end of the tape. (Note that the true run of M on input x certainly does not run forever, since M is computing an FPSPACE(poly) function and FPSPACE(poly) is a class of total functions, and our model of function computing requires M to halt in order for it to compute a value. Recall that we assume that on no true run of M on input x will M attempt to move off the left end

of the tape. We did not explicitly discuss the semantics of attempting to move off the left end of the tape, but the point of the comment above is that even if our model of computing FPSPACE(poly) functions is such that moving off the left end of the tape is considered like running forever and makes a function be undefined on the input, and so never happens on a true run of a machine computing an FPSPACE(poly) function, it nonetheless may be the case that such a machine when started at some "unreachable" configuration might attempt to run off the left end of the tape.)

We define a *move* over $\texttt{eID}$ via a function $\mu : \Sigma^* \to \Sigma^*$ that we will define now. An important consideration in the design of μ is to exploit the additional information present in the enhanced IDs to guarantee that μ never loops and that it always "ends" (i.e., returns the value undefined) "gracefully" (in a sense that will soon become clear, including, for example, that it does not blindly try to move off the left end of the tape).

For each $x \in \Sigma^*$, $c \in \{0,1\}^{s(|x|)}$, $w \in \{0,1\}^{r(|x|)}$, $X_0, X_1, \ldots, X_{2^{r(|x|)}-1} \in \{0,1\}^m$, and $q \in \{0,1\}^m - \{1^m\}$,

$$\mu(xqcwX_0X_1\cdots X_{2^{r(|x|)}-1}) =_{\text{def}} xq'c'w'X_0X_1\cdots X_{\nu(w)-1}YX_{\nu(w)+1}X_{\nu(w)+2}\cdots X_{2^{r(|x|)}-1} \tag{1}$$

if

$$\delta'(q, X_{\nu(w)}) \text{ is defined } \wedge\, c \neq 1^{s(|x|)} \wedge 0 \leq \nu(w) + i < 2^{r(|x|)}, \tag{2}$$

where

$$\delta'(q, X_{\nu(w)}) = (q', Y, i),\ c' \in \{0,1\}^{s(|x|)},\ w' \in \{0,1\}^{r(|x|)},$$
$$\nu(c') = \nu(c) + 1, \text{ and } \nu(w') = \nu(w) + i,$$

and

$$\mu(xqcwX_0X_1\cdots X_{2^{r(|x|)}-1}) =_{\text{def}} x1^mcwX_0X_1\cdots X_{2^{r(|x|)}-1} \tag{3}$$

otherwise. If $q = 1^m$, $\mu(xqcwX_0X_1\cdots X_{2^{r(|x|)}-1})$ is undefined. For all $y \notin \texttt{eID}$, $\mu(y)$ is undefined. It is easy to see that the behavior of μ described by (1) is roughly analogous to the behavior of δ. Indeed, for all $x \in \Sigma^*$, there exists a number $j \in \mathbb{N}$ such that $\mu^{(j)}(i_{M,x}) = x1^mcwz$, where $c \in \{0,1\}^{s(|x|)}$, $w \in \{0,1\}^{r(|x|)}$, $z \in \{0,1\}^{t(|x|)}$, $\nu(c) = j$, and $\nu(\hat{\theta}^{-1}(z)) = f(x)$. Equation (3) enforces "gracefulness" by detecting when the configuration encoded by the input string is about to move off the left end of the tape or is about to use too much tape or has a "c" value that has already reached $2^{s(|x|)}$ (note that no actual run can ever run more than $2^{s(n)}$ steps without running forever, but running forever can never happen on actual runs since all functions in FPSPACE(poly) are total). In such cases, μ simply changes the state bits to represent the final state (i.e., 1^m).

Proposition 6.11 collects several easy-to-see properties of μ.

PROPOSITION 6.11.

1. *The function μ is polynomial-time computable.*
2. *The function μ is length-preserving, i.e., for all $w \in \Sigma^*$, if $\mu(w)$ is defined, then $|w| = |\mu(w)|$.*
3. *For all $x \in \Sigma^*$, all $w \in \{0,1\}^{2s(|x|)-m}$, and all $q \in \{0,1\}^m$, $\mu(xqw)$ is defined if and only if $q \neq 1^m$.*
4. *For all $w \in \Sigma^*$, there exists a number j such that $\mu^{(j)}(w)$ is undefined.*

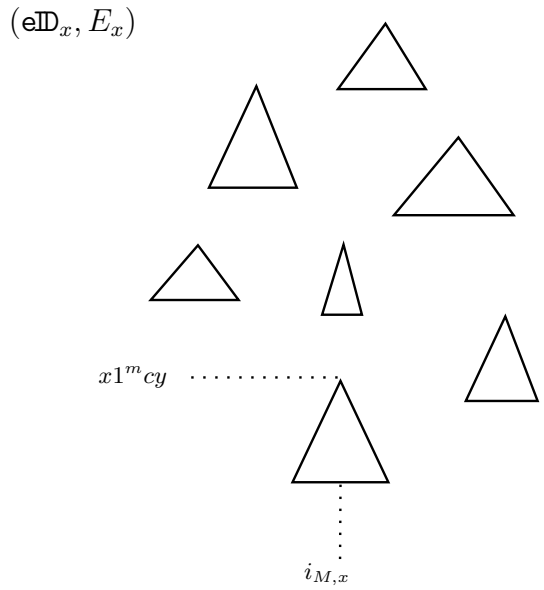

FIG. 3. *The directed forest* $(\mathbb{eID}_x, E_x)$. *Note that precisely one tree in the digraph* $(\mathbb{eID}_x, E_x)$ *has* $i_{M,x}$ *as a node, and note that in that tree* $i_{M,x}$ *will be a leaf node. For some* c *and* y *satisfying* $c \in \{0,1\}^{2s(|x|)-t(|x|)-m}$, $y \in \{0,1\}^{t(|x|)}$, *and* $\nu(\hat{\theta}^{-1}(y)) = f(x)$, *that tree will have as its root node* $x1^m cy$.

5. *In polynomial time we can, for each* $z \in \Sigma^*$, *enumerate all* y *such that* $\mu(y) = z$.
6. *For each* $w \in \mathbb{eID}$ *and each* $j \in \mathbb{N}^+$, *if* $\mu^{(j)}(w)$ *is defined, then* $\mu^{(j)}(w) \neq w$.

Proof. All items are easy to see. However, item 5 deserves some additional explanation. To perform this enumeration, if $z \notin \mathbb{eID}$, then there is no y such that $\mu(y) = z$. If $z \in \mathbb{eID}$, then examine the next move function of M to determine the configurations from which M in one step will move into the configuration encoded by z. There are only a constant number of such configurations. Output the strings of length $|z|$ that encode these configurations. This takes care of all preimages of z that satisfy equation (2). If, for some $x \in \Sigma^*$, $c \in \{0,1\}^{s(|x|)}$, $w \in \{0,1\}^{r(|x|)}$, and $X_0, X_1, \ldots, X_{2^{r(|x|)}-1} \in \{0,1\}^m$ it holds that $z = x1^m cwX_0X_1 \cdots X_{2^{r(|x|)}-1}$ (i.e., if z satisfies the conditions of equation (3)) then, for each $q \in \{0,1\}^m - \{1^m\}$ such that $xqcwX_0X_1 \cdots X_{2^{r(|x|)}-1}$ does not satisfy equation (2), output $xqcwX_0X_1 \cdots X_{2^{r(|x|)}-1}$. This takes care of all preimages of z that do not satisfy equation (2). □

Phase 3: Building trees. For each $x \in \Sigma^*$, let

$$\mathbb{eID}_x = \{xw \mid w \in \{0,1\}^{2s(|x|)}\}$$

and

$$E_x = \{(xw, xz) \mid xw, xz \in \mathbb{eID}_x \wedge \mu(xw) = xz\}.$$

A directed forest is an acyclic digraph in which all nodes have outdegree at most one. Note that the digraph $(\mathbb{eID}_x, E_x)$ has outdegree at most one. By Proposition 6.11.6, $(\mathbb{eID}_x, E_x)$ is acyclic. Thus, $(\mathbb{eID}_x, E_x)$ is a directed forest (see Figure 3).

For each $x \in \Sigma^*$, let (keep in mind that given the string $xw \in \mathbb{eID}$, it is easy to identify x and w)

$$\mathbb{eID}'_x = \{xwy \mid xw \in \mathbb{eID}_x \wedge y \in \{0,1\}^{t(|x|)}\}$$

and

$$E'_x = \{(xwy, xzy) \mid w \in \{0,1\}^{2s(|x|)} \wedge y \in \{0,1\}^{t(|x|)} \wedge xwy \in \mathbb{eID}'_x \wedge \mu(xw) = xz\}.$$

Note that the digraph $(\mathbb{eID}'_x, E'_x)$ is a directed forest, and that, for each tree in $(\mathbb{eID}_x, E_x)$, there are exactly $2^{t(|x|)}$ corresponding trees in $(\mathbb{eID}'_x, E'_x)$ (see Figure 4 for a pictorial preview of this part of the construction).

Let $\mathrm{R}_x =_{\mathrm{def}} \{xwy \in \mathbb{eID}'_x \mid w \in \{0,1\}^{2s(|x|)} \wedge y \in \{0,1\}^{t(|x|)} \wedge (\mu(xw) \text{ is undefined})\}$. Note that, by Proposition 6.11.3, $\mathrm{R}_x = \{xwy \in \mathbb{eID}'_x \mid w \in \{0,1\}^{2s(|x|)} \wedge y \in \{0,1\}^{t(|x|)} \wedge (xw \text{ is the root of a tree in } (\mathbb{eID}_x, E_x))\} = \{x1^m wy \in \mathbb{eID}'_x \mid w \in \{0,1\}^{2s(|x|)-m} \wedge y \in \{0,1\}^{t(|x|)}\}$. Let $\leq_{\mathrm{R}_x}$ denote the order (with $<_{\mathrm{R}_x}$ and $\prec_{\mathrm{R}_x}$ denoting the corresponding "less than" and "predecessor" relations, respectively) defined over R_x that is determined by the following sequence. (The reader is cautioned that in what follows "w" is used as a variable to catch substrings of various lengths other than the $2s(|x|)$-length strings it has been primarily used for so far.)

- First come the elements of $\{xwyy \in \mathrm{R}_x \mid w \in \{0,1\}^{2s(|x|)-t(|x|)} \wedge y \in \{0,1\}^{t(|x|)}\}$ in lexicographic order. Note that the last element in this sequence is $x1^{2s(|x|)+t(|x|)}$.
- Next come the elements of $\{xwdy \in \mathrm{R}_x \mid w \in \{0,1\}^{2s(|x|)-t(|x|)} \wedge d, y \in \{0,1\}^{t(|x|)} \wedge d \neq y\}$ in lexicographic order. Note that the last element in this sequence is $x1^{2s(|x|)+t(|x|)-1}0$.

For each $x \in \Sigma^*$, $w \in \{0,1\}^{2s(|x|)}$, and $y \in \{0,1\}^{t(|x|)}$, we define $\mu_1 : \Sigma^* \to \Sigma^*$, on input xwy, as

$$\mu_1(xwy) = \begin{cases} \mu(xw)y & \text{if } xwy \notin \mathrm{R}_x \\ xz & \text{if } xwy \in \mathrm{R}_x \wedge xwy \neq x1^{2s(|x|)+t(|x|)-1}0, \text{ where } xwy \prec_{R_x} xz. \end{cases}$$

In all other cases, μ_1 is undefined. Informally speaking, μ_1 is an "augmented next move" function based on μ but with the difference that μ_1 in effect strings together all the trees in $(\mathbb{eID}'_x, E'_x)$ into one giant tree $T_{M,x}$ (see Figure 4 again).

PROPOSITION 6.12. *For each $x \in \Sigma^*$, let $E''_x =_{\mathrm{def}} \{(w,z) \mid w \in \mathbb{eID}'_x \wedge \mu_1(w) = z\}$, and define $T_{M,x}$ to be the digraph $(\mathbb{eID}'_x, E''_x)$.*

1. *The function μ_1 is polynomial-time computable.*
2. *The function μ_1 is length-preserving (i.e., on inputs a for which it is not undefined, $|\mu_1(a)| = |a|$).*
3. *In polynomial time we can, for any $z \in \Sigma^*$, enumerate all $y \in \Sigma^*$ such that $\mu_1(y) = z$.*
4. *For every $x \in \Sigma^*$ and every $w \in \{0,1\}^{2s(|x|)+t(|x|)}$, there exists a number $j \in \mathbb{N}$ such that $\mu_1^{(j)}(xw) = x1^{2s(|x|)+t(|x|)-1}0$. (See also Figure 4.)*
5. *For every $x \in \Sigma^*$ and every $w \in \{0,1\}^{2s(|x|)+t(|x|)}$, $\mu_1(xw)$ is undefined if and only if $w = 1^{2s(|x|)+t(|x|)-1}0$.*
6. *For each $x \in \Sigma^*$ and each $w \in \{0,1\}^{2s(|x|)}$, there is a unique $y \in \{0,1\}^{t(|x|)}$ such that, for some $k \in \mathbb{N}$, $\mu_1^{(k)}(xwy) = x1^{2s(|x|)+t(|x|)}$. (Again, viewing Figure 4—paying particular attention to the black trees—will help make this clear).*
7. *For each $x \in \Sigma^*$, $\|\{w \mid (\exists j \in \mathbb{N})[\mu_1^{(j)}(w) = x1^{2s(|x|)+t(|x|)}]\}\| = 2^{2s(|x|)}$.*

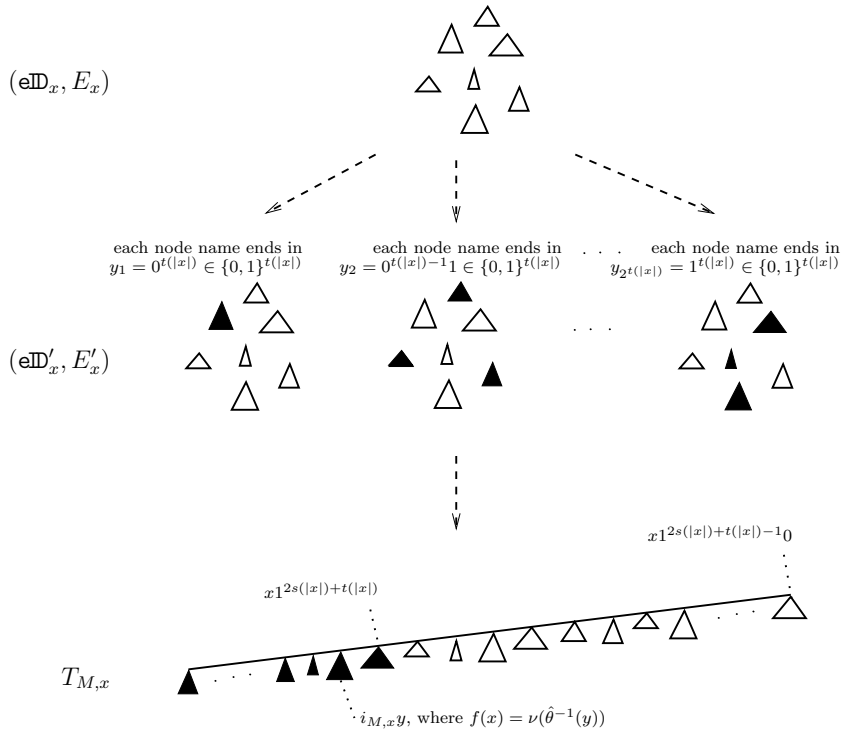

FIG. 4. *Transforming the directed forest* $(\mathbb{eID}_x, E_x)$ *into* $T_{M,x}$. *First,* $2^{t(|x|)}$ *copies of each tree in* $(\mathbb{eID}_x, E_x)$ *are made by appending* $t(|x|)$ *"guess" bits to each node in each original tree, creating the directed forest* $(\mathbb{eID}'_x, E'_x)$. *Next, the trees in* $(\mathbb{eID}'_x, E'_x)$ *are strung together into a single tree* $T_{M,x}$ *in such a way that a subtree of* $T_{M,x}$ *is formed by the trees in* $(\mathbb{eID}'_x, E'_x)$ *having (note:* R_x *will be defined in the main text) roots in* $\{xwyy \in \mathrm{R}_x \mid w \in \{0,1\}^{2(|s|)-t(|x|)} \wedge y \in \{0,1\}^{t(|x|)}\}$ *(represented in the figure by the black trees), i.e., the trees whose "guess" bits equal the contents of the machine tape at the end of the computation. This subtree has exactly one node for each string in* $\mathbb{eID}_x$, *including* $i_{M,x}$, *and the node associated with* $i_{M,x}$ *has as its "guess" bits the true output of* M *on input* x. *We will later exploit this information when we define a traversal of this tree.*

8. *For each* $x \in \Sigma^*$, *the unique (by item 6)* $y \in \{0,1\}^{t(|x|)}$, *and each* $k \in \mathbb{N}$ *such that* $\mu_1^{(k)}(i_{M,x}y) = x1^{2s(|x|)+t(|x|)}$, *it holds that* $f(x) = \nu(\hat{\theta}^{-1}(y))$.
9. *For each* $x \in \Sigma^*$, *the digraph* $T_{M,x}$ *is a tree.*
10. *The subtree of* $T_{M,x}$ *rooted at* $x1^{2s(|x|)+t(|x|)}$ *has exactly* $2^{2s(|x|)}$ *nodes.*

Proof. Items 1–5 follow from the definition of μ_1.

For item 6, choose an arbitrary $x \in \Sigma^*$, $w \in \{0,1\}^{2s(|x|)}$, and $y \in \{0,1\}^{t(|x|)}$, and let $j \in \mathbb{N}$, $v \in \{0,1\}^{2s(|x|)-t(|x|)}$, and $d \in \{0,1\}^{t(|x|)}$ be such that $\mu^{(j)}(xw) = xvd$ and $\mu(xvd)$ is undefined (such j, v, and d exist by Propositions 6.11.4 and 6.11.2). By the definition of R_x, $xvdy \in \mathrm{R}_x$. By the definition of $\leq_{\mathrm{R}_x}$, $\mu^{(j)}(xw)d \leq_{\mathrm{R}_x} x1^{2s(|x|)+t(|x|)}$ and so, by the definition of μ_1, there exists a number $k \geq j$ such that $\mu_1^{(k)}(xwd) = x1^{2s(|x|)+t(|x|)}$. On the other hand, for all $y \in \{0,1\}^{t(|x|)}$ such that $y \neq d$, by the definition of $\leq_{\mathrm{R}_x}$, $x1^{2s(|x|)+t(|x|)} <_{\mathrm{R}_x} \mu^{(j)}(xw)y$, and so, by items 4 and 5 (which guarantee that μ_1 does not cycle), there is no k such that $\mu_1^{(k)}(xwy) = x1^{2s(|x|)+t(|x|)}$.

Item 7 follows from item 6.

For item 8, choose an arbitrary $x \in \Sigma^*$, and by item 6 let y be the unique member of $\{0,1\}^{t(|x|)}$ such that, for some $k \in \mathbb{N}$, $\mu_1^{(k)}(i_{M,x}y) = x1^{2s(|x|)+t(|x|)}$. Choose

$j \in \mathbb{N}$ such that $\mu^{(j)}(i_{M,x})y \in \mathrm{R}_x$. By the definition of μ_1, there exists a number $v \in \{0,1\}^{2s(|x|)-t(|x|)}$ such that $\mu^{(j)}(i_{M,x}) = xvy$ and, by the definition of μ, M on input x halts with y on its tape. Thus, $f(x) = \nu(\hat{\theta}^{-1}(y))$.

Item 9 follows from items 4 and 5.

Item 10 follows from item 7 and the observation that, for any $x \in \Sigma^*$ and any $w, y \in \mathtt{eID}'$, w is in the subtree of $T_{M,x}$ rooted at y if and only if y is a node of $T_{M,x}$ and there exists a number $k \in \mathbb{N}$ such that $\mu_1^{(k)}(w) = y$. □

Phase 4: Defining a traversal. We define $\mathtt{dwn} : \Sigma^* \to \Sigma^* \cup \{\perp\}$, on input w, as

$$\mathtt{dwn}(w) = \begin{cases} \max_{\mathrm{lex}} \mu_1^{-1}(w) & \text{if } \mu_1^{-1}(w) \neq \emptyset \\ \perp & \text{otherwise,} \end{cases}$$

where $\max_{\mathrm{lex}}$ returns the maximal element (with respect to the lexicographical order) of a set of strings and we define $\mathtt{acr} : \Sigma^* \to \Sigma^* \cup \{\perp\}$ on input w as

$$\mathtt{acr}(w) = \begin{cases} \max_{\mathrm{lex}}\{w' \mid w' \in \mu_1^{-1}(\mu_1(w)) \wedge w' <_{\mathrm{lex}} w\} & \text{if } \mu_1(w) \text{ is defined} \\ & \quad \wedge\, w \neq \min_{\mathrm{lex}} \mu_1^{-1}(\mu_1(w)) \\ \perp & \text{otherwise,} \end{cases}$$

where $\min_{\mathrm{lex}}$ returns the minimal element (with respect to the lexicographical order) of a set of strings. Clearly, both $\mathtt{dwn}$ and $\mathtt{acr}$ are polynomial-time computable. The function $\mathtt{dwn}$ is named "$\mathtt{dwn}$" because it describes a descent down the tree $T_{M,x}$, and $\mathtt{acr}$ is named "$\mathtt{acr}$" because it describes movement across the tree (i.e., from one sibling node to another). Note that, for all $x \in \Sigma^*$ and all $w \in \{0,1\}^{2s(|x|)+t(|x|)}$ satisfying $xw \in \mathrm{R}_x - \{x1^m0^{2s(|x|)+t(|x|)-m}\}$, it holds that $\mathtt{dwn}(xw) \in \mathrm{R}_x$.

Now, for each $x \in \Sigma^*$, $w \in \{0,1\}^{2s(|x|)}$, $a \in \{0,1\}$, and $y, z \in \{0,1\}^{t(|x|)}$, we define $D_M : \Sigma^* \to \Sigma^*$, a "depth-first"-like traversal of $T_{M,x}$, on input $xwyza$, as

$$D_M(xwyza) = \begin{cases} \mathtt{dwn}(xwy)z0 & \text{if } a = 0 \wedge \mathtt{dwn}(xwy) \neq \perp \wedge \nu(z) = 0 \\ xwyz1 & \text{if } a = 0 \wedge \mathtt{dwn}(xwy) = \perp \wedge xw \neq i_{M,x} \wedge \nu(z) = 0 \\ xwyz'0 & \text{if } a = 0 \wedge \mathtt{dwn}(xwy) = \perp \wedge xw = i_{M,x} \wedge \\ & \qquad \nu(z) < \nu(\hat{\theta}^{-1}(y)), \text{ where } z \prec_{\mathrm{lex}} z' \\ xwy0^{t(|x|)}1 & \text{if } a = 0 \wedge \mathtt{dwn}(xwy) = \perp \wedge xw = i_{M,x} \wedge \\ & \qquad \nu(z) = \nu(\hat{\theta}^{-1}(y)) \\ \mathtt{acr}(xwy)z0 & \text{if } a = 1 \wedge \mathtt{acr}(xwy) \neq \perp \wedge \nu(z) = 0 \\ \mu_1(xwy)z1 & \text{if } a = 1 \wedge \mathtt{acr}(xwy) = \perp \wedge \nu(z) = 0. \end{cases}$$

On all other inputs, D_M is undefined. Figure 5 illustrates the action of D_M and Proposition 6.13 formally establishes the most important aspects of D_M's action, most of which we will draw on soon.

PROPOSITION 6.13.

1. *The function D_M is polynomial-time computable.*
2. *The function D_M is length-preserving (i.e., for each v, either $D_M(v)$ is undefined or $|D_M(v)| = |v|$).*
3. *For each $x \in \Sigma^*$, each subtree (and here we really mean each subtree, i.e., not just those corresponding to the trees in digraph $(\mathtt{eID}'_x, E'_x)$—the purpose of this item is to provide insight into how D_M describes a traversal of $T_{M,x}$) T of $T_{M,x}$, each $w \in \{0,1\}^{2s(|x|)}$, and each $y \in \{0,1\}^{t(|x|)}$, xwy is a node of T if and only if there exist i, j, and k such that $|v| = |xwy|$ (where v is the*

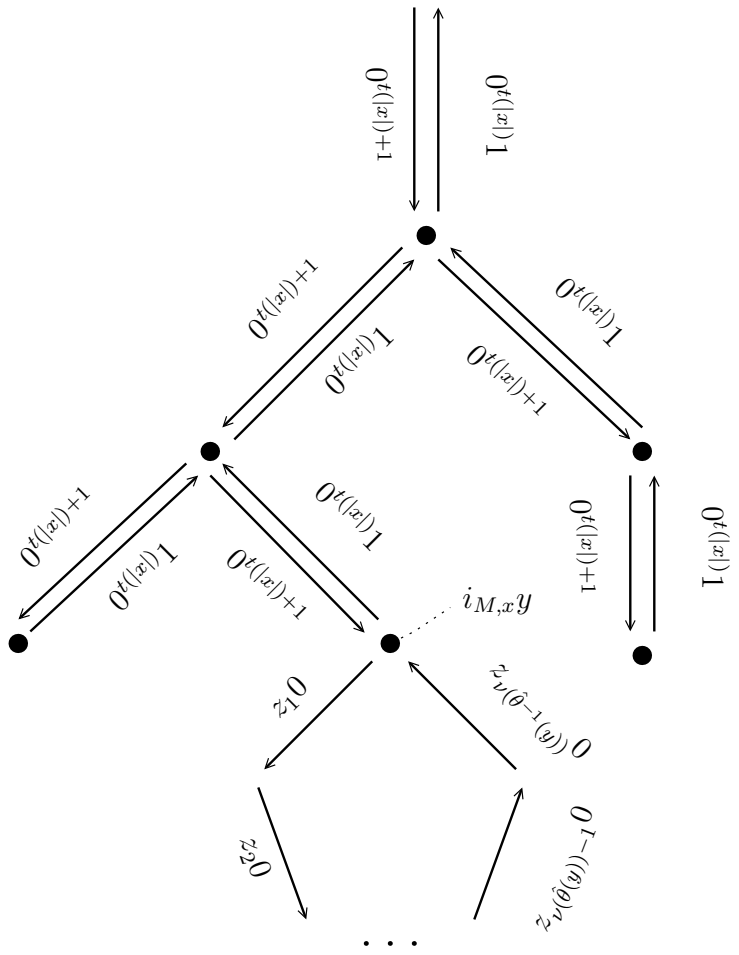

FIG. 5. *The traversal described by D_M. Pictured is a portion of $T_{M,x}$ that contains a node in the initial configuration. The arrows represent the strings associated with the node below them (in the case of the initial configuration node, the arrows below are also associated with it) by padding. The string that is the actual padding appears next to each arrow. D_M is defined over these padded strings. The last bit of each padding string can be seen as controlling the "direction" in which D_M "moves." Note that $y \in \{0,1\}^{t(|x|)}$ and $z_1 = 0^{t(|x|)-1}1, z_2 = 0^{t(|x|)-2}10, \ldots$.*

root of T), $D_M^{(i)}(v0^{t(|x|)+1}) = xwy0^{t(|x|)+1}$, $D_M^{(j)}(xwy0^{t(|x|)+1}) = xwy0^{t(|x|)}1$, and $D_M^{(k)}(xwy0^{t(|x|)}1) = v0^{t(|x|)}1$.

4. *For every $x \in \Sigma^*$, $w \in \{0,1\}^{2s(|x|)}$, $a \in \{0,1\}$, and $y, z \in \{0,1\}^{t(|x|)}$, $D_M(xwyza)$ is defined if and only if $xwyza = x1^{2s(|x|)+t(|x|)-1}0^{t(|x|)+2} \vee (wy \in \{0,1\}^{2s(|x|)+t(|x|)} - \{1^{2s(|x|)+t(|x|)-1}0\} \wedge z = 0^{t(|x|)}) \vee (xw = i_{M,x} \wedge \nu(z) \leq \nu(\hat{\theta}^{-1}(y)) \wedge a = 0)$.*
5. *For every $x \in \Sigma^*$ and every $w \in \{0,1\}^{2(s(|x|)+t(|x|))+1}$, if $D_M(xw)$ is defined, then there exists an $i \in \mathbb{N}$ such that $D_M^{(i)}(x1^{2s(|x|)+t(|x|)-1}0^{t(|x|)+2}) = xw$.*
6. *For all $x \in \Sigma^*$, all $w \in \{0,1\}^{2s(|x|)+t(|x|)}$, all $z \in \{0,1\}^{t(|x|)+1}$, and all $i \in \mathbb{N}$, if $D_M^{(i)}(xwz) = x1^{2s(|x|)+t(|x|)}0^{t(|x|)+1}$, then $xw \in \mathrm{R}_x$.*
7. *The function $\lambda y.\min_{\mathrm{lex}}\{w \mid y <_{\mathrm{lex}} w \wedge (D_M(w)$ is undefined$)\}$ is polynomial-time computable.*

Proof. Items 1 and 2 follow from the definition of D_M.

For item 3, choose an arbitrary $x \in \Sigma^*$. We prove item 3 by induction over the depth of the subtrees of $T_{M,x}$.

For the base case, choose an arbitrary subtree T of $T_{M,x}$ having depth 1. Let v be the (only) node of T. Thus, $\mathtt{dwn}(v) = \perp$. If, for all $y \in \{0,1\}^{t(|x|)}$, $v \neq i_{M,x}y$, then, by the definition of D_M, $D_M^{(0)}(v0^{t(|x|)+1}) = v0^{t(|x|)+1}$, $D_M(v0^{t(|x|)+1}) = v0^{t(|x|)}1$, and $D_M^{(0)}(v0^{t(|x|)}1) = v0^{t(|x|)}1$. Otherwise, let $y \in \{0,1\}^{t(|x|)}$ be such that $v = i_{M,x}y$. Then $D_M^{(0)}(v0^{t(|x|)+1}) = v0^{t(|x|)+1}$, $D_M^{(\nu(\hat{\theta}^{-1}(y))+1)}(v0^{t(|x|)+1}) = v0^{t(|x|)}1$, and $D_M^{(0)}(v0^{t(|x|)}1) = v0^{t(|x|)}1$.

For the induction case, suppose, for some n that is less than the depth of $T_{M,x}$ and all subtrees T of $T_{M,x}$ having depth at most n, that the induction hypothesis holds. Let S be a subtree of $T_{M,x}$ of depth $n+1$, and let v be the root of S. Let $\{a_1, \ldots, a_b\} = \mu_1^{-1}(v)$, where $a_b <_{\text{lex}} \cdots <_{\text{lex}} a_1$. It follows that each $a_1, \ldots, a_b$ is the root of a subtree of S of depth at most n. By the definition of D_M, $D_M(v0^{t(|x|)+1}) = a_1 0^{t(|x|)+1}$, $D_M(a_1 0^{t(|x|)}1) = a_2 0^{t(|x|)+1}, \ldots, D_M(a_{b-1}0^{t(|x|)}1) = a_b 0^{t(|x|)+1}$, and $D_M(a_b 0^{t(|x|)}1) = v0^{t(|x|)}1$. By applying the induction hypothesis to the subtrees of S rooted at $a_1, \ldots, a_b$, we conclude that z is a node of S if and only if there exist i, j, k such that $D_M^{(i)}(v0^{t(|x|)+1}) = z0^{t(|x|)}1$, $D_M^{(j)}(z0^{t(|x|)+1}) = z0^{t(|x|)}1$, and $D_M^{(k)}(z0^{t(|x|)}1) = v0^{t(|x|)}1$.

Item 4 follows from the definition of D_M (to see the case where $xwyza = x1^{2s(|x|)+t(|x|)-1}0^{t(|x|)+2}$, it helps to note that μ_1 is undefined on $x1^{2s(|x|)+t(|x|)-1}0$ and thus $D_M(x1^{2s(|x|)+t(|x|)-1}0^{t(|x|)+2})$ is defined but $D_M(x1^{2s(|x|)+t(|x|)-1}0^{t(|x|)+1}1)$ is not).

For item 5, choose arbitrary $x \in \Sigma^*$, $w \in \{0,1\}^{2s(|x|)}$, $a \in \{0,1\}$, and $y, z \in \{0,1\}^{t(|x|)}$. If $xwyza = x1^{2s(|x|)+t(|x|)-1}0^{t(|x|)+2} \vee (wy \in \{0,1\}^{2s(|x|)+t(|x|)} - \{1^{2s(|x|)+t(|x|)-1}0\} \wedge z = 0^{t(|x|)})$, then, by item 3, there exists an $i \in \mathbb{N}$ such that $D_M^{(i)}(x1^{2s(|x|)+t(|x|)-1}0^{t(|x|)+2}) = xwyza$. If $xw = i_{M,x} \wedge \nu(z) \leq \nu(\hat{\theta}^{-1}(y)) \wedge a = 0$, then, by the definition of D_M, $D_M^{(\nu(z))}(xwy0^{t(|x|)+1}) = xwyza$. Since, by item 3, there exists an $i \in \mathbb{N}$ such that $D_M^{(i)}(x1^{2s(|x|)+t(|x|)-1}0^{t(|x|)+2}) = xwy0^{t(|x|)+1}$, it holds that $D_M^{(i+\nu(z))}(x1^{2s(|x|)+t(|x|)-1}0^{t(|x|)+2}) = xwyza$.

For item 6, choose an arbitrary $x \in \Sigma^*$. Recall that, for all $xw \in \mathrm{R}_x - \{x1^m 0^{2s(|x|)+t(|x|)-m}\}$, $\mathtt{dwn}(xw) \in \mathrm{R}_x$. Thus, since $x1^{2s(|x|)+t(|x|)} \in \mathrm{R}_x$ and $x1^{2s(|x|)+t(|x|)-1}0 \in \mathrm{R}_x$, it follows from the definitions of $\mathtt{dwn}$ and $\leq_{\mathrm{R}_x}$ that, for some $i \in \mathbb{N}$, $\mathtt{dwn}^{(i)}(x1^{2s(|x|)+t(|x|)-1}0) = x1^{2s(|x|)+t(|x|)}$, and for all $j \in \mathbb{N}$ such that $0 \leq j \leq i$, it holds that $\mathtt{dwn}^{(j)}(x1^{2s(|x|)+t(|x|)-1}0) \in \mathrm{R}_x$. Thus, by the definition of D_M, $D_M^{(i)}(x1^{2s(|x|)+t(|x|)-1}0^{t(|x|)+2}) = x1^{2s(|x|)+t(|x|)}0^{t(|x|)+1}$, and for all $j \in \mathbb{N}$ such that $0 \leq j \leq i$, it holds that $D_M^{(j)}(x1^{2s(|x|)+t(|x|)-1}0^{t(|x|)+2}) = w0^{t(|x|)+1}$, where $w \in \mathrm{R}_x$.

For item 7, note that, by item 4, for all $w, y, z \in \Sigma^*$ such that $w \prec_{\text{lex}} y \prec_{\text{lex}} z$, either $D_M(y)$ is undefined or $D_M(z)$ is undefined. □

Phase 5: Creating *A*. We are now ready to define A. A is the same as the lexicographical ordering except that the strings between $x0^{2(s(|x|)+t(|x|))+1}$ and $x1^{2(s(|x|)+t(|x|))+1}$ are ordered as follows (let $z = x1^{2s(|x|)+t(|x|)-1}0^{t(|x|)+1}$).

- First come the strings $D_M^{(0)}(z0) = z0$, $D_M^{(1)}(z0) = D_M(z0)$, $D_M^{(2)}(z0), \ldots, z1$, in the order just stated.
- Next come the strings $\{xw \mid w \in \{0,1\}^{2(s(|x|)+t(|x|))+1} \wedge D_M(xw)$ is undefined

$\wedge xw \neq z1\}$, in lexicographical order.
By Proposition 6.13.2, A is a p-order. By Proposition 6.13.4, A is total. By Propositions 6.13.1 and 6.13.7, A has efficient adjacency checks.

End of Construction

We are now ready to prove Lemma 6.5.

Proof of Lemma 6.5. For each $f \in$ FPSPACE(poly), we define A as above. We define $b : \Sigma^* \to \Sigma^*$, $t : \Sigma^* \to \Sigma^*$, and $b' : \Sigma^* \to \Sigma^*$ on input $x \in \Sigma^*$ as, respectively, $b(x) =_{\text{def}} x1^{2s(|x|)+t(|x|)}0^{t(|x|)+1}$, $t(x) =_{\text{def}} x1^{2s(|x|)+t(|x|)}0^{t(|x|)}1$, and $b'(x) =_{\text{def}} i_{M,x}y0^{t(|x|)+1}$, where $y = \theta(1)0^{t(|x|)-|\theta(1)|}$ (thus $\nu(\hat{\theta}^{-1}(y)) = 1$). Note that each of these functions is in FP.

For item 1, note that s is polynomially bounded.

For item 2, we prove that, for all $x \in \Sigma^*$, $\|\{z \mid b(x) <_A z <_A t(x)\}\| = 2^{2s(|x|)+1} + f(x) - 2$. Choose an arbitrary $x \in \Sigma^*$. By Proposition 6.13.4, both $D_M(x1^{2s(|x|)+t(|x|)}0^{t(|x|)+1})$ and $D_M(x1^{2s(|x|)+t(|x|)}0^{t(|x|)}1)$ are defined. Thus, by the definition of A, $\{z \mid b(x) <_A z <_A t(x)\} = \{z \mid (\exists i, k \in \mathbb{N} : i > 0 \wedge k > 0)[D_M^{(i)}(b(x)) = z \wedge D_M^{(k)}(z) = t(x)]\}$. By Proposition 6.12.10, there are exactly $2^{2s(|x|)}$ strings in the subtree of $T_{M,x}$ rooted at $x1^{2s(|x|)+t(|x|)}$. Let $S = \{xwy0^{t(|x|)}a \mid w \in \{0,1\}^{2s(|x|)} \wedge a \in \{0,1\} \wedge y \in \{0,1\}^{t(|x|)} \wedge b(x) <_A xwy0^{t(|x|)}a <_A t(x)\}$. By Proposition 6.13.3, $\|S\| = 2^{2s(|x|)+1} - 2$. By Propositions 6.12.6 and 6.13.3, there is a unique $y' \in \{0,1\}^{t(|x|)}$ such that $i_{M,x}y'0^{t(|x|)+1} \in \{z \mid b(x) <_A z <_A t(x)\}$. Moreover, by Proposition 6.12.8, $\nu(\hat{\theta}^{-1}(y')) = f(x)$. By the definition of D_M, $D_M^{(\nu(\hat{\theta}^{-1}(y'))+1)}(i_{M,x}y'0^{t(|x|)+1}) \in S$, and for each $i \in \mathbb{N}$ such that $0 < i \leq \nu(\hat{\theta}^{-1}(y'))$, it holds that $D_M^{(i)}(i_{M,x}y'0^{t(|x|)+1}) \notin S$. For each of the remaining $2^{2s(|x|)+1} - 3$ strings w in S, $D_M(w) \in S \cup \{t(x)\}$. Thus $\|\{z \mid b(x) <_A z <_A t(x)\}\| = 2^{2s(|x|)+1} + f(x) - 2$.

For item 3, we prove that $\|\{z \mid b'(x) <_A z <_A t(x)\}\| > 0$ if and only if $f(x) = 1$. Choose $x \in \Sigma^*$ and let $y = \theta(1)0^{t(|x|)-|\theta(1)|}$. Suppose that $f(x) = 1$. Then, by Proposition 6.12.8, $xi_{M,x}y$ is in the subtree of $T_{M,x}$ rooted at $x1^{2s(|x|)+t(|x|)}$. Thus, by Proposition 6.13.3, there exists a k such that $D_M^{(k)}(b'(x)) = t(x)$. By the definitions of D_M, b', and t, $D_M(b'(x)) \neq t(x)$, thus $k > 1$. By the definition of A, $\|\{z \mid b'(x) <_A z <_A t(x)\}\| > 0$. Now, suppose $f(x) \neq 1$. Since $f(x) \neq \nu(\hat{\theta}^{-1}(y))$, it follows from Proposition 6.12.8 that $i_{M,x}y$ is not in the subtree of $T_{M,x}$ rooted at $x1^{2s(|x|)+t(|x|)}$. Thus, by Proposition 6.13.3, for all $k \in \mathbb{N}$, $D_M^{(k)}(b'(x)) \neq t(x)$. Thus $b'(x) \not<_A t(x)$, and so $\|\{z \mid b'(x) <_A z <_A t(x)\}\| = 0$. □

7. The complexity of counting divisors. Consider the function $\#\text{DIV} : \mathbb{N} \to \mathbb{N}$, defined on input $m \in \mathbb{N}$ as

$$\#\text{DIV}(m) =_{\text{def}} \begin{cases} \|\{n \in \mathbb{N} \mid n \neq 1, n \neq m, \text{ and } n \text{ divides } m\}\| & \text{if } m \geq 1 \\ 0 & \text{otherwise.} \end{cases}$$

What can we say about its complexity? We claim that #DIV belongs to the interval size function class IF_{p}.

THEOREM 7.1. #DIV *is in* IF_{p}.

Proof. Let PRIMES be the set of all prime numbers. Observe that #DIV $\in$ #P and PRIMES $= \{x \mid \#\text{DIV}(x) = 0\}$. PRIMES $\in$ P [AKS04]. Thus Theorem 7.1 follows from Theorem 5.3. □

8. The complexity of counting satisfying assignments of monotone formulas. In this section, we show that the #MONSAT function fits into our collection of function classes. A *monotone boolean function* is any boolean function such that

changing an input from 0 to 1 (while keeping all other inputs fixed) never changes the value of the function from 1 to 0. A *positive boolean formula* is a boolean formula that computes a monotone boolean formula. A *monotone boolean formula* is a formula that is built from propositional variables and the connectives $\wedge$ and $\vee$. Note that the class of functions computed by monotone boolean formulas is exactly the monotone boolean functions. Monotone computing models have long been studied (see, e.g., Grigni and Sipser [GS92] and the references therein).

Define

$$\#\mathrm{MONSAT}(F) =_{\mathrm{def}} \begin{cases} \|\{(a_1,\ldots,a_n) \mid \\ \quad (\forall i : 1 \le i \le n)[a_i \in \{0,1\}] \wedge F(a_1,\ldots,a_n) = 1\}\| \\ \qquad\qquad \text{if } F \text{ is a monotone boolean formula} \\ 0 \quad \text{otherwise,} \end{cases}$$

i.e., $\#\mathrm{MONSAT}(F)$ counts the number of satisfying assignments of monotone boolean formulas. For the remainder of this section, we identify each assignment $(a_1,\ldots,a_n)$ to the n variables of F with the n-bit string $a_1\ldots a_n \in \{0,1\}^n$. Theorem 8.5 states that #MONSAT belongs to the class IF_{t}. To prove this theorem, we will use the following proposition.

PROPOSITION 8.1. *Let φ be the function that is defined for every boolean formula $F(x_1,\ldots,x_n)$, $a \in \{0,1\}^n$, and $r \in \{0,1\}$ as $\varphi(F,a,r) =_{\mathrm{def}} \min\{\, b \mid b \in \{0,1\}^n \wedge a \le_{\mathrm{lex}} b \wedge F(b) = r \,\}$ if $\{\, b \mid b \in \{0,1\}^n \wedge a \le_{\mathrm{lex}} b \wedge F(b) = r \,\}$ is nonempty and F is a monotone boolean formula, and $\varphi(F,a,r) =_{\mathrm{def}} \perp$ otherwise, where the* min *in the above definition is taken with respect to the lexicographical order. The function φ is polynomial-time computable.*

Proof. To prove this proposition we use two natural properties of monotone boolean formulas. First, note that, for each monotone boolean formula F of arity n and for each $a = a_1\ldots a_n \in \{0,1\}^n$ and $b = b_1\ldots b_n \in \{0,1\}^n$, it holds that $F(a) \le F(b)$ whenever $(\forall i \le n)[a_i \le b_i]$. Second, there is an assignment making F true (respectively, false) if and only if $F(1^n) = 1$ (respectively, $F(0^n) = 0$). Consider the algorithm of Figure 6 running on an n-ary monotone boolean formula F, $a \in \{0,1\}^n$, and $r \in \{0,1\}$.

The algorithm works as follows. If none of the boundary conditions in lines [1] through [6] are met, then assume that the assignments to the variables of F are just the labels of the leaves of a complete binary tree having 2^n leaves, i.e., the leftmost leaf is 0^n, and the rightmost leaf 1^n. The algorithm starts in the leaf numbered a, and searches the next node u on the path from a to the root such that the path comes into u from the left, and the right subtree below u contains an assignment b with $F(b) = r$ (lines [6] to [9]). The least b of the subtree having this property is determined via binary search (lines [10] to [18]). Thus, the algorithm is correct and runs in polynomial time with respect to the input length. □

We state as Proposition 8.2 some subcases of Proposition 8.1. (A "part 2 of Proposition 8.2" parallel to the first sentence of part 1 of Proposition 8.2 is not included since that trivially holds (test the all-0 assignment).) Though we could not find Proposition 8.2 in the literature, it is sufficiently fundamental that we believe it may well be known or a folk theorem.

PROPOSITION 8.2.

1. *The problem of finding the least satisfying assignment for monotone boolean formulas has a polynomial-time algorithm. Indeed, the problem of finding the least satisfying assignment lexicographically greater than or equal to a given assignment has, for monotone boolean formulas, a polynomial-time algorithm.*

```
[1]   b ← a
[2]   if (b = 1^n and F(b) ≠ r) or F(r^n) ≠ r
[3]      then
[4]         return ⊥
[5]      else
[6]         while b ≠ ε and F(br^{n−|b|}) ≠ r do
[7]            b ← the string which succeeds b in lexicographical order
[8]            b ← longest prefix of b which ends with 1
[9]         endwhile
[10]        m ← |b| + 1
[11]        for j ← m to n do
[12]           if F(b0r^{n−|b|−1}) = r
[13]              then
[14]                 b ← b0
[15]              else
[16]                 b ← b1
[17]           endif
[18]        endfor
[19]        return b
[20]  endif
```

FIG. 6. *An algorithm used in the proof of Proposition* 8.1.

2. *The problem of finding the least unsatisfying assignment lexicographically greater than or equal to a given assignment has, for monotone boolean formulas, a polynomial-time algorithm.*

This section has, so far, spoken of monotone boolean formulas. However, note that if we view the algorithm from Figure 6 as accessing a black-box boolean *function*, the algorithm in fact shows that the *query complexity* of the task is polynomial—indeed linear—if the black-box function is a monotone boolean function. Thus we have the following results.

PROPOSITION 8.3. *Let φ be the function that is defined for every $n \geq 1$, every boolean formula $f(x_1, \ldots, x_n)$, every $a \in \{0,1\}^n$, and every $r \in \{0,1\}$ as*

$$\varphi^f(a,r) =_{\text{def}} \begin{cases} \min\{b \mid b \in \{0,1\}^n \wedge a \leq_{\text{lex}} b \wedge f(b) = r\} \\ \quad \textit{if } \{b \mid b \in \{0,1\}^n \wedge a \leq_{\text{lex}} b \wedge f(b) = r\} \neq \emptyset \\ \bot \quad \textit{otherwise,} \end{cases}$$

where the min *in the above definition is taken with respect to the lexicographical order. When restricted to monotone boolean functions, the function φ is of linear (in the number of variables) query complexity (and polynomial, in the number of variables, time complexity). That is, there exist a Turing machine M and a linear function q and a polynomial s such that for each $n \geq 1$, each monotone boolean n-variable function f, each $a \in \{0,1\}^n$, and each $r \in \{0,1\}$ it holds that*

1. *$M^f(a,r)$ makes at most $q(n)$ queries to f, and*
2. *$M^f(a,r)$ halts within $s(n)$ steps with $\varphi^f(a,r)$ on its output tape.*

Similarly to Proposition 8.2, we have the following (where the time and query complexities are relative to the number of variables or, equivalently, relative to the size of the "input," i.e., $|a| + |r|$).

PROPOSITION 8.4.

1. *The problem of finding the least satisfying assignment when restricted to monotone boolean functions has a linear-query-complexity algorithm (that in addition is of polynomial-time complexity). Indeed, the problem of finding the least satisfying assignment lexicographically greater than or equal to a given assignment has, when restricted to monotone boolean functions, a linear-query-complexity algorithm (that in addition is of polynomial-time complexity).*
2. *The problem of finding the least unsatisfying assignment lexicographically greater than or equal to a given assignment has, when restricted to monotone boolean functions, a polynomial-time algorithm.*

Note that in neither Proposition 8.3 nor Proposition 8.4 do we make any claims about what the procedure will compute if the black-box function is not a monotone boolean formula.

We now relate #MONSAT to interval functions.

THEOREM 8.5. $\#\mathrm{MONSAT} \in \mathrm{IF_t}$.

Proof. We assume that F is given as a string over the alphabet Σ. We construct a total p-order $A \in \mathrm{P}$ having efficient adjacency checks as follows. Generally, A coincides with the lexicographical order on Σ^* except that, for each monotone boolean formula F of arity n, the interval between $1^{|F|}0F0000^n$ and $1^{|F|}0F1001^n$ is ordered in the following way.

- First comes $\{1^{|F|}0F000y \mid |y| = n\}$ in lexicographical order (we always use $n = n_F$ to denote the arity of F).
- Next comes the set $\{1^{|F|}0F001a \mid a \text{ is a satisfying assignment of } F\}$ in lexicographical order.
- Next comes $\{1^{|F|}0F010y \mid |y| = n\}$ in lexicographical order.
- Next comes the set $\{1^{|F|}0F011a \mid a \text{ is not a satisfying assignment of } F\}$ in lexicographical order.
- Finally comes the set $\{1^{|F|}0F100y \mid |y| = n\}$ in lexicographical order.

Clearly, A is a total p-order that is decidable in polynomial time. In light of the function φ from Proposition 8.1 it is not hard to see that A has efficient adjacency checks. Also, for any monotone boolean formula $F(x_1, \ldots, x_n)$, let $b(F) =_{\mathrm{def}} 1^{|F|}0F0001^n$ and $t(F) =_{\mathrm{def}} 1^{|F|}0F0100^n$. Obviously, $b, t \in \mathrm{FP}$, and we obtain $\#\mathrm{MONSAT}(F) = \|\{z \mid b(F) <_A z <_A t(F)\}\|$. Thus, $\#\mathrm{MONSAT} \in \mathrm{IF_t}$. □

Valiant [Val79] showed that counting the number of satisfying assignments of 2CNF monotone formulas is Turing complete for #P. Since #2CNFMONSAT metrically reduces to #MONSAT, we immediately obtain from this theorem that #MONSAT is complete for $\mathrm{IF_t}$ under Turing reductions, and we get an alternate proof for Corollary 5.8.

9. Cluster computations. Finally, we discuss the complexity of computing the size of intervals for which the boundaries are not required to be polynomial-time computable. This leads to the notion of cluster computation, as introduced in [Kos99] for the case of the lexicographical order. We first review the formal definitions related to cluster computation, but here we present a more general version of the definitions than what previously appeared in [Kos99].

Let M be any nondeterministic Turing machine that is "balanced" in the sense that, on every input, the graph of the nondeterministic choices M makes is a complete, balanced, binary tree. Let y and z encode computation paths of M on x. By the above assumption that M is "balanced," $|y| = |z|$. Fix a total order A on Σ^*. We say

that $y \sim_{A,M,x} z$ if and only if (a) $y \prec_A z$ or $z \prec_A y$, and (b) M on x accepts on path y if and only if M on x accepts on path z. Let $\equiv_{A,M,x}$ be the equivalence closure (i.e., the reflexive-symmetric-transitive closure) of $\sim_{A,M,x}$. Then the relation $\equiv_{A,M,x}$ is an equivalence relation and thus induces a partitioning of the computation tree of M on x. An A-cluster is an equivalence class whose representatives are accepting paths. Additionally, we consider $\emptyset$ to be a valid A-cluster.

For a nondeterministic Turing machine M, let $acc_M(x) \subseteq \Sigma^*$ denote the set of all accepting paths of M on input x. Let $\#acc_M : \Sigma^* \to \mathbb{N}$ be the function defined as $\#acc_M(x) =_{\text{def}} \|acc_M(x)\|$. Let $out_M(x) \subseteq \Sigma^*$ denote the set of all distinct outputs of accepting paths of M on input x. A nondeterministic Turing machine M is a *lexicographical cluster machine* if and only if M is balanced in the sense defined earlier and, for every x, there is a computation path y of M on x such that

$$acc_M(x) = \{z \mid z \equiv_{\text{lex},M,x} y \text{ and } y \in acc_M(x)\}.$$

The intuition here is simple: Such machines on each input in the set have a single, nonempty, contiguous stretch of accepting paths.

DEFINITION 9.1 (Kosub [Kos99]).

c#P $=_{\text{def}} \{\#acc_M \mid M$ *is a polynomial-time lexicographical cluster machine*$\}$.

We mention some basic properties of the class c#P.

DEFINITION 9.2. *A nondeterministic Turing machine* computes a function f almost-uniquely *if and only if, for each* x,

1. $f(x) > 0$ *implies* $out_M(x) = \{f(x)\}$ *and* $\#acc_M(x) = 1$, *and*
2. $f(x) = 0$ *implies* $out_M(x) = \emptyset$.

Recalling from section 6.1 the definition of $\ominus$, we have the following.

PROPOSITION 9.3 (Kosub [Kos99]).

1. *A function* f *lies in* c#P *if and only if there exists a nondeterministic polynomial-time Turing machine that computes* f *almost-uniquely.*
2. $\text{UPSV}_\text{t} \subseteq \text{c\#P} = \text{c\#P} \ominus \text{FP} \subseteq \#\text{P}$.
3. $\text{UPSV}_\text{t} \cap \text{Nonzero} = \text{c\#P} \cap \text{Nonzero}$.
4. c#P $= \#$P *if and only if* UP $=$ PP.

PROPOSITION 9.4.

1. $\exists \cdot \text{c\#P} = \exists \cdot (\text{c\#P} - \text{FP}) = \text{UP}$.
2. *If* $\text{IF}_\text{t} \subseteq \text{c\#P}$, *then* UP $=$ PP.
3. *If* $\text{c\#P} \subseteq \text{IF}_\text{t}$, *then* P $=$ UP.

Proof. (1): It is easy to see that UP $\subseteq \exists \cdot$ c#P, since any balanced machine for a given UP language already implicitly shows that that language is in $\exists \cdot$ c#P due to the unique paths being each a size-one equivalence class. It follows from the definitions that $\exists \cdot (\text{c\#P} \ominus \text{FP}) \subseteq \exists \cdot (\text{c\#P} - \text{FP})$ and from Proposition 9.3.2 we have $\exists \cdot \text{c\#P} = \exists \cdot (\text{c\#P} \ominus \text{FP})$. However, in light of Proposition 9.3.1, we can see that each set in $\exists \cdot (\text{c\#P} - \text{FP})$ is in fact in UP.

(2): By Theorem 5.7, $\text{IF}_\text{t} \subseteq$ c#P implies $\#\text{P} - \text{FP} \subseteq \text{c\#P} - \text{FP}$. From this, Proposition 2.2.4, and the first part of the present result we have $\text{PP} = \exists \cdot (\#\text{P} - \text{FP}) \subseteq \exists \cdot (\text{c\#P} - \text{FP}) = \text{UP}$.

(3): Apply the operator $\exists$ to both sides of the inclusion, and apply Lemma 5.9 and the first part of the present result. □

Proposition 9.3, which in essence says that c#P functions are relatively simple, is *extremely* dependent on the fact that c#P is built based on lexicographical order. In particular, the results reflect the fact that it is easy, given two strings, a and b, to compute $\|\{c \mid a \leq_{\text{lex}} c \leq_{\text{lex}} b\}\|$. Proposition 9.3.1 for example is driven in large part

by the fact that one can, for inputs where the function is not zero, guess (and check the guess of) the rightmost and leftmost accepting paths, and then, since one knows that the complete set of accepting paths is simply the contiguous block between and including these, one can easily compute the number of accepting paths.

It is natural to wish to remove the focus here on lexicographic order, and to instead study machines whose set of accepting paths is always a contiguous block—with respect to some total order that has efficient adjacency checks like lexicographic order, but that perhaps does not satisfy the extremely restrictive "interval sizes are always trivial to compute" property of lexicographic order. We introduce the class CL#P, which captures exactly this more flexible, natural notion of cluster computing. (The work of this paper led to further study of CL#P in [HHK06], which studies the closure properties of, alternate definitions of, and classes related to CL#P.)

An order A on Σ^* is said to be *length-respecting* if and only if, for all x, y, $|x| < |y|$ implies $x <_A y$. Note that a length-respecting order is always a p-order.

DEFINITION 9.5. *A function f belongs to the class* CL#P *if and only if there exist a nondeterministic polynomial-time Turing machine M, a polynomial p, and a length-respecting total order A with efficient adjacency checks such that, for all x, the following conditions hold.*

1. *All computation paths of M on x have length exactly $p(|x|)$.*[1]
2. *The set of all accepting paths of M on x is an A-cluster.*
3. *$f(x) = \#acc_M(x)$.*

As might be expected, the class $\mathrm{IF_t}$ is included in CL#P. Indeed, the following inclusions hold.

THEOREM 9.6. $\mathrm{c\#P} \cup \mathrm{IF_t} \subseteq \mathrm{CL\#P} \subseteq \#\mathrm{P}$.

Proof. The inclusions $\mathrm{c\#P} \subseteq \mathrm{CL\#P}$ and $\mathrm{CL\#P} \subseteq \#\mathrm{P}$ are trivial. It remains to prove the inclusion $\mathrm{IF_t} \subseteq \mathrm{CL\#P}$. Choose $f \in \mathrm{IF_t}$ via a total p-order $A \in \mathrm{P}$ having polynomial-time adjacency checks, functions $b, t \in \mathrm{FP}$, and a polynomial p that witnesses that A is a p-order. We may without loss of generality assume that p is monotonic. For each $x \in \Sigma^*$, let $S_x = \{x0^{p(|x|)-|y|}1y0 \mid y \leq_A x\}$. Define A' as follows. Generally, A' corresponds to the lexicographical order on Σ^*, except that, for every $x \in \Sigma^*$, the interval between $x0^{p(|x|)+2}$ and $x1^{p(|x|)+2}$ is defined as follows.

- First come all strings in S_x, such that, for any strings $x0^{p(|x|)-|y_1|}1y_10$, $x0^{p(|x|)-|y_2|}1y_20 \in S_x$, let $x0^{p(|x|)-|y_1|}1y_10 \leq_{A'} x0^{p(|x|)-|y_2|}1y_20$ if and only if $y_1 \leq_A y_2$.
- Next come all the strings not in S_x, in lexicographical order.

We claim that A' is a total, polynomial-time computable p-order having efficient adjacency checks. Clearly, A' is total. Also, it is clear that, for any $s \in \Sigma^*$, it is possible to determine in polynomial time whether there is an $x \in \Sigma^*$ such that $s \in S_x$. It follows by this and by the definition of A that A' is polynomial-time computable. We claim that A' has efficient adjacency checks. For any $x \in \Sigma^*$, the lexicographically smallest element in S_x is $x0^{p(|x|)-|s_A|}1s_A0$, where $s_A \in \Sigma^*$ is the smallest element in the ordering imposed by A, and the lexicographically largest element is $x0^{p(|x|)-|x|}1x0$. If $x0^{p(|x|)-|y_1|}1y_10, x0^{p(|x|)-|y_2|}1y_20 \in S_x$, then $x0^{p(|x|)-|y_1|}1y_10 \prec_{A'} x0^{p(|x|)-|y_2|}1y_20$ if and only if $y_1 \prec_A y_2$ (this is true because, for every $y \in \Sigma^*$ such that $y \leq_A x$, it holds

[1] As we do in many places, we take it here as tacitly clear that the length of a path is its number of nondeterministic guesses, all of which in this model must be binary guesses. Note also that in the context of our model "All computation paths of M on x have length exactly $p(|x|)$" certainly implies that M is balanced in the sense defined at the start of this section: It will have every (and only) path corresponding to a guess sequence from $\{0,1\}^{p(|x|)}$. We mention, however, that we do not require a machine to make nondeterministic guesses at each step.

that $x0^{p(|x|)-|y|}1y0 \in S_x$; and thus, for such y_1 and y_2, it is impossible for some string longer than $p(|x_0|)$ to be "wedged between" them). The lexicographically smallest element not in S_x is $x0^{p(|x|)+2}$ and the largest is $x1^{p(|x|)+2}$. For any $w_1, w_2 \in \Sigma^*$ and $b_1, b_2 \in \{0,1\}$ such that both w_1b_1 and w_2b_2 are lexicographically between $x0^{p(|x|)+2}$ and $x1^{p(|x|)+2}$ but neither is in S_x, $w_1b_1 \prec_A w_2b_2$ if and only if $(w_1b_1 \prec_{\text{lex}} w_2b_2)$ or $(w_1b_1 \not\prec_{\text{lex}} w_2b_2$ and $b_1 = b_2 = 1$ and $w_1 \prec_{\text{lex}} w_2$ and $w_20 \in S_x)$. All other cases are handled in the way obvious from the above, e.g., for any $w_1, w_2 \in \Sigma^*$ and $b_1, b_2 \in \{0,1\}$ such that both of w_1b_1 and w_2b_2 are lexicographically between $x0^{p(|x|)+2}$ and $x1^{p(|x|)+2}$, and exactly one of them—say w_1b_1—is in S_x, the above makes it clear that $w_1b_1 \prec_{A'} w_2b_2$ exactly if $w_1b_1 = x0^{p(|x|)-|x|}1x0$ and $w_2b_2 = x0^{p(|x|)+2}$.

Define M to be a Turing machine that, on input $x \in \Sigma^*$, guesses a string $w \in \Sigma^{p(|t(x)|)+2}$. If $t(x)w \notin S_{t(x)}$, then M rejects. Otherwise, M accepts if and only if $t(x)0^{p(|t(x)|)-|b(x)|}1b(x)0 <_{A'} t(x)w <_{A'} t(x)0^{p(|t(x)|)-|t(x)|}1t(x)0$. Clearly, M runs in polynomial time and has computation paths of length exactly $p(t(|x|)) + 2$. Also, the number of accepting paths of M on x equals $f(x)$. By construction, the set of accepting computation paths of M on x is an A'-cluster. Thus, $f \in \text{CL\#P}$. □

From Proposition 9.4 and Theorem 9.6, it is clear that CL#P is different from both c#P and IF_t unless some surprising complexity class collapses occur. In particular, the following holds.

COROLLARY 9.7.

1. *If* c#P = CL#P, *then* UP = PP.
2. *If* IF_t = CL#P, *then* P = UP.

Nonetheless, when considering only polynomially bounded functions, c#P and CL#P do coincide.

THEOREM 9.8. c#P ∩ PolyBounded = CL#P ∩ PolyBounded.

Proof. The inclusion "⊆" is immediate. For the inclusion "⊇," choose $f \in \text{CL\#P}$ via a nondeterministic polynomial-time Turing machine M, a polynomial p, and a length-respecting total order A having efficient adjacency checks, all three of which have the properties and behaviors described in Definition 9.5. Recall that all accepting paths of M on any input x will be of length $p(|x|)$. Let q be a polynomial such that, for all $x \in \Sigma^*$, $f(x) \le q(|x|)$. We now will define a nondeterministic polynomial-time Turing machine N that almost-uniquely computes f in the sense of Definition 9.2. Define N to be a Turing machine that, on input $x \in \Sigma^*$, does the following.

1. If ϵ is an accepting path of $M(x)$, then accept and output 1.
2. N nondeterministically guesses strings $y, z \in \Sigma^{p(|x|)}$, $y' \in \Sigma^{p(|x|)-1} \cup \Sigma^{p(|x|)}$, and $z' \in \Sigma^{p(|x|)} \cup \Sigma^{p(|x|)+1}$.
3. N checks whether all of the following hold.
   (a) $y' \prec_A y$ and $z \prec_A z'$.
   (b) $y' \notin acc_M(x)$.
   (c) $z' \notin acc_M(x)$.
   (d) $y \in acc_M(x)$ and $z \in acc_M(x)$.
4. If (3) does not hold, then N rejects, otherwise if $y = z$, N accepts and outputs 1.
5. If (3) does hold and $y \neq z$, then N proceeds as follows.
   (a) N nondeterministically guesses an integer r with $0 \le r \le q(|x|) - 2$.
   (b) N nondeterministically guesses r strings $v_1, \ldots, v_r \in \Sigma^{p(|x|)}$.
   (c) N checks whether $y \prec_A v_1 \prec_A v_2 \prec_A \cdots \prec_A v_r \prec_A z$.
   (d) If (5c) does not hold, then N rejects. Otherwise, N accepts and outputs $r + 2$.

N is a nondeterministic polynomial-time Turing machine that, on each input, has one accepting path if $f(x) > 0$ and no accepting paths if $f(x) = 0$. If $f(x) > 0$, then N on x outputs $f(x)$ on its accepting path. Thus, N almost-uniquely computes f, and so by Proposition 9.3.1 $f \in \text{c\#P}$. □

For a class $\mathcal{F}$ of functions, let $\exists! \cdot \mathcal{F}$ be the class of all sets L for which there exists a function $f \in \mathcal{F}$ such that, for all x, $x \in L \Leftrightarrow f(x) = 1$.

THEOREM 9.9.

1. $\exists! \cdot \text{IF}_\text{p} = \text{coNP}$.
2. $\exists! \cdot \text{c\#P} = \exists! \cdot \text{CL\#P} = \text{UP}$.

Proof. For (1), $\text{coNP} \subseteq \exists! \cdot \text{IF}_\text{p}$ follows from Corollary 5.4 and the observation that any language in coNP is also (via considering the NP machine for the language's complement but with one extra accepting path added on each input) in $\exists! \cdot (\#\text{P} \cap \text{Nonzero})$. To see $\exists! \cdot \text{IF}_\text{p} \subseteq \text{coNP}$, choose $L \in \exists! \cdot \text{IF}_\text{p}$, via $f \in \text{IF}_\text{p}$. Let boundary functions $b, t \in \text{FP}$ and partial, polynomial-time computable p-order A having efficient adjacency checks witness that $f \in \text{IF}_\text{p}$. Let M be a nondeterministic polynomial-time Turing machine that, on input x, (i) guesses $y, z \in \Sigma^*$ such that $y \neq z$ and (ii) accepts if $b(x) \prec_A t(x) \vee (b(x) <_A y <_A t(x) \wedge b(x) <_A z <_A t(x))$. It is easy to see that M accepts $\overline{L}$, thus $L \in \text{NP}$.

For (2), $\text{UP} \subseteq \exists! \cdot \text{c\#P}$ is obvious. To see that $\exists! \cdot \text{CL\#P} \subseteq \text{UP}$, choose $L \in \exists! \cdot \text{CL\#P}$. Thus there exists a function $f \in \text{CL\#P}$ such that, for all x, $x \in L \Leftrightarrow f(x) = 1$. Let M be a machine that computes f via total order A having efficient adjacency checks and polynomial p (where M, A, and p are in the sense of Definition 9.5). Recall that all accepting paths of $M(x)$ are of length $p(x)$. Let N be a nondeterministic polynomial-time Turing machine that, on input x, guesses strings $y \in \Sigma^{p(|x|)}$ and $x, z \in \Sigma^{p(|x|)-1} \cup \Sigma^{p(|x|)} \cup \Sigma^{p(|x|)+1}$, and accepts if and only if all the following hold.

1. $y \prec_A z \wedge y \in acc_M(x) \wedge (w \prec_A y \vee w = y = \epsilon)$.
2. $w \notin acc_M(x) \vee w = y = \epsilon$.
3. $z \notin acc_M(x)$.

Clearly, N has on any input at most one accepting path and N accepts L. □

The next result shows that CL#P is probably not powerful enough to capture #P.

THEOREM 9.10. *If* $\text{CL\#P} = \#\text{P}$, *then* $\text{UP} = \text{PH}$.

Proof. Using Theorem 5.2 and both parts of Theorem 9.9, we have $\text{coNP} \subseteq \exists! \cdot \#\text{P} = \exists! \cdot \text{CL\#P} = \text{UP}$. □

On the other hand, proving CL#P to be different from #P is at least as hard as proving that $\text{P} \neq \text{NP}$ and $\text{UP} \neq \text{PP}$.

PROPOSITION 9.11. *If* $\text{P} = \text{NP}$ *or* $\text{UP} = \text{PP}$, *then* $\text{CL\#P} = \#\text{P}$.

Proof. Suppose $\text{UP} = \text{PP}$. Then by Proposition 9.3.4 $\text{c\#P} = \#\text{P}$, and so (see Theorem 9.6) $\text{CL\#P} = \#\text{P}$. Suppose that $\text{P} = \text{NP}$. Then by Theorem 5.10 it holds that $\text{IF}_\text{t} = \#\text{P}$, and so (see Theorem 9.6) $\text{CL\#P} = \#\text{P}$. □

Unfortunately, the necessary and sufficient conditions we have obtained for the equality of #P and CL#P differ, i.e., they do not yield a complete characterization. However, if we consider polynomially bounded functions, then such a complete characterization can be established in terms of the classes UP [Val76] and Few [CH90] (see section 2 for a review of their definitions). Note that $\text{UP} = \text{Few} \Leftrightarrow \text{UP} = \text{coUP} = \text{FewP} = \text{Few}$ and so in light of Theorem 9.12 we easily have that $\text{CL\#P} \cap \text{PolyBounded} = \#\text{P} \cap \text{PolyBounded}$ implies $\text{UP} = \text{coUP} = \text{FewP}$.

THEOREM 9.12. $\text{CL\#P} \cap \text{PolyBounded} = \#\text{P} \cap \text{PolyBounded}$ *if and only if* $\text{UP} = \text{Few}$.

Proof. [⇒]: Suppose that $L \in \text{Few}$ via a function $f \in \#\text{P}$, a set $B \in \text{P}$, and a polynomial p such that, for all x, $f(x) \leq p(|x|)$, and $x \in L \Leftrightarrow (x, 1^{f(x)}) \in B$. Let $g(x) =_{\text{def}} 1+f(x)$. Then $g \in \#\text{P}$, and g is polynomially bounded. From our hypothesis and Theorem 9.8, we obtain $g \in \text{c}\#\text{P}$. Since $g(x) > 0$, by Proposition 9.3.3 we have that $g \in \text{UPSV}_{\text{t}}$ via some nondeterministic polynomial-time (function-computing) Turing machine M whose behavior is UPSV_{t}-like. Define N to be a Turing machine that, on input x, nondeterministically guesses a computation path y of M on input x, simulates M on input x along computation path y, and accepts (on its current path) if and only if y is an accepting path with output z satisfying $(x, 1^{z-1}) \in B$. Clearly, N is a nondeterministic polynomial-time Turing machine with at most one accepting path on each input. Furthermore, it holds that N on x has an accepting computation path if and only if $(x, 1^{f(x)}) \in B$. This gives $L \in \text{UP}$.

[⇐]: Let f be any polynomially bounded #P function. Define $A =_{\text{def}} \{(x, 1^y) \mid y \leq f(x)\}$. Note that $A \in \text{Few}$. So by our hypothesis $A \in \text{UP}$. Indeed, since Few is closed under complementation and Few = UP by hypothesis, $A \in \text{UP} \cap \text{coUP}$. Via binary search using A as an oracle, we can compute f in polynomial time. That is, f is in $\text{FP}^{\text{UP}\cap\text{coUP}} = \text{UPSV}_{\text{t}} \subseteq \text{c}\#\text{P}$. Thus, $\text{CL}\#\text{P} \cap \text{PolyBounded} = \#\text{P} \cap \text{PolyBounded}$. □

From Corollary 9.7, we know that CL#P and c#P probably are different classes. However, under the ∃ operator the difference disappears, since both are mapped to UP. (Recall that Proposition 9.4.1 established $\exists \cdot \text{c}\#\text{P} = \text{UP}$.)

THEOREM 9.13. $\exists \cdot \text{CL}\#\text{P} = \text{UP}$.

Proof. The inclusion $\text{UP} \subseteq \exists \cdot \text{CL}\#\text{P}$ is immediate from Proposition 9.4.1 and the fact that $\text{c}\#\text{P} \subseteq \text{CL}\#\text{P}$. To show the inclusion $\exists \cdot \text{CL}\#\text{P} \subseteq \text{UP}$, choose an arbitrary $L \in \exists \cdot \text{CL}\#\text{P}$. Let $L \in \exists \cdot \text{CL}\#\text{P}$ via some function $f \in \text{CL}\#\text{P}$ with $x \in L \Leftrightarrow f(x) > 0$. Let $f \in \text{CL}\#\text{P}$ be witnessed (in the sense of the M, p, and A of Definition 9.5) by some Turing machine M, polynomial p, and total order A with efficient adjacency checks. Define N to be a Turing machine that, on input $x \in \Sigma^*$, does the following.

1. N nondeterministically guesses $z \in \Sigma^{p(|x|)}$ and $z' \in \Sigma^{p(|x|)} \cup \Sigma^{p(|x|)+1}$.
2. N checks whether each of the following conditions holds.
   (a) $z \prec_A z'$.
   (b) $z \in acc_M(x)$.
   (c) $z' \notin acc_M(x)$.
3. N accepts if and only if 2 holds.

Clearly, N runs in polynomial time and always has at most one accepting path. Also, it holds that $\#acc_N(x) = 1 \Leftrightarrow x \in L$. Thus, $L \in \text{UP}$. □

It is known that c#P is not closed under increment unless UP = coUP [Kos99]. We note that CL#P displays the same behavior.

THEOREM 9.14. *If* CL#P *is closed under increment, then* UP = coUP.

Proof. Observe that $\text{co}(\exists \cdot \mathcal{F}) \subseteq \exists! \cdot (\mathcal{F} + 1)$ is true for every class $\mathcal{F}$ of total functions, where $\mathcal{F} + 1$ denotes $\{g \mid (\exists f \in \mathcal{F})(\forall x)[g(x) = f(x) + 1]\}$. Thus by our hypothesis and Theorem 9.13 we have $\text{coUP} = \text{co}(\exists \cdot \text{CL}\#\text{P}) \subseteq \exists! \cdot (\text{CL}\#\text{P} + 1) \subseteq \exists! \cdot \text{CL}\#\text{P} = \text{UP}$. □

As a corollary, we obtain that CL#P is incomparable to IF_{p} unless some unexpected complexity class collapse occurs.

COROLLARY 9.15.

1. *If* $\text{CL}\#\text{P} \subseteq \text{IF}_{\text{p}}$, *then* P = UP.
2. *If* $\text{IF}_{\text{p}} \subseteq \text{CL}\#\text{P}$, *then* UP = PH.

Proof. Regarding (1), from our hypothesis and Theorem 9.13 we have UP =

$\exists \cdot \mathrm{CL\#P} \subseteq \exists \cdot \mathrm{IF_p} = \mathrm{P}$. To verify (2), observe that from our hypothesis, Theorem 9.9.1, and Theorem 9.13 we obtain $\mathrm{coNP} \subseteq \exists! \cdot \mathrm{IF_p} \subseteq \exists! \cdot \mathrm{CL\#P} = \mathrm{UP}$. □

10. Conclusion and open problems. We introduced interval size functions over p-orders and used them to provide an alternate definition of #P as the set of all interval size functions over polynomial-time decidable p-orders. We also introduced the classes $\mathrm{IF_p}$ and $\mathrm{IF_t}$, the interval size functions over partial and total polynomial-time computable p-orders with efficient adjacency checks. We proved that $\mathrm{IF_p}$ is the class of all functions in #P whose support is in P. We also proved that $\mathrm{IF_t}$ - FP = #P - FP and $\mathrm{IF_p}$ - $\mathcal{O}(1)$ = #P - $\mathcal{O}(1)$, but that $\mathrm{IF_p}$ = #P if and only if P = NP, and that $\mathrm{IF_t} = \mathrm{IF_p}$ only if UP = PH.

We also introduced the classes $\mathrm{IF_p^*}$ and $\mathrm{IF_t^*}$, the interval size functions over partial and total p-orders with efficient adjacency checks. We proved that $\exists \cdot \mathrm{IF_t^*} = \exists \cdot \mathrm{IF_t^*} =$ PSPACE.

Finally, we introduced CL#P, the set of all functions that count the number of accepting paths of polynomial-time cluster machines whose underlying orders are total and have efficient adjacency checks, and we studied the relationship between CL#P and the previously studied cluster computing class c#P.

Reviewing all the results on the interval size function classes $\mathrm{IF_p}$, $\mathrm{IF_p^*}$, $\mathrm{IF_t}$, and $\mathrm{IF_t^*}$, it seems that we have a good understanding of the computational power of the classes $\mathrm{IF_p}$, $\mathrm{IF_p^*}$, and $\mathrm{IF_t^*}$. Regarding the class $\mathrm{IF_t}$, we commend as an open issue obtaining an understanding of the class $\mathrm{IF_t}$ - $\mathcal{O}(1)$, which can be loosely considered to be a kind of "total order" #P.

In section 8, we showed that #MONSAT is complete for $\mathrm{IF_t}$ under Turing reductions. Valiant showed that #2CNFMONSAT is complete for #P under Turing reductions (and thus of course #MONSAT is complete for #P under Turing reductions). In light of this, a referee suggested as interesting open issues such questions as the following: Can one more broadly determine which #P-complete problems fall in $\mathrm{IF_t}$ and which fall in $\mathrm{IF_p}$? And what can one say about the downward closure, under various reductions, of #MONSAT, of $\mathrm{IF_t}$, and of $\mathrm{IF_p}$? In particular, what reductions are sufficiently restrictive as to leave $\mathrm{IF_t}$ and/or $\mathrm{IF_p}$ closed downward under the reductions, and relatedly, which reductions are sufficiently restrictive as to have the class of sets reducing to #MONSAT under the reductions be a subset of $\mathrm{IF_t}$ and/or $\mathrm{IF_p}$?

Acknowledgments. We are grateful to J. Rothe, H. Spakowski, and M. Thakur for proofreading an earlier draft of this paper, and to E. Hemaspaandra and K.-J. Lange for helpful discussions. We also thank the anonymous referees for their careful, helpful reviews and for comments that improved the presentation of the paper.

CHOSEN-CIPHERTEXT SECURITY FROM IDENTITY-BASED ENCRYPTION*

DAN BONEH†, RAN CANETTI‡, SHAI HALEVI‡, AND JONATHAN KATZ§

Abstract. We propose simple and efficient CCA-secure public-key encryption schemes (i.e., schemes secure against adaptive chosen-ciphertext attacks) based on any identity-based encryption (IBE) scheme. Our constructions have ramifications of both theoretical and practical interest. First, our schemes give a new paradigm for achieving CCA-security; this paradigm avoids "proofs of well-formedness" that have been shown to underlie previous constructions. Second, instantiating our construction using known IBE constructions we obtain CCA-secure encryption schemes whose performance is competitive with the most efficient CCA-secure schemes to date. Our techniques extend naturally to give an efficient method for securing IBE schemes (even hierarchical ones) against adaptive chosen-ciphertext attacks. Coupled with previous work, this gives the first efficient constructions of CCA-secure IBE schemes.

Key words. identity-based encryption, public-key encryption, chosen-ciphertext security

1. Introduction.

Security against adaptive chosen-ciphertext attacks [49, 50, 28, 2] is the de facto level of security required for public-key encryption schemes used in practice. This security notion is appropriate for encryption schemes used in the presence of *active* attackers who may potentially modify messages in transit, and schemes proven secure with respect to this notion may be securely "plugged in" to higher-level protocols deployed in unauthenticated networks that were designed and analyzed under the idealized assumption of "secure channels" (see, e.g., [15, 19]). Unfortunately, only a handful of approaches are known for constructing encryption schemes that meet this notion of security. In this work we put forward a new approach for constructing such schemes.

1.1. Background.

Security for public-key encryption was first defined formally by Goldwasser and Micali [38]. Their notion of *semantic security*, roughly speaking, requires that observation of a ciphertext does not enable an adversary to compute anything about the underlying plaintext message that it could not have computed on its own (i.e., prior to observing the ciphertext); this should hold even if the adversary has some a priori information about the message. Goldwasser and Micali (see also [47, 35, 36]) proved that semantic security is equivalent to the notion of *indistinguishability* that requires (roughly) the following: for any two messages, given a "challenge" ciphertext C that is an encryption of one of these messages it is infeasible to determine (with any noticeable advantage over a random guess) which message was

actually encrypted. Because these definitions imply security even when the adversary can mount a *chosen-plaintext attack* to obtain encryptions of messages of its choice, we will refer to these notions using the commonly accepted term "CPA-security."

CPA-security does not guarantee any security against *chosen-ciphertext attacks* by which an adversary may obtain decryptions of ciphertexts of its choice (note that attacks of this sort may arise in practice [5, 53]). Indistinguishability-based definitions appropriate for this setting were given by Naor and Yung [49] and Rackoff and Simon [50]. Naor and Yung consider a *nonadaptive* chosen-ciphertext attack in which the adversary may request decryptions only *before* it obtains the challenge ciphertext. Rackoff and Simon define the stronger notion of security against *adaptive* chosen-ciphertext attacks whereby the adversary may request decryptions even after seeing the challenge ciphertext, under the natural limitation that the adversary may not request decryption of the challenge ciphertext itself. (We will refer to the latter notion as "CCA-security.") See [28, 2, 36] for further discussion of these definitions. Extensions of semantic security to the case of chosen-ciphertext attacks were considered in [36, 37, 55], where it is shown that, as in the case of CPA-security, these definitions are equivalent to the indistinguishability-based ones.

As we have already mentioned, CCA-security is now the de facto level of security for public-key encryption due to its numerous advantages (some of which were summarized earlier). Unfortunately, only a handful of public-key encryption schemes have been proven secure against adaptive chosen-ciphertext attacks without resorting to heuristics such as the random oracle methodology [3], a controversial and problematic approach [16].

In fact, prior to this work only two approaches were known for constructing CCA-secure cryptosystems. The first follows the paradigm introduced by Naor and Yung [49] to achieve nonadaptive chosen-ciphertext security, later extended to the case of adaptive chosen-ciphertext security by Dolev, Dwork, and Naor [28] and Sahai [51]. This technique uses as building blocks any CPA-secure public-key encryption scheme and any noninteractive zero-knowledge (NIZK) proof system for all of $\mathcal{NP}$ [6, 31]. Consequently, this approach can be based on general cryptographic assumptions [31]: specifically, the existence of enhanced trapdoor permutations [36, sect. C.4.1]. Encryption schemes resulting from this approach, however, are highly impractical because they employ generic NIZK proofs which in turn require a Karp reduction from the $\mathcal{NP}$ language of interest to some $\mathcal{NP}$-complete language. Thus, given the current state of the art, this approach serves as a feasibility result for the existence of CCA-secure cryptosystems based on general assumptions but does not lead to any practical constructions.

The second technique is due to Cramer and Shoup [21, 22] and is based on algebraic constructs with particular homomorphic properties (namely, those admitting "smooth hash proof systems" in the terminology of [22]). Algebraic constructs of the appropriate type are known to exist based on some specific number-theoretic assumptions [21, 22], including the decisional Diffie–Hellman (DDH) assumption. Other constructions relying on this technique have been given recently [32, 23, 42], leading to a number of practical schemes.

Interestingly, Elkind and Sahai have observed [29] that both the above approaches for constructing CCA-secure encryption schemes can be viewed as special cases of a single paradigm. In this paradigm one starts with a CPA-secure cryptosystem in which certain "ill-formed" ciphertexts are indistinguishable from honestly generated ciphertexts. A CCA-secure cryptosystem is then obtained by having the sender honestly generate a ciphertext using the underlying CPA-secure scheme, and then append

a "proof of well-formedness" (satisfying certain criteria) to this ciphertext. The NIZK proofs used by Sahai [51] as well as the smooth hash proof systems used by Cramer and Shoup [21, 22] are shown by Elkind and Sahai to satisfy the appropriate criteria.

1.2. Summary of our results. We propose two new approaches for constructing CCA-secure public-key encryption schemes based on any CPA-secure identity-based encryption (IBE) scheme[1] (see sections 2.1 and 3.1 for definitions of the latter notion). A number of IBE schemes based on specific number-theoretic assumptions are known [17, 7, 8, 56, 34]; thus, our techniques yield new constructions of CCA-secure encryption schemes based on these same assumptions.

From a theoretical perspective, our work offers new ways of constructing CCA-secure encryption schemes that do not use "proofs of well-formedness" and hence do not seem to fit within the Elkind–Sahai characterization mentioned above. From a practical perspective, we show that a specific instantiation of our construction yields a practical CCA-secure scheme with efficiency close to that of the best previous construction (cf. section 7). This efficient instantiation is based on the *decisional bilinear Diffie–Hellman (BDH) assumption*, described in section 7.3. Comparing this assumption to those used in prior constructions of CCA-secure encryption schemes, we note the following:

- The decisional BDH assumption seems incomparable to the assumption of enhanced trapdoor permutations that underlies the standard construction of generic NIZK as used in the schemes of [28, 51]. Nevertheless, the decisional BDH assumption is known to imply the existence of generic NIZK proof systems for all of $\mathcal{NP}$ [17, Appendix B] and hence was already known to imply CCA-secure encryption via [28, 51]. We stress again that the schemes shown here are orders of magnitude more efficient than schemes constructed via generic NIZK.
- The decisional BDH assumption implies the DDH assumption that underlies the schemes of [21, 42]. However, less efficient variants of our scheme can be proven secure using assumptions that are incomparable to the DDH assumption; see footnote 6 in section 7.3. In addition, our scheme lends itself to threshold encryption much more efficiently than previous schemes; see below.

Further extensions and applications. Both our approaches extend to give a transformation from any CPA-secure $(\ell+1)$-level hierarchical identity-based encryption (HIBE) scheme [41, 33] to a CCA-secure ℓ-level HIBE scheme (HIBE is described in section 3.2). In particular, applying our technique to any 2-level HIBE scheme gives a CCA-secure IBE scheme. Using this approach with known HIBE schemes [17, 7, 8, 56, 9] yields the first efficient constructions of CCA-secure IBE schemes.

Our first approach, when instantiated with an appropriate IBE scheme, serves as the basis for the first CCA-secure threshold encryption scheme with *noninteractive* decryption [7, 10]. (In a threshold encryption scheme [25] the secret key is shared among multiple servers, some fraction of whom must cooperate in order to decrypt a given ciphertext.) Security in this case crucially relies on specific properties of our construction and, in particular, on the feature that a certain class of "valid" ciphertexts can be efficiently recognized without knowledge of the global secret key; the reader is referred to [7, 10] for further discussion.

[1] Our constructions use other primitives, but these can all be constructed based on one-way functions which are in turn implied by CPA-secure encryption.

Our approaches are generic and can be used to construct a CCA-secure encryption scheme from an *arbitrary* IBE scheme. Extending our work, Boyen, Mei, and Waters [14] show that for some concrete IBE schemes (e.g., the one of Waters [56]) a more efficient and direct construction of a CCA-secure encryption scheme is possible.

1.3. Organization. In the following section, we provide an informal overview of IBE and HIBE as well as some high-level intuition regarding our techniques. Formal definitions of all relevant cryptographic notions (including IBE and CCA-secure public-key encryption) appear in section 3 and the appendix. The first of our transformations is discussed in section 4, and the second transformation is presented in section 5. We discuss the extension to HIBE in section 6.

The treatment in the above sections is generic and does not rely on any specific cryptographic assumptions. In section 7 we recall one specific number-theoretic assumption under which an IBE scheme is known to exist, describe a concrete instantiation of our construction based on this assumption, and compare the efficiency of the resulting CCA-secure encryption scheme to the most efficient such construction that was previously known (namely, the Kurosawa–Desmedt variant [42] of the Cramer–Shoup encryption scheme [21]).

2. Overview of our techniques.

2.1. Identity-based encryption. Before sketching our constructions, we first recall the notion of IBE as introduced by Shamir [52]. Informally, an IBE scheme is a public-key encryption scheme in which any string (i.e., identity) can serve as a public key. In more detail, a trusted authority called a *private-key generator* (PKG) is assumed to initialize the system by running a key-generation algorithm to generate "master" public and secret keys. The master public key PK is published, while the PKG stores the master secret key. Given the master secret key and an arbitrary string ID (viewed as the identity of a party in the system), the PKG can derive a "personal secret key" SK_{ID} and give it to this party. Any sender can encrypt a message for this party using only the master public key PK and the string ID; we denote such encryption by $\mathcal{E}_{PK}(ID, \cdot)$. The resulting ciphertext can be decrypted using the personal secret key SK_{ID}, but the following extension of CPA-security is required to hold:

> For any two messages and any identity ID, given a challenge ciphertext C that is an encryption of one of these messages (with respect to ID) it is infeasible to determine (with any noticeable advantage over a random guess) which message was actually encrypted. *This should hold even if the adversary is given $SK_{ID'}$ for multiple identities $ID' \neq ID$ chosen adaptively by the adversary.*

The first formal definition of security for IBE was given by Boneh and Franklin [11]. In their definition, the adversary may choose the "target identity" (ID in the above) in an adaptive manner, based on the master public key PK and any keys $\{SK_{ID'}\}$ the adversary has obtained thus far; we call such schemes "fully secure." A weaker notion, proposed by Canetti, Halevi, and Katz [17] and called "selective-ID" security there, requires the adversary to specify the target identity *in advance*, before the master public key is published. Fully secure IBE schemes in the random oracle model were first demonstrated by Boneh and Franklin [11] and Cocks [20]. Canetti, Halevi, and Katz [17], building on earlier work of Gentry and Silverberg [33], constructed an IBE scheme satisfying selective-ID security in the standard model; more efficient constructions were given by Boneh and Boyen [7]. More recently, Boneh

and Boyen [8] have shown a fully secure IBE scheme in the standard model, and more efficient constructions were subsequently given by Waters [56] and Gentry [34].

Both our constructions of CCA-secure encryption from IBE require an IBE scheme satisfying only the weaker notion of selective-ID security. Our transformation from any CPA-secure $(\ell + 1)$-level HIBE scheme to a CCA-secure ℓ-level HIBE scheme preserves the level of security in the above sense; i.e., if the original scheme is fully secure then so is the derived scheme, but selective-ID security of the original scheme is sufficient for selective-ID security of the derived scheme.

2.2. Our techniques.

Our first construction. Given an IBE scheme, we construct a CCA-secure public-key encryption scheme as follows: The public key of the new scheme is the master public key PK of the IBE scheme and the secret key is the corresponding master secret key. To encrypt a message with respect to public key PK, the sender first generates a key-pair (vk, sk) for a strong[2] one-time signature scheme, and then encrypts the message with respect to the "identity" vk. The resulting ciphertext $C \leftarrow \mathcal{E}_{PK}(vk, m)$ is then signed using sk to obtain a signature σ. The final ciphertext consists of the verification key vk, the IBE ciphertext C, and the signature σ. To decrypt a ciphertext $\langle vk, C, \sigma \rangle$, the receiver first verifies the signature on C with respect to vk and outputs $\perp$ if the verification fails. Otherwise, the receiver derives the secret key SK_{vk} corresponding to the "identity" vk, and uses SK_{vk} to decrypt the ciphertext C using the underlying IBE scheme.

Security of the above scheme against adaptive chosen-ciphertext attacks can be informally understood as follows. Say a ciphertext $\langle vk, C, \sigma \rangle$ is *valid* if σ is a valid signature on C with respect to vk. Now consider a challenge ciphertext $c^* = \langle vk^*, C^*, \sigma^* \rangle$ given to the adversary. We may first notice that any valid ciphertext $c = \langle vk, C, \sigma \rangle$ submitted by the adversary to its decryption oracle (implying $c \neq c^*$) must, except with negligible probability, have $vk \neq vk^*$ by the strong security of the one-time signature scheme. The crux of the security proof is then to show that (selective-ID) security of the IBE scheme implies that obtaining the decryption of C does not help the adversary in deciding which message the ciphertext C^* corresponds to. Intuitively, this is because the adversary cannot guess the message corresponding to C^* with probability better than $1/2$ *even if it were given the secret key* SK_{vk}. (This is so since $vk \neq vk^*$, and C^* was encrypted for "identity" vk^* using an IBE scheme.) But giving SK_{vk} to the adversary only makes the adversary more powerful, since it could then decrypt C itself.

Our use of a strong one-time signature scheme to force the adversary's decryption queries to differ from the challenge ciphertext in a specific way is reminiscent of prior work in the context of CCA-security [28, 51]. The key difference is that prior work used the verification key vk to implement "unduplicatable set selection" (cf. [51]) which requires $\Theta(k)$ invocations of some underlying encryption scheme, where k is the security parameter. Furthermore, prior work also required some sort of "proof of consistency" for the resulting ciphertext, leading (as described earlier) to an impractical scheme. In contrast, our construction gives a CCA-secure encryption scheme with relatively minimal overhead as compared to the original IBE scheme.

We note also independent work of MacKenzie, Reiter, and Yang [45], who introduce a weaker notion of CCA-secure encryption and use essentially the same con-

[2] A "strong" signature scheme has the property that it is infeasible to create a new, valid signature even for a previously signed message. A formal definition is given in the appendix.

struction to convert any scheme satisfying their weaker definition into a full-fledged CCA-secure encryption scheme. Their work, however, shows only efficient realizations of schemes in the random oracle model.

We remark that if the signature scheme used is only unforgeable in the standard sense (rather than *strongly* unforgeable), we obtain an encryption scheme satisfying the slightly weaker notion of *replayable* CCA-security [19]. Also, a simple modification of the above construction gives an encryption scheme secure against *nonadaptive* chosen-ciphertext attacks [49, 28, 2] but with essentially no overhead as compared to the underlying IBE scheme. Namely, replace the verification key vk by a randomly chosen string $r \in \{0,1\}^{\omega(\log k)}$; the resulting ciphertext is simply $\langle r, C\rangle$, where C is encrypted with respect to the "identity" r. Since an adversary cannot guess in advance (with better than negligible probability) which r will be used for the challenge ciphertext, an argument similar to the above shows that this scheme is secure against nonadaptive chosen-ciphertext attacks.

Improving the efficiency. Focusing again on security against *adaptive* chosen-ciphertext attacks, the previous construction—although conceptually simple and efficient—does add noticeable overhead in practice to the underlying IBE scheme: encryption requires the sender to generate signing/verification keys and sign a message; the ciphertext length is increased by the size of a verification key plus the size of a signature; and decryption requires the receiver to perform a signature verification. Although one-time signatures are "easy" to construct in theory and are more efficient than full-fledged signatures (i.e., those which are strongly unforgeable under adaptive chosen-message attack), they still have their price.

- Known one-time signature schemes based on general one-way functions [43, 30] allow very efficient *signing*; key generation and signature verification, on the other hand, require $\Theta(k)$ evaluations of the one-way function and are relatively expensive. More problematic, perhaps, is that such schemes have very long public keys and/or signatures (with combined length $\Theta(k^2)$), resulting in very long ciphertexts in our construction above.
- One-time signature schemes can of course be based on number-theoretic assumptions (say, by adapting full-fledged signature schemes); this yields schemes whose computational cost for key generation, signing, and verifying is more expensive, but which (may) have the advantage of short(er) public keys and signatures.

Motivated by the above, we modify the previous construction by using a message authentication code (MAC) in place of a one-time signature scheme in the following way: the secret signing key is replaced by a secret MAC key r and the public verification key (which was used as the "identity" for the IBE scheme) is replaced by a commitment to r. In more detail, encryption of a message m is performed by first committing to a random MAC key r, resulting in a commitment com and a corresponding decommitment dec. The ciphertext is $\langle \mathsf{com}, C, \mathsf{tag}\rangle$, where C is an encryption of the "message" $m \circ \mathsf{dec}$ with respect to the "identity" com (i.e., $C \leftarrow \mathcal{E}_{PK}(\mathsf{com}, m \circ \mathsf{dec})$) and tag is a message authentication code computed on C using key r. Decryption of ciphertext $\langle \mathsf{com}, C, \mathsf{tag}\rangle$ is done in the natural way: the receiver first decrypts C with respect to "identity" com to obtain $m \circ \mathsf{dec}$, and then recovers r using com and dec. The receiver then tries to verify tag using key r, outputting m if verification succeeds and $\perp$ otherwise.

In fact, a weaker form of commitment than the standard one suffices for our purposes (cf. section 5.1); we refer to this weaker notion as "encapsulation." The

advantage of the former is that encapsulation schemes can potentially be more efficient than full-fledged commitment schemes.

The intuition for the security of this construction is quite similar to that discussed previously. Consider a challenge ciphertext $\langle \mathsf{com}^*, C^*, \mathsf{tag}^* \rangle$ that was constructed using MAC key r^*. As before, decryption queries that use a different "identity" $\mathsf{com} \neq \mathsf{com}^*$ are useless to the attacker due to the security of the underlying IBE scheme. For decryption queries $\langle \mathsf{com}^*, C, \mathsf{tag} \rangle$ that use the same "identity" we note that either (1) C decrypts to $m \circ \mathsf{dec}$, where dec is a valid decommitment of com^* to some $r \neq r^*$, or (2) the attacker was able to compute a valid tag on $C \neq C^*$ with respect to the MAC key r^*. The first case is easily shown to violate the binding property of the commitment scheme. The second case can be shown to violate the secrecy of the commitment scheme (i.e., the adversary learns something about r^* from com^*), the secrecy of the encryption (i.e., the adversary learns something about r^* from C^*), or the security of the MAC (i.e., the adversary generates a valid tag without learning anything about r^*).

The actual proof for this scheme is more difficult than for the previous case due to the fact that here C must be decrypted *before* validity of the ciphertext as a whole can be checked. We thus must be careful to avoid the seeming circularity which arises since the MAC key r is used to authenticate a string (namely, C) that depends on r (via dec).

The idea of using a MAC and a commitment to the key was suggested previously in the context of nonmalleable commitment (e.g., [26, 27]), but our application of this technique is *qualitatively* different precisely due to the apparent circularity (and the resulting complications to the proof) discussed above. In particular, in the context of nonmalleable commitment the MAC key can be revealed by the sender during the decommitment phase and hence the key is not used to authenticate a message which depends on itself. In contrast, here the MAC key must be transmitted to the receiver as part of the ciphertext. The idea of encapsulating the MAC key (rather than using full-fledged commitment), as well as the encapsulation scheme we propose, are new to this work.

3. Definitions. We use the standard definitions of public-key encryption schemes and their security against adaptive chosen-ciphertext attacks strong one-time signature schemes, and MACs. For convenience and to fix notation, we recall these definitions in the appendix. Our definitions of IBE and HIBE schemes have also appeared previously; however, since these definitions are less familiar yet are central to our work, we include the appropriate definitions in this section. Encapsulation schemes are defined in section 5.1. Our definitions and proofs are phrased with respect to uniform adversaries but can be easily extended to the nonuniform setting. We let "PPT" stand for "probabilistic polynomial-time."

If Σ is a set then Σ^n denotes the set of n-tuples of elements of Σ, with Σ^0 denoting the set containing only the empty tuple. Thus, using this notation, $\{0,1\}^n$ denotes the set of binary strings of length n. We also define $\Sigma^{<n} \stackrel{\text{def}}{=} \bigcup_{0 \leq i < n} \Sigma^i$ and $\Sigma^{\leq n} \stackrel{\text{def}}{=} \bigcup_{0 \leq i \leq n} \Sigma^i$.

3.1. Identity-based encryption. We begin by reviewing the functional definition of an IBE scheme [11].

DEFINITION 1. *An* identity-based encryption scheme *for identities of length n (where n is a polynomially bounded function) is a tuple of* PPT *algorithms* $(\mathsf{Setup}, \mathsf{Der}, \mathcal{E}, \mathcal{D})$ *such that the following hold:*

- *The randomized* setup algorithm Setup *takes as input a security parameter* 1^k. *It outputs a master public key* PK *and a master secret key* msk. *(We assume that* k *and* $n = n(k)$ *are implicit in* PK *and* msk.*)*
- *The (possibly randomized)* key-derivation algorithm Der *takes as input the master secret key* msk *and an identity* $ID \in \{0,1\}^n$. *It returns the corresponding decryption key* SK_{ID}. *We write* $SK_{ID} \leftarrow \mathsf{Der}_{\mathsf{msk}}(ID)$.
- *The randomized* encryption algorithm $\mathcal{E}$ *takes as input the master public key* PK, *an identity* $ID \in \{0,1\}^n$, *and a message* m *in some implicit*[3] *message space; it outputs a ciphertext* C. *We write* $C \leftarrow \mathcal{E}_{PK}(ID, m)$.
- *The (possibly randomized)* decryption algorithm $\mathcal{D}$ *takes as input an identity* ID, *an associated decryption key* SK_{ID}, *and a ciphertext* C. *It outputs a message* m *or the symbol* $\perp$ *(which is not in the message space). We write* $m \leftarrow \mathcal{D}_{SK_{ID}}(ID, C)$.

We require that for all (PK, msk) *output by* Setup, *all* $ID \in \{0,1\}^n$, *all* SK_{ID} *output by* $\mathsf{Der}_{\mathsf{msk}}(ID)$, *all* m *in the message space, and all* C *output by* $\mathcal{E}_{PK}(ID, m)$ *we have* $\mathcal{D}_{SK_{ID}}(ID, C) = m$.

We now define security for IBE. As mentioned in the introduction, the definition we give is weaker than that considered by Boneh and Franklin [11] and conforms to "selective-ID" security [17] where the "target" identity is selected by the adversary before the public key is generated.

DEFINITION 2. *An identity-based encryption scheme* Π *for identities of length* n *is* selective-ID secure against chosen-plaintext attacks *if the advantage of any* PPT *adversary* $\mathcal{A}$ *in the following game is negligible in the security parameter* k*:*

1. $\mathcal{A}(1^k)$ *outputs a "target" identity* $ID^* \in \{0,1\}^{n(k)}$.
2. $\mathsf{Setup}(1^k)$ *outputs* (PK, msk). *The adversary is given* PK.
3. *The adversary* $\mathcal{A}$ *may make polynomially many queries to an oracle* $\mathsf{Der}_{\mathsf{msk}}(\cdot)$, *except that it may not request a secret key corresponding to the target identity* ID^*.
   The adversary is allowed to query this oracle repeatedly using the same identity*; if* Der *is randomized, then a different secret key may possibly be returned each time.*
4. *At some point,* $\mathcal{A}$ *outputs two messages* m_0, m_1 *with* $|m_0| = |m_1|$. *A bit* b *is randomly chosen and the adversary is given a "challenge" ciphertext* $C^* \leftarrow \mathcal{E}_{PK}(ID^*, m_b)$.
5. $\mathcal{A}$ *may continue to query its oracle* $\mathsf{Der}_{\mathsf{msk}}(\cdot)$ *as above. Finally,* $\mathcal{A}$ *outputs a guess* b'.

We say that $\mathcal{A}$ succeeds *if* $b' = b$ *and denote the probability of this event by* $\Pr^{\mathsf{IBE}}_{\mathcal{A},\Pi}[\mathsf{Succ}]$. *The adversary's* advantage *is defined as* $\mathsf{Adv}^{\mathsf{IBE}}_{\mathcal{A},\Pi}(k) \stackrel{\text{def}}{=} \left|\Pr^{\mathsf{IBE}}_{\mathcal{A},\Pi}[\mathsf{Succ}] - 1/2\right|$.

The definition may be extended to take into account security against adaptive chosen-ciphertext attacks. In this case, the adversary additionally has access to an oracle $\widehat{\mathcal{D}}(\cdot)$ such that $\widehat{\mathcal{D}}(C)$ returns $\mathcal{D}_{SK_{ID^*}}(C)$, where SK_{ID^*} is the secret key associated with the target identity ID^* (computed using $\mathsf{Der}_{\mathsf{msk}}(ID^*)$).[4] The adversary has access to this oracle throughout the entire game but cannot submit the challenge ciphertext C^* to $\widehat{\mathcal{D}}$.

On deterministic versus randomized key derivation. For simplicity, when

[3] For example, the message space may consist of all strings of length $p(k)$, where p is polynomially bounded.

[4] Note that decryption queries for identities $ID \neq ID^*$ are superfluous, as $\mathcal{A}$ may make the corresponding Der query itself and thereby obtain SK_{ID}.

dealing with chosen-ciphertext security for IBE schemes we will assume that Der is *deterministic*. If Der is not deterministic, a definition of chosen-ciphertext security is complicated by the question of whether different invocations of the decryption oracle $\widehat{\mathcal{D}}$ should use the *same* secret key SK_{ID^*} (computed using Der the first time $\widehat{\mathcal{D}}$ is invoked) or a *fresh* secret key (computed by running Der using fresh random coins each time). The resulting security definitions obtained in each case seem incomparable, and there does not appear to be any reason to prefer one over the other. A related difficulty arises in the case of HIBE (discussed next) even in the case of chosen-plaintext attacks. These distinctions all become irrelevant when Der is deterministic.

Assuming deterministic key derivation is anyway without much loss of generality: given an IBE scheme with randomized key-derivation algorithm Der we can construct an IBE scheme with deterministic key derivation by (1) including a random key sk for a pseudorandom function F as part of the master secret key msk; and (2) generating the decryption key for identity ID by running $\mathsf{Der}_{\mathsf{msk}}(ID)$ using "randomness" $F_{sk}(ID)$. A similar idea applies to the case of HIBE.

3.2. Hierarchical identity-based encryption. Hierarchical identity-based encryption (HIBE) is an extension of IBE suggested by Horwitz and Lynn [41]. In an ℓ-level HIBE scheme, there is again assumed to be a trusted authority who generates master public and secret keys. As in the case of IBE, it is possible to derive a personal secret key SK_{ID_1} for any identity ID_1 using the master secret key. The additional functionality provided by a HIBE scheme is that this personal secret key SK_{ID_1} may now be used to derive a personal secret key SK_{ID_1,ID_2} for the "ID-vector" (ID_1, ID_2), and so on, with the scheme supporting the derivation of keys in this way for ID-vectors of length at most ℓ. As in the case of IBE, any sender can encrypt a message for the ID-vector $v = (ID_1, \ldots, ID_L)$ using only the master public key and v; the resulting ciphertext can be decrypted by anyone who knows $SK_{ID_1,\ldots,ID_L}$. Security is defined as the natural analogue of security in the case of IBE: informally, indistinguishability should hold for ciphertexts encrypted with respect to a target ID-vector $v = (ID_1, \ldots, ID_L)$ as long as the adversary does not know the secret keys of any identity of the form $(ID_1, \ldots, ID_{L'})$ for $L' \leq L$.

Before formally defining an ℓ-level HIBE scheme, we first introduce some notation to deal with ID-vectors $v \in (\{0,1\}^n)^{\leq \ell}$. For an ID-vector $v = (v_1, \ldots, v_L)$ (with $v_i \in \{0,1\}^n$), we define the *length of* v as $|v| = L$ and let $v.r$ (for $r \in \{0,1\}^n$) denote the ID-vector $(v_1, \ldots, v_L, r)$ of length $|v|+1$. We let ε denote the ID-vector of length 0. Given v as above and an ID-vector $v' = (v'_1, \ldots, v'_{L'})$, we say that v *is a prefix of* v' if $|v| \leq |v'|$ and $v_i = v'_i$ for $i \leq |v|$.

Rephrased using the above notation, the functional property of an ℓ-level HIBE scheme is this: given the secret key SK_v associated with the ID-vector v it is possible to derive a secret key $SK_{v'}$ associated with the ID-vector v' (assuming $|v'| \leq \ell$) whenever v is a prefix of v'. Similarly, the security provided by a HIBE scheme is that indistinguishability should hold for ciphertexts encrypted with respect to an ID-vector v even if the adversary has multiple keys $\{SK_{v'}\}_{v' \in V}$ for some set V *as long as no* $v' \in V$ *is a prefix of* v.

Formal definitions follow. The functional definition is essentially from [33], although we assume for simplicity that the key derivation algorithm is deterministic (cf. the remark in the previous section). As in the case of IBE, the definition of security we give is the one proposed by Canetti, Halevi, and Katz [17], which is weaker than the one considered in [33].

DEFINITION 3. *An* ℓ*-level HIBE scheme for identities of length* n *(where* ℓ, n *are*

polynomially bounded functions) is a tuple of PPT *algorithms* $(\mathsf{Setup}, \mathsf{Der}, \mathcal{E}, \mathcal{D})$ *such that the following hold:*

- *The randomized* setup algorithm Setup *takes as input a security parameter* 1^k. *It outputs a master public key* PK *and a master secret key denoted* SK_ε. *(We assume that* $k, \ell = \ell(k)$, *and* $n = n(k)$ *are implicit in* PK *and all node secret keys.)*
- *The deterministic* key-derivation algorithm Der *takes as input an ID-vector* $v \in (\{0,1\}^n)^{<\ell}$, *its associated secret key* SK_v, *and a string* $r \in \{0,1\}^n$. *It returns the secret key* $SK_{v.r}$ *associated with the ID-vector* $v.r$. *We write this as* $SK_{v.r} := \mathsf{Der}_{SK_v}(v, r)$.
- *The randomized* encryption algorithm $\mathcal{E}$ *takes as input the master public key* PK, *an ID-vector* $v \in (\{0,1\}^n)^{\leq \ell}$, *and a message* m *in some implicit message space. It outputs a ciphertext* C. *We write this as* $C \leftarrow \mathcal{E}_{PK}(v, m)$.
- *The (possibly randomized)* decryption algorithm $\mathcal{D}$ *takes as input an ID-vector* $v \in (\{0,1\}^n)^{\leq \ell}$, *its associated secret key* SK_v, *and a ciphertext* C. *It returns a message* m *or the symbol* $\perp$ *(which is not in the message space). We write* $m \leftarrow \mathcal{D}_{SK_v}(v, C)$.

We require that for all (PK, SK_ε) *output by* Setup, *all* $v \in (\{0,1\}^n)^{\leq \ell}$, *any secret key* SK_v *correctly generated (in the obvious way) for* v, *and any message* m *we have* $m = \mathcal{D}_{SK_v}(v, \mathcal{E}_{PK}(v, M))$.

DEFINITION 4. *An* ℓ*-level HIBE scheme* Π *for identities of length* n *is* selective-ID secure against chosen-plaintext attacks *if the advantage of any* PPT *adversary* $\mathcal{A}$ *in the following game is negligible in the security parameter* k*:*

1. *Let* $\ell = \ell(k)$, $n = n(k)$. *Adversary* $\mathcal{A}(1^k)$ *outputs a "target" ID-vector* $v^* \in (\{0,1\}^n)^{\leq \ell}$.
2. *Algorithm* $\mathsf{Setup}(1^k)$ *outputs* (PK, SK_ε). *The adversary is given* PK.
3. *The adversary may adaptively ask for the secret key(s) corresponding to any ID-vector(s)* v, *as long as* v *is not a prefix of the target ID-vector* v^*. *The adversary is given the secret key* SK_v *correctly generated for* v *using* SK_ε *and (repeated applications of)* Der.
4. *At some point, the adversary outputs two messages* m_0, m_1 *with* $|m_0| = |m_1|$. *A bit* b *is randomly chosen, and the adversary is given a "challenge" ciphertext* $C^* \leftarrow \mathcal{E}_{PK}(v^*, m_b)$.
5. *The adversary can continue asking for secret keys as above. Finally,* $\mathcal{A}$ *outputs a guess* b'.

We say that $\mathcal{A}$ succeeds *if* $b' = b$, *and denote the probability of this event by* $\Pr^{\mathsf{HIBE}}_{\mathcal{A},\Pi}[\mathsf{Succ}]$. *The adversary's* advantage *is defined as* $\mathsf{Adv}^{\mathsf{HIBE}}_{\mathcal{A},\Pi}(k) \stackrel{\text{def}}{=} \left| \Pr^{\mathsf{HIBE}}_{\mathcal{A},\Pi}[\mathsf{Succ}] - 1/2 \right|$.

As in the case of IBE, it is easy to modify the above to take into account security against adaptive chosen-ciphertext attacks. Here, the adversary may additionally query an oracle $\widehat{\mathcal{D}}(\cdot,\cdot)$ such that $\widehat{\mathcal{D}}(v, C)$ returns $\mathcal{D}_{SK_v}(v, C)$ using key SK_v correctly generated for v. The only restriction is that the adversary may not query $\widehat{\mathcal{D}}(v^*, C^*)$ after receiving the challenge ciphertext C^*.

4. Chosen-ciphertext security from identity-based encryption. Given an IBE scheme $\Pi' = (\mathsf{Setup}, \mathsf{Der}, \mathcal{E}', \mathcal{D}')$ for identities of length n which is selective-ID secure against chosen-plaintext attacks, we construct a public-key encryption scheme $\Pi = (\mathsf{Gen}, \mathcal{E}, \mathcal{D})$ secure against adaptive chosen-ciphertext attacks. In the construction, we use a strong one-time signature scheme $\mathsf{Sig} = (\mathcal{G}, \mathsf{Sign}, \mathsf{Vrfy})$ (cf. Definition 11 in the appendix) in which the verification key output by $\mathcal{G}(1^k)$ has length $n = n(k)$.

The construction of Π proceeds as follows:

Key generation. $\mathsf{Gen}(1^k)$ runs $\mathsf{Setup}(1^k)$ to obtain (PK, msk). The public key is PK and the secret key is msk.

Encryption. To encrypt message m using public key PK, the sender first runs $\mathcal{G}(1^k)$ to obtain verification key vk and signing key sk (with $|vk| = n$). The sender then computes $C \leftarrow \mathcal{E}'_{PK}(vk, m)$ (i.e., the sender encrypts m with respect to the "identity" vk) and $\sigma \leftarrow \mathsf{Sign}_{sk}(C)$. The final ciphertext is $\langle vk, C, \sigma \rangle$.

Decryption. To decrypt ciphertext $\langle vk, C, \sigma \rangle$ using secret key msk, the receiver first checks whether $\mathsf{Vrfy}_{vk}(C, \sigma) \stackrel{?}{=} 1$. If not, the receiver simply outputs $\perp$. Otherwise, the receiver computes $SK_{vk} \leftarrow \mathsf{Der}_{\mathsf{msk}}(vk)$ and outputs $m \leftarrow \mathcal{D}'_{SK_{vk}}(vk, C)$.

It is clear that the above scheme satisfies correctness. We give some intuition as to why Π is secure against chosen-ciphertext attacks. Let $\langle vk^*, C^*, \sigma^* \rangle$ be the challenge ciphertext (cf. Definition 8). It should be clear that, without any decryption oracle queries, the plaintext corresponding to this ciphertext remains "hidden" to the adversary; this is so because C^* is output by Π' which is CPA-secure (and the additional components of the ciphertext provide no additional help).

We claim that decryption oracle queries cannot further help the adversary in determining the plaintext (i.e., guessing the value of b; cf. Definition 8). On one hand, if the adversary submits to its decryption oracle a ciphertext $\langle vk, C, \sigma \rangle$ that is different from the challenge ciphertext but with $vk = vk^*$ then (with all but negligible probability) the decryption oracle will reply with $\perp$ since the adversary is unable to forge new, valid signatures with respect to vk. On the other hand, if $vk \neq vk^*$ then (informally) the decryption query will not help the adversary since the eventual decryption using $\mathcal{D}'$ (in the underlying scheme Π') will be done with respect to a different "identity" vk. In the proof below, we formalize these ideas.

THEOREM 1. *If Π' is an identity-based encryption scheme which is selective-ID secure against chosen-plaintext attacks and Sig is a strong one-time signature scheme, then Π is a public-key encryption scheme secure against adaptive chosen-ciphertext attacks.*

Proof. Assume we are given a PPT adversary $\mathcal{A}$ attacking Π in an adaptive chosen-ciphertext attack. Say a ciphertext $\langle vk, C, \sigma \rangle$ is *valid* if $\mathsf{Vrfy}_{vk}(C, \sigma) = 1$. Let $\langle vk^*, C^*, \sigma^* \rangle$ denote the challenge ciphertext received by $\mathcal{A}$ during a particular run of the experiment, and let Forge denote the event that $\mathcal{A}$ submits a valid ciphertext $\langle vk^*, C, \sigma \rangle$ to the decryption oracle. (We may assume that vk^* is chosen at the outset of the experiment so this event is well defined even before $\mathcal{A}$ is given the challenge ciphertext. Recall also that $\mathcal{A}$ is disallowed from submitting the challenge ciphertext to the decryption oracle once the challenge ciphertext is given to $\mathcal{A}$.) We prove the following claims.

CLAIM 1. $\Pr^{\mathsf{PKE}}_{\mathcal{A},\Pi}[\mathsf{Forge}]$ *is negligible.*

CLAIM 2. $\left| \Pr^{\mathsf{PKE}}_{\mathcal{A},\Pi}[\mathsf{Succ} \wedge \overline{\mathsf{Forge}}] + \frac{1}{2} \Pr^{\mathsf{PKE}}_{\mathcal{A},\Pi}[\mathsf{Forge}] - \frac{1}{2} \right|$ *is negligible.*

To see that these imply the theorem, note that

$$\begin{aligned}
&\left| \Pr^{\mathsf{PKE}}_{\mathcal{A},\Pi}[\mathsf{Succ}] - \tfrac{1}{2} \right| \\
&\leq \left| \Pr^{\mathsf{PKE}}_{\mathcal{A},\Pi}[\mathsf{Succ} \wedge \mathsf{Forge}] - \tfrac{1}{2} \Pr^{\mathsf{PKE}}_{\mathcal{A},\Pi}[\mathsf{Forge}] \right| \; + \; \left| \Pr^{\mathsf{PKE}}_{\mathcal{A},\Pi}[\mathsf{Succ} \wedge \overline{\mathsf{Forge}}] + \tfrac{1}{2} \Pr^{\mathsf{PKE}}_{\mathcal{A},\Pi}[\mathsf{Forge}] - \tfrac{1}{2} \right| \\
&\leq \tfrac{1}{2} \Pr^{\mathsf{PKE}}_{\mathcal{A},\Pi}[\mathsf{Forge}] + \left| \Pr^{\mathsf{PKE}}_{\mathcal{A},\Pi}[\mathsf{Succ} \wedge \overline{\mathsf{Forge}}] + \tfrac{1}{2} \Pr^{\mathsf{PKE}}_{\mathcal{A},\Pi}[\mathsf{Forge}] - \tfrac{1}{2} \right|,
\end{aligned}$$

which is negligible given the stated claims. (A concrete security bound can be derived easily.)

Proof of Claim 1. The proof is quite straightforward. We construct a PPT forger $\mathcal{F}$ who forges a signature with respect to signature scheme Sig (in the sense of Definition 11) with probability exactly $\mathrm{Pr}^{\mathsf{PKE}}_{\mathcal{A},\Pi}[\mathsf{Forge}]$. Security of Sig implies the claim.

$\mathcal{F}$ is defined as follows: given input 1^k and verification key vk^* (output by $\mathcal{G}$), $\mathcal{F}$ first runs $\mathsf{Setup}(1^k)$ to obtain (PK, msk), and then runs $\mathcal{A}(1^k, PK)$. Note that $\mathcal{F}$ can answer any decryption queries of $\mathcal{A}$. If $\mathcal{A}$ happens to submit a valid ciphertext $\langle vk^*, C, \sigma\rangle$ to its decryption oracle before requesting the challenge ciphertext, then $\mathcal{F}$ simply outputs the forgery (C, σ) and stops. Otherwise, when $\mathcal{A}$ outputs messages m_0, m_1, forger $\mathcal{F}$ proceeds as follows: it chooses a random bit b, computes $C^* \leftarrow \mathcal{E}'_{PK}(vk^*, m_b)$, and obtains (from its signing oracle) a signature σ^* on the "message" C^*. Finally, $\mathcal{F}$ hands the challenge ciphertext $\langle vk^*, C^*, \sigma^*\rangle$ to $\mathcal{A}$. If $\mathcal{A}$ submits a valid ciphertext $\langle vk^*, C, \sigma\rangle$ to its decryption oracle, note that we must have $(C, \sigma) \neq (C^*, \sigma^*)$. In this case, $\mathcal{F}$ simply outputs (C, σ) as its forgery. It is easy to see that $\mathcal{F}$'s success probability (in the sense of Definition 11) is exactly $\mathrm{Pr}^{\mathsf{PKE}}_{\mathcal{A},\Pi}[\mathsf{Forge}]$. □

Proof of Claim 2. We use $\mathcal{A}$ to construct a PPT adversary $\mathcal{A}'$ which attacks the IBE scheme Π' in the sense of Definition 2. Relating the advantages of $\mathcal{A}$ and $\mathcal{A}'$ gives the desired result.

Define adversary $\mathcal{A}'$ as follows:

1. $\mathcal{A}'(1^k)$ runs $\mathcal{G}(1^k)$ to generate (vk^*, sk^*) and outputs the "target" identity $ID^* = vk^*$.
2. $\mathcal{A}'$ is given a master public key PK. Adversary $\mathcal{A}'$, in turn, runs $\mathcal{A}(1^k, PK)$.
3. When $\mathcal{A}$ makes decryption oracle query $\mathcal{D}(\langle vk, C, \sigma\rangle)$, adversary $\mathcal{A}'$ proceeds as follows:
   (a) If $vk = vk^*$ then $\mathcal{A}'$ checks whether $\mathsf{Vrfy}_{vk^*}(C, \sigma) = 1$. If so, $\mathcal{A}'$ aborts and outputs a random bit. Otherwise, it simply responds with $\perp$.
   (b) If $vk \neq vk^*$ and $\mathsf{Vrfy}_{vk}(C, \sigma) = 0$ then $\mathcal{A}'$ responds with $\perp$.
   (c) If $vk \neq vk^*$ and $\mathsf{Vrfy}_{vk}(C, \sigma) = 1$ then $\mathcal{A}'$ makes the oracle query $\mathsf{Der}_{\mathsf{msk}}(vk)$ to obtain SK_{vk}. It then computes $m \leftarrow \mathcal{D}'_{SK_{vk}}(vk, C)$ and responds with m.
4. At some point, $\mathcal{A}$ outputs two equal-length messages m_0, m_1. These messages are output by $\mathcal{A}'$ as well. In return, $\mathcal{A}'$ is given a challenge ciphertext C^*; adversary $\mathcal{A}'$ then computes $\sigma^* \leftarrow \mathsf{Sign}_{vk^*}(C^*)$ and returns $\langle vk^*, C^*, \sigma^*\rangle$ to $\mathcal{A}$.
5. $\mathcal{A}$ may continue to make decryption oracle queries, and these are answered by $\mathcal{A}'$ as before.
6. Finally, $\mathcal{A}$ outputs a guess b'; this same guess is output by $\mathcal{A}'$.

Note that $\mathcal{A}'$ represents a legal adversarial strategy for attacking Π'; in particular, $\mathcal{A}'$ never requests the secret key corresponding to the "target" identity vk^*. Furthermore, $\mathcal{A}'$ provides a perfect simulation for $\mathcal{A}$ until event Forge occurs. It is thus easy to see that

$$\left|\mathrm{Pr}^{\mathsf{IBE}}_{\mathcal{A}',\Pi'}[\mathsf{Succ}] - \tfrac{1}{2}\right| = \left|\mathrm{Pr}^{\mathsf{PKE}}_{\mathcal{A},\Pi}[\mathsf{Succ} \wedge \overline{\mathsf{Forge}}] + \tfrac{1}{2}\,\mathrm{Pr}^{\mathsf{PKE}}_{\mathcal{A},\Pi}[\mathsf{Forge}] - \tfrac{1}{2}\right|,$$

and the left-hand side of the above is negligible by the assumed security of Π'. □

This concludes the proof of the theorem. □

5. A more efficient construction. We show here how the idea from the previous section can be implemented using a MAC and a primitive we call an "encapsulation

scheme" instead of a one-time signature scheme. As argued in the introduction, this results in more efficient constructions of CCA-secure encryption schemes than the previous approach. However, using MACs rather than signatures—which, in particular, will imply that ciphertext validity can no longer be determined efficiently without an appropriate decryption key—complicates the security proof somewhat.

5.1. Encapsulation. We begin by defining a notion of "encapsulation" which may be viewed as a weak variant of commitment. In terms of functionality, an encapsulation scheme commits the sender to a *random string* as opposed to a string chosen by the sender as in the case of commitment. In terms of security, encapsulation only requires binding to hold for *honestly generated encapsulations*; this is analogous to assuming an honest sender during the first phase of a commitment scheme.

DEFINITION 5. *An* encapsulation scheme *is a triple of* PPT *algorithms* $(\mathsf{Init}, \mathcal{S}, \mathcal{R})$ *such that the folllowing hold:*

- Init *takes as input the security parameter* 1^k *and outputs a string* pub.
- $\mathcal{S}$ *takes as input* 1^k *and* pub *and outputs* $(r, \mathsf{com}, \mathsf{dec})$ *with* $r \in \{0,1\}^k$. *We refer to* com *as the* commitment string *and* dec *as the* decommitment string.
- $\mathcal{R}$ *takes as input* $(\mathsf{pub}, \mathsf{com}, \mathsf{dec})$ *and outputs* $r \in \{0,1\}^k \cup \{\perp\}$.

We require that for all pub *output by* Init *and for all* $(r, \mathsf{com}, \mathsf{dec})$ *output by* $\mathcal{S}(1^k, \mathsf{pub})$, *we have* $\mathcal{R}(\mathsf{pub}, \mathsf{com}, \mathsf{dec}) = r$. *We also assume for simplicity that* com *and* dec *have fixed lengths for any given value of the security parameter.*

As in the case of commitment, an encapsulation scheme satisfies notions of binding and hiding. Informally, "hiding" requires that com should not reveal information about r; formally, r should be indistinguishable from random even when given com (and pub). "Binding" requires that an honestly generated com can be "opened" to only a single (legal) value of r; see below.

DEFINITION 6. *An encapsulation scheme is* secure *if it satisfies both hiding and binding as follows:*

Hiding: *The following is negligible for all* PPT $\mathcal{A}$*:*

$$\left| \Pr\left[\begin{array}{c} \mathsf{pub} \leftarrow \mathsf{Init}(1^k); r_0 \leftarrow \{0,1\}^k; \\ (r_1, \mathsf{com}, \mathsf{dec}) \leftarrow \mathcal{S}(1^k, \mathsf{pub}); b \leftarrow \{0,1\} : \mathcal{A}(1^k, \mathsf{pub}, \mathsf{com}, r_b) = b \end{array} \right] - \frac{1}{2} \right|.$$

Binding: *The following is negligible for all* PPT $\mathcal{A}$*:*

$$\Pr\left[\begin{array}{c} \mathsf{pub} \leftarrow \mathsf{Init}(1^k); \\ (r, \mathsf{com}, \mathsf{dec}) \leftarrow \mathcal{S}(1^k, \mathsf{pub}); \quad : \quad \mathcal{R}(\mathsf{pub}, \mathsf{com}, \mathsf{dec}') \notin \{\perp, r\} \\ \mathsf{dec}' \leftarrow \mathcal{A}(1^k, \mathsf{pub}, \mathsf{com}, \mathsf{dec}) \end{array} \right].$$

Both hiding and binding are required to hold only computationally. The encapsulation scheme we will later construct achieves *statistical* hiding (and computational binding).

Since encapsulation is a weaker primitive than commitment, we could use any commitment scheme as an encapsulation scheme. We will be interested, however, in optimizing the efficiency of the construction (in particular, the lengths of com and dec for a fixed value of k) and therefore focus on satisfying only the weaker requirements given above. See further discussion in section 7.2.

5.2. The construction. Let $\Pi' = (\mathsf{Setup}, \mathsf{Der}, \mathcal{E}', \mathcal{D}')$ be an IBE scheme for identities of length $n = n(k)$ which is selective-ID secure against chosen-plaintext attacks, let $(\mathsf{Init}, \mathcal{S}, \mathcal{R})$ be a secure encapsulation scheme in which commitments com output by $\mathcal{S}$ have length n, and let $(\mathsf{Mac}, \mathsf{Vrfy})$ be a MAC. We construct a public-key encryption scheme Π as follows:

Key generation. Keys for our scheme are generated by running $\mathsf{Setup}(1^k)$ to generate (PK, msk) and $\mathsf{Init}(1^k)$ to generate pub. The public key is (PK, pub), and the secret key is msk.

Encryption. To encrypt a message m using public key (PK, pub), a sender first encapsulates a random value by running $\mathcal{S}(1^k, \mathsf{pub})$ to obtain $(r, \mathsf{com}, \mathsf{dec})$. The sender then encrypts the "message" $m \circ \mathsf{dec}$ with respect to the "identity" com; that is, the sender computes $C \leftarrow \mathcal{E}'_{PK}(\mathsf{com}, m \circ \mathsf{dec})$. The resulting ciphertext C is then authenticated by using r as a key for a message authentication code; i.e., the sender computes $\mathsf{tag} \leftarrow \mathsf{Mac}_r(C)$. The final ciphertext is $\langle \mathsf{com}, C, \mathsf{tag} \rangle$.

Decryption. To decrypt a ciphertext $\langle \mathsf{com}, C, \mathsf{tag} \rangle$, the receiver derives the secret key SK_{com} corresponding to the "identity" com, and uses this key to decrypt the ciphertext C as per the underlying IBE scheme; this yields a "message" $m \circ \mathsf{dec}$ (if decryption fails, the receiver outputs $\perp$). Next, the receiver runs $\mathcal{R}(\mathsf{pub}, \mathsf{com}, \mathsf{dec})$ to obtain a string r; if $r \neq \perp$ and $\mathsf{Vrfy}_r(C, \mathsf{tag}) = 1$, the receiver outputs m. Otherwise, the receiver outputs $\perp$.

THEOREM 2. *If Π' is an identity-based encryption scheme which is selective-ID secure against chosen-plaintext attacks, the encapsulation scheme is secure (in the sense of Definition 6), and $(\mathsf{Mac}, \mathsf{Vrfy})$ is a strong one-time message authentication code, then Π a public-key encryption scheme secure against adaptive chosen-ciphertext attacks.*

Proof. Let $\mathcal{A}$ be a PPT adversary attacking Π in an adaptive chosen-ciphertext attack. On an intuitive level, the proof here is the same as the proof of Theorem 1 in the following sense: Say a ciphertext $\langle \mathsf{com}, C, \mathsf{tag} \rangle$ is *valid* if decryption of this ciphertext (using msk) does *not* result in $\perp$. Let $\langle \mathsf{com}^*, C^*, \mathsf{tag}^* \rangle$ denote the challenge ciphertext received by $\mathcal{A}$. We will show that (1) $\mathcal{A}$ submits to its decryption oracle a valid ciphertext $\langle \mathsf{com}^*, C, \mathsf{tag} \rangle$ (with $\langle C, \mathsf{tag} \rangle \neq \langle C^*, \mathsf{tag}^* \rangle$) only with negligible probability; and (2) assuming that the previous event does not occur, the decryption queries made by $\mathcal{A}$ do not help $\mathcal{A}$ to "learn" the underlying plaintext. The second statement is relatively easy to prove based on the security of Π'; the first, however, is now more challenging to prove since validity of a ciphertext cannot be determined without knowledge of msk. Because of this, we structure the proof as a sequence of games to make it easier to follow. We let $\Pr_i[\cdot]$ denote the probability of a particular event occurring in game i.

Game 0 is the original game in which $\mathcal{A}$ attacks Π in a chosen-ciphertext attack as described in Definition 8. Let $r^*, \mathsf{com}^*, \mathsf{dec}^*$ denote the values that are used in computing the challenge ciphertext, and notice that we may assume these values are generated at the outset of the experiment (since these values are generated independently of $\mathcal{A}$'s actions). We are interested in upper-bounding $\left|\Pr_0[\mathsf{Succ}] - \frac{1}{2}\right|$, where (recall) Succ denotes the event that $\mathcal{A}$'s output bit b' is identical to the bit b used in constructing the challenge ciphertext.

In Game 1, we modify the experiment as follows: on input of a ciphertext of the form $\langle \mathsf{com}^*, C, \mathsf{tag} \rangle$, the decryption oracle simply outputs $\perp$. Let Valid denote the event that $\mathcal{A}$ submits a ciphertext $\langle \mathsf{com}^*, C, \mathsf{tag} \rangle$ to its decryption oracle which is valid, and note that

$$\left|\Pr_1[\mathsf{Succ}] - \Pr_0[\mathsf{Succ}]\right| \leq \Pr_0[\mathsf{Valid}] = \Pr_1[\mathsf{Valid}].$$

The above holds since Games 0 and 1 are identical until Valid occurs.

Let NoBind denote the event that $\mathcal{A}$ at some point submits a ciphertext $\langle \mathsf{com}^*, C, \mathsf{tag}\rangle$ to its decryption oracle such that: (1) C decrypts to $m \circ \mathsf{dec}$ (using the secret key SK_{com^*} derived from msk) and (2) $\mathcal{R}(\mathsf{pub}, \mathsf{com}^*, \mathsf{dec}) = r$ with $r \notin \{r^*, \perp\}$. Let Forge denote the event that $\mathcal{A}$ at some point submits a ciphertext $\langle \mathsf{com}^*, C, \mathsf{tag}\rangle$ to its decryption oracle such that $\mathsf{Vrfy}_{r^*}(C, \mathsf{tag}) = 1$. We clearly have $\Pr_1[\mathsf{Valid}] \leq \Pr_1[\mathsf{NoBind}] + \Pr_1[\mathsf{Forge}]$.

It is relatively easy to see that $\Pr_1[\mathsf{NoBind}]$ is negligible assuming the binding property of the encapsulation scheme. Formally, consider an adversary $\mathcal{B}$ acting as follows: given input $(1^k, \mathsf{pub}, \mathsf{com}^*, \mathsf{dec}^*)$, adversary $\mathcal{B}$ generates (PK, msk) by running $\mathsf{Setup}(1^k)$ and then runs $\mathcal{A}$ on inputs 1^k and (PK, pub). Whenever $\mathcal{A}$ makes a query to its decryption oracle, $\mathcal{B}$ can respond to this query as required by Game 1; specifically, $\mathcal{B}$ simply responds with $\perp$ to a decryption query of the form $\langle \mathsf{com}^*, C, \mathsf{tag}\rangle$, and responds to other queries using msk. When $\mathcal{A}$ submits its two messages m_0, m_1, adversary $\mathcal{B}$ simply chooses $b \in \{0, 1\}$ at random and encrypts m_b in the expected way to generate a completely valid challenge ciphertext $\langle \mathsf{com}^*, C^*, \mathsf{tag}^*\rangle$. (Note that $\mathcal{B}$ can easily do this since it has dec^* and can compute r^*.) At the end of the experiment, $\mathcal{B}$ can decrypt every query of the form $\langle \mathsf{com}^*, C, \mathsf{tag}\rangle$ that $\mathcal{A}$ made to its decryption oracle to see whether NoBind occurred and, if so, to learn a value dec such that $\mathcal{R}(\mathsf{pub}, \mathsf{com}^*, \mathsf{dec}) \notin \{r^*, \perp\}$. But this exactly violates the binding property of encapsulation scheme $(\mathsf{Init}, \mathcal{S}, \mathcal{R})$, implying that $\Pr_1[\mathsf{NoBind}]$ must be negligible.

Game 2 is derived by modifying the way the challenge ciphertext is computed. Specifically, when $\mathcal{A}$ submits its two messages m_0, m_1 we now compute $C^* \leftarrow \mathcal{E}'_{PK}(\mathsf{com}^*, 0^{|m_0|} \circ 0^n)$ followed by $\mathsf{tag}^* \leftarrow \mathsf{Mac}_{r^*}(C^*)$. The challenge ciphertext is $\langle \mathsf{com}^*, C^*, \mathsf{tag}^*\rangle$. (A random bit b is still chosen, but is only used to define event Succ.) Since the challenge ciphertext is independent of b, it follows immediately that $\Pr_2[\mathsf{Succ}] = \frac{1}{2}$.

We claim that $|\Pr_2[\mathsf{Succ}] - \Pr_1[\mathsf{Succ}]|$ is negligible. To see this, consider the following adversary $\mathcal{A}'$ attacking the IBE scheme Π' via a chosen-plaintext attack:

- Algorithm $\mathcal{A}'(1^k)$ first runs $\mathsf{Init}(1^k)$ to generate pub and then runs $\mathcal{S}(1^k, \mathsf{pub})$ to obtain $(r^*, \mathsf{com}^*, \mathsf{dec}^*)$. It outputs com^* as the target identity and is then given the master public key PK. Finally, $\mathcal{A}'$ runs $\mathcal{A}$ on inputs 1^k and (PK, pub).
- Decryption queries of $\mathcal{A}$ are answered in the natural way:
  - Queries of the form $\langle \mathsf{com}^*, C, \mathsf{tag}\rangle$ are answered with $\perp$.
  - Queries of the form $\langle \mathsf{com}, C, \mathsf{tag}\rangle$ with $\mathsf{com} \neq \mathsf{com}^*$ are answered by first querying $\mathsf{Der}_{\mathsf{msk}}(\mathsf{com})$ to obtain SK_{com}, and then decrypting in the usual way.
- Eventually, $\mathcal{A}$ submits two equal-length messages m_0, m_1. $\mathcal{A}'$ selects a bit b at random, and sends $m_b \circ \mathsf{dec}^*$ and $0^{|m_0|} \circ 0^n$ to its encryption oracle. It receives in return a challenge ciphertext C^*, and uses this to generate a ciphertext $\langle \mathsf{com}^*, C^*, \mathsf{tag}^*\rangle$ in the natural way.
- Further decryption queries of $\mathcal{A}$ are answered as above.
- Finally, $\mathcal{A}$ outputs a bit b'. If $b = b'$, then $\mathcal{A}'$ outputs 0; otherwise, $\mathcal{A}'$ outputs 1.

Note that $\mathcal{A}'$ is a valid adversary. When the encryption query of $\mathcal{A}'$ is answered with an encryption of $m_b \circ \mathsf{dec}^*$, then the view of $\mathcal{A}$ is exactly as in Game 1; on the other hand, when the encryption query of $\mathcal{A}'$ is answered with an encryption of $0^{|m_0|} \circ 0^n$,

then the view of $\mathcal{A}$ is exactly as in Game 2. Thus,

$$\begin{aligned}\mathsf{Adv}^{\mathsf{IBE}}_{\mathcal{A}',\Pi'}(k) &= \left|\tfrac{1}{2}\Pr_1[\mathsf{Succ}] + \tfrac{1}{2}\Pr_2[\overline{\mathsf{Succ}}] - \tfrac{1}{2}\right| \\ &= \tfrac{1}{2}\cdot\left|\Pr_1[\mathsf{Succ}] - \Pr_2[\mathsf{Succ}]\right|.\end{aligned}$$

Security of Π' implies that $\mathsf{Adv}^{\mathsf{IBE}}_{\mathcal{A}',\Pi'}$ is negligible, implying that $|\Pr_2[\mathsf{Succ}]-\Pr_1[\mathsf{Succ}]|$ is negligible. An exactly analogous argument shows that $|\Pr_2[\mathsf{Forge}] - \Pr_1[\mathsf{Forge}]|$ is negligible as well. (The only difference is that $\mathcal{A}'$ runs $\mathcal{A}$ to completion and then checks whether $\mathcal{A}$ has made any decryption query of the form $\langle \mathsf{com}^*, C, \mathsf{tag}\rangle$ for which $\mathsf{Vrfy}_{r^*}(C,\mathsf{tag}) = 1$. If so, then $\mathcal{A}'$ outputs 1; otherwise, it outputs 0.)

In Game 3, we introduce one final change. The components com^* and C^* of the challenge ciphertext are computed as in Game 2; however, the component tag^* is computed by choosing a random key $r \in \{0,1\}^k$ and setting $\mathsf{tag}^* = \mathsf{Mac}_r(C^*)$. Event Forge in this game is defined as before, but using the key r; that is, Forge is now the event that $\mathcal{A}$ makes a decryption query of the form $\langle \mathsf{com}^*, C, \mathsf{tag}\rangle$ for which $\mathsf{Vrfy}_r(C,\mathsf{tag}) = 1$.

We claim that $|\Pr_3[\mathsf{Forge}] - \Pr_2[\mathsf{Forge}]|$ is negligible. To see this, consider the following algorithm $\mathcal{B}$ attacking the hiding property of the encapsulation scheme:

- $\mathcal{B}$ is given input 1^k and $(\mathsf{pub}, \mathsf{com}^*, \tilde{r})$. It then runs $\mathsf{Setup}(1^k)$ to generate (PK, msk), and runs $\mathcal{A}$ on inputs 1^k and (PK, pub).
- Decryption queries of $\mathcal{A}$ are answered in the natural way.
- Eventually, $\mathcal{A}$ submits messages m_0, m_1. $\mathcal{B}$ computes $C^* \leftarrow \mathcal{E}'_{PK}(\mathsf{com}^*, 0^{|m_0|} \circ 0^n)$, computes $\mathsf{tag}^* = \mathsf{Mac}_{\tilde{r}}(C^*)$, and returns the challenge ciphertext $\langle \mathsf{com}^*, C^*, \mathsf{tag}^*\rangle$ to $\mathcal{A}$.
- Further decryption queries of $\mathcal{A}$ are answered as above.
- When $\mathcal{A}$ halts, $\mathcal{B}$ checks whether $\mathcal{A}$ has made any decryption query of the form $\langle \mathsf{com}^*, C, \mathsf{tag}\rangle$ for which $\mathsf{Vrfy}_{\tilde{r}}(C,\mathsf{tag}) = 1$. If so, $\mathcal{B}$ outputs 1; otherwise, it outputs 0.

Now, if $\tilde{r}$ is such that $(\tilde{r}, \mathsf{com}^*, \mathsf{dec}^*)$ was output by $\mathcal{S}(1^k, \mathsf{pub})$, then the view of $\mathcal{A}$ is exactly as in Game 2 and so $\mathcal{B}$ outputs 1 with probability $\Pr_2[\mathsf{Forge}]$. On the other hand, if $\tilde{r}$ is chosen at random independently of com^*, then the view of $\mathcal{A}$ is exactly as in Game 3 and so $\mathcal{B}$ outputs 1 with probability $\Pr_3[\mathsf{Forge}]$. The hiding property of the encapsulation scheme thus implies that $|\Pr_3[\mathsf{Forge}] - \Pr_2[\mathsf{Forge}]|$ is negligible.

To complete the proof, we show that $\Pr_3[\mathsf{Forge}]$ is negligible. This follows rather easily from the security of the MAC, but we sketch the details here. Let $q = q(k)$ be an upper bound on the number of decryption oracle queries made by $\mathcal{A}$, and consider the following forging algorithm $\mathcal{F}$: first, $\mathcal{F}$ chooses a random index $j \leftarrow \{1,\ldots,q\}$. Next, $\mathcal{F}$ begins simulating Game 3 for $\mathcal{A}$ in the natural way. If the jth decryption query $\langle \mathsf{com}_j, C_j, \mathsf{tag}_j\rangle$ occurs before $\mathcal{A}$ makes its encryption query, then $\mathcal{F}$ simply outputs (C_j, tag_j) and halts. Otherwise, in response to the encryption query (m_0, m_1) of $\mathcal{A}$, forger $\mathcal{F}$ computes $(r^*, \mathsf{com}^*, \mathsf{dec}^*) \leftarrow \mathcal{S}(1^k, \mathsf{pub})$ followed by $C^* \leftarrow \mathcal{E}'_{PK}(\mathsf{com}^*, 0^{|m_0|} \circ 0^n)$. Next, $\mathcal{F}$ submits C^* to its Mac oracle and receives in return tag^*. Forger $\mathcal{F}$ then gives the challenge ciphertext $\langle \mathsf{com}^*, C^*, \mathsf{tag}^*\rangle$ to $\mathcal{A}$ and continues running $\mathcal{A}$ until $\mathcal{A}$ submits its jth decryption query $\langle \mathsf{com}_j, C_j, \mathsf{tag}_j\rangle$. At this point, $\mathcal{F}$ outputs (C_j, tag_j) and halts.

It is not difficult to see that the success probability of $\mathcal{F}$ in outputting a valid forgery is at least $\Pr_3[\mathsf{Forge}]/q$. Since $(\mathsf{Mac}, \mathsf{Vrfy})$ is a strong one-time MAC and q is polynomial, this shows that $\Pr_3[\mathsf{Forge}]$ is negligible.

Putting everything together, we have

$$\begin{aligned}\left|\Pr_0[\mathsf{Succ}] - \tfrac{1}{2}\right| &\le \left|\Pr_0[\mathsf{Succ}] - \Pr_1[\mathsf{Succ}]\right| + \left|\Pr_1[\mathsf{Succ}] - \tfrac{1}{2}\right| \\ &\le \Pr_1[\mathsf{NoBind}] + \Pr_1[\mathsf{Forge}] + \left|\Pr_1[\mathsf{Succ}] - \Pr_2[\mathsf{Succ}]\right| + \left|\Pr_2[\mathsf{Succ}] - \tfrac{1}{2}\right| \\ &= \Pr_1[\mathsf{NoBind}] + \Pr_1[\mathsf{Forge}] + \left|\Pr_1[\mathsf{Succ}] - \Pr_2[\mathsf{Succ}]\right| \\ &\le \Pr_1[\mathsf{NoBind}] + \Pr_3[\mathsf{Forge}] + \left|\Pr_2[\mathsf{Forge}] - \Pr_3[\mathsf{Forge}]\right| \\ &\quad + \left|\Pr_1[\mathsf{Forge}] - \Pr_2[\mathsf{Forge}]\right| + \left|\Pr_1[\mathsf{Succ}] - \Pr_2[\mathsf{Succ}]\right|,\end{aligned}$$

and all terms in the final equation are negligible. (A concrete security analysis follows easily from the above.) □

6. Chosen-ciphertext security for IBE and HIBE schemes. The techniques of the previous two sections extend relatively easily to enable construction of an ℓ-level HIBE scheme secure against chosen-ciphertext attacks based on any $(\ell+1)$-level HIBE scheme secure against chosen-plaintext attacks. (Note that an IBE scheme is simply a 1-level HIBE scheme.) We give the details for the signature-based approach of section 4. For arbitrary $\ell \ge 1$, let $\Pi' = (\mathsf{Setup}', \mathsf{Der}', \mathcal{E}', \mathcal{D}')$ be an $(\ell+1)$-level HIBE scheme handling identities of length $n+1$, and let $\mathsf{Sig} = (\mathcal{G}, \mathsf{Sign}, \mathsf{Vrfy})$ be a signature scheme in which the verification key output by $\mathcal{G}(1^k)$ has length $n = n(k)$. We construct an ℓ-level HIBE scheme Π handling identities of length n. The intuition behind the construction is simple: the ID-vector $v = (v_1, \ldots, v_L) \in (\{0,1\}^n)^L$ in Π will be mapped to the ID-vector

$$\mathsf{Encode}(v) \stackrel{\text{def}}{=} (0v_1, \ldots, 0v_L) \in (\{0,1\}^{n+1})^L$$

in Π'. We will maintain the invariant that the secret key SK_v for ID-vector v in Π will be the secret key $SK'_{\hat{v}}$ for ID-vector $\hat{v} = \mathsf{Encode}(v)$ in Π'. When encrypting a message m to ID-vector v in Π, the sender will generate a verification key vk and then encrypt m to the ID-vector $\hat{v}.(1vk)$ using Π'. (The resulting ciphertext will then be signed as in section 4.) The extra 0 and 1 bits used as "padding" ensure that any decryption queries asked by an adversary (in Π) correspond (in Π') to nodes that are not ancestors of the target ID-vector.

In more detail, Π is constructed as follows:

Setup. The Setup algorithm is the same as in Π'. (Note that $\mathsf{Encode}(\varepsilon) = \varepsilon$ so the master secret key $SK_\varepsilon = SK'_\varepsilon$ satisfies the desired invariant.)

Key derivation. $\mathsf{Der}_{SK_v}(v, r)$ runs as follows: let $\hat{v} = \mathsf{Encode}(v)$ and $\hat{r} = \mathsf{Encode}(r)$. Run $\mathsf{Der}'_{SK_v}(\hat{v}, \hat{r})$ and output the result as $SK_{v.r}$. (To see that key derivation maintains the desired invariant given that $SK_v = SK'_{\hat{v}}$, note that $\mathsf{Encode}(v.r) = \mathsf{Encode}(v).\mathsf{Encode}(r)$.)

Encryption. $\mathcal{E}_{PK}(v, m)$ first runs $\mathcal{G}(1^k)$ to obtain (vk, sk). Let $\hat{v} = \mathsf{Encode}(v).(1vk)$. The algorithm then computes $C \leftarrow \mathcal{E}'_{PK}(\hat{v}, m)$ and $\sigma \leftarrow \mathsf{Sign}_{sk}(C)$. The final ciphertext is $\langle vk, C, \sigma \rangle$.

Decryption. $\mathcal{D}_{SK_v}(v, \langle vk, C, \sigma \rangle)$ proceeds as follows: first check whether $\mathsf{Vrfy}_{vk}(C, \sigma) \stackrel{?}{=} 1$. If not, output $\perp$. Otherwise, let $\hat{v} = \mathsf{Encode}(v)$ and run $\mathsf{Der}'_{SK_v}(\hat{v}, (1vk))$ to generate the key $SK^* = SK'_{\hat{v}.(1vk)}$. Then output $m := \mathcal{D}'_{SK^*}(\hat{v}, C)$.

It can be verified easily that the above scheme is correct. An analogous construction can be given using the MAC-based construction of section 5. We now state the main result of this section.

THEOREM 3. *If* Π' *is selective-ID secure against chosen-plaintext attacks and* Sig *is a strong one-time signature scheme, then* Π *is selective-ID secure against chosen-ciphertext attacks.*

Proof. The proof is similar to that of Theorem 1. Given any PPT adversary $\mathcal{A}$ attacking Π in a selective-ID chosen-ciphertext attack, we define an event Forge and then prove the analogues of Claims 1 and 2 in our setting. For visual comfort, we use $\Pr[\cdot]$ instead of $\Pr^{\mathsf{HIBE}}_{\mathcal{A},\Pi}[\cdot]$.

Let v^* denote the "target" ID-vector initially output by $\mathcal{A}$, and let $\langle vk^*, C^*, \sigma^*\rangle$ be the challenge ciphertext received by $\mathcal{A}$. Let Forge be the event that $\mathcal{A}$ makes a decryption query $\widehat{\mathcal{D}}(v^*, \langle vk^*, C, \sigma\rangle)$ with $\mathsf{Vrfy}_{vk^*}(C, \sigma) = 1$. (As in the previous proof, we may assume vk^* is chosen at the beginning of the experiment and so this event is defined even before $\mathcal{A}$ receives the challenge ciphertext. Recall again that $\mathcal{A}$ is disallowed from submitting the challenge ciphertext to its decryption oracle once this ciphertext has been given to $\mathcal{A}$.) A proof exactly as in the case of Claim 1, relying again on the fact that Sig is a strong one-time signature scheme, shows that $\Pr[\mathsf{Forge}]$ is negligible.

We next show that $|\Pr[\mathsf{Succ} \wedge \overline{\mathsf{Forge}}] + \frac{1}{2}\Pr[\mathsf{Forge}] - \frac{1}{2}|$ is negligible. To do so, we define adversary $\mathcal{A}'$ attacking Π' in a selective-ID chosen-plaintext attack. $\mathcal{A}'$ is defined as follows:

1. $\mathcal{A}'(1^k)$ runs $\mathcal{A}(1^k)$ who, in turn, outputs an ID-vector $v^* \in (\{0,1\}^n)^{\leq \ell}$. Adversary $\mathcal{A}'$ runs $\mathcal{G}(1^k)$ to generate (vk^*, sk^*) and outputs the target ID-vector $V^* = \mathsf{Encode}(v^*).(1vk^*)$.
2. $\mathcal{A}'$ is given PK, which it gives to $\mathcal{A}$.
3. When $\mathcal{A}$ requests the secret key for ID-vector v, $\mathcal{A}'$ requests the secret key $SK'_{\hat{v}}$ for ID-vector $\hat{v} = \mathsf{Encode}(v)$ and returns this secret key to $\mathcal{A}$. Note that since v is not a prefix of the target ID-vector v^* of $\mathcal{A}$, it follows that $\hat{v}$ is not a prefix of the target ID-vector V^* of $\mathcal{A}'$.
4. When $\mathcal{A}$ makes a decryption query $\widehat{\mathcal{D}}(v, \langle vk, C, \sigma\rangle)$, adversary $\mathcal{A}'$ proceeds as follows:
   (a) If $v = v^*$ then $\mathcal{A}'$ checks whether $\mathsf{Vrfy}_{vk}(C, \sigma) = 1$. If so, then $\mathcal{A}'$ aborts and outputs a random bit. Otherwise, it simply responds with $\perp$.
   (b) If $v \neq v^*$, or if $v = v^*$ and $vk \neq vk^*$, then $\mathcal{A}'$ sets $\hat{v} = \mathsf{Encode}(v)$ and requests the secret key $SK'_{\hat{v}.(1vk)}$. (Note that $\hat{v}.(1vk)$ is not a prefix of the target ID-vector V^* of $\mathcal{A}'$, so $\mathcal{A}'$ is allowed to submit this request.) It then honestly decrypts the submitted ciphertext and returns the result to $\mathcal{A}$.
5. When $\mathcal{A}$ outputs its two messages m_0, m_1, these same messages are output by $\mathcal{A}'$. In return, $\mathcal{A}'$ receives a challenge ciphertext C^*. Adversary $\mathcal{A}'$ computes $\sigma^* \leftarrow \mathsf{Sign}_{sk^*}(C^*)$ and returns challenge ciphertext $\langle vk^*, C^*, \sigma^*\rangle$ to $\mathcal{A}$.
6. Any of $\mathcal{A}$'s subsequent decryption queries, or requests for secret keys, are answered as before.
7. Finally, $\mathcal{A}$ outputs a guess b'; this same guess is output by $\mathcal{A}'$.

Note that $\mathcal{A}'$ represents a legal adversarial strategy for attacking Π'. As in the proof of Claim 2, it follows from the security of Π' that $|\Pr[\mathsf{Succ} \wedge \overline{\mathsf{Forge}}] + \frac{1}{2}\Pr[\mathsf{Forge}] - \frac{1}{2}|$ is negligible. This completes the proof. □

We remark that when Π' is fully secure against chosen-plaintext attacks [11, 33], then Π is fully secure against chosen-ciphertext attacks. A proof for this case is easily derived from the proof above.

Canetti, Halevi, and Katz [17] define a slightly stronger notion of HIBE which

requires the HIBE scheme to support an arbitrary (polynomial) number of levels ℓ and identities of arbitrary (polynomial) length n (where ℓ, n are provided as input to the initial Setup algorithm). We refer to HIBE schemes of this type as *unbounded*. Security is defined as in Definition 4, except that the adversary's advantage must be negligible for all adversaries $\mathcal{A}$ as well as for all polynomially bounded functions ℓ, n. Since the above construction requires only a strong one-time signature scheme, which can be constructed based on any one-way function (and hence from any secure HIBE scheme), we have the following.

COROLLARY 1. *If there exists an unbounded HIBE scheme which is selective-ID secure (resp., fully secure) against chosen-plaintext attacks, then there exists an unbounded HIBE scheme which is selective-ID secure (resp., fully secure) against adaptive chosen-ciphertext attacks.*

The analogous result for the case of (standard) public-key encryption is not known.

7. An efficient instantiation. Here, we describe one instantiation of our generic construction of CCA-secure cryptosystems from section 5. We then compare the efficiency of this construction with the most efficient previously known CCA-secure scheme. To instantiate our construction, we need to specify a message authentication code, an encapsulation scheme, and an IBE scheme which is selective-ID secure against chosen-plaintext attacks. We consider each of these in turn.

7.1. Message authentication code. A number of efficient (strong, one-time) MACs are known. Since the computational cost of these schemes will be dominated by the computational cost of the IBE scheme, we focus instead on minimizing the lengths of the key and the tag. For concreteness, we suggest using CBC-MAC with 128-bit AES as the underlying block cipher. (In this scheme, both the secret key and the tag are 128 bits long.) We remark, however, that strong one-time MACs with information-theoretic security [57, 54] could also be used.

7.2. Encapsulation scheme. Adapting earlier work of Damgård, Pedersen, and Pfitzmann [24] and Halevi and Micali [39], we propose an encapsulation scheme based on any universal one-way hash function (UOWHF) family $\{H_s : \{0,1\}^{k_1} \to \{0,1\}^k\}$ (where $k_1 \geq 3k$ is a function of the security parameter k). Our scheme works as follows:

- Init chooses a hash function h from a family of pairwise-independent hash functions mapping k_1-bit strings to k-bit strings, and also chooses at random a key s defining UOWHF H_s. It outputs $\mathsf{pub} = (h, s)$.
- The encapsulation algorithm $\mathcal{S}$ takes pub as input, chooses a random $x \in \{0,1\}^{k_1}$, and then outputs $(r = h(x), \mathsf{com} = H_s(x), \mathsf{dec} = x)$.
- The recovery algorithm $\mathcal{R}$ takes as input $((h, s), \mathsf{com}, \mathsf{dec})$ and outputs $h(\mathsf{dec})$ if $H_s(\mathsf{dec}) = \mathsf{com}$, and $\perp$ otherwise.

We prove the following regarding the above scheme.

THEOREM 4. *The scheme above is a secure encapsulation scheme. Specifically, the scheme is computationally binding under the assumption that $\{H_s\}$ is a UOWHF family, and statistically hiding (without any assumptions).*

Proof. The binding property is easy to see. In particular, violation of the binding property implies that an adversary finds $\mathsf{dec}' \neq \mathsf{dec}$ for which $H_s(\mathsf{dec}') = H_s(\mathsf{dec})$. Since dec is chosen independently of the key s in an honest execution of $\mathcal{S}$, security of the UOWHF family implies that binding can be violated with only negligible probability. We omit the straightforward details. (Note, however, that a UOWHF rather

than a collision-resistant hash function is sufficient here since the binding property we require is weaker than that required by a standard commitment scheme.)

We next prove the following claim, which immediately implies statistical hiding.

CLAIM 3. *For the encapsulation scheme described above, the statistical difference between the following distributions is at most* $2 \cdot 2^{\frac{2k-k_1}{3}} \leq 2 \cdot 2^{-k/3}$*:*

$$(1)\{\mathsf{pub} \leftarrow \mathsf{Setup}; (r, \mathsf{com}, \mathsf{dec}) \leftarrow \mathcal{S}(\mathsf{pub}) : (\mathsf{pub}, \mathsf{com}, r)\},$$
$$(2)\{\mathsf{pub} \leftarrow \mathsf{Setup}; (r, \mathsf{com}, \mathsf{dec}) \leftarrow \mathcal{S}(\mathsf{pub}); r' \leftarrow \{0,1\}^k : (\mathsf{pub}, \mathsf{com}, r')\}.$$

The proof of this claim is loosely based on [24, 39], but our proof is much simpler. Let $\alpha \stackrel{\text{def}}{=} \frac{2k_1-k}{3}$, and assume for simplicity that k_1, k are multiples of 3. Fix an arbitrary s for the remainder of the discussion. For any fixed $x \in \{0,1\}^{k_1}$, let $N_x \stackrel{\text{def}}{=} \{x' \mid H_s(x') = H_s(x)\}$; this is simply the set of elements hashing to $H_s(x)$. Call x *good* if $|N_x| \geq 2^\alpha$, and *bad* otherwise. Since the output length of H_s is k bits, there are at most $2^\alpha \cdot 2^k = 2^{\alpha+k}$ bad x's; thus, the probability that an x chosen uniformly at random from $\{0,1\}^{k_1}$ is bad is at most

$$2^{\alpha+k-k_1} \;=\; 2^{\frac{2k-k_1}{3}} \;\leq\; 2^{-k/3}$$

(using the fact that $k_1 \geq 3k$).

When x is good, the min-entropy of x—given (h, s) and $H_s(x)$—is at least α since every $\tilde{x} \in N_x$ is equally likely. Let U_k represent the uniform distribution over $\{0,1\}^k$. Viewing h as a strong extractor (or, equivalently, applying the leftover-hash lemma [40]) we see that the statistical difference between $\{h, s, H_s(x), h(x)\}$ and $\{h, s, H_s(x), U_k\}$ is at most

$$2^{-(\alpha-k)/2} \;=\; 2^{\frac{2k-k_1}{3}} \;\leq\; 2^{-k/3}.$$

The claim, and hence the theorem, follows. □

A practical setting of the above parameters (and one that we will use when discussing the efficiency of our scheme, below) is $k_1 = 448$, $k = 128$ which yields a 128-bit r with statistical difference at most $2 \cdot 2^{\frac{256-448}{3}} = 2^{-63}$ from uniform.[5] Also, in practice one would likely replace the UOWHF by a suitable modification of a cryptographic hash function such as SHA-1.

7.3. IBE scheme. Boneh and Boyen [7] recently proposed two efficient IBE schemes satisfying the definition of security needed for our purposes. In the interest of space, we explore an instantiation of our construction using their first scheme only. (Of course, their second scheme could also be used. Doing so yields a mild efficiency improvement at the expense of requiring a stronger cryptographic assumption.)

We briefly discuss the cryptographic assumption on which the Boneh–Boyen IBE scheme is based. Let $\mathcal{IG}$ denote an efficient algorithm which, on input 1^k, outputs descriptions of two cyclic groups $\mathbb{G}, \mathbb{G}_1$ of prime order q (with $|q| = k$), a generator $g \in \mathbb{G}$, and an efficiently computable function $\hat{e} : \mathbb{G} \times \mathbb{G} \to \mathbb{G}_1$ which is a *nontrivial bilinear map*; namely, (1) for all $\mu, \nu \in \mathbb{G}$ and $a, b \in \mathbb{Z}_q$ we have $\hat{e}(\mu^a, \nu^b) = \hat{e}(\mu, \nu)^{ab}$ and (2) $\hat{e}(g, g)$ is a generator of $\mathbb{G}_1$. (See [11] for a discussion about realizing an algorithm $\mathcal{IG}$ with these properties.) Following the standard terminology, we refer to $\hat{e}$ as a *pairing*.

[5] Note that since only second-preimage resistance is needed to achieve the binding property, a 128-bit output length provides sufficient security.

The *computational bilinear Diffie-Hellman (BDH) problem with respect to* $\mathcal{IG}$ is the following: given $(\mathbb{G}, \mathbb{G}_1, g, \hat{e})$ as output by $\mathcal{IG}$ along with g^α, g^β, and g^γ (for random $\alpha, \beta, \gamma \in \mathbb{Z}_q$), compute $\hat{e}(g,g)^{\alpha\beta\gamma}$. Informally, we say that $\mathcal{IG}$ *satisfies the computational BDH assumption* if the computational BDH assumption with respect to $\mathcal{IG}$ is hard for any PPT algorithm.

The *decisional BDH problem with respect to* $\mathcal{IG}$ is to distinguish between tuples of the form $(g^\alpha, g^\beta, g^\gamma, \hat{e}(g,g)^{\alpha\beta\gamma})$ and $(g^\alpha, g^\beta, g^\gamma, \hat{e}(g,g)^\mu)$ for random $\alpha, \beta, \gamma, \mu \in \mathbb{Z}_q$ (note that $\hat{e}(g,g)^\mu$ is simply a random element of $\mathbb{G}_1$). Informally, we say $\mathcal{IG}$ *satisfies the decisional BDH assumption* if no PPT algorithm can solve the decisional BDH problem with respect to $\mathcal{IG}$ with probability significantly better than $\frac{1}{2}$. We refer to [11] for formal definitions and further discussion.

A concrete IBE scheme. We refer to [7] for the full details and content ourselves with giving only a high-level description of their first IBE scheme here, modified slightly for our eventual application. We assume for simplicity that system parameters $(\mathbb{G}, \mathbb{G}_1, g, \hat{e})$ have already been established by running $\mathcal{IG}(1^k)$ (of course, it is also possible for $\mathcal{IG}$ to be run during key generation). Let $G : \mathbb{G}_1 \to \{0,1\}^k$ be a function whose output is indistinguishable from uniform when its input is uniformly distributed in $\mathbb{G}_1$ (however, G need not expand its input). The IBE scheme is defined as follows:

Setup. Pick random generators $g_1, g_2 \in \mathbb{G}$ and a random $x \in \mathbb{Z}_q$. Set $g_3 = g^x$ and $Z = \hat{e}(g_1, g_3)$. The master public key is $PK = (g, g_1, g_2, g_3, Z)$ and the master secret key is $\mathsf{msk} = x$.

Derive. To derive the secret key for the identity $ID \in \mathbb{Z}_q$ using $\mathsf{msk} = x$, choose a random $t \in \mathbb{Z}_q$, and return the key $SK_{ID} = (g_1^x g_2^t g_3^{t \cdot ID},\ g^t)$.

Encrypt. To encrypt a message $M \in \{0,1\}^k$ with respect to the identity $ID \in \mathbb{Z}_q$, choose a random $s \in \mathbb{Z}_q$, and output the ciphertext $(g^s,\ g_2^s g_3^{s \cdot ID},\ G(Z^s) \oplus M)$.

Decrypt. To decrypt ciphertext (A, B, C) using private key (K_1, K_2), output

$$C \oplus G(\hat{e}(A, K_1)/\hat{e}(B, K_2)). \tag{7.1}$$

Correctness can be easily verified. Security of the above scheme is based on the decisional[6] BDH assumption. For efficiency, the master secret key msk may also contain the discrete logarithms of g_1, g_2 (with respect to g), in which case the key-derivation algorithm requires only two exponentiations with respect to the fixed base g.

7.4. Putting it all together. Given the above, we now fully describe a CCA-secure encryption scheme. In describing the scheme, we focus on the case of encrypting "long" messages (say, 10^4 bits or longer). Focusing on this case allows for a more accurate comparison with the scheme of [42] (which also focuses on this case).

Let $(\mathsf{Mac}, \mathsf{Vrfy})$ denote the CBC-MAC using 128-bit AES as the underlying block cipher. Let $H : \{0,1\}^{448} \to \{0,1\}^{128}$ represent a hash function assumed to be second-preimage resistant (constructed, e.g., via a suitable modification of SHA-1). Let $G : \mathbb{G}_1 \to \{0,1\}^*$ denote a pseudorandom generator with sufficiently long output length (constructed, e.g., by first hashing elements of $\mathbb{G}_1$ and then using a suitable modification of a block/stream cipher). We assume that $|q| > 128$ so that strings in $\{0,1\}^{128}$ may be mapped to $\mathbb{Z}_q$ in a one-to-one manner. Using the IBE scheme

[6] Note that if G instead represents a hard-core predicate for the *computational* BDH assumption, we obtain a scheme (encrypting a single bit) secure under this, possibly weaker, assumption. Running the scheme in parallel we obtain a scheme encrypting longer messages, as needed by our construction.

TABLE 7.1
Efficiency comparison for CCA-secure encryption schemes. See text for discussion.

	Encryption	Decryption	Key generation	Ciphertext overhead
Our scheme	3.5 f-exps.	1.5 exp. + 1 pairing	4 f-exps.	$2 \cdot L_{\text{BG}} + 704$
KD-CS [42]	3.5 f-exps.	1.5 exps.	3 f-exps.	$2 \cdot L_{\text{DDH}} + 128$

outlined above, we obtain the following (we assume that $G, H, q, \mathbb{G}, \mathbb{G}_1, \hat{e}, g$, and $\hat{e}(g,g)$ are provided as universal parameters):

Key generation. Choose $\alpha_1, \alpha_2, x \leftarrow \mathbb{Z}_q$ and set $g_1 = g^{\alpha_1}$, $g_2 = g^{\alpha_2}$, and $g_3 = g^x$. Also set $Z = \hat{e}(g,g)^{\alpha_1 x}$. Finally, choose hash function h from a family of pairwise-independent hash functions. The public key is $PK = (g_1, g_2, g_3, Z, h)$ and the secret key is $SK = (\alpha_1, \alpha_2, x)$.

Encryption. To encrypt message M using public key (g_1, g_2, g_3, Z, h), first choose random $r \in \{0,1\}^{448}$ and set $k_1 = h(r)$ and $ID = H(r)$. Choose random $s \in \mathbb{Z}_q$ and then set $C = (g^s, g_2^s g_3^{s \cdot ID}, G(Z^s) \oplus (M \circ r))$. Output the ciphertext

$$\langle ID, C, \mathsf{Mac}_{k_1}(C) \rangle.$$

Decryption. To decrypt ciphertext $\langle ID, C, \mathsf{tag} \rangle$, first parse C as $(A, B, \hat{C})$. Then pick a random $t \in \mathbb{Z}_q$ and compute the values $(M \circ r) = \hat{C} \oplus G(\hat{e}(A^{\alpha_1 x + t(\alpha_2 + x \cdot ID)} B^{-t}, g))$. Set $k_1 = h(r)$. If $\mathsf{Vrfy}_{k_1}(C, \mathsf{tag}) \stackrel{?}{=} 1$ and $H(r) \stackrel{?}{=} ID$ output M; otherwise, output $\perp$.

We have changed the steps used in decryption for efficiency purposes, but it is easily checked that decryption yields the same result as deriving a secret key for identity ID and then using this key to decrypt C.

We tabulate the efficiency of our scheme, and compare it to the Kurosawa–Desmedt variant of Cramer–Shoup encryption [42, 21] (which we refer to as KD–CS) in Table 7.1. In tabulating computational efficiency, "private-key" operations (that is, evaluations of G, H, and h) and group multiplications are ignored; "exp" stands for exponentiation; "f-exp" refers to exponentiation relative to a fixed base (where efficiency can be improved using precomputation); and one multiexponentiation is counted as 1.5 exponentiations [46, p. 618]. Ciphertext overhead is the difference (in bits) between the lengths of the ciphertext and the message. L_{BG} is the bit-length of an element in a group $\mathbb{G}$ suitable for our scheme, and L_{DDH} is the bit-length of an element in a group suitable for the KD–CS scheme.

Although performance of the two systems looks similar, efficiency of the KD–CS scheme scales better with the security parameter. To see why, fix the measure of hardness to be the difficulty of computing discrete logarithms in the respective groups. (Although the underlying computational problems used to prove security of the above two schemes are not known to be equivalent to the discrete logarithm problem, in each case the best currently known algorithms for solving the problem rely on a discrete logarithm computation.) Consider two concrete settings:

80-bit security. Suppose we wish to use groups in which solving the discrete logarithm problem (using the best currently known algorithms) is roughly equivalent to the security attained by 80-bit symmetric-key cryptography.

- Our scheme can use groups based on the elliptic curves suggested by Miyaji, Nakabayashi, and Takano[48]. In this case, the discrete logarithm problem in a group $\mathbb{G}$ in which elements can be written using $L_{\text{BG}} = \log q$ bits (q prime) can be reduced to a discrete logarithm problem in $\mathbb{F}^*_{q^6}$. (See [13, section

4.3].) 80-bit security for the latter is obtained by setting $q^6 \approx 2^{1024}$ [44, 1] (specifically, our numbers throughout this discussion are taken from [1, Table 2]). We thus need $L_{\text{BG}} \approx 1024/6 \approx 171$.

- The KD–CS scheme can use standard elliptic curve groups, for which the best-known algorithm for computing discrete logarithms is Pollard's rho algorithm that runs in time proportional to $\sqrt{q}$ for groups of order q. This gives $L_{\text{DDH}} = \log q \approx 160$ [1].

We see that for this level of security, both schemes have ciphertexts of roughly the same length and group operations take roughly the same amount of time. Still, the KD–CS scheme outperforms our scheme (even if by a relatively small margin in some cases) in all parameters; this is especially true for decryption since a pairing calculation is computationally expensive compared to an exponentiation.

256-bit security. Now, the KD–CS scheme performs even better relative to ours.

- For our scheme, we can use groups based on a certain class of elliptic curves suggested by Barreto and Naehrig [4] (note that such curves will give worse performance for the case of 80-bit security considered above). Now, the discrete logarithm problem in a group $\mathbb{G}$ in which elements can be written using $L_{\text{BG}} = \log q$ bits (q prime) can be reduced to a discrete logarithm problem in $\mathbb{F}^*_{q^{12}}$. 256-bit security for the latter is obtained by setting $q^{12} \approx 2^{15360}$. We thus need $L_{\text{BG}} \approx 15386/12 \approx 1280$.
- Using the same the analysis as before, the KD–CS scheme can use $L_{\text{DDH}} = \log q \approx 512$.

We conclude that for currently acceptable settings of the security parameter the schemes have comparable performance, though the KD–CS scheme is more efficient. We stress that our goal is not to displace the KD–CS system but rather to show another approach to building practical CCA-secure systems. Our construction also has advantages not present in the KD–CS scheme, such as being readily amenable to a threshold implementation [10].

8. Conclusions. We presented in this paper new paradigms for constructing CCA-secure public-key encryption schemes using IBE as a building block. Our paradigms extend to enable constructions of CCA-secure (hierarchical) IBF schemes as well. Instantiating our constructions with an existing IBE system yields a CCA-secure encryption scheme whose performance, for standard settings of the security parameter, is competitive with the best CCA-secure schemes known to date.

Appendix. Review of standard definitions. We provide the standard definitions of public-key encryption schemes and their security against adaptive chosen-ciphertext attacks, as well as appropriate definitions for strong one-time signature schemes and message authentication codes.

A.1. Public-key encryption.

DEFINITION 7. *A* public-key encryption scheme *is a triple of* PPT *algorithms* $(\mathsf{Gen}, \mathcal{E}, \mathcal{D})$ *such that the following hold:*

- *The randomized* key generation algorithm Gen *takes as input a security parameter* 1^k *and outputs a public key* PK *and a secret key* SK.
- *The randomized* encryption algorithm $\mathcal{E}$ *takes as input a public key* PK *and a message* m *(in some implicit message space), and outputs a ciphertext* C. *We write* $C \leftarrow \mathcal{E}_{PK}(m)$.

- *The (possibly randomized)* decryption algorithm $\mathcal{D}$ *takes as input a ciphertext* C *and a secret key* SK*. It returns a message* m *or the symbol* $\perp$ *(which is not in the message space). We write* $m \leftarrow \mathcal{D}_{SK}(C)$*.*

We require that for all (PK, SK) *output by* Gen*, all* m *in the message space, and all* C *output by* $\mathcal{E}_{PK}(m)$ *we have* $\mathcal{D}_{SK}(C) = m$*.*

We recall the standard definition of security against adaptive chosen-ciphertext attacks (cf. [2]).

DEFINITION 8. *A public-key encryption scheme* Π *is* secure against adaptive chosen-ciphertext attacks *(i.e., "CCA-secure") if the advantage of any* PPT *adversary* $\mathcal{A}$ *in the following game is negligible in the security parameter* k*:*

1. $\mathsf{Gen}(1^k)$ *outputs* (PK, SK)*. Adversary* $\mathcal{A}$ *is given* 1^k *and* PK*.*
2. *The adversary may make polynomially many queries to a decryption oracle* $\mathcal{D}_{SK}(\cdot)$*.*
3. *At some point,* $\mathcal{A}$ *outputs two messages* m_0, m_1 *with* $|m_0| = |m_1|$*. A bit* b *is randomly chosen and the adversary is given a "challenge ciphertext"* $C^* \leftarrow \mathcal{E}_{PK}(m_b)$*.*
4. $\mathcal{A}$ *may continue to query its decryption oracle* $\mathcal{D}_{SK}(\cdot)$ *except that it may not request the decryption of* C^**.*
5. *Finally,* $\mathcal{A}$ *outputs a guess* b'*.*

We say that $\mathcal{A}$ succeeds *if* $b' = b$*, and we denote the probability of this event by* $\Pr^{\mathsf{PKE}}_{\mathcal{A},\Pi}[\mathsf{Succ}]$*. The adversary's* advantage *is defined as* $\mathsf{Adv}^{\mathsf{PKE}}_{\mathcal{A},\Pi}(k) \stackrel{\text{def}}{=} \left|\Pr^{\mathsf{PKE}}_{\mathcal{A},\Pi}[\mathsf{Succ}] - 1/2\right|$*.*

A.2. Signatures and MACs. We remind the reader of the standard functional definitions for signature schemes and MACs, followed by a definition of strong one-time security appropriate for each.

DEFINITION 9. *A* signature scheme *is a triple of* PPT *algorithms* $(\mathcal{G}, \mathsf{Sign}, \mathsf{Vrfy})$ *such that the following hold:*

- *The randomized* key generation algorithm $\mathcal{G}$ *takes as input the security parameter* 1^k *and outputs a verification key* vk *and a signing key* sk*. We assume for simplicity that the length of* vk *is fixed for any given value of* k*.*
- *The* signing algorithm Sign *takes as input a signing key* sk *and a message* m *(in some implicit message space), and outputs a signature* σ*. We write* $\sigma \leftarrow \mathsf{Sign}_{sk}(m)$*.*
- *The* verification algorithm Vrfy *takes as input a verification key* vk*, a message* m*, and a signature* σ*, and outputs a bit* $b \in \{0,1\}$ *(where* $b = 1$ *signifies "acceptance" and* $b = 0$ *signifies "rejection"). We write this as* $b := \mathsf{Vrfy}_{vk}(m, \sigma)$*.*

We require that for all (vk, sk) *output by* $\mathcal{G}$*, all* m *in the message space, and all* σ *output by* $\mathsf{Sign}_{sk}(m)$*, we have* $\mathsf{Vrfy}_{vk}(m, \sigma) = 1$*.*

A MAC is similar in spirit to a signature scheme, except that here the signing key and verification key are identical. We review the definition for convenience.

DEFINITION 10. *A* message authentication code *is a pair of* PPT *algorithms* $(\mathsf{Mac}, \mathsf{Vrfy})$ *such that the following hold:*

- *The* tagging algorithm Mac *takes as input a key* $sk \in \{0,1\}^k$ *(where* k *is the security parameter) and a message* m *(in some implicit message space). It outputs a tag* tag*, and we denote this by* $\mathsf{tag} \leftarrow \mathsf{Mac}_{sk}(m)$*.*
- *The* verification algorithm Vrfy *takes as input a key* sk*, a message* m*, and a tag* tag*; it outputs a bit* $b \in \{0,1\}$ *(where* $b = 1$ *signifies "acceptance" and* $b = 0$ *signifies "rejection"). We write this as* $b := \mathsf{Vrfy}_{sk}(m, \mathsf{tag})$*.*

We require that for all sk, all m in the message space, and all tag *output by* $\mathsf{Mac}_{sk}(m)$, *we have* $\mathsf{Vrfy}_{sk}(m, \mathsf{tag}) = 1$.

We next turn to definitions of security for signature schemes and MACs. The definition of security is analogous in each case: the adversary should be unable to forge a valid message/signature (resp., message/tag) pair, after receiving a signature (resp., tag) on any *single* message m of the adversary's choice. Note that we require so-called *strong* security in each case, so that it should be infeasible for the adversary to generate even a different signature (resp., tag) on the same message m.

DEFINITION 11. *A signature scheme* Sig *is a* strong one-time signature scheme *if the success probability of any* PPT *adversary* $\mathcal{A}$ *in the following game is negligible in the security parameter* k:

1. $\mathcal{G}(1^k)$ *outputs* (vk, sk) *and the adversary is given* 1^k *and* vk.
2. $\mathcal{A}(1^k, vk)$ *may do one of the following:*
   (a) $\mathcal{A}$ *may output a pair* (m^*, σ^*) *and halt. In this case* (m, σ) *are undefined.*
   (b) $\mathcal{A}$ *may output a message* m, *and is then given in return* $\sigma \leftarrow \mathsf{Sign}_{sk}(m)$. *Following this,* $\mathcal{A}$ *outputs* (m^*, σ^*).

We say the adversary succeeds *if* $\mathsf{Vrfy}_{vk}(m^*, \sigma^*) = 1$ *but* $(m^*, \sigma^*) \neq (m, \sigma)$ *(assuming* (m, σ) *are defined). We stress that the adversary may succeed even if* $m^* = m$.

DEFINITION 12. *A message authentication code* $(\mathsf{Mac}, \mathsf{Vrfy})$ *is a* strong one-time message authentication code *if the success probability of any* PPT *adversary* $\mathcal{A}$ *in the following game is negligible in the security parameter* k:

1. *A random key* $sk \in \{0,1\}^k$ *is chosen.*
2. $\mathcal{A}(1^k)$ *may do one of the following:*
   (a) $\mathcal{A}$ *may output* (m^*, tag^*). *In this case,* (m, tag) *are undefined.*
   (b) $\mathcal{A}$ *may output a message* m *and is then given in return* $\mathsf{tag} \leftarrow \mathsf{Mac}_{sk}(m)$. *Following this,* $\mathcal{A}$ *outputs* (m^*, tag^*).

We say the adversary succeeds *if* $\mathsf{Vrfy}_{sk}(m^*, \mathsf{tag}^*) = 1$ *but* $(m^*, \mathsf{tag}^*) \neq (m, \mathsf{tag})$ *(assuming* (m, tag) *are defined). We stress that the adversary may succeed even if* $m^* = m$.

Acknowledgments. We thank Eu-Jin Goh for pointing out that our techniques imply a conversion from IBE to nonadaptive CCA-security with essentially no overhead. We also thank the anonymous referees for their helpful comments, and in particular for suggesting a way to simplify the presentation of the proof of Theorem 2.

A DETERMINISTIC ALGORITHM FOR FINDING ALL MINIMUM k-WAY CUTS*

YOKO KAMIDOI†, NORIYOSHI YOSHIDA†, AND HIROSHI NAGAMOCHI‡

Abstract. Let $G = (V, E)$ be an edge-weighted undirected graph with n vertices and m edges. We present a deterministic algorithm to compute a minimum k-way cut of G for a given k. Our algorithm is a divide-and-conquer method based on a procedure that reduces an instance of the minimum k-way cut problem to $O(n^{2k-5})$ instances of the minimum $(\lfloor (k+\sqrt{k})/2 \rfloor + 1)$-way cut problem, and can be implemented to run in $O(n^{4k/(1-1.71/\sqrt{k})-31})$ time. With a slight modification, the algorithm can find all minimum k-way cuts in $O(n^{4k/(1-1.71/\sqrt{k})-16})$ time.

Key words. minimum cut, multiway cut, divide-and-conquer

1. Introduction.

For an edge-weighted graph $G = (V, E)$, a subset F of edges is called a *k-way cut* if removal of F from G results in at least k connected components. The *minimum k-way cut problem* asks to find a minimum weight k-way cut in G. Given k vertices (called *terminals*), a k-way cut F is called a *k-terminal cut* if no two terminals are in the same connected component after removal of F. The problem of finding a minimum weight k-terminal cut is called the *minimum k-terminal cut problem*. These problems have several important applications such as VLSI design [1, 6, 26], task allocation in distributed computing systems [25, 34], graph strength [4, 9, 32], and network reliability [3, 35].

For $k = 2$, the minimum 2-terminal cut problem in a graph can be solved by applying a maximum flow algorithm. Let $F(n, m)$ denote the time complexity of a maximum flow algorithm in an edge-weighted graph with n vertices and m edges. The complexity $F(n, m)$ was found to be $O(n^3)$ in [24] and $O(nm \log(n^2/m))$ in [7]. Dahlhaus et al. [5] proved that the minimum k-terminal cut problem is NP-hard for any fixed $k \geq 3$. Several approximation algorithms have been proposed [2, 5, 21], among which a 1.3438-approximation algorithm is obtained by Karger et al. [21]. An extension of this problem to a general setting defined by submodular set functions can be found in the articles by Zhao, Nagamochi, and Ibaraki [39, 40]. For planar graphs, the minimum k-terminal cut problem admits a polynomial time algorithm [5], and currently an $O(k4^k n^{2k-4} \log n)$ time algorithm in [14] and an $O((k-\frac{3}{2})^{k-1}(n-k)^{2k-4}[nk - \frac{3}{2}k^2 + \frac{1}{2}k]\log(n-k))$ time algorithm in [37] are known.

On the other hand, Goldschmidt and Hochbaum [8] proved that the minimum k-way cut problem is NP-hard if k is an input parameter but admits a polynomial time algorithm if k is regarded as a constant. The minimum 2-way cut problem (i.e.,

the problem of computing edge-connectivity) can be solved by $O(nm + n^2 \log n)$ and $O(nm \log(n^2/m))$ time deterministic algorithms [12, 28] and by $O(n^2(\log n)^3)$ and $O(m(\log n)^3)$ time randomized algorithms [20, 22, 23]. Approximation algorithms for a minimum k-way cut problem of G have been proposed in [16, 33, 38]. Saran and Vazirani [33] first proposed a $2(1-1/k)$-approximation algorithm for the minimum k-way cut problem, which runs in $O(nF(n,m))$ time. Kapoor [16] also gave a $2(1-1/k)$-approximation algorithm for the minimum k-way cut problem of G, which requires $O(k(nm+n^2 \log n))$ time. Zhao et al. [38] also presented an approximation algorithm by using a set of minimum 3-way cuts. Their algorithm has the performance ratio $2-3/k$ for an odd k and $2-(3k-4)/(k^2-k)$ for an even k, and runs in $O(kmn^3 \log(n^2/m))$ time. Approximation algorithms for a multiway cut problem defined by submodular set functions are discussed in the articles by Zhao, Nagamochi, and Ibaraki [39, 40].

Goldschmidt and Hochbaum [8] presented an $O(n^{k^2/2-3k/2+4}F(n,m))$ time algorithm for solving the minimum k-way cut problem. This running time is polynomial for any fixed k. The algorithm is based on a divide-and-conquer approach. Suppose that we can choose a family $\mathcal{X}$ of subsets of V such that at least one subset $X \in \mathcal{X}$ has a property that a minimum $(k-1)$-way cut $\{V_1, \ldots, V_{k-1}\}$ in the subgraph $G[V-X]$ induced by $V-X$ gives rise to a minimum k-way cut $\{X, V_1, \ldots, V_{k-1}\}$ in the original graph G. Then we can find a minimum k-way cut in G by solving the $(k-1)$-way cut problem instances $G[V-X]$ for all $X \in \mathcal{X}$. Goldschmidt and Hochbaum [8] proved that such a family $\mathcal{X}$ of $O(n^{2k-3})$ subsets of V can be found in polynomial time, implying an $O(n^{O(k^2)})$ time algorithm for the minimum k-way cut problem.

For small $k \leq 6$ or planar graphs, faster algorithms have been obtained [16, 17, 18, 29, 30, 31]. For $k \leq 6$, the above family $\mathcal{X}$ can be constructed in polynomial time by collecting $O(n)$ subsets of V, and an $O(mn^k \log(n^2/m))$ time algorithm is known [29, 30, 31]. For planar graphs, Hartvigsen [13] gave an $O(n^{2k-1})$ time algorithm, and Nagamochi and Ibaraki [30] and Nagamochi, Katayama, and Ibaraki [31] showed that the problem can be solved in $O(n^k)$ time if $k \leq 6$. The case of unweighted planar graphs with $k = 3$ can be solved in $O(n \log n)$ time [15].

Randomized algorithms have been developed for the k-way cut problem. Karger and Stein [23] proposed a Monte Carlo algorithm for the minimum k-way cut problem which runs in $O(n^{2(k-1)} \log^3 n)$ time. Afterward, Levine [27] gave a Monte Carlo algorithm for $k \leq 6$ that runs in $O(mn^{k-2} \log^3 n)$ time. However, for a general k and a general graph G, no faster deterministic algorithm has been discovered since Goldschmidt and Hochbaum [8] found an $O(n^{O(k^2)})$ time algorithm.

In this paper, we present the first $O(n^{O(k)})$ time deterministic algorithm to compute a minimum k-way cut of G. Our algorithm is based on a divide-and-conquer method which consists of a procedure that reduces an instance of the minimum k-way cut problem to $O(n^{2k-5})$ instances of the minimum $(\lfloor (k+\sqrt{k})/2 \rfloor + 1)$-way cut problem, and can be implemented to run in $O(n^{4k/(1-1.71/\sqrt{k})-31})$ time. With a slight modification, we can also find all minimum k-way cuts in $O(n^{4k/(1-1.71/\sqrt{k})-16})$ time.

The paper is organized as follows. Section 2 introduces notation and reviews basic properties of 2-way cuts. Section 3 presents our divide-and-conquer algorithm, assuming an efficient procedure for computing a family $\mathcal{X}$ of subsets required to reduce a given problem instance, which is discussed in section 5, after proving a key property on crossing 2-way cuts in section 4. Section 6 analyzes the runtime of our algorithm. Section 7 shows how to modify the algorithm so that all minimum k-way cuts can be computed, and section 8 makes some concluding remarks.

2. Preliminaries. Let $G = (V, E)$ stand for an edge-weighted undirected graph consisting of a vertex set V and an edge set E with an edge weight function $cost : E \to R^+$, where R^+ is the set of nonnegative real numbers. Let $n = |V|$ be the number of vertices and $m = |E|$ be the number of edges. We may simply call G a graph. Let $comp(G)$ denote the number of connected components in G. An edge $e \in E$ with end vertices u and v may be denoted by $e = (u, v)$, and its weight is denoted by $cost(e)$. For a nonempty subset $F \subseteq E$, we let $cost(F)$ denote $\sum_{e \in F} cost(e)$. Let $X_1, X_2, \ldots, X_p$ be mutually disjoint subsets of V.

We denote the set of edges $e = (u, v)$ with $u \in X_i$ and $v \in X_j$ for some $i \neq j$ by $(X_1; X_2; \ldots; X_p)$, and the sum of the weights of these edges by $cost(X_1; X_2; \ldots; X_p)$, which is defined to be 0 if $(X_1; X_2; \ldots; X_p) = \emptyset$. For a subset X of V, we may denote $f(X) = cost(X; V-X)$, where f is called a *cut function* of G and satisfies the following identities:

$$f(X) + f(Y) = f(X \cap Y) + f(X \cup Y) + 2cost(X - Y, Y - X) \quad \text{for all } X, Y \subseteq V, \tag{2.1}$$

$$f(X) + f(Y) = f(X - Y) + f(Y - X) + 2cost(X \cap Y, V - (X \cup Y)) \quad \text{for all } X, Y \subseteq V. \tag{2.2}$$

Let F be a subset of E in G. We denote by $G - F$ the graph obtained from G by deleting edges in F. We call F a *k-way cut* if $comp(G - F) \geq k$. A k-way cut F is *minimum* if it has the minimum $cost(F)$ over all k-way cuts. Given a graph G and an integer $k(\geq 2)$, the *minimum k-way cut problem* asks to find a minimum k-way cut in G. We denote the cost of a minimum k-way cut in G by $opt(G, k)$. Note that $opt(G, k) = 0$ if and only if the set of edges with positive weights induces a subgraph of G with at least k connected components. Any inclusionwise minimal k-way cut F is given by $F = (X_1; X_2; \ldots; X_k)$ for some partition $\{X_1, X_2, \ldots, X_k\}$ of V. Conversely, for any partition $\{V_1, V_2, \ldots, V_k\}$ of V, $F' = (V_1; V_2; \ldots; V_k)$ is a k-way cut, where possibly $comp(G - F') > k$. For a set $\mathcal{C}$ of subsets F of E, we denote the union $\cup_{F \in \mathcal{C}} F$ by $E(\mathcal{C})$.

Given a nonempty vertex subset X, let $G[X] = (X, E_X)$ be the subgraph of G induced by X, where $G[X]$ has the edge weight function $cost_X : E_X \to R^+$, which is defined such that $cost_X(e) = cost(e)$ for every edge $e \in E_X$. For a subset Y of vertices of V, we denote $V - Y$ by $\overline{Y}$ if V is clear from the context.

Given p mutually disjoint nonempty subsets $T_1, T_2, \ldots, T_p$ of V, called *terminal sets*, a subset $F \subseteq E$ is called a *$(T_1, T_2, \ldots, T_p)$-terminal cut* of G if the removal of F from G disconnects each terminal set from the others. A $(T_1, T_2, \ldots, T_p)$-terminal cut is called minimum if it has the minimum $cost(F)$ among all $(T_1, T_2, \ldots, T_p)$-terminal cuts.

3. Divide-and-conquer algorithm. Each of the previously known deterministic algorithms reduces a minimum k-way cut problem instance to a set of minimum $(k-1)$-way cut problem instances, where the target k on the number of components is reduced only by 1. In this paper, we reduce a minimum k-way cut problem instance to a set of minimum k'-way cut problem instances with k' nearly equal to $k/2$. For this, we first observe the following property.

LEMMA 3.1. *Let $(V_1; V_2; \ldots; V_k)$ be a minimum k-way cut in a graph $G = (V, E)$, where $k \in [2, n]$.*

Then for any integer $p \in [1, k-1]$, there is a union X of p subsets in $\{V_1, V_2, \ldots, V_k\}$ such that

$$f(X) \leq \frac{2(kp - p^2)}{(k^2 - k)} opt(G, k).$$

Proof. Let $\mathcal{X}$ be the family of all such unions X. Then $|\mathcal{X}| = \binom{k}{p}$. For each edge $e = (u, v) \in (V_1; V_2; \ldots; V_k)$, there are $2\binom{k-2}{p-1}$ unions $X \in \mathcal{X}$ such that $u \in X$ and $v \in \overline{X}$ or $u \in \overline{X}$ and $v \in X$. Therefore it holds that $\sum_{X \in \mathcal{X}} f(X) = 2\binom{k-2}{p-1} opt(G, k)$, and the average of $f(X)$ over all $X \in \mathcal{X}$ is $[2\binom{k-2}{p-1} opt(G, k)]/\binom{k}{p} = 2(kp - p^2)/(k^2 - k) opt(G, k)$. This implies the lemma. □

Let $p = \lceil (k - \sqrt{k})/2 \rceil - 1$, which satisfies $2(kp - p^2)/(k^2 - k) < 1/2$ for $k \geq 5$. Then there exists a set $X \subseteq V$ such that

$$f(X) < opt(G, k)/2$$

and X is a union of p subsets in $\{V_1, V_2, \ldots, V_k\}$ for a minimum k-way cut $(V_1; V_2; \ldots; V_k)$ in G. For such a subset X, we can reduce the current instance (G, k) into two instances $(G[X], p)$ and $G([V - X], k - p)$, where a minimum k-way cut F for (G, k) is obtained from a minimum p-way cut F' for $(G[X], p)$ and a minimum $(k - p)$-way cut F'' for $(G[V - X], k - p)$ by constructing a k-way cut $F = (X; V - X) \cup F' \cup F''$. Note that the size k is reduced to at most $k - \lceil (k - \sqrt{k})/2 \rceil + 1 = \lfloor (k + \sqrt{k})/2 \rfloor + 1$, which is nearly a half of k for a large k.

Section 5 shows that the number of such subsets $X \in V$ with $f(X) < opt(G, k)/2$ is at most n^{2k-5} and a family $\mathcal{X}$ of n^{2k-5} subsets including these subsets X (possibly together with some other subsets) can be obtained in $O(n^{2k-5} F(n, m))$ time. With this property, our divide-and-conquer algorithm can be described as follows.

Algorithm MULTIWAY(G, k)
Input: A graph $G = (V, E)$ and an integer $k \in [1, |V|]$.
Output: A minimum k-way cut F in G.

```
1.  if opt(G,k) = 0 then Return F := ∅
2.  else /* opt(G,k) > 0 */
3.    if k ≤ 2 then Return a minimum k-way cut F of G in the time of O(1)
        maximum flow computations
4.    else if k ≤ 6 then Return a minimum k-way cut F of G by O(|V|^{k-1})
        maximum flow computations
5.    else /* k ≥ 7 */
6.      Compute a set X of at most |V|^{2k-5} subsets of V such that any 2-way cut
        with cost less than opt(G,k)/2 is given by (X; V−X) for some X ∈ X;
7.      p := ⌈(k − √k)/2⌉ − 1;
8.      for each X ∈ X with |X| ≥ p and |V−X| ≥ k − p do
9.        F_X := (X; V−X) ∪ MULTIWAY(G[X], p) ∪ MULTIWAY(G[V−X], k − p);
10.     end /* for */
11.     Choose a k-way cut F_X with the minimum cost over all X, and return
        F := F_X
12.   end /* if */
13. end. /* if */
```

For the correctness of algorithm MULTIWAY, we have only to give a procedure in line 5, which will be discussed in section 5. The runtime of MULTIWAY will be analyzed in section 6.

4. A crossing property. This section provides a property on crossing 2-way cuts, based on which a procedure for collecting all subsets $X \subset V$ with $f(X) < opt(G,k)/2$ is designed in section 5.

LEMMA 4.1. *For a graph $G = (V, E)$, let $\{Y_1, Y_2, \ldots, Y_q, W, Z\}$ be a partition of V, and let Q be a subset of V such that each subset in $\{Y_1 - Q, Y_2 - Q, \ldots, Y_q - Q, W \cap Q, Q \cap Z, Z - Q\}$ is nonempty. Then partition $\{Y'_i = Y_i - Q \ (i = 1, 2, \ldots, q), Y'_{q+1} = Q \cap Z, W' = (W \cup Q) - Z, Z' = Z - Q\}$ of V satisfies*

$$\begin{aligned} &2cost(Y_1; Y_2; \ldots; Y_q; W; Z) - f(Y_{1,q}) + f(Q) \\ &\quad \geq 2cost(Y'_1; Y'_2; \ldots; Y'_q; Y'_{q+1}; W'; Z') - f(Y'_{1,q+1}) + f(W \cap Q), \end{aligned}$$

where we denote $Y_{1,i} = Y_1 \cup Y_2 \cup \cdots \cup Y_i$ and $Y'_{1,j} = Y'_1 \cup Y'_2 \cup \cdots \cup Y'_j$.

Proof. We obtain

(4.1)
$$\begin{aligned} &f(Y_1) + f(Y_2) + \cdots + f(Y_q) + f(Y'_{1,q+1}) \\ &\quad \geq f(Y'_1) + f(Y'_2) + \cdots + f(Y'_q) + f(Y_{1,q} \cup (Q \cap Z)) + 2cost(Y_{1,q} \cap Q; Q \cap Z), \end{aligned}$$

by summing up the following q inequalities implied by (2.1):

$$\begin{aligned} &f(Y_1) + f((Y_{1,q} - Q) \cup (Q \cap Z)) \\ &\quad \geq f(Y_1 - Q) + f(Y_1 \cup (Y_{1,q} - Q) \cup (Q \cap Z)) + 2cost(Y_1 \cap Q; Q \cap Z), \\ &f(Y_2) + f(Y_1 \cup (Y_{1,q} - Q) \cup (Q \cap Z)) \\ &\quad \geq f(Y_2 - Q) + f(Y_{1,2} \cup (Y_{1,q} - Q) \cup (Q \cap Z)) + 2cost(Y_2 \cap Q; Q \cap Z) \\ &\qquad\qquad \cdots \\ &f(Y_q) + f(Y_{1,q-1} \cup (Y_{1,q} - Q) \cup (Q \cap Z)) \\ &\quad \geq f(Y_q - Q) + f(Y_{1,q} \cup (Y_{1,q} - Q) \cup (Q \cap Z)) + 2cost(Y_q \cap Q; Q \cap Z). \end{aligned}$$

On the other hand, (2.1) and (2.2) mean

(4.2)
$$\begin{aligned} &f(Z) + f(W) + f(Q) \geq f(Z) + f(W \cap Q) + f(W \cup Q) \\ &\quad \geq f((W \cup Q) - Z) + f(Z - Q) + 2cost(Y_{1,q} - Q; Q \cap Z) + f(W \cap Q). \end{aligned}$$

From (4.1) and (4.2), we have

$$\begin{aligned} &f(Y_1) + f(Y_2) + \cdots + f(Y_q) + f(W) + f(Z) + f(Y'_{1,q+1}) + f(Q) \\ &\geq f(Y'_1) + f(Y'_2) + \cdots + f(Y'_q) + f((W \cup Q) - Z) + f(Z - Q) \\ &\quad + f(Y_{1,q} \cup (Q \cap Z)) + 2cost(Y_{1,q} \cap Q; Q \cap Z) + 2cost(Y_{1,q} - Q; Q \cap Z) + f(W \cap \mathrm{Q}) \\ &= f(Y'_1) + f(Y'_2) + \cdots + f(Y'_q) + f(W') + f(Z') + f(Q \cap Z) + f(Y_{1,q}) + f(W \cap Q), \end{aligned}$$

implying the lemma. ∎

LEMMA 4.2. *For a graph $G = (V, E)$ and an integer $k \in [5, n-1]$, let $(X; \overline{X})$ be a 2-way cut of G, R be a nonempty subset of $\overline{X}$, and $T = \{t_1, t_2, \ldots, t_p\}$ be a set of $p \geq 2$ vertices in $\overline{X} - R$. Assume that, for each t_i, there exists a minimum $(X, T \cup R - \{t_i\})$-terminal cut $(X_i; \overline{X_i})$ which satisfies $X \cup \{t_i\} \subseteq X_i$ (see Figure 4.1). Let $\mathcal{C} = \{(X_i; \overline{X_i}) \mid 1 \leq i \leq p\}$. Then $E(\mathcal{C})$ is a $(p+2)$-way cut which partitions V into $p+2$ subsets*

$$Z = \cap_{1 \leq i \leq p} \overline{X_i}, \quad W = \cup_{1 \leq i < j \leq p} (X_i \cap X_j), \ \text{and} \ \ Y_i = X_i - W \ (i = 1, 2, \ldots, p).$$

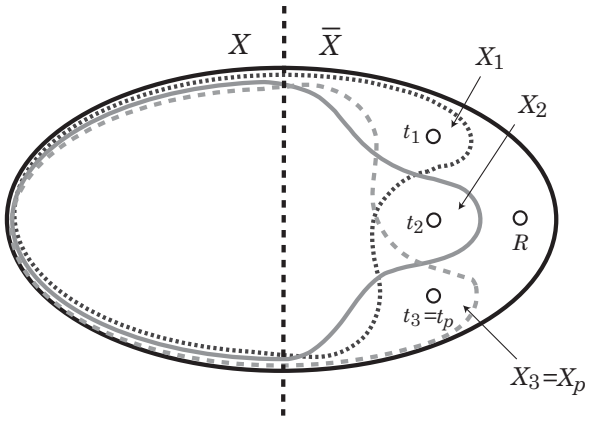

FIG. 4.1. *Illustration for a 2-way cut* $(X;\overline{X})$ *and a minimum* $(X;T\cup R-\{t_i\})$*-terminal cut* $(X_i;\overline{X_i})$*,* $i=1,2,3\ (=p)$*.*

Furthermore $(p+2)$*-way cut* $E(\mathcal{C})=(Y_1;Y_2;\ldots;Y_p;Z;W)$ *satisfies*

$$cost(E(\mathcal{C}))+cost(Z;W)+cost(Y_1;Y_2;\ldots;Y_p)\le f(X_1)+f(X_2). \tag{4.3}$$

Proof. Since $X\subseteq W$, $t_i\in Y_i$ $(1\le i\le p)$, and $R\subseteq Z$ hold, we see that $E(\mathcal{C})$ is a $(p+2)$-way cut. We prove (4.3) by an induction on p.

Basis case. For $p=2$, $Z=V-(X_1\cup X_2)$, $W=X_1\cap X_2$, $Y_1=X_1-X_2$, and $Y_2=X_2-X_1$. Then it holds that $cost(Y_1;Y_2;Z;W)+cost(Z;W)+cost(Y_1;Y_2)$ $=cost(X_1-X_2;X_2-X_1;V-(X_1\cup X_2);X_1\cap X_2)+cost(V-(X_1\cup X_2);X_1\cap X_2)$ $+cost(X_1-X_2;X_2-X_1)=f(X_1)+f(X_2)$, as required.

Inductive case. Let $q\ge 2$. Assuming that (4.3) holds for $p=q$, we prove that (4.3) holds for $p=q+1$. Let R', $T'=\{t_1,t_2,\ldots,t_{q+1}\}\subset\overline{X}-R'$ and $\mathcal{C}'$ be subsets of $\overline{X}$ and a set of $q+1$ 2-way cuts satisfying the condition of the lemma for $q+1$. We here consider $R=R'\cup\{t_{p+1}\}$, $T=T'-\{t_{q+1}\}$, and $\mathcal{C}=\mathcal{C}'-\{(X_{q+1};\overline{X_{q+1}})\}$, which satisfy the condition of the lemma for q (see Figure 4.2). Hence, by the induction

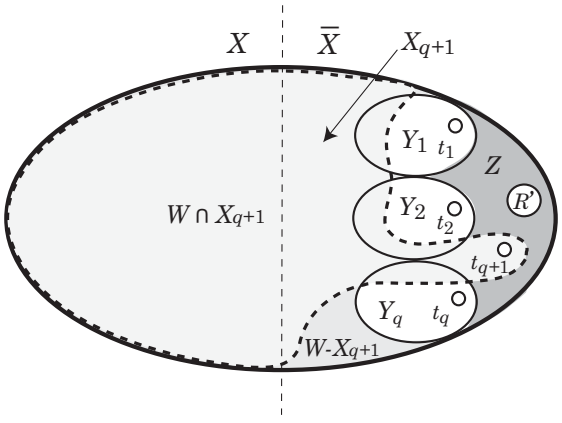

FIG. 4.2. *Illustration for a minimum* $(X,T'\cup R'-\{t_p\})$*-terminal cut* $(X_p;\overline{X_p})$ *and subsets* $Y_1,Y_2,\ldots,Y_{p-1}$*.*

hypothesis, we have

$$\begin{aligned} & f(X_1) + f(X_2) \\ & \quad \geq cost(E(\mathcal{C})) + cost(Z; W) + cost(Y_1; Y_2; \ldots; Y_q) \\ & \quad = 2cost(E(\mathcal{C})) - f(Y_{1,q}), \end{aligned} \tag{4.4}$$

where $Z = \cap_{1 \leq i \leq q} \overline{X_i}$, $W = \cup_{1 \leq i < j \leq q} (X_i \cap X_j)$, and $Y_i = X_i - W$ $(i = 1, 2, \ldots, q)$. By Lemma 4.1 to $Y_1, \ldots, Y_q$, W, Z, and $Q = X_{q+1}$, we obtain

$$\begin{aligned} 2cost(E(\mathcal{C})) - f(Y_{1,q}) &\geq 2cost(E(\mathcal{C}')) - f(Y'_{1,q+1}) + f(W \cap X_{q+1}) - f(X_{q+1}) \\ &\geq 2cost(E(\mathcal{C}')) - f(Y_{1,q+1}), \end{aligned}$$

where $f(W \cap X_{q+1}) \geq f(X_{q+1})$ holds since $(W \cap X_{q+1}; \overline{W \cap X_{q+1}})$ is an $(X, T' \cup R' - \{t_{q+1}\})$-terminal cut in G. This implies that (4.3) holds for p. ∎

5. Computing small cuts. With Lemma 4.2, we are ready to present an $O(n^{2k-5}F(n,m))$ time procedure for collecting all subsets $X \in V$ with $f(X) < opt(G,k)/2$.

THEOREM 5.1. *For a graph $G = (V, E)$ and an integer $k \in [5, n-1]$, let $(X; \overline{X})$ be a 2-way cut with $f(X) < opt(G,k)/2$. Then, for any vertices $s^* \in X$ and $t^* \in \overline{X}$, there are subsets $S \subseteq X$ and $T \subseteq \overline{X}$ with $|S| \leq k-3$ and $|T| \leq k-3$ such that $(X; \overline{X})$ is a unique minimum $(S \cup \{s^*\}, T \cup \{t^*\})$-terminal cut in G.*

Proof. Let $(X; \overline{X})$ be a 2-way cut with $f(X) \leq opt(G,k)/2$. We first prove the next claim.

CLAIM 5.2. *A set T of at most $k-3$ vertices in $\overline{X}$ can be chosen so that $(X; \overline{X})$ becomes a unique minimum $(X, T \cup \{t^*\})$-terminal cut.*

Proof. Let $\mathcal{Y}$ be the family of all subsets Y with $X \subset Y \subseteq V - \{t^*\}$ such that

$$f(Y) \leq f(X).$$

We choose a subset T of $\overline{X} - \{t^*\}$ so that T becomes a minimal transversal of $\mathcal{Y}$ (i.e., T is an inclusion-wise minimal subset of $\overline{X} - \{t^*\}$ such that $Y \cap T \neq \emptyset$ for all $Y \in \mathcal{Y}$). Since T is a transversal of $\mathcal{Y}$, no other $(X, T \cup \{t^*\})$-terminal cut than $(X; \overline{X})$ has cost less than or equal to $f(X)$. Hence, to prove the claim, it suffices to show that $|T| \leq k-3$.

For each $t \in T$, let $(X_t; \overline{X}_t)$ denote a minimum $(X, (T - \{t\}) \cup \{t^*\})$-terminal cut. We show that

$$f(X_t) \leq f(X), \quad t \in X_t.$$

By the minimality of T, each vertex $t \in T$ has a subset $Y' \in \mathcal{Y}$ such that $t \in Y'$ and $Y' \cap (T - \{t\}) \cup \{t^*\}) = \emptyset$. Hence $f(X_t) \leq f(Y') \leq f(X)$. This also implies that $X_t \in \mathcal{Y}$ and hence t must belong to X_t (since otherwise $X_t \cap T = \emptyset$ would hold). See Figure 4.1, where $R = \{t^*\}$.

The above sets $R = \{t^*\}$, T, $\mathcal{C} = \{(X_t; \overline{X}_t) \mid t \in T\}$ satisfy the condition of Lemma 4.2. By Lemma 4.2 and the assumption on $f(X)$, $E(\mathcal{C})$ is a $(|T|+2)$-way cut with $cost(E(\mathcal{C})) \leq 2\max\{f(X_t) \mid t \in T\} \leq 2f(X) < opt(G,k)$. Therefore $|T| \leq k-3$ holds, since otherwise $comp(G - E(\mathcal{C})) \geq |T| + 2 \geq k$ would hold, contradicting the definition of $opt(G,k)$. This proves the claim. ∎

By applying the above claim to X, we see that a set S of at most $k-3$ vertices in X can be chosen so that $(X; \overline{X})$ becomes a unique minimum $(S \cup \{s^*\}, \overline{X})$-terminal cut.

Finally we show that $(X;\overline{X})$ is a unique minimum $(S\cup\{s^*\},T\cup\{t^*\})$-terminal cut in G. Assume indirectly that G has another minimum $(S\cup\{s^*\},T\cup\{t^*\})$-terminal cut $(Z;\overline{Z})$. By the property of S and T, neither $Z\subseteq X$ nor $Z\supseteq X$; the remaining case is $X-Z\neq\emptyset\neq Z-X$. In this case, by the submodularity of cost function,

$$f(X)+f(Z)\geq f(X\cap Z)+f(Z\cup X)$$

holds, and we see that at least one of $(X\cap Z;\overline{X\cap Z})$ and $(Z\cup X;\overline{Z\cup X})$ is a minimum $(S\cup\{s^*\},T\cup\{t^*\})$-terminal cut. This, however, contradicts the above property of S and T. This completes the proof of the theorem. □

Based on this theorem, we can find all 2-way cuts $(X;\overline{X})$ with $f(X)<opt(G,k)/2$ by $O(n^{2k-5})$ maximum flow computations. For this, choose a vertex $s^*\in V$, and execute the following procedure for each vertex $t^*\in V-\{s^*\}$: Choose disjoint sets $S,T\subseteq V-\{s^*,t^*\}$ with $2\leq|S|\leq k-3$ and $2\leq|T|\leq k-3$, and compute a minimum $(S\cup\{s^*\},T\cup\{t^*\})$-terminal cut $(X;\overline{X})$ in G. Then the set of these 2-way cuts $(X;\overline{X})$ for all $t^*\in V-\{s^*\}$ include those with cost less than $opt(G,k)/2$. For fixed s^* and t^*, there are at most n^{2k-6} such pairs of S and T. Hence, we need $O(n^{2k-6}\cdot n)=O(n^{2k-5})$ maximum flow computations. We also have the following corollary.

COROLLARY 5.3. *Let $G=(V,E)$ be a graph, $k\in[5,n]$ be an integer, and $opt(G,k)>0$. Then the number of subsets $X\subset V$ such that $f(X)<(1/2)opt(G,k)$ is $O(n^{2k-5})$.*

6. Runtime of MULTIWAY. In this section, we analyze the runtime of algorithm MULTIWAY.

THEOREM 6.1. *For a graph $G=(V,E)$ with n vertices, m edges, and an integer $k\in[1,n]$,* MULTIWAY(G,k) *runs in $O(n^{k-1}F(n,m))$ time for $k\leq 6$ and in $O(n^{4k/(1-1.71/\sqrt{k})-34}F(n,m))$ time for $k\geq 7$, where $F(n,m)$ denotes the time complexity for computing a maximum flow in a graph with n vertices and m edges.*

Proof. We derive an upper bound $N(k,n)$ on the number of maximum flow computations to execute MULTIWAY(G,k) for a graph G with n vertices, where we assume that $N(k,n)$ is an increasing function with respect to k and n. For $k\leq 6$, it is known that a minimum k-way cut can be obtained by at most 1 (resp., $2n^2$, $4n^3$, $60n^4$, and $900n^5$) maximum flow computations for $k=2$ [12] (resp., $k=3,4,5,6$ [29, 30, 31]). For $k\geq 5$, it suffices to consider $N(k,n)$ such that

$$\begin{aligned}N(k,n)&\leq n^{2k-5}+n^{2k-5}N(k-\lceil(k-\sqrt{k})/2\rceil+1,n-\lceil(k-\sqrt{k})/2\rceil+1)\\&\leq n^{2k-5}N(\lfloor(k+\sqrt{k})/2\rfloor+1,n).\end{aligned}$$

Then we define $M(k)$ by a recursive formula $M(k)=2k-5+M(\lfloor(k+\sqrt{k})/2\rfloor+1)$ for $k\geq 7$ and $M(2)=0$, $M(3)=2$, $M(4)=3$, $M(5)=4$, and $M(6)=5$. We see that $900n^{M(k)}$ gives an upper bound on the number of maximum flow computations needed to execute MULTIWAY(G,k). We see that $M(k)\leq 4k/(1-1.71/\sqrt{k})-34$ holds for $k\leq 1.3\times 10^6$ by generating all those $M(k)$ with a computer program. We prove that $M(k)\leq 4k/(1-1.71/\sqrt{k})-34$ holds for $k>1.3\times 10^6$ with the recursive formula. Let $a=1.71$, and $k'=\lfloor(k+\sqrt{k})/2\rfloor+1\leq(k+\sqrt{k}+2)/2$. Then by the induction hypothesis we have

$$M(k)=2k-5+M(k')\leq 2k-5+4k'\sqrt{k'}/(\sqrt{k'}-a)-34.$$

Then it suffices to show that

$$4k\sqrt{k}/(\sqrt{k}-a)-34-(2k-5)-2(k+\sqrt{k}+2)\sqrt{k+\sqrt{k}+2}/(\sqrt{k+\sqrt{k}+2}-\sqrt{2}a)+34$$

is nonnegative for $k > 1.3 \times 10^6$. For this, we prove the following is nonnegative:

$$\begin{aligned} & 4k\sqrt{k}(\sqrt{k+\sqrt{k}+2}-\sqrt{2}a) - (\sqrt{k}-a)(2k-5)(\sqrt{k+\sqrt{k}+2}-\sqrt{2}a) \\ & \quad - (\sqrt{k}-a)2(k+\sqrt{k}+2)\sqrt{k+\sqrt{k}+2} \\ & = \Big((4a-2)k+(2a+1)\sqrt{k}-a\Big)\sqrt{k+\sqrt{k}+2} \\ & \quad + \sqrt{2}a(-2k\sqrt{k}-2ak-5\sqrt{k}+5a). \end{aligned} \tag{6.1}$$

Since $(4a-2)k+(2a+1)\sqrt{k}-a > 0$ for $k > 1.3 \times 10^6$, (6.1) is at least

$$\begin{aligned} & ((4a-2)k+(2a+1)\sqrt{k}-a)\sqrt{k}+\sqrt{2}a(-2k\sqrt{k}-2ak-5\sqrt{k}) \\ & \quad = \sqrt{k}\Big[((4-2\sqrt{2})a-2)k+(2a(1-\sqrt{2}a)+1)\sqrt{k}-(1+5\sqrt{2})a\Big], \end{aligned}$$

which is nonnegative, since $4a-2\sqrt{2}a-2 > 0$ holds for $k = 1.3 \times 10^6$ and in this case it holds that

$$\begin{aligned} & ((4-2\sqrt{2}) \times 1.71 - 2) \times 1.3 \times 10^6 + (2 \cdot 1.71 \times (1-\sqrt{2} \cdot 1.71)+1) \times \sqrt{1.3 \times 10^6} \\ & \qquad - (1+5\sqrt{2}) \times 1.71 > 0. \end{aligned}$$

This proves that $M(k) \le 4k/(1-1.71/\sqrt{k}) - 34$ holds for $k > 1.3 \times 10^6$. □

7. Enumerating all minimum k-way cuts. In this section, we show that algorithm MULTIWAY can be modified so that all minimum k-way cuts in G can be enumerated in nearly the same time complexity. Given a graph $G = (V, E)$ and integer k, we can construct all minimum k-way cuts F by combining a minimum p-way cut F' in $G[X]$ and a minimum $(k-p)$-way cut F'' in $G[V-X]$ for all possible subsets $X \subset V$ such that X is a union of p subsets in $\{V_1, \ldots, V_k\}$ for a minimum k-way cut in G.

However, we cannot apply Corollary 5.3 to instances (G, k) with $k \le 4$. From Lemma 3.1 with $p = 1$, we see that for any minimum k-way cut $(V_1; V_2; \ldots; V_k)$ in a graph $G = (V, E)$, there is a subset $X \in \{V_1, V_2, \ldots, V_k\}$ such that

$$f(X) \le (2/k)opt(G, k).$$

For $k \in \{2, 3, 4\}$, we derive an upper bound on the number of subsets $X \subset V$ with $f(X) \le (2/k)opt(G, k)$.

LEMMA 7.1. *Let $G = (V, E)$ be a graph, $k \in [2, 4]$ be an integer, and $opt(G, k) > 0$. Then the number of subsets $X \subset V$ such that $f(X) \le (2/k)opt(G, k)$ for $k = 2$ (resp., $k = 3, 4$) is $O(n^2)$, (resp., $O(n^4)$ and $O(n^4)$).*

Proof. Let $\mathcal{X}_k$ be the family of subsets X with $f(X) \le (2/k)opt(G, k)$. Let $\lambda(G)$ denote the edge-connectivity of G (i.e., $\lambda(G) = opt(G, 2)$). It is known [19] that, for $\lambda(G) > 0$, there are $O(n^{2\alpha})$ subsets X with $f(X) \le \alpha\lambda(G)$.

(i) Let $k = 2$. Then $\lambda(G) > 0$ holds by assumption $opt(G, 2) > 0$. This proves that $|\mathcal{X}_2| = O(n^{2\alpha}) = O(n^2)$ holds for $\alpha = 1$.

For $k \in \{3, 4\}$, we assume that $\mathcal{X}_k$ contains two subsets X_1 and X_2 such that each of $Y_1 = X_1 \cap X_2$, $Y_2 = X_1 - X_2$, $Y_3 = V - (X_1 \cup X_2)$, and $Y_4 = X_2 - X_1$ is nonempty (otherwise $|\mathcal{X}_k| \le 2n$ holds).

(ii) Let $k = 3$. If $\lambda(G) = 0$, then the edges with positive weights induce from G exactly two connected components G_1 and G_2, where we see that a minimum 3-way cut in G is a minimum 2-way cut in G_1 or G_2. By the result of (i) we have $|\mathcal{X}_k| = O(n_1^2 + n_2^2) = O(n^2)$, where n_i is the number of vertices in G_i. We next assume $\lambda(G) > 0$. Then for the above two crossing subsets $X_1, X_2 \in \mathcal{X}_3$, we have

$$\begin{aligned} 4opt(G,3) &\leq cost(Y_1; Y_2; V - (Y_1 \cup Y_2)) + cost(Y_2; Y_3; V - (Y_2 \cup Y_3)) \\ &\quad + cost(Y_3; Y_4; V - (Y_3 \cup Y_4)) + cost(Y_4; Y_1; V - (Y_4 \cup Y_1)) \\ &= 3(f(X_1) + f(X_2)) - 2cost(Y_1; Y_3) - 2cost(Y_2; Y_4) \\ &\leq 3((2/3)opt(G,3) + (2/3)opt(G,3)) - 2cost(Y_1; Y_3) - 2cost(Y_2; Y_4) \\ &= 4opt(G,3) - 2cost(Y_1; Y_3) - 2cost(Y_2; Y_4), \end{aligned}$$

implying that $f(X_1) = f(X_2) = (2/3)opt(G,3)$ and $cost(Y_1; Y_3) = cost(Y_2; Y_4) = 0$. Hence no two subsets $X, X' \in \mathcal{X}_3$ with $f(X) < (2/3)opt(G,3)$ and $f(X') < (2/3)opt(G,3)$ cross each other, indicating that the number of subsets X with $f(X) < (2/3)opt(G,3)$ is $O(n)$. If $\lambda(G) < (1/3)opt(G,3)$, then there is a subset $Z \subset V$ with $f(Z) = \lambda(G) < (1/3)opt(G,3) (< f(X_1))$, where $Z \neq X_1 \neq V - Z$ holds, and $F = (Z; V-Z) \cup (X_1; V-X_1)$ is a 3-way cut with $cost(F) < (1/3)opt(G,3) + (2/3)opt(G,3) = opt(G,3)$, which is a contradiction. Therefore, $\lambda(G) \geq (1/3)opt(G,3)$ holds, and $f(X) = (2/3)opt(G,3) \leq 2\lambda(G)$ holds for every subset X with $f(X) = (2/3)opt(G,3)$, implying that $|\mathcal{X}_3| = O(n^{2\alpha}) = O(n^4)$ holds for $\alpha = 2$.

