SCHEDULING SPLIT INTERVALS*

R. BAR-YEHUDA†, M. M. HALLDÓRSSON‡, J. (S.) NAOR†, H. SHACHNAI†, AND I. SHAPIRA†

Abstract. We consider the problem of scheduling jobs that are given as *groups* of nonintersecting segments on the real line. Each job J_j is associated with an interval, I_j, which consists of up to t segments, for some $t \geq 1$, and a weight (profit), w_j; two jobs are in conflict if their intervals intersect. Such jobs show up in a wide range of applications, including the transmission of continuous-media data, allocation of linear resources (e.g., bandwidth in linear processor arrays), and computational biology/geometry. The objective is to schedule a subset of nonconflicting jobs of maximum total weight.

Our problem can be formulated as the problem of finding a *maximum weight independent set* in a *t-interval* graph (the special case of $t = 1$ is an ordinary interval graph). We show that, for $t \geq 2$, this problem is APX-hard, even for highly restricted instances. Our main result is a $2t$-approximation algorithm for general instances. This is based on a novel *fractional* version of the Local Ratio technique. One implication of this result is the first constant factor approximation for nonoverlapping alignment of genomic sequences. We also derive a bicriteria *polynomial time approximation scheme* for a restricted subclass of t-interval graphs.

1. Introduction.

We consider the problem of scheduling jobs that are given as *groups* of nonintersecting segments on the real line. Each job J_j is associated with a *t-interval*, I_j, which consists of up to t disjoint segments, for some $t \geq 1$, and a weight (profit), w_j; two jobs are in conflict if any of their segments intersect. The objective is to schedule on a single machine a subset of nonconflicting jobs whose total weight is maximum.

An instance of our problem can be modeled as the intersection graph of t-intervals, known as a *t-interval graph*. Each vertex in the graph corresponds to an interval that has been *"split"* into t parts, or segments, such that two vertices u and v are adjacent if and only if some segment in the interval corresponding to u intersects with some segment in the interval corresponding to v (see Figure 1). In the special case where intersections can occur only between the ith segments of two intervals, $1 \leq i \leq t$, we get the subclass of *t-union graphs*. (A precise definition is given in section 2.1.) Note that 1-interval graphs are precisely interval graphs. Our problem can be viewed as the *maximum weight independent set (MWIS) problem* restricted to a weighted t-interval graph $G(V, E)$, where we seek a subset of nonadjacent vertices $U \subseteq V$, such that the weight of U is maximized.

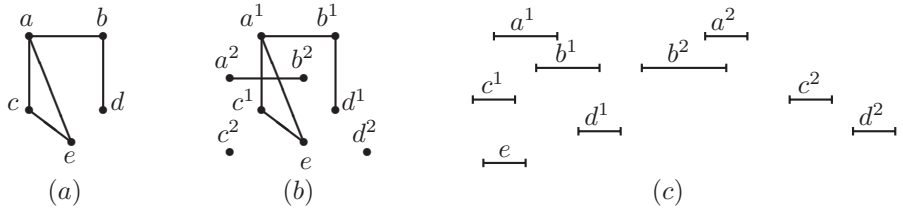

FIG. 1. *A* 2*-interval graph* (a), *corresponding interval (segment intersection) graph* (b), *and interval system* (c).

We describe below several practical scenarios involving t-interval graphs.

Transmission of continuous-media data. Traditional multimedia servers transmit data to the clients by *broadcasting* video programs at prespecified times. Modern systems allow us to replace broadcasts with the allocation of video data streams to individual clients *upon request* for some time interval (see, e.g., [34, 6]). In this operation mode, a client may wish to take a break and resume viewing the program at some later time. This scenario is natural in, for example, video programs that are used in remote education [25].

Suppose that a client starts viewing a program at time t_0. At time t_1 the client takes a break and resumes viewing the program at t_2, until the end of the program (at t_3). This scenario can be described by a *split interval*, I, that consists of two segments: $I^1 = (t_0, t_1)$ and $I^2 = (t_2, t_3)$.

The scheduler may get many requests formed as split intervals; each request is associated with a profit which is gained by the system only if *all* of the segments corresponding to the request are scheduled. The goal is to schedule a subset of nonoverlapping requests that maximizes the total profit, i.e., find an MWIS in the intersection graph of the split intervals.

Most of the previous work in this area describes analytic models (e.g., [31]) or experimental studies in which VCR-like operations can be used by the clients (see [6, 12, 34, 45]); however, these studies focus on the efficient use of system resources while supporting such operations rather than on the scheduling problem.

Linear resource allocation. Another application is allocation of multiple linear resources [22]. Requests for a linear resource can be modeled as intervals on a line; two requests for a resource can be scheduled together unless their intervals overlap. A disk drive is a linear resource when requests are for contiguous blocks [38]. A linear array network is a linear resource, since a request for bandwidth between processors i and j requires that bandwidth be allocated on *all* intervening edges. Consider a computer system that consists of a linear array network and a large disk, shared by a set of processors. A scheduler must decide when to schedule requests, where each request may comprise of distinct requests to these two linear resources, e.g., "a certain amount of bandwidth between processors 4 and 7, and a lock on blocks 1000-1200 of the disk." Two requests are in conflict if they overlap on the disk or in their bandwidth requirements. Thus, when the goal is to maximize the number of requests satisfied by the system, we get an instance of the MWIS problem on the subclass of 2-*union* graphs. Indeed, each segment in a 2-interval represents an allocation of one of the resources (e.g., the first segment is bandwidth allocation, and the second segment is the allocation of blocks on the disk to a given request). In general, with t different resources we get an instance of the MWIS on a t-union graph.

Genomic sequence similarity. One of the more fundamental problems in computational biology is to determine the similarity of substructures. We consider here genomic sequences (DNA, protein) and define the substructures to be contiguous subsequences. The similarity score of a substructure is generally related to the local alignment, or editing distance, between the two subsequences.

When considering the total similarity of two whole sequences, we can view this as being made up by the combination of individual substructures. Due to genomic rearrangements, the order of the subsequences need not be preserved between the two genomes. The nonoverlapping local alignment problem seeks a collection of substructures, each corresponding to pairs (S_i, T_i) of subsequences of the genomes S and T, where none of the subsequences overlap (neither in S nor in T). The objective is to maximize the sum of the similarity scores of the substructures.

As an example, suppose $S = xxxAxxBC$ and $T = C'yyA'zzB'$, where A, B, and C are sequences with similarity scores of 15, 20, and 11 to sequences A', B', and C', respectively. Then, the total similarity of S and T would be 46.

We may assume that the input sequences have been preprocessed to give subsequence pairs with nonzero similarity. Each such substructure (S_i, T_i) corresponds to a 2-interval, formed by the interval that S_i forms with S one on hand, and the interval that T_i forms with T on the other hand. The nonoverlapping restriction of the problem implies that the set of 2-intervals that we find needs to be mutually independent. Hence, the nonoverlapping local alignment problem corresponds to the MWIS in 2-union graphs.

The common total similarity of t sequences simultaneously can similarly be modeled as the MWIS problem in t-union graphs. Previously, the problem was considered only in the case where the projections of input boxes did not contain one another, i.e., the case of proper t-union graphs. While making the problem easier, this restriction is not intrinsic to the biological problem.

Computational geometry. The problem of finding an independent set among a set of multidimensional axis-parallel boxes is of independent interest in computational geometry. It corresponds to the MWIS problem in t-union graphs.

1.1. Our results. We provide a comprehensive study of the MWIS problem in t-interval graphs. In section 2, we show that the problem is APX-hard even on highly restricted instances, namely, on $(2, 2)$-union graphs (defined in section 2.1). In section 3 we discuss some structural properties of t-interval graphs. In particular, we derive a bound on the inductiveness of a t-interval graph. As a corollary, we extend the best bound known on the chromatic number of t-interval graphs of Gyárfás [18]. We show this bound to be asymptotically optimal.

In section 3.2, we study the MWIS problem on 2-interval graphs. We show that a simple greedy algorithm achieves the factor $O(\min\{\log R, \log n\})$, where R is the ratio between the longest and shortest segments in the instance.

Our main result (in section 4) is a $2t$-approximation algorithm for the MWIS in any t-interval graph, for $t \geq 2$, which is based on a novel *fractional* version of the Local Ratio technique. (The Local Ratio technique was first developed in [5] and later extended by [2, 4].) We use the fractional Local Ratio technique to round a fractional solution obtained from a linear programming relaxation of our problem. We expect that our nonstandard use of the Local Ratio technique will find more applications. Indeed, recently, this technique was used for obtaining improved bounds for the MWIS in the intersection graph of axis-parallel rectangles in the plane [32].

As we shall see, the MWIS in t-interval graphs properly includes the k-dimensional

matching problem. For this unweighted problem the best approximation factor known is $k/2+\epsilon$, for any $\epsilon > 0$ [26]. Hazan, Safra, and Schwartz [24] have recently shown that it is hard to approximate the k-dimensional matching problem within an $O(k/\log k)$ factor unless P = NP. Thus, our results are close to best possible.

For the class of t-union graphs, we develop (in section 5) a $(1, 1+\epsilon)$-approximation scheme with respect to the optimal profit and the latest completion time of any interval in some optimal solution. In particular, our scheme gets as parameter $T_{\mathcal{O}}$ the latest completion time of an interval in some optimal schedule and outputs a subset of intervals of optimal profit, in which the latest completion time of any interval is at most $T_{\mathcal{O}}(1+\epsilon)$.

1.2. Related work. We mention below several works that are related to ours.

Split interval graphs. Many NP-hard problems, including the MWIS problem [15, 16], can be solved efficiently in interval graphs. Split interval graphs have a long history in graph theory [43, 17, 39, 44], and more recently, union graphs have been studied under the name of *multitrack* interval graphs [30, 19, 29]. We mention some of the main results. For any fixed $t \geq 2$, determining whether a given graph is a t-interval (t-union) graph is NP-complete [44] ([19], respectively). 2-union graphs contain trees [43, 30] and more generally all outerplanar graphs [29], while 3-interval graphs contain the class of planar graphs [39]. Graphs of maximum degree Δ are $\lceil \frac{1}{2}(\Delta+1) \rceil$-interval graphs [17]. The complete bipartite graph, $K_{m,n}$, is a t-interval and t-union graph for $t = \lceil (mn+1)/(m+n) \rceil$ [43, 19].

Union graphs, which constitute a subfamily of split interval graphs, were also considered in several papers. Bafna, Narayanan, and Ravi [3] considered the problem of finding a weighted independent set in t-union graphs in the context of an application coming from computational biology. The union graphs considered in [3] are *proper*; i.e., there is no containment between segments. For the weighted independent set problem in proper t-union graphs, the paper [3] shows that the problem is NP-hard and gives a $(2^t - 1 + 1/2^t)$-approximation algorithm. This is obtained by mapping the problem to the MWIS in (2^t+1)-claw free graphs, noting that proper t-union graphs are (2^t+1)-claw free. Recently, Chlebík and Chlebíkova [11] showed that proper t-union graphs are $(2t+1)$-claw free. Using an algorithm of Berman [7] this gives a $(t+1/2)$-approximation of the MWIS in proper t-union graphs. Berman, DasGupta, and Muthukrishnan showed in [8] that a simple $O(n \log n)$ algorithm (based on the Local Ratio technique) yields a factor of 3 for proper 2-union graphs.

Coupled-task and flow shop scheduling. The problem of scheduling 2-intervals (known as *coupled-task scheduling*) was considered in the area of machine scheduling, with the objective of minimizing the overall completion time, or *makespan* (see, e.g., [35, 41]). Relaxed versions of the problem that require only a lower bound on the time that elapses between the schedules of the two tasks of each job (also called *time-lag problems*) were studied, e.g., in [37, 13, 10].

An instance of our problem can be viewed as an instance of the *flow shop* problem, in which the segments and break times are represented by *tasks* that need to be processed on a set of $m = 2t+1$ machines. (The precise transformation is given in section 5.) In general, the flow shop problem, where the objective is to minimize the makespan, is NP-complete even on three machines [14]. The best result known is the $O(\log^2(m\mu)/\log\log(m\mu))$-approximation algorithm, where μ is the maximum number of operations per job, and m is the number of machines [40, 42]. Hall [20] gave a polynomial time approximation scheme (PTAS) for this problem in the case where m is fixed (but arbitrary).

2. Preliminaries.

2.1. Definitions and notation. Given a t-interval graph, $G = (V, E)$, we assume that each vertex $v \in V$ is mapped to a set of at most t segments, and we call v a *split interval*. Suppose that segment I is one of the segments that vertex v is mapped to; then we say that I belongs to v and denote it by (v, I). We denote by $\mathcal{I}(\mathcal{G})$ the collection of segments (or intervals) on the real line, partitioned into disjoint *groups*, where each group is associated with a split interval. A t-interval graph is *proper* if no segment properly contains another segment.

In the subfamily of t-union graphs, the segments associated with each vertex can be labeled in such a way that for any two vertices u and v, the ith segment of u and the ℓth segment of v never intersect for $1 \leq i, \ell \leq t$, and $i \neq \ell$. Union graphs correspond also to certain geometric intersection graphs. The t segments are viewed as intervals on orthogonal axes, corresponding to a t-dimensional box; two boxes intersect if their projections on any of the t axes do. We further define subclasses of union graphs, where coordinates are all integral and segments are half-open. In (a, b)-union graphs, a subclass of 2-union graphs, all x-segments are of length a and all y-segments are of length b.

Given a graph $G = (V, E)$, we denote by $N(v)$ the set of neighbors of $v \in V$, and by $N[v]$ the closed neighborhood of v, $\{v\} \cup N(v)$. A $(k+1)$-*claw* is a graph consisting of a center vertex adjacent to $k+1$ mutually nonadjacent vertices. A graph is called $(k+1)$-*claw free* if it contains no k-claw as an induced subgraph.

Finally, we define our performance measures. Denote by OPT an optimal algorithm. The *approximation factor* of an algorithm $\mathcal{A}$ is r if for every finite input instance I, $\mathcal{A}(I)/OPT(I) \geq 1/r$, where $\mathcal{A}(I)$ and $OPT(I)$ are the values of $\mathcal{A}$ and OPT on I. A *polynomial time approximation scheme (PTAS)* is an algorithm which takes as input both the instance I and an error bound ϵ, has performance guarantee $R(I, \epsilon) \leq (1 + \epsilon)$, and runs in time polynomial in $|I|$. A (β, ϵ) *bicriteria PTAS* is a PTAS which is a β-approximation in one optimization criterion and a $(1 + \epsilon)$-approximation in the other criterion.

2.2. Hardness results. The independent set problem in interval graphs is easy to solve exactly, since interval graphs always contain a *simplicial* vertex, i.e., a vertex whose neighborhood is a clique. In fact, most approximation algorithms for independent sets on geometric intersection graphs are based on a related relaxed property: there always exists a vertex whose neighborhood does not contain a large independent set. We first show that for general t-interval graphs this property does not hold.

Observation 2.1. For any $n \geq 2$, there exists a 2-interval graph G on n vertices, in which every vertex has $\Omega(\sqrt{n})$ independent neighbors.

Proof. We show how to construct a 2-interval graph, in which every vertex has k independent neighbors. We construct the graph from $(k+1)$ sets of intervals; each set consists of k intervals, and each interval is composed of two segments: a *short* segment and a *long* segment. All the short segments in the input are of the same length, and likewise for all the long segments.

The graph is constructed as follows. For $\ell = 1, \ldots, k$, all the short segments of the intervals in the ℓth set, $I^\ell_1, \ldots, I^\ell_k$, intersect the long segments of the ℓth intervals in the sets $1, \ldots, k+1$, i.e., $I^1_\ell, \ldots, I^{k+1}_\ell$, excluding I^ℓ_ℓ. Finally, all the short segments of the intervals in the $(k+1)$th set intersect the long segment of the interval I^ℓ_ℓ, $1 \leq \ell \leq k$ (see Figure 2). Thus, we get that any interval I^ℓ_j with $\ell \neq j$ intersects k nonintersecting intervals in the jth set, and I^ℓ_ℓ intersects k nonintersecting intervals

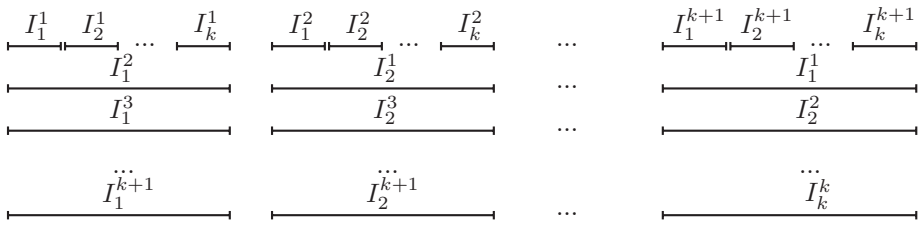

FIG. 2. *A 2-interval graph in which every vertex has k independent neighbors.*

in the $(k+1)$th set.

Note that since $k(k+1) \leq n$, we may have some remaining intervals, which are not contained in any set. We can place the segments of each such interval on the line such that its long segment intersects all the intervals in the ℓth set, for some $1 \leq \ell \leq k+1$, providing that interval with k independent neighbors. □

We note that the above construction can be modified to hold for 2-union graphs. We now give a structural result that implies hardness of approximation for a highly restricted class of proper 2-union graphs. A *degree-3 graph* is one of maximum degree 3.

THEOREM 2.2. *The class of* $(2,2)$*-union graphs includes the class of degree* 3.

Proof. A *linear forest* is a collection of disjoint paths. A path can be represented as a collection of length-2 half-closed intervals between integral endpoints, e.g., $[0,2), [1,3), [2,4)$, etc. Thus, a union of a pair of linear forests can be represented as a $(2,2)$-union graph. Akiyama, Exoo, and Harary [1] showed that degree-3 graphs can be represented as a union of two linear forests. Namely, they showed that for a degree-3 graph G, we have that $la(G) = 2$, where $la(G)$ denotes the *linear arboricity* of G or the minimum number of classes in a partition of $E(G)$ such that each class induces a linear forest. □

It follows that the MWIS problem is APX-hard on unweighted $(2,2)$-union graphs, since the (unweighted) MIS problem is APX-hard on degree-3 graphs (see [9, 23]). It also implies equivalent hardness results for other optimization problems that are hard to approximate on degree-3 graphs.

COROLLARY 2.3. *The MWIS problem is APX-hard on unweighted* $(2,2)$*-union graphs.*

Segments of unit size, whose start points are integral, are called *unit segments*. t-interval graphs of unit segments can be characterized precisely.

For some $k > 1$, let $S = \{1, 2, \ldots, n\}$, and let C be a collection of subsets of S, where each subset is of size at most k. The *k-set packing* problem is that of finding a maximum cardinality subcollection $C' \subseteq C$, such that the intersection of any two sets in C' is empty. In the *weighted* version, each subset has a weight, and we seek a subcollection C' of maximum weight.

LEMMA 2.4. *The k-set packing problem is equivalent to the MWIS in the special class of k-interval graphs of unit segments.*

Proof. There is a bijective mapping between unit segments and the set S, where $[i, i+1)$ maps to i for all values of i. Thus, there is a bijective mapping between sets of up to k elements from S and sets of up to k unit segments. □

A special case of k-set packing is the *k-dimensional matching* problem. Here, S is partitioned into subsets $S_1, S_2, \ldots, S_k$, and each set in C contains exactly one element from each S_i. The k-dimensional matching problem is similarly equivalent to

the MWIS in the special class of k-union graphs of unit segments. The former problem is NP-hard to approximate within factor $O(k/\log k)$ [24], while the best factor known is $k/2+\epsilon$ for any $\epsilon > 0$ [26]. We note that the 2-set packing problem is equivalent to the (polynomially solvable) edge cover problem, while 3-dimensional matching is APX-hard [36].

COROLLARY 2.5. *The MWIS problem in* $(1,1)$*-interval graphs is polynomial solvable. The MWIS problem in* $(1,1,1)$*-union graphs is APX-hard.*

The correspondence between $(1,1)$-union graphs to line graphs of bipartite graphs, and the resulting polynomial solvability of the MWIS problem, was shown by Halldórsson et al. [22].

3. Greedy algorithms.

3.1. Coloring t-interval graphs. For a t-interval graph G (see in Figure 1(a) for $t=2$), let G^* denote the graph formed by the intersection of the segments of the intervals (Figure 1(b)). The clique number, $\omega(G^*)$, denotes the maximum number of segments crossing a point on the real line.

THEOREM 3.1. *For any t-interval graph G, there is a vertex v in G such that*

$$d(v) \leq 2t(\omega(G^*)-1)-1.$$

Proof. Since each vertex in G corresponds to up to t vertices of G^*, $|V(G^*)| \leq t\cdot|V(G)|$, and since each edge in G corresponds to one or more edges in G^*, $|E(G)| \leq |E(G^*)|$. Since G^* is an interval graph, there is a simplicial ordering of the graph so that each vertex v_i has at most $\omega(G^*)-1$ neighbors among the vertices $v_{i+1},\ldots$. Thus, the number of edges in G^* is at most $(\omega(G^*)-1)|V(G^*)|$; in fact, it must be strictly less, since the last vertex has later neighbors. It follows that the average degree of G is bounded by

$$\overline{d}(G) = \frac{2|E(G)|}{|V(G)|} \leq 2t\frac{|E(G^*)|}{|V(G^*)|} < 2t(\omega(G^*)-1).$$

Hence, the minimum degree of G is at most $2t(\omega(G^*)-1)-1$. ∎

This leads to a simple coloring algorithm: find a vertex v satisfying the lemma, color the remaining graph $G\setminus v$, and finally color v with the smallest color not used by previously colored neighbors. This results in a $2t(\omega(G^*)-1)$-coloring.

The above gives a $2t$-approximation for coloring t-interval graphs via a greedy algorithm. Gyárfás [18] showed that the chromatic number of a t-interval graph G is at most $2t(\omega(G)-1)$, where $\omega(G)$ is the clique number of the graph.

COROLLARY 3.2. *A greedy algorithm colors G using $2t(\omega(G^*)-1)$ colors.*

Observe that this bound is obtained without knowledge of the underlying interval representation of G^*; this is important since deducing the representation is known to be NP-hard [44]. We show that this is about the best bound on $\chi(G)$ one can obtain in terms of $\omega(G^*)$, within a constant factor.

LEMMA 3.3. *For infinitely many t, there is a proper t-interval graph G such that $\omega(G) = (t-1)\omega(G^*)$.*

Proof. Let p be any prime number and $\mathbb{Z}_p$ be the finite field over $\{0,1,\ldots,p-1\}$. Let $t=p+1$. Let $C_{i,j}$ and D_i, $i,j\in\mathbb{Z}_p$, be any disjoint unit segments. We shall construct a system of t-intervals $I_{x,y}$, $x,y\in\mathbb{Z}_p$, and show that the t-intervals are pairwise overlapping, i.e., that any pair contains a common segment.

Let $I_{x,y} = \{C_{i,ix+y \bmod p} : i\in\mathbb{Z}_p\}\cup\{D_x\}$ for each $x,y\in\mathbb{Z}_p$. Clearly, the sets contain t segments each. Consider a pair of t-intervals $I_{x,y}$, $I_{x',y'}$. If $x=x'$, then both

t-intervals contain the segment $D_x = D_{x'}$. Otherwise, there exists an $i \in \mathbb{Z}_p$ that is a solution to the modular equation $i(x - x') \equiv (y' - y) (\mathrm{mod} p)$. Then, both t-intervals $I_{x,y}$ and $I_{x',y'}$ contain the segment $C_{i,ix+y \bmod p} = C_{i,ix'+y' \bmod p}$.

It follows that the intersection graph on these t-intervals is a clique on $p^2 = (t-1)^2$ vertices. On the other hand, each segment $C_{i,j}$ is contained in exactly $(t-1)$ t-intervals $I_{x,y}$ (namely, those for which $j = ix+y \bmod p$) and the same holds for each D_i. Thus, the clique number of G^* is $t - 1$. □

3.2. Greedy independent set algorithms. We study here a greedy algorithm for the special case where $t = 2$, in order to motivate the use of more complicated techniques in later sections.

Recall from Observation 2.1 that, in a 2-interval graph, the neighborhood of every vertex may include many independent vertices. Thus, purely greedy methods are bound to fail. Consider, for instance, the optimal greedy algorithm for independent sets in interval graphs that iteratively adds the interval with the leftmost right endpoint. An analogous method for 2-interval graphs could be to iteratively select the 2-interval with the leftmost right endpoint of the *first segment*, among all 2-intervals that do not intersect previously chosen 2-intervals. This algorithm, which we call Sort-and-Select, cannot be expected to perform well on all 2-interval graphs. However, it performs well under certain circumstances, which allows us to partition the instance into well-solvable subcases.

THEOREM 3.4. *Let G be a 2-interval graph where*

- *the first segment is no shorter than the second, and*
- *the ratio between the length of the shortest and longest second segment is at most* 4.

Then, the approximation factor of Sort-and-Select is 6.

Proof. Let I be the interval chosen first by Sort-and-Select. We claim that I intersects at most six independent intervals. Namely, the second segment of I is at most four times the length of the shortest segment in the graph; as a result, it intersects at most five independent segments/vertices. Also, since the first segment is furthest to the left of all segments in the graph, it does not intersect two independent vertices. Thus, among the intervals eliminated by the addition of I to the solution, the optimal solution can contain at most six. By induction, the algorithm then achieves an approximation factor of 6. □

Using the Local Ratio technique, which is discussed in depth in the next section, one can obtain the same factor for the weighted case. Also, by a similar argument, one can argue a factor of 3 for the case of proper 2-interval graphs.

Given a general 2-interval graph, we first divide the intervals into those where the first segment is shorter than the second segment and those where the first segment is at least as long as the second. This gives us two instances, which can be viewed as symmetric by reversing the direction of the real line. Thus, by increasing the approximation factor by a factor of 2, we can assume that in our instance the first segments are no shorter than the second segments.

We can partition the instance into $(\lg R)/2$ subinstances, or *buckets*, where R is the ratio between the longest to shortest (S) second segment. The bucket G_i consists of intervals with second segments in the range $[4^{i-1}S, 4^i S)$ for $i = 1, 2, \ldots, \lceil (\lg R)/2 \rceil$. Each bucket satisfies the conditions of Theorem 3.4; thus, the largest of the independent sets found in each bucket by Sort-and-Select is a $6 \lg R$ approximation.

Note that we can represent the n second segments in the input by $2n$ endpoints

on the line, and we define the length of each segment as the number of endpoints that lie between its left and right endpoints plus one. Then, the maximal possible length of a segment is $2n-1$, and the number of buckets is $B = \min\{\lg R, \lg(2n-1)\}$. Hence, we obtain the following result.

THEOREM 3.5. *There is a greedy partitioning algorithm for the maximum independent set in 2-interval graphs achieving a factor of* $O(\min\{\log R, \log 2n\})$.

4. A $2t$-approximation algorithm. We describe here a $2t$-approximation algorithm for the MWIS problem in a t-interval graph $G = (V, E)$. The algorithm is based on rounding a fractional solution derived from a linear programming relaxation of the problem. The standard linear programming relaxation of the MWIS problem is the following. For each $v \in V$, let $x(v)$ be the linear relaxation of the indicator variable for v, i.e., whether v belongs to the independent set. Let $\mathbf{w}, \mathbf{x} \in \mathbb{R}^{|V|}$ be a weight vector and a relaxed indicator vector, respectively.

maximize	$\mathbf{w} \cdot \mathbf{x}$	*subject to:*
for each clique $\mathcal{C} \in G$:	$\sum_{v \in \mathcal{C}} x(v) \leq 1$	

A feasible solution for the above linear program, whose value is an upper bound on the MWIS problem in the graph, can be obtained from the Lovász ϑ-function [33]. However, as we shall see, it is not necessary to optimize over all cliques in the case of t-interval graphs. We say that a clique $\mathcal{C}$ in the graph is an *interval clique* if for every vertex $v \in \mathcal{C}$, there is a segment $I \in v$ such that the intersection of $((v, I)|v \in \mathcal{C})$ is nonempty. It is easy to see that the interval cliques are defined by the set of right endpoints of the segments in $\mathcal{I}(\mathcal{G})$ as follows. Each right endpoint z corresponds to the clique defined by the vertices containing z. (See Figure 3 for an example.) Therefore, the number of interval cliques in a t-interval graph is linear in the number of segments.

We now further relax the MWIS problem and consider only interval cliques. In the integral case, let $x(v)$ denote the indicator variable of vertex v, and for each $I \in v$, $x(v, I) = x(v)$. In the linear relaxation (P), for each interval clique $\mathcal{C}$, we require that the sum of the variables $(v, I) \in \mathcal{C}$ is at most 1. It suffices to require, for each vertex v and $I \in v$, $x(v, I) \geq x(v)$, since only $x(v)$ participates in the objective function, and therefore in an optimal solution, without loss of generality, $x(v, I) = x(v)$.

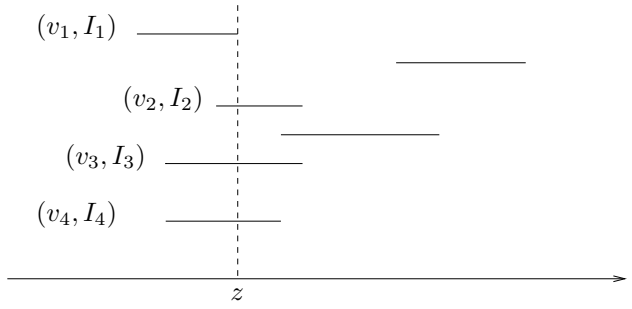

FIG. 3. *The interval clique* (v_1, v_2, v_3, v_4) *is defined by* z*, the right endpoint of* (v_1, I_1).

(P) maximize $\mathbf{w} \cdot \mathbf{x}$ *subject to:*			
for each interval clique $\mathcal{C}$:	$\sum_{(v,I)\in\mathcal{C}} x(v,I)$	$\leq$	1
for each $v \in V$ and $I \in v$:	$x(v,I) - x(v)$	$\geq$	0
for each $v \in V$ and $I \in v$:	$x(v), x(v,I)$	$\geq$	0

Since the number of interval cliques in a t-interval graph is linear in the number of segments, an optimal solution to (P) can be computed in polynomial time.

The heart of our rounding algorithm is the following lemma. It can be viewed as a fractional analogue of Theorem 3.1.

LEMMA 4.1. *Let* $\mathbf{x}$ *be a feasible solution to* (P). *Then, there exists a vertex* $v \in V$ *satisfying*

$$\sum_{u\in N[v]} x(u) \leq 2t.$$

Proof. For two adjacent vertices u and v, define $y(u,v) = x(v) \cdot x(u)$. Define $y(u,u) = x(u)^2$. For a segment I, let $R(I)$ be the interval clique defined by the right endpoint of I ($I \in R(I)$). We prove the claim using a *weighted* averaging argument, where the weights are the values $y(u,v)$ for all pairs of adjacent vertices, u and v.

Consider the sum $\sum_{v\in V}\sum_{u\in N[v]} y(u,v)$. An upper bound on this sum can be obtained as follows. For each $v \in V$, consider all segments $I \in v$, and for each (v,I), add up $y(u,v)$ for all (u,J) that intersect with (v,I) (including (v,I)). In fact, it suffices to add up $y(u,v)$ only for segments (u,J) such that $(u,J) \in R(I)$, and then multiply the total sum by 2. This suffices because of the following: (a) If, for segments (v,I) and (u,J), the right endpoint of I precedes the right endpoint of J, then (v,I) "sees" (u,J) and vice-versa. Since $y(u,v) = y(v,u)$, each of them contributes the same value to the other. (b) For segments (v,I) and (u,J), the constraints of (P) imply that $x(v,I) = x(v)$ and $x(u,J) = x(u)$. Hence, it follows from (a) and (b) that the mutual contribution of two segments (u,J) and (v,I) that intersect depends only on u and v; i.e., it is $y(u,v)$. Thus,

$$\sum_{v\in V}\sum_{u\in N[v]} y(u,v) \leq 2 \cdot \sum_{v\in V}\sum_{I\in v}\sum_{(u,J)\in R(I)} y(u,v).$$

Since

$$\sum_{(u,J)\in R(I)} y(u,v) \leq \; x(v) \cdot \sum_{(u,J)\in R(I)} x(u) \leq x(v),$$

we get that

$$\sum_{v\in V}\sum_{u\in N[v]} y(u,v) \leq 2t \cdot \sum_{v\in V} x(v).$$

Hence, there exists a vertex v satisfying

$$\sum_{u\in N[v]} y(u,v) \leq 2t \cdot x(v). \tag{1}$$

By factoring out $x(v)$ from both sides of inequality (1), the statement of the lemma is obtained. □

We now define a fractional version of the Local Ratio technique. The proof of the next lemma is immediate.

LEMMA 4.2. *Let* $\mathbf{x}$ *be a feasible solution to* (P). *Let* $\mathbf{w_1}$ *and* $\mathbf{w_2}$ *be a decomposition of the weight vector* $\mathbf{w}$ *such that* $\mathbf{w} = \mathbf{w_1} + \mathbf{w_2}$. *Let* $r > 0$. *Suppose that* $\mathbf{y}$ *is a feasible integral solution vector to* (P) *satisfying* $\mathbf{w_1} \cdot \mathbf{y} \geq r(\mathbf{w_1} \cdot \mathbf{x})$ *and* $\mathbf{w_2} \cdot \mathbf{y} \geq r(\mathbf{w_2} \cdot \mathbf{x})$. *Then,*

$$\mathbf{w} \cdot \mathbf{y} \geq r(\mathbf{w} \cdot \mathbf{x}).$$

The rounding algorithm will apply a Local Ratio decomposition of the weight vector $\mathbf{w}$ with respect to an optimal solution $\mathbf{x}$ to linear program (P). The algorithm proceeds as follows.

1. If no vertices remain, return the empty set. Otherwise, proceed to the next step.
2. Define $V_0 = \{v \in V | w(v) < 0\}$. If V_0 is nonempty, return $\mathcal{I}$, the recursive solution for $V \setminus V_0$. Otherwise, proceed to the next step.
3. Let $v' \in V$ be a vertex satisfying $\sum_{u \in N[v']} x(u) \leq 2t$. Decompose $\mathbf{w}$ by $\mathbf{w} = \mathbf{w_1} + \mathbf{w_2}$ as follows:

$$w_1(u) = \begin{cases} w(v') & \text{if } u \in N[v'], \\ 0 & \text{otherwise.} \end{cases}$$

   (In the decomposition, the component $\mathbf{w_2}$ may be nonpositive.)
4. Solve the problem recursively using $\mathbf{w_2}$ as the weight vector. Let $\mathcal{I}'$ be the independent set returned.
5. If $\mathcal{I}' \cup \{v'\}$ is an independent set, return $\mathcal{I} = \mathcal{I}' \cup \{v'\}$. Otherwise, return $\mathcal{I} = \mathcal{I}'$.

Clearly, the set $\mathcal{I}$ is an independent set. We now analyze the quality of the solution produced by the algorithm.

THEOREM 4.3. *Let* $\mathbf{x}$ *be an optimal solution to linear program* (P). *Then, it holds for the independent set* $\mathcal{I}$ *computed by the algorithm that* $w(\mathcal{I}) \geq \frac{1}{2t} \cdot \mathbf{w} \cdot \mathbf{x}$.

Proof. The proof is by induction on the number of vertices having positive weight. Any vertex deleted by the algorithm is considered to have zero weight. At the basis of the induction (Step 1), the inductive hypothesis holds, since the weight vector is considered to be zero. We now prove the inductive step.

In Step 2, if V_0 is nonempty, by the inductive hypothesis, $w(\mathcal{I}) \geq \frac{1}{2t} \cdot \mathbf{w} \cdot \mathbf{x}$. Extending $\mathbf{w}$ to include the nonpositive components that were deleted in Step 2 can only decrease the right-hand side, and therefore the inequality still holds.

In Steps 3–5, let $\mathbf{y}$ and $\mathbf{y}'$ be the indicator vectors of the sets $\mathcal{I}$ and $\mathcal{I}'$, respectively. By the decomposition in Step 3, weight vector $\mathbf{w_2}$ has fewer positive weight vertices than $\mathbf{w}$. Therefore, by the inductive hypothesis, $\mathbf{w_2} \cdot \mathbf{y}' \geq (1/2t) \cdot \mathbf{w_2} \cdot \mathbf{x}$. Since $w_2(v') = 0$, it also holds that $\mathbf{w_2} \cdot \mathbf{y} \geq (1/2t) \cdot \mathbf{w_2} \cdot \mathbf{x}$. From Step 5 of the algorithm it follows that at least one vertex from $N[v']$ belongs to $\mathcal{I}$. Hence, $\mathbf{w_1} \cdot \mathbf{y} \geq (1/2t) \cdot \mathbf{w_1} \cdot \mathbf{x}$. Thus, by Lemma 4.2, it follows that

$$\mathbf{w} \cdot \mathbf{y} \geq \frac{1}{2t} \cdot \mathbf{w} \cdot \mathbf{x}.$$

We have thus proved that $\mathcal{I}$ is a $2t$-approximate solution to the MWIS problem. □

We now outline an alternative way of using Lemma 4.1 to obtain the same approximation factor. Given an optimal solution $\mathbf{x}$ to linear program (P), a *multicoloring* of V by a set X is a mapping $\psi : V \to 2^X$ such that $|\psi(v)| = x(v)$ for each vertex v, and $\psi(v) \cap \psi(u) = \emptyset$ for each edge $(u, v) \in E(G)$. Since $\mathbf{x}$ is a feasible solution to (P), a repeated application of Lemma 4.1 results in a multicoloring with values in the closed interval $[0, 2t]$.

To view this as a multicoloring, it may be easier to discretize the instance within any desired precision by multiplying the $x(v)$'s by a sufficiently large integer L. Then the values assigned are positive integers in the range $1, \ldots, 2tL$. A continuous viewpoint is to assign each vertex a collection of contiguous segments; if we use Lemma 4.1 to assign the values one by one, we can always guarantee that a vertex v can be mapped to segments from $[0, 2t]$ of combined length $x(v)$ without overlapping any of the segments to which its neighbors are mapped to. In fact, by always mapping a vertex to the smallest available values, we need never use more than n disjoint segments for any vertex.

Let $0 = z_0 < z_1 < \cdots < z_{k-1}$ denote the values where the multicoloring changes, and let $z_k = 2t$. Thus, the coloring remains unchanged in the segment $[z_i, z_{i+1})$, $i = 0, \ldots, k-1$. Consider the sets $S_i = \{v \in V : x_i \in \psi(v)\}$ for $i = 0, \ldots, k-1$. Since ψ is a multicoloring, the S_i's are independent sets in G. Let $\mathcal{I}$ be the set S_i of maximum weight, $\sum_{v \in S_i} w(v)$.

THEOREM 4.4. *$w(\mathcal{I})$ is a $2t$-approximate independent set.*

Proof. Observe that the number of color values to which vertex v is mapped is $x(v)$, and we can represent them by $\sum_{S_i \ni v}(z_i - z_{i+1}) = x(v)$. We have that

$$\sum_{v \in V} w(v)x(v) = \sum_{v \in V} w(v) \sum_{S_i \ni v} (z_{i+1} - z_i) = \sum_{S_i} (z_{i+1} - z_i) \sum_{v \in S_i} w(v)$$
$$= \sum_{i=0}^{k-1} (z_{i+1} - z_i) w(S_i) \leq \sum_{i=0}^{k-1} (z_{i+1} - z_i) w(\mathcal{I}) = 2t w(\mathcal{I}). \qquad \square$$

5. A bicriteria approximation scheme for union graphs. Recall that the MWIS problem is APX-hard already on $(2, 2)$-union graphs. We consider below the larger subclass of t-union graphs in which the possible number of segment lengths is bounded by some constant. For this subclass we develop a *bicriteria* PTAS, which finds an MWIS by allowing some delays in the schedule.

Let c_i denote the number of distinct lengths of the ith segment, $1 \leq i \leq t$, where t is some constant. Recall that, in the flow shop problem, we are given a set of n jobs, $J_1, \ldots, J_n$, that need to be processed on m machines, $M_1, \ldots, M_m$; each job, J_j, consists of m operations, $O_{j,1}, \ldots, O_{j,m}$, where $O_{j,i}$ must be processed without interruptions on the machine M_i for $p_{j,i}$ time units. Any machine, M_i, can process either a *single* operation at a time or an *unbounded* number of operations; in the latter case we call M_i a *nonbottleneck* machine. Each job may be processed by at most one machine at any time. For a given schedule, let C_j be the completion time of J_j. The objective is to minimize the *maximum completion time* (or makespan), given by $C_{max} = \max_j C_j$. Denote by C^*_{max} the optimal makespan.

An instance of our problem can be transformed to an instance of the flow shop problem, where each job has $2t + 1$ operations, and the machines M_{2i+1}, $0 \leq i \leq t - 1$, are nonbottleneck machines. In our transformation, we apply some ideas from [27, 21, 28]. We represent each t-interval, I_j, as a job J_j, where each segment is associated with an "operation" of the job. In addition, we simulate the breaks with

operations of the same lengths that need to be processed on nonbottleneck machines. Similarly, to include the release time r_j of I_j, we add to J_j the operation $O_{j,1}$, whose length is equal to r_j; the machine M_1 is a nonbottleneck machine. Thus, if I_j has t segments, J_j has $2t$ operations.

Recall that, in a union graph, each interval has a due date, d_j, that is equal to its release time plus the sum of its processing times and break times. To simulate these due dates we define a *delivery time*, q_j, for each job, J_j. Let $q_j = -d_j$. We add to J_j the operation $O_{j,(2t+1)}$, where $p_{j,(2t+1)} = q_j$, and M_{2t+1} is a nonbottleneck machine. Our objective then is to minimize the maximum *delivery completion time*, given by $\max_j\{C_j + q_j\} = \max_j\{C_j - d_j\}$. This is equivalent to minimizing the maximum *lateness* of any job, given by $L_j = C_j - d_j$. Hence, our objective can be viewed as minimization of $L_{max} = \max_j L_j$.

Denote by $T_{\mathcal{O}}$ the maximum completion time of an optimal solution for the MWIS instance. Since we look for an MWIS that can be scheduled with maximum lateness at most $\epsilon T_{\mathcal{O}}$, we slightly modify the definition of *lateness*. Let $\tilde{d}_j = d_j - T_{\mathcal{O}}$; then, for any j, $\tilde{d}_j \leq 0$. By setting $q_j = -\tilde{d}_j$, we get that all the delivery times are positive. The maximum lateness is now given by $L_{max} = \max_j\{C_j - d_j + T_{\mathcal{O}}\}$. Indeed, for any job J_j, $C_j \geq d_j$; therefore, $L_{max} \geq T_{\mathcal{O}}$, and since in any optimal schedule there are no "late" jobs, the minimal lateness is $L^*_{max} = T_{\mathcal{O}}$.

Our scheme uses as procedure a PTAS for finding a $(1+\epsilon)$-approximation for the flow shop makespan problem with a fixed number of machines (see, e.g., [20]). We represent a t-interval I_j by a $(2t+1)$-vector $(p_{j,1}, \ldots, p_{j,2t+1})$, where $p_{j,1}$ is the release time, $p_{j,2i}$ ($p_{j,2i+1}$), is the length of the ith segment (break), $1 \leq i < t$, and $p_{j,2t+1}$ $(= q_j)$ is the delivery time of the corresponding job, J_j.

Below we summarize the steps of our scheme, which gets as parameters the value of $T_{\mathcal{O}}$ and some $\epsilon > 0$.

1. We scale the parameter values for J_j; that is, we divide the processing and release times by $T_{\mathcal{O}}$ and round each release time down and each break time up to the nearest multiple of ϵ.
2. We guess $\mathcal{O}$, the number of intervals scheduled by OPT.
3. We guess the subset $S_{\mathcal{O}}$ of $\mathcal{O}$ intervals of maximal weight, scheduled by OPT. This is done by guessing the set of vectors representing $S_{\mathcal{O}}$, among which we choose the subset of intervals of maximum weight.
4. Using a PTAS for minimizing the makespan in the flow shop instance of $S_{\mathcal{O}}$, we find a schedule of $S_{\mathcal{O}}$ for which $L_{max} \leq (1+\epsilon)L^*_{max}$.

Note that due to the above rounding, we need to add ϵ to the release times; also, each break time may delay the optimal completion time by ϵ. Therefore, by taking $\epsilon' = \epsilon/2t$ we guarantee that the delay of each interval is at most $(1+\epsilon)$ times $T_{\mathcal{O}}$. Finally, we set $L_j = L_j - T_{\mathcal{O}}$; thus, the maximum lateness of any job in our schedule is equal to at most $\epsilon T_{\mathcal{O}} = \epsilon C^*_{max}$.

For the complexity of the scheme, note that Steps 1 and 2 take linear time, and since the possible number of vectors $(p_{j,1}, \ldots p_{j,2t+1})$ is $(2t/\epsilon)^t \prod_{i=1}^{t} c_i$, we can guess $S_{\mathcal{O}}$ in $O(n^{(t^t \prod_{i=1}^{t} c_i)/\epsilon^t})$ steps. This is multiplied by the complexity of the PTAS for the flow shop.

THEOREM 5.1. *Let $t \geq 1$ be some fixed constant. Given a t-union graph with a constant number of distinct segment lengths, let $\mathcal{W}$ be the weight of an optimal MWIS, whose latest completion time is $T_{\mathcal{O}}$. Then, for any $\epsilon > 0$, there is a PTAS that schedules an independent set of weight at least $\mathcal{W}$, such that* any *interval is late by at most $\epsilon T_{\mathcal{O}}$.*

A SIMPLE ALGORITHM FOR MAL'TSEV CONSTRAINTS*

ANDREI BULATOV† AND VÍCTOR DALMAU‡

Abstract. A Mal'tsev operation is a ternary operation φ that satisfies the identities $\varphi(x,y,y) = \varphi(y,y,x) = x$. Constraint satisfaction problems involving constraints invariant under a Mal'tsev operation constitute an important class of constraint satisfaction problems, which includes the affine satisfiability problem, subgroup and near subgroup constraints, and many others. It is also known that any tractable case of the counting constraint satisfaction problem involves only Mal'tsev constraints.

The first algorithm solving the arbitrary constraint satisfaction problem with Mal'tsev constraints has been given by Bulatov. However, this algorithm is very sophisticated and relies heavily on advanced algebraic machinery. In this paper, we give a different and much simpler algorithm for this type of constraint.

DOI. 10.1137/050628957

1. Introduction. Constraint satisfaction problems arise in a wide variety of areas, such as combinatorics, logic, algebra, and artificial intelligence. An instance of the constraint satisfaction problem (CSP) consists of a set of variables, a set of values (which can be taken by the variables) that is called a domain, and a set of constraints (where a constraint is a pair given by a list of variables, called the constraint scope, and a relation indicating the valid combinations of values for the variables in the scope, called the constraint relation). The goal in a CSP is to decide whether or not there is an assignment of values to the variables satisfying all of the constraints. It is sometimes customary to cast the CSP as a relational homomorphism problem [15], namely, the problem of deciding, given a pair $(\mathbf{A}, \mathbf{B})$ of relational structures, whether or not there is a homomorphism from $\mathbf{A}$ to $\mathbf{B}$. In this formalization, each relation of $\mathbf{A}$ contains tuples of variables that are constrained together, and the corresponding relation of $\mathbf{B}$ contains the allowed tuples of values that the variable tuples may take.

The CSP is NP-complete in general, motivating the search for polynomial-time tractable cases of the CSP. A particularly useful way to restrict the CSP in order to obtain tractable cases is to restrict the types of constraints that may be expressed, by requiring the relations appearing in a constraint to belong to a given fixed set Γ. Such a restricted version of the CSP is denoted by CSP(Γ). This form of restriction can capture and place into a unified framework many particular cases of the CSP that have been independently investigated, for instance, the HORN SATISFIABILITY, 2-SATISFIABILITY, and GRAPH H-COLORABILITY problems. Schaefer was the first to consider the class of problems CSP(Γ); he proved a now famous dichotomy theorem,

showing that for every set Γ of relations over a two-element domain, CSP(Γ) is either solvable in polynomial time or NP-complete [23].

In recent years, much effort has been invested toward the program of isolating all sets Γ of relations (or *constraint languages*) over a finite domain that give rise to a class of instances of CSP, CSP(Γ), solvable in polynomial time. Impressive progress has been made along these lines leading to the identification of several broad conditions on Γ that guarantee tractability. It was initiated by [2, 17, 19], where it has been shown that the complexity of CSP(Γ) depends only on the *algebraic invariance properties* of relations from Γ.

Some important recent achievements in the field include a complete classification of CSPs over a three-element domain [4] and the conservative CSP [6]. Remarkably, one of the main ingredients in both results is the recent result due to the first author [5] stating that every set Γ of relations on a finite set invariant with respect to a Mal'tsev operation, that is, a ternary operation φ satisfying $\varphi(x, y, y) = \varphi(y, y, x) = x$ for all x, y, gives rise to a tractable problem class. This result also encompasses and generalizes several previously known tractable cases of the CSP, such as affine problems [19, 23], constraint satisfaction problems on finite groups with near subgroups and their cosets [14, 15], and paraprimal CSPs [11].

Another reason Mal'tsev constraints are so important is that, to date, almost all CSPs known to be solvable in polynomial time can be solved using *local propagation algorithms*. In this type of algorithm we identify forbidden combinations of values for sets of variables of fixed size and then propagate the original problem by imposing new constraints that use this information. The only known exception is CSPs involving constraints invariant under a Mal'tsev operation. Thus, Mal'tsev constraints constitute a conceptually important class of constraints that require a completely different approach in solution techniques. Feder and Vardi attempted to capture this distinction in [15], where they used Datalog programs to simulate local propagation algorithms and suggested the term *problems with ability to count* for those problems which cannot be solved using Datalog. We also note another appearance of Mal'tsev constraints [8]. In that paper, we show that invariance with respect to a Mal'tsev operation is a necessary condition for the tractability of the counting CSP.

It is fair to say that the original proof of the tractability of Mal'tsev constraints [5] is very complicated. Furthermore, it makes intensive use of advanced algebraic techniques and thus is hardly comprehensible for a nonalgebraist. In this paper we give a different proof of the tractability of Mal'tsev constraints. The proof presented in this paper is notably simpler than the original proof and does not require the use of any previous algebraic result; indeed the proof is completely self-contained.

2. Preliminaries.

2.1. Constraint satisfaction problem. Let A be a finite set and let n be a positive integer. An n-ary relation on A is any subset of A^n. In what follows, for every positive integer n, $[n]$ will denote the set $\{1, \dots, n\}$.

A constraint satisfaction problem is a natural way to express simultaneous requirements for values of variables. This is stated more precisely in the following definition.

DEFINITION 2.1. *An instance* $\mathcal{P} = (V; A; \{C_1, \dots, C_m\})$ *of a* constraint satisfaction problem *consists of*

- *a finite set of variables,* $V = \{v_1, \dots, v_n\}$*;*
- *a finite domain of values,* A*;*

- *a finite set of constraints,* $\{C_1, \dots, C_m\}$*; each constraint* C_l*,* $l \in [m]$*, is a pair* $((v_{i_1}, \dots, v_{i_{k_l}}), S_l)$*, where*
  - $(v_{i_1}, \dots, v_{i_{k_l}})$ *is a tuple of variables of length* k_l*, called the* constraint scope*, and*
  - S_l *is a* k_l*-ary relation on* A*, called the* constraint relation.

A solution *to a CSP instance is a mapping* $s : V \to A$ *such that for each constraint* C_l*,* $l \in [m]$*, we have that* $(s(v_{i_1}), \dots, s(v_{k_l})) \in S_l$*.*

The question in the CSP instance $\mathcal{P}$ *is to decide whether or not there exists a solution to* $\mathcal{P}$*.*

The CSP is NP-complete in general, even when the constraints are restricted to binary constraints [21] or when the domain of values has size 2 [10].

Example 1. An instance of the standard propositional 3-SATISFIABILITY problem [16, 22] is specified by giving a formula of propositional logic consisting of a conjunction of clauses, each of which contains exactly three literals, and asking whether there are values for the variables which make the formula true.

Suppose that $\Phi = F_1 \wedge \dots \wedge F_n$ is such a formula, where the F_i are clauses. The satisfiability question for Φ can be expressed as the CSP instance $(V, \{0,1\}, \mathcal{C})$, where V is the set of all variables appearing in the clauses F_i and $\mathcal{C}$ is the set of constraints $\{(s_1, R_1), \dots, (s_n, R_n)\}$, where each constraint (s_k, R_k) is constructed as follows:

- $s_k = (x_1^k, x_2^k, x_3^k)$, where x_1^k, x_2^k, x_3^k are the variables appearing in clause F_k;
- $R_k = \{0,1\}^3 \setminus \{(a_1, a_2, a_3)\}$, where $a_i = 1$ if x_i^k is negated in F_k and $a_i = 0$ otherwise (i.e., R_k contains exactly those 3-tuples that make F_k true).

The solutions of this instance are exactly the assignments which make the formula Φ true.

Example 2. An instance of the GRAPH k-COLORABILITY problem consists of a graph G. The question is whether the vertices of G can be labeled with k colors so that adjacent vertices are assigned different colors.

This problem can be expressed as a CSP instance as follows. Let $G = (V, E)$ be a graph. Then we treat V as the set of variables (thus interpreting vertices of G as variables). For the domain we use a k-element set A of colors. Finally, for each edge $(u, v) \in E$ we introduce a constraint $((u, v), \neq_A)$, where $\neq_A$ is the disequality relation on A, defined by

$$\neq_A \ = \{(a, b) \in A^2 \mid a \neq b\}.$$

In applications of the CSP, we normally need just some restricted versions of the problem. One of the most natural and useful ways to restrict the CSP is to impose restrictions on the allowed constraint relations.

DEFINITION 2.2. *For any set of relations* Γ*,* CSP(Γ) *is defined to be the class of decision problems with*

- *Instance: A constraint satisfaction problem instance* $\mathcal{P}$*, in which all constraint relations are elements of* Γ*.*
- *Question: Does* $\mathcal{P}$ *have a solution?*

Example 1 (continued). If we define $\Gamma_{\text{3-SAT}}$ to be the constraint language on $\{0,1\}$ consisting of all relations expressible by 3-clauses, then any instance of 3-SATISFIABILITY can be expressed as an instance of CSP($\Gamma_{\text{3-SAT}}$) and vice versa. In other words, 3-SATISFIABILITY is equivalent to CSP($\Gamma_{\text{3-SAT}}$).

Example 2 (continued). Similarly, the GRAPH k-COLORABILITY can be viewed as CSP($\{\neq_A\}$).

In the two examples we have given, even the restricted problems are NP-complete. However, in many cases restricting the allowed form of constraint relations, we arrive at a problem solvable in polynomial time (we refer to such problems as *tractable* problems).

Example 3. An instance of Graph Unreachability consists of a graph, $G = (V, E)$, and a pair of vertices, $v, w \in V$. The question is whether there is no path in G from v to w.

This can be expressed as the CSP instance $(V, \{0,1\}, \mathcal{C})$, where

$$\mathcal{C} = \{(e, \{=_{\{0,1\}}\}) \mid e \in E\} \cup \{((v), \{(0)\}), ((w), \{(1)\})\},$$

where $=_{\{0,1\}}$ denotes the equality relation on the set $\{0,1\}$.

If we define Γ_{Unreach} to be the constraint language on $\{0,1\}$ containing just the relations $=_{\{0,1\}}$, $\{(0)\}$, and $\{(1)\}$, then any instance of Graph Unreachability can be expressed as an instance of $\mathrm{CSP}(\Gamma_{\text{Unreach}})$ in this way.

The research project, which this paper is a part of, aims to distinguish those constraint languages Γ which give rise to a tractable problem $\mathrm{CSP}(\Gamma)$ from those which do not.

In the CSP literature, it is usual to assume constraint languages to be finite. This is motivated by certain difficulties of representing infinite collections of relations, by the fact that applications of the CSP in discrete mathematics normally require only some fixed variety of relations, and also by some traditions well established in the area. The algebraic approach we introduce in the next section makes it very natural to deal with infinite constraint languages. Thus, in this paper, the constraint languages we consider are allowed to be infinite. This implies, in particular, that the arity of relations is not necessarily bounded.

Example 4. Let A be a finite field, and let Γ_{LIN} be the constraint language consisting of all relations over A which consist of all solutions to some linear equation over A. Any relation from Γ_{LIN}, and therefore any instance of $\mathrm{CSP}(\Gamma_{\text{LIN}})$, can be represented by a system of linear equations over A (for more details, see [3]).

Clearly, Γ_{LIN} is infinite and yet every instance of $\mathrm{CSP}(\Gamma_{\text{LIN}})$ can be easily defined and it can be solved in polynomial time (e.g., by Gaussian elimination).

2.2. Polymorphisms and invariants. We briefly introduce the basics of the algebraic approach to the CSP. For more details the reader is referred to [2].

Definition 2.3. *Let $\varphi : A^m \to A$ be an m-ary operation on A and let R be an n-ary relation over A. We say that R is* invariant *under φ and φ is said to be a* polymorphism *of R if for all (not necessarily different) tuples $\mathbf{t_1} = (t_1^1, \ldots, t_n^1), \ldots, \mathbf{t_m} = (t_1^m, \ldots, t_n^m)$ in R, the tuple $\varphi(\mathbf{t_1}, \ldots, \mathbf{t_m})$ defined as*

$$(\varphi(t_1^1, \ldots, t_1^m), \ldots, \varphi(t_n^1, \ldots, t_n^m))$$

belongs to R.

Let C be a set of operations on A and let Γ be a constraint language. Then $\mathrm{Inv}(C)$ denotes the set of all relations invariant under each operation from C, and $\mathrm{Pol}(\Gamma)$ denotes the set of all operations which are polymorphisms of every relation from Γ.

Example 5. Let R be the solution space of a system of linear equations over a field F. Then the operation $\varphi(x, y, z) = x - y + z$ is a polymorphism of R. Indeed, let $A \cdot \mathbf{x} = \mathbf{b}$ be the system defining R, and suppose that $\mathbf{x}, \mathbf{y}, \mathbf{z} \in R$. Then

$$A \cdot \varphi(\mathbf{x}, \mathbf{y}, \mathbf{z}) = A \cdot (\mathbf{x} - \mathbf{y} + \mathbf{z}) = A \cdot \mathbf{x} - A \cdot \mathbf{y} + A \cdot \mathbf{z} = \mathbf{b} - \mathbf{b} + \mathbf{b} = \mathbf{b}.$$

In fact, the converse can also be shown: If R is invariant under φ, then it is the solution space of a certain system of linear equations.

The cornerstone theorem proved by Jeavons [17] and Jeavons, Cohen, and Gyssens [19] provides a link between the complexity of CSP(Γ) and the properties of the polymorphisms of Γ. It amounts to saying that, for every *finite* constraint language Γ, the complexity of CSP(Γ) depends solely on the set Pol(Γ). In other words, if Pol(Γ_1) = Pol(Γ_2), then CSP(Γ_1) and CSP(Γ_2) are polynomial-time reducible to each other (provided Γ_1 and Γ_2 are finite). This also motivates the prior study of constraint languages of the form Inv(C) for some set C of operations. In fact, most of the existing tractability results on constraint languages may be formulated as the tractability of problems CSP(Inv(C)), where C consists of a single operation! (See, e.g., [1, 9, 12, 13, 17, 18, 20].)

One such type of operation that guarantees the tractability of the corresponding CSP is Mal'tsev operations.

DEFINITION 2.4. *A ternary operation $\varphi : A^3 \to A$ on a finite set A is called Mal'tsev if it satisfies the following identities:*

$$\varphi(x, y, y) = \varphi(y, y, x) = x \quad \forall x, y \in A.$$

For instance, operation φ defined in Example 5 is Mal'tsev.

The following theorem was first proved in [5].

THEOREM 2.5. *Let φ be a Mal'tsev operation. Then* CSP(Inv(φ)) *is solvable in polynomial time.*

The proof given in [5] employs a sophisticated algorithm that relies heavily on algebraic techniques and can hardly be understood without extensive knowledge of universal algebra. In this paper, we give a much shorter and simpler proof that is completely self-contained. Although the two algorithms have been designed mostly independently, they have a similar structure. To complete this section we outline the structure of the two algorithms and describe the main differences between them.

Both algorithms use *compact representations* of relations invariant under a Mal'tsev operation. Clearly, the size of an n-ary relation can be exponential in n. Therefore, if n is, for example, the number of variables in a CSP instance, then to represent an n-ary relation we need something more sophisticated than just a list of tuples. One possible form of such representation is introduced in the next section; representations used in [5] are very similar, but have a much finer structure. Both representations exploit the *rectangularity* of relations invariant under a Mal'tsev operation (see the next section).

Given a CSP instance $\mathcal{P} = (V, A, \{C_1, \dots, C_k\})$, both algorithms progressively construct compact representations of the complete sets of solutions of the instances $\mathcal{P}_0, \mathcal{P}_1, \mathcal{P}_2, \dots, \mathcal{P}_k = \mathcal{P}$, where $\mathcal{P}_i = (V, A, \{C_1, \dots, C_i\})$. In [5], this is done by constructing, in a certain complicated way, and then solving a system of linear equations such that a representation of $\mathcal{P}_{i+1}$ can be found as a basis of its solution space. Later, when working on [7], the second author observed that the same task can be fulfilled in a much more straightforward and simple way. This observation is the core of the present paper.

3. Signatures and representations. Let A be a finite set, let n be a positive integer, let $\mathbf{t} = (t_1, \dots, t_n)$ be an n-ary tuple, and let $i_1, \dots, i_j$ be (not necessarily

different) elements from $[n]$. By $\mathrm{pr}_{i_1,\dots,i_j}\,\mathbf{t}$ we denote the tuple $(t_{i_1},\dots,t_{i_j})$. Similarly, for every n-ary relation R on A and for every $i_1,\dots,i_j \in [n]$, we denote by $\mathrm{pr}_{i_1,\dots,i_j} R$ the j-ary relation given by $\{\mathrm{pr}_{i_1,\dots,i_j}\,\mathbf{t} : \mathbf{t} \in R\}$.

Given a relation R and an operation φ, we denote by $\langle R\rangle_\varphi$ the smallest relation R' that contains R and is invariant under φ. Very often, the operation φ will be clear from the context and we will drop it, writing $\langle R\rangle$ instead of $\langle R\rangle_\varphi$.

Let n be a positive integer, let A be a finite set, let $\mathbf{t},\mathbf{t}'$ be n-ary tuples, and let (i,a,b) be any element in $[n]\times A^2$. We say that $(\mathbf{t},\mathbf{t}')$ *witnesses* (i,a,b) if $\mathrm{pr}_{1,\dots,i-1}\,\mathbf{t} = \mathrm{pr}_{1,\dots,i-1}\,\mathbf{t}'$, $\mathrm{pr}_i\,\mathbf{t} = a$, and $\mathrm{pr}_i\,\mathbf{t}' = b$. We also say that $\mathbf{t}$ and $\mathbf{t}'$ witness (i,a,b), meaning that $(\mathbf{t},\mathbf{t}')$ witnesses (i,a,b).

Let R be any n-ary relation on A. We define the *signature* of R, $\mathrm{Sig}_R \subseteq [n]\times A^2$, as the set containing all those $(i,a,b)\in[n]\times A^2$ witnessed by tuples in R; that is

$$\mathrm{Sig}_R = \{(i,a,b)\in[n]\times A^2 : \exists \mathbf{t},\mathbf{t}'\in R \text{ such that } (\mathbf{t},\mathbf{t}') \text{ witnesses } (i,a,b)\}.$$

A subset R' of R is called a *representation* of R if $\mathrm{Sig}_{R'} = \mathrm{Sig}_R$. If, furthermore, $|R'| \le 2|\,\mathrm{Sig}_R\,|$, then R' is called a *compact* representation of R. Observe that every relation R has compact representations. Indeed, in order to construct such a compact representation R' we need only select, for each (i,a,b) in Sig_R, a couple of tuples $\mathbf{t},\mathbf{t}'$ in R that witness (i,a,b) and include them in R'.

Example 6. Fix a set A, an element $d\in A$, and an integer n. For every $(i,a)\in [n]\times A$ we define the tuple $\mathbf{e}^d_{i,a}$ as the only tuple satisfying

$$\mathrm{pr}_j\,\mathbf{e}^d_{i,a} = \begin{cases} a & \text{if } i=j \\ d & \text{otherwise} \end{cases} \quad \text{for all } j\in[n].$$

It is easy to observe that for every $(i,a,b)\in[n]\times A^2$, $(\mathbf{e}^d_{i,a},\mathbf{e}^d_{i,b})$ witnesses (i,a,b). Consequently, for a fixed d, the set of tuples $\{\mathbf{e}^d_{i,a} : i\in[n],\, a\in A\}$ is a representation of the relation A^n. Notice also that it is indeed a compact representation.

The algorithm we propose relies on Lemma 3.1, which follows from the property of *rectangularity* of relations invariant under a Mal'tsev operation φ. Let R be an n-ary relation invariant under φ and let $\mathbf{t_1},\mathbf{t_2},\mathbf{t_3}\in R$ be such that $\mathrm{pr}_{1,\dots,n-1}\,\mathbf{t_2} = \mathrm{pr}_{1,\dots,n-1}\,\mathbf{t_3}$ and $\mathrm{pr}_n\,\mathbf{t_1} = \mathrm{pr}_n\,\mathbf{t_2}$. Then the tuple $\mathbf{t}$ with $\mathrm{pr}_{1,\dots,n-1}\,\mathbf{t} = \mathrm{pr}_{1,\dots,n-1}\,\mathbf{t_1}$ and $\mathrm{pr}_n\,\mathbf{t} = \mathrm{pr}_n\,\mathbf{t_3}$ belongs to R. Indeed, we can choose $\mathbf{t} = \varphi(\mathbf{t_1},\mathbf{t_2},\mathbf{t_3})\in R$. Let us see that $\mathbf{t}$ satisfies the required conditions. Since φ is Mal'tsev we can infer that

$$\mathrm{pr}_{1,\dots,n-1}\,\mathbf{t} = \mathrm{pr}_{1,\dots,n-1}\,\varphi(\mathbf{t_1},\mathbf{t_2},\mathbf{t_3}) = \mathrm{pr}_{1,\dots,n-1}\,\varphi(\mathbf{t_1},\mathbf{t_2},\mathbf{t_2}) = \mathrm{pr}_{1,\dots,n-1}\,\mathbf{t_1}.$$

Also, we have that

$$\mathrm{pr}_n\,\mathbf{t} = \mathrm{pr}_n\,\varphi(\mathbf{t_1},\mathbf{t_2},\mathbf{t_3}) = \mathrm{pr}_n\,\varphi(\mathbf{t_2},\mathbf{t_2},\mathbf{t_3}) = \mathrm{pr}_n\,\mathbf{t_3}.$$

LEMMA 3.1. *Let A be a finite set, let $\varphi : A^3\to A$ be a Mal'tsev operation, let R be a relation on A invariant under φ, and let R' be a representation of R. Then $\langle R'\rangle_\varphi = R$.*

Proof. Let n be the arity of R. By induction on i, we shall show that, for every $i\in[n]$, $\mathrm{pr}_{1,\dots,i}\langle R'\rangle = \mathrm{pr}_{1,\dots,i} R$. The case $i=1$ follows easily from the fact that for each $\mathbf{t}\in R$, $(1,\mathrm{pr}_1\,\mathbf{t},\mathrm{pr}_1\,\mathbf{t})$ is in Sig_R and hence in $\mathrm{Sig}_{R'}$.

So, let us assume that the claim holds for $i<n$ and let $\mathbf{t}$ be any tuple in R. We show that $\mathrm{pr}_{1,\dots,i+1}\,\mathbf{t}\in \mathrm{pr}_{1,\dots,i+1}\langle R'\rangle$. By induction hypothesis there exists a tuple $\mathbf{t_1}$ in $\langle R'\rangle$ such that $\mathrm{pr}_{1,\dots,i}\,\mathbf{t_1} = \mathrm{pr}_{1,\dots,i}\,\mathbf{t}$. We have that $(i+1,\mathrm{pr}_{i+1}\,\mathbf{t_1},\mathrm{pr}_{i+1}\,\mathbf{t})$

belongs to Sig_R, and therefore, there exist some tuples $\mathbf{t_2}$ and $\mathbf{t_3}$ in R' witnessing it. To complete the proof we just need to observe that since $\mathbf{t_2}$ and $\mathbf{t_3}$ witness $(i+1, \mathrm{pr}_{i+1}\mathbf{t}, \mathrm{pr}_{i+1}\mathbf{t_1})$, we have that $\mathrm{pr}_{1,\dots,i}\mathbf{t_2} = \mathrm{pr}_{1,\dots,i}\mathbf{t_3}$ and that $\mathrm{pr}_{i+1}\mathbf{t_1} = \mathrm{pr}_{i+1}\mathbf{t_2}$ and $\mathrm{pr}_{i+1}\mathbf{t} = \mathrm{pr}_{i+1}\mathbf{t_3}$. Then the equality $\mathrm{pr}_{1,\dots,i+1}\mathbf{t} = \mathrm{pr}_{1,\dots,i+1}\varphi(\mathbf{t_1}, \mathbf{t_2}, \mathbf{t_3})$ follows from the rectangularity of $\mathrm{pr}_{1,\dots,i+1}R$. □

4. Proof of Theorem 2.5. We prove Theorem 2.5 by giving a polynomial-time algorithm that correctly decides whether a CSP(Inv(φ)) instance has a solution.

Let $\mathcal{P} = (\{v_1, \dots, v_n\}, A, \{C_1, \dots, C_m\})$ be a CSP(Inv(φ)) instance which will be the input of the algorithm.

For each $l \in \{0, \dots, m\}$ we define $\mathcal{P}_l$ as the CSP instance that contains the first l constraints of $\mathcal{P}$, that is, $\mathcal{P}_l = (\{v_1, \dots, v_n\}, A, \{C_1, \dots, C_l\})$. Furthermore, we shall denote by R_l the n-ary relation on A defined as

$$R_l = \{(s(v_1), \dots, s(v_n)) : s \text{ is a solution of } \mathcal{P}_l\}.$$

As we have already mentioned, in a nutshell, the algorithm introduced in this section computes for each $l \in \{0, \dots, m\}$ a compact representation R'_l of R_l. In the initial case ($l = 0$), $\mathcal{P}_0$ does not have any constraint at all and, consequently, $R_0 = A^n$. Hence, a compact representation of R_0 can be easily obtained as in Example 6. Once a compact representation R'_0 of R_0 has been obtained, then the algorithm starts an iterative process in which a compact representation R'_{l+1} of R_{l+1} is obtained from R'_l and the constraint C_{l+1}. This is achieved by calling Procedure `Next`, which constitutes the core of the algorithm. The algorithm then goes as follows:

Algorithm `Solve`$((\{v_1, \dots, v_n\}, A, \{C_1, \dots, C_m\}))$
Step 1 **select** an arbitrary element d in A
Step 2 **set** $R'_0 := \{\mathbf{e}^d_{i,a} : (i, a) \in [n] \times A\}$
Step 3 **for each** $l \in \{0, \dots, m-1\}$ **do**
(let C_{l+1} be $((v_{i_1}, \dots, v_{i_{l+1}}), S_{l+1})$)
Step 3.1 **set** $R'_{l+1} :=$ `Next`$(R'_l, i_1, \dots, i_{l+1}, S_{l+1})$
endfor
Step 4 **if** $R'_m \neq \emptyset$ **return yes**
Step 5 **otherwise return no**

Observe that if we modify Step 4 so that the algorithm returns an arbitrary tuple in R'_m instead of "yes," then we have an algorithm that does not merely solve the decision question but actually provides a solution.

Correctness and polynomial-time complexity of the algorithm are direct consequences of the correctness and the running time of Procedure `Next`: As shown in section 4.3 (Lemma 4.1), at each iteration of Step 3.1, the output of the call `Next`$(R'_l, i_1, \dots, i_{l+1}, S_{l+1})$ is a compact representation of the relation $\{\mathbf{t} \in R_l : \mathrm{pr}_{i_1,\dots,i_{l+1}}\mathbf{t} \in S_{l+1}\}$, which is indeed R_{l+1}. Furthermore, the time complexity of `Solve` is obviously polynomial in the time complexity of `Next`. Thus to finish the proof of Theorem 2.5, we need to design `Next` and show that it is correct and has polynomial time complexity.

The remainder of the paper is devoted to defining and analyzing Procedure `Next`. In order to define Procedure `Next` it is convenient to introduce first two simple procedures, namely `Nonempty` and `Fix-values`, which will be intensively used by our Procedure `Next`.

4.1. Procedure `Nonempty`. This procedure receives as an input a compact representation R' of a relation R invariant under φ, a sequence $i_1, \dots, i_j$ of elements in

$[n]$, where n is the arity of R, and a j-ary relation S also invariant under φ. The output of the procedure is either an n-ary tuple $\mathbf{t} \in R$ such that $\mathrm{pr}_{i_1,\ldots,i_j}\,\mathbf{t} \in S$ or "no," meaning that such a tuple does not exist.

Procedure `Nonempty`$(R', i_1, \ldots, i_j, S)$
Step 1 **set** $U := R'$
Step 2 **while** $\exists \mathbf{t_1}, \mathbf{t_2}, \mathbf{t_3} \in U$ such that $\mathrm{pr}_{i_1,\ldots,i_j}\,\varphi(\mathbf{t_1}, \mathbf{t_2}, \mathbf{t_3}) \notin \mathrm{pr}_{i_1,\ldots,i_j}\,U$ **do**
Step 2.1 **set** $U := U \cup \{\varphi(\mathbf{t_1}, \mathbf{t_2}, \mathbf{t_3})\}$
endwhile
Step 3 **if** $\exists \mathbf{t}$ in U such that $\mathrm{pr}_{i_1,\ldots,i_j}\,\mathbf{t} \in S$ **then return t**
Step 4 **else return** "no"

We shall start by studying the procedure's correctness. First observe that every tuple in U belongs initially to R' (and hence to R) or it has been obtained by applying φ to some tuples $\mathbf{t_1}, \mathbf{t_2}, \mathbf{t_3}$ that previously belonged to U. Therefore, since R is invariant under φ, we can conclude that $U \subseteq R$. Consequently, if a tuple $\mathbf{t}$ is returned in Step 3, then it belongs to R and also satisfies the condition $\mathrm{pr}_{i_1,\ldots,i_j}\,\mathbf{t} \in S$, as desired. It remains only to show that if a "no" is returned in Step 4, then there exists no tuple $\mathbf{t}$ in R such that $\mathrm{pr}_{i_1,\ldots,i_j}\,\mathbf{t} \in S$. In order to do this we need to show some simple facts about U. Notice that at any point of the execution of the procedure $R' \subseteq U$. Then U is also a representation of R and hence $\langle U \rangle = R$. Therefore we have that

$$\langle \mathrm{pr}_{i_1,\ldots,i_j}\,U \rangle = \mathrm{pr}_{i_1,\ldots,i_j} \langle U \rangle = \mathrm{pr}_{i_1,\ldots,i_j}\,R.$$

By the condition on the "while" of Step 2 we have that when the procedure leaves the execution of Step 2 it must be the case that for all $\mathbf{t_1}, \mathbf{t_2}, \mathbf{t_3} \in U$, $\mathrm{pr}_{i_1,\ldots,i_j}\,\varphi(\mathbf{t_1}, \mathbf{t_2}, \mathbf{t_3}) \in \mathrm{pr}_{i_1,\ldots,i_j}\,U$ and, consequently, $\mathrm{pr}_{i_1,\ldots,i_j}\,U = \langle \mathrm{pr}_{i_1,\ldots,i_j}\,U \rangle = \mathrm{pr}_{i_1,\ldots,i_j}\,R$. Hence, if there exists some $\mathbf{t}$ in R such that $\mathrm{pr}_{i_1,\ldots,i_j} \in S$, then there must exist some $\mathbf{t'}$ in U such that $\mathrm{pr}_{i_1,\ldots,i_j} \in S$, and we are done.

Let us study now the running time of the procedure. It is only necessary to focus on Steps 2 and 3. At each iteration of the loop in Step 2, cardinality of U increases by one. So we can bound the number of iterations by the size $|U|$ of U at the end of the execution of the procedure.

The cost of each iteration is basically dominated by the cost of checking whether there exist some tuples $\mathbf{t_1}, \mathbf{t_2}, \mathbf{t_3} \in U$ such that $\mathrm{pr}_{i_1,\ldots,i_j}\,\varphi(\mathbf{t_1}, \mathbf{t_2}, \mathbf{t_3}) \notin \mathrm{pr}_{i_1,\ldots,i_j}\,U$ which is done in Step 2. In order to try all possible combinations for $\mathbf{t_1}, \mathbf{t_2}, \mathbf{t_3}$ in U, $|U|^3$ steps suffice. Each one of these steps requires time $O(|U|n)$, as tuples have arity n and checking whether $\varphi(\mathbf{t_1}, \mathbf{t_2}, \mathbf{t_3})$ belongs to U can be done naively by a sequential search in U. Thus, the running time of `Nonempty` is polynomial in n and in the possible size of U.

Notice now that this is not enough. Indeed, as we do not restrict the arity of the relations used, j may be comparable with n, which implies that the size of U may be exponential in n. To solve this problem, we organize invoking `Nonempty` in such a way that the size of U is bounded by a polynomial in $|S|$, n, and $|A|$. In order to accomplish this, we shall ensure that at each call to `Nonempty` the following condition is satisfied:

$$|\,\mathrm{pr}_{i_1,\ldots,i_j}\,R| \leq |S| \cdot |A|^2. \tag{4.1}$$

Later (see Procedures `Next` and `Next-beta`) we show how this can be achieved. It is not difficult to see that if (4.1) is true, then the size of U can be bounded by a

polynomial. More precisely, the size of U can be bounded by the initial size of R', which is at most $n \cdot |A|^2$ (since R' is compact) plus the number of iterations of Step 2, which is bounded by $|\operatorname{pr}_{i_1,\dots,i_j} R| \leq |S| \cdot |A|^2$.

4.2. Procedure `Fix-values`. This procedure receives as an input a compact representation R' of a relation R invariant under φ and a sequence $a_1, \dots, a_m$, $m \leq n$, of elements of A (n is the arity of R). The output is a compact representation of the relation given by

$$\{\mathbf{t} \in R : \operatorname{pr}_1 \mathbf{t} = a_1, \dots, \operatorname{pr}_m \mathbf{t} = a_m\}.$$

Procedure `Fix-values`$(R', a_1, \dots, a_m)$
Step 1 **set** $j := 0$; $U_j := R'$
Step 2 **while** $j < m$ **do**
Step 2.1 **set** $U_{j+1} := \emptyset$
Step 2.2 **for each** $(i, a, b) \in [n] \times A^2$ **do**
Step 2.2.1 **if** $\exists \mathbf{t_2}, \mathbf{t_3} \in U_j$ witnessing (i, a, b)
(we assume that if $a = b$ then $\mathbf{t_2} = \mathbf{t_3}$) and
`Nonempty`$(U_j, j+1, i, \{(a_{j+1}, a)\}) \neq$ "no" and
$(i > j+1$ or $a = b = a_i)$ **then**
(let $\mathbf{t_1}$ be the tuple returned
by the call to `Nonempty`$(U_j, j+1, i, \{a_{j+1}, a\})$)
set $U_{j+1} := U_{j+1} \cup \{\mathbf{t_1}, \varphi(\mathbf{t_1}, \mathbf{t_2}, \mathbf{t_3})\}$
endfor
Step 2.4 **set** $j := j + 1$
endwhile
Step 3 **return** U_m

Let us study the correctness of the procedure. We shall show by induction on $j \in \{0, \dots, m\}$ that U_j is a compact representation of $R_j = \{\mathbf{t} \in R : \operatorname{pr}_1 \mathbf{t} = a_1, \dots, \operatorname{pr}_j \mathbf{t} = a_j\}$. The case $j = 0$ is correctly settled in Step 1. Hence it is only necessary to show that at every iteration of the **while** loop in Step 2, if U_j is a compact representation of R_j, then U_{j+1} is a compact representation of R_{j+1}. It is easy to see that if any of the conditions of the **if** in Step 2.2.1 is falsified, then (i, a, b) is not in $\operatorname{Sig}_{R_{j+1}}$. So it remains only to see that when the **if** in Step 2.2.1 is satisfied, we have that (a) $\mathbf{t_1}$ and $\varphi(\mathbf{t_1}, \mathbf{t_2}, \mathbf{t_3})$ are tuples in R_{j+1}, and (b) $(\mathbf{t_1}, \varphi(\mathbf{t_1}, \mathbf{t_2}, \mathbf{t_3}))$ witnesses (i, a, b).

Proof of (a). As $\mathbf{t_1} =$ `Nonempty`$(U_j, j+1, i, \{(a_{j+1}, a)\})$, we can conclude that $\mathbf{t_1}$ belongs to R_j, $\operatorname{pr}_{j+1} \mathbf{t_1} = a_{j+1}$, and $\operatorname{pr}_i \mathbf{t_1} = a$. Consequently $\mathbf{t_1}$ belongs to R_{j+1}. Furthermore, as $\mathbf{t_1}$, $\mathbf{t_2}$, and $\mathbf{t_3}$ are in R_j and R_j is invariant under φ, $\varphi(\mathbf{t_1}, \mathbf{t_2}, \mathbf{t_3})$ belongs to R_j. Let us see now that $\operatorname{pr}_{j+1} \mathbf{t_2} = \operatorname{pr}_{j+1} \mathbf{t_3}$ by means of a case analysis. If $i > j+1$, then we have that $\operatorname{pr}_{j+1} \mathbf{t_2} = \operatorname{pr}_{j+1} \mathbf{t_3}$ as $(\mathbf{t_2}, \mathbf{t_3})$ witnesses (i, a, b). If $i \leq j+1$, then $a = b = a_i$ and hence $\mathbf{t_2}$ and $\mathbf{t_3}$ are identical.

Finally, since φ is Mal'tsev, $\operatorname{pr}_{j+1} \varphi(\mathbf{t_1}, \mathbf{t_2}, \mathbf{t_3}) = \operatorname{pr}_{j+1} \mathbf{t_1} = a_{j+1}$ and hence $\varphi(\mathbf{t_1}, \mathbf{t_2}, \mathbf{t_3})$ belongs to R_{j+1}. □

Proof of (b). Since $(\mathbf{t_2}, \mathbf{t_3})$ witnesses (i, a, b), we have that $\operatorname{pr}_{1,\dots,i-1} \mathbf{t_2} = \operatorname{pr}_{1,\dots,i-1} \mathbf{t_3}$. Consequently, $\operatorname{pr}_{1,\dots,i-1} \varphi(\mathbf{t_1}, \mathbf{t_2}, \mathbf{t_3}) = \operatorname{pr}_{1,\dots,i-1} \mathbf{t_1}$. Furthermore, we also have that $\operatorname{pr}_i \varphi(\mathbf{t_1}, \mathbf{t_2}, \mathbf{t_3}) = \operatorname{pr}_i \varphi(a, a, b) = b$.

Notice that each iteration adds at most two tuples for some (i, a, b) in $\operatorname{Sig}_{R_{j+1}}$. Consequently, U_{j+1} is compact. This completes the proof of its correctness. □

Let us study now the time complexity of `Fix-values`. The **while** loop at Step 2 is performed $m \leq n$ times. At each iteration the procedure executes another loop

(Step 2.2). The **for each** loop at Step 2.2 is executed for each (i, a, b) in $[n] \times A^2$, that is, a total number of $n|A|^2$ times. The cost of each iteration of the loop is basically dominated by the cost of the call to Procedure `Nonempty`. Therefore, the time complexity of the procedure is polynomial in n and the maximal time complexity of `Nonempty`. Observe that in this case condition (4.1) in the call of `Nonempty` is satisfied.

4.3. Procedure `Next`. We are now almost in a position to introduce Procedure `Next`. Procedure `Next` receives as input a compact representation R' of a relation R invariant under φ, a sequence $i_1, \dots, i_j$ of elements in $[n]$ where n is the arity of R, and a j-ary relation S invariant under φ. The output of `Next` is a compact representation of the relation $R^* = \{\mathbf{t} \in R : \mathrm{pr}_{i_1,\dots,i_j}\, \mathbf{t} \in S\}$. It is an easy exercise to verify that R^* is also invariant under φ.

We shall start by defining a procedure called `Next-beta` that is equivalent to `Next` but has a worse time complexity running time. In particular, the running time of `Next-beta` might be exponential in the size of its input.

Procedure `Next-beta`$(R', i_1, \dots, i_j, S)$
Step 1 **set** $U := \emptyset$
Step 2 **for each** $(i, a, b) \in [n] \times A^2$ **do**
Step 2.1 **if** `Nonempty`$(R', i_1, \dots, i_j, i, S \times \{a\}) \neq$ "no" **then**
(let $\mathbf{t}$ be the tuple returned by `Nonempty`$(R', i_1, \dots, i_j, i, S \times \{a\})$)
Step 2.2 **if** `Nonempty`(`Fix-values`$(R', \mathrm{pr}_1\, \mathbf{t}, \dots, \mathrm{pr}_{i-1}\, \mathbf{t})$, $i_1, \dots, i_j, i, S \times \{b\}) \neq$ "no"
(let $\mathbf{t}'$ be the tuple returned by `Nonempty`(`Fix-values`$(R', \mathrm{pr}_1\, \mathbf{t}, \dots, \mathrm{pr}_{i-1}\, \mathbf{t}), i_1, \dots, i_j, i, S \times \{b\})$)
set $U := U \cup \{\mathbf{t}, \mathbf{t}'\}$
endfor
Step 3 **return** U

The overall structure of Procedure `Next-beta` is similar to that of Procedure `Fix-values`. Observe that the condition of the **if** statement

$$\texttt{Nonempty}(R', i_1, \dots, i_j, i, S \times \{a\}) \neq \text{“no”}$$

of Step 2.1 is satisfied if and only if there exists a tuple $\mathbf{t} \in R$ such that $\mathrm{pr}_{i_1,\dots,i_j}\, \mathbf{t} \in S$ and $\mathrm{pr}_i\, \mathbf{t} = a$. Hence if such a tuple does not exist, then (i, a, b) is not in Sig_{R^*} and nothing needs to be done for (i, a, b). Now consider the condition of the **if** statement in Step 2.2 which is given by

$$\texttt{Nonempty}(\texttt{Fix-values}(R', \mathrm{pr}_1\, \mathbf{t}, \dots, \mathrm{pr}_{i-1}\, \mathbf{t}), i_1, \dots, i_j, i, S \times \{b\}) \neq \text{“no”}.$$

This condition is satisfied if and only if there exists some $\mathbf{t}'$ in R such that $\mathrm{pr}_{i_1,\dots,i_j}\, \mathbf{t}' \in S$ such that $\mathrm{pr}_{1,\dots,i-1}\, \mathbf{t}' = \mathrm{pr}_{1,\dots,i-1}\, \mathbf{t}$ and $\mathrm{pr}_i\, \mathbf{t}' = b$. It is immediate to see that if the condition holds, then $(\mathbf{t}, \mathbf{t}')$ witnesses (i, a, b). It only remains to show that if $(i, a, b) \in \mathrm{Sig}_{R^*}$, then such a $\mathbf{t}'$ must exist. In order to do this, it is necessary only to verify that if $\mathbf{t_a}, \mathbf{t_b}$ are tuples in R^* witnessing (i, a, b), then, since φ is Mal'tsev, the tuple $\varphi(\mathbf{t}, \mathbf{t_a}, \mathbf{t_b})$ satisfies the desired properties (here $\mathbf{t}$ is the tuple returned by the call to Procedure `Nonempty` in Step 2.1).

Again, the cardinality of U is bounded by $2|\,\mathrm{Sig}_{R^*}\,|$, and hence, U is a compact representation.

Let us study the running time of Procedure `Next-beta`. The loop of Step 2 is performed $n|A|^2$ times and the cost of each iteration is basically the cost of Steps

2.1 and 2.2 in which other procedures are called. Therefore, the running time of `Next-beta` is polynomial in n and the running time of `Nonempty` and `Fix-values`. However, when invoking `Nonempty` on Steps 2.1 and 2.2, we cannot be sure that condition (4.1) holds, and therefore the running time of `Nonempty` and consequently `Next-beta` may be exponential in the size of the input. To avoid this problem, we define a new procedure, `Next`, which makes a sequence of calls to `Next-beta` such that the following condition is satisfied:

$$|\operatorname{pr}_{i_1,\dots,i_j} R| \le |S| \cdot |A|. \tag{4.2}$$

It is easy to observe that if condition (4.2) in the call of `Next-beta` is guaranteed, then condition (4.1) in every call of `Nonempty` is also satisfied. Consequently, if `Next-beta` is called with parameters satisfying condition (4.2), then its running time is polynomial on n, S, and $|A|$.

Procedure `Next`$(R', i_1, \dots, i_j, S)$
Step 1 **set** $l := 0$, $U_l := R'$
Step 2 **while** $l < j$ **do**
Step 2.1 **set** $U_{l+1} :=$ `Next-beta`$(U_l, i_1, \dots, i_{l+1}, \operatorname{pr}_{i_1,\dots,i_{l+1}} S)$
end while
Step 3 **return** U_j

Let us show that condition (4.2) is satisfied in any call to Procedure `Next-beta` in Step 2.1. In the first iteration ($l = 0$), condition (4.2) holds as $\operatorname{pr}_{i_1} R' \subseteq A$. For every subsequent iteration $l \in \{1, \dots, j-1\}$ observe that at the beginning of the iteration,

$$\operatorname{pr}_{i_1,\dots,i_l}\langle U_l\rangle = \operatorname{pr}_{i_1,\dots,i_l} S.$$

Consequently, at each call to Procedure `Next-beta` we have

$$|\operatorname{pr}_{i_1,\dots,i_{l+1}}\langle U_l\rangle| \le |\operatorname{pr}_{i_1,\dots,i_l} S||A| \le |S| \cdot |A|.$$

Therefore, condition (4.2) holds and the running time of the call is polynomial in n, $|S|$, and $|A|$.

Therefore, we have just proved the following lemma.

LEMMA 4.1. *For every $n \ge 1$, every n-ary relation R invariant under φ, every compact representation R' of R, every $i_1, \dots, i_j \in [n]$, and every j-ary relation S invariant under φ,* `Next`$(R', i_1, \dots, i_j, S)$ *computes a compact representation of $R^* = \{\mathbf{t} \in R : \operatorname{pr}_{i_1,\dots,i_j} \in S\}$ in time polynomial in n, $|S|$, and $|A|$. Furthermore, R^* is invariant under φ.*

COROLLARY 4.2. *Algorithm* `Solve` *decides correctly if an arbitrary instance $\mathcal{P}$ of* $\mathrm{CSP}(\mathrm{Inv}(\varphi))$ *is satisfiable in time polynomial in n, s, and $|A|$, where n is the number of variables of $\mathcal{P}$, s is the total number of tuples in the constraint relations, and A is the domain.*

IDENTIFYING CLUSTERS FROM POSITIVE DATA*

JOHN CASE†, SANJAY JAIN‡, ERIC MARTIN§, ARUN SHARMA¶, AND FRANK STEPHAN‖

Abstract. The present work studies clustering from an abstract point of view and investigates its properties in the framework of inductive inference. Any class S considered is given by a hypothesis space, i.e., numbering, $A_0, A_1, \ldots$ of nonempty recursively enumerable (r.e.) subsets of $\mathbb{N}$ or $\mathbb{Q}^k$. A clustering task is a finite and nonempty set of r.e. indices of pairwise disjoint such sets. The class S is said to be *clusterable* if there is an algorithm which, for every clustering task I, converges in the limit on any text for $\bigcup_{i\in I} A_i$ to a finite set J of indices of pairwise disjoint clusters such that $\bigcup_{j\in J} A_j = \bigcup_{i\in I} A_i$. A class is called *semiclusterable* if there is such an algorithm which finds a J with the last condition relaxed to $\bigcup_{j\in J} A_j \supseteq \bigcup_{i\in I} A_i$.

The relationship between natural topological properties and clusterability is investigated. Topological properties can provide sufficient or necessary conditions for clusterability, but they cannot characterize it. On the one hand, many interesting conditions make use of both the topological structure of the class and a well-chosen numbering. On the other hand, the clusterability of a class does not depend on which numbering of the class is used as a hypothesis space for the clusterer.

These ideas are demonstrated in the context of naturally geometrically defined classes. Besides the text for the clustering task, clustering of many of these classes requires the following additional information: the class of convex hulls of finitely many points in a rational vector space can be clustered with the number of clusters as additional information. Interestingly, the class of polygons (together with their interiors) is clusterable if the number of clusters and the overall number of vertices of these clusters is given to the clusterer as additional information. Intriguingly, this additional information is not sufficient for classes including figures with holes.

While some classes are unclusterable due to their topological structure, others are only computationally intractable. An oracle might permit clustering all computationally intractable clustering tasks but fail on some classes which are topologically difficult. It is shown that an oracle E permits clustering all computationally difficult classes iff $E \geq_T K \wedge E' \geq_T K''$. Furthermore, no 1-generic oracle below K and no 2-generic oracle permits clustering any class which is not clusterable without an oracle.

Key words. inductive inference, clustering, hypothesis space, numbering, Turing degree, topological and geometric properties of clusterable classes

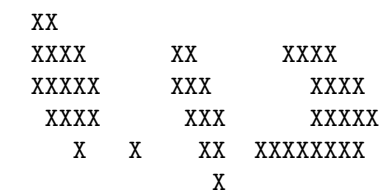
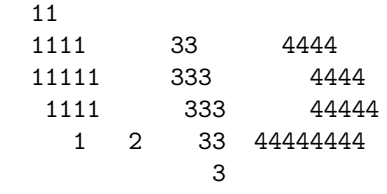
1. Introduction. The basic idea of clustering, given a set of points



is to find a natural way to group the points into clusters (sets) such that every point belongs to exactly one cluster; the current example gives four clusters:



Clustering has been widely studied in several forms in the fields of machine learning and statistics [2, 5, 10, 17, 19]. Abstract treatments of the topic are rare; however, Kleinberg [14] provides an axiomatic approach to clustering. The present work investigates clustering from the perspective of Gold-style learning theory [9, 11], where limitations can stem from uncomputable phenomena.

The purpose of this paper is to study the roles of computation, topology, and geometry in the clustering process. In this interest, the following topics are investigated in an abstract model of clustering:

1. necessary or sufficient topological conditions for clustering;
2. various relationships between clustering, learning, and hypothesis spaces;
3. clusterability of many natural classes of geometrically defined objects;
4. oracles as a method to distinguish between topological and computational aspects of clustering.

The basic setting is that a hypothesis space of potential clusters is given. This space is recursively enumerable. A finite set I of (r.e. indices of) pairwise disjoint clusters from the given class is called a *clustering task*. Given such a clustering task, the clusterer—which might be any algorithmic device—receives a text containing all the data occurring in these clusters and is supposed to find in the limit a set J of (indices of) pairwise disjoint clusters which cover all the data to be seen. There are two variants with respect to a third condition: if one requires that the union of the clusters given by I is the same as the union of the clusters given by J, then one refers to this problem as *clustering*; if this condition is omitted, then one refers to this problem as *semiclustering*.

Clustering is, in some cases, more desirable than semiclustering; for example, the clustering tasks from the class $S_{\mathrm{conv},k}$ defined in Definition 8.1 are collections of convex sets having a positive distance from each other. The solution to such a clustering task is unique since each of these sets corresponds to a cluster. A clusterer has to identify these sets, while a semiclusterer can just converge to the convex hull of all data to be seen. Such a solution is legitimate for semiclustering since it is again a member of the class $S_{\mathrm{conv},k}$. But it fails to meet the intuition behind clustering since it does not distinguish the data from the various clearly different clusters.

Note that in the process of clustering, it is sufficient to find the set J of indices mentioned above. From this J one can find, for every data-item x in the set $\bigcup_{j\in J} A_j$ of all permitted data, the unique cluster to which x belongs. One just enumerates the

sets with the indices in J until the data-item appears in one of them and then uses an index of this set as a description for the cluster to which this data-item belongs. Thus, from a recursion-theoretic point of view, finding the set J is the relevant part of a given clustering problem.

For every indexed class of recursively enumerable sets, there is a canonical translation from these indices to type-0 grammars in the Chomsky hierarchy which generate the corresponding sets. This links the current setting of clustering to grammatical inference, although there is no need herein to exploit the detailed structure of the grammars obtained by such a translation.

We now summarize some of our results.

1. A class has the finite containment property iff any finite union of its members contains only finitely many other members. In section 5 it is shown that classes satisfying this natural property separate the basic notions of clusterability, semiclusterability, and learnability. There is no purely topological characterization of clusterable classes: if a class contains an infinite set C and all singleton sets disjoint from C, then the class is clusterable iff C is recursive. Proposition 6.1 gives a further characterization, which depends on the numbering: a class of disjoint sets is clusterable iff it has a numbering in which every set occurs only finitely often. Section 6 provides some further sufficient criteria for clusterability that take into account topological aspects as well as properties of the given hypothesis space. These criteria are refinements of the finite containment property.