(iii) Let $k = 4$. If $\lambda(G) = 0$, then it is not difficult to see that $|\mathcal{X}_3| = O(n^4)$ holds by using the results in (i)–(ii). Assume $\lambda(G) > 0$. For the above two crossing subsets $X_1, X_2 \in \mathcal{X}_4$, we have

$$\begin{aligned} opt(G,4) &\leq cost(Y_1; Y_2; Y_3; Y_4) \\ &= f(X_1) + f(X_2) - cost(Y_1; Y_3) - cost(Y_2; Y_4) \\ &\leq (1/2)opt(G,4) + (1/2)opt(G,4) - cost(Y_1; Y_3) - cost(Y_2; Y_4) \\ &= opt(G,4) - cost(Y_1; Y_3) - cost(Y_2; Y_4), \end{aligned}$$

implying that $f(X_1) = f(X_2) = (1/2)opt(G,4)$ and $cost(Y_1; Y_3) = cost(Y_2; Y_4) = 0$. From this, the number of subsets X with $f(X) < (1/2)opt(G,4)$ is $O(n)$. Let $\mathcal{X}_4' = \{X \in \mathcal{X}_4 \mid f(X) = (1/2)opt(G,4)\}$. If $\lambda(G) \geq (1/4)opt(G,4)$, then $f(X) = (1/2)opt(G,4) \leq 2\lambda(G)$ holds for every subset X with $f(X) = (1/2)opt(G,4)$, implying that $|\mathcal{X}_4'| = O(n^{2\alpha}) = O(n^4)$ holds for $\alpha = 2$. Assume $\lambda(G) < (1/4)opt(G,4)$. Let Z be a subset of V with $f(Z) = \lambda(G)$. Consider two crossing subsets $X_1, X_2 \in \mathcal{X}_4'$ with $Z \cap X_1 \neq \emptyset \neq Z \cap X_2$. As observed above, we have $f(X_1) = f(X_2) = (1/2)opt(G,4)$ and $cost(Y_1; Y_3) = cost(Y_2; Y_4) = 0$, indicating that one of the 3-way cuts $F_1 = (Y_1; Y_2; Y_3 \cup Y_4)$, $F_2 = (Y_1; Y_2 \cup Y_3; Y_4)$, $F_3 = (Y_1 \cup Y_2; Y_3; Y_4)$, and $F_4 = (Y_1 \cup Y_4; Y_2; Y_3)$ has cost at most $(3/4)opt(G,4)$. Such a 3-way cut F_i and $(Z; V-X)$ have $cost(F_i) + cost(Z; V-X) \leq (3/4)opt(G,4) + \lambda(G) < (3/4)opt(G,4) + (1/4)opt(G,4) = opt(G,4)$, and this means that $F_i \cup (Z; V-X)$ remains a 3-way cut, i.e., $X_1 \cap X_2 = Z$ (otherwise $F_i \cup (Z; V-X)$ would be a 4-way cut with cost less than $opt(G,4)$). Hence we have a property that, for two crossing subsets $X, X' \in \mathcal{X}_4'$ with $Z \cap X \neq \emptyset \neq Z \cap X'$, $X - Z$ and $X' - Z$ are disjoint, and we see that there are $O(n)$ subsets $X \in \mathcal{X}_4'$ with $Z \cap X \neq \emptyset$. Since there are $O(n^2)$ subsets Z with $f(Z) = \lambda(G)$, we have $|\mathcal{X}_4'| = O(n^2 \cdot n) = O(n^3)$. This completes the proof of the lemma. □

It is known that the h minimum 2-way cuts can be enumerated in $O(hnF(n,m))$ time [10, 11, 36]. Thus, for $k = 2, 3, 4$ (resp., $k \geq 5$), all subsets X with $f(X) \leq$

$(2/k)opt(G,k)$ (resp., $f(X) < (1/2)opt(G,k)$) can be obtained in $O(n^3F(n,m))$ time for $k=2$, in $O(n^5F(n,m))$ time for $k=3,4$ (by Lemma 7.1), and in $O(n^{2k-5}F(n,m))$ time for $k \geq 5$ (by Theorem 5.1).

We are ready to describe our algorithm for enumerating all minimum k-way cuts.

Algorithm ALL_CUTS(G,k)
Input: A graph $G=(V,E)$ and an integer $k \in [1,|V|]$.
Output: The set $\mathcal{F}$ of all minimum k-way cuts in G.

1. **if** $opt(G,k)=0$ **then** Return $\mathcal{F} := \emptyset$
2. **else** /* $opt(G,k) > 0$ */
3. **if** $k=2$ **then** Return $\{(X; V-X) \mid f(X) = \lambda(G)\}$
4. **else if** $k \in \{3,4\}$ **then**
   Compute the set $\mathcal{X}_k$ of all subsets $X \subset V$ such that $f(X) \leq (2/k)opt(G,k)$ and $|V-X| \geq k-1$;
5. $\mathcal{F} := \{(X; V-X) \cup F_2 \mid X \in \mathcal{X}_k,\ F_2 \in \text{ALL\_CUTS}(G[V-X], k-1)\}$;
6. Return $\mathcal{F} := \mathcal{F} - \{F \in \mathcal{F} \mid cost(F) > opt(G,k)\}$ /* $\min_{F\in\mathcal{F}} cost(F) = opt(G,k)$ */
7. **else** /* $k \geq 5$ */
8. Compute the set $\mathcal{X}_k$ of all subsets $X \subset V$ such that $f(X) < (1/2)opt(G,k)$;
9. $p := \lceil (k-\sqrt{k})/2 \rceil - 1$;
10. $\mathcal{F} := \bigcup_{X\in\mathcal{X}_k : |X|\geq p,\ |V-X|\geq k-p} \{F_1 \cup F_2 \mid F_1 \in \text{ALL\_CUTS}(G[X], p),\ F_2 \in \text{ALL\_CUTS}(G[V-X], k-p)\}$;
11. Return $\mathcal{F} := \mathcal{F} - \{F \in \mathcal{F} \mid cost(F) > opt(G,k)\}$ /* $\min_{F\in\mathcal{F}} cost(F) = opt(G,k)$ */
12. **end** /* if */
13. **end** /* if */
14. **end**. /* if */

We have the same recursive formula on the number of instances generated during the execution of ALL_CUTS, where the difference from the analysis for the runtime of MULTIWAY is some of initial terms in $M(k)$. By checking a solution to the formula up to 1.3×10^6 by a computer program, we see that the total number of instances is $O(n^{4k/(1-1.71/\sqrt{k})-20})$. Since each subset $X \in \mathcal{X}_k$ is generated in $O(nF(n,m)) = O(n^4)$ time, we establish the next result.

THEOREM 7.2. *For a graph $G=(V,E)$ with n vertices m edges and an integer $k \in [3,n]$,* ALL_CUTS(G,k) *finds all minimum k-way cuts in $O(n^{4k/(1-1.71/\sqrt{k})-19}F(n,m))$ time, where $F(n,m)$ denotes the time complexity for computing a maximum flow in a graph with n vertices and m edges.*

8. Concluding remarks. In this paper, we have shown that, for general k, all minimum k-way cuts can be computed in $O(n^{4k/(1-1.71/\sqrt{k})-16})$ time. This is the first deterministic algorithm with time complexity whose exponent is $O(k)$ for a general graph. The new time bound improves the previous time bound $O(n^{k^2/2-3k/2+4}F(n,m))$ for deterministic algorithms but is still higher than the bound $O(n^{2(k-1)}\log^3 n)$ of a Monte Carlo algorithm due to Karger and Stein [23]. So, it is left open to derive a better upper bound on the number of subsets X with $f(X) < opt(G,k)/2$. The key property for our algorithm is Theorem 5.1. A similar property is found in the article by Goldschmidt and Hochbaum [8], but we have a simpler proof for this property under a less constrained setting, which allows us to apply Lemma 3.1 to generate

instances with nearly halved k. However, based on Theorem 5.1, we can find *all* minimum k-way cuts, requiring a high time complexity. Another future work is to find a more restricted characterization for a family $\mathcal{X}$ of subsets X from which we can construct *at least one* minimum k-way cut.

Acknowledgments. The authors would like to thank the referees for their thorough reading of this article, which led to many useful suggestions for improving presentation, and the editor for the effort of coordinating.

ONLINE CONFLICT-FREE COLORING FOR INTERVALS*

KE CHEN†, AMOS FIAT‡, HAIM KAPLAN‡, MEITAL LEVY‡, JIŘÍ MATOUŠEK§, ELCHANAN MOSSEL¶, JÁNOS PACH‖, MICHA SHARIR#, SHAKHAR SMORODINSKY††, ULI WAGNER‡‡, AND EMO WELZL††

Abstract. We consider an online version of the conflict-free coloring of a set of points on the line, where each newly inserted point must be assigned a color upon insertion, and at all times the coloring has to be *conflict-free*, in the sense that in every interval I there is a color that appears exactly once in I. We present deterministic and randomized algorithms for achieving this goal, and analyze their performance, that is, the maximum number of colors that they need to use, as a function of the number n of inserted points. We first show that a natural and simple (deterministic) approach may perform rather poorly, requiring $\Omega(\sqrt{n})$ colors in the worst case. We then derive two efficient variants of this simple algorithm. The first is deterministic and uses $O(\log^2 n)$ colors, and the second is randomized and uses $O(\log n)$ colors with high probability. We also show that the $O(\log^2 n)$ bound on the number of colors used by our deterministic algorithm is tight on the worst case. We also analyze the performance of the simplest proposed algorithm when the points are inserted in a random order and present an incomplete analysis that indicates that, with high probability, it uses only $O(\log n)$ colors. Finally, we show that in the extension of this problem to two dimensions, where the relevant ranges are disks, n colors may be required in the worst case.

Key words. conflict-free coloring, online algorithms, randomized algorithms, branching processes

1. Introduction.

Let P be a set of n points in $\mathbb{R}^d$ and $\mathcal{R}$ a set of subsets of $\mathbb{R}^d$, called *ranges* (e.g., the set of all disks in the plane). A coloring of P is called

conflict-free (CF) with respect to $\mathcal{R}$ if for each $r \in \mathcal{R}$ with $P \cap r \neq \emptyset$, there is at least one color that appears exactly once in r.

We consider the following dynamic scenario of CF coloring of points on the line, with respect to interval ranges. We maintain a finite set $P \subset \mathbb{R}$. Initially, P is empty, and we repeatedly insert points into P, one point at a time. We denote by $P(t)$ the set P after the tth point has been inserted. Each time we insert a point p, we need to assign a color $c(p)$ to it, which is a positive integer. Once the color has been assigned to p, it cannot be changed in the future. The coloring should remain CF at all times. That is, as in the static case, for any interval I that contains points of $P(t)$, there is a color that appears exactly once in I.

The static version of CF coloring has been studied recently in several papers [9, 10, 12, 14, 15] in considerably more general settings, involving point sets in higher dimensions and ranges that are disks, balls, axis-parallel boxes, or more general ranges that satisfy certain geometric conditions. The study of this problem is motivated by the problem of frequency-assignment in cellular networks. Specifically, cellular networks are heterogeneous networks with two different types of nodes: *base stations* (that act as servers) and *clients*. The base stations are interconnected by an external fixed backbone network. Clients are connected only to base stations; connections between clients and base stations are implemented by radio links. Fixed frequencies are assigned to base stations to enable links to clients. Clients, on the other hand, continuously scan frequencies in search of a base station with good reception. The fundamental problem of frequency-assignment in cellular networks is to assign frequencies to base stations so that every client, located within the receiving range of at least one station, can be served by some base station, in the sense that the client is located within the range of the station and no other station within its reception range has the same frequency (such a station would be in "conflict" with the given station due to mutual interference). The goal is to minimize the number of assigned frequencies ("colors") since the frequency spectrum is limited and costly.

Suppose we are given a set of n base stations, also referred to as *antennae*. Assume, for simplicity, that the area covered by a single antenna is given as a disk in the plane. Namely, the location of each antenna (base station) and its radius of transmission are fixed and given (the transmission radii of the antennae are not necessarily equal). Even et al. [10] have shown that one can find an assignment of frequencies to the antennae with a total of at most $O(\log n)$ frequencies such that each antenna is assigned one of the frequencies and the resulting assignment is free of conflicts, in the preceding sense. Furthermore, it has been shown that this bound is worst-case optimal [10, 13, 14]. When the given antennae all have the same radius of transmission (say, unit radius), the problem is easily seen to be equivalent to that of coloring n points in the plane such that for any unit radius disk that contains more than one of the given points, at least one of the colors in that disk is unique. This is the scenario whose online version is studied in this paper. We do not address the dual version, in which the goal is to color n given ranges so that, for each point p that lies in their union, there is a color that appears exactly once among the ranges that contain p. See [10, 12, 14] for many variants of both (static) versions of the problem.

To capture a dynamic scenario where antennae can be added to the network, we introduce and study an online version of the CF coloring problem, as described above. As we show in this paper, the online version of the problem is considerably harder, even in the one-dimensional case, where the static version is trivial and fully understood. We begin by proposing a natural, simple, and obvious coloring algorithm (which we call the UniMax greedy algorithm), but show that in the worst case it

has poor performance. Specifically, the UniMax greedy algorithm may require $\Omega(\sqrt{n})$ colors in the worst case. We still do not have any nontrivial (i.e., sublinear) upper bound on the performance of the algorithm.

The UniMax greedy algorithm is indeed greedy in nature, but there are several different greedy approaches, and we briefly discuss another greedy alternative, about which almost nothing is known.

We next remedy the situation by presenting two more efficient algorithms. We describe a 2-stage deterministic variant of the UniMax greedy algorithm and show that the maximum number of colors that it uses is $\Theta(\log^2 n)$. We also describe a randomized version of the UniMax greedy algorithm which uses, with high probability,[1] only $O(\log n)$ colors.

The best known general lower bound for this problem is $\Omega(\log n)$, which holds also for the static case (see [10, 13, 14]), so there still remains a gap between the upper and lower bounds in the deterministic case.

Our randomized algorithm works against an oblivious adversary. That is, we assume that the sequence of points is fixed by the adversary before starting to feed them one by one to the online algorithm. The adversary cannot choose its next point based on the actions or the random choices that the online algorithm has made so far. The coloring that our algorithm produces is CF no matter which random choices it makes. For further discussion on different kinds of adversaries in online computations, see [4] for the general case and [2] for the specific case of online CF coloring.

Next, we return to the UniMax greedy algorithm, which can be inefficient in the worst case, and analyze its performance when the points are inserted in a *random order*. We reduce the problem to a certain stationary stochastic process, and present partial analysis of its performance, as well as a fairly reasonable set of conjectures, strongly supported by simulations, that indicate that the expected number of colors that the simple algorithm uses in this case is only $O(\log n)$.

Finally, we consider the extension of the online version to point sets in the plane. Unfortunately, we show that, in the simple case where the ranges that are required to be CF are disks (or arbitrary radii), n colors may be needed in the worst case. Nevertheless, (much) better solutions might still exist for random distributions of the points, for other ranges, or for relaxed versions of the problem, in which each range has a color that appears in it at least once and at most k times for some constant k [14]. A recent follow-up study by Chen, Kaplan, and Sharir [6] (see also [5]) gives randomized online CF coloring algorithms for points in the plane, with respect to half-planes, unit disks, or nearly equal axis-parallel rectangles. The algorithms use $O(\log n)$ colors with high probability. An even more recent result of Bar-Noy, Cheilaris, and Smorodinsky [3] provides a general randomized online CF coloring algorithm, which achieves the same performance as [6] in the special cases just mentioned.

There are many open problems that our study raises: Obtain, if possible, an improved algorithm-independent deterministic lower bound for online CF coloring for intervals; get a better understanding of the problem behavior in the plane and in higher dimensions; design and analyze other strategies, and so on (see additional problems posed throughout the paper). We note that CF coloring is closely related to the problem of *vertex ranking* in graphs (see, e.g., [8]). Some of our algorithms, which maintain the property that the *maximum* color in any interval is unique, actually per-

[1] This means that the probability of failure is at most $1/p(n)$, where $p(n)$ is polynomial in n, whose degree can be made arbitrarily large by adjusting the constants of proportionality in the performance bound.

form online vertex ranking in *paths*. Extending our analysis to online vertex ranking in other kinds of graphs (trees, for example) raises yet another set of interesting open problems.

2. The UniMax greedy coloring algorithm. Instead of the usual CF property, we wish to maintain the following stronger *unique maximum invariant* (in which we assume that the colors are positive integers):

> *At any given step t and for any interval I that contains points of $P(t)$, there is only one element of $P(t) \cap I$ that attains the* maximum *color in that set.*

This invariant implies that the coloring of $P(t)$ is CF at any time t. It is indeed a stronger condition: CF coloring requires only that for each interval there exists a color (not necessarily the maximum) that appears there only once.

We employ the following simple-minded algorithm for inserting a point p into the current set $P(t)$. In a nutshell, the rule is simply to assign to p the *smallest* possible color that maintains the invariant. This rule is implemented as follows. We say that the newly inserted point p *sees* a point x if all the colors of the points between p and x (exclusive) are smaller than $c(x)$. In this case we also say that p sees the color $c(x)$. We then give p the smallest color that it does not see. (Note that a color can be seen from p either to the left or to the right, but not in both directions; see below.) We refer to this algorithm as the *Unique Maximum Greedy* algorithm, or the UniMax greedy algorithm, for short.

Below is an illustration of the coloring rule of the UniMax greedy algorithm. The left column gives the colors (integers in the range $1, 2, \ldots, 6$) assigned to the points in the current set P and the location of the next point to be inserted (indicated by a period). The right column gives the colors "seen" by the new point. The colors seen to the left precede the $\cdot$, and those seen to the right succeed the $\cdot$.

$1\cdot$	$[1\cdot]$
$1 \cdot 2$	$[1 \cdot 2]$
$1 \cdot 32$	$[1 \cdot 3]$
$12 \cdot 32$	$[2 \cdot 3]$
$121 \cdot 32$	$[21 \cdot 3]$
$121 \cdot 432$	$[21 \cdot 4]$
$121 \cdot 3432$	$[21 \cdot 34]$
$1215 \cdot 3432$	$[5 \cdot 34]$
$1215 \cdot 13432$	$[5 \cdot 134]$
$12152 \cdot 13432$	$[52 \cdot 134]$
$121526 \cdot 13432$	$[6 \cdot 134]$

Correctness. The correctness of the algorithm is established by induction on the insertion order. First, note that no color can be seen twice from p: This is obvious for two points that lie both to the left or both to the right of p. If p sees the same color at a point u to its left and at a point v to its right, then the interval $[u, v]$, before p is inserted, does not have a unique maximum color; thus this case is impossible, too. Next, if p is assigned color c, any interval that contains p still has a unique maximum color: This follows by induction when the maximum color is greater than c. If the maximum color is c, then it cannot be shared by another point u in the interval, because then p would have seen the nearest such point and thus would not be assigned color c. It is also easy to see that the algorithm assigns to each newly inserted point the smallest possible color that maintains the invariant of a unique

maximum color in each interval. This makes the algorithm *greedy* with respect to the unique maximum condition.

Special insertion orders. Denote by $C(P(t))$ the sequence of colors assigned to the points of $P(t)$, in left-to-right order along the line. Let $c_{\max}(P(t))$ denote the maximum color in $C(P(t))$.

The *complete binary tree sequence* S_k of order k is defined recursively as $S_1 = (1)$ and $S_k = S_{k-1} \| (k) \| S_{k-1}$, for $k > 1$, where $\|$ denotes concatenation. Clearly, $|S_k| = 2^k - 1$.

For each pair of integers $a < b$, denote by $C_0(a, b)$ the following special sequence. Let k be the integer satisfying $2^{k-1} \le b < 2^k$. Then $C_0(a, b)$ is the subsequence of S_k from the ath place to the bth place (inclusive). For example, $C_0(5, 12)$ is the subsequence $(1, 2, 1, 4, 1, 2, 1, 3)$ of $(1, 2, 1, 3, 1, 2, 1, 4, 1, 2, 1, 3, 1, 2, 1)$.

LEMMA 2.1. (a) *If each point is inserted into P to the right of all preceding points, then $C(P(t)) = C_0(1, t)$.*

(b) *If each point is inserted into P to the left of all preceding points, then $C(P(t)) = C_0(2^k - t, 2^k - 1)$, where k satisfies $2^{k-1} \le t < 2^k$.*

(c) *If each point is inserted into P either from the left or from the right, then $C(P(t))$ is some subsequence of the form $C_0(a, b)$, where $b \le |P(t)|$.*

Proof. The proof is easy and therefore omitted. □

2.1. Lower bound for the UniMax greedy algorithm.

THEOREM 2.2. *The UniMax greedy algorithm may require $\Omega(\sqrt{n})$ colors in the worst case for a set of n points.*

Proof. For each integer k, define the sequence

$$C_k = (1, 2, 1, 3, 2, 1, \ldots, k-1, k-2, \ldots, 1, k, k-1, \ldots, 1).$$

Note that C_k is the concatenation of k sequences $D_1 \| D_2 \| \cdots \| D_k$, where $D_j = (j, j-1, \ldots, 2, 1)$. Put $n_k = k(k+1)/2$. We prove the following property, from which the assertion of the theorem is an immediate corollary.

$(*)$ There exists an insertion order of n_k points for which the color sequence produced by the UniMax greedy algorithm is C_k.

The proof proceeds by induction on k. We note that the claim easily holds for $k = 1, 2$. Suppose that there is an insertion sequence S_k for which the UniMax greedy algorithm produces the color sequence C_k. We insert the next point between D_{k-1} and D_k and observe that it is assigned color $k+1$. We then insert a point between D_{k-2} and D_{k-1}, which is assigned color k. Proceeding in this manner from right to left, we insert k points between consecutive subsequences D_{j-1}, D_j. The color sequence now becomes

$$D_2 \| D_3 \| D_4 \| \cdots \| D_k \| D_{k+1}.$$

To complete the step, we insert one additional point to the left of the whole sequence, which gets the color 1, thereby producing the color sequence C_{k+1}. This completes the proof of $(*)$ and thus of the theorem. □

Open problem. Obtain an upper bound for the maximum number of colors that the algorithm uses for n inserted points. We conjecture that the bound is close to the $\Omega(\sqrt{n})$ lower bound. At the moment, we do not have any sublinear upper bound.

2.2. Related algorithms.

The First-Fit algorithm—another greedy strategy. The UniMax greedy algorithm is greedy for maintaining the unique maximum invariant, namely, that in each interval

the *maximum color* appears exactly once. Perhaps it is more natural to consider a greedy approach in which we want only to enforce the standard CF property. That is, we want to assign to each newly inserted point the *smallest* color for which the CF property continues to hold. There are cases where this *First-Fit* greedy algorithm uses fewer colors than the UniMax greedy algorithm: Consider an insertion of five points in the order (1 3 2 4 5). The UniMax greedy algorithm produces the color sequence (1 3 2 1 4), whereas the First-Fit algorithm produces the coloring (1 3 2 1 2).

Very recently, after the original submission of this paper, Bar-Noy, Cheilaris, and Smorodinsky [2] have shown that in the worst case the First-Fit algorithm uses about $n/2$ colors. More precisely, there are sequences with $2i + 3$ elements that force the algorithm to use $i + 3$ colors, and this bound is tight.

CF coloring for unit intervals. Consider the special case where we want the CF property to hold only for *unit intervals*. In this case, $O(\log n)$ colors suffice: Partition the line into the unit intervals $J_i = [i, i + 1)$ for $i \in \mathbb{Z}$. Color the intervals J_i with even i as white, and those with odd i as black. Note that any unit interval meets only one white and one black interval. We color the points in each J_i independently, using the same set of "light colors" for each white interval and the same set of "dark colors" for each black interval. For each J_i, we color the points that it contains using the UniMax greedy algorithm, except that new points inserted into J_i between two previously inserted points get a special color, color 0. It is easily checked that the resulting coloring is CF with respect to unit intervals. Since we effectively insert points into any J_i only to the left or to the right of the previously inserted points, Lemma 2.1(c) implies that the algorithm uses only $O(\log n)$ (light and dark) colors. We remark that this algorithm satisfies the unique maximum color property for unit-length intervals.

We note that, in contrast to the static case (which can always be solved with $O(1)$ colors), $\Omega(\log n)$ colors may be needed in the worst case. Indeed, consider a left-to-right insertion of n points into a sufficiently small interval. Each contiguous subsequence σ of the points will be a suffix of the whole sequence at the time the rightmost element of σ is inserted. Since such a suffix can be cut off the current set by a unit interval, it must have a unique color. Hence, at the end of insertion, *every* subsequence must have a unique color, which implies (see [10, 14]) that $\Omega(\log n)$ colors are needed.

3. An efficient deterministic algorithm. In this section we modify the UniMax greedy algorithm into a deterministic 2-stage coloring scheme and show that it uses only $O(\log^2 n)$ colors. We refer to this algorithm as the *leveled UniMax greedy algorithm*.

Let x be the point which we currently insert. We assign a color to x in two steps. First we assign x to a *level*, denoted by $\ell(x)$. Once x is assigned to level $\ell(x)$ we give it an actual color among the set of colors dedicated to $\ell(x)$. We maintain the invariant that each color is used by at most one level. Formally, the colors that we use are pairs $(\ell(x), c(x)) \in \mathbb{Z}^2$, where $\ell(x)$ is the level of x and $c(x)$ is its integer color within that level.

Modifying the definition from the UniMax greedy algorithm, we say that point x *sees* point y (or that point y is *visible* to x) if and only if for every point z between x and y, $\ell(z) < \ell(y)$. When x is inserted, we set $\ell(x)$ to be the smallest level ℓ such that either to the left of x or to the right of x (or in both directions) there is no point y visible to x at level ℓ.

To give x a color, we now consider only the points of level $\ell(x)$ that x can see.

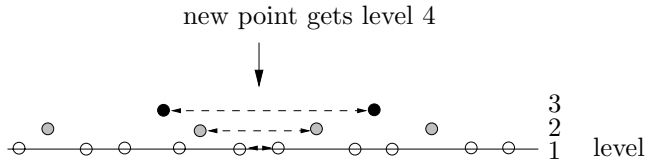

FIG. 3.1. *Illustrating the* 2*-stage deterministic algorithm. An insertion order that realizes the depicted assignment of levels to points is to first insert all level-*1 *points from left to right, then insert the level-*2 *points from left to right, and then the level-*3 *points.*

That is, we discard every point y such that $\ell(y) \neq \ell(x)$, and every point y such that $\ell(y) = \ell(x)$ and there is a point z between x and y such that $\ell(z) > \ell(y)$. We apply the UniMax greedy algorithm so as to color x with respect to the sequence P_x of the remaining points, using the colors of level $\ell(x)$ only. That is, we give x the color $(\ell(x), c(x))$, where $c(x)$ is the smallest color that ensures that the coloring of P_x maintains the unique maximum color condition. This completes the description of the algorithm. See Figure 3.1 for an illustration.

We begin the analysis of the algorithm by making a few observations on its performance.

(a) Suppose that a point x is inserted and is assigned to level $i > 1$. Since x was not assigned to any level $j < i$, it must see a point ℓ_j at level j that lies to its left, and another such point r_j that lies to its right. Let $E_j(x)$ denote the interval $[\ell_j, r_j]$. Note that, by definition, these intervals are *nested*, that is, $E_j(x) \subset E_k(x)$ for $j < k < i$. See Figure 3.1.

(b) We define a *run* at level i to be a maximal sequence of points $x_1 < x_2 < \cdots < x_k$ at level i, such that all points between x_1 and x_k that are distinct from $x_2, x_3, \ldots, x_{k-1}$ are assigned to levels smaller than i. Whenever a new point x is assigned to level i and is inserted into a run of that level, it is always inserted either to the left or to the right of all points in the run. Moreover, the actual color that x gets is determined solely from the colors of the points already in the run. See Figure 3.1.

(c) The runs keep evolving as new points are inserted. A run may either grow when a new point of the same level is inserted at its left or right ends (note that other points at smaller levels may separate the new point from the former end of the run) or split into two runs when a point of a higher level is inserted somewhere between its ends.

(d) As in observation (a), the points at level i define *intervals*, called *i-intervals*. Any such interval E is a contiguous subsequence $[x, y]$ of P, so that x and y are both at level i and all the points between x and y have smaller levels. E is formed when the second of its endpoints, say x, is inserted. We say that x *closes* the interval E and refer to it as a *closing point*. Note that, by construction, x cannot close another interval.

(e) Continuing observation (a), when x is inserted, it *destroys* the intervals $E_j(x)$, for $j < i$, into which it is inserted, and only these intervals. That is, each of these intervals now contains a point with a level greater than that of its endpoints, so it is no longer a valid interval. We charge x to the set of the closing endpoints of all these intervals. Clearly, none of these points will ever be charged again by another insertion (since it is the closing endpoint of only one interval, which is now destroyed). We maintain a forest F, whose nodes are all the points of P. The leaves of F are all the points at level 1. When a new point x is inserted, we make it a new root of F, and the parent of all the closing points that it charges. Since these points have smaller

levels than x, and since none of these points becomes a child of another parent, it follows that F is indeed a forest.

Note that the nonclosing points can only be roots of trees of F. Note also that a node at level i has exactly $i-1$ children, exactly one at each level $j < i$. Hence, each tree of F is a *binomial tree* (see [7]); if its root has level i, then it has 2^i nodes.

This implies that if m is the maximal level assigned after n points have been inserted, then we must have $2^m \le n$, or $m \le \log n$. That is, the algorithm uses at most $\log n$ levels.

We next prove that our algorithm uses only $O(\log n)$ colors at each level. We recall the way runs evolve: They grow by adding points at their right or left ends, and split into prefix and suffix subruns, when a point with a larger level is inserted in their middle.

LEMMA 3.1. *At any time during the insertion process, the colors assigned to the points in a run form a sequence of the form $C_0(a,b)$ (as defined in section 2). Moreover, when the jth smallest color of level i is given to a point x, the run to which x is appended has at least $2^{j-2}+1$ elements (including x).*

Proof. The proof proceeds by induction through the sequence of insertion steps and is based on the following observation. Let σ be a contiguous subsequence of the complete binary tree sequence S_{k-1}, and let x be a point added, say, to the left of σ. If we assign to x color $c(x)$, using the UniMax greedy algorithm, then $(c(x))\|\sigma$ is a contiguous subsequence of either S_{k-1} or S_k. The latter happens only if σ contains $S_{k-2}\|(k-1)$ as a prefix. Symmetric properties hold when x is inserted to the right of σ. We omit the straightforward proof of this observation. □

As a consequence, we obtain the following result.

THEOREM 3.2. (a) *The algorithm uses at most $(2+\log n)\log n$ colors.*

(b) *At any time, the coloring is CF.*

(c) *In the worst case the algorithm may be forced to use $\Omega(\log^2 n)$ colors after n points are inserted.*

Proof. (a) We have already argued that the number of levels is at most $\log n$. Within a level i, the kth smallest color is assigned when a run contains at least 2^{k-2} points. Hence $2^{k-2} \le n$, or $k \le 2+\log n$, and (a) follows.

To show (b), consider an arbitrary interval I. Let ℓ be the highest level of a point in I. Let $\sigma = (y_1, y_2, \ldots, y_j)$ be the sequence of the points in I of level ℓ. Since ℓ is the highest level in I, σ is a contiguous subsequence of some run, and, by Lemma 3.1, the sequence of the colors of its points is also of the form $C_0(a', b')$. Hence, there is a point $y_i \in \sigma$ which is uniquely colored among $y_1, y_2, \ldots, y_j$ by a color of level ℓ.

To show (c), we construct a sequence P so as to force its coloring to proceed level by level. We first insert 2^{k-1} points from left to right, thereby making them all be assigned to level 1 and colored with k different colors of that level. Let P_1 denote the set of these points. We next insert a second batch of 2^{k-2} points from left to right. The first point is inserted between the first and second points of P_1, the second point between the third and fourth points of P_1, and so on, where the jth new point is inserted between the $(2j-1)$th and $(2j)$th points of P_1. By construction, all points in the second batch are assigned to level 2, and they are colored with $k-1$ different colors of that level. Let P_2 denote the set of all points inserted so far. P_2 is the concatenation of 2^{k-2} triples, where the levels in each triple are $(1,2,1)$. We now insert a third batch of 2^{k-3} points from left to right. The first point is inserted between the first and second triples of P_2, the second point between the third and fourth triples of P_2, and so on, where the jth new point is inserted between the $(2j-1)$th and $(2j)$th triples of P_2. By construction, all points in the third batch are

assigned to level 3, and they are colored with $k-2$ different colors of that level.

The construction is continued in this manner. Just before inserting the ith batch of 2^{k-i} points, we have a set P_{i-1} of $2^{k-1}+\cdots+2^{k-i+1}$ points, which is the concatenation of 2^{k-i+1} tuples, where the sequences of levels in each of these tuples are all identical and equal to the "complete binary tree sequence" $C_0(1, 2^{i-1}-1)$, as defined in section 2 (whose elements now encode levels rather than colors). The points of the ith batch are inserted from left to right, where the jth point is inserted between the $(2j-1)$th and $(2j)$th tuples of P_{i-1}. By construction, all points in the ith batch are assigned to level i and are colored with $k-i+1$ different colors of that level. Proceeding in this manner, we end the construction by inserting the $(k-1)$th batch, which consists of a single point that is assigned to level k. Altogether we have inserted $n = 2^k - 1$ points and forced the algorithm to use $k+(k-1)+\cdots+1 = k(k+1)/2 = \Omega(\log^2 n)$ different colors. □

Remark. One can modify the algorithm so that the set of colors that it uses can be identified with (a subset of a prefix of) the integers, and so that it maintains the property of the UniMax greedy algorithm: At any time t and for any interval I, there is a unique point in I with maximum color. The modified algorithm also uses $O(\log^2 n)$ colors.

Specifically, we proceed as follows. Suppose first that n is known in advance. Order the pairs $(k,i) \in \{1,\ldots,\log n\}\times\{1,\ldots,2+\log n\}$ lexicographically, i.e., $(k,i) < (k',i')$ if $k<k'$ or $(k=k'$ and $i<i')$. Let $f(k,i)$ be the rank of the pair (k,i) in this lexicographic order. Then the set of numbers $f(k(p),i(p))$, where $p \in P$ is assigned level $k(p)$ and the $i(p)$th color within that level, is (a subset of) a prefix of the integers, and the unique maximum color property is satisfied.

If n is not known in advance, we apply the same strategy as the one discussed at the end of the preceding section. That is, when the number of inserted points reaches one of the values 2^{2^i} for $i \geq 0$, we start coloring new points with a completely new set of colors, which are mapped lexicographically onto integer values that are larger than the largest integer color used so far.

4. An efficient randomized algorithm. We next modify the UniMax greedy deterministic algorithm into the following randomized algorithm, which we call the *randomized UniMax greedy algorithm.* The randomized UniMax greedy algorithm does not partition the points into levels but assigns a color directly, using the following randomized variant of the UniMax greedy strategy.

Let p be the next point inserted. Recall that p *sees* a point x (alternatively, the color $c(x)$) if all the colors of points between p and x (exclusive) have color smaller than $c(x)$. We say that p is *eligible* for color m if p does not see m. To give p a color, we scan all colors in increasing order. For each color i, if p is not eligible for color i, we continue to color $i+1$. Otherwise, if p is eligible for color i, we set $c(p)=i$ with probability $1/2$ and continue to color $i+1$ with probability $1/2$.

By the same reasoning as for the UniMax greedy algorithm, the coloring produced by the randomized UniMax greedy algorithm is CF at any stage. We next show that it uses $O(\log n)$ colors with high probability.

LEMMA 4.1. *If the algorithm reaches color i when processing a point p, then p gets the color i with probability at least $1/8$. More formally, let C_i (resp., $C_{\geq i}$) be the random variable which is equal to the set of points of color i (resp., of color $\geq i$). Then*

$$\mathbf{Pr}\Big\{p \in C_i \mid p \in C_{\geq i}\Big\} \geq \frac{1}{8}.$$

Proof. Assume first that p is neither the leftmost nor the rightmost point at the time of its insertion. Let Q be the set of points inserted before p. Fix a point $p_\ell \in Q$ to the left of p, and a point $p_r \in Q$ to the right of p. Consider all random choices (which we refer to as "executions") of the randomized UniMax algorithm, in which p_ℓ, p, and p_r end up as three consecutive points in $C_{\geq i}$.

In at least $1/2$ of these executions p_ℓ gets a color greater than i (either because it is ineligible for color i or because the coin toss has moved it to color $i+1$); similarly, in at least $1/2$ of these executions p_r gets a color greater than i. Since the coin tosses of p_r are independent of those of p_ℓ, both p_ℓ and p_r get color greater than i in at least $1/4$ of these executions. In these cases, p is eligible for color i and with probability $1/2$ does get that color. Hence, in at least $1/8$ of the above executions p gets color i. Since this is true for every choice of p_ℓ and p_r, the lemma follows.

If p is the leftmost or rightmost point, then it is eligible for color i (assuming it has reached $C_{\geq i}$) with probability $1/2$, and if p is the first inserted point, then it is eligible for color i with probability 1. Hence, the preceding argument implies the lemma in this case too. □

THEOREM 4.2. *The randomized UniMax greedy algorithm uses $O(\log n)$ colors with high probability.*

Proof. Using the same notation as above, Lemma 4.1 implies that

$$\mathbf{E}\left(|C_{\geq i+1}|\right) \leq \frac{7}{8}\mathbf{E}\left(|C_{\geq i}|\right).$$

Since $|C_{\geq 1}| = n$, we have for $i \geq 1$

$$\mathbf{E}\left(|C_{\geq i+1}|\right) \leq \left(\frac{7}{8}\right)^i n.$$

For $i = c\log_{8/7} n$, we get that $\mathbf{E}\left(|C_{\geq i+1}|\right) \leq 1/n^{c-1}$. Hence, by Markov's inequality,

$$\mathbf{Pr}\left\{|C_{\geq i+1}| \geq 1\right\} \leq 1/n^{c-1},$$

from which the lemma follows. □

Remark. We leave it as an open problem to determine whether a nonoblivious adversary can cause the algorithm to use more than $\Theta(\log n)$ colors.

5. Random insertion order. In this section we consider the special case where the points are inserted in a *random* order, and where we color them by the UniMax greedy algorithm of section 2. We have simulated the execution of the UniMax greedy algorithm under such an insertion order. The results of the simulation strongly suggest the following conjecture.

CONJECTURE 5.1. *For each integer $k \geq 1$, the expected frequency of the color k in $C(P(t))$, as generated by the UniMax greedy algorithm, converges to $\frac{1}{3}\left(\frac{2}{3}\right)^{k-1}$ as $t \to \infty$.*

Assuming Conjecture 5.1, the following is an easy consequence.

COROLLARY 5.2. *If each point is inserted into P at a random place, the expected value of $c_{\max}(P(t))$, under the UniMax greedy algorithm, is $O(\log t)$. This also holds with high probability if the constant of proportionality is chosen sufficiently large.*

Proof. Let $P(n)$ be a set of n points inserted in a random order. Let X_k be a random variable counting the number of points in $P(n)$ that were colored with k

by the UniMax greedy algorithm. Let I_k be the indicator variable for the color k to appear at all.

We are interested in the number of colors used, that is, $Y := \sum_k I_k$.

Assume that $\mathbf{E}(X_k) = \frac{1}{3}(\frac{2}{3})^{k-1}n$. Then, using Markov's inequality, $\mathbf{E}(I_k) = \mathbf{Pr}\{I_k = 1\} = \mathbf{Pr}\{X_k \geq 1\} \leq \mathbf{E}(X_k)$. Hence,

$$\begin{aligned}\mathbf{E}(Y) = \mathbf{E}\left(\sum_{1\leq k} I_k\right) &= \mathbf{E}\left(\sum_{1\leq k<1+\log_{3/2} n} I_k\right) + \mathbf{E}\left(\sum_{k\geq 1+\log_{3/2} n} I_k\right)\\ &\leq 1 + \log_{3/2} n + \sum_{k\geq 1+\log_{3/2} n} \frac{1}{3}\left(\frac{2}{3}\right)^k n\\ &\leq 1 + \log_{3/2} n + \sum_{i\geq 0} \frac{1}{3}\left(\frac{2}{3}\right)^i\\ &= \log_{3/2} n + 2.\end{aligned}$$

Arguing as in the proof of Theorem 4.2, we also have

$$\begin{aligned}\mathbf{Pr}\Big\{\text{more than } c\log_{3/2} n \text{ colors are used}\Big\} &= \mathbf{Pr}\Big\{I_{\lceil c\log_{3/2} n\rceil} = 1\Big\}\\ &\leq \frac{1}{3}\left(\frac{2}{3}\right)^{\lceil c\log_{3/2} n\rceil - 1} n \leq \frac{1}{2n^{c-1}}.\end{aligned}$$ □

At this stage, we do not have a complete proof of Conjecture 5.1. We do have some partial results that we now present. In particular, they show that Conjecture 5.1 holds for $k = 1, 2, 3$. Completing the proof is one of the major open problems raised in this paper.

LEMMA 5.3. *The expected number of points assigned the color* 1*, after a random insertion of* t *points, is* $\frac{t+1}{3}$ *for* $t \geq 2$.

Proof. Denote by X_i the random variable whose value is the number of 1's after the insertion of the first i points. Then $X_{i+1} = X_i + Y_i$, where Y_i is an indicator variable, equal to 1 if the $(i+1)$st point p_{i+1} is colored by 1, and to 0 otherwise. Note that p_{i+1} is colored by 1 if and only if it is inserted at a place that is not adjacent to any point colored 1. Each of the current X_i 1-colored points has two adjacent insertion places, and all these places are distinct, because $P(i)$ does not contain two adjacent points colored 1. Hence, out of the $i+1$ available insertion places, $i+1-2X_i$ will cause p_{i+1} to be colored 1. Taking expectations, we obtain

$$\begin{aligned}&\mathbf{E}(X_{i+1}) = \mathbf{E}(X_i) + \mathbf{E}(Y_i) = \mathbf{E}(X_i) + \mathbf{E}(\mathbf{E}(Y_i \mid X_i))\\ &= \mathbf{E}(X_i) + \mathbf{E}\left(\frac{i+1-2X_i}{i+1}\right) = \mathbf{E}(X_i) + \frac{i+1-2\mathbf{E}(X_i)}{i+1},\end{aligned}$$

or $\mathbf{E}(X_{i+1}) = \frac{i-1}{i+1}\mathbf{E}(X_i)+1$, for $i \geq 2$. The solution of this recurrence, with the initial value $\mathbf{E}(X_2) = 1$, is easily seen to be $\mathbf{E}(X_t) = \frac{t+1}{3}$ for $t \geq 2$. □

Analysis for $k \geq 2$. We next present a framework for estimating the expected number of points that are assigned the color k for $k \geq 2$. We apply this framework to get a complete solution for $k = 2, 3$. We fix k, and define a *k-state* to be any valid contiguous sequence of colors in $\{1, \ldots, k\}$ that may show up in $C(P(t))$, delimited on both sides by $*$, which designates a color greater than k. The validity of a state

means that it satisfies the unique maximum color invariant: Any contiguous nonempty subsequence of s has a unique largest element. We refer to the portion of a state that excludes the $*$'s as its *core*.

Denote by S_k the set of all k-states. For example, the set S_2 consists of the following states:

(5.1)
$$s_1 = \langle **\rangle, \quad s_2 = \langle *1* \rangle, \quad s_3 = \langle *2* \rangle, \quad s_4 = \langle *12* \rangle, \quad s_5 = \langle *21* \rangle, \quad s_6 = \langle *121* \rangle.$$

For example, the sequence $C(P(t)) = (1\ 2\ 1\ 3\ 2\ 4\ 2\ 1\ 3\ 5\ 1\ 2\ 3)$ is decomposed into the following sequence of 2-states:

$$\big(\langle *121* \rangle, \quad \langle *2* \rangle, \quad \langle *21* \rangle, \quad \langle ** \rangle, \quad \langle *12* \rangle, \quad \langle ** \rangle\big).$$

We denote by S_k^+ the subset of S_k consisting of those k-states that contain the color k (necessarily at a unique location), and by S_k^- the subset of those states that do not contain k. We refer to states in S_k^+ (resp., S_k^-) as *major* k-states (resp., *minor* k-states). The *size* $|s|$ of a k-state s is the length of its core plus 1; it designates the number of places in s at which a new point can be inserted. For example, for 2-states we have $S_2^- = \{s_1, s_2\}$, $S_2^+ = \{s_3, s_4, s_5, s_6\}$. Also, we have $|s_1| = 1$, $|s_2| = |s_3| = 2$, $|s_4| = |s_5| = 3$, and $|s_6| = 4$.

Let $s \in S_k^+$. It has the form $(*ukv*)$, where u and v can be regarded as the cores of two respective $(k-1)$-states, s_L and s_R. We refer to s_L and s_R as the *left wing* and the *right wing* of s, respectively. We have $|s| = |s_L| + |s_R|$. Care should be exercised in the treatment of s_L and s_R. Specifically, we will consider the actual sequence of colors $C(P(t))$ as a concatenation of states, which depends on the choice of k. We denote by $C^{(k)}(t)$ the (unique) partition of $C(P(t))$ into the concatenation of k-states, and refer to it as the *k-scenario*. Then, for a major state $s \in S_k^+$, its left and right wings are not counted as separate states in the k-scenario but as states in the $(k-1)$-scenario.

We need one more notion. When we insert a new point into a k-state s, there are two possible outcomes: (i) The point gets a color smaller than or equal to k, in which case s is transformed to another, *single* state in S_k. (ii) The point gets a color greater than k, in which case s is split into two new k-states. Note that, for case (ii) to occur, s must be a *major* state (if s were minor, we could have assigned the color k to the new point). Moreover, in this case one of the two new states, s', must be a major state, and the other, s'', must be minor. We refer to this case by saying that *s spawns s''* and is *transformed* into s'. (Note that not every insertion into a major state necessarily causes a spawning.)

It is easy to show that the size $|S_k|$ of S_k satisfies $|S_{k+1}| = |S_k| + |S_k|^2$; thus $|S_k|$ is doubly exponential in k. We have $|S_1| = 2$, $|S_2| = 6$, $|S_3| = 42$, and $|S_4| = 1806$.

Let k be fixed. For states $s, r \in S_k$, we denote by a_{sr} the expected change in the number of states r that are generated by an insertion of a new point, conditioned on having chosen an insertion place at a state s (within $C^{(k)}$). For example, for $k = 2$ we have (see (5.1) for the notation)

$$a_{s_4 s_1} = a_{s_4 s_2} = a_{s_4 s_3} = a_{s_4 s_6} = \frac{1}{3} \quad \text{and} \quad a_{s_4 s_4} = -\frac{2}{3}$$

(in two of the three possible insertion places, s_4 is destroyed by the insertion, and in the third insertion it survives, so the net expected increase in the number of s_4-states

is $0 \cdot \frac{1}{3} + (-1) \cdot \frac{2}{3} = -\frac{2}{3}$). Put $w_{sr} = |s|a_{sr}$, and let W denote the resulting matrix (w_{sr}).

We first provide some intuitive and informal derivation of the equations that we will rigorously derive shortly. Let $M_s^{(t)}$ denote the random variable equal to the number of k-states s in $C(P(t))$. Define the *frequency* of state s at time t to be $X_s^{(t)} = M_s^{(t)}/(t+1)$. Note that $|s|X_s^{(t)}$ is the frequency of the insertion places that belong to occurrences of s in $C(P(t))$. In particular, $\sum_{s \in S_k} |s|X_s^{(t)} = 1$ for each t. We also have

$$(t+2)\mathbf{E}(X_r^{(t+1)}) = (t+1)\mathbf{E}(X_r^{(t)}) + \sum_{s \in S_k} |s|a_{sr}\mathbf{E}(X_s^{(t)}). \tag{5.2}$$

Indeed, $|s|X_s^{(t)}$ is the probability that the next insertion place belongs to an occurrence of state s in $C(P(t))$, and a_{sr} is the corresponding conditional expected change in the number of occurrences of state r. Since $M_r^{(t)} = (t+1)X_r^{(t)}$ (resp., $M_r^{(t+1)} = (t+2)X_r^{(t+1)}$) is the number of occurrences of state r at time t (resp., $t+1$), the equality follows.

Letting $t \to \infty$, applying an informal limit process to (5.2), and denoting the limit of $\mathbf{E}(X_s^{(t)})$ as X_s for $s \in S_k$, we arrive at the equations

$$X_r = \sum_{s \in S_k} |s|a_{sr}X_s = \sum_{s \in S_k} w_{sr}X_s.$$

We now proceed to justify this process rigorously.

Existence of limiting frequencies. The random insertion order defines in a natural way a *multitype branching process* (see [1]). We briefly review the ingredients of the theory of branching processes that we need to apply. A (discrete) branching process of this kind manipulates objects (referred to as "particles") that can have a finite number m of types. Each type i is associated with weights $(\xi_{i,J})$, where J is a multiset of types. The weight $\xi_{i,J}$ should be thought of as the relative frequency at which a particle of type i gives birth to the multiset J (for each type j that appears μ times in J, the particle generates μ new particles of type j). Each particle giving birth dies immediately after doing so. Set $\xi_i = \sum_J \xi_{i,J}$. The process may then be formally defined as follows. Let $S(t)$ be the population at time t. Choose $x \in S(t)$ with probability $\xi_{i(x)}/\sum_{y \in S(t)} \xi_{i(y)}$, where $i(u)$ is the type of particle u. Then x gives birth to the multiset J with probability $\xi_{i(x),J}/\xi_{i(x)}$ and then dies.

In our case, the different particle types correspond to different state types in S_k. A state s of length ℓ has total weight ℓ. If some insertions into s produce the single state s' (without spawning), then $\xi_{s,\{s'\}} = j$, where j is the number of places at which this occurs. If some j insertions produce two states s', s'' (by spawning), then $\xi_{s,\{s',s''\}} = j$. The entries of our transition matrix W are then defined as $w_{sr} = \sum_{r \in J} \xi_{s,J}$ for $r \neq s$, and $w_{ss} = \left(\sum_{r \in J} \xi_{s,J}\right) - |s|$. See pp. 200–202 in [1] for a similar construction of a transition matrix for general multitype processes (where the matrix is called the *infinitesimal generator* of a corresponding semigroup of mean matrices).

A standard trick in the theory of branching processes is to embed discrete branching processes of the kind described above into continuous-time branching processes, in which particles give birth in continuous time. More specifically, $S(t)$ evolves in continuous time. For any fixed time t, we associate, with each $x \in S(t)$ and each multiset J, an exponential random variable with rate $w_{i(x),J}$. We then take the one

with the smallest actual value—suppose this is the variable $w_{i(x'),J'}$ and that it has the value h. Now the population at time $t+h$ is obtained from the population at time t by killing x' and replacing it by J'. We now obtain a new population $S(t+h)$ and a new collection of exponential random variables, and the process continues.

If we extract from the continuous branching process only those times at which new particles are born, we obtain exactly the same discrete process that we started with (see [1] for details). In the terminology of the theory of branching processes, the discrete and continuous processes are the same, up to a time change. The reason for this roundabout reasoning is that the theory of the continuous-time branching process is better developed and provides machinery for proving the existence of limit frequencies and for analyzing their properties. In particular, the limiting frequencies for the new continuous process (whose existence is established next) are identical to those of the original discrete process.

It is easy to see that the (continuous) branching process just defined is *supercritical* and satisfies the $Z \log Z$ moment condition (see, e.g., [1] for background and details). It therefore follows (see, e.g., Theorem 2, p. 206, in [1]) that the limiting frequencies exist almost surely. We let X_s denote the expected limit relative frequency of state s in $C(P(t))$ when $t \to \infty$, where the nonlimit frequencies are as defined above.

In addition, the just cited Theorem 2, p. 206, in [1] asserts that the limiting distribution $X = (X_s)_{s \in S_k}$ is given by the eigenvector of W^T corresponding to the largest eigenvalue. In our case, this does indeed coincide with our informal derivation and means that X satisfies the linear system

$$(W^T X)_r = \sum_{s \in S_k} w_{sr} X_s = X_r, \qquad r \in S_k. \tag{5.3}$$

For example, for $k=2$, the transition weights a_{sr} between the six states listed in (5.1) are given in the following matrix A, where $A_{ij} = a_{s_i s_j}$ (the fourth row of A has already been discussed):

$$A = \begin{pmatrix} -1 & 1 & 0 & 0 & 0 & 0 \\ 0 & -1 & 0 & \frac{1}{2} & \frac{1}{2} & 0 \\ 0 & 0 & -1 & \frac{1}{2} & \frac{1}{2} & 0 \\ \frac{1}{3} & \frac{1}{3} & \frac{1}{3} & -\frac{2}{3} & 0 & \frac{1}{3} \\ \frac{1}{3} & \frac{1}{3} & \frac{1}{3} & 0 & -\frac{2}{3} & \frac{1}{3} \\ \frac{1}{2} & \frac{1}{2} & 0 & \frac{1}{4} & \frac{1}{4} & -\frac{1}{2} \end{pmatrix},$$

and

$$W = \begin{pmatrix} -1 & 1 & 0 & 0 & 0 & 0 \\ 0 & -2 & 0 & 1 & 1 & 0 \\ 0 & 0 & -2 & 1 & 1 & 0 \\ 1 & 1 & 1 & -2 & 0 & 1 \\ 1 & 1 & 1 & 0 & -2 & 1 \\ 2 & 2 & 0 & 1 & 1 & -2 \end{pmatrix}.$$

The system of equations for the limit distribution is $W^T X = X$. To normalize X, we extend it by the equation

$$\sum_i |s_i| X_i = X_1 + 2X_2 + 2X_3 + 3X_4 + 3X_5 + 4X_6 = 1,$$

which expresses the fact that the sum of lengths of the 2-states that compose $C(P(t))$ is equal to $|C(P(t))|$ (see above for a similar equation for the nonlimit frequencies $X_s^{(t)}$). The solution of the extended system is

$$X = \left(\frac{1}{9}, \frac{1}{9}, \frac{2}{45}, \frac{1}{15}, \frac{1}{15}, \frac{2}{45}\right).$$

In particular, the expected limit frequency of color 1 is $X_2 + X_4 + X_5 + 2X_6 = \frac{1}{3}$ (in accordance with Lemma 5.3), and the expected limit frequency of color 2 is $X_3 + X_4 + X_5 + X_6 = \frac{2}{9}$. We have thus verified Conjecture 5.1 for $k = 2$.

LEMMA 5.4. *The limit frequency of color* 2 *is* 2/9.

Analysis of 3*-states.* The same machinery can be applied to the 42 states in S_3. The solution of (5.3) for $k = 3$ is presented in Table 5.1.

By adding up the frequencies of all major 3-states (those that contain the color 3), we verify Conjecture 5.1 for $k = 3$.

LEMMA 5.5. *The limit frequency of color* 3 *is* 4/27.

Open problem. Find closed-form expressions for the state frequencies for $k = 3$ (using the data in Table 5.1) and for $k > 3$. This may lead to a simple inductive proof of Conjecture 5.1.

Further analysis of k*-states.* The system (5.3) becomes considerably harder to solve explicitly for larger values of k, so we look for simpler relationships. Put

$$N_k = \sum_{s \in S_k^+} X_s, \qquad Z_k = \sum_{s \in S_k^-} X_s.$$

Note that N_k is the expected frequency of color k. Recall that Conjecture 5.1 says that $N_k = \frac{1}{3}\left(\frac{2}{3}\right)^{k-1}$.

LEMMA 5.6. *For each* $k \geq 2$ *we have* $2N_k + Z_k = N_{k-1} + Z_{k-1}$.

Proof. Let s be a state in S_k^+, and let s_L (resp., s_R) denote the state obtained by taking the portion of s to the left (resp., right) of (the unique) k and appending $*$ at the right (resp., left). If we repeat this splitting process to each state of S_k^+ in $C(P(t))$ and add to the output all states in S_k^- (which we leave intact), we obtain the set of all states of S_{k-1} that appear in $C(P(t))$. The sum of the frequencies of these states is clearly $N_{k-1} + Z_{k-1}$. On the other hand, by our construction, this sum is $2N_k + Z_k$; thus the lemma follows. □

The following conjecture is *equivalent* to Conjecture 5.1.

CONJECTURE 5.7. $N_k = Z_k$ *for each* $k \geq 1$.

We verify the conjecture for $k = 1$, where $N_1 = Z_1 = \frac{1}{3}$; for $k = 2$, where $N_2 = Z_2 = \frac{2}{9}$; and for $k = 3$, where $N_3 = Z_3 = \frac{4}{27}$ (see Table 5.1).

Assuming that Conjecture 5.7 holds and combining it with Lemma 5.6, we obtain $3N_k = 2N_{k-1}$, for $k \geq 2$, and $N_1 = \frac{1}{3}$. Hence

$$N_k = \frac{1}{3}\left(\frac{2}{3}\right)^{k-1}.$$

The converse direction is established in a similar manner: Conjecture 5.1 and Lemma 5.6 imply

$$Z_k = Z_{k-1} + N_{k-1} - 2N_k = Z_{k-1} - \frac{1}{9}\left(\frac{2}{3}\right)^{k-2},$$

for $k \geq 2$, and $Z_1 = \frac{1}{3}$. The solution of this recurrence is $Z_k = \frac{1}{3}\left(\frac{2}{3}\right)^{k-1} = N_k$, thus showing that the two conjectures are indeed equivalent.

TABLE 5.1

The frequencies of 3-states. The second column is the numerator of the frequency under the common denominator $47628000 = 2^5 3^5 5^3 7^2$.

6. Lower bound for online CF coloring in the plane. We finally show that online CF coloring of points in the plane, with respect to disks (of arbitrary radii), may require n colors in the worst case and is therefore quite impractical. (Nevertheless, as mentioned in the introduction, the problem can be solved with many fewer colors for other kinds of ranges; see [5, 6].)

THEOREM 6.1. *There exists a sequence P of n points in the plane, so that when these points are inserted according to their order in P, any online CF coloring scheme with respect to disks has to use n different colors.*

Proof. We construct a sequence $P = (p_1, p_2, \ldots, p_n)$ with the following property:

(*) *For every $t = 2, 3, \ldots, n$, the edges of the Delaunay triangulation of the set $\{p_1, p_2, \ldots, p_t\}$ include all the edges $\{p_i, p_t\}$, $i =$*

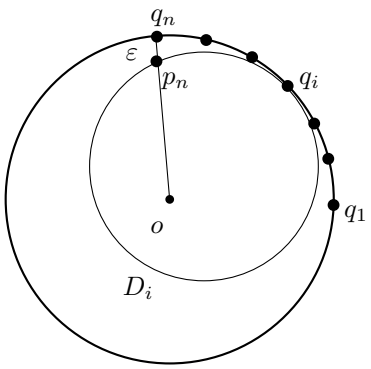

FIG. 6.1. *The construction that requires n colors for the planar case with disk ranges.*

$1, 2, \ldots, t-1$.

We prove the following stronger statement by induction on n:

For every n, every choice of distinct points $q_1, q_2, \ldots, q_n$ on the unit circle $\mathbb{S}^1$, and every $\varepsilon > 0$, there exists a sequence $(p_1, p_2, \ldots, p_n)$ with the property (*) such that $\|p_i - q_i\| \leq \varepsilon$ and p_i lies on the radius oq_i for every i.

For the induction step, given $q_1, \ldots, q_n$ and $\varepsilon < \frac{1}{2}$, let p_n be obtained by moving q_n by ε towards the center o of $\mathbb{S}^1$. We note that the Delaunay graph of $\{q_1, q_2, \ldots, q_{n-1}, p_n\}$ contains all edges $\{q_i, p_n\}$, $i = 1, 2, \ldots, n$. Indeed, there is a circle γ_i tangent to $\mathbb{S}^1$ from the inside at q_i and passing through p_n, and the closed disk D_i bounded by γ_i contains q_i, p_n, and no other q_j. See Figure 6.1. Let $\delta_i > 0$ denote the minimum distance from any q_j, $j \neq i$, to D_i.

We apply the induction hypothesis with $q_1, \ldots, q_{n-1}$ and with $\varepsilon^* < \min\{\varepsilon, \delta_1, \ldots, \delta_{n-1}\}$, obtaining a sequence $(p_1, \ldots, p_{n-1})$. We can now verify that, by construction, for every $i = 1, 2, \ldots, n-1$, the disk D_i contains p_i and p_n but no other p_j. □

7. Conclusion. The paper still leaves many open problems, some of which have been listed earlier. Here are several concluding open problems.

(a) Theorem 6.1 and the initial encouraging results of Chen, Kaplan, and Sharir [6] and of Bar-Noy, Cheilaris, and Smorodinsky [3], as reviewed in the introduction, raise many interesting open problems, such as the following: (i) Obtain *deterministic* algorithms with good performance for the cases studied in [6], viz. where the ranges are half-planes, congruent disks, and nearly equal axis-parallel rectangles. (ii) Improve further the performance of the algorithms of [6]. (iii) Find solutions with good performance for other ranges, such as arbitrary axis-parallel rectangles. (iv) Extend the results to $d \geq 3$ dimensions.

(b) It is likely that the bound in Theorem 6.1 improves significantly if the points are chosen from some random distribution, extending our conjectured bounds of section 5.2 to two (and higher?) dimensions.

(c) Can one obtain better upper bounds for online *k-CF coloring* ($k \geq 2$) of points in the plane with respect to disks? Namely, online color the points so that, at any given time t and for any disk D, there is at least one color that is assigned to at least one but at most k points of $P(t) \cap D$. For $k = 1$, this is the CF coloring problem, where we have just shown a lower bound of n, but perhaps this can be improved when $k \geq 2$. See [14] for results concerning k-CF coloring in the static case.

(d) Finally, can one obtain an efficient randomized algorithm, for the online CF coloring problem on the line, that works against an adaptive adversary (that is, an adversary that observes the actions of the randomized online algorithm and decides where to insert the next point based on these actions)?

IMPROVED COMBINATORIAL GROUP TESTING ALGORITHMS FOR REAL-WORLD PROBLEM SIZES*

DAVID EPPSTEIN†, MICHAEL T. GOODRICH†, AND DANIEL S. HIRSCHBERG†

Abstract. We study practically efficient methods for performing combinatorial group testing. We present efficient nonadaptive and two-stage combinatorial group testing algorithms, which identify the at most d items out of a given set of n items that are defective, using fewer tests for all practical set sizes. For example, our two-stage algorithm matches the information-theoretic lower bound for the number of tests in a combinatorial group testing regimen.

1. Introduction.

The problem of combinatorial group testing dates back to World War II, for the problem of determining which in a group of n blood samples contain the syphilis antigen (hence, are contaminated). Formally, in combinatorial group testing, we are given a set of n items, at most d of which are defective (or contaminated), and we are interested in identifying exactly which of the n items are defective. In addition, items can be "sampled" and these samples can be "mixed" together, and so tests for contamination can be applied to arbitrary subsets of these items. The result of a test may be positive, indicating that at least one of the items of that subset is defective, or negative, indicating that all items in that subset are good. Example applications that fit this framework include the following:

- *Screening blood samples for diseases.* In this application, items are blood samples and tests are disease detections done on mixtures taken from selected samples.
- *Screening vaccines for contamination.* In this case, items are vaccines and tests are cultures done on mixtures of samples taken from selected vaccines.
- *Clone libraries for a DNA sequence.* Here, the items are DNA subsequences (called *clones*) and tests are done on pools of clones to determine which clones contain a particular DNA sequence (called a *probe*) [10].
- *Data forensics.* In this case, items are documents and the tests are applications of one-way hash functions with known expected values applied to selected collections of documents. The differences from the expected values are then used to identify which, if any, of the documents have been altered.

The primary goal of a testing algorithm is to identify all defective items using as few tests as possible. That is, we wish to minimize the following function:

- $t(n, d)$: the number of tests needed to identify up to d defectives among n items.

This minimization may be subject to possibly additional constraints, as well. For example, we may wish to identify all the defective items in a single (*nonadaptive*)

round of testing, we may wish to do this in two (*partially-adaptive*) rounds, or we may wish to perform the tests sequentially one after the other in a *fully adaptive* fashion.

In this paper we are interested in efficient solutions to combinatorial group testing problems for realistic problem sizes, which could be applied to solve the motivating examples given above. That is, we wish for solutions that minimize $t(n, d)$ for practical values of n and d as well as asymptotically. Because of the inherent delays that are built into fully adaptive, sequential solutions, we are interested only in solutions that can be completed in one or two rounds. Moreover, we desire solutions that are efficient not only in terms of the total number of tests performed but also for the following measures:

- $A(n, t)$: the *analysis* time needed to determine which items are defective.
- $S(n, d)$: the *sampling* rate—the maximum number of tests any item may be included in.

An analysis algorithm is said to be *efficient* if $A(n, t)$ is $O(tn)$, where n is the number of items and t is the number of tests conducted. It is *time-optimal* if $A(n, t)$ is $O(t)$. Likewise, we desire efficient sampling rates for our algorithms; that is, we desire that $S(n, d)$ be $O(t(n, d)/d)$. Moreover, we are interested in this paper in solutions that improve previous results, either asymptotically or by constant factors, for realistic problem sizes. We do not define such "realistic" problem sizes formally, but we may wish to consider as unrealistic a problem that is larger than the total memory capacity (in bytes) of all CDs and DVDs in the world ($< 10^{25}$), the number of atomic particles in the earth ($< 10^{50}$), or the number of atomic particles in the universe ($< 10^{80}$).

Viewing testing regimens as matrices. A single round in a combinatorial group testing algorithm consists of a test regimen and an analysis algorithm (which, in a nonadaptive (one-stage) algorithm, must identify all the defectives). The test regimen can be modeled by a $t \times n$ Boolean matrix, M. Each of the n columns of M corresponds to one of the n items. Each of the t rows of M represents a test of items whose corresponding column has a 1-entry in that row. All tests are conducted before the results of any test are made available. The analysis algorithm uses the results of the t tests to determine which of the n items are defective.

As described by Du and Hwang [6, p. 133], the matrix M is *d-disjunct* if the Boolean sum of any d columns does not contain any other column. In the analysis of a *d-disjunct* testing algorithm, items included in a test with negative outcome can be identified as pure. Using a d-disjunct matrix enables the conclusion that if there are d or fewer items that cannot be identified as pure in this manner, then all those items must be defective and there are no other defective items. If more than d items remain, then at least $d + 1$ of them are defective. Thus, using a d-disjunct matrix enables an efficient analysis algorithm, with $A(n, t)$ being $O(tn)$.

M is *d-separable* (*$\overline{d}$-separable*) if the Boolean sums of d (up to d) columns are all distinct. The $\overline{d}$-separable property implies that each selection of up to d defective items induces a different set of tests with positive outcomes. Thus, it is possible to identify which are the up to d defective items by checking, for each possible selection, whether its induced positive test set is exactly the obtained positive outcomes. However, it might not be possible to detect that there are more than d defective items. This analysis algorithm takes time $\Theta(n^d)$ or requires a large table mapping t-subsets to d-subsets.

Generally, $\overline{d}$-separable matrices can be constructed with fewer rows than can d-disjunct matrices having the same number of columns. Although the analysis algorithm described above for d-separable matrices is not efficient, some $\overline{d}$-separable matrices that are not d-disjunct have an efficient analysis algorithm.

Previous related work. Combinatorial group testing is a rich research area with many applications to many other areas, including communications, cryptography, and networking [3]. For an excellent discussion of this topic, the reader is referred to the book by Du and Hwang [6]. For general d, Du and Hwang [6, p. 149] describe a slight modification of the analysis of a construction due to Hwang and Sós [11] that results in a $t \times n$ d-disjunct matrix, with $n \geq (2/3)3^{t/16d^2}$, and so $t \leq 16d^2(1 + \log_3 2 + (\log_3 2)\lg n)$. For two-stage testing, De Bonis, Gasieniec, and Vaccaro [5] provide a scheme that achieves a number of tests within a factor of $7.54(1 + o(1))$ of the information-theoretic lower bound of $d\log(n/d)$. For $d = 2$, Kautz and Singleton [12] construct a 2-disjunct matrix with $t = 3^{q+1}$ and $n = 3^{2^q}$, for any positive integer q. Macula and Reuter [13] describe a $\overline{2}$-separable matrix and a time-optimal analysis algorithm with $t = (q^2 + 3q)/2$ and $n = 2^q - 1$, for any positive integer q. For $d = 3$, Du and Hwang [6, p. 159] describe the construction of a $\overline{3}$-separable matrix (but do not describe the analysis algorithm) with $t = 4\binom{3q}{2} = 18q^2 - 6q$ and $n = 2^q - 1$, for any positive integer q.

Our results. In this paper, we consider problems of identifying defectives using nonadaptive or two-stage protocols with efficient analysis algorithms. We present several such algorithms that require fewer tests than do previous algorithms for practical-sized sets, although we omit the proofs of some supporting lemmas in this paper, due to space constraints. Our general case algorithm, which is based on a method we call the Chinese remainder sieve, improves the construction of Hwang and Sós [11] for all values of d for real-world problem instances as well as for $d \geq n^{1/5}$ and $n \geq e^{10}$. Our two-stage algorithm achieves a bound for $t(n, d)$ that is within a factor of $4(1+o(1))$ of the information-theoretic lower bound. This bound improves the bound achieved by De Bonis, Gasieniec, and Vaccaro [5] by almost a factor of 2. Likewise, our algorithm for $d = 2$ improves on the number of tests required for all real-world problem sizes and is time-optimal (that is, with $A(n, t) \in O(t)$). Our algorithm for $d = 3$ is the first known time-optimal testing algorithm for that d-value. Moreover, our algorithms all have efficient sampling rates.

2. The Chinese remainder sieve. In this section, we present a solution to the problem for determining which items are defective when we know that there are at most $d < n$ defectives. Using a simple number-theoretic method, which we call the *Chinese remainder sieve* method, we describe the construction of a d-disjunct matrix with $t = O(d^2 \log^2 n/(\log d + \log\log n))$. As we will show, our bound is superior to that of the method of Hwang and Sós [11] for all realistic instances of the combinatorial group testing problem.

Suppose we are given n items, numbered $0, 1, \ldots, n-1$, such that at most $d < n$ are defective. Let $\{p_1^{e_1}, p_2^{e_2}, \ldots, p_k^{e_k}\}$ be a sequence of powers of distinct primes, multiplying to at least n^d. That is, $\prod_j p_j^{e_j} \geq n^d$. We construct a $t \times n$ matrix M as the vertical concatenation of k submatrices, $M_1, M_2, \ldots, M_k$. Each submatrix M_j is a $t_j \times n$ testing matrix, where $t_j = p_j^{e_j}$; hence, $t = \sum_{j=1}^{k} p_j^{e_j}$. We form each row of M_j by associating it with a nonnegative value x less than $p_j^{e_j}$. Specifically, for each x, $0 \leq x < p_j^{e_j}$, we form a test in M_j consisting of the item indices (in the range $0, 1, \ldots, n-1$) that equal $x \pmod{p_j^{e_j}}$. For example, if $x = 2$ and $p_j^{e_j} = 3^2$, then the row for x in M_j has a 1 only in columns 2, 11, 20, and so on.

The following lemma shows that the test matrix M is d-disjunct.

LEMMA 1. *If there are at most d defective items, and all tests in M are positive for i, then i is defective.*

Proof. If all k tests for i (one for each prime power $p_j^{e_j}$) are positive, then there exists at least one defective item. With each positive test that includes i (that is, it has a 1 in column i), let $p_j^{e_j}$ be the modulus used for this test, and associate with j a defective index i_j that was included in that test (choosing i_j arbitrarily in case test j includes multiple defective indices). For any defective index i', let

$$P_{i'} = \prod_{j \text{ s.t. } i_j = i'} p_j^{e_j}.$$

That is, $P_{i'}$ is the product of all the prime powers such that i' caused a positive test that included i for that prime power. Since there are k tests that are positive for i, each $p_j^{e_j}$ appears in exactly one of these products, $P_{i'}$. So $\prod P_{i'} = \prod p_j^{e_j} \geq n^d$. Moreover, there are at most d products, $P_{i'}$. Therefore, $\max_{i'} P_{i'} \geq (n^d)^{1/d} = n$; hence, there exists at least one defective index i' for which $P_{i'} \geq n$. By construction, i' is congruent to the same values to which i is congruent, modulo each of the prime powers in $P_{i'}$. By the Chinese remainder theorem, the solution to these common congruences is unique modulo the least common multiple of these prime powers, which is $P_{i'}$ itself. Therefore, i is equal to i' modulo a number that is at least n, and so $i = i'$; hence, i is defective. □

The important role of the Chinese remainder theorem in the proof of the above lemma gives rise to our name for this construction—the Chinese remainder sieve.

Analysis. As mentioned above, the total number of tests, $t(n, d)$, constructed in the Chinese remainder sieve is $\sum_{j=1}^{k} p_j^{e_j}$, where $\prod p_j^{e_j} \geq n^d$. If we let each $e_j = 1$, we can simplify our analysis to note that $t(n, d) = \sum_{j=1}^{k} p_j$, where p_j denotes the jth prime number and k is chosen so that $\prod_{j=1}^{k} p_j \geq n^d$. To produce a closed-form upper bound for $t(n, d)$, we make use of the prime counting function, $\pi(x)$, which is the number of primes less than or equal to x. We also use the well-known *Chebyshev function*, $\theta(x) = \sum_{j=1}^{\pi(x)} \ln p_j$. In addition, we make use of the following (less well-known) prime summation function, $\sigma(x) = \sum_{j=1}^{\pi(x)} p_j$. Using these functions, we bound the number of tests in the Chinese remainder sieve method as $t(n, d) \leq \sigma(x)$, where x is chosen so that $\theta(x) \geq d \ln n$, since $\ln \prod_{p_j \leq x} p_j = \theta(x)$. For the Chebyshev function, it can be shown [1] that $\theta(x) \geq x/2$ for $x > 4$ and that $\theta(x) \sim x$ for large x. So if we let $x = \lceil 2d \ln n \rceil$, then $\theta(x) \geq d \ln n$. Thus, we can bound the number of tests in our method as $t(n, d) \leq \sigma(\lceil 2d \ln n \rceil)$. To further bound $t(n, d)$, we use the following lemma, which may be of mild independent interest.

LEMMA 2. *For integer $x \geq 2$,*

$$\sigma(x) < \frac{x^2}{2 \ln x} \left(1 + \frac{1.2762}{\ln x}\right).$$

Proof. Let $n = \pi(x)$. Dusart [7, 8] shows that, for $n \geq 799$,

$$\frac{1}{n} \sum_{j=1}^{n} p_j < \frac{1}{2} p_n;$$

that is, the average of the first n primes is half the value of the nth prime. Thus,

$$\sigma(x) = \sum_{j=1}^{\pi(x)} p_j < \frac{\pi(x)}{2} p_n \leq \frac{\pi(x)}{2} x$$

for integer $x \geq 6131$ (the 799th prime). Dusart [7, 8] also shows that

$$\pi(x) < \frac{x}{\ln x}\left(1 + \frac{1.2762}{\ln x}\right)$$

for $x \geq 2$. Therefore, for integer $x \geq 6131$,

$$\sigma(x) < \frac{x^2}{\ln x}\left(1 + \frac{1.2762}{\ln x}\right).$$

In addition, we have verified by an exhaustive computer search that this inequality also holds for all integers $2 \leq x < 6131$. This completes the proof. □

Thus, we can characterize the Chinese remainder sieve method as follows.

THEOREM 1. *Given a set of n items, at most d of which are defective, the Chinese remainder sieve method can identify the defective items using a number of tests*

$$t(n,d) < \frac{\lceil 2d \ln n \rceil^2}{2 \ln \lceil 2d \ln n \rceil}\left(1 + \frac{1.2762}{\ln \lceil 2d \ln n \rceil}\right).$$

The sample rate can be bounded by

$$S(n,d) < \frac{\lceil 2d \ln n \rceil}{2 \ln \lceil 2d \ln n \rceil}\left(1 + \frac{1.2762}{\ln \lceil 2d \ln n \rceil}\right),$$

and the analysis time, $A(n,t)$, is $O(nt(n,d))$.

By calculating the exact numbers of tests required by the Chinese remainder sieve method for particular parameter values and comparing these numbers to the claimed bounds for Hwang and Sós [11], we see that our algorithm is an improvement when

- $d = 2$ and $n \leq 10^{57}$
- $d = 3$ and $n \leq 10^{66}$
- $d = 4$ and $n \leq 10^{70}$
- $d = 5$ and $n \leq 10^{74}$
- $d = 6$ and $n \leq 10^{77}$
- $d \geq 7$ and $n \leq 10^{80}$.

Of course, these are the most likely cases for any expected actual instance of the combinatorial group testing problem. In addition, our analysis shows that our method is superior to the claimed bounds of Hwang and Sós [11] for $d \geq n^{1/5}$ and $n \geq e^{10}$. Less precisely, we can say that $t(n,d)$ is $O(d^2 \log^2 n/(\log d + \log\log n))$, that $S(n,d)$ is $O(d \log n/(\log d + \log\log n)$, and that $A(n,t)$ is $O(tn)$, which is $O(d^2 n \log^2 n/(\log d + \log\log n))$.

Heuristic improvements. Although it will not reduce the asymptotic complexity of t, we can reduce the number of tests by starting with a sequence of primes up to some upper bound x and efficiently constructing a set of good prime powers from this sequence. We can allow some powers, e_j, to be zero (meaning that we do not use this prime), while giving others values greater than one. The objective is to choose carefully the values e_j in order to minimize the number of tests while maintaining the property that $\prod p_j^{e_j} \geq n^d$. This typically yields a savings of between five and ten percent.

An example implementation in Python 2.3 is shown in the appendix in Figures A.1 and A.2. This implementation starts with the $e_j = 1$ solution to determine an initial suitable sequence of primes, p_j, to use. It then does a backtracking search to find the optimal set of e_j for these p_j, subject to the constraint that each $p_j^{e_j}$ is not greater than the largest prime in the original solution (with each $e_j = 1$). Since the number of e_j powers is sublogarithmic, and most of them must be 0 or 1, this backtracking search takes time sublinear in n for fixed d.

Comparison of the number of tests required. Table 2.1 lists the number of tests required by the Hwang–Sós (HS) algorithm, our general algorithm (using the initial set of primes p_j having exponents $e_j = 1$), and our improved backtrack algorithm, for some values of n. As can be seen, for moderate values of n our algorithms require a small fraction of the number of tests required by the HS algorithm. However, asymptotically for fixed d, the HS algorithm requires fewer tests.

3. A two-stage rake-and-winnow protocol. In this section, we present a randomized construction for two-stage group testing. This two-stage method uses a number of tests within a constant factor of the information-theoretic lower bound. It improves previous upper bounds [5] by almost a factor of 2. In addition, it has an efficient sampling rate, with $S(n, d)$ being only $O(\log(n/d))$. All the constant factors "hiding" behind the big-ohs in these bounds are small.

Preliminaries. One of the important tools we use in our analysis is the following lemma for bounding the tail of a certain distribution. It is a form of Chernoff bound [14].

LEMMA 3. *Let X be the sum of n independent indicator random variables, such that $X = \sum_{i=1}^{n} X_i$, where each $X_i = 1$ with probability p_i, for $i = 1, 2, \ldots, n$. If $E[X] = \sum_{i=1}^{n} p_i \le \hat{\mu} < 1$, then, for any integer $k > 0$,*

$$\Pr(X \ge k) \le \left(\frac{e\hat{\mu}}{k}\right)^k.$$

Proof. Let $\mu = E[X]$ be the actual expected value of X. Then, by a well-known Chernoff bound [14], for any $\delta > 0$,

$$\Pr[X \ge (1+\delta)\mu] \le \left[\frac{e^\delta}{(1+\delta)^{1+\delta}}\right]^\mu.$$

(The bound in [14] is for strict inequality, but the same bound holds for nonstrict inequality.) We are interested in the case when $(1+\delta)\mu = k$, that is, when $1+\delta = k/\mu$. Observing that $\delta < 1 + \delta$, we can therefore deduce that

$$\Pr(X \ge k) \le \left[\frac{e^{k/\mu}}{(k/\mu)^{k/\mu}}\right]^\mu = \frac{e^k}{(k/\mu)^k} = \left(\frac{e\mu}{k}\right)^k.$$

Finally, noting that $\mu \le \hat{\mu}$,

$$\Pr(X \ge k) \le \left(\frac{e\hat{\mu}}{k}\right)^k. \qquad \square$$

In addition to this lemma, we also use the following.

LEMMA 4. *If $d < n$, then*

$$\binom{n}{d} < \left(\frac{en}{d}\right)^d.$$

Proof.

$$\begin{aligned}\binom{n}{d} &= \frac{n!}{(n-d)!\,d!} \\ &= \frac{n(n-1)(n-2)\cdots(n-d+1)}{d!} \\ &< \frac{n^d}{d!}.\end{aligned}$$

By Stirling's approximation [4],

$$d! = \sqrt{2\pi n}\left(\frac{d}{e}\right)^d\left(1+\theta\left(\frac{1}{n}\right)\right).$$

Thus, $d! > (d/e)^d$. Therefore,

$$\frac{n^d}{d!} < \frac{n^d}{(d/e)^d} = \left(\frac{en}{d}\right)^d. \qquad \square$$

Identifying defective items in two stages. As with our Chinese remainder sieve method, our randomized combinatorial group testing construction is based on the use of a Boolean matrix M where columns correspond to items and rows correspond to tests, so that if $M[i,j] = 1$, then item j is included in test j. Let C denote the set of columns of M. Given a set D of d columns in M, and a specific column $j \in C - D$, we say that j is *distinguishable* from D if there is a row i of M such that $M[i,j] = 1$ but i contains a 0 in each of the columns in D. Such a property is useful in the context of group testing, for the set D could correspond to the defective items, and if a column j is distinguishable from the set D, then there would be a test in our regimen that would determine that the item corresponding to column j is not defective.

An alternate and equivalent definition [6, p. 165] for a matrix M to be *d-disjunct* is if, for any d-sized subset D of C, each column in $C - D$ is distinguishable from D. Such a matrix determines a powerful group testing regimen, but, unfortunately, building such a matrix requires M to have $\Omega(d^2 \log n / \log d)$ rows, by a result of Ruszinkó [15] (see also [6, p. 139]). The best known constructions have $\Theta(d^2 \log(n/d))$ rows [6], which is a factor of d greater than information-theoretic lower bound, which is $\Omega(d \log(n/d))$.

Instead of trying to use a matrix M to determine all the defectives immediately, we will settle for a weaker property for M, which nevertheless is still powerful enough to define a good group testing regimen. We say that M is *(d,k)-resolvable* if, for any d-sized subset D of C, there are fewer than k columns in $C - D$ that are not distinguishable from D. Such a matrix defines a powerful group testing regimen, for defining tests according to the rows of a d-resolvable matrix allows us to restrict the set of defective items to a group D' of smaller than $d + k$ size. Given this set, we can then perform an additional round of individual tests on all the items in D'. This two-stage approach is sometimes called the trivial two-stage algorithm; we refer to this two-stage algorithm as the *rake-and-winnow* approach.

Thus, a (d, k)-resolvable matrix determines a powerful group testing regimen. Of course, a matrix is d-disjunct iff it is $(d, 1)$-resolvable. Unfortunately, as mentioned above, constructing a $(d, 1)$-resolvable matrix requires that the number of rows (which correspond to tests) be significantly greater than the information-theoretical lower bound. Nevertheless, if we are willing to use a (d, k)-resolvable matrix, for a reasonably small value of k, we can come within a constant factor of the information-theoretical lower bound.

Our construction of a (d, k)-resolvable matrix is based on a simple, randomized *sample-injection* strategy, which itself is based on the approach popularized by the Bloom filter [2]. This novel approach also allows us to provide a strong worst-case bound for the sample rate, $S(n, d)$, of our method. Given a parameter t, which is a multiple of d that will be set in the analysis, we construct a $2t \times n$ matrix M in a columnwise fashion. For each column j of M, we choose t/d rows at random and set the values of these entries to 1. The other entries in column j are set to 0. In other words, we "inject" the sample j into each of the t/d random tests we pick for the corresponding column (since rows of M correspond to tests and the columns correspond to samples). Note, then, that for any set of d defective samples, there are at most t tests that will have positive outcomes and, therefore, at least t tests that will have negative outcomes. The columns that correspond to samples that are distinguishable from the defectives ones can be immediately identified. The remaining issue, then, is to determine the value of t needed so that, for a given value of k, M is a (d, k)-resolvable matrix with high probability.

Let D be a fixed set of d defectives samples. For each (column) item i in $C - D$, let X_i denote the indicator random variable that is 1 if i is falsely identified as a positive sample by M (that is, i is not included in the set of (negative) items distinguished from those in D), and is 0 otherwise. Observe that the X_i's are independent, since X_i depends only on whether the choice of rows we picked for column i collide with the at most t rows of M that we picked for the columns corresponding to items in D. Furthermore, this observation implies that any X_i is 1 (a false positive) with probability at most $2^{-t/d}$. Therefore, the expected value of X, $E[X]$, is at most $\hat{\mu} = n/2^{t/d}$. This fact allows us to apply Lemma 3 to bound the probability that M does not satisfy the (d, k)-resolvable property for this particular choice, D, of d defective samples. In particular,

$$\Pr(X \geq k) \leq \left(\frac{e\hat{\mu}}{k}\right)^k = \frac{\left(\frac{en}{k}\right)^k}{2^{(t/d)k}}.$$

Note that this bound immediately implies that if $k = 1$ and $t \geq d(e+1)\log n$, then M will be completely $(d, 1)$-resolvable with high probability $(1 - 1/n)$ for any particular set of defective items, D.

We are interested, however, in a bound implying that for *any* subset D of d defectives (of which there are $\binom{n}{d} < (en/d)^d$, by Lemma 4), our matrix M is (d, k)-resolvable with high probability, that is, probability at least $1 - 1/n$. That is, we are interested in the value of t such that the above probability bound is $(en/d)^{-d}/n$. From the above probability bound, therefore, we are interested in a value of t such that

$$\frac{2^{(t/d)k}}{\left(\frac{en}{k}\right)^k} \geq \left(\frac{en}{d}\right)^d n.$$

That is, we would like

$$2^{(t/d)k} \geq \left(\frac{en}{d}\right)^d \left(\frac{en}{k}\right)^k n.$$

This bound will hold whenever

$$t \geq (d^2/k)\log(en/d) + d\log(en/k) + (d/k)\log n.$$

Thus, we have the following.

THEOREM 2. *If* $t \geq (d^2/k)\log(en/d) + d\log(en/k) + (d/k)\log n$, *then a* $2t \times n$ *random matrix* M *constructed by sample-injection is* (d,k)*-resolvable with high probability, that is, with probability at least* $1 - 1/n$.

Taking $k = 1$, therefore, we have an alternative method for constructing a d-disjunct matrix M with high probability.

COROLLARY 1. *If* $t \geq d^2\log(en/d) + d\log en + d\log n$, *then a* $2t \times n$ *random matrix* M *constructed by sample-injection is* d*-disjunct with high probability.*

That is, we can construct a one-round group test based on sample-injection that uses $O(d^2\log(n/d))$ tests.

As mentioned above, a productive way of using the sample-injection construction is to build a (d,k)-resolvable matrix M for a reasonably small value of k. We can then use this matrix as the first round in a two-round rake-and-winnow testing strategy, where the second round simply involves our individual testing of the at most $d + k$ samples left as potential positive samples from the first round.

COROLLARY 2. *If* $t \geq 2d\log(en/d) + \log n$, *then the* $2t \times n$ *random matrix* M *constructed by sample-injection is* (d,d)*-resolvable with high probability.*

This corollary implies that we can construct a rake-and-winnow algorithm where the first stage involves performing $O(d\log(n/d))$ tests, which is within a (small) constant factor of the information theoretic lower bound, and the second round involves individually testing at most $2d$ samples.

4. Improved bounds for small *d* values. In this section, we consider efficient algorithms for the special cases when $d = 2$ and $d = 3$. We present time-optimal algorithms for these cases, that is, with $A(n,t)$ being $O(t)$. Our algorithm for $d = 3$ is the first known such algorithm.

Finding up to two defectives. Consider the problem of determining which items are defective when we know that there are at most two defectives. We describe a $\overline{2}$-separable matrix and a time-optimal analysis algorithm with $t = (q^2 + 5q)/2$ and $n = 3^q$, for any positive integer q.

Let the number of items be $n = 3^q$, and let the item indices be expressed in radix 3. Index $X = X_{q-1}\cdots X_0$, where each digit $X_p \in \{0,1,2\}$.

Hereafter, X ranges over the item index numbers $\{0,\ldots,n-1\}$, p ranges over the radix positions $\{0,\ldots,q-1\}$, and v ranges over the digit values $\{0,1,2\}$.

For our construction, matrix M is partitioned into submatrices B and C. Matrix B is the submatrix of M consisting of its first $3q$ rows. Row $\langle p,v\rangle$ of B is associated with radix position p and value v. $B[\langle p,v\rangle, X] = 1$ iff $X_p = v$.

Matrix C is the submatrix of M consisting of its last $\binom{q}{2}$ rows. Row $\langle p,p'\rangle$ of C is associated with distinct radix positions p and p', where $p < p'$. $C[\langle p,p'\rangle, X] = 1$ iff $X_p = X_{p'}$.

Let $test_B(p,v)$ be the result (1 for positive, 0 for negative) of the test of items having a 1-entry in row $\langle p,v\rangle$ in B. Similarly, let $test_C(p,p')$ be the result of testing row $\langle p,p'\rangle$ in C. Let $test1(p)$ be the number of different values held by defectives in radix position p. $test1(p)$ can be computed by $test_B(p,0) + test_B(p,1) + test_B(p,2)$.

The analysis algorithm is shown in the appendix in Figure A.3.

It is easy to determine how many defective items are present. There are no defective items when $test1(0) = 0$. There is only one defective item when $test1(p) = 1$

for all p, since if there were two defective items, then there must be at least one position p in which their indices differ and $test1(p)$ would then have value 2. The one defective item has index $D = D_{q-1} \cdots D_0$, where digit D_p is the value v for which $test_B(p, v) = 1$.

Otherwise, there must be two defective items, $D = D_{q-1} \cdots D_0$ and $E = E_{q-1} \cdots E_0$. We iteratively determine the values of the digits of indices D and E.

For radix positions in which defective items exist for only one value of that digit, both D and E must have that value for that digit. For each other radix position, two distinct values for that digit occur in the defective items.

The first radix position in which D and E differ is recorded in the variable p^* and the value of that digit in D (respectively, E) is recorded in v_1^* (respectively, v_2^*).

For any subsequent position p in which D and E differ, the digit values of the defectives in that position are v_a and v_b, which are two distinct values from $\{0, 1, 2\}$, as are v_1^* and v_2^*, and therefore there must be at least one value in common between $\{v_a, v_b\}$ and $\{v_1^*, v_2^*\}$.

Let a common value be v_a and, without loss of generality, let $v_a = v_1^*$.

LEMMA 5. *The digit assignment for position p is $D_p = v_a$ and $E_p = v_b$ iff $test_C(p^*, p) = 1$.*

Proof. We consider the two possibilities of which defective item has v_a as its digit in position p.

Case 1. $D_p = v_a$.

We see that $D_p = v_a = v_1^*$. Accordingly, a defective (D) would be among the items tested in $test_C(p^*, p)$. Therefore, $test_C(p^*, p) = 1$.

Case 2. $E_p = v_a$.

We see that $D_p \neq v_1^*$, because $D_p \neq E_p = v_a = v_1^*$, and also that $E_p \neq v_2^*$, because $E_p = v_a = v_1^* \neq v_2^*$. Accordingly, neither of the defective items would be among the items tested in $test_C(p^*, p)$. Therefore, $test_C(p^*, p) = 0$. □

We have determined the values of defectives D and E for all positions—those where they are the same and those where they differ. For each position, only a constant amount of work is required to determine the assignment of digit values. Therefore, we have proven the following theorem.

THEOREM 3. *A $\overline{2}$-separable matrix that has a time-optimal analysis algorithm can be constructed with $t = (q^2 + 5q)/2$ and $n = 3^q$, for any positive integer q.*

Comparison of the number of tests required for the $d = 2$ method. A $\overline{2}$-separable or a 2-disjunct $t \times n$ matrix enables determination of up to two defective items from among n *or fewer* items using t tests. An algorithm is more competitive at or just below one of its breakpoints, values of n for which increasing n by one significantly increases t. The Macula–Reuter (MR) algorithm has breakpoints at one under all powers of 2, our (d=2) algorithm at all powers of 3, and the Kautz–Singleton (KS) algorithm at only certain powers of 3. Our general-d algorithms do not have significant breakpoints.

Table 4.1 lists the number of tests required by these algorithms for some small values of n. For all $n \leq 3^{63}$, our $d = 2$ algorithm uses the smallest number of tests. For higher values of $n \leq 3^{130}$, the KS and our $d = 2$ and general (Chinese remainder sieve) algorithms alternate being dominant. The alternations are illustrated in Table 4.2. For all $n \geq 3^{131}$, the HS algorithm uses the fewest tests.

Finding up to three defectives. Consider the problem of determining which items are defective when we know that there are at most three defectives. We describe a $\overline{3}$-separable matrix and a time-optimal analysis algorithm with $t = 2q^2 - 2q$ and $n = 2^q$, for any positive integer q.

Let the number of items be $n = 2^q$, and let the item indices be expressed in radix 2. Index $X = X_{q-1} \cdots X_0$, where each digit $X_p \in \{0, 1\}$.

Hereafter, X ranges over the item index numbers $\{0, \ldots, n-1\}$, p ranges over the radix positions $\{0, \ldots, q-1\}$, and v ranges over the digit values $\{0, 1\}$.

Matrix M has $2q^2 - 2q$ rows. Row $\langle p, p', v, v' \rangle$ of M is associated with distinct radix positions p and p', where $p < p'$, and with values v and v', each of which is in {0,1}. $M[\langle p, p', v, v' \rangle, X] = 1$ iff $X_p = v$ and $X_{p'} = v'$.

Let $test_M(p, p', v, v')$ be the result (1 for positive, 0 for negative) of testing items having a 1-entry in row $\langle p, p', v, v' \rangle$ in M. For $p' > p$, define $test_M(p', p, v', v) = test_M(p, p', v, v')$.

The following three functions can be computed in terms of $test_M$.

- $test_B(p, v)$ has value 1 (0) if there are (not) any defectives having value v in radix position p, i.e., $test_B(0, v) = 0$ if $test_M(0, 1, v, 0) + test_M(0, 1, v, 1) = 0$, and 1 otherwise. For $p > 0$, $test_B(p, v) = 0$ if

$$test_M(p, 0, v, 0) + test_M(p, 0, v, 1) = 0,$$

  and 1 otherwise.
- $test1(p)$ is the number of different binary values held by defectives in radix position p. Thus, $test1(p) = test_B(p, 0) + test_B(p, 1)$.
- $test2(p, p')$ is the number of different ordered pairs of binary values held by defectives in the designated ordered pair of radix positions. Therefore,

$$test2(p, p') = test_M(p, p', 0, 0) + test_M(p, p', 0, 1) + test_M(p, p', 1, 0) + test_M(p, p', 1, 1).$$

The analysis algorithm is shown in the appendix in Figure A.4.

We determine the number of defective items and the value of their digits. There are no defective items when $test1(0) = 0$. Moreover, at each radix position p in which $test1(p) = 1$, all defective items have the same value of that digit. If all defectives agree on all digit values, then there is only one defective. Otherwise there are at least two defectives, and we need to consider how to assign digit values for only the set of

positions P in which there is at least one defective having each of the two possible binary digit values.

LEMMA 6. *There are only two defectives iff, for* $p, p' \in P, test2(p, p') = 2$.

Proof. A defective item can contribute at most one new combination of values in positions p, p', and so $test2(p, p') \leq$ the number of defectives. Accordingly, if there are fewer than two defectives, then $test2(p, p') < 2$.

If there are exactly two defectives, then $test2(p, p') \leq 2$. Since $p \in P$, both binary values appear among defectives, and so $test2(p, p') \geq 2$, and therefore $test2(p, p') = 2$.

Consider the case in which there are three defectives. In any position p_1 in which both binary values appear at that digit among the set of defectives, one of the defectives (say, D) has one binary value (say, v_1) and the other two defectives (E, F) have the other binary value $(\overline{v}_1)$. Since E and F are distinct, they must differ in value at some other position p_2. Therefore, there will be three different ordered pairs of binary values held by defectives in positions p_1 and p_2, and so $test2(p_1, p_2) = 3$. □

Accordingly, if there is no pair of positions for which $test2$ has value 3, we can conclude that there are only two defectives. Otherwise, there are positions p_1, p_2 for which $test2(p_1, p_2) = 3$, and one of the four combinations of two binary values will not appear. Let that missing combination be v_1, v_2. Thus, while position p_1 uniquely identifies one defective, say D, as the only defective having value v_1 at that position, position p_2 uniquely identifies one of the other defectives, say E, as having value v_2.

LEMMA 7. *If the position* p^* *uniquely identifies the defective* X *to have value* v^*, *then the value of the defective* X *at any other position* p *will be that value* v *such that* $test_M(p^*, p, v^*, v) = 1$.

Proof. If position p^* uniquely identifies defective X as having value v^*, then $X_{p^*} = v^*$ and, for any other defective Y, $Y_{p^*} \neq v^*$.

Let $v = X_p$ for any $p \neq p^*$. Then $test_M(p^*, p, v^*, v) = 1$, since X is a defective that has the required values at the required positions to be included in this test.

Also, $test_M(p^*, p, v^*, \overline{v}) = 0$, because none of the defectives is included in this test. Defective X is not included, because $X_p \neq \overline{v}$. Any other defective, $Y \neq X$, is not included, because $Y_{p^*} \neq v^*$. □

Since we have positions that uniquely identify D and E, we can determine the values of all their other digits, and the only remaining problem is to determine the values of the digits of defective F.

Since position p_1 uniquely identifies D, we know that $F_{p_1} = \overline{v}_1$. For any other position p, after determining that $E_p = v$, we note that if $test_M(p_1, p, \overline{v}_1, \overline{v}) = 1$, then there must be at least one defective, X, for which $X_{p_1} = \overline{v}_1$ and $X_p = \overline{v}$. Defective D is ruled out, since $D_{p_1} = v_1$, and defective E is ruled out, since $E_p = v$. Therefore, it must be that $F_p = \overline{v}$. Otherwise, if that $test_M = 0$, then $F_p = v$, since $F_p = \overline{v}$ would have caused $test_M = 1$.

We have determined the values of defectives D, E, and F for all positions. For each position, only a constant amount of work is required to determine the assignment of digit values. Therefore, we have proven the following theorem.

THEOREM 4. *A* $\overline{3}$*-separable matrix that has a time-optimal analysis algorithm can be constructed with* $t = 2q^2 - 2q$ *and* $n = 2^q$, *for any positive integer* q.

Comparison of the number of tests required for the $d = 3$ *method.* The general d algorithm due to Hwang and Sós [11] requires fewer tests than does the Du–Hwang (DH) algorithm for $d = 3$ suggested in [6]. For $n < 10^{10}$, our $(d = 3)$ algorithm requires even fewer tests and our general (Chinese remainder sieve) algorithm the fewest. However, asymptotically the algorithm of Hwang and Sós uses the fewest

THE HARDNESS OF METRIC LABELING*

JULIA CHUZHOY† AND JOSEPH (SEFFI) NAOR‡

Abstract. The metric labeling problem is an elegant and powerful mathematical model capturing a wide range of classification problems. The input to the problem consists of a set L of labels and a weighted graph $G = (V, E)$. Additionally, a metric distance function on the labels is defined, and for each label and each vertex, an assignment cost is given. The goal is to find a minimum-cost assignment of the vertices to the labels. The cost of the solution consists of two parts: the assignment costs of the vertices and the separation costs of the edges (where each edge pays its weight times the distance between the two labels to which its endpoints are assigned). Due to the simple structure and the variety of applications, the problem and its special cases (with various distance functions on the labels) have recently received much attention. Metric labeling is known to have a logarithmic approximation, and it has been an open question for some time whether a constant approximation exists. We refute this possibility and prove that no constant factor approximation algorithm exists for metric labeling unless P=NP. Moreover, we prove that the problem is $\Omega((\log |V|)^{1/2-\delta})$-hard to approximate for any constant $\delta : 0 < \delta < 1/2$, unless NP has quasi-polynomial time algorithms.

1. Introduction.

The metric labeling problem, first formulated by Kleinberg and Tardos [18], captures a broad range of classification problems that arise in computer vision and related fields. In such classification problems, the goal is to assign labels to some given set of objects in a way consistent with observed data or some other form of prior knowledge. Formally, the input to the metric labeling problem consists of an n-vertex undirected graph $G(V, E)$, with weights w on edges, and a set L of labels with metric distance function $d : L \times L \to R$ associated with them. Additionally, for each vertex $v \in V$ and label $\ell \in L$, an assignment cost $c(v, \ell)$ is specified. The problem output is an assignment $f : V \to L$ of the vertices to the labels. Intuitively, the vertices are the objects we would like to classify, and the assignment function f provides such a classification. The prior knowledge is modeled by the means of the vertex assignment costs $c(v, \ell)$, which can be used to express an estimate of how likely it is that ℓ is the correct label for vertex v, and by the edge weights, which define pairwise relations between the objects. The weights of the edges express a prior estimate on how likely it is that the endpoints of the given edge should be assigned to close or identical labels.

Given a solution $f : V \to L$ to the metric labeling problem, its cost $Q(f)$ consists of two components.

Vertex labeling cost: For each $v \in V$, this cost is $c(v, f(v))$.

Edge separation cost: For each edge $e = (u, v)$ the cost is $w(u, v) \cdot d(f(u), f(v))$.

Thus,

$$Q(f) = \sum_{u \in V} c(u, f(u)) + \sum_{(u,v) \in E} w(u,v) \cdot d(f(u), f(v)),$$

and the goal is to find a labeling $f : V \to L$ minimizing $Q(f)$.

Metric labeling has rich connections to some well-known problems in combinatorial optimization. A special case of metric labeling is the 0-*extension* problem, studied by Karzanov [16, 17]. In this problem, there are no assignment costs. However, the graph contains a set $\{t_1, \ldots, t_k\}$ of terminals, where the label of terminal t_i is fixed in advance to i, while the nonterminals are free to be assigned to any of the labels. As in the metric labeling problem, a metric is defined on the set of labels. The cost of an assignment consists only of the *edge separation cost*. The 0-extension problem generalizes the well-studied *multiway cut* problem [9, 6, 14], which is defined exactly like 0-extension except that the metric on the label set is the uniform metric.

The first approximation algorithm for the metric labeling problem was shown by Kleinberg and Tardos [18]. This algorithm uses the probabilistic tree embedding technique [4, 5], and its approximation factor is $O(\log k \log\log k)$, where k denotes the number of labels in L. This bound was recently improved to $O(\log k)$ [11] and it is currently the best known approximation factor for the metric labeling problem. Some special cases of metric labeling, where the metric on the terminals belongs to some restricted class of metrics, were shown to have better approximation factors [18, 13, 8].

Chekuri et al. [8] proposed a natural linear programming formulation for the general metric labeling problem. A solution to this linear program is an embedding of the graph in a k-dimensional simplex, where the distance between points in the simplex is defined by a special metric, the *earth mover's distance metric* (EMD), and not by the (standard) ℓ_1 metric. It was also shown in [8] that the integrality gap of this formulation is at most the distortion of a probabilistic tree embedding of the given metric d, i.e., $O(\log k)$ [11]. Archer et al. [1] presented an approximation algorithm which is based on rounding the EMD solution to the linear program of [8] and achieves an $O(\log |V|)$ approximation factor.

Călinescu, Karloff, and Rabani [7] considered approximation algorithms for the 0-extension problem via a metric relaxation, originally studied by Karzanov [16], and obtained an $O(\log k)$-approximation algorithm for general metrics. This result was improved to $O(\log k / \log\log k)$ by Fakcharoenphol et al. [10].

Our results. A question that has intrigued many researchers since the appearance of [18] is whether there exists a constant factor approximation algorithm for the metric labeling problem. We answer this question in the negative and prove an $\Omega((\log n)^{1/2-\delta})$-hardness of approximation for any constant $\delta : 0 < \delta < 1/2$, assuming NP $\not\subseteq$ DTIME$(n^{\mathrm{poly}(\log n)})$. We also prove that there is no constant factor approximation algorithm for metric labeling unless P = NP. For the sake of simplicity, we focus on a problem called *restricted metric labeling*, which was shown by Chekuri et al. [8] to be equivalent to metric labeling. In the restricted metric labeling problem, the assignment costs of the vertices are restricted to be either 0 or ∞, or equivalently each vertex $v \in V$ has a list of labels, $L(v)$, to which it is allowed to be assigned. The solution cost then consists only of the edge separation cost.

Following our work, Karloff et al. [15] showed that the 0-extension problem is $\Omega((\log n)^{1/4-\epsilon})$-hard to approximate for any constant ϵ, unless NP has quasi-polynomial time algorithms. Their proof builds on ideas presented in this work.

Organization. We start in section 2 with some preliminaries, and we present in section 3 a simple $(3-\delta)$-hardness proof (for any constant $0 < \delta < 1$) for the restricted metric labeling problem. This proof provides the intuition and motivation for the new ideas needed to obtain the stronger hardness bounds shown in section 4.

2. Preliminaries. We prove our hardness results for the restricted metric labeling problem, defined as follows. The input consists of an undirected graph $G(V, E)$ with weights w on edges, and a set L of labels with distance function $d : L \times L \to R$. Additionally, for each vertex $v \in V$, there is a subset $L(v) \subseteq L$ of labels to which v can be assigned. The goal is to find an assignment $f : V \to L$ such that for each $v \in V$, $f(v) \in L(v)$. The solution cost is the sum, over all edges $e = (u, v)$, of the edge separation cost $w(e)d(f(u), f(v))$. We notice that our hardness results work even for the uniform weight function, i.e., for each edge $e \in E$, $w(e) = 1$.

We perform our reduction from the gap version of Max 3SAT(5). The input to the problem is a conjunctive normal form (CNF) formula ϕ with n variables and $\frac{5n}{3}$ clauses. Each clause consists of three literals, and each variable participates in five clauses, appearing in each clause at most once.

Let $\epsilon : 0 < \epsilon < 1$ be a constant, and let ϕ be an instance of Max 3SAT(5). Then ϕ is called a *Yes-instance* if there is an assignment that satisfies all the clauses, and it is called a *No-instance* (with respect to ϵ) if any assignment satisfies at most a fraction $(1 - \epsilon)$ of the clauses. Following is one of the several equivalent statements of the probabilistically checkable proofs (PCP) theorem [2, 3].

THEOREM 2.1. *There is a constant ϵ, $0 < \epsilon < 1$, such that it is NP-hard to distinguish between Yes-instances and No-instances of the Max 3SAT(5) problem.*

In our reduction, we start from a 3SAT(5) formula ϕ and produce an instance of the restricted metric labeling problem. Our first step is describing and analyzing a (standard) two-prover protocol for the 3SAT(5) problem. This protocol will help us translate 3SAT(5) instances into instances of restricted metric labeling, and analyze the reduction.

The one-round two-prover protocol for 3SAT(5) is defined as follows. Given a 3SAT(5) formula ϕ on n variables, we have the following:

- The verifier randomly chooses a clause C from the formula ϕ and one of the variables x belonging to C. Variable x is called the *distinguished variable*.
- Prover 1 receives clause C and is expected to return an assignment to all the variables appearing in the clause. Prover 2 receives variable x and is expected to return an assignment to x.
- After receiving the answers of the provers, the verifier checks that the answer of prover 1 defines a satisfying assignment for clause C and that the assignments of prover 1 and prover 2 to variable x are identical.

The following well-known theorem easily follows from Theorem 2.1.

THEOREM 2.2. *If ϕ is a Yes-instance, then there is a strategy of the provers such that the verifier always accepts. If ϕ is a No-instance, then for any strategy of the provers, the acceptance probability is at most $(1 - \frac{\epsilon}{3})$.*

3. A simple $(3 - \delta)$-hardness. In this section we present a simple $(3 - \delta)$-hardness for the restricted metric labeling problem (for any constant $0 < \delta < 1$), and also provide some intuition as to the new ideas needed to improve this bound.

We start by amplifying the soundness of the two-prover protocol presented above by means of parallel repetitions, a usual practice in PCP reductions. The number of repetitions is a sufficiently large constant l. The new protocol proceeds as follows:

- The verifier chooses, randomly and independently, l clauses $C_1, \ldots, C_l$ from the input formula ϕ. For each i, $1 \leq i \leq l$, the verifier chooses, randomly and independently, one variable x_i belonging to C_i.
- Prover 1 receives clauses $C_1, \ldots, C_l$ and is expected to return an assignment to all the variables appearing in the clauses, such that all clauses are satisfied. Prover 2 receives variables $x_1, \ldots, x_l$ and is expected to return an assignment to these variables.
- After receiving the answers of the provers, the verifier checks that the answer of prover 1 defines satisfying assignments for clauses $C_1, \ldots, C_l$ and that the assignments of prover 1 and prover 2 to variables $x_1, \ldots, x_l$ are identical.

The following theorem follows from the well-known Raz parallel repetition theorem [19], which bounds the error probability of the above protocol.

THEOREM 3.1. *There is a constant $\alpha > 0$ such that if ϕ is a Yes-instance, there is a strategy of the provers for which the verifier always accepts, and if ϕ is a No-instance, then for any strategy of the provers, the acceptance probability is at most $2^{-\alpha l}$.*

Let Q_1 denote the set of all the possible queries to prover 1 (i.e., each query $q \in Q_1$ is an l-tuple of clauses). Given a query $q_1 \in Q_1$, let $A(q_1)$ denote the set of all the assignments to the variables that appear in the clauses of q_1 that satisfy these clauses. Similarly, Q_2 denotes the set of all the possible queries to prover 2 (each query is an l-tuple of variables), and given $q_2 \in Q_2$, $A(q_2)$ is the set of all the possible answers of prover 2 to query q_2.

We assume that, at the beginning of the protocol, the verifier chooses a random string r, which determines the choice of the clauses and the variables sent to the provers. Let R denote the set of all the possible random strings. Given a random string $r \in R$, let $q_1(r), q_2(r)$ be the queries sent to prover 1 and prover 2, respectively, when the verifier chooses r.

The set of labels is defined as follows. For every possible query of each one of the two provers, and for every possible answer to this query, there is a label, i.e.,

$$L = \{\ell(q, A) \mid q \in Q_1 \cup Q_2, A \in A(q)\}.$$

In order to define the metric distance function on the labels, we construct a label graph G_L. The vertices of this graph are the labels, and the metric distance between the labels is defined to be the length of the shortest path in this graph. We now define the edges of graph G_L. Consider some random string r of the verifier, and let $q_1 = q_1(r)$, $q_2 = q_2(r)$. Let $A_1 \in A(q_1), A_2 \in A(q_2)$ be any pair of consistent answers to these queries. Then there is an edge of length 1 between $\ell(q_1, A_1)$ and $\ell(q_2, A_2)$ in G_L. Note that since each edge connects a label belonging to prover 1 and a label belonging to prover 2, the graph is bipartite. Therefore, for any random string r, if $q_1 = q_1(r)$ and $q_2 = q_2(r)$, and if $A_1 \in A(q_1)$, $A_2 \in A(q_2)$ are inconsistent answers to these queries, then the distance between labels $\ell(q_1, A_1)$ and $\ell(q_2, A_2)$ in graph G_L is at least 3.

We now proceed to define the input graph. For every query $q \in Q_1 \cup Q_2$, there is a vertex $v(q)$. This vertex can be assigned only to those labels that correspond to query q, i.e.,

$$V = \{v(q) \mid q \in Q_1 \cup Q_2\},$$
$$L(v(q)) = \{\ell(q, A) \mid A \in A(q)\}.$$

The edge set is defined as follows. For each random string r of the verifier, there is an edge connecting $v(q_1(r))$ and $v(q_2(r))$. All edges have unit weight.

Yes-instance. If ϕ is a Yes-instance, then there is a strategy of the provers such that their answers are always accepted by the verifier. This strategy defines the assignments of the vertices to the labels, namely, vertex $v(q)$ for $q \in Q_1 \cup Q_2$ is assigned to label $\ell(q, A)$, where $A \in A(q)$ is the answer of the corresponding prover to query q under the above strategy. Consider some random string r of the verifier and the corresponding queries $q_1 = q_1(r), q_2 = q_2(r)$. Let $A_1 \in A(q_1)$, $A_2 \in A(q_2)$ be the answers of the provers according to the above strategy. Note that vertices $v(q_1)$, $v(q_2)$ are assigned to labels $\ell(q_1, A_1)$, $\ell(q_2, A_2)$ and that the answers A_1 and A_2 of the provers are consistent. Therefore, there is an edge in the label graph between the labels $\ell(q_1, A_1)$ and $\ell(q_2, A_2)$, and thus the distance between the two labels (and the cost incurred by the edge connecting $v(q_1)$ and $v(q_2)$) is 1. The total cost of the solution is therefore $|R|$, where R is the set of all the random strings of the verifier.

No-instance. Consider any solution to the problem. Note that the assignments of the vertices to the labels define a strategy of the provers. (The assignment of vertex $v(q)$, $q \in Q_1 \cup Q_2$, to label $\ell(q, A)$, $A \in A(q)$, implies that the answer of the corresponding prover to query q is A.) Let $R' \subseteq R$ be the set of random strings of the verifier for which the answers of the two provers are inconsistent. From Theorem 3.1, $|R'| \geq (1 - 2^{-\alpha l})|R|$. Consider a random string $r \in R'$ and let $q_1 = q_1(r), q_2 = q_2(r)$. Let $\ell(q_1, A_1)$, $\ell(q_2, A_2)$ be the labels to which the vertices $v(q_1)$, $v(q_2)$ are assigned. As the answers A_1, A_2 of the provers are inconsistent, the distance between the two labels (and hence the separation cost paid by the edge between $v(q_1)$ and $v(q_2)$) is at least 3. Therefore, the total cost of the solution is at least $3(1 - 2^{-\alpha l})|R|) = 3(1 - \delta)|R|$, where δ is an arbitrarily small constant.

It follows that the gap between the costs of Yes- and No-instances is $3(1-\delta)$, and since the size of the construction is polynomial in n, we have that restricted metric labeling is $3(1 - \delta)$-hard to approximate for any constant δ, unless P=NP.

It is not hard to see that the analysis is tight. Consider some random string r and the corresponding queries $q_1 = q_1(r)$, $q_2 = q_2(r)$. Let A_1, A_2 be a pair of inconsistent answers to queries q_1, q_2. We show that there is a path of length 3 in the graph G_L between the pair of labels $\ell(q_1, A_1)$, $\ell(q_2, A_2)$. We denote $q_1 = (C_{i_1}, \ldots, C_{i_l})$ and $q_2 = (x_{i_1}, \ldots, x_{i_l})$, and recall that for each $j : 1 \leq j \leq l$, x_{i_j} is one of the variables of clause C_{i_j}. Let x'_{i_j} and x''_{i_j} denote the other two variables. The path of length 3 connecting the two labels starts at label $\ell(q_1, A_1)$. The second label on this path is $\ell(q'_2, A'_2)$, where $q'_2 = (x'_{i_1}, \ldots, x'_{i_l})$ and A'_2 contains assignments to $(x'_{i_1}, \ldots, x'_{i_l})$ identical to those in A_1. The third label is $\ell(q_1, A'_1)$ (we define A'_1 below), and the final fourth label is $\ell(q_2, A_2)$. In order to define A'_1, fix some $j : 1 \leq j \leq l$, and consider the jth entry of q_1, a clause whose variables are x_{i_j}, x'_{i_j}, and x''_{i_j}. We need to specify the assignments to these variables in A'_1. The assignment to x_{i_j} is defined to be the same assignment that appears in A_2, the assignment to x'_{i_j} is the same as in A'_2, and the assignment to x''_{i_j} is set in such a way that clause C_{i_j} is satisfied.

Thus, even though the two answers A_1 and A_2 of the provers might be inconsistent in many coordinates, there is still a short path between the two labels. In order to improve the hardness bound, it would be helpful (and enough) to ensure that if two answers are inconsistent in almost all the coordinates, then the length of the shortest path between the two corresponding labels is $\Omega(l)$. This is the intuition behind the construction and the k-prover protocol described in the next section.

4. The main hardness result. In this section we prove an $\Omega((\log n)^{1/2-\delta})$-hardness of restricted metric labeling, for any constant $\delta : 0 < \delta < \frac{1}{2}$. We start by

defining a new k-prover protocol for 3SAT(5). The protocol is then used in a way which is similar to the construction in section 3 to obtain the stronger hardness result.

4.1. A new k-prover protocol. We define a new k-prover protocol, where the k provers are denoted by $P_1, \ldots, P_k$, and k will be later set to poly$(\log n)$. This protocol is based on the basic one-round two-prover protocol, and it proceeds as follows.

- The verifier sends one query to each prover. Each one of the queries has $\binom{k}{2}$ entries, which are determined in the following way. For each pair (i, j) of provers, where $1 \leq i < j \leq k$, the verifier chooses, uniformly, independently at random, a clause C_{ij} and a distinguished variable x_{ij} belonging to this clause. The entry (i, j) in the queries of the provers is then defined as follows. In the query sent to prover P_i, this entry contains clause C_{ij}. In the query sent to prover P_j, this entry contains variable x_{ij}. For each other prover P_a, where $a \neq i, j$, the entry (i, j) of its query contains both clause C_{ij} and variable x_{ij}.
  Thus, in general, for any prover P_h, $1 \leq h \leq k$, coordinate (y, z) of its query (where $1 \leq y < z \leq k$), is defined as follows:
  - if $h = y$, then the entry contains C_{yz}.
  - if $h = z$, then the entry contains x_{yz}.
  - if $h \neq y, z$, then the entry contains both C_{yz} and x_{yz}.
- Each one of the provers responds with an assignment to all the variables appearing in its query, both as parts of clauses and as distinguished variables.
- After receiving the answers of the provers, the verifier checks, for each coordinate (i, j), $1 \leq i < j \leq k$, that the answers of all the provers are consistent, i.e., all the provers P_a, $a \neq j$, return an identical assignment to the variables of C_{ij}, and the assignment of prover P_j to variable x_{ij} matches the assignments of all the other provers.

We note that our k-prover system departs from standard protocols in several ways. First, we do not use the parallel repetitions theorem here, as there is no need to amplify the soundness of the protocol. Observe also that for each prover P_a, for each coordinate $(i, j) : i, j \neq a$, the prover receives both the clause C_{ij} and the distinguished variable x_{ij}. It may appear that some of the information the prover receives is redundant. Indeed, in k-prover systems (e.g., [12]), the provers usually receive either the clause or the distinguished variable, but not both. However, this sending of redundant information to the provers is essential for our reduction. Intuitively, it will ensure that if, for some random string r, the answers of the k provers are inconsistent in many coordinates, then the distances between the corresponding labels are long.

We assume again that all the random choices of the verifier are made at the beginning of the protocol, by choosing a random string r out of the set R of all the possible random strings of the desired length. Given a random string $r \in R$, for each i, $1 \leq i \leq k$, let $q_i(r)$ be the query sent to prover P_i when the verifier chooses the random string r, and let Q_i be the set of all the possible queries of prover i. For each $i : 1 \leq i \leq k$, for each $q_i \in Q_i$, let $A(q_i)$ denote the set of all the possible answers of prover P_i to query q_i, which satisfy all the clauses appearing in the query.

DEFINITION 4.1. *Consider a pair of provers P_i and P_j, $1 \leq i < j \leq k$, and let $q_i \in Q_i$, $q_j \in Q_j$ be a pair of queries such that for some random string $r \in R$, $q_i = q_i(r), q_j = q_j(r)$. Let A_i and A_j denote the respective answers of the provers to the queries. We say that the answers are* weakly consistent *if the assignments to C_{ij} and x_{ij} in A_i and A_j, respectively, are consistent. The answers are called* strongly consistent *if they are also consistent in every other coordinate, i.e., for each (a, b), $1 \leq a < b \leq k$, where $(a, b) \neq (i, j)$, the following hold:*

- *If both entries $q_i(a,b)$ and $q_j(a,b)$ contain clause C_{ab} and variable x_{ab}, then the assignments to the variables of clause C_{ab} in A_i and A_j are identical.*
- *If one of the entries $q_i(a,b)$ and $q_j(a,b)$ contains clause C_{ab} and the other contains clause C_{ab} and variable x_{ab}, then the assignments to the variables of the clause C_{ab} in A_i and A_j are identical.*
- *If one of the entries $q_i(a,b)$ and $q_j(a,b)$ contains variable x_{ab} and the other contains clause C_{ab} and variable x_{ab}, then the assignments to the variables of clause C_{ab} and variable $x_{a,b}$ in A_i and A_j are consistent.*

THEOREM 4.2. *If ϕ is a Yes-instance, then there is a strategy of the k provers such that the verifier always accepts. If ϕ is a No-instance, then for any strategy of the provers, for every pair of provers P_i and P_j, $1 \le i < j \le k$, the probability that their answers are weakly consistent is at most $(1 - \frac{\epsilon}{3})$.*

Proof. For the Yes-instance, the theorem follows immediately. We now prove that the theorem holds for the No-Instance. Assume otherwise. Let P_i and P_j be a pair of provers such that the probability that their answers are weakly consistent is more than $(1 - \frac{\epsilon}{3})$. We partition the set of random strings R into classes such that within each class the random strings are identical except for the clause C_{ij} and the distinguished variable x_{ij}. Each such class (together with the corresponding queries and answers to the queries) can be viewed as a two-prover protocol (while we ignore all the coordinates of the queries and the answers except for (i,j)). As the probability of obtaining a pair of weakly consistent answers is more than $(1 - \frac{\epsilon}{3})$, at least for one of the classes, the probability that the verifier accepts is greater than $(1 - \frac{\epsilon}{3})$. This defines a strategy for the two-prover protocol in which the acceptance probability of the verifier is greater than $(1 - \frac{\epsilon}{3})$, contradicting Theorem 2.2. □

4.2. The graph and the label set. In this section we construct an instance of the restricted metric labeling problem from an input 3SAT(5) formula ϕ. Our construction is based on the k-prover system described above.

The set of labels L consists of two subsets:

Query labels: For each prover P_i, $1 \le i \le k$, for each query $q \in Q_i$, and for each answer $A \in A(q)$ to the query q, there is a label $\ell(P_i, q, A)$.

Constraint labels: Consider a random string r of the verifier. Let $A_1, \ldots, A_k$, be any collection of possible answers of the provers to the queries $q_1(r), \ldots, q_k(r)$; i.e., for each $1 \le i \le k$, $A_i \in A(q_i(r))$. Moreover, assume that these answers are accepted by the verifier, (i.e., $A_1, \ldots, A_k$ are strongly consistent). Then, there is a label $\ell(r, A_1, A_2, \ldots, A_k)$.

We now define a graph $G_L(L, E')$ on the label set. The metric on the label set is implied by the shortest path distance function in the graph. The vertices of G_L are the labels, and the edges are defined as follows. Consider a constraint label $\ell = \ell(r, A_1, A_2, \ldots, A_k)$, Then, for each i, $1 \le i \le k$, there is an edge of length $\frac{1}{2}$ between ℓ and $\ell(P_i, q_i(r), A_i)$ (see Figure 4.1).

Thus, the graph is a collection of stars, while some stars share some of their leaves.

We now proceed to define graph $G(V, E)$. The vertex set V is the union of two vertex sets: a set of *query vertices*, denoted by V_1, and a set of *constraint vertices*, denoted by V_2.

Query vertices: For each prover P_i, $1 \le i \le k$, and for each query $q \in Q_i$, there is a vertex $v(P_i, q)$. Thus,

$$V_1 = \{v(P_i, q) \mid 1 \le i \le k \text{ and } q \in Q_i\}.$$

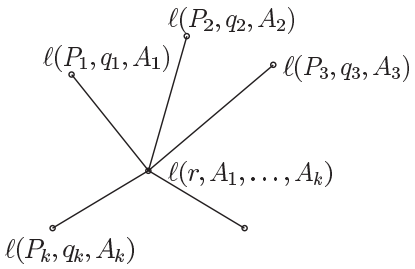

FIG. 4.1. *Edges in the graph of labels incident to* $\ell(r, A_1, \ldots, A_k)$.

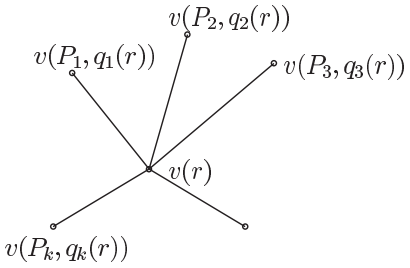

FIG. 4.2. *Edges incident to* $v(r)$.

Vertex $v(P_i, q)$ can be assigned only to the labels corresponding to (P_i, q_i), i.e.,

$$L(v(P_i, q)) = \{\ell(P_i, q, A) \mid A \in A(q)\}.$$

Note that assigning $v(P_i, q)$ to a label in $L(v(P_i, q))$ defines an answer of prover P_i to query q.

Constraint vertices: For each random string r, there is a vertex $v(r)$, i.e.,

$$V_2 = \{v(r) \mid r \in R\}.$$

Vertex $v(r)$ can be assigned only to labels corresponding to r; i.e., $L(v(r))$ consists of labels $\ell(r, A_i, \ldots, A_k)$ such that $\forall i$, $A_i \in A(q_i(r))$ and $(A_1, \ldots, A_k)$ are strongly consistent.

The edges of the graph are as follows. Every constraint vertex $v(r)$ is connected to every assignment vertex $v(P_i, q_i(r))$ by a unit-weight edge (see Figure 4.2).

The graph is therefore a collection of stars that can have common leaves.

4.3. Hardness of approximation proof.

4.3.1. Yes-instances. Assume that the input 3SAT(5) formula ϕ is a Yes-instance. Consider a strategy of the provers for which the acceptance probability of the verifier is 1. For every prover P_i, $1 \le i \le k$, for every query $q \in Q_i$, let $f(q) \in A(q)$ be the answer of prover P_i to query q under this strategy. Note that for each random string r, $f(q_1(r)), \ldots, f(q_k(r))$ are strongly consistent. We define the following labeling of the graph G (see Figure 4.3):

- For each random string $r \in R$, vertex $v(r)$ is assigned to label $\ell(r, f(q_1(r)), \ldots, f(q_k(r)))$.

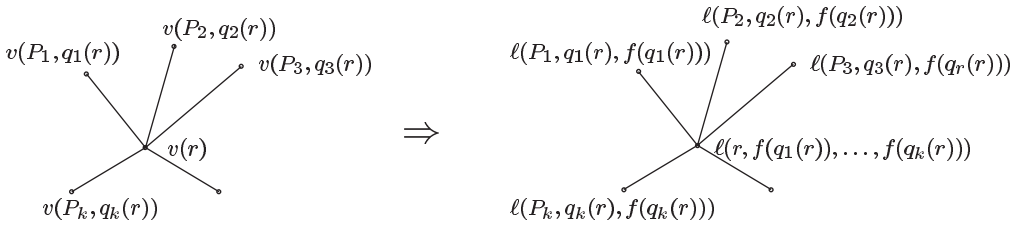

FIG. 4.3. *Yes-instance: the embedding of edges incident to $v(r)$.*

- For each $i : 1 \le i \le k$, $q \in Q_i$, vertex $v(P_i, q)$ is assigned to label $\ell(P_i, q, f(q))$.

Consider an edge in the graph G between $v(r)$ and $v(P_i, q_i(r))$, $r \in R$, $1 \le i \le k$. Vertex $v(r)$ is assigned to label $\ell(r, f(q_1(r)), \ldots, f(q_k(r)))$, and vertex $v(P_i, q_i(r))$ is assigned to label $\ell((P_i, q_i(r), f(q_i(r)))$. Thus, the separation cost of the edge is $\frac{1}{2}$, since the distance between the two labels is $\frac{1}{2}$. Hence, the total cost of the solution is $\frac{1}{2} \cdot k \cdot |R|$.

4.3.2. No-instances. Assume that the input 3SAT(5) formula ϕ is a No-instance. We prove that the cost of any solution to the metric labeling instance is at least $\binom{k}{2} \cdot \frac{\epsilon}{3} \cdot |R|$, and thus the gap between the Yes- and the No-instances is $\Omega(k)$. Observe that the assignment of the query vertices to query labels defines a strategy of the provers. We concentrate on this strategy and define the set $T \subseteq R \times [k] \times [k]$.

DEFINITION 4.3. *For $r \in R$, $1 \le i < j \le k$, $(r, i, j) \in T$ if and only if the answers of provers P_i and P_j to queries $q_i(r)$ and $q_j(r)$, respectively, are not weakly consistent (under the above strategy).*

The following proposition is a direct consequence of Theorem 4.2.

PROPOSITION 4.4. $|T| \ge \binom{k}{2} \cdot \frac{\epsilon}{3} \cdot |R|$.

Consider an edge $e \in E$, and assume that the endpoints of the edge are assigned to labels ℓ_1 and ℓ_2. We denote by $\mathcal{P}_e$ the shortest path between the labels ℓ_1 and ℓ_2 in the graph of labels G_L. Note that the length of $\mathcal{P}_e$ is exactly the cost paid by edge e, and the solution cost is $\sum_{e \in E} |\mathcal{P}_e|$. We define the set $T' \subseteq R \times [k] \times [k]$ as follows. Consider a random string $r \in R$ and a pair of provers P_i and P_j, $1 \le i, j \le k$, $i \ne j$. Let e be the edge between $v(r)$ and $v(P_i, q_i(r))$. Then, $(r, i, j) \in T'$ if and only if the path $\mathcal{P}_e$ contains a label belonging to prover P_j (i.e., a label of the form $\ell(P_j, q, A)$, for some $q \in Q_j, A \in A(q)$). Observe that the cost of the solution is at least $|T'|$.

LEMMA 4.5. *For $r \in R$, suppose $(r, i, j) \in T$, where $1 \le i < j \le k$. Then, either $(r, i, j) \in T'$ or $(r, j, i) \in T'$.*

Proof. Suppose that vertex $v(r)$ is assigned to label $\ell(r, A_1, \ldots, A_k)$, and suppose vertices $v(P_i, q_i(r))$ and $v(P_j, q_j(r))$ are assigned to labels $\ell(P_i, q_i(r), A'_i)$ and $\ell(P_j, q_j(r), A'_j)$, respectively. As $(r, i, j) \in T$, the answers A'_i and A'_j of provers P_i and P_j cannot be weakly consistent. However, the answers A_i and A_j are strongly consistent. Therefore, either the (i, j) coordinates in A_i and A'_i differ (recall that this coordinate contains an assignment to a clause C_{ij}), or the (i, j) coordinates in A_j and A'_j differ (this coordinate contains an assignment to a distinguished variable x_{ij}). Assume that the former is true (the other case is handled similarly).

Let e be the edge between $v(r)$ and $v(P_i, q_i(r))$. It is enough to show that the path $\mathcal{P}_e$ contains a label corresponding to prover P_j. Suppose that this is not the case. Let $\ell(P_a, q_a, A)$ and $\ell(P_b, q_b, A')$ be two consecutive query labels on the path. As the two labels are at distance 1, there must be an $r' \in R$ such that $q_a = q_a(r')$ and $q_b = q_b(r')$ and the answers A and A' are strongly consistent. As $a, b \ne j$, the (i, j)

coordinate in q_a and in q_b must contain some clause, and the two clauses are identical. Moreover, coordinate (i, j) of A and A' must contain an identical assignment to the variables of this clause. Therefore, if path $\mathcal{P}_e$ starts at $\ell(P_i, q_i(r), A'_i)$ and does not pass through any label belonging to prover P_j, then for every query label $\ell(P_s, q_s, A)$ appearing on the path, coordinate (i, j) of q_s contains the same clause as that of $q_i(r)$, and coordinates (i, j) in A and A'_i are identical. This is also true for the last query label on the path, denoted by $\ell(P_d, q_d, A_d)$. But this label is connected by an edge to label $\ell(r, A_1, \ldots, A_k)$, and therefore coordinates (i, j) of A_d and A_i must be identical, which is impossible. □

It follows from the lemma that $|T'| \geq |T|$, yielding that the solution cost is at least $\binom{k}{2} \cdot \frac{\epsilon}{3} \cdot |R|$.

4.3.3. The hardness factor. The gap between the cost of the Yes-instance and the No-instance solutions is $\Omega(k)$. The size of the construction is dominated by the number of labels. For each i, $1 \leq i \leq k$, $|Q_i| \leq (5n)^{k^2}$, and for each $q \in Q_i$, $|A(q)| \leq 7^{k^2}$, and therefore the number of query labels is at most $k(5n)^{k^2} \cdot 7^{k^2}$. The size of R is at most $(5n)^{k^2}$ and for each $r \in R$ the number of k-tuples of consistent answers is at most 7^{k^2}. Hence, the number of constraint labels is bounded by $(5n)^{k^2} \cdot 7^{k^2}$. The construction size is therefore $N = n^{O(k^2)}$. If k is a constant, then it is polynomial in n. Choosing $k = \text{poly}(\log n)$, we get that $k = (\log N)^{\frac{1}{2}-\delta}$ for arbitrarily small constant $\delta > 0$.

Thus, we have proved the following result.

THEOREM 4.6. *There is no efficient constant factor approximation algorithm for the metric labeling problem, unless P=NP. Moreover, for any constant* $0 < \delta < 1/2$, *there is no* $\Omega((\log N)^{\frac{1}{2}-\delta})$*-approximation algorithm for the problem, unless NP* $\subseteq$ *DTIME*$(n^{poly(\log n)})$.

Acknowledgment. The authors would like to thank Sanjeev Khanna for helpful comments on the presentation of the paper.

PSEUDORANDOM BITS FOR CONSTANT-DEPTH CIRCUITS WITH FEW ARBITRARY SYMMETRIC GATES*

EMANUELE VIOLA†

Abstract. We exhibit an explicitly computable pseudorandom generator stretching l bits into $m(l) = l^{\Omega(\log l)}$ bits that look random to constant-depth circuits of size $m(l)$ with $\log m(l)$ arbitrary symmetric gates (e.g., PARITY, MAJORITY). This improves on a generator by Luby, Velickovic, and Wigderson [*Proceedings of the Second Israel Symposium on Theory of Computing Systems*, 1993, pp. 18–24] that achieves the same stretch but fools only circuits of depth 2 with one arbitrary symmetric gate at the top. Our generator fools a strictly richer class of circuits than Nisan's generator for constant-depth circuits (but Nisan's generator has a much bigger stretch) [*Combinatorica*, 11 (1991), pp. 63–70]. In particular, we conclude that every function computable by uniform poly(n)-size *probabilistic* constant-depth circuits with $O(\log n)$ arbitrary symmetric gates is in $TIME(2^{n^{o(1)}})$. This seems to be the richest probabilistic circuit class known to admit a subexponential derandomization. Our generator is obtained by constructing an explicit function $f : \{0,1\}^n \to \{0,1\}$ that is very hard *on average* for constant-depth circuits of size $s(n) = n^{\Omega(\log n)}$ with $\log s(n)$ arbitrary symmetric gates, and plugging it into the Nisan–Wigderson pseudorandom generator construction [*J. Comput. System Sci.*, 49 (1994), pp. 149–167]. The proof of the average-case hardness of this function is a modification of arguments by Razborov and Wigderson [*Inform. Process. Lett.,* 45 (1993), pp. 303–307] and Hansen and Miltersen [*Proceedings of the* 29*th International Symposium on Mathematical Foundations of Computer Science*, Lecture Notes in Comput. Sci. 3153, Springer-Verlag, Berlin, 2004, pp. 334–345] and combines Håstad's switching lemma [*Computational Limitations of Small-Depth Circuits*, MIT Press, Cambridge, MA, 1987] with a multiparty communication complexity lower bound by Babai, Nisan, and Szegedy [*J. Comput. System Sci.*, 45 (1992), pp. 204–232].

1. Introduction.

A *pseudorandom generator* $G : \{0,1\}^l \to \{0,1\}^m$ is an efficient procedure that stretches l input bits into $m \gg l$ output bits such that the output distribution of the generator *fools* small circuits. That is, for every circuit C of size m we have

$$\left| \Pr_{x \in \{0,1\}^l}[C(G(x)) = 1] - \Pr_{x \in \{0,1\}^m}[C(x) = 1] \right| \leq \frac{1}{m}.$$

Pseudorandom generators have found a striking variety of applications in complexity theory, most notably to *derandomize* probabilistic algorithms.

Starting with the seminal work of Nisan and Wigderson [21], a series of results (e.g., [3, 28, 26, 29]) show how to construct pseudorandom generators starting from an explicit function that requires circuits of superpolynomial size. However, no such function is known to exist.

On the other hand, pseudorandom generators that fool *restricted* kinds of circuits, such as *constant-depth* circuits with unbounded fan-in, are already very interesting. They also have a large variety of applications (e.g., [21, 16]) and are central to understanding the power of randomness in restricted classes of algorithms. While there has been exciting progress in constructing explicit functions that require superpolynomial-size constant-depth circuits with certain kinds of gates (e.g., [14, 23, 27, 15, 22, 13]), no explicit function is known to require superpolynomial-size constant-depth circuits with MAJORITY gates (cf. [25]). This is an obstacle to constructing pseudorandom generators, as most constructions need such a function. This need is due to the fact that the reductions in the proofs of correctness of these constructions use (a polynomial number of) MAJORITY gates (cf. [1], [30, section 10], and [32, Chapter 6]).

But when starting from an *average-case* hard function, the reduction in the proof of correctness of the Nisan–Wigderson construction [21] does not require MAJORITY gates. (A function $f : \{0,1\}^n \to \{0,1\}$ is average-case hard if polynomial-size circuits fail to compute f with probability at least $1/2 - 1/n^{\omega(1)}$ over random input.) Thus, one can plug average-case lower bounds into the Nisan–Wigderson construction to get a generator that fools small constant-depth circuits. This approach is used in a celebrated work by Nisan [20] (which actually predates the more general construction in [21]) in which he exhibits a generator $G : \{0,1\}^l \to \{0,1\}^{2^{l^{\Omega(1)}}}$ that fools small AC^0 circuits (i.e., constant-depth circuits with AND and OR gates). This generator is based on the fact that PARITY is very average-case hard for small AC^0 circuits [14].

Subsequently, Luby, Velickovic, and Wigderson (Theorem 2 in [19]) built a generator $G : \{0,1\}^l \to \{0,1\}^{l^{\Omega(\log l)}}$ that fools small SYM $\circ$ AND circuits, i.e., depth-2 circuits with one *arbitrary symmetric gate* at the top and AND gates at the bottom. By arbitrary symmetric gate we mean a gate that computes an arbitrary function whose value depends only on the number of input bits being 1, important examples being PARITY and MAJORITY. This generator is based on the fact that the generalized inner product function is average-case hard for small SYM $\circ$ AND circuits with small bottom fan-in [4, 15].

The above two generators ([20] and Theorem 2 in [19]) fool two incomparable classes of circuits (i.e., small AC^0 circuits and small SYM $\circ$ AND circuits). In this work we exhibit a generator that fools a class of circuits strictly richer than both of them, namely, small constant-depth circuits with few arbitrary symmetric gates.

1.1. Our results. In this paper we exhibit the following generator.

THEOREM 1. *For every constant d there is a constant $\epsilon > 0$ such that for every l there is a generator $G : \{0,1\}^l \to \{0,1\}^m$, where $m = m(l) := l^{\epsilon \log l}$, such that for every circuit C of size m and depth d with $\log m(l)$ arbitrary symmetric gates, we have*

$$\left| \Pr_{x \in \{0,1\}^m}[C(x) = 1] - \Pr_{x \in \{0,1\}^l}[C(G(x)) = 1] \right| \leq \frac{1}{m},$$

and given $x \in \{0,1\}^l, i \leq m$, we can compute the ith output bit of $G(x)$ in time $\mathrm{poly}(l)$.

The generator in Theorem 1 improves on the generator by Luby, Velickovic, and Wigderson (Theorem 2 in [19]) that achieves the same stretch (up to a different constant ϵ) but fools only circuits of depth 2 (as opposed to any constant depth) with one symmetric gate at the top. We elaborate more on the difference between the two

generators in section 6. The generator in Theorem 1 also fools a strictly richer class of circuits than Nisan's generator, which fools constant-depth circuits [20]. However, Nisan's generator has a much bigger stretch: it stretches l bits to $2^{l^{\Omega(1)}}$ bits, as opposed to $l^{\Omega(\log l)}$ in Theorem 1.

As a standard consequence of Theorem 1 we obtain the following subexponential derandomization of probabilistic polynomial-size constant-depth circuits with a logarithmic number of arbitrary symmetric gates. This seems to be the richest probabilistic circuit class known to admit a subexponential derandomization. See [21] for the connection between generators and derandomization.

COROLLARY 2. *Let a function f be computed by a polynomial-time uniform family of probabilistic* $\mathrm{poly}(n)$*-size constant-depth circuits with $O(\log n)$ arbitrary symmetric gates. Then f can be computed in deterministic time* $\exp(2^{O(\sqrt{\log n})}) = 2^{n^{o(1)}}$.

1.2. Techniques. The generator in Theorem 1 is obtained by plugging into the Nisan–Wigderson pseudorandom generator construction [21] a function that is very hard on average for "small" constant-depth circuits with "few" arbitrary symmetric gates (cf. Theorem 3).

Here a simple and crucial observation is that the reduction in the proof of correctness of the Nisan–Wigderson generator does not increase the number of arbitrary symmetric gates.

Given our average-case hardness result (Theorem 3), the construction of our generator is simpler than the construction of the generator by Luby, Velickovic, and Wigderson (Theorem 2 in [19]) that uses more involved combinatorial arguments than those in [21]. These more involved combinatorial arguments were probably used because the generator in [19] builds on a function that is hard on average for circuits of depth 2 (as opposed to any constant depth), and thus one cannot use directly the Nisan–Wigderson construction [21] since the reduction in its proof of correctness increases the depth by 1.

We now state our average-case hardness result.

THEOREM 3. *There is a function $f : \{0,1\}^* \to \{0,1\}$ computable in polynomial time such that for every constant d there is a constant $\epsilon > 0$ such that for every n and every circuit C of size $n^{\epsilon \log n}$ and depth d with $\epsilon \log^2 n$ arbitrary symmetric gates, the following holds:*

$$\Pr_{x \in \{0,1\}^n}[C(x) \neq f(x)] \geq 1/2 - 1/n^{\epsilon \log n}.$$

We now explain the techniques involved in proving Theorem 3.

To simplify the discussion we first focus on how to prove an average-case hardness result for small constant-depth circuits with *one* arbitrary symmetric gate at the top, i.e., small $\mathrm{SYM} \circ \mathrm{AC}^0$ circuits (Theorem 4). The extension to circuits with more arbitrary symmetric gates is deferred to the later subsection on circuits with more arbitrary symmetric gates.

We obtain our average-case hardness result for small $\mathrm{SYM} \circ \mathrm{AC}^0$ circuits through a modification of previous lower bounds. We now discuss these previous lower bounds, then discuss why they are not sufficient for our purposes, and then sketch the proof of our average-case hardness result for small $\mathrm{SYM} \circ \mathrm{AC}^0$ circuits.

Previous lower bounds. Babai, Nisan, and Szegedy [4] proved that the generalized inner product function (i.e., $GIP_{n,s}(x) := \bigoplus_{i \leq n} \bigwedge_{j \leq s} x_{i,j}$) is very hard *on average* for multiparty communication complexity protocols among few parties that communicate little.

Håstad and Goldmann [15] noticed that any function computed by a small depth-2 circuit with an arbitrary symmetric gate of unbounded fan-in at the top and (arbitrary) gates of small fan-in at the bottom can be computed by a multiparty communication complexity protocol among few parties communicating little.

Thus, by the above result [4], they obtain that *GIP* is average-case hard for that class of circuits. Now, by the so-called ϵ-discriminator lemma[1] of Hajnal et al. [12] they conclude that *GIP* cannot be computed, in the *worst case*, by small depth-3 circuits with one majority gate of unbounded fan-in at the top, arbitrary symmetric gates of unbounded fan-in in the middle, and (arbitrary) gates of small fan-in at the bottom.

Razborov and Wigderson [22] eliminated the constraint on the bottom fan-in: they exhibited a new function *RW* that cannot be computed, in the worst case, by small depth-3 circuits with one majority gate at the top, symmetric gates in the middle, and AND gates at the bottom, where all the gates have unbounded fan-in (MAJ $\circ$ SYM $\circ$ AND circuits). Their function *RW* is obtained from *GIP* by replacing each input variable with a parity function, i.e., $RW(x) := \bigoplus_{i \le n} \bigwedge_{j \le \log n} \bigoplus_{k \le n} x_{i,j,k}$.

To explain their argument we introduce *restrictions* [11]. A restriction on m variables $x_1, x_2, \ldots, x_m$ is a map $\rho : \{x_1, x_2, \ldots, x_m\} \to \{0, 1, *\}$. For a circuit C we denote by $C|_\rho$ the circuit we get by doing the substitutions prescribed by ρ, followed by all obvious cancellations made possible by applying ρ. The input variables of $C|_\rho$ are the variables which were given the value * by ρ.

The argument in [22] is as follows. Suppose that *RW* is computable by a small MAJ $\circ$ SYM $\circ$ AND circuit C. Then there is a restriction ρ that accomplishes simultaneously two things: (1) $C|_\rho$ has small bottom fan-in and (2) $C|_\rho$ is still computing *GIP* as a subfunction. Note that by definition of *RW* and by the nature of parity, (2) happens whenever for every i, j there is k such that $\rho(x_{i,j,k}) = *$. But (1) and (2) contradict the above result by Håstad and Goldmann.

Finally, Hansen and Miltersen [13] observed that *RW* actually cannot be computed by small circuits of *any* constant depth with one majority gate at the top, and one layer of arbitrary symmetric gates immediately below it, where all the gates have unbounded fan-in (MAJ $\circ$ SYM $\circ$ AC^0 circuits). The argument in [13] goes as follows. Suppose that *RW* is computable by a small MAJ $\circ$ SYM $\circ$ AC^0 circuit C. Then there is a restriction ρ that accomplishes simultaneously two things: (1′) $C|_\rho$ is equivalent to a small MAJ $\circ$ SYM $\circ$ AND circuit and (2′) $C|_\rho$ is still computing *RW* on an input of polynomially related size. (1′) is obtained through Håstad's switching lemma [14], and for (2′) they show that for every i, j there are many k such that $\rho(x_{i,j,k}) = *$. But (1′) and (2′) contradict the above result by Razborov and Wigderson.

Why previous lower bounds are not sufficient to our purposes. The main problem with these previous lower bounds is that they give only a function that is *worst-case* hard for SYM $\circ$ AC^0 circuits, while as explained before we need a function that is *average-case* hard. In fact, the choice of parameters in the definition of *RW* implies that $\Pr_x[RW(x) = 0] = 1/2 + \Omega(1)$, and thus *RW* cannot be average-case hard (since the constant-size circuit that always outputs 0 computes the function fairly well on average). Moreover the choice of parameters for the restrictions in [22] does not guarantee that the reduction holds with high probability, which is needed to establish average-case hardness.

Proof sketch of our average-case hardness result for $\mathbf{SYM \circ AC^0}$ *circuits.* We

[1] This lemma states that if a function is computed by a small circuit with a MAJORITY gate at the top, then some input circuit to the MAJORITY gate computes the function well on average.

define a function f (similar to RW, but with a different choice of parameters), and we show that f is average-case hard for $\mathrm{SYM} \circ \mathrm{AC}^0$ circuits. Our argument simplifies the previous ones and goes as follows. Suppose that C is a small $\mathrm{SYM} \circ \mathrm{AC}^0$ circuit computing f. We argue that with high probability $\left(1 - n^{-\Omega(\log n)}\right)$ over the choice of a random restriction ρ, both of the following events happen:

- Event $E_1 :=$ the function computed by $C|_\rho$ is computable by a multiparty communication complexity protocol among few parties communicating little.
- Event $E_2 := C|_\rho$ is computing GIP as a subfunction.

To show E_1 we use Håstad's switching lemma to argue that with high probability over ρ, $C|_\rho$ is equivalent to a small depth-2 circuit with a symmetric gate at the top (of unbounded fan-in) and AND gates of small fan-in at the bottom, and then we use Håstad and Goldmann's connection [15] between these circuits and multiparty communication complexity protocols (cf. the subsection on previous lower bounds). Now, when ρ satisfies both E_1 and E_2 we have that $\Pr_y[C|_\rho(y) \neq GIP(y)] \geq 1/2 - n^{-\Omega(\log n)}$ by the multiparty communication complexity lower bound by Babai, Nisan, and Szegedy [4]. Since we can think of a random input x as being generated by first choosing a random restriction ρ and then choosing a random input y for the * of ρ (so that $C(x) = C|_\rho(y)$), we have that

$$\begin{aligned}
&\Pr_x[C(x) \neq f(x)] \\
&\geq \Pr_y\left[C|_\rho(y) \neq GIP(y) \;\middle|\; \rho \text{ satisfies } E_1 \text{ and } E_2\right] \cdot \Pr_\rho\left[\rho \text{ satisfies } E_1 \text{ and } E_2\right] \\
&\geq \left(1/2 - n^{-\Omega(\log n)}\right) \cdot \left(1 - n^{-\Omega(\log n)}\right) \\
&= 1/2 - n^{-\Omega(\log n)}.
\end{aligned}$$

We show that the above argument goes through for $\mathrm{SYM} \circ \mathrm{AC}^0$ circuits C of size $n^{\Omega(\log n)}$ and this proves our average-case hardness result for $\mathrm{SYM} \circ \mathrm{AC}^0$ circuits.

Circuits with more arbitrary symmetric gates. We now discuss how to extend our techniques to obtain an average-case hardness result for constant-depth circuits of size $n^{\epsilon \cdot \log n}$ with $\epsilon \log^2 n$ arbitrary symmetric gates (Theorem 3). The proof of this result has the same structure of our result for $\mathrm{SYM} \circ \mathrm{AC}^0$ circuits discussed in the previous subsection. The only difference is proving that if C is a small constant-depth circuit with $\epsilon \log^2 n$ arbitrary symmetric gates, then with high probability over a random restriction ρ the function computed by $C|_\rho$ is computable by a multiparty communication complexity protocol P among few parties communicating little (cf. event E_1 in the previous subsection). The idea is to let the protocol P compute the outputs of each arbitrary symmetric gate in order. Specifically, first fix a topological order of the arbitrary symmetric gates. (The simple order induced by reading the gates level by level from the inputs to the output node will do.) Now consider the $\mathrm{SYM} \circ \mathrm{AC}^0$ subcircuit C_1 whose root is the first arbitrary symmetric gate in this order. We know that with high probability over the restriction ρ, the function computed by $C_1|_\rho$ is computable by a multiparty communication complexity protocol P_1 exchanging few bits (cf. event E_1 in the previous subsection). Our protocol P first simulates P_1 to determine the output b_1 of $C_1|_\rho$. Then it considers the $\mathrm{SYM} \circ \mathrm{AC}^0$ circuit C_2 whose root is the second arbitrary symmetric gate, and where the first arbitrary symmetric gate is replaced with the constant b_1. Again, we argue that the function computed by $C_2|_\rho$ is computable by a multiparty communication complexity protocol P_2 exchanging few bits. Our protocol P now simulates P_2 to determine the output b_2 of $C_2|_\rho$. We continue in this way until all the arbitrary symmetric gates are computed.

Assuming without loss of generality that the output gate of the circuit is included in the arbitrary symmetric gates, the protocol P computes $C|_\rho$.

Comparison with the work by Chattopadhyay and Hansen. The work described in this paper proceeded at the same time as closely related work by Chattopadhyay and Hansen. These next paragraphs give the chronology of the papers that led to the current results, along with relevant citations. A similar discussion appears at the end of section 1 in [10].

An earlier version of this work, (I, unpublished, 2005) proved an average-case hardness result for constant-depth circuits with a constant number of arbitrary symmetric gates. This result was obtained by first proving an average-case hardness result for constant-depth circuits with *one* arbitrary symmetric gate (Theorem 4) and then combining this with a result by Beigel [6, Theorem 5.1] that shows that for every circuit of size S and depth d with σ arbitrary symmetric gates there is another circuit of size $S^{2^\sigma+1}$ and depth $d+1$ with *one* arbitrary symmetric gate at the top computing the same function.

Independently of (I), Chattopadhyay and Hansen [10, Theorem 1] proved a *worst-case* hardness result for constant-depth circuits of size $n^{\epsilon \cdot \log n}$ with $\epsilon \log^2 n$ arbitrary symmetric gates. (Note that the results in [10, Theorem 1] and (I) are incomparable.)

Subsequent to (I), Chattopadhyay and Hansen (II, personal communication, 2005) proved an average-case hardness result for constant-depth circuits of size $n^{\epsilon \cdot \log n}$ but having only $\epsilon \log n$ arbitrary symmetric gates. (Note that the average-case hardness result of Chattopadhyay and Hansen (II) does not directly imply their worst-case hardness result [10, Theorem 1], because it deals with a smaller number of arbitrary symmetric gates.)

The current paper takes inspiration from the average-case hardness result of Chattopadhyay and Hansen (II) and proves an average-case hardness result for constant-depth circuits of size $n^{\epsilon \cdot \log n}$ with $\epsilon \log^2 n$ arbitrary symmetric gates (Theorem 3); thus we obtain results that are stronger than those of either (I) or (II).

1.3. Organization. This paper is organized as follows. In section 2 we fix some notation. In section 3 we show how our average-case hardness result (Theorem 3) implies our generator (Theorem 1). In section 4 we prove our average-case hardness result for $\mathrm{SYM} \circ \mathrm{AC}^0$ circuits. In section 5 we extend this to our average-case hardness result for constant-depth circuits with few arbitrary symmetric gates, thus proving Theorem 3. In section 6 we elaborate on why our generator improves on the generator by Luby, Velickovic, and Wigderson (Theorem 2 in [19]). In section 7 we discuss some open problems.

2. Preliminaries. A *symmetric gate* is a gate that computes a symmetric function (i.e., a function whose value depends only on the number of input bits being 1, such as PARITY or MAJORITY). Our theorems hold regardless of which symmetric functions are computed by the gates; different functions can be used for circuits for inputs of different lengths, or even for different gates within the same circuit. To emphasize that our results hold *no matter what* symmetric functions are computed by the gates, we call them *arbitrary symmetric gates*. We use standard definitions of constant-depth circuits, which we now briefly recall. Constant-depth circuits consist of AND, OR, and possibly other gates (e.g., arbitrary symmetric gates). It is intended that all gates whose type is not specified are either AND or OR and that AND and OR gates are not counted toward arbitrary symmetric gates. All circuit gates, unless specified otherwise, have unbounded fan-in. Circuits take both input variables and their negations as input. *Bottom* gates are the one adjacent to the input bits. The

top gate is the output gate. Levels are numbered from the bottom. So the input bits are at level 0, the bottom gates at level 1, and so on. Gates at level i are connected to gates at levels $i-1$ and $i+1$ only. The *depth* of a circuit is the longest path from any input to the output. The *size* of a circuit is the number of gates in it. Multiple edges between pairs of nodes in the circuit are not allowed (otherwise an arbitrary symmetric gate can compute any function; this convention is standard in the literature, e.g., [15]).

3. From average-case hardness to pseudorandomness. In this section we show how our average-case hardness result (Theorem 3) implies our generator (Theorem 1). We restate the theorems for the reader's convenience.

THEOREM 1 (restated). *For every constant d there is a constant $\epsilon > 0$ such that for every l there is a generator $G : \{0,1\}^l \to \{0,1\}^m$, where $m = m(l) := l^{\epsilon \log l}$, such that for every circuit C of size m and depth d with $\log m(l)$ arbitrary symmetric gates, we have*

$$\left| \Pr_{x \in \{0,1\}^m}[C(x) = 1] - \Pr_{x \in \{0,1\}^l}[C(G(x)) = 1] \right| \leq \frac{1}{m},$$

and given $x \in \{0,1\}^l, i \leq m$, we can compute the ith output bit of $G(x)$ in time $\mathrm{poly}(l)$.

THEOREM 3 (restated). *There is a function $f : \{0,1\}^* \to \{0,1\}$ computable in polynomial time such that for every constant d there is a constant $\epsilon > 0$ such that for every n and every circuit C of size $n^{\epsilon \cdot \log n}$ and depth d with $\epsilon \log^2 n$ arbitrary symmetric gates, the following holds:*

$$\Pr_{x \in \{0,1\}^n}[C(x) \neq f(x)] \geq 1/2 - 1/n^{\epsilon \cdot \log n}.$$

Proof of Theorem 1*, assuming Theorem* 3. The generator is obtained by plugging the function from Theorem 3 into Nisan and Wigderson's pseudorandom generator construction [21]. Specifically, they show how given a function $f : \{0,1\}^{\sqrt{l/2}} \to \{0,1\}$ and a parameter m (which we set to be $m(l) := l^{\epsilon \cdot \log l}$) to construct a generator $G : \{0,1\}^l \to \{0,1\}^m$ such that every circuit C for which

$$\left| \Pr_{x \in \{0,1\}^m}[C(x) = 1] - \Pr_{x \in \{0,1\}^l}[C(G(x)) = 1] \right| > 1/m$$

can be transformed into another circuit C' of size $|C| + \mathrm{poly}(m)$ that computes the function f correctly with probability (over random input) greater than $1/2 + 1/m^2 = 1/2 + 1/l^{2\epsilon \log l}$.

As observed in [20, 21], C' is simply C with one more layer of AND (or OR) gates at the bottom, and possibly negating the output. Adding one layer of AND (or OR) gates at the bottom clearly does not increase the number of arbitrary symmetric gates in C, and negations can be removed using De Morgan's laws for AND and OR gates and absorbing them in the arbitrary symmetric gates. Thus, if C is a circuit of size $m = m(l) = l^{\epsilon \log l}$ of depth d with $\log m(l) = \epsilon \log^2 l$ arbitrary symmetric gates, we obtain another circuit C' of size $l^{O(\epsilon \log l)}$ of depth $d+1$ with $1 + \epsilon \log^2 l$ arbitrary symmetric gates that computes $f : \{0,1\}^{\sqrt{l/2}} \to \{0,1\}$ with probability greater than $1/2 + 1/l^{2\epsilon \log l}$. This contradicts Theorem 3 for sufficiently small ϵ.

The complexity of the generator follows from the arguments in [20, 21] and the fact that f is computable in time $\mathrm{poly}(l)$. □

4. Average-case hardness for SYM ∘ AC^0 circuits. In this section we prove our average-case hardness result for small constant-depth circuits with one arbitrary symmetric gate at the top.

THEOREM 4. *There is a function $f : \{0,1\}^* \to \{0,1\}$ computable in polynomial time such that for every constant d there is a constant $\epsilon > 0$ such that for every n and every circuit C of size $n^{\epsilon \cdot \log n}$ and depth d with 1 arbitrary symmetric gate at the top, the following holds:*

$$\Pr_{x \in \{0,1\}^n}[C(x) \neq f(x)] \geq 1/2 - 1/n^{\epsilon \cdot \log n}.$$

In the rest of this section we prove Theorem 4. In the proof we use two results which we describe in the following two subsections. The first is Håstad's switching lemma [14], and the second is the multiparty communication complexity lower bound for *GIP* by Babai, Nisan, and Szegedy [4].

4.1. Switching lemma. We now describe the switching lemma we use in the proof of Theorem 4. As in [13], the crucial property that we need is that the DNF obtained after applying the restriction is such that all the terms are mutually contradictory, i.e., no input satisfies more than one term. This allows us to merge the top OR gate of the DNF in the symmetric gate at the top (cf. Fact 6). That this property holds for Håstad's switching lemma was noted by Boppana and Håstad in [14] (inside the proof of Lemma 8.3). A proof of this fact appears in [9]. In this paper we instead use a version of Håstad's switching lemma which is due to Beame [5] and is inspired by a proof given by Razborov [24]. We prefer to use this version because its proof [5, 24] seems simpler than the proof in [14, 9]. A *restriction* on m variables $x_1, x_2, \ldots, x_m$ is a map $\rho : \{x_1, x_2, \ldots, x_m\} \to \{0, 1, *\}$. For a function $f : \{0,1\}^m \to \{0,1\}$ we denote by $f|_\rho$ the function we get by doing the substitutions prescribed by ρ. $f|_\rho$ will be a function of the variables that were given the value * by ρ. Similar conventions hold for circuits. If ρ and ρ' are restrictions, and ρ' is defined on the variables mapped to * by ρ, we write $\rho\rho'$ for the restriction obtained by combining ρ and ρ', so that $f|_{\rho\rho'} = (f|_\rho)|_{\rho'}$. Let $R_m^{\delta \cdot m}$ denote the uniform distribution on restrictions on m variables assigning exactly δm variables to $*$ and assigning random values to the others. A *decision tree* on m variables is a labeled binary tree where edges and leaves are labeled with 0 or 1 and internal nodes with variables. A decision tree computes a function in the intuitive way, starting at the root and following the path according to the values of the input variables and outputting the value at the reached leaf.

LEMMA 5 (see [5]). *Let φ be a DNF or a CNF formula in m variables with bottom fan-in at most r. For every $s \geq 0, p < 1/7$, the probability over $\rho \in R_m^{p \cdot m}$ that the function computed by $\varphi|_\rho$ is not computable by a decision tree of height strictly less than s is less than $(7pr)^s$.*

We will use Lemma 5 in combination with the following fact.

FACT 6. *Let f be a symmetric function of S decision trees of height h. Then f is computable by a depth-2 circuit of size $S \cdot 2^h + 1$ with a symmetric gate of unbounded fan-in at the top and AND gates of fan-in h at the bottom.*

Proof. Write each decision tree as a DNF with bottom fan-in h, where each term corresponds to a path leading to 1. The number of terms in each DNF is at most 2^h, i.e., at most the number of paths in a decision tree of height h. Because every input to a decision tree follows a unique path, each DNF we construct has the property that every input satisfies at most one term. Thus we can merge the top OR gate of all these DNFs with the top symmetric gate of the circuit. Specifically, if the original symmetric

gate was $\psi(x_1, x_2, \ldots, x_S) = g(\sum_{i \le S} x_i)$ for some arbitrary function $g : [S] \to \{0,1\}$, the new symmetric gate is simply $\overline{\psi}'(x_1, x_2, \ldots, x_{S \cdot 2^h}) := g(\sum_{i \le S \cdot 2^h} x_i)$. □

4.2. Multiparty communication complexity. In this section we describe some results on communication complexity that will be used in the proof of our main results. The model of interest is the *multiparty communication complexity model*. In this model there are s parties, each having unlimited computational power, who wish to collaboratively compute a certain function. The input bits to the function are partitioned in s blocks, and the ith party knows all the input bits except those corresponding to the ith block in the partition. The communication between the parties is by "writing on a blackboard" (broadcast): any bit sent by any party is seen by all the others. The parties exchange messages according to a fixed protocol. The measure of interest is the number of bits exchanged by the parties. See the book by Kushilevitz and Nisan [17] for background on this model.

Babai, Nisan, and Szegedy [4] proved a multiparty communication complexity lower bound for the generalized inner product function $GIP_{n,s} : \{0,1\}^{n \cdot s} \to \{0,1\}$, which is defined as follows:

$$GIP_{n,s}(x) := \bigoplus_{i=1}^{n} \bigwedge_{j=1}^{s} x_{i,j}.$$

LEMMA 7 (see [4]). *There is a partition of the inputs to $GIP_{n,s}$ in s blocks such that the following holds. Let P be an s-party communication complexity protocol exchanging at most $0.1 \cdot (n/4^s - \log(1/\gamma))$ bits of communication; then*

$$\Pr_{x \in \{0,1\}^{n \cdot s}} \Big[P(x) \neq GIP_{n,s}(x) \Big] \geq 1/2 - \gamma.$$

Håstad and Goldmann [15] showed that the function computed by a small SYM ∘ AND circuit with small bottom fan-in can be computed by a multiparty communication complexity protocol among few parties exchanging few bits.

LEMMA 8 (see [15]). *Let C be a depth-2 circuit of size S with an arbitrary symmetric gate (of unbounded fan-in) at the top and AND gates of fan-in strictly less than s at the bottom. Then the function computed by C can be computed (under any partition of the input) by an s-party communication complexity protocol exchanging $1 + s \log S$ bits.*

The idea in Lemma 8 is that since each bottom AND gate has fan-in strictly less than s, then, for any partition of the input in s blocks, the input bits to each AND can lie in at most $s - 1$ distinct blocks. Therefore we can assign each AND gate to some party that knows all the input bits necessary to compute it. Now each party broadcasts the number of AND gates assigned to him that evaluate to 1, which takes at most $\log S$ bits. Since the top gate is symmetric this information is sufficient to compute the output of the circuit.

Our next lemma combines the above observation by Håstad and Goldmann with the switching lemma results from the previous section to argue the following: for every small SYM ∘ AC^0 circuit, with high probability over a suitable restriction ρ, the function computed by $C|_\rho$ can be computed by a multiparty communication complexity protocol among few parties exchanging few bits.

LEMMA 9. *For every constant d there is a constant $\epsilon > 0$ such that the following holds. Let $C : \{0,1\}^n \to \{0,1\}$ be a circuit of size $n^{\epsilon \cdot \log n}$ and depth d with 1 arbitrary symmetric gate at the top. Let ρ be a random restriction on the n input variables*

*that assigns * to a subset of the variables of relative size* $1/n^{0.1}$*; i.e., let* $\rho \in R_n^{n/n^{0.1}}$*. Then with probability at least* $1 - n^{-\Omega(\log n)}$ *over* ρ*, the function computed by* $C|_\rho$ *is computable (under any partition of the input) by a* $0.3 \log n$*-party communication complexity protocol exchanging* $\log^3 n$ *bits of communication.*

Proof. The proof amounts to a combination of the previous lemmas for some specific setting of parameters. ∎

CLAIM 10. *With probability* $1-n^{-\Omega(\log n)}$ *over* $\rho \in R_n^{n/n^{0.1}}$*, the function computed by* $C|_\rho$ *is computable by a depth-2 circuit of size* $|C| \cdot 2^{0.3 \log n}$ *with a symmetric gate (of unbounded fan-in) at the top and AND gates of fan-in strictly less than* $0.3 \log n$ *at the bottom.*

The lemma follows by the above claim using Lemma 8, which implies that the function computed by a depth-2 circuit of size $S = |C| \cdot 2^{0.3 \log n} \leq n^{\log n}$ with a symmetric gate (of unbounded fan-in) at the top and AND gates of fan-in strictly less than $0.3 \log n$ at the bottom is computable by a $0.3 \log n$-party communication complexity protocol exchanging $1 + (0.3 \log n) \log S \leq \log^3 n$ bits.

We now prove Claim 10. Similar calculations have already been done elsewhere (e.g., Lemma 2 in [18]). However, we have not found the exact claim we need in the literature.

Proof of Claim 10. We see the restriction ρ as $d-1$ successive applications of restrictions $\rho_1, \rho_2, \ldots, \rho_{d-1}$ each mapping to * a subset of variables of relative size $1/n^\alpha$ of the (remaining) variables. Taking $\alpha = 0.1/(d-1)$ we have that, after applying all $d-1$ restrictions, the total number of variables mapped to * is $n \cdot (1/n^\alpha)^{d-1} = n/n^{0.1}$, and so this distribution on restrictions is exactly $R_n^{n/n^{0.1}}$.

For every $i \in [d-1]$ let DT_i be the event that, after applying the first i restrictions $\rho_1, \rho_2, \ldots, \rho_i$, the function computed by every gate at level i is computable by a decision tree of height strictly less than $0.3 \log n$. We now bound $\Pr_\rho[\text{ not } DT_{d-1}]$. Note that it is at most

$$\Pr_{\rho_1}[\text{ not } DT_1] + \Pr_{\rho_1,\rho_2}[\text{ not } DT_2 | DT_1] + \cdots + \Pr_{\rho_1,\rho_2,\ldots,\rho_{d-1}}[\text{ not } DT_{d-1} | DT_{d-2}].$$

We now bound each term. Fix any $i \leq d-1$ and consider $\Pr_{\rho_1,\rho_2,\ldots,\rho_i}[\text{ not } DT_i | DT_{i-1}]$. (If $i = 1$, think of the input variables as functions computed by decision trees of depth 1, and define $DT_0 :=$ TRUE.) Fix any gate φ at level i. Without loss of generality, assume φ is an OR gate (otherwise we can consider its negation, apply the same reasoning, and then negate again). Since we are conditioning over DT_{i-1}, all the functions computed by gates at level $i-1$ can be computed by decision trees of height (strictly) less than $0.3 \log n$. Write each such function as a DNF with terms of size at most $0.3 \log n$ (where each term corresponds to a path in the decision tree leading to 1). Merging the top OR gates of all these DNFs with φ we see that, given DT_{i-1}, the function computed by φ is a DNF with terms of size at most $r = 0.3 \log n$. By Lemma 5 the probability over the choice of the ith restriction ρ_i that the function computed by $\varphi|_{\rho_1\rho_2\cdots\rho_i}$ cannot be computed by a decision tree of depth strictly less than $s = 0.3 \log n$ is at most

$$(7pr)^s = (7 \cdot (1/n^\alpha) \cdot (0.3 \log n))^{0.3 \log n} = n^{-\Omega(\log n)}.$$

Thus by a union bound we have that

$$\Pr_{\rho_1,\rho_2,\ldots,\rho_i}[\text{ not } DT_i | DT_{i-1}]$$

is at most $n^{-\Omega(\log n)}$ times the number of gates at level i. Therefore, if the circuit C has size $n^{\epsilon \log n}$ for sufficiently small ϵ we have

$$\Pr_{\rho}[\text{ not } DT_{d-1}] \leq n^{-\Omega(\log n)} \cdot |C| = n^{-\Omega(\log n)}.$$

We have shown that with probability $1-n^{-\Omega(\log n)}$ (over ρ) the function computed by $C|_\rho$ is computable by a symmetric function of $|C|$ decision trees of height strictly less than $0.3 \log n$. By Fact 6 we can write each decision tree as a DNF and merge the top OR gates of these DNFs into the top symmetric gate of C, thus proving the claim. □

4.3. Proof of Theorem 4. We now prove Theorem 4. We restate the theorem for the reader's convenience.

THEOREM 4 (restated). *There is a function $f : \{0,1\}^* \to \{0,1\}$ computable in polynomial time such that for every constant d there is a constant $\epsilon > 0$ such that for every n and every circuit C of size $n^{\epsilon \cdot \log n}$ and depth d with 1 arbitrary symmetric gate at the top, the following holds:*

$$\Pr_{x \in \{0,1\}^n}[C(x) \neq f(x)] \geq 1/2 - 1/n^{\epsilon \cdot \log n}.$$

Proof of Theorem 4. Similarly to [22], we consider the function obtained by attaching PARITY gates on n bits at the bottom of $GIP_{n,0.3\log n}$. That is, let $f_n : \{0,1\}^{n^2(0.3\log n)} \to \{0,1\}$ be defined as

$$f_n(x) := \bigoplus_{i=1}^{n} \bigwedge_{j=1}^{0.3\log n} \bigoplus_{k=1}^{n} x_{i,j,k}.$$

We will prove Theorem 4 with f_n as the hard function. While f_n is a function on $m = m(n) := n^2(0.3 \log n)$ bits, it will be convenient to parameterize it by n. Since we will prove $n^{\Omega(\log n)}$ lower bounds for f_n and the input length of f_n is $m = \text{poly}(n)$, we also obtain $m^{\Omega(\log m)}$ lower bounds for f_n (for a different hidden constant in the $\Omega(\cdot)$).

It is easy to see that f_n is computable in polynomial time.

Let $C : \{0,1\}^m \to \{0,1\}$ be a circuit of size $n^{\epsilon \cdot \log n}$ and depth d with 1 arbitrary symmetric gate at the top, for a sufficiently small constant ϵ. Let ρ be a random restriction on the m input variables that assigns * to a subset of the variables of relative size $1/m^{0.1}$; i.e., let $\rho \in R_m^{m/m^{0.1}}$.

Consider the following two events:

- Event E_1 := the function computed by $C|_\rho$ is computable (under every partition of the input) by a $0.3 \log n$-party communication complexity protocol exchanging $n^{0.2}$ bits.
- Event E_2 := for every $i \in [n], j \in [0.3 \log n]$ there is $k \in [n]$ such that $\rho(x_{i,j,k}) = *$. (In other words, for each of the $n \cdot (0.3 \log n)$ bottom parity functions of f_n, ρ maps some of its input variable to *.)

CLAIM 11. $\Pr_{\rho \in R_m^{m/m^{0.1}}}[E_1 \wedge E_2] \geq 1 - n^{-\Omega(\log n)}$.

Before proving Claim 11 let us see how we can use it to prove Theorem 4. Suppose that some $\rho \in R_m^{m/m^{0.1}}$ satisfies both E_1 and E_2. Then

$$\Pr_{y \in \{0,1\}^{m/m^{0.1}}}[C|_\rho(y) \neq f_n|_\rho(y)] \geq 1/2 - n^{-\Omega(\log n)}. \tag{1}$$

This holds by Lemma 7. Specifically, fix any restriction ρ' taken on the variables mapped to * by ρ, such that for every $i \in [n], j \in [0.3 \log n]$ there is *exactly one* $k \in [n]$ such that $\rho\rho'(x_{i,j,k}) = *$. We then have that $f_n|_{\rho\rho'}$ equals $GIP_{n,0.3\log n}$ (up to possibly negating some input variables). If the function computed by $C|_\rho$ is computable by an s-party communication complexity protocol exchanging $n^{0.2}$ bits, then clearly the same holds for the function computed by $C|_{\rho\rho'}$. Therefore by the multiparty communication complexity lower bound for *GIP* (Lemma 7) we obtain (noticing that for $s = 0.3 \log n, \gamma = 2^{-n^{0.3}}$ we have $0.1 \cdot (n/4^s - \log(1/\gamma)) = \Omega(n^{0.4} - n^{0.3}) > n^{0.2}$)

$$\Pr_{z \in \{0,1\}^{n(0.3\log n)}}[C|_{\rho\rho'}(z) \neq f_n|_{\rho\rho'}(y)] \geq 1/2 - 1/2^{n^{\Omega(1)}} \geq 1/2 - n^{-\Omega(\log n)}.$$

Equation (1) follows, noticing that we can think of a random y as choosing first a random ρ' as above and then a random $z \in \{0,1\}^{n(0.3\log n)}$ for the *'s of ρ' (so that $C|_\rho(y) = C|_{\rho\rho'}(z)$).

Thus we have

$$\begin{aligned}
&\Pr_x[C(x) \neq f_n(x)] \\
&= \Pr_{\rho \in R_m^{m/m^{0.1}}, y \in \{0,1\}^{m/m^{0.1}}}[C|_\rho(y) \neq f_n|_\rho(y)] \\
&\geq \Pr_{\rho \in R_m^{m/m^{0.1}}, y \in \{0,1\}^{m/m^{0.1}}}[C|_\rho(x) \neq f_n|_\rho(x) | E_1 \wedge E_2] \cdot \Pr_{\rho \in R_m^{m/m^{0.1}}}[E_1 \wedge E_2] \\
&\geq \left(1/2 - n^{-\Omega(\log n)}\right) \cdot \left(1 - n^{-\Omega(\log n)}\right) \qquad \text{(by (1) and Claim 11)} \\
&= 1/2 - n^{-\Omega(\log n)},
\end{aligned}$$

which proves Theorem 4. □

It is only left to prove Claim 11.

Proof of Claim 11. We show that E_1 and E_2 each do not happen with probability at most $n^{-\Omega(\log n)}$.

The bound on $\Pr_\rho[\text{not } E_1]$ is given by Lemma 9. (The direct application of Lemma 9 gives communication complexity $\text{poly}\log(n) \ll n^{0.2}$ for circuits of size $m^{\epsilon \log m} \geq n^{\epsilon \log n}$.)

We now bound $\Pr_\rho[\text{not } E_2]$. Fix $i \in [n], j \in [0.3 \log n]$. The probability that for every $k \in [n]$ we have $\rho(x_{i,j,k}) \neq *$ is the probability that a random subset $A \subseteq [m]$ of size $m/m^{0.1} = m^{0.9}$ does not intersect a fixed subset $B \subseteq [m]$ of size n. This probability is at most the probability that $m^{0.9}$ *independent* random elements uniformly distributed in $[m]$ all fall outside B. (To see this, think of choosing the random subset A one element at a time, and note that when an element falls outside B it is more likely for the next element to fall inside B.) This latter probability is

$$\left(1 - \frac{n}{m}\right)^{m^{0.9}} \leq \exp(-m^{0.9} n/m) \leq \exp(-m^{\Omega(1)}) \ll n^{-\Omega(\log n)},$$

where we used that $m = n^2 \cdot (0.3 \log n)$. By a union bound we have

$$\Pr[\text{not } E_2] \leq n \cdot (0.3 \log n) \cdot n^{-\Omega(\log n)} = n^{-\Omega(\log n)}. \qquad \square$$

We point out that Theorem 4 is tight for the particular choice of

$$f_n(x) = \bigoplus_{i=1}^{n} \bigwedge_{j=1}^{0.3\log n} \bigoplus_{k=1}^{n} x_{i,j,k}.$$

Namely, f_n is computable by PARITY $\circ$ AND circuits of size $n^{O(\log n)}$. This can be seen by writing the function computed by each AND as a PARITY of $n^{O(\log n)}$ ANDs (cf. [22]).

5. Fooling circuits with more arbitrary symmetric gates. In this section we prove our average-case hardness result for constant-depth circuits of size $n^{\epsilon \log n}$ with $\epsilon \log^2 n$ arbitrary symmetric gates (Theorem 3). The proof has the same structure as the proof of our average-case hardness result for circuits with *one* arbitrary symmetric gate (Theorem 4). The only difference is that now we want to argue that event E_1 happens with high probability even for circuits with $\epsilon \log^2 n$ arbitrary symmetric gates; i.e., we want to show that with high probability over the restriction ρ, the function computed by $C|_\rho$ is computable by a multiparty communication complexity protocol among few parties exchanging few bits. Thus the proof of Theorem 3 follows from the next lemma.

LEMMA 12. *For every constant d there is a constant $\epsilon > 0$ such that the following holds. Let $C : \{0,1\}^n \to \{0,1\}$ be a circuit of size $n^{\epsilon \cdot \log n}$ and depth d with $\epsilon \log^2 n$ arbitrary symmetric gates. Let ρ be a random restriction on the n input variables that assigns * to a subset of the variables of relative size $1/n^{0.1}$; i.e., let $\rho \in R_n^{n/n^{0.1}}$. Then with probability at least $1 - n^{-\Omega(\log n)}$ over ρ, the function computed by $C|_\rho$ is computable (under every partition of the input) by a $0.3 \log n$-party communication complexity protocol exchanging $\log^5 n$ bits of communication.*

Proof. Assume without loss of generality that the output gate of the circuit C is included in the arbitrary symmetric gates. Fix a topological order of the arbitrary symmetric gates (the simple order induced by reading the gates level by level from the inputs to the output node will do). For every $i \in \{1, \ldots, \epsilon \log^2 n\}$, $z \in \{0,1\}^{i-1}$, define $C_{i,z}$ as the subcircuit of C whose output gate is the ith arbitrary symmetric gate but where the previous arbitrary symmetric gates are replaced with z (i.e., the jth gate is replaced with the jth bit in z). Note that $C_{i,z}$ is a SYM $\circ$ AC^0 circuit. □

CLAIM 13. *For a sufficiently small constant $\epsilon > 0$, with probability $1 - n^{-\Omega(\log n)}$ over $\rho \in R_n^{n/n^{0.1}}$ we have that for every $i \in \{1, \ldots, \epsilon \log^2 n\}$ and $z \in \{0,1\}^{i-1}$ the function computed by $C_{i,z}|_\rho$ is computable (under every partition of the input) by a $0.3 \log n$-party communication complexity protocol $P_{i,z}$ exchanging $\log^3 n$ bits of communication.*

Proof. The claim follows by noting that the number of SYM $\circ$ AC^0 circuits $C_{i,z}$ is at most

$$\left(\epsilon \log^2 n\right) \cdot 2^{\epsilon \log^2 n} \leq n^{1+\epsilon \log n},$$

and then using a union bound and Lemma 9, which states that for each fixed circuit $C_{i,z}$, with probability $1 - n^{-\Omega(\log n)}$ over ρ, the function computed by $C_{i,z}|_\rho$ is computable by a $0.3 \log n$-party communication complexity protocol exchanging $\log^3 n$ bits. □

The lemma follows by noting that whenever ρ satisfies the conclusion of the above claim we have (under any partition of the input bits) the following $0.3 \log n$-party communication complexity protocol P for $C|_\rho$. On input x compute $C|_\rho(x)$ as follows. Simulate P_1 to compute $b_1 = C_1|_\rho(x)$. Then simulate P_{2,b_1} to compute $b_2 = C_{2,b_1}|_\rho(x)$. Then simulate $P_{3,b_1 \circ b_2}$ to compute $b_3 = C_{3,b_1 \circ b_2}|_\rho(x)$. Continue in this way until $C_{\epsilon \log^2 n, z}(x) = C|_\rho(x)$. (This last equality is easy to verify.)

Since each protocol $P_{i,z}$ exchanges at most $\log^3 n$ bits of communication, and we simulate $\epsilon \log^2 n$ of these protocols, the total number of bits exchanged by the protocol P is at most $\log^5 n$.

It is perhaps interesting to note that, unlike the corresponding protocol in the proof of Theorem 4, the protocol in the above lemma is not simultaneous; i.e., the bits sent by a party in general depend on the bits previously sent by other parties (cf. [17] for background on simultaneous protocols). Thus in our proof we are taking advantage of the fact that the lower bound for *GIP* (Lemma 7) holds even for non-simultaneous protocols. We do not know how to prove the same result starting from a multiparty communication complexity lower bound for simultaneous protocols.

6. Our generator versus Luby, Velickovic, and Wigderson's. In this section we elaborate on why our generator (Theorem 1) improves on the generator by Luby, Velickovic, and Wigderson (Theorem 2 in [19]). Recall that the generator in [19] fools small depth-2 circuits with one arbitrary symmetric gate at the top (SYM $\circ$ AND circuits). On the other hand, our generator fools small circuits of any constant depth with few arbitrary symmetric gates.

We note that there are several results (e.g., [23, 27, 2, 33, 7, 8]) showing that small circuits in certain rich constant-depth circuit classes can be converted into not-too-big SYM $\circ$ AND circuits. Thus one may wonder whether we can use these results to deduce that the generator in [19] is already powerful enough to give our main result (Theorem 1), i.e., whether it can fool small constant-depth circuits with few arbitrary symmetric gates.

The problem with this idea is that in all these conversion results, *the blow-up in the circuit size is bigger than the saving of the generator.* More specifically, these conversion results show how to convert, say, an AC^0 circuit of size S into a SYM $\circ$ AND circuit of size *quasi*-polynomial, i.e., $S^{\log^{O(1)} S}$, where the constant in the $O(1)$ depends on the depth of the original circuit. However, to fool a circuit of size $S^{\log^{O(1)} S}$, the generator in [19] needs a seed of length at least S, and therefore it is of no use in this particular setting.

It seems natural to ask whether the known conversion results are the best possible, i.e., if the quasi-polynomial blow-up is inherent in the conversion. There are works (e.g., [2, 22]) suggesting that this is indeed the case. We give another result of this flavor.

Specifically, we show how to modify the lower bound in Theorem 4 to get a function computable by polynomial-size PARITY $\circ$ AC^0 circuits that is average-case hard for superpolynomial-size SYM $\circ$ AND circuits. The idea is to change the fan-in of the bottom parities of f so that they are computable by polynomial-size AC^0 circuits (specifically, we change their fan-in from n to $\log^3 n$). While our lower bound is only slightly superpolynomial (i.e., $n^{\Omega(\log\log n)}$), it shows that the parameters of our generator (Theorem 1) *cannot* be obtained combining a conversion result with Theorem 2 in [19], even if we only want to fool PARITY $\circ$ AC^0 circuits.

THEOREM 14. *There is a function $f : \{0,1\}^* \to \{0,1\}$ computable by polynomial-time uniform polynomial-size* PARITY $\circ$ AC^0 *circuits and a constant $\epsilon > 0$ such that for every n and every* SYM $\circ$ AND *circuit C of size $n^{\epsilon \cdot \log\log n}$, the following holds:*

$$\Pr_{x \in \{0,1\}^n}[C(x) \neq f(x)] \geq 1/2 - 1/n^{\epsilon \cdot \log\log n}.$$

Proof of Theorem 14. The proof follows closely the proof of Theorem 4. Let

$$g_n : \{0,1\}^{n(0.3\log n)\log^3 n} \to \{0,1\}$$

be defined as

$$g_n(x) := \bigoplus_{i=1}^{n} \bigwedge_{j=1}^{0.3\log n \log^3 n} \bigoplus_{k=1} x_{i,j,k}.$$

We will prove Theorem 14 with g_n as the hard function. While g_n is a function on $m = m(n) := n \cdot (0.3 \log n) \cdot (\log^3 n)$ bits, it will be convenient to parameterize it by n. Since we will prove $n^{\Omega(\log \log n)}$ lower bounds for g_n and the input length of g_n is $m = n \cdot \operatorname{poly} \log n$, we also obtain $m^{\Omega(\log \log m)}$ lower bounds for g_n (for a different hidden constant in the $\Omega(\cdot)$).

Note that g_n is computable by a (uniform) polynomial-size circuit of depth 5 with one PARITY gate at the top. To see this, note that each of the bottom parities in the definition of g_n is only on $\log^3 n$ bits, and therefore it can be computed by a (uniform) circuit of size $\operatorname{poly}(n)$ and depth 4 (see, e.g., [14, Theorem 2.2]).

Let $C : \{0,1\}^m \to \{0,1\}$ be a SYM $\circ$ AND circuit of size $n^{\epsilon \cdot \log \log n}$ for a sufficiently small constant ϵ. Let ρ be a random restriction on the m input variables that assigns * to a subset of the variables of relative size $1/\log(n)$; i.e., let $\rho \in R_m^{m/\log(n)}$.

Consider the following two events:

- Event E_1' := the function computed by $C|_\rho$ is computable (under any partition of the input) by a $0.3 \log n$-party communication complexity protocol exchanging $n^{0.2}$ bits.
- Event E_2' := for every $i \in [n], j \in [0.3 \log n]$ there is $k \in [\log^3 n]$ such that $\rho(x_{i,j,k}) = *$. (In other words, for each of the $n \cdot (0.3 \log n)$ bottom parity functions of f_n, ρ maps some of its input variable to *.)

As before, Theorem 14 follows from the next claim (cf. the proof of Theorem 4). □

CLAIM 15. $\Pr_{\rho \in R_m^{m/\log(n)}}[E_1' \wedge E_2'] \geq 1 - n^{-\Omega(\log \log n)}$.

Proof. We show that E_1' and E_2' each do not happen with probability at most $n^{-\Omega(\log \log n)}$.

We now bound $\Pr_\rho[\text{not } E_1']$. Analogously to the proof of Lemma 9, the main step is proving the following claim: with high probability $\left(1 - n^{-\Omega(\log \log n)}\right)$ over $\rho \in R_m^{m/\log(n)}$, the function computed by $C|_\rho$ is computable by a depth-2 circuit of size $|C| \cdot 2^{0.3 \log n} = n^{\epsilon \cdot \log \log n} \cdot 2^{0.3 \log n}$ with a single symmetric gate (of unbounded fan-in) at the top and AND gates of fan-in strictly less than $0.3 \log n$ at the bottom. While this probability can be bounded directly, similarly to what is done in [22], it seems simpler to use again the switching lemma. Fix a bottom AND gate φ of C, and think of the input variables to φ as clauses of size $r = 1$. By Lemma 5 the probability over the choice of ρ that the function computed by $\varphi|_\rho$ cannot be computed by a decision tree of depth strictly less than $s = 0.3 \log n$ is at most

$$(7pr)^s = (7 \cdot (1/\log(n)) \cdot 1)^{0.3 \log n} = n^{-\Omega(\log \log n)}.$$

Therefore if the circuit C has size $n^{\epsilon \log \log n}$ for sufficiently small ϵ we have, by a union bound, that with probability $1 - n^{-\Omega(\log \log n)}$ (over ρ) the function computed by $C|_\rho$ is computable by a symmetric function of $|C|$ decision trees of height strictly less than $0.3 \log n$. By Fact 6 we can write each decision tree as a DNF and merge the top OR gates of these DNFs into the top symmetric gate of C, and thus E_1' holds. We now bound $\Pr_\rho[\text{not } E_2']$. Fix $i \in [n], j \in [0.3 \log n]$. The probability that for every $k \in [\log^3 n]$ we have $\rho(x_{i,j,k}) \neq *$ is the probability that a random subset $A \subseteq [m]$ of size $m/\log(n)$ does not intersect a fixed subset $B \subseteq [m]$ of size $\log^3 n$. This probability is at most the probability that $m/\log(n)$ *independent* random elements uniformly distributed in $[m]$ all fall outside B. (To see this, think of choosing the

random subset A one element at a time, and note that when an element falls outside B it is more likely for the next element to fall inside B.) This latter probability is

$$\left(1 - \frac{\log^3 n}{m}\right)^{m/\log(n)} \leq \exp(-\Omega(\log^2 n)) \ll n^{-\Omega(\log\log n)}.$$

By a union bound we have

$$\Pr[\text{not } E_2'] \leq n \cdot (0.3 \log n) \cdot n^{-\Omega(\log\log n)} = n^{-\Omega(\log\log n)}. \qquad \square$$

7. Open problems. Can we improve the stretch of our generator? We remark that an explicitly computable generator $G : \{0,1\}^l \to \{0,1\}^m$ that fools circuits of size m in some class $\mathcal{C}$ (e.g., $\mathcal{C} = \text{SYM} \circ \text{AC}^0$) implies the existence of an explicit function $f : \{0,1\}^{l+1} \to \{0,1\}$ that requires $\mathcal{C}$ circuits of size m (see, e.g., [21]). Thus, improving the stretch of our generator requires establishing stronger lower bounds on the size of circuits computing explicit functions, a notoriously difficult problem. In particular, using a famous result by Yao [33] and Beigel and Tarui [8], we obtain that improving the stretch of our generator to $m(l) = l^{\log^{\omega(1)} l}$, even if we only want to fool $\text{SYM} \circ \text{AND}$ circuits, would imply the existence of an explicit function that cannot be computed by polynomial-size constant-depth circuits with MOD_a gates for constant a (i.e., ACC^0 circuits), thus answering a long-standing open question (cf. [17, section 11.4]). We note that the size lower bound obtained with the approach in [15, 22, 13] and in this paper is limited by the number of players in the known multiparty communication complexity lower bounds (cf. [17, Problems 6.21]).

A direction that seems to have been investigated less is that of trying to increase the number of arbitrary symmetric gates in our results, which is currently logarithmic in the circuit size. Specifically, we ask whether the techniques in this paper can be used to prove (average-case) hardness results for small constant-depth circuits with $\omega(\log^2 n)$ arbitrary symmetric gates. Such a hardness result would follow from a positive answer to the following open question. Let C be a constant-depth circuit of size $n^{\epsilon \log n}$ with $\omega(\log^2 n)$ arbitrary symmetric gates, and let ρ be a restriction as in the statement of Lemma 9. Is it true that with high probability over ρ the function computed by $C|_\rho$ is computable by a $0.9 \log n$-party communication complexity protocol exchanging $n^{0.9}$ bits?

Acknowledgments. We thank Salil Vadhan for his helpful reading of this paper. We thank Arkadev Chattopadhyay and Kristoffer Arnsfelt Hansen for sending us their paper [10] and the anonymous referees for helpful comments.

LOCALLY DECODABLE CODES WITH TWO QUERIES AND POLYNOMIAL IDENTITY TESTING FOR DEPTH 3 CIRCUITS*

ZEEV DVIR† AND AMIR SHPILKA‡

Abstract. In this work we study two, seemingly unrelated, notions. *Locally decodable codes* (LDCs) are codes that allow the recovery of each message bit from a constant number of entries of the codeword. *Polynomial identity testing* (PIT) is one of the fundamental problems of algebraic complexity: we are given a circuit computing a multivariate polynomial and we have to determine whether the polynomial is identically zero. We improve known results on LDCs and on polynomial identity testing and show a relation between the two notions. In particular we obtain the following results: (1) We show that if $E : \mathbb{F}^n \mapsto \mathbb{F}^m$ is a linear LDC with two queries, then $m = \exp(\Omega(n))$. Previously this was known only for fields of size $\ll 2^n$ [O. Goldreich et al., *Comput. Complexity*, 15 (2006), pp. 263–296]. (2) We show that from every depth 3 arithmetic circuit ($\Sigma\Pi\Sigma$ circuit), $\mathcal{C}$, with a bounded (constant) top fan-in that computes the zero polynomial, one can construct an LDC. More formally, assume that $\mathcal{C}$ is minimal (no subset of the multiplication gates sums to zero) and simple (no linear function appears in all the multiplication gates). Denote by d the degree of the polynomial computed by $\mathcal{C}$ and by r the rank of the linear functions appearing in $\mathcal{C}$. Then we can construct a linear LDC with two queries that encodes messages of length $r/\text{polylog}(d)$ by codewords of length $O(d)$. (3) We prove a structural theorem for $\Sigma\Pi\Sigma$ circuits, with a bounded top fan-in, that compute the zero polynomial. In particular we show that if such a circuit is simple, minimal, and of polynomial size, then its rank, r, is only polylogarithmic in the number of variables (a priori it could have been linear). (4) We give new PIT algorithms for $\Sigma\Pi\Sigma$ circuits with a bounded top fan-in: (a) a deterministic algorithm that runs in quasipolynomial time, and (b) a randomized algorithm that runs in polynomial time and uses only a polylogarithmic number of random bits. Moreover, when the circuit is multilinear, our deterministic algorithm runs in polynomial time. Previously deterministic subexponential time algorithms for PIT in bounded depth circuits were known only for depth 2 circuits (in the black box model) [D. Grigoriev, M. Karpinski, and M. F. Singer, *SIAM J. Comput.*, 19 (1990), pp. 1059–1063; M. Ben-Or and P. Tiwari, *Proceedings of the* 20*th Annual ACM Symposium on Theory of Computing*, ACM Press, New York, 1988, pp. 301–309; A. R. Klivans and D. Spielman, *Proceedings of the* 33*rd Annual ACM Symposium on Theory of Computing*, ACM Press, New York, 2001, pp. 216–223]. In particular, for the special case of depth 3 circuits with three multiplication gates our result resolves an open question asked by Klivans and Spielman.

1. Introduction.

Locally decodable codes (LDCs) are error correcting codes that allow the recovery of each symbol of the message from a constant number of entries of the codeword. Polynomial identity testing (PIT) is one of the fundamental problems of algebraic complexity: we are given a circuit computing a multivariate polynomial, and we have to determine whether the polynomial is identically zero. In this paper we show a relation between these two notions—roughly, from every depth 3 circuit which is identically zero, one can construct an LDC. Using this relation and a new lower bound on LDCs, we devise new PIT algorithms for depth 3 circuits.

1.1. Locally decodable codes. LDCs are error correcting codes that allow the recovery of each symbol of the message, from a corrupted codeword, by looking at only a constant number of entries of the corrupted word. Roughly, a (q, δ, ϵ)-*locally decodable code* encodes $x \in \mathbb{F}^n$ to $E(x) \in \mathbb{F}^m$ such that for each index $i \in [n]$, x_i can be recovered from $E(x)$ with probability[1] $> \frac{1}{|\mathbb{F}|} + \epsilon$ by reading only q (random) entries, even if $E(x)$ was corrupted in δm positions.

LDCs have many applications—they are related to private information retrieval (PIR) schemes [13, 26, 18], and they can be used for amplification of hardness [19, 20, 3] and for the construction of hard-core predicates for one-way permutations [30, 15]. (See [49] for a survey on LDCs.)

The notion of LDCs was explicitly discussed in [4] and explicitly defined in [26]. Implicit constructions of local decoders can be found in the context of random self-reducibility and self-correcting computations (see, e.g., [32, 6, 16, 17, 15]). There are two main questions related to LDCs: finding explicit constructions and proving limits of such constructions (i.e., proving lower bounds on the length of the encoding). Explicit constructions were given by [4, 7, 8]. The best current construction is due to Beimel et al. [8], who gave an LDC with q queries of length $m = \exp(n^{O(\log\log q/q \log q)})$.

The problem of proving lower bounds was first studied by Katz and Trevisan [26], who proved that for every LDC with q queries, the length of the codeword, m, is at least $n^{1+\frac{1}{q-1}}$. This is currently the best lower bound for general LDCs (see also [14]). It is a very challenging open question to give tight lower bounds (or upper bounds) on the length of LDCs. Due to the difficulty of the problem many works focused on the case of codes with two queries ($q = 2$). Exponential lower bounds were first proved for linear codes [18, 37] and then, by techniques from quantum computation, for nonlinear codes over $GF(2)$ [28]. The bound of Goldreich et al. [18] actually holds for linear LDCs with two queries over any finite field, namely, that m is at least $2^{\Omega(n)-\log(|\mathbb{F}|)}$, where $\mathbb{F}$ is the underlined field. This result is (nearly) tight when the field is of constant size; however, it gives no significant bound for infinite fields.

1.2. Polynomial identity testing. PIT is a fundamental problem in algebraic complexity: we are given a multivariate polynomial (in some representation) over some field $\mathbb{F}$, and we have to determine whether it is identically zero.[2] The importance of this problem follows from its many applications: algorithms for primality testing [1, 2], for deciding if a graph contains a perfect matching [33, 34, 11], and more, are based on reductions to the PIT problem. (See the introduction of [31] for more applications.)

Determining the complexity of PIT is one of the greatest challenges of theoretical computer science. It is one of a few problems (and in some sense PIT is the most general problem) for which we have *coRP* algorithms but no deterministic subexponential time algorithms. Kabanets and Impagliazzo [25] suggested an explanation for the lack of algorithms. They showed that efficient deterministic algorithms for PIT imply that $NEXP$ does not have polynomial size arithmetic circuits. Specifically, if PIT has deterministic polynomial time algorithms, then either the permanent cannot be computed by polynomial size arithmetic circuits or $NEXP \not\subset P/\text{poly}$.

The first randomized algorithm for PIT was discovered independently by Schwartz [42] and Zippel [50]. Their well-known algorithm simply evaluates the polynomial at a random point and accepts iff the polynomial vanishes at the point. If the polynomial

[1] If $\mathbb{F}$ is infinite, then the probability of success is $> \epsilon$.

[2] Note that we want the polynomial to be identically zero and not just to be equal to the zero function. For example, $x^2 - x$ is the zero function over $GF(2)$ but not the zero polynomial.

is of degree d and each variable is randomly chosen from a domain S, then the error probability is bounded by $d/|S|$. Two kinds of works followed the Schwartz–Zippel algorithm: randomized algorithms that use fewer random bits [12, 31, 1] and algorithms for restricted models of arithmetic circuits. In [22, 9, 29] polynomial time deterministic PIT algorithms for depth 2 arithmetic circuits were given. More recently, [41] gave a polynomial time PIT algorithm for noncommutative formulas. All algorithms, with the exception of [1, 41], are black box algorithms. That is, these algorithms do not have access to a circuit computing the polynomial, and they can evaluate it only on different inputs (as in the Schwartz–Zippel algorithm).

A result of a different nature was proved by Kabanets and Impagliazzo [25]. They designed a deterministic quasi-polynomial time algorithm based on unproved hardness assumptions. Namely, in Theorem 7.7 of [25] it is shown that if there is a family $\{p_n\}$ of exponential time computable polynomials in n variables over $\mathbb{Z}$ such that the arithmetic circuit complexity of p_n is $\exp(n^{\Omega(1)})$, then there is an $\exp(\text{poly}(\log n))$ time algorithm for identity testing for any polynomial size arithmetic circuit that computes polynomials with at most a polynomial degree and polynomial size coefficients.

1.3. Depth 3 arithmetic circuits. Proving lower bounds for general arithmetic circuits is the greatest challenge of algebraic complexity. Unfortunately, except for the lower bounds of Strassen [47] and Baur and Strassen [5], no lower bounds are known for general arithmetic circuits. Due to the difficulty of the problem, research focused on restricted models such as monotone circuits and bounded depth circuits. Exponential lower bounds were proved on the size of monotone arithmetic circuits [43, 24], and linear lower bounds were proved on their depth [44, 48]. However, unlike the situation in the Boolean case, only weak lower bounds were proved for bounded depth arithmetic circuits [38, 40]. Thus, a more restricted model was considered—the model of depth 3 arithmetic circuits (also known as $\Sigma\Pi\Sigma$ circuits). A $\Sigma\Pi\Sigma$ circuit computes a polynomial of the form

$$\mathcal{C} = \sum_{i=1}^{k} \prod_{j=1}^{d_i} L_{ij}(x), \tag{1}$$

where the L_{ij} are linear functions. Grigoriev and Karpinski [21] and Grigoriev and Razborov [23] proved exponential lower bounds on the size of $\Sigma\Pi\Sigma$ circuits computing the permanent and determinant over finite fields. Over infinite fields exponential lower bounds are known only for the restricted models of *multilinear*[3] $\Sigma\Pi\Sigma$ circuits and for *homogeneous* $\Sigma\Pi\Sigma$ circuits [35, 36]. For general $\Sigma\Pi\Sigma$ circuits over infinite fields only the quadratic lower bound of [46] is known. Thus, proving exponential lower bounds for $\Sigma\Pi\Sigma$ circuits over $\mathbb{C}$ is a major open problem in arithmetic circuit complexity.

In this work we are interested in the problem of PIT for depth 3 circuits. As mentioned earlier there are no efficient PIT algorithms for arithmetic circuits, even if we just consider bounded depth circuits. Thus, finding efficient algorithms for PIT in $\Sigma\Pi\Sigma$ circuits seems like the first step toward proving more general results.

1.4. Our results. Lower bounds for linear LDCs with two queries. We study linear LDCs with two queries over arbitrary fields and prove lower bounds on their length. The first such lower bound was proved by Goldreich et al. [18], as follows.

[3]More accurately for pure multilinear $\Sigma\Pi\Sigma$ circuits.

THEOREM 1.1 (Theorem 1.4 of [18]). *Let $\delta, \epsilon \in [0,1]$, $\mathbb{F}$ be a field, and let $E : \mathbb{F}^n \to \mathbb{F}^m$ be a linear $(2, \delta, \epsilon)$-LDC. Then*

$$m \geq 2^{\frac{\epsilon\,\delta\,n}{16} - 1 - \log_2 |\mathbb{F}|}.$$

Note that this result makes sense only when $|\mathbb{F}|$ is finite. We prove the following theorem.

THEOREM 1.2. *Let $\delta, \epsilon \in [0,1]$, $\mathbb{F}$ be a field, and let $E : \mathbb{F}^n \to \mathbb{F}^m$ be a linear $(2, \delta, \epsilon)$-LDC. Then*

$$m \geq 2^{\frac{\epsilon\,\delta\,n}{4} - 1}.$$

Compared with Theorem 1.4 of [18], our result removes the dependance on the size of the field in the exponent and works for every field size, finite and infinite. The idea of the proof is similar to the one in [18]—we show that, given a linear 2-LDC over an arbitrary field $\mathbb{F}$, we can construct from it a linear 2-LDC over $GF(2)$, with almost the same parameters, and then we use the lower bound of [18] for codes over $GF(2)$.

Relation between depth 3 circuits and LDCs. The main result of the paper is that from every $\Sigma\Pi\Sigma$ circuit that computes the zero polynomial, one can construct a linear LDC with two queries. Relations between arithmetic circuits and error correcting codes were known before [10, 45]; however, this is the first time that LDCs appear in the context of arithmetic circuits. More formally, let $\mathcal{C}$ be a $\Sigma\Pi\Sigma$ circuit, as in (1), computing the zero polynomial. We say that $\mathcal{C}$ is minimal if no proper subset of the multiplication gates sums to zero. We say that $\mathcal{C}$ is simple if there is no linear function that appears in all the multiplication gates (up to a multiplicative constant). Denote with r the rank of the linear functions appearing in $\mathcal{C}$.

THEOREM 1.3. *Let $k \geq 3$, $d \geq 2$, and let $\mathcal{C} \equiv 0$ be a simple and minimal $\Sigma\Pi\Sigma$ circuit of degree d, with k multiplication gates and n inputs. Let $r = \operatorname{rank}(\mathcal{C})$. Then we can construct a linear $(2, \frac{1}{12}, \frac{1}{4})$-LDC $E : \mathbb{F}^{n_1} \to \mathbb{F}^{n_2}$ with*

$$\frac{r}{2^{O(k^2)} \log(d)^{k-3}} \leq n_1 \quad \text{and} \quad n_2 \leq k \cdot d.$$

Thus, if k is a constant, then we can construct a linear $(2, \frac{1}{12}, \frac{1}{4})$-LDC that encodes messages of length $r/\text{polylog}(d)$ by codewords of length $O(d)$. As a corollary of Theorems 1.2 and 1.3 we get the next theorem.

THEOREM 1.4. *Let $k \geq 3$, $d \geq 2$, and let $\mathcal{C} \equiv 0$ be a simple and minimal $\Sigma\Pi\Sigma$ circuit of degree d with k multiplication gates and n inputs; then $r \leq 2^{O(k^2)} \log(d)^{k-2}$.*

Notice that the bound on r depends only on the degree and the number of multiplication gates and not on the number of variables! If the degree is polynomial in n (i.e., the circuit is of polynomial size), then the rank is bounded by $\text{polylog}(n)$, where a priori the rank could have been n.

PIT algorithms for depth 3 circuits. We design algorithms for PIT of depth 3 circuits with a constant number of multiplication gates. In particular we get a deterministic quasi-polynomial time algorithm and a randomized polynomial time algorithm that uses only polylog random bits. If the circuit is multilinear, i.e., every multiplication gate computes a multilinear polynomial, then we give a deterministic polynomial time algorithm for PIT. Our algorithms are non black box—all of them use the circuit computing the polynomial. The basic idea is to look for a minimal zero subcircuit and then, using Theorem 1.4, to write the linear functions in the circuit

as linear functions in $r \leq 2^{O(k^2)} \log(d)^{k-2}$ variables. Then we expand the monomials computed by the circuit and verify in a brute force manner that the resulting polynomial is zero. Thus the running time of our algorithm is the combined time that it takes to go over all subcircuits and the time that it takes to write all the monomials of a degree d polynomial in $\leq 2^{O(k^2)} \log(d)^{k-2}$ variables. We thus obtain the following result.

THEOREM 1.5. *Let $\mathcal{C}$ be a $\Sigma\Pi\Sigma$ circuit of degree d, with k multiplication gates and n inputs. Then we can check if $\mathcal{C} \equiv 0$:*

1. *Deterministically, in time* $\exp\left(2^{O(k^2)} \log^{k-1}(d)\right)$. *Thus, for a constant k the running time is* $\exp(\text{polylog}(d))$.
2. *Probabilistically, in time* $2^{O(k)} \text{poly}(d, \frac{1}{\epsilon})$, *using* $2^{O(k^2)} \log^{k-2}(d) \log(1/\epsilon)$ *random bits, with error probability ϵ. For constant k the running time is* $\text{poly}(d, \frac{1}{\epsilon})$, *and the number of random bits is* $\text{polylog}(d) \log(1/\epsilon)$.
3. *If $\mathcal{C}$ is also multilinear, then we can check if $\mathcal{C}$ is identically zero deterministically in time* $\exp(2^{O(k^2)}) \cdot \text{poly}(d)$. *For constant k the running time is* $\text{poly}(d)$.

Prior to our work the only algorithms that were designed for bounded depth circuits were the deterministic algorithm of [41] for pure multilinear depth 3 circuits and the black box algorithms of [22, 9, 29] for polynomials computed by depth 2 circuits (also known as sparse polynomials). None of the algorithms for sparse polynomials work in the case of depth 3 circuits, as such circuits can compute polynomials with exponentially many monomials. In fact, Klivans and Spielman [29] ask whether one could derandomize PIT for $\Sigma\Pi\Sigma$ circuits with only three multiplication gates ($k = 3$ in our notation). We give a deterministic algorithm that runs in quasi-polynomial time for this case, thus resolving the question of [29]. We note that a complete derandomization is to give a polynomial time algorithm for the problem, as was recently achieved by Kayal and Saxena [27]. We discuss their result in the next subsection.

1.5. Recent results. Kayal and Saxena [27] managed to give a polynomial time algorithm for PIT of depth 3 circuits with bounded top fan-in. Namely, they give an algorithm that runs in time polynomial in d^k, n, where k is the top fan-in, d is the degree of the circuit, and n is the number of variables. This result gives a complete derandomization of identity testing for depth 3 circuits with bounded top fan-in. In addition Kayal and Saxena give constructions of identically zero depth 3 circuits over $\mathbb{F} = GF(p)$ with $k = p$ for odd p, and $k = 3$ for $p = 2$, of degree d and rank $r = \log_p(d)$ (see Theorem 1.4).

We note, however, that for multilinear depth 3 circuits we give a polynomial time algorithm even when the top fan-in is $O(\sqrt{\log \log n})$ (Theorem 1.5, item 3), whereas [27] is polynomial time only when the top fan-in is constant.

1.6. Organization. In section 2 we analyze linear LDCs and derive Theorem 1.2. Section 3 is devoted to $\Sigma\Pi\Sigma$ circuits and their properties and serves as an introduction to the main part of the paper. In section 4 we give the proof of Theorem 1.3 and discuss the relation between $\Sigma\Pi\Sigma$ circuits and LDCs. Finally, in sections 5 and 6 we use our results to prove a structural theorem for zero $\Sigma\Pi\Sigma$ circuits and devise PIT algorithms based on this theorem.

2. Locally decodable codes. In this section we prove Theorem 1.2. We start by formally defining LDCs.

For a natural number n, let $[n] \triangleq \{1, \ldots, n\}$. Let $\mathbb{F}$ be a field. For a vector $x \in \mathbb{F}^n$ we write x_i for the ith coordinate of x. We denote by e_i the ith unit vector. For two

vectors $y, z \in \mathbb{F}^m$, denote by $\Delta(y,z)$ the number of coordinates in which y and z differ.

DEFINITION 2.1. *Let $\delta, \epsilon \in [0,1]$, and let q be an integer. We say that $E : \mathbb{F}^n \to \mathbb{F}^m$ is a* (q,δ,ϵ)-locally decodable code *if there exists a probabilistic oracle machine A such that*

- *in every invocation, A makes at most q queries (nonadaptively);*
- *for every $x \in \mathbb{F}^n$, for every $y \in \mathbb{F}^m$ with $\Delta(y, E(x)) < \delta m$, and for every $i \in [n]$, we have*

$$|\mathbb{F}| < \infty : \quad \boldsymbol{Pr}[A^y(i) = x_i] \geq \tfrac{1}{|\mathbb{F}|} + \epsilon,$$
$$|\mathbb{F}| = \infty : \quad \boldsymbol{Pr}[A^y(i) = x_i] \geq \epsilon,$$

where the probability is taken over the internal coin tosses of A.

We say that the code E is a linear *code if E is a linear transformation between $\mathbb{F}^n$ and $\mathbb{F}^m$.*

We are now ready to prove Theorem 1.2. We repeat its formulation here.

THEOREM 1.2 (restated). *Let $\delta, \epsilon \in [0,1]$, $\mathbb{F}$ be a field, and let $E : \mathbb{F}^n \to \mathbb{F}^m$ be a linear $(2,\delta,\epsilon)$-LDC. Then*

$$m \geq 2^{\frac{\epsilon\,\delta\,n}{4}-1}.$$

Our proof will build on the methods of [18], together with a novel reduction from LDCs over arbitrary fields to LDCs over $GF(2)$. We start by reviewing the results of [18]. The first step of their proof, given by the following lemma, is a reduction from the problem of proving lower bounds for LDCs to a graph-theoretic problem. The first such reduction was given in [26], where it was used to prove lower bounds on general LDCs. We note that in [18] the lemma was proved only over finite fields; however, it is easy to modify the proof to work for infinite fields as well.

LEMMA 2.2 (*implicit in* [18]). *Let $E : \mathbb{F}^n \to \mathbb{F}^m$ be a linear $(2,\delta,\epsilon)$-LDC, and let $a_1, \ldots, a_m \in \mathbb{F}^m$ be vectors such that*

$$E(x) = (\langle a_1, x\rangle, \ldots, \langle a_m, x\rangle)$$

($\langle\cdot,\cdot\rangle$ denotes the standard inner product). Then, for every $i \in [n]$, there exists a set $M_i \subset [m] \times [m]$ of at least $\frac{\epsilon\,\delta\,m}{4}$ disjoint pairs such that for every $(j_1, j_2) \in M_i$, $e_i \in Span\{a_{j_1}, a_{j_2}\}$.

From Lemma 2.2 we see that to prove lower bounds for two-query LDCs, it is sufficient to deal with the more combinatorial setting in which a given multiset of vectors contains many disjoint pairs spanning each unit vector.

The next step in the proof of [18] is a reduction from arbitrary finite fields to $GF(2)$. The next lemma summarizes the reduction given by [18].

LEMMA 2.3 (*implicit in* [18]). *Let $\mathbb{F}$ be a finite field, and let $a_1, \ldots, a_m \in \mathbb{F}^n$. For every $i \in [n]$ let $M_i \subset [m] \times [m]$ be a set of disjoint pairs of indices such that $e_i \in Span\{a_{j_1}, a_{j_2}\}$ for every $(j_1, j_2) \in M_i$. Then, there exist m' vectors $b_1, \ldots, b_{m'} \in \{0,1\}^n$ and n sets $M'_1, \ldots, M'_n \subset [m'] \times [m']$ of disjoint pairs such that*

1. *for every $(j_1, j_2) \in M'_i$, $b_{j_1} \oplus b_{j_2} = e_i$,*
2. *$m' = (|\mathbb{F}| - 1)m$, and*
3. *$\sum_{i=1}^n |M_i| \leq 2m + \frac{2}{|\mathbb{F}|-1} \sum_{i=1}^n |M'_i|$.*

The third and final step in the proof of [18] is a lemma which bounds the size of the matchings M_i, when the underlying field is $GF(2)$.

LEMMA 2.4 (*see* [18]). *Let $a_1, \ldots, a_m$ be elements of $\{0,1\}^n$. For every $i \in [n]$ let $M_i \subset [m] \times [m]$ be a set of disjoint pairs of indices such that $e_i = a_{j_1} \oplus a_{j_2}$ for every $(j_1, j_2) \in M_i$. Then*

$$\sum_{i=1}^{n} |M_i| \leq \frac{1}{2} m \log(m).$$

Notice that by Lemma 2.3 we have that $m = m'/|\mathbb{F}|$. Therefore, to get significant bounds from the combination of Lemmas 2.2, 2.3, and 2.4, we need $|\mathbb{F}|$ to be much smaller than 2^n. Thus, for very large fields (in particular, infinite fields) we do not get a significant result.

Our proof differs from that of [18] only in its second part—the reduction from $\mathbb{F}$ to $GF(2)$. Our reduction holds for any field, in particular for infinite $\mathbb{F}$, and does not involve the field size as a parameter.

LEMMA 2.5. *Let $\mathbb{F}$ be any field, and let $a_1, \ldots, a_m \in \mathbb{F}^n$. For every $i \in [n]$ let $M_i \subset [m] \times [m]$ be a set of disjoint pairs of indices such that $e_i \in Span\{a_{j_1}, a_{j_2}\}$ for every $(j_1, j_2) \in M_i$. Then, there exist m vectors $b_1, \ldots, b_m \in \{0,1\}^n$, and n sets $M_1'', \ldots, M_n'' \subset [m] \times [m]$ of disjoint pairs, such that*

1. *for every $(j_1, j_2) \in M_i''$, $b_{j_1} \oplus b_{j_2} = e_i$, and*
2. *$\sum_{i=1}^{n} |M_i| \leq 2 \sum_{i=1}^{n} |M_i''| + m$.*

Before giving the proof of the lemma we combine Lemmas 2.2, 2.5, and 2.4 to prove Theorem 1.2.

Proof of Theorem 1.2. Let $a_1, \ldots, a_m \in \mathbb{F}^n$ be vectors such that

$$E(x) = (\langle a_1, x \rangle, \ldots, \langle a_m, x \rangle).$$

From Lemma 2.2, we know that there exist n sets, $M_1, \ldots, M_n \subset [m] \times [m]$, of disjoint pairs of indices, such that for every $(j_1, j_2) \in M_i$ we have $e_i \in Span\{a_{j_1}, a_{j_2}\}$. We also know that

$$\forall\, i \in [n],\ |M_i| \geq \frac{\epsilon\, \delta\, m}{4}.$$

Now, let $b_1, \ldots, b_m \in \{0,1\}^n$ and $M_1'', \ldots, M_n'' \subset [m] \times [m]$ be as in Lemma 2.5. That is,

1. for every $(j_1, j_2) \in M_i''$, $b_{j_1} \oplus b_{j_2} = e_i$, and
2. $\sum_{i=1}^{n} |M_i| \leq 2 \sum_{i=1}^{n} |M_i''| + m$.

Using Lemma 2.4, we now have

$$\sum_{i=1}^{n} |M_i''| \leq \frac{1}{2} m \log(m).$$

This implies

$$n \cdot \frac{\epsilon\, \delta\, m}{4} \leq \sum_{i=1}^{n} |M_i| \leq 2 \sum_{i=1}^{n} |M_i''| + m \leq m \log(m) + m,$$

which, after division by m, gives the bound stated by the theorem. □

We now give the proof of Lemma 2.5.

Proof of Lemma 2.5. The proof will consist of two stages. First, we will remove a relatively small number of "bad" pairs from the given matchings $\{M_i\}$; then we

will transform the vectors $a_1, \ldots, a_m$ to vectors in $\{0,1\}^n$, while preserving a large portion of the pairs spanning the unit vectors.

Let (j_1, j_2) be a pair in M_i for some i such that either a_{j_1} or a_{j_2} are parallel to the unit vector e_i. Without loss of generality (w.l.o.g.) assume $a_{j_1} = c \cdot e_i$. We replace this pair with the pair (j_1, j_1). We do the same for all pairs containing a vector parallel to the unit vector spanned by this pair. This change does not affect the parameters of the lemma and is done only to simplify the analysis.

Next, we define a function $\theta : \mathbb{F}^n \backslash \{0\} \to [n]$ by

$$\theta(v) = \min\{i : v_i \neq 0\}.$$

For the rest of the proof we assume w.l.o.g. that in each pair (j_1, j_2) we have $\theta(a_{j_1}) \leq \theta(a_{j_2})$. (Note that we can assume w.l.o.g. that the vectors $a_1, \ldots, a_m$ are all different from zero.) We remove from each matching M_i all the pairs (j_1, j_2) in which $\theta(a_{j_1}) = i$. (This includes all pairs (j_1, j_1) described in the previous paragraph, and more.) Denote the resulting matching by M_i'. We claim that the total number of pairs removed in this stage is at most m.

Claim 2.6.

$$\sum_{i=1}^{n} |M_i| \leq \sum_{i=1}^{n} |M_i'| + m. \tag{2}$$

Proof. Let $p_1 = (j_1, j_2)$ and $p_2 = (k_1, k_2)$ be two removed pairs. If p_1 and p_2 were in the same matching M_i, then they would be disjoint, and so $j_1 \neq k_1$. If the pairs belonged to two different matchings, say, M_{i_1} and M_{i_2}, then $\theta(a_{j_1}) = i_1$ and $\theta(a_{k_1}) = i_2$, and again we get that $j_1 \neq k_1$. It follows that every removed pair has a distinct first element in the set $[m]$. Therefore, the total number of removed pairs cannot exceed m. ∎

In the following we assume w.l.o.g. that the first nonzero coordinate of each a_j is one. (We can assume that because we are allowed to use arbitrary linear combinations of the a_j when spanning the e_i.) The next claim asserts an important property of the matchings M_i'.

Claim 2.7. *For every $i \in [n]$ and $(j_1, j_2) \in M_i'$,*

$$e_i \in \mathit{Span}\{a_{j_1} - a_{j_2}\}.$$

Proof. Let $u = a_{j_1}$, $v = a_{j_2}$. We know that there exist two nonzero coefficients $\alpha, \beta \in \mathbb{F}$ such that $\alpha u + \beta v = e_i$. (Both coefficients are nonzero because we removed from M_i all pairs containing a vector parallel to e_i.) From this property it is clear that $\theta(u) \leq i$ (remember that $\theta(u) \leq \theta(v)$). As we removed all pairs in which $\theta(a_{j_1}) = i$ we conclude that $\theta(u) < i$. This in turn implies that $\theta(u) = \theta(v) < i$, because if $\theta(v) > \theta(u)$, then the vector $\alpha u + \beta v = e_i$ would have a nonzero coordinate in position $\theta(u) < i$. Now, since $v_{\theta(v)} = u_{\theta(u)} = 1$ we have that $\alpha + \beta = (\alpha u + \beta v)_{\theta(u)} = (e_i)_{\theta(u)} = 0$. Hence $e_i \in \mathit{Span}\{a_{j_1} - a_{j_2}\}$. ∎

Let us now proceed to the second stage of the proof of Lemma 2.5, in which we move from the field $\mathbb{F}$ to $GF(2)$. We will use a probabilistic argument to show the existence of a transformation that maps $\mathbb{F}$ to $GF(2)$, while preserving a large portion of the pairs that span a given unit vector.

For each $i \in [n]$, let a_{ji} denote the ith coordinate of the vector a_j. Let $V = \{a_{ji}\}_{j \in [m],\, i \in [n]}$ be the set of all field elements appearing in one of the vectors $a_1, \ldots, a_m$.

We pick a random function $f : V \to \{0,1\}$ and apply f to all the coordinates in all the vectors. Let

$$b_j = (f(a_{j1}), \ldots, f(a_{jn}))$$

be the vector in $\{0,1\}^n$ obtained from a_j after the transformation. We say that a pair $(j_1, j_2) \in M_i'$ "survived" the transformation if $e_i = b_{j_1} \oplus b_{j_2}$.

CLAIM 2.8. *The expected number of surviving pairs is* $\frac{1}{2}\sum_{i=1}^{n} |M_i'|$.

Proof. Consider a pair $(j_1, j_2) \in M_i'$. Since $e_i \in Span\{a_{j_1} - a_{j_2}\}$ we know that the vectors a_{j_1}, a_{j_2} are identical in all coordinates different from i. Hence, the vectors b_{j_1}, b_{j_2} will also be identical in those coordinates. From this we see that $e_i = b_{j_1} \oplus b_{j_2}$ iff b_{j_1} and b_{j_2} differ in their ith coordinate. This happens with probability of one-half. By linearity of expectation we can conclude that the expected number of surviving pairs is at least half the number of original pairs, which was $\sum_{i=1}^{n} |M_i'|$. ∎

From the above claim we can assert that there exists a function f for which the number of surviving pairs is at least $\frac{1}{2}\sum_{i=1}^{n} |M_i'|$. Thus, we have shown that there exist a set of vectors $b_1, \ldots, b_m \in \{0,1\}^n$ and matchings $M_i'' \subset [m] \times [m]$ such that for every $(j_1, j_2) \in M_i''$, we have $e_i = b_{j_1} \oplus b_{j_2}$. Furthermore, we can assume that

$$\sum_{i=1}^{n} |M_i'| \leq 2 \sum_{i=1}^{n} |M_i''|, \tag{3}$$

which completes the proof of the lemma, since now

$$\sum_{i=1}^{n} |M_i| \leq \sum_{i=1}^{n} |M_i'| + m \leq 2 \sum_{i=1}^{n} |M_i''| + m. \qquad \square$$

The next corollary combines the results of Lemmas 2.5 and 2.4 in a compact form. This corollary will be used in the proof given in section 4.

COROLLARY 2.9. *Let* $\mathbb{F}$ *be any field, and let* $a_1, \ldots, a_m \in \mathbb{F}^n$. *For every* $i \in [n]$ *let* $M_i \subset [m] \times [m]$ *be a set of disjoint pairs of indices* (j_1, j_2) *such that* $e_i \in Span\{a_{j_1}, a_{j_2}\}$. *Then*

$$\sum_{i=1}^{n} |M_i| \leq m \log(m) + m.$$

3. ΣΠΣ circuits. In this section we give some definitions related to ΣΠΣ circuits and describe some elementary operations that can be preformed on them. These definitions and operations will be used in the following sections.