2. Clusterable classes are learnable, but learnable classes may not be clusterable. Although clusterable classes are, by definition, uniformly recursively enumerable, the set of clustering tasks might fail to be. Proposition 3.2 shows that a class that can be clustered using a class comprising hypothesis space, that is, a hypothesis space which enumerates the members of a superclass, can also be clustered using any hypothesis space which enumerates the members of the class only. But by Example 3.3, a clusterable class might not be clusterable with respect to some class comprising hypothesis space.

3. In sections 7 and 8 it is demonstrated how one can map concrete examples into this general framework. These concrete examples are geometrically defined subsets of $\mathbb{Q}^k$: affine sets, classes of sets with distinct accumulation points, and convex hulls of finite sets. This third example is not clusterable, but it turns out to be clusterable if some additional information about the clustering task given to the clusterer is revealed. While there are several natural candidates for the additional information in the case of convex hulls of finite sets, this approach becomes much more difficult when dealing with clusters of other shapes. In the case of polygons in the 2-dimensional space, the additional information provided can consist of the number of clusters plus the overall number of vertices in the polygons considered. Still, this additional information is insufficient for clustering classes of geometrical objects, some of which have holes. But the k-dimensional area is sufficient additional information as long as one rules out that the symmetric difference of two clusters has k-dimensional area 0.

4. Oracles are a way to distinguish between topological and computational difficulty of a clustering problem. In section 4 the relationship between an oracle E and the classes clusterable relative to E is investigated. For example, every 1-generic oracle E which is Turing reducible to the halting problem is trivial: every class which is clusterable relative to E is already clusterable without any oracle. On the other hand, some classes are not clusterable relative to any oracle. Proposition 4.3 characterizes the maximal oracles which permit clustering of any class which is clusterable relative to *some* oracle; in particular, it is shown that such oracles exist.

2. The basic model. Most of the notation follows the books [11, 18]. The next paragraph summarizes the most important notions used in the present work.

Basic notation. A class S is assumed to consist of recursively enumerable subsets of a countable underlying set $\mathbb{U}$ where, in sections 3–6, $\mathbb{U}$ is the set of natural numbers $\mathbb{N}$ and where, in sections 7 and 8, $\mathbb{U}$ is a rational vector space of finite positive dimension. Most of the time, S is even required to be *uniformly recursively enumerable*, which means that there is a sequence $A_0, A_1, \ldots$ of subsets of $\mathbb{U}$ such that first, $S = \{A_0, A_1, \ldots\}$, and second, $\{(i, x) \in \mathbb{N} \times \mathbb{U} : x \in A_i\}$ is recursively enumerable. Such a sequence $A_0, A_1, \ldots$ is called a *numbering* for S. The only exceptions are Proposition 3.9 and Remark 4.2, where clusterability is used for general classes as defined in Definition 3.8.

The letters I, J, H always range over finite subsets of $\mathbb{N}$. The norm is used to induce a one-one ordering of the finite sets: it is defined as $\mathrm{norm}(I) = \sum_{i \in I} 2^i$. Note that $\mathrm{norm}(I) \leq \mathrm{norm}(J)$ whenever $I \subseteq J$. Define A_I as $\bigcup_{i \in I} A_i$. Let $A_{i,s}$ denote the set of elements enumerated into A_i within s steps, and let $A_{I,s} = \bigcup_{i \in I} A_{i,s}$. Without loss of generality, $A_{i,s} \subseteq \{0, 1, \ldots, s\}$ for all s. The sets $A_{i,s}$ are uniformly recursive; that is, $\{(i, s, x) : x \in A_{i,s}\}$ is recursive.

Let $\mathrm{disj}(S)$ contain all finite sets I such that $A_i \cap A_j = \emptyset$ for all different $i, j \in I$. The sets in $\mathrm{disj}(S)$ are called *clustering tasks*. There is an approximation $\mathrm{disj}_s(S)$ to $\mathrm{disj}(S)$ such that $I \in \mathrm{disj}_s(S)$ if $A_{i,s} \cap A_{j,s} = \emptyset$ for all different $i, j \in I$.

For any set A, let $|A|$ be the cardinality of A. Let A^* be the set of all finite sequences of members of A and $|\sigma|$ be the length of a string $\sigma \in A^*$.

A text for a nonempty set $A \subseteq \mathbb{U}$ is any infinite sequence containing all elements, but no nonelements, of A. Clusterers and semiclusterers are recursive functions from $\mathbb{U}^*$ to finite subsets of $\mathbb{N}$; learners are recursive functions from $\mathbb{U}^*$ to $\mathbb{N}$. Also, mappings M^E represented by a machine M having access to an oracle E are considered. An element $\sigma \in A^*$ is called a *stabilizing sequence* (*for A and M*) if $M(\sigma\tau) = M(\sigma)$ for all $\tau \in A^*$.

The sequence $W_0, W_1, \ldots$ denotes an acceptable numbering of all recursively enumerable sets, and W_e can be interpreted as the domain of the eth partial-recursive function φ_e. The set $K = \{e : e \in W_e\}$ is called the halting problem and this notion can be generalized to computation relative to oracles: A' is the halting problem relative to A; in particular, K' is the halting problem relative to K, and K'' is relative to K'. For more information on iterated halting problems, see [18, p. 450].

An oracle G is k-generic if for every Σ^0_k-set T of strings there is a prefix $\eta \preceq G$ such that either $\eta \in T$ or $\eta' \notin T$ for all $\eta' \succeq \eta$. There are 1-generic sets but no 2-generic sets below K. Nevertheless, k-generic sets exist for all $k \in \{1, 2, \ldots\}$.

DEFINITION 2.1. *A class $S = \{A_0, A_1, \ldots\}$ of clusters is called* clusterable *iff there is a clusterer M which, for every $I \in \mathit{disj}(S)$, converges on every text for A_I to a $J \in \mathit{disj}(S)$ with $A_J = A_I$. Such an M is called a* clusterer for S.

S is called semiclusterable *if one replaces $A_J = A_I$ with the weaker condition that $A_J \supseteq A_I$.*

S is called learnable in the limit from positive data with respect to the hypothesis space $A_0, A_1, \ldots$ *iff there is a learner M which, for every $L \in S$, converges on every text for L to a $j \in \mathbb{N}$ with $A_j = L$. In the following, "learnable" stands for "learnable in the limit from positive data with respect to the hypothesis space $A_0, A_1, \ldots$."*

Note that every learner, clusterer, or semiclusterer M which succeeds on A has a stabilizing sequence $\sigma \in A^*$. Furthermore, $M(\sigma)$ is then also a correct hypothesis for A.

Remark 2.2. A clusterer M for $S = \{A_0, A_1, \ldots\}$ might also use a different hypothesis space instead of the default one. Here a numbering $B_0, B_1, \ldots$ is called the *hypothesis space of* M iff for every clustering task I and any text for A_I, M converges on this text to a finite set J such that $B_J = A_I$ and $B_i \cap B_j = \emptyset$ for all different $i, j \in J$. The hypothesis space is *class preserving* if $S = \{B_0, B_1, \ldots\}$ and *class comprising* if $S \subseteq \{B_0, B_1, \ldots\}$. Nevertheless, in light of Proposition 3.2, it is assumed that a clusterer uses the default numbering $A_0, A_1, \ldots$ as its hypothesis space unless explicitly stated otherwise.

Remark 2.3. Many learning criteria have analogous definitions for clustering. For example, a machine M is confident iff it converges on every input to some hypothesis. Thus, one could consider the notion of confidently clusterable classes. This notion is more restrictive; that is, there are classes which are clusterable but not confidently clusterable. In many respects, the theory developed on the basis of these notions is very similar to the corresponding one for learning due to the following reason.

Many separations of different criteria C_1 and C_2 in learning from positive data can be carried over to separations of the corresponding criteria $\tilde{C}_1$ and $\tilde{C}_2$ in clustering. Given a class S separating the learning criterion C_1 from C_2, one can consider the class

$$\tilde{S} = \{\tilde{A} : A \in S\} \text{ where } \tilde{A} = \{0\} \cup \{x + 1 : x \in A\}$$

to separate $\tilde{C}_1$ from $\tilde{C}_2$. The main idea is to use the 0 in order to avoid any two members of $\tilde{S}$ being disjoint. Then every clustering task and every reasonable hypothesis is a singleton set. Learners for S and clusterers for $\tilde{S}$ can be translated into each other.

For example, there is a class S which is learnable but not confidently learnable. Then the class $\tilde{S}$ is clusterable but not confidently clusterable. That is, $\tilde{S}$ witnesses that the notion of confident clustering is more restrictive than the notion of clustering.

This explains some of the many similarities between learning and clustering. Thus, the present work does not focus on the introduction and study of clusterability notions parallel to the many variants of learning in the limit. Instead, emphasis is given more on the relations between clusterability on the one hand and topological, recursion-theoretic, and geometrical properties of classes under consideration on the other.

3. Numberings and clustering. The main topic of this section is the investigation of the role of numberings in clustering. A natural question is whether clustering is independent of the numbering chosen as the hypothesis space. Another important issue is the relationship between numberings of the class of clusters and numberings of the class of finite disjoint unions of clusters. The latter, which represents the clustering tasks, might not have a numbering despite the fact that the former does, as shown in the next example. The class of sets representing the clustering tasks in this example cannot be made recursively enumerable by changing the numbering of the class of clusters.

EXAMPLE 3.1. *For every* $i \in \mathbb{N}$, *let*

$$A_i = \begin{cases} \{i+1\} & \text{if } i \notin K, \\ \{0, i+1\} & \text{if } i \in K. \end{cases}$$

The class $S = \{A_0, A_1, \ldots\}$ *is uniformly recursively enumerable, but the class* $\{A_I : I \in \mathit{disj}(S)\}$ *is not. Taking* i *to be the minimum of* K, *one has for all* $j > i$,

$$j \notin K \Leftrightarrow (\exists I \in \mathit{disj}(S))\,[\{0, i+1, j+1\} \subseteq A_I].$$

This connection holds for all numberings of S but fails for any numbering of the superclass of all finite sets.

Thus, there are clusterable classes in which the corresponding class of all clustering tasks does not have a numbering. Nevertheless, a fundamental result of de Jongh and Kanazawa [4] carries over to clustering: whenever a class is clusterable with respect to a class comprising hypothesis space, the class is also clusterable with respect to every class-preserving hypothesis space. Actually, the following result is even a bit stronger since it does not require that the hypothesis space $B_0, B_1, \ldots$ be class comprising but only that it satisfy the following more technical, but also more general, condition:

$$S \subseteq \{B_J : (\forall i, j \in J)\,[i = j \vee B_i \cap B_j = \emptyset]\}.$$

Thus, for every $I \in \mathrm{disj}(S)$ there is a finite set J such that $\{B_j : j \in J\}$ is pairwise disjoint and $A_I = B_J$. Note that this condition is indeed more general than the class-comprising condition, as it holds in the case that $A_0, A_1, \ldots$ is an enumeration of all two-element sets and $B_0, B_1, \ldots$ is an enumeration of all one-element sets. An application of the next result is that every uniformly recursively enumerable class consisting only of finite sets is clusterable.

PROPOSITION 3.2. *Let $A_0, A_1, \ldots$ be a numbering of a class S and $B_0, B_1, \ldots$ be another numbering (of a possibly different class) such that for every $I \in disj(S)$ there is a J with $A_I = B_J$. If there is a clusterer for S using the hypothesis space $B_0, B_1, \ldots$, then there is another clusterer that uses the original numbering $A_0, A_1, \ldots$ as its hypothesis space.*

Proof. Assume that M is a clusterer for S using the numbering $B_0, B_1, \ldots$ as its hypothesis space. Note that M is required to be correct only on clustering tasks from S, whereas the superclass $\{B_0, B_1, \ldots\}$ is not required to be clusterable.

The clusterer M has on every A_I with $I \in \mathrm{disj}(S)$ a stabilizing sequence σ_I which can be found in the limit: $\sigma_I = \lim_s \sigma_{I,s}$ with $\sigma_I, \sigma_{I,s} \in A_I^*$ and $M(\sigma_I\tau) = M(\sigma_I)$ for all $\tau \in A_I^*$. Then the following clusterer N uses $A_0, A_1, \ldots$ as its hypothesis space.

ALGORITHM N. On input of length s, N computes the output J of M fed with the same input and searches for the set $H \subseteq \{0, 1, \ldots, s\}$ of least norm satisfying the following conditions:

- $H \in \mathrm{disj}_s(S)$;
- $\sigma_{H,s} \in B_{J,s}^*$;
- $M(\sigma_{H,s}\tau) = M(\sigma_{H,s})$ for all $\tau \in B_{J,s}^*$ of length up to s.

If H is found, then output H, else output $\emptyset$.

Verification. Given a clustering task and a text for this task, let J be the hypothesis to which M converges. Let I be the set of least norm such that $A_I = B_J$ and $I \in \mathrm{disj}(S)$. Note that for all H with $\mathrm{norm}(H) < \mathrm{norm}(I)$, either $H \notin \mathrm{disj}(S)$, or $\mathrm{range}(\sigma_H) \not\subseteq B_J$, or there is a $\tau \in B_J^*$ such that $M(\sigma_H\tau) \neq M(\sigma_H)$. Thus, if the length s of the part of the text fed into N is sufficiently large, then the following properties hold:

- $I \subseteq \{0, 1, \ldots, s\}$;
- for all H with $\mathrm{norm}(H) \leq \mathrm{norm}(I)$, $H \in \mathrm{disj}_s(S) \Leftrightarrow H \in \mathrm{disj}(S)$;
- for all $H \in \mathrm{disj}(S)$ with $\mathrm{norm}(H) \leq \mathrm{norm}(I)$, $\sigma_{H,s} = \sigma_H$;
- $\sigma_I \in B_{J,s}^*$ and $M(\sigma_I)$ outputs J;
- for all $H \in \mathrm{disj}(S)$ with $\mathrm{norm}(H) < \mathrm{norm}(I)$, either $\sigma_H \notin B_J^*$ or there is a $\tau \in B_{J,s}^*$ of length up to s with $M(\sigma_H\tau) \neq M(\sigma_H)$.

Hence I satisfies the search conditions of N, but no H with $\mathrm{norm}(H) < \mathrm{norm}(I)$ does. Thus, N converges on a text for B_J to the set I and N witnesses that S is clusterable using the hypothesis space $A_0, A_1, \ldots$ for S. □

EXAMPLE 3.3. *The converse of Proposition* 3.2 *does not hold: there is a clusterable class S and a numbering of a superclass of S such that no clusterer for S can use this numbering as a hypothesis space.*

Proof. For every i, let $A_i = \{\langle i, x\rangle : x \leq |W_i|\}$ and let $S = \{A_0, A_1, \ldots\}$. It is easy to see that S is clusterable using the numbering $A_0, A_1, \ldots$ as the hypothesis space: on input σ the clusterer just outputs $\{i : \langle i, 0\rangle \in \mathrm{range}(\sigma)\}$.

For better readability, the second numbering has two indices. One defines that $B_{i,j} = \{\langle i, x\rangle : \min(\{j, x\}) \leq |W_i|\}$. Note that $B_{i,j} = \{\langle i, 0\rangle, \langle i, 1\rangle, \ldots\}$ iff either W_i is infinite or $j \leq |W_i|$. Furthermore $\{A_i : i \in \mathbb{N}\} \subseteq \{B_{i,j} : i, j \in \mathbb{N}\}$; that is, the hypothesis space of the $B_{i,j}$ is class comprising.

Assume by way of contradiction that M is a clusterer for S using the numbering of the $B_{i,j}$ as its hypothesis space. Given any i, M converges on every text for A_i to a singleton $\{(i, j)\}$ with $A_i = B_{i,j}$. If W_i is finite, then $j > |W_i|$. Thus, one can compute relative to K whether W_i is finite as follows:

1. Taking a default enumeration of A_i, one can use K to determine j such that M—using this enumeration as a text for A_i—converges to $\{(i, j)\}$;
2. one can use K to determine whether $|W_i| > j$;
3. if $|W_i| > j$, W_i is infinite; if not, W_i is finite.

This K-recursive algorithm contradicts the fact that the set $\{i : W_i \text{ is finite}\}$ has the same Turing degree as K' and gives the desired contradiction. □

Although there are classes $S = \{A_0, A_1, \ldots\}$ such that $\{A_I : I \in \mathrm{disj}(S)\}$ is not uniformly recursively enumerable, the superclass $\{A_I : I \subseteq \mathbb{N} \wedge |I| \text{ is finite}\}$ is uniformly recursively enumerable. A clusterer for S can easily be converted to a learner for S using the hypothesis space given by the numbering $B_0, B_1, \ldots$, which satisfies $B_{\mathrm{norm}(I)-1} = A_I$ for all nonempty sets I. But learnability of uniformly recursively enumerable classes does not depend on the hypothesis space; following a result of de Jongh and Kanazawa [4], there is also a learner for S which uses $A_0, A_1, \ldots$ as its hypothesis space. Thus, every clusterable class is learnable, although the converse direction does not hold.

Property 3.4. Every clusterable class is learnable.

EXAMPLE 3.5. (a) *The class S_{gold} consisting of $\mathbb{N}$ and all its finite subsets is neither learnable nor clusterable. But S_{gold} is semiclusterable.*

(b) *The class S_{sing} consisting of all singletons and the set $\mathbb{N}$ is learnable and semiclusterable but not clusterable.*

(c) *Let C be infinite and recursively enumerable. The class S_C consisting of C and all singletons disjoint from C is learnable. Furthermore, S_C is clusterable iff S_C is semiclusterable iff C is recursive.*

Proof. (a) Gold [9] observed that S_{gold} is not learnable. By Property 3.4, the class S_{gold} is also not clusterable. But S_{gold} is semiclusterable by the trivial algorithm, which always conjectures an index for $\mathbb{N}$.

(b) The class S_{sing} is learnable by the algorithm which conjectures an index for $\mathrm{range}(\sigma)$ if $|\mathrm{range}(\sigma)| = 1$ and an index for $\mathbb{N}$ if $|\mathrm{range}(\sigma)| \neq 1$. Since every finite set belongs to a clustering task from S_{sing}, the structure of the clustering tasks of S_{sing} is equal to that of S_{gold}. Thus, S_{sing} is semiclusterable but not clusterable.

(c) Note that the class S_C has a numbering by taking $A_i = C$ if $i \in C$ and $A_i = \{i\}$ otherwise. One first enumerates i into A_i and, whenever i shows up in C, one enumerates also the other elements of C into A_i.

The class S_C can be learned by conjecturing the cluster A_i for the first number i occurring in the text; once selected, the output is kept forever.

If C is recursive, then S_C is clusterable: on input σ, one outputs $\text{range}(\sigma)$ if $\text{range}(\sigma) \cap C = \emptyset$ and $\{\min(C)\} \cup (\text{range}(\sigma) - C)$ otherwise. What this algorithm does is output the set containing the minimal indices of the clusters which intersect the set of data items seen so far. Note that every clusterer is also a semiclusterer. Thus, S_C is semiclusterable as well.

It remains to show that C is recursive whenever there is a semiclusterer M for S_C. The set C has a stabilizing sequence σ with respect to M. Now let $J = M(\sigma)$. There is a finite and possibly empty set D disjoint from C such that $A_J = C \cup D$. Thus, one has that

$$x \notin C \Leftrightarrow x \in D \vee (\exists \tau \in C^*)\,[M(\sigma x \tau) \neq M(\sigma)].$$

These formulas witness that $\overline{C}$ is recursively enumerable. Since C itself is also recursively enumerable, the set C is actually recursive. □

The classes S_{sing} and S_C, where C is nonrecursive, are learnable but not clusterable. Both have the property that they are not closed under disjoint union. The next, easy-to-verify, result shows that this property is essential for getting examples which are learnable but not clusterable.

Property 3.6. Let a class S be closed under disjoint union, that is, $A \cup B \in S$ for all disjoint $A, B \in S$. Then S is clusterable iff S is learnable.

A learner M for a class S is called *prudent* if it outputs only indices of sets it learns. One can enumerate all possible hypotheses $e_0, e_1, \ldots$ of M and thus obtain a numbering $B_0, B_1, \ldots$ with $B_i = W_{e_i}$ of a learnable superclass of S. Fulk [8] showed that every learnable class has a prudent learner. Therefore, it is sufficient to consider only uniformly recursively enumerable classes for learning. So Fulk's result can be stated as follows.

Property 3.7 [see 11, Proposition 5.20]. Every learnable class has a prudent learner. In particular, every learnable class is contained in some learnable and uniformly recursively enumerable class.

Thus, every learnable class can be extended to one which is learnable and uniformly recursively enumerable. But in contrast to learning in the limit, this requirement turns out to be restrictive for clustering. Indeed, Proposition 3.9 below gives for every $\{0,1\}$-valued function $F \not\leq_T K''$ a clusterable class which is not contained in any uniformly recursively enumerable clusterable class. Furthermore, the union of any two such classes, given by different functions F, F', is no longer clusterable. So one cannot cover these classes by countably many clusterable superclasses. Most interesting results are based on Definition 2.1 with the consequence that only countably many classes are clusterable. The more general notion below expands the collection of clusterable classes to an uncountable one. Although the latter collection contains many irregular classes of limited interest, it still gives some fundamental insights.

This notion of "clustering in the general sense" is formally introduced in Definition 3.8 and used only in Proposition 3.9 and Remark 4.2 below. As the enumeration $A_0, A_1, \ldots$ is not available, a fixed acceptable numbering $W_0, W_1, \ldots$ is used as hypothesis space instead.

DEFINITION 3.8. *A class S of recursively enumerable sets is* clusterable in the general sense *iff there is a machine M which converges on every text for the union of finitely many disjoint sets $L_0, L_1, \ldots, L_n \in S$ to a finite set J of indices of pairwise disjoint members of S such that $L_0 \cup L_1 \cup \cdots \cup L_n = \bigcup_{e \in J} W_e$.*

PROPOSITION 3.9. *Let F be a $\{0,1\}$-valued function which is not computable relative to the oracle K''. For all $x, y \in \mathbb{N}$ and $z \in \{0,1\}$, let $A_{x,z}, B_{x,y}$ be defined as*

$$A_{x,z} = \{\langle x, 0, z\rangle, \langle x, 1, z\rangle, \langle x, 2, z\rangle, \ldots\},$$
$$B_{x,y} = \{\langle x, y, 0\rangle, \langle x, y, 1\rangle\}.$$

Then the class S containing all sets $A_{x,z}$ and $B_{x,y}$ with $x, y \in \mathbb{N}$ and $z = F(x)$ is clusterable in the general sense but not contained in any clusterable class which is uniformly recursively enumerable.

Proof. A clustering algorithm outputs on input σ a set J which contains indices of the following sets:

- $A_{x,z}$ whenever $\langle x, 0, z\rangle \in \text{range}(\sigma)$ but $\langle x, 0, 1-z\rangle \notin \text{range}(\sigma)$;
- $B_{x,y}$ whenever $B_{x,y} \subseteq \text{range}(\sigma)$.

The verification of the correctness of this algorithm can be carried out by taking into account that for every x the following holds: S contains exactly one of the sets $A_{x,0}, A_{x,1}$; every clustering task never contains both $A_{x,z}$ and $B_{x,y}$.

Assume by way of contradiction that $C_0, C_1, \ldots$ is a numbering of a clusterable superclass of S. This numbering contains exactly one, and only one, of the sets $A_{x,0}, A_{x,1}$ since $A_{x,F(x)} \in S$ and every class containing both $A_{x,0}, A_{x,1}$ together with the sets $B_{x,y}$ for all $y \in \mathbb{N}$ is not clusterable. The class of all $A_{x,0}, A_{x,1}$, and $B_{x,y}$ has a basic principle in common with the class S_{sing} from Example 3.5: the set $A_{x,0} \cup A_{x,1}$ is the disjoint union of the subsets $B_{x,0}, B_{x,1}, \ldots$, and therefore no clusterable superclass of S contains both sets $A_{x,0}$ and $A_{x,1}$. Thus, one can get F from the numbering $C_0, C_1, \ldots$ as follows:

$$F(x) = z \Leftrightarrow (\exists i)\,[C_i = A_{x,z}].$$

Since the equality of two recursively enumerable sets can be tested relative to the oracle K', the function F would be computable relative to K'' in contradiction to the choice of F. □

4. Clustering and oracles. Oracles are a method for measuring the complexity of a problem. Some classes are clusterable with a suitable oracle, while others cannot be clustered with any oracle. Thus, the use of oracles permits us to distinguish problems caused by the computational difficulty of the class involved from those which are unclusterable for topological reasons. This is illustrated in the following remark.

Remark 4.1. Recall the classes S_C and S_{gold} from Example 3.5. The class S_C is clusterable iff the set C in its definition is recursive. It is easy to see that supplying C as an oracle to the clusterer resolves all computational problems in the case that C is not recursive. But the class S_{gold} is unclusterable because of its topological structure and remains unclusterable relative to every oracle.

Oracles have been extensively studied in the context of inductive inference [1, 6, 13, 16]. These studies considered arbitrary classes but not uniformly recursively enumerable ones. The results for arbitrary classes carry over directly from learning to clustering in the general sense.

Remark 4.2. Fortnow and coworkers [6] investigated for many settings of learning the question of which oracles are *maximal for learning* in the sense that they enable us to solve all principally solvable learning problems. Jain and Sharma [13] showed that in the setting of learning languages from positive data there is no maximal oracle. The same holds for clustering: for every oracle E, the class S^E_{jump} consisting of all

sets $\{2x, 2x+1\}$ with $x \in E'$ and $\{2x\}, \{2x+1\}$ with $x \notin E'$ is clusterable in the general sense relative to an oracle F iff $E' \leq_T F'$. The reason is that a clusterer M^F on a text for $\{2x, 2x+1\}$ can figure out in the limit how many clusters of S^E_{jump} are needed to cover $\{2x, 2x+1\}$:

$$x \in E' \Leftrightarrow M^F \text{ converges on } 2x\,(2x+1)\,(2x+1)\ldots \text{ to } I \text{ with } |I| = 1;$$
$$x \notin E' \Leftrightarrow M^F \text{ converges on } 2x\,(2x+1)\,(2x+1)\ldots \text{ to } I \text{ with } |I| = 2.$$

Thus, there is no oracle E which is *maximal for clustering in the general sense*, meaning that every class which is clusterable in the general sense relative to some oracle is also clusterable in the general sense relative to E.

An oracle is called *trivial for clustering in the general sense* iff every class which is clusterable in the general sense relative to this oracle is also clusterable in the general sense without it. Now it is shown that a nonrecursive oracle E is trivial for clustering in the general sense iff it has a 1-generic degree and is Turing reducible to the halting problem, that is, Case 1 below is satisfied.

Case 1. $E \leq_T G$ *for a* 1*-generic set* $G \leq_T K$. Let S be any class which is clusterable in the general sense relative to E. By [6, Lemma 4.19] there is a clusterer M^G which asks on every text belonging to any clustering task from S only finitely many queries to G. The answers to these queries can be successfully figured out in the limit—thus there is a recursive clusterer for S which converges on every text of any finite disjoint union of sets in S to exactly the same output as M^G. In particular, G (and thus E) is trivial for clustering in the general sense.

Case 2. $E \not\leq_T G$ *for any* 1*-generic set* $G \leq_T K$. Kummer and Stephan [16, Theorem 10.5] showed that there is a class S^E_{func} which is learnable relative to E but not without any oracle. This class S^E_{func} consists of graphs of recursive functions and, following Remark 2.3, one can assume without loss of generality that $f(0) = 0$ for every function whose graph is in S^E_{func}. The class S^E_{func} is, on the one hand, clusterable in the general sense relative to E and, on the other hand, not clusterable in the general sense without any oracle. In particular, S^E_{func} witnesses that E is not trivial for clustering in the general sense.

The previous remark completes the investigation of clustering in the general sense within the present work. From now on, S denotes again a uniformly recursively enumerable family of clusters. That is, $S = \{A_0, A_1, \ldots\}$, and the set $\{(i, x) \in \mathbb{N}^2 : x \in A_i\}$ is recursively enumerable.

The usefulness of oracles with respect to clustering differs much from the case of clustering in the general sense. Dealing only with uniformly recursively enumerable classes reduces our ability to separate oracles by suitable classes. The definitions for maximal and trivial oracles for clustering are the following.

Call an oracle E *maximal for clustering* if every uniformly recursively enumerable class which is clusterable relative to some oracle is already clusterable relative to E. Call an oracle E *trivial for clustering* if every uniformly recursively enumerable class which is clusterable relative to E is already clusterable without any oracle.

Here the word "maximal" instead of "omniscient" is used since by Remark 4.1 some classes are not clusterable with any oracle. In contrast, omniscient oracles for learning functions permit us to learn the class of all recursive functions [1] and do not leave any function learning problem unsolved.

The next result shows that, in contrast to the case of clustering in the general sense, there are maximal oracles for clustering. It turns out that for an oracle E below K the following three conditions are equivalent: E is trivial for clustering, E is trivial

for learning sets, E is trivial for learning functions; see [6] for the equivalence of the last two statements.

PROPOSITION 4.3. *For every oracle E the following statements are equivalent:*

(a) *$E \geq_T K$ and $E' \geq_T K''$;*

(b) *the oracle E is maximal for learning from positive data—every uniformly recursively enumerable class is either not learnable with any oracle or learnable with oracle E;*

(c) *the oracle E is maximal for clustering—every uniformly recursively enumerable class is either not clusterable with any oracle or clusterable with oracle E.*

Proof. Assume that E satisfies $E \geq_T K$ and $E' \geq_T K''$ and assume that $S = \{A_0, A_1, \ldots\}$ is clusterable relative to some oracle. Then S satisfies Angluin's telltale condition below and one can actually give an algorithm which succeeds with the oracle E.

Angluin's condition (see [3]). The class S is clusterable with the help of some oracle iff for every $I \in \mathrm{disj}(S)$, there is a finite set D, called a *telltale set for I*, such that $D \subseteq A_I$ and no $J \in \mathrm{disj}(S)$ satisfies $D \subseteq A_J \subset A_I$.

Note that one can test with oracle K'' whether the telltale condition holds for given I, D: $F(D, I) = 1 \Leftrightarrow (\forall J \in \mathrm{disj}(S))\,[D \not\subseteq A_J \vee A_J \not\subset A_I]$. This condition has an E-recursive approximation $F_s(D, I)$ which converges for $s \to \infty$ to 1 if $F(D, I) = 1$ holds and to 0 otherwise.

ALGORITHM M. Given an E-recursive enumeration of $\{(D, J) : D$ is a finite subset of $\mathbb{N}$ and $J \in \mathrm{disj}(S)\}$, $M(\sigma)$ outputs J from the first pair (D, J) satisfying the following conditions:

- $D \subseteq \mathrm{range}(\sigma) \subseteq A_J$;
- $F_{|\sigma|}(D, J) = 1$.

In order to guarantee that M is total, the search is limited to the first $|\sigma|$ pairs, and $M(\sigma)$ outputs $\emptyset$ if none of the first $|\sigma|$ pairs qualifies.

Verification. Since every clustering task $I \in \mathrm{disj}(S)$ has a telltale set D' such that $D' \subseteq A_I$ and $F(D', I) = 1$, the algorithm converges to some pair (D, J) with $F(D, J) = 1$. One has that $D \subseteq A_I \subseteq A_J$ and it then follows from Angluin's condition that $A_I = A_J$.

Complete class. It remains to show that condition (a) on E is necessary. The class S_{comp} considered here consists of the sets $A_{i,D}$ defined below, where $i \in \mathbb{N}$ and D is a finite subset of $\mathbb{N}$. Note that below, the entry for $\emptyset$ is given explicitly, and therefore $D \neq \emptyset$ in the second entry; in particular, $\max(D)$ is defined there:

$$\begin{aligned} A_{i,\emptyset} &= \{\langle i, x\rangle : x \in W_i \cup \{0\}\}, \\ A_{i,D} &= \{\langle i, x\rangle : x \in D \cup \{0\} \\ &\qquad \vee\ (x > \max(D) \wedge \{z : \max(D) \leq z < x\} \subseteq W_i) \\ &\qquad \vee\ (x \leq \max(D) \wedge \{z : x \leq z \leq \max(D)\} \subseteq W_i)\}. \end{aligned}$$

Clusterer N with oracle K''. Given input σ, $N^{K''}$ determines the sets

$$B_i = \mathrm{range}(\sigma) \cap \{\langle i, 0\rangle, \langle i, 1\rangle, \ldots\}.$$

Then J consists of the pairs (i, D), where $B_i \neq \emptyset$ and D is a finite set of least norm satisfying one of the following conditions:

1. $A_{i,D} = B_i$;
2. $D = \emptyset$, $B_i \subseteq A_{i,\emptyset}$, and W_i coinfinite;

3. $A_{i,D} = B_i \cup \{\langle i, x\rangle : x \geq \max(D)\}$.

Then $N^{K''}$ outputs J.

Verification. Given a clustering task I, the clusterer obviously finds all i, where $(i, C) \in I$ for some C. Furthermore, there is at most one C with $(i, C) \in I$ since $A_{i,C}$ always contains $\langle i, 0\rangle$. It can be seen that the above cases 1, 2, 3 in the algorithm of $N^{K''}$ are disjoint and that $N^{K''}$ converges syntactically whenever $N^{K''}$ converges semantically:

- If $A_{i,C}$ is finite, then eventually all elements show up and $N^{K''}$ outputs an index for this set.
- If $A_{i,C}$ is infinite and W_i coinfinite, then $C = \emptyset$ and no finite subset of $A_{i,\emptyset}$ is in S_{comp}. Thus, the first case does not apply and $N^{K''}$ puts $(i, \emptyset)$ into J according to the second case.
- If $A_{i,C}$ is infinite and W_i cofinite, then let a_i be the first number such that all $x \geq a_i$ are in W_i. In particular, the set $D = \{x \leq a_i : \langle i, x\rangle \in A_{i,C}\}$ satisfies $A_{i,D} = A_{i,C}$, and therefore (i, D) or some equivalent index goes into J whenever B_i contains all $\langle i, x\rangle \in A_{i,C}$ with $x \leq a_i$.

This completes the verification of the clusterer $N^{K''}$. It is easy to see that S_{comp} is also learnable relative to K''. Furthermore, S_{comp} is clusterable and learnable relative to any oracle which is maximal for clustering.

Hardness. It is sufficient to show that learning is hard since no member of S_{comp} is the disjoint finite union of two or more other members of S_{comp}, and every clusterer therefore has to find for every $L \in S_{\text{comp}}$ a singleton $\{(i, D)\}$ such that $A_{i,D} = L$. In the following, assume that an oracle E and a learner O^E using the oracle E are given. Note that every set $A_{i,\emptyset}$ has a stabilizing sequence. Let σ_i be the first stabilizing sequence found by a search applying the oracle E'. Note that $O^E(\sigma_i)$ has to be an index for $A_{i,\emptyset}$ since $O^E(\sigma_i\tau) = O^E(\sigma_i)$ for all $\tau \in (A_{i,\emptyset})^*$ by the definition of a stabilizing sequence. Let b_i be the maximum of all y with $\langle i, y\rangle \in \text{range}(\sigma_i)$.

Let $H_1 \oplus H_2$ denote the set $\{2x : x \in H_1\} \cup \{2x+1 : x \in H_2\}$. There is an index i such that $W_i = \mathbb{N} \oplus K$. Then $A_{i,\emptyset} = \{\langle i, y\rangle : y \in W_i\}$. Now consider any x with $2x > b_i$ and $A_{i,D}$, where D consists of $2x$ and all y with $\langle i, y\rangle \in \text{range}(\sigma_i)$. If $x \in K$, then $\text{range}(\sigma_i) \cup \{\langle i, 2x+1\rangle\} \subseteq A_{i,\emptyset}$. If $x \notin K$, then $A_{i,D} - A_{i,\emptyset} = \{\langle i, 2x+1\rangle\}$. Therefore,

$$x \in K \Leftrightarrow 2x+1 \in W_i,$$

$$x \notin K \Leftrightarrow (\exists \tau \in (A_{i,\emptyset})^*)\,[O^E(\sigma_i\langle i, 2x+1\rangle\tau) \neq O^E(\sigma_i)].$$

A finite modification of the above formula takes care of the x with $2x \leq b_i$ and shows that K is computable relative to E.

Assume that the set W_i is cofinite and a_i is, as above, the minimum of all x with $\{x, x+1, \ldots\} \subseteq W_i$. Now consider any $y < a_i$ with $y \in W_i$. Then $A_{i,\emptyset} - \{\langle i, y\rangle\}$ is in S_{comp}. Since σ_i is a stabilizing sequence for $A_{i,\emptyset}$, $\langle i, y\rangle$ occurs in σ_i. Thus, there are no elements of W_i strictly between b_i and a_i. In particular, W_i is cofinite iff every $x > b_i$ with $x \in W_i$ actually satisfies $\{x, x+1, \ldots\} \subseteq W_i$. As it is already known that $K \leq_T E$, one has that $K' \leq E'$, and the following algorithm decides relative to E' whether W_i is cofinite.

Given i, compute relative to E' the sequence σ_i and the number b_i. Check whether there is an $x > b_i$ with $x \in W_i$. If not, then W_i is finite and thus coinfinite. If so, one can find such an x with oracle E. Then W_i is cofinite iff $\{x, x+1, \ldots\} \subseteq W_i$, which can again be checked with oracle E'.

Thus, exploiting that $E \geq_T K$ and $E' \geq_T K'$, one can derive that $E' \geq_T K''$ since K'' and the index-set $\{i : W_i \text{ is cofinite}\}$ have the same Turing degree. This completes the proof. □

PROPOSITION 4.4. *Let E be a nonrecursive oracle with $E \leq_T K$.*

(a) *If E has 1-generic degree, then E is trivial and permits us to cluster only classes which can already be clustered without any oracle.*

(b) *If E does not have 1-generic degree, then there is a uniformly recursively enumerable class which can be clustered using the oracle E but not without any oracle.*

The same characterizations hold for learning in place of clustering.

Proof. (a) Clustering S and learning $\tilde{S} = \{A_I : I \in \text{disj}(S)\}$ have the same difficulty if one does not require the use of the hypothesis space $\{A_0, A_1, \ldots\}$. Therefore, if one can cluster S with the help of oracle E, then one can also learn $\tilde{S}$ with the help of the same oracle. Thus, by Kummer and Stephan [16, Theorem 10.5], $\tilde{S}$ can be learned without any oracle. This learner can be interpreted as a clusterer which outputs only singleton classes and uses an acceptable numbering of all recursively enumerable sets as its hypothesis space. By Proposition 3.2 one can translate this learner into a clusterer using $A_0, A_1, \ldots$ as its hypothesis space.

(b) By [16, Theorem 10.5] there is a class S^E_{func} of graphs of recursive functions which can be learned relative to oracle E but not without any oracle. Suppose M^E learns S^E_{func}. The main task is to build a uniformly recursively enumerable superclass which still can be learned with oracle E. Without loss of generality, all functions f with a graph in S^E_{func} satisfy that $f(0) = 0$. Therefore, $\langle 0, 0\rangle$ is in all members of S^E_{func}. Furthermore, $\langle 0, 0\rangle$ will also be in all the members of the superclass S of S^E_{func} to be constructed. Thus, S is clusterable iff it is learnable.

Since $E \leq_T K$, the oracle E has a recursive approximation $E_0, E_1, \ldots$ and the machine M^E has also approximations $M^{E_0}, M^{E_1}, \ldots$ such that M^{E_s} works with E_s instead of E. The sequence of these approximations to M^E is uniformly recursive.

The class S. For every given $i, j, k \in \mathbb{N}$, let $A_{i,j,k}$ contain all pairs $\langle x, y\rangle$ which satisfy one of the three conditions below. The class S consists of all $A_{i,j,k}$ with $i, j, k \in \mathbb{N}$.

Condition 1. The pair $\langle x, y\rangle$ is just $\langle 0, 0\rangle$.

Condition 2. There is a number $s \geq \max(\{i, j, k, x\})$ such that the following statements hold:

- $\varphi_i(z)$ is defined for all $z \leq \max(\{j, x\})$, $\varphi_i(0) = 0$, and $\varphi_i(x) = y$;
- for all t with $k \leq t \leq s$, $M^{E_t}(\langle 0, \varphi_i(0)\rangle\langle 1, \varphi_i(1)\rangle \ldots \langle j, \varphi_i(j)\rangle) = \{i\}$;
- for $z = j, j+1, \ldots, \max(\{j, x\})$, $M^{E_s}(\langle 0, \varphi_i(0)\rangle\langle 1, \varphi_i(1)\rangle \ldots \langle z, \varphi_i(z)\rangle) = \{i\}$;
- either $j = 0$ or $M^{E_s}(\langle 0, \varphi_i(0)\rangle\langle 1, \varphi_i(1)\rangle \ldots \langle j-1, \varphi_i(j-1)\rangle) \neq \{i\}$.

Condition 3. This condition does not depend on $\langle x, y\rangle$ since it covers the case in which the parameters do not permit us to construct a desired set but might already have caused the enumeration of pairs different from $\langle 0, 0\rangle$:

- φ_i is defined on $0, 1, \ldots, j$;
- $M^{E_s}(\eta) \neq M^{E_k}(\eta)$ for some $s > k$ and $\eta \preceq \langle 0, \varphi_i(0)\rangle\langle 1, \varphi_i(1)\rangle \ldots \langle j, \varphi_i(j)\rangle$.

It is easy to see that this class is uniformly recursively enumerable. The intuition behind the conditions is the following. Condition 1 makes the set $A_{i,j,k}$ nonempty and enforces that S is clusterable relative to E iff S is learnable relative to E. Condition 2 tries to put information on the graph of φ_i into $A_{i,j,k}$, where j, k serve as additional information. Condition 3 takes care of the class when the choice of the parameters j, k is inadequate. Note that whenever M^E converges for a total function f to $\{i\}$ such that $\varphi_i = \text{graph}(f)$, there is a position j from which on M^E has converged to $\{i\}$. In

particular, $A_{i,j,k} = \text{graph}(f)$ where k is the least number such that $M^{E_s}(\eta) = M^E(\eta)$ for all $s \geq k$ and $\eta \preceq \langle 0, f(0)\rangle\langle 1, f(1)\rangle \ldots \langle j, f(j)\rangle$. Let $(i_{zero}, j_{zero}, k_{zero})$ be an index of $\{\langle 0,0\rangle\}$ and $(i_{all}, j_{all}, k_{all})$ be an index of $\{\langle x, y\rangle : x, y \in \mathbb{N}\}$.

ALGORITHM N WITH ORACLE E. On input σ, N^E does the following steps:

1. Let $f(m)$ be the least number y such that $\langle m, y\rangle$ is in range(σ);
2. if $f(0)$ or $f(1)$ cannot be recovered from range(σ), then output $(i_{zero}, j_{zero}, k_{zero})$ and halt;
3. if there is $\langle m, z\rangle \in \text{range}(\sigma)$ with $z > f(m)$, then output $(i_{all}, j_{all}, k_{all})$ and halt;
4. find the largest n such that $f(0), f(1), \ldots, f(n)$ can be recovered from range(σ);
5. compute for $m = 0, 1, \ldots, n$ the indices i_m such that
$$M^E(\langle 0, f(0)\rangle\langle 1, f(1)\rangle \ldots \langle m, f(m)\rangle) = \{i_m\}$$
and let $k_{m,|\sigma|}$ be the least number o such that $\langle 0, 1\rangle$ is not enumerated into $A_{i_m,m,o}$ within $|\sigma| - o$ steps;
6. determine all numbers $m \in \{1, 2, \ldots, n\}$ such that either range(σ) consists of the elements enumerated into $A_{i_m,m,k_{m,|\sigma|}}$ within $|\sigma|$ steps or m is the least number with $i_m = i_{m+1} = \cdots = i_n$;
7. output $\{(i_m, m, k_{m,|\sigma|})\}$ for the least m that was selected in step 6 and halt.

Verification. Let L be any set in S. It is easy to see that N^E identifies the sets $A_{i_{zero},j_{zero},k_{zero}}$ and $A_{i_{all},j_{all},k_{all}}$. Thus, one can consider any set $L \in S$ which is of the form $\{\langle x, f(x)\rangle : x < b\}$, where $b \in \{2, 3, \ldots, \infty\}$ and f is a recursive function. It is obvious that any $\langle x, y\rangle \in \text{range}(\sigma)$ satisfies $f(x) = y$, thus f is correctly recovered by N^E and n is the largest integer such that all pairs $\langle x, f(x)\rangle$ with $x \leq n$ occur in σ.

Let j be the least number such that $j < b$ and for $i_j = M^E(f(0), f(1), \ldots, f(j))$, there is a k with $A_{i_j,j,k} = L$. Now fix this k to be the minimal one with $A_{i_j,j,k} = L$. Then $A_{i_j,j,o} \neq L$ for all $o < k$; indeed $A_{i_j,j,o} = A_{i_{all},j_{all},k_{all}}$ for these o. Note that $m, k_{m,|\sigma|}$ as chosen in step 7 of the algorithm, respectively, converge to j and k from below, where k is the least integer such that the $f(0), f(1), \ldots, f(j)$ chosen by the algorithm satisfy

$$(\forall m' \leq j)\,(\forall s \geq k)[M^{E_s}(\langle 0, f(0)\rangle\langle 1, f(1)\rangle \ldots \langle m', f(m')\rangle) = M^E(\langle 0, f(0)\rangle\langle 1, f(1)\rangle \ldots \langle m', f(m')\rangle)\,].$$

Given any text for L, assume that σ is so long that the following statements hold:

1. All pairs $\langle m, f(m)\rangle$ with $m \leq j$ have occurred in σ, and thus N^E knows $f(0), f(1), \ldots, f(j)$;
2. if L is finite, then $L = \text{range}(\sigma)$ and all elements of L are enumerated into $A_{i_j,j,k}$ within $|\sigma|$ steps;
3. for all $m \leq j$ and $t > |\sigma|$, $k_{m,t} = k_{m,|\sigma|}$;
4. an element of $A_{i_m,m,k_{m,|\sigma|}} - L$ is enumerated into $A_{i_m,m,k_{m,|\sigma|}}$ within $|\sigma|$ steps whenever this difference is not empty and $m \leq j$;
5. an element of $L - A_{i_m,m,k_{m,|\sigma|}}$ has occurred in σ whenever this difference is not empty and $m \leq j$.

The first statement implies that N^E can recover the relevant part of f. The second statement implies that whenever L is finite, its elements and the finitely many elements of $A_{i_j,j,k}$ are explicitly known to the learner. The third statement enforces that $k_{j,|\sigma|} = k$, and thus k is known to the learner. The fourth and fifth statements guarantee for all $m < j$ that N^E does not output $\{(i_m, m, k_{m,|\sigma|})\}$ whenever $A_{i_m,m,k_{m,|\sigma|}} \neq L$. By

the choice of j, this holds for all $m < j$ and N^E outputs $\{(i_j, j, k)\}$ on input σ. Thus, N^E identifies L. □

The following example shows that there is a difference between the trivial oracles for clustering in the general sense and clustering of uniformly recursively enumerable classes.

EXAMPLE 4.5. *Every 2-generic oracle is trivial for clustering.*

Proof. Assume that G is 2-generic and $S = \{A_0, A_1, \ldots\}$ is clusterable relative to G via an oracle machine M^G. Without loss of generality, M^E is total for every oracle E. Now consider the following sets of strings:

$$T = \{\eta : (\exists I, J)\,(\exists x, t)\,(\exists \sigma \in A_I^*)\,(\forall \tau \in A_I^*)\,(\forall E \succeq \eta)\,(\forall s \geq t)$$
$$[(J \notin \mathrm{disj}_s(S) \vee A_{I,s}(x) \neq A_{J,s}(x)) \wedge I \in \mathrm{disj}_s(S) \wedge M^E(\sigma\tau) = J]\};$$
$$U_{I,\sigma} = \{\vartheta : (\exists \tau \in A_I^*)\,(\forall E \succeq \vartheta)\,[M^E(\sigma\tau) \neq M^E(\sigma)]\}.$$

The oracles quantified in the definitions above are evaluated only up to a certain point. Thus, one can make the definitions of the sets to be Σ_2^0.

Given any $I \in \mathrm{disj}(S)$, M^G has a stabilizing sequence σ for A_I. If σ is not also a stabilizing sequence for M^E, then there is a τ and a prefix $\vartheta \preceq E$ with $M^E(\sigma\tau) \neq M^E(\sigma)$, where all queries to E while computing these two values target only the domain of ϑ. Thus, $\vartheta \in U_{I,\sigma}$. Since G is 2-generic and σ is a stabilizing sequence for M^G, there is a prefix $\alpha \preceq G$ such that no extension $\vartheta \succeq \alpha$ is in $U_{I,\sigma}$. In particular, σ is a stabilizing sequence for A_I and M^E whenever the oracle E satisfies $E \succeq \alpha$. Thus, the stabilizing sequence σ is uniform for all M^E with $E \succeq \alpha$.

The set T contains all η such that for some $I \in \mathrm{disj}(S)$, for some J and a uniform stabilizing sequence σ for A_I with respect to η, $M^E(\sigma) = J$ for all $E \succeq \eta$ and either $J \notin \mathrm{disj}(S)$ or $A_J \neq A_I$. It follows again that $\eta \not\preceq G$ for all $\eta \in T$. Thus there is a prefix $\theta \preceq G$ such that no extension of θ is in T.

ALGORITHM N. The clusterer N is a variant of the locking sequence hunting construction and searches simultaneously for an $\eta \succeq \theta$ and σ built from the data and a J such that $M^E(\sigma\tau) = J$ for all $E \succeq \eta$ and τ obtained from data seen so far. That is, if at stage s the set D is the range of all data seen so far, N searches the first pair (σ, η) in an enumeration of $\mathbb{N}^* \times \{0,1\}^*$ such that

1. $\sigma \in D^*$ and $\eta \in \theta \cdot \{0,1\}^*$;
2. for all $\tau \in D^*$ with $|\tau| \leq s - |\sigma|$ and all $E, F \succeq \eta$, $M^E(\sigma\tau) = M^F(\sigma)$.

Let $J = M^F(\sigma)$ for the set $F = \{x : \eta(x) \downarrow = 1\}$; N outputs J.

Verification. First, note that the search always terminates, as any $\sigma \in D^*$ with $|\sigma| > s$ and any η extending ϑ trivially satisfy the requirements. Furthermore, there is a pair (σ, η) which is a uniform stabilizing sequence for A_I satisfying $\eta \succeq \theta$, and N finds such a sequence in the limit. Since G strongly avoids T in the sense that no extension of the prefix θ is in T, any pair (σ, η) considered by N infinitely often is a correct uniform stabilizing sequence, and thus N converges to an index $J \in \mathrm{disj}(S)$ of A_I. □

5. The finite containment property. The main topic of this section is to investigate the relationship between the topological structure of the class S and the question of whether S is clusterable. Recall that the classes S_{gold} and S_{sing} are not clusterable for topological reasons: they contain a cluster which is the disjoint infinite union of some other clusters. Thus, one might impose the following natural condition in order to overcome this problem.

DEFINITION 5.1. *A class $S = \{A_0, A_1, \ldots\}$ has the* finite containment property *if every finite union of clusters contains only finitely many clusters. That is, for all i there are only finitely many sets $B \in S$ with $B \subseteq A_{\{0,1,\ldots,i\}}$.*

Note that the finite containment property is not necessary for clusterability. The class $\{\{i, i+1, \ldots\} : i \in \mathbb{N}\}$ is learnable and clusterable but does not satisfy the finite containment property.

It is easy to see that the finite containment property implies Angluin's condition: for every set A_I, there are only finitely many sets A_J with $A_J \subset A_I$. If one takes D to be the set $\{\min(A_I - A_J) : A_J \subset A_I\}$, then D is finite and there is no A_J with $D \subseteq A_J \subset A_I$. Thus, from the proof of Proposition 4.3 one has the following.

Property 5.2. *If $S = \{A_0, A_1, \ldots\}$ has the finite containment property, then S is clusterable relative to every oracle E with $E \geq_T K$ and $E' \geq_T K''$.*

Although the finite containment property guarantees clusterability from the topological point of view, it fails to guarantee clusterability from the recursion-theoretic point of view. Indeed, the class S_{comp} given in the proof of Proposition 4.3 satisfies the finite containment property. If W_i is cofinite, then there are only finitely many subsets of $\{\langle i, 0\rangle, \langle i, 1\rangle, \ldots\}$ in S_{comp}. If W_i is coinfinite, then $A_{i,\emptyset}$ is the only infinite subset of $\{\langle i, 0\rangle, \langle i, 1\rangle, \ldots\}$ in S_{comp} and all further subsets of $\{\langle i, 0\rangle, \langle i, 1\rangle, \ldots\}$ are finite sets which are not contained in $A_{i,\emptyset}$.

Note that the class S_C from Example 3.5 is, for the case that C is nonrecursive, a witness for a class satisfying the finite containment property which is learnable but not semiclusterable. This gives the following property.

Property 5.3. There is a class satisfying the finite containment property which is learnable but neither clusterable nor semiclusterable.

Since the topological structure of S_C is the same whenever C is infinite, clusterability of the class S_C is not determined by its topological structure.

Property 5.4. Clusterability cannot be characterized in topological terms only.

If one takes C to be the halting problem K, then S_C (from Example 3.5) witnesses that the oracle K is necessary for semiclustering, even in the case where classes have to satisfy the finite containment property. Proposition 5.5 below shows that semiclustering is much easier than clustering: every uniformly recursively enumerable class is semiclusterable using the halting problem as an oracle. In particular, no topological condition can make semiclustering impossible, but only computational conditions can.

Furthermore, every uniformly recursive class is semiclusterable. But this condition is not necessary for either semiclusterable or clusterable classes. For example, the class $\{\{x : \varphi_x(x) \downarrow = i\} : i \in \mathbb{N}\}$ is clusterable but consists of pairwise disjoint and recursively inseparable sets.

PROPOSITION 5.5. *Every r.e. class has a semiclusterer using the halting problem as an oracle. Furthermore, a class $S = \{A_1, A_2, \ldots\}$ is semiclusterable without any oracle if the representation of the class is a uniformly recursive family, that is, if $\{(i, x) \in \mathbb{N}^2 : x \in A_i\}$ is recursive and not only recursively enumerable.*

Proof. It is sufficient to assume that M can check whether some x is in A_i. This can be done either by using the halting problem as an oracle or by assuming that the sequence $A_0, A_1, \ldots$ is uniformly recursive.

Now M on input σ determines all $J \subseteq \{0, 1, \ldots, |\sigma|\}$ such that $J \in \text{disj}_{|\sigma|}(S)$ and $\text{range}(\sigma) \subseteq A_J$. If there are several such sets, M outputs the one with the least norm. If there are none, M outputs $\emptyset$.

Note that all J which either do not represent disjoint sets or do not contain all data showing up in the limit are eventually disqualified. On the other hand, the set I representing the clustering task is among the determined sets whenever $|\sigma| \geq \max(I)$.

Thus, M converges in the limit to some J such that $\mathrm{norm}(J) \leq \mathrm{norm}(I)$, $J \in \mathrm{disj}(S)$, and $A_I \subseteq A_J$. Therefore M witnesses that S is semiclusterable. □

By Property 5.3 one can separate learnability from clusterability and semiclusterability by a class satisfying the finite containment property. The next results show that there are no implications between the notions of learnability, clusterability, and semiclusterability except the following two: "clusterable ⇒ semiclusterable" and "clusterable ⇒ learnable." All nonimplications are witnessed by classes satisfying the finite containment property.

PROPOSITION 5.6. *There is a class with the finite containment property which is semiclusterable and learnable but not clusterable.*

Proof. Let S consist of the clusters

$$\begin{aligned} A_{3i} &= \{\langle i, x\rangle : x \in \mathbb{N}\};\\ A_{3i+1} &= \{\langle i, x\rangle : x \text{ is even and } x < 2 + |W_i|\};\\ A_{3i+2} &= \{\langle i, x\rangle : x \text{ is odd and } x < 2 + |W_i|\}. \end{aligned}$$

If W_i is infinite, then A_{3i+1} consists of the $\langle i, x\rangle$ where x is even and W_{3i+2} consists of those $\langle i, x\rangle$ where x is odd. Since the union $A_0 \cup A_1 \cup \cdots \cup A_{3i+2}$ contains only the clusters $A_0, A_1, \ldots, A_{3i+2}$, the class S has the finite containment property. Furthermore, S is semiclusterable by assigning to every input σ the set

$$\{3i : (\exists x \in \mathbb{N})\,[\langle i, x\rangle \in \mathrm{range}(\sigma)]\}.$$

Now it is shown that S is not clusterable. Thus, assume by way of contradiction that a recursive M witnesses S to be clusterable.

For each A_{3i}, one finds by using the oracle K a stabilizing sequence $\sigma_i \in (A_{3i})^*$. One can reduce the question of whether W_i is infinite to the question of whether $\mathrm{range}(\sigma_i) \subseteq A_{\{3i+1,3i+2\}}$, which is decidable relative to K: if W_i is infinite, then $\mathrm{range}(\sigma_i) \subseteq A_{\{3i+1,3i+2\}}$; if W_i is finite, then $\mathrm{range}(\sigma_i) \not\subseteq A_{\{3i+1,3i+2\}}$. The latter holds, since otherwise σ_i would also be a stabilizing sequence for $A_{\{3i+1,3i+2\}}$, and M cannot have the same stabilizing sequence for two different sets in which one set is a subset of the other. The reduction of $\{i : W_i \text{ is infinite}\}$ to the oracle K contradicts the fact that $\{i : W_i \text{ is infinite}\}$ is Turing equivalent to K'.

It remains to show that the class S is learnable. This can be done by considering the following learner N.

ALGORITHM N. On input σ, let i be the least number such that a pair of the form $\langle i, x\rangle$ occurs in $\mathrm{range}(\sigma)$. Then

$$N(\sigma) = \begin{cases} 3i & \text{if there are even and odd } y \text{ with } \langle i, y\rangle \in \mathrm{range}(\sigma);\\ 3i+1 & \text{if there are only even } y \text{ with } \langle i, y\rangle \in \mathrm{range}(\sigma);\\ 3i+2 & \text{if there are only odd } y \text{ with } \langle i, y\rangle \in \mathrm{range}(\sigma). \end{cases}$$

The correctness of the learner N can easily be verified. □

EXAMPLE 5.7. *The class containing all sets $A_{3i}, A_{3i+1}, A_{3i+2}, A_{\{3i+1,3i+2\}}$ from the numbering $A_0, A_1, \ldots$ in the proof of Proposition* 5.6 *is neither learnable nor clusterable. But it satisfies the finite containment property and is semiclusterable.*

A natural variant of the finite containment property is the *finite meet property*, which says that each member of the class S meets only finitely many other members (that is, for each $A \in S$, $|\{A' \in S : A \cap A' \neq \emptyset\}|$ is finite). The class S_C, from Example 3.5, witnesses that for $C = K$ one might need the oracle K to cluster a class satisfying the finite meet property. Since the class given in the proof of Proposition 4.3

satisfies the finite containment property and can be clustered only relative to maximal oracles, the next result shows that classes satisfying the finite meet property are easier and require only the oracle K.

PROPOSITION 5.8. *If a class satisfies the finite meet property, then it is clusterable with the halting-problem oracle K.*

Proof. Let $S = \{A_0, A_1, \ldots\}$ satisfy the finite meet property. Let $b_0, b_1, \ldots$ be a text for A_I with $I \in \mathrm{disj}(S)$; without loss of generality, I consists of minimal indices; that is, for all $i \in I$ and for all j, if $A_i = A_j$, then $i \leq j$. Relative to K and the text, one can enumerate the set

$$H = \{h : A_h \cap \{b_0, b_1, \ldots\} \neq \emptyset \wedge (\forall j < h)\,[A_j \neq A_h]\,\}.$$

Now one considers all subsets $J \subseteq H$ with $J \in \mathrm{disj}(S)$. Note that $I \subseteq H$ and $I \in \mathrm{disj}(S)$, and thus I is among the considered sets. Due to the finite meet property, H is finite and only finitely many J are considered. Since these sets are uniformly recursive relative to K, one can find in the limit a considered set J which satisfies $A_J = \{b_0, b_1, \ldots\}$, that is, $A_J = A_I$. Thus S is clusterable using the oracle K. □

6. Numbering-based properties. Every uniformly recursively enumerable class of pairwise disjoint sets is learnable: the learner just waits until it finds $x \in \mathrm{range}(\sigma)$ and $i \leq |\sigma|$ such that x is enumerated into A_i within $|\sigma|$ steps; from then on the learner outputs the index i. But for nonrecursive sets C, the class S_C witnesses that such a class is not clusterable. Thus, one has to consider not only properties of the class but also properties of some of its numberings. A class $\{A_0, A_1, \ldots\}$ has the *numbering-based finite containment property* if for every I there are only finitely many j with $A_j \subseteq A_I$.

PROPOSITION 6.1. *A class of pairwise disjoint sets has the numbering-based finite containment property iff it is clusterable.*

Proof. Let $S = \{A_0, A_1, \ldots\}$ be a class of pairwise disjoint sets. Due to the numbering-based finite containment property there are, for every i, only finitely many j with $A_j = A_i$. Now consider the following clusterer.

ALGORITHM M. On input σ, find the J of the largest norm which satisfies the following three conditions:

1. $J \subseteq \{0, 1, \ldots, |\sigma|\}$;
2. $J \in \mathrm{disj}_{|\sigma|}(S)$;
3. $A_j \cap \mathrm{range}(\sigma) \neq \emptyset$ for all $j \in J$.

Then output this J.

Verification. Note that the algorithm always terminates since $\emptyset$ satisfies the search conditions. Fix a clustering task I. The set $H = \{h : A_h \cap A_I \neq \emptyset\}$ is finite. Since M always outputs subsets of H, it follows that M converges to some $J \subseteq H$. This J is the set of the highest norm such that $J \subseteq H$ and $J \in \mathrm{disj}(S)$. Since the members of S are pairwise disjoint, it holds for every $j \in J$ that A_j not only meets A_I but, moreover, is contained in A_I. Furthermore, if $i \in I$, then $A_i \cap A_J$ is not empty, since otherwise $J \cup \{i\}$ is also a subset of H, is in $\mathrm{disj}(S)$, and has a norm larger than that of J. Thus, $A_i \subseteq A_J$. Since this holds for all $i \in I$, $A_J = A_I$ and M is a clusterer for S.

Converse direction. Assume that N is a clusterer for S and consider the set

$$E = \{i : (\forall j < i)\,(\forall \sigma \in A^*_{j,i}, |\sigma| \leq i)\,(\exists \tau \in (A_i \cup A_j)^*)\,[N(\sigma\tau) \neq N(\sigma)]\}.$$

The set E is recursively enumerable since the universal quantifiers are bounded and the second one runs over strings of the finite set $A_{j,i}$ of all elements enumerated into

A_j within i steps. Given any set in S, let i be its minimal index. Let $j < i$. Since $A_j \neq A_i$, A_j is disjoint from A_i, $\{j, i\} \in \mathrm{disj}(S)$, and $A_{\{j,i\}}$ is a proper superset of A_i. The clusterer N must converge on texts for A_j and $A_{\{i,j\}}$ to different outputs. Thus, there is no $\sigma \in A_j^*$ with $N(\sigma) = N(\sigma\tau)$ for all $\tau \in A_{\{i,j\}}^*$. The index i is eventually enumerated into E. The set A_i has a stabilizing sequence σ. For all sufficiently large j with $A_i = A_j$, the length of σ is shorter than j and its range enumerated into A_i within j steps. It follows that σ prevents j from being enumerated into E and E contains only finitely many indices of A_i. The set E has a recursive enumeration $e_0, e_1, \ldots$, which defines by $B_h = A_{e_h}$ a new numbering $B_0, B_1, \ldots$ of S having the desired properties. □

Remark 6.2. Proposition 5.6 gives a class which satisfies the numbering-based finite containment property but is not clusterable. A variant of the class S_{comp} given in the proof of Proposition 4.3 satisfies the numbering-based finite containment property but is clusterable only relative to maximal oracles.

Let the numbering-based finite meet property denote that every A_i meets A_j only for finitely many j. It follows from Proposition 5.8 that a class satisfying the numbering-based finite meet property is clusterable with the oracle K. But even this property is not sufficient for clustering without oracles. The class in Example 5.7 actually satisfies the numbering-based finite meet property but is not clusterable.

A further example of a class which satisfies the numbering-based finite meet property but is not clusterable can be constructed using the following result of Jain and Sharma [12]: there is no learner which identifies all recursively enumerable sets from any text for the set plus an upper bound on its least index. The class

$$\{\{\langle i, x\rangle : x \in W_j\} : j \leq i \wedge W_j \neq \emptyset\}$$

has a numbering witnessing that it satisfies the numbering-based finite meet property. But it consists of copies of sets W_j, having coded an upper bound of an index of W_j into its first coordinate. This class cannot be learnable or clusterable because one would get a contradiction to the result of Jain and Sharma otherwise.

In the following, two conditions are presented which are more restrictive than the numbering-based finite containment property and guarantee that a class is clusterable.

PROPOSITION 6.3. *Assume that $A_i \not\subseteq \bigcup_{j \neq i} A_j$ for all i and that it is decidable whether two sets A_i, A_j intersect. Then $S = \{A_0, A_1, \ldots\}$ is clusterable.*

Proof. The clusterer M uses the fact that one can check disjointness effectively, that is, that $\mathrm{disj}(S)$ is recursive.

ALGORITHM M. On input $b_0, b_1, \ldots, b_s$, M considers all $J \subseteq \{0, 1, \ldots, s\}$ satisfying the following conditions:

1. $A_{i,s} \cap \{b_0, b_1, \ldots, b_s\} \neq \emptyset$ for all $i \in J$;
2. $J \in \mathrm{disj}(S)$;
3. there is no $j \in \{0, 1, \ldots, s\} - J$ such that $A_{j,s} \cap \{b_0, b_1, \ldots, b_s\} \neq \emptyset$ and $J \cup \{j\} \in \mathrm{disj}(S)$.

If there are several sets $J_1, J_2, \ldots, J_n \subseteq \{0, 1, \ldots, s\}$ which satisfy all three conditions, then M computes for $m = 1, 2, \ldots, n$ the number

$$c_m = \max\{h \leq s + 1 : \{b_j : j < h\} \subseteq J_{m,s}\}$$

and outputs J_m for the m which maximizes c_m; if there are still several options, M outputs the one with the least norm.

Verification. Assume that a clustering task $I \in \mathrm{disj}(S)$ is given and that $b_0 b_1 \ldots$ is a text for A_I. Let s be so large that there is a c satisfying the following conditions:

- $s \geq \max(I)$;
- for any $i \in I$ there exists an $h \leq c$ with $b_h \in A_i - \bigcup_{j \neq i} A_j$;
- $\{b_0, b_1, \ldots, b_c\} \subseteq A_{I,s}$.

Then I clearly satisfies the first two search conditions of M. The third is also satisfied since, whenever $A_j \cap A_I = \emptyset$, A_j does not contain any of the elements $b_0, b_1, \ldots, b_s$. Thus, any set $J \neq I$ satisfying all three conditions is not a superset of I. In particular, there is an $i \in I - J$ and an $h \leq c$ such that $b_h \in A_i - A_J$. Since $\{b_0, b_1, \ldots, b_c\} \subseteq A_{I,s}$ and $\{b_0, b_1, \ldots, b_c\} \not\subseteq A_J$, M outputs I and not J. Thus, M converges on a text for A_I to I, and M is a clusterer for S. □

PROPOSITION 6.4. *Assume that $S = \{A_0, A_1, \ldots\}$ satisfies the following three conditions:*

1. *Every A_i is infinite;*
2. *if $i \neq j$, then $A_i \cap A_j$ is finite;*
3. *S is uniformly recursive, that is, $\{(i, x) : x \in A_i\}$ is recursive.*

Then S is clusterable. But no two of these three conditions are sufficient for being clusterable.

Proof. On input σ, the clusterer M searches for the J of the least norm satisfying the following properties:

- $J \subseteq \{0, 1, \ldots, |\sigma|\}$;
- $\mathrm{range}(\sigma) \subseteq A_J$;
- $J \in \mathrm{disj}_{|\sigma|}(S)$.

If such a J is found, then M outputs J, else M outputs $\emptyset$.

First, one can easily see that M is recursive since the search space is limited to $2^{|\sigma|+1}$ candidate sets. Second, one considers any clustering task I and any text for it. Every sufficiently long prefix σ of the text satisfies $i \leq |\sigma|$ and $A_i \cap \mathrm{range}(\sigma) \neq \emptyset$ for all $i \in I$. Thus, I satisfies for all sufficiently long σ the three search conditions, and hence M converges to a set J with $\mathrm{norm}(J) \leq \mathrm{norm}(I)$. For every $i \in I$, the set A_i is not a subset of $A_{J-\{i\}}$ since A_i is infinite and $A_i \cap A_{J-\{i\}}$ is finite. Thus, $I \subseteq J$. Since $\mathrm{norm}(J) \leq \mathrm{norm}(I)$ (from above), it follows that $I = J$.

Recall the definition of S_C from Example 3.5. The class $\{A \times \mathbb{N} : A \in S_C\}$ for a nonrecursive parameter-set C satisfies conditions 1 and 2 but is not clusterable. The class of all cofinite sets satisfies conditions 1 and 3 but is neither learnable [11, section 3.6.2] nor clusterable. The class S_{gold} satisfies conditions 2 and 3 but is not clusterable. □

7. Geometric examples. The major topic of this and the following sections is to look at sets of clusters which are characterized by basic geometric properties. Therefore, the underlying set is no longer $\mathbb{N}$ but the k-dimensional rational vector space $\mathbb{Q}^k$, where $k \in \{1, 2, \ldots\}$ is fixed. The classes considered consist of natural subsets of $\mathbb{Q}^k$. This is quite common practice in computer science; for example, the real numbers used in standard programming languages are indeed rationals, as they normally consist only of finitely many binary digits multiplied by a power of 2; furthermore, dealing with rationals avoids the uncountability of the set of reals and also *uncomputable* real points. Except for the class $S_{\mathrm{accu},k}$ in Definition 7.2 below, the following hold: The clusters are built from finitely many parameter-points in $\mathbb{Q}^k$; the clusters are connected sets; and every clustering task consists of clusters having a positive distance from each other. Thus, there is a unique natural way of breaking down a clustering task into clusters.

The space $\mathbb{Q}^k$ is a metric space. The standard metric d between two points is given by the square root of the sum of the squares of the differences of the coordinates, for example, $d((1,2,3),(0,0,5)) = \sqrt{(1-0)^2+(2-0)^2+(3-5)^2} = \sqrt{1+4+4} = 3$ in $\mathbb{Q}^3$. d is also called *distance*.

Recall that a subset $U \subseteq \mathbb{Q}^k$ is *affine* iff for every fixed $x \in U$ the set $V = \{y \in \mathbb{Q}^k : x+y \in U\}$ is a rational vector space, that is, closed under scalar multiplication and addition. The dimension of U is the dimension of V as a vector space; it is independent of the choice of x.

EXAMPLE 7.1. *Let $S_{\mathrm{aff},k}$ be the class of all affine subspaces of $\mathbb{Q}^k$ which have dimension $k-1$. The class $S_{\mathrm{aff},k}$ is clusterable but the class $S_{\mathrm{aff},k} \cup \{\mathbb{Q}^k\}$ is not.*

Proof. If one considers a one-one numbering $A_0, A_1, \ldots$ of $S_{\mathrm{aff},k}$, one can easily verify the following properties:

1. Every A_i has dimension $k-1$;
2. if $i \neq j$, then $A_i \cap A_j$ is either empty or an affine subspace of dimension up to $k-2$;
3. the set $\{(i,x) : x \in A_i\}$ is recursive.

Properties 1 and 2 enforce that $A_i \not\subseteq A_{J-\{i\}}$ for every finite set J. Thus, one can adapt the clusterer for the class in Proposition 6.4 to a clusterer for $S_{\mathrm{aff},k}$. The verification can also easily be transferred.

The class $S_{\mathrm{aff},k} \cup \{\mathbb{Q}^k\}$ is just the geometric version of the class S_{sing} from Example 3.5. Let U be a $(k-1)$-dimensional vector space and W be a 1-dimensional vector space with $U+W = \mathbb{Q}^k$. Furthermore let $U_x = \{x+y : y \in U\}$. Since every U_x is in $S_{\mathrm{aff},k}$ and $\mathbb{Q}^k$ is the disjoint union of all U_x with $x \in W$, it follows that $S_{\mathrm{aff},k} \cup \{\mathbb{Q}^k\}$ is not clusterable. □

DEFINITION 7.2. *Let k be a positive natural number and $S_{accu,k}$ be a class $\{A_0, A_1, \ldots\}$ of bounded subsets of $\mathbb{Q}^k$ for which there is a recursive and one-one sequence $a_0, a_1, \ldots$ of points in $\mathbb{Q}^k$ satisfying the following:*

1. *Every A_i has exactly one accumulation point which is a_i;*
2. *no accumulation point of the set $\{a_0, a_1, \ldots\}$ is contained in this set.*

Comment. Every set $A_i \cup \{a_i\}$ is compact, but it is not required that $a_i \in A_i$, and therefore the set A_i itself might fail to be compact.

PROPOSITION 7.3. *The class $S_{accu,k}$ is clusterable.*

Proof. The following machine M witnesses that $S_{\mathrm{accu},k}$ is clusterable.

ALGORITHM M. On input $b_0 b_1 \ldots b_s$, let

$$H_s = \{i \leq s : (\exists h \leq s)\,(\forall j \leq h, j \neq i)\,[b_h \notin \{b_0, b_1, \ldots, b_i\} \wedge d(a_i, b_h) < d(a_j, b_h)]\},$$

$$J_s = \{i \in H_s : (\exists h)\,(\forall j \in H_s - \{i\})\,[b_h \in A_{i,s} - A_{j,s}]\}$$

and output J_s.

Verification. Since a_i is an accumulation point of A_i but not of $\{a_0, a_1, \ldots\}$, and since $a_i \neq a_j$ whenever $i \neq j$, for every i there is a threshold $\epsilon_i > 0$ such that

- for all $q \in \mathbb{Q}^k$ there is at most one i with $d(a_i, q) < \epsilon_i$;
- for almost all $q \in A_i$, $d(a_i, q) < \epsilon_i$.

Consider now a text $b_0 b_1 \ldots$ for a set A_I with $I \in \mathrm{disj}(S_{\mathrm{accu},k})$. Let $H = \bigcup_{s \in \mathbb{N}} H_s$ where H_s, J_s are the sets constructed by the algorithm with input $b_0, b_1, \ldots, b_s$. There are only finitely many $q \in A_I$ which do not satisfy $d(a_i, q) < \epsilon_i$ for an $i \in I$, and there is a stage $t \geq \max(I)$ such that $\{b_0, b_1, \ldots, b_t\}$ contains all these q. It follows that $H \subseteq \{0, 1, \ldots, t\}$. Note that the intersection $A_i \cap A_j$ is finite for any different i, j since

the sets A_i, A_j are bounded and have different accumulation points. So all sufficiently large s satisfy the following conditions:

- $H = H_s$;
- for all different $i, j \in H$, $A_i \cap A_j = A_{i,s} \cap A_{j,s}$;
- for all $i \in I$, there is an $h \leq s$ such that $b_h \in A_i - (\bigcup_{j \in H} A_j \cup \{b_0, b_1, \ldots, b_i\})$ and $d(b_h, a_i) < \epsilon_i$.

It follows that on the one hand, $I \subseteq H_s$, and on the other hand, that every $j \in H_s - I$ satisfies $A_I \cap A_j \subseteq A_{I,s}$. Since $b_0, b_1, \ldots$ is a text for A_I, it follows that $J_s = I$ and M is a clusterer for $S_{\mathrm{accu},k}$. □

The class $S_{\mathrm{accu},k}$ is clusterable but the machine M makes use of the sequence $a_0, a_1, \ldots$ as an auxiliary source of information. Nevertheless, this information is implicit. One can build a program for it into the machine M, which simulates this program, in order to get some further information on $S_{\mathrm{accu},k}$.

8. Clustering with additional information. Freivalds and Wiehagen [7] introduced a learning model in which the learner receives—in addition to the graph of the function to be learned—an upper bound on the size of some program for this function. This additional information increases the learning power and enables a machine to learn the class of all recursive functions.

Similarly, a machine receiving adequate additional information can solve every clustering task for the class $S_{\mathrm{conv},k}$ defined below. But without that additional information, $S_{\mathrm{conv},k}$ is not clusterable. Thus, the main goal of this section is to determine which pieces of additional information are sufficient to cluster certain geometrically defined classes where clustering without additional information is impossible.

Recall that the convex hull of a set $D = \{x_0, x_1, \ldots, x_n\}$, denoted by $\mathrm{hull}(D)$, is the set given by

$$\mathrm{hull}(D) = \{q_0 x_0 + q_1 x_1 + \cdots + q_n x_n : q_0, q_1, \ldots, q_n \in \mathbb{Q} \\ \wedge q_0, q_1, \ldots, q_n \geq 0 \wedge q_0 + q_1 + \cdots + q_n = 1\}.$$

Given a set E as a convex hull of a finite set, there is a unique minimal set D such that $E = \mathrm{hull}(D)$.

DEFINITION 8.1. *For a given positive natural number k, the class $S_{conv,k}$ contains all subsets of $\mathbb{Q}^k$ which are the rational points in the convex hull of a finite subset of $\mathbb{Q}^k$.*

Note that $S_{\mathrm{conv},k}$ has the following nice properties, which will be used in the proofs implicitly: every cluster is ϵ-connected for all $\epsilon > 0$; any two clusters A_i, A_j have either a point in common or have a positive distance from each other, where the distance is defined as $d(A_i, A_j) = \inf\{d(x, y) : x \in A_i, y \in A_j\}$.

PROPOSITION 8.2. *The class $S_{conv,k}$ is semiclusterable but not clusterable.*

Proof. A semiclusterer M for $S_{\mathrm{conv},k}$ works as follows.

ALGORITHM M. On input σ, M searches for the first $i \in \{0, 1, \ldots, |\sigma|\}$ such that $\mathrm{range}(\sigma) \subseteq \mathrm{hull}(A_{i,|\sigma|})$. If this i is found, then M outputs $\{i\}$, else M outputs $\emptyset$.

Verification. Let I be the clustering task and i be the least index of a set with $A_I \subseteq A_i$. Given any text for A_I, every sufficiently long prefix σ of the text satisfies the following three conditions:

- $|\sigma| \geq i$;
- $\mathrm{range}(\sigma) \not\subseteq A_j$ for all $j < i$;
- $\mathrm{hull}(A_{i,|\sigma|}) = A_i$.

It is easy to see that $M(\sigma) = \{i\}$ for the input σ. Therefore, M converges to i and $S_{\mathrm{conv},k}$ is semiclusterable.

Gold's condition. Note that every singleton in $\mathbb{Q}^k$ belongs to $S_{\mathrm{conv},k}$ and that there are also infinite clusters. Then, given an M and an infinite A_i, M has a stabilizing sequence $\sigma \in (A_i)^*$. Thus, either M fails on the clustering task I representing all singletons $\{x\}$ with $x \in \mathrm{range}(\sigma)$ or M fails on the clustering task $\{i\}$ representing A_i. □

PROPOSITION 8.3. *The class $S_{conv,k}$ is clusterable with additional information if for any clustering task I one of the following pieces of information is also provided to the machine M:*

- *the number $|I|$ of clusters of the clustering task;*
- *a positive lower bound ϵ for $\gamma = \min(\{1\} \cup \{d(A_i, A_j) : i, j \in I \wedge i \neq j\})$;*
- *the minimal number p of points which are needed to generate all the convex sets A_i with $i \in I$.*

Proof. The algorithm tries to identify in the limit the following pieces of information:

- finite sets $E_0, E_1, \ldots, E_m$;
- for each $l \in \{0, 1, \ldots, m\}$, an index j_l such that $A_{j_l} = \mathrm{hull}(E_l)$.

The final conjecture of the algorithm will then be the set $J = \{j_0, j_1, \ldots, j_m\}$.

The algorithm uses the notion of an ϵ-component. Given $\epsilon > 0$, a subset $E \subseteq U$ is an ϵ-component of U if the following two conditions hold:

- For any $x, y \in E$, there is a sequence $z_1, z_2, \ldots, z_h$ of elements of E such that $x = z_1, y = z_h$, and $d(z_l, z_{l+1}) < \epsilon$ for all l with $1 \leq l < h$;
- $d(x, y) \geq \epsilon$ for any $x \in E$ and $y \in U - E$.

Note that for every ϵ and finite set U, the partition of U into ϵ-components is unique.

ALGORITHM M. On input σ, the clusterer goes into the first case applicable from the following:

- If $|I|$ is given and there is a maximal $\epsilon \in \{\frac{1}{|\sigma|}, \frac{2}{|\sigma|}, \ldots\}$ such that $\mathrm{range}(\sigma)$ has exactly $|I|$ ϵ-components, then let $m = |I|$ and $F_0, F_1, \ldots, F_{m-1}$ be these components. For $l = 0, 1, \ldots, m-1$, let E_l be the smallest subset of F_l with $\mathrm{hull}(E_l) = \mathrm{hull}(F_l)$.
- If ϵ is given, then let m be the number of ϵ-components $F_0, F_1, \ldots, F_{m-1}$ of $\mathrm{range}(\sigma)$. For $l = 0, 1, \ldots, m-1$, let E_l be the smallest subset of F_l with $\mathrm{hull}(E_l) = \mathrm{hull}(F_l)$.
- If p is given and there is a number $m \in \{0, 1, \ldots, p-1\}$, an $\epsilon \in \{\frac{1}{|\sigma|}, \frac{2}{|\sigma|}, \ldots\}$, and $E_0, E_1, \ldots, E_{m-1} \subseteq \mathrm{range}(\sigma)$ such that
  - $p = |E_0| + |E_1| + \cdots + |E_{m-1}|$,
  - each set E_l consists of the corners of $\mathrm{hull}(E_l)$, and
  - the sets $\mathrm{hull}(E_l) \cap \mathrm{range}(\sigma)$ are the ϵ-components of $\mathrm{range}(\sigma)$,

  then fix m and the sets $E_0, E_1, \ldots, E_{m-1}$.
- If none of the previous cases hold, then let $m = |\sigma|$ and $E_0, E_1, \ldots, E_{m-1}$ be the m singleton subsets of $\mathrm{range}(\sigma)$.

Now find for each $l \in \{0, 1, \ldots, m-1\}$ the least $s \geq |\sigma|$ such that there is a $j_l \leq s$ with $\mathrm{hull}(E_l) = \mathrm{hull}(A_{j_l,s})$; if there are several candidates for this j_l, then choose the least one. Having found m and $j_0, j_1, \ldots, j_{m-1}$, the output is the set $J = \{j_0, j_1, \ldots, j_{m-1}\}$.

Verification. It is easy to verify that M is computable and is defined on every σ. Fix a clustering task $I \in \mathrm{disj}(S_{\mathrm{conv},k})$ and a text for A_I. In the case of additional information of the second type, let δ be the given lower bound ϵ for γ; otherwise let $\delta = 1$ if $|I| = 1$ and $\delta = \min\{d(A_i, A_j) : i, j \in I \wedge i \neq j\}$ if $|I| > 1$. Assume that a prefix σ of the given text is so long that for each $i \in I$, the following conditions hold:

- For all $j \in \{0, 1, \ldots, i\}$, $\mathrm{hull}(A_{j,|\sigma|}) = A_i$ iff $A_j = A_i$;

- $\mathrm{hull}(\mathrm{range}(\sigma) \cap A_{i,|\sigma|}) = A_i$;
- for all $x \in A_i$, there is a $y \in \mathrm{range}(\sigma)$ such that $d(x,y) < \frac{\delta}{10}$;
- $\frac{1}{|\sigma|} < \frac{\delta}{10}$.

Then one can verify that the algorithm will come up with a lower bound ϵ for δ such that the ϵ-components of $\mathrm{range}(\sigma)$ coincide with the δ-components. Furthermore, the parameter m is the cardinality $|I|$, and the sets $E_0, E_1, \ldots, E_{m-1}$ are sets of minimal cardinality such that

$$\{\mathrm{hull}(E_0), \mathrm{hull}(E_1), \ldots, \mathrm{hull}(E_{m-1})\} = \{A_i : i \in I\}.$$

Since σ is a sufficiently long prefix of the text, the output of the algorithm is a finite set J with $\{A_j : j \in J\} = \{A_i : i \in I\}$. It follows that M solves the clustering task I. □

The last results of the present work deal with conditions under which nonconvex geometrical objects can be clustered. Our first approach is to look at unions of convex objects which are still connected. For $k = 1$, this class is the same as $S_{\mathrm{conv},1}$. But for $k = 2$, this class is larger. There the type of additional information used for clustering $S_{\mathrm{conv},k}$ is no longer sufficient. Given both the number of clusters and the number of vertices as additional information, it is possible to cluster the natural subclass $S_{\mathrm{polygon},2}$ of all classes considered. But if one permits holes inside the clusters, this additional information is no longer sufficient. An alternative parameter is the k-dimensional area covered by a geometric object. In Example 8.8 a natural class $S_{\mathrm{area},k}$ is introduced which can be clustered with the area of a clustering task given as additional information. The class $S_{\mathrm{area},2}$ contains $S_{\mathrm{polygon},2}$ and the class from Example 8.7 as subclasses.

DEFINITION 8.4. *A polygon is given by n vertices $q_1, q_2, \ldots, q_n \in \mathbb{Q}^2$ and is the union of n sides, which are the convex hulls of $\{q_1, q_2\}, \{q_2, q_3\}, \ldots, \{q_n, q_1\}$. The sides do not cross each other, and exactly two sides contain one vertex. Every side has positive length and the angle between the two sides meeting at a vertex is never 0, 180, or 360 degrees. Let $p_0, p_1, \ldots$ be an enumeration of the polygons, and let P_i be the set of all points in $\mathbb{Q}^2$ which are on the polygon p_i or in its interior. Let n_i denote the minimum number of vertices to define the polygon p_i, and let $S_{polygon,2}$ be the class $\{P_0, P_1, \ldots\}$.*

Remark 8.5. Note that every polygon has the same number of sides as vertices. The length 0 of sides and the angle of 180 degrees are forbidden in order to make the representation unique up to some permutation of the vertices. The angles of 0 and 360 degrees are forbidden in order to avoid irregularities.

The following fact will be used below. Assume that $P_i \subseteq P_j$, $n_i \leq n_j$, and every side of p_j contains at least $n_j + 2$ points of P_i. Then $P_i = P_j$. To see this, consider any side T of p_j. Let $c_0, c_1, \ldots, c_{n_j}, c_{n_j+1}$ be $n_j + 2$ points on $T \cap P_i$. These points are all on p_i since they are on p_j and $P_i \subseteq P_j$. There is a $u \in \{0, 1, \ldots, n_j\}$ such that no vertex of p_i is properly between c_u and c_{u+1}. Then the convex hull of $\{c_u, c_{u+1}\}$ is part of a side U_T of P_i. So every side T of p_j has at least two points in common with some side U_T of p_i.

The first claim is that for $T \neq \tilde{T}$, $U_T \neq U_{\tilde{T}}$. So suppose by way of contradiction that there are two sides $T, \tilde{T}$ of P_j such that $U_T = U_{\tilde{T}}$. Let $d_1 \in T \cap U_T$ and $d_2 \in \tilde{T} \cap U_{\tilde{T}}$. Then U_T contains $\mathrm{hull}(\{d_1, d_2\})$ and is a subset of P_j, although not a side of P_j. Since U_T touches two sides of P_j and goes through the interior of P_j, U_T splits P_j into two halves, each of which has some sides different from U_T. On these sides are points of $p_i \cap p_j$, and thus P_i would also be split into two halves by U_T, a

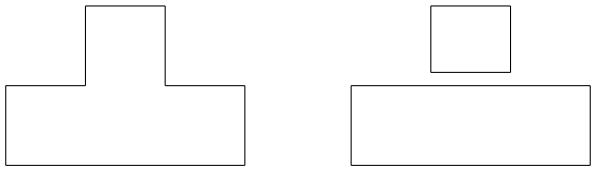


FIG. 1. *Left and right hand clusters. Each has* 8 *vertices and* 8 *sides.*

contradiction. Thus, $n_i = n_j$.

The next claim is that if U_T and $U_{\tilde{T}}$ are neighbors, then so are T and $\tilde{T}$ (and thus, the intersection point of U_T and $U_{\tilde{T}}$ is the same as that of T and $\tilde{T}$). To see this, suppose otherwise. Then the angle $U_T, U_{\tilde{T}}$ splits P_j into two halves, each of which has some sides different from U_T and $U_{\tilde{T}}$. On these sides are points of $p_i \cap p_j$, and thus P_i would also be split into two halves by the angle $U_T, U_{\tilde{T}}$, a contradiction.

It follows from above that $T = U_T$, $U_{\tilde{T}} = \tilde{T}$, and thus $p_i = p_j$.

Note that this property no longer holds if one permits a set of polygons instead of a single polygon. So there is a polygon p_j such that one can find, for any finite subset $F \subseteq P_j$, a set $\{i_1, i_2\} \in \mathrm{disj}(S_{\mathrm{polygon},2})$ with $F \subseteq P_{\{i_1,i_2\}} \subseteq P_j$. More precisely, let p_j be given by $(0,0), (0,1), (1,1), (1,2), (2,2), (2,1), (3,1), (3,0)$, and let F be any finite subset of P_j. Then take $q = \min(\{y : (\exists x)\,[(x,y) \in F \wedge y > 1]\})$ and take i_1, i_2 representing the rectangles given by $(0,0), (0,1), (3,1), (3,0)$ and $(1,q), (1,2), (2,2), (2,q)$.

Figure 1 illustrates the last counterexample. More information on polygons can be found in textbooks on geometry such as [15].

PROPOSITION 8.6. *The class $S_{polygon,2} = \{P_0, P_1, \ldots\}$ is clusterable with additional information in the sense that it is clusterable from the following input provided to a clusterer for clustering task I in addition to a text for P_I: the cardinality $|I|$ and the number $\sum_{i \in I} n_i$. Clustering is impossible if only one of these two pieces of information is available.*

Proof. Assume that the algorithm M knows $|I|$ and $\sum_{i \in I} n_i$ and receives as input a prefix σ of a text for A_I. Then M searches for the $J \subseteq \{0, 1, \ldots, |\sigma|\}$ of least norm which satisfies the following conditions:

1. $J \in \mathrm{disj}(S_{\mathrm{polygon},2})$;
2. $|J| = |I|$;
3. $\sum_{j \in J} n_j = \sum_{i \in I} n_i$;
4. $\mathrm{range}(\sigma) \subseteq P_J$;
5. the vertices of the p_j with $j \in J$ are in $\mathrm{range}(\sigma)$;
6. if T is a side of p_j and $j \in J$, then $|T \cap \mathrm{range}(\sigma)| \geq \sum_{i \in I} n_i + 2$.

M outputs J if J is found, and $\emptyset$ otherwise.

For the verification, it is easy to see that M is recursive. Now consider any clustering task $I \in \mathrm{disj}(S_{\mathrm{polygon},2})$. Since I satisfies the search conditions for all sufficiently long prefixes σ of the text, the clusterer converges to a J with $\mathrm{norm}(J) \leq \mathrm{norm}(I)$, $P_I \subseteq P_J$, $|J| = |I|$, and $\sum_{j \in J} n_j = \sum_{i \in I} n_i$. If $i \in I$, then $P_i \subseteq P_J$. If $P_i \not\subseteq P_j$ for any single $j \in J$, then the P_j with $j \in J$ intersecting P_i would have a positive distance from each other; but since P_i is connected, some points of P_i would not be in any P_j with $j \in J$. Thus, this case cannot happen. Furthermore, if P_j is disjoint from P_I, then the vertices of P_j never show up in the input, and thus $j \notin J$. It follows that there is a one-one correspondence between the $i \in I$ and $j \in J$ such that $P_i \subseteq P_j$. Since $\sum_{j \in J} n_j = \sum_{i \in I} n_i$, there are $i \in I$ and $j \in J$ with $P_i \subseteq P_j$ and $n_i \leq n_j$. Furthermore $P_j \cap P_{I - \{i\}} = \emptyset$, and thus all points of P_j which have

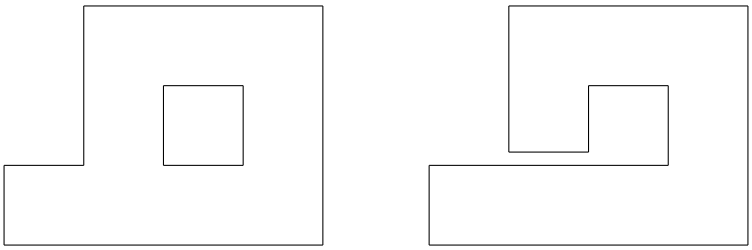

FIG. 2. *Opening a hole while preserving* 10 *vertices and* 10 *sides.*

shown up in the input are actually from P_i. It follows for every side T of p_j that $n_j + 2 \leq |T \cap \text{range}(\sigma)| \leq |T \cap P_i|$. Thus, by Remark 8.5, $P_i = P_j$ and $n_i = n_j$. In particular, there are no $i \in I$, $j \in J$ with $P_i \subseteq P_j$ and $n_i < n_j$. Since $|I| = |J|$ and $\sum_{j \in J} n_j = \sum_{i \in I} n_i$, one can conclude that there are also no $i \in I$, $j \in J$ with $P_i \subseteq P_j$ and $n_i > n_j$. Thus, $n_i = n_j$ whenever $i \in I, j \in J, P_i \subseteq P_j$. By the previous considerations, this gives that $P_i = P_j$ whenever $i \in I, j \in J, P_i \subseteq P_j$. In particular, $P_J = P_I$ and M is a clusterer for $S_{\text{polygon},2}$ which succeeds whenever it receives on the input, in addition to a text for P_I, the numbers $|I|$ and $\sum_{i \in I} n_i$.

Now it is shown that, in addition to the text, the other two pieces of information given to M are needed. That is, M cannot succeed while receiving only one of them.

If only the additional information $|I|$ is given, then consider a stabilizing sequence σ for the rectangle P_i with vertices $(0,0), (0,2), (1,2), (1,0)$. Since $\text{range}(\sigma)$ is finite, there are rationals q_1, q_2 with $0 < q_1 < q_2 < 1$ such that no point of the form (q, r) with $q_1 < q < q_2$ is in $\text{range}(\sigma)$. Thus σ is also a stabilizing sequence for the P_j given by the polygon through the vertices $(0,0), (0,2), (q_1,2), (q_1,1), (q_2,1), (q_2,2), (1,2), (1,0)$ and $P_j \subset P_i$. Thus, the clusterer fails to identify either the clustering task $\{i\}$ or the clustering task $\{j\}$.

If only the additional information $\sum_{i \in I} n_i$ is given, one can take $I = \{i\}$ such that p_i, P_i is given by $(0,0), (0,1), (1,1), (1,2), (2,2), (2,1), (3,1), (3,0)$, and $n_i = 8$ as done in Remark 8.5 (see Figure 1). Now let $\sigma \in P_i^*$ be a stabilizing sequence for P_i and $q = \min(\{y : (\exists x)\,[(x,y) \in \text{range}(\sigma) \wedge y > 1]\})$. Then σ is also a stabilizing sequence for a cluster consisting of the two rectangles which are given as $(0,0), (0,1), (3,1), (3,0)$ and $(1,q), (1,2), (2,2), (2,q)$. See Figure 1 for an illustration. □

EXAMPLE 8.7. *Let $B_{i,j} = p_j \cup (P_i - P_j)$ and $m_{i,j} = n_i + n_j$ if $P_j \subseteq P_i - p_i$; otherwise let $B_{i,j} = P_i$ and $m_{i,j} = n_i$. Let $S_{\text{hole},2}$ consist of all sets $B_{i,j}$. Then it is impossible to cluster $S_{\text{hole},2}$ if besides a text the only pieces of additional information supplied are $|I|$ and $\sum_{(i,j) \in I} m_{i,j}$.*

Proof. The counterexample here is an adaptation of the counterexample from Proposition 8.6. The idea is just to connect the two parts by a bridge and to cutout only the lower connection.

Now take i, j such that the polygons p_i, p_j are given by $(0,0), (0,1), (1,1), (1,3), (4,3), (4,0)$ and $(2,1), (2,2), (3,2), (3,1)$. Note that $m_{i,j} = 10$. Let $\sigma \in B_{i,j}^*$ be a stabilizing sequence for $B_{i,j}$ and

$$q = \min(\{y : (\exists x)\,[(x,y) \in \text{range}(\sigma) \wedge y > 1]\}).$$

Then σ is also a stabilizing sequence for a polygon $P_h \subseteq B_{i,j}$ given by $(0,0), (0,1), (3,1), (3,2), (2,2), (2,q), (1,q), (1,3), (4,3), (4,0)$. The polygon P_h has also 10 vertices and is obtained by connecting the hole with the outside world. Figure 2 illustrates this counterexample. □

Alternatively, one might not restrict the dimension but require that the class under consideration be the union of convex hulls of finite sets which have a positive k-dimensional area. Then this area is a natural parameter for clustering with additional information. Note that in the 2-dimensional case the class $S_{\mathrm{hole},2}$ from Example 8.7 is a subclass of $S_{\mathrm{area},k}$ as defined below, and thus is clusterable using the area as additional information.