3.1. Definitions. In the following we treat vectors in $\mathbb{F}^n$ also as linear forms in $\mathbb{F}[x_1, \ldots, x_n]$.

DEFINITION 3.1. *Let* $u \in \mathbb{F}^n$, $u = (u_1, \ldots, u_n)$. *Then*

$$u(x) = u_1 x_1 + u_2 x_2 + \cdots + u_n x_n.$$

DEFINITION 3.2. *Let* $v, u \in \mathbb{F}^n \backslash \{0\}$. *We write* $u \sim v$ *if there exists* $c \in \mathbb{F}$ *such that* $u = c \cdot v$.

We proceed to the main definition of this section.

DEFINITION 3.3. *Let $\mathbb{F}$ be a field. A $\Sigma\Pi\Sigma$ circuit, $\mathcal{C}$, over $\mathbb{F}$, with n inputs and k multiplication gates (i.e., top fan-in is k), is the formal expression*

$$\mathcal{C}(x) = \sum_{i=1}^{k} c_i \prod_{j=1}^{d_i} L_{ij}(x),$$

where for each $i \in [k]$, $j \in [d_i]$, L_{ij} is a nonconstant linear function,

$$L_{ij}(x) = L_{ij}^0 + L_{ij}^1 \cdot x_1 + \cdots + L_{ij}^n \cdot x_n,$$

and $c_i, L_{ij}^t \in \mathbb{F}$ for all i, j, t.

For every $i \in [k]$ define N_i to be the ith multiplication gate of $\mathcal{C}$:

$$N_i(x) \triangleq \prod_{j=1}^{d_i} L_{ij}(x).$$

For each $i \in [k]$, d_i is the degree of N_i. The number k denotes the number of different multiplication gates and is referred to as the top fan-in of the circuit. The total degree of $\mathcal{C}$ is $\max\{d_i\}$, and the size of $\mathcal{C}$ is $\sum_{i=1}^{k} d_i$. We denote with $\operatorname{rank}(\mathcal{C})$ the rank of $\mathcal{C}$:

$$\operatorname{rank}(\mathcal{C}) \triangleq \dim(Span\{L_{ij} : i \in [k],\, j \in [d_i]\}).$$

Remark. When dealing with $\Sigma\Pi\Sigma$ circuits, we will always assume that all the linear functions appearing in the circuit are different from zero.

We are interested in $\Sigma\Pi\Sigma$ circuits that compute the zero polynomial in $\mathbb{F}[x_1, \ldots, x_n]$. If $\mathcal{C}$ is such a circuit, we write $\mathcal{C} \equiv 0$. When dealing with circuits of this kind, it is sufficient to consider circuits of limited structure. This notion is made precise by the following definition and the lemma that follows.

DEFINITION 3.4. *Let $k, d > 0$ be integers. A $\Sigma\Pi\Sigma$ circuit $\mathcal{C}$ is called a $\Sigma\Pi\Sigma(k, d)$ circuit if the following three conditions hold:*

- *the top fan-in of $\mathcal{C}$ is k;*
- *$d_1 = d_2 = \cdots = d_k = d$; and*
- *for every $i \in [k]$ and $j \in [d]$, L_{ij} is a homogeneous linear form, that is, $L_{ij}(x) = L_{ij}^1 \cdot x_1 + \cdots + L_{ij}^n \cdot x_n$. (The free coefficient in each linear function is zero.)*

When dealing with $\Sigma\Pi\Sigma(k, d)$ circuits we will treat the linear functions L_{ij} also as vectors in $\mathbb{F}^n$, that is, $L_{ij} = (L_{ij}^1, \ldots, L_{ij}^n)$.

LEMMA 3.5. *There exists a polynomial time algorithm such that, given as input a $\Sigma\Pi\Sigma$ circuit $\mathcal{C}$, with top fan-in k and total degree $d > 0$, it outputs a $\Sigma\Pi\Sigma(k, d)$ circuit $\mathcal{C}'$ such that $\mathcal{C} \equiv 0$ iff $\mathcal{C}' \equiv 0$. The circuit $\mathcal{C}'$ is called the corresponding $\Sigma\Pi\Sigma(k, d)$ circuit of $\mathcal{C}$.*

Proof. We introduce a new variable y and define $\mathcal{C}'$ to be a circuit with input variables $x_1, \ldots, x_n, y$. Let

$$L_{ij}(x) = L_{ij}^0 + \sum_{t=1}^{n} L_{ij}^t \cdot x_t$$

be a linear function appearing in $\mathcal{C}$. Define

$$L'_{ij}(x, y) = L_{ij}^0 \cdot y + \sum_{t=1}^{n} L_{ij}^t \cdot x_t,$$

and define $\mathcal{C}'$ to be

$$\mathcal{C}'(x,y) = \sum_{i=1}^{k} c_i\, y^{d-d_i} \prod_{j=1}^{d_i} L'_{ij}(x,y).$$

Clearly, $\mathcal{C}'$ is a $\Sigma\Pi\Sigma(k,d)$ circuit and can be computed from $\mathcal{C}$ in time polynomial in the size of $\mathcal{C}$. Note that if we write

$$\mathcal{C}(x) = \sum_{i=0}^{d} P_i(x),$$

where $P_i(x)$ denotes the homogeneous part of degree i of $\mathcal{C}(x)$, then

$$\mathcal{C}'(x,y) = \sum_{i=0}^{d} P_i(x) y^{d-i}.$$

Therefore $\mathcal{C} \equiv 0$ iff $\mathcal{C}' \equiv 0$. □

Lemma 3.5 shows that to achieve our final goal, which is to derive PIT algorithms for $\Sigma\Pi\Sigma$ circuits, it is sufficient to consider $\Sigma\Pi\Sigma(k,d)$ circuits. For the rest of the paper we will deal only with $\Sigma\Pi\Sigma(k,d)$ circuits, and we shall sometimes refer to them simply as $\Sigma\Pi\Sigma$ circuits, omitting the suffix (k,d) where it is not needed.

3.2. Identically zero $\Sigma\Pi\Sigma$ circuits.

Simple circuits. It might be the case that there exists a linear function, L, that appears (up to a constant) in all multiplication gates of $\mathcal{C}$. In this case, we can divide each multiplication gate by L and get a simpler circuit $\mathcal{C}'$, whose degree is smaller than that of $\mathcal{C}$ by one. Clearly $\mathcal{C} \equiv 0$ iff $\mathcal{C}' \equiv 0$. The next two definitions deal with this case in a more general way.

DEFINITION 3.6. *Let $\mathcal{C}$ be a $\Sigma\Pi\Sigma$ circuit, and let $N_1, \ldots, N_k$ be its multiplication gates. Define*[4]

$$\gcd(\mathcal{C}) \triangleq \text{g.c.d.}(N_1(x), \ldots, N_k(x)).$$

Since each multiplication gate is a product of linear forms, $N_i(x) = \prod_{j=1}^{d_i} L_{ij}(x)$, we get that $\gcd(\mathcal{C})$ is the product of all the linear forms that appear in all the multiplication gates (up to multiplication by constants). Note also that $\gcd(\mathcal{C})$ can be easily computed from $\mathcal{C}$.

It is clear that $\mathcal{C} \equiv 0$ iff $\frac{\mathcal{C}}{\gcd(\mathcal{C})} \equiv 0$. This fact motivates the following definition.

DEFINITION 3.7. *A $\Sigma\Pi\Sigma$ circuit $\mathcal{C}$ is called* simple *if $\gcd(\mathcal{C}) = 1$. Let us also define $\mathrm{sim}(\mathcal{C})$ to be the simple circuit obtained from $\mathcal{C}$ by dividing each multiplication gate by $\gcd(\mathcal{C})$. It is clear that $sim(\mathcal{C})$ is always simple and that*

$$\mathcal{C}(x) = sim(\mathcal{C})(x) \cdot \gcd(\mathcal{C})(x).$$

Example 3.8. Let

$$\begin{aligned}\mathcal{C}(x) = {} & (\mathbf{x_1} + \mathbf{2x_2} + \mathbf{x_3} + \mathbf{1})(2x_1 + 4x_2 + 5x_3 + 2)(2x_1 + 4x_2 + 2x_3) \\ & + (\mathbf{x_1} + \mathbf{2x_2} + \mathbf{x_3} + \mathbf{1})(6x_1 + 4x_2 + 5x_3)(1x_1 + 1x_2 + 2x_3 + 4) \\ & + (\mathbf{2x_1} + \mathbf{4x_2} + \mathbf{2x_3} + \mathbf{2})(4x_2 + 1x_3)(7x_1 + 4x_2 + 2x_3).\end{aligned}$$

[4] g.c.d. stands for greatest common divisor.

Then

$$\gcd(\mathcal{C}) = x_1 + 2x_2 + x_3 + 1,$$

and

$$\begin{aligned} sim(\mathcal{C})(x) = &(2x_1 + 4x_2 + 5x_3 + 2)(2x_1 + 4x_2 + 2x_3) \\ &+ (6x_1 + 4x_2 + 5x_3)(1x_1 + 1x_2 + 2x_3 + 4) \\ &+ 2 \cdot (4x_2 + 1x_3)(7x_1 + 4x_2 + 2x_3). \end{aligned}$$

Minimal circuits. Suppose we have two $\Sigma\Pi\Sigma$ circuits $\mathcal{C}_1$ and $\mathcal{C}_2$, both of them equal to zero. Let k_1, k_2 denote the top fan-in of $\mathcal{C}_1$ and of $\mathcal{C}_2$, respectively. We can add $\mathcal{C}_1$ to $\mathcal{C}_2$ to create a new circuit $\mathcal{C} = \mathcal{C}_1 + \mathcal{C}_2$, with top fan-in $k_1 + k_2$, that will also be equal to zero. This new circuit $\mathcal{C}$, however, can be broken down into two smaller subcircuits that are zero. In the following we will be interested in circuits that *cannot* be broken down into smaller subcircuits that are equal to zero. The next two definitions deal with circuits of this type.

DEFINITION 3.9. *Let $\mathcal{C}$ be a $\Sigma\Pi\Sigma$ circuit, and let $\emptyset \neq T \subseteq [k]$. Then $\mathcal{C}_T$ is defined to be the subcircuit of $\mathcal{C}$ composed of the multiplication gates whose indices appear in T:*

$$\mathcal{C}_T(x) \triangleq \sum_{i \in T} c_i \prod_{j=1}^{d_i} L_{ij}(x) = \sum_{i \in T} c_i N_i(x).$$

DEFINITION 3.10. *Let $\mathcal{C} \equiv 0$ be a $\Sigma\Pi\Sigma$ circuit. We say that $\mathcal{C}$ is* minimal *if for every nonempty subset $T \subset [k]$, apart from $[k]$ itself, we have $\mathcal{C}_T \not\equiv 0$.*

The following easy claim shows that most properties of a $\Sigma\Pi\Sigma$ circuit $\mathcal{C}$ remain when we move to the corresponding $\Sigma\Pi\Sigma(k, d)$ circuit. The proof is immediate from the proof of Lemma 3.5.

CLAIM 3.11. *Let $\mathcal{C}$ be a $\Sigma\Pi\Sigma$ circuit, and let $\mathcal{C}'$ be the corresponding $\Sigma\Pi\Sigma(k, d)$ circuit (as defined in Lemma 3.5). Then we have the following:*

- $\operatorname{rank}(\mathcal{C}) \leq \operatorname{rank}(\mathcal{C}') \leq \operatorname{rank}(\mathcal{C}) + 1$.
- *$\mathcal{C}$ is simple iff $\mathcal{C}'$ is simple.*
- *$\mathcal{C}$ is minimal iff $\mathcal{C}'$ is minimal.*

Taking a linear transformation. We start with a simple operation of setting one of the variables to zero. This operation can be looked at as projecting all the linear functions in the circuit on a subspace of codimension 1.

DEFINITION 3.12. *Let $\mathcal{C}$ be a $\Sigma\Pi\Sigma$ circuit, and let $t \in [n]$. Define $\mathcal{C}|_{x_t=0}$ to be the circuit obtained from $\mathcal{C}$ by setting the variable x_t to zero. (This is the same as changing the tth coordinate in each linear form L_{ij} to zero.) The polynomial computed by $\mathcal{C}|_{x_t=0}$ is therefore*

$$(\mathcal{C}|_{x_t=0})(x) = \mathcal{C}(x_1, \ldots, x_{t-1}, 0, x_{t+1}, \ldots, x_n).$$

We can generalize the operation just defined by applying a general linear transformation on the linear functions of the circuit.

DEFINITION 3.13. *Let*

$$\mathcal{C}(x) = \sum_{i=1}^{k} c_i \prod_{j=1}^{d} L_{ij}(x)$$

be a $\Sigma\Pi\Sigma(k,d)$ circuit on n variables, and let $\pi : \mathbb{F}^n \to \mathbb{F}^n$ be a linear transformation. Define $\pi(\mathcal{C})$ to be the circuit obtained from $\mathcal{C}$ by applying π on all linear forms appearing in the circuit.[5] *That is,*

$$\pi(\mathcal{C})(x) = \sum_{i=1}^{k} c_i \prod_{j=1}^{d} \pi(L_{ij})(x).$$

The following claim is easy to verify.

CLAIM 3.14. *Let $\mathcal{C}$ be a $\Sigma\Pi\Sigma(k,d)$ circuit, and let $\pi : \mathbb{F}^n \to \mathbb{F}^n$ be an invertible linear transformation. Then*

- *$\mathcal{C} \equiv 0$ iff $\pi(\mathcal{C}) \equiv 0$,*
- *$\mathcal{C}$ is simple iff $\pi(\mathcal{C})$ is simple,*
- *$\mathcal{C}$ is minimal iff $\pi(\mathcal{C})$ is minimal, and*
- *$\operatorname{rank}(\mathcal{C}) = \operatorname{rank}(\pi(\mathcal{C}))$.*

4. ΣΠΣ circuits and LDCs. In this section we prove Theorem 1.3, which is the main result of the paper. This theorem shows the relation between $\Sigma\Pi\Sigma$ circuits and linear LDCs. It is more convenient to us to prove the theorem for $\Sigma\Pi\Sigma(k,d)$ circuits instead of general $\Sigma\Pi\Sigma$ circuits. From Claim 3.11, we know that moving from $\mathcal{C}$ to its corresponding $\Sigma\Pi\Sigma(k,d)$ circuit does not affect any of the relevant properties of $\mathcal{C}$, so the following theorem is equivalent to Theorem 1.3.

THEOREM 4.1. *Let $k \geq 3$, $d \geq 2$, and let $\mathcal{C} \equiv 0$ be a simple and minimal $\Sigma\Pi\Sigma(k,d)$ circuit, on n inputs, over a field $\mathbb{F}$. Then, there exists a linear $(2, \frac{1}{12}, \frac{1}{4})$-LDC $E : \mathbb{F}^{n_1} \to \mathbb{F}^{n_2}$, with*

$$\frac{\operatorname{rank}(\mathcal{C})}{P(k)\log(d)^{k-3}} \leq n_1 \quad \text{and} \quad n_2 \leq k \cdot d, \quad \text{where} \quad P(k) = 2^{O(k^2)}.$$

We prove Theorem 4.1 by induction on k. We devote section 4.1 to the base case of $k = 3$ and give the proof of the inductive step in section 4.2.

Before moving on to the proof of Theorem 4.1 we should explain why we are dealing only with circuits whose top fan-in is at least 3. The reason for this is that the structure of a zero $\Sigma\Pi\Sigma(k,d)$ circuit with $k = 1, 2$ is trivial. If $\mathcal{C}$ has only one multiplication gate ($k = 1$), then it is zero iff one of the linear functions appearing in it is the zero function. The case of $k = 2$ is equally trivial, as seen by the next claim.

CLAIM 4.2. *Let $\mathcal{C} = c_1 N_1(x) + c_2 N_2(x)$ be a $\Sigma\Pi\Sigma(2,d)$ circuit. Suppose $\mathcal{C} \equiv 0$. Then, the linear functions, appearing in the two multiplication gates N_1 and N_2, are the same, up to an ordering and multiplication by constants.*

Proof. Since $\mathcal{C} \equiv 0$, we have that $c_1 N_1(x) \equiv -c_2 N_2(x)$. Each multiplication gate N_i is a product of linear functions. Since every polynomial can be written, in a unique way, as a product of irreducible polynomials, and since every linear function is irreducible, we have that the linear functions in the two gates must be the same (up to an ordering and multiplication by constants). ∎

4.1. Proof of Theorem 4.1 for $k = 3$. Let $r = \operatorname{rank}(\mathcal{C})$. Then there exist r linearly independent functions $L_1, \ldots, L_r$ in $\mathcal{C}$. Using Claim 3.14, we can assume w.l.o.g. that for every $t \in [r]$, $L_t(x) = x_t$ (or in other words, $L_t = e_t$). Consider the circuit $\mathcal{C}|_{x_t=0}$ for some $t \in [r]$. Clearly $\mathcal{C}|_{x_t=0} \equiv 0$. From the fact that the function $L_t = e_t$ appears in one of the multiplication gates, we know that this gate

[5] Remember that we identify linear forms with vectors in $\mathbb{F}^n$.

will become zero in $\mathcal{C}|_{x_t=0}$. The following claim assures us that neither of the other two multiplication gates will become zero in $\mathcal{C}|_{x_t=0}$.

CLAIM 4.3. *Let L and L' be two linear functions appearing in two different multiplication gates of $\mathcal{C}$. Then $L \not\sim L'$.*

Proof. Assume for a contradiction that L divides both N_1 and N_2. As $c_3N_3(x) = -c_1N_1(x) - c_2N_2(x)$ we get that $N_3(x)$ is also divisible by L. But $\mathcal{C}$ is simple, so this is a contradiction. □

How can a circuit with two nonzero multiplication gates be zero? From Claim 4.2, this is possible only if the two gates contain the same linear functions, up to an ordering and multiplication by constants.

We thus get that every variable x_t, $t \in [r]$, induces a matching on the linear functions of the circuit. This matching contains d pairs of linear functions such that for every pair (L, L') in the matching, we have that L and L' belong to two different multiplication gates and that $L|_{x_t=0} \sim L'|_{x_t=0}$. Denote with M_t the matching induced by x_t. The next claim gives us more information about the pairs appearing in those matchings.

CLAIM 4.4. *Let $t \in [n]$, and let $L, L' \in \mathbb{F}^n$ such that $L \not\sim L'$, and $L|_{x_t=0} \sim L'_{x_t=0}$. Then*

$$e_t \in Span\{L, L'\}.$$

Proof. Let $L = (a_1, \ldots, a_n)$, $L' = (b_1, \ldots, b_n)$. Since $L|_{x_t=0} \sim L'|_{x_t=0}$, we know that there exists a constant $c \in \mathbb{F}$ such that for all $j \neq t$ we have $a_j = c \cdot b_j$. The fact that $L \not\sim L'$ implies that $a_t \neq c \cdot b_t$. It follows that $e_t \sim L - c \cdot L'$. In particular we get that $e_t \in Span\{L, L'\}$. □

From Claim 4.4 we see that every pair $(L, L') \in M_t$ spans the vector e_t. We also have that all the matchings $\{M_t\}_{t \in r}$ are contained in a set of $3d$ linear functions and that each matching contains d pairs. We can now construct a linear LDC in the following way. For each $i \in [3]$, $j \in [d]$, let $l_{ij} \in \mathbb{F}^r$ be the projection of L_{ij} on the first r coordinates. Define $E : \mathbb{F}^r \to \mathbb{F}^{3d}$ by

$$E_{ij}(x) = l_{ij}(x).$$

To show that E is a $(2, \frac{1}{12}, \frac{1}{4})$-LDC, we need to show a decoding algorithm for it. For each $t \in [r]$ we know that there are d disjoint pairs of code positions that span e_t. (Note that taking the projection on the first r coordinates does not affect this property.) To decode x_t we simply pick a random pair, uniformly, among these d pairs, and compute the linear combination giving e_t. Suppose we picked $l_{ij}(x)$ and $l_{i'j'}(x)$. We know that there exist constants $a, b \in \mathbb{F}$ such that

$$a \cdot l_{ij} + b \cdot l_{i'j'} = e_t.$$

Therefore

$$a \cdot E_{i,j}(x) + b \cdot E_{i',j'}(x) = a \cdot l_{ij}(x) + b \cdot l_{i'j'}(x) = e_t(x) = x_t.$$

If our codeword has at most $\frac{1}{12}(3d) = \frac{d}{4}$ corrupted positions, then at least $\frac{3}{4}$ of the d pairs are uncorrupted, and our algorithm will succeed with probability greater than $\frac{3}{4}$.

In the notation of the theorem, we have $n_1 = r$ and $n_2 = 3d = kd$. Let $P(3) = 1$; then

$$n_1 = r \geq \frac{r}{P(k)\log(d)^{k-3}},$$

and the theorem follows for $k = 3$.

4.2. Proof of Theorem 4.1 for $k \geq 4$. The proof is by induction on k. The idea behind the proof is the following. Assume that x_1 appears as a linear function in the circuit. A natural thing to do is to consider $\mathcal{C}|_{x_1=0}$. This circuit contains fewer multiplication gates, and so we would like to find an LDC in it by induction. A possible problem is that the rank of every minimal subcircuit is low. We can overcome this problem by showing that there are many variables $x_1, \ldots, x_m$ ($m \geq r/2^k$) such that there exists $I \subset [k]$ for which $\mathcal{C}_I \not\equiv 0$, but for every $t \in [m]$, $(\mathcal{C}_I)|_{x_t=0}$ is identically zero and minimal. In particular we show that this implies that the rank of $\mathcal{C}_I$ is at least m. We would like to construct a code from $\mathcal{C}_I$, so we consider, say, $(\mathcal{C}_I)|_{x_1=0}$. This circuit is identically zero and minimal, but it is not necessarily simple. Therefore we take $sim((\mathcal{C}_I)|_{x_t=0})$. However, it might be the case that the rank of this circuit is very small, i.e., that we lost a lot of rank when we removed the g.c.d. We overcome this difficulty by proving that there are relatively few ($\approx \log d$) variables, say, $x_1, \ldots, x_{\log d}$, such that the span of the linear functions in $sim((\mathcal{C}_I)|_{x_t=0})_{t=1,\ldots,\log d}$ contains almost all the functions of $\mathcal{C}_I$. In particular, for some t, the rank of $sim((\mathcal{C}_I)|_{x_t=0})$ is relatively high, so we can apply the induction hypothesis on this circuit. Proving the existence of such t is the main technical difficulty of the proof (Claim 4.8). We now give the formal proof.

Let $k \geq 4$, and assume the correctness of Theorem 4.1 for all $3 \leq k' < k$. Let

$$\mathcal{C}(x) = \sum_{i=1}^{k} c_i \prod_{j=1}^{d} L_{ij}(x)$$

be a $\Sigma\Pi\Sigma(k,d)$ circuit satisfying the conditions of the theorem. As in the proof for $k = 3$, let $r = \text{rank}(\mathcal{C})$, and w.l.o.g. assume that the circuit contains the first r unit vectors $e_1, \ldots, e_r$. We can also assume that

$$r \geq P(k) \log(d)^{k-3}, \tag{4}$$

for otherwise the theorem is trivially true, since we can always construct a two-query LDC whose message size is 1, satisfying the requirements of the theorem.

CLAIM 4.5. *For every $t \in [r]$ there exists a set $I_t \subset [k]$ such that*

1. $2 \leq |I_t| \leq k-1$ *and*
2. $(\mathcal{C}|_{x_t=0})_{I_t}$ *is identically zero and minimal.*

Proof. Let $t \in [r]$. Clearly $\mathcal{C}|_{x_t=0} \equiv 0$. Denote with k' the number of multiplication gates in $\mathcal{C}$ that become zero when $x_t = 0$. (These are exactly those multiplication gates that contain a linear function parallel to e_t.) Since we assumed that $\mathcal{C}$ contains e_t, we know that $k' \geq 1$. It is also easy to verify that $k' \leq k-2$. (If $k' = k$, then $\mathcal{C}$ is not simple, and if $k' = k-1$, then $\mathcal{C}$ is not divisible by x_t—as in Claim 4.3.) Therefore, the circuit $\mathcal{C}|_{x_t=0}$ is identically zero and contains at least two (and at most $k-1$) nonzero multiplication gates. Hence, we can decompose $\mathcal{C}|_{x_t=0}$ into minimal subcircuits, each of top fan-in at least two and at most $k-1$. Take I_t to be the index set of any one of these minimal subcircuits. ∎

From Claim 4.5 we can conclude that there are $m \geq \frac{r}{2^k}$ variables (w.l.o.g. $x_1, \ldots, x_m$) that have the same set I_t. Let $I = I_1 = \cdots = I_m$, and define

$$\hat{\mathcal{C}} = sim(\mathcal{C}_I).$$

The next claim summarizes several facts we know about the circuit $\hat{\mathcal{C}}$.

CLAIM 4.6.
1. $\hat{\mathcal{C}}$ *is a* $\Sigma\Pi\Sigma(\hat{k},\hat{d})$ *circuit with* $2 \le \hat{k} \le k-1$, $0 < \hat{d} \le d$.
2. $\hat{\mathcal{C}}$ *is simple.*
3. $\hat{\mathcal{C}} \not\equiv 0$.
4. *For all* $t \in [m]$, $\hat{\mathcal{C}}|_{x_t=0} \equiv 0$ *and is minimal.*
5. *For all* $t \in [m]$, e_t *does not appear in* $\hat{\mathcal{C}}$.

Proof. Parts 1 and 2 follow from the definition of $\hat{\mathcal{C}}$ (the fact that $0 < \hat{d}$ follows from 3 and 4). Part 3 is true because we assumed that $\mathcal{C}$ is minimal. Part 4 follows from the fact that $\hat{\mathcal{C}} = sim(\mathcal{C}_I)$ and that $(\mathcal{C}_I)|_{x_t=0} \equiv 0$ is minimal for all $t \in [m]$. Finally, 5 is a direct consequence of 4. □

Let $\hat{r} \triangleq \text{rank}(\hat{\mathcal{C}})$. The next claim shows that the rank of our chosen subcircuit $\hat{\mathcal{C}}$ is not considerably smaller than the rank of $\mathcal{C}$.

CLAIM 4.7. $\hat{r} \ge m$ $(\ge \frac{r}{2^k})$.

Proof. To prove the claim, we will show that the linear functions of $\hat{\mathcal{C}}$ span the unit vectors $e_1, \ldots, e_m$. Suppose, on the contrary, that there exists an index $t \in [m]$ for which e_t is not spanned by the linear functions of $\hat{\mathcal{C}}$. Assume w.l.o.g. that $t = 1$. There exists an invertible linear transformation $\pi : \mathbb{F}^n \to \mathbb{F}^n$ that satisfies the following two constraints:

- $\pi(e_1) = e_1$.
- The variable x_1 does not appear in the circuit $\pi(\hat{\mathcal{C}})$. (Equivalently, all the linear functions in $\pi(\hat{\mathcal{C}})$ are orthogonal to e_1.)

From Claim 4.6 we know that $\hat{\mathcal{C}} \not\equiv 0$ and that $\hat{\mathcal{C}}|_{x_1=0} \equiv 0$. Hence $\hat{\mathcal{C}}(x)$ can be written as

$$\hat{\mathcal{C}}(x) \equiv x_1 \cdot g(x),$$

where $g(x)$ is a nonzero polynomial. We can look at the transformation π as a linear change of variables and denote with $\pi(g)$ the polynomial obtained from $g(x)$ after this change. Thus,

$$\pi(\hat{\mathcal{C}})(x) \equiv \pi(x_1) \cdot \pi(g)(x) \equiv x_1 \cdot \pi(g)(x). \tag{5}$$

Now, since $g(x) \not\equiv 0$, and since π is invertible, Claim 3.14 implies[6] that $\pi(g)(x) \not\equiv 0$. From this and from (5) we see that $\pi(\hat{\mathcal{C}})(x)$ is a nonzero polynomial divisible by x_1. This is a contradiction, since we assumed that x_1 does not appear in $\pi(\hat{\mathcal{C}})$. □

We would like to use the inductive hypothesis on a well-chosen circuit among $\hat{\mathcal{C}}|_{x_1=0}, \ldots, \hat{\mathcal{C}}|_{x_m=0}$. However, there are two obstacles in the way. The first is that the top fan-in of $\hat{\mathcal{C}}$ might be equal to 2 (the theorem holds only for $k \ge 3$). This case is rather simple, since we can use the analysis given in section 4.1 to construct an LDC satisfying the conditions of the theorem. (A detailed analysis of this special case is deferred to the end of this section.) From now on we assume that $\hat{k} \ge 3$. The second obstacle is that these circuits are not necessarily simple. We overcome this obstacle by using the inductive hypothesis on $sim(\hat{\mathcal{C}}|_{x_t=0})$ instead. The next claim, whose proof is deferred to section 4.3, tells us which of these circuits we should pick.

For each $t \in [m]$, let $r_t \triangleq \text{rank}(sim(\hat{\mathcal{C}}|_{x_t=0}))$.

CLAIM 4.8. *There exists* $t \in [m]$ *such that*

$$r_t \ge \frac{\hat{r}}{2^{k+1}\log(d)}.$$

[6] It is easy to see that this part of Claim 3.14 holds also for general polynomials and not just $\Sigma\Pi\Sigma$ circuits.

Claim 4.8 assures us that one of the r_t is large (we assume w.l.o.g. that $t = 1$). We get that

$$r_1 \geq \frac{\hat{r}}{2^{k+1}\log(d)}. \tag{6}$$

Our next step is to apply the induction hypothesis to the circuit $sim(\hat{\mathcal{C}}|_{x_1=0})$. However, to use Theorem 4.1, we require that the degree of the given circuit be at least two. The next claim shows that the degree of $sim(\hat{\mathcal{C}}|_{x_1=0})$ is indeed at least two.

CLAIM 4.9. *Let d_1 denote the degree of $sim(\hat{\mathcal{C}}|_{x_1=0})$. Then $d_1 \geq 2$.*

Proof. If $d_1 < 2$, then $r_1 < k$. (The number of linear functions is at most $\hat{k} < k$.) By (6) we get that

$$\hat{r} \leq k2^{k+1}\log(d).$$

Now, using the fact that $\hat{r} \geq m \geq \frac{r}{2^k}$ (Claim 4.7), we conclude that

$$r \leq 2^k\hat{r} \leq k2^{2k+1}\log(d),$$

contradicting (4), for an appropriate choice of $P(k) = 2^{O(k^2)}$. ∎

Therefore $sim(\hat{\mathcal{C}}|_{x_1=0})$ satisfies all the conditions of Theorem 4.1. The induction hypothesis, applied on $sim(\hat{\mathcal{C}}|_{x_1=0})$, asserts that there exists a $(2, \frac{1}{12}, \frac{1}{4})$-LDC, $E : \mathbb{F}^{n_1} \to \mathbb{F}^{n_2}$, with

$$n_1 \geq \frac{r_1}{P(\hat{k})\log(d_1)^{\hat{k}-3}} \quad \text{and} \quad n_2 \leq \hat{k} \cdot d_1 \ (\leq k \cdot d).$$

Using (6) and the facts that $\hat{k} \leq k - 1$ and $\hat{r} \geq m \geq \frac{r}{2^k}$, we derive the following inequalities:

$$\begin{aligned} n_1 &\geq \frac{r_1}{P(\hat{k})\log(d_1)^{\hat{k}-3}} \\ &\geq \frac{r_1}{P(k-1)\log(d)^{k-4}} \\ &\geq \frac{\hat{r}}{2^{k+1}P(k-1)\log(d)^{k-3}} \\ &\geq \frac{r}{2^{2k+1}P(k-1)\log(d)^{k-3}} \\ &\geq \frac{r}{P(k)\log(d)^{k-3}} \end{aligned}$$

(for an appropriate choice of $P(k) = 2^{O(k^2)}$). This completes the proof of the inductive step and of Theorem 4.1.

4.2.1. A special case: $\hat{k} = 2$. In this subsection we analyze a special case of the proof of Theorem 4.1. This case is when $\hat{k}$ (the top fan-in of the circuit $\hat{C}$, whose properties are detailed in Claim 4.6) is equal to 2. The analysis of this case differs from the analysis of the general ($\hat{k} \geq 3$) case because we cannot apply the inductive hypothesis on $\hat{C}$ (or more precisely, on the circuits $C|_{x_t=0}$). We now show how to complete the proof of the theorem (that is, to construct an LDC satisfying the requirements of the thorem) in this case.

Denote by $\hat{N}_1$ and $\hat{N}_2$ the two multiplication gates of $\hat{\mathcal{C}}$. We can write

$$\hat{\mathcal{C}}(x) \equiv c_1\hat{N}_1(x) + c_2\hat{N}_2(x).$$

Now, since $\hat{\mathcal{C}}$ is simple and nonzero, we have

$$\gcd(\hat{\mathcal{C}}) \equiv \text{g.c.d.}(\hat{N}_1(x), \hat{N}_2(x)) \equiv 1.$$

Next, let $t \in [m]$, and consider what happens to $\hat{\mathcal{C}}$ after we set x_t to zero. We know that $\hat{\mathcal{C}}|_{x_t=0} \equiv 0$, and so

$$c_1\hat{N}_1|_{x_t=0} \equiv -c_2\hat{N}_2|_{x_t=0}.$$

Now, since $\hat{N}_1|_{x_t=0}$ and $\hat{N}_2|_{x_t=0}$ are both nonzero (by Claim 4.6, $e_1, \ldots, e_m$ do not appear in $\hat{\mathcal{C}}$), we can deduce, as we did in section 4.1, that there exist m matchings M_t, $t \in [m]$, of size $|M_t| = \hat{d}$, of linear functions appearing in $\hat{\mathcal{C}}$, such that for every pair $(L, L') \in M_t$, $e_t \in Span\{L, L'\}$. Projecting each linear function in $\hat{\mathcal{C}}$ on the first m coordinates, and using the construction from section 4.1, we see that there exists a $(2, \frac{1}{12}, \frac{1}{4})$-LDC,[7] $E : \mathbb{F}^m \to \mathbb{F}^{2\hat{d}}$. In the notation of the theorem, we have

$$n_2 = 2\hat{d} \leq kd$$

and

$$n_1 = m \geq \frac{r}{2^k} \geq \frac{r}{P(k)\log(d)^{k-3}},$$

as required by the theorem.

4.3. Proof of Claim 4.8. In this section we prove Claim 4.8. The following notation is required for the proof.

4.3.1. Notation. Let $\hat{N}_1, \ldots, \hat{N}_{\hat{k}}$ denote the multiplication gates of $\hat{\mathcal{C}}$. We will treat $\hat{\mathcal{C}}, \hat{N}_1, \ldots, \hat{N}_{\hat{k}}$ also as sets of indices. We shall abuse notation and write

$$\hat{\mathcal{C}} = \{(i,j) \mid i \in [\hat{k}],\, j \in [\hat{d}]\},$$

$$\hat{N}_i = \{(i,j) \mid j \in [\hat{d}]\}.$$

For a set $H \subset \hat{\mathcal{C}}$, we denote with $\text{rank}(H)$ the dimension of the vector space spanned by the linear functions whose indices appear in H. That is,

$$\text{rank}(H) \triangleq \dim\left(Span\{L_{ij} : (i,j) \in H\}\right).$$

For the rest of the proof we will treat subsets of $\hat{\mathcal{C}}$ interchangeably as sets of indices and as (multi)sets of linear functions.

We would next like to define, for each $t \in [m]$, certain subsets of $\hat{\mathcal{C}}$ that capture the structure of $\hat{\mathcal{C}}|_{x_t=0}$. Fix some $t \in [m]$, and consider what happens to $\hat{\mathcal{C}}$ when we set x_t to be zero. The resulting circuit $\hat{\mathcal{C}}|_{x_t=0}$ is generally not simple and can therefore be partitioned (see Definition 3.7) into two disjoint sets: a set containing the indices of the linear functions appearing in $\gcd(\hat{\mathcal{C}}|_{x_t=0})$, and a set containing the indices of the

[7] We could have taken δ to be $\frac{1}{8}$ instead of $\frac{1}{12}$, because the number of multiplication gates is two and not three.

remaining linear functions (these are the linear functions appearing in $sim(\hat{\mathcal{C}}|_{x_t=0})$). To be more precise, denote by δ_t the degree of $\gcd(\hat{\mathcal{C}}|_{x_t=0})$. In every multiplication gate $\hat{N}_i$, there are δ_t linear functions such that the restriction of their product to the linear space defined by the equation $x_t = 0$ is equal to $\gcd(\hat{\mathcal{C}}|_{x_t=0})$. In other words, the product of these δ_t linear functions is equal to $\gcd(\hat{\mathcal{C}})$ under the restriction $x_t = 0$. Denote the set of indices of these functions by G_t^i, and let $R_t^i \triangleq \hat{N}_i \backslash G_t^i$ be the set of indices of the remaining linear functions of this multiplication gate. We thus have (for some choice of constants $\{c_i\}$)

$$sim(\hat{\mathcal{C}}|_{x_t=0}) = \sum_{i=1}^{\hat{k}} c_i \prod_{(i,j)\in R_t^i} (L_{ij}|_{x_t=0})$$

and

$$\forall i \in [\hat{k}], \qquad \gcd(\hat{\mathcal{C}}|_{x_t=0}) = \prod_{(i,j)\in G_t^i} (L_{ij}|_{x_t=0}).$$

We now define, for each $t \in [m]$, the sets $R_t \triangleq \bigcup_{i=1}^{\hat{k}} R_t^i$ and $G_t \triangleq \bigcup_{i=1}^{\hat{k}} G_t^i$. The following claim summarizes some facts that we will later need.

CLAIM 4.10. *For every $t \in [m]$,*

1. $R_t \cap G_t = \emptyset$.
2. $\hat{\mathcal{C}} = R_t \cup G_t$.
3. $|G_t^i| = |G_t^{i'}|$ *for all* i, i'.
4. $|G_t| = \hat{k} \cdot deg(\gcd(\hat{\mathcal{C}}|_{x_t=0})) = \hat{k} \cdot \delta_t$.
5. R_t *contains the indices of the linear functions appearing in* $sim(\hat{\mathcal{C}}|_{x_t=0})$.
6. $r_t = \mathrm{rank}(sim(\hat{\mathcal{C}}|_{x_t=0})) = \mathrm{rank}(R_t)$.

Proof. Items 1 and 2 follow directly from the definition of R_t and G_t as R_t^i and G_t^i give a partition of the indices in $\hat{N}_i$. Items 3 and 4 hold as the linear factors of $\gcd(\hat{\mathcal{C}}|_{x_t=0})$ belong to all the multiplication gates. By definition, R_t^i is the set of linear functions in $\hat{N}_i$ that belong to $sim(\hat{\mathcal{C}}|_{x_t=0})$, which implies item 5. Finally, by definition, $r_t = \mathrm{rank}(sim(\hat{\mathcal{C}}|_{x_t=0}))$ and by item 5 we have that R_t is the set of linear functions appearing in $sim(\hat{\mathcal{C}}|_{x_t=0})$. ∎

4.3.2. The proof. We finally give the proof of Claim 4.8. For convenience we restate it here.

CLAIM 4.8 (restated). *There exists $t \in [m]$ such that*

$$r_t \geq \frac{\hat{r}}{2^{k+1}\log(d)}.$$

We start by assuming that the claim is false. In other words, we assume that for every $t \in [m]$

$$r_t < \frac{\hat{r}}{2^{k+1}\log(d)}. \tag{7}$$

Having defined, for each $t \in [m]$, the sets R_t and G_t, we would now like to show that there exist a small ($\sim \log(d)$) number of sets R_t such that their union covers almost all of $\hat{\mathcal{C}}$. As $\mathrm{rank}(\hat{\mathcal{C}})$ is relatively high, and for each t, $r_t = \mathrm{rank}(R_t)$ is (assumed to be) relatively small, we will get a contradiction. We construct the cover step by step, and in each step we will find an index $t \in [m]$ such that the set R_t covers

at least half the linear functions not yet covered. This idea is made precise by the following claim.

CLAIM 4.11. *For every integer* $1 \le q \le \log(\hat{d})$ *there exist* q *indices* $t_1, \ldots, t_q \in [m]$ *for which*

$$\left| \bigcup_{s=1}^{q} R_{t_s} \right| \ge \hat{k}\hat{d}(1 - 2^{-q}).$$

Proof. The proof proceeds by induction on q.

Base case $q = 1$. To prove the claim for $q = 1$, it is sufficient to show that there exists $t \in [m]$ for which $|R_t| \ge \frac{1}{2}\hat{k}\hat{d}$. Suppose, on the contrary, that for all $t \in [m]$, $|R_t| < \frac{1}{2}\hat{k}\hat{d}$. Claim 4.10 implies that for all $t \in [m]$, $|G_t| \ge \frac{1}{2}\hat{k}\hat{d}$. This in turn implies (by item 3 of Claim 4.10) that for all $t \in [m]$

$$|G_t^1| \ge \frac{1}{2}\hat{d}. \tag{8}$$

The next lemma shows that, under the conditions just described, the linear functions of $\hat{\mathcal{C}}$ "contain" a two-query LDC. We will then apply our results on LDCs from section 2 (namely, Corollary 2.9) to derive a contradiction. Lemma 4.12 is more general than what is required at this point; however, we will need it in its full generality when we handle $q > 1$.

LEMMA 4.12. *Let* $\mathcal{C}$ *be a simple* $\Sigma\Pi\Sigma(k, d)$ *circuit with* n *inputs. Let* $t \in [n]$, $i_t \in [k]$. *Denote* $\delta_t = deg(\gcd(\mathcal{C}|_{x_t=0}))$. *Suppose that the linear functions in* N_{i_t} *are ordered such that*

$$\gcd(\mathcal{C}|_{x_t=0}) = (L_{i_t 1}|_{x_t=0})(x) \cdot (L_{i_t 2}|_{x_t=0})(x) \cdot \cdots \cdot (L_{i_t \delta_t}|_{x_t=0})(x).$$

Then, there exists a matching, $M = \{\mathcal{P}_1, \ldots, \mathcal{P}_g\} \subseteq \mathcal{C} \times \mathcal{C}$, *consisting of* δ_t *disjoint pairs of linear functions, such that for each* $j \in [\delta_t]$,

- *the two linear functions in* $\mathcal{P}_j$ *span* e_t, *and*
- *the first element of* $\mathcal{P}_j$ *is* $L_{i_t j}$.

Proof. As the linear factors of $\gcd(\mathcal{C}|_{x_t=0})$ belong to all the multiplication gates (of $\mathcal{C}|_{x_t=0}$) we can reorder the linear functions in each gate N_i, $i \ne i_t$, such that

$$\forall j \in [\delta_t] \quad : \quad L_{1j}|_{x_t=0} \sim L_{2j}|_{x_t=0} \sim \cdots \sim L_{i_t j}|_{x_t=0} \sim \cdots \sim L_{kj}|_{x_t=0}.$$

As $\mathcal{C}$ is simple, it cannot be the case that, for some j, $L_{i_t j}$ divides all the multiplication gates. Therefore, for every $j \in [\delta_t]$ there exists an index $\alpha(j) \in [k]$ such that $L_{i_t j} \not\sim L_{\alpha(j) j}$. From Claim 4.4 it follows that

$$\forall j \in [\delta_t] \quad : \quad e_t \in Span\{L_{i_t j}, L_{\alpha(j) j}\}.$$

For each $j \in [\delta_t]$ let $\mathcal{P}_j = (L_{i_t j}, L_{\alpha(j) j})$. Set $M = \{\mathcal{P}_1, \ldots, \mathcal{P}_{\delta_t}\}$. It is clear that each $\mathcal{P}_j$ satisfies the two conditions of the lemma and that the $\mathcal{P}_j$ are disjoint. ∎

We continue with the proof of Claim 4.11. From (8) and Lemma 4.12 we conclude that for each $t \in [m]$ there exists a matching $M_t \subset \mathcal{C} \times \mathcal{C}$, containing at least $\frac{1}{2}\hat{d}$ disjoint pairs of linear functions, such that every pair in M_t spans e_t. Corollary 2.9 implies that

$$\frac{1}{2}\hat{d}m \le \sum_{t=1}^{m} |M_t| \le \hat{k}\hat{d}\log(\hat{k}\hat{d}) + \hat{k}\hat{d},$$

which gives

$$m \leq 2\hat{k}\log(\hat{k}\hat{d}) + 2\hat{k} < \log(d)^{k-3}P(k)2^{-k}$$

(for an appropriate choice of $P(k) = 2^{O(k^2)}$). Now, since $m \geq \frac{r}{2^k}$, we have that

$$r < \log(d)^{k-3}P(k),$$

contradicting (4). Therefore our initial assumption was wrong and we conclude that there exists t_1 with $|R_{t_1}| \geq \frac{1}{2}\hat{k}\hat{d}$. This completes the proof of Claim 4.11 for the case of $q = 1$.

Induction step. Let us now assume that we have found $q-1$ indices $t_1, \ldots, t_{q-1} \in [m]$ for which

$$\left|\bigcup_{s=1}^{q-1} R_{t_s}\right| \geq \hat{k}\hat{d}(1 - 2^{-(q-1)}).$$

Let

$$R \triangleq \bigcup_{s=1}^{q-1} R_{t_s}, \tag{9}$$

$$S \triangleq \hat{\mathcal{C}} \backslash R. \tag{10}$$

Then, by our assumption,

$$|S| \leq \hat{k}\hat{d}2^{-(q-1)}. \tag{11}$$

The proof goes along the same lines as the proof for $q = 1$: we show that there exists an index $t \in [m]$ such that R_t covers at least half of S. We will argue that if such an index does not exist, then a contradiction to (4) can be derived. Our main tools in doing so are Lemma 4.12 and Corollary 2.9.

CLAIM 4.13. *There exists $t \in [m]$ such that for all $i \in [\hat{k}]$,*

$$|G_t^i \cap S| < \hat{d}2^{-q}.$$

Roughly, the lemma states that there exists some variable, x_t, such that most of the linear functions in S do not belong to $\gcd(\hat{\mathcal{C}}|_{x_t=0})$. In particular it implies that R_t covers a large fraction of S, as needed.

Proof. Assume, on the contrary, that for every $t \in [m]$ there exists $i_t \in [\hat{k}]$ for which

$$|G_t^{i_t} \cap S| \geq \hat{d}2^{-q}.$$

From Lemma 4.12 we get that, for every $t \in [m]$, there exists a matching M_t, consisting of $\hat{d}2^{-q}$ disjoint pairs of linear functions, such that each pair spans e_t, and that the first element in each pair is in $G_t^{i_t} \cap S$ (from the lemma we actually get that M_t contains $deg(\gcd(\hat{\mathcal{C}}|_{x_t=0}))$ number of pairs, but we are interested only in the pairs whose first element is in $G_t^{i_t} \cap S$).

We would now like to apply Corollary 2.9 on the matchings $\{M_t\}_{t\in[m]}$; however, for our needs, we would also like that all the linear functions in all the matchings will belong to S. We achieve this by projecting all functions in R to zero. As the

dimension of the linear functions in R is small (by our assumption that each r_{t_s} is small) we can find a linear transformation that sends the linear functions in R to zero but leaves many of the linear functions $\{x_t\}$ linearly independent. This is formalized in the next claim.

CLAIM 4.14. *There exists a subset $A \subset [m]$ of size $|A| \geq \frac{m}{2}$ and a linear transformation $\pi : \mathbb{F}^n \to \mathbb{F}^n$ such that*

- $\ker(\pi) = Span(R)$,
- *for all $t \in A$, $\pi(e_t) = e_t$.*

Proof. Calculating, we get that

$$\begin{aligned} \operatorname{rank}(R) &= \operatorname{rank}\left(\bigcup_{s=1}^{q-1} R_{t_s}\right) \leq \sum_{s=1}^{q-1} \operatorname{rank}(R_{t_s}) = \sum_{s=1}^{q-1} r_{t_s} \\ &\leq (q-1)\frac{\hat{r}}{\log(d)2^{k+1}} \leq \frac{r}{2^{k+1}} \leq \frac{m}{2}, \end{aligned} \tag{12}$$

where the second inequality follows from (7), the third inequality follows from the fact that $q \leq \log \hat{d} \leq \log d$ and $\hat{r} \leq r$, and the last inequality follows from the fact that $\frac{r}{2^k} \leq m$. Let $m' = m - \operatorname{rank}(R)$. From (12) we get that $m' \geq m/2$. In particular, there exists a subset $A \subset [m]$, of size $|A| = m'$, such that $Span(\{x_t \mid t \in A\}) \cap Span(R) = \{0\}$. Hence, there exists a linear transformation $\pi : \mathbb{F}^n \to \mathbb{F}^n$ such that

- $\ker(\pi) = Span(R)$,
- for all $t \in A$, $\pi(e_t) = e_t$.

This completes the proof of Claim 4.14. ∎

Let A be the set obtained from the above claim and π the corresponding linear transformation. We assume, w.l.o.g., that $A = [m']$. From here on, we consider only variables x_t such that $t \in [m']$ (i.e., $t \in A$). Fix such $t \in [m']$, and let $M'_t = \pi(M_t)$. In other words, $M'_t = \{(\pi(L), \pi(L'))\}_{(L,L') \in M_t}$. Clearly,

$$|M'_t| = |M_t| \geq \hat{d}2^{-q}. \tag{13}$$

Note that the pairs in M'_t still span e_t, as for any pair $(L.L') \in M_t$, with $e_t = \alpha L + \beta L'$, we have that

$$e_t = \pi(e_t) = \pi(\alpha L + \beta L') = \alpha\pi(L) + \beta\pi(L').$$

Since all the linear functions appearing in R were projected to zero, we know that all the pairs in each M'_t are contained in the multiset[8] $S' \triangleq \{\pi(L) : L \in S\}$.

After this long preparation we apply Corollary 2.9 to the matchings M'_t and derive the following inequality:

$$\sum_{t=1}^{m'} |M'_t| \leq |S'| \log(|S'|) + |S'|. \tag{14}$$

As $|S'| = |S|$ (remember that S' is a multiset), we get by (11) that

$$|S'| \leq \hat{k}\hat{d}2^{-(q-1)}. \tag{15}$$

[8] Note that, as in the proof of Lemma 2.5, we can replace each pair in M'_t that contains the zero vector with a singleton.

By (13), (14), and (15), it follows that

$$m' \cdot (\hat{d}2^{-q}) \leq \sum_{t=1}^{m'} |M'_t| \leq |S'| \log(|S'|) + |S'| \\ \leq \hat{k}\hat{d}2^{-(q-1)} \log(\hat{k}\hat{d}2^{-(q-1)}) + \hat{k}\hat{d}2^{-(q-1)}.$$

From the fact that $k \geq 4$ and $m' \geq m/2$ (and some simple manipulations), we see that for an appropriate choice of $P(k) = 2^{O(k^2)}$

$$m < 2^{-k} P(k) \log(d)^{k-3}.$$

As $m \geq \frac{r}{2^k}$, we get that

$$r < P(k) \log(d)^{k-3},$$

contradicting (4). This completes the proof of Claim 4.13. □

Let us now proceed with the proof of Claim 4.11. Take t_q to be the index described by Claim 4.13, that is,

$$\forall i \in [\hat{k}] \quad : \quad |G^i_{t_q} \cap S| < \hat{d}2^{-q}.$$

In particular,

$$|G_{t_q} \cap S| < \hat{k}\hat{d}2^{-q}.$$

Notice that by (9) and (10) and by the fact that R_{t_q} and G_{t_q} give a partition of $\hat{\mathcal{C}}$, we get that the complement of $\bigcup_{s=1}^{q} R_{t_s}$ is exactly $G_{t_q} \cap S$. From this we get that adding R_{t_q} to R gives

$$\left| \bigcup_{s=1}^{q} R_{t_s} \right| \geq \hat{k}\hat{d}(1 - 2^{-q}).$$

This completes the proof of Claim 4.11. □

Having proved Claim 4.11, we are now just steps away from completing the proof of Claim 4.8. Taking q to be $\lfloor \log(\hat{d}) \rfloor$ in Claim 4.11, we get that there exist indices $t_1, \ldots, t_{\lfloor \log(\hat{d}) \rfloor} \in [m]$ such that

$$\left| \bigcup_{s=1}^{\lfloor \log(\hat{d}) \rfloor} R_{t_s} \right| \geq \hat{k}\hat{d} - 2\hat{k} \ldots.$$

Thus

$$\hat{r} - 2\hat{k} \leq \operatorname{rank} \left(\bigcup_{s=1}^{\lfloor \log(\hat{d}) \rfloor} R_{t_s} \right) \leq \sum_{s=1}^{\lfloor \log(\hat{d}) \rfloor} r_{t_s}.$$

The last inequality tells us that there exists some $t \in [m]$ for which

$$r_t \geq \frac{\hat{r} - 2\hat{k}}{\lfloor \log(\hat{d}) \rfloor} \geq \frac{\hat{r} - 2\hat{k}}{\log(d)}. \tag{16}$$

In order to finish the proof of Claim 4.8 we prove the following inequality.

CLAIM 4.15.

$$\hat{r} - 2\hat{k} \geq \frac{\hat{r}}{2^{k+1}}.$$

Proof. Using (4), we get

$$\hat{r} \geq m \geq 2^{-k} r \geq 2^{-k} P(k) \log(d)^{k-3}.$$

Therefore we can choose $P(k) = 2^{O(k^2)}$ such that

$$\hat{r} > 2\hat{k} \frac{2^{k+1}}{2^{k+1} - 1}.$$

This implies the inequality in the claim. □

Combining Claim 4.15 with (16), we conclude that there exists $t \in [m]$ for which

$$r_t \geq \frac{\hat{r}}{\log(d) 2^{k+1}},$$

which contradicts our initial assumption (7). This completes the proof of Claim 4.8.

5. A structural theorem for zero ΣΠΣ circuits. The main result of this section is a structural theorem for ΣΠΣ circuits which are identically zero. The proof is based on the results of section 4. To ease the notation we will prove our results only for $\Sigma\Pi\Sigma(k, d)$ circuits; however, from Claim 3.11 it will follow that all the results also hold for ΣΠΣ circuits with k multiplication gates of degree d.

THEOREM 5.1 (*structural theorem*). *Let $\mathcal{C} \equiv 0$ be a $\Sigma\Pi\Sigma(k, d)$ circuit. Then, there exists a partition of $[k]$: $T_1, \ldots, T_s \subset [k]$ with the following properties:*

- $\mathcal{C} = \sum_{i=1}^{s} \mathcal{C}_{T_i} = \sum_{i=1}^{s} \gcd(\mathcal{C}_{T_i}) \cdot sim(\mathcal{C}_{T_i})$.
- *For all $i \in [s]$, $sim(\mathcal{C}_{T_i}) \equiv 0$ and is simple and minimal.*
- *For all $i \in [s]$, $\operatorname{rank}(sim(\mathcal{C}_{T_i})) \leq 2^{O(k^2)} \log(d)^{k-2}$.*

In other words, the theorem says that every zero ΣΠΣ circuit can be broken down into zero subcircuits of low rank (ignoring the g.c.d.). This fact will be used in the next section, in which we devise PIT algorithms for ΣΠΣ circuits.

Before giving the proof of the theorem we prove a lemma that bounds the rank of a zero, simple, and minimal ΣΠΣ circuit. Note that Theorem 1.4 follows from this lemma and Claim 3.11.

LEMMA 5.2. *Let $k \geq 3$, $d \geq 2$, and let $\mathcal{C} \equiv 0$ be a simple and minimal $\Sigma\Pi\Sigma(k, d)$ circuit. Then*

$$\operatorname{rank}(\mathcal{C}) \leq 2^{O(k^2)} \log(d)^{k-2}.$$

Proof. From Theorem 4.1 we know that there exists a linear $(2, \frac{1}{12}, \frac{1}{4})$-LDC $E : \mathbb{F}^{n_1} \to \mathbb{F}^{n_2}$ with

$$\frac{\operatorname{rank}(\mathcal{C})}{P(k) \log(d)^{k-3}} \leq n_1 \quad \text{and} \quad n_2 \leq k \cdot d, \quad \text{where} \quad P(k) = 2^{O(k^2)}.$$

Theorem 1.2 now tells us that

$$n_2 \geq 2^{\frac{1}{96} n_1 - 1}.$$

Combining the above inequalities, we get the required bound on $\text{rank}(\mathcal{C})$. ∎

We now use Lemma 5.2 to prove Theorem 5.1.

Proof of Theorem 5.1. Since $\mathcal{C}$ is equal to zero, we can find a partition $T_1, \ldots, T_s \subset [k]$ such that the circuits $\mathcal{C}_{T_1}, \ldots, \mathcal{C}_{T_s}$ are all zero and minimal. Thus, the circuits $sim(\mathcal{C}_{T_1}), \ldots, sim(\mathcal{C}_{T_s})$ are all zero, simple, and minimal. By Lemma 5.2 we get that if $|T_i| \geq 3$ and $\deg(sim(\mathcal{C}_{T_i})) \geq 2$, then

$$\text{rank}(sim(\mathcal{C}_{T_i})) \leq 2^{O(k^2)} \log(d)^{k-2}.$$

If $|T_i| = 2$, then by Claim 4.2 we get that $\deg(sim(\mathcal{C}_{T_i})) = 0$ and so its rank is 1. If $\deg(sim(\mathcal{C}_{T_i})) \leq 1$, then its rank is at most k. Thus, we have covered all the possible cases, and the lemma follows.

6. PIT algorithms. In this section we use the structural theorem (Theorem 5.1), proved in the previous section, to devise the PIT algorithms of Theorem 1.5. Again, to simplify the notation, we give algorithms for $\Sigma\Pi\Sigma(k, d)$ circuits, which work in the same manner also for $\Sigma\Pi\Sigma$ circuits with k multiplication gates of degree d. We state our results for a general k; however, our algorithms will be most applicable when k is a constant.[9]

From Theorem 5.1 we know that every zero $\Sigma\Pi\Sigma$ circuit can be broken down into zero subcircuits whose ranks are small. The next two lemmas show that checking whether these low-rank circuits are zero can be done efficiently.

LEMMA 6.1. *Let $\mathcal{C}$ be a $\Sigma\Pi\Sigma(k, d)$ circuit with $\text{rank}(\mathcal{C}) = r$. Then, there exists a polynomial time algorithm, transforming $\mathcal{C}$ into a $\Sigma\Pi\Sigma(k, d)$ circuit $\mathcal{C}'$, such that*

- *$\mathcal{C} \equiv 0$ iff $\mathcal{C}' \equiv 0$,*
- *$\mathcal{C}'$ contains only r variables.*

Proof. The proof is a direct consequence of Claim 3.14: we apply an invertible linear transformation on $\mathcal{C}$, taking a set of r linearly independent vectors to $e_1, \ldots, e_r$. The transformed circuit will contain only the first r variables and will be zero iff $\mathcal{C}$ is zero. ∎

LEMMA 6.2. *Let $\mathcal{C}$ be a $\Sigma\Pi\Sigma(k, d)$ circuit, and let $r = \text{rank}(\mathcal{C})$, $s = size(\mathcal{C})$. Then we can check if $\mathcal{C} \equiv 0$*

1. *deterministically, in time $\text{poly}(s) \cdot (r + d)^r$;*
2. *probabilistically, in time $\text{poly}(s + \frac{1}{\epsilon})$, using $r \cdot \left(\log(d) + \log(\frac{1}{\epsilon})\right)$ random bits, with error probability ϵ.*

Proof. Using Lemma 6.1, we can transform $\mathcal{C}$ into a circuit $\mathcal{C}'$ with at most r variables, such that $\mathcal{C} \equiv 0$ iff $\mathcal{C}' \equiv 0$. Since $\mathcal{C}'$ contains only r variables, the number of different monomials in $\mathcal{C}'(x)$ is bounded by $\binom{r+d-1}{r-1} < (r + d)^r$. We can thus check if $\mathcal{C}' \equiv 0$ by computing the coefficients of all the monomials and seeing if they are all zero. This can be done in time $\text{poly}(s) \cdot (r + d)^r$. For the second part of the corollary, note that we can also check if $\mathcal{C}' \equiv 0$ probabilistically using the well-known Schwartz–Zippel algorithm [42, 50]. ∎

We are now ready to describe our PIT algorithm for $\Sigma\Pi\Sigma(k, d)$ circuits.

THEOREM 6.3. *Let $\mathcal{C}$ be a $\Sigma\Pi\Sigma(k, d)$ circuit, $s = size(\mathcal{C})$. Then, Algorithm 1 will check if $\mathcal{C} \equiv 0$. Further, the algorithm will run in time $\text{poly}(s) \cdot \exp\left(2^{O(k^2)} \log(d)^{k-1}\right)$.*

Proof. First, note that if $\mathcal{C}$ is nonzero, then the algorithm will never accept. (The algorithm accepts only when a partition of $\mathcal{C}$ into zero subcircuits is found.) Assume that $\mathcal{C}$ is zero. Then, by Theorem 5.1, there exists a partition, $T_1, \ldots, T_s \subset [k]$, of

[9] Our methods give subexponential time ($2^{o(n)}$) algorithms also if $k = o(\sqrt{\log n})$.

ALGORITHM 1. Deterministic algorithm.

input: A $\Sigma\Pi\Sigma(k,d)$ circuit $\mathcal{C}$.

(1) For every subset $T \subset [k]$ do the following:
- (1.1) Compute $r_T = \text{rank}(sim(\mathcal{C}_T))$.
- (1.2) If $r_T \leq 2^{O(k^2)} \log(d)^{k-2}$, then:
- check if $sim(\mathcal{C}_T) \equiv 0$ using part 1 of Lemma 6.2.

(2) If there exists a partition of $[k]$, such that for every set $T \subset [k]$ in the partition $sim(\mathcal{C}_T) \equiv 0$, then **accept**. Otherwise **reject**.

$[k]$ such that the circuits $sim(\mathcal{C}_{T_1}), \ldots, sim(\mathcal{C}_{T_s})$ are all zero and that for all $i \in [s]$ the rank of $sim(\mathcal{C}_{T_i})$ is bounded by $2^{O(k^2)} \log(d)^{k-2}$. Therefore, for every $\mathcal{C}_{T_i}$ we will check whether $sim(\mathcal{C}_{T_i}) \equiv 0$ in step (1.2) of the algorithm. Since we go over all subsets of $[k]$, we are bound to find the above partition and accept.

As for the running time of the algorithm, notice that we apply the algorithm from Lemma 6.2 only on circuits whose rank is smaller than $2^{O(k^2)} \log(d)^{k-2}$. Therefore, by Lemma 6.2, the time spent in each invocation of step (1.2) is at most

$$\text{poly}(s) \cdot \exp\left(2^{O(k^2)} \log(d)^{k-1}\right).$$

Step (1.2) is run at most 2^k times, and so the total running time is also

$$\text{poly}(s) \cdot \exp\left(2^{O(k^2)} \log(d)^{k-1}\right).$$

(The running times of all the other steps of the algorithm are "swallowed up" by the running time of step (1.2).) □

We can modify Algorithm 1 so that it will use a probabilistic check in step (1.2). This will result in a probabilistic PIT algorithm for $\Sigma\Pi\Sigma$ circuits, which uses fewer random bits than previous algorithms.

ALGORITHM 2. Probabilistic algorithm.

input: A $\Sigma\Pi\Sigma(k,d)$ circuit $\mathcal{C}$. An error probability ϵ.

(1) For every subset $T \subset [k]$ do the following:
- (1.1) Compute $r_T = \text{rank}(sim(\mathcal{C}_T))$.
- (1.2) If $r_T \leq 2^{O(k^2)} \log(d)^{k-2}$, then: check if $sim(\mathcal{C}_T) \equiv 0$ probabilistically,
- using part 2 of Lemma 6.2, with error probability $\epsilon 2^{-k}$.

(2) If there exists a partition of $[k]$, such that for every set $T \subset [k]$ in the partition $sim(\mathcal{C}_T) \equiv 0$, then **accept**. Otherwise **reject**.

THEOREM 6.4. *Let $\mathcal{C}$ be a $\Sigma\Pi\Sigma(k,d)$ circuit, $s = size(\mathcal{C})$. Then, Algorithm 2 will check if $\mathcal{C} \equiv 0$. Further, the algorithm will run in time* $\text{poly}\left(s + \frac{2^k}{\epsilon}\right)$, *will use $2^{O(k^2)} \log(d)^{k-1} \log(\frac{1}{\epsilon})$ random bits, and will make an error with probability less than ϵ.*

Proof. Using the same reasoning as in the proof of Theorem 6.3, we see that the algorithm can make an error only if one of the checks in step (1.2) fails. By the union bound, this happens with probability of at most ϵ.

Each check in step (1.2) takes time poly $\left(s+\frac{2^k}{\epsilon}\right)$. And so the total running time is

$$2^k \cdot \text{poly}\left(s+\frac{2^k}{\epsilon}\right) = \text{poly}\left(s+\frac{2^k}{\epsilon}\right).$$

By part 2 of Lemma 6.2, the number of random bits used in step (1.2) is at most $r_T \cdot \left(\log(d)+\log(\frac{1}{\epsilon})\right)$. Since we run the probabilistic check only when $r_T \leq 2^{O(k^2)}\log(d)^{k-2}$, it follows that the number of random bits used in each invocation of step (1.2) is bounded by $2^{O(k^2)}\log(d)^{k-1}\log(\frac{1}{\epsilon})$. As we can use the same random bits in all tests, this is also the total number of random bits needed. □

We restate the last two theorems for the case when k is a constant.

THEOREM 6.5. *Let $\mathcal{C}$ be a $\Sigma\Pi\Sigma(k,d)$ circuit, k a constant, $s = size(\mathcal{C})$. Then we can check if $\mathcal{C} \equiv 0$*

1. *deterministically, in quasi-polynomial time,*
2. *probabilistically, in time* $\text{poly}(s+\frac{1}{\epsilon})$*, using* $O\left(\log(d)^{k-1}\log(\frac{1}{\epsilon})\right)$ *random bits, with error probability ϵ.*

Note that Theorems 6.3, 6.4, and 6.5 imply the first two claims of Theorem 1.5.

6.1. Multilinear circuits. This section deals with a special kind of $\Sigma\Pi\Sigma$ circuit, described by the following definition.

DEFINITION 6.6. *A $\Sigma\Pi\Sigma$ circuit $\mathcal{C}$ is* multilinear *if each of its multiplication gates computes a multilinear polynomial. (A polynomial is multilinear if the degree of every variable is at most one.)*

Let

$$\mathcal{C}(x) = \sum_{i=1}^{k} c_i \prod_{j=1}^{d_i} L_{ij}(x)$$

be a $\Sigma\Pi\Sigma$ circuit. Denote by $V_{ij} \subset [n]$ the set of variables appearing in the linear form L_{ij}. From Definition 6.6 we see that $\mathcal{C}$ is multilinear iff for every $i \in [k]$, and for every $j_1 \neq j_2$, we have

$$V_{ij_1} \cap V_{ij_2} = \emptyset.$$

This condition implies that for every $i \in [k]$ the linear functions $\{L_{ij}\}_{j\in[d_i]}$ are linearly independent. This leads to the following observation.

Observation 6.7. If $\mathcal{C}$ is a multilinear $\Sigma\Pi\Sigma$ circuit of degree d, then $\text{rank}(\mathcal{C}) \geq d$.

Combining this observation and Theorem 1.4, we get the following theorem.

THEOREM 6.8. *Let $\mathcal{C} \equiv 0$ be a multilinear $\Sigma\Pi\Sigma$ circuit with k multiplication gates ($k \geq 3$), which is simple and minimal. Let $d = deg(\mathcal{C})$; then*

$$d \leq 2^{O(k^2)}\log(d)^{k-2}. \tag{17}$$

COROLLARY 6.9. *There exists an integer function $D(k) = 2^{O(k^2)}$ such that every multilinear $\Sigma\Pi\Sigma$ circuit $\mathcal{C}$ with k multiplication gates, which is simple and equal to zero, and of degree $d = deg(\mathcal{C}) > D(k)$, is not minimal.*

Proof. Fix k, and consider (17). This inequality holds only if $d \leq 2^{O(k^2)} = D(k)$. Thus, if $d > D(k)$, then the conditions of Theorem 6.8 are not satisfied. In particular, if $\mathcal{C} \equiv 0$ and is simple, then it is not minimal. □

We can use Corollary 6.9 to improve the algorithm given in section 6, in the case that the given circuit is multilinear.

THEOREM 6.10. *Let $\mathcal{C}$ be a multilinear $\Sigma\Pi\Sigma$ circuit, of size s, with k multiplication gates. We can check if $\mathcal{C} \equiv 0$ in time* $\mathrm{poly}(s) \cdot \exp\left(2^{O(k^2)}\right)$. *Thus, if k is constant, the algorithm runs in polynomial time.*

Proof. The algorithm is the same as Algorithm 1. (It does not matter that our circuit is not a $\Sigma\Pi\Sigma(k,d)$ circuit.) The only difference is that by Corollary 6.9 we only have to consider subcircuits $\mathcal{C}_T$ such that the degree of $sim(\mathcal{C}_T)$ is less than $D(|T|) = 2^{O(k^2)}$. The running time is computed in a similar fashion. In step (1) we go over at most $2^{O(k^2)}$ partitions of $[k]$. Computing the rank of the subcircuit $\mathcal{C}_T$ can be done in polynomial time in s. Finally, by part 1 of Lemma 6.2, step (1.2) requires time $O\left(D(|T|)^{2^{O(k^2)}}\right) = \exp\left(2^{O(k^2)}\right)$. ∎

Theorem 6.10 implies the third claim of Theorem 1.5, thus completing the proof of the theorem.

7. Conclusions and open problems. Finding efficient deterministic PIT algorithms for general arithmetic circuits is a long-standing open problem. We made the first step toward an efficient algorithm for PIT for depth 3 circuits by giving PIT algorithms for depth 3 circuits with bounded top fan-in; however, the general case of depth 3 circuits is still open. In view of [25] it is natural to look for algorithms for PIT for restricted models of arithmetic circuits in which lower bounds are known. Raz [39] proved a quasi-polynomial lower bound for *multilinear* arithmetic formulas computing the determinant and the permanent. Thus, giving PIT algorithms for multilinear formulas is a very interesting, and maybe even a solvable, problem.

The key to our result is the relation we have found between LDCs and depth 3 circuits. Previously, relations between circuits and error correcting codes were known only for bilinear circuits over finite fields [10, 45]. It should be very interesting to find new relations between codes and arithmetic circuits. Another interesting question is whether the relation that we have found is tight. In particular we believe that in Theorem 1.3 one should be able to replace $r/2^{O(k^2)}\log(d)^{k-3}$ with $O(r/k)$. A related question regards how to improve Theorem 1.4. We believe that for minimal and simple circuits over fields of characteristic zero the rank should be $O(k)$. We have found circuits that are minimal and simple, with $r = 3k-2$, and we think that it would be an interesting task to come up with (minimal and simple) circuits that have larger rank. As mentioned in the introduction, [27] showed that over characteristic p there are identically zero depth 3 circuits with top fan-in p for odd p (for $p = 2$ the top fan-in is 3) whose rank is $\log_p(d)$.

We conclude this section with a geometrical problem related to depth 3 circuits with three multiplication gates. The famous Sylvester–Gallai theorem states that every set of n points in the plane having the property that every line that contains two points from the set also contains a third point from the set is contained in a line. Consider the following generalization of the problem (colored version in the projective plane): instead of one set of points we have three different sets. Each set is of size n. The points in the sets correspond to vectors from the r-dimensional sphere, and every two such vectors are linearly independent. The condition on the sets is that every two-dimensional subspace that contains points from two different sets also contains a point from the third set.[10] What can be said about r in this case? Clearly the

[10] Alternatively, the points belong to the r-dimensional projective space, and every line that contains points from two different sets also contains a point from the third set.

r-dimensional sphere can be embedded into the $(r+1)$-dimensional sphere so we only consider "irreducible" arrangements in which the vectors corresponding to the points span the whole space. Using our lower bound on LDCs, we can show that r is at most $O(\log n)$; however, we think that this can be improved. In particular we conjecture that r is bounded (maybe even $r = 2$). If our conjecture is true, then it will serve as evidence that for $k = 3$ the rank of every simple and minimal depth 3 circuit, which is identically zero, is bounded.

We now give an example that shows the relation of the problem to identically zero depth 3 circuits with three multiplication gates. Consider the following equality $x_1^n - x_2^n = \prod_{i=0}^{n-1}(x_1 - w^i x_2)$, where w is a primitive nth root of unity. We get that

$$\sum_{i=1}^{k-1}\prod_{j=0}^{n-1}(x_i - w^j x_{i+1}) + \prod_{j=0}^{n-1}(x_k - w^j x_1) = 0.$$

Notice that this is an identically zero depth 3 circuit with k multiplication gates. For the special case of $k = 3$ we get that

$$\prod_{j=0}^{n-1}(x_1 - w^j x_2) + \prod_{j=0}^{n-1}(x_2 - w^j x_3) + \prod_{j=0}^{n-1}(x_3 - w^j x_1) = 0.$$

Each multiplication gate corresponds to a different set of points. We map each linear function $x_1 - w^j x_2$ from the first gate to the point $(\frac{1}{\sqrt{2}}, \frac{-w^j}{\sqrt{2}}, 0)$; similarly, we map the functions of the second multiplication gate to $\{(0, \frac{1}{\sqrt{2}}, \frac{-w^j}{\sqrt{2}})\}_{j=0,\ldots,n-1}$, etc. Clearly all the points belong to the two-dimensional sphere in $\mathbb{C}^3$. It is easy to see that for each point from the first set (i.e., points coming from the first multiplication gate) and each point from the second set there is a unique point from the third set that belongs to the same two-dimensional space (similarly if we pick the first and third sets, etc.). Therefore this construction satisfies our requirements. Our question is, Can such arrangements be found in higher dimensions?

Acknowledgments. The authors would like to thank Ran Raz and Avi Wigderson for helpful discussions during various stages of this work. A. S. would like to thank Boaz Barak, Valentine Kabanets, and Salil Vadhan for useful conversations on the topic of the work. We are grateful to Ran Raz for many valuable comments that improved the presentation of the results.

THE PROBABILISTIC RELATIONSHIP BETWEEN THE ASSIGNMENT AND ASYMMETRIC TRAVELING SALESMAN PROBLEMS*

ALAN FRIEZE† AND GREGORY B. SORKIN‡

Abstract. We consider the gap between the cost of an optimal assignment in a complete bipartite graph with random edge weights, and the cost of an optimal traveling salesman tour in a complete directed graph with the same edge weights. Using an improved "patching" heuristic, we show that with high probability the gap is $O((\ln n)^2/n)$, and that its expectation is $\Omega(1/n)$. One of the underpinnings of this result is that the largest edge weight in an optimal assignment has expectation $\Theta(\ln n/n)$. A consequence of the small assignment–TSP gap is an $e^{\tilde{O}(\sqrt{n})}$-time algorithm which, with high probability, exactly solves a random asymmetric traveling salesman instance. In addition to the assignment–TSP gap, we also consider the expected gap between the optimal and second-best assignments; it is at least $\Omega(1/n^2)$ and at most $O(\ln n/n^2)$.

1. Introduction.

The *assignment problem* (AP) is the problem of finding a minimum-weight perfect matching in an edge-weighted bipartite graph. An instance of the AP can be specified by an $n \times n$ matrix $C = (C(i,j))$; here $C(i,j)$ represents the weight (or "cost") of the edge between $i \in X$ and $j \in Y$, where X and Y are disjoint copies of $[n] = \{1, 2, \ldots, n\}$ and X is the set of "left vertices" and Y is the set of "right vertices" in the complete bipartite graph $K_{X,Y}$. The AP can be stated in terms of the matrix C as follows: Find a permutation π of $[n] = \{1, 2, \ldots, n\}$ that minimizes $\sum_{i=1}^{n} C(i, \pi(i))$. Let $\mathrm{AP}(C)$ be the optimal value of the instance of the AP specified by C.

The *asymmetric traveling salesman problem* (ATSP) is the problem of finding a Hamiltonian circuit of minimum weight in an edge-weighted directed graph. An instance of the ATSP can be specified by an $n \times n$ matrix $C = (C(i,j))$ in which $C(i,j)$ denotes the weight of edge (i,j). The ATSP can be stated in terms of the matrix C as follows: Find a *cyclic* permutation π of $[n]$ that minimizes $\sum_{i=1}^{n} C(i, \pi(i))$; here a cyclic permutation is one whose cycle structure consists of a single cycle. Let $\mathrm{ATSP}(C)$ be the optimal value of the instance of the ATSP specified by C.

It is evident from the parallelism between the above two definitions that $\mathrm{AP}(C) \leq \mathrm{ATSP}(C)$. The ATSP is NP-hard, whereas the AP is solvable in time $O(n^3)$. Several authors, e.g., Balas and Toth [5], have investigated whether the AP can be used effectively in a branch-and-bound method to solve the ATSP and have observed that the AP gives extremely good bounds on random instances.

Karp was able to explain this in an important paper [14]. He assumed that the entries of C were independent uniform [0,1] random variables and proved the surprising result that

$$\mathbf{E}(\mathrm{ATSP}(C) - \mathrm{AP}(C)) = o(1). \tag{1}$$

Since whp[1] $\mathrm{AP}(C) > 1$ we see that this rigorously explains the quality of the assignment bound, a significant victory for probabilistic analysis. Karp proved (1) constructively, analyzing an $O(n^3)$ *patching heuristic* that transformed an optimal AP solution into a good TSP solution. Karp and Steele [15] simplified and sharpened this analysis, and Dyer and Frieze [7] improved the error bound in (1) to $O(\frac{(\ln n)^4}{n \ln \ln n})$. Our first theorem sharpens this further.

THEOREM 1. *Over random cost matrices C,*

$$\mathrm{ATSP}(C) - \mathrm{AP}(C) \le c_1 \frac{(\ln n)^2}{n} \qquad \textit{whp}$$

and

$$\mathbf{E}(\mathrm{ATSP}(C) - \mathrm{AP}(C)) \ge \frac{c_0}{n}.$$

In this paper, $c_0, c_1, \ldots$ are positive absolute constants whose precise values are not too important to us.

As in previous works, we will prove the upper bound in Theorem 1 by analyzing an $O(n^3)$ heuristic which patches an optimal AP solution into a good ATSP solution. We note a related discretized result of Frieze, Karp, and Reed [11], who consider the $C(i,j)$ to be random positive *integers* chosen from a range $[0, L = L(n)]$, and determine for what functions $L(n)$ one has ATSP = AP whp.

Karp and Steele showed that whp the greatest cost of an edge used in the optimal assignment was $O(\frac{(\ln n)^2}{n})$; our next theorem improves upon this. Let $C_{\max} = C_{\max}(C)$ denote the maximum cost of an edge used in an optimal assignment.

THEOREM 2. *Whp over random cost matrices C,*

$$(1 - o(1))\frac{\ln n}{n} \le C_{\max} \le c_2 \frac{\ln n}{n}.$$

It is also of interest to estimate the expected difference Δ_1 between the cheapest and second-cheapest assignments. A better understanding of this difference may be of use in studying the expected performance of branch-and-bound algorithms based on the assignment relaxation.

THEOREM 3. *Over random cost matrices C,*

$$\frac{1}{n^2}(1 - o(1)) \le \mathbf{E}(\Delta_1) \le c_3 \frac{\ln n}{n^2}.$$

The algorithm with the best known worst-case time for solving the ATSP exactly is the $O(n^2 2^n)$ dynamic programming algorithm of Held and Karp [12]. The next theorem describes a probabilistic improvement.

THEOREM 4. *Whp, a random instance of the* ATSP *can be solved exactly in time $e^{\tilde{O}(\sqrt{n})}$.*

Here $\tilde{O}$ is the standard notation for ignoring logarithmic factors.

[1] With high probability, i.e., with probability $1 - o(1)$ as $n \to \infty$.

2. Analysis of the assignment problem. In this section we will prove Theorem 2. The difficult part of the proof—showing that the longest edge in an optimal assignment has length $O(\ln n/n)$—has its essence in Lemma 5 below.

In this section we will exploit the fact that C can be considered to be the matrix giving the edge weights of the complete bipartite graph $K_{X,Y}$. In this interpretation π corresponds to a perfect matching $(i, \pi(i))$, $i \in X$, $\pi(i) \in Y$.

Define the k-neighborhood of a vertex to be the k vertices nearest it, where distance is given by the matrix C; let the k-neighborhood of a set be the union of the k-neighborhoods of its vertices. In particular, for a complete bipartite graph $K_{X,Y}$ and any $S \subseteq X$, $T \subseteq Y$,

(2)
$$N_k(S) \doteq \{y \in Y : \exists s \in S \text{ such that } (s, y) \text{ is one of the } k \text{ shortest arcs out of } s\},$$

(3)
$$N_k(T) \doteq \{x \in X : \exists t \in T \text{ such that } (x, t) \text{ is one of the } k \text{ shortest arcs into } t\}.$$

Given the complete bipartite graph $K_{X,Y}$, any permutation $\pi : X \to Y$ has an associated matching $M_\pi = \{(x, y) : x \in X, y \in Y, y = \pi(x)\}$. Given a cost matrix C and permutation π, define the digraph

$$\vec{D} = \vec{D}_{C,\pi} = (X \cup Y, \vec{E}) \tag{4}$$

consisting of *backward* matching edges and forward "short" edges:

$$\vec{E} = \{(y, x) : y \in Y, x \in X, y = \pi(x)\} \cup \{(x, y) : x \in X, y \in N_{40}(x)\} \cup \{(x, y) : y \in Y, x \in N_{40}(y)\}. \tag{5}$$

We stress that $\vec{D}$ is different from the complete weighted digraph D_n in which we wish to find a minimum length tour.

The arcs of directed paths in $\vec{D}$ are alternately forward $X \to Y$ and backward $Y \to X$ and so they correspond to *alternating paths* with respect to the perfect matching defined by π. Since "adding" an alternating circuit[2] to a matching produces a new matching, finding low-cost alternating paths is key to all our constructions. In particular, an alternating path's backward edges (from the old matching) will be replaced by its forward ones, and so it helps to know (see Lemma 5 below) that given $x \in X$, $y \in Y$ we can find an alternating path from x to y with $O(\log n)$ edges. The forward edges have expected length $O(1/n)$, and we will be able to show (Lemma 7 below) that we can whp be guaranteed to find an alternating path from x to y in which the *difference* in weight between forward and backward edges is $O(\log n/n)$. It is then simple to prove the upper bound in Theorem 2. A long edge can be removed by the use of such an alternating path.

LEMMA 5. *Whp over random cost matrices C, for every permutation π, the (unweighted) diameter of $\vec{D} = \vec{D}_{C,\pi}$ is at most $k_0 = \lceil 3 \log_4 n \rceil$.*

Proof. For $S \subseteq X$, $T \subseteq Y$, let

$$N_{\vec{D}}(S) = \{y \in Y : \exists s \in S \text{ such that } (s, y) \in \vec{E}\},$$
$$N_{\vec{D}}(T) = \{x \in X : \exists t \in T \text{ such that } (x, t) \in \vec{E}\}.$$

[2]We use circuit to distinguish from the cycles of the permutations.

We first prove an expansion property: Whp, for all $S \subseteq X$ with $|S| \le \lceil n/5 \rceil$, $|N_{\vec{D}}(S)| \ge 4|S|$. (Note that only the cheap edges out of S, and not the backward matching edges into it, are involved here. Thus $N_{\vec{D}}(S), N_{\vec{D}}(T)$ do not depend on π.)

$$\begin{aligned}
\mathbf{Pr}(\exists S:\ |S| \le \lceil n/5 \rceil\,,\ |N_{\vec{D}}(S)| < 4|S|) &\le \sum_{s=1}^{\lceil n/5 \rceil} \binom{n}{s}\binom{n}{4s}\left(\frac{\binom{4s}{40}}{\binom{n}{40}}\right)^s \\
&\le \sum_{s=1}^{\lceil n/5 \rceil} \left(\frac{ne}{s}\right)^s \left(\frac{ne}{4s}\right)^{4s} \left(\frac{4s}{n}\right)^{40s} \\
&= \sum_{s=1}^{\lceil n/5 \rceil} \left(\frac{e^5 4^{36} s^{35}}{n^{35}}\right)^s \\
&= o(1). \qquad (6)
\end{aligned}$$

Explanation. Summing over all possible ways of choosing s vertices and $4s$ "targets," we take the probability that for each of the s vertices, all 40 out-edges fall among the $4s$ out of the n possibilities.

Similarly, whp, for all $T \subseteq Y$ with $|T| \le \lceil n/5 \rceil$, $|N_{\vec{D}}(T)| \ge 4|T|$. (Again only the cheap edges, not the matching edges, are involved.) Thus by the union bound, whp both these events hold. In the remainder of this proof we assume that we are in this "good" case, in which all small sets S and T have a large vertex expansion.

Now, choose an arbitrary $x \in X$, and define $S_0, S_1, S_2, \ldots$ as the endpoints of all cheap alternating paths starting from x and of lengths $0, 2, 4, \ldots$. That is,

$$S_0 = \{x\} \text{ and } S_i = \pi^{-1}(N_{\vec{D}}(S_{i-1})).$$

Since we are in the good case, $|S_i| \ge 4|S_{i-1}|$ provided $|S_{i-1}| \le n/5$, and so there exists a smallest index i_S such that $|S_{i_S-1}| > n/5$, and $i_S - 1 \le \log_4(n/5) \le \log_4 n - 1$. Arbitrarily discard vertices from S_{i_S-1} to create a smaller set S'_{i_S-1} with $|S'_{i_S-1}| = \lceil n/5 \rceil$, so that $S'_{i_S} = N_{\vec{D}}(S'_{i_S-1})$ has cardinality $|S'_{i_S}| \ge 4|S'_{i_S-1}| \ge 4n/5$.

Similarly, for an arbitrary $y \in Y$, define $T_0, T_1, \ldots$ by

$$T_0 = \{y\} \text{ and } T_i = \pi(N_{\vec{D}}(T_{i-1})).$$

Again, we will find an index $i_T \le \log_4 n$ whose modified set has cardinality $|T'_{i_T}| \ge 4n/5$.

With both $|S'_{i_S}|$ and $|T'_{i_T}|$ larger than $n/2$, there must be some $x' \in S'_{i_S}$ for which $y' = \pi(x') \in T'_{i_T}$. This establishes the existence of an alternating walk and hence (removing any circuits) an alternating path of length at most $2(i_S + i_T) \le 2\log_4 n$ from x to y in $\vec{D}$.

We have proved there is a short path from any $x \in X$ to any $y \in Y$. A short path from x to x' both in X can be formed by finding a path from x to $y = \pi(x')$ and appending the backward edge to x'; a path from y to x' by starting with the backward edge from y to $x = \pi^{-1}(y)$ and then pursuing a path to x'; and a path from y to y' by taking a path from y to $x' = \pi^{-1}(y')$ and discarding its final backward edge. ∎

Let the weight of a forward edge (x, y) be $C(x, y)$ and the weight of a backward edge (y, x) be $-C(x, y)$.

We will need the following inequality, Lemma 4.2(b) of [10].

LEMMA 6. *Suppose that* $k_1+k_2+\cdots+k_M \le a\ln N$, *and* $Y_1, Y_2, \ldots, Y_M$ *are independent random variables with* Y_i *distributed as the* k_i*th minimum of* N *independent uniform* [0,1] *random variables. If* $\lambda > 1$, *then*

$$\mathbf{Pr}\left(Y_1+\cdots+Y_M \ge \frac{\lambda a \ln N}{N+1}\right) \le N^{a(1+\ln\lambda-\lambda)}.$$

LEMMA 7. *Whp over random* C, *for all* π, *the weighted diameter of* $\vec{D} = \vec{D}_{C,\pi}$ *is* $\le c_2 \frac{\ln n}{n}$.

Proof. Let

$$Z_1 = \max\left\{\sum_{i=0}^{k} C(x_i, y_i) - \sum_{i=0}^{k-1} C(y_i, x_{i+1})\right\}, \tag{7}$$

where the maximum is over sequences $x_0, y_0, x_1, \ldots, x_k, y_k$ where (x_i, y_i) is one of the 40 shortest arcs leaving x_i for $i = 0, 1, \ldots, k \le k_0 = \lceil 3\log_4 n\rceil$, and (y_i, x_{i+1}) is a backward matching edge.

We compute an upper bound on the probability that Z_1 is large. For any $\zeta > 0$ we have

$$\mathbf{Pr}\left(Z_1 \ge \zeta\frac{\ln n}{n}\right) \le \sum_{k=0}^{k_0} n^{2k+2}\frac{1}{(n-1)^{k+1}} \times \int_{y=0}^{\infty}\left[\frac{1}{(k-1)!}\left(\frac{y\ln n}{n}\right)^{k-1} \sum_{\rho_0+\rho_1+\cdots+\rho_k\le 40(k+1)} q(\rho_0,\rho_1,\ldots,\rho_k;\zeta+y)\right] dy,$$

where

$$q(\rho_0,\rho_1,\ldots,\rho_k;\eta) = \mathbf{Pr}\left(X_0+X_1+\cdots+X_k \ge \eta\frac{\ln n}{n}\right),$$

$X_0, X_1, \ldots, X_k$ are independent, and X_j is distributed as the ρ_jth minimum of $n-1$ uniform [0,1] random variables. (When $k=0$, there is no term $\frac{1}{(k-1)!}(\frac{y\ln n}{n})^{k-1}$.)

Explanation. We have $\le n^{2k+2}$ choices for the sequence $x_0, y_0, x_1, \ldots, x_k, y_k$. The term $\frac{1}{(k-1)!}(\frac{y\ln n}{n})^{k-1}dy$ bounds the probability that the sum of k independent uniforms, $C(y_0,x_1)+\cdots+C(y_{k-1},x_k)$, is in $\frac{\ln n}{n}[y, y+dy]$. (We approximate this probability by the area of the simplex face $\{y_1+y_2+\cdots+y_k = \frac{y\ln n}{n},\ y_1, y_2, \ldots, y_k \ge 0\}$ multiplied by dy.) We integrate over y. $\frac{1}{n-1}$ is the probability that (x_i, y_i) is the ρ_ith shortest edge leaving x_i, and these events are independent for $0 \le i \le k$. The final summation bounds the probability that the associated edge lengths sum to at least $\frac{(\zeta+y)\ln n}{n}$.

It follows from Lemma 6 that if ζ is sufficiently large, then for all $y \ge 0$, $q(\rho_1,\ldots,\rho_k;\zeta+y) \le n^{-(\zeta+y)/2}$, and since the number of choices for $\rho_0, \rho_1, \ldots, \rho_k$

is at most $\binom{41k+40}{k}$ (the number of nonnegative integral solutions to $x_0 + x_1 + \cdots + x_{k+1} = 40(k+1)$) we have

$$\begin{aligned}\mathbf{Pr}\left(Z_1 \geq \zeta\frac{\ln n}{n}\right) &\leq 2n^{2-\zeta/2}\sum_{k=0}^{k_0}\frac{(\ln n)^{k-1}}{(k-1)!}\binom{42k}{k}\int_{y=0}^{\infty} y^{k-1}n^{-y/2}dy\\ &\leq 2n^{2-\zeta/2}\sum_{k=0}^{k_0}\frac{(\ln n)^{k-1}}{(k-1)!}\left(\frac{42e}{\ln n}\right)^k\Gamma(k)\\ &\leq 2n^{2-\zeta/2}(k_0+1)(42e)^{k_0+2}\\ &= o(n^{-2}).\end{aligned}$$

Similarly, whp $Z_2 \leq \zeta\frac{\ln n}{n}$, where Z_2 is the maximum of the RHS of expression (7) over sequences $y_0, x_0, y_1, \ldots, y_k, x_k$ where (x_i, y_{i+1}) is one of the 40 shortest arcs leaving y_i.

If $x \in X$ and $y \in Y$, then Lemma 5 implies that whp there is a path of length at most k_0 from x to y, and by the above it will whp have length at most $Z_1 \leq \zeta\frac{\ln n}{n}$. For paths from $y \in Y$ to $x \in X$ we bound the path length with Z_2. For a path from $x \in X$ to $x' \in X$ we find a low weight path P' from x to $y' = \pi(x')$ and extend it to x', at lower cost. (x' cannot be on P'; otherwise y' appears at least twice on P'.) For a path between $y \in Y$ and $y' \in Y$ we add (y, x) to a low weight path from $x = \pi^{-1}(y)$ to y'. □

We can now prove Theorem 2, repeated here for convenience.

THEOREM 2. *Whp over random cost matrices C,*

$$(1 - o(1))\frac{\ln n}{n} \leq C_{\max} \leq c_2\frac{\ln n}{n}.$$

Proof. The lower bound follows easily from the fact that $\frac{\ln n}{n}$ is the threshold probability for a random bipartite graph to have a perfect matching, as shown by Erdős and Rényi [9].

For the upper bound, define $\vec{D} = \vec{D}_{C,\pi}$ as per (4) and (5). From the preceding lemma, we can assume the existence of a cheap alternating path P_x from any x to $\pi(x)$,

$$x = x_0, y_0, x_1, y_1, \ldots, x_k, y_k = \pi(x), \qquad k \leq k_0 + 1, \tag{8}$$

consisting of cheap forward edges and backward matching edges.

Suppose any edge in the optimal matching had cost $C(x, \pi(x)) > \frac{c_2 \ln n}{n}$. $P(x)$, followed by the backward edge $(\pi(x), x)$, is an alternating circuit, which in this case has cost $\leq \frac{c_2 \ln n}{n} - C(x, \pi(x)) < 0$. "Adding" the alternating circuit to the matching (adding its forward edges to the matching and deleting the backward ones from it) results in a new matching of lower cost, contradicting the hypothesis that the original matching was optimal. □

3. Analysis of the traveling salesman problem. Our goal in this section is to prove Theorem 1, recalled here for convenience.

THEOREM 1. *Over random cost matrices C,*

$$\mathrm{ATSP}(C) - \mathrm{AP}(C) \leq c_1\frac{(\ln n)^2}{n} \qquad \textit{whp}$$

and

$$\mathbf{E}(\mathrm{ATSP}(C) - \mathrm{AP}(C)) \geq \frac{c_0}{n}.$$

We prove the theorem's first assertion in sections 3.1 through 3.3, and the second in section 3.4.

If $(i, \pi(i))$, $i \in X$, is a perfect matching of $K_{X,Y}$, then $(i, \pi(i))$ also defines a *permutation digraph* (PD), i.e., a set of vertex-disjoint directed cycles which cover all n vertices of the complete directed graph $\vec{K}_n$ associated with $K_{X,Y}$. The *size* $|\pi|$ of π is the number of cycles in the permutation.

Similarly, a near-perfect matching gives rise to a near-permutation digraph (NPD), i.e., a digraph obtained from a PD by removing one edge. Thus an NPD Γ consists of any number of directed cycles and a single directed path PATH(Γ).

The edges (i, j) will be colored: red for $C(i, j) \in [0, c_2 \frac{\ln n}{n}]$; blue for $C(i, j) \in (c_2 \frac{\ln n}{n}, 2c_2 \frac{\ln n}{n}]$; green for $C(i, j) \in (2c_2 \frac{\ln n}{n}, 3c_2 \frac{\ln n}{n}]$; and black otherwise.

We will use a *three phase* method as outlined below.

Phase 1. Solve the assignment problem to obtain an optimal assignment Π and perfect matching M_π in $K_{X,Y}$; whp, only red edges are used.

Phase 2. Whp, at cost $O(\frac{(\ln n)^2}{n})$ we increase the minimum cycle length in the PD to at least $n_0 = \lceil \frac{n \ln \ln n}{\ln n} \rceil$. We use red and blue edges.

Phase 3. Whp, at cost $O(\frac{(\ln n)^2}{n})$ we convert the Phase 2 PD to a tour. We use green edges.

The point is that each phase uses cheap edges that are essentially probabilistically independent from those in earlier phases. Also, we need Phase 2 because it is hard to cheaply patch together short cycles.

3.1. Phase 1. That whp only red edges are used in an optimal assignment is immediate from Theorem 2. Furthermore, given the optimal assignment, and conditioning upon its use only of red edges, the edges which are not red can be thought of as having *independent* lengths, uniform in $[c_2 \frac{\ln n}{n}, 1]$.

Also, whp, the optimal assignment π's associated PD Π_1 is of size $|\Pi_1| \leq 2 \ln n$. This holds because π is a random permutation; we will elaborate on this in Phase 2.

3.2. Phase 2. In this phase, to increase the minimum cycle length in the PD, we will deal with each small cycle in turn. Let us describe the essence of how one small cycle C of a PD is repaired, setting aside the combinatorial and probabilistic issues. One edge (a, b) of the cycle is chosen. From vertex a, a path $P_a = (x_0 = a, y_0, x_1, y_1, \ldots, x_k)$ is grown, using red forward non-PD edges (starting with an edge out of a) alternating with PD edges traversed backward (see Figure 1). P_a corresponds to an alternating path in the bipartite digraph $\vec{D}$. From b a similar path $P_b = (y'_0 = b, x'_0, y'_1, x'_1, \ldots, y'_l)$ is grown, alternating non-PD edges traversed backward (starting with a nonmatching edge into b traversed backward) with PD edges traversed forward. The a-path, followed by the edge joining its terminal x_k to the terminal y'_l of the b-path, followed by the reversed b-path, followed by the edge (b, a), defines an alternating circuit. The "sum" of this circuit and the original PD is a new PD. If the two paths, and the edge (x_k, y'_l) bridging their endpoints, are cheap, the new PD is not much more expensive than the old one. Furthermore, if done properly, we will have at least one less small cycle.

It is important to see how these changes are viewed in the context of our PD. Consider the sum of the original PD and the path P_a as this path grows. After removing (a, b) alone we have an NPD which contains a path $Q = C \setminus \{(a, b)\}$ from b to a. As we grow P_a we change Q. It will always start at b, and at some stage suppose its other endpoint is x_i. Suppose now that the next y_i lies on a PD cycle A which is disjoint from Q. In this case x_{i+1} is the predecessor of y_i on A, and Q grows by

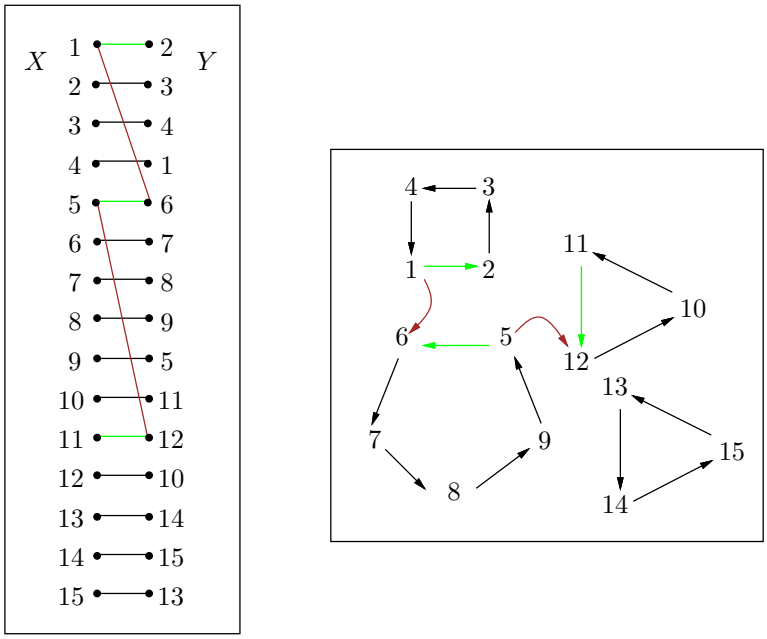

FIG. 1. *In the left box is a bipartite graph with matching edges shown as horizontals (black or grey). The right box shows the corresponding oriented cycle cover indicated by straight arrows (black or grey), for example, the arrow* $1 \longrightarrow 2$ *indicating that* X *vertex* 1 *is matched to* Y *vertex* 2. *We imagine that only the pentagon is a "long" cycle, and all the others are short cycles needing repair.*

Suppose that to repair the cycle $1, 2, 3, 4$ *we had selected edge* $(1, 2)$. *In the bipartite graph we find a path, rooted at* 1, *of cheap (red) forward edges (shown as slanted grey lines in the left box) alternating with matching edges (horizontal solid lines), in this case the path* $x_1, y_6, x_5, y_{12}, x_{11}$. *The right box shows the NPD obtained from this alternating path—the light grey edges being removed from the cycle cover and the bent edges added to it.*

Suppose that in symmetry to the alternating path $1, 6, 5, 12, 11$ *we found a cheap alternating path such as* $2, 7, 8$, *this time taking nonmatching edges backward and matching edges forward. Furthermore suppose the edge* $(11, 8)$ *happened to be cheap (red or blue). Then taking the first path, the edge* $(11, 8)$, *the reversal of the second path, and the reversed edge* $(1, 2)$ *gives a cheap alternating cycle* $1, 6, 5, 12, 11, 8, 7, 2$.

Adding this alternating cycle to the PD repairs the short cycle $1, 2, 3, 4$, *yielding instead the cycle* $1, 6, 7, 2, 3, 4$. *In this case we also serendipitously repair the cycle* $10, 11, 12$, *instead getting the cycle* $8, 9, 5, 12, 10, 11$. *The cycle* $13, 14, 15$ *(like most cycles, most of the time) is uninvolved.*

adding the path $A \setminus \{(x_{i+1}, y_i)\}$. On the other hand, if y_i is a vertex of Q, then x_{i+1} will be the predecessor of y_i on Q. In this case removing (x_{i+1}, y_i) leaves a shorter Q plus a new cycle which has been "split off."

When we construct P_b, we can think of starting with the NPD, and in particular with the Q constructed from P_a, and now extending Q from the b end. As long as no cycles split off are small, and either y_0 or x'_0 is on a large cycle, the new cycle containing a and b, and any other new cycles formed, will be large. We will try to arrange for this to be the case, otherwise declaring the attempt a failure.

In fact we will construct this alternating path from a to b as the conjunction of a path P_a directed out of a to some vertex z and a path P_b directed from some vertex z' into b, plus the edge (z, z'). We will require (z, z') to be a blue edge. In order to find such a pair z, z' whp, we will have to produce *many* candidates for P_a, P_b.

If we fail to remedy a small cycle, then the entire algorithm fails. If we succeed,

we proceed to the next small cycle, until all small cycles are repaired.

Of course the "new" PD of one case becomes the "original" PD of the next one, and the most difficult part of the analysis will be to handle conditioning that might be introduced by this evolving cycle structure. (We will rely on the fact that a PD is induced by a bipartite matching *when the two sets of vertices are put into correspondence by a labeling*, and until that labeling is established, the PD and the matching are in a sense independent.)

The reader will notice that we are using red edges twice, once to find the optimal assignment π and again in Phase 2 to get rid of small cycles. Thus we have to be very careful about conditioning. It would be much simpler to give up another $\log n$ factor by using blue edges for this phase, but we feel that we are getting close to the true upper bound and that the effort is worthwhile. As we will see, the crucial new idea is to condition on the sizes of the cycles in the optimum PD for the assignment problem.

The first detail is the construction of the cheap alternating paths out of vertices a and b. Paths alternating with respect to a PD as described above are—equivalently—alternating with respect to the corresponding bipartite matching. We begin by finding a cheap "alternating tree" (really an alternating directed acyclic graph, or DAG), rooted at a, containing many cheap alternating paths. After doing the same for b, we hope to find a cheap edge between some a-leaf and some b-leaf, and we use the paths determined by these leaves.

To define the trees, recall the definitions (2) and (3) of $N_k(S)$ and $N_k(T)$. For the remainder of this section let K be a suitably large constant. Let $E_K = \{(x,y) \in E(K_{X,Y}) : y \in N_K(x) \text{ or } x \in N_K(y)\}$.

LEMMA 8. *For any fixed K, whp over random matrices C, every set of $s \le s^* = \frac{\ln n}{2 \ln \ln n}$ vertices spans at most s edges from E_K.*

Proof. Since K is large, we know that whp every edge in E_K has length at most $2K\frac{\ln n}{n}$. (Chernoff bounds imply that whp there are at least K edges of length $\le 2K\frac{\ln n}{n}$ leaving and entering *every* vertex.) Starting with the $o(1)$ failure probability for that event, the probability there exists a small set S containing $|S|+1$ edges (even counting loops) is at most

$$\begin{aligned}
&o(1) + \sum_{s=1}^{s^*} \binom{n}{s}\binom{s^2}{s+1}\left(2K\frac{\ln n}{n}\right)^{s+1} \\
&\le o(1) + \sum_{s=1}^{s^*} \left(\frac{ne}{s}\right)^s \left(\frac{s^2 e}{s+1}\right)^{s+1}\left(2K\frac{\ln n}{n}\right)^{s+1} \\
&\le o(1) + \sum_{s=1}^{s^*} \frac{s}{n}(2e^2 K \ln n)^{s+1} \\
&= o(1)
\end{aligned}$$

(that is, the number of ways of choosing s vertices, the number of ways of choosing $s+1$ edges from the s^2 edge slots including loops, times the probability that all these edge slots are realized by edges). ∎

LEMMA 9. *Whp over random matrices C, for all $S \subseteq X$, $T \subseteq Y$, with $|S|, |T| \le n^{3/4}$,*

$$|N_K(S)| \ge (K-2)|S| \text{ and } N_K(T)| \ge (K-2)|T|. \tag{9}$$

Proof. Just as in deriving (6),

$$\begin{aligned}
&\mathbf{Pr}(\exists S \text{ or } T:\ \neg(9)) \\
&\le 2\sum_{s=1}^{n^{3/4}} \binom{n}{s}\binom{n}{(K-2)s}\left(\frac{\binom{(K-2)s}{K}}{\binom{n}{K}}\right)^s \\
&\le 2\sum_{s=1}^{n^{3/4}} \left(\frac{ne}{s}\right)^s \left(\frac{ne}{(K-2)s}\right)^{(K-2)s} \left(\frac{(K-2)s}{n}\right)^{Ks} \\
&= 2\sum_{s=1}^{n^{3/4}} \left(\frac{e^{K-1}(K-2)^2 s}{n}\right)^s \\
&= o(1). \qquad \square
\end{aligned}$$

We say that a cycle C of Π_1 is *small* if $|C| < n_0$; recall that we defined

$$n_0 = \left\lceil \frac{n \ln\ln n}{\ln n} \right\rceil.$$

Detailed analyses of random permutations have been performed by Arratia, Barbour, and Tavaré [3], in which the joint distribution of counts k_i of cycles of length i is approximated by independent Poissons $Z_i \sim \mathrm{Pois}(1/i)$, and by Arratia and Tavaré [4], who provide a tighter bound on the variation distance between the true distribution and the Poisson approximation. From these (or more elementary analyses) we observe first that the expected number of vertices on small cycles is $n_0 - 1$, and so with probability $1 - O(n_0/n)$,

(10) there are less than $2n_0$ vertices on small cycles.

(The distance between the true distribution and independent Poisson estimate dominates the bound; the probability the Poissons exceed their expectation of n_0 by a factor of 2 is much smaller.) Assume from now on that π satisfies (10).

Let the small cycles of Π_1 be $C_1, C_2, \ldots, C_\lambda$. At the start of Phase 2, from each small cycle C we choose an edge (a, b) of C. Let the chosen edges be $(a_i, b_i), i = 1, 2, \ldots, \lambda$. We now describe how we try to remove a C_i without creating any new small cycles. (See Figure 1.)

As before, we use expansion to create many short alternating paths. Let a bijection (matching) ρ_i between X and Y be given, and let one matching edge (a_i, b_i) be specified. Define branching factors

$$r_1 = \lceil K \ln n \rceil \qquad \text{and} \qquad r_t = K,$$

respectively, for a first generation, $t = 1$, and for all subsequent generations, $t \ge 2$. For each i we construct a pair of "trees" (actually DAGs), S_i rooted at a_i and T_i at b_i, which we will use to modify bijection $\rho = \rho_i$. Their depth-t nodes consist of the sets $S_i^{(t)}$ and $T_i^{(t)}$, respectively. The depth-0 node sets are the singletons

$$S_i^{(0)} = \{a_i\} \text{ and } T_i^{(0)} = \{b_i\}.$$

Define

$$s_0 = \frac{\ln n}{12 \ln\ln n},$$

and for $1 \le t \le s_0$ let

$$S_i^{(t)} = \rho^{-1}(N_{r_t}(S_i^{(t-1)})) \text{ and } T_i^{(t)} = \rho(N_{r_t}(T_i^{(t-1)})).$$

For $t > s_0$ let

$$S_i^{(t)} = \rho^{-1}(N_{r_t}(S_i^{(t-1)})) \setminus \left(\bigcup_{i'=1}^{i-1} \bigcup_{u=1}^{\ln\ln n} S_{i'}^{(u)} \cup \bigcup_{i'=1}^{i-1} \bigcup_{u=1}^{\ln\ln n} \rho^{-1}(T_{i'}^{(u)}) \right)$$

$$T_i^{(t)} = \rho(N_{r_t}(T_i^{(t-1)})) \setminus \left(\bigcup_{i'=1}^{i-1} \bigcup_{u=1}^{\ln\ln n} T_{i'}^{(u)} \cup \bigcup_{i'=1}^{i-1} \bigcup_{u=1}^{\ln\ln n} \rho(S_{i'}^{(u)}) \right).$$

It is immediate that $|S_i^{(1)}| = |T_i^{(1)}| = r_1$. For $t \ge 2$ and (as will always be the case) $i < 4\ln n$, it follows from Lemmas 8 and 9 that whp $|S_i^{(t)}| \ge (K-4)|S_i^{(t-1)}|$ and $|T_i^{(t)}| \ge (K-4)|T_i^{(t-1)}|$ as long as both $S_i^{(t-1)}$ and $T_i^{(t-1)}$ are of size at most $n^{3/4}$. Indeed, Lemma 8 implies that whp for all $i' < i$,

$$\left| \bigcup_{t=1}^{s_0} S_i^{(t)} \cap \bigcup_{t=1}^{s_0} S_{i'}^{(t)} \right| \le 2. \tag{11}$$

(Otherwise, if the repeated points are x_1, x_2, x_3, then the paths between $a_i, a_{i'}$ and x_1, x_2, x_3 form a bicyclic graph with at most $6s_0$ vertices, contradicting Lemma 8.) Combining this with Lemma 9 means that for $t \le s_0$, $|S_i^{(t)}| \ge (K-4)|S_i^{(t-1)}|$. For generations $t > s_0$, for each i' the sets subtracted out are of size $O(K^{\ln\ln n})$, and so as long as $i < 4\ln n$, in all, the sets subtracted out are of size $O(K^{\ln\ln n}\ln n)$, much smaller than the size $\Omega((K-4)^{s_0})$ to which the set $S_i^{(t)}$ has by then grown. By throwing away vertices if necessary, we can assume that $|S_i^{(t)}| = (K-4)|S_i^{(t-1)}|$ and $|T_i^{(t)}| = (K-4)|T_i^{(t-1)}|$. Thus if

$$\tau = \lceil 1 + \log_{K-4}(n^{3/4}/\lceil K\ln n\rceil)\rceil,$$

then whp

$$\forall i:\ n^{3/4} \le |S_i^{(\tau)}| = |T_i^{(\tau)}| \le Kn^{3/4}. \tag{12}$$

Each $x \in S_i^{(t)}$ defines a *walk* from a_i to x, of length $2t$, which is alternating with respect to the matching M_ρ; prune it to define a *path* $P[i,x]$. Similarly, each $y \in T_i^{(t)}$ defines a path $Q[i,y]$ from y to b_i, of length at most $2t$, which is alternating with respect to M_ρ.

Suppose that we have removed $C_1, C_2, \ldots, C_{i-1}$ and that the original permutation π has become $\rho = \rho_i$. Assume that we have not already serendipitously removed C_i as well. Let (a_i, b_i) be the chosen edge of C_i.

Each alternating path $P[i,x]$ starts with a "forward" edge which is one of the $K\ln n$ shortest edges leaving a_i (the first branching factor was $r_1 = K\ln n$), has up to $\tau - 1$ other forward edges,[3] each of which is one of the K shortest edges leaving a vertex, and has an additional up to τ "backward" matching edges (edges in M_ρ). A symmetric condition holds for $Q[i,y]$.

[3]Fewer than $\tau - 1$ if the path $P[i,x]$ resulted from nontrivially pruning a $(\tau-1)$-long walk.

It follows from the proof of Lemma 7 that whp each of these paths is such that the total length of its forward edges minus the total length of its backward edges is bounded by $c_4 \frac{\ln n}{n}$.

We now see that if we find $\xi_i \in S_i^{(\tau)}$ and $\eta_i \in T_i^{(\tau)}$ such that (ξ_i, η_i) is red or blue (recall the definition from the start of section 3) then it—together with the edge (a_i, b_i) and the paths $P[i, \xi_i]$ and $Q[i, \eta_i]$—defines an alternating cycle whose action on the current perfect matching increases the matching's cost by at most $(2c_4 + 2c_2)\frac{\ln n}{n}$. We now show that we can whp find at least one such alternating cycle whose action *does not create any new small cycles*. Furthermore, if such a path contains an edge of $C_{i'}$, $i' > i$, then this alternating cycle will also remove the small cycle $C_{i'}$.

Let ϕ be a random permutation of $[n]$ associating the vertices of X to those of Y, and let matrix $\hat{C}$ be defined by $\hat{C}(i,j) = C(i, \phi(j))$. If ψ is the (with probability 1, unique) minimum solution to the assignment problem with matrix $\hat{C}$, then $\pi = \phi\psi$ is the minimum solution to the original problem. We exploit the randomness of ϕ, which produces a random permutation π from ψ. Instead of taking π as given, we assume that ψ is given and π is to be obtained through a random permutation ϕ. We condition on the cycle structure of π. Defining k_i as the number of cycles of length i in π, we assume that (i) $\sum_{i=1}^{n_0} i k_i \le 2n_0$ and that (ii) $\sigma = \sum_{i=1}^{n} k_i \le 2 \ln n$; these conditions hold whp.

How do we sample a random permutation conditioned upon having a cycle structure dictated by $k_1, k_2, \ldots$, i.e., dictated by the multiset $\{k_i \times i : i \in [n]\}$ in which cycle length i appears k_i times? Let Π denote the set of permutations of X with the given cycle structure. Let γ be any fixed permutation with the given cycle structure. (For example, if $t_1 = 0$, $t_{\sigma+1} = n$, and the multisets $\{t_{j+1} - t_j : j \in [\sigma]\}$ and $\{k_i \times i : i \in [n]\}$ coincide, then we may define γ by the following: If $x, y \in C_j$ and $y = x + 1 \bmod t_{j+1} - t_j$, then $\gamma(x) = y$.) Then given a bijection $f : X \to X$ we define a permutation π_f on X by $\pi_f = f^{-1}\gamma f$. Each permutation $\pi \in \Pi$ appears precisely $\prod_{i=1}^{n} k_i! i^{k_i}$ times as π_f. Thus choosing a random mapping f chooses a random π_f from Π. (This is equivalent to randomly choosing $\phi = f^{-1}\gamma f \psi^{-1}$.)

The most natural way to look at this is to think of having oriented cycles on the plane whose vertices are at points $P_1, P_2, \ldots, P_n$ and then randomly labeling these points with X. Then if P' follows P on one of the cycles and P, P' are labeled x, x' by f, then $\pi_f(x) = x'$.

To give a concrete example, Figure 1 included a "canonical" digraph 4-cycle, labeled $1, 2, 3, 4$, arising from a corresponding canonically labeled structure in the bipartite graph, the matching edges (x_1, y_2), (x_2, y_3), (x_3, y_4), (y_4, x_1). In a random labeling dictated by a random permutation f, these matching edges would be labeled $(x_{f(1)}, y_{f(2)})$, $(x_{f(2)}, y_{f(3)})$, $(x_{f(3)}, y_{f(4)})$, $(x_{f(4)}, y_{f(1)})$, and the digraph's 4-cycle would be labeled $f(1)$, $f(2)$, $f(3)$, $f(4)$.

As we proceed through Phase 2 we have to expose parts of f (equivalently ϕ). x is *clean* if $f(x)$ is unexposed (the label x has not yet been used) and *dirty* otherwise. Thus imagine that we have cycles, mostly unlabeled, but with a few vertices labeled. Let us use $\tilde{}$ to denote a partially labeled graph.

We can now add the final layer to our description of how to eliminate the small cycles. We proceed in order through the selected edges $i \in [\lambda]$. At stage i we should have eliminated $C_1, C_2, \ldots, C_{j-1}$ for some j, and have a current perfect matching M_i, defining ρ_i. (Consider M_i to be fully revealed, but the labels on its vertices not revealed except for the selected edges in short cycles; thus all that is revealed of ρ_i is its cycle structure and labels on these few edges.)

We construct the trees S_i and T_i and then seek red or blue edges between the leaves $S_i^{(\tau)}$ of S_i and $T_i^{(\tau)}$ of T_i. We will consider only vertices of $S_i^{(t)}$ and $T_i^{(t)}$ that are clean and whose paths to their respective roots also contain only clean vertices; call these vertices *squeaky clean*. We take the squeaky clean vertices $v \in S_i^{(\tau)}$ in some fixed order. For each such vertex v we look, again in some fixed order, at each squeaky clean vertex $w \in T_i^{(\tau)}$. Each such edge (v, w) is either red or has length uniform in $[c_2 \frac{\ln n}{n}, 1]$. Thus the probability that it is red or blue is at least $c_2 \frac{\ln n}{n}$. This lower bound holds conditionally on the current history—see the comment at the beginning of section 3.1. We assert that

(13) whp there are $\geq n^{3/5}$ squeaky clean vertices in each of $S_i^{(\tau)}$ and $T_i^{(\tau)}$;

this will be shown in the last paragraph in this subsection. Thus if we run through $n^{2/5}$ squeaky clean vertices $v \in S_i^{(\tau)}$, the expected number of red or blue edges to squeaky clean vertices $w \in T_i^{(\tau)}$ is $\geq c_2 \frac{\ln n}{n} \cdot n^{2/5} \cdot n^{3/5}$, and with probability $\geq 1 - e^{-c_2 \ln n} = 1 - n^{-c_2}$, we find at least one red or blue edge. For a given v, if we find no red or blue edge to any w, we move on to the next v. If we find a red or blue edge (v, w), we test it for *acceptability* as described in the following paragraphs. If the edge is acceptable, the cycle can be repaired and we move on to the next cycle i. If the edge is not acceptable, v and w have been dirtied in the course of the testing, and we move on to the next v. Because we find a red or blue edge after exploring about $n^{2/5}$ vertices from $S_i^{(\tau)}$, and $|S_i^{(\tau)}| \geq n^{3/5}$, we can find at least $n^{1/5}$ red or blue edges to test; we will soon see that the failure probability is $\ll n^{-1/5}$, so eventual success is assured whp.

Now consider squeaky clean $\xi_i \in S_i^{(\tau)}, \eta_i \in T_i^{(\tau)}$ such that (ξ_i, η_i) is red or blue. In the bipartite graph, there is a squeaky clean alternating circuit $C = P[i, \xi_i]$, (ξ_i, η_i), $Q[i, \eta_i]$, (b_i, a_i). (C may start life with vertices crossed multiple times, but we can prune it down to a circuit containing (b_i, a_i).) We will define what it means for a cycle to be "acceptable" and show that C is acceptable with probability at least $(\ln n)^{-\alpha}$, where

$$\alpha = 7(\ln K)^{-1} < 1/2.$$

For any $x \in S_i^{(t)}$, consider $P[i, x] = (x_0 = a_i, y_1, x_1, y_2, \ldots, y_t, x_t = x)$, where $y_j = \rho_i(x_j)$ for $j \geq 1$. $P[i, x]$ defines a sequence $M^{(0)}, M^{(1)}, \ldots, M^{(t)}$ of near-perfect matchings (see Figure 2) $M^{(s)} = (M^{(s-1)} \cup \{(x_{s-1}, y_s)\}) \setminus \{(x_s, y_s)\}$. Let $\Gamma^{(0)}, \Gamma^{(1)}, \ldots, \Gamma^{(t)}$ be the associated NPDs. We say that $\Gamma^{(s)}$ is *acceptable* if (i) $|\mathrm{PATH}(\Gamma^{(s)})| \geq n_0$ and (ii) the small cycles of $\Gamma^{(s)}$ are a subset of $\{C_{i+1}, \ldots, C_\lambda\}$. We say that x is acceptable if $\Gamma^{(0)}, \Gamma^{(1)}, \ldots, \Gamma^{(t)}$ are all acceptable.

Going back to $P[i, x = x_t]$, let us estimate the probability that x_t is acceptable, given that it is clean and x_{t-1} is acceptable. Assume that we have revealed $f(x_{t-1})$ and that we have a partially labeled NPD $\tilde{\Gamma}_i^{(t-1)}$. We randomly choose $f(x_t)$ from the unlabeled points and label it with x_t. We then replace the arc $(f(x_t), \cdot)$ of $\tilde{\Gamma}_i^{(t-1)}$ with $(f(x_{t-1}), \cdot)$.[4] When $t = 1$, x_1 is acceptable unless $f(x_1)$ lies in a small cycle; it follows from (10) that given the previous exposures, this has probability at most $p_1 = 3 \frac{\ln \ln n}{\ln n}$. For $t > 1$, x_t will be acceptable if $f(x_t)$ is not within n_0 of an endpoint

[4]When dealing with the path from b_i to η_i we randomly choose $f(x_t)$ and then replace the arc $(f(x_{t-1}), \cdot)$ with $(f(x_t), \cdot)$.

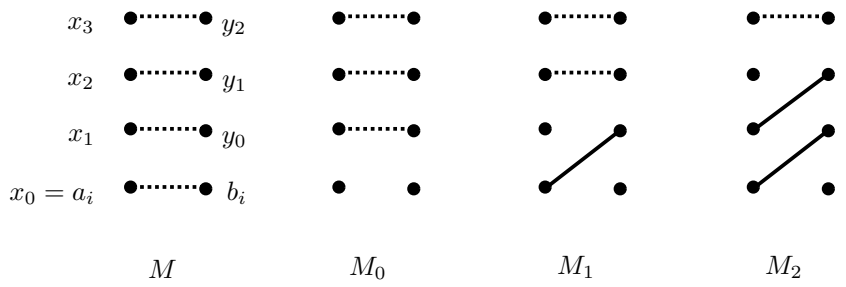

FIG. 2. *For $t = 3$, a perfect matching (dashed edges) and the sequence of near-perfect matchings (dashed and solid edges) defined by an alternating path $(x_0 = a_i, y_1, x_1, y_2, \ldots, x_t = x)$ (the union of all edges shown).*

of PATH($\tilde{\Gamma}_i^{(t-1)}$). We will see that

whp only $O((\ln n)^{2\alpha})$ squeaky clean alternating circuits need to be checked before an acceptable one is found.

Since each path has $O(\ln n)$ points, $|S_i^{(\tau)}|, |T_i^{(\tau)}| = O(n^{3/4})$ (12), and we repeat for $O(\ln n)$ cycles, in all, at most $\tilde{O}(n^{3/4})$ values of f are exposed.[5] So if x_t is clean, it will be unacceptable with probability at most $p_2 = \frac{2n_0}{n-\tilde{O}(n^{3/4})} \le \frac{3\ln\ln n}{\ln n}$ conditional on previous exposures. A similar analysis holds for the paths $Q[i, y]$.

If all vertices on C are clean, then the probability that C is not acceptable is at most $p_1 + 1 - (1-p_2)^{2\tau} \le \frac{3\ln\ln n}{\ln n} + 1 - \big(1 - \frac{3\ln\ln n}{\ln n}\big)^{2\tau} \le 1 - (\ln n)^{-\alpha}$. Thus if we can find $(\ln n)^{2\alpha}$ clean cycles, then one of them will succeed, with probability at least $1 - (1 - (\ln n)^{-\alpha})^{(\ln n)^{2\alpha}} \ge 1 - \exp\{-(\ln n)^{\alpha}\}$. As remarked earlier, we can find far more clean cycles than this—in fact around $n^{1/5}$ of them—as long as there are around $n^{3/5}$ squeaky clean vertices in each of $S_i^{(\tau)}$ and $T_i^{(\tau)}$; this is all that remains to be shown.

Let $A_i^{(t)}$ denote the squeaky clean vertices of $S_i^{(t)}$, $t = 1, 2, \ldots, \tau$. It follows from Lemmas 8 and 9 that $|A_i^{(1)}| \ge K \ln n - 4\lambda - (\ln n)^{2\alpha}$ (λ is the number of small cycles) and that $|A_i^{(t)}| \ge (K-4)|A_i^{(t-1)}| - 4\lambda - (\ln n)^{2\alpha}$ for $2 \le t \le \ln\ln n$. Here we use (11) to argue that for $i' < i$, the first $\ln\ln n$ levels of each $S_{i'}, T_{i'}$ dirty at most 2 vertices of the first $\ln\ln n$ levels of S_i, giving the 4λ term. The $(\ln n)^{2\alpha}$ term comes from vertices dirtied during failed acceptability tests for the current cycle i, one dirtied vertex per level t per failed test. The higher levels of $S_{i'}, T_{i'}$ do not dirty any of the lower levels of S_i, by construction. In general, for $t > \ln\ln n$, Lemma 9 implies that $|A_i^{(t+1)}| \ge (K-4)|A_i^{(t)}| - 4\lambda\tau(\ln n)^{2\alpha}$. Thus, $|A_i^{(\tau)}| \ge n^{3/5}$. A similar argument holds for squeaky clean vertices of $T_i^{(\tau)}$, verifying assertion (13).

3.3. Phase 3. For Phase 3 we use the green edges. We can assert that whp at the end of Phase 2, all cycles are of length at least n_0 and so there are $o(\ln n)$ cycles. Given two cycles C_1, C_2 each of length at least n_0, the probability that we cannot patch them together (delete edges (a_i, b_i) from C_i, $i = 1, 2$ and replace them with red or blue or green edges $(a_1, b_2), (a_2, b_1)$) is at most $(1 - \frac{c_2^2(\ln n)^2}{n^2})^{n_0^2} \le e^{-c_2^2(\ln\ln n)^2}$.

[5] Recall that $\tilde{O}$ suppresses $\ln n$ factors.

Doing this $o(\ln n)$ times increases the cost by at most $o(\frac{(\ln n)^2}{n})$ and so Phase 3 succeeds whp.

This completes the proof of the high-probability upper bound on ATSP − AP.

We now consider the lower bound of Theorem 1.

3.4. Proof of the lower bound. The AP can be expressed as a *linear program*:

(LP)

$$\text{Minimize } \sum_{i,j} C(i,j)z_{i,j} \text{ subject to } \sum_i z_{i,k} = \sum_j z_{k,j} = 1, \forall k, 0 \le z_{i,j} \le 1, \forall i,j.$$

This has the dual linear program:

$$\text{(DLP)} \qquad \text{Maximize } \sum_i u_i + \sum_j v_j \text{ subject to } u_i + v_j \le C(i,j),\ \forall i,j.$$

Remark 10 (condition on an optimal basis for (LP)). We may w.l.o.g. take $u_1 = 0$ in (DLP), whereupon with probability 1 the other dual variables are uniquely determined. Furthermore, the reduced costs of the *nonbasic* variables $\bar{C}(i,j) = C(i,j) - u_i - v_j$ are independently and uniformly distributed, with $\bar{C}(i,j) \in_{\text{unif}} [\max\{0, -u_i - v_j\}, 1 - u_i - v_j]$.[6]

Proof. The $2n-1$ dual variables are unique with probability 1 because they satisfy $2n-1$ linear equations. The only conditions on the nonbasic edge costs are that $C(i,j) \in [0,1]$ (equivalently $\bar{C}(i,j) \in [-u_i - v_j, 1 - u_i - v_j]$) and $\bar{C}(i,j) \ge 0$; intersecting these intervals yields the last claim. ∎

LEMMA 11. *Whp*

$$\max_{i,j} \{|u_i|, |v_j|\} \le c_5 \frac{\ln n}{n}. \tag{14}$$

Proof. Optimal dual values u_i, v_j can be characterized as shortest distances, as follows [1]. Consider a directed bipartite digraph Γ on $X \cup Y$ with "forward" edges (x_i, y_j), $i,j \in [n]$, $j \ne \pi(i)$, of length $C(i,j)$; and "backward" edges (y_j, x_i), $i,j \in [n]$, $j = \pi(i)$, of length $-C(i,\pi(i))$. If $u_1 = 0$, then $-u_i$ is the shortest distance $d(x_1, x_i)$ from x_1 to x_i in Γ, and v_j is the shortest distance from x_1 to y_j.[7]

Lemma 7 implies that $-u_i, v_i \le c_6 \frac{\ln n}{n}$ for $i \in [n]$. Furthermore, using the fact that a cheapest path is also a cheapest walk (derived from the optimal assignment, Γ has no negative-cost cycles), $-u_j = d(x_1, x_j) \le d(x_1, x_i) + d(x_i, x_j) \le -u_i + c_6 \frac{\ln n}{n}$ implies $u_i - u_j \le c_6 \frac{\ln n}{n}$. Immediately, $|u_i| \le c_6 \frac{\ln n}{n}$ and also, with $\bar{u} = \sum u_i/n$, $|\bar{u}| \le c_6 \frac{\ln n}{n}$. Likewise, $v_i - v_j \le c_6 \frac{\ln n}{n}$, from which $|v_i - \bar{v}| \le c_6 \frac{\ln n}{n}$. But we know that whp the optimal assignment cost satisfies $(1-\epsilon)\pi^2/6 < \sum_i u_i + \sum_j v_j < (1+\epsilon)\pi^2/6$ for any fixed positive ϵ [2, 16], so $\bar{v} \in (1.6/n - \bar{u},\ 1.7/n - \bar{u})$, giving $|\bar{v}| \le c_6 \frac{\ln n}{n} + O(1/n)$ and finally $|v_j| \le c_7 \frac{\ln n}{n}$. (While the tight assignment bounds from [2, 16] are elegant, for our purposes older bounds from [8, 13] would suffice.) ∎

[6] Do not be misled by the notation: $-u_i - v_j$ can be (and often is) positive.

[7] It is easy to see this from the graph with edge costs $\bar{C}(i,j) = C(i,j) - u_i - v_j \ge 0$. This graph includes a spanning tree of 0-cost edges, so all distances are 0. The C-cost of any path is almost the same as its $\bar{C}$-cost: Of the two directed edges leading into and out of any intermediate node, one has a u_i (or v_j) added, and the other has the same quantity subtracted. The cancellation fails only at the path's source (but we defined $u_1 = 0$) and at its terminal, resulting in C-distance $-u_i$ or $+v_j$ as claimed.

Having solved (LP) we will have n basic variables $z_{i,j}$, $(i,j) \in I_1$, with value 1 and $n-1$ basic variables $z_{i,j}$, $(i,j) \in I_2$, with value 0. The edges (x_i, y_j), $(i,j) \in I = I_1 \cup I_2$ form a tree T^* in $K_{X,Y}$. We show that with probability at least $c_9 > 0$ there exists $(i,i) \in I_1$ (a loop) such that (x_i, y_i) is a pendant edge in T^*; w.l.o.g. suppose x_i is its leaf. In this case the optimal TSP tour, viewed as a bipartite matching, cannot use the edge (x_i, y_i) (a loop), and must use some other edge $(x_i, y_{i'})$; since x_i is a leaf in T^*, $z_{i,i'}$ is not a basic LP variable. The expected value of the reduced cost of $z_{i,i'}$ is at least $\frac{c_{10}}{n}$, and so $\mathbf{E}(\mathrm{ATSP} - \mathrm{AP}) \geq \frac{c_9 c_{10}}{n}$ and the lower bound follows.

To prove the existence of (i,i) we show that whp the optimal assignment ψ for $\hat{C}$ of section 3 has at least $c_{11} n$ leaves L. After applying the random permutation ϕ, the number of leaves giving rise to loops is, at least, a random variable whose distribution is asymptotically Poisson with density c_{11}; thus

$$\mathbf{Pr}(\exists \text{ at least one leaf-loop}) \geq (1 - o(1))(1 - e^{-c_{11}}).$$

By taking a spanning tree T of $K_{X,Y}$ that contains a perfect matching M, and shrinking the edges of M, we obtain a tree isomorphic to a spanning tree T' of K_n. Each T arises from exactly 2^{n-1} trees T' because we have two choices as to how to configure each non-M edge. (An (i,j) edge in T' can in T be expanded to (x_i, y_j) or to (x_j, y_i).) Let $b(T) = b(T')$ denote the number of branching nodes (degree ≥ 3) of T and T'. A tree T' is ϵ-bushy if $b(T') \leq \epsilon n$. Bohman and Frieze used this concept in [6] and showed that the number of ϵ-bushy trees is at most $n! e^{\theta(\epsilon) n}$, where $\theta(\epsilon) \to 0$ as $\epsilon \to 0$. It follows that the number of ϵ-bushy trees of $K_{X,Y}$ which have a perfect matching is at most $e^{\theta(\epsilon) n} 2^{n-1} n!$. Observe that the number of leaves in T is at least $b(T)$. We complete the proof by showing that, for a sufficiently small constant ϵ,

$$\mathbf{Pr}(T^* \text{ is } \epsilon\text{-bushy}) = o(1). \tag{15}$$

For any tree T with a perfect matching, we can put $u_1 = 0$ and then solve the equations $u_i + v_j = C(i,j)$ for $(x_i, y_j) \in T$ to obtain the associated dual variables. T is optimal if $\bar{C}(i,j) = C(i,j) - u_i - v_j \geq 0$ for all $(x_i, y_j) \notin T$. Let $Z_T = \sum_i u_i + \sum_j v_j$. Now whp the optimal tree T^* satisfies $Z_{T^*} \in [1.6, 1.7]$, because Z_{T^*} is the optimal assignment cost, and it is known both that expectation is in the stated range [2] and that the actual value is concentrated about the expectation [16]. Then if $\mathcal{E}$ denotes the event $\{(14) \text{ and } Z_T \in [1.6, 1.7]\}$, for any tree T, over random matrices $C(i,j)$,

$$\begin{aligned}
&\mathbf{Pr}(Z_T \in [1.6, 1.7] \text{ and } (14) \text{ and } \bar{C}(i,j) \geq 0 \ \forall (i,j) \notin I) \\
&\quad \leq \mathbf{Pr}(\bar{C}(i,j) \geq 0 \ \forall (i,j) \notin T \mid \mathcal{E}) \times \mathbf{Pr}(Z_T \in [1.6, 1.7]) \\
&\quad \leq \frac{1.7^n}{n!} \mathbf{E}\left(\prod_{(x_i,y_j) \notin T} (1 - (u_i + v_j)^+) \mid \mathcal{E} \right) \\
&\quad \leq \mathbf{E}\left(\exp\left\{ - \sum_{(x_i,y_j) \notin T} (u_i + v_j) \right\} \mid \mathcal{E} \right) \frac{1.7^n}{n!} \\
&\quad \leq \mathbf{E}\left(e^{-n Z_T} \exp\left\{ \sum_{(x_i,y_j) \in T} (u_i + v_j) \right\} \mid \mathcal{E} \right) \frac{1.7^n}{n!} \\
&\quad \leq e^{-1.6n} n^{2c_5} \frac{1.7^n}{n!}.
\end{aligned}$$

Explanation. $\frac{1.7^n}{n!}$ bounds the probability that the sum of the lengths of the edges in the perfect matching of T is at most 1.7. The product term is the probability that each nonbasic reduced cost is nonnegative.

Thus

$$\begin{aligned}&\mathbf{Pr}(\exists \text{ an } \epsilon\text{-bushy tree } T : Z_T \in [1.6, 1.7] \text{ and (14) and } \bar{C}(i,j) \geq 0 \ \forall (i,j) \notin I)\\ &\quad \leq n! 2^n e^{\theta(\epsilon)n} \times e^{-1.6n} n^{2c_5} \frac{1.7^n}{n!}\\ &\quad = o(1)\end{aligned}$$

for ϵ sufficiently small. This implies (15). □

Remark 12. The above proof of Theorem 1's lower bound relies on there being a positive probability that the optimal AP solution includes loops. However, loops (unlike other cycles) can easily be excluded from an AP solution by changing the weight matrix C to give weight 1 to each loop. Since this potentially increases the AP cost but leaves the ATSP cost unchanged, it would be interesting to prove the Theorem 1 lower bound for random cost matrices C with diagonal entries 1.

4. An enumerative algorithm. We can now prove Theorem 4, restated here for convenience.

THEOREM 4. *Whp, a random instance of the* ATSP *can be solved exactly in time* $e^{\tilde{O}(\sqrt{n})}$.

Proof. Let I_k denote the interval $[2^{-k} c_1 \frac{(\ln n)^2}{n},\ 2^{-(k-1)} c_1 \frac{(\ln n)^2}{n}]$ for $k \geq 1$. It follows from Remark 10 and Lemma 11 that whp (i) there are $\leq c_1 2^{-(k-1)} n \ln n$ nonbasic variables $z_{i,j}$ whose reduced cost is in $I_k, 1 \leq k \leq k_0 = \frac{1}{2}\log_2 n$, and (ii) there are $\leq 2c_1\sqrt{n}\ln n$ nonbasic variables $z_{i,j}$ whose reduced cost is $\leq c_1 \frac{(\ln n)^2}{n^{3/2}}$.

We can search for an optimal solution to the ATSP by choosing a set of nonbasic variables, setting them to 1 and then re-solving the AP. If we try all sets and choose the best tour we find, then we will clearly solve the problem exactly. However, it follows from Theorem 1 that whp we need only consider sets which contain $\leq 2^k$ variables with reduced costs in I_k and none with reduced cost $\geq c_1 \frac{(\ln n)^2}{n}$. Thus whp we need only check at most

$$\begin{aligned}2^{2c_1\sqrt{n}\ln n} \prod_{k=1}^{k_0} \sum_{t=1}^{2^k} \binom{c_1 2^{-(k-1)} n \ln n}{t} &\leq 2^{2c_1\sqrt{n}\ln n} \prod_{k=1}^{k_0} (2(c_1 2^{-(k-1)} n \ln n)^{2^k})\\ &\leq 2^{2c_1\sqrt{n}\ln n} (2(c_1 2^{-(k_0-1)} n \ln n)^{2^{k_0}})^{k_0}\\ &= e^{\tilde{O}(\sqrt{n})}\end{aligned}$$

sets, using the fact that $(A/x)^x$ is monotone increasing for $x \leq A/e$. □

5. Second-best assignment. We recall and prove Theorem 3, on the gap Δ_1 between the costs of the cheapest and second-cheapest assignments.

THEOREM 3. *Over random cost matrices* C,

$$\frac{1}{n^2}(1 - o(1)) \leq \mathbf{E}(\Delta_1) \leq c_3 \frac{\ln n}{n^2}.$$

Proof. Δ_1 is equal to the minimum nonbasic reduced cost.[8] From Lemma 11 and $\sum_i u_i + \sum_j v_j > 1.6$ whp, it follows that whp there are at least $n_1 = c_7 \frac{n^2}{\ln n}$ pairs i, j such that $u_i + v_j > 0$. Each such pair corresponds to a nonbasic variable $\bar{C}(i, j)$, and it follows from Remark 10 that the minimum reduced cost among this set is at most $\frac{1}{n_1+1}$ in expectation, proving the upper bound.

For the lower bound, again from Remark 10, the $n^2 - 2n + 1$ nonbasic reduced costs $\bar{C}(i, j)$ are independent, with $\bar{C}(i, j) \in_{\text{unif}} [a_{i,j}, b_{i,j}]$, where each $a_{i,j} \geq 0$ and (from Lemma 11) each $b_{i,j} \geq 1 - 2c_5 \ln n/n$. The minimum of this collection satisfies $\mathbf{E}(\min\{\bar{C}(i, j)\}) \geq \frac{1}{n^2-2n}(1 - 2c_5 \ln n/n) = \frac{1}{n^2}(1 - o(1))$. □

[8] From linear programming, Δ_1 is at least the minimum nonbasic reduced cost. Also, Δ_1 is no more than this: For the assignment problem, edges corresponding to basic variables form a tree. Adding any nonbasic edge creates an alternating cycle, whose symmetric difference with the optimal matching gives a second matching. The cost increase is the cost of the cycle, which is the sum of its (signed) edge costs. The sum of the signed costs of the edges around a cycle is equal to the same sum of the reduced costs, because each u_i, for example, is added twice, with opposite signs, to the two edges incident on x_i. The cycle in question contains only a single nonbasic edge, so the sum of its reduced edge costs is just the cost of this edge.

THE WAKE-UP PROBLEM IN MULTIHOP RADIO NETWORKS*

MAREK CHROBAK†, LESZEK GĄSIENIEC‡, AND DARIUSZ R. KOWALSKI‡

Abstract. We study the problem of waking up a collection of n processors connected by a multihop ad hoc ratio network with unknown topology, no access to a global clock, and no collision detection mechanism available. Each node in the network either wakes up spontaneously or gets activated by receiving a wake-up signal from another node. All active nodes transmit the wake-up signals according to a given protocol $\mathcal{W}$. The running time of $\mathcal{W}$ is the number of steps counted from the first spontaneous wake-up until all nodes become activated. We provide two protocols for this problem. The first one is a deterministic protocol with running time $O(n^{5/3} \log n)$. Our protocol is based on a novel concept of a shift-tolerant selector to which we refer as a *(radio) synchronizer*. The second protocol is randomized, and its expected running time is $O(D \log^2 n)$, where D is the diameter of the network. Subsequently we show how to employ our wake-up protocols to solve two other communication primitives: leader election and clock synchronization.

Key words. radio network, wake-up, gossiping, broadcasting, probabilistic method

1. Introduction.

We define an ad hoc multihop radio network as a directed strongly connected graph with n nodes (also referred to as vertices or processors). The nodes of this graph represent computing devices that can transmit and receive radio signals. The directed edges represent transmission ranges of the nodes: if a signal transmitted from u can be heard by a node v, then G contains the corresponding edge (u, v). The execution time is divided into discrete time steps, the same for all processors. We assume that each processor is assigned a unique integer label (or identifier) from a range of size $O(n)$. The processors know the range of the labels, but they do not know the network's topology.

We consider the fundamental problem of waking up the processors of an ad hoc multihop radio network. Initially, all nodes are assumed to be asleep. Each node in the network can wake up spontaneously, or it can be activated by receiving a wake-up signal from another node. Once a node v is activated, it starts executing its wake-up protocol $\mathcal{W}$. This protocol dictates during which time steps v will transmit a wake-up signal. In our model, the network does not have a global clock, so $\mathcal{W}$ depends only on the local clock of v (the number of steps since activation) and possibly additional information received earlier from other nodes. The wake-up signal from v is sent, during the same time step, to all out-neighbors of v. However, an out-neighbor u of v receives this signal only if no collision occurred, that is, if no other in-neighbor of u transmitted at the same time. Furthermore, we do not assume any collision detection

capability, so if u does not receive a signal at time t, it has no way to decide whether a collision occurred or none of its neighbors transmitted. The running time of $\mathcal{W}$ is the number of time steps, counting from the first spontaneous wake-up until all nodes become activated.

While other important communication primitives, such as *broadcasting* (one-to-all communication), *gossiping* (all-to-all communication), and *multicast* (some-to-some communication) have been explored extensively in the context of ad hoc multihop radio networks (e.g., see [5, 7, 8, 9, 10, 12, 14, 15, 16, 17, 21, 24, 25, 26, 30]), the wake-up and synchronization problems were studied primarily for *one-hop* networks (i.e., in the presence of a complete graph of connections). For one-hop networks, Gąsieniec, Pelc, and Peleg [20] presented a deterministic protocol with running time $O(n^2 \log n)$. They also gave a probabilistic argument showing that there exists a wake-up protocol with running time $O(n \log^2 n)$. Later, Indyk [21] showed that the same proof can be turned into a constructive argument, with only a slight increase in the running time. In the randomized case, in [20] one can find an algorithm that, for any given $\epsilon > 0$, completes the wake-up process in time $O(n \log(1/\epsilon))$ with probability at least $1 - \epsilon$. This result was subsequently improved by Jurdziński and Stachowiak [23], who gave a protocol with running time $O(\log n \log(1/\epsilon))$.

Note that broadcasting can be reduced to wake-up, in the following sense. Given a wake-up protocol $\mathcal{W}$, we can use it to perform broadcasting by waking up only the node s that wants to initiate the broadcast, and then using the transmissions of $\mathcal{W}$ to transmit the broadcast message instead of the wake-up signal. Therefore the wake-up problem can be thought of as a generalization of broadcasting.

Our results. We study the wake-up problem in ad hoc multihop radio networks when the network has an arbitrary topology—a more general setting than the one considered in [20, 23]. Further, we assume that this topology is not known to the algorithm. We provide two protocols for this problem.

First, we give a probabilistic construction of a deterministic wake-up protocol with running time $O(n^{5/3} \log n)$. Our construction works in several stages. In the first stage, we construct certain combinatorial structures called *(radio) synchronizers*. Later, we take a random protocol $\mathcal{P}$ that consists of a synchronizer followed by a random sequence of transmissions, where each transmission is executed with probability $1/n$. We prove that, with very high probability, this random protocol completes the wake-up task in time $O(n^{5/3} \log n)$ in so-called *path graphs*. This implies, via the probabilistic method, that there exists a deterministic protocol $\mathcal{D}$ for path graphs with the same running time. Finally, we prove that $\mathcal{D}$ works, in fact, for arbitrary strongly connected graphs.

As our second result, we give a randomized wake-up protocol $\mathcal{R}$ whose expected running time is $O(D \log^2 n)$, where D is the diameter of the network. (Unlike in the deterministic case, this randomized protocol does not use node labels.)

We subsequently study two other communication primitives: leader election and clock synchronization. In the *leader election* problem, we want to designate one node, typically the one with minimum label, as the leader. All nodes have to be informed about the leader identity (label). In the *clock synchronization* problem, we require that, after the completion of the protocol, all nodes agree on some integer value (typically, the local time of one selected node) as the current global time. Assuming that all node labels are integers drawn from an $O(n)$-size range, we show that both tasks, leader election and clock synchronization, can be achieved deterministically in time $O(n^{5/3} \log^2 n)$, and in expected time $O(D \log^3 n)$ with randomization.

Other related work. Recall that in our model all nodes are identified by unique labels of size $O(n)$. A comprehensive discussion of the wake-up problem in one-hop networks with unbounded labels can be found in [20, 23].

Zheng, Hou, and Sha [31] study a similar wake-up problem in ad hoc symmetric wireless networks, with the main focus on energy efficiency. They also provide an extensive discussion of existing wake-up mechanisms and related practical and theoretical issues.

The problem of waking up a collection of processing units is not specific to radio networks. In fact, one can formulate analogous problems for other distributed computing models. The general idea is that we have a number of agents that are initially in arbitrary unpredictable states (including clock values), and the goal is to achieve some degree of synchronization sufficient to perform communication or parallel computation, while minimizing resources like time, memory, etc. One such variant of the wake-up problem in the asynchronous shared memory model in the presence of faults was introduced by Fischer et al. [19]. On the more practical side, challenges similar to those in the wake-up problem arise, for example, after crashes or malicious attacks in distributed systems.

An unrelated, although similar in spirit, offline problem called the *freeze-tag problem* was studied by Arkin et al. [2]. Here, the goal is to design an optimal wake-up schedule for a swarm of robots.

The leader election problem has been, of course, widely studied in the area of distributed computing; see, e.g., [28]. In the context of radio networks, leader election has been studied mainly for one-hop networks. For example, Jurdziński, Kutyłowski, and Zatopiański [22] investigated the energy-efficient randomized algorithms for this problem. (See [22] for more references to work on this case.) To our knowledge, the only work on leader election in multihop radio networks is that by Bar-Yehuda, Goldreich, and Itai [6], who proposed an efficient algorithm for undirected networks.

Finally, Awerbuch et al. [4] considered synchronization-like problems in an asynchronous message-passing distributed system. We also point out that the term "synchronizer" was used in other contexts in distributed computing (see [3]). However, our definition of synchronizers is different than those used in the setting of asynchronous distributed message-passing systems.

Comments about the model. Concluding the introduction, we offer a few general comments about our model in relation to past and contemporary network technologies.

In addition to the initial lack of synchronization, discussed above, any wake-up protocol in our model needs to overcome three other obstacles: lack of information about the topology, unidirectionality of links, and channel contention (transmission collisions.)

In today's wireless ad hoc networks, it would be unrealistic to assume that the nodes have accurate information about the network's topology. Our model of a completely unknown topology, although rather extreme in this respect, allows us to focus on the fundamental principles of communication in such networks, and, to our knowledge, it has been studied only from the theoretical perspective.

Networks with shared communication channels have been widely used since 1970s, starting with Abramson's pioneering work [1] on radio-based Aloha. (The version called Slotted Aloha allows communication to take place only at discrete time steps, thus bearing some resemblance to our model.) The ideas behind Aloha were adapted to Ethernet local area networks [29], in which communication takes place over a

common bus (wire). The use of shared channels is, in fact, still common in today's wireless networks.

Reliable communications over a random-access shared channel typically employ some control mechanism that detects collisions and subsequently retransmits the lost messages. Unlike in our model, protocols used in practice are based on symmetric connections, where collision detection can be implemented through a feedback mechanism that allows the sending node to detect whether its transmission was successful. (In Aloha, this is accomplished with message acknowledgements and a timeout mechanism, while in Ethernet by sensing the signal level on the shared channel.) To deal with potential instability due to retransmission of lost messages, appropriate backoff protocols are employed. The exponential backoff mechanism used in Ethernet decreases the frequency of retransmissions by doubling the expected waiting time after each collision. (The backoff mechanism was not specified in Aloha.) We find it somewhat intriguing that our randomized protocol in section 5 does exactly the opposite, as it exponentially *increases* the transmission frequency over time.

2. Radio networks. A *radio network* is modeled as a directed strongly connected graph G with n *nodes* (also called *vertices* or *processors*). The nodes of G represent transmitting/receiving devices, and directed edges represent their ranges: if a node v is within the range of a node u, then G contains an edge (u, v).

If there is an edge from u to v, then we say that v is an *out-neighbor* of u and that u is an *in-neighbor* of v. The set of all in-neighbors of v is denoted by $N_G(v)$, or simply $N(v)$ if G is understood from context.

To simplify presentation, throughout the paper we assume, without loss of generality, that n is a power of 2. Further, we often use other functions of n, say $n^{1/3}$, $n^{5/3}$, etc., as if their values were integer. All the calculations can be easily formalized by using the appropriately rounded values instead, say $\lfloor n^{1/3} \rfloor$, $\lceil n^{1/3} \rceil$, etc., although we choose not to do it in order to avoid clutter.

Each node v is assigned a unique *label* ℓ_v, also called an *identifier*. The labels are integer numbers from an interval $\{\ell_{\min}, \ldots, \ell_{\max}\}$, where $\ell_{\max} - \ell_{\min} = O(n)$. Initially, each node knows only its label and the bounds $\ell_{\min}$, $\ell_{\max}$. In the paper we assume that $\ell_{\min} = 0$, since otherwise a node v instead of label ℓ_v can use an auxiliary label $\ell_v - \ell_{\min}$ for execution. In the construction of synchronizers and wake-up protocols, we further simplify the notation by assuming, without loss of generality, that the label set is $V = \{0, 1, \ldots, n-1\}$, so that we can identify nodes by consecutive integers. (Note that we cannot make this assumption in the leader election and synchronization protocols, because then node 0 could be always selected as the leader, making both problems trivial.)

The execution time is divided into discrete time steps. For the sake of clarity, we make a distinction between the terms "time" and "time step." A *time* t is the point t on the time axis. A *time step* t is the unit time interval $(t, t+1]$. Any actions (activations, transmissions, etc.) take place during time steps. Properties of the network (for example, the set of active nodes) are observed at time points. If some action takes place at time step t, its effect will be reflected by the change of the state of the network from time t to $t+1$.

Since our focus is on communication, we assume that processors have unlimited computing power and can perform arbitrary computations within one time step. However, only one transmission or message receipt is allowed in one time step. Each processor has its own local clock whose initial value, at the time of activation, is 0. All local clocks run at the same speed.

By a *wake-up schedule* we mean any vector $\omega = (\omega_x)_{x \in V}$, where ω_x denotes the time step in which x wakes up spontaneously. For any set $X \subseteq V$, by ω_X we denote the earliest wake-up time step in X; that is, $\omega_X = \min_{x \in X} \omega_x$. For our convenience, we will be assuming that $\omega_V = \min_{x \in V} \omega_x = 0$. A node v with $\omega_v = 0$ is referred to as a *start node*. Note that there may be several start nodes present. A node x is called *active* at time t if it either awakened spontaneously or was activated by another active node u by receiving its wake-up signal in some time step $t' \leq t - 1$.

A *wake-up protocol* $\mathcal{W}$ is a function that, for each label ℓ and for each $\tau = 1, 2, 3, \ldots$, given all past messages received by the node v with label $\ell_v = \ell$, specifies whether v will transmit the wake-up signal in time step τ (since its activation.)

A message M transmitted in step t from a node v is sent instantly to all its out-neighbors. However, an out-neighbor u of v receives M in time step t only if no collision occurred, i.e., if the other in-neighbors of u do not transmit in step t at all. Further, collisions cannot be distinguished from the background noise. If u does not receive any message in step t, it knows that either none of its in-neighbors transmitted in step t, or that at least two did, but it does not know which of these two events occurred.

Given a network G and a wake-up schedule ω, by a *wake-up network* we will mean the pair $\langle G, \omega \rangle$. The wake-up network, together with a (deterministic) wake-up protocol $\mathcal{W}$, fully determines the state of the network at each time. Let $acttime_v(\mathcal{W}, G, \omega)$ denote the activation time step of node v, that is, either ω_v or the time step when v received a wake-up message, whichever comes first. Note that, by the definition of active nodes, v is active for the first time at time $acttime_v(\mathcal{W}, G, \omega)+1$. By $ActSet_t(\mathcal{W}, G, \omega)$ we denote the set of all active nodes at time t. We will often simplify this notation and omit the arguments that are well understood from context, writing $acttime_v(\omega)$, $ActSet_t$, etc.

The running time of a wake-up protocol $\mathcal{W}$ is the smallest T such that, for any wake-up network $\langle G, \omega \rangle$ with vertex set V, all nodes are activated by time T; that is, $ActSet_T(\mathcal{W}, G, \omega) = V$. Note that according to this definition some nodes may continue transmissions after time T. However, without loss of generality we can assume that each node stops transmitting after T steps from its activation (any further transmissions are redundant.) Then the total termination time—from the first wake-up until all nodes complete their transmissions—is at most $2T$.

Protocols for leader election and synchronization, as well as their running times, are defined in an analogous manner. We remark here, however, that in our wake-up and leader election protocols, nodes transmit only wake-up signals to their neighbors; no other messages are used. For clock synchronization, messages include numerical values representing the global time.

3. Synchronizers. The notion of *selectors* was introduced in the context of time efficient distributed communication protocols in synchronized radio networks [14], and later studied by DeBonis, Gąsieniec, and Vaccaro [18] as a tool in weakly adaptive combinatorial group testing. In particular, an (n, k, m)-selector $\mathcal{T}$ is defined in [18] as follows: $\mathcal{T} = \{\mathcal{T}^x\}_{x \in V}$, where each $\mathcal{T}^x$ is a 0-1 sequence of length m, and for each subset $X \subseteq V$ of size k there exists a position $1 \leq t \leq m$ such that exactly one sequence $\mathcal{T}^x$ has 1 on position t. In radio network applications, $\mathcal{T}$ represents a transmission protocol for the network, where a node x transmits at time t if the tth bit of $\mathcal{T}^x$ is 1. The main intuition behind the condition on $\mathcal{T}$ is that if a set $X = N(v)$ of k nodes follows this protocol, then within at most m steps a successful (that is, collision-free) transmission from X to v will occur.

The selectors as defined in [14] are not sufficient for the wake-up problem, due to the lack of clock synchronization. Intuitively, as the nodes wake up at different times and start transmitting, their transmission sequences may be shifted with respect to each other. To deal with this difficulty, we now introduce a new type of selector-like structures called *radio synchronizers* (or *synchronizers*, for short), that tolerate arbitrary shifts.

Formally, let $\mathcal{S} = \{\mathcal{S}^x\}_{x\in V}$, where each $\mathcal{S}^x = S_1^x S_2^x \dots S_m^x$ is a 0-1 sequence of length m. We say that $\mathcal{S}$ is a (n,k,m)-*synchronizer* if it satisfies the following property:

($*$) For any nonempty set $X \subseteq V$ of cardinality at most k, and for any wake-up schedule ω, there exists t, where $\omega_X < t \le \omega_X + m$, such that

$$\sum_{x\in X} S^x_{t-\omega_x} = 1.$$

We assume here that $S_i^x = 0$, for $i \le 0$.

As explained earlier, we will interpret $\mathcal{S}$ as a transmission protocol, where $S_i^x = 1$ indicates that node x transmits in step $\omega_x + i$. Thus the condition ($*$) states that, in at most m steps after the first node in X wakes-up, there will be a time step when exactly one node in X transmits.

LEMMA 1. *Let $C \ge 31$ be an integer constant. For each n and $k \le n$, there exists an (n,k,m)-synchronizer with $m = Ck^2 \log n$.*

Proof. We use here a probabilistic argument. Without loss of generality, we can assume that $n \ge k \ge 2$. For all $x \in V$ and $i = 1, \dots, m$, independently, assign $S_i^x = 1$ with probability $1/k$, and 0 otherwise. We show that, with very high probability, $\mathcal{S} = \{\mathcal{S}^x\}_{x\in V}$ is an (n,k,m)-synchronizer.

Initially, we fix a set of nodes X with $1 \le |X| \le k$ and a wake-up schedule ω. Let $z \in X$ be the node with the earliest wake-up time in X, which is $\omega_z = \omega_X$. Fix a time $t \in (\omega_X, \omega_X + m]$, and let $X' = \{x \in X : \omega_x < t\}$ be the set of nodes in X that are "awakened" at time t. The probability that $S^x_{t-\omega_x} = 1$ for exactly one $x \in X$ is not smaller than the probability that z is the only one with $S^z_{t-\omega_z} = 1$. Using this inequality, the independence of the random variables S_i^x, for $x \in X$, and some routine calculations, we get

$$\begin{aligned}
\Pr\left[\sum_{x\in X} S^x_{t-\omega_x} = 1\right] &\ge \Pr\left[S^z_{t-\omega_z} = 1 \;\&\; \sum_{x\in X'-\{z\}} S^x_{t-\omega_x} = 0\right] \\
&= \frac{1}{k}\left(1-\frac{1}{k}\right)^{|X'|-1} \\
&\ge \frac{1}{k-1}\left(1-\frac{1}{k}\right)^{k} \\
&\ge \frac{1}{4k},
\end{aligned}$$

where the last inequality holds because $(1-1/k)^k \ge \frac{1}{4}$ for $k \ge 2$.

For different times t, the events "$\sum_{x\in X} S^x_{t-\omega_x} \ne 1$" are independent. Therefore, using the bound above, we get that the probability that no such time step exists is

$$\begin{aligned}
\Pr\left[\sum_{x\in X} S^x_{t-\omega_x} \ne 1 \;\; \forall t \in (\omega_X, \omega_X + m]\right] &\le \left(1-\frac{1}{4k}\right)^m \\
&\le \beta^{m/k}
\end{aligned}$$

for $\beta = e^{-1/4} < 1$.

The probability that $\mathcal{S}$ violates the definition of the (n,k,m)-synchronizer for a fixed X can be estimated by multiplying the above probability by the number of choices of ω. It is sufficient to count only those wake-up schedules ω that satisfy $\omega_X \le \omega_x \le \omega_X + m$ for $x \in X$, and $\omega_x = \omega_X$ for $x \notin X$. This is because, given an arbitrary ω, we can define another wake-up schedule ω' as $\omega'_x = \min\{\omega_x, \omega_X + m\}$ for $x \in X$, and $\omega'_x = \omega_X$ for $x \notin X$. Then $\mathcal{S}$ satisfies $(*)$ for X and ω iff $\mathcal{S}$ satisfies $(*)$ for X and ω'. The number of such relevant wake-up schedules is not greater than $(m+1)^{|X|} \le (2m)^k$, so the probability that $\mathcal{S}$ violates $(*)$ for X is at most $(2m)^k \beta^{m/k}$.

Now, to estimate the probability that $\mathcal{S}$ is not an (n,k,m)-synchronizer, we can multiply the above probability by the number of ways in which X can be chosen, which is at most $\sum_{j=1}^{k} \binom{n}{j} \le \sum_{j=1}^{k} n^j \le n^{2k}$. Thus

$$\begin{aligned}\Pr[\,\mathcal{S} \text{ is not a } (n,k,m)\text{-synchronizer}\,] &\le n^{2k}(2m)^k \beta^{m/k} \\ &\le n^{2k}(2Ck^2 \log n)^k \beta^{Ck \log n} \\ &\le \left[n^{6+\log C + C \log \beta}\right]^k \\ &< 1,\end{aligned}$$

as long as $C \ge 31$. Since this probability is smaller than 1, there exists an (n,k,m)-synchronizer $\mathcal{S}$ with $m = Ck^2 \log n$. ∎

4. A deterministic wake-up protocol. In this section we propose a wake-up protocol based on synchronizers and random transmission patterns. We also show later (using the probabilistic method) the existence of a deterministic protocol that completes the wake-up task in n-vertex directed graphs in time $O(n^{5/3} \log n)$. We proceed in four steps:

(1) We define a random protocol $\mathcal{P}$ and a class of graphs that we call *path graphs*. We also define a slightly different communication model for those graphs, which we call the *restricted model*.

(2) We show that, with probability exponentially close to 1, $\mathcal{P}$ will complete the wake-up task in time $O(n^{5/3} \log n)$, according to the restricted model, for an arbitrary n-vertex path graph and a wake-up schedule.

(3) Using the bound on the failure probability in (2), we show that there exists a *deterministic* protocol $\mathcal{D}$ for path graphs with running time $O(n^{5/3} \log n)$, in the restricted model.

(4) Finally, we prove that (3) implies that our protocol $\mathcal{D}$ works in fact also in arbitrary directed graphs, with running time $O(n^{5/3} \log n)$.

We point out here that applying the probabilistic method to path graphs, rather than directly to arbitrary graphs, is crucial, since the number of path graphs is substantially smaller than the number of arbitrary directed graphs—roughly n^n instead of $2^{n(n-1)}$.

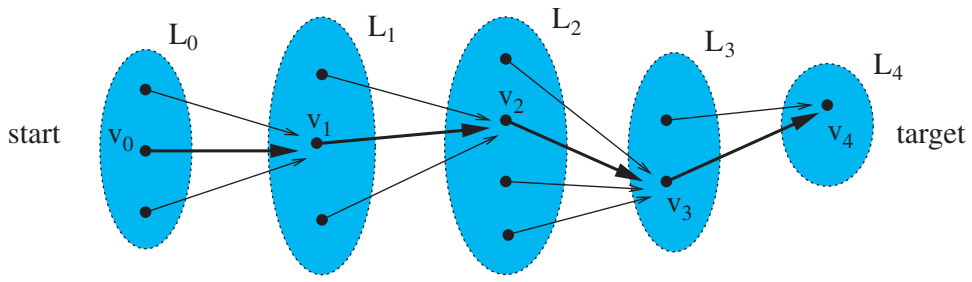
Random protocol. We now define our *random protocol* $\mathcal{P}$ (that is, a probability distribution on deterministic protocols.) Let $\mathcal{S} = \{\mathcal{S}^x\}_{x \in V}$ be an (n,k,m)-synchronizer with $k = n^{1/3}$ and $m = Cn^{2/3} \log n$, where $C = 31$. The existence of $\mathcal{S}$ has been established in Lemma 1. For each $x \in V$, we define a random 0-1 sequence $\mathcal{P}^x$ as

$$\mathcal{P}^x = \mathcal{S}^x \mathcal{U}^x,$$

where $\mathcal{U}^x$ is a random 0-1 sequence of length $O(n^{5/3} \log n)$ in which each bit is chosen, independently, to be 1 with probability $1/n$ and 0 with probability $1 - 1/n$. (The exact length of $\mathcal{U}^x$ will be determined later in this section.) Then $\mathcal{P} = \{\mathcal{P}^x\}_{x \in V}$ is a random

protocol, where the 1's in $\mathcal{P}^x$ indicate the times when node x transmits the wake-up signal. We refer to the sequence $\mathcal{S}^x$ as the *S-stage* and $\mathcal{U}^x$ as the *U-stage* of $\mathcal{P}^x$. We emphasize that for any given node x, its S-stage transmissions are fixed; only the transmissions in its U-stage vary randomly.

Path graphs and restricted executions. A directed graph H is called a *path graph* if it has the following structure: the nodes of H can be partitioned into sets L_i, $i = 0, \ldots, D$, called *layers*, each with a distinguished node $v_i \in L_i$. The edges of H are of the form (v, v_{i+1}), where $0 \le i < D$ and $v \in L_i$. We refer to D as the *depth* of H. The path $\pi = v_0, v_1, \ldots, v_D$ is called the *main path* of H. Node v_0 is the *start node* and v_D is the *target node* (see the figure below). We assume that $L_D = \{v_D\}$. If H is a path graph and μ is a wake-up schedule, we refer to the pair $\langle H, \mu \rangle$ as a *path wake-up network*.



In path wake-up networks, we consider only wake-up schedules μ with v_0 as the start node, that is, $\mu_{v_0} = 0$ and $\mu_v \ge 0$ for $v \ne v_0$. The wake-up task is also different: our objective is to wake up only the target node v_D, and not necessarily all nodes.

We will consider a *restricted communication model* for path graphs, which differs slightly from the standard model described in section 2. Let H be a path graph and μ a wake-up schedule. Assume that the sets of active nodes are already defined for times $1, \ldots, t$. (As in a standard radio wake-up execution, if a node becomes active, it remains active through the end of the execution.) We denote by h_t the greatest index i of an active layer L_i (that is, a layer with at least one active node) at time t. We refer to L_{h_t} as the *head layer* at time t. A nonactive node v becomes activated in step t either if v wakes up spontaneously, or if v is on the main in the layer right after the head layer and is activated by some in-neighbor from the active layer. More formally,

(Act1) $\mu_v = t$, or

(Act2) $v = v_{h_t+1}$ and exactly one node in L_{h_t} transmits in step t.

Thus the difference between the standard and restricted models in path graphs is that the nodes v_i, for $i \le h_t$, cannot be activated by their in-neighbors in H even if exactly one of these in-neighbors transmits. (Nodes v_i, for $i > h_t + 1$, cannot be activated by their in-neighbors in either model, by the choice of h_t.) Given a protocol $\mathcal{P}$, we refer to the execution of $\mathcal{P}$ on $\langle H, \mu \rangle$ under the restricted model as a *restricted execution*. By $acttime^*_u(\mathcal{D}, H, \mu)$ and $ActSet^*_t(\mathcal{D}, H, \mu)$, respectively, we denote the activation time step of u and the set of active notes at time t in the restricted execution of $\mathcal{D}$ on $\langle H, \mu \rangle$ (with the asterisk indicating a restricted execution).

Recall that $m = Cn^{2/3} \log n$ is the length of our synchronizer, where $C = 31$ is the constant from Lemma 1.

LEMMA 2. *Let $B \geq 15$ be an integer constant. Consider the restricted execution of protocol $\mathcal{P}$ on a path wake-up network $\langle H, \mu \rangle$ with vertices from V. The probability that $\mathcal{P}$ does not activate the target node of H in time $T = (B + C)n^{5/3} \log n$ is at most $n^{-\frac{1}{16}Bn}$.*

Proof. Let $L_0, \ldots, L_D$ be the layers of H and $\pi = v_0, \ldots, v_D$ be the main path. The activation time step of a layer L_i is a random variable that is equal to t either if $t = \mu_{L_i}$, or if $h_t = i - 1$ and v_i receives the wake-up signal from L_{i-1} in time step t, whichever comes first.

Whenever the head index h_t increases, we call it an *advance*. Recall that v_0 is assumed to wake up at time step 0. We want to bound the probability of failure, i.e., that v_D is still not awakened at time $T = (B + C)n^{5/3} \log n$ or, equivalently, that $h_T < D$.

Given some fixed execution of $\mathcal{P}$ (that is, with fixed random choices), we group all time steps t in this execution into two categories:

S-steps: time steps t when at least one node in a head layer L_{h_t} executes its S-stage, and

U-steps: time steps t when all active nodes in L_{h_t} execute their U-stage.

Suppose that layer L_i was activated in this execution at time step t'. If the number of active nodes in L_i at time $t' + m$ is at most $n^{1/3}$, then we say that L_i is *fast*. Otherwise, we call L_i *slow*. (We emphasize that the notions of fast and slow layers are relative to a particular execution of $\mathcal{P}$; the same layer can be slow or fast, depending on the outcomes of random choices before t'.)

We now make two important observations. First, if L_i is fast, then, since $\mathcal{S}$ is an (n, k, m)-synchronizer with $k = n^{1/3}$, an advance to L_{i+1} will occur during the time period $[t' + 1, t' + m]$ with probability 1 (unless some nodes in layers after L_{i+1} wake up spontaneously, in which case we advance even further). The second observation, following from the previous one, is that U-steps occur only when the head layer is slow and thus has size at least $n^{1/3}$.

Now we look at the execution of $\mathcal{P}$ on $\langle H, \mu \rangle$ globally. The total number of S-steps is at most $nm = Cn^{5/3} \log n$. During these S-steps, $\mathcal{P}$ will complete advances from all fast layers in its execution with probability 1.

Since each slow layer has size at least $n^{1/3}$, the number of slow layers in any execution cannot exceed $n^{2/3}$. The total number of U-steps is at least $J \stackrel{\text{def}}{=} T - Cn^{5/3} \log n = Bn^{5/3} \log n$. Let X_i be a random variable such that $X_i = 1$ if there is an advance in the ith U-step, and 0 otherwise. Thus, it is sufficient to prove that

$$\Pr\left[\sum_{i=1}^{J} X_i < n^{2/3}\right] \leq n^{-\frac{1}{16}Bn}. \tag{1}$$

Consider one U-step, say the ith one, for some fixed execution history Ψ (that is, all random choices up to this point). At this step, the head layer has $x \geq n^{1/3}$ active nodes, and all these nodes transmit with probability $1/n$. The probability of an advance is the probability that exactly one of them transmits, so

$$\Pr[\, X_i = 1 \mid \Psi \,] \;=\; x \cdot \frac{1}{n} \cdot \left(1 - \frac{1}{n}\right)^{x-1} \;\geq\; \tfrac{1}{4} n^{-2/3} \;\stackrel{\text{def}}{=}\; p. \tag{2}$$

The last inequality holds because it is true for $x = n^{1/3}$ and $x(1 - 1/n)^{x-1}$ is a nondecreasing function for $x < n$. (Recall that $n \geq 2$.) Therefore $\Pr[\, X_i = 1 \,] \geq p$.

The idea behind the proof of (1) is this: we can think of the X_i's as a sequence of Bernoulli trials in which the probability of a success (an advance) is p. Then the

probability that in this process the number of advances in J U-steps is less than $n^{2/3}$ can be bounded by $n^{-\Omega(n)}$ using an appropriate tail inequality.

The flaw in the above argument is that the advance events (variables X_i) are not fully independent, and thus this is not truly a Bernoulli process. To make the argument more rigorous, we introduce independent random variables $Y_i \in \{0,1\}$, where $\Pr[\,Y_i = 1\,] = p$. For these variables, the Chernoff bound (see [27], for example), states that $\Pr[\,\sum_{i=1}^{J} Y_i < K\,] \le \exp\left[-\frac{1}{2}Jp(1-K/(Jp))^2\right]$, for any $0 \le K < Jp$. For $K = n^{2/3}$ and $B \ge 15$ we have

$$\left(1 - \frac{n^{2/3}}{Jp}\right)^2 \;=\; \left(1 - \frac{4}{Bn^{1/3}\log n}\right)^2 \;\ge\; \left(1 - \frac{4}{B}\right)^2 \ge \frac{1}{2}\,.$$

Therefore

$$\begin{aligned}\Pr\left[\sum_{i=1}^{J} Y_i < n^{2/3}\right] &\le e^{-\frac{1}{2}Jp(1-n^{2/3}/(Jp))^2} \\ &\le e^{-\frac{1}{16}Bn\log n} \\ &\le n^{-\frac{1}{16}Bn}.\end{aligned}$$

To complete the proof it is now sufficient to show that

$$\Pr\left[\sum_{i=1}^{J} X_i < K\right] \le \Pr\left[\sum_{i=1}^{J} Y_i < K\right] \tag{3}$$

for each K. To show (3), we introduce new random variables $Z_i \in \{0,1\}$, $i = 1,\ldots,J$, where, for each history Ψ (the random choices up to before the ith U-step), we define

$$\begin{aligned}\Pr[\,Z_i = 1 \mid \Psi \;\&\; Y_i = 1\,] &= 0, \\ \Pr[\,Z_i = 1 \mid \Psi \;\&\; Y_i = 0\,] &= \frac{\Pr[\,X_i = 1|\Psi\,] - p}{1-p}.\end{aligned}$$

Then processes $\{X_i\}$ and $\{Y_i + Z_i\}$ are stochastically equivalent. More precisely, for $i = 1,\ldots,J$ and any history Ψ,

$$\begin{aligned}\Pr[\,Y_i + Z_i = 1 \mid \Psi\,] &= \Pr[\,Y_i = 1 \,\&\, Z_i = 0 \mid \Psi\,] + \Pr[\,Y_i = 0 \,\&\, Z_i = 1 \mid \Psi\,] \\ &= p + (1-p)\cdot\frac{\Pr[\,X_i = 1 \mid \Psi\,] - p}{1-p} \\ &= \Pr[\,X_i = 1 \mid \Psi\,],\end{aligned}$$

and thus $\Pr[\,Y_i + Z_i = 1\,] = \Pr[\,X_i = 1\,]$ as well. Therefore

$$\Pr\left[\sum_{i=1}^{J} X_i < K\right] \;=\; \Pr\left[\sum_{i=1}^{J}(Y_i + Z_i) < K\right] \;\le\; \Pr\left[\sum_{i=1}^{M} Y_i < K\right],$$

completing the proof of (3). This also completes the proof of (1) and the whole lemma. □

LEMMA 3. *There exists a deterministic protocol $\mathcal{D}$ that, under the restricted model, for any path wake-up network $\langle H, \mu\rangle$ with at most n nodes, activates the target node of H in time $O(n^{5/3}\log n)$.*

Proof. Let $T = (B + C)n^{5/3} \log n$ be the running time from Lemma 2, where $C = 31$ and $B \geq 15$. Each path graph has out-degree 1, so the number of (labeled) n-vertex path graphs is at most n^n. We need to be concerned only with wake-up schedules μ that satisfy $0 \leq \mu_v \leq T + 1 \leq 2T$ for all v and $\mu_{v_0} = 0$ (where v_0 is the start node). There are at most $(2T)^n$ such wake-up schedules. Thus, by Lemma 2, the probability that $\mathcal{P}$ does not complete the wake-up during a restricted execution on some n-vertex path graph and some wake-up schedule is at most

$$\begin{aligned} n^{-\frac{1}{16}Bn} \cdot n^n (2T)^n &\leq \left[n^{-\frac{1}{16}B} \cdot n \cdot 2(B + C)n^{5/3} \log n \right]^n \\ &\leq \left[n^{-\frac{1}{16}B + \log(B+C) + 5} \right]^n \\ &< 1, \end{aligned}$$

as long as $B \geq 15$ and $-\frac{1}{16}B + \log(B + C) + 5 < 0$. Any $B \geq 207$ satisfies these conditions. This implies that there exists a deterministic protocol $\mathcal{D}$ that, for any n-vertex path graph and any wake-up schedule, completes the wake-up task (under the restricted model) in time $O(n^{5/3} \log n)$. ∎

THEOREM 1. *There exists a deterministic protocol that completes the wake-up process in each n-vertex strongly connected directed graph in time $O(n^{5/3} \log n)$.*

Proof. We prove that protocol $\mathcal{D}$ from Lemma 3 satisfies the theorem. Let $T = O(n^{5/3} \log n)$ be the running time of protocol $\mathcal{D}$ from Lemma 3, in the restricted model, on any path wake-up network $\langle H, \mu \rangle$, where the vertex set of H is a subset of V. We show that $\mathcal{D}$ completes the wake-up in *any* graph with vertex set V under any wake-up schedule in time $T = O(n^{5/3} \log n)$.

Fix a wake-up network $\langle G, \omega \rangle$, and denote by v_0 the start node, where $\omega_{v_0} = 0$ and $\omega_u \geq 0$ for all $u \in G$. Let v be some arbitrary but fixed target node $v \in G$, and let $\pi = v_0, v_1, \ldots, v_d = v$ be the shortest path from v_0 to v. We define a subgraph H_v of G as follows: the vertices of H_v are all nodes $v_0, \ldots, v_d$ and all in-neighbors of nodes $v_1, \ldots, v_d$. The edges of H_v are all edges (u, v_i) in G such that $u \in H_v$ and $(u, v_j) \notin G$ for $j > i$. Clearly, H_v is a path graph with main path $\pi = v_0, v_1, \ldots, v_d = v$. As usual, we denote the layers of H_v by $L_0, \ldots, L_d$. (See Figure 1.)

Define a wake-up schedule μ for nodes $u \in H_v$ by $\mu_u = acttime_u(\mathcal{D}, G, \omega)$, the activation time of u in G under protocol $\mathcal{D}$ and wake-up schedule ω. We compare the two following executions of $\mathcal{D}$:

(i) the execution of $\mathcal{D}$ on G with wake-up schedule ω, and

(ii) the restricted execution of $\mathcal{D}$ on H_v with wake-up schedule μ.

The difficulty we need to address is that the nodes v_i may have different neighborhoods in G and in H_v. All in-neighbors of v_i in H_v are in L_{i-1}, while in G, v_i may also have in-neighbors in layers $L_i, \ldots, L_d$. Nevertheless, we claim that the following invariant holds at each time $t = 0, 1, \ldots, T$:

$$\forall\, u \in H_v : \quad u \in ActSet_t(\mathcal{D}, G, \omega) \text{ iff } u \in ActSet_t^*(\mathcal{D}, H_v, \mu). \tag{4}$$

If (4) holds, then the activation times of each node (in particular, the target node) in both executions are the same. Since v was chosen arbitrarily, the theorem follows from Lemma 3. Thus, to complete the proof of the theorem, it is sufficient to prove (4).

The proof of invariant (4) is by induction on times $t = 0, \ldots, T$. For $t = 0$, (4) holds by the very definition of μ. Suppose that (4) is satisfied up to time t. We show that it is also satisfied at time $t + 1$.

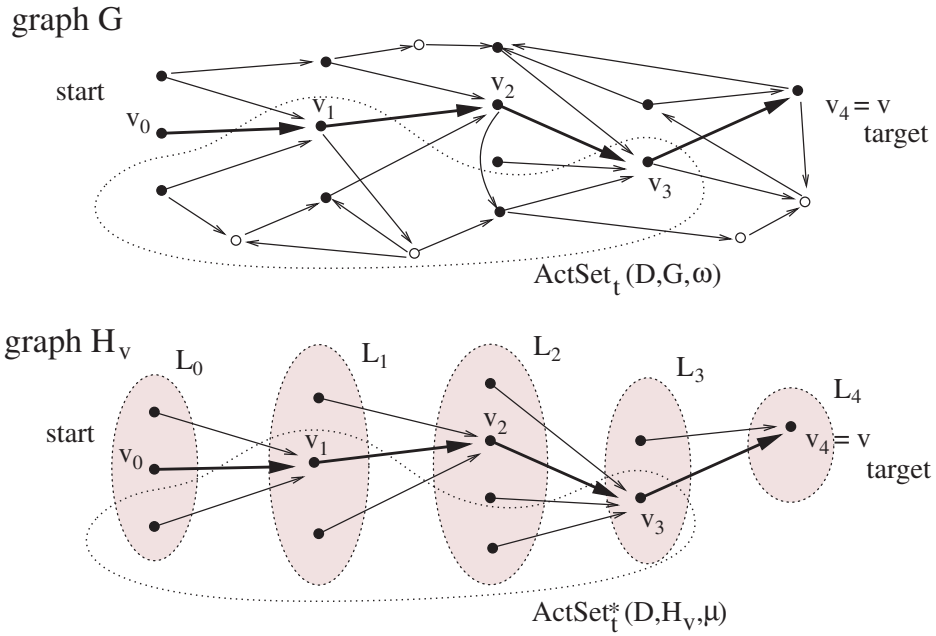


FIG. 1. *An illustration of the construction of H_v. The main path in G is shown with thick arrows. Vertices that belong to H_v are represented with filled circles.*

Note first that for each node $u \in H_v - \pi$, its activation times in both executions are the same, $acttime^*_u(\mathcal{D}, H_v, \mu) = acttime_u(\mathcal{D}, G, \omega) = \mu_u$. Thus (4) holds for nodes $u \in H - \pi$. The implication ($\Rightarrow$) is also immediate from the definition of μ. It is thus sufficient to prove the only implication ($\Leftarrow$) for $u \in \pi$.

It follows directly from invariant (4) applied to times $1, \ldots, t$ that the activation time steps (up to step $t-1$) of active nodes in H_v are the same in both executions of $\mathcal{D}$, the execution on $\langle G, \omega \rangle$, and the restricted execution on $\langle H_v, \mu \rangle$. Consequently, any $u \in ActSet^*_t(\mathcal{D}, H_v, \mu)$ performs the same action in step t in both executions. (This is because $\mathcal{D}^u$ does not depend on whether u woke up spontaneously or was activated by another node.)

As before, let h_t be the head layer of $\langle H_v, \mu \rangle$ at time t. For any node v_i, where $i \neq h_t + 1$, it follows directly from the definition of H_v and the rules of the restricted model that v_i is activated in step t of the execution of $\mathcal{D}$ on $\langle G, \omega \rangle$ iff it is activated in step t of the restricted execution of $\mathcal{D}$ on $\langle H_v, \mu \rangle$.

Consider v_i, for $i = h_t + 1$, and suppose that v_i is activated in H_v at time step $t \leq \mu_{v_i}$. It is sufficient to prove that $t < \mu_{v_i}$ is not possible. Toward contradiction, suppose $t < \mu_{v_i}$, that is, v_i was activated at step t using rule (Act2) by a wake-up signal from some node in L_{i-1}. Then, by the definitions of H_v and h_t, and also by invariant (4), we have $N_G(v_i) \cap ActSet_t(\mathcal{D}, G, \omega) = N_{H_v}(v_i) \cap ActSet^*_t(\mathcal{D}, H_v, \mu)$, and all nodes in this set are in the same state in both executions. It follows that v_i would have received the same message in G in step t as well—a contradiction with the assumption that $\mu_i > t$. This implies that (4) holds at time $t+1$, completing the proof. □

We emphasize that the above proof is not valid for arbitrary protocols, as we strongly use the fact that in our protocol $\mathcal{D}$ the active nodes do not use any information about how they have been activated (spontaneously or by a wake-up signal).

Recall that in this section we made a simplifying assumption that the node labels are consecutive integers $1, 2, \ldots, n$. Theorem 1 remains valid, however, if the node labels are chosen from a range $\ell_{\min}, \ldots, \ell_{\max}$, where $\ell_{\max} - \ell_{\min} \le An$, for some constant A, for in this case we can simply use a protocol for auxiliary labels $0, 1, \ldots, An$ (that is, a node with label ℓ uses label $\ell - \ell_{\min}$ to identify itself). This will not affect the asymptotic performance of the protocol.

5. A randomized wake-up protocol. In [23], the authors presented a randomized wake-up protocol for complete graphs. We now give a randomized Monte-Carlo wake-up protocol $\mathcal{R}$ for general multihop radio networks (even without node labels.) $\mathcal{R}$ receives on input a parameter $\epsilon > 0$, which is the desired bound on the probability of failure.

PROTOCOL $\mathcal{R}$. The pseudocode of the protocol for an arbitrary node v is

for $s \leftarrow 0, 1, \ldots, \log n - 1$ **do**
  repeat $b = 22 \log(n/\epsilon)$ **times** *// stage s starts*
    TRANSMIT with probability $2^s/n$

We start with the following technical lemma from [23].

LEMMA 4 (see [23]). *Suppose we have k numbers, $p_1, p_2, \ldots, p_k \in (0, \frac{1}{2}]$, such that $\frac{1}{2} \le \sum_{i=1}^{k} p_i \le 2$. Then*

$$\sum_{i=1}^{k} p_i \prod_{\substack{j=1 \\ j \neq i}}^{k} (1 - p_j) \ge \frac{1}{32}.$$

THEOREM 2. *Let $\epsilon > 0$ and let $\langle G, \omega \rangle$ be any wake-up network with n nodes and diameter D. With probability at least $1 - \epsilon$, $\mathcal{R}$ completes wake-up in $\langle G, \omega \rangle$ in time $O(D \log n \log(n/\epsilon))$.*

Proof. We divide the execution of $\mathcal{R}$ into $\log n$ stages, where stage s is simply the s-th iteration of the **for** loop. Recall that $b = 22 \log(n/\epsilon)$ is the number of iterations of the inner **repeat** loop. By $B = b \log n$ we denote the total execution time of $\mathcal{R}$ (for a single node).

Fix a wake-up network $\langle G, \omega \rangle$, and consider an execution of $\mathcal{R}$ on $\langle G, \omega \rangle$. Let v_0 be the start node (the one that wakes up first). For any node v, let $t_v = \mathit{acttime}_v$ and $\bar{t}_v = \min_{u \in N_v} \mathit{acttime}_u$. Thus $t_v - \bar{t}_v$ is the time (a random variable) it takes for v to become activated after the time when the first of its in-neighbors gets activated.

Call a node v an *obstruction* during an execution of $\mathcal{R}$ if $\bar{t}_v < \infty$ but $t_v > \bar{t}_v + B$. If there is no obstruction, then, clearly, the execution of $\mathcal{R}$ completes after at most $DB = O(D \log n \log(n/\epsilon))$ steps. Thus it remains to prove that the probability that there exists an obstruction during an execution of $\mathcal{R}$ is at most ϵ.

Consider some fixed node v, and fix some value of $\bar{t}_v$. To simplify notation, we can in fact assume that $\bar{t}_v = 0$. If $\omega_v < B$, then v is not an obstruction with probability 1, and we are done, so we can assume that $\omega_v \ge B$. We now need to estimate the probability that v will receive a wake-up signal from N_v in at most B steps.

For $u \in N_v$, let $p_{u,t}$ be the probability that u transmits at time step t (that is, $p_{u,t} = 2^s/n$ if u is in stage s at time t), and let $\pi_t = \sum_{u \in N_v} p_{u,t}$. We have $\pi_0 = 0$, $\pi_{B-b+1} \ge \frac{1}{2}$, and π_t is nondecreasing. By the definition of $\mathcal{R}$, for any $t = 1, \ldots, B - b$, we have $\pi_{t+b} \le 2\pi_t + 1$, since in b steps the active nodes will double their probability of transmission, and each other node contributes at most $1/n$ to π_{t+b}. Choose the largest t' for which $\pi_{t'-1} < \frac{1}{2}$. Then $\pi_{t'} \ge \frac{1}{2}$ and $\pi_{t'+b-1} \le 2\pi_{t'-1} + 1 \le 2$. We

conclude that

$$\frac{1}{2} \;\le\; \pi_t \;\le\; 2 \quad \text{for } t = t', t'+1, \ldots, t'+b-1. \tag{5}$$

Thus, by Lemma 4, for each time $t = t', t'+1, \ldots, t'+b-1$, the probability that v receives a wake-up signal from N_v at time t is

$$\sum_{u \in N_v} p_{u,t} \prod_{z \in N_v \setminus \{u\}} (1 - p_{z,t}) \ge \frac{1}{32}.$$

Then the probability that v will not receive a wake-up signal in steps $1, 2, \ldots, B$ is at most $(\frac{31}{32})^b$. We conclude that the probability that v is an obstruction is bounded by $(\frac{31}{32})^b$ as well. Therefore the probability that there exists an obstruction node during the execution of $\mathcal{R}$ is at most

$$n\left(\frac{31}{32}\right)^b \;=\; n\left(\frac{31}{32}\right)^{22\log(n/\epsilon)} \;\le\; n\left(\frac{1}{2}\right)^{\log(n/\epsilon)} \;\le\; \epsilon,$$

completing the proof. □

We can modify $\mathcal{R}$ to obtain a Las Vegas protocol with low expected running time. Let $\mathcal{R}_0$ be $\mathcal{R}$ with $\epsilon = n^{-3}$, so that the running time of $\mathcal{R}_0$ is $T_0 = O(D \log^2 n)$. Let $T = O(n^{5/3} \log n)$ be the running time of the deterministic protocol $\mathcal{D}$ from the previous section. In this Las Vegas protocol $\mathcal{R}'$, each node executes the following steps: (1) run $\mathcal{R}_0$, and then suspend itself for time T_0, (2) repeat n times: run $\mathcal{D}$ and then suspend itself for time T. At least one run of $\mathcal{D}$ will complete without interference from nodes that wake up spontaneously and execute $\mathcal{R}_0$. Thus $\mathcal{R}'$ will wake up all nodes in time T_0 with probability at least $1 - \epsilon$, and in time $O(n^{8/3} \log n)$ with probability 1. By the choice of ϵ, its expected running time will be $O(D \log^2 n)$.

THEOREM 3. *Let $\langle G, \omega \rangle$ be any wake-up network with n nodes. Protocol $\mathcal{R}'$ described above completes wake-up in $\langle G, \omega \rangle$ in expected time $O(D \log^2 n)$.*

6. Leader election and clock synchronization. In the leader election problem, we want to designate one node as *the leader*, and to announce its identity to all nodes in the network. In the clock synchronization problem, upon the completion of the protocol, all nodes must agree on a common global time. In this section we show that any wake-up protocol $\mathcal{W}$ (deterministic or randomized) can be transformed into a leader election protocol or a clock synchronization protocol with only a logarithmic overhead.

Let $\mathcal{W}$ be a wake-up protocol. For any node v, let $\mathcal{W}^v$ be the instance of $\mathcal{W}$ executed by node v. (Formally, the execution of $\mathcal{W}$ depends on the label, but, for simplicity of notation, we write $\mathcal{W}^v$ instead of $\mathcal{W}^{\ell_v}$.) Fix n, and by $w = w(n)$ denote the running time of $\mathcal{W}$ if all node labels are drawn from the range $\ell_{\min}, \ldots, \ell_{\max}$, where $\ell_{\max} - \ell_{\min} \le An$, for some constant A. We can assume, without loss of generality, that in protocol $\mathcal{W}$ each node transmits only for at most w time steps since activation. Note that our wake-up protocols described earlier in the paper satisfy this requirement.

Recall that, without loss of generality, we assume that $\ell_{\min} = 0$. We can then think of the labels as binary strings of length $\log(An)$, and by $\ell_v[i, \ldots, j]$ we denote the string consisting of the bits of ℓ_v on positions $i, i+1, \ldots, j$, counting from left to right (that is, highest bits first).

6.1. Leader election. The leader election protocol consists of two stages: the *wake-up stage* and the *election stage*. We first describe both stages informally, and then give a pseudocode for the complete protocol.

Wake-up stage. In this stage all nodes become activated. Each node v, once it wakes up, starts executing its wake-up protocol $\mathcal{W}^v$. After completing this protocol, v suspends itself for w time steps. The purpose of this suspension period is to ensure that the wake-up stage does not overlap with the election stage that follows.

Election stage. In this stage, all nodes in the network select the leader to be the node $\hat{v}$ that possesses the smallest label. The selection process is performed in $\log(An)$ rounds, where in round r, for $r = 0, 1, \ldots, \log(An) - 1$, the ith highest bit of $\ell_{\hat{v}}$ is announced. At the beginning of round r all nodes know the top r bits of $\ell_{\hat{v}}$. Let $min\_label = \ell_{\hat{v}}[0, \ldots, r-1]$ be the string consisting of these bits. Nodes v for which $\ell_v[0, \ldots, r-1] = min\_label$ are potential candidates for the leader. If such a candidate node v also has a 0 on the rth bit, it informs other nodes about its existence by initiating a wake-up process. If no wake-up process is initiated in round r, by the end of the round all nodes conclude that the ith most significant bit in $\ell_{\hat{v}}$ is 1.

The difficulty that we need to overcome is that, due to lack of synchronization, the division into consecutive rounds must be based on the local clocks. This means that very likely there will be some time overlaps (of size at most w—the maximum offset between the activation times of any two nodes) between neighboring rounds of different nodes. In order to avoid simultaneous transmissions of signals belonging to two different rounds, we will pad each round with two wait periods of length w, one at the beginning and one at the end. More specifically, every round is split into four subrounds, each of length w. If a node v is a candidate for the leader and initiates the transmission process by itself, this is always done in the beginning of the second subround. On the other hand, v can be activated to start its wake-up process by another node u at any time during the first, second, or third subround.

Leader election protocol $\mathcal{E}$. Below, we give a pseudocode for the protocol $\mathcal{E}^v$ executed by a node v. We use small capitals font, START, EXECUTE, etc., for commands related to timing. Variable *clock* measures the local time of a node. The scopes of compound statements are indicated by indentation. The chosen leader $\hat{v}$ is the node whose local variable *am_leader* has value *true* after the protocol is complete.

```
SLEEPUNTIL wake_up_signal (spontaneous or external)
START clock ← 0
EXECUTE 𝒲^v (w steps)
WAITUNTIL clock = 2w
min_label ← [ ]                          // empty string
for r ← 0, 1, ..., log(An) − 1 do
    bit ← 1                              // round r starts, local time is clock = (4r + 2)w
    if ℓ_v[0, ..., r] = min_label ∘ 0 then
        bit ← 0
        WAITUNTIL wake_up_signal or clock = (4r + 3)w
    else
        WAITUNTIL wake_up_signal or clock = (4r + 5)w
        if wake_up_signal then bit ← 0
    if bit = 0 then EXECUTE W^v (w steps)
    min_label ← min_label ∘ bit
    WAITUNTIL clock = (4r + 6)w
am_leader ← (ℓ_v = min_label)
```

One detail that we should clarify is that, when we simulate $\mathcal{W}$ in protocol $\mathcal{E}$ during the election stage, all nodes "pretend" to be asleep during the wait periods,

and nodes that initiate wake-up "pretend" to be awakened spontaneously. During the simulation of a wake-up process, each node uses an auxiliary clock to simulate a local clock used by $\mathcal{W}$.

To justify correctness, it is sufficient to show that there will be no interference between wake-up processes from different rounds. The crucial property used in the argument is that the (global) activation times (in the wake-up phase) of any two nodes differ by at most w. This implies, in particular, that two rounds of different nodes can overlap only if they are consecutive, and if so, they can overlap on at most w time steps. More specifically, the only possible overlap is when the fourth subround of a node in round r overlaps the first subround of another node that is in round $r+1$. (In our argument, to avoid dealing separately with the wake-up phase, we can treat the wake-up phase as round -1 of the election phase.)

If a wake-up process in round r is initiated at a (global) time t, then all nodes will be activated by time $t+w$, and they will have completed their transmissions at time $t+2w$. Since wake-ups are initiated at the beginning of the second subround, and the local times are shifted by at most w, it follows that, in each round r, each node will be activated no later than at the end of its third subround and thus complete its transmissions by the end of its round r.

Fix a node v that is first to execute its transmission from round $r+1$. This means that v initiates a wake-up process, and it starts transmitting in the first step of its second subround. But, again, using the fact that the offset between different rounds is at most w, by that time all other nodes completed their transmissions from round r.

Thus we obtain the following result.

THEOREM 4. (a) *Suppose that $\mathcal{W}$ is a deterministic wake-up protocol with running time $w(n)$. Then $\mathcal{W}$ can be converted into a leader election protocol $\mathcal{E}$ with running time $O(w(n)\log n)$.*

(b) *Suppose that $\mathcal{W}$ is a randomized wake-up protocol that completes the wake-up task in time $w_\epsilon(n)$ with probability at least $1-\epsilon$. Then $\mathcal{W}$ can be converted into a randomized leader election protocol $\mathcal{E}$ that completes the election task in time $O(w_\epsilon(n)\log n)$ with probability at least $1-O(\epsilon\log n)$.*

6.2. Clock cynchronization. It is not difficult to extend the leader election protocol $\mathcal{E}$ from the previous subsection to perform clock synchronization. We first run $\mathcal{E}$. Once the leader $\hat{v}$ has been elected, $\hat{v}$ waits for w steps and then broadcasts its local time to all other nodes using some broadcasting protocol $\mathcal{B}$ (see, for example [14]). When the nodes perform $\mathcal{B}$, they increment their global time counter at each step, to make sure that the correct value is transmitted. (A similar idea appeared in [30].) As explained in the introduction, broadcasting can be reduced to wake-up, so we can assume that the running time of $\mathcal{B}$ is at most $w(n)$.

Thus we obtain the following result.

THEOREM 5. (a) *Suppose that $\mathcal{W}$ is a deterministic wake-up protocol with running time $w(n)$. Then $\mathcal{W}$ can be converted into a deterministic clock synchronization protocol $\mathcal{C}$ with running time $O(w(n)\log n)$.*

(b) *Suppose that $\mathcal{W}$ is a randomized wake-up protocol that completes the wake-up task in time $w_\epsilon(n)$ with probability at least $1-\epsilon$. Then $\mathcal{W}$ can be converted into a randomized clock synchronization protocol $\mathcal{C}$ that completes the election task in time $O(w_\epsilon(n)\log n)$ with probability at least $1-O(\epsilon\log n)$.*

6.3. New protocols. Recall that our deterministic wake-up protocol $\mathcal{D}$ runs in time $O(n^{5/3}\log n)$, our Monte Carlo protocol $\mathcal{R}$ in time $O(D\log n\log(n/\epsilon))$ and with failure probability ϵ, and our Las Vegas protocol $\mathcal{R}'$ runs in expected time $O(D\log^2 n)$.

For broadcasting, we can use protocols from [14] or [24, 17], and any randomized broadcasting protocol in [5, 25, 17], or, alternatively, we can adapt wake-up protocols from our paper. Summarizing the results in this section, we obtain the following corollary.

COROLLARY 1. *There exist protocols for leader election and clock synchronization in radio networks with the following performance in n-node networks:*

(a) *a deterministic protocol with running time* $O(n^{5/3}\log^2 n)$,

(b) *a Monte Carlo protocol with running time* $O(D\log n\log(n/\epsilon))$ *and failure probability at most* ϵ *for any* $\epsilon > 0$,

(c) *a Las Vegas protocol with expected running time* $O(D\log^3 n)$.

Results in Corollary 1(a) and (b) are straightforward from Theorems 1, 2, 4, 5. (To obtain part (b), choose the error probability of $\mathcal{W}$ in Theorem 5(b) to be $\epsilon' = A\epsilon/\log n$, for some sufficiently small constant $A > 0$.)

The randomized Las Vegas protocols in Corollary 1(c) are obtained in the similar way as was the algorithm Las Vegas for the wake-up problem: by taking the corresponding Monte Carlo protocol with sufficiently small failure probability, say $\epsilon = n^{-3}$, followed by n repetitions of a deterministic protocol. These algorithms succeed in time $O(D\log^3 n)$ with probability at least $1-\epsilon\log n$, and in time $O(n^{8/3}\log n)$ with probability 1, so their expected running time will be $O(D\log^3 n)$.

7. Final comments. In this paper, we initiated the study of wake-up protocols in a general model of multihop radio networks without collision detection, where the topology of the network is unknown.

In our model we assume that all nodes know n (the number of nodes) and that the labels are integers not greater than $O(n)$ (except for the randomized wake-up protocol that does not use labels at all). Some of these assumptions can be relaxed. For example, it is not necessary that n be known, for otherwise the protocols can employ the standard doubling technique: the computation is divided into phases, where in phase $i = 1, 2, \ldots$ we run the protocol for $n = 2^i$, with appropriate waiting periods to take into account lack of initial synchronization. (See the discussion in [14].) These modified algorithms still work correctly, in fact, when the labels are unique but unbounded, although then the running time depends on the maximum label value.

Since the lower bounds for radio broadcasting (see, e.g., [8, 15, 16, 26]) apply to the wake-up problem, no randomized wake-up protocol can be faster than $\Omega(D\log(n/D))$. Thus our randomized protocol is within a polylogarithmic factor from the optimum. However, in the deterministic case, our results still leave a substantial gap between the lower bound of $\Omega(n\log n)$ and the upper bound $O(n^{5/3}\log n)$ achieved by our protocol $\mathcal{D}$.

Subsequent to the submission of this paper, new work has appeared where this gap has been significantly reduced. First, in [13], Chlebus and Kowalski improved the upper bound to $O(n^{3/2}\log n)$. More recently, Chlebus et al. [11] designed a deterministic protocol with running time $\Omega(n\log^2 n)$—within only an $O(\log n)$-factor from the optimum.

The optimum complexity of the wake-up problem (as well as a seemingly simpler broadcasting problem), in both deterministic and randomized cases, remains unknown.

Acknowledgments. We wish to express our gratitude to the anonymous referees whose numerous and insightful comments helped us improve presentation and correct some inaccuracies in the earlier version of this paper. We also would like to thank Mart Molle for useful discussions on network protocols.

QUANTUM AND CLASSICAL STRONG DIRECT PRODUCT THEOREMS AND OPTIMAL TIME-SPACE TRADEOFFS*

HARTMUT KLAUCK†, ROBERT ŠPALEK‡, AND RONALD DE WOLF‡

Abstract. A strong direct product theorem says that if we want to compute k independent instances of a function, using less than k times the resources needed for one instance, then our overall success probability will be exponentially small in k. We establish such theorems for the classical as well as quantum query complexity of the OR-function. This implies slightly weaker direct product results for all total functions. We prove a similar result for quantum communication protocols computing k instances of the disjointness function. Our direct product theorems imply a time-space tradeoff $T^2S = \Omega(N^3)$ for sorting N items on a quantum computer, which is optimal up to polylog factors. They also give several tight time-space and communication-space tradeoffs for the problems of Boolean matrix-vector multiplication and matrix multiplication.

1. Introduction.

1.1. Direct product theorems.

For every reasonable model of computation one can ask the following fundamental question:

> How do the resources that we need for computing k independent instances of f scale with the resources needed for one instance and with k?

Here the notion of "resource" needs to be specified. It could refer to time, space, queries, or communication. Similarly we need to define what we mean by "computing f," for instance, whether we allow the algorithm some probability of error and whether this probability of error is average-case or worst-case.

In this paper we consider two kinds of resources, queries and communication, and allow our algorithms some error probability. An algorithm is given k inputs $x^1, \ldots, x^k$ and has to output the vector of k answers $f(x^1), \ldots, f(x^k)$. The issue is how the algorithm can optimally distribute its resources among the k instances it needs to compute. We focus on the relation between the total amount T of resources available and the best-achievable success probability σ (which could be average-case or worst-case). Intuitively, if every algorithm with t resources must have some constant error probability when computing *one* instance of f, then for computing k instances we expect a constant error on each instance and hence an exponentially small success

probability for the k-vector as a whole. Such a statement is known as a *weak* direct product theorem:

If $T \approx t$, then $\sigma = 2^{-\Omega(k)}$.

Here "$T \approx t$" informally means that T is not much smaller than t. However, even if we give our algorithm roughly kt resources, on average it still has only t resources available per instance. So even here we expect a constant error per instance and an exponentially small success probability overall. Such a statement is known as a *strong* direct product theorem:

If $T \approx kt$, then $\sigma = 2^{-\Omega(k)}$.

Strong direct product theorems (SDPTs), though intuitively very plausible, are generally hard to prove and sometimes not even true. Shaltiel [Sha01] exhibits a general class of examples where SDPTs fail. This applies, for instance, to query complexity, communication complexity, and circuit complexity. In his examples, success probability is taken under the uniform probability distribution on inputs. The function is chosen such that for most inputs, most of the k instances can be computed quickly and without any error probability. This leaves enough resources to solve the few hard instances with high success probability. Hence for his functions, with $T \approx tk$, one can achieve average success probability close to 1.

Accordingly, we can establish direct product theorems only in special cases. Examples are the SDPT for "decision forests" by Nisan, Rudich, and Saks [NRS94], the direct product theorem for "forests" of communication protocols by Parnafes, Raz, and Wigderson [PRW97], and Shaltiel's SDPT for "fair" decision trees and his discrepancy bound for communication complexity [Sha01]. Shaltiel's result for discrepancy was recently strengthened to an SDPT for the "corruption" measure under product distributions on the inputs by Beame et al. [BPSW05]. There also has been recent progress on the related issue of *direct sum* results; see, e.g., [CSWY01, BJKS02b, BJKS02a] and the references therein. A direct sum theorem states that computing k instances with overall error ε requires roughly k times as many resources as computing one instance with error ε. Clearly, SDPTs always imply direct sum results, since they state the same resource lower bounds even for algorithms whose overall error is allowed to be exponentially close to 1, rather than at most ε.

In the quantum case, much less work has been done. Aaronson [Aar04, Theorem 10] established a direct product result for the unordered search problem that lies between the weak and the strong theorems: Every T-query quantum algorithm for searching k marked items among $N = kn$ input bits will have success probability $\sigma \leq \mathrm{O}\big(T^2/N\big)^k$. In particular, if $T \ll \sqrt{N} = \sqrt{kn}$, then $\sigma = 2^{-\Omega(k)}$.

Our main contributions in this paper are SDPTs for the OR-function in various settings. First consider the case of classical randomized algorithms. Let OR_n denote the n-bit OR-function, and let $f^{(k)}$ denote k independent instances of a function f. Any randomized algorithm with fewer than, say, $n/2$ queries will have a constant error probability when computing OR_n. Hence we expect an exponentially small success probability when computing $\mathrm{OR}_n^{(k)}$ using $\ll kn$ queries. We prove the following in section 3:

> *SDPT for classical query complexity.* Every randomized algorithm that computes $\mathrm{OR}_n^{(k)}$ using $T \leq \alpha kn$ queries has worst-case success probability $\sigma = 2^{-\Omega(k)}$ (for $\alpha > 0$ a sufficiently small constant).

For simplicity we have stated this result with σ being *worst-case* success probability, but the statement is also valid for the *average* success probability under a hard k-fold product distribution that is implicit in our proof.

This statement for OR actually implies a somewhat weaker strong product theorem for all *total* functions f, via the notion of *block sensitivity* $bs(f)$. Using techniques of Nisan and Szegedy [NS94], we can embed $\mathrm{OR}_{bs(f)}$ in f (with the promise that the weight of the OR's input is 0 or 1), while on the other hand we know that the classical bounded-error query complexity $R_2(f)$ is upper bounded by $bs(f)^3$ [BBC+01]. This implies the following:

> Every randomized algorithm that computes $f^{(k)}$ using $T \leq \alpha k R_2(f)^{1/3}$ queries has worst-case success probability $\sigma = 2^{-\Omega(k)}$ (for $\alpha > 0$ a sufficiently small constant).

This theorem falls short of being a true SDPT in having $R_2^{1/3}(f)$ instead of $R_2(f)$ in the resource bound. However, the other two main aspects of an SDPT remain valid: the linear dependence of the resources on k and the exponential decay of the success probability.

Next we turn our attention to *quantum* algorithms. Buhrman et al. [BNRW05] actually proved that roughly k times the resources for one instance suffices to compute $f^{(k)}$ with success probability *close to* 1 rather than exponentially small: $Q_2(f^{(k)}) = \mathrm{O}(kQ_2(f))$, where $Q_2(f)$ denotes the quantum bounded-error query complexity of f (such a result is not known to hold in the classical world). For instance, $Q_2(\mathrm{OR}_n) = \Theta(\sqrt{n})$ by Grover's search algorithm; thus $\mathrm{O}(k\sqrt{n})$ quantum queries suffice to compute $\mathrm{OR}_n^{(k)}$ with high success probability. In section 4 we show that if we make the number of queries slightly smaller, the best-achievable success probability suddenly becomes exponentially small:

> *SDPT for quantum query complexity.* Every quantum algorithm that computes $\mathrm{OR}_n^{(k)}$ using $T \leq \alpha k\sqrt{n}$ queries has worst-case success probability $\sigma = 2^{-\Omega(k)}$ (for $\alpha > 0$ a sufficiently small constant).

Our proof uses the polynomial method [BBC+01] and is completely different from the classical proof. The polynomial method was also used by Aaronson [Aar04] in his proof of a weaker quantum direct product theorem for the search problem, mentioned above. Our proof takes its starting point from his proof, analyzing the degree of a single-variate polynomial that is 0 on $\{0, \ldots, k-1\}$, at least σ on k, and between 0 and 1 on $\{0, \ldots, kn\}$. The difference between his proof and ours is that we partially factor this polynomial, which gives us some nice extra properties over Aaronson's approach of differentiating the polynomial, and that we use a strong result of Coppersmith and Rivlin [CR92]. In both cases (different) extremal properties of Chebyshev polynomials finish the proofs.

Again, using block sensitivity we can obtain a weaker result for all total functions:

> Every quantum algorithm that computes $f^{(k)}$ using $T \leq \alpha k Q_2(f)^{1/6}$ queries has worst-case success probability $\sigma = 2^{-\Omega(k)}$.

The third and last setting where we establish an SDPT is quantum communication complexity. Suppose Alice has an n-bit input x and Bob has an n-bit input y. These x and y represent sets, and $\mathrm{DISJ}_n(x, y) = 1$ if and only if those sets are disjoint. Note that DISJ_n is the negation of $\mathrm{OR}_n(x \wedge y)$, where $x \wedge y$ is the n-bit string obtained by bitwise AND-ing x and y. In many ways, DISJ_n has the same central role in communication complexity as OR_n has in query complexity. In particular, it is "co-NP complete" [BFS86]. The communication complexity of DISJ_n has been well studied: It takes $\Theta(n)$ bits of communication in the classical world [KS92, Raz92] and $\Theta(\sqrt{n})$ in the quantum world [BCW98, HW02, AA03, Raz03]. For the case where Alice and Bob want to compute k instances of disjointness, we establish the following SDPT in section 5:

SDPT for quantum communication complexity. Every quantum protocol that computes $\mathrm{DISJ}_n^{(k)}$ using $T \leq \alpha k\sqrt{n}$ qubits of communication has worst-case success probability $\sigma = 2^{-\Omega(k)}$ (for $\alpha > 0$ a sufficiently small constant).

Our proof uses Razborov's lower bound technique [Raz03] to translate the quantum protocol to a polynomial, at which point the polynomial results established for the quantum query SDPT take over. We can obtain similar results for other symmetric predicates. The same bound was obtained independently by Beame et al. [BPSW05, Corollary 9] for classical protocols under a specific input distribution, as a corollary of their SDPT for corruption.[1] We conjecture that the optimal result in the classical case has a communication bound of αkn rather than $\alpha k\sqrt{n}$, but cannot prove this.

One may also consider algorithms that compute the *parity* of the k outcomes instead of the vector of k outcomes. This issue has been well studied, particularly in circuit complexity, and generally goes under the name of *XOR lemmas* [Yao82, GNW95]. In this paper we focus mostly on the vector version but can prove similar strong bounds for the parity version. In particular, we state a classical strong XOR lemma in section 3.3 and can get similar strong XOR lemmas for the quantum case using the technique of Cleve et al. [CDNT98, section 3]. They show how the ability to compute the parity of any subset of k bits with probability $1/2 + \varepsilon$ suffices to compute the full k-vector with probability $4\varepsilon^2$. Hence our strong quantum direct product theorems imply strong quantum XOR lemmas.

1.2. Time-space and communication-space tradeoffs. Apart from answering a fundamental question about the computational models of (quantum) query complexity and communication complexity, our direct product theorems also imply a number of new and optimal time-space tradeoffs.

First, we consider the tradeoff between the time T and space S that a quantum circuit needs for *sorting* N numbers. Classically, it is well known that $TS = \Omega\big(N^2\big)$ and that this tradeoff is achievable [Bea91]. In the quantum case, Klauck [Kla03] constructed a bounded-error quantum algorithm that runs in time $T = \mathrm{O}((N \log N)^{3/2}/\sqrt{S})$ for all $(\log N)^3 \leq S \leq N/\log N$. He also claimed a lower bound $TS = \Omega\big(N^{3/2}\big)$, which would be close to optimal for small S but not for large S. Unfortunately there is an error in the proof presented in [Kla03] (Lemma 5 appears to be wrong). Here we use our SDPT to prove the tradeoff $T^2S = \Omega\big(N^3\big)$. This is tight up to polylogarithmic factors.

Secondly, we consider time-space and communication-space tradeoffs for the problems of *Boolean matrix-vector product* and *Boolean matrix product*. In the first problem there are an $N \times N$ matrix A and a vector b of dimension N, and the goal is to compute the vector $c = Ab$, where $c_i = \vee_{j=1}^{N} (A[i,j] \wedge b_j)$. In the setting of time-space tradeoffs, the matrix A is fixed and the input is the vector b. In the problem of matrix multiplication, two matrices have to be multiplied with the same type of Boolean product, and both are inputs.

Time-space tradeoffs for Boolean matrix-vector multiplication have been analyzed in an average-case scenario by Abrahamson [Abr90], whose results give a worst-case lower bound of $TS = \Omega\big(N^{3/2}\big)$ for classical algorithms. He conjectured that a worst-case lower bound of $TS = \Omega\big(N^2\big)$ holds. Using our classical direct product result we are able to confirm this; i.e., there is a matrix A, such that computing Ab requires

[1] We proved our result in February 2004 and published it on the quant-ph preprint server in the same month (http://www.arxiv.org/abs/quant-ph/0402123), while they proved theirs in the summer of 2004, unaware of our paper (personal communication with Paul Beame).

$TS = \Omega(N^2)$. We also show a lower bound of $T^2S = \Omega(N^3)$ for this problem in the quantum case. Both bounds are tight (the second within a logarithmic factor) if T is taken to be the number of queries to the inputs. We also get a lower bound of $T^2S = \Omega(N^5)$ for the problem of multiplying two matrices in the quantum case. This bound is close to optimal for small S; it is open whether it is close to optimal for large S.

Research on communication-space tradeoffs in the classical setting has been initiated by Lam, Tiwari, and Tompa [LTT92] in a restricted setting and by Beame, Tompa, and Yan [BTY94] in a general model of space-bounded communication complexity. In the setting of communication-space tradeoffs, players Alice and Bob are modeled as space-bounded circuits, and we are interested in the communication cost when given particular space bounds. For the problem of computing the matrix-vector product Alice receives the matrix A (now an input) and Bob receives the vector b. Beame, Tompa, and Yan gave tight lower bounds, e.g., for the matrix-vector product and matrix product over GF(2), but stated the complexity of Boolean matrix-vector multiplication as an open problem. Using our direct product result for quantum communication complexity, we are able to show that any quantum protocol for this problem satisfies $C^2S = \Omega(N^3)$. This is tight within a polylogarithmic factor. We also get a lower bound of $C^2S = \Omega(N^5)$ for computing the product of two matrices, which again is tight.

Note that no classical lower bounds for these problems were known previously and that finding better classical lower bounds than these remains open. The ability to show good quantum bounds comes from the deep relation between quantum protocols and polynomials implicit in Razborov's lower bound technique [Raz03].

2. Preliminaries.

2.1. Quantum query algorithms. We assume familiarity with quantum computing [NC00] and sketch the model of quantum query complexity, referring to [BW02] for more details, including details on the close relation between query complexity and degrees of multivariate polynomials. Suppose we want to compute some function f. For input $x \in \{0,1\}^N$, a *query* gives us access to the input bits. It corresponds to the unitary transformation

$$O : |i, b, z\rangle \mapsto |i, b \oplus x_i, z\rangle.$$

Here $i \in [N] = \{1, \ldots, N\}$ and $b \in \{0,1\}$; the z-part corresponds to the workspace, which is not affected by the query. We assume the input can be accessed only via such queries. A T-query quantum algorithm has the form $A = U_T O U_{T-1} \cdots O U_1 O U_0$, where the U_k are fixed unitary transformations, independent of x. This A depends on x via the T applications of O. The algorithm starts in initial S-qubit state $|0\rangle$, and its *output* is the result of measuring a dedicated part of the final state $A|0\rangle$. For a Boolean function f, the output of A is obtained by observing the leftmost qubit of the final superposition $A|0\rangle$, and its *acceptance probability* on input x is its probability of outputting 1.

One of the most interesting quantum query algorithms is Grover's search algorithm [Gro96, BBHT98]. It can find an index of a 1-bit in an n-bit input in expected number of $O(\sqrt{n/(|x|+1)})$ queries, where $|x|$ is the Hamming weight (number of 1's) in the input. If we know that $|x| \leq 1$, we can solve the search problem exactly using $\lceil \frac{\pi}{4}\sqrt{n} \rceil$ queries [BHMT02].

For investigating time-space tradeoffs we use the circuit model. A circuit accesses its input via an oracle such as a query algorithm. Time corresponds to the number

of gates in the circuit. We will, however, usually consider the number of queries to the input, which is obviously a lower bound on time. A quantum circuit uses space S if it works with S qubits only. We require that the outputs are made at predefined gates in the circuit, by writing their value to some extra qubits that may not be used later on. Similar definitions are made for classical circuits.

2.2. Communicating quantum circuits. In the model of quantum communication complexity, two players Alice and Bob compute a function f on distributed inputs x and y. The complexity measure of interest in this setting is the amount of communication. The players follow some predefined protocol that consists of local unitary operations and the exchange of qubits. The communication cost of a protocol is the maximal number of qubits exchanged for any input. In the standard model of communication complexity, Alice and Bob are computationally unbounded entities, but we are also interested in what happens if they have bounded memory, i.e., they work with a bounded number of qubits. To this end we model Alice and Bob as communicating quantum circuits, following Yao [Yao93].

A pair of communicating quantum circuits is actually a single quantum circuit partitioned into two parts. The allowed operations are local unitary operations and access to the inputs that are given by oracles. Alice's part of the circuit may use oracle gates to read single bits from her input, and Bob's part of the circuit may do so for his input. The communication C between the two parties is simply the number of wires carrying qubits that cross between the two parts of the circuit. A pair of communicating quantum circuits uses space S if the whole circuit works on S qubits.

In the problems we consider, the number of outputs is much larger than the memory of the players. Therefore we use the following output convention: The player who computes the value of an output sends this value to the other player at a predetermined point in the protocol. In order to make the models as general as possible, we furthermore allow the players to do local measurements and to throw qubits away as well as pick up some fresh qubits. The space requirement demands only that at any given time no more than S qubits are in use in the whole circuit.

A final comment regarding upper bounds: Buhrman, Cleve, and Wigderson [BCW98] showed how to run a query algorithm in a distributed fashion with small overhead in the communication. In particular, if there is a T-query quantum algorithm computing N-bit function f, then there is a pair of communicating quantum circuits with $O(T \log N)$ communication that computes $f(x \wedge y)$ with the same success probability. We refer to the book of Kushilevitz and Nisan [KN97] for more on communication complexity in general and to the surveys [Kla00, Buh00, Wol02] for more on its quantum variety.

3. Strong direct product theorem for classical queries. In this section we prove an SDPT for classical randomized algorithms computing k independent instances of OR_n. By Yao's principle, it is sufficient to prove it for deterministic algorithms under a fixed hard input distribution.

3.1. Nonadaptive algorithms. We first establish an SDPT for nonadaptive algorithms. We call an algorithm *nonadaptive* if, for each of the k input blocks, the maximum number of queries in that block is fixed before the first query. Note that this definition is nonstandard in fixing only the *number* of queries in each block rather than fixing all queried *indices* in advance. Let $\mathrm{Suc}_{t,\mu}(f)$ be the success probability of the best algorithm for f under μ that queries at most t input bits.

LEMMA 1. *Let $f : \{0,1\}^n \to \{0,1\}$, and let μ be an input distribution. Every nonadaptive deterministic algorithm for $f^{(k)}$ under μ^k with $T \le kt$ queries has success probability $\sigma \le \mathrm{Suc}_{t,\mu}(f)^k$.*

Proof. The proof has two steps. First, we prove by induction that nonadaptive algorithms for $f^{(k)}$ under general product distribution $\mu_1 \times \cdots \times \mu_k$ that spend t_i queries in the ith input x^i have success probability $\le \prod_{i=1}^k \mathrm{Suc}_{t_i,\mu_i}(f)$. Second, we argue that, when $\mu_i = \mu$, the value is maximal for $t_i = t$.

Following [Sha01, Lemma 7], we prove the first part by induction on $T = t_1 + \cdots + t_k$. If $T = 0$, then the algorithm has to guess k independent random variables $x^i \sim \mu_i$. The probability of success is equal to the product of the individual success probabilities, i.e., $\prod_{i=1}^k \mathrm{Suc}_{0,\mu_i}(f)$.

For the induction step $T \Rightarrow T+1$, pick some $t_i \neq 0$ and consider two input distributions $\mu'_{i,0}$ and $\mu'_{i,1}$ obtained from μ_i by fixing the queried bit x^i_j (jth bit in the ith input). By the induction hypothesis, for each value $b \in \{0,1\}$, there is an optimal nonadaptive algorithm A_b that achieves the success probability $\mathrm{Suc}_{t_i-1,\mu'_{i,b}}(f) \cdot \prod_{j\neq i} \mathrm{Suc}_{t_j,\mu_j}(f)$. We construct a new algorithm A that calls A_b as a subroutine after it has queried x^i_j with b as an outcome. A is optimal and has success probability

$$\left(\sum_{b=0}^{1} \Pr_{\mu_i}[x^i_j = b] \cdot \mathrm{Suc}_{t_i-1,\mu'_{i,b}}(f)\right) \cdot \prod_{j\neq i} \mathrm{Suc}_{t_j,\mu_j}(f) = \prod_{i=1}^{k} \mathrm{Suc}_{t_i,\mu_i}(f).$$

Since we are dealing with nonadaptive algorithms here, symmetry reasons imply that if all k instances x^i are independent and identically distributed, then the optimal distribution of queries $t_1 + \cdots + t_k = kt$ is uniform, i.e., $t_i = t$. (Note that counterexamples to the analogous property for the general nonadaptive case, like those given by Shaltiel [Sha01], do not apply here.) In such a case, the algorithm achieves the success probability $\mathrm{Suc}_{t,\mu}(f)^k$. □

3.2. Adaptive algorithms. In this section we prove a similar statement also for adaptive algorithms.

Remark. The SDPT is not always true for adaptive algorithms. Following [Sha01], define $h(x) = x_1 \vee (x_2 \oplus \cdots \oplus x_n)$. Clearly $\mathrm{Suc}_{\frac{2}{3}n,\mu}(h) = 3/4$ for μ uniform. By a Chernoff bound, $\mathrm{Suc}_{\frac{2}{3}nk,\mu^k}(h^{(k)}) = 1 - 2^{-\Omega(k)}$, because approximately half of the blocks can be solved using just 1 query and the unused queries can be used to answer exactly also the other half of the blocks.