EXAMPLE 8.8. *Let $S_{area,k} = \{A_0, A_1, \ldots\}$ be the class of finite unions of members of $S_{conv,k}$ which are connected and have a positive k-dimensional area. Without loss of generality, the set $\{(i,x) : x \in A_i\}$ and the function mapping i to the area of A_i are recursive. Then there is a clusterer for $S_{area,k}$ which uses the area of the members of a cluster as additional information. But $S_{area,k}$ cannot be clustered without additional information.*

Proof. Assume that $A_I \subset A_J$, and let $x \in A_J - A_I$ be given. The point x has a positive distance r from A_I. But the area of $A_J \cap R$, where R is the k-dimensional cube of side-length $\frac{r}{10k}$ with center x, is positive. It follows that the area of A_J is at least the sum of the areas of A_I and $R \cap A_J$. So whenever two sets A_I, A_J have the same area, they are either equal or incomparable. Thus, one can use the following algorithm.

For any given clustering task I, M receives the additional information q and a prefix σ of a text for A_I. Then M outputs the first J such that $J \in \mathrm{disj}_{|\sigma|}(S_{\mathrm{area},k})$, $\mathrm{range}(\sigma) \subseteq A_J$, and A_J has the k-dimensional area q.

It is easy to see that M is recursive and total. Furthermore, M converges to the least J with $\mathrm{norm}(J) = \mathrm{norm}(I)$, A_J having the area q and $A_I \subseteq A_J$. It follows from the arguments above that $A_I = A_J$ and that M satisfies the required properties. □

9. Conclusion. Clustering is a process which makes important use of prior assumptions. Indeed, not every set of points in an underlying space is a potential cluster; for instance, geometric conditions play an important role in the definition of the class of admissible clusters. Whereas such conditions have been taken into account in previous studies, none of those has investigated the consequences of the more fundamental requirement that clustering be a computable process. This paper shows that recursion-theoretic and geometric conditions can both yield substantial insights on whether or not clustering is possible. It also explores the extent to which clustering depends on computational properties by characterizing the power of oracles for clustering. It is expected that further studies of the interaction between topological, recursion-theoretic, and geometrical properties will turn out to be fruitful.

FAULT-TOLERANT GATHERING ALGORITHMS FOR AUTONOMOUS MOBILE ROBOTS*

NOA AGMON† AND DAVID PELEG‡

Abstract. This paper studies fault-tolerant algorithms for the problem of gathering N autonomous mobile robots. A gathering algorithm, executed independently by each robot, must ensure that all robots are gathered at one point within finite time. In a failure-prone system, a gathering algorithm is required to successfully gather the nonfaulty robots, independently of the behavior of the faulty ones. Both crash and Byzantine faults are considered. It is first observed that most existing algorithms fail to operate correctly in a setting allowing crash failures. Subsequently, an algorithm tolerant against one crash-faulty robot in a system of three or more robots is presented.

It is then observed that all known algorithms fail to operate correctly in a system prone to Byzantine faults, even in the presence of a single fault. Moreover, it is shown that in an asynchronous environment it is impossible to perform a successful gathering in a 3-robot system, even if at most one of them might fail in a Byzantine manner. Thus, the problem is studied in a fully synchronous system. An algorithm is provided in this model for gathering $N \geq 3$ robots with at most a single faulty robot, and a more general gathering algorithm is given in an N-robot system with up to f faults, where $N \geq 3f + 1$.

1. Introduction.

Background. Systems of multiple autonomous mobile robots engaged in cooperative activities have been extensively studied throughout the past decade [10, 5, 16, 17, 7, 11, 3, 27]. This subject is of interest for a number of reasons. For one, it may be possible to use a multiple robot system in order to accomplish tasks that no single spatially limited robot can achieve. Another advantage of multiple robot systems has to do with the decreased cost due to the use of simpler and cheaper individual robots. Also, these systems have immediate applicability in a wide variety of tasks, such as military operations and space missions. Subsequently, studies of autonomous mobile robot systems can be found in different disciplines, from engineering to artificial intelligence (e.g., [18, 4, 15, 19]).

Our interest is in problems related to the *distributed control* of systems of autonomous mobile robots. Most studies on robot control problems resulted in the design of algorithms based on heuristics, with little emphasis on formal analysis of the correctness, termination, or complexity properties of the algorithms. During the last few years, various aspects of this problem have been studied from the point of view of distributed computing (cf. [5, 20, 25, 26, 23, 2]), where the focus is on trying to model an environment consisting of mobile robots, and studying the capabilities the robots must have in order to achieve their common goal. A number of computational

models were proposed in the literature, and some studies attempted to characterize the influence of the models on the ability of a group of robots to perform certain basic tasks under different constraints.

The primary motivation of the studies presented in [23, 26, 20, 21, 25] is to identify the minimal capabilities a collection of distributed robots must have in order to accomplish certain basic tasks and produce interesting interaction. Consequently, the models adopted in these studies assume the robots to be relatively weak and simple. In particular, these robots are generally assumed to be dimensionless (namely, treated as points that do not obstruct each other's visibility or movement), oblivious (or memoryless; namely, they do not remember their previous actions or the previous positions of the other robots), lacking a common coordinate system, orientation, or scale, using no explicit communication, and anonymous (some of these assumptions are modified in order to achieve goals that are otherwise unfeasible). They operate in simple "look-compute-move" cycles. Thus the robots base their movement decisions on viewing their surroundings and analyzing the configuration of robot locations. A robot is capable of locating all robots within its visibility range (which can be either limited or unlimited) and laying them in its private coordinate system, thereby calculating their position (distance and angles) with respect to one another and with respect to itself. Hence, from the "distributed computing" angle, such problems are particularly interesting since they give rise to a different type of communication model, based solely on "positional" or "geometric" information exchange.

A basic task that has received considerable attention is the *gathering* problem, defined as follows. Given an initial configuration of N autonomous mobile robots, all N robots should occupy a single point within a finite number of steps. The closely related *convergence* problem is defined similarly, except that the robots are required only to converge to a single point, rather than reach it. Namely, instead of demanding that the robots gather to one point within finite time, the convergence requirement is that for every $\epsilon > 0$, there is a time t_ϵ by which all robots are within distance of at most ϵ of each other.

Fault tolerance. As the common models of multiple robot systems assume cheap, simple, and relatively weak robots, the issue of resilience to failure becomes prominent, since in such systems one cannot possibly rely on assuming fail-proof hardware or software, especially when such robot systems are expected to operate in hazardous or harsh environments. At the same time, one of the main attractive features of multiple-robot systems is their potential for enhanced fault tolerance. It seems plausible that the inherent redundancy of such systems may be exploited in order to enable them to perform their tasks even in the presence of faults.

Following the common "f of N" classification often used in the area, a fault-tolerant algorithm for a given task is required to ensure that in a system consisting of N robots where it is assumed that at most f robots might fail in any execution, the task is achieved by all nonfaulty robots, regardless of the actions taken by the faulty ones. In the gathering task, for example, when faults are introduced into the system, the requirement applies only for the nonfaulty robots; i.e., if f' robots fail, then all the remaining $N - f'$ nonfaulty robots are required to occupy a single point within a finite time.

Perhaps surprisingly, however, this aspect of multiple robot systems has been explored to very little extent so far. In fact, almost all results we are aware of in the literature rely on the assumption that all robots function properly and follow their protocol without any deviation. One exception concerns *transient* failures. As

observed in [26, 23, 13], any algorithm that works correctly on oblivious robots is necessarily *self-stabilizing*; i.e., it guarantees that after any transient failure the system will return to a correct state and the goal will be achieved. Yet another line of study concerns a fault model where it is assumed that restricted sensor and control failures might occur, but if faults do occur in the system, then the identity of the faulty robots becomes known to all robots [23]. This may be an unrealistic assumption in many typical settings, and it clearly provides an easy means of overcoming the faults: Each nonfaulty robot may simply ignore the failed ones, effectively removing them from the group of robots, so the algorithm continues to function properly. However, in case unidentified faults occur in the system, it is no longer guaranteed that the algorithms of [23, 26] remain correct; i.e., the goal might not be achieved. The only concrete attempt we are aware of for dealing with crash faults is described in [29], where an algorithm is given for the *active robot selection problem* (ARSP) in the presence of initial crash faults. The ARSP creates a subgroup of nonfaulty robots from a group that also includes initially crashed robots and makes the robots in that subgroup recognize one another. This allows the nonfaulty robots in the subgroup to overcome the existence of faults in the system, and they can further execute any algorithm within the group.

Hence the design of fault-tolerant distributed control algorithms for multiple robot systems is still a largely unexplored direction, which the current paper investigates.

Related work. A number of basic mobile robot coordination problems were considered in the literature. One class of problems involves the formation of geometric patterns. The robots are required to arrange themselves in a given geometric form, such as a circle, a simple polygon or a line, within finite time (see, e.g., [23, 9, 12]). The task of *flocking*, requiring the robots to follow the movement of a predefined leader, was studied in [22]. The even distribution problem, requiring the robots to spread out uniformly over a specified region of a simple geometric shape, and the related task of partitioning the robots into groups were studied in [23].

The problem of gathering autonomous mobile robots, dealt with in this paper, requires the robots to gather to the same point within finite time (see, e.g., [24, 25, 14, 7, 6, 8]). This problem was studied extensively in two computational models. The first is the model of [23, 26], hereafter referred to as the *semisynchronous* ($\mathcal{SSYNC}$) model. The second is the closely related CORDA model [20, 21, 25], hereafter referred to as the *asynchronous* ($\mathcal{ASYNC}$) model.

The gathering problem was first discussed in [25, 26] in the $\mathcal{SSYNC}$ model. It was proved there that it is impossible to achieve gathering of *two* oblivious autonomous mobile robots that have no common sense of orientation under the $\mathcal{SSYNC}$ model. The algorithms presented therein for $N \geq 3$ robots rely on the assumption that a robot can identify a point p^* occupied by two or more robots (also known as *multiplicity point*). This assumption was later proved to be essential for achieving gathering in all asynchronous and semisynchronous models [22]. Another necessary requirement for solvability in the $\mathcal{SSYNC}$ and $\mathcal{ASYNC}$ models is that the input configuration does not include more than one multiplicity point of nonfaulty robots (it is easy to show that if two multiplicity points of nonfaulty robots are allowed, the situation is equivalent to the 2-robot system, and thus gathering is impossible). In fact, all known gathering algorithms for $N \geq 3$ rely on a strategy by which a single multiplicity point p^* is formed during the execution of the algorithm, and once this happens, all robots move to the point p^*. Under these assumptions, an algorithm is developed in [26] for gathering $N \geq 3$ robots in the $\mathcal{SSYNC}$ model. In the $\mathcal{ASYNC}$ model, an algorithm

for gathering $N = 3, 4$ robots is brought in [22, 7], and an algorithm for gathering $N \geq 5$ robots is described in [6].

The gathering problem was also studied (in both the $\mathcal{SSYNC}$ and $\mathcal{ASYNC}$ models) in a system where the robots have limited visibility. The visibility conditions are modelled by means of a *visibility graph*, representing the (symmetric) visibility relation of the robots with respect to one another; i.e., an edge exists between R_i and R_j if and only if R_i and R_j are visible to each other. It was shown that the problem is unsolvable in the case that the visibility graph is not connected [14]. In [1] a convergence algorithm was provided for any N in limited visibility systems. An algorithm that achieves gathering in the $\mathcal{ASYNC}$ model is described in [14], under the assumption that all robots share a compass (i.e., agree on a direction in the plane).

Our results. This paper presents a systematic study of failure-prone robot systems through examining the gathering problem under the crash and Byzantine fault models. An (N, f)-*fault system* is a system consisting of N robots, of which at most f might fail at any execution. An (N, f)-*crash system* (resp., (N, f)-*Byzantine system*) is an (N, f)-fault system where the faults considered are according to the crash or Byzantine model. A fault-tolerant algorithm for a given task in an (N, f)-fault system is required to ensure that so long as at most f robots have failed, the task is achieved by all nonfaulty robots, regardless of the actions taken by the faulty ones.

Under the crash fault model, we show that the gathering problem is solvable in current computational models such as the $\mathcal{SSYNC}$ model, though most existing algorithms fail to deal correctly with such faults and, in particular, there is currently no algorithm for $N \geq 4$ that solves the gathering problem in the presence of one faulty robot under the crash fault model. We propose an algorithm that solves the gathering problem in an $(N, 1)$-crash system, for any $N \geq 3$, under the $\mathcal{SSYNC}$ model.

We then consider (N, f)-Byzantine systems for $N \geq 3$. We first observe that all existing algorithms fail to deal correctly with this situation. Moreover, we show that it is impossible to perform a successful gathering in $(3, 1)$-Byzantine systems under the $\mathcal{SSYNC}$ model. We then introduce the *fully synchronous* ($\mathcal{FSYNC}$) model, which is similar to the synchronous model mentioned in [26], and present an algorithm solving the gathering problem under this model in (N, f)-Byzantine systems for every[1] $N \geq 3f + 1$.

2. The model. We follow the common computational model of distributed robot systems. In particular, we make the following assumptions: The visibility range of the robots is assumed to be unlimited. The robots are treated as points (dimensionless objects) which do not obstruct each other's visibility or movement. The robots are anonymous and cannot communicate with each other. For the sake of analysis, denote the robots in the system by $R_1, \ldots, R_N$. Each robot R_i has its private coordinate system, consisting of the position of the origin, direction of the positive x-axis, and the size of one unit distance. It is assumed that the direction of the positive y-axis is 90° counterclockwise of the direction of the positive x-axis. The coordinate systems of the various robots might all be different and not share the same direction or scale.

Following most previous papers on the gathering problem in the literature [24, 25, 14, 7, 22], the model adopted throughout this paper is the *oblivious* model, where it is assumed that the robots cannot remember their previous states, and thus the

[1] A peculiarity of our algorithms is that $N = 3$ robots can tolerate $f = 1$ failures, but $N > 3$ robot systems require $N \geq 3f + 1$ rather than $N \geq 3f$.

decisions they make in each step are based only on the current configuration. The main motivation for developing algorithms for the oblivious model is twofold. First, solutions developed on the basis of assuming nonobliviousness do not necessarily work in a dynamic environment where the robots are activated in different cycles or might be added/removed from the system dynamically. Second, as mentioned earlier, any algorithm that works correctly for oblivious robots is inherently self-stabilizing, i.e., it withstands transient errors. More generally, it is advantageous to develop algorithms for the weakest robot types possible, as an algorithm that works correctly for weak robots will clearly work correctly in a system of stronger robot types. In contrast, our lower bounds serve mainly to draw the borderlines where the various models become too weak to allow solutions.

Robot operation cycle. Each robot R_i in the system is assumed to operate individually in simple cycles. Every cycle consists of three steps, Look, Compute, and Move. In the $\mathcal{FSYNC}$ and $\mathcal{SSYNC}$ models the length of this cycle is uniform for all robots.

- *Look*: Identify the locations of all robots in R_i's private coordinate system; the result of this step is a multiset of points $P = \{p_1, \ldots, p_N\}$ defining the current *configuration*. As the robots are indistinguishable, each robot R_i knows its own location p_i but does not know the identity of the robots at each of the other points.
- *Compute*: Execute the given algorithm, resulting in a goal point p_G.
- *Move*: Move towards the point p_G. The robot might stop before reaching its goal point p_G but is promised to traverse a distance of at least S (unless it has reached the goal).

Note that the Look and Move steps are carried out identically in every cycle, independently of the algorithm used. The differences between different algorithms occur in the Compute step. Moreover, the procedure carried out in the Compute step is identical for all robots. If the robots are oblivious, then the algorithm cannot rely on information from previous cycles; thus the procedure can be fully specified by describing a single Compute step, and its only input is the current configuration $P = \{p_1, \ldots, p_N\}$, giving the robot locations. Throughout, we may denote the location of R_i in the configuration P by $p(R_i)$. Also, whenever no confusion may arise, we identify $p(R_i)$ as the point p_i.

Three synchronization models. As mentioned earlier, our computational model for studying and analyzing problems of coordinating and controlling a set of autonomous mobile robots follows two well-studied models: the $\mathcal{SSYNC}$ model and the $\mathcal{ASYNC}$ model. The semisynchronous ($\mathcal{SSYNC}$) model is partially synchronous, in the sense that all robots operate according to the same clock cycles, but not all robots are necessarily active in all cycles. The activation of the different robots can be thought of as managed by a hypothetical "scheduler," whose only "fairness" obligation is that each robot must be activated and given a chance to operate infinitely often in any infinite execution. The fully asynchronous ($\mathcal{ASYNC}$) model differs from the $\mathcal{SSYNC}$ model in that each robot acts independently in a cycle composed of *four* steps: Wait, Look, Compute, Move. The length of this cycle is finite, but not bounded. Consequently, there is no bound on the length of the walk in a single cycle, and different cycles of the same robot may vary in length. In contrast, in the $\mathcal{SSYNC}$ model a bound exists on the cycle length due to the common clock, and as a result the robot will not necessarily reach the target point p in the current cycle but stop somewhere on its trajectory to p.

In this paper we also consider the extreme *fully synchronous* ($\mathcal{FSYNC}$) model.

This model is similar to the $\mathcal{SSYNC}$ model, where the robots operate according to the same clock cycles, except that here all robots are active on all cycles. In this model we assume discrete time $0, 1, \ldots$, and let $p_i(t)$ denote the position of R_i at time t, where $p_i(0)$ is the initial position of R_i. In each cycle t, the set of positions is a multiset, as two robots are not prohibited from occupying the same position simultaneously. In each cycle t, each robot R_i is capable of moving over distance at least $S > 0$ in one step (S is unknown to the robots). Therefore it is guaranteed that if $\text{dist}(p_G^i, p_i(t)) \leq S$, where p_G^i is R_i's goal point in the current cycle, then R_i will reach its goal in the current cycle. Otherwise, it will traverse a distance of at least S towards p_G^i.

Failure models. The fault models discussed throughout the paper are the *crash* fault model and the *Byzantine* fault model. In the *Byzantine* fault model, it is assumed that a faulty robot might behave in arbitrary and unforeseeable ways. For the sake of analysis, it is convenient to model the behavior of the system by means of an *adversary* which has the ability to control the behavior of the faulty robots, as well as the "undetermined" features in the behavior of the nonfaulty processors (e.g., the distance to which they move). Specifically, in each cycle the adversary has the following roles. For each faulty robot, it determines its course of action in that cycle, which can be arbitrary. For each nonfaulty robot, it determines the distance to which the robot will move in this cycle (for a robot R_i located at p_i and headed for the goal point p_G, if $\text{dist}(p_i, p_G) \leq S$, then the robot must be allowed to reach p_G; else, the adversary may stop R_i at any point on the line segment $\overline{p_i p_G}$ that is at least distance S away from p_i).

In the *crash* fault model, the behavior of the system is similar to the one described in the Byzantine fault model, except that for each faulty robot the adversary is only allowed to stop its movement. This may be done at any point in time during the cycle, i.e., either during the movement toward the goal point or before it has started. Once the adversary has crashed the faulty robot, that robot will remain stationary indefinitely.

3. Gathering under the crash fault model.

3.1. Inadequacy of known algorithms. Most gathering algorithms proposed in the literature fail to withstand even a single crash failure because they depend, in certain configurations, on the movement of a single robot. More formally, let $\mathcal{A}$ be a gathering algorithm for an N-robot system. In every configuration C, the algorithm instructs some robots to move and some to remain stationary. Denote the number of robots $\mathcal{A}$ instructs to move in configuration C by $M(C, \mathcal{A})$, and let

$$\check{M}(N, \mathcal{A}) \;=\; \min\{M(C, \mathcal{A}) \mid C \text{ is a configuration in an } N\text{-robot system}\}.$$

LEMMA 3.1. *In an (N, f)-crash system, an algorithm $\mathcal{A}$ with $\check{M}(N, \mathcal{A}) \leq f$ will fail in achieving gathering or convergence.*

Proof. Consider an (N, f)-crash system and a gathering algorithm $\mathcal{A}$ with $\check{M}(N, \mathcal{A}) \leq f$, and let C' be the configuration of the system realizing $\check{M}$, i.e., such that $M(C', \mathcal{A}) \leq f$. Starting in that configuration, the adversary can fail the (f or fewer) robots instructed by the algorithm to move. This will cause the next configuration to be identical to C' again, and the $N - f$ nonfaulty robots will remain in the same configuration C' indefinitely. □

In fact, every gathering algorithm $\mathcal{A}$ we are aware of in the $\mathcal{SSYNC}$ and $\mathcal{ASYNC}$ models [24, 25, 26, 7] has $\check{M}(N, \mathcal{A}) = 1$ for $N \geq 4$, and, consequently, by Lemma 3.1,

these algorithms fail to achieve gathering even in the presence of one crash faulty robot. The algorithm described in [6] for gathering $N \geq 5$ robots in the $\mathcal{ASYNC}$ model can also fail in the presence of one crash faulty robot if that robot lies between some other robot and its goal point. On the positive side, it turns out that the gathering algorithm given in [7] for $N = 3$ under the $\mathcal{ASYNC}$ model can be shown to operate correctly also in the presence of one crashed robot (we give a slightly simpler algorithm for this case in the $\mathcal{SSYNC}$ model below), and the algorithm given therein for $N = 4$ can be transformed into an algorithm for $(4, 1)$-crash systems with some minor changes.

An additional difficulty in handling a robot system with crash faults is caused by the assumption, made by all current algorithms, that only a single multiplicity point is created throughout the execution of the algorithm. In the presence of faults, the fact that the adversary has the ability to stop the nonfaulty robots after traversing a minimal distance S and the ability to crash the faulty robots at any step during the execution makes it easy for the adversary to create a second multiplicity point once the first is created, whenever the trajectories of two or more robots moving towards their goals intersect. In particular, it is easy to see that in a collinear configuration with $N > 3$ robots and given an algorithm that instructs all robots to move towards a point on the line, the adversary can create two multiplicity points on the line, simply by crashing some robot R at a point p between the multiplicity point and another robot R', thus forcing R' to pass through p, and stopping it there.

3.2. An algorithm for a $(3, 1)$-crash system. Consider the following Procedure $\mathsf{3\text{-}Gather}_{\mathrm{crash}}$ for gathering in a $(3, 1)$-crash system in the $\mathcal{SSYNC}$ model. As discussed earlier, we need only present the procedure used for the Compute step. The input to this procedure is the configuration $P = \{p_1, p_2, p_3\}$. The procedure classifies the configuration according to its state, and acts in each case as follows.

Procedure $\mathsf{3\text{-}Gather}_{\mathrm{crash}}(P)$

1. **State [MULT]:** P contains a multiplicity point p^*:
   Set $p_G \leftarrow p^*$.
2. **State [Collinear]:** p_1, p_2, p_3 are collinear (say, with p_2 in the middle):
   Set $p_G \leftarrow p_2$.
3. **State [Obtuse]:** $\exists i \in \{1, 2, 3\}$ such that $\angle p_j p_i p_k \geq \pi/2$:
   Set $p_G \leftarrow p_i$.
4. **State [Acute]:** p_1, p_2, p_3 form an acute triangle:
   Set p_G to be the intersection point of the three angle bisectors.

Note that state [Collinear] is redundant, since it is covered by state [Obtuse]. It is included merely for convenience of presentation.

Analysis. In analyzing our algorithms, we use the following notation regarding points and lines in the Euclidean plane. Denote the Euclidean distance between two points p and q by $\mathrm{dist}(p, q)$. Also, denote the Euclidean distance between two current locations p_i and p_j of the two robots R_i and R_j, respectively, by $\mathrm{dist}(R_i, R_j)$. Denote the line segment between the points p and q by $\overline{pq}$. We use the following well-known fact.

LEMMA 3.2. *In a triangle $\triangle p_1 p_2 p_3$, the intersection point p_M of the three angle bisectors satisfies $\angle p_i p_M p_j \geq \pi/2$ for every $1 \leq i < j \leq 3$.*

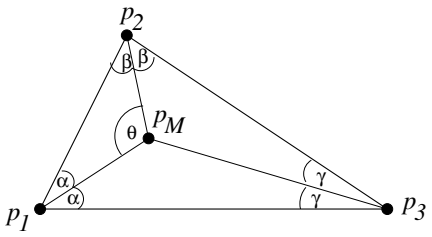

FIG. 1. *Proof of Lemma* 3.2.

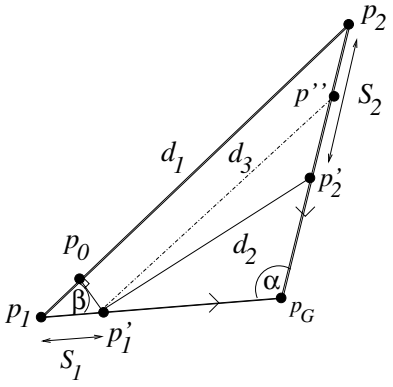

FIG. 2. *Proof of Lemma* 3.3.

Proof. Let $\alpha = \angle p_M p_1 p_2$, $\beta = \angle p_M p_2 p_3$, $\gamma = \angle p_M p_3 p_1$, and $\theta = \angle p_1 p_M p_2$ (see Figure 1). It follows that $2\alpha + 2\beta + 2\gamma = \pi$; hence $\alpha + \beta = \pi/2 - \gamma < \pi/2$, and since in the triangle $\triangle p_M p_1 p_2$, $\theta + \alpha + \beta = \pi$, it follows that $\theta > \pi/2$. A similar argument applies in $\triangle p_M p_2 p_3$ and $\triangle p_M p_1 p_3$. ∎

LEMMA 3.3. *If two robots R_1 and R_2, initially located at the points p_1 and p_2, respectively, move towards a common meeting point p_G and $\alpha = \angle p_1 p_G p_2 \geq \pi/2$, then the distance between them decreases by at least* $0.7S$.

Proof. For $i = 1, 2$, let S_i denote the distance traversed by the robot R_i, and let p_i' denote the new location of R_i. Consider the triangle $\triangle p_1 p_2 p_G$, and let $\beta = \angle p_2 p_1 p_G$ (see Figure 2). Denote the distance between the robot locations before and after the movement by $d_1 = \text{dist}(p_1, p_2)$ and $d_2 = \text{dist}(p_1', p_2')$, respectively. Without loss of generality, suppose that p_1' is closer than p_2' to the line $\overline{p_1 p_2}$. Draw a line parallel to d_1 through p_1', denote its intersection with $\overline{p_2 p_G}$ by p'', and let $d_3 = \text{dist}(p_1', p'')$.

We need to prove that $d_1 - d_2 > 0.7S$. Since it is clear that $d_2 \leq d_3$, it suffices to show that $\Delta = d_1 - d_3 > 0.7S$. Drop a perpendicular line from p_1' to $\overline{p_1 p_2}$, and let p_0 be its intersection point with the line $\overline{p_1 p_2}$. Let $\Delta' = \text{dist}(p_0, p_1)$. It is also clear that $\Delta' \leq \Delta$; hence it remains to prove that $\Delta' \geq 0.7S$. Since $\alpha \geq \pi/2$, the remaining two angles in $\triangle p_1 p_2 p_G$ sum to at most $\pi/2$. Without loss of generality, let $\beta \leq \pi/4$. Also, according to our model assumption, each robot moves a distance of at least S in each cycle, i.e., $S_i \geq S$ for $i = 1, 2$. Therefore, by the sine theorem on the triangle $\triangle p_1 p_1' p_0$ (see Figure 3), $S \leq S_1 = \frac{S_1}{\sin(\pi/2)} = \frac{\Delta'}{\sin(\pi/2 - \beta)}$, and hence $\Delta' \geq S \cdot \cos(\beta) \geq S \cdot \cos(\pi/4) \geq 0.7S$, completing the proof. ∎

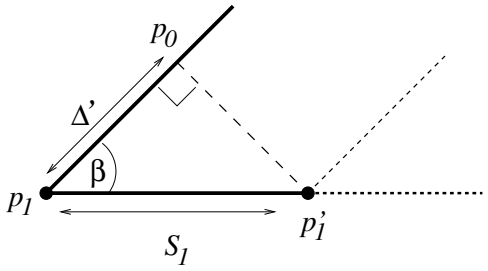

FIG. 3. *Triangle enlargement from proof of Lemma* 3.3.

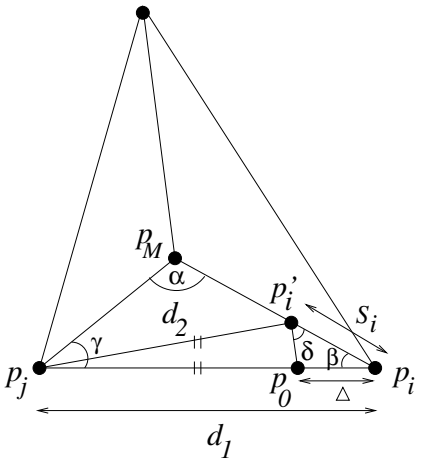

FIG. 4. *Proof of Lemma* 3.4.

LEMMA 3.4. *There exists a constant $c > 0$ such that, given three robots R_1, R_2, and R_3 located at points p_1, p_2, and p_3, respectively, where $\triangle p_1p_2p_3$ is an acute triangle, if one or more of the robots traverses a distance of at least S towards the intersection point p_M of the three angle bisectors, then the circumference of the triangle decreases by at least cS.*

Proof. By Lemma 3.2, $p_ip_Mp_j > \pi/2$ for every $1 \leq i, j \leq 3$. Thus, by Lemma 3.3, if two of the three robots move towards p_M, then the distance between them decreases by at least $0.7S$, and as the other distances do not increase, the circumference of the triangle decreases by at least $0.7S$. It remains to show that even if only one robot moves towards p_M it decreases the distance between itself and its neighbors by at least $c'S$ for some constant c'; thus altogether the circumference of the triangle decreases by at least $2c'S = cS$.

Consider the triangle $\triangle p_ip_Mp_j$, $1 \leq i, j \leq 3$. Let $\alpha = \angle p_ip_Mp_j$, $\beta = \angle p_Mp_ip_j$, and $\gamma = \angle p_Mp_jp_i$ (see Figure 4). Since $\triangle p_1p_2p_3$ is acute, it follows that $2\beta < \pi/2$; thus $\beta < \pi/4$ and, similarly, $\gamma < \pi/4$. Assume, without loss of generality, that robot R_i traversed a distance $S_i \geq S$ towards p_M and lies on a point p'_i. Let $d_1 = \text{dist}(p_i, p_j)$, $d_2 = \text{dist}(p'_i, p_j)$, and $\Delta = d_1 - d_2$. By the sine theorem on the triangles $\triangle p_ip_jp_M$ and $\triangle p'_ip_jp_M$ it follows that $\frac{d_1}{d_2} = \frac{\sin(\angle p_jp'_ip_M)}{\sin\beta}$, and since $\angle p_jp'_ip_M > \beta$, it follows that $d_1 > d_2$. Let p_0 be the point on the segment $\overline{p_ip_j}$ that creates an isosceles triangle

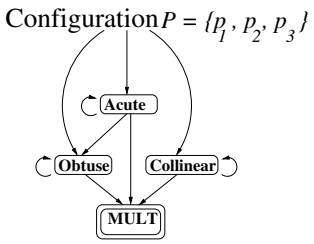

FIG. 5. *Statechart for Procedure* 3-Gather$_{\text{crash}}$.

$\triangle p_0 p_j p_i'$; i.e., $\text{dist}(p_j, p_0) = d_2$. Note that $\text{dist}(p_0, p_i) = \Delta$. Let $\delta = \angle p_i p_i' p_0$. Since

$$3\pi/8 < \frac{\pi - \gamma}{2} < \frac{\pi - \angle p_i p_j p_i'}{2} = \angle p_j p_0 p_i' = \angle p_j p_i' p_0 < \pi/2,$$

it follows that $3\pi/8 < \beta + \delta < \pi/2$, and as $\beta < \pi/4$, we have $\pi/8 < \delta < \pi/2$. By the sine theorem on the triangle $\triangle p_i p_i' p_0$ it follows that

$$\Delta = S_i \frac{\sin\delta}{\sin(\delta+\beta)} \geq S \frac{\sin\delta}{\sin(\delta+\beta)} \geq S \frac{\sin(\pi/8)}{\sin(\pi/2)} > 0.3S.$$

Therefore by choosing $c' = 0.3$, the lemma holds for $c = 0.6$. ∎

THEOREM 3.5. *Algorithm* 3-Gather$_{\text{crash}}$ *solves the gathering problem in a* $(3,1)$*-crash system under the* $\mathcal{SSYNC}$ *model.*

Proof. Consider an initial configuration $P = \{p_1, p_2, p_3\}$. It suffices to show that the algorithm causes the system to reach state [MULT]; i.e., either it gathers all robots together in one point or it causes the creation of one multiplicity point, since if the remaining robot is nonfaulty, then it will join the multiplicity point in finite time by step 1 of the algorithm, and if it is faulty, then gathering has been achieved. Consider the flow of states the system could be in. It suffices to show that the states used for classifying the configurations in Procedure 3-Gather$_{\text{crash}}$ form a finite connected directed acyclic graph (DAG) (possibly with self-loops), where all paths lead to a final state [MULT] in which a multiplicity point exists (see Figure 5), such that starting with a configuration in any of the states, we reach the final state within a finite number of cycles.

If in the initial configuration p_1, p_2, p_3 are collinear, then the configuration will remain collinear, and within finite time, either both extreme robots will arrive at the location of the middle robot (if both are nonfaulty) or only one of them will arrive (if one of the extreme robots is faulty); thus in any case a multiplicity point will be created in the location of the middle robot, leading to state [MULT].

Next, suppose that the initial configuration is not collinear but obtuse; i.e., there exists a point p_i such that $\angle p_j p_i p_k \geq \pi/2$. Then the configuration remains obtuse until one robot reaches R_i. Since at least one of the robots instructed to move towards R_i is nonfaulty, it will reach its goal point within finite time, thus reaching state [MULT].

Finally, if p_1, p_2, p_3 create an acute triangle in cycle t, then one of the following two cases holds. In the first case, at least one robot was active in the current cycle and traversed a distance of at least S towards p_M. There are two subcases to be examined. If the system remains in state [Acute], then by Lemma 3.4 the circumference of $\triangle p_1 p_2 p_3$ decreases by at least $0.6S$. Therefore, if the robots constantly remain in state [Acute], then at least two robots will eventually meet in p_M, leading to state [MULT]. The other subcase is that this movement causes $\triangle p_1 p_2 p_3$ to become

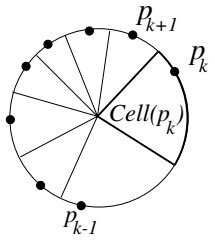

FIG. 6. *Example of a circle division according to the Voronoi cells.*

obtuse. In this case, the system changes to state [Obtuse]. In the second case, all active robots in this cycle traversed a distance smaller than S towards p_M; thus they are now located at p_M. Again there are two subcases. If two or more robots were active, then they meet at p_M, leading to state [MULT]. Otherwise, only one robot, say R_i, is located in p_M. Then by Lemma 3.2, $\angle p_j p_i p_k \geq \pi/2$; thus $\triangle p_1 p_2 p_3$ becomes obtuse, and the system changes to state [Obtuse], leading to gathering as discussed above. □

3.3. An algorithm for an $(N, 1)$-crash system, $N \geq 3$. Let us start with some terminology. A *legal* configuration in the $(N, 1)$-crash system is a set P of robot locations that has at most one multiplicity point. Denote the *smallest enclosing circle* of the set P by $\mathcal{SEC}(P)$ and the points on its circumference by $\mathcal{C}_{cir}(P)$ and let $\mathcal{C}_{\rm int}(P) = P \setminus \mathcal{C}_{\rm cir}(P)$. For a circle C and the set of points $P = \{p_1, \ldots, p_l\}$ on its circumference, denote the partition of the circle C into Voronoi cells according to the points in P by $\mathrm{Vor}(C, P)$, and denote by $\mathrm{Cell}(p_k)$ the cell defined by the point $p_k \in P$ (see Figure 6). Two points q and q' in C are said to share the cell $\mathrm{Cell}(p_k)$ if they both lie inside the cell or on its boundary.

Consider the following Algorithm $\mathsf{Gather}_{\rm crash}$ for gathering all nonfaulty robots in an $(N, 1)$-crash system under the $\mathcal{SSYNC}$ model. The input to this algorithm is a legal configuration $P = \{p_1, \ldots, p_N\}$. The algorithm classifies the configuration according to its state and acts in each case as follows. If there are no multiplicity points in the configuration, then each robot performs Procedure $\mathsf{Create\_Mult}$ in order to reach a configuration with a multiplicity point. Figure 7 illustrates the three possible cases of substate [IN2] in this procedure. Once a multiplicity point p^* is detected, each robot performs Procedure $\mathsf{GoTo\_Mult}$ in order to achieve gathering of all nonfaulty robots in p^*, while avoiding creation of additional multiplicity points.

Algorithm $\mathsf{Gather}_{\rm crash}(P)$

1. **State [Singletons]:** The configuration P does not contain a multiplicity point: Invoke Procedure $\mathsf{Create\_Mult}(P)$.
2. **State [MULT]:** The configuration P contains a single multiplicity point p^*: Invoke Procedure $\mathsf{GoTo\_Mult}(P)$.

The input to Procedure $\mathsf{GoTo\_Mult}$ is the configuration $P = \{p_1, \ldots, p_N\}$. We say that robot R_i has a *"free corridor"* to the point p if no other robot is currently located on the straight line segment $\overline{p_i p}$. Note that as robots are viewed as dimensionless objects, the availability of a free corridor is not necessarily a prerequisite for allowing a robot to get home free. However, allowing a robot to follow a trajectory through the location of another robot makes the algorithm prone to the creation of more

Invoke Procedure 3-Gather$_{\text{crash}}$ on p_1, p_2, p_3.
State [N4+]: $N \geq 4$:

1. **Substate [IN0]:** $|\mathcal{C}_{\text{int}}(P)| = 0$:
   Set p_G to be the center of $\mathcal{SEC}(P)$.
2. **Substate [IN1]:** $|\mathcal{C}_{\text{int}}(P)| = 1$ with p_j as the single point in $\mathcal{C}_{\text{int}}(P)$:
   Set $p_G \leftarrow p_j$.
3. **Substate [IN2]:** $|\mathcal{C}_{\text{int}}(P)| = 2$ with p_i and p_j as the two points in $\mathcal{C}_{\text{int}}(P)$:
   Each robot R_k in $\mathcal{C}_{\text{cir}}(P)$ sets $p_G(R_k) \leftarrow p(R_k)$.
   The two robots R_i and R_j in $\mathcal{C}_{\text{int}}(P)$ do:
   (a) Compute the Voronoi partition $\text{Vor}(\mathcal{SEC}(P), \mathcal{C}_{cir}(P))$.
   (b) **Substate [IN2(a)]:** p_i and p_j do not share cells:
   R_i and R_j move towards the center of $\mathcal{SEC}(P)$.
   (c) **Substate [IN2(b)]:** p_i and p_j share a single cell, Cell(R_k):
   R_i and R_j move towards R_k.
   (d) **Substate [IN2(c)]:** p_i and p_j share two cells; i.e., both robots lie on the radius forming the boundary between two adjacent cells Cell(R_k) and Cell(R_{k+1}):
   The robot closer to the circle, say R_i, chooses the first of R_k, R_{k+1} in its clockwise direction, say R_k, and sets $p_G(R_i) \leftarrow p(R_k)$.
   The other robot, R_j, sets $p_G(R_j) \leftarrow p(R_i)$.
4. **Substate [IN3]:** $|\mathcal{C}_{\text{int}}(P)| \geq 3$:
   Each robot R_k in $\mathcal{C}_{\text{cir}}(P)$ sets $p_G(R_k) \leftarrow p(R_k)$.
   Each robot R_k in $\mathcal{C}_{\text{int}}(P)$ recursively invokes Procedure Create_Mult($\mathcal{C}_{\text{int}}(P)$).

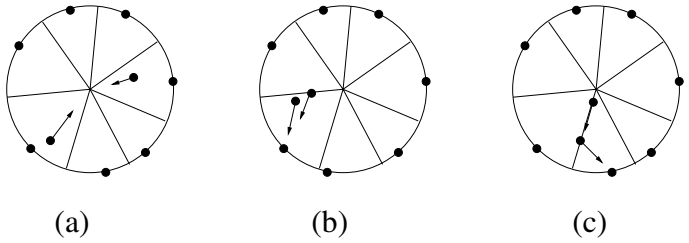

FIG. 7. *Illustration of the three substates of substate* [IN2] *in Procedure* Create_Mult.

than one multiplicity point. Therefore Procedure GoTo_Mult attempts to avoid such trajectories.

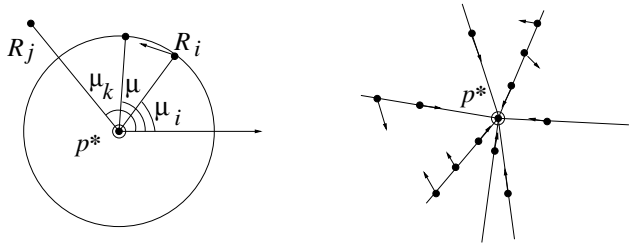
Analysis.

LEMMA 3.6. *If the initial configuration is in state* [Singletons]*, i.e., it contains no multiplicity points, then Procedure* Create_Mult *leads, within finite time, to a configuration in state* [MULT]*, i.e., including a single multiplicity point.*

Proof. We prove the lemma by looking at the flow of states the system could be in. It suffices to show that the states used for classifying the configurations in Procedure Create_Mult form a finite connected DAG (possibly with self-loops), where all paths lead to a final state [MULT] in which a multiplicity point exists (see Figure 9), such that starting with a configuration in any of the states, we reach the final state within a finite number of cycles.

Procedure GoTo_Mult(P) (for robot R_i)
/* The configuration contains a multiplicity point p^* */

1. **State [Free]:** R_i has a free corridor to p^*:
   Set $p_G \leftarrow p^*$.
2. **State [Blocked]:** There exist one or more robots on R_i's trajectory towards p^*:
   a. Translate your coordinate system to be centered at p^*.
   b. Compute for each robot R_j the angle μ_j of $\overrightarrow{p^*p_j}$ counterclockwise from the x-axis.
   c. Find the robot R_k with smallest angle $\mu_k > \mu_i$.
   Let $\mu = (\mu_k + 2\mu_i)/3$, and $d = \text{dist}(R_i, R_k)$ (see Figure 8(a)).
   d. Let p'_i be the point at distance d and angle μ from p^*.
   e. Set $p_G \leftarrow p'_i$.



(a) (b)

FIG. 8. *Illustration of state* [Blocked] *in Procedure* GoTo_Mult.

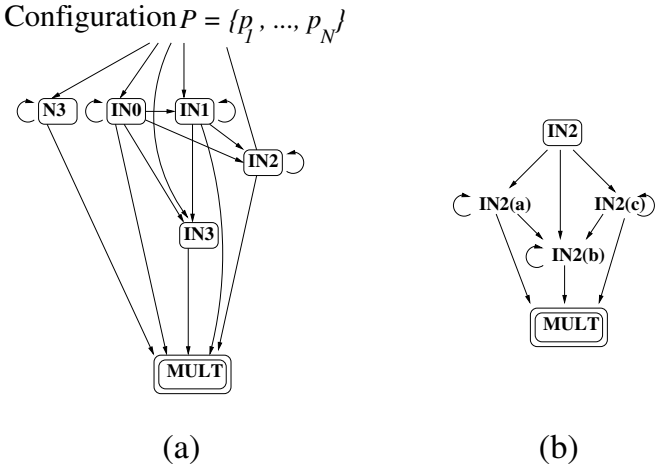


FIG. 9. *Statechart for Procedure* Create_Mult. (a) *The general statechart.* (b) *The substates of state* [IN2].

State [N3]: If $N = 3$, then by Theorem 3.5, Procedure 3-Gather$_{\text{crash}}$ achieves gathering, and in particular one multiplicity point is created.

State [IN0]: If $N \geq 4$ and $|\mathcal{C}_{\text{int}}(P)| = 0$, then if not all robots move together

to the same distance, the system changes either to state [MULT] or to a state where $|\mathcal{C}_{\text{int}}(P)| \geq 1$, i.e., [IN1], [IN2], or [IN3]. If robots on the circumference move to a new configuration P' in which they are all again on $\mathcal{SEC}(P')$, then the system remains in the same state, [IN0], but the radius of $\mathcal{SEC}(P)$ is reduced by at least S, since each of the robots moved by at least S towards the center of $\mathcal{SEC}(P)$. Therefore the self-loop at state [IN0] can be repeated only finitely many times, ending in a configuration where either $|\mathcal{C}_{\text{int}}(P)| \geq 1$, two robots meet and create a multiplicity point, or all robots meet. Note also that if a multiplicity point is created after this step, then it is necessarily unique, as it could be created only by two or more robots from $\mathcal{C}_{\text{cir}}(P)$ meeting at the center point of $\mathcal{SEC}(P)$, which is the only possible intersection point for the trajectories of the robots.

State [IN1]: If $N \geq 4$ and $|\mathcal{C}_{\text{int}}(P)| = 1$, then a similar argument holds; thus also here the self-loop can be taken only finitely many times or the system's state changes to a state where $|\mathcal{C}_{\text{int}}(P)| \geq 2$, namely, [IN2] or [IN3], or a multiplicity point is created, leading to state [MULT]. If a multiplicity point is created as a result of this step, then it is unique, as it could be created only by one or more robots from $\mathcal{C}_{\text{cir}}(P)$ and the inner robot R_i, since the trajectories of any two robots moving towards R_i intersect only at the location of R_i.

State [IN2]: If $N \geq 4$ and $|\mathcal{C}_{\text{int}}(P)| = 2$, then the only outcome of this state could be a single multiplicity point, as can be verified by inspecting the possible substates. In this state, only two robots are active and move towards one goal point; thus the multiplicity point is unique.

State [IN2(a)]: If p_i and p_j do not share a cell, then both robots are instructed to go to the center of $\mathcal{SEC}(P)$. Eventually, either both robots will meet there, leading to state [MULT], or only one will arrive at the center; thus the two robots now share a cell, leading to state [IN2(b)].

State [IN2(b)]: If p_i and p_j share a single cell, $\text{Cell}(R_k)$, then either they meet on their way to R_k or one or both meet R_k at location p_k, thus leading to state [MULT].

State [IN2(c)]: If p_i and p_j share two cells, then the following possibilities may occur. Either the robot closer to $\mathcal{C}_{\text{cir}}(P)$, say R_i, meets with its target, say R_k, or R_j will meet R_i on its way, thus creating a multiplicity point, leading to state [MULT], or R_j enters the interior of the sector $\text{Cell}(R_k)$, thus leading to state [IN2(b)].

State [IN3]: Finally, if $N \geq 4$ and $|\mathcal{C}_{\text{int}}(P)| \geq 3$, then the procedure is applied recursively on the inner robots, while the outer robots remain stationary. Thus, as seen above, a single multiplicity point is created on the lowest level of the recursion. □

LEMMA 3.7. *In an $(N, 1)$-crash system, if the initial configuration is in state* [MULT]*, i.e., it contains a single multiplicity point p^*, then Procedure* GoTo_Mult *guarantees that within finite time all nonfaulty robots gather at p^* while avoiding the creation of additional multiplicity points.*

Proof. Every robot with a free corridor towards p^* is instructed to go towards p^*; thus all nonfaulty robots will arrive at p^* within a finite time. If a robot R_i detects another robot on its trajectory towards p^*, it looks for a free corridor by moving orthogonally to the multiplicity point, while making sure that it does not obstruct the free corridor of any other robot. This is ensured by moving only so as to change its angle with respect to the x-axis and p^* by a third of the angle to the closest-angle neighboring robot R_j (see Figure 8(a)). Note that it is possible that R_j will also enter the same sector, due to the lack of consistent coordinate system (and in particular,

the absence of common orientation, which may cause the R_jth clockwise sector to be the same as the R_ith clockwise sector). However, even if R_j enters that clear sector, it will be in the "far" third of the sector.

It is also possible for $k \geq 3$ robots $R_{i_1}, \ldots, R_{i_k}$ to share a common corridor to p^* (see Figure 8(b)). In this case the one closest to p^*, say R_{i_1}, will move towards p^*, and the others might take the same new trajectory to p^*. However, on this new trajectory, only $k-1$ robots collide, so the closest to p^* has a free corridor, and only $k-2$ robots must shift orthogonally again. Hence if a robot has more than one robot on its trajectory towards p^*, then it will remain in state [Blocked] during finitely many cycles until it has a free corridor towards p^*; thus it will eventually switch to state [Free] and arrive at p^*. □

THEOREM 3.8. *Algorithm* $\mathsf{Gather}_{\mathrm{crash}}$ *solves the gathering problem in an* $(N, 1)$*-crash system under the* $\mathcal{SSYNC}$ *model for any* $N \geq 3$.

Proof. Since the initial configuration is legal, by Lemma 3.6 it is guaranteed that Procedure Create_Mult will lead to a single multiplicity point. By Lemma 3.7, applying Procedure GoTo_Mult on a system with one multiplicity point leads to the gathering of all nonfaulty robots at that point. □

4. Impossibility of gathering under Byzantine faults.

4.1. Impossibility results in the $\mathcal{SSYNC}$ and $\mathcal{ASYNC}$ models. In [21] it is shown that the class of problems solvable in $\mathcal{ASYNC}$ is contained in the class of problems solvable in the $\mathcal{SSYNC}$ model. It follows that proving impossibility of gathering in an $(N, 1)$-Byzantine system in $\mathcal{SSYNC}$ also proves impossibility in $\mathcal{ASYNC}$. We next prove that in the $\mathcal{SSYNC}$ model it is impossible for any algorithm to achieve either gathering or convergence of three robots in the Byzantine fault model, even in the presence of at most one faulty robot.

Definition. A gathering algorithm $\mathcal{A}$ is called *hyperactive* if it instructs every robot to make a move in every cycle until the task is achieved; i.e., $\check{M}(N, \mathcal{A}) = N$.

THEOREM 4.1. *In a* $(3, 1)$*-Byzantine system under the* $\mathcal{SSYNC}$ *model, any non-hyperactive gathering algorithm will fail in achieving gathering or convergence.*

Proof. Suppose the system consists of three robots R_1, R_2, R_3, and there exists a scenario σ in which at some configuration C_1, R_1 is active, but the algorithm instructs it to stay in place. In this system, the adversary can do the following. It designates R_3 as faulty and executes the scenario σ with R_3 acting correctly up to a configuration C_1. At this cycle, it makes R_1 active and R_2 passive. As a result, neither R_1 nor R_2 moves in this cycle. In addition, the adversary moves R_3 to create a configuration C_2 that from R_2's point of view is equivalent to what R_1 has seen in C_1 (see Figure 10). The adversary now makes R_1 passive and R_2 active. Since R_2's state is equivalent to R_1's state in the previous configuration, the algorithm will now instruct R_2 to stay in place. The adversary can now switch from configuration C_1 to C_2 and back, forcing R_1 and R_2 to stay in place indefinitely. Therefore the algorithm fails to achieve gathering or convergence of the nonfaulty robots. □

Definition. A distributed robot algorithm is N*-diverging* if there exists an (N, f)-Byzantine system and a configuration in which the instructions of the algorithm combined with the actions of the adversary can cause two nonfaulty robots to increase the distance between them. An example of divergence caused by the instructions of the algorithm is illustrated in Figure 11(a). An example of divergence caused by the intervention of the adversary is illustrated in Figure 11(b), where robot R_1 is stopped short of reaching its goal point.

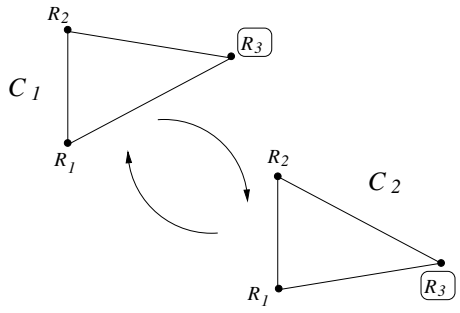

FIG. 10. *Theorem* 4.1.

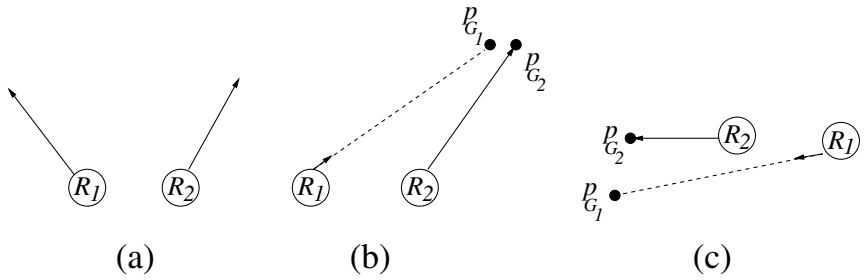

FIG. 11. *Divergence of robots.*

The premature-stopping technique. Our impossibility proofs make extensive use of the following technique. In order to cause two robots to diverge in some given configuration C of a given system $\mathcal{T}$, the adversary can stop a nonfaulty robot R_i after traversing a relatively small distance S_i. Note that S_i might be smaller than S in the current system, in which case the adversary is not permitted to stop R_i prematurely. However, as the algorithm is required to be valid in any system, it is intuitively clear that we may always consider a different system $\mathcal{T}'$ with S small enough to allow a movement of distance S_i. Moreover, since the algorithm is unaware of the value of S, it cannot distinguish between identical configurations in the two systems $\mathcal{T}$ and $\mathcal{T}'$ and will issue the same instructions to each robot in configuration C in $\mathcal{T}$ and $\mathcal{T}'$. Therefore the premature-stopping technique can be applied with any movement length greater than zero. We make this argument more formal in the proofs that follow.

As for the applicability of the premature-stopping technique, the adversary can apply it to cause the robots to diverge in any case where two robots move towards their respective goals on nonintersecting trajectories (see Figure 11(c)). In addition, even if the trajectories do intersect, the adversary can still apply the technique in some cases and again cause divergence, as seen in Figure 11(b). (One example for a case in which the premature stopping technique cannot help the adversary to force divergence is when the trajectories of the two robots R_1 and R_2 intersect and the angle between $p(R_1)$, $p(R_1)$ and the intersection point is at least $\pi/2$; see Lemma 3.3 and Figure 2.)

LEMMA 4.2. *In the $\mathcal{SSYNC}$ (or even the $\mathcal{FSYNC}$) model, a 3-diverging algorithm will fail to achieve gathering or convergence.*

Proof. Suppose, towards contradiction, that there exists a 3-diverging algorithm $\mathcal{A}$ that solves the gathering problem. Consider a $(3, 1)$-Byzantine system $\mathcal{T}$ with robots

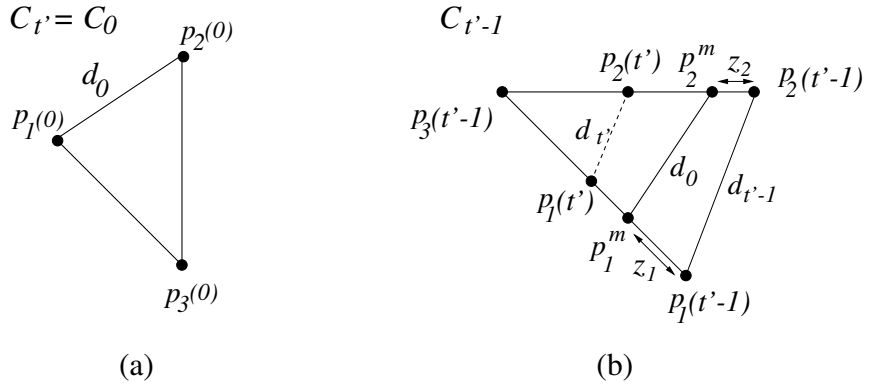

FIG. 12. *Lemma* 4.2.

R_1, R_2, and R_3, and a configuration C_0 on which $\mathcal{A}$'s instructions and the adversary's actions cause R_1 and R_2 to increase their distance. For $t \geq 0$ and $i = 1, 2$, denote by $p_i(t)$ the location of robot R_i in configuration C_t, and let $d_t = \text{dist}(p_1(t), p_2(t))$. Let $\sigma = \{C_0, C_1, \ldots, C_k\}$ be the sequence of configurations in an execution of the algorithm in which the adversary intervenes on the transition from C_0 to C_1 so as to increase $\text{dist}(R_1, R_2)$ but does not intervene thereafter, and in C_k all robots are gathered in one point. Note that $d_1 > d_0$. Let $t' = \min\{t \mid d_t \leq d_0, 2 \leq t \leq k\}$. By continuity considerations, as $d_{t'-1} > d_0$ and $d_{t'} \leq d_0$, there must be a time during the transition from $C_{t'-1}$ to $C_{t'}$ in which the robots R_1 and R_2 were located in middle points p_1^m and p_2^m, respectively, at distance exactly $\text{dist}(p_1^m, p_2^m) = d_0$. For $i = 1, 2$, let $z_i = \text{dist}(p_i(t'-1), p_i^m)$ (see Figure 12) and denote the minimum distance any robot traversed at any cycle $0 \leq t \leq t'-1$ by z_3.

Now replace the $(3,1)$-Byzantine system $\mathcal{T}$ by another system $\mathcal{T}'$ where $S = \min\{z_1, z_2, z_3\}$ and consider the following scenario. The adversary designates R_3 as faulty and executes the scenario σ up to $C_{t'-1}$. At this cycle, it stops R_1 and R_2 at points p_1^m and p_2^m, respectively, and moves the faulty robot R_3 to the exact same position it occupied in C_0. Thus, the new configuration $\tilde{C}_t$ is identical to C_0; hence the robots R_1 and R_2 will diverge again, and the system can be made to cycle through the configuration sequence $\{C_0, \ldots, \tilde{C}_t\}$ indefinitely, and thus R_1 and R_2 will never meet, contradicting the assumption. □

OBSERVATION 4.3. *Let $\mathcal{A}$ be an algorithm operating in a $(3,1)$-Byzantine system. Let $\vec{L}_{i,j}$ be the straight half-line starting at p_i and going through p_j. Suppose that in some configuration C, $\mathcal{A}$ instructs R_i and R_j to move on vectors $\vec{\mathrm{v}}_i$ and $\vec{\mathrm{v}}_j$ towards destination points g_i and g_j, respectively. Denote the angle between $\vec{L}_{i,j}$ and $\vec{\mathrm{v}}_i$ (measured from $\vec{L}_{i,j}$ in the counterclockwise direction) by μ_i, and the angle between $\vec{L}_{i,j}$ and $\vec{\mathrm{v}}_j$ by μ_j (see Figure 13). Then each of the following is a sufficient condition for $\mathcal{A}$ to be 3-diverging:*

(C1) $0 \leq \mu_j \leq \mu_i \leq \pi$.
(C2) $\pi \leq \mu_i \leq \mu_j \leq 2\pi$.
(C3) $0 \leq \mu_i \leq \pi \leq \mu_j \leq 2\pi$ *or* $0 \leq \mu_j \leq \pi \leq \mu_i \leq 2\pi$.
(C4) $0 \leq \mu_i < \mu_j \leq \pi$ *and either* $\mu_i \geq \pi/2$ *or* $\mu_j \leq \pi/2$.
(C5) $\pi \leq \mu_j < \mu_i \leq 2\pi$ *and either* $\mu_i \leq 3\pi/2$ *or* $\mu_j \geq 3\pi/2$.

Proof. To show that $\mathcal{A}$ is 3-diverging in each of these cases, we have to show a scenario in which the instructions of $\mathcal{A}$ combined with the actions of the adversary will

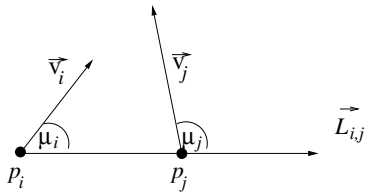

FIG. 13. *Observation* 4.3.

cause R_i and R_j to increase the distance between them. Denote the current distance between R_i and R_j by d_1, the location of R_i after traversing a distance S_i by p'_i, and the location of R_j after traversing a distance S_j by p'_j. Let $d_2 = \text{dist}(p'_i, p'_j)$.

Case (C1). It is easy to see that if $\mu_i = \mu_j = \pi/2$ and the robots move in different distances towards their goals, then $d_2 > d_1$ (as the hypotenuse in a right triangle is the longest side in the triangle). Therefore, in a system where $S = \min\{S_i, S_j\}, S_i \neq S_j$, it is enough that the adversary applies the premature-stopping technique, stops R_i after exactly a distance S_i, and stops R_j after traversing S_j. If $\mu_i = \mu_j < \pi/2$, then, applying again the premature-stopping technique, the adversary stops R_j after exactly a distance S and lets R_i continue traversing any distance greater than S. Similarly, if $\mu_i = \mu_j > \pi/2$, then the adversary stops R_i after traversing exactly a distance S and lets R_j traverse any distance greater than S. Finally, if $0 < \mu_j < \mu_i < \pi$, then the adversary can apply the premature-stopping technique and stop R_j after traversing a small distance and let R_j continue its movement as planned. In all cases, $d_1 > d_2$.

Case (C2). This case is simply a reflection of Case (C1).

Case (C3). It is easy to see that the trajectories of R_i and R_j diverge and never intersect. Traversing on those trajectories might not always cause divergence (for example, if the trajectory of R_j runs close to the current location of R_i as in Figure 11(c)), but by applying the premature-stopping technique as explained earlier, the adversary can cause divergence.

Case (C4). If $0 \leq \mu_i < \mu_j \leq \pi$ and either $\mu_i \geq \pi/2$ or $\mu_j \leq \pi/2$, then $\vec{v}_i$ and $\vec{v}_j$ intersect at some point, p^I. Without loss of generality let $\mu_i \geq \pi/2$. Drop a perpendicular line from p_j to the line going through p^I and p_i and let q_0 be the intersection point (see Figure 14). Let $d_3 = \text{dist}(p_j, p'_i)$. Consider the triangle $\triangle p'_i p_j q_0$. Clearly $d_3 > d_1$; therefore as $S_j \to 0$, $d_2 \to d_3$, and hence $d_2 > d_1$. Now apply the premature-stopping technique by stopping R_j after traversing a distance of exactly S, where S is very small (tending to 0), and allow R_i to traverse a distance S_i, thus causing $d_2 > d_1$.

Case (C5). This case is a reflection of Case (C4). □

THEOREM 4.4. *In a* $(3,1)$*-Byzantine system under the* $\mathcal{SSYNC}$ *model it is impossible to perform successful gathering or convergence.*

Proof. Consider a gathering algorithm $\mathcal{A}$ and an initial setting in which the three robots R_1, R_2, and R_3 are collinear, with R_2 in the middle. If the algorithm instructs R_2 to remain stationary, then it is nonhyperactive and by Theorem 4.1 will not achieve gathering. From Observation 4.3 it follows that if $0 \leq \mu_1, \mu_2, \mu_3 \leq \pi$, then in order to avoid being 3-diverging, necessarily $\mu_3 > \mu_2 > \mu_1$ (see Figure 15). But under this assumption, if $\mu_2 \geq \pi/2$, then applying Case (C4) of Observation 4.3 with respect to p_2 and p_3 yields that $\mathcal{A}$ is 3-diverging. If, on the other hand, $\mu_2 \leq \pi/2$, then applying Case (C4) of Observation 4.3 with respect to p_1 and p_2 yields the same conclusion.

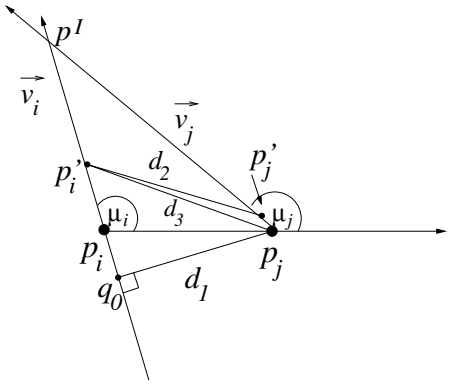

FIG. 14. *Observation* 4.3*, Case* (C4).

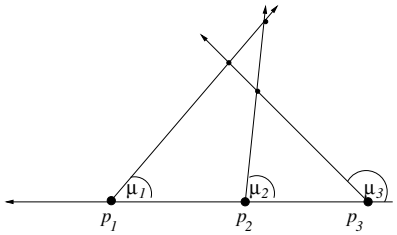

FIG. 15. *Illustration of proof of Theorem* 4.4.

A similar argument applies in case $\pi \leq \mu_1, \mu_2, \mu_3 \leq 2\pi$. Finally, if $\mu_1 > \pi$ and $\mu_2, \mu_3 < \pi$ or $\mu_1, \mu_2 > \pi$ and $\mu_3 < \pi$, then algorithm $\mathcal{A}$ is 3-diverging by Case (C3) of Observation 4.3. Thus, by Lemma 4.2, algorithm $\mathcal{A}$ fails to achieve gathering or convergence. □

We remark that in the $\mathcal{FSYNC}$ model, an N-diverging algorithm for $N > 3$ will not necessarily fail. In particular, the algorithms suggested in subsection 5.3 for the $\mathcal{FSYNC}$ model might be diverging yet still achieve gathering. Also, in the $\mathcal{FSYNC}$ model, a nonhyperactive algorithm will not necessarily fail. In particular, the gathering algorithm for $N = 3$ suggested in section 5 for the $\mathcal{FSYNC}$ model is not always hyperactive (for example, when the three robots are collinear, the robot lying in the middle is instructed to remain still). In fact, the converse may hold; namely, in the $\mathcal{FSYNC}$ model, a *hyperactive* algorithm might be problematic. For example, it is shown in the following lemma that in a one-dimensional setting, the adversary can cause failure of every hyperactive algorithm.

LEMMA 4.5. *In the $\mathcal{FSYNC}$ model, a hyperactive algorithm for a one-dimensional $(3,1)$-Byzantine system will fail to achieve gathering or convergence.*

Proof. Consider a $(3,1)$-Byzantine system on the line. Consider an arbitrary configuration C in which all robots are instructed by the algorithm to move. Without loss of generality suppose that at least two of the robots, say R_1 and R_2, are instructed to move to the right. Let ϵ_i denote the distance traversed by the robot R_i in the current round, and without loss of generality suppose $\epsilon_1 \leq \epsilon_2$. Then the same behavior will occur in a robot system in which $S \leq \epsilon_1$. In such a system, the adversary can stop R_2 after traversing a distance of only ϵ_1. The adversary can also fail the third robot R_3,

making it move to the right to distance ϵ_1. The resulting configuration is identical to the original C, implying that the adversary can keep the system at this configuration indefinitely. □

4.2. Intuition: Problems with previous approaches. The difficulty of handling a system of autonomous mobile robots with Byzantine faults is due to, among other reasons, the conventions regarding multiplicities on which most existing algorithms rely. In particular, these algorithms are based on enforcing the following conventions: (a) No more than one multiplicity point is created throughout the execution of the algorithm until successful gathering is achieved. (b) All robots lying in a multiplicity point remain stationary. (c) Robots lying in a multiplicity point are never separated again. These conventions are used for both gathering algorithms and other pattern formation algorithms; see [9].

All of the above assumptions no longer hold in a system where Byzantine faults might occur. First, the adversary could create a second multiplicity point as soon as it detects one such point, by "failing" a robot that does not lie in the multiplicity point and sending it to the location of yet another currently single robot. As a result, in the gathering problem assumption (b) cannot be relied on. Assumption (c) is violated even if the algorithm instructs all robots lying on the same point to move towards the *same* destination point, as the adversary could stop their movement in different locations.

Since all known algorithms rely on conventions (a)–(c) listed above, which can be violated in a system consisting of N robots with even one Byzantine faulty robot, it is clear that those algorithms fail to achieve gathering.

To get a feel for the possible complications that may occur in this model, let us consider some simple solutions one might propose for the problem. One natural general approach for attacking the problem is to try to gradually reduce the number of distinct points where the robots reside, by gathering partial subsets of robots at different points. A possible algorithm attempting to achieve that is one that requires each robot, in each cycle, to move towards its *closest* neighbor. This may lead to deadlocks once the robots pair up, since each one's closest neighbor already resides at the same location. Therefore the algorithm should instruct each robot to move towards the closest robot among those currently residing at locations *other* than its own. One problem that arises is that sets of robots that have already met might break up again; hence "progress" is hard to measure. Another obvious problem is that of symmetry breaking. Even ignoring this problem, this approach can still lead to nonconverging scenarios. For instance, suppose that the N robots are located on a straight line, with R_i at location $x_i = i(i-1)/2$. Then the algorithm requires R_1 to move towards R_2 and R_i to move towards R_{i-1} for every $2 \le i \le N$. However, if R_1 is faulty and chooses to move *away* from R_2, and all robots traverse exactly a distance S, then the configuration is translated by S in the $-x$ direction and is otherwise unchanged. (See Figure 16.)

Another natural algorithm is based on computing the center of gravity p_G of the configuration and going to p_G. This algorithm can be failed by the adversary in

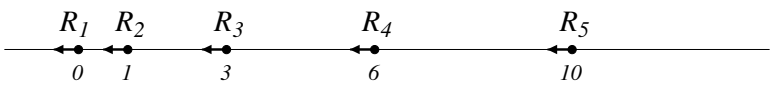

FIG. 16. *Bad scenario for nearest-neighbor algorithm.*

similar manner, by failing a robot located far from the rest and taking it to a walk towards infinity, forcing the entire pack of nonfaulty robots to be dragged along.

5. Fault-tolerant gathering in the $\mathcal{FSYNC}$ model.

5.1. Preliminaries. We now discuss the problem of gathering N autonomous mobile robots in an (N, f)-Byzantine system under the fully synchronous model. We use the following notation. Denote the *geometric span* (or *diameter*) of the set of points P by

$$\mathrm{Span}(P) \;=\; \max\{\mathrm{dist}(p,q) \mid p,q \in P\}.$$

Denote the convex hull of a multiset of points P by $H(P)$, and the set of vertices of $H(P)$ by $V_{\mathrm{H}}(P)$. Denote the set of (N to $N-f$) nonfaulty robots by $\mathcal{R}_{NF}$. Denote the *center of gravity* (or barycenter) of a multiset P of $n \geq 3$ points $p_i = (x_i, y_i), i = 1, \ldots, N$ by

$$C_{\mathrm{grav}}(P) = \left(\frac{\sum_{i=i}^{N} x_i}{N} \;,\; \frac{\sum_{i=i}^{N} y_i}{N} \right).$$

Define the sum of distances between all pairs of nonfaulty robots as

$$D_{\mathrm{tot}}(P) = \sum_{R_i, R_j \in \mathcal{R}_{NF}} \mathrm{dist}(R_i, R_j).$$

Note that for any set of points P, while the center of gravity $C_{\mathrm{grav}}(P)$ is defined in terms of the point coordinates in some specific coordinate system, the resulting point is independent of the particular coordinate system in use. Hence for a set of robots in some arbitrary configuration C in the plane, whenever each of the robots computes $C_{\mathrm{grav}}(P)$, the resulting point computed by the different robots is the same, even if each robot has its own coordinate system.

Definition. A robot algorithm is *concentrating* if it satisfies the following properties:

1. It is nondiverging; i.e., no two nonfaulty robots will increase the distance between them in any round.
2. There exists a constant $c > 0$ such that at each step, at least one pair of nonfaulty robots that are at different locations either meets or decreases the distance between them by at least c.

LEMMA 5.1. *Let $\mathcal{A}$ be a concentrating algorithm. Then in a $(3,1)$-Byzantine system under the $\mathcal{FSYNC}$ model, $\mathcal{A}$ achieves gathering.*

Proof. If in each cycle D_{tot} decreases by a constant amount c, then within a finite number of cycles $\mathcal{A}$ achieves gathering of all nonfaulty robots (since D_{tot} must reach 0). If there is indeed one faulty robot, then there may be only one pair of nonfaulty robots. The algorithm $\mathcal{A}$ ensures that the distance between the two nonfaulty robots decreases by at least a constant c in each cycle; hence $D_{\mathrm{tot}}^{new} \leq D_{\mathrm{tot}}^{old} - c$ and therefore these two robots will eventually meet. If all three robots are nonfaulty, then $\mathcal{A}$ ensures that the distance between at least one pair, say R_1 and R_2, decreases by at least c while $\mathrm{dist}(R_1, R_3)$ and $\mathrm{dist}(R_2, R_3)$ do not increase (since $\mathcal{A}$ is nondiverging); hence $D_{\mathrm{tot}}^{new} \leq D_{\mathrm{tot}}^{old} - c$ and $\mathcal{A}$ achieves gathering. ∎

Definition. A distributed robot algorithm $\mathcal{A}$ is said to *dictate* 2*-pair convergence* in a given cycle if in that cycle it instructs two distinct pairs of robots to decrease the distance between them by a constant amount. A distributed robot algorithm $\mathcal{A}$

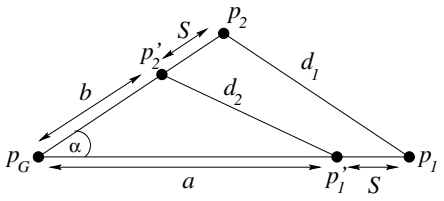

FIG. 17. *Proof of Lemma* 5.2.

is said to *dictate triple convergence* in a given cycle if in that cycle it instructs three robots to decrease by a constant amount the distance between every pair of them.

Note that for $N = 3$, triple convergence implies also nondivergence and hence also concentration. Note also that these conditions do not require that the robots involved be nonfaulty; in particular, one of them may fail and disobey the algorithm's instructions, in which case its distances will not decrease as needed. Nevertheless, these conditions turn out to be sufficient for gathering in certain settings.

LEMMA 5.2. *Consider two robots R_1 and R_2, initially located at the points p_1 and p_2, which traverse the same distance S' towards a common meeting point p_G, and let $\alpha = \angle p_1 p_G p_2$. If $\alpha \le \pi/2$, then the distance between them decreases by at least $S'(1 - \cos\alpha)$.*

Proof. Let p_1' and p_2' denote the new location of R_1 and R_2 after moving a distance S' towards p_G, and let $d_1 = \mathrm{dist}(p_1, p_2)$, $d_2 = \mathrm{dist}(p_1', p_2')$, $a = \mathrm{dist}(p_1', p_G)$, and $b = \mathrm{dist}(p_1', p_G)$ (see Figure 17).

By the cosine theorem on the triangles $\triangle p_1 p_G p_2$ and $\triangle p_1' p_G p_2'$, it follows that

$$d_1^2 = (a + S')^2 + (b + S')^2 - 2(a + S')(b + S')\cos\alpha,$$
$$d_2^2 = a^2 + b^2 - 2ab\cos\alpha.$$

Therefore

$$d_1 - d_2 = \frac{2a + 2b + S'}{d_1 + d_2} \cdot S'(1 - \cos\alpha).$$

By the triangle inequality on triangles $\triangle p_1 p_G p_2$ and $\triangle p_1' p_G p_2'$ it follows that $a + b + 2S' > d_1$ and $a + b > d_2$. Therefore $\frac{2a+2b+S'}{d_1+d_2} > 1$, so $d_1 - d_2 > S'(1 - \cos\alpha)$. In the range $(0, \pi/2]$ this value is always greater than 0 and is equal to 0 if and only if $\alpha = 0$. □

5.2. Gathering on a (3, 1)-Byzantine system in the $\mathcal{FSYNC}$ model. Let us next describe a gathering algorithm for three robots in an $\mathcal{FSYNC}$ model with at most one Byzantine fault. The input to this procedure is a configuration $P = \{p_1, p_2, p_3\}$.

Procedure 3-Gather$_{\mathrm{Byz}}(P)$

1. **State [Collinear]:** p_1, p_2, p_3 are collinear with p_2 in the middle:
   Set $p_G \leftarrow p_2$.
2. **State [Triangle]:** The three points form a triangle:
   Set p_G to be the intersection point of the three angle bisectors of the triangle $\triangle p_1 p_2 p_3$.

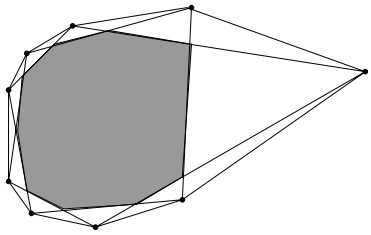

FIG. 18. *Illustration of* H^1_{int}.

Observe that the case of two robots residing at the same point, say $p_1 = p_2$, is handled by step 1 of the procedure. In this case, $p_G = p_1$; thus R_1 and R_2 stay in place and R_3 is required to move towards them.

Analysis.

THEOREM 5.3. *Algorithm* 3-Gather$_{\text{Byz}}$ *solves the gathering problem in a* $(3,1)$*-Byzantine system under the* $\mathcal{FSYNC}$ *model.*

Proof. Let us first consider the case when R_1, R_2, and R_3 are collinear, say, with R_2 in the middle. Since both extreme robots are instructed to move towards R_2, and R_2 is instructed to stay in place, it is clear that the instructions of the algorithm ensure that $\text{dist}(R_1, R_3)$ decreases in each cycle by at least S (or they meet), and also that $\text{dist}(R_1, R_2)$ and $\text{dist}(R_2, R_3)$ decrease by at least S (or they meet). Hence the algorithm dictates triple convergence in each cycle.

Next, suppose that R_1, R_2, and R_3 are not collinear. By Lemma 3.2, the angle between every two robots and p_G is greater than $\pi/2$. Therefore, by Lemma 3.3, we again have triple convergence.

Therefore in each cycle, whether the robots are collinear or not, triple convergence is ensured. Since for $N = 3$ triple convergence implies nondivergence as well, the algorithm achieves gathering by Lemma 5.1. ∎

5.3. Gathering for $f \geq 1$ and $N \geq 3f + 1$ in the $\mathcal{FSYNC}$ model. In this section we propose an algorithm for solving the gathering problem in an (N, f)-Byzantine system, where $N \geq 3f + 1$ in the $\mathcal{FSYNC}$ model. The main idea of the algorithm is to ensure that the goal point selected in each cycle falls in the convex hull of the *nonfaulty* robot locations. As shown later, this ensures that the geometric span of the set of locations of the nonfaulty robots decreases by at least $0.25S$; thus the robots will meet within a finite number of cycles. Due to its high complexity, this algorithm is only of theoretical merit, except for small values of f.

Definition. The *hull intersection* $H^k_{\text{int}}(P)$ is the convex set created as the intersection of all $\binom{N}{k}$ sets $H(P \setminus \{p_{i_1}, \ldots, p_{i_k}\})$ for $1 \leq k \leq N$, $p_{i_j} \in P$. (See Figure 18 for $k = 1$.)

The algorithm. Consider the following Procedure Gather$_{\text{Byz}}$ for determining the goal point p_G in each cycle. The input to this procedure is a configuration $P = \{p_1, \ldots, p_N\}$, and f is the maximum number of faulty robots.

Procedure Gather$_{\text{Byz}}(P)$

1. Compute $Q \leftarrow V_{\text{H}}(H^f_{\text{int}}(P))$.
2. Set $p_G \leftarrow C_{\text{grav}}(Q)$.

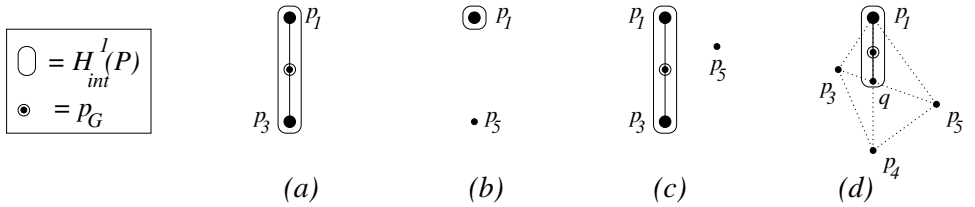

FIG. 19. *Illustration of Procedure* $\mathsf{Gather}_{\mathrm{Byz}}$ *in a* $(5,1)$*-Byzantine system.*

To illustrate the algorithm, let us consider a number of possible configurations of a $(5,1)$-Byzantine system (see Figure 19).

(a) $p_1 = p_2$, and $p_3 = p_4 = p_5$. Then $H^1_{\mathrm{int}}(P)$ is the segment $\overline{p_1p_3}$, and p_G is its midpoint.
(b) $p_1 = p_2 = p_3 = p_4 \neq p_5$. Then $H^1_{\mathrm{int}}(P) = \{p_1\}$, and $p_G = p_1$.
(c) $p_1 = p_2$, $p_3 = p_4$, and p_5 is distinct. Then $H^1_{\mathrm{int}}(P)$ is the segment $\overline{p_1p_3}$, and p_G is its midpoint.
(d) $p_1 = p_2$, and p_3, p_4, p_5 are distinct. Then $H^1_{\mathrm{int}}(P)$ is some segment $\overline{qp_1}$, and p_G is its midpoint.

Analysis. Let us first prove that the algorithm is well defined. For this we have to show that the set Q is nonempty.

Helly's theorem for $d = 2$ (cf. [28, Theorem 4.1.1]). Let $\mathcal{S}$ be a finite family of at least three convex sets in $\mathbb{R}^2$. If every three members of $\mathcal{S}$ have a point in common, then there is a point common to all members of $\mathcal{S}$.

LEMMA 5.4. *For a multiset* $P = \{p_1, \ldots, p_N\}, N \geq 3k+1$, $H^k_{\mathrm{int}}(P)$ *is convex and nonempty.*

Proof. $H^k_{\mathrm{int}}(P)$ is convex as it is the intersection of $\binom{N}{k}$ convex sets. We prove that it is nonempty by Helly's theorem. Consider three arbitrary sets $P^l = \{p^l_1, \ldots, p^l_k\} \subseteq P, 1 \leq l \leq 3$, and let $Q^l = H(P \setminus P^l)$, $1 \leq l \leq 3$. Then $Q^1 \cap Q^2 \cap Q^3$ contains at least $P' = P \setminus (P^1 \cup P^2 \cup P^3)$. As $|P| \geq 3k+1$, $|P'| \geq 1$. It follows that the intersection of every three such sets is nonempty, and by Helly's theorem $V_{\mathrm{H}}(H^k_{\mathrm{int}}(P))$ is nonempty as well. ∎

The analysis of Procedure $\mathsf{Gather}_{\mathrm{Byz}}$ is based on showing that if a set of K robots $R_1, \ldots, R_K$ initially located at the points $P = \{p_1, \ldots, p_K\}$ move towards a point p_G in their convex hull $H(P)$ and their new positions are at the points $P' = \{p'_1, \ldots, p'_K\}$, then their geometric span decreases by at least cS for some constant $c \geq 1/4$; i.e., $\mathrm{Span}(P') \leq \mathrm{Span}(P) - cS$. Consequently, the robots will meet within a finite number of cycles.

LEMMA 5.5. *Let* $P = \{p_1, \ldots, p_k\}$ *be a set of points in the plane.*

1. $\mathrm{Span}(P) \geq \mathrm{dist}(p, p')$ *for every two points* p, p' *in the convex hull* $H(P)$.
2. *The geometric span is attained by two points* $p_a, p_b \in P$ *that occur as vertices in* $H(P)$.
3. *Moreover, for every point* p_G *in* $H(P)$, $\angle p_a p_G p_b \geq \pi/4$.

Proof. Consider two arbitrary points p, p' inside $H(P)$. By the definition of the convex hull, it is clear that the segment $\overline{pp'}$ falls entirely within the convex hull of P. Therefore this segment can be extended in both directions towards the circumference of $H(P)$, hitting it at the points q, q'. Hence $\mathrm{dist}(p, p') \leq \mathrm{dist}(q, q')$. If the points q and q' are vertices of the convex hull, then $q, q' \in P$, and we are done. So now suppose this is not the case. If q is not a vertex of $H(P)$, then it occurs on an edge $\overline{p_i p_{i+1}}$. In this case, at least one of the two adjacent vertices of the convex hull,

without loss of generality p_i, satisfies that $\mathrm{dist}(q', p_i) > \mathrm{dist}(q', q)$. Similarly, if q' is not a vertex, then it occurs on an edge $\overline{p_j p_{j+1}}$, and again without loss of generality $\mathrm{dist}(p_j, p_i) > \mathrm{dist}(q', p_i)$. Hence combined, $\mathrm{Span}(P) \geq \mathrm{dist}(p, p')$. Therefore for each such segment $\overline{pp'}$ there exists a segment $\overline{p_i p_j}$, $p_i, p_j \in P$, whose length is greater than or equal to $\mathrm{dist}(q, q')$.

The proof used to establish the first claim of the lemma also yields the second claim, as it shows that for any two points q, q' that are not both vertices of $H(P)$, there exist two vertices $p_i, p_j \in P$ of $H(P)$ satisfying $\mathrm{dist}(p_i, p_j) > \mathrm{dist}(q, q')$; hence $\mathrm{Span}(P)$ cannot be attained by those points q, q'.

The third claim of the lemma is proved as follows. Let p_a, p_b be the two vertices of $H(P)$ attaining $\mathrm{Span}(P)$, and suppose, towards contradiction, that there exists a point p_G in $H(P)$ such that $\alpha = \angle p_a p_G p_b < \pi/4$. Consider the triangle $\triangle p_a p_G p_b$. Let $\beta = \angle p_a p_b p_G$ and $\gamma = \angle p_b p_a p_G$. Without loss of generality assume that $\beta \geq \gamma$. Then

$$\alpha < \pi/4 < 3\pi/8 < (\pi - \alpha)/2 = (\beta + \gamma)/2 < \beta < \beta + \gamma = \pi - \alpha.$$

Hence $\sin\beta > \sin\alpha$. Also, by the sine theorem on the triangle $\triangle p_a p_G p_b$,

$$\frac{\mathrm{dist}(p_a, p_b)}{\mathrm{dist}(p_a, p_G)} = \frac{\sin\alpha}{\sin\beta}.$$

It follows that $\mathrm{dist}(p_a, p_G) > \mathrm{dist}(p_a, p_b)$. By part 1 of the lemma, $\mathrm{Span}(P) \geq \mathrm{dist}(p_a, p_G) > \mathrm{dist}(p_a, p_b)$, contradicting the assumption. □

LEMMA 5.6. *For every two sets of points P and Q, if $H(P) \subseteq H(Q)$, then* $\mathrm{Span}(P) \leq \mathrm{Span}(Q)$.

Proof. Let $p_a, p_b \in P$ be the vertices attaining the geometric span of P. As $P \subseteq H(P) \subseteq H(Q)$, also $p_a, p_b \in H(Q)$. Thus by Lemma 5.5, $\mathrm{Span}(P) = \mathrm{dist}(p_a, p_b) \leq \mathrm{Span}(Q)$. □

LEMMA 5.7. *If a set of K robots $R_1, \ldots, R_K$ initially located at the points $P = \{p_1, \ldots, p_K\}$ traverse the same distance S towards a point p_G in the convex hull $H(P)$ and their new positions are at the points $P' = \{p'_1, \ldots, p'_K\}$, then their geometric span decreases by at least cS for some constant $c \geq 1/4$; i.e.,* $\mathrm{Span}(P') \leq \mathrm{Span}(P) - cS$.

Proof. Let p_a, p_b be the two vertices of $H(P)$ attaining $\mathrm{Span}(P)$, and let p'_i, p'_j be the two vertices of $H(P')$ attaining $\mathrm{Span}(P')$. Note that p_G is internal also to $H(P')$. Hence, by part 3 of Lemma 5.5, it follows that $\alpha = \angle p_a p_G p_b \geq \pi/4$. If $\pi/4 \leq \alpha < \pi/2$, then according to Lemma 5.2, $\mathrm{dist}(p'_a, p'_b) \leq \mathrm{dist}(p_a, p_b) - (1 - \cos\alpha) \leq \mathrm{dist}(p_a, p_b) - 0.25S$. Also, if $\alpha \geq \pi/2$, then by Lemma 3.3, $\mathrm{dist}(p'_a, p'_b) \leq \mathrm{dist}(p_a, p_b) - 0.7S$. Therefore, in any case $\mathrm{dist}(p'_a, p'_b) \leq \mathrm{dist}(p_a, p_b) - 0.25S$. Also, since p_a, p_b attains $\mathrm{Span}(P)$, it follows that $\mathrm{dist}(p_a, p_b) \geq \mathrm{dist}(p_i, p_j)$; therefore

$$\begin{aligned}\mathrm{Span}(P') &= \mathrm{dist}(p'_i, p'_j) \leq \mathrm{dist}(p_i, p_j) - S/4 \leq \mathrm{dist}(p_a, p_b) - S/4 \\ &= \mathrm{Span}(P) - S/4. \qquad \square\end{aligned}$$

COROLLARY 5.8. *If a set of K robots $R_1, \ldots, R_K$ initially located at the points $P = \{p_1, \ldots, p_K\}$ move towards a point p_G in the convex hull $H(P)$ and their new positions are at the points $P' = \{p'_1, \ldots, p'_K\}$, then their geometric span decreases by at least cS for some constant $c \geq 1/4$; i.e.,* $\mathrm{Span}(P') \leq \mathrm{Span}(P) - cS$.

Proof. By the model assumption, each robot traverses a distance of at least S towards p_G. Let p''_i denote the point at a distance *exactly* S from p_i in the direction of p_G, and let $P'' = \{p''_1, \ldots, p''_K\}$. Clearly $H(P') \subseteq H(P'')$. By Lemma 5.6, $\mathrm{Span}(P') \leq \mathrm{Span}(P'')$. By Lemma 5.7, $\mathrm{Span}(P'') \leq \mathrm{Span}(P) - cS$. The claim follows. □

LEMMA 5.9. *If a set of K robots $R_1, \ldots, R_K$ move in every cycle t towards a point p_G in their convex hull, then the robots will meet within a finite number of cycles.*

Proof. For $t \geq 1$, denote by H_t the convex hull of the robot configuration at the beginning of cycle t. In each cycle, the robots move a distance of at least S towards a point p_G in the convex hull. Thus, by Corollary 5.8, $\mathrm{Span}(H_{t+1}) \leq \mathrm{Span}(H_t) - 0.25S$ for every t. Therefore within at most $4 \cdot \mathrm{Span}(H_1)/S$ cycles, the geometric span of the robot configuration will be 0; thus all robots meet. ∎

THEOREM 5.10. *Algorithm* $\mathsf{Gather}_{\mathrm{Byz}}$ *solves the gathering problem in an (N, f)-Byzantine system under the $\mathcal{FSYNC}$ model for any $N \geq 3f + 1$.*

Proof. By Lemma 5.9 it is sufficient to show that the goal point p_G selected in the cycle falls in $H(\mathcal{R}_{NF})$, the convex hull of the nonfaulty robots. To prove this, we check the goal point p_G determined in each cycle.

By definition, the set $H^f_{\mathrm{int}}(P)$ is contained in its entirety in $H(P)$ as well as in the convex hull of every $N - f$ points of P; thus, in particular, it falls in $H(\mathcal{R}_{NF})$. Since the center of gravity of a set of points is inside its convex hull, it follows that p_G is in $H(\mathcal{R}_{NF})$. By Lemma 5.4, it follows that $H^f_{\mathrm{int}}(P)$ is nonempty; thus the center of gravity of the set $V_{\mathrm{H}}(H^f_{\mathrm{int}}(P))$ is well defined. ∎

6. Open problems. The design of fault-tolerant distributed control algorithms for multiple robot systems is still far from being fully explored. Directions for future research include the following. To begin with, it may be useful to study other kinds of fault models in addition to the crash and Byzantine models, such as a model in which the robots might lose some of their movement control (for instance, lose control of their movement length), or a model in which robots might diverge from their original movement direction up to a certain percentage of error. It is also necessary to develop fault-tolerant algorithms for tasks other than gathering (e.g., formation of geometric patterns). The maximum number of faults under which a solution is still feasible, for gathering and other tasks, has yet to be established. Finally, it would be interesting to examine the effect of changes in some initial assumptions on the model's fault tolerance properties. Examples for possible model changes include partial nonobliviousness of the robots (e.g., robots equipped with a small amount of memory, say, allowing them to remember the subsequence of X most recent cycles), robots capable of partial agreement on their orientation, or robots capable of explicit communication (perhaps under certain limitations, e.g., only with nearby robots).

DISPROVING THE SINGLE LEVEL CONJECTURE*

STASYS JUKNA†

Abstract. We consider the size of monotone circuits for quadratic Boolean functions, that is, disjunctions of length-2 monomials. Our motivation is that a good (linear in the number of variables) lower bound on the monotone circuit size for a certain type of quadratic function would imply a good (even exponential) lower bound on the general nonmonotone circuit size.

To get more insight into the structure of monotone circuits for quadratic functions, we consider the so-called single level conjecture posed explicitly in the early 1990s. The conjecture claims that monotone single level circuits, that is, circuits which have only one level of AND gates, for quadratic functions are not much larger than arbitrary monotone circuits. In this paper we disprove the conjecture as follows: there exist quadratic functions whose monotone circuits have linear size but whose monotone single level circuits require almost quadratic size.

Key words. quadratic functions, monotone circuits, Boolean sums, graph complexity, clique covering number, Kneser graph, Sylvester graph

DOI. 10.1137/S0097539705447001

1. Introduction.

A quadratic Boolean function is a monotone Boolean function in which all prime implicants have length 2. There is an obvious correspondence between such functions and graphs: every graph $G = (V, E)$ defines a natural quadratic function

$$f_G(X) = \bigvee_{uv \in E} x_u x_v, \tag{1.1}$$

and every quadratic function defines a unique graph. We consider the complexity of computing such functions by monotone circuits, that is, by circuits over the standard monotone basis $\{\vee, \wedge, 0, 1\}$ of fanin-2 AND and OR gates. Single level circuits are circuits in which every path from an input to an output gate contains at most one AND gate. Note that every quadratic Boolean function f_G in n variables can be computed by a trivial monotone single level circuit with at most $n-1$ AND gates using the form

$$\bigvee_{u \in S} x_u \wedge \left(\bigvee_{v : uv \in E} x_v \right), \tag{1.2}$$

where $S \subseteq V$ is an arbitrary vertex cover of G, that is, a set of vertices such that every edge of G is incident with a vertex in S.

SINGLE LEVEL CONJECTURE. *For quadratic functions, single level circuits are almost as powerful as unrestricted ones.*

Here "almost" means "up to a constant factor." This conjecture—first explicitly framed as the "single level conjecture" by Lenz and Wegener in [14]—was considered by several authors; see [12, 4, 5, 17, 14, 2] among others. That the conjecture holds

for *almost all* quadratic functions was shown by Bloniarz [4] more than 25 years ago and, so far, no (even constant) gap between the size of general and single level circuits for quadratic functions is known.

In this paper we disprove the single level conjecture in a strong sense as follows: There exist quadratic functions in n variables whose monotone circuits have linear size but whose monotone single level circuits require size $\Omega(n^2/\log^3 n)$. A similar gap is also shown for Boolean formulas. We also discuss the single level conjecture in the case of monotone circuits with unbounded fanin gates.

Why should we care about monotone circuits for quadratic functions when we already can prove high (even exponential) lower bounds for monotone circuits? There are several reasons for this, as follows:

1. Any explicit n-vertex graph G that cannot be represented (in a sense described later in section 3) by a monotone circuit using fewer than cn gates for a sufficiently large constant $c > 0$ would give us an explicit *exponential* lower bound for general (nonmonotone) circuits. Let us briefly sketch how this happens. Every bipartite $n \times n$ graph $G \subseteq U \times W$ with $n = 2^m$ and $U = W = \{0,1\}^m$ gives us a Boolean function f (the characteristic function of G) in $2m$ variables such that $f(uv) = 1$ iff $uv \in G$. Suppose now that we have a *nonmonotone* circuit $F(y_1, \ldots, y_{2m})$ computing f whose inputs are variables y_i and negated variables $\overline{y}_i$; the rest of the circuit is monotone (consists of AND and OR gates). Then, according to the so-called "magnification lemma" [10], it is possible to replace its $4m = 4\log n$ input literals (both positive and negative) with appropriate Boolean sums (ORs) of variables in $X = \{x_v : v \in U \cup W\}$ so that the resulting *monotone* circuit $F_+(X)$ in $|X| = 2n$ variables represents G. It can be shown (see [21] or Lemma 3.6 below) that all $4\log n$ Boolean sums can be simultaneously computed by a monotone circuit of size cn for a constant c. Therefore, the size of F cannot be much smaller than that of F_+: $\text{size}(F) \geq \text{size}(F_+) - cn$. Hence, a lower bound $cn + n^\epsilon$ on the size of *monotone* circuits representing G would yield a lower bound $n^\epsilon = 2^{\epsilon m}$ on the *nonmonotone* circuit size of an explicit Boolean function f in $2m$ variables.

2. Better yet, for some graphs G, f_G is the *only* monotone Boolean function representing G. Such graphs are, in particular, complements of triangle-free graphs (see Observation 3.5 below). Hence, one could obtain large (even exponential) lower bounds for general nonmonotone circuits by proving a good (but only linear) lower bound on the monotone circuit size of such quadratic functions.

3. Unlike Boolean functions, graphs have been studied for a long time, and explicit constructions of graphs with very special properties are already known. We therefore hope to design a lower bound proof that is highly specialized for some particular graph or some small class of graphs. This could (probably) lead to a lower bound proof, which will not fulfill the "largeness" condition in the notion of "natural proofs" [23].

4. When applied to quadratic functions, known lower bound arguments for monotone circuits, such as Razborov's method of approximations [22] and its modifications, cannot yield lower bounds larger than n. The reason for this is that these arguments are lower bounding the *minimum* of AND gates and of OR gates needed to compute the function, and (as we already noted above) every quadratic Boolean function f_G in n variables can be computed by a trivial monotone single level circuit with at most n AND gates.

We therefore need entirely new lower bound arguments for monotone circuits

computing quadratic functions. For this, it is important to better understand the *structure* of such circuits. The (long-studied) single level conjecture seems to be a good starting point in this direction.

2. Results. Let us first introduce some notation. By the *size* of a circuit we will always mean the number of gates in it. For a monotone Boolean function f, let $C(f)$ denote the minimum number of gates and $C_{\&}(f)$ the minimum number of AND gates in a monotone circuit computing f. Let also $C^1(f)$ and $C^1_{\&}(f)$ denote the single level counterparts of these measures. Further, let $L(f)$ and $L^1(f)$ denote the minimum length of a monotone (resp., of a monotone single level) formula computing f. Recall that a *formula* is a circuit in which all gates have fanout-1, i.e., the underlying graph is a tree; the *length* of the formula is the number of leaves of this tree.

In Table 2.1 we summarize known upper and lower bounds on the *maximum* possible complexity of quadratic functions f_G over all n-vertex graphs; the upper bounds here hold for all graphs and the lower bounds for almost all graphs.

TABLE 2.1
Known bounds on the maximum complexity of quadratic functions.

Upper bounds	Lower bounds
$C^1(n) = O(n^2/\log n)$ [4]	$C(n) = \Omega(n^2/\log n)$ [4]
$L^1(n) = O(n^2/\log n)$ [26, 5, 21]	$L(n) = \Omega(n^2/\log n)$
$C^1_{\&}(n) \le n - \lfloor \log n \rfloor + 1$ [26, 14]	$C^1_{\&}(n) \ge n - c\log n$ [24]
	$C_{\&}(n) = \Omega(n/\log n)$ [14]
	$C_{\&}(n) = \Omega(n)$ [2]

In this paper we are interested in the corresponding gaps between general and single level complexities for *individual* graphs, as follows:

1. circuit gap $\mathrm{Gap}(G) = C^1(f_G)/C(f_G)$;
2. multiplicative gap $\mathrm{Gap}_{\mathrm{mult}}(G) = C^1_{\&}(f_G)/C_{\&}(f_G)$;
3. formula gap $\mathrm{Gap}_{\mathrm{form}}(G) = L^1(f_G)/L(f_G)$.

Note that the single level conjecture claims that $\mathrm{Gap}(G) = O(1)$ for all graphs G. Table 2.1 shows that, for almost all graphs, the conjecture is indeed true.

An even stronger support for the single level conjecture was given by Mirwald and Schnorr [17] as follows: if we consider circuits over the basis $\{\oplus, \wedge, 1\}$ computing (algebraic) quadratic forms $\sum_{uv\in E} x_u x_v$ over GF(2) and if we count only AND gates, then *every* optimal (with respect to the number of AND gates) circuit is a single level circuit. But the case of circuits over the basis $\{\vee, \wedge, 0, 1\}$ has remained unclear.

In the case of formulas, Krichevski [12] proved that $\mathrm{Gap}_{\mathrm{form}}(K_n) = 1$ for the complete graph K_n on n vertices, even if negation is allowed as an operation. A graph with $\mathrm{Gap}_{\mathrm{form}}(G) \ge 8/7$ was given by Bublitz [5]. In the case of multiplicative complexity, a graph with $\mathrm{Gap}_{\mathrm{mult}}(G) \ge 4/3$ was given by Lenz and Wegener [14]. Recently, this gap was substantially enlarged to $\mathrm{Gap}_{\mathrm{mult}}(G) = \Omega(n/\log n)$ by Amano and Maruoka in [2]; this was implicit also in [10]. Using a construction of Tarjan [25] (which, in its turn, was used by Tarjan for disproving that AND gates are powerless for computing Boolean sums), Amano and Maruoka [2] have also shown the gap $\mathrm{Gap}(\mathcal{F}) \ge 29/28$ for circuits computing a *set* $\mathcal{F}$ of quadratic functions. However, even the existence of a *single* graph G with $\mathrm{Gap}(G) > 1$ was not known.

Our main result is the following.

THEOREM 2.1. *There exist n-vertex graphs G such that $C(f_G) = O(n)$ but $C^1(f_G) = \Omega(n^2/\log^3 n)$. Hence,* $\mathrm{Gap}(G) = \Omega(n/\log^3 n)$.

The graphs used in Theorem 2.1 are saturated extensions of Sylvester-type graphs,

that is, of bipartite graphs whose vertices are particular vectors in $\mathrm{GF}(2)^r$, and where two vertices are adjacent iff their scalar product over $\mathrm{GF}(2)$ is 1. The *saturated extension* of a bipartite graph $H \subseteq U \times W$ is a (nonbipartite) graph $G = (V, E)$ with $V = U \cup W$ such that $E \cap (U \times W) = H$ and the induced subgraphs of G on U as well as on W are complete graphs. The reason for considering graphs of this special form lies in the simple fact (see Lemma 3.8 below) that by having a small circuit representing H we can construct a small circuit computing f_G.

To disprove the single level conjecture for formulas, we consider a bipartite version of graphs introduced by Lovász [15] in his famous proof of Kneser's conjecture [11]. A bipartite *Kneser* $n \times n$ graph is a bipartite graph $K \subseteq U \times W$, where U and W consist of all $n = 2^r$ subsets u of $\{1, \ldots, r\}$, and $uv \in K$ iff $u \cap v = \emptyset$.

THEOREM 2.2. *If G is the saturated extension of a bipartite Kneser $n \times n$ graph, then $L(f_G) = O(n \log n)$, but $L^1(f_G) \geq n^{1+c}$ for a constant $c > 0$. Hence,* $\mathrm{Gap}_{\mathrm{form}}(G) = n^{\Omega(1)}$.

Next, we consider the single level conjecture for monotone *unbounded fanin* circuits and formulas. Note that in this case single level circuits are precisely the Σ_3 circuits: the bottom (next to the inputs) level consists of OR gates, the middle level consists of AND gates, and the top level consists of a single OR gate. For a monotone Boolean function f, let $C_*(f)$ (resp., $L_*(f)$) be the minimum size of a monotone unbounded fanin circuit (resp., formula) computing f. Let also $C^1_*(f)$ and $L^1_*(f)$ denote the corresponding measures in a class of monotone Σ_3 circuits (i.e., the single level versions of these measures). Note that, also in the case of formulas, we now count the number of gates, not the number of leaves.

Single level circuits of unbounded fanin are interesting for at least two reasons, as follows:

1. The presence of unbounded fanin gates may *exponentially* increase the power of single level circuits: if, say, G is the saturated extension of an n to n matching, then $C^1(f_G) = \Omega(n)$ but $C^1_*(f_G) = O(\log n)$ (by Lemmas 3.8, 3.10, and 3.13 below).

2. By the reduction due to Valiant [27], a lower bound of the form $n^{\Omega(1)}$ on the size of a monotone Σ_3 formula representing an explicit n-vertex graph would give us a *superlinear* lower bound on nonmonotone (fanin-2) circuits of logarithmic depth, and thus, would resolve an old and widely open problem in circuit complexity (see [10] for details).

The form (1.2) implies that $C^1_*(f_G) = O(n)$ for all n-vertex graphs. On the other hand, easy counting shows $C_*(f_G) = \Omega(n)$ for almost all n-vertex graphs: every gate in a circuit of size t can have at most 2^t possible sets of immediate predecessors, implying an upper bound $2^{O(t^2)}$ on the total number of such circuits. Hence, also in the case of unbounded fanin circuits, the single level conjecture holds for *almost all* quadratic functions. The following theorem gives a stronger result: the conjecture holds for *explicit* (and large) classes of quadratic functions.

Recall that a set $S \subseteq V$ is a *vertex cover* of $G = (V, E)$ if every edge of G is incident with a vertex in S. Let $\tau(G)$ denote the minimum cardinality of a vertex cover of G. Note that for every n-vertex graph $G = (V, E)$ of maximum degree d we have $|E|/d \leq \tau(G) \leq n - 1$. Let also $\mathrm{m}(G)$ denote the maximum possible number m such that G contains a matching with m edges as an *induced* subgraph. Representation (1.2) gives us the upper bound $C^1_*(f_G) \leq L^1_*(f_G) \leq 2\tau(G) + 1$. On the other hand, we have the following lower bounds.

THEOREM 2.3. *For every graph G we have $C_*(f_G) \geq \mathrm{m}(G) + 1$. Moreover,*

$L^1_*(f_G) \geq \tau(G)/d$ and $C^1_*(f_G) \geq \sqrt{\tau(G)/d}$, where d is the maximum degree of G.

Hence, if we consider circuits with *unbounded* fanin gates, then the single level conjecture is true for all n-vertex graphs containing an induced matching with $\Omega(n)$ edges: for all such graphs we have $C_*(f_G) = \Omega(n)$ and $C^1_*(f_G) = O(n)$.

In the case of multiplicative complexity (where we count only AND gates) we have the following gap.

THEOREM 2.4. *If G is the saturated extension of an n to n matching, then $C_\&(f_G) = O(\log n)$, but $C^1_\&(f_G) = \Omega(n)$. Hence,* $\mathrm{Gap}_{\mathrm{mult}}(G) = \Omega(n/\log n)$.

This result was implicit in [10] (and even in [1]; cf. Lemma 3.10 below), where it was shown that an n to n matching M (a bipartite $n \times n$ graph consisting of n vertex disjoint edges) can be represented by a monotone conjunctive normal form (CNF) with $O(\log n)$ clauses. The proof in this case is particularly simple, and we include it just for completeness. Amano and Maruoka [2] have used a somewhat different argument to show the same gap.

TABLE 2.2
Summary of results concerning the single level conjecture.

	Known	This paper
Circuits (all gates)	$\mathrm{Gap}(\mathcal{F}) \geq 29/28$ [2] (for a set of graphs; no known gap for a single graph)	$\mathrm{Gap}(G) = \Omega(n/\log^3 n)$ Sylvester-type graphs (main result)
Formulas (all gates)	$\mathrm{Gap}_{\mathrm{form}}(K_n) = 1$ [12] $\mathrm{Gap}_{\mathrm{form}}(G) \geq 8/7$ [5]	$\mathrm{Gap}_{\mathrm{form}}(G) = n^{\Omega(1)}$ Kneser-type graphs
Circuits (AND gates)	No gap over GF(2) [17] $\mathrm{Gap}_{\mathrm{mult}}(G) \geq 4/3$ [14] $\mathrm{Gap}_{\mathrm{mult}}(G) = O(n/\log\log n)$ [2]	$\mathrm{Gap}_{\mathrm{mult}}(G) = \Omega(n/\log n)$ Perfect matchings (also in [2]; implicit in [1, 10])
Unbounded fanin (all gates)		$C_*(f_G) \geq \mathrm{m}(G) + 1$ $\tau(G)/d \leq L^1_*(f_G) \leq 2\tau(G) + 1$ $C^1_*(f_G) \geq \sqrt{\tau(G)/d}$ $\forall$ G of maximal degree d

The rest of the paper is organized as follows. In the next section we collect some preliminary definitions and technical facts. We then use these facts to prove Theorems 2.1–2.4 in sections 4–7. We conclude with several open problems.

3. Preliminaries. In this section we first recall from [10] the notion of graph representation, expose some properties of quadratic functions of saturated graphs, and recall some results about Boolean sums. We then prove some general (graph theoretic) bounds on the circuit complexity of quadratic functions.

We shall use standard graph theory notation. A set of vertices is *independent* if no two of its vertices are adjacent. A *nonedge* is a pair of nonadjacent vertices; if the graph is bipartite, then a nonedge is a pair of nonadjacent vertices from different parts (color classes); that is, pairs of vertices in one color class are neither edges nor nonedges. A *subgraph* (or a *spanning subgraph*) of a graph is obtained by deleting its edges. An *induced subgraph* is obtained by deleting vertices (together with all the edges incident to them). The main difference between these two types of subgraphs is that every nonedge of an induced subgraph is also a nonedge of the original graph. A bipartite clique $K_{a,b}$ is a complete bipartite graph with color classes of sizes a and b.

3.1. Graph representation. Every graph $G = (V, E)$ gives us a set of Boolean functions "representing" this graph in the following sense. We associate with each vertex v a Boolean variable x_v, and consider Boolean functions $f(X)$ with $X =$

$\{x_v : v \in V\}$. Such a function accepts or rejects a subset of vertices $S \subseteq V$ if it accepts or rejects the incidence vector of S. We are interested in the behavior of such functions on edges and nonedges of G, viewed as 2-element sets of their endpoints.

DEFINITION 3.1 (see [10]). *A Boolean function* represents *a given graph if it accepts all edges and rejects all nonedges.*

Hence, $f(X)$ represents the graph G if for every input vector $a \in \{0,1\}^X$ with precisely two 1's in, say, positions u and v, $f(a) = 1$ if uv is an edge, and $f(a) = 0$ if uv is a nonedge of G. If uv is neither an edge nor a nonedge (in the bipartite case) or if a contains more or less than two 1's, then the value $f(a)$ may be arbitrary.

Note that the quadratic function f_G represents the graph G in a strong sense: for every subset $S \subseteq V$, $f_G(S) = 0$ iff S is an independent set of G. But, in general, there may be many other Boolean functions representing the same graph, because they do not need to reject independent sets with more than two vertices. Hence, there are more chances to design a small circuit representing a given graph than to (directly) design a small circuit computing its quadratic function. We will use this possibility later to upper bound the circuit size of quadratic functions.

A *complete star* around a vertex u in a graph with n vertices is a set of $n-1$ edges sharing u as one of their endpoints. If the graph is bipartite, then a complete star is a set of edges joining all vertices of one part with a fixed vertex of the other part. A graph is *star-free* if it contains no complete stars. The only property of star-free graphs we will use later is given by the following simple observation.

Observation 3.2. Any monotone Boolean function representing a star-free graph must reject all its single vertices.

This is true because $f(\{u\}) = 1$, together with the monotonicity of f, implies that f must accept all edges of a complete star around u.

3.2. Saturated graphs. As noted above, besides the quadratic function f_G, there may be many other monotone Boolean functions representing G—these functions may "wrongly" accept some independent sets of G of cardinality larger than 2. The simplest way to exclude this possibility is to "kill off" all such independent sets by "saturating" the graph, i.e., by adding new edges. This way we come to the following definition.

DEFINITION 3.3. *A graph G is* saturated *if it has no independent sets with more than two vertices, that is, if the complement of G is a triangle-free graph.*

The first interesting property of quadratic functions of saturated graphs is that these functions belong to a fundamental class of so-called "slice functions" for which negation is almost powerless (see, e.g., [29, sections 6.13–6.14]). Recall that a *k-slice function* is a monotone Boolean function f such that $f(a) = 0$ for inputs a with less than k 1's, and $f(a) = 1$ for inputs a with more than k 1's, that is, $f = f \wedge T_k^n \vee T_{k+1}^n$.

Observation 3.4. If G is a saturated graph, then f_G is a 2-slice function.

Proof. Let $G = (V, E)$ be a saturated graph, and let $S \subseteq V$. If $|S| < 2$, then $f_G(S) = 0$ by the definition of quadratic functions (they cannot have prime implicants shorter than 2). If $|S| > 2$, then S cannot be an independent set since G is saturated; hence, $f_G(S) = 1$. □

The next interesting property of saturated graphs is their unique function representation.

Observation 3.5. If G is a saturated star-free graph, then f_G is the only monotone Boolean function representing G.

Proof. Let f be an arbitrary monotone Boolean function representing G. We have

to show that $f(S) = f_G(S)$ for all subsets $S \subseteq V$. If $f_G(S) = 1$, then S contains both endpoints of some edge. This edge must be accepted by f and, since f is monotone, $f(S) = 1$. If $f_G(S) = 0$, then S is an independent set of G, and $|S| \leq 2$ since G is saturated. Hence, S is either a single vertex or a nonedge. In both cases we have that $f(S) = 0$ because f must reject all nonedges and, by Observation 3.2, must also reject all single vertices. □

3.3. Boolean sums. We shall also use the following two facts about the monotone complexity of Boolean sums. The *disjunctive complexity* of a collection of Boolean sums $\bigvee_{i\in S_1} x_i, \ldots, \bigvee_{i\in S_m} x_i$ (or of the corresponding family of sets $S_1, \ldots, S_m$) is the minimum size of a circuit consisting solely of fanin-2 OR gates and simultaneously computing all these m Boolean sums.

LEMMA 3.6 (Pudlák–Rödl–Savický [21]). *For every $m \geq k \geq 1$, the disjunctive complexity of any family of m subsets of $\{1, \ldots, n\}$ does not exceed*

$$kn + k2^{\lceil m/k\rceil+1}.$$

In particular, any collection of $k \log n$ Boolean sums in n variables can be simultaneously computed by a circuit consisting solely of at most $3kn$ fanin-2 OR gates.

By this lemma, Boolean sums may not necessarily be computed separately: one partial sum computed at some OR gate may be used many times. Still, the overlap of gates cannot be too large if the sums are "disjoint enough." A family of sets is (h, k)-*disjoint* if no $h + 1$ of its members share more than k elements in common.

LEMMA 3.7 (Wegener [28]; Mehlhorn [16]). *Any (h, k)-disjoint family $S_1, \ldots, S_m$ has disjunctive complexity at least*

$$\frac{1}{kh}\sum_{i=1}^{m} |S_i| - \frac{m}{h}.$$

Proof sketch. At least $|S_i| - 1$ gates are necessary for computation of the ith sum and at least $|S_i|/k - 1$ of the functions computed at these gates are Boolean sums of more than k summands. We count only these gates. Since the family is (h, k)-disjoint, each of these gates can be useful for at most h outputs. Hence, we need at least $\sum_{i=1}^{m}(|S_i|/k - 1)/h$ gates to compute all m sums. □

3.4. Upper bounds for general circuits. An *extension* of a bipartite graph $H \subseteq U \times W$ is a (nonbipartite) graph $G = (V, E)$ with $V = U \cup W$ such that $E \cap (U \times W) = H$. The *saturated extension* is an extension whose induced subgraphs on U as well as on W are complete graphs. That is, saturated extensions consist of two disjoint cliques with some edges between these cliques. A useful property of such graphs (besides that they are saturated) is that the complexity of *computing* f_G cannot be much larger than the complexity of *representing* H: to determine the value $f_G(S)$, it is enough to additionally test whether S has more than two elements.

By the *length* of a CNF we mean the number of clauses in it.

LEMMA 3.8. *Let $H \subseteq U \times W$ be a bipartite $n \times n$ graph, G the saturated extension of H, and f a monotone Boolean function representing H. Then $f_G = (f \wedge g) \vee h$, where g is a monotone CNF of length 2 and h is an OR of $O(\log n)$ monotone CNFs of length 2. Moreover, if H is star-free, then $f_G = f \vee h$.*

Remark. Note that $C_{\&}(h) = O(\log n)$, $L(h) = O(n \log n)$, and $C(h) = O(n)$. The first two upper bounds are obvious. The third follows from Lemma 3.6.

Proof. Let $g = \left(\bigvee_{u\in U} x_u\right) \wedge \left(\bigvee_{w\in W} x_w\right)$ and $h = K_U \vee K_W$, where $K_U(S) = 1$ iff $|S \cap U| \geq 2$; that is, K_U is the quadratic function of a complete graph on U. Since

the edges of a complete graph n-vertex graph can be covered by $m \leq \lceil \log n \rceil$ bipartite cliques, each of the functions K_U and K_W has the form

$$\bigvee_{i=1}^{m} \left(\bigvee_{u \in A_i} x_u \right) \wedge \left(\bigvee_{v \in B_i} x_v \right) \tag{3.1}$$

with $m \leq \lceil \log n \rceil$ and $A_i \cap B_i = \emptyset$ for all $i = 1, \ldots, m$. Hence, h can be computed by an OR of m monotone CNFs of length 2. It remains to show that $(f \wedge g) \vee h$ coincides with f_G.

If $f_G(S) = 1$, then S contains both endpoints of some edge uv of G. This edge must be accepted either by $f \wedge g$ (if $uv \in H$) or by h (if both u and v are in the same color class). Since both $f \wedge g$ and h are monotone, the function $(f \wedge g) \vee h$ accepts S.

If $f_G(S) = 0$, then S is an independent set of G; that is, S is either a single vertex or a nonedge of H. In both cases, $h(S) = 0$ because none of the color classes can contain more than one vertex from S. Moreover, $g(S) = 0$ if S is a single vertex, and $f(S) = 0$ if S is a nonedge of H. Hence, the function $(f \wedge g) \vee h$ rejects S.

If H is star-free, then the function f alone must reject all single vertices, implying that in this case $f_G = f \vee h$. □

Lemma 3.8 gives us a simple (but useful) tool to show that a quadratic function f_G of the saturated extension of a bipartite graph H can be *computed* by a small monotone circuit: it is enough to *represent* H by a small circuit. To achieve this last goal, it is often enough to show that H has small "intersection representation."

Say that a graph G admits an *intersection representation of size* r if it is possible to associate with every vertex u a subset A_u of $\{1, \ldots, r\}$ so that $A_u \cap A_v = \emptyset$ if uv is an edge, and $A_u \cap A_v \neq \emptyset$ if uv is a nonedge of G. Let $\mathrm{int}(G)$ denote the smallest r for which G admits such a representation.

Let $\mathrm{cnf}(G)$ denote the minimum length of a monotone CNF representing the graph G, and let $\mathrm{cov}(G)$ denote the minimum number of independent sets of G covering all nonedges of G.

LEMMA 3.9 (see [9, 10]). *For every graph G, $\mathrm{cnf}(G) = \mathrm{int}(G) = \mathrm{cov}(G)$.*

The first equality was observed in [10], and the second in [9]. Both are easy to verify. If a graph $G = (V, E)$ can be represented by a CNF $\bigwedge_{i=1}^{r} \bigvee_{v \in S_i} x_v$, then the sets $A_u = \{i : u \notin S_i\}$ give the desired intersection representation of G, the r sets $I_i = \{u \in V : i \in A_u\}$ are independent and cover all nonedges of G, and the CNF of the form above with $S_i = V \setminus I_i$ represents the graph G.

Alon [1] used probabilistic arguments to prove that $\mathrm{cov}(G) = O(d^2 \log n)$ for every n-vertex graph G of maximum degree d. Hence, we have the following general upper bound.

LEMMA 3.10 (Alon [1]). *For every n-vertex graph G of maximum degree d, we have $\mathrm{cnf}(G) = O(d^2 \log n)$.*

Another possible way to show that a graph H can be represented by a small monotone circuit is to design a small nonmonotone circuit representing H, and then use the fact that negation is (almost) powerless in the context of graph representation.

LEMMA 3.11. *Let H be a bipartite $n \times n$ graph. If H can be represented by a circuit of size L over the basis $\{\vee, \wedge, \neg\}$, then H can be represented by a monotone circuit of size at most $2L + O(n)$.*

Proof. The proof is reminiscent of the proof, due to Berkowitz [3], that negation is (almost) powerless for slice functions (see also Theorem 13.1 in [29]).

Let F be a circuit of size L over the basis $\{\vee, \wedge, \neg\}$ representing a bipartite graph $H \subseteq U \times W$. Using DeMorgan rules we can transform this circuit into an equivalent

circuit F' of size at most $2L$ such that negation is used only on inputs. We then replace each negated input $\overline{x}_u$ with $u \in U$ by a Boolean sum $g_u = \bigvee_{v \in U \setminus \{u\}} x_v$, and replace each negated input $\overline{x}_w$ with $w \in W$ by a Boolean sum $h_w = \bigvee_{v \in W \setminus \{w\}} x_v$. Since all these Boolean sums can be simultaneously computed by a trivial circuit consisting of $O(n)$ OR gates (see, e.g., [29, p. 198] for a more general result), the size of the new circuit F_+ does not exceed $2L + O(n)$. Since the only difference of F_+ from the original circuit F is that negated inputs are replaced by Boolean sums, it remains to show that on arcs $ab \in U \times W$ these sums take the same values as the corresponding inputs.

Take an arbitrary set $S = \{a, b\}$ with $a \in U$ and $b \in W$. The incidence vector of this set has precisely two 1's in positions a and b. Hence, $g_u(S) = 1$ iff $a \neq u$ iff $x_u(S) = 0$ iff $\overline{x}_u(S) = 1$. Similarly, $h_w(S) = 1$ iff $b \neq w$ iff $x_w(S) = 0$ iff $\overline{x}_w(S) = 1$. Hence, on edges and nonedges of H the functions g_u and h_w take the same values as the negated variables $\overline{x}_u$ and $\overline{x}_w$, implying that F_+ represents H. □

3.5. Lower bounds for single level circuits. Given a covering $E = \bigcup_{i=1}^m A_i \times B_i$ of the edges of a graph $G = (V, E)$ by bipartite cliques, its *size* is the number m of cliques, and its *weight* is the total number $\sum_{i=1}^m (|A_i| + |B_i|)$ of vertices in these cliques. Let $\mathrm{cc}(G)$ denote the minimum size and $\mathrm{cc_w}(G)$ the minimum weight of a bipartite clique covering of G. These measures were first studied by Erdős, Goodman, and Pósa in [9], and now are the subject of an extensive literature. In particular, it is known that the maximum of $\mathrm{cc}(G)$ over all n-vertex graphs is $n - \Theta(\log n)$ [6, 26, 24], and that the maximum of $\mathrm{cc_w}(G)$ is $\Theta(n^2/\log n)$ [4, 7, 5].

For a graph G, let $\mu(G)$ be the minimum of $(a+b)/ab$ over all pairs $a, b \geq 1$ such that G contains a copy of a complete bipartite $a \times b$ graph $K_{a,b}$.

LEMMA 3.12. *For every graph G, $C^1_{\&}(f_G) = \mathrm{cc}(G)$ and $L^1(f_G) \geq \mu(G) \cdot |E|$. Moreover, if G is an extension of a bipartite graph H, then $\mathrm{cc}(G) \geq \mathrm{cc}(H)/2$ and $\mathrm{cc_w}(G) \geq \mathrm{cc_w}(H)$.*

Proof. The equalities $C^1_{\&}(f_G) = \mathrm{cc}(G)$ and $L^1(f_G) = \mathrm{cc_w}(G)$ follow immediately from the fact (shown in [4, 14]) that monotone single level circuits for quadratic functions have the form (3.1), where m is the number of AND gates in the circuit.

To show that $\mathrm{cc_w}(G) \geq \mu(G) \cdot |E|$, let $E = A_1 \times B_1 \cup \cdots \cup A_m \times B_m$ be a bipartite clique covering of $G = (V, E)$ of minimal weight. Select subsets $E_i \subseteq A_i \times B_i$ so that the E_i's are disjoint and cover the same set E of edges. Then

$$\mathrm{cc_w}(G) = \sum_{i=1}^m (|A_i| + |B_i|) = \sum_{i=1}^m \sum_{e \in E_i} \frac{|A_i| + |B_i|}{|E_i|} \geq \sum_{i=1}^m \sum_{e \in E_i} \mu(G) = \mu(G) \cdot |E|.$$

To prove the last claim, let $G = (V, E)$ be an extension of $H \subseteq U \times W$; hence, $E \cap (U \times W) = H$. If $A_i \times B_i$, $i = 1, \ldots, m$, is a bipartite clique covering of G, then $(A_i \cap U) \times (B_i \cap W)$, $(B_i \cap U) \times (A_i \cap W)$, $i = 1, \ldots, m$, is a bipartite clique covering of H. The number of bipartite cliques in this new covering is at most twice that in the original covering, and the total number of vertices in the new covering does not increase at all. □

The case of circuits, in which we count all gates (not just AND gates), is a bit more complicated because Boolean sums (entering AND gates) may not necessarily be computed separately: one partial sum computed at some OR gate may be used many times. Still, by Lemma 3.7, we know that the overlap of gates cannot be too large if the sums are disjoint enough. The disjointedness of a collection of sums $\bigvee_{i \in S_1} x_i, \ldots, \bigvee_{i \in S_m} x_i$ is naturally related to the absence of large cliques in the

incidence $m \times n$ graph of this collection, where i and j are adjacent iff $j \in S_i$: the collection of sums is (h,k)-disjoint precisely when this graph has no copies of $K_{h+1,k+1}$. Amano and Maruoka [2] used this relation to show that $C^1(f_G) \geq |E|$ for any graph $G = (V,E)$ with no copies of $K_{2,2}$; in this case the corresponding sums are $(1,1)$-disjoint. Their argument can be easily extended to yield a lower bound of the form $C^1(f_G) \geq |E|/t^{O(1)}$ for $K_{t,t}$-free graphs. However, we need superlinear lower bounds on $C^1(f_G)$ for graphs G, which are *saturated extensions* of bipartite $n \times n$ graphs H, and such graphs already have copies of $K_{t,t}$ with $t = n/4$, even if the graph H itself is $K_{2,2}$-free.

To get rid of this problem, we use a tighter analysis of single level circuits to prove a stronger result, namely, a lower bound on the minimum size $C^1(H)$ of monotone single level circuits *representing* H (recall that such a circuit must behave correctly only on edges and nonedges of H; on other inputs it may take arbitrary values). If G is an extension of H, then nonedges of H are also nonedges of G, and hence must be rejected by f_G. This means that every circuit *computing* f_G must also represent H, implying that $C^1(f_G) \geq C^1(H)$ for every extension G of H.

LEMMA 3.13. *Let $H \subseteq U \times W$ be a bipartite star-free $n \times n$ graph with no copies of $K_{t,t}$. Then $C^1(H) = \Omega(|H|/t^3)$.*

Proof. Take a minimal monotone single level circuit F representing H. The circuit F has the form $\bigvee_{i=1}^m g_i \wedge h_i$, where

$$g_i = \bigvee_{u \in S_i} x_u \text{ and } h_i = \bigvee_{v \in T_i} x_v$$

with $S_i, T_i \subseteq U \cup W$ are Boolean sums computed at the inputs of the ith AND gate. Our goal is to show that we need many OR gates to compute these sums. We cannot apply Lemma 3.7 directly to these sums because the corresponding families may not be disjoint enough. Still, we can use the absence of $K_{t,t}$ in H to show that the restriction of these families to the left part U or to the right part W of the bipartition must contain a large enough (t,t)-disjoint subfamily.

First, observe that $S_i \cap T_i = \emptyset$ because the graph H is star-free (single variables represent complete stars). Also, if for some i, both S_i and T_i lie entirely in the same part of the bipartition, then we could just remove the ith AND gate—the resulting circuit would still represent H (recall that on pairs of vertices within one part of the bipartition the circuit can take arbitrary values). Thus, we may assume that this does not happen. Hence, H is the union of bipartite cliques

$$A_i \times B_i = (S_i \cap U) \times (T_i \cap W),$$
$$A'_i \times B'_i = (T_i \cap U) \times (S_i \cap W)$$

for $i = 1, \ldots, m$. We may assume w.l.o.g. that the union H' of cliques $A_i \times B_i$, $i = 1, \ldots, m$, contains at least $|H'| \geq |H|/2$ edges of H (if not, then take the remaining bipartite cliques).

Since H' has no copies of $K_{t,t}$, for every $i = 1, \ldots, m$, at least one of the sets A_i and B_i must have fewer than t elements. Hence, if we set $I = \{i : |A_i| < t\}$, then $|B_i| < t$ for all $i \notin I$. We may assume that the bipartite graph

$$H_1 = \bigcup_{i \in I} A_i \times B_i$$

contains at least $|H_1| \geq |H'|/2 \geq |H|/4$ edges of H (if not, then let H_1 be the union of bipartite cliques $A_i \times B_i$ with $i \notin I$ and replace the roles of the A_i's and the B_i's).

This way we obtain a bipartite $K_{t,t}$-free graph $H_1 \subseteq A \times B$ with parts $A = \bigcup_{i \in I} A_i$ and $B = \bigcup_{i \in I} B_i$, and with $|H_1| \geq |H|/4$ edges. We are going to represent this graph by a monotone (single level) circuit F_1 of size not much larger than that of F, and to apply Lemma 3.7 in order to show that the size of F_1 must be large; this will yield the desired lower bound on size(F).

To achieve the first goal, we collect the Boolean sums $h_i, i \in I$, computed in F into a circuit F_1, by the construction

$$F_1(X) = \bigvee_{u \in A} x_u \wedge \left(\bigvee_{i \in I_u} h_i \right) = \bigvee_{u \in A} x_u \wedge \left(\bigvee_{i \in I_u} \bigvee_{v \in T_i} x_v \right),$$

where $I_u = \{i \in I : u \in A_i\}$. For every vertex $u \in A$, the circuit F_1 accepts an arc $uv \in A \times B$ iff $v \in T_i \cap W = B_i$ for some $i \in I$ such that $u \in A_i$. Hence, F_1 represents the graph H_1. Since all Boolean sums h_i with $i \in I$ are already computed in F, we need at most

$$\sum_{u \in A} |I_u| = \sum_{i \in I} |A_i| \leq t \cdot |I|$$

new gates to compute all functions $x_u \wedge \left(\bigvee_{i \in I_u} h_i\right)$ with $u \in A$. To compute the disjunction of these functions, we need at most $|A| \leq \sum_{i \in I} |A_i| \leq t \cdot |I|$ additional OR gates. Hence, size$(F_1) \leq$ size$(F) + 2t \cdot |I| \leq 3t \cdot$ size(F).

On the other hand, by the construction, the circuit F_1 simultaneously computes all Boolean sums $\bigvee_{i \in I_u} h_i = \bigvee_{v \in T_u} x_v$ with $u \in A$ and $T_u = \bigcup_{i \in I_u} T_i$ using only fanin-2 OR gates. Hence, size(F_1) is at least the disjunctive complexity of the family $\mathcal{T} = \{T_u : u \in A\}$. This, in its turn, is at least the disjunctive complexity of the restriction $\mathcal{T}' = \{T_u \cap W : u \in A\}$ of $\mathcal{T}$ to the set W: having a circuit for $\mathcal{T}$ we can get a circuit for $\mathcal{T}'$ just by setting to 0 all variables x_u with $u \notin W$. Observe that for every $u \in A$,

$$T_u \cap W = \bigcup_{i : u \in A_i} T_i \cap W = \bigcup_{i : u \in A_i} B_i$$

is the set of all neighbors of u in H_1. Since H_1 has no copies of $K_{t,t}$, no t vertices in A can have t common neighbors. This means that the family $\mathcal{T}'$ must be (t,t)-disjoint (in fact, even $(t-1, t-1)$-disjoint). Since $|H_1| = \sum_{u \in A} |T_u \cap W|$, Lemma 3.7 yields

$$\text{size}(F_1) \geq \frac{1}{t^2} \sum_{u \in A} |T_u \cap W| - \frac{|A|}{t} = \frac{|H_1|}{t^2} - \frac{|A|}{t}.$$

Together with the previous estimate size$(F_1) \leq 3t \cdot$ size(F) and an obvious estimate $|A| \leq t \cdot |I| \leq t \cdot$ size(F), this yields

$$\text{size}(F) \geq \frac{1}{3t} \cdot \text{size}(F_1) \geq \frac{|H_1|}{3t^3} - \frac{|A|}{3t^2} \geq \frac{|H_1|}{3t^3} - \text{size}(F).$$

Since $|H_1| \geq |H|/4$, the desired lower bound size$(F) = \Omega(|H|/t^3)$ follows. □

Now we turn to the actual proofs of Theorems 2.1–2.4.

4. Circuits: Proof of Theorem 2.1. In order to prove the gap claimed in Theorem 2.1, we need (by Lemma 3.13) a bipartite $n \times n$ graph which

1. is dense, i.e., has $\Omega(n^2)$ edges,
2. has no copies of $K_{t,t}$ with t about $\log n$,
3. can be represented by a small (linear size) monotone circuit.

The existence of graphs, satisfying the first two conditions, is a classical result of Erdős [8]. However, its proof is probabilistic and gives no idea of how to ensure the third condition. To get rid of this problem, we just reverse the order of the argument: we first choose an appropriate graph G whose induced subgraphs satisfy the third condition. Then we use the probabilistic argument to show that G must contain a sufficiently large induced subgraph satisfying the first two conditions.

Let $\mathbb{F} = \mathrm{GF}(2)$, and let r be a sufficiently large even integer. With every subset $S \subseteq \mathbb{F}^r$ we associate a bipartite graph $H_S \subseteq S \times S$ such that two vertices u and v are adjacent iff $u \cdot v = 1$, where $u \cdot v$ is the scalar product over $\mathbb{F}$. We will need the following Ramsey-type property of such graphs.

LEMMA 4.1 (Pudlák–Rödl [20]). *Suppose every vector space $V \subseteq \mathbb{F}^r$ of dimension $\lfloor (r+1)/2 \rfloor$ intersects S in less than t elements. Then neither H_S nor the bipartite complement $\overline{H}_S$ contains $K_{t,t}$.*

Proof sketch. The proof is based on the observation that any copy of $K_{t,t}$ in H_S would give us a pair of subsets X and Y of S of size t such that $x \cdot y = 1$ for all $x \in X$ and $y \in Y$. Viewing the vectors in X as the rows of the coefficient matrix and the vectors in Y as unknowns, we obtain that the sum $\dim(X') + \dim(Y')$ of the dimensions of vector spaces X' and Y', spanned by X and Y, respectively, cannot exceed $r+1$. Hence, at least one of these dimensions is at most $(r+1)/2$, implying that either $|X' \cap S| < t$ or $|Y' \cap S| < t$. However, this is impossible because both X' and Y' contain subsets X and Y of S of size t. □

In the next lemma we use the following versions of Chernoff's inequality (see, e.g., [18], section 4.1): If X is the sum of n independent Bernoulli random variables with the success probability p, then $\Pr(|X| \le (1-c)pn) \le e^{-c^2 pn/2}$ for $0 < c \le 1$, and $\Pr(|X| \ge cpn) \le 2^{-cpn}$ for $c > 2e$.

LEMMA 4.2. *There exists a subset $S \subseteq \mathbb{F}^r$ of size $|S| = 2^{r/2}$ such that neither H_S nor the bipartite complement $\overline{H}_S$ contains a copy of $K_{r,r}$.*

Proof. Let $N = 2^r$, and let $\mathbf{S} \subseteq \mathbb{F}^r$ be a random subset where each vector $u \in \mathbb{F}^r$ is included in $\mathbf{S}$ independently with probability $p = 2^{1-r/2} = 2/\sqrt{N}$. By Chernoff's inequality, $|\mathbf{S}| \ge pN/2 = 2^{r/2}$ with probability at least $1 - e^{-\Omega(pN)} = 1 - o(1)$.

Now let $V \subseteq \mathbb{F}^r$ be a subspace of $\mathbb{F}^r$ of dimension $\lfloor (r+1)/2 \rfloor = r/2$ (remember that r is even). Then $|V| = 2^{r/2} = \sqrt{N}$ and we may expect $p|V| = 2$ elements in $|\mathbf{S} \cap V|$. By Chernoff's inequality, $\Pr(|\mathbf{S} \cap V| \ge 2c) \le 2^{-2c}$ holds for any $c > 2e$. The number of vector spaces in $\mathbb{F}^r$ of dimension $r/2$ does not exceed $\binom{r}{r/2} \le 2^r/\sqrt{r}$. We can therefore take $c = r/2$ and conclude that the set $\mathbf{S}$ intersects some $(r/2)$-dimensional vector space V in $2c = r$ or more elements with probability at most $2^{r-(\log r)/2-r} = r^{-1/2} = o(1)$. Hence, with probability $1 - o(1)$, the set $\mathbf{S}$ has cardinality at least $2^{r/2}$ and $|\mathbf{S} \cap V| < r$ for every $(r/2)$-dimensional vector space V. Fix such a set S' and take an arbitrary subset $S \subseteq S'$ of cardinality $|S| = 2^{r/2}$. By Lemma 4.1, neither H_S nor $\overline{H}_S$ contains a copy of $K_{r,r}$. □

Now we turn to the actual proof of Theorem 2.1.

Proof of Theorem 2.1. Let $S \subseteq \mathbb{F}^r$ be a subset of cardinality $|S| = n = 2^{r/2}$ guaranteed by Lemma 4.2. We may assume that $u \cdot v = 1$ holds for at least half of the pairs in S (otherwise take the bipartite complement of H_S). Hence, $H = H_S$ is a

bipartite $n \times n$ graph with $n = |S|$ vertices in each part and with $|H| \geq |S|^2/2 = n^2/2$ edges. Moreover, this graph contains no copy of $K_{r,r}$ where $r = 2 \log n$.

Now let G be the saturated extension of H. By removing the centers of complete stars, we obtain an *induced* star-free subgraph H' of H. Since the graph H has no copies of $K_{r,r}$, it can have at most $2(r-1)$ complete stars, implying that the resulting subgraph H' still has $|H'| \geq |H| - 2(r-1)n = \Omega(n^2)$ edges. Moreover, every circuit representing H must also represent H' because edges/nonedges of H' are also edges/nonedges of H (this is a property of *induced* subgraphs that is not shared by spanning subgraphs) and every circuit for H must correctly accept/reject them. Therefore, $C^1(f_G) \geq C^1(H) \geq C^1(H')$ where, by Lemma 3.13, $C^1(H') = \Omega(|H'|/r^3) = \Omega(n^2/\log^3 n)$. Hence, $C^1(f_G) = \Omega(n^2/\log^3 n)$.

To get an upper bound on $C(f_G)$, let us identify each vector $w \in S$ with the set of 1-coordinates of w. Hence, two vertices u and v are adjacent in H iff $|u \cap v|$ is odd. It is not difficult to verify that (for even r) the graph H can be represented by a depth-2 formula $F(X) = \bigoplus_{i=1}^{r} \bigvee_{w \in S_i} x_w$ with $S_i = \{w \in S : i \notin w\}$. Indeed, the ith clause $\bigvee_{w \in S_i} x_w$ accepts an arc $uv \in S \times S$ iff $u \in S_i$, or $v \in S_i$ iff $i \notin u \cap v$. Hence, the formula F accepts uv iff uv is accepted by an odd number of clauses iff $|\{i : i \notin u \cap v\}| = r - |u \cap v|$ is odd iff $|u \cap v|$ is odd iff $uv \in H$.

By Lemma 3.6, all $r = 2 \log n$ Boolean sums in the formula $F(X)$ above can be simultaneously computed by a circuit of linear (in n) size. Hence, the graph H can be represented by a linear size circuit over the basis $\{\vee, \wedge, \neg\}$ and, by Lemma 3.11, can be represented by a *monotone* circuit of linear size. Since G is the saturated extension of H, Lemma 3.8 implies that $C(f_G) = O(n)$. Hence, $\mathrm{Gap}(G) = C^1(f_G)/C(f_G) = \Omega\left(n/\log^3 n\right)$. □

5. Formulas: Proof of Theorem 2.2. Let G be the saturated extension of the bipartite Kneser $n \times n$ graph $K \subseteq U \times V$. Recall that in this case U and W consist of all $n = 2^r$ subsets u of $\{1, \ldots, r\}$, and $uv \in K$ iff $u \cap v = \emptyset$. Since $\log_2 3 > 1.58$, the graph K has $|K| = \sum_{u \in U} 2^{r-|u|} = 3^r \geq n^{3/2+c}$ edges with $c \geq 0.08$. Moreover, the graph K can contain a complete bipartite $a \times b$ subgraph $\emptyset \neq A \times B \subseteq K$ only if $a \leq 2^k$ and $b \leq 2^{r-k}$ for some $0 \leq k \leq r$, because then it must hold that $\left(\bigcup_{u \in A} u\right) \cap \left(\bigcup_{v \in B} v\right) = \emptyset$. Since $a \leq a'$ and $b \leq b'$ imply $(a+b)/ab \geq (a'+b')/a'b'$, we have $\mu(K) \geq (2^k + 2^{r-k})/2^r \geq 2^{-r/2} = n^{-1/2}$. By Lemma 3.12, $L^1(f_G) = \mathrm{cc_w}(G) \geq \mathrm{cc_w}(K) \geq \mu(K) \cdot |K| \geq n^{1+c}$.

On the other hand, by its definition the graph K admits an intersection representation of size r and, by Lemma 3.9, can be represented by a monotone CNF with $\mathrm{int}(K) \leq r = \log n$ clauses, and hence, by a monotone formula with $O(n \log n)$ fanin-2 AND and OR gates. Together with Lemma 3.8, this implies that $L(f_G) = O(n \log n)$. Hence, $\mathrm{Gap}_{\mathrm{form}}(G) = L^1(f_G)/L(f_G) = \Omega(n^c/\log n)$. □

6. Unbounded fanin circuits: Proof of Theorem 2.3. To prove the lower bound $C_*(f_G) \geq \mathrm{m}(G) + 1$ we use the communication complexity argument. By an observation due to Nisan (see [19] or [13, Lemma 11.2]), $C_*(f_G)$ is at least the deterministic two-party communication complexity of f_G under the worst-case partition of its input variables (this holds for arbitrary, not necessarily quadratic, functions and for arbitrary, not necessarily monotone, circuits). Now let M be an induced matching in G with $|M| = \mathrm{m}(G)$ edges. By setting to 0 all the variables corresponding to vertices outside this matching, we obtain that $C_*(f_G) \geq C_*(f_M)$ (recall that M is an *induced* subgraph of G). The function f_M itself has the form $f_M = \bigvee_{i=1}^{|M|} x_i y_i$, i.e., is

the negation of the set disjointedness function, and its deterministic communication complexity under the natural partition, where one player gets all x_i's and the other gets all y_i's, is well known to be $|M|+1$. Hence, $C_*(f_G) \geq C_*(f_M) \geq |M|+1 = \mathrm{m}(G)+1$.

For the proof of the second part of Theorem 2.3 we need the following fact. Let $\mathrm{cnf}(f_G)$ denote the minimum length of (i.e., the number of clauses in) a monotone CNF computing f_G.

LEMMA 6.1. *For every graph G of maximum degree d, $\mathrm{cnf}(f_G) \geq \tau(G)/d$.*

Proof. Let F be a monotone CNF of length $t = \mathrm{cnf}(f_G)$ computing f_G. Since f_G has no prime implicants of length 1 (by its definition (1.1)), this CNF must contain at least two clauses. Take any of these clauses $C = \bigvee_{u \in S} x_u$ and consider the shrunken CNF $F' = F \setminus \{C\}$. Since C must accept all edges of G, each of these edges must have at least one endpoint in S. Hence, S must be a vertex cover of G, implying that $|S| \geq \tau(G)$.

Since F is a shortest CNF computing f_G, the shrunken CNF F' must make an error; i.e., it must (wrongly) accept some independent set of G. That is, there must be an independent set I such that every clause of F' contains a variable x_v with $v \in I$. Since F' has only $t-1$ clauses, we may assume that $|I| \leq t-1$. This error must be corrected by the clause C, implying that every vertex $u \in S$ must be adjacent (in G) to at least one vertex in I, for otherwise F would wrongly accept the independent set $I \cup \{u\}$ of G. Hence, at least one vertex $v \in I$ must have at least $|S|/|I| \geq \tau(G)/t$ neighbors in S. Since the degree of v cannot exceed d, the desired lower bound $t \geq \tau(G)/d$ follows. □

Now take an arbitrary graph $G = (V, E)$ of maximum degree d, and let F be a smallest monotone Σ_3 circuit computing f_G. We first consider the case when F is a formula, i.e., all gates have fanout-1. This formula is an OR $F = F_1 \vee \cdots \vee F_s$ of monotone CNFs, and $\mathrm{size}(F) \geq \sum_{i=1}^{s} r_i$, where r_i is the length of the ith CNF F_i. The CNFs F_i, $i = 1, \ldots, s$, compute quadratic functions of subgraphs $G_i = (V, E_i)$ of G such that $E_1 \cup \cdots \cup E_s = E$. Note that $\tau(G) \leq \sum_{i=1}^{s} \tau(G_i)$. Since each of these subgraphs has maximum degree at most d, Lemma 6.1 implies that the entire formula F must have size at least $\sum_{i=1}^{s} r_i \geq \sum_{i=1}^{s} \tau(G_i)/d \geq \tau(G)/d$. If F is not a formula (i.e., some OR gates on the bottom level have fanout larger than 1), then we still have that $\mathrm{size}(F) \geq t = \max\{s, r_1, \ldots, r_s\}$. Take a CNF F_i for which $\tau(G_i) \geq \tau(G)/s$. By Lemma 6.1, F_i has length $r_i \geq \tau(G_i)/d \geq \tau(G)/sd$. Since both r_i and s do not exceed t, this yields $t^2 \geq \tau(G)/d$, and the desired lower bound $t \geq \sqrt{\tau(G)/d}$ on the number of gates in F follows. □

7. Multiplicative complexity: Proof of Theorem 2.4. Let G be the saturated extension of an n to n matching M. Then, by Lemma 3.12, $C^1_{\&}(f_G) = \mathrm{cc}(G) \geq \mathrm{cc}(M)/2 = n/2$. On the other hand, M can be represented by a monotone CNF of length $O(\log n)$. This follows from the more general Lemma 3.10, but can also be shown directly as follows (see [10]): Let $r = 2\log n$, and associate with each vertex u_i on the left side its *own* $(r/2)$-element subset A_i of $\{1, \ldots, r\}$, and assign to the unique matched vertex v_i on the right side the complement B_i of A_i. It is clear then that $A_i \cap B_j = \emptyset$ iff $i = j$. Hence, $\mathrm{cnf}(M) = \mathrm{int}(M) \leq r = 2\log n$. Together with Lemma 3.8, this implies that $C_{\&}(f_G) = O(\log n)$. Hence, $\mathrm{Gap}_{\mathrm{mult}}(G) = \Omega(n/\log n)$. □

8. Concluding remarks and open problems. As we mentioned in section 2, the unbounded fanin version of the single level conjecture is true for almost all graphs.

Better yet, Theorem 2.3 implies that the conjecture is true for all n-vertex graphs containing an induced matching with $\Omega(n)$ edges. Still, it seems very unlikely that the conjecture is true for all graphs.

PROBLEM 8.1. *Does there exist n-vertex graphs G of maximal degree d with $L_*(f_G) = o(\tau(G)/d)$ or $C_*(f_G) = o(\sqrt{\tau(G)/d})$?*

Another open problem is to prove *superlinear* lower bounds on the size of monotone (fanin-2) circuits computing explicit quadratic functions in n variables. For formulas (fanout-1 circuits) lower bounds $L(f_G) = \Omega(n^{3/2})$ can be proved using the rank argument [10]. However, the case of *circuits* is more complicated because (as mentioned in the introduction) known lower bounds for monotone circuits—the method of approximations due to Razborov [22] and its derivatives—cannot yield lower bounds larger than n.

PROBLEM 8.2. *Prove $C(f_G) \geq n^{1+\epsilon}$ for an explicit n-vertex graph G.*

What can be said about the single level conjecture in the context of graph representation, that is, if we consider circuits *representing* graphs G instead of circuits *computing* their quadratic functions f_G? For circuits with fanin-2 gates the question is already answered in section 4: the gap between single level and general circuits is $\Omega(n/\log^3 n)$ also in this context. But what about circuits with unbounded fanin gates? For a graph G, let $C_*(G)$ be the minimum size of a monotone unbounded fanin circuit representing G, and let $C^1_*(G)$ be the single level version of this measure. Note that, for some graphs G, circuits representing G may be exponentially smaller than circuits computing the quadratic function f_G. If, say, M_n is a matching with n edges, then $\mathrm{cnf}(M_n) = O(\log n)$ (by Lemma 3.10) but $C_*(f_{M_n}) = \Omega(n)$ (by Theorem 2.3). This also shows that, in the context of graph representation, Lemma 6.1 no longer holds.

PROBLEM 8.3 (Pudlák–Rödl–Savický [21]). *Prove that $C^1_*(G)$ may be much larger than $C_*(G)$.*

Easy counting shows that $C^1_*(G) = \Omega(n)$ for almost all n-vertex graphs. On the other hand, as mentioned in section 2, a lower bound $n^{\Omega(1)}$ for an explicit graph G would yield a superlinear lower bound for nonmonotone log-depth circuits. Actually, even a much more moderate lower bound $2^{\alpha\sqrt{\log n}}$ with $\alpha \to \infty$ would have interesting consequences (see [10]).

PROBLEM 8.4. *Prove $C^1_*(G) \geq 2^{\alpha\sqrt{\log n}}$ for an explicit n-vertex graph G.*

Although, as mentioned above, we already can prove lower bounds $L(f_G) = \Omega(n^{3/2})$ for some explicit graphs G, doing this for *saturated* graphs is a much more difficult task. Bloniarz [4] used counting arguments to show that $C(f_G) = \Omega(n^2/\log n)$ for almost all n-vertex graphs G; this remains true also in the class of saturated graphs. The problem, however, is the *explicitness*: we want a lower bound for explicitly constructed graphs. As mentioned in the introduction, a lower bound $C(f_G) \geq cn$ for a sufficiently large constant $c > 0$ would have great consequences in circuit complexity. A (potentially) less ambitious problem is to do this for formulas.

PROBLEM 8.5. *Exhibit an explicit saturated star-free graph on n-vertices with $L(f_G) = \Omega(n \log^k n)$.*

Since, by Observation 3.5, for such graphs we have the equality $L(G) = L(f_G)$, this would yield an explicit Boolean function in $m = \Theta(\log n)$ variables requiring nonmonotone formulas of size $\Omega(m^k)$ (see [10] for details).

Acknowledgments. I am grateful to Georg Schnitger and Ingo Wegener for interesting discussions, and to the referees for numerous and very helpful suggestions concerning the presentation.

RECONSTRUCTING CHROMOSOMAL EVOLUTION*

LI-SAN WANG† AND TANDY WARNOW‡

Abstract. Chromosomes evolve through genome rearrangement events, including inversions, transpositions, and inverted transpositions, that change the order and strandedness of genes within chromosomes. In this paper we present a method for estimating evolutionary histories for chromosomes based upon such events. The fundamental mathematical challenge of our approach is to estimate the *true evolutionary distance* between every pair of chromosomes, where the true evolutionary distance is the number of rearrangement events that took place in the evolutionary history between the chromosomes. We present two techniques, `Exact-` and `Approx-IEBP`, for estimating true evolutionary distances and prove guarantees about the accuracy of these techniques under a very general stochastic model of chromosomal evolution. We then show how we can use these estimated distances to obtain highly accurate estimates of chromosomal evolutionary history, significantly improving upon the previous best techniques.

Key words. phylogeny reconstruction, genome rearrangements, Markov chain, distance correction, neighbor joining, Nadeau–Taylor model, inversions, transpositions

1. Introduction.

Evolutionary tree reconstructions have for the most part been based upon analyses of biomolecular sequences evolving through *site substitutions* (also called *point mutations*). Yet, point mutations can accumulate quickly, and extensive research (both theoretical and experimental) has shown that when enough point mutations have occurred, existing approaches for estimating evolutionary histories will generally produce highly inaccurate trees [1, 8, 15, 19]. Thus, obtaining a good estimate of the evolutionary history of some datasets can be very difficult when using point mutations alone as the source of evolutionary signal.

In the last two decades, biologists have become increasingly interested in reconstructing evolution using large-scale features of whole chromosomes. The hope is that if the events that led these chromosomes to change were sufficiently rare, it might be possible to obtain better (i.e., more accurate) evolutionary history reconstructions through a proper analysis of these data.

Two of the more promising types of mutational events that have been considered by biologists are inversions and transpositions (defined later); these events affect chromosomes in two ways: they can *rearrange* the order of genes within chromosomes, and they can change the strand on which these genes appear. Since these events are much less frequent than point mutations, biologists were hopeful that evolutionary histories estimated using these rearrangement events might be more accurate than histories estimated from point mutations [24].

In this paper we show how to estimate evolutionary histories for chromosomes that have evolved under inversions and transpositions. Our approach is "distance-based," which means that we first estimate a matrix of "evolutionary distances" between every pair of chromosomes in the input and then apply a tree reconstruction method which uses distances (such as neighbor joining [25]). This is a standard approach in phylogenetics, and it has been used very successfully for phylogenetic analyses from molecular sequences. However, this approach requires a mathematical technique for estimating evolutionary distances.

Techniques for estimating evolutionary distances between chromosomes have been developed prior to this work, but all have been restricted to inversion-only evolution. For example, several polynomial time methods for computing the inversion distance (see [2, 10, 14]) have been developed. However, the inversion distance is an edit distance, and hence it may underestimate the actual number of events; that is, the actual transformation of one chromosome into another may not take the shortest path. Using the inversion distance as a proxy for the evolutionary distance can thus lead in turn to inaccurate phylogenies. In addition, Sankoff and Blanchette [26] developed a technique which enabled the estimation of evolutionary distances under inversion-only models of evolution; this technique, however, was never used in phylogeny reconstruction. No technique before this work has addressed the problem of estimating evolutionary distances between chromosomes when inversions and transpositions are both allowed.

This paper makes the following progress towards the challenge of estimating evolutionary histories for chromosomes:

- We present a statistical model of the evolutionary process which allows for inversions, transpositions, and inverted transpositions; this model generalizes the *Nadeau–Taylor* model [18], and thus is called the generalized Nadeau–Taylor (GNT) model.
- We present mathematical techniques for estimating evolutionary distances and prove theorems about the accuracy of these estimations under the GNT model.
- We present a simulation study evaluating the relative performance of our new distance estimators by comparison to earlier distance estimators, as well as evaluating the accuracy of phylogenies reconstructed by neighbor joining (the benchmark distance-based method) using different ways of estimating evolutionary distances. This study shows how our new distance estimation techniques dramatically improve upon the estimation of true evolutionary distances, and also improve the accuracy of phylogeny reconstruction from chromosomes when used with neighbor joining, by comparison to early distance estimation techniques.

The organization of this paper is as follows. We define our notation in section 2 and give an overview of our mathematical technique for estimating evolutionary distances in section 3. Fundamental to our estimation technique is the ability to compute the expected "breakpoint distance" produced by a sequence of k random events in the GNT model; techniques (both exact and approximate) for these computations are presented in sections 4 and 5. In section 6, we then show how to use these computations to estimate evolutionary distances under the GNT model from whole chromosomes; part of this requires that we establish theoretical results about the fast mixing of a Markov chain we define. We provide a simulation study in section 7, evaluating both the accuracy of new distance estimators in comparison to earlier techniques and how these new distance estimation techniques impact the accuracy of phylogenies estimated using the neighbor joining [25] method. We summarize our results in section 9.

2. Definitions.

2.1. Representations of chromosomes. The genomes of some organisms have a single chromosome or contain single chromosome organelles (such as mitochondria [4, 21] or chloroplasts [20, 23]). These chromosomes can be linear or circular, depending upon their type. Whether from gene maps or from whole chromosome sequencing projects, it is possible to obtain highly accurate information about the ordering and strandedness (since chromosomes are double-stranded) of the genes within the chromosome.

In this paper, we will explore evolutionary history reconstruction for single chromosome genomes, under the assumption that the chromosomes have evolved under inversions, transpositions, and inverted transpositions. Since genes are never lost or added under these processes, our inputs are sets of chromosomes in which each gene appears once in each chromosome.

We now describe how we can represent each chromosome as a signed permutation of the integers $1, 2, \ldots, n$, where there are n genes. We assign a number to the same gene in each chromosome, arbitrarily pick one strand out of each chromosome to be the positive orientation, and thus assign each gene either a positive or negative sign to indicate its strand. In this way, each chromosome can be represented by a signed permutation of $\{1, \ldots, n\}$. Note that this representation is not unique. Each linear chromosome can be represented in two ways, so that $(1, 2, \ldots, 9, 10)$ and $(-10, -9, \ldots, -2, -1)$ represent the same linear chromosome. To represent a circular permutation, we simply break the circular permutation at an arbitrary gene and pick one of the two directions to follow; thus, circular permutations admit many representations. For example, $(1, 2, 3), (2, 3, 1)$, and $(-1, -3, -2)$ are representations for the same circular chromosome. The *canonical representation* for a circular chromosome is obtained by having gene 1 at the first position in its positive sign. Thus, the first representation in the previous example is the canonical representation.

2.2. Chromosomal rearrangement events. We now define inversions, transpositions, and inverted transpositions. Starting with a chromosome $G = (g_1, g_2, \ldots, g_n)$ an *inversion* between indices a and b, $1 \leq a < b \leq n + 1$, produces the chromosome with linear ordering

$$(g_1, g_2, \ldots, g_{a-1}, -g_{b-1}, \ldots, -g_a, g_b, \ldots, g_n).$$

If $b < a$, we can still apply an inversion to a circular (but not linear) chromosome by simply rotating the circular ordering until g_a precedes g_b in the representation, since we consider all rotations of the complete circular ordering of a circular chromosome as equivalent.

A *transposition* on the (linear or circular) chromosome G acts on three indices, a, b, c, with $1 \leq a < b \leq n$ and $2 \leq c \leq n + 1$, $c \notin [a, b]$, and operates by picking up the interval $g_a, g_{a+1}, \ldots, g_{b-1}$ and inserting it immediately after g_{c-1}. Thus, the chromosome G above (with the additional assumption of $c > b$) is replaced by

$$(g_1, \ldots, g_{a-1}, g_b, g_{b+1}, \ldots, g_{c-1}, g_a, g_{a+1}, \ldots, g_{b-1}, g_c, \ldots, g_n).$$

An *inverted transposition* is the combination of a transposition and an inversion on the transposed substring so that G is replaced by

$$(g_1, \ldots, g_{a-1}, g_b, g_{b+1}, \ldots, g_{c-1}, -g_{b-1}, -g_{b-2}, \ldots, -g_a, g_c, \ldots, g_n).$$

Inversions, transpositions, and inverted transpositions are particular examples of *chromosomal rearrangements*, which are events that change the order and strandedness of genes within chromosomes. Thus, any function that maps signed gene orders

to signed gene orders on the same set of genes is a chromosomal rearrangement. We may also consider rearrangements that change the number of copies of each gene within a chromosome; such events include duplications, insertions, and deletions of strings. However, in this paper, we will be most interested in studying just inversions, transpositions, and inverted transpositions.

2.3. Breakpoint distances. A standard way of computing a distance between chromosomes is the *breakpoint distance* [3], which we now define. Let G and G' be two chromosomes on the same set of genes, and assume each gene appears exactly once in each of the two chromosomes. Two genes x and y are *adjacent* in chromosome G if x is immediately followed by y in G or, equivalently, if $-y$ is immediately followed by $-x$ (recall that chromosomes have several equivalent representations). We then define a *breakpoint* in G with respect to G' to be an ordered pair of signed genes (x, y) such that x and y are adjacent in G but are not adjacent in G'. Just as we consider chromosomes to have equivalent representations, we consider the ordered pair (x, y) to be equivalent to $(-y, -x)$. The *breakpoint distance* between two chromosomes G and G' is the number of nonequivalent breakpoints in G with respect to G'. Therefore, the breakpoint distance is a metric since it is the cardinality of the symmetric difference between two sets. In particular, it is a symmetric function: the number of breakpoints in G with respect to G' is the same as the number of breakpoints in G' with respect to G.

An example should make this clear. Let G and G' be circular chromosomes defined by $G = (1, 2, 3, 4)$ and $G' = (1, -3, -2, 4)$. There are two breakpoints in G' with respect to G, and these are $(1, -3)$ and $(-2, 4)$. There are also two breakpoints in G with respect to G', namely $(1, 2)$ and $(3, 4)$. Thus, the breakpoint distance between G and G' is two. Note also that the pair $(2, 3)$ is not a breakpoint in either chromosome with respect to the other chromosome.

We will let $d_{BP}(G, G')$ denote the breakpoint distance between G and G'.

2.4. The Nadeau–Taylor model. The Nadeau–Taylor model was introduced in [18] and was the first stochastic model of chromosome evolution. In the Nadeau–Taylor model there is a fixed binary evolutionary tree, and the ancestral chromosome (that is, the chromosome at the root of the tree) has a single copy of each gene. This chromosome evolves down the tree solely through inversions, and any two inversions are equiprobable. The number of inversions that takes place on an edge e is a random variable which is Poisson distributed with mean λ_e. (Note that λ_e depends upon the edge e, and so the expected number of inversions can differ between the different edges.) A Nadeau–Taylor model tree is fully specified by the chromosome at the root, the tree, and the parameters λ_e (one for each edge).

2.5. The generalized Nadeau–Taylor model. The *generalized Nadeau–Taylor (GNT) model* is obtained by generalizing the Nadeau–Taylor model [18] to allow for transpositions and inverted transpositions, in addition to inversions. As in the Nadeau–Taylor model, we assume that there is a fixed binary evolutionary tree T, and the ancestral chromosome has a single copy of each gene. In the GNT model, inversions, transpositions, and inverted transpositions can occur on each edge, but any two events of the same type (two inversions, two transpositions, or two inverted transpositions) are equiprobable. We fix the relative probabilities of the three types of events across the tree. Thus, we have three parameters w_I, w_T, and w_{IT}, which denote the probability that a rearrangement is an inversion, a transposition, and an

inverted transposition, respectively. Thus, $w_I + w_T + w_{IT} = 1$. As in the Nadeau–Taylor model, we assume the number of events on each edge e is Poisson distributed with mean λ_e. Thus, the tree T, the parameters λ_e on each edge, and the three parameters w_I, w_T, and w_{IT} define the model exactly. We let $GNT(w_I, w_T, w_{IT})$ denote the set of GNT model trees with the triplet (w_I, w_T, w_{IT}).

2.6. Additive distances and trees. Let T be a binary tree with leaves labeled $s_1, s_2, \ldots, s_m$. Assume that every edge e in T has a positive length w_e. Then the *additive distance* matrix corresponding to the edge-weighted tree (T, w) is

$$D_{ij} = \sum_{e \in P_{ij}} w(e),$$

where P_{ij} is the path in T between leaves s_i and s_j.

It is well known that given the matrix $[D_{ij}]$ it is possible to reconstruct T and its edge weights w_e but not the location of the root of T (so that only the unrooted underlying tree can be reconstructed from its additive distance matrix) [29]. In fact, given a matrix $[d_{ij}]$ such that $\max_{ij} |d_{ij} - D_{ij}| < f/2$, where $f = \min\{w_e : e \in E(T)\}$, the tree T (but not its edge weights) can be reconstructed exactly [1, 15].

2.7. True evolutionary distances. Let T be the true tree for a set of chromosomes, let e be any edge in T, and let k_e be the actual number of events (whether inversions, transpositions, or inverted transpositions) that took place on edge e. Then the matrix $D_{ij} = \sum_{e \in P_{ij}} k_e$ is the matrix of *true evolutionary distances*. By construction, the matrix of true evolutionary distances is additive, and thus defines the true evolutionary tree.

3. An overview of our technique for estimating true evolutionary distances. By construction, given the matrix of true evolutionary distances we can compute the true tree and the number of events on each edge of the tree in polynomial time. Furthermore, by our earlier discussion, given a bounded inaccurate estimation of true evolutionary distances, we can still compute the true tree in polynomial time. Because highly accurate estimations of true evolutionary distances enable accurate estimations of phylogenies, statisticians have developed techniques for estimating true evolutionary distances under various stochastic models of evolution (see [15, 17] for more on this). It is for this reason that we are interested in estimating true evolutionary distances for chromosomes that have evolved under the GNT model. We now describe our basic technique for estimating true evolutionary distances between chromosomes that have evolved under the GNT model.

Suppose we are given the triplet (w_I, w_T, w_{IT}) and a positive integer k. Let G be an arbitrary (but fixed) chromosome on genes $1, 2, \ldots, n$, and let G_k be the chromosome that is the result of applying k random events to G under the $GNT(w_I, w_T, w_{IT})$ model. Note that $d_{BP}(G, G_k)$ is a random variable that depends only upon n, k, and the triplet (w_I, w_T, w_{IT}). We will show that we can compute the expected value of this random variable (i.e., $E[d_{BP}(G, G_k)]$) in polynomial time, and we can also compute a highly accurate approximation of $E[d_{BP}(G, G_k)]$ somewhat faster. Once we have an estimate of this expected breakpoint distance, we can then estimate the true evolutionary distance between an arbitrary pair of chromosomes as follows.

We begin by making a simple but significant observation. Given any pair G, G' of chromosomes, we can always relabel the genes so that under this relabeling G becomes G_0 (the unrearranged chromosome) and G' becomes G''. Because all inversions (as well as transpositions and inverted transpositions) are equally likely, we

know $E[d_{BP}(G, G')]$ and $E[d_{BP}(G_0, G'')]$ will have the same distribution; this was first mentioned explicitly in [5]. In subsequent sections, we assume one of the two input chromosomes is always the unrearranged chromosome.

- *Input*: G and G', two chromosomes on n genes, and the triplet (w_I, w_T, w_{IT}).
- *Output*: An estimation of the actual number of events (inversions, transpositions, and inverted transpositions) that took place in the evolutionary history between G and G', under the $GNT(w_I, w_T, w_{IT})$ model.
- *Method*:
  - Compute the breakpoint distance $y = d_{BP}(G, G')$ between G and G'.
  - Return the integer k that minimizes $|E[d_{BP}(G, G_k)] - y|$.

Thus, our approach for estimating true evolutionary distances relies explicitly upon techniques for estimating (or computing exactly) the expected breakpoint distance produced by k random events under the $GNT(w_I, w_T, w_{IT})$ model. Our exact calculation for the expected breakpoint distance produced by k random events takes $O(kn^2)$ time for signed circular chromosomes and $O((k+n)n^4)$ time for signed linear chromosomes. We also provide an approximation algorithm for computing the expected breakpoint distance and prove that it has very low error; furthermore, it is a simple closed form formula which can be computed in constant time, and hence it is much faster than our exact algorithm. In addition, our approximation algorithm can be applied to circular/linear and signed/unsigned chromosomes easily, and thus is a more flexible analytical tool. Both techniques, therefore, are of interest.

4. Exact calculation of the expected breakpoint distance. We show how to calculate exactly the expected breakpoint distance produced by k random events in the $GNT(w_I, w_T, w_{IT})$ model. Here we will assume that we know the triplet (w_I, w_T, w_{IT}) and thus do not need to estimate this from the data. Later in the paper we will investigate the empirical performance of using our techniques for estimating evolutionary distances and examine the consequences of using incorrect values for the triplet. We will show that even under these conditions, the trees we obtain using these distance estimates will still improve significantly upon trees obtained using standard distance estimation techniques.

4.1. Preliminaries.

Circular chromosomes. Let $G_0 = (1, 2, \ldots, n)$ be the "unrearranged" chromosome of n genes at the beginning of the evolutionary process. For any $k \geq 1$, let $\rho_1, \rho_2, \ldots \rho_k$ be k random events drawn from the $GNT(w_I, w_T, w_{IT})$ model, and let $G_k = \rho_k \rho_{k-1} \cdots \rho_1 G_0$ (i.e., G_k is the result of applying these k rearrangements to G_0). We define the function $B_i(G), 1 \leq i \leq n-1$, by setting $B_i(G) = 0$ if G has the form $(\ldots, i, i+1, \ldots)$ after some rotation and/or flipping and $B_i(G) = 1$ if not; in other words, $B_i(G) = 1$ if and only if the unrearranged chromosome G_0 has a breakpoint between i and $i+1$ with respect to G. We also set $B_n(G)$ to reflect a breakpoint between n and 1; i.e., $B_n(G) = 0$ if and only if gene 1 follows gene n in G. Let $P_{i,k} = \Pr(B_i(G_k) = 1)$; then $E[d_{BP}(G_0, G_k)] = \sum_{i=1}^{n} P_{i,k}$.

Linear chromosomes. First, we modify the representation of the linear chromosome by adding "sentinel" genes 0 and $n+1$ at the beginning and end of the ancestral chromosome G_0; these sentinel genes exist just to make the discussion easier and are never moved during the evolution of the chromosome. Thus, every chromosome we consider will begin with gene 0 and end with gene $n+1$.

Given a linear chromosome $G = (g_0 = 0, g_1, g_2, \ldots, g_n, g_{n+1} = n+1)$, we define the function $B_i(G), 0 \leq i \leq n$, as we did for circular chromosomes; thus, $B_i(G) = 1$ if and only if the unrearranged chromosome G_0 has a breakpoint between i and $i+1$

with respect to G. We define $P_{i,k}$ identically as in the case of circular chromosomes and obtain $E[d_{BP}(G_0, G_k)] = \sum_{i=0}^{n} P_{i,k}$.

4.2. Calculating the expected breakpoint distance for inversion-only evolution (i.e., under the Nadeau–Taylor model). We begin by showing how the calculation proceeds when $w_I = 1$, so that only inversions occur. This calculation was first obtained by Sankoff and Blanchette in [26].

THEOREM 1 (see [26]). *Let* $\Pr((G_k)_i = h)$ *be the probability gene* h *(with the given sign) at the* ith *position after* k *random inversions. Then*

$$\Pr((G_k)_i = h) = \Pr((G_{k-1})_i = h)\left(1 - \binom{n}{2}^{-1}(i-1)(n+1-i)\right) + \binom{n}{2}^{-1}\sum_{j=2}^{n}(\Pr((G_{k-1})_j = h)\min\{i-1, n+1-j, j-1, n+1-j\}).$$

By setting $i = 2$ and $h = 2$, and using $\Pr((G_k)_2 \neq 2) = 1 - \Pr((G_k)_2) = 2)$, we can compute the probability that a breakpoint occurs between genes 1 and 2 after k random inversions for any $k \geq 0$.

4.3. Exact calculation of the expected breakpoint distance for circular chromosomes. The previous section presented a technique for calculating the expected breakpoint distance after k random equiprobable inversions. Here we show how to use the same idea in calculating the expected breakpoint after k random events in the GNT model for circular chromosomes. We begin with some notation.

Notation. Under the GNT model, $P_{i,k}$ has the same distribution for all i, $1 \leq i \leq n$, and so $E[d_{BP}(G_0, G_k)] = nP_{1,k}$. Therefore, we will focus on the breakpoint between genes 1 and 2. Let $\mathcal{G}_n^C$ be the set of all signed circular chromosomes with n genes, and let $W_n^C = \{\pm 1, \pm 2, \ldots, \pm(n-1)\}$.

The *state representation* $L(G)$ of chromosome G is an element of W_n^C defined as follows:

- In G, do genes 1 and 2 have the same sign? If the signs are the same, then $L(G) > 0$; otherwise, $L(G) < 0$.
- To determine $|L(G)|$, we transform G into the canonical representation (so gene 1 is at the first position with positive sign). Then $|L(G)|$ is one less than the position where gene 2 is found (either in its positive or negated form) in G.

For example, for the case where $G = (1, 3, 5, 4, -2, 6)$ we have $L(G) = -4$, since gene 2 appears (in its negated form) in position 5 in the canonical representation for G.

Since $P_{1,k}$ is the probability that $B_1 = 1$ (i.e., that there is a breakpoint between g_1 and g_2) after k random events, the sign and the position of gene 2 uniquely determine $P_{1,k}$. Hence, $\{L(G_k) : k \geq 0\}$ is a homogeneous Markov chain whose state space is W_n^C. We will use these states for indexing elements in the transition matrix and the distribution vectors. For example, if M is the transition matrix for $\{L(G_k) : k \geq 0\}$, then for all i, j in W_n^C, $M_{i,j}$ is the probability of jumping to state i from state j in one step in the Markov chain.

The transition matrix for signed circular chromosomes. Let R_I, R_T, and R_{IT} be the set of all inversions, transpositions, and inverted transpositions, respectively. For every rearrangement $\rho \in R_I \cup R_T \cup R_{IT}$, we construct the 0, 1-matrix M_ρ as follows:

- For every i and j in W_n^C, $(M_\rho)_{i,j} = 1$ if $L(G) = j$ implies $L(\rho G) = i$ (i.e., ρ corresponds to a transition from state j to state i).

We then let

$$M_I = \frac{1}{|R_I|} \sum_{\rho \in R_I} M_\rho,$$

$$M_T = \frac{1}{|R_T|} \sum_{\rho \in R_T} M_\rho,$$

and

$$M_{IT} = \frac{1}{|R_{IT}|} \sum_{\rho \in R_{IT}} M_\rho.$$

The transition matrix M for $\{L(G_k) : k \geq 0\}$ is therefore

$$M = (1 - w_T - w_{IT})M_I + w_T M_T + w_{IT} M_{IT}.$$

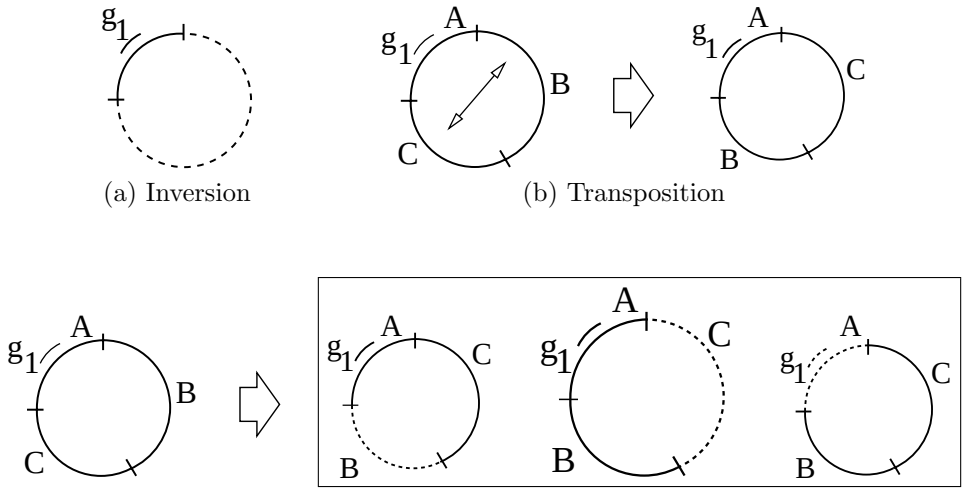
Let x_k be the distribution vector for $L(G_k)$. The following can then be easily established:

$$\begin{aligned} (x_0)_2 &= 1, \\ (x_0)_i &= 0, \quad i \in W_n^C,\ i \neq 2, \\ x_k &= M^k x_0, \\ E[d_{BP}(G_0, G_k)] &\triangleq nP_{1,k} = n(1 - (x_k)_2). \end{aligned}$$

Note that the result in Theorem 1 is just this result for the case in which only inversions occur, i.e., for which $w_I = 1$ and $w_T = w_{IT} = 0$.

We now derive closed-form formulas for the transition matrix M for the $GNT(w_I, w_T, w_{IT})$ model on signed circular chromosomes with n genes. Let $\binom{a}{b}$ denote the binomial coefficient, with $\binom{a}{b} = 0$ if $b > a$. First, consider the number of rearrangement events in each class:

1. *Inversions.* By symmetry of circular chromosomes and the model, each inversion has a corresponding inversion that inverts the complementary substring (the solid vs. the dotted arc in Figure 1(a)); thus we need only to consider the $\binom{n}{2}$ inversions that do not invert gene 1.
2. *Transpositions.* In Figure 1(b), given the three indices in a transposition, the chromosome is divided into three substrings, and the transposition swaps two substrings without changing the signs. Let the three substrings be A, B, and C, where A contains gene 1. A takes the form $(A_1, 1, A_2)$, where A_1 and A_2 may be empty. In the canonical representation there are only two possible unsigned permutations: $(1, A_2, B, C, A_1)$ and $(1, A_2, C, B, A_1)$. This means we need only to consider transpositions that swap the two substrings not containing gene 1.
3. *Inverted transpositions.* There are $3\binom{n}{3}$ inverted transpositions. In Figure 1(c), given the three endpoints in an inverted transposition, exactly one of the three substrings changes signs. Using the canonical representation, we interchange the two substrings that do not contain gene 1 and invert one of them (the first two chromosomes right of the arrow in Figure 1(c)), or we invert both substrings without swapping (the rightmost chromosome in Figure 1(c)).



(a) Inversion (b) Transposition

(c) Inverted transposition

FIG. 1. *The three types of rearrangement events in the GNT model on a signed circular chromosome.* (a) *We need only to consider inversions that do not invert gene* 1. (b) *A transposition corresponds to swapping two substrings.* (c) *The three types of inverted transpositions. Starting from the left chromosome, the three distinct results are shown here; the broken arc represents the substring being transposed and inverted.*

For all u and v in W_n^C, let $\iota_n(u,v)$, $\tau_n(u,v)$, and $\nu_n(u,v)$ be the numbers of inversions, transpositions, and inverted transpositions that bring a gene in state u to state v. Then

$$M_{u,v} = (1 - w_T - w_{IT})(M_I)_{u,v} + w_T(M_T)_{u,v} + w_{IT}(M_{IT})_{u,v}$$

$$= \frac{1 - w_T - w_{IT}}{\binom{n}{2}}\iota_n(u,v) + \frac{w_T}{\binom{n}{3}}\tau_n(u,v) + \frac{w_{IT}}{3\binom{n}{3}}\nu_n(u,v).$$

The following lemma gives formulas for $\iota_n(u,v)$, $\tau_n(u,v)$, and $\nu_n(u,v)$.

LEMMA 1. *For all u and v in W_n^C, let $\iota_n(u,v)$, $\tau_n(u,v)$, and $\nu_n(u,v)$ be the numbers of inversions, transpositions, and inverted transpositions that bring a gene in state u to state v (n is the number of genes in each chromosome). Then*

$$\text{(a) } \iota_n(u,v) = \begin{cases} \min\{|u|, |v|, n-|u|, n-|v|\} & \text{if } uv < 0, \\ 0 & \text{if } u \neq v, uv > 0, \\ \binom{|u|}{2} + \binom{n-|u|}{2} & \text{if } u = v, \end{cases}$$

$$\text{(b) } \tau_n(u,v) = \begin{cases} 0 & \text{if } uv < 0, \\ (\min\{|u|, |v|\})(n - \max\{|u|, |v|\}) & \text{if } u \neq v, uv > 0, \\ \binom{|u|}{3} + \binom{n-|u|}{3} & \text{if } u = v, \end{cases}$$

$$\text{(c) } \nu_n(u,v) = \begin{cases} (n-2)\iota_n(u,v) & \text{if } uv < 0, \\ \tau_n(u,v) & \text{if } u \neq v, uv > 0, \\ 3\tau_n(u,v) & \text{if } u = v. \end{cases}$$

Proof. The proof of (a) was provided in [26] and is omitted.

We now prove (b). Consider the gene with state u. Let v be the new state of that gene after the transposition with indices (a, b, c), $2 \le a < b < c \le n+1$. Since transpositions do not change the sign, $\tau_n(u, v) = \tau_n(-u, -v)$, and $\tau_n(u, v) = 0$ if $uv < 0$. Therefore we need only to analyze the case where $u, v > 0$.

We first analyze the case when $u = v$. Assume that either $a \le u < b$ or $b \le u < c$. In the first case, from the definition in section 2 we immediately have $v = u + (c - b)$, from which it follows that $v - u = c - b > 0$. In the second case, we have $v = u + (a - b)$, so that $v - u = a - b < 0$. Both cases contradict the assumption that $u = v$, and the only remaining possibilities that make $u = v$ are when $1 \le u = v < a - 1$ or $c - 1 \le u = v \le n - 1$. This leads to the third line in the $\tau_n(u, v)$ formula. Next, the total number of solutions (a, b, c) for the following two problems is $\tau_n(u, v)$ when $u \ne v$ and $u, v > 0$:

(i) $u < v : b = c - (v - u)$, $2 \le a \le u + 1 < b < c \le n + 1, u < v \le c$.

(ii) $u > v : b = a + (u - v)$, $2 \le a < b \le u + 1 < c \le n + 1, a \le v < u$.

In the first case $\tau_n(u, v) = u(n - v)$, and in the second case $\tau_n(u, v) = v(n - u)$. The second line in the $\tau_n(u, v)$ formula follows by combining the two results.

For inverted transpositions there are three distinct subclasses of rearrangement events. The result in (c) follows by applying the above method to the three cases. ∎

We now derive the running time for this exact method.

THEOREM 2. *It takes $O(kn^2)$ time to compute the expected breakpoint distance produced by k random events under the GNT model on circular chromosomes on n genes, using the exact technique.*

Proof. We first compute the $2(n-1) \times 2(n-1)$ transition matrices M_I, M_T, M_{IT} in $O(n^2)$ time using the closed-form formulas above (each entry takes $O(1)$ time). Computing M from the three matrices takes $O(n^2)$ time. Finally, computing the expected breakpoint distance requires k matrix-vector multiplications, which takes $O(kn^2)$ time. ∎

4.4. Exact calculation of the expected breakpoint distance for linear chromosomes. When the chromosomes are linear, different breakpoints will have different distributions. Thus, to compute the distribution of a given breakpoint, we will need to consider the positions and the signs of the genes involved at the same time. We begin with some notation.

Notation. Let $\mathcal{G}_n^L$ be the set of all signed linear chromosomes, and let $W_n^L = \{(u, v) : u, v = \pm 1, \ldots, \pm n, |u| \ne |v|\}$. We define the state representations $J_i : \mathcal{G}_n^L \to W_n^L$, $i = 1, \ldots, n-1$, as follows. For any chromosome $G \in \mathcal{G}_n^L$, $J_i(G) = (u, v)$, where

- $|u|$ is the position of gene i, and the sign of u is the same as that of gene i;
- $|v|$ is the position of gene $i + 1$, and the sign of v is the same as that of gene $i + 1$.

For example, in the chromosome $G = (1, 4, 2, 5, 6, -3, -7, 8)$ we have $J_3(G) = (-6, 2)$ (based on the positions and signs of genes 3 and 4), and $J_7(G) = (-7, 8)$ (based on the positions and signs of genes 7 and 8). Thus, by examining $J_i(G)$ we can determine if the genes i and $i + 1$ are "adjacent" (meaning that gene $i + 1$ *follows* gene i) in G; thus, genes i and $i + 1$ are adjacent if and only if $J_i(G_k) = (u, u + 1)$ for some integer u (note that u could be negative).

Therefore $\{J_i(G_k) : k \ge 0\}, 1 \le i \le n - 1$, forms a homogeneous Markov chain with state space W_n^L. As before we use the states in W_n^L as indices to the transition matrix and the distribution vectors.

Let $x_{\langle i,k\rangle}$ be the distribution vector of $J_i(G_k)$. For every rearrangement $\rho \in R_I, R_T$, and R_{IT}, the matrix M_ρ is defined as for circular chromosomes, with different dimensions. We let

$$M_I = \frac{1}{|R_I|} \sum_{\rho \in R_I} M_\rho,$$

$$M_T = \frac{1}{|R_T|} \sum_{\rho \in R_T} M_\rho,$$

and

$$M_{IT} = \frac{1}{|R_{IT}|} \sum_{\rho \in R_{IT}} M_\rho.$$

The transition matrix M for linear chromosomes has the same form as the transition matrix for circular chromosomes, i.e.,

$$M = (1 - w_T - w_{IT})M_I + w_T M_T + w_{IT} M_{IT}.$$

Let e be a vector where $e_{(u,v)} = 1$ whenever $v = u + 1$, and 0 otherwise. Then

$$e^T x_{\langle i,k\rangle} = \sum_{u=v+1} (x_{\langle i,k\rangle})_{(u,v)}$$

is the probability there is no breakpoint between genes i and $i+1$ in G_0 with respect to G_k. Therefore

$$\begin{aligned}
(x_{\langle i,0\rangle})_{(i,i+1)} &= 1, \\
(x_{\langle i,0\rangle})_{(u,v)} &= 0, \quad (u,v) \in W_n^L,\ (u,v) \neq (i,i+1), \\
x_{\langle i,k\rangle} &= M^k x_{\langle i,0\rangle}, \\
P_{i,k} &= 1 - e^T x_{\langle i,k\rangle} \ = \ 1 - e^T M^k x_{\langle i,0\rangle}.
\end{aligned}$$

Since the two sentinel genes 0 and $n+1$ never change their positions and signs, the distributions of the two breakpoints B_0 and B_n depend on the state of one gene each (1 and n, respectively). Hence we can use the results from circular chromosomes to estimate $P_{0,k}$ and $P_{n,k}$. Since these two quantities have the same distribution under the GNT model, the expected breakpoint distance after k events is

$$\begin{aligned}
E[d_{BP}(G_0, G_k)] &= \sum_{i=0}^{n} P_{i,k} = 2P_{0,k} + \sum_{i=1}^{n-1} P_{i,k} = 2P_{0,k} + \sum_{i=1}^{n-1} (1 - e^T M^k x_{\langle i,0\rangle}) \\
&= 2P_{0,k} + (n-1) - e^T M^k \sum_{i=1}^{n-1} x_{\langle i,0\rangle}. \qquad (1)
\end{aligned}$$

Constructing transition matrices. We do not have a simple closed-form formula to construct M_I, M_T, or M_{IT} as in the circular-chromosome case. Instead, we compute M_ρ for every rearrangement ρ and sum over them to obtain the three matrices according to their definition. We use the following lemma to simplify the computation.

LEMMA 2. *For every rearrangement ρ transforming $G_0 = (0, 1, 2, \ldots, n, n+1)$ into $G = (0, g_1, g_2, \ldots, g_n, n+1)$, we have $(M_\rho)_{(x,x'),(y,y')} = 1$ (i.e., ρ transforms state (y, y') into (x, x')) if*

1. *gene $|y|$ is the $|x|$th gene in G (g_1 is the first gene), and the sign of gene $|y|$ in G is the same as the sign of xy;*
2. *gene $|y'|$ is the $|x'|$th gene in G (g_1 is the first gene), and the sign of gene $|y'|$ in G is the same as the sign of $x'y'$.*

$(M_\rho)_{(x,x'),(y,y')} = 0$ otherwise.

Proof. Consider any chromosome G'. If $L_i(G') = (y, y')$, then gene i is at position $|y|$ having the same sign as the number y. Assume in ρG_0 that gene $|y|$ is at position $|x|$, and the sign of gene $|y|$ is the same as the sign of number x; this implies that gene i is in position $|x|$ in $\rho G'$. Moreover, gene i changes sign if and only if $x < 0$; so the sign of gene i is the same as xy. □

The lemma above provides us with an efficient algorithm for constructing M_I, M_T, and M_{IT}. We give the details in the next theorem.

THEOREM 3. *Assume the chromosome is linear with n distinct genes. It takes $O((k+n)n^4)$ time to compute the expected breakpoint distance produced by k random events under the GNT model, using the exact technique.*

Proof. By (1), we need to compute $M^k \sum_{i=1}^{n-1} x_{\langle i,0\rangle}$ and $P_{0,k}$. $P_{0,k}$ is easy because it is equal to $P_{1,k}$ for circular chromosomes. On the other hand, computing $M^k \sum_{i=1}^{n-1} x_{\langle i,0\rangle}$ means we have to compute M_I, M_T, and M_{IT}, for which we do not have simple closed-form formulas (unlike for the case of circular chromosomes). Moreover, the number of states (and the number of rows or columns for the transition matrix) is $O(n^2)$.

To compute M_I, M_T, and M_{IT}, we need only to apply every rearrangement to the unrearranged chromosome and check which entry is set to 1 for each column in the matrix. We use M_I as an example:

1. We first initialize every entry in M_I to 0.
2. For every inversion ρ, we apply it to the unrearranged chromosome G_0 to obtain $G = \rho G_0$ and do the following:
   (a) For each column with corresponding state (y, y'), we use the lemma above together with G to find the resulting state (x, x'); we then increase $(M_I)_{(x,x'),(y,y')}$ by 1.
3. We divide M_I by $\binom{n}{2}$ to obtain the final matrix.

We now analyze the running time for the algorithm above. Initializing M_I takes $O(n^4)$ time, since there are $2^2\binom{n}{2}$ distinct states. There are $\binom{n}{2}$ distinct inversions; for each inversion ρ, computing ρG_0 takes $O(n)$ time. Line 2(a) takes $O(n^2)$ time for each ρ, since there are $2^2\binom{n}{2}$ columns in M_I. So the total running time is $O(n^4 + \binom{n}{2} \times (n + 2^2\binom{n}{2})) = O(n^4)$. Similar arguments show the running times for constructing M_T and M_{IT} are both $O(n^5)$, since there are $O(n^3)$ distinct transpositions and inverted transpositions.

Computing $P_{0,k}$ and $P_{n,k}$ takes $O(kn^2)$ time using the circular-chromosome algorithm. To compute $P_{i,k}$, $1 \le i \le n-1$, we first compute M_I in $O(n^4)$ time and M_T and M_{IT} in $O(n^5)$ time. Computing $\sum_{i=1}^{n-1} x_{\langle i,0\rangle}$ takes $O(n^3)$ time. We then evaluate k matrix-vector multiplications to obtain $M^k \sum_{i=1}^{n-1} x_{\langle i,0\rangle}$; this step takes $O(kn^4)$ time. It then takes $O(n^2)$ time to obtain $E[d_{BP}(G_0, G_k)]$ from these results. □

Note that if only inversions are present, the running time becomes $O(kn^4)$.

5. Approximating the expected breakpoint distance.

5.1. Introduction. In this section we present a faster, but approximate rather than exact, technique, $\mathcal{F}_k$, for estimating the expected breakpoint distance produced by k random events under the GNT model. Our estimation is obtained through averaging tight lower and upper bounds, and we show the relative and absolute error of the approximation is small.

5.2. Extending the model. We use a model more general than the GNT model for the derivation to allow more general results for our approximation. We formulate this more general model as follows. A rearrangement class $\mathcal{E}$ acting on $\mathcal{G}_n$ (depending on the context of the problem, $\mathcal{G}_n$ can be either circular or linear) is a pair $(A(\mathcal{E}), f_{\mathcal{E}})$, where $A(\mathcal{E})$ is a set of rearrangements with nonzero probability of taking place, and $f_{\mathcal{E}}(\rho|G)$ is the probability that rearrangement ρ takes place on chromosome G, for a given $\rho \in A(\mathcal{E})$ and $G \in \mathcal{G}_n$. We say the random variable ρ is of rearrangement class $\mathcal{E}$ acting on chromosome G if ρ is in $A(\mathcal{E})$ and has distribution $f_{\mathcal{E}}(\rho|G)$.

Following the notation in section 2, we now present the derivation of our approximation algorithm. Assume the rearrangement to act on G is ρ. We recall the definitions of $B_i, 1 \le i \le n$, and $P_{i,k}$: $B_i(G) = 0$ if genes i and $i+1$ are adjacent in G_0 (with respect to G) and $B_i(G) = 1$ if not. G_k is the result of applying k random events to the unrearranged chromosome $(1, 2, \ldots, n)$. $P_{i,k}$ is defined to be $\Pr(B_i(G_k) = 1)$. Thus, $E[d_{BP}(G_0, G_k)] = \sum_{i=1}^{n} P_{i,k}$ for circular chromosomes and $E[d_{BP}(G_0, G_k)] = \sum_{i=0}^{n} P_{i,k}$ for linear chromosomes.

We make the following definitions:

- $s(i|G, \mathcal{E}) = \Pr(B_i(\rho G) = 1 \mid B_i(G) = 0)$,
- $u(i|G, \mathcal{E}) = \Pr(B_i(\rho G) = 0 \mid B_i(G) = 1)$,
- $\mathrm{Sep}(i|G, \mathcal{E}) = \{\rho \in A(\mathcal{E}) : B_i(\rho G) = 1\}$, and
- $\mathrm{Uni}(i|G, \mathcal{E}) = \{\rho \in A(\mathcal{E}) : B_i(\rho G) = 0\}$.

We focus on rearrangement classes $\mathcal{E}$ where $f_{\mathcal{E}}$ is independent of k and G, and $s(i|G, \mathcal{E})$ is independent of G. All three rearrangement classes in the GNT model, namely the class of random inversions, the class of random transpositions, and the class of random inverted transpositions, satisfy these requirements.

We now show the derivation and properties of our true evolutionary distance estimator. We start in section 5.3 with the simple case of rearrangement event classes where the breakpoints satisfy the Markov property and find the expected number of breakpoints after k random rearrangements. The result is extended in section 5.4, where the requirement on the Markov property is relaxed; the result is an approximation to the expected number of breakpoints. The error bounds on the approximation are shown in section 5.5. The main result is in section 5.6, where we develop the technique for rearrangement classes that are mixtures of other rearrangement classes. The technique is then applied to the GNT model of chromosome evolution in section 5.7.

5.3. Single rearrangement class models where the breakpoints satisfy the Markov property. We start with a simple case by considering any rearrangement class $\mathcal{E}$ for which $s(i|G, \mathcal{E})$ and $u(i|G, \mathcal{E})$ are independent of the past history and the current chromosome G to be acted upon. Then $\{B_i(G_k), k \ge 0\}$ is a Markov process (see Figure 2), as is shown in the following theorem.