However, the SDPT is valid for $\mathrm{OR}_n^{(k)}$ under ν^k, where $\nu(0^n) = 1/2$ and $\nu(e_i) = 1/2n$ for e_i an n-bit string that contains a 1 only at the ith position. It is simple to prove that $\mathrm{Suc}_{\alpha n,\nu}(\mathrm{OR}_n) = \frac{\alpha+1}{2}$. Nonadaptive algorithms for $\mathrm{OR}_n^{(k)}$ under ν^k with αkn queries thus have $\sigma \le (\frac{\alpha+1}{2})^k = 2^{-\log(\frac{2}{\alpha+1})k}$. We can achieve any $\gamma < 1$ by choosing α sufficiently small. We prove that adaptive algorithms cannot be much better. Without loss of generality, we assume the following:

1. The adaptive algorithm is deterministic. By Yao's principle [Yao77], if there exists a randomized algorithm with success probability σ under some input distribution, then there exists a deterministic algorithm with success probability σ under that distribution.
2. Whenever the algorithm finds a 1 in some input block, it stops querying that block.
3. The algorithm spends the same number of queries in all blocks where it does not find a 1. This is optimal due to the symmetry between the blocks (we

omit the straightforward calculation that justifies this). It implies that the algorithm spends at least as many queries in each "empty" input block as in each "nonempty" block.

LEMMA 2. *If there is an adaptive T-query algorithm A computing $\mathrm{OR}_n^{(k)}$ under ν^k with success probability σ, then there is a nonadaptive $3T$-query algorithm A' computing $\mathrm{OR}_n^{(k)}$ with success probability $\sigma - 2^{-\Omega(k)}$.*

Proof. Let Z be the number of empty blocks. $\mathrm{E}[Z] = k/2$, and, by a Chernoff bound, $\delta = \Pr[Z < k/3] = 2^{-\Omega(k)}$. If $Z \geq k/3$, then A spends at most $3T/k$ queries in each empty block. Define nonadaptive A' that spends $3T/k$ queries in *each* block. Then A' queries all the positions that A queries and maybe some more. Compare the overall success probabilities of A and A':

$$\begin{aligned}\sigma_A &= \Pr[Z < k/3] \cdot \Pr[A \text{ succeeds} \mid Z < k/3] \\ &\quad + \Pr[Z \geq k/3] \cdot \Pr[A \text{ succeeds} \mid Z \geq k/3] \\ &\leq \delta \cdot 1 + \Pr[Z \geq k/3] \cdot \Pr[A' \text{ succeeds} \mid Z \geq k/3] \\ &\leq \delta + \sigma_{A'}.\end{aligned}$$

We conclude that $\sigma_{A'} \geq \sigma_A - \delta$. (*Remark.* By replacing the $k/3$-bound on Z by a βk-bound for some $\beta > 0$, we can obtain arbitrary $\gamma < 1$ in the exponent $\delta = 2^{-\gamma k}$, while the number of queries of A' becomes T/β.) □

Combining the two lemmas establishes the following theorem.

THEOREM 3 (SDPT for OR). *For every $0 < \gamma < 1$, there exists an $\alpha > 0$ such that every randomized algorithm for $\mathrm{OR}_n^{(k)}$ with $T \leq \alpha kn$ queries has success probability $\sigma \leq 2^{-\gamma k}$.*

3.3. A bound for the parity instead of the vector of results. Here we give an SDPT for the *parity* of k independent instances of OR_n. The parity is a Boolean variable; hence we can always guess it with probability at least $\frac{1}{2}$. However, we prove that the advantage (instead of the success probability) of our guess must be exponentially small.

Let X be a random bit with $\Pr[X = 1] = p$. We define the *advantage of X* by $\mathrm{Adv}(X) = |2p - 1|$. Note that a uniformly distributed random bit has advantage 0 and a bit known with certainty has advantage 1. It is well known that if $X_1, \ldots, X_k$ are independent random bits, then $\mathrm{Adv}(X_1 \oplus \cdots \oplus X_k) = \prod_{i=1}^k \mathrm{Adv}(X_i)$. Compare this with the fact that the probability of correctly guessing the complete vector $(X_1, \ldots, X_k)$ is the product of the individual probabilities.

We have proved a lower bound for the computation of $\mathrm{OR}_n^{(k)}$ (vector of ORs). By the same technique, replacing the success probability by the advantage in all claims and proofs, we can also prove a lower bound for the computation of $\mathrm{OR}_n^{\oplus k}$ (parity of ORs).

THEOREM 4 (SDPT for parity of ORs). *For every $0 < \gamma < 1$, there exists an $\alpha > 0$ such that every randomized algorithm for $\mathrm{OR}_n^{\oplus k}$ with $T \leq \alpha kn$ queries has advantage $\tau \leq 2^{-\gamma k}$.*

3.4. A bound for all functions. Here we show that the SDPT for OR actually implies a weaker direct product theorem for all functions. In this weaker version, the success probability of computing k instances still goes down exponentially with k, but we need to start from a polynomially smaller bound on the overall number of queries.

DEFINITION 5. *For $x \in \{0,1\}^n$ and $S \subseteq [n]$, we use x^S to denote the n-bit string obtained from x by flipping the bits in S. Consider a (possibly partial) function*

$f : \mathcal{D} \to Z$, with $\mathcal{D} \subseteq \{0,1\}^n$. The block sensitivity *$bs_x(f)$ of $x \in \mathcal{D}$ is the maximal b for which there are disjoint sets $S_1, \ldots, S_b$ such that $f(x) \neq f(x^{S_i})$. The* block sensitivity *of f is $\max_{x \in \mathcal{D}} bs_x(f)$.*

Block sensitivity is closely related to deterministic and bounded-error classical query complexity as shown in the following theorem.

THEOREM 6 (see [Nis91, BBC+01]). *$R_2(f) = \Omega(bs(f))$ for all f, and $D(f) \leq bs(f)^3$ for all total Boolean f.*

Nisan and Szegedy [NS94] showed how to embed a $bs(f)$-bit OR-function (with the promise that the input has weight ≤ 1) into f. Combined with our SDPT for OR, this implies the following direct product theorem for all functions in terms of their block sensitivity.

THEOREM 7. *For every $0 < \gamma < 1$, there exists an $\alpha > 0$ such that for every f, every classical algorithm for $f^{(k)}$ with $T \leq \alpha k bs(f)$ queries has success probability $\sigma \leq 2^{-\gamma k}$.*

This is optimal whenever $R_2(f) = \Theta(bs(f))$, which is the case for most functions. For total functions, the gap between $R_2(f)$ and $bs(f)$ is not more than cubic; hence, we have the following corollary.

COROLLARY 8. *For every $0 < \gamma < 1$, there exists an $\alpha > 0$ such that for every total Boolean f, every classical algorithm for $f^{(k)}$ with $T \leq \alpha k R_2(f)^{1/3}$ queries has success probability $\sigma \leq 2^{-\gamma k}$.*

4. Strong direct product theorem for quantum queries. In this section we prove an SDPT for quantum algorithms computing k independent instances of OR. Our proof relies on the polynomial method of [BBC+01].

4.1. Bounds on polynomials. We use three results about polynomials, also used in [BCWZ99]. The first is by Coppersmith and Rivlin [CR92, p. 980] and gives a general bound for polynomials bounded by 1 at integer points.

THEOREM 9 (see Coppersmith and Rivlin [CR92]). *Every polynomial p of degree $d \leq n$ that has absolute value*

$$|p(i)| \leq 1 \text{ for all integers } i \in [0, n]$$

satisfies

$$|p(x)| < ae^{bd^2/n} \text{ for all real } x \in [0, n],$$

where $a, b > 0$ are universal constants (no explicit values for a and b are given in [CR92]*).*

The other two results concern the Chebyshev polynomials T_d, defined by (see, e.g., [Riv90]):

$$T_d(x) = \frac{1}{2}\left(\left(x + \sqrt{x^2-1}\right)^d + \left(x - \sqrt{x^2-1}\right)^d\right).$$

T_d has degree d, and its absolute value $|T_d(x)|$ is bounded by 1 if $x \in [-1, 1]$. On the interval $[1, \infty)$, T_d exceeds all other polynomials with those two properties ([Riv90, p. 108] and [Pat92, Fact 2]).

THEOREM 10. *If q is a polynomial of degree d such that $|q(x)| \leq 1$ for all $x \in [-1, 1]$ then $|q(x)| \leq |T_d(x)|$ for all $x \geq 1$.*

Paturi [Pat92, before Fact 2] proved the following lemma.

LEMMA 11 (see Paturi [Pat92]). *$T_d(1 + \mu) \leq e^{2d\sqrt{2\mu+\mu^2}}$ for all $\mu \geq 0$.*

Proof. For $x = 1+\mu$, $T_d(x) \le (x+\sqrt{x^2-1})^d = (1+\mu+\sqrt{2\mu+\mu^2})^d \le (1+2\sqrt{2\mu+\mu^2})^d \le e^{2d\sqrt{2\mu+\mu^2}}$ (using that $1+z \le e^z$ for all real z). □

The following key lemma is the basis for all our direct product theorems.

LEMMA 12. *Suppose p is a degree-D polynomial such that for some $\delta \ge 0$*

$-\delta \le p(i) \le \delta$ *for all* $i \in \{0,\dots,k-1\}$,

$p(k) = \sigma$,

$p(i) \in [-\delta, 1+\delta]$ *for all* $i \in \{0,\dots,N\}$.

Then for every integer $1 \le C < N-k$ and $\mu = 2C/(N-k-C)$ we have

$$\sigma \le a\left(1+\delta+\frac{\delta(2N)^k}{(k-1)!}\right) \cdot \exp\left(\frac{b(D-k)^2}{(N-k-C)} + 2(D-k)\sqrt{2\mu+\mu^2} - k\ln(C/k)\right) + \delta k 2^{k-1},$$

where a, b are the constants given by Theorem 9.

Before establishing this gruesome bound, let us reassure the reader by noting that we will apply this lemma with δ either 0 or negligibly small, $D = \alpha\sqrt{kN}$ for sufficiently small α, and $C = ke^{\gamma+1}$, giving

$$\sigma \le \exp\Big((b\alpha^2 + 4\alpha e^{\gamma/2+1/2} - 1 - \gamma)k\Big) \le e^{-\gamma k} \le 2^{-\gamma k}.$$

Proof of Lemma 12. Divide p with remainder by $\prod_{j=0}^{k-1}(x-j)$ to obtain

$$p(x) = q(x)\prod_{j=0}^{k-1}(x-j) + r(x),$$

where $d = \deg(q) = D-k$ and $\deg(r) \le k-1$. We know that $r(x) = p(x) \in [-\delta,\delta]$ for all $x \in \{0,\dots,k-1\}$. Decompose r as a linear combination of polynomials e_i, where $e_i(i) = 1$ and $e_i(x) = 0$ for $x \in \{0,\dots,k-1\} - \{i\}$:

$$r(x) = \sum_{i=0}^{k-1} p(i)e_i(x) = \sum_{i=0}^{k-1} p(i) \prod_{\substack{j=0\\ j\ne i}}^{k-1} \frac{x-j}{i-j}.$$

We bound the values of r for all real $x \in [0,N]$ by

$$|r(x)| \le \sum_{i=0}^{k-1} \frac{|p(i)|}{i!(k-1-i)!} \prod_{\substack{j=0\\ j\ne i}}^{k-1} |x-j|$$

$$\le \frac{\delta}{(k-1)!}\sum_{i=0}^{k-1}\binom{k-1}{i}N^k \le \frac{\delta(2N)^k}{(k-1)!},$$

$$|r(k)| \le \delta k 2^{k-1}.$$

This implies the following about the values of the polynomial q:

$$|q(k)| \ge (\sigma - \delta k 2^{k-1})/k!$$

$$|q(i)| \le \frac{(i-k)!}{i!}\left(1+\delta+\frac{\delta(2N)^k}{(k-1)!}\right) \quad \text{for } i \in \{k,\dots,N\}.$$

In particular,

$$|q(i)| \le C^{-k}\left(1+\delta+\frac{\delta(2N)^k}{(k-1)!}\right) = A \quad \text{for } i \in \{k+C,\dots,N\}.$$

Theorem 9 implies that there are constants $a, b > 0$ such that

$$|q(x)| \le A \cdot ae^{bd^2/(N-k-C)} = B \quad \text{for all real } x \in [k+C, N].$$

We now divide q by B to normalize it and rescale the interval $[k+C, N]$ to $[1, -1]$ to get a degree-d polynomial t satisfying

$$|t(x)| \le 1 \quad \text{for all } x \in [-1,1],$$
$$t(1+\mu) = q(k)/B \quad \text{for } \mu = 2C/(N-k-C).$$

Since t cannot grow faster than the degree-d Chebyshev polynomial, we get

$$t(1+\mu) \le T_d(1+\mu) \le e^{2d\sqrt{2\mu+\mu^2}}.$$

Combining our upper and lower bounds on $t(1+\mu)$, we obtain

$$\frac{(\sigma-\delta k 2^{k-1})/k!}{C^{-k}\left(1+\delta+(\delta(2N)^k/(k-1)!)\right)ae^{bd^2/(N-k-C)}} \le e^{2d\sqrt{2\mu+\mu^2}}.$$

Rearranging gives the bound. ∎

4.2. Consequences for quantum algorithms. The previous result about polynomials implies a strong tradeoff between queries and success probability for quantum algorithms that have to find k 1's in an N-bit input. A *k-threshold algorithm with success probability σ* is an algorithm on N-bit input x that outputs 0 with certainty if $|x| < k$, and outputs 1 with probability at least σ if $|x| = k$.

THEOREM 13. *For every $\gamma > 0$, there exists an $\alpha > 0$ such that every quantum k-threshold algorithm with $T \le \alpha\sqrt{kN}$ queries has success probability $\sigma \le 2^{-\gamma k}$.*

Proof. Fix $\gamma > 0$ and consider a T-query k-threshold algorithm. By [BBC+01], its acceptance probability is an N-variate polynomial of degree $D \le 2T \le 2\alpha\sqrt{kN}$ and can be symmetrized to a single-variate polynomial p with the properties

$p(i) = 0$ if $i \in \{0,\dots,k-1\}$,
$p(k) \ge \sigma$,
$p(i) \in [0,1]$ for all $i \in \{0,\dots,N\}$,

Choosing $\alpha > 0$ sufficiently small and $\delta = 0$, the result follows from Lemma 12. ∎

This implies an SDPT for k instances of the n-bit search problem. For each such instance, the goal is to find the index of a 1-bit among the n input bits of the instance (or to report that none exists).

THEOREM 14 (SQDPT for Search). *For every $\gamma > 0$, there exists an $\alpha > 0$ such that every quantum algorithm for* $\text{Search}_n^{(k)}$ *with $T \le \alpha k\sqrt{n}$ queries has success probability $\sigma \le 2^{-\gamma k}$.*

Proof. Set $N = kn$, and fix a $\gamma > 0$ and a T-query algorithm A for $\text{Search}_n^{(k)}$ with success probability σ. Now consider the following algorithm that acts on an N-bit input x:

1. Apply a random permutation π to x.
2. Run A on $\pi(x)$.

3. Query each of the k positions that A outputs, and return 1 if and only if at least $k/2$ of those bits are 1.

This uses $T + k$ queries. We will show that it is a $k/2$-threshold algorithm. First, if $|x| < k/2$, it always outputs 0. Second, consider the case $|x| = k/2$. The probability that π puts all $k/2$ 1's in distinct n-bit blocks is

$$\frac{N}{N} \cdot \frac{N-n}{N-1} \cdots \frac{N-\frac{k}{2}n}{N-\frac{k}{2}} \geq \left(\frac{N-\frac{k}{2}n}{N}\right)^{k/2} = 2^{-k/2}.$$

Hence our algorithm outputs 1 with probability at least $\sigma 2^{-k/2}$. Choosing α sufficiently small, the previous theorem implies $\sigma 2^{-k/2} \leq 2^{-(\gamma+1/2)k}$; hence $\sigma \leq 2^{-\gamma k}$. □

Our bounds are quite precise for $\alpha \ll 1$. We can choose $\gamma = 2\ln(1/\alpha) - \mathrm{O}(1)$ and ignore some lower-order terms to get roughly $\sigma \leq \alpha^{2k}$. On the other hand, it is known that Grover's search algorithm with $\alpha\sqrt{n}$ queries on an n-bit input has success probability roughly α^2 [BBHT98]. Doing such a search on all k instances gives overall success probability α^{2k}.

THEOREM 15 (SQDPT for OR). *There exist $\alpha, \gamma > 0$ such that every quantum algorithm for $\mathrm{OR}_n^{(k)}$ with $T \leq \alpha k\sqrt{n}$ queries has success probability $\sigma \leq 2^{-\gamma k}$.*

Proof. An algorithm A for $\mathrm{OR}_n^{(k)}$ with success probability σ can be used to build an algorithm A' for $\mathrm{Search}_n^{(k)}$ with slightly worse success probability:

1. Run A on the original input and remember which blocks contain a 1.
2. Run simultaneously (at most k) binary searches on the nonzero blocks. Iterate this $s = 2\log(1/\alpha)$ times. Each iteration is computed by running A on the parts of the blocks that are known to contain a 1, halving the remaining instance size each time.
3. Run the exact version of Grover's algorithm on each of the remaining parts of the instances to look for a 1 there (each remaining part has size $n/2^s$).

This new algorithm A' uses $(s+1)T + \frac{\pi}{4}k\sqrt{n/2^s} = \mathrm{O}(\alpha \log(1/\alpha)k\sqrt{n})$ queries. With probability at least σ^{s+1}, A succeeds in all iterations, in which case A' solves $\mathrm{Search}_n^{(k)}$. By the previous theorem, for every $\gamma' > 0$ of our choice we can choose $\alpha > 0$ such that

$$\sigma^{s+1} \leq 2^{-\gamma' k},$$

which implies the theorem with $\gamma = \gamma'/(s+1)$. □

Choosing our parameters carefully, we can actually show that for every $\gamma < 1$ there is an $\alpha > 0$ such that $\alpha k\sqrt{n}$ queries give success probability $\sigma \leq 2^{-\gamma k}$. Clearly, $\sigma = 2^{-k}$ is achievable without any queries by random guessing.

4.3. A bound for all functions. As in section 3.4, we can extend the SDPT for OR to a slightly weaker theorem for all total functions. Block sensitivity is closely related to bounded-error quantum query complexity as shown in the following theorem.

THEOREM 16 (see [BBC+01]). *$Q_2(f) = \Omega(\sqrt{bs(f)})$ for all f, and $D(f) \leq bs(f)^3$ for all total Boolean f.*

By embedding an OR of size $bs(f)$ in f, we obtain the following theorem.

THEOREM 17. *There exist $\alpha, \gamma > 0$ such that for every f, every quantum algorithm for $f^{(k)}$ with $T \leq \alpha k\sqrt{bs(f)}$ queries has success probability $\sigma \leq 2^{-\gamma k}$.*

This is close to optimal whenever $Q_2(f) = \Theta(\sqrt{bs(f)})$. For total functions, the gap between $Q_2(f)$ and $\sqrt{bs(f)}$ is no more than a 6th power; hence the following corollary holds.

COROLLARY 18. *There exist $\alpha, \gamma > 0$ such that for every total Boolean f, every quantum algorithm for $f^{(k)}$ with $T \leq \alpha k Q_2(f)^{1/6}$ queries has success probability $\sigma \leq 2^{-\gamma k}$.*

5. Strong direct product theorem for quantum communication. In this section we establish an SDPT for quantum communication complexity, specifically for protocols that compute k independent instances of the disjointness problem. Our proof relies crucially on the beautiful technique that Razborov introduced to establish a lower bound on the quantum communication complexity of (one instance of) disjointness [Raz03]. It allows us to translate a quantum communication protocol to a single-variate polynomial that represents, roughly speaking, the protocol's acceptance probability as a function of the size of the intersection of x and y. Once we have this polynomial, the results from section 4.1 suffice to establish an SDPT.

5.1. Razborov's technique. Razborov's technique relies on the following linear algebraic notions. The *operator norm* $\| A \|$ of a matrix A is its largest singular value σ_1. The *trace inner product* (also known as Hilbert–Schmidt inner product) between A and B is $\langle A, B \rangle = \mathrm{Tr}(A^* B)$. The *trace norm* is $\| A \|_{tr} = \max\{|\langle A, B \rangle| : \| B \| = 1\} = \sum_i \sigma_i$, the sum of all singular values of A. The *Frobenius norm* is $\| A \|_F = \sqrt{\sum_{ij} |A_{ij}|^2} = \sqrt{\sum_i \sigma_i^2}$. The following lemma is implicit in Razborov's paper.

LEMMA 19. *Consider a Q-qubit quantum communication protocol on N-bit inputs x and y, with acceptance probabilities denoted by $P(x, y)$. Define*

$$P(i) = \mathrm{E}_{|x|=|y|=N/4, |x \wedge y|=i|}[P(x, y)],$$

where the expectation is taken uniformly over all x, y that each have weight $N/4$ and that have intersection i. For every $d \leq N/4$ there exists a degree-d polynomial q such that $|P(i) - q(i)| \leq 2^{-d/4+2Q}$ for all $i \in \{0, \ldots, N/8\}$.

Proof. We only consider the $\mathcal{N} = \binom{N}{N/4}$ strings of weight $N/4$. Let P denote the $\mathcal{N} \times \mathcal{N}$ matrix of the acceptance probabilities on these inputs. We know from Yao and Kremer [Yao93, Kre95] that we can decompose P as a matrix product $P = AB$, where A is an $\mathcal{N} \times 2^{2Q-2}$ matrix with each entry at most 1 in absolute value, and similarly for B. Note that $\| A \|_F, \| B \|_F \leq \sqrt{\mathcal{N} 2^{2Q-2}}$. Using Hölder's inequality we have

$$\| P \|_{tr} \leq \| A \|_F \cdot \| B \|_F \leq \mathcal{N} 2^{2Q-2}.$$

Let μ_i denote the $\mathcal{N} \times \mathcal{N}$ matrix corresponding to the uniform probability distribution on $\{(x, y) : |x \wedge y| = i\}$. These "combinatorial matrices" have been well studied [Knu03]. Note that $\langle P, \mu_i \rangle$ is the expected acceptance probability $P(i)$ of the protocol under that distribution. One can show that the different μ_i commute; thus they have the same eigenspaces $E_0, \ldots, E_{N/4}$ and can be simultaneously diagonalized by some orthogonal matrix U. For $t \in \{0, \ldots, N/4\}$, let $(UPU^T)_t$ denote the block of UPU^T corresponding to E_t, and let $a_t = \mathrm{Tr}((UPU^T)_t)$ be its trace. Then we have

$$\sum_{t=0}^{N/4} |a_t| \leq \sum_{j=1}^{\mathcal{N}} \left|(UPU^T)_{jj}\right| \leq \| UPU^T \|_{tr} = \| P \|_{tr} \leq \mathcal{N} 2^{2Q-2},$$

where the second inequality is a property of the trace norm.

Let λ_{it} be the eigenvalue of μ_i in eigenspace E_t. It is known [Raz03, section 5.3] that λ_{it} is a degree-t polynomial in i, and that $|\lambda_{it}| \leq 2^{-t/4}/\mathcal{N}$ for $i \leq N/8$

(the factor 1/4 in the exponent is implicit in Razborov's paper). Consider the high-degree polynomial p defined by

$$p(i) = \sum_{t=0}^{N/4} a_t \lambda_{it}.$$

This satisfies

$$p(i) = \sum_{t=0}^{N/4} \mathrm{Tr}((UPU^T)_t)\lambda_{it} = \langle UPU^T, U\mu_i U^T\rangle = \langle P, \mu_i\rangle = P(i).$$

Let q be the degree-d polynomial obtained by removing the high-degree parts of p:

$$q(i) = \sum_{t=0}^{d} a_t \lambda_{it}.$$

Then P and q are close on all integers i between 0 and $N/8$:

$$|P(i) - q(i)| = |p(i) - q(i)| = \left| \sum_{t=d+1}^{N/4} a_t \lambda_{it} \right| \leq \frac{2^{-d/4}}{\mathcal{N}} \sum_{t=0}^{N/4} |a_t| \leq 2^{-d/4+2Q}. \qquad \square$$

5.2. Consequences for quantum protocols. Combining Razborov's technique with our polynomial bounds, we can prove the following theorem.

THEOREM 20 (SQDPT for disjointness). *There exist $\alpha, \gamma > 0$ such that every quantum protocol for $\mathrm{DISJ}_n^{(k)}$ with $Q \leq \alpha k\sqrt{n}$ qubits of communication has success probability $p \leq 2^{-\gamma k}$.*

Proof sketch. By doing the same trick with $s = 2\log(1/\alpha)$ rounds of binary search as for Theorem 15, we can tweak a protocol for $\mathrm{DISJ}_n^{(k)}$ to a protocol that satisfies, with $P(i)$ defined as in Lemma 19, $N = kn$ and $\sigma = p^{s+1}$:

$P(i) = 0$ if $i \in \{0, \ldots, k-1\}$,
$P(k) \geq \sigma$,
$P(i) \in [0,1]$ for all $i \in \{0, \ldots, N\}$

(a subtlety: instead of exact Grover we use an exact version of the $\mathrm{O}(\sqrt{n})$-qubit disjointness protocol of [AA03]; the [BCW98]-protocol would lose a $\log n$-factor). Lemma 19, using $d = 12Q$, then gives a degree-d polynomial q that differs from P by at most $\delta \leq 2^{-Q}$ on all $i \in \{0, \ldots, N/8\}$. This δ is sufficiently small to apply Lemma 12, which in turn upper bounds σ and hence p. $\square$

This technique also gives SDPTs for symmetric predicates other than DISJ_n. As mentioned in the introduction, the same bound was obtained independently by Beame et al. [BPSW05, Corollary 9] for classical protocols.

6. Time-space tradeoff for quantum sorting. We will now use our SDPT to get near-optimal time-space tradeoffs for quantum circuits for sorting. In our model, the numbers $a_1, \ldots, a_N$ that we want to sort can be accessed by means of queries, and the number of queries lower bounds the actual time taken by the circuit. The circuit has N output gates and in the course of its computation outputs the N numbers in sorted (say, descending) order, with success probability at least 2/3.

THEOREM 21. *Every bounded-error quantum circuit for sorting N numbers that uses T queries and S qubits of workspace satisfies $T^2 S = \Omega(N^3)$.*

Proof. We "slice" the circuit along the time-axis into $L = T/\alpha\sqrt{SN}$ slices, each containing $T/L = \alpha\sqrt{SN}$ queries. Each such slice has a number of output gates. Consider any slice. Suppose it contains output gates $i, i+1, \ldots, i+k-1$ for $i \leq N/2$, so that it is supposed to output the ith up to $(i+k-1)$th largest elements of its input. We want to show that $k = \mathrm{O}(S)$. If $k \leq S$, then we are done, so assume $k > S$. We can use the slice as a k-threshold algorithm on $N/2$ bits, as follows. For an $N/2$-bit input x, construct a sorting input by taking $i-1$ copies of the number 2, the $N/2$ bits in x, and $N/2 - i + 1$ copies of the number 0, and append their position behind the numbers.

Consider the behavior of the sorting circuit on this input. The first part of the circuit has to output the $i-1$ largest numbers, which all start with 2. We condition on the event that the circuit succeeds in this. It then passes on an S-qubit state (possibly mixed) as the starting state of the particular slice we are considering. This slice then outputs the k largest numbers in x with probability at least $2/3$. Now, consider an algorithm that runs just this slice, starting with the completely mixed state on S-qubits, and that outputs 1 if it finds k numbers starting with 1, and outputs 0 otherwise. If $|x| < k$, this new algorithm always outputs 0 (note that it can verify finding a 1 since its position is appended), but if $|x| = k$, then it outputs 1 with probability at least $\sigma \geq \frac{2}{3} \cdot 2^{-S}$, because the completely mixed state has "overlap" 2^{-S} with the "good" S-qubit state that would have been the starting state of the slice in the run of the sorting circuit. On the other hand, the slice has only $\alpha\sqrt{SN} < \alpha\sqrt{kN}$ queries, so by choosing α sufficiently small, Theorem 13 implies $\sigma \leq 2^{-\Omega(k)}$. Combining our upper and lower bounds on σ gives $k = \mathrm{O}(S)$. Thus we need $L = \Omega(N/S)$ slices, so $T = L\alpha\sqrt{SN} = \Omega(N^{3/2}/\sqrt{S})$. □

As mentioned, our tradeoff is achievable up to polylog factors [Kla03]. Interestingly, the near-optimal algorithm uses only a polylogarithmic number of qubits and otherwise just classical memory. For simplicity we have shown the lower bound for the case when the outputs have to be made in their natural ordering only, but we can show, using a slightly different proof, the same lower bound for any ordering of the outputs that does not depend on the input.

7. Time-space tradeoffs for Boolean matrix products. First we show a lower bound on the time-space tradeoff for Boolean matrix-vector multiplication on *classical* machines.

THEOREM 22. *There is an $N \times N$ matrix A such that every classical bounded-error circuit that computes the Boolean matrix-vector product Ab with T queries and space $S = \mathrm{o}(N/\log N)$ satisfies $TS = \Omega(N^2)$.*

The bound is tight if T measures queries to the input.

Proof. Fix $k = \mathrm{O}(S)$ large enough. First we have to find a hard matrix A. We pick A randomly by setting $N/(2k)$ random positions in each row to 1. We want to show that with positive probability for all sets of k rows $A[i_1], \ldots, A[i_k]$ many of the rows $A[i_j]$ contain at least $N/(6k)$ 1's that are not 1's in any of the $k-1$ other rows.

This probability can be bounded as follows. We will treat the rows as subsets of $\{1, \ldots, N\}$. A row $A[j]$ is called *bad* with respect to $k-1$ other rows $A[i_1], \ldots, A[i_{k-1}]$ if $|A[j] - \cup_\ell A[i_\ell]| \leq N/(6k)$. For fixed $i_1, \ldots, i_{k-1}$, the probability that some $A[j]$ is bad with respect to the $k-1$ other rows is at most $e^{-\Omega(N/k)}$ by the Chernoff bound and the fact that k rows can together contain at most $N/2$ elements. Since $k = \mathrm{o}(N/\log N)$ we may assume this probability is at most $1/N^{10}$.

Now fix any set $I = \{i_1, \ldots, i_k\}$. The probability that for $j \in I$ it holds that $A[j]$ is bad with respect to the other rows is at most $1/N^{10}$, and this also holds if we

condition on the event that some other rows are bad, since this condition makes it only less probable that another row is also bad. So for any fixed $J \subset I$ of size $k/2$ the probability that all rows in J are bad is at most N^{-5k}, and the probability that there exists such J is at most

$$\binom{k}{k/2} N^{-5k}.$$

Furthermore, the probability that there is a set I of k rows for which $k/2$ are bad is at most

$$\binom{N}{k}\binom{k}{k/2} N^{-5k} < 1.$$

So there is an A as required and we may fix such an A.

Now suppose we are given a circuit with space S that computes the Boolean product between the rows of A and b in some order. We again proceed by "slicing" the circuit into $L = T/\alpha N$ slices, each containing $T/L = \alpha N$ queries. Each such slice has a number of output gates. Consider any slice. Suppose it contains output gates $i_1 < \cdots < i_k \leq N/2$; thus it is supposed to output $\vee_{\ell=1}^{N} (A[i_j, \ell] \wedge b_\ell)$ for all i_j with $1 \leq j \leq k$.

Such a slice starts on a classical value of the "memory" of the circuit, which is in general a probability distribution on S bits (if the circuit is randomized). We replace this probability distribution by the uniform distribution on the possible values of S bits. If the original circuit succeeds in computing the function correctly with probability at least $1/2$, then so does the circuit slice with its outputs, and replacing the initial value of the memory by a uniformly random value decreases the success probability to no less than $(1/2) \cdot 1/2^S$.

If we now show that any classical circuit with αN queries that produces the outputs $i_1, \ldots, i_k$ can succeed only with exponentially small probability in k, we get that $k = \mathrm{O}(S)$, and hence $(T/\alpha N) \cdot \mathrm{O}(S) \geq N$, which gives the claimed lower bound for the time-space tradeoff.

Each set of k outputs corresponds to k rows of A, which contain $N/(2k)$ 1's each. Thanks to the construction of A, there are $k/2$ rows among these, such that $N/(6k)$ of the 1's in each such row are in a position where none of the other contains a 1. So we get $k/2$ sets of $N/(6k)$ positions that are unique to each of the $k/2$ rows. The inputs for b will be restricted to contain 1's only at these positions, and so the algorithm naturally has to solve $k/2$ independent OR problems on $n = N/(6k)$ bits each. By Theorem 3, this is only possible with αN queries if the success probability is exponentially small in k. □

An absolutely analogous construction can be done in the quantum case. Using circuit slices of length $\alpha\sqrt{NS}$, we can prove the following theorem.

THEOREM 23. *There is an $N \times N$ matrix A such that every quantum bounded-error circuit that computes the Boolean matrix-vector product Ab with T queries and space $S = \mathrm{o}(N/\log N)$ satisfies $T^2 S = \Omega\big(N^3\big)$.*

Note that this is tight within a logarithmic factor (needed to improve the success probability of Grover's search).

THEOREM 24. *Every classical bounded-error circuit that computes the $N \times N$ Boolean matrix product AB with T queries and space S satisfies $TS = \Omega\big(N^3\big)$.*

While this is near-optimal for small S, it is probably not tight for large S, a likely tight tradeoff being $T^2 S = \Omega\big(N^6\big)$. It is also no improvement compared to Abrahamson's average-case bounds [Abr90].

Proof. Suppose that $S = o(N)$; otherwise the bound is trivial, since time N^2 is always needed. We can proceed in a manner similar to that of the proof of Theorem 22. We slice the circuit so that each slice has only αN queries. Suppose a slice makes k outputs. We are going to restrict the inputs to get a direct product problem with k instances of size N/k each; hence a slice with αN queries has exponentially small success probability in k and thus can produce only $\mathrm{O}(S)$ outputs. Since the overall number of outputs is N^2, we get the tradeoff $TS = \Omega\big(N^3\big)$.

Suppose a circuit slice makes k outputs, where an output labeled (i, j) needs to produce the vector product of the ith row $A[i]$ of A and the jth column $B[j]$ of B. We may partition the set $\{1, \ldots, N\}$ into k mutually disjoint subsets $U(i, j)$ of size N/k, each associated to an output (i, j).

Assume that there are ℓ outputs $(i, j_1), \ldots, (i, j_\ell)$ involving $A[i]$. Each such output is associated to a subset $U(i, j_t)$, and we set $A[i]$ to zero on all positions that are not in any of these subsets, and to 1 on all positions that are in one of these subsets. When there are ℓ outputs $(i_1, j), \ldots, (i_\ell, j)$ involving $B[j]$, we set $B[j]$ to zero on all positions that are not in any of the corresponding subsets, and allow the inputs to be arbitrary on the other positions.

If the circuit computes on these restricted inputs, it actually has to compute k instances of OR of size $n = N/k$ in B, for it is true that $A[i]$ and $B[j]$ contain a single block of size N/k in which $A[i]$ contains only 1's, and $B[j]$ "free" input bits, if and only if (i, j) is one of the k outputs. Hence the SDPT is applicable. □

The application to the quantum case is analogous.

THEOREM 25. *Every quantum bounded-error circuit that computes the $N \times N$ Boolean matrix product AB with T queries and space S satisfies $T^2S = \Omega\big(N^5\big)$.*

If $S = \mathrm{O}(\log N)$, then N^2 applications of Grover can compute AB with $T = \mathrm{O}\big(N^{2.5} \log N\big)$. Hence our tradeoff is near-optimal for small S. We do not know whether it is optimal for large S.

8. Quantum communication-space tradeoffs for matrix products. In this section we use the strong direct product result for quantum communication (Theorem 20) to prove communication-space tradeoffs. We later show that these are close to optimal.

THEOREM 26. *Every quantum bounded-error protocol in which Alice and Bob have bounded space S and that computes the N-dimensional Boolean matrix-vector product satisfies $C^2S = \Omega\big(N^3\big)$.*

Proof. In a protocol, Alice receives a matrix A, and Bob receives a vector b as inputs. Given a circuit that multiplies these with communication C and space S, we again proceed to slice it. This time, however, a slice contains a limited amount of communication. Recall that in communicating quantum circuits the communication corresponds to wires carrying qubits that cross between Alice's and Bob's circuits. Hence we may cut the circuit after $\alpha\sqrt{NS}$ qubits have been communicated and so on. Overall there are $C/\alpha\sqrt{NS}$ circuit slices. Each starts with an initial state that may be replaced by the completely mixed state at the cost of decreasing the success probability to $(1/2)\cdot 1/2^S$. We want to employ the direct product theorem for quantum communication complexity to show that a protocol with the given communication has success probability at most exponentially small in the number of outputs it produces and thus that a slice can produce at most $\mathrm{O}(S)$ outputs. Combining these bounds with the fact that N outputs have to be produced gives the tradeoff.

To use the direct product theorem we restrict the inputs in the following way: Suppose a protocol makes k outputs. We partition the vector b into k blocks of size

N/k, and each block is assigned to one of the k rows of A for which an output is made. This row is made to contain zeros outside of the positions belonging to its block, and hence we arrive at a problem where disjointness has to be computed on k instances of size N/k. With communication $\alpha\sqrt{kN}$, the success probability must be exponentially small in k due to Theorem 20. Hence $k = \mathrm{O}(S)$ is an upper bound on the number of outputs produced. □

THEOREM 27. *Every quantum bounded-error protocol in which Alice and Bob have bounded space S and that computes the N-dimensional Boolean matrix product satisfies $C^2S = \Omega(N^5)$.*

Proof. The proof uses the same slicing approach as in the other tradeoff results. Note that we can assume that $S = \mathrm{o}(N)$, since otherwise the bound is trivial. Each slice contains communication $\alpha\sqrt{NS}$, and as before a direct product result showing that k outputs can be computed only with success probability exponentially small in k leads to the conclusion that a slice can compute only $\mathrm{O}(S)$ outputs. Therefore $(C/\alpha\sqrt{NS}) \cdot \mathrm{O}(S) \geq N^2$, and we are done.

Consider a protocol with $\alpha\sqrt{NS}$ qubits of communication. We partition the universe $\{1, \ldots, N\}$ of the disjointness problems to be computed into k mutually disjoint subsets $U(i,j)$ of size N/k, each associated to an output (i,j), which in turn corresponds to a row/column pair $A[i]$, $B[j]$ in the input matrices A and B. Assume that there are ℓ outputs $(i,j_1), \ldots, (i,j_\ell)$ involving $A[i]$. Each output is associated to a subset of the universe $U(i,j_t)$, and we set $A[i]$ to zero on all positions that are not in one of these subsets. Then we proceed analogously with the columns of B.

If the protocol computes on these restricted inputs, it has to solve k instances of disjointness of size $n = N/k$ each, since $A[i]$ and $B[j]$ contain a single block of size N/k in which both are not set to 0 if and only if (i,j) is one of the k outputs. Hence Theorem 20 is applicable. □

We now want to show that these tradeoffs are not too far from optimal.

THEOREM 28. *There is a quantum bounded-error protocol with space S that computes the Boolean product between an $N \times N$ matrix and an N-dimensional vector within communication $C = \mathrm{O}((N^{3/2} \log^2 N)/\sqrt{S})$.*

There is a quantum bounded-error protocol with space S that computes the Boolean product between two $N \times N$ matrices within communication $C = \mathrm{O}((N^{5/2} \log^2 N)/\sqrt{S})$.

Proof. We begin by showing a protocol for the following scenario: Alice gets S N-bit vectors $x_1, \ldots, x_S$, Bob gets an N-bit vector y, and they want to compute the S Boolean inner products between these vectors. The protocol uses space $\mathrm{O}(S)$.

In the following, we interpret Boolean vectors as sets. The main idea is that Alice can use the union z of the x_i and then Alice and Bob can find an element in the intersection of z and y using the protocol for the disjointness problem described in [BCW98]. Alice then marks all x_i that contain this element and removes them from z.

A problem with this approach is that Alice cannot store z explicitly, since it might contain many more than S elements. Alice may, however, store in an array of length S the indices of those sets x_i for which an element in the intersection of x_i and y has already been found. This array and the input given as an oracle work as an implicit representation of z.

Now suppose at some point during the protocol that the intersection of z and y has size k. Then Alice and Bob can find one element in this intersection within $\mathrm{O}(\sqrt{N/k})$ rounds of communication, in each of which $\mathrm{O}(\log N)$ qubits are exchanged. Furthermore, in $\mathrm{O}(\sqrt{Nk})$ rounds all elements in the intersection can be found. So if

$k \leq S$, then all elements are found within communication $O(\sqrt{NS}\log N)$, and the problem can be solved completely. On the other hand, if $k \geq S$, finding one element costs $O(\sqrt{N/S}\log N)$, but finding such an element removes at least one x_i from z, and hence this has to be done at most S times, giving the same overall communication bound.

It is not hard to see that this process can be implemented with space $O(S)$. The protocol from [BCW98] is a distributed Grover's search that uses only space $O(\log N)$. Bob can work as in this protocol. For each search, Alice has to start with a superposition over all indices in z. This superposition can be computed from her oracle and her array. In each step she has to apply the Grover iteration. This can also be implemented from these two resources.

To get a protocol for the matrix-vector product, the above procedure is repeated N/S times; hence the communication is $O((N/S)\cdot\sqrt{NS}\log^2 N)$, where one logarithmic factor stems from improving success probability to $1/\mathrm{poly}(N)$.

For the product of two matrices, the matrix-vector protocol may be repeated N times. □

These near-optimal protocols use only $O(\log N)$ qubits, and apart from that S bits of classical memory.

9. Open problems. We mention some open problems. The first is to determine tight time-space tradeoffs for the Boolean matrix product on both classical and quantum computers. Second, regarding communication-space tradeoffs for the Boolean matrix-vector and matrix product, we did not prove any classical bounds that were better than our quantum bounds. Klauck [Kla04] recently proved classical tradeoffs $CS^2 = \Omega(N^3)$ and $CS^2 = \Omega(N^2)$ for the Boolean matrix product and matrix-vector product, respectively, by means of a *weak* direct product theorem for disjointness. A classical *strong* direct product theorem for disjointness (with communication bound αkn instead of our current $\alpha k\sqrt{n}$) would imply optimal tradeoffs, but we do not know how to prove this at the moment. Third, we would like to know whether an SDPT holds in the query and communication setting for all Boolean functions if we consider worst-case error probability (Shaltiel [Sha01] disproved this for *average-case* error probability). Finally, it would be interesting to get any lower bounds on time-space or communication-space tradeoffs for decision problems in the quantum case, for example, for element distinctness [BDH+01, Amb04] or the verification of matrix multiplication [BŠ06].

Acknowledgments. Many thanks to Scott Aaronson for email discussions about the evolving results in his work [Aar04] that motivated some of our proofs, Harry Buhrman for useful discussions, Paul Beame for communication about [BPSW05], and the anonymous referees for comments that improved the presentation of the paper.

INTEGRALITY RATIO FOR GROUP STEINER TREES AND DIRECTED STEINER TREES*

ERAN HALPERIN†, GUY KORTSARZ‡, ROBERT KRAUTHGAMER§, ARAVIND SRINIVASAN¶, AND NAN WANG‖

Abstract. The natural relaxation for the group Steiner tree problem, as well as for its generalization, the directed Steiner tree problem, is a flow-based linear programming relaxation. We prove new lower bounds on the integrality ratio of this relaxation. For the group Steiner tree problem, we show that the integrality ratio is $\Omega(\log^2 k)$, where k denotes the number of groups; this holds even for input graphs that are *hierarchically well-separated trees*, introduced by Bartal [in *Proceedings of the 37th Annual IEEE Symposium on Foundations of Computer Science*, 1996, pp. 184–193], in which case this lower bound is tight. This also applies for the directed Steiner tree problem. In terms of the number n of vertices, our results for the directed Steiner problem imply an $\Omega(\frac{\log^2 n}{(\log\log n)^2})$ integrality ratio. For both problems, these are the first lower bounds on the integrality ratio that are superlogarithmic in the input size. This exhibits, for the first time, a relaxation of a natural optimization problem whose integrality ratio is known to be superlogarithmic but subpolynomial. Our results and techniques have been used by Halperin and Krauthgamer [in *Proceedings of the 35th Annual ACM Symposium on Theory of Computing*, 2003, pp. 585–594] to show comparable inapproximability results, assuming that NP has no quasi-polynomial Las Vegas algorithms. We also show algorithmically that the integrality ratio for the group Steiner tree problem is much better for certain families of instances, which helps pinpoint the types of instances (parametrized by optimal solutions to their flow-based relaxations) that appear to be most difficult to approximate.

1. Introduction.

GROUP-STEINER-TREE is a network design problem that generalizes both SET-COVER and STEINER-TREE. DIRECTED-STEINER-TREE is a further generalization of GROUP-STEINER-TREE. The natural relaxation for these two problems is a flow-based linear programming (LP) relaxation. We show a polylogarithmic (about log squared) lower bound on the integrality ratio of this relaxation.

For both problems, these are the first such lower bounds that are superlogarithmic in the input size, and our bounds are, in fact, nearly tight in the important special case of input graphs which are tree networks. Let n be the number of vertices and k the number of groups. Our probabilistic approach and our analysis have been used in [HK03] to show that for every fixed $\epsilon > 0$, Group-Steiner-Tree and Directed-Steiner-Tree admit no efficient $\Omega(\log^{2-\epsilon} k)$ and $\Omega(\log^{2-\epsilon} n)$ approximations, respectively, unless NP has quasi-polynomial time Las Vegas algorithms. We also present improved approximation algorithms for certain families of instances of Group-Steiner-Tree, shedding light on the type of instances that appear to be most difficult for the flow-based relaxation.

1.1. The group Steiner tree problem. The (undirected) group Steiner tree problem is as follows. Given an undirected graph $G = (V, E)$, a collection of subsets (called groups) $g_1, g_2, \ldots, g_k$ of V, and a weight $w_e \geq 0$ for each edge $e \in E$, the problem is to construct a minimum-weight tree in G that spans at least one vertex from each group. We can assume without loss of generality that there is a distinguished vertex $r \in V$ (called the root) that must be included in the output tree. The case where $|g_i| = 1$ for all i is just the classical Steiner tree problem; the case where G is a star can be used to model Set-Cover (cf. [GKR00]).

A natural flow-based relaxation for this problem is as follows. Find a *capacity* $x_e \in [0, 1]$ for each edge $e \in E$ so that the capacities can support one unit of flow from r to g_i, separately for each g_i (as opposed to supporting a unit flow simultaneously for all g_i). Subject to this constraint, we want to minimize $\sum_e w_e x_e$. It is easy to check that the feasible solutions which satisfy $x_e \in \{0, 1\}$ for all e exactly correspond to feasible solutions for the group Steiner tree problem; hence, the above flow-based relaxation is indeed a valid LP relaxation for the problem. This is a natural relaxation for this problem (and for some of its generalizations) and is the main subject of investigation in this paper.

We start with a useful definition from [Bar96].

Definition 1.1. *Let $c > 1$. A c-hierarchically well-separated tree (c-HST) is a rooted weighted tree such that* (i) *all leaves are at the same distance from the root,* (ii) *the edges in the same level are equal-weighted, and* (iii) *the weight of an edge is exactly $1/c$ times the weight of its parent edge.*

(Remark. Item (ii) *is slightly stronger than the original definition from* [Bar96]*, but can be assumed without loss of generality due to the analyses of* [Bar96, Bar98, KRS01]*.)*

We simply say "HST" when referring to a c-HST for an arbitrary constant $c > 1$.

The first polylogarithmic approximation algorithm for Group-Steiner-Tree was achieved in the elegant work of Garg, Konjevod, and Ravi [GKR00]. A brief sketch of their $O(\log n \log\log n \log N \log k)$-approximation algorithm, where $n = |V|$ and $N = \max_i |g_i|$, is as follows. First, the powerful results of [Bar98] are used to reduce the problem to the case where G is a *tree* T, with an $O(\log n \log\log n)$ factor loss in the approximation ratio. Furthermore, T can be assumed to be a c-HST for any desired constant $c > 1$. Next, solve the flow-based LP relaxation on T and round the fractional solution into an integral solution for T by applying a novel randomized rounding approach that is developed in [GKR00]. It is established in [GKR00] that for any tree T, this randomized rounding leads to an $O(\log N \log k)$-approximation. Thus, for the input graph G, we get an $O(\log n \log\log n \log N \log k)$-approximation. From a technical viewpoint, one of the main difficulties in [GKR00] is that a nontrivial analysis of the randomized process is required. The analysis uses Janson's inequality

[Jan90] in an interesting way. The work of [GKR00] has been extended and expanded in several ways: Their algorithm was derandomized in [CCGG98, Sri01]; an alternative (combinatorial) algorithm is devised in [CEK06]; and the loss incurred by the reduction to an HST is improved to $O(\log n)$ in [FRT04].

Since the first appearance of a polylogarithmic approximation for Group-Steiner-Tree (in the conference version of [GKR00] in 1998), there has been much interest in whether the approximation ratio can be improved. One concrete notable question in this regard has been the following: Can we achieve an approximation ratio better than $O(\log N \log k)$ for trees? This is interesting for at least two reasons. First, since [GKR00] shows a reduction to the case of trees as seen above, an improved approximation for trees (or even for the case of c-HSTs for some constant $c > 1$) would lead directly to an improved approximation for general graphs. Further, even the case where G is a star (which is a tree) captures Set-Cover, for which $o(\log k)$-approximation is hard [LY94, Fei98, RS97]; thus there is an intriguing gap even on trees.

Our main technical result is that the integrality ratio of the flow-based relaxation for HSTs is $\Omega(\log^2 k)$. This bound is, in fact, tight—an $O(\log^2 k)$ bound on the integrality ratio holds for HSTs, as we show in section 2.7. Both bounds hold for c-HSTs where $c > 1$ is any fixed constant. Recall that the upper bound of [GKR00] for trees in general is $O(\log N \log k)$; our methods show an $\Omega(\log N \log k / \log\log N)$ lower bound on the integrality ratio, even for a class of HSTs. The same lower bounds also hold for trees where all weights are the same (i.e., unit-weight trees). Finally, we show randomized rounding algorithms for the flow-based relaxation that lead to improved approximation algorithms for certain special families of HSTs; this sheds light on the type of instances that are most difficult to approximate.

A log-squared lower bound on the integrality ratio for trees was conjectured circa 1998 by Uri Feige. The specific (randomly constructed) instance he suggested for this purpose (see section 2 for more details) has proved to be quite difficult to analyze. Our lower bound is shown via a slightly different random instance, which eliminates one source of correlation in the random choices, and makes the construction more amenable to analysis. Nevertheless, we are required to do intricate estimates that delve into low-order terms, in particular when crafting the precise induction hypothesis lying at the heart of the proof.

1.2. The directed Steiner tree problem. This is the directed version of the (undirected) Steiner tree problem. Given an edge-weighted directed graph $G = (V, E)$ that specifies a *root* vertex r and k *terminal* nodes $v_1, v_2, \ldots, v_k$, the goal is to construct a minimum-weight outbranching rooted at r, which spans all the terminals. This problem is easily seen to generalize the undirected Group-Steiner-Tree, as well as to be equivalent to the directed Group-Steiner-Tree. Aside from intrinsic interest, this problem is also of current interest, e.g., in the context of multicasting in the Internet (where internode distances are often not symmetric). The polynomial time approximation ratio currently known for this problem is k^ϵ for any constant $\epsilon > 0$ [CCC+99]; their algorithm extends to a polylogarithmic approximation ratio in quasi-polynomial running time. The flow-based relaxation here is similar: Install for every edge $e \in E$ a capacity $x_e \in [0, 1]$, so that a unit of flow can be shipped from r to v_i, separately for any given i. Intriguingly, it was recently shown in [ZK02] that this relaxation has an integrality ratio of $\Omega(\sqrt{k})$, precluding a polylog(k)-approximation algorithm based on this relaxation. However, the examples constructed in [ZK02] have $k = \Theta(\frac{\log^2 n}{(\log\log n)^2})$; hence, the result of [ZK02] does not exclude an $O(\log n)$

integrality ratio. Our GROUP-STEINER-TREE lower-bound result above also proves an $\Omega(\frac{\log^2 n}{(\log\log n)^2})$ lower bound on the integrality gap for DIRECTED-STEINER-TREE. The only lower bound known previously for DIRECTED-STEINER-TREE was $\Omega(\log n)$, since this problem generalizes SET-COVER.

As mentioned above, our results have paved the way to the improved hardness of approximation results of [HK03], which show that, for any fixed $\epsilon > 0$, GROUP-STEINER-TREE cannot be approximated within ratio $\log^{2-\epsilon} k$, and DIRECTED-STEINER-TREE cannot be approximated within ratio $\log^{2-\epsilon} n$, unless NP has quasi-polynomial time Las Vegas algorithms. The influence of our work on these hardness results is threefold. First, our lower bounds on the integrality ratio have motivated working on a hardness of approximation result. Second, the insights our analysis provides regarding the (edge-weight) structure of instances that are difficult to approximate inspired specific details of the hardness reduction. Third, our main technical lemma (whose proof is rather nontrivial) is, in fact, crucial to [HK03].

Organization. Our lower bounds on the integrality ratio of GROUP-STEINER-TREE and DIRECTED-STEINER-TREE are shown in section 2. We then prove algorithmically that the integrality ratio of the former problem is much better for certain families of instances in section 3; this pinpoints the type of instances that appear difficult for this relaxation. Finally, concluding remarks are made in section 4.

2. Lower bounds on the integrality ratio. In this section we prove a lower bound of $\Omega(\log^2 k)$ on the integrality ratio of the flow-based relaxation of GROUP-STEINER-TREE even on HSTs. In terms of n, the gap is $\Omega(\frac{\log^2 n}{(\log\log n)^2})$. We start (section 2.1) by describing the LP relaxation and constructing a family of 2-HST instances, accompanied by an overview of the analysis; then, the main technical parts (sections 2.2 and 2.3) analyze the fractional and the integral solutions of this linear program. We also show how simple modifications to this construction extend the integrality ratio to unit-weight trees (section 2.4) and to c-HSTs for an arbitrary constant $c > 1$ (section 2.5). We further point out how this immediately leads to a lower bound of $\Omega(\frac{\log^2 n}{(\log\log n)^2})$ on the integrality ratio for DIRECTED-STEINER-TREE (section 2.6). Finally, the lower bound of $\Omega(\log^2 k)$ is shown to be tight (in section 2.7).

2.1. The relaxation and the instance. The cut-based relaxation (that is equivalent to the flow-based relaxation) for GROUP-STEINER-TREE is as follows (here, $\delta(S)$ is the set of edges with exactly one endpoint in $S \subset V$):

(1)

$$\begin{aligned} \text{Minimize} \quad & \sum_{e\in E} w_e x_e, \\ & \sum_{e\in\delta(S)} x_e \geq 1 \quad \forall S \subseteq V \text{ s.t. } r \in S \text{ and } S \cap g_j = \emptyset \text{ for some group } g_j, \\ & 0 \leq x_e \leq 1 \quad \forall e \in E. \end{aligned}$$

Let $\mathbb{T}_n$ be a 2-HST tree with n nodes defined by the following random process. Let the collection of groups be $\mathcal{G} = \{g_1, g_2, \ldots, g_k\}$. The groups are defined by a random process. The value of k, as well as those of two other parameters H and d, will be defined shortly (in terms of n). The height (i.e., depth) of $\mathbb{T}_n$ is H, and every nonleaf vertex has d children. The root of $\mathbb{T}_n$ is denoted r. The *level* of a vertex is its depth; r is at level 0, and there are $H + 1$ levels. An edge is said to be at level

i if and only if it connects a vertex at level $i-1$ to a vertex at level i. Each edge at level i has weight $1/2^i$; thus, for instance, edges incident at r have weight $1/2$. Each group g_j is a subset of the leaves, described as follows. We shall associate a subset $A(\ell) \subseteq \mathcal{G}$ of the groups with each leaf ℓ and define each group g_j to be the set of leaves ℓ for which $g_j \in A(\ell)$. Thus, a solution that reaches a leaf ℓ by a path from r covers all groups in $A(\ell)$. To define $A(\ell)$ for each leaf ℓ, we now recursively and randomly define a set $A(v)$ for every node v in the tree (including nonleaf nodes) as follows. Proceed *independently* for each group g_j as follows. We start by letting $g_j \in A(r)$ with probability 1. In general, if $g_j \in A(u)$ for some nonleaf node u, then for each child v of u, we independently put g_j in $A(v)$ with probability $1/2$. Thus, this random process goes top-down in the tree, independently for each group. Note that the number of vertices in $\mathbb{T}_n$ is $n \simeq d^H$, where H is the height of the tree. Clearly, the expected size of every group is $d^H/2^H$.

Parameters and notation. We set $d = c_0 \log n$ for some universal constant $c_0 > 0$; this will be used in some Chernoff bound arguments in section 2.2. It then follows that $H = \frac{\log n}{\log d} = \Theta(\log n / \log\log n)$. We further set $k = 2^{2H}$; thus, $\log k = \Theta(\log n / \log\log n)$. Throughout, *with high probability* means with probability that is at least, say, $1 - 1/n$. All probabilities refer to the randomness in constructing the instance $\mathbb{T}_n$.

Feige's instance. The construction suggested by Feige circa 1998 is the following: Take a complete tree of arity 4 (i.e., every nonleaf vertex has four children) and height $\log_2 k$; now generate k groups, each containing k leaves, by an independent randomized branching process that starts from the root and randomly picks two out of four children until the leaves are reached. This random instance differs from $\mathbb{T}_n$ in its degree, which is constant rather than logarithmic, and in that the choices made (when generating a single group) at each child of a vertex are correlated (rather than independent).

Overview of the analysis. We first show (section 2.2) that with high probability the instance $\mathbb{T}_n$ has a feasible fractional solution of cost $O(H)$. In this solution, all edges e in the same level of the tree are assigned the same value x_e, and this value is chosen so that the total cost of every level in the tree is the same, namely, $O(1)$. The feasibility of this solution is shown by employing a sequence of Chernoff bound arguments, and this is the reason why the degree d of the tree must be (at least) logarithmic. This is in contrast to Feige's instance, where the feasibility (of a similar fractional solution) is guaranteed by construction, i.e., with probability 1, and thus the tree can have a constant degree.

We then show (section 2.3) that with high probability the cost of any integral solution for $\mathbb{T}_n$ is lower bounded by $\Omega(H^2 \log k)$. At a high level, we imitate the argument known for Set-Cover; we show that for any single low-cost integral solution (i.e., subtree of $\mathbb{T}_n$), with high probability over the randomness in constructing the groups, this solution is infeasible (i.e., does not cover all the groups), and then we take a union bound over all possible integral solutions. In fact, any single vertex of $\mathbb{T}_n$ together with its children is essentially a "standard" Set-Cover instance with integrality ratio $\Omega(\log k)$.

The main technical work is to estimate the probability that an arbitrary (but fixed in advance) integral solution is feasible. Unlike in the Set-Cover scenario, where this is a straightforward calculation, in the Group-Steiner-Tree instance $\mathbb{T}_n$ the solution's structure comes into play. For instance, the integral solution might not be a regular subtree of $\mathbb{T}_n$, and its cost need not be split evenly among the different levels (of $\mathbb{T}_n$). We prove some upper bound on the probability that this solution for $\mathbb{T}_n$ is

feasible. Our analysis shows that to maximize this upper bound on the probability, it is essentially best to have an even "split" of the cost used under a vertex v (i.e., the edges of the solution that belong to the subtree rooted at v). While we do not claim that this is the worst case for the *exact* probability of feasibility, our upper bound gives a good enough estimate. However, the analysis does not specify how many children of v should have a nonzero cost under them; in fact, this value is very sensitive to lower-order tradeoffs between different levels in the tree.

The main difficulty in the analysis is to distill the effect of H, the height of the tree, on the feasibility probability. Our proof is by induction on the height of the tree and uncovers a very delicate tradeoff between the height of a subtree and its cost. This tradeoff eventually translates to the cost of the integral solution for $\mathbb{T}_n$ having, on top of the $\log k$ term which comes from Set-Cover (i.e., a single level), also a linear dependence on the height H. Due to seemingly technical limitations this proof works only for $H \leq \frac{1}{2}\log k$, but we show in section 2.7 that this is unavoidable. Interestingly, there is an analogy with the approximation algorithm of [GKR00], whose rounding procedure pays, at some intermediate stage, an $O(H \log k)$ factor, and then shows that, in effect, H can be upper bounded by $O(\log N)$.

2.2. The fractional solution. Recall that $d = c_0 \log n$. We start with a couple of propositions which show that if the constant c_0 is sufficiently large, then certain quantities related to our randomly chosen groups stay close to their mean. Henceforth, the phrase "with high probability" will mean "with a probability of $1 - o(1)$."

Proposition 2.1. *Let c_0 be a sufficiently large constant. Then, with high probability, all groups have size at least $(d/2)^H/3$.*

Proof. Fix j. We now show that if c_0 is large enough, then $\Pr\left[|g_j| < (d/2)^H/3\right] \leq 1/n^2$. We may then apply the union bound over all j to conclude the proof.

Let $\delta = 1/4$. Let X_1 be the number of vertices u at level 1 (i.e., children of r) such that $g_j \in A(u)$. Then X_1 has binomial distribution $X_1 \sim B(d, 1/2)$, so by a Chernoff bound on the lower-tail (see, e.g., [MR95]),

$$\Pr\left[X_1 \leq (1-\delta)\frac{d}{2}\right] \leq e^{-\frac{1}{2}\delta^2 \cdot \frac{d}{2}}.$$

Let X_2 be the number of vertices u at level 2 such that $g_j \in A(u)$. Then X_2 has binomial distribution $X_2 \sim B(X_1 \cdot d, 1/2)$. Suppose that $X_1 > (1-\delta)\mathbb{E}[X_1] = (1-\delta)\frac{d}{2}$. Then, it is immediate that $X_2 \mid (X_1 > (1-\delta)\frac{d}{2})$ stochastically dominates a random variable $X_2' \sim B((1-\delta)\frac{d}{2} \cdot d, 1/2)$, i.e., $\Pr[X_2 \leq t] \leq \Pr[X_2' \leq t]$ for all t. By applying the Chernoff bound on X_2' we get

$$\Pr\left[X_2' \leq \left(1 - \frac{\delta}{2}\right)(1-\delta)\left(\frac{d}{2}\right)^2\right] \leq e^{-\frac{1}{2}(\frac{\delta}{2})^2 \cdot (1-\delta)(\frac{d}{2})^2}.$$

Continue similarly for $i = 3, \ldots, H$ by defining X_i to be the number of vertices u at level i such that $g_j \in A(u)$, and by assuming that $X_{i-1} > (1 - \frac{\delta}{2^{i-2}}) \cdot \ldots \cdot (1 - \frac{\delta}{2})(1-\delta)(\frac{d}{2})^i$. We get by the Chernoff bound that

(2)
$$\Pr\left[X_i' \leq \left(1 - \frac{\delta}{2^{i-1}}\right) \cdot \ldots \cdot \left(1 - \frac{\delta}{2}\right)(1-\delta)\left(\frac{d}{2}\right)^i\right] \leq e^{-\frac{1}{2}(\frac{\delta}{2^{i-1}})^2 \cdot (1 - \frac{\delta}{2^{i-2}}) \cdot \ldots \cdot (1-\frac{\delta}{2})(1-\delta)(\frac{d}{2})^i}.$$

For any $0 < \delta' \le \frac{1}{2}$ we have $1-\delta' \ge \frac{1}{1+2\delta'} \ge e^{-2\delta'}$. Thus, $(1-\frac{\delta}{2^{i-1}})\cdot\ldots\cdot(1-\frac{\delta}{2})(1-\delta) \ge e^{-\frac{\delta}{2^{i-2}}-\ldots-\delta-2\delta} \ge e^{-4\delta} > \frac{1}{3}$. It follows that the tail bound obtained in the right-hand side of (2) is at most $e^{-\Omega((d/8)^i)}$. Applying the union bound on these H events, we get that with high probability none of them happens (if the constant c_0 is sufficiently large), and in particular, $X_H \ge (1-\frac{\delta}{2^{H-1}})\cdot\ldots\cdot(1-\frac{\delta}{2})(1-\delta)(\frac{d}{2})^H \ge \frac{1}{3}(\frac{d}{2})^H$. This concludes the proof of Proposition 2.1. □

The following proposition has a similar proof; the main difference is that we will now employ Chernoff bounds on the upper-tail.

PROPOSITION 2.2. *Suppose that the constant c_0 is large enough. Then with high probability, the following holds for every level i and every group g_j: If a vertex u at level i is such that $g_j \in A(u)$, then the number of leaves ℓ in the subtree rooted at u which satisfy $g_j \in A(\ell)$ is at most $3(d/2)^{H-i}$.*

Proof. Fix a pair (i,j) and a vertex u at level i such that $g_j \in A(u)$. Let $L(u)$ be the set of leaves of the subtree rooted at u. We now show that if c_0 is large enough, then $\Pr\left[|g_j \bigcap L(u)| > 3(d/2)^{H-i}\right] \le 1/n^3$. We then apply a union bound over all (i,j,u) to conclude the proof.

Let $\delta = 1/4 < \frac{\ln 3}{2}$. Let X_1 be the number of vertices v at level 1 of the subtree rooted at u (i.e., children of u) such that $g_j \in A(v)$. Then X_1 has binomial distribution $X_1 \sim B(d, 1/2)$, so by a Chernoff bound on the upper-tail (see, e.g., [MR95]),

$$\Pr\left[X_1 \ge (1+\delta)\frac{d}{2}\right] \le e^{-\frac{\delta^2}{3}\cdot\frac{d}{2}}.$$

Let X_2 be the number of vertices v at level 2 of the subtree rooted at u such that $g_j \in A(v)$. Then X_2 has binomial distribution $X_2 \sim B(X_1 \cdot d, 1/2)$. Suppose that $X_1 < (1+\delta)\mathbb{E}[X_1] = (1+\delta)\frac{d}{2}$. Then, it is immediate that $X_2 \mid (X_1 < (1+\delta)\frac{d}{2})$ is stochastically dominated by a random variable $X_2' \sim B((1+\delta)\frac{d}{2}\cdot d, 1/2)$; i.e., $\Pr[X_2 \ge t] \le \Pr[X_2' \ge t]$ for all t. By applying the Chernoff bound on X_2' we get

$$\Pr\left[X_2' \ge \left(1+\frac{\delta}{2}\right)(1+\delta)\left(\frac{d}{2}\right)^2\right] \le e^{-\frac{1}{3}(\frac{\delta}{2})^2\cdot(1+\delta)(\frac{d}{2})^2}.$$

Continue similarly for $l = 3,\ldots,H-i$ by defining X_l to be the number of vertices v at level l of the subtree rooted at u such that $g_j \in A(v)$, and by assuming that $X_l < (1+\frac{\delta}{2^{l-1}})\cdot\ldots\cdot(1+\frac{\delta}{2})(1+\delta)(\frac{d}{2})^l$. We get by the Chernoff bound that

(3)
$$\Pr\left[X_l' \ge \left(1+\frac{\delta}{2^{l-1}}\right)\cdot\ldots\cdot\left(1+\frac{\delta}{2}\right)(1+\delta)\left(\frac{d}{2}\right)^l\right] \le e^{-\frac{1}{3}(\frac{\delta}{2^{l-1}})^2\cdot(1+\frac{\delta}{2^{l-2}})\cdot\ldots\cdot(1+\frac{\delta}{2})(1+\delta)(\frac{d}{2})^l}.$$

The tail bound obtained in the right-hand side of (3) is clearly at most $e^{-\Omega((d/8)^l)}$. Applying the union bound on these $H-i \le H$ events, we get that with probability at least $1-1/n^3$ none of these events happens if the constant c_0 is sufficiently large; in particular, $X_{H-i} \le (1+\frac{\delta}{2^{H-i-1}})\cdot\ldots\cdot(1+\frac{\delta}{2})(1+\delta)(\frac{d}{2})^{H-i} \le 3(\frac{d}{2})^{H-i}$. (This is because of the following. For any δ' we have $1+\delta' \le e^{\delta'}$. Thus, $(1+\frac{\delta}{2^{l-1}})\cdot\ldots\cdot(1+\frac{\delta}{2})(1+\delta) \le e^{\frac{\delta}{2^{l-1}}+\ldots+\frac{\delta}{2}+\delta} \le e^{2\delta} < 3$.) This concludes the proof of Proposition 2.2. □

We now upper bound the value of LP (1) for the tree $\mathbb{T}_n$ by exhibiting a feasible solution for it: Let each edge e at each level i have value $\hat{x}_e = 9\cdot(2/d)^i$.

LEMMA 2.3. *With high probability, $\hat{x}$ is a feasible solution to LP* (1). *Its value is* $9H$.

Proof. Observe that $\hat{x}$ satisfies the constraints of LP (1) if (see also [GKR00]), for every group g_j, every cut $(S, \bar{S})$ separating r from all the vertices of g_j has capacity at least 1, where the capacity of each edge e is $\hat{x}_e$. By the (single-source) max-flow min-cut theorem (or, say, weak duality) it suffices to show that for every group g_j, a unit of flow can be shipped from the root r to the vertices of g_j while obeying the "capacity" $\hat{x}_e$ of each edge e. To this end, fix a group g_j and define the flow f as follows. For every vertex v in g_j (i.e., for every leaf v such that $g_j \in A(v)$), ship $3 \cdot (2/d)^H$ units of flow along the unique simple path from r to v. By Proposition 2.1, the total flow shipped to g_j is at least $|g_j| \cdot 3 \cdot (2/d)^H \geq 1$ with high probability. Next, consider an edge connecting a node u at some level i to its parent. If $g_j \notin A(u)$, no flow is shipped through this edge; if $g_j \in A(u)$, the total flow shipped through this edge (i.e., through u) is, by Proposition 2.2, at most $3(d/2)^{H-i} \cdot 3(2/d)^H = 9(2/d)^i$ with high probability. In both cases, the flow along the edge obeys the edge's capacity. We conclude that with high probability $\hat{x}$ is a feasible solution to LP (1).

The value of the solution $\hat{x}$ is $\sum_{i=1}^{H} d^i \cdot 1/2^i \cdot 9(2/d)^i = 9H$ since each level i contains d^i edges of weight $1/2^i$. □

2.3. The integral solution. We now show that with probability $1 - o(1)$ (over the random choice of the groups), all integral solutions have value $\Omega(H^2 \log k)$. Whenever we say that some T' is a subtree of $\mathbb{T}_n$, we allow T' to be an arbitrary connected subgraph of $\mathbb{T}_n$. Since $\mathbb{T}_n$ is rooted, any subtree T' of $\mathbb{T}_n$ is also thought of as rooted in the obvious way: the node in T' of the smallest depth is the root of T' (and is denoted $\text{root}(T')$). Also, when we say that some T' is a subtree of $\mathbb{T}_n$ with root u, we allow T' to be an arbitrary connected subgraph of $\mathbb{T}_n$ with root u.

Let $M(c)$ be the number of subtrees of $\mathbb{T}_n$ which are rooted at r and have total weight at most c. Fix $g_j \in \mathcal{G}$. For any given subtree T' of $\mathbb{T}_n$, let $p_j(T')$ be the probability that no leaf of T' belongs to the group g_j, conditioned on the event that $g_j \in A(\text{root}(T'))$. Since by symmetry $p_j(T') = p_i(T')$ for all i, j, we will simply denote it by $p(T')$. We now define a key value $f(H, i, c)$ as follows. Choose an arbitrary vertex u at level i. Then $f(H, i, c)$ is the minimum value of $p(T')$, taken over all possible subtrees T' that are rooted at u and have total weight at most c. (If there is no such T', then $f(H, i, c) = 1$. Also, it is easy to see by symmetry that $f(H, i, c)$ does not depend upon the choice of j or u.) Let P_c be the probability that there exists an integral solution of weight c. We wish to show that $P_c = o(1)$ for c that is smaller than a certain threshold of the order $H^2 \log k$. Using the independence between the different groups and applying a union bound over all possible subtrees rooted at r that have total weight c, we obtain

$$P_c \leq M(c)(1 - f(H, 0, c))^k. \tag{4}$$

We now have to lower bound f and upper bound M. We employ the following crude bound on $M(c)$. Note that it suffices to count only subtrees of $\mathbb{T}_n$ that span distinct sets of leaves (since the groups g_i contain only leaves). Observing that $\mathbb{T}_n$ has d^H leaves, and a subtree of total weight at most c spans at most $c2^H$ leaves (since each spanned leaf requires a distinct edge at level H), we get that

$$M(c) \leq \binom{d^H}{c2^H} \leq d^{cH2^H}. \tag{5}$$

Our goal in the next subsection is to prove the following key lemma.

LEMMA 2.4. *For $H \le \frac{1}{2}\log k$ and a constant $\gamma > 0$ that is sufficiently large, we have $f(H,0,c) \ge e^{-\gamma c/H^2}$. Thus $P_c \le M(c)(1-f(H,0,c))^k \le M(c)\cdot\exp\{-k\cdot e^{-\gamma c/H^2}\}$.*

2.3.1. Bounding $f(H,0,c)$. We start with some preliminaries. The main technical result is Lemma 2.7. It gives a more general bound for f than that stated in Lemma 2.4, and hence the proof of Lemma 2.4 would follow quite easily.

PROPOSITION 2.5. *Let $l \ge 2$ and $\beta > 0$. The minimum of $\sum_{S\subseteq\{1,\ldots,l\}}\prod_{i\in S} e^{-\beta x_i}$ over all $(x_1,\ldots,x_l)$ with a given $\sum_{i=1}^{l} x_i$ is then attained when all x_i are equal.*

Proof. The minimum is clearly attained at some point $(x_1,\ldots,x_l)$, so assume to the contrary that at this point not all x_i are equal, say without loss of generality that $x_1 > \sum_i x_i/l > x_2$. We will show that changing both x_1 and x_2 to $\frac{x_1+x_2}{2}$ decreases the above sum while maintaining $\sum_i x_i$, which contradicts the assumption that $(x_1,\ldots,x_l)$ is a minimum point. Actually, it suffices to prove that

$$\sum_{S'\subseteq\{1,2\}}\prod_{i\in S'} e^{-\beta x_i} > \sum_{S'\subseteq\{1,2\}}\prod_{i\in S'} e^{-\beta\cdot\frac{x_1+x_2}{2}}\ , \tag{6}$$

since multiplying (6) by $\prod_{i\in S''} e^{-\beta x_i}$ and summing over all $S'' \subseteq \{3,\ldots,l\}$ shows that changing x_1, x_2 indeed decreases the abovementioned sum. To prove (6), observe that it simplifies to

$$e^{-\beta x_1} + e^{-\beta x_2} > 2e^{-\beta(x_1+x_2)/2},$$

which follows from the arithmetic mean-geometric mean inequality since $x_1 \ne x_2$. This completes the proof of Proposition 2.5. □

It is easy to check (by considering higher derivatives) that for all $B \ge 0$,

$$e^{-B} \ge 1 - B + \frac{B^2}{2} - \frac{B^3}{6}. \tag{7}$$

PROPOSITION 2.6. *For all $B_0 > 0$ there exists $\delta > 0$ such that for all $B \ge B_0$ we have $\frac{1+e^{-B}}{2} \ge e^{-\frac{B}{2+\delta}}$.*

Proof. Fix $B_0 > 0$. We first make sure that the inequality holds at B_0. By the arithmetic mean-geometric mean inequality $\frac{1+e^{-B_0}}{2} > e^{-B_0/2}$ (since $B_0 > 0$), so a sufficiently small $\delta > 0$ satisfies $\frac{1+e^{-B_0}}{2} > e^{-B_0/(2+\delta)}$. It now suffices to make sure that for all $B \ge B_0$ the derivative of the left-hand side is at least that of the right-hand side, i.e., that $-\frac{1}{2}e^{-B} \ge -\frac{1}{2+\delta}e^{-B/(2+\delta)}$. This holds for any $0 < \delta < B_0$ since $\frac{2+\delta}{2} = 1 + \delta/2 \le 1 + B_0/2 \le e^{B_0/2} \le e^{B/2} \le e^{B-B/(2+\delta)}$, completing the proof of Proposition 2.6. □

LEMMA 2.7. *Let γ be a sufficiently large constant. Then $f(H,h,c) \ge \exp(-\frac{\gamma c 2^h}{(H-h)^2})$ for all $c > 0$ and all $0 \le h \le H-1$.*

Proof. Fix B_0 to be an arbitrary positive constant, and let $\delta > 0$ be the corresponding constant from Proposition 2.6.

The proof is by backward induction on h; i.e., we assume that the claim holds for $h+1$ and prove it for h, where $h \le H-2$. We will consider the base case, which is the case that $h \ge H-1-\frac{6}{\delta}$, later on. In order to bound f, we derive a recurrence relation for $f(H,h,c)$. Recall the definition of $f(H,h,c)$: fix an arbitrary vertex u at level h, and take the minimum value of $p(T')$ over all possible subtrees T' rooted at u such that

the total weight of T' is at most c. We bound $f(H,h,c)$ by considering all possibilities of u having $l = 1, 2, \ldots, d$ children and all possible partitions $\vec{x}^{(l)} = (x_1, x_2, \ldots, x_l)$ of the weight c to (the subtrees under) these l children; since the edge from u to each of its children has weight $\frac{1}{2^{h+1}}$, we get that $\sum_{i=1}^{l} x_i = c - \frac{l}{2^{h+1}}$. We then get that

$$f(H,h,c) \geq \min_{1\leq l\leq d} \left\{ \min_{\vec{x}^{(l)}: x_i \geq 0, \sum_i x_i = c - \frac{l}{2^{h+1}}} \left\{ \frac{1}{2^l} \sum_{S\subseteq\{1,\ldots,l\}} \prod_{i\in S} f(H,h+1,x_i) \right\} \right\};$$

since once the l children of u are chosen, we need only consider the subset S of all children with g_j in their $A(\cdot)$ set. (Each such set S occurs with probability $1/2^l$.) Plugging in the induction hypothesis, we get that

$$f(H,h,c) \geq \min_{1\leq l\leq d} \left\{ \min_{\vec{x}^{(l)}: x_i \geq 0, \sum x_i = c - \frac{l}{2^{h+1}}} \left\{ \frac{1}{2^l} \sum_{S\subseteq\{1,\ldots,l\}} \prod_{i\in S} \exp\left(-\frac{\gamma x_i 2^{h+1}}{(H-h-1)^2} \right) \right\} \right\}. \tag{8}$$

For any l, we have by Proposition 2.5 that the right-hand side of (8) is minimized when all x_i are equal to $\frac{c}{l} - \frac{1}{2^{h+1}}$. We thus get that

$$\begin{aligned} f(H,h,c) &\geq \min_{1\leq l\leq d} \frac{1}{2^l} \sum_{S\subseteq\{1,\ldots,l\}} \left(\exp\left(-\frac{\gamma(\frac{c}{l} - \frac{1}{2^{h+1}})2^{h+1}}{(H-h-1)^2} \right) \right)^{|S|} \\ &= \min_{1\leq l\leq d} \frac{1}{2^l} \sum_{i=0}^{l} \binom{l}{i} \left(\exp\left(-\frac{\gamma(\frac{c}{l} - \frac{1}{2^{h+1}})2^{h+1}}{(H-h-1)^2} \right) \right)^{i} \\ &= \min_{1\leq l\leq d} \left(\frac{1 + \exp\left(-\frac{\gamma(\frac{c}{l} - \frac{1}{2^{h+1}})2^{h+1}}{(H-h-1)^2} \right)}{2} \right)^{l}. \end{aligned}$$

Fix l arbitrarily such that $1 \leq l \leq d$. Let $B = \left(\gamma(\frac{c}{l} - \frac{1}{2^{h+1}})2^{h+1}\right)/\left((H-h-1)^2\right)$ and $C = \left(\gamma\frac{c}{l}2^h\right)/\left((H-h)^2\right)$. To complete the induction, we want to prove that $\left(\frac{1+e^{-B}}{2}\right)^l \geq e^{-Cl}$, i.e., that

$$\frac{1+e^{-B}}{2} \geq e^{-C}. \tag{9}$$

We have four cases.

Case 1. In this case we assume that $C \geq \frac{B}{2}$. By the arithmetic mean-geometric mean inequality we have that $\frac{1+e^{-B}}{2} \geq e^{-B/2} \geq e^{-C}$, which proves (9).

Case 2. In this case we assume that $B \geq B_0$ and $\frac{B}{2+\delta} \leq C \leq \frac{B}{2}$; recall that δ is the constant from Proposition 2.6. Then we have from Proposition 2.6 that $\frac{1+e^{-B}}{2} \geq e^{-\frac{B}{2+\delta}} \geq e^{-C}$, which proves (9).

Case 3. In this case we assume that $C \leq \frac{B}{2}$ and $B < B_0$. Then by (7) we have $\frac{1+e^{-B}}{2} \geq 1 - \frac{B}{2} + \frac{B^2}{4} - \frac{B^3}{12}$. Since $C \geq 0$, we have (by Taylor's theorem) that $e^{-C} \leq 1 - C + \frac{C^2}{2}$. Thus, it suffices to prove that

$$1 - \frac{B}{2} + \frac{B^2}{4} - \frac{B^3}{12} \geq 1 - C + \frac{C^2}{2}.$$

Since $B < B_0 \leq \frac{1}{2}$ we have that $\frac{B^3}{12} \leq \frac{B^2}{24}$, and then since $2C \leq B$, we have that $\frac{B^2}{4} - \frac{B^3}{12} \geq \frac{5B^2}{24} \geq \frac{5C^2}{6}$. It therefore suffices to prove that

$$C + \frac{C^2}{3} \geq \frac{B}{2}.$$

Note that

$$\frac{B}{2} - C \leq \frac{\gamma 2^{h+1}\frac{c}{l}}{(H-h-1)^2(H-h)} - \frac{\gamma}{2(H-h-1)^2}.$$

Plugging in the values of B and C and simplifying, we get that it suffices to prove that

$$\frac{\gamma 2^{h+1}\frac{c}{l}}{(H-h-1)^2(H-h)} \leq \frac{\gamma}{2(H-h-1)^2} + \frac{\gamma^2\frac{c^2}{l^2}2^{2h}}{3(H-h)^4}.$$

If $\frac{2^{h+2}\frac{c}{l}}{H-h} \leq 1$, then the desired inequality indeed holds since $\frac{\gamma 2^{h+1}\frac{c}{l}}{(H-h-1)^2(H-h)} \leq \frac{\gamma}{2(H-h-1)^2}$. Otherwise, the inequality holds for any $\gamma \geq 96$, since then,

$$\frac{\gamma^2\frac{c^2}{l^2}2^{2h}}{3(H-h)^4} = \frac{\gamma}{6} \cdot \frac{2^{h+2}\frac{c}{l}}{H-h} \cdot \frac{\gamma\frac{c}{l}2^{h-1}}{(H-h)^3} \geq 16\frac{\gamma\frac{c}{l}2^{h-1}}{(H-h)^3} \geq \frac{\gamma 2^{h+1}\frac{c}{l}}{(H-h-1)^2(H-h)}.$$

Case 4. In this case we assume that $C < \frac{B}{2+\delta}$. Note that for $h \leq H-2$,

$$2+\delta \leq \frac{B}{C} = 2\frac{\frac{c}{l} - \frac{1}{2^{h+1}}}{\frac{c}{l}} \cdot \frac{(H-h)^2}{(H-h-1)^2} \leq 2\frac{(H-h)^2}{(H-h-1)^2} \leq 2 + \frac{6}{H-h-1}.$$

Thus, $h \geq H - 1 - \frac{6}{\delta}$. Since $\delta > 0$ is a constant, this is really the base case of the induction, which we shall prove directly. Consider a subtree T' of weight at most c that is rooted at a vertex u at level h. Since u has at most $c2^{h+1}$ children in T', each *not* having the group g_j in its $A(\cdot)$ set independently with probability $1/2$, with probability at least $2^{-c2^{h+1}}$ the subtree T' does not cover g_j. Thus, $f(H,h,c) \geq e^{-c2^{h+1}}$. Choosing a constant $\gamma \geq 2(1+\frac{6}{\delta})^2$, we get that $\gamma \geq 2(H-h)^2$, and thus

$$f(H,h,c) \geq e^{-c2^{h+1}} \geq \exp\left(-\frac{c2^h \cdot \gamma}{(H-h)^2}\right).$$

This concludes the proof of Lemma 2.7. □

Proof of Lemma 2.4. Lemma 2.7 implies that $f(H,0,c) \geq e^{-\gamma c/H^2}$. Plugging this into (4), we get that

$$P_c \leq M(c)(1-f(H,0,c))^k \leq M(c) \cdot \exp\{-k \cdot e^{-\gamma c/H^2}\}. \qquad \square$$

2.3.2. Bounding the weight of an integral solution. By Lemma 2.4 in conjunction with (5), we have

$$P_c \leq \exp\{cH2^H \log d - ke^{-\gamma\frac{c}{H^2}}\}.$$

Now, suppose that $c \leq \frac{1}{4\gamma}H^2 \ln k$. Then $cH2^H = O(2^H H^3 \log k)$. Recalling that $H = \frac{1}{2}\log k$, we have

$$P_c \leq \exp\{\tilde{O}(\sqrt{k}) - \Omega(k^{3/4})\} = o(1).$$

We conclude that with high probability no subtree of weight at most $\frac{1}{4\gamma}H^2 \log k$ covers all groups, and thus an optimal integral solution has value at least $\Omega(H^2 \log k)$. Since LP (1) has a fractional feasible solution of value $9H$, we get the following theorem.

THEOREM 2.8. *The integrality ratio of the relaxation* (1) *for* GROUP-STEINER-TREE *is* $\Omega(\log^2 k)$. *In terms of* N, k, *the integrality gap is* $\Omega(\log k \log N / \log\log N)$ *and in terms of* n *it is* $\Omega\big(\frac{\log^2 n}{(\log\log n)^2}\big)$.

2.4. Integrality ratio for unit-weight trees. The above analysis gives a lower bound on the integrality gap for GROUP-STEINER-TREE in HSTs. A consequent interesting question is whether the LP is tighter for unit-weight trees. We show that a slight modification of the trees described above gives the same integrality ratio lower bounds for unit-weight trees. The idea is very simple—recall that in our random construction $\mathbb{T}_n$, edges at level i had weight $1/2^i$; replacing each such edge by a path of 2^{H-i} unit-weight edges does not really change our integrality ratio argument, because the resulting instance $\mathbb{T}'_n$ is essentially equivalent to the instance $\mathbb{T}_n$ with edge weights scaled up by a factor of 2^H. Formally, it is easy to verify that our fractional solution for $\mathbb{T}_n$ naturally yields a fractional solution for $\mathbb{T}'_n$ with value $9H2^H$, and that an optimal integral solution for $\mathbb{T}'_n$ with value OPT' corresponds to an integral solution with value $\mathrm{OPT}'/2^H$ for $\mathbb{T}_n$. Since we know the latter value is at least $\Omega(H^2 \log k)$, we conclude that $\mathrm{OPT}' = \Omega(H^2 2^H \log k)$, and the integrality ratio of $\mathbb{T}'_n$ is $\Omega(H \log k) = \Omega(\log^2 k) = \Omega(\log k \log N / \log\log N)$. Furthermore, the total number of vertices in $\mathbb{T}'_n$ is at most $2^H n = O(n^2)$, and hence the integrality ratio is also $\Omega(\frac{\log^2 n}{(\log\log n)^2})$ in terms of the number of vertices in $\mathbb{T}'_n$.

2.5. Integrality ratio for c-HSTs. Straightforward modifications of our integrality ratio proof for GROUP-STEINER-TREE in 2-HSTs lead to the same lower bounds for c-HSTs, for arbitrary constant $c > 1$. Here, we take an alternative approach; instead of going through the whole proof, we show that our lower bounds for 2-HSTs imply (in a black-box manner) similar bounds for c-HSTs, where $c > 1$ is an arbitrary constant. We first consider the case $c > 2$ and then use it to handle the case $1 < c < 2$.

An arbitrary constant $c > 2$. In this case our 2-HST instance $\mathbb{T}_n$ can be modified into a c-HST instance $\mathbb{T}'_n$ as follows. The set of vertices of $\mathbb{T}'_n$ is a subset of the vertices of $\mathbb{T}_n$. For every $j = 0, 1, 2, \ldots$ iteratively (up to about $\log_c 2^H$), let $i = i(j)$ be the (unique) integer such that $2^i \le c^j < 2^{i+1}$, and include all the level i vertices of $\mathbb{T}_n$ as the level j vertices in $\mathbb{T}'_n$. For example, at $j = 0$, we include the root of $\mathbb{T}_n$ as the root of $\mathbb{T}'_n$ because $1 \le c^0 < 2$. We may assume that the height of $\mathbb{T}_n$ is chosen so that at some iteration j_0, we include in $\mathbb{T}'_n$ the leaves of $\mathbb{T}_n$ (i.e., $i(j_0) = H$), at which point the iterations are stopped. With this assumption (and since all the groups in $\mathbb{T}_n$ contain only leaves), we also get that $\mathbb{T}_n$ and $\mathbb{T}'_n$ have exactly the same k groups. Finally, two vertices at two consecutive levels $j-1, j$ in $\mathbb{T}'_n$ are connected by an edge of weight $1/c^j$ whenever, in $\mathbb{T}_n$, one of the two vertices is an ancestor of the other. For example, the edges incident at the root of $\mathbb{T}'_n$ have weight $1/c$. Notice that $\mathbb{T}'_n$ is a c-HST with height $j_0 \simeq \log_c 2^H = H/\log_2 c$.

A fractional solution LP for $\mathbb{T}_n$, of value LP, say, naturally induces a fractional solution to $\mathbb{T}'_n$ with value at most LP. Indeed, we let the fractional value of an edge connecting a vertex u to its parent v' in $\mathbb{T}'_n$ be equal to the fractional value of the edge connecting (the same vertex) u to its parent v in $\mathbb{T}_n$. It is easy to see that whenever this fractional solution for $\mathbb{T}'_n$ pays (fractionally) $1/c^j$ for an edge, the solution LP

pays $1/2^i$ for the corresponding edge in $\mathbb{T}_n$, with $1/c^j \le 1/2^i$. Since the corresponding edges in $\mathbb{T}_n$ are distinct, the value of the constructed solution for $\mathbb{T}'_n$ is at most LP.

An optimal integral solution OPT′ for $\mathbb{T}'_n$, of value OPT′, say, naturally induces an integral solution INT for $\mathbb{T}_n$ with value at most $O(c) \cdot \text{OPT}'$. Indeed, simply take in $\mathbb{T}_n$ the (minimal) subtree that spans exactly the same leaves (that are spanned by the solution for $\mathbb{T}'_n$). It is easy to see that whenever OPT′ pays $1/c^j$ for an edge connecting a vertex u to its parent v' in $\mathbb{T}'_n$, the solution INT has to pay for the path between u and its ancestor v' in $\mathbb{T}_n$. The total weight of this path is at most $1/2^{i'} + 1/2^{i'-1} + \cdots + 1/2^i = O(1/2^{i'}) = O(c) \cdot 1/2^i = O(c) \cdot 1/c^j$. We thus get an integral solution for $\mathbb{T}_n$ with value $O(c) \cdot \text{OPT}'$.

Combining these arguments with our bounds on the fractional and integral solutions for $\mathbb{T}_n$ yields a lower bound of $\Omega(\frac{1}{c} H \log k)$ on the integrality ratio in c-HSTs. Notice also that the number of vertices in $\mathbb{T}'_n$ is similar to that in $\mathbb{T}_n$ because they have the same leaves. For fixed $c > 2$, we thus get the same integrality ratio lower bounds in c-HSTs as in 2-HSTs, namely, $\Omega(\log^2 k) = \Omega(\log k \log N / \log\log N)$ and also $\Omega(\frac{\log^2 n}{(\log\log n)^2})$ in terms of the number of vertices in $\mathbb{T}'_n$.

An arbitrary constant $1 < c < 2$. Let t be the smallest integer such that $c^t > 2$, and define $q = 1 + c + c^2 + \cdots + c^{t-1}$. The above construction then yields a c^t-HST instance $\mathbb{T}'_n$. Now replace every edge of weight $1/(c^t)^j$ in $\mathbb{T}'_n$ with a path of t edges having weights $1/(qc^{tj-(t-1)}), 1/(qc^{tj-(t-2)}), \ldots, 1/(qc^{tj})$. Clearly, the resulting instance $\mathbb{T}''_n$ is a c-HST. Notice further that the total weight of the above t-path in $\mathbb{T}''_n$ is $(c^{t-1} + c^{t-2} + \cdots + 1)/(qc^{tj}) = 1/c^{tj}$, i.e., equal to the edge in $\mathbb{T}'_n$ it replaced. Hence, any fractional solution for $\mathbb{T}'_n$ yields a fractional solution for $\mathbb{T}''_n$ with the same value, and also an optimal integral solution in $\mathbb{T}'_n$ yields an integral solution for $\mathbb{T}''_n$ with the same value. Since the number of vertices in $\mathbb{T}''_n$ is larger than that in $\mathbb{T}'_n$ by only a constant factor of $t \le \log_c 4 = O(\frac{1}{c-1})$, we get the same integrality ratio lower bounds in c-HSTs as in 2-HSTs, namely, $\Omega(\log^2 k) = \Omega(\log k \log N / \log\log N)$ and also $\Omega(\frac{\log^2 n}{(\log\log n)^2})$ in terms of the number of vertices in $\mathbb{T}'_n$.

2.6. Integrality ratio for directed Steiner tree. The above results immediately lead to a lower bound of $\Omega(\frac{\log^2 n}{(\log\log n)^2})$ on the integrality ratio for DIRECTED-STEINER-TREE. Let $\mathbb{T}_n$ be an instance as described above with $\Omega(\frac{\log^2 n}{(\log\log n)^2})$ integrality ratio for GROUP-STEINER-TREE, and construct a DIRECTED-STEINER-TREE instance as follows. Orient all the edges of $\mathbb{T}_n$ away from the root r. Then introduce new nodes $v_1, v_2, \ldots, v_k$, and for each j and each $u \in g_j$, introduce a zero-weight arc from u to v_j. This defines a DIRECTED-STEINER-TREE instance I which is essentially the same as I: fractional solutions for the two problems map bijectively, with identical total weights, and the same holds also for integral solutions. Observe that the number of vertices in the resulting graph is $n + k \le 2n$, and thus the lower bound of $\Omega(\frac{\log^2 n}{(\log\log n)^2})$ on the integrality ratio for $\mathbb{T}_n$ holds also for I.

2.7. An $O(\log^2 k)$-approximation for the group Steiner tree problem in HSTs. We now show a tight $O(\log^2 k)$-approximation algorithm for GROUP-STEINER-TREE on HSTs. This was obtained jointly with Anupam Gupta and R. Ravi, and we thank them for allowing us to include this algorithm here.

Our algorithm uses the rounding procedure of [GKR00] as a subroutine and takes advantage of the geometrically-decreasing-weights property of HSTs. Let T be the HST instance of GROUP-STEINER-TREE. We assume this tree is a 2-HST; i.e., the weight of each edge in the $(i+1)$st level equals half the weight of its parent edge in

the ith level, and each edge in the first level has weight exactly *one*; the algorithm extends in a simple way to c-HSTs. We also assume that the height of the tree is $H > \log k$; otherwise, the approximation ratio $O(H \log k)$ in [GKR00] already implies the $O(\log^2 k)$ upper bound. It is not difficult to arrange that all members of each group are at the leaves of the HST (with only a constant factor increase in the optimum value). Our algorithm is as follows:

1. Create a new tree T' consisting of only the first $H' = \log k$ levels of T. For each leaf ℓ' in T' find its corresponding node ℓ in level $\log k$ of T, and assign to ℓ' all groups that appear in the subtree rooted at ℓ in T.
2. Run the approximation algorithm of [GKR00] on the GROUP-STEINER-TREE instance T'. Let SOL' be the value of the solution obtained and let OPT' be the value of the optimal solution in T'. The analysis of [GKR00] shows that $\mathrm{SOL}' = O(H' \log k \cdot \mathrm{OPT}') = O(\log^2 k \cdot \mathrm{OPT}')$.
3. From the solution SOL' (which is a subtree of T'), we construct a solution SOL for T as follows:
   (a) Find the subtree S in T that corresponds to SOL', and include S in SOL.
   (b) For each group $g \in \mathcal{G}$, repeat the following steps. Find a leaf ℓ' in SOL' that belongs to g (there must be such a leaf since SOL' covers g), and let ℓ be the level H' vertex in T corresponding to ℓ'. Now find in the subtree under ℓ in T a leaf u that belongs to g (there must be such a leaf because of the way we assigned groups in T'), and add to SOL the path that connects ℓ to its descendant u.

It is easy to verify that the above procedure produces a valid solution SOL to the 2-HST instance T. We claim that $\mathrm{SOL} = O(\log^2 k \cdot \mathrm{OPT})$, where OPT is the optimum solution value in T. Indeed, SOL consists of SOL' and at most k paths (one path per group) added in step 3(b). Because T is an HST, each of these paths has total weight $O(1/k)$ (since its edges have geometrically decreasing weights), and thus, $\mathrm{SOL} = \mathrm{SOL}' + O(1)$. Since the optimal solution must contain at least one edge in the first level (and thus having weight *one*), we get that $\mathrm{OPT} \geq 1$. It is also obvious that $\mathrm{OPT}' \leq \mathrm{OPT}$ and, therefore, $\mathrm{SOL} = \mathrm{SOL}' + O(1) = O(\log^2 k \cdot \mathrm{OPT}') + O(1) = O(\log^2 k \cdot \mathrm{OPT})$.

3. Improved approximations for certain families of trees. To better understand the approximability of GROUP-STEINER-TREE, one may consider the following question: What are the instances (in particular, trees) that are difficult to approximate better than within ratio $O(\log k \log N)$? We partially answer this question by presenting a significantly better approximation ratio for a certain family of trees, which differs from the trees constructed in section 2 in a crucial way.

This improved approximation also sheds light on the instances $\mathbb{T}_n$ constructed in section 2. For example, it may be tempting to believe, at first glance, that the edge weights pose an unnecessary complication to $\mathbb{T}_n$. Notice that the *uniform weight* version of $\mathbb{T}_n$ (i.e., a tree similar to $\mathbb{T}_n$, except that all its edges have the same weight) has the same fractional solutions as $\mathbb{T}_n$. Furthermore, it can be verified that for both $\mathbb{T}_n$ and its uniform weight version, the fractional solution presented in section 2.2 is, with high probability, near-optimal, and that applying to it the rounding procedure of [GKR00] yields an integral solution with value larger by a $\Theta(\log k \log N)$ factor than the relaxation value. However, in the uniform weight version of $\mathbb{T}_n$, the contribution of level-i edges to the relaxation value increases significantly with i, and as we shall soon see, this implies that an approximation ratio better than $O(\log k \log N)$ is possible.

This explains why the weights in $\mathbb{T}_n$ are necessary—they make every level have the same contribution to the relaxation value. This also elucidates the disparity between the performance of a rounding procedure for a relaxation and the integrality ratio of the relaxation—the uniform weight version of $\mathbb{T}_n$ exhibits a large ratio according to the former measure, but a significantly smaller ratio according to the latter.

Technically, fix a GROUP-STEINER-TREE instance T on a tree of height H, and an optimal solution x_e to its flow-based relaxation LP (1). Define z_i^* to be the total contribution of the edges at level i (of T) to the objective function of the relaxation. We show that the relationship between the different z_i^* plays a crucial role in the strength/weakness of the LP: If for some constant $\alpha > 1$ we have $z_{i+1}^* \geq \alpha z_i^*$ for all i, then we can achieve an $O(\log k \cdot \log\log(kN)/\log\alpha) = O(\log k \cdot \log\log(kN))$-approximation. This may suggest that instances with $z_i^* \simeq z_{i+1}^*$ for all or most i are among the worst cases for the relaxation.

The following lemma proves the improved approximation ratio for the case where $\alpha = 2$. The argument easily extends to any constant factor $\alpha > 1$. We sometimes refer to a valid integral solution simply as a cover.

LEMMA 3.1. *If $z_{i+1}^* \geq 2z_i^*$ for all i, then we can find an integral solution of value $O(z^* \cdot \log k \cdot \log\log(kN))$, where $z^* = \sum_{i=1}^{H} z_i^*$ denotes the optimal LP value.*

Before getting into the formal proof, let us outline the main ideas. We separate the tree T into a lower part that contains the lowest $\Theta(\log\log(kN))$ levels of the tree and an upper part that contains the rest of the tree. Let $z^*(U), z^*(L)$ be the contributions of the upper and lower parts to the fractional solution value z^*. Notice that $z^*(U) \leq z^*/\text{polylog}(kN)$ since $z_{i+1}^* \geq 2z_i^*$ for all i. We can thus take care of the upper part as follows. We use the same randomized rounding as in [GKR00] for the upper part, only now we repeat the process about $O(\log N)$ more times (multiplicatively)—this results in a solution that is considerably more expensive with respect to $z^*(U)$ but is still not too much with respect to the total fractional solution z^*. Since we repeat the rounding procedure more times, we cover each group more "times" (in a way that is formalized in the proof). Now every leaf of the upper part that we managed to cover can be regarded, in the lower part, as the root of a subtree. This allows us to apply the algorithm of [GKR00] to some of the subtrees in the lower part, namely, to those subtrees whose root was covered by our upper part solution. By the analysis of [GKR00] we need only pay proportionally to the height of the lower part (times $O(\log k)$); i.e., the lower part solution has value $O(z^*(L)\log k \log\log(kN))$. In the case where $z_{i+1}^* \geq \alpha z_i^*$ for all i, we define the lower part to be the lowest $\Theta(\log\log(kN)/\log\alpha)$ levels of the tree.

Proof. We may assume that all groups contain only leaves of T, by adding zero weight edges. Let L_i be the set of edges at level i. Let $h = 2\log\log(kN)$. Let $U = \{e : e \in L_i \text{ for } i \leq H - h\}$ and $L = \{e : e \in L_i \text{ for } i > H - h\}$. For every $e \in U$, let y_e be x_e rounded upwards to the nearest power of 2, increasing the LP value by a factor of at most 2.

We first find a cover of U, as follows. Let $c_1 > 0$ be a suitably large constant. For every $e \in U$, assign $\hat{x}_e = \min\{1, x_e \cdot c_1 \log k \log^2(kN)\}$, and use one iteration of the rounding scheme presented in [GKR00] (with respect to $\hat{x}_e$) to solve the problem in U. The expected total weight of this solution is at most $O(z^*(U)\log k \log^2(kN)) \leq O(z^* \log k)$, where $z^*(U) = \sum_{i=1}^{H-h} z_i^*$ is the total contribution to z^* of the edges in U.

Using arguments similar to those in [GKR00], we now wish to show that from the perspective of U, every group g is covered "sufficiently many times," with high probability. Let $e_1, \ldots, e_m$ be the leaves of (the subtree induced on) U that "lead" to g

(i.e., g contains at least one of their descendants in T'). A unit amount of flow can be shipped in T from the root to g, under the LP values x_e (as capacities), because x_e is a feasible solution. Let $f_1, \ldots, f_m$ be the corresponding flows on the edges $e_1, \ldots, e_m$. Clearly, $\sum_j f_j = 1$. Partition the m flows, letting $A_i = \{j : \frac{1}{2^i} < f_j \leq \frac{1}{2^{i-1}}\}$. Let $B(g) = \{i : i \leq 2 \log N \text{ and } \sum_{j \in A_i} f_j > 1/4 \log N\}$. It is easy to see that the flow in the remaining sets A_i is at most $(\frac{2}{N^2} + \frac{2}{2N^2} + \cdots) + (2 \log N)\frac{1}{4 \log N} < 3/4$, and thus $\sum_{i \in B(g)} \sum_{j \in A_i} f_j \geq 1/4$. We can therefore ignore the remaining sets and focus on the flows in $B(g)$. Fix $i \in B(g)$ and let V_i be the set of leaves (of U) e_j, for $j \in A_i$, that are chosen by the [GKR00] procedure in U according to $\hat{x}_e$.

For the sake of upper bounding the lower-tail of $|V_i|$, we may assume that the capacity x_e on every edge e equals the total flow shipped along the edge e (since a larger capacity x_e just increases $|V_i|$). Thus, the expectation of $|V_i|$ is $\mu_i = \sum_{j \in A_i} \min\{1, f_j \cdot c_1 \log k \log^2(kN)\}$. If $\frac{c_1}{2^i} \cdot \log k \log^2(kN) \geq 1$, then $|V_i| = |A_i| = \mu_i$ with probability 1. Otherwise, $\mu_i \geq \sum_{j \in A_i} \frac{c_1 f_j}{2} \cdot \log k \log^2(kN) \geq \frac{c_1 \log k \log(kN)}{8}$, and by Janson's inequality [Jan90],

$$\Pr[|V_i| \leq \mu_i/2] \leq e^{-\Omega(\frac{\mu_i}{2+\Delta_i/\mu_i})},$$

where $\Delta_i = \sum_{e \sim e'} \Pr[e \text{ and } e' \text{ are chosen}]$; here, the sum is over pairs of distinct edges $e \in A_i$ and $e' \in A_i$ whose events of being chosen are not independent. By the proofs in [GKR00, KRS02], it is easy to see that $\Delta_i \leq O(\mu_i \log k)$, where the constant in the "$O(\cdot)$" is an absolute constant that is independent of c_1. Thus,

$$\Pr[|V_i| \leq \mu_i/2] \leq e^{-\Omega(\mu_i/\log k)} \leq e^{-\Omega(c_1 \log(kN))},$$

where the constants in the "$\Omega(\cdot)$" are absolute constants that are independent of c_1. There are only k groups, and for each one $|B(g)| \leq O(\log N)$. Thus, by choosing c_1 sufficiently large, we get by the union bound (over a polynomial in kN number of V_i's) that with high probability, for every group g and every $i \in B(g)$, $|V_i| \geq \mu_i/2$. Recall that at least $1/4$ of the total flow in $f_1, \ldots, f_m$ is shipped through sets A_i with $i \in B(g)$ and that the flows among each such set A_i are all equal up to a constant factor. Hence, at least $\Omega(1)$ of the unit amount of flow into g must be shipped using the leaves of U chosen by the [GKR00] procedure.

We next apply the rounding algorithm of [GKR00] to L with the values x_e, starting from every chosen vertex of U. Since we know from above that one can ship to any group g an $\Omega(1)$ amount of flow from the level $H - h$ vertices chosen in the solution for U, we get that x_e satisfies the LP constraints up to a constant factor. It is proved in [GKR00] that after $O(h \log k)$ iterations of the rounding scheme, with high probability all the groups are covered. We now claim that the expected cost of each such iteration is at most z^*. Indeed, the probability to choose an edge e is proportional to its fractional value x_e, and the claim follows by the linearity of expectation.

Therefore, the expected cost of this solution is $O(z^* h \log k + z^* \log k) = z^* \cdot O(\log k \cdot \log\log(kN))$. ∎

4. Discussion. Our results improve the current understanding of the integrality ratio of the flow-based relaxation for the group Steiner tree problem, but some very intriguing gaps still remain. Although for HSTs our $\Omega(\log^2 k)$ lower bound is tight, for general trees there is a slight slack between our $\Omega(\log k \log N / \log\log N)$ lower bound and the $O(\log k \log N)$ upper bound of [GKR00]. Interestingly, an $O(\log^2(kN)/\log\log(kN))$-approximation by a quasi-polynomial time algorithm is

devised in [CEK06]; their algorithm is combinatorial (i.e., not LP-based). Does their algorithm hint that the known upper bound on the integrality ratio in trees is not tight? Or perhaps there is a separation between polynomial and quasi-polynomial (approximation) algorithms? A possible step toward closing this small gap (in the integrality ratio on trees) is to analyze the random instance suggested by Feige (see our description in section 2).

For general graphs, there is an even bigger slack, as the known upper bound is $O(\log n \log k \log N)$ [GKR00, FRT04] and the lower bound is just the lower bound for trees described above. It is worth noting that a significantly better upper bound can be achieved in (general) graphs of small diameter. In particular, an $O(\log k)$ upper bound for expander graphs is shown in [BM04]; this bound is tight since expanders contain a large star metric. We therefore set forth the following question, which was formulated together with Yair Bartal: What is the integrality ratio of Group-Steiner-Tree on the (say two-dimensional) grid graph?

The shortest-path metric of a grid contains, up to constant distortion, an HST which is a complete regular tree (see, e.g., [BBM01]). This tree is similar to our tree $\mathbb{T}_n$ (and to Feige's tree described above), but differs in parameters like arity and edge weight; thus, one may suspect that the integrality ratio in grids is at least as large as in HSTs. In comparison, the best upper bound that we are aware of for two-dimensional grids is the one known for general graphs.

A broader message of our paper is that in some cases the study of inapproximability lower bounds is well served by proving a preliminary integrality gap result. If for no other reason, the proof of an integrality gap might be somewhat easier. Recall that in our case, the hardness of approximation result of [HK03] uses our integrality gap as a "gadget." Recently, in yet another breakthrough along these lines (an integrality gap result that was strengthened into an inapproximability result), an $\Omega(\log^* n)$ hardness was obtained for Asymmetric k-Center [CGH$^+$05]. It would be nice to see how far this paradigm can be taken.

On the other hand, if a proof of integrality gap does not seem to be possible, one should perhaps try to improve the approximation algorithm. For example, for Covering-Steiner (another generalization of Group-Steiner-Tree), a logarithmic term appearing in the approximation ratio of [KRS02] was not known to have a counterpart in the integrality ratio. Recently it turned out that this term is spurious—the approximation algorithm is improved in [GS06] by designing a better rounding procedure.

ZAPS AND THEIR APPLICATIONS*

CYNTHIA DWORK† AND MONI NAOR‡

Abstract. A *zap* is a 2-round, public coin witness-indistinguishable protocol in which the first round, consisting of a message from the verifier to the prover, can be fixed "once and for all" and applied to any instance. We present a zap for every language in NP, based on the existence of noninteractive zero-knowledge proofs in the shared random string model. The zap is in the *standard* model and hence requires no common guaranteed random string. We present several applications for zaps, including 3-round concurrent zero-knowledge and 2-round concurrent deniable authentication, in the timing model of Dwork, Naor, and Sahai [*J. ACM*, 51 (2004), pp. 851–898], using moderately hard functions. We also characterize the existence of zaps in terms of a primitive called *verifiable pseudorandom bit generators*.

Key words. zero-knowledge, nonmalleable cryptosystems

1. Introduction.

The concept of zero-knowledge, introduced in the groundbreaking paper of Goldwasser, Micali, and Rackoff [36], has proved to be an invaluable tool in the design of cryptographic primitives and protocols. For example, consider an identification protocol based on pseudorandom function evaluation: I am identified by my ability to evaluate a function f_s, where only I know the seed s and there is some form of public commitment to f_s. Given a challenge x, I produce y and prove that $y = f_s(x)$ critically without revealing any information about s.

An appealing and frequently useful relaxation of zero-knowledge, called *witness-indistinguishability*, was proposed by Feige and Shamir [28]. Roughly speaking, in the context of NP, the difference is as follows: an interactive proof system is zero-knowledge if a prover, knowing a witness for membership of a string x in an NP language L, can correctly "convince" a verifier to accept x while revealing no information whatsoever about the witness. If there are two witnesses for $x \in L$, a proof system is witness-indistinguishable if the verifier cannot tell which of the two witnesses is being used by the prover to carry out the proof, even if the verifier knows both witnesses. We restrict our attention to NP because we are interested in the realistic setting in which parties are restricted to probabilistic polynomial-time computations.[1]

In this work we obtain surprising results on the number of rounds needed to achieve zero-knowledge and witness-indistinguishability. For this purpose we introduce and investigate zaps. A zap is a 2-round witness-indistinguishable protocol in which

(i) the first round, consisting of a message from the verifier to the prover, can be

[1] The literature on these subjects is extensive. See in particular the papers [18, 27, 33], the lecture notes [19], and the textbooks [29, 43].

fixed "once and for all" and applied to any instance, and
(ii) the verifier uses only *public coins*.

That is, the system remains sound and witness-indistinguishable even if the statements to be proved are chosen after the first-round message is fixed. Thus, if we think of the participating parties as families of *nonuniform*, rather than uniform, probabilistic polynomial-time-bounded Turing machines, the existence of a zap for a language L implies the existence of a 1-message witness-indistinguishable proof system for L.

Throughout the paper we distinguish between the *shared random string model*, in which the parties have access to a common *guaranteed random* string, and what we call the *standard* model, in which no such assumption is made. Whenever we refer to noninteractive zero-knowledge proofs (NIZKs), we mean in the shared random string model (the definition of NIZK forces a shared object). We present zaps for every language $L \in \mathrm{NP}$ based on the existence of a NIZK system for L in the shared random string model. The zap is in the standard model and hence requires no common guaranteed-random string. Using current NIZK technology, this means that zaps can be based on any family of enhanced certified trapdoor permutation [30].

Not only can zaps be constructed from NIZKs, but the converse holds as well: if every language in NP has a zap and one-way functions exist, then every language in NP has a NIZK. In fact, the NIZKs we obtain from zaps are zero-knowledge against adaptive selection of the theorem to be proved. This yields a proof that if NIZKs secure against nonadaptive selection exist and one-way functions exist, then adaptive NIZKs exist.

This result (and its proof) gives a somewhat formal view of zaps but yields little intuition for why zaps and NIZKs exist at all. Indeed, our first constructions of zaps were not based on NIZKs, but relied on the new notion of a *verifiable pseudorandom bit generator* (VPRG). Roughly speaking, a pseudorandom sequence is *verifiable* if a party knowing the pseudorandom seed can construct verifiable proofs of the bits of the pseudorandom sequence. Moreover, a VPRG with some number k of output bits passes what we call the ith bit test for all $1 \leq i \leq k$: given proofs of the values of all but the ith bit in the sequence, it is computationally infeasible to guess the ith bit with a nonnegligible advantage over $1/2$. Thus, VPRGs can be viewed as a special case of the verifiable pseudorandom functions (VPRFs) of Micali, Rabin, and Vadhan [45], in which the domain is very small. We give constructions for VPRGs and a relaxation, *approximate VPRGs*.

The importance of VPRGs is this: Zaps (and NIZKs) exist if and only if approximate VPRGs exist in the standard model. In this paper we construct VPRGs using multiple certified trapdoor permutations with a common domain; this yields the first NIZK construction for which the trapdoor permutations need not be enhanced. In addition, recent constructions of VPRFs based on assumptions on bilinear maps [44, 16, 17] also necessarily yield NIZKs (and zaps).

1.1. Applications of zaps. We present applications of zaps in several models. Specifically, we construct faster implementations of important cryptographic primitives in each of the standard, timing-based, and resettable models. Although in some cases the absolute improvement in rounds may be modest, the number of rounds that we achieve in each case is within one of the best possible. For example, all previous witness-indistinguishable proof systems require at least *three* rounds of communication, while zaps achieve witness-indistinguishability in two rounds. The fact that zaps also yield nonuniform 1-round witness-indistinguishability suggests that *proving* a lower bound of two rounds is unlikely. (See also the recent work of Barak, Ong, and Vadhan [3].)

An interesting set of applications for zaps is in the *timing* model of Dwork, Naor, and Sahai [23], where, using moderately hard functions [20] and timed commitments [11], we obtain 3-round *concurrent* black-box[2] zero-knowledge proofs of knowledge for all of NP. A 3-round black-box zero-knowledge protocol with timing (even without concurrency) is interesting in its own right: it is known that in the standard model (no timing) this is impossible to achieve (with negligible soundness error assuming NP $\not\subset$ BPP) [32], while the possibility of concurrency implies that at least $\Omega(\log n/\log\log n)$ rounds are required [14]; thus, adding timing allows us to go well below the lower bounds in the standard model. Recently, using zaps, Dwork and Stockmeyer obtained 2-round timing-based black-box (concurrent) zero-knowledge interactive proofs under the assumption that certain functions have no fast *auditors*; they also provide a prover-advice–based variant for which soundness is absolute (in this variant the prover can have arbitrary computation time) [25]. We note that even in the timing-based model, zero-knowledge proof systems for languages outside of BPP require two rounds of interaction. No such result is known for the bounded-advice model.

Still more recently, Barak and Pass obtained 1-round *weak* zero-knowledge arguments, under (less) nonstandard assumptions [4]. Under the weakened definition, soundness holds only against uniform probabilistic polynomial-time cheating provers, and the zero-knowledge condition is obtained using a simulator that runs in quasi-polynomial (rather than polynomial) time.

We also use zaps to construct 2-round deniable authentication protocols [18, 21, 23, 24]. Intuitively, deniable authentication is like a signature scheme in that it permits one party to authenticate messages to another party, based on a public key; however, unlike in the case of digital signatures, the authenticating conversation leaves no trace, for example, it may be simulatable and hence can be *effectively* repudiated.

The relative ease with which we are able to reduce the amount of interaction provides further motivation for the timing model of [23]—in our opinion a more realistic one than the shared guaranteed random string model (see, e.g., [15])—and a complexity theory of moderately hard functions [20].

Using zaps and timed commitments we also obtain a different type of improvement on the results in [23, 24]. The timing model requires a mild (α, β) assumption about the relative rates of the clocks of nonfaulty processors, and the protocols in [23] require processors (typically, the prover), to wait until an interval of at least $\beta \geq \alpha$ time has elapsed (as measured on the processor's own clock). α and β are chosen so as to tolerate actual system and communication delays. The proofs in [23, 24] require the parameters to be set according to the slowest nonfaulty processors. Our new techniques permit flexibility in this respect: fast verifiers with good communication links to the prover are not forced to suffer delays due to slower concurrent verifiers.

In the standard model, without timing assumptions, we give a 2-round oblivious transfer protocol based on the quadratic residuousity assumption and using public keys; without previously established public keys the protocol requires three rounds.

Finally, we consider a model of computation in which the prover's use of randomness is severely restricted, as, for example, in the case of a smart card, in which the prover may have a short embedded truly random seed and read-only memory. Canetti et al. [13] give one formalization, termed *resettable* zero-knowledge (rZK). Informally, a protocol protects a witness (either in the zero-knowledge sense or in the indistin-

[2] A protocol is black-box zero-knowledge if there is a universal simulator, which when given "black-box" access to any verifier strategy is able to simulate an interaction of that verifier with the prover. Virtually all zero-knowledge proofs until very recently were black-box (but see [1] for an example of a protocol which does not fit this category).

guishability sense) in the resettable model if the protection holds even if the prover may be restarted (reset) many times and forced to repeatedly use the same random tape. (The prover may also be restarted using a different, but still random, tape.)

Using zaps and timed commitments, we construct a 3-round timing-based rZK proof system for any language in NP. As noted in [13], rZK proofs *cannot* be proofs of knowledge, so, despite the connections between the smart-card setting as described above, resettable, and concurrent zero-knowledge [13, 38], this result is incomparable with our 3-round concurrent-ZK proofs of knowledge.

We also observe that 2-round (and even nonconstructive 1-round) resettable witness-indistinguishability is easily obtained from a zap, simply by having the prover's random bits in the zap be a pseudorandom function of the verifier's initial message and the input. This improves (both in conceptual and round complexity) upon the 5-round resettable witness-indistinguishability results in [13].

In all our protocols that employ timing, only the verifier needs access to a (local) clock. This is particularly appealing in the resettable case, in which the prover may be a smart card, since the card may not be equipped with a clock.

1.2. Outline. In section 2 we review the definitions of known cryptographic primitives. A formal definition of a zap is given in section 3. In section 4 we prove the existential equivalence of zaps (in the standard model) and NIZKs (in the shared random string model). Section 5 defines and constructs VPRGs and approximate VPRGs, together with a proof that zaps (and hence, by the above-mentioned result, NIZKs) exist if and only if approximate VPRGs exist in the standard model. Section 6 contains our zap-based oblivious transfer protocol. In section 7 we discuss the timing-based applications (3-round concurrent zero-knowledge and 2-round deniable authentication). In section 8 we discuss uses of zaps in the resettable model of [13]. Finally, open questions are discussed in section 9.

2. Brief review of cryptographic primitives. We now review the cryptographic primitives used in this paper. For the standard ones we follow Goldreich [29]. Throughout this paper, unless otherwise noted, all "good" parties (the nonfaulty prover and verifier) are uniform probabilistic polynomial-time Turing machines. However, our protocols remain sound regardless of the computational power of the prover, and we achieve zero-knowledge against nonuniform probabilistic polynomial time cheating verifiers. (This is assuming the classical underlying primitives are secure against nonuniform adversaries. Security against nonuniform adversaries is not essential to our work and we chose to express it this way for simplicity.)

In general we will be using n as our security parameter and the input length, but in some places we will also be using k_s to denote the length of the input to a cryptographic primitive which is sufficient for obtaining hardness, for instance, a one-way function or a trapdoor permutation. In general n and k_s are polynomially related. While we do not emphasize efficiency in this paper (rather our aim is to point out feasibility of various constructions), we prefer to have two parameters for future comparisons. Let $\nu(n)$ denote a function that grows more slowly than the inverse of any polynomial, i.e., for all $c > 0$ there is an n_0 such that $\nu(n) < 1/n^c$ for all $n \geq n_0$. We say such a $\nu(\cdot)$ is *negligible*. We use the term *with overwhelming probability* to mean with probability that is at least $1 - \nu(n)$ for negligible ν.

2.1. Witness-indistinguishability. The concept of *witness-indistinguishability* was proposed by Feige and Shamir [28] as a relaxation of zero-knowledge. Unlike the case with zero-knowledge, witness-indistinguishability is closed under parallel and

concurrent composition. Let L be an NP language accepted by a nondeterministic polynomial-time Turing machine M_L. A computation path is a sequence of nondeterministic choices made by M_L. The set of accepting computation paths on input $x \in L$ is the *witness set* of x, denoted $w(x)$.

DEFINITION 2.1 (witness-indistinguishability). *A proof system (P, V) for language L is witness-indistinguishable if for any polynomial time V', for all $x \in L$, for all $w_1, w_2 \in w(x)$, and for all auxiliary inputs z to V', the distribution on the views of V' following an execution $(P, V')(x, w_1, z)$ is indistinguishable from the distribution on the views of V' following an execution $(P, V')(x, w_2, z)$ to a nonuniform probabilistic polynomial-time distinguisher receiving one of the above transcripts as well as (x, w_1, w_2, z).*

Note that the auxiliary input z can even be the two witnesses w_1, w_2. Thus, *even knowing both witnesses*, V' should not be able to distinguish which witness is being used by P.

THEOREM 2.2 (see [28]). *Every zero-knowledge protocol is witness-indistinguishable.*

THEOREM 2.3 (see [28]). *Witness-indistinguishability is preserved under parallel and concurrent composition of protocols.*

2.2. Noninteractive zero-knowledge proof systems. The following discussion is based on [18, 27, 49]: a (single-theorem) noninteractive proof system for a language L allows one party P to prove membership in L to another party V for any $x \in L$. P and V initially share a string σ, of length polynomial in the security parameter n, which is trusted to have been chosen at random. To prove membership of a string x in $L_n = L \cap \{0,1\}^n$, P sends a message π as a proof of membership. V decides whether to accept or to reject the proof π as function of x and σ. Noninteractive zero-knowledge proof systems were introduced in [8, 7]. Noninteractive zero-knowledge schemes for proving membership in any language in NP may be based on any enhanced certified trapdoor permutation. (See [27, 40] and [30] for a discussion of enhancement.) As for the complexity of the NIZKs, assuming a trapdoor permutation on k_s bits, the length of a proof of a satisfiable circuit of size M (and the size of the shared random string) is $O(Mk_s^2)$.

We assume that the shared string σ is generated according to the uniform distribution on strings of length polynomial in the security parameter n, where the polynomial depends on the particular protocol. The running time of the verifier is also polynomial in n.

Let L be in NP and for any $x \in L$, $n = |x|$, let $w(x)$ be the set of strings that witness the membership of x in L, as described above. For the proof system to be of any use, P must be able to operate in polynomial in n time if it is given a witness $w \in w(x)$. We call this the *tractability* assumption for P. In general w is *not* available to V.

Let $PN(x, w, \sigma)$ be the distribution of the proofs generated by P on input x, witness w, and shared string σ. Suppose that P sends V a proof π when the shared random string is σ. Then the pair (σ, π) is called the *conversation*. Any $x \in L$ and $w \in w(x)$ induces a probability distribution $CONV(x, w)$ on conversations (σ, π), where σ is a shared string and $\pi \in PN(x, w, \sigma)$ is a proof.

For the system to be zero-knowledge, there must exist a simulator Sim which, on input x, generates a conversation (σ, p). Let $Sim(x)$ be the distribution on the conversations that Sim generates on input x, let $Sim_U(x) = Sim_U$ be the distribution on the σ part of the conversation, and let $Sim_P(x)$ be the distribution on the proof

component. In the definitions of [7, 27] the simulator has two steps: it first outputs Sim_U without knowing x, and then, given x, it outputs $Sim_P(x)$.

DEFINITION 2.4. *A pair of probabilistic polynomial-time machines (P, V) with shared random string σ is a* noninteractive zero-knowledge proof system *for the language $L \in NP$ if*

- *Completeness: For all $x \in L_n$, for all $w \in w(x)$ and for random σ, with overwhelming probability over $\pi \in_R PN(x, w, \sigma)$, we have that V accepts on input (σ, x, π). The probability is over the choice of the shared string σ and the internal coin flips of P.*
- *Soundness: For all $y \notin L$ we have that $\Pr_\sigma[\exists \pi' \in \{0,1\}^*$ such that (s.t.) V accepts $(\sigma, y, \pi')]$ is negligible. Note that the probability is* only *over the choices of the shared string σ.*
- *Zero-knowledge: There is a probabilistic polynomial-time machine Sim which is a simulator for the system: for all nonuniform polynomial time distinguishers $\mathcal{T}$, for all nonnegligible $\nu(\cdot)$, for all sufficiently large $x \in L$, and $w \in w(x)$,*

$$\left|\Pr[\mathcal{T}(s, x, w) = 1 | s \in_R Sim(x)] - \Pr[\mathcal{T}(s, x, w) = 1 | s \in_R \mathcal{CONV}(x, w)]\right| \leq \nu(n),$$

where the probability space is taken over the random choices of σ and over the random choices of the Sim and $\mathcal{P}$.

Remark 2.5. This definition of NIZK does not require that the system be *sound* if the instance x is adaptively chosen, that is, selected after the public random string is known. Nevertheless, it is sufficiently strong for our purposes; also it is easy to reduce the soundness error in NIZK by parallel repetition. Similarly, we do not assume zero-knowledge against adaptive choice of x. As we will see in Corollary 4.4, going through zaps allows us to transform any NIZK satisfying Definition 2.4 into one that allows adaptive selection of x.

As shown in [27], any NIZK satisfying Definition 2.4 is also *general witness-indistinguishable* in the following sense.

CLAIM 2.1 (see [27]). *Any NIZK for a language L in NP is general witness-indistinguishable; that is, for all polynomial distinguishers $\mathcal{T}$ for a random string σ, for any (nonadaptively chosen[3]) sequence $\{(x_i, w_i^1, w_i^2)\}_{i=1}^m$ chosen by $\mathcal{T}$, where $x_i \in L_n$ and $w_i^1, w_i^2 \in w(x_i)$ for all $1 \leq i \leq m$, we have*

$$\left|\Pr[\mathcal{T}(\pi_1^1, \pi_2^1, \ldots, \pi_m^1) = 1] - \Pr[\mathcal{T}(\pi_1^2, \pi_2^2, \ldots, \pi_m^2) = 1]\right| < \nu(n),$$

where for all $1 \leq i \leq m$ and $b \in \{0,1\}$ we let $\pi_i^b \in_R PN(x_i, w_i^b, \sigma)$. The probability space is over $\mathcal{P}$'s and $\mathcal{T}$'s random coins and the choice of σ.

Note that general witness-indistinguishability implies witness-indistinguishability even if $x_1 = \cdots = x_m$, which will be the case of interest here.

2.3. Deniable authentication. A *public key authentication* scheme permits an authenticator $A\mathcal{P}$ to convince a second party V, only having access to $A\mathcal{P}$'s public key, that $A\mathcal{P}$ is willing to authenticate a message m. However, unlike in the case of digital signatures, deniable authentication does not permit V to convince a third party that $A\mathcal{P}$ has authenticated m—there is no "paper trail" of the conversation (say, other than what could be produced by V alone). Thus, deniable authentication

[3] If the NIZK is nonadaptive, then the claim refers to nonadaptively chosen sequences; if the NIZK is adaptive, then the claim also holds for adaptively chosen sequences. In our case, we have assumed the weaker NIZK.

is incomparable with digital signatures. Deniable authentication first appeared in [18, 21] and was formalized in [23] (see also [24]). Several 4-round timed concurrent deniable authentication protocols are given in [23, 24].

The authentication protocol should satisfy the following.

- Completeness: For any message m, if the prover and verifier follow the protocol for authenticating m, then the verifier accepts.
- Soundness—existential unforgeability against concurrent chosen message attack: Suppose that the copies of $A\mathcal{P}$ are willing to authenticate any polynomial number of messages $m_1, m_2, \ldots$, which may be chosen adaptively and in a concurrent manner by an adversary $\mathcal{A}$ who also controls the verifier V'. We say that $\mathcal{A}$ successfully attacks the scheme if a forger C, under control of $\mathcal{A}$ and pretending to be $A\mathcal{P}$, succeeds in authenticating to a third-party D (running the protocol of the original verifier V) a message $m \neq m_i$, $i = 1, 2, \ldots$. The soundness requirement is that all probabilistic polynomial-time $\mathcal{A}$ will succeed with at most negligible probability.
- Zero-knowledge—deniability: Consider an adversary $\mathcal{A}$ as above and suppose that the copies of $A\mathcal{P}$ are willing to authenticate any polynomial number of messages. Then for each $\mathcal{A}$ there exists a polynomial-time simulator that outputs an indistinguishable transcript from the one $\mathcal{A}$ produces from its interaction with $A\mathcal{P}$.

  Two natural variants are (1) the distinguisher has access to the secret authentication key and (2) the distinguisher does not have access to the secret authentication key. The first best captures our intuitive notion of deniable authentication, since even obtaining access to the key, say, via legal compulsion, will not destroy the deniability.

2.4. Security of encryption. We will need public-key cryptosystems for two of our applications: resettable zero-knowledge (section 8.2) and deniable authentication (section 7.2). The security requirements of these two applications are different. To specify the security of an encryption scheme, one must describe the power of the attacker in terms of access to the system (chosen plaintext, chosen ciphertext) and what it means to break the system (semantic-security, nonmalleability). See [18] or [5] for a discussion of notions of security. The deniable authentication application requires a system that is nonmalleable against chosen-ciphertext attacks in the postprocessing mode (called CCA-2 in [5]). The resettable zero-knowledge application requires semantic security against chosen plaintext attacks. (There are some other requirements from the encryption scheme which transcend security.)

2.5. Using time in the design of protocols. Dwork, Naor, and Sahai [23] have shown the power of time in the design of zero-knowledge protocols through the use of an (α, β) assumption. This says that all good parties are assumed to have clocks that satisfy the (α, β)-*constraint* (where $\alpha \leq \beta$): for any two (possibly the same) nonfaulty parties P_1 and P_2, if P_1 measures α elapsed time on its local clock and P_2 measures β elapsed time on its local clock, and P_2 begins its measurement in real time after P_1 begins, then P_2 will finish after P_1 does.

The protocols in [23, 24] use time in two explicit ways: (i) delays—one party must delay the sending of some message until at least some specified time β has elapsed on its local clock; (ii) time-outs—one party requires that the other deliver its next message before some specified time α has elapsed on its (first party's) local clock. In this work we are able to eliminate the use of delays; the protocols use only time-outs. Furthermore, we do not require a *global* (α, β)-constraint, rather each instantiation of

the protocol can fix its own values based on the local characteristics of the network. An essential ingredient of our protocols is the *implicit* use of time via *moderately hard functions* [20]. In particular, we use *timed commitments with verifiable recovery,* described next.

Timed commitment. A string commitment protocol allows a sender to commit, to a receiver, to some value. The protocol has two phases. At the end of the *commit* phase the receiver has gained no information about the committed value, while after the *reveal* phase the receiver is assured that the revealed value is indeed the one to which the sender originally committed. Timed commitments, defined and constructed by Boneh and Naor [11], are an extension of the standard notion of commitments in which there is a potential forced opening phase permitting the receiver, by computation of some moderately hard function, to recover the committed value without the help of the committer. The price paid in terms of security is that the committed value is hidden for only a limited amount of time.

DEFINITION 2.6. *A* (T, t, ϵ) timed commitment *scheme for a string* $y \in_R \{0,1\}^n$ *enables Alice to give Bob a commitment* C *to the string. At a later time, Alice can prove to Bob that* C *represents a commitment to the value* y*. However, if Alice refuses to reveal the value of* C*, then Bob can spend time* T *to forcibly retrieve this value. Alice is assured that within time* t *on a parallel machine with polynomially many processors, where* $t < T$*, Bob will succeed in obtaining* y *with probability at most* ϵ*. Formally, a* (T, t, ϵ) *timed commitment scheme consists of three phases:*

- *Commit phase: To commit to a string* $y \in \{0,1\}^n$ *Alice and Bob execute a protocol whose outcome is a* commitment string $C = TC(y)$ *which is given to Bob.*
- *Open phase: At a later time Alice may reveal the string* y *to Bob. They execute a protocol so that at the end of the protocol Bob has a proof that* y *is the committed value.*
- *Forced open phase: Suppose Alice refuses to execute the* open *phase and does not reveal* y*. Then there exists an algorithm, called* forced-open*, that takes the commitment string* C *as input and outputs* y *and a proof that* y *is the committed value. The algorithm's running time is at most* T*.*

The commitment scheme must satisfy a number of security constraints:

- *Binding: During the open phase Alice cannot convince Bob that* C *is a commitment to* $y' \neq y$*. That is, binding is absolute, independent of computational power: there is at most one "de-commitment,"* y*, consistent with* $TC(y)$*.*
- *Soundness: At the end of the* commit *phase Bob is convinced that, given* C*, the* forced-open *algorithm will produce the committed string* y *in time* T*.*
- *Privacy: Every PRAM algorithm* $\mathcal{A}$ *whose running time is at most* t *for* $t < T$ *on polynomially many processors will succeed in distinguishing* y *from a random string, given the transcript of the commit protocol as input, with advantage at most* ϵ*. In other words,*

$$\left|\Pr[\mathcal{A}(\textit{transcript}, y) = \textit{"yes"}] - \Pr[\mathcal{A}(\textit{transcript}, R) = \textit{"yes"}]\right| < \epsilon,$$

where the probability is over the random choice of y *and* R *and the random bits used to create* C *from* y *during the commit phase.*

The important requirements of timed commitments are (i) the future recoverability of the committed value is verifiable: if the commit phase ends successfully, then the receiver is correctly convinced that forced opening will yield the value; (ii) forcibly

recovered values and decommitments are verifiable: the receiver obtains not only the value but also a proof of its validity, so that anyone who has the commitment (or the transcript of the commit phase) can verify the value *without going through a recovery process*, i.e., in fixed amount of time; (iii) the commitment is immune to parallel attacks, i.e., even if the receiver has much more computing power than assumed, it cannot recover the value substantially more quickly than a single-processor receiver. We denote by T the bound on the time below which it is safe to assume that the timed commitment cannot be broken with nonnegligible probability, even by a PRAM.

Specifically, we are interested in timed commitment schemes with the following structure. The committer sends to the receiver a string ζ, which constitutes the commitment. For every "valid" commitment ζ, it is possible, through moderately hard computation, to recover a pair (y, π) such that π is an easily checked witness to the fact that ζ is a commitment to y. The set of valid commitments is in NP: for every valid commitment ζ there is a witness to the statement "ζ is a valid commitment to a string that can be recovered through the forced recovery process." Finally, the forced recovery time is relatively large compared to the time of all other operations in the protocol (such as constructing ζ, verifying a correctly decommitted value, verifying future recoverability, etc.). Thus, we think of all other operations as "easy" while recovery is "moderately hard." The scheme in [11] has this structure and properties, albeit based on a nonstandard assumption regarding the computation of number of the form g^{2^k} mod N for composites N without knowing the factorization of N.

2.6. Oblivious transfer. In a 1-*out-of*-2 *oblivious transfer (OT)* protocol, one party, the *sender*, has two strings (M_1, M_2) as its input, and the second party, the *chooser*, has a bit b. The chooser should learn M_b and nothing regarding M_{1-b}, while the sender should gain no information about b. 1-out-of-2 OT was suggested by Even, Goldreich, and Lempel [26] as a generalization of Rabin's "oblivious transfer" [50].

3. Formal definition of a zap. A *zap* is a 2-round (2-message) protocol for proving membership of $x \in L$, where L is a language in NP. Let the first-round (verifier to prover) message be denoted ρ and the second-round (prover to verifier) response be denoted π satisfying the following conditions:

- Public coins: There is a polynomial $k(\cdot)$ such that the first-round messages form a distribution on strings of length $k(n)$ which depends only on the *length* n of x. The verifier's decision whether to accept or reject is a polynomial-time function of x, ρ, and π only.
- Completeness: Given x, a witness $w \in w(x)$, and a first-round ρ, the prover, running in time polynomial in $|x|$, can generate a proof π that will be accepted by the verifier. Note that this is *perfect completeness*. We can relax this requirement and ask the prover to succeed with overwhelming probability over the choices made by the prover and the verifier.
- Soundness: With overwhelming probability over the choice of ρ, there exists no $x' \notin L$ and second-round message π such that the verifier accepts (x', ρ, π).
- Witness-indistinguishability: Let $w, w' \in w(x)$ for $x \in L$. Then for all ρ, the distribution on π when the prover has input (x, w) and the distribution on π when the prover has input (x, w') are nonuniform probabilistic polynomial-time (in $n = |x|$) indistinguishable, even given both witnesses w, w'.

It follows immediately from the definitions that every zap yields a *nonconstructive* nonuniform single-round witness-indistinguishable protocol; that is, the first-round message can be fixed once and for all. Also since we require unconditional soundness

(soundness against unbounded provers) the private coins versus secret coins really does not show up.

CLAIM 3.1. *Every zap yields a* nonconstructive *nonuniform single round witness-indistinguishable protocol: for each n, there exists a string $\hat{\rho}_n$ such that, letting $L_n = L \cap \{0,1\}^n$, the following hold:*

1. *Given $x \in L_n$ and a witness $w \in w(x)$, the prover can generate a proof π that will be accepted by the verifier. Moreover, the verifier's decision whether to accept or reject is a polynomial-time function of $x, \hat{\rho}_n$, and π.*
2. *There exists no $x' \notin L_n$ and message π such that the verifier accepts $(x', \hat{\rho}_n, \pi)$.*
3. *For all $x \in L_n$ and all $w, w' \in w(x)$, the distributions $\mathcal{P}(x, w, \hat{\rho}_n)$ and $\mathcal{P}(x, w', \hat{\rho}_n)$ are indistinguishable by any nonuniform probabilistic polynomial-time distinguisher.*

Comparison with NIZKs. Zaps differ from NIZKs in two respects, making the two concepts incomparable. On the one hand, zaps do not require that the prover and verifier have access to a common guaranteed random string. On the other hand, NIZKs provide more provable protection of the witness than do zaps, since NIZKs can be simulated without access to the witness while zaps provide no such guarantee.

4. The NIZK-based construction. Assume we have a NIZK system (in the shared string model) satisfying Definition 2.4 for a language L. We will construct a zap for L (in the standard model). We will first provide some intuition for the construction. Consider a NIZK in the shared string model; we try to convert it into a zap by somehow generating the shared string σ. Suppose we let the verifier choose a string B and fix $\sigma = B$. The danger with this approach is that there may be "bad" choices for σ that leak information about the witness, and the verifier might choose B to be one of them, thus harming the witness protection. If, to compensate, we have the prover choose its own random string C and we set $\sigma = B \oplus C$ (that is, σ is the bitwise exclusive-OR of B with C), then the danger is that the prover will use the simulator to come up with a σ' that "proves" that $x \in L$ (that is, causing V to accept x), even for $x \notin L$. The prover could then set $C = \sigma' \oplus B$, violating soundness.

The actual protocol strikes a balance between these two ideas: a NIZK is repeated many times in parallel, but not quite independently, as follows. The jth instance has common string σ_j, defined to be the bitwise exclusive-OR of two strings, one chosen by the prover and the other chosen by the verifier. The verifier's choice for the jth instance may be any string B_j; however, the prover may choose only a single string C that is used in all instances. This sort of idea can be called reverse randomization and has been previously used in the bit commitment protocol of Naor [46] and can be traced back to Lautemann's proof that BPP is in the second level of the hierarchy [42]; it has since been applied by Dwork, Naor, and Reingold [22] for removing decryption errors.

Choice of parameters (general construction). We now specify the parameters we need. Note that in general it is possible to reduce the soundness error of a NIZK by repetition (with a fresh part of the shared random string for each repetition) without hurting the zero-knowledge properties. Note that parallel repetition reduces the error in a straightforward manner here, since it is combinatorial. The price of course is in the string and proof length.

Assume that we have a NIZK for L which, for proving membership of strings of length $|x|$, with security parameter n, uses a common shared string of length $\ell = \ell(n, |x|)$. Assume further that on any input $y \notin L$ of length $|x|$ the NIZK errs with probability at most $q = q(n)$ over the choice of the common random string σ. In (4.1),

$k = k(n, |x|) = |\rho|$, the number of random bits sent by the verifier in the first-round message. The number of copies $m = m(n, |x|)$ of the NIZK will be k/ℓ. To achieve soundness guarantee δ for the zap (that is, a cheating prover should succeed with probability at most δ), we choose k satisfying

$$q^{k/\ell} < \frac{\delta}{2^{|x|+\ell}}. \tag{4.1}$$

4.1. Protocol Z: A zap. To achieve soundness against an arbitrarily powerful prover and yet to require only feasible computation from the "good" prover, we must assume the existence of a NIZK with these properties, such as the systems in [27, 40].

Let $x \in L$ be an NP-statement to be proved to the verifier. We do not need x to be fixed before execution of the protocol begins. Let w be the witness to $x \in L$ known by the prover, let n be the security parameter, and let $PN(x, w, \sigma)$ be the distribution on messages sent in the NIZK by a (noncheating) prover when the common random string is σ of length $\ell(n, |x|)$. For simplicity, in the remainder of this discussion we assume n and $|x|$ are related by some fixed polynomial so that it suffices to think of $\ell(n, |x|)$ as a function solely of n. Let $k = k(n)$ and $m = m(n)$ satisfy (4.1).

First round: $V \longrightarrow P$. The verifier sends to the prover a random k-bit string $\rho = b_1 \dots b_k$, which is interpreted as $B_1 \dots B_m$, where B_j denotes the jth block of ℓ consecutive bits and ℓ is the length of the common random string used by the NIZK.

Second round: $P \longrightarrow V$. The prover responds as follows. First, it chooses a random ℓ-bit string $C = c_1 \dots c_\ell$. For $j = 1 \dots m$ define σ_j to be the bitwise exclusive-OR of B_j and C:

$$\sigma_j = B_j \oplus C.$$

Then the prover sends to the verifier x, C, and the m noninteractive proofs

$$\{\pi_j \in_R PN(x, w, \sigma_j)\}_{j=1\dots m}.$$

Final check. The verifier V checks that each of the m NIZKs $\pi_1, \pi_2, \dots, \pi_m$ with common strings $\sigma_1, \sigma_2, \dots, \sigma_m$, where $\sigma_j = C \oplus B_j$ results in acceptance; if so, then the verifier accepts the zap; otherwise the verifier rejects. This completes the description of Protocol Z.

LEMMA 4.1. *Protocol Z is sound; moreover, for all n, there exists a choice $\hat{\rho_n} = \hat{b}_1 \dots \hat{b}_{k(n)}$ for the first-round message that yields perfect soundness: for all $x \notin L_n$ for all π $V(x, \hat{\rho_n}, \pi)$ rejects.*

Proof. Let $\ell = \ell(n)$ and $k = k(n)$. Fix an $x \notin L$ and random bit string $C = c_1 \dots c_\ell$. Recall that in a NIZK the faulty prover's probability of succeeding on an $x \notin L$ is a function of the common random string only, and this probability is at most q. We will show that with overwhelming probability, over the choice of $b_1, \dots, b_k$, the prover will fail to convince the verifier to accept x. The key point is that once everything but the b has been fixed, the σ_j are truly random—because the B_j are. Therefore each copy of the NIZK proof has probability at most q of failing to cause rejection. Since each proof is independent (because the random b_i used in each copy of the NIZK proof are independent), the overall probability that all $m = k/\ell$ copies fail to reject is at most q^m.

The number of possible assignments to pairs (c, x) where $c \in \{0,1\}^\ell$ and $x \notin L$ is at most $2^{\ell+|x|}$. Hence, as long as

$$2^{\ell+|x|} q^m = 2^{\ell+|x|} q^{k/\ell} \leq \delta$$

(which is guaranteed by our choice of k in (4.1)), the probability over $b_1, \ldots, b_k$ that there even exists a "bad" choice of $c_1 \ldots c_\ell$, an $x \notin L$, and a zap π that erroneously causes the verifier to accept x is at most δ (cf. the soundness requirement in Definition 2.4). Since $\delta < 1$, there must exist some $\hat{\rho_n} = \hat{b}_1 \ldots \hat{b}_k$ that provides soundness against all $x \notin L_n$: for all $x \notin L_n$ for all π $V(x, \hat{\rho_n}, \pi)$ rejects. □

LEMMA 4.2. *Protocol Z is witness-indistinguishable.*

Proof. We prove witness-indistinguishability *for every* ρ. We will be using only the witness-indistinguishability property of the proof system (Theorem 2.2). Thus, fix an arbitrary ρ for the entire proof. We will carry out a standard hybrid argument with the following steps along the chain. Let w and w' be two witnesses that $x \in L$, and let $n = |x|$. At one extreme of the chain the witness w is used in each of the m NIZKs; at the other extreme the witness w' is used in every copy. At each step along the chain we increase by one the number of copies of the NIZK in which w' is used (and decrease the number in which w is used).

Let $\langle w, w', i \rangle$ denote the distribution on transcripts in which the first i copies of the NIZK are constructed using w and the remaining $m - i$ copies are constructed using w'. The transcripts also include x, w, w'. The distribution is over random choices made by the prover (since ρ is fixed). Let $\mathcal{T}$ be a nonuniform polynomial-time test that takes as input a transcript and outputs a single bit. We write $\mathcal{T}(\langle w, w', i \rangle)$ to denote $\mathcal{T}$'s behavior on a transcript chosen uniformly from $\langle w, w', i \rangle$.

Assume for the sake of contradiction that there exists a probabilistic polynomial-time test $\mathcal{T}$ and $1 \leq j \leq m$ such that for some fixed a and infinitely many n

$$\Pr[\mathcal{T}(\langle w, w', j-1 \rangle) = 1] - \Pr[\mathcal{T}(\langle w, w', j \rangle) = 1] \geq \frac{1}{n^a}.$$

The probability space is over the choices made by the prover and the randomness of $\mathcal{T}$. We will show that this contradicts the witness-indistinguishability of the underlying NIZK.

Let $(\widehat{P}, \widehat{V})$ be the underlying NIZK protocol (running in the shared random string model). Let τ be a truly random string of ℓ bits. Choose $u \in_R \{w, w'\}$ and give u to $\widehat{P}$. Let $\widehat{P}$ generate a proof $\pi \in_R PN(x, u, \tau)$. By the witness-indistinguishability of the NIZK, with overwhelming probability over choice of τ, no nonuniform probabilistic polynomial-time machine, even given w and w', has nonnegligible advantage of guessing the value of u from π. We will show how to use T to violate this indistinguishability.

Using w and w', construct a simulated transcript of Protocol Z as follows. Break $\rho = b_1, \ldots, b_k$ into $m = k/\ell$ blocks $B_1, \ldots, B_m$. Set $C = \tau \oplus B_j$, so that $\sigma_j = B_j \oplus C = \tau$, which is truly random by assumption. For all $i < j$, construct $\pi_i \in_R PN(x, w, \sigma_i)$. For all $i > j$, construct $\pi_i \in_R PN(x, w', \sigma_i)$. Set $\pi_j = \pi$, which, by assumption, is a uniformly chosen element of $PN(x, u, \tau)$. Let Π denote the resulting transcript.

Run $\mathcal{T}$ on Π. Since τ is truly random and uniformly distributed, C is uniformly distributed as well, so the resulting transcript of m NIZKs is a uniformly chosen element of either $\langle w, w', j-1 \rangle$ (if $u = w'$) or $\langle w, w', j \rangle$ (if $u = w$). We can therefore use $\mathcal{T}$'s assumed ability to distinguish these two cases to obtain a nonnegligible advantage in guessing whether $u = w$ or $u = w'$. □

THEOREM 4.3. *Protocol Z is a zap.*

Proof. Soundness and witness-indistinguishability have been argued. If the underlying NIZK has perfect completeness, then the resulting zap inherits this property. Otherwise, if the underlying NIZK has negligible chance of failure, then completeness for Protocol Z follows from the fact that for any $\hat{\rho}$, since C is random, the probability

that there is some block $\hat{B}_i$ such that $\pi \in_R PN(x, w, \hat{B}_i \oplus C)$ but $V^*(\hat{B}_i \oplus C, x, \pi)$ does not accept is negligible. (Here, as earlier, $\hat{B}_i$ is the ith consecutive block of ℓ bits in $\hat{\rho}$.) In fact, by resampling C, the prover can actually achieve perfect completeness even if the underlying NIZK has negligible chance of failure. □

Our main conclusion is therefore the following corollary.

COROLLARY 4.4. *Let $L \in NP$ be arbitrary.*

1. *If there exists a NIZK for L in the common guaranteed-random string model, then there exists a zap for L in the standard model.*
2. *If there exist zaps in the standard model for* every *language in NP, and if there exist nonuniform one-way functions, then there is a NIZK for L in the common guaranteed-random string model. Furthermore, this NIZK remains zero-knowledge under an adaptive selection of x, that is, when x may depend on σ.*

Proof. The first claim is immediate from the construction and correctness of Protocol Z.

For the second claim we directly apply the idea of Feige, Lapidot, and Shamir [27] of transforming the proof of the statement $x \in L$ into a witness-indistinguishable proof for the statement, "The common shared random string σ is pseudorandom OR $x \in L$." As we will explain, to carry out this approach it is sufficient to have

- a pseudorandom generator G that, say, doubles the length of the seed (in this case a random string is unlikely to be the output of the generator for any seed), and
- a zap for the language $L' = \{(x, \sigma) | x \in L \text{ or } \exists s\ \sigma = G(s)\}$.

The desired pseudorandom generators exist if and only if nonuniform one-way functions exist [37]; moreover, since L' is clearly in NP, it has a zap by the hypothesis. We assume for simplicity (and without loss of generality) that the verifier's message in the zap is chosen uniformly at random.

Recall that we are trying to show that if one-way functions and zaps exist, then there exists a NIZK in the shared random string model. Given a shared random string, treat it as (σ, ρ), where ρ is the verifier's first-round message in the zap for the language L'. The prover simply transforms its witness for $x \in L$ to a witness for $(x, \sigma) \in L'$. Soundness follows from the fact that most σ are not equal to $G(s)$ for any s (this holds because G is length-doubling and σ is truly random).

The system is zero-knowledge since, critically, the simulator for a NIZK is permitted to choose the common string and may in particular choose it to be $G(s)$ for some random s. Then for a random ρ it uses s as the witness for $(x, G(s)) \in L'$. The nonuniform probabilistic polynomial-time indistinguishability of outputs of G from truly random strings, and the witness-indistinguishability of the zaps for L', imply that the output of the simulator is indistinguishable from a real transcript.

Note that since a zap maintains its witness-indistinguishability even when x is chosen after the first-round message is known, we get that the zero-knowledge is maintained even if x is selected in an adaptive manner. □

5. Zaps and verifiable pseudorandom bit generators. In this section we characterize zaps in terms of a new cryptographic primitive: the VPRG, which is inspired by the definition of VPRF [45] (but note the differences). A VPRG is a pseudorandom generator where the holder of the seed can generate proofs of consistency for some parts of the sequence without hurting the unpredictability of the remaining bits. In the standard model we will exhibit a construction of zaps from VPRGs (Protocol VZ below). As we will see, the construction works even if the

VPRG is *approximate*, in that the proofs of the bit values are occasionally incorrectly accepted, so it is possible to cheat a little (this "little" need not be polynomial). We will also show that if zaps exist, then so do approximate VPRGs. Very roughly, *approximate* VPRGs can be designed to have multiple witnesses, so zaps, with their witness-indistinguishability, are sufficiently strong to yield the necessary proofs π of consistency with some member of the set of vectors related to the public verification string (denoted $S(\mathrm{VK})$). In contrast, we do not know how to design *strict* VPRGs to have multiple witnesses.

The following summarizes the relationships between zaps, VPRGs, and NIZKs, both in the standard model and in the common guaranteed-random string model.

SUMMARY 5.1.

1. *NIZKs exist in the common guaranteed-random string model if and only if VPRGs exist in the common guaranteed-random string model (Theorem* 5.10*).*
2. *NIZKs exist in the common guaranteed-random string model if and only if zaps exist in the standard model (Theorem* 4.3 *and Corollary* 4.4*).*
3. *Zaps exists in the standard model if and only if approximate VPRGs (with certain parameters) exist in the standard model (Corollary* 5.7 *and Theorem* 5.8*).*

DEFINITION 5.2. *An (s,k) VPRG is a pseudorandom sequence generator which, for security parameter 1^n, maps a random seed v of length $s(n)$ to an output sequence $a_1,\ldots,a_k$ of length $k=k(n)$ and a verification key* VK *where $s(n)$ and $k(n)$ and the length of* VK *are fixed polynomials. The mapping should satisfy the following requirements:*

- *Verifiability: For any subset $I\subseteq\{1,\ldots,k\}$ of indices, given the seed $v\in\{0,1\}^{s(n)}$ it is possible to construct a proof π of the consistency, with* VK*, of the values of $\{a_i\}_{i\in I}$. We call this a* proof for $\{a_i\}_{i\in I}$*. The construction takes polynomial time and the proof is of polynomial length. Given* VK*, the verifier can check the proof π in polynomial time. The generation of π may be randomized.*
- *Binding: The public verification key* VK *binds the sequence. That is, for each* VK *there is* at most one *associated sequence $a_1,a_2,\ldots,a_k$:*
  1. *This sequence is in the range of the generator on input a seed of length $s(n)$.*
  2. *For all subsets $I\subseteq\{1,\ldots,k\}$, if the verifier accepts a proof π of values $\{b_i\}_{i\in I}$, then there exists a sequence $a_1,\ldots,a_k$ associated with* VK *and $b_i=a_i$ for all $i\in I$. (There can be two different seeds v and v' that yield that same* VK*; in this case they will yield the same $a_1,a_2,\ldots,a_k$.)*
- *Passing the ith bit test: For all $1\le i\le k$ and nonuniform polynomial-time adversaries $\mathcal{T}$ the following holds. Suppose that $\mathcal{T}$ receives for a random $v\in\{0,1\}^{s(n)}$ the verification key* VK *and*

$$a_1,a_2,\ldots,a_{i-1},a_{i+1},\ldots,a_k.$$

The adversary $\mathcal{T}$ selects $I\subset\{1,\ldots,k\}$ such that $i\notin I$ and receives a randomly generated proof π for $\{a_j\}_{j\in I}$. It then attempts to guess a_i. The probability, over the choice of the seed, the random choices in the construction of the proof π, and the random choices by $\mathcal{T}$, that $\mathcal{T}$ guesses a_i correctly is negligibly in n close to $1/2$.

Remark 5.3. Consider a *subset* test, i.e., instead of a single $1\le i\le k$ there is a missing subset of indices and the distinguisher gets the values of $a_{i'}$ at all other locations plus candidate values for the missing locations. It can then ask to see a

proof of consistency for any subset I not including any of the missing indices and then has to guess if the candidate values are correct or just random. This test is equivalent to the ith bit test, just as the distinguishing test and the next bit test are equivalent for regular pseudorandom generators. Note that in the case of VPRF such an equivalence is not clear. The relation between VPRGs and VPRFs is further discussed in sections 5.2 and 9.

We also use a relaxation of VPRGs, which we call $d(n)$-*approximate* VPRGs. The differences are as follows:

- *Relaxed binding:* Intuitively, for any VK, there are at most $d(n)$ values for the revealed string that are accepted as consistent with VK. Rigorously, for each seed v (of length $s(n)$) there are at most $d(n)$ associated sequences of length k, $\mathcal{S}_v = \{\vec{a}_1, \vec{a}_2, \ldots, \vec{a}_{d(n)}\}$ such that for all subsets $I \subseteq \{1, \ldots, k\}$, if the verifier accepts a proof π of values $\{b_i\}_{i \in I}$, then there exists a $1 \leq j \leq d(n)$ such that $\{b_i\}_{i \in I}$ is consistent with $\vec{a}_j$ (same j for all the $i \in I$). In addition, for each "claimed" VK (including those for which there is no corresponding seed) there exists at most one consistent $\mathcal{S}$, and this $\mathcal{S}$ is in fact $\mathcal{S}_v$ for some $v \in \{0,1\}^{s(n)}$.
- *Two-round communication:* The proof of consistency may be "zap-like." On a first round the verifier sends a public-coins message ρ and only then VK and the subset to be proven are chosen. The binding and verifiability conditions hold with high probability over the choice of message of the first round.

Finally, for completeness, we also consider VPRGs in the shared random string model. The binding and verifiability conditions hold with high probability over the choice of the shared string.

5.1. Zaps based on VPRG.

Proofs based on hidden random strings. We find the following "physical" intuition helpful for describing certain types of proofs of membership. The prover is dealt a sequence of ℓ binary cards, where each card has value 1 with probability 1/2. The prover knows the values of the cards and can choose any subset to reveal to the verifier. The verifier learns absolutely nothing about the values of cards that are not explicitly revealed. The prover has no control over the values of the cards. The sequence of cards is a *hidden random string* (HRS).

To prove that $x \in L$, the prover, holding witness $w \in w(x)$, can choose any subset of the hidden bits to reveal to the verifier (cards to turn over). Let α be the locations and values of the revealed bits in the HRS. In addition to α, the prover may send extra information, β, to the verifier. The verifier decides whether to accept or reject x as a function of α, β, and x.

The *soundness* requirement is that for some $q < 1$ such that $1 - q$ is nonnegligible (that is, q is nonnegligibly far from 1), the probability (over the values of the hidden random bits) that the prover can cause the verifier to accept an $x \notin L$ is at most q, even if the prover is arbitrarily powerful. That is, with nonnegligible probability $1 - q$ there is no triple (x, α, β) such that $x \notin L$ and the verifier accepts (x, α, β).

The *witness protection* requirement is that there exist a simulator that on input $x \in L$ (but without a witnesses to $x \in L$),

1. can create (α, β) identically distributed to the (α, β) pairs created in real executions of the proof;
2. given α, β, and *any* witness w^* to $x \in L$, can generate an assignment to the remaining cards so that the distribution on *extended transcripts*, that is, the hidden cards, the revealed cards α, and β, is *identical* to the distribution on

extended transcripts in real executions by a prover holding witness w^*. We call this "completing the simulation with w^*," or "forming a completion with w^*."

Again, α and β are chosen without access to a witness; then, given any witness $w^* \in w(x)$, the simulator can create a completion with w^*, that is, an assignment to all the cards, hidden and exposed, so that the distribution on triples containing α, β, and the values for all the cards is exactly the distribution on these values in real executions with witness w^*.

The concept of an HRS-based proof is exemplified by the noninteractive zero-knowledge proof systems of Feige, Lapidot, and Shamir [27] and of Kilian and Petrank [40]. The idea is to implement the HRS using the output of the VPRG and the opening using the proof capabilities of the VPRG (in contrast to the reliance on the trapdoor properties in [27, 40]). We do not provide new HRS-based proofs in this paper. Our results work with any (existing or future) HRS-based scheme.

Note that although an implementation of an HRS-based proof may be cryptographic, an HRS-based proof is itself a combinatorial, and hence unconditional, object.

Protocol VZ: A VPRG-based zap. The choice of parameters for VPRG-based zaps differs slightly from the choice in the case of NIZK-based zaps. This is because in the case of the VPRG we have less freedom: $k = k(n)$ (the length of ρ) is tied to the parameters of the VPRG.

Choice of parameters. Assume we have an HRS-based proof that for string x and security parameter n polynomially related to $|x|$ uses $\ell(n)$ cards, and on any input x errs with probability at most q. Let $s = s(n)$ be the length of a seed permitting the VPRG to output $k = k(n, |x|)$ bits. To achieve soundness guarantee δ (that is, a cheating prover should succeed with probability at most δ), we require that $k(n, |x|)$ will sufficiently expand the input: it should satisfy

$$q^{k(n,|x|)/\ell(n)} < \frac{\delta}{2^{n+s(n)+\ell(n)}}.$$

The protocol. Let $m = k/\ell$. The HRS proof will be repeated m times. The verifier sends to the prover random bits $\rho = b_1, \ldots, b_k$.

The prover chooses ℓ random bits $C = c_1, \ldots, c_\ell$ and a random seed $v \in \{0,1\}^s$ for the VPRG. Let VK and $a_1, a_2, \ldots, a_k$ be the output of the VPRG on v. The ith bit of the HRS is defined to be

$$a_i \oplus b_i \oplus c_{(i-1 \bmod \ell)+1}.$$

The prover sends to the verifier: VK, $c_1, \ldots, c_\ell$, and m HRS-based proofs that $x \in L$, where the jth proof uses the jth block of ℓ bits of the HRS. For all revealed cards $1 \le i \le k$ the prover provides a_i and a proof π for the consistency of the revealed values.

Let (α_j, β_j) be the values of the revealed cards and additional information in the jth copy of the HRS-based proof, for $j = 1, \ldots, m$. For the revealed cards the verifier, using VK, checks that the value revealed is the correct one. If not, the verifier rejects; otherwise the verifier accepts if and only if, for all m instances of the HRS-based proof, the HRS-based verifier accepts.

LEMMA 5.4. *Protocol VZ is witness-indistinguishable.*

Proof. The proof involves a pair of nested hybrid arguments. The outer hybrid moves from a case in which all copies of the NIZK use one witness (w) to a case in which

all copies use the other witness (w'). Once a distinguishing gap has been identified, the inner hybrid is over proof strings: one extreme has completion γ consistent with w, and the other has completion γ' consistent with w'.

Let w and w' be two witnesses that $x \in L$. Assume there exists a sequence $b_1^*, \ldots, b_k^*$ and a distinguisher $\mathcal{T}$ that, given (x, w, w') and a transcript consisting of $b_1^*, \ldots, b_k^*$ followed by the responses of the m HRS-based proofs of $x \in L$, succeeds with nonnegligible advantage ε to guess which witness, w or w', was used by the prover in generating the response.

By the pigeonhole argument used in hybrid argument, for some $1 \leq j \leq m$ there exists a distinguisher for the following two types of transcripts that distinguishes between them with advantage at least ε/m:

1. The prover uses witness w for the first $j-1$ copies of the HRS-based proof and w' for copies $j \ldots m$.
2. The prover uses witness w for the first j copies of the HRS-based proof and w' for copies $j+1 \ldots m$.

Let us fix such a j for the remainder of the proof.

We first use the simulator, whose existence is guaranteed by the definition of an HRS-based proof, to choose α and β for the jth copy of the HRS-based proof. For a given seed v to the VPRG, for the positions $1 \leq i \leq \ell$ indicated by α, we choose c_i so that the value $a_{(j-1)\ell+i} \oplus b_{(j-1)\ell+i} \oplus c_i$ opened is the value indicated by α.

By the definition of witness-indistinguishability for an HRS-based proof, the simulator, now given w and w', can efficiently find a completion (choices for the unopened values) γ corresponding to the case in which the witness used is w, as well as a completion γ', corresponding to the case in which the witness used is w'. Together with the seed v, the completions γ and γ' determine, respectively, the values of the bits c_i for each position i that is *not* indicated by α. (The values for the positions indicated by α were fixed above and will remain unchanged throughout the rest of the proof.) Let $r = |\gamma| = |\gamma'|$. For $0 \leq d \leq r$, we denote by $c(\gamma, \gamma')_{[d]}$ values for the c not indicated by α that agree with γ in positions $1, \ldots, d$ and agree with γ' in positions $d+1, \ldots, r$. Thus, when $d = 0$ the values all agree with γ', while when $d = r$ the values all agree with γ.

We will now form a hybrid chain on proof strings. In every element in the chain, the seed v remains unchanged, as do the b^* and the values for the c in the positions indicated by α. Only the c not indicated by α will change as we move from one element in the chain to the next. The first element in the chain has values $c(\gamma, \gamma')_{[r]}$ for the c not indicated by α. Thus, these values all agree with γ, where the witness is w. Having fixed all the c for this element of the chain, we can complete the description of the first element of the chain. The first $j-1$ blocks are HRS-based proofs constructed with witness w, and blocks $j+1$ through m are constructed with witness w'. Moreover, by choice of the c, the jth block has been completed with w.

The next element in the chain has values $c(\gamma, \gamma')_{[r-1]}$ for the c not indicated by α. Everything else remains the same: the values for the remaining c that were fixed in the description of the first element in the chain are again used here. Then, having again fixed all the c, the first $j-1$ blocks are HRS-based proofs constructed with witness w, and blocks $j+1$ through m are constructed with witness w'. Note that the jth block might not really be something that could have been generated by the prover, since it is not completely consistent with a proof constructed using either w or w'.

In general, for $0 \leq d \leq r$, the $d+1$th element in the chain has values $c(\gamma, \gamma')_{[r-d]}$ for the c not indicated by α, for $0 \leq d \leq r$. The last element in the chain has values $c(\gamma, \gamma')_{[0]}$, that is, it agrees completely with γ'.

We note that the chain is nonempty, since otherwise the behavior of the prover on witnesses w and w' is identical and therefore yields no possibility of distinguishing between the two witnesses. Thus, the number of steps in the $\gamma \to \gamma'$ hybrid chain is $1 \le r \le \ell$ (including the endpoints, the chain has $r+1$ elements). We assumed an ε/m advantage in distinguishing the two endpoints of the chain, hence there is an $i \le \ell + 1$ where the adversary has advantage at least $\varepsilon/(m\ell)$ to distinguish between the $i-1$ and ith elements in the chain. The pseudorandomness of the VPRG can be broken at this location. The subset I is the one determined by α and the HRS proofs used in the other $m-1$ blocks. □

LEMMA 5.5. *Protocol VZ is sound; moreover, the first round can be fixed nonuniformly.*

Proof. Let $x \notin L$, $c_1, \ldots, c_\ell$, and let the VPRG verification key VK be fixed. We will show that with overwhelming probability, over the choice of $b_1, \ldots, b_k$, the prover will fail to convince the verifier to accept x. The key point is that once everything but the b has been fixed, the hidden random string is truly random—because $b_1, \ldots, b_k$ have not been chosen yet and are to be chosen at random. Therefore each copy of the HRS-based proof has probability at most q of failing to cause rejection. Since each proof is independent (because the b_i used in each copy of the HRS-based proof are independent), the overall probability that all $m = k/\ell$ copies fail is at most q^m.

The number of possible assignments to the c, VK,[4] and $x \notin L$ is at most $2^{\ell+s+|x|}$. Hence, as long as

$$2^{\ell+s+|x|} q^m \le \delta$$

for a *random* $b_1, \ldots, b_k$, the probability that there even exists a "bad" choice of $c_1, \ldots, c_\ell$, VK, and x that erroneously causes the verifier to accept is at most δ. Therefore, not only is the protocol sound, but also the first message (the b) can be fixed nonuniformly. □

THEOREM 5.6. *Given an HRS proof system for a language L using ℓ cards and with probability of error at most q and given a VPRG mapping a seed s to k bits, if*

$$q^{k/\ell} < \frac{\delta}{2^{|x|+s+\ell}},$$

then protocol VZ is a zap for L.

Note that if instead of a VPRG we use a $d(n)$-approximate VPRG, then we can obtain a similar result by adjusting the counting argument to accommodate the $d(n)$ possible openings consistent with VK; see the next corollary.

COROLLARY 5.7. *Given an HRS proof system for L using ℓ cards and with probability of error at most q and given a $d(n)$-approximate VPRG mapping a seed s to k bits, if*

$$q^{k/\ell} < \frac{1}{d(n)} \frac{\delta}{2^{|x|+s+\ell}},$$

then protocol VZ is a zap for L.

As we show next, the converse holds as well and we can use zaps to obtain *approximate* VPRGs.

[4]Note that we should count only the number of seeds $v \in \{0,1\}^s$ and not the various possible public commitment strings, since what matters is the value $a_1, a_2, \ldots, a_k$ of the sequence associated with VK, and this sequence, by Definition 5.2, must correspond to one in the range of the generator on input (seed) of length $s(n)$.

THEOREM 5.8. *Let $\ell(n)$ be any polynomial. Fix $m \geq 2$. Let G be any pseudorandom generator taking a seed of length $s(n)$ and producing an output of length $\ell(n)$. Then, assuming every language $L \in NP$ has a zap, one can construct a $d(n)$-approximate VPRG expanding a seed of length $m \cdot s(n)$ to a string of length $k(n) = m \cdot \ell(n)$, where $d(n) = m2^{\ell(n)}$.*

Note that the expansion is arbitrary, since $\ell(n)$ is an arbitrary polynomial and pseudorandom generators exist for any polynomial expansion, based on any one-way function.

Proof. We use the commitment scheme of [46]. (In this scheme, the receiver sends an initial message, which can be fixed nonuniformly.) The prover commits to m seeds of length $s(n)$; VK is the concatenation of the m commitments. Using the pseudorandom generator, each seed yields a block of length $\ell(n)$, for a total output length of $m \cdot \ell(n)$. For any set I of indices, the prover can reveal the values of the pseudorandom bits $\{a_i\}_{i \in I}$ and can prove using a zap that the revealed bits in at least $m - 1$ of the blocks are consistent with VK. (This is certainly in NP, so it has a zap by assumption.)

Verifiability is immediate from the zap. Relaxed binding is also simple, since given VK, the number of possible strings the prover can convince the verifier to accept is $m2^{\ell(n)} = d(n)$. (The prover has freedom to choose one of m blocks on which he can cheat and which of $2^{\ell(n)}$ values to plug in there.)

It remains to show passing of the ith bit test. Suppose the construction fails this test with some bias δ. We will use the block B containing i to distinguish pairs of the form $(C(v), \tau)$ from $(C(v), G(v))$, where $C(v)$ is a commitment to a seed v of length $s(n)$ and τ is random of length $k(n)$. Given a pair $(C(v), \mu)$, construct a key VK as follows. Choose $m-1$ seeds $v_1, \ldots, v_{m-1}$, and arrange commitments to these seeds and the commitment $C(v)$ so that $C(v)$ is the commitment to the supposed seed for block B. Open the values for all positions other than i, and provide a zap of approximate consistency with VK, using the chosen seeds $v_1, \ldots, v_{m-1}$ as the witnesses to the fact that the revealed bits in at least $m - 1$ of the blocks are consistent with VK.

If μ is pseudorandom with seed v, then by the witness-indistinguishability of the zap, the advantage in guessing the ith bit is close to δ. (The witness-indistinguishability may introduce a negligible error, so we don't get exact advantage δ.) On the other hand, if μ is truly random, then there can be no bias. Therefore we have a distinguisher for $(C(v), \tau)$ from $(C(v), G(v))$. ∎

Remark 5.9. In the case of ordinary pseudorandom generators, it is known that the ability to expand by even one bit can be used to obtain arbitrary expansion. Is the same true of (approximate) verifiable pseudorandom generators? From Corollary 4.4, Theorem 5.10, and Corollary 5.7 we have only a higher threshold: if any *polynomial* expansion is possible (from n to $n^{1+\varepsilon}$ for fixed ε), then we can build zaps and hence arbitrary expansion. See more open problems in section 9.

5.2. Construction of VPRGs. A nontrivial VPRG, with a given desired (polynomial) expansion from seed to output, can be constructed from any VPRF. The idea is simply that a VPRG is a VPRF with a small domain. This is almost true, except for some technical issues, which we describe next.

There is a difference in the binding requirement for a VPRF, according to the definition in [45], and the binding requirement for a VPRG (Definition 5.2): a VPRF allows the total number of "legitimate" functions (accepted by the verifier) to be proportional to the number of public keys, whereas a VPRG counts them according to the seeds. We can take the domain of the VPRG to be any polynomial that we

wish. We therefore take it to be larger than the length of the public key of the VPRF plus the security parameter n. We must ensure that for any public key of the VPRF accepted by the verifier (of both the VPRF and the VPRG), there is a corresponding seed mapping to this public key. We therefore modify the mapping of VPRG seeds to VPRG public keys to allow any public key of the VPRF. Specifically, the new seed is of length n + the maximum of the seed length of the VPRF and the length of the public key of the VPRF. The VPRG is now as follows: If the first n bits are all 0, then map the suffix (or as many bits as the public key needs) to the public key; otherwise operate as in our original VPRG construction. Note that the event that the leading bits are all 0 occurs with negligible probability, so the security of the VPRF is preserved.

However, such a construction is overkill; moreover, the only known constructions we have of VPRFs require specific assumptions such as the strong-RSA assumption [45] or various Diffie–Hellman assumptions for groups with bilinear mappings [44, 16, 17].[5]

The goal of this section is to provide an alternate construction of VPRGs, based on general trapdoor permutations. We do not require the "enhanced" property, as defined in [30]. The construction follows along the lines of the trapdoor-based synthesizer construction of Naor and Reingold [48]. To obtain (nonapproximate) VPRGs we require that the trapdoor permutation be certified (see [6]).

We assume the existence of a family $\mathcal{F}_n$ of certified trapdoor permutations with common domain $\mathcal{D}_n$, together with a hard-core predicate (n is a security parameter). The VPRG output is given as a binary matrix (say, in row-major order). The matrix has r rows and c columns, where $rc = k$. Choose r functions $f_1, \ldots, f_r$ from $\mathcal{F}$ (one for each row) and c random y (one for each column) in the common range of all the trapdoor permutations, $\mathcal{D}_n$. The (i, j) entry of the matrix will be the hard-core predicate of $f_i^{-1}(y_j)$.

Let VK $= f_1, \ldots, f_r, y_1, \ldots, y_c$. To prove the value of the (i, j) entry, reveal $f_i^{-1}(y_j)$. Verification is immediate using VK and the fact that each f_i is a permutation that is easy to compute in the forward direction.

The length of the seed s is $r \log |\mathcal{F}_n| + c \log |\mathcal{D}_n|$. As n is fixed and k grows, the expansion is roughly quadratic. This completes the description of our VPRG construction. The proof that it satisfies the ith bit test closely follows the proof in [48].

An alternative to trapdoor permutations is to use Diffie–Hellman in groups with efficient bilinear mappings where the computational Diffie–Hellman is assumed to be hard [10, 39]. The easiness of the decisional Diffie–Hellman problem in these groups yields a simple method for verification. (These are less stringent requirements than in the existing constructions of VPRFs in [44, 16, 17].)

The standard example of a certifiable trapdoor function is RSA with a *prime* public exponent e satisfying $e > N$. This assures that e and $\phi(N)$ are relatively prime. If we relax the *perfect* binding requirement and instead aim for an approximate VPRG, then we can use certain uncertified trapdoor permutations, as in the next example, which is inspired by Shamir's pseudorandom generator [52].

Consider RSA with small exponent. Choose a random RSA modulus N and $y_1, \ldots, y_c \in Z_{N^*}$. These form the verification key. Associate with the ith row the ith smallest prime. The (i, j)th output bit is the hard-core bit of $y_j^{1/p_i} \bmod N$. The

[5] In light of Corollary 4.4 and Theorem 5.6, we therefore get zaps and NIZKs based on the same assumptions.

possible problem is that p_i may divide $\phi(N)$. In this case y_j may have multiple p_ith roots, possibly with different hard-core bits, and the owner of the generator can cheat. However, even if the key is incorrectly chosen, so that N is *not* a product of two primes, there can be at most $\log N/\log\log N$ such primes, and hence we get *relaxed* binding. (Note that if N is not a product of two primes, then presumably the output sequence is not even close to that of a legal (two prime modulus) output; but this can be resolved by allowing a small probability of any N being chosen, which does not affect the pseudorandomness property.) We can take this into account in setting the parameters.

5.3. Shared string VPRGs and NIZKs.

THEOREM 5.10. *VPRGs in the* shared random string *model exist if and only if NIZKs exist in the shared random string model. Moreover, in the shared random string model NIZKs imply VPRGs of arbitrary expansion.*

Proof sketch. To construct VPRGs from NIZKs in the shared random string model, commit (say, using the protocol of [46], taking the first several bits of the common random string to be the first-round message of the receiver) to the seed of a pseudorandom sequence and use a NIZK to prove that the revealed value is the correct one. For the converse, given a VPRG in the common random string model, construct essentially the NIZK of Feige, Lapidot, and Shamir [27], in which the bits of the hidden random string (see more about them above) are the bits of the VPRG. □

6. Oblivious transfer in the standard model. Although there are many protocols under various assumptions for oblivious transfer, to date no 3-round protocol has been shown secure, without resorting to a random oracle model. We provide a protocol for 1-out-of-2 OT for which we are able to prove that the chooser's privacy is protected by the quadratic residuousity assumption (QRA) [35], and the sender's privacy is protected statistically (that is, with overwhelming probability over choices made by the sender, at most one value is transmitted to the chooser).[6] The protocol is not known to ensure correctness, that is, the sender may choose what to send as a function of the chooser's message.

For simplicity, we describe the protocol for the case in which the sender's two inputs are bits b_0, b_1. The first round of the protocol, described next, can be eliminated if the sender has a public key. In this case, the public key is chosen to be a random first-round message ρ for zaps.

1. If the sender has no public key, then it chooses a first-round message ρ for a zap and sends it to the chooser. (If the sender instead has a public key, then this round is not needed.)
2. Let $i \in \{0,1\}$ be the chooser's input. The chooser chooses a random 2-prime modulus N and two random strings y_0, y_1 in $\mathbb{Z}_N^*$ such that y_{1-i} is a quadratic residue modulo N and y_i is a nonresidue with Jacobi symbol 1. Using ρ, the chooser gives a zap π of the statement: "y_0 is a QR mod N OR y_1 is a QR mod N."
3. The sender verifies the zap (ρ, π) and, if verification fails, the sender aborts. If verification succeeds, the sender chooses $x_0, x_1 \in_R \mathbb{Z}_N^*$ and sends the following two values to the chooser in any order: $\{y_{b_0}^{b_0} x_0^2 \bmod N, y_{b_1}^{b_1} x_1^2 \bmod N\}$.

We now give a proof sketch of correctness of the protocol. Assume first that both parties are following the protocol correctly. Let y_i be the unique quadratic nonresidue modulo N among y_0, y_1. Then $y_i^{b_i} x_i^2$ is a quadratic residue modulo N if and only if

[6] Previous applications of QRA to OT appear, for example, in [12, 41].

$b_i = 0$. On the other hand, since y_{1-i} is a quadratic residue modulo N, so is $y_{1-i}^{b_{1-i}} x_{1-i}^2$, independent of the value of b_{1-i}. Thus, the ability of the chooser to compute quadratic residuousity yields only and exactly the value of b_i.

Now assume the sender follows the protocol correctly but the chooser does not. The soundness of the zap ensures that at least one of y_0, y_1 is a quadratic residue modulo N. Assume then that y_j is a quadratic residue modulo N. Then $y_j^{b_j} x_j^2 \bmod N$ is always a quadratic residue, independent of b_j, and independent of how N is chosen. Thus, the chooser can learn at most one of b_0, b_1. Finally, by the QRA and the way in which a good chooser constructs N, y_0, y_1, the sender cannot distinguish which of y_0, y_1 is the quadratic residue. In particular, the (polynomial-time bounded) sender cannot distinguish among the following four distributions $(N, y_0, y_1, (\rho, \pi))$, where ρ is fixed in step 1, N is chosen according to the protocol, and the other elements are chosen as follows:

1. y_0 is a random quadratic residue modulo N, y_1 is a random nonresidue with Jacobi symbol 1, and y_0 is the witness used in constructing π;
2. y_0 and y_1 are both quadratic residues modulo N and y_0 is the witness used in constructing π;
3. y_0 and y_1 are both quadratic residues modulo N and y_1 is the witness used in constructing π; and
4. y_1 is a random quadratic residue modulo N, y_0 is a random nonresidue with Jacobi symbol 1, and y_1 is the witness used in constructing π.

Distributions 2 and 3 are indistinguishable by the witness-indistinguishability of the zap. Distributions 1 and 2 (and, similarly, distributions 3 and 4) are indistinguishable by the QRA. Thus, distributions 1 and 4 are computationally indistinguishable, so the sender does not learn which of b_0, b_1 has been transferred to the chooser.

Remark 6.1. Naor and Pinkas [47] were able to modify this approach to produce a different protocol with similar security properties; their protocol is based on decisional Diffie–Hellman and does not explicitly use zaps.

7. Timing-based applications. In this section we describe two delay-free timing-based (see section 2.5) applications for zaps:

- 3-round concurrent zero-knowledge proofs of knowledge for any language $L \in$ NP, and
- 2-round deniable authentication.

7.1. 3-round concurrent zero-knowledge proofs of knowledge. At a high level, the protocol consists of two steps. Let $x \in L$ be the statement to be proved. First, the verifier chooses a statement S and proves, using a zap, that S is true. Second, the prover gives a proof of knowledge of a witness to the statement "$x \in L \vee S$." Intuitively, soundness comes from the fact that the verifier's proof does not reveal a witness to S. This is achieved by constructing S to be the logical-OR of two independent statements—in such a case witness-indistinguishability is known to imply witness-hiding [28]. A single preprocessing step is needed for both the proof of knowledge and to provide the first-round ρ for the verifier's zap of S.

In a little more detail, the statement S is a claim that of two given timed commitments to two random strings, at least one is *valid*—forced recovery of the committed value is possible (see the discussion in section 2.5). Verifiable recovery implies the existence of a knowledge extractor. The extractor is used in constructing the simulator for proving zero-knowledge.

Let f be a one-way function. Let $f^{(k)}(s)$ be the kth iterate of f applied to s.

Associated with any randomly chosen s, there is a k-bit pseudorandom string B consisting of the hard-core bits of

$$s, f(s), f^{(2)}(s), \ldots, f^{(k-1)}(s),$$

respectively (this is the Blum–Micali [9] generator). The basic technique for proving knowledge of a witness $w \in w(x)$ is to commit to B^0 and B^1 by giving a pair $f^{(k)}(s^0), f^{(k)}(s^1)$. The verifier then chooses one of the two blocks, say, B^i, to be revealed. The prover releases s^i and gives $w \oplus B^{1-i}$, together with a proof of consistency with the initial commitment $f^{(k)}(s^{1-i})$. Because this gives only a probability $1/2$ of detecting cheating, the process is repeated p many times in parallel. (Choose p, the number of parallel repetitions, according to the required probability of soundness error.) The preprocessing step (step 1 in the protocol) is just the transmission of sufficiently many pairs of the form $f^{(k)}(s^0), f^{(k)}(s^1)$, together with a ρ for the verifier's zap in step 2.

3-*round timed concurrent ZK POK for* $L \in$ NP. Common input $x \in L$, input to prover $w \in w(x)$.

1. (a) Let f be a fixed one-way permutation (f is part of the protocol, known to both parties). The prover sends to the verifier $2p$ pairs $(f^{(k)}(s_1^0), f^{(k)}(s_1^1), \ldots, (f^{(k)}(s_{2p}^0), f^{(k)}(s_{2p}^1)))$ for randomly chosen s_i^j, $i = 1, \ldots, 2p$, and $j = 0, 1$.
   (b) The prover also sends to the verifier ρ, a round-one message for a zap.
2. (a) The verifier selects a random $2p$-bit string $c_1 \ldots c_{2p}$.
   (b) The verifier chooses two random values y_0 and y_1 of length p and constructs from them two commitment strings $\zeta_0 \in_R TC(y_0)$ and $\zeta_1 \in_R TC(y_1)$ using the timed commitment protocol. Using ρ, the verifier sends π, proving that at least one of the ζ_i is valid ((ρ, π) constitutes a zap).
   (c) The verifier sends to the prover a new round-one message ρ'.
3. (a) For each $1 \le i \le p$, the prover sends to the verifier $s_i^{c_i}$. For each such i the prover also computes B_i, the pseudorandom k-bit string consisting of the hard-core bits of
$$s_i^{1-c_i}, f(s_i^{1-c_i}), f^{(2)}(s_i^{1-c_i}), \ldots, f^{(k-1)}(s_i^{1-c_i}).$$
   (b) The prover checks the zap $(\zeta_0, \zeta_1, \rho, \pi)$. If the proof is invalid, the prover terminates the protocol.
   (c) The prover chooses z at random.
   (d) Using $B_1, \ldots, B_p$ the prover commits to z and w. Specifically, it sends $z \oplus B_1, \ldots, z \oplus B_p$; similarly it commits to w, using blocks $B_{p+1} \ldots B_{2p}$. We call the commitments to z the *first group*, and the commitments to w the *second group*. Using ρ', the prover constructs a proof π' that at least one of the following two statements holds: (1) there exists z consistent with all of the commitments in the first group and z is the value committed to in one of the timed commitments ζ_0 or ζ_1; or (2) there exists w consistent with all of the commitments in the second group and $w \in w(x)$. The witness used for constructing the zap is the set of strings $\{s_{p+1}^{1-c_{p+1}}, \ldots, s_{2p}^{1-c_{2p}}\}$.

Timing constraints: V accepts P's round-three message only if it arrives within time α on V's local clock from the time at which V sent its round-two message. α and β (for the timing assumption) should be chosen to satisfy $\alpha \le \beta$ and $2\beta + \gamma < t$, where

the value t is the time below which it is safe to assume that the timed commitment cannot be broken, even by a PRAM, and γ is an upper bound on the time it takes to create a zap by a program that is given a witness. For completeness, α must be sufficiently large to permit the necessary computations by P and the round-trip message delay.

The protocol is concurrent zero-knowledge because it is *straight-line simulatable* via the forced openings: every interaction can be simulated without rewinding the prover [24]. To see this, consider a single interaction. The simulator generates a real round-one message, which is given to the verifier. The verifier constructs its timed commitments and their proof π. The simulator checks π and, if it is correct, continues with the protocol. The clocks are frozen and the simulator computes the forced opening of the timed commitments, obtaining y, the decommitment of one of ζ_0 and ζ_1. The clocks are started again, the simulator sets $z = y$, commits to z and a random string (instead of w), and constructs π' using the commitment to z as the witness. When the adversarial scheduler schedules P's next message, the simulator sends π'.

Now consider four classes of transcripts: they differ according to the value committed to in the first block (random or $z = y$), the value committed to in the second block (w or random), and which witness is used in creating the zap π' (w or z). Only four of the eight possibilities are relevant:

1. First block: random; second block: w; witness is w.
2. First block: $z = y$; second block: random; witness is y.
3. First block: $z = y$; second block: w; witness is w.
4. First block: $z = y$; second block: w; witness is y.

The real transcripts are the first class. The simulator outputs the second class. Classes 1 and 3 are computationally indistinguishable by the one-wayness of f and the properties of hard-core bits. Classes 2 and 4 are indistinguishable for the same reason. Classes 3 and 4 are indistinguishable by the witness-indistinguishability of zaps. Hence, classes 1 and 2 are computationally indistinguishable.

We now argue that the interaction is sound and a proof of knowledge. If the prover completes the proof with probability δ, then standard extraction techniques, i.e., forcing P to explore two computational paths, can be used to obtain a witness (strings $s_i^{1-c_i}$ for the appropriate set of indices i) with probability negligibly close to δ^2.

Suppose $x \notin L$, and that a cheating prover succeeds with nonnegligible probability δ to cause the verifier to accept. Then the timed commitment scheme can be broken with probability negligibly close to $\delta^2/2$, as follows. Consider a (possibly fictitious) nonfaulty process running a perfect clock. By the (α, β) assumption, if V is nonfaulty and measures time at most α on its own clock between the time at which it sent its round-two message and the time at which it received P's round-three reply, at most β real time has elapsed.

Assume we are given a timed commitment $\xi_1 \in_R TC(y)$. Run the cheating prover for one step. Choose $c_1 \dots c_p$ at random. Choose y' and give $\xi_1 \in_R TC(y')$; then, using the witness based on y', act as the verifier and in step 2 give a zap that at least one of ξ_1 and ξ_2 is valid. By definition, such a zap can be constructed within time γ. If the prover responds (which it will do with probability at least δ), repeat steps 2 and 3, using the same timed commitments and zap in step 2, but with a new random string $c'_1, \dots, c'_p$. If the prover responds again, use the revealed $s_{c'_i}$ to obtain at least one of $y, y', w \in w(x)$. Since $x \notin L$, the value obtained is either y or y'. By the witness-indistinguishability of the verifier's zap, the value will be y with probability

1/2. The total time required for extraction is at most $2\beta + \gamma < t$, contradicting the assumption that breaking the timed commitment requires time at least $t < T$. Thus, the system is sound. That the system is a proof of knowledge is immediate from the extraction procedure described above.

THEOREM 7.1. *If TC is a timed commitment protocol satisfying the requirements of section* 2.5*, then the protocol described above is a* 3*-round timed concurrent zero-knowledge proof of knowledge system for any language L in NP.*

Remark 7.2. The straight-line simulability also permits the prover to use differing (α, β) pairs for the different verifiers.

7.2. Timed 2-round deniable authentication. We now describe a 2-round timed concurrent deniable authentication protocol (see section 2.3 for definition and discussion), based on zaps and timed commitments.

The $A\mathcal{P}$ has a public key $\langle E_1, E_2, \rho \rangle$, where E_1 and E_2 are public encryption keys chosen according to a public-key cryptosystem generator that is nonmalleable against chosen-ciphertext attacks in the postprocessing mode, and ρ is a first-round message for a zap.

1. The verifier chooses random strings y_0, y_1, r and sends to the prover $c \in_R E_1(m \circ r)$ and timed commitments $\zeta_0 \in_R TC(y_0)$ and $\zeta_1 \in_R TC(y_1)$. In addition, using ρ, the verifier gives a zap that at least one of the ζ_i is valid. Finally, the verifier also sends to the prover a first-round message ρ' for a zap.
2. The prover checks the zap (ρ, π) and aborts if verification fails. Otherwise, the prover sends to the verifier $\eta \in_R E_1(r)$, $\delta \in_R E_2(s)$ for a randomly chosen s. Using ρ', the prover sends a zap π' that at least one of the following holds: $\eta \in E_1(r)$ or $s \in \{y_0, y_1\}$. (More specifically, π' is a proof that η is an encryption under E_1 of the suffix of the message encrypted by ciphertext c OR δ is an encryption under E_2 of one of the values committed to by ζ_1, ζ_2.) The witness used in creating π' is the set of random bits in creating η or δ. In a regular execution η is used.

V accepts if and only if both (1) the zap (ρ', π') is accepted and (2) P's response is received in a *timely* fashion, as specified in the timing constraints.

Timing constraints. P's round-two message must arrive within time α on V's local clock from the time at which V sent its round-one message. α and β are chosen to satisfy $\alpha \leq \beta$ and $\beta + \gamma < t$, where the value t is the time below which it is safe to assume that the timed commitment cannot be broken, even by a PRAM, and γ is an upper bound on the time it takes to create a zap by a program that is given a witness. For completeness, α must be sufficiently large to permit the necessary computations by P and the round-trip message delay.

This completes the description of the deniable authentication protocol.

THEOREM 7.3. *If TC is a timed commitment protocol satisfying the requirements of section* 2.5*, then the* 2*-round protocol is sound and deniable to a distinguisher that has access to the public key of $A\mathcal{P}$.*

Proof. We first argue unforgeability. Suppose that the adversary is trying to forge message m and is given by the verifier the "challenge" $E(m \circ r)$. Then by the nonmalleability of E_1 it cannot produce $E_1(r)$, even if it has access to a decrypting oracle for E_1 on all messages with prefix different than m.[7] Therefore, given that the

[7] Actually it seems that we do not need E_1 to resist any chosen-ciphertext attacks and it is enough that it is nonmalleable against chosen-plaintext attacks. The reason is that we can give the adversary an encryption of a random string instead of $E_1(r)$ and use the forced opening of the timed commitment to obtain a zap in the second step.

adversary provides a zap at step 2, it must be the case that $s = y_i$ for some $i \in \{0, 1\}$. In this case, the real prover, who knows D_2, and the adversary together can be used to break the timed commitment scheme with probability 1/2: given $TC(y)$, choose y' at random and give $TC(y')$; then, using the witness based on y', give a zap that at least one of $TC(y)$ or $TC(y')$ (in random order) is recoverable. By definition, such a zap can be constructed within time γ. If the forger gives back $s = y$ within time α, then TC has been broken in time at most $\beta + \gamma < T$.

We now argue deniability. The simulator extracts from $TC(y_0)$ and $TC(y_1)$ either y_0 or y_1 (for at least one of them this should be possible). It then creates $\eta = E_1(r')$ for a random r' and creates $\delta = E_2(y_i)$ and uses it as a witness to a zap that $\eta \in E_1(r)$ or $s = y_i$. The proof of indistinguishability of simulated and real transcripts is analogous to the proof of Theorem 7.1 and relies on the indistinguishability of encryptions of E_1 and E_2.

Note that there is no real need to choose E_2 different from E_1. □

The need to add ρ to the public key of the authenticator may increase its size significantly. However, ρ is used only to show the recoverability of TC. If we are equipped with a timed commitment where recoverability is self-evident, then there is no need to have it at all and we can use any public key of a sufficiently strong encryption.

Deniability when the distinguisher has the private keys of $A\mathcal{P}$. We now describe a protocol that is deniable even for a distinguisher who has the private keys of $A\mathcal{P}$, based on the (not deniable) authentication protocol given in [18]. The $A\mathcal{P}$ has a public key $\langle E, \sigma \rangle$, where E is a public encryption key chosen according to a public-key cryptosystem generator that is nonmalleable against chosen-ciphertext attacks in the postprocessing mode, and σ is a random string to be used in a NIZK of a language defined below:

1. The verifier chooses a random string r and sends to the prover $c \in_R E_1(m \circ r)$ and timed commitment $\zeta \in_R TC(r)$. In addition, using σ, the verifier gives a NIZK proof π that ζ is valid and the committed value equals the suffix of the plaintext of c.
2. The prover checks the proof (σ, π) and aborts if verification fails. Otherwise, the prover decrypts c and obtains m and r and sends to the verifier r in the clear (of course only if the decrypted m equals the value it wishes to authenticate).

V accepts if and only if both (1) the received r' equals the value r he selected and (2) P's response is received in a *timely* fashion, as specified in the timing constraints.

Timing constraints. P's round-two message must arrive within time α on V's local clock from the time at which V sent its round-one message. α and β are chosen to satisfy $\alpha \leq \beta$ and $\beta < t$, where the value t is the time below which it is safe to assume that the timed commitment cannot be broken, even by a PRAM. For completeness, α must be sufficiently large to permit the necessary computations by P and the round-trip message delay.

THEOREM 7.4. *If TC is a timed commitment protocol satisfying the requirements of section* 2.5*, then the* 2*-round protocol is sound and deniable to a distinguisher that has access to the public and private keys of $A\mathcal{P}$.*

Proof. Unforgeability follows along the lines of the unforgeability in [18], the zero-knowledge property of (σ, π), and the timing requirements. We now argue deniability. The simulator extracts from $\zeta = TC(r)$ the value r and by the soundness of the NIZK proof system this is the same r as in the ciphertext. It then adds r to the transcript. □

8. Witness protection in the resettable model.

8.1. Resettable witness-indistinguishability. For a formal definition of resettable witness-indistinguishability, see [13]. We will motivate the definition informally by focusing on smart cards. Intuitively, a smart card is loaded with x, $w \in w(x)$, and a seed s for a pseudorandom function, at the time it is created. This seed is the only source of randomness the card has; furthermore, we assume that the card is stateless, i.e., does not change its internal memory between sessions (so it cannot store a counter and use it in conjunction with the seed to define the randomness of the current session). Our interest is in protecting the prover from a verifier V^* that runs the prover many times on the same x, w, s. Let us use the notation $(P(x, w, s), V^*(x, z))$ to denote the transcript of exactly this kind of attack where z is auxiliary information known to V^* (in particular, we may even have $z = w, w'$). Letting $w, w' \in w(x)$, a proof that $x \in L$ is resettable witness-indistinguishable if for all probabilistic polynomial-time T, V^*, and z

$$\left|\Pr_{(V^*,s)}[T(P(x,w,s)V^*(x,z))] - \Pr_{(V^*,s')}[T(P(x,w',s')V^*(x,z))]\right| \leq \nu(n).$$

Every zap for a language $L \in NP$ yields a 2-round resettable witness-indistinguishable proof system for L as follows. On input ρ, the prover computes $R = f_s(x, \rho)$, where f_s is a pseudorandom function with seed s. It then uses the bits R as the random bits in computing the zap response π.

Soundness holds because the round-one message ρ is not needed for *unpredictability*—indeed, soundness holds even if some $\hat{\rho}$ is fixed nonuniformly and before x is chosen. As for witness-indistinguishability, from the WI of the zap it follows that an assumed distinguisher for the resettable system can be used to distinguish the output of the pseudorandom function from truly random, a contradiction.

8.2. Resettable zero-knowledge. We first present our 3-round timing-based rZK protocol for any $L \in NP$ and then compare it to previous results.

Let (E, D) be the encryption and decryption algorithms of a semantically secure against chosen-plaintext attack (CPA) encryption method. The scheme need not be public-key, but there should be a public description pd of the encryption key with the following two properties: (1) it is easy to verify that decryption is unique, that is, given ciphertext c and a public description pd there should be at most one p satisfying $c \in E(p)$; and (2) given pd it is easy to verify that there exists decryption key dk such that given $c \in E(p)$ we have $D_{dk}(c) = p$.

An example of such an encryption scheme can be based on RSA with large public exponent, as in section 5.2. That is, the public key is (e, N), in which the exponent e is prime and sufficiently large (so that e cannot possibly divide $\phi(N)$), $pd = (e, N)$ in this case, and the actual encryption is done using the hard-core predicate of the exponentiation with e function. Alternatively, E could be a pseudorandom permutation cipher, which can be turned into a semantically secure against CPA encryption scheme using random padding, and where pd is a (perfectly binding) commitment to the seed. The fact that E is a permutation assures unique decryption.

For this application, we require that the timed commitment scheme be secure *nonuniformly*, i.e., that there does not exist a PRAM with fixed advice tape that can break the commitment scheme with nonnegligible probability in time less than t. This is one of the cases where security against nonuniform adversaries is used in an essential way.

3-*round timing-based rZK for* $L \in NP$.

1. The prover chooses pd (the public description of the encryption key of E) and a random string ρ and sends both to the verifier.
2. The verifier checks that encryptions under E are uniquely decryptable (as discussed above) and if not, rejects. Assuming E passes the test, the verifier chooses random strings y_0, y_1 and sends to the prover timed commitments $\zeta_0 \in_R TC(y_0), \zeta_1 \in_R TC(y_1)$ and, using ρ, a zap π that at least one of the two timed commitments is valid. The verifier also sends a string ρ' to the prover.
3. The prover checks (π, ρ). If it is accepted, then the prover uses the random bits defined by an application of its pseudorandom function on the message sent by the verifier to generate $a \in_R E(w)$ and $b \in_R E(z)$, where $w \in w(x)$ and z is random. Using ρ' and part of the output of the pseudorandom function the prover also generates a zap π' that $w \in w(x)$ OR $z \in \{y_0, y_1\}$. The witness used consists of the random bits used in generating a. a, b, and π' are sent.

The verifier checks that (ρ', π') is accepted, that b has unique decryption, and that the prover's response was timely, as defined by the timing constraints, accepting if and only if all conditions are satisfied.

Timing constraints. P's round-two message must arrive within time α on V's local clock from the time at which V sent its round-one message. α and β (from the timing assumption) are chosen to satisfy $\alpha \leq \beta$ and $\beta + \gamma < t$, where the value t is the time below which it is safe to assume that the timed commitment cannot be broken, even by a PRAM, and γ is an upper bound on the time it takes to create a zap by a program that is given a witness. For completeness, α must be sufficiently large to permit the necessary computations by P and the round-trip message delay.

Note that the only party that has to measure time is V, which is considered more resourceful than the prover (who may be a smart card with no independent clock) in the resettable setting.

THEOREM 8.1. *If TC is a timed commitment protocol satisfying the requirements of section* 2.5*, then for any $L \in NP$ the above protocol is rZK.*

Proof. A straight-line simulator can be constructed in a similar fashion to the construction in the proof of Theorem 7.1, thus settling the zero-knowledge issue. For soundness we use the *existence* of a decryption algorithm D with decryption key dk. If the protocol is not sound, then this key can be used to break the timed commitment in exactly the same way as the proof of knowledge was used in the proof of Theorem 7.1, violating the assumed nonuniform security of the timed commitment.

The properties of the encryption and decryption algorithms (E, D) assure us that given pd a decryption key dk exists (or the verifier will reject in step 2). Suppose now that there is a soundness adversary, succeeding on infinitely many sizes to make the verifier accept nontrue statements. For each such size we can have a slightly different prover, one that sends for size n the same key pd_n, the key that maximizes his chance of proving a false statement. This prover has at least as high a chance of proving false statements than the original adversary. Let dk_n be the decryption key of pd_n. Since the zaps generally prove true statements, the prover's chance of giving a false proof is only if $b \in_R E(z)$ (uniquely) corresponds to a $z \in \{y_0, y_1\}$. Given dk_n as the advice for size n, it is possible to obtain $z \in \{y_0, y_1\}$ and guess the value of the timed commitments. So the nonuniform advice for breaking the timed commitments is d_n, contradicting the assumption that it is secure against nonuniform adversaries.

We therefore have a nonconstructive reduction: given an algorithm for providing false proofs for L we know that there exists an algorithm for breaking the timed commitment; however, the reduction does not yield an effective method for the conversion (since there is no effective way of finding dk).

Note that a proof of security which does not yield an effective procedure to break the underlying assumptions is rare. □

9. Open questions. One vein of open problems induced by this work is with respect to the new primitive VPRG: can VPRGs be composed "á la GGM," as can ordinary pseudorandom generators? This is related to the issue of constructing VPRGs with better expansion as well as to the question whether there is a general construction of VPRFs from VPRGs. A different issue is whether VPRGs can be based on an assumption weaker than trapdoor permutations. For example, is it possible to base VPRGs on the Diffie–Hellman assumption (either computational or the decisional version, for groups without a bilinear mapping)?

What is the relationship between NIZKs in the public parameters model and NIZKs in the public random string model? The answer to this will clarify the relationship between VPRGs and NIZKs in the public parameters model.

A second vein of questions deals with efficiency and practicality. We have used general NIZKs; thus any proof must go through a reduction to an NP-complete problem. It would be useful to have more efficient, special-purpose zaps, for instance, a zap that one of x and y is a quadratic residue modulo N. Another concrete question regarding zaps is to construct one in conjunction with a timed commitment, so that it will be simple to prove consistency.

A third vein of questions deals with round efficiency: in which cases are our protocols round-optimal? It is not hard to argue that 2-round (non-black-box) zero-knowledge proofs *of knowledge* are impossible, even using timing. It is also known that, assuming $P \neq NP$, there is no 2-round proof system *with perfect completeness* for NP-hard languages either with [34] or without [2] auxiliary input. As mentioned earlier, 2-round and 1-round argument systems do exist under nonstandard assumptions [24, 4].

Acknowledgment. We thank the anonymous referees for their zealous reading of the paper and helpful suggestions.

COMPLEXITY OF SELF-ASSEMBLED SHAPES*

DAVID SOLOVEICHIK† AND ERIK WINFREE†

Abstract. The connection between self-assembly and computation suggests that a shape can be considered the output of a self-assembly "program," a set of tiles that fit together to create a shape. It seems plausible that the size of the smallest self-assembly program that builds a shape and the shape's descriptional (Kolmogorov) complexity should be related. We show that when using a notion of a shape that is independent of scale, this is indeed so: in the tile assembly model, the minimal number of distinct tile types necessary to self-assemble a shape, at some scale, can be bounded both above and below in terms of the shape's Kolmogorov complexity. As part of the proof, we develop a universal constructor for this model of self-assembly that can execute an arbitrary Turing machine program specifying how to grow a shape. Our result implies, somewhat counterintuitively, that self-assembly of a scaled-up version of a shape often requires fewer tile types. Furthermore, the independence of scale in self-assembly theory appears to play the same crucial role as the independence of running time in the theory of computability. This leads to an elegant formulation of languages of shapes generated by self-assembly. Considering functions from bit strings to shapes, we show that the running-time complexity, with respect to Turing machines, is polynomially equivalent to the scale complexity of the same function implemented via self-assembly by a finite set of tile types. Our results also hold for shapes defined by Wang tiling—where there is no sense of a self-assembly process—except that here time complexity must be measured with respect to nondeterministic Turing machines.

Key words. Kolmogorov complexity, scaled shapes, self-assembly, Wang tiles, universal constructor

1. Introduction.

Self-assembly is the process by which an organized structure can spontaneously form from simple parts. The tile assembly model [22, 21], based on Wang tiling [20], formalizes the two-dimensional self-assembly of square units called "tiles" using a physically plausible abstraction of crystal growth. In this model, a new tile can adsorb to a growing complex if it binds strongly enough. Each of the four sides of a tile has an associated bond type that interacts with a certain strength with matching sides of other tiles. The process of self-assembly is initiated by a single seed tile and proceeds via the sequential addition of new tiles. Confirming the physical plausibility and relevance of the abstraction, simple self-assembling systems of tiles have been built out of certain types of DNA molecules [23, 15, 14, 12, 10]. The possibility of using self-assembly for nanofabrication of complex components such as circuits has been suggested as a promising application [6].

The view that the "shape" of a self-assembled complex can be considered the output of a computational process [2] has inspired recent interest [11, 1, 3, 9, 4]. While it was shown through specific examples that self-assembly can be used to construct interesting shapes and patterns, it was not known in general which shapes could be self-assembled from a small number of tile types. Understanding the complexity of

†California Institute of Technology, Pasadena, CA 91125 (dsolov@caltech.edu, winfree@caltech.edu).

shapes is facilitated by an appropriate definition of shape. In our model, a tile system generates a particular shape if it produces any scaled version of that shape (section 3). This definition may be thought to formalize the idea that a structure can be made up of arbitrarily small pieces, but more importantly this leads to an elegant theory that is impossible to achieve without ignoring scale. Computationally, it is analogous to disregarding computation time and is thus more appropriate as a notion of output of a *universal* computation process.[1] Using this definition of shape, we show (section 4) that for any shape $\tilde{S}$, if $K_{sa}(\tilde{S})$ is the minimal number of distinct tile types necessary to self-assemble it, then $K_{sa}(\tilde{S}) \log K_{sa}(\tilde{S})$ is within multiplicative and additive constants (independent of $\tilde{S}$) of the shape's Kolmogorov complexity. This theorem is proved by developing a universal constructor [19] for self-assembly which uses a program that outputs a fixed size shape as a list of locations to make a scaled version of the shape (section 5). This construction, together with a new proof technique for showing that a tile set produces a unique assembly (*local determinism*), might be of independent interest. Our result ties the computation of a shape and its self-assembly and, somewhat counterintuitively, implies that it may often require fewer tile types to self-assemble a larger instance of a shape than a smaller instance thereof. Another consequence of the theorem is that the minimal number of tile types necessary to self-assemble an arbitrary scaling of a shape is uncomputable. Answering the same question about shapes of a fixed size is computable but NP-complete [1].

The tight correspondence between computation (ignoring time) and self-assembly (ignoring scale) suggests that complexity measures based on time (for computation) and on scale (for self-assembly) could also be related. To establish this result, we consider "programmable" tile sets that will grow a particular member of a family of shapes, dependent upon input information present in an initial seed assembly. We show that, as a function of the length of the input information, the number of tiles present in the shape (a measure of its scale) is polynomially related to the time required for a Turing machine (TM) to produce a representation of the same shape. Furthermore, we discuss the relationship between complexities for Wang tilings (in which the existence of a tiling rather than its creation by self-assembly is of relevance) and for self-assembly, and we show that while the Kolmogorov complexity is unchanged, the scale complexity for Wang tilings is polynomially related to the time for *nondeterministic* TMs. These results are presented in section 6.

2. The tile assembly model. We present a description of the tile assembly model based on Rothemund and Winfree [11] and Rothemund [9]. We will be working on a $\mathbb{Z} \times \mathbb{Z}$ grid of unit square locations. The *directions* $\mathcal{D} = \{N, E, S, W\}$ are used to indicate relative positions in the grid. Formally, they are functions $\mathbb{Z} \times \mathbb{Z} \to \mathbb{Z} \times \mathbb{Z}$: $N(i, j) = (i, j + 1)$, $E(i, j) = (i + 1, j)$, $S(i, j) = (i, j - 1)$, and $W(i, j) = (i - 1, j)$. The inverse directions are defined naturally: $N^{-1}(i, j) = S(i, j)$, etc. Let Σ be a set of *bond types*. A *tile type* t is a 4-tuple $(\sigma_N, \sigma_E, \sigma_S, \sigma_W) \in \Sigma^4$ indicating the associated bond types on the north, east, south, and west sides. Note that tile types are oriented; thus a rotated version of a tile type is considered to be a different tile type. A special bond type *null* represents the lack of an interaction, and the

[1] The production of a shape of a fixed size cannot be considered the output of a universal computation process. Whether a universal process will output a given shape is an undecidable question, whereas this can be determined by exhaustive enumeration in the tile assembly model. Thus it is clear that the connection between Kolmogorov complexity and the number of tile types we obtain in our main result (section 4) cannot be achieved for fixed-scale shapes: this would violate the uncomputability of Kolmogorov complexity.

special tile type $empty = (null, null, null, null)$ represents an empty space. If T is a set of tile types, a *tile* is a pair $(t, (i, j)) \in T \times \mathbb{Z}^2$ indicating that location (i, j) contains the tile type t. Given the tile $t = (t, (i, j))$, $type(t) = t$ and $pos(t) = (i, j)$. Further, $bond_D(t)$, where $D \in \mathcal{D}$, is the bond type of the respective side of t, and $bond_D(t) = bond_D(type(t))$. A *configuration* is a set of non*empty* tiles, with types from T, such that there is no more than one tile in every location $(i, j) \in \mathbb{Z} \times \mathbb{Z}$. For any configuration A, we write $A(i, j)$ to indicate the tile at location (i, j) or the tile $(empty, (i, j))$ if there is no tile in A at this location.

A *strength function* $g : \Sigma \times \Sigma \to \mathbb{Z}$, where $null \in \Sigma$, defines the interactions between adjacent tiles: we say that a tile t_1 interacts with its neighbor t_2 with strength $\Gamma(t_1, t_2) = g(\sigma, \sigma')$, where σ is the bond type of tile t_1 that is adjacent to the bond type σ' of tile t_2.[2] The *null* bond has a zero interaction strength (i.e., $\forall \sigma \in \Sigma$, $g(null, \sigma) = 0$). We say that a strength function is *diagonal* if it is nonzero only for $g(\sigma, \sigma')$ such that $\sigma = \sigma'$. Unless otherwise noted, a tile system is assumed to have a diagonal strength function. Our constructions use diagonal strength functions with the range $\{0, 1, 2\}$. We say that a bond type σ has *strength* $g(\sigma, \sigma)$. Two tiles are *bonded* if they interact with a positive strength. For a configuration A, we use the notation $\Gamma^A_D(t) = \Gamma(t, A(D(pos(t))))$.[3] For $L \subseteq \mathcal{D}$ we define $\Gamma^A_L(t) = \sum_{D \in L} \Gamma^A_D(t)$.

A *tile system* $\mathbf{T}$ is a quadruple (T, t_s, g, τ) where T is a finite set of nonempty tile types, t_s is a special *seed tile*[4] with $type(t_s) \in T$, g is a strength function, and τ is the threshold parameter. Self-assembly is defined by a relation between configurations. Suppose A and B are two configurations, and t is a tile such that $A = B$ except at $pos(t)$ and $A(pos(t)) = null$ but $B(pos(t)) = t$. Then we write $A \to_{\mathbf{T}} B$ if $\Gamma^A_{\mathcal{D}}(t) \geq \tau$. This means that a tile can be added to a configuration if and only if the sum of its interaction strengths with its neighbors reaches or exceeds τ. The relation $\to^*_{\mathbf{T}}$ is the reflexive transitive closure of $\to_{\mathbf{T}}$.

Whereas a configuration can be any arrangement of tiles (not necessarily connected), we are interested in the subclass of configurations that can result from a self-assembly process. Formally, the tile system and the relation $\to^*_{\mathbf{T}}$ define the partially ordered set of *assemblies*, $Prod(\mathbf{T}) = \{A \text{ such that (s.t.) } \{t_s\} \to^*_{\mathbf{T}} A\}$, and the set of *terminal assemblies*, $Term(\mathbf{T}) = \{A \in Prod(\mathbf{T}) \text{ and } \nexists B \neq A \text{ s.t. } A \to^*_{\mathbf{T}} B\}$. A tile system $\mathbf{T}$ *uniquely produces* A if $\forall B \in Prod(\mathbf{T})$, $B \to^*_{\mathbf{T}} A$ (which implies $Term(\mathbf{T}) = \{A\}$).

An *assembly sequence* $\vec{A}$ of $\mathbf{T}$ is a sequence of pairs (A_n, t_n), where $A_0 = \{t_0\} = \{t_s\}$ and $A_{n-1} \to_{\mathbf{T}} A_n = A_{n-1} \cup \{t_n\}$. Here we will exclusively consider finite assembly sequences. If a finite assembly sequence $\vec{A}$ is implicit, A indicates the last assembly in the sequence.

The tile systems used in our constructions have $\tau = 2$ with the strength function ranging over $\{0, 1, 2\}$. It is known that $\tau = 1$ systems with strength function ranging over $\{0, 1\}$ are rather limited [11, 9]. In our drawings, the bond type σ may be

[2] More formally,

$$\Gamma(t_1, t_2) = \begin{cases} g(bond_{D^{-1}}(t_1), bond_D(t_2)) \text{ if } \exists D \in \mathcal{D} \text{ s.t. } pos(t_1) = D(pos(t_2)), \\ 0 \text{ otherwise.} \end{cases}$$

[3] Note that $t \neq A(pos(t))$ is a valid choice. In that case $\Gamma^A_D(t)$ tells us how t would bind if it were in A.

[4] While having a single seed tile is appropriate to the complexity discussion of the main part of this paper, it is useful to consider whole *seed assemblies* (made up of tiles not necessarily in T) when considering tile systems capable of producing multiple shapes (section 6.5).

illustrated by a combination of shading, various graphics, and symbols. Strength-2 bond types will always contain two dots in their representation. All markings must match for two bond types to be considered identical. For example, the north bond type of the following tile has strength 2, and the others have strength 1.

The constructions in this paper do not use strength-0 bond types (other than in *empty* tiles); thus, there is no confusion between strength-1 and strength-0 bond types. Strength-0 interactions due to mismatches between adjacent tiles do occur in our constructions.

2.1. Guaranteeing unique production. When describing tile systems that produce a desired assembly, we would like an easy method for showing that this assembly is uniquely produced. While it might be easy to find an assembly sequence that leads to a particular assembly, there might be many other assembly sequences that lead elsewhere. Here we present a property of an assembly sequence that guarantees that the assembly it produces is indeed the uniquely produced assembly of the tile system.

Rothemund [9] describes the deterministic-RC property of an assembly that guarantees its unique production and is very easy to check. However, this property is satisfied only by convex (in the sense of polyaminos) assemblies and thus cannot be directly invoked when making arbitrary shapes.[5] A more general poly-time test for unique production was also shown by Rothemund [9], but it can be difficult to prove that a particular assembly would satisfy this test. On the other hand, the notion of locally deterministic assembly sequences introduced here is easily checkable and sufficient for the constructions in this paper.

DEFINITION 2.1. *For an assembly sequence $\vec{A}$ we define the following sets of directions for $\forall i, j \in \mathbb{Z}$, letting $t = A(i, j)$:*

- $inputsides^{\vec{A}}(t) = \{D \in \mathcal{D} \text{ s.t. } t = t_n \text{ and } \Gamma_D^{A_n}(t_n) > 0\}$,
- $propsides^{\vec{A}}(t) = \{D \in \mathcal{D} \text{ s.t. } D^{-1} \in inputsides^{\vec{A}}(A(D(pos(t))))\}$, *and*
- $termsides^{\vec{A}}(t) = \mathcal{D} - inputsides^{\vec{A}}(t) - propsides^{\vec{A}}(t)$.

Intuitively, *inputsides* are the sides with which the tile initially binds in the process of self-assembly; these sides determine its identity. *propsides* propagate information by being the sides to which neighboring tiles bind. *termsides* are sides that do neither. Note that by definition *empty* tiles have four *termsides*.

DEFINITION 2.2. *A finite assembly sequence $\vec{A}$ of $\mathbf{T} = (T, t_s, g, \tau)$ is called* locally deterministic *if $\forall i, j \in \mathbb{Z}$, letting $t = A(i, j)$,*

(1) $\Gamma^A_{inputsides^{\vec{A}}(t)}(t) \leq \tau$, *and*

(2) $\forall t'$ *s.t.* $type(t') \in T$, $pos(t') = pos(t)$ *but* $type(t') \neq type(t)$,

$$\Gamma^A_{\mathcal{D}-propsides^{\vec{A}}(t)}(t') < \tau.$$

We allow the possibility of $<$ in property (1) in order to account for the seed and *empty* tiles. Intuitively, the first property says that when a new tile binds to

[5] Additionally, assemblies satisfying the deterministic-RC property must have no strength-0 interactions between neighboring nonempty tiles. However, such interactions are used in our construction.

a growing assembly, it binds "just barely." The second property says that nothing can grow from nonpropagating sides except "as desired." We say that $\mathbf{T}$ is locally deterministic if there exists a locally deterministic assembly sequence for it.

It is clear that if $\vec{A}$ is a locally deterministic assembly sequence of $\mathbf{T}$, then $A \in Term(\mathbf{T})$. Otherwise, the *empty* tile in the position where a new (nonempty) tile can be added to A would violate the second property. However, the existence of a locally deterministic assembly sequence leads to the following much stronger conclusion.

THEOREM 2.3. *If there exists a locally deterministic assembly sequence $\vec{A}$ of $\mathbf{T}$, then $\mathbf{T}$ uniquely produces A.*

Proof. See Appendix A. □

3. Arbitrarily scaled shapes and their complexity. In this section, we introduce the model for the output of the self-assembly process used in this paper. Let S be a finite set of locations on $\mathbb{Z} \times \mathbb{Z}$. The adjacency graph $G(S)$ is the graph on S defined by the adjacency relation where two locations are considered adjacent if they are directly north/south or east/west of one another. We say that S is a *coordinated shape* if $G(S)$ is connected.[6] The *coordinated shape of assembly* A is the set $S_A = \{pos(t) \text{ s.t. } t \in A\}$. Note that S_A is a coordinated shape because A constitutes a single connected component.

For any set of locations S, and any $c \in \mathbb{Z}^+$, we define a *c-scaling of* S as

$$S^c = \{(i, j) \text{ s.t. } (\lfloor i/c \rfloor, \lfloor j/c \rfloor) \in S\}.$$

Geometrically, this represents a "magnification" of S by a factor c. Note that a scaling of a coordinated shape is itself a coordinated shape: every node of $G(S)$ gets mapped to a c^2-node connected subgraph of $G(S^c)$, and the relative connectivity of the subgraphs is the same as the connectivity of the nodes of $G(S)$. A parallel argument shows that if S^c is a coordinated shape, then so is S. We say that coordinated shapes S_1 and S_2 are *scale-equivalent* if $S_1^c = S_2^d$ for some $c, d \in \mathbb{Z}^+$. Two coordinated shapes are *translation-equivalent* if they can be made identical by translation. We write $S_1 \cong S_2$ if S_1^c is translation-equivalent to S_2^d for some $c, d \in \mathbb{Z}^+$. Scale-equivalence, translation-equivalence, and $\cong$ are equivalence relations (see Appendix B). This defines the equivalence classes of coordinated shapes under $\cong$. The equivalence class containing S is denoted $\tilde{S}$ and we refer to it as the *shape* $\tilde{S}$. We say that $\tilde{S}$ is the *shape of assembly* A if $S_A \in \tilde{S}$. The view of computation performed by the self-assembly process espoused here is the production of a shape as the "output" of the self-assembly process, with the understanding that the scale of the shape is irrelevant. Physically, this view may be appropriate to the extent that a physical object can be constructed from arbitrarily small pieces. However, the primary reason for this view is that there does not seem to be a comprehensive theory of complexity of coordinated shapes akin to the theory we develop here for shapes ignoring scale.

Having defined the notion of shapes, we turn to their descriptional complexity. As usual, the Kolmogorov complexity of a binary string x with respect to a universal TM U is $K_U(x) = \min\{|p| \text{ s.t. } U(p) = x\}$. (See the exposition of Li and Vitanyi [13] for an in-depth discussion of Kolmogorov complexity.) Let us fix some "standard" universal machine U. We call the Kolmogorov complexity of a coordinated shape S

[6] We say "coordinated" to make explicit that a fixed coordinate system is used. We reserve the unqualified term "shape" for when we ignore scale and translation.

to be the size of the smallest program outputting it as a list of locations:[7,8]

$$K(S) = \min\{|s| \text{ s.t. } U(s) = \langle S\rangle\}.$$

The Kolmogorov complexity of a shape $\tilde{S}$ is

$$K(\tilde{S}) = \min\left\{|s| \text{ s.t. } U(s) = \langle S\rangle \text{ for some } S \in \tilde{S}\right\}.$$

We define the *tile-complexity* of a coordinated shape S and shape $\tilde{S}$, respectively, as

$$K_{sa}(S) = \min\left\{\begin{array}{l} n \text{ s.t. } \exists \text{ a tile system } \mathbf{T} \text{ of } n \text{ tile types that uniquely produces} \\ \text{assembly } A \text{ and } S \text{ is the coordinated shape of } A \end{array}\right\},$$

$$K_{sa}(\tilde{S}) = \min\left\{\begin{array}{l} n \text{ s.t. } \exists \text{ a tile system } \mathbf{T} \text{ of } n \text{ tile types that uniquely produces} \\ \text{assembly } A \text{ and } \tilde{S} \text{ is the shape of } A \end{array}\right\}.$$

4. Relating tile-complexity and Kolmogorov complexity. The essential result of this paper is the description of the relationship between the Kolmogorov complexity of any shape and the number of tile types necessary to self-assemble it.