THEOREM 4. *Assume $\mathcal{E}$ is a class of rearrangements such that $s(i|G, \mathcal{E})$ and $u(i|G, \mathcal{E})$ do not depend upon chromosome G. Let their common values be $s(i|\mathcal{E})$ and*

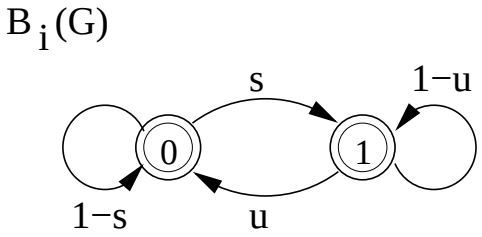


FIG. 2. *Each breakpoint can be regarded as a two-state stochastic process with two parameters s and u (see section 5.4).*

$u(i|\mathcal{E})$, *respectively. Then*

$$P_{i,k} = s(i|\mathcal{E}) \left(\frac{1 - (1 - s(i|\mathcal{E}) - u(i|\mathcal{E}))^k}{1 - (1 - s(i|\mathcal{E}) - u(i|\mathcal{E}))} \right).$$

Proof. We have the following recurrence:

$$\begin{aligned}
s(i|\mathcal{E}) &= \Pr(\rho_k \in \mathrm{Sep}(i|G_k, \mathcal{E}) \mid B_i(i|G_k) = 0) \\
&= \Pr(B_i(G_{k+1}) = 1 \mid B_i(G_k) = 0) \\
&= \frac{\Pr(B_i(G_{k+1}) = 1 \cap B_i(G_k) = 0)}{1 - P_{i,k}}, \\
u(i|\mathcal{E}) &= \Pr(\rho_k \in \mathrm{Uni}(i|G_k, \mathcal{E}) \mid B_i(G_k) = 1), \\
&= \Pr(B_i(G_{k+1}) = 0 \mid B_i(G_k) = 1) \\
&= \frac{\Pr(B_i(G_{k+1}) = 0 \cap B_i(G_k) = 1)}{P_{i,k}}, \\
P_{i,k+1} &= \Pr(B_1(G_{k+1}) = 1) = (1 - P_k)s(i|\mathcal{E}) + P_k(1 - u(i|\mathcal{E})), \\
&= P_k(1 - s(i|\mathcal{E}) - u(i|\mathcal{E})) + s(i|\mathcal{E}), \\
P_{i|0} &= 0.
\end{aligned}$$

The proof follows by solving the recurrence. □

COROLLARY 1. *Let G_k be the result of applying k random inversions to the unsigned linear chromosome G_0 having n genes. If G_k is linear,*

$$E[d_{BP}(G_0, G_k)] = (n-1)\left(1 - \left(\frac{n-3}{n-1}\right)^k\right),$$

and if G_k is circular,

$$E[d_{BP}(G_0, G_k)] = \frac{n(n-3)}{n-1}\left(1 - \left(\frac{n-4}{n-2}\right)^k\right).$$

Proof. The proof follows from Theorem 4, with parameters from Table 1. The linear case is originally in [5] with similar arguments, and the circular case is a simple extension. □

5.4. The lower and upper bounds technique for single rearrangement class models. For many other classes of rearrangements, the parameters regarding transitions of $B_i(G)$'s state depend not only on $B_i(G)$ but on other properties of G as

well. For example, the number of inversions that makes genes 1 and 2 adjacent depends on the number of genes between these two genes. However, for the rearrangement classes $\mathcal{E}$ where $s(i|G,\mathcal{E})$ does not depend on G, we can obtain upper and lower bounds on the expected number of breakpoints, as we now show.

Let $u_{min}(i|\mathcal{E})$ and $u_{max}(i|\mathcal{E})$ be the lower and upper bounds of $u(i|G,\mathcal{E})$ over all chromosomes G. Observe that a larger value of $u(i|G,\mathcal{E})$ means that genes i and $i+1$ are more likely to be made adjacent, given that they are currently not adjacent. This means $P_{i,k}$, the probability of having a breakpoint between gene i and $i+1$ after k rearrangements, is monotone decreasing on $u(i|G,\mathcal{E})$.

THEOREM 5. *Assume $\mathcal{E}$ is a class of rearrangements such that $s(i|\mathcal{E})$ is independent of the chromosome G currently acted upon. Let $u_{min}(i|\mathcal{E})$ and $u_{max}(i|\mathcal{E})$ be defined as in the previous paragraph. We have $P^L_{i,k} \le P_{i,k} \le P^H_{i,k}$ for all k, where*

$$P^L_{i,k} = s(i|\mathcal{E})\left(\frac{1-(1-s(i|\mathcal{E})-u_{max}(i|\mathcal{E}))^k}{1-(1-s(i|\mathcal{E})-u_{max}(i|\mathcal{E}))}\right),$$
$$P^H_{i,k} = s(i|\mathcal{E})\left(\frac{1-(1-s(i|\mathcal{E})-u_{min}(i|\mathcal{E}))^k}{1-(1-s(i|\mathcal{E})-u_{min}(i|\mathcal{E}))}\right).$$

Proof. The two recursions determined by $u_{min}(i|\mathcal{E})$ and $u_{max}(i|\mathcal{E})$ can be solved using Theorem 4. We prove the inequality bounding $P_{i,k}$ by $P^L_{i,k}$ and $P^H_{i,k}$ for all $k \ge 0$ by induction. When $k = 0$, all three quantities are 0, and so the base case holds. The induction step is as follows:

$$\begin{aligned} P^L_{i,k+1} &= P^L_{i,k}(1-s(i|\mathcal{E})-u_{max}(i|\mathcal{E})) + s(i|\mathcal{E}) \\ &\le P_{i,k}(1-s(i|\mathcal{E})-u(i|G_k,\mathcal{E})) + s(i|\mathcal{E}) = P_{i,k+1} \\ &\le P^H_{i,k}(1-s(i|\mathcal{E})-u_{min}(i|\mathcal{E})) + s(i|\mathcal{E}) = P^H_{i,k+1}. \end{aligned}$$ □

COROLLARY 2. *Given two random signed circular chromosomes G and G' on n genes, $n \ge 2$,*

$$E[d_{BP}(G,G')] = \frac{n(n-1.5)}{n-1}.$$

Proof. The expected breakpoint distance between two random chromosomes is the same as the breakpoint distance between an unrearranged chromosome G_0 and a random chromosome G. In the canonical representation, gene 1 is always positive and at the first position in both chromosomes.

Since G_0 is the unrearranged chromosome, $G_0 = (1, 2, \ldots, n)$; however, there are $2(n-1)$ equally probable choices regarding the sign and position of gene 2 in G. The probability of a breakpoint between genes 1 and 2 in G (with respect to G_0) is thus exactly $(2(n-1)-1)/(2(n-1)) = (n-1.5)/(n-1)$. The theorem follows since the other breakpoints $(i, i+1)$ have the same probability as $(1, 2)$. □

This result is apparently new; see [4] for a previous estimate, which this corrects.

DEFINITION 1. *Given any class of rearrangements $\mathcal{E}$ that satisfies the assumption in Theorem* 5, *we set*

$$\mathcal{F}_k = \sum_{i=0}^{n} \frac{P^L_{i,k} + P^H_{i,k}}{2}.$$

The function $\mathcal{F}_k$ is an approximation to the expected number of breakpoints after k random rearrangements drawn from $\mathcal{E}$.

Note that $\mathcal{F}_k$ is strictly monotone increasing with respect to k, since both $P^L_{i,k}$ and $P^H_{i,k}$ are strictly monotone increasing with respect to k. This observation guarantees that the integer k minimizing $|\mathcal{F}_k - x|$ is unique (up to a possible tie between two integers that differ by 1).

5.5. Error bounds on the technique using upper and lower bounds. In this section we bound the absolute and relative errors of the estimator $\mathcal{F}_k$ with respect to $E[d_{BP}(G_0, G_k)]$. Let

- $R^L_i = 1 - s(i|\mathcal{E}) - u_{max}(i|\mathcal{E})$, and
- $R^H_i = 1 - s(i|\mathcal{E}) - u_{min}(i|\mathcal{E})$.

Note $(R^L_i)^k \le (R^H_i)^k$ for all $k \ge 0$. We now bound the error of the estimator $\mathcal{F}_k$.

LEMMA 3.

$$\frac{1}{2}(P^H_{i,k} - P^L_{i,k}) \le \frac{u_{max}(i|\mathcal{E}) - u_{min}(i|\mathcal{E})}{2\ s(i|\mathcal{E})}.$$

Proof.

$$\frac{1}{2}(P^H_{i,k} - P^L_{i,k}) = \frac{1}{2}s(i|\mathcal{E})\left(\frac{1-(R^H_i)^k}{1-R^H_i} - \frac{1-(R^L_i)^k}{1-R^L_i}\right) = \frac{1}{2}s(i|\mathcal{E})\sum_{j=0}^{k-1}((R^H_i)^j - (R^L_i)^j)$$

$$\le \frac{1}{2}s(i|\mathcal{E})\sum_{j=0}^{\infty}((R^H_i)^j - (R^L_i)^j) = \frac{1}{2}s(i|\mathcal{E})\left(\frac{1}{1-R^H_i} - \frac{1}{1-R^L_i}\right)$$

$$= \frac{s(i|\mathcal{E})(u_{max}(i|\mathcal{E}) - u_{min}(i|\mathcal{E}))}{2(s(i|\mathcal{E}) + u_{min}(i|\mathcal{E}))(s(i|\mathcal{E}) + u_{max}(i|\mathcal{E}))}$$

$$\le \frac{u_{max}(i|\mathcal{E}) - u_{min}(i|\mathcal{E})}{2\ s(i|\mathcal{E})}. \qquad \square$$

THEOREM 6.

$$|\mathcal{F}_k - E[d_{BP}(G_0, G_k)]| \le \sum_{i=0}^{n} \frac{u_{max}(i|\mathcal{E}) - u_{min}(i|\mathcal{E})}{2s(i|\mathcal{E})} \quad \forall k \ge 0.$$

In addition, if $u_{max}(i|\mathcal{E})$ (and thus $u_{min}(i|\mathcal{E})$) is $O(s(i|\mathcal{E})/n)$, for all $i : 0 \le i \le n$ (as is the case for random inversions, transpositions, and inverted transpositions), then $|\mathcal{F}_k - E[d_{BP}(G_0, G_k)]| = O(1)$.

Proof. The error is at most one half of the maximum difference between $\sum_{i=0}^{n} P^H_{i,k}$ and $\sum_{i=0}^{n} P^L_{i,k}$; the result follows from Lemma 3.

When both $u_{min}(i|\mathcal{E})$ and $u_{max}(i|\mathcal{E})$ are $O(\frac{s(i|\mathcal{E})}{n})$, the error is at most

$$\sum_{i=0}^{n} \frac{u_{max}(i|\mathcal{E}) - u_{min}(i|\mathcal{E})}{2\ s(i|\mathcal{E})} = \sum_{i=0}^{n} O\left(\frac{1}{n}\right) = O(1). \qquad \square$$

THEOREM 7. *Let $s_l = \min_{0\le i\le n}\{s(i|\mathcal{E})\}$, $s_h = \max_{0\le i\le n}\{s(i|\mathcal{E})\}$, $r_l = \min_{0\le i\le n}\{s(i|\mathcal{E}) + u_{min}(i|\mathcal{E})\}$, and $r_h = \max_{0\le i\le n}\{s(i|\mathcal{E}) + u_{max}(i|\mathcal{E})\}$. For all $k \ge 1$,*

$$\frac{s_l r_l}{s_h r_h} \le \frac{\mathcal{F}_k}{E[d_{BP}(G_0, G_k)]} \le \frac{s_h r_h}{s_l r_l}.$$

In addition, if $s_h/s_l = 1 + \Theta(\frac{1}{n})$ and $u_{max}(i|\mathcal{E})$ (and thus $u_{min}(i|\mathcal{E})$) is $O(s(i|\mathcal{E})/n)$, for all $i : 0 \le i \le n$, then

$$\frac{\mathcal{F}_k}{E[d_{BP}(G_0, G_k)]} = 1 + O\left(\frac{1}{n}\right).$$

Proof. We prove only the upper bound, as the lower bound is the reciprocal of the upper bound and can be proved similarly. Let $w = 1 - r_l$ and $v = 1 - r_h$; we have $v \le w$, $1 - w^k \le 1 - v^k$, and

$$\frac{\mathcal{F}_k}{E[d_{BP}(G_0, G_k)]} = \frac{\sum_{i=0}^{n} P_{i,k}^H}{\sum_{i=0}^{n} P_{i,k}^L} \le \frac{\max\limits_{0 \le i \le n} P_{i,k}^H}{\min\limits_{0 \le i \le n} P_{i,k}^L} \le \frac{s_h(1 + w + w^2 + \cdots + w^{k-1})}{s_l(1 + v + v^2 + \cdots + v^{k-1})}$$

$$= \frac{s_h \dfrac{1 - w^k}{1 - w}}{s_l \dfrac{1 - v^k}{1 - v}} = \left(\frac{s_h(1 - v)}{s_l(1 - w)}\right)\left(\frac{1 - w^k}{1 - v^k}\right) \le \frac{s_h(1 - v)}{s_l(1 - w)} = \frac{s_h r_h}{s_l r_l}. \qquad \square$$

In Table 1 is a list of the parameters of the three rearrangement classes in the GNT model.

5.6. Upper and lower bounds estimation with multiple rearrangement classes. We can easily extend the results to a mixture of different rearrangement classes. Consider m classes of rearrangements, $\mathcal{E}_1, \ldots, \mathcal{E}_m$, where $\mathcal{E}_i = (A(\mathcal{E}_i), f_{\mathcal{E}_i}), 1 \le i \le m$. For any rearrangement ρ, let $\gamma_j = \Pr(\rho \in \mathcal{E}_j), 1 \le j \le m$. Assume γ_j does not depend on chromosome G, the chromosome currently acted upon. Let $s(i|\mathcal{E}_j)$, $u(i|G, \mathcal{E}_j)$, $u_{min}(i|\mathcal{E}_j)$, and $u_{max}(i|\mathcal{E}_j)$ be the parameters corresponding to $\mathcal{E}_j$ as defined in Theorem 5. Let $\mathcal{E} = (A(\mathcal{E}), f_{\mathcal{E}})$ be the rearrangement class such that $A(\mathcal{E}) = \cup_{j=1}^{m} A(\mathcal{E}_j)$, and $f_{\mathcal{E}}(r|G) = \sum_{j=1}^{m} \gamma_j \ f_{\mathcal{E}_j}(r|G)$. Then $\mathrm{Sep}(i|G, \mathcal{E}) = \cup_{j=1}^{m} \mathrm{Sep}(i|G, \mathcal{E}_j)$, and $\mathrm{Uni}(i|G, \mathcal{E}) = \cup_{j=1}^{m} \mathrm{Uni}(i|G, \mathcal{E}_j)$.

The hierarchical way of choosing rearrangements (first, choose rearrangement class, and then choose one rearrangement among others in the class chosen) during evolution allows two rearrangements in different rearrangement classes to produce the same results, while retaining the additivity of probability:

$$\begin{aligned}\Pr(\rho = \rho_0 | G = G_0) &= \sum_{j=1}^{m} \Pr(\rho = \rho_0 | G = G_0, \mathcal{E}_j \text{ is chosen}) \Pr(\mathcal{E}_j \text{ is chosen} | G = G_0) \\ &= \sum_{j=1}^{m} \gamma_j f_{\mathcal{E}_j}(\rho_0 | G_0).\end{aligned}$$

The new recurrence is

$$\begin{aligned}s(i|\mathcal{E}) = \Pr(B_i(G_{k+1}) = 1 | B_i(G_k) = 0) &= \Pr(\rho_k \in \mathrm{Sep}(i|G_k, \mathcal{E}) \mid B_i(G_k) = 0) \\ = \sum_{j=1}^{m} \Pr(\rho_k \in \mathrm{Sep}(i|G_k, \mathcal{E}_j) \mid B_i(G_k) = 0) &= \sum_{j=1}^{m} \gamma_j s(i|\mathcal{E}_j).\end{aligned}$$

Similarly,

$$\begin{aligned}u(i|G_k, \mathcal{E}) = \Pr(B_i(G_{k+1}) = 0 | B_i(G_k) = 1) &= \sum_{j=1}^{m} \gamma_j u_j(i|G_k, \mathcal{E}_j) \quad \forall k \ge 0, \\ u_{min}(i|\mathcal{E}) = \sum_{j=1}^{m} \gamma_j u_{min}(i|\mathcal{E}_j), \quad u_{max}(i|\mathcal{E}) &= \sum_{j=1}^{m} \gamma_j u_{max}(i|\mathcal{E}_j), \\ P_{i,k+1} &= (1 - P_{i,k}) s(i|\mathcal{E}) + P_{i,k}(1 - u(i|G_k, \mathcal{E})) \\ &= P_{i,k}(1 - s(i|\mathcal{E}) - u(i|G_k, \mathcal{E})) + s(i|\mathcal{E}), \\ P_{i|0} &= 0.\end{aligned}$$

TABLE 1

Recurrence parameters for rearrangement classes in the GNT model. The three rearrangement classes are inversion (Inv), transposition (Trp), and inverted transposition (ITrp). For circular chromosomes, $B_i(G_k)$ has the same distribution for $1 \leq i \leq n$, and $B_0(G_k)$ is always set to 0.

Results similar to Theorems 6 and 7 on error bounds can be obtained for multiple classes. Recall that we defined $\mathcal{F}_k = \sum_{i=0}^{n} \frac{P_{i,k}^L + P_{i,k}^H}{2}$.

THEOREM 8. *Consider the estimator $\mathcal{F}_k$ with the parameters $s(i|\mathcal{E})$, $u_{min}(i|\mathcal{E})$, and $u_{max}(i|\mathcal{E})$ given in the previous paragraphs. If the assumptions in Theorems 6 and 7 regarding these parameters are satisfied, then*

$$|\mathcal{F}_k - E[d_{BP}(G_0, G_k)]| = O(1)$$

and

$$\phi^{-1} \leq \frac{\mathcal{F}_k}{E[d_{BP}(G_0, G_k)]} \leq \phi,$$

where $\phi = 1 + O(\frac{1}{n})$.

Proof. The proof follows from Theorems 6 and 7. □

5.7. Approximating the breakpoint distance under the GNT model. We now show how to compute an approximation to the expected breakpoint distance under the $GNT(w_I, w_T, w_{IT})$ model. We use the notation defined in earlier sections (i.e., $\mathcal{F}_k$,$s(i)$, $u(i)$, $u_{min}(i)$, and $u_{max}(i)$) and provide the parameters for the upper and lower bounds technique in Table 2.

Recall that $\mathcal{F}_k = \sum_{i=0}^{n} \frac{P_{i,k}^L + P_{i,k}^H}{2}$. Under the GNT model we can tighten the error bounds for $\mathcal{F}_k$ obtained in Theorem 6 as follows.

THEOREM 9. *We assume the chromosomes evolve under the GNT model. For all $k > 0$,*

$$|\mathcal{F}_k - E[d_{BP}(G_0, G_k)]| \leq 1 + \frac{1}{n-1}$$

and

$$\phi^{-1} \leq \frac{\mathcal{F}_k}{E[d_{BP}(G_0, G_k)]} \leq \phi,$$

where $\phi = 1 + \frac{2+4w_T+2w_{IT}}{2+w_T+w_{IT}} n^{-1} + O(n^{-2})$.

Proof. The proof follows from Theorems 6 and 7 with parameters $s(i)$, $u_{min}(i)$, and $u_{max}(i)$. See Table 2 for details. The relative error bound can be obtained by examining $\frac{\sum_{i=0}^{n} P_{i,k}^H}{\sum_{i=1}^{n} P_{i,k}^L}$ directly. □

6. Estimating evolutionary distances under the GNT model. In the previous two sections we presented methods (one exact and one approximate) for estimating the expected breakpoint distance produced by a sequence of random events under the GNT model. In this section we show how to use those methods to estimate evolutionary distances under the GNT model.

Recall the discussion in the overview section, in which we described the basic technique for estimating evolutionary distances. We assumed we had a method for estimating the expected breakpoint distance produced by a sequence of k random events in the GNT model (denoted by $E[d_{BP}(G, G_k)]$) and that we knew the parameters of the model (i.e., the triplet (w_I, w_T, w_{IT})). Our technique was as follows:

- Compute the breakpoint distance $y = d_{BP}(G, G')$ between G and G'.
- Return the integer k that minimizes $|E[d_{BP}(G, G_k)] - y|$.

TABLE 2

Recurrence parameters and error bounds for the GNT model. The probabilities that a rearrangement is an inversion, a transposition, or an inverted transposition are $1 - w_T - w_{IT}$, w_T, and w_{IT}, respectively, for linear (Lin) or circular (Cir) chromosomes. For circular chromosomes, the parameters $s(n)$, $u_{min}(n)$, and $u_{max}(n)$ agree with those for $i = 1, \ldots, n-1$, and $B_0(G) = 0$ for all chromosomes G.

† See Theorems 7 and 9 for details. Only the upper bounds are shown here; the lower bounds are their reciprocals.

In the previous two sections we presented methods (one exact and one approximate) for estimating the expected breakpoint distance produced by k random events under the $GNT(w_I, w_T, w_{IT})$ model. Thus, each of these methods can be used in this general technique to estimate evolutionary distances under the GNT model. Since each involves inverting an expected breakpoint distance, we call these methods `Exact-IEBP` and `Approx-IEBP`. However, in order to precisely define these methods and compute their running time, we need to answer the following questions:

- For which values of k will we compute $E[d_{BP}(G, G_k)]$ (the expected breakpoint distance produced by k random events under the GNT model)?
- Given a set of these expected breakpoint distances, how do we find k minimizing $|E[d_{BP}(G, G_k)] - y|$?

We present the answers to these questions in this section. These answers will then let us prove our main theorem (Theorem 12), which shows that we can compute the pairwise `Exact-IEBP` distances of m circular chromosomes in $O(m^2n + \min\{m^2, n\} \log n + n^3 \log n)$ time, and $O(m^2n + \min\{m^2, n\} \log n + n^5 \log n)$ time if the chromosomes are linear, and we can compute the `Approx-IEBP` distances of all $\binom{m}{2}$ pairs of chromosomes in $O(m^2n + \min\{m^2, n\} \log n$ time for both linear and circular chromosomes. Thus, the `Approx-IEBP` method is much faster than the `Exact-IEBP` method for typical values of n and m that would be encountered in practice (where $n \gg m$ is likely). Since we will also establish that `Approx-IEBP` provides highly accurate estimates of evolutionary distances, and that phylogenies obtained using `Approx-IEBP` are comparable to phylogenies obtained using `Exact-IEBP`, `Approx-IEBP` is a competitive technique.

6.1. Fast mixing of the GNT model. Both the `Exact-IEBP` and the `Approx-IEBP` algorithms require a finite upper limit to the number of actual rearrangements allowed to occur on the chromosome. However, distance-based phylogeny reconstruction methods require finite entries in distance matrices, and so we need some upper bound on the estimated true evolutionary distance. This means we need only to compute $\mathcal{F}_i$ for all i up to the smallest k such that $E[d_{BP}(G_0, G_\infty)] - \mathcal{F}_k = o(1)$. Since the approximate expected breakpoint distance $\mathcal{F}_k$ in `Approx-IEBP` has absolute error $O(1)$, the upper limit for `Approx-IEBP` should be sufficient for `Exact-IEBP` as well.

Intuitively, the following question provides us with a reasonable upper limit: what is the number of rearrangements required for the resulting chromosome to be almost random? The answer was shown, for the inversion-only scenario, to be $\Theta(n \ln n)$ in [7].

THEOREM 10 (see [7]). *Assume we apply k random inversions to the linear unrearranged chromosome with n genes, $(1, 2, \ldots, n)$. Let P_k be the distribution of linear gene orders after k random inversions, and let $J_n = 2^n n!$ be the number of distinct linear gene orders with n genes. Let $D_k = \max_G |P_k(G) - \frac{1}{J_n}|$ be the total variational distance between P_k and the uniform distribution of gene orders. Then*

1. *if $c < 1/2$, then $\lim_{n\to\infty} D_{cn \ln n} = 1$;*
2. *if $c > 2$, then $\lim_{n\to\infty} D_{cn \ln n} = 0$.*

The result above is applicable only to the inversion-only scenario. Using results in the derivation for `Approx-IEBP`, we show in Theorem 11 that the upper limit our algorithms need is smaller than $2n \ln n$: when $k = \frac{1}{2+w_T+w_{IT}} n \ln n$, the expected breakpoint distance is already "saturated," in the sense the expected breakpoint distance reaches its maximum value.

We assume the chromosomes are signed and circular, and we fix (w_I, w_T, w_{IT}); then s, u_{min}, u_{max}, P_k^L, and P_k^H all are independent of the position of breakpoints. We set $\mathcal{F}_\infty = \lim_{k\to\infty} \mathcal{F}_k$. (More generally, given a definition for X_k, we set $X_\infty =$

$\lim_{k\to\infty} X_k$.)

LEMMA 4.

1. $\mathcal{F}_\infty = n(1 - \frac{u_{max}}{2(s+u_{max})})$.
2. *Let* $c = \frac{v}{2+w_T+w_{IT}} \ln n$ $(v > 1)$. *Then* $P^H_{cn} \geq 1 - \frac{1}{n^v}$.
3. *Let* $c = \frac{v}{3+w_T+w_{IT}} \ln n$ $(v > 1)$. *Then* $P^L_{cn} \geq (1 - \frac{u_{max}}{s+u_{max}})(1 - \frac{1}{n})$.

Proof.

1. We have

$$\begin{aligned} s &= \frac{2 + w_T + w_{IT}}{n}, \\ u_{min} &= 0, \\ u_{max} &= \frac{2(n-2) + 4w_T(n-2) + 2w_{IT}n}{n(n-1)(n-2)}. \end{aligned}$$

Since

$$\begin{aligned} P^H_k &= s\frac{1 - (1 - s - u_{min})^k}{1 - (1 - s - u_{min})}, \\ P^L_k &= s\frac{1 - (1 - s - u_{max})^k}{1 - (1 - s - u_{max})}. \end{aligned}$$

We have

$$\begin{aligned} P^H_\infty &= s\frac{1}{1 - (1 - s - u_{min})} = \frac{s}{s + u_{min}} = 1, \\ P^L_\infty &= s\frac{1}{1 - (1 - s - u_{max})} = \frac{s}{s + u_{max}} \\ \Rightarrow \mathcal{F}_\infty &= \frac{n}{2}\left(P^H_\infty + P^L_\infty\right) \\ &= \frac{n}{2}\left(\frac{2s + u_{max}}{s + u_{max}}\right) \\ &= n\left(1 - \frac{u_{max}}{2(s + u_{max})}\right). \end{aligned}$$

2.

$$\begin{aligned} P^H_{cn} &= 1 - (1 - s)^{cn} \\ &\geq 1 - \exp(-c(2 + w_T + w_{IT})) \\ &= 1 - \frac{1}{n^v}. \end{aligned}$$

3. We have

$$\begin{aligned} u_{max} &= \frac{2(n-2) + 4w_T(n-2) + 2w_{IT}n}{n(n-1)(n-2)} \leq \frac{2 + 4w_T + 2w_{IT}}{n(n-2)} \leq \frac{6}{n(n-2)}, \\ s + u_{max} &= \frac{2(n-2) + 4w_T(n-2) + 2w_{IT}n}{n(n-1)(n-2)} + \frac{2 + w_T + w_{IT}}{n} \leq \frac{3 + w_T + w_{IT}}{n}. \end{aligned}$$

So

$$(1 - (s + u_{max}))^{cn} \leq \exp(-cn(s + u_{max})) \leq \exp(-c(3 + w_T + w_{IT})).$$

The lemma follows:

$$\begin{aligned}
P_{cn}^{L} &= \frac{s}{s+u_{max}}\left(1-(1-s-u_{max})^{cn}\right)\\
&\geq \frac{s}{s+u_{max}}\left(1-\exp(-cn(s+u_{max}))\right)\\
&\geq \left(1-\frac{u_{max}}{s+u_{max}}\right)\left(1-\exp(-cn(s+u_{max}))\right)\\
&\geq \left(1-\frac{u_{max}}{s+u_{max}}\right)\left(1-\exp(-c(3+w_T+w_{IT}))\right)\\
&= \left(1-\frac{u_{max}}{s+u_{max}}\right)\left(1-\frac{1}{n^v}\right). \qquad \square
\end{aligned}$$

THEOREM 11. *Let* $k = \frac{vn}{2+w_T+w_{IT}}\ln n$ *(*$v > 1$*). Then* $\mathcal{F}_\infty - \mathcal{F}_{cn} \leq n^{1-v}$.

Proof.

$$\begin{aligned}
\mathcal{F}_k &= \frac{n}{2}(P_k^L + P_k^H)\\
&\geq \frac{n}{2}\left(1-\frac{1}{n^v}+\left(1-\frac{u_{max}}{s+u_{max}}\right)\left(1-\frac{1}{n^v}\right)\right)\\
&= \frac{n}{2}\left(1-\frac{1}{n^v}\right)\left(2-\frac{u_{max}}{s+u_{max}}\right)\\
&= \left(n-\frac{1}{n^{v-1}}\right)\left(1-\frac{u_{max}}{2(s+u_{max})}\right)\\
\Rightarrow \mathcal{F}_\infty - \mathcal{F}_k &\leq \frac{1}{n^{v-1}}\left(1-\frac{u_{max}}{2(s+u_{max})}\right) \leq n^{1-v}. \qquad \square
\end{aligned}$$

6.2. Running time analysis. We prove the following result regarding the running time.

THEOREM 12. *Let* S *be a set of* m *chromosomes, each on the same set of* n *genes, with each gene appearing once in each chromosome. If each chromosome in* S *is circular, then we can compute the* `Exact-IEBP` *distance matrix in* $O(m^2n + \min\{m^2, n\}\log n + n^3\log n)$ *time; if the chromosomes in* S *are each linear, then the* `Exact-IEBP` *distance matrix can be computed in* $O(m^2n+\min\{m^2, n\}\log n+n^5\log n)$ *time. For both linear and circular chromosomes, we can compute the* `Approx-IEBP` *distance matrix in* $O(m^2n + \min\{m^2, n\}\log n)$ *time.*

Proof. As shown in Theorem 11, we can assume that no more than $r = vn\ln n$ rearrangements occur in the evolutionary history. We will use this as an upper limit for the maximum number of rearrangement events, in order to obtain a faster algorithm for `Exact-IEBP` and `Approx-IEBP`.

We begin by deriving the running time for `Approx-IEBP`. For each pair of chromosomes we compute the breakpoint distance; this takes $O(m^2n)$ time. For each of the $\binom{m}{2}$ breakpoint distances that appears (of which there are at most $O(\min\{m^2, n\})$ distinct ones) we will need to compute the `Approx-IEBP` distance; this, we will show, can be done in $O(\min\{m^2, n\}\log n)$ time, yielding the desired result. Recall that $\mathcal{F}_k$ is the approximation of the expected breakpoint distance produced by k random events in the GNT model. For each k, the value k that minimizes $|\mathcal{F}_k - d_{BP}(G, G_k)|$ can be found in $O(\log r) = O(\log n)$ time using the binary search method; whenever a new $\mathcal{F}_k$ is required in the binary search, we compute it, which takes constant time.

To compute the `Exact-IEBP` distance matrix, we begin as with `Approx-IEBP`, by computing all pairwise breakpoint distances. We then compute the table of expected breakpoint distances after k events for every k between 1 and r. To do this, we compute Mx, $M^2x = M(Mx)$, up to M^rx, where M is the transition matrix and x is the distribution vector for G_0, the unrearranged chromosome. Then, for $k = 1$ to r, we compute $E[d_{BP}(G_0, G_k)]$ from M^kx in $O(1)$ time for each k. So the running time for building the table is dominated by r matrix-vector multiplications, which takes $O(rn^2)$ time for circular chromosomes and $O((r+n)n^4) = O(n^5 \log n)$ time for linear chromosomes. The table allows us to perform binary search in $O(\log n)$ time for each distinct breakpoint distance. □

7. Experiments. We studied four distance estimators with respect to estimating the evolutionary distances and with respect to their impact on phylogeny reconstruction. The four distance estimators we studied are

1. `BP`, the breakpoint distance between two chromosomes,
2. `INV`, the minimum number of inversions needed to transform one chromosome into another,
3. `Approx-IEBP`, and
4. `Exact-IEBP`.

7.1. Software. We use PAUP* 4.0 [27] to compute the neighbor joining (NJ) method and the topological error rate of the computed trees. We implemented a simulator [6] for the GNT model. The input consists of a rooted leaf-labeled tree and the associated parameters (i.e., edge lengths and the relative probabilities of inversions, transpositions, and inverted transpositions). On each edge, the simulator applies random rearrangement events to the circular chromosome at the ancestral node according to the model with given parameters w_T and w_{IT}. We use `tgen` [11] to generate random trees. These trees have topologies drawn from the uniform distribution, and edge lengths drawn from the discrete uniform distribution on intervals $[a, b]$, where we specify a and b.

7.2. Accuracy of the estimators. In this section we study the behavior of the `Exact-IEBP` and `Approx-IEBP` distances by comparing each to the actual number of rearrangement events. We simulate the GNT model on a circular chromosome with 37 genes (the typical number of genes in the animal mitochondrial chromosomes [4]) and 120 genes (the typical number of genes in the plant chloroplast chromosomes [13]). Starting with the unrearranged chromosome G_0, we apply k events to it to obtain the chromosome G_k for $k = 1, \ldots, 300$ when the number of genes is 120 and $k = 1, \ldots, 100$ when the number of genes is 37. For each value of k we simulate 500 runs. We then compute the four distances.

The simulation results are shown in Figures 3 and 4 for inversion-only evolution and Figure 5 when all three types of events are equiprobable. Note that both `BP` and `INV` distances underestimate the actual number of events (except for very small numbers of events) under all conditions. Note also that the error increases more rapidly with the number of events, when the model allows transpositions and inverted transpositions. When the number of genes increases, the standard deviations of both methods decrease. By contrast, `Approx-IEBP` and `Exact-IEBP` provide much better estimates of the true evolutionary distances.

We then compute the absolute error (that is, the difference between the measured distance and the actual number of events) for each of the distance estimators. Using

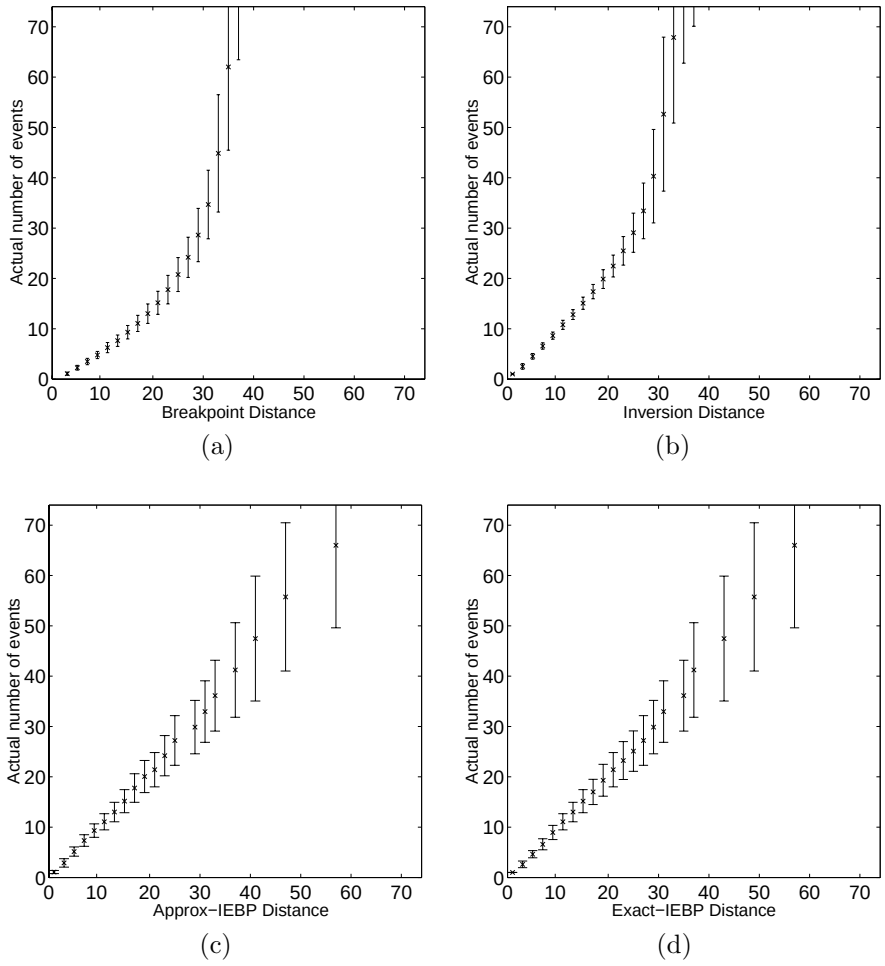

FIG. 3. *Accuracy of the estimators (see section* 7.2*). The number of genes is* 37 *(the typical value for mitochondrial chromosomes). Each plot is a comparison between some distance measures and the actual number of rearrangements. The evolutionary model is inversion-only. The x-axis is divided into* 25 *bins; the length of the vertical bars indicate the standard deviation. The distance estimators are* (a) *BP,* (b) *INV,* (c) *Approx-IEBP, and* (d) *Exact-IEBP.*

the same data in the previous experiment, we generate the plots as follows. The x-axis is the actual number of events. For each distance estimator D we plot the curve f_D, where $f_D(x)$ is the mean of the set $\{|\frac{1}{c}D(G_0, G_k) - k| : 1 \leq k \leq x\}$ over all observations G_k, where we pick a constant c for each distance estimator in order to reduce the bias. Thus, for example, we use $c = 1$ for the `Approx-IEBP` and the `Exact-IEBP` distances since they estimate the actual number of events. For the `BP` distance we let $c = 2(1 - w_T - w_{IT}) + 3(w_T + w_{IT}) = 2 + w_T + w_{IT}$ since this is the expected number of breakpoints created by each event in the model when the number of events is very low. Similarly for the `INV` distance we let $c = (1 - w_T - w_{IT}) + 3w_T + 2w_{IT} = 1 + 2w_T + w_{IT}$ since each transposition can be replaced by three inversions, and each inverted transposition can be replaced by two inversions.

The result is in Figure 6. We consistently observe that `Exact-IEBP` is the best, and that `INV` and `BP` are the worst, and the difference between `Exact-IEBP` and `BP` or `INV`

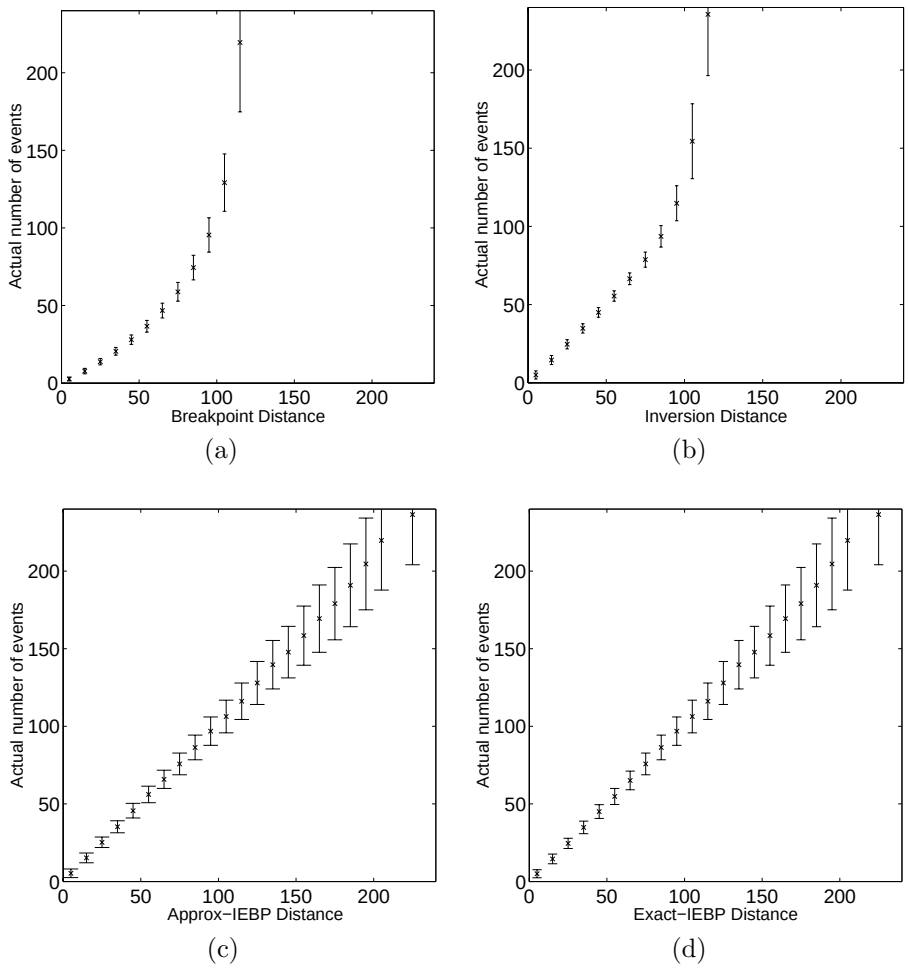

FIG. 4. *Accuracy of the estimators (see section* 7.2*). The number of genes is* 120 *(the typical value for chloroplast chromosomes). Each plot is a comparison between some distance measures and the actual number of rearrangements. The evolutionary model is inversion-only. The x-axis is divided into* 25 *bins; the length of the vertical bars indicate the standard deviation. The distance estimators are* (a) *BP,* (b) *INV,* (c) *Approx-IEBP, and* (d) *Exact-IEBP.*

is significant. The relative performance of `Approx-IEBP` is variable; in most cases it is a close second to `Exact-IEBP` (in most cases they are essentially indistinguishable), but in one case (transposition-only evolution on 37 genes) it is actually worse than all the methods for large numbers of events. Note also that all methods get worse with increasing numbers of events—accuracy is greatest for the smallest distances, with error increasing as the number of events increases.

7.3. Accuracy of NJ using different estimators. Based upon the relative performance of the distance estimators with respect to estimating true evolutionary distances, we would conjecture that phylogenies constructed using either `Approx-IEBP` or `Exact-IEBP` would be better than phylogenies constructed using either `BP` or `INV` and that, in general, phylogenies constructed using `Exact-IEBP` would be better than those constructed using `Approx-IEBP`. In this section we evaluate this conjecture. See Table 3 for the settings for the experiment.

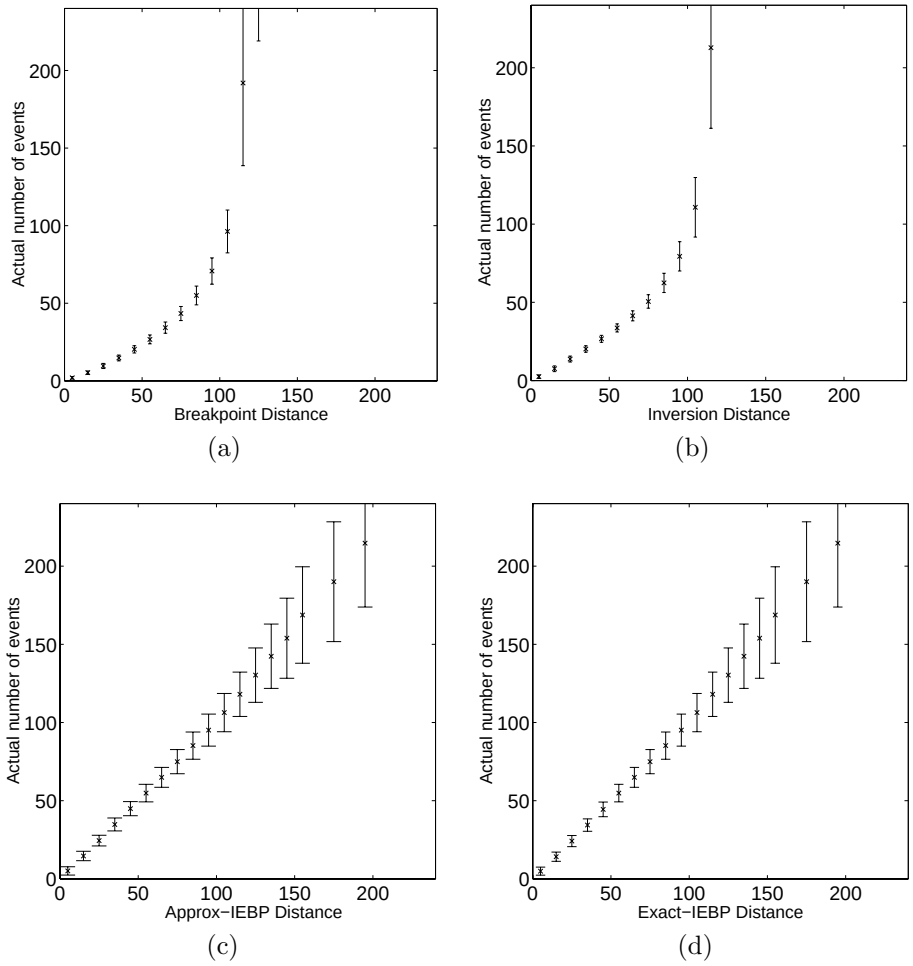

FIG. 5. *Accuracy of the estimators (see section* 7.2*). The number of genes is* 120 *(the typical value for chloroplast chromosomes). Each plot is a comparison between some distance measures and the actual number of rearrangements. The evolutionary model is such that the three types of rearrangement events are equiprobable ($w_I = w_T = w_{IT} = 1/3$). The x-axis is divided into* 25 *bins; the length of the vertical bars indicate the standard deviation. The distance estimators are* (a) `BP`, (b) `INV`, (c) `Approx-IEBP`, *and* (d) `Exact-IEBP`.

TABLE 3
Settings for the NJ performance simulation study.

Parameter	Value
1. Number of genes	37, 120
2. Number of leaves	160
3. Expected number of rearrangements in each edge	Discrete uniform within the following intervals: [1,3], [1,5], [1,10], [3,5], [3,10], and [5,10]
4. Probability settings: $(w_I, w_T, w_{IT})^\dagger$	(1,0,0) (Inversion only) $(0, 1, 0)$ (Transposition only) $(\frac{1}{3}, \frac{1}{3}, \frac{1}{3})$ (The three rearrangement classes are equally likely)
5. Datasets for each setting	100

† The probabilities that a rearrangement is an inversion, a transposition, or an inverted transposition are $1 - w_T - w_{IT}$, w_T, and w_{IT}, respectively.

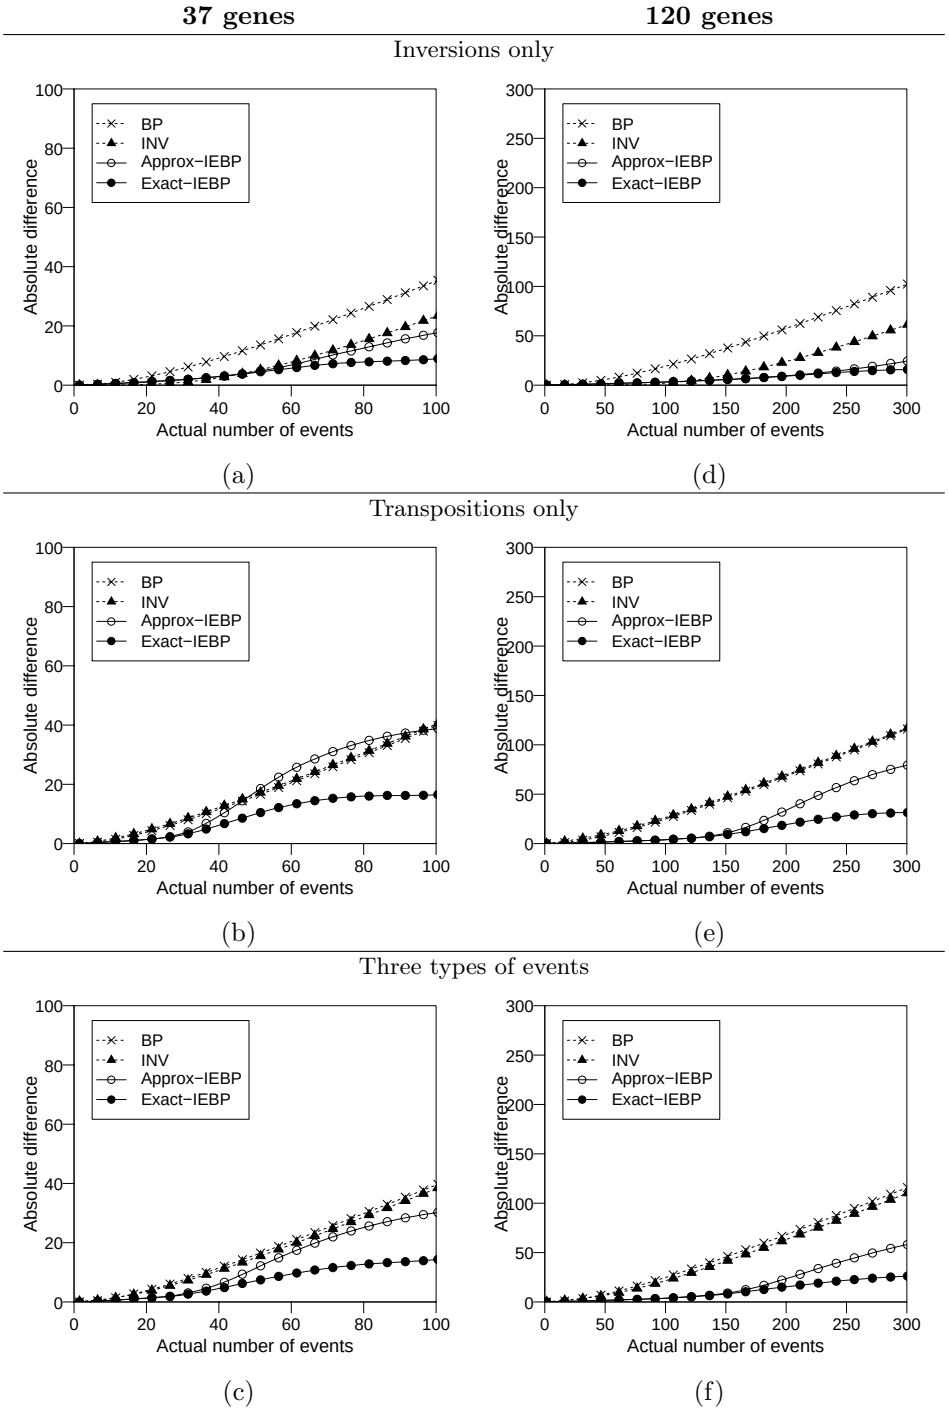

FIG. 6. *Accuracy of the estimators by absolute difference (see section* 7.2 *for the details). We simulate the evolution on* 37 *and* 120 *genes.*

We begin by defining the criteria by which we will evaluate the accuracy of the reconstructed trees.

Topological accuracy. During the evolutionary process, some edges of the model tree may have no changes (i.e., evolutionary events) on them. Since reconstructing such edges is at best guesswork, we are not interested in these edges. Hence, we define the "true tree" to be the tree that is obtained by *contracting* the edges in the model tree on which there are no changes [9, 16].

We now define how we score an inferred tree, by comparison to the true tree. Note that both trees are on the same set of leaves.

Let T be any tree on the set S of taxa, and let e be an edge in T. The removal of e (but not its endpoints) from T produces a bipartition π_e on the leaf set S. The set $C(T) = \{\pi_e : e \in E(T)\}$ is called the "character encoding" of T, and it uniquely identifies T (up to nodes of degree two). Now suppose that T_0 is the true tree and T_1 is the inferred tree. The *missing edges* are the edges in T_0 which do not correspond to bipartitions in $C(T_1)$; these are also referred to as *false negatives*. Note that the external edges (i.e., edges incident to a leaf) are trivial in the sense that they are present in every tree with the same set of leaves. Thus, the *false negative rate* is the number of false negatives, divided by the number of internal edges in T_0 (that set of internal edges is denoted by $E_I(T_0)$). In other words, the false negative rate is

$$FN(T_0, T_1) = \frac{|C(T_0) - C(T_1)|}{|E_I(T_0)|}.$$

Experimental setting. For each setting of the parameters (number of leaves, probabilities of rearrangements, and edge lengths), we generate 100 datasets of chromosomes as follows. First, we generate a random leaf-labeled tree (from the uniform distribution on topologies). The leaf-labeled tree and the parameter settings thus define a model tree in the GNT model. We run the simulator on the model tree and produce a set of chromosomes at the leaves.

For each set of chromosomes, we compute the four distances. We then compute NJ trees on each of the four distance matrices and compare the resultant trees to the true tree. The results of this experiment are in Figure 7. Distance matrices with some normalized edit distances equal to 1 are said to be "saturated"; it is well known that it is very difficult to obtain highly accurate phylogenies from datasets whose distance matrices are close to being saturated [12]. For this reason, we study the impact of the largest distance in the matrix on the accuracy of the phylogeny reconstructed for the data. Therefore, we bin the datasets according to their maximum distance, and we let the x-axis be the maximum normalized inversion distance (as computed by the linear time algorithm for minimum inversion distances given in [2]) between any two chromosomes in the input. The y-axis is the false negative rate (i.e., the proportion of missing edges) of the computed tree. False negative rates of less than 5% are excellent, but false negative rates of up to 10% can be tolerated.

We use NJ(D) to denote the tree returned by NJ using distance D; thus we have NJ(`BP`), NJ(`INV`), NJ(`Approx-IEBP`), and NJ(`Exact-IEBP`).

Observations. We begin with some general observations. First, under all conditions (number of genes and evolutionary model), for each of the distance estimator techniques, the topological error of the NJ trees increases with the diameter of the dataset; this is consistent with the observation made earlier that errors in estimating distances increase with the number of events. Second, independent largely of the evolutionary model and the distance estimator, trees reconstructed on 120 genes are

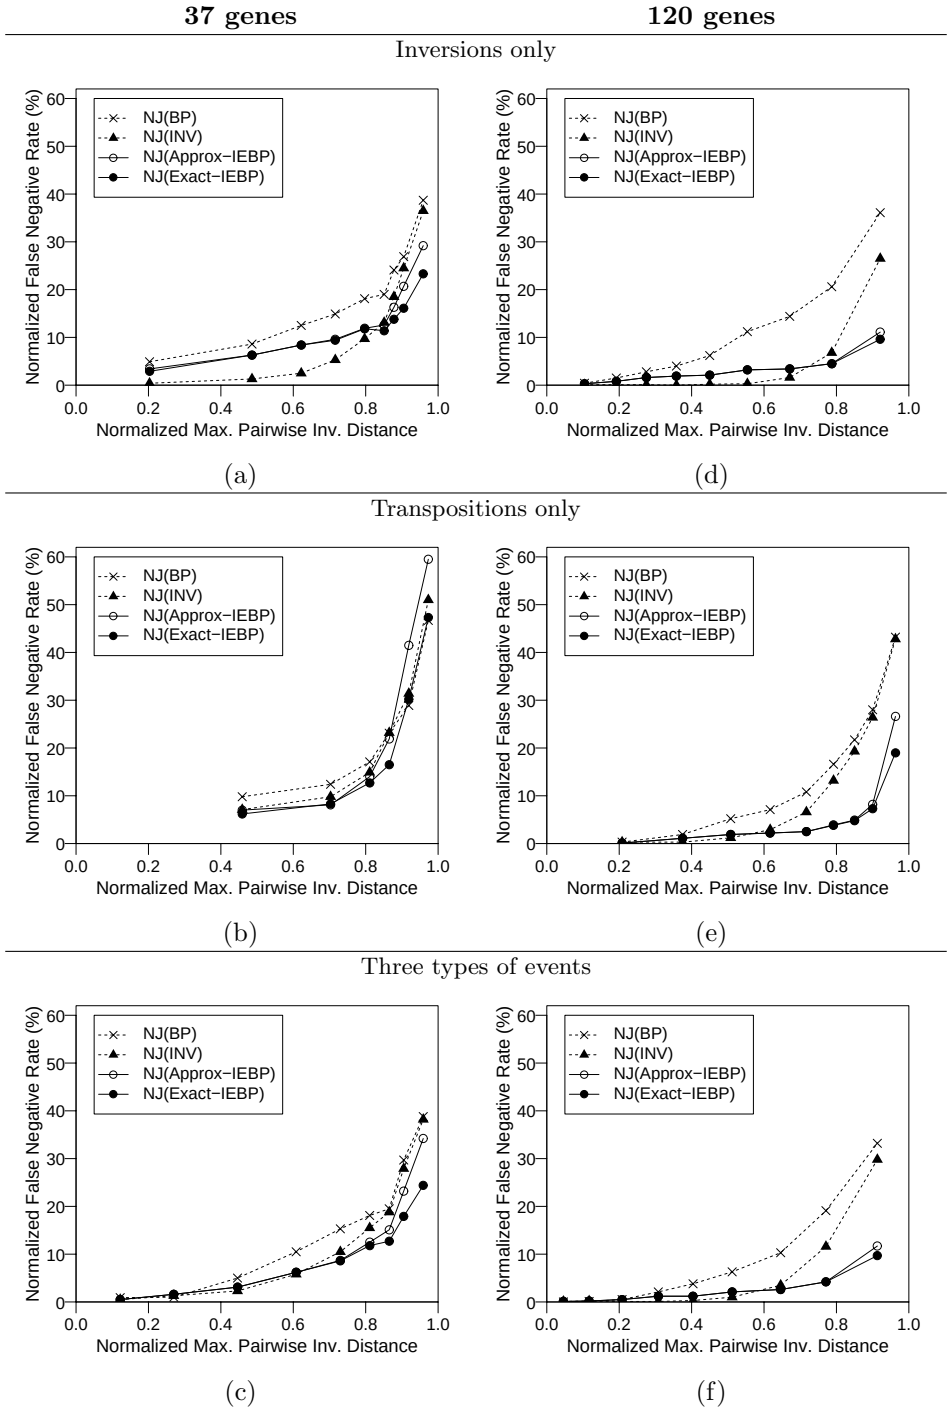

FIG. 7. *NJ performance under several distances (see section* 7.3*). See Table* 3 *for the settings in the experiment.*

more accurate than trees reconstructed on 37 genes, once the diameter is fixed (this observation fails only for high diameter datasets analyzed using BP). Also, NJ(BP) provides the worst trees, and (except for inversion-only evolution, as we will discuss below) NJ(Exact-IEBP) provides the best trees.

Trends specific to the number of genes, or the model of evolution, are as follows. First, inversion-only evolution is generally most accurately reconstructed using INV distances, rather than our new estimators; however, once the diameter of the dataset is large enough, our new estimators provide better phylogenies than INV. On datasets with 120 genes, there is very little difference between Exact-IEBP and Approx-IEBP, and both (except for very low diameter datasets) produce significantly better trees than BP or INV.

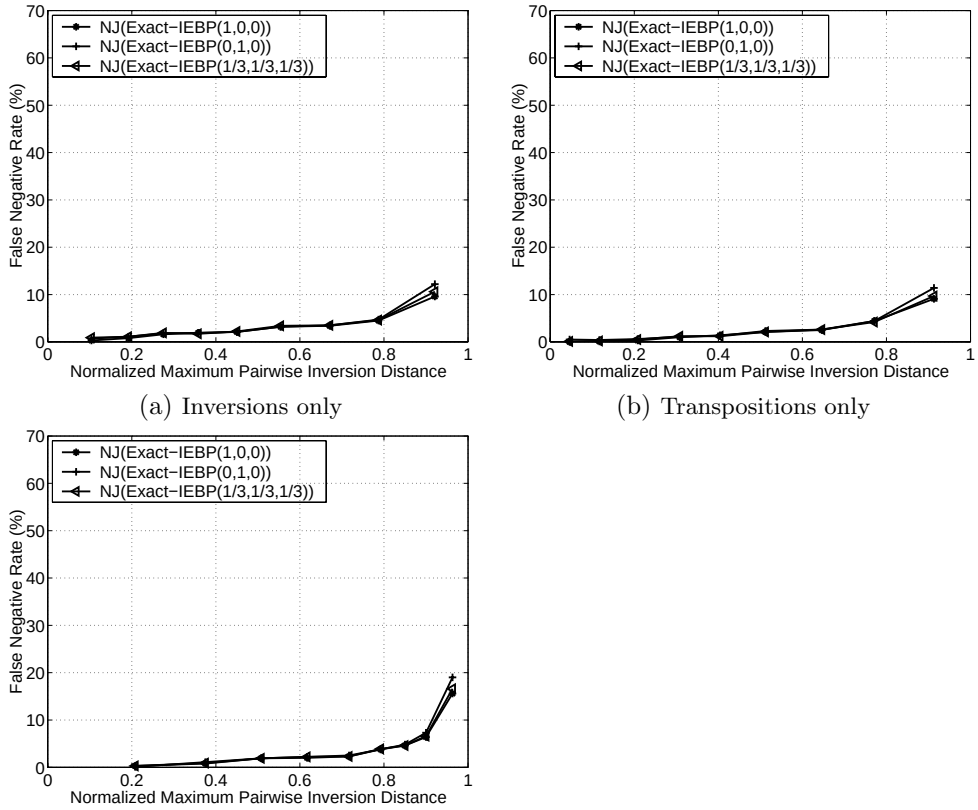
7.4. Robustness to unknown model parameters. In this section we consider the problem where the model parameters (w_I, w_T, w_{IT}) are unknown when using Exact-IEBP and Approx-IEBP, as will in general be the case in any real data analysis. Though it may be possible to estimate these parameters from the data, we will approach the problem here by assuming that the parameters are simply incorrectly specified: thus, the data evolve under one model (perhaps inversion-only), but distances are estimated under the assumption of another model (perhaps transposition-only). We will examine the consequences of these incorrect assumptions on the phylogenies reconstructed using these distances.

We explore this question for NJ(Exact-IEBP) in Figure 8; for the study of NJ(Approx-IEBP), see [28], which shows comparable robustness. The settings are given in Table 3. The experiment is similar to the previous experiment, except here we use both the correct and the incorrect values of (w_I, w_T, w_{IT}) for the Exact-IEBP distance. Note that all the constructed trees, whether using correct or highly incorrect model parameters, are indistinguishable with respect to topological error, showing that NJ(Exact-IEBP) is highly robust against errors in (w_I, w_T, w_{IT}).

8. Extension to other models. Approx-IEBP is applicable to rearrangement models that are more general than the GNT model, as long as the probability a rearrangement occurs depends on the rearrangement itself but not on the chromosome it acts upon.

For example, Pinter and Skiena proposed an inversion-only stochastic model of chromosomal evolution in [22] which assumes that the probability of an inversion depends only on its length (the number of genes being inverted) and that any two inversions with the same length are equiprobable. Our method can be used to estimate true evolutionary distances under this model, since this model is a mixture where we put all inversions of the same length into the same class.

9. Conclusion. We presented two polynomial time algorithms, Exact-IEBP and Approx-IEBP, for estimating the actual number of rearrangements that have taken place in the evolutionary history between two chromosomes that have evolved under the GNT model. Exact-IEBP uses exact estimates of the expected breakpoint distance under the GNT model, while Approx-IEBP uses approximate estimates but can be easily applied to more general models and is much faster. Thus, these techniques provide the only general purpose polynomial time methods for computing evolutionary distances between chromosomes that have evolved under inversions, transpositions, and inverted transpositions. We demonstrated the impact of these tools on phylogenetic reconstruction through the simulation study we presented, showing that many more



(a) Inversions only

(b) Transpositions only

(c) Three types of events equally likely

FIG. 8. *Robustness of the* `Exact-IEBP` *method to incorrectly specified parameters (see section* 7.4*). See Table* 3 *for the settings in the experiment. The three values in the legend are the* w_I*,* w_T*, and* w_{IT} *values used in the* `Exact-IEBP` *method, where* w_I*,* w_T*, and* w_{IT} *are the probabilities that a rearrangement event is an inversion, a transposition, or an inverted transposition.*

accurate trees can be reconstructed using these two estimators than using previously defined estimators, including the polynomial time inversion or breakpoint distances.

FAST MONTE CARLO ALGORITHMS FOR MATRICES I: APPROXIMATING MATRIX MULTIPLICATION*

PETROS DRINEAS†, RAVI KANNAN‡, AND MICHAEL W. MAHONEY§

Abstract. Motivated by applications in which the data may be formulated as a matrix, we consider algorithms for several common linear algebra problems. These algorithms make more efficient use of computational resources, such as the computation time, random access memory (RAM), and the number of passes over the data, than do previously known algorithms for these problems. In this paper, we devise two algorithms for the matrix multiplication problem. Suppose A and B (which are $m \times n$ and $n \times p$, respectively) are the two input matrices. In our main algorithm, we perform c independent trials, where in each trial we randomly sample an element of $\{1, 2, \ldots, n\}$ with an appropriate probability distribution $\mathcal{P}$ on $\{1, 2, \ldots, n\}$. We form an $m \times c$ matrix C consisting of the sampled columns of A, each scaled appropriately, and we form a $c \times n$ matrix R using the corresponding rows of B, again scaled appropriately. The choice of $\mathcal{P}$ and the column and row scaling are crucial features of the algorithm. When these are chosen judiciously, we show that CR is a good approximation to AB. More precisely, we show that

$$\|AB - CR\|_F = O(\|A\|_F \|B\|_F / \sqrt{c}),$$

where $\|\cdot\|_F$ denotes the Frobenius norm, i.e., $\|A\|_F^2 = \sum_{i,j} A_{ij}^2$. This algorithm can be implemented without storing the matrices A and B in RAM, provided it can make two passes over the matrices stored in external memory and use $O(c(m+n+p))$ additional RAM to construct C and R. We then present a second matrix multiplication algorithm which is similar in spirit to our main algorithm. In addition, we present a model (the pass-efficient model) in which the efficiency of these and other approximate matrix algorithms may be studied and which we argue is well suited to many applications involving massive data sets. In this model, the scarce computational resources are the number of passes over the data and the additional space and time required by the algorithm. The input matrices may be presented in any order of the entries (and not just row or column order), as is the case in many applications where, e.g., the data has been written in by multiple agents. In addition, the input matrices may be presented in a sparse representation, where only the nonzero entries are written.

1. Introduction.

We are interested in developing and analyzing fast Monte Carlo algorithms for performing useful computations on large matrices. Examples of such computations include matrix multiplication, the computation of the singular value decomposition of a matrix, and the computation of compressed approximate decompositions of a matrix. In this paper, we present a computational model for computing on massive data sets (the pass-efficient model) in which our algorithms

may naturally be formulated; we also present two algorithms for the approximation of the product of two matrices. In a second paper we present two algorithms for the computation of low-rank approximations to a matrix [11]. Finally, in a third paper we present two algorithms to compute a compressed approximate decomposition to a matrix that has several appealing properties [12]. We expect our algorithms to be useful in many applications where data sets are modeled by matrices and are extremely large. For example, in information retrieval and data mining (two rapidly growing areas of research in computer science and scientific computation that build on techniques and theories from fields such as statistics, linear algebra, database theory, pattern recognition, and learning theory) a large collection of m objects, e.g., documents, genomes, images, or web pages, is implicitly presented as a set of points in an n-dimensional Euclidean space, where n is the number of features that describe the object. This collection may be represented by an $m \times n$ matrix A, the rows of which are the object vectors and the columns of which are the feature vectors.

Recent interest in computing with massive data sets has led to the development of computational models in which the usual notions of time efficiency and space efficiency have been modified [23, 19, 3, 14, 10, 5]. In the applications that motivate these data-streaming models [19, 5], e.g., the observational sciences and the monitoring and operation of large networked systems, the data sets are much too large to fit into main memory. Thus, they are either not stored or are stored in a secondary storage device which may be read sequentially as a data stream but for which random access is very expensive. Typically, algorithms that compute on a data stream examine the data stream, keep a small "sketch" of the data, and perform computations on the sketch. Thus, these algorithms are usually randomized and approximate, and their performance is evaluated by considering resources such as the time to process an item in the data stream, the number of passes over the data, the additional workspace and additional time required, and the quality of the approximations returned. (Note that in some cases the term "data-streaming model" refers to a model in which only a single pass over the data is allowed [19, 5].)

The motivation for our particular "pass-efficient" approach is that in modern computers the amount of external memory (e.g., disk storage or tape storage) has increased enormously, while RAM and computing speeds have increased, but at a substantially slower pace. Thus, we have the ability to store large amounts of data, but not in RAM, and we do not have the computational ability to process these data with algorithms that require superlinear time. A related motivation is that input-output rates have not increased proportionally. Thus, the size of the data inputs (as limited, e.g., by the size of disks) has increased substantially faster than the rate at which we can access the data randomly.

In order to provide a framework in which to view the algorithms presented herein, we first introduce and describe the pass-efficient model of data-streaming computation [10]. In the pass-efficient model the computational resources are the number of sequential-access passes over the data and the additional RAM space and the additional time required. Thus, our algorithms are quite different from traditional numerical analysis approaches and generally fit within the following framework. Our algorithms will be allowed to read the matrices from external storage a few—e.g., one or two or three—times and keep a small randomly chosen and rapidly computable "sketch" of the matrices in RAM. Our algorithms will also be permitted additional RAM space and additional time in order to perform computations on the "sketch." The results of these computations will be returned as approximations to the solution of the original problem.

In all of our algorithms, an important implementation issue will be how to form the random sample. An obvious choice is to use uniform sampling, where each data object is equally likely to be picked. Uniform sampling can be performed blindly, in which case the sample to be chosen can be decided before seeing the data. Even when the number of data elements is not known in advance an element can be selected uniformly at random in one pass over the data; see Lemma 1. Uniform sampling fits within our framework and is useful for certain (restricted) classes of problems. To obtain much more generality, we will sample according to a judiciously chosen (and data-dependent) set of nonuniform sampling probabilities. This nonuniform sampling, in which in the first pass through the data we compute sampling probabilities (e.g., we may keep rows or columns of a data matrix with probability proportional to the square of their lengths) and in the second pass we draw the sample, offers substantial gains. For example, it allows us to approximately solve problems in sparse matrices as well as dense matrices.

The idea of sampling rows or columns of matrices in order to approximate various operations is not new; indeed, a motivation for our main matrix multiplication algorithm came from [15]. In this paper and accompanying work [11, 12], we extend those ideas and develop algorithms with provable error bounds for a variety of matrix operations. One of the main contributions of our work is to demonstrate that a "sketch" consisting of a small judiciously chosen random sample of rows and/or columns of the input matrix or matrices is adequate for provably rapid and efficient approximation of several common matrix operations. We believe that the underlying principle of using nonuniform sampling to create "sketches" of the data in a small number of passes (and "pass-efficient" approaches more generally) constitutes an appealing and fruitful direction for algorithmic research in order to address the size and nature of modern data sets.

In the present paper, we present two simple and intuitive algorithms which, when given an $m \times n$ matrix A and an $n \times p$ matrix B, compute an approximation to the product AB. In the first algorithm, the BasicMatrixMultiplication algorithm of section 4, we perform c independent trials, where in each trial we randomly sample an element of $\{1, 2, \ldots, n\}$ with an appropriate probability distribution $\mathcal{P}$ on $\{1, 2, \ldots, n\}$. We form an $m \times c$ matrix C consisting of the sampled columns of A, each scaled appropriately, and we form a $c \times n$ matrix R using the corresponding rows of B, again scaled appropriately. The choice of $\mathcal{P}$ and the column and row scaling are crucial features of the algorithm. When these are chosen judiciously, we show that CR is a good approximation to AB. More precisely, we show that

$$\|AB - CR\|_F = O(\|A\|_F \|B\|_F / \sqrt{c}),$$

where $\|\cdot\|_F$ denotes the Frobenius norm, i.e., $\|A\|_F^2 = \sum_{i,j} A_{ij}^2$, holds in expectation and with high probability. Thus, in particular, when $B = A^T$ we have that if $c = \Omega(1/\epsilon^2)$, then $\|AA^T - CC^T\|_F \leq \epsilon \|A\|_F^2$ holds with high probability. This algorithm can be implemented without storing the matrices A and B in RAM, provided it can make two passes over the matrices stored in external memory and use $O(c(m+n+p))$ additional RAM; thus it will be efficient in the pass-efficient model.

In the second algorithm, the ElementwiseMatrixMultiplication algorithm of section 5, which is an extension of ideas from [2, 1], elements of A and B, rather than columns and rows, are randomly either zeroed out or kept and rescaled, thereby constructing matrices $\tilde{A}$ and $\tilde{B}$. Although this algorithm lacks a useful bound on

$\|AB - \tilde{A}\tilde{B}\|_F$, under appropriate assumptions a bound on the spectral norm of the form

$$\|AB - \tilde{A}\tilde{B}\|_2 = O(\|A\|_F \|B\|_F / \sqrt{c})$$

holds with high probability.

After this introduction, we provide in section 2 a review of the relevant linear algebra, and in section 3 we introduce the pass-efficient model of data-streaming computation and discuss several technical sampling lemmas. In section 4 we introduce and analyze in detail the BasicMatrixMultiplication algorithm to approximate the product of two matrices. Then, in section 5 we describe and analyze the ElementwiseMatrixMultiplication algorithm which is based on the ideas of [2, 1]. Finally, in section 6 we provide a discussion and conclusion. In the appendix, we provide further analysis of the BasicMatrixMultiplication algorithm.

2. Review of linear algebra. This section contains a review of some linear algebra that will be useful throughout the paper. For more detail, see [18, 20, 25, 6] and the references therein.

For a vector $x \in \mathbb{R}^n$ we let $|x| = \left(\sum_{i=1}^n |x_i|^2\right)^{1/2}$ denote its Euclidean length. For a matrix $A \in \mathbb{R}^{m \times n}$ we let $A^{(j)}$, $j = 1, \ldots, n$, denote the jth column of A as a column vector and $A_{(i)}$, $i = 1, \ldots, m$, denote the ith row of A as a row vector. We denote matrix norms by $\|A\|_\xi$, using subscripts to distinguish between various norms. Of particular interest will be the Frobenius norm which is defined by

$$\|A\|_F = \sqrt{\sum_{i=1}^m \sum_{j=1}^n A_{ij}^2}, \tag{1}$$

and the spectral norm which is defined by

$$\|A\|_2 = \sup_{x \in \mathbb{R}^n,\ x \neq 0} \frac{|Ax|}{|x|}. \tag{2}$$

These norms are related to each other as $\|A\|_2 \leq \|A\|_F \leq \sqrt{n}\,\|A\|_2$.

3. The pass-efficient model and sampling lemmas. In this section, we informally define a computational model in which the computational resources are the number of passes over the data and the additional space and additional time required. In addition, we present several technical sampling lemmas.

3.1. The pass-efficient model. The pass-efficient model of data-streaming computation is a model that is motivated by the observation that in modern computers the amount of disk storage, i.e., sequential access memory, has increased very rapidly while random access memory (RAM) and computing speeds have increased at a substantially slower pace [10]. Thus, one has the ability to store very large amounts of data but does not have random access to the data. Additionally, processing the data with algorithms that take low polynomial time or linear time with large constants is prohibitive.

To model this phenomenon, we consider the pass-efficient model, in which the three computational resources of interest are the number of passes over the data and the additional space and time required [10]. The data are assumed to be stored in an external disk space, to consist of elements whose size is bounded by a constant, and to be presented to an algorithm on a read-only tape. The only access an algorithm has

to the data is via a pass, where a *pass* over the data is a sequential read of the entire input from disk where only a constant amount of processing time is permitted per bit read. Note that this is a more restrictive notion of a pass over the data than in other data-streaming models [23, 19, 14]; in particular, in the pass-efficient model only a constant rather than a logarithmic (in the data input length) amount of computation is permitted per bit read. In addition to the external disk space to store the data and to a small number of passes over the data, an algorithm in the pass-efficient model is permitted to use *additional RAM space* and *additional computation time*. An algorithm operating in this model is considered *pass-efficient* if it requires a fixed number of passes, independent of the input size, and additional space and time which are sublinear in the length of the data stream in order to compute a "description" of the solution, which is then returned by the algorithm. A *description* of the solution is either an explicit solution (if that is possible within the specified additional space and time) or an implicit representation of the solution that can be computed in the allotted additional space and time, and that can be expanded into an explicit solution with the additional expense of one pass over the data and linear (in the data input length) additional space and time. Note that, depending on the application, this last step may or may not be necessary. Note also that if the data are represented by an $m \times n$ matrix, then the data stream has length $O(mn)$ and an algorithm which uses additional space and time that is linear in the number of data points or in the dimensionality of the data points, i.e., that is $O(m)$ or $O(n)$, is sublinear in the length of the data stream and thus is pass-efficient. We will be primarily interested in models that require additional space and time that is either $O(m+n)$ or constant with respect to m and n.

The *sparse-unordered representation* of data is a form of data representation in which each element of the data stream consists of a pair $((i, j), A_{ij})$ where the elements in the data stream may be unordered with respect to the indices (i, j), and only the nonzero elements of the matrix A need to be presented. This very general form is suited to applications where, e.g., multiple agents may write parts of a matrix to a central database and where one cannot make assumptions about the rules for write-conflict resolution. The data stream read by algorithms in the pass-efficient model is assumed to be presented in the *sparse-unordered representation*. Other related methods of data representation have been studied within the data-streaming context; see, e.g., [17] for applications to the problem of dynamic histogram maintenance.

3.2. Sampling lemmas. In this section we present two sampling primitives that will be used by our algorithms. Consider the SELECT algorithm presented in Figure 1. The following lemma establishes that in one pass over the data one can sample an element according to certain probability distributions.

LEMMA 1. *Suppose that* $\{a_1, \ldots, a_n\}$, $a_i \geq 0$, *are read in one pass, i.e., one sequential read over the data, by the* SELECT *algorithm. Then the* SELECT *algorithm requires* $O(1)$, *i.e., constant with respect to* n, *additional storage space and returns a random* i^* *sampled from the probability distribution* $\mathbf{Pr}[i^* = i] = a_i / \sum_{i'=1}^{n} a_{i'}$.

Proof. First, note that retaining the selected value and the running sum requires $O(1)$ additional space. The remainder of the proof is by induction. After reading the first element a_1, $i^* = 1$ with probability $a_1/a_1 = 1$. Let $D_\ell = \sum_{i'=1}^{\ell} a_{i'}$ and suppose that the algorithm has read $a_1, \ldots, a_\ell$ thus far and has retained the running sum D_ℓ and a sample i^* such that $\mathbf{Pr}[i^* = i] = a_i/D_\ell$. Upon reading $a_{\ell+1}$ the algorithm lets $i^* = \ell + 1$ with probability $a_{\ell+1}/D_{\ell+1}$ and retains i^* at its previous value otherwise. At that point, clearly $\mathbf{Pr}[i^* = \ell + 1] = a_{\ell+1}/D_{\ell+1}$; furthermore for

SELECT Algorithm.

Input: $\{a_1, \ldots, a_n\}$, $a_i \geq 0$, read in one pass, i.e., one sequential read, over the data.

Output: i^*, a_{i^*}.

1. $D = 0$.
2. For $i = 1$ to n,
   (a) $D = D + a_i$.
   (b) With probability a_i/D, let $i^* = i$ and $a_{i^*} = a_i$.
3. Return i^*, a_{i^*}.

FIG. 1. *The* SELECT *algorithm.*

$i = 1, \ldots, \ell$, $\mathbf{Pr}[i^* = i] = \frac{a_i}{D_\ell}(1 - \frac{a_{\ell+1}}{D_{\ell+1}}) = \frac{a_i}{D_{\ell+1}}$. By induction this result holds when $\ell + 1 = n$ and the lemma follows. □

In a single pass over the data this algorithm can be run in parallel with $O(s)$ total memory units to return s independent samples $i_1^*, \ldots, i_s^*$ such that for each i_t^*, $t = 1, \ldots, s$, we have $\mathbf{Pr}[i_t^* = i] = a_i / \sum_{i'=1}^n a_{i'}$.

The next lemma is a modification of the previous lemma to deal with the case where a matrix is read in the sparse-unordered representation and one wants to choose a row label with a certain probability. This can also be implemented in $O(1)$ additional space and time. Note that a trivial modification would permit choosing a column label.

LEMMA 2. *Suppose that $A \in \mathbb{R}^{m \times n}$ is presented in the sparse-unordered representation and is read in one pass, i.e., one sequential read over the data, by the* SELECT *algorithm. Then the algorithm requires $O(1)$, i.e., constant with respect to m and n, additional storage space and returns i^*, j^* such that $\mathbf{Pr}[i^* = i \wedge j^* = j] = A_{ij}^2 / \|A\|_F^2$ and thus $\mathbf{Pr}[i^* = i] = |A_{(i)}|^2 / \|A\|_F^2$.*

Proof. Since $A_{i^*j^*}^2 > 0$ the first claim follows from Lemma 1; the second follows since

$$\mathbf{Pr}[i^* = i] = \sum_{j=1}^n \mathbf{Pr}[i^* = i \wedge j^* = j] = \sum_{j=1}^n \frac{A_{ij}^2}{\|A\|_F^2} = \frac{|A_{(i)}|^2}{\|A\|_F^2}. \qquad \square$$

Algorithms such as the SELECT algorithm, which select elements from a large pool of elements whose size is initially unknown, have been called reservoir algorithms [28].

4. The basic matrix multiplication approximation algorithm. In this section, which describes the main result of the paper, the BASICMATRIXMULTIPLICATION algorithm to approximate the product of two matrices is presented; it is analyzed in this section and in the appendix. After describing the algorithm in section 4.1 we describe its implementation and running time issues in section 4.2. In section 4.3 we analyze the algorithm and provide error bounds for arbitrary probability distributions; in section 4.4 error bounds are derived for probability distributions which are nearly optimal in a well-defined sense. We provide further discussion of the algorithm in section 6, and in the appendix we provide further analysis of the BASICMATRIXMULTIPLICATION algorithm.

BasicMatrixMultiplication Algorithm.

Input: $A \in \mathbb{R}^{m\times n}$, $B \in \mathbb{R}^{n\times p}$, $c \in \mathbb{Z}^+$ such that $1 \le c \le n$, and $\{p_i\}_{i=1}^n$ such that $p_i \ge 0$ and $\sum_{i=1}^n p_i = 1$.

Output: $C \in \mathbb{R}^{m\times c}$ and $R \in \mathbb{R}^{c\times p}$.

1. For $t = 1$ to c,
   (a) Pick $i_t \in \{1, \ldots, n\}$ with $\mathbf{Pr}[i_t = k] = p_k$, $k = 1, \ldots, n$, independently and with replacement.
   (b) Set $C^{(t)} = A^{(i_t)}/\sqrt{cp_{i_t}}$ and $R_{(t)} = B_{(i_t)}/\sqrt{cp_{i_t}}$.
2. Return C, R.

Fig. 2. *The* BasicMatrixMultiplication *algorithm.*

4.1. The algorithm. Recall that for $A \in \mathbb{R}^{m\times n}$ and $B \in \mathbb{R}^{n\times p}$, the product AB may be written as the sum of n rank-one matrices

$$AB = \sum_{t=1}^{n} A^{(t)} B_{(t)}. \tag{3}$$

When matrix multiplication is formulated in this manner, a simple randomized algorithm to approximate the product matrix AB suggests itself: randomly sample with replacement from the terms in the summation c times according to a probability distribution $\{p_i\}_{i=1}^n$, scale each term in an appropriate manner, and output the sum of the scaled terms. If $m = p = 1$, then $A^{(t)}, B_{(t)} \in \mathbb{R}$ and it is straightforward to show that this sampling procedure produces an unbiased estimator for the sum. When the terms in the sum are rank-one matrices, as in (3), we show that similar results hold.

Consider the BasicMatrixMultiplication algorithm described in Figure 2. When this algorithm is given as input two matrices A and B, a probability distribution $\{p_i\}_{i=1}^n$, and a number c of column-row pairs to choose, it returns as output matrices C and R such that the product CR is an approximation to AB. Observe that since

$$CR = \sum_{t=1}^{c} C^{(t)} R_{(t)} = \sum_{t=1}^{c} \frac{1}{cp_{i_t}} A^{(i_t)} B_{(i_t)}$$

the procedure for sampling and scaling column and row pairs that is used in the BasicMatrixMultiplication algorithm corresponds to sampling terms in (3) and rescaling by dividing by cp_{i_t} if the tth term is sampled. Alternatively, one could define the sampling matrix $S \in \mathbb{R}^{n\times c}$ to be the zero-one matrix where $S_{ij} = 1$ if the ith column of A (and thus also the ith row of B) is chosen in the jth independent random trial, and $S_{ij} = 0$ otherwise. If the rescaling matrix $D \in \mathbb{R}^{c\times c}$ is the diagonal matrix with $D_{tt} = 1/\sqrt{cp_{i_t}}$, then

$$C = ASD \quad \text{and} \quad R = (SD)^T B$$

so that $CR = ASD(SD)^T B \approx AB$. Figure 3 presents a diagram illustrating the action of the BasicMatrixMultiplication algorithm. The product AB is shown as B and then A operating between the high-dimensional $\mathbb{R}^p$ and $\mathbb{R}^m$ via the high-dimensional $\mathbb{R}^n$; this is approximated by CR, which is shown as R and then C operating between $\mathbb{R}^p$ and $\mathbb{R}^m$ via the low-dimensional subspace $\mathbb{R}^c$. Also shown are the sampling matrix S and the diagonal rescaling matrix D.

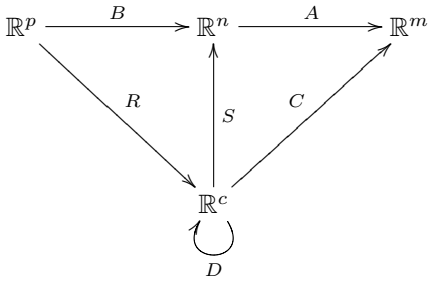

FIG. 3. *Diagram for the* BASICMATRIXMULTIPLICATION *algorithm.*

An important issue is the choice of the probabilities $\{p_i\}_{i=1}^n$ and the scaling. It is easily seen that the scaling of $1/\sqrt{cp_{i_t}}$ used in the BASICMATRIXMULTIPLICATION algorithm makes CR an unbiased estimator of AB; see Lemma 3. Lemma 3 also computes $\mathbf{Var}\left[(CR)_{ij}\right]$ under general probabilities $\{p_i\}_{i=1}^n$. We then compute $\mathbf{E}[\,\|AB - CR\|_F^2]$ and see that probabilities of the form $p_k = |A^{(k)}||B_{(k)}|/N, k = 1, \ldots, n$, where N is a normalization, are optimal in that they minimize this quantity; see Lemma 4.

This approach for approximating matrix multiplication has several advantages. First, it is conceptually simple, and in some cases it can be generalized to approximate the product of more than two matrices; see section A.1 for more on the latter point. Second, since the heart of the algorithm involves matrix multiplication of smaller matrices, it can use any algorithm in the literature for performing the desired matrix multiplication [18, 26, 8]. Third, this approach does not tamper with the sparsity of the matrices, unlike an algorithm that would project both A and B to the same random c-dimensional subspace and take the product of the projections. Finally, the algorithm can be easily implemented; see sections 4.2 and 6 for more discussion.

4.2. Implementation of the sampling and running time. To implement the BASICMATRIXMULTIPLICATION algorithm, it must be decided which elements of the input to sample and those elements must then be sampled. In the case of uniform sampling one can decide before the input is seen which column-row pairs to sample. Then, a single pass over the matrices is sufficient to sample the columns and rows of interest and to construct C and R; this requires $O(c(m+p))$ additional time and space. We will see below that it is useful to sample according to a nonuniform probability distribution that depends on column and row lengths, e.g., see (5) and (7). In order to decide which column-row pairs to sample in such a case, one pass through the matrices and $O(n)$ additional time and space is sufficient; in the additional space running totals of $|A^{(k)}|^2$ and $|B_{(k)}|^2$ are kept, so that after the first pass $|A^{(k)}|$, $|B_{(k)}|$, $k = 1, \ldots, n$, and thus the probabilities, can be calculated in $O(n)$ additional time. Then in a second pass the columns and rows of interest can be sampled and C and R can be constructed and stored; this requires $O(c(m+p))$ additional space and time. Thus, in addition to either one or two passes over the data, for both uniform and nonuniform sampling, $O(c(m+n+p))$ additional space and time is sufficient to sample from the matrices A and B of the input and to construct the matrices C and R.

If $B = A^T$ and nonuniform sampling is performed (assuming probabilities of the form (5) or (7)), the resource requirements are slightly different. Due to Lemma 2 we can select which columns of A to choose using constant (with respect to n) additional

space and time during the first pass. Then, during the second pass, these columns may be extracted and the matrices C and $R = C^T$ may be constructed using $O(cm)$ additional space and time; this will be used in the LINEARTIMESVD algorithm of [11]. Note that if only a constant-sized part of the columns of C is needed, as, for example, in the CONSTANTTIMESVD algorithm of [11], then extracting and storing this constant-sized subset of the samples desired may be performed using constant additional space and time.

4.3. Analysis of the algorithm for arbitrary probabilities. In this section we prove upper bounds for $\|AB - CR\|_F^2$, where C and R are returned from the BASICMATRIXMULTIPLICATION algorithm. Recall that by Jensen's inequality bounding $\|AB - CR\|_F^2$ (in expectation) implies a bound for $\|AB - CR\|_F$. Recall also that a bound on $\|AB - CR\|_F$ immediately provides a bound on $\|AB - CR\|_2$ since $\|AB - CR\|_2 \leq \|AB - CR\|_F$.

Our first lemma proves that the expectation of the (i,j)th element of the approximation is equal to the (i,j)th element of the exact product; it also describes the variance of the approximation of the (i,j)th element.

LEMMA 3. *Suppose $A \in \mathbb{R}^{m\times n}$, $B \in \mathbb{R}^{n\times p}$, $c \in \mathbb{Z}^+$ such that $1 \leq c \leq n$, and $\{p_i\}_{i=1}^n$ are such that $p_i \geq 0$ and $\sum_{i=1}^n p_i = 1$. Construct C and R with the* BASICMATRIXMULTIPLICATION *algorithm, and let CR be an approximation to AB. Then*

$$\mathbf{E}\left[(CR)_{ij}\right] = (AB)_{ij}$$

and

$$\mathbf{Var}\left[(CR)_{ij}\right] = \frac{1}{c}\sum_{k=1}^{n}\frac{A_{ik}^2 B_{kj}^2}{p_k} - \frac{1}{c}(AB)_{ij}^2.$$

Proof. Fix i, j. For $t = 1, \ldots, c$, define $X_t = \left(\frac{A^{(i_t)}B_{(i_t)}}{cp_{i_t}}\right)_{ij} = \frac{A_{ii_t}B_{i_t j}}{cp_{i_t}}$. Thus,

$$\mathbf{E}\left[X_t\right] = \sum_{k=1}^{n} p_k \frac{A_{ik}B_{kj}}{cp_k} = \frac{1}{c}(AB)_{ij} \quad \text{and} \quad \mathbf{E}\left[X_t^2\right] = \sum_{k=1}^{n}\frac{A_{ik}^2 B_{kj}^2}{c^2 p_k}.$$

Since by construction $(CR)_{ij} = \sum_{t=1}^c X_t$, we have $\mathbf{E}\left[(CR)_{ij}\right] = \sum_{t=1}^c \mathbf{E}\left[X_t\right] = (AB)_{ij}$. Since $(CR)_{ij}$ is the sum of c independent random variables, $\mathbf{Var}\left[(CR)_{ij}\right] = \sum_{t=1}^c \mathbf{Var}\left[X_t\right]$. Since $\mathbf{Var}\left[X_t\right] = \mathbf{E}\left[X_t^2\right] - \mathbf{E}\left[X_t\right]^2$, we see that

$$\mathbf{Var}\left[X_t\right] = \sum_{k=1}^{n}\frac{A_{ik}^2 B_{kj}^2}{c^2 p_k} - \frac{1}{c^2}(AB)_{ij}^2$$

and the lemma follows. ∎

Using this lemma, we bound $\mathbf{E}\left[\,\|AB - CR\|_F^2\,\right]$ in the next lemma. In addition, we note how this measure of the error depends on the p_i's.

LEMMA 4. *Suppose $A \in \mathbb{R}^{m\times n}$, $B \in \mathbb{R}^{n\times p}$, $c \in \mathbb{Z}^+$ such that $1 \leq c \leq n$, and $\{p_i\}_{i=1}^n$ are such that $p_i \geq 0$ and $\sum_{i=1}^n p_i = 1$. Construct C and R with the* BASICMATRIXMULTIPLICATION *algorithm, and let CR be an approximation to AB.*

Then

$$\mathbf{E}\left[\,\|AB-CR\|_F^2\right]=\sum_{k=1}^{n}\frac{\left|A^{(k)}\right|^2\left|B_{(k)}\right|^2}{cp_k}-\frac{1}{c}\,\|AB\|_F^2\,. \tag{4}$$

Furthermore, if

$$p_k=\frac{\left|A^{(k)}\right|\left|B_{(k)}\right|}{\sum_{k'=1}^{n}\left|A^{(k')}\right|\left|B_{(k')}\right|}, \tag{5}$$

then

$$\mathbf{E}\left[\,\|AB-CR\|_F^2\right]=\frac{1}{c}\left(\sum_{k=1}^{n}\left|A^{(k)}\right|\left|B_{(k)}\right|\right)^2-\frac{1}{c}\,\|AB\|_F^2\,. \tag{6}$$

This choice of p_k minimizes $\mathbf{E}\left[\,\|AB-CR\|_F^2\,\right]$ among possible choices for the sampling probabilities.

Proof. First, note that

$$\mathbf{E}\left[\,\|AB-CR\|_F^2\right]=\sum_{i=1}^{m}\sum_{j=1}^{p}\mathbf{E}\left[(AB-CR)_{ij}^2\right]=\sum_{i=1}^{m}\sum_{j=1}^{p}\mathbf{Var}\left[(CR)_{ij}\right].$$

Thus, from Lemma 3 it follows that

$$\begin{aligned}\mathbf{E}\left[\,\|AB-CR\|_F^2\right]&=\frac{1}{c}\sum_{k=1}^{n}\frac{1}{p_k}\left(\sum_i A_{ik}^2\right)\left(\sum_j B_{kj}^2\right)-\frac{1}{c}\,\|AB\|_F^2\\&=\frac{1}{c}\sum_{k=1}^{n}\frac{1}{p_k}\left|A^{(k)}\right|^2\left|B_{(k)}\right|^2-\frac{1}{c}\,\|AB\|_F^2\,.\end{aligned}$$

If the value $p_k=\frac{\left|A^{(k)}\right|\left|B_{(k)}\right|}{\sum_{k'=1}^{n}\left|A^{(k')}\right|\left|B_{(k')}\right|}$ is used in this expression, then

$$\mathbf{E}\left[\,\|AB-CR\|_F^2\right]=\frac{1}{c}\left(\sum_{k=1}^{n}\left|A^{(k)}\right|\left|B_{(k)}\right|\right)^2-\frac{1}{c}\,\|AB\|_F^2\,.$$

Finally, to prove that this choice for the p_k's minimizes $\mathbf{E}\left[\,\|AB-CR\|_F^2\,\right]$ define the function

$$f(p_1,\ldots,p_n)=\sum_{k=1}^{n}\frac{1}{p_k}\left|A^{(k)}\right|^2\left|B_{(k)}\right|^2,$$

which characterizes the dependence of $\mathbf{E}\left[\,\|AB-CR\|_F^2\,\right]$ on the p_k's. To minimize f subject to $\sum_{k=1}^{n}p_k=1$, introduce the Lagrange multiplier λ and define the function

$$g(p_1,\ldots,p_n)=f(p_1,\ldots,p_n)+\lambda\left(\sum_{k=1}^{n}p_k-1\right).$$

We then have at the minimum that

$$0 = \frac{\partial g}{\partial p_i} = \frac{-1}{p_i^2}\left|A^{(i)}\right|^2 \left|B_{(i)}\right|^2 + \lambda.$$

Thus,

$$p_i = \frac{\left|A^{(i)}\right| \left|B_{(i)}\right|}{\sqrt{\lambda}} = \frac{\left|A^{(i)}\right| \left|B_{(i)}\right|}{\sum_{i'=1}^{n} \left|A^{(i')}\right| \left|B_{(i')}\right|},$$

where the second equality comes from solving for $\sqrt{\lambda}$ in $\sum_{k=1}^{n-1} p_k = 1$. That these probabilities are a minimum follows since $\frac{\partial^2 g}{\partial p_i^2} > 0 \ \forall i$ such that $|A^{(i)}|^2 |B_{(i)}|^2 > 0$. □

4.4. Analysis of the algorithm for nearly optimal probabilities. With Lemma 4 and using Jensen's inequality, upper bounds on quantities such as $\mathbf{E}\left[\|AB - CR\|_F^2\right]$ and $\mathbf{E}\left[\|AB - CR\|_F\right]$ may be obtained for various sampling probabilities $\{p_i\}_{i=1}^n$. In many cases, by using a martingale argument to show that the error is tightly concentrated around its mean, the expectations in these bounds may be removed and the corresponding results can be shown to hold with high probability.

Rather than presenting these results in their full generality, we restrict our attention to two particular sets of probabilities. We will say that the sampling probabilities $p_k = \frac{|A^{(k)}||B_{(k)}|}{\sum_{k'=1}^{n} |A^{(k')}||B_{(k')}|}$ are the *optimal probabilities* since they minimize $\mathbf{E}\left[\, \|AB - CR\|_F^2 \,\right]$, which as Lemma 4 shows is one natural measure of the error. We will say that a set of sampling probabilities $\{p_i\}_{i=1}^n$ are *nearly optimal probabilities* if $p_k \geq \frac{\beta |A^{(k)}||B_{(k)}|}{\sum_{k'=1}^{n} |A^{(k')}||B_{(k')}|}$ for some positive constant $\beta \leq 1$.

We now prove, for nearly optimal sampling probabilities, results analogous to those of Lemma 4, and also that the corresponding results with the expectations removed hold with high probability. Notice that if $\beta \neq 1$, then we suffer a small β-dependent loss in accuracy.

THEOREM 1. *Suppose $A \in \mathbb{R}^{m \times n}$, $B \in \mathbb{R}^{n \times p}$, $c \in \mathbb{Z}^+$ such that $1 \leq c \leq n$, and $\{p_i\}_{i=1}^n$ are such that $\sum_{i=1}^n p_i = 1$ and such that for some positive constant $\beta \leq 1$*

$$p_k \geq \frac{\beta \left|A^{(k)}\right| \left|B_{(k)}\right|}{\sum_{k'=1}^{n} \left|A^{(k')}\right| \left|B_{(k')}\right|}. \tag{7}$$

Construct C and R with the BASICMATRIXMULTIPLICATION *algorithm, and let CR be an approximation to AB. Then*

$$\mathbf{E}\left[\, \|AB - CR\|_F^2 \right] \leq \frac{1}{\beta c} \|A\|_F^2 \, \|B\|_F^2 . \tag{8}$$

Furthermore, let $\delta \in (0,1)$ and $\eta = 1 + \sqrt{(8/\beta)\log(1/\delta)}$. Then, with probability at least $1 - \delta$,

$$\|AB - CR\|_F^2 \leq \frac{\eta^2}{\beta c} \|A\|_F^2 \, \|B\|_F^2 . \tag{9}$$

Proof. Following reasoning similar to that of Lemma 4 and using the probabilities

of (7), we see that

$$\begin{aligned}\mathbf{E}\left[\|AB-CR\|_F^2\right] &\le \frac{1}{c}\sum_{k=1}^{n}\frac{1}{p_k}\left|A^{(k)}\right|^2\left|B_{(k)}\right|^2\\ &\le \frac{1}{\beta c}\left(\sum_{k=1}^{n}\left|A^{(k)}\right|\left|B_{(k)}\right|\right)^2\\ &\le \frac{1}{\beta c}\|A\|_F^2\,\|B\|_F^2,\end{aligned}$$

where the last inequality follows due to the Cauchy–Schwarz inequality. Next, define the event $\mathcal{E}_2$ to be

$$\|AB-CR\|_F \le \frac{\eta}{\sqrt{\beta c}}\|A\|_F\,\|B\|_F \tag{10}$$

and note that to prove the remainder of the theorem it suffices to prove that $\mathbf{Pr}[\mathcal{E}_2] \ge 1-\delta$. To that end, note that C and R and thus $CR = \sum_{t=1}^{c}\frac{1}{cp_{i_t}}A^{i_t}B_{i_t}$ are formed by randomly selecting c elements from $\{1,\ldots,n\}$, independently and with replacement. Let the sequence of elements chosen be $\{i_t\}_{t=1}^{c}$. Consider the function

$$F(i_1,\ldots,i_c) = \|AB-CR\|_F. \tag{11}$$

We will show that changing one i_t at a time does not change F too much; this will enable us to apply a martingale inequality. To this end, consider changing one of the i_t to i_t' while keeping the other i_t's the same. Then construct the corresponding C' and R'. Note that C' differs from C in only a single column and that R' differs from R in only a single row. Thus,

$$\|CR-C'R'\|_F = \left\|\frac{A^{(i_t)}B_{(i_t)}}{cp_{i_t}} - \frac{A^{(i_t')}B_{(i_t')}}{cp_{i_t'}}\right\|_F \tag{12}$$

$$\le \frac{1}{cp_{i_t}}\left\|A^{(i_t)}B_{(i_t)}\right\|_F + \frac{1}{cp_{i_t'}}\left\|A^{(i_t')}B_{(i_t')}\right\|_F \tag{13}$$

$$= \frac{1}{cp_{i_t}}\left|A^{(i_t)}\right|\left|B_{(i_t)}\right| + \frac{1}{cp_{i_t'}}\left|A^{(i_t')}\right|\left|B_{(i_t')}\right| \tag{14}$$

$$\le \frac{2}{c}\max_{\alpha}\frac{\left|A^{(\alpha)}\right|\left|B_{(\alpha)}\right|}{p_\alpha}. \tag{15}$$

Equation (12) follows by construction and (14) follows since $\|xy^T\|_F = |x|\,|y|$ for $x\in\mathbb{R}^n$ and $y\in\mathbb{R}^n$. Thus, using the probabilities (7) and employing the Cauchy–Schwarz inequality we see that

$$\|CR-C'R'\|_F \le \frac{2}{\beta c}\sum_{k=1}^{n}\left|A^{(k)}\right|\left|B_{(k)}\right| \tag{16}$$

$$\le \frac{2}{\beta c}\|A\|_F\,\|B\|_F. \tag{17}$$

Therefore, using the triangle inequality we see that

$$\begin{aligned}\|AB-CR\|_F &\le \|AB-C'R'\|_F + \|C'R'-CR\|_F\\ &\le \|AB-C'R'\|_F + \frac{2}{\beta c}\|A\|_F\,\|B\|_F.\end{aligned} \tag{18}$$

By similar reasoning, we can derive

$$\|AB - C'R'\|_F \leq \|AB - CR\|_F + \frac{2}{\beta c} \|A\|_F \|B\|_F . \tag{19}$$

Define $\Delta = \frac{2}{\beta c} \|A\|_F \|B\|_F$; thus,

$$|F(i_1, \ldots, i_k, \ldots, i_c) - F(i_1, \ldots, i'_k, \ldots, i_c)| \leq \Delta. \tag{20}$$

Let $\gamma = \sqrt{2c \log(1/\delta)}\Delta$ and consider the associated Doob martingale. By the Hoeffding–Azuma inequality [22],

$$\mathbf{Pr}\left[\|AB - CR\|_F \geq \frac{1}{\sqrt{\beta c}} \|A\|_F \|B\|_F + \gamma \right] \leq \exp\left(-\gamma^2/2c\Delta^2\right) = \delta \tag{21}$$

and the theorem follows. □

An immediate consequence of Theorem 1 is that by choosing enough column-row pairs, the error in the approximation of the matrix product can be made arbitrarily small. In particular, if $c \geq 1/\beta\epsilon^2$, then by using Jensen's inequality it follows that

$$\mathbf{E}\left[\|AB - CR\|_F \right] \leq \epsilon \|A\|_F \|B\|_F \tag{22}$$

and if, in addition, $c \geq \eta^2/\beta\epsilon^2$, then with probability at least $1 - \delta$

$$\|AB - CR\|_F \leq \epsilon \|A\|_F \|B\|_F . \tag{23}$$

In certain applications, e.g., [11, 12], one is interested in an application of Theorem 1 to the case that $B = A^T$, i.e., one is interested in approximating $\left\|AA^T - CC^T\right\|_F^2$. In this case, sampling column-row pairs corresponds to sampling columns of A, and nearly optimal probabilities will be those such that $p_k \geq \frac{\beta \left|A^{(k)}\right|^2}{\|A\|_F^2}$ for some positive $\beta \leq 1$. By taking $B = A^T$ and applying Jensen's inequality, we have the following theorem as a corollary of Theorem 1.

THEOREM 2. *Suppose $A \in \mathbb{R}^{m \times n}$, $c \in \mathbb{Z}^+$, $1 \leq c \leq n$, and $\{p_i\}_{i=1}^n$ are such that $\sum_{i=1}^n p_i = 1$ and such that $p_k \geq \frac{\beta \left|A^{(k)}\right|^2}{\|A\|_F^2}$ for some positive constant $\beta \leq 1$. Furthermore, let $\delta \in (0,1)$ and $\eta = 1 + \sqrt{(8/\beta)\log(1/\delta)}$. Construct C (and $R = C^T$) with the* BASICMATRIXMULTIPLICATION *algorithm, and let CC^T be an approximation to AA^T. Then*

$$\mathbf{E}\left[\left\|AA^T - CC^T\right\|_F \right] \leq \frac{1}{\sqrt{\beta c}} \|A\|_F^2 \tag{24}$$

and with probability at least $1 - \delta$,

$$\left\|AA^T - CC^T\right\|_F \leq \frac{\eta}{\sqrt{\beta c}} \|A\|_F^2 . \tag{25}$$

5. A second matrix multiplication algorithm. In this section we describe the ELEMENTWISEMATRIXMULTIPLICATION algorithm to approximate the product of two matrices. First, in section 5.1, we describe the algorithm, its implementation, and running time issues; then in section 5.2 we analyze the algorithm and bound its error with respect to both the Frobenius and spectral norms. We will see that the algorithm returns good approximations with respect to the spectral norm but not with respect to the Frobenius norm.

ElementwiseMatrixMultiplication Algorithm.

Input: $A \in \mathbb{R}^{m\times n}$, $B \in \mathbb{R}^{n\times p}$, $\{p_{ij}\}_{i,j=1}^{m,n}$ such that $0 \le p_{ij} \le 1$, and $\{q_{ij}\}_{i,j=1}^{n,p}$ such that $0 \le q_{ij} \le 1$.

Output: $S \in \mathbb{R}^{m\times n}$ and $R \in \mathbb{R}^{n\times p}$.

Algorithm:

1. For $i = 1$ to m and $j = 1$ to n, independently,
   (a) Set
$$S_{ij} = \begin{cases} A_{ij}/p_{ij} & \text{with probability } p_{ij}, \\ 0 & \text{otherwise.} \end{cases}$$
2. For $i = 1$ to n and $j = 1$ to p, independently,
   (a) Set
$$R_{ij} = \begin{cases} B_{ij}/q_{ij} & \text{with probability } q_{ij}, \\ 0 & \text{otherwise.} \end{cases}$$
3. Return S, R.

Fig. 4. *The* ElementwiseMatrixMultiplication *algorithm.*

5.1. The algorithm and its implementation. The method to approximate the product of two matrices that is presented in this section differs from the previous algorithm and is inspired by [2] and [1]. In [2] the singular value decomposition of a matrix is approximated using elementwise uniform sampling; in [1] this approach is extended to include nonuniform sampling probabilities of a certain natural form. Since neither of these papers applies these methods to approximate matrix multiplication, we do so here for comparison with the BasicMatrixMultiplication algorithm.

Consider the ElementwiseMatrixMultiplication algorithm presented in Figure 4. When this algorithm is given as input two matrices $A \in \mathbb{R}^{m\times n}$ and $B \in \mathbb{R}^{n\times p}$ it creates two matrices $S \in \mathbb{R}^{m\times n}$ and $R \in \mathbb{R}^{n\times p}$ by keeping a few elements of A and a few elements of B, respectively, scaling in an appropriate manner those elements that are kept, and zeroing out the remaining elements. The algorithm then returns matrices S and R such that the product SR is an approximation to AB. Note that since S and R are formed independently of each other the algorithm does not keep "corresponding" elements; doing so would introduce dependence that would complicate the analysis.

The ElementwiseMatrixMultiplication algorithm can be implemented with the nonuniform probabilities used in this section with two passes over the data; we leave it as an open problem whether a single pass suffices when working within the pass-efficient framework. This algorithm differs from the BasicMatrixMultiplication algorithm in that we get an expected number of elements so we have an expected additional space required for storage and an expected additional time required for the associated sparse matrix multiplication. We do not provide a detailed analysis of these random variables.

5.2. Analysis of the algorithm. In this section we present error bounds for both $\|AB - SR\|_F$ and $\|AB - SR\|_2$. While the Frobenius norm error bound for this algorithm is rather easy to derive using very intuitive probability distributions, the spectral norm bound is more complicated and requires some additional technicalities.

Since whether or not (for a given i,j) $S_{ij}=0$ or $S_{ij}=A_{ij}/p_{ij}$ we have that $A_{ij}-S_{ij}$ is large (and similarly for the matrix R and thus the matrix SR) it is plausible that the ElementwiseMatrixMultiplication algorithm does not have a good bound for $\mathbf{E}\left[\,\|AB-SR\|_F^2\,\right]$. This intuition is formalized in the following lemma. Note that ℓ and ℓ' are chosen such that not more than ℓ and ℓ' of the elements of the matrices A and B are retained in expectation, respectively.

Lemma 5. *Suppose $A\in\mathbb{R}^{m\times n}$ and $B\in\mathbb{R}^{n\times p}$, let $\ell,\ell'\in\mathbb{Z}^+$, and let $p_{ij}=\min\{1,\ell A_{ij}^2/\|A\|_F^2\}$ and $q_{ij}=\min\{1,\ell' B_{ij}^2/\|B\|_F^2\}$. Construct S and R with the* ElementwiseMatrixMultiplication *algorithm, and let SR be an approximation to AB. Then, $\forall i,j$,*

$$\mathbf{E}\left[(SR)_{ij}\right]=(AB)_{ij},$$

$$\mathbf{Var}\left[(SR)_{ij}\right]=\sum_{k=1}^{n}\frac{A_{ik}^2}{p_{ik}}\frac{B_{kj}^2}{q_{kj}}-\sum_{k=1}^{n}A_{ik}^2B_{kj}^2$$

$$\mathbf{E}\left[\,\|AB-SR\|_F^2\right]\geq\frac{mpn}{\ell\ell'}\,\|A\|_F^2\,\|B\|_F^2-\sum_{k=1}^{n}\left|A^{(k)}\right|^2\left|B_{(k)}\right|^2. \tag{26}$$

Proof. Let us first fix i,j. Then, since for every k we have that $S_{ik}=A_{ik}/p_{ik}$ with probability p_{ik} and $S_{ik}=0$ with probability $1-p_{ik}$, we have that $\mathbf{E}\left[S_{ik}\right]=A_{ik}$; similarly for R_{kj}, we have that $\mathbf{E}\left[R_{kj}\right]=B_{kj}$. Thus, since S and R have been constructed independently, we have that

$$\mathbf{E}\left[(SR)_{ij}\right]=\mathbf{E}\left[\sum_{k=1}^{n}S_{ik}R_{kj}\right]=\sum_{k=1}^{n}\mathbf{E}\left[S_{ik}\right]\mathbf{E}\left[R_{kj}\right]=(AB)_{ij}.$$

Since $\mathbf{Var}\left[(SR)_{ij}\right]=\mathbf{E}\left[(SR)_{ij}^2\right]-\mathbf{E}\left[(SR)_{ij}\right]^2$ and since $(SR)_{ij}=\sum_{k=1}^{n}S_{ik}R_{kj}$ we get that

$$\begin{aligned}
\mathbf{Var}\left[(SR)_{ij}\right]&=\sum_{k_1=1}^{n}\sum_{k_2=1}^{n}\mathbf{E}\left[S_{ik_1}R_{k_1j}S_{ik_2}R_{k_2j}\right]-\mathbf{E}\left[(SR)_{ij}\right]^2\\
&=\sum_{k=1}^{n}\mathbf{E}\left[S_{ik}^2\right]\mathbf{E}\left[R_{kj}^2\right]+\sum_{k_1=1}^{n}\sum_{k_2\neq k_1}\mathbf{E}\left[S_{ik_1}\right]\mathbf{E}\left[R_{k_1j}\right]\mathbf{E}\left[S_{ik_2}\right]\mathbf{E}\left[R_{k_2j}\right]-(AB)_{ij}^2\\
&=\sum_{k=1}^{n}\frac{A_{ik}^2}{p_{ik}}\frac{B_{kj}^2}{q_{kj}}+\sum_{k_1=1}^{n}\sum_{k_2\neq k_1}A_{ik_1}B_{k_1j}A_{ik_2}B_{k_2j}-(AB)_{ij}^2\\
&=\sum_{k=1}^{n}\frac{A_{ik}^2}{p_{ik}}\frac{B_{kj}^2}{q_{kj}}-\sum_{k=1}^{n}A_{ik}^2B_{kj}^2,
\end{aligned}$$

where the last line follows by adding and subtracting $\sum_{k_1=1}^{n}\sum_{k_2=k_1}A_{ik_1}B_{k_1j}A_{ik_2}B_{k_2j}$ from the second-to-last line.

Thus, since $\mathbf{E}\left[\,\|AB-SR\|_F^2\,\right]=\sum_{i=1}^{m}\sum_{j=1}^{p}\mathbf{Var}\left[(SR)_{ij}\right]$ and since the probabilities p_{ij} and q_{ij} are such that $1/p_{ik}\geq\|A\|_F^2/\ell A_{ik}^2$ and $1/q_{kj}\geq\|B\|_F^2/\ell' B_{kj}^2$ we get

that

$$\mathbf{E}\left[\,\|AB-SR\|_F^2\right] = \sum_{i=1}^{m}\sum_{j=1}^{p}\sum_{k=1}^{n}\frac{A_{ik}^2}{p_{ik}}\frac{B_{kj}^2}{q_{kj}} - \sum_{i=1}^{m}\sum_{j=1}^{p}\sum_{k=1}^{n}A_{ik}^2B_{kj}^2$$
$$\geq \sum_{i,j=1}^{m,p}\sum_{k=1}^{n}\frac{\|A\|_F^2\,\|B\|_F^2}{\ell\ell'} - \sum_{k=1}^{n}\left|A^{(k)}\right|^2\left|B_{(k)}\right|^2.$$

The lemma then follows. □

Next we show that although the ElementwiseMatrixMultiplication algorithm does not yield a nice error bound for the Frobenius norm, it does for the spectral norm. In order to prove Theorem 4, which provides our bound on $\|AB-SR\|_2$, we will use the following theorem, which follows immediately from a result that was proved in [1] and which shows that with high probability the spectrum of a random matrix is close to its expectation. The theorem is proved by using a generalization of a result of Füredi and Komlós [16], combined with a more recent concentration result of Krivelevich and Vu based on Talagrand's inequality [21].

Theorem 3. *Given an $n\times n$ matrix A, let $\hat{A}$ be any random matrix whose entries are independent random variables such that $\forall i,j$, $\mathbf{E}\big[\hat{A}_{ij}\big]=A_{ij}$, $\mathbf{Var}\big[\hat{A}_{ij}\big]\leq\sigma^2$, and*

$$\left|\hat{A}_{ij}-A_{ij}\right| \leq \frac{\sigma\sqrt{2n}}{\log^3(2n)}. \tag{27}$$

For any $n\geq 10$, with probability at least $1-1/(2n)$,

$$\|A-\hat{A}\|_2 < 7\sigma\sqrt{2n}. \tag{28}$$

Prior to stating the main result of this section, we must address a technical issue that arises in our effort to apply the above theorem in order to bound $\|AB-SR\|_2$. Note that the construction of the matrices S and R by the ElementwiseMatrixMultiplication algorithm may be viewed as adding carefully constructed random matrices E and D such that $S=A+E$ and $R=B+D$; see [2] and [1] for a discussion. As we will see below, if we can bound $\|E\|_2$ and $\|D\|_2$, then a bound for $\|AB-SR\|_2$ follows easily. Since we will apply Theorem 3 in order to obtain such bounds, we need to satisfy the range constraint (27). Sampling with respect to the nonuniform probability distribution of Lemma 5 might violate this constraint since, in the unlikely event that a small element is kept, the resulting entry $S_{ij}=A_{ij}/p_{ij}$ will be very large (and similarly for R). Thus, following [1], we modify our sampling probabilities so that small elements are kept with a slightly larger probability which is proportional to $|A_{ij}|$ instead of A_{ij}^2:

$$p_{ij} = \begin{cases} \min\{1,\ell A_{ij}^2/\|A\|_F^2\} & \text{if } |A_{ij}| > \frac{\|A\|_F\log^3(2n)}{\sqrt{2n\ell}},\\ \min\left\{1,\frac{\sqrt{\ell}|A_{ij}|\log^3(2n)}{\sqrt{2n}\|A\|_F}\right\} & \text{otherwise,}\end{cases} \tag{29}$$

$$q_{ij} = \begin{cases} \min\{1,\ell' B_{ij}^2/\|B\|_F^2\} & \text{if } |B_{ij}| > \frac{\|B\|_F\log^3(2n)}{\sqrt{2n\ell'}},\\ \min\left\{1,\frac{\sqrt{\ell'}|B_{ij}|\log^3(2n)}{\sqrt{2n}\|B\|_F}\right\} & \text{otherwise.}\end{cases} \tag{30}$$

We now state and prove our main theorem of this section. In the interests of clarity we make several simplifying assumptions in the statement of the theorem.

THEOREM 4. *Suppose $A \in \mathbb{R}^{m\times n}$, $B \in \mathbb{R}^{n\times p}$, and let p_{ij} and q_{ij} be as specified in (29) and (30) with $\ell = \ell' \geq 1$. Assume that $\ell \leq \|A\|_F^2 / \max_{i,j} A_{ij}^2$ and that $\ell \leq \|B\|_F^2 / \max_{i,j} B_{ij}^2$; assume also that $m = n = p$ and that n is large enough so that $2n \geq \log^6(2n)$. Construct S and R with the* ELEMENTWISEMATRIXMULTIPLICATION *algorithm, and let SR be an approximation to AB. Then, with probability at least $1 - 1/n$,*

$$\|AB - SR\|_2 \leq \left(20\sqrt{\frac{n}{\ell}} + \frac{100n}{\ell}\right) \|A\|_F \|B\|_F . \tag{31}$$

Proof. By the assumptions on n and ℓ, neither p_{ij} nor q_{ij} exceed 1 for any i, j. Letting $E = S - A$ and $D = R - B$, we have

$$SR = (A + E)(B + D) = AB + AD + EB + ED. \tag{32}$$

Thus, by the triangle inequality and submultiplicitivity, we have that

$$\|AB - SR\|_2 \leq \|A\|_2 \|D\|_2 + \|E\|_2 \|B\|_2 + \|E\|_2 \|D\|_2 . \tag{33}$$

In order to apply Theorem 3 to $\|E\|_2$ and $\|D\|_2$ we first verify that the assumptions of the theorem are satisfied. From the proof of Lemma 5, we have that $\mathbf{E}[S_{ij}] = A_{ij}$. In addition,

$$\mathbf{Var}[S_{ij}] \leq \mathbf{E}\left[S_{ij}^2\right] = \frac{A_{ij}^2}{p_{ij}} \leq \frac{\|A\|_F^2}{\ell}$$

holds regardless of whether $|A_{ij}|$ is larger or smaller than the threshold. Similarly, we get that $\mathbf{E}[R_{ij}] = B_{ij}$ and that $\mathbf{Var}[D_{ij}] \leq \frac{\|B\|_F^2}{\ell}$. It is straightforward to show that regardless of whether or not $|A_{ij}|$ is above or below the threshold and regardless of whether or not $S_{ij} = 0$ or $S_{ij} = A_{ij}/p_{ij}$ we have that

$$|A_{ij} - S_{ij}| \leq \frac{\|A\|_F \sqrt{2n}}{\sqrt{\ell}\log^3(2n)}. \tag{34}$$

Similarly, one can show that

$$|B_{ij} - R_{ij}| \leq \frac{\|B\|_F \sqrt{2n}}{\sqrt{\ell}\log^3(2n)}. \tag{35}$$

Thus, the conditions of Theorem 3 are satisfied and with probability at least $1 - 1/2n$ each of the following holds:

$$\|E\|_2 \leq 7\|A\|_F \sqrt{2n}/\sqrt{\ell}, \tag{36}$$

$$\|D\|_2 \leq 7\|B\|_F \sqrt{2n}/\sqrt{\ell}. \tag{37}$$

Thus, with probability at least $1 - 1/n$ both of these inequalities hold. Combining the bounds (36) and (37) with (33), and since $\|\cdot\|_2 \leq \|\cdot\|_F$, we have

$$\begin{aligned}
\|AB - SR\|_2 &\leq \|A\|_2 \|D\|_2 + \|E\|_2 \|B\|_2 + \|E\|_2 \|D\|_2 \\
&\leq \frac{7\sqrt{2n}\|A\|_F \|B\|_F}{\sqrt{\ell}} + \frac{7\sqrt{2n}\|A\|_F \|B\|_F}{\sqrt{\ell}} + \frac{98n\|A\|_F \|B\|_F}{\ell} \\
&\leq \left(20\sqrt{n/\ell} + 100n/\ell\right) \|A\|_F \|B\|_F . \qquad \square
\end{aligned}$$

Notice that if we let $\ell = cn$ in Theorem 4, then the error bound (31) becomes

$$\|AB - SR\|_2 \leq \left(\frac{20}{\sqrt{c}} + \frac{100}{c}\right) \|A\|_F \|B\|_F = O(1/\sqrt{c}) \|A\|_F \|B\|_F .$$

Comparison with (9) of Theorem 1 reveals that (since $\|\cdot\|_2 \leq \|\cdot\|_F$) both of our matrix multiplication algorithms have, asymptotically, a similar bound with respect to the spectral norm.

6. Discussion and conclusion. To the best of our knowledge, the only previous randomized algorithm that approximates the product of two matrices is that of Cohen and Lewis [7]. This algorithm is based on random walks in a graph representation of the input matrices and attempts to identify all high-valued entries in nonnegative matrix products in order to improve estimates (relative to exact sparse multiplication) by spending less time on small-valued entries. Their algorithm is more complicated than ours, it requires different graph representations of the input matrices if the matrices are allowed to contain negative entries, it needs to store the complete input matrices, and it is especially useful when the matrices are not sparse.

It is worth emphasizing how the BasicMatrixMultiplication algorithm behaves when A and B are well approximated by low-rank matrices. Since a low-rank matrix or a matrix that is well approximated by a low-rank matrix is a matrix whose rows and columns contain much redundant information in terms of the subspaces they span, it is plausible that if the range of B overlaps appropriately with the domain of A, then we can get a good approximation to AB by carefully sampling a small number c of appropriately rescaled rank-one approximations to AB. Theorem 1 shows that if the $\{p_i\}_{i=1}^n$ are chosen judiciously, then this is the case and Figure 3 illustrates this.

We emphasize that in the case of sampling with nonuniform probabilities our sampling can be viewed as a two-pass algorithm; in the first pass the algorithm reads the matrix, it then decides which columns and rows to keep, and then in the second pass it extracts these columns and rows. In certain applications, two passes through the matrix are not possible and only one pass is allowed [14]. In these cases, we can still perform uniform sampling; in this case, if column-row pairs are all approximately the same size, i.e., $|A^{(k)}||B_{(k)}|$ is close to its mean value (more precisely, if there exists some positive constant $\beta \leq 1$ such that $\forall k \ |A^{(k)}||B_{(k)}| \leq \frac{1}{\beta n} \sum_{k'=1}^{n} |A^{(k')}||B_{(k')}|$), then the uniform probabilities are nearly optimal and we can sample uniformly with a small β-dependent loss in accuracy.

Note that although larger columns and rows get picked more often, the scaling is such that their weight is deemphasized in the estimator sum. One could imagine a situation when detailed information about the elements of, e.g., A may be obtained after a single pass but no information or no information except general bounds on the size of the elements may be possible for B. In this case, a set of sampling probabilities other than those discussed in section 4 may be appropriate. See Table 1 for a summary of the results for different probability distributions; these results are proven in section A.3

The ElementwiseMatrixMultiplication algorithm has been presented for completeness and because in some applications its use may be more appropriate than the use of the BasicMatrixMultiplication algorithm. It is worth emphasizing that the ElementwiseMatrixMultiplication algorithm achieves its spectral norm bound since its sampling procedure may be viewed as adding a carefully constructed random perturbation to every element of the original matrix; see [2, 1] for a nice discussion of these ideas.

Recent work has focused on establishing lower bounds on the number of queries a sampling algorithm is required to perform in order to approximate a given function accurately with low probability of error; see, e.g., [4]. See also [24, 27] for recent related work.

Appendix. Further analysis of the basic matrix multiplication algorithm. In this section we provide further analysis of the BASICMATRIXMULTIPLICATION algorithm. In section A.1 we consider approximating the product of more than two matrices by a similar sampling process. Then, in section A.2 we examine element-wise error bounds for the algorithm, and in section A.3 we consider error bounds for probability distributions which are not nearly optimal in the sense of section 4.4.

A.1. Approximating the product of more than two matrices. In this section we consider the task of approximating the product of three or more matrices using the ideas of the BASICMATRIXMULTIPLICATION algorithm of section 4. For simplicity our exposition will be restricted to the case of approximating the product ABC of three matrices. Recall that given matrices $A \in \mathbb{R}^{m\times n}$, $B \in \mathbb{R}^{n\times p}$, $C \in \mathbb{R}^{p\times q}$, the product ABC may be written as

$$ABC = \sum_{s=1}^{n}\sum_{t=1}^{p} A^{(s)}B_{st}C_{(t)}. \tag{38}$$

One possible way of extending the ideas of section 4.1 is the following. Randomly choose $i_s \in \{1,\ldots,n\}$ independently and with replacement c_1 times according to a probability distribution $\{p_i\}_{i=1}^n$ and randomly choose $j_t \in \{1,\ldots,p\}$ independently

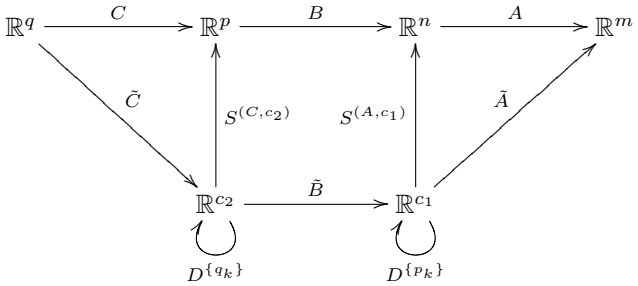

FIG. 5. *Diagram for the algorithm to approximately multiply three matrices.*

and with replacement c_2 times according to a probability distribution $\{q_j\}_{j=1}^{p}$. Then form the matrix $\tilde{A} \in \mathbb{R}^{m\times c_1}$ with columns $\tilde{A}^{(s)} = A^{(i_s)}/\sqrt{c_1 p_{i_s}}$, the matrix $\tilde{B} \in \mathbb{R}^{c_1\times c_2}$ with elements $\tilde{B}_{st} = B_{i_s j_t}/\sqrt{c_1 c_2 p_{i_s} q_{j_t}}$, and the matrix $\tilde{C} \in \mathbb{R}^{c_2\times q}$ with rows $\tilde{C}_{(t)} = C_{(j_t)}/\sqrt{c_2 q_{j_t}}$ so that

$$\tilde{A}\tilde{B}\tilde{C} = \sum_{s=1}^{c_1}\sum_{t=1}^{c_2} \frac{A^{(i_s)} B_{i_s j_t} C_{(j_t)}}{c_1 c_2 p_{i_s} q_{j_t}}.$$

Figure 5 presents a diagram illustrating the action of the algorithm just described to approximate the product of three matrices. One could then define sampling matrices $S^{(A,c_1)}$ and $S^{(C,c_2)}$ and diagonal rescaling matrices $D^{\{p_k\}}$ and $D^{\{q_k\}}$ in a manner analogous to that of section 4.1 and as indicated in Figure 5. Then $\tilde{A}\tilde{B}\tilde{C} = AS^{(A,c_1)}{D^{\{p_k\}}}^2 {S^{(A,c_1)}}^T BS^{(C,c_2)}{D^{\{q_k\}}}^2 {S^{(C,c_2)}}^T C \approx ABC$. An intuitively appealing aspect of this algorithm is that the product ABC is shown as C, B, and then A operating between the high-dimensional $\mathbb{R}^q$ and $\mathbb{R}^m$ via the high-dimensional $\mathbb{R}^p$ and $\mathbb{R}^n$; this is approximated by $\tilde{A}\tilde{B}\tilde{C}$, which acts between $\mathbb{R}^q$ and $\mathbb{R}^m$ via the low-dimensional subspaces $\mathbb{R}^{c_2}$ and $\mathbb{R}^{c_1}$. One difficulty with this algorithm is that its analysis is quite complicated due to the correlation in the nonindependent sampling of the elements of the matrix B.

A second way of extending the ideas of section 4.1 is the following. Randomly choose $(i_s, j_t) \in \{1,\ldots,n\}\times\{1,\ldots,p\}$ independently and with replacement c times according to a probability distribution $\{p_{kl}\}_{(k,l)=1}^{n,p}$. This corresponds to sampling c terms from the sum (38). Then define

$$P = \sum_{u\equiv(s,t)=1}^{c} \frac{1}{c p_{k_s l_t}} A^{(k_s)} B_{k_s l_t} C_{(l_t)},$$

where the summation is a single sum over the c pairs $(k_s, l_t) \in \{1,\ldots,n\}\times\{1,\ldots,p\}$ chosen by the algorithm. In this second algorithm the subspace interpretation of the first algorithm is lost but the analysis simplifies considerably. Using ideas similar to those in section 4 we can prove the following lemma about this algorithm.

LEMMA 6. *Given matrices $A \in \mathbb{R}^{m\times n}$, $B \in \mathbb{R}^{n\times p}$, $C \in \mathbb{R}^{p\times q}$, construct an approximation P to the product ABC by sampling as described in the second algorithm above with probabilities $\{p_{k,l}\}_{(k,l)=1}^{np}$. Then, for every i, j we have that $\mathbf{E}[(P)_{ij}] = (ABC)_{ij}$ and that*

$$\mathbf{Var}\left[\,(P)_{ij}\,\right] = \frac{1}{c}\sum_{k=1}^{n}\sum_{l=1}^{p}\frac{1}{p_{kl}} A_{ik}^2 B_{kl}^2 C_{lj}^2 - \frac{1}{c}\,(ABC)_{ij}^2\,.$$

In addition,

$$\mathbf{E}\left[\,\|ABC-P\|_F^2\right]=\frac{1}{c}\sum_{k=1}^{n}\sum_{l=1}^{p}\frac{1}{p_{kl}}\left|A^{(k)}\right|^2B_{kl}^2\left|C_{(l)}\right|^2-\frac{1}{c}\,\|ABC\|_F^2$$

and the probabilities

$$p_{kl}=\frac{\left|A^{(k)}\right|\,|B_{kl}|\,\left|C_{(l)}\right|}{\sum_{k'}\sum_{l'}\,\left|A^{(k')}\right|\,|B_{k'l'}|\,\left|C_{(l')}\right|}$$

minimize $\mathbf{E}\left[\,\|ABC-P\|_F^2\,\right]$

Proof. The proof is similar to those of Lemmas 3 and 4. □

As in section 4.4 we will define probabilities $\{p_{kl}\}$ to be nearly optimal if

$$p_{kl}\geq\beta\frac{\left|A^{(k)}\right|\,|B_{kl}|\,\left|C_{(l)}\right|}{\sum_{k'}\sum_{l'}\,\left|A^{(k')}\right|\,|B_{k'l'}|\,\left|C_{(l')}\right|}$$

for some $\beta\leq 1$. If sampling is performed with these probabilities, one can show that

$$\mathbf{E}\left[\,\|ABC-P\|_F^2\right]\leq\frac{1}{c\beta}\sum_k\sum_l\left|A^{(k)}\right|\,|B_{kl}|\,\left|C_{(l)}\right|,$$

and a similar result can be shown to hold with high probability.

Unfortunately, computing the optimal probabilities in the general case is not pass-efficient since it would require $O(np)$ additional space and time. This situation would be relatively worse if one wanted to compute the product of more than three matrices, rendering this method uncompetitive with the exact algorithm. On the other hand, if the matrices are known to have a special structure or if the data are presented in a more specialized format, then this algorithm may be useful. For example, if it is known that none of the elements of B are too big, i.e., that the elements of B are such that there exists a ξ_B such that $\forall i,j$ we have that $B_{ij}\leq\xi_B\,\|B\|_F^2/np$, then there will exist a set of probabilities that are nearly optimal that do not depend on B and that can be computed efficiently.

A.2. Elementwise error bounds. In this section we provide elementwise error bounds on $|(AB)_{ij}-(CR)_{ij}|$ for the BasicMatrixMultiplication algorithm for two different probability distributions. We have the following lemma.

Lemma 7. *Suppose* $A\in\mathbb{R}^{m\times n}$, $B\in\mathbb{R}^{n\times p}$, $c\in\mathbb{Z}^+$ *such that* $1\leq c\leq n$, *and* $\{p_i\}_{i=1}^n$ *are such that* $p_i\geq 0$ *and* $\sum_{i=1}^n p_i=1$. *Let* M *be such that* $|A_{ij}|\leq M$ *and* $|B_{ij}|\leq M$ *for every appropriate* i,j. *Construct* C *and* R *with the* BasicMatrixMultiplication *algorithm, and let* CR *be an approximation to* AB. *If* $p_k=1/n$ *for every* k, *then for every* $\delta>0$ *with probability at least* $1-\delta$

$$|(AB)_{ij}-(CR)_{ij}|<\frac{nM^2}{\sqrt{c}}\sqrt{8\ln(2mp/\delta)}\quad\forall i,j. \tag{39}$$

If $p_k\geq\frac{\beta\left|A^{(k)}\right|\left|B_{(k)}\right|}{\sum_{k'=1}^n\left|A^{(k')}\right|\left|B_{(k')}\right|}$ *for some positive constant* $\beta\leq 1$, *then for every* $\delta>0$ *with probability at least* $1-\delta$

$$|(AB)_{ij}-(CR)_{ij}|<\frac{n\sqrt{mp}M^2}{\sqrt{\beta c}}\sqrt{(8/\beta)\ln(2mp/\delta)}\quad\forall i,j. \tag{40}$$

Proof. Let us first consider the case of uniform sampling probabilities, i.e., when $p_k = 1/n$. First, fix attention on one particular $(i,j) \in (\{1,\ldots,m\},\{1,\ldots,p\})$. Define $X_t^{(ij)} = \left(\frac{A^{(i_t)}B_{(i_t)}}{cp_{i_t}}\right)_{ij} = \frac{A_{ii_t}B_{i_tj}}{cp_{i_t}}$. From Lemma 3 we see that $\mathbf{E}\left[X_t^{(ij)}\right] = \frac{1}{c}(AB)_{ij}$. Define $Y_t^{(ij)} = X_t^{(ij)} - \frac{1}{c}(AB)_{ij}$, $t = 1,\ldots,c$, and note that the Y_t's are independent random variables with $\mathbf{E}\left[Y_t^{(ij)}\right] = 0$ for every $t = 1,\ldots,c$. In addition,

$$\begin{aligned}\left|Y_t^{(ij)}\right| &\le \left|\frac{A_{ii_t}B_{i_tj}}{cp_{i_t}}\right| + \left|\frac{1}{c}(AB)_{ij}\right| \\ &\le \left|\frac{A_{ii_t}B_{i_tj}}{cp_{i_t}}\right| + \frac{nM^2}{c} \qquad (41)\\ &\le \frac{2nM^2}{c}. \qquad (42)\end{aligned}$$

Inequality (42) follows since for the uniform probabilities $|\frac{A_{ii_t}B_{i_tj}}{cp_{i_t}}| \le \frac{nM^2}{c}$. By combining the upper and lower bounds provided by (42) with Hoeffding's inequality, we have that for any $t > 0$

$$\mathbf{Pr}\left[\left|\sum_{t=1}^{c} Y_t^{(ij)}\right| \ge ct\right] \le 2\exp\left(-\frac{2c^2t^2}{\sum_{i=1}^{c}\left(4nM^2/c\right)^2}\right) = 2\exp\left(-\frac{c^3t^2}{8n^2M^4}\right). \qquad (43)$$

Define the event $\mathcal{E}_{ij}$ to be $|\sum_{t=1}^{c} Y_t^{(ij)}| \ge ct$ and the event $\mathcal{E} = \bigcup_{i=1}^{m}\bigcup_{j=1}^{p}\mathcal{E}_{ij}$. If we then let $t = nM^2\frac{2\sqrt{2}}{c^{3/2}}\sqrt{\ln(2mp/\delta)}$, then by (43) we have that $\mathbf{Pr}[\mathcal{E}_{ij}] \le \frac{\delta}{mp}$. Thus, (39) then follows since

$$\mathbf{Pr}[\mathcal{E}] \le \sum_{i=1}^{m}\sum_{j=1}^{p}\mathbf{Pr}[\mathcal{E}_{ij}] \le \sum_{ij}\delta/mp = \delta.$$

When applied to the nonuniform probabilities $p_k \ge \frac{\beta|A^{(k)}||B_{(k)}|}{\sum_{k'=1}^{n}|A^{(k')}||B_{(k')}|}$ a similar line of reasoning establishes (40). The key step is to note that when using these probabilities we have that

$$\left|\frac{A_{ii_t}B_{i_tj}}{cp_{i_t}}\right| \le \left|\frac{A_{ii_t}B_{i_tj}}{c\beta\left|A^{(k)}\right|\left|B_{(k)}\right|}\sum_{k'=1}^{n}\left|A^{(k')}\right|\left|B_{(k')}\right|\right| \le \left|\frac{n\sqrt{mp}}{c\beta}M^2\right|. \qquad (44)$$

Since $nM^2/c \le n\sqrt{mp}M^2/(c\beta)$ this, when combined with (41), implies that

$$\left|Y_t^{(ij)}\right| \le \frac{2n\sqrt{mp}M^2}{c\beta}, \qquad (45)$$

which provides the upper and lower bounds on the random variable required to apply Hoeffding's inequality. □

When the uniform probabilities are used

$$\|AB - CR\|_F^2 = \sum_{ij}|(AB)_{ij} - (CR)_{ij}|^2 \le \frac{mn^2pM^4}{c}8\log(2mp/\delta)$$

holds with probability greater than $1-\delta$. The difference between this result and the result of Theorem 1 or its variants such as Lemma 11 is that Lemma 7 guarantees that

every element of the approximation will have small additive error, while Theorem 1 provides a tighter Frobenius norm bound but not elementwise guarantees.

It may seem counterintuitive that by sampling with respect to the optimal probabilities of section 4 the bound of (40) is worse than that of (39) by a factor of $\sqrt{mp/\beta}$. (Relatedly, when the nonuniform probabilities of Lemma 7 are used, we have that

$$\|AB - CR\|_F^2 \leq \frac{m^2 n^2 p^2 M^4}{\beta^2 c} 8 \log(2mp/\delta)$$

with probability greater than $1 - \delta$.) The reason for this is that the optimal probabilities are optimal with respect to minimizing $\mathbf{E}\left[\, \|AB - CR\|_F^2 \,\right]$, in which case elements corresponding to smaller columns and rows contribute relatively little. On the other hand, the two statements of Lemma 7 are required to hold for every i and j. Thus (whether or not the uniform probabilities are nearly optimal) because the optimal sampling probabilities bias toward elements corresponding to larger columns and rows an extra factor of $\sqrt{mp}$ is needed.

A.3. Analysis of the algorithm for nonnearly optimal probabilities. Note that the nearly optimal probabilities (7) use information from both matrices A and B in a particular form. In some cases, such detailed information about both matrices may not be available. Thus, we present results for the BasicMatrixMultiplication algorithm for several other sets of probabilities. See Table 1 in section 6 for a summary of these results.

In the first case, to estimate the product AB one could use the probabilities (46) which use information from the matrix A only. In this case $\|AB - CR\|_F$ can still be shown to be small in expectation, and under an additional assumption the expectation can be removed and the corresponding result can be shown to hold with high probability.

Lemma 8. *Suppose $A \in \mathbb{R}^{m \times n}$, $B \in \mathbb{R}^{n \times p}$, $c \in \mathbb{Z}^+$ such that $1 \leq c \leq n$, and $\{p_i\}_{i=1}^n$ are such that $\sum_{i=1}^n p_i = 1$ and such that*

$$p_k \geq \frac{\beta \left| A^{(k)} \right|^2}{\|A\|_F^2} \tag{46}$$

for some positive constant $\beta \leq 1$. Construct C and R with the BasicMatrixMultiplication *algorithm, and let CR be an approximation to AB. Then*

$$\mathbf{E}\left[\, \|AB - CR\|_F^2 \right] \leq \frac{1}{\beta c} \|A\|_F^2 \, \|B\|_F^2 . \tag{47}$$

Furthermore, let $\mathcal{M} = \max_\alpha \frac{|B_{(\alpha)}|}{\left|A^{(\alpha)}\right|}$, let $\delta \in (0,1)$, and let $\eta = 1 + \frac{\|A\|_F}{\|B\|_F} \mathcal{M} \sqrt{(8/\beta) \log(1/\delta)}$. Then with probability at least $1 - \delta$,

$$\|AB - CR\|_F^2 \leq \frac{\eta^2}{\beta c} \|A\|_F^2 \, \|B\|_F^2 . \tag{48}$$

Proof. The proof is similar to that of Theorem 1 except that the indicated probabilities are used. ∎

Alternatively, to estimate the product AB one could use the probabilities (49) which also use information from the matrix A only, but in a different form than the probabilities (46). In this case, under an additional assumption $\|AB - CR\|_F$ can still be shown to be small both in expectation and with high probability.

LEMMA 9. *Suppose* $A \in \mathbb{R}^{m\times n}$, $B \in \mathbb{R}^{n\times p}$, $c \in \mathbb{Z}^+$ *such that* $1 \le c \le n$, *and* $\{p_i\}_{i=1}^n$ *are such that* $\sum_{i=1}^n p_i = 1$ *and such that*

$$p_k \ge \frac{\beta \left|A^{(k)}\right|}{\sum_{k'=1}^n \left|A^{(k')}\right|} \tag{49}$$

for some positive constant $\beta \le 1$. *Let* $\mathcal{M} = \max_\alpha |B_{(\alpha)}|$. *Construct* C *and* R *with the* BASICMATRIXMULTIPLICATION *algorithm, and let* CR *be an approximation to* AB. *Then*

$$\mathbf{E}\left[\, \|AB - CR\|_F^2 \right] \le \frac{1}{\beta c} \|A\|_F^2 \, n\mathcal{M}^2. \tag{50}$$

Furthermore, let $\delta \in (0,1)$ *and* $\eta = 1 + \sqrt{(8/\beta)\log(1/\delta)}$. *Then with probability at least* $1-\delta$,

$$\|AB - CR\|_F^2 \le \frac{\eta^2}{\beta c} \|A\|_F^2 \, n\mathcal{M}^2. \tag{51}$$

Proof. The proof is similar to that of Theorem 1 except that the indicated probabilities are used. □

The probabilities (46) and (49) depend on only the lengths of the columns of A. Results similar to those of the previous two lemmas hold if the probabilities depend on the rows of B rather than the columns of A; see Table 1.

Alternatively, to estimate the product of AB one could use the probabilities (52); interestingly, although the probabilities differ from those of (7) we are able to derive the same bounds as those of Theorem 1 without additional assumptions.

LEMMA 10. *Suppose* $A \in \mathbb{R}^{m\times n}$, $B \in \mathbb{R}^{n\times p}$, $c \in \mathbb{Z}^+$ *such that* $1 \le c \le n$, *and* $\{p_i\}_{i=1}^n$ *are such that* $\sum_{i=1}^n p_i = 1$ *and such that*

$$p_k \ge \frac{\beta \left|A^{(k)}\right| \left|B_{(k)}\right|}{\|A\|_F \|B\|_F} \tag{52}$$

for some positive constant $\beta \le 1$. *Construct* C *and* R *with the* BASICMATRIXMULTIPLICATION *algorithm, and let* CR *be an approximation to* AB. *Then*

$$\mathbf{E}\left[\, \|AB - CR\|_F^2 \right] \le \frac{1}{\beta c} \|A\|_F^2 \, \|B\|_F^2 . \tag{53}$$

Furthermore, let $\delta \in (0,1)$ *and* $\eta = 1 + \sqrt{(8/\beta)\log(1/\delta)}$. *Then with probability at least* $1-\delta$,

$$\|AB - CR\|_F^2 \le \frac{\eta^2}{\beta c} \|A\|_F^2 \, \|B\|_F^2 . \tag{54}$$

Proof. The proof is similar to that of Theorem 1 except that the indicated probabilities are used. □

Of course one could estimate the product AB using the uniform probabilities (55). In this case for simplicity we consider bounding $\|AB - CR\|_F$ directly.

LEMMA 11. *Suppose* $A \in \mathbb{R}^{m\times n}$, $B \in \mathbb{R}^{n\times p}$, $c \in \mathbb{Z}^+$ *such that* $1 \le c \le n$, *and* $\{p_i\}_{i=1}^n$ *are such that*

$$p_k = \frac{1}{n}. \tag{55}$$

Construct C and R with the BasicMatrixMultiplication *algorithm, and let CR be an approximation to AB. Then*

$$\mathbf{E}\left[\,\|AB-CR\|_F\right] \leq \sqrt{\frac{n}{c}}\left(\sum_{k=1}^{n}\left|A^{(k)}\right|^2\left|B_{(k)}\right|^2\right)^{1/2}. \tag{56}$$

Furthermore, let $\delta \in (0,1)$ and $\gamma = \frac{n}{\sqrt{c}}\sqrt{8\log(1/\delta)}\max_\alpha \left|A^{(\alpha)}\right|\left|B_{(\alpha)}\right|$. Then with probability at least $1-\delta$,

$$\|AB-CR\|_F \leq \sqrt{\frac{n}{c}}\left(\sum_{k=1}^{n}\left|A^{(k)}\right|^2\left|B_{(k)}\right|^2\right)^{1/2} + \gamma. \tag{57}$$

Proof. The proof is similar to that of Theorem 1 except that the indicated probabilities are used. ∎

Acknowledgments. We would like to thank Dimitris Achlioptas for bringing to our attention the results of [21] and the National Science Foundation for partial support of this work. In addition, we would like to thank an anonymous reviewer for providing a careful reading of this paper, for making numerous constructive suggestions, and for bringing [28] to our attention.

FAST MONTE CARLO ALGORITHMS FOR MATRICES II: COMPUTING A LOW-RANK APPROXIMATION TO A MATRIX*

PETROS DRINEAS†, RAVI KANNAN‡, AND MICHAEL W. MAHONEY§

Abstract. In many applications, the data consist of (or may be naturally formulated as) an $m \times n$ matrix A. It is often of interest to find a low-rank approximation to A, i.e., an approximation D to the matrix A of rank not greater than a specified rank k, where k is much smaller than m and n. Methods such as the singular value decomposition (SVD) may be used to find an approximation to A which is the best in a well-defined sense. These methods require memory and time which are superlinear in m and n; for many applications in which the data sets are very large this is prohibitive. Two simple and intuitive algorithms are presented which, when given an $m \times n$ matrix A, compute a description of a low-rank approximation D^* to A, and which are qualitatively faster than the SVD. Both algorithms have provable bounds for the error matrix $A - D^*$. For any matrix X, let $\|X\|_F$ and $\|X\|_2$ denote its Frobenius norm and its spectral norm, respectively. In the first algorithm, c columns of A are randomly chosen. If the $m \times c$ matrix C consists of those c columns of A (after appropriate rescaling), then it is shown that from $C^T C$ approximations to the top singular values and corresponding singular vectors may be computed. From the computed singular vectors a description D^* of the matrix A may be computed such that $\text{rank}(D^*) \leq k$ and such that

$$\|A - D^*\|_\xi^2 \leq \min_{D:\text{rank}(D)\leq k} \|A - D\|_\xi^2 + poly(k, 1/c)\,\|A\|_F^2$$

holds with high probability for both $\xi = 2, F$. This algorithm may be implemented without storing the matrix A in random access memory (RAM), provided it can make two passes over the matrix stored in external memory and use $O(cm + c^2)$ additional RAM. The second algorithm is similar except that it further approximates the matrix C by randomly sampling r rows of C to form a $r \times c$ matrix W. Thus, it has additional error, but it can be implemented in three passes over the matrix using only constant additional RAM. To achieve an additional error (beyond the best rank k approximation) that is at most $\epsilon\|A\|_F^2$, both algorithms take time which is polynomial in k, $1/\epsilon$, and $\log(1/\delta)$, where $\delta > 0$ is a failure probability; the first takes time linear in $\max(m, n)$ and the second takes time independent of m and n. Our bounds improve previously published results with respect to the rank parameter k for both the Frobenius and spectral norms. In addition, the proofs for the error bounds use a novel method that makes important use of matrix perturbation theory. The probability distribution over columns of A and the rescaling are crucial features of the algorithms which must be chosen judiciously.

1. Introduction.

We are interested in developing and analyzing fast Monte Carlo algorithms for performing useful computations on large matrices. In this paper we consider the singular value decomposition (SVD); in two related papers we consider matrix multiplication and a new method for computing a compressed approximate decomposition of a large matrix [13, 14]. Since such computations generally require

time which is superlinear in the number of nonzero elements of the matrix, we expect our algorithms to be useful in many applications where data sets are modeled by matrices and are extremely large. In all these cases, we assume that the input matrices are prohibitively large to store in random access memory (RAM) and thus that only external memory storage is possible. Our algorithms will be allowed to read the matrices a few, e.g., one, two or three, times and keep a small randomly chosen and rapidly computable "sketch" of the matrices in RAM; computations will then be performed on this "sketch." We will work within the framework of the pass-efficient computational model, in which the scarce computational resources are the number of passes over the data, the additional RAM space required, and the additional time required [13, 12].

In many applications, the data consist of (or may be naturally formulated as) an $m \times n$ matrix A which is either low-rank or is well approximated by a low-rank matrix [7, 9, 25, 3, 26, 28, 29, 24, 22]. In these application areas, e.g., latent semantic indexing, DNA microarray analysis, facial and object recognition, and web search models, the data may consist of m points in $\mathbb{R}^n$. Let $A \in \mathbb{R}^{m \times n}$ be the matrix with these points as rows. Two methods for dealing with such high-dimensional data are the SVD (and the related principal components analysis) and multidimensional scaling [18, 23]. Thus, it is often of interest to find a low-rank approximation to A, i.e., an approximation D, of rank no greater than a specified rank k, to the matrix A, where k is much smaller than m and n. For example, this rank reduction is used in many applications of linear algebra and statistics as well as in image processing, lossy data compression, text analysis, and cryptography [6]. The SVD may be used to find an approximation to A which is the best in a well-defined sense [18, 19], but it requires a superlinear (in m and n) polynomial time dependence that is prohibitive for many applications in which the data sets are very large. Another method that has attracted interest recently is the traditional "random projection" method where one projects the problem into a randomly chosen low-dimensional subspace [21, 30, 20]. This dimensional reduction requires performing an operation that amounts to premultiplying the given $m \times n$ matrix A by an $s \times m$ matrix which takes time dependent in a superlinear manner on $m + n$.

In this paper we present two simple and intuitive algorithms which, when given an $m \times n$ matrix A, compute a description of a low-rank approximation D^* to A, and which are qualitatively faster than the SVD. Both algorithms have provable bounds for the error matrix $A - D^*$. For any matrix X, let $\|X\|_F$ and $\|X\|_2$ denote its Frobenius norm and its spectral norm (as defined in section 3.1), respectively. In the first algorithm, the LinearTimeSVD algorithm of section 4, c columns of A are randomly chosen. If the $m \times c$ matrix C consists of those c columns of A (after appropriate rescaling), then it is shown that from $C^T C$ approximations to the top singular values and corresponding singular vectors of A may be computed. From the computed singular vectors a description D^* of the matrix A may be computed such that $\text{rank}(D^*) \leq k$ and such that

$$\|A - D^*\|_\xi^2 \leq \min_{D:\text{rank}(D)\leq k} \|A - D\|_\xi^2 + poly(k, 1/c)\, \|A\|_F^2 \tag{1}$$

holds with high probability for each of $\xi = 2, F$. This algorithm may be implemented without storing the matrix A in RAM, provided it can make two passes over the matrix stored in external memory and use $O(cm + c^2)$ additional RAM. The second algorithm, the ConstantTimeSVD algorithm of section 5, is similar except that it further approximates the matrix C by randomly sampling r rows of C to form an $r \times c$

TABLE 1
Summary of sampling complexity.

Additional error for:	LINEARTIMESVD	CONSTANTTIMESVD	REF. [16, 17]
$\|A - D^*\|_2^2$	$1/\epsilon^2$	$1/\epsilon^4$	k^4/ϵ^3
$\|A - D^*\|_F^2$	k/ϵ^2	k^2/ϵ^4	k^4/ϵ^3

matrix W. Thus, it has additional error but can be implemented in three passes over the matrix using additional RAM that is $O(cr)$, i.e., that is constant for constant c and r. To achieve an additional error that is at most $\epsilon \|A\|_F^2$, both algorithms take time which is polynomial in k, $1/\epsilon$, and $\log(1/\delta)$, where $\delta > 0$ is a failure probability; see Table 1 for a summary of the dependence of the sampling complexity on k and ϵ. The first algorithm takes time linear in $\max(m, n)$ and the other takes time independent of m and n. Our bounds improve previously published results with respect to the rank parameter k for both the Frobenius and the spectral norms. In addition, the proofs for the error bounds use a novel method that makes important use of matrix perturbation theory. The probability distribution over columns of A and the rescaling are crucial features of the algorithms which must be chosen judiciously.

It is worth emphasizing how this work fits into recent work on computing low-rank matrix approximations. In the original work of Frieze, Kannan, and Vempala [16] (see also [17]) it was shown that by working with a randomly chosen and constant-sized submatrix of A, one could obtain bounds of the form (1) for the Frobenius norm (and thus indirectly for the spectral norm). To achieve an additional error that is at most $\epsilon \|A\|_F^2$, the size of the submatrix was a constant with respect to m and n but depended polynomially on k and $1/\epsilon$; although the submatrix was constant-sized, its construction (in particular, the construction of the sampling probabilities) required space and thus time that was linear in $m + n$. In this work, we modify the algorithm of [16] so that both the construction of *and* the computation on the constant-sized submatrix requires only constant additional space and time; thus, it fits within the framework of the pass-efficient model of data-streaming computation [12, 13]. In addition, we provide a different proof of the main result of [16] for the Frobenius norm and improve the polynomial dependence on k. Our proof method is quite different than that of [16]; it relies heavily on the approximate matrix multiplication result of [13] and [11] and it uses the Hoffman–Wielandt inequality. In addition, we provide a proof of a direct and significantly improved bound with respect to the spectral norm. Since these results are technically quite complex, we also present the corresponding proofs for both norms in the linear additional space and time framework [12, 13]. These latter results have been presented in the context of clustering applications [10], but are included here for completeness and to provide motivation and clarity for the more complex constant time results. Table 1 provides a summary of our results, for both the linear and the constant time models, and shows the number of rows and columns to be sampled sufficient to ensure, with high probability, an additional error of $\epsilon \|A\|_F^2$ in (1); see section 6 for more discussion.

In other related work, Achlioptas and McSherry have also computed low-rank approximations using somewhat different sampling techniques [2, 1]. The primary focus of their work was in introducing methods to accelerate orthogonal iteration and Lanczos iteration, which are two commonly used methods for computing low-rank approximations to a matrix. Also included in [2, 1] is a comparison of their methods with those of [10, 12, 16] and thus with the results we present here. Our algorithms

and those of [16] and [2, 1] come with mathematically rigorous guarantees of the running time and of the quality of the approximation produced. As far as we know, so-called incremental SVD algorithms, which bring as much of the data as possible into memory, compute the SVD, and then update this SVD in an incremental fashion with the remaining data, do not come with such guarantees.

In section 2 several applications areas that deal with large matrices are discussed, and in section 3 we provide a review of relevant linear algebra, the pass-efficient model, and an approximate matrix multiplication result that will be used extensively. Then, in section 4 our linear additional space and time approximation algorithm, the LINEARTIMESVD algorithm, is presented and analyzed; in section 5 our constant additional space and time approximation algorithm, the CONSTANTTIMESVD algorithm, is presented and analyzed. Finally, in section 6 a discussion and conclusion are presented.

2. Some applications. There are numerous applications in which the data are well approximated by a low-rank matrix. In this section we discuss several such applications to provide motivation for our algorithms.

2.1. Latent semantic indexing. Latent semantic indexing (LSI) is a general technique for analyzing a collection of documents which are assumed to be related [7, 9, 25]. Approaches to retrieving textual information from databases that depend on a lexical match between words in the query and words in the document can be inaccurate, both because often users want to retrieve information on the basis of conceptual content and because individual words do not in general provide reliable evidence about the conceptual topic of a document. LSI is an alternative matching method that attempts to overcome problems associated with lexical matching; it does so by assuming that there is some underlying or latent semantic structure that is partially obscured by variability in word choice and then using techniques such as SVD to remove the noise and estimate this latent structure.

Suppose that there are m documents and n terms which occur in the documents. Latent semantic structure analysis starts with a term-document matrix, e.g., a matrix $A \in \mathbb{R}^{m \times n}$, where A_{ij} is frequency of the jth term in the ith document. A topic is modeled as an n-vector of nonnegative reals summing to 1, where the jth component of a topic vector is interpreted as the frequency with which the jth term occurs in a discussion of the topic. By assumption, the number of topics that the documents are about is small relative to the number of unique terms n. It can be argued that, for a given k, finding a set of k topics which best describe the documents corresponds to keeping only the top k singular vectors of A; most of the important underlying structure in the association of terms and documents will then be kept and most of the noise or variability in word usage will be removed.

2.2. DNA microarray data. DNA microarray technology has been used to study a variety of biological processes since it permits the monitoring of the expression levels of thousands of genes under a range of experimental conditions [3, 26, 28]. Depending on the particular technology, either the absolute or the relative expression levels of m genes, which for model organisms may constitute nearly the entire genome, are probed simultaneously by a single microarray. A series of n arrays probe genome-wide expression levels in n different samples, i.e., under n different experimental conditions. The data from microarray experiments may thus be represented as a matrix $A \in \mathbb{R}^{m \times n}$, where A_{ij} represents the expression level of gene i under experimental condition j. From this matrix, both the relative expression level of the

ith gene under every condition and also the relative expression level of every gene under the jth condition may be easily extracted.

This matrix is low-rank and thus a small number of eigengenes and corresponding eigenarrays (left and right singular vectors) are sufficient to capture most of the gene expression information. Removing the rest, which correspond to noise or experimental artifacts, enables meaningful comparison of the expression levels of different genes. When processing and modeling genome-wide expression data, the SVD and its low-rank approximation provides a framework such that the mathematical variables and operations suggest assigned biological meaning, e.g., in terms of cellular regulatory processes and cellular states, that may be hidden in the original data due to experimental noise or hidden dependencies. Expression data has been used for inference tasks such as to identify genes based on coexpression, predict regulatory elements, and reverse-engineer transcription networks, but this inference is difficult with noise or dependencies.

2.3. Eigenfaces and facial recognition. Applications of SVD and low-rank approximations in computer vision include pattern estimation, image compression and restoration, and facial and object recognition, where the concept of eigenfaces has been useful [29, 24].

The goal of facial recognition is to recognize a certain face given a database of photographs of human faces under variations in lighting conditions and pose viewpoints. A common approach is to represent the database as a matrix in which the rows of the matrix are the images represented as vectors. Thus, if there are m images, each of which is of size $n \times n$, the matrix $A \in \mathbb{R}^{m \times n^2}$ represents the database of images, where A_{ij} is the jth pixel value in the ith image. Typically, $m \ll n^2$ and, although many of the singular vectors are needed for very accurate reconstruction of an image, often only a few of the singular vectors are needed to extract the major appearance characteristics of an image. The right singular vectors of the matrix A are known as eigenfaces since they are the principal components or eigenvectors of the associated correlation matrix of the set of face images. The eigenfaces are computed and they are used to project the database of photographs to a lower-dimensional space that spans the significant variations among known facial images. Then, given a new image, it is projected to the same low-dimensional space, and its position is then compared to the images in the database.

2.4. Web search model. The problem of how to extract information from the network structure of a hyperlinked environment such as the World Wide Web was considered by Kleinberg [22]. This is of interest, for example, if one wants to find web pages that are relevant to a given query and one is using a keyword-based web search program, since there is no obvious endogenous measure of an authoritative page that would favor it under a text-based ranking system.

Starting with a set of pages returned by a text-based search engine, a document is defined to be an authority if many other documents returned by the search point to it, i.e., have a hypertext link to it. A document is defined to be a hub if it points to many other documents. More generally, suppose n documents are returned by the search engine. Then, a matrix $A \in \mathbb{R}^{m \times n}$ is defined, where A_{ij} is 1 or 0 depending on whether the ith document points to the jth document. Kleinberg attempts to find two n-vectors, x and y, where x_i is the hub weight of document i and y_j is the authority weight of document j. He then argues that it is desirable to find $\max_{|x|=|y|=1} x^T A y$, where $|\cdot|$ denotes the Euclidean length, since in maximizing x, y one expects the hub weights and authority weights to be mutually consistent. This is simply the problem of

finding the singular vectors of A. Since A is large, he judiciously chooses a submatrix of A and computes only the singular vectors of it. In the case when the key word has multiple meanings, not only the top but also some of the other singular vectors with large singular values are interesting. Thus, it is of interest to find the k largest singular vectors form some small k. This is the problem we are considering, and we also find the singular vectors of a submatrix, but a randomly chosen one.

3. Review of relevant background. This section contains a review of linear algebra that will be useful throughout the paper; for more detail, see [18, 19, 27, 8] and the references therein. This section also contains a review of the pass-efficient model of data-streaming computation (which provides a framework within which our SVD results may be viewed) and a matrix multiplication result that will be used extensively in our proofs; see [11, 12, 13] for more details.

3.1. Review of linear algebra. For a vector $x \in \mathbb{R}^n$ we let x_i, $i = 1, \ldots, n$, denote the ith element of x and we let $|x| = (\sum_{i=1}^n |x_i|^2)^{1/2}$. For a matrix $A \in \mathbb{R}^{m \times n}$ we let $A^{(j)}$, $j = 1, \ldots, n$, denote the jth column of A as a column vector and $A_{(i)}$, $i = 1, \ldots, m$, denote the ith row of A as a row vector; thus, if A_{ij} denotes the (i, j)th element of A, $A_{ij} = (A^{(j)})_i = (A_{(i)})_j$. The range of an $A \in \mathbb{R}^{m \times n}$ is

$$\text{range}(A) = \{y \in \mathbb{R}^m : \ y = Ax \ \text{ for some } \ x \in \mathbb{R}^n\} = \mathbf{span}(A^{(1)}, \ldots, A^{(n)}).$$

The rank of A, $\text{rank}(A)$, is the dimension of $\text{range}(A)$ and is equal to the number of linearly independent columns of A; since this is equal to $\text{rank}(A^T)$ it also equals the number of linearly independent rows of A. The null space of A is

$$\text{null}(A) = \{x \in \mathbb{R}^n : Ax = 0\}.$$

For a matrix $A \in \mathbb{R}^{m \times n}$ we denote matrix norms by $\|A\|_\xi$, using subscripts to distinguish between various norms. Of particular interest will be the Frobenius norm, which is defined by

$$\|A\|_F = \sqrt{\sum_{i=1}^m \sum_{j=1}^n A_{ij}^2}. \tag{2}$$

If $\mathbf{Tr}\,(A)$ is the matrix trace which is the sum of the diagonal elements of A, then $\|A\|_F^2 = \mathbf{Tr}(A^T A) = \mathbf{Tr}(AA^T)$. Also of interest is the spectral norm, which is defined by

$$\|A\|_2 = \sup_{x \in \mathbb{R}^n, \ x \neq 0} \frac{|Ax|}{|x|}. \tag{3}$$

Both of these norms are submultiplicative and unitarily invariant and they are related to each other as

$$\|A\|_2 \leq \|A\|_F \leq \sqrt{n}\, \|A\|_2 .$$

Both of these norms provide a measure of the "size" of the matrix A. Note that if $A \in \mathbb{R}^{m \times n}$, then there exists an $x \in \mathbb{R}^n$ such that $|x| = 1$ and $A^T Ax = \|A\|_2^2\, x$ and that if $\{x^1, x^2, \ldots, x^n\}$ is any basis of $\mathbb{R}^n$ and if $A \in \mathbb{R}^{m \times n}$, then $\|A\|_F^2 = \sum_{i=1}^n \left|Ax^i\right|^2$.

If $A \in \mathbb{R}^{m\times n}$, then there exist orthogonal matrices $U = [u^1 u^2 \dots u^m] \in \mathbb{R}^{m\times m}$ and $V = [v^1 v^2 \dots v^n] \in \mathbb{R}^{n\times n}$ where $\{u^t\}_{t=1}^m \in \mathbb{R}^m$ and $\{v^t\}_{t=1}^n \in \mathbb{R}^n$ are such that

$$U^T A V = \Sigma = \mathbf{diag}(\sigma_1, \dots, \sigma_\rho), \tag{4}$$

where $\Sigma \in \mathbb{R}^{m\times n}$, $\rho = \min\{m, n\}$, and $\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_\rho \geq 0$. Equivalently,

$$A = U\Sigma V^T.$$

The three matrices U, V, and Σ constitute the SVD of A. The σ_i are the singular values of A and the vectors u^i, v^i are the ith left and the ith right singular vectors, respectively. The columns of U and V satisfy the relations $Av^i = \sigma_i u^i$ and $A^T u^i = \sigma_i v^i$. For symmetric matrices the left and right singular vectors are the same. The singular values of A are the nonnegative square roots of the eigenvalues of $A^T A$ and of AA^T; furthermore, the columns of U, i.e., the left singular vectors, are eigenvectors of AA^T and the columns of V, i.e., the right singular vectors, are eigenvectors of $A^T A$.

The SVD can reveal important information about the structure of a matrix. If we define r by $\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_r > \sigma_{r+1} = \cdots = \sigma_\rho = 0$, then $\mathrm{rank}(A) = r$, $\mathrm{null}(A) = \mathbf{span}(v^{r+1}, \dots, v^\rho)$, and $\mathrm{range}(A) = \mathbf{span}(u^1, \dots, u^r)$. If we let $U_r \in \mathbb{R}^{m\times r}$ denote the matrix consisting of the first r columns of U, $V_r \in \mathbb{R}^{r\times n}$ denote the matrix consisting of the first r columns of V, and $\Sigma_r \in \mathbb{R}^{r\times r}$ denote the principal $r \times r$ submatrix of Σ, then

$$A = U_r \Sigma_r V_r^T = \sum_{t=1}^{r} \sigma_t u^t v^{tT}. \tag{5}$$

Note that this decomposition property provides a canonical description of a matrix as a sum of r rank-one matrices of decreasing importance. If $k \leq r$ and we define

$$A_k = U_k \Sigma_k V_k^T = \sum_{t=1}^{k} \sigma_t u^t v^{tT}, \tag{6}$$

then $A_k = U_k U_k^T A = (\sum_{t=1}^k u^t u^{tT})A$ and $A_k = AV_k V_k^T = A(\sum_{t=1}^k v^t v^{tT})$, i.e., A_k is the projection of A onto the space spanned by the top k singular vectors of A. Furthermore, the distance (as measured by both $\|\cdot\|_2$ and $\|\cdot\|_F$) between A and any rank-k approximation to A is minimized by A_k, i.e.,

$$\min_{D\in\mathbb{R}^{m\times n}:\mathrm{rank}(D)\leq k} \|A - D\|_2 = \|A - A_k\|_2 = \sigma_{k+1}(A) \tag{7}$$

and

$$\min_{D\in\mathbb{R}^{m\times n}:\mathrm{rank}(D)\leq k} \|A - D\|_F^2 = \|A - A_k\|_F^2 = \sum_{t=k+1}^{r} \sigma_t^2(A). \tag{8}$$

Thus, A_k constructed from the k largest singular triplets of A is the optimal rank-k approximation to A with respect to both $\|\cdot\|_F$ and $\|\cdot\|_2$. More generally, one can also show that $\|A\|_2 = \sigma_1$ and that $\|A\|_F^2 = \sum_{i=1}^r \sigma_i^2$.

From the perturbation theory of matrices it is known that the size of the difference between two matrices can be used to bound the difference between the singular value spectrum of the two matrices [27, 8]. In particular, if $A, E \in \mathbb{R}^{m\times n}, m \geq n$, then

$$\max_{t:1\leq t\leq n} |\sigma_t(A + E) - \sigma_t(A)| \leq \|E\|_2 \tag{9}$$

and

$$\sum_{k=1}^{n}(\sigma_k(A+E)-\sigma_k(A))^2 \le \|E\|_F^2 . \tag{10}$$

The latter inequality is known as the Hoffman–Wielandt inequality.

3.2. Review of the pass-efficient model. The pass-efficient model of data-streaming computation is a computational model that is motivated by the observation that in modern computers the amount of disk storage, i.e., sequential access memory, has increased very rapidly, while RAM and computing speeds have increased at a substantially slower pace [13, 12]. In the pass-efficient model the three scarce computational resources are number of passes over the data and the additional RAM space and additional time required by the algorithm. The data are assumed to be stored on a disk, to consist of elements whose size is bounded by a constant, and to be presented to an algorithm on a read-only tape. See [13] for more details.

3.3. Review of matrix multiplication. The BasicMatrixMultiplication algorithm to approximate the product of two matrices is presented and analyzed in [13]. When this algorithm is given as input two matrices, $A \in \mathbb{R}^{m\times n}$ and $B \in \mathbb{R}^{n\times p}$, a probability distribution $\{p_i\}_{i=1}^n$, and a number $c \le n$, it returns as output two matrices, C and R, such that $CR \approx AB$; $C \in \mathbb{R}^{m\times c}$ is a matrix whose columns are c randomly chosen columns of A (suitably rescaled) and $R \in \mathbb{R}^{c\times p}$ is a matrix whose rows are the c corresponding rows of B (also suitably rescaled). An important aspect of this algorithm is the probability distribution $\{p_i\}_{i=1}^n$ used to choose column-row pairs. Although one could always use a uniform distribution, superior results are obtained if the probabilities are chosen judiciously. In particular, a set of sampling probabilities $\{p_i\}_{i=1}^n$ are *nearly optimal probabilities* if they are of the form (11) and are the *optimal probabilities* (with respect to approximating the product AB) if they are of the form (11) with $\beta = 1$. In [13] we prove the following theorem.

Theorem 1. *Suppose $A \in \mathbb{R}^{m\times n}$, $B \in \mathbb{R}^{n\times p}$, $c \in \mathbb{Z}^+$ such that $1 \le c \le n$, and $\{p_i\}_{i=1}^n$ are such that $p_i \ge 0$, $\sum_{i=1}^n p_i = 1$ and such that for some positive constant $\beta \le 1$*

$$p_k \ge \frac{\beta \left|A^{(k)}\right| \left|B_{(k)}\right|}{\sum_{k'=1}^{n} \left|A^{(k')}\right| \left|B_{(k')}\right|}. \tag{11}$$

Construct C and R with the BasicMatrixMultiplication *algorithm of* [13] *and let CR be an approximation to AB. Then*

$$\mathbf{E}\left[\, \|AB-CR\|_F^2 \,\right] \le \frac{1}{\beta c}\, \|A\|_F^2\, \|B\|_F^2 . \tag{12}$$

Furthermore, let $\delta \in (0,1)$ and $\eta = 1+\sqrt{(8/\beta)\log(1/\delta)}$. Then, with probability at least $1-\delta$,

$$\|AB-CR\|_F^2 \le \frac{\eta^2}{\beta c}\, \|A\|_F^2\, \|B\|_F^2 . \tag{13}$$

In [13] it is shown that after one pass over the matrices nearly optimal probabilities can be constructed. In the present paper, we will be particularly interested in the case that $B = A^T$. In this case, using the Select algorithm of [13] random samples can be drawn according to nearly optimal probabilities using $O(1)$ additional space and time.

LINEARTIMESVD Algorithm.

Input: $A \in \mathbb{R}^{m \times n}$, $c, k \in \mathbb{Z}^+$ such that $1 \leq k \leq c \leq n$, $\{p_i\}_{i=1}^n$ such that $p_i \geq 0$ and $\sum_{i=1}^n p_i = 1$.

Output: $H_k \in \mathbb{R}^{m \times k}$ and $\sigma_t(C), t = 1, \ldots, k$.

1. For $t = 1$ to c,
   (a) Pick $i_t \in 1, \ldots, n$ with $\mathbf{Pr}[i_t = \alpha] = p_\alpha$, $\alpha = 1, \ldots, n$.
   (b) Set $C^{(t)} = A^{(i_t)}/\sqrt{cp_{i_t}}$.
2. Compute $C^T C$ and its SVD; say $C^T C = \sum_{t=1}^c \sigma_t^2(C) y^t y^{t^T}$.
3. Compute $h^t = Cy^t/\sigma_t(C)$ for $t = 1, \ldots, k$.
4. Return H_k, where $H_k^{(t)} = h^t$, and $\sigma_t(C), t = 1, \ldots, k$.

FIG. 1. *The* LINEARTIMESVD *algorithm.*

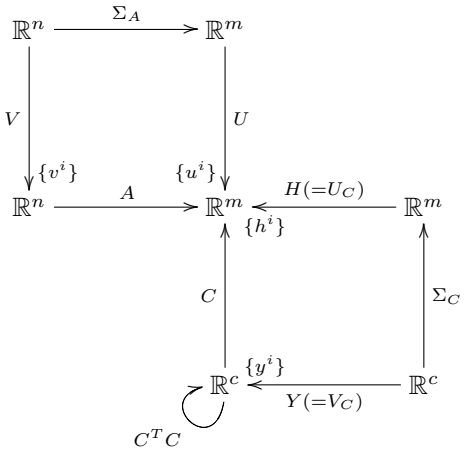

FIG. 2. *Diagram for the* LINEARTIMESVD *algorithm.*

4. Linear time SVD approximation algorithm.

4.1. The algorithm. Given a matrix $A \in \mathbb{R}^{m \times n}$ we wish to approximate its top k singular values and the corresponding singular vectors in a constant number of passes through the data and $O(cm + c^2)$ additional space and $O(c^2 m + c^3)$ additional time. The strategy behind the LINEARTIMESVD algorithm is to pick c columns of the matrix A, rescale each by an appropriate factor to form a matrix $C \in \mathbb{R}^{m \times c}$, and then compute the singular values and corresponding left singular vectors of the matrix C, which will be approximations to the singular values and left singular vectors of A, in a sense we make precise later. These are calculated by performing an SVD of the matrix $C^T C$ to compute the right singular vectors of C and from them calculating the left singular vectors of C.

The LINEARTIMESVD algorithm is described in Figure 1; it takes as input a matrix A and returns as output an approximation to the top k left singular values and the corresponding singular vectors. Note that by construction the SVD of C is

$C = H\Sigma_C Y^T$. A diagram illustrating the action of the LINEARTIMESVD algorithm is presented in Figure 2. The transformation represented by the matrix A is shown along with its SVD, and the transformation represented by the matrix C is also shown along with its SVD. It will be shown that if the probabilities $\{p_i\}_{i=1}^n$ are chosen judiciously, then the left singular vectors of C are with high probability approximations to the left singular vectors of A.

In section 4.2 we discuss running-time issues, and in section 4.3 we will prove the correctness of the algorithm.

4.2. Analysis of the implementation and running time. Assuming that nearly optimal sampling probabilities (as defined in section 3.3) are used, then in the LINEARTIMESVD algorithm the sampling probabilities p_k can be used to select columns to be sampled in one pass and $O(c)$ additional space and time using the SELECT algorithm of [13]. Given the elements to be sampled, the matrix C can then be constructed in one additional pass; this requires additional space and time that is $O(mc)$. Given $C \in \mathbb{R}^{m\times c}$, computing C^TC requires $O(mc)$ additional space and $O(mc^2)$ additional time, and computing the SVD of C^TC requires $O(c^3)$ additional time. Then computing H_k requires k matrix-vector multiplications for a total of $O(mck)$ additional space and time. Thus, overall $O(cm + c^2)$ additional space and $O(c^2m + c^3)$ additional time are required by the LINEARTIMESVD algorithm. Note that the "description" of the solution that is computable in the allotted additional space and time is the explicit approximation to the top k singular values and corresponding left singular vectors.

4.3. Analysis of the sampling step. Approximating A by $A_k = U_kU_k^TA$ incurs an error equal to $\|A - A_k\|_F^2 = \sum_{t=k+1}^r \sigma_t^2(A)$ and $\|A - A_k\|_2 = \sigma_{k+1}(A)$, since A_k is the "optimal" rank-k approximation to A with respect to both $\|\cdot\|_F$ and $\|\cdot\|_2$. We will show that in addition to this error the matrix $H_kH_k^TA$ has an error that depends on $\|AA^T - CC^T\|_F$. Then, using the results of Theorem 1, we will show that this additional error depends on $\|A\|_F^2$. We first consider obtaining a bound with respect to the Frobenius norm.

THEOREM 2. *Suppose $A \in \mathbb{R}^{m\times n}$ and let H_k be constructed from the* LINEARTIMESVD *algorithm. Then*

$$\left\|A - H_kH_k^TA\right\|_F^2 \le \|A - A_k\|_F^2 + 2\sqrt{k}\left\|AA^T - CC^T\right\|_F.$$

Proof. Recall that for matrices X and Y, $\|X\|_F^2 = \mathbf{Tr}(X^TX)$, $\mathbf{Tr}(X+Y) = \mathbf{Tr}(X) + \mathbf{Tr}(Y)$, and also that $H_k^TH_k = I_k$. Thus, we may express $\left\|A - H_kH_k^TA\right\|_F^2$ as

$$\begin{aligned}\left\|A - H_kH_k^TA\right\|_F^2 &= \mathbf{Tr}\left((A - H_kH_k^TA)^T(A - H_kH_k^TA)\right)\\ &= \mathbf{Tr}\left(A^TA - 2A^TH_kH_k^TA + A^TH_kH_k^TH_kH_k^TA\right)\\ &= \mathbf{Tr}\left(A^TA\right) - \mathbf{Tr}\left(A^TH_kH_k^TA\right)\\ &= \|A\|_F^2 - \left\|A^TH_k\right\|_F^2. \qquad (14)\end{aligned}$$

We may relate $\left\|A^T H^k\right\|_F^2$ and $\sum_{t=1}^k \sigma_t^2(C)$ by the following:

$$\begin{aligned}
\left| \left\|A^T H_k\right\|_F^2 - \sum_{t=1}^k \sigma_t^2(C) \right| &\leq \sqrt{k} \left(\sum_{t=1}^k \left(\left|A^T h^t\right|^2 - \sigma_t^2(C) \right)^2 \right)^{1/2} \\
&= \sqrt{k} \left(\sum_{t=1}^k \left(\left|A^T h^t\right|^2 - \left|C^T h^t\right|^2 \right)^2 \right)^{1/2} \\
&= \sqrt{k} \left(\sum_{t=1}^k \left({h^t}^T (AA^T - CC^T) h^t \right)^2 \right)^{1/2} \\
&\leq \sqrt{k} \left\|AA^T - CC^T\right\|_F . \qquad (15)
\end{aligned}$$

The first inequality follows by applying the Cauchy–Schwarz inequality; the last inequality follows by writing AA^T and CC^T with respect to a basis containing $\{h^t\}_{t=1}^k$. By again applying the Cauchy–Schwarz inequality, noting that $\sigma_t^2(X) = \sigma_t(XX^T)$ for a matrix X, and applying the Hoffman–Wielandt inequality (10), we may also relate $\sum_{k=1}^k \sigma_t^2(C)$ and $\sum_{k=1}^k \sigma_t^2(A)$ by the following:

$$\begin{aligned}
\left| \sum_{t=1}^k \sigma_t^2(C) - \sum_{t=1}^k \sigma_t^2(A) \right| &\leq \sqrt{k} \left(\sum_{t=1}^k \left(\sigma_t^2(C) - \sigma_t^2(A) \right)^2 \right)^{1/2} \\
&= \sqrt{k} \left(\sum_{t=1}^k \left(\sigma_t(CC^T) - \sigma_t(AA^T) \right)^2 \right)^{1/2} \\
&\leq \sqrt{k} \left(\sum_{t=1}^m \left(\sigma_t(CC^T) - \sigma_t(AA^T) \right)^2 \right)^{1/2} \\
&\leq \sqrt{k} \left\|CC^T - AA^T\right\|_F . \qquad (16)
\end{aligned}$$

Combining the results of (15) and (16) allows us to relate $\left\|A^T H_k\right\|_F^2$ and $\sum_{t=1}^k \sigma_t^2(A)$ by the following:

$$\left| \left\|A^T H_k\right\|_F^2 - \sum_{t=1}^k \sigma_t^2(A) \right| \leq 2\sqrt{k} \left\|AA^T - CC^T\right\|_F . \qquad (17)$$

Combining (17) with (14) yields the theorem. ∎

We next prove a similar result for the spectral norm; note that the factor $\sqrt{k}$ is not present.

THEOREM 3. *Suppose $A \in \mathbb{R}^{m \times n}$ and let H_k be constructed from the* LINEARTIMESVD *algorithm. Then*

$$\left\|A - H_k H_k^T A\right\|_2^2 \leq \|A - A_k\|_2^2 + 2 \left\|AA^T - CC^T\right\|_2 .$$

Proof. Let $\mathcal{H}_k = \text{range}(H_k) = \mathbf{span}(h^1, \ldots, h^k)$ and let $\mathcal{H}_{m-k}$ be the orthogonal complement of $\mathcal{H}_k$. Let $x \in \mathbb{R}^m$ and let $x = \alpha y + \beta z$, where $y \in \mathcal{H}_k$, $z \in \mathcal{H}_{m-k}$, and

$\alpha^2 + \beta^2 = 1$; then

$$\begin{aligned}
\left\|A - H_k H_k^T A\right\|_2 &= \max_{x \in \mathbb{R}^m, |x|=1} \left|x^T (A - H_k H_k^T A)\right| \\
&= \max_{y \in \mathcal{H}_k, |y|=1, z \in \mathcal{H}_{m-k}, |z|=1, \alpha^2+\beta^2=1} \left|(\alpha y^T + \beta z^T)(A - H_k H_k^T A)\right| \\
&\leq \max_{y \in \mathcal{H}_k, |y|=1} \left|y^T (A - H_k H_k^T A)\right| + \max_{z \in \mathcal{H}_{m-k}, |z|=1} \left|z^T (A - H_k H_k^T A)\right| \qquad (18) \\
&= \max_{z \in \mathcal{H}_{m-k}, |z|=1} \left|z^T A\right|. \qquad (19)
\end{aligned}$$

Inequality (18) follows since $\alpha, \beta \leq 1$ and (19) follows since $y \in \mathcal{H}_k$ and $z \in \mathcal{H}_{m-k}$. We next bound (19):

$$\begin{aligned}
\left|z^T A\right|^2 &= z^T C C^T z + z^T \left(A A^T - C C^T\right) z \\
&\leq \sigma_{k+1}^2(C) + \|A A^T - C C^T\|_2 \qquad (20) \\
&\leq \sigma_{k+1}^2(A) + 2\|A A^T - C C^T\|_2 \qquad (21) \\
&= \|A - A_k\|_2^2 + 2\|A A^T - C C^T\|_2. \qquad (22)
\end{aligned}$$

Inequality (20) follows since $\max_{z \in \mathcal{H}_{m-k}} |z^T C|$ occurs when z is the $(k+1)$st left singular vector, i.e., the maximum possible in the $\mathcal{H}_{m-k}$ subspace. Inequality (21) follows since $\sigma_{k+1}^2(C) = \sigma_{k+1}(C C^T)$ and since by (9) we have that $\sigma_{k+1}^2(C) \leq \sigma_{k+1}(A A^T) + \|A A^T - C C^T\|_2$; (22) follows since $\|A - A_k\|_2 = \sigma_{k+1}(A)$. The theorem then follows by combining (19) and (22). □

Theorems 2 and 3 hold regardless of the sampling probabilities $\{p_i\}_{i=1}^n$. Since $\|A - A_k\|_\xi$, $\xi = 2, F$, is a property of the matrix A, the choice of sampling probabilities enters into the error of $\|A - H_k H_k^T A\|_\xi^2$ only through the term involving the additional error beyond the optimal rank-k approximation, i.e., the term $\|A A^T - C C^T\|_\xi$. Although the additional error in Theorem 3 depends on $\|A A^T - C C^T\|_2$, we note that $\|A A^T - C C^T\|_2 \leq \|A A^T - C C^T\|_F$ and will use a bound for the latter quantity to bound the former in the following. Note that the prefactor of the additional error is $2\sqrt{k}$ for $\|\cdot\|_F^2$, while that for $\|\cdot\|_2^2$ is only 2.

In the following theorem we specialize the sampling probabilities to be those that are nearly optimal; by choosing enough columns, the error in the approximation of the SVD can be made arbitrarily small.

THEOREM 4. *Suppose $A \in \mathbb{R}^{m \times n}$; let H_k be constructed from the* LINEARTIMESVD *algorithm by sampling c columns of A with probabilities $\{p_i\}_{i=1}^n$ such that $p_i \geq \beta \left|A^{(i)}\right|^2 / \|A\|_F^2$ for some positive $\beta \leq 1$, and let $\eta = 1 + \sqrt{(8/\beta)\log(1/\delta)}$. Let $\epsilon > 0$. If $c \geq 4k/\beta\epsilon^2$, then*

$$\mathbf{E}\left[\left\|A - H_k H_k^T A\right\|_F^2\right] \leq \|A - A_k\|_F^2 + \epsilon \|A\|_F^2, \qquad (23)$$

and if $c \geq 4k\eta^2/\beta\epsilon^2$, then with probability at least $1 - \delta$,

$$\left\|A - H_k H_k^T A\right\|_F^2 \leq \|A - A_k\|_F^2 + \epsilon \|A\|_F^2. \qquad (24)$$

In addition, if $c \geq 4/\beta\epsilon^2$, then

$$\mathbf{E}\left[\left\|A - H_k H_k^T A\right\|_2^2\right] \leq \|A - A_k\|_2^2 + \epsilon \|A\|_F^2, \qquad (25)$$

and if $c \geq 4\eta^2/\beta\epsilon^2$*, then with probability at least* $1-\delta$*,*

$$\left\|A - H_k H_k^T A\right\|_2^2 \leq \|A - A_k\|_2^2 + \epsilon \|A\|_F^2 . \tag{26}$$

Proof. By combining Theorems 2 and 3 with Theorem 1 we have that

$$\mathbf{E}\left[\, \left\|A - H_k H_k^T A\right\|_F^2 \,\right] \leq \|A - A_k\|_F^2 + \left(\frac{4k}{\beta c}\right)^{1/2} \|A\|_F^2 , \tag{27}$$

$$\mathbf{E}\left[\, \left\|A - H_k H_k^T A\right\|_2^2 \,\right] \leq \|A - A_k\|_2^2 + \left(\frac{4}{\beta c}\right)^{1/2} \|A\|_F^2 , \tag{28}$$

and that with probability at least $1-\delta$,

$$\left\|A - H_k H_k^T A\right\|_F^2 \leq \|A - A_k\|_F^2 + \left(\frac{4\eta^2 k}{\beta c}\right)^{1/2} \|A\|_F^2 , \tag{29}$$

$$\left\|A - H_k H_k^T A\right\|_2^2 \leq \|A - A_k\|_2^2 + \left(\frac{4\eta^2}{\beta c}\right)^{1/2} \|A\|_F^2 . \tag{30}$$

The theorem follows by using the appropriate value of c. □

Note that alternatively one could sample rows instead of columns of a matrix; in this case, a modified version of the LinearTimeSVD algorithm leads to results analogous to Theorems 2 through 4.

5. Constant time SVD approximation algorithm.

5.1. The algorithm. Given a matrix $A \in \mathbb{R}^{m\times n}$ we now wish to approximate its top k singular values and the corresponding singular vectors in a constant number of passes through the data and additional space and time that are $O(1)$, independent of m and n. The strategy behind the ConstantTimeSVD algorithm is to pick c columns of the matrix A, rescale each by an appropriate factor to form a matrix $C \in \mathbb{R}^{m\times c}$, and then compute approximations to the singular values and left singular vectors of the matrix C, which will then be approximations to the singular values and left singular vectors of A. In the LinearTimeSVD algorithm of section 4, the left singular vectors of the matrix C are computed exactly; as the analysis of section 4.2 showed, this computation takes additional space and time that is linear in $m+n$ (assuming that c is constant). With the ConstantTimeSVD algorithm, in order to use only a constant $O(1)$ additional space and time, sampling is performed again, drawing rows of C to construct a matrix $W \in \mathbb{R}^{w\times c}$. The SVD of W^TW is then computed; let $W^TW = Z\Sigma_{W^TW}Z^T = Z\Sigma_W^2 Z^T$. The singular values and corresponding singular vectors so obtained are with high probability approximations to the singular values and singular vectors of C^TC and thus to the singular values and right singular vectors of C. Note that this is simply using the LinearTimeSVD algorithm to approximate the right singular vectors of C by randomly sampling rows of C.

The ConstantTimeSVD algorithm is described in Figure 3; it takes as input a matrix A and returns as output a "description" of an approximation to the top k left singular values and the corresponding singular vectors. This "description" of the approximations to the left singular vectors of A may, at the expense of one additional pass and linear additional space and time, be converted into an explicit

ConstantTimeSVD Algorithm.

Input: $A \in \mathbb{R}^{m \times n}$, $c, w, k \in \mathbb{Z}^+$ such that $1 \leq w \leq m$, $1 \leq c \leq n$, and $1 \leq k \leq \min(w, c)$, and $\{p_i\}_{i=1}^n$ such that $p_i \geq 0$ and $\sum_{i=1}^n p_i = 1$.

Output: $\sigma_t(W), t = 1, \ldots, \ell$ and a "description" of $\tilde{H}_\ell \in \mathbb{R}^{m \times \ell}$.

1. For $t = 1$ to c,
   (a) Pick $i_t \in 1, \ldots, n$ with $\mathbf{Pr}[i_t = \alpha] = p_\alpha$, $\alpha = 1, \ldots, n$, and save $\{(i_t, p_{j_t}) : t = 1, \ldots, c\}$.
   (b) Set $C^{(t)} = A^{(i_t)}/\sqrt{cp_{i_t}}$. (Note that C is not explicitly constructed in RAM.)
2. Choose $\{q_j\}_{j=1}^m$ such that $q_j = \left|C_{(j)}\right|^2 / \|C\|_F^2$.
3. For $t = 1$ to w,
   (a) Pick $j_t \in 1, \ldots, m$ with $\mathbf{Pr}[j_t = \alpha] = q_\alpha$, $\alpha = 1, \ldots, m$.
   (b) Set $W_{(t)} = C_{(j_t)}/\sqrt{wq_{j_t}}$.
4. Compute $W^T W$ and its SVD. Say $W^T W = \sum_{t=1}^c \sigma_t^2(W) z^t z^{tT}$.
5. If a $\|\cdot\|_F$ bound is desired, set $\gamma = \epsilon/100k$,
   Else if a $\|\cdot\|_2$ bound is desired, set $\gamma = \epsilon/100$.
6. Let $\ell = \min\{k, \max\{t : \sigma_t^2(W) \geq \gamma \|W\|_F^2\}\}$.
7. Return singular values $\{\sigma_t(W)\}_{t=1}^\ell$ and their corresponding singular vectors $\{z^t\}_{t=1}^\ell$.

Fig. 3. *The* ConstantTimeSVD *algorithm.*

approximation to the left singular vectors of A by using $C = \tilde{H}\Sigma_W Z^T$ to compute $\tilde{H}$, whose columns are approximations of the left singular vectors of C. Note that γ in the ConstantTimeSVD algorithm is introduced to bound small singular values of C that may be perturbed by the second level of sampling; as indicated, the particular value of γ that is chosen depends on the norm bound which is desired. Note also that the probabilities $\{q_j\}_{j=1}^m$ used in the algorithm are optimal (in the sense of section 3.3), as will be the probabilities $\{p_i\}_{i=1}^n$ which will enter into Theorem 5.

A diagram illustrating the action of the ConstantTimeSVD algorithm is presented in Figure 4. The transformation represented by the matrix A is represented along with its SVD, and the transformation represented by the matrix C is also shown (but note that its SVD is not shown). The transformation represented by the matrix W, which is constructed from C with the second level of sampling, is also shown along with its SVD. In addition, approximations to the right singular vectors of C and to the left singular vectors of C calculated from $C = \tilde{H}\Sigma_W Z^T$ are shown.

In section 5.2 we will show that this algorithm takes $O(1)$, i.e., a constant with respect to m and n, additional space and time, assuming that c and w are constant. In section 5.3 we will state Theorem 5, which will establish the correctness of the algorithm; this theorem is the main result of this section and is the analogue of Theorem 4. Finally, in section 5.4 we will prove Theorem 5.