THEOREM 4.1. *There exist constants a_0, b_0, a_1, b_1 such that for any shape $\tilde{S}$,*

$$a_0 K(\tilde{S}) + b_0 \leq K_{sa}(\tilde{S}) \log K_{sa}(\tilde{S}) \leq a_1 K(\tilde{S}) + b_1. \tag{4.1}$$

Note that since any tile system of n tile types can be described by $O(n \log n)$ bits, the theorem implies that there is a way to construct a tiling system such that asymptotically at least a constant fraction of these bits is used to "describe" the shape rather than any other aspect of the tiling system.

Proof of Theorem 4.1. To see that $a_0 K(\tilde{S}) + b_0 \leq K_{sa}(\tilde{S}) \log K_{sa}(\tilde{S})$, realize that there exists a constant size program p_{sa} that, given a binary description of a tile system, simulates its self-assembly, making arbitrary choices where multiple tile additions are possible. If the self-assembly process terminates, p_{sa} outputs the coordinated shape of the terminal assembly as the binary encoding of the list of locations in it. Any tile system $\mathbf{T}$ of n tile types with any diagonal strength function and any threshold τ can be represented[9] by a string $d_{\mathbf{T}}$ of $4n\lceil \log 4n\rceil + 16n$ bits: for each tile type, the first of which is assumed to be the seed, specify the bond types on its four sides. There are no more than $4n$ bond types. In addition, for each tile type t specify for which of the 16 subsets $L \subseteq \mathcal{D}$, $\sum_{D\in L} g(bond_D(t)) \geq \tau$. If $\mathbf{T}$ is a tile system uniquely producing an assembly that has shape $\tilde{S}$, then $K(\tilde{S}) \leq |p_{sa} d_{\mathbf{T}}|$. The left inequality in (4.1) follows with the multiplicative constant $a_0 = 1/4 - \varepsilon$ for arbitrary $\varepsilon > 0$.

We prove the right inequality in (4.1) by developing a construction (section 5) showing how, for any program s s.t. $U(s) = \langle S\rangle$, we can build a tile system $\mathbf{T}$ of

[7] Note that $K(S)$ is within an additive constant of $K_U(x)$ where x is some other effective description of S, such as a computable characteristic function or a matrix. Since our results are asymptotic, they are independent of the specific representation choice. One might also consider invoking a two-dimensional computing machine, but it is not fundamentally different for the same reason.

[8] Notation $\langle\cdot\rangle$ indicates some standard binary encoding of the object(s) in the brackets. In the case of coordinated shapes, it means an explicit binary encoding of the set of locations. Integers, tuples, or other data structures are similarly given simple explicit encodings.

[9] Note that this representation could also be used in the case that negative bond strengths are allowed so long as the strength function is diagonal.

$15\frac{|p|}{\log|p|} + b$ tile types, where b is a constant and p is a string consisting of a fixed program p_{sb} and s (i.e., $|p| = |p_{sb}| + |s|$), that uniquely produces an assembly whose shape is $\tilde{S}$. Program p_{sb} and constant b are both independent of S. The right inequality in (4.1) follows with the multiplicative constant $a_1 = 15 + \varepsilon$ for arbitrary $\varepsilon > 0$. □

Our result can be used to show that the tile-complexity of shapes is uncomputable.

COROLLARY 4.2. *K_{sa} of shapes is uncomputable. In other words, the following language is undecidable: $\tilde{L} = \{(l, n)$ s.t. $l = \langle S\rangle$ for some S and $K_{sa}(\tilde{S}) \leq n\}$.*

Language $\tilde{L}$ should be contrasted with $L = \{(l, n)$ s.t. $l = \langle S\rangle$ and $K_{sa}(S) \leq n\}$ which is decidable (but hard to compute in the sense of NP-completeness [1]).

Proof of Corollary 4.2. We essentially parallel the proof that Kolmogorov complexity is uncomputable. If $\tilde{L}$ were decidable, then we could make a program that computes $K_{sa}(\tilde{S})$ and subsequently uses Theorem 4.1 to compute an effective lower bound for $K(\tilde{S})$. Then we can construct a program p that, given n, outputs some coordinated shape S (as a list of locations) such that $K(\tilde{S}) \geq n$ by enumerating shapes and testing with the lower bound, which we know must eventually exceed n. But this results in a contradiction since $p\langle n\rangle$ is a program outputting $S \in \tilde{S}$ and so $K(\tilde{S}) \leq |p| + \lceil \log n\rceil$. But for large enough n, $|p| + \lceil \log n\rceil < n$. □

5. The programmable block construction.

5.1. Overview. The uniquely produced terminal assembly A of our tile system logically will consist of square "blocks" of $c \times c$ tiles. There will be one block for each location in S. Consider the coordinated shape in Figure 5.1(a). An example assembly A is graphically represented in Figure 5.1(b), where each square represents a block containing c^2 tiles. Self-assembly initiates in the *seed block*, which contains the seed tile, and proceeds according to the arrows illustrated between blocks. Thus if there is an arrow from one block to another, it indicates that the growth of the second block (a *growth block*) is initiated from the first. A terminated arrow indicates that the block does not initiate the self-assembly of an adjacent block in that direction—in fact, the boundary between such blocks consists of strength-0 interactions (i.e., mismatches). Figure 5.1(c) describes our nomenclature: an arrow comes into a block on its input side, arrows exit on propagating output sides, and terminated arrows indicate terminating output sides. The seed block has four output sides, which can be either propagating or terminating. Each growth block has one input and three output sides, which are also either propagating or terminating. The overall pattern of bonding of the finished target assembly A is as follows. Tiles on terminal output sides are not bound to the tiles on the adjacent terminal output side (i.e., there is no bonding along the dotted lines in Figure 5.8(a)), but all other neighboring tiles are bound. We will program the growth such that terminating output sides abut only other terminating output sides or *empty* tiles, and input sides exclusively abut propagating output sides, and vice versa.

The input/output connections of the blocks form a spanning tree rooted at the seed block. During the progress of the self-assembly of the seed block, a computational process determines the input/output relationships of the rest of the blocks in the assembly. This information is propagated from block to block during self-assembly (along the arrows in Figure 5.1(b)) and describes the shape of the assembly. By following the instructions each growth block receives in its input, the block decides where to start the growth of the next block and what information to pass to it in turn. The scaling factor c is set by the size of the seed block. The computation in

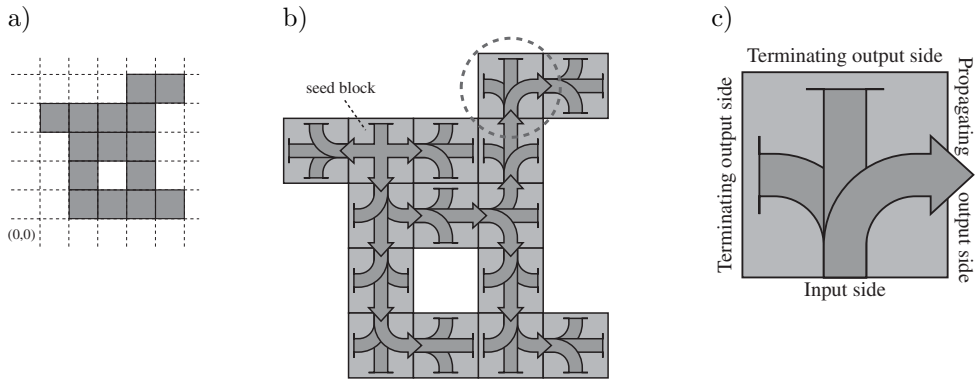

FIG. 5.1. *Forming a shape out of blocks:* (a) *A coordinated shape S.* (b) *An assembly composed of $c \times c$ blocks that grow according to transmitted instructions such that the shape of the final assembly is $\tilde{S}$ (not drawn to scale). Arrows indicate information flow and order of assembly. The seed block and the circled growth block are schematically expanded in Figure* 5.2. (c) *The nomenclature describing the types of block sides.*

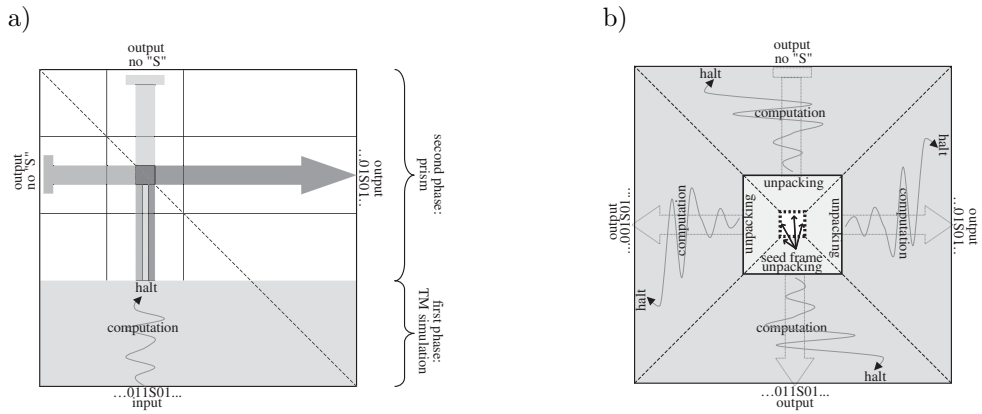

FIG. 5.2. *Internal structure of a growth block* (a) *and seed block* (b).

the seed block ensures that c is large enough so that there is enough space to do the necessary computation within the other blocks.

We present a general construction that represents a Turing-universal way of guiding large-scale self-assembly of blocks based on an input program p. In the following section, we describe the architecture of seed and growth blocks on which arbitrary programs can be executed. In section 5.3 we describe how program p can be encoded using few tile types. In section 5.4 we discuss the programming of p that is required to grow the blocks in the form of a specific shape and bound the scaling factor c. In section 5.5 we demonstrate that the target assembly A is *uniquely* produced.

5.2. Architecture of the blocks.

5.2.1. Growth blocks. There are four types of growth blocks depending upon where the input side is, which will be labeled by $\uparrow$, $\rightarrow$, $\downarrow$, or $\leftarrow$. The internal structure of a $\uparrow$ growth block is schematically illustrated in Figure 5.2(a). The other three types of growth block are rotated versions of the $\uparrow$ block. The specific tile types used for a

↑ growth block are shown in Figure 5.3, and a simple example is presented in Figure 5.4. The first part is a TM simulation, which is based on [18, 11]. The machine simulated is a universal TM that takes its input from the propagating output side of the previous block. This TM has an output alphabet $\{0, 1, S\}^3$ and an input alphabet $\{(000), (111)\}$ on a two-way tape (with λ used as the blank symbol). The output of the simulation, as 3-tuples, is propagated until the diagonal. The diagonal propagates each member of the 3-tuples crossing it to one of the three output sides, like a prism separating the colors of the spectrum. This allows the single TM simulation to produce three separate strings targeted for the three output sides. The "S" symbol in the output of the TM simulation is propagated like the other symbols. However, it acts in a special way when it crosses the boundary tiles at the three output sides of the block, where it starts a new block. The output sides that receive the "S" symbol become propagating output sides, and the output sides that do not receive it become terminating output sides. In this way, the TM simulation decides which among the three output sides will become propagating output sides, and what information they should contain, by outputting appropriate tuples. Subsequent blocks will use this information as a program, as discussed in section 5.4.

5.2.2. Seed block. The internal structure of the seed block is schematically shown in Figure 5.2(b). It consists of a small square containing all the information pertaining to the shape to be built (the seed frame), a larger square in which this information is unpacked into usable form, and finally four TM simulations whose computations determine the size of the seed block and the information transmitted to the growth blocks. For simplicity we first present a construction without the unpacking process (the *simple* seed block) and then explain the unpacking process separately and show how it can be used to create the full construction. The tile types used for the simple seed block are presented in Figure 5.5, and an example is given in Figure 5.6. While growth blocks contain a single TM simulation that outputs a different string to each of the three output sides, the seed block contains four *identical* TM simulations that output different strings to each of the four output sides. This is possible because the border tile types transmit information selectively: the computation in the seed block is performed using 4-tuples as the alphabet in a manner similar to that of the growth blocks, but on each side of the seed block only one of the elements of the 4-tuple traverses the border. As with growth blocks, if the transmitted symbol is "S," the outside edge initiates the assembly of the adjoining block. The point of having four identical TM simulations is to ensure that the seed block is square: while a growth block uses the length of its input side to set the length of its output sides (via the diagonal), the seed block does not have any input sides. (Remember that it is the seed block that sets the size of all the blocks.)

The initiation of the TM simulations in the seed block is done by tile types encoding the program p that guides the block construction. The natural approach to providing this input is using four rows (one for each TM) of unique tiles encoding one bit per tile, as illustrated in Figures 5.5 and 5.6. However, this method does not result in an asymptotically optimal encoding.

5.3. The unpacking process. To encode bits much more effectively we follow Adleman et al. [3] and encode on the order of $\log n / \log \log n$ bits per tile, where n is the length of the input. This representation is then unpacked into a one-bit-per-tile representation used by the TM simulation. The method of Adleman et al. requires $O(n/\log n)$ tiles to encode n bits, leading to the asymptotically optimal result of Theorem 4.1.

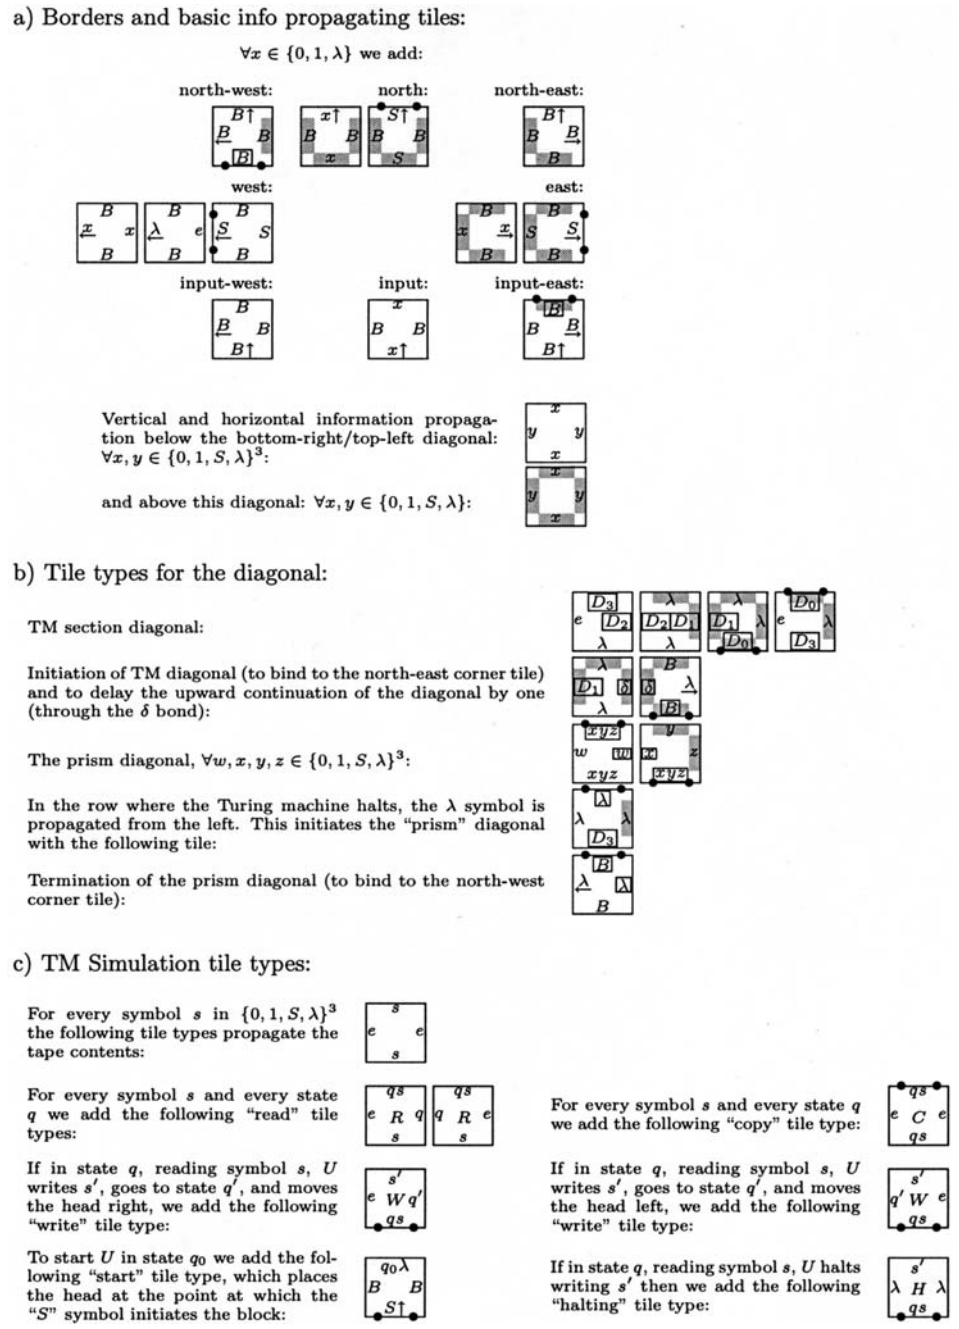

FIG. 5.3. *Growth block $\uparrow$ tile types. All bond types in which a block type symbol is omitted have the block type symbol "$\uparrow$" to prevent inadvertent incorporation of tiles from a different block type. We assume that in bond types above, a single symbol $x \in \{0,1,S,\lambda\}$ is the same as the tuplet (xxx). The tile types for other growth block types are formed by $90°, 180°$, and $270°$ rotations of the tile types of the $\uparrow$ block where the block type symbols $\{\uparrow,\downarrow,\leftarrow,\rightarrow\}$ are replaced by a corresponding $90°, 180°$, and $270°$ rotation of the symbol: i.e.,*  *($\uparrow$ growth block) $\Rightarrow$*  *($\rightarrow$ growth block). Looking at the border tile types, note that external sides of tiles on output sides of blocks have block type symbols compatible with the tiles on an input side of a block. However, tiles on output sides cannot bind to the tiles on an adjacent output side because of mismatching block type symbols.*

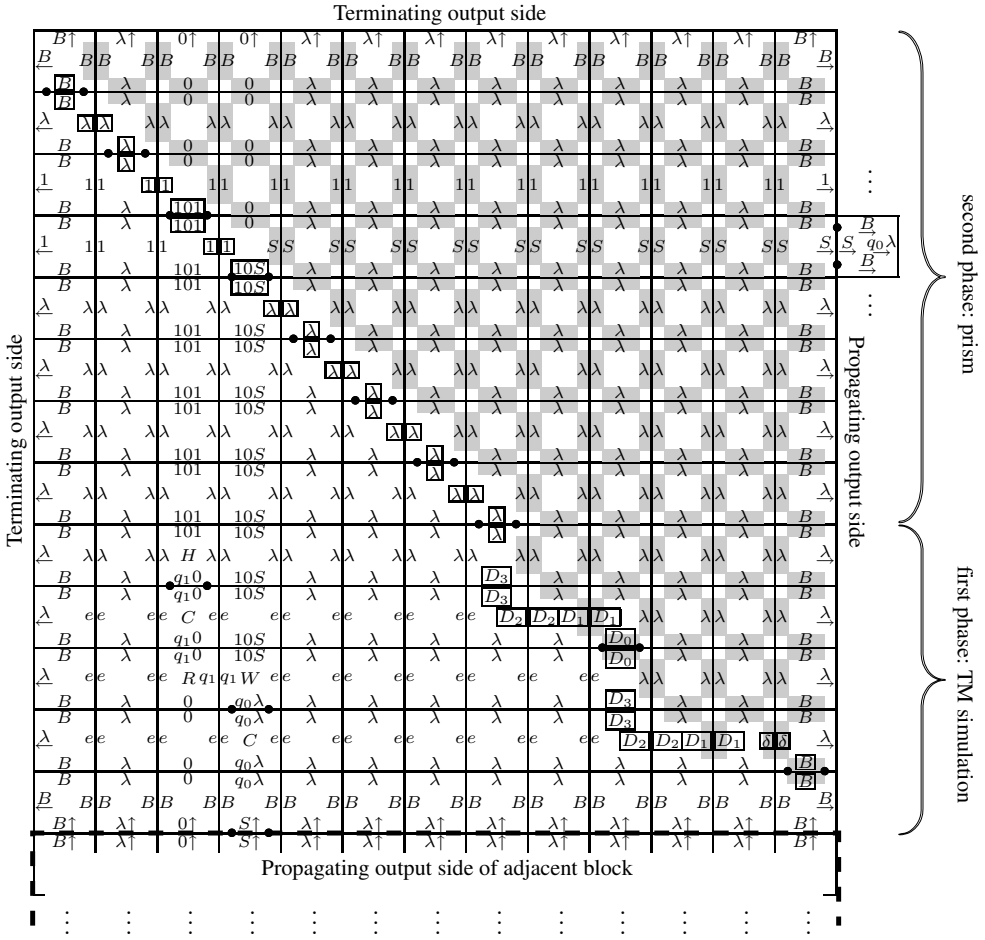

FIG. 5.4. *A trivial example of a ↑ growth block. Here, the TM makes one state transition and halts. All bond types in which a block type symbol is omitted have the block type symbol "↑." We assume that in bond types above, a single symbol $x \in \{0, 1, S, \lambda\}$ is the same as the tuplet (xxx). The natural assembly sequence to consider is adding tiles row by row from the south side (in which a new row is started by the strength-2 bond).*

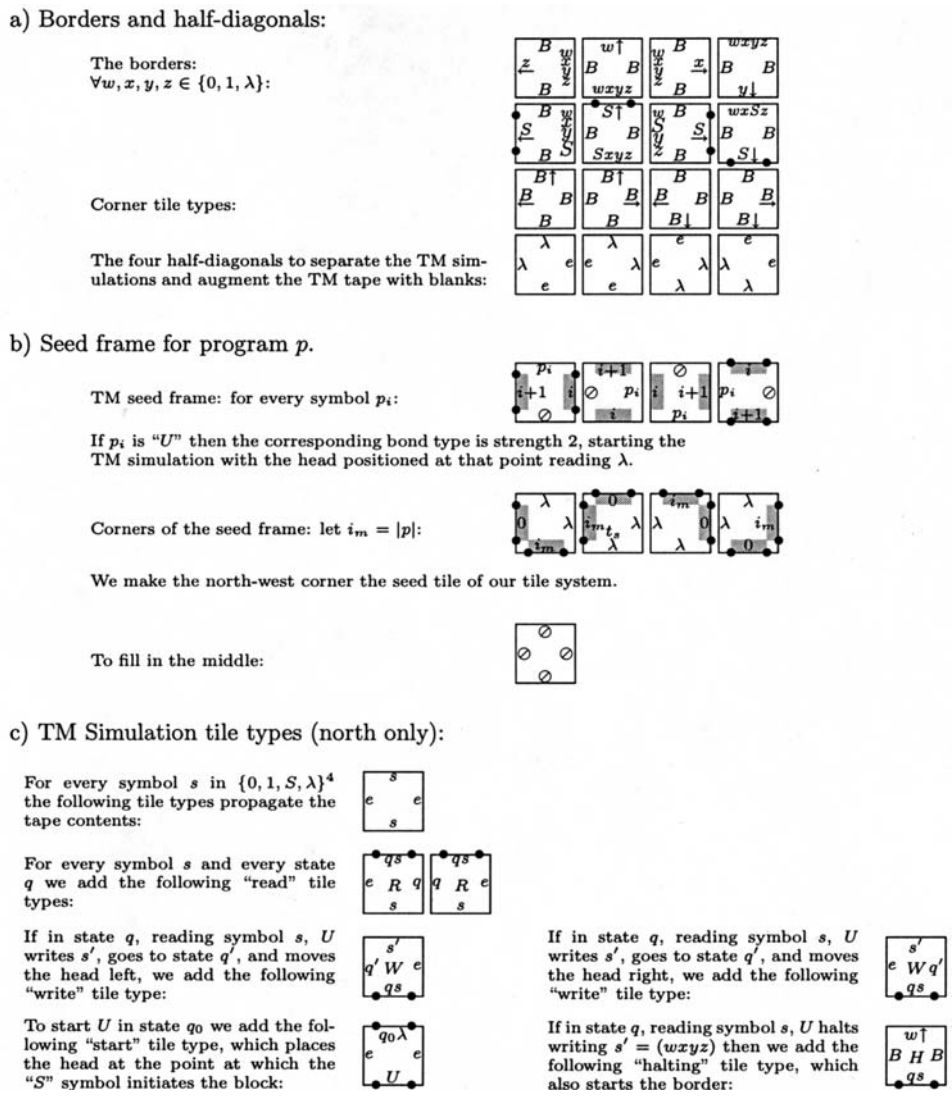

FIG. 5.5. *Seed block tile types without unpacking. All bond types in which a block type symbol is omitted have the block type symbol "☆" to prevent inadvertent incorporation of tiles from a different block type. We assume that in bond types above, a single symbol $x \in \{0, 1, S, \lambda\}$ is the same as the tuplet $(xxxx)$. Note that as with output sides of growth blocks, the external sides of seed block border tiles have block type symbols compatible with the tiles on an input side of a growth block. The three other TM simulations consist of tile types that are rotated versions of the north TM simulation shown. The halting tile types propagate one of the members of the tuple on which the TM halts, analogous to the border tile types. The bond types of TM tile types have a symbol from $\mathcal{D}$ which indicates which simulation they belong to (omitted above).*

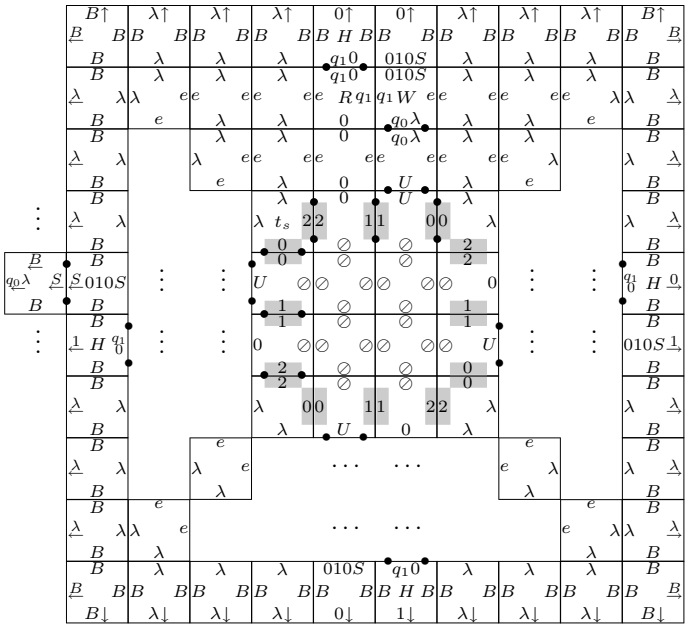

FIG. 5.6. *A simple seed block without unpacking showing the north TM simulation and the selective transmission of information through the borders. As shown, only the west side is a propagating output side; the other three sides are terminating output sides. All bond types in which a block type symbol is omitted have the block type symbol "☆." We assume that in bond types above, a single symbol $x \in \{0, 1, S, \lambda\}$ is the same as the tuplet $(xxxx)$. The natural assembly sequence to consider is growing the seed frame first band and then adding tiles row by row from the center (where a new row is started by the strength-2 bond).*

Our way of encoding information is based on Adleman et al. [3] but modified to work in a $\tau = 2$ tile system (with strength function ranging over $\{0, 1, 2\}$) and to fit our construction in its geometry. We express a length-n binary string using a concatenation of $\lceil n/k \rceil$ binary substrings of length k, padding with 0's if necessary.[10] We choose k such that it is the least integer satisfying $\frac{n}{\log n} \leq 2^k$. Clearly, $2^k < \frac{2n}{\log n}$. See Figure 5.7 for the tile types used in the unpacking for the north TM simulation and for a simple unpacking example (which for the sake of illustration uses $k = 4$).

Let us consider the number of tile types used to encode and unpack the n-bit input string for a single TM simulation (i.e., north). There are $2\lceil n/k \rceil \leq 2\lceil \frac{n}{\log \frac{n}{\log n}} \rceil = 2\lceil \frac{n}{\log n - \log\log n} \rceil$ unique tile types in each seed row. This implies that there exists a constant h such that $2\lceil n/k \rceil \leq \frac{3n}{\log n} + h$ for all n. We need at most $2^k + 2^{k-1} + \cdots + 4 < 2^{k+1}$ "extract bit" tile types and $2^{k-1} + 2^{k-2} + \cdots + 4 < 2^k$ "copy remainder" tile types. To initiate the unpacking of new substrings we need 2^k tile types. To keep on copying substrings that are not yet unpacked we need $2(2^k)$ tile types. The quantity of the other tile types is independent of n, k. Thus, in total, to unpack the n-bit input string for a single TM simulation we need no more than $\frac{3n}{\log n} + h + 2^{k+1} + 2^k + 2^k + 2(2^k) \leq 15\frac{n}{\log n} + O(1)$ tile types. Since there are 4 TM simulations in the seed block, we need $60\frac{n}{\log n} + O(1)$ tile types to encode and unpack the n-bit input string.

If the seed block requires only one propagating output side, then a reduced construction using fewer tile types can be used: only one side of the seed frame is specified, and only one direction of unpacking tiles are used. A constant number of additional tile types are used to fill out the remaining three sides of the square. These additional tile types must perform two functions. First, they must properly extend the diagonal on either side of the unpacking and TM simulation regions. In the absence of the other three unpacking and TM simulation processes, this requires adding strength-2 bonds that allow the diagonal to grow to the next layer. Second, the rest of the square must be filled in to the correct size. This can be accomplished by adding tiles that extend one diagonal to the other side of the seed frame (using the same logic as a construction in [11]). Altogether, a seed block with only one propagating output side requires only $15\frac{n}{\log n} + O(1)$ tile types. We will see in the next section that this is sufficient for growing any shape.

5.4. Programming blocks and the value of the scaling factor *c*. In order for our tile system to produce some assembly whose shape is $\tilde{S}$, instructions encoded in p must guide the construction of the blocks by deciding on which side of which block a new block begins to grow and what is encoded on the edge of each block. For our purposes, we take $p = p_{sb}\langle s \rangle$ (i.e., p_{sb} takes s as input), where s is a program that outputs the list of locations in the shape S. p_{sb} runs s to obtain this list and plans out a spanning tree t over these locations (it can just do a depth-first search) starting from some arbitrarily chosen location that will correspond to the seed block.[11] The information passed along the arrows in Figure 5.1(b) is $p_{gb}\langle t, (i, j) \rangle$, which is the concatenation of a program p_{gb} to be executed within each growth block, and an encoding of the tree t and the location (i, j) of the block into which the arrow is heading. When executed, $p_{gb}\langle t, (i, j) \rangle$ evaluates to a 3-tuple encoding of $p_{gb}\langle t, D(i, j) \rangle$ together with symbol "S" for each propagating output side D. Thus, each growth

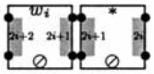
[10] We can assume that our universal TM U treats trailing 0's just as λ's.

[11] We can opt to always choose a leaf, in which case the seed block requires only one propagating output side. In this case the multiplicative factor a_1 is $15 + \varepsilon$, although the tile set used will depend upon the direction of growth from the leaf.

a) Unpacking tile types for the north side of the seed frame:

We use n/k coding tiles in the input row, each encoding a binary substring (w_i) of length k. These tiles are interspersed with buffer tiles holding the symbol "$*$". $\forall 0 \geq i \geq k/n - 1$:

The last tile of the seed row has symbol "U" which indicates the end of the input string.

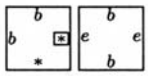


To initiate the unpacking of new substrings: $\forall x \in \{0,1\}^{k-1}$, $b \in \{0,1\}$:

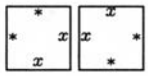
The following "extract bit" tile types perform the actual unpacking: $\forall j \in \{1,\ldots,k-1\}, \forall x \in \{0,1\}^j, b \in \{0,1\}$:

The following "copy remainder" tile types pass the remaining bits to the next extraction: $\forall j \in \{2,\ldots,k-1\}, \forall x \in \{0,1\}^j$:

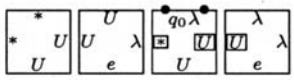
To copy a single bit in the last step of the unpacking of a substring and after unpacking every bit: $b \in \{0,1\}$:



These tile types keep on copying substrings that are not yet being unpacked: $\forall x \in \{0,1\}^k$:



Finally, the following tile types propagate the symbol "U", which indicates the end of the input string, and initiate the TM simulation once the unpacking process finishes:



b) North unpacking example:

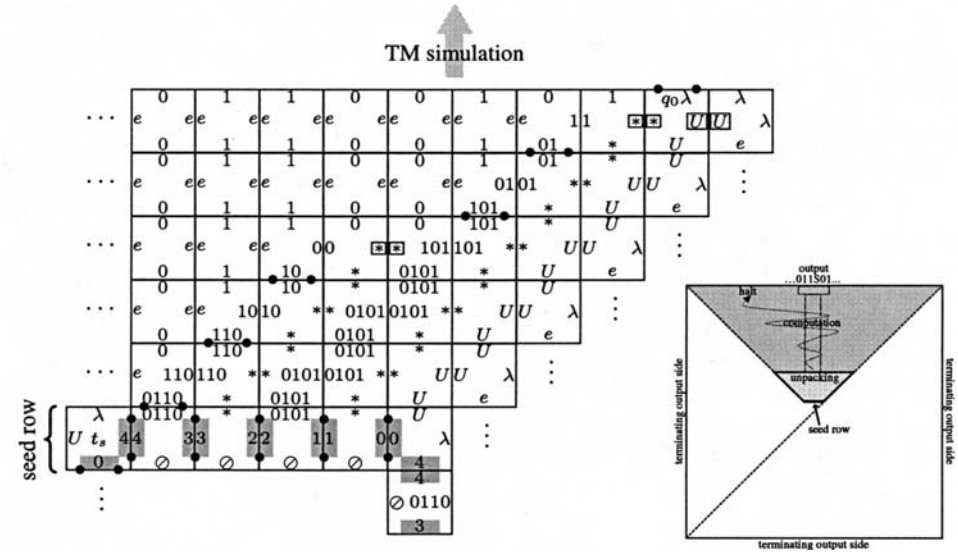


FIG. 5.7. *The unpacking for the north side of the seed frame.* (a) *The tile types used.* (b) *An example showing the unpacking of the string* 01100101 *if* $k = 4$ *for a seed block with up to four propagating output sides. Note that the unpacking process can be inserted immediately prior to the TM simulation without modifying other tile types. The inset shows the internal structure of a seed block with only one propagating output side.*

block passes $p_{gb}\langle t, D(i,j)\rangle$ to its Dth propagating output side as directed by t. Note that program p_{sb} in the seed tile must also run long enough to ensure that c is large enough that the computation in the growth blocks has enough space to finish without running into the sides of the block or into the diagonal. Nevertheless, the scaling factor c is dominated by the building of t in the seed block, as the computation in the growth blocks takes only $poly(|S|)$.[12] Since the building of t is dominated by the running time of s, we have $c = poly(time(s))$.

5.5. Uniqueness of the terminal assembly. By Theorem 2.3 it is enough to demonstrate a locally deterministic assembly sequence ending in our target terminal assembly to be assured that this terminal assembly is uniquely produced. Consider the assembly sequence $\vec{A}$ in which the assembly is constructed *block by block* such that every block is finished before the next one is started and each block is constructed by the natural assembly sequence described in the captions of Figures 5.4 and 5.6. It is enough to confirm that in this natural assembly sequence every tile addition satisfies the definition of local determinism (Definition 2.2). It is easy to confirm that every tile not adjacent to a terminal output side of a block indeed satisfies these conditions. Other than on a terminal output side of a block (and on *null* tiles) there are no *termsides*: every side is either an *inputside* or a *propside*. In our construction, each new tile binds through either a single strength-2 bond or two strength-1 bonds (thus condition 1 is satisfied since $\tau = 2$) such that no other tile type can bind through these *inputsides* (condition 2 is satisfied if the tile has no *termsides*). Note that inadvertent binding of a tile type from a different block type is prevented by the block type symbols.

Now let us consider *termsides* around the terminal output sides of blocks (Figure 5.8(a)). Here block type symbols come to the rescue again and prevent inadvertent binding. Let $t \in A$ be a tile with a *termside* (t can be *null*). We claim that $\forall t'$ s.t. $type(t') \in T$ and $pos(t') = pos(t)$, if $\Gamma^A_{termsides^{\vec{A}}(t)}(t') > 0$, then $\Gamma^A_{\mathcal{D}-propsides^{\vec{A}}(t)}(t') < \tau = 2$. In other words, if t' binds on a *termside* of t, then it cannot bind strongly enough to violate local determinism, implying we can ignore *termsides*. Figure 5.8(a) shows in dotted lines the *termsides* that could potentially be involved in bonding. These *termsides* cannot have a strength-2 bond because symbol "S" is not propagated to terminal output sides of blocks. Thus t' binding only on a single *termside* of t is not enough. Can t' bind on two *termsides* of t? To do so, it must be in a corner between two blocks, binding two terminal output sides of different blocks. But to bind in this way would require t' to bond to the block type symbol pattern[13] shown in Figure 5.8(b) (or its rotation), which none of the tile types in our tile system can do. Can t' bind on one *termside* and one *inputside* of t? Say the *termside* of t that t' binds on is the west side (Figure 5.8(c)). The tile to the west of t must be on the east terminal output side of a block, and thus it has symbol "$\rightarrow$" on its east side. So t' must have "$\rightarrow$" on the west, and depending on the type of block t is in, one of the other block type symbols as shown in Figure 5.8(c). But again none of the tile types in our tile system has the necessary block type symbol pattern.

[12] Note that fewer than n rows are necessary to unpack a string of length n (section 5.3). Since we can presume that p_{sb} reads its entire input and the universal TM needs to read the entire input program to execute it, the number of rows required for the unpacking process can be ignored with respect to the asymptotics of the scaling factor c.

[13] The block type symbol pattern of a tile type consists of the block type symbols among its four bond types. For instance, the tile type 

has block type symbol pattern 

. If two bond types do not have matching block type symbols, then obviously they cannot bind.

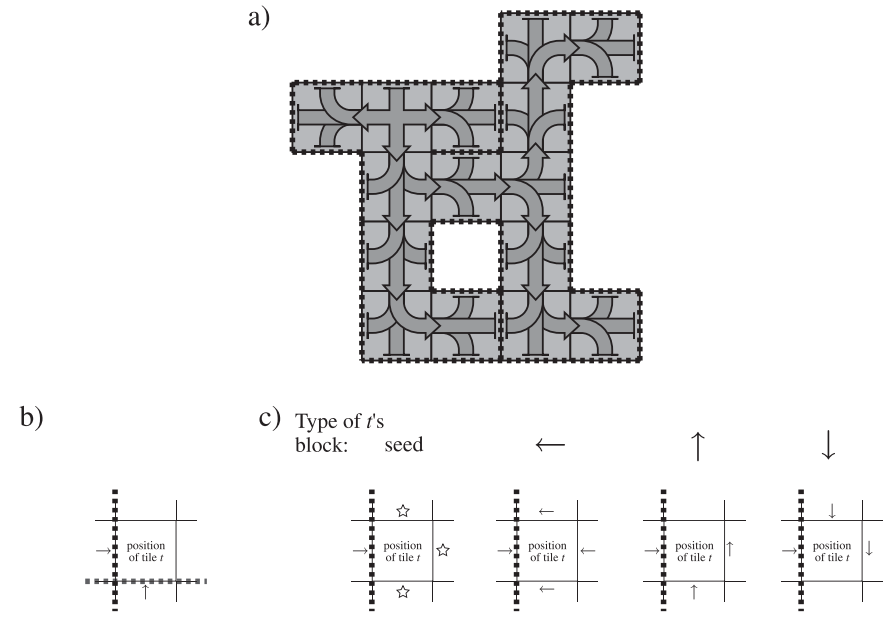

FIG. 5.8. (a) *The target terminal assembly with the dotted lines indicating the edges that have termsides with nonnull bonds.* (b) *The block type symbols of adjacent tiles on two termsides of t (west and south in this case).* (c) *The block type symbols of adjacent tiles on a termside (west side in this case) and an inputside of t. If t is in the seed block or ← growth block, then the north, east, and south sides may be the inputsides. If t is in a ↑ block, then the east and south sides may be the inputsides. If t is in a ↓ block, then the north and east sides may be the inputsides.*

6. Generalizations of shape complexity. In this work we have established both upper and lower bounds relating the descriptional complexity of a shape to the number of tile types needed to self-assemble the shape within the standard tile assembly model. The relationship is dependent upon a particular definition of shape that ignores its size. Disregarding scale in self-assembly appears to play a role similar to that of disregarding time in theories of computability and decidability. Those theories earned their universal standing by being shown to be identical for all "reasonable" models of computation. To what extent do our results depend on the particular model of self-assembly? Can one define a complexity theory for families of shapes in which the absolute scale is the critical resource being measured? In this section we discuss the generality and limitations of our result.

6.1. Optimizing the main result (section 4). Since the Kolmogorov complexity of a string depends on the universal TM chosen, the complexity community adopted a notion of additive equivalence, where additive constants are ignored. However, Theorem 4.1 includes multiplicative constants as well, which are not customarily discounted. It might be possible to use a more clever method of unpacking (section 5.2) and a seed block construction that reduces the multiplicative constant a_1 of Theorem 4.1. Correspondingly, there might be a more efficient way to encode any tile system than that described in the proof of the theorem, and thereby increase a_0.

Recall that s is the program for U producing the target coordinated shape S as a list of locations. For cases where our results are of interest, the scaling factor $c = poly(time(s))$ is extremely large since $|S|$ is presumably enormous and s must output every location in S. The program s' that, given (i, j), outputs 0/1, indicating whether S contains that location, may run much faster than s for large shapes. Can

our construction be adapted to use s' in each block rather than s in the seed block to obtain smaller scale? The problem with doing this directly is that the scale of the blocks, which sets the maximum allowed running time of computation in each block, must be set in the seed block. As a result, there must be some computable time bound on s' that is given to the seed block.

For any particular shape, there must be a range of achievable parameters: the number of tile types and the scaling factor. We know that we can obtain scaling factor 1 by using a unique tile type for each location. On the other extreme is our block construction which allows us to obtain an asymptotically optimal number of tile types at the expense of an enormous scaling factor. Presumably there is a gradual tradeoff between the number of tile types and the scale that can be achieved by a range of tile systems. The characterization of this tradeoff is a topic for future study.

In this vein, an important open problem remains of determining lower bounds on the scales of shapes produced by tile systems with an asymptotically optimal number of tile types. As an initial result of this kind, consider the following proof that an arbitrarily large scaling factor may need to be used if we stick to asymptotically optimal tile systems. Consider the coordinated shape that is a rectangle of width m and height 1. Clearly, it is an instance of the following shape $\tilde{S}$: a long, thin rectangle that is m times as long as it is high. According to Aggarwal et al. [4], the number of tile types required to self-assemble a long, thin rectangle that is n tiles long and k tiles high is $\Omega(\frac{n^{1/k}}{k})$. This implies that to produce any coordinated instance of $\tilde{S}$ at scale c requires $|T| = \Omega(\frac{(mc)^{1/c}}{c})$ tile types. Now we can define what an asymptotically optimal tile system means for us by choosing a_1, b_1 and requiring that the number of tile types $|T|$ satisfies $|T| \log |T| \leq a_1 K(\tilde{S}) + b_1$. Since $K(\tilde{S}) = O(\log m)$, it follows through simple algebra that no matter what a_1, b_1 are, for large enough m, the scaling factor c needs to get arbitrarily large to avoid a contradiction.

6.2. Strength functions. In most previous works on self-assembly, as in this work, strength functions are restricted by the following properties: (1) the effect that one tile has on another is equal to the effect that the other has on the first (i.e., g is *symmetric*: $g(\sigma, \sigma') = g(\sigma', \sigma)$); (2) the lack of an interaction is normalized to zero (i.e., $g(\sigma, null) = 0$); (3) there are no "adverse" interactions counteracting other interactions (i.e., g is *nonnegative*); (4) only sides with matching bond types interact (i.e., g is *diagonal*: $g(\sigma, \sigma') = 0$ if $\sigma \neq \sigma'$).

Properties 1 and 2 seem natural enough. Our results are independent of property 3 because the encoding used for the lower bound of Theorem 4.1 is valid for strength functions taking on negative values. Property 4, which reflects the roots of the tile assembly model in the Wang tiling model, is essential for the quantitative relationship expressed in Theorem 4.1: recent work by Aggarwal et al. [4] shows that permitting nondiagonal strength functions allows information to be encoded more compactly. Indeed, if property 4 is relaxed, then replacing our unpacking process with the method of encoding used in that work and using the lower bound of Aggarwal et al. leads to the following form of Theorem 4.1: assuming the maximum threshold τ is bounded by a constant, there exist constants a_0, b_0, a_1, b_1 such that for any shape $\tilde{S}$,

$$a_0 K(\tilde{S}) + b_0 \leq \left(K_{sa}^{nd}(\tilde{S})\right)^2 \leq a_1 K(\tilde{S}) + b_1,$$

where K_{sa}^{nd} is the tile-complexity when nondiagonal strength functions are allowed. It is an open question whether the constant bound on τ can be relaxed.

6.3. Wang tiling versus self-assembly of shapes. Suppose one is solely concerned with the existence of a configuration in which all sides match, and not with the process of assembly. This is the view of classical tiling theory [7]. Since finite tile sets can enforce uncomputable tilings of the plane [8, 16], one might expect greater computational power when the existence, rather than production, of a tiling is used to specify shapes. In this section we develop the notion of shapes in the Wang tile model [20] and show that results almost identical to the tile assembly model hold. One conclusion of this analysis is that making a shape "practically constructible" (i.e., in the sense of the tile assembly model) does not necessitate an increase in tile-complexity.

We translate the classic notion of the origin-restricted Wang tiling problem[14] as follows. An *(origin-restricted) Wang tiling system* is a pair (T, t_s), where T is a set of tile types and t_s is a *seed tile* with $type(t_s) \in T$. A configuration A is a valid tiling if all sides match and it contains the seed tile. Formally, A is a *valid tiling* if $\forall (i,j) \in \mathbb{Z}^2, D \in \mathcal{D}$, (1) $type(A(i,j)) \in T$, (2) $t_s \in A$, and (3) $bond_D(A(i,j)) = bond_{D^{-1}}(A(D(i,j)))$.

Since valid tilings are infinite objects, how can they define finite coordinated shapes? For tile sets containing the *empty* tile type, we can define shapes analogously to the tile assembly model. However, we cannot simply define the coordinated shape of a valid tiling to be the set of locations of nonempty tiles. For one thing, the set of nonempty tiles can be disconnected, unlike in self-assembly where any produced assembly is a single connected component. So we take the coordinated shape S_A of a valid tiling A to be the smallest region of nonempty tiles containing t_s that can be extended to infinity by *empty* tiles. Formally, S_A is the coordinated shape of the smallest subset of A that is a valid tiling containing t_s. If S_A is finite, then it is the *coordinated shape of valid tiling* A.[15] Shape $\tilde{S}$ is the *shape of a valid tiling* A if $S_A \in \tilde{S}$.

Produced assemblies of a tile system (T, t_s, g, τ) are not necessarily valid tilings of Wang tiling system (T, t_s) because the tile assembly model allows mismatching sides. Further, valid tilings of (T, t_s) are not necessarily produced assemblies of (T, t_s, g, τ). Even if one considers only valid tilings that are connected components, there might not be any sequence of legal tile additions that assembles these configurations. Nonetheless, if a tile system uniquely produces a valid tiling A, then all valid tilings of the corresponding Wang tile system agree with A and have the same coordinated shape as A.

LEMMA 6.1. *If* $empty \in T$ *and the tile system* $\mathbf{T} = (T, t_s, g, \tau)$ *uniquely produces assembly* A *such that* A *is a valid tiling of the Wang tiling system* (T, t_s)*, then for all valid tilings* A'*, it holds that* (1) $\forall (i,j) \in \mathbb{Z}^2$*,* $type(A(i,j)) \neq empty \Rightarrow A'(i,j) = A'(i,j)$*, and* (2) $S_{A'} = S_A$.

Proof. Consider an assembly sequence $\vec{A}$ of $\mathbf{T}$ ending in assembly A and let A' be a valid tiling of (T, t_s). Suppose t_n is the first tile added in this sequence such that $t' = A'(pos(t_n)) \neq t_n$. Since A' is a valid tiling, t' must match on all sides, including $inputsides^{\vec{A}}(t_n)$. But this implies that two different tiles can be added in the same location in $\vec{A}$, which means that A is not uniquely produced. This implies part (1) of the lemma. Now, to be a valid tiling, all exposed sides of assembly A must be null. Thus if A' and A agree on all places where A is nonempty, then $S_{A'} = S_A$, and part (2) of the lemma follows. □

[14] The *unrestricted* Wang tile model does not have a seed tile [20, 5, 18].

[15] S_A can be finite only if $empty \in T$ because otherwise no configuration containing an *empty* tile can be a valid tiling.

Define the *tile-complexity* K_{wt} of a shape $\tilde{S}$ in the origin-restricted Wang tiling model as the minimal number of tile types in a Wang tiling system with the property that a valid tiling exists and there is a coordinated shape $S \in \tilde{S}$ such that for every valid tiling A, $S_A = S$.

THEOREM 6.1. *There exist constants a_0, b_0, a_1, b_1 such that for any shape $\tilde{S}$,*

$$a_0 K(\tilde{S}) + b_0 \leq K_{wt}(\tilde{S}) \log K_{wt}(\tilde{S}) \leq a_1 K(\tilde{S}) + b_1.$$

Proof sketch. The left inequality follows in a manner similar to the proof of Theorem 4.1. Suppose every valid tiling of our Wang tile system has coordinated shape S. Any Wang tiling system of n tile types can be represented using $O(n \log n)$ bits. Making use of this information as input, we can use a constant-size program to find, through exhaustive search, the smallest region containing t_s surrounded by *null* bond types in some valid tiling. Thus, $O(n \log n)$ bits are enough to compute an instance of $\tilde{S}$. To prove the right inequality, our original block construction almost works, except that there are mismatches between a terminal output side of a block and the abutting terminal output side of the adjacent block or the surrounding *empty* tiles (i.e., along the dotted lines in Figure 5.8(a)). Consequently, the original construction does not yield a valid tiling. Nonetheless, a minor variant of our construction overcomes this problem. Instead of relying on mismatching bond type symbols to prevent inadvertent binding to terminal output sides of blocks, we can add an explicit capping layer that covers the terminal output sides with *null* bond types but propagates information through propagating output sides. This way, the terminal output sides of blocks are covered by *null* bond types and match the terminal output sides of the adjacent block and *empty* tiles. These modifications can be made preserving local determinism, which, by Lemma 6.1, establishes that the coordinated shape of any valid tiling is an instance of $\tilde{S}$. □

There may still be differences in the computational power between Wang tilings and self-assembly processes. For example, consider the smallest Wang tiling system and the smallest self-assembly tile system that produce instances of $\tilde{S}$. The instance produced by the Wang tiling system might be much smaller than the instance produced by self-assembly. Likewise, there might be *coordinated* shapes that can be produced with significantly fewer tile types by a Wang tiling system than by a self-assembly system.

Keep in mind that the definition we use for saying when a Wang tiling system produces a shape was chosen as a natural parallel to the definition used for self-assembly, but alternative definitions may highlight other interesting phenomena specific to Wang tilings. For example, one might partition tiles into two subsets, "solution" and "substance" tiles, and declare shapes to be connected components of substance tiles within valid tilings. In such tilings—reminiscent of "vicinal water" in chemistry—the solution potentially can have a significant (even computational) influence that restricts possible shapes of the substance, and hence the size of produced shapes need not be so large as to contain the full computation required to specify the shape.

6.4. Sets of shapes. Any coordinated shape S can be trivially produced by a self-assembly tile system or by a Wang tiling of $|S|$ tile types. Interesting behavior occurs only when the number of tile types is somehow restricted and the system is forced to perform some nontrivial computation to produce a shape. Previously in this paper, we restricted the number of tile types in the sense that we ask what is the minimal number of tile types that can produce a given shape. We saw that ignoring scale in this setting allows for an elegant theory. In the following two sections the restriction on the number of tile types is provided by the infinity of shapes they must

be able to produce. Here we will see as well that ignoring scale allows for an elegant theory.

Adleman [2] asks, "What are the 'assemblable [sic] shapes' - (analogous to what are the 'computable functions')?" While this is still an open question for coordinated shapes, our definition of a shape ignoring scale and translation leads to an elegant answer. A set of binary strings $\tilde{L}$ is a language of shapes if it consists of (standard binary) encodings of lists of locations that are coordinated shapes in some set of shapes: $\tilde{L} = \{\langle S \rangle \text{ s.t. } S \in \tilde{S} \text{ and } \tilde{S} \in R\}$ for some set of shapes R. Note that every instance of every shape in R is in this language. The language of shapes $\tilde{L}$ is recursively enumerable if there exists a TM that halts upon receiving $\langle S \rangle \in \tilde{L}$ and does not halt otherwise. We say a tile system $\mathbf{T}$ produces the language of shapes $\tilde{L}$ if $\tilde{L} = \{\langle S \rangle \text{ s.t. } S \in \tilde{S_A} \text{ for some } A \in Term(\mathbf{T})\}$. We may want $\tilde{L}$ to be *uniquely produced* in the sense that the $A \in Term(\mathbf{T})$ is unique for each shape. Further, to prevent infinite spurious growth we may also require $\mathbf{T}$ to satisfy the following *noncancerous* property: $\forall B \in Prod(\mathbf{T}), \exists A \in Term(\mathbf{T}) \text{ s.t. } B \rightarrow_{\mathbf{T}}^{*} A$. The following lemma is valid whether or not these restrictions are made.

LEMMA 6.2. *A language of shapes $\tilde{L}$ is recursively enumerable if and only if it is (uniquely) produced by a (noncancerous) tile system.*

Proof sketch. First of all, for any tile system $\mathbf{T}$ we can make a TM that, given a coordinated shape S as a list of locations, starts simulating all possible assembly sequences of $\mathbf{T}$ and halts if and only if it finds a terminal assembly that has shape $\tilde{S}$. Therefore, if $\tilde{L}$ is produced by a tile system, $\tilde{L}$ is recursively enumerable. In the other direction, if $\tilde{L}$ is recursively enumerable, then there is a program p that, given n, outputs the nth shape from $\tilde{L}$ (in some order) without repetitions. Our programmable block construction can be modified to execute a nondeterministic universal TM in the seed block by having multiple possible state transitions. We make a program that nondeterministically guesses n, feeds it to p, and proceeds to build the returned shape. Note that since every computation path terminates, this tile system is noncancerous, and since p enumerates without repetitions, the language of shapes is uniquely produced. □

Note that the above lemma does not hold for languages of coordinated shapes, defined analogously. Many simple recursively enumerable languages of coordinated shapes cannot be produced by any tile system. For example, consider the language of equilateral width-1 crosses centered at $(0, 0)$. No tile system produces this language. Scale-equivalence is crucial because it allows arbitrary amounts of information to be passed between different parts of a shape; otherwise, the amount of information is limited by the width of a shape.

The same lemma can be attained for the Wang tiling model in an analogous manner using the construction from section 6.3. Let us say a Wang tiling system (T, t_s) produces the language of shapes $\tilde{L}$ if $\tilde{L} = \{\langle S \rangle \text{ s.t. } S \in \tilde{S_A} \text{ for some valid tiling } A \text{ of } (T, t_s)\}$. Analogously to tile systems, we may require the *unique production* property that there is exactly one such A for each shape. Likewise, corresponding to the noncancerous property of tile systems, we may also require the tiling system to have the *noncancerous* property that every valid tiling has a coordinated shape (i.e., is finite). Again, the following lemma is true whether or not these restrictions are made.

LEMMA 6.3. *A language of shapes $\tilde{L}$ is recursively enumerable if and only if it is (uniquely) produced by a (noncancerous) Wang tiling system.*

6.5. Scale complexity of shape functions. Expanding upon the notion of a shape being the output of a universal computation process as mentioned in the in-

troduction, let us consider tile systems effectively computing a function from binary strings to shapes. The universal "programmable block" constructor presented in section 5 may be taken as an example of such a tile set if the full seed block is considered as an initial seed assembly rather than as part of the tile set per se. In this case, the remaining tile set is of constant size and will construct an arbitrary algorithmic shape when presented with a seed assembly containing the relevant program. The universal constructor tile set's efficiency, then, can be measured in terms of the scale of the produced shape. Similarly, other "programmable" tile sets may produce a limited set of shapes, but potentially with greater efficiency. (Such tile sets can be thought to produce a language of shapes (section 6.4) such that the choice of the produced shape can be deterministically specified.) For tile systems outputting shapes in this manner, we can show that the total number of tiles (not tile *types*) in the produced shape is closely connected to the time complexity of the corresponding function from binary strings to shapes in terms of TMs. The equivalent connection can be made between nondeterministic TMs and the size of valid tilings in the Wang tiling model.

Let f be a function from binary strings to shapes. We say that a TM M computes this function if for all x, $f(x) = \tilde{S} \Leftrightarrow \exists S \in \tilde{S}$ s.t. $M(x) = \langle S \rangle$. The standard notion of time complexity applies: $f \in TIME_{TM}(t(n))$ if there is a TM computing it running in time bounded by $t(n)$, where n is the size of the input. In section 5.2.2 we saw how binary input can be provided to a tile system via a seed frame wherein all four sides of a square present the bit string. Let us apply this convention here.[16] Extending the notion of the seed in self-assembly to the entire seed frame and using this as the input for a computation [17], we say a tile system computes f if the following holds: [starting with the seed frame encoding x the tile system uniquely produces an assembly of shape $\tilde{S}$] if and only if $f(x) = \tilde{S}$. We say that $f \in TILES_{SA}(t(n))$ if there is a tile system computing it and the size of coordinated shapes produced (in terms of the number of nonempty locations) for inputs of size n is upper bounded by $t(n)$. Similar definitions can be made for nondeterministic TMs (NDTMs) and Wang tiling systems. We say that an NDTM N computes f if the following holds: [every computation path of N on input x ending in an accept state (as opposed to a reject state) outputs $\langle S \rangle$ for some $S \in \tilde{S}$] if and only if $f(x) = \tilde{S}$. For NDTMs, $f \in TIME_{NDTM}(t(n))$ if there is an NDTM computing f such that every computation path halts after $t(n)$ steps. Extending the notion of the seed for Wang tilings to the entire seed frame as well, we say a Wang tiling system computes f if all valid tilings containing the seed frame have a coordinated shape and this coordinated shape is the same for all such valid tilings, and it is an instance of the shape $f(x)$. We say that $f \in TILES_{WT}(t(n))$ if there is a tiling system computing it and the size of coordinated shapes produced for inputs of size n is upper bounded by $t(n)$.

THEOREM 6.4.

(a) *If* $f \in TILES_{SA}(t(n))$, *then* $f \in TIME_{TM}(O(t(n)^4))$.

(b) *If* $f \in TIME_{TM}(t(n))$, *then* $f \in TILES_{SA}(O(t(n)^3))$.

(c) *If* $f \in TILES_{WT}(t(n))$, *then* $f \in TIME_{NDTM}(O(t(n)^4))$.

(d) *If* $f \in TIME_{NDTM}(t(n))$, *then* $f \in TILES_{WT}(O(t(n)^3))$.

Proof sketch. (a) Let $\mathbf{T}$ be a tile system computing f such that the total number of tiles used on an input of size n is $t(n)$. A TM with a two-dimensional tape can simulate the self-assembly process of $\mathbf{T}$ with an input of size n in $O(t(n)^2)$ time: for each of the $t(n)$ tile additions, it needs to search $O(t(n))$ locations for the next addition. This

[16] Any other similar method would do. For the purposes of this section, it does not matter whether we use the one-bit-per-tile encoding or the encoding requiring unpacking (section 5.3).

two-dimensional TM can be simulated by a regular TM with a quadratic slowdown.[17]

(b) Let M be a deterministic TM that computes f and runs in time $t(n)$. Instead of simulating a universal TM in the block construction, we simulate a TM M' which runs M on input x encoded in the seed frame and acts as program p_{sb} in section 5.4. Then the scale of each block is $O(t(n))$, which implies that each block consists of $O(t(n)^2)$ tiles. Now the total number of blocks cannot be more than the running time of M since M outputs every location that corresponds to a block. Thus the total number of tiles is $O(t(n)^3)$.

(c) An argument similar to (a) applies to the Wang tiling system with the following exception. A Wang tiling system can simulate an NDTM and still be able to output a unique shape. The tiling system can be designed such that if a reject state is reached, the tiling cannot be a valid tiling. For example, the tile representing the reject state can have a bond type that no other tile matches. Thus all valid tilings correspond to accepting computations.

(d) Simulation of Wang tiling systems can, in turn, be done by an NDTM as follows. Suppose every valid tiling of our Wang tile system has coordinated shape S. The simulating NDTM acts in a manner similar to that of the TM simulating self-assembly above, except that every time two or more different tiles can be added in the same location, it nondeterministically chooses one. If the NDTM finds a region containing the seed frame surrounded by *null* bond types, it outputs the shape of the smallest such region and enters an accept state. Otherwise, at some point no compatible tile can be added, and the NDTM enters a reject state. The running time of accepting computations is $O(t(n)^2)$ via the same argument as for (b). □

If, as is widely believed, NDTMs can compute some functions in polynomial time that require exponential time on a TM, then it follows that there exist functions from binary strings to shapes that can be computed much more efficiently by Wang tiling systems than by self-assembly, where efficiency is defined in terms of the size of the coordinated shape produced.

The above relationship between $TIME$ and $TILES$ may not be the tightest possible. As an alternative approach, very small-scale shapes can be created as Wang tilings by using an NDTM that recognizes tuples (i, j, x), rather than one that generates the full shape. This will often yield a compact construction. As a simple example, this approach can be applied to generating circles with radius x at scale $O(n^2)$, where $n = O(\log x)$. It remains an open question how efficiently circles can be generated by self-assembly.

6.6. Other uses of programmable growth. The programmable block construction is a general way of guiding the large-scale growth of the self-assembly process and may have applications beyond those explored so far. For instance, instead of constructing shapes, the block construction can be used to simulate other tile systems in a scaled manner using fewer tile types. It is easy to reprogram it to simulate, using few tile types, a large deterministic $\tau = 1$ tile system for which a short algorithmic description of the tile set exists. We expect that a slightly extended version of the

[17] The rectangular region of the two-dimensional tape previously visited by the two-dimensional head (the arena) is represented row by row on a one-dimensional tape separated by special markers. The current position of the two-dimensional head is also represented by a special marker. If the arena is $l \times m$, a single move of the two-dimensional machines which does not escape the current arena requires at most $O(m^2)$ steps, while a move that escapes it in the worst case requires an extra $O(ml^2)$ steps to increase the arena size. We have $m, l = O(t(n))$, and the number of times the arena has to be expanded is at most $O(t(n))$.

block construction can also be used to provide compact tile sets that simulate other $\tau = 2$ tile systems that have short algorithmic descriptions.

To self-assemble a circuit, it may be that the shape of the produced complex is not the correct notion. Rather one may consider finite patterns, where each location in a shape is "colored" (e.g., resistor, transistor, wire). Further, assemblies that can grow arbitrarily large may be related to infinite patterns. What is the natural way to define the self-assembly complexity of such patterns? Do our results (section 4) still hold?

Appendix A. Local determinism guarantees unique production: Proof of Theorem 2.3.

LEMMA A.1. *If $\vec{A}$ is a locally deterministic assembly sequence of $\mathbf{T}$, then for every assembly sequence $\vec{A}'$ of $\mathbf{T}$ and for every tile $t' = t'_n$ added in $\vec{A}'$, the following conditions hold, where $t = A(pos(t'))$:*

(i) $inputsides^{\vec{A}'}(t') = inputsides^{\vec{A}}(t)$.

(ii) $t' = t$.

Proof. Suppose $t' = t'_n$ is the first tile added that fails to satisfy one of the above conditions. Consider any $D \in inputsides^{\vec{A}'}(t')$. Tile $t_D = A'(D(pos(t')))$ must have been added before t' in $\vec{A}'$ and so $D^{-1} \notin inputsides^{\vec{A}'}(t_D) = inputsides^{\vec{A}}(t_D)$. This implies $D \notin propsides^{\vec{A}}(t)$ and thus,

$$inputsides^{\vec{A}'}(t') \cap propsides^{\vec{A}}(t) = \emptyset. \tag{A.1}$$

Now, $\forall D, \Gamma_D^{A'_n}(t') \leq \Gamma_D^A(t')$ because A'_n has no more tiles than A and except at $pos(t)$ they all agree. Equation (A.1) implies

$$\Gamma^A_{inputsides^{\vec{A}'}(t')}(t') \leq \Gamma^A_{\mathcal{D}-propsides^{\vec{A}}(t)}(t').$$

Therefore,

$$\Gamma^{A'_n}_{inputsides^{\vec{A}'}(t')}(t') \leq \Gamma^A_{\mathcal{D}-propsides^{\vec{A}}(t)}(t').$$

So by property (2) of Definition 2.2, no tile of type $\neq type(t)$ could have been sufficiently bound here by $inputsides^{\vec{A}'}(t')$ and thus $t' = t$. Therefore, t' cannot fail the second condition (ii).

Now, suppose t' fails the first condition (i). Because of property (1) of Definition 2.2, this can happen only if $\exists D \in inputsides^{\vec{A}'}(t') - inputsides^{\vec{A}}(t')$. Since $D \notin inputsides^{\vec{A}}(t')$, t_D must have been added after t' in $\vec{A}$. So since t_D binds t', $D^{-1} \in inputsides^{\vec{A}}(t_D)$, and so $D \in propsides^{\vec{A}}(t)$. But by (A.1) this is impossible. Thus we conclude $A' \subseteq A$. ∎

Lemma A.1 directly implies that if there exists a locally deterministic assembly sequence $\vec{A}$ of $\mathbf{T}$, then $\forall A' \in Prod(\mathbf{T}), A' \subseteq A$. Theorem 2.3 immediately follows: if there exists a locally deterministic assembly sequence $\vec{A}$ of $\mathbf{T}$, then $\mathbf{T}$ uniquely produces A.

Since local determinism is a property of the *inputsides* classification of tiles in a terminal assembly, Lemma A.1 also implies the following corollary.

COROLLARY A.2. *If there exists a locally deterministic assembly sequence $\vec{A}$ of $\mathbf{T}$, then every assembly sequence ending in A is locally deterministic.*

Appendix B. Scale-equivalence and "≅" are equivalence relations. Translation-equivalence is clearly an equivalence relation. Let us write $S_0 \overset{tr}{=} S_1$ if the two coordinated shapes are translation-equivalent.

LEMMA B.1. *If $S = S_0^d$ and $S_0 = S_m^k$, then $S = S_m^{dk}$.*

Proof. $S(i,j) = S_0(\lfloor i/d \rfloor, \lfloor j/d \rfloor) = S_m(\lfloor \lfloor i/d \rfloor / k \rfloor, \lfloor \lfloor j/d \rfloor / k \rfloor) = S_m(\lfloor i/dk \rfloor, \lfloor j/dk \rfloor)$. □

LEMMA B.2. *If $S_0 \overset{tr}{=} S_1$, then $S_0^d \overset{tr}{=} S_1^d$.*

Proof. $S_0^d(i,j) = S_0(\lfloor i/d \rfloor, \lfloor j/d \rfloor) = S_1(\lfloor i/d \rfloor + \Delta i, \lfloor j/d \rfloor + \Delta j) = S_1(\lfloor \frac{i+d\Delta i}{d} \rfloor, \lfloor \frac{j+d\Delta j}{d} \rfloor) = S_1^d(i + d\Delta i, j + d\Delta j)$. □

To show that scale-equivalence is an equivalence relation, the only nontrivial property is transitivity. Suppose $S_0^c = S_1^d$ and $S_1^{d'} = S_2^{c'}$ for some $c, c', d, d' \in \mathbb{Z}^+$. $(S_1^d)^{d'} = (S_1^{d'})^d = S_1^{d'd}$ by Lemma B.1. Thus, $S_1^{d'd} = (S_0^c)^{d'} = (S_2^{c'})^d$, and by Lemma B.1, $S_0^{cd'} = S_2^{c'd}$.

To show that "≅" is an equivalence relation, again only transitivity is nontrivial. Suppose $S_0 \cong S_1$ and $S_1 \cong S_2$. In other words, $S_0^c \overset{tr}{=} S_1^d$ and $S_1^{d'} \overset{tr}{=} S_2^{c'}$ for some $c, c', d, d' \in \mathbb{Z}^+$. By Lemma B.2, $(S_0^c)^{d'} \overset{tr}{=} (S_1^d)^{d'}$ and $(S_1^{d'})^d \overset{tr}{=} (S_2^{c'})^d$. Then by Lemma B.1, $S_0^{cd'} \overset{tr}{=} S_1^{d'd}$ and $S_1^{d'd} \overset{tr}{=} S_2^{c'd}$, which implies $S_0^{cd'} \overset{tr}{=} S_2^{c'd}$ by the transitivity of translation-equivalence. In other words, $S_0 \cong S_2$.

Acknowledgments. We thank Len Adleman, members of his group, Ashish Goel, and Paul Rothemund for fruitful discussions and suggestions. We also thank Rebecca Schulman and David Zhang for useful and entertaining conversations about descriptional complexity of tile systems, and an anonymous reviewer for a very careful reading of this paper and helpful comments.

FIRST-ORDER LANGUAGES EXPRESSING CONSTRUCTIBLE SPATIAL DATABASE QUERIES*

BART KUIJPERS†, GABRIEL KUPER‡, JAN PAREDAENS§, AND LUC VANDEURZEN†

Abstract. The research presented in this paper is situated in the framework of constraint databases introduced by Kanellakis, Kuper, and Revesz in their seminal paper of 1990, specifically, the language with real polynomial constraints ($\mathsf{FO} + \mathsf{poly}$). For reasons of efficiency, this model is implemented with only *linear* polynomial constraints, but this limitation to linear polynomial constraints has severe implications on the expressive power of the query language. In particular, when used for modeling spatial data, important queries that involve Euclidean distance are not expressible. The aim of this paper is to identify a class of two-dimensional constraint databases and a query language within the constraint model that go beyond the linear model and allow the expression of queries concerning distance. We seek inspiration in the Euclidean constructions, i.e., constructions by ruler and compass. We first present a programming language that captures exactly the first-order ruler-and-compass constructions that are expressible in a first-order language with real polynomial constraints. If this language is extended with a **while** operator, we obtain a language that is complete for all ruler-and-compass constructions in the plane. We then transform this language in a natural way into a query language on finite point databases, but this language turns out to have the same expressive power as $\mathsf{FO} + \mathsf{poly}$ and is therefore too powerful for our purposes. We then consider a *safe* fragment of this language and use this to construct a query language that allows the expression of Euclidean distance without having the full power of $\mathsf{FO} + \mathsf{poly}$.

Key words. constraint databases, real algebraic geometry, first-order logic, query languages, ruler-and-compass constructions

1. Introduction and motivation.

Kanellakis, Kuper, and Revesz [28, 29] (see also [30]) introduced the framework of *constraint databases* which provides a rather general model for spatial databases [32]. Spatial database systems [1, 7, 10, 21, 22, 37] are concerned with the representation and manipulation of data that have a geometrical or topological interpretation. In the context of the constraint model, a spatial database, although conceptually viewed as a possibly infinite set of points in the real space, is represented as a finite union of systems of polynomial equations and inequalities. For example, the spatial database consisting of the set of points on the northern hemisphere together with the points on the equator of the unit sphere in the three-dimensional space $\mathbf{R}^3$ can be represented by the formula $x^2+y^2+z^2 = 1 \wedge z \geq 0$. The set $\{(x, y) \mid (y-x^2)(x^2-y+1/2) > 0\}$ of points in the real plane lying strictly above the parabola $y = x^2$ and strictly below the parabola $y = x^2 + 1/2$ is an example of a two-dimensional database in the constraint model. These are called *semi-algebraic* sets [6].

Several query languages on databases using the constraint model have been stud-

ied. One such query language is obtained by extending the relational calculus with polynomial inequalities [32]. This language is usually referred to as $\mathsf{FO} + \mathsf{poly}$. The query deciding whether the two-dimensional database S is a straight line, for instance, can be expressed in this language by the sentence

$$\exists a \exists b \exists c \big(\neg(a = 0 \wedge b = 0) \wedge \forall x \forall y (S(x, y) \leftrightarrow ax + by + c = 0) \big) .$$

Although variables in such expressions range over the real numbers, queries expressed in this calculus can still be computed effectively. In particular, the closure property holds: Any $\mathsf{FO} + \mathsf{poly}$ query, when evaluated on a spatial database in the constraint model, yields a spatial database in the constraint model. This follows immediately from Tarski's quantifier-elimination procedure for the first-order theory of real closed fields [38].

However, Tarski's quantifier-elimination procedure is computationally very expensive. Since the 1970s various more efficient algorithms have been proposed, including Cylindrical Algebraic Decomposition [8, 9], which are still unsuitable for practice. The best known algorithms were proposed in the 1990s [4, 34], and, by the use of alternative data structures [14], in the best case, quantifier elimination is exponential in the number of quantifier blocks. (A recent textbook on this matter is [36], and for a discussion on the influence of data structures we refer the reader to [25]). Due to this complexity it seems to be infeasible for real spatial database applications to rely on quantifier elimination (we discuss this further below). In existing implementations of the constraint model, such as the DEDALE system [15, 16, 17], the constraints are restricted to *linear* polynomial constraints, and the sets definable in this restricted model are called *semi-linear*. It is argued that linear polynomial constraints provide a sufficiently general framework for spatial database applications [17, 40]. Indeed, in one of the main application domains, geographical information systems, linear approximations are used to model geometrical objects (for an overview of this field since the early '90s, see [1, 7, 10, 21, 22, 37]).

When we extend the relational calculus with linear polynomial inequalities, we obtain an effective language which has the same closure property as above but this time with respect to linear databases. We refer to this language as $\mathsf{FO} + \mathsf{lin}$, and therefore an $\mathsf{FO} + \mathsf{lin}$ query evaluated on a linear constraint database yields a linear constraint database.

We return to the complexity of query evaluation by quantifier elimination. Although for both $\mathsf{FO} + \mathsf{poly}$ and $\mathsf{FO} + \mathsf{lin}$ the cost of quantifier elimination grows exponentially with the number of blocks of quantifiers to be eliminated, an argument in favor of the language $\mathsf{FO} + \mathsf{lin}$ is that there exists a conceptually "easier" way (Fourier's method [27, 31]) to eliminate quantifiers for this language which makes an effective implementation feasible [15, 16, 17]. This algorithm has the same asymptotic complexity as the quantifier-elimination procedure for $\mathsf{FO} + \mathsf{poly}$, though there is a slight gain in data complexity: Grumbach and Su have shown that the data complexity for $\mathsf{FO} + \mathsf{lin}$ is NC^1, while it is NC for $\mathsf{FO} + \mathsf{poly}$ (for certain restrictions of $\mathsf{FO} + \mathsf{lin}$, namely ℓ-bounded instances, an AC^0 bound is obtained) [19]. From the practical point of view, a more significant advantage of the linear model is the existence of numerous efficient algorithms for geometrical operations [33].

There are, however, a number of serious disadvantages to the restriction to linear polynomial constraints, related to the limited expressive power of the query language $\mathsf{FO} + \mathsf{lin}$. The expressive power of the language $\mathsf{FO} + \mathsf{lin}$ has been extensively studied (see, e.g., [2, 3, 18, 20, 40, 41] and references therein). Among the limitations of

$\mathsf{FO} + \mathsf{lin}$, one of the most important is that the language is incapable of expressing queries that involve Euclidean distance, betweenness, and collinearity. A query like "Return all cities in Belgium that are further than 100 km away from Brussels" is, however, a query that is of importance in spatial database applications. The goal of this paper is to overcome these limitations of $\mathsf{FO} + \mathsf{lin}$ for the special case of two-dimensional spatial databases.

We note that languages whose expressive power on semi-linear databases is strictly between that of $\mathsf{FO} + \mathsf{lin}$ and $\mathsf{FO} + \mathsf{poly}$ have already been studied. Vandeurzen, Gyssens, and Van Gucht [40, 41] have shown that, even though $\mathsf{FO} + \mathsf{lin}$ extended with a primitive for collinearity yields a language with the complete expressive power of $\mathsf{FO} + \mathsf{poly}$, a "careful" extension with a collinearity operator yields a language whose expressive power is strictly between that of $\mathsf{FO} + \mathsf{lin}$ and that of $\mathsf{FO} + \mathsf{poly}$ on semi-linear databases. However, even this extension does not allow the expression of queries involving distance.

In this paper, we define a new query language, $\mathsf{SafeEuQL}^{\uparrow}$, and a class of two-dimensional constraint databases on which this language is closed, called *semi-circular* databases. The language $\mathsf{SafeEuQL}^{\uparrow}$ allows the expression of queries concerning distance, betweenness, and collinearity. The class of semi-circular databases obviously is a strict superclass of the class of linear databases, since $\mathsf{SafeEuQL}^{\uparrow}$ allows for the definition of data by means of distance. Semi-circular databases are describable by means of polynomial equalities, inequalities that involve linear polynomials, and polynomials that define circles. The language $\mathsf{SafeEuQL}^{\uparrow}$ is strictly more powerful on linear databases than $\mathsf{FO} + \mathsf{lin}$, and on semi-circular databases is strictly less powerful than $\mathsf{FO} + \mathsf{poly}$.

To define this language, we have turned, for inspiration, to the *Euclidean constructions*, i.e., the constructions by ruler and compass that we know from high-school geometry. These constructions were first described in the 4th century B.C. by Euclid of Alexandria in the 13 books of his *Elements* [24]. Of the 465 propositions to be found in these volumes only 60 are concerned with ruler-and-compass constructions. Most of these constructions belong to the mathematical folklore and are known to all of us. "Construct the perpendicular from a given point on a given line" or "construct a regular pentagon" are well-known examples. Since the 19th century, we also know that a certain number of constructions are *not* performable by ruler and compass, e.g., the trisection of an arbitrary angle or the squaring of the circle. For a 20th century description of these constructions and the main results concerning them, we refer the reader to [26].

An alternative to considering languages based on ruler and compass constructions would be to use a constraint language based on the field of the constructible real numbers. It follows from a result by Ziegler that this theory is undecidable [42], however. Ziegler showed, among other results, that any finitely axiomatizable subtheory of the reals with addition, multiplication, and order is undecidable (as conjectured by Tarski).

We define and study in the current paper three languages for ruler-and-compass constructions.

First, we define a programming language that describes Euclidean constructions. We will refer to this procedural language as EuPL (short for Euclidean Programming Language). Engeler [11, 12] studied a similar programming language in the '60s, but his language contains a while-loop and therefore goes beyond first-order logic-based languages. His language also differs from ours in that EuPL also contains a choice

statement. This statement corresponds to choosing arbitrary points, which satisfy some conditions, in the plane, something that is often done in constructions with ruler and compass on paper. We claim that EuPL captures exactly the planar geometrical constructions, i.e., the first-order expressible ruler-and-compass constructions. We show that the choice statement, at least for deterministic programs, can be omitted. We also prove a number of useful decidability properties of EuPL programs: that equivalence and satisfiability of EuPL programs are decidable, and that it is decidable whether a program is deterministic.

We then transform the programming language EuPL into a query language for finite point databases, called EuQL (short for Euclidean Query Language). It turns out that this calculus can express nonconstructible queries—in fact, we show that EuQL has the same expressive power on finite point databases as FO + poly. It is therefore too powerful for our purposes.

We then study a *safe* fragment of EuQL, in which all queries are constructible. In particular, a SafeEuQL query returns constructible finite point relations from given finite point relations.

SafeEuQL is the key ingredient in our query language SafeEuQL$^{\uparrow}$ for semi-circular databases. Since SafeEuQL works on finite point databases, we interpret these queries to work on intensional representations of semi-circular databases. We then give FO + poly-definable mappings from databases to their representation and back. Using these mappings, we can "lift" SafeEuQL to a query language on semi-circular databases. This "lifting" technique has also been used by Benedikt and Libkin [5] and Gyssens, Vandeurzen, and Van Gucht [23].

We then compare the expressive power of SafeEuQL$^{\uparrow}$ with the expressive power of FO + poly on semi-circular databases, and show that on semi-linear databases FO + poly is more expressive than SafeEuQL$^{\uparrow}$. Finally, we compare the expressive power of SafeEuQL$^{\uparrow}$ and FO + lin on semi-linear databases.

Overview of the query languages. The following scheme gives an overview of the different languages. A horizontal arrow indicates that a language is closed on the given class of databases. A subscheme of the form

$$\begin{array}{ccc} B & \xrightarrow{\mathcal{L}_1} & B \\ & \subsetneq \uparrow & \\ A & \xrightarrow{\mathcal{L}_2} & A \end{array}$$

means that on databases in the class A, the language $\mathcal{L}_1$, mapping databases in class A to databases in class A, is more expressive than the language $\mathcal{L}_2$, mapping databases in class B to databases in class B (where B is a larger class of databases than A). The top part of Figure 1, for instance, expresses that SafeEuQL$^{\uparrow}$ is strictly more expressive than FO + poly on semi-circular databases.

Organization of the paper. In the next section, we define FO + poly and FO + lin. In section 3, we introduce the class of semi-circular databases and describe a complete and lossless representation of them by means of finite point databases. We devote the next three sections to the study of the three languages for ruler-and-compass constructions: EuPL, EuQL, and SafeEuQL. The query language for semi-circular databases is given in section 7, where we show that it is closed and compare its expressive power with that of FO + lin on semi-linear databases and FO + poly on semi-circular databases.

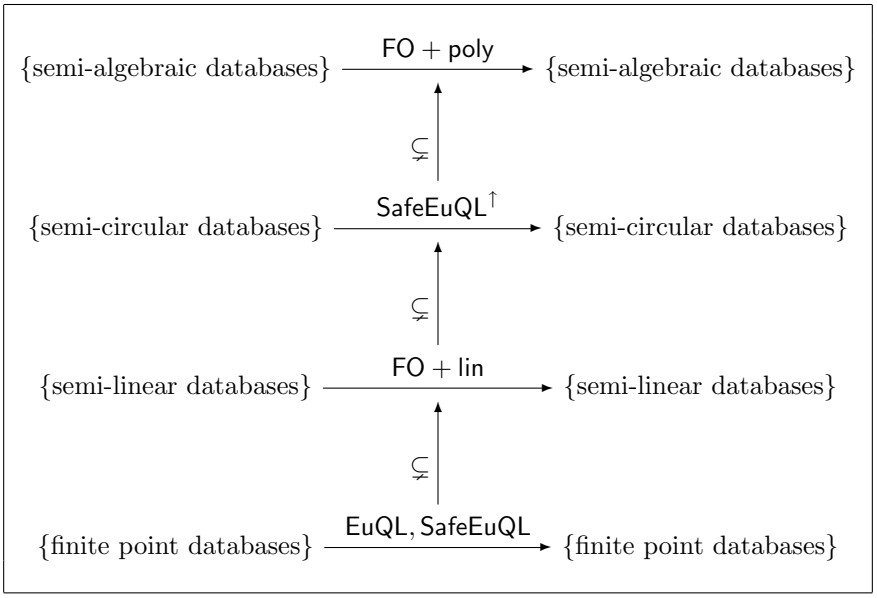

FIG. 1. *Comparison of the expressive power of the different languages.*

2. Constraint-based database models. In this section, we provide the necessary background for the polynomial and linear constraint database models and formally define two query languages, FO + poly and FO + lin, for the polynomial and the linear database model, respectively. Since the linear database model is a submodel of the polynomial database model, we start with the latter. We denote the set of the real numbers by $\mathbf{R}$.

2.1. The polynomial database model. A *polynomial formula* is a well-formed first-order logic formula over the theory of the real numbers, i.e., over $(+, \times, <, 0, 1)$. In other words, a polynomial formula is built with the logical connectives $\wedge$, $\vee$, and $\neg$ and the quantifiers $\exists$ and $\forall$ from atomic formulas of the form $p(x_1, \ldots, x_n) > 0$, where $p(x_1, \ldots, x_n)$ is a polynomial with real algebraic coefficients and real variables $x_1, \ldots, x_n$.

Every polynomial formula $\varphi(x_1, \ldots, x_n)$ with n free variables $x_1, \ldots, x_n$ defines a point set

$$\{(x_1, \ldots, x_n) \in \mathbf{R}^n \mid \varphi(x_1, \ldots, x_n)\}$$

in the n-dimensional Euclidean space $\mathbf{R}^n$ in the standard manner. Point sets defined by a polynomial formula are called *semi-algebraic sets*. We shall also refer to them as *semi-algebraic relations*, since they can be seen as n-ary relations over the real numbers.

We remark that, by the quantifier-elimination theorem of Tarski [38], it is always possible to represent a semi-algebraic set by a quantifier-free formula. The same theorem also guarantees the decidability of the equivalence of two polynomial formulas.

A *polynomial database* is a finite set of *semi-algebraic relations*, and a query in the polynomial database model is a computable mapping from m-tuples of semi-algebraic relations to a semi-algebraic relation.

The most natural query language for the polynomial data model is the relational

calculus augmented with polynomial equalities and inequalities, i.e., the first-order language which contains as atomic formulas polynomial inequalities and formulas of the form $R_i(y_1, \ldots, y_n)$, where R_i $(i = 1, \ldots, m)$ are semi-algebraic relation names for the input parameters of the query, and $y_1, \ldots, y_n$ are real variables. In the literature, this query language is commonly referred to as $\mathsf{FO} + \mathsf{poly}$ [30].

Example 2.1. The $\mathsf{FO} + \mathsf{poly}$ formula

$$R(x, y) \wedge \forall\varepsilon(\varepsilon \leq 0 \vee \exists v \exists w(\neg R(v, w) \wedge (x - v)^2 + (y - w)^2 < \varepsilon))$$

has x and y as free variables. For a given binary semi-algebraic relation R, it computes the set of points with coordinates (x, y) that belong to the intersection of R and its topological border.

Tarski's quantifier-elimination procedure ensures that every $\mathsf{FO} + \mathsf{poly}$ query is effectively computable and yields a polynomial database as result [28, 29] (this property is commonly referred to as "closure").

2.2. The linear database model. Polynomial formulas built from atomic formulas that contain only linear polynomials with real algebraic coefficients are called *linear formulas*. Point sets defined by linear formulas are called *semi-linear sets* or *semi-linear relations*.

We remark that there is also a quantifier-elimination property for the linear model: Any linear formula that contains quantifiers can be converted to an equivalent quantifier-free linear formula. There is a conceptually easy algorithm, usually referred to as Fourier's method, for eliminating quantifiers in the linear model (this method is described in [27, 31]).

A *linear database* is a finite set of *semi-linear relations*. As in the polynomial model, queries in the linear model are defined as mappings from m-tuples of semi-linear relations to a semi-linear relation. A very appealing query language for the semi-linear data model, called $\mathsf{FO} + \mathsf{lin}$, is obtained by restricting the polynomial formulas in $\mathsf{FO} + \mathsf{poly}$ to contain only linear polynomials. Using algebraic computation techniques for the elimination of variables, one can see that the result of every $\mathsf{FO} + \mathsf{lin}$ query is a semi-linear relation [27, 31, 30].

Example 2.2. The $\mathsf{FO} + \mathsf{lin}$ formula

$$R(x, y) \wedge \forall\varepsilon(\varepsilon \leq 0 \vee \exists v \exists w(\neg R(v, w) \wedge x - \varepsilon < v < x + \varepsilon \wedge y - \varepsilon < w < y + \varepsilon))$$

has two free variables: x and y. For a given binary semi-linear relation R, it computes the set of points with coordinates (x, y) that belong to the intersection of R and its topological border. In fact, this formula is equivalent to the one in Example 2.1, even though it makes use of a different metric to compute the topological border. It should be clear that not every $\mathsf{FO} + \mathsf{poly}$ formula has an equivalent $\mathsf{FO} + \mathsf{lin}$ formula.

3. Semi-circular relations. We now describe a class of planar relations in the constraint model that can be described by linear polynomials and those quadratic polynomials that describe circles, and then describe an encoding of these relations as finite relations of points. This encoding will be *complete*, meaning that every such relation has an encoding, and *lossless*, meaning that the original relation can be recovered from the encoding (even in $\mathsf{FO} + \mathsf{poly}$).

DEFINITION 3.1. *We call a subset of* $\mathbf{R}^2$ *a* semi-circular set *or* semi-circular relation *if and only if it can be defined as a Boolean combination of sets of the form*

$$\{(x, y) \mid ax + by + c\ \theta\ 0\},$$

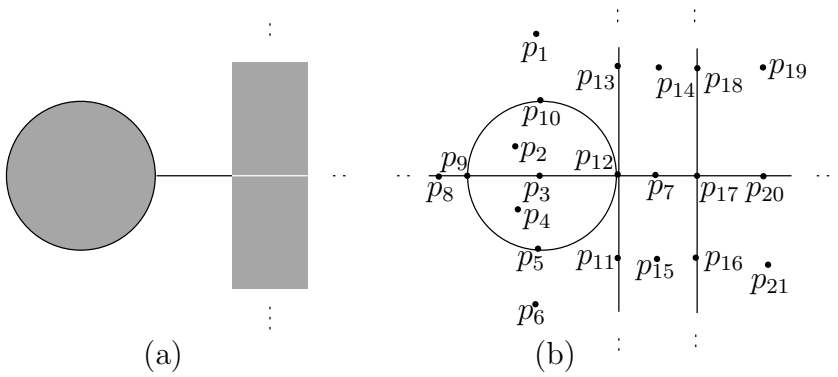

FIG. 2. *A semi-circular relation* (a) *and its carrier* (b).

where a, b, and c are real algebraic numbers with $a \neq 0$ or $b \neq 0$, and θ is either $\geq$ or $>$; or

$$\{(x, y) \mid (x - a)^2 + (y - b)^2 \; \theta \; c^2\} \, ,$$

where a, b, and c are real algebraic numbers with $c \neq 0$, and θ is either $\geq$ or $>$.

As far as planar figures are concerned, the class of semi-circular relations clearly contains the class of semi-linear relations.

Example 3.1. Figure 2(a) shows an example of a semi-circular relation. It is the set

$$\{(x, y) \mid x^2 + y^2 \leq 1 \vee (y = 0 \wedge 1 \leq x < 2) \vee (x > 2 \wedge \neg y = 0)\} \, .$$

Given such a semi-circular database, we consider all of the sets of the form $\{(x, y) \mid p(x, y) = 0\}$ for each polynomial $p(x, y)$ that occurs in the definition of the semi-circular relation.

For the semi-circular relation of Figure 2(a), these sets are shown in Figure 2(b) and are defined by the equations $x^2 + y^2 - 1 = 0$, $y = 0$, $x - 1 = 0$, and $x - 2 = 0$. We refer to these lines and circles as *a carrier* of the semi-circular relation (or as *the carrier* of a particular representation of the semi-circular relation). The carrier in Figure 2(b) partitions the plane $\mathbf{R}^2$ into 21 classes, each of which belongs either entirely to the semi-circular relation or to its complement. In general, these partition classes can be disconnected. We then pick a representative of each of these classes, illustrated by points $p_1, \ldots, p_{21}$ in Figure 2(b). We can then represent a semi-circular relation R by a finite point database[1] that consists of three relations, L, P, and C, as follows:

1. L contains, for each line in the carrier of R, a pair of its points;
2. C contains, for each circle in the carrier of R, its center and one of its points;
3. P contains a representative of each class in the partition induced by the carrier of R that belongs to R.

The sets L and C are binary relations of points in the plane, while the set P is a unary relation of points.

[1]These points can be represented explicitly by their real algebraic coordinates, or implicitly by a real polynomial formula. Equality of such points can therefore be decided by Tarski's theorem [38].

We refer to such a finite representation of a semi-circular relation as an *intensional LPC-representation*. Clearly, a semi-circular relation can have more than one intensional LPC-representation, for example, because there may be more than one constraint formula describing it.

For the semi-circular database of Figure 2(a) we can have the following finite representation: L consists of the tuples (p_7, p_8), (p_{11}, p_{12}), and (p_{16}, p_{17}); C consists of the single tuple (p_3, p_5); and P consists of the points p_2, p_3, p_4, p_5, p_7, p_9, p_{10}, p_{12}, p_{19}, and p_{21}.

The complete plane $\mathbf{R}^2$ can be represented by $L = \emptyset$, $C = \emptyset$, and $P = \{p\}$ for any point p in $\mathbf{R}^2$.

We remark that an intensional LPC-representation of a semi-circular relation is lossless in the sense that the semi-circular relation can be reconstructed from the representation. In section 7, we show how to compute in $\mathsf{FO} + \mathsf{poly}$ an LPC-representation of a semi-circular relation and how to reconstruct, also in $\mathsf{FO} + \mathsf{poly}$, the semi-circular relation from its LPC-representation.

As an immediate consequence of the existence of quantifier-elimination algorithms for the real closed field, we get the following property.

PROPOSITION 3.1. *It is decidable whether two LPC-representations of semi-circular relations represent the same semi-circular relation.*

4. The language EuPL. We now define our first programming language, EuPL, for expressing Euclidean constructions. This language is modeled after the language of Engeler [11], with two key differences. The language of Engeler uses iteration, but we are interested only in first-order database query languages. We therefore first explore the consequences of defining a Euclidean programming language without iteration. An additional feature of EuPL is that it includes a nondeterministic choice operator. We decided to include this operator as it is used frequently in the Euclidean constructions that we want to model, but we shall show that this choice operator is redundant, since, under appropriate assumptions, it can be simulated by other operations.

EuPL has one basic type $\langle \text{var} \rangle$ which ranges over points in the Euclidean plane. We use p, $q, \ldots$ to denote variables. There is no basic notion of lines and circles, since lines are represented by pairs of points (p_1, p_2) and circles by triples (p_1, p_2, p_3), where (p_1, p_2) represents the line through the points p_1 and p_2 (assuming p_1 and p_2 are distinct) and (p_1, p_2, p_3) (assuming p_2 and p_3 are distinct) represents the circle with center p_1 and radius equal to $d(p_2, p_3)$, the distance between p_2 and p_3.[2]

Our language corresponds to one view of Euclidean constructions, as it is known that all ruler-and-compass constructions can be carried out on lines and circles that are represented by points (see [13]). The main reason that we have chosen to use a point representation in EuPL is to make the language similar to the database languages in the following sections, where such an encoding really is necessary. As far as EuPL is concerned, however, we could have defined a similar language with lines and circles as primitive notions—all of the results in the current section, apart from Theorem 4.2, would still hold.

The basic predicates in EuPL are as follows:

1. **defined**(p),
2. $p_1 = p_2$,
3. (i) p_1 **is on line** (p_2, p_3),

[2] We could also represent circles by pairs (p_1, p_2), where p_1 is the center and p_2 a point on the circle, or in other ways. Our choice is arbitrary, but tends to make actual constructions simpler.

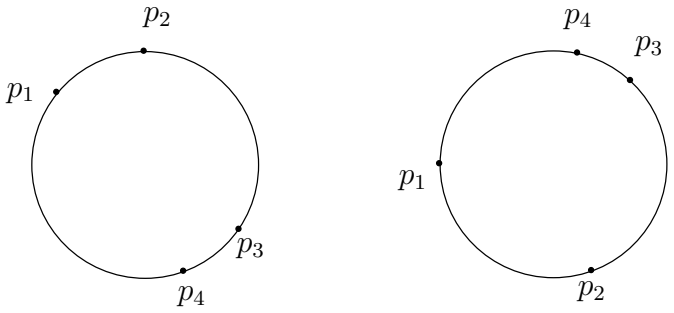

FIG. 3. *The two orientations for* **c-order**(p_1, p_2, p_3, p_4).

(ii) p_1 **is on circle** (p_2, p_3, p_4),
(iii) p_1 **is in circle** (p_2, p_3, p_4),
(iv) p_1 **is on the same side as** p_2 **of line** (p_3, p_4),

4. (i) **l-order**(p_1, p_2, p_3),
(ii) **c-order**(p_1, p_2, p_3, p_4).

The first condition means that the variable p represents a point. Such a test is needed, as a variable may be undefined if it is the result of an intersection of two disjoint objects, such as parallel lines.

Given our encoding of lines and circles, the meaning of the predicates in 3(a–d) should be clear. For example, p_1 **is in circle** (p_2, p_3, p_4) means that p_1 is in the circle with center p_2 and radius $d(p_3, p_4)$. The predicates in 4(a), 4(b) are order relations. The predicate **l-order**(p_1, p_2, p_3) (line-order) means that p_1, p_2, and p_3 are on the same line, and that p_2 is between p_1 and p_3. **c-order**(p_1, p_2, p_3, p_4) (circle-order) means that p_1, p_2, p_3, and p_4 are all on the same circle, in this order, in either the clockwise or the counterclockwise direction (see Figure 3). Note that whenever pairs (respectively, triples) of points do not define lines (respectively, circles), the corresponding predicates are false.

The basic operations in EuPL to compute intersections of objects correspond to the combinations line/line, line/circle, and circle/circle.

1. $q :=$ **l-l-crossing**(p_1, p_2, p_3, p_4);
2. $q_1, q_2 :=$ **l-c-crossing**$(p_1, p_2, p_3, p_4, p_5)$;
3. $q_1, q_2 :=$ **c-c-crossing**$(p_1, p_2, p_3, p_4, p_5, p_6)$.

The semantics of these operators in most cases should be clear, except that the choice of which intersection point to assign to q_1 and which to q_2 is arbitrary.[3] In the case of the intersection of two parallel lines (identical or not), q is undefined, and similarly for the intersection of two disjoint circles, or for the intersection of a disjoint circle and line. In the case of a line tangent to a circle or two circles that meet in a single point, q_1 and q_2 will be identical.

The choice operator, whose syntax is

$$\textbf{choose } p \textbf{ such that } \langle \text{condition} \rangle ,$$

assigns to p, in a nondeterministic manner, a point p that satisfies the given condition. When $\langle$condition$\rangle$ is unsatisfiable, p is undefined.

[3]This actually introduces an additional nondeterminism into the language. This can be handled by straightforward modifications of the proofs that follow and will be ignored from now on.

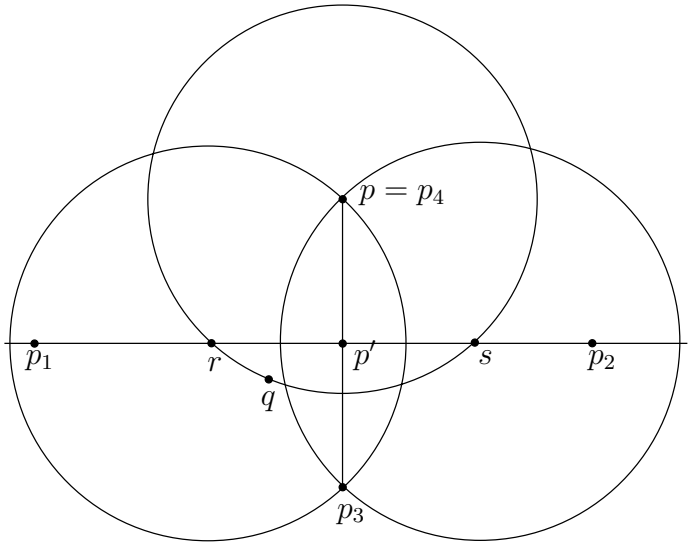

FIG. 4. *Construction of the perpendicular.*

The language also has a conditional statement **if** C **then** S_1 **else** S_2 with the usual semantics. A formal specification of the language appears in the appendix. The basic notion is that of a *multifunction* with n input variables and m output variables, representing points in the plane. Each multifunction is defined by a sequence of assignment statements and conditional statements, without looping, and its result is returned by a **result** statement.

We illustrate the language by several examples, showing how to express several Euclidean constructions in EuPL.

Example 4.1. Given a line (p_1, p_2) and a point p not on the line, construct the perpendicular (p, p') to the given line from p (see Figure 4).

multifunction perp$(p, p_1, p_2) = (p')$;
begin
choose q **such that not**(q **is on the same side as** p **of line** (p_1, p_2));
  $r, s :=$ **l-c-crossing**(p_1, p_2, p, p, q);
  $p_3, p_4 :=$ **c-c-crossing**(r, r, p, s, s, p);
  $p' :=$ **l-l-crossing**(p_1, p_2, p_3, p_4);
  result(p');
end

For another example, we show how to construct an arbitrary point on an ellipse. Given collinear points a, b, p, and q, we construct, for each r between a and b, points r' and r'' "corresponding" to r such that (a) r' and r'' are on the ellipse through a and b with foci p and q and (b) as r ranges from a to b all the points on this ellipse are constructed. Note that the ellipse itself is not constructible with ruler and compass and therefore, as we shall see in Theorem 4.3, cannot be defined by an EuPL program.

Example 4.2. Given the collinear points a, b, p, and q, with $d(a, p) = d(b, q)$, p between a and q, and q between p and b, r' is constructed as follows (see Figure 5):

multifunction put-ellipse$(a, b, p, q) = (r')$;
begin
choose r **such that** **l-order**(a, r, b);

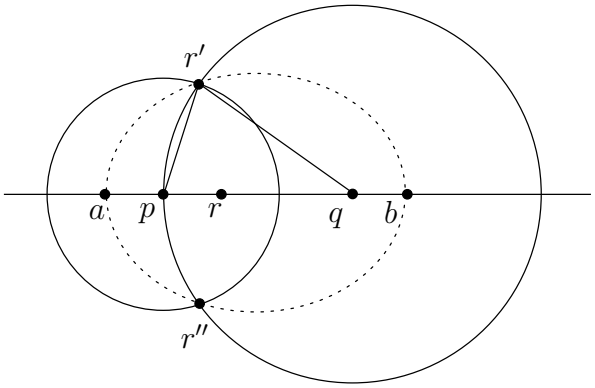

FIG. 5. *Construction of a point on an ellipse.*

$r', r'' :=$ **c-c-crossing**(p, a, r, q, b, r);
result(r');
end

The point r' is on the ellipse with foci p and q and major axis $d(a, b)$ since $d(p, r') + d(q, r') = d(a, r) + d(r, b) = d(p, a) + d(q, a) = d(p, b) + d(q, b)$.

4.1. Consequences of quantifier elimination: Representation independence. As pointed out above, EuPL is at least as powerful as a language with lines and circles as primitives. But EuPL is actually more powerful than desired. For example, if we are given a line represented by points (p_1, p_2), the EuPL program that returns p_1 would have no natural geometric interpretation.

This leads to the following problem: Given an EuPL program, does the result depend on the representation of the input lines and circles or not? The inputs and outputs of an EuPL program are just points, with no indication as to what they "really" represent. We therefore first need to impose an interpretation on these points, i.e., specify which of these points represent lines or circles.

For example, given a program with inputs $(p_1, p_2, p_3, p_4, p_5)$ and outputs (q_1, q_2), we could interpret (p_1, p_2) as a line, (p_3, p_4, p_5) as a circle, and (q_1, q_2) as a line. Other interpretations of the inputs and outputs of the program are also possible: Given a specific interpretation we shall refer to P as an *interpreted* EuPL program.

The formal definition of an interpreted program is very simple. As objects (points, lines, or circles) are represented by 1, 2, or 3 points, respectively, all we need are two equivalence relations on the input and output.

DEFINITION 4.1. *An* interpretation *of an* EuPL *program P is a pair of equivalence relations E_i and E_o on the input and output variables of P, such that each equivalence class has between* 1 *and* 3 *elements.*

Remark. Note that all of the language primitives are well defined, regardless of the interpretations of the variables. For example, q **is in circle** (p_1, p_2, p_3) is well defined even if (p_1, p_2) represents a line and (p_3, q) another line, though it is unlikely to have an intuitive result or be representation-independent. This means that we do not need to address the issue of an interpretation of the internal variables of a program.

We now address the issue of whether an EuPL program P is representation-dependent or not. It turns out that, given an interpretation of P, this is decidable.

First, we define representation dependence.

DEFINITION 4.2. *Let P be an* EuPL *program with input parameters $(p_1, \ldots, p_n)$ and output parameters $(q_1, \ldots, q_m)$ for which an interpretation is fixed. We call P* representation-independent *if for any two inputs values $(a_1, \ldots, a_n)$ and $(a'_1, \ldots, a'_n)$ that represent the same points, lines, and circles in the plane (taking into account the fixed interpretation), P returns outputs $(b_1, \ldots, b_m)$ and $(b'_1, \ldots, b'_m)$, respectively, that also represent the same points, lines, and circles in the plane (taking into account the fixed interpretation).*

The following theorem follows from the fact that the input-output transformations in EuPL can be expressed in first-order logic over the reals and from the fact that the truth of sentences in this logic can be decided (via quantifier elimination) [38].

THEOREM 4.1. *It is decidable whether the output of an interpreted* EuPL *program depends on the representation of its inputs or not.*

Proof. Let P be an EuPL multifunction, with inputs $\vec{\mathbf{p}} = (p_1, \ldots, p_n)$ and outputs $\vec{\mathbf{q}} = (q_1, \ldots, q_m)$. We shall write (p^x, p^y) for the x- and y-coordinates of a point p, and shall also write expressions such as $tp = q$ and $d(p, q) = t$ for $(tp^x = q^x \wedge tp^y = q^y)$ and $(p^x - q^x)^2 + (p^y - q^y)^2 = t^2 \wedge t \geq 0$, respectively.

We define two formulas, $\phi_P(\vec{\mathbf{p}}, \vec{\mathbf{q}}, \vec{\mathbf{r}})$ and $\psi_P(\vec{\mathbf{p}}, \vec{\mathbf{q}}, \vec{\mathbf{r}})$, over the theory of real closed fields, where $\vec{\mathbf{r}}$ is the list of internal variables of P. Intuitively, ϕ_P describes how $\vec{\mathbf{q}}$ depends on $\vec{\mathbf{p}}$, given $\vec{\mathbf{r}}$ as the results of the choice operations, while ψ_P describes the conditions that $\vec{\mathbf{r}}$ and $\vec{\mathbf{q}}$ must satisfy. In what follows, whenever ψ_S is not defined explicitly, it will be a tautology. The separation between ϕ and ψ is not really needed for the current theorem, but will be used later in Theorem 4.2. The basic idea is that for each intersection operation we add a conjunct that says when the corresponding objects are defined and have an intersection, while for each choice operation we add a conjunct that says that the condition is satisfiable. The construction of ϕ and ψ is by induction on the rules defining P. We omit some of the straightforward cases. As a first step, rename variables if needed, to ensure they are not assigned a value more than once.

1. P is the sequence of statements $S_1; S_2; \ldots; S_k$. ϕ_P is defined as $\phi_{S_1} \wedge \cdots \wedge \phi_{S_k}$ and ψ_P as $\psi_{S_1} \wedge \cdots \wedge \psi_{S_k}$.
2. Assignment statements:
   (i) S is $q := \textbf{l-l-crossing}(p_1, p_2, p_3, p_4)$. ϕ_S can be informally given as

   $$\exists! t \exists! t' (q = tp_1 + (1-t)p_2 \wedge q = t'p_3 + (1-t')p_4).$$

   Note that this formula is unsatisfiable whenever q is undefined.
   (ii) S is $q,\ q' := \textbf{l-c-crossing}(p_1, p_2, p_3, p_4, p_5)$. Let $\phi'_S(q, p_1, p_2, p_3, p_4, p_5)$ be

   $$\exists t (q = tp_1 + (1-t)p_2 \wedge d(q, p_3) = d(p_4, p_5)),$$

   which means that q is one of the intersection points. Then ϕ_S is

   $$\phi'_S(q, p_1, p_2, p_3, p_4, p_5) \wedge \phi'_S(q', p_1, p_2, p_3, p_4, p_5) \\ \wedge (q \neq q' \vee (q = q' \wedge \neg \exists q''(\phi'_S(q'', p_1, p_2, p_3, p_4, p_5) \wedge q'' \neq q)));$$

   i.e., q and q' are distinct intersection points if such exist, and both are equal to the unique intersection point if only one exists.
   (iii) S is $q,\ q' := \textbf{c-c-crossing}(p_1, p_2, p_3, p_4, p_5, p_6)$. This is similar to the previous case.

3. S is the conditional

$$\textbf{if } C \textbf{ then } S_1 \textbf{ else } S_2 \textbf{ end}.$$

ϕ_S is

$$\phi_C \to \phi_{S_1} \wedge \phi_{\textbf{not } C} \to \phi_{S_2},$$

and ψ_S is

$$\phi_C \to \psi_{S_1} \wedge \phi_{\textbf{not } C} \to \psi_{S_2}.$$

4. S is the choice statement

$$\textbf{choose } v \textbf{ such that } C.$$

ϕ_S is a tautology, and ψ_S is equal to ϕ_C.

5. Conditionals. Most of the conditionals, such as $p_1 \textbf{ is on line } (p_2, p_3)$ are handled in a similar way to assignments. The most complicated one is when C is $\textbf{c-order}(p_1, p_2, p_3, p_4)$. Here ϕ_C first computes the center of the circle through p_1, p_2, and p_3 and tests whether p_4 is on this circle. If so, $\textbf{c-order}(p_1, p_2, p_3, p_4)$ is true when p_2 and p_4 are not on the same side of the line through p_1 and p_3.
6. C is **defined** ($\langle \text{var} \rangle$). ϕ_C is defined as the appropriate Boolean value.

Assume now that $\vec{\mathbf{p}}$ and $\vec{\mathbf{p}}'$ are two inputs to P that are equivalent with respect to the given interpretation. Let $\vec{\mathbf{q}}$ and $\vec{\mathbf{q}}'$ be the outputs of P on these inputs. From the definition of ϕ_P and the semantics of P, it follows that $\exists \vec{\mathbf{r}}(\phi_P(\vec{\mathbf{p}}, \vec{\mathbf{q}}, \vec{\mathbf{r}}) \wedge \psi_P(\vec{\mathbf{p}}, \vec{\mathbf{q}}, \vec{\mathbf{r}}))$ and $\exists \vec{\mathbf{r}}'(\phi_P(\vec{\mathbf{p}}', \vec{\mathbf{q}}', \vec{\mathbf{r}}') \wedge \psi_P(\vec{\mathbf{p}}', \vec{\mathbf{q}}', \vec{\mathbf{r}}'))$ hold.

Given the interpretation (E_i, E_o) we write formulas $\xi_i(\vec{\mathbf{p}}, \vec{\mathbf{p}}')$ and $\xi_o(\vec{\mathbf{q}}, \vec{\mathbf{q}}')$ that specify when the inputs and outputs are equivalent. For example, if $\{p_1, p_2\}$ is an equivalence class in E_i, then

$$\phi_{p_1'} \textbf{ is on line}_{(p_1, p_2)} \wedge \phi_{p_2'} \textbf{ is on line}_{(p_1, p_2)} \wedge p_1' = p_2'$$

is a conjunct in ξ_i, whereas if $\{q_1, q_2, q_3\}$ is in E_o, then

$$q_1' = q_1 \wedge d(q_2', q_3') = d(q_2, q_3)$$

is a conjunct in ξ_o.

The output of P is then independent of the representation if and only if the formula

$$\forall \vec{\mathbf{p}} \forall \vec{\mathbf{p}}' \forall \vec{\mathbf{q}} \forall \vec{\mathbf{q}}' \exists \vec{\mathbf{r}} \exists \vec{\mathbf{r}}' ((\xi_i(\vec{\mathbf{p}}, \vec{\mathbf{p}}') \wedge \phi_P(\vec{\mathbf{p}}, \vec{\mathbf{q}}, \vec{\mathbf{r}}) \wedge \psi_P(\vec{\mathbf{p}}, \vec{\mathbf{q}}, \vec{\mathbf{r}}) \\ \wedge \phi_P(\vec{\mathbf{p}}', \vec{\mathbf{q}}', \vec{\mathbf{r}}') \wedge \psi_P(\vec{\mathbf{p}}', \vec{\mathbf{q}}', \vec{\mathbf{r}}')) \to \xi_o(\vec{\mathbf{q}}, \vec{\mathbf{q}}'))$$

holds in the real numbers.

As this is a first-order formula over the theory of real closed fields, the result follows from Tarski's theorem. □

Using the formulas ϕ_P and ψ_P, given in the proof of Theorem 4.1, it is clear that we can write an $\mathsf{FO} + \mathsf{poly}$-sentence that expresses that two programs have the same input-output behavior. Therefore, we have the following corollary.

COROLLARY 4.1. *Equivalence of* EuPL *programs is decidable.*

Note that there were two different ways we could have interpreted the choice operator in the above theorem. Either, for equivalent inputs, we make the same choices, obtaining equivalent outputs, or we make different choices for both inputs, resulting in equivalent outputs. We have chosen the first approach above, but modifying the proof to use the latter approach is trivial. As discussed below, "good" programs should be choice-independent anyway, so that the distinction is not very important.

The result of the program in Example 4.1 (computation of a perpendicular) does not depend on the choice made by the choice operator. This is true for the classic Euclidean constructions as well as for all other "reasonable" EuPL programs. As with representation independence, the question whether the result of a program depends on the results of the choice operators is decidable.

The following result holds both for interpreted and for uninterpreted EuPL programs.

COROLLARY 4.2. *It is decidable whether the result of an* EuPL *program depends on the choices made by* **choose** *operators.*

COROLLARY 4.3. *It is decidable whether the result of an interpreted* EuPL *program depends on the representation of its inputs and on the results of the choice operations.*

We now show that given two fixed points and a representation- and choice-independent program P, the use of choice is actually redundant. This means that P can be converted (effectively) into an equivalent deterministic program.

We now consider a variant EuPL^{2c} of EuPL, which is just EuPL with two additional distinct constant points p_0 and p_0'.

THEOREM 4.2. *Every representation- and choice-independent* EuPL^{2c} *program P is equivalent to a program P' which does not use the* **choose** *operator.*

Proof. Let P be an EuPL^{2c} program that is representation- and choice-independent. The choice independence of P implies that the outcome of the program does not depend on the particular value of p that is chosen in any expression

$$\textbf{choose } p \textbf{ such that } \psi(p, p_1, \ldots, p_n)$$

appearing in P. Therefore, any expression **choose** p **such that** $\psi(p, p_1, \ldots, p_n)$ appearing in P may be replaced by a series of EuPL^{2c} statements, among which there is no choice statement, provided that the result is a point p satisfying $\psi(p, p_1, \ldots, p_n)$. We shall now construct such a sequence.

Note first that $\psi(p, p_1, \ldots, p_n)$ is a Boolean combination of basic choice predicates in EuPL^{2c}. We now show that there exists a formula $\psi'(p, p_1, \ldots, p_n)$, equivalent to $\psi(p, p_1, \ldots, p_n)$, such that ψ' is a Boolean combination of atomic predicates in all of which the variable p is the first variable. It will then follow that p belongs to an equivalence class of the plane determined by the lines and circles in these atomic predicates, as these predicates describe how p is located with respect to certain lines and circles determined by the points $p_1, \ldots, p_n$.

We show how to move the variable p to the first position for one specific case; the treatment of the other cases is similar. Consider the predicate

$$p_1 \textbf{ is on the same side as } p_2 \textbf{ of line } (p, p_3).$$

For points p, p_1, p_2, and p_3 that form a quadrangle, this expression is equivalent to $\neg((\varphi_1 \wedge \varphi_2) \vee (\neg\varphi_1 \wedge \neg\varphi_2))$, where φ_1 and φ_2 are, respectively,

$$p \textbf{ is on the same side as } p_1 \textbf{ of line } (p_2, p_3)$$

and

$$p \textbf{ is on the same side as } p_2 \textbf{ of line } (p_1, p_3).$$

We now define an EuPL^{2c} program that produces a set $S_{\psi'}$ containing at least one representative point of each of the equivalence classes of the plane determined by the lines and circles in the formula $\psi'(p, p_1, \ldots, p_n)$. We then replace

$$\textbf{choose } p \textbf{ such that } \psi(p, p_1, \ldots, p_n)$$

by a formula that computes these representative points, checks for each of them whether the condition $\psi'(p, p_1, \ldots, p_n)$ holds, and returns the first such point.

To start with, let $S_{\psi'}$ be the set $\{p_1, \ldots, p_n\}$. Then for each predicate $\textbf{c-order}(p, p_i, p_j, p_k)$ in ψ', construct the center of the circle through p_i, p_j, and p_k, and add it to $S_{\psi'}$. For each circle appearing in ψ' such that no point of $S_{\psi'}$ occurs in the circle, take the intersections of the circle and the line that connects the center to the fixed points p_0 or p_0', and them to $S_{\psi'}$. Next, construct all of the intersection points of the circles and lines in the formula and add them to $S_{\psi'}$. This deals with all equivalence classes that are single points.

Next, for every pair of points in $S_{\psi'}$ add their midpoints to $S_{\psi'}$; for all pairs of points on a circle then add the midpoints of the arc segments between them, and for each unbounded line segment add the intersection of this segment and a circle whose center is the start of the segment and whose radius is the distance between p_0 and p_0'. This deals with the one-dimensional equivalence classes.

Finally, for all triples of points in $S_{\psi'}$, add their centroids to $S_{\psi'}$ This deals with the two-dimensional equivalence classes and completes the proof. □

All of the languages that we shall discuss from now on are deterministic. We should point out that the discussion of choice operators in this section is designed to *motivate* the subsequent sections, not to apply directly to them. We have illustrated why a language without choice operators is appropriate as a language for modeling Euclidean constructions. This will still be the case for the database languages below, even though some of our current results (such as decidability) no longer hold in the presence of a database.

4.2. Euclidean constructions. We now compare the expressiveness of EuPL with the Euclidean constructions it is intended to model. Our first result in this direction follows directly from the definitions.

THEOREM 4.3. *All* EuPL *multifunctions are constructible with ruler and compass.*

What about the converse? The converse does not hold because our language models *first-order* ruler-and-compass constructions. For an example of a non–first-order ruler-and-compass construction, consider the following.

Example 4.3. Let p, q, r, and s be four different points as in Figure 6. Consider the following construction: First we construct the point q_1 on the line through p and q such that $d(q_1, q) = d(q, p)$ such that $q_1 \neq p$. Then we repeat this construction until we get to the other side of the line through r and s. The result will be the first point to the right of the vertical line (q_n with $n = 10$ in Figure 6).

The computation of this point requires iteration, as stated in the following lemma.

LEMMA 4.1. *The above construction cannot be expressed by an* EuPL *program.*

Proof. From the proof of Theorem 4.1 it follows that any EuPL program can be expressed in FO + poly. If the construction from Example 4.3 would be expressible

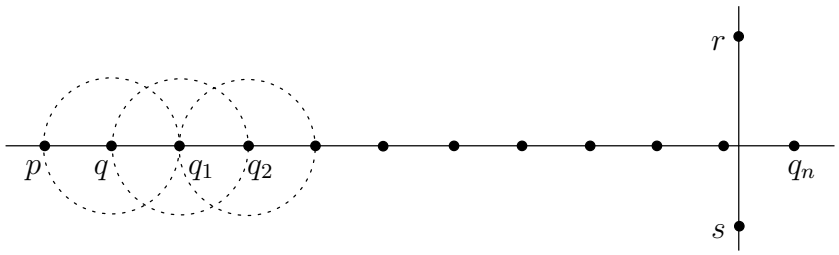

FIG. 6. *Non–first-order construction.*

by an EuPL-program, it would therefore be possible in FO + poly to test whether the distance from p to the vertical through r and s is a multiple of $d(p, q)$, which would allow integers to be definable in FO + poly. Results in [35] would imply the undecidability of FO + poly, a contradiction. □

5. The language EuQL. Our goal is to define a database query language for Euclidean geometry. In this section we describe an initial attempt, EuQL, at defining such a language. EuQL should be a declarative database language, so assignment statements are replaced by predicates. For example, the crossing-point operators become predicates rather than assignments. In addition, the **defined** predicate is not needed, as existential quantifiers can be used instead.

The relations of the input database are finite two-dimensional point relations, i.e., finite tuples of two-dimensional points, represented by real polynomial formulas. The relation R_i, of arity m_i, is an m_i-ary finite two-dimensional point relation, i.e., a $2m_i$-ary relation over the reals. An EuQL query over a schema $R_1, \ldots, R_n$ is of the form

$$Q(R_1, \ldots, R_n) = \{(v_1, \ldots, v_m) \mid \varphi(R_1, \ldots, R_n, v_1, \ldots, v_m)\} ,$$

where φ is a formula in the first-order logic with equality, database predicates, all constant points with real algebraic coordinates, and the following predicates:

1. ⟨var⟩ **is on line** (⟨var⟩, ⟨var⟩),
2. ⟨var⟩ **is on circle** (⟨var⟩, ⟨var⟩, ⟨var⟩),
3. ⟨var⟩ **is in circle** (⟨var⟩, ⟨var⟩, ⟨var⟩),
4. ⟨var⟩ **is on the same side as** ⟨var⟩ **of line** (⟨var⟩, ⟨var⟩),
5. **l-order**(⟨var⟩, ⟨var⟩, ⟨var⟩),
6. **c-order**(⟨var⟩, ⟨var⟩, ⟨var⟩, ⟨var⟩),
7. ⟨var⟩ **is l-l-crossing point of** (⟨var⟩, ⟨var⟩, ⟨var⟩, ⟨var⟩),
8. ⟨var⟩ **is l-c-crossing point of** (⟨var⟩, ⟨var⟩, ⟨var⟩, ⟨var⟩, ⟨var⟩),
9. ⟨var⟩ **is c-c-crossing point of** (⟨var⟩, ⟨var⟩, ⟨var⟩, ⟨var⟩, ⟨var⟩, ⟨var⟩),

EuQL has three constant points o, e_1, and e_2, with (o, e_1) perpendicular to (o, e_2). We shall refer to the line through o and e_1 as the *x-axis* and to the line through o and e_2 as the *y-axis*.

The semantics of EuQL are defined as a function

$$S(Q) : \mathcal{R}_1 \times \cdots \times \mathcal{R}_n \to \mathcal{R} ,$$

where $\mathcal{R}_i$ is the type of relation R_i and $\mathcal{R}$ the type of the result relation of Q. The interpretations of variables, logical connectives, etc., are standard. The other predicates are interpreted in the natural way.

For example, we have the following:

1. $S(v_1 \textbf{ is on line } (v_2, v_3))(r_1, \ldots, r_n)$ is the set of those tuples $(a_{v_1}, a_{v_2}, a_{v_3})$ for which a_{v_2} and a_{v_3} are distinct and a_{v_1}, a_{v_2}, and a_{v_3} are collinear.
2. $S(v_1 \textbf{ is on circle } (v_2, v_3, v_4))(r_1, \ldots, r_n)$ is the set of those tuples $(a_{v_1}, a_{v_2}, a_{v_3}, a_{v_4})$ for which a_{v_1} is on the circle with center a_{v_2} and radius $d(a_{v_3}, a_{v_4})$ and a_{v_3} and a_{v_4} are distinct.

The three special points are interpreted as a coordinate system.

Example 5.1. Given a binary relation R that consists of pairs of points, return the unary relation with the midpoints of each tuple of R:

$$\begin{aligned}\{(p) \mid \exists p_1 \exists p_2 ((&R(p_1,p_2) \wedge p_1 = p_2 \wedge p = p_1)\\ &\vee (R(p_1,p_2) \wedge \neg(p_1 = p_2) \wedge p \textbf{ is on line } (p_1,p_2)\\ &\wedge \exists p_3 \exists p_4 (p_3 \textbf{ is on circle } (p_1,p_1,p_2)\\ &\qquad \wedge p_3 \textbf{ is on circle } (p_2,p_2,p_1)\\ &\qquad \wedge p_4 \textbf{ is on circle } (p_1,p_1,p_2)\\ &\qquad \wedge p_4 \textbf{ is on circle } (p_2,p_2,p_1)\\ &\qquad \wedge \neg(p_3 = p_4) \wedge p \textbf{ is on line } (p_3,p_4))))\}.\end{aligned}$$

Unfortunately, it turns out that EuQL is too powerful. To show why, we define a query that constructs an ellipse, and thus show that EuQL expresses more than just the Euclidean constructions. The construction is similar to the construction of an arbitrary point on an ellipse in EuPL, but by using first-order quantifiers we can essentially simulate choice operators and iterate over all possible choices.

Example 5.2. Given a 4-ary relation of points, for each tuple t return the ellipse with foci t_1 and t_2, and major axis equal to $d(t_3, t_4)$:

$$\begin{aligned}\{(p) \mid \exists t_1 \exists t_2 \exists t_3 \exists t_4 \exists q\\ (R(t_1,t_2,t_3,t_4) \wedge t_2 \textbf{ is on circle } (t_4,t_1,t_3) \wedge \textbf{l-order}(t_3,t_1,t_2)\\ \wedge \textbf{l-order}(t_1,t_2,t_4) \wedge \neg(t_3 = t_4) \wedge \textbf{l-order}(t_3,q,t_4)\\ \wedge p \textbf{ is on circle } (t_1,t_3,q) \wedge p \textbf{ is on circle } (t_2,t_4,q))\}.\end{aligned}$$

THEOREM 5.1. EuQL *can express queries that are not constructible in Euclidean geometry.*

While this shows that EuQL does not match the intuition we had in mind, one might hope that it would still serve as a language between FO + lin and FO + poly. This is not the case, however, as the following result shows.

From Euclid, we know that multiplication can be performed with ruler and compass, and so the following theorem holds.

THEOREM 5.2. *On finite point databases,*[4] EuQL *has the same expressive power*[5] *as* FO + poly.

In order to obtain the desired language, we shall now restrict EuQL in an appropriate way.

[4]We define *finite point databases* as database instances over some database schema $R_1, \ldots, R_n$ in which the interpretation of each relation R_i is a finite set of points in $\mathbf{R}^2$.

[5]Let *can* be the canonical bijection mapping a point p of $\mathbf{R}^2$ to the pair (p^x, p^y) of its real coordinates. An EuQL query Q over an input schema $R_1, \ldots, R_n$ has the same expressive power as an FO + poly query Q' over the schema $R'_1, \ldots, R'_n$, where the arity of R'_i is double the arity of R_i if for any instance $A_1, \ldots, A_n$ over $R_1, \ldots, R_n$, $can(Q(A_1, \ldots, A_n)) = Q'(can(A_1), \ldots, can(A_n))$.

6. The language SafeEuQL. In this section we define a subset of EuQL, called SafeEuQL, that consists of queries whose results, on finite databases, are constructible in Euclidean geometry. This subset consists of those EuQL queries that satisfy a syntactically defined *safety* condition, whose intuition is to restrict the domain over which variables range to be finite, as soon as the input database is finite.

A ⟨disjunction⟩ is defined as a disjunction of ⟨conjunction⟩'s, and a ⟨conjunction⟩ is a conjunction of ⟨factor⟩'s. A ⟨factor⟩ is a ⟨term⟩ or a $\neg$ ⟨term⟩. Finally, a ⟨term⟩ is either $\exists$ ⟨var⟩ (⟨disjunction⟩) or is an EuQL primitive, including the three constant points. We say that an EuQL expression is in *safe-range normal form* if it can be defined as a ⟨disjunction⟩.

We now define the set of variables which are *safe* in an EuQL expression in safe-range normal form. Let R be a relation with attributes of type point. Denote the set of safe variables of an expression φ, with φ in safe-range normal form, by $\mathcal{S}v(\varphi)$. The set $\mathcal{S}v(\varphi)$ then is defined as follows:

1. $\mathcal{S}v(R(v_1, \ldots, v_p))$ equals $\{v_1, \ldots, v_p\}$.
2. For each of the EuQL primitives φ, $\mathcal{S}v(\varphi)$ equals the empty set.
3. $\mathcal{S}v(\exists v\varphi)$ equals $\mathcal{S}v(\varphi) - \{v\}$.
4. $\mathcal{S}v(\neg\varphi)$ equals the empty set.
5. $\mathcal{S}v(\varphi_1 \wedge \varphi_2)$ equals the smallest set S, with respect to $\subseteq$, such that the following properties hold:
   (i) if φ_i is the expression "$v_1 = v_2$" with v_1 or v_2 in S, then both v_1 and v_2 are in S;
   (ii) if φ_i is the expression "v_1 **is l-l-crossing point of** (v_2, v_3, v_4, v_5)" and the variables $v_2, \ldots, v_5$ are in S, then v_1 is in S;
   (iii) if φ_i is the expression "v_1 **is l-c-crossing point of** $(v_2, v_3, v_4, v_5, v_6)$" and the variables $v_2, \ldots, v_6$ are in S, then v_1 is in S;
   (iv) if φ_i is the expression "v_1 **is c-c-crossing point of** $(v_2, v_3, v_4, v_5, v_6, v_7)$" and the variables $v_2, \ldots, v_7$ are in S, then v_1 is in S; and
   (v) $\mathcal{S}v(\varphi_1) \cup \mathcal{S}v(\varphi_2)$ is a subset of S.
   All the above cases also hold for the appropriate variables when the remaining variables are constants. Showing existence of the set S is straightforward.
6. $\mathcal{S}v(\varphi_1 \vee \varphi_2)$ equals $\mathcal{S}v(\varphi_1) \cap \mathcal{S}v(\varphi_2)$.

DEFINITION 6.1. *An* EuQL *query* $\{(v_1, \ldots, v_m) \mid \varphi(R_1, \ldots, R_n, v_1, \ldots, v_m)\}$*, with* φ *in safe-range normal form, is called* safe *if*

1. *for each subformula of* φ *of the form* $\exists v\psi$*, it is the case that* $v \in \mathcal{S}v(\psi)$*, and*
2. *every free variable* v_i *of* φ *is in* $\mathcal{S}v(\varphi)$.

Example 6.1. Consider again the query which computes the midpoints of all tuples of a binary relation R. This query can be expressed with a safe EuQL query as follows:

$$\begin{aligned}\{(p) \mid\ & \exists p_1 \exists p_2 (p_1 = p_2 \wedge R(p_1, p_2) \wedge p = p_1) \\ & \vee \exists p_1 \exists p_2 \exists p_3 \exists p_4 (\neg(p_1 = p_2) \wedge \neg(p_3 = p_4) \wedge R(p_1, p_2) \\ & \quad \wedge p_3 \textbf{ is c-c-crossing point of } (p_1, p_1, p_2, p_2, p_1, p_2) \\ & \quad \wedge p_4 \textbf{ is c-c-crossing point of } (p_1, p_1, p_2, p_2, p_1, p_2) \\ & \quad \wedge p \textbf{ is l-l-crossing point of } (p_1, p_2, p_3, p_4))\}.\end{aligned}$$

The variables p_1 and p_2 are safe in both parts of the disjunction because of the EuQL term $R(p_1, p_2)$. The variables p_3 and p_4 in the second part of the disjunction are safe since they are the two intersection points of circles defined in terms of the safe variables p_1 and p_2. Finally, p is safe because it denotes the intersection point of two lines defined by safe variables.

To show that safety of an EuQL query is a syntactical requirement, consider the query that computes the midpoint of two points as given in Example 5.1. This time, the formula is not safe because p_3, p_4, and p are not safe.

The set of all safe EuQL queries will be called SafeEuQL. The following closure property holds.

THEOREM 6.1. *A* SafeEuQL *query applied to a finite point database yields a finite point database which can be constructed by ruler and compass from the input.*

Proof. Let B be a finite point database and φ a SafeEuQL expression. We show that, when φ is applied to B, every variable v in $\mathcal{S}v(\varphi)$ ranges over a finite domain.

First, let φ be quantifier-free. We prove the claim on the safe variable v in φ by induction on the length of φ, i.e., on the number of propositional connectives in φ.

For the basis, observe that the only SafeEuQL expressions with v as a safe variable are those of the form $R(\ldots, v, \ldots)$, $v = c_1$, v **is l-l-crossing point of** (c_1, c_2, c_3, c_4), v **is l-c-crossing point of** $(c_1, c_2, c_3, c_4, c_5)$, or v **is c-c-crossing point of** $(c_1, c_2, c_3, c_4, c_5, c_6)$ with $c_1, \ldots, c_6$ safe. By assumption the relation R is finite, and thus the claim holds.

Now assume that the claim holds for safe variables in quantifier-free SafeEuQL expressions of length at most k. Let v be a safe variable in the quantifier-free SafeEuQL expression φ of length $k+1$. There are two cases:

1. $\varphi \equiv \psi_1 \vee \psi_2$. From the definition of safety it follows that v is safe in both ψ_1 and ψ_2. By the induction hypotheses, we know that for ψ_1 and ψ_2 applied to B, v ranges over finite domains, say D_1 and D_2. Then when φ is applied to B, v must range over a domain contained in $D_1 \cup D_2$.
2. $\varphi \equiv \psi_1 \wedge \psi_2$. Denote by S the union of $\mathcal{S}v(\psi_1)$ and $\mathcal{S}v(\psi_2)$. By the induction hypothesis, when ψ_1 and ψ_2 are applied to B, each variable of S ranges over a finite domain. Let D be the union of all these domains. Repeat the following process until v is in S. Consider every SafeEuQL primitive in φ which does not occur in any $\neg\psi$, where $\neg\psi$ is a subformula of ψ_1 or ψ_2.
   If the primitive is of the form $v_1 = v_2$ with $v_1 \in S$, then add v_2 to S. If the primitive has the form v_1 **is l-l-crossing point of** (v_2, v_3, v_4, v_5), v_1 **is l-c-crossing point of** $(v_2, v_3, v_4, v_5, v_6)$, or v_1 **is c-c-crossing point of** $(v_2, v_3, v_4, v_5, v_6, v_7)$, where the points $v_2, \ldots, v_7$ are all in S, then add v_1 to S and let D' be the finite set of crossing-points obtained by letting the variables $v_2, \ldots, v_7$ range over the points of D. Add the points in D' to D. The resulting set is still finite, and every variable of S ranges over at most the points in D. Since, by assumption, v is safe in φ, it follows that this process terminates after a finite number of steps. Thus, for φ applied on B, v ranges over a finite set of points.

Note that the case $\varphi \equiv \neg\psi$ cannot occur because it has no safe variables.

Next, consider a SafeEuQL term of the form $\exists v\psi$ with ψ quantifier-free. By the definition of safety, v must be safe in ψ. As a consequence of the first part of the proof, when ψ is applied on B, v ranges over a finite domain, say D_v. Replace the formula $\exists v\psi$ in φ by $D_v(v) \wedge \psi$, which results in a SafeEuQL expression with the same result on B as φ. Since φ has only a finite number of quantifiers, we can repeat this process until we obtain a quantifier-free SafeEuQL expression with the same result as φ on the finite point database B. All (free) variables in this expression range over a finite domain, and thus the result of the expression will also be finite.

Finally, observe that every EuQL primitive can be simulated with ruler and compass. Since every variable in a SafeEuQL expression applied to a finite point database

ranges over a finite set of points, there exists a finite sequence of ruler-and-compass constructions which yields the same set of points as the SafeEuQL expression. Thus, for every SafeEuQL expression, the finite output database can be constructed with ruler and compass from the input database, which concludes the proof. □

THEOREM 6.2. *SafeEuQL has full arithmetical power on the coordinates of safe variables; i.e., we can subtract, add, multiply, and divide coordinates of such variables.*

Proof. Assume that p and q are safe variables. Using the three fixed points as a coordinate system, we write SafeEuQL queries to compute the points with coordinates $(p_1, 0)$, $(0, p_2)$, $(q_1, 0)$, and $(0, q_2)$, where p_1, p_2, q_1, and q_2 are the coordinates of the points p and q, respectively. Without loss of generality, we can therefore assume that p and q are safe variables with coordinates of the form $(p_1, 0)$ and $(q_1, 0)$. If we then consider the well-known ruler-and-compass constructions for multiplication and division, it is easy to see that they can be expressed as SafeEuQL queries. This concludes the proof. □

7. The main results. We now define two query languages which are closed on semi-circular relations. The first, $\mathsf{SafeEuQL}^{\uparrow}$, captures those first-order geometrical constructions that can be described by ruler and compass. The second captures all $\mathsf{FO} + \mathsf{poly}$ expressible queries that map semi-circular relations to semi-circular relations.

To define these languages, we lift the query language SafeEuQL, which is defined on finite point databases, to a language called $\mathsf{SafeEuQL}^{\uparrow}$, which is defined on semi-circular databases. This is done by interpreting these $\mathsf{SafeEuQL}^{\uparrow}$ queries to work on the intensional representations of semi-circular databases defined in section 3.

We use the following convention: R_{poly} refers to a two-dimensional semi-algebraic relation, R_{circ} to a semi-circular relation, and R_{lin} to a two-dimensional semi-linear relation.

Given an LPC-database which, by definition, consists of finite relations of points in the plane, there exists a database consisting of three relations containing the coordinates of the points in the relations L, P, and C, respectively. Indeed, for every point appearing in the relations L, P, or C, we can compute the coordinates of that point with respect to the coordinate system defined by the constant points o, e_1, and e_2, by constructing parallel lines with the line oe_2 (respectively, oe_1) through the points in the finite relations, and then taking the intersection of these lines with the line oe_1 (respectively, oe_2).

In the following, we shall not distinguish between the point and coordinate representation of an LPC-database; i.e., given L, P, and C relations, we will interpret them as points or coordinates depending on the context in which they are used.

7.1. The query language $\mathsf{SafeEuQL}^{\uparrow}$. Before defining $\mathsf{SafeEuQL}^{\uparrow}$, we need two lemmas. The first is straightforward.

LEMMA 7.1. *There exists an* $\mathsf{FO} + \mathsf{poly}$ *query* $Q_{(L,P,C)\to R_{\text{circ}}}$ *that maps the coordinate representation of every intensional LPC-representation of a semi-circular relation to the semi-circular relation it represents.*

LEMMA 7.2. *There exists an* $\mathsf{FO} + \mathsf{poly}$ *query*

$$Q_{R_{\text{circ}}\to(L,P,C)}$$

that maps any semi-circular relation to the coordinate representation of an intensional LPC-representation of this relation.

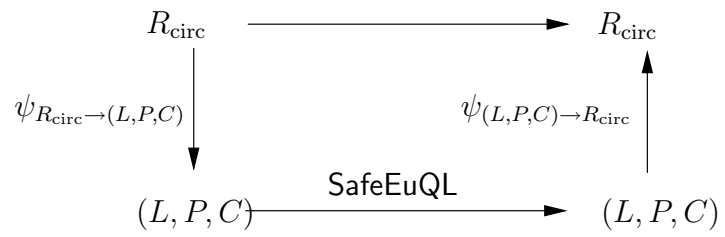

FIG. 7. *The query language* $\mathsf{SafeEuQL}^{\uparrow}$ *is closed on semi-circular relations.*

Proof. Let S be a semi-circular set. It is well known that the topological boundary of S, ∂S can be expressed in $\mathsf{FO}+\mathsf{poly}$ (e.g., using the first-order definition of ε-environments of points). The same is obviously true for the complement of S, S^c and therefore also for the boundary of the complement of S, ∂S^c.

Consider the following sets. Let L_S be the set of all triples (a,b,c) of $\mathbf{R}^3$ such that the line $ax+by+c=0$ has infinitely many points in common with ∂S or with ∂S^c. Let C_S be the set of all triples (a,b,r) of $\mathbf{R}^3$ such that the circle $(x-a)^2+(y-b)^2-r^2=0$ has infinitely many points in common with ∂S or with ∂S^c. Next, let us denote by $\partial^2 S$ the set consisting of all isolated points of ∂S and of ∂S^c and of all end points of half-lines, line segments, and circle segments on ∂S or ∂S^c (a point p is said to be an *end point* of a line segment l with carrier c if there exists an $\varepsilon>0$ and a point q such that $d(p,q)<\varepsilon$ and $q\in c\setminus l$; and end point of a circle segment is defined in a similar way). Let I_S be the set of all triples $(1,0,-a)$ and $(0,1,-b)$ of $\mathbf{R}^3$ such that (a,b) are the coordinates of a point of $\partial^2 S$.

It is clear that all lines and circles in a carrier of S are appearing in $L_S\cup I_S$, respectively C_S, albeit multiple times (except for the lines given by I_S). We can consider the first-order definable equivalence relation $\sim_L$ on $L_S\cup I_S$, defined as $(a,b,c)\sim_L(a',b',c')$ if and only if the equations $ax+by+c=0$ and $a'x+b'y+c'=0$ define the same line (i.e., if and only if $ac'=a'c$ and $bc'=b'c$). We can also consider the first-order definable equivalence relation $\sim_C$ on C_S, defined as $(a,b,r)\sim_L(a',b',r')$ if and only if the equations $(x-a)^2+(y-b)^2-r^2=0$ and $(x-a')^2+(y-b')^2-r'^2=0$ define the same circle (i.e., if and only if $a=a'$, $b=b'$, and $r=\pm r'$). By the definable choice property (see, e.g., Property 1.2 in Chapter 6 of [39]), representatives of each equivalence class can be first-order defined. Once this is done it is easy to obtain two representative points on each line in the L relation of S and the center and a representative point on each circle in the C relation of S.

It remains to be shown that also the P relation of S can be first-order defined. The sets $L_S\cup I_S$ and C_S partition $\mathbf{R}^2$ according to the following first-order definable equivalence relation $\sim_S$: $(x,y)\sim_S(x',y')$ if and only if for all $(a,b,c)\in L_S\cup I_S$, $ax+by+c$ and $ax'+by'+c$ have the same *sign* ($=0$, <0, or >0) and for all $(a,b,r)\in C_S$, $(x-a)^2+(y-b)^2-r^2$ and $(x'-a)^2+(y'-b)^2-r^2$ have the same sign.

Since $\sim_S$ is first-order definable, again by the definable choice property, representatives of each equivalence class of $\sim_S$ can be first-order defined and added to the P relation of S whenever these representatives belong to S. ∎

DEFINITION 7.1. $\mathsf{SafeEuQL}^{\uparrow}$ *is the set of all queries* Q *of the form*

$$Q_{(L,P,C)\to R_{\text{circ}}}\circ Q_{\mathsf{SafeEuQL}}\circ Q_{R_{\text{circ}}\to(L,P,C)},$$

where Q_{SafeEuQL} *is a* SafeEuQL *query (see Figure* 7*).*

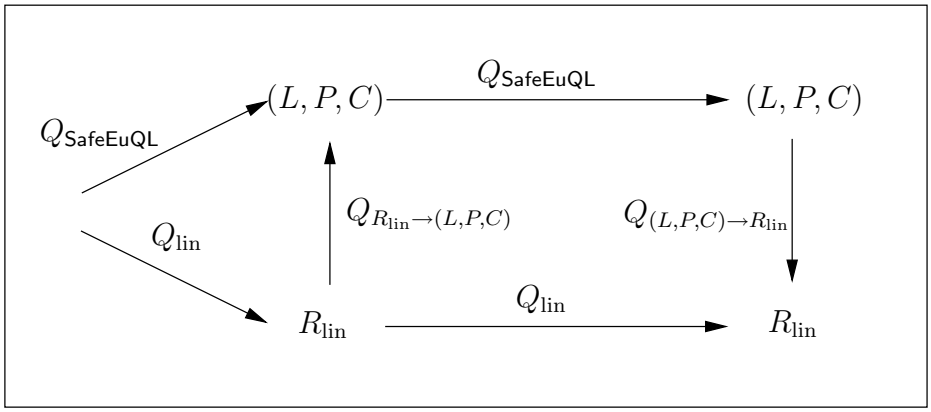

FIG. 8. *Any* $\mathsf{FO}+\mathsf{lin}$ *query on semi-linear relations can be simulated in* SafeEuQL *on the intensional level. The two arrows at the left denote the property that any semi-linear relation can be defined in the language* $\mathsf{FO}+\mathsf{lin}$ *and that any LPC-database can be defined in* SafeEuQL.

A $\mathsf{SafeEuQL}^{\uparrow}$ query is therefore a composition of three queries. First, the query maps a semi-circular relation to its *LPC*-representation. The point representation of this *LPC*-database then is the input of a SafeEuQL query which produces another *LPC*-database. Finally, the coordinate representation of this *LPC*-database is mapped to the semi-circular relation it represents. (A similar "lifting" idea is used in [5].)

The language $\mathsf{SafeEuQL}^{\uparrow}$ is closed on the class of semi-circular relations. This is illustrated in Figure 7. We thus have a syntactically defined subclass of $\mathsf{FO}+\mathsf{poly}$ that is closed on semi-circular relations.

7.2. On semi-linear relations the language $\mathsf{SafeEuQL}^{\uparrow}$ is more expressive than $\mathsf{FO}+\mathsf{lin}$. As discussed in section 3 and Lemma 7.2, every two-dimensional semi-linear relation can be intensionally represented as a finite *LPC*-database. We will show that every $\mathsf{FO}+\mathsf{lin}$ query on semi-linear relations can be simulated in SafeEuQL on the intensional level. Therefore, we can conclude that $\mathsf{SafeEuQL}^{\uparrow}$, on semi-linear databases, can express every $\mathsf{FO}+\mathsf{lin}$ query. On the other hand, it is clear that $\mathsf{SafeEuQL}^{\uparrow}$ is more expressive than $\mathsf{FO}+\mathsf{lin}$ on linear inputs, simply because the latter can output linear databases only, while the former can also produce semi-circular ones.

This is illustrated in Figure 8 and stated more precisely in the following theorem, whose proof follows later in this section.

THEOREM 7.1. *There exist* $\mathsf{FO}+\mathsf{poly}$ *queries* $Q_{R_{\mathrm{lin}}\to(L,P,C)} : R_{\mathrm{lin}} \mapsto (L,P,C)$ *and* $Q_{(L,P,C)\to R_{\mathrm{lin}}} : (L,P,C) \mapsto R_{\mathrm{lin}}$ *such that, for every* $\mathsf{FO}+\mathsf{lin}$ *query* $Q_{\mathrm{lin}} : R_{\mathrm{lin}} \mapsto R_{\mathrm{lin}}$*, there exists a* SafeEuQL *query* $Q_{\mathsf{SafeEuQL}} : (L,P,C) \mapsto (L,P,C)$ *such that*

$$Q_{\mathrm{lin}} = Q_{(L,P,C)\to R_{\mathrm{lin}}} \circ Q_{\mathsf{SafeEuQL}} \circ Q_{R_{\mathrm{lin}}\to(L,P,C)}.$$

The main difficulty is to prove the existence of the SafeEuQL query which simulates a given $\mathsf{FO}+\mathsf{lin}$ query. From Lemmas 7.1 and 7.2, it follows that there exist $\mathsf{FO}+\mathsf{poly}$ queries which translate a linear relation into the coordinate representation of a corresponding *LPC*-database, and vice versa. Moreover, an examination of the proofs of Lemmas 7.1 and 7.2 shows that the corresponding *LPC*-database for a linear relation has an empty *C*-relation; we shall refer to such an encoding as an *LP*-database.

The main difficulty in simulating an FO + lin expression by a SafeEuQL expression is that, in general, subformulas of FO + lin expressions operate in a higher dimensional space, due to the quantifiers that may be present in the expression. Therefore, the LP-representation technique for two-dimensional linear relations has to be generalized to allow the representation of higher dimensional linear relations. For any semi-linear set of $\mathbf{R}^n$, there exist a finite number of n-dimensional hyperplanes which partition $\mathbf{R}^n$ into topologically open, convex cells, such that a finite number of these cells constitute the given semi-linear set. These $(n-1)$-dimensional hyperplanes are finitely represented with n linearly independent points. An n-dimensional point p can be represented within SafeEuQL as a tuple of n two-dimensional points as $((p_1,0),\ldots,(p_n,0))$, where p_i is the ith coordinate of p. Based on this, each n-dimensional semi-linear set is represented in SafeEuQL by a pair of relations (H^n, P^n), where H^n is a $2n^2$-ary relation containing the representation of a finite number of $(n-1)$-dimensional hyperplanes, and where P^n is a $2n$-ary relation containing the representations of the representatives of the partition classes that constitute the semi-linear set. More precisely, the hyperplane in $\mathbf{R}^n$ through the points $\overline{p_i} = (p_{i,1},\ldots,p_{i,n}) \in \mathbf{R}^n$, $1 \le i \le n$, is stored in H^n by the $2n^2$-ary tuple $(((p_{1,1},0)\ldots,(p_{1,n},0)),\ldots,((p_{n,1},0)\ldots,(p_{n,n},0)))$. As an example, the semi-linear subset $\{(x,y,z) \in \mathbf{R}^3 \mid z > 0 \wedge y > 0\}$ of $\mathbf{R}^3$ could be given by (H^3, P^3), with $H^3 = \{((0,0),(0,0),(0,0),(1,0),(0,0),(0,0),(0,0),(1,0),(0,0),(0,0),(0,0),(0,0),(1,0),(0,0),(0,0),(0,0),(0,0),(1,0))\}$ and $P_3 = \{((1,0),(1,0),(1,0))\}$.

Before giving the proof of Theorem 7.1, we prove two lemmas.

The first follows immediately from the fact that we can do arithmetic with Euclidean constructions.

LEMMA 7.3. *Denote by H^n the $2n^2$-ary point relation containing the representation of a finite number of hyperplanes of the n-dimensional space. Assume that x and y are safe variables. There exists a* SafeEuQL *expression SameSide$(H^n; p, q)$ which decides whether the two n-dimensional points p and q are on the same side of each hyperplane of H^n.*

LEMMA 7.4. *Denote by H^n the $2n^2$-ary point relation containing the representation of a finite number of hyperplanes of the n-dimensional space. There exists a* SafeEuQL *expression which computes the relation P^n that contains at least one representative point for every partition class induced by the hyperplanes of H^n.*

Proof. First, add the representation of every coordinate-plane of the n-dimensional space to the relation H^n. The partition induced by the hyperplanes of this new relation H^n is a refinement of the partition induced by the old relation H^n. Therefore, a finite set of representatives of this new partition is also a set of representatives of the old partition.

Next, take n hyperplanes from the relation H^n which are linearly independent, i.e., if no pair is either parallel or equal. We can test this in SafeEuQL as follows. Let p be an arbitrary point on the first hyperplane and q on the second. If, for each point r on the first hyperplane, the point as $r+q-p$ belongs to the second hyperplane, the two hyperplanes are equal or parallel. Since p, q, and r have to be in H^n, they must be safe variables, and by Theorem 6.2 we obtain a SafeEuQL expression which computes $r+q-p$. From Lemma 7.3 we can test in SafeEuQL whether a point belongs to a given hyperplane, and so we can test linear independence of hyperplanes in SafeEuQL.

Every set of n linearly independent hyperplanes of the n-dimensional space intersects in exactly one point. Using Theorem 6.2 again, we construct a SafeEuQL expression for computing this intersection point. Denote by I the set of all of inter-

section points of all sets of n linearly independent hyperplanes of H^n. (I cannot be empty since each hyperplane of H^n intersects at least $n-1$ coordinate planes and therefore contributes at least one point to I.)

We now compute representative points of the *bounded* partition classes induced by the hyperplanes of H^n. Each bounded partition class is convex, since it is the intersection of a finite number of open half-planes. Therefore, the topological closure of a partition class can be written as the convex hull of a finite number of points, the *corner points*, which must be in I, and the barycenter of these corner points can be taken as a representative, which can be expressed in SafeEuQL.

For unbounded partition classes, the set I may not suffice to compute the representative points. To handle this case we use a "bounding box": Each partition class will have a nonempty intersection with this bounding box, and we can choose a representative of the intersection of the partition class with the bounding box.

We now show how to construct this bounding box. For each coordinate plane of the n-dimensional space, we compute, in SafeEuQL, two hyperplanes parallel with this coordinate plane such that all points of I are between these hyperplanes.

Denote by H_B the resulting set of $2n$, and let B be the open n-dimensional bounding box defined by the hyperplanes of H_B. We claim that B has a nonempty intersection with each partition class induced by the hyperplanes of H^n. Indeed, each unbounded partition class has at least one corner point: It intersects at least $n-1$ coordinate planes which were added to H^n. This corner point was obtained from intersections of hyperplanes of H^n and is therefore contained in B. Since B is open, there exists a neighborhood of the corner point which is completely contained within B. The corner point, however, is also in the topological closure of its partition class, and therefore, this neighborhood has a nonempty intersection with the partition class. Therefore B has a nonempty intersection with the partition class. Finally, bounded partition classes are completely contained within B, since their topological closure can be written as the convex hull of points of I.

Let I' be the set of all intersection points of n linearly independent hyperplanes of $H^n \cup H_B$, which can be computed in SafeEuQL. The finite set of points P^n containing the barycenter of each n-tuple of points from I' contains, for each partition class induced by the hyperplanes of H^n, a representative of the intersection of that partition class with B. Since each partition class has a nonempty intersection with B, the set P^n contains a representative for each partition class induced by the hyperplanes of H^n. □

Proof of Theorem 7.1. Assume that Q_{lin} is an FO + lin query defined by a formula φ of FO + lin. Let I_{lin} be an arbitrary two-dimensional linear relation, and let O_{lin} be the result of Q_{lin} applied on I_{lin}.

Denote the LP-representations for I_{lin} and O_{lin} by I_L, I_P and O_L, O_P, respectively, which can be computed in FO + poly (see Lemma 7.2). We now construct SafeEuQL queries Q_L and Q_P such that for any input relation I_{lin} with LP-representation I_L and I_P, $Q_L(I_L, I_P) = O_L$ and $Q_P(I_L, I_P) = O_P$, where O_L and O_P are an LP-representation of the output $O_{lin} = Q_{lin}(I_{lin})$.

We prove this by induction on the structure of φ. For each subformula of φ with n free variables, we construct two SafeEuQL queries that construct the relations H^n and P^n, corresponding to the two parts of the LP-representation of the result.

1. *Atomic formula of the form $I_{lin}(x, y)$.* For each tuple (p, q) of I_L, H^2 should contain a tuple of the form $((p_x, 0), (p_y, 0), (q_x, 0), (q_y, 0))$, where p_x, p_y, q_x, q_y are the coordinates of p and q. For each tuple (p) of I_P, P_I should contain

a tuple $((p_x, 0), (p_y, 0))$. This can easily be expressed in SafeEuQL.

2. *Atomic formula of the form* $\sum_{i=1}^{n} a_i x_i \ \theta \ 0$*, with* $\theta \in \{=, <, >\}$. There exist n linearly independent points $p_1, \ldots, p_n$ such that the smallest affine space containing $p_1, \ldots, p_n$ is precisely the hyperplane given by $\sum_{i=1}^{n} a_i x_i = 0$, and there also exists a point p satisfying $\sum_{i=1}^{n} a_i x_i \ \theta \ 0$. Furthermore, the coordinates of these points can be computed in SafeEuQL. From this, it follows immediately that H^n and P^n can be expressed in SafeEuQL.
3. $\varphi_1(x_1, \ldots, x_m) \vee \varphi_2(x_1, \ldots, x_n)$. If $m \neq n$, assume without loss of generality that $m < n$. Assume that we have already computed the sets (H_1^m, P_1^m) and (H_2^m, P_2^m) in SafeEuQL. We first convert (H_1^n, P_1^n) to a representation of the formula $\varphi_1(x_1, \ldots, x_m, \ldots, x_n)$ in n-dimensional space by padding the representation of each point with $n - m$ zeros.
   The representation (H^n, P^n) of $\varphi_1(x_1, \ldots, x_n) \vee \varphi_2(x_1, \ldots, x_n)$ is then computed as follows. H^n is the union of H_1^n and H_2^n. Let P be a set of representatives of all the partition cells induced by the hyperplanes represented by H^n. The set P^n is then obtained from P as

$$\{x \mid P(x) \wedge \exists y((P_1^m(y) \wedge \mathit{SameSide}(H_1^m; x, y)) \vee (P_2^m(y) \wedge \mathit{SameSide}(H_2^m; x, y)))\} .$$

4. $\neg\varphi_1(x_1, \ldots, x_m)$. In this case, $H^m = H_1^m$ and $P^m = \{x \mid P(x) \wedge \neg\exists y(P_1^m(y) \wedge \mathit{SameSide}(H_1^m; x, y))\}$.
5. $\exists x_i \varphi_1(x_1, \ldots, x_m)$. Let H^m and P^m be the representation of φ_1. For every two hyperplanes of H^m, compute a finite representation of their intersection, and project this representation onto the appropriate $m-1$ dimensions. If the projection of two points coincides, introduce an arbitrary new point, so that we obtain $(m-1)$ linearly independent points denoting a hyperplane in the ith coordinate plane, and add a tuple with these $(m-1)$ points to H^{m-1}. To compute P^{m-1}, let P be the set of all representatives of the partition induced by the hyperplanes in H^{m-1}. Let p be a point of P and q a point of P^m. Compute the intersection point r of the perpendicular to the ith coordinate plane through p with the hyperplane through q parallel with the ith coordinate plane. If q and r belong to the same partition class induced by the hyperplanes of H^m, add p to P^{m-1}. It is straightforward to verify that this can be computed in SafeEuQL.

We have obtained two SafeEuQL queries that compute the relations

$$\{((p_1, 0), (p_2, 0), (q_1, 0), (q_2, 0)) \mid O_L((p_1, p_2), (q_1, q_2))\}$$

and

$$\{((p_1, 0), (p_2, 0)) \mid O_P((p_1, p_2))\}.$$

From these, computing O_L and O_P is trivial. ∎

7.3. On both semi-circular and semi-linear relations, FO + poly is more expressive than SafeEuQL$^{\uparrow}$. We define the fragment of FO + poly that maps semi-circular relations to semi-circular relations. Later on, we will show that this language also allows for the formulation of "nonconstructible" queries and therefore is more powerful than SafeEuQL$^{\uparrow}$.

DEFINITION 7.2. *Let* FO + poly$_{\text{circ}}$ *be the set of* FO + poly *queries that map semi-circular relations to semi-circular relations.*

The following result follows immediately from Lemma 7.5 below.

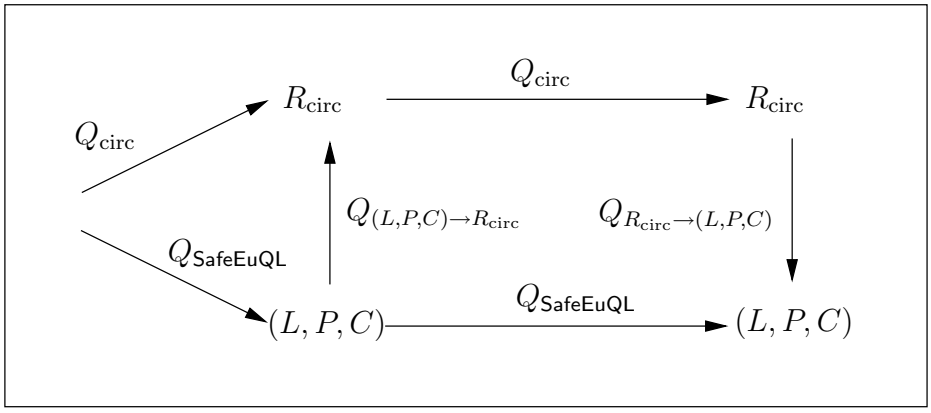

FIG. 9. *The query languages* $\mathsf{SafeEuQL}^{\uparrow}$ *and* $\mathsf{FO}+\mathsf{poly}_{\text{circ}}$. *Again, the arrows at the left denote which relations and databases can be defined in the respective languages.*

THEOREM 7.2. $\mathsf{SafeEuQL}^{\uparrow}$ *is a strict subset of* $\mathsf{FO}+\mathsf{poly}_{\text{circ}}$.

LEMMA 7.5 (Figure 9). *For every* SafeEuQL *query, there exists an* $\mathsf{FO}+\mathsf{poly}_{\text{circ}}$ *query* $Q_{\text{circ}} : R_{\text{circ}} \mapsto R_{\text{circ}}$ *such that*

$$Q_{\mathsf{SafeEuQL}} = Q_{R_{\text{circ}}\to(L,P,C)} \circ Q_{\text{circ}} \circ Q_{(L,P,C)\to R_{\text{circ}}},$$

but not conversely.

Proof. First, we show the existence of the $\mathsf{FO}+\mathsf{poly}_{\text{circ}}$ query Q_{circ}. From Theorem 5.2, it follows that every query expressible in EuQL can be simulated in $\mathsf{FO}+\mathsf{poly}$. The same holds for SafeEuQL, since it is a sublanguage of EuQL. Let $\tilde{Q}_{\text{circ}}$ be the $\mathsf{FO}+\mathsf{poly}$ query which simulates the SafeEuQL query Q_{SafeEuQL}; i.e., $\tilde{Q}_{\text{circ}}$ applied to the coordinate representation of an LPC-database has the same result as Q_{SafeEuql} applied to the LPC-database. Then let Q_{circ} be the query $Q_{(L,P,C)\to R_{\text{circ}}} \circ \tilde{Q}_{\text{circ}} \circ Q_{R_{\text{circ}}\to(L,P,C)}$. Clearly, Q_{circ} is an $\mathsf{FO}+\mathsf{poly}_{\text{circ}}$ query which satisfies the above conditions.

For the second part, consider the query that maps a semi-circular relation consisting of a line segment qr and a point p that is not collinear with q and r to the same relation augmented with two line segments ps and pt such that the angles $\angle pqs$, $\angle pst$, and $\angle ptr$ are equal. This query is expressible in $\mathsf{FO}+\mathsf{poly}$. Since the query maps every semi-circular relation to a semi-circular relation, it belongs to $\mathsf{FO}+\mathsf{poly}_{\text{circ}}$. However, it is not expressible in $\mathsf{SafeEuQL}^{\uparrow}$, since the trisection of an angle cannot be done with ruler and compass, and is therefore not expressible in SafeEuQL. □

We conclude with a remark on $\mathsf{FO}+\mathsf{poly}$, which is defined on R_{poly} relations. The richer class of 2-dimensional figures on which $\mathsf{FO}+\mathsf{poly}$ is defined allows us to express, for example, the construction of an ellipse. Once restricted to semi-circular relations, however, it follows immediately from the definitions that $\mathsf{FO}+\mathsf{poly}$ and $\mathsf{FO}+\mathsf{poly}_{\text{circ}}$ have the same expressive power.

8. Conclusion. Figure 10 summarizes our results.

1. On the bottom level of Figure 10, we have $\mathsf{FO}+\mathsf{lin}$ as a query language on semi-linear relations. Recall that queries concerning Euclidean distance are not expressible in this language. Not only does the data model only

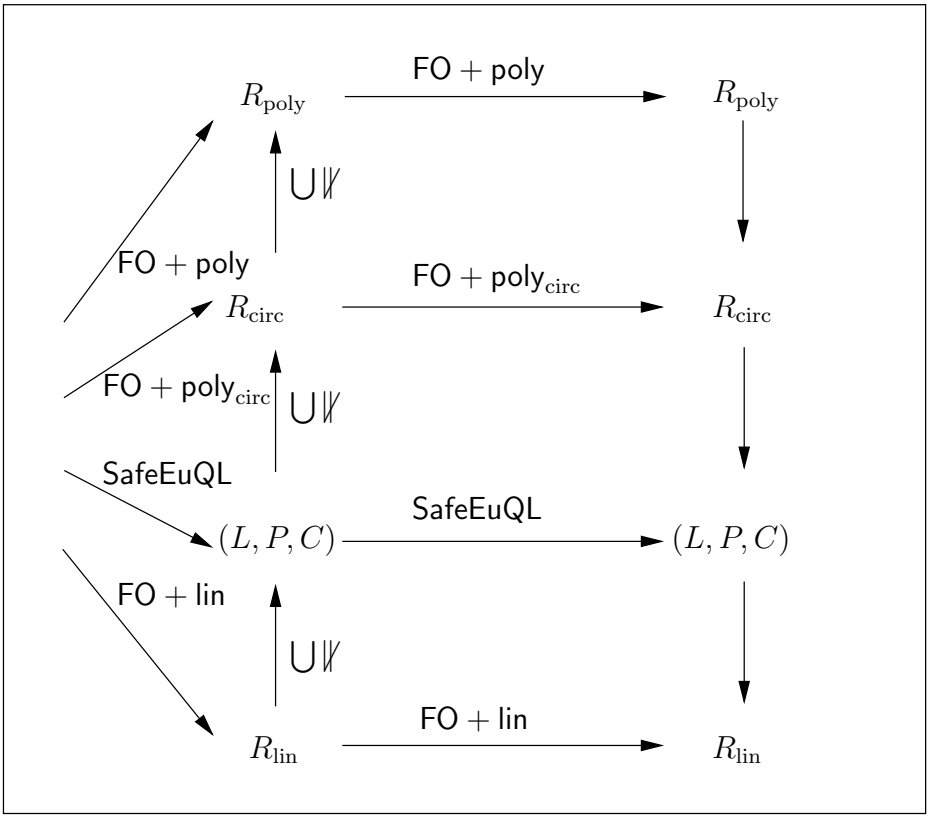

FIG. 10. *Comparison of the different query languages.*

allow semi-linear relations, but, moreover, there are FO + poly queries mapping semi-linear relations to semi-linear relations that are not expressible in FO + lin, for example, the transformation of a relation into its convex hull [41].

2. On the next level, we have more expressive power on (the intensional representation of) semi-linear relations. We can also express queries that involve Euclidean distance. The data model also supports a larger class of relations than the semi-linear ones. All queries expressible in SafeEuQL are constructible by ruler and compass. So, the trisection of a given angle, for instance, is *not* expressible in SafeEuQL.
3. In FO + $\text{poly}_{\text{circ}}$, we gain in expressive power compared to the previous level. For example, trisection of an angle is expressible in this language. The language FO + $\text{poly}_{\text{circ}}$ has the same expressive power as FO + poly on semi-circular relations.
4. On the top level, we have FO + poly. Here, the data model supports all relations definable with polynomial constraints, including queries (e.g., construction of an ellipse) that are not expressible in FO + $\text{poly}_{\text{circ}}$.

Appendix. Formal specification of EuPL. The formal specification of EuPL is as follows. The basic notion is that of a "multifunction," a function that takes a fixed number of input points and constructs a fixed (possibly more than one) number

of output points.

⟨multifunction⟩ →
multifunction ⟨name⟩ '(' ⟨var⟩ (, ⟨var⟩) ∗ ')'
= '(' ⟨type⟩ (, ⟨type⟩) ∗ ')';
begin
⟨statement⟩ (; ⟨statement⟩)∗
end

⟨choice-condition⟩ →
true | false |
⟨var⟩ = ⟨var⟩ |
⟨var⟩ **is on line** '(' ⟨var⟩ , ⟨var⟩ ')' |
⟨var⟩ **is on circle** '(' ⟨var⟩ , ⟨var⟩ , ⟨var⟩ ')' |
⟨var⟩ **is in circle** '(' ⟨var⟩ , ⟨var⟩ , ⟨var⟩ ')' |
⟨var⟩ **is on the same side as** ⟨var⟩ **of line** '(' ⟨var⟩ , ⟨var⟩ ')' |
l-order '(' ⟨var⟩ , ⟨var⟩ , ⟨var⟩ ')' |
c-order '(' ⟨var⟩ , ⟨var⟩ , ⟨var⟩ , ⟨var⟩ ')' |
⟨choice-condition⟩ **and** ⟨choice-condition⟩ |
⟨choice-condition⟩ **or** ⟨choice-condition⟩ |
not ⟨choice-condition⟩ |

Eu-conditions are those used in **if** clauses. They are slightly more general than the conditions used in choice statements.

⟨eu-condition⟩ →
⟨choice-condition⟩ |
defined (⟨var⟩) |
⟨eu-condition⟩ **and**⟨eu-condition⟩ |
⟨eu-condition⟩ **or**⟨eu-condition⟩ |
not⟨eu-condition⟩⟨statement⟩ →
⟨empty statement⟩ |
⟨assignment⟩ |
⟨conditional statement⟩ |
⟨choice⟩ |
⟨result⟩
⟨empty statement⟩ →
⟨assignment⟩ →
⟨var⟩ := **l-l-crossing**(⟨var⟩ , ⟨var⟩ , ⟨var⟩ , ⟨var⟩) |
⟨var⟩ , ⟨var⟩ := **l-c-crossing**(⟨var⟩ , ⟨var⟩ , ⟨var⟩ , ⟨var⟩ , ⟨var⟩) |
⟨var⟩ , ⟨var⟩ := **c-c-crossing**(⟨var⟩ , ⟨var⟩ , ⟨var⟩ , ⟨var⟩ , ⟨var⟩ , ⟨var⟩) |
⟨conditional statement⟩ →
if⟨eu-condition⟩
then⟨statement⟩(;⟨statement⟩)*
else⟨statement⟩(;⟨statement⟩)*
end
⟨choice⟩ →
choose ⟨var⟩**such that** ⟨choice-condition⟩
⟨result⟩ →
result⟨var⟩ (, ⟨var⟩)∗

QUICKEST FLOWS OVER TIME*

LISA FLEISCHER† AND MARTIN SKUTELLA‡

Abstract. Flows over time (also called dynamic flows) generalize standard network flows by introducing an element of time. They naturally model problems where travel and transmission are not instantaneous. Traditionally, flows over time are solved in time-expanded networks that contain one copy of the original network for each discrete time step. While this method makes available the whole algorithmic toolbox developed for static flows, its main and often fatal drawback is the enormous size of the time-expanded network. We present several approaches for coping with this difficulty. First, inspired by the work of Ford and Fulkerson on maximal s-t-flows over time (or "maximal dynamic s-t-flows"), we show that static length-bounded flows lead to provably good multicommodity flows over time. Second, we investigate "condensed" time-expanded networks which rely on a rougher discretization of time. We prove that a solution of arbitrary precision can be computed in polynomial time through an appropriate discretization leading to a condensed time-expanded network of polynomial size. In particular, our approach yields fully polynomial-time approximation schemes for the NP-hard quickest min-cost and multicommodity flow problems. For single commodity problems, we show that storage of flow at intermediate nodes is unnecessary, and our approximation schemes do not use any.

Key words. network flows, flows over time, dynamic flows, quickest flows, earliest arrival flows, approximation algorithms

1. Introduction.

While standard network flows are useful to model a variety of optimization problems, they fail to capture a crucial element of many routing problems: routing occurs over time. In their seminal paper on the subject, Ford and Fulkerson [12, 13] introduced flows with transit times to remedy this and described a polynomial-time algorithm to solve the maximum flow over time, also called the maximum dynamic flow problem.[1] In addition to the normal input for classical network flow problems, each arc also has a transit time. The *transit time* is the amount of

[1]Earlier work on this topic referred to the problems as *dynamic flow* problems. Recently the term *dynamic* has been used in many algorithmic settings to refer to problems with input data that arrives online or changes over time, and the goal of the algorithms described is to modify the current solution quickly to handle the slightly modified input. For the problem of dynamic flows, the input data is available at the start. The solution to the problem involves describing how the optimal flow changes over time. For these reasons, we use the term "flows over time" instead of "dynamic flows" to refer to these problems.

time it takes for the flow to travel from the tail to the head of that arc. In contrast to the classical case of static flows, a *flow over time* in such a network specifies a flow rate entering an arc for each point in time. In this setting, the capacity of an arc limits the rate of flow into the arc at each point in time. In order to get an intuitive understanding of flows over time, one can associate arcs of the network with pipes in a pipeline system for transporting some kind of fluid.[2] The length of each pipeline determines the transit time of the corresponding arc while the width determines its capacity. A precise definition of flows over time is given later in section 2.

Flows over time may be applied to various areas of operations research and have many real-world applications such as traffic control, evacuation plans, production systems, communication networks (e.g., the Internet), and financial flows. Examples and further applications can be found in the survey articles of Aronson [2] and Powell, Jaillet, and Odoni [33]. However, flows over time are most likely significantly harder than their standard flow counterparts. For example, both minimum cost flows over time and fractional multicommodity flows over time are NP-hard [19, 25], even for very simple series-parallel networks.

1.1. Results from the literature.

Maximum flows over time. Ford and Fulkerson [12, 13] consider the problem of sending the maximal possible amount of flow from a source node s to a sink node t within a given time T. This problem can be solved efficiently using one min-cost flow computation on the given network. Ford and Fulkerson show that an optimal solution to this min-cost flow problem can be turned into a maximal flow over time by first decomposing it into flows on paths. The corresponding flow over time starts to send flow on each path at time zero and continues to send flow on each path so long as there is enough time left in the T time units for the flow along the path to arrive at the sink. A flow over time featuring this structure is called *temporally repeated*.

Quickest flows. A problem closely related to the problem of computing a maximal s-t-flow over time is the *quickest s-t-flow problem*: Send a given amount of flow from the source to the sink in the shortest possible time. This problem can be solved in polynomial time by incorporating the algorithm of Ford and Fulkerson in a binary search framework. Using Megiddo's method of parametric search [27], Burkard, Dlaska, and Klinz [3] present a faster algorithm which solves the quickest s-t-flow problem in strongly polynomial time.

Earliest arrival flows. An *earliest arrival flow* is an s-t-flow over time which simultaneously maximizes the amount of flow arriving at the sink before time θ for all $\theta \in [0, T)$. Gale [14] observes that these flows exist, and Wilkinson [35] and Minieka [28] give equivalent pseudo-polynomial-time algorithms to find them. These algorithms essentially use the successive shortest path algorithm (where the transit times are interpreted as arc lengths) in order to find a static flow which is then turned into a flow over time similar to Ford and Fulkerson's algorithm. The resulting solution is also a *latest departure flow*, i.e., a flow over time which simultaneously maximizes the amount of flow departing from the source after time θ for all $\theta \in [0, T)$ (subject to the constraint that the flow is finished by time T). A flow over time which is both an earliest arrival flow and a latest departure flow is called *universally maximal flow over time*. Hoppe and Tardos [23, 22] describe a polynomial-time approximation scheme for the universally maximal flow problem that routes a $1-\varepsilon$ fraction of the maximum

[2] We take a purely macroscopic point of view which does not involve any fluid dynamics.

possible flow that can reach the sink t by time θ for all $0 \leq \theta < T$. Problems with time-dependent arc capacities have been considered by Ogier [29] and Fleischer [10].

Flows over time with costs. Natural generalization of the quickest flows and maximum flows over time can be defined on networks with costs on the arcs. The problem can be to find either a minimum cost flow with a given time horizon or a quickest flow within a given cost budget. Klinz and Woeginger [25] show that the search for a quickest or a maximum s-t-flow over time with minimal cost cannot be restricted to the class of temporally repeated flows. In fact, adding costs has also a considerable impact on the complexity of these problems. Klinz and Woeginger prove NP-hardness results even for the special case of series parallel graphs. Moreover, they show that the problem of computing a maximal temporally repeated flow with minimal cost is strongly NP-hard.

Orlin [30] describes a polynomial-time algorithm to compute an infinite horizon, minimum cost flow over time that maximizes throughput. The infinite horizon problem does not have specified demand and is not concerned with computing how a flow starts and stops, issues that are crucial when flow demands are changing over time.

Quickest transshipments. Another generalization of quickest flows is the quickest transshipment problem: Given a vector of supplies and demands at the nodes, the task is to find a flow over time that satisfies all supplies and demands within minimal time. Unlike the situation for standard (static) network flow problems, this multiple source, multiple sink, single commodity flow over time problem is not equivalent to an s-t maximum flow over time problem. Hoppe and Tardos describe the first polynomial-time algorithm to solve this problem [24, 22]. They introduce the use of *chain decomposable flows* which generalize the class of temporally repeated flows and can also be compactly encoded as a collection of paths. However, in contrast to temporally repeated flows, these paths may also contain backward arcs. Therefore, a careful analysis is necessary to show feasibility of the resulting flows over time. Moreover, the algorithm of Hoppe and Tardos is not practical as it requires a submodular function minimization oracle for a subroutine.

Quickest multicommodity flows over time. In many applications, there are several commodities that must be routed through the same network. While there is substantial literature on the static multicommodity flow problem, hardly any results on multicommodity flows over time are known. Only recently, Hall, Hippler, and Skutella [19] showed that, already in the setting without costs, multicommodity flows over time are NP-hard. Indeed, it is not known if there always exists an optimal solution that can be described in polynomial space.

Discrete vs. continuous time model. All results mentioned so far were originally developed for a discrete time model, i.e., time is discretized into steps of unit length. In each step, flow can be sent from a node v through an arc (v, w) to the adjacent node w, where it arrives $\tau_{(v,w)}$ time steps later; here, $\tau_{(v,w)}$ denotes the given integral transit time of arc (v, w). In particular, the time-dependent flow on an arc is represented by a time-indexed vector in this model. In contrast to this, in the continuous time model the flow on an arc e is a function $f_e : \mathbb{R}^+ \to \mathbb{R}^+$. Fleischer and Tardos [11] point out a strong connection between the two models. They show that many results and algorithms which have been developed for the discrete time model can be carried over to the continuous time model. Since in this paper we mainly concentrate on the continuous time model, we give a more detailed discussion of the interrelation of the two models in section 4.1.

Time-expanded networks. In the discrete time model, flows over time can be described and computed in *time-expanded networks* which were introduced by Ford and Fulkerson [12, 13]. Here we assume that all transit times are integral. A time-expanded network contains a copy of the node set of the underlying "static" network for every discrete time step. Moreover, for every arc e in the static network with transit time τ_e, there is a copy between each pair of time layers with distance τ_e in the time-expanded network. A precise description of time-expanded networks is given in section 4.1. Unfortunately, due to the time expansion, the size of the resulting network grows linearly in T. In the worst case, T is exponential in the input size of the problem. This difficulty has already been pointed out by Ford and Fulkerson.

On the other hand, the advantage of this approach is that it turns the problem of determining an optimal flow over time into a classical static network flow problem on the time-expanded network. This problem can then be solved by well-known network flow algorithms, an approach which is also used in practice to solve flow over time problems. Due to the linear dependency of the size of the time-expanded network on T, such algorithms are termed "pseudopolynomial" since the run time of the algorithm depends on T and not $\log T$. In general, the size of these networks makes the problem solution prohibitively expensive.

1.2. Contributions of this paper. We describe approximation algorithms for flow over time problems. All of our algorithms approximate the minimum time horizon of an optimal flow. Thus an α-approximate solution is a flow that solves the original problem and requires at most α times the optimal time horizon to complete. Different parts of this work have appeared in a preliminary form in [6, 7].

Temporally repeated solutions. Inspired by the work of Ford and Fulkerson, we show in section 3 that static, *length-bounded* flows in the underlying static network lead to provably good multicommodity flows over time that can also be computed efficiently. The resulting approximation algorithm computes temporally repeated solutions and has performance ratio 2. For the more general problem with bounded cost, this approach yields a $(2+\varepsilon)$-approximation algorithm. In this context it is interesting to remember that the problem of computing a quickest temporally repeated flow with bounded cost is strongly NP-hard [25] and therefore does not allow a fully polynomial-time approximation scheme (FPTAS), unless P=NP. The same hardness result holds for quickest multicommodity flows without intermediate node storage and simple flow paths [19]. Finally, since a temporally repeated flow does not use intermediate node storage, our result implies a bound of 2 on the "power of intermediate node storage," i.e., the makespan of a quickest multicommodity flow without intermediate node storage is at most twice as long as the makespan of a quickest flow that is allowed to store flow at intermediate nodes.

Approximation schemes. Another main contribution of this paper is to show that problems that can be solved exactly in the time-expanded network can be solved close to optimally by a static flow computation in a network with polynomial size. A straightforward idea is to reduce the size of time-expanded networks by replacing the time steps of unit length by larger steps. In other words, applying a sufficiently rough discretization of time leads to a *condensed* time-expanded network of polynomial size. However, there is a tradeoff between the necessity to reduce the size of the time-expanded network and the desire to limit the loss of precision of the resulting flow model since the latter results in a loss of quality of achievable solutions.

In section 4 we show that there is a satisfactory solution to this tradeoff problem. An appropriate choice of the step length leads to a condensed time-expanded

network of polynomial size that permits a solution completing within $(1+\varepsilon)$ times the completion of a comparable flow in the continuous-time model, any $\varepsilon > 0$. More precisely, a condensed time-expanded network achieving this precision has n/ε^2 time layers where n is the number of nodes in the given network. One can thus say that the cost of $(1+\varepsilon)$-approximate temporal dynamics for network flow problems is a factor of n/ε^2 in the size of the network.

This observation has potential applications for many problems involving flows over time. In particular, it yields an FPTAS for the NP-hard quickest multicommodity flow problem. Since costs can easily be incorporated into time-expanded networks, our approach can be generalized to yield FPTASs for quickest multicommodity flow problems with cost constraints. Notice that already quickest s-t-flows with bounded cost are NP-hard.

Apart from NP-hard problems, we believe that our result is also of interest for flow problems, like the quickest transshipment problem, which are known to be solvable in polynomial time. While the algorithm of Hoppe and Tardos [24, 22] for the quickest transshipment problem relies on submodular function minimization, the use of condensed time-expanded networks leads to an FPTAS which simply consists of a series of max-flow computations.

No storage. Flows over time raise issues that do not arise in standard network flows. One issue is storage at intermediate nodes. In most applications (such as, e.g., traffic routing, evacuation planning, and telecommunications), storage is limited, undesired, or even prohibited at intermediate nodes. For single commodity problems, most generally the transportation problem with costs, we prove that storage is unnecessary, and our FPTAS does not use any.

Earliest arrival flows. Finally, in section 5 we discuss a variant of time-expanded networks which are suitable for approximating earliest arrival flows. We address the following problem: Given a set of sources with supplies and a single sink, send the supplies to the sink so that the amount of flow arriving at the sink by time θ is $D_t^*(\theta)$, the maximum possible, for all $0 \le \theta$. Instead of using a uniform discretization of time, we introduce "geometrically condensed time-expanded networks" which rely on geometrically increasing time steps. We use this network to obtain a flow that sends $D_t^*(\theta)$ units of flow to the sink by time $\theta(1+\varepsilon)$ for all $0 \le \theta$.

2. Preliminaries. We consider routing problems on a network $\mathcal{N} = (V, A)$ with $n := |V|$ nodes and $m := |A|$ arcs. Each arc $e \in A$ has an associated integral *transit time* or *length* τ_e and a capacity u_e. In the setting with costs, each arc e also has a cost coefficient c_e, which determines the per unit cost for sending flow through the arc. An arc e from node v to node w is sometimes also denoted (v, w); in this case, we write $\text{head}(e) = w$ and $\text{tail}(e) = v$.

2.1. Static flows. We start with the definition of single-commodity flows: Let $S \subseteq V$ be a set of terminals which can be partitioned into a subset of sources S^+ and sinks S^-. Every source node $v \in S^+$ has a supply $D_v \ge 0$ and every sink $v \in S^-$ has a demand $D_v \le 0$ such that $\sum_{v \in S} D_v = 0$. We often consider the case with only one source $s \in V$ and one sink $t \in V$. In this case, we let $d := D_s = -D_t$.

A *static flow* x on $\mathcal{N}$ assigns every arc e a nonnegative flow value x_e such that the *flow conservation constraints*

$$\sum_{e \in \delta^+(v)} x_e \; - \sum_{e \in \delta^-(v)} x_e \; = \; 0 \qquad \text{for all } v \in V \setminus S$$

are obeyed. Here, $\delta^+(v)$ and $\delta^-(v)$ denote the set of arcs e leaving node v ($\text{tail}(e) = v$) and entering node v ($\text{head}(e) = v$), respectively. The static flow x *satisfies the supplies and demands* if

$$\sum_{e\in\delta^+(v)} x_e \;-\; \sum_{e\in\delta^-(v)} x_e \;=\; D_v \qquad\qquad \text{for all } v \in S.$$

For the case of a single source s and a single sink t we also use the term *s-t-flow*. An s-t-flow x satisfying supply $d = D_s = -D_t$ has *value* $|x| = d$. Finally, a flow x is called *feasible* if it obeys the *capacity constraints* $x_e \le u_e$ for all $e \in A$. The cost of a static flow x is defined as

$$c(x) \;:=\; \sum_{e\in A} c_e\, x_e.$$

In the multiple-commodity setting, there is a set of commodities $K = \{1, \dots, k\}$, each of which is defined by a set of terminals $S_i = S_i^+ \cup S_i^- \subseteq V$ and demands and supplies $D_{v,i}$ for $v \in S_i$ and $i \in K$. A *static multicommodity flow* x on $\mathcal{N}$ assigns every arc-commodity pair (e, i) a nonnegative flow value x_e^i such that $x^i := (x_e^i)_{e\in A}$ is a single-commodity flow as defined above for all $i \in K$. The multicommodity flow x satisfies the demands and supplies if x^i satisfies the demands and supplies $D_{v,i}$ for $v \in S_i$. Finally, x is called *feasible* if it obeys the *capacity constraints* $x_e := \sum_{i\in K} x_e^i \le u_e$ for all $e \in A$. In the setting with costs, the cost of a static multicommodity flow x is defined as

$$c(x) \;:=\; \sum_{e\in A}\sum_{i\in K} c_{e,i}\, x_e^i, \tag{1}$$

where $c_{e,i}$ is the cost coefficient associated with arc e and commodity i.

2.2. Flows over time. In many applications of flow problems, static routing of flow as discussed in section 2.1 does not satisfactorily capture the real structure of the problem since not only the amount of flow to be transmitted but also the time needed for the transmission plays an essential role.

A *(multicommodity) flow over time* f on $\mathcal{N}$ with time horizon T is given by a collection of Lebesgue-measurable functions $f_{e,i} : [0, T) \to \mathbb{R}^+$, where $f_{e,i}(\theta)$ determines the rate of flow (per time unit) of commodity i entering arc e at time θ. Transit times are fixed throughout so that flow on arc e progresses at a uniform rate. In particular, the flow $f_{e,i}(\theta)$ of commodity i entering arc e at time θ arrives at head(e) at time $\theta + \tau_e$. Thus, in order to obey the time horizon T, we require that $f_{e,i}(\theta) = 0$ for $\theta \in [T - \tau_e, T)$. In order to simplify notation, we sometimes use $f_{e,i}(\theta)$ for $\theta \notin [0, T)$, implicitly assuming that $f_{e,i}(\theta) = 0$ in this case.

With respect to flow conservation, there are two different models of flows over time. In the model with storage of flow at intermediate nodes, it is possible to hold inventory at a node which is neither a source nor a sink before sending it onward. Thus, the flow conservation constraints are integrated over time to prohibit deficit at any node:

$$\int_0^{\xi} \left(\sum_{e\in\delta^+(v)} f_{e,i}(\theta) \;-\; \sum_{e\in\delta^-(v)} f_{e,i}(\theta - \tau_e) \right) d\theta \;\le\; 0 \tag{2}$$

for all $i \in K$, $\xi \in [0, T)$, $v \in V \setminus S_i^+$. Moreover, we require that equality holds in (2) for $i \in K$, $\xi = T$, and $v \in V \setminus S_i$, meaning that no flow should remain in the

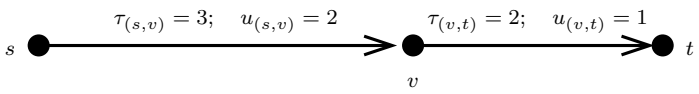

FIG. 1. *An instance of s-t-flows over time given by a network with transit times and capacities on the arcs.*

network after time T. In the model without storage of flow at intermediate nodes we additionally require that equality holds in (2) for all $i \in K$, $\xi \in [0, T)$, and $v \in V \setminus S_i$.

The flow over time f satisfies the supplies and demands if by time T the net flow out of each terminal $v \in S_i$ of commodity i equals its supply $D_{v,i}$:

$$\int_0^T \left(\sum_{e \in \delta^+(v)} f_{e,i}(\theta) \; - \sum_{e \in \delta^-(v)} f_{e,i}(\theta - \tau_e) \right) d\theta \; = \; D_{v,i} \tag{3}$$

for all $i \in K$ and $v \in S_i$. An *s-t-flow over time* is a single commodity flow from a single source s to a single sink t. An s-t-flow over time satisfying supply $d = D_s = -D_t$ has *value* $|f| = d$.

A flow over time f is *feasible* if it obeys the capacity constraints. Here, capacity u_e is interpreted as an upper bound on the rate of flow entering arc e, i.e., a capacity per time unit. Thus, the capacity constraints are $f_e(\theta) \le u_e$ for all $\theta \in [0, T)$ and $e \in A$, where $f_e(\theta) := \sum_{i \in K} f_{e,i}(\theta)$ is the total flow into arc e at time θ.

In the setting with costs, the cost of a flow over time f is defined as

$$c(f) \; := \; \sum_{e \in A} \sum_{i \in K} \int_0^T c_{e,i} \, f_{e,i}(\theta) \; d\theta. \tag{4}$$

Notice that we overload notation here since $c(x)$ is already used to denote the cost of a static flow x. This should not lead to any confusion in the following.

In Figure 1 we give a small illustrating example of s-t-flows over time. In order to send 2 units of flow from s to t in minimum time in the depicted network, one can choose between several alternatives. One is to send flow at rate 2 into the first arc during the time interval $[0, 1)$. Since the transit time of the first arc is 3, the two units of flow will arrive at the intermediate node v during the time interval $[3, 4)$. Thus, one can start to send flow at rate 1 into the second arc at time 3, and it will take 2 time units until time 5 before everything has been sent into the arc. Then, the flow finally arrives at the sink t within the time interval $[5, 7)$. The optimal time horizon is 7. Notice that in this solution flow is stored at the intermediate node v. An alternate solution also with time horizon 7 which avoids storing flow at v can be obtained by sending flow at rate 1 into the first arc during the time interval $[0, 2)$.

2.3. Maximum flows over time and quickest flows. Ford and Fulkerson [12, 13] show how to compute a maximum s-t-flow over time by reducing this problem to a static min-cost flow problem. More precisely, one can turn an optimal solution x to the static s-t-flow problem with objective function[3]

$$\max T\,|x| \; - \; \sum_e \tau_e \, x_e \tag{5}$$

[3]The objective function considered by Ford and Fulkerson is slightly different from (5) since T is replaced by $T + 1$. In contrast to our work, Ford and Fulkerson consider a discrete time setting where time horizon T means that flow can be sent at $T + 1$ discrete points in time $0, 1, 2, \ldots, T$. For more details on the relation between the two models we refer to [11].

into a maximal s-t-flow over time: It is a well-known result from network flow theory that any static flow x in $\mathcal{N}$ can be decomposed into a sum of flows x_P on simple paths $P \in \mathcal{P}$ and flow on cycles. Without loss of generality, flow on cycles is neglected (i.e., canceled) such that x can be written as a sum of path-flows: $x_e = \sum_{P \in \mathcal{P} : e \in P} x_P$ for all $e \in A$. The resulting temporally repeated flow f sends flow at rate x_P into each path $P \in \mathcal{P}$ during the time interval $[0, T - \tau(P))$, where $\tau(P) := \sum_{e \in P} \tau_e$. In other words, f is the sum of path-flows over time f_P with $f_P(\theta) = x_P$ for $\theta \in [0, T - \tau(P))$ and $f_P(\theta) = 0$ otherwise. Feasibility of f immediately follows from feasibility of x. Moreover, the flow value is

$$|f| \;=\; \sum_{P \in \mathcal{P}} (T - \tau(P))\, x_P \;=\; T\,|x| \;-\; \sum_e \tau_e\, x_e. \tag{6}$$

The second equality follows since $(x_P)_{P \in \mathcal{P}}$ is a path-decomposition of x.

For flows over time, a natural objective is to minimize the *makespan*, also called *time horizon*: the time T necessary to satisfy all demands. The *quickest s-t-flow problem* asks for an s-t-flow over time with given value d and minimum time horizon T. This problem can be generalized to the setting with bounded flow cost and multiple sources and sinks (*quickest transshipment problem*) and to the case of multiple commodities.

The most general problem that we consider here is the *quickest (multicommodity) transshipment problem (with bounded cost)* which is defined as follows.

QUICKEST MULTICOMMODITY TRANSSHIPMENT PROBLEM WITH BOUNDED COST
Given: A network (digraph) with capacities, costs, and transit times on the arcs; k commodities, each specified by a set of sources and sinks with supplies and demands; and a cost budget C.
Task: Find a multicommodity flow over time satisfying all supplies and demands with cost at most C and with minimal time horizon T.

Since this problem is NP-hard, we will mostly deal with finding approximate quickest flow. A natural variant of the stated problem is to bound the cost for every single commodity i by a budget C_i, i.e.,

$$\sum_{e \in A} c_{e,i} \int_0^T f_{e,i}(\theta)\; d\theta \;\le\; C_i$$

for all $i \in K$. All of our results also apply to problems with these additional cost constraints.

A note on time and size bounds. Our time bounds are sometimes expressed in terms of T^*, the optimal makespan. Since capacities and transit times are integers, we can assume that at every moment of time some flow is either progressing towards a sink or arriving at the sink. Thus, we obtain a gross upper bound on the optimal makespan: $T^* \le \sum_i d_i + \sum_e \tau_e$. As long as the dependency on T^* is polylogarithmic, the resulting bound is polynomial in size of the input.

3. A simple two-approximation algorithm. In this section we generalize the basic approach of Ford and Fulkerson [12, 13] to the case of multiple commodities (with multiple sources and sinks each) and costs. However, in contrast to the algorithm of Ford and Fulkerson which is based on a (static) min-cost flow computation, the method we propose employs length-bounded static flows.

3.1. Length-bounded static flows. While static flows are not defined with reference to transit times, we are interested in static flows that suggest reasonable routes with respect to transit times. To account for this, we consider decompositions of static flows into paths. We denote the set of all paths starting at some source of commodity i and leading to one of its sinks by $\mathcal{P}_i$. A static (multicommodity) flow x is called *T-length-bounded* if the flow of each commodity $i \in K$ can be decomposed into the sum of flows x^i_P on paths $P \in \mathcal{P}_i$ such that the length $\tau(P)$ of any path $P \in \mathcal{P}_i$ with $x^i_P > 0$ is at most T.

While the problem of computing a feasible static flow that satisfies the multicommodity demands can be solved efficiently, it is NP-hard to find such a flow which is in addition T-length-bounded, even for the special case of a single commodity. This follows by a straightforward reduction from the NP-complete PARTITION problem. On the other hand, the length-bounded flow problem can be approximated within arbitrary precision in polynomial time.

LEMMA 3.1. *If there exists a feasible T-length-bounded static flow x which satisfies the multicommodity demands, then for any $\varepsilon > 0$, a feasible $(1+\varepsilon)T$-length-bounded static flow x' of cost $c(x') \le c(x)$ satisfying all demands can be computed in time polynomial in the input size and $1/\varepsilon$.*

Proof. We first formulate the problem of finding a feasible T-length-bounded static flow as a linear program in path-variables. We assume without loss of generality that each commodity $i \in K$ has exactly one source s_i and one sink t_i with supply and demand $d_i := D_{s_i} = -D_{t_i}$; the general case with several sources and sinks can be handled by introducing one supersource and one supersink for each commodity. Let

$$\mathcal{P}^T_i \;:=\; \{P \in \mathcal{P}_i \mid \tau(P) \le T\} \subseteq \mathcal{P}_i$$

be the set of all s_i-t_i-paths whose lengths are bounded from above by T. The cost of path $P \in \mathcal{P}_i$ is defined as $c_i(P) := \sum_{e \in P} c_{e,i}$. The length-bounded min-cost flow problem can then be written as

$$\begin{aligned}
\min \quad & \sum_{i \in K} \sum_{P \in \mathcal{P}^T_i} c_i(P)\, x^i_P \\
\text{s.t.} \quad & \sum_{P \in \mathcal{P}^T_i} x^i_P \;\ge\; d_i && \text{for all } i \in K, \\
& \sum_{i \in K} \sum_{P \in \mathcal{P}^T_i : e \in P} x^i_P \;\le\; u_e && \text{for all } e \in A, \\
& x^i_P \;\ge\; 0 && \text{for all } i \in K,\ P \in \mathcal{P}^T_i.
\end{aligned}$$

Unfortunately, the number of paths in $\mathcal{P}^T_i$ and thus the number of variables in this linear program are in general exponential in the size of the underlying network $\mathcal{N}$. If we take the dual of the program we get

$$\begin{aligned}
\max \quad & \sum_{i \in K} d_i\, z_i \;-\; \sum_{e \in A} u_e\, y_e \\
\text{s.t.} \quad & \sum_{e \in P} (y_e + c_{e,i}) \;\ge\; z_i && \text{for all } i \in K,\ P \in \mathcal{P}^T_i, \\
& z_i, y_e \;\ge\; 0 && \text{for all } i \in K,\ e \in A.
\end{aligned}$$

The corresponding separation problem can be formulated as a length-bounded shortest path problem: Find a shortest s_i-t_i-path P with respect to the arc weights $y_e + c_{e,i}$

whose length $\tau(P)$ is at most T, i.e., $P \in \mathcal{P}_i^T$. While this problem is NP-hard [15], it can be solved approximately in the following sense: For any $\varepsilon > 0$, one can find in time polynomial in the size of the network $\mathcal{N}$ and $1/\varepsilon$ an s_i-t_i-path $P \in \mathcal{P}_i$ with $\tau(P) \leq (1+\varepsilon)T$ whose length with respect to the arc weights $y_e + c_{e,i}$ is bounded from above by the length of a shortest path in $\mathcal{P}_i^T$ [21, 26, 31]. Using the equivalence of optimization and separation [17], this means for our problem that we can find in polynomial time an optimal solution to a modified dual program which contains additional constraints corresponding to paths of length at most $(1+\varepsilon)T$. To be more precise, we find an optimal solution to a linear program that is more constrained than the above dual:

$$\begin{aligned} \max \quad & \sum_{i \in K} d_i \, z_i \;-\; \sum_{e \in A} u_e \, y_e & & \\ \text{s.t.} \quad & \sum_{e \in P} (y_e + c_{e,i}) \;\geq\; z_i & & \text{for all } i \in K,\ P \in \tilde{\mathcal{P}}_i, \\ & z_i, y_e \;\geq\; 0 & & \text{for all } i \in K,\ e \in A, \end{aligned}$$

where $\mathcal{P}_i^T \subseteq \tilde{\mathcal{P}}_i \subseteq \mathcal{P}_i^{(1+\varepsilon)T}$ for all $i \in K$. From this dual solution we get a primal solution that sends flow of commodity i only on paths in $\tilde{P}_i$. In particular, since $\tilde{\mathcal{P}}_i \subseteq \mathcal{P}_i^{(1+\varepsilon)T}$, this flow is $(1+\varepsilon)T$-length-bounded. □

Notice that the method described in the proof above relies on the ellipsoid method and is therefore of rather restricted relevance for solving length-bounded flow problems in practice. However, the FPTASs developed in [8, 16] for multicommodity flow problems can be generalized to the case of length-bounded flows: Those algorithms iteratively send flow on shortest paths with respect to some length function. In order to get a T-length-bounded solution, these shortest path computations must be replaced by a procedure that computes the $(1+\varepsilon)T$-length-bounded shortest path.[4]

3.2. The approximation algorithm. Any feasible flow over time f with time horizon T and cost at most C naturally induces a feasible static flow x on the underlying network $\mathcal{N}$ by averaging the flow on every arc over time, i.e.,

$$x_e^i \;:=\; \frac{1}{T} \int_0^T f_{e,i}(\theta) \; d\theta$$

for all $e \in A$ and $i \in K$. By construction, the static flow x is feasible, and it satisfies the following three properties, as explained below:

(i) it is T-length-bounded;
(ii) it satisfies a fraction of $1/T$ of the supplies and demands covered by the flow over time f;
(iii) $c(x) = c(f)/T$.

Due to the fixed time horizon T, flow f can travel only on paths of length at most T. Thus property (3.2) is fulfilled. Property (3.2) follows from (3). Finally, property (3.2) is a consequence of (1) and (4).

On the other hand, given an arbitrary feasible static flow x meeting requirements (3.2), (3.2), and (3.2), it can easily be turned into a feasible flow over time g

[4]The algorithms in [8, 16] return a solution of cost at most $1+\varepsilon$ times the minimum cost, which obeys capacities and serves at least $\frac{1}{1+\varepsilon}$ fraction of the demand. In the context of the approximation algorithm described in the next subsection, this approximate result is sufficient to still obtain the $2+\varepsilon$-approximation guarantee. This is because flow can be sent just a little longer on the chosen paths to fulfill all the demand.

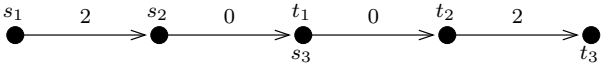

FIG. 2. *An instance of the quickest multicommodity flow problem containing three commodities $i = 1, 2, 3$, each with a single source s_i and a single sink t_i. Commodities* 1 *and* 3 *have demand value* 1*; commodity* 2 *has demand value* 2*. The numbers at the arcs indicate the transit times; all arcs have unit capacity. Note that an arc with* 0 *transit time and capacity* 1 *takes no additional time to cross but lets only one unit of flow through per unit time. A quickest flow with waiting at intermediate nodes allowed takes three time units and stores one unit of commodity* 2 *at the intermediate node $t_1 = s_3$ for two time units. However, if flow cannot be stored at intermediate nodes, an optimal solution takes time* 4*.*

with time horizon $2T$, meeting the same supplies and demands at the same cost as f: For every commodity $i \in K$, pump flow into every path P given by the length-bounded path decomposition of x at the corresponding flow rate x^i_P for T time units; then wait for at most T additional time units until all flow has arrived at its destination. In particular, no flow is stored at intermediate nodes in this solution. Therefore we can state the following structural result on the power of intermediate node storage.

LEMMA 3.2. *Allowing the storage of flow at intermediate nodes in $\mathcal{N}$ saves at most a factor of* 2 *in the optimal makespan. On the other hand, there are instances where the optimal makespan without storage at intermediate nodes is* 4/3 *times the optimal makespan with storage.*

Proof. The bound of 2 follows from the discussion above. In Figure 2 we give an instance with a gap of 4/3 between the optimal makespan without storing and the optimal makespan with storing at intermediate nodes. □

Notice that the gap of 4/3 is not an artifact of the small numbers in the instance depicted in Figure 2. It holds for more general demands and transit times as well: For instance, scale all transit times and capacities of arcs by a factor of q, and multiply all pairwise demands by a factor of q^2. For the new instance, there is still a gap of 4/3 between the optimal makespan without storing and the optimal makespan with storing at intermediate nodes.

In view of the discussion before Lemma 3.2, we can now state the core of our approximation algorithm; see Figure 3. If the given time horizon T is at least as large as the optimum makespan of the given instance, a static flow fulfilling requirements (3.2), (3.2), and (3.2) exists. In the first step of Algorithm LENGTHBOUNDED (Figure 3), we relax the length bound in property (3.2) by a factor $1 + \varepsilon$ so that the step can be performed in polynomial time; see section 3.1.

We state the main result of this section.

THEOREM 3.3. *For the quickest multicommodity transshipment problem with bounded cost, there exists a polynomial-time algorithm that, for any $\varepsilon > 0$, finds a solution of cost at most C (cost budget) with makespan at most $2 + \varepsilon$ times the optimal makespan. Moreover, the computed solution does not store flow at intermediate nodes.*

Proof. We embed Algorithm LENGTHBOUNDED into a binary search for the optimal makspan T^*. After $O(\log T^*/\varepsilon')$ steps, we get a guess of the optimal makespan with precision $1 + \varepsilon'/4$ for any $\varepsilon' > 0$. That is, we get T with

$$T^* \;\le\; T \;\le\; (1 + \varepsilon'/4)T^*.$$

If we call Algorithm LENGTHBOUNDED using T and $\varepsilon := \varepsilon'/4$, we get a flow over

ALGORITHM LENGTHBOUNDED

Input: An instance of the quickest multicommodity transshipment problem with cost bound C; tentative time horizon T; precision $\varepsilon > 0$.

Output: A flow over time satisfying all supplies and demands with makespan at most $(2+\varepsilon)T$ and cost bounded by C; or the information that T is strictly smaller than the optimal makespan.

1. Compute a static flow x such that
   - x is $(1+\varepsilon)T$-length bounded;
   - x satisfies a fraction $1/T$ of the supplies and demands;
   - $c(x) \le C/T$;

   or decide that no such flow exists. In the latter case stop and output "$T < T^*$".
2. Turn x into a flow over time satisfying all supplies and demands with makespan at most $(2+\varepsilon)T$ and cost bounded by C (see discussion in section 3.2).

FIG. 3. *The core of the* $(2+\varepsilon)$*-approximation algorithm.*

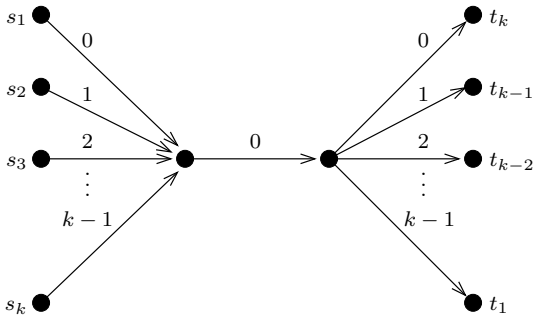

FIG. 4. *An instance with* k *commodities showing that the analysis in the proof of Theorem* 3.3 *is tight. All arcs have unit capacity and transit times as depicted above. The demand value of every commodity is* 1. *A quickest flow needs* $T^* = k$ *time units. However, any static flow can satisfy at most a fraction of* $1/k$ *of the demands. In particular, the makespan of the resulting flow over time is at least* $2k-1$.

time with makespan $(2+\varepsilon)T \le (2+\varepsilon')T^*$. In the last inequality we assume that ε' is chosen *small enough* (i.e., $\varepsilon' \le 4$). □

In Figure 4 we present an instance which shows that the analysis in the proof of Theorem 3.3 is tight. That is, the performance guarantee of the discussed approximation algorithm is not better than 2.

3.3. Avoiding the length-bounded flow computation. In contrast to Ford's and Fulkerson's temporally repeated flows, the flows over time resulting from T-length-bounded static flows described before Lemma 3.2 do not necessarily use flow-carrying paths as long as possible with respect to the time horizon $2T$. Instead, we stop sending flow into all paths at the same time T. In the following we argue that such a flow over time can easily be turned into a temporally repeated flow.

We simply extend the time interval $[0, T)$ during which flow is being sent into each path P such that the last flow on path P arrives at the sink exactly at time $2T$. Thus, the extended time interval for path P is $[0, 2T - \tau(P))$. On the other hand, we

compensate for the enlarged time interval by scaling the flow rate x_P^i on each path P to

$$\tilde{x}_P^i \;:=\; \frac{T}{2T-\tau(P)}\, x_P^i \;\le\; x_P^i.$$

Notice that the resulting temporally repeated flow obeys capacities since we have not increased the flow rate on any path. Moreover, by choice of $\tilde{x}_P^i$ the amount of flow that is sent on any path P has remained unchanged because $\tilde{x}_P^i(2T-\tau(P)) = x_P^i T$.

For the setting without costs, this observation also implies that the length-bounded flow computation in our algorithm can be replaced by a standard (and presumably faster) flow computation with costs, where transit times on arcs are interpreted as cost coefficients. To simplify the presentation of this result, we restrict to the case of only one source s_i and one sink t_i for every commodity $i \in K$. The scaled flow rates $\tilde{x}_P^i$ discussed above define a static multicommodity flow $\tilde{x}$. Let $|\tilde{x}^i|$ be the s_i-t_i-flow value of commodity i in $\tilde{x}$, and let d_i be the demand of commodity i. Since the temporally repeated flow with time horizon $2T$ and flow rates $\tilde{x}_P^i$ sends exactly d_i units of commodity i from s_i to t_i, it follows from (6) that

$$2T\,|\tilde{x}^i| \;-\; \sum_{e\in A} \tau_e\, \tilde{x}_e^i \;=\; d_i \qquad \text{for all } i \in K. \tag{7}$$

On the other hand, any feasible static multicommodity flow $\tilde{x}$ fulfilling (7) can easily be turned into a temporally repeated flow over time satisfying all demands within time $2T$: Compute any path decomposition of $\tilde{x}$ and send flow into every path at the corresponding flow rate as long as there is enough time left for the flow to arrive at its sink before time $2T$. This follows again from (6). We can now prove the following slightly improved approximation result which does not rely on a length-bounded static flow computation.

THEOREM 3.4. *There exists a 2-approximation algorithm for the quickest multicommodity transshipment problem. Moreover, the computed solution does not store flow at intermediate nodes.*

Proof. For the sake of simplicity, we again restrict to the case of one single source s_i and one sink t_i for every commodity $i \in K$. The algorithm first solves the following flow problem

$$\begin{aligned} &\min\ T \\ &\text{s.t.}\quad 2T\,|\tilde{x}^i| \;-\; \sum_{e\in A} \tau_e\, \tilde{x}_e^i \;=\; d_i \qquad \text{for every } i \in K, \\ &\qquad (\tilde{x}_e^i)_{e\in A,\, i\in K} \text{ is a feasible multicommodity flow.} \end{aligned}$$

Notice that this program is nonlinear since both T and the flow values $|x^i|$ are variables. On the other hand, it can be seen as a parametric multicommodity circulation problem by introducing an arc of infinite capacity and cost $2T$ from t_i to s_i for all $i \in K$. The problem can thus be solved in polynomial time.

It follows from (7) and the discussion above that the optimal solution value T is a lower bound on the time horizon of a quickest flow. Finally, the static flow $\tilde{x}$ can be turned into a temporally repeated flow over time with time horizon $2T$ by taking an arbitrary path-decomposition of $\tilde{x}$.[5] ∎

[5]If the path-decomposition contains paths of length longer than $2T$, these paths contribute negatively to the right-hand side of (7). Thus we can remove them along with flow on a set of shorter paths and obtain a smaller path-decomposition.

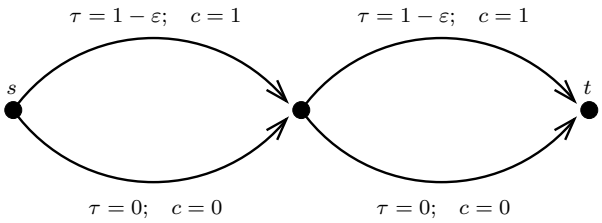

FIG. 5. *An instance showing that the cost of a temporally repeated flow depends on the particular path-decomposition of the underlying static s-t-flow. Consider the static flow of value* 2 *in the depicted network with flow value* 1 *on every arc. The time horizon is set to* 2*. There are two possible decompositions of this static flow into a sum of two path-flows. One of them leads to a temporally repeated flow of cost* $2 + 2\varepsilon$*; the other one has cost* 2ε*.*

Unfortunately, this result cannot be generalized to the quickest multicommodity transshipment problem with costs. The reason is that the cost of a temporally repeated flow is not uniquely determined by the underlying static flow but also depends on the chosen path decomposition. This has already been observed in [25]. We give an example in Figure 5. In fact, it can be shown by a reduction of the NP-complete problem PARTITION that finding a path-decomposition of a given static flow x yielding a cheapest temporally repeated flow is NP-hard.

4. Approximation schemes for quickest flows. In this section we present a framework for obtaining FPTASs for various quickest flow problems. In section 4.1 we introduce special time-expanded networks of polynomial size which are the backbone of this framework. In section 4.2 we present the basic idea of our approach and point out fundamental problems that need to be solved in order to make it work. Then, in section 4.3 we discuss the special case of acyclic graphs. Under the assumption that storage of flow at intermediate nodes is allowed, acyclic graphs are amenable to a simple analysis. On the other hand, we show in section 4.4 that optimal single commodity flows over time (with costs) do not require storage. Based on this insight, we give an FPTAS for the quickest transshipment problem with bounded cost which does not use storage at intermediate nodes in section 4.5. We describe a generalization of our approach to the multicommodity flow setting in section 4.6.

4.1. Condensed time-expanded networks. Traditionally, flows over time are solved in a time-expanded network. Given a network $\mathcal{N} = (V, A)$ with integral transit times on the arcs and an integral time horizon T, the *T-time-expanded network* of $\mathcal{N}$ denoted $\mathcal{N}^T$ is obtained by creating T copies of V, labeled V_0 through V_{T-1}, with the θth copy of node v denoted v_θ, $\theta = 0, \ldots, T-1$. The flow that passes through V_θ corresponds to flow over time in the interval $[\theta, \theta + 1)$. For every arc $e = (v, w)$ in A and $0 \leq \theta < T - \tau_e$, there is an arc e_θ from v_θ to $w_{\theta+\tau_e}$ with the same capacity and cost as arc e. For each terminal $v \in S_i$, $i \in K$, there is an additional infinite capacity *holdover arc* from v_θ to $v_{\theta+1}$ for all $0 \leq \theta < T - 1$, which models the possibility to hold flow at node v in the time interval $[\theta, \theta+1)$. We assume without loss of generality that a source (sink) has no incoming (outgoing) arc in $\mathcal{N}$. Thus, a terminal is never an intermediate node on a path flow.[6] We treat the first copy v_0 of a source $v \in S_i^+$ as the corresponding source in $\mathcal{N}^T$ and treat the last copy v_{T-1} of a sink $v \in S_i^-$ as the corresponding sink in $\mathcal{N}^T$. In the model with storage of flow at intermediate nodes, we introduce holdover arcs for all nodes $v \in V$. An illustration of a time-expanded network is given in Figures 6(a) and (b).

[6]Under this assumption, the flow storage level of commodity i at $v \in S_i$ never exceeds $D_{v,i}$.

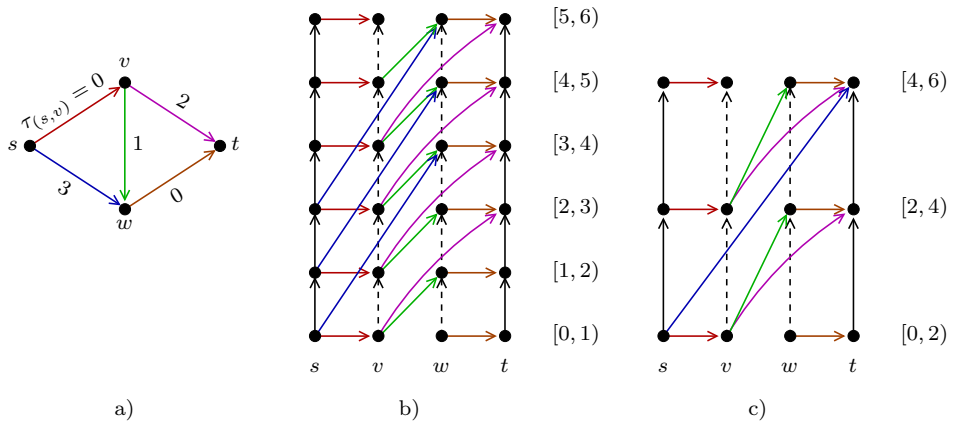

FIG. 6. (a) *A static network $\mathcal{N}$ with transit times on the arcs, one source s, and one sink t;* (b) *the corresponding time-expanded network $\mathcal{N}^T$ with time horizon $T = 6$;* (c) *the condensed time-expanded network $\mathcal{N}^T/\Delta$ with $\Delta = 2$. Notice that the transit time of arc (s, w) has been rounded up to 4 in $\mathcal{N}^T/\Delta$ since the original transit time 3 is not a multiple of Δ (see also section 4.2).*

Any static (multicommodity) flow in this time-expanded network corresponds to a (multicommodity) flow over time of equal cost: For any commodity, interpret the flow on arc e_θ as the flow rate entering arc $e = (v, w)$ in the time interval $[\theta, \theta + 1)$. Similarly, any flow over time completing by time T corresponds to a flow in $\mathcal{N}^T$ of the same value and cost obtained by setting the flow on e_θ to be the average flow rate into e over the interval $[\theta, \theta+1)$. More details can be found below in Lemma 4.1 (set $\Delta := 1$). Thus, we may solve any flow over time problem by solving the corresponding static flow problem in the time-expanded graph.

One problem with this approach is that the size of $\mathcal{N}^T$ depends linearly on T so that if T is not bounded by a polynomial in the input size, this is not a polynomial-time method of obtaining the required flow over time. However, if all arc lengths are a multiple of $\Delta > 0$ such that $\lceil T/\Delta \rceil$ is bounded by a polynomial in the input size, then instead of using the T-time-expanded network, we may rescale time and use a condensed time-expanded network that contains only $\lceil T/\Delta \rceil$ copies of V. Since in this setting every arc corresponds to a time interval of length Δ, capacities are multiplied by Δ. We denote this condensed time-expanded network by $\mathcal{N}^T/\Delta$ and the copies of V in this network by $V_{\rho\Delta}$ for $\rho = 0, \ldots, \lceil T/\Delta \rceil - 1$. Copy $V_{\rho\Delta}$ corresponds to flow through V in the interval $[\rho\Delta, (\rho + 1)\Delta)$. An illustration is given in Figure 6(c).

LEMMA 4.1. *Suppose that all arc lengths are multiples of Δ and T/Δ is an integer. Then, any (multicommodity) flow over time that completes by time T corresponds to a static (multicommodity) flow of equal cost in $\mathcal{N}^T/\Delta$, and any flow in $\mathcal{N}^T/\Delta$ corresponds to a flow over time of equal cost that completes by time T.*

Proof. Given an arbitrary (multicommodity) flow over time, a modified flow over time of equal value and cost can be obtained by averaging the flow value of every commodity on any arc in each time interval $[\rho\Delta, (\rho + 1)\Delta)$, $\rho = 0, \ldots, T/\Delta - 1$. This modified flow over time defines a static (multicommodity) flow in $\mathcal{N}^T/\Delta$ in a canonical way. Notice that the capacity constraints are obeyed since the total flow starting on arc e in interval $[\rho\Delta, (\rho + 1)\Delta)$ is bounded by Δu_e. The flow values on the holdover arcs are defined in such a way that flow conservation is obeyed in every node of $\mathcal{N}^T/\Delta$.

On the other hand, a static (multicommodity) flow on $\mathcal{N}^T/\Delta$ can easily be turned into a flow over time. The static flow on an arc with tail in $V_{\rho\Delta}$ is divided by Δ and

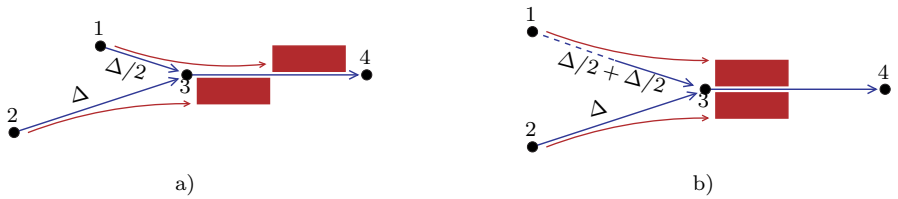

FIG. 7. (a) *A flow over time in the original network. The two packets of flow originating at nodes* 1 *and* 2 *are sent one after another into arc* $(3,4)$. (b) *The "same" flow over time in the network with rounded transit times causes congestion on arc* $(3,4)$ *since the two packets of flow arrive simultaneously on the arc.*

sent for Δ time units starting at time $\rho\Delta$. If the head of the arc is in $V_{\sigma\Delta}$ for $\sigma \geq \rho$, then the length of the arc is $(\sigma - \rho)\Delta$, and the last flow (sent before time $(\rho+1)\Delta$) arrives before time $(\sigma+1)\Delta$. Note that if costs are assigned to arcs of $\mathcal{N}^T/\Delta$ in the natural way, then the cost of the flow over time is the same as the cost of the corresponding flow in the time-expanded graph. □

If we drop the condition that T/Δ is integral, we get the following slightly weaker result.

COROLLARY 4.2. *Suppose that all arc lengths are multiples of* Δ. *Then, any (multicommodity) flow over time that completes by time* T *corresponds to a static (multicommodity) flow of equal value and cost in* $\mathcal{N}^T/\Delta$, *and any flow in* $\mathcal{N}^T/\Delta$ *corresponds to a flow over time of equal value that completes before time* $T+\Delta$.

4.2. Outline of an approximation scheme. The basic idea of our algorithm is to round up transit times to the nearest multiple of Δ for an appropriately chosen Δ, solve the static flow problem in the corresponding Δ-condensed time-expanded network, and then translate this flow back to the setting of the original transit times. In order to obtain provably good solutions in this way, one has to make sure that the following two conditions are fulfilled:

I. the makespan of an optimal solution to the instance with increased transit times (represented by the condensed time-expanded network) approximates the makespan of an optimal solution in the original setting;

II. the solution to the instance with increased transit times can be transformed into a flow over time with original arc lengths without too much loss in flow value.

Before discussing how to fulfill these conditions, we first give some simple examples to show that nontrivial problems have to be dealt with to address both I and II.

Consider first a (sub)network consisting of four nodes $\{1,2,3,4\}$ and three arcs $(1,3)$, $(2,3)$, and $(3,4)$ with unit capacity depicted in Figure 7(a). The transit times are $\tau_{(1,3)} = \Delta/2$, $\tau_{(2,3)} = \Delta$, and $\tau_{(3,4)} = \Delta$. A flow in the graph without rounded transit times can send $\Delta/2$ units of flow in interval $[0, \Delta/2)$ on each path $P_1 = 1 \to 3 \to 4$ and $P_2 = 2 \to 3 \to 4$. Path P_1 will use arc $(3,4)$ in interval $[\Delta/2, \Delta)$, and path P_2 will use arc $(3,4)$ in interval $[\Delta, 3\Delta/2)$. However, if we send flow simultaneously on paths P_1 and P_2 in the network with transit times rounded up to the nearest multiple of Δ, then this will cause a bottleneck on arc $(3,4)$; see Figure 7(b).

Now consider the unit capacity (sub)network depicted in Figure 8. If all transit times are rounded up to the nearest multiple of Δ, we may send Δ units of flow simultaneously on each path from s to t, and each path will use arc (v,t) in a distinct interval of time. If we try to interpret this flow in the network with original transit times, however, each path-flow will try to use arc (v,t) in the same time interval, causing a large bottleneck.

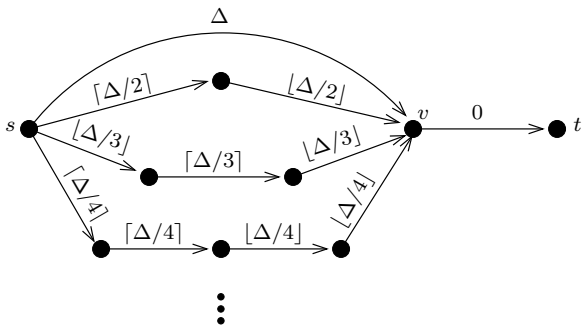

FIG. 8. *In this partially drawn unit capacity network, there are Δ paths from s to v. The i^{th} path contains i arcs, each with transit time roughly Δ/i.*

Condition II can be enforced by allowing storage of flow at nodes: If arc $e = (v, w)$ has length increased by $\Delta' \leq \Delta$, then this can be emulated in the original network by holding flow arriving at w for Δ' time units.[7] More generally, we can state the following observation.

Observation 4.3. Consider a network $\mathcal{N} = (V, A)$ and two transit time vectors $\tau, \tau' \in \mathbb{R}_+^A$ with $\tau_e \leq \tau'_e$ for all $e \in A$. Then, a flow over time in $\mathcal{N}$ with transit times τ' can be emulated in $\mathcal{N}$ with transit times τ by introducing waiting time $\tau'_e - \tau_e$ at the head of every arc e.

For the case of acyclic graphs, we give a simple argument in section 4.3 to show how to uphold condition I when storage is allowed. In section 4.5 we describe a more sophisticated approach that works for general graphs even when storage of flow at nodes is not allowed.