5.2. Analysis of the implementation and running time. Assuming that optimal sampling probabilities (as defined in section 3.3) are used, then in the ConstantTimeSVD algorithm the sampling probabilities p_k can be used to select columns to be sampled in one pass and $O(c)$ additional space and time using the Select algorithm of [13]. Given the columns of A to be sampled, we do not explicitly construct the

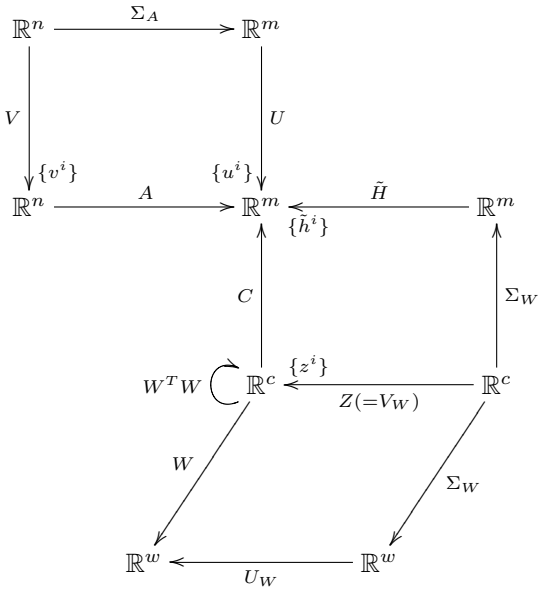

FIG. 4. *Diagram for the* CONSTANTTIMESVD *algorithm.*

matrix C but instead perform a second level of sampling and select w rows of C with probabilities $\{q_i\}_{i=1}^m$ (as described in the CONSTANTTIMESVD algorithm) in order to construct the matrix W. We do this by performing a second pass and using $O(w)$ additional space and time, again using the SELECT algorithm. Then in a third pass we explicitly construct W; this requires additional space and time that is $O(cw)$. Then, given W, computing W^TW requires $O(cw)$ additional space and $O(c^2w)$ additional time, and computing the SVD of W^TW requires $O(c^3)$ additional time. The singular values and corresponding singular vectors thus computed can then be returned as the "description" of the solution. The total additional time for the CONSTANTTIMESVD algorithm is then $O(c^3 + cw^2)$; this is a constant if c and w are assumed to be a constant. To explicitly compute $\tilde{H}_k$ would require k matrix-vector multiplications which would require another pass over the data and $O(mck)$ additional space and time.

5.3. Statement of Theorem 5. This subsection and the next provide an analysis of the CONSTANTTIMESVD algorithm similar to the analysis of the LINEARTIMESVD algorithm found in section 4.3. Recall that in section 4 we were interested in bounding $\left\|A - H_k H_k^T A\right\|_\xi^2$, where $\xi = F, 2$. In that case, $H_k^T H_k = I_k$, $H_k H_k^T$ was an orthonormal projection, and $H_k H_k^T A$ was our rank at most k approximation to A. In the constant time model, we do not have access to H_k but instead to $\tilde{H}_\ell$, where the columns of $\tilde{H}_\ell$, i.e., $\tilde{h}^t = Cz^t/\sigma_t(W), t = 1, \ldots, \ell$, do *not* form an orthonormal set. However, by Lemma 2 of section 5.4.1, if C and W are constructed by sampling with optimal probabilities, then with high probability the columns of $\tilde{H}_\ell$ are approximately orthonormal, $\tilde{H}_\ell^T \tilde{H}_\ell \approx I_\ell$, and $\tilde{H}_\ell \tilde{H}_\ell^T = \sum_{t=1}^\ell \tilde{h}^t \tilde{h}^{t^T}$ is approximately an orthonormal projection. Applying this to A, we will get our low-rank approximation. Note that in dealing with this nonorthonormality the original proof of [16] contained a small error which was corrected in the journal version [17].

In this section and the next we use the following notation. Recall that the SVD of $W^TW \in \mathbb{R}^{c\times c}$ is

$$W^TW = \sum_{t=1}^{c} \sigma_t^2(W) z^t z^{tT} = Z\Sigma_W^2 Z^T, \tag{31}$$

where $Z \in \mathbb{R}^{c\times c}$. Define $Z_{\alpha,\beta} \in \mathbb{R}^{c\times(\beta-\alpha+1)}$ to be the matrix whose columns are the αth through the βth singular vectors of W^TW. Then

$$\tilde{H}_\ell = CZ_{1,\ell}T, \tag{32}$$

where $T \in \mathbb{R}^{\ell\times\ell}$ is the diagonal matrix with elements $T_{tt} = 1/\sigma_t(W)$. In addition, let the SVD of $\tilde{H}_\ell$ be

$$\tilde{H}_\ell = B_\ell \Sigma_{\tilde{H}_\ell} D_\ell^T, \tag{33}$$

and let us define the matrix $\Delta \in \mathbb{R}^{\ell\times\ell}$ to be

$$\Delta = TZ_{1,\ell}^T(C^TC - W^TW)Z_{1,\ell}T. \tag{34}$$

We will see that Δ is a measure of the degree to which the columns of $\tilde{H}_\ell$ are not orthonormal.

Theorem 5 is the constant time analogue of Theorem 4 and is the main result of this section. Note that since the results from sampling at the second step, i.e., sampling from the matrix C to form the matrix W, depend on the samples chosen in the first sampling step, we do not state the following results in expectation, but instead state them with high probability.

THEOREM 5. *Suppose $A \in \mathbb{R}^{m\times n}$; let a description of $\tilde{H}_\ell$ be constructed from the* ConstantTimeSVD *algorithm by sampling c columns of A with probabilities $\{p_i\}_{i=1}^n$ and w rows of C with probabilities $\{q_j\}_{j=1}^m$ where $p_i = |A^{(i)}|^2/\|A\|_F^2$ and $q_j = |C_{(j)}|^2/\|C\|_F^2$. Let $\eta = 1+\sqrt{8\log(2/\delta)}$ and $\epsilon > 0$.*

If a Frobenius norm bound is desired, and hence the ConstantTimeSVD *algorithm is run with $\gamma = \epsilon/100k$, then by choosing $c = \Omega(k^2\eta^2/\epsilon^4)$ columns of A and $w = \Omega(k^2\eta^2/\epsilon^4)$ rows of C we have that with probability at least $1-\delta$,*

$$\left\|A - \tilde{H}_\ell\tilde{H}_\ell^T A\right\|_F^2 \le \|A - A_k\|_F^2 + \epsilon\|A\|_F^2. \tag{35}$$

If a spectral norm bound is desired, and hence the ConstantTimeSVD *algorithm is run with $\gamma = \epsilon/100$, then by choosing $c = \Omega(\eta^2/\epsilon^4)$ columns of A and $w = \Omega(\eta^2/\epsilon^4)$ rows of C we have that with probability at least $1-\delta$,*

$$\left\|A - \tilde{H}_\ell\tilde{H}_\ell^T A\right\|_2^2 \le \|A - A_k\|_2^2 + \epsilon\|A\|_F^2. \tag{36}$$

Proof. See section 5.4 for the proof. ∎

Recall that in section 4 we first proved Theorems 2 and 3, which provided a bound on $\left\|A - H_kH_k^TA\right\|_F^2$ and $\left\|A - H_kH_k^TA\right\|_2^2$, respectively, for arbitrary probabilities, and then we proved Theorem 4 for the nearly optimal probabilities. Although a similar presentation strategy could be adopted in this section, in the interests of simplicity (due to the technically more complicated proofs in the constant time model) we instead immediately restrict ourselves in Theorem 5 to the case of optimal sampling probabilities and defer the proofs of the supporting lemmas to section 5.4.

5.4. Proof of Theorem 5. In this section, we prove Theorem 5. We start in section 5.4.1 with several lemmas that are common to both the Frobenius and spectral norms. Then in section 5.4.2 we provide the proof of (35). Finally, in section 5.4.3 we provide the proof of (36).

5.4.1. General lemmas. In this section, we prove four lemmas that are used in the proofs of both the Frobenius and spectral norm results.

First, we relate $\left\|A - \tilde{H}_\ell \tilde{H}_\ell^T A\right\|_\xi^2$, for $\xi = 2, F$, to $\left\|A - B_\ell B_\ell^T A\right\|_\xi^2$ plus an error term; we do so since the columns of B_ℓ are orthonormal, which will allow us to bound $\left\|A - B_\ell B_\ell^T A\right\|_\xi^2$ using arguments similar to those used to bound $\left\|A - H_k H_k^T A\right\|_\xi^2$ in Theorems 2 and 3.

LEMMA 1. *For $\xi = 2, F$ and for any $\epsilon > 0$,*

$$\left\|A - \tilde{H}_\ell \tilde{H}_\ell^T A\right\|_\xi^2 \leq \left(1 + \frac{\epsilon}{100}\right) \left\|A - B_\ell B_\ell^T A\right\|_\xi^2 + \left(1 + \frac{100}{\epsilon}\right) \left\|B_\ell B_\ell^T - \tilde{H}_\ell \tilde{H}_\ell^T\right\|_\xi^2 \|A\|_\xi^2 .$$

Proof. By subadditivity and submultiplicitivity,

$$\left\|A - \tilde{H}_\ell \tilde{H}_\ell^T A\right\|_\xi^2 \leq \left(\left\|A - B_\ell B_\ell^T A\right\|_\xi + \left\|B_\ell B_\ell^T - \tilde{H}_\ell \tilde{H}_\ell^T\right\|_\xi \|A\|_\xi \right)^2.$$

The lemma follows since $(\alpha + \beta)^2 \leq (1 + \varepsilon)\alpha^2 + (1 + 1/\varepsilon)\beta^2$ for all $\varepsilon \geq 0$. ∎

Second, although the vectors $\tilde{h}^t = Cz^t/\sigma_t(W)$, $t = 1, \ldots, \ell$, do not in general form an orthonormal set, one would expect from their construction that if the matrix $W^T W$ is close to the matrix $C^T C$, then with high probability they will be approximately orthonormal. Lemma 2 establishes that Δ, defined in (34), characterizes how far $\tilde{H}_\ell$ is from having orthonormal columns and shows that the error introduced due to this nonorthonormality is bounded by a simple function of γ and the error introduced at the second level of sampling.

LEMMA 2. *When written in the basis with respect to Z,*

$$\tilde{H}_\ell^T \tilde{H}_\ell = I_\ell + \Delta.$$

Furthermore, for $\xi = 2, F$

$$\|\Delta\|_\xi \leq \frac{1}{\gamma \|W\|_F^2} \left\|C^T C - W^T W\right\|_\xi .$$

Proof. Recall that $\tilde{H}_\ell = C Z_{1,\ell} T$ and that $T^T Z_{1,\ell}^T W^T W Z_{1,\ell} T = I_\ell$, so that

$$\left\|\tilde{H}_\ell^T \tilde{H}_\ell - I_\ell\right\|_\xi = \left\|T^T Z_{1,\ell}^T C^T C Z_{1,\ell} T - T^T Z_{1,\ell}^T W^T W Z_{1,\ell} T\right\|_\xi \tag{37}$$

$$= \left\|T^T Z_{1,\ell}^T \left(C^T C - W^T W\right) Z_{1,\ell} T\right\|_\xi . \tag{38}$$

Using the submultiplicativity properties of the 2-norm, and in particular

$$\|AB\|_\xi \leq \|A\|_2 \|B\|_\xi , \tag{39}$$

$$\|AB\|_\xi \leq \|A\|_\xi \|B\|_2 , \tag{40}$$

for both $\xi = 2, F$, we get

$$\left\|\tilde{H}_\ell^T \tilde{H}_\ell - I_\ell\right\|_\xi \leq \left\|T^T Z_{1,\ell}^T\right\|_2 \left\|C^T C - W^T W\right\|_\xi \left\|Z_{1,\ell} T\right\|_2 \tag{41}$$

$$\leq \|T\|_2^2 \left\|C^T C - W^T W\right\|_\xi \tag{42}$$

$$\leq \max_{t=1,\ldots,\ell} \left(1/\sigma_t^2(W)\right) \left\|C^T C - W^T W\right\|_\xi, \tag{43}$$

since $\|Z_{1,\ell}\|_2 = 1$. The lemma follows since $\sigma_t^2(W) \geq \gamma \|W\|_F^2$ for all $t = 1, \ldots, \ell$ by the definition of ℓ. □

Third, we consider the second term in Lemma 1, $\left\|B_\ell B_\ell^T - \tilde{H}_\ell \tilde{H}_\ell^T\right\|_\xi^2$ and show that it can be related to $\|\Delta\|_\xi$.

LEMMA 3. *For* $\xi = 2, F$

$$\left\|B_\ell B_\ell^T - \tilde{H}_\ell \tilde{H}_\ell^T\right\|_\xi = \|\Delta\|_\xi.$$

Proof. Since $\tilde{H}_\ell = B_\ell \Sigma_{\tilde{H}_\ell} D_\ell^T$, we have

$$\begin{aligned}\left\|B_\ell B_\ell^T - \tilde{H}_\ell \tilde{H}_\ell^T\right\|_\xi &= \left\|B_\ell \left(I_\ell - \Sigma_{\tilde{H}_\ell}^2\right) B_\ell^T\right\|_\xi \\ &= \left\|I_\ell - \Sigma_{\tilde{H}_\ell}^2\right\|_\xi \\ &= \left\|D_\ell \left(I_\ell - \Sigma_{\tilde{H}_\ell}^2\right) D_\ell^T\right\|_\xi \\ &= \left\|I_\ell - \tilde{H}_\ell^T \tilde{H}_\ell\right\|_\xi. \qquad \square\end{aligned}$$

Fourth, Lemma 4 considers the special case in which the probabilities $\{p_i\}_{i=1}^n$ that are entered into the CONSTANTTIMESVD algorithm are optimal, as is the case for Theorem 5.

LEMMA 4. *Let* $A \in \mathbb{R}^{m \times n}$ *and let* $\tilde{H}_\ell$ *be constructed from the* CONSTANTTIMESVD *algorithm by sampling* c *columns of* A *with probabilities* $\{p_i\}_{i=1}^n$ *and* w *rows of* C *with probabilities* $\{q_j\}_{j=1}^m$, *where* $p_i = \mathbf{Pr}[i_t = i] = |A^{(i)}|^2 / \|A\|_F^2$ *and* $q_j = \mathbf{Pr}[j_t = j] = |C_{(j)}|^2 / \|C\|_F^2$. *Then*

$$\|W\|_F = \|C\|_F = \|A\|_F.$$

Proof. If $p_i = \left|A^{(i)}\right|^2 / \|A\|_F^2$, we have that $\|C\|_F^2 = \sum_{t=1}^c \left|C^{(t)}\right|^2 = \sum_{t=1}^c \frac{\left|A^{(i_t)}\right|^2}{c p_{i_t}}$ $= \|A\|_F^2$. Similarly, if $q_j = \left|C_{(j)}\right|^2 / \|C\|_F^2$, we have that $\|W\|_F^2 = \sum_{t=1}^w \left|W_{(t)}\right|^2$ $= \sum_{t=1}^w \frac{\left|C_{(i_t)}\right|^2}{w q_{i_t}} = \|C\|_F^2$. The lemma follows. □

5.4.2. Lemmas for the Frobenius norm proof. In this section we prove (35). We do this by first proving lemmas sufficient to bound $\|A - B_\ell B_\ell^T A\|_F^2$; when this is combined with the lemmas of section 5.4.1 we obtain a bound on $\|A - \tilde{H}_\ell \tilde{H}_\ell^T A\|_F^2$. The bound on $\|A - B_\ell B_\ell^T A\|_F^2$ depends on the error for the optimal rank-k approximation to A, i.e., $\|A - A_k\|_F^2$, and additional errors that depend on the quality of the sampling approximations, i.e., on $\|AA^T - CC^T\|_F$ and $\|C^T C - W^T W\|_F$. This will be the analogue of Theorem 2 applied to the constant additional space and time model. The result and associated proof will have a similar structure to that of Theorem 2, but will be more complicated due to the nonorthonormality of the vectors $\tilde{h}^t, t = 1, \ldots, \ell$, and will involve additional error terms since two levels of approximation are involved.

We now prove several lemmas which will provide a bound for the first term in Lemma 1 when applied to the Frobenius norm. We first rewrite the $\left\|A - B_\ell B_\ell^T A\right\|_F^2$ term from Lemma 1. Note that Lemma 5 is the constant time analogue of (14).

LEMMA 5.

$$\left\|A - B_\ell B_\ell^T A\right\|_F^2 = \|A\|_F^2 - \left\|B_\ell^T A\right\|_F^2.$$

Proof.

$$\begin{aligned}\left\|A - B_\ell B_\ell^T A\right\|_F^2 &= \mathbf{Tr}\left(\left(A - B_\ell B_\ell^T A\right)^T \left(A - B_\ell B_\ell^T A\right)\right) \\ &= \mathbf{Tr}\left(A^T A - A^T B_\ell B_\ell^T A\right). \qquad \square\end{aligned}$$

Next, we want to provide a lower bound for $\left\|B_\ell^T A\right\|_F^2$ in terms of the singular values of W. We do so in several steps. First, we relate $\|B_\ell^T A\|_F^2$ to $\|\tilde{H}_\ell^T A\|_F^2$. We note that the assumption $\|\Delta\|_F < 1$ is made since in Theorem 5 optimal probabilities are used and sufficiently many columns and rows are drawn; if this assumption is dropped, then bounds of the form in Theorem 5 may be obtained with slightly worse sampling complexity.

LEMMA 6. *If* $\|\Delta\|_F < 1$, *then*

$$\left\|B_\ell^T A\right\|_F^2 \geq (1 - \|\Delta\|_F) \left\|\tilde{H}_\ell^T A\right\|_F^2.$$

Proof. Since $\tilde{H}_\ell = B_\ell \Sigma_{\tilde{H}_\ell} D_\ell^T$

$$\left\|\tilde{H}_\ell^T A\right\|_F^2 = \left\|\Sigma_{\tilde{H}_\ell} B_\ell^T A\right\|_F^2 \leq \left\|\Sigma_{\tilde{H}_\ell}\right\|_2^2 \left\|B_\ell^T A\right\|_F^2 = \left\|\tilde{H}_\ell^T \tilde{H}_\ell\right\|_2^2 \left\|B_\ell^T A\right\|_F^2, \tag{44}$$

using (39). From the triangle inequality

$$\left\|\tilde{H}_\ell^T \tilde{H}_\ell\right\|_2 \geq \left| \|I_\ell\|_2 - \left\|\tilde{H}_\ell^T \tilde{H}_\ell - I_\ell\right\|_2 \right| = |1 - \|\Delta\|_2|. \tag{45}$$

The lemma follows since $\|\Delta\|_2 \leq \|\Delta\|_F < 1$ and by observing that $1 + x \leq 1/(1-x)$ for all $x \leq 1$. $\square$

Second, we relate $\|\tilde{H}_\ell^T A\|_F^2$ to $\|\tilde{H}_\ell^T C\|_F^2$.

LEMMA 7.

$$\left\|\tilde{H}_\ell^T A\right\|_F^2 \geq \left\|\tilde{H}_\ell^T C\right\|_F^2 - \left(k + \sqrt{k}\|\Delta\|_F\right) \left\|AA^T - CC^T\right\|_F.$$

Proof. Since $\|\tilde{H}_\ell^T A\|_F^2 = \mathbf{Tr}(\tilde{H}_\ell^T A A^T \tilde{H}_\ell^T)$, we have that

$$\begin{aligned}\left\|\tilde{H}_\ell^T A\right\|_F^2 &= \mathbf{Tr}\left(\tilde{H}_\ell^T C C^T \tilde{H}_\ell^T\right) + \mathbf{Tr}\left(\tilde{H}_\ell^T (AA^T - CC^T) \tilde{H}_\ell^T\right) \\ &\geq \left\|\tilde{H}_\ell^T C\right\|_F^2 - \left\|AA^T - CC^T\right\|_2 \left\|\tilde{H}_\ell\right\|_F^2,\end{aligned}$$

where the inequality follows since

$$\begin{aligned}\left|\mathbf{Tr}\left(\tilde{H}_\ell^T (AA^T - CC^T) \tilde{H}_\ell^T\right)\right| &\leq \sum_t \left|(\tilde{H}_\ell^T)_{(t)} (AA^T - CC^T) (\tilde{H}_\ell)^{(t)}\right| \\ &\leq \left\|AA^T - CC^T\right\|_2 \left\|\tilde{H}_\ell\right\|_F^2.\end{aligned}$$

The lemma follows since $\|\cdot\|_2 \leq \|\cdot\|_F$ and since

$$\left\|\tilde{H}_\ell\right\|_F^2 = \sum_{t=1}^{\ell} \left|\tilde{h}^{t^T} \tilde{h}^t\right| = \sum_{t=1}^{\ell} 1 + \Delta_{tt} \leq k + \sqrt{k}\|\Delta\|_F. \qquad \square$$

Third, we relate $\|\tilde{H}_\ell^T C\|_F^2$ to $\sum_{t=1}^{\ell} \sigma_t^2(W)$.

LEMMA 8.

$$\left\|\tilde{H}_\ell^T C\right\|_F^2 \geq \sum_{t=1}^{\ell} \sigma_t^2(W) - \frac{2}{\sqrt{\gamma}} \left\|C^T C - W^T W\right\|_F .$$

Proof. Since $\|\tilde{H}_\ell^T C\|_F^2 = \|C^T \tilde{H}_\ell\|_F^2 = \|C^T C Z_{1,\ell} T\|_F^2$, we have

$$\begin{aligned}\left\|\tilde{H}_\ell^T C\right\|_F^2 &\geq \left(\left\|W^T W Z_{1,\ell} T\right\|_F - \left\|(C^T C - W^T W) Z_{1,\ell} T\right\|_F \right)^2 \\ &\geq \left(\left(\sum_{t=1}^{\ell} \sigma_t^2(W) \right)^{1/2} - \frac{1}{\sqrt{\gamma}\,\|W\|_F} \left\|(C^T C - W^T W)\right\|_F \right)^2 ,\end{aligned}$$

where the second inequality uses that $\|XZ\|_F \leq \|X\|_F$ for any matrix X if the matrix Z has orthonormal columns. By multiplying out the right-hand side and ignoring terms that reinforce the inequality, the lemma follows since $(\sum_{t=1}^{\ell} \sigma_t^2(W))^{1/2} / \|W\|_F \leq 1$. □

By combining Lemmas 6, 7, and 8, we have our desired bound on $\|B_\ell^T A\|_F^2$ in terms of the singular values of W. Finally, we use matrix perturbation theory to relate $\sum_{t=1}^{\ell} \sigma_t^2(W)$ to $\sum_{t=1}^{k} \sigma_t^2(A)$.

LEMMA 9.

$$\sum_{t=1}^{\ell} \sigma_t^2(W) \geq \sum_{t=1}^{k} \sigma_t^2(A) - \sqrt{k} \left\|AA^T - CC^T\right\|_F - \sqrt{k} \left\|C^T C - W^T W\right\|_F - (k-\ell)\gamma \|W\|_F^2 .$$

Proof. Recalling the Hoffman–Wielandt inequality, we see that

$$\begin{aligned}\left| \sum_{t=1}^{k} \left(\sigma_t^2(C) - \sigma_t^2(A)\right) \right| &\leq \sqrt{k} \left(\sum_{t=1}^{k} \left(\sigma_t^2(C) - \sigma_t^2(A)\right)^2 \right)^{1/2} \\ &\leq \sqrt{k} \left(\sum_{t=1}^{k} \left(\sigma_t(CC^T) - \sigma_t(AA^T)\right)^2 \right)^{1/2} \\ &\leq \sqrt{k} \left\|AA^T - CC^T\right\|_F , \qquad (46)\end{aligned}$$

and, similarly, that

$$\begin{aligned}\left| \sum_{t=1}^{k} \left(\sigma_t^2(W) - \sigma_t^2(C)\right) \right| &\leq \sqrt{k} \left(\sum_{t=1}^{k} \left(\sigma_t^2(W) - \sigma_t^2(C)\right)^2 \right)^{1/2} \\ &\leq \sqrt{k} \left(\sum_{t=1}^{k} \left(\sigma_t(WW^T) - \sigma_t(CC^T)\right)^2 \right)^{1/2} \\ &\leq \sqrt{k} \left\|C^T C - W^T W\right\|_F . \qquad (47)\end{aligned}$$

By combining (46) and (47) we see that

$$\left| \sum_{t=1}^{k} \sigma_t^2(W) - \sum_{t=1}^{k} \sigma_t^2(A) \right| \leq \sqrt{k} \left\|AA^T - CC^T\right\|_F + \sqrt{k} \left\|C^T C - W^T W\right\|_F . \qquad (48)$$

Since $\sigma_t^2(W) < \gamma \|W\|_F^2$ for all $t = \ell+1, \ldots, k$ we have that $\sum_{t=\ell+1}^{k} \sigma_t^2(W) \leq (k-\ell)\gamma \|W\|_F^2$. Combining this with (48) allows us to relate $\sum_{t=1}^{\ell} \sigma_t^2(W)$ and $\sum_{t=1}^{k} \sigma_t^2(A)$, thus establishing the lemma. □

Now we combine these results in order to prove (35). Let $E_{AA^T} = AA^T - CC^T$ and $E_{C^TC} = C^TC - W^TW$. First, we establish a lower bound on $\left\|B_\ell^T A\right\|_F^2$. By combining Lemmas 6 and 7 and dropping terms that reinforce the inequality, we have that

$$\left\|B_\ell^T A\right\|_F^2 \geq \left\|\tilde{H}_\ell^T C\right\|_F^2 - \|\Delta\|_F \left\|\tilde{H}_\ell^T C\right\|_F^2 - \left(k + \sqrt{k}\,\|\Delta\|_F\right) \|E_{AA^T}\|_F .$$

By combining this with Lemmas 8 and 9 and dropping terms that reinforce the inequality, we have that

$$\begin{aligned}\left\|B_\ell^T A\right\|_F^2 \geq & \sum_{t=1}^{k} \sigma_t^2(A) - \left(k + \sqrt{k}\right) \|E_{AA^T}\|_F - \left(\sqrt{k} + \frac{2}{\sqrt{\gamma}}\right) \|E_{C^TC}\|_F \\ & - \|\Delta\|_F \sum_{t=1}^{k} \sigma_t^2(A) - \sqrt{k}\,\|\Delta\|_F \, \|E_{AA^T}\|_F - (k-\ell)\gamma \|W\|_F^2 .\end{aligned} \tag{49}$$

From Lemma 5 this immediately leads to the upper bound on $\left\|A - B_\ell B_\ell^T A\right\|_F^2$,

$$\begin{aligned}\left\|A - B_\ell B_\ell^T A\right\|_F^2 \leq & \|A - A_k\|_F^2 + \left(k + \sqrt{k}\right) \|E_{AA^T}\|_F + \left(\sqrt{k} + \frac{2}{\sqrt{\gamma}}\right) \|E_{C^TC}\|_F \\ & + \|\Delta\|_F \sum_{t=1}^{k} \sigma_t^2(A) + \sqrt{k}\,\|\Delta\|_F \, \|E_{AA^T}\|_F + (k-\ell)\gamma \|W\|_F^2 .\end{aligned} \tag{50}$$

From Lemmas 1 and 3,

$$\left\|A - \tilde{H}_\ell \tilde{H}_\ell^T A\right\|_F^2 \leq \left(1 + \frac{\epsilon}{100}\right) \left\|A - B_\ell B_\ell^T A\right\|_F^2 + \left(1 + \frac{100}{\epsilon}\right) \|\Delta\|_F^2 \, \|A\|_F^2 . \tag{51}$$

Recall that $\gamma = \epsilon/100k$, that $\sum_{t=1}^{k} \sigma_t^2(A) \leq \|A\|_F^2$, that $\|\Delta\|_F \leq \|E_{C^TC}\|_F / \gamma \|W\|_F^2$ by Lemma 2, and that $\|W\|_F = \|C\|_F = \|A\|_F$ by Lemma 4; (35) then follows by combining (50) and (51), using the sampling probabilities indicated in the statement of the theorem, and by choosing $c, w = \Omega(k^2\eta^2/\epsilon^4)$.

5.4.3. Lemmas for the spectral norm proof. In this section we prove (36). We do this by first proving lemmas sufficient to bound $\|A - B_\ell B_\ell^T A\|_2^2$; when this is combined with the lemmas of section 5.4.1, we obtain a bound on $\|A - \tilde{H}_\ell \tilde{H}_\ell^T A\|_2^2$. The bound on $\|A - B_\ell B_\ell^T A\|_2^2$ depends on the error for the optimal rank-k approximation to A, i.e., $\|A - A_k\|_2^2$, and additional errors that depend on the quality of the sampling approximations, i.e., on $\|AA^T - CC^T\|_2$ and $\|C^TC - W^TW\|_2$. This will be the analogue of Theorem 3 applied to the constant additional space and time model. The result and associated proof will have a similar structure to that of Theorem 3, but will be more complicated due to the nonorthonormality of the vectors $\tilde{h}^t, t = 1, \ldots, \ell$, and will involve additional error terms since two levels of approximation are involved.

We now prove three lemmas which will provide a bound for the first term in Lemma 1 when applied to the spectral norm. We first rewrite the $\|A - B_\ell B_\ell^T A\|_2^2$ term from Lemma 1.

LEMMA 10.

$$\left\|A - B_\ell B_\ell^T A\right\|_2^2 \leq \left\|Z_{k+1,c}^T C^T C Z_{k+1,c}\right\|_2 + \left\|Z_{\ell+1,k}^T C^T C Z_{\ell+1,k}\right\|_2 + \left\|AA^T - CC^T\right\|_2.$$

Proof. In order to bound $\|A - B_\ell B_\ell^T A\|_2$ we will project onto the subspace spanned by B_ℓ and its orthogonal complement in a manner analogous to that used in the proof of Theorem 3. Let $\mathcal{B}_\ell = \text{range}(B_\ell)$ and let $\mathcal{B}_{m-\ell}$ be the orthogonal complement of $\mathcal{B}_\ell$. Let $x = \alpha y + \beta z$, where $y \in \mathcal{B}_\ell$, $z \in \mathcal{B}_{m-\ell}$, and $\alpha^2 + \beta^2 = 1$. Then

$$\begin{aligned}
\left\|A - B_\ell B_\ell^T A\right\|_2 &= \max_{x \in \mathbb{R}^m, |x|=1} \left|x^T (A - B_\ell B_\ell^T A)\right| \\
&= \max_{y \in \mathcal{B}_\ell, |y|=1, z \in \mathcal{B}_{m-\ell}, |z|=1, \alpha^2+\beta^2=1} \left|(\alpha y^T + \beta z^T)(A - B_\ell B_\ell^T A)\right| \\
&\leq \max_{y \in \mathcal{B}_\ell, |y|=1} \left|y^T (A - B_\ell B_\ell^T A)\right| + \max_{z \in \mathcal{B}_{m-\ell}, |z|=1} \left|z^T (A - B_\ell B_\ell^T A)\right| \qquad (52) \\
&= \max_{z \in \mathcal{B}_{m-\ell}, |z|=1} \left|z^T A\right|. \qquad (53)
\end{aligned}$$

Inequality (52) follows since $\alpha, \beta \leq 1$ and (53) follows since $y \in \mathcal{B}_\ell$ and $z \in \mathcal{B}_{m-\ell}$. To bound (53), let $z \in \mathcal{B}_{m-\ell}$, $|z| = 1$; then

$$\begin{aligned}
\left|z^T A\right|^2 &= z^T (AA^T) z \\
&= z^T (CC^T) z + z^T (AA^T - CC^T) z \\
&= z^T (CC^T - CZ_{1,k} Z_{1,k}^T C^T) z + z^T (CZ_{1,k} Z_{1,k}^T C^T) z + z^T (AA^T - CC^T) z \qquad (54) \\
&= z^T (CZ_{k+1,c} Z_{k+1,c}^T C^T) z + z^T (CZ_{\ell+1,k} Z_{\ell+1,k}^T C^T) z + z^T (AA^T - CC^T) z. \qquad (55)
\end{aligned}$$

Equation (55) follows since $I_c = ZZ^T = Z_{1,k} Z_{1,k}^T + Z_{k+1,c} Z_{k+1,c}^T$ and, since

$$CZ_{1,\ell} Z_{1,\ell}^T C^T = \sum_{t=1}^{\ell} Cz^t z^{t^T} C^T = \sum_{t=1}^{\ell} \sigma_t^2(W) \tilde{h}^t \tilde{h}^{t^T},$$

implies that

$$z^T CZ_{1,\ell} Z_{1,\ell}^T C^T z = 0 \qquad (56)$$

for $z \in \mathcal{B}_{m-\ell}$. Thus, by combining (53) and (55)

$$\left\|A - B_\ell B_\ell^T A\right\|_2^2 \leq \left\|CZ_{k+1,c} Z_{k+1,c}^T C^T\right\|_2 + \left\|CZ_{\ell+1,k} Z_{\ell+1,k}^T C^T\right\|_2 + \left\|AA^T - CC^T\right\|_2.$$

The lemma follows since $\|X^T X\|_2 = \|XX^T\|_2$ for any matrix X. ∎

We next bound the $\|Z_{k+1,c}^T C^T C Z_{k+1,c}\|_2$ term from Lemma 10; note that matrix perturbation theory is used in (59).

LEMMA 11.

$$\left\|Z_{k+1,c}^T C^T C Z_{k+1,c}\right\|_2 \leq \|A - A_k\|_2^2 + \left\|AA^T - CC^T\right\|_2 + 2\left\|C^T C - W^T W\right\|_2.$$

Proof. First note that

$$\left\|Z_{k+1,c}^T C^T C Z_{k+1,c}\right\|_2 \leq \left\|Z_{k+1,c}^T W^T W Z_{k+1,c}\right\|_2 + \left\|Z_{k+1,c}^T (C^T C - W^T W) Z_{k+1,c}\right\|_2. \tag{57}$$

Since

$$\begin{aligned}\left\|Z_{k+1,c}^T (C^T C - W^T W) Z_{k+1,c}\right\|_2 &\leq \left\|C^T C - W^T W\right\|_2 \|Z_{k+1,c}\|_2^2 \\ &= \left\|C^T C - W^T W\right\|_2\end{aligned}$$

and

$$\left\|Z_{k+1,c}^T W^T W Z_{k+1,c}\right\|_2 = \sigma_{k+1}^2(W),$$

it follows from (57) that

$$\left\|Z_{k+1,c}^T C^T C Z_{k+1,c}\right\|_2 \leq \sigma_{k+1}^2(W) + \left\|C^T C - W^T W\right\|_2. \tag{58}$$

By a double application of (9), we see that

$$\sigma_{k+1}^2(W) \leq \sigma_{k+1}^2(A) + \left\|AA^T - CC^T\right\|_2 + \left\|C^T C - W^T W\right\|_2. \tag{59}$$

The lemma follows by combining (58) and (59) since $\|A - A_k\|_2 = \sigma_{k+1}(A)$. ∎

Finally, we bound the $\left\|Z_{\ell+1,k}^T C^T C Z_{\ell+1,k}\right\|_2$ term from Lemma 10; note that if $\ell = k$, it is unnecessary.

LEMMA 12.

$$\left\|Z_{\ell+1,k}^T C^T C Z_{\ell+1,k}\right\|_2 \leq \left\|C^T C - W^T W\right\|_2 + \gamma \|W\|_F^2.$$

Proof. First note that

$$\left\|Z_{\ell+1,k}^T C^T C Z_{\ell+1,k}\right\|_2 \leq \left\|Z_{\ell+1,k}^T \left(C^T C - W^T W\right) Z_{\ell+1,k}\right\|_2 + \left\|Z_{\ell+1,k}^T W^T W Z_{\ell+1,k}\right\|_2. \tag{60}$$

Since

$$\begin{aligned}\left\|Z_{\ell+1,k}^T \left(C^T C - W^T W\right) Z_{\ell+1,k}\right\|_2 &\leq \left\|C^T C - W^T W\right\|_2 \|Z_{\ell+1,k}\|_2^2 \\ &= \left\|C^T C - W^T W\right\|_2\end{aligned}$$

and

$$\left\|Z_{\ell+1,k}^T W^T W Z_{\ell+1,k}\right\|_2 = \sigma_{\ell+1}^2(W),$$

it follows from (60) that

$$\left\|Z_{\ell+1,k}^T C^T C Z_{\ell+1,k}\right\|_2 \leq \left\|C^T C - W^T W\right\|_2 + \sigma_{\ell+1}^2(W). \tag{61}$$

The lemma follows since $\sigma_t^2(W) < \gamma \|W\|_F^2$ for all $t = \ell + 1, \ldots, k$. ∎

Now we combine these results in order to prove (36). Recall that $E_{AA^T} = AA^T - CC^T$ and $E_{C^TC} = C^TC - W^TW$. By combining Lemmas 10, 11, and 12, we have that

$$\left\|A - B_\ell B_\ell^T A\right\|_2^2 \leq \|A - A_k\|_2^2 + 2\|E_{AA^T}\|_2 + 3\|E_{C^TC}\|_2 + \gamma\|W\|_F^2. \tag{62}$$

From Lemmas 1 and 3,

$$\left\|A - \tilde{H}_\ell \tilde{H}_\ell^T A\right\|_2^2 \leq \left(1 + \frac{\epsilon}{100}\right)\left\|A - B_\ell B_\ell^T A\right\|_2^2 + \left(1 + \frac{100}{\epsilon}\right)\|\Delta\|_2^2\,\|A\|_2^2. \tag{63}$$

Recall that $\gamma = \epsilon/100$, that $\|\cdot\|_2 \leq \|\cdot\|_F$, and that $\|\Delta\|_2 \leq \|E_{C^TC}\|_2/\gamma\|W\|_F^2$ by Lemma 2; (36) follows by combining (62) and (63), using the sampling probabilities indicated in the statement of the theorem, and by choosing $c, w = \Omega(\eta^2/\epsilon^4)$.

6. Discussion and conclusion. We have presented two algorithms to compute approximations to the SVD of a matrix $A \in \mathbb{R}^{m\times n}$ which do not require that A be stored in RAM, but for which the additional space and time required (in addition to a constant number of passes over the matrix) is either linear in $m+n$ or is a constant independent of m and n; we have also proven error bounds for both algorithms with respect to both the Frobenius and spectral norms. Table 1 in section 1 presents a summary of the dependence of the sampling complexity on k and ϵ. With the LINEARTIMESVD algorithm, the additional error (beyond the optimal rank-k approximation) in the spectral norm bound can be made less than $\epsilon\|A\|_F^2$ by sampling $\Theta(1/\epsilon^2)$ columns, and the additional error in the Frobenius norm can be made less than $\epsilon\|A\|_F^2$ by sampling $\Theta(k/\epsilon^2)$ columns. Likewise, with the CONSTANTTIMESVD algorithm, the additional error in the spectral norm can be made less than $\epsilon\|A\|_F^2$ by sampling $\Theta(1/\epsilon^4)$ columns and rows, and the additional error in the Frobenius norm can be made less than $\epsilon\|A\|_F^2$ by sampling $\Theta(k^2/\epsilon^4)$ columns and rows. The results of [16] require $\Theta(k^4/\epsilon^3)$ columns and rows for the Frobenius (and thus the spectral) norm bound.

Recent work has focused on developing new techniques for proving lower bounds on the number of queries a sampling algorithm is required to perform in order to approximate a given function accurately with a low probability of error [4, 5]. In [5] these methods have been applied to the low-rank matrix approximation problem (defined as approximating the SVD with respect to the Frobenius norm) and to the matrix reconstruction problem. It is shown that any sampling algorithm that with high probability finds a good low-rank approximation requires $\Omega(m+n)$ queries. In addition, it is shown that even if the algorithm is given the exact weight distribution over the columns of a matrix, it will still require $\Omega(k/\epsilon^2)$ column queries to approximate A. Thus, the LINEARTIMESVD algorithm (see also the original [10]) is optimal with respect to Frobenius norm bounds for the rank parameter k and the CONSTANTTIMESVD algorithm (see also the original [16]) is optimal with respect to Frobenius norm bounds up to polynomial factors.

Acknowledgments. We would like to thank the following individuals for comments and fruitful discussions: Dimitris Achlioptas, Alan Frieze, Mauro Maggioni, Frank McSherry, and Santosh Vempala. We would also like to thank Dimitris Achlioptas and Frank McSherry for providing us with a preprint of [1], i.e., the journal version of [2], which provides a useful comparison of their results with ours. We would like to

thank the National Science Foundation for partial support of this work. Finally, we would like to thank an anonymous reviewer for carefully reading the paper and making numerous useful suggestions; in particular, the reviewer provided elegant, short proofs for Lemmas 2 and 6.

FAST MONTE CARLO ALGORITHMS FOR MATRICES III: COMPUTING A COMPRESSED APPROXIMATE MATRIX DECOMPOSITION*

PETROS DRINEAS†, RAVI KANNAN‡, AND MICHAEL W. MAHONEY§

Abstract. In many applications, the data consist of (or may be naturally formulated as) an $m \times n$ matrix A which may be stored on disk but which is too large to be read into random access memory (RAM) or to practically perform superlinear polynomial time computations on it. Two algorithms are presented which, when given an $m \times n$ matrix A, compute approximations to A which are the product of three smaller matrices, C, U, and R, each of which may be computed rapidly. Let $A' = CUR$ be the computed approximate decomposition; both algorithms have provable bounds for the error matrix $A - A'$. In the first algorithm, c columns of A and r rows of A are randomly chosen. If the $m \times c$ matrix C consists of those c columns of A (after appropriate rescaling) and the $r \times n$ matrix R consists of those r rows of A (also after appropriate rescaling), then the $c \times r$ matrix U may be calculated from C and R. For any matrix X, let $\|X\|_F$ and $\|X\|_2$ denote its Frobenius norm and its spectral norm, respectively. It is proven that

$$\left\|A - A'\right\|_\xi \leq \min_{D:\mathrm{rank}(D)\leq k} \|A - D\|_\xi + poly(k, 1/c)\, \|A\|_F$$

holds in expectation and with high probability for both $\xi = 2, F$ and for all $k = 1, \ldots, \mathrm{rank}(A)$; thus by appropriate choice of k

$$\left\|A - A'\right\|_2 \leq \epsilon \|A\|_F$$

also holds in expectation and with high probability. This algorithm may be implemented without storing the matrix A in RAM, provided it can make two passes over the matrix stored in external memory and use $O(m + n)$ additional RAM (assuming that c and r are constants, independent of the size of the input). The second algorithm is similar except that it approximates the matrix C by randomly sampling a constant number of rows of C. Thus, it has additional error but it can be implemented in three passes over the matrix using only constant additional RAM. To achieve an additional error (beyond the best rank-k approximation) that is at most $\epsilon\|A\|_F$, both algorithms take time which is a low-degree polynomial in k, $1/\epsilon$, and $1/\delta$, where $\delta > 0$ is a failure probability; the first takes time linear in $\max(m, n)$ and the second takes time independent of m and n. The proofs for the error bounds make important use of matrix perturbation theory and previous work on approximating matrix multiplication and computing low-rank approximations to a matrix. The probability distribution over columns and rows and the rescaling are crucial features of the algorithms and must be chosen judiciously.

1. Introduction. We are interested in developing and analyzing fast Monte Carlo algorithms for performing useful computations on large matrices. In this paper we consider a new method for computing a compressed approximate decomposition of a large matrix; in two related papers we consider matrix multiplication and the singular value decomposition (SVD) [10, 11]. Since such computations generally require time which is superlinear in the number of nonzero elements of the matrix, we expect our algorithms to be useful in many applications where data sets are modeled by matrices and are extremely large. In all of these cases, we assume that the input matrices are prohibitively large to store in random access memory (RAM) and thus that only external memory storage is possible. Thus, our algorithms will be allowed to read the matrices a few, e.g., one, two, or three, times and keep a small randomly chosen and rapidly computable "sketch" of the matrices in RAM; computations will then be performed on this "sketch." We will work within the framework of the pass-efficient computational model, in which the scarce computational resources are the number of passes over the data, the additional RAM space required, and the additional time required [10, 9].

In many applications, an $m \times n$ matrix A is stored on disk and is too large to be read into RAM or to practically perform superlinear polynomial time computations on it; thus, one may be interested in a succinctly described, easily computed $m \times n$ matrix A' that is an approximation to A. Let c and r be positive, usually constant, integers that we choose, and for any matrix X let $\|X\|_F$ and $\|X\|_2$ denote its Frobenius and spectral norms (as defined in section 2.1), respectively. We present two algorithms that compute an approximation A' to the matrix A that has the following properties:

(i) $A' = CUR$, where C is an $m \times c$ matrix consisting of c randomly picked columns of A, R is an $r \times n$ matrix consisting of r randomly picked rows of A, and U is a $c \times r$ matrix computed from C, R.

(ii) C, U, and R can be defined after making a small constant number of passes (2 or 3 for the two algorithms presented in this paper) through the whole matrix A from disk.

(iii) U can be constructed using additional RAM space and time that is $O(m + n)$ (for the LINEARTIMECUR algorithm) or is $O(1)$ (for the CONSTANTTIMECUR algorithm), assuming that c and r are constant.

(iv) For every $\epsilon > 0$ and every k such that $1 \leq k \leq \text{rank}(A)$ we can choose c and r (to be specified below) such that, with high probability, A' satisfies

$$\|A - A'\|_2 \leq \min_{D:\text{rank}(D)\leq k} \|A - D\|_2 + \epsilon \|A\|_F ,$$

and thus we can choose c and r such that $\|A - A'\|_2 \leq \epsilon \|A\|_F$.

(v) For every $\epsilon > 0$ and every k such that $1 \leq k \leq \text{rank}(A)$ we can choose c and r (to be specified below) such that, with high probability, A' satisfies

$$\|A - A'\|_F \leq \min_{D:\text{rank}(D)\leq k} \|A - D\|_F + \epsilon \|A\|_F .$$

In the first algorithm, the LINEARTIMECUR algorithm of section 3, c columns of A and r rows of A are randomly sampled. If the $m \times c$ matrix C consists of those c columns of A (after appropriate rescaling) and the $r \times n$ matrix R consists of those R rows of A (also after appropriate rescaling), then from C and R the $c \times r$ matrix U is computed. This algorithm may be implemented without storing the matrix A in RAM, provided it can make two passes over the matrix stored in external memory

TABLE 1
Summary of sampling complexity.

Additional error for:	LINEARTIMECUR	CONSTANTTIMECUR
$\|A - A'\|_2$	$c, r = \frac{\eta^2}{\epsilon^4}, \frac{k}{\delta^2\epsilon^2}$	$c, w, r = \frac{\eta^2}{\epsilon^8}, \frac{\eta^2}{\epsilon^8}, \frac{k}{\delta^2\epsilon^2}$
$\|A - A'\|_F$	$c, r = \frac{k\eta^2}{\epsilon^4}, \frac{k}{\delta^2\epsilon^2}$	$c, w, r = \frac{k^2\eta^2}{\epsilon^8}, \frac{k^2\eta^2}{\epsilon^8}, \frac{k}{\delta^2\epsilon^2}$

and use $O(m+n)$ additional RAM. The second algorithm, the CONSTANTTIMECUR algorithm of section 4, is similar except that it approximates the matrix C by randomly sampling a constant number w of rows of C. Thus, our second algorithm requires only constant additional RAM but uses a third pass over the data and has additional error. To achieve an additional error (beyond the best rank-k approximation) that is at most $\epsilon \|A\|_F$, both algorithms take time which is a low-degree polynomial in k, $1/\epsilon$, and $1/\delta$, where $\delta > 0$ is a failure probability; the first algorithm takes time linear in $\max(m, n)$ and the second takes time independent of m and n. See Table 1 for a summary of the dependence of the sampling complexity on k and ϵ, δ, and $\eta = 1 + \sqrt{8 \log(1/\delta)}$. (Note that the two algorithms we present in this paper are most interesting when the matrix A is well approximated by a rank-k matrix, where k is assumed to be constant with respect to m and n. In this case, c, r, and w are also constant with respect to m and n. This is assumed throughout the remainder of this paper.)

The proofs for the error bounds make important use of linear algebra and matrix perturbation theory; see [19, 22, 28, 6] for an overview of these topics. In particular, the proofs use the approximate matrix multiplication results of [10] and the approximate SVD results of [11]. As with those previous works, the probability distribution over the columns, the probability distribution over the rows, and the respective rescaling are crucial features of the algorithms which must be chosen judiciously. In addition, as a by-product of the CUR decomposition, we can estimate the top k singular values of A.

Our CUR approximations may be viewed as a "dimension reduction" technique. Two common techniques for dimension reduction are the SVD and multidimensional scaling; see [19, 25]. Another method that has attracted renewed interest recently is the traditional "random projection" method where one projects the problem into a randomly chosen low-dimensional subspace [24, 29, 23]. These methods do not share properties (i) and (ii) and thus are not suited for very large problems. Our algorithms achieve (i) and (ii) at the cost of the $\epsilon \|A\|_F$ error. In addition, our CUR approximations may be viewed as an approximate decomposition of a matrix $A \approx CUR$; as with other decompositions, the CUR decomposition both reveals information about the structure of the matrix and allows computations to be performed more efficiently. For example, in applications of the LINEARTIMECUR algorithm, A' could be stored in RAM since it can be stored in $O(m+n)$ space (instead of $O(mn)$ space); in addition, A' could then be operated upon by, e.g., applying $A' = CUR$ to a query vector $x \in \mathbb{R}^n$, which is an operation that can be performed in $O(m+n)$ space (instead of $O(mn)$ space if A is used).

Our CUR approximations have been used in applications such as the reconstruction of a matrix given a sample of the matrix in a recommendation systems context and for "similarity query" problems which are widely used in areas such as information retrieval [14]. In this application, after A has been preprocessed, one gets "query" vectors x and must find the similarity of x to each row of A. Here, the similarity of

two vectors is defined to be their dot product or their normalized dot product; our technique can handle both. See [7] for related discussion. Note that the measure $\|A\|_2$ is a worst-case measure and that this is more useful in many contexts than an average-case measure like $\|A\|_F$, since the relevant query x often comes from a small-dimensional subspace and is not random. See also [2, 1] for a nice discussion of these issues. Our CUR approximations have also been used in theoretical applications such as designing and analyzing approximation algorithms for the max-cut problem [13]. In these applications, the use of the constant additional space and time framework is essential.

In other related work, Achlioptas and McSherry have also computed succinctly described matrix approximations using somewhat different sampling techniques [2, 1]. Also included in [2, 1] is a comparison of their methods with those of [8, 9, 18] and thus with the results we present here. When compared with our LinearTimeCUR algorithm, they achieve the same results for the Frobenius norm bound and slightly better results (with respect to $1/\epsilon$) for the spectral norm bound [1]; in their work, however, there is no analogue of our ConstantTimeCUR algorithm.

After this introduction, we provide in section 2 reviews of linear algebra, the pass-efficient model, and of several previous results from [10, 11] that are used in this paper. In section 3 we describe and analyze the LinearTimeCUR algorithm which computes an approximate CUR decomposition of a matrix A using linear (in m and n) additional space and time, and in section 4 we describe and analyze the ConstantTimeCUR algorithm which computes a description of an approximate CUR decomposition of a matrix A using only constant additional space and time. Finally, in section 5 we provide a discussion and conclusion.

Finally, note that c and r enter into the asymptotic analysis; for improved clarity, however, we generally take them to be constants that do not vary.

2. Review of relevant background.

2.1. Review of linear algebra. This section contains a review of linear algebra that will be useful throughout the paper; for more details, see [19, 22, 28, 6] and the references therein.

For a vector $x \in \mathbb{R}^n$ we let $|x| = (\sum_{i=1}^n |x_i|^2)^{1/2}$ denote its Euclidean length. For a matrix $A \in \mathbb{R}^{m\times n}$ we let $A^{(j)}$, $j = 1, \ldots, n$, denote the jth column of A as a column vector and $A_{(i)}$, $i = 1, \ldots, m$, denote the ith row of A as a row vector. We denote matrix norms by $\|A\|_\xi$, using subscripts to distinguish between various norms. Of particular interest will be the Frobenius norm, the square of which is $\|A\|_F^2 = \sum_{i=1}^m \sum_{j=1}^n A_{ij}^2$, and the spectral norm, which is defined by $\|A\|_2 = \sup_{x\in\mathbb{R}^n,\ x\neq 0} \frac{|Ax|}{|x|}$. These norms are related to each other as $\|A\|_2 \leq \|A\|_F \leq \sqrt{n}\,\|A\|_2$.

If $A \in \mathbb{R}^{m\times n}$, then there exist orthogonal matrices $U = [u^1 u^2 \ldots u^m] \in \mathbb{R}^{m\times m}$ and $V = [v^1 v^2 \ldots v^n] \in \mathbb{R}^{n\times n}$, where $\{u^t\}_{t=1}^m \in \mathbb{R}^m$ and $\{v^t\}_{t=1}^n \in \mathbb{R}^n$ are such that

$$U^T A V = \Sigma = \mathbf{diag}(\sigma_1, \ldots, \sigma_\rho),$$

where $\Sigma \in \mathbb{R}^{m\times n}$, $\rho = \min\{m, n\}$, and $\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_\rho \geq 0$. Equivalently, $A = U\Sigma V^T$. The three matrices U, V, and Σ constitute the SVD of A. The σ_i are the singular values of A and the vectors u^i, v^i are the ith left and the ith right singular vectors, respectively. If $k \leq r = \mathrm{rank}(A)$ and we define $A_k = U_k \Sigma_k V_k^T = \sum_{t=1}^k \sigma_t u^t v^{t^T}$, then the distance (as measured by both $\|\cdot\|_2$ and $\|\cdot\|_F$) between A and

any rank-k approximation to A is minimized by A_k, i.e.,

$$\min_{D\in\mathbb{R}^{m\times n}:\mathrm{rank}(D)\leq k} \|A-D\|_2 = \|A-A_k\|_2 = \sigma_{k+1}(A), \tag{1}$$

$$\min_{D\in\mathbb{R}^{m\times n}:\mathrm{rank}(D)\leq k} \|A-D\|_F^2 = \|A-A_k\|_F^2 = \sum_{t=k+1}^{r} \sigma_t^2(A). \tag{2}$$

2.2. Review of the pass-efficient model. The pass-efficient model of data-streaming computation is a computational model that is motivated by the observation that in modern computers the amount of disk storage, i.e., sequential access memory, has increased very rapidly, while RAM and computing speeds have increased at a substantially slower pace [10, 9]. In the pass-efficient model the three scarce computational resources are number of passes over the data and the additional RAM space and additional time required by the algorithm. The data are assumed to be stored on a disk, to consist of elements whose sizes are bounded by a constant, and to be presented to an algorithm on a read-only tape. See [10] for more details.

2.3. Review of approximate matrix multiplication. The BasicMatrixMultiplication algorithm to approximate the product of two matrices is presented and analyzed in [10]. When this algorithm is given as input two matrices, $A\in\mathbb{R}^{m\times n}$ and $B\in\mathbb{R}^{n\times p}$, a probability distribution $\{p_i\}_{i=1}^n$, and a number $c\leq n$, it returns as output two matrices, C and R, such that $CR\approx AB$; $C\in\mathbb{R}^{m\times c}$ is a matrix whose columns are c randomly chosen columns of A (suitably rescaled) and $R\in\mathbb{R}^{c\times p}$ is a matrix whose rows are the c corresponding rows of B (also suitably rescaled). An important aspect of this algorithm is the probability distribution $\{p_i\}_{i=1}^n$ used to choose column-row pairs. Although one could always use a uniform distribution, superior results are obtained if the probabilities are chosen judiciously. In particular, a set of sampling probabilities $\{p_i\}_{i=1}^n$ are the *optimal probabilities* (with respect to approximating the product AB) if they are of the form (3); for an explanation and discussion, see [10], where we prove the following.

Theorem 1. *Suppose $A\in\mathbb{R}^{m\times n}$, $B\in\mathbb{R}^{n\times p}$, $c\in\mathbb{Z}^+$ such that $1\leq c\leq n$, and $\{p_i\}_{i=1}^n$ are such that $p_i\geq 0$ and $\sum_{i=1}^n p_i = 1$. Construct C and R with the* BasicMatrixMultiplication *algorithm of* [10] *and let CR be an approximation to AB. If the probabilities $\{p_i\}_{i=1}^n$ are such that*

$$p_k = \frac{\left|A^{(k)}\right|\left|B_{(k)}\right|}{\sum_{k'=1}^n \left|A^{(k')}\right|\left|B_{(k')}\right|}, \tag{3}$$

then

$$\mathbf{E}\left[\|AB-CR\|_F\right] \leq \frac{1}{\sqrt{c}}\|A\|_F\|B\|_F. \tag{4}$$

If, in addition, we let $\delta\in(0,1)$ and $\eta = 1+\sqrt{8\log(1/\delta)}$, then with probability at least $1-\delta$,

$$\|AB-CR\|_F \leq \frac{\eta}{\sqrt{c}}\|A\|_F\|B\|_F. \tag{5}$$

Furthermore, if the probabilities $\{p_i\}_{i=1}^n$ are such that

$$p_k = \frac{\left|B_{(k)}\right|^2}{\|B\|_F^2}, \tag{6}$$

then

$$\mathbf{E}\left[\,\|AB - CR\|_F\right] \leq \frac{1}{\sqrt{c}}\,\|A\|_F\,\|B\|_F\,. \tag{7}$$

Note that with probabilities of the form (6), we do not get a bound of the form $\|AB - CR\|_F \leq \frac{1}{\sqrt{c}}\,\|A\|_F\,\|B\|_F$ by sampling $O(\log(1/\delta))$ columns without making additional, awkward assumptions on the input matrices; see [10]. Of course, by Markov's inequality we can (and will) obtain such a bound by sampling $O(1/\delta)$ columns.

2.4. Review of approximate SVD. The LINEARTIMESVD algorithm is presented in [11]. It is an algorithm which, when given a matrix $A \in \mathbb{R}^{m\times n}$, uses $O(m+n)$ additional space and time to compute an approximation to the top k singular values and the corresponding left singular vectors of A by randomly choosing c columns of A and rescaling each appropriately to construct a matrix $C \in \mathbb{R}^{m\times c}$, computing the top k singular values and corresponding right singular vectors of C, and using them to construct a matrix $H_k \in \mathbb{R}^{m\times k}$ consisting of approximations to the top k left singular vectors of A. In [11] we prove the following.

THEOREM 2. *Suppose $A \in \mathbb{R}^{m\times n}$ and let H_k be constructed from the* LINEARTIMESVD *algorithm of* [11]. *Then*

$$\left\|A - H_k H_k^T A\right\|_F^2 \leq \|A - A_k\|_F^2 + 2\sqrt{k}\left\|AA^T - CC^T\right\|_F, \tag{8}$$

$$\left\|A - H_k H_k^T A\right\|_2^2 \leq \|A - A_k\|_2^2 + 2\left\|AA^T - CC^T\right\|_2. \tag{9}$$

The CONSTANTTIMESVD algorithm is also presented in [11]. It is an algorithm which, when given a matrix $A \in \mathbb{R}^{m\times n}$, uses constant additional space and time to compute a description of an approximation to the top k singular values and the corresponding left singular vectors of A. It does so in a manner similar to that of the LINEARTIMESVD algorithm except that it performs a second level of sampling in order to estimate (rather than compute exactly) the top k singular values and corresponding singular vectors of C. The γ in the following theorem is a parameter of the CONSTANTTIMESVD algorithm of [11] that is related to the second level of sampling; it also appears in our CONSTANTTIMECUR algorithm, and is thus discussed in section 4. In [11] we prove the following.

THEOREM 3. *Suppose $A \in \mathbb{R}^{m\times n}$; let a description of $\tilde{H}_\ell$ be constructed from the* CONSTANTTIMESVD *algorithm of* [11] *by sampling c columns of A with probabilities $\{p_i\}_{i=1}^n$ and w rows of C with probabilities $\{q_j\}_{j=1}^m$ where $p_i = |A^{(i)}|^2/\|A\|_F^2$ and $q_j = |C_{(j)}|^2/\|C\|_F^2$. Let $\eta = 1 + \sqrt{8\log(2/\delta)}$ and $\epsilon > 0$.*

If a Frobenius norm bound is desired, and hence the CONSTANTTIMESVD *algorithm is run with $\gamma = \epsilon/100k$, then by choosing $c = \Omega(k^2\eta^2/\epsilon^4)$ columns of A and $w = \Omega(k^2\eta^2/\epsilon^4)$ rows of C we have that with probability at least $1 - \delta$,*

$$\left\|A - \tilde{H}_\ell \tilde{H}_\ell^T A\right\|_F^2 \leq \|A - A_k\|_F^2 + \epsilon\,\|A\|_F^2. \tag{10}$$

If a spectral norm bound is desired, and hence the CONSTANTTIMESVD *algorithm is run with $\gamma = \epsilon/100$, then by choosing $c = \Omega(\eta^2/\epsilon^4)$ columns of A and $w = \Omega(\eta^2/\epsilon^4)$ rows of C we have that with probability at least $1 - \delta$,*

$$\left\|A - \tilde{H}_\ell \tilde{H}_\ell^T A\right\|_2^2 \leq \|A - A_k\|_2^2 + \epsilon\,\|A\|_F^2. \tag{11}$$

3. The linear time *CUR* decomposition. In this section we describe and analyze the LINEARTIMECUR algorithm, which computes an approximate CUR decomposition of a matrix $A \in \mathbb{R}^{m \times n}$ using linear (in m and n) additional space and time. In section 4 we describe and analyze the CONSTANTTIMECUR algorithm which computes a description of an approximate CUR decomposition of a matrix A using only constant additional space and time. Both algorithms will make extensive use of the corresponding results from [11] for approximating the SVD of a matrix as well as results from [10] on approximating the product of two matrices. As with the SVD algorithms, the CONSTANTTIMECUR algorithm has a similar flavor to the LINEARTIMECUR algorithm, but is technically more complex due to the second level of sampling required. Thus, in this section we provide an extensive description of the LINEARTIMECUR algorithm and the motivation and intuition behind it, and in section 4 we highlight the differences between the linear additional time framework and the constant additional time framework.

3.1. The algorithm. Given a matrix $A \in \mathbb{R}^{m \times n}$, we wish to compute a succinctly described, easily computed matrix A' that is decomposable as $A' = CUR \in \mathbb{R}^{m \times n}$ and that satisfies properties (i)–(v) of section 1. The LINEARTIMECUR algorithm, which is presented in Figure 1, accomplishes this by first forming a matrix $C \in \mathbb{R}^{m \times c}$ by rescaling a randomly chosen subset of c columns of A; the columns are chosen in c independent identical trials where in each trial the αth column of A is chosen with probability q_α, and if the αth column is chosen, it is rescaled by $1/\sqrt{cq_\alpha}$ before inclusion in C. The algorithm then forms a matrix $R \in \mathbb{R}^{r \times n}$ by rescaling a randomly chosen subset of r rows of A; the rows are chosen in r independent identical trials where in each trial the αth row of A is chosen with the probability p_α, and if the αth row is chosen, it is rescaled by $1/\sqrt{rp_\alpha}$ before inclusion in R. Using the same randomly chosen rows to construct R from A the algorithm also constructs a matrix Ψ from C in an identical manner. Thus, $\Psi \in \mathbb{R}^{r \times c}$ and $\Psi_{ij} = A_{i_{t_1} j_{t_2}} / \sqrt{crp_{i_{t_1}} q_{j_{t_2}}}$, where i_{t_1} is the element of $\{1, \ldots, m\}$ selected in the t_1th row sampling trial and j_{t_2} is the element of $\{1, \ldots, n\}$ selected in the t_2th column sampling trial.

The following sampling matrix formalism provides a convenient representation of our ideas, and will be used extensively in this section and the next. (See [10] for another use of this sampling matrix formalism.) Let us define the column sampling matrix $S_C \in \mathbb{R}^{n \times c}$ to be the zero-one matrix where $(S_C)_{ij} = 1$ if the ith column of A is chosen in the jth independent random trial, and $S_{ij} = 0$ otherwise; let us also define the associated rescaling matrix $D_C \in \mathbb{R}^{c \times c}$ to be the diagonal matrix with $(D_C)_{tt} = 1/\sqrt{cp_{i_t}}$, where i_t is the element of $\{1, \ldots, n\}$ chosen in the tth sampling trial. Let us similarly define $S_R \in \mathbb{R}^{r \times m}$ and $D_R \in \mathbb{R}^{r \times r}$ to be the row sampling matrix and associated diagonal rescaling matrix, respectively. In this notation,

$$C = AS_C D_C \qquad \text{and} \qquad R = D_R S_R A, \tag{12}$$

where $S_C D_C$ postmultiplies (and thus samples and rescales columns of) A to form C, and where $D_R S_R$ premultiplies (and thus samples and rescales rows of) A to form R. Thus, in this notation,

$$\Psi = D_R S_R C = D_R S_R A S_C D_C. \tag{13}$$

Given C, the LINEARTIMECUR algorithm computes the top k singular values, $\sigma_t^2(C)$, $t = 1, \ldots, k$, and the corresponding singular vectors, y^t, $t = 1, \ldots, k$, of $C^T C$. Note that these are also the squares of the singular values and the corresponding right

LINEARTIMECUR Algorithm.

Input: $A \in \mathbb{R}^{m \times n}$, $r, c, k \in \mathbb{Z}^+$ such that $1 \leq r \leq m$, $1 \leq c \leq n$, and $1 \leq k \leq \min(r, c)$, $\{p_i\}_{i=1}^m$ such that $p_i \geq 0$ and $\sum_{i=1}^m p_i = 1$, and $\{q_j\}_{j=1}^n$ such that $q_j \geq 0$ and $\sum_{j=1}^n q_j = 1$.

Output: $C \in \mathbb{R}^{m \times c}$, $U \in \mathbb{R}^{c \times r}$, and $R \in \mathbb{R}^{r \times n}$.

1. For $t = 1$ to c,
   (a) Pick $j_t \in \{1, \ldots, n\}$ with $\mathbf{Pr}[j_t = \alpha] = q_\alpha$, $\alpha = 1, \ldots, n$.
   (b) Set $C^{(t)} = A^{(j_t)} / \sqrt{cq_{j_t}}$.
2. Compute $C^T C$ and its SVD; say $C^T C = \sum_{t=1}^c \sigma_t^2(C) y^t y^{t^T}$.
3. If $\sigma_k(C) = 0$, then let $k = \max\{k' : \sigma_{k'}(C) \neq 0\}$.
4. For $t = 1$ to r,
   (a) Pick $i_t \in \{1, \ldots, m\}$ with $\mathbf{Pr}[i_t = \alpha] = p_\alpha$, $\alpha = 1, \ldots, m$.
   (b) Set $R_{(t)} = A_{(i_t)} / \sqrt{rp_{i_t}}$.
   (c) Set $\Psi_{(t)} = C_{(i_t)} / \sqrt{rp_{i_t}}$.
5. Let $\Phi = \sum_{t=1}^k \frac{1}{\sigma_t^2(C)} y^t y^{t^T}$ and let $U = \Phi \Psi^T$.
6. Return C, U, and R.

FIG. 1. *The* LINEARTIMECUR *algorithm.*

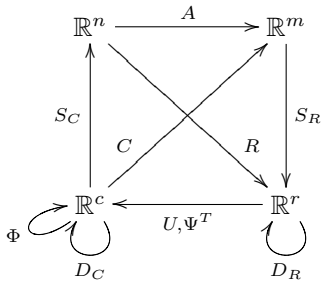

FIG. 2. *Diagram for the* LINEARTIMECUR *algorithm.*

singular vectors of C. Using these quantities, a matrix $\Phi \in \mathbb{R}^{c \times c}$ may be defined as

$$\Phi = \sum_{t=1}^{k} \frac{1}{\sigma_t^2(C)} y^t y^{t^T}, \tag{14}$$

from which $U \in \mathbb{R}^{c \times r}$ is constructed as $U = \Phi \Psi^T$. We could, of course, have defined a matrix Φ (and thus constructed a matrix U) from the singular vectors and singular values of RR^T in a manner analogous to that described above; in that case, the roles of the row sampling and column sampling would be reversed relative to the discussion below.

Figure 2 presents a diagram illustrating the action of the LINEARTIMECUR algorithm. The matrix A is shown as operating between the high-dimensional spaces $\mathbb{R}^n$ and $\mathbb{R}^m$. In addition, the matrix C is shown as operating between $\mathbb{R}^c$ and $\mathbb{R}^m$ and the matrix R is shown as operating between $\mathbb{R}^n$ and $\mathbb{R}^r$. Intuitively, one may think of $\mathbb{R}^c$ and $\mathbb{R}^r$ as being the most significant parts of $\mathbb{R}^n$ and $\mathbb{R}^m$, respectively, in terms of the action of A. Indeed, this will be the case when the sampling probabilities $\{p_i\}_{i=1}^m$

and $\{q_j\}_{j=1}^n$ satisfy certain conditions, as stated, e.g., in Theorem 4. The diagram also illustrates that $C = AS_CD_C$, $R = D_RS_RA$, and the matrix U which can be seen to be $U = \Phi\Psi^T = \Phi C^T(D_RS_R)^T$.

The matrix A is thus approximated by a matrix $A' = CUR$, where C is an $m \times c$ matrix consisting of c randomly chosen columns of A, R is an $r \times n$ matrix consisting of r randomly chosen rows of A, and $U = \Phi\Psi^T$ is a $c \times r$ matrix computed from C and R. As we shall see, if the column and row sampling probabilities are chosen judiciously, then c and r can be chosen to be constants (independent of m and n but depending on k and ϵ). Thus, (pictorially) we have that

$$\left(\begin{array}{c} \\ A \\ \\ \end{array}\right) \approx \left(\begin{array}{c} \\ C \\ \\ \end{array}\right) \left(\begin{array}{c} \\ U \\ \\ \end{array}\right) \left(\begin{array}{c} \\ R \\ \\ \end{array}\right). \tag{15}$$

The length of our succinct representation is $O(m+n)$. Note that if C and R are not explicitly needed, the length of the representation is a constant $O(1)$; this is because U is of constant size and only a constant number of bits are needed to specify which columns and rows of A are kept (along with their associated rescaling factors) in the construction of C and R, respectively.

Before proving the theorem, we would like to give some intuition as to why, if $\{p_i\}_{i=1}^m$ and $\{q_j\}_{j=1}^n$ satisfy certain conditions, the product CUR, as computed from the LinearTimeCUR algorithm, then becomes a good approximation to A in the sense of requirements (iv) and (v) of section 1. Let $h^t = Cy^t/\sigma_t(C)$ be the left singular vectors of C. Thus, if $H_k = (h^1\ h^2 \dots h^k) \in \mathbb{R}^{m\times k}$, then $H_kH_k^TA$ is the projection of A onto the subspace spanned by the top k left singular vectors of C. If the column sampling probabilities $\{q_j\}_{j=1}^n$ satisfy certain conditions, then the top k of the h^t's are approximations to the top k left singular vectors of A in the sense that their projection can be shown to "capture" *almost* as much of A as the projection of A onto the space spanned by its own top k left singular vectors. Indeed, the content of the SVD results of [11] (which in turn depend on the matrix multiplication results of [10]) is that if the column sampling probabilities $\{q_j\}_{j=1}^n$ are chosen judiciously, then the error in $\|A - H_kH_k^TA\|_\xi$ beyond the error for the best rank-k approximation can be made arbitrarily small both in expectation and with high probability.

Although $H_kH_k^TA$ is an approximation to A, one might wonder whether the approximation $H_kH_k^TA$ can be approximated so as to satisfy properties (i)–(v). Indeed, this is exactly what the CUR decomposition does! Using our sampling matrix formalism, let us define

$$\widetilde{H_k^T} = H_k^T(D_RS_R)^T \qquad \text{and} \qquad \widetilde{A} = D_RS_RA \tag{16}$$

to be the column-sampled and rescaled version of H_k^T and row-sampled and rescaled version of A, respectively. (We will see that $\widetilde{H_k^T}\widetilde{A} \approx H_k^TA$ by Theorem 1.) Lemma 1 states that

$$\begin{aligned} CUR &= H_kH_k^T(D_RS_R)^TD_RS_RA \\ &= H_k\widetilde{H_k^T}\widetilde{A}. \end{aligned} \tag{17}$$

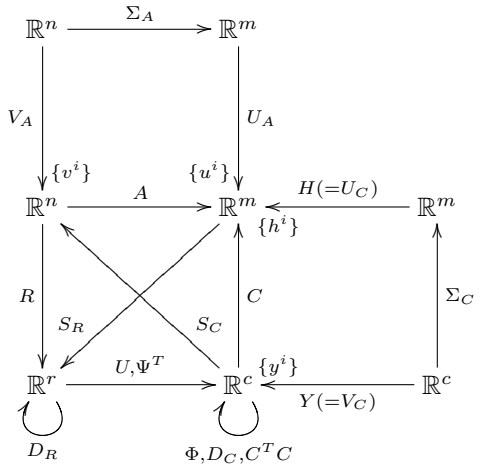

FIG. 3. *Another diagram for the* LINEARTIMECUR *algorithm.*

Thus, in order to provide a bound for $\|A - CUR\|_\xi$ for $\xi = 2, F$ we can first note that by the triangle inequality

$$\|A - CUR\|_\xi \leq \left\|A - H_k H_k^T A\right\|_\xi + \left\|H_k H_k^T A - CUR\right\|_\xi, \tag{18}$$

and then we can bound the two terms separately. The first term in (18) can be bounded using the SVD results of [11] if the column sampling probabilities satisfy certain conditions; in particular we will require that they be the optimal probabilities. Since $H_k^T H_k = I_k$, Lemma 2 states that

$$\begin{aligned} \left\|H_k H_k^T A - CUR\right\|_F &= \left\|H_k^T A - H_k^T (D_R S_R)^T D_R S_R A\right\|_F \\ &= \left\|H_k^T A - \widetilde{H_k^T} \widetilde{A}\right\|_F. \end{aligned} \tag{19}$$

Thus, the second term in (18) can be bounded by the matrix multiplication results of [10]; it will follow that if the sampling probabilities $\{p_i\}_{i=1}^m$ satisfy certain conditions, then $\widetilde{H_k^T} \widetilde{A} \approx H_k^T A$ in the sense that the error in $\|H_k^T A - \widetilde{H_k^T} \widetilde{A}\|_F$ can be bounded. Note that since the optimal probabilities depend on both H^T and A, and since we do not have access to H^T, our probabilities will not be optimal; nevertheless, although we will not obtain bounds with very high probability, as in [10] and [11], we will be able to apply Markov's inequality and thus achieve the bounds we desire.

A diagram illustrating the method (just described) that will be used to prove the correctness of the CUR algorithm is presented in Figure 3. In this figure, the locations of $\mathbb{R}^c$ and $\mathbb{R}^r$ and thus the directions of R, S_R, C, S_C, and U have been switched relative to their location in Figure 2. This presentation has several advantages: first, the SVD of C and the SVD of A can both be presented in the same figure as the CUR decomposition of A; second, one can see that bounding $\|A - H_k H_k^T A\|_\xi$ well in terms of $\|AA^T - CC^T\|_\xi$ depends on the probabilities used to sample the columns of A; and third, one can also see that bounding $\|H_k^T A - \widetilde{H_k^T} \widetilde{A}\|_F$ well depends on the probabilities used to sample the (columns of H_k^T and the corresponding) rows of A. See the corresponding figures in [10] and [11] for a comparison.

3.2. Analysis of the implementation and running time. In the LINEARTIMECUR algorithm the sampling probabilities $\{p_i\}_{i=1}^m$ and $\{q_j\}_{j=1}^n$ (if they are chosen to be of the form used in Theorems 4 and 5) can be computed in one pass and $O(c+r)$ additional space and time using the SELECT algorithm of [10]. Given the elements to be sampled, the matrix C can then be constructed in one additional pass; this requires additional space and time that is $O(mc)$. Similarly, the matrix R can then be constructed in the same pass using additional space and time that is $O(nr)$. Given $C \in \mathbb{R}^{m\times c}$, computing C^TC requires $O(mc)$ additional space and $O(mc^2)$ additional time, and computing the SVD of C^TC requires $O(c^3)$ additional time. The matrix Ψ can be computed in the same second pass by sampling the same r rows of C that were used to construct R from A; this requires additional space and time that is $O(cr)$. The matrix Φ can be explicitly computed using $O(c^2k)$ additional time, and then the matrix $U = \Phi\Psi^T$ can be computed using $O(c^2r)$ additional time. Thus, since c, r, and k are assumed to be a constant, overall $O(m+n)$ additional space and time are required by the LINEARTIMECUR algorithm, and requirements (i)–(iii) of section 1 are satisfied. Note that the "description" of the solution that is computable in the allotted additional space and time is the explicit matrices C, U, and R.

3.3. Analysis of the sampling step. Before stating and proving the main theorem of this section, we will first prove two useful lemmas. Lemma 1 will establish (17) and Lemma 2 will establish (19).

LEMMA 1.

$$CUR = H_k\widetilde{H_k^T}\widetilde{A}.$$

Proof. Note that the SVD of C is $C = \sum_{t=1}^c \sigma_t(C)h^t y^{t^T}$, that the matrix $\Psi = D_RS_RC$, and that $U = \Phi\Psi^T$, where Φ is given by (14). Thus, we have that

$$\begin{aligned} CUR &= C\left(\sum_{t=1}^k \frac{1}{\sigma_t^2(C)} y^t y^{t^T}\right) C^T (D_RS_R)^T R \\ &= \left(\sum_{t_1} \sigma_{t_1}(C) h^{t_1} y^{t_1 T}\right)\left(\sum_{t_2=1}^k \frac{1}{\sigma_{t_2}^2(C)} y^{t_2} y^{t_2 T}\right)\left(\sum_{t_3} \sigma_{t_3}(C) y^{t_3} h^{t_3 T}\right)(D_RS_R)^T R \\ &= \left(\sum_{t=1}^k h^t h^{t^T}\right)(D_RS_R)^T R. \end{aligned}$$

The lemma follows since $\sum_{t=1}^k h^t h^{t^T} = H_kH_k^T$, since $R = D_RS_RA$, and from the definitions (16). ∎

LEMMA 2.

$$\left\|H_kH_k^TA - CUR\right\|_F = \left\|H_k^TA - \widetilde{H_k^T}\widetilde{A}\right\|_F.$$

Proof. From Lemma 1 we have that $CUR = H_k\widetilde{H_k^T}\widetilde{A}$. Let us define the matrix $\Omega \in \mathbb{R}^{k\times n}$ as

$$\Omega = H_k^TA - H_k^T(D_RS_R)^TD_RS_RA = H_k^TA - \widetilde{H_k^T}\widetilde{A}.$$

In addition, note that

$$\left\|H_kH_k^TA - H_k\widetilde{H_k^T}\widetilde{A}\right\|_F^2 = \|H_k\Omega\|_F^2 = \mathbf{Tr}\left(\Omega^TH_k^TH_k\Omega\right).$$

The lemma follows since $H_k^TH_k = I_k$ and since $\mathbf{Tr}\left(\Omega^T\Omega\right) = \|\Omega\|_F^2$. ∎

Here is our main theorem regarding the LINEARTIMECUR algorithm described in section 3.1. Note that in this theorem we restrict ourselves to sampling probabilities that are optimal in the sense of section 2.3.

THEOREM 4. *Suppose $A \in \mathbb{R}^{m\times n}$, and let C, U, and R be constructed from the* LINEARTIMECUR *algorithm by sampling c columns of A with probabilities $\{q_j\}_{j=1}^n$ and r rows of A with probabilities $\{p_i\}_{i=1}^m$. Assume that $p_i = |A_{(i)}|^2 / \|A\|_F^2$ and $q_j = |A^{(j)}|^2 / \|A\|_F^2$. Then*

$$\mathbf{E}\left[\,\|A - CUR\|_F\right] \le \|A - A_k\|_F + \left(\left(\frac{4k}{c}\right)^{1/4} + \left(\frac{k}{r}\right)^{1/2}\right)\|A\|_F\,, \tag{20}$$

$$\mathbf{E}\left[\,\|A - CUR\|_2\right] \le \|A - A_k\|_2 + \left(\left(\frac{4}{c}\right)^{1/4} + \left(\frac{k}{r}\right)^{1/2}\right)\|A\|_F\,. \tag{21}$$

In addition, if we let $\eta_c = 1 + \sqrt{8\log(1/\delta_c)}$ and let $\delta = \delta_r + \delta_c$, then with probability at least $1-\delta$,

$$\|A - CUR\|_F \le \|A - A_k\|_F + \left(\left(\frac{4k\eta_c^2}{c}\right)^{1/4} + \left(\frac{k}{\delta_r^2 r}\right)^{1/2}\right)\|A\|_F\,, \tag{22}$$

$$\|A - CUR\|_2 \le \|A - A_k\|_2 + \left(\left(\frac{4\eta_c^2}{c}\right)^{1/4} + \left(\frac{k}{\delta_r^2 r}\right)^{1/2}\right)\|A\|_F\,. \tag{23}$$

Proof. By the triangle inequality we have that

$$\|A - CUR\|_\xi \le \left\|A - H_k H_k^T A\right\|_\xi + \left\|H_k H_k^T A - CUR\right\|_\xi \tag{24}$$

for both $\xi = 2, F$; thus by Lemmas 1 and 2 we have that

$$\|A - CUR\|_\xi \le \left\|A - H_k H_k^T A\right\|_\xi + \left\|H_k^T A - H_k^T (D_R S_R)^T D_R S_R A\right\|_F \tag{25}$$

$$= \left\|A - H_k H_k^T A\right\|_\xi + \left\|H_k^T A - \widetilde{H_k^T}\,\widetilde{A}\right\|_F \tag{26}$$

for both $\xi = 2, F$, where (26) follows from the definitions (16). Then, note that the column sampling satisfies the requirements for the LINEARTIMESVD algorithm of [11]. Thus, by Theorem 2 it follows from (25) that

$$\|A - CUR\|_F \le \|A - A_k\|_F + (4k)^{1/4}\left\|AA^T - CC^T\right\|_F^{1/2} + \left\|H_k^T A - \widetilde{H_k^T}\,\widetilde{A}\right\|_F, \tag{27}$$

$$\|A - CUR\|_2 \le \|A - A_k\|_2 + \sqrt{2}\left\|AA^T - CC^T\right\|_F^{1/2} + \left\|H_k^T A - \widetilde{H_k^T}\,\widetilde{A}\right\|_F. \tag{28}$$

Note that from the LINEARTIMECUR algorithm the column sampling probabilities are of the form (3) with $B = A^T$; thus, they are optimal and $\mathbf{E}\left[\|AA^T - CC^T\|_F\right] \le \frac{1}{\sqrt{c}}\|A\|_F^2$. In addition, although the row sampling probabilities are not optimal, they are of the form (6); thus, since $\|H_k^T\|_F = \sqrt{k}$ we have that

$$\mathbf{E}\left[\left\|H_k^T A - \widetilde{H_k^T}\,\widetilde{A}\right\|_F\right] \le \sqrt{\frac{k}{r}}\,\|A\|_F\,. \tag{29}$$

Thus, by taking expectations of (27) and (28), by using Jensen's inequality and Theorem 1, (20) and (21) follow.

To establish (22) and (23) first let the events $\mathcal{E}_\xi, \xi = c, r$ be defined as follows:

$$\mathcal{E}_c : \left\|AA^T - CC^T\right\|_F \leq \frac{\eta_c}{\sqrt{c}} \|A\|_F^2 ,$$

$$\mathcal{E}_r : \left\|H_k^T A - \widetilde{H_k^T}\widetilde{A}\right\|_F \leq \frac{1}{\delta_r}\sqrt{\frac{k}{r}} \|A\|_F .$$

Thus, from Theorem 1 we have that $\mathbf{Pr}[\mathcal{E}_c] \geq 1-\delta_c$. By applying Markov's inequality to $\left\|H_k^T A - \widetilde{H_k^T}\widetilde{A}\right\|_F$ and using (29) we see that

$$\mathbf{Pr}\left[\left\|H_k^T A - \widetilde{H_k^T}\widetilde{A}\right\|_F \geq \frac{1}{\delta_r}\sqrt{\frac{k}{r}} \|A\|_F\right] \leq \delta_r$$

and thus that $\mathbf{Pr}[\mathcal{E}_r] \geq 1 - \delta_r$. The theorem then follows from (27) and (28) by considering the event $\mathcal{E}_c \bigcap \mathcal{E}_r$. □

Note that in the proof of Theorem 4 (and similarly in that of Theorem 6 in section 4) $\|A - CUR\|_\xi$ is bounded by bounding each of the terms $\|A - H_k H_k^T A\|_\xi$ and $\|H_k H_k^T A - CUR\|_\xi$ independently. In order to bound $\|A - H_k H_k^T A\|_\xi$, the SVD results for arbitrary probabilities from [11] are used, and then it is noted that the column sampling probabilities used in the LINEARTIMECUR algorithm are optimal for bounding $\|AA^T - CC^T\|_F$. Then, independently, $\|H_k H_k^T A - CUR\|_\xi$ is bounded by using the matrix multiplication results of [10]. Since the probabilities that are used for the row sampling are not optimal with respect to bounding $\|H_k^T A - \widetilde{H_k^T}\widetilde{A}\|_F$, we do not obtain that bound with high probability. Due to the use of Markov's inequality, we must sample a number of rows that is $O(1/\delta)$, whereas we only need to sample a number of columns that is $O(\log(1/\delta))$.

As a corollary of Theorem 4 we have the following theorem. In this theorem, in addition to using sampling probabilities that are optimal in the sense of section 2.3, we choose sufficiently many columns and rows to ensure that the additional error is less than $\epsilon' \|A\|_F$.

THEOREM 5. *Suppose $A \in \mathbb{R}^{m\times n}$, and let C, U, and R be constructed from the* LINEARTIMECUR *algorithm by sampling c columns of A with probabilities $\{q_j\}_{j=1}^n$ and r rows of A with probabilities $\{p_i\}_{i=1}^m$. Assume that $p_i = |A_{(i)}|^2/\|A\|_F^2$ and $q_j = |A^{(j)}|^2/\|A\|_F^2$ and let $\epsilon, \epsilon' > 0$ with $\epsilon = \epsilon'/2$.*

If $c \geq 4k/\epsilon^4$ and $r \geq k/\epsilon^2$, then

$$\mathbf{E}[\|A - CUR\|_F] \leq \|A - A_k\|_F + \epsilon' \|A\|_F , \tag{30}$$

and if $c \geq 4/\epsilon^4$ and $r \geq k/\epsilon^2$, then

$$\mathbf{E}[\|A - CUR\|_2] \leq \|A - A_k\|_2 + \epsilon' \|A\|_F . \tag{31}$$

In addition, if we let $\eta_c = 1 + \sqrt{8\log(1/\delta_c)}$ and let $\delta = \delta_r + \delta_c$, and if $c \geq 4k\eta_c^2/\epsilon^4$ and $r \geq k/\delta_r^2\epsilon^2$, then with probability at least $1 - \delta$,

$$\|A - CUR\|_F \leq \|A - A_k\|_F + \epsilon' \|A\|_F , \tag{32}$$

and if $c \geq 4\eta_c^2/\epsilon^4$ and $r \geq k/\delta_r^2\epsilon^2$, then with probability at least $1 - \delta$,

$$\|A - CUR\|_2 \leq \|A - A_k\|_2 + \epsilon' \|A\|_F . \tag{33}$$

The results of Theorems 4 and 5 for both the Frobenius norm and the spectral norm hold for all k and are of particular interest when A is well approximated by a matrix of low rank since then one may choose $k = O(1)$ and obtain a good approximation. In addition, since $\|A - A_t\|_2 \leq \|A\|_F / \sqrt{t}$ for all $t = 1, 2, \ldots, r$, the bounds with respect to the spectral norm have the following interesting property: from (31) we can see that

$$\mathbf{E}\left[\|A - CUR\|_2\right] \leq \left(1/\sqrt{k} + \epsilon'\right) \|A\|_F,$$

and similarly for (33). Thus, under the assumptions of Theorem 5 if we choose $k = 1/\epsilon'^2$ and let $\epsilon'' = 2\epsilon'$, then we have that

$$\mathbf{E}\left[\|A - CUR\|_2\right] \leq \epsilon'' \|A\|_F \tag{34}$$

and that

$$\|A - CUR\|_2 \leq \epsilon'' \|A\|_F \tag{35}$$

holds with probability at least $1 - \delta$.

4. The constant time $C\tilde{U}R$ decomposition.

4.1. The algorithm. The ConstantTimeCUR algorithm is very similar in spirit to the LinearTimeCUR algorithm; thus, we only highlight its main features with an emphasis on similarities and differences between the two algorithms. Given a matrix $A \in \mathbb{R}^{m \times n}$, we wish to compute a description of a succinctly described, easily computed matrix A' that is decomposable as $A' = C\tilde{U}R \in \mathbb{R}^{m \times n}$ and that satisfies requirements (i)–(v) of section 1, where the additional RAM space and time to compute $\tilde{U}$ is $O(1)$. The ConstantTimeCUR algorithm, which is presented in Figure 4, accomplishes this by forming a matrix $C \in \mathbb{R}^{m \times c}$ by rescaling a randomly chosen subset of c columns of A, forming a matrix $R \in \mathbb{R}^{r \times n}$ by rescaling a randomly chosen subset of r rows of A, and forming a matrix $\Psi \in \mathbb{R}^{r \times c}$ from C by choosing the same randomly chosen rows used to construct R from A and rescaling appropriately. Given C, the ConstantTimeCUR algorithm randomly chooses and rescales w rows of C to form a matrix $W \in \mathbb{R}^{w \times c}$ and then computes the top ℓ singular values, $\sigma_t^2(W)$, $t = 1, \ldots, \ell$, and the corresponding singular vectors, z^t, $t = 1, \ldots, \ell$, of $W^T W$. Note that these are also approximations to the (squares of the) singular values and the corresponding right singular vectors of C. Using these quantities, a matrix $\tilde{\Phi} \in \mathbb{R}^{c \times c}$ may be defined as

$$\tilde{\Phi} = \sum_{t=1}^{\ell} \frac{1}{\sigma_t^2(W)} z^t z^{t^T}, \tag{36}$$

from which $\tilde{U} \in \mathbb{R}^{c \times r}$ is constructed as $\tilde{U} = \tilde{\Phi}\Psi^T$. Note that in the constant additional space and time framework the actual matrices C and R are not explicitly computed; instead the constant-sized matrix $\tilde{U}$ is computed and only a constant number of bits are stored to specify which columns and rows of A are kept (along with their associated rescaling factors) in the construction of C and R, respectively. Thus, the length of the succinct representation of A is a constant.

Figure 2 of section 3 provides a diagram illustrating the action of LinearTimeCUR algorithm, but the diagram and associated discussion are also relevant for the ConstantTimeCUR algorithm. Figure 5 also provides a diagram illustrating the

ConstantTimeCUR Algorithm.

Input: $A \in \mathbb{R}^{m \times n}$, $r, c, k \in \mathbb{Z}^+$ such that $1 \leq r \leq m$, $1 \leq c \leq n$, and $1 \leq k \leq \min(r, c)$, $\{p_i\}_{i=1}^m$ such that $p_i \geq 0$ and $\sum_{i=1}^m p_i = 1$, and $\{q_j\}_{j=1}^n$ such that $q_j \geq 0$ and $\sum_{j=1}^n q_j = 1$.

Output: $\tilde{U} \in \mathbb{R}^{c \times r}$ and a "description" of $C \in \mathbb{R}^{m \times c}$ and $R \in \mathbb{R}^{r \times n}$.

1. For $t = 1$ to c,
   (a) Pick $j_t \in \{1, \ldots, n\}$ with $\mathbf{Pr}[j_t = \alpha] = q_\alpha$, and save $\{(j_t, q_{j_t}) : t = 1, \ldots, c\}$.
   (b) Set $C^{(t)} = A^{(j_t)}/\sqrt{cq_{j_t}}$. (Note that C is not explicitly constructed in RAM.)
2. Choose $\{\pi_i\}_{i=1}^m$ such that $\pi_i = \left|C_{(i)}\right|^2 / \|C\|_F^2$.
3. For $t = 1$ to w,
   (a) Pick $i_t \in 1, \ldots, m$ with $\mathbf{Pr}[i_t = \alpha] = \pi_\alpha$, $\alpha = 1, \ldots, m$.
   (b) Set $W_{(t)} = C_{(i_t)}/\sqrt{w\pi_{i_t}}$.
4. Compute $W^T W$ and its SVD; say $W^T W = \sum_{t=1}^c \sigma_t^2(W) z^t z^{t^T}$.
5. If a $\|\cdot\|_F$ bound is desired, set $\gamma = \epsilon/100k$,
   Else if a $\|\cdot\|_2$ bound is desired, set $\gamma = \epsilon/100$.
6. Let $\ell = \min\{k, \max\{t : \sigma_t^2(W) \geq \gamma \|W\|_F^2\}\}$.
7. Keep singular values $\{\sigma_t(W)\}_{t=1}^\ell$ and their corresponding singular vectors $\{z^t\}_{t=1}^\ell$.
8. For $t = 1$ to r,
   (a) Pick $i_t \in \{1, \ldots, m\}$ with $\mathbf{Pr}[i_t = \alpha] = p_\alpha$, and save $\{(i_t, p_{i_t}) : t = 1, \ldots, r\}$.
   (b) Set $R_{(t)} = A_{(i_t)}/\sqrt{rp_{i_t}}$. (Note that R is not explicitly constructed in RAM.)
   (c) Set $\Psi_{(t)} = C_{(i_t)}/\sqrt{rp_{i_t}}$.
9. Let $\tilde{\Phi} = \sum_{t=1}^\ell \frac{1}{\sigma_t^2(W)} z^t z^{t^T}$ and let $\tilde{U} = \tilde{\Phi}\Psi^T$.
10. Return $\tilde{U}$, c column labels $\{(j_t, q_{j_t}) : t = 1, \ldots, c\}$, and r row labels $\{(i_t, p_{i_t}) : t = 1, \ldots, r\}$.

Fig. 4. *The* ConstantTimeCUR *algorithm.*

action of the ConstantTimeCUR algorithm, and is the analogue for the constant time $C\tilde{U}R$ of Figure 3; Figure 5 also illustrates that the matrix Y $(= V_C)$ (of Figure 3) consisting of the top k right singular vectors of C is not exactly computed, but is instead approximated by the matrix Z $(= V_W)$, where Z is a matrix whose columns $Z^{(t)} = z^t$ consist of the right singular vectors of W. Thus, the matrix H_k consisting of the left singular vectors of C is not exactly computed but is only approximated by $\tilde{H}_\ell$, where $\tilde{H}_\ell^{(t)} = \tilde{h}^t = Cz^t/\sigma_t(W)$ for $t = 1, \ldots, \ell$. Since by construction it is still the case that $R = D_R S_R A$ (and also that $C = AS_C D_C$ and $\Psi = D_R S_R C$), where the sampling matrices and the diagonal rescaling matrices are defined as in section 3.1, it follows from Lemma 3 that

$$C\tilde{U}R = \tilde{H}_\ell \tilde{H}_\ell^T (D_R S_R)^T D_R S_R A. \tag{37}$$

In the linear time case we had that $H_k^T H_k = I_k$ since the columns of H_k were k of the left singular vectors of C. This allowed us to prove Lemma 2, as described

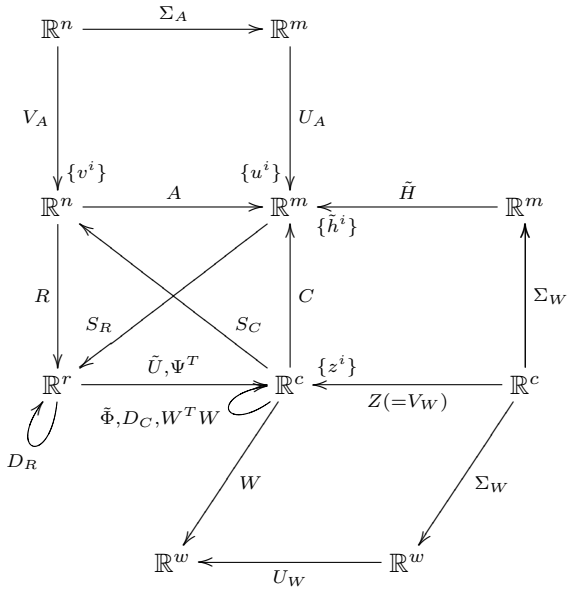

FIG. 5. *Diagram for the* CONSTANTTIMECUR *algorithm.*

in section 3.1. In the constant additional time setting, the columns of $\tilde{H}_\ell$ are only approximations to k of the left singular vectors of C, but we still have that $\tilde{H}_\ell^T \tilde{H}_\ell \approx I_\ell$. To quantify this, define $Z_{\alpha,\beta} \in \mathbb{R}^{c \times (\beta-\alpha+1)}$ to be the matrix whose columns are the αth through the βth singular vectors of $W^T W$ and $T \in \mathbb{R}^{\ell \times \ell}$ to be the diagonal matrix with elements $T_{tt} = 1/\sigma_t(W)$. If we define the matrix $\Delta \in \mathbb{R}^{\ell \times \ell}$ to be

$$\Delta = T Z_{1,\ell}^T (C^T C - W^T W) Z_{1,\ell} T, \tag{38}$$

then Lemma 5 will establish that

$$\left\| \tilde{H}_\ell \tilde{H}_\ell^T A - C\tilde{U}R \right\|_F \leq (1 + \|\Delta\|_F^{1/2}) \left\| \tilde{H}_\ell^T A - \tilde{H}_\ell^T (D_R S_R)^T D_R S_R A \right\|_F, \tag{39}$$

and Lemma 4 establishes that $\tilde{H}_\ell^T \tilde{H}_\ell = I_\ell + \Delta$. Thus, as in the linear time case, we can split

$$\left\| A - C\tilde{U}R \right\|_\xi \leq \left\| A - \tilde{H}_\ell \tilde{H}_\ell^T A \right\|_\xi + \left\| \tilde{H}_\ell \tilde{H}_\ell^T A - C\tilde{U}R \right\|_\xi$$

for $\xi = 2, F$ and then bound the two terms separately. The first term can be bounded by the constant time SVD results of [11], the second term can be bounded by the matrix multiplication results of [10], and bounding the overall error depends on both results. Due to the two levels of sampling, the additional error will be larger than in the linear additional time framework, but it can be made arbitrarily small by choosing a constant number of rows and columns.