4.3. Acyclic graphs with storage. For acyclic graphs, the existence of a topological ordering of the nodes makes the problems illustrated above fairly easy to resolve. The algorithm is simple: For an appropriate guess of T, choose $\Delta := \frac{\varepsilon}{n}T$, and round transit times up to the nearest multiple of Δ. Form the Δ-condensed time-expanded network, and compute a solution f in this network. Output the solution f' obtained by modifying f by emulating the rounded transit times as described above.

It remains to show condition I: There exists a feasible flow of cost at most C (the given cost budget) satisfying the given (multicommodity) demands D by time $T^*(1+\varepsilon)$ in the network with transit times rounded up to the nearest multiple of Δ. Let f^* be a flow over time of cost at most C that satisfies demands D by time T^*. Moreover, let $\{v_0, v_1, \ldots, v_{n-1}\}$ be a topological ordering of V. Modify f^* to obtain $\hat{f}$ by setting $\hat{f}_e(\theta) = f^*_e(\theta - i\Delta)$ for $e = (v_i, v_j)$ and for all $\theta \in [0, \infty)$. With these modifications, flow traveling on any path that includes v_i is delayed from its original departure from i by exactly $i\Delta$ time units. Thus, flow arriving at node v_j in $\hat{f}$ arrives at most $j\Delta$ time units later than its arrival in f^*, and the time horizon of $\hat{f}$ is $T^* + \Delta(n-1) \leq T^*(1+\varepsilon)$. Since f^* is feasible, so is $\hat{f}$. Since flow travels on the same paths in f^* and $\hat{f}$, we have $c(f^*) = c(\hat{f})$, and $\hat{f}$ satisfies the same multicommodity demands as f^*.

Notice that $\hat{f}$ induces a flow in the network with the transit time of an arc (v_i, v_j) equal to $\tau_{ij} + \Delta(j - i) \geq \tau_{ij} + \Delta$. An alternate and equivalent view is that $\hat{f}$ induces a flow with storage in the network with transit time of (v_i, v_j) rounded up to $\tau_{ij} + \delta_{ij}$,

[7] If Δ' is large, then this requires a large amount of additional storage.

the nearest multiple of Δ. In this view, flow sent on (v_i, v_j) is then held at v_j for an additional $\Delta(j-i)-\delta_{ij} \geq 0$ units of time. This latter flow is a flow in the Δ-rounded network, implying the following theorem.

THEOREM 4.4. *In acyclic graphs with node storage, a* $(1+\varepsilon)$*-approximate solution to the quickest cost-bounded multicommodity flow problem can be obtained with a static flow computation in a network with* $O(n^2/\varepsilon)$ *nodes and* $O(nm/\varepsilon)$ *arcs.*

4.4. Minimum cost flows without storage. It follows from the work of Hoppe and Tardos [24, 22] that for the quickest transshipment problem there always exists an optimal solution which does not store flow at intermediate nodes. We generalize this result to the problem with costs and also to the more general case when the flow cost on an arc is a nondecreasing, convex function of the flow rate into the arc. As mentioned in section 4.1, when transit times are integers, the min-cost transshipment over time problem with or without storage at intermediate nodes can be solved by solving the corresponding static flow problem in the time-expanded network[8] $\mathcal{N}^T$.

THEOREM 4.5. *For nondecreasing, convex cost functions, the cost of a minimum cost transshipment over time that does not use intermediate node storage is no more than the cost of a minimum cost transshipment over time using intermediate node storage.*

The details of this proof are not essential for understanding the remainder of the paper.

Proof. Consider a minimum cost transshipment over time with intermediate node storage and a corresponding static min-cost flow x in the time-expanded network $\mathcal{N}^T$. Notice that the set X of all min-cost solutions x is the intersection of the polytope formed by all feasible solutions with a closed convex set given by the convex cost constraint. In particular, X is convex and compact.

For a node $z \in V$, let $x(\delta(z_\theta))$ be the net amount of flow leaving z in the time interval $[\theta, \theta+1)$:

$$x(\delta(z_\theta)) \;:=\; \sum_{e \in \delta^+(z)} x_{e_\theta} - \sum_{e \in \delta^-(z)} x_{e_{\theta-\tau_e}}.$$

Since X is compact, there exists an $x \in X$ minimizing the convex function $F(x) := \sum_{z \in V} \sum_{\theta=0}^{T-1} |x(\delta(z_\theta))|$. We show that x does not send flow along holdover arcs of nodes in $V \setminus S$.

By contradiction, let v_φ be the earliest copy of node $v \notin S$ to send flow along a holdover arc. We have that $x(\delta(v_\varphi)) = -x_{v_\varphi, v_{\varphi+1}} < 0$. Let $[\varphi+q, \varphi+q+1)$ for $q > 0$ and integral be the first time interval after $[\varphi, \varphi+1)$ in which v has more flow leaving it than entering it; i.e., $x(\delta(v_{\varphi+q})) > 0$. We show in the following that $F(x)$ can be decreased by augmenting flow along a cycle in the time-expanded network $\mathcal{N}^T$. This is a contradiction to the choice of x.

Consider a time-expanded network that is infinite in both directions, $\mathcal{N}^{(-\infty,+\infty)}$. Note that $\mathcal{N}^{(-\infty,+\infty)}$ looks the same at v_φ as it does at $v_{\varphi+q}$. However, x in this network looks different at each of these copies of v. We indicate this difference by

[8] Notice that the averaging argument used in the proof of Lemma 4.1 to turn an arbitrary flow over time into a static flow in the time-expanded network also works for the case of convex costs since averaging never increases cost.

coloring the arcs of $\mathcal{N}^{(-\infty,+\infty)}$ as follows. Color transit arc $(i_{\theta-\tau_{ij}}, j_\theta)$

$$\begin{aligned} \text{red} \quad \text{if} \quad & x_{(i_{\theta-\tau_{ij}},j_\theta)} < x_{(i_{\theta-\tau_{ij}-q},j_{\theta-q})} \\ \text{blue} \quad \text{if} \quad & x_{(i_{\theta-\tau_{ij}},j_\theta)} > x_{(i_{\theta-\tau_{ij}-q},j_{\theta-q})} \\ \text{no color} \quad \text{if} \quad & x_{(i_{\theta-\tau_{ij}},j_\theta)} = x_{(i_{\theta-\tau_{ij}-q},j_{\theta-q})}. \end{aligned}$$

All holdover arcs remain colorless. Note that there are no blue arcs leaving V_θ for $\theta \geq T-1$ and there are no red arcs entering V_θ for $\theta \leq q$.

Let P be a simple path consisting of backward red arcs and forward blue arcs from $v_{\varphi+q}$ to a node w_μ with the property that $x(\delta(w_\mu)) < x(\delta(w_{\mu-q}))$. We claim that such a P exists: Since $x(\delta(v_{\varphi+q})) - x(\delta(v_\varphi)) > 0$, node $v_{\varphi+q}$ has either a red arc entering it or a blue arc leaving it. Consider the set of all nodes which can be reached from $v_{\varphi+q}$ on a path consisting of backward red arcs and forward blue arcs. Since $x(\delta(v_{\varphi+q})) - x(\delta(v_\varphi)) > 0$, it follows from flow conservation that there must exist a node w_μ with $x(\delta(w_\mu)) - x(\delta(w_{\mu-q})) < 0$ in this set.

Note that $V(P) \subset \bigcup_{\theta=q}^{T-1} V_\theta$. We define the capacity $u(P)$ of P to be

$$u(P) := \min_{(i_\theta, j_{\theta+\tau_{ij}}) \in P} |x_{(i_\theta, j_{\theta+\tau_{ij}})} - x_{(i_{\theta-q}, j_{\theta-q+\tau_{ij}})}|.$$

We modify x to reduce $|x(\delta(v_\varphi))|$ and $|x(\delta(v_{\varphi+q}))|$. Let

$$\kappa := \min\{u(P),\ -x(\delta(v_\varphi)),\ x(\delta(v_{\varphi+q})),\ x(\delta(w_{\mu-q})) - x(\delta(w_\mu))\} > 0.$$

If an arc $(i_\theta, j_{\theta+\tau_{ij}}) \in P$ is red, then we modify x on $(i_\theta, j_{\theta+\tau_{ij}})$ and $(i_{\theta-q}, j_{\theta-q+\tau_{ij}})$ to

$$x_{(i_\theta, j_{\theta+\tau_{ij}})} := x_{(i_\theta, j_{\theta+\tau_{ij}})} + \kappa \quad \text{and} \quad x_{(i_{\theta-q}, j_{\theta-q+\tau_{ij}})} := x_{(i_{\theta-q}, j_{\theta-q+\tau_{ij}})} - \kappa.$$

If $(i_\theta, j_{\theta+\tau_{ij}}) \in P$ is blue, then

$$x_{(i_\theta, j_{\theta+\tau_{ij}})} := x_{(i_\theta, j_{\theta+\tau_{ij}})} - \kappa \quad \text{and} \quad x_{(i_{\theta-q}, j_{\theta-q+\tau_{ij}})} := x_{(i_{\theta-q}, j_{\theta-q+\tau_{ij}})} + \kappa.$$

Finally, we remove κ units of flow from the path of holdover arcs from v_φ to $v_{\varphi+q}$ and add κ to the path of holdover arcs from $w_{\mu-q}$ to w_μ. Notice that we have augmented flow on a cycle in $\mathcal{N}^T$ by κ. Since the domain of P is restricted to $V(P) \subset \bigcup_{\theta=q}^{T-1} V_\theta$, the flow x is still a feasible solution to our problem.

We next argue that the cost of x is not increased so that x is still in X. Since the flow augmentation transfers an equal amount of flow from one copy of an arc to a parallel copy, if flow costs are linear, this does not change the cost of our solution. Since the sum of flow on these two arcs does not change and we simply move flow so that the flow on each is closer to the average flow on each, if our flow costs are convex and nondecreasing, then the cost of our solution does not increase.

Finally, the augmentation by κ ensures that $|x(\delta(v_\varphi))|$ and $|x(\delta(v_{\varphi+q}))|$ are each reduced by κ and $|x(\delta(w_\mu))| + |x(\delta(w_{\mu-q}))|$ is not increased. (Either $|x(\delta(w_{\mu-q}))| > \kappa$ and $|x(\delta(w_\mu))| < -\kappa$ or, since $\kappa \leq x(\delta(w_{\mu-q})) - x(\delta(w_\mu))$, the quantities $|x(\delta(w_\mu))|$ and $|x(\delta(w_{\mu-q}))|$ exchange values.) Thus, $F(x) = \sum_{z \in V} \sum_{\theta=0}^{T-1} |x(\delta(z_\theta))|$ is decreased by at least $2\kappa > 0$. This concludes the proof. □

Theorem 4.5 implies that we can find a minimum cost flow over time in the time-expanded network *without* holdover arcs for intermediate nodes. We can even state the following stronger result.

COROLLARY 4.6. *For every instance of the minimum cost transshipment over time problem, when costs are nondecreasing convex functions of the flow rate, there exists an optimal solution without intermediate node storage such that any infinitesimal unit of flow visits every node at most once.*

Proof. We first consider the case that there is no cycle of zero cost in $\mathcal{N}$. If some path-flow in an optimal flow visits a node v more than once, it travels along a cycle in $\mathcal{N}$. Therefore the cost of the solution can be decreased by letting the flow wait at v. This is a contradiction to the optimality of the solution.

If there exists zero cost cycles in $\mathcal{N}$, we can increase the cost of every arc by a small amount such that an optimal solution to the modified problem always yields an optimal solution to the original problem. This eliminates cycles of zero cost and thus concludes the proof. □

4.5. General graphs without storage. Here we describe how to adapt the outline given in section 4.2 to yield an FPTAS for the quickest transshipment problem with bounded cost in general graphs. The computed solution does not use any intermediate node storage.

The approach has two main steps. First, we choose Δ small enough so that we can increase the time horizon by a sufficiently large amount relative to Δ to satisfy condition I. Second, we average the flow computed in the rounded network over sufficiently large intervals relative to Δ so that the resulting flow is almost feasible, satisfying condition II. This second step also increases the total time horizon of the flow, but again, by careful choice of Δ, by a sufficiently small amount.

The core of the FPTAS consists of an algorithm which gets as input an instance of the quickest transshipment problem with bounded cost together with a tentative time horizon T and precision $\varepsilon > 0$. The algorithm either finds a feasible solution (i.e., flow over time) with makespan at most $(1 + O(\varepsilon))T$ or decides that T is smaller than the optimal makespan. Throughout this section we denote the optimal makespan by T^*. A detailed description of the algorithm is given in Figure 9.

Before we discuss and analyze this algorithm in more detail, we first remark the following. A $(1 + O(\varepsilon))$-approximate flow over time can be computed by embedding Algorithm FPTAS-CORE into a binary search framework. We can begin with a standard binary search to find lower and upper bounds on the optimal makespan T^*

ALGORITHM FPTAS-CORE

Input: Network $\mathcal{N}$, capacities u, linear costs c, transit times τ, demand vector D, cost bound C, time horizon T, and precision $\varepsilon > 0$.

Output: Feasible flow over time f with time horizon $(1 + O(\varepsilon))T$ satisfying demands D at cost at most C; or the information that $T < T^*$.

1. set $\Delta := \varepsilon^2 T/n$ and $T' := \lceil (1+\varepsilon)^3 T/\Delta \rceil \Delta$;
2. compute static flow x in $\mathcal{N}^{T'}/\Delta$ satisfying demands $(1+\varepsilon)D$ at cost at most $(1+\varepsilon)C$; if no such flow exists, then stop and output "$T < T^*$";
3. transform x into a flow over time f in $\mathcal{N}$ with time horizon $(1+\varepsilon)T'$ satisfying demands D at cost at most C.

FIG. 9. *The core component of an FPTAS.*

that are within a constant multiple of each other. This requires $\log T^*$ calls of Algorithm FPTAS-Core.[9] Based on these upper and lower bounds, an estimate T with $T^* \le T \le (1+O(\varepsilon))\,T^*$ can be obtained by a geometric mean binary search[10] with $O(\log(1/\varepsilon))$ calls of Algorithm FPTAS-Core. In particular, the last call of Algorithm FPTAS-Core then returns a solution to the quickest flow problem with time horizon at most $(1+\varepsilon)\,T'$. By definition of T' and Δ, this makspan is bounded from above by $(1+\varepsilon)^4 T + (1+\varepsilon)\,\Delta$ and thus in $(1+O(\varepsilon))T^*$. The correctness of Algorithm FPTAS-Core follows from the next proposition.

Proposition 4.7. *Let $T \ge T^*$, $\Delta := \varepsilon^2 T/n$, and $T' := \lceil (1+\varepsilon)^3 T/\Delta \rceil\,\Delta$.*

(a) *There exists a static flow x in the Δ-condensed time-expanded network $\mathcal{N}^{T'}/\Delta$ satisfying demands $(1+\varepsilon)D$ at cost at most $(1+\varepsilon)C$.*

(b) *Given a flow x as in* (a)*, one can compute a flow over time f in $\mathcal{N}$ with time horizon at most $(1+\varepsilon)\,T'$ satisfying demands D at cost at most C.*

We start by proving the following lemma.

Lemma 4.8. *For any $\delta \ge 1$ and any $T \ge T^*$, there exists a flow over time $\tilde{f}$ with time horizon δT satisfying supplies and demands δD at cost at most δC.*

Proof. Consider an optimal solution f^* to the quickest flow problem. That is, f^* is a flow over time with time horizon $T^* \le T$ satisfying supplies and demands D at cost at most C. By rescaling time, we can assume without loss of generality that T and all transit times are integral. Let x^* be the static flow in the T-time-expanded network which corresponds to f^*. Consider a modified instance where all transit times of arcs are increased by a factor of δ. Then, the δ-condensed time-expanded network of the modified instance with time horizon δT is identical to the time-expanded network $\mathcal{N}^T$ but with arc capacities multiplied by δ. In particular, δx^* defines a feasible flow over time with time horizon δT and cost $\delta c(f^*) \le \delta C$ satisfying demands and supplies δD for the modified instance. Since transit times in the original instance are smaller, it can be seen as a relaxation of the modified instance. This yields the existence of $\tilde{f}$ and concludes the proof. ∎

In the following we denote the rounded transit time function by τ'; i.e., $\tau'_e := \lceil \tau_e/\Delta \rceil \Delta$ and $0 \le \tau'_e - \tau_e < \Delta$ for all $e \in A$.

Proof of Proposition 4.7(a). In order to prove the existence of a static flow x in $\mathcal{N}^{T'}/\Delta$ with the claimed properties, Lemma 4.1 implies that it suffices to show the following: In the network $\mathcal{N}$ with transit times τ' there exists a flow over time $\bar{f}$ with time horizon T' satisfying demands $(1+\varepsilon)D$ at cost at most $(1+\varepsilon)C$.

By Corollary 4.6 there exists a flow over time $\tilde{f}$ as in Lemma 4.8 with $\delta = (1+\varepsilon)^2$ that in addition sends flow only on simple paths and that never stores flow at intermediate nodes. This means that $\tilde{f}$ can be written as a sum of path-flows over time $\tilde{f}_P$, $P \in \mathcal{P}$: Consider an arbitrary arc $e = (v,w) \in A$. The total flow into arc e at time θ is

$$\tilde{f}_e(\theta) \;=\; \sum_{P \in \mathcal{P} \,:\, e \in P} \tilde{f}_P\big(\theta - \tau(P,e)\big), \tag{8}$$

where $\tau(P,e)$ denotes the length of the subpath of P which is obtained by removing arc e and all its successors.

[9] Alternatively, the constant factor approximation algorithm for the quickest transshipment problem with bounded cost presented in section 3 yields a lower bound L and an upper bound U on T^* with $U \in O(L)$.

[10] For details on this variant of binary search we refer to [21].

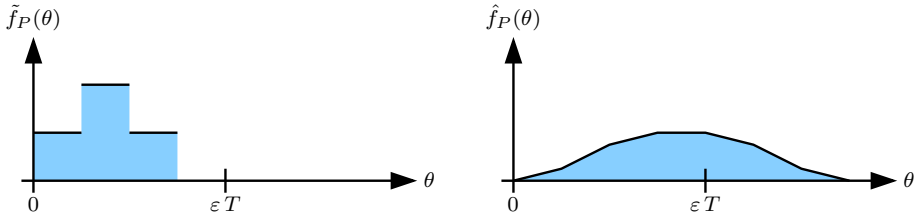

FIG. 10. *The "smoothed" path flow over time $\hat{f}_P$ in comparison to the original flow over time f'_P sent into path P.*

From $\tilde{f}$ we obtain a "smoothed" flow over time $(\hat{f}_P)_{P\in\mathcal{P}}$ which has a time horizon of $(1+\varepsilon)^2T + \varepsilon T$ by defining

$$\hat{f}_P(\theta) \;:=\; \frac{1}{\varepsilon T}\int_{\theta-\varepsilon T}^{\theta} \tilde{f}_P(\xi)\,d\xi \tag{9}$$

for $\theta \in [0, (1+\varepsilon)^2T + \varepsilon T)$ and $P \in \mathcal{P}$. An illustrative example is given in Figure 10. It is easy to check that $\hat{f}$ obeys capacity constraints and the total amount of flow sent on a path $P \in \mathcal{P}$ is the same in $\tilde{f}$ and $\hat{f}$. In particular, $c(\hat{f}) = c(\tilde{f}) \le (1+\varepsilon)^2 C$, and $\hat{f}$ satisfies demands $(1+\varepsilon)^2 D$.

Notice that $(\hat{f}_P)_{P\in\mathcal{P}}$ still describes a (not necessarily feasible) flow over time in $(\mathcal{N}, \tau')$. Since every path $P \in \mathcal{P}$ is simple, it contains at most $n-1$ arcs; therefore, $0 \le \tau'(P) - \tau(P) \le \varepsilon^2 T$, and

$$0 \;\le\; \tau'(P,e) - \tau(P,e) \;\le\; \varepsilon^2 T \tag{10}$$

for all $e \in P$. Thus, if we interpret $\hat{f}$ as a flow over time in $(\mathcal{N}, \tau')$, we get, for all $e \in A$ and $\theta \in [0, (1+\varepsilon)^2T + \varepsilon T + \varepsilon^2 T)$,

$$\begin{aligned}
\hat{f}_e(\theta) &\overset{(8)}{=} \sum_{P\in\mathcal{P}\,:\,e\in P} \hat{f}_P(\theta - \tau'(P,e)) \\
&\overset{(9)}{=} \frac{1}{\varepsilon T}\sum_{P\in\mathcal{P}\,:\,e\in P} \int_{\theta-\tau'(P,e)-\varepsilon T}^{\theta-\tau'(P,e)} \tilde{f}_P(\xi)\;d\xi \\
&\overset{(10)}{\le} \frac{1}{\varepsilon T}\sum_{P\in\mathcal{P}\,:\,e\in P} \int_{\theta-\tau(P,e)-\varepsilon^2 T-\varepsilon T}^{\theta-\tau(P,e)} \tilde{f}_P(\xi)\;d\xi \\
&= \frac{1}{\varepsilon T}\int_{\theta-\varepsilon^2 T-\varepsilon T}^{\theta} \sum_{P\in\mathcal{P}\,:\,e\in P} \tilde{f}_P\big(\xi - \tau(P,e)\big)\;d\xi \\
&\overset{(8)}{=} \frac{1}{\varepsilon T}\int_{\theta-\varepsilon^2 T-\varepsilon T}^{\theta} \tilde{f}_e(\xi)\;d\xi \\
&\le \frac{\varepsilon^2 T + \varepsilon T}{\varepsilon T}\,u_e \;=\; (1+\varepsilon)\,u_e.
\end{aligned} \tag{11}$$

(Above, a number over a relation indicates that the corresponding equation is used to obtain the right-hand side. In (11), we use (10) and the fact that $\tilde{f}_P(\xi) \ge 0$ for all ξ.) Thus, by dividing $\hat{f}$ by $1+\varepsilon$, we establish the existence of a feasible flow over time—namely $\bar{f} := \hat{f}/(1+\varepsilon)$—in $(\mathcal{N}, \tau')$. The time horizon of $\bar{f}$ is at

most $(1+\varepsilon)^2T+\varepsilon T+\varepsilon^2 T \le (1+\varepsilon)^3 T \le T'$, its cost is $c(\hat{f})/(1+\varepsilon) \le (1+\varepsilon)\,C$, and it satisfies demands $(1+\varepsilon)\,D$. □

We now turn to the second part of Proposition 4.7. The static flow x in $\mathcal{N}^{T'}/\Delta$ naturally induces a flow over time f' in $(\mathcal{N},\tau')$ with time horizon T'. If we choose to allow storage of flow at intermediate nodes, we may simplify the algorithm by finding a flow x satisfying demands D at cost C in step 2. Then the corresponding flow over time can be simulated in the network with transit times τ by holding flow at nodes.

If, however, storage of flow at intermediate nodes is not allowed, deriving the final flow over time f in $(\mathcal{N},\tau)$ from the static flow x computed in step 2 is a nontrivial task. The static flow x corresponds to a flow over time f' in $(\mathcal{N},\tau')$ with time horizon T' that satisfies demands $(1+\varepsilon)D$ at cost at most $(1+\varepsilon)C$. Since x lives in a (condensed) time-expanded network without holdover arcs at intermediate nodes, f' never stores flow at intermediate nodes in $(\mathcal{N},\tau')$. Moreover, using the same argument as in Corollary 4.6, we can assume that x is such that f' sends flow only on simple paths in the underlying network $\mathcal{N}$. This means that f' can be written as a sum of path-flows over time f'_P, $P \in \mathcal{P}$.

In the following lemma we show that a path-decomposition of the static flow x can be turned into a path-decomposition of the flow over time f' which features a simple structure. Notice that the number of arcs of the condensed time-expanded network $\mathcal{N}^{T'}/\Delta$ is in $O(mn/\varepsilon^2)$.

LEMMA 4.9. *A path-decomposition of x into flows on r paths in $\mathcal{N}^{T'}/\Delta$ can be turned into a path-decomposition $(f'_P)_{P\in\mathcal{P}}$ of f' on r paths such that the time interval $[0,T')$ can be partitioned into $T'/\Delta \in O(n/\varepsilon^2)$ subintervals where f'_P is constant for all $P \in \mathcal{P}$.*

Proof. Any path P used in a path-decomposition of x connects a source to a sink in $\mathcal{N}^{T'}/\Delta$. Each path P consists of a sequence of holdover arcs at the source, followed by a path of copies of arcs in $\mathcal{N}$, followed by a sequence of holdover arcs at the sink. The static path-flow in $\mathcal{N}^{T'}/\Delta$ of value x_P along P thus induces a path-flow over time $f'_{P'} : [0,T') \to \mathbb{R}^+$ along path P' in $\mathcal{N}$ such that the flow function $f'_{P'}$ is 0 except for an interval of length Δ where it is equal to x_P/Δ. Since there can be several paths in $\mathcal{N}^{T'}/\Delta$ that correspond to the same path P' in $\mathcal{N}$, the flow function on path P' in the final decomposition of f' is a piecewise constant function where the number of intervals with constant flow value is bounded by the number of time layers of $\mathcal{N}^{T'}/\Delta$ which is equal to T'/Δ. □

We are now ready to prove the second part of Proposition 4.7.

Proof of Proposition 4.7(b). Given x, we first derive the corresponding flow over time f' in $(\mathcal{N},\tau')$ with a path-decomposition $(f'_P)_{P\in\mathcal{P}}$ as in Lemma 4.9. Similar to the proof of Proposition 4.7(a), we consider a "smoothed" flow over time $\check{f}$ in $(\mathcal{N},\tau')$ defined by

$$\check{f}_P(\theta) \;:=\; \frac{1}{\varepsilon\,T'} \int_{\theta-\varepsilon\,T'}^{\theta} f'_P(\xi)\,d\xi \tag{12}$$

for $\theta \in [0,(1+\varepsilon)\,T')$ and $P \in \mathcal{P}$. The flow over time $(\check{f}_P)_{P\in\mathcal{P}}$ can be interpreted as a (not necessarily feasible) flow over time in $(\mathcal{N},\tau)$ with time horizon $(1+\varepsilon)T'$ satisfying demands $(1+\varepsilon)\,D$ at cost at most $(1+\varepsilon)\,C$. Moreover, by using essentially the same arguments as for $\hat{f}$ in the proof of Proposition 4.7(a), we get, for all $e \in A$

and $\theta \in [0, (1+\varepsilon)T')$,

$$
\begin{aligned}
\check{f}_e(\theta) &= \sum_{P\in\mathcal{P}\,:\,e\in P} \check{f}_P(\theta - \tau(P,e)) \\
&\overset{(12)}{=} \frac{1}{\varepsilon\,T'} \sum_{P\in\mathcal{P}\,:\,e\in P} \int_{\theta-\tau(P,e)-\varepsilon\,T'}^{\theta-\tau(P,e)} f'_P(\xi)\; d\xi \\
&\overset{(10)}{\leq} \frac{1}{\varepsilon\,T'} \sum_{P\in\mathcal{P}\,:\,e\in P} \int_{\theta-\tau'(P,e)-\varepsilon\,T'}^{\theta-\tau'(P,e)+\varepsilon^2 T'} f'_P(\xi)\; d\xi \qquad (13)\\
&= \frac{1}{\varepsilon\,T'} \int_{\theta-\varepsilon\,T'}^{\theta+\varepsilon^2 T'} \sum_{P\in\mathcal{P}\,:\,e\in P} f'_P\big(\xi - \tau'(P,e)\big)\; d\xi \\
&= \frac{1}{\varepsilon\,T'} \int_{\theta-\varepsilon\,T'}^{\theta+\varepsilon^2 T'} f'_e(\xi)\; d\xi \\
&\leq \frac{\varepsilon^2\,T' + \varepsilon\,T'}{\varepsilon\,T'}\,u_e \;=\; (1+\varepsilon)\,u_e.
\end{aligned}
$$

(Above, a number over a relation indicates that the corresponding equation is used to obtain the right-hand side.) Thus, by dividing $\check{f}$ by $1+\varepsilon$, we get the desired flow over time f in $(\mathcal{N}, \tau)$ with time horizon $(1+\varepsilon)\,T'$ satisfying demands D at cost at most C.

It remains to discuss the issue of how to actually compute f in step 3 of Algorithm FPTAS-Core. According to Lemma 4.9, a path-decomposition of x yields a path-decomposition of the corresponding flow over time f' such that f'_P is piecewise constant for all $P \in \mathcal{P}$ and has at most $O(n/\varepsilon^2)$ breakpoints. Since by definition

$$
f_P(\theta) \;=\; \frac{1}{1+\varepsilon}\frac{1}{\varepsilon\,T'} \int_{\theta-\varepsilon\,T'}^{\theta} f'_P(\xi)\,d\xi,
$$

by Lemma 4.9, the functions f_P, $P \in \mathcal{P}$, are piecewise linear (see Figure 10) and can be efficiently computed. This concludes the proof. □

It remains to discuss the running time of Algorithm FPTAS-Core. The condensed time-expanded network $\mathcal{N}^{T'}/\Delta$ (without holdover arcs) contains $O(n^2/\varepsilon^2)$ nodes and $O(mn/\varepsilon^2)$ arcs. Thus the static flow x' in step 2 can be computed in polynomial time. Since step 3 of Algorithm FPTAS-Core also takes polynomial time (see the proof of Proposition 4.7(b)), the overall running time of the algorithm is polynomial in the input size.

Theorem 4.10. *For an arbitrary $\varepsilon > 0$, a $(1+\varepsilon)$-approximate solution to the quickest transshipment problem with bounded cost can be obtained from $O(\log(1/\varepsilon))$ static min-cost flow computations in a condensed time-expanded network containing $O(n^2/\varepsilon^2)$ nodes and $O(mn/\varepsilon^2)$ arcs (without holdover arcs). In particular, this solution does not use intermediate node storage.*

For the case of the quickest transshipment problem without costs, the min-cost flow computations in the condensed time-expanded network can be replaced by max-flow computations.

4.6. Quickest multicommodity flows. The result of Theorem 4.10 can be generalized to the quickest multicommodity flow problem with bounded cost. Figure 2 shows that the optimal solution to the quickest multicommodity flow problem may require the use of storage of flow at intermediate nodes. On the other hand, if storing

at intermediate nodes is not allowed, then the optimal solution may contain nonsimple flow paths. The analysis in (11) and (13) relies on the fact that one can restrict to simple flow paths, since it uses (10). Indeed, it is shown in [19] that, unless P=NP, there is no FPTAS for the quickest multicommodity flow problem when intermediate node storage is prohibited and flow may only be sent on simple paths. If, however, intermediate node storage is allowed, then there exists an optimal solution that uses only simple flow paths: Instead of flow traveling around a cycle, it can simply wait at the start node of the cycle. In this case, the approach described in section 4.5 can be modified as follows.

A flow over time f which stores flow at intermediate nodes can no longer be decomposed into path-flows over time as described in (8). In order to handle the setting with storage of flow at intermediate nodes in a path-based model, we introduce the following notation: A *path with delays* P^δ is given by a path P in $\mathcal{N}$ consisting of nodes $(v_0, v_1, \dots, v_p)$ and a vector of nonnegative delays $\delta = (\delta_1, \dots, \delta_p)$. The value δ_i, $i = 1, \dots, p$, specifies the amount of time that flow is stored at node v_i before it continues its journey towards node v_{i+1} in a flow over time on P^δ. Thus, flow entering P^δ at time θ enters arc $e = (v_\ell, v_{\ell+1})$, $\ell = 0, \dots, p-1$, at time $\theta + \tau(P^\delta, e)$ with $\tau(P^\delta, e) := \sum_{j=1}^{\ell} (\tau_{(v_{j-1}, v_j)} + \delta_j)$.

Since in a given flow over time f with time horizon T every infinitesimal unit of flow describes a path with delays in $\mathcal{N}$, the flow over time f can be decomposed into (possibly infinitely many) flows over time f_{P^δ} on paths with delays P^δ. In this setting, (8) is replaced by

$$f_e(\theta) \;=\; \sum_{P^\delta \,:\, e \in P} f_{P^\delta}\big(\theta - \tau(P^\delta, e)\big) \tag{14}$$

for all $e \in A$. If f is given by a corresponding static flow x in a (condensed) time-expanded network with holdover arcs, then there exists a decomposition of f into flows over time on paths with delays in $\mathcal{N}$ whose number is bounded by the number of arcs in the (condensed) time-expanded network: Consider an arbitrary path-decomposition of x, and notice that any path in the (condensed) time-expanded network with holdover arcs yields a path with delays in $\mathcal{N}$.

Summarizing, a straightforward modification of the analysis in section 4.5 (i.e., replacing (8) by (14)) yields the following result.

THEOREM 4.11. *Consider an instance of the quickest multicommodity transshipment problem with bounded cost and intermediate node storage. For any $\varepsilon > 0$, a $(1+\varepsilon)$-approximate solution can be found by $O(\log(1/\varepsilon))$ static multicommodity flow computations with bounded cost in a condensed time-expanded network with $O(n^2/\varepsilon^2)$ nodes and $O(mn/\varepsilon^2)$ arcs (including holdover arcs).*

5. Earliest arrival flows. In this section, we address the multiple source, earliest arrival flow problem: Given a set of sources S with supplies $D_v > 0$ for $v \in S$ and a single sink t, send the supplies to the sink so that the amount of supplies arriving at the sink by time θ is the maximum possible for all $\theta \geq 0$. We show how the result from section 4 can be generalized to this problem.

We use the following notion of approximation for the problem of computing an earliest arrival flow. A flow over time is an α-approximate solution to this problem if, for all $d' \leq d := \sum_{v \in S} D_v$, the earliest point in time when d' units have arrived at the sink is within a factor of α of the earliest possible time. An algorithm which computes such a flow over time in polynomial time is called an α-approximation algorithm. In order to stress the property that the performance guarantee α is achieved *for all* $d' \leq d$, we

say that such an algorithm has *universal* performance guarantee α. For the earliest arrival problem, we find a solution with universal performance guarantee $(1+\varepsilon)$.

In section 5.2 we show that a unit-interval discretization may not be sufficiently fine to achieve this guarantee, and we describe how to determine a good initial discretization. This discretization may be too large, and it will be necessary to condense it. However, a uniformly crude discretization will not work, so in section 5.3, we introduce a general framework for nonuniform condensed time-expanded networks and prove some useful properties. Finally, in section 5.4 we derive a polynomial-time algorithm that yields a univeral performance guarantee for the earliest arrival flow problem by using a nonuniform, condensed time-expanded network with intervals of geometrically increasing size.

5.1. Previous work. In the discrete time model, a universally maximal s-t-flow over time can be computed in the time-expanded network by using lexicographically maximal flows introduced by Minieka [28]. A *lexicographically maximal flow* is defined in a static network with multiple sources and/or sinks. There is a strict ordering on the sources and sinks, e.g., $\{\nu_1, \nu_2, \ldots, \nu_k\}$, where ν_i is used here to denote either a source or a sink. A lexicographically maximal flow is a flow that simultaneously maximizes the flow leaving each ordered subset of sources and sinks $\{\nu_1, \nu_2, \ldots, \nu_i\}$, $i = 1, \ldots, k$. In the discrete time model, a universally maximal s-t-flow over time with time horizon T is a lexicographically maximal flow in the time-expanded graph with ordering of sources and sinks as

$$s_{T-1}, s_{T-2}, \ldots, s_1, s_0, t_{T-1}, t_{T-2}, \ldots, t_1, t_0.$$

However, due to the exponential size of the time-expanded network, this insight does not lead to an efficient algorithm for the problem. As mentioned above, the algorithms of Wilkinson [35] and Minieka [28] are based on the successive shortest path algorithm. These also are not efficient algorithms for computing universally maximal dynamic flows since the successive shortest path algorithm requires an exponential number of iterations in the worst case; see, e.g., Zadeh [36].

While the results of Wilkinson and Minieka were originally derived for the discrete time model, they also hold for the continuous time model. In this setting, the existence of universally maximal dynamic flows was first observed by Philpott [32]. Fleischer and Tardos [11] show how the algorithms for the discrete time model mentioned above can be carried over to the continuous time setting.

In the continuous time model, an equivalent problem is the *universally quickest flow problem* which asks for a flow over time of value d such that the earliest point in time when d' units have arrived at the sink is simultaneously minimized for all $d' \leq d$ and the earliest point in time when d' units have left the source is simultaneously maximized for all $d' \leq d$.

Hoppe and Tardos [23] compute a single-source single-sink universally maximal dynamic flow where the amount of flow is approximately optimal at any moment of time. Our Lemma 4.8 implies that this algorithm also achieves a universal guarantee.

An earliest arrival flow also exists for the case of multiple sources and a single sink [34]. In the discrete time model, such a flow over time can again be found by a lexicographically maximal flow computation in the time-expanded network. On the other hand, Fleischer [9] presents an instance with two sources and two sinks for which an earliest arrival flow does not exist.

Nonuniform time-expanded networks have been used previously to obtain exact algorithms for the quickest transshipment problem in the setting of zero transit

times [9]. Partitioning time into intervals of geometrically increasing size has been used previously in conjunction with dynamic programming to derive approximation algorithms for problems in the area of machine scheduling [20, 4, 5, 1].

5.2. A sufficiently fine discretization of time. Unfortunately, a lexicographically maximal flow in a time-expanded network does not necessarily yield a universal performance guarantee for the quickest flow problem in the continuous time model. Although we can interpret a static flow in a time-expanded network as a continuous flow over time (see proof of Lemma 4.1), in doing so, all the solutions we get are such that the rate of flow arriving at the sink is constant (i.e., averaged) within each discrete time interval. While this effect is negligible for late intervals in time, as the following example shows, it could be significant in the first time intervals.

Example 1. The network is a single arc from source s to sink t with capacity 2 and transit time 0. There is a unit of supply at s and a unit of demand at t. A universally quickest flow sends flow from s to t at rate 2 during the interval $[0, \frac{1}{2})$ so that flow arrives at t at rate 2 in the interval $[0, \frac{1}{2})$. Averaging the flow over unit intervals yields a flow that arrives at t at rate 1 in the interval $[0, 1)$. Thus this flow has universal performance guarantee of at most 2.

The problem illustrated by this example can be resolved as follows. For an arbitrary $\varepsilon > 0$ with $1/\varepsilon$ integral, we discretize time into intervals of size ε. Then, averaging flow within each such interval delays flow that arrives at the sink after time 1 by at most a factor of $1 + \varepsilon$. It thus remains to take care of what happens until time 1.

Notice that flow arriving at the sink before time 1 can use only arcs with transit time 0. In particular, an earliest arrival flow until time 1 can be computed by restricting attention to the subnetwork consisting of these arcs. Hajek and Ogier [18] describe an algorithm that finds an earliest arrival flow in a network with a single sink and zero transit times using $O(n)$ maximum flow computations. Fleischer [9] gives an improved algorithm that solves the problem in the same asymptotic time as one maximum flow computation. Moreover, the analysis of this algorithm shows that the function describing the optimal rate of inflow into the sink is piecewise constant and has at most k breakpoints $\theta_1, \ldots, \theta_k$, where k is the number of sources. These breakpoints are independent of the discretization after time 1 and can be computed without this information in polynomial time. They can then be used to determine the appropriate discretization in $[0, 1)$. Thus, a sufficiently fine discretization of time guarantees that an earliest arrival flow until time 1 can be computed in the corresponding time-expanded network. In the example given above, a discretization of time into intervals of size $1/2$ is sufficient. Together with the observation stated above, this yields the following result.

LEMMA 5.1. *Consider an instance of the earliest arrival problem with multiple sources with supply vector D and a single sink, and let $\theta_1, \ldots, \theta_k$ be defined as above. Then, a $(1 + \varepsilon)$-approximate earliest arrival flow can be obtained from a lexicographically maximal flow computation in the time-expanded network $\mathcal{N}^T/\Delta$, where Δ is chosen such that $\theta_1, \ldots, \theta_k$ and ε are multiples of Δ.*

By discussion in [9] (specifically, Theorem 3.6 and Theorem 4.1), we can bound Δ from below by $(m \sum_{e \in A} u_e)^{-k}$. Thus, the size of the resulting time-expanded network $\mathcal{N}^T/\Delta$ is pseudopolynomial in the input size of the problem. Since time can be rescaled by a factor of $1/\Delta$, we can and will assume without loss of generality that $\Delta = 1$ and thus $\mathcal{N}^T/\Delta = \mathcal{N}^T$. In the next subsection we show how $\mathcal{N}^T$ can be turned into a network of polynomial size while only losing another factor of $1 + \varepsilon$ in the performance guarantee of the resulting polynomial-time algorithm.

5.3. Nonuniform condensed time-expanded networks. As we mentioned above, the size of the time-expanded network $\mathcal{N}^T$ is only pseudopolynomial in the input size. In contrast to the situation for the quickest flow problem discussed in section 4, using a uniformly rough discretization can lead to a much worse performance guarantee for the earliest arrival flow problem. Instead we will use a nonuniform discretization. In this section we describe a general framework for nonuniform time-expanded networks and establish, where possible, the appropriate generalizations of properties of uniform time-expanded networks.

Overloading the notation introduced in section 4.1, for a sorted list $L = \langle \theta_0, \dots, \theta_r \rangle$ with

$$0 \;=\; \theta_0 \;<\; \theta_1 \;<\; \cdots \;<\; \theta_{r-1} \;<\; \theta_r \;=\; T,$$

the *L-time-expanded network* of $\mathcal{N} = (V, A)$ denoted by $\mathcal{N}^L$ is obtained by creating r copies of V, labeled V_0 through V_{r-1}, with the qth copy of node v denoted v_q for $q = 0, \dots, r-1$. For every arc $e = (v, w) \in A$ and for every $q \geq 0$ with $\theta_q + \tau_e \leq \theta_{r-1}$, there is an arc e_q from v_q to $w_{q'_e}$ with

$$q'_e \;:=\; \min\{q'' \mid \theta_q + \tau_e \leq \theta_{q''}\}. \tag{15}$$

When e is clear from context, we use q' instead of q'_e. The capacity of arc e_q is set to $u_e\,(\theta_{q+1} - \theta_q)$. In addition, there is a holdover arc from v_q to v_{q+1} with infinite capacity for all $v \in V$ and $0 \leq q < r-1$. Notice that this definition generalizes the definition of the T-time-expanded network $\mathcal{N}^T$; in particular, $\mathcal{N}^T = \mathcal{N}^L$ for $L = \langle 0, 1, \dots, T \rangle$.

Whenever we consider a static flow in $\mathcal{N}^L$, we implicitly assume that t_{r-1} is its only sink; all flow arriving at t_q for $q < r-1$ is sent to this sink on holdover arcs.

LEMMA 5.2. *Let $L = \langle 0 = \theta_0, \dots, \theta_r \rangle$ with $\theta_q - \theta_{q-1} \leq \theta_{q+1} - \theta_q$ for all $q = 1$ to $r-1$. Then any static flow in $\mathcal{N}^L$ corresponds to a flow over time in $\mathcal{N}$ such that the amount of flow reaching t in $\mathcal{N}$ by time θ_{q+1}, $q = 0, \dots, r-1$, is the same as the amount of flow reaching node t_q in $\mathcal{N}^L$.*

Proof. Let x be a static flow in $\mathcal{N}^L$. We interpret x as a "generalized" flow over time f' where, in contrast to "standard" flows over time, transit times can now vary over time. Interpret the flow x_{e_q} on arc $e_q = (v_q, w_{q'})$ as flow f'_e sent at the constant rate $x_{e_q}/(\theta_{q+1} - \theta_q)$ into arc $e = (v, w)$ during the time interval $[\theta_q, \theta_{q+1})$ and arriving at node w during the time interval $[\theta_{q'}, \theta_{q'+1})$ at the constant rate $x_{e_q}/(\theta_{q'+1} - \theta_{q'})$. In particular, in the time interval $[\theta_q, \theta_{q+1})$, the transit time on arc e varies between $\theta_{q'} - \theta_q$ (flow entering the arc at time θ_q) and $\theta_{q'+1} - \theta_{q+1}$ (flow entering the arc immediately before time θ_{q+1}) in f'. Thus, since the sizes of the time intervals $[\theta_q, \theta_{q+1})$, $q = 0, \dots, r-1$, are nondecreasing and by choice of q', the transit time on arc e in f' is never smaller than τ_e.

By design, f' obeys flow rate capacity constraints and flow conservation. Moreover, for $q = 0, \dots, r-1$, the amount of flow reaching t in f' by time θ_{q+1} is the same as the amount of flow reaching node t_q in x. Finally, since transit times in f' are always lower bounded by the actual transit times τ_e of arcs $e \in A$ (by (15)), it can easily be interpreted as a regular flow over time f in $\mathcal{N}$ by introducing appropriate waiting times for every infinitesimal flow unit at the head of each arc. ∎

LEMMA 5.3. *Let $L = \langle 0 = \theta_0, \dots, \theta_r \rangle$ with $\theta_q - \theta_{q-1} \leq \theta_{q+1} - \theta_q$ for all $q = 1$ to $r-1$. Let f be any flow over time that completes by time θ_r in the network $\mathcal{N}$ modified so that all transit times are increased by $\Delta := \theta_r - \theta_{r-1}$. Then, f induces a feasible static flow in $\mathcal{N}^L$ of the same value.*

Proof. For all $e \in A$ and $0 \le q \le r-1$, define x_{e_q} to be the total f-flow into e in interval $[\theta_q, \theta_{q+1})$. Since f is feasible, it obeys the capacity constraints; then by construction so does x. By design, the value of x equals the value of f.

To establish flow conservation, consider the path $P = \langle w^0, w^1, \ldots, w^h = t\rangle$ traveled by an infinitesimal unit of flow in f. This infinitesimal unit of flow arrives at w_i at time φ_i and leaves w_i at some time $\xi_i \ge \varphi_i$. We argue that the corresponding unit of flow in x arrives at $w^i_{p_i}$ for some p_i satisfying $\theta_{p_i} \le \varphi_i$. Thus it is available to be sent along P in $\mathcal{N}^L$ on arc $(w^i_{q_i}, w^{i+1}_{q'_i})$, where q_i is the maximum index ℓ satisfying $\theta_\ell \le \xi_i$. This will show that x satisfies flow conservation.

Set $q := q_{i-1}$. By design of x, the infinitesimal unit of flow leaves w^{i-1}_q in $\mathcal{N}^L$ and thus arrives at $w^i_{q'}$, where q' is defined according to (15). By definition of q', we have that

$$\begin{aligned}\theta_{q'} - \theta_q &= \theta_{q'-1} - \theta_q + (\theta_{q'} - \theta_{q'-1}) \\ &< \tau_{(w^{i-1},w^i)} + (\theta_r - \theta_{r-1}) = \tau_{(w^{i-1},w^i)} + \Delta.\end{aligned}$$

This yields $\theta_{q'} < \theta_q + \tau_{(w^{i-1},w^i)} + \Delta \le \xi_{i-1} + \tau_{(w^{i-1},w^i)} + \Delta = \varphi_i \le \xi_i$. (The second inequality follows by definition of $q := q_{i-1} \le \xi_{i-1}$ at the end of the previous paragraph; the subsequent equality follows by definition of φ_i.) This implies that $\theta_{q'} \le \theta_{q_i}$, and thus the flow obeys conservation constraints. ∎

5.4. An approximation scheme. To obtain a $(1+\varepsilon)$-universal guarantee for the earliest arrival flow problem, we use a geometrically increasing time discretization. Let $p := \lceil 2n/\varepsilon^2 \rceil$, and define the list

$$\begin{aligned}L \;:=\; \langle &0, 1, 2, \ldots, 2p, \\ &2(p+1), 2(p+2), \ldots, 4p, \\ &4(p+1), 4(p+2), \ldots, 8p, \\ &\ldots \\ &2^{\ell-1}(p+1), 2^{\ell-1}(p+2), \ldots, 2^\ell p\rangle.\end{aligned}$$

Here $\ell \in \mathbb{N}_0$ is chosen such that the resulting time-expanded network $\mathcal{N}^L$ is large enough to allow for a $(1+O(\varepsilon))$-approximate time horizon. To be more precise, we choose the smallest ℓ such that $2T^* \le 2^\ell p$, where T^* is the time horizon of an optimal flow over time. Notice that the length of the list L is in $O(p \log T^*)$ and hence polynomially bounded in the input size and $1/\varepsilon$. It thus remains to be shown that a lexicographically maximal flow in the corresponding *geometrically condensed time-expanded network* $\mathcal{N}^L$ yields a flow over time with universal performance guarantee $1+O(\varepsilon)$.

LEMMA 5.4. *A lexicographically maximal flow in $\mathcal{N}^L$ induces a flow over time in $\mathcal{N}$ with universal performance guarantee $1+O(\varepsilon)$.*

Proof. Let $T \le T^*$ be the minimal time required to send $d' \le d$ units of flow to the sink. We consider the time-expanded network $\mathcal{N}^{L'}$ defined by the sublist $L' := \langle \theta_0, \ldots, \theta_{r'}\rangle$ of L with $r' := \min\{q \mid \theta_q \ge (1+\varepsilon)^2 T\}$. In other words, $\mathcal{N}^{L'}$ is obtained from $\mathcal{N}^L$ by removing all time layers V_q with $q \ge r'$ and all incident arcs. We show below that there is a flow in $\mathcal{N}^{L'}$ of value d'. Then, since in a lexicographically maximum flow in $\mathcal{N}^L$ at least d' units of flow reach $t_{r'-1}$, the corresponding flow over time in $\mathcal{N}$ sends at least d' to t by time $\theta_{r'}$ by Lemma 5.2. Hence this flow yields a universal performance guarantee of $1+O(\varepsilon)$.

Let $\Delta' = \theta_{r'} - \theta_{r'-1}$. By choice of p and since we can assume that $\theta_{r'} \leq 2T$, we have that

$$\Delta' \;=\; \theta_{r'} - \theta_{r'-1} \;\leq\; \theta_{r'}/p \;\leq\; \varepsilon^2 T/n. \tag{16}$$

Since there is flow of value d' in $\mathcal{N}$ by time T, Lemma 4.8 implies that there is flow of value $d'(1+\varepsilon)$ in $\mathcal{N}$ by time $T(1+\varepsilon)$. Then, the same argument as in the proof of Proposition 4.7(a) (together with (16)) implies that there is flow of value d' that completes by time $(1+\varepsilon)T + \varepsilon\, T + \varepsilon^2\, T = (1+\varepsilon)^2 T$ in the network $\mathcal{N}$ with all transit times increased by Δ'. By Lemma 5.3, this implies that there is flow of value d' in $\mathcal{N}^{L'}$. □

We have now established the main result of this section.

THEOREM 5.5. *There exists an FPTAS for the problem of computing an earliest arrival flow in a network with multiple sources and a single sink.*

A CONSTANT-FACTOR APPROXIMATION ALGORITHM FOR OPTIMAL 1.5D TERRAIN GUARDING*

BOAZ BEN-MOSHE†, MATTHEW J. KATZ‡, AND JOSEPH S. B. MITCHELL§

Abstract. We present the first constant-factor approximation algorithm for a nontrivial instance of the optimal guarding (coverage) problem in polygons. In particular, we give an $O(1)$-approximation algorithm for placing the fewest point guards on a 1.5D terrain, so that every point of the terrain is seen by at least one guard. While polylogarithmic-factor approximations follow from set cover results, our new results exploit the geometric structure of terrains to obtain a substantially improved approximation algorithm.

Key words. geometric optimization, guarding, approximation algorithms

1. Introduction.

For a geometric domain $\mathcal{D}$, the *optimal guarding (coverage) problem* is to determine the smallest number, k^*, of *guards* (e.g., points) that can be placed in $\mathcal{D}$ so that each point of $\mathcal{D}$ is *seen* by at least one guard. The optimal guarding problem is an instance of a set cover problem that is induced by a geometric setting. The many related problems, both combinatorial and algorithmic, fall into the general category known as *art gallery problems*, which have been studied extensively; see, e.g., [12, 14, 16, 17].

We give the first constant-factor approximation algorithm for a nontrivial instance of the optimal guarding problem. All prior approximation bounds were polylogarithmic in n and/or k^*.

The instance we study here is the 1.5D *terrain guarding problem*, in which the input domain is the two-dimensional region above an x-monotone polygonal chain having n vertices. We restrict guards to being placed at points on the terrain; with no restriction on guard placement, a single guard (at a high enough altitude) suffices to see the terrain.

Related work. The classical combinatorial result, the "art gallery theorem," states that $\lfloor n/3 \rfloor$ guards are sufficient, and sometimes necessary, to guard an n-vertex simple polygon [14]. Combinatorial results on the number of guards needed for various forms of guarding on terrains are given in [2].

The optimal guarding problem is known to be NP-hard, even if $\mathcal{D}$ is a simple polygon [15]. Thus, efforts have concentrated on the approximability of optimal

guarding problems. Ghosh [10] gave an $O(\log n)$-approximation for optimal coverage of a polygon by vertex guards, based on standard set cover results. Recent interest [6, 11] has focused on methods of efficiently applying the Brönnimann–Goodrich technique [3], which exploits finiteness of VC-dimension. Efrat and Har-Peled [6] obtain an $O(\log k^*)$-approximation algorithm for polygon guarding with vertex guards, using time $O(n(k^*)^2 \log^4 n)$, where k^* is the optimal number of vertex guards. Their technique can be applied to nonvertex guards lying at points of a dense grid, adding to the running time a factor polylogarithmic in the grid density. (No approximation algorithm is known if the guards are completely unrestricted and all of the polygon is to be guarded.) Their results apply also to polygons with holes and to 2.5D terrains, still with polylogarithmic approximation factors. Most recently, Cheong, Efrat, and Har-Peled [5] have shown how to place k guards in order to optimize (approximately) the total area seen by the guards.

Eidenbenz [7], and Eidenbenz, Stamm, and Widmayer [9] have shown that it is APX-hard to solve the optimal guarding problem in simple polygons; thus, there exists an $\epsilon > 0$ such that it is NP-hard to obtain a $(1+\epsilon)$-approximation algorithm. They further show that guarding polygons with holes, as well as guarding 2.5D terrains, is as hard as set cover; these problems do not have polynomial-time algorithms with approximation ratio less than $c \ln n$, for some $c > 0$, unless $P = NP$ (and do not have approximation ratio $\frac{1-\epsilon}{12} \ln n$, for any $\epsilon > 0$, unless $NP \subset TIME(n^{O(\log \log n)})$). These hardness of approximation results are complemented by $O(\log n)$-approximation algorithms based on greedy set cover [8].

For 1.5D terrains, Chen, Estivill-Castro, and Urrutia [4] claim that a modification of the hardness proof of [15] shows that the problem is NP-hard (details are omitted and are still to be verified). In the very restricted setting where all guards are to be placed at a constant altitude (above "sea level," not above the terrain surface), the optimal guarding problem is readily solved in polynomial time (it reduces to a one-dimensional problem on intervals); in fact, it can be solved in linear time [7, 13].

Motivation. The terrain guarding problem arises in optimal placement of antennas for communication networks. We are motivated to study the problem in two dimensions, in an effort to understand better the much more difficult three-dimensional (2.5D) terrain guarding problem (which Eidenbenz shows has no better than a log-approximation). Further, the two-dimensional problem shows up as a subproblem in heuristics for solving the three-dimensional problem, and it arises directly in applications of coverage along a highway, and security lamp and camera placement along walls and streets. In some applications, one needs to cover only a portion of the input domain; our results can be extended to yield an algorithm for covering a subset of the terrain surface optimally.

Our results. Our main result is an efficient $O(1)$-approximation algorithm for the terrain guarding problem in two dimensions. Our results rely on developing several geometric properties of terrains, in order that our algorithm can exploit the special structure.

The main difficulty in proving our main result is in showing that one can obtain a constant-factor approximation to the dominating set problem in graphs that can be realized as the visibility graph of the vertices of a terrain polygon (i.e., to the problem of placing vertex guards on a terrain in order to see all other vertices). It is then relatively straightforward to extend this result to apply to placing arbitrary guards on the terrain in order to guard all of the terrain.

It is worth noting that some natural and simple approaches to the problem do

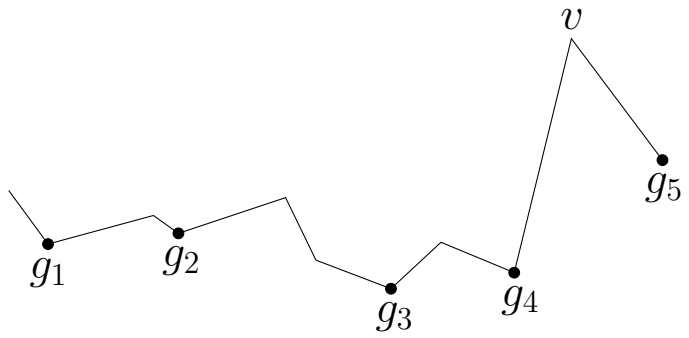

FIG. 1. *None of the guards $g_1, \ldots, g_5$ is redundant, but a single guard at v would suffice.*

not yield $O(1)$-approximations: One can give examples showing a subset of vertices guarding T, without redundant vertices, that is arbitrarily bad with respect to optimal (see Figure 1); similarly, simple sweep approaches that add guards "as needed" can be arbitrarily bad.

We begin with some definitions and basic structural results.

2. Preliminaries. Let T be a terrain of complexity n in the plane; more precisely, let T be an x-monotone polygonal curve specified by n vertices, $v_1, \ldots, v_i = (x_i, y_i), \ldots, v_n$, indexed in x-increasing order. We refer to the *terrain polygon*, P_T, which is the closed region of the plane bounded from below by T and from the sides by the upwards vertical rays emanating from v_1 and v_n, respectively.

Let $p = (p_x, p_y)$ and $q = (q_x, q_y)$ be two points on the polygonal curve T. We say that p *sees* q (and q *sees* p) if and only if the line segment $\overline{pq}$ is contained in P_T. We write $p < q$ if p is to the left of q (i.e., $p_x < q_x$). For any two vertices $u, v \in T$ with $u < v$, the *subterrain* $[u, v]$ of T is simply the portion of T between u and v (including u and v). For a point $p \in T$, let $L(p)$ (resp., $R(p)$) denote the leftmost (resp., rightmost) point on T that sees p. It is easy to see that $L(p)$ and $R(p)$ are necessarily vertices of T.

A *guard* is a point of P_T that we consider to be able to view ("guard" or "cover") other points of P_T. A *terrain guard* is any point on T; a *vertex guard* is a vertex of T.

The *must-guard set*, M, is a subset of P_T that we require to be seen by a set of guards. The *dominating set problem on terrains* (DSPT) is to compute a minimum-cardinality set of vertex guards for $M = \{v_1, \ldots, v_n\}$, the vertex set of T. We spend most of our effort in obtaining an approximation algorithm for the DSPT; then, we describe how this result extends to the case of terrain guards and to the case of $M = T$. (Note that a set of guards that sees $M = T$ necessarily sees all of P_T; however, it is not the case that guarding the boundary of a general simple polygon P implies guarding the interior of P.)

We say that a subterrain $[u, v]$ *can be guarded from the right (resp., left)* if there exists a set of vertex guards to the right of v (resp., to the left of u) that covers $M \cap [u, v]$.

CLAIM 2.1 (order claim). *Let $a < b < c < d$ be four points on T. If a sees c and b sees d, then a sees d.*

Proof. Since a sees c, b lies below the line segment $\overline{ac}$; similarly, c lies below $\overline{bd}$. Thus, $\overline{ac}$ and $\overline{bd}$ cross each other at a point ξ (above T), and T lies below the chain (a, ξ, d), implying that a sees d. ∎

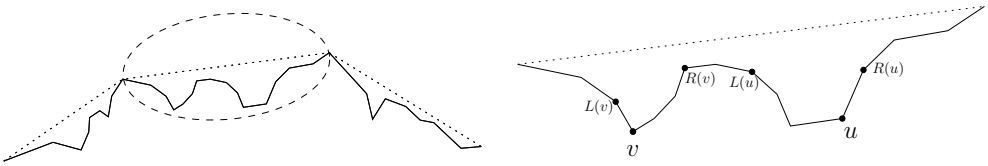

FIG. 2. *The overall structure of the algorithm.*

3. The main algorithm. In this section we outline a constant-factor approximation algorithm for the DSPT: Find a minimum-size subset G of vertices of T such that each vertex of T is visible from one of the vertices in G. (The missing details are presented in section 4.)

We begin by computing the (upper) convex hull of T, denoted $CH(T)$. Notice that if m is the number of vertices in $CH(T)$, then at least $\lfloor \frac{m}{2} \rfloor$ guards are needed in order to guard T. In the first stage, we thus place a guard at each vertex of $CH(T)$. Notice that if T' is a subterrain defined by two consecutive vertices of $CH(T)$, then no point in its interior is visible from outside T'. We therefore may consider each of the $m-1$ subterrains that are defined by the vertices of $CH(T)$ separately (see Figure 2).

Let $T'' = [u, v]$ be a subterrain of T'. We say that T'' *requires a local guard* if there exists a vertex w in the interior of T'' that is not seen from $(T' - T'') \cup \{u, v\}$, or, in other words, $u < L(w) < R(w) < v$.

Let T' be one of the subterrains obtained from the first stage. In the second stage we partition T' into subterrains such that each of them does not require a local guard. We do this as follows. For each internal vertex v of T', we compute the points (vertices) $L(v)$ and $R(v)$. Let $T(v)$ denote the subterrain $[L(v), R(v)]$. Viewing the subterrains $T(v)$ as open horizontal intervals and considering only *minimal* intervals (i.e., intervals that do not contain other intervals), we compute a maximal set $\mathcal{S}$ of disjoint such intervals. Let $\mathcal{S}'$ be the complementary set of subterrains; thus, any two consecutive subterrains in $\mathcal{S}$ define at most one subterrain in $\mathcal{S}'$.

CLAIM 3.1. *Let T'' be a subterrain in $\mathcal{S} \cup \mathcal{S}'$. Then T'' does not require a local guard.*

Proof. The proof follows immediately from the construction. □

We place guards at the end vertices of the subterrains in $\mathcal{S}$. In addition, for each $T'' \in \mathcal{S} \cup \mathcal{S}'$, we place guards at the at most four vertices $R(a_l), R(a_r), L(b_l), L(b_r)$, where a_l (resp., a_r) is the leftmost (resp., rightmost) internal vertex of T'' that is seen from the right of T'', and b_l (resp., b_r) is the leftmost (resp., rightmost) internal vertex of T'' that is seen from the left of T''. Since $|\mathcal{S}|/2$ is clearly a lower bound on the number of guards needed to guard T', we increase the number of vertices by only a constant factor.

We now "solve" each of the subterrains in $\mathcal{S} \cup \mathcal{S}'$ *separately*. Each such subterrain is considered to be a *base case*, in that it does not require a local guard, and is solved using the base-case algorithms detailed in section 4. The *independence property* (based on Claims 3.3–3.4) shown below justifies this approach, i.e., that the subterrains in $\mathcal{S} \cup \mathcal{S}'$ may be solved separately without hurting the approximation bound.

The overall structure of the algorithm is thus as follows:

- Given a terrain T, compute its (upper) convex hull, place guards at the vertices of the convex hull, and solve each subterrain T' separately.
- Given a subterrain T', partition it into subterrains $\mathcal{S} \cup \mathcal{S}'$, as described above.

For each subterrain $T'' \in \mathcal{S} \cup \mathcal{S}'$, place guards at the end vertices of T'' and at the vertices $R(a_l), R(a_r), L(b_l), L(b_r)$, and solve the remaining unguarded fragments of T'' separately, using the base-case algorithms detailed in section 4.

The rest of this section deals with the independence property and its proof.

LEMMA 3.2 (the independence property). *Let T be a terrain, and let $T_1, \ldots, T_k$ be k disjoint subterrains of T. (Two subterrains may have a common end vertex.) Assume that the size l of an optimal solution for $T_1 \cup \cdots \cup T_k$ (by placing guards on T) is greater than or equal to k/c_1, for some constant c_1. Also assume that for each subterrain T_i we can compute a c_2-solution for (the yet unguarded fragments of) T_i, for some constant c_2. Then we can compute a c-solution for $T_1 \cup \cdots \cup T_k$, for some constant c. (A c_0-solution is a solution whose size is at most c_0 times the size of an optimal solution; thus a c-solution is of size at most cl.)*

We construct a c-solution for $T_1 \cup \cdots \cup T_k$. We begin by placing at most $2k$ guards at the end vertices of the subterrains $T_1, \ldots, T_k$. We need the following two claims.

CLAIM 3.3. *Let $r_1 < r_2 < \cdots < r_m$ be the internal vertices of T_i that can be seen from the right of T_i. Then*

1. *$R(r_1) \geq R(r_2) \geq \cdots \geq R(r_m)$.*
2. *If r_i, for $1 < i < m$, cannot be seen both from $R(r_m)$ and from $R(r_1)$, then it can be seen only (when viewing from the right of T_i) from vertices in the interior of the subterrain $[R(r_m), R(r_i)] \subseteq [R(r_m), R(r_1)]$.*

Proof. The first part follows immediately from Claim 2.1. If $R(r_2) > R(r_1)$, then by Claim 2.1, r_1 must see $R(r_2)$, which is impossible since r_1 does not see beyond $R(r_1)$. Similarly, we argue that $R(r_2) \geq R(r_3)$, etc.

To prove the second part, assume that r_i (for some $1 < i < m$) cannot be seen from $R(r_m)$ or from $R(r_1)$. Then r_i cannot be seen from a vertex to the left of $R(r_m)$ (and to the right of T_i), since if r_i is seen from such a vertex, then, by Claim 2.1, it is also seen from $R(r_m)$. Similarly, r_i cannot be seen from a vertex to the right of $R(r_1)$, since if it is seen from such a vertex, then, by Claim 2.1, r_1 is also seen from this vertex, which is impossible (by the definition of $R(r_1)$). ∎

Set $R(T_i) = [R(r_m), R(r_1)]$, and let $L(T_i)$ be the symmetric subterrain that is defined by considering the internal vertices of T_i that can be seen from the left of T_i .

CLAIM 3.4. *Let T_i, T_j be two of the subterrains above, such that T_j lies to the right of T_i. Let $R_j(T_i) \subseteq R(T_i)$ be the subterrain defined by considering only the internal vertices in T_i that can be seen from the right of T_j. Then $R(T_j)$ lies to the left of $R_j(T_i)$, where the right end vertex of $R(T_j)$ and the left end vertex of $R_j(T_i)$ may coincide.*

Proof. Assume there is an internal vertex in T_i that can be seen from the right of T_j. (Otherwise, $R_j(T_i)$ is empty.) Let u be the leftmost vertex in T_j that can be seen from the right of T_j. Then $R(u)$ defines the right end vertex of $R(T_j)$. By Claim 2.1, if v is any vertex in T_i that can be seen from the right of T_j, then $R(v) \geq R(u)$. ∎

A symmetric claim can be formulated using the subterrains $L(T_i)$ and $L_i(T_j)$ instead of $R(T_j)$ and $R_j(T_i)$, respectively.

We are now ready to continue the construction of a c-solution for $T_1 \cup \cdots \cup T_k$. For each T_i, we place guards at the end vertices of the subterrains $R(T_i)$ and $L(T_i)$. We have thus placed at most $4k$ guards in this step (and at most $6k$ guards in the first two steps). Next, for each T_i we compute a c_2-solution $\mathcal{V}_i$ for (the yet unguarded fragments of) T_i. We claim that the at most $6k$ guards of the first two steps together with the sets $\mathcal{V}_i$ form a c-solution for $T_1 \cup \cdots \cup T_k$.

Let $\mathcal{V}_{opt}$ be an optimal solution for $T_1 \cup \cdots \cup T_k$. Recall that we are assuming that $|\mathcal{V}_{opt}| \geq k/c_1$, for some constant c_1. Let $\mathcal{U}$ denote the set of at most $4k$ vertices that are the end vertices of the subterrains $R(T_i)$ and $L(T_i)$. Let $v \in \mathcal{V}_{opt} - \mathcal{U}$. We observe that there is at most one subterrain T_i to the left of v, which has an internal vertex that is not seen by a vertex of $\mathcal{U}$ but is seen from v. If there are two such subterrains T_i and T_j, where T_j is to the right of T_i, then, by Claim 3.3, v is an internal vertex of both $R(T_i)$ and of $R(T_j)$. More precisely, v is in $R_j(T_i)$ (but not its right end vertex), and v is an internal vertex of $R(T_j)$. But this is impossible by Claim 3.4. Thus v can help guarding at most one subterrain to its left, at most one subterrain to its right, and possibly the subterrain in which it lies. Our construction replaces v with at most $3c_2$ guards.

4. Base-case algorithms. Let T be a terrain with n vertices, and let $\mathcal{G}$ be the subset of vertices of T where guards have already been placed. Let A be a subterrain of T that does not require a local guard, and let A' be the subset of vertices of A that cannot be seen by $\mathcal{G}$. We wish to compute a set of guards $\mathcal{V}(A')$ located at vertices of T, some of which may be located within A, that together see all vertices in A', and such that the size of $\mathcal{V}(A')$ is within some constant factor of the size of an optimal such set of guards.

We distinguish between three base cases:

Case 0. We require that $\mathcal{V}(A')$ consist only of vertices that lie to the *left* of subterrain A.

Case 1. We require that $\mathcal{V}(A')$ consist only of vertices that lie to the *left* of or *within* subterrain A.

Case 2. We make no requirements of the set $\mathcal{V}(A')$ of vertices of T that guard subterrain A.

Each subterrain $T'' \in \mathcal{S} \cup \mathcal{S}''$ (see section 3) is passed to the Case 2 algorithm, which in turn may pass it on to the Case 1 algorithm; see Figure 3.

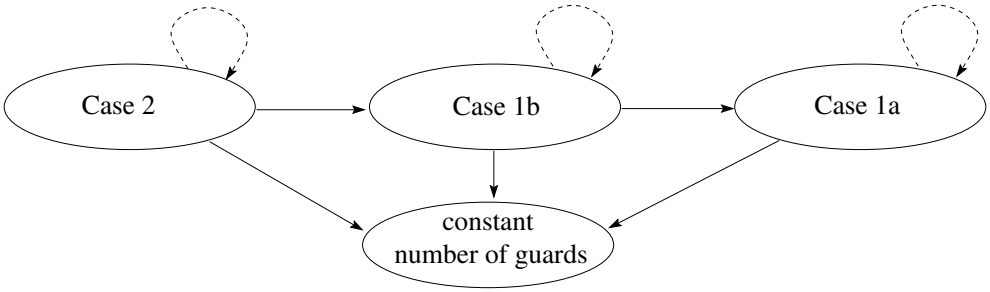

FIG. 3. *The program flow of the base-case algorithms: A dashed line denotes a recursive call, while a solid line denotes a call to another (simpler) algorithm.*

DEFINITION 4.1. *Let T be a terrain, and let $\mathcal{G}$ be the subset of vertices of T at which guards have already been placed. Let T' be the subset of vertices of T that cannot be seen by $\mathcal{G}$. We say that two subterrains $T_1, T_2 \subset T$ are* guard-independent with respect to $\mathcal{G}$ *if the set of vertices of T that are seen by $T_1 \cap T'$ and the set of vertices seen by $T_2 \cap T'$ are disjoint. In other words, T_1 and T_2 are* guard-independent *subterrains if any guard g that can see a vertex in $T_1 \cap T'$ cannot see a vertex in $T_2 \cap T'$ and vice versa.*

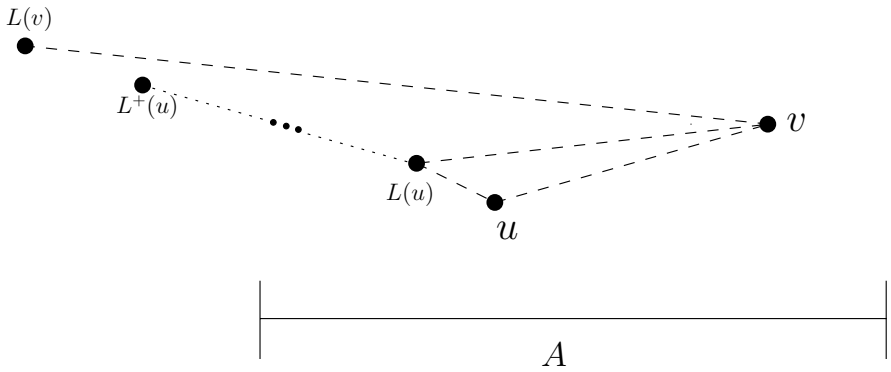

FIG. 4. *If u can see v, then $L(u)$ can also see v. If $L(u) \in A$, we apply Claim 4.3 to $L(u)$ to conclude that $L(L(u))$ dominates $L(u)$ and therefore also sees v, etc., until we reach a vertex that is not in A that dominates u.*

4.1. Case 0. Let A be a subterrain of T such that it is possible to guard the set of (so far unguarded) vertices A' using only guards at vertices of T to the left of A. Our goal is to determine a minimum-cardinality such set of *left guards* for A'. In this specially constrained case, we are able to determine an *optimal* set, $\mathcal{V}(A')$, of guards, using the following algorithm.

While A' contains an unguarded vertex, **do**

Place a guard at $L(a)$, where a is the leftmost vertex in A' that is not yet guarded.

LEMMA 4.2. *The algorithm above computes an optimal subset of left guards for A'.*

Proof. When the algorithm locates a guard at vertex $L(a)$, no vertex to the left of $L(a)$ can see a (by the definition of $L(a)$), and any vertex v to the right of $L(a)$ (and still to the left of A) that sees a is "dominated" by $L(a)$ (by Claim 2.1), in that a guard at $L(a)$ will see any vertex of A' that v sees. We continue by induction. ∎

4.2. Case 1. Let $A = [a, b]$ be a subterrain that does not require a local guard, let A' be the subset of vertices of A that remain to be guarded, and assume that A' can be guarded from the left of A, that is, by placing guards only at vertices of T to the left of A.

In this case (Case 1), our goal is to compute a set of guards $\mathcal{V}(A')$ for A' such that each guard in $\mathcal{V}(A')$ is either to the left of A or within A (but not to the right of A). We present a constant-factor approximation algorithm for computing a minimum-cardinality such set of guards.

We will need the following claim, which tells us that it does not make sense to place a guard within A if its sole purpose is to view rightwards.

CLAIM 4.3. *Let $A = [a, b]$ be a subterrain as above. Let $u \neq b$ be any vertex in A. Then $L(u)$ dominates u, in the sense that any vertex $v \in A'$ to the right of u that is seen by u is also seen by $L(u)$.*

Proof. Let $v \in A'$ be a vertex to the right of u that is seen by u. Recall that by our assumption, $L(v)$ lies to the left of A. We may also assume that $L(u) \neq L(v)$, since otherwise $L(u)$ clearly sees v. Now, on the one hand, both u and $L(u)$ must lie below the line $l(L(v), v)$, and, on the other hand, $L(u)$ must lie above the line $l(L(v), u)$. Thus $L(u)$ can see v (see Figure 4). ∎

COROLLARY 4.4. *There is always a vertex to the left of A that dominates u (with*

respect to the vertices of A' to the right of u). We shall denote by $L^+(u)$ any such vertex.

Proof. If $L(u) \in A$, then we apply Claim 4.3 to $L(u)$ to conclude that $L(L(u))$ also sees v, etc., until we reach a vertex that is not in A. This vertex clearly dominates u. □

COROLLARY 4.5. *$L^+(u)$ dominates any vertex w that lies between $L^+(u)$ and u (with respect to the vertices of A' to the right of u).*

Proof. The proof follows from the fact that w must lie below the chain $u, L(u)$, $L(L(u)), \ldots, L^+(u)$. □

We consider two subcases, according to whether or not the endpoints of A see each other.

4.2.1. Case 1a. The endpoints of A see each other. Let $A = [a, b]$ be a subterrain such that a and b see each other. For a vertex $q \in A$, $q \neq b$, that is visible from b, we denote by $A'_l(q)$ the vertices of A' that lie to the left of q and are not visible from b or $L^+(q)$. Similarly, let $A'_r(q)$ denote the vertices of A' that lie to the right of q and are not visible from b or $L^+(q)$. If both $A'_l(q)$ and $A'_r(q)$ are nonempty, we say that q implies a *nontrivial division.*

CLAIM 4.6. *If there exists a vertex $q \in A$, $q \neq b$, such that, b sees q, and both $A'_l(q)$ and $A'_r(q)$ are nonempty (i.e., q implies a nontrivial division), then $A'_l(q)$ and $A'_r(q)$ are guard-independent.*

Proof. The vertices that can see one or more vertices of $A'_l(q)$ can lie either to the right of $L^+(q)$ and to the left of A, or in the subterrain $[a, q]$. This follows from the fact that b can see q, and that any vertex to the left of $L^+(q)$ cannot see into $A'_l(q)$. Similarly, the vertices that can see one or more vertices in $A'_r(q)$ can lie either to the left of $L^+(q)$ or in the subterrain (q, b). Notice that q cannot see a vertex of $A'_r(q)$, since $L^+(q)$ cannot see such a vertex and, according to Claim 4.3, $L^+(q)$ dominates q with respect to the subterrain to the right of q. □

We say that A is in the *single-pocket case* if each vertex $q \in A$ to the left of b that is visible from b implies a trivial division (either $A'_l(q)$ is empty or $A'_r(q)$ is empty).

CLAIM 4.7. *Consider a subterrain A that is in the single-pocket case. Then there exists an (open) subterrain $A^* = (c, d) \subset A$, $d \neq b$, such that b cannot see any vertex in A^*, and all the vertices of A' that are not visible from b, $L^+(c)$, and $L^+(d)$ are in A^*.*

Proof. We may assume that there is no vertex q (to the left of b and visible from b) for which *both* $A'_l(q)$ and $A'_r(q)$ are empty; otherwise, we could place guards at b and $L^+(q)$ to see all of A'. Let c be the rightmost vertex (to the left of b and visible from b) that implies a (trivial) division in which $A'_l(c)$ is empty. Let d be the first vertex to the right of c that is visible from b. Then d implies a (trivial) division in which $A'_r(d)$ is empty. Set $A^* = (c, d)$. By definition, b cannot see any vertex in A^*. Also, any vertex in A' that is not visible from b, $L^+(c)$, or $L^+(d)$ must lie in A^*, since, by definition, b and $L^+(c)$ cover $[a, c) \cap A'$ as well as c, and b and $L^+(d)$ cover $(d, b] \cap A'$ as well as d. □

The single-pocket case. Consider the single-pocket case, where $A^* = (c, d)$ denotes the "pocket." Notice that (i) none of the vertices in $(d, b]$ can see into the pocket A^* (by Claim 2.1), and (ii) the vertices c and d see each other (since b sees both c and d but does not see any vertex in A^*). Also we know that b, $L^+(c)$, and $L^+(d)$ together cover $A' - A^*$.

For a subset of vertices S, we denote by $V(S, p)$ the subset of vertices of S that are visible from a vertex p, and by $V(S, P)$ the subset of vertices of S that are visible

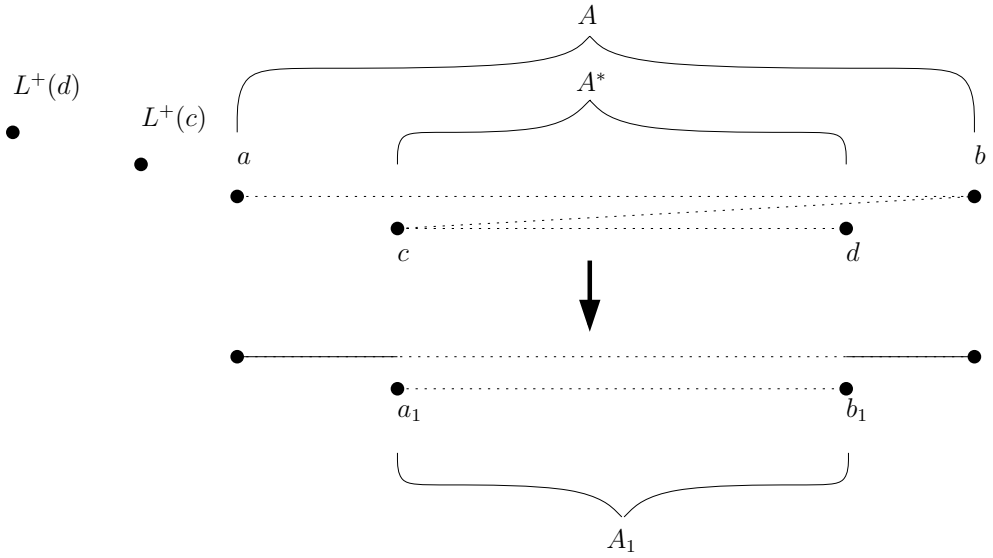

FIG. 5. *We can reduce the problem A to the Case* 1a *problem* $A_1 = [a_1, b_1] = [c, d]$, *since* $A' - A^* \subseteq V(A', L^+(d)) \cup V(A', d)$.

from at least one of the vertices of P.

LEMMA 4.8. *If* $V(A', L^+(d)) \cup V(A', d) \not\supseteq A' - A^*$, *then* (i) *one must place at least one guard outside of* A^* *in order to guard* $A' - A^*$, *and* (ii) *there exists a constant-size set of guards* U *that guards* $A' - A^*$, *and any other set of guards* U' *that guards* $A' - A^*$ *includes a guard* g' *such that* $V(A' \cap A^*, U) \supseteq V(A' \cap A^*, g')$.

Proof. To prove the first part, we observe that $L^+(d)$ dominates any vertex in A^* with respect to the subterrain to the right of d (applying Corollary 4.5), and d dominates any vertex in A^* with respect to the subterrain to the left of c (applying Claim 2.1 to d and c). Now let $v \in A' - A^*$ be a vertex that is not seen from $L^+(d)$ or from d (such a vertex exists by our assumption). Clearly any guard that sees v cannot lie in A^*.

To prove the second part, set $U = \{L^+(d), L^+(c), b\}$. We already know that U guards $A' - A^*$. We now show that if g' is a guard that sees v, then $V(A' \cap A^*, U) \supseteq V(A' \cap A^*, g')$. If v is to the right of A^*, then in order to guard v one must locate a guard g' either to the left of $L^+(d)$ or to the right of d. In both cases $V(A' \cap A^*, g') = \emptyset$. Otherwise, if v is to the left of A^*, then in order to guard v one must locate a guard g' either in $[L^+(c), c]$ or to the right of d. In the former case it is possible that g' sees into A^*, but it is dominated by $L^+(c)$. □

The lemma above implies that if $V(A', L^+(d)) \cup V(A', d) \not\supseteq A' - A^*$, then we may place three guards at $L^+(d)$, $L^+(c)$, and b and charge these guards to the guard g' (in the proof above).

We now consider the case in which $V(A', L^+(d)) \cup V(A', d) \supseteq A' - A^*$ (see Figure 5). In this case we say that A is *reducible*, and reduce $A_0 = A$ to the Case 1a problem $A_1 = [a_1, b_1] = [c, d]$. Now, if A_1 is also reducible, that is, if A_1 is a single-pocket case with pocket $A_1^* = (c_1, d_1)$, and $V(A', L^+(d_1)) \cup V(A', d_1) \supseteq A' - A_1^*$, where A' is the *original* A', then we reduce A_1 to the Case 1a problem $A_2 = [a_2, b_2] = [c_1, d_1]$. This process continues until we reach a problem $A_i = [a_i, b_i]$, $i > 0$, that is not reducible.

Notice that if we now place two guards at b_i and at $L^+(b_i)$, then all remaining unguarded vertices in A' will necessarily lie in the interior of A_i. This is because $b_i = d_{i-1}$ and A_{i-1} was reducible. Thus we place these two guards and proceed as follows, according to the state that we entered. There are three possible such states:

- A_i is not a single-pocket case; i.e., there is a vertex $q \in A_i$ that implies a nontrivial division.
- A_i is a single-pocket case, but $V(A', L^+(d_i)) \cup V(A', d_i) \not\supseteq A' - A_i^*$.
- A_i has a constant-size solution.

In the first state, we divide A_i into two guard-independent subterrains (see Claim 4.6) as follows. Let q_l be the leftmost vertex in A_i that is seen from b_i and implies a nontrivial division. Let a_i' be the rightmost vertex to the left of q_l that is seen by b_i. Notice that q_l and a_i' see each other, since b_i sees both of them and does not see any vertex between them. Also notice that b_i and $L^+(a_i')$ together cover the subterrain $[a_i, a_i']$, since a_i' implies a (left) trivial division. (Notice that it is impossible that a_i' implies a right trivial division, since, if it did, then so would q_l.)

Thus, in addition to the two guards that were already placed (i.e, at b_i and at $L^+(b_i)$), we also place guards at $L^+(q_l)$ and at $L^+(a_i')$. We now solve the two guard-independent subterrains $A_l = [a_i', q_l]$ and $A_r = (q_l, b_i]$ by applying to each of them the Case 1a algorithm. We charge the four guards that were placed to the increase by one of the lower bound due to the presence of a vertex that implies a nontrivial division.

In the second state we also place guards at $L^+(d_i)$ and $L^+(c_i)$ (in addition to the guards at b_i and $L^+(b_i)$) according to Lemma 4.8 above, and solve the subproblem $[c_i, d_i]$ by applying the Case 1a algorithm. We charge the four guards that were placed to the guard g' (see above). In the third state we simply solve the original problem with a constant number of guards.

All the above implies the following algorithm for Case 1a.

ALGORITHM 4.9. (Case 1a)

1. *If there exist two guards that together see all vertices in A'—done.*
2. *Let Q be the set of all vertices $q \in A$ that imply a nontrivial division.*
3. *If $Q \neq \emptyset$, let q_l be the leftmost vertex in Q. Locate three guards at b, $L^+(q_l)$, and $L^+(a')$, where a' is the rightmost vertex to the left of q_l that is visible from b. Solve each of the (guard-independent) subterrains $A_l = [a', q_l]$ and $A_r = (q_l, b]$ recursively using the Case* 1a *algorithm.*
4. *If $Q = \emptyset$ (the single-pocket case)*
   (a) *Compute the pocket $A^* = (c_0, d_0)$.*
   (b) *If $A = A_0$ is not reducible, place a guard at b. Otherwise, reduce until a subterrain $A_i = [a_i, b_i]$ that is not reducible is reached, and place guards at b_i and $L^+(b_i)$.*
   (c) *If A_i, $i \geq 0$, is a single-pocket case, then place guards at $L^+(c_i)$ and $L^+(d_i)$ and solve $[c_i, d_i]$ recursively using the Case* 1a *algorithm.*
   (d) *Else, solve A_i recursively using the Case* 1a *algorithm.*

The following lemma summarizes the result for Case 1a.

LEMMA 4.10. *Algorithm* 4.9 *computes a set of guards $\mathcal{V}(A')$ for A', whose size is bounded by some constant times the size of a minimum-cardinality such set of guards.*

We now turn to the general case, where A's endpoints do not see each other.

4.2.2. Case 1b: The endpoints of A do not see each other. We begin by computing the (upper) convex hull of A. Each of the edges of this convex hull corresponds to a subterrain whose endpoints see each other. Some of these subterrains

may already be fully guarded (by $\mathcal{G}$); we consider only those that are not yet fully guarded. Let $A_1 = [a, b]$ be the leftmost subterrain that is not yet fully guarded, let A_1' be the subset of vertices in A_1 that are not yet guarded, and let u be the leftmost vertex in A_1'. If there exists a single vertex to the left of A that sees all vertices in A_1', then $L(u)$ is necessarily such a vertex. (Note that $L(u)$ is necessarily to the left of A since $u \in A_1'$.) Moreover, in this case, any vertex g (either to the left of A or in A) that sees u is dominated by the pair of vertices $L(u)$ and $L(b)$. Thus, in this case we can place guards at $L(u)$ and at $L(b)$ and charge this to the guard of the optimal solution that sees u.

Assume now that A_1' cannot be fully guarded by a single vertex to the left of A. In this case, we place a guard at $L(b)$ and distinguish between two cases. If after placing a guard at $L(b)$ there is no vertex to the right of b that remains to be guarded, then apply Algorithm 4.9 to subterrain A_1 and charge the guard at $L(b)$ to the one-time event of leaving Case 1b. If, however, there still remains an unguarded vertex to the right of b, then the two subterrains A_1 and $A_2 = A - A_1$ are guard-independent. Indeed, any guard that can help guarding A_1' must lie in $(L(b), b]$, and any guard that can help guarding A_2' must lie either in A_2 or to the left of $L(b)$. Notice that b cannot help in guarding A_2', since $L(b)$ dominates b with respect to visibility to the right of b.

ALGORITHM 4.11. (Case 1b)

1. *If all of A is guarded—done.*
2. *Let $A_1 = [a, b]$ be the leftmost subterrain that is not yet fully guarded, let A_1' be the subset of remaining unguarded vertices in A_1, and let u be the leftmost vertex in A_1'.*
3. *If there exists a single vertex to the left of A_1 that sees all vertices in A_1', then locate guards at $L(u)$ and at $L(b)$, go to Step #1.*
4. *Else, locate a guard at $L(b)$ and solve the two guard-independent subproblems A_1, using the Case* 1a *algorithm, and $A - A_1$, using the Case* 1b *algorithm.*

The following lemma summarizes the result for Case 1b.

LEMMA 4.12. *Algorithm* 4.11 *computes a set of guards $\mathcal{V}(A')$ for A', whose size is bounded by some constant times the size of a minimum-cardinality such set of guards.*

4.3. Case 2. Given a terrain T, let $A = [a, b]$ be a subterrain that does not require a local guard, let A' be the subset of all vertices in A that are not yet guarded. In this case (Case 2), our goal is to compute a set of guards $\mathcal{V}(A')$ for A', where the guards in $\mathcal{V}(A')$ may be located anywhere in T. We present a constant-factor approximation algorithm for computing a minimum-cardinality such set of guards.

We may assume that the endpoints of A are in A', because otherwise we can simply replace A with the subterrain $[a', b']$, where a' (resp., b') is the leftmost (resp., rightmost) vertex in A', and any (Case 2) solution to A is also a (Case 2) solution to $[a', b']$ and vice versa. In particular, we may assume that a and b are not vertices of the convex hull of the initial terrain (since A is contained in a subterrain defined by two consecutive vertices v_1, v_2 of the convex hull of the initial terrain, and we already placed guards at these vertices).

We will need the following observation.

OBSERVATION 4.13. *For any vertex $v \in A$, the vertices $L(v)$ and $R(v)$ can see each other.*

(If there were a vertex v for which $L(v)$ and $R(v)$ could not see each other, then the upper angle formed by $L(v)$, v, and $R(v)$ would be greater than π, and v would be a vertex of the convex hull of the original terrain (in between v_1 and v_2), contradicting

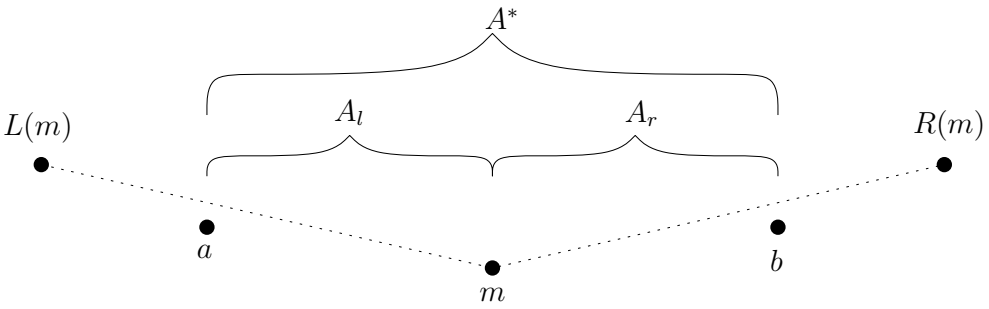

FIG. 6. *The two subterrains defined by a shared vertex that implies a nontrivial division are guard-independent.*

our assumptions above.)

A vertex $m \in A$ is called a *shared vertex* if m can be seen both from the left of A and from the right of A. For a shared vertex m, let $A'_l(m)$ (resp., $A'_r(m)$) denote the subset of vertices of A' that lie to the left (resp., to the right) of m and are not visible from $L(m)$, m, or $R(m)$. As in Case 1a, we say that m implies a *nontrivial division* if both $A'_l(m)$ and $A'_r(m)$ are not empty.

CLAIM 4.14. *Let m be a shared vertex that implies a nontrivial division. Then the two subterrains $A_l = [a, m)$ and $A_r = (m, b]$ are guard-independent.*

Proof. Any guard that can see a vertex in $A'_l(m)$ must lie either between $L(m)$ and m or to the right of $R(m)$, while any guard that can see a vertex in $A'_r(m)$ must lie either to the left of $L(m)$ or between m and $R(m)$. See Figure 6. ∎

CLAIM 4.15. *There is at least one shared vertex in $A = [a, b]$.*

Proof. a is surely seen from the left of A (e.g., by the vertex immediately to its left), and b is surely seen from the right of A. Let c be the rightmost vertex in A that is seen from the left of A. (If $c = b$, then let c be the previous vertex in A that is seen from the left of A.) Let d be the vertex immediately to the right of c. Then d is necessarily seen from the right of A. We observe that either $L(c)$ or $R(d)$ must lie above the line through c and d. (Otherwise, c and d are vertices of the convex hull of the original terrain—impossible; see assumptions and observation above.) Thus, either c or d is a shared vertex; e.g., if $L(c)$ lies above the line through c and d, it must also see d, so d is a shared vertex in this case. ∎

Let M be the set of all shared vertices in A. According to the claim above, $M \neq \emptyset$. We next show that any subterrain of A without shared vertices (i.e., vertices of M) can be nicely divided into two subterrains.

CLAIM 4.16. *Let $A^* = [l, r] \subset A$ be a subterrain such that $A^* \cap M = \emptyset$. Let u be a vertex in A^*. If u can be seen from the left of A, then any vertex in A^* to the right of u can also be seen from the left of A (and therefore cannot be seen from the right of A).*

Proof. Since A does not require a local guard, any vertex in A^* can be seen either from the left of A or from the right of A, but since $A^* \cap M = \emptyset$, it can be seen from only one of these sides. Assume that there is a vertex to the right of u that is seen from the right of A. Let v be the leftmost such vertex, and let u' be the vertex immediately to the left of v. Then u' (which is possibly u) is seen from the left of A. Observe that either $L(u')$ or $R(v)$ must lie above the line through u' and v (since otherwise u' and v would be vertices of the convex hull of the original terrain), and therefore at least one of the two vertices u', v is a shared vertex—contradicting our

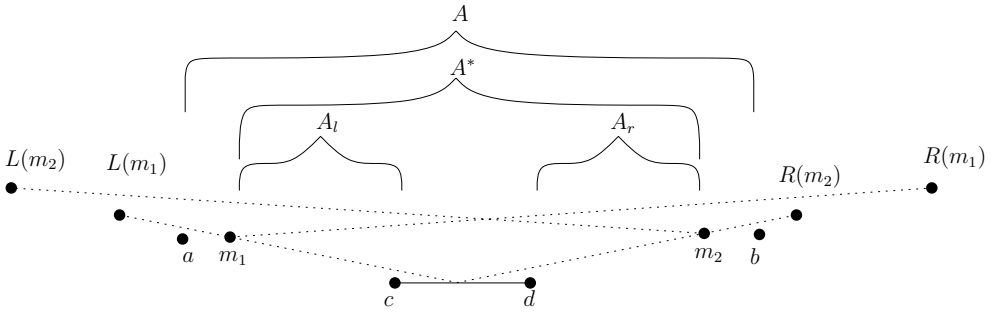

FIG. 7. *By locating guards at $L(m_1)$, m_1, m_2, and $R(m_2)$, we obtain two guard-independent subproblems, A_l and A_r, both of Case* 1.

assumption. We conclude that there is no vertex to the right of u that is seen from the right of A.

Now let d be the leftmost vertex in A^* that can be seen from the left of A. If there is no such d, then every vertex in A^* is seen from the right of A but not from the left of A, and if $d = l$, then any vertex in A^* is seen from the left of A but not from the right of A. Otherwise, let c be the vertex immediately to the left of d. Then every vertex in the subterrain $A_l = [l, c]$ is seen from the right of A but not from the left of A, and every vertex in the subterrain $A_r = [d, r]$ is seen from the left of A but not from the right of A. □

CLAIM 4.17. *Assume that for each $m \in M$, m implies a trivial division. Then, by placing a constant number of guards, one can reduce A either to a single instance of Case* 1*, or to two guard-independent instances of Case* 1*.*

Proof. Let $m \in M$ be a shared vertex (such a vertex exists as shown in Claim 4.15). We know that m implies a trivial division. Assume, e.g., that (after placing guards at $L(m)$, m, and $R(m)$) A_l is fully guarded but A_r is not. Let m_1 be the rightmost shared vertex for which A_l is fully guarded. We now distinguish between two possible situations: (i) there exists another shared vertex to the right of m_1, and (ii) m_1 is the rightmost shared vertex. In both cases the subterrain $[a, m_1]$ is fully guarded by $L(m_1)$, m_1, and $R(m_1)$. Consider the former more general situation. Let m_2 be the shared vertex immediately to the right of m_1. Now m_2 implies a trivial division such that A_r is fully guarded (after placing guards at $L(m_2)$, m_2, and $R(m_2)$). Set $A^* = (m_1, m_2)$. A^* does not have a shared vertex, and $[m_2, b]$ is fully guarded by $L(m_2)$, m_2, and $R(m_2)$. We now use Claim 4.16 to divide (m_1, m_2) into two subterrains $A_l = (m_1, c]$, $A_r = [d, m_2)$ (one of them might be empty) such that any vertex in A_l is seen from the right of A but not from the left of A, and any vertex in A_r is seen from the left of A but not from the right of A. Observe that $L(m_1)$ and m_1 dominate the visibility of any vertex in $[a, m_1)$ with respect to A_l, so none of the vertices to the left of A_l can help in guarding the remaining unguarded vertices in A_l. Similarly, $R(m_2)$ and m_2 dominate the visibility of any vertex in $(m_2, b]$ with respect to A_r. Also if we place guards at c and $R(c)$ and at d and $L(d)$, then the two subterrains A_l and A_r are guard-independent, and both can be treated as Case 1 problems (see Figure 7).

Consider the second situation (i.e., there is no shared vertex in $A_r = (m_1, b]$). We apply Claim 4.15 to observe that no vertex in A_r can be seen from left of A. (b can be seen from right of A, and therefore any vertex in A_r can be seen from the right of A, and if there were a vertex that could also be seen from the left of A, then we would

have a shared vertex.) Thus, locating guards at $L(m_1)$, m_1, and $R(m_1)$ guarantees that the only vertices that can help guarding A_r are within A_r or to the right of A_r, which is a Case 1 problem. (Once again none of the vertices in $[a, m_1)$ can help guard A_r, since $L(m_1)$ and m_1 dominate these vertices with respect to A_r.) ∎

ALGORITHM 4.18. (Case 2)

1. *If there exist two (or any constant number of) guards that together see all vertices in A'—done.*
2. *Compute the set M of all shared vertices.*
3. *If there exists $m \in M$ that implies a nontrivial division, then locate guards at $L(m)$, m, and $R(m)$ and solve (recursively) each of the two subproblems A_l and A_r.*
4. *Else, for each $m \in M$ one of the sides is fully guarded by $L(m)$, m, and $R(m)$, and the other is not. Use Claim* 4.17 *in order to reduce A (by placing a constant number of guards) either to a single instance of Case* 1 *or to two guard-independent instances of Case* 1*. (Notice that if A is reduced to a single instance of Case* 1*, we charge the guards that were placed in doing so to the one-time event of leaving Case* 2*.)*

The following lemma summarizes the result for Case 2.

LEMMA 4.19. *Algorithm* 4.18 *computes a set of guards $\mathcal{V}(A')$ for A', whose size is bounded by some constant times the size of a minimum-cardinality such set of guards.*

5. Algorithm analysis. Throughout our description of the approximation algorithm for the DSPT, whenever guards were placed we gave an appropriate charging argument to justify why we could afford to place them. Consequently, we have shown that the size of the guarding set that is computed by the algorithm is bounded by a constant times the size of a minimum-size such set: We have obtained an $O(1)$-approximation, as desired. We have not attempted to minimize the constant factor; we leave this task to future work.

Concerning the running time of the algorithm, it is clear that it is polynomial. The following lemma shows that the running time is $O(n^2)$.

LEMMA 5.1. *The running time of the constant-factor approximation algorithm for the DSPT is $O(n^2)$.*

Proof. As a preliminary stage, we compute the *visibility graph*, $\mathrm{V}G_T(V)$, of the terrain vertices. This can be done easily in $O(n^2)$ time (or in output-sensitive time, but this does not yield an improved overall time bound for our algorithm). For each vertex $v \in V$, we compute in linear time the subset of vertices in V that lie to the left (alternatively, to the right) of v and are visible from v; the vertices in these subsets are found one-by-one in decreasing (alternatively, increasing) x-order. In particular the vertices $L(v)$ and $R(v)$ are the leftmost in the left list and rightmost in the right list, respectively. It remains to show that the subsequent stages of the algorithm can be carried out within the quadratic time bound.

In the first stage, we simply compute the (upper) convex hull of T in $O(n)$ time. In the second stage, we partition each "concave" subterrain (corresponding to an edge of the convex hull) into subterrains that do not require a *local guard* (see section 3). This can be done in $O(m \log m)$ time per "concave" subterrain of m vertices, and therefore in overall $O(n \log n)$ time.

In the final stage, each of the subterrains obtained in the second stage is solved separately, using the base-case algorithms, in $O(m^2)$ time, where m is the size of the subterrain (see Lemma 5.2 below). Since the subterrains are disjoint, the overall running time of this stage is $O(n^2)$. ∎

LEMMA 5.2. *Let A, $A \subset T$, be a subterrain that does not require a* local guard. *Then A can be solved using the base-case algorithms (with minor modifications) in $O(m^2)$ time, where m is the size of A.*

Proof. For the lemma to be true, we need to modify the first step in each of the base-case algorithms, so that, unless all vertices in A' are already guarded, one must continue by recursive calls. This change increases the depth of the recursion by only a constant number of levels.

Case 2. The condition in the modified step 1 can be checked in constant time. In step 2 all *shared vertices* can be computed in linear time, since one needs to consider only the *ranges* of the vertices in A (which were computed in the preliminary stage of the main algorithm). Checking in step 3 whether a *nontrivial division* is possible is also done in linear time, since for each shared vertex one needs to consider only a constant number of vertices. Moreover, the number of such divisions is clearly $O(m)$. In step 4 we reduce the problem to two guard-independent instances of Case 1; the reduction is done in constant time.

Case 1b. Step 2 is clearly linear in m. In steps 3 and 4 we reduce the problem to a smaller one; therefore the number of these reductions is $O(m)$.

Case 1a. Computing all vertices that imply a nontrivial division (in step 2) is done in linear time (since, for each vertex $q \in A$, one needs to consider only a constant number of vertices). In step 3 we reduce the problem to two guard-independent and disjoint problems, so the number of these reductions is $O(m)$; the reduction itself takes only constant time. In step 4 we reduce the problem to a smaller one. Again, the number of these reductions is clearly $O(m)$, and the reduction itself takes only constant time. ∎

The following theorem summarizes this section.

THEOREM 5.3. *The algorithm of sections* 3 *and* 4 *computes a constant-factor approximation for the DSPT in $O(n^2)$ time.*

6. The terrain guarding algorithm. In this section we generalize the constant-factor approximation algorithm for the DSPT to the general 1.5D terrain guarding problem, where guards can be placed anywhere on the terrain, and all points of the terrain (not only its vertices) must be guarded. For this we present a reduction from the general 1.5D terrain guarding problem to the DSPT. Figure 8 (right) shows that a solution to the DSPT is not necessarily a solution to the general 1.5D terrain guarding problem.

Let V be the set of vertices of T, and set $n = |V|$.

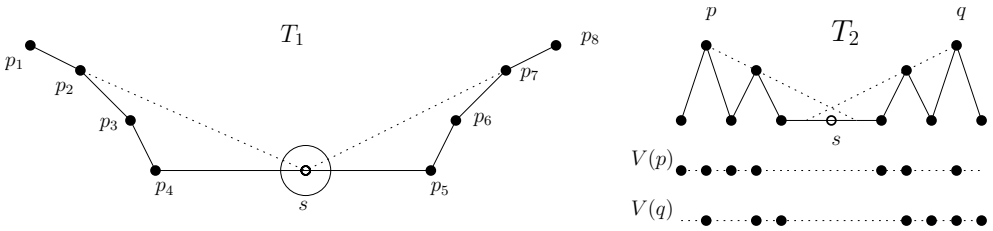

FIG. 8. *Left: A single guard at s sees all points of the terrain T_1, but if one may locate guards only at vertices, then two guards are needed. Right: All vertices of the terrain T_2 can be guarded with two guards (at p and at q), but in order to guard all points of T_2 three guards are needed.*

OBSERVATION 6.1. *Any solution to the general* 1.5*D terrain guarding problem can be transformed into another solution whose size is at most twice the size of the original solution, such that all guards in the new solution are vertex guards, i.e., located at vertices of the terrain.*

Proof. Replace each guard g in the original solution that is not a vertex of the terrain with the two endpoints v_i, v_{i+1} of the edge T on which g lies. Clearly, any point of T that is seen by g is also seen by at least one of these two vertices. □

LEMMA 6.2. *There exists a set U of points on T such that every subset of vertices $V' \subseteq V$ that guards U also guards T. Moreover, $|U| = O(n^2)$ and U can be computed in $O(n^2)$ time.*

Proof. Let p be a point on T, and let $\mathrm{vis}(p)$ denote the set of all points on T that are visible from p. $\mathrm{vis}(p)$ is the union of a linear number of maximal subterrains. For such a subterrain A, it is easy to see that if $p \in A$, then both endpoints of A must be vertices of T, and if $p \notin A$, then the farther of the two endpoints of A must be a vertex of T. We refer to the endpoints of the maximal subterrains in $\mathrm{vis}(p)$ as the *visibility events* induced by p.

Let U' be the set of visibility events induced by the vertices in V. Let U'' be the set that is obtained by picking an arbitrary point of T between each pair of consecutive points in U'. Set $U = V \cup U' \cup U''$. It is clear that $|U| = O(n^2)$ and that U can be computed in $O(n^2)$ time.

The set U' induces a partition of T into $O(n^2)$ intervals. Observe that if p is a point in the interior of an interval s of this partition and p' is the point of U'' that lies in the interior of s, then $\mathrm{vis}(p) \cap V = \mathrm{vis}(p') \cap V$. This follows immediately from the definition of U', since if there were a vertex $v \in V$ such that p saw v and p' did not see v (or vice versa), then there would be a visibility event somewhere in the interior of s.

Now let V' be a subset of V that guards U, and let p be any point on T, $p \notin U$. We need to show that p is guarded by V'. Let s be the interval of the partition of T induced by U' such that p lies in its interior, and let p' be the point of U'' that lies in the interior of s. Then by our assumption p' is guarded by V', and, therefore, by the observation above, so is p. □

We are now ready to present the algorithm for the general 1.5D terrain guarding problem.

ALGORITHM 6.3. General 1.5D terrain guarding.

1. *Given a terrain T with vertex set V, compute the set U.*
2. *Solve the DSPT with U as the vertex set (using the DSPT algorithm as a "black box"). Let $\mathcal{G}'$, $\mathcal{G}' \subseteq U$, denote the solution obtained.*
3. *Replace each point $g \in \mathcal{G}' - V$ with the two vertices of V adjacent to it. Let $\mathcal{G}$ be the resulting set.*
4. *Return $\mathcal{G}$.*

From Observation 6.1 and Lemma 6.2 it is clear that $\mathcal{G}$ is indeed a solution to the general 1.5D terrain guarding problem. Moreover, $\mathcal{G}$ can be computed in $O(n^4)$ time (since $|U| = O(n^2)$ and the running time of the DSPT algorithm is $O(|U|^2)$). It remains to prove that the size of $\mathcal{G}$ is bounded by some constant times the size of an optimal solution.

Let $opt(A, B)$ be an optimal solution to the problem of guarding A by placing guards at points of B, where A (alternatively, B) is either a subterrain of T or a discrete set of points of T. In particular, $opt(T, T)$ is an optimal solution to the general 1.5D terrain guarding problem. Notice that if $A' \subseteq A$ and $B' \subseteq B$, then

$|opt(A,B)| \geq |opt(A',B)|$ and $|opt(A,B')| \geq |opt(A,B)|$.

LEMMA 6.4. *Let c' be the (constant) approximation factor of the DSPT algorithm. Then $|\mathcal{G}| \leq 4c'|opt(T,T)|$.*

Proof. Using the observation above and Observation 6.1, $|opt(T,T)| \geq |opt(U,T)| \geq |opt(U,V)|/2 \geq |opt(U,U)|/2 \geq \mathcal{G}'/(2c') \geq \mathcal{G}/(4c')$. □

The following theorem summarizes the main result of this section.

THEOREM 6.5. *Algorithm* 6.3 *computes a constant-factor approximation for the general* 1.5*D terrain guarding problem in $O(n^4)$ time.*

7. Conclusion. There are two notable open problems: (1) Are the DSPT and 1.5D terrain guarding problems NP-hard? (the hardness claim in [4] has gaps in the proof); and (2) is there an approximation algorithm for guarding a simple polygon? So far, our attempts to generalize our methods to simple polygons have failed; our method strongly exploits the special structure of 1.5D terrains.

FINDING PATHS AND CYCLES OF SUPERPOLYLOGARITHMIC LENGTH*

HAROLD N. GABOW†

Abstract. Let ℓ be the number of edges in a longest cycle containing a given vertex v in an undirected graph. We show how to find a cycle through v of length $\exp(\Omega(\sqrt{\log \ell / \log\log \ell}))$ in polynomial time. This implies the same bound for the longest cycle, longest vw-path, and longest path. The previous best bound for longest path is length $\Omega((\log \ell)^2/\log\log \ell)$ due to Björklund and Husfeldt. Our approach, which builds on Björklund and Husfeldt's, uses cycles to enlarge cycles. This self-reducibility allows the approximation method to be iterated.

Key words. approximation algorithms, graph algorithms, long paths, long cycles

DOI. 10.1137/S0097539704445366

1. Introduction.

Interest in approximating the longest path of a graph was rekindled by Karger, Motwani, and Ramkumar [13], who were motivated by the large gap between known performance guarantees and known hardness results. We make some progress in reducing the gap by presenting the best known polynomial time approximation algorithm. In particular we show how to find paths of greater than polylogarithmic length in polynomial time.

Previous work. Monien [15] investigated fixed parameter algorithms for long paths and cycles. In particular he showed how to find a vw-path of length (exactly) k for all pairs of vertices v, w for which such a path exists, in time $O(k!nm)$. (Throughout this paper, n and m denote the number of vertices and edges, respectively, of the given graph.) Monien also proved a fact about undirected cycle length that is useful in finding cycles of length $\geq k$; a variant of this fact is stated below.

In other early work, Fellows and Langston showed how to find undirected cycles of length $\geq k$ using Robertson–Seymour theory [9]. Bodlaender [2] used dynamic programming to find long undirected paths and cycles, improving Monien's bounds.

Alon, Yuster, and Zwick [1] introduced the technique of color coding to find paths, cycles, and other subgraphs of guaranteed size. For example, in a directed or undirected graph, color coding finds a path whose length is either the greatest possible or $\geq \log n$ in polynomial time. The same holds for vw-paths. For cycles, for any $k \leq \log n$, color coding finds a cycle of length exactly k in polynomial time if one exists.

Björklund and Husfeldt [3] find an undirected path of length $\Omega((\log \ell/\log\log \ell)^2)$ in polynomial time, for ℓ the longest path length. Gabow and Nie [11] observe that the length guarantee is actually $\Omega(\log^2 \ell/\log\log \ell)$. This is the best known bound to date for undirected paths.

Better results are known for undirected graphs of low degree. Feder, Motwani, and Subi [8] find a cycle of length $\geq \ell^{\log_9 2} > \ell^{0.315}$ in graphs of maximum degree

three; here ℓ is the longest cycle length, and the algorithm runs in polynomial time. A similar result holds for longest path. The length guarantee improves on 3-connected cubic graphs.

Gabow and Nie [11] investigate long directed cycles. They also prove a variant of Monien's undirected cycle structure theorem: If a connected undirected graph has a cycle of $\geq k$ edges, either every depth-first search spanning tree has a fundamental cycle of $\geq k$ edges or some cycle has between k and $2k$ edges. This result, or Monien's, allows color coding to be applied to the problem of finding a cycle of $\geq k$ edges. (For example, it allows color coding to find a cycle of length $\geq \log n$ in polynomial time, if one exists.)

The best known hardness results are due to Karger, Motwani, and Ramkumar [13]. They showed that getting a constant factor approximation to the longest undirected path is NP-hard. Furthermore for any $\epsilon > 0$, approximating to within a factor $2^{O(\log^{1-\epsilon} n)}$ is quasi-NP-hard. Stronger hardness results for directed graphs are given in [4].

Our work also draws on previous work on a different problem on cycles: finding a cycle through three given vertices. Robertson and Seymour showed that more generally the fixed vertex subgraph homeomorphism problem can be solved in polynomial time [16]. However, huge constants are involved in this approach. Instead we use the algorithm of LaPaugh and Rivest [14], which finds a cycle through three given vertices in linear time with no large hidden constants. (See also [18].)

Our contribution. A *v-cycle* is a cycle containing the vertex v. We take the basic problem to be approximating the longest v-cycle, where v is a given vertex of degree two. The problems of approximating a longest cycle, a longest vw-path, and a longest path are all easily reduced to our problem in polynomial time.

Let ℓ be the length of a longest v-cycle in an undirected graph. We show that a v-cycle of length $\exp(\Omega(\sqrt{\log \ell / \log\log \ell}))$ can be found in polynomial time. This implies the same bound for the longest cycle, longest vw-path, and longest path. This improves the previous best bound of Björklund and Husfeldt for longest path given above. It also improves the previous best bound for longest vw-paths and cycles, which was only $\log n$ using color coding.

We note that our results give further evidence of the difference in complexity between the directed and undirected versions of the long path and cycle problems. The best known length guarantees for long directed paths and cycles are only logarithmic: a directed path (cycle) of length $\log n$ ($\log n / \log\log n$) remains the best that can be found in polynomial time even when a Hamiltonian path (Hamiltonian cycle) exists [1, 11]. Further, [4] provides hardness results that support the relative difficulty of the directed problem.

Our approach builds on Björklund and Husfeldt's idea of using cycles to enlarge paths. We use cycles to enlarge cycles, giving a self-reducibility property that allows the construction to be iterated. We note that the hardness results of Karger, Motwani, and Ramkumar [13] are based on a self-improvability property of the longest path problem involving graph products; it is unclear whether this has any relation to our self-reducibility property.

Our results hinge on properties of biconnected components, cutpoints, and separating pairs. The self-reducibility gives rise to a family of recursive algorithms. We can recur only a limited number of times because of the need to keep the graphs large.

The paper is organized as follows. Section 2 presents the facts on cutpoints and separation pairs that underlie our algorithm. Section 3 presents the algorithm. The

next two sections give the analysis: section 4 proves the length guarantee, and section 5 provides details of the implementation and uses them to prove the polynomial time bound. Section 6 gives some concluding remarks. We close this section with our terminology.

Terminology. A fraction a/bc is always an abbreviation of $a/(bc)$, e.g., $a/2k$. All logarithms are base two unless noted otherwise. When used as a number, e is the base of natural logarithms. $\exp(x)$ denotes e^x.

Our graph terminology is consistent with [19] whenever possible. All graphs in this paper are undirected and simple. $G[X]$ denotes the subgraph induced by vertex set X. For X and Y disjoint vertex sets, $E[X,Y]$ consists of all edges joining X and Y. Furthermore, by convention, writing $xy \in E[X,Y]$ means $x \in X$ and $y \in Y$.

All paths and cycles in this paper are simple. In contrast a walk can have repeated vertices. (So a path is a simple walk.) Let x and y be vertices. An *xy-path* is a path from x to y. For $x \neq y$, $d(x,y)$ denotes the length of a shortest xy-path. If the graph of interest is unclear in some notation, we include it as a subscript, e.g., $d_G(x,y)$.

We represent a path as a list of vertices, e.g., x, y, z. We also allow paths in the list; e.g., if xy is an edge and Z is a path starting at y, then x, Z denotes a path that is one edge longer than Z. Sometimes we write x, y, Z for the same path to remind the reader of the first edge xy. This will not cause any confusion.

If P is a path containing x and y with x preceding y, then $P[x,y]$ denotes the subpath of P from x to y. We occasionally write $P[y,x]$ to refer to the subpath from y to x in the reverse path of P; however, to prevent confusion we always indicate when this extended notation is being used. If C is a cycle containing x, y, and v, then $C_v[x,y]$ ($C_{\overline{v}}[x,y]$) denotes the subpath of C from x to y that contains (avoids) v, respectively. We extend the subpath notation to allow open-sided intervals; e.g., $P(v,w]$ is the path $P[v,w] - v$.

If P is a path, we use P to denote a set of vertices or edges, as is convenient; if the exact meaning is not clear from context, we state it explicitly. $|P|$ always denotes the number of edges in P.

2. Approach. Throughout this paper G is a given connected undirected graph. Our main algorithm finds a long v-cycle, where v is a given vertex of degree two. This algorithm can be used to find a long xy-path, by adding a new vertex v with edges vx, vy. Letting x and y vary, we can approximate the longest path in the graph. Similarly we can approximate the longest cycle.

Extending v-cycles. The overall approach is due to Björklund and Husfeldt [3]. They use a cycle to find a long path. Since our algorithm seeks a long cycle rather than a long path, the approach must be modified. This section presents the combinatoric ideas on which our algorithm is based.

The setting for our algorithm is illustrated in Figure 1: C is a v-cycle. X is a connected component of $G - V(C)$. We sometimes write $G[X]$ to emphasize that we are dealing with the graph induced by vertices X. P is an a_0a_1-path through X, more precisely for distinct vertices $a_0, a_1 \in C$, $P = a_0, P[x_0,x_1], a_1$ with $P[x_0,x_1] \subseteq X$.

Here is how the figure relates to the algorithm of the next section. Let C^* be a longest v-cycle. C will be a v-cycle already found by the algorithm. The algorithm is attempting to enlarge C to a longer v-cycle. P will be either a path that our algorithm has found recursively (in Lemma 2.1(i) below) or a subpath of C^* (in Lemma 2.1(ii)).

We use two main techniques to enlarge C. The first is similar to Björklund and Husfeldt's idea to use cycles to extend paths.

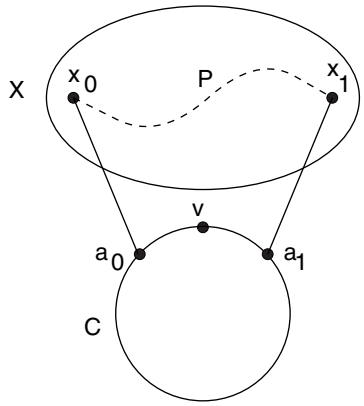

FIG. 1. *A v-cycle C and an a_0a_1-path P passing through a connected component X of $G - V(C)$.*

LEMMA 2.1. *Consider a v-cycle C and a connected component X of $G - V(C)$. Let P be an a_0a_1-path with $P(a_0, a_1) \subseteq X$.*

(i) *$P, C_v[a_1, a_0]$ is a v-cycle of length $> |P| + d_C(a_0, v)$.*

(ii) *For any vertex $c \in C$ adjacent to X, there is a path $Q \subseteq X$ and a vertex $c' \in C - c$ such that c, Q, c' is a cc'-path of length $\geq |P|/2 + 1$.*

Proof. (i) Note $|C_v[a_1, a_0]| > d_C(a_0, v)$ since a_1 is distinct from the degree two vertex v.

(ii) Let P start with the edge a_0x_0 and end with edge x_1a_1. So $P(a_0, a_1) = P[x_0, x_1] \subseteq X$. Choose $x \in X$ a neighbor of c as follows. If $c = a_i$ for $i \in \{0, 1\}$, then $x = x_i$. Otherwise x is arbitrary.

Take any minimal path R from x to P in X. Let R end at vertex $r \in P$. Choose index $j \in \{0, 1\}$ so that $|P[r, x_j]| \geq |P[r, x_{1-j}]|$. (One of these two subpaths of P actually involves the reverse of P.) The desired path c, Q, c' is $c, R, P[r, x_j], a_j$. This walk is simple since the choice of x guarantees $c \neq a_j$. The path's length is $\geq 1 + (|P| - 2)/2 + 1 = |P|/2 + 1$. □

When at least one distance $d_C(a_i, v)$ is large, part (i) allows us to make good progress in enlarging C. When both distances $d_C(a_i, v)$ are small another method is needed. The idea, illustrated in Figure 2, is to take two recursively found paths P (e.g., the two paths P in Figure 2) and find a v-cycle that contains both paths. We use the following strategy to guarantee that the desired v-cycle exists: for two components X of $G - V(C)$ we find a separation pair r_0, r_1 of G (e.g., the two separation pairs r_0, r_1 in Figure 2) with both vertices r_0, r_1 contained in C^*. Each path P will be a (recursively found) r_0r_1-path in X. No matter what r_0r_1-paths P the algorithm chooses, they will be contained in a v-cycle (since portions of C^* provide such a v-cycle). Of course the algorithm does not know C^*, so some guessing will be involved in finding the right separation pairs. Furthermore the separation pairs need not even exist. But once some other cases have been treated the existence of the separators will be guaranteed.

The next several lemmas give tools that allow us either to enlarge C or to find these separation pairs r_0, r_1. Our discussion uses connected components, biconnected components, and a form of triconnected components. For clarity we use terminology that explicitly differentiates all these types of components.

Bicomponents. A *bicomponent* is the set of edges of a biconnected component. The following characterization is often used as the definition of a biconnected component (see e.g., [17]).

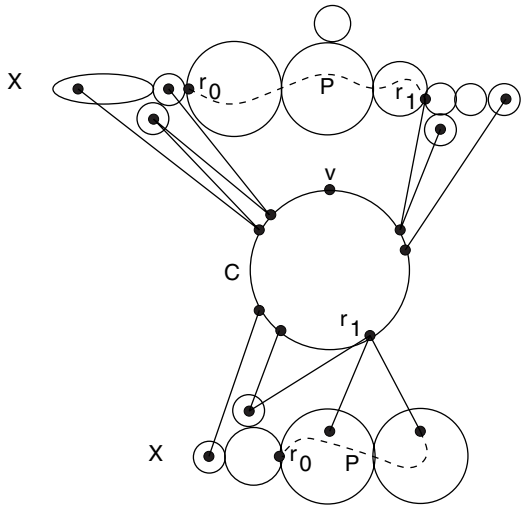

FIG. 2. *A v-cycle C with two connected components X of $G - V(C)$. Each component X has a separation pair r_0, r_1 and a corresponding r_0r_1-path P.*

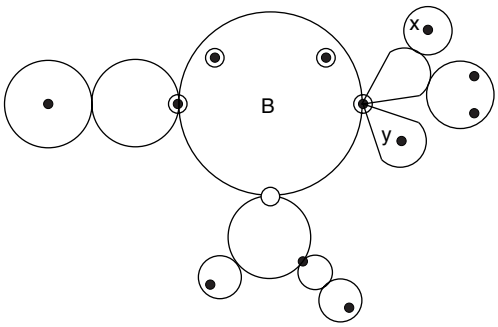

FIG. 3. *A bicomponent B and twelve vertices (drawn solid) that determine five distinct projections $\pi_B(v)$ (circled or drawn hollow).*

FACT 1. *Two edges belong to the same bicomponent if and only if some cycle contains both of them.*

We are interested in when a bicomponent B separates two vertices. By definition, the edge set B separates vertices x and y if every xy-path includes an edge of B. Note that it is possible for two vertices to be separated by a vertex of $V(B)$ but not separated by B, e.g., x and y in Figure 3.

The following notation, illustrated in Figure 3, elucidates the concept. Let B be the union of one or more bicomponents forming a connected subgraph. (In most of our applications B will be a single bicomponent, as in Figure 3.) For any vertex v, the *projection of v onto B*, denoted $\pi_B(v)$, is the vertex of $V(B)$ that is the end of every minimal path from v to $V(B)$ ("minimal" means that no vertex but the last one belongs to $V(B)$). For example, a vertex $v \in V(B)$ has $\pi_B(v) = v$.

Assuming the graph is connected, any projection $\pi_B(v)$ is unique. In proof, suppose not. So there are two minimal paths from v to $V(B)$, say P_1 and P_2, with P_i ending in vertex $b_i \in V(B)$ and $b_1 \neq b_2$. Let Q be a b_1b_2-path in B. $P_1 \cup Q \cup P_2$

contains a cycle C that includes edges belonging to B as well as edges not belonging to B. So the same holds for some bicomponent B_0 contained in B, i.e., C includes edges belonging to B_0 as well as edges not belonging to B_0. But this contradicts Fact 1.

Projection gives this alternate characterization of separation: v and w are separated by B if and only if their projections are distinct, $\pi_B(v) \neq \pi_B(w)$. We use the characterization only when B is a bicomponent, but the following proof of the characterization holds for B a connected union of bicomponents too: If $\pi_B(v) = \pi_B(w)$, then by definition there is a vw-path avoiding B; i.e., B does not separate v and w. To prove the opposite direction a vw-path avoiding B gives a $\pi_B(v)\pi_B(w)$-walk avoiding B. In general any xy-walk avoiding B and having $x, y \in V(B)$ has $x = y$ (by Fact 1). So $\pi_B(v) = \pi_B(w)$.

We now give some basic properties of separation by a bicomponent. Say that vertex s *weakly separates* sets $A, B \subseteq V$ if every path from A to B contains s. It is possible that s belongs to A or B.

LEMMA 2.2. *Let G be connected, and let B be a bicomponent.*

(i) *Any two distinct vertices in $V(B)$ are separated by B.*

(ii) *Any two distinct vertices x, y are separated by B if and only if every xy-path contains an edge of B if and only if some xy-path contains an edge of B.*

(iii) *For any set of vertices W, either B separates some two vertices of W, or some vertex of $V(B)$ weakly separates W and $V(B)$.*

Proof. (i) and (ii) follow easily from the characterization of separation in terms of projections. For (iii) note that if B does not separate any two vertices of W, then every $w \in W$ has the same projection $\pi_B(w)$ (by (ii)). By definition, this vertex $\pi_B(w)$ weakly separates W and $V(B)$. □

For any real value $b > 2$, a bicomponent is *b-round* if it contains a cycle of $\geq b$ edges. $D(x, y)$ denotes the length of a longest xy-path.

LEMMA 2.3. *Consider a connected graph and two distinct vertices x, y.*

(i) *If x and y are separated by a b-round bicomponent, then $D(x, y) \geq b/2$.*

(ii) *If $b = D(x, y)/d(x, y) > 2$, then x and y are separated by a b-round bicomponent.*

Remark. (ii) is consistent with x and y being vertices of the same biconnected component.

Proof. (i) Let B be a bicomponent containing a cycle A of length $\geq b$. First suppose that x and y are distinct vertices of $V(B)$. Biconnectedness implies there are distinct vertices $r, s \in A$ with an xr-path and a ys-path that are disjoint and also both disjoint from A until their last vertex. (This fact is well known [19, Exercise 4.2.9]. It is also easy to see by adding edge xy to the graph if it is not already present and applying Fact 1 to xy and an edge of A.) Piece these paths together to form an xy-path of length $\geq b/2$. (Specifically, follow the xr-path, then a path $A[r, s]$ of length $\geq b/2$, and then the ys-path reversed.)

Now suppose that x and y are arbitrary vertices separated by B. Take an xy-path. It contains an $x\pi_B(x)$-subpath and a $y\pi_B(y)$-subpath. We have $\pi_B(x) \neq \pi_B(y)$, so the subpaths are disjoint. Form the desired xy-path from the two subpaths plus the $\pi_B(x)\pi_B(y)$-path of length $\geq b/2$ constructed above (this path is contained in B, so our overall path is simple).

(ii) We'll prove a slightly more general statement: $D(x, y) > d(x, y)$ implies that x and y are separated by a $(D(x, y)/d(x, y) + 1)$-round bicomponent.

Let L (S) be a longest (shortest) xy-path. Let the vertices of $L \cap S$ be $x = s_0, s_1, \ldots, s_r = y$, ordered as they occur in S. (This need not be their order in L.) For each consecutive pair s_i, s_{i+1}, paths $L[s_i, s_{i+1}]$ and $S[s_i, s_{i+1}]$ are internally

vertex-disjoint. ($L[s_i, s_{i+1}]$ may actually be a subpath of the reverse of L.) The various paths $L[s_i, s_{i+1}]$ can share vertices and edges, but certainly some $L[s_j, s_{j+1}]$ has length $\geq |L|/r \geq |L|/|S|$. Thus $L[s_j, s_{j+1}], S[s_{j+1}, s_j]$ is a cycle A. (A is simple, and its length is $\geq 1 + \lceil |L|/|S| \rceil \geq 3$.) A is contained in some bicomponent B. A makes B $(|L|/|S| + 1)$-round. Since S contains an edge of B, B separates x and y. □

Finding separation pairs. Recall that two edges are *independent* if all four endpoints are distinct. A set of edges forms a *star* if some vertex (its *center*) is incident to each of the edges. For a star that is a single edge we choose the center as follows: the stars in this paper are always subsets of edge sets $E[X, Y]$, where X and Y partition the vertex set; we always choose the center to be in the set named X. For an edge $e \in E[X, Y]$, let $X(e)$ denote the endpoint of e in X. For $F \subseteq E[X, Y]$, $X(F)$ denotes $\{X(e) : e \in F\}$.

LEMMA 2.4. *Let the vertex set of graph G be partitioned into sets X and Y, with $G[X]$ connected. Let B be a bicomponent of $G[X]$, and let $F = E[X, Y]$ with F nonempty.*

Suppose that no two independent edges $e_1, e_2 \in F$ have their ends $X(e_1), X(e_2)$ separated by B, in graph $G[X]$. Then either F is a star or no two vertices of $X(F)$ are separated by B.

Proof. Suppose that F is not a star. Our goal is to prove that every vertex $x \in X(F)$ has the same projection $\pi_B(x)$. (All projections in this argument are calculated in graph $G[X]$.)

The supposition on F implies that there are independent edges $xy, x'y' \in E[X, Y]$. (A quick way to see this is by König's theorem: in a bipartite graph a maximum matching and a minimum vertex cover have the same size.) The lemma's hypothesis implies $\pi_B(x) = \pi_B(x')$. Consider any edge $zw \in E[X, Y]$ with $z \neq x, x'$. This edge is independent with either xy or $x'y'$ (or both). Hence the lemma's hypothesis implies $\pi_B(z) = \pi_B(x')$. □

The next two lemmas are used by the algorithm to find the separation pairs r_0, r_1 described earlier (recall Figure 2). Each vertex r_i is found separately. The first of the lemmas shows how to find one vertex r_i. The construction is based on a function $\Pi(F, x)$ that we now define.

We start by extending the projection operation, as follows. Consider a connected graph G and a set S of at least two vertices. Let B denote the union of all bicomponents that separate some two vertices of S. We'll use this alternate characterization of B: let T be a minimal tree of G that spans S. Minimality means that every leaf belongs to S. Then B is the union of all bicomponents that contain an edge of T. This characterization of B follows from Lemma 2.2(ii).

For any vertex v define the projection $\pi_S(v)$ to be $\pi_B(v)$, i.e., the vertex of $V(B)$ that is the end of every minimal path from v to $V(B)$. The construction gives these two properties:

(a) For any vertex v, $\pi_S(v)$ weakly separates S from v.

(b) For any vertices $v \in V$ and $s \in S$, the bicomponents that separate two vertices of S collectively contain an $s\pi_S(v)$-path.

Now consider a graph G whose vertices are partitioned into sets X and Y, with $G[X]$ connected. For any nonempty set of edges $F \subseteq E[X, Y]$ and any vertex $x \in X$, define the *near separator* $\Pi(F, x)$ as follows:

(i) if F is a star, then $\Pi(F, x)$ is its center;

(ii) if F is not a star, then $\Pi(F, x) = \pi_{X(F)}(x)$ (where the latter is calculated in $G[X]$).

In (i) if F is just a single edge, then recall that our convention chooses $\Pi(F,x)$ to be the vertex $X(F)$. In (ii) note that $|X(F)| \geq 2$. Hence $\pi_{X(F)}(x)$ is defined.

Continuing with this G, X, and Y, for any real value $b > 2$ call a set of edges $F \subseteq E[X,Y]$ *b-close* if no two independent edges $e_1, e_2 \in F$ have their ends $X(e_1), X(e_2)$ separated by a b-round bicomponent in $G[X]$. Observe that if F is b-close and B is a b-round bicomponent of $G[X]$, then Lemma 2.4 applies. It shows that either F is a star or no two vertices of $X(F)$ are separated by B.

LEMMA 2.5. *Let the vertex set of graph G be partitioned into sets X and Y, with $G[X]$ connected. Let $F = E[X,Y]$ be b-close for some $b > 2$.*

Let P be an x_0x_1-path in $G[X]$, with $x_0 \in X(F)$. Suppose $|P| \geq d_X(x_0,x_1)b > 0$.

Then either F is a star or the near separator $r = \Pi(F,x_1)$ has these properties: $r \in P$, r weakly separates $X(F)$ from $V(P(r,x_1])$ in graph $G[X]$, and $|P[x_0,r]| < d_X(x_0,x_1)b$.

Remark. The lemma is illustrated four times in Figure 2. First discard all edges incident to C except the four in the upper left. These four edges constitute set F. Extend P of the figure to the left so it begins at one of the three vertices of $X(F)$. Now r_0 is vertex r of the lemma. Similarly for r_0 in the lower left. In the upper right, r_1 is r of the lemma, this time a weak separator. The lower right illustrates the case of F a star.

Proof. Suppose that F is not a star. Property (a) above shows that r weakly separates $X(F)$ from x_1. Hence $r \in P$. Furthermore (a) shows that r weakly separates $X(F)$ from $V(P(r,x_1])$.

It remains only to deduce the inequality of the lemma. Clearly it suffices to show these two inequalities:

$$|P[x_0,r]| < d_X(x_0,r)b, \qquad d_X(x_0,r) \leq d_X(x_0,x_1).$$

The second inequality is true because r weakly separates x_0 and x_1. For the first inequality, property (b) above shows there is an x_0r-path within the bicomponents that separate two vertices of $X(F)$. None of these bicomponents is b-round. (As mentioned in the definition of b-closeness, this follows from Lemma 2.4.) So no b-round bicomponent separates x_0 and r. Now Lemma 2.3(ii) implies $|P[x_0,r]| < d_X(x_0,r)b$. □

Recall that two vertices a, b in a biconnected graph G form a *separation pair* if $G - \{a,b\}$ is disconnected. In that case an *a,b-tricomponent* T is a maximal set of edges, any two of which are joined by a path that does not contain a or b internally [12]. Alternatively, T is a connected component of $G - \{a,b\}$ plus the edges from the component to a or b. (Note that T needn't be 3-connected.) The next lemma shows how we combine two near separators r_0, r_1 of the previous lemma into a separation pair.

LEMMA 2.6. *Let G be a biconnected graph whose vertex set is partitioned into sets X and Y, with $G[X]$ connected. Let $E[X,Y] = F_0 \cup F_1$ with $Y(E[X,Y]) \neq Y$. For some $b > 2$ let both sets F_i be b-close.*

Let x_i, $i = 0,1$, be distinct vertices with $x_i \in X(F_i)$. Let P be an x_0x_1-path in $G[X]$. Suppose $|P| \geq 2d_X(x_0,x_1)b + 2$. For $i = 0,1$ let r_i be the near separator $\Pi(F_i, x_{1-i})$. Then

(i) *r_0, r_1 is a separation pair of G.*

(ii) *For $i = 0,1$ if F_i is a star centered in $r_i \in Y$, then extend P by the edge x_i, r_i. Let $\overline{P}$ be the resulting path. $\overline{P}$ contains r_0 and r_1, and $\overline{P}[r_0,r_1]$ is contained in an r_0r_1-tricomponent that is contained in $G[X \cup \{r_0,r_1\}]$.*

Remark. $\overline{P}$ is equal to either P (if both $r_i \in X$), or P plus an edge at one end (if exactly one $r_i \in Y$), or P plus an edge at both ends (if both $r_i \in Y$).

Proof. Note that Lemma 2.5 applies to both sets F_i. Note also that in (ii), $\overline{P}$ is a path, even if both vertices r_0, r_1 belong to Y. This follows from the biconnectivity of G. It is clear that in all cases $\overline{P}$ contains both r_0 and r_1.

The argument treats P and $\overline{P}$ as oriented paths. In particular, the notation $\overline{P}[a,b]$ is well formed only if a precedes b in P. Take a vertex $x \in \overline{P}(r_0, r_1)$. (More precisely, x must occur after r_0 and before r_1.) We claim that such an x exists. In particular this claim implies that r_0 precedes r_1 in $\overline{P}$.

To prove the claim first observe that $r_i \in X$ implies

$$|P[x_i, r_i]| < d_X(x_0, x_1)b.$$

If F_i is not a star, this inequality follows from Lemma 2.5. If F_i is a star, then r_i is its center, so $r_i \in X$ implies $r_i = x_i$ and $|P[x_i, r_i]| = 0 < d_X(x_0, x_1)b$.

Hence if both $r_i \in X$, the displayed inequality plus the hypothesized lower bound on $|P|$ imply $|P[r_0, r_1]| \geq 2$; i.e., r_0 precedes r_1 in P and $V(P(r_0, r_1)) \neq \emptyset$, as desired (recall that $\overline{P} = P$ in this case). On the other hand, if some $r_i \in Y$, then we can simply take x to be the vertex x_i. It is easy to check that $x_i \neq r_{1-i}$, again using the hypothesized bound on $|P|$. The claim now follows in all cases.

We prove (i) by showing that r_0, r_1 separates vertex x and $Y - \{r_0, r_1\}$. Let Q be a path from $Y - \{r_0, r_1\}$ to x; we must show that Q contains r_0 or r_1. To get from Y to X, Q contains an edge of $E[Y, X]$. Let $yz \in E[Y, X]$ be the last such edge in Q. For definiteness assume $yz \in F_0$; we will show $r_0 \in V(Q)$. If F_0 is a star, then clearly Q contains its center, which is r_0. Suppose that F_0 is not a star. Lemma 2.5 shows that r_0 weakly separates $z \in X(F_0)$ and $x \in V(P(r_0, x_1])$ in graph $G[X]$. The choice of yz ensures that $Q[z, x]$ is contained in X. Hence $r_0 \in V(Q[z, x])$.

It is easy to see that we have also proved (ii). In particular the last part of (ii) follows since $x \in \overline{P}(r_0, r_1)$. □

Here's how the algorithm uses the separation pairs r_0, r_1 (recall Figure 2). Say that a path P *traverses* a subgraph H if P contains a subpath of ≥ 3 edges, where the first and last subpath edge do not belong to H but all other subpath edges do belong to H. Let a, b be a separation pair. Clearly any path P traversing an a, b-tricomponent T contains both a and b. Furthermore P traverses T only once; i.e., $E(P) \cap T = E(P[a, b])$.

Let C^* be a v-cycle. Let r_0, r_1 be a separation pair of G contained in C^*, and abbreviate $C^*_v[r_0, r_1]$ to C^*_1. Let T_1 be the r_0, r_1-tricomponent of G that contains C^*_1. Thus C^* traverses T_1. Let Q_1 be an arbitrary $r_0 r_1$-path contained in T_1. Next define C^*_2, T_2, and Q_2 similarly from a second separation pair r'_0, r'_1 that is also contained in C^*. Assume that C^*_1 and C^*_2 are edge-disjoint; e.g., T_1 and T_2 are edge-disjoint.

The *gluing principle* states that regardless of the choice of Q_i, a v-cycle containing paths Q_1 and Q_2 exists. In proof, the edge set $A = (C^* - \cup_{i=1}^2 C^*_i) \cup \cup_{i=1}^2 Q_i$ is such a cycle. This hinges on the fact that A is guaranteed to be simple, because C^* traverses each tricomponent T_1, T_2 only once.

The algorithm will identify the above separation pairs r_0, r_1 and r'_0, r'_1 and the corresponding tricomponents T_1 and T_2. The algorithm will find its own $r_0 r_1$-path Q_1 and $r'_0 r'_1$-path Q_2 (recursively). The gluing principle guarantees a v-cycle through Q_1 and Q_2. We shall see that such a cycle can be found efficiently.

The existence of the separating pairs r_0, r_1 will be guaranteed by applying Lemma 2.6. The lemma's $x_0 x_1$-path P will be a subpath of C^*, and $\overline{P}[r_0, r_1]$ will be the above

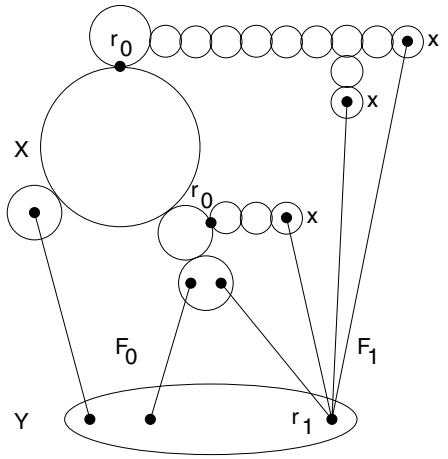

FIG. 4. *Finding a tricomponent cover on X. In this figure F_0 is not a star, F_1 is a star centered at $r_1 \in Y$, and there are two possible vertices $r_0 = \Pi(F_0, x)$.*

path C_1^* (or C_2^*). Since the algorithm doesn't know P, x_0, or x_1, it doesn't know the separation pair r_0, r_1 (since r_i is defined in terms of x_i). Similarly the algorithm doesn't know the corresponding tricomponent containing $\overline{P}[r_0, r_1]$. To compensate, the algorithm finds a set of tricomponents that includes the desired tricomponent containing $\overline{P}[r_0, r_1]$. The set is captured in the following definition.

Consider sets G, X, Y, F_0, and F_1 of Lemma 2.6. As in the lemma, the sets F_i are b-close. A *tricomponent cover* on X is a collection $\mathcal{T}$ of triplets of the form (r_0, r_1, T) satisfying the following conditions:

(i) r_0, r_1 is a separation pair of G with T an r_0r_1-tricomponent, where $r_0, r_1 \in X \cup Y(E[X, Y])$ and $V(T) \subseteq X \cup \{r_0, r_1\}$.

(ii) The edge sets T of $\mathcal{T}$ are pairwise disjoint.

(iii) Let P be any x_0x_1-path satisfying the conditions of Lemma 2.6. Then the lemma gives the separation pair r_0, r_1. $\mathcal{T}$ must include a triplet (r_0, r_1, T), where, as in the lemma, $r_i = \Pi(F_i, x_{1-i})$ for $i = 0, 1$ and T is the r_0r_1-tricomponent containing $\overline{P}[r_0, r_1]$.

$\mathcal{T}$ may include other triplets besides those required by (iii).

Characterizing a tricomponent cover depends on how many sets F_0, F_1 are stars. Lemma 2.7 below is the heart of the characterization. Part (ii) of the lemma, which handles the case of exactly one star, is illustrated in Figure 4.

LEMMA 2.7. *Suppose that an application of Lemma* 2.6 *determines the separation pair r_0, r_1 from G, X, Y, F_0, F_1, and P. Suppose that F_0 is not a star.*

(i) *Suppose that F_1 is also not a star. Then every vertex $x \in X(F_1)$ determines the same near separator; i.e., $\Pi(F_0, x) = r_0$.*

(ii) *Suppose that F_1 is a star and its center r_1 belongs to Y. For two vertices $x_j \in X(F_1)$, $j = 1, 2$, let $\Pi(F_0, x_j), r_1$ be a separation pair with T_j a corresponding tricomponent such that $x_j \in V(T_j) - \Pi(F_0, x_j)$. Then T_1 and T_2 are either identical or edge-disjoint.*

Proof. Recall that the notion $\Pi(F, x)$ is defined in terms of the notion $\pi_S(v)$, whose definition in turn is based on the set B of bicomponents that separate two vertices of S.

(i) For $i = 0, 1$ let B_i be the set of bicomponents used to define $\Pi(F_i, \cdot)$. Observe that $r_0 \notin V(B_1)$. To see this recall that, by definition, $r_1 = \Pi(F_1, x_0)$ is the first

vertex of the path $P[x_0, r_1]$ that belongs to $V(B_1)$. The proof of Lemma 2.6 shows that r_0 precedes r_1 in P. Hence $r_0 \notin V(B_1)$.

Any $x \in X(F_1)$ is joined to x_1 by a path Q contained in $V(B_1)$ (by construction). Q avoids $V(B_0)$. To see this assume the contrary. Then Q contains a path from x_1 to $V(B_0)$. Hence Q contains r_0, since r_0 is defined as $\Pi(F_0, x_1)$. But we have just seen that this is not the case.

Combining Q and $P[r_0, x_1]$ gives a path from x to r_0 whose first vertex in $V(B_0)$ is r_0. So, by definition, $r_0 = \Pi(F_0, x)$.

(ii) The lemma is obvious if $\Pi(F_0, x_1) = \Pi(F_0, x_2)$. So assume $\Pi(F_0, x_1) \neq \Pi(F_0, x_2)$. To treat this case it suffices to show that in general, for any separation pair $\Pi(F_0, x), r_1$ with tricomponent T having $x \in V(T) - \Pi(F_0, x)$, every vertex $v \in V(T) - r_1$ has the same near separator $\Pi(F_0, v) = \Pi(F_0, x)$.

Let B_0 be the set of bicomponents used to define $\Pi(F_0, \cdot)$. Let Q be a path from v to x that avoids $\Pi(F_0, x)$ and r_1. (Q exists by the definition of tricomponent.) Let Q' be a path from x to $\Pi(F_0, x)$ that contains no vertex of $V(B_0)$ besides $\Pi(F_0, x)$. (Q' exists by the definition of $\Pi(F_0, x)$.) Combining Q and Q' gives a path from v to $\Pi(F_0, x)$ containing no vertex of $V(B_0)$ besides $\Pi(F_0, x)$. This shows $\Pi(F_0, v) = \Pi(F_0, x)$. □

Using the lemma, a tricomponent cover $\mathcal{T}$ on X can be found as follows. Let P be an x_0x_1-path satisfying the conditions of Lemma 2.6, and let (r_0, r_1, T_0) be the corresponding triplet that must be included in $\mathcal{T}$. Consider the following three cases that, taking into account the symmetry between F_0 and F_1, cover all possibilities.

Case 1. Neither set F_i is a star. We construct $\mathcal{T}$ containing just one triplet, the desired one: Lemma 2.7(i) shows how to identify the two separating vertices r_0, r_1. T_0 is the (unique) r_0r_1-tricomponent that is contained in X (Lemma 2.6(ii)).

Case 2. F_1 is a star centered in X, or both F_0 and F_1 are stars. Both near separators are known: the near separator of a star is its center. If F_0 is not a star and F_1 is a star centered in $r_1 \in X$, then Lemma 2.6 shows $r_0 = \Pi(F_0, r_1)$.

In $\mathcal{T}$ the tricomponents T that correspond to the separation pair r_0, r_1 range over all the r_0r_1-tricomponents whose vertices are in $X \cup \{r_0, r_1\}$. There may be any number of such tricomponents. However, these tricomponents are clearly edge-disjoint, and one of them is the desired tricomponent T_0 containing $\overline{P}[r_0, r_1]$.

Case 3. F_1 is a star centered in Y and F_0 is not a star. (This case is illustrated in Figure 4.) Construct $\mathcal{T}$ as follows. r_1 is the center of star F_1. For each vertex $x \in X(F_1)$, set $r_0 = \Pi(F_0, x)$. If $r_0 \neq x$ and r_0, r_1 is a separation pair, then let T be the corresponding tricomponent containing x and add (r_0, r_1, T) to $\mathcal{T}$.

Lemma 2.7(ii) shows that all tricomponents so constructed are pairwise edge-disjoint.

To show that $\mathcal{T}$ contains the required triplet for P, recall that the proof of Lemma 2.6 shows $x_1 \neq r_0$ (where x_1 is the last vertex of P). In other words, $x_1 \neq \Pi(F_0, x_1)$. Thus $\mathcal{T}$ contains $(\Pi(F_0, x_1), r_1, T_0)$, as required.

The algorithm of the next section constructs tricomponent covers on a number of vertex sets X. These sets X are pairwise vertex-disjoint. (Specifically each X is a connected component of $G - V[C]$, where C is the algorithm's current cycle.) It is clear that property (ii) of the definition of tricomponent cover extends to this context: any two edge sets T from the same or different tricomponent covers $\mathcal{T}$ are disjoint.

We end this section with an observation that is not needed for the logical development but may prevent misconceptions. It is possible that two edge-disjoint subpaths of C^* both satisfy the hypothesis of Lemma 2.6 and both traverse the same set X (where, as just mentioned, X is a connected component of $G - V[C]$). This can oc-

cur in Case 3 above. For instance, in Figure 4, C^* enters X on the left edge of F_0, goes through the upper r_0 vertex and the upper row of bicomponents to an edge xr_1, then goes through the lower row of bicomponents to the lower r_0 vertex, and finally proceeds to the right edge of F_0.

3. Algorithm. This section presents an algorithm to approximate the longest cycle C^* through a given vertex v of degree two in a given graph G. Sections 4–5 give the analysis (as well as some lower level details of the algorithm in section 5).

Let ℓ be the length of C^*. For every integer $p \geq 1$ we give an algorithm $\mathcal{A}_p$ that finds a v-cycle of length $\Omega((\log \ell / \log\log \ell)^p)$. $\mathcal{A}_p$ uses $\mathcal{A}_{p-1}$ as a subroutine, and the hidden constant decreases with p. We choose an appropriate value p^* of p to get the desired overall result on superpolylogarithmic cycles.

For brevity the presentation of $\mathcal{A}_p$ is not optimized. Slight asymptotic improvements are possible by using more detailed versions of $\mathcal{A}_1$ and $\mathcal{A}_2$. Also we make no attempt to keep the constants small, preferring instead to keep the arithmetic simple.

We will guess a value ℓ^* as the length of C^*. Write

$$a^* = \log \ell^*, \qquad k^* = \log a^* = \log\log \ell^*.$$

For $p \leq p^*$, algorithm $\mathcal{A}_p$ will be given a smaller graph derived from the given one, along with a degree two vertex v. When describing $\mathcal{A}_p$ we will use C^* to denote the longest v-cycle in this recursive call. $\mathcal{A}_p$ uses variables a and k that play roles similar to the roles of a^* and k^* above. The formulas for these quantities are

$$a = \frac{pa^*}{p^*}, \qquad k = k^*. \tag{1}$$

The values of a decrease slowly from a^* as p decreases (in recursive calls). This allows us to find the longest v-cycle possible. The reader should think of variable k as $\log a$, in analogy with the definition of k^*. However since $\log a$ is difficult to compute, we actually define k to be the slightly larger value k^*.

Algorithm $\mathcal{A}_p$ has this length guarantee: given a graph with a v-cycle of length $\geq 2^a$ for a defined by (1), $\mathcal{A}_p$ returns a v-cycle of length at least

$$\alpha_p \left(\frac{a}{k}\right)^p.$$

Here $\alpha_p \leq 1$ is a factor depending on p that we will derive. The length guarantee is proved in Lemma 4.1.

We start with a driving routine. It ensures that a is large, in all calls to routines $\mathcal{A}_{p^*}, \mathcal{A}_{p^*-1}, \ldots, \mathcal{A}_1$.

Main Routine.

Step 1. If $|C^*| \leq 2^{2^8}$, use color coding to find a longest v-cycle, and return it.

Step 2. For k^* taking on consecutive integral values from 8 to $\lfloor \log\log n \rfloor$ set $a^* = 2^{k^*}$, $p^* = \lfloor \sqrt{a^*/24k^*} \rfloor$, and call $\mathcal{A}_{p^*}$. Return the longest v-cycle found by any of these routines.

To implement Step 1 note that for any integer k, color coding can find the longest v-cycle having length $\leq k$ in time $2^{O(k)} n \log n$. Applying this with $k = 2^{2^8}$ almost accomplishes Step 1. But it doesn't suffice, since it doesn't prove $|C^*| \leq k$. In [11] color coding is supplemented with the undirected cycle structure theorem stated in section 1 to accomplish Step 1. Specifically [11] shows that for any undirected graph and any integer k, a v-cycle of length $\geq k$ can be found in time $O(m) + 2^{O(k)} n \log n$, if one exists. This gives a complete implementation of Step 1.

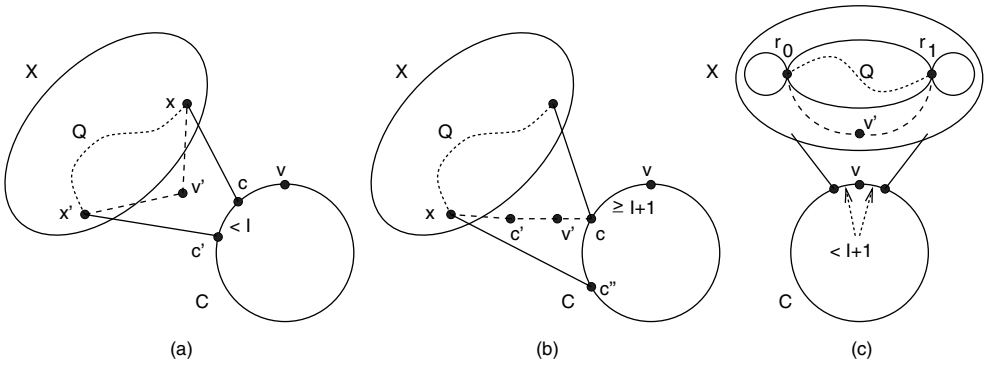

FIG. 5. *Recursive calls of* $\mathcal{A}_{p+1}$ *(see next page):* (a) *Step* 2.1 *calls* $\mathcal{A}_p$*;* (b) *Step* 3.1 *and* (c) *Step* 5.3 *call* $\mathcal{A}_{p+1}$.

Algorithm $\mathcal{A}_1$ is again implemented using the algorithm of [11]. It can find a v-cycle of length $\min\{|C^*|, \log n\}$ in polynomial time. This implies that our length guarantee for $\mathcal{A}_1$ is satisfied with $\alpha_1 = 1$, since clearly $a \le \log n$.

For $p^* > p \ge 1$ Algorithm $\mathcal{A}_{p+1}$ uses $\mathcal{A}_p$. We give an overview of $\mathcal{A}_{p+1}$ before stating it precisely. $\mathcal{A}_{p+1}$ begins by using $\mathcal{A}_p$ to find a v-cycle C. Then $\mathcal{A}_{p+1}$ recurses on each connected component X of $G - V(C)$, to find a long path P illustrated in Figure 1. The idea is to enlarge one of these recursively found paths P, using C or another recursively found cycle, to get a longer cycle $\overline{C}$. Specifically each level of recursion in $\mathcal{A}_{p+1}$ enlarges the cycle (or path) of the previous level by the additive "increment" I defined by

$$\widetilde{a} = \frac{pa}{p+1}, \qquad I = \frac{\alpha_p}{2}\left(\frac{\widetilde{a}}{k}\right)^p. \tag{2}$$

Observe from (1) that $\widetilde{a}$ is the value of a in the recursive calls that $\mathcal{A}_{p+1}$ makes to $\mathcal{A}_p$. So recalling the length guarantee stated above, I is half the length of a recursively found cycle. The enlarged v-cycle $\overline{C}$ gets returned by $\mathcal{A}_{p+1}$.

$\mathcal{A}_{p+1}$ uses several different strategies to construct $\overline{C}$. The first strategy (Step 3 below) is the analogue of Björklund and Husfeldt's algorithm [3] (their algorithm also provides the organization described in the previous paragraph): we apply Lemma 2.1(i) (and Figure 1), using the recursive call to find a long path through X and combining this path with C to get $\overline{C}$. In Step 3 (and Figure 5(b)) the long path through X is denoted c, Q, c'', where $c, c'' \in C$ and $Q \subseteq X$. This method is effective if $d_C(c, v)$ is large.

The second major strategy involves using the gluing principle to piece together two recursively found paths into $\overline{C}$, as in Figure 2. We implement this strategy as follows. Partition the edges of C^* into maximal subpaths that are internally disjoint from C. (Recall that two paths are internally disjoint if any common vertex is an end of both paths.) Call each of these subpaths a *segment* of C^*. Both edges incident to v are themselves segments. In general a segment is either an edge or chord of C or a path traversing a connected component X of $G - V(C)$ (i.e., a path through X plus two connecting edges). Note that more than one segment may traverse a given component X.

In the next paragraph we apply Lemma 2.6 to a segment S that traverses a connected component X. This is interpreted as follows. In the lemma define Y as the vertex complement of X, and P as $S[x_0, x_1]$ for x_0 and x_1 the second and

penultimate vertices, respectively, of S (since the first and last vertices of S belong to C; the variables F_i and b of the lemma are defined in Step 5 below).

Now consider two "long" segments of C^* and their corresponding connected components X. We will apply Lemma 2.6 (to each X and its segment) to find a separation pair r_0, r_1 and corresponding r_0r_1-tricomponent T contained in $X \cup \{r_0, r_1\}$, where T contains a (long) portion of C^*, $C^*[r_0, r_1]$. We will use recursive calls to approximate $C^*[r_0, r_1]$. (This is done in Step 5.3, Figure 5(c).) To be precise for $i = 1, 2$ let X_i be the two components X, let C_i^* be the subpath $C^*[r_0, r_1]$ contained in X_i, and let Q_i be the r_0r_1-path returned by the recursive call (on the identified r_0r_1-tricomponent T). The gluing principle guarantees the existence of a cycle containing Q_1, Q_2, and v. The algorithm can find such a v-cycle using a routine for subgraph homeomorphism. This is done in Step 6.

To implement this strategy based on the separation pairs r_0, r_1 given by Lemma 2.6, we must ensure that the lemma's hypothesis holds. In particular we must ensure that F_0 and F_1 are b-close. This is done using Lemma 2.3(i), in Step 2 (Figure 5(a)). Then (in Step 5.2) we use Lemma 2.7 to find a tricomponent cover, thereby finding the desired separation pairs r_0, r_1.

A special case of the second strategy occurs when the first strategy is not applicable but C^* has only one long segment (so gluing is not applicable). As before, the long segment traverses a component X as in Figure 5(c). This possibility is easy to handle: it suffices to return a cycle constructed from the cycle found recursively in X (Step 7).

We have now sketched the major pieces of the algorithm. Because our two strategies use differing recursive calls (Figure 5(b)–(c)) the algorithm maintains numeric quantities like I to decide which strategy to use.

We proceed to give a high level statement of the algorithm. The details that are postponed to section 5 are indicated in the algorithm statement.

$\mathcal{A}_{p+1}$ has parameters G the graph, v the vertex of degree two, and ρ the recursion level. It is assumed that G has a v-cycle. Parameter ρ is used to prevent too many levels of recursion (which might violate the time bound). ρ equals 0 in the initial call.

The algorithm knows the values a and k of (1), $\widetilde{a}$ and I of (2). In addition it uses the values

$$b = 2^{\widetilde{a}+1}, \qquad g = \left(\frac{\widetilde{a}}{k}\right)^{p+1}. \tag{3}$$

The algorithm generates a number of v-cycles. It maintains $\overline{C}$ as the longest v-cycle ever generated, and eventually returns $\overline{C}$. If a cycle of length $\geq g$ is ever generated, that cycle is immediately returned.

ALGORITHM $\mathcal{A}_{p+1}(G, v, \rho)$. /* The algorithm also knows the values defined in (1)–(3): $a, k, \widetilde{a}, I, b, g$ */

Step 0. Initialize $\overline{C}$ to any v-cycle. If $\rho \geq a^{p+1}$, then return $\overline{C}$. Otherwise prune G to the (unique) biconnected component containing v. Let w_0, w_1 be the two neighbors of v in G. Thus $W = \{vw_0, vw_1\}$ is a w_0w_1-tricomponent. For every other w_0w_1-tricomponent U, execute all the steps below for the graph G' whose edge set is $U \cup W$. Then return $\overline{C}$.

Step 1. Find a v-cycle C by calling $\mathcal{A}_p(G', v, 0)$.

Step 2. Repeat Step 2.1 until either it makes $|C| \geq g$ or no further enlargement of C is possible. In the former case return $\overline{C} = C$.

Step 2.1 (This step is illustrated in Figure 5(a).) Suppose for some connected component X of $G' - V(C)$ that $E[C, X]$ contains independent edges $cx, c'x'$ such that $|C_{\overline{v}}[c, c']| < I$ and some b-round bicomponent of $G[X]$ separates x and x'. Call $\mathcal{A}_p$ to find an xx'-path Q in X. Specifically create a new vertex v' along with new edges $v'x, v'x'$, and call $\mathcal{A}_p(H, v', 0)$ for H the graph induced by $V[X] \cup \{v'\}$. In C replace $C_{\overline{v}}[c, c']$ by c, Q, c'. (The implementation of this step is given in section 5. Section 4 shows that this replacement enlarges C.)

In the rest of the algorithm the variable X ranges over every connected component of $G' - V(C)$. (There may not be any.)

Step 3. Execute Step 3.1 for each component X that has a neighbor $c \in C$ with $d_C(c, v) \geq I + 1$ (if X has more than one such neighbor choose c arbitrarily).

Step 3.1. (This step is illustrated in Figure 5(b).) Create two new vertices v', c' along with new edges $v'c, v'c'$, plus an edge $c'x$ for each vertex $x \in X$ that is a neighbor of $C - c$. Call $\mathcal{A}_{p+1}(H, v', \rho + 1)$ recursively for H, the graph induced by $V[X] \cup \{c, c', v'\}$. The cycle returned corresponds to a path c, Q, c'' in G', where $Q \subseteq X$ and $c'' \in C - c$. Update $\overline{C}$ for the v-cycle $c, Q, c'', C_v[c'', c]$ of G.

Step 4. For each component X, check whether $E[C, X]$ contains two independent edges $cx, c'x'$ that have $d_X(x, x') \geq g$. If so, let Q be an $x'x$-path in X and return the cycle $x', Q, x, C_v[c, c'], x'$.

Step 5. This step applies Lemma 2.6. Initialize a set of paths $\mathcal{Q}$ to $\emptyset$. For each component X not processed in Step 3 (i.e., every neighbor $c \in C$ of X has $d_C(c, v) < I + 1$) execute Steps 5.1–5.3. (Note that if every component X was processed in Step 3 then Steps 5–7 do nothing.)

Step 5.1. Partition $E[C, X]$ into sets F_0 and F_1, where F_0 contains the edges $cx \in E[C, X]$ with $d_C(c, w_0) \leq d_C(c, w_1)$ and F_1 contains the remaining edges. If F_0 or F_1 is empty, skip Steps 5.2–5.3 and proceed to the next component X.

Step 5.2. As described in section 2 use Lemma 2.7 to construct a tricomponent cover $\mathcal{T}$ on X. Then each triplet (r_0, r_1, T) of $\mathcal{T}$ has $r_0, r_1 \in X \cup C$ and $T \subseteq E(X) \cup E[C, X]$.

(Observe the following property of $\mathcal{T}$. Consider any segment of C^* that traverses X such that Lemma 2.6 guarantees a separation pair r_0, r_1 when applied to X and the portion of the segment in X. Then $\mathcal{T}$ contains (r_0, r_1, T), where T is the r_0r_1-tricomponent in $X \cup \{r_0, r_1\}$ containing $C^*_{\overline{v}}[r_0, r_1]$.)

Step 5.3. (This step is illustrated in Figure 5(c).) For each $(r_0, r_1, T) \in \mathcal{T}$, call $\mathcal{A}_{p+1}$ to find an r_0r_1-path Q. Specifically create a new vertex v' along with new edges $v'r_0, v'r_1$, and call $\mathcal{A}_{p+1}(H, v', \rho+1)$ recursively for H the graph induced by $V[T] \cup \{v'\}$. Add Q to $\mathcal{Q}$.

Step 6. For every pair of paths in $\mathcal{Q}$, search for a cycle containing v and the two paths. Update $\overline{C}$ for every cycle found. (The implementation of this step is given in section 5.)

Step 7. Let Q be a longest path of $\mathcal{Q}$. Extend Q to a v-cycle. (As shown below, this can be done since Q and v are in different r_0r_1-tricomponents). Update $\overline{C}$ for this cycle.

We leave the following implementation details to section 5: checking for the existence of the separating b-round bicomponent in Step 2.1, finding the desired cycle in Step 6, and computing all the numeric quantities like I, b, etc. The rest of the implementation of the algorithm is clear.

To clarify the difference in recursive calls to $\mathcal{A}_p$ and $\mathcal{A}_{p+1}$, observe that $\mathcal{A}_p$ essentially initializes C, in Steps 1 and 2. $\mathcal{A}_{p+1}$ processes C, in Steps 3 and 5.

We close this section by verifying that the algorithm is well specified. First note that each graph G' constructed in Step 0 is biconnected. This follows easily from Fact 1.

Recall that we assume $\mathcal{A}_{p+1}$ is called with a graph that has a v-cycle. It is easy to check that this property is maintained in all the recursive calls. In particular for Step 3.1 the biconnectivity of G' guarantees that X has neighbors in $C - c$.

Finally, we note that the v-cycle of Step 7 always exists. In proof, Step 5.2 shows that v does not belong to the r_0r_1-tricomponent T containing Q. The biconnectivity of G' and Fact 1 show there is an r_1r_0-path R containing v that is edge-disjoint from T. Now Q, R is the desired v-cycle for Step 7.

4. Length analysis. Before diving into the analysis we restate the high level purpose of Algorithm $\mathcal{A}_{p+1}$, for some intuition. Recall the length guarantee given for $\mathcal{A}_p$ at the start of last section. Step 1 initializes C to a v-cycle of length $\geq \alpha_p \left(\frac{\widetilde{a}}{k}\right)^p = 2I$. This can be proved by the same simple argument as given for Claim 2 below. The task for the rest of $\mathcal{A}_{p+1}$ is to enlarge the cycle to the length guarantee's quantity $\alpha_{p+1}\left(\frac{a}{k}\right)^{p+1}$. As mentioned in the last section, this is accomplished by having each level of recursion (of $\mathcal{A}_{p+1}$) increase the cycle length by $\geq I$. This fact is the heart of the analysis. It is stated formally as the Assertion of the Lemma 4.1 below.

We start the formal analysis with some inequalities that result from the basic parameters being large. Step 2 of the Main Routine has

$$k^* \geq 8, \qquad a^* = 2^{k^*} \geq 2^8, \qquad \ell^* = 2^{a^*} \geq 2^{2^8}.$$

Recall that algorithm $\mathcal{A}_p$ is called for all $1 \leq p \leq p^*$, and $\mathcal{A}_p$ uses the value $a = pa^*/p^*$. We claim that $\mathcal{A}_p$ always has

$$a \geq 2^4, \qquad a \geq 24kp^2. \tag{4}$$

For the first inequality the Main Routine's Step 2 shows $p^* \leq \sqrt{a^*}$. Hence $a \geq a^*/p^* \geq \sqrt{a^*} \geq 2^4$. For the second inequality write $a = pp^*a^*/(p^*)^2$. The Main Routine's Step 2 shows $p^* \leq \sqrt{a^*/24k^*}$, so we get $a \geq pp^*a^*/(a^*/24k^*) = 24k^*pp^*$.

We need to verify two inequalities to ensure that the algorithm makes sense: $p^* \geq 1$ (since the Main Routine's Step 2 calls $\mathcal{A}_{p^*}$) and $b > 2$ (since Step 2.1 looks for b-round components). The first inequality is equivalent to $\sqrt{a^*/24k^*} \geq 1$, i.e., $a^*/k^* \geq 24$. This holds since, remembering that $x/\log x$ is an increasing function for $x \geq e$, we have $a^*/k^* = a^*/\log a^* \geq 2^8/8 = 2^5$. The inequality $b > 2$ holds since $b = 2^{\widetilde{a}+1}$, $\widetilde{a} \geq 2^4$.

Define the decreasing sequence α_p for integers $p \geq 1$ by

$$\alpha_p = \frac{1}{24^{p-1}(p!)^2}.$$

Let us show that this implies that every algorithm $\mathcal{A}_{p+1}$, $p \geq 1$, has

$$I \geq 2. \tag{5}$$

By definition (2), $I = \frac{\alpha_p}{2}\left(\frac{\widetilde{a}}{k}\right)^p$. Since $\widetilde{a}$ represents the quantity a in algorithm $\mathcal{A}_p$, the second inequality of (4) amounts to $\widetilde{a} \geq 24kp^2$. Thus

$$I \geq \frac{1}{2 \cdot 24^{p-1}p^{2p}}\left(\frac{24kp^2}{k}\right)^p = 12 > 2.$$

The main task of this section is to prove the following length guarantee (already mentioned at the start of section 3).

LEMMA 4.1. *For any $p^* > p \geq 0$, suppose Algorithm $\mathcal{A}_{p+1}$ is called with graph G having a v-cycle of length $\geq 2^a$, and $\rho = 0$. Here a is defined by the general equation (1), i.e., $a = (p+1)a^*/p^*$. Then $\mathcal{A}_{p+1}$ returns a v-cycle of length $\geq \alpha_{p+1}(a/k)^{p+1}$.*

Proof. We induct on p. The base case $p = 0$ (i.e., Algorithm $\mathcal{A}_1$) was verified after the statement of the Main Routine in section 3. So assume that $p \geq 1$ and algorithm $\mathcal{A}_p$ fulfills the length guarantee. We prove that $\mathcal{A}_{p+1}$ also fulfills the length guarantee.

We begin by showing that the claim made in Step 2.1 is true, as follows.

CLAIM 0. *Every replacement done by Step* 2.1 *gives a longer cycle C.*

Proof. Applying Lemma 2.3(i) to the vertices x and x' of Step 2.1 shows that $D_X(x, x') \geq b/2 = 2^{\widetilde{a}}$. Thus the inductive assumption applies to $\mathcal{A}_p$ and shows it gives an xx'-path of length $\geq \alpha_p \left(\frac{\widetilde{a}}{k}\right)^p - 2 = 2I - 2$. Hence the length of C increases by $> (2I-2) + 2 - I = I > 0$. □

Let $\mathcal{R}$ be the recursion tree of $\mathcal{A}_{p+1}$. As usual, identify each node of $\mathcal{R}$ with the corresponding invocation of $\mathcal{A}_{p+1}$. By definition, $\mathcal{R}$ does not contain nodes for calls to $\mathcal{A}_p$. For any node τ of $\mathcal{R}$ let C_τ denote the cycle returned by τ.

CLAIM 1. *Any child σ of any node τ of $\mathcal{R}$ has $|C_\sigma| < |C_\tau|$.*

Proof. First suppose that σ is called from Step 3.1 of τ. Lemma 2.1(i) implies $|C_\tau| > (|C_\sigma| - 2) + (I + 1) > |C_\sigma|$.

Next suppose that σ is called from Step 5.3. It suffices to assume that C_σ corresponds to the longest path Q in $\mathcal{Q}$. Step 5.3 shows that $|C_\sigma| = |Q| + 2$. Step 7 shows that this quantity is $< |C_\tau|$ unless $\{r_0, r_1\} = \{w_0, w_1\}$, where Q is an r_0r_1-path and w_0, w_1 are the neighbors of v defined in Step 0. So suppose $\{r_0, r_1\} = \{w_0, w_1\}$. Step 0 then implies that the r_0r_1-tricomponent T containing Q equals $G' - \{vw_0, vw_1\}$. But this is impossible since the edge sets T and C are disjoint (Step 5.2 defines $T \subseteq E(X) \cup E[C, X]$). □

Claim 1 implies that if Step 0 ever returns because $\rho \geq a^{p+1}$, the cycle returned by the root of $\mathcal{R}$ has more than the desired length. Now assume $\mathcal{R}$ has height $< a^{p+1}$. We can also assume that no invocation of Step 2 or 4 returns a cycle of length $\geq g$. To check this we need only show $g \geq \alpha_{p+1}(a/k)^{p+1}$, equivalently $\left(\frac{p}{p+1}\right)^{p+1} \geq \alpha_{p+1}$. The latter follows from $p \geq 1$, since the left-hand side equals $(1 - 1/(p+1))^{p+1} \geq (1 - 1/2)^2 = 1/4 > \alpha_2 \geq \alpha_{p+1}$.

Define the values

$$\delta = a^{2(p+1)}, \qquad d = \log \delta = 2(p+1)\log a, \qquad \epsilon = 4/a^{p+1}. \tag{6}$$

The core of the argument is the following.

ASSERTION. *Consider a node τ of $\mathcal{R}$ at depth $\geq j$, where j is an integer in $0 \leq j < a^{p+1}$. Let C^* be a longest v-cycle for τ. Assume for some integer i, $1 \leq i \leq \frac{a}{(p+1)d}$,*

$$|C^*| \geq 2^{\widetilde{a} + id - j\epsilon}.$$

Then $|C_\tau| \geq iI$.

Before proving the assertion let us show that it implies the lemma. The root γ of $\mathcal{R}$ has depth $j = 0$. Set $i_0 = \lfloor \frac{a}{(p+1)d} \rfloor$. We will show that the assertion for $i = i_0$ implies the lemma's conclusion.

We begin by showing that i_0 satisfies the assertion's lower bound on $|C^*|$. Recall that the lemma assumes $|C^*| \geq 2^a$. Since $a = \widetilde{a} + a/(p+1) \geq \widetilde{a} + i_0 d$, this implies the desired lower bound.

Next we show the two inequalities

$$i_0 \geq 1 \quad \text{and} \quad i_0 \geq \frac{a}{4(p+1)^2 k}.$$

The first inequality completes the proof that i_0 satisfies all hypotheses of the assertion. The second inequality is used below.

To prove the inequalities, recall $\log a \leq \log a^* = k$. Thus the definition (6) of d shows that i_0 is the floor of the quantity

$$\frac{a}{(p+1)d} = \frac{a}{2(p+1)^2 \log a} \geq \frac{a}{2(p+1)^2 k}.$$

Thus it suffices to show that the rightmost quantity is at least one (since $x \geq 1$ implies $\lfloor x \rfloor \geq x/2$). Inequality (4) applied to algorithm $\mathcal{A}_{p+1}$ shows $a \geq 24k(p+1)^2$. Hence the rightmost quantity is $\geq 24k(p+1)^2/2(p+1)^2 k = 12 > 1$, as desired.

Since $(1+1/p)^p \leq e < 3$,

$$I = \frac{\alpha_p}{2} \frac{1}{(1+1/p)^p} \left(\frac{a}{k}\right)^p \geq \frac{\alpha_p}{6} \left(\frac{a}{k}\right)^p.$$

Using the assertion along with the second displayed lower bound for i_0 and the lower bound for I gives

$$|C_\gamma| \geq i_0 I \geq \frac{\alpha_p}{24(p+1)^2} \left(\frac{a}{k}\right)^{p+1} = \alpha_{p+1} \left(\frac{a}{k}\right)^{p+1},$$

thus establishing the lemma.

We turn to proving the assertion. We use an inner induction, this time inducting on the quantity $i - j$. (This induction is well founded since $i - j > 1 - a^{p+1}$.) For future reference observe the inequality

$$d \geq j\epsilon.$$

It follows since (6) implies $d \geq 2(p+1) \geq 4 = a^{p+1}\epsilon$. The next claim provides the base case of the inner induction.

CLAIM 2. *For any integers $1 \leq i \leq 2$ and $0 \leq j < a^{p+1}$, $|C_\tau| \geq 2I \geq iI$.*

Proof. Since $id - j\epsilon \geq d - j\epsilon \geq 0$, the assertion's lower bound on $|C^*|$ implies $|C^*| \geq 2^{\widetilde{a}}$. So when Step 1 is executed for the tricomponent containing C^*, $\mathcal{A}_p$ returns a cycle of length $\geq \alpha_p(\widetilde{a}/k)^p = 2I$. Here we have used the lemma for $\mathcal{A}_p$ (true by the inductive assumption on p) and the definition (2) of $\widetilde{a}$ and I. □

To do the inductive step (of the inner induction) assume $i \geq 3$. It suffices to show that some execution of Step 3.1, Step 6, or Step 7 constructs a cycle of length $\geq iI$. Fix C as its value after Step 2 has completed. Call a segment of C^* *large* if it has length $\geq 2|C^*|/\delta$. We establish the inductive step by focusing on the large segments. (Claim 6 below shows that they exist. Also note that $2|C^*|/\delta$ is a relatively big quantity, $|C^*|/\delta \geq 2^{3d-j\epsilon}/2^d = 2^{2d-j\epsilon} \geq 2^d = \delta$, and δ is much bigger than the cycle to be returned by $\mathcal{A}_{p+1}$.) Claims 3, 5, and 6 below exhaust all possibilities for the large segments and show that the assertion holds in each case. This establishes the inductive step.

CLAIM 3. *$|C_\tau| \geq iI$ if some large segment traverses a component X that has a neighbor $c \in C$ with $d_C(c,v) \geq I+1$.*

Proof. Lemma 2.1(ii) shows that in Step 3.1 graph H has a v'-cycle of length $\geq (2|C^*|/2\delta+1)+2 > |C^*|/\delta \geq 2^{\widetilde{a+(i-1)d-j\epsilon}}$. The recursive call to $\mathcal{A}_{p+1}$ has depth $\geq j+1$. Hence the inductive assertion implies that the recursive call finds a cycle of length $\geq (i-1)I$. Lemma 2.1(i) shows that the v-cycle constructed has length $\geq ((i-1)I-2)+d_C(c,v)+1 \geq iI$. □

Now assume that the hypothesis of Claim 3 never holds. Our next goal is to derive the bound (8) below for estimating the performance of Step 5. For the rest of the lemma's proof, the notation $C^*[x,y]$ abbreviates $C^*_{\overline{v}}[x,y]$, i.e., all subpaths of C^* that we will refer to avoid v.

CLAIM 4. *Consider any component X that contains a large segment, say the segment $a_0, C^*[x_0,x_1], a_1$. Define sets F_0 and F_1 as in Step 5.1 and value b as in (3). Let path P be $C^*[x_0,x_1]$. Then all hypotheses of Lemma 2.6 are satisfied.*

Proof. We start with a useful inequality:

$$2 + 2d_X(x_0,x_1)b \leq |C^*|/\delta a^{p+1}. \tag{7}$$

To prove this recall from Step 4 that we have assumed $d_X(x_0,x_1) < g$. Furthermore, $g \leq (a/k)^{p+1} \leq (a/8)^{p+1}$. Hence

$$2 + 2d_X(x_0,x_1)b \leq 4d_X(x_0,x_1)b \leq 8\left(\frac{a}{8}\right)^{p+1} 2^{\widetilde{a}} \leq a^{p+1}2^{\widetilde{a}} = \left(\frac{\delta}{a^{p+1}}\right)2^{\widetilde{a}} = \frac{2^{\widetilde{a+d}}}{a^{p+1}}.$$

Using $i \geq 3$ and $d \geq j\epsilon$ gives $d \leq (i-1)d - j\epsilon$. Hence

$$2^{\widetilde{a+d}} \leq 2^{\widetilde{a+(i-1)d-j\epsilon}} \leq \frac{|C^*|}{\delta}.$$

Combining the last two displayed inequalities gives (7).

We proceed to verify the hypotheses of Lemma 2.6:

(i) $Y(E[X,Y]) \neq Y$. This holds since $v \notin Y(E[X,Y])$.

(ii) Each set F_i is b-close. From Claim 3 we have assumed that any edge $cx \in E[C,X]$ has $d_C(c,v) < I+1$. So the definition of F_i (Step 5.1) shows any two edges $cx, c'x'$ in F_i have $|C_{\overline{v}}[c,c']| < I$. Recalling that Step 2 cannot enlarge C any further, this inequality implies that F_i is b-close.

(iii) $|P| \geq 2d_X(x_0,x_1)b+2$. Since $P = C^*[x_0,x_1]$ comes from a large segment, (7) gives

$$\frac{2|C^*|}{\delta} - 2 \geq \frac{|C^*|}{\delta} \geq \frac{|C^*|}{\delta a^{p+1}} \geq 2 + 2d_X(x_0,x_1)b.$$

(iv) $x_i \in X(F_i)$ for $i = 0,1$. We can assume $x_0 \in X(F_0)$, by possibly renaming vertices w_0 and w_1. So we must show $x_1 \in X(F_1)$. The inequality of (iii) gives $D_X(x_0,x_1) \geq d_X(x_0,x_1)b$, so $D_X(x_0,x_1)/d_X(x_0,x_1) \geq b$. Now Lemma 2.3(ii) shows that x_0 and x_1 are separated by a b-round bicomponent in X. Since F_0 is b-close, the independent edges a_0x_0 and a_1x_1 show $x_1 \notin X(F_0)$, i.e., $x_1 \in X(F_1)$. □

Claim 4 shows that any large segment $a_0, C^*[x_0,x_1], a_1$ has a corresponding triplet (r_0,r_1,T) in the tricomponent cover $\mathcal{T}$ constructed in Step 5.2. Here r_0 and r_1 are the near separators of Lemma 2.6, and T is the r_0r_1-tricomponent containing $C^*[r_0,r_1]$. Thus Step 5.3 adds to $\mathcal{Q}$ a path Q corresponding to the triplet (r_0,r_1,T).

Furthermore, the large segment satisfies

$$|C^*[r_0, r_1]| > |C^*[a_0, a_1]| - \frac{|C^*|}{\delta a^{p+1}}. \tag{8}$$

To prove this first observe that if F_0 is not a star, then Lemma 2.5 shows $|C^*[x_0, r_0]| < d_X(x_0, x_1)b$. A similar statement holds for F_1, so if neither set is a star, then

$$|C^*[r_0, r_1]| > |C^*[x_0, x_1]| - 2d_X(x_0, x_1)b.$$

It is easy to check that the above inequality continues to hold when either set F_i is a star, since in that case r_i is the star's center x_i or a_i. The right-hand side is equal to $|C^*[a_0, a_1]| - 2 - 2d_X(x_0, x_1)b$. Applying (7) to this quantity gives (8).

To help bound the right-hand side of (8) we use the following estimate:

$$|C^*| \left(1 - \frac{1}{a^{p+1}}\right) \geq 2^{\widetilde{a}+id-(j+1)\epsilon}. \tag{9}$$

To prove this recall that $\ln(1-x) \geq -2x$ for $0 \leq x \leq 1/2$. Hence $\log(1 - 1/a^{p+1}) = \log e \ \ln(1 - 1/a^{p+1}) \geq 2(-2/a^{p+1}) = -4/a^{p+1} = -\epsilon$. Combining this with the assertion's assumption $|C^*| \geq 2^{\widetilde{a}+id-j\epsilon}$ gives (9).

We now analyze the two remaining possibilities for the inner inductive step. Recall that the inductive quantity is $i - j$.

Claim 5. *$|C_\tau| \geq iI$ if two large segments exist.*

Proof. (8) and (9) show that each large segment satisfies

$$|C^*[r_0, r_1]| > \left(\frac{2|C^*|}{\delta}\right)\left(1 - \frac{1}{a^{p+1}}\right) \geq 2^{\widetilde{a}+(i-1)d-(j+1)\epsilon+1}.$$

Step 5.3 makes a recursive call for the triplet of $\mathcal{T}$ corresponding to each large segment. This call gives a node of depth $\geq j+1$ in the recursion tree $\mathcal{R}$. Hence by the inner inductive assertion the recursive call finds an r_0r_1-path Q of length $\geq (i-1)I - 2$.

Step 6 eventually considers the pair consisting of these two paths Q. The gluing principle ensures that Step 6 finds a v-cycle containing the two paths. The cycle has length $\geq 2((i-1)I - 2) + 2 = iI + (i-2)I - 2 \geq iI$, where we have used $i \geq 3$ and $I \geq 2$ (from (5)). □

Claim 6. *$|C_\tau| \geq iI$ if at most one large segment exists.*

Proof. Let us first show that a large segment must exist. C^* has $\leq |C|$ segments, and we have assumed (from Step 2) that $|C| \leq g$. So the segments that are not large have total length $\leq (2|C^*|/\delta)(a/k)^{p+1} \leq 2|C^*|/(ak)^{p+1}$. The last quantity is $< |C^*|$. So the longest segment must be large.

Denote the longest segment as $a_0, C^*[x_0, x_1], a_1$. The previous paragraph and the hypothesis of Claim 5 shows that its length is $\geq |C^*| - 2|C^*|/(ak)^{p+1}$. Applying (8) and (9) to this segment, and using the inequalities $\delta, k \geq 2$, and $p \geq 1$, gives

$$|C^*[r_0, r_1]| > \left(|C^*| - \frac{2|C^*|}{(ak)^{p+1}}\right) - \frac{|C^*|}{\delta a^{p+1}} \geq |C^*| \left(1 - \frac{1}{a^{p+1}}\right) \geq 2^{\widetilde{a}+id-(j+1)\epsilon}.$$

Step 5.3 makes a recursive call for the triplet of $\mathcal{T}$ for this segment. The call gives a node of depth $\geq j+1$ in $\mathcal{R}$. Hence by the inner inductive assertion the recursive call finds an r_0r_1-path of length $\geq iI - 2$. Step 7 enlarges this path to a v-cycle of length $\geq (iI - 2) + 2 = iI$, as desired. □

Suppose an iteration of Step 2 of the Main Routine has $|C^*| \geq 2^{a^*}$. We show that $\mathcal{A}_{p^*}$ returns a cycle of length $\geq e^{p^*}$. For notational simplicity we drop the asterisks and write a, p, k for a^*, p^*, k^*.

Lemma 4.1 shows that $\mathcal{A}_p$ returns a cycle of length $\geq \alpha_p(a/k)^p$. The definition of α_p and (4) give

$$\alpha_p \left(\frac{a}{k}\right)^p \geq \frac{1}{24^{p-1}(p!)^2}\,(24p^2)^p \geq 24\frac{p^{2p}}{(p!)^2}.$$

Any $p \geq 1$ satisfies $p! \leq 3\sqrt{p}(p/e)^p$ [5, p. 55]. Hence the rightmost quantity is at least

$$24\frac{p^{2p}}{9p(p/e)^{2p}} \geq \frac{e^{2p}}{p} \geq e^p.$$

This gives the desired inequality.

LEMMA 4.2. *The Main Routine returns a v-cycle having length that is at least* $\exp(c\sqrt{\log \ell / \log\log \ell})$, *where ℓ is the length of a longest v-cycle and c is some positive constant.*

Proof. Assume that Step 1 of the Main Routine does not find a longest cycle, so $\log \ell > 2^8$. Step 2 of the Main Routine eventually chooses k^* so that

$$a^* \leq \log \ell \leq 2a^*.$$

(This is true even if $\ell = n$, since the last value for a^* in Step 2 is $\geq 2^{\log\log n - 1} = (\log n)/2$.) The first inequality gives $|C^*| \geq 2^{a^*}$, so, as shown above, $\mathcal{A}_{p^*}$ returns a cycle of length $\geq e^{p^*}$.

Step 2 shows $p^* \geq \sqrt{a^*/24k^*}/2$ (since $x \geq 1$ implies $\lfloor x \rfloor \geq x/2$). The displayed inequalities imply $a^* \geq (\log \ell)/2$ and $k^* \leq \log\log \ell$. Thus $a^*/k^* \geq (\log \ell)/2\log\log \ell$. Hence $p^* \geq c\sqrt{\log \ell / \log\log \ell}$ for some constant $c > 0$. The lemma follows. □

5. Implementation and timing analysis. This section starts by presenting the remaining implementation details of the algorithm, thus allowing a complete timing analysis. The section ends by showing that the algorithm runs in polynomial time.

Implementation of Step 2.1. We break this step into a number of "passes." Each pass but the last one ends by enlarging C. Each pass examines each bicomponent B of each connected component X, as follows.

Consider a bicomponent B that separates two independent edges $cx, c'x'$ selected as in Step 2.1 (Figure 5(a)), i.e., $|C_{\overline{v}}[c, c']| < I$. (If there is more than one such pair of edges for B, choose arbitrarily. If there is no such pair for B, proceed to the next bicomponent.) Let y be the projection $\pi_B(x)$, i.e., the vertex of $V(B)$ on every minimal path from x to B. Similarly let y' be $\pi_B(x')$. So $y \neq y'$. Call $\mathcal{A}_p$ to find a yy'-path Y in B (creating an artificial vertex v' as in Step 2.1). If $|Y| \geq I$, enlarge Y to a path from cx to $c'x'$, and use that cc'-path to enlarge C. Then begin the next pass. (If $|Y| < I$, just continue to the next bicomponent B.)

Step 2 ends when $|C| \geq g$ or a pass examines every bicomponent B without enlarging C.

The argument for Claim 0 in Lemma 4.1 (applied to y, y') shows that if B is b-round, $|Y| \geq 2I - 2 \geq I$. Hence we enlarge C in this case. It is possible that $|Y| \geq I$ even if B is not b-round. It causes no harm that we enlarge C in this case too. Thus the implementation of Step 2.1 is correct.

For the efficiency analysis, observe that in each pass, an edge of G belongs to the graph of at most one call to $\mathcal{A}_p$.

Implementation of Step 6. Consider the search for a v-cycle containing two paths of $\mathcal{Q}$. Let the paths be Q, corresponding to triplet (r_0, r_1, T), and Q', corresponding to triplet (r_0', r_1', T'). Choose an internal vertex q (resp., q') of Q (resp., Q'). Find a cycle A through v, q, and q', if one exists. The pair r_0, r_1 separates q and v, by construction. Hence A traverses T, the r_0r_1-tricomponent containing q. Replace the subpath $A_q[r_0, r_1]$ by Q. Do the same for Q'. This gives the desired cycle. (In particular, the new cycle is simple.)

A can be found by the algorithm of LaPaugh and Rivest [14]. This algorithm finds a cycle through three given vertices. It uses linear time (with no large hidden constants). For the efficiency analysis observe that $\mathcal{Q}$ contains $\leq n$ paths (recall property (ii) of the definition of tricomponent cover). Hence Step 6 processes $O(n^2)$ pairs of paths.

Implementation of arithmetic. We show how to implement all the tests involving numeric quantities in polynomial time. This will be straightforward since the algorithm has been written to avoid computing $\log a$ (using instead the unchanging value k^*). We will use these simple inequalities:

$$p, p^*, k \leq a^* \leq \log n.$$

Note that p, p^*, k, and a^* are integers. Also in this subsection and the next the largest number we need to estimate is $(a^*)^{2(p^*)^2}$. This number is sublinear (in n):

$$\log (a^*)^{2(p^*)^2} = 2(p^*)^2 \log a^* \leq 2\frac{a^*}{24k^*}k^* = \frac{a^*}{12} \leq \frac{\log n}{12}. \tag{10}$$

In the Main Routine, Step 2 computes $p^* = \lfloor \sqrt{a^*/24k^*} \rfloor$. Equivalently, p^* is the unique integer satisfying $24k^*(p^*)^2 \leq a^* < 24k^*(p^*+1)^2$. Since all variables here are integers $\leq \log n$ we can find p^* in polynomial time by enumeration.

We turn to Algorithm $\mathcal{A}_{p+1}$. We can assume the algorithm is given integers $a^*, p^*, k = k^*$ and p (as well as ρ). We list below all numeric quantities q computed by $\mathcal{A}_{p+1}$. We further observe that the only use of each of these quantities q is in a comparison with a known integral quantity i; i.e., the algorithm needs to determine only which relation $i \prec q$ holds for $\prec \in \{<, =, >\}$:

$$a^{p+1} = \left(\frac{(p+1)a^*}{p^*}\right)^{p+1} \quad \text{(Step 0)}, \qquad g = \left(\frac{pa^*}{kp^*}\right)^{p+1} \quad \text{(Steps 2 and 4)},$$
$$I = \frac{\alpha_p}{2}\left(\frac{pa^*}{kp^*}\right)^{p} \quad \text{(Steps 2.1 and 3)}.$$

Recall also the quantity $\alpha_p = 1/24^{p-1}(p!)^2$.

Recall that $p + 1 \leq p^* \leq \log n$. Treat each of the quantities q as a fraction, computing its numerator and denominator in $O(p^*)$ integer multiplications. We will show that each numerator and denominator is an integer $\leq n$. So, performing the comparison with i presents no problem.

The numerator and denominator of the first two quantities a^{p+1} and g are $\leq (a^*)^{2p^*}$. So (10) gives the desired conclusion. For the third quantity I the numerator is again $\leq (a^*)^{2p^*}$. The denominator is the product of three integers each $\leq (a^*)^{2p^*}$, since $24 < 2^8 \leq a^*$ and $(p!)^2 \leq p^{2p} \leq (a^*)^{2p^*}$. So again (10) gives the desired conclusion.

Wrapup.

THEOREM 5.1. *The Main Routine returns a v-cycle having length that is $\exp(\Omega(\sqrt{\log \ell / \log\log \ell}))$ in polynomial time, where ℓ is the length of a longest v-cycle.*

Proof. Lemma 4.2 proves the length guarantee, so we need only establish the polynomial time bound. For this we need only show that each execution of $\mathcal{A}_{p^*}$ by Step 2 of the Main Routine uses polynomial time. Throughout this argument, G^* denotes the given graph.

First observe (Figure 5) that every invocation of a routine $\mathcal{A}_p$, $p \le p^*$, is given a graph G that consists of two edges incident to v plus edges that are either in G^* or images of such edges. (An image of an edge in G^* is created in Step 3.1: an edge $c'x$ comes from an edge from $C - c$ to x.) This follows by a simple induction.

The pseudocode in section 3 plus the implementation details of this section show that if we ignore the recursive calls that $\mathcal{A}_{p+1}$ makes to itself or $\mathcal{A}_p$, Algorithm $\mathcal{A}_{p+1}$ takes polynomial time. Specifically note that Step 2.1 repeats at most g times, and g is sublinear (by (10)). Step 4 uses breadth-first search, and Step 5.2 finds a tricomponent cover using a routine for biconnected components [5, 17]. Step 6 uses polynomial time, as we noted in its implementation.

Hence it suffices to show there are a polynomial number of invocations of all routines $\mathcal{A}_p$, $p \le p^*$. We have shown that each invocation of a routine $\mathcal{A}_p$ uses a graph that contains an edge of G^* (or its image). Hence it suffices to show that each edge e of G^* is in the graph of a polynomial number of invocations $\mathcal{A}_p$, $p \le p^*$.

Take any $p \le p^*$. Let $\mathcal{R}$ be the recursion tree of $\mathcal{A}_p$. As in the previous section, $\mathcal{R}$ contains nodes only for calls to $\mathcal{A}_p$. Suppose that edge e of G^* (or its image) belongs to the graph of a node τ of $\mathcal{R}$. Then e belongs to the graph of at most one child of τ. In proof, the recursive calls to $\mathcal{A}_p$ occur in Steps 3.1 and 5.3. A component X is processed in only one of the Steps 3 or 5. Step 5.2 ensures that all tricomponents T are pairwise disjoint (property (ii) of the definition of tricomponent cover). So a given edge is involved in only one recursive call in Step 5.3.

We conclude that e occurs in $\le a^p$ nodes τ of $\mathcal{R}$. (Since we're discussing $\mathcal{A}_p$ rather than $\mathcal{A}_{p+1}$, we reduce p in the pseudocode of section 3 by 1; e.g., Step 0 guarantees that $\rho \le a^p$.)

In each such node τ, e occurs in $\le g \le a^p$ graphs for calls to $\mathcal{A}_{p-1}$ in Steps 1 and 2.1. This follows since each pass of Step 2.1 except the last enlarges C, and e belongs to ≤ 1 graph per pass. We conclude that e occurs in at most $a^p \times a^p = a^{2p}$ calls from this invocation of $\mathcal{A}_p$ to $\mathcal{A}_{p-1}$.

Any routine $\mathcal{A}_p$ has $a \le a^*$, $p \le p^*$. So overestimating, edge e is in the initial graph of $\le ((a^*)^{2(p^*)})^i$ recursion trees for routine $\mathcal{A}_{p^*-i}$, for any $0 \le i < p^*$. In each of these recursion trees, we have already noted that e occurs in $\le (a^*)^{p^*}$ nodes. This gives a total of $\le (a^*)^{2p^*i} \times (a^*)^{p^*} \le (a^*)^{2p^*(i+1)}$ nodes in recursion trees for calls to $\mathcal{A}_{p^*-i}$.

Summing for i going from 0 to $p^* - 1$, we have shown that e occurs in a total of $\le p^*(a^*)^{2(p^*)^2}$ nodes (i.e., recursive invocations). Using $p^* \le \log n$ and (10), this bound is polynomial (in fact sublinear), as desired. ∎

6. Conclusions. Despite many levels of recursion, we leave the long cycle problem with a large gap between our guaranteed length bound (which is a cycle of length $\exp(\Omega(\sqrt{\log \ell / \log\log \ell}))$) and the best-known hardness result (the quasi-NP-hardness of a factor $2^{O(\log^{1-\epsilon} n)}$ approximation to the longest path).

Since the initial appearance of this paper [10] some surprising progress has been made. Feder and Motwani [7] have shown how to find a cycle whose length is

$\exp(\Omega(\log n/\log\log n))$ in Hamiltonian graphs, in time $O(n^3)$. Their results also improve our length guarantee in graphs that are very close to Hamiltonian ($\ell \geq n/\exp(o(\sqrt{\log n \log\log n}))$) as well as in some other cases. Their algorithm, like ours, combines two recursively found paths through tricomponents, using the algorithm of [14] for a cycle through three given vertices. In addition, they use a variety of other new ideas, starting with a result of Chen, Xu, and Yu [6]: in a 3-connected graph of maximum degree d, a cycle of length $\geq n^{\log_b 2}$ exists and can be found efficiently, for $b = 2(d-1)^2 + 1$.

Abstract. We develop an optimal cache-oblivious priority queue data structure, supporting insertion, deletion, and delete-min operations in $O(\frac{1}{B}\log_{M/B}\frac{N}{B})$ amortized memory transfers, where M and B are the memory and block transfer sizes of any two consecutive levels of a multilevel memory hierarchy. In a cache-oblivious data structure, M and B are not used in the description of the structure. Our structure is as efficient as several previously developed external memory (cache-aware) priority queue data structures, which all rely crucially on knowledge about M and B. Priority queues are a critical component in many of the best known external memory graph algorithms, and using our cache-oblivious priority queue we develop several cache-oblivious graph algorithms.

Key words. cache-oblivious algorithms, priority queue

1. Introduction.

As the memory systems of modern computers become more complex, it is increasingly important to design algorithms that are sensitive to the structure of memory. One of the characteristic features of modern memory systems is that they are made up of a hierarchy of several levels of cache, main memory, and disk. While traditional theoretical computational models have assumed a "flat" memory with uniform access time, the access times of different levels of memory can vary by several orders of magnitude in current machines. Thus algorithms for hierarchical memory have received considerable attention in recent years. Very recently, the *cache-oblivious* model was introduced as a way of achieving algorithms that are efficient in arbitrary memory hierarchies without the use of complicated multilevel memory models. In this paper we develop an optimal cache-oblivious priority queue and use it to develop several cache-oblivious graph algorithms.

1.1. Background and previous results. Traditionally, most algorithmic work has been done in the *random access machine* (RAM) model of computation, which models a "flat" memory with uniform access time. Recently, some attention has turned to the development of theoretical models and algorithms for modern complicated hierarchical memory systems; refer, e.g., to [3, 4, 5, 7, 53, 59]. Developing models that are both simple and realistic is a challenging task since a memory hierarchy is described by many parameters. A typical hierarchy consists of a number of memory levels, with memory level ℓ having size M_ℓ and being composed of M_ℓ/B_ℓ blocks of size B_ℓ. In any memory transfer from level ℓ to $\ell-1$, an entire block is moved atomically. Each memory level also has an associated *replacement strategy*, which is used to decide what block to remove in order to make room for a new block being brought into that level of the hierarchy. Further complications are the limited *associativity* of some levels of the hierarchy, meaning that a given block can only be loaded into a limited number of memory positions, as well as the complicated *prefetching strategies* employed by many memory systems. In order to avoid the complications of multilevel memory models, a body of work has focused on two-level memory hierarchies. Most of this work has been done in the context of problems involving massive datasets, because the extremely long access times of disks compared to the other levels of the hierarchy means that I/O between main memory and disk is often the bottleneck in such problems.

1.1.1. Two-level I/O model. In the two-level *I/O model* (or *external memory model*) introduced by Aggarwal and Vitter [6], the memory hierarchy consists of an internal memory of size M and an arbitrarily large external memory partitioned into blocks of size B. The efficiency of an algorithm in this model (a so-called *I/O* or *external memory* algorithm) is measured in terms of the number of block transfers it performs between these two levels (here called *memory transfers*). An algorithm has complete control over the placement of blocks in main memory and on disk. The simplicity of the I/O model has resulted in the development of a large number of external memory algorithms and techniques. See, e.g., [10, 59] for recent surveys.

The number of memory transfers needed to read N contiguous elements from disk is $scan(N) = \Theta(\frac{N}{B})$ (the *linear* or *scanning* bound). Aggarwal and Vitter [6] showed that $\Theta(\frac{N}{B}\log_{M/B}\frac{N}{B})$ memory transfers are necessary and sufficient to sort N elements. In this paper, we use $\mathrm{sort}(N)$ to denote $\frac{N}{B}\log_{M/B}\frac{N}{B}$ (the *sorting* bound). The number of memory transfers needed to search for an element among a set of N elements is $\Omega(\log_B N)$ (the *searching* bound), and this bound is matched by the B-tree, which also supports updates in $O(\log_B N)$ memory transfers [17, 36, 40, 39]. An important consequence of these bounds is that, unlike in the RAM model, one cannot sort optimally with a search tree—inserting N elements in a B-tree takes $O(N\log_B N)$ memory transfers, which is a factor of $(B\log_B N)/(\log_{M/B}\frac{N}{B})$ from optimal. Finally, permuting N elements according to a given permutation takes $\Theta(\min\{N, \mathrm{sort}(N)\})$ memory transfers, and for all practical values of N, M, and B this is $\Theta(\mathrm{sort}(N))$ [6]. This represents another fundamental difference between the RAM and I/O model, since N elements can be permuted in $O(N)$ time in the RAM model.

The I/O model can also be used to model the two-level hierarchy between cache and main memory; refer, e.g., to [54, 42, 44, 60, 50, 52]. Some of the main shortcomings of the I/O model on this level are the lack of explicit application control of placement of data in the cache and the low associativity of many caches. However, as demonstrated by Sen, Chatterjee, and Dumir [54], I/O model results can often be used to obtain results in more realistic two-level cache main memory models. Algorithms that are

efficient on the two-level cache main memory levels have also been considered by, e.g., LaMarca and Ladner [42, 43].

1.1.2. Cache-oblivious model. One of the main disadvantages of two-level memory models is that they force the algorithm designer to focus on a particular level of the hierarchy. Nevertheless, the I/O model has been widely used because it is convenient to consider only two levels of the hierarchy. Very recently, a new model that combines the simplicity of the I/O mode with the realism of more complicated hierarchical models was introduced by Frigo et al. [38]. The idea in the *cache-oblivious model* is to design and analyze algorithms in the I/O model but without using the parameters M and B in the algorithm description. It is assumed that when an algorithm accesses an element that is not stored in main memory, the relevant block is automatically fetched into memory with a *memory transfer*. If the main memory is full, the *ideal* block in main memory is elected for replacement based on the future characteristics of the algorithm; that is, an *optimal* offline paging strategy is assumed. While this model may seem unrealistic, Frigo et al. [38] showed that it can be simulated by essentially any memory system with only a small constant-factor overhead. For example, the least recently used (LRU) block-replacement strategy approximates the omniscient strategy within a constant factor, given a cache larger by a constant factor [38, 55]. The main advantage of the cache-oblivious model is that it allows us to reason about a simple two-level memory model, but prove results about an unknown, multilevel memory hierarchy; because an analysis of an algorithm in the two-level model holds for any block and main memory size, it holds for *any* level of the memory hierarchy. As a consequence, if the algorithm is optimal in the two-level model, it is optimal on *all* levels of a multilevel memory hierarchy.

Frigo et al. [38] developed optimal cache-oblivious algorithms for matrix multiplication, matrix transposition, fast Fourier transform, and sorting. Subsequently, several authors developed dynamic cache-oblivious B-trees with a search and update cost of $O(\log_B N)$ matching the standard (cache-aware) B-tree [21, 27, 22, 49, 20]. Recently, several further results have been obtained, e.g., [23, 57, 24, 25, 26, 18, 2, 14, 16, 19, 28, 33]. See also the survey in [13]. Some of these results assume that $M \geq B^2$ (the *tall-cache* assumption), and we will also make that assumption in this paper. Brodal and Fagerberg [26] showed that an assumption of this type (actually $M = \Omega(B^{1+\epsilon})$ for some $\epsilon > 0$) is necessary to obtain the I/O model sorting bound in the cache-oblivious model.

1.1.3. Priority queues. A priority queue maintains a set of elements each with a priority (or key) under *insert* and *delete-min* operations, where a delete-min operation finds and deletes the element with the minimum key in the queue. Sometimes *delete* of an arbitrary element is also supported, often, as in this paper, assuming that the key of the element to be deleted is known. The heap is a standard implementation of a priority queue, and a balanced search tree can, of course, also easily be used to implement a priority queue. In the I/O model, a priority queue based on a B-tree would support all operations in $O(\log_B N)$ memory transfers. The standard heap can also be easily modified (to have fanout B) so that all operations are supported in the same bound (see, e.g., [44]). The existence of a cache-oblivious B-tree immediately implies the existence of an $O(\log_B N)$ cache-oblivious priority queue.

As discussed in section 1.1.1, the use of an $O(\log_B N)$ search tree (or priority queue) to sort N elements results in an I/O model algorithm that is a factor of $(B \log_B N)/(\log_{M/B}(N/B))$ from optimal. To sort optimally we need a data structure

supporting the relevant operations in $O(\frac{1}{B}\log_{M/B}\frac{N}{B})$ memory transfers. Note that for reasonable values of N, M, and B, this bound is less than 1 and we can, therefore, only obtain it in an amortized sense. To obtain such a bound, Arge developed the *buffer tree technique* and showed how it can be used on a B-tree to obtain a priority queue supporting all operations in $O(\frac{1}{B}\log_{M/B}\frac{N}{B})$ amortized memory transfers [11]. This structure seems hard to make cache-oblivious since it involves periodically finding the $\Theta(M)$ smallest key elements in the structure and storing them in internal memory. Efficient I/O model priority queues have also been obtained by using the buffer tree technique on heap structures [37, 41]. The heap structure by Fadel et al. [37] seems hard to make cache-oblivious because it requires collecting $\Theta(M)$ insertions and performing them all on the structure at the same time. The structure by Kumar and Schwabe [41] avoids this by using the buffer technique on a tournament tree data structure. However, they only obtained $O(\frac{1}{B}\log_2 N)$ bounds, mainly because their structure was designed to also support an *update* operation. Finally, Brodal and Katajainen [29] developed a priority queue structure based on an M/B-way merging scheme. Very recently, and after the appearance of the conference version of this paper, Brodal and Fagerberg [25] managed to develop a similar merging based cache-oblivious priority queue based on ideas they developed in [24]. Brodal et al. [28], as well as Chowdhury and Ramachandran [33], have also developed cache-oblivious priority queues that support updates in the same bound as the I/O-efficient structure of Kumar and Schwabe [41].

1.1.4. I/O model graph algorithms. The superlinear lower bound on permutation in the I/O model has important consequences for the I/O complexity of graph algorithms, because the solution of almost any graph problem involves somehow permuting the V vertices or E edges of the graph. Thus $\Omega(\min\{V, \text{sort}(V)\})$ is in general a lower bound on the number of memory transfers needed to solve most graph problems. Refer to [9, 31, 46]. As mentioned in section 1.1.1, this bound is $\Omega(\text{sort}(V))$ in all practical cases. Still, even though a large number of I/O model graph algorithms have been developed (see [59, 61] and references therein), not many algorithms match this bound. Below we review the results most relevant to our work.

As with PRAM graph algorithms [51], list ranking—the problem of ranking the elements in a linked list stored as an unordered sequence in memory—is the most fundamental I/O model graph problem. Using PRAM techniques, Chiang et al. [31] developed the first efficient I/O model list ranking algorithm. Using an I/O-efficient priority queue, Arge [11] showed how to solve the problem in $O(\text{sort}(V))$ memory transfers. The list ranking algorithm and PRAM techniques can be used in the development of $O(\text{sort}(V))$ algorithms for many problems on trees, such as computing an Euler tour, breadth-first search (BFS), depth-first search (DFS), and centroid decomposition [31]. The best known DFS and BFS algorithms for general directed graphs use $O(V + \frac{EV}{BM})$ [31] or $O((V + E/B)\log_2 V + \text{sort}(E))$ [30] memory transfers. For undirected graphs, improved $O(V + \text{sort}(E))$ and $O(\sqrt{\frac{V \cdot E}{B}} + \text{sort}(E))$ BFS algorithms have been developed [46, 45]. The best known algorithms for computing the connected components and the minimum spanning forest of a general undirected graph both use $O(\text{sort}(E) \cdot \log_2 \log_2(\frac{VB}{E}))$ or $O(V + \text{sort}(E))$ memory transfers [46, 15].

1.2. Our results. The main result of this paper is an optimal cache-oblivious priority queue. Our structure supports insert, delete, and delete-min operations in $O(\frac{1}{B}\log_{M/B}\frac{N}{B})$ amortized memory transfers and $O(\log N)$ amortized computation time; it is described in section 2. The structure is based on a combination of several

TABLE 1.1
Summary of our results (priority queue bounds are amortized).

Problem	Our cache-oblivious result	Best cache-aware result	
Priority queue	$O(\frac{1}{B}\log_{M/B}\frac{N}{B})$	$O(\frac{1}{B}\log_{M/B}\frac{N}{B})$	[11]
List ranking	$O(\text{sort}(V))$	$O(\text{sort}(V))$	[31, 11]
Tree algorithms	$O(\text{sort}(V))$	$O(\text{sort}(V))$	[31]
Directed BFS and DFS	$O((V+E/B)\log_2 V + \text{sort}(E))$	$O((V+E/B)\log_2 V + \text{sort}(E))$	[30]
		$O(V + \frac{EV}{BM})$	[31]
Undirected BFS	$O(V + \text{sort}(E))$	$O(V + \text{sort}(E))$	[46]
		$O(\sqrt{\frac{V\cdot E}{B}} + \text{sort}(E))$	[45]
MSF	$O(\text{sort}(E)\cdot\log_2\log_2 V)$	$O(\text{sort}(E)\cdot\log_2\log_2\frac{VB}{E})$	[15]
	$O(V + \text{sort}(E))$	$O(V + \text{sort}(E))$	[15]

new ideas with ideas used in previous recursively defined cache-oblivious algorithms and data structures [38, 21], the buffer technique of Arge [11, 41], and the M/B-way merging scheme utilized by Brodal and Katajainen [29]. When the conference version of this paper appeared, our structure was the only cache-oblivious priority queue to obtain the same bounds as in the cache-aware case.

In the second part of the paper, section 3, we use our priority queue to develop several cache-oblivious graph algorithms. We first show how to solve the list ranking problem in $O(\text{sort}(V))$ memory transfers. Using this result we develop $O(\text{sort}(V))$ algorithms for fundamental problems on trees, such as the Euler tour, BFS, and DFS problems. The complexity of all of these algorithms matches the complexity of the best known cache-aware algorithms. Next we consider DFS and BFS on general graphs. Using modified versions of the data structures used in the $O((V + E/B)\log_2 V + \text{sort}(E))$ DFS and BFS algorithms for directed graphs [30], we make these algorithms cache-oblivious. We also discuss how the $O(V+\text{sort}(E))$ BFS algorithm for undirected graphs [46] can be made cache-oblivious. Very recently, and after the appearance of the conference version of this paper, Brodal et al. [28] developed two other cache-oblivious algorithms for undirected BFS based on the ideas in [45]. Finally, we develop two cache-oblivious algorithms for computing a minimum spanning forest (MSF), and thus also for computing connected components, of an undirected graph using $O(\text{sort}(E)\cdot\log_2\log_2 V)$ and $O(V + \text{sort}(E))$ memory transfers, respectively. The two algorithms can be combined to compute the MSF in $O(\text{sort}(E)\cdot\log_2\log_2\frac{V}{V'} + V')$ memory transfers for any V' independent of B and M. Table 1.1 summarizes our results. Note that, recently, cache-oblivious algorithms for undirected shortest path computation have also been developed [28, 33].

2. Priority queue. In this section we describe our optimal cache-oblivious priority queue. In section 2.1 we define the data structure and in section 2.2 we describe the supported operations.

2.1. Structure.

2.1.1. Levels. Our priority queue data structure containing N elements consists of $\Theta(\log\log N_0)$ *levels* whose sizes vary from $N_0 = \Theta(N)$ to some small size $c > 1$ beneath a constant threshold c_t. The size of a level corresponds (asymptotically) to the number of elements that can be stored within it. The ith level from above has size

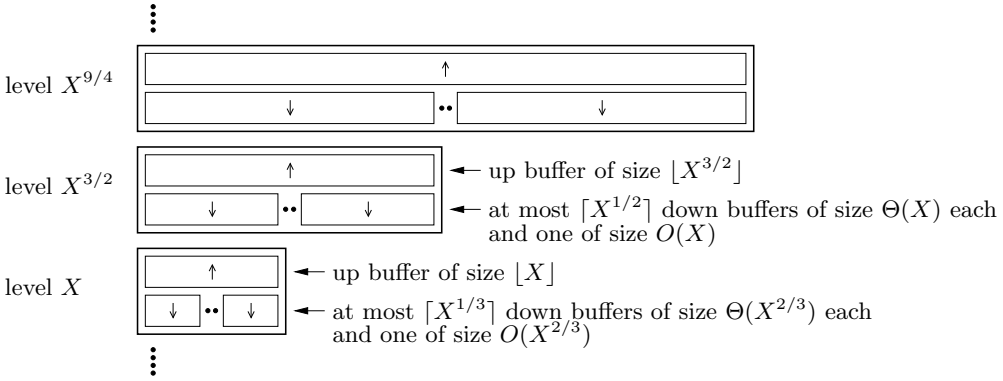

FIG. 2.1. *Levels X, $X^{3/2}$, and $X^{9/4}$ of the priority queue data structure.*

$N_0^{(2/3)^{i-1}}$, and for convenience we refer to the levels by their size. Thus the levels from largest to smallest are level N_0, level $N_0^{2/3}$, level $N_0^{4/9}$, ..., level $X^{9/4}$, level $X^{3/2}$, level X, level $X^{2/3}$, level $X^{4/9}$, ..., level $c^{9/4}$, level $c^{3/2}$, and level c. Intuitively, smaller levels store elements with smaller keys or elements that were recently inserted. In particular, the element with minimum key and the most recently inserted element in the structure are in the smallest (lowest) level c. Both insertions and deletions are initially performed on the smallest level and may propagate up through the levels.

2.1.2. Buffers. A level stores elements in a number of *buffers*, which are also used to transfer elements between levels. Refer to Figure 2.1. Level $X^{3/2}$ consists of one *up buffer* $u^{X^{3/2}}$ and at most $\lceil X^{1/2} \rceil + 1$ *down buffers* $d_1^{X^{3/2}}, \ldots, d_{\lceil X^{1/2} \rceil + 1}^{X^{3/2}}$. The up buffer can store up to $\lfloor X^{3/2} \rfloor$ elements and the first down buffer can store up to $2\lfloor X \rfloor - 1$ elements, while each of the other down buffers can store between $\lfloor X \rfloor$ and $2\lfloor X \rfloor - 1$ elements. We refer to the maximum possible number of elements that can be stored in a buffer or level as its *size*; we refer to the number of elements currently in a buffer or level as the *occupancy*. Thus the size of level $X^{3/2}$ is $\Theta(X^{3/2})$. Note that the size of a down buffer at one level matches the size (up to a constant factor) of the up buffer one level down.

We maintain three invariants about the relationships between the elements in buffers of various levels.

INVARIANT 1. *At level $X^{3/2}$, elements are sorted* among *the down buffers, that is, elements in $d_i^{X^{3/2}}$ have smaller keys than elements in $d_{i+1}^{X^{3/2}}$, but the elements within $d_i^{X^{3/2}}$ are unordered.*

The element with largest key in each down buffer $d_i^{X^{3/2}}$ is called a *pivot element*. Pivot elements mark the boundaries between the ranges of the keys of elements in down buffers.

INVARIANT 2. *At level $X^{3/2}$, elements in the down buffers have smaller keys than the elements in the up buffer $u^{X^{3/2}}$.*

INVARIANT 3. *The elements in the down buffers at level $X^{3/2}$ have smaller keys than the elements in the down buffers at the next higher level $X^{9/4}$.*

The three invariants ensure that the keys of the elements in the down buffers get larger as we go from smaller to larger levels of the structure. Furthermore, there is an order between the buffers on one level; keys of elements in the up buffer are larger than keys of elements in down buffers. Therefore, down buffers are drawn below up

buffers in Figure 2.1. However, the keys of the elements in an up buffer are unordered relative to the keys of the elements in down buffers one level up. Intuitively, up buffers store elements that are "on their way up"; that is, they have yet to be resolved as belonging to a particular down buffer in the next (or higher) level. Analogously, down buffers store elements that are "on their way down"—these elements are partitioned into several clusters so that we can quickly find the cluster of elements with smallest keys of size roughly equal to the next level down. In particular, the first down buffer of level X contains the smallest element in level X and higher levels.

2.1.3. Layout. We store the priority queue in a linear array as follows. The levels are stored consecutively from smallest to largest with each level occupying a single region of memory. For level $X^{3/2}$ we reserve space for the up buffers of size $\lfloor X^{3/2} \rfloor$ and for $\lceil X^{1/2} \rceil + 1$ possible down buffers of size $2\lfloor X \rfloor$. The up buffer is stored first, followed by the down buffers stored in an arbitrary order but linked together to form an ordered linked list. Thus the total size of the array is $\sum_{i=0}^{\log_{3/2} \log_c N_0} O(N_0^{(2/3)^i}) = O(N_0)$.

2.2. Operations. To implement the priority queue operations we will use two general operations, *push* and *pull*. Push inserts $\lfloor X \rfloor$ elements (with larger keys than all elements in the down buffers of level X) into level $X^{3/2}$, and pull removes and returns the $\lfloor X \rfloor$ elements with smallest keys from level $X^{3/2}$ (and above). Generally, whenever an up buffer on level X overflows we push the $\lfloor X \rfloor$ elements in the buffer into level $X^{3/2}$, and whenever the down buffers on level X become too empty we pull $\lfloor X \rfloor$ elements from level $X^{3/2}$. In sections 2.2.1 and 2.2.2 below, the push and pull operations are described in detail. Note that we will assume that we never push elements from level N_0 and that we never try to pull more elements from level N_0 than it contains, that is, that level N_0 never runs full or empty. As described in section 2.2.3, we will ensure this by periodically rebuilding the entire structure.

2.2.1. Push. We push $\lfloor X \rfloor$ elements (with larger keys than all elements in the down buffers of level X) into level $X^{3/2}$ as follows: We first sort the elements. Then we distribute them into the down buffers of level $X^{3/2}$ by scanning through the sorted list and simultaneously visiting the down buffers in (linked) order. More precisely, we append elements to the end of the current down buffer $d_i^{X^{3/2}}$, and advance to the next down buffer $d_{i+1}^{X^{3/2}}$ as soon as we encounter an element with larger keys than the pivot of $d_i^{X^{3/2}}$. Elements with larger keys than the pivot of the last down buffer are inserted in the up buffer $u^{X^{3/2}}$. During the distribution of elements a down buffer may become overfull, that is, contain $2\lfloor X \rfloor$ elements. In this case, we split the buffer into two down buffers each containing $\lfloor X \rfloor$ elements. If the level has at most $\lceil X^{1/2} \rceil + 1$ down buffers after the split, we place the new buffer in any free down-buffer spot for the level and update the linked list accordingly. Otherwise, we first remove the last down buffer by moving its at most $2\lfloor X \rfloor - 1$ elements into the up buffer; then we place the new buffer in the free down-buffer spot and update the linked list. If the up buffer runs full during the process, that is, contains more than $\lfloor X^{3/2} \rfloor$ elements, we recursively push $\lfloor X^{3/2} \rfloor$ elements into level $X^{9/4}$ (the next level up), leaving at most $\lfloor X^{3/2} \rfloor$ elements in the up buffer.

The invariants are all maintained during a push of $\lfloor X \rfloor$ elements into level $X^{3/2}$. Because we sort the elements to distribute them among the down buffers, it is clear we maintain Invariant 1. Only elements with keys larger than the pivot of the last down buffer are placed in the up buffer, so Invariant 2 is also maintained. Finally, Invariant 3 is maintained since (by definition) the $\lfloor X \rfloor$ elements all have keys larger than the

elements in the down buffers of level X, and since by Invariant 2 all recursively pushed elements have keys larger than all elements in the down buffers (as required to perform the recursive push).

Ignoring the cost of recursive push operations, a push of $\lfloor X \rfloor$ elements into level $X^{3/2}$ can be performed cache-obliviously in $O(\frac{X}{B} \log_{M/B} \frac{X}{B})$ memory transfers and $O(X \log_2 X)$ time using $O(M)$ of main memory. First note that since $M = \Omega(B^2)$ (the tall-cache assumption), all levels of size less than B^2 (of total size $O(B^2)$) fit in memory. If all these levels are kept in main memory at all times, all push costs associated with them would be eliminated. The optimal paging strategy is able to do so. Thus we only need to consider push costs when $X^{3/2} > B^2$, that is, when $X > B^{4/3}$ (note that in that case $\frac{X}{B} > 1$). When performing the push operation, the initial sort of the $\lfloor X \rfloor$ elements can then be performed cache-obliviously using $O(\frac{X}{B} \log_{M/B} \frac{X}{B})$ memory transfers and $O(X \log_2 X)$ time [38]. The scan of the elements in the distribution step then takes $O(X/B)$ memory transfers and $O(X)$ time. However, even though we do not insert elements in every down buffer, we still might perform a memory transfer for each of the $\lceil X^{1/2} \rceil + 1$ possible buffers; a block of each buffer may have to be loaded and written back without transferring a full block of elements into the buffer. If $X \geq B^2$, we trivially have that $\lceil X^{1/2} \rceil + 1 = O(\frac{X}{B})$. If, on the other hand, $B^{4/3} < X < B^2$, the $\lceil X^{1/2} \rceil + 1$ term can dominate the memory transfer bound and we have to analyze the cost more carefully. In this case we are working on a level $X^{3/2}$ where $B^2 < X^{3/2} < B^3$. There is only one such level and because $X^{1/2} < B$ and $M = \Omega(B^2)$ (the tall-cache assumption), a block for each of its down buffers can fit into main memory. Consequently, if a fraction of the main memory is used to keep a partially filled block of each buffer of level $X^{3/2}$ ($B^2 \leq X^{3/2} \leq B^3$) in memory at all times, and full blocks are written to disk, the $X^{1/2} + 1$ cost is eliminated at this level. The optimal paging strategy is able to do so. Thus the total cost of distributing the $\lfloor X \rfloor$ elements is $O(X/B)$ memory transfers and $O(X + X^{1/2}) = O(X)$ time.

The split of an overfull down buffer during the distribution, that is, split of a buffer of occupancy $2\lfloor X \rfloor$, can be performed in $O(X/B)$ memory transfers and $O(X)$ time by first finding the median of the elements in the buffer in $O(X/B)$ transfers and $O(X)$ time [38], and then partitioning the elements into the two new buffers of occupancy $\lfloor X \rfloor$ in a simple scan. Since we maintain that any new down buffer has occupancy $\lfloor X \rfloor$, and thus that $\lfloor X \rfloor$ elements have to be inserted in it before it splits, the amortized splitting cost per element is $O(1/B)$ transfers and $O(1)$ time. Thus, in total, the amortized number of memory transfers and time used on splitting buffers while distributing the $\lfloor X \rfloor$ elements are $O(X/B)$ and $O(X)$, respectively.

LEMMA 2.1. *Using $O(M)$ main memory, a push of $\lfloor X \rfloor$ elements into level $X^{3/2}$ can be performed in $O(\frac{X}{B} \log_{M/B} \frac{X}{B})$ memory transfers and $O(X \log_2 X)$ amortized time, not counting the cost of any recursive push operations, while maintaining Invariants* 1–3.

2.2.2. Pull. To pull the $\lfloor X \rfloor$ elements with smallest keys from level $X^{3/2}$ (and above), we consider three different cases.

If the occupancy of the first down buffer of level $X^{3/2}$ is $Y \geq \lfloor X \rfloor$, we sort the $Y < 2\lfloor X \rfloor$ elements in the down buffer, remove the $\lfloor X \rfloor$ elements with smallest keys, and leave the remaining $Y - \lfloor X \rfloor$ elements in the buffer. We return the $\lfloor X \rfloor$ removed elements, since by Invariants 1–3 they are the elements with smallest keys in level $X^{3/2}$ (and above). It is easy to see that Invariants 1–3 are maintained is this case.

If the occupancy of the first down buffer of level $X^{3/2}$ is $Y < \lfloor X \rfloor$ but level $X^{3/2}$ has at least one other down buffer, we first remove the Y elements in the first buffer.

Next we sort the between $\lfloor X \rfloor$ and $2\lfloor X \rfloor - 1$ elements in the new first down buffer, remove the $\lfloor X \rfloor - Y$ elements with smallest keys, and leave the remaining elements in the buffer. We return the $\lfloor X \rfloor$ removed elements, since by Invariants 1–3 they are the elements with smallest keys in level $X^{3/2}$ (and above). As in the first case, it is easy to see that Invariants 1–3 are maintained.

Finally, if the occupancy of the first down buffer of level $X^{3/2}$ is $Y < \lfloor X \rfloor$ and level $X^{3/2}$ has no other down buffers, we remove the Y elements and then we recursively pull the $\lfloor X^{3/2} \rfloor$ elements with smallest keys from level $X^{9/4}$ (and above). Because these $\lfloor X^{3/2} \rfloor$ elements do not necessarily have smaller keys than the U elements in the up buffer $u^{X^{3/2}}$, we then sort all the $\lfloor X^{3/2} \rfloor + U \leq 2\lfloor X^{3/2} \rfloor$ elements, insert the U elements with largest keys in the up buffer, and remove the $\lfloor X \rfloor - Y$ elements with smallest keys. Finally, we distribute the remaining $\lfloor X^{3/2} \rfloor + Y - \lfloor X \rfloor < \lfloor X^{3/2} \rfloor \leq X \cdot X^{1/2} \leq (\lfloor X \rfloor + 1) \cdot X^{1/2} = \lfloor X \rfloor \cdot X^{1/2} + X^{1/2} \leq \lfloor X \rfloor \cdot \lceil X^{1/2} \rceil + \lfloor X \rfloor$ sorted elements into one down buffer with occupancy between 1 and $\lfloor X \rfloor$ and at most $\lceil X^{1/2} \rceil$ down buffers of occupancy $\lfloor X \rfloor$ each. As in the first two cases, we return the $\lfloor X \rfloor$ removed elements, since Invariant 1 and the sorting of the recursively pulled elements and the elements in the up buffer ensure that they are the elements with the smallest keys in level $X^{3/2}$ (and above). As in the first two cases, it is relatively easy to see that Invariants 1–3 are also maintained in this case: Invariant 1 is fulfilled since we place elements in down buffers in sorted order, Invariant 2 is fulfilled since we explicitly place the U elements (among the original U elements and the $\lfloor X^{3/2} \rfloor$ recursively pulled elements) with largest keys in the up buffer, and Invariant 3 is fulfilled since all the elements we place in down buffers have smaller keys than elements in level $X^{9/4}$.

To analyze a pull operation we assume, as in the push case, that all levels of size $O(B^2)$ are kept in main memory (so that we only need to consider levels $X^{3/2}$ with $X^{3/2} > B^2$, that is, the case where $X > B^{4/3}$). The first two cases are both performed by sorting and scanning $O(X)$ elements using $O(\frac{X}{B} \log_{M/B} \frac{X}{B}) + O(\frac{X}{B})$ memory transfers and $O(X \log_2 X) + O(X)$ time. In the third case we also sort and scan (distribute) $O(X^{3/2})$ elements. However, the cost of doing so is dominated by the cost of the recursive pull operation itself. Thus, ignoring these costs (charging them to the recursive pull), we have the following lemma.

LEMMA 2.2. *Using $O(M)$ main memory, a pull of $\lfloor X \rfloor$ elements from level $X^{3/2}$ can be performed in $O(\frac{X}{B} \log_{M/B} \frac{X}{B})$ memory transfers and $O(X \log_2 X)$ amortized time, not counting the cost of any recursive pull operations, while maintaining Invariants* 1–3.

2.2.3. Insert and delete-min. To support insert and delete-min operations using push and pull on our structure we (or rather, the optimal paging strategy does) maintain an insertion and a deletion buffer of at most $\lfloor c^{2/3} \rfloor$ elements each in main memory. The deletion buffer contains elements that have smaller keys than all other elements in the structure, while intuitively the insertion buffer contains the most recently inserted elements. We perform an insertion simply by comparing the key of the element to be inserted with the maximal key of an element in the deletion buffer: if the key of the new element is largest, we simply insert it into the insertion buffer; otherwise we insert it into the deletion buffer and move the element with largest key from the deletion buffer to the insertion buffer. In both cases, the occupancy of the insertion buffer is increased by one, and if it runs full we empty it by pushing its $\lfloor c^{2/3} \rfloor$ elements into level c. Similarly, we perform a delete-min by deleting and returning the element with smallest key in the deletion buffer; if the deletion buffer becomes

empty, we pull $\lfloor c^{2/3} \rfloor$ elements from level c and fill up the deletion buffer with the $\lfloor c^{2/3} \rfloor$ smallest of these elements and the elements in the insertion buffer (without changing the occupancy of the insertion buffer). The correctness of the insert and delete-min operations follows directly from Invariants 1–3 and the definition of the push and pull operations.

Except for the possible push and pull operations on level c, which may require recursive pushes or pulls on higher levels, the insert and delete-min operations are performed in constant time without incurring any memory transfers. Below we will use a credit argument to prove that including all push and pull operations the amortized cost of an insert or delete-min is $O(\frac{1}{B} \log_{M/B} \frac{N_0}{B})$ memory transfers; then we will argue that the operations take $O(\log_2 N_0)$ amortized computation time.

We define a *level-X push coin* as well as a *level-$X^{3/2}$ pull coin* to be worth $\Theta(\frac{1}{B} \log_{M/B} \frac{X}{B})$ memory transfers each, that is, $\lfloor X \rfloor$ level-X push coins can pay for a push of $\lfloor X \rfloor$ elements into level $X^{3/2}$, and $\lfloor X \rfloor$ level-$X^{3/2}$ coins can pay for a pull of $\lfloor X \rfloor$ elements from level $X^{3/2}$. We maintain the following *coin invariants*.

INVARIANT 4. *On level $X^{3/2}$, each element in the first half of a down buffer has a pull coin for level $X^{3/2}$ and each level below.*

INVARIANT 5. *On level $X^{3/2}$, each element in the second half of a down buffer and in the up buffer has a push coin for level $X^{3/2}$ and each level above, as well as pull coins for all levels.*

INVARIANT 6. *Each element in the insertion buffer has a push and a pull coin for each level.*

Intuitively, the first two coin invariants mean that an element in the first half of a down buffer can pay for being pulled down through all lower levels, while elements in the second half of a down buffer and in an up buffer can pay for being pushed up through all higher levels and pulled down through all levels.

To fulfill Invariant 6, we simply have to give each inserted element a push and a pull coin for each level, since an insert operation increases the occupancy of the insertion buffer by one and a delete-min does not change the occupancy. We will show that we can then pay for all recursive push and pull operations with released coins while maintaining Invariants 4 and 5. Thus a delete-min is free amortized and an insertion costs $O(\sum_{i=0}^{\infty} \frac{1}{B} \log_{M/B}(N_0^{(2/3)^i}/B)) = O(\frac{1}{B} \log_{M/B} \frac{N_0}{B})$ amortized memory transfers.

First consider an insertion that results in a sequence of push operations. We will show that we can maintain the coin invariants while paying for each push operation with released coins, if we require that when pushing $\lfloor X \rfloor$ elements into level $X^{3/2}$, each of the pushed elements has a push coin for level X and each level above, as well as a pull coin for all levels (the *push requirement*). Note that Invariants 5 and 6 ensure that the push requirement is fulfilled, since the pushed elements come from the insertion buffer or the up buffer of level X.

When performing a push on level $X^{3/2}$ we first distribute the $\lfloor X \rfloor$ elements into the down and the up buffers. In the worst case (when all elements are placed in the second half of a down buffer or in the up buffer) each element needs a push coin for level $X^{3/2}$ and each level above and pull coins for all levels to fulfill Invariants 4 and 5. Since they have a push coin for level X and each level above and pull coins for all levels, this leaves us with $\lfloor X \rfloor$ level-X push coins, which we can use to pay the $O(\frac{X}{B} \log_{M/B} \frac{X}{B})$ push cost (Lemma 2.1). If a down buffer of occupancy $2\lfloor X \rfloor$ splits into two buffers of occupancy $\lfloor X \rfloor$ during the distribution process, $\lfloor X \rfloor$ push coins for level $X^{3/2}$ and each level above and $\lfloor X \rfloor$ pull coins for level $X^{9/4}$ and each level above

are released, since the $\lfloor X \rfloor$ elements in the second half of the full buffer must fulfill Invariant 5 before the split but only Invariant 4 after the split. On the other hand, if splitting a down buffer results in the movement of the elements in the last down buffer to the up buffer, the at most $\lfloor X \rfloor$ elements in the first half of the down buffer need $\lfloor X \rfloor$ push coins for level $X^{3/2}$ and each level above and $\lfloor X \rfloor$ pull coins for level $X^{9/4}$ and each level above, since they must fulfill Invariant 5 after the move but only Invariant 4 before the move. Since we never move elements from a down buffer to the up buffer without having split a down buffer, we can reestablish Invariants 4 and 5 with the released coins. Finally, as mentioned above, if the up buffer runs full and we perform a recursive push of $\lfloor X^{3/2} \rfloor$ elements into level $X^{9/4}$, each of the pushed elements has a push coin for level $X^{3/2}$ and each level above, as well as pull coins for all levels, as required (Invariant 5).

Next consider a delete-min that results in a sequence of pull operations. We will show that we can maintain the coin invariants while paying for each pull operation with released coins, if we require that when pulling $\lfloor X \rfloor$ elements from level $X^{3/2}$ down to level X, each of the pulled elements has a pull coin for level X and each level below (the *pull requirement*).

When performing a pull on level $X^{3/2}$ with at least $\lfloor X \rfloor$ elements in the down buffers (the first two cases), we effectively remove the $\lfloor X \rfloor$ smallest elements from the first two down buffers. It is straightforward to see that the remaining elements still fulfill Invariants 4 and 5. From Invariants 4 and 5 we know that each of the removed (pulled) elements (at least) has a pull coin for level $X^{3/2}$ and each level below. Thus, since they only need a pull coin for level X and each level below to fulfill the pull requirement, this leaves us with $\lfloor X \rfloor$ level-$X^{3/2}$ pull coins, which we can use to pay the $O(\frac{X}{B} \log_{M/B} \frac{X}{B})$ pull cost (Lemma 2.2). If, on the other hand, level $X^{3/2}$ contains $Y < \lfloor X \rfloor$ elements in the down buffers (the third case), we perform a recursive pull of $\lfloor X^{3/2} \rfloor$ elements from level $X^{9/4}$, and effectively remove the $\lfloor X \rfloor$ elements with smallest keys among the $\lfloor X^{3/2} \rfloor + Y$ elements. Before the recursive pull, level $X^{3/2}$ has one down buffer with Y elements and an up buffer with U elements; after the recursive pull and removal of the $\lfloor X \rfloor$ elements, it has one down buffer with fewer than $\lfloor X \rfloor$ elements, at most $\lceil X^{1/2} \rceil$ down buffers with $\lfloor X \rfloor$ elements, and an up buffer with U elements. The coins on the U elements in the up buffer before the recursive pull can be used to fulfill Invariant 5 for the U elements in the up buffer after the recursive pull. By the pull requirement, each of the $\lfloor X^{3/2} \rfloor$ pulled elements has a pull coin for level $X^{3/2}$ and each level below. The same is true for each of the Y original elements (Invariant 4). Thus we have enough coins for all the elements in the down buffers after the pull, since each down buffer contains at most $\lfloor X \rfloor$ elements and each element therefore only needs to fulfill Invariant 4. Similarly, since each of the $\lfloor X \rfloor$ removed (pulled) elements only needs a pull coin for level X and each level below to fulfill the pull requirement, the pull cost can (as in the first two cases) be payed by the remaining $\lfloor X \rfloor$ level-$X^{3/2}$ pull coins.

The above argument shows that all pushes and pulls can be paid if each inserted element is given a push and a pull coin for each level of the structure, that is, that a delete-min is free amortized and an insertion costs $O(\frac{1}{B} \log_{M/B} \frac{N_0}{B})$ amortized memory transfers. By a completely analogous argument, it is easy to see that the operations are performed in $O(\sum_{i=0}^{\infty} \log_2(N_0^{(2/3)^i})) = O(\log_2 N_0)$ amortized time.

Finally, to maintain that $N_0 = \Theta(N)$ we completely rebuild the structure bottom-up after every $N_0/4$ operations (often referred to as *global rebuilding* [47]). We choose the size N_0 of the largest level to be $2N$ and compute the largest value $c < c_t$ such

that $c^{(3/2)^i} = 2N$ for some integer i. Then we construct levels $c, c^{3/2}, \ldots, N_0^{2/3}$ such that all up buffers are empty and such that each level-$X^{3/2}$ has exactly $\lceil X^{1/2} \rceil$ down buffers of size $\lfloor X \rfloor$. The remaining elements are placed in level N_0 such that it has at most $\lceil N_0^{1/3} \rceil$ down buffers of size exactly $\lfloor N_0^{2/3} \rfloor$ and one of size less than $\lfloor N_0^{2/3} \rfloor$. We can easily perform the rebuilding in a sorting and a scanning step using a total of $O(\frac{N}{B} \log_{M/B} \frac{N}{B})$ memory transfers. At the same time, we can place pull coins on the elements in order to fulfill Invariant 4; no elements need to fulfill Invariant 5—in particular, no push coins are needed. The cost of these pull coins is bounded by the cost if all elements were placed in level N_0, that is, by $O(N_0 \cdot \sum_{i=1}^{\infty} \frac{1}{B} \log_{M/B}(N_0^{(2/3)^i}/B)) = O(\frac{N_0}{B} \log_{M/B} \frac{N_0}{B})$ memory transfers. Thus the rebuilding adds only $O(\frac{1}{B} \log_{M/B} \frac{N_0}{B})$ amortized transfers to the cost of an insert or delete-min operation. In the same way we can argue that it adds only $O(\log_2 N_0)$ amortized time per operation.

Since the up buffer of level N_0 is of size $\lfloor 2N \rfloor = 2N$ after the rebuilding, we will not need further levels during the next $N_0/4 = N/2$ operations (insertions). At the same time, the size N_0 of the largest level remains $\Theta(N)$ during the next $N/2$ operations (deletions). Thus the size of our structure remains linear in N and it supports insert and delete-min operations in $O(\frac{1}{B} \log_{M/B} \frac{N}{B})$ amortized memory transfers and $O(\log_2 N)$ amortized computation time.

LEMMA 2.3. *Using $O(M)$ main memory, a set of N elements can be maintained in a linear-space cache-oblivious priority queue data structure supporting each insert and delete-min operation in $O(\frac{1}{B} \log_{M/B} \frac{N}{B})$ amortized memory transfers and $O(\log_2 N)$ amortized computation time.*

2.2.4. Delete. Using standard techniques we can also easily support a delete operation in $O(\frac{1}{B} \log_{M/B} \frac{N}{B})$ memory transfers and $O(\log_2 N)$ amortized time, provided that we are given the id and key of the element to be deleted.

To perform a deletion, we simply insert a special delete element in the priority queue, with id and key equal to the element to be deleted. Furthermore, whenever two elements in the queue need to be compared (for example when sorting elements during push or pull operations) their keys are first compared; in case of equal keys their id's are then compared. When performing a delete-min we first remove the smallest key element from the deletion buffer in main memory. Then we consider the removed element and the new smallest key element in the deletion buffer: If the two elements have the same id's (which means that one of the elements is a special delete element) we also remove the new smallest key element (and delete both elements without reporting any of them). We repeat this process of looking at the two smallest key elements until they have different id's; in that case we return and delete the removed element. Finally, we modify the rebuilding algorithm (performed after every $N_0/4$ operations) to first remove all special delete elements and the elements they should delete, before choosing a new N_0 and building the new structure. We can easily do so in a simple sorting and scanning step without changing the asymptotic rebuilding cost, since the way we compare elements (keys) ensures that an element that should have been deleted and its corresponding special deletion element appear consecutively in the list of sorted elements. Note that this also means that the structure cannot contain more than a constant fraction of special elements and elements that should have been deleted (that is, N_0 is always $\Theta(N)$).

The correctness of the delete (and delete-min) operation(s) follows directly from the discussion in the previous subsection and the fact that if the smallest key element

in the deletion buffer should really have been deleted, then the elements and the corresponding special delete element will appear consecutively in the buffer. To analyze the modified structure, we first note that a delete operation basically behaves like an insertion. As previously, all pushes and pulls can therefore be paid if each special delete element is also given a push and a pull coin for each level of the structure. Thus the cost of an insertion or deletion is $O(\frac{1}{B}\log_{M/B}\frac{N}{B})$ amortized memory transfers. That the modified delete-min operation is free amortized then follows, since it basically consists of a sequence of the unmodified delete-min operations (where the deleted elements are not reported).

THEOREM 2.4. *Using $O(M)$ main memory, a set of N elements can be maintained in a linear-space cache-oblivious priority queue data structure supporting each insert, delete-min, and delete operation in $O(\frac{1}{B}\log_{M/B}\frac{N}{B})$ amortized memory transfers and $O(\log_2 N)$ amortized computation time.*

3. Graph algorithms. In this section we discuss how our cache-oblivious priority queue can be used to develop several cache-oblivious graph algorithms. We first consider the simple list ranking problem and algorithms on trees, and then we go on and consider BFS, DFS, and MSF algorithms for general graphs.

3.1. List ranking. In the list ranking problem we are given a linked list of V nodes stored as an unordered sequence. More precisely, we have an array with V nodes, each containing the position of the next node in the list (an edge). The goal is to determine the *rank* of each node v, that is, the number of edges from v to the end of the list. In a more general version of the problem, each edge has a weight and the goal is to find for each node v the sum of the weights of edges from v to the end of the list. Refer to Figure 3.1.

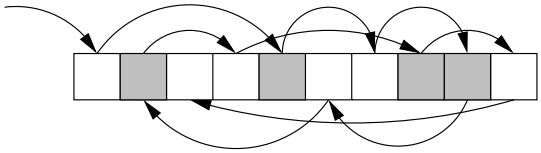

FIG. 3.1. *List ranking problem. An independent set of size* 4 *is marked. There are two forward lists (on top) and two backward lists (on bottom).*

Based on ideas from efficient PRAM algorithms [8, 34], Chiang et al. [31] designed an $O(\text{sort}(V))$ I/O model list ranking algorithm. The main idea in the algorithm is as follows. An *independent set* of $\Theta(V)$ nodes (nodes without edges to each other) is found, nodes in the independent set are "bridged out" (edges incident to nodes in this set are contracted), the remaining list is recursively ranked, and finally the contracted nodes are reintegrated into the list (their ranks are computed). The main innovation in the algorithm by Chiang et al. [31] was an $O(\text{sort}(V))$ memory transfer algorithm for computing an independent set of size V/c for some constant $c > 0$. The rest of the nonrecursive steps of the algorithm can easily be performed in $O(\text{sort}(V))$ memory transfers using a few scans and sorts of the nodes of the list as follows. To bridge out the nodes in the independent set, we first identify nodes with a successor in the independent set. We do so by creating a copy of the list of nodes, sorting it by successor position, and simultaneously scanning the two lists. During this process, we can also mark each predecessor of an independent set node v with the position of the successor w of v, as well as with the weight of the edge (v, w). Next, in a simple scan, we create a new list where the two edges incident to each independent set node

v have been replaced with an edge from the predecessor of v to the successor of v. The new edge has weight equal to the sum of that of the two old edges. Finally, we create the list to be ranked recursively by removing the independent set nodes and "compressing" the remaining nodes, that is, storing them in an array of size $V(1-1/c)$. We do so by scanning through the list while creating a list of the nodes not in the independent set, as well as a list that indicates the old and new position of each node (that is, the position of each node in the old and new array). Then we update the successor fields of the first list by sorting it by successor position, and simultaneously scanning it and the list of new positions. After having ranked the compressed list recursively, we reintegrate the removed nodes while computing their ranks. The rank of an independent set node v is simply the rank of its successor w minus the weight of edge (v, w). The reintegration of the independent set nodes can be performed in a few scans and sorts similar to the way we bridged out the independent set. Overall, not counting the independent set computation, the number of memory transfers used to rank a V node list is $T(V) = O(\text{sort}(V)) + T(V/c) = O(\text{sort}(V))$.

Since we only use scans and sorts in the above algorithm, all that remains in order to obtain a cache-oblivious list ranking algorithm is to develop a cache-oblivious independent set algorithm. Under different assumptions about the memory and block size, Chiang et al. [31] developed several independent set algorithms based on 3-coloring; in a 3-coloring every node is colored with one of three colors such that adjacent nodes have different colors. The independent set (of size at least $V/3$) then consists of the set of nodes with the most popular color. Arge [11] and Kumar and Schwabe [41] later removed the main memory and block assumptions.

One way of computing a 3-coloring is as follows [11, 31]: We call an edge (v, w) a *forward* edge if v appears before w in the (unordered) sequence of nodes—otherwise it is called a *backward* edge. First we imagine splitting the list into two sets consisting of forward running segments (forward lists) and backward running segments (backward lists). Each node is included in at least one of these sets, and nodes at the head or tail of a segment (nodes at which there is a reversal of the direction) will be in both sets. Refer to Figure 3.1. Next we color the nodes in the forward lists red or blue by coloring the head nodes red and the other nodes alternately blue and red. Similarly, the nodes in the backward lists are colored green and blue, with the head nodes being colored green. In total, every node is colored with one color, except for the heads/tails, which have two colors. It is easy to see that we obtain a 3-coloring if we color each head/tail node the color it was colored as the head of a list [31].

In the above 3-coloring algorithm we can cache-obliviously color the forward lists as follows (the backward lists can be colored similarly). In a single sort and scan we identify the head nodes, and for each such node v we insert a red element in a cache-oblivious priority queue with key equal to the position of v in the unordered list. We then repeatedly extract the minimal key element e from the queue. If e corresponds to a node v, we access v in the list, color it the same color as e, and insert an element corresponding to its successor in the queue. We color the inserted element in the opposite color of e. After processing all elements in the queue we have colored all forward lists. The initial sort and scan is performed cache-obliviously in $O(\text{sort}(V))$ memory transfers, and since we use a cache-oblivious priority queue we can also perform the $O(V)$ priority queue operations in $O(\text{sort}(V))$ memory transfers. Apart from this, we also perform what appears to be random accesses to the $O(V)$ nodes in the list. However, since we only process the forward list nodes in position order, the accesses overall end up corresponding to a scan of the list. Thus they only

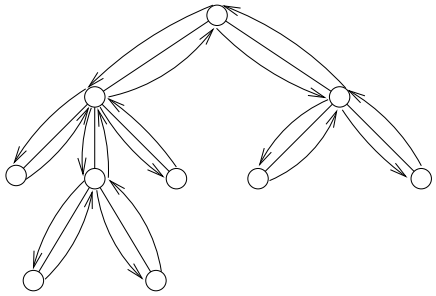

FIG. 3.2. *An undirected tree and an Euler tour of the corresponding directed graph.*

require $O(V/B)$ transfers. Therefore, we can compute a 3-coloring cache-obliviously in $O(\text{sort}(V))$ memory transfers, and thus overall we obtain the following.

THEOREM 3.1. *The list ranking problem on a V node list can be solved cache-obliviously in $O(\text{sort}(V))$ memory transfers.*

3.2. Algorithms on trees. Many efficient PRAM algorithms on undirected trees use Euler tour techniques [56, 58]. An Euler tour of a graph is a cycle that traverses each edge exactly once. Not every graph has an Euler tour, but a tree where each undirected edge has been replaced with two directed edges does (refer to Figure 3.2). When, in the following, we refer to an Euler tour of an undirected tree, we mean a tour in the graph obtained by replacing each edge in the tree with two directed edges.

To cache-obliviously compute an Euler tour of an undirected tree, that is, to compute an ordered list of the edges along the tour, we use ideas from similar PRAM algorithms. Consider imposing a (any) cyclic order on the nodes adjacent to each node v in the tree. In [51] it is shown that an Euler tour is obtained if we traverse the tree such that a visit to v from u (through the incoming edge (u, v)) is followed by a visit to the node w following u in the cyclic order (through the outgoing edge (v, w)). Thus we can compute the successor edge of each edge e, that is, the edge following e in the Euler tour, as follows: We first construct a list of incoming edges to each node v sorted according to the cyclic order. If two edges (u, v) and (w, v) are stored next to each other in this list, the successor edge for the (incoming) edge (u, v) is simply the (outgoing) edge (v, w). Therefore, we can compute all successor edges in a scan of the list. Given a list of all edges augmented with their successor edge, we can then compute the Euler tour simply by ranking the list and the sorting the edges by their rank. Thus overall we compute an Euler tour of an undirected tree using a few sorts and scans and a list ranking step, that is, using $O(\text{sort}(V))$ memory transfers.

Using our cache-oblivious Euler tour algorithm, we can easily compute a DFS numbering of the nodes of a tree starting at a source node s [51]. First note that if we start a walk of the Euler tour in the source node s it is actually a DFS tour of the tree. To compute the numbering, we therefore first classify each edge as being either a *forward* or a *backward* edge; an edge is a forward edge if it is traversed before its reverse in the tour. After numbering the edges along the tour and sorting the list of edges such that reverse edges appear consecutively, we can classify each edge in a simple scan of the list. Then we assign each forward edge weight 1 and each backward edge weight 0. The DFS number of a node v is then simply the sum of the weights on the edges from s to v. Thus we can obtain the DFS numbering by solving the general version of list ranking. Since we only use Euler tours computation, list

ranking, sorting, and scanning, we compute the DFS numbering cache-obliviously in a total of $O(\text{sort}(V))$ memory transfers.

Using an Euler tour, list ranking, and sorting, we can also compute a BFS numbering of the nodes of a tree cache-obliviously in $O(\text{sort}(V))$ memory transfers in a similar way [51]. Using standard PRAM ideas, and the tools developed here, we can also, e.g., compute the centroid decomposition of a tree in $O(\text{sort}(V))$ memory transfers [56, 58, 31]. The centroid of a tree is the node that, if removed, minimizes the size of the largest of the remaining subtrees. The centroid decomposition of a tree is a recursive partition of a tree into subtrees around the centroid.

THEOREM 3.2. *The Euler tour, BFS, DFS, and centroid decomposition problems on a tree with V nodes can be solved cache-obliviously in $O(\text{sort}(V))$ memory transfers.*

3.3. DFS and BFS. We now consider the DFS and BFS numbering problems for general graphs. We first describe a cache-oblivious DFS algorithm for directed graphs and then we modify it to compute a BFS numbering. Finally, we develop an improved BFS algorithm for undirected graphs.

3.3.1. Depth-first search. In the RAM model, directed DFS can be solved in linear time using a stack S containing vertices v that have not yet been visited but have an edge (w, v) incident to a visited vertex w, as well as an array A containing an element for each vertex v, indicating if v has been visited or not. The top vertex v of S is repeatedly popped and A is accessed to determine if v has already been visited. If v has not yet been visited, it is marked as visited in A and all vertices adjacent to v are pushed onto S. It is easy to realize that if the stack S is implemented using a doubling array then a *push* or *pop* requires $O(1/B)$ amortized cache-oblivious memory transfers, since the optimal paging strategy can always keep the last block of the array (accessed by both push and pop) in main memory. However, each access to A may require a separate memory transfer resulting in $\Omega(E)$ memory transfers in total.

In the I/O model, Chiang et al. [31] modified the above algorithm to obtain an $O(V + \frac{E}{B}\frac{V}{M})$ algorithm. In their algorithm all visited vertices (marked vertices in array A) are stored in main memory. Every time the number of visited vertices grows larger than the main memory, all visited vertices and all their incident edges are removed from the graph. Since this algorithm relies crucially on knowledge of the main memory size, it seems hard to make it cache-oblivious. Buchsbaum et al. [30] described another $O((V + \frac{E}{B}) \log_2 V + \text{sort}(E))$ I/O model algorithm. In the following we describe how to make it cache-oblivious. The algorithm uses a number of data structures: V priority queues, a stack, and a so-called *buffered repository tree*. As discussed above, a stack can trivially be made cache-oblivious. Below we first describe how to make the buffered repository tree cache-oblivious. Next we describe what we call a *buffered priority tree* that we use in the algorithm rather than our cache-oblivious priority queue; we cannot simply use our priority queue since it requires $O(M)$ space. Finally, we describe the algorithm by Buchsbaum et al. [30] and how the use of the cache-oblivious structures leads to a cache-oblivious version of it.

Buffered repository tree. A buffered repository tree (BRT) maintains $O(E)$ elements with keys in the range $[1..V]$ under operations *insert* and *extract*. The insert operation inserts a new element, while the extract operation reports and deletes all elements with a certain key.

Our cache-oblivious version of the BRT consists of a static binary tree with the keys 1 through V in sorted order in the leaves. A buffer is associated with each node and leaf of the tree. The buffer of a leaf v contains elements with key v and the buffers

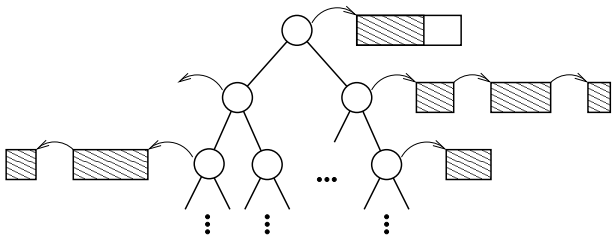

FIG. 3.3. *Buffered repository tree (BRT). Each nonroot node has a buffer of elements stored as a linked list of buckets. The root node buffer is implemented using a doubling array.*

of the internal nodes are used to perform insertions in a batched manner. We perform an insertion simply by inserting the new element into the root buffer. To perform an extraction of elements with key v we traverse the path from the root to the leaf containing v. At each node μ on this path we scan the associated buffer and report and delete elements with key v. During the scan we also distribute the remaining elements among the two buffers associated with the children of μ; we distribute an element with key w to the buffer of the child of μ on the path to w. We place elements inserted in a buffer during the same scan consecutively in memory (but not necessarily right after the other elements in the buffer). This way the buffer of a node μ can be viewed as consisting of a linked list of *buckets* of elements in consecutive memory locations, with the number of buckets being bounded by the number of times the buffer of μ's parent buffer has been emptied since the last time μ's buffer was emptied. To avoid performing a memory transfer on each insertion, we implement the root buffer slightly differently, namely as a doubling array (like a stack). Since only the root buffer is implemented this way, the optimal paging strategy can keep the last block of the array in main memory and we obtain an $O(1/B)$ amortized root buffer insertion bound. Refer to Figure 3.3 for an illustration of a BRT.

LEMMA 3.3. *A cache-oblivious BRT uses $\Theta(B)$ main memory space and supports insert and extract operations in $O(\frac{1}{B}\log_2 V)$ and $O(\log_2 V)$ amortized memory transfers, respectively.*

Proof. As discussed, an insertion in the root buffer requires $O(1/B)$ amortized memory transfers. During an extract operation, we use $O(X/B+K)$ memory transfers to empty the buffer of a node μ containing X elements in K buckets (since we access each element and each bucket). We charge the X/B-term to the insert operations that inserted the X elements in the BRT. Since each element is charged at most once on each level of the tree, an insert is charged $O(\frac{1}{B}\log_2 V)$ transfers. We charge the K-term to the extract operations that created the K buckets. Since an extract operation creates two buckets on each level of the tree, it is charged a total of $O(\log_2 V)$ memory transfers. □

Buffered priority tree. A buffered priority tree is constructed on E_v elements with E_v distinct keys, and maintains these elements under *buffered delete* operations. Given E' elements, all of which are currently stored in the structure, a buffered delete operation first deletes the E' elements and then deletes and reports the minimal key element among the remaining elements in the structure.

The buffered priority tree is implemented similarly to the BRT. It consists of a static binary tree with the E_v keys in sorted order in the leaves, where a buffer is associated with each internal node. Initially, the E_v elements are stored in the leaves containing their keys. The buffers are used to store elements intended to be

deleted from the structure, and with each node v we maintain a counter storing the number of (undeleted) elements stored in the tree rooted in v. To perform a buffered delete we first insert the E' elements in the buffer of the root and update its counter. Next we traverse the path from the root to the leaf l containing the minimal key elements (among the undeleted elements), while emptying the buffers associated with the encountered nodes: At the root, we scan the buffer and distribute the elements among the two buffers associated with the children (exactly as in the BRT). During the distribution, we also update the counters in the two children. If the counter of the left child v_l is still greater than zero, i.e., the minimal element is in the tree rooted in v_l, we then recursively visit v_l. Otherwise we visit the right child v_r. (Note that when reaching leaf l it has an empty buffer.) After finding l, we report and delete the element stored in l. Finally, we decrement the counters on the path from the root to l.

LEMMA 3.4. *Using no permanent main memory, a cache-oblivious buffered priority tree supports buffered deletes of E' elements in $O((\frac{E'}{B}+1)\log_2 V)$ amortized memory transfers. It can be constructed in $O(\mathrm{sort}(E_v))$ memory transfers.*

Proof. The number of transfers needed to construct the tree is dominated by the $O(\mathrm{sort}(E_v))$ memory transfers needed to sort the E_v elements and construct the leaves; after that, the tree can be constructed in $O(E_v/B)$ transfers level-by-level bottom-up. The amortized cost of a buffered delete is equal to the cost of inserting E' elements into a BRT, plus the cost of extracting an element from a BRT, that is, $O((\frac{E'}{B}+1)\log_2 V)$ memory transfers. □

DFS algorithm. As mentioned, the directed DFS numbering algorithm by Buchsbaum et al. [30] utilizes a number of data structures: a stack S containing vertices on the path from the root of the DFS tree to the current vertex, a priority queue $P(v)$ for each vertex v containing edges (v, w) connecting v with a possibly unvisited vertex w, as well as one BRT D containing edges (v, w) incident to a vertex w that has already been visited but where (v, w) is still present in $P(v)$. The key of an edge (v, w) is v in D and w in $P(v)$. For the priority queues $P(v)$ we use our buffered priority tree.

Initially each $P(v)$ is constructed on the E_v edges (v, w) incident to v, the source vertex is placed on the stack S, and the BRT D is empty. To compute a DFS numbering, the vertex u on the top of the stack is repeatedly considered. All edges in D of the form (u, w) are extracted and deleted from $P(u)$ using a buffered delete operation. If $P(u)$ is now empty, so that no minimal element (edge (u, v)) is returned, all neighbors of u have already been visited and u is popped off S. Otherwise, if edge (u, v) is returned, vertex v is visited next: It is numbered and pushed on S, and all edges (w, v) (with $w \neq u$) incident to it are inserted in D. In [30] it is shown that this algorithm correctly computes a DFS numbering.

To analyze the above algorithm, we first note that each vertex is considered on the top of S a number of times equal to one greater than its number of children in the DFS tree. Thus the total number of times we consider a vertex on top of S is $2V - 1$. When considering a vertex u we first perform a stack operation on S, an extract operation on D, and a buffered delete operation on $P(u)$. The stack operation requires $O(1/B)$ memory transfers and the extraction $O(\log_2 V)$ transfers, since the optimal paging strategy can keep the relevant $O(1)$ blocks of S and D in main memory at all times. Thus overall these costs add up to $O(V \log_2 V)$. The buffered delete operation requires $O((1+\frac{E'}{B})\log_2 V)$ memory transfers if E' is the number of deleted elements (edges). Each edge is deleted once, so overall the buffered deletes costs add up to $O((V+\frac{E}{B})\log_2 V)$. Next we insert the, say E'', edges incident to v in D. This

requires $O(1 + \frac{E''}{B} \log_2 V)$ memory transfers, or $O(V + \frac{E}{B} \log_2 V)$ transfers over the whole algorithm. (Note that the E'' edges are not immediately deleted directly from the relevant $P(w)$'s since that could cost a memory transfer per edge.) In addition, the initial construction of the buffered priority trees requires $O(\text{sort}(E))$ memory transfers. Thus overall the algorithm uses $O((V + \frac{E}{B}) \log_2 V + \text{sort}(E))$ memory transfers.

3.3.2. Breadth-first search. The DFS algorithm described above can be modified to perform a BFS simply by replacing the stack S with a queue. Queues, like stacks, can be implemented using a doubling array, and the optimal paging strategy can keep the two partial blocks in use by the *enqueue* and *dequeue* operations in memory, such that each queue operation requires $O(1/B)$ amortized memory transfers. Thus we also obtain an $O((V + \frac{E}{B}) \log_2 V)$ directed BFS numbering algorithm.

Our directed DFS and BFS algorithms can of course also be used on undirected graphs. For undirected graphs, improved $O(V + \text{sort}(E))$ and $O(\sqrt{\frac{V \cdot E}{B}} + \text{sort}(E))$ I/O model algorithms have been developed [46, 45]. The idea in the algorithm by Munagala and Ranade [46], which can immediately be made cache-oblivious, is to visit the vertices in "layers" of vertices of equal distance from the source vertex s. The algorithm utilizes the fact that in an undirected graph any vertex adjacent to a vertex in layer i is either in layer $i-1$, layer i, or layer $i+1$. It maintains two sorted lists of vertices in the last two layers i and $i-1$. To create a sorted list of vertices in layer $i+1$, a list of possible layer $i+1$ vertices is first produced by collecting all vertices with a neighbor in level i (using a scan of the adjacency lists of layer i vertices). Then this list is sorted, and in a scan of the list and the (sorted) lists of vertices in level i and $i-1$ all previously visited vertices are removed. Apart from the sorting steps, overall this algorithm uses $O(V + E/B)$ memory transfers to access the edge lists for all vertices, as well as $O(E/B)$ transfers to scan the lists. Since each vertex is included in a sort once for each of its incident edges, the total cost of all sorting steps is $O(\text{sort}(E))$. Thus in total the algorithm uses $O(V + \text{sort}(E))$ memory transfers. Since it uses only scans and sorts, it is cache-oblivious without modification. Refer to [46] for full details. As mentioned in the introduction, Brodal et al. [28] have developed other undirected BFS algorithms based on the ideas in [45].

THEOREM 3.5. *The DFS or BFS numbering of a directed graph can be computed cache-obliviously in* $O((V + \frac{E}{B}) \log_2 V + \text{sort}(E))$ *memory transfers. The BFS numbering of an undirected graph can be computed cache-obliviously in* $O(V + \text{sort}(E))$ *memory transfers.*

3.4. Minimum spanning forest. In this section we consider algorithms for computing the MSF of an undirected weighted graph. Without loss of generality, we assume that all edge weights are distinct. In the I/O model, a sequence of algorithms has been developed for the problem [31, 1, 41, 15], culminating in an algorithm using $O(\text{sort}(E) \cdot \log_2 \log_2(\frac{VB}{E}))$ memory transfers developed by Arge, Brodal, and Toma [15]. This algorithm consists of two phases. In the first phase, an edge contraction algorithm inspired by PRAM algorithms [32, 35] is used to reduce the number of vertices to $O(E/B)$. In the second phase, a modified version of Prim's algorithm [48] is used to complete the MSF computation. Using our cache-oblivious priority queue we can relatively easily modify both of the phases to work cache-obliviously. However, since we cannot decide cache-obliviously when the first phase has reduced the number of vertices to $O(E/B)$, we are not able to combine the two phases as effectively as in the I/O model. Below, we first describe how to make the algorithms used in the two phases cache-oblivious. Then we discuss their combination.

3.4.1. Phase 1. The basic edge contraction based MSF algorithm proceeds in stages [32, 31, 41]. In each stage the minimum weight edge incident to each vertex is selected and output as part of the MSF, and the vertices connected by the selected edges are contracted into supervertices (that is, the connected components of the graph of selected edges are contracted). See, e.g., [15] for a proof that the selected edges along with the edges in a MSF of the contracted graph constitute a MSF for the original graph.

In the following we sketch how we can perform a contraction stage on a graph G cache-obliviously in $O(\text{sort}(E))$ memory transfers as in [15]. We can easily select the minimum weight edges in $O(\text{sort}(E))$ memory transfers using a few scans and sorts. To perform the contraction, we select a *leader vertex* in each connected component of the graph G_s of selected edges, and replace every edge (u, v) in G with the edge $(\mathit{leader}(u), \mathit{leader}(v))$. To select the leaders, we use the fact that the connected components of G_s are trees, except that one edge in each component (namely, the minimal weight edge) appears twice [15]. In each component, we simply use one of the vertices incident to the edge appearing twice as leader. This way we can easily identify all the leaders in $O(\text{sort}(E))$ memory transfers using a few sorts and scans (by identifying all edges that appear twice). We can then use our cache-oblivious tree algorithms developed in section 3.2 to distribute the identity of the leader to each vertex in each component in $O(\text{sort}(V))$ memory transfers: We add an edge between each leader in G_s and a pseudo root vertex s and perform a DFS numbering of the resulting tree starting in s; since all vertices in the same connected component (tree) will have consecutive DFS numbers, we can then mark each vertex with its leader using a few sorts and scans. Finally, after marking each vertex v with $\mathit{leader}(v)$, we can easily replace each edge (u, v) in G with $(\mathit{leader}(u), \mathit{leader}(v))$ in $O(\text{sort}(E))$ memory transfers using a few sort and scan steps on the vertices and edges.

Since each contraction stage reduces the number of vertices by a factor of two, and since a stage is performed in $O(\text{sort}(E))$ memory transfers, we can reduce the number of vertices to $V' = V/2^i$ in $O(\text{sort}(E) \cdot \log_2(V/V'))$ memory transfers by performing i stages after each other. Thus we obtain an $O(\text{sort}(E) \cdot \log_2 V)$ algorithm by continuing the contraction until we are left with a single vertex. In the I/O model, Arge, Brodal, and Toma [15] showed how to improve this bound to $O(\text{sort}(E) \cdot \log_2 \log_2 V)$ by grouping the stages into "superstages" and working only on a subset of the edges of G in each superstage. The extra steps involved in their improvement are all sorting or scanning of the edges and vertices, and therefore the improvement is immediately cache-oblivious.

LEMMA 3.6. *The MFS of an undirected weighted graph can be computed cache-obliviously in* $O(\text{sort}(E) \cdot \log_2 \log_2 V)$ *memory transfers.*

3.4.2. Phase 2. Prim's algorithm [48] grows a minimum spanning tree (MST) of a connected graph iteratively from a source vertex using a priority queue P on the vertices not already included in the MST. The key of a vertex v in P is equal to the weight of the minimal weight edge connecting v to the current MST. In each step of the algorithm a delete-min is used to obtain the next vertex u to add to the MST, and the keys of all neighbors of u in P are (possibly) updated. A standard implementation of this algorithm uses $\Omega(E)$ memory transfers, since a transfer is needed to obtain the current key of each neighbor vertex. In the I/O model, Arge, Brodal, and Toma [15] showed how to modify the algorithm to use $O(V + \text{sort}(E))$ memory transfers by storing edges rather than vertices in the priority queue. Below we describe this algorithm in order to show that it can be implemented cache-obliviously.

Like Prim's algorithm, the algorithm in [15] grows the MST iteratively. We maintain a priority queue P containing (at least) all edges connecting vertices in the current MST with vertices not in the tree; P can also contain edges between two vertices in the MST. Initially it contains all edges incident to the source vertex. In each step of the algorithm we extract the minimum weight edge (u, v) from P. If v is already in the MST we discard the edge; otherwise we include v in the MST and insert all edges incident to v, except (v, u), in the priority queue. We can efficiently determine if v is already in the MST, since if u and v are both already in the MST, then (u, v) must be in the priority queue twice; thus, if the next edge we extract from P is (v, u), then v is already in the MST.

The correctness of the above algorithm follows immediately from the correctness of Prim's algorithm. During the algorithm we access the edges in the adjacency list of each vertex v once (when v is included in the MST) for a total of $O(V+E/B)$ memory transfers. We also perform $O(E)$ priority queue operations, for a total of $O(\text{sort}(E))$ memory transfers. Thus the algorithm uses $O(V + \text{sort}(E))$ memory transfers. All of the above can easily be modified to compute a MSF for an unconnected graph rather than a MST for a connected graph. Thus we have obtained the following.

LEMMA 3.7. *The MSF of an undirected weighted graph can be computed cache-obliviously in $O(V + \text{sort}(E))$ memory transfers.*

3.4.3. Combined algorithm. In the I/O model, an $O(\text{sort}(E) \cdot \log_2 \log_2(\frac{VB}{E}))$ MSF algorithm can be obtained by running the phase 1 algorithm until the number of vertices has been reduced to $V' = E/B$ using $O(\text{sort}(E) \cdot \log_2 \log_2(\frac{VB}{E}))$ memory transfers, and then finishing the MSF in $O(V' + \text{sort}(E)) = O(\text{sort}(E))$ memory transfers using the phase 2 algorithm. As mentioned, we cannot combine the two phases as effectively in the cache-oblivious model. In general, however, we can combine the two algorithms to obtain an $O(\text{sort}(E) \cdot \log_2 \log_2(V/V') + V')$ algorithm for any V' independent of B and M.

THEOREM 3.8. *The MSF of an undirected weighted graph can be computed cache-obliviously in $O(\text{sort}(E) \cdot \log_2 \log_2(V/V') + V')$ memory transfers for any V' independent of B and M.*

4. Conclusions. In this paper, we presented an optimal cache-oblivious priority queue and used it to develop efficient cache-oblivious algorithms for several graph problems. We believe that the ideas utilized in the development of the priority queue and our graph algorithms will prove useful in the development of other cache-oblivious data structures.

Many important problems still remain open in the area of cache-oblivious algorithms and data structures. In the area of graph algorithms, for example, it remains open to develop a cache-oblivious MSF algorithm with complexity matching the best known cache-aware algorithm.

Acknowledgments. The authors wish to thank an anonymous reviewer for pointing out a mistake in an earlier draft of this paper, and all the reviewers for numerous suggestions for improving the presentation.

ONLINE LEARNING AND RESOURCE-BOUNDED DIMENSION: WINNOW YIELDS NEW LOWER BOUNDS FOR HARD SETS*

JOHN M. HITCHCOCK†

Abstract. We establish a relationship between the online mistake-bound model of learning and resource-bounded dimension. This connection is combined with the Winnow algorithm to obtain new results about the density of hard sets under adaptive reductions. This improves previous work of Fu [*SIAM J. Comput.*, 24 (1995), pp. 1082–1090] and Lutz and Zhao [*SIAM J. Comput.*, 30 (2000), pp. 1197–1210], and solves one of Lutz and Mayordomo's "twelve problems in resource-bounded measure" [*Bull. Eur. Assoc. Theor. Comput. Sci. EATSC*, 68 (1999), pp. 64–80].

Key words. computational complexity, polynomial-time reductions, resource-bounded dimension, resource-bounded measure, sparse sets

AMS subject classification. 68Q15

DOI. 10.1137/050647517

1. Introduction.

This paper has two main contributions: (i) establishing a close relationship between resource-bounded dimension and Littlestone's online mistake-bound model of learning, and (ii) using this relationship along with the Winnow algorithm to resolve an open problem in computational complexity. In this introduction we briefly describe these contributions.

1.1. Online learning and dimension.

Lindner, Schuler, and Watanabe [15] studied connections between computational learning theory and resource-bounded measure, primarily working with the probably approximately correct (PAC) model. They also included the observation that any "admissible" subclass of P/poly that is polynomial-time learnable in Angluin's exact learning model [2] must have p-measure 0. The proof of this made use of the essential equivalence between Angluin's model and Littlestone's online mistake-bound model [16].

In the online mistake-bound model, a learner is presented a sequence of examples and is asked to predict whether or not they belong to some unknown target concept. The concept is drawn from some concept class, which is known to the learner, and the examples may be chosen by an adversary. After making a prediction about each example, the learner is told the correct classification for the example, and learner may use this knowledge in making future predictions. The mistake bound of the learner is the maximum number of incorrect predictions the learner will make, over any choice of target concept and sequence of examples.

We push the observation of [15] much further, developing a powerful, general framework for showing that classes have resource-bounded *dimension* 0. Resource-bounded measure and dimension involve betting on the membership of strings in an unknown set. To prove that a class has dimension 0, we show that it suffices to give a reduction to a family of concept classes that has a good mistake-bound learning algorithm. It is possible that the reduction can take exponential-time and that the

learning algorithm can also take exponential-time, as long as the mistake bound of the algorithm is subexponential. If we have a reduction from the unknown set to a concept in the learnable concept class, we can view the reduction as generating a sequence of examples, apply the learning algorithm to these examples, and use the learning algorithm's predictions to design a good betting strategy. Formal details of this framework are given in section 3.

1.2. Density of hard sets. The two most common notions of polynomial-time reductions are many-one ($\leq^{\mathrm{p}}_{\mathrm{m}}$) and Turing ($\leq^{\mathrm{p}}_{\mathrm{T}}$). A many-one reduction from A to B maps instances of A to instance of B, preserving membership. A Turing reduction from A to B makes many, possibly adaptive, queries to B in order to solve A. Many-one reductions are a special case of Turing reductions. In between $\leq^{\mathrm{p}}_{\mathrm{m}}$ and $\leq^{\mathrm{p}}_{\mathrm{T}}$ is a wide variety of polynomial-time reductions of different strengths.

A common use of reductions is to demonstrate hardness for a complexity class. Let $\leq^{\mathrm{p}}_{\tau}$ be a polynomial-time reducibility. For any set B, let $\mathrm{P}_{\tau}(B) = \{A \mid A \leq^{\mathrm{p}}_{\tau} B\}$ be the class of all problems that $\leq^{\mathrm{p}}_{\tau}$-reduce to B. We say that B is $\leq^{\mathrm{p}}_{\tau}$-*hard* for a complexity class $\mathcal{C}$ if $\mathcal{C} \subseteq \mathrm{P}_{\tau}(B)$, that is, every problem in $\mathcal{C}$ $\leq^{\mathrm{p}}_{\tau}$-reduces to B. For a class $\mathcal{D}$ of sets, a useful notation is $\mathrm{P}_{\tau}(\mathcal{D}) = \bigcup_{B\in\mathcal{D}} \mathrm{P}_{\tau}(B)$.

A problem B is *dense* if there exists $\epsilon > 0$ such that $|B_{\leq n}| > 2^{n^{\epsilon}}$ for all but finitely many n. All known hard sets for the exponential-time complexity classes $\mathrm{E} = \mathrm{DTIME}(2^{O(n)})$ or $\mathrm{EXP} = \mathrm{DTIME}(2^{n^{O(1)}})$ are dense. Whether every hard set must be dense has been often studied. First, Meyer (see his result reported by Berman and Hartmanis [5, pp. 317–318]) showed that every $\leq^{\mathrm{p}}_{\mathrm{m}}$-hard set for E must be dense, and he observed that proving the same for $\leq^{\mathrm{p}}_{\mathrm{T}}$ reductions would imply that E does not have polynomial-size circuits. Since then, a line of research has obtained results for a variety of reductions between $\leq^{\mathrm{p}}_{\mathrm{m}}$ and $\leq^{\mathrm{p}}_{\mathrm{T}}$, specifically the conjunctive ($\leq^{\mathrm{p}}_{\mathrm{c}}$) and disjunctive ($\leq^{\mathrm{p}}_{\mathrm{d}}$) reductions, and for various functions $f(n)$, the bounded query $\leq^{\mathrm{p}}_{f(n)-\mathrm{tt}}$ and $\leq^{\mathrm{p}}_{f(n)-\mathrm{T}}$ reductions:

1. Watanabe [27, 10] showed that every hard set for E under the $\leq^{\mathrm{p}}_{\mathrm{c}}$, $\leq^{\mathrm{p}}_{\mathrm{d}}$, or $\leq^{\mathrm{p}}_{O(\log n)-\mathrm{tt}}$ reductions is dense.
2. Lutz and Mayordomo [21] showed that for all $\alpha < 1$, the class $\mathrm{P}_{n^{\alpha}-\mathrm{tt}}(\mathrm{DENSE}^c)$ has p-measure 0, where DENSE is the class of all dense sets. Since E does not have p-measure 0, their result implies that every $\leq^{\mathrm{p}}_{n^{\alpha}-\mathrm{tt}}$-hard set for E is dense.
3. Fu [8] showed that for all $\alpha < 1/2$, every $\leq^{\mathrm{p}}_{n^{\alpha}-\mathrm{T}}$-hard set for E is dense, and that for all $\alpha < 1$, every $\leq^{\mathrm{p}}_{n^{\alpha}-\mathrm{T}}$-hard set for EXP is dense.
4. Lutz and Zhao [23] gave a measure-theoretic strengthening of Fu's results, showing that for all $\alpha < 1/2$, $\mathrm{P}_{n^{\alpha}-\mathrm{T}}(\mathrm{DENSE}^c)$ has p-measure 0, and that for all $\alpha < 1$, $\mathrm{P}_{n^{\alpha}-\mathrm{T}}(\mathrm{DENSE}^c)$ has p_2-measure 0.

This contrast between E and EXP in the last two references was left as a curious open problem and stated as follows by Lutz and Mayordomo [22, Problem 6] as one of their "twelve problems in resource-bounded measure."

> *For* $\frac{1}{2} \leq \alpha < 1$, *is it the case that* $\mathrm{P}_{n^{\alpha}-\mathrm{T}}(\mathrm{DENSE}^c)$ *has* p-measure 0 (*or at least, that* $\mathrm{E} \not\subseteq \mathrm{P}_{n^{\alpha}-\mathrm{T}}(\mathrm{SPARSE})$)?

We resolve this problem, showing the much stronger conclusion that the classes in question have p-dimension 0. But first, in section 4, we prove a theorem about disjunctive reductions that illustrates the basic idea of our technique. We show that the class $\mathrm{P}_{\mathrm{d}}(\mathrm{DENSE}^c)$ has p-dimension 0. The proof uses the learning framework

of section 3 and Littlestone's Winnow algorithm [16]. Suppose that $A \leq^{\mathrm{p}}_{\mathrm{d}} S$, where S is a nondense set. Then there is a reduction g mapping strings to sets of strings such that $x \in A$ if and only if at least one string in $g(x)$ belongs to S. We view the reduction g as generating examples that we can use to learn a disjunction based on S. Because S is subexponentially dense, the target disjunction involves a subexponential number of variables out of exponentially many variables. This is truly a case "when irrelevant attributes abound" [16], and the Winnow algorithm perfoms exceedingly well to establish our dimension result. In the same section we also use the learning framework to show that $\mathrm{P_c}(\mathrm{DENSE}^c)$ has p-dimension 0. These results give new proofs of Watanabe's aforementioned theorems about $\leq^{\mathrm{p}}_{\mathrm{d}}$-hard and $\leq^{\mathrm{p}}_{\mathrm{c}}$-hard sets for E.

Our main theorem, presented in section 5, is that for all $\alpha < 1$, $\mathrm{P}_{n^\alpha-\mathrm{T}}(\mathrm{DENSE}^c)$ has p-dimension 0. This substantially improves the results of [21, 8, 23]. The resource-bounded measure proofs in [21, 23] use the concept of *weak stochasticity*. As observed by Mayordomo [25], this stochasticity approach can be extended to show a $-1st$-*order scaled dimension* [12] result, but it seems a different technique is needed for an (unscaled) dimension result. Our learning framework turns out to be just what is needed. We reduce the class $\mathrm{P}_{n^\alpha-\mathrm{T}}(\mathrm{DENSE}^c)$ to a family of learnable disjunctions. For this, we make use of a technique that Allender et al. [1] used to prove a surprising result converting bounded-query reductions to sparse sets into disjunctive reductions to sparse sets: $\mathrm{P_{btt}}(\mathrm{SPARSE}) \subseteq \mathrm{P_d}(\mathrm{SPARSE})$. Carefully applying the same technique on a sublinear-query Turing-reduction to a nondense set results in a disjunction with a nearly exponential blowup, but it can still be learned by Winnow in our dimension setting.

The density of complete and hard sets for NP has also been studied often, with motivation coming originally from the Berman–Hartmanis isomorphism conjecture [5]: all many-one complete sets are dense if the isomorphism conjecture holds. Since no absolute results about the density of NP-complete or NP-hard sets can be proved without separating P from NP, the approach has been to prove conditional results under a hypothesis on NP. Mahaney [24] showed that if $\mathrm{P} \neq \mathrm{NP}$, then no sparse set is $\leq^{\mathrm{p}}_{\mathrm{m}}$-hard for NP. Ogiwara and Watanabe [26] extended Mahaney's theorem to the $\leq^{\mathrm{p}}_{\mathrm{btt}}$-hard sets. Deriving a result from $\mathrm{P} \neq \mathrm{NP}$ about NP-hard sets under unbounded truth-table reductions is still an open problem, but a measure-theoretic assumption yields very strong consequences. Lutz and Zhao [23] showed that under the hypothesis "NP does not have p-measure 0," every $\leq^{\mathrm{p}}_{n^\alpha-\mathrm{T}}$-hard set for NP must be dense, for all $\alpha < 1$. In section 6 we present the same conclusion under the weaker hypothesis "NP has positive p-dimension," and some additional consequences.

2. Preliminaries. The set of all binary strings is $\{0,1\}^*$. The length of a string $x \in \{0,1\}^*$ is $|x|$. We write λ for the empty string. For $n \in \mathbb{N}$, $\{0,1\}^n$ is the set of strings of length n and $\{0,1\}^{\leq n}$ is the set of strings of length at most n. We write $s_0 = \lambda$, $s_1 = 0$, $s_2 = 1$, $s_3 = 00$, ... for the standard lexicographic enumeration of $\{0,1\}^*$.

A *language* is a subset $L \subseteq \{0,1\}^*$. We write $L_{\leq n} = L \cap \{0,1\}^{\leq n}$ and $L_{=n} = L \cap \{0,1\}^n$. We say that L is *sparse* if there is a polynomial $p(n)$ such that for all n, $|L_{=n}| \leq p(n)$. We say that L is *(exponentially) dense* if there is a constant $\epsilon > 0$ such that $|L_{\leq n}| > 2^{n^\epsilon}$ for all sufficiently large n. We write SPARSE and DENSE for the classes of all sparse languages and all dense languages. The complement DENSE^c of DENSE is the class of all *nondense* languages.

2.1. Polynomial-time reductions. We use the following standard notions of polynomial-time reducibilities:

- *Turing reducibility:* $A \leq_{\mathrm{T}}^{\mathrm{p}} B$ if there is a polynomial-time oracle machine M such that $A = L(M^B)$.
- *Truth-table reducibility:* $A \leq_{\mathrm{tt}}^{\mathrm{p}} B$ if there is a polynomial-time oracle machine M that makes nonadaptive queries such that $A = L(M^B)$.
- *Disjunctive reducibility:* $A \leq_{\mathrm{d}}^{\mathrm{p}} B$ if there is a polynomial-time computable $f : \{0,1\}^* \to \mathcal{P}(\{0,1\}^*)$ such that for all x, $x \in A$ if and only if $f(x) \cap B \neq \emptyset$.
- *Conjunctive reducibility:* $A \leq_{\mathrm{c}}^{\mathrm{p}} B$ if there is a polynomial-time computable $f : \{0,1\}^* \to \mathcal{P}(\{0,1\}^*)$ such that for all x, $x \in A$ if and only if $f(x) \subseteq B$.

We write $\leq_{q(n)-\mathrm{T}}^{\mathrm{p}}$ or $\leq_{q(n)-\mathrm{tt}}^{\mathrm{p}}$ to indicate that the reduction makes at most $q(n)$ queries on any input of length n. The bounded reducibility $A \leq_{\mathrm{btt}}^{\mathrm{p}} B$ means $A \leq_{k-\mathrm{tt}}^{\mathrm{p}} B$ for some constant k.

Let $\leq_\tau^{\mathrm{p}}$ be a polynomial-time reducibility. For any language B, we define $\mathrm{P}_\tau(B) = \{A \mid A \leq_\tau^{\mathrm{p}} B\}$. A language B is $\leq_\tau^{\mathrm{p}}$*-hard* for a class $\mathcal{C}$ if $\mathcal{C} \subseteq \mathrm{P}_\tau(B)$. For any class $\mathcal{D}$ of languages, $\mathrm{P}_\tau(\mathcal{D}) = \bigcup_{B \in \mathcal{D}} \mathrm{P}_\tau(B)$.

2.2. Resource-bounded measure and dimension. Resource-bounded measure and dimension were introduced by Lutz [17, 19], and resource-bounded strong dimension by Athreya et al. [4]. Here we briefly review the definitions and basic properties. We refer to the original sources and also the surveys [18, 22, 20, 13] for more information.

The *Cantor space* is $\mathbf{C} = \{0,1\}^\infty$. Each language $A \subseteq \{0,1\}^*$ is identified with its characteristic sequence $\chi_A \in \mathbf{C}$ according to the standard (lexicographic) enumeration of $\{0,1\}^*$. We typically write A in place of χ_A. In this way a complexity class $\mathcal{C} \subseteq \mathcal{P}(\{0,1\}^*)$ is viewed as a subset $\mathcal{C} \subseteq \mathbf{C}$. We use the notation $S \upharpoonright n$ to denote the first n bits of a sequence $S \in \mathbf{C}$.

Let $s > 0$ be a real number. An *s-gale* is a function $d : \{0,1\}^* \to [0, \infty)$ such that for all $w \in \{0,1\}^*$,

$$d(w) = \frac{d(w0) + d(w1)}{2^s}.$$

A *martingale* is a 1-gale.

The goal of an s-gale is to obtain large values on sequences as follows.

DEFINITION. *Let d be an s-gale and $S \in \mathbf{C}$.*

1. *d succeeds on S if* $\limsup_{n\to\infty} d(S \upharpoonright n) = \infty$.
2. *d succeeds strongly on S if* $\liminf_{n\to\infty} d(S \upharpoonright n) = \infty$.
3. *The* success set *of d is* $S^\infty[d] = \{S \in \mathbf{C} \mid d \text{ succeeds on } S\}$.
4. *The* strong success set *of d is* $S^\infty_{\mathrm{str}}[d] = \{S \in \mathbf{C} \mid d \text{ succeeds strongly on } S\}$.

Notice that the smaller s is, the more difficult it is for an s-gale to obtain large values. Succeeding martingales ($s = 1$) imply measure 0, and the infimum s for which an s-gale can succeed (or strongly succeed) gives the dimension (or strong dimension) as follows.

DEFINITION. *Let $X \subseteq \mathbf{C}$.*

1. *X has* p-measure 0*, written $\mu_{\mathrm{p}}(X) = 0$, if there is a polynomial-time computable martingale d such that $X \subseteq S^\infty[d]$.*
2. *The* p-dimension *of X, written $\dim_{\mathrm{p}}(X)$, is the infimum of all s such that there exists a polynomial-time computable s-gale d with $X \subseteq S^\infty[d]$.*
3. *The* strong p-dimension *of X, written $\mathrm{Dim}_{\mathrm{p}}(X)$, is the infimum of all s such that there exists a polynomial-time computable s-gale d with $X \subseteq S^\infty_{\mathrm{str}}[d]$.*

We now summarize some of the basic properties of the p-dimensions and p-measure.

PROPOSITION 2.1 (see [19, 4]). *Let* $X, Y \subseteq \mathbf{C}$.

1. $0 \leq \dim_{\mathrm{p}}(X) \leq \mathrm{Dim}_{\mathrm{p}}(X) \leq 1$.
2. *If* $\dim_{\mathrm{p}}(X) < 1$, *then* $\mu_{\mathrm{p}}(X) = 0$.
3. *If* $X \subseteq Y$, *then* $\dim_{\mathrm{p}}(X) \leq \dim_{\mathrm{p}}(Y)$ *and* $\mathrm{Dim}_{\mathrm{p}}(X) \leq \mathrm{Dim}_{\mathrm{p}}(Y)$.

The following theorem indicates that the p-dimensions are useful for studies within the complexity class E.

THEOREM 2.2 (see [17, 19, 4]).

1. $\mu_{\mathrm{p}}(\mathrm{E}) \neq 0$. *In particular,* $\dim_{\mathrm{p}}(\mathrm{E}) = \mathrm{Dim}_{\mathrm{p}}(\mathrm{E}) = 1$.
2. *For all* $c \in \mathbb{N}$, $\mathrm{Dim}_{\mathrm{p}}(\mathrm{DTIME}(2^{cn})) = 0$.

2.3. Online mistake-bound model of learning. A *concept* is a set $C \subseteq U$, where U is some *universe*. A concept C is often identified with its characteristic function $f_C : U \to \{0,1\}$. In this paper the universe is always a set of binary strings. A *concept class* is a set of concepts $\mathcal{C} \subseteq \mathcal{P}(U)$.

Given a concept class $\mathcal{C}$ and a universe U, a learning algorithm tries to learn an unknown target concept $C \in \mathcal{C}$. The algorithm is given a sequence of examples x_1, x_2, ... in U. When given each example x_i, the algorithm must predict if $x_i \in C$ or $x_i \notin C$. The algorithm is then told the correct answer and given the next example. The algorithm makes a *mistake* if its prediction for membership of x_i in C is wrong. This proceeds until every member of U is given as an example.

The goal is to minimize the number of mistakes. The *mistake bound* of a learning algorithm A for a concept class $\mathcal{C}$ is the maximum over all $C \in \mathcal{C}$ of the number of mistakes A makes when learning C, over all possible sequences of examples. The *running time* of A on $\mathcal{C}$ is the maximum time A takes to make a prediction.

2.4. Disjunctions and Winnow. An interesting concept class is the class of monotone disjunctions, which can be efficiently learned by Littlestone's Winnow algorithm [16]. A monotone disjunction on $\{0,1\}^n$ is a formula of the form $\phi_V = \bigvee_{i \in V} x_i$, where $V \subseteq \{1, \ldots, n\}$ and we write a string $x \in \{0,1\}^n$ as $x = x_1 \cdots x_n$. The concept ϕ_V can also be viewed as the set $\{x \in \{0,1\}^n \mid \phi_V(x) = 1\}$ or equivalently as $\{A \subseteq \{1, \ldots, n\} \mid A \cap V \neq \emptyset\}$.

The Winnow algorithm has two parameters α (a weight update multiplier) and θ (a threshold value). Initially, each variable x_i has a weight $w_i = 1$. To classify a string x, the algorithm predicts that x is in the concept if $\sum_i w_i x_i > \theta$, and not in the concept otherwise. The weights are updated as follows whenever a mistake is made.

- If a negative example x is incorrectly classified, then set $w_i := 0$ for all i such that $x_i = 1$. (Certainly these x_i's are not in the disjunction.)
- If a positive example x is incorrectly classified, then set $w_i := \alpha \cdot w_i$ for all i such that $x_i = 1$. (It is considered more likely that these x_i's are in the disjunction.)

A useful setting of the parameters is $\alpha = 2$ and $\theta = n/2$. With these parameters, Littlestone proved that Winnow will make at most $2k \log n + 2$ mistakes when the target disjunction has at most k literals. Also, the algorithm uses $O(n)$ time to classify each example and update the weights.

3. Learning and dimension. In this section we present a framework relating online learning to resource-bounded dimension. This framework is based on reducibility to learnable concept class families.

DEFINITION. *A sequence* $\mathcal{C} = (\mathcal{C}_n \mid n \in \mathbb{N})$ *of concept classes is called a* concept class family.

We consider two types of reducibility: a strong reduction that works for almost all input lengths and a weak reduction that is only required to work infinitely often.

DEFINITION. *Let* $L \subseteq \{0,1\}^*$, $\mathcal{C} = (\mathcal{C}_n \mid n \in \mathbb{N})$ *be a concept class family, and* $r(n)$ *be a time bound.*

1. *We say* L strongly reduces to $\mathcal{C}$ in $r(n)$ time*, and we write* $L \leq^r_{str} \mathcal{C}$*, if there exist a sequence of target concepts* $(c_n \in \mathcal{C}_n \mid n \in \mathbb{N})$ *and a reduction* f *computable in* $O(r(n))$ *time such that for all but finitely many* n*, for all* $x \in \{0,1\}^n$*,* $x \in L$ *if and only if* $f(x) \in c_n$*.*
2. *We say* L weakly reduces to $\mathcal{C}$ in $r(n)$ time*, and we write* $L \leq^r_{wk} \mathcal{C}$*, if there exists a reduction* f *computable in* $O(r(n))$ *time such that for infinitely many* n*, there is a concept* $c_n \in \mathcal{C}_n$ *such that for all* $x \in \{0,1\}^{\leq n}$*,* $x \in L$ *if and only if* $f(0^n, x) \in c_n$*.*

It is necessary to quantify both the time complexity and mistake bound for learning a concept class family.

DEFINITION. *Let* $t, m : \mathbb{N} \to \mathbb{N}$ *and let* $\mathcal{C} = (\mathcal{C}_n \mid n \in \mathbb{N})$ *be a concept class family. We say that* $\mathcal{C} \in \mathcal{L}(t,m)$ *if there is an algorithm that learns* $\mathcal{C}_n$ *in* $O(t(n))$ *time with mistake bound* $m(n)$*.*

Combining the two previous definitions we arrive at our central technical concept.

DEFINITION. *Let* $r, t, m : \mathbb{N} \to \mathbb{N}$*.*

1. $\mathcal{RL}_{\mathrm{str}}(r,t,m)$ *is the class of all languages that* $\leq^r_{str}$*-reduce to some concept class family in* $\mathcal{L}(t,m)$*.*
2. $\mathcal{RL}_{\mathrm{wk}}(r,t,m)$ *is the class of all languages that* $\leq^r_{wk}$*-reduce to some concept class family in* $\mathcal{L}(t,m)$*.*

A remark about the parameters in this definition is in order. If $A \in \mathcal{RL}_{\mathrm{str}}(r,t,m)$, then $A \leq^r_{str} \mathcal{C}$ for some concept class family $\mathcal{C} = (\mathcal{C}_n \mid n \in \mathbb{N})$. Then $x \in A_{=n}$ if and only if $f(x) \in c_n$, where $c_n \in \mathcal{C}_n$ is the target concept and f is the reduction. We emphasize that the complexity of learning $\mathcal{C}_n$ is measured in terms of $n = |x|$, and not the size of c_n or $f(x)$. Instead $\mathcal{C}_n$ is learnable in time $O(t(n))$ with mistake bound $m(n)$.

The following theorem is the main technical tool in this paper. Here we consider exponential-time reductions to concept classes that can be learned in exponential-time, but with subexponentially many mistakes.

THEOREM 3.1. *Let* $c \in \mathbb{N}$*.*

1. $\mathcal{RL}_{\mathrm{str}}(2^{cn}, 2^{cn}, o(2^n))$ *has strong* p*-dimension* 0*.*
2. $\mathcal{RL}_{\mathrm{wk}}(2^{cn}, 2^{cn}, o(2^n))$ *has* p*-dimension* 0*.*

Proof. We prove only that $\mathcal{RL}_{\mathrm{wk}}(2^{cn}, 2^{cn}, o(2^n))$ has p-dimension 0. The other part of the theorem is proved similarly. Let $s > 0$ such that 2^s is rational. It suffices to show that the class has p-dimension at most s.

Let $A \in \mathcal{RL}_{\mathrm{wk}}(2^{cn}, 2^{cn}, o(2^n))$. Then there is a concept class family $\mathcal{C} = \{\mathcal{C}_n \mid n \in \mathbb{N}\} \in \mathcal{L}(2^{cn}, o(2^n))$ such that $A \leq^{2^{cn}}_{wk} \mathcal{C}$. Let f be this reduction from A to $\mathcal{C}$. Then for infinitely many n, there is a target concept $c_n \in \mathcal{C}_n$ such that

$$x \in A_{\leq n} \iff f(x) \in c_n.$$

Let J be the set of all n such that this concept exists. Let $\mathcal{A}$ be a 2^{cn}-time learning algorithm for $\mathcal{C}$ with mistake bound $o(2^n)$.

Fix an n and let $N = 2^{n+1} - 2$. We view the reduction f as generating a sequence

of examples

$$f(s_0), f(s_1), \ldots, f(s_N),$$

one for each string in $\{0,1\}^{\leq n}$. The idea is to run the algorithm $\mathcal{A}$ on this sequence of examples, trying to learn c_n. We will use $\mathcal{A}$'s predictions to define an s-gale d_n inductively as follows.

1. Let $N_0 = 2^{n/2}$. For all strings w with $|w| < N_0$, $d_n(w) = 2^{(s-1)|w|}$.
2. Let ϵ be a small rational number to be determined later. Let w be any string with $N_0 \leq |w| < N$. Run $\mathcal{A}$ on the sequence of examples $f(s_{N_0}), \ldots, f(s_{|w|})$, telling $\mathcal{A}$ that for each i, $N_0 \leq i < |w|$,
   - if $w[i] = 1$, then $f(s_i)$ is a positive example.
   - if $w[i] = 0$, then $f(s_i)$ is a negative example.

   At the end $\mathcal{A}$ will output a prediction for $f(s_{|w|})$:
   - If $\mathcal{A}$ predicts that $f(s_{|w|})$ is a member of the target concept c_n, then we let
     - $d_n(w1) = 2^s(1-\epsilon)d(w)$,
     - $d_n(w0) = 2^s\epsilon d(w)$.
   - Otherwise, $\mathcal{A}$ predicts that $f(s_{|w|})$ is not a member of the target concept c_n, and we let
     - $d_n(w0) = 2^s(1-\epsilon)d(w)$,
     - $d_n(w1) = 2^s\epsilon d(w)$.
3. For w with $|w| \geq N$, we set $d_n(w0) = d_n(w1) = 2^{(s-1)}d_n(w)$.

The reason for making d_n wait until N_0 to bet is computational efficiency. For $|w| < N_0$, $d_n(w)$ is computable in $O(|w|)$ time. If $|w| \geq N_0$, then to compute $d_n(w)$ we need to execute $\mathcal{A}$ on at most $|w|$ examples, each execution taking $O(2^{cn})$ time to compute the example and $O(2^{cn})$ to compute the label, for a total time of $O(|w|2^{cn})$. Because $|w| \geq 2^{n/2}$, this simplifies to $O(|w|^{2c+1})$.

Each time $\mathcal{A}$ makes a correct prediction, the value of the s-gale is increased by a $2^s(1-\epsilon)$ factor. When $\mathcal{A}$ makes a mistake, the value is multiplied by $2^s\epsilon$. Let w_n be the length N prefix of A's characteristic sequence and suppose that $n \in J$. In the computation of $d_n(w_n)$, observe that $\mathcal{A}$ is told the correct labels for the examples according to the target concept c_n. Let m_n be the number of mistakes that $\mathcal{A}$ makes on this sequence of examples when learning c_n; we know that $m_n = o(2^n)$. Then

$$\begin{aligned} d_n(w_n) &= 2^{s(N-N_0)} \cdot (1-\epsilon)^{N-N_0-m_n} \cdot \epsilon^{m_n} \cdot 2^{(s-1)N_0} \\ &= 2^{sN+[(N-N_0-m_n)\log(1-\epsilon)]+[m_n \log \epsilon]-N_0} \\ &\geq 2^{sN-\left(N \log \frac{1}{1-\epsilon}+m_n \log \frac{1-\epsilon}{\epsilon}\right)-N_0}. \end{aligned}$$

We choose $\epsilon \in \mathbb{Q}$ so that $\log \frac{1}{1-\epsilon} < s$ and let $0 < \delta < s - \log \frac{1}{1-\epsilon}$. Then since m_n and N_0 are both $o(N)$, when $n \in J$ is large enough we have

$$d_n(w_n) \geq 2^{\delta N}.$$

Let d be the s-gale $d = \sum_{n=1}^{\infty} 2^{-n} d_n$. Then $A \in S^\infty[d]$. A standard technique is that taking the first $|w| + r$ terms of the sum, we can approximate $d(w)$ to precision 2^{-r} in time $O((|w|+r) \cdot \max\{|w|+r, |w|^{2c+1}\})$. Such an s-gale can be defined for every set in $\mathcal{RL}_{\mathrm{wk}}(2^{cn}, 2^{cn}, o(2^n))$. These gales are all computable within the same time bound, so we can apply a union lemma [19] to conclude that $\mathcal{RL}_{\mathrm{wk}}(2^{cn}, 2^{cn}, o(2^n))$ has p-dimension at most s. □

4. Disjunctive and conjunctive reductions. In this section, as a warmup to our main theorem, we present two basic applications of Theorem 3.1. First, we consider disjunctive reductions.

THEOREM 4.1. $\mathrm{P_d}(\mathrm{DENSE}^c)$ *has* p-*dimension* 0.

Proof. We will show that $\mathrm{P_d}(\mathrm{DENSE}^c) \subseteq \mathcal{RL}_{\mathrm{wk}}(2^{2n}, 2^{2n}, o(2^n))$. For this, let $A \in \mathrm{P_d}(\mathrm{DENSE}^c)$ be arbitrary. Then there is a set $S \in \mathrm{DENSE}^c$ and a reduction $f : \{0,1\}^* \to \mathcal{P}(\{0,1\}^*)$ computable in polynomial time $p(n)$ such that for all $x \in \{0,1\}^*$, $x \in A$ if and only if $f(x) \cap S \neq \emptyset$. Note that on an input of length n, all queries of f have length bounded by $p(n)$. Also, since S is nondense, for any $\epsilon > 0$ there are infinitely many n such that

$$|S_{\leq p(n)}| \leq 2^{n^\epsilon}. \tag{4.1}$$

Let $Q_n = \bigcup_{|x|\leq n} f(x)$ be the set of all queries made by f up through length n. Then $|Q_n| \leq 2^{n+1}p(n)$. Enumerate Q_n as $q_1, \ldots, q_N$. Then each subset of $R \subseteq Q_n$ can be identified with its characteristic string $\chi_R \in \{0,1\}^N$ according to this enumeration. We define $\mathcal{C}_n$ to be the concept class of all monotone disjunctions on $\{0,1\}^N$ that have at most 2^{n^ϵ} literals. Our target disjunction is

$$\phi_n = \bigvee_{i:q_i \in S} q_i,$$

which is a member of $\mathcal{C}_n$ whenever (4.1) holds. For any $x \in \{0,1\}^{\leq n}$,

$$x \in A \iff \phi_n(\chi_{f(x)}) = 1.$$

Given x, $\chi_{f(x)}$ can be computed in $O(2^{2n})$ time. Therefore $A \leq_{wk}^{O(2^{2n})} \mathcal{C} = (\mathcal{C}_n \mid n \in \mathbb{N})$. Since Winnow [16] learns $\mathcal{C}_n$ making at most $2 \cdot 2^{n^\epsilon} \log |Q_n| + 2 = o(2^n)$ mistakes in time $O(2^{2n})$, it follows that $A \in \mathcal{RL}_{\mathrm{wk}}(2^{2n}, 2^{2n}, o(2^n))$. □

Next, we consider conjunctive reductions.

THEOREM 4.2. $\mathrm{P_c}(\mathrm{DENSE}^c)$ *has* p-*dimension* 0.

Proof. We will show that $\mathrm{P_c}(\mathrm{DENSE}^c) \subseteq \mathcal{RL}_{\mathrm{wk}}(2^n, 2^{2n}, o(2^n))$. For this, let $A \leq_{\mathrm{c}}^{\mathrm{p}} S \in \mathrm{DENSE}^c$. Then there is a reduction $f : \{0,1\}^* \to \mathcal{P}(\{0,1\}^*)$ computable in polynomial time $p(n)$ such that for all $x \in \{0,1\}^*$, $x \in A$ if and only if $f(x) \subseteq S$.

Fix an input length n, and let $Q_n = \bigcup_{|x|\leq n} f(x)$. Let $\epsilon > 0$ and consider the concept class

$$\mathcal{C}_n = \{\mathcal{P}(X) \mid X \subseteq Q_n \text{ and } |X| \leq 2^{n^\epsilon}\}.$$

Our target concept is

$$C_n = \mathcal{P}(S \cap Q_n).$$

For infinitely many n, $|S \cap Q_n| \leq |S_{\leq p(n)}| \leq 2^{n^\epsilon}$, in which case $C_n \in \mathcal{C}_n$. For any $x \in \{0,1\}^{\leq n}$, we have

$$x \in A \iff f(x) \in C_n.$$

Therefore $A \leq_{wk}^{p(n)} \mathcal{C} = (\mathcal{C}_n \mid n \in \mathbb{N})$.

The class $\mathcal{C}_n$ can be learned by a simple algorithm that makes at most $|X|$ mistakes when learning $\mathcal{P}(X)$. The hypothesis for X is simply the union of all positive examples

seen so far. More explicitly, the algorithm begins with the hypothesis $H = \emptyset$. In any stage, given an example Q, the algorithm predicts "yes" if $Q \subseteq H$ and "no" otherwise. If the prediction is no, but Q is revealed to be a positive example, then the hypothesis is updated as $H := H \cup Q$. The algorithm will never make a mistake on a negative example, and can make at most $|X|$ mistakes on positive examples.

This algorithm shows that $\mathcal{C} \in \mathcal{L}(2^{2n}, o(2^n))$, so $A \in \mathcal{RL}_{\mathrm{wk}}(p(n), 2^{2n}, o(2^n))$. It follows that $\mathrm{P_c}(\mathrm{DENSE}^c) \subseteq \mathcal{RL}_{\mathrm{wk}}(2^n, 2^{2n}, o(2^n))$. □

Since $\dim_{\mathrm{p}}(\mathrm{E}) = 1$, we have new proofs of the following results of Watanabe.

COROLLARY 4.3 (Watanabe [27]). $\mathrm{E} \not\subseteq \mathrm{P_d}(\mathrm{DENSE}^c)$ *and* $\mathrm{E} \not\subseteq \mathrm{P_c}(\mathrm{DENSE}^c)$. *That is, every* $\leq^{\mathrm{p}}_{\mathrm{d}}$*-hard or* $\leq^{\mathrm{p}}_{\mathrm{c}}$*-hard set for* E *is dense.*

5. Adaptive reductions. In this section we prove our main theorem, which concerns adaptive reductions that make a sublinear number of queries to a nondense set. It turns out that this problem can also be reduced to learning disjunctions.

In a surprising result (refuting a conjecture of Ko [14]), Allender et al. [1] showed that $\mathrm{P_{btt}}(\mathrm{SPARSE}) \subseteq \mathrm{P_d}(\mathrm{SPARSE})$. The disjunctive reduction they obtain will not be polynomial-time computable if the original reduction has more than a constant number of queries. However, in the proof of the following theorem we are still able to exploit their technique, and obtain an exponential-time reduction to a disjunction. Then we can apply the Winnow algorithm as in the previous section.

THEOREM 5.1. *For all* $\alpha < 1$, $\mathrm{P}_{n^\alpha - \mathrm{T}}(\mathrm{DENSE}^c)$ *has* p*-dimension* 0.

Proof. Let $L \leq^{\mathrm{p}}_{n^\alpha - \mathrm{T}} S \in \mathrm{DENSE}^c$ via some oracle machine M. We will show how to reduce L to a class of disjunctions and obtain $\mathrm{P}_{n^\alpha - \mathrm{T}}(\mathrm{DENSE}^c) \subseteq \mathcal{RL}_{\mathrm{wk}}(2^{2n}, 2^{2n}, o(2^n))$.

Fix an input length n. For an input $x \in \{0,1\}^{\leq n}$, consider using each $z \in \{0,1\}^{n^\alpha}$ as the sequence of yes/no answers to M's queries. Each z causes M to produce a sequence of queries $w_0^{x,z}, \ldots, w_{k(x,z)}^{x,z}$, where $k(x,z) < n^\alpha$, and an accepting or rejecting decision. Let $Z_x \subseteq \{0,1\}^{n^\alpha}$ be the set of all query answer sequences that cause M to accept x. Then we have $x \in L$ if and only if

$$(\exists z \in Z_x)(\forall 0 \leq j \leq k(x,z))\ S[w_j^{x,z}] = z[j],$$

which is equivalent to

$$(\exists z \in Z_x)(\forall 0 \leq j \leq k(x,z))\ z[j] \cdot w_j^{x,z} \in S^c \oplus S,$$

where $S^c \oplus S$ is the disjoint union $\{0x \mid x \in S^c\} \cup \{1x \mid x \in S\}$.

A key part of the proof that $\mathrm{P_{btt}}(\mathrm{SPARSE}) \subseteq \mathrm{P_d}(\mathrm{SPARSE})$ in [1] is to show that $\mathrm{P_{1-tt}}(\mathrm{SPARSE})$ is contained in $\mathrm{P_d}(\mathrm{SPARSE})$. The same argument yields that

$$\mathrm{P_{1-tt}}(\mathrm{DENSE}^c) \subseteq \mathrm{P_d}(\mathrm{DENSE}^c).$$

Therefore, there is a set $U \in \mathrm{DENSE}^c$ such that $S^c \oplus S \leq^{\mathrm{p}}_{\mathrm{d}} U$. Letting g be this polynomial-time disjunctive reduction, we have $x \in L$ if and only if

$$(\exists z \in Z_x)(\forall 0 \leq j \leq k(x,z))\ g(z[j] \cdot w_j^{x,z}) \cap U \neq \emptyset.$$

For each $z \in Z_x$, let

$$H_{x,z} = \{\langle u_0, \ldots, u_{k(x,z)} \rangle \mid (\forall 0 \leq j \leq k(x,z))\ u_j \in g(z[j] \cdot w_j^{x,z})\}.$$

Let $r(n)$ be a polynomial bounding the running time of g on inputs of the form $z[j] \cdot w_j^{x,z}$, where $|x| \leq n$. Define

$$A_n = \{\langle u_0, \ldots, u_k \rangle \mid k < n^\alpha \text{ and } (\forall 0 \leq j \leq k)\ u_j \in U_{\leq r(n)}\}.$$

Then we have $x \in L$ if and only if

$$(\exists z \in Z_x)(\exists v \in H_{x,z})\ v \in A_n.$$

Letting

$$H_x = \bigcup_{z \in Z_x} H_{x,z},$$

we can rewrite this as

$$x \in L \iff H_x \cap A_n \neq \emptyset. \tag{5.1}$$

Because $|H_{x,z}| \leq r(n)^{n^\alpha}$ we have

$$|H_x| \leq |Z_x| \cdot r(n)^{n^\alpha} \leq 2^{n^\alpha \cdot (1+\log r(n))}. \tag{5.2}$$

Also,

$$|A_n| \leq n^\alpha \cdot |U_{\leq r(n)}|^{n^\alpha}.$$

Let $\epsilon \in (0, 1-\alpha)$, and let $\delta \in (\alpha+\epsilon, 1)$. Then since U is nondense, for infinitely many n, we have $|U_{\leq r(n)}| \leq 2^{n^\epsilon}$. This implies

$$(\exists^\infty n)\ |A_n| \leq n^\alpha \cdot 2^{n^{\alpha+\epsilon}} \leq 2^{n^\delta}. \tag{5.3}$$

Let

$$H_n = \bigcup_{x \in \{0,1\}^{\leq n}} H_x.$$

Then from (5.2), $|H_n| \leq 2^{2n}$ if n is sufficiently large.

Enumerate H_n as $h_1, \ldots, h_N$. We identify any $R \subseteq H_n$ with its characteristic string $\chi_R^{(n)} \in \{0,1\}^N$ according to this enumeration. Let $\mathcal{C}_n$ be the concept class of all monotone disjunctions on $\{0,1\}^N$ that have at most 2^{n^δ} literals.

Define the disjunction

$$\phi_n = \bigvee_{i : h_i \in A_n} h_i,$$

which by (5.3) is in $\mathcal{C}_n$ for infinitely many n. For any $x \in \{0,1\}^{\leq n}$, from (5.1) it follows that

$$x \in L \iff \phi_n(\chi_{H_x}^{(n)}) = 1.$$

Given $x \in \{0,1\}^{\leq n}$, we can compute $\chi_{H_x}^{(n)}$ in $O(2^n \cdot \mathrm{poly}(n) + |H_n|)$ time. Therefore, letting $\mathcal{C} = (\mathcal{C}_n \mid n \in \mathbb{N})$, we have $L \leq_{wk}^{2^{2n}} \mathcal{C}$. Since $\mathcal{C}_n$ is learnable by Winnow with at most $2 \cdot 2^{n^\delta} \cdot \log |H_n| + 2 = o(2^n)$ mistakes, it follows that $L \in \mathcal{RL}_{\mathrm{wk}}(2^{2n}, 2^{2n}, o(2^n))$. □

As a corollary, we have a positive answer to the question of Lutz and Mayordomo [22] mentioned in our introduction.

COROLLARY 5.2. *For all* $\alpha < 1$, $\mathrm{P}_{n^\alpha\text{-T}}(\mathrm{DENSE}^c)$ *has* p*-measure* 0.

COROLLARY 5.3. *For all* $\alpha < 1$, $\mathrm{E} \not\subseteq \mathrm{P}_{n^\alpha-\mathrm{T}}(\mathrm{DENSE}^c)$. *That is, every* $\leq^{\mathrm{p}}_{n^\alpha-\mathrm{T}}$*-hard set for* E *is dense.*

If we scale down from nondense sets to sparse sets, the same proof technique can handle more queries.

THEOREM 5.4. $\mathrm{P}_{o(n/\log n)-\mathrm{T}}(\mathrm{SPARSE})$ *has strong* p*-dimension* 0.

Proof. Let $L \leq^{\mathrm{p}}_{f(n)-\mathrm{T}} S \in \mathrm{SPARSE}$ via some oracle machine M, where $f(n) = o(n/\log n)$.

Fix an input length n. For an input $x \in \{0,1\}^n$, each query answer sequence $z \in \{0,1\}^{f(n)}$ causes M to produce a sequence of queries $w_0^{x,z}, \ldots, w_{k(x,z)}^{x,z}$, where $k(x,z) < f(n)$, and an accepting or rejecting decision. Let $Z_x \subseteq \{0,1\}^{f(n)}$ be the set of all query answer sequences that cause M to accept x. Then we have $x \in L$ if and only if

$$(\exists z \in Z_x)(\forall 0 \leq j \leq k(x,z))\ z[j] \cdot w_j^{x,z} \in S^c \oplus S.$$

Since $\mathrm{P}_{1-\mathrm{tt}}(\mathrm{SPARSE}) \subseteq \mathrm{P}_{\mathrm{d}}(\mathrm{SPARSE})$, there is a set $U \in \mathrm{SPARSE}$ such that $S^c \oplus S \leq^{\mathrm{p}}_{\mathrm{d}} U$. Letting g be this polynomial-time disjunctive reduction, we have $x \in L$ if and only if

$$(\exists z \in Z_x)(\forall 0 \leq j \leq k(x,z))\ g(z[j] \cdot w_j^{x,z}) \cap U \neq \emptyset.$$

As before, we can define sets H_x and A_n so that

$$x \in L \iff H_x \cap A_n \neq \emptyset.$$

Let $r(n)$ be a polynomial bounding the running time of g outputs on inputs of the form $z[j] \cdot w_j^{x,z}$, where $|x| = n$. Then

$$|H_x| \leq |Z_x| \cdot r(n)^{f(n)} \leq 2^{f(n)\cdot(1+\log r(n))},$$

so we have $|H_x| \leq 2^n$ if n is sufficiently large because $f(n) = o(n/\log n)$. Letting $H_n = \bigcup_{x\in\{0,1\}^n} H_x$, we have $|H_n| \leq 2^{2n}$.

Also,

$$|A_n| \leq f(n) \cdot |U_{\leq r(n)}|^{f(n)}.$$

Let $q(n)$ be a polynomial such that $|U_{\leq r(n)}| \leq q(n)$ for all n. Then

$$|A_n| \leq f(n) \cdot q(n)^{f(n)} \leq 2^{f(n)\log q(n) + \log f(n)}.$$

Let $v(n) = f(n)\log q(n) + \log f(n)$. Notice that $v(n) = o(n)$ because $f(n) = o(n/\log n)$.

As before, we enumerate H_n as $h_1, \ldots, h_N$ and identify any $R \subseteq H_n$ with its characteristic string $\chi_R^{(n)} \in \{0,1\}^N$. Let $\mathcal{C}_n$ be the concept class of all monotone disjunctions on $\{0,1\}^N$ that have at most $2^{v(n)}$ literals. The disjunction $\phi_n = \bigvee_{i:h_i\in A_n} h_i$ is in $\mathcal{C}_n$ for every n. For any $x \in \{0,1\}^n$, we have

$$x \in L \iff \phi_n(\chi_{H_x}^{(n)}) = 1.$$

Given $x \in \{0,1\}^n$, we can compute $\chi_{H_x}^{(n)}$ in $O(2^n \cdot \mathrm{poly}(n) + |H_n|)$ time. Therefore, letting $\mathcal{C} = (\mathcal{C}_n \mid n \in \mathbb{N})$, we have $L \leq^{2^{2n}}_{str} \mathcal{C}$. Since $\mathcal{C}_n$ is learnable by

Winnow with at most $2 \cdot 2^{v(n)} \cdot \log |H_n| + 2 = o(2^n)$ mistakes, it follows that $L \in \mathcal{RL}_{\mathrm{str}}(2^{2n}, 2^{2n}, o(2^n))$. □

The following corollary improves the result of Fu [8] that $\mathrm{E} \not\subseteq \mathrm{P}_{o(n/\log n)-\mathrm{T}}(\mathrm{TALLY})$.

COROLLARY 5.5. $\mathrm{E} \not\subseteq \mathrm{P}_{o(n/\log n)-\mathrm{T}}(\mathrm{SPARSE})$.

Since Wilson constructed an oracle relative to which $\mathrm{E} \subseteq \mathrm{P}_{O(n)-\mathrm{tt}}(\mathrm{SPARSE})$ [28, 21], Corollary 5.5 is near the limits of relativizable techniques.

In Theorem 5.4, we used strong dimension, which raises a technical point. The results about reductions to DENSE^c cannot be strengthened to strong p-dimension simply because the class DENSE^c itself has strong dimension 1. This is because being nondense is an infinitely often property [9]. However, if we replace DENSE^c with by SPARSE in any of our results, the proofs can be adapted to show that the resulting class has strong p-dimension 0. We can also obtain strong dimension results by substituting the larger class $\mathrm{DENSE}^c_{\mathrm{i.o.}}$, where $\mathrm{DENSE}_{\mathrm{i.o.}}$ is the class of all L that satisfy $(\exists \epsilon > 0)(\exists^\infty n)\ |L_{\leq n}| > 2^{n^\epsilon}$.

6. Hard sets for NP. The hypothesis "NP has positive p-dimension," written $\dim_{\mathrm{p}}(\mathrm{NP}) > 0$, was first used in [11] to study the inapproximability of MAX3SAT. This positive dimension hypothesis is apparently much weaker than Lutz's often-investigated $\mu_{\mathrm{p}}(\mathrm{NP}) \neq 0$ hypothesis, but is a stronger assumption than $\mathrm{P} \neq \mathrm{NP}$:

$$\mu_{\mathrm{p}}(\mathrm{NP}) \neq 0 \Rightarrow \dim_{\mathrm{p}}(\mathrm{NP}) = 1 \Rightarrow \dim_{\mathrm{p}}(\mathrm{NP}) > 0 \Rightarrow \mathrm{P} \neq \mathrm{NP}.$$

The measure hypothesis $\mu_{\mathrm{p}}(\mathrm{NP}) \neq 0$ has many plausible consequences that are not known to follow from $\mathrm{P} \neq \mathrm{NP}$ (see, e.g., [22]). So far, few consequences of $\dim_{\mathrm{p}}(\mathrm{NP}) > 0$ are known. The following corollary of our results begins to remedy this.

THEOREM 6.1. *If* $\dim_{\mathrm{p}}(\mathrm{NP}) > 0$*, then every set that is hard for* NP *under* $\leq^{\mathrm{p}}_{\mathrm{d}}$ *reductions,* $\leq^{\mathrm{p}}_{\mathrm{c}}$ *reductions, or* $\leq^{\mathrm{p}}_{n^\alpha-\mathrm{T}}$ *reductions* ($\alpha < 1$) *is dense, and every set that is hard under* $\leq^{\mathrm{p}}_{o(n/\log n)-\mathrm{T}}$ *reductions is not sparse.*

The consequences in Theorem 6.1 are much stronger than what is known to follow from $\mathrm{P} \neq \mathrm{NP}$. If $\mathrm{P} \neq \mathrm{NP}$, then no $\leq^{\mathrm{p}}_{\mathrm{btt}}$-hard or $\leq^{\mathrm{p}}_{\mathrm{c}}$-hard set is sparse [26, 3], but it is not known whether hard sets under disjunctive reductions or unbounded Turing reductions can be sparse.

Another result is that if $\mathrm{NP} \neq \mathrm{RP}$, then no $\leq^{\mathrm{p}}_{\mathrm{d}}$-hard set for NP is sparse [7, 6]. It is interesting to see that while the hypotheses $\dim_{\mathrm{p}}(\mathrm{NP}) > 0$ and $\mathrm{NP} \neq \mathrm{RP}$ are apparently incomparable, they both have implications for the density of the disjunctively hard sets for NP.

7. Conclusion. Our connection between online learning and resource-bounded dimension appears to be a powerful tool for computational complexity. We have used it to give relatively simple proofs and improvements of several previous results.

An interesting observation is that for all reductions $\leq^{\mathrm{p}}_\tau$ for which we know how to prove "every $\leq^{\mathrm{p}}_\tau$-hard set for E is dense," by the results presented here we can actually prove "$\mathrm{P}_\tau(\mathrm{DENSE}^c)$ has p-dimension 0." Indeed, we have proven the strongest results for Turing reductions in this way.

Acknowledgment. I thank the anonymous referees for helpful comments and corrections.

ONLINE SCHEDULING OF EQUAL-LENGTH JOBS: RANDOMIZATION AND RESTARTS HELP*

MAREK CHROBAK†, WOJCIECH JAWOR†, JIŘÍ SGALL‡, AND TOMÁŠ TICHÝ‡

Abstract. We consider the following scheduling problem. The input is a set of jobs with equal processing times, where each job is specified by its release time and deadline. The goal is to determine a single-processor nonpreemptive schedule that maximizes the number of completed jobs. In the online version, each job arrives at its release time. We give two online algorithms with competitive ratios below 2 and show several lower bounds on the competitive ratios. First, we give a barely random 5/3-competitive algorithm that uses only one random bit. We also show a lower bound of 3/2 on the competitive ratio of barely random algorithms that randomly choose one of two deterministic algorithms. If the two algorithms are selected with equal probability, we can further improve the bound to 8/5. Second, we give a deterministic 3/2-competitive algorithm in the model that allows restarts, and we show that in this model the ratio 3/2 is optimal. For randomized algorithms with restarts we show a lower bound of 6/5.

Key words. job scheduling, online algorithms, competitive analysis, randomization

1. Introduction.

We consider the following fundamental problem in the area of real-time scheduling. The input is a collection of jobs with equal processing times p, where each job j is specified by its release time r_j and deadline d_j. (All numbers are assumed to be positive integers.) The desired output is a single-processor nonpreemptive schedule. Naturally, each scheduled job must be executed between its release time and deadline, and different jobs cannot overlap. The term "nonpreemptive" means that each job must be executed without interruptions, in a contiguous interval of length p. The objective is to maximize the number of completed jobs.

In the *online version*, each job j arrives at time r_j, and its deadline d_j is revealed at this time. The number of jobs and future release times are unknown. At each time step when no job is running, we have to decide whether to start a job and, if so, to choose which one, based only on the information about the jobs released so far. An online algorithm is called *c-competitive* if on every input instance it schedules at least $1/c$ as many jobs as the optimum schedule.

Our results. It is known that a simple greedy algorithm is 2-competitive for this problem and that this ratio is optimal for deterministic algorithms. We present two ways to improve the competitive ratio of 2.

First, addressing an open question in [13, 14], we give a 5/3-competitive randomized algorithm. Interestingly, our algorithm is *barely random*; it chooses with probability 1/2 one of two deterministic algorithms, i.e., it uses only one random bit.

These two algorithms are two *identical* copies of the same deterministic algorithm that are run concurrently and use a shared lock to break the symmetry and coordinate their behaviors. We are not aware of previous work in the design of randomized online algorithms that uses such a mechanism to coordinate identical algorithms; thus, this technique may be of its own independent interest.

We then show a lower bound of 3/2 on the competitive ratio of barely random algorithms that choose one of two deterministic algorithms with any probability. If these algorithms are each chosen with probability 1/2, we improve the lower bound to 8/5.

Second, we give a deterministic 3/2-competitive algorithm in the *preemption–restart* model. In this model, an online algorithm is allowed to abort a job during execution in order to start another job. The algorithm gets credit only for jobs that are executed contiguously from beginning to end. Aborted jobs can be restarted (from scratch) and completed later. Note that the final schedule produced by such an algorithm is *not* preemptive. Thus the distinction between nonpreemptive and preemption–restart models makes sense only in the online case. (The optimal solutions are always the same.) In addition to the algorithm, we give a matching lower bound, by showing that no deterministic online algorithm with restarts can be better than 3/2-competitive. We also show a lower bound of 6/5 for randomized algorithms with restarts.

We remark that both our algorithms are natural and easy to state and implement. The competitive analysis is, however, fairly involved, and it relies on some structural lemmas about schedules of equal-length jobs.

An extended abstract of this paper appeared as [9].

Previous work. The problem of scheduling equal-length jobs to maximize the number of completed jobs has been well studied in the literature. In the offline case, an $O(n \log n)$-time algorithm for the feasibility problem (checking if *all* jobs can be completed) was given by Garey *et al.* [12] (see also [23, 7]). The maximization version can also be solved in polynomial time [8, 2], although the known algorithms are rather slow. (Carlier [7] claimed an $O(n^3 \log n)$ algorithm but, as pointed out in [8], his algorithm is not correct.)

As the first positive result on the online version, Baruah, Haritsa, and Sharma [4, 5] show that a deterministic greedy algorithm is 2-competitive; in fact, they show that any nonpreemptive deterministic algorithm that is never idle at times when jobs are available for execution is also 2-competitive.

Goldman, Parwatikar, and Suri [13] gave a lower bound of 4/3 on the competitive ratio of randomized algorithms and the tight bound of 2 for deterministic algorithms. We briefly sketch these lower bounds, as they illustrate well what situations an online algorithm needs to avoid in order to achieve a small competitive ratio. Let $p \geq 2$. The jobs, written in the form $j = (r_j, d_j)$, are $1 = (0, 2p + 1)$, $2 = (1, p + 1)$, and $3 = (p, 2p)$. The instance consists of jobs 1,2 or jobs 1,3; in both cases the optimum is 2. Figure 1.1 illustrates the input instance and the adversary strategy. (In this figure, and later throughout the paper, the horizontal dimension corresponds to the time axis, each job j in the input instance is drawn as a line segment spanning the interval $[r_j, d_j]$, and jobs that appear in the schedules are represented by rectangles of length p positioned at the actual time of execution.) In the deterministic case, release job 1. If at time 0 the online algorithm starts job 1, then release job 2; otherwise, release job 3. The online algorithm completes only one job and the competitive ratio is no better than 2. In the randomized case, using Yao's principle [24, 6], we choose

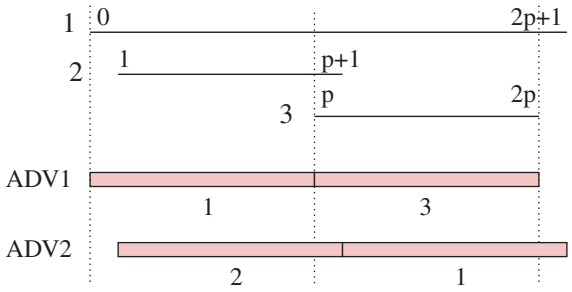

FIG. 1.1. *Jobs used in the lower bound proof.*

each of the two instances with probability 1/2. The expected number of completed jobs of any deterministic online algorithm is at most 1.5, as on one of the instances it completes only one job. Thus the competitive ratio is no better than $2/1.5 = 4/3$.

Goldman, Parwatikar, and Suri [13] show that the lower bound of 2 can be beaten if the jobs on input have sufficiently large "slack": more specifically, they prove that a greedy algorithm is 3/2-competitive for instances where $d_j - r_j \geq 2p$ for all jobs j. This is closely related to our algorithm with restarts: On such instances, our algorithm never uses restarts and becomes identical to the greedy algorithm. Thus in this special case our result constitutes an alternative proof of the result from [13]. Exploring further this direction, Goldwasser [14] obtained a parameterized extension of this result: if $d_j - r_j \geq \lambda p$ for all jobs j, where $\lambda \geq 1$ is an integer, then the competitive ratio is $1 + 1/\lambda$.

In our brief overview of the literature given above, we focused on the case when jobs are of equal length and the objective function is the number of completed jobs. We need to stress though that, in addition to the work cited above, there is a vast literature on real-time scheduling problems where a variety of other models is considered: other or no restrictions can be placed on processing times, jobs may have different weights (benefits), we can have multiple processors, and preemptions may be allowed. For example, once arbitrary processing times and/or weights are introduced, no constant-competitive nonpreemptive algorithms exist. Therefore it is common in the literature to allow preemption with resumption, where a job can be preempted and later started from where it was stopped.

The model with restarts was studied by Hoogeveen, Potts, and Woeginger [17]. They present a 2-competitive deterministic algorithm with restarts for jobs with arbitrary processing times and the objective to maximize the number of completed jobs. They also give a matching lower bound. Their algorithm does not use restarts on the instances with equal processing times, and thus it is no better than 2-competitive for our problem.

Real-time scheduling is an area where randomized algorithms have been found quite effective. Most randomized algorithms in the general scenarios use the classify-and-randomly-select technique by Lipton and Tomkins [20]. Typically, this method decreases the dependence of the competitive ratio from linear to logarithmic in certain parameters (e.g., the maximum ratio between job weights), but it does not apply to the case of jobs with equal lengths and weights. Our randomized algorithm is based on entirely different ideas.

Barely random algorithms have been successfully applied in the past to a variety of online problems, including the list update problem [21], the k-server problem [3], and makespan scheduling [1, 11, 22]. In particular, the algorithm of Albers [1] involves two

deterministic processes in which the second one keeps track of the first and corrects its potential "mistakes"—a coordination idea somewhat similar to ours, although in [1] the two processes are not symmetric. Closer to the topic of this paper, for the general throughput maximization problem with arbitrary processing times and with preemption, Kalyanasundaram and Pruhs [19] showed that a constant competitive ratio can be achieved with a barely random algorithm, even though no constant-competitive deterministic algorithms are possible in that model.

The area of real-time scheduling is of course well motivated by multitudes of applied scenarios. In particular, the model of equal-length jobs—without or with limited preemption—is related to applications in packet switched networks. When different weights are considered, the problem has further connections to the "quality of service" issues (recently a fashionable phrase). Nevertheless, we shamelessly admit that this work has been partially driven by plain curiosity. It is quite intriguing, after all, that so little is known about the competitiveness of such a fundamental scheduling problem.

2. Preliminaries. The input consists of a set of jobs $J = \{1, 2, \ldots\}$, where each job j is given by its release time r_j and deadline d_j. All jobs have processing time p. (We assume that all numbers are positive integers and that $d_j \geq r_j + p$ for all j.) The *expiration time* of a job j is $x_j = d_j - p$, i.e., the last time when it can be started. A job j is called *admissible* at time t if $r_j \leq t \leq x_j$. A job j is called *tight* if $x_j - r_j < p$.

A *nonpreemptive schedule* $\mathcal{A}$ assigns to each completed job j an interval $[S_j^{\mathcal{A}}, C_j^{\mathcal{A}})$, with $r_j \leq S_j^{\mathcal{A}} \leq x_j$ and $C_j^{\mathcal{A}} = S_j^{\mathcal{A}} + p$, during which j is executed. These intervals are disjoint for distinct jobs. $S_j^{\mathcal{A}}$ and $C_j^{\mathcal{A}}$ are called the *start time* and *completion time* of job j. Without loss of generality, both are assumed to be an integer. The number of jobs completed in $\mathcal{A}$ is denoted $|\mathcal{A}|$. We adopt a convention in which "job running (a schedule being idle, etc.) at time t" is an equivalent shorthand for "job running (a schedule being idle, etc.) in the interval $[t, t+1)$." Given a schedule $\mathcal{A}$, a job is *pending* at time t in $\mathcal{A}$ if it is admissible at t (i.e., $r_j \leq t \leq x_j$) but not yet completed in $\mathcal{A}$. Note that according to this definition a job that is being executed at t may also be considered pending. When $\mathcal{A}$ is understood from context, we will typically use notation P_t to denote the set of jobs pending at time t.

For any set of jobs Q, we say that Q is *feasible* at time t if there exists a schedule which completes all jobs in Q such that no job is started before t. Q is *flexible* at time t if it is feasible at time $t + p$.

Applying the Jackson rule [18], it is quite easy to determine whether a set P of pending jobs is feasible at t: Order the jobs in P in order of increasing deadlines, and schedule them at times t, $t + p$, $t + 2p$, etc. Then P is feasible if and only if all jobs in P meet their deadlines. Furthermore, if we want to compute the maximum-size feasible subset $P' \subseteq P$, we can start with $P' = \emptyset$, and then add jobs $j \in P - P'$ to P', one by one and in arbitrary order, as long as P' remains feasible. This means, in particular, that P' is a maximum-size feasible subset of P if and only if P' is a $\subseteq$-maximal feasible subset of P. All those properties can be proven by elementary exchange arguments, and the proofs are left to the reader.

We say that a job started by a schedule $\mathcal{A}$ at time t is *flexible in* $\mathcal{A}$ if the set of all jobs pending in $\mathcal{A}$ at t is flexible; otherwise, the job is called *urgent*. Intuitively, a job is flexible if we could possibly postpone it and stay idle for time p without losing any of the currently pending jobs; this could improve the schedule if a tight job arrives. On the other hand, postponing an urgent job can bring no advantage to the algorithm.

An *online algorithm* constructs a schedule incrementally: at each step t making decisions based only on the jobs released at or before t. The information about each

job j, including its deadline, is revealed to the algorithm at its release time r_j. A *nonpreemptive online algorithm* can start a job only when no job is running; thus, if a job is started at time t, the algorithm has no choice but to let it run to completion at time $t + p$. An *online algorithm with restarts* can start a job at any time. If we start a job j when another job, say k, is running, then k is aborted and started from scratch when (and if) it is started again later. The unfinished portion of k is removed from the final schedule, which is considered to be idle during this time interval. Thus the final schedule generated by an online algorithm with restarts is nonpreemptive.

An online algorithm is called *c-competitive* if, for any set of jobs J and any schedule $\mathcal{Z}$ for J, the schedule $\mathcal{A}$ generated by the algorithm on J satisfies $|\mathcal{Z}| \leq c|\mathcal{A}|$. If the algorithm is randomized, the expression $|\mathcal{A}|$ is replaced by the expected (average) number of jobs completed on the given instance.

The definitions above assume the model—standard in the scheduling literature—with integer release times and deadlines, which implicitly makes the time discrete. Some papers on real-time scheduling work with continuous time. Both our algorithms can be modified to the continuous time model and unit processing time jobs without any change in performance, at the cost of a somewhat more technical presentation.

Properties of schedules. For every instance J, we fix a *canonical linear ordering* $\prec$ of J such that $j \prec k$ implies $d_j \leq d_k$. In other words, we order the jobs by their deadlines, breaking the ties arbitrarily but consistently for all applications of the deadline ordering. The term "earliest-deadline" (ED) now refers to the $\prec$-minimal job.

A schedule $\mathcal{A}$ is called "earliest-deadline-first" (EDF) if, whenever it starts a job, it chooses the ED job of all the pending jobs that are later completed in $\mathcal{A}$. (Note that this may not be the overall ED pending job.)

A schedule $\mathcal{A}$ is *normal* if it satisfies the following two properties:

(n1) when $\mathcal{A}$ starts a job, it chooses the ED job from the set of all pending jobs;

(n2) if the set of all pending jobs in $\mathcal{A}$ at some time t is not flexible, then some job is running at t.

Obviously, any normal schedule is EDF, but the reverse is not true. All algorithms presented in this paper generate normal schedules. The properties (n1) and (n2) are reasonable, as the online algorithm cannot make a mistake by enforcing them. Formally, any online algorithm can be modified, using a standard exchange argument, to produce normal schedules without reducing the number of scheduled jobs. (We omit the proof as we do not need this fact in the paper.)

The following property will be crucial in our proofs.

LEMMA 2.1. *Suppose that a job j is urgent in a normal schedule $\mathcal{A}$. Then at any time t, $S_j^{\mathcal{A}} \leq t \leq x_j$, an urgent job is running in $\mathcal{A}$.*

Proof. Denote by P the set of jobs pending at time $S_j^{\mathcal{A}}$ (including j). By the assumption about j, P is not flexible at $S_j^{\mathcal{A}}$. Towards contradiction, suppose that $\mathcal{A}$ is idle or starts a flexible job at time t, where $C_j^{\mathcal{A}} \leq t \leq x_j$. Then the set Q of jobs pending at time t is flexible at t. Since j is the ED job from P (by the normality of $\mathcal{A}$) and $t \leq x_j$, all other jobs in P have not expired until t, and thus Q contains all the jobs from P that are not completed in $\mathcal{A}$ until time t.

Using the above properties, we can rearrange the schedule as follows. Since Q is flexible at t, we can schedule all jobs of Q at time $t + p$ or later, start j at t, and schedule all jobs in $P - Q - \{j\}$ as in $\mathcal{A}$. But this shows that P is flexible at time $S_j^{\mathcal{A}}$—a contradiction. □

Two schedules $\mathcal{D}$ and $\mathcal{D}'$ for an instance J are called *equivalent* if they satisfy the following conditions for each time t:

(eq1) $\mathcal{D}$ starts a job at t if and only if $\mathcal{D}'$ starts a job at t.

(eq2) Suppose that $\mathcal{D}$ starts a job j at time t and $\mathcal{D}'$ starts a job j' at time t. Then j is flexible in $\mathcal{D}$ if and only if j' is flexible in $\mathcal{D}'$. Furthermore, if they are both flexible then $j = j'$.

Obviously, if $\mathcal{D}$, $\mathcal{D}'$ are equivalent, then $|\mathcal{D}| = |\mathcal{D}'|$.

To facilitate competitive analysis, we modify normal schedules into equivalent EDF schedules with better structural properties. In particular, the next lemma gives us more control over the choice of jobs that we can include in the schedule, in situations where there are several choices. The modified schedules are no longer normal (only EDF, which is a weaker requirement); nevertheless, as they are equivalent to normal schedules, they inherit some of their important properties, including Lemma 2.1.

LEMMA 2.2. *Let $\mathcal{X}$ be a normal schedule for a set of jobs J. Let $f : J \to J$ be a partial function such that if $f(k)$ is defined then k is scheduled as flexible in $\mathcal{X}$ and $r_{f(k)} \le C_k^{\mathcal{X}} \le x_{f(k)}$. Then there exists an EDF schedule $\mathcal{A}$ equivalent to $\mathcal{X}$ such that the following hold:*

(1) *All jobs $f(k)$ are completed in $\mathcal{A}$.*

(2) *Consider a time t when either $\mathcal{A}$ is idle or it starts a job and the set of all its pending jobs is feasible at t. Then all jobs pending at t are completed in $\mathcal{A}$. In particular, each job that is pending when $\mathcal{A}$ starts a flexible job is completed in $\mathcal{A}$.*

Furthermore, if $\mathcal{X}$ is constructed by an online algorithm and $f(k)$ can be determined online at time $C_k^{\mathcal{X}}$ for each flexible job k in $\mathcal{X}$, then $\mathcal{A}$ can be produced by an online algorithm.

Remark. Property (1) is useful in our proofs, since it allows us to modify the schedule computed by the algorithm to resemble more the optimal schedule. Property (2) guarantees that any job planned to be scheduled is indeed scheduled in the future.

Since $\mathcal{A}$ and $\mathcal{X}$ are equivalent, flexible jobs are the same and scheduled at the same times in $\mathcal{A}$ and $\mathcal{X}$. In particular, all the jobs k on which $f(k)$ is defined are scheduled at the same time in both $\mathcal{A}$ and $\mathcal{X}$—a property that will play an important role in our later arguments.

The basic idea of the construction of $\mathcal{A}$ is quite straightforward: Maintain a set Q_t of jobs that we plan to schedule. If the set of all pending jobs is feasible, we always plan to schedule them all. In addition, if we start a flexible job k at time t, the flexibility of k allows us to add to Q_{t+p} an extra job released during the execution of k; so if $f(k)$ is defined, we add $f(k)$.

Proof. We construct $\mathcal{A}$ iteratively. Throughout the proof, t ranges over times when $\mathcal{X}$ is idle or starts a job. For each such t, let P_t and P'_t denote the set of jobs pending in $\mathcal{X}$ and $\mathcal{A}$, respectively.

We will maintain an auxiliary set of jobs Q_t that are pending at t in $\mathcal{X}$ and $\mathcal{A}$, i.e., $Q_t \subseteq P_t \cap P'_t$. Simultaneously with the construction, we prove inductively that, for all t, the following invariant holds:

$(*)$ Q_t is a $\subseteq$-maximal feasible subset of each of P_t and P'_t.

Before describing the construction, we make two observations. First, recall that condition $(*)$ implies that Q_t is also maximum with respect to size. Second, if any of sets P_t, P'_t, Q_t is flexible, then $Q_t = P_t = P'_t$ by the maximality of Q_t.

We now describe the construction. Initially, choose Q_0 as an arbitrary maximal feasible set of the jobs released at time 0.

Assume we have already defined Q_t. If $\mathcal{X}$ is idle at t, we let $\mathcal{A}$ idle and choose an arbitrary $Q_{t+1} \supseteq Q_t$ by adding to Q_t the jobs released at $t+1$, as long as the set

remains feasible. Since $\mathcal{X}$ is idle, P_t is flexible at t, and thus $Q_t = P_t = P'_t$. Therefore Q_t is feasible at $t+1$, $P_{t+1} = P'_{t+1}$, and we can conclude that $(*)$ holds at time $t+1$.

Now suppose that $\mathcal{X}$ starts a job k at time t. We consider two subcases, depending on whether k is flexible or urgent.

Case 1. Job k is flexible in $\mathcal{X}$. Then $\mathcal{A}$ starts k, too. This is possible since in this case we have $Q_t = P_t = P'_t$, and thus k is pending in $\mathcal{A}$ at time t. Note that k is executed as flexible in $\mathcal{A}$. Further, we also have $P'_{t+p} = P_{t+p}$.

Since Q_t is flexible, it is feasible at $t+p$. To construct Q_{t+p}, we start with $Q_{t+p} = Q_t - \{k\}$ and expand it by processing newly released jobs, one by one, adding each processed job into Q_{t+p} if Q_{t+p} remains feasible. We process first the job $f(k)$, if it is defined, pending, and not yet in Q_{t+p}. Then we process the remaining jobs h with $t < r_h \le t+p$ in an arbitrary order. Since Q_t is feasible at $t+p$ and k is the ED job in Q_t, $Q_t - \{k\} \cup \{f(k)\}$ is feasible at $t+p$ as well, so $f(k)$ can always be added to Q_{t+p} without violating feasibility. By the construction, $(*)$ is satisfied at time $t+p$.

Case 2. Job k is urgent in $\mathcal{X}$. $\mathcal{A}$ starts the ED (more precisely, $\prec$-minimal) job k' from Q_t. Since Q_t is a maximal feasible set both for $\mathcal{X}$ and $\mathcal{A}$, it is nonempty whenever $\mathcal{X}$ starts a job. Furthermore, we know that Q_t is not flexible at t and thus k' is urgent.

Let $T = Q_t - \{k'\}$. We claim that

(t1) T is a maximal subset of P_t (resp., P'_t) that is feasible at time $t+p$, and

(t2) $T \subseteq P_{t+p} \cap P'_{t+p}$.

That T is feasible at $t+p$ follows directly from the definition of T and the fact that k' is the ED job in Q_t. For the same reason, all jobs in T are pending in $\mathcal{A}$ at time $t+p$. Since k' is pending in $\mathcal{X}$ at t, and $\mathcal{X}$ schedules the ED pending job (as $\mathcal{X}$ is normal), we have $k \prec k'$. Therefore all jobs in T are pending at time $t+p$ in $\mathcal{X}$ as well. We conclude that (t2) holds.

No job in $P'_t - Q_t$ can be feasibly added to T at time $t+p$, as otherwise it could be feasibly added to Q_t at time t, contradicting the maximality of Q_t for $\mathcal{A}$. The same argument applies to $\mathcal{X}$. Thus, T satisfies condition (t1) for both P_t and P'_t.

We construct Q_{t+p} as in the previous case. We start with $Q_{t+p} = T$ and process newly released jobs in an arbitrary order, one by one, adding each processed job into Q_{t+p} if Q_{t+p} remains feasible. Again, the maximality of T and the construction implies that Q_{t+p} satisfies $(*)$ at time $t+p$.

This completes the construction. Obviously, $\mathcal{X}$ and $\mathcal{A}$ are equivalent. Also, $\mathcal{A}$ is EDF since, whenever it schedules a job, it chooses the ED job of Q_t, and jobs in $P'_t - Q_t$ are never added to Q_s for $s > t$, so they will not be scheduled in $\mathcal{A}$.

By the construction, $\mathcal{A}$ schedules all the jobs that are in some Q_t. At any time t when $\mathcal{A}$ is idle or starts a flexible job, Q_t is flexible and thus $Q_t = P'_t$. This proves Lemma 2.2(2). This also implies Lemma 2.2(1) since, for $t = S_k^{\mathcal{X}}$, $f(k)$ is either completed by time $t+p$ or $f(k) \in Q_{t+p}$. □

Lemma 2.2 gives an easy proof that any normal schedule $\mathcal{X}$ schedules at least half as many jobs as the optimum. Take the modified schedule $\mathcal{A}$ from Lemma 2.2 (with f undefined). Charge any job j completed in an optimal schedule $\mathcal{Z}$ to a job completed in $\mathcal{A}$ as follows: (a) If $\mathcal{A}$ is running a job k at time $S_j^{\mathcal{Z}}$, charge j to k; (b) otherwise, charge j to j. This is well defined since if j is admissible and $\mathcal{A}$ is idle at time $S_j^{\mathcal{Z}}$, then $\mathcal{A}$ completes j by Lemma 2.2(2). Furthermore, only one job can be charged to k using rule (a), as all jobs have the same processing time and only one job can be started in $\mathcal{Z}$ during the interval when k is running in $\mathcal{A}$. Thus overall at most two jobs in $\mathcal{Z}$ are charged to each job in $\mathcal{A}$, and $|\mathcal{Z}| \le 2|\mathcal{A}| = 2|\mathcal{X}|$, as claimed.

This shows that any online algorithm that generates a normal schedule is 2-competitive. In particular, this includes the known result that the greedy algorithm which always schedules the ED pending job when there are any pending jobs is 2-competitive. We use similar but more refined charging schemes to analyze our improved algorithms.

Goldwasser and Kerbikov [15] introduced a concept of online algorithms that upon release of a job immediately commit whether it will be completed or not. We do not formulate our algorithms in this form, but Lemma 2.2 can be applied to normal schedules generated by our algorithms (with f undefined) to obtain equivalent online algorithms with immediate notification. (For the model with restarts, this implies that any preempted job is completed later.) Since the construction produces equivalent schedules, the performance is also the same.

3. Randomized algorithms. In this section we present our 5/3-competitive barely random algorithm. This algorithm uses only one random bit, namely, at the beginning of computation it chooses with probability 1/2 between two deterministic algorithms. We also show two lower bounds for barely random algorithms: Any randomized algorithm that randomly chooses between two schedules has a ratio of at least 3/2. Furthermore, if the two algorithms are selected with equal probability, the competitive ratio is at least 8/5.

Algorithm RandLock. We describe our algorithm in terms of two identical processes that are denoted by $\mathcal{X}$ and $\mathcal{Y}$. Each process is, in essence, a scheduling algorithm that receives its own copy of the input instance J and computes its own schedule for J. (This means that a given job can be executed by both processes, at the same or different times.) We chose to use the term "process" rather than "algorithm" since $\mathcal{X}$ and $\mathcal{Y}$ are not fully independent: they both have access to a shared lock mechanism used to coordinate their behavior.

Each process $\mathcal{X}$ and $\mathcal{Y}$ is defined as follows:

(RL1) If there are no pending jobs, wait until some job is released.

(RL2) If the set of pending jobs is not flexible, execute the ED pending job.

(RL3) If the set of pending jobs is flexible and the lock is available, acquire the lock (ties broken arbitrarily), execute the ED pending job, and release the lock upon its completion.

(RL4) Otherwise, wait until the lock becomes available or the set of pending jobs becomes nonflexible (due to progress of time or new jobs being released).

Algorithm RandLock selects initially one of the two processes $\mathcal{X}$ or $\mathcal{Y}$, each with probability 1/2. Then it simulates the two processes on a given instance, outputting the schedule generated by the selected process.

By the description of the algorithm, at each step only one process, namely, the one that possesses the lock, can be executing a flexible job.

Before we analyze the algorithm, we illustrate its behavior on the instance in Figure 3.1. Both processes schedule only three jobs, while the optimal schedule has five jobs. Thus RandLock is not better than 5/3-competitive.

Theorem 3.1. RandLock *is a* 5/3*-competitive nonpreemptive randomized algorithm for scheduling equal-length jobs.*

Proof. Overloading the notation, let $\mathcal{X}$ and $\mathcal{Y}$ denote the schedules generated by the corresponding processes on a given instance J. By rules (RL2) and (RL3), both schedules are normal. Fix an arbitrary schedule $\mathcal{Z}$ for the given instance J.

We start by modifying the schedules $\mathcal{X}$ and $\mathcal{Y}$ according to Lemma 2.2. Define a partial function $f^{\mathcal{A}} : J \to J$ as follows. Let $f^{\mathcal{A}}(k) = h$ if k is a flexible job completed

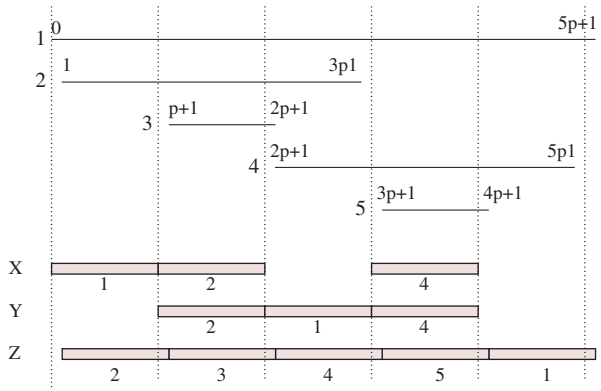

FIG. 3.1. *An instance on which* RANDLOCK *schedules three jobs out of five. At time* 0*, process* $\mathcal{X}$ *acquires the lock and executes job* 1*. Process* $\mathcal{Y}$ *must then wait to execute job* 2 *until it becomes urgent at time* p*. At time* $2p$*,* $\mathcal{Y}$ *acquires the lock and executes* 1*, while* $\mathcal{X}$ *waits with job* 4 *until it becomes urgent at time* $3p$*. Overall, job* 1 *is executed as flexible by both processes; the other jobs are executed as urgent.*

in $\mathcal{X}$ and h is a job started in $\mathcal{Z}$ during the execution of k in $\mathcal{X}$ and admissible at the completion of k in $\mathcal{X}$, i.e., $S_k^{\mathcal{X}} \le S_h^{\mathcal{Z}} < C_k^{\mathcal{X}} \le x_h$. Otherwise (if k is urgent or no such h exists), $f^{\mathcal{A}}(k)$ is undefined. Note that if h exists, it is unique for a given k. Then we define $\mathcal{A}$ to be the schedule constructed from $\mathcal{X}$ in Lemma 2.2 using function $f^{\mathcal{A}}(\cdot)$. Analogously we define function $f^{\mathcal{B}}(\cdot)$, and we modify schedule $\mathcal{Y}$ to obtain schedule $\mathcal{B}$. We stress that these new schedules $\mathcal{A}$ and $\mathcal{B}$ cannot be constructed online as their definition depends on $\mathcal{Z}$; they only serve as tools for the analysis of RANDLOCK.

Since $\mathcal{A}$ (resp., $\mathcal{B}$) is equivalent to a normal schedule $\mathcal{X}$ (resp., $\mathcal{Y}$), Lemma 2.1 still applies to $\mathcal{A}$ (resp., $\mathcal{B}$) and the number of completed jobs remains the same as well.

Throughout the proof we use the convention that whenever $\mathcal{D}$ denotes one of the schedules $\mathcal{A}$ and $\mathcal{B}$, then $\bar{\mathcal{D}}$ denotes the other one. □

LEMMA 3.2. *Let* $\mathcal{D} \in \{\mathcal{A}, \mathcal{B}\}$*, and let* $\bar{\mathcal{D}}$ *be the other process of* RANDLOCK*. Suppose that at time* t $\mathcal{D}$ *is idle or is executing an urgent job and* $\bar{\mathcal{D}}$ *is idle. Then each job admissible at time* t *is completed in* $\bar{\mathcal{D}}$ *as a flexible job by time* t*.*

Proof. The lemma is a direct consequence of the lock mechanism. By the assumption, the lock is available at time t, yet the process corresponding to $\bar{\mathcal{D}}$ does not schedule any job. This is possible only if no job is pending. Consequently, any job k admissible at time t must have been completed in $\bar{\mathcal{D}}$ by time t. Furthermore, if k would be executed as urgent in $\mathcal{D}$ before time t then, since $S_k^{\mathcal{D}} \le t \le x_k$, Lemma 2.1 implies that $\mathcal{D}$ could not be idle at time t. This shows that k is completed as a flexible job. □

The charging scheme. Our proof is based on a charging scheme. The fundamental principle of this scheme is the same as in the proof for the greedy algorithm in section 2. Each adversary job will generate a charge of 1. This charge will be distributed among the jobs in schedules $\mathcal{A}$ and $\mathcal{B}$ in such a way that each job in these schedules will receive a charge of at most 5/6. This will imply the 5/3 bound on the competitive ratio of RANDLOCK.

Let j be a job started in $\mathcal{Z}$ at time $t = S_j^{\mathcal{Z}}$. This job generates several charges of different weights to (the occurrences of) the jobs in schedules $\mathcal{A}$ and $\mathcal{B}$. Each charge

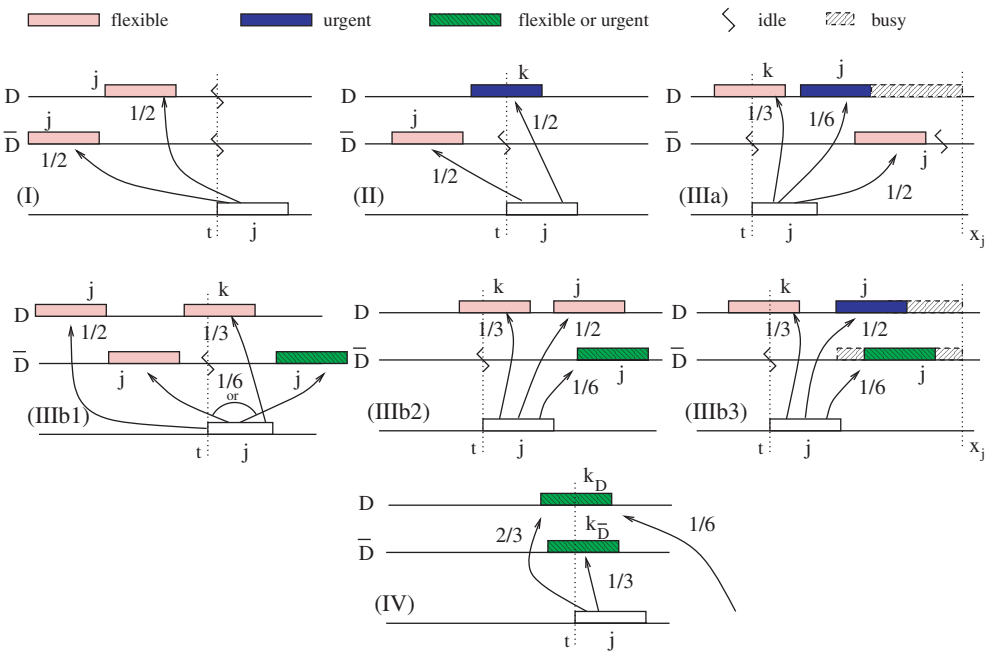

FIG. 3.2. *Illustration of the charging scheme in the analysis of Algorithm* RANDLOCK. *The figure gives examples of different types of charges. In case* (IIIb)*, there are several illustrations that cover possibilities playing a different role in the proof. (To reduce the number of cases, in the figures for case* (III) *we assume that* $j \neq k$ *and* j *is executed in* $\mathcal{D}$ *before it is executed in* $\bar{\mathcal{D}}$*.)*

is uniquely labeled as a *self-charge* or an *up-charge*. Self-charges from j go to the occurrences of j in $\mathcal{A}$ or $\mathcal{B}$, and up-charges from j go to the jobs running at time t in $\mathcal{A}$ and $\mathcal{B}$. If one of the processes runs j at time t, then the charge to this job may be designated as either an up-charge or a self-charge; in case (III) below such a j can even receive both a self-charge and an up-charge from j. The total of charges generated by j is always 1. The charges depend on the status of $\mathcal{A}$ and $\mathcal{B}$ at time t. (See Figure 3.2.)

(I) Both schedules $\mathcal{A}$ and $\mathcal{B}$ are idle. By Lemma 3.2, in both $\mathcal{A}$ and $\mathcal{B}$, j is completed as flexible by time t. We generate two self-charges of $1/2$ to the two occurrences of j in $\mathcal{A}$ and $\mathcal{B}$.

(II) One schedule $\mathcal{D} \in \{\mathcal{A}, \mathcal{B}\}$ is running an urgent job k and the other schedule $\bar{\mathcal{D}}$ is idle. By Lemma 3.2, in $\bar{\mathcal{D}}$, j is completed as flexible by time t. We generate a self-charge of $1/2$ to the occurrence of j in $\bar{\mathcal{D}}$ and an up-charge of $1/2$ to k in $\mathcal{D}$.

(III) One schedule $\mathcal{D} \in \{\mathcal{A}, \mathcal{B}\}$ is running a flexible job k and the other schedule $\bar{\mathcal{D}}$ is idle. We claim that j is completed in both $\mathcal{A}$ and $\mathcal{B}$. For $\bar{\mathcal{D}}$, this follows directly from Lemma 2.2(2). We now prove it for $\mathcal{D}$. If $r_j \leq S_k^{\mathcal{D}}$, then Lemma 2.2(2) applied to time $t' = S_k^{\mathcal{D}}$ implies that $\mathcal{D}$ completes j. If $x_j \geq C_k^{\mathcal{D}}$, then $f^{\mathcal{D}}(k) = j$, so $\mathcal{D}$ completes j by Lemma 2.2(1). The remaining case, namely, $S_k^{\mathcal{D}} < r_j \leq t \leq x_j < C_k^{\mathcal{D}}$, cannot happen, since this condition implies that j is tight and thus the set of jobs pending at time t for $\bar{\mathcal{D}}$ is not flexible. So $\bar{\mathcal{D}}$ would not be idle at t, contradicting the case condition.

In this case we generate one up-charge of $1/3$ to k in $\mathcal{D}$ and two self-charges of $1/2$ and $1/6$ to the occurrences of j according to the two subcases below. Let $\mathcal{E} \in \{\mathcal{A}, \mathcal{B}\}$ be the schedule which starts j first (breaking ties arbitrarily).

(IIIa) If $\mathcal{E}$ schedules j as an urgent job and the other schedule $\bar{\mathcal{E}}$ is idle at some time t' satisfying $S_j^{\mathcal{E}} \le t' \le x_j$, then charge $1/6$ to the occurrence of j in $\mathcal{E}$ and $1/2$ to the occurrence of j in $\bar{\mathcal{E}}$.

We make here a few observations that will be useful later in the proof. Since in this case j is urgent in $\mathcal{E}$ and $\mathcal{E}$ is either idle or executes a flexible job at time t, Lemma 2.1 implies that j is executed in $\mathcal{E}$ after time t. It also implies that $\mathcal{E}$ runs urgent jobs between $S_j^{\mathcal{E}}$ and x_j. This means that $\mathcal{E}$ runs an urgent job at t'. Since $\bar{\mathcal{E}}$ is idle at time t' by the case condition, Lemma 3.2 implies that $\bar{\mathcal{E}}$ schedules j as flexible before time t'.

(IIIb) Otherwise, charge $1/2$ to the occurrence of j in $\mathcal{E}$ and $1/6$ to the occurrence of j in $\bar{\mathcal{E}}$.

(IV) Both processes $\mathcal{A}$ and $\mathcal{B}$ are running jobs $k_{\mathcal{A}}$ and $k_{\mathcal{B}}$, respectively, at time t. We show below in Lemma 3.4 that in the previous cases either $k_{\mathcal{A}}$ or $k_{\mathcal{B}}$ receives a self-charge of at most $1/6$ from its occurrence in $\mathcal{Z}$. We generate an up-charge of $2/3$ from j to this job and an up-charge of $1/3$ to the other one. No self-charge is generated in this case.

This completes the description of the charging scheme. Before we resume the proof of the theorem, we prove two lemmas, the purpose of which is to justify the correctness of the charges in case (IV).

LEMMA 3.3. *Assume that case* (IV) *applies to j. Suppose also that $k_{\mathcal{F}}$ for some $\mathcal{F} \in \{\mathcal{A}, \mathcal{B}\}$ is scheduled before j in $\mathcal{Z}$ (i.e., $S_{k_{\mathcal{F}}}^{\mathcal{Z}} \le t - p$), and that $k_{\mathcal{F}}$ in $\mathcal{F}$ receives a self-charge of* $1/2$ *generated in case* (IIIb) *applied to $k_{\mathcal{F}}$. Then $k_{\bar{\mathcal{F}}} \prec k_{\mathcal{F}}$ or $k_{\bar{\mathcal{F}}} = k_{\mathcal{F}}$.*

Proof. Since $k_{\mathcal{F}}$ receives a charge of $1/2$ in (IIIb), the choice of $\mathcal{E}$ in case (III) implies that $k_{\mathcal{F}}$ is executed in $\bar{\mathcal{F}}$ later than in $\mathcal{F}$, i.e., $S_{k_{\mathcal{F}}}^{\bar{\mathcal{F}}} \ge S_{k_{\mathcal{F}}}^{\mathcal{F}} > t - p$. On the other hand, $S_{k_{\bar{\mathcal{F}}}}^{\bar{\mathcal{F}}} \le t$, so $k_{\mathcal{F}}$ must be executed in $\bar{\mathcal{F}}$ after $k_{\bar{\mathcal{F}}}$. Furthermore, $S_{k_{\bar{\mathcal{F}}}}^{\bar{\mathcal{F}}} > t - p \ge S_{k_{\mathcal{F}}}^{\mathcal{Z}} \ge r_{k_{\mathcal{F}}}$, and thus $k_{\mathcal{F}}$ is pending in $\bar{\mathcal{F}}$ when $k_{\bar{\mathcal{F}}}$ is started. Since $\bar{\mathcal{F}}$ is EDF, we have $k_{\bar{\mathcal{F}}} \prec k_{\mathcal{F}}$ or $k_{\bar{\mathcal{F}}} = k_{\mathcal{F}}$, completing the proof. □

LEMMA 3.4. *Assume that case* (IV) *applies to j. Then for some $\mathcal{D} \in \{\mathcal{A}, \mathcal{B}\}$ the self-charge to $k_{\mathcal{D}}$ in $\mathcal{D}$ does not exceed* $1/6$.

Proof. Note that self-charges are generated only in cases (I)–(III) and any self-charge has weight $1/2$ or $1/6$. Assume, towards contradiction, that both $k_{\mathcal{A}}$ and $k_{\mathcal{B}}$ receive a self-charge of $1/2$. At least one of $k_{\mathcal{A}}$ and $k_{\mathcal{B}}$ is scheduled as urgent in the corresponding schedule, due to the lock mechanism. Thus $k_{\mathcal{A}} \ne k_{\mathcal{B}}$, as (I) is the only case when two self-charges $1/2$ to the same job are generated and then both occurrences are flexible. Furthermore, if $j = k_{\mathcal{G}}$ for some $\mathcal{G} \in \{\mathcal{A}, \mathcal{B}\}$, then $k_{\mathcal{G}}$ would not receive any self-charge. Thus $k_{\mathcal{A}}$, $k_{\mathcal{B}}$, and j are three distinct jobs.

Choose $\mathcal{D}$ such that $k_{\mathcal{D}}$ is urgent in $\mathcal{D}$ (as noted above, such $\mathcal{D}$ exists). The only case when an urgent job receives a self-charge of $1/2$ is (IIIb). By Lemma 2.1, $\mathcal{D}$ executes urgent jobs at all times t', $t \le t' \le x_{k_{\mathcal{D}}}$, which, together with the condition for case (III) applied to $k_{\mathcal{D}}$ (namely, that $\mathcal{D}$ is either idle or executes a flexible job at $S_{k_{\mathcal{D}}}^{\mathcal{Z}}$), implies that $S_{k_{\mathcal{D}}}^{\mathcal{Z}} \le t$. As $j \ne k_{\mathcal{D}}$, it follows that $S_{k_{\mathcal{D}}}^{\mathcal{Z}} \le t - p$. By Lemma 3.3, $k_{\bar{\mathcal{D}}} \prec k_{\mathcal{D}}$ and $x_{k_{\bar{\mathcal{D}}}} \le x_{k_{\mathcal{D}}}$. Furthermore, since (IIIa) does not apply to $k_{\mathcal{D}}$, $\bar{\mathcal{D}}$ is also not idle at any time t', $t \le t' \le x_{k_{\mathcal{D}}}$.

We now show that the assumption of a self-charge of 1/2 to $k_{\bar{\mathcal{D}}}$ in $\bar{\mathcal{D}}$ leads to a contradiction. The proof is accomplished by considering several cases. In most cases the contradiction is with the fact that, as shown in the previous paragraph, both processes are busy at all times between t and $x_{k_{\mathcal{D}}}$ (keeping in mind that $x_{k_{\bar{\mathcal{D}}}} \le x_{k_{\mathcal{D}}}$).

If this charge is generated in case (I) or (II), then by the case conditions, $\bar{\mathcal{D}}$ would be idle at time $S^{\mathcal{Z}}_{k_{\bar{\mathcal{D}}}}$, and we would have $S^{\mathcal{Z}}_{k_{\bar{\mathcal{D}}}} \ge S^{\bar{\mathcal{D}}}_{k_{\bar{\mathcal{D}}}}$ and thus $t \le S^{\mathcal{Z}}_{k_{\bar{\mathcal{D}}}} \le x_{k_{\bar{\mathcal{D}}}}$, which is a contradiction.

Suppose that this self-charge is generated in case (III). Similarly as before, the condition of this case implies that one process is idle at time $S^{\mathcal{Z}}_{k_{\bar{\mathcal{D}}}}$, so we must have $S^{\mathcal{Z}}_{k_{\bar{\mathcal{D}}}} \le t$, for otherwise we would again have an idle time between t and $x_{k_{\bar{\mathcal{D}}}}$.

We have now two subcases. If the self-charge originated from case (IIIa), the condition of this case implies that there is an idle time t' between $S^{\mathcal{Z}}_{k_{\bar{\mathcal{D}}}}$ and $x_{k_{\bar{\mathcal{D}}}}$. As $t \le t' \le x_{k_{\bar{\mathcal{D}}}}$, this is again a contradiction.

The last possibility is that this self-charge originated from case (IIIb). But then $S^{\mathcal{Z}}_{k_{\bar{\mathcal{D}}}} \le t - p$ as $j \ne k_{\bar{\mathcal{D}}}$, and Lemma 3.3 above applies to $k_{\bar{\mathcal{D}}}$. However, the conclusion that $k_{\mathcal{D}} \prec k_{\bar{\mathcal{D}}}$ contradicts the linearity of $\prec$ as $k_{\mathcal{D}} \ne k_{\bar{\mathcal{D}}}$, and we have already shown that $k_{\bar{\mathcal{D}}} \prec k_{\mathcal{D}}$.

Summarizing, we get a contradiction in all the cases, completing the proof of the lemma. □

Continuing the proof of the theorem, we now show that the total charge to each occurrence of a job in $\mathcal{A}$ or $\mathcal{B}$ is at most 5/6. Suppose that k is executed in $\mathcal{D} \in \{\mathcal{A}, \mathcal{B}\}$. During the execution of k at most one job is started in $\mathcal{Z}$; thus, k gets at most one up-charge in addition to a possible self-charge. If k does not receive any up-charge, it is self-charged 1/2 or 1/6, i.e., less than 5/6.

If k receives an up-charge in (II), then k is an urgent job and, since $\bar{\mathcal{D}}$ is idle, it is already completed in $\bar{\mathcal{D}}$, so $S^{\bar{\mathcal{D}}}_k < S^{\mathcal{D}}_k$. The only case where the occurrence of k that is later in time is urgent and receives a self-charge is case (IIIb), and in this case this self-charge is 1/6. So the total charge would be at most $1/6 + 1/2 < 5/6$.

If a job receives an up-charge in (III), the up-charge is only 1/3, and thus the total is at most $1/3 + 1/2 = 5/6$.

If a job receives an up-charge in (IV), Lemma 3.4 implies that the up-charges can be defined as claimed in the case description. The total charge is then bounded by $1/6 + 2/3 = 5/6$ and $1/2 + 1/3 = 5/6$, respectively.

The expected number of jobs completed by RandLock is $(|\mathcal{A}| + |\mathcal{B}|)/2$. Since each job in $\mathcal{A}$ and $\mathcal{B}$ receives a charge of at most 5/6 and all jobs in $\mathcal{Z}$ generate a charge of 1, we have $(5/3) \cdot (|\mathcal{A}| + |\mathcal{B}|)/2 = (5/6) \cdot (|\mathcal{A}| + |\mathcal{B}|) \ge |\mathcal{Z}|$. This implies that RandLock is 5/3-competitive. □

As discussed in the introduction, a lower bound of 4/3 is known for randomized algorithms [13]. For barely random algorithms that choose between two deterministic algorithms, we can improve this bound to 3/2. Assuming also that the two algorithms are selected with equal probability, we can further improve the bound to 8/5.

THEOREM 3.5. *Suppose that $\mathcal{R}$ is a barely random nonpreemptive algorithm for scheduling equal-length jobs that chooses one of two deterministic algorithms. Then $\mathcal{R}$ is not better than 3/2-competitive.*

Proof. Assume that $\mathcal{R}$ chooses randomly one of two deterministic algorithms, $\mathcal{A}$ or $\mathcal{B}$, with some arbitrary probabilities. Let $p \ge 3$, and write the jobs as $j = (r_j, d_j)$. We start with job $1 = (0, 4p)$. Let t be the first time when one of the algorithms, say $\mathcal{A}$, schedules job 1. If $\mathcal{B}$ schedules it at t as well, release a job $1' = (t+1, t+p+1)$; the optimum schedules both jobs while both $\mathcal{A}$ and $\mathcal{B}$ schedule only one, so the competitive ratio is at least 2.

So we may assume that $\mathcal{B}$ is idle at t. Release job $2 = (t+1, t+2p+2)$. If $\mathcal{B}$ starts any job (1 or 2) at $t+1$, release job $3 = (t+2, t+p+2)$; otherwise, release job $4 = (t+p+1, t+2p+1)$. $\mathcal{B}$ completes only one of the jobs 2, 3, or 4. Since $\mathcal{A}$ is busy with job 1 until time $t+p$, it also completes only one of the jobs 2, 3, or 4 as their deadlines are smaller than $t+3p$. So each of $\mathcal{A}$ and $\mathcal{B}$ completes at most two jobs.

The optimal schedule completes three jobs: If 3 is issued, schedule 3 and 2, back to back, starting at time $t+2$. If 4 is issued, schedule 2 and 4, back to back, starting at time $t+1$. In either case, two of jobs 2, 3, and 4 fit in the interval $[t+1, t+2p+2)$. If $t \geq p-1$, schedule job 1 at time 0; otherwise, schedule job 1 at time $3p \geq t+2p+2$. Thus the competitive ratio of $\mathcal{R}$ is at least $3/2$. □

THEOREM 3.6. *Suppose that $\mathcal{R}$ is a barely random nonpreemptive algorithm for scheduling equal-length jobs that chooses one of two deterministic algorithms, each with probability $1/2$. Then $\mathcal{R}$ is not better than $8/5$-competitive.*

Proof. Assume that $\mathcal{R}$ chooses one of two deterministic algorithms, $\mathcal{A}$ or $\mathcal{B}$, each with probability $1/2$. Let $p \geq 3$, and write the jobs in the format $j = (r_j, d_j)$. We start with job $1 = (0, 6p)$. Let t be the first time when one of the algorithms, say $\mathcal{A}$, schedules job 1.

At time $t+1$ release job $2 = (t+1, t+p+1)$. If $\mathcal{B}$ does not start 2 at time $t+1$, then no more jobs will be released and the ratio is at least 2.

We may thus assume that $\mathcal{B}$ starts 2 at time $t+1$ and then starts 1 at some time $t' \geq t+p+1$. Release job $3 = (t'+1, t'+2p+2)$. If $\mathcal{A}$ starts job 3 at $t'+1$, release job $4 = (t'+2, t'+p+2)$; otherwise, release $5 = (t'+p+1, t'+2p+1)$. By the choice of the last job, $\mathcal{A}$ can complete only one of the jobs 3, 4, or 5. Since $\mathcal{B}$ is busy with job 1 until time $t'+p \geq t'+3$, it also can complete only one of the jobs 3, 4, or 5 as their deadlines are strictly smaller than $t'+3p$. So $\mathcal{A}$ can complete 2 jobs only, and $\mathcal{B}$ can complete 3 jobs.

The optimal schedule can complete all four released jobs. If 4 is issued, schedule 4, and 3, back to back, starting at time $t'+2$. If 5 is issued, schedule 3, and 5, back to back, starting at time $t'+1$. In either case, both jobs fit in the interval $[t'+1, t'+2p+2)$. This interval is disjoint with the interval $[t+1, t+p+1)$ where 2 is scheduled. Finally, these two intervals occupy length $3p+1$ of the interval $[0, 6p)$ and divide it into at most 3 contiguous pieces; thus, one of the remaining pieces has a length of at least p, and job 1 can be scheduled.

Summarizing, $\mathcal{R}$ completes at most $(2+3)/2 = 2.5$ jobs on average, while the optimal schedule completes 4 jobs. Therefore the competitive ratio is at least $4/2.5 = 8/5$, as claimed. □

4. Scheduling with restarts. Our algorithm with restarts is very natural. At any time, it greedily schedules the ED job. However, if a tight job arrives that would expire before the running job is completed, we consider a preemption. A preemption occurs only if it guarantees to increase the number of completed jobs among those that are known to the algorithm, which includes the currently executed job and all pending jobs.

To formalize this idea, we need an auxiliary definition. Suppose that a job k is started at time s by the online algorithm. We call a job h a *preemption candidate* for k if $s < r_h \leq x_h < s+p$.

The exact statement of the algorithm is somewhat technical, as it needs to properly handle the case when two preemption candidates arrive at the same time and also the case when some other jobs arrive between the start of a job and the arrival of the first preemption candidate.

ALGORITHM TIGHTRESTART. At time t, do the following.

(TR1) If no job is running, start the ED pending job, providing there is at least one pending job; otherwise, stay idle until some job is released.

(TR2) Otherwise, let k be the running job. If k was started as urgent or if no preemption candidate is released at t, continue running k.

(TR3) Otherwise, the running job k was started as flexible. Let P_t^* be the set of all jobs pending at time t, including k but excluding any preemption candidates. If P_t^* is flexible at t, preempt k and start (at time t) a preemption candidate; choose the ED preemption candidate, if more are admissible at time t. Otherwise, continue running k.

Note that in case (TR3) job k is indeed still pending at time t, for its flexibility at its start time implies that k is still admissible at t. (Recall that only admissible jobs are considered pending, and a job that is partially executed is pending as well, as long as it is still admissible.)

Let $\mathcal{X}$ be the final schedule generated by TIGHTRESTART, after removing the preempted parts of jobs. For any time t, as before, we denote as P_t the set of jobs that are pending in $\mathcal{X}$ at time t. We stress that we distinguish between $\mathcal{X}$ being idle and TIGHTRESTART being idle: At some time steps TIGHTRESTART can process a job that will be preempted later, in which case $\mathcal{X}$ is considered idle at these steps but TIGHTRESTART is not.

LEMMA 4.1. *Schedule $\mathcal{X}$ is normal.*

Proof. By rules (TR1) and (TR3), TIGHTRESTART always starts the ED pending job; in (TR3) note that, by definition, any preemption candidate is tight and thus it has an earlier deadline than any job in the flexible set P_t^* of the remaining pending jobs. The property (n1) of normal schedules follows as, obviously, at each time step, the pending jobs in TIGHTRESTART and $\mathcal{X}$ are the same.

If TIGHTRESTART is idle then there is no pending job. Thus, to show the property (n2), it remains to verify that $P_{t'}$ is flexible at any time t' when $\mathcal{X}$ is idle but TIGHTRESTART is not. This means that TIGHTRESTART is running a job which is later preempted.

Suppose TIGHTRESTART starts a job k at time s and preempts it at time t. By (TR2), k is started as flexible. Let t' be any time such that $s < t' < t$. Since k is flexible at s and it is the ED job in P_s, no job in P_s expires before $s + p > t$. Thus we have $P_s \subseteq P_{t'}^* \subseteq P_t^*$ by the definition of $P_{t'}^*$ and P_t^* in (TR3). As TIGHTRESTART preempts at time t, P_t^* is flexible at t. Consequently, $P_{t'}^* \subseteq P_t^*$ is flexible at t and also at $t' < t$. Using this for all t', we conclude that the first preemption candidate for k is released at t, as otherwise k would be preempted earlier. Thus no preemption candidate is admissible at any t', $s < t' < t$, and $P_{t'} = P_{t'}^*$ which we have shown is flexible at t'. Thus (n2) holds, and $\mathcal{X}$ is normal. □

THEOREM 4.2. TIGHTRESTART *is a 3/2-competitive algorithm with restarts for scheduling equal-length jobs.*

Proof. As usual, by $\mathcal{Z}$ we denote an optimal schedule. The proof is based on a charging scheme, where each job in $\mathcal{Z}$ generates a charge of 1 and each job in TIGHTRESTART's schedule receives a charge of at most 3/2.

Let us start by giving some intuition behind the charging scheme. Suppose that a job j is started at time t in $\mathcal{Z}$. If TIGHTRESTART is running a job k at t and k is not preempted later, we want to charge j to k. If TIGHTRESTART is running a job k which is later preempted by a job h, we charge 1/2 to h and 1/2 to j (using Lemma 2.2 to guarantee that the modified schedule completes j). The main problem

is to handle the case when TightRestart is idle when j starts in $\mathcal{Z}$; we call such a j a *free* job. In this case, TightRestart was "tricked" into scheduling j too early. We would like to charge j to itself. However, it may happen that then j would be charged twice, so we need to split this charge and find another job that we can charge $1/2$. The definition of $f(j)$ below chooses such a job and Lemma 2.2 again guarantees that the modified schedule completes $f(j)$. The rule (f2) in the definition of f below chooses a value of f to be a job not scheduled in $\mathcal{Z}$, which is opposite to the general intuition that the modified schedule is more similar to $\mathcal{Z}$; however, it guarantees that this job may be charged that additional $1/2$. Another difficulty that arises in the above scheme is that, due to preemptions in TightRestart's schedule and to idle times in $\mathcal{Z}$, the jobs can become misaligned. To deal with this problem, we define a matching M between the jobs in $\mathcal{X}$ and $\mathcal{Z}$. Typically, a job k in $\mathcal{X}$ is matched to the first unmatched job in $\mathcal{Z}$ that starts later than k. In some situations we match a free job k to itself.

We now proceed with the formal proof. First, we define a partial function $f : J \to J$. For any job k scheduled as flexible in $\mathcal{X}$, we define $f(k)$ as follows.

(f1) If at some time t, $S_k^{\mathcal{X}} \le t < C_k^{\mathcal{X}}$, $\mathcal{Z}$ starts a job h which is not a preemption candidate, then let $f(k) = h$.

(f2) Otherwise, if there exists a job h with $S_k^{\mathcal{X}} < r_h \le C_k^{\mathcal{X}} \le x_h$ such that $\mathcal{Z}$ does not complete h, then let $f(k) = h$ (choose arbitrarily if there are more such h's).

(f3) Otherwise, $f(k)$ is undefined.

Notice that $f(\cdot)$ is one-to-one, for the first two cases are disjoint, and in each case k is uniquely determined by $h = f(k)$: If $h = f(k)$ and (f1) applied to k, then k is the job that is being executed by $\mathcal{X}$ when $\mathcal{Z}$ starts h. If (f2) applied to k, then k is the job being executed by $\mathcal{X}$ at time $r_h - 1$. □

According to Lemma 4.1, $\mathcal{X}$ is a normal schedule. Let $\mathcal{A}$ be the schedule constructed in Lemma 2.2 from $\mathcal{X}$ and function $f(\cdot)$. Since $\mathcal{A}$ is equivalent to $\mathcal{X}$, it also satisfies Lemma 2.1.

Call a job j scheduled in $\mathcal{Z}$ a *free* job if TightRestart is idle at time $S_j^{\mathcal{Z}}$. This condition implies that at time $S_j^{\mathcal{Z}}$ no job is pending in $\mathcal{A}$; in particular, by Lemma 2.1, j is completed as a flexible job by time $S_j^{\mathcal{Z}}$ in $\mathcal{A}$.

Now define a partial function $M : J \to J$ which is a matching of (some) occurrences of jobs in $\mathcal{A}$ to those in $\mathcal{Z}$. Process the jobs k scheduled in $\mathcal{A}$ in the order of increasing $S_k^{\mathcal{A}}$. For a given k, let j be the first unmatched job in $\mathcal{Z}$ started at or after $S_k^{\mathcal{A}}$ or, more formally, the job with smallest $S_j^{\mathcal{Z}}$ among those with $S_j^{\mathcal{Z}} \ge S_k^{\mathcal{A}}$ and such that $j \ne M(k')$ for all k' in $\mathcal{A}$ with $S_{k'}^{\mathcal{A}} < S_k^{\mathcal{A}}$. If no such j exists, $M(k)$ is undefined. Else, do the following.

(m1) If $S_j^{\mathcal{Z}} \ge C_k^{\mathcal{A}}$ and k is a free job which is not in the current range of M, then let $M(k) = k$.

(m2) Otherwise, let $M(k) = j$.

The definition implies that M is one-to-one. See Figure 4.1 for an example.

Lemma 4.3. *Let j be a job executed in $\mathcal{Z}$.*

(1) *If $\mathcal{A}$ executes some job when j starts in $\mathcal{Z}$, i.e., $S_k^{\mathcal{A}} \le S_j^{\mathcal{Z}} < C_k^{\mathcal{A}}$ for some k, then j is in the range of M.*

(2) *If j is free and $f(j)$ is undefined, then j is in the range of M.*

Proof. Part (2) is simple: Suppose that $\mathcal{A}$ is executing some job k at $S_j^{\mathcal{Z}}$, and consider the step in the construction of M when we are about to define $M(k)$. If j is not in the range of M at this time, then we would define $M(k)$ as j.

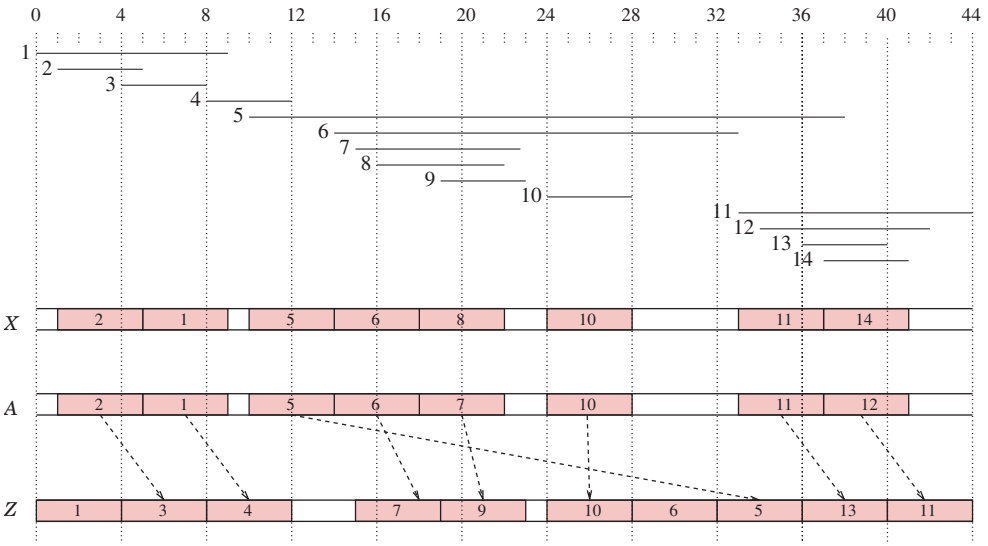

FIG. 4.1. *An example of an instance, the schedule $\mathcal{X}$ produced by* TIGHTRESTART*, the modified schedule $\mathcal{A}$, and the construction of M (represented by directed edges). The processing time is $p = 4$. Jobs are identified by positive integers. Preempted pieces of jobs are not shown. In $\mathcal{X}$, jobs* 5, 6, *and* 11 *are flexible, and the other jobs are urgent. Note that $f(5)$ is undefined, $f(6) = 7$ (since* 7 *is not a preemption candidate), and $f(11) = 12$ (since* 13 *is a preemption candidate and* 12 *is not, and* 12 *is not executed in X).*

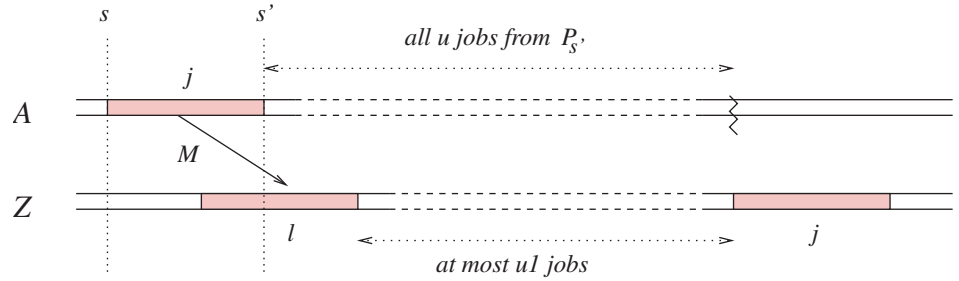

FIG. 4.2. *Illustration to the proof of Lemma* 4.3(2).

We now prove (2). Let $s = S_j^{\mathcal{A}}$ be the start time of j in $\mathcal{A}$ and $s' = C_j^{\mathcal{A}} = s + p$ its completion time. Since j is free, it is completed in $\mathcal{A}$ before it is started in $\mathcal{Z}$, i.e., $S_j^{\mathcal{Z}} \geq s'$ and j is flexible in $\mathcal{A}$.

Suppose for a contradiction that j is not in the range of M. By the definition of M, this implies that $M(j) = l$ for some job l with $s \leq S_l^{\mathcal{Z}} < s'$. Otherwise, during the construction of M when we are about to define $M(j)$, we would set $M(j) = j$.

Since $f(j)$ is undefined, by condition (f1), l must be a preemption candidate for j, i.e., $s < r_l \leq x_l < s'$. Furthermore, as TIGHTRESTART does not preempt j when l is released, the set $P^*_{r_l}$ is not flexible.

Figure 4.2 illustrates the argument that follows. The idea is this: Since j is not preempted even though a preemption candidate l arrives, $\mathcal{A}$ must be nearly full between s' and d_j. So, intuitively, one of the jobs scheduled in this interval should overlap in time with the occurrence of j in $\mathcal{Z}$, and this job would end up being

matched to j. The rigorous argument gets a bit technical because of possible gaps in the schedules.

Let $H = \{h \mid s < r_h \le s' \le x_h\}$ be the set of all jobs released during the execution of j in $\mathcal{A}$ or exactly at $C_j^{\mathcal{A}}$, excluding preemption candidates. Since $f(j)$ is undefined, by condition (f2), all these jobs are completed in $\mathcal{Z}$, and obviously they cannot be completed before $S_l^{\mathcal{Z}}$. Also, $l \notin H$. Thus H is feasible at $C_l^{\mathcal{Z}}$ and also at $s' \le C_l^{\mathcal{Z}}$.

Since $\mathcal{A}$ is an EDF schedule and j is flexible in $\mathcal{A}$, all jobs $h \in P_s - \{j\}$ have $x_h \ge x_j \ge s'$, so they are still pending at s'. Therefore $P_{s'} = P_s \cup H - \{j\} = P^*_{r_l} \cup H - \{j\}$. (Job j is not pending at s' since it is already completed.)

We claim that $P_{s'}$ is feasible at s'. Suppose, towards contradiction, that it is not. Let d be smallest time such that $R = \{h \in P_{s'} \mid d_h \le d\}$ is not feasible; i.e., R is the smallest infeasible initial segment of $P_{s'}$ ordered by $\prec$. Then TightRestart would execute urgent jobs from s' until time $d - p + 1$, as always the ED job is started as urgent and then the set of pending jobs cannot become feasible before or at time $d-p$. Since $\mathcal{X}$ is idle at time $S_j^{\mathcal{Z}}$, this implies that $d < C_j^{\mathcal{Z}}$. Since all jobs $h \in P_{s'}$ with $d_h < d_j$ are in H, this implies that $R \subseteq H$, which is a contradiction with feasibility of H. We conclude that $P_{s'}$ is feasible at s', as claimed.

Since $P_{s'}$ is feasible at s', Lemma 2.2(2) implies that $\mathcal{A}$ completes all jobs in $P_{s'}$. Furthermore, all jobs in $P_{s'}$ are scheduled between s' and $S_j^{\mathcal{Z}}$, as TightRestart is idle at $S_j^{\mathcal{Z}}$.

Let $u = |P_{s'}|$. Next we claim that

(i) $S_j^{\mathcal{Z}} - C_l^{\mathcal{Z}} < up$, and

(ii) $\mathcal{Z}$ does not schedule any of the jobs in $P_{s'}$ after j.

If either of (i) or (ii) were violated, $P_{s'} \cup \{j\}$ would be feasible at $C_l^{\mathcal{Z}}$, for we can first schedule H, which is feasible at $C_l^{\mathcal{Z}}$, and then the remaining jobs from $P_{s'}$: If (i) is violated, we can complete all jobs in $P_{s'}$ by the time $S_j^{\mathcal{Z}}$, which is smaller than the deadlines in $P^*_{r_l} - H$, and start j at $S_j^{\mathcal{Z}}$. If (ii) is violated, let j' be the job in $P_{s'}$ scheduled after j in $\mathcal{Z}$. We know that $S_j^{\mathcal{Z}} - C_l^{\mathcal{Z}} > S_j^{\mathcal{Z}} - s' - p \ge (u-1)p$; thus, we can complete all jobs in $P_{s'}$ by the time $S_j^{\mathcal{Z}}$ and schedule j and j' as in $\mathcal{Z}$.

By the previous paragraph, if either (i) or (ii) does not hold, then $P^*_{r_l} \cup \{j\} \subseteq P_{s'} \cup \{j\}$ is feasible at $r_l + p \le C_l^{\mathcal{Z}}$ and thus flexible at r_l, contradicting the assumption that l (which is a preemption candidate) did not cause preemption. We thus obtain that (i) and (ii) are true, as claimed.

Summarizing, $\mathcal{A}$ completes the u jobs in $P_{s'}$ between s' and $S_j^{\mathcal{Z}}$, and by (ii), these jobs are not executed after $S_j^{\mathcal{Z}}$ in $\mathcal{Z}$. Therefore, if j were not in the range of M, the jobs in $P_{s'}$ would have to be matched to the jobs in $\mathcal{Z}$ between $C_l^{\mathcal{Z}}$ and $S_j^{\mathcal{Z}}$, which is not possible, because there are at most $u-1$ such jobs by (i). We can thus conclude that j is indeed in the range of M. □

Charging scheme. Let j be a job started at time $t = S_j^{\mathcal{Z}}$ in $\mathcal{Z}$. We charge j to jobs in $\mathcal{A}$ according to the following cases.

(I) $j = M(k)$ for some k. Charge j to k. By Lemma 4.3(1), this case always applies when $\mathcal{A}$ is not idle at t, so in the remaining cases $\mathcal{A}$ is idle at t.

(II) Otherwise, if j is free, then charge 1/2 of j to the occurrence of j in $\mathcal{A}$ and 1/2 of j to the occurrence of $f(j)$ in $\mathcal{A}$. Note that, since (I) does not apply, Lemma 4.3(2) implies that $f(j)$ is defined, and then Lemma 2.2 implies that both j and $f(j)$ are completed in $\mathcal{A}$.

(III) Otherwise, $\mathcal{A}$ is idle at t, but TightRestart is running some job k at t which is later preempted by another job h. Charge 1/2 of j to j and 1/2 to

h. By Lemma 2.2(2), j is completed in $\mathcal{A}$. Job h is urgent, and thus it is completed as well.

Analysis. We prove that each job scheduled in $\mathcal{A}$ is charged at most 3/2. Each job is charged at most 1 in case (I), as M defines a matching.

We claim that each job receives at most one charge of 1/2. For the rest of the proof, we will distinguish two types of charges of 1/2: *self-charges*, when j is charged to itself, and *non-self-charges*, when j is charged to a different job.

Suppose first that k receives a self-charge. (Obviously, it can receive only one.) Then $\mathcal{A}$ is idle at time $S_k^{\mathcal{Z}}$, for otherwise case (I) would apply to k in $\mathcal{Z}$. This implies two things. First, k is not tight, so it cannot receive a non-self-charge in case (III). Second, k cannot be in the range of $f(\cdot)$, since each job $f(j)$ is either not in $\mathcal{Z}$ or, if it is, $\mathcal{A}$ is executing some job at time $S_{f(j)}^{\mathcal{Z}}$. Therefore k cannot receive a non-self-charge in case (II).

Next, suppose that k does not receive a self-charge. Since $f(\cdot)$ is one-to-one, k can receive at most one non-self-charge in case (II). If k receives a non-self-charge in case (III) from a job j, then k is started in $\mathcal{A}$ while $\mathcal{Z}$ is executing j, so k can receive only one such charge. Finally, if k receives a non-self-charge in case (II), then by the definition of $f(\cdot)$, k is not a preemption candidate, so it cannot receive a non-self-charge in case (III).

We conclude that each job completed in $\mathcal{A}$ gets at most one charge of 1 and at most one charge of 1/2 and thus is charged a total of at most 3/2. Each job in $\mathcal{Z}$ generates a charge of 1. Thus, by summation over all jobs in $\mathcal{Z}$, we have $|\mathcal{Z}| \le 3|\mathcal{A}|/2$, completing the proof of the theorem. □

We now show that the competitive ratio of our algorithm is in fact optimal.

THEOREM 4.4. *For scheduling equal-length jobs with restarts, no deterministic algorithm is better than* 3/2*-competitive and no randomized algorithm is better than* 6/5*-competitive.*

Proof. For $p \ge 2$, consider four jobs given in the form $j = (r_j, d_j)$: $1 = (0, 3p+1)$, $2 = (1, 3p)$, $3 = (p, 2p)$, and $4 = (p+1, 2p+1)$. The instance consists of jobs 1, 2, and 3 or jobs 1, 2, and 4.

There exist schedules that schedule three jobs 1, 3, and 2 or three jobs 2, 4, and 1, in this order. (See Figure 4.3.) Therefore the optimal solution consists of three jobs.

In the deterministic case, release jobs 1 and 2. If the online algorithm starts job 2 at time 1, release job 3; otherwise, release job 4. The online algorithm completes only two jobs. As the optimal schedule has three jobs, the competitive ratio is no better than 3/2.

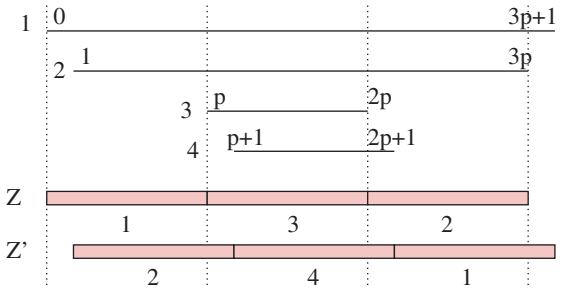

FIG. 4.3. *Jobs used in the lower bounds with restarts.*

Our proof for randomized algorithms is based on Yao's principle [24, 6]. We define a probability distribution on our two instances as follows: Always release jobs 1 and 2, and then one randomly chosen job from 3 and 4, each with probability 1/2. If $\mathcal{A}$ is any deterministic online algorithm, then the expected number of jobs completed by $\mathcal{A}$ is at most 2.5, as on one of the instances it completes only 2 jobs. Using Yao's principle, we conclude that no randomized algorithm can have a competitive ratio smaller than $3/2.5 = 6/5$. □

5. Final comments. For equal processing times, closing the gap between our upper bound of 5/3 and the lower bound of 4/3 is a challenging open problem. It would also be interesting to close these gaps for barely random algorithms which—in our view—are of their own interest (even in the case when we use only one fair random bit).

Barely random algorithms with a single random bit intuitively seem to be somewhat similar to deterministic algorithms for two machines for the same problem. In particular, one might expect that lower bounds will carry over to the problem with two machines when each job is duplicated. However, subsequent to our work, independently Ding and Zhang [10] and Goldwasser and Pedigo [16] designed 3/2-competitive deterministic algorithms for two machines. Thus, somewhat surprisingly, the answers for the two problems are different. Still, it remains a possibility that algorithms for more machines will bring some insight into the randomized scheduling on a single machine.

Beyond our simple lower bound of 6/5, nothing is known about the effect of allowing both randomness and restarts. The best upper bound of 3/2 is achieved by a deterministic algorithm. Can randomization help in the model with restarts?

Acknowledgment. We wish to express our gratitude to the anonymous referees, whose numerous and insightful suggestions helped us simplify some arguments and significantly improve the presentation of the paper.

PHYSICAL LIMITS OF HEAT-BATH ALGORITHMIC COOLING*

LEONARD J. SCHULMAN†, TAL MOR‡, AND YOSSI WEINSTEIN‡

Abstract. Simultaneous near-certain preparation of qubits (quantum bits) in their ground states is a key hurdle in quantum computing proposals as varied as liquid-state NMR and ion traps. "Closed-system" cooling mechanisms are of limited applicability due to the need for a continual supply of ancillas for fault tolerance and to the high initial temperatures of some systems. "Open-system" mechanisms are therefore required. We describe a new, efficient initialization procedure for such open systems. With this procedure, an n-qubit device that is originally maximally mixed, but is in contact with a heat bath of bias $\varepsilon \gg 2^{-n}$, can be almost perfectly initialized. This performance is optimal due to a newly discovered threshold effect: For bias $\varepsilon \ll 2^{-n}$ no cooling procedure can, even in principle (running indefinitely without any decoherence), significantly initialize even a single qubit.

1. Introduction.

Quantum computation poses a difficult experimental challenge. Simultaneous near-certain preparation of qubits (quantum bits) in their ground states is a key hurdle in proposals as varied as NMR and ion traps [8, 19, 9, 13, 10, 11]. Such "cooling" (also known as "biasing" or "polarizing") is required both for initiation of the computation [2] and in order to supply ancillas for fault tolerance as the computation proceeds.

Cooling of quantum systems has long been essential in a variety of experimental contexts unrelated to quantum computation, and is performed by processes that directly cool the system such as laser cooling in ion traps or application of strong magnetic fields in NMR. Spin exchange has also been employed in order to transfer highly cooled states into the desired system from another that is more readily directly cooled [4, 14, 24]. In all these methods, the temperature is limited by the original cooling process.

Algorithmic cooling. It is in principle possible, however, to reach even lower temperatures, by application of certain logic gates among the qubits [22]. (Even prior to quantum computation the need for signal amplification in NMR imaging led to the implementation of a basic 3-qubit logic gate [23].) In several quantum computation proposals this kind of improvement in cooling is necessary due to the requirement that a large number of qubits all be, with high probability, simultaneously in their ground states.

We distinguish between closed- and open-system algorithmic cooling methods. In the former [22] an initial phase of physical cooling is performed which reduces the

entropy of the system. Then in the closed phase an entropy preserving (unitary) algorithmic process is performed on the qubits. By contrast in an open process [5] some of the qubits of the system can be cooled by external interaction even during (or at interruptions in) the quantum computation. Open-system cooling places an additional experimental difficulty: Computation qubits must not decohere during the process of cooling other qubits which, at another stage, they must interact with. Nonetheless closed-system cooling appears to be insufficient for two reasons. The first applies specifically to liquid-state NMR quantum computing, where the initial entropy-reducing preparation is quite weak: the probability of the ground state of each qubit exceeds the probability of the excited state by the small factor of $e^{2\varepsilon} \approx 1+10^{-5}$. In the subsequent closed phase an ε^2 fraction of the qubits can be prepared in highly cooled states [22] (and see [23, 7] for experimental demonstrations of key steps); for information-theoretic reasons this fraction is best possible, but at the current value of ε it is too small for effective implementation of a quantum computer. The second reason applies more broadly. Any quantum computing implementation must cope with noise. Fault-tolerance mechanisms have been designed that can do so [1], if the noise level is below a specified threshold (estimated to be between 10^{-4} and 10^{-2} per qubit per operation [16]) and if a continual supply of "ancillas" (qubits which are initialized in a known state) is available. Ancilla initialization need not be perfect, but the error cannot exceed the same fault-tolerance threshold. In ion traps, for example, direct cooling can place qubits in their ground states with probability ≈ 0.95, a level that necessitates further cooling to exceed the threshold [15, 3]. Since fresh ancillas are needed in each time step, either a very large supply must be chilled in advance and maintained without substantial decoherence, or—more likely—an open-system approach must be adopted in which registers are cooled on a regular basis.

It is necessary, therefore, to study effective means for open-system algorithmic cooling. A suggested framework (called the "heat-bath" approach) was made in [5]. A heat-bath device comprises two types of qubits—some that are hard to cool (but relax slowly) and others that are readily cooled (but relax rapidly). The former are computation qubits and the latter are "refrigerants." At chosen times, the computation and refrigerant qubits can undergo joint unitary interaction (such as spin exchange). A similar framework is contemplated for ion trap quantum computers [3]—the computation ions are not cooled directly, due to the decoherence that this causes; instead they are cooled by interaction with separate refrigerant ions that have been directly laser-cooled.

Results. In this paper we establish the theoretical limits for cooling on heat-bath devices. We introduce a cooling mechanism achieving much higher bias amplification than given previously. We explicitly bound the number of cooling steps required in our amplification process, a crucial matter, since any cooling process must be carried out within the relaxation times of the computation qubits. Finally, we show that our method is optimal in terms of entropy extraction per cooling step. In the course of doing so we discover a threshold phenomenon: significant initialization cannot be achieved at all unless ε, the bias that can be imparted to the rapidly relaxing qubits, is asymptotically above 2^{-n}. The proof uses majorization inequalities to convert the problem to analysis of a certain combinatorial "chip game."

For specificity we assume that the quantum computer has $n-1$ computation qubits, and an nth refrigerant qubit that is in contact with the heat bath. The cooling step, ι, has the effect of changing the traced density matrix of the nth qubit

to

$$\rho_\varepsilon = \frac{1}{e^\varepsilon + e^{-\varepsilon}} \begin{pmatrix} e^\varepsilon & 0 \\ 0 & e^{-\varepsilon} \end{pmatrix} \tag{1.1}$$

(no matter what the previous state was). In between cooling steps, reversible (unitary) quantum logic gates can be applied to the register of n qubits. Let $\mathcal{I}_n$ be the density matrix of the maximally mixed state over the 2^n-dimensional Hilbert space ($\mathcal{I}_n = 2^{-n}\times$ the identity matrix of dimension 2^n). The question is, Starting from $\mathcal{I}_n$, and using these operations, how different from $\mathcal{I}_n$ can we make the density matrix of the device?

There is little a priori reason to expect any limit on the difference. To speak (imprecisely) in terms of temperature, we have already pointed out that the temperature of the heat bath is not a lower bound on the achievable temperature of the device, because we can use logic gates and energy to implement a heat engine (refrigerator). This being so, there is no natural lower bound on the achievable temperature short of absolute zero. It is therefore fascinating that a positive lower bound exists. The bound derives not from entropic considerations but from finite-size effects. The precise statement is not in terms of temperature but in terms of the maximum probability of any state. (For a Gibbs distribution this would be a ground state.)

THEOREM 1.1 (physical limit). *No heat-bath method can increase the probability (i.e., $|amplitude|^2$) of any basis state from its initial value, 2^{-n}, to any more than* $\min\{2^{-n}e^{\varepsilon 2^{n-1}}, 1\}$. *This conclusion holds even under the idealization that an unbounded number of cooling and logic steps can be applied without error or decoherence.*

This shows that if $\varepsilon \ll 2^{-n}$, then the variation distance between the uniform distribution, and any distribution reachable by cooling, is $\ll 1$.

On the flip side, it was shown in [12] how to produce (at small ε) a qubit of bias $(3/2)^{(n-2)/2}\varepsilon$. We improve on this result and establish a converse to Theorem 1.1, using a specific cooling procedure, the PPA, described below. For convenience let $\tilde{\varepsilon} = \tanh\varepsilon$. (For small ε, $\tilde{\varepsilon} \approx \varepsilon$.) We present the converse in two slightly incomparable forms.

THEOREM 1.2 (threshold effect). *If $\tilde{\varepsilon} \geq 2^{4-n}$, the PPA increases the variation distance from uniform to $\Theta(1)$. This occurs within $\tilde{\varepsilon}^{-2}$ cooling steps.*

THEOREM 1.3 (cold qubit extraction). *Within $4n\tilde{\varepsilon}^{-2}(1+\log(1/\tilde{\varepsilon}))$ cooling steps, the PPA creates a probability distribution in which with probability at least $1-O(\frac{1}{1+\log 1/\tilde{\varepsilon}})$, all of the first $n-(1+o(1))\log_2 1/\tilde{\varepsilon}$ bits are $|0\rangle$'s (where $o(1)$ denotes a term tending to 0 as $\tilde{\varepsilon}$ tends to 0).*

This extraction procedure is useful for quantum computing (it extracts qubits of bias almost 1, i.e., that are almost certainly in their ground state) so long as ε is above $n2^{-n}$.

The notion that the computation qubits are entirely insulated from the environment is of course merely a simplification good for moderate time spans. To be useful, algorithms must converge to the desired state within the relaxation time of the computation qubits. Next we show that the PPA is near-optimal in terms of the number of cooling steps.

THEOREM 1.4 (cooling steps required). *Any algorithm which creates a bit of constant bias requires $\Omega(\tilde{\varepsilon}^{-2})$ cooling steps.*

Finally, since the computations in the PPA vary in a complex way depending upon the value of n, we accompany the above results with another simpler cooling

procedure that applies transpositions and reversible 3-qubit majorities in a recursive pattern, and performs fairly effective cooling. This procedure is a slight modification, to achieve better asymptotics, of one given in [12]. Let $\phi = (1+\sqrt{5})/2$, let F_k be the kth Fibonacci number, and let $N = \min\{n, \lceil \log_\phi 1/\tilde{\varepsilon} \rceil\}$; the cooling algorithm $\mathcal{F}$ mentioned in the theorem is described in section 8.

THEOREM 1.5 (simple cooling algorithm). *The cooling algorithm $\mathcal{F}$ is NC1-uniform and, when run on an N-bit device, creates a bit of bias $\Omega(\tilde{\varepsilon} F_N)$ within runtime (counting both cooling steps and logic gates)* $\exp(O(N \log N))$.

Comment. The reader will have noticed that while we speak of "cooling," the algorithms are characterized not in terms of the final temperatures achieved in the qubits but in terms of other desirable properties of the final probability distributions. There are two reasons for this. The first is that other properties, especially as in Theorem 1.3, are more germane to the application to quantum computing. The second is that unambiguous assignment of a temperature to a probability distribution depends on the latter being a Gibbs distribution for some Hamiltonian describing the system; but the distributions produced by algorithmic cooling need not be Gibbs distributions. In particular, the PPA does not produce a Gibbs distribution.

Other applications of algorithmic cooling. A central point of this paper is the firm limit that Theorem 1.1 sets on the cooling parameter ε in order that the heat-bath method be useful for quantum computation. However, it is important to note that heat-bath cooling algorithms (the PPA or others) may be viable for other applications even at smaller ε. Specifically, algorithmic cooling is likely to find significant application in the scientific and medical imaging applications for which NMR technology is already in wide use. The signal-to-noise ratio in NMR imaging is proportional to the polarization of the nuclear spins and to the square root of the duration of the scan; since the duration is often limited in medicine by the need to immobilize the patient, improved sensitivity demands increased polarization. In other applications the benefit of increased polarization is in decreased scan times. Algorithmic cooling of a few nuclear spins may therefore be highly beneficial even in the range $\varepsilon \ll 2^{-n}$ that is not adequate for quantum computation. For example, perfect implementation of the PPA on a 5-qubit molecule (four computation qubits and one refrigerant) would yield a qubit of bias 8ε, implying a 64-fold decrease in scan duration compared to cooling without algorithmic amplification.

An abridged version of this paper appeared in [21].

2. Reduction of quantum to classical cooling. In preparation for the proofs of Theorems 1.1–1.5 we start with a reduction that significantly simplifies the rest of our task. Recall that the heat-bath quantum computer is assumed to start in the maximally mixed density matrix, $\mathcal{I}_n$. Any cooling step ι changes the traced density matrix on the nth qubit to the matrix given in (1.1). To see how this affects the entire density matrix, suppose that before the cooling step, the quantum computer is in a $2^n \times 2^n$ density matrix

$$M = \begin{pmatrix} M_{11} & M_{12} \\ M_{12}^\dagger & M_{22} \end{pmatrix}, \tag{2.1}$$

where the states $|0\rangle$ and $|1\rangle$ of the nth qubit partition the density matrix into these four parts. Application of ι effects the following transformation:

$$M \xrightarrow{\iota} \rho_\varepsilon \otimes (M_{11} + M_{22}) = \frac{1}{e^\varepsilon + e^{-\varepsilon}} \begin{pmatrix} e^\varepsilon (M_{11} + M_{22}) & 0 \\ 0 & e^{-\varepsilon}(M_{11} + M_{22}) \end{pmatrix}. \tag{2.2}$$

Between cooling steps, quantum logic gates can be applied to the system. These act on the density matrix as conjugations by unitary operators. If there are $r+1$ cooling steps, let these unitaries be $u_1, \ldots, u_r$. These unitary operators are constrained to be implementable by local quantum logic gates; for the limit on achievable cooling (Theorem 1.1), we may ignore this constraint and allow the unitaries to be arbitrary. For unitary u let $\overline{u}$ denote the corresponding conjugation operator.

The eigenvalues of a density matrix are the probabilities with which the spectral basis states are measured; by an inequality of Schur, the spectral basis gives measurement probabilities that are furthest from uniform, in the sense of majorization (see [18, section 9B]). A probability vector $p = (p_1, \ldots)$ is said to majorize another $p' = (p'_1, \ldots)$ (written $p \succeq p'$) if there exists a doubly stochastic matrix D such that $(p_1, \ldots)D = (p'_1, \ldots)$. This is a partial (pre-)order on probability distributions in which the singular distribution $(1, 0, 0, \ldots)$ dominates all others, while the uniform distribution is dominated by all. Schur's inequality is that the eigenvalues of a Hermitian matrix majorize its diagonal entries. A density matrix h is said to majorize another h' (written $h \succeq h'$) if the eigenvalues of h majorize those of h'.

Domination in majorization implies domination in any of the other measures we are interested in, such as variation distance from uniform, or the sum of the largest K probabilities (for a fixed K). So our concern is the following: If $\overline{u_1}, \ldots, \overline{u_r}$ represent the reversible actions of an algorithm between its cooling steps (each acting on the density matrix as conjugation by a unitary operator), how different can the eigenvalues of $\iota\, \overline{u_r}\, \iota\, \cdots\, \overline{u_1}\, \iota\, \mathcal{I}_n$ be from those of $\mathcal{I}_n$ (in which all equal 2^{-n})?

A *classical* cooling algorithm is one that uses only reversible (deterministic) classical logic gates between cooling steps. In this case each operator $\overline{u_i}$ acts on the density matrix as conjugation by a permutation matrix. Observe that a $2^n \times 2^n$ diagonal density matrix represents a probability distribution over the basis states $|0 \ldots 0\rangle, \ldots, |1 \ldots 1\rangle$.

PROPOSITION 2.1 (classical cooling). *Let h be a $2^n \times 2^n$ diagonal density matrix. Given any quantum logic steps $\overline{u_1}, \ldots, \overline{u_r}$, there are classical steps $\overline{\pi_1}, \ldots, \overline{\pi_r}$ such that $\iota\, \overline{\pi_r}\, \iota\, \cdots\, \overline{\pi_1}\, \iota\, h$ majorizes $\iota\, \overline{u_r}\, \iota\, \cdots\, \overline{u_1}\, \iota\, h$.*

For a density matrix M with eigenvectors $v_1, \ldots, v_{2^n}$ listed in decreasing order of their eigenvalues $\lambda_1 \geq \cdots \geq \lambda_{2^n}$, let w be a unitary operator which arranges the eigenvectors so that they correspond, in order, to the vectors $|0..00\rangle, |0..01\rangle, |0..10\rangle, \ldots, |1..11\rangle$ (recall that the "cooling bit" that is in contact with the reservoir is the nth or rightmost bit). Then, acting on M with $\overline{w}$, and representing the new matrix as in (2.1), it will have the diagonal entries $\lambda_1, \lambda_3, \ldots, \lambda_{2^n-1}$ in order in the upper left and the diagonal entries $\lambda_2, \lambda_4, \ldots, \lambda_{2^n}$ in order in the lower right. To prove the proposition we use the following lemma.

LEMMA 2.2. *Let M and M' be density matrices and let $M \succeq M'$. Then $\iota\overline{w}M \succeq \iota M'$.*

Proof of Proposition 2.1. Consider any sequence of conjugations $\overline{u_1}, \ldots, \overline{u_r}$. Applying the lemma, induction on r shows that

$$\iota\, \overline{w}\, \iota\, \cdots\, \overline{w}\, \iota\, h \succeq \iota\, \overline{u_r}\, \iota\, \cdots\, \overline{u_1}\, \iota\, h. \tag{2.3}$$

Observe that for each r, the left-hand side of this expression is a diagonal density matrix. Hence each application of $\overline{w}$ is a classical operation, a permutation of the basis states. ∎

Proof of Lemma 2.2. For a density matrix

$$A = \begin{pmatrix} A_{11} & A_{12} \\ A_{12}^\dagger & A_{22} \end{pmatrix}, \tag{2.4}$$

let $\alpha_1, \ldots, \alpha_{2^{n-1}}$ be the eigenvalues of $A_{11} + A_{22}$. Then the eigenvalues of ιA are $\frac{e^\varepsilon}{e^\varepsilon+e^{-\varepsilon}}\alpha_1, \frac{e^{-\varepsilon}}{e^\varepsilon+e^{-\varepsilon}}\alpha_1, \ldots, \frac{e^\varepsilon}{e^\varepsilon+e^{-\varepsilon}}\alpha_{2^{n-1}}, \frac{e^{-\varepsilon}}{e^\varepsilon+e^{-\varepsilon}}\alpha_{2^{n-1}}$. It follows that if another density matrix B is given (and partitioned in the same way) and if $A_{11} + A_{22} \succeq B_{11} + B_{22}$, then $\iota A \succeq \iota B$. So it remains to show that $(\overline{w}M)_{11} + (\overline{w}M)_{22} \succeq M'_{11} + M'_{22}$.

Let $\lambda_1 \geq \cdots \geq \lambda_{2^n}$ be the eigenvalues of M and let $\lambda'_1 \geq \ldots \geq \lambda'_{2^n}$ be the eigenvalues of M'. Then $(\overline{w}M)_{11}$ is the diagonal matrix with diagonal $(\lambda_1, \lambda_3, \ldots, \lambda_{2^n-1})$, and $(\overline{w}M)_{22}$ is the diagonal matrix with diagonal $(\lambda_2, \lambda_4, \ldots, \lambda_{2^n})$. The eigenvalues of $(\overline{w}M)_{11} + (\overline{w}M)_{22}$ are $(\lambda_1 + \lambda_2, \lambda_3 + \lambda_4, \ldots, \lambda_{2^n-1} + \lambda_{2^n})$; by the assumption that $M \succeq M'$, this majorizes the sequence $(\lambda'_1 + \lambda'_2, \lambda'_3 + \lambda'_4, \ldots, \lambda'_{2^n-1} + \lambda'_{2^n})$. It remains to show that the latter majorizes the eigenvalues of $M'_{11} + M'_{22}$.

A simple inequality (see [18, section 9G]) states that the eigenvalues of $M'_{11} + M'_{22}$ are majorized by the sequence $(\beta_1 + \gamma_1, \ldots, \beta_{2^{n-1}} + \gamma_{2^{n-1}})$, where $\beta_1 \geq \cdots \geq \beta_{2^{n-1}}$ are the eigenvalues of M'_{11} and $\gamma_1 \geq \cdots \geq \gamma_{2^{n-1}}$ are the eigenvalues of M'_{22}. The argument is completed by an inequality of Fan (see [18, section 9C]) which states that for any Hermitian H,

$$\begin{pmatrix} H_{11} & H_{12} \\ H_{12}^\dagger & H_{22} \end{pmatrix} \succeq \begin{pmatrix} H_{11} & 0 \\ 0 & H_{22} \end{pmatrix}; \tag{2.5}$$

applied to $H = M'$, this yields $(\lambda'_1, \lambda'_2, \ldots, \lambda'_{2^n}) \succeq (\beta_1, \ldots, \beta_{2^{n-1}}, \gamma_1, \ldots, \gamma_{2^{n-1}})$. ∎

We may therefore restrict our attention to classical cooling algorithms. Observe that every intermediate density matrix created by a classical algorithm is diagonal. Hence the classical cooling steps are equivalent to the following discrete process on probability distributions on the set $\{0,1\}^n$: begin with the uniform distribution on $\{0,1\}^n$. The only tool for modifying the probability distribution is "discrete cooling steps," which have the effect of transforming the current distribution (denoted p) to a new distribution (denoted p'), related to p by

$$\left.\begin{aligned} p'_{w0} &= (p_{w0} + p_{w1})\tfrac{e^\varepsilon}{e^\varepsilon+e^{-\varepsilon}} \\ p'_{w1} &= (p_{w0} + p_{w1})\tfrac{e^{-\varepsilon}}{e^\varepsilon+e^{-\varepsilon}} \end{aligned}\right\} \quad \begin{array}{l}\text{for each binary string} \\ w \text{ of length } n-1.\end{array} \tag{2.6}$$

There is no way of *directly* cooling the first $n-1$ bits, but in between cooling steps we can perform arbitrary permutations of the binary strings. In the discrete process, the role of a permutation of the basis states is to properly pair off the current probabilities before the next cooling step.

Due to Proposition 2.1, Theorem 1.1 is equivalent to showing that the above discrete process cannot increase any probability from its initial value, 2^{-n}, to any more than $2^{-n}e^{\varepsilon 2^{n-1}}$, while Theorem 1.4 is equivalent to showing that the discrete process cannot create a bit of constant bias in less than $\Omega(\tilde{\varepsilon}^{-2})$ cooling steps.

3. Preliminaries.

3.1. Special configurations. The set of probabilities of the basis states, $\{P(w) : w \in \{0,1\}^n\}$, will be referred to as the configuration of the computer.

Definition 3.1. *A "special" configuration is one of*

(a) *a configuration that can be created (out of any configuration, and by any pairing) by a cooling step;*

(b) *the starting configuration, in which all probabilities equal* 2^{-n}.

Note that in a special configuration of type (a), two states that were paired in the previous round, and now have probabilities p and p', satisfy $|\log p - \log p'| = 2\varepsilon$.

3.2. The PPA. If the basis states of the computer are relabeled so that their probabilities are $p_0 \geq \cdots \geq p_{2^n-1}$ (ties broken in arbitrary but fixed fashion), then for each even i we will refer to the states i and $i+1$ as each other's "partners."

The PPA or "partner-pairing algorithm" is simply the following process: In each cooling step, pair partners together. (This completely specifies the algorithm save only for the number of iterations.)

LEMMA 3.2. *In a special configuration, if states with probabilities p and p' are partners, then* $|\log p - \log p'| \leq 2\varepsilon$.

Proof. For the configuration of type (b) this is automatic; for those of type (a) let p be the probability of a state for which the lemma is violated and let q be the probability of the state with which it was paired in the previous round. Suppose $q > p$; the other case is similar. So p is now paired with a probability r for some $r < pe^{-2\varepsilon}$, and the interval (r, p) is empty of state probabilities. The interval $(-\infty, r]$ therefore contains only intact pairs from the previous round and hence an even number of state probabilities. So it cannot be that p's partner in this round is r. ∎

The next step in demonstrating Theorems 1.1 and 1.4 concerns the relation between the output of an arbitrary cooling algorithm B and that of the PPA.

COROLLARY 3.3. *Given any initial probability distribution* $p = \{p_0, \ldots, p_{2^n-1}\}$, *and any cooling algorithm B, the distribution which results from applying the PPA for r cooling steps majorizes the distribution which results from applying B for r cooling steps.*

Proof. This follows from Proposition 2.1 because the PPA is the restriction to probability distributions of the operator $\overline{w}$ defined in section 2. ∎

As a consequence, in pursuit of a bound on the maximum achievable probability of any one string, we can focus on the PPA. (The same lesson applies to any Schur-convex function of the probabilities, of which the maximum probability is but one example; see [18].)

4. Proof of Theorem 1.1.

4.1. Dynamics of cooling algorithms: Assemblies of chips. It is useful to apply the map $p \to \log(2^n p)$ to all the probabilities of a configuration, to obtain a set of 2^n "chips" arrayed on the real axis. Two chips at z_1 and z_2 which are paired by a cooling step are carried to two new chips at $T(z_1, z_2) \pm \varepsilon$, where T is given by

$$e^{T(z_1,z_2)+\varepsilon} + e^{T(z_1,z_2)-\varepsilon} = e^{z_1} + e^{z_2}. \tag{4.1}$$

We now need to understand more about the dynamics of the PPA. A central tool will be to designate certain subsets of the chips as *assemblies.* With an assembly S we associate a *center* $c(S)$ which is the arithmetic mean of the chips, a *radius* $r(S)$ which is $\varepsilon/2$ times the number of chips in the assembly, and an *interval* I_S which is the closed interval $[c(S) - r(S), c(S) + r(S)]$. (We define assemblies only for special configurations.) A set of chips qualifies as an assembly if either

1. it is a pair of chips z_1 and z_2 which are partners (note that the center of this assembly is $(z_1 + z_2)/2$ and its radius is ε);
2. it is the union of two assemblies whose intervals intersect (we will refer to this as merging the two assemblies).

A maximal assembly is one which cannot be merged with any other assembly.

4.2. The modified PPA. The nonlinear map T (defined in (4.1)) is difficult to work with directly, but it has a linearization which suits our needs. In the modified process, chips at z_1 and z_2 are carried to the pair $M(z_1, z_2) \pm \varepsilon$, where

$$M(z_1, z_2) = (z_1 + z_2)/2. \tag{4.2}$$

(The modified process does not preserve the identity $2^{-n} \sum e^{z_i} = 1$.) In the modified PPA, partners are defined among the chips just as before, but the map M rather than the map T is applied to each pair. That the modified process is a useful approximation to the true process is due to the twin facts that ε is small and that in a special configuration, partners z_1 and z_2 are close. The bearing of the modified process on the true process is expressed in the following lemma.

LEMMA 4.1. *Consider two sets of chips in special configurations $x_0 \geq \cdots \geq x_{2^n-1}$ and $y_0 \geq \cdots \geq y_{2^n-1}$, such that $x_i \leq y_i$ for all i. Apply a step of the true PPA to $x_0, \ldots, x_{2^n-1}$, resulting in the set of chips $x'_0 \geq \cdots \geq x'_{2^n-1}$. Apply a step of the modified PPA to $y_0, \ldots, y_{2^n-1}$, resulting in the set of chips $y'_0 \geq \cdots \geq y'_{2^n-1}$. Then $x'_i \leq y'_i$ for all i.*

Proof. We have only to show that for any even i, $T(x_i, x_{i+1}) \leq M(y_i, y_{i+1})$. We have that

$$e^{T(x_i,x_{i+1})} = e^{M(x_i,x_{i+1})} \frac{\cosh((x_i - x_{i+1})/2)}{\cosh(\varepsilon)}. \tag{4.3}$$

Since the configuration $x_1, \ldots, x_{2^n}$ is special, $|x_i - x_{i+1}| \leq 2\varepsilon$ by Lemma 3.2, and so $T(x_i, x_{i+1}) \leq M(x_i, x_{i+1})$. Since $M(x_i, x_{i+1}) \leq M(y_i, y_{i+1})$ directly from the assumptions, we conclude that $T(x_i, x_{i+1}) \leq M(y_i, y_{i+1})$. ∎

Applying each of the processes T and M repeatedly starting from a common special configuration, we conclude by induction that after any number of iterations, the greatest achievable probability of any state in the modified process is an upper bound on the probability of any state in the true process.

The chip game. The modified process given by (4.2) describes the following chip game: 2^n chips are placed initially at the origin of the real line. In each step you choose a pairing of the chips, and then the positions of each pair of chips (say z_1 and z_2) are moved to $(z_1 + z_2)/2 \pm \varepsilon$. Your goal is to move any one chip as far to the right as possible. Theorem 1.1 has been reduced to showing that no chip can be moved to distance more than $\varepsilon 2^{n-1}$ from the origin. Section 4.3 is devoted to a somewhat lengthy combinatorial proof of this fact.

Fortunately, there is a simpler proof of a bound that is weaker by a factor of 2: i.e., no chip can be moved to distance more than $\varepsilon 2^n$ from the origin. This is sufficient to establish our fundamental physical conclusions—to wit: unbounded cooling is impossible using finitely many computation qubits at a fixed heat-bath temperature; moreover, for large n there is a threshold at $(-\log_2 \tilde{\varepsilon})/n = 1$ for the feasibility of cooling. The reader interested only in these conclusions can read the following and skip section 4.3.

The bound of $\varepsilon 2^n$ rests on showing that the modified PPA, starting from the initial configuration having all chips at the origin, never creates a separation of more than 2ε between adjacent chips: Suppose the gaps within a set of chips $x_0 \geq \cdots \geq x_{2^n-1}$ are bounded by 2ε, and that a step of the modified PPA is applied to these chips, carrying x_{2i} to $x'_{2i} = (x_{2i} + x_{2i+1})/2 + \varepsilon$, and x_{2i+1} to $x'_{2i+1} = (x_{2i} + x_{2i+1})/2 - \varepsilon$. Note that for even i, $x'_i \geq x_i$, while for odd i, $x'_i \leq x_i$. The $\{x'_i\}$ are generally not in sorted order, but x'_{2^n-1} is a smallest chip, and so it is enough to show that for every

$i < 2^n - 1$, $x'_{i+1} \geq x'_i - 2\varepsilon$ (i.e., there are no descents by more than 2ε in the sequence $x'_0, \ldots, x'_{2^n-1}$). For even i, $x'_{i+1} \geq x'_i - 2\varepsilon$ is satisfied with equality. For odd i, using the inductive hypothesis, $x'_{i+1} \geq x_{i+1} \geq x_i - 2\varepsilon \geq x'_i - 2\varepsilon$.

Finally, a configuration of chips whose mean is 0 and in which all gaps are bounded by 2ε has no chip beyond distance $\varepsilon 2^n$ from the origin. For if any gap is less than 2ε, the configuration does not achieve greatest possible distance, since the chips to the right and left of this gap can be shifted outward while preserving the mean, while a configuration in which all the gaps are exactly 2ε is an arithmetic sequence centered at the origin.

We return to the proof of the full statement of Theorem 1.1.

4.3. Preservation of maximal assemblies. The most lengthy technical portion of this paper goes into establishing the following proposition.

PROPOSITION 4.2.

1. *The maximal assemblies of a special configuration partition the set of chips. (Equivalently, we can arrive at the list of all maximal assemblies by merging assemblies in any order until no further mergers are possible.)*
2. *Maximal assemblies are preserved by the modified PPA (i.e., the partition of the chips of a special configuration into maximal assemblies is unchanged by a cooling step).*

We begin with a sequence of arguments that do not depend on whether the true or modified PPA is applied but only on the fact that each step pairs partners together.

LEMMA 4.3. *In a special configuration, if $a, b \in \mathbb{R}$, $a \leq b$, and the intervals $[a - 2\varepsilon, a)$ and $(b, b + 2\varepsilon]$ are empty of chips, then the interval $[a, b]$ contains an even number of chips.*

Proof. In a special configuration, two chips that were paired in the previous round are separated by 2ε. The fact that $[a - 2\varepsilon, a)$ is empty of chips therefore implies that there are an even number of chips in $(-\infty, a)$; similar reasoning shows there are an even number of chips in (b, ∞). □

LEMMA 4.4. *Let $k \geq 0$, k even, and let D be an assembly of cardinality at most k.*

1. *(Bounded gap). If $S \subseteq D$ consists of some of the partner pairs of D, then $I_S \cap I_{D-S} \neq \emptyset$.*
2. *(Monotonicity). If an assembly B is a subset of D, then I_B is contained in I_D.*

Proof. The proof is by induction on k.

Part 1, Bounded gap: Let $P_1, \ldots, P_{k/2}$ be the partner pairs of D, listed in their order on the line. Suppose the lemma fails for $S = P_1 \cup \cdots \cup P_\ell$, for some $0 < \ell < k/2$. Fix a sequence of mergers that forms D out of $P_1, \ldots, P_{k/2}$. We may assume these mergers always combine adjacent assemblies, since if an assembly B is between A and C which are being merged, I_B must intersect one of I_A or I_C (say I_A); B can be merged with A. By part 2 of the lemma (for $k - 2$), all subsequent merger steps which are supposed to be performed with the assembly containing A or B can still be performed (in particular the very next step of merging $A \cup B$ with C). So the mergers describe a binary tree T_0 of assemblies, whose leaves are the partner pairs and whose internal nodes are the assemblies constructed during the merging process; the left and right children of any internal node are always two disjoint assemblies which are adjacent to each other in the left-right order on the line. Moreover, the children of any internal node are two disjoint assemblies whose intervals intersect, since this is a tree of mergers. The root of T_0 is D.

We will also use other trees in the proof. The internal nodes of these trees might not be assemblies, but each internal node will still be a sequence of partner pairs that are laid out consecutively on the line; the left and right children of an internal node will still consist of two sequences which are disjoint, adjacent to each other on the line, and in the same left-right order. While the set at an internal node may not be an assembly, we will still associate with such a set of partner pairs a center, a radius, and an interval, all defined just as they are for an assembly.

We will say that an internal node is "cohesive" if the intervals of its two children intersect. Every internal node in T_0 is cohesive. The claim will follow from the existence of another tree T_F in which the left child of the root is S, the right child is $D - S$, and the root is cohesive.

We will show the existence of T_F by converting T_0 into it through a sequence of "tree rotations." In a tree rotation a tree T' is changed into a tree T'' as follows. Let A, B, and C each be a sequence of consecutive partner pairs, and let these sequences be disjoint, and arranged adjacent to each other on the line from left to right in the order A, B, C. Suppose that each occurs as a node in T' and that there are internal nodes $A \cup B$ and $A \cup B \cup C$. Then a right tree rotation "at $A \cup B \cup C$" is the conversion of T' into the tree T'' that differs only in that instead of an internal node $A \cup B$, it has an internal node $B \cup C$. (A left tree rotation would be the replacement of a node $B \cup C$ by a node $A \cup B$.) We will demonstrate the following property of right tree rotations; the analogous property holds for left tree rotations and is shown in the same way.

(*) If $A \cup B$ and $A \cup B \cup C$ are cohesive in T', then $A \cup B \cup C$ is cohesive in T''.

Using (*) we will obtain the desired tree T_F by beginning with T_0, in which all internal nodes are cohesive, and repeatedly doing the following: Find the least common ancestor J of P_ℓ and $P_{\ell+1}$, let K be its parent, and rotate at K. After the rotation, K becomes the new least common ancestor of P_ℓ and $P_{\ell+1}$; by (*), it is still cohesive. The cohesiveness of nodes outside the subtree rooted at K is unaffected by the rotation. Hence the process continues until a last rotation at the root, at which time the root is cohesive, and is the least common ancestor of P_ℓ and $P_{\ell+1}$.

Finally, we show (*). For simplicity of notation and without loss of generality we will assume the center of B is 0. Let A have center $-r_1$ and radius s_1; let B have radius s_2; and let C have center r_3 and radius s_3. Note $s_1, s_2, s_3, r_1, r_3 \geq 0$. Cohesiveness of $A \cup B$ in T' means that

$$r_1 \leq s_1 + s_2, \tag{4.4}$$

while cohesiveness of $A \cup B \cup C$ in T' means that

$$r_3 + \frac{r_1 s_1}{s_1 + s_2} \leq s_1 + s_2 + s_3. \tag{4.5}$$

Sum these inequalities with the respective nonnegative coefficients $\frac{s_2(s_1+s_2+s_3)}{(s_1+s_2)(s_2+s_3)}$ and $\frac{s_3}{(s_1+s_2)(s_2+s_3)}$ to obtain

$$r_1 + \frac{r_3 s_3}{s_2 + s_3} \leq s_1 + s_2 + s_3, \tag{4.6}$$

which indicates the cohesiveness of $A \cup B \cup C$ in T''.

Part 2, Monotonicity: The proof is in two sections. (a) We argue that we can form D in a sequence of strict mergers that create B as an intermediate step. (A

strict merger is one that forms the union of two assemblies neither of which contains the other.) (b) We argue that in any strict merger, forming assembly $C = B_1 \cup B_2$ from B_1 and B_2, the interval of C contains those of B_1 and B_2.

Proof of (a). First, carry out the mergers that create B from the original pairs. Now consider the mergers that create D from the original pairs. Carry out those steps, each time replacing the arguments E_1 and E_2 of a desired merger $E_1 \cup E_2$, with the present (greatest) assemblies that contain E_1 and E_2. We must check that this makes sense: that each of E_1 and E_2 are a subset of a present assembly, and that the intervals of those assemblies intersect. The latter claim holds by induction because, until D has been formed, those assemblies are smaller than D (and because after D has been formed, all mergers are trivial). To see the former claim, observe (by induction on the step number) that at any time, the present greatest assembly containing E_i is either E_i, or $E_i \cup B$, depending on whether any of the pairs in E_i intersects B.

Proof of (b). Let $s = |B_1 \cap B_2|$, $s_1 = |B_1 - B_2|$, and $s_2 = |B_2 - B_1|$. Let c be the arithmetic mean of $B_1 \cap B_2$, c_1 the arithmetic mean of $B_1 - B_2$, and c_2 the arithmetic mean of $B_2 - B_1$.

The arithmetic mean of B_1 is $\overline{c}_1 = (cs + c_1 s_1)/(s + s_1)$, and the arithmetic mean of B_2 is $\overline{c}_2 = (cs + c_2 s_2)/(s + s_2)$. Let $\overline{c}$ be the arithmetic mean of $B_2 \cup B_1$, so $\overline{c} = (cs + c_1 s_1 + c_2 s_2)/(s + s_1 + s_2)$. To demonstrate the containment of intervals, we show that the left-hand boundary of I_C, $\overline{c} - s - s_1 - s_2$, is to the left of the left-hand boundary of I_{B_1}, $\overline{c}_1 - s - s_1$; in other words, $\overline{c}_1 - s - s_1 \geq \overline{c} - s - s_1 - s_2$. The remaining three cases are similar.

By part 1 of the lemma we know

$$s + s_2 \geq c_2 - c, \tag{4.7}$$

$$s + s_1 \geq c - c_1. \tag{4.8}$$

Inequality (4.7) is equivalent to $c_2 - \overline{c}_1 \leq s + s_2 + c - \overline{c}_1$. Inequality (4.8) is equivalent to $c - \overline{c}_1 \leq s_1$. Together these give

$$c_2 - \overline{c}_1 \leq s + s_1 + s_2, \tag{4.9}$$

which is equivalent to

$$\overline{c} - \overline{c}_1 \leq s_2. \tag{4.10}$$ □

We now prove Proposition 4.2(1): *The maximal assemblies of a special configuration partition the set of chips. (Equivalently, we can arrive at the list of all maximal assemblies by merging assemblies in any order until no further mergers are possible.)*

Proof. The initial pairing of chips is fixed. Let $S_1, \ldots, S_k$ be the maximal assemblies obtained by a particular sequence of mergers. Write, in terms of the initial pairs, $S_1 = P_{11} \cup \cdots \cup P_{1\ell_1}$, $S_2 = P_{21} \cup \cdots \cup P_{2\ell_1}$, and so forth. Fixing an alternate merger sequence, consider the first step in which that sequence joins pairs from some two different S_i's; suppose those are S_1 and S_2. Let $S_1' \subseteq S_1$ and $S_2' \subseteq S_2$ be the two assemblies merged in this step. Then the intervals of S_1' and S_2' intersect, which contradicts Lemma 4.4(2), since the intervals of S_1 and S_2 do not intersect. □

COROLLARY 4.5. *Let D be an assembly and let $S \subseteq D$ be a set of even cardinality. Then I_S is contained in I_D.*

Proof. We show that the right end of I_S is less than the right end of I_D; a similar argument shows that the left end of I_S is greater than the left end of I_D. The set S' consisting of the rightmost $|S|$ chips in D consists of several partner pairs. By Lemma 4.4(1), $I_{S'}$ intersects $I_{D-S'}$; this implies that $I_{S'} \subseteq I_D$. ∎

LEMMA 4.6. *Given a cooling step, form a corresponding set of intervals S as follows. For each two chips paired by the cooling step, S contains the interval between the poststep positions of those chips. Also, for each pair of partners in the poststep configuration, S contains the interval between the partners. Consider any point that coincides with no poststep chips. Then there is an even number of intervals of S containing that point.*

Proof. Moving from left to right, at every chip the number of partner intervals covering the line alternates between 0 and 1. The parity of the contribution of the pair intervals also alternates at every chip. Therefore, between chips, the parity is the same as it is beyond the last chip: 0. ∎

LEMMA 4.7. *Two chips which are paired in a cooling step (of any algorithm) are in a common maximal assembly after that cooling step.*

Proof. For specificity suppose this step was numbered t. Let x be such that the positions of the two chips after step t are $x \pm \varepsilon$. We will use the terms "righties" and "lefties" to refer to members of pairs depending on whether they are, respectively, the higher or lower probability chip (after the step); e.g., $x + \varepsilon$ is the righty (or t-righty, to specify the step) and $x - \varepsilon$ is the t-lefty of their pair.

We consider several cases.

Case 1. $x \pm \varepsilon$ are partners poststep. The lemma follows.

Otherwise, for $-\varepsilon \le s_1, s_2 \le \varepsilon$, let $x - \varepsilon$ be partnered with a chip at $x - \varepsilon + 2s_1$ and let $x+\varepsilon$ be partnered with a chip at $x+\varepsilon+2s_2$. The number of chips, m, between the pairs $\{x-\varepsilon, x-\varepsilon+2s_1\}$ and $\{x+\varepsilon, x+\varepsilon+2s_2\}$ is even; we consider several cases.

Case 2. $s_1 \ge s_2$. In this case the assembly $\{x-\varepsilon, x-\varepsilon+2s_1\}$ (whose right-hand boundary is at $x+s_1$) and the assembly $\{x+\varepsilon, x+\varepsilon+2s_2\}$ (whose left-hand boundary is at $x + s_2$) intersect geometrically, and the lemma follows.

Case 3. $s_1 < s_2$. We start by showing that $m > 0$, which is to say that the interval $[x-\varepsilon+2s_1, x+\varepsilon+2s_2]$ contains chips other than $x-\varepsilon$ or $x+\varepsilon$. The interval between $\max\{x-\varepsilon, x-\varepsilon+2s_1\}$ and $\min\{x+\varepsilon, x+\varepsilon+2s_2\}$ is nonempty, and since it is contained in $[x-\varepsilon, x+\varepsilon]$, it must by Lemma 4.6 intersect some interval between two chips that were paired in the last cooling step; neither $x-\varepsilon+2s_1$ nor $x+\varepsilon+2s_2$ can be one of the chips generating such an interval, since the distance between them is greater than 2ε. Hence m is positive; we continue with two cases depending on its value.

Case 3a. $s_1 < s_2$ and $m = 2$. Let the two points be z_1 and z_2, with $z_1 \le z_2$; note that these are paired together poststep and that $x-\varepsilon \le z_1 \le z_2 \le x+\varepsilon$. By the parity argument of Lemma 4.6, there must be two chips that were paired in step t, for which the interval between the poststep chip positions covers the interval between $x-\varepsilon+2s_1$ and z_1; therefore $z_1 \le x+\varepsilon+2s_1$. For a similar reason, $z_2 \ge x-\varepsilon+2s_2$. We examine three pair assemblies: $A = \{x-\varepsilon, x-\varepsilon+2s_1\}$, $B = \{z_1, z_2\}$, and $C = \{x+\varepsilon, x+\varepsilon+2s_2\}$. Their intervals are $I_A = [x-2\varepsilon+s_1, x+s_1]$, $I_B = [(z_1+z_2)/2-\varepsilon, (z_1+z_2)/2+\varepsilon]$, and $I_C = [x+s_2, x+2\varepsilon+s_2]$. If I_B does not intersect I_A, then $x+s_1+\varepsilon < (z_1+z_2)/2$. If in addition I_B does not intersect I_C, then $(z_1+z_2)/2 < x+s_2-\varepsilon$, together implying $s_1+2\varepsilon < s_2$, which is impossible, since $-\varepsilon \le s_1, s_2 \le \varepsilon$. Hence I_B intersects at least one of I_A or I_C. The rest of the argument is symmetric for these two cases, and so we spell out only the case that I_B intersects I_A.

If I_B intersects I_A, the four points of A and B form an assembly $A \cup B$ whose right-hand boundary is at $(2(x-\varepsilon)+2s_1+z_1+z_2)/4+2\varepsilon$ which, by the lower bounds for z_1 and z_2, is at least $x+\varepsilon+(s_1+s_2)/2$. Subtracting the left-hand boundary of I_C gives $\varepsilon+(s_1-s_2)/2$, which by the constraints on s_1 and s_2 is at least 0. Hence the interval of the assembly $A \cup B$ intersects that of the assembly C, and the lemma follows.

Case 3b. $s_1 < s_2$ and $m \geq 4$. In this case there are at least four points $z_1, \ldots, z_m$ arranged as $x-\varepsilon \leq z_1 \leq \cdots \leq z_m \leq x+\varepsilon$; the same argument used for Case 3a shows that either the assembly of $\{z_1, z_2\}$ intersects that of $\{x-\varepsilon, x-\varepsilon+2s_1\}$, or the assembly of $\{z_{m-1}, z_m\}$ intersects that of $\{x+\varepsilon, x+\varepsilon+2s_2\}$. The cases are symmetric, and so suppose that the first of these occurs. Then the assembly formed by $D = \{z_1, z_2, x-\varepsilon, x-\varepsilon+2s_1\}$ has its right-hand boundary at $(2(x-\varepsilon)+2s_1+z_1+z_2)/4+2\varepsilon$. Using the lower bound $x-\varepsilon$ for z_1 and z_2 places a lower bound of $x+\varepsilon+s_1/2$ on this boundary. For the interval of the assembly $\{z_{m-1}, z_m\}$ not to intersect this, we must have $(z_{m-1}+z_m)/2 > x+s_1/2+2\varepsilon$. The right-hand boundary of the assembly $\{z_{m-1}, z_m\}$ must therefore be at a position greater than $x+s_1/2+3\varepsilon$, which in turn is at least $x+5\varepsilon/2$. Hence the four points $E = \{z_{m-1}, z_m, x+\varepsilon, x+\varepsilon+2s_2\}$ form an assembly. Using the upper bound $x+\varepsilon$ on z_{m-1} and z_m places an upper bound of $x-\varepsilon+s_2/2$ on the left-hand boundary of this assembly. The intervals of the assemblies D and E intersect because $(x+\varepsilon+s_1/2)-(x-\varepsilon+s_2/2) = 2\varepsilon+(s_1-s_2)/2 \geq \varepsilon \geq 0$. The lemma follows. ∎

We can now finally prove Proposition 4.2(2): *Maximal assemblies are preserved by the modified PPA.*

We show, equivalently, that every prestep assembly is contained in a poststep assembly. Lemma 4.7 establishes this for prestep pairs. Now suppose that the prestep assembly D was formed by merging assemblies B and C. By induction B and C are each contained in a poststep assembly; call these B' and C'. By Corollary 4.5, the intervals of B' and C' contain those of the poststep sets of chips B and C. In the modified chip process, these last two intervals are identical, respectively, to the intervals of the prestep assemblies B and C. Therefore $I_B \subseteq I_{B'}$ and $I_C \subseteq I_{C'}$. Since I_B intersects I_C, $B' \cup C'$ is an assembly, and it contains D. ∎

Proof of Theorem 1.1. Proposition 4.2 implies that in a configuration reachable from the start state by the modified chip process there is just a single maximal assembly, whose interval is $[-\varepsilon 2^{n-1}, \varepsilon 2^{n-1}]$. Consider a chip that is furthest from the origin: by Lemma 3.2, it lies within the interval of the assembly formed by itself and its partner; by Lemma 4.4(2), this interval is contained within the interval of the maximum assembly. Hence all chips lie within distance $\varepsilon 2^{n-1}$ of the origin. Due to Corollary 3.3 (applied to the initial uniform distribution which corresponds to the maximally mixed state $\mathcal{I}_n$) and Lemma 4.1, this shows that no cooling process can increase any probability above $2^{-n}e^{\varepsilon 2^{n-1}}$, establishing the theorem. ∎

5. Proof of Theorem 1.2. Here we prove Theorem 1.2, which is a complement to the "impossibility" result of Theorem 1.1: *For $\tilde{\varepsilon} \geq 2^{4-n}$, heat-bath cooling using the PPA produces a distribution at variation distance $\Theta(1)$ from uniform, within $T = \tilde{\varepsilon}^{-2}$ cooling steps.* To a state with probability p assign the potential $g(p) = \log\cosh(2^n(p-2^{-n}))$, and to a configuration c assign the potential $g(c) = \sum_p g(p)$. Observe that $g(\text{initial configuration}) = 0$.

Let c be any special configuration and let c' be the configuration it is carried to by the PPA. Let $\Delta g(c) = g(c') - g(c)$. If p_1 and p_2 are paired in c, then their

contribution to $\Delta g(c)$ is

$$g(p_1') + g(p_2') - g(p_1) - g(p_2), \tag{5.1}$$

where without loss of generality $p_1 \le p_2$, and we have written $p_1' = (p_1+p_2)(1-\tilde{\varepsilon})/2$ and $p_2' = (p_1+p_2)(1+\tilde{\varepsilon})/2$. This is nonnegative because g is convex, $p_1+p_2 = p_1'+p_2'$, and because due to Lemma 3.2, $[p_1,p_2] \subseteq [p_1',p_2']$.

Since g is strictly convex, the potential of a special configuration increases strictly unless each of its pairs $\{p_1,p_2\}$ satisfies $|\log p_2 - \log p_1| = 2\varepsilon$.

If sometime within T rounds it happens that there are at least $2^{n-1}-2$ probabilities outside of the interval $[2^{-n-1}, 3\cdot 2^{-n-1}]$, then we are done.

Otherwise, suppose that c is a special configuration having at least $2^{n-1}+2$ probabilities within the interval $[2^{-n-1}, 3\cdot 2^{-n-1}]$. We want to show a lower bound on $\Delta g(c)$. The PPA must form at least 2^{n-2} pairs among these probabilities , and at least 2^{n-3} of those pairs must be of length (separation between the probabilities) at most 2^{3-2n}. The contribution of such a pair to $\Delta g(c)$ is least if its length is indeed 2^{3-2n}; for a lower bound on $\Delta g(c)$ we also assume that the poststep probabilities are as close to each other as possible, which (since their ratio is fixed at $e^{2\varepsilon}$) occurs when the average of the probabilities is as small as possible, namely $2^{-n-1}\cdot 2\tilde{\varepsilon} = 2^{-n}\tilde{\varepsilon}$. Letting the probabilities of the pair, before the cooling step, be $y \pm 2^{2-2n}$, and letting Δ_1 be the contribution of these two probabilities to $\Delta g(c)$, we can write

$$\Delta_1 = \log \frac{\cosh 2^n(y(1+\tilde{\varepsilon}) - 2^{-n}) \cosh 2^n(y(1-\tilde{\varepsilon}) - 2^{-n})}{\cosh 2^n(y + 2^{2-2n} - 2^{-n}) \cosh 2^n(y - 2^{2-2n} - 2^{-n})}. \tag{5.2}$$

Let $x = 2^n y - 1$; note that $|x| \le 1/2$. Let $\eta = 2^n y\tilde{\varepsilon}$; since $y \ge 2^{-n-1}$, $\eta \ge \tilde{\varepsilon}/2$.

$$\Delta_1 = \log \frac{\cosh(x+\eta)\cosh(x-\eta)}{\cosh(x+2^{2-n})\cosh(x-2^{2-n})} = \log \frac{\cosh 2x + \cosh 2\eta}{\cosh 2x + \cosh 2^{3-n}}. \tag{5.3}$$

Since this is increasing in η for $\eta > 0$, we have

$$\Delta_1 \ge \log \frac{\cosh 2x + \cosh \tilde{\varepsilon}}{\cosh 2x + \cosh 2^{3-n}}. \tag{5.4}$$

Now let $h(z) = \log \frac{\cosh 2x + \cosh(\tilde{\varepsilon}/2+z)}{\cosh 2x + \cosh 2^{3-n}}$. Then $\Delta_1 \ge h(\tilde{\varepsilon}/2)$. Now

$$h'(z) = \frac{\sinh(\tilde{\varepsilon}/2+z)}{\cosh 2x + \cosh(\tilde{\varepsilon}/2+z)}, \tag{5.5}$$

$$h''(z) = \frac{1+\cosh(\tilde{\varepsilon}/2+z)\cosh 2x}{(\cosh 2x + \cosh(\tilde{\varepsilon}/2+z))^2} \ge 0. \tag{5.6}$$

Thus $h(z) \ge h(0) + zh'(0)$, and in particular, since $\tilde{\varepsilon}/2 \ge 2^{3-n}$, $h(0) \ge 0$, and

$$\Delta_1 \ge h\left(\frac{\tilde{\varepsilon}}{2}\right) \ge 0 + \frac{\tilde{\varepsilon}}{2}\frac{\sinh(\tilde{\varepsilon}/2)}{\cosh 2x + \cosh(\tilde{\varepsilon}/2)} \ge \frac{\tilde{\varepsilon}^2}{8\cosh 1}, \tag{5.7}$$

the last inequality being implied by $|x| \le 1/2$, $\tilde{\varepsilon} \le 1$, and $\sinh(\tilde{\varepsilon}/2) \ge \tilde{\varepsilon}/2$. Consequently, if for T rounds it does not occur that at least $2^{n-1}-2$ probabilities are

outside of the interval $[2^{-n-1}, 3 \cdot 2^{-n-1}]$, then due to the 2^{n-3} pairs to which this analysis applies, g increases to at least

$$\frac{T 2^{n-6} \tilde{\varepsilon}^2}{\cosh 1}. \tag{5.8}$$

Observe now that for any p, $|p - 2^{-n}| \geq g(p) 2^{-n}$. So the variation distance from uniform after $T = \tilde{\varepsilon}^{-2}$ steps rises to at least

$$\frac{2^{-6}}{\cosh 1}. \tag{5.9}$$ □

6. Proof of Theorem 1.3. Here we prove Theorem 1.3, the second form (and the one more directly relevant to quantum computation) of the complement to the "impossibility" result of Theorem 1.1. *Within* $4n\tilde{\varepsilon}^{-2}(1 + \log(1/\tilde{\varepsilon}))$ *cooling steps, the PPA creates a probability distribution in which with probability at least* $1 - O(\frac{1}{1+\log 1/\tilde{\varepsilon}})$, *all of the first* $n - (1 + o(1)) \log_2 1/\tilde{\varepsilon}$ *bits are* $|0\rangle$*'s.*

Proof. As in the previous section we use a potential function, but now we use a different function—the entropy of the distribution—and we use it only for the runtime analysis, rather than using low entropy to imply that many cold bits are extracted.

Let $\mathcal{H}$ be the entropy function, and for $0 \leq \delta \leq 1$ let $H(\delta) = \mathcal{H}(\{(1-\delta)/2, (1+\delta)/2\}) = \frac{1-\delta}{2} \log \frac{2}{1-\delta} + \frac{1+\delta}{2} \log \frac{2}{1+\delta}$. Let $(1 \pm \delta)p/2$ be two probabilities paired in a cooling step. The change in their contribution to the distribution entropy due to the cooling step is $(H(\tilde{\varepsilon}) - H(\delta))p$; due to Lemma 3.2, $\delta \leq \tilde{\varepsilon}$, and so this contribution is nonpositive. Thus the distribution entropy is weakly decreasing in each cooling step.

LEMMA 6.1. *Within* $\frac{n \log 2}{(H(\delta) - H(\tilde{\varepsilon}))\gamma}$ *cooling steps, at least* $1 - \gamma$ *of the probability resides in partners* $\{p_1, p_2\}$ *for which* $|\log p_1 - \log p_2| \geq 2\delta$.

Proof. So long as the condition is unfulfilled, at least γ of the probability resides in partners for which $|\log p_1 - \log p_2| \leq 2\delta$, and so the distribution entropy (which begins as $n \log 2$) decreases in each cooling step by at least $(H(\delta) - H(\tilde{\varepsilon}))\gamma$. □

LEMMA 6.2. *If at least* $1 - \gamma$ *of the probability resides in partners* $\{p_1, p_2\}$ *for which* $|\log p_1 - \log p_2| \geq 2\delta$, *then for positive even* y, *at least* $(1-\gamma)(1 - e^{-(y+2)\delta})$ *of the probability resides in just* y *of the states.*

Proof. The probability of the y most likely states is at least equal to the probability of the y most likely states in partner pairs for which $|\log p_1 - \log p_2| \geq 2\delta$. That probability is maximized by the distribution in which the partners pairs are adjacent, which is to say that each probability occurs twice (except at the ends), once as the smaller and once as the larger of two partners. A short calculation shows that the sum of the top y probabilities is at least $(1-\gamma)(1 - e^{-(y+2)\delta})$. □

Finally, we can establish Theorem 1.3. Let $\gamma = \frac{\log 2}{1+\log 1/\tilde{\varepsilon}}$, $y = \frac{2 \log 1/\gamma}{\tilde{\varepsilon}}$, and $\delta = \tilde{\varepsilon}/2$. The total probability of these y most likely states is $1 - O(\frac{1}{1+\log 1/\tilde{\varepsilon}})$, and once indexed lexicographically in decreasing likelihood from 0 to $2^n - 1$, they all share $|0\rangle$'s in their first $n - \lg y \geq n - (1 + o(1)) \lg 1/\tilde{\varepsilon}$ bits. □

7. Proof of Theorem 1.4. We demonstrate here the lower bound of $\Omega(\tilde{\varepsilon}^{-2})$ on the number of cooling steps required in order to create even a single bit of constant bias. As in section 6, we examine the entropy of the distribution. The initial entropy is $n \log 2$. A distribution in which some bit has bias bounded away from 0 has entropy $(n - \Omega(1)) \log 2$. From the calculations in section 6 we see that the entropy of the distribution can decrease by at most $\log 2 - H(\tilde{\varepsilon}) \leq \tilde{\varepsilon}^2$ in a single cooling step. Hence a total of $\Omega(\tilde{\varepsilon}^{-2})$ cooling steps is required. □

8. Proof of Theorem 1.5. To this point we have concentrated on what can be achieved by alternating *arbitrary* permutations with cooling steps. It is not known whether the quality of initialization achieved in Theorems 1.2 and 1.3 can also be efficiently produced if the permutations must be implemented with one of the standard bases of reversible gates. However, we now outline why slightly weaker cooling can indeed be achieved using a simple sequence of standard reversible gates. Theorems 1.2 and 1.3 guarantee good initialization, provided, respectively, that $\tilde{\varepsilon} \geq 2^{4-n}$ and $\tilde{\varepsilon} \in \Omega(n2^{-n})$; the simple procedure provided in this section initializes a bit with bias $\Omega(1)$ within time $O((1/\tilde{\varepsilon})^{\log\log 1/\tilde{\varepsilon}})$, provided that $\tilde{\varepsilon} \in \Omega(\phi^{-n})$. (Recall that $\phi = (1+\sqrt{5})/2$.) More generally, for $N \leq \min\{n, \lceil \log_\phi 1/\tilde{\varepsilon} \rceil\}$, the procedure prepares a bit of bias $\Omega(\tilde{\varepsilon}F_N)$ within time $\exp(O(N \log N))$ using an N-bit device. In what follows set $N = \min\{n, \lceil \log_\phi 1/\tilde{\varepsilon} \rceil\}$.

Recall that $F_k = (2\phi/5 - 1/5)\phi^k - (2\phi/5 - 1/5)(1-\phi)^k$. For notational convenience we assume in this section that bit 1 (rather than n) is the special bit that can be directly cooled by the heat bath.

The procedure $\mathcal{F}$, taking argument $2 \leq N \leq \lceil \log_\phi 1/\tilde{\varepsilon} \rceil$, produces statistically independent bits $1, \ldots, N$, such that bit k (for every $1 \leq k \leq N$) has bias $\approx \tilde{\varepsilon}F_k$, or more specifically, bias $\geq \tilde{\varepsilon}F_k(1 - 2^{k-N-1})$. The sequence of quantum gates to be applied in this simple recursive procedure is easily generated by an NC1 circuit (whose input is the elapsed time in the cooling procedure).

Procedure $\mathcal{F}(N)$*:* Run $\mathcal{F}'(N, N)$.

Procedure $\mathcal{F}'(N, k)$*:*

(a) If $k = 2$, run the cooling step on bits 1 and (by exchange) 2.

(b) If $k > 2$, repeat steps (b1) and (b2) $O(N - k)$ times until the bias of bit k is at least $\tilde{\varepsilon}F_k(1 - 2^{k-N-1})$:

  (b1) Use a reversible majority gate to set bit k to be the majority of bits $k-2, k-1$, and k.

  (b2) Run $\mathcal{F}'(N, k-1)$.

(There are various ways to implement a reversible majority gate. Conceptually perhaps the simplest is the transformation of a triple of bits (a, b, c) into the triple $(\mathrm{MAJ}(a, b, c), a \oplus b, a \oplus c)$.)

We start with an imprecise version of the analysis. The effect of the majority gate in (b1) is, roughly, to transform bits with biases $\tilde{\varepsilon}\phi^{k-2}, \tilde{\varepsilon}\phi^{k-1}$, and $\tilde{\varepsilon}x$ into a bit of bias $\approx \tilde{\varepsilon}(\phi^{k-2} + \phi^{k-1} + x)/2$ (this is an approximation accurate for biases $\ll 1$). In each iteration within step (b), x converges toward the unique fixed point of this transformation, $x = \phi^k$. Convergence of the loop inside step (b) is rapid: in each iteration, the Lyapunov function $(\phi^k - x)^2$ decreases by a factor of almost 4. (When step (b) is very close to completion the factor is no longer close to 4 but remains bounded away from 1.) This is why $O(N - k)$ repetitions are enough.

The more careful analysis of $\mathcal{F}'(N, k)$ is this: by definition, the last recursive call to $\mathcal{F}'(N, k-1)$ terminated with bits $k-1$ and $k-2$ being independent and having biases at least $\tilde{\varepsilon}F_k(1 - 2^{k-N-2})$ and $\tilde{\varepsilon}F_k(1 - 2^{k-N-3})$. A few lines of calculation show that if the bias of bit k was $\tilde{\varepsilon}F_k(1-y)$ (before application of (b1)), then after the application it is at least $\tilde{\varepsilon}F_k(1-cy)$ for a fixed positive constant $c < 1$. Therefore $O(N - k)$ rounds suffice to drive the bias up to $\tilde{\varepsilon}F_k(1 - 2^{k-N-1})$.

Since procedure $\mathcal{F}'(N, k)$ makes $O(N - k)$ recursive calls to $\mathcal{F}'(N, k-1)$, the overall runtime of $\mathcal{F}'(N, N)$, and hence $\mathcal{F}(N)$, is $(N!)^{O(1)} = \exp(O(N \log N))$. This establishes Theorem 1.5. ∎

Historical notes. The application of majority gates to amplify bias began at least with von Neumann's work on fault tolerance [27]. The idea was later used as part of the design for algorithmic heat engines in [22]. An experiment to demonstrate the three-bit-majority primitive was conducted in [7]; a similar experiment was conducted by Sørensen [23], for NMR imaging amplification, before NMR quantum computers had been suggested. A simpler two-bit process, also pioneered by von Neumann [26] (for the quite different purpose of extracting fair from biased coin flips), was used for cooling in [22] and then in [5]. However, since the two-bit process amplifies bias only by order $\tilde{\varepsilon}^2$ rather than by order $\tilde{\varepsilon}$, majority gates were subsequently employed in [12]. In this section we have followed that approach but use a slightly different recursive procedure $\mathcal{F}$ to achieve scaling of the bias in powers of ϕ.

9. Discussion. *Numerical estimates.* We depict a specific way of using the PPA. Consider an ion trap quantum computer in which four qubits are reserved for preparation of ancillas, all others being devoted to the main quantum algorithm (including the fault-tolerance mechanism). Of the reserved qubits, three are "computation qubits" and one is the "refrigerant." Ion trap technology is capable of placing the refrigerant in its ground state with probability 0.95 (i.e., $\tilde{\varepsilon} = \operatorname{arctanh} 0.9 \approx 1.47$). Calculation shows that application of the PPA on the quadruple for just nine cooling steps suffices to prepare one of the qubits in the ground state with probability $1 - 10^{-4}$. This is at the conservative end of the estimates of between 10^{-4} and 10^{-2} for the fault-tolerance threshold for quantum computation. Hence after every nine cooling steps the PPA can prepare an ancilla, ready to be moved by spin exchange into the main bank of qubits (in place of a "warm" qubit generated by the fault-tolerance mechanism).

Implementation objectives. It is necessary to study the sensitivity of the model to imperfections in the cooling steps as well as in the logic gates between cooling steps, in specific experimental implementations.

Experimental algorithmic cooling also has the opportunity to produce a physically meaningful result well before producing a quantum computer. A series of papers [28, 25, 6] shows that if k qubits have bias less than 2^{-2k}, then their joint state is separable. Conversely, in the ball of radius $2^{-k/2}$ there exist nonseparable states. Liquid-state NMR experiments have not, to date, produced a demonstrably nonseparable state. Achieving this goal will require some combination of an increase in the number of coherently manipulated qubits and an increase in the individual polarization of these qubits. The latter demands implementation of new cooling techniques.

In the simple model adopted in this paper we have assumed that there is only a single refrigerant qubit. One may ask how the model is affected if the number of such qubits is proportional to the number of computation qubits. (In liquid-state NMR, for example, we can expect that nuclei of various types will be present in fixed proportions.) The answer is that while some gain is likely, the fundamental limits of the model are unchanged because with a slowdown in the cooling process by a factor of $O(n)$, the same effect can be achieved by spin exchange with a single refrigerant qubit.

The present paper leaves open whether there is a simple implementation of the PPA or whether some other simply implemented algorithm can achieve the same $\varepsilon \approx 2^{-n}$ threshold.

The necessity of cooling many qubits for quantum computation. In view of the difficulty of cooling certain kinds of quantum computers, the question was posed of whether this was truly necessary [17]. Since a uniformly mixed state is unchanged by reversible (unitary) operations, computation is impossible (the statistics of the final

state do not depend on the computation steps) unless the initial mixture can be transformed into something other than the uniform mixture. Interestingly, this does not rule out the possibility of quantum-over-classical computational speedups on devices that are initialized in a highly (though not completely) mixed state. A key example was provided in [17]: the trace of a unitary operator of dimension 2^n can be computed on a device with n qubits, of which just one is strongly biased while the others are maximally mixed. (For related recent work see [20].) However, it was demonstrated in [2] that there is no way of directly simulating general quantum computers on highly mixed devices such as this. Hence computations on such devices can be accomplished, if at all, only with tailor-made algorithms. The available evidence suggests that such devices, even if noise-free, would be strictly weaker than general-purpose quantum computers, and so the suggestion in [17] is unlikely to circumvent the need for effective cooling. The necessity of using ancillas to compensate for noise buttresses this conclusion.

Summary. We have studied the fundamental limits of open-system "heat-bath" cooling, with a view to the significance of such methods for quantum computation as well as for imaging tasks limited by imperfect state preparation. We have provided a cooling (bias amplification) method and shown the following: (a) The bias it achieves is substantially higher than in previous methods, and the ground-state probability after any number of cooling steps is highest possible. (b) The number of cooling steps it requires is asymptotically close to best possible. (c) There is a sharp threshold for the heat-bath temperature, above which substantial cooling is impossible in any method, and below which it is achieved by ours.

WHOLE GENOME DUPLICATIONS AND CONTRACTED BREAKPOINT GRAPHS*

MAX A. ALEKSEYEV† AND PAVEL A. PEVZNER†

Abstract. The genome halving problem, motivated by the whole genome duplication events in molecular evolution, was solved by El-Mabrouk and Sankoff in the pioneering paper [*SIAM J. Comput.*, 32 (2003), pp. 754–792]. The El-Mabrouk–Sankoff algorithm is rather complex, inspiring a quest for a simpler solution. An alternative approach to the genome halving problem based on the notion of the contracted breakpoint graph was recently proposed in [M. A. Alekseyev and P. A. Pevzner, *IEEE/ACM Trans. Comput. Biol. Bioinformatics*, 4 (2007), pp. 98–107]. This new technique reveals that while the El-Mabrouk–Sankoff result is correct in most cases, it does not hold in the case of unichromosomal genomes. This raises a problem of correcting a flaw in the El-Mabrouk–Sankoff analysis and devising an algorithm that deals adequately with all genomes. In this paper we efficiently classify all genomes into two classes and show that while the El-Mabrouk–Sankoff theorem holds for the first class, it is incorrect for the second class. The crux of our analysis is a new combinatorial invariant defined on duplicated permutations. Using this invariant we were able to come up with a full proof of the genome halving theorem and a polynomial algorithm for the genome halving problem.

1. Introduction.

In 1970 Susumu Ohno came up with two fundamental theories of chromosome evolution that were the subjects of many controversies in the last 35 years [31]. The first, random breakage theory, was embraced by biologists from the very beginning but was refuted by Pevzner and Tesler in 2003 [35] and Murphy et al. in 2005 [30]. The second, whole genome duplication theory, postulated a new type of evolutionary event and had a very different fate. It was subject to controversy in the first 35 years and only recently was proven to be correct [27, 15]. Kellis, Birren, and Lander in 2004 [27] sequenced the yeast *K. waltii* genome, compared it with the yeast *S. cerevisiae* genome, and demonstrated that nearly every region in *K. waltii* corresponds to two regions in *S. cerevisiae*, thus proving that there was a whole genome duplication event in the course of yeast evolution. This discovery was quickly followed by the discovery of whole genome duplications in vertebrates [24, 36, 12] and plants [21]. Finally, in September, 2005 Dehal and Boore [14] found evidence of two rounds of whole genome duplications on the evolutionary path from early vertebrates to humans. Shortly afterwards, Meyer and Van de Peer [28] found evidence of yet another (third) round of whole genome duplications in ray-finned fishes, thus implying that nearly every human gene could have existed in as many as eight copies at different stages of evolution.

These recent studies provided irrefutable evidence that whole genome duplications represent a new type of event that may explain phenomena which classical evolutionary studies have had difficulty explaining (e.g., emergence of new metabolic

pathways [27]). At the same time, they raised the problem of reconstructing the genomic architecture of the ancestral preduplicated genomes. Unfortunately, since the El-Mabrouk–Sankoff algorithm for solving this problem [20] has not yet resulted in a software tool, the recent studies of whole genome duplications did not attempt to rigorously reconstruct the architecture of the preduplicated genomes. We revisited the El-Mabrouk–Sankoff result, found a flaw in their approach, reformulated and proved the genome halving theorem, and developed a new algorithm and software tool for studies of genome duplications.

Whole genome duplications double the gene content of a genome R and result in a *perfect duplicated genome* $R \oplus R$ that contains two identical copies of each chromosome. The genome then becomes subject to rearrangements that shuffle the genes in $R \oplus R$, resulting in some *rearranged duplicated genome* P. The *genome halving problem* is to reconstruct the ancestral *preduplicated genome* R from the rearranged duplicated genome P (Figure 1(a)).

From an algorithmic perspective, the genome is a collection of chromosomes, and each chromosome is a *signed sequence* over a finite alphabet. DNA has two strands, and genes on a chromosome have directionality that reflects the strand of the genes. We represent the order and directions of the genes on each chromosome as a sequence of *signed elements*, i.e., elements with signs "+" and "-". In this paper we focus on the basic *unichromosomal* case, where the genomes consist of just one chromosome, and assume that the genomes are *circular*. A unichromosomal genome, where each gene appears in a single copy, is referred to as *signed permutation*. For unichromosomal genomes the rearrangements are limited to *reversals* that "flip" genes $x_i \dots x_j$ in a genome $x_1 x_2 \dots x_n$ as follows:

$$x_1 \dots x_{i-1} \underrightarrow{x_i \quad x_{i+1} \dots \quad x_j} x_{j+1} \dots x_n \longrightarrow x_1 \dots x_{i-1} \underleftarrow{-x_j - x_{j-1} \cdots - x_i} x_{j+1} \dots x_n.$$

The *reversal distance* between two genomes is defined as the minimum number of reversals required to transform one genome into the other (see Chapter 10 of [34] for a review of genome rearrangement algorithms).

We represent a circular genome R as a cycle formed by directed edges encoding the genes and their directions (Figure 2(b), center). There are two natural ways to represent duplication of the genome R resulting in a unichromosomal genome $R \oplus R$ (Figure 1(b), left) and a multichromosomal genome $2R$ (Figure 1(b), right) but only the former is applicable to unichromosomal genomes.

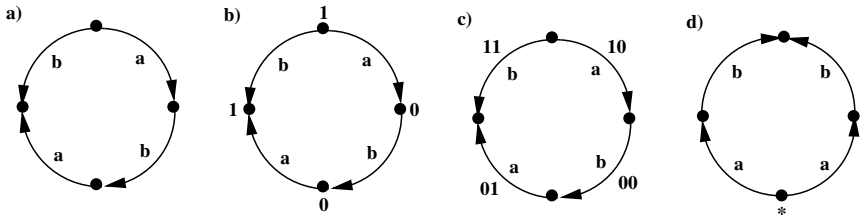

FIG. 2. (a) *Circular genome* $P = +a - b + a + b$ *represented as a cycle with directed edges.* (b) 01*-labeling of the vertices of the cycle defined by* P. (c) *Induced labeling of the genes of* P *that is consistent.* (d) *For some genomes consistent labelings do not exist: for genome* $Q = +a + b - b - a$ *the labels of both copies of gene* a *start with the same digit ("*$*$*") so they cannot be inversions of each other.*

For unichromosomal genomes, *whole genome duplication* is a concatenation of the genome R with itself, resulting in a *perfect duplicated genome* $R \oplus R$. The genome $R \oplus R$ becomes subject to reversals that change the order and signs of the genes and transform $R \oplus R$ into a *duplicated* genome P. The genome halving problem is formulated as follows.

GENOME HALVING PROBLEM. *Given a duplicated genome* P*, recover an ancestral preduplicated genome* R *minimizing the reversal distance* $d(P, R \oplus R)$ *from the perfect duplicated genome* $R \oplus R$ *to* P.

The genome halving problem was solved in a series of papers [18, 19, 17] culminating in a rather complex algorithm by El-Mabrouk and Sankoff in [20]. The El-Mabrouk–Sankoff algorithm is one of the most technically challenging results in computational biology and its proof spans over 30 pages in [20]. Recently Alekseyev and Pevzner [1] revisited the El-Mabrouk–Sankoff work and presented an alternative approach based on the notion of a *contracted breakpoint graph*.

After paper [1] was submitted, our studies of the contracted breakpoint graph led us to realize that the El-Mabrouk–Sankoff analysis has a flaw and that the problem of finding $\min_R d(P, R \oplus R)$ remains unsolved in the simplest case when P is a unichromosomal genome. Below we show that this flaw is a rule rather than a pathological case: it affects a large family of duplicated genomes. We further proceed to give a full analysis of the genome halving problem that is based on introducing an invariant that divides the set of all rearranged duplicated genomes into two classes. We show that the El-Mabrouk–Sankoff formula is correct for the first class but is off by 1 for the second class. We remark that our approach is very different from [20] and we do not know whether the technique in [20] can be adjusted to address the described complication.

To introduce a new combinatorial invariant of duplicated genomes, consider labelings of vertices in the cycle defined by the duplicated rearranged genome P with numbers 0 and 1 (Figure 2(b)). Every such labeling induces a two-digit labeling of the genes (edges): a label of each gene is formed by the labels of the incident vertices (Figure 2(c)). A 01-labeling of the vertices is called *consistent* if for every pair of identical genes in P the label of one copy is an inversion of the other. If there exists a consistent labeling of genome P, we define the *parity index* of P as the number of genes labeled "01" modulo 2. Below we prove that the parity index is well defined, i.e., the parity index is the same for all consistent labelings of a genome. It turns out that the El-Mabrouk–Sankoff theorem fails on genomes with the parity index 0.

The paper is organized as follows. Section 2 presents the concept of contracted

breakpoint graph and reviews some results from [1]. Section 3 describes a flaw in the El-Mabrouk–Sankoff analysis. Section 4 presents a solution to the genome halving problem (for unichromosomal circular genomes) and a classification of the genomes for which the original El-Mabrouk–Sankoff theorem is incorrect. Section 5 outlines our genome halving algorithm. Finally, section 6 discusses potential biological applications of the presented algorithm.

2. Reversal distance between duplicated genomes and contracted breakpoint graphs. A duality theorem and a polynomial algorithm for computing reversal distance between two signed permutations was proposed by Hannenhalli and Pevzner [23] and later was generalized for multichromosomal genomes [22]. The algorithm was further simplified and improved in a series of papers [6, 25, 3, 7, 42, 26] and applied in a variety of biological studies [29, 10, 8, 33, 5].

A signed permutation on n elements can be transformed into an unsigned permutation on $2n$ elements (see [4]) by substituting every element x in the signed permutation with two elements x^t and x^h in the unsigned permutation (indices t and h stand for tail and head, respectively). Each element $+x$ in the permutation P is replaced with $x^t x^h$, and each element $-x$ is replaced with $x^h x^t$, resulting in an unsigned permutation $\pi(P)$. For example, a permutation $+a+b-c$ will be transformed into $a^t a^h b^t b^h c^h c^t$. Element x^t is called the *obverse* of element x^h, and vice versa.

Let P and Q be two circular signed permutations on the same set of elements $\mathcal{G}$, and let $\pi(P)$ and $\pi(Q)$ be corresponding unsigned permutations. The *breakpoint graph* $G = G(P, Q)$ is defined on the set of vertices $V = \{x^t, x^h \mid x \in \mathcal{G}\}$ with edges of three colors: obverse, black, and gray (Figure 1(c)). Edges of each color form a matching on V as follows:

- pairs of obverse elements form an *obverse matching*;
- adjacent elements in $\pi(P)$, other than obverses, form a *black matching*;
- adjacent elements in $\pi(Q)$, other than obverses, form a *gray matching*.

Every pair of matchings forms a collection of *alternating* cycles in G, called *black-gray*, *black-obverse*, and *gray-obverse*, respectively (a cycle is alternating if colors of its edges alternate). The permutation $\pi(P)$ can be read along a single black-obverse cycle, while the permutation $\pi(Q)$ can be read along a single gray-obverse cycle in G. The black-gray cycles in the breakpoint graph play an important role in computing the reversal distance. According to the Hannenhalli–Pevzner theorem, the reversal distance between permutations P and Q is given by the formula

$$d(P, Q) = |P| - c(P, Q) + h(P, Q), \tag{1}$$

where $|P| = |Q|$ is the size of P and Q, $c(P, Q) = c(G(P, Q))$ is the number of black-gray cycles in the breakpoint graph G, and $h(G)$ is an easily computable combinatorial parameter. While this result leads to a fast algorithm for computing reversal distance between two signed permutations, the problem of computing reversal distance between two genomes with duplicated genes remains unsolved.

Let P and Q be duplicated genomes on the same set of genes $\mathcal{G}$. If one labels copies of each gene x as x_1 and x_2, then the genomes P and Q become signed permutations and (1) applies. The breakpoint graph $G(P, Q)$ of the labeled genomes P and Q has a vertex set $V = \{x_1^t, x_1^h, x_2^t, x_2^h \mid x \in \mathcal{G}\}$ and uniquely defines permutations $\pi(P)$ and $\pi(Q)$. We remark that different labelings may lead to different breakpoint graphs (on the same vertex set) for the same genomes P and Q (Figure 3) and it is not clear how to choose a labeling that results in the minimum reversal distance between the labeled copies of P and Q. We also remark that pairs of vertices x_1^j and x_2^j form yet another

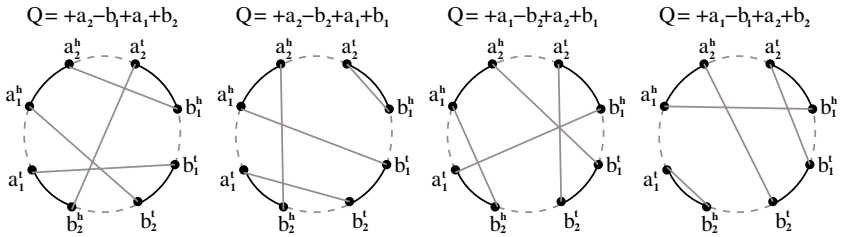

FIG. 3. *Breakpoint graphs for $P = +a - a - b + b$ and four different labelings $Q = +a - b + a + b$ (we assume that the labeling of $P = +a_1 - a_2 - b_1 + b_2$ is fixed). Two out of four breakpoint graphs have $c(G) = 1$, while two others have $c(G) = 2$. The counterpart matching in these graphs is formed by pairs (a_1^t, a_2^t), (a_1^h, a_2^h), (b_1^t, b_2^t), (b_1^h, b_2^h).*

matching in the breakpoint graph G called *counterpart*. Counterpart of a vertex v is denoted $\bar{v}$ so that $\bar{x}_1^j = x_2^j$ and $\bar{x}_2^j = x_1^j$ (see legend for Figure 3).

Recently there were many attempts to generalize the Hannenhalli–Pevzner theory for genomes with duplicated and deleted genes [9, 11, 16, 37, 40, 41]. However, the only known option for solving the reversal distance problem for duplicated genomes *exactly* is to consider all possible labelings, to compute the reversal distance problem for each labeling, and to choose the labeling with the minimal reversal distance. For duplicated genomes with n genes this leads to 2^n invocations of the Hannenhalli–Pevzner algorithm, rendering this approach impractical. Moreover, the problem remains open if one of the genomes is perfectly duplicated (i.e., computing $d(P, R \oplus R)$). Surprisingly, the problem of computing $\min_R d(P, R \oplus R)$ that we address in this paper is solvable in polynomial time.

Using the concept of the breakpoint graph and formula (1), the genome halving problem can be posed as follows. For a duplicated genome P, find a perfect duplicated genome $R \oplus R$ and a labeling of gene copies such that the breakpoint graph $G(P, R \oplus R)$ of the labeled genomes P and $R \oplus R$ attains the minimum value of $|P| - c(P, Q) + h(P, Q)$. Since $|P|$ is constant and $h(G)$ is typically small (see [34]), the value of $d(P, Q)$ depends mainly on $c(P, Q)$. El-Mabrouk and Sankoff [20] established that the problems of maximizing $c(P, Q)$ and minimizing $h(P, Q)$ can be solved separately in a consecutive manner.[1] In this paper we focus on the former and harder problem as follows.

WEAK GENOME HALVING PROBLEM. *For a given duplicated genome P, find a perfect duplicated genome $R \oplus R$ and a labeling of gene copies that maximizes the number of black-gray cycles $c(P, R \oplus R)$ in the breakpoint graph $G(P, R \oplus R)$ of the labeled genomes P and $R \oplus R$.*

From now on, we will find it convenient to represent a circular signed permutation as an alternating cycle formed by edges of two colors with one color reserved for obverse edges. For example, Figures 4(a),(b) show a black-obverse cycle representation of permutation $P = +a - a - b + b$ and a gray-obverse cycle representation of permutation $Q = +a - b + a + b$ (the obverse edges in these cycles are labeled and directed). Given a set of edge-labeled graphs, the *de Bruijn graph* of this set is defined as the result of "gluing"[2] edges with the same label in all graphs in the set (compare with Pevzner,

[1] In paper [2] we describe an analogue of formula (1) without the "$h(G)$" term and give a short proof of the genome halving theorem (for multichromosomal genomes) that does not rely on the analysis in [20].

[2] Gluing takes into account the directions of edges; i.e., tails (or heads) of all edges with a given label are glued into a single vertex.

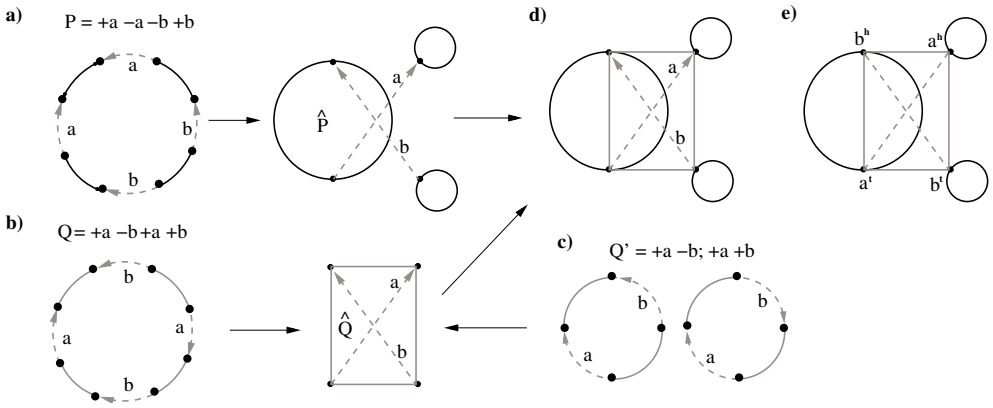

FIG. 4. (a) *Genome $P = +a - a - b + b$ as a black-obverse cycle and its transformation into $\hat{P}$ by gluing identically labeled edges.* (b) *Genome $Q = +a - b + a + b$ as a gray-obverse cycle and its transformation into $\hat{Q}$ by gluing identically labeled edges.* (c) *Two-chromosomal genome $Q' = (+a - b)(+a + b)$ that is equivalent to the genome Q (i.e., $\hat{Q}' = \hat{Q}$).* (d) *The de Bruijn graph of genomes P and Q.* (e) *The contracted breakpoint graph $G'(P, Q)$.*

Tang, and Tesler [32]). The de Bruijn graph for two cycles in Figures 4(a),(b) is shown in Figure 4(d).

For any genome P (represented as a cycle) we define $\hat{P}$ as the graph obtained from P by gluing identically labeled edges. Obviously, the de Bruijn graph of P and Q coincides with the de Bruijn graph of $\hat{P}$ and $\hat{Q}$ (Figure 4). For a duplicated genome P, the black edges of $\hat{P}$ form a set of vertex-disjoint black cycles. We denote by $b_e(P)$ the number of even black cycles in $\hat{P}$.

The conventional breakpoint graph [4] of signed permutations P and Q on n elements can be defined as the gluing of n *pairs* of identically labeled obverse edges in the corresponding permutations (represented as black-obverse and gray-obverse cycles). The *contracted breakpoint graph* of duplicated genomes P and Q on n elements is simply the gluing of n *quartets* of obverse edges. Below we give a somewhat more formal definition of the contracted breakpoint graph.

Let P and Q be duplicated genomes on the same set of genes $\mathcal{G}$ and let G be a breakpoint graph defined by some labeling of P and Q. The *contracted breakpoint graph* $G'(P, Q)$ is the result of contracting every pair of vertices x_1^j, x_2^j (where $x \in \mathcal{G}$, $j \in \{t, h\}$) in the breakpoint graph G into a single vertex x^j. So the contracted breakpoint graph $G' = G'(P, Q)$ is a graph on the set of vertices $V' = \{x^t, x^h \mid x \in \mathcal{G}\}$ with each vertex incident to two black, two gray, and a *pair* of parallel obverse edges (Figure 4(e)). The contracted breakpoint graph $G'(P, Q)$ does not depend on a particular labeling of P and Q. The following theorem gives a characterization of the contracted breakpoint graphs (for unichromosomal genomes).

THEOREM 1 (see [1]). *A graph H with black, gray, and obverse edges is a contracted breakpoint graph for some duplicated genomes if and only if*

- *each vertex in H is incident to two black edges, two gray edges, and two parallel obverse edges;*
- *H is connected with respect to black and obverse edges (black-obverse connected);*
- *H is connected with respect to gray and obverse edges (gray-obverse connected).*

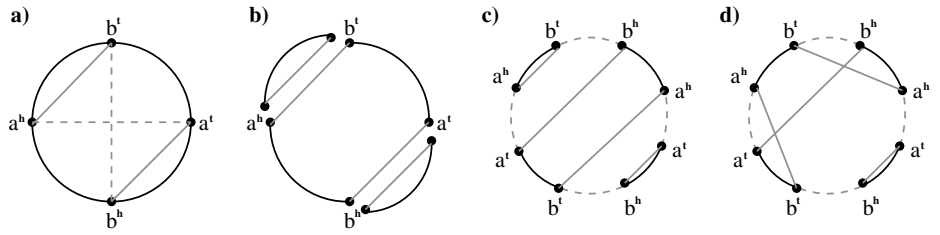

FIG. 5. (a) *Contracted breakpoint graph* $G'(P, R \oplus R)$ *for* $P = +a + b - a - b$ *and* $R = +a + b$. (b) *Black-gray cycle decomposition* C *of* G' *which is not induced by any labeling of* P *and* $R \oplus R$. (c) *Breakpoint graph* $G(P, 2R)$ *inducing* C. (d) *Breakpoint graph* $G(P, R \oplus R)$ *(unique up to relabeling of vertices) with* $c(G) = 2 < |C| = 3$.

In the case when $Q = R \oplus R$ is a perfect duplicated genome, the gray edges in the contracted breakpoint graph $G'(P, Q)$ form pairs of parallel gray edges that we refer to as *double* gray edges. Similar to the double obverse edges, the double gray edges form a matching in G' (Figure 5(a)).

Let $G(P, Q)$ be a breakpoint graph for some labeling of P and Q. A set of black-gray cycles in $G(P, Q)$ is contracted into a set of black-gray cycles in the contracted breakpoint graph $G'(P, Q)$, thus forming a black-gray cycle decomposition of $G'(P, Q)$. Therefore, each labeling induces a black-gray cycle decomposition of $G'(P, Q)$. We are interested in the reverse problem as follows.

LABELING PROBLEM. *Given a black-gray cycle decomposition of the contracted breakpoint graph* $G'(P, Q)$ *of duplicated genomes* P *and* Q*, find a labeling of* P *and* Q *that induces this cycle decomposition.*

This problem may not always have a solution for unichromosomal genomes (Figure 5) and this is exactly the factor that leads to a counterexample in section 3. This complication will be addressed in section 4 using the following three theorems proved in [1].

THEOREM 2 (see [1]). *Let* P *and* $R \oplus R$ *be unichromosomal duplicated genomes and* C *be a black-gray cycle decomposition of the contracted breakpoint graph* $G'(P, R \oplus R)$. *Then there exists some labeling of* P *and either* $R \oplus R$ *or* $2R$ *that induces the cycle decomposition* C.

Let $c_{max}(P, R \oplus R) = c_{max}(G'(P, R \oplus R))$ be the number of cycles in a maximal black-gray cycle decompositions of the contracted breakpoint graph $G'(P, R \oplus R)$. Theorem 2 motivates the following problem that will later help us to solve the weak genome halving problem.

CYCLE DECOMPOSITION PROBLEM. *For a given duplicated genome* P*, find a perfect duplicated genome* $R \oplus R$ *maximizing* $c_{max}(P, R \oplus R)$.

Although the maximal black-gray cycle decomposition of $G'(P, R \oplus R)$ may correspond to a breakpoint graph $G(P, 2R)$ (Figure 5), we will prove below that there exists a breakpoint graph $G(P, R \oplus R)$ having "almost" the same number of black-gray cycle as $G(P, 2R)$ (Figure 5(d)). Later we will classify all the cases in which there exists a labeled genome $R' \oplus R'$ such that $c(P, R' \oplus R') = c(P, 2R)$.

The solution to the cycle decomposition problem is given by the following two theorems.

THEOREM 3 (see [1]). *For a given duplicated genome* P *and any perfect duplicated genome* $R \oplus R$,

$$c_{max}(P, R \oplus R) \leq |P|/2 + b_e(P),$$

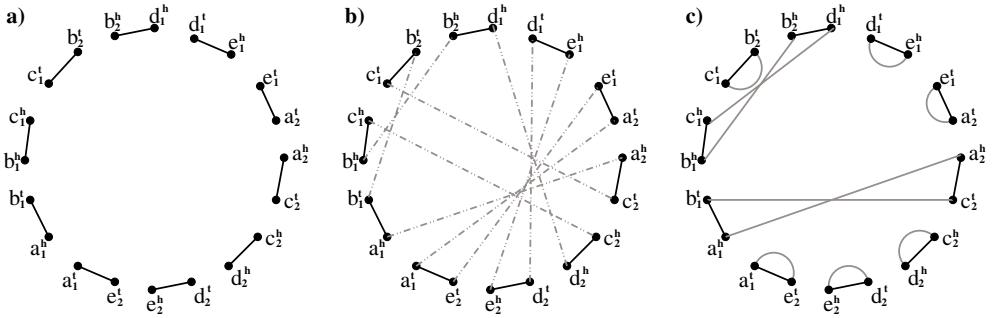

FIG. 6. (a) *A set of black edges forming the partial graph* $\mathcal{G}(\mathbf{V}, A)$ *corresponding to the genome* $P = +a+b-c+b-d-e+a+c-d-e$. (b) *Natural graphs as connected components in the partial graph with counterpart edges.* (c) *A completed graph* $\mathcal{G}(\mathbf{V}, A, \Gamma)$ *with maximum number of cycles* $c(G) = 8$. $\mathcal{G}(\mathbf{V}, A, \Gamma)$ *is a breakpoint graph of the circular genome* $P = +a_1+b_1-c_1+b_2-d_1-e_1+a_2+c_2-d_2-e_2$ *and a perfect duplicated genome* $(-a_1 + e_2 + d_2 - c_2 + b_1)(-b_2 + c_1 - d_1 - e_1 + a_2)$ *(of the form* $R \ominus R$*).*

where $|P|/2$ *represents the number of unique genes in* P *and* $b_e(P)$ *is the number of even black cycles in* $\hat{P}$*. Moreover, if* $c_{max}(P, R \oplus R) = |P|/2 + b_e(P)$*, then each black-gray connected component of* $G'(P, R \oplus R)$ *contains either a single even black cycle (simple component) or a pair of odd black cycles (paired component).*

THEOREM 4 (see [1]). *For any duplicated genome* P*, there exists a perfect duplicated genome* $R \oplus R$ *such that*

$$c_{max}(P, R \oplus R) = |P|/2 + b_e(P)$$

and each paired component of $G'(P, R \oplus R)$ *contains a single interedge (a double gray edge connecting distinct black cycles).*

3. A flaw in the El-Mabrouk–Sankoff analysis. El-Mabrouk and Sankoff came up with a theorem describing the minimum distance from the given rearranged duplicated genome to a perfect duplicated genome. Given a rearranged duplicated genome P, the crux of their approach is an algorithm for computing $c(G)$—the number of cycles of a so-called *maximal completed graph*, i.e., a breakpoint graph[3] with the maximum number of black-gray cycles. In [20] they demonstrate that $c(G)$ equals the number of genes plus $\gamma(G)$, where $\gamma(G)$ is the parameter defined below. We illustrate the concepts from [20] using the genome $P = +a + b - c + b - d - e + a + c - d - e$ on the set of genes $\mathcal{B} = \{a, b, c, d, e\}$ (page 757 in [20]). El-Mabrouk and Sankoff first arbitrarily label two copies of each gene x as x_1 and x_2 for each $x \in \mathcal{B}$ and further transform the signed permutation G into an unsigned permutation $a_1^t a_1^h b_1^t b_1^h c_1^h c_1^t b_2^t b_2^h d_1^h d_1^t e_1^h e_1^t a_2^t a_2^h c_2^t c_2^h d_2^h d_2^t e_2^h e_2^t$.

Let $\mathbf{V} = \{x_1^t, x_1^h, x_2^t, x_2^h \mid x \in \mathcal{B}\}$. The *partial graph* $\mathcal{G}(\mathbf{V}, A)$ associated with P has the edge set A of black edges linking adjacent terms (other than obverses x_i^t and x_i^h) in the corresponding unsigned permutation (Figure 6(a)).

Black edges together with counterpart edges (i.e., edges between x_1^t and x_2^t or between x_1^h and x_2^h) form a graph shown in Figure 6(b). The connected components of this graph are called *natural graphs* in [20]. There are four connected components (natural graphs) in the graph in Figure 6(b), two of them have three black edges (odd

[3]Following El-Mabrouk and Sankoff [20] we ignore obverse edges in breakpoint graphs throughout section 3.

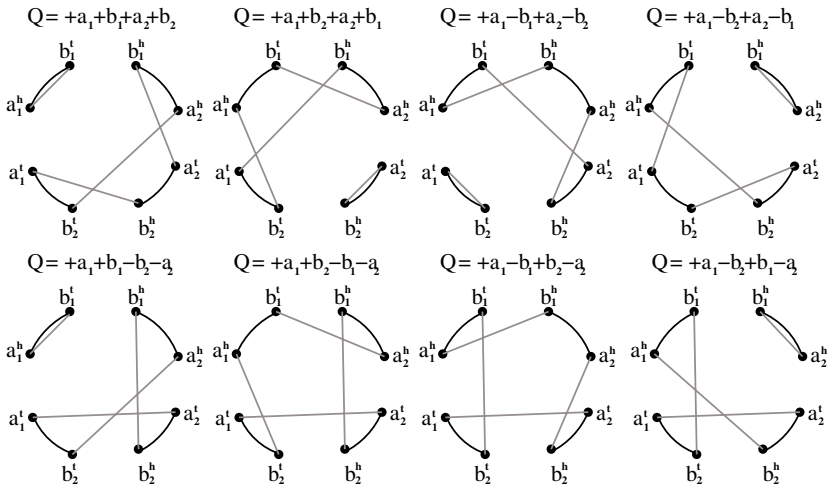

FIG. 7. *Breakpoint graphs of the circular genome $P = +a + b - a - b$ and all possible labelings of all possible perfect duplicated genomes Q (without loss of generality, we assume that labeling of $P = +a_1 + b_1 - a_2 - b_2$ is fixed). In terms of* [20]*, the top four graphs correspond to an $R \oplus R$ duplication pattern, while the bottom four graphs correspond to an $R \ominus R$ duplication pattern.*

natural graphs) and two of them have two black edges (even natural graphs). Let NE be the number of even natural graphs ($NE = 2$ in Figure 6(b)).

El-Mabrouk and Sankoff define the parameter

$$\gamma(G) = \begin{cases} NE & \text{if all natural graphs are even,} \\ NE + 1 & \text{otherwise.} \end{cases}$$

A graph $\mathcal{G}(\mathbf{V}, A, \Gamma)$ obtained from the partial graph $\mathcal{G}(\mathbf{V}, A)$ by introducing a set of gray edges Γ is called a *completed graph* if $\mathcal{G}(\mathbf{V}, A, \Gamma)$ is a breakpoint graph for some genomes on the set of genes $\{x_1, x_2 \mid x \in \mathcal{B}\}$. The following theorem (Theorem 7.7 in [20]) characterizes the maximum number of cycles in the completed graph $\mathcal{G}(\mathbf{V}, A, \Gamma)$.

THEOREM. *The maximal number of cycles in a completed graph of $\mathcal{G}(\mathbf{V}, A)$ is $c(G) = \frac{|A|}{2} + \gamma(G)$.*

For the genome in Figure 6 we have $\gamma(G) = NE + 1 = 3$ and $c(G) = \frac{|A|}{2} + \gamma(G) = \frac{10}{2} + 3 = 8$. A completed graph $\mathcal{G}(\mathbf{V}, A, \Gamma)$ with eight cycles is shown at Figure 6(c).[4] Below we provide a counterexample to Theorem 7.7 from [20].

Consider a circular genome $P = +a + b - a - b$ labeled as $+a_1 + b_1 - a_2 - b_2$. The genome P defines a partial graph $\mathcal{G}(\mathbf{V}, A)$ with a single natural graph of even size implying $\gamma(G) = 1$. It follows from Theorem 7.7 in [20] that there exists a perfect duplicated genome Q such that the breakpoint graph $G = G(P, Q)$ consists of $\frac{|A|}{2} + \gamma(G) = 3$ cycles. However, the direct enumeration of all possible perfect duplicated genomes Q shows that there is no breakpoint graph $G(P, Q)$ with three cycles. There exist eight distinct labeled perfect duplicated genomes Q giving rise to eight breakpoint graphs $G(P, Q)$ shown in Figure 7. All of them have less than three cycles. In the next section we explain what particular property of the genome $+a + b - a - b$ was not addressed properly in the El-Mabrouk–Sankoff analysis.

[4] While we do not explicitly consider $R \ominus R$ duplications shown in this figure (see [20] for details), our counterexample works for both $R \oplus R$ and $R \ominus R$ duplications.

4. Classification of duplicated genomes. The labeling problem can be addressed by considering *multichromosomal* genomes.[5] A multichromosomal duplicated genome is a set of circular chromosomes with every gene present in two copies. For example, Figure 4(c) presents a multichromosomal duplicated genome Q' consisting of two circular chromosomes $+a-b$ and $+a+b$, each of which forms a gray-obverse cycle. We remark that the de Bruijn graph of the genome Q' coincides with the de Bruijn graph of a unichromosomal genome $Q = +a-b+a+b$ (Figure 4(b)) and, hence, the contracted breakpoint graphs $G'(P,Q)$ and $G'(P,Q')$ are the same for any genome P (Figure 4(d)). We call genomes Q and Q' *equivalent* if their de Bruijn graphs are the same, i.e., $\hat{Q} = \hat{Q}'$.

It is easy to see that $R \oplus R$ is equivalent to $2R$ and, thus, $G'(P, R \oplus R) = G'(P, 2R)$ for any duplicated genome P. But in contrast to the breakpoint graph $G(P, R \oplus R)$ (for any labeling of P and $R \oplus R$) that contains a single gray-obverse cycle, the breakpoint graph $G(P, 2R)$ contains two gray-obverse cycles. The following theorem reveals the relationship between $G(P, R \oplus R)$ and $G(P, 2R)$.

THEOREM 5. *For any labeling of the genomes P and $2R$, there exists a labeling of the genome $R \oplus R$ such that $|c(P, R \oplus R) - c(P, 2R)| \leq 1$. Moreover, if there are two gray edges (x, y) and $(\bar{x}, \bar{y})$ belonging to the same black-gray cycle in $G(P, 2R)$, then there exists a labeling of $R \oplus R$ with $c(P, R \oplus R) \geq c(P, 2R)$.*

Proof. Let (x, y) be a gray edge in the breakpoint graph $G(P, 2R)$. Since the genome $2R$ is perfect duplicated there exists a gray edge $(\bar{x}, \bar{y})$ connecting counterparts of x and y. Define a graph H having the same vertices and edges as $G(P, 2R)$ except the gray edges (x, y) and $(\bar{x}, \bar{y})$ that are replaced with the gray edges $(x, \bar{y})$ and $(\bar{x}, y)$. Since the graph $G(P, 2R)$ consists of two gray-obverse cycles, the gray edges (x, y) and $(\bar{x}, \bar{y})$ belong to different gray-obverse cycles. Therefore, the graph H contains a single gray-obverse cycle (as well as a single black-obverse cycle inherited from $G(P, 2R)$). This implies that H is a breakpoint of the genomes P and $R \oplus R$ (i.e., $H = G(P, R \oplus R)$), where the labeling of P is the same as in $G(P, 2R)$.

If the gray edges (x, y) and $(\bar{x}, \bar{y})$ belong to the same black-gray cycle in $G(P, 2R)$, then this cycle may be split into two in H, while the other black-gray cycles are not affected. Conversely, if the gray edges (x, y) and $(\bar{x}, \bar{y})$ belong to different black-gray cycles in $G(P, 2R)$, then these cycles may be joined into a single cycle in H. In either case the difference $|c(P, R \oplus R) - c(P, 2R)|$ does not exceed 1. ∎

We redefine the notion of parity of a genome P in terms of the de Bruijn graph $\hat{P}$. A genome P is called *singular* if all black cycles in $\hat{P}$ are even. For a nonsingular genome P, define parity$(P) = \infty$. For a singular genome P, we clockwise label edges of each black cycle in $\hat{P}$ with alternating numbers $\{0, 1\}$ so that every two adjacent edges are labeled differently (Figure 8(a)). Labels of black edges in cycle P classify obverse edges in P into two classes: *even* if its flanking black edges have the same labels, and *odd* if its flanking black edges have different labels (Figure 8(b)). Let m_{even} and m_{odd} be the number of even/odd obverse edges in P correspondingly. Obviously, both m_{even} and m_{odd} are even numbers. We define parity$(P) = m_{odd}/2 \bmod 2$.

This definition of the parity index coincides with the one given in the introduction. To establish a correspondence between them one can consider a genome P as a black-obverse cycle and contract each black edge into a single vertex that inherits the label from the black edge. Since every pair of adjacent black edges of $\hat{P}$ is labeled differently, every pair of counterpart vertices is labeled differently as well. This implies that two-

[5] We emphasize that in this paper we consider only the genome halving problem for unichromosomal genomes and use multichromosomal genomes only to prove some auxiliary results.

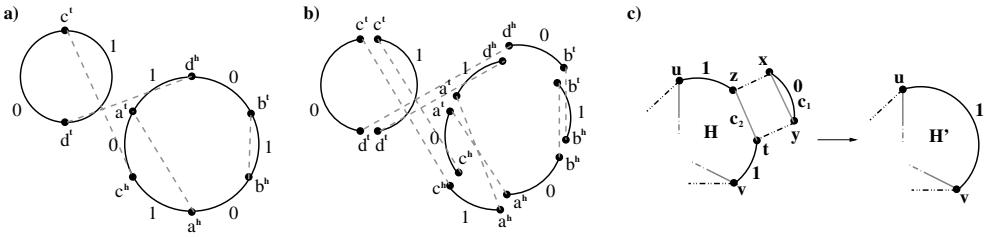

FIG. 8. *For the genome* $P = +a-b-b-d+c-a-d+c$, (a) 01*-labeling of the de Bruijn graph* $\hat{P}$; (b) *induced labeling of black-obverse cycle* P *with* $m_{odd} = 4$ *and* $m_{even} = 4$; (c) *transformation of the graph* H *into* H' *by removing vertices* x, y, z, t *and incident edges and adding a black edge* (u, v) *labeled the same as* (u, x) *and* (v, t).

digit labels of every pair of obverse edges are inversions of each other.

THEOREM 6. *The parity index of a singular genome is well defined.*

Proof. Let P be a singular genome. If $\hat{P}$ has k black cycles, then there are 2^k different 01-labelings of its black edges (two possible labelings per cycle). Therefore, it is sufficient to show that a change of 01-labeling of a particular black cycle c does not affect parity(P).

Let m^c_{even} and m^c_{odd} be the number of even/odd obverse edges in cycle P connecting black edges of c with black edges outside c. Since double obverse edges form a matching in the de Bruijn graph $\hat{P}$, the total number of double obverse edges connecting c with other black cycles is even and, thus, $m^c_{even} + m^c_{odd}$ is a multiple of 4.

Changing the 01-labeling of the black cycle c reverses the labels $0 \leftrightarrow 1$ in c. Reversed labeling of c does not change parity of obverse edges connecting two black edges in c (since both endpoint labels change) or two black edges outside of c (since neither of the endpoint labels changes). At the same time, each of the $m^c_{even} + m^c_{odd}$ obverse edges connecting black edges in c with black edges outside of c changes its parity (i.e., even edges become odd and vice versa). Then m_{odd} changes as follows:

$$m'_{odd} = m_{odd} - m^c_{odd} + m^c_{even} = m_{odd} - (m^c_{odd} + m^c_{even}) + 2m^c_{even}.$$

Since both $m^c_{odd} + m^c_{even}$ and $2m^c_{even}$ are multiples of 4, the parity of $m'_{odd}/2$ and $m_{odd}/2$ is the same, implying that parity(P) is well defined. □

Our goal is to prove the following theorem.

THEOREM 7. *For a duplicated genome* P,

$$\max_R c(P, R \oplus R) = \begin{cases} |P|/2 + b_e(P) & \text{if parity}(P) \neq 0, \\ |P|/2 + b_e(P) - 1 & \text{otherwise.} \end{cases}$$

The proof of Theorem 7 is split into two cases depending on whether P is singular or nonsingular.

THEOREM 8. *For a nonsingular genome* P, $\max_R c(P, R \oplus R) = |P|/2 + b_e(P)$.

Proof. If P is a nonsingular genome, then $\hat{P}$ has an odd black cycle. According to Theorem 4 there exists a perfect duplicated genome $R \oplus R$ such that $c_{max}(P, R \oplus R) = |P|/2 + b_e(P)$. Theorem 2 ensures that the maximum cycle decomposition of the contracted breakpoint graph $G'(P, R \oplus R)$ is induced by a labeling of either $R \oplus R$ or $2R$. If it is $R \oplus R$, then the theorem holds. Otherwise, consider a paired component in $G'(P, R \oplus R)$ (which exists since $\hat{P}$ has an odd black cycle) and an interedge e in it. Let (x, y) and $(\bar{x}, \bar{y})$ be gray edges in $G(P, 2R)$ corresponding to the interedge e in $G'(P, R \oplus R)$. Since e is the only bridge between two different black cycles (Theorem 4)

in $G'(P, R \oplus R)$, the gray edges (x, y) and $(\bar{x}, \bar{y})$ must belong to the same black-gray cycle in $G(P, 2R)$. Applying Theorem 5 to these gray edges, we obtain a labeled genome $R \oplus R$ with $c(P, R \oplus R) = c(P, 2R) = |P|/2 + b_e(P)$. □

For a singular genome P, we first fix some alternating 01-labeling of black edges in every black cycle of $\hat{P}$. The labeling of edges imposes labeling of vertices of any breakpoint graph $G(P, Q)$ (for any genome Q) so that each vertex inherits a label from an incident black edge. Note that every pair of counterpart vertices get different labels, as their incident black edges are adjacent in $\hat{P}$. A labeling of vertices of $G(P, Q)$ is called *uniform* if endpoints of every gray edge have identical labels (i.e., every gray edge is even). We will need the following theorem.

THEOREM 9. *Let P be a singular genome and Q be a perfect duplicated genome with $c(P, Q) = |P|/2 + b_e(P)$. Then every alternating* 01*-labeling of $\hat{P}$ imposes a uniform labeling on vertices of $G(P, Q)$.*

While the definition of the breakpoint graph does not explicitly specify the counterpart edges, one can derive them for $G(P, Q)$ in Theorem 9 from the vertex labels. Also, it is easy to see that gray and counterpart edges in $G(P, Q)$ form cycles of length 4 as soon as Q is a perfect duplicated genome. We take the liberty of restating the condition $c(P, Q) = |P|/2 + b_e(P)$ as $c_{bg}(G) = n + c_{bc}(G)$, where $c_{bg}(G)$ is the number of black-gray edges in G, n is the number of unique genes in P, and $c_{bc}(G)$ is the number of black-counterpart cycles in G. Also, every alternating 01-labeling of $\hat{P}$ corresponds to an alternating labeling of black edges within black-counterpart cycles. This leads to the following reformulation of Theorem 9.

THEOREM 10. *Let H be a graph on $4n$ vertices consisting of three perfect matchings black, gray, and counterpart such that* (i) *gray and counterpart matchings form cycles of length* 4*, and* (ii) *$c_{bg}(H) = n + c_{bc}(H)$. Then every alternating* 01*-labeling of black edges within black-counterpart cycles imposes a uniform labeling on vertices of H.*

Proof. The proof is done by induction on n. If $n = 1$, then the graph H consists of a gray-counterpart cycle with two black edges parallel to the gray edges, and the theorem holds. Assume that the theorem holds for graphs with less than $4n$ vertices.

Since H has $2n$ black edges and $c_{bg}(H) = n + c_{bc}(H) > n$, the pigeonhole principle implies that there exists a black-gray cycle c_1 of length 2 in H. Let $e_1 = (x, y)$ be a gray edge in the cycle c_1 (thus, e_1 is even) and let (x, z) and (y, t) be adjacent counterpart edges. Then there is a gray edge $e_2 = (z, t)$ belonging to the same gray-counterpart cycle as e_1. Let c_2 be a black-gray cycle c_2 containing the gray edge e_2.

If the cycle c_2 has length 2, then the endpoints of e_2 have identical labels. In this case we define a new graph H' as the graph H without vertices x, y, z, t and all incident edges. It is easy to see that H' is a graph on $4(n-1)$ vertices satisfying the conditions of the theorem. Indeed, the number of black-gray cycles in H' is reduced by 2 and the number of black-counterpart cycles is reduced by 1 (as compared to H), i.e., $c_{bg}(H') = c_{bg}(H) - 2$ and $c_{bc}(H') = c_{bc}(H) - 1$. Therefore, $c_{bg}(H') = (n-1) + c_{bc}(H')$. By the induction assumption, every alternating 01-labeling of H' imposes uniform labeling on vertices of H'. It implies that every alternating 01-labeling of H imposes uniform labeling on vertices of H.

If the cycle c_2 has length greater than 2, let (u, z) and (t, v) be black edges adjacent to e_2. These black edges are neighbors of the black edge (x, y) on a black-counterpart cycle (passing through the vertices u, z, x, y, t, v), so they have the same label l which is different from the label of (x, y). Therefore, the endpoints of the gray edge e_2 have identical labels. We define a new graph H' as the graph H with vertices x, y, z, t and all incident edges removed but with a single black edge (u, v) labeled l added

(Figure 8(c)). The graph H' has $4(n-1)$ vertices, $c_{bc}(H') = c_{bc}(H)$ black-counterpart cycles, and $c_{bg}(H') = c_{bg}(H) - 1$ black-gray cycles; thus, $c_{bg}(H') = n - 1 + c_{bc}(H')$ and the induction applies. □

To complete the proof of Theorem 7 we need one more theorem.

THEOREM 11. *For a singular genome P and a perfect duplicated genome Q with $c(P,Q) = |P|/2 + b_e(P)$,*

- *$Q = R \oplus R$ if and only if parity$(P) = 1$;*
- *$Q = 2R$ if and only if parity$(P) = 0$.*

Proof. According to Theorem 2, the graph $G(P,Q)$ has either a single gray-obverse cycle (i.e., $Q = R \oplus R$) or two symmetric gray-obverse cycles (i.e., $Q = 2R$). Theorem 9 implies that all gray edges in G are even (i.e., have identically labeled endpoints) for every alternating 01-labeling of black edges of P.

Case 1. Graph G has a single gray-obverse cycle c. Consider an arbitrary vertex v in G and its counterpart $\overline{v}$. Vertices v and $\overline{v}$ break c into two paths: c' (from v to $\overline{v}$) and c'' (from $\overline{v}$ to v). For every path (cycle) c denote c_{odd} as the number of odd obverse edges in c. Note that obverse edges are evenly divided between c' and c'', i.e., for every pair of obverse edges connecting counterpart vertices, one edge belongs to c' and the other edge belongs to c''. Therefore, $c'_{odd} = c''_{odd}$. Note that the start (vertex v) and the end (vertex $\overline{v}$) vertices of path c' are labeled differently. Since the total number of odd edges is odd for every path with differently labeled ends, and since all gray edges are even (Theorem 9), the total number of odd obverse edges in the path c' is odd. Therefore, $c_{odd}/2 = c'_{odd}$ is odd, implying that parity$(P) = 1$.

Case 2. Graph G has two gray-obverse cycles c' and c''. Note that obverse edges are evenly divided between c' and c''; i.e., for every pair of obverse edges connecting counterpart vertices, one edge belongs to c' and the other edge belongs to c''. Therefore, $c'_{odd} = c''_{odd}$. Since the total number of odd edges in every cycle is even, and since all gray edges are even (Theorem 9), the total number of odd obverse edges in every cycle is even. Since c'_{odd} is even, the overall number of odd obverse edges is a multiple of 4, implying that parity$(P) = 0$. □

For a singular genome P with parity$(P) = 1$ Theorem 11 implies Theorem 7, while for a singular genome P with parity$(P) = 0$ it implies that there is no genome R for which $c(P, R \oplus R) = |P|/2 + b_e(P)$. In the latter case, there exists a genome R and a labeling of P and $2R$ for which $c(P, 2R) = |P|/2 + b_e(P)$ (Theorem 4). The genome $2R$ can be transformed into a labeled genome $R \oplus R$ with $c(P, R \oplus R) = c(P, 2R) - 1 = |P|/2 + b_e(P) - 1$ (Theorem 5). This completes the proof of Theorem 7.

5. Genome halving algorithm. The classification of circular genomes leads to the following algorithm for the weak genome halving problem.[6]

1. For a given duplicated genome P, find a perfect duplicated genome $R \oplus R$ such that $c_{max}(P, R \oplus R) = |P|/2 + b_e(P)$ (Theorem 4) and decompose $G'(P, R \oplus R)$ into the maximum number of black-gray cycles [1].
2. Find a labeling of the genomes P and Q ($Q = R \oplus R$ or $Q = 2R$) and a breakpoint graph $G(P,Q)$ inducing the maximum black-gray cycle decomposition of $G'(P, R \oplus R)$ (Theorem 2).
3. If $Q = R \oplus R$, then output the breakpoint graph $G(P, R \oplus R)$.
4. If $Q = 2R$ and P is nonsingular, then there is a paired component in $G'(P, R \oplus R)$ with a single interedge (Theorem 4) that corresponds to two gray

[6] The algorithm outputs the breakpoint graph $G(P, R \oplus R)$ (in addition to the preduplicated genome R). This allows one to reconstruct a sequence of reversals transforming $R \oplus R$ into P with the reversal distance algorithm.

edges (x, y) and $(\bar{x}, \bar{y})$ in $G(P, 2R)$. Find a labeling of the genome $R \oplus R$ for which $c(P, R \oplus R) = c(P, 2R)$ (Theorems 5 and 8) and output $G(P, R \oplus R)$.

5. If $Q = 2R$ and P is singular, then parity$(P) = 0$ (Theorem 11). Find a labeling of the genome $R \oplus R$ for which $c(P, R \oplus R) = c(P, 2R) - 1$ (Theorem 5) and output $G(P, R \oplus R)$.

We illustrate the algorithm for a genome $P = +a + b - a - b$ (assuming a fixed labeling of P as $(+a_1 + b_1 - a_2 - b_2)$) using Figure 5. At step 1, we use the algorithm from [1] to construct $R = +a + b$ such that the contracted breakpoint graph $G'(P, R \oplus R)$ (Figure 5(a)) has a black-gray cycle decomposition with $|P|/2 + b_e(P) = 3$ cycles (Figure 5(b)). At step 2, we find a breakpoint graph $G(P, Q)$ (Figure 5(c)) inducing this cycle decomposition (see [1]). The breakpoint graph $G(P, Q)$ has two gray-obverse cycles (Figure 5(c)), thus implying that $Q = 2R$. Since the genome P is singular, we proceed to step 5 and perform a transformation of $Q = 2R$ into a new genome, as described in Theorem 5. We first find a pair of gray edges from two different cycles in $2R$ as described in Theorem 5, for example, a pair of edges labeled (a^h, b^t) in Figure 5(c). Afterwards, we replace these edges with a new pair of gray edges also labeled (a^h, b^t), as shown in Figure 5(d). This operation transforms two cycles in the genome Q into a single cycle (unichromosomal genome) that we represent as $R \oplus R$. According to Theorems 5 and 7, this genome represents a solution to the weak genome halving problem.

The first two steps of the genome halving algorithm can be implemented in $O(|P|^2)$ time (see [1]) while the remaining steps fit this time bound as well. In practice, our genome halving software takes less than a second to halve a "random" duplicated genome with 1000 unique genes on a standard Intel PIII-900MHz CPU.

6. Conclusion. While whole genome duplications in multichromosomal genomes are well established, there are relatively few examples of whole genome duplications in unichromosomal genomes. Undoubtedly, bacterial genomes have undergone a large number of duplications, but it is difficult to distinguish between partial and whole genome duplication scenarios in the case of these genomes (Coissac, Maillier, and Netter [13]). Matters are further complicated by the fact that even a few rearrangements can quickly "randomize" gene orders in bacterial genomes (due to a relatively small number of genes).

Recently, Sugaya et al. [38] studied *Cyanobacterium Anabaena* and came to the conclusion that it has undergone whole genome duplications rather than a series of (tandem) segmental duplications. Indeed, the arrangement of genes in *Cyanobacterium Anabaena* points to whole genome duplications as the most likely scenario (it also has an unusually large genome as compared to other organisms in the *Cyanobacteria* phylum). Also, the recent discovery and sequencing of *Acanthamoeba polyphaga* (the largest known virus to date) revealed an unusually large number of duplicated regions that point to a large duplication event (Suhre [39]). While it remains unclear whether this large segmental duplication represents whole genome duplications or extremely large partial duplication(s), one can argue that it is only a matter of time until ongoing sequencing efforts will reveal traces of whole genome duplications in many unichromosomal (bacterial and viral) genomes.

These recent discoveries raise a new algorithmic challenge that we refer to as the partial genome duplication problem. Let R be a genome with n unique genes (represented as a signed permutation) and R' be a set of m consecutive genes in this genome. We define $R \oplus R'$ as a *perfect partially duplicated genome*. Let P be a genome with $n + m$ genes in which m genes from R' are duplicated and the remaining

$n - m$ genes are unique. Given a genome P, the partial genome duplication problem is to find a perfect partially duplicated genome $R \oplus R'$ such that the reversal distance between $R \oplus R'$ and P is minimal.

Acknowledgments. We are grateful to Mohan Paturi and Dekel Tsur for many insightful comments.

APPROXIMATING THE RADII OF POINT SETS*

KASTURI VARADARAJAN†, S. VENKATESH‡, YINYU YE§, AND JIAWEI ZHANG¶

Abstract. We consider the problem of computing the outer-radii of point sets. In this problem, we are given integers n, d, and k, where $k \leq d$, and a set P of n points in $\Re^d$. The goal is to compute the *outer k-radius* of P, denoted by $\mathcal{R}_k(P)$, which is the minimum over all $(d-k)$-dimensional flats F of $\max_{p \in P} d(p, F)$, where $d(p, F)$ is the Euclidean distance between the point p and flat F. Computing the radii of point sets is a fundamental problem in computational convexity with many significant applications. The problem admits a polynomial time algorithm when the dimension d is constant [U. Faigle, W. Kern, and M. Streng, *Math. Program.*, 73 (1996), pp. 1–5]. Here we are interested in the general case in which the dimension d is not fixed and can be as large as n, where the problem becomes NP-hard even for $k = 1$. It is known that $R_k(P)$ can be approximated in polynomial time by a factor of $(1 + \varepsilon)$ for any $\varepsilon > 0$ when $d - k$ is a fixed constant [M. Bădoiu, S. Har-Peled, and P. Indyk, in *Proceedings of the ACM Symposium on the Theory of Computing*, 2002; S. Har-Peled and K. Varadarajan, in *Proceedings of the ACM Symposium on Computing Geometry*, 2002]. A polynomial time algorithm that guarantees a factor of $O(\sqrt{\log n})$ approximation for $R_1(P)$, the width of the point set P, is implied by the results of Nemirovski, Roos, and Terlaky [*Math. Program.*, 86 (1999), pp. 463–473] and Nesterov [*Handbook of Semidefinite Programming Theory, Algorithms*, Kluwer Academic Publishers, Norwell, MA, 2000]. In this paper, we show that $R_k(P)$ can be approximated by a ratio of $O(\sqrt{\log n})$ for any $1 \leq k \leq d$, thus matching the previously best known ratio for approximating the special case $R_1(P)$, the width of point set P. Our algorithm is based on semidefinite programming relaxation with a new mixed deterministic and randomized rounding procedure. We also prove an inapproximability result that gives evidence that our approximation algorithm is doing well for a large range of k. We show that there exists a constant $\delta > 0$ such that the following holds for any $0 < \varepsilon < 1$: there is no polynomial time algorithm that approximates $R_k(P)$ within $(\log n)^\delta$ for all k such that $k \leq d - d^\varepsilon$ unless NP $\subseteq$ DTIME $[2^{(\log m)^{O(1)}}]$. Our inapproximability result for $R_k(P)$ extends a previously known hardness result of Brieden [*Discrete Comput. Geom.*, 28 (2002), pp. 201–209] and is proved by modifying Brieden's construction using basic ideas from probabilistically checkable proofs (PCP) theory.

mining, statistics, and clustering, and it has received considerable attention in the computational geometry literature [20, 21, 22]. In this problem, we are given integers n, d, and k, where $k \leq d$, and a set P of n points in $\Re^d$. A *flat* or *affine subspace* F in $\Re^d$ is specified by a point $q \in \Re^d$ and a linear subspace H; it is defined as $F = \{q + h | h \in H\}$. The dimension of the flat F is defined to be the dimension of the linear subspace H. For any flat F, let $R(P, F) = \max_{p \in P} d(p, F)$ denote the *radius* of the flat F with respect to P, where $d(p, F)$ is the Euclidean distance between the point p and the flat F. The goal is to compute the *outer k-radius* of P, denoted by $R_k(P)$, which is the minimum of $R(P, F)$ over all $(d-k)$-dimensional flats F. A $(d-k)$-flat is simply a flat of dimension $d-k$. Roughly speaking, the outer k-radius $R_k(P)$ measures how well the point set P can be approximated by an affine subspace of dimension $d-k$. A few special cases of $R_k(P)$ which have received particular attention include $R_1(P)$, half of the *width* of P; $R_d(P)$, the radius of the minimum enclosing ball of P; and $R_{d-1}(P)$, the radius of the minimum enclosing cylinder of P.

When the dimension d is a fixed constant, $R_k(P)$ can be computed exactly in polynomial time [15]. It is also known that $R_k(P)$ can be approximated by a factor of $(1+\varepsilon)$ for any $\varepsilon > 0$ in $O(n + f_d(\frac{1}{\varepsilon}))$ time [2, 6], where f_d is a polynomial for every fixed d. In this paper, we are interested in the general scenario when the dimensions k and d are not fixed and d can be as large as n.

When the dimensions k and d are part of the input, the complexity of computing/approximating $R_k(P)$ depends on the parameter $d-k$. It is well known that the problem is polynomial time solvable when $d-k=0$, i.e., the minimum enclosing ball of a set of points can be computed in polynomial time (Gritzmann and Klee [20]). Megiddo [25] shows that the problem of determining whether there is a line that intersects a set of balls is NP-hard. In his reduction, the balls have the same radius, which implies that computing the radius $R_{d-1}(P)$ of the min-enclosing cylinder of a set of points P is NP-hard. Bădoiu, Har-Peled, and Indyk [7] show that $R_{d-1}(P)$ can be approximated in polynomial time by a factor of $(1+\varepsilon)$ for any $\varepsilon > 0$. Har-Peled and Varadarajan [22, 23] generalize the result and show that $R_k(P)$ can be approximated by a factor of $(1+\varepsilon)$ for any $\varepsilon > 0$ when $d-k$ is constant.[1]

More hardness results are known when $d-k$ becomes large or when k becomes small. Bodlaender et al. [10] show that the problem is NP-hard when $k=1$. This is true even for the case $n = d+1$ [20]. Gritzmann and Klee [20] also show that it is NP-hard to compute $R_k(P)$ if $k \leq c \cdot d$ for any fixed $0 < c < 1$. These negative results are further improved by Brieden, Gritzmann, and Klee [11] and Brieden [14], the latter of which has shown that it is NP-hard to approximate $R_1(P)$, the width of a point set, to within *any* constant factor.

On the positive side, the algorithms of Nemirovski, Roos, and Terlaky [26] and Nesterov [27] imply that $R_1(P)$, or equivalently the width of the point set P, can be approximated within a factor of $O(\sqrt{\log n})$. Another algorithm for approximating the width of a point set is given by Brieden et al. [12, 13], and their algorithm has a performance guarantee $\sqrt{d/\log d}$ that is measured in the dimension d. Their algorithm in fact works for any convex body given in terms of appropriate "oracles"; the number of calls to the oracle is polynomial in the dimension d. They also show that this is the best possible result in the oracle model even if randomization is allowed. (Their algorithm actually gives a $\sqrt{d/\log n}$ approximation with poly(n) calls to the oracle, where n is the number of points in the set.) It is not clear if their algorithm can be extended to compute $R_k(P)$.

[1] Note that R_k^{opt} in [23] is the same as R_{d-k} in this paper

The problem of efficiently computing the low-rank approximation of matrices has received considerable attention recently; see [1, 5, 17] and the references cited in these papers. This problem corresponds to computing the best $(d-k)$-dimensional subspace that fits a point set, where the quality of a subspace is the *sum* of the square of the distance of each point from the flat. The problem is therefore related to the one we study in this paper, where the quality of a flat is the maximum over the point-flat distances. However, the low-rank approximation problem can be solved in polynomial time for any $1 \leq k \leq d$.

Our results and an overview. We show that $R_k(P)$ can be approximated in polynomial time by a factor of $O(\sqrt{\log n})$ for all $1 \leq k \leq d$, thereby generalizing the result of Nemirovski, Roos, and Terlaky [26] to all values of k. Our algorithm is based on a semidefinite programming (SDP) relaxation with a mixed deterministic and randomized rounding procedure, in contrast to all other purely randomized rounding procedures used for semidefinite programming approximation.

Generally speaking, the problem of computing $R_k(P)$ can be formulated as a quadratic minimization problem. SDP problems (where the unknowns are represented by positive semidefinite matrices) have recently been developed for approximating such problems; see, for example, Goemans and Williamson [18]. In the case of $k = 1$, computing $R_1(P)$ corresponds to a SDP problem plus an additional requirement that the rank of the unknown matrix equals 1. Removing the rank requirement, the SDP problem becomes a relaxation of the original problem and can be solved within any given accuracy $\epsilon > 0$ in time polynomial in $\ln \frac{1}{\epsilon}$ and the dimension of the data specifying the problem. Once obtaining an optimal solution, say X, of the SDP relaxation, one would like to generate a rank-1 matrix, say $\hat{X} = yy^T$, from X, where y is a column vector and serves as a solution to the original problem. Such rank reduction is called "rounding." Many rounding procedures are proposed, and almost all of them are randomized; see, for example, [9].

One particular procedure has been proposed by Nemirovski, Roos, and Terlaky [26] which can be used for approximating $R_1(P)$. Their procedure is a simple randomized rounding that can be described as follows: an optimal solution X of the SDP relaxation, whose rank could be as large as d, can be represented as (for example, by eigenvector decomposition)

$$X = \lambda_1 v_1 v_1^T + \lambda_2 v_2 v_2^T + \cdots + \lambda_d v_d v_d^T.$$

Then one can generate a single vector y by taking a random linear combination of the vectors $\sqrt{\lambda_1} v_1, \sqrt{\lambda_2} v_2, \ldots, \sqrt{\lambda_d} v_d$, where the coefficients of the combination take values of -1 or 1 uniformly and independently.

For the case $k \geq 2$, the SDP relaxation that we describe is best viewed as a direct relaxation of the problem of computing $R_k(P)$, rather than one that is obtained via a quadratic program formulation of $R_k(P)$. We then need to generate k rank-1 matrices from X, the optimal solution of the SDP relaxation, such that

$$\hat{X} = \sum_{i=1}^{k} y_i y_i^T,$$

where y_is are orthogonal to each other. Our rounding procedure works as follows: having obtained an optimal solution for the SDP relaxation with

$$X = \lambda_1 v_1 v_1^T + \lambda_2 v_2 v_2^T + \cdots + \lambda_d v_d v_d^T,$$

we deterministically partition the vectors $v_1, v_2, \ldots, v_d$ into k groups where group j may contain n_j vectors and each group can be seen as a single semidefinite matrix with rank n_j. We then generate one vector from each group using the randomized rounding procedure similar to that of Nemirovski, Roos, and Terlaky [26]. The k vectors generated by this rounding procedure will automatically satisfy the condition that any pair of them must be orthogonal to each other. We then manage to show that the quality of these vectors yields an approximation ratio of no more than $O(\sqrt{\log n})$.

We also prove an inapproximability result that gives evidence that our approximation algorithm is close to the best possible for a large range of k. We show that there exists a constant $\delta > 0$ such that the following holds for any $0 < \varepsilon < 1$: there is no polynomial time algorithm that approximates $R_k(P)$ within $(\log n)^\delta$ for all k such that $k \leq d - d^\varepsilon$ unless NP $\subseteq \tilde{P}$. $\tilde{P}$ denotes the complexity class DTIME$[2^{(\log m)^{O(1)}}]$, which is sometimes referred to as deterministic quasi-polynomial time. That is, $\tilde{P}$ contains the set of all problems for which there is an algorithm that runs in time $2^{(\log m)^{O(1)}}$ on inputs of size m.

To prove the lower bound result, we start with a two-prover protocol for 3SAT in which the verifier has very low error probability. Such a protocol is obtained as a consequence of the probabilistically checkable proofs (PCP) theorem of Arora et al. [3], and Arora and Safra [4] and the parallel repetition theorem of Raz [28]. The construction of Brieden [14] then implies a reduction from Max-3SAT to width computation such that the ratio of the width of point sets that correspond to satisfiable instances to those that correspond to unsatisfiable instances is large. This separation gives us the inapproximability result for the width. This result can then be extended to an inapproximability result for $R_k(P)$ for a large range of k.

The remainder of this paper is organized as follows: in section 2, we present our algorithm for approximating the outer k-radius $R_k(P)$ of a point set P. In section 3, we describe our inapproximability results. We make some concluding remarks in section 4.

2. Approximating the radius. We now present the quadratic program formulation of the outer k-radius problem and its SDP relaxation. It will be helpful to first introduce some notation that will be used later. The trace of a given square matrix A, denoted by $\mathrm{Tr}(A)$, is the sum of the entries on the main diagonal of A. We use I to denote the identity matrix whose dimension will be clear in the context. The inner product of two vectors p and q is denoted by $\langle p, q\rangle$. The 2-norm of a vector x, denoted by $\|x\|$, is defined by $\sqrt{\langle x, x\rangle}$. For a matrix X, we use the notation $X \succeq 0$ to mean that X is a positive semidefinite matrix. For simplicity, we assume that P is symmetric in the sense that if $p \in P$, then $-p \in P$. This is without loss of generality for the following reason: we may, by performing a translation if necessary, assume that $0 \in P$. Denote the set $\{-p | p \in P\}$ by $-P$, and let $Q = P \cup -P$. It is clear that $R_k(P) \leq R_k(Q) \leq 2R_k(P)$. Therefore, if we found a good approximation for $R_k(Q)$, then it must also be a good approximation for $R_k(P)$.

Since P is a symmetric point set, the best $(d-k)$-flat for P contains the origin so that it is a subspace. Thus, the square of $R_k(P)$ can be defined by the optimal value of the following quadratic minimization problem:

$$
\begin{array}{rlll}
R_k(P)^2 := & \text{Minimize} & \alpha & \\
& \text{Subject to} & \sum_{i=1}^{k} \langle p, x_i\rangle^2 \leq \alpha \ \forall p \in P, & \\
& & \|x_i\|^2 = 1, \ i = 1, \ldots, k, & \\
& & \langle x_i, x_j\rangle = 0 \ \forall i \neq j. &
\end{array} \tag{1}
$$

Assume that $x_1, x_2, \ldots, x_k \in \Re^d$ is the optimal solution of (1). Then one can easily verify that the matrix $X = x_1x_1^T + x_2x_2^T + \cdots + x_kx_k^T$ is a feasible solution for the following semidefinite program:

$$\begin{array}{rll} \alpha_k^* := & \text{Minimize} & \alpha \\ & \text{Subject to} & \mathrm{Tr}(pp^TX)\ (= p^TXp) \le \alpha\ \forall p \in P, \\ & & \mathrm{Tr}(X) = k, \\ & & I - X \succeq 0,\ X \succeq 0. \end{array} \tag{2}$$

It follows that $\alpha_k^* \le R_k(P)^2$. The following lemma follows from the above observations.

LEMMA 1. *There exists an integer $r \ge k$ such that we can compute, in polynomial time, r nonnegative reals $\lambda_1, \lambda_2, \ldots, \lambda_r$ and r orthogonal unit vectors $v_1, v_2, \ldots, v_r$ such that*

1. $\sum_{i=1}^r \lambda_i = k$.
2. $\max_{1 \le i \le r} \lambda_i \le 1$.
3. $\sum_{i=1}^r \lambda_i \langle p, v_i \rangle^2 \le R_k(P)^2$ *for any* $p \in P$.

Proof. We solve the semidefinite program (2) and let X^* be an optimal solution of (2). We claim that the rank of X^*, say r, is at least k. This follows from the fact that $\mathrm{Tr}(X^*) = k$ and $I - X^* \succeq 0$. In other words, $\mathrm{Tr}(X^*) = k$ implies that the sum of the eigenvalues of X^* is equal to k, and $I - X^* \succeq 0$ implies that all the eigenvalues are less than or equal to 1. Therefore, X^* has at least k nonzero eigenvalues, which implies that the rank of X^* is at least k. Let $\lambda_1, \lambda_2, \ldots, \lambda_r$ be the r nonnegative eigenvalues and $v_1, v_2, \ldots, v_r$ be the corresponding eigenvectors (see [26, p. 466] for details on computing the eigenvalues and eigenvectors in polynomial time). Then we have $\sum_{i=1}^r \lambda_i = k$ and $\max_{1 \le i \le r} \lambda_i \le 1$. Furthermore, for any $p \in P$,

$$\sum_{i=1}^r \lambda_i \langle p, v_i \rangle^2 = \mathrm{Tr}(pp^T \sum_{i=1}^r \lambda_i v_i v_i^T) = \mathrm{Tr}(pp^TX^*) \le \alpha_k^* \le R_k(P)^2. \qquad \square$$

2.1. Deterministic first rounding. In this section, we prove a lemma concerning how to deterministically group the eigenvalues and their eigenvectors. The proof of the lemma is elementary, but it plays an important role for proving our main result.

LEMMA 2. *The index set $\{1, 2, \ldots, r\}$ can be partitioned into k sets $I_1, I_2, \ldots, I_k$ such that, for any $i : 1 \le i \le k$, $\sum_{j \in I_i} \lambda_j \ge \frac{1}{2}$.*

Proof. Recall that $\sum_{j=1}^r \lambda_j = k$ and $0 \le \lambda_j \le 1$ for all j. Without loss of generality, we can assume that $\lambda_1 \ge \lambda_2 \ge \cdots \ge \lambda_r$. Our partitioning algorithm is the same as the longest-processing-time heuristic algorithm for the parallel machine scheduling problem. The algorithm works as follows:

1. For $i = 1, 2, \ldots, k$, set $I_i = \emptyset$, and let $L_i = 0$. Let $I = \{1, 2, \ldots, r\}$.
2. While $I \ne \emptyset$,
   choose j from I with the smallest index;
   choose set i with the smallest value L_i.
   Let $I_i := I_i \cup \{j\}$, $L_i := L_i + \lambda_j$, and $I := I - \{j\}$.

It is clear that when the algorithm stops, the sets $I_1, I_2, \ldots, I_k$ are a partition of $\{1, 2, \ldots, r\}$. Now we prove the lemma by contradiction. Assume that there exists some t such that $\sum_{j \in I_t} \lambda_j < \frac{1}{2}$.

We now claim that, for all i, $\sum_{j \in I_i} \lambda_j \le 1$. Otherwise, suppose $\sum_{j \in I_{t'}} \lambda_j > 1$ for some t'. Note that $\lambda_j \le 1$, for every j, and thus there are at least two eigenvalues

assigned to $I_{t'}$. Denote the last element within $I_{t'}$ by s'. It follows that $\sum_{j\in I_{t'}} \lambda_j - \lambda_{s'} = \sum_{j\in I_{t'}\setminus\{s'\}} \lambda_j \le \sum_{j\in I_t} \lambda_j$ since, otherwise, we would have not assigned $\lambda_{s'}$ to $I_{t'}$ in the algorithm. However, since $\sum_{j\in I_t} \lambda_j < \frac{1}{2}$, we must have $\sum_{j\in I_{t'}} \lambda_j - \lambda_{s'} = \sum_{j\in I_{t'}\setminus\{s'\}} \lambda_j < \frac{1}{2}$. Thus, $\lambda_{s'} > \sum_{j\in I_{t'}} \lambda_j - \frac{1}{2} > \frac{1}{2}$. This is impossible since $\lambda_{s'}$ is the last eigenvalue assigned to $I_{t'}$, which implies $\lambda_{s'} \le \lambda_j$ for every $j \in I_{t'}$, and we have already proved that there must exist an l such that $s' \ne l \in I_{t'}$ and $\lambda_l \le \sum_{j\in I_{t'}\setminus\{s'\}} \lambda_j < \frac{1}{2}$. Therefore, $\sum_{j\in I_i} \lambda_j \le 1$ for all i, and in particular $\sum_{j\in I_t} \lambda_j < \frac{1}{2}$. It follows that $\sum_{i=1}^{k} \sum_{j\in I_i} \lambda_j < k$. However, we know that since $I_1, I_2, \ldots, I_k$ is a partition of the index set $\{1, 2, \ldots, r\}$, $\sum_{i=1}^{k} \sum_{j\in I_i} \lambda_j = \sum_{j=1}^{r} \lambda_j = k$. This results in a contradiction. Therefore, such a t does not exist, and the proof is completed. ∎

Notice that the running time of the partitioning algorithm is bounded by $O(r\cdot k)$.[2]

2.2. Randomized second rounding. Let us now assume that we have found $I_1, I_2, \ldots, I_k$. Then our next randomized rounding procedure works as follows:

1. Generate an r-dimensional random vector ϕ such that each entry of ϕ takes value, independently, -1 or 1 with probability $\frac{1}{2}$ each way.
2. For $i = 1, 2, \ldots, k$, let

$$x_i = \frac{\sum_{j\in I_i} \phi_j \sqrt{\lambda_j}\cdot v_j}{\sqrt{\sum_{j\in I_i} \lambda_j}}.$$

The following lemmas show that $x_1, x_2, \ldots, x_k$ form a feasible solution for the original problem. In other words, they are k orthogonal unit vectors.

LEMMA 3. *For $i = 1, 2, \ldots, k$, $\|x_i\| = 1$.*

Proof. Recall that $\langle v_l, v_j\rangle = 0$ for any $l \ne j$ and $\|v_j\| = 1$. By definition,

$$\begin{aligned}
\|x_i\|^2 &= \left\langle \frac{\sum_{j\in I_i} \phi_j \sqrt{\lambda_j} v_j}{\sqrt{\sum_{j\in I_i} \lambda_j}}, \frac{\sum_{j\in I_i} \phi_j \sqrt{\lambda_j} v_j}{\sqrt{\sum_{j\in I_i} \lambda_j}} \right\rangle \\
&= \frac{1}{\sum_{j\in I_i} \lambda_j} \sum_{j\in I_i} \langle \phi_j \sqrt{\lambda_j} v_j, \phi_j \sqrt{\lambda_j} v_j\rangle \\
&= \frac{1}{\sum_{j\in I_i} \lambda_j} \sum_{j\in I_i} (\phi_j)^2 \lambda_j \|v_j\|^2 \\
&= 1. \qquad \blacksquare
\end{aligned}$$

LEMMA 4. *If $s \ne t$, then $\langle x_s, x_t\rangle = 0$.*

Proof. Since for any $j \in I_s$ and $l \in I_t$, $\langle v_j, v_l\rangle = 0$,

$$\begin{aligned}
\langle x_s, x_t\rangle &= \left\langle \frac{\sum_{j\in I_s} \phi_j \sqrt{\lambda_j} v_j}{\sqrt{\sum_{j\in I_s} \lambda_j}}, \frac{\sum_{j\in I_t} \phi_j \sqrt{\lambda_j} v_j}{\sqrt{\sum_{j\in I_t} \lambda_j}} \right\rangle \\
&= \frac{1}{\sqrt{\sum_{j\in I_s} \lambda_j \cdot \sum_{j\in I_t} \lambda_j}} \left\langle \sum_{j\in I_s} \phi_j \sqrt{\lambda_j} v_j, \sum_{j\in I_t} \phi_j \sqrt{\lambda_j} v_j \right\rangle \\
&= 0. \qquad \blacksquare
\end{aligned}$$

[2] An alternative way of partitioning the eigenvalues is the following: first, put the eigenvalues that are greater than or equal to 1/2 into distinct subsets. If the number of such eigenvalues, say l, is not less than k, then we are done. Otherwise, arbitrarily put the remaining eigenvalues into $k - l$ subsets such that the sum of eigenvalues in each subset is greater than or equal to 1/2. This method was suggested by an anonymous referee of a preliminary version of this paper.

Now we establish a bound on the performance of our algorithm. First, let us introduce Bernstein's theorem (see, for example, [26]), which is a form of the Chernoff bound.

LEMMA 5. *Let ϕ be a random vector whose entries are independent and either* 1 *or* -1 *with probability* $\frac{1}{2}$ *each way. Then, for any vector* e *and* $\beta > 0$,

$$\text{prob}\{\langle \phi, e\rangle^2 > \beta \|e\|^2\} < 2 \cdot \exp\left(-\frac{\beta}{2}\right).$$

Let $C_{ip} = \sum_{j \in I_i} \lambda_j \langle p, v_j\rangle^2$. Then we have

LEMMA 6. *For each* $i = 1, 2, \ldots, k$ *and each* $p \in P$, *we have*

$$\text{prob}\{\langle p, x_i\rangle^2 > 12 \log(n) \cdot C_{ip}\} < \frac{2}{n^3}.$$

Proof. Given i and p, define an $|I_i|$-dimensional vector e such that its entries are $\sqrt{\lambda_j}\langle p, v_j\rangle$, $j \in I_i$, respectively. Furthermore, we define the $|I_i|$-dimensional vector $\phi|_{I_i}$ whose entries are those of ϕ with indices in I_i. First notice that

$$\|e\|^2 = \sum_{j \in I_i} (\sqrt{\lambda_j}\langle p, v_j\rangle)^2 = \sum_{j \in I_i} \lambda_j \cdot \langle p, v_j\rangle^2 = C_{ip}.$$

On the other hand, since $\sum_{j \in I_i} \lambda_j \geq \frac{1}{2}$,

$$\begin{aligned}
\langle p, x_i\rangle^2 &= \left\langle p, \frac{\sum_{j \in I_i} \sqrt{\lambda_j} v_j \phi_j}{\sqrt{\sum_{j \in I_i} \lambda_j}} \right\rangle^2 \\
&\leq 2 \left\langle p, \sum_{j \in I_i} \sqrt{\lambda_j} v_j \phi_j \right\rangle^2 \\
&= 2 \left(\sum_{j \in I_i} \sqrt{\lambda_j} \phi_j \langle p, v_j\rangle \right)^2 \\
&= 2 \left\langle \phi|_{I_i}, e \right\rangle^2.
\end{aligned}$$

Thus

$$\text{prob}\{\langle p, x_i\rangle^2 > 12 \log(n) C_{ip}\} \leq \text{prob}\{\langle \phi|_{I_i}, e\rangle^2 > 6 \log(n) \|e\|^2\}.$$

Therefore, the conclusion of the lemma follows by using Lemma 5 and by letting $\beta = 6 \log(n)$. ∎

THEOREM 1. *We can compute in polynomial time a* $(d-k)$*-flat such that, with probability at least* $1 - \frac{2}{n}$, *the distance between any point* $p \in P$ *and* F *is at most* $\sqrt{12 \log(n)} \cdot R_k(P)$.

Proof. For given $i = 1, 2, \ldots, k$ and $p \in P$, consider the event

$$B_{ip} = \{\phi | \langle p, x_i\rangle^2 > 12 \log(n) \cdot C_{ip}\}$$

and $B = \bigcup_{i,p} B_{ip}$. The probability that the event B happens is bounded by

$$\sum_{i,p} \text{prob}\{\langle p, x_i\rangle^2 > 12 \log(n) \cdot C_{ip}\} < \frac{2kn}{n^3} \leq \frac{2}{n}.$$

If B does not happen, then for any i and p,

$$\langle p, x_i\rangle^2 \le 12\log(n)\cdot C_{ip}.$$

Therefore, for each $p \in P$,

$$\sum_{i=1}^{k}\langle p, x_i\rangle^2 \le 12\log(n)\sum_{i=1}^{k} C_{ip} \le 12\log(n)\cdot R_k(P)^2.$$

The last inequality follows from Lemma 1. This completes the proof by taking F as the subspace which is orthogonal to the vectors $x_1, x_2, \ldots, x_k$. ∎

3. The inapproximability results. We start with formal definitions of the problems that will be used in the sequence of reductions from 3SAT to computing the outer k-radius $R_k(P)$ of a set P of points. Our starting point will be the classic 3SAT problem, in which we are given a 3CNF formula and we want to know if there is an assignment to its variables that simultaneously satisfies all its clauses. The next problem we consider is the resricted quadratic programming problem as defined by Brieden [14].

DEFINITION 1 (ζ-restricted quadratic programming). *We are given nonnegative integers λ, τ, κ, and σ and nonnegative rational numbers $c_{p,q,a,b}$ for $p \in [\lambda]$, $q \in [\tau]$, $a \in [\kappa]$, and $b \in [\sigma]$. (For a nonnegative integer n, $[n]$ denotes the set $\{1, 2, \ldots, n\}$.) Our goal is to maximize*

$$f(x) = \sum_{p,q,a,b} c_{p,q,a,b}x_{p,a}y_{q,b}$$

over the polytope $P \subseteq \Re^{\lambda\kappa+\tau\sigma}$ described by

$$\sum_{a\in[\kappa]} x_{p,a} = 1 \text{ for } p \in [\lambda],$$

$$\sum_{b\in[\sigma]} y_{q,b} = 1 \text{ for } q \in [\tau],$$

$$0 \le x_{p,a} \le 1 \text{ for } p \in [\lambda], a \in [\kappa],$$

$$0 \le y_{q,b} \le 1 \text{ for } q \in [\tau], b \in [\sigma].$$

We denote instances in which $\kappa, \sigma \le \zeta$ and $\lambda, \tau \le \Delta$ by ζ-restricted $QP[\Delta]$.

DEFINITION 2 (symmetric full-dimensional norm maximization). *We are given a string (n, m, A), where n and m are natural numbers and A is a rational $m \times n$ matrix. Our goal is to maximize*

$$f(x) = ||x||_2$$

over all vectors x that belong to the polytope $P = \{x| -1 \le Ax \le 1\}$. We denote an instance in which the number of rows of A is at most m and the number of columns is at most n by $NM[m, n]$.

We first prove an inapproximability result for the case $k = 1$ and later extend it to a large range of k using a simple reduction. The crux of the proof is the following lemma.

LEMMA 7. *There is a constant $c > 1$ such that for any sufficiently large integer parameter $t \ge 1$, there is a reduction T from 3SAT formulas of size m to computing R_1 for a point set of size $n = 2^{O(t2^{3t}\log m)}$ in $d = 2^{O(t\log m)}$ dimensions such that the following hold:*

1. *If ψ is satisfiable, then $R_1(T(\psi)) \geq w$ for some w.*
2. *If ψ is unsatisfiable, then $R_1(T(\psi)) \leq w'$ for some w'.*
3. $\frac{w}{w'} \geq c^t$.

This reduction, including the computation of w and w', runs in time $2^{O(t2^{3t}\log m)}$.

Proof. The proof involves a sequence of three reductions.

From 3SAT to quadratic programming. Bellare and Rogaway [8, section 4] give a reduction from 3SAT to quadratic programming via a two-prover protocol for 3SAT. We use their reduction, but in order to get the right parameters in the hardness of approximation result for quadratic programming, we need to replace the one-round two-prover protocol that they start off with by a different one that is described in Feige [16, section 2.2]. For completeness, we now describe this two-prover protocol for 3SAT.

The two-prover protocol. Feige [16, Proposition 2.1.2] shows there exists a polynomial time reduction T from 3CNF formulas to 3CNF formulas such that each clause of $T(\psi)$ has exactly three literals (corresponding to three different variables) and each variable appears in exactly five clauses and furthermore the following hold:

1. If ψ is satisfiable, then $T(\psi)$ is satisfiable.
2. If ψ is not satisfiable, then $T(\psi)$ is at most $(1-\epsilon)$-satisfiable for some constant $0 < \epsilon < 1$. That is, any assignment satisfies at most a fraction $(1-\varepsilon)$ of all clauses in $T(\psi)$.

Without the requirement that each variable appears in exactly five clauses, such a reduction is known to be a consequence of the PCP theorem [3]. We now describe the steps taken by the verifier in the two-prover protocol.

1. Convert ψ to $T(\psi)$.

2. Choose t clauses uniformly at random (with replacement) from $T(\psi)$. Ask prover P_1 for an assignment to the variables in each clause chosen.

3. From each chosen clause, choose one of the three variables in that clause uniformly at random. We get t *distinguished* variables, possibly with repetitions. Ask the prover P_2 for an assignment to each of these t variables.

4. Accept if, for each chosen clause, it is satisfied by the assignment received from prover P_1 and the assignments made by the two provers to the distinguished variable from the clause are consistent. (Acceptance means that the verifier declares ψ to be satisfiable.) For example, suppose $t = 2$ and the verifier chose the clauses $(\neg x \vee y \vee z)$ and $(\neg y \vee z \vee w)$ and chose x and w as the respective distingushed variables. Suppose that P_1 returned the values x_1, y_1, and z_1 for the variables in the first clause and the values y_2, z_2, and w_2 for the variables in the second clause. Suppose that P_2 returned values x_3 and w_3 for the distinguished variables. Then the verifier accepts if both $(\neg x_1 \vee y_1 \vee z_1)$ and $(\neg y_2 \vee z_2 \vee w_2)$ evaluate to true, $x_1 = x_3$, and $w_2 = w_3$.

The prover P_1 is any function that on seeing ψ and the identity of the t clauses in $T(\psi)$ returns $3t$ bits that the verifier interprets as an assignment to the $3t$ variables in these clauses. Similarly, the prover P_2 is any function that on seeing ψ and the identity of the t distinguished variables returns t bits that the verifier interprets as an assignment to the distinguished variables.

If ψ is satisfiable, so is $T(\psi)$, and there exist provers (functions) that will cause the verifier to accept on every outcome of the random choices. This can be seen by picking a satisfying assignment to $T(\psi)$ and defining the two provers so that they answer according to this assignment. If ψ is unsatisfiable, what is the maximum probability, over all choices of provers (functions) P_1 and P_2, that the verifier accepts ψ? By Raz's parallel repetition theorem [28], this *error probability* is bounded above by s^t for some $s < 1$ (where the s depends on ε). We refer the reader to Feige [16,

section 2.2] for a discussion of this and to the paper by Håstad [24] for more details on the use of two-prover protocols in inapproximability results. Also, note that in this protocol the questions to the two provers are at most $O(t \log m)$ bits long, where m is the input size, since $O(\log m)$ bits suffice to identify a clause or variable in $T(\psi)$. The answers from the two-provers P_1 and P_2 are $3t$ and t bits long.

We now plug this two-prover protocol into the reduction of Bellare and Rogaway [8, section 4] from SAT to restricted quadratic programming via two-prover protocols. Their description assumes for simplicity that the question and answer lengths of the two-prover protocol are the same, but their reduction works even if these sizes are different. Using the fact that the answer length is at most $3t$, we obtain the following.[3]

LEMMA 8 (Bellare and Rogaway [8]). *There is a constant $f > 1$ such that, for any sufficiently large integer $t \geq 1$, there is a reduction T_1 that maps 3CNF formulas of size m to 2^{3t}-restricted $QP[2^{O(t \log m)}]$ such that the following hold:*

1. *If ψ is satisfiable, then $OPT(T_1(\psi)) = w_1$ for some w_1.*
2. *If ψ is unsatisfiable, then $OPT(T_1(\psi)) \leq w_2$ for some w_2.*
3. *$\frac{w_1}{w_2} \geq f^t$.*

Moreover, this reduction, including the computation of w_1 and w_2, runs in time $2^{O(t \log m)}$.

From quadratic programming to norm maximization. Brieden [14, Theorem 3.4] describes a set of interesting reductions that converts an instance of quadratic programming to an instance of the norm maximization problem. Using this reduction, we obtain the following.

LEMMA 9 (Brieden [14]). *For any $\lambda > 0$, there is a reduction T_2 from restricted quadratic programming to symmetric full-dimensional norm maximization that maps 2^{3t}-restricted $QP[2^{O(t \log m)}]$ into $NM[2^{O(t2^{3t} \log m)}, 2^{O(t \log m)}]$ with the following property: for any input L of QP to T_2,*

$$\frac{OPT(L)}{(1+\lambda)} \leq OPT(T_2(L)) \leq (1+\lambda)OPT(L).$$

Moreover, the reduction T_2 runs in time $2^{O(t2^{3t} \log m)}$.

From norm maximization to width computation. The reduction from symmetric full-dimensional norm maximization to width computation is simple [19] and is in fact used by Brieden [14]. Let $a_i \in \Re^n$ be the vector that corresponds to the ith row of matrix A which is input to the norm-maximation problem for $1 \leq i \leq m$. Thus the norm-maximization problem is

$$\gamma := \begin{array}{ll} \text{Maximize} & ||x||_2 \\ \text{Subject to} & \langle a_i, x \rangle^2 \leq 1 \text{ for } 1 \leq i \leq m. \end{array} \tag{3}$$

The reduction T_3 simply constructs a set B of points by adding, for each $1 \leq i \leq m$, the points a_i and $-a_i$ to B. Since B is a symmetric point set, $R_1(B)^2$ is given by the program

$$\begin{array}{ll} \text{Minimize} & \alpha \\ \text{Subject to} & \langle a_i, x \rangle^2 \leq \alpha \text{ for } 1 \leq i \leq m, \\ & \|x\|^2 = 1. \end{array} \tag{4}$$

[3] In Bellare's and Rogaway's reduction, the connection between the parameters of the two-prover protocol for 3SAT and the parameters of the resulting ζ-restricted $QP[\Delta]$ instance is as follows: ζ is exponential in the answer length, Δ is exponential in the question length, and the "gap" f^t in Lemma 8 is the reciprocal of the error probability of the protocol.

It is easy to verify that $\gamma = 1/R_1(B)$.

The reduction T claimed in Lemma 7 is obtained by composing the reductions T_1, T_2, and T_3. In particular, choose λ such that $(1+\lambda)^2 < f$, and let

$$c = \frac{1}{(1+\lambda)^2} f > 1.$$

It can now be checked that Lemma 7 holds with this choice of c. □

THEOREM 2.

1. *There exists a constant $\delta > 0$ such that the following holds: there is no quasi-polynomial time algorithm that approximates $R_1(P)$ within $(\log n)^\delta$ unless NP $\subseteq \tilde{P}$.*
2. *Fix any constant $b \geq 1$. Then there is no quasi-polynomial time algorithm that approximates $R_1(P)$ within $(\log d)^b$ unless NP $\subseteq \tilde{P}$.*

Proof. To prove part 1, we apply the reduction of Lemma 7 with $t = \log\log m$ to obtain an instance of computing R_1 for a set of $n = 2^{O(t2^{3t}\log m)}$ in $d = 2^{O(t\log m)}$ dimensions. Choose $\delta' < \frac{\log c}{5}$. Then

$$\frac{c^t}{(t2^{3t})^{\delta'}} \geq \frac{c^t}{(2^{4t})^{\delta'}} \geq \left(\frac{c}{2^{4\delta'}}\right)^t > (2^{\delta'})^t \geq (\log m)^{\delta'}.$$

Thus $c^t > (t2^{3t}\log m)^{\delta'}$. Since $n = 2^{O(t2^{3t}\log m)}$, we can choose $\delta < \delta'$ such that, for n large enough,

$$c^t > (\log n)^\delta.$$

To prove part 2, we apply the reduction of Lemma 7 with $t = \frac{2p\log\log m}{\log c}$ for some sufficiently large constant p. Then,

$$\frac{c^t}{t^p} \geq \frac{2^{2p\log\log m}}{t^p} \geq 2^{p\log\log m}\frac{2^{p\log\log m}}{t^p} = 2^{p\log\log m}\left(\frac{\log m}{t}\right)^p > 2^{p\log\log m}$$

since $\log m > t$ for sufficiently large m.

Thus, $c^t > t^p 2^{p\log\log m} = (t\log m)^p$. Since the dimension d is $2^{O(t\log m)}$, it follows that for every constant $b \geq 1$, we can choose p large enough such that

$$c^t > (\log d)^b.$$

Observe that the reduction runs in quasi-polynomial time for our choice of t in both cases and hence the theorem follows. □

We now give the easy reduction from width to the outer k-radius that proves the main result of this section.

THEOREM 3.

1. *There exists a constant $\delta > 0$ such that the following holds for any $0 < \varepsilon < 1$: there is no quasi-polynomial time algorithm that approximates $R_k(P)$ within $(\log n)^\delta$ for all k such that $k \leq d - d^\varepsilon$ unless NP $\subseteq \tilde{P}$.*
2. *Fix any $\varepsilon > 0$. Fix any constant $c \geq 1$. Then there is no quasi-polynomial time algorithm that approximates $R_k(P)$ within $(\log d)^c$ for all k such that $k \leq d - d^\varepsilon$ unless NP $\subseteq \tilde{P}$.*

Proof. Let P be a set of n points in $\Re^d$. We map P to a set P' of n points in $\Re^{d+k-1}$ using the function that takes a point $(x_1, \ldots, x_d) \in \Re^d$ to the point $(x_1, \ldots, x_d, 0, \ldots, 0)$. It is easily checked that $R_1(P) = R_k(P')$. Theorem 3 follows

from this reduction and some simple calculations: observe that the reduction runs in polynomial time even if we set k to be $d^{1/\varepsilon} - d + 1$. With this choice, the target dimension $d' := d + k - 1$ equals $d^{1/\varepsilon}$. Thus $k = d^{1/\varepsilon} - d + 1 \geq d' - d'^{\varepsilon}$. Theorem 3(1) now follows by applying Theorem 2(1). For part (2), we apply Theorem 2(2) with $b = 2c$. Since

$$(\log d)^{2c} \geq (\varepsilon \log d')^{2c} = (\varepsilon^2 \log d')^c (\log d')^c \geq (\log d')^c$$

for sufficiently large d', Theorem 3(2) also follows. ∎

4. Conclusions. Finding efficient rounding methods for SDP relaxation plays a key role in constructing better approximation algorithms for various hard optimization problems. All of them developed to date are randomized in nature. Therefore, the mixed deterministic and randomized rounding procedure developed in this paper may have its own independent value. We expect to see more applications of the procedure in approximating various computational geometry and space embedding problems.

LINEAR RECURRENCES WITH POLYNOMIAL COEFFICIENTS AND APPLICATION TO INTEGER FACTORIZATION AND CARTIER–MANIN OPERATOR*

ALIN BOSTAN†, PIERRICK GAUDRY‡, AND ÉRIC SCHOST‡

Abstract. We study the complexity of computing one or several terms (not necessarily consecutive) in a recurrence with polynomial coefficients. As applications, we improve the best currently known upper bounds for factoring integers deterministically and for computing the Cartier–Manin operator of hyperelliptic curves.

Key words. linear recurrences, factorization, Cartier–Manin operator

AMS subject classifications. 11Y16, 68Q25, 11Y05

DOI. 10.1137/S0097539704443793

1. Introduction. We investigate complexity questions for linear recurrent sequences. Our main focus is on the computation of one term, or several terms not necessarily consecutive, in a recurrence with polynomial coefficients. As applications, we improve the deterministic complexity of factoring integers and of computing the Cartier–Manin operator of hyperelliptic curves.

A well-known particular case is that of linear recurrences with constant coefficients. In this case, the Nth term can be computed with a complexity logarithmic in N, using binary powering. In the general case, there is a significant gap, as no algorithm with a complexity polynomial in $(\log N)$ is known. However, Chudnovsky and Chudnovsky showed in [11] how to compute one term in such a sequence without computing all intermediate ones. This algorithm is closely related to Strassen's algorithm [48] for integer factorization; using baby steps/giant steps (BSGS) techniques, it requires a number of operations which are roughly linear in $\sqrt{N}$ to compute the Nth term.

Precisely, let R be a commutative ring with unity and let M (resp., MM) be a function $\mathbb{N} \to \mathbb{N}$ such that polynomials of degree less than d (resp., matrices of size $n \times n$) can be multiplied in $\mathsf{M}(d)$ (resp., $\mathsf{MM}(n)$) operations $(+, -, \times)$; for $x \in \mathbb{R} - \mathbb{N}$, we write $\mathsf{M}(x) = \mathsf{M}(\lceil x \rceil)$. Next let $M(X)$ be an $n \times n$ matrix with entries in $R[X]$ of degree at most 1. Given a vector of initial conditions $U_0 \in R^n$, define the sequence (U_i) of vectors in R^n by the vector recurrence

$$U_{i+1} = M(i+1)U_i \text{ for all } i \geq 0.$$

Then, assuming that $2, \ldots, \lceil \sqrt{N} \rceil$ are units in R, Chudnovsky and Chudnovsky showed that U_N can be computed using

$$O\big(\mathsf{MM}(n)\mathsf{M}(\sqrt{N}) + n^2\mathsf{M}(\sqrt{N})\log N\big)$$

operations. Both terms in this estimate describe basic operations on polynomial matrices of degree $\sqrt{N}$ (resp., multiplication and multipoint evaluation); using FFT-based multiplication, the cost becomes linear in $\sqrt{N}$, up to polylogarithmic factors. Our goal in this paper is to improve, generalize, and give applications of this algorithm.

- We prove that the Nth term in the sequence (U_i) above can be computed in

$$O\big(\mathsf{MM}(n)\sqrt{N} + n^2\,\mathsf{M}\big(\sqrt{N}\big)\big)$$

  operations. Compared to [11], the dependence in n stays the same; however, for fixed n, we save polylogarithmic factors in N. Chudnovsky and Chudnovsky suggested a lower bound of about $\sqrt{N}$ base ring operations for this problem; thus, our improvement gets us closer to the possible optimal bound. Furthermore, in practice, saving such polylogarithmic factors is far from negligible, since in some instances of an application, as detailed below (Cartier–Manin operator computation), N may be of order 2^{32}.
- We give a generalization to the computation of *several* selected terms, which are of indices $N_1 < \cdots < N_r = N$. When the number r of terms to be computed does not exceed $\sqrt{N}$, we show that all of them can be obtained in a time complexity which is the same as above, that is, essentially linear in $\sqrt{N}$, so we are close to the optimal.
- Along the way, we consider a question of basic polynomial arithmetic: Given the values taken by a univariate polynomial P on a large enough set of points, how fast can we compute the values of P on a shift of this set of points? An obvious solution is to use fast interpolation and evaluation techniques, but we show that this can be done faster when the evaluation points form an arithmetic progression.

In all these algorithms, we will consider polynomial matrices with coefficients of degree at most 1, which is quite frequent in applications, e.g., in the two applications presented below. However, this is not a real restriction: the case of coefficients of larger degree can be handled mutatis mutandis at the cost of a more involved presentation.

A first application is the deterministic factorization of integers. To find the prime factors of an integer N, we note that Strassen's algorithm [48] has a complexity of

$$O\big(\mathsf{M}_{\mathrm{int}}(\sqrt[4]{N}\log N)\log N\big)$$

bit operations, where we denote by $\mathsf{M}_{\mathrm{int}}$ a function such that integers of bit-size d can be multiplied in $\mathsf{M}_{\mathrm{int}}(d)$ bit operations (as above, we extend this function to take arguments in $\mathbb{R}$). Chudnovsky and Chudnovsky's algorithm generalizes Strassen's; thus, our modifications apply here as well. We prove that there exists a deterministic algorithm that outputs the complete factorization of an integer N with a bit complexity in

$$O\big(\mathsf{M}_{\mathrm{int}}(\sqrt[4]{N}\log N)\big).$$

To our knowledge, this gives the fastest deterministic integer factorization algorithm. Prior to Strassen's work, the record was held by Pollard's algorithm [35]; for any $\delta > 0$, its bit complexity is in $O(\mathsf{M}_{\mathrm{int}}(\sqrt[4]{N}\log N)N^{\delta})$. Other deterministic factorization algorithms exist [36, 30]; some have a better conjectured complexity, whose validity relies on unproved number-theoretic conjectures. The fastest probabilistic algorithm for integer factorization, with a fully established complexity bound, is due to Lenstra, Jr. and Pomerance [27], with a bit complexity polynomial in

$\exp(\sqrt{\log N \log\log N})$. The number field sieve [26] has a better conjectured complexity, expected to be polynomial in $\exp(\sqrt[3]{\log N(\log\log N)^2})$.

In accordance with these estimates, the latter algorithms are better suited for practical computations than our deterministic variant, and all recent record-sized computations rely on the number field sieve. However, as already pointed out by Pollard [35], proving unconditional, deterministic upper bounds remains an important challenge.

Our second application is point-counting in cryptography, related to the computation of the Cartier–Manin operator [10, 28] of hyperelliptic curves over finite fields.

The basic ideas already appear for elliptic curves [44, Chapter V]. Suppose we are to count the number n of solutions of the equation $y^2 = f(x)$ over $\mathbb{F}_p$, where $p > 2$ is prime and f has degree 3. Let $\chi : \mathbb{F}_p \to \mathbb{F}_p$ be the map $x \mapsto x^{(p-1)/2}$. For $x \neq 0$, $\chi(x) = 1$ when x is a square, and $\chi(x) = -1$ otherwise. Hence, n equals $\sum_{x\in\mathbb{F}_p} \chi(f(x))$ modulo p. For $i \neq 0$, $\sum_{x\in\mathbb{F}_p} x^i$ equals -1 if $p-1$ divides i, and 0 otherwise; one deduces that n modulo p is the opposite of the coefficient of x^{p-1} in $f(x)^{(p-1)/2}$.

Generalizing these ideas to hyperelliptic curves leads to the notions of the Hasse–Witt matrix and Cartier–Manin operator. Using a result of Manin [28], the Hasse–Witt matrix can be used as part of a point-counting procedure. As above, for hyperelliptic curves given by an equation $y^2 = f(x)$, the entries of this matrix are coefficients of $h = f^{(p-1)/2}$.

The coefficients of h satisfy a linear recurrence with rational function coefficients. Using our results on linear recurrences, we deduce an algorithm to compute the Hasse–Witt matrix whose complexity is essentially linear in $\sqrt{p}$. For instance, in a fixed genus, for a curve defined over the finite field $\mathbb{F}_p$, the complexity of our algorithm is

$$O\big(\mathsf{M}_{\mathrm{int}}(\sqrt{p}\log p)\big)$$

bit operations. This improves the methods of [18] and [29] which have a complexity essentially linear in p. Note that when p is small enough, other methods, such as the p-adic methods used in Kedlaya's algorithm [24], also provide very efficient point-counting procedures, but their complexity is at least linear in p; see [17].

Main algorithmic ideas. We briefly recall Strassen's factorization algorithm and Chudnovsky and Chudnovsky's generalization, and describe our modifications.

To factor an integer N, trial division with all integers smaller than $\sqrt{N}$ has a cost linear in $\sqrt{N}$. To do better, Strassen proposed to group all integers smaller than $\sqrt{N}$ into c blocks of c consecutive integers, where $c \in \mathbb{N}$ is of order $\sqrt[4]{N}$. Write $f_0 = 1\cdots c \mod N$, $f_1 = (c+1)\cdots(2c) \mod N, \ldots, f_{c-1} = (c^2-c+1)\cdots(c^2) \mod N$. If the values $f_0, \ldots, f_{c-1}$ can be computed efficiently, then finding a prime factor of N becomes easy, using the gcd's of $f_0, \ldots, f_{c-1}$ with N. Thus, the main difficulty lies in computing the values f_i, whose cost will actually dominate the whole complexity.

To perform this computation, let $R = \mathbb{Z}/N\mathbb{Z}$ and let F be the polynomial $(X+1)\cdots(X+c) \in R[X]$. The "baby steps" part of the algorithm consists of computing F: using the subproduct tree algorithm [15, Chapter 10], this is done in $O(\mathsf{M}(c)\log c)$ operations in R. Then, the "giant steps" consist of evaluating F at $0, c, \ldots, (c-1)c$, since $F(ic) = f_i$. Using fast evaluation, these values can be computed in $O(\mathsf{M}(c)\log c)$ operations. Since c has order $\sqrt[4]{N}$, the whole process has a complexity of $O(\mathsf{M}(\sqrt[4]{N})\log N)$ operations in R. This is the core of Strassen's factorization algorithm; working out the complexity estimates in a boolean complexity model yields the bounds given before.

Independently of the factorization question, one sees that multiplying the values $f_0, f_1, \ldots, f_{c-1}$ yields the product $1 \cdots c^2$ modulo N. Thus, this algorithm can be used to compute factorials: the analysis above shows that in any ring R, for any $N \geq 0$, the product $1 \cdots N$ can be computed in $O(\mathsf{M}(\sqrt{N}) \log N)$ operations in R. Note the improvement obtained over the naive iterative algorithm, whose complexity is linear in N.

Now, the sequence $U_N = N!$ is a basic example of a solution of a linear recurrence with polynomial coefficients, namely $U_N = NU_{N-1}$. Chudnovsky and Chudnovsky thus generalized the above BSGS process to compute the Nth term of an $n \times n$ matrix recurrence with polynomial coefficients of degree at most 1. The main tasks are the same as above. Computing the matrix equivalent of the polynomial F can be done using $O(\mathsf{MM}(n)\mathsf{M}(\sqrt{N}))$ operations if $2, \ldots, \lceil \sqrt{N} \rceil$ are units in R, and $O(\mathsf{MM}(n)\mathsf{M}(\sqrt{N}) \log N)$ otherwise. Then, the subsequent evaluation can be done using $O(n^2 \mathsf{M}(\sqrt{N}) \log N)$ operations. This gives the complexity estimate mentioned before.

Let us now describe our approach for the factorial (the matrix case is similar). We are not interested in the coefficients of the polynomial F, but in its values on suitable points. Now, both F and the evaluation points have special structures: F is the product of $(X+1)$, $(X+2)$, $\ldots$, $(X+c)$, whereas the evaluation points form the arithmetic progression $0, c, \ldots, (c-1)c$. This enables us to reduce the cost of evaluating F from $O(\mathsf{M}(c) \log c)$ to $O(\mathsf{M}(c))$. We use a divide-and-conquer approach; the recursive step consists of evaluating a polynomial akin to F, with degree halved, on an arithmetic progression of halved size. Putting this idea into practice involves the following operation, which is central to all our algorithms: Given the values of a polynomial P on an arithmetic progression, compute the values of P on a shift of this arithmetic progression.

In the general case of an $n \times n$ matrix recurrence, our fast solution to this problem will enable us to dispense completely with polynomial matrix multiplications, and to reduce by a logarithmic factor all costs related to multipoint evaluation. However, it will impose suitable invertibility conditions in R; we will pay special attention to such conditions, since in our two applications the base ring contains zero-divisors.

Organization of the paper. Section 2 introduces notation and previous results. Section 3 gives our algorithm for shifting a polynomial given by its values on an arithmetic progression; it is used in section 4 to evaluate some polynomial matrices, with an application in section 5 to integer factorization. In section 6, we give our modification on Chudnovsky and Chudnovsky's algorithm for computing one term in a recurrence with polynomial coefficients; a generalization to several terms is given in section 7. In section 8, we apply these results to the computation of the Cartier–Manin operator.

2. Notation and basic results. We use two computational models. Our algorithms for linear recurrent sequences apply over arbitrary rings, so their complexity is expressed in an algebraic model, counting at unit cost the base ring operations. Algorithms for integer factorization and Cartier–Manin operator computation require us to count bit operations: for this purpose, we will use the multitape Turing machine model.

Our algorithms use BSGS techniques. As usual with such algorithms, the memory requirements essentially follow the time complexities (whereas naive iterative algorithms for linear recurrences run in constant memory). We will thus give memory estimates for all our algorithms.

In what follows, $\log x$ is the base-2 logarithm of x; $\lfloor x \rfloor$ and $\lceil x \rceil$ denote, respectively, the largest integer less than or equal to x, and the smallest integer larger than or equal to x.

To make some expressions below well defined, if f is defined as a map $\mathbb{N} \to \mathbb{N}$ we may implicitly extend it to a map $\mathbb{R} \to \mathbb{N}$ by setting $f(x) = f(\lceil x \rceil)$ for $x \in \mathbb{R} - \mathbb{N}$.

All our rings will be commutative and unitary. If R is such a ring, the map $\mathbb{N} \to R$ sending n to $1 + \cdots + 1$ (n times) extends to a map $\varphi : \mathbb{Z} \to R$; we will still denote by $n \in R$ the image $\varphi(n)$.

2.1. Algebraic complexity model. The algorithms of sections 3, 4, 6, and 7 apply over arbitrary rings. To give complexity estimates, we use the straight-line program model, counting at unit cost the operations $(+, -, \times)$ in the base ring; see [8]. Hence, the time complexity of an algorithm is the size of the underlying straight-line program; we will simply speak of "ring operations." Branching and divisions are not used; thus, if we need the inverses of some elements, they will be given as inputs to the algorithm.

To assign a notion of space complexity to a straight-line program, we play a pebble game on the underlying directed acyclic graph; see [3] for a description. However, we will not use such a detailed presentation: we will simply speak of the number of ring elements that have to be stored, or of "space requirements"; such quantities correspond to the number of pebbles in the underlying pebble game.

Basic operations. Let R be a ring. The following lemma (see [32] and [33, p. 66]) shows how to trade inversions (when they are possible) for multiplications.

LEMMA 1. *Let $r_0, \ldots, r_d$ be units in R. Given $(r_0 \cdots r_d)^{-1}$, one can compute $r_0^{-1}, \ldots, r_d^{-1}$ in $O(d)$ operations and space $O(d)$.*

Proof. We first compute $R_0 = r_0$, $R_1 = r_0 r_1, \ldots, R_d = r_0 r_1 \cdots r_d$ in d multiplications. The inverse of R_d is known; by d more multiplications we deduce $S_d = R_d^{-1}$, $S_{d-1} = r_d S_d, \ldots, S_0 = r_1 S_1$, so that S_i equals $(r_0 \cdots r_i)^{-1}$. We obtain the inverse s_i of r_i by computing $s_0 = S_0$, $s_1 = R_0 S_1, \ldots, s_d = R_{d-1} S_d$ for d additional operations. ∎

In what follows, we need to compute some constants in R. For $i, d \in \mathbb{N}$, and $a \in R$, set

$$\delta(i,d) = \prod_{j=0,\ j \neq i}^{d} (i-j) \quad \text{and} \quad \Delta(a,i,d) = \prod_{j=0}^{d} (a+i-j). \tag{1}$$

Then, we have the following results.

LEMMA 2. *Suppose that $2, \ldots, d$ are units in R. Given their inverses, one can compute the inverses of $\delta(0,d), \ldots, \delta(d,d)$ in $O(d)$ operations and space $O(d)$.*

Suppose that $a-d, \ldots, a-1$ are units in R. Given their inverses, one can compute $\Delta(a,0,d), \ldots, \Delta(a,d,d)$ in $O(d)$ operations and space $O(d)$.

Proof. We use the following formulas, where i ranges from 1 to d:

$$\frac{1}{\delta(0,d)} = \frac{1}{\prod_{j=1}^{d}(-j)}, \qquad \frac{1}{\delta(i,d)} = \frac{i-d-1}{i} \frac{1}{\delta(i-1,d)},$$

$$\Delta(a,0,d) = \prod_{j=0}^{d} (a-j), \qquad \Delta(a,i,d) = \frac{a+i}{a+i-d-1} \Delta(a,i-1,d). \qquad ∎$$

Algorithms for polynomials. We denote by $\mathsf{M} : \mathbb{N} - \{0\} \to \mathbb{N}$ a function such that over any ring, the product of polynomials of degree less than d can be computed in $\mathsf{M}(d)$ ring operations. Using the algorithms of [41, 39, 9], $\mathsf{M}(d)$ can be taken in $O(d \log d \log\log d)$. Following [15, Chapter 8], we suppose that for all d and d', M satisfies the inequalities

$$\frac{\mathsf{M}(d)}{d} \leq \frac{\mathsf{M}(d')}{d'} \quad \text{if } d \leq d' \quad \text{and} \quad \mathsf{M}(dd') \leq d^2\mathsf{M}(d'), \tag{2}$$

and that the product in degree less than d can be computed in space $O(d)$. These assumptions are satisfied for naive, Karatsuba, and Schönhage–Strassen multiplications. The first inequality implies that $\mathsf{M}(d) + \mathsf{M}(d') \leq \mathsf{M}(d + d')$ and that $d \leq \mathsf{M}(d)$; the second one is used to derive the inclusion $\mathsf{M}(O(d)) \subset O(\mathsf{M}(d))$.

We use the following results for arithmetic over a ring R. The earliest references we know of are [22, 31, 47, 4], and [7] gives more recent algorithms.

Evaluation. If P is in $R[X]$, of degree at most d, and $r_0, \ldots, r_d$ are in R, then $P(r_0), \ldots, P(r_d)$ can be computed in time $O(\mathsf{M}(d) \log d)$ and space $O(d \log d)$. Using the algorithm of [16, Lemma 2.1], space can be reduced to $O(d)$, but this will not be used here.

Interpolation. For simplicity, we consider only interpolation at $0, \ldots, d$. Suppose that $2, \ldots, d$ are units in R; given their inverses, from the values $P(0), \ldots, P(d)$, one can recover the coefficients of P using $O(\mathsf{M}(d) \log d)$ operations, in space $O(d \log d)$.

See the appendix for a description of the underlying algorithmic ideas.

Matrix multiplication. We denote by $\mathsf{MM} : \mathbb{N} - \{0\} \to \mathbb{N}$ a function such that the product of $n \times n$ matrices over any ring can be computed in $\mathsf{MM}(n)$ base ring operations, in space $O(n^2)$. Thus, one can take $\mathsf{MM}(n) \in O(n^3)$ using classical multiplication, and $\mathsf{MM}(n) \in O(n^{\log 7}) \subset O(n^{2.81})$ using Strassen's algorithm [46]. We do not know whether the current record estimate [13] of $O(n^{2.38})$ satisfies our requirements. Note that $n^2 \leq \mathsf{MM}(n)$; see [8, Chapter 15].

2.2. Boolean complexity model. In sections 5 and 8, we discuss the complexity of factoring integers and of computing the Cartier–Manin operator on curves over finite fields. For these applications, the proper complexity measure is bit complexity. For this purpose, our model will be the multitape Turing machine; see, for instance, [40]. We will speak of *bit operations* to estimate time complexities in this model. Storage requirements will be expressed in bits as well, taking into account input, output, and intermediate data size.

Boolean algorithms will be given through high-level descriptions, and we shall not give the details of their multitape Turing implementations. We just mention the following relevant fact: for each algorithm, there is a corresponding multitape Turing machine. Using previously designed algorithms as subroutines is then possible; each of the corresponding machines is attributed a special band that plays the role of a stack to handle subroutine calls. We refer to [40] for examples of detailed descriptions along these lines.

Integer operations. Integers are represented in base 2. The function $\mathsf{M}_{\text{int}} : \mathbb{N} \to \mathbb{N}$ is such that the product of two integers of bit-size d can be computed within $\mathsf{M}_{\text{int}}(d)$ bit operations. Hence, multiplying integers bounded by N takes at most $\mathsf{M}_{\text{int}}(\log N)$ bit operations.

We suppose that M_{int} satisfies inequalities (2), and that product in bit-size d can be done in space $O(d)$. Using the algorithm of [41], $\mathsf{M}_{\text{int}}(d)$ can be taken in

$O(d \log d \log\log d)$. Euclidean division in bit-size d can be done in time $O(\mathsf{M}_{\mathrm{int}}(d))$ and space $O(d)$; see [12]. The extended gcd of two bit-size d integers can be computed in time $O(\mathsf{M}_{\mathrm{int}}(d)\log d)$ and space $O(d)$; see [25, 38].

Effective rings. We next introduce effective rings as a way to obtain results of a general nature in the Turing model.

Let R be a finite ring, let ℓ be in $\mathbb{N}$, and consider an injection $\sigma : R \hookrightarrow \{0,1\}^\ell$. We use σ to represent the elements of R. Polynomials in $R[X]$ are represented by the sequence of the σ-values of their coefficients. Matrices over R are represented in *row-major ordering*: an $m \times n$ matrix $A = (a_{i,j})$ is represented as $\sigma(a_{1,1}), \ldots, \sigma(a_{1,n}), \ldots, \sigma(a_{m,1}), \ldots, \sigma(a_{m,n})$.

An *effective ring* is the data of such R, ℓ, and σ, together with constants $\mathsf{m}_R, \mathsf{s}_R \in \mathbb{N}$, and maps $\mathsf{M}_R, \mathsf{S}_R$ and $\mathsf{MM}_R, \mathsf{SM}_R : \mathbb{N} - \{0\} \to \mathbb{N}$ meeting the following criteria. First, through the σ representation, we ask that

- the sum and product of elements in R can be computed in time $\mathsf{m}_R \geq \ell$ and space $\mathsf{s}_R \geq \ell$;
- the product of polynomials of degree less than d in $R[X]$ can be computed in time $\mathsf{M}_R(d)$ and space $\mathsf{S}_R(d)$;
- the product of size n matrices over R can be computed in time $\mathsf{MM}_R(n)$ and space $\mathsf{SM}_R(n)$.

We ask that for all d and d', M_R satisfies the inequalities (2),

$$\frac{\mathsf{M}_R(d)}{d} \leq \frac{\mathsf{M}_R(d')}{d'} \quad \text{if } d \leq d' \quad \text{and} \quad \mathsf{M}_R(dd') \leq d^2 \mathsf{M}_R(d'),$$

as well as $d\mathsf{m}_R \leq \mathsf{M}_R(d)$. We also ask that, for all d and d', S_R satisfies

$$\mathsf{s}_R \leq \mathsf{S}_R(d) \quad \text{and} \quad \mathsf{S}_R(dd') \leq d^2 \mathsf{S}_R(d').$$

Finally, as to matrix multiplication, we require that for all n, MM_R and SM_R satisfy

$$n^2 \mathsf{m}_R \leq \mathsf{MM}_R(n) \quad \text{and} \quad \mathsf{s}_R \leq \mathsf{SM}_R(n).$$

In what follows, our results will be first given in the algebraic model, and then on an effective ring, with a bit complexity estimate; note that for both algebraic and Turing models, all constants hidden in the $O(\ )$ estimates will be independent of the base ring.

Effective rings will enable us to state bit complexity results similar to algebraic complexity ones. We have, however, no general transfer theorem from algebraic to bit complexity. First, nonarithmetic operations (loop handling, stack managing for recursive calls) are not taken into account in the former model. In most cases however, the corresponding cost is easily seen to be negligible, so we will not spend time discussing this. A more important difference is that the algebraic model does not count time to access data, that is, the number of tape movements done in the Turing model. This point will be checked for the algorithms we will discuss on Turing machines.

For concrete applications, the following lemma, proved in the appendix, gives the basic examples of effective rings. The results for matrix multiplication are not the sharpest possible, since this would take us too far afield.

LEMMA 3. *Let N be in $\mathbb{N}$, let $R_0 = \mathbb{Z}/N\mathbb{Z}$, and let P be monic of degree m in $R_0[T]$. Then $R = R_0[T]/P$ can be made an effective ring, with*

- $\ell = m\lceil \log N \rceil$,
- $\mathsf{m}_R \in O(\mathsf{M}_{\mathrm{int}}(m \log(mN)))$ *and* $\mathsf{s}_R \in O(m \log(mN))$,

- $\mathsf{M}_R(d) \in O(\mathsf{M}_{\mathrm{int}}(dm\log(dmN)))$ *and* $\mathsf{S}_R(d) \in O(dm\log(dmN))$,
- $\mathsf{MM}_R(n) \in O(n^{\log 7}\mathsf{m}_R)$ *and* $\mathsf{SM}_R(n) \in O(n^2\ell + \mathsf{s}_R)$.

Finally, the results given before in the algebraic model have the following counterpart in the Turing model, using again the notation $\delta(i,d)$ and $\Delta(a,i,d)$ introduced in (1). The proofs are given in the appendix.

LEMMA 4. *Let R be an effective ring. Then the following hold:*

1. *Suppose that $r_0,\dots,r_d$ are units in R. Given $r_0,\dots,r_d,(r_0\cdots r_d)^{-1}$, one can compute $r_0^{-1},\dots,r_d^{-1}$ in time $O(d\mathsf{m}_R)$ and space $O(d\ell+\mathsf{s}_R)$.*
2. *Suppose that $2,\dots,d$ are units in R. Given their inverses, one can compute the inverses of $\delta(0,d),\dots,\delta(d,d)$ in time $O(d\mathsf{m}_R)$ and space $O(d\ell+\mathsf{s}_R)$.*
3. *Suppose that $a-d,\dots,a-1$ are units in R. Given their inverses, one can compute $\Delta(a,0,d),\dots,\Delta(a,d,d)$ in time $O(d\mathsf{m}_R)$ and space $O(d\ell+\mathsf{s}_R)$.*
4. *Let $P=\sum_{i=0}^d p_iX^i$ be in $R[X]$. Given $p_0,\dots,p_d$ and elements $r_0,\dots,r_d$ in R, $P(r_0),\dots,P(r_d)$ can be computed in time $O(\mathsf{M}_R(d)\log d)$ and space $O(\ell d\log d+\mathsf{S}_R(d))$.*
5. *Suppose that $2,\dots,d$ are units in R. If $P\in R[X]$ has degree at most d, then given $P(0),\dots,P(d)$ and the inverses of $2,\dots,d$, one can compute the coefficients of P in time $O(\mathsf{M}_R(d)\log d)$ and space $O(\ell d\log d+\mathsf{S}_R(d))$.*

3. Shifting evaluation values. We now address a special case of the question of *shifting evaluation values* of a polynomial. Let R be a ring, let P be of degree d in $R[X]$, and let a and $r_0,\dots,r_d$ be in R. Given $P(r_0),\dots,P(r_d)$, how fast can we compute $P(r_0+a),\dots,P(r_d+a)$? We stress the fact that the coefficients of P are *not* part of the input.

Suppose that all differences r_i-r_j, $i\neq j$ are units in R. Then using fast interpolation and evaluation, the problem can be solved using $O(\mathsf{M}(d)\log d)$ operations in R. We propose an improved solution, in the special case when $r_0,\dots,r_d$ form an arithmetic progression; its complexity is in $O(\mathsf{M}(d))$, so we gain a logarithmic factor.

Our algorithm imposes invertibility conditions on the sample points slightly more general than those above. Given α,β in R and d in $\mathbb{N}$, we define the following property: $\mathsf{h}(\alpha,\beta,d)$**:** β, $2,\dots,d$ and $\alpha-d\beta$, $\alpha-(d-1)\beta,\dots,\alpha+(d-1)\beta$, $\alpha+d\beta$ are units. We then define $\mathsf{d}(\alpha,\beta,d)=\beta\cdot 2\cdots d\cdot(\alpha-d\beta)\cdots(\alpha+d\beta)\in R$. Assumption $\mathsf{h}(\alpha,\beta,d)$ holds if and only if $\mathsf{d}(\alpha,\beta,d)$ is a unit.

THEOREM 5. *Let α,β be in R and d be in $\mathbb{N}$ such that $\mathsf{h}(\alpha,\beta,d)$ holds, and suppose that the inverse of $\mathsf{d}(\alpha,\beta,d)$ is known. Let F be in $R[X]$ of degree at most d and $r\in R$. Given*

$$F(r),F(r+\beta),\dots,F(r+d\beta),$$

one can compute

$$F(r+\alpha),F(r+\alpha+\beta),\dots,F(r+\alpha+d\beta),$$

in time $2\mathsf{M}(d)+O(d)$ and space $O(d)$, in the algebraic model. If R is effective, then the bit complexity is $2\mathsf{M}_R(d)+O(d\mathsf{m}_R)$ and the space complexity is $O(\mathsf{S}_R(d))$ bits.

Proof. Our algorithm reduces to the multiplication of two suitable polynomials of degrees at most d and $2d$; $O(d)$ additional operations come from pre- and post-processing operations. All operations below on integer values take place in R.

First, we perform a change of variables. Define $P(X)=F(\beta X+r)$; then our assumption is that the values $P(0),P(1),\dots,P(d)$ are known. Let us write $a=\alpha/\beta$;

our objective is then to determine the values $P(a), \dots, P(a+d)$. To this effect, assumption $\mathsf{h}(\alpha, \beta, d)$ enables us to write the Lagrange interpolation formula:

$$P = \sum_{i=0}^{d} P(i) \frac{\prod_{j=0, j\neq i}^{d} (X-j)}{\prod_{j=0, j\neq i}^{d} (i-j)} = \sum_{i=0}^{d} \widetilde{P}_i \prod_{j=0, j\neq i}^{d} (X-j),$$

with $\widetilde{P}_i = P(i)/\delta(i,d)$, where $\delta(i,d)$ is defined in (1). For k in $0, \dots, d$, let us evaluate P at $a+k$:

$$P(a+k) = \sum_{i=0}^{d} \widetilde{P}_i \prod_{j=0, j\neq i}^{d} (a+k-j).$$

Assumption $\mathsf{h}(\alpha, \beta, d)$ implies that $a-d, \dots, a+d$ are units. We can thus complete each product by the missing factor $a+k-i$:

$$P(a+k) = \sum_{i=0}^{d} \widetilde{P}_i \frac{\prod_{j=0}^{d} (a+k-j)}{a+k-i} = \left(\prod_{j=0}^{d} (a+k-j) \right) \cdot \left(\sum_{i=0}^{d} \widetilde{P}_i \frac{1}{a+k-i} \right). \tag{3}$$

We now use the sequence $\Delta(a,k,d)$ introduced in (1) and define $Q_k = P(a+k)/\Delta(a,k,d)$. Using these values, (3) reads

$$Q_k = \sum_{i=0}^{d} \widetilde{P}_i \frac{1}{a+k-i}. \tag{4}$$

Let $\widetilde{P}$ and S be the polynomials

$$\widetilde{P} = \sum_{i=0}^{d} \widetilde{P}_i X^i, \quad S = \sum_{i=0}^{2d} \frac{1}{a+i-d} X^i;$$

then by (4), for $k = 0, \dots, d$, Q_k is the coefficient of degree $k+d$ in the product $\widetilde{P}S$. From the knowledge of Q_k, we easily deduce $P(a+k)$.

Let us analyze the complexity of this algorithm, first in the algebraic model. Using Lemma 1, from the inverse of $\mathsf{d}(\alpha, \beta, d)$, we obtain those of β, $2, \dots, d$ and $\alpha - d\beta, \dots, \alpha + d\beta$ in $O(d)$ operations. Using the equality $(a+id)^{-1} = \beta(\alpha + id\beta)^{-1}$, we obtain the inverses of $a-d, \dots, a+d$ in $O(d)$ further operations. Lemma 2 then gives all $\Delta(a,i,d)$ and the inverses of all $\delta(i,d)$ for $O(d)$ operations as well. The sequence $\widetilde{P}_i$ is deduced for $O(d)$ operations.

The coefficients Q_i are then obtained by a polynomial multiplication in degrees d and $2d$; this can be reduced to two polynomial multiplications in degrees less than d, and $O(d)$ additional operations, for a complexity of $2\mathsf{M}(d) + O(d)$. Given $Q_0, \dots, Q_d$, we deduce $P(a), \dots, P(a+d)$ by multiplications with the coefficients $\Delta(a,i,d)$; this requires $O(d)$ ring operations. This concludes the algebraic complexity estimates, since space requirements are easily seen to be in $O(d)$.

When R is effective, we have to implement this algorithm on a multitape Turing machine. For this simple algorithm, there is no difficulty; we give details to show the manipulations that need to be made, making no effort to minimize the number of tapes. For the next algorithms, we will be more sketchy and concentrate on difficult points.

Initially, $P(0), \ldots, P(d)$ and the inverse of $\mathsf{d}(\alpha, \beta, d)$ are contiguous blocks of ℓ bits on the input tape. First, we produce on an auxiliary tape T_1 all elements whose inverses will be used, *in a suitable order*, namely β, $2, \ldots, d, \alpha - d\beta, \ldots, \alpha + d\beta$. Then the inverse of $\mathsf{d}(\alpha, \beta, d)$ is appended to these elements; using Lemma 4, we obtain β^{-1}, $2^{-1}, \ldots, d^{-1}$ and $(\alpha - d\beta)^{-1}, \ldots, (\alpha + d\beta)^{-1}$ on a tape T_2. As before, we deduce $(a-d)^{-1}, \ldots, (a+d)^{-1}$; this is done is a single sweep of T_2, and the results are stored on a tape T_3. Then, using Lemma 4, all $\delta(i, d)^{-1}$ are computed and stored on a tape T_4, and all $\Delta(a, i, d)$ on a tape T_5. The whole cost up to now is $O(d\mathsf{m}_R)$, the cost of the tape movements being $O(d\ell)$. The space complexity is in $O(d\ell + \mathsf{s}_R)$.

The coefficients of S are copied from T_3 to a tape T_6, and those of $\widetilde{P}$ are computed and stored on a tape T_7; the cost is $O(d\mathsf{m}_R)$, since the data are well organized on tapes. We then compute the product of S and $\widetilde{P}$. The result is the list of coefficients Q_k, stored on a tape T_8 after a time $2\mathsf{M}_R(d) + O(d\mathsf{m}_R)$. Finally the target values $P(a+k)$ are computed at an additional cost of $O(d\mathsf{m}_R)$, since again everything is well organized. This concludes the time analysis. The space complexity is easily seen to fit the required bound. □

Remark 1. In [20], the operation called *middle product* is defined: Given a ring R, and A, B in $R[X]$ of respective degrees at most d and $2d$, write $AB = C_0 + C_1 X^{d+1} + C_2 X^{2d+2}$, with all C_i of degree at most d; then the middle product of A and B is the polynomial C_1. This is precisely what is needed in the algorithm above.

Up to considering the reciprocal polynomial of A, the middle product by A can be seen as the transpose of the map of multiplication by A. General program transformation techniques then show that it can be computed in time $\mathsf{M}(d) + O(d)$ (but with a possible loss in space complexity): this is the *transposition principle* for linear algorithms, which is an analogue of results initiated by Tellegen [49] and Bordewijk [2] in circuit theory. Thus, the time complexity of the algorithm above can be reduced to $\mathsf{M}(d) + O(d)$ ring operations, but possibly with an increased space complexity. We refer to [23, Problem 6] for a longer discussion and [8, Theorem 13.20] for a proof; see also [20] for the independent discovery of the middle product, and [7] for additional applications.

Remark 2. Using the notation of the proof above, we mention an alternative $O(\mathsf{M}(d))$ algorithm which does *not* require any invertibility assumption, in the special case when $a = d + 1$. The key fact is that for any polynomial P of degree d, the sequence $P(0), P(1), \ldots$ is linearly recurrent, of characteristic polynomial $Q(X) = (1 - X)^{d+1}$. Thus, if the first terms $P(0), \ldots, P(d)$ are known, the next $d + 1$ terms $P(d + 1), \ldots, P(2d + 1)$ can be recovered in $O(\mathsf{M}(d))$ using the algorithm in [43, Theorem 3.1].

4. Algorithms for polynomial matrix evaluation. In Strassen's algorithm sketched in the introduction, an important part of the effort lies in evaluating polynomials on points that form an arithmetic progression. A generalization of this question appears in Chudnovsky and Chudnovsky's algorithm for matrix recurrences, where one has to evaluate a polynomial matrix at points in an arithmetic progression. We now present such an evaluation algorithm, in the special case when the polynomial matrix has the form

$$M_k(X) = M(X + \alpha k) \cdots M(X + \alpha),$$

where $M(X)$ is a given $n \times n$ polynomial matrix with entries of degree at most 1: this is enough to handle both Strassen's and Chudnovsky and Chudnovsky's algorithms. Using the result of the previous section, we propose a divide-and-conquer approach,

which, for fixed n, saves a logarithmic factor in k compared to classical multipoint evaluation techniques.

Let R be a ring. We will need several invertibility assumptions in R, in order to apply Theorem 5 along all recursive steps of the algorithm; we discuss this first. With a positive integer k, we associate the sequence $k_0, \dots, k_{\lfloor \log k \rfloor}$ defined by $k_0 = k$ and $k_{i+1} = \lfloor k_i/2 \rfloor$, so that $k_{\lfloor \log k \rfloor} = 1$.

Then, given α, β in R and k in $\mathbb{N}$, we say that assumption $\mathsf{H}(\alpha, \beta, k)$ holds if assumptions $\mathsf{h}(\beta(k_i+1), \beta, k_i)$ and $\mathsf{h}(\alpha k_i, \beta, k_i)$ of the previous section hold for $i = 1, \dots, \lfloor \log k \rfloor$: this is what we need for the algorithm below. We write $\mathsf{D}(\alpha, \beta, k)$ for the product

$$\prod_{i=1}^{\lfloor \log k \rfloor} \mathsf{d}(\beta(k_i+1), \beta, k_i)\, \mathsf{d}(\alpha k_i, \beta, k_i);$$

note that $\mathsf{H}(\alpha, \beta, k)$ holds if and only if $\mathsf{D}(\alpha, \beta, k)$ is a unit in R. We mention a few basic results related to this definition; the straightforward proofs are left to the reader.

LEMMA 6. *Given α, β, and k, $\mathsf{D}(\alpha, \beta, k)$ can be computed in time and space $O(k)$, in the algebraic model. If R is effective, this can be done in time $O(k\mathsf{m}_R)$ and space $O(k\ell + \mathsf{s}_R)$.*

Condition $\mathsf{H}(\alpha, \beta, k)$ asserts that $O(k)$ elements are units in R. It is easy, but cumbersome, to give the list of these elements. It will be enough to note the following particular cases.

LEMMA 7.

- $\mathsf{H}(k, 1, k)$ *holds if and only if* $2, \dots, 2k_i+1$ *and* $kk_i - k_i, \dots, kk_i + k_i$ *are units in R, for* $i = 1, \dots, \lfloor \log k \rfloor$.
- $\mathsf{H}(1, 2^s, 2^s)$ *holds if and only if* $2, \dots, 2^s + 1$ *are units in R.*

We can now state the main result of this section.

THEOREM 8. *Suppose that $\mathsf{H}(\alpha, \beta, k)$ holds and that the inverse of $\mathsf{D}(\alpha, \beta, k)$ is known. Then the scalar matrices $M_k(0), M_k(\beta), \dots, M_k(k\beta)$ can be computed in*

$$O(\mathsf{MM}(n)k + n^2\mathsf{M}(k))$$

ring operations, in space $O(n^2k)$. If R is effective, then the bit complexity is

$$O\big(\mathsf{MM}_R(n)k + n^2\mathsf{M}_R(k) + n^2\ell k \min(\log k, \log n)\big),$$

and the space complexity is $O(n^2k\ell + \mathsf{S}_R(k) + \mathsf{SM}_R(n))$ bits.

Proof. We first deal with inverses. Let $k_0, \dots, k_{\lfloor \log k \rfloor}$ be defined as above. In the following we need the inverses of all

$$\mathsf{d}(\alpha k_i, \beta, k_i) \quad \text{and} \quad \mathsf{d}(\beta(k_i+1), \beta, k_i) \quad \text{for } i = 1, \dots, \lfloor \log k \rfloor.$$

For any i, both $\mathsf{d}(\alpha k_i, \beta, k_i)$ and $\mathsf{d}(\beta(k_i+1), \beta, k_i)$ can be computed in $O(k_i)$ ring operations; hence, all of them can be computed in $O(k)$ operations. Using Lemma 1, their inverses can be deduced from that of $\mathsf{D}(\alpha, \beta, k)$ for $O(\log k)$ products.

We will then give an estimate on the complexity of computing the values of $M_{k_i}(X)$ on $0, \beta, \dots, k_i\beta$, for decreasing values of i. The case $i = \lfloor \log k \rfloor$ is obvious, since then $k_i = 1$ and $M_{k_i}(X) = M(X + \alpha)$, which can be evaluated at 0 and β in $O(n^2)$ operations.

Then, for some $i = \lfloor \log k \rfloor, \dots, 1$, suppose that the values of $M_{k_i}(X)$ are known on $0, \beta, \dots, k_i\beta$. We now show how to deduce the values of $M_{k_{i-1}}(X)$ on $0, \beta, \dots, k_{i-1}\beta$.

To this effect, we will use Theorem 5, using the fact that all entries of $M_{k_i}(X)$ have degree at most k_i. To keep control on the $O(\ )$ constants, we let C be a constant such that the complexity estimate in Theorem 5 is upper-bounded by $2\mathsf{M}(d) + \mathsf{C}d$.

- Applying Theorem 5 to each entry of $M_{k_i}(X)$ to perform a shift by $(k_i+1)\beta$, we see that the values of $M_{k_i}(X)$ on $(k_i+1)\beta, \dots, (2k_i+1)\beta$ can be computed for $n^2(2\mathsf{M}(k_i)+\mathsf{C}k_i)$ ring operations, since $\mathsf{d}(\beta(k_i+1), \beta, k_i)^{-1}$ is known. We then have at our disposal the values of $M_{k_i}(X)$ at $0, \beta, \dots, (2k_i+1)\beta$.
- Applying Theorem 5 to each entry of $M_{k_i}(X)$ to perform shifts by $k_i\alpha$ and then by $(k_i+1)\beta$, we see that the values of $M_{k_i}(X+k_i\alpha)$ on $0, \beta, \dots, (2k_i+1)\beta$ can be computed for $2n^2(2\mathsf{M}(k_i) + \mathsf{C}k_i)$ ring operations. For the first shift we need $\mathsf{d}(\alpha k_i, \beta, k_i)^{-1}$ and for the second we need $\mathsf{d}(\beta(k_i+1), \beta, k_i)^{-1}$; they have both been precomputed in the preamble.

From these values, it is easy to deduce the values of $M_{k_{i-1}}(X)$ at $0, \beta, \dots, k_{i-1}\beta$. We distinguish two cases, according to the parity of k_{i-1}.

- Suppose first that k_{i-1} is even, so that $k_{i-1} = 2k_i$. Using the equality
$$M_{k_{i-1}}(X) = M_{k_i}(X + \alpha k_i) \cdot M_{k_i}(X),$$
we obtain the values of $M_{k_{i-1}}(X)$ at $0, \beta, \dots, k_{i-1}\beta$ by multiplying the known values of $M_{k_i}(X + \alpha k_i)$ and $M_{k_i}(X)$ at $0, \beta, \dots, k_{i-1}\beta$. This takes $(k_{i-1} + 1)\mathsf{MM}(n)$ operations.
- Suppose now that k_{i-1} is odd, so that $k_{i-1} = 2k_i + 1$. Using the equality
$$M_{k_{i-1}}(X) = M(X + \alpha k_{i-1}) \cdot M_{k_i}(X + \alpha k_i) \cdot M_{k_i}(X),$$
we obtain the values of $M_{k_{i-1}}(X)$ at $0, \beta, \dots, k_{i-1}\beta$ as follows. We first multiply the values of $M_{k_i}(X + \alpha k_i)$ and $M_{k_i}(X)$ at $0, \beta, \dots, k_{i-1}\beta$, for $(k_{i-1}+1)\mathsf{MM}(n)$ operations. Then we evaluate $M(X+\alpha k_{i-1})$ at these points for $2n^2(k_{i-1} + 1)$ operations, from which we deduce the requested values of $M_{2k_i+1}(X)$ for $(k_{i-1} + 1)\mathsf{MM}(n)$ operations.

Let us denote by $T(k_{i-1})$ the cost of these operations. From the analysis above, we deduce the inequality

$$T(k_{i-1}) \le T(k_i) + 2(k_{i-1} + 1)\mathsf{MM}(n) + 6n^2\mathsf{M}(k_i) + n^2\mathsf{C}'k_i$$

for a constant C' that can be taken to be $\mathsf{C}' = 3\mathsf{C} + 4$. Using the definition of the sequence k_i and our assumptions on the function M, we deduce the estimate $T(k) = T(k_0) \in O(\mathsf{MM}(n)k + n^2\mathsf{M}(k))$. The space complexity estimate is easily dealt with, since all computations at step i can be done in space $O(n^2k_i)$.

We now come to the last statement, where R is effective. In the Turing context, we have to pay attention to the way matrices and vectors are represented. The preamble, where inverses are precomputed, poses no problem; it suffices to organize the elements to invert in the correct order. However, at the heart of the procedure, we have to switch between two representations of matrices of vectors over R. This is free in an algebraic model but has to be justified to have negligible cost in a Turing model.

At the input of the inner loop on i, we have on a tape the values of $M_{k_i}(X)$ at $0, \beta, \dots, k_i\beta$. They are stored as a sequence of matrices over R, each in row-major representation. In order to apply Theorem 5, we need its input to be contiguous on a tape. Hence, we must first reorganize the data, switching to a representation as a matrix of vectors, with vectors of size $k_i + 1$: Corollary 19 in the appendix shows how to do this in cost $O(\ell n^2 k_i \min(\log k_i, \log n))$. After the applications of Theorem 5, we

have at our disposal the values of $M_{k_i}(X)$ and of $M_{k_i}(X+k_i\alpha)$ at $0, \beta, \dots, (2k_i+1)\beta$, organized as matrices of vectors. We switch back to their representation as a sequence of matrices over R to perform the matrix multiplications. This is the converse problem as before, and it admits the same $O(\ell n^2 k_i \min(\log k_i, \log n))$ solution. The matrix products can then be done at the expected cost, since the input data is contiguous, and finally we are ready to enter again the loop with the next value of i.

Putting together the costs of these operations, the additional cost compared to the algebraic model is $O(\ell n^2 k \min(\log k, \log n))$. The memory requirements consist of $O(n^2 k\ell)$ for storing all intermediate matrices and polynomials, plus a term in $O(\mathsf{S}_R(k))$ coming from Theorem 5, and the term $\mathsf{SM}_R(n)$ for matrix multiplication. □

The case $\alpha = \beta = 1$ is not covered in the last theorem. However, this case is easier to handle (note also that there are no invertibility conditions).

PROPOSITION 9. *Suppose that $\alpha = 1$, that is, $M_k(X) = M(X+k)\cdots M(X+1)$. Then the scalar matrices $M_k(0), M_k(1), \dots, M_k(k)$ can be computed using $O(\mathsf{MM}(n)k)$ ring operations, in space $O(n^2k)$. If R is effective, the bit complexity is $O(\mathsf{MM}_R(n)k)$ and the space requirement is $O(n^2k\ell + \mathsf{SM}_R(n))$ bits.*

Proof. We first evaluate all matrices $M(1), \dots, M(2k)$; this requires $O(n^2k)$ operations and takes space $O(n^2k)$. The conclusion is now similar to the proof of Lemma 1. Denoting by I the $n \times n$ identity matrix, we first compute the products

$$R_k = I, \quad R_{k-1} = R_k M(k), \quad R_{k-2} = R_{k-1}M(k-1), \dots, R_0 = R_1 M(1)$$

and

$$L_0 = I, \quad L_1 = M(k+1)L_0, \quad L_2 = M(k+2)L_1, \dots, L_k = M(2k)L_{k-1}.$$

This takes $O(\mathsf{MM}(n)k)$ ring operations, and $O(n^2k)$ space. We conclude by computing the matrices $M_k(i) = L_i R_i$ for $0 \le i \le k$. This also takes $O(\mathsf{MM}(n)k)$ ring operations and $O(n^2k)$ space. The estimates in the Turing model come similarly. □

In section 7, we have to deal with a similar evaluation problem, but with arbitrary sample points. The following corollary of Proposition 9 will then be useful; compared to the particular case of Theorem 8, we lose a logarithmic factor in the evaluation process.

COROLLARY 10. *Let notation be as in Proposition 9 and assume that $2, \dots, k$ are units in R, and that their inverses are known. Then for any set of $k+1$ elements β_i of R, the matrices $M_k(\beta_0), M_k(\beta_1), \dots, M_k(\beta_k)$ can be computed in*

$$O(\mathsf{MM}(n)k + n^2\mathsf{M}(k)\log k)$$

operations, in space $O(kn^2 + k\log k)$. If R is effective, the bit complexity is

$$O(\mathsf{MM}_R(n)k + n^2\mathsf{M}_R(k)\log k),$$

and the space requirement is $O(k\ell n^2 + \mathsf{SM}_R(n) + \ell k \log k + \mathsf{S}_R(k))$ bits.

Proof. We start by evaluating $M_k(X)$ on $0, \dots, k$; by Proposition 9, this takes $O(\mathsf{MM}(n)k)$ operations and space $O(n^2k)$. Using the inverses of $2, \dots, k$, it is then possible to interpolate all entries of $M_k(X)$ in $O(n^2\mathsf{M}(k)\log k)$ operations, in space $O(k\log k)$. Then, we can evaluate all entries of this matrix at the points $\beta_0, \beta_1, \dots, \beta_k$, with the same cost.

In the Turing model, we face the same problem as in Theorem 8. The output of Proposition 9 is given as a sequence of scalar matrices, so we switch to a matrix of

vectors to apply interpolation and evaluation, and convert it back to a sequence of matrices. Proposition 9 gives the cost for evaluation at $0, \dots, k$; Lemma 4 gives that for interpolation at these points, and for evaluation at $\beta_0, \dots, \beta_k$; Corollary 19 gives the cost for changing the data's organization. The conclusion follows. ∎

5. Application to integer factorization. In this section, we apply the algorithm of Theorem 8 to reduce by a logarithmic factor the best upper bound for deterministic integer factorization, due to Strassen [48]. Strassen's result is that a positive integer N can be completely factored using at most $O\big(\mathsf{M}_{\mathrm{int}}(\sqrt[4]{N}\log N)\log N\big)$ bit operations. The following theorem improves this result.

THEOREM 11. *There exists a deterministic algorithm that outputs the complete factorization of any positive integer N using at most $O(\mathsf{M}_{\mathrm{int}}(\sqrt[4]{N}\log N))$ bit operations. The space complexity is $O(\sqrt[4]{N}\log N)$ bits.*

Our proof closely follows that of Strassen, in the presentation of [15], the main ingredient being now Theorem 8; some additional complications arise due to the nontrivial invertibility conditions required by that theorem. First, applying Lemma 3 (with $m = 1$) gives the data describing $\mathbb{Z}/N\mathbb{Z}$ as an effective ring:

- $\ell = \lceil \log N \rceil$,
- $\mathsf{m}_R \in O(\mathsf{M}_{\mathrm{int}}(\log N))$ and $\mathsf{s}_R \in O(\log N)$,
- $\mathsf{M}_R(d) \in O(\mathsf{M}_{\mathrm{int}}(d\log(dN)))$ and $\mathsf{S}_R(d) \in O(d\log(dN))$.

The data for matrix multiplication is not required here, since all matrices have size 1.

LEMMA 12. *Let $f_0, \dots, f_{k-1}$ be in $\mathbb{Z}/N\mathbb{Z}$. Then one can decide whether all f_i are invertible modulo N and, if not, find a noninvertible f_i in time*

$$O\big(k\,\mathsf{M}_{\mathrm{int}}(\log N) + \log k\,\mathsf{M}_{\mathrm{int}}(\log N)\log\log N\big)$$

and space $O(k\log N)$ bits.

Proof. For $i \le k-1$, we will denote by F_i the canonical preimage of f_i in $[0, \dots, N-1]$. Hence, our goal is to find one F_i such that $\gcd(F_i, N) > 1$.

We first form the "subproduct tree" associated with the values F_i. By completing with enough 1's, we can assume that k is a power of 2, i.e., that $k = 2^m$. First, we define $F_{i,m} = F_i$ for $i = 0, \dots, k-1$; then iteratively we let $F_{i,j-1} = F_{2i,j}F_{2i+1,j} \bmod N$, for $j = m, \dots, 1$ and $i = 0, \dots, 2^{j-1}-1$. These numbers are organized in a tree similar to the one described in the appendix for evaluation and interpolation; see also [15, Chapter 10]. The number of multiplications to perform in $\mathbb{Z}/N\mathbb{Z}$ is at most k; hence, their total cost is $O(k\,\mathsf{M}_{\mathrm{int}}(\log N))$, the number of tape movements being a negligible $O(k\log N)$. The space complexity is $O(k\log N)$ bits as well.

By computing $\gcd(F_{0,0}, N)$, we can decide whether all of $F_0, \dots, F_{k-1}$ are invertible modulo N. If this is not the case, finding one i for which $\gcd(F_i, N) > 1$ amounts to going down the tree from the root to one leaf. Suppose indeed that we have determined that $\gcd(F_{i,j}, N) > 1$ for some $j < m$. Computing $\gcd(F_{2i,j+1}, N)$ enables us to determine one of $F_{2i,j+1}$ or $F_{2i+1,j+1}$ which has a nontrivial gcd with N.

The cost of a gcd is $O(\mathsf{M}_{\mathrm{int}}(\log N)\log\log N)$. Since the tree has depth $\log k$, we compute only $\log k$ gcd's. Again, since the tree is well organized on the tape, going down the tree is done in a one pass process; so our claim on the time complexity is proved. The space complexity does not increase, concluding the proof. ∎

Our second intermediate result is the cornerstone of the algorithm; we improve the estimate of [15, Theorem 19.3] using Theorem 8.

LEMMA 13. *Let b and N be positive integers with $2 \le b < N$. Then one can compute a prime divisor of N bounded by b, or prove that no such divisor exists, in*

$$O\big(\mathsf{M}_{\mathrm{int}}(\sqrt{b}\log N) + \log b\,\mathsf{M}_{\mathrm{int}}(\log N)\log\log N\big)$$

bit operations. The space complexity is $O(\sqrt{b}\log N)$ bits.

Proof. Let $c = \lfloor\sqrt{b}\rfloor$ and let us consider the polynomials of $\mathbb{Z}/N\mathbb{Z}[X]$ given by $f(X) = X + 1 - c$ and

$$F(X) = \prod_{k=0}^{c-1}(X + ck + 1) = f(X + c^2)\cdots f(X + 2c)f(X + c).$$

Our first goal is to compute the values

$$F(0) = \prod_{k=0}^{c-1}(ck + 1) \bmod N, \ldots, F(c-1) = \prod_{k=0}^{c-1}(ck + c) \bmod N.$$

To this effect, we want to apply Theorem 8 with $n = 1$, $\alpha = c$, $\beta = 1$, and $k = c$. This can be done under suitable invertibility conditions: by Lemma 7, $O(\sqrt{b})$ integers bounded by $c^2 \le b$ must be invertible modulo N. All these integers are easily computable and less than N. Using Lemma 12, we can test whether one of these integers is not invertible modulo N and, if this is the case, find one such integer in

$$O\big(\sqrt{b}\,\mathsf{M}_{\mathrm{int}}(\log N) + \log b\,\mathsf{M}_{\mathrm{int}}(\log N)\log\log N\big)$$

bit operations. Then, by trial division, we can find a prime factor of N bounded by b in $O(\sqrt{b}\,\mathsf{M}_{\mathrm{int}}(\log N))$ bit operations; in this case, the result is proved. Thus, we can now assume that all invertibility conditions are satisfied.

By Lemma 6, computing $\mathsf{D}(c, 1, c) \in \mathbb{Z}/N\mathbb{Z}$ has a cost of $O(\sqrt{b}\,\mathsf{M}_{\mathrm{int}}(\log N))$; computing its inverse has a cost in $O(\mathsf{M}_{\mathrm{int}}(\log N)\log\log N)$. Applying Theorem 8, we deduce that all the values $F(i)$, for $i = 0, \ldots, c-1$, can be computed in time $O(\mathsf{M}_{\mathrm{int}}(\sqrt{b}\log(bN)))$; since $b < N$, this is in $O(\mathsf{M}_{\mathrm{int}}(\sqrt{b}\log N))$.

Suppose that N admits a prime factor bounded by c^2; then, some $F(i)$ is not invertible modulo N. By Lemma 12, such an i can be found in time

$$O\big(\sqrt{b}\,\mathsf{M}_{\mathrm{int}}(\log N) + \log b\,\mathsf{M}_{\mathrm{int}}(\log N)\log\log N\big).$$

Since $F(i)$ is not invertible, $\gcd(ck+i+1, N)$ is nontrivial for some $k \le c-1$. Applying Lemma 12 again, the element $ck + i + 1$ can be found in time

$$O\big(\sqrt{b}\,\mathsf{M}_{\mathrm{int}}(\log N) + \log b\,\mathsf{M}_{\mathrm{int}}(\log N)\log\log N\big).$$

By definition, $ck + i + 1 \le b$, so by trial division, we can then find a prime factor of N bounded by b in $O(\sqrt{b}\,\mathsf{M}_{\mathrm{int}}(\log N))$ bit operations.

At this point, if we have not found any prime divisor, then we have certified that N has no prime divisor in $2, \ldots, c^2$, so we finally inspect the range $c^2 + 1, \ldots, b$. Since $b - c^2 \in O(\sqrt{b})$, and since all these numbers are in $O(b)$, we can finish using trial division with the same time complexity bounds as above. The space complexity is dominated by those of Theorem 8 and Lemma 12. ∎

The proof of Theorem 11 follows from successive applications of the lemma above with increasing values of b. Starting with $b = 2$, the algorithm of Lemma 13 is run

with the same value of b until no more factors smaller than b remain in N; then the value of b is doubled. The algorithm stops as soon as $b \geq \sqrt{N}$.

The space complexity estimate comes immediately. However, analyzing the time complexity requires more work. Indeed, since there are at most $(\log N)$ prime factors of N, a rough upper bound on the runtime of the whole factorization would be $(\log N)$ times the runtime of Lemma 13 with $b = \sqrt{N}$, which is too high for our purposes. We show now that this $(\log N)$ factor can in fact be avoided, thus proving Theorem 11.

When Lemma 13 is run with a given parameter b, all prime divisors of N less than $b/2$ have already been found and divided out. Therefore the primes that can be detected are greater than $b/2$; since their product is bounded by N, we deduce that the number of runs of Lemma 13 for the parameter b is upper-bounded by $O(\log N/\log b)$.

In the complexity estimate of Lemma 13, the sum of all $\mathsf{M}_{\mathrm{int}}(\log N)\log b \log\log N$ terms is bounded by a polynomial in $(\log N)$, so its contribution in the total runtime is negligible. We are thus left with the problem of evaluating the following quantity:

$$\sum_{i=1}^{\lceil(\log N)/2\rceil} \frac{\log N}{\log(2^i)} \mathsf{M}_{\mathrm{int}}(2^{i/2}\log N) \leq \mathsf{M}_{\mathrm{int}}\left(\log N \sum_{i=1}^{\lceil(\log N)/2\rceil} \left\lceil \frac{\log N}{i} \right\rceil 2^{i/2}\right),$$

where the upper bound follows from the first assumption of (2). Then, the sum is upper-bounded by a constant times $N^{1/4}$, giving the runtime of Theorem 11.

6. Computing one term in a linear recurrence. We now address the following problem: given an $n \times n$ matrix $M(X)$ with entries in $R[X]$, all of them of degree at most 1, and a vector of initial conditions U_0, define the sequence (U_i) of elements in R^n by the linear recurrence

$$U_{i+1} = M(i+1)U_i \text{ for all } i \geq 0.$$

Our question is to compute the vector U_N for some $N \in \mathbb{N}$. In the introduction, we gave the complexity of Chudnovsky and Chudnovsky's algorithm for this task. Our modification is similar to the one for integer factorization in the previous section.

THEOREM 14. *Let N be a positive integer and $s = \lfloor \log_4 N \rfloor$, such that $2, \ldots, 2^s+1$ are units in R. Given the inverses of $\mathsf{D}(1, 2^t, 2^t)$, $t \leq s$, U_N can be computed in*

$$O\big(\mathsf{MM}(n)\sqrt{N} + n^2\,\mathsf{M}(\sqrt{N})\big)$$

operations, in space $O(n^2\sqrt{N})$. If R is effective, then the bit complexity is

$$O\big(\mathsf{MM}_R(n)\sqrt{N} + n^2\mathsf{M}_R(\sqrt{N}) + n^2\ell\sqrt{N}\min(\log N, \log n)\big),$$

using $O(n^2\ell\sqrt{N} + \mathsf{SM}_R(n) + \mathsf{S}_R(\sqrt{N}))$ bits.

Proof. The proof is divided into two steps. We begin by proving the assertion in the particular case when N is a power of 4; then we treat the general case. Dealing with powers of 4 makes it possible to control the list of elements that need to be units.

- *The case when N is a power of 4.* Let us suppose that $k = 2^s$ and $N = k^2$, so that $N = 4^s$. Let $M_k(X)$ be the $n \times n$ matrix over $R[X]$ defined by

  $$M_k(X) = M(X+k)\cdots M(X+1);$$

  then, the requested output U_N can be obtained by the equation

  $$U_N = M_k(k(k-1))\cdots M_k(k)\,M_k(0)\,U_0. \tag{5}$$

Taking $\alpha = 1$ and $\beta = k = 2^s$, Lemma 7 shows that condition $\mathsf{H}(1, 2^s, 2^s)$ of Theorem 8 is satisfied. Thus, $M_k(0), M_k(k), \ldots, M_k((k-1)k)$ can be computed within the required time and space complexities. Then, by formula (5), the result is obtained by performing $\sqrt{N}$ successive matrix-vector products, which has a cost in both time and space of $O(n^2\sqrt{N})$. There is no additional complication in the Turing model, since in the row-major representation of matrices, matrix-vector products do not involve expensive tape movements.

- *The general case.* Let $N = \sum_{i=0}^{s} N_i 4^i$ be the 4-adic expansion of N, with $N_i \in \{0, 1, 2, 3\}$ for all i. Given any $t \geq 0$, we will denote by $\lceil N \rceil^t$ the integer $\sum_{i=0}^{t-1} 4^i N_i$. Using this notation, we define a sequence $(V_t)_{0 \leq t \leq s}$ as follows: We let $V_0 = U_0$ and, for $0 \leq t \leq s$ we set

$$\begin{aligned} &V_{t+1} = M(\lceil N \rceil^t + 4^t N_t) \cdots M(\lceil N \rceil^t + 1) V_t \quad \text{if } N_t \in \{1, 2, 3\}, \\ &V_{t+1} = V_t \quad \text{if } N_t = 0. \end{aligned} \tag{6}$$

One checks that $V_t = U_{\lceil N \rceil^t}$ for all t, and in particular that $V_{s+1} = U_N$. We will compute all V_t successively. Suppose thus that the term V_t is known. If N_t is zero, we have nothing to do. Otherwise, we let $V_{t+1}^{(0)} = V_t$, and, for $1 \leq j \leq N_t$, we let

$$M^{(j)}(X) = M\left(X + \lceil N \rceil^t + 4^t(j-1)\right).$$

Then we define $V_{t+1}^{(j)}$ by

$$V_{t+1}^{(j)} = M^{(j)}(4^t) \cdots M^{(j)}(1) V_{t+1}^{(j-1)}, \quad j = 1, \ldots, N_t.$$

By (6), we have $V_{t+1}^{(N_t)} = V_{t+1}$. Thus, passing from V_t to V_{t+1} amounts to computing N_t selected terms of a linear recurrence of the special form treated in the previous case, for indices of the form $4^t \leq 4^s$. With all necessary assumptions being satisfied, using the complexity result therein and the fact that all N_t are bounded by 3 we see that the total cost of the general case is thus

$$O\left(\sum_{t=0}^{s} \left(\mathsf{MM}(n) 2^t + n^2\, \mathsf{M}(2^t)\right)\right) = O\left(\mathsf{MM}(n) 2^s + n^2 \left(\sum_{t=0}^{s} \mathsf{M}(2^t)\right)\right).$$

Using the fact that $2^s \leq \sqrt{N} \leq 2^{s+1}$ and the assumptions on the function M, we easily deduce that the whole complexity fits into the bound $O\big(\mathsf{MM}(n)\sqrt{N} + n^2\, \mathsf{M}\big(\sqrt{N}\big)\big)$, and the bound concerning the memory requirements follows. As before, porting this algorithm on a Turing machine does not raise any difficulty. □

7. Computing several terms in a linear recurrence. We now study the case when several terms in a linear recurrence are questioned; this will be applied in the next section for the computation of the Cartier–Manin operator. We use the same notation as before: $M(X)$ is an $n \times n$ matrix whose entries are degree 1 polynomials over a ring R; we consider the sequence (U_i) defined for all $i \geq 0$ by $U_{i+1} = M(i+1)U_i$, and let U_0 be a vector in R^n. Given r indices $N_1 < N_2 < \cdots < N_r$, we want to compute all the values $U_{N_i}, 1 \leq i \leq r$.

An obvious solution is to repeatedly apply Theorem 14 to each interval $[N_i, N_{i-1}]$, leading to a time complexity of

$$O\left(\mathsf{MM}(n)\sum_{i=1}^{r}\sqrt{N_i - N_{i-1}} + n^2\sum_{i=1}^{r}\mathsf{M}\left(\sqrt{N_i - N_{i-1}}\right)\right)$$

and with a memory requirement of $O(n^2 \max_{i=1}^{r}\sqrt{N_i - N_{i-1}})$, where we have set $N_0 = 0$. In special cases, this might be close to optimal, for instance if $N_1, \ldots, N_{r-1}$ are small compared to N_r. However, in most cases it is possible to improve on this: we now present an alternative algorithm, which improves on the time complexity, at the cost, however, of increased memory requirements.

THEOREM 15. *Let $N_1 < N_2 < \cdots < N_r = N$ be positive integers. Suppose that $2, \ldots, 2^s + 1$ are units in R, where $s = \lfloor \log_4 N \rfloor$, and that the inverse of $\mathsf{D}(1, 2^s, 2^s)$ is known. Suppose also that $r < N^{\frac{1}{2}-\varepsilon}$, with $0 < \varepsilon < \frac{1}{2}$. Then $U_{N_1}, \ldots, U_{N_r}$ can be computed within*

$$O\big(\mathsf{MM}(n)\sqrt{N} + n^2\mathsf{M}(\sqrt{N})\big)$$

ring operations in space $O(n^2\sqrt{N})$. If R is effective, the bit complexity is in

$$O\big(\mathsf{MM}_R(n)\sqrt{N} + n^2\mathsf{M}_R(\sqrt{N}) + n^2\ell\sqrt{N}\min(\log N, \log n)\big),$$

and the space complexity is $O(n^2\ell\sqrt{N} + \mathsf{SM}_R(n) + \mathsf{S}_R(\sqrt{N}))$ bits.

In other words, the complexity of computing several terms is essentially the same as that of computing the one of largest index, as long as the total number of terms to compute is not too large. If the N_i form an arithmetic progression, and if the multiplication function M is essentially linear, we gain a factor of $\sqrt{r}$ compared to the naive approach. In the limiting case, where $r = \sqrt{N}$, and for fixed size n, our algorithm is optimal up to logarithmic factors, as it takes a time essentially linear in the size of the output.

Proof. The algorithm proceeds as follows: we start by applying Theorem 8 with $k \approx \sqrt{N}$, so as to compute k terms in the sequence with indices separated by intervals of size about $\sqrt{N}$. If all indices N_i have been reached, then we are done. Otherwise, we have reached r indices that are within a distance of about $\sqrt{N}$ of $N_1, \ldots, N_r$. A recursive refining procedure is then done simultaneously for all these r indices. When we get close enough to the wanted indices, we finish with a divide-and-conquer method. The refining and the final steps make use of Corollary 10.

We now describe more precisely the first step (named Step 0), the ith refining step, and the final step. In what follows, given $k \in \mathbb{N}$, we denote by $M_k(X)$ the polynomial matrix $M_k(X) = M(X + k) \cdots M(X + 1)$.

Step 0. Let $k_0 = 2^s$. As a preliminary, from the inverse of $\mathsf{D}(1, 2^s, 2^s)$, we deduce using Lemma 1 the inverses of all integers $1, \ldots, k_0$ in R. This will be used later on.

Define $N_j^{(0)} = k_0\lfloor \frac{N_j}{k_0} \rfloor$ for $j \le r$, so that $N_j^{(0)} \le N_j < N_j^{(0)} + k_0$. Step 0 consists of computing $U_{N_1^{(0)}}, \ldots, U_{N_r^{(0)}}$. This is done by computing all vectors $U_{k_0}, U_{2k_0}, \ldots, U_{4k_0^2}$; this sequence contains all requested vectors, since all wanted indices are multiples of k_0 and upper-bounded by $4k_0^2$. Lemma 7 shows that the assumptions of Theorem 8 with $\alpha = 1$ and $\beta = k = k_0$ are satisfied. We use it to compute the matrices

$$M_{k_0}(0), M_{k_0}(k_0), \ldots, M_{k_0}((k_0 - 1)k_0);$$

the vector U_0 is then successively multiplied by these matrices, yielding the vectors $U_{k_0}, U_{2k_0}, \dots, U_{k_0^2}$. To complete the sequence, we repeat three times the same strategy, starting with $V_0 = U_{k_0^2}$ and shifting the matrix $M(X)$ accordingly. Among all the resulting vectors, we collect the requested values $U_{N_1^{(0)}}, \dots, U_{N_r^{(0)}}$.

Step i. We assume that after step $(i-1)$, we are given an integer k_{i-1} and indices $N_j^{(i-1)}$, where for all $j \le r$, we have $N_j^{(i-1)} \le N_j < N_j^{(i-1)} + k_{i-1}$. We also suppose that $U_{N_1^{(i-1)}}, \dots, U_{N_r^{(i-1)}}$ are known. In other words, we know r vectors whose indices are within a distance of k_{i-1} of the wanted ones. Then, the ith refining step is as follows. Set

$$k_i = \left\lceil \sqrt{r k_{i-1}} \right\rceil;$$

then the new terms that we want to compute correspond to the indices

$$N_1^{(i)} = N_1^{(i-1)} + k_i \left\lfloor \frac{N_1 - N_1^{(i-1)}}{k_i} \right\rfloor, \dots, N_r^{(i)} = N_r^{(i-1)} + k_i \left\lfloor \frac{N_r - N_r^{(i-1)}}{k_i} \right\rfloor,$$

which satisfies the induction assumption for entering step $(i+1)$. To compute these values, we evaluate the new polynomial matrix $M_{k_i}(X)$ at the points

$$\begin{aligned}
\mathbf{N}_1^{(i)} &= \left\{ N_1^{(i-1)},\ N_1^{(i-1)} + k_i, \dots, N_1^{(i-1)} + \left(\left\lfloor \frac{k_{i-1}}{k_i} \right\rfloor - 1 \right) k_i \right\} \\
&\ \ \vdots \qquad\qquad\qquad\qquad \vdots \\
\mathbf{N}_r^{(i)} &= \left\{ N_r^{(i-1)},\ N_r^{(i-1)} + k_i, \dots, N_r^{(i-1)} + \left(\left\lfloor \frac{k_{i-1}}{k_i} \right\rfloor - 1 \right) k_i \right\}.
\end{aligned}$$

There are $r\lfloor \frac{k_{i-1}}{k_i} \rfloor \le k_i$ points of evaluation. We have already computed the inverses of $1, \dots, k_0$ in R; in particular, we know the inverses of $1, \dots, k_i$, so Corollary 10 can be applied to perform the evaluation. Then, for all $j \le r$, we successively multiply $U_{N_j^{(i-1)}}$ by the values taken by $M_{k_i}(X)$ at all indices in $\mathbf{N}_j^{(i)}$. By construction, $N_j^{(i)} - k_i$ belongs to $\mathbf{N}_j^{(i)}$, so we obtain in particular the requested value $U_{N_j^{(i)}}$.

Final step. The refining process stops when k_i is close to r, namely $k_i \le 2r$. In this situation, we have at our disposal r indices $N_1', \dots, N_r'$ such that $N_j' \le N_j < N_j' + 2r$ for all j, and such that all values $U_{N_1'}, \dots, U_{N_r'}$ are known. Then another recursive algorithm is used: $M_r(X)$ is computed, evaluated at all N_j' using Corollary 10, and used to reduce all gaps that were of size between r and $2r$; again, the invertibility conditions cause no problem. As a result, all the gaps are now of size at most r. Then $M_{\frac{r}{2}}(X)$ is computed and used to reduce the gaps to at most $\frac{r}{2}$, and so on until we get the result.

It remains to perform the complexity analysis. The cost of Step 0 is dominated by that of evaluating the matrix $M_{k_0}(X)$; by Theorem 8, it can be done in

$$O\big(\mathsf{MM}(n)\sqrt{N} + n^2 \mathsf{M}(\sqrt{N})\big)$$

operations in R, and space $O(n^2\sqrt{N})$. By Corollary 10, the ith refining step has a cost of

$$O\left(\mathsf{MM}(n) k_i + n^2 \mathsf{M}(k_i) \log k_i\right)$$

operations, and requires $O(n^2 k_i + k_i \log k_i)$ temporary memory allocation; the total cost of this phase is thus

$$O\left(\sum_{i=1}^{i_{\max}} \mathsf{MM}(n)k_i + n^2\mathsf{M}(k_i)\log k_i\right),$$

where $i_{\max}$ is the number of refining steps. Our hypotheses on the function M show that this fits into the bound

$$O\left(\mathsf{MM}(n)\sum_{i=1}^{i_{\max}} k_i + n^2\mathsf{M}\left(\sum_{i=1}^{i_{\max}} k_i\right)\log\left(\sum_{i=1}^{i_{\max}} k_i\right)\right).$$

An easy induction shows that k_i is at most $(4r)^{\frac{2^i-1}{2^i}} N^{\frac{1}{2^{i+1}}}$, whence $i_{\max} = O(\log\log N)$. Furthermore, using $r < N^{\frac{1}{2}-\varepsilon}$, we get

$$k_i \le 4N^{\frac{1}{2}}\left(N^{-\varepsilon}\right)^{\frac{2^i-1}{2^i}}.$$

For any $0 < \ell \le 1$ we have $\sum_{i=1}^{i_{\max}} \ell^{\frac{2^i-1}{2^i}} \le i_{\max}\ell^{\frac{1}{2}}$; therefore we deduce

$$\sum_{i=1}^{i_{\max}} k_i = O\big(N^{\frac{1-\varepsilon}{2}}\log\log N\big).$$

Using the second assumption in (2), the cost of the refining steps is negligible compared with that of the first step, since the $N^{-\varepsilon/2}$ compensates for all logarithmic factors. The memory requirement also is negligible compared with that of Step 0.

Using Corollary 10, the cost of the first reduction in the final step is

$$O\left(\mathsf{MM}(n)r + n^2\mathsf{M}(r)\log r\right)$$

ring operations and $O(n^2 r + r\log r)$ temporary space. Due to our hypotheses on the function M, the second reduction costs at most half as much, the third reduction costs at most $\frac{1}{4}$ of it, etc. Summing up, we see that the whole cost of the final step is bounded by twice that of the first reduction, which is itself less than the cost of Step 0.

There is no complication in the Turing model. Indeed, between the calls to Theorem 8, to Corollary 10, and the successive matrix-vector products, there is no need to reorganize data, so the tape movements' cost is negligible. Furthermore, our assumptions on M_R and S_R imply that, as in the arithmetic model, the time and space costs of Step 0 are predominant. □

8. Application to the Cartier–Manin operator. Let $\mathcal{C}$ be a hyperelliptic curve of genus g defined over the finite field $\mathbb{F}_{p^d}$ with p^d elements, where $p > 2$ is prime. We suppose that the equation of $\mathcal{C}$ is of the form $y^2 = f(x)$, where f is monic and square free, of degree $2g+1$. The generalization to hyperelliptic curves of the Hasse invariant for elliptic curves is the Hasse–Witt matrix [21]: Let h_k be the coefficient of degree x^k in the polynomial $f^{(p-1)/2}$. The Hasse–Witt matrix is the $g \times g$ matrix with coefficients in $\mathbb{F}_{p^d}$ given by $H = (h_{ip-j})_{1\le i,j\le g}$. It represents, in a suitable basis, the operator on differential forms introduced by Cartier [10]; Manin [28] showed that this matrix is strongly related to the action of the Frobenius endomorphism on

the p-torsion part of the Jacobian of $\mathcal{C}$. The article [50] provides a complete survey about these facts; they are summarized in the following theorem.

THEOREM 16 (Manin). *Let $H_\pi = HH^{(p)} \cdots H^{(p^{d-1})}$, where the notation $H^{(q)}$ means elementwise raising to the power q. Let $\kappa(t)$ be the characteristic polynomial of the matrix H_π and $\chi(t)$ the characteristic polynomial of the Frobenius endomorphism of the Jacobian of $\mathcal{C}$. Then $\chi(t) \equiv (-1)^g t^g \kappa(t) \bmod p$.*

This result provides a method to compute the characteristic polynomial of the Frobenius endomorphism. As such, it can be used in a point-counting algorithm, which is the main application we have in mind; see the end of this section for more comments.

To compute the entries of the Hasse–Witt matrix, the obvious solution consists of expanding the product $f^{(p-1)/2}$. Using binary powering, this can be done in $O(\mathsf{M}(gp))$ base ring operations, whence a time complexity that is essentially linear in p, if g is kept constant. In what follows, we show how to obtain a complexity essentially linear in $\sqrt{p}$ using the results of the previous sections. We will make the additional assumption that the constant term of f is not zero; otherwise, the problem is actually simpler.

Introduction of a linear recurrent sequence. In [14], Flajolet and Salvy already treated the question of computing a selected coefficient in a high power of some given polynomial, as an answer to a SIGSAM challenge. The key point of their approach is that $h = f^{(p-1)/2}$ satisfies the following first-order linear differential equation

$$fh' - \frac{p-1}{2} f'h = 0.$$

This shows that coefficients of h satisfy a linear recurrence of order $2g+1$, with polynomial coefficients of degree 1. Explicitly, denote by h_k the coefficient of degree k of h, and for convenience, set $h_k = 0$ for $k < 0$. Similarly, the coefficient of degree k of f is denoted by f_k. Then the differential equation above implies that, for all k in $\mathbb{Z}$,

$$(k+1)f_0 h_{k+1} + \left(k - \frac{p-1}{2}\right) f_1 h_k + \cdots + \left(k - 2g - \frac{(2g+1)(p-1)}{2}\right) f_{2g+1} h_{k-2g} = 0.$$

We set $U_k = [h_{k-2g}, h_{k-2g+1}, \ldots, h_k]^t$, and let $A(k)$ be the companion matrix:

$$A(k) = \begin{pmatrix} 0 & 1 & 0 & \cdots & 0 \\ 0 & 0 & 1 & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \ddots & 1 \\ \frac{f_{2g+1}((2g+1)(p-1)/2-(k-2g-1))}{f_0 k} & \cdots & \cdots & \cdots & \frac{f_1((p-1)/2-k+1)}{f_0 k} \end{pmatrix}.$$

The initial vector $U_0 = [0, \ldots, 0, f_0^{(p-1)/2}]^t$ can be computed using binary powering techniques in $O(\log p)$ operations; then for $k \geq 0$, we have $U_{k+1} = A(k+1)U_k$. Thus, to answer our specific question, it suffices to note that the vector U_{ip-1} gives the coefficients h_{ip-j} for $j = 1, \ldots, g$ that form the ith row of the Hasse–Witt matrix of $\mathcal{C}$.

Theorems 14 and 15 cannot be directly applied to this sequence, because $A(k)$ has entries that are rational functions, not polynomials. Though the algorithm could be adapted to handle the case of rational functions, we rather use the very specific form of the matrix $A(k)$, so only a small modification is necessary. Let us define a new

sequence V_k by $V_k = f_0^k k! U_k$. Then, this sequence is linearly generated and we have $V_{k+1} = B(k+1)V_k$, where $B(k) = f_0 k A(k)$. Therefore, the entries of the matrix $B(k)$ are polynomials of degree at most 1. Note also that the denominators $f_0^k k!$ satisfy the recurrence relation $f_0^{k+1}(k+1)! = (f_0(k+1)) \cdot (f_0^k k!)$.

We can apply the results of the previous sections to compute separately the required vectors V_k, as well as the corresponding denominators: specifically, we will compute $V_{p-1}, V_{2p-1}, \ldots, V_{gp-1}$ as well as $f_0^{p-1}(p-1)!, \ldots, f_0^{gp-1}(gp-1)!$. Then the vectors $U_{p-1}, U_{2p-1}, \ldots, U_{gp-1}$ are deduced using the relation $f_0^k k!\, U_k = V_k$.

Lifting to characteristic zero. A difficulty arises from the fact that the characteristic is too small compared to the degrees we are aiming for, so $p!$ is zero in $\mathbb{F}_{p^d}$. The workaround is to do computations in the unramified extension K of $\mathbb{Q}_p$ of degree d, whose residual field is $\mathbb{F}_{p^d}$. The ring of integers of K will be denoted by $\mathcal{O}_K$, so that any element of $\mathcal{O}_K$ can be reduced modulo p to give an element of $\mathbb{F}_{p^d}$. On the other hand, K has characteristic 0, so p is invertible in K.

We consider an arbitrary lift of f to $\mathcal{O}_K[X]$. The reformulation in terms of linear recurrent sequence made in the paragraph above can be performed over K; the coefficients of $f^{(p-1)/2}$ are computed as elements of K and then projected back onto $\mathbb{F}_{p^d}$. This is possible, as they all belong to $\mathcal{O}_K$. We separately compute the values in K of the vectors V_{ip-1} and the denominators $f_0^{ip-1}(ip-1)!$, for $i = 1, \ldots, g$. To this effect, we can apply any of the strategies mentioned in section 7.

The first one is the plain iteration based on Theorem 14; iterating g times, it performs $O\left(\mathsf{MM}(g) g\sqrt{p} + g^3 \mathsf{M}(\sqrt{p})\right)$ operations in K and requires storing $O(g^2\sqrt{p})$ elements. The second strategy is to apply Theorem 15. In this case, we need to have $g \leq (gp)^{1/2-\varepsilon'}$, for some $0 < \varepsilon' < \frac{1}{2}$; this is equivalent to imposing that $g \leq p^{1-\varepsilon}$ for some $0 < \varepsilon < 1$. Then, with increased memory requirements of $O(g^2\sqrt{gp})$, the number of operations in K reduces to $O\left(\mathsf{MM}(g)\sqrt{gp} + g^2 \mathsf{M}(\sqrt{gp})\right)$.

Computing at fixed precision. We do not want to compute in K at arbitrary precision, since this is not an effective ring (even in a much weaker sense than the one we defined). For our purposes, it suffices to truncate all computations modulo a suitable power of p. To evaluate the required precision of the computation, we need to check when the algorithm operates a division by p.

To compute the vectors V_{ip-1} and the denominators $f_0^{ip-1}(ip-1)!$, for $i = 1, \ldots, g$, we use either Theorem 14 or Theorem 15. In the worst case, it might be required to invert all integers up to $\sqrt{gp}$. With the condition $g \leq p^{1-\varepsilon}$, these numbers are strictly smaller than p, and they are thus units in $\mathcal{O}_K$. Hence no division by p occurs in this first phase. Then, for all $i = 1, \ldots, g$, to deduce U_{ip-1} from V_{ip-1}, we need to divide by $f_0^{ip-1}(ip-1)!$. The element f_0 is a unit in $\mathcal{O}_K$, so the only problem comes from the factorial. If $i < p$, then the p-adic valuation of $(ip-1)!$ is exactly $i-1$. Therefore the worst case is $i = g$, for which we have to divide by p^{g-1}. Hence computing the vectors V_{ip-1} modulo p^g is enough to know the vectors U_{ip-1} modulo p, and then to deduce the Hasse–Witt matrix.

Overall complexity. Since the ring $R = \mathcal{O}_K/p^g\mathcal{O}_K$ is isomorphic to $(\mathbb{Z}/p^g\mathbb{Z})[X]/P$ for some monic polynomial P of degree d, Lemma 3 shows that R is an effective ring with

- $\ell = d\lceil g \log p \rceil$,
- $\mathsf{m}_R \in O(\mathsf{M}_{\mathrm{int}}(dg \log(dp)))$ and $\mathsf{s}_R \in O(dg \log(dp))$,
- $\mathsf{M}_R(k) \in O(\mathsf{M}_{\mathrm{int}}(dkg \log(dkp)))$ and $\mathsf{S}_R(k) \in O(dkg \log(dkp))$,
- $\mathsf{MM}_R(n) \in O(n^{\log 7} \mathsf{m}_R)$ and $\mathsf{SM}_R(n) \in O(n^2\ell + \mathsf{s}_R)$.

From the results of sections 6 and 7, we deduce the following theorem on the complexity of computing the Hasse–Witt matrix. We give two variants that follow the two strategies described above. The first one follows from applying g times Theorem 14 with $n = 2g+1, N = p, \ell = d\lceil g \log p \rceil$; the second one come from applying Theorem 15 with $n = 2g+1, N = gp, \ell = d\lceil g \log p \rceil$. Both theorems require us to compute the inverses of some integers in R as prerequisites; the cost of their computation is negligible.

THEOREM 17. *Let $p > 2$ be a prime, $d \geq 0$, and $\mathcal{C}$ be a hyperelliptic curve defined over $\mathbb{F}_{p^d}$ by the equation $y^2 = f(x)$, with f of degree $2g+1$. Assuming $g < p^{1-\varepsilon}$ for some $0 < \varepsilon < 1$, one can compute the Hasse–Witt matrix of $\mathcal{C}$ using one of the two following strategies:*

1. *A memory-efficient strategy gives a complexity of*

$$O\left(g^{1+\log 7} p^{\frac{1}{2}} \mathsf{M}_{\mathrm{int}}(dg \log(dp)) + g^3 \mathsf{M}_{\mathrm{int}}(dgp^{\frac{1}{2}} \log(dp)) + dg^4 p^{\frac{1}{2}} \log g \log p\right)$$

   bit operations and $O(dg^3 p^{\frac{1}{2}} \log p + dgp^{\frac{1}{2}} \log d)$ storage.
2. *A time-efficient strategy gives a complexity of*

$$O\left(g^{\frac{1}{2}+\log 7} p^{\frac{1}{2}} \mathsf{M}_{\mathrm{int}}(dg \log(dp)) + g^2 \mathsf{M}_{\mathrm{int}}(dg^{\frac{3}{2}} p^{\frac{1}{2}} \log(dgp)) + dg^{\frac{7}{2}} p^{\frac{1}{2}} \log g \log p\right)$$

   bit operations, with $O(dg^{\frac{7}{2}} p^{\frac{1}{2}} \log p + dg^{\frac{3}{2}} p^{\frac{1}{2}} \log d)$ storage.

The matrix H already gives information on the curve $\mathcal{C}$: for instance, H is invertible if and only if the Jacobian of $\mathcal{C}$ is ordinary [50, Corollary 2.3]. However, as stated in Theorem 16, the matrix H_π, and in particular its characteristic polynomial κ, tells much more and is required if the final goal is point-counting.

From now on, all operations are done in the effective ring $R' = \mathbb{F}_{p^d}$; hence the cost of the basic operations becomes $\mathsf{m}_{R'} \in O(\mathsf{M}_{\mathrm{int}}(d \log(dp)))$ and $\mathsf{s}_{R'} \in O(d \log(dp))$. The matrix H_π is the "norm" of H and as such can be computed with a binary powering algorithm. For simplicity, we assume that d is a power of 2; then, denoting

$$H_{\pi,i} = H H^{(p)} \cdots H^{(p^{2^i-1})},$$

we have

$$H_{\pi,i+1} = H_{\pi,i} \cdot (H_{\pi,i})^{(p^{2^i})}.$$

Hence computing $H_{\pi,i+1}$ from $H_{\pi,i}$ costs one matrix multiplication and 2^i matrix conjugations. A matrix conjugation consists of raising all the entries to the power p; therefore it costs $O(g^2 \mathsf{M}_{\mathrm{int}}(d \log(dp)) \log p)$ bit operations. The matrix we need to compute is $H_\pi = H_{\pi, \log d}$. Hence the cost of computing H_π is

$$O\left(\left(dg^2 \log p + g^{\log 7} \log d\right) \mathsf{M}_{\mathrm{int}}(d \log(dp))\right)$$

bit operations. The general case, where d is not a power of 2, is handled by adjusting the recursive step according to the binary expansion of d and yields the same complexity up to a constant factor.

The cost of the characteristic polynomial computation of an $n \times n$ matrix defined over an effective ring can be bounded by $O(n^4)$ operations in the ring using a sequential version of Berkowitz's algorithm [1]. This adds a negligible $O(g^4 \mathsf{M}_{\mathrm{int}}(d \log(dp)))$ contribution to the complexity.

If we are interested only in the complexity in p and d, i.e., if we assume that the genus is fixed, then the two strategies of Theorem 17 become equivalent, up to constant factors. Then, to summarize, the reduction modulo p of the characteristic polynomial χ of the Frobenius endomorphism can be computed in time

$$O\big(\mathsf{M}_{\mathrm{int}}(dp^{\frac{1}{2}}\log(dp)) + d\log p\,\mathsf{M}_{\mathrm{int}}(d\log(dp))\big)$$

bit operations and $O(dp^{\frac{1}{2}}\log(dp))$ storage.

Case of large genus. If $g \geq p$, then our analysis is no longer valid. In this paragraph, we assume that the function $\mathsf{M}_{\mathrm{int}}$ is essentially linear, i.e., we do not count logarithmic factors. Then the cost of strategy 1 of Theorem 17 is of order $dg^4p^{\frac{1}{2}}$ bit operations, the cost of strategy 2 is of order $dg^{\frac{7}{2}}p^{\frac{1}{2}}$, and that of the naive algorithm is in $O(dgp)$.

It turns out that for $p^{1/6} < g < p^{1-\varepsilon}$, the algorithms of Theorems 14 and 15 are not the fastest. Assume that $g > p^{1/6}$. Then it follows that $g^4p^{\frac{1}{2}} > gp$, and therefore the naive algorithm is faster than strategy 1 of Theorem 17. If further $g > p^{1/5}$, then $g^{\frac{7}{2}}p^{\frac{1}{2}} > gp$, and the naive algorithm is also faster than strategy 2. Thus, whatever the strategy used in Theorem 17, the parameter range for which our algorithms are interesting is far from the limit induced by the technical condition $g < p^{1-\varepsilon}$.

Combination with other point-counting algorithms. Computing the characteristic polynomial of H_π is not enough to deduce the group order of the Jacobian of $\mathcal{C}$, since only $\chi \bmod p$ is computed. We now survey different ways to complete the computation; we give rough complexity estimates, neglecting the logarithmic factors.

If p is small compared to g or d, p-adic algorithms [24, 37] have the best asymptotic complexity. These algorithms compute χ modulo high powers of p, so they necessarily recompute the information that has been obtained via the Cartier–Manin operator. Hence, our approach is of no interest here.

Consider next the extensions of Schoof's algorithm [34]. These algorithms have a complexity that is polynomial in $d\log p$ and exponential in g. For fixed g, our algorithm will be faster only if p is small compared to d, so that the power of d in the complexity of Schoof's algorithm can compensate the $\sqrt{p}$ complexity of our method. But in that case, our algorithm gives only very small information, and therefore the overall complexity of point counting is unchanged.

The combination with approaches based on the baby steps/giant steps algorithm (or low memory variants) is more fruitful, and can be of practical interest. Indeed, as far as we know, there is no implementation of any Schoof-like approach for genus greater than 2, and even for genus 2, the current record computations [19, 29] are obtained by combining many methods, including the baby steps/giant steps approach. Here is thus a short description of known approaches using BSGS ideas:

1. *BSGS method*: This is the generic method for finding the order of a group. If the order is known to be in an interval of width w, then the complexity is in $O(\sqrt{w})$. In the case of the Jacobian of $\mathcal{C}$, Hasse–Weil bounds give $w = O(p^{d(g-\frac{1}{2})})$, so the complexity is in $O(p^{d(\frac{g}{2}-\frac{1}{4})})$.
2. Computing the number of points of $\mathcal{C}$ in small degree extensions of $\mathbb{F}_{p^d}$ reduces the width of the search interval. Counting (naively) the points of $\mathcal{C}$ up to extension degree k costs $O(p^{dk})$, and the cost of the BSGS algorithm becomes $O(q^{d(\frac{g}{2}-\frac{k+1}{4})})$. This method (and additional practical improvements) is from [45]. We call it "approximation method" below.
3. When χ is known modulo some integer M, the group order is also known modulo M and therefore the BSGS method can be sped up by a factor of

$\sqrt{M}$. In [29] it is shown that in some cases a full factor M can be gained by doing a BSGS search on the coefficients of χ instead of just the group order. We abbreviate this method as MCT (from the names of the authors).

Thus, in genus 2, the complexity of the BSGS algorithm is in $O(p^{\frac{3d}{4}})$. For prime fields, our $O(p^{\frac{1}{2}})$ method is faster and gives essentially the complete information. For extension fields, our method gives the characteristic polynomial modulo p at a cost of $O(p^{\frac{1}{2}})$, from which we can recover the whole characteristic polynomial using the MCT algorithm at a cost of $O(p^{\frac{3d}{4}-1})$. Thus, for $d = 2$, the complexity is improved from $O(p^{\frac{3}{2}})$ to $O(p^{\frac{1}{2}})$, and for $d = 3$, from $O(p^{\frac{9}{4}})$ to $O(p^{\frac{5}{4}})$.

In genus 3, using the approximation method with $k = 1$ yields a complexity in $O(p^d)$. For prime fields, our method yields most of the information, the remaining part being computable using BSGS in time $O(p^{\frac{1}{4}})$. Hence, the cost drops from $O(p)$ to $O(p^{\frac{1}{2}})$; this is of practical interest, since the $O(p)$ algorithm is currently used for genus 3 point-counting over prime fields. For extension fields, the complexity drops from $O(p^d)$ to $O(p^{d-\frac{1}{2}})$.

The complexities for small degrees and genera are summarized in the following table. For each parameter set (g, d), there are two columns: the left-hand column describes the previously best known combination of methods; the right-hand one gives the new best combination with our algorithm (written "CM"). In each column we put an X in front of the algorithms that are used in the combination, and at the bottom list the total complexity.

	$g=2$						$g=3$					
	$d=1$		$d=2$		$d=3$		$d=1$		$d=2$		$d=3$	
BSGS	X		X		X		X	X	X	X	X	X
Approx.							X		X	X	X	X
MCT				X		X						
CM		X		X		X		X		X		X
Cplx.	$p^{3/4}$	$p^{1/2}$	$p^{3/2}$	$p^{1/2}$	$p^{9/4}$	$p^{5/4}$	p	$p^{1/2}$	p^2	$p^{3/2}$	p^3	$p^{5/2}$

Computer experiments. We have implemented our algorithm using Shoup's NTL C++ library [42]. NTL does not provide any arithmetic of local fields or rings, but allows one to work in finite extensions of rings of the form $\mathbb{Z}/p^g\mathbb{Z}$, as long as no divisions by p occur; the divisions by p are well isolated in the algorithm, so we could handle them separately. Furthermore, NTL multiplies polynomials defined over this kind of structure using an asymptotically fast FFT-based algorithm.

To illustrate that our method can be used as a tool in point-counting algorithms, we have computed the Zeta function of a (randomly chosen) genus 2 curve defined over $\mathbb{F}_{p^3}$, with $p = 2^{32} - 5$. Such a Jacobian has therefore about 2^{192} elements and should be suitable for cryptographic use if the group order has a large prime factor. Note that previous computations were limited to p of order 2^{23} [29].

The characteristic polynomial χ of the Frobenius endomorphism was computed modulo p in 3 hours and 41 minutes, using 1 GB of memory, on an AMD Athlon MP 2200+. Then we used the Schoof-like algorithms of [19] to compute χ modulo $128 \times 9 \times 5 \times 7$, and finally we used the modified BSGS algorithm of [29] to finish the computation. These other parts were implemented in Magma [5] and were performed in about 15 days of computation on an Alpha EV67 at 667 MHz. This computation was meant as an illustration of the possible use of our method, so little time was spent optimizing our code. In particular, the Schoof-like part and the final BSGS computations are done using a generic code that is not optimized for extension fields. Still, to our knowledge, on the same computers, such a computation would not have been possible with previous algorithms.

Appendix. Computations in the Turing model. In this appendix we discuss basic complexity results for polynomials and matrices over effective rings, in the multitape Turing machine model. We do not consider the operations used to control the computations, like incrementing an index in a loop: this is done on separate tapes, and the corresponding cost is negligible.

Proof of Lemma 3. Let $N \in \mathbb{N}$, $R_0 = \mathbb{Z}/N\mathbb{Z}$, and $R = R_0[T]/P$, with $P \in R_0[T]$ monic of degree m. We show here how to make R an effective ring. Elements of R_0 will be represented as integers in $0, \ldots, N-1$, and elements of R as sequences of m elements of R_0; representing such an element requires $\ell = m\lceil \log N \rceil$ bits.

Polynomials in $R_0[T]$ are multiplied as polynomials in $\mathbb{Z}[T]$; then their coefficients are reduced modulo N. Using Kronecker's substitution [15, Corollary 8.27], the multiplication in degree d is done in time $\mathsf{M}_{\mathrm{int}}(d\log(dN))$ and space $O(d\log(dN))$; the subsequent reduction is done by fast integer Euclidean division, using Cook's algorithm [12], which adds a negligible cost. Using Cook's algorithm again, Euclidean division in degree d in $R_0[T]$ can be done in time $O(\mathsf{M}_{\mathrm{int}}(d\log(dN)))$ and space $O(d\log(dN))$. In particular, taking $d = m$, this establishes the bounds on m_R and s_R given in the lemma.

Polynomials in $R[X]$ are multiplied as polynomials in $\mathbb{Z}[T, X]$, and then reduced modulo N and P, where the product in $\mathbb{Z}[T, X]$ is reduced to an integer product by bivariate Kronecker's substitution. In degree d, this yields time and space complexities M_R and S_R of, respectively, $O(\mathsf{M}_{\mathrm{int}}(dm\log(dmN)))$ and $O(dm\log(dmN))$.

We finally discuss matrix multiplication, contenting ourselves with the description of Strassen's algorithm [46, 15] for matrices of size $n = 2^k$ (which is enough to establish our claim). Each step of the algorithm requires us to compute 14 linear combinations of the 4 quadrants of the input matrices before entering recursive calls; 4 linear combinations of the 7 subproducts are performed after the recursive calls.

At each step in the recursion, the data has to be reorganized. The row-major representation of each input matrix is replaced with the consecutive row-major representations of its four quadrants, from which the linear combinations can be performed; a similar unfolding is done after the recursive calls. Taking into account the cost of this reorganization does not alter the complexity of this algorithm. This yields estimates for MM_R and SM_R, respectively, in $O(n^{\log 7}\mathsf{m}_R)$ and $O(n^{\log 7}\ell + \mathsf{s}_R)$, the term s_R standing for temporary memory used for scalar multiplications.

Finally, checking all required conditions on m_R, s_R, M_R, S_R, MM_R, and SM_R is straightforward.

Proof of Lemma 4. Let now R be an effective ring, with elements represented on ℓ bits. We prove here the assertions in Lemma 4.

- Trading inverses for multiplications: proof of Lemma 4, item 1. We use the notation of the proof of Lemma 1. Looking at the proof, one sees that all quantities R_i can be computed and stored on a tape T_1 in a single forward sweep of the input $r_0, \ldots, r_d$; reading the input backward, we compute all S_i and store them on a tape T_2. Finally, the output values s_i are computed by a single forward sweep of T_1 and T_2. The time complexity is $O(d\mathsf{m}_R)$ for multiplications, plus $O(d\ell)$ for tape movements; hence it fits in $O(d\mathsf{m}_R)$. The space complexity is $O(d\ell)$ bits for storage, plus s_R temporary bits for multiplications.
- Computing constants: proof of Lemma 4, items 2 and 3. We apply the same formulas as in the proof of Lemma 2. The cost of all operations is in $O(d\mathsf{m}_R)$; it is easy to check that the tape movements contribute with a negligible $O(d\ell)$ cost. As above, the space complexity is $O(d\ell)$ bits for storage,

plus s_R temporary bits for multiplications.

- Evaluation and interpolation: proof of Lemma 4, items 4 and 5. Let $r_0, \dots, r_d$ be in R. For simplicity, we suppose that the number of points is a power of 2, that is, $d+1 = 2^k$; the general case is handled similarly and presents only notational difficulties. All algorithms below are classical [15, Chapter 10]; our focus is on their adaptation in the Turing model.

For $i \le d$, set $A_{i,k} = X - r_i \in R[X]$; then, for $0 \le j \le k-1$ and $0 \le i \le 2^j - 1$, set $A_{i,j} = A_{2i,j+1}A_{2i+1,j+1}$. These polynomials will be arranged in a "subproduct tree," where $A_{2i,j+1}$ and $A_{2i+1,j+1}$ are the children of $A_{i,j}$. We now show how to compute this tree, writing A_j for the sequence $A_{0,j}, \dots, A_{2^j-1,j}$. Note that the sum of the degrees of the polynomials in A_j is $d+1$.

Given the sequence A_j, one can compute the extended sequence A_j, A_{j-1} in $O(\mathsf{M}_R(d))$ bit operations and space $O(d\ell + \mathsf{S}_R(2^{k-j}))$. It suffices to read the input once and to compute on the fly the products $A_{2i,j}A_{2i+1,j}$, storing them on an auxiliary tape, before appending all results to the input; the cost estimate follows from the superadditivity of M_R. Applying this $k = \log d$ times, one can compute the sequences $A_k, \dots, A_0$ in time $O(\mathsf{M}_R(d)\log d)$ and space $O(\ell d \log d + \mathsf{S}_R(d))$.

The evaluation algorithm uses the subproduct tree as follows. Let $P = P_{0,0}$ be of degree at most d, and set $P_{2i,j+1} = P_{i,j} \bmod A_{2i,j+1}$ and $P_{2i+1,j+1} = P_{i,j} \bmod A_{2i+1,j+1}$, for $0 \le i \le 2^j - 1$ and $0 \le j \le k$. We write P_j for the sequence $P_{0,j}, \dots, P_{2^j-1,j}$.

On input the sequences P_j and A_{j+1}, given on two distinct tapes, one can compute P_j, P_{j+1} in $O(\mathsf{M}_R(d))$ bit operations and space $O(\ell d + \mathsf{S}_R(2^{k-j}))$: we read once the input sequences and compute on the fly the remainders $P_{2i,j+1}$ and $P_{2i+1,j+1}$, storing them on an auxiliary tape; then they are appended to the sequence P_j. The estimates for Euclidean division and the superadditivity property then give the complexity estimate. Applying this $k = \log d$ times, given P and the sequence $A_k, \dots, A_0$, one can compute all $P_{i,k} = P(r_i)$ in time $O(\mathsf{M}_R(d)\log d)$ and space $O(\ell d \log d + \mathsf{S}_R(d))$.

It remains to deal with interpolation. Difficulties come from the inversion of quantities associated with the sample points. We thus suppose that $a_i = i$ for all $i \le d$ (this is what is used in this article), that $2, \dots, d$ are units in R, and that their inverses are known. Interpolating a polynomial P at $0, \dots, d$ is done by computing $\sum_{i \le d} P_i \prod_{j \ne i}(X - j)$, where $P_i = P(i)/\delta(i,d)$. The inverses of all $\delta(i,d)$ can be computed in time $O(d\mathsf{m}_R)$, by Lemma 4, item 2. Then, from [15, Chapter 10], the sum can be computed "going up" the subproduct tree, just as evaluation amounts to "going down" the tree. One checks that as above, it can be performed in time $O(\mathsf{M}_R(d)\log d)$ and space $O(\ell d \log d + \mathsf{S}_R(d))$.

Matrix of vectors and vectors of matrices. Let R be an effective ring, with elements represented using ℓ bits. Two representations for matrices with vector entries are used in this paper:

1. the row-major representation, where each entry is a vector over R, say of size k;
2. the vector representation, through a sequence of k scalar matrices, each in row-major representation.

In the Turing model, we must take care of data contiguity. We now give an algorithm that converts efficiently from one representation to the other; we start with a lemma on matrix transposition.

LEMMA 18. *In row-major representation, the transpose of an $m \times n$ matrix A can be computed in bit complexity $O(\ell mn \min(\log m, \log n))$ and space $O(\ell mn)$.*

Proof. Suppose that $n \leq m$. We first copy A from the input tape to an auxiliary tape, and pad on the fly the end of each line with an arbitrary symbol to make the column dimension equal to a power of 2. Thus we obtain an $m \times n'$ matrix A', where n' is a power of 2; the cost is in $O(mn\ell)$. We describe now a recursive algorithm that transposes A'; the transpose of A can be deduced as the top-left $n \times m$ submatrix of the transpose of A', and it can be copied on the output tape at a cost of $O(mn\ell)$.

We are thus reduced to transposing an $m \times n$ matrix A with n a power of 2. First, note that if $n = 1$, then the representations of A and of its transpose are the same. For $n \geq 2$ we proceed as follows. Let A_1 be the submatrix of A formed of the $n/2$ first coefficients of each row and A_2 the submatrix of A formed of their $n/2$ last coefficients. Then, the row-major representation of the transpose of A is the row-major representation of the transpose of A_1 followed by the row-major representation of the transpose of A_2. Hence computing the transpose of A amounts to the following operations:

- Uninterleaving: put A_1 followed by A_2 on a tape in place of the original A, using a temporary auxiliary tape.
- Recursively call to replace A_1 by its transpose at the same place, using a temporary auxiliary tape, and do the same with A_2.

The number $T(m, n)$ of tape movements verifies an equation of the form

$$T(m, n) \leq \lambda \ell mn + 2T(m, n/2),$$

for some constant λ. Therefore the overall cost is $O(\ell mn \log n)$ and the number of cells visited on each tape is at most ℓmn. This concludes the proof in the case $n \leq m$.

In the case $m \leq n$, we use essentially the same recursive algorithm but with the matrix split in two blocks of complete rows. Hence the algorithm for size m decomposes in two recursive calls at size $m/2$ and one subsequent step of interleaving the resulting matrices. In this way the $\log n$ factor is replaced with $\log m$. ∎

COROLLARY 19. *Let M be an $n \times n$ matrix, with entries in R^k. Switching between the two possible representations of M has bit complexity in $O(\ell n^2 k \min(\log n, \log k))$ and space complexity in $O(\ell n^2 k)$.*

Proof. Let M be represented on tape as a matrix of vectors. We can see the data of this tape as the row-major representation of an $n^2 \times k$ matrix over R. Let us compute the transpose of this matrix using the algorithm of Lemma 18. We obtain the representation of a $k \times n^2$ matrix over R; for $i \leq k$, its ith entry is the row-major representation of the $n \times n$ matrix made of the ith entries of M. ∎

Acknowledgments. We thank Bruno Salvy for his comments on this paper, Joachim von zur Gathen and Jürgen Gerhard for answering our questions on the complexity of integer factorization, and the referees for their helpful comments.