4.2. Analysis of the implementation and running time. In the CONSTANTTIMECUR algorithm the sampling probabilities $\{p_i\}_{i=1}^m$ and $\{q_j\}_{j=1}^n$ (if they are chosen to be of the form used in Theorem 6) can be computed in one pass and $O(c + r)$ additional space and time using the SELECT algorithm of [10]. Given the columns of A to be sampled, we do not explicitly construct the matrix C but instead

perform a second level of sampling and select w rows of C with probabilities $\{\pi_i\}_{i=1}^m$ in order to construct the matrix W; this requires a second pass and $O(w)$ additional space and time. Then, in a third pass we explicitly construct W; this requires additional space and time that is $O(cw)$. Similarly, a description of the matrix R can then be constructed in the same third pass using additional space and time that is $O(r)$. Then, given W, computing W^TW requires $O(c^2w)$ additional time and computing the SVD of W^TW requires $O(c^3)$ additional time. The matrix Ψ can be computed in the same third pass by sampling the same r rows of C that were used to construct R from A; this requires additional time that is $O(cr)$. The matrix $\tilde{\Phi}$ can be explicitly computed using $O(c^2k)$ additional time and then the matrix $U = \tilde{\Phi}\Psi^T$ can be computed using $O(c^2r)$ additional time. Thus, since c, r, and k are assumed to be constants, overall $O(1)$ additional space and time are required by the ConstantTimeCUR algorithm, and requirements (i)–(iii) of section 1 are satisfied. Note that the "description" of the solution that is computable in the allotted additional space and time is the matrix $\tilde{U}$, with the labels $i_1, \ldots, i_r$ and $j_1, \ldots, j_c$ indicating the rows chosen to construct C and R as well as the corresponding probabilities $\{p_{i_t}\}_{t=1}^r$ and $\{q_{j_t}\}_{t=1}^c$; we note that we need to know p_i only for the sampled rows i and q_j only for the sampled columns j.

4.3. Analysis of the sampling step. Before stating and proving the main theorem of this section, we will first prove several useful lemmas. First, in Lemma 3 we will establish (37).

Lemma 3.

$$C\tilde{U}R = \tilde{H}_\ell \tilde{H}_\ell^T (D_R S_R)^T D_R S_R A.$$

Proof. Since $\tilde{h}^t = Cz^t/\sigma_t(W)$ for $t = 1, \ldots, \ell$, we have that $C = \sum_{t=1}^c \sigma_t(W)\tilde{h}^t z^{t^T}$. Thus, we have that

$$\begin{aligned} C\tilde{U}R &= C\left(\sum_{t=1}^{\ell} \frac{1}{\sigma_t^2(W)} z^t z^{t^T}\right) C^T (D_R S_R)^T R \\ &= \left(\sum_{t=1}^{\ell} \tilde{h}^t \tilde{h}^{t^T}\right) (D_R S_R)^T R. \end{aligned}$$

The lemma follows since $\sum_{t=1}^{\ell} \tilde{h}^t \tilde{h}^{t^T} = \tilde{H}_\ell \tilde{H}_\ell^T$ and since $R = D_R S_R A$. ∎

Next, Lemma 4 will characterize, in terms of Δ, the degree to which the columns of $\tilde{H}_\ell$ are not orthonormal. Note that it appeared in [11].

Lemma 4. *When written in the basis with respect to Z,*

$$\tilde{H}_\ell^T \tilde{H}_\ell = I_\ell + \Delta.$$

Furthermore, for $\xi = 2, F$,

$$\|\Delta\|_\xi \leq \frac{1}{\gamma \|W\|_F^2} \left\|C^T C - W^T W\right\|_\xi.$$

Proof. Recall that $\tilde{H}_\ell = CZ_{1,\ell}T$ and that $T^T Z_{1,\ell}^T W^T W Z_{1,\ell} T = I_\ell$, so that

$$\left\|\tilde{H}_\ell^T \tilde{H}_\ell - I_\ell\right\|_\xi = \left\|T^T Z_{1,\ell}^T C^T C Z_{1,\ell} T - T^T Z_{1,\ell}^T W^T W Z_{1,\ell} T\right\|_\xi \tag{40}$$

$$= \left\|T^T Z_{1,\ell}^T \left(C^T C - W^T W\right) Z_{1,\ell} T\right\|_\xi. \tag{41}$$

Using the submultiplicativity properties of the 2-norm, and in particular

$$\|AB\|_\xi \leq \|A\|_2 \|B\|_\xi , \tag{42}$$

$$\|AB\|_\xi \leq \|A\|_\xi \|B\|_2 , \tag{43}$$

for both $\xi = 2, F$, we get

$$\left\|\tilde{H}_\ell^T \tilde{H}_\ell - I_\ell\right\|_\xi \leq \left\|T^T Z_{1,\ell}^T\right\|_2 \left\|C^T C - W^T W\right\|_\xi \|Z_{1,\ell} T\|_2 \tag{44}$$

$$\leq \|T\|_2^2 \left\|C^T C - W^T W\right\|_\xi \tag{45}$$

$$\leq \max_{t=1,\ldots,\ell} \left(1/\sigma_t^2(W)\right) \left\|C^T C - W^T W\right\|_\xi , \tag{46}$$

since $\|Z_{1,\ell}\|_2 = 1$. The lemma follows since $\sigma_t^2(W) \geq \gamma \|W\|_F^2$ for all $t = 1, \ldots, \ell$ by the definition of ℓ. □

Next, in Lemma 5 we will establish (39).

LEMMA 5.

$$\left\|\tilde{H}_\ell \tilde{H}_\ell^T A - C\tilde{U}R\right\|_F \leq (1 + \|\Delta\|_F^{1/2}) \left\|\tilde{H}_\ell^T A - \tilde{H}_\ell^T (D_R S_R)^T D_R S_R A\right\|_F .$$

Proof. From Lemma 3 we have that $C\tilde{U}R = \tilde{H}_\ell \tilde{H}_\ell^T (D_R S_R)^T D_R S_R A$. Let us define the matrix $\Omega \in \mathbb{R}^{\ell \times n}$ as

$$\Omega = \tilde{H}_\ell^T A - \tilde{H}_\ell^T (D_R S_R)^T D_R S_R A.$$

Thus, since $\mathbf{Tr}\left(XX^T\right) = \|X\|_F^2$ for a matrix X, we have

$$\begin{aligned} \left\|\tilde{H}_\ell \Omega\right\|_F^2 &= \mathbf{Tr}(\Omega^T \tilde{H}_\ell^T \tilde{H}_\ell \Omega) \\ &= \mathbf{Tr}(\Omega^T (I_\ell + \Delta)\Omega) \qquad (47) \\ &= \|\Omega\|_F^2 + \mathbf{Tr}(\Omega^T \Delta \Omega) \\ &\leq \|\Omega\|_F^2 + \|\Delta\|_2 \|\Omega\|_F^2 , \qquad (48) \end{aligned}$$

where (47) follows from Lemma 4 and (48) follows since $\left|\mathbf{Tr}(\Omega^T \Delta \Omega)\right| \leq \|\Delta\|_2 \mathbf{Tr}(\Omega^T \Omega)$. Thus,

$$\left\|\tilde{H}_\ell \tilde{H}_\ell^T A - C\tilde{U}R\right\|_F \leq (1 + \|\Delta\|_2)^{1/2} \left\|\tilde{H}_\ell^T A - \tilde{H}_\ell^T (D_R S_R)^T D_R S_R A\right\|_F ,$$

and the lemma then follows. □

Finally, in Lemma 6 we show that $\|W\|_F = \|C\|_F = \|A\|_F$ when optimal probabilities are used. It also appeared in [11].

LEMMA 6. *Suppose $A \in \mathbb{R}^{m \times n}$, and run the* ConstantTimeCUR *algorithm by sampling c columns of A with probabilities $\{q_j\}_{j=1}^n$ (and then sampling w rows of C with probabilities $\{\pi_i\}_{i=1}^m$ to construct W) and r rows of A with probabilities $\{p_i\}_{i=1}^m$. Assume that $p_i = |A_{(i)}|^2 / \|A\|_F^2$ and $q_j = |A^{(j)}|^2 / \|A\|_F^2$. Then $\|W\|_F = \|C\|_F = \|A\|_F$.*

Proof. If $p_i = |A^{(i)}|^2 / \|A\|_F^2$, then we have that $\|C\|_F^2 = \sum_{t=1}^c |C^{(t)}|^2 = \sum_{t=1}^c \frac{|A^{(i_t)}|^2}{c p_{i_t}} = \|A\|_F^2$. Similarly, if $q_j = |C_{(j)}|^2 / \|C\|_F^2$, then we have that $\|W\|_F^2 = \sum_{t=1}^w \left|W_{(t)}\right|^2 = \sum_{t=1}^w \frac{|C_{(i_t)}|^2}{w q_{i_t}} = \|C\|_F^2$. The lemma follows. □

Here is our main theorem regarding the ConstantTimeCUR algorithm described in section 4.1. It is the constant time analogue of Theorem 5. Note that

in this theorem we restrict ourselves to sampling probabilities that are optimal in the sense of section 2.3, and to choosing sufficiently many columns and rows to ensure that the additional error is less than $\epsilon \|A\|_F$.

THEOREM 6. *Suppose $A \in \mathbb{R}^{m\times n}$, and let C, $\tilde{U}$, and R be constructed from the* CONSTANTTIMECUR *algorithm by sampling c columns of A with probabilities $\{q_j\}_{j=1}^n$ (and then sampling w rows of C with probabilities $\{\pi_i\}_{i=1}^m$ to construct W) and r rows of A with probabilities $\{p_i\}_{i=1}^m$. Assume that $p_i = |A_{(i)}|^2/\|A\|_F^2$ and $q_j = |A^{(j)}|^2/\|A\|_F^2$. Let $\eta = 1+\sqrt{8\log(3/\delta)}$ and $\epsilon > 0$.*

If a Frobenius norm bound is desired, and hence the CONSTANTTIMESVD *algorithm is run with $\gamma = \epsilon/100k$, then if we let $c = \Omega(k^2\eta^2/\epsilon^8)$, $w = \Omega(k^2\eta^2/\epsilon^8)$, and $r = \Omega(k/\delta^2\epsilon^2)$, then with probability at least $1-\delta$,*

$$\left\|A - C\tilde{U}R\right\|_F \leq \|A - A_k\|_F + \epsilon \|A\|_F . \tag{49}$$

If a spectral norm bound is desired, and hence the CONSTANTTIMESVD *algorithm is run with $\gamma = \epsilon/100$, then if we let $c = \Omega(\eta^2/\epsilon^8)$, $w = \Omega(\eta^2/\epsilon^8)$, and $r = \Omega(k/\delta^2\epsilon^2)$, then with probability at least $1-\delta$,*

$$\left\|A - C\tilde{U}R\right\|_2 \leq \|A - A_k\|_2 + \epsilon \|A\|_F . \tag{50}$$

Proof. Let us define the events:

$$\mathcal{E}_c : \left\|AA^T - CC^T\right\|_F \leq \frac{\eta}{\sqrt{c}} \|A\|_F^2 , \tag{51}$$

$$\mathcal{E}_w : \left\|C^TC - W^TW\right\|_F \leq \frac{\eta}{\sqrt{w}} \|A\|_F^2 , \tag{52}$$

$$\mathcal{E}_r : \left\|\tilde{H}_\ell^T A - \tilde{H}_\ell^T (D_R S_R)^T D_R S_R A\right\|_F \leq \frac{3}{\delta\sqrt{r}} \left\|\tilde{H}_\ell\right\|_F \|A\|_F . \tag{53}$$

Under the assumptions of this theorem, event $\mathcal{E}_c$ holds with probability greater than $1-\delta/3$ by Theorem 1, and similarly for event $\mathcal{E}_w$. Next, we claim that $\mathcal{E}_r$ holds with probability greater than $1-\delta/3$. To prove this it suffices to prove that

$$\mathbf{E}\left[\left\|\tilde{H}_\ell^T A - \tilde{H}_\ell^T (D_R S_R)^T D_R S_R A\right\|_F\right] \leq \frac{1}{\sqrt{r}} \left\|\tilde{H}_\ell^T\right\|_F \|A\|_F , \tag{54}$$

since the claim that $\mathbf{Pr}[\mathcal{E}_r] \geq 1-\delta/3$ follows immediately from (54) by Markov's inequality; but (54) follows from Theorem 1 since the probabilities $\{p_i\}_{i=1}^m$ used to sample the columns of $\tilde{H}_\ell$ and the corresponding rows of A are of the form (6). Thus, under the assumptions of the theorem,

$$\mathbf{Pr}[\mathcal{E}_\xi] \geq 1-\delta/3 \quad \text{for } \xi = c, w, r.$$

Next, from Lemma 4 and the Cauchy–Schwarz inequality, it follows that

$$\left\|\tilde{H}_\ell\right\|_F^2 = \sum_{t=1}^{\ell} \left|\tilde{h}^{t^T} \tilde{h}^t\right| = \sum_{t=1}^{\ell} 1 + \Delta_{tt} \leq k + \sqrt{k} \|\Delta\|_F . \tag{55}$$

Since $\sqrt{1+x} \leq 1 + \sqrt{x}$ for $x \geq 0$ it follows from (55) and (53) that under the event $\mathcal{E}_r$ we have

$$\left\|\tilde{H}_\ell^T A - \tilde{H}_\ell^T (D_R S_R)^T D_R S_R A\right\|_F \leq \frac{3}{\delta\sqrt{r}} \left(\sqrt{k} + k^{1/4} \|\Delta\|_F^{1/2}\right) \|A\|_F . \tag{56}$$

By combining (56) with Lemma 5 we have that

$$\begin{aligned}
\left\|\tilde{H}_\ell \tilde{H}_\ell^T A - C\tilde{U}R\right\|_F &\leq \frac{3}{\delta\sqrt{r}} \left(1 + \|\Delta\|_F^{1/2}\right) \left(\sqrt{k} + k^{1/4} \|\Delta\|_F^{1/2}\right) \|A\|_F \\
&\leq \left(\frac{9k}{\delta^2 r}\right)^{1/2} \left(1 + \|\Delta\|_F^{1/2}\right)^2 \|A\|_F \qquad (57) \\
&\leq \left(\frac{9k}{\delta^2 r}\right)^{1/2} \left(1 + 3\|\Delta\|_F^{1/2}\right) \|A\|_F \qquad (58) \\
&\leq \left(\frac{9k}{\delta^2 r}\right)^{1/2} \left(1 + \frac{3\left\|C^T C - W^T W\right\|_F^{1/2}}{\sqrt{\gamma}\|W\|_F}\right) \|A\|_F , \qquad (59)
\end{aligned}$$

where (57) follows since $k^{1/4} \leq \sqrt{k}$, (58) follows by multiplying out terms and since $\|\Delta\|_F \leq 1$ under the assumptions of the theorem, and (59) follows from the bound on $\|\Delta\|_F$ in Lemma 4.

Let us first consider establishing the Frobenius norm bound of (49). Recall that in this case we have set $\gamma = \epsilon/100k$. We will use the triangle inequality to get

$$\left\|A - C\tilde{U}R\right\|_F \leq \left\|A - \tilde{H}_\ell \tilde{H}_\ell^T A\right\|_F + \left\|\tilde{H}_\ell \tilde{H}_\ell^T A - C\tilde{U}R\right\|_F \tag{60}$$

and will bound each term separately. First, using the probabilities $\{q_j\}_{j=1}^n$ and the values of $c, w = \Omega(k^2\eta^2/\epsilon^8)$, then under the event $\mathcal{E}_c \bigcap \mathcal{E}_w$ we have that

$$\left\|A - \tilde{H}_\ell \tilde{H}_\ell^T A\right\|_F \leq \|A - A_k\|_F + \frac{\epsilon}{2}\|A\|_F \tag{61}$$

by Theorem 3; see also [11]. In addition, using the sampling probabilities $\{p_i\}_{i=1}^m$ and values of $r = \Omega(k/\delta^2\epsilon^2)$ and $w = \Omega(k^2\eta^2/\epsilon^8)$, and noting Lemma 6, it follows from (59) that under the event $\mathcal{E}_r \bigcap \mathcal{E}_w$,

$$\left\|\tilde{H}_\ell \tilde{H}_\ell^T A - C\tilde{U}R\right\|_F \leq \frac{\epsilon}{2}\|A\|_F . \tag{62}$$

Thus, under the event $\mathcal{E}_c \bigcap \mathcal{E}_w \bigcap \mathcal{E}_r$, which has probability at least $1-\delta$, by combining (61) and (62) we see that (49) follows.

Let us next consider establishing the spectral norm bound of (50). Recall that in this case we have set $\gamma = \epsilon/100$ and that

$$\left\|A - C\tilde{U}R\right\|_2 \leq \left\|A - \tilde{H}_\ell \tilde{H}_\ell^T A\right\|_2 + \left\|\tilde{H}_\ell \tilde{H}_\ell^T A - C\tilde{U}R\right\|_F \tag{63}$$

by the submultiplicitivity of $\|\cdot\|_2$ and since $\|\cdot\|_2 \leq \|\cdot\|_F$. First, using the probabilities $\{q_j\}_{j=1}^n$ and the values of $c, w = \Omega(\eta^2/\epsilon^8)$, under the event $\mathcal{E}_c \bigcap \mathcal{E}_w$ we have that

$$\left\|A - \tilde{H}_\ell \tilde{H}_\ell^T A\right\|_2 \leq \|A - A_k\|_2 + \frac{\epsilon}{2}\|A\|_F \tag{64}$$

by Theorem 3; see also [11]. In addition, using the sampling probabilities $\{p_i\}_{i=1}^m$ and values of $r = \Omega(k/\delta^2\epsilon^2)$ and $w = \Omega(\eta^2/\epsilon^8)$, and noting Lemma 6, it follows from (59) that under the event $\mathcal{E}_r \bigcap \mathcal{E}_w$,

$$\left\|\tilde{H}_\ell \tilde{H}_\ell^T A - C\tilde{U}R\right\|_F \leq \frac{\epsilon}{2} \|A\|_F . \tag{65}$$

Thus, under the event $\mathcal{E}_c \bigcap \mathcal{E}_w \bigcap \mathcal{E}_r$, which has probability at least $1-\delta$, by combining (64) and (65) we see that (50) follows. □

As in the linear additional time framework, the results of Theorem 6 hold for all k and are of particular interest when A is well approximated by a matrix of low rank since then one may choose $k = O(1)$ and obtain a good approximation. In addition, it follows from (50) that

$$\left\|A - C\tilde{U}R\right\|_2 \leq (1/\sqrt{k} + \epsilon') \|A\|_F .$$

Thus, under the assumptions of Theorem 6 if we choose $k = 1/\epsilon'^2$ and let $\epsilon'' = 2\epsilon'$, then we have that

$$\|A - CUR\|_2 \leq \epsilon'' \|A\|_F \tag{66}$$

holds with probability at least $1 - \delta$.

We note the following lemma. This result is not needed in this paper, but is included for future reference [13].

LEMMA 7.

$$\left\|\tilde{U}\right\|_2 \leq \frac{O(1)}{\gamma \|A\|_F}.$$

Proof. First note that $\|\tilde{U}\|_2 = \|\tilde{\Phi}\Psi^T\|_2 \leq \|\tilde{\Phi}\|_2 \|\Psi^T\|_2$. Since $\tilde{\Phi} = \sum_{t=1}^{\ell} \frac{1}{\sigma_t^2(W)} z^t z^{tT}$, we see that $\|\tilde{\Phi}\|_2 = \frac{1}{\sigma_\ell^2(W)} \leq \frac{1}{\gamma \|W\|_F^2}$. The lemma follows since, when using the probabilities of Theorem 6, we have that $\|\Psi^T\|_F \leq O(1)\|A\|_F$ and that $1/\|W\|_F^2 \leq O(1)/\|A\|_F^2$. □

5. Discussion and conclusion. To put the CUR decomposition into context, it will be useful to contrast it with the SVD. The SVD of A expresses A as $A = \sum_{t=1}^{\rho} \sigma_t(A) u^t v^{tT}$. Keeping the first k terms of this expansion, i.e., keeping $A_k = \sum_{t=1}^{k} \sigma_t(A) u^t v^{tT} = U_k \Sigma_k V_k^T$, gives us the "optimal" rank-k approximation to A with respect to both the spectral norm and the Frobenius norm [19, 22]. Thus, computing the SVD gives us a good succinct approximation, since it only takes space $O(k(m+n))$ to write down U_k, Σ_k, V_k. However, the computational problem of finding the SVD cannot be carried out in a small constant number of passes. Our theorems say that weaker bounds, which are similar in spirit, may be achieved by CUR. Note, however, that although the SVD may be thought of as a rotation followed by a rescaling followed by a rotation, the CUR decomposition is quite different; both C and R perform an action like A and thus U must involve a pseudoinverse-like operation. Note also that the last upper bound, i.e., (v), is much smaller than $\|A\|_F$ when A has a good low-rank approximation. This is indeed the case for matrices occurring in many contexts, such as matrices for which principal component analysis is used.

Recent work has focused on developing new techniques for proving lower bounds on the number of queries a sampling algorithm is required to perform in order to

approximate a given function accurately with a low probability or error [3, 4]. In [4] these methods have been applied to the low-rank matrix approximation problem and to the matrix reconstruction problem. In the latter problem, the input is a matrix $A \in \mathbb{R}^{m \times n}$ and the goal is to find a matrix B that is close to A. In [4] it is shown that finding a B such that $\|A - B\|_F \leq \epsilon \|A\|_F$ requires $\Omega(mn)$ queries and that finding a B such that $\|A - B\|_2 \leq \epsilon \|A\|_F$ requires $\Omega(m + n)$ queries. Thus, our algorithm is optimal for constant ϵ.

During the time since this manuscript was submitted for journal publication we have become aware of other low-rank matrix decompositions of the form $A \approx CUR$, where C is a matrix consisting of a small number of columns of A, R is a matrix consisting of a small number of rows of A, and U is an appropriately defined low-dimensional matrix. Work by Stewart [26, 27, 5] and independently work by Goreinov, Tyrtyshnikov, and Zamarashkin [21, 20] have considered matrix decompositions with structural (but not algorithmic) properties quite similar to the CUR decompositions we have considered in this paper. Drineas and Mahoney have extended the CUR decompositions of this paper to kernel-based statistical learning [15, 16] and large tensor-based data [17]. These latter papers also contain a discussion of the relationship between the work presented in this paper and the related work of Stewart and Goreinov, Tyrtyshnikov, and Zamarashkin.

Acknowledgments. We would like to thank Dimitris Achlioptas for fruitful discussions and the National Science Foundation for partial support of this work. In addition, we would like to thank an anonymous reviewer for carefully reading the paper and making numerous useful suggestions; in particular, the reviewer provided an elegant, short proof for Lemma 4.

A COMPLETE CLASSIFICATION OF THE COMPLEXITY OF PROPOSITIONAL ABDUCTION*

NADIA CREIGNOU† AND BRUNO ZANUTTINI‡

Abstract. Abduction is the process of explaining a given query with respect to some background knowledge. For instance, p is an explanation for the query q given the knowledge $p \to q$. This problem is well known to have many applications, particularly in artificial intelligence (AI), and has been widely studied from both an AI and a complexity-theoretic point of view. In this paper we completely classify the complexity of propositional abduction in Schaefer's famous framework. We consider the case where knowledge bases are taken from a class of formulas in generalized conjunctive normal form. This means that the propositional formulas considered are conjunctions of constraints taken from a fixed finite language. We show that according to the properties of this language, deciding whether at least one explanation exists is either polynomial, NP-complete, or Σ_2P-complete. Our results are stated for a query consisting of a single, positive literal and for assumption-based solutions, i.e., the solutions must be formed upon a distinguished subset of the variables that is part of the input. We show, however, that our results can be interpreted "dually" for negative queries, and thus also for unrestricted (positive or negative) queries.

Key words. abduction, propositional logic, complexity, Boolean constraints

1. Introduction.

Abduction is a fundamental mode of reasoning which consists in searching for an *explanation*, or *plausible cause*, of a given *observed manifestation* and given some *background knowledge base*. For instance, given the knowledge base $p \to q$, the fact p is an explanation for the observation q, which means that p may have caused q. Viewing abduction as an inference problem, the conclusion p can be inferred from $p \to q$ and q; q is usually called the *query*, since it is the varying part of the input of the problem, while the background knowledge base is intended to be more persistent, as a description of how the universe behaves. Finally, an abduction problem is usually constrained by a set of *hypotheses* from which the explanations must be taken; in our framework as in many others, the set of hypotheses will be given *in intension* by a set of *abducible variables* upon which the explanations will have to be formed.

Note that the abduction process is nonmonotonic, i.e., logically strengthening (or weakening) the knowledge base may rule out or add some solutions of the problem. It is also not truth-preserving, in the sense that observing some query and inferring some explanation for it does not guarantee that the explanation did indeed occur.

From an artificial intelligence (AI) point of view, abduction has many applications. The most natural one is *medical diagnosis* (see, e.g., [5, section 6]), where a physician attempts to identify a patient's disease from some observed symptoms: here the query models the symptoms, the knowledge base describes the relations between diseases and symptoms, and finally the abducible variables model the diseases (since we do

not want to explain a symptom by another symptom). In the same vein, *system diagnosis* [6, 27], where one wants to discover the faulty components of a system that does not behave as desired (e.g., an electronic device), can be modeled as an abduction problem. Another application is *configuration* [1], and still another one is text interpretation [16]. Abduction has also been studied with temporal knowledge bases [4]. Closer to the reasoning processes themselves, abduction is a fundamental part of the CMS/ATMS [24], and it has many relations with default reasoning [26].

From a complexity-theoretic point of view, abduction is in general very hard, since in its full generality propositional abduction as a decision problem is Σ_2P-complete; that is to say, it is at the second level of the polynomial hierarchy. However, many restrictions on the syntactic form of the knowledge base have been identified that make the problem easier, even polynomial for some of them: 2-CNF and monotone knowledge bases (see, e.g., [20]), definite Horn CNF [26, 11] and affine [28] bases, CNF bases with unit-refutable pseudocompletion [14] or with bounded kernel width [10], Horn bases given by their characteristic models [19], and some classes of DNF bases [28]. Among those restrictions some impose *local* properties on the knowledge bases, such as being in definite Horn CNF, and some impose *global* properties, such as being in Horn-renamable DNF or having a unit-refutable pseudocompletion.

Our work takes place in the framework of propositional classes of formulas defined by *local* properties. More precisely, we investigate the computational complexity of propositional abduction in Schaefer's framework. This now famous framework consists in considering propositional formulas in generalized conjunctive form. These formulas are conjunctions of constraints built over a fixed finite set L of Boolean relations. In his seminal paper [25], Schaefer studied the computational complexity of the satisfiability problem in this setting, SAT(L), and established a dichotomy theorem which asserts that for each finite set of relations L, SAT(L) is either NP-complete or in P. In a nutshell, Schaefer's dichotomy theorem asserts that there are exactly four (nontrivial) polynomial-time cases of SAT(L): every relation in L is bijunctive; every relation in L is Horn; every relation in L is dual Horn; every relation in L is affine. Moreover, this dichotomy is polynomial-time decidable, that is, there is a polynomial-time algorithm that, given a finite set of Boolean relations L, decides whether SAT(L) is NP-complete or in P.

Our main contribution is a trichotomy theorem for the computational complexity of propositional abduction (seen as a decision problem) in Schaefer's framework. We consider that hypotheses are the terms formed upon a given set of variables, and that queries are given by a single positive literal. In this framework, we prove that depending on the set of relations L the abduction problem is either polynomial or NP-complete or Σ_2P-complete. More precisely, we show that the abduction problem with positive queries is polynomial-time solvable if every relation in the language is bijunctive, affine, definite Horn, IHS-$B-$, or IHS-$B+$;[1] otherwise, NP-complete if the language is Horn or dual Horn; and, finally, Σ_2P-complete in every other case. The first essential difference from Schaefer's dichotomy theorem is that, unlike the satisfiability problem, the abduction problem for Horn relations and for dual Horn relations need not to be in P. Instead, the abduction problem is in P for certain classes of Horn relations (namely, definite Horn, IHS-$B-$) and for certain classes of dual Horn relations (namely, IHS-$B+$), while it is NP-complete for all other classes of Horn relations and all other classes of dual Horn relations. Furthermore, the abduction problem is Σ_2P-complete for every finite set of relations for which the satisfiability is

[1] See [18] for the definition of IHS-$B-$ and IHS-$B+$ relations.

NP-complete.

From this result we derive two additional trichotomy results by considering the variants of abduction in which the query to be explained is a negative literal, or an unrestricted (positive or negative) literal.

In order to obtain these results, on one hand we exhibit new tractable languages for abduction (namely, IHS-$B-$ and IHS-$B+$ languages), and on the other hand we identify new minimal sets of relations that make abduction within a given language NP- or Σ_2P-hard, in the sense that any language able to express these relations defines a hard problem.

In addition to these new results, we revisit known ones and unify all of them into the same framework, while they were originally stated within (slightly) different formalizations of the abduction process, thus making our classification self-contained. We also wish to emphasize that our results are *constructive*, in the sense that we give efficient algorithms for the polynomial cases and exhibit effective reductions for the hard ones.

For use in AI applications, our results allow the designers of knowledge-based systems to choose among different languages for their knowledge bases; this choice can be made according to the importance of the abduction process for the precise application and maybe to other constraints.

The paper is organized as follows. Sections 2 and 3 present the basic definitions and the abduction problem. Sections 4 to 7 are devoted to the proof of our main result (Theorem 31), which completely classifies the computational complexity of the abduction problem with a positive query in Schaefer's framework. In section 8 we extend these results to negative and unrestricted queries. Finally, in section 9 we conclude and identify interesting future work.

2. Preliminaries. We introduce in this section the basic definitions and the main tools that we will use throughout the paper.

2.1. Propositional formulas. Let V be a set of variables. A *propositional formula over* V is any well-formed formula built upon the variables in V and the connectives $\neg$ (negation), $\vee$ (disjunction), and $\wedge$ (conjunction); given a propositional formula φ we denote by $\mathit{Vars}(\varphi)$ the set of all the variables that occur in φ.

A *literal* is either a variable x (*positive* literal) or the negation $\neg x$ of one (*negative* literal); we write $\mathit{Lits}(V)$ for the set of all literals over V, and we write $\overline{\ell}$ for the opposite of literal ℓ. A *clause* is a finite disjunction of literals of the form $C = (\ell_1 \vee \cdots \vee \ell_k)$ $(k \geq 0)$; slightly abusing notation we write, e.g., $\ell_1 \in C$. A formula is said to be in *conjunctive normal form* (CNF) if it is written as a conjunction of clauses, and, dually, in *disjunctive normal form* (DNF) if it is written as a disjunction of terms (conjunctions of literals).

An *assignment* to a set of variables V is a mapping from V to $\{0,1\}$; we also see a mapping from a superset of V to $\{0,1\}$ as an assignment to V by considering its restriction to V. When the variables under consideration and their order are clear from the context, we will sometimes denote an assignment m to, say, $\{x_1,\ldots,x_n\}$ by the word $m(x_1)\ldots m(x_n)$. A *model* m of a propositional formula φ is an assignment to $\mathit{Vars}(\varphi)$ that satisfies φ with the usual rules for the connectives; we also write $m \models \varphi$. Finally, a formula is said to be *satisfiable* if it has at least one model, and two formulas φ, φ' are said to be *logically equivalent*, written $\varphi \equiv \varphi'$, if their sets of models are equal.

If V is some set of variables, φ is a propositional formula over V, and V' is a subset of V, we will sometimes use the notation $\exists V'\varphi$. This defines a propositional

formula over $V\backslash V'$; its models are these assignments m to $V\backslash V'$ such that there is an assignment m' to V' with $mm' \models \varphi$; note that this corresponds to projecting the set of models of φ over $V\backslash V'$, in the sense of relational algebra. The other notions are extended in a straightforward manner.

2.2. Relations and *L*-formulas. An *n-ary (logical) relation* R is a Boolean relation of arity n, i.e., a subset of $\{0,1\}^n$. Thus the elements of an n-ary relation R are n-ary Boolean vectors of the form $m = (m_1, \ldots, m_n) \in \{0,1\}^n$; we also write vectors as words, e.g., 011 for the ternary vector $(0,1,1)$.

Let V be a set of variables. A *constraint over* V is an application of an n-ary relation R to an n-tuple $(x_1, \ldots, x_n)$ of variables from V, which we write $R(x_1, \ldots, x_n)$; note in particular that repetition of variables is allowed. An assignment m to V is said to *satisfy* a constraint $C = R(x_1, \ldots, x_n)$ if $(m(x_1), \ldots, m(x_n)) \in R$ holds; we also write $m \models C$, and m is said to be a *model* of C.

Example 1. We will often use some standard relations. First of all, the unary relations $\mathsf{F} = \{(0)\}$ and $\mathsf{T} = \{(1)\}$, which force the value of a variable to 0 and 1, respectively. We will also use the k-ary relation $\mathsf{OR}_{k,j}$, which is defined $\forall k \geq 2, j \leq k$ by

$$\mathsf{OR}_{k,j} = \{0,1\}^k \backslash \{1 \ldots 1 0 \ldots 0\} \ (j \text{ times } 1).$$

Note that the constraint $\mathsf{OR}_{k,j}(x_1, \ldots, x_k)$ has the same models as the formula $(\neg x_1 \vee \cdots \vee \neg x_j \vee x_{j+1} \vee \cdots \vee x_k)$. In particular, we will use the binary relations $\mathsf{OR}_{2,0} = \{0,1\}^2\backslash\{00\}$, $\mathsf{OR}_{2,1} = \{0,1\}^2\backslash\{10\}$, and $\mathsf{OR}_{2,2} = \{0,1\}^2\backslash\{11\}$. Finally, we will use the ternary relation $\mathsf{SymOR}_{2,1}$, which is defined by

$$\mathsf{SymOR}_{2,1}(x,y,z) \equiv (\mathsf{OR}_{2,1}(x,y) \wedge \mathsf{T}(z)) \vee (\mathsf{OR}_{2,1}(y,x) \wedge \mathsf{F}(z)).$$

Example 2. Given the ternary relations $R_{\text{nae}} = \{0,1\}^3\backslash\{000, 111\}$ and $R_{1/3} = \{001, 010, 100\}$, an assignment m to $\{x,y,z\}$ satisfies the constraint $R_{\text{nae}}(x,y,z)$ if m does not map all three variables to the same value, and it satisfies the constraint $R_{1/3}(x,y,z)$ if it maps exactly one of them to 1.

Now let L be a finite set of Boolean relations, not necessarily of the same arities; we also call L a *(finite) language*. An *L-formula (over V)* is a finite conjunction of constraints over V with all relations taken from L. An assignment m to V is said to *satisfy* an L-formula φ if it satisfies every constraint in φ; m is then said to be a *model* of φ, written $m \models \varphi$. The notions of satisfiability and logical equivalence are defined as for propositional formulas, and we also define logical equivalence between a propositional and an L-formula, with obvious meaning.

2.3. Properties of relations. Throughout this paper we study different types of Boolean relations and languages following Schaefer's terminology [25]. Let R be an n-ary relation and $(x_1, \ldots, x_n)$ a tuple of pairwise distinct variables; we say that a propositional formula φ over $\{x_1, \ldots, x_n\}$ *describes* R if φ is logically equivalent to the $\{R\}$-formula $R(x_1, \ldots, x_n)$. Then R is said to be

- *bijunctive* if it can be described by a *bijunctive* formula, i.e., a formula in CNF having at most two literals in each clause;
- *affine* if it can be described by an *affine* formula, i.e., a system of linear equations over the two-element field $\{0,1\}$;
- *Horn* (resp., *dual Horn*) if it can be described by a *Horn* (resp., *dual Horn*) formula, i.e., a formula in CNF having at most one positive (resp., negative) literal in each clause;

- *definite Horn* (resp., *definite dual Horn*) if it can be described by a *definite Horn* (resp., *definite dual Horn*) formula, i.e., a formula in CNF having exactly one positive (resp., negative) literal in each clause; note that any definite (dual) Horn relation (resp., formula) is (dual) Horn;
- *IHS-B−* (for *implicative hitting set-bounded−* [18]) if it can be described by an *IHS-B−* formula, i.e., a formula in CNF whose clauses are all of one of the following types: (x_i), or $(\neg x_{i_1} \vee x_{i_2})$, or $(\neg x_{i_1} \vee \cdots \vee \neg x_{i_k})$ for some $k \geq 0$ (which is not necessarily the same for every clause); note that any IHS-$B-$ relation (resp., formula) is Horn;
- *IHS-B+* if it can be described by an *IHS-B+* formula, i.e., a formula in CNF whose clauses are all of one of the following types: $(\neg x_i)$, or $(\neg x_{i_1} \vee x_{i_2})$, or $(x_{i_1} \vee \cdots \vee x_{i_k})$ for some $k \geq 0$; note that any IHS-$B+$ relation (resp., formula) is dual Horn;
- *complementive* if for all $(m_1, \ldots, m_n) \in R$ the vector $(m_1 \oplus 1, \ldots, m_n \oplus 1)$ is also in R;
- 1-*valid* (resp., 0-valid) if the vector $(1, \ldots, 1)$ (resp., $(0, \ldots, 0)$) is in R.

Some of these properties have equivalent definitions in terms of *closure properties*. Extend any operation *op* on $\{0,1\}$ to the vectors in $\{0,1\}^n$ by

$$(m_1, \ldots, m_n)\ op\ (m'_1, \ldots, m'_n) = (m_1\ op\ m'_1, \ldots, m_n\ op\ m'_n).$$

Then a relation R is

- *bijunctive* if and only if $\forall m, m', m'' \in R, (m \wedge m') \vee (m \wedge m'') \vee (m' \wedge m'') \in R$;
- *affine* if and only if $\forall m, m', m'' \in R, m \oplus m' \oplus m'' \in R$;
- *Horn* if and only if $\forall m, m' \in R, m \wedge m' \in R$;
- *dual Horn* if and only if $\forall m, m' \in R, m \vee m' \in R$.

The first equivalence is proved in, e.g., [25], the second one is a classical result from linear algebra, the third one is proved in, e.g., [9], and the fourth one is dual.

We will use them several times in the paper and wish to emphasize that they are the basis of many results that we will use from, in particular, [7].

We also generalize the above definitions to languages. For instance, a language L is said to be *Horn* if every relation in L is Horn. Additionally, we refer to a language L as a *Schaefer language* if L is bijunctive, affine, Horn, or dual Horn.

The properties listed above play a central role in determining whether a given computational task is easy, versus when it is hard (see [7] for a survey). For instance, Schaefer's theorem [25] states that the satisfiability problem for the class of all L-formulas is in P if L is Schaefer or if it is 0- or 1-valid, and that it is NP-complete otherwise.

A very important problem is the one of deciding whether a given language has a given property, in particular for identifying the tractable cases of PQ-ABDUCTION(L). This problem is called *structure identification* in [9]. It turns out that all the properties listed above can be recognized in polynomial time for a given set of relations written as sets of tuples (in extension).

PROPOSITION 3 (recognizing properties of relations). *One can decide in polynomial time whether a relation given in extension is bijunctive, affine, (dual) Horn, definite (dual) Horn, IHS-B−, IHS-B+, complementive,* 1*-valid, or* 0*-valid.*

Proof. This is obvious for bijunctive, affine, and (dual) Horn languages given the closure properties above; more efficient algorithms are also given in [9, 29, 15]. As for definite Horn languages, simply observe that a relation is definite Horn if and only if it is Horn and contains the vector $(1, \ldots, 1)$, which can again be tested efficiently; the

test is dual for definite dual Horn languages. Complementive, 1- and 0-valid relations can also be recognized efficiently by applying their definition. Finally, IHS-$B-$ and IHS-$B+$ relations can be recognized efficiently by testing closure under the mappings $(m, m', m'') \mapsto m \wedge (m' \vee m'')$ and $(m, m', m'') \mapsto m \vee (m' \wedge m'')$, respectively; this is proved in [8] and can also be derived from [3].[2] □

2.4. Complexity classes. This paper concerns the *computational complexity* of the abduction problem and, more precisely, of the associated *decision* problem. We assume knowledge of the basic notions of complexity but briefly recall the definition of the classes we are interested in; for more details we refer the reader to Papadimitriou's book [22]. First of all, the class P is the class of all decision problems that are solvable in deterministic polynomial time. The class NP is that of all decision problems that are solvable in *nondeterministic* polynomial time, or, equivalently, for which every positive instance has a witness of polynomial size and that can be checked in *deterministic* polynomial time. A problem A is said to be NP-*hard* if there is a polynomial-time reduction from every problem in NP to A, and NP-*complete* if both NP-hard and in NP. Finally, the class $\Sigma_2\mathrm{P} = \mathrm{NP}^{\mathrm{NP}}$ is the class of all decision problems that can be solved in nondeterministic polynomial time with an oracle for a problem in NP, or, equivalently, such that every positive instance has a witness of polynomial size and that can be checked in *nondeterministic* polynomial time; as for NP-hardness, Σ_2P-hardness is established by polynomial-time reductions from already known Σ_2P-complete problems. Note that the prototypical Σ_2P-complete problem is the one of deciding the validity of a formula of the form $\exists V\ \forall V' \psi$, where V and V' are disjoint sets of variables and ψ is a propositional formula in DNF over $V \cup V'$.

3. The abduction problem. We formalize in this section the abduction problem that we will study, and we give some general, well-known results about its complexity, for use later in the paper.

3.1. Definition. We are interested in the *abduction problem* that is defined below. Recall from Example 1 that T is the relation $\{1\}$ and F is the relation $\{0\}$. Given a set of literals E, we write $\bigwedge E$ for the $\{\mathsf{T}, \mathsf{F}\}$-formula $\bigwedge_{x \in E} \mathsf{T}(x) \wedge \bigwedge_{\neg x \in E} \mathsf{F}(x)$.

We define and study the problem first for *positive literal queries* (whence "PQ"), i.e., the query to be explained consists of a single, positive literal. In section 8 we will briefly state the complexity of the problem for *negative* and *unrestricted* literal queries.

PROBLEM 4 (PQ-ABDUCTION(L)). *Let L be a language.* PQ-ABDUCTION(L) *is the following decision problem:*

- *Input: An L-formula φ, a set of variables $A \subseteq Vars(\varphi)$, and a variable $q \in Vars(\varphi) \backslash A$.*
- *Question: Is there a set $E \subseteq Lits(A)$ such that the $L \cup \{\mathsf{T}, \mathsf{F}\}$-formula $\varphi \wedge \bigwedge E$ is satisfiable but the $L \cup \{\mathsf{T}, \mathsf{F}\}$-formula $\varphi \wedge \bigwedge E \wedge \mathsf{F}(q)$ is not?*

If one exists, such a set E is called a solution *of the abduction problem.*

This definition corresponds to the intuition of an abduction problem, where the goal is to find an explanation for some observed phenomenon, in the following manner. The phenomenon to observe is modeled by the query of the problem and the explanation by the set E. The first condition on E ensures that the explanation

[2] We wish to point out that [3] and [8] are posterior to the submission of this article, and that the results presented here actually motivated the study in [8].

may indeed have occurred, and the second condition, which can be read "φ and $\bigwedge E$ together entail q," ensures that E may indeed have caused q.

Example 5. Consider the language $L = \{\mathsf{OR}_{3,1}, \mathsf{OR}_{2,1}\}$ and recall that the constraint $\mathsf{OR}_{3,1}(x, y, z)$ can be read $x \to y \vee z$, while $\mathsf{OR}_{2,1}(x, y)$ can be read $x \to y$. Let $V = \{x, y, z, t, q\}$ be a set of variables and let φ be the following L-formula over V:

$$\mathsf{OR}_{3,1}(x, t, q) \wedge \mathsf{OR}_{2,1}(t, y) \wedge \mathsf{OR}_{2,1}(z, q) \wedge \mathsf{OR}_{2,1}(z, x).$$

Let $A = \{x, y, z\}$; then (φ, A, q) is an instance of the problem PQ-ABDUCTION(L). It can be seen that $\{x, \neg y\}$ and $\{z\}$ are both solutions for this problem. On the other hand, $\{\neg x, \neg z\}$ is not a solution, since, e.g., the assignment 00000 to V satisfies $\varphi \wedge \mathsf{F}(x) \wedge \mathsf{F}(z) \wedge \mathsf{F}(q)$. The set $\{\neg x, z\}$ is not a solution either, since the formula $\varphi \wedge \mathsf{F}(x) \wedge \mathsf{T}(z)$ is not satisfiable ($\mathsf{F}(x) \wedge \mathsf{T}(z)$ contradicts the constraint $\mathsf{OR}_{2,1}(z, x)$), and finally $\{x, \neg t\}$ is not a solution because it is not included in $Lits(A)$.

Note that the definition implies that a solution E for an abduction problem does not contain both x and $\neg x$ for any variable x. Indeed, if this were the case, then obviously the formula $\varphi \wedge \bigwedge E$ would not be satisfiable, thus violating the first condition on solutions.

Note also that the problem as defined above is a *decision problem*, whereas abduction is seen in general as an *inference* problem, where the goal is to compute a solution or assert that there is none. It is, however, easily seen that whenever the decision problem is hard, then so is the inference one, and conversely, as the proofs in the paper will show, whenever it is easy the inference problem is easy as well. In the same vein, note that in general the goal of abduction is to compute a *preferred* solution, i.e., a solution that is best with respect to some criteria; but obviously, there is a preferred solution for an abduction problem if and only if there is at least one (unrestricted) solution, and that is why we ignore that point in our definition.

Finally, we wish to emphasize that the language L *parameterizes* the problem; it is not part of the input. Thus, since L is finite, an algorithm for the problem PQ-ABDUCTION(L) may include a preliminary step for transforming a input formula φ into any desirable form, at least by enumerating the (finite number of) translations of every relation in L into the desired form; what we will use most often is translation into CNF. In all cases it is easily seen that this preliminary step will only take linear time, since the size of every translated form will be bounded (because L is fixed and finite).

3.2. Prime implicates. An important notion that we will use many times in the paper is that of a *prime implicate*. Let φ be a propositional formula. A clause $C = \bigvee_{i \in I} \ell_i$ is said to be a *prime implicate* of φ if φ entails C but entails no proper subset of C, i.e., if the formula $\varphi \wedge \bigwedge\{\neg \ell_i \mid i \in I\}$ is unsatisfiable but $\forall i_0 \in I$ the formula $\varphi \wedge \bigwedge\{\neg \ell_i \mid i \in I, i \neq i_0\}$ is satisfiable. The notion is defined similarly for an L-formula φ (given some language L), considering the formula $\varphi \wedge \bigwedge_{x \in C} \mathsf{F}(x) \wedge \bigwedge_{(\neg x) \in C} \mathsf{T}(x)$. We will often use the fact that if $C = \bigvee_{i \in I} x_i \vee \bigvee_{i' \in I'} \neg x_{i'}$ is a prime implicate of φ, then there is no model of φ that maps every x_i ($i \in I$) to 0 and every $x_{i'}$ ($i' \in I'$) to 1, but for every $i_0 \in I$ (resp., $i'_0 \in I'$) there is one that maps every x_i to 0 ($i \in I$) except for x_{i_0} and every $x_{i'}$ ($i' \in I'$) to 1 (resp., every x_i to 0 and every $x_{i'}$ to 1 except for $x_{i'_0}$).

We will also often use the well-known fact that all the prime implicates of a given formula φ in CNF can be generated by repeatedly applying *resolution* to φ [23]. Recall that resolution is the process of adding the clause $C_1 \vee C_2$ to φ if there is a variable x such that both clauses $(x \vee C_1)$ and $(\neg x \vee C_2)$ are in φ and C_1, C_2 do not contain two opposite literals.

We will use prime implicates mainly through the following well-known result.

LEMMA 6. *An abduction problem (φ, A, q) has a solution if and only if there is a prime implicate of φ of the form $(\ell_1 \vee \cdots \vee \ell_k \vee q)$, where $\forall i$, ℓ_i is a literal built upon a variable in A.*

Proof. Let $E = \{\ell_1, \ldots, \ell_n\}$ be a solution for (φ, A, q). Then, by definition of a solution, $\varphi \wedge \bigwedge E \wedge \neg q$ is unsatisfiable but $\varphi \wedge \bigwedge E$ is satisfiable. We conclude that (without loss of generality) there is a $k \leq n$ such that $(\neg\ell_1 \vee \cdots \vee \neg\ell_k \vee q)$ is a prime implicate of φ.

Conversely, if $(\ell_1 \vee \cdots \vee \ell_k \vee q)$ is a prime implicate of φ, write $E = \{\neg\ell_i \mid i = 1, \ldots, k\}$. Then, by definition of a prime implicate, the formula $\varphi \wedge \bigwedge E \wedge \neg q$ is unsatisfiable and (in particular) the formula $\varphi \wedge \bigwedge E$ is satisfiable. Thus E is a solution for (φ, A, q). □

3.3. Preliminary results. We will make heavy use of some results about the abduction problem for propositional formulas. We define the abduction problem PQ-ABDUCTION($\mathcal{C}$) for a class $\mathcal{C}$ of propositional formulas similarly to the problem PQ-ABDUCTION(L); in this particular context $\bigwedge E$ denotes the conjunction of all the literals in E.

The following result concerns the class of all propositional CNF formulas. Note that this class captures the whole complexity of abduction since, as can be seen in the proof, the abduction problem for unrestricted propositional formulas is in Σ_2P.

PROPOSITION 7 (general problem [11]). *If $\mathcal{C}$ is the class of all propositional CNF formulas, then* PQ-ABDUCTION *($\mathcal{C}$) is Σ_2P-complete.*

Proof. (Membership.) By definition of the problem, and since the formulas $\varphi \wedge \bigwedge E$ and $\varphi \wedge \bigwedge E \wedge \neg q$ are in CNF as soon as φ is in CNF, verifying a solution E for an instance (φ, A, q) can be done in polynomial time with an oracle for the satisfiability problem of $\mathcal{C}$. Since this problem is in NP and E is obviously of size polynomial in the one of A, we have the result.

(Hardness.) Let $\Psi = \exists V\ \forall V' \psi$, where V and V' are disjoint sets of variables and ψ is a propositional formula in DNF over $V \cup V'$. Let q be a new variable (i.e., $q \notin V \cup V'$) and let φ be a formula in CNF that is logically equivalent to the formula $\neg\psi \vee q$. Since ψ is in DNF, such a φ can be computed in polynomial time from Ψ with De Morgan's laws. We show that Ψ is valid if and only if the abduction problem (φ, V, q) has a solution, which will prove the result since deciding the validity of such a Ψ is a Σ_2P-complete problem.

Assume first that Ψ is valid, and let E be an assignment to V that witnesses this fact. On one hand, it is easily seen that the formula $\neg\psi \wedge \bigwedge E$ is unsatisfiable, and thus that the formula $(\neg\psi \vee q) \wedge \bigwedge E \wedge \neg q$, which is logically equivalent to $\varphi \wedge \bigwedge E \wedge \neg q$, is unsatisfiable as well. On the other hand, since q is a new variable, any assignment to $V \cup V' \cup \{q\}$ that satisfies $\bigwedge E \wedge q$ satisfies $(\neg\psi \vee q) \wedge \bigwedge E$, and thus the formula $\varphi \wedge \bigwedge E$ is satisfiable. We conclude that E is a solution for the problem (φ, V, q).

Conversely, let E be a solution for the problem (φ, V, q). In order to obtain a contradiction suppose that the formula $\neg\psi \wedge \bigwedge E$ is satisfiable; write m for one of its models. So, it is easily seen that the assignment m' to $V \cup V' \cup \{q\}$ defined by $m(q) = 0$ and $\forall x \in V \cup V', m'(x) = m(x)$, satisfies $\neg\psi \wedge \bigwedge E$ as well, since q is a new variable, and thus m' satisfies $\varphi \wedge \bigwedge E \wedge \neg q$; this contradicts the fact that E is a solution. Hence, we deduce that the formula $\neg\psi \wedge \bigwedge E$ is unsatisfiable. Therefore, E witnesses the fact that the formula $\exists V\ \forall V' \psi = \Psi$ is valid. □

We now turn to "easier" cases. Recall that a propositional formula in CNF is said to be *Horn* (resp., *dual Horn*) if each of its clauses has at most one positive (resp., negative) literal.

PROPOSITION 8 ((dual) Horn abduction [26]). *If $\mathcal{C}$ is the class of all propositional Horn formulas, then* PQ-ABDUCTION $(\mathcal{C})$ *is* NP*-complete. The same holds if $\mathcal{C}$ is the class of all propositional dual Horn formulas.*

Proof. We first consider the Horn case. Membership in NP follows from the fact that the satisfiability of a Horn formula can be decided in linear time, and from the fact that if φ is Horn, then so are $\varphi \wedge \bigwedge E$ and $\varphi \wedge \bigwedge E \wedge \neg q$. As for hardness, we reduce the satisfiability problem for propositional CNF formulas to this one. Let $\Psi = \bigwedge_{i \in I} C_i$ $(I \neq \emptyset)$ be a CNF formula where $\forall i \in I$, C_i is a clause. For all $i \in I$, let c_i be a new variable (i.e., $c_i \notin \mathit{Vars}(\Psi)$). For every variable $x \in \mathit{Vars}(\Psi)$, let p_x, n_x, v_x be three new variables (intuitively, p stands for "positive" and n for "negative"), and finally let q be a new variable. Let φ be the propositional formula

$$\bigwedge_{x \in \mathit{Vars}(\Psi)} ((\neg p_x \vee \neg n_x) \wedge (\neg p_x \vee v_x) \wedge (\neg n_x \vee v_x))$$
$$\wedge \bigwedge_{x \in C_i} (\neg p_x \vee c_i) \wedge \bigwedge_{(\neg x) \in C_i} (\neg n_x \vee c_i) \wedge \left(\bigvee_{x \in \mathit{Vars}(\Psi)} \neg v_x \vee \bigvee_{i \in I} \neg c_i \vee q \right).$$

It is easily seen that φ is Horn and can be built in polynomial time from Ψ. Now let $A = \{p_x, n_x \mid x \in \mathit{Vars}(\Psi)\}$; we show that the abduction problem (φ, A, q) has a solution if and only if Ψ is satisfiable.

Assume first that Ψ is satisfiable, write m for one of its models and define E to be $\{p_x \mid m(x) = 1\} \cup \{n_x \mid m(x) = 0\}$. Let m' be the assignment to $\mathit{Vars}(\varphi)$ defined by

$$\begin{cases} \forall x \in \mathit{Vars}(\Psi),\ m'(p_x) = m(x), \\ \forall x \in \mathit{Vars}(\Psi),\ m'(n_x) = m(x) \oplus 1, \\ \forall x \in \mathit{Vars}(\Psi),\ m'(v_x) = 1, \\ \forall i \in I,\ m'(c_i) = 1, \\ m'(q) = 1. \end{cases}$$

It is easily seen that m' is a model of the formula $\varphi \wedge \bigwedge E$, which is therefore satisfiable. To obtain a contradiction suppose that the formula $\varphi \wedge \bigwedge E \wedge \neg q$ is satisfiable, and write m' for one of its models. Since m' satisfies $\bigwedge E$, because of the clauses $(\neg p_x \vee v_x)$ and $(\neg n_x \vee v_x)$ we get $\forall x \in \mathit{Vars}(\Psi), m'(v_x) = 1$. Now, since m satisfies Ψ it satisfies at least one literal in each clause of Ψ, and because of the clauses $(\neg p_x \vee c_i)$ and $(\neg n_x \vee c_i)$ we deduce $\forall i \in I, m'(c_i) = 1$. Since by assumption $m'(q) = 0$, we conclude $m' \not\models (\bigvee_{x \in \mathit{Vars}(\Psi)} \neg v_x \vee \bigvee_{i \in I} \neg c_i \vee q)$, which is a contradiction.

Conversely, let E be a solution for the abduction problem (φ, A, q). Then $\varphi \wedge \bigwedge E$ is satisfiable; write m for one of its models. Because of the clauses $(\neg p_x \vee \neg n_x)$ we know that $\forall x \in \mathit{Vars}(\Psi)$, either $m(p_x) = 0$ or $m(n_x) = 0$. In order to obtain a contradiction suppose that for some x_0, $m(p_{x_0}) = m(n_{x_0}) = 0$, and define the assignment m' to $\mathit{Vars}(\varphi)$ as follows:

$$\begin{cases} \forall x \in \mathit{Vars}(\Psi),\ m'(p_x) = m(p_x), \\ \forall x \in \mathit{Vars}(\Psi),\ m'(n_x) = m(n_x), \\ m'(v_{x_0}) = 0, \\ \forall x \in \mathit{Vars}(\Psi),\ x \neq x_0 \Rightarrow m'(v_x) = 1, \\ \forall i \in I,\ m(c_i) = 1, \\ m(q) = 0. \end{cases}$$

It is easily seen that m' satisfies the formula $\varphi \wedge \bigwedge E \wedge \neg q$, a contradiction. Thus $\forall x \in \mathit{Vars}(\Psi)$, $m(p_x) \neq m(n_x)$. Define the assignment m_0 to $\mathit{Vars}(\Psi)$ by $\forall x \in \mathit{Vars}(\Psi), m_0(x) = m(p_x)$ or, equivalently, $m_0(x) = m(n_x) \oplus 1$. We show that m_0 satisfies Ψ. To obtain a contradiction, suppose that $m_0 \not\models \Psi$. Then there is a clause C_{i_0} in Ψ such that $\forall x \in C_{i_0}, m_0(x) = 0$ and $\forall(\neg x) \in C_{i_0}, m_0(x) = 1$. We deduce $\forall x \in C_{i_0}, m(p_x) = 0$ and $\forall(\neg x) \in C_{i_0}, m(n_x) = 0$. Then it is easily seen that the assignment m' defined to be equal to m except on c_{i_0} ($m'(c_{i_0}) = 0$) and on q ($m'(q) = 0$) satisfies the formula $\varphi \wedge \bigwedge E \wedge \neg q$, a contradiction. Thus m_0 satisfies Ψ, which concludes the proof for the Horn case since the satisfiability problem for the class of all formulas in CNF is NP-complete.

As for the dual Horn case, the proof is similar to the one for the Horn case by replacing every variable except q with its negation, and simplifying double negations, in the formula φ built there. This yields the following formula (for sake of clarity, n_x—resp., p_x—is now better read "x is positive—resp., negative—" and c_i, "Clause C_i is not satisfied"):

$$\bigwedge_{x \in \mathit{Vars}(\Psi)} ((p_x \vee n_x) \wedge (p_x \vee \neg v_x) \wedge (n_x \vee \neg v_x)) \wedge \bigwedge_{x \in C_i} (p_x \vee \neg c_i) \wedge \bigwedge_{(\neg x) \in C_i} (n_x \vee \neg c_i) \wedge \left(\bigvee_{x \in \mathit{Vars}(\Psi)} v_x \vee \bigvee_{i \in I} c_i \vee q \right).$$

Note that this formula is IHS-$B+$. Obviously, such a renaming of variables (excluding q) does not affect the existence of a solution for a given abduction problem. □

4. Polynomial languages. In this section we identify all the properties of a language L that make the problem PQ-ABDUCTION(L) polynomial. We wish to emphasize that all the results given here are constructive, in the sense that efficient algorithms for the problem PQ-ABDUCTION(L) can be easily derived from the proofs.

We first recall the result for the affine case, which has been considered in [28]. Note that [28] considers the class of *all* affine propositional formulas instead of classes of L-formulas, but recall from section 3.1 that since L parameterizes the problem, an affine formula equivalent to a given L-formula φ can be built in linear time from φ.

PROPOSITION 9 (affine [28]). *If L is an affine language, then the problem* PQ-ABDUCTION(L) *is in* P.

Proof. Given an instance (φ, A, q), first compute an affine formula ψ equivalent to φ in time linear in the size of φ. Next, compute a projection of the (still affine) formula $\psi \wedge (q = 0)$ onto A, i.e., an affine formula ψ' over A whose models are exactly the restrictions of the models of $\psi \wedge (q = 0)$ to A. As shown in [28], this step can be performed in polynomial time by first upper-triangulating $\psi \wedge (q = 0)$ with the variables in A put rightmost, and second selecting only those resulting equations that are formed over A. Finally, decide whether the formula $\psi \wedge \neg\psi'$ has a model by deciding whether the affine formula $\psi \wedge (\bigoplus \ell = a \oplus 1)$ has a model for at least one equation $(\bigoplus \ell = a)$ of ψ'. Indeed, such a model exists if and only if the abduction problem (φ, A, q) has a solution. Since satisfiability of affine formulas can be decided in polynomial time with Gaussian elimination, the whole algorithm is polynomial. For more details we refer the reader to [28]. □

We now use the characterization of explanations through prime implicates (Lemma 6) for deriving the following four results. Note that the first two of them are well known, although hard to trace back in the literature. Marquis [20] and Eiter and Gottlob [11], however, prove, respectively, the first and second ones in a slightly different formalization.

PROPOSITION 10 (bijunctive). *If L is a bijunctive language, then the problem* PQ-ABDUCTION(L) *is in* P.

Proof. If every relation in L is bijunctive, then given an L-formula one can compute in linear time an equivalent bijunctive propositional formula. Since all the prime implicates of a given CNF formula can be generated by resolution alone, it is easily seen that the only prime implicates that a 2-CNF formula can have are bijunctive clauses. Therefore Lemma 6 implies that there is a solution for an instance of PQ-ABDUCTION(L) if and only if there is one containing zero or one literal. Hence, if there are n abducible variables, then one can simply test the $O(n)$ literals built upon them for being a solution. This test can be performed in linear time for each literal since the satisfiability problem for bijunctive CNF formulas is linear and that class is stable under conjunction of unary clauses. □

PROPOSITION 11 (definite Horn). *If L is a definite Horn language, then the problem* PQ-ABDUCTION(L) *is in* P.

Proof. Again because the prime implicates of a given formula can be generated by resolution alone, it is easily seen that every prime implicate of a definite Horn formula is a definite Horn clause. Since q is assumed to be positive, the other literals in the clause have to be negative. It follows that if L is definite Horn, any instance (φ, A, q) of PQ-ABDUCTION(L) has a solution if and only if it has a positive solution. Since the assignment E of 1 to every variable in A is consistent with a definite Horn CNF formula φ, it is enough to decide whether $\varphi \wedge \bigwedge E \wedge \neg q$ is unsatisfiable (which can be done in linear time since φ is Horn). Indeed, if $\varphi \wedge \bigwedge E \wedge \neg q$ is unsatisfiable, then E is a solution for the abduction problem, and if it is satisfiable, then $\forall E' \subseteq E$ the formula $\varphi \wedge \bigwedge E' \wedge \neg q$ is also satisfiable (with the same model), and hence (φ, A, q) has no positive solution and, by the remark above, no solution at all. □

Finally, the next two propositions examine IHS-B languages. Those languages can be seen in some sense as maximal (dual) Horn languages that do not have the full expressive power of the class of all propositional (dual) Horn formulas, which explains their special properties. As far as we know these results are new, although easy. Note, however, that the class of IHS-B+ languages includes that of *positive* languages (i.e., sets of relations that can be described by a formula in CNF with only positive literals), and that it is already known that abduction can be performed efficiently with positive formulas (this is proved in, e.g., [20]).

Note finally that the proof for the IHS-B+ case can be used for the IHS-B− case as well, but that the algorithm described for the latter case is more efficient.

PROPOSITION 12 (IHS-B−). *If L is an IHS-B− language, then the problem* PQ-ABDUCTION(L) *is in* P.

Proof. Since an instance φ of this problem is IHS-B− and all the prime implicates of a given formula can be generated by resolution, it is easily seen that the only prime implicates of φ that can contain at least one positive literal are unary or binary. Thus, as for the bijunctive case (Proposition 10), any solution for the problem contains zero or one literal, and such candidates can be tested efficiently since φ is Horn. □

PROPOSITION 13 (IHS-B+). *If L is an IHS-B+ language, then the problem* PQ-ABDUCTION(L) *is in* P.

Proof. Since an instance φ of this problem is dual Horn, one can generate all its unary and binary prime implicates in polynomial time by a generate-and-test algorithm. Now observe that once this is done, the remaining prime implicates of φ cannot be obtained by resolving two positive clauses together, so the only new prime implicates can be obtained by resolving a binary or unary clause with a positive one.

This can only yield a positive clause of size at most that of the original positive one. Hence, if there are n variables occurring in φ and the largest positive clause in the CNF form of the relations in L is of arity k, then φ has $O(n^k)$ prime implicates, which again can be generated efficiently by a generate-and-test algorithm.

Observe that the polynomial complexity obtained here strongly relies on the fact that L, and thus k, is fixed and finite. □

Remark 14. The algorithm given in the proof of Proposition 11 shows that the following problem is in P:

- *Input:* A definite Horn formula φ in CNF, a set of variables $A \subseteq Vars(\varphi)$, and a variable $q \in Vars(\varphi)\backslash A$.
- *Question:* Is there a set $E \subseteq Lits(A)$ such that the propositional formula $\varphi \wedge \bigwedge E$ is satisfiable but the formula $\varphi \wedge \bigwedge E \wedge \neg q$ is not?

In the same manner, the corresponding problem is polynomial for affine formulas (this is proved in [28]), for bijunctive formulas in CNF (Proposition 10), and for IHS-$B-$ formulas in CNF (Proposition 12). On the contrary, the corresponding problem for IHS-$B+$ formulas in CNF is NP-complete, as the proof of Proposition 8 shows. This asymmetric behavior of the abduction problem is due to the fact that q is always a positive literal; we will observe this asymmetry again for the definite dual Horn case.

5. Useful tools for proving hardness results. We present in this section the main tools for getting hardness results, which we will use in the two following sections.

5.1. Implementations and reductions. We first introduce the definition of implementation, which has often been used for exhibiting reductions between various satisfiability problems (see [7, Definition 5.1]).

DEFINITION 15 (implementation). *A language L is said to* implement *a Boolean relation R if for all sets of variables V there exist a set of variables V' disjoint from V and an L-formula φ over $V \cup V'$ such that $R(V) \equiv \exists V' \varphi$.*

Example 16. Let $L = \{\mathsf{OR}_{3,2}\}$. Then for any $k \geq 2$, L implements the relation $\mathsf{OR}_{k,k-1}$. Indeed, for $k \geq 3$ it is easily seen that for all variables $x_1, x_2, \ldots, x_k$ the constraint $\mathsf{OR}_{k,k-1}(x_1, \ldots, x_k)$ is logically equivalent to the formula

$$\exists y_1, y_2, \ldots, y_{k-3} \mathsf{OR}_{3,2}(x_1, x_2, y_1) \wedge \left(\bigwedge_{i=2}^{k-3} \mathsf{OR}_{3,2}(y_{i-1}, x_{i+1}, y_i) \right) \wedge \mathsf{OR}_{3,2}(y_{k-3}, x_{k-1}, x_k)$$

and for $k = 2$ we have $\mathsf{OR}_{2,1}(x, y) = \mathsf{OR}_{3,2}(x, x, y)$.

It can also be seen that the language $L \cup \{\mathsf{F}\}$ implements $\mathsf{OR}_{2,2}$, since for any x, y we have $\mathsf{OR}_{2,2}(x, y) \equiv \exists z \mathsf{OR}_{3,2}(x, y, z) \wedge \mathsf{F}(z)$.

Finally, it can be seen that for any $k \geq 2$, the language $\{\mathsf{OR}_{3,1}, T\}$ implements $\mathsf{OR}_{k,0}$. Indeed, for $k \geq 2$ and any variables $x_1, \ldots, x_k$ the constraint $\mathsf{OR}_{k,0}(x_1, \ldots, x_k)$ is logically equivalent to the formula

$$\exists y_0, y_1, \ldots, y_{k-2} \mathsf{T}(y_0) \wedge \left(\bigwedge_{i=0}^{k-3} \mathsf{OR}_{3,1}(y_i, x_{i+1}, y_{i+1}) \right) \wedge \mathsf{OR}_{3,1}(y_{k-2}, x_{k-1}, x_k).$$

As is easily seen, the composition of two implementations is still an implementation. The following lemma shows a connection between implementations and reductions.

LEMMA 17. *Let φ, φ', A, q be such that the projection of the models of φ and φ' onto $A \cup \{q\}$ are the same, i.e., writing $Vars(\varphi)\backslash(A \cup \{q\}) = \{x_1, \ldots, x_m\}$ and*

$Vars(\varphi')\backslash(A \cup \{q\}) = \{x'_1, \ldots, x'_n\}$, such that the formulas $\exists x_1, \ldots, x_m, \varphi$ and $\exists x'_1, \ldots, x'_n, \varphi'$ are equivalent. Then the instances (φ, A, q) and (φ', A, q) for the abduction problem have the same solutions.

Proof. By symmetry, let E be a solution for (φ, A, q). Then there is an assignment m to $Vars(\varphi)$ that satisfies E. Consider the assignment m' to $A \cup \{q\}$ defined by $\forall x \in A \cup \{q\}, m'(x) = m(x)$. By construction m' satisfies both E and the formula $\exists x_1, \ldots, x_m, \varphi$. Thus, by assumption m' satisfies both E and the formula $\exists x'_1, \ldots, x'_m \varphi'$, and hence the formula $\varphi' \wedge \bigwedge E$ is satisfiable. The proof is dual for showing that if the formula $\varphi' \wedge \bigwedge E \wedge \neg q$ is satisfiable, then so is the formula $\varphi \wedge \bigwedge E \wedge \neg q$. This shows that every solution E for (φ, A, q) is a solution for (φ', A, q) as well, and by symmetry of the roles of φ and φ' this concludes the proof. □

As for the CNF forms of relations, if every relation in L can be implemented by L', an algorithm can look up these implementations in a catalog, and given an L-formula one can build in linear time an equivalent L'-formula (modulo existentially quantified variables). This allows us to state the following corollary of Lemma 17.

COROLLARY 18. *Let L, L' be two languages. If* PQ-ABDUCTION(L) *is* NP*-hard (resp., Σ_2P-hard) and every relation of L can be implemented by L', then* PQ-ABDUCTION$(L)'$ *is also* NP*-hard (resp., Σ_2P-hard).*

Proof. Given an instance (φ, A, q) for the problem PQ-ABDUCTION(L), let V' be a set of new variables and φ' a L'-formula such that the formulas $\exists V' \varphi'$ and φ are equivalent. Lemma 17 shows that the problems (φ, A, q) and (φ', A, q) have the same solutions. Since L' implements L and L is finite and parameterizes the problem PQ-ABDUCTION(L), one can compute φ' in polynomial time given φ (at least by including the finite number of implementations as steps of an algorithm), and thus we have a polynomial-time reduction from the problem PQ-ABDUCTION(L) to the problem PQ-ABDUCTION$(L)'$, which completes the proof. □

5.2. Useful reductions. We now state three lemmas which allow us to get rid of some unary constraints that we will introduce in our reductions. Since these lemmas do not directly add to the understanding of the complexity of abduction, their rather technical proofs are postponed to the appendices.

LEMMA 19. *Let L be a language. The problem* PQ-ABDUCTION$(L \cup \{\mathsf{T}\})$ *is polynomial-time reducible to the problem* PQ-ABDUCTION$(L \cup \{\mathsf{OR}_{2,1}\})$.

LEMMA 20. *Let L be a language. The problem* PQ-ABDUCTION$(L \cup \{\mathsf{F}\})$ *is polynomial-time reducible to the problem* PQ-ABDUCTION$(L \cup \{\mathsf{OR}_{3,1}\})$.

Note that there is a lack of symmetry in the statement of these two lemmas. This is due to the lack of symmetry with respect to the query literal (q is always a positive literal).

For the next lemma, recall from section 2 that the ternary relation $\mathsf{SymOR}_{2,1}$ is defined by

$$\mathsf{SymOR}_{2,1}(x, y, z) \equiv (\mathsf{OR}_{2,1}(x, y) \wedge \mathsf{T}(z)) \vee (\mathsf{OR}_{2,1}(y, x) \wedge \mathsf{F}(z)).$$

LEMMA 21. *Let L be a language. The problem* PQ-ABDUCTION$(L \cup \{\mathsf{F}\})$ *is polynomial-time reducible to the problem* PQ-ABDUCTION$(L \cup \{\mathsf{SymOR}_{2,1}\})$.

6. NP-complete languages. The following hardness results for basic Horn and dual Horn problems will be the cornerstones of the identification of NP-hard cases.

LEMMA 22. PQ-ABDUCTION$(\{\mathsf{OR}_{3,2}, \mathsf{F}\})$ *is* NP*-complete.*

Proof. As shown in Example 16, $\{\mathsf{OR}_{3,2}, \mathsf{F}\}$ implements $\mathsf{OR}_{2,2}$ and $\mathsf{OR}_{k,k-1}$ $\forall k \geq 2$; moreover, it can be seen that the implementation of $\mathsf{OR}_{k,k-1}$ is linear in k. Thus

the problem (φ, A, q) built in the proof of Proposition 8 for the Horn case can be reduced in polynomial time to PQ-ABDUCTION($\{\mathsf{OR}_{3,2}, \mathsf{F}\}$). Since the former problem is shown to be NP-complete there, the latter one also is. □

For dual Horn relations we can get an even stronger result, which emphasizes the asymmetric behavior of Horn and dual Horn relations.

LEMMA 23. PQ-ABDUCTION($\{\mathsf{OR}_{3,1}\}$) *is* NP*-complete.*

Proof. We first show that PQ-ABDUCTION($\{\mathsf{OR}_{3,1}, \mathsf{T}\}$) is NP-complete with a proof similar to the one of Lemma 22. Indeed, as shown in Example 16, $\{\mathsf{OR}_{3,1}, \mathsf{T}\}$ implements $\mathsf{OR}_{k,0}$ $\forall k \geq 2$, and this implementation is linear in k; since it also implements $\mathsf{OR}_{2,1}$ ($\mathsf{OR}_{2,1}(x, y) = \mathsf{OR}_{3,1}(x, y, y)$), we can reduce the problem built in the proof of Proposition 8 for the dual Horn case to PQ-ABDUCTION($\{\mathsf{OR}_{3,1}, \mathsf{T}\}$). The conclusion then follows from Lemma 19. □

Based upon these lemmas, the next propositions identify the NP-complete languages. We wish to point out that a Horn (resp., dual Horn) relation that is not IHS-$B-$ (resp., IHS-$B+$) cannot be either bijunctive, affine, or dual Horn (resp., Horn). Indeed, if R is both Horn and bijunctive, then by [29, Proposition 3] every prime implicate of any formula describing R is both Horn and bijunctive, thus IHS-$B-$, and thus R itself is IHS-$B-$, contradicting the hypothesis. Now if R is Horn and affine, then by the closure properties given in the preliminaries we get $\forall m, m', m'' \in R, (m \wedge m') \oplus (m \wedge m'') \oplus (m' \wedge m'') = (m \wedge m') \vee (m \wedge m'') \vee (m' \wedge m'') \in R$, which characterizes bijunctive relations, and R is IHS-$B-$ by the reasoning above. Finally, if R is both Horn and dual Horn, then by [29, Proposition 3] and the same reasoning as above, R is once again bijunctive.

PROPOSITION 24 (dual Horn languages). *If L is a dual Horn language that is not IHS-$B+$, then the problem* PQ-ABDUCTION(L) *is* NP*-complete.*

Proof. Membership in NP follows from Proposition 8. We first observe that L is not complementive. Indeed, if L were complementive, then since it is Horn it would be dual Horn, which can be concluded easily from the closure properties given in the preliminaries and from the equality $\forall b, b' \in \{0, 1\}, b \vee b' = ((b \oplus 1) \wedge (b' \oplus 1)) \oplus 1$. Now being Horn and dual Horn L would be bijunctive, as pointed out above, and finally it would be IHS-$B+$, contradicting the hypothesis. Thus L is not complementive. We now distinguish two cases.

First, if L is not 1-valid, it follows from [7, Lemma 5.25 (2)] that L implements F. Then from [7, Lemma 5.27] it follows that L implements $\mathsf{OR}_{3,1}$ (the proof does not use the constant relation T). The conclusion follows from Corollary 18 and Lemma 23.

Now assume that L is 1-valid. We first show that $L \cup \{\mathsf{OR}_{2,1}\}$ implements $\mathsf{OR}_{3,1}$, which will allow us to conclude that PQ-ABDUCTION($L \cup \{\mathsf{OR}_{2,1}\}$) is NP-hard with Lemma 23, and we will then show that L implements $\mathsf{OR}_{2,1}$, thus concluding the proof.

($L \cup \{\mathsf{OR}_{2,1}\}$ implements $\mathsf{OR}_{3,1}$.) First observe that by assumption L contains a relation R which is dual Horn but not IHS-$B-$. Considering a description ψ of R over $\{x_1, \ldots, x_n\}$ it is then easily seen that ψ has a prime implicate C of the form (without loss of generality) $C = (\neg x_1 \vee x_2 \vee \cdots \vee x_k)$ with the x_{i_j}'s pairwise distinct and $k \geq 3$. Let us consider the formula ψ' over $\{x_1, \ldots, x_k\}$ defined by $\psi' = \exists x_{k+1}, \ldots, x_n R(x_1, \ldots, x_k)$. Finally consider the formula ψ'' over $\{x_1, x_2, x_3\}$ defined by

$$\psi'' = \exists x_4, \ldots, x_k, \psi' \wedge \bigwedge_{i=4}^{k} \mathsf{OR}_{2,1}(x_i, x_2).$$

Every model of ψ'' that maps x_2 to 0 maps x_i to 0 $\forall i \in \{4, \ldots, k\}$ because of the

clauses $\mathsf{OR}_{2,1}(x_i, x_2)$. It follows that $100 \not\models \psi''$ by definition of a prime implicate. Now by definition of a prime implicate again, $110 \models \psi''$, since the clauses $\mathsf{OR}_{2,1}(x_i, x_2)$ do not impose any constraint on the value of any x_i. Finally, still by definition of a prime implicate, the assignments $0000\ldots0$ and $1010\ldots0$ to $\{x_1, x_2, \ldots, x_k\}$ satisfy ψ'; it is easily seen that $\forall i \in \{4, \ldots, k\}$ they satisfy the clause $\mathsf{OR}_{2,1}(x_i, x_2)$ as well, and thus 000 and 101 satisfy ψ''. Now denote by R'' the ternary relation described by ψ''; R'' satisfies exactly the assumptions of [7, Lemma 5.27], and it follows that $\{R, \mathsf{OR}_{2,1}\}$, and a fortiori $L \cup \{\mathsf{OR}_{2,1}\}$ implements $\mathsf{OR}_{3,1}$.

(L implements $\mathsf{OR}_{2,1}$.) We use once again the prime implicate C exhibited above. Let us consider the assignments to $\{x_1, x_2, \ldots, x_n\}$. By definition of a prime implicate we first get $10\ldots0 \notin R$. Since C is a prime implicate we also have $00\ldots0 \in R$ and $\forall i \geq 2$, $10\ldots010\ldots0 \in R$ (where i is the index of the second variable mapped to 1). Since R is dual Horn and thus closed under bitwise-or, we also get that for every set of indices $I \subseteq \{2, \ldots, k\}, I \neq \emptyset$, the assignment m_I that maps x_1 and every x_i with $i \in I$ to 1 and every other x_i to 0 is in R. In particular, $11\ldots1 \in R$, and for every i, $11\ldots101\ldots1 \in R$ (where i is the index of the only variable mapped to 0). Now we only need to distinguish two cases. First assume $01\ldots1 \in R$; then for every two variables x, y we have $R(x, y, \ldots, y) \equiv \mathsf{OR}_{2,1}(x, y)$. Now assume $01\ldots1 \notin R$; then since R is dual Horn and thus closed under bitwise-or, there is at least one index i such that $00\ldots010\ldots0 \notin R$ (where i is the index of the only variable mapped to 1); then $R(y, y, \ldots, y, x, y, \ldots, y) \equiv \mathsf{OR}_{2,1}(x, y)$. Hence, in both cases R implements $\mathsf{OR}_{2,1}$, thus concluding the proof. □

PROPOSITION 25 (Horn languages). *If L is a Horn language that is neither definite Horn nor IHS-B−, then the problem* PQ-ABDUCTION(L) *is* NP*-complete.*

Proof. A proof symmetric to that of Proposition 24 shows that L can implement the relation $\mathsf{OR}_{3,2}$. Since L is not definite Horn, L is not 1-valid. Moreover, as observed in the previous proposition, L is not complementive. Hence, according to [7, Lemma 5.25] L can implement F. Thus L implements $\{\mathsf{OR}_{3,2}, \mathsf{F}\}$. Finally, the conclusion follows from Corollary 18 and Lemma 22. □

7. Σ_2P-complete languages. Recall that a language L is said to be *Schaefer* if it is either affine, bijunctive, Horn, or dual Horn. If L is not Schaefer, then it does not fall in any of the cases explored in the two previous sections. We will prove in this section that if L is not Schaefer, then the problem PQ-ABDUCTION(L) is Σ_2P-complete.

We first need two lemmas.

LEMMA 26. *Let S_3 be the (finite) set of all ternary relations. The problem* PQ-ABDUCTION(S_3) *is* Σ_2P*-complete.*

Proof. It is well known that given any CNF formula ψ over some set of variables V, one can build in polynomial time a formula of the form $\exists V' \varphi$ such that φ is a propositional formula in CNF over $V \cup V'$, every clause of which is of length at most 3 and such that $\psi \equiv \exists V' \varphi$. Lemma 17 then shows that this construction yields a polynomial-time reduction from the general abduction problem (where the input is any CNF formula) to the problem PQ-ABDUCTION(S_3), and we can conclude from Proposition 7. □

LEMMA 27. *Let L be a non-Schaefer language.*

1. *If L is neither* 0- *nor* 1*-valid, nor complementive, then L implements every Boolean relation.*
2. *If L is neither* 0- *nor* 1*-valid but is complementive, then L implements* $\mathsf{SymOR}_{2,1}$.
3. *If L is* 0*-valid but not* 1*-valid, then L implements* $\mathsf{OR}_{2,1}$.

4. *If L is* 1*-valid but not* 0*-valid, then L implements* $\mathsf{OR}_{3,1}$.

5. *If L is both* 0*- and* 1*-valid, then L implements either* $\mathsf{SymOR}_{2,1}$ *or* $\mathsf{OR}_{2,1}$*, depending on whether L is complementive or not.*

Proof. For the sake of completeness we demonstrate or cite the implementations in the appendices, but the five points may be obtained by techniques from universal algebra and Post's lattice [17, 2]. □

We now make a case distinction depending on whether L is 0-valid (resp., 1-valid) or not.

PROPOSITION 28 (neither 0- nor 1-valid). *If L is neither Schaefer nor* 0*-valid nor* 1*-valid, then the problem* PQ-ABDUCTION(L) *is* Σ_2P*-complete.*

Proof. According to Lemma 27, if L is not complementive, then L implements the whole class of Boolean relations. We conclude with Lemma 26 (and Corollary 18).

Now if L is complementive, still according to Lemma 27 L implements $\mathsf{SymOR}_{2,1}$, and thus PQ-ABDUCTION(L) is as hard as PQ-ABDUCTION($L \cup \{\mathsf{F}\}$) by Lemma 21. Since $L \cup \{\mathsf{F}\}$ is neither 0-valid nor 1-valid nor complementive, PQ-ABDUCTION($L \cup \{\mathsf{F}\}$) is Σ_2P-hard, which concludes the proof. □

PROPOSITION 29 (1-valid xor 0-valid). *Let L be a* 0*-valid set of Boolean relations. If L is neither Schaefer nor* 1*-valid, then the problem* PQ-ABDUCTION(L) *is* Σ_2P*-complete. The same holds if L is* 1*-valid but neither Schaefer nor* 0*-valid.*

Proof. Membership in Σ_2P is obvious. Observe that L cannot be complementive since it is either 0-valid or 1-valid but not both.

We first consider the 0-valid case. Obviously $L \cup \{\mathsf{T}\}$ is neither Schaefer nor 0-valid nor 1-valid. We can thus conclude from Proposition 28 that the problem PQ-ABDUCTION($L \cup \{\mathsf{T}\}$) is Σ_2P-complete. From Lemma 19 it follows that the problem PQ-ABDUCTION($L \cup \{\mathsf{OR}_{2,1}\}$) is Σ_2P-complete. Now, according to Lemma 27 we know that L can implement $\mathsf{OR}_{2,1}$. From Corollary 18 we finally deduce that PQ-ABDUCTION(L) is Σ_2P-complete.

The 1-valid case can be handled in a similar way by first considering the set $L \cup \{\mathsf{F}\}$ and then successively using Lemmas 20 and 27 and Corollary 18. □

PROPOSITION 30 (0-valid and 1-valid). *Let L be a* 0*-valid and* 1*-valid set of Boolean relations. If L is not Schaefer, then the problem* PQ-ABDUCTION(L) *is* Σ_2P*-complete.*

Proof. First assume L is not complementive. Then $L \cup \{\mathsf{T}\}$ is 1-valid but neither Schaefer nor 0-valid. Thus, by Proposition 29 the problem PQ-ABDUCTION($L \cup \{\mathsf{T}\}$) is Σ_2P-complete, and we conclude as in the proof of the previous proposition.

Now if L is complementive, then according to Lemma 27 L can implement $\mathsf{SymOR}_{2,1}$. We then conclude with Lemma 21 after observing that $L \cup \{\mathsf{F}\}$ is 0-valid but neither Schaefer nor 1-valid. □

We have finally completely classified the complexity of abduction for the case when the query is a single, positive literal. Moreover, given any finite set of Boolean relations L one can efficiently decide whether the abduction problem PQ-ABDUCTION(L) is either polynomial, NP-complete, or Σ_2P-complete (see Proposition 3).

THEOREM 31 (main result). *Let L be a language.*

- *If L is bijunctive, affine, definite Horn, IHS-B+, or IHS-B−, the problem* PQ-ABDUCTION(L) *is polynomial.*
- *Otherwise, if L is Horn or dual Horn, the problem* PQ-ABDUCTION(L) *is* NP*-complete.*
- *In all other cases, the problem* PQ-ABDUCTION(L) *is* Σ_2P*-complete.*

Each of these conditions can be checked in polynomial time given a language written in extension.

8. Negative and unrestricted queries. We show briefly in this section how the previous results can be carried over to the case where the query q is a negative literal instead of a positive one, and to the case where it is unrestricted. Given some language L, write NQ-ABDUCTION(L) for the problem defined as the problem PQ-ABDUCTION(L) except that the query q in the instance is a *negative literal*, and ABDUCTION(L) for that defined for any literal query, i.e., q is either a positive or a negative literal.

PROPOSITION 32 (negative queries). *Let L be a language.*

- *If L is bijunctive, affine, definite dual Horn, IHS-B+, or IHS-B−, the problem* NQ-ABDUCTION(L) *is polynomial.*
- *Otherwise, if L is Horn or dual Horn, the problem* NQ-ABDUCTION(L) *is* NP*-complete.*
- *In all other cases, the problem* NQ-ABDUCTION(L) *is* Σ_2P*-complete.*

Each of these conditions can be checked in polynomial time given a language written in extension.

Proof. Given an n-ary relation R, define the n-ary relation $Ren(R)$ to be $\{(m_1 \oplus 1, \ldots, m_n \oplus 1) \mid (m_1, \ldots, m_n) \in R\}$. Given a language L, write $Ren(L) = \{Ren(R) \mid R \in L\}$, and given an L-formula $\varphi = \bigwedge_{i \in I} R_i(x_{i,1}, \ldots, x_{i,k_i})$, define the $Ren(L)$-formula $Ren(\varphi)$ to be $\bigwedge_{i \in I} Ren(R_i)(x_{i,1}, \ldots, x_{i,k_i})$. Then all the results can be derived from those for positive queries by observing that given a language L and an L-formula φ, the problem (φ, A, q) has a solution if and only if the problem $(Ren(\varphi), A, \neg q)$ has one. Since a relation R is Horn (resp., dual Horn) if and only if the relation $Ren(R)$ is dual Horn (resp., Horn), and similarly for the definite and IHS-B restrictions, and since all the other properties of interest are invariant under the operator Ren, we get the result. □

PROPOSITION 33 (unrestricted queries). *Let L be a language.*

- *If L is bijunctive, affine, IHS-B+, or IHS-B−, the problem* ABDUCTION(L) *is polynomial.*
- *Otherwise, if L is Horn or dual Horn, the problem* ABDUCTION(L) *is* NP*-complete.*
- *In all other cases, the problem* ABDUCTION(L) *is* Σ_2P*-complete.*

Each of these conditions can be checked in polynomial time given a language written in extension.

Proof. The result easily follows from that for positive queries and that for negative ones. □

9. Conclusion. We have completely classified the computational complexity of propositional abduction in Schaefer's framework of L-formulas. The problem appears to be either polynomial, NP-complete, or Σ_2P-complete depending on the properties satisfied by the language L. We have given the results for finite languages and for positive, negative, and unrestricted queries, which gives a fine comprehension of the influence of the polarity of the query on the complexity of the problem. Our results are summarized in Table 1.

As evoked in the introduction, various restrictions have been studied on the formalization of the abduction problem, mainly depending on the hypotheses and queries allowed. Our model is certainly one for which the problem is the easiest. At another extreme, Nordh and Zanuttini have recently studied the formalization in which the query is a term (conjunction of literals) and abducible *literals* are given instead of

TABLE 1
Summary of results for the problem PQ-ABDUCTION(L). *Membership of L in one class assumes it does not belong to any class upper in the table.*

Query	Pos.	Neg.	Any
L affine	P	P	P
L bijunctive	P	P	P
L IHS-$B-$	P	P	P
L IHS-$B+$	P	P	P
L definite Horn	P	NP-c.	NP-c.

None of the above	Σ_2P-c.	Σ_2P-c.	Σ_2P-c.

variables; that is, the literals occurring in an explanation are restricted, instead of only the variables upon which they are formed. It turns out that a trichotomy has also been found for this problem [21]. Current work aims at classifying every intermediate model, considering various restrictions on the queries and hypotheses, with the goal of understanding what really makes the complexity of abduction jump from one level to another in the polynomial hierarchy.

Another interesting direction for future work is the study of other problems closely related to that of deciding the existence of a solution, and an attempt to establish a trichotomy in the complexity of them as well. Among these problems are those of deciding the relevance or the necessity of an abducible variable [11]. An abducible variable is said to be relevant (resp., necessary) to a given abduction problem if it is part of at least one of its solution (resp., of all its solutions). The necessity problem is quite close to that of deciding the existence of a solution, since α is necessary to $(\varphi, A \cup \{\alpha\}, q)$ if and only if (φ, A, q) has no solution, but no such relation is known for relevance. Other interesting issues concern the complexity of counting or enumerating the solutions. For this latter point we refer the reader to Eiter and Makino's work [12, 13]. We believe that for such studies one would first need to determine the properties that are preserved by implementations (e.g., the variables involved in a solution, the number of solutions, etc.), considering both preferred and unconstrained solutions.

Appendix A. Proof of Lemma 19. Let (φ, A, q) be an instance of PQ-ABDUCTION($L \cup \{\mathsf{T}\}$), and write

$$\varphi = \varphi_0 \wedge \bigwedge_{i \in I} \mathsf{T}(x_i),$$

where φ_0 is an L-formula.

We first assume $q \notin \{x_i \mid i \in I\}$. Define the formula

$$\varphi' = \varphi_0 \wedge \bigwedge_{i \in I} \mathsf{OR}_{2,1}(q, x_i)$$

and define furthermore A' to be $A \cup \{x_i \mid i \in I\}$. We show that the problem (φ', A', q) has a solution if and only if the problem (φ, A, q) has one.

(Solution of $(\varphi, A, q) \to$ solution of (φ', A', q).) Let E be a solution of the problem (φ, A, q), and define E' to be $E \cup \{x_i \mid i \in I\}$. It is easily seen that every model of

$\varphi' \wedge \bigwedge E'$ satisfies $\varphi \wedge \bigwedge E$ as well, and thus that $\varphi' \wedge \bigwedge E' \wedge \mathsf{F}(q)$ is unsatisfiable since by assumption so is $\varphi \wedge \bigwedge E \wedge \mathsf{F}(q)$. Now let m be a model of $\varphi \wedge \bigwedge E$. Because of the constraints $\mathsf{T}(x_i)$ in φ we know that for every $i \in I, m(x_i) = 1$, and it follows that m satisfies $\varphi' \wedge \bigwedge E'$. Thus E' is a solution for the problem (φ', A', q).

(Solution of $(\varphi', A', q) \rightarrow$ solution of (φ, A, q).) Let E' be a solution of the problem (φ', A', q), and define E to be $E' \backslash \{x_i, \neg x_i \mid i \in I, x_i \notin A\}$. Since $\varphi' \wedge \bigwedge E' \wedge \mathsf{F}(q)$ is unsatisfiable, we know that every model of $\varphi' \wedge \bigwedge E'$ maps q to 1 and thus, because of the constraint $\mathsf{OR}_{2,1}(q, x_i)$ $\forall i \in I$, that it maps x_i to 1 $\forall i \in I$. Since by definition of a solution there is at least one such model, $\varphi \wedge \bigwedge E'$ is satisfiable, and a fortiori $\varphi \wedge \bigwedge E$ is. For the same reason, we know that for every $i \in I$, E' does not contain $\neg x_i$. In order to obtain a contradiction suppose that $\varphi \wedge \bigwedge E \wedge \mathsf{F}(q)$ is satisfiable. It follows from the previous remark that $\varphi \wedge \bigwedge E' \wedge \mathsf{F}(q)$ is satisfiable and, since every model of φ satisfies φ', that $\varphi' \wedge \bigwedge E' \wedge \mathsf{F}(q)$ is satisfiable as well, which contradicts the fact that E' is a solution. Thus E is a solution for the problem (φ, A, q), which concludes the proof for the case $q \notin \{x_i \mid i \in I\}$.

We now consider the case $q \in \{x_i \mid i \in I\}$. The reduction above does not work anymore since the query is not allowed to be abducible in the definition of the problem. However, we observe that in this case the problem (φ, A, q) has a solution if and only if φ is satisfiable. Indeed, if this is the case, then $E = \emptyset$ is a solution, (because the constraint $\mathsf{T}(q)$ in φ forces the value of q to 1 in every model of φ), and if φ is unsatisfiable, then no E can be found such that $\varphi \wedge \bigwedge E$ is satisfiable, as required for a solution. Thus in this case, we introduce a new variable q' ($q' \notin \mathit{Vars}(\varphi)$) and reduce the problem (φ, A, q) to the problem $(\varphi', A' = \{q\}, q')$ with

$$\varphi' = \varphi_0 \wedge \bigwedge_{i \in I} \mathsf{OR}_{2,1}(q, x_i) \wedge \mathsf{OR}_{2,1}(q, q') \wedge \mathsf{OR}_{2,1}(q', q).$$

Note first that φ' is an $(L \cup \{\mathsf{OR}_{2,1}\})$-formula. Note also that $\mathsf{OR}_{2,1}(q, q') \wedge \mathsf{OR}_{2,1}(q', q)$ forces the values of q and q' to be the same in every model of φ'. We show that (φ', A', q') has a solution if and only if φ is satisfiable, which will conclude the proof by the remark above.

If φ is satisfiable, write m for one of its models. On one hand, by definition m satisfies φ_0 and $\mathsf{T}(x_i)$ $\forall i \in I$ (in particular, $\mathsf{T}(q)$). On the other hand, since q and q' are forced to the same value by φ', the formula $\varphi' \wedge \mathsf{T}(q) \wedge \mathsf{F}(q')$ is unsatisfiable. It follows that $E = \{q\}$ is a solution of (φ', A', q'). Conversely, if E is a solution of the problem (φ', A', q'), let m be a model of $\varphi' \wedge \bigwedge E \wedge \mathsf{T}(q')$. Because of the constraints $\mathsf{OR}_{2,1}(q, q')$ and $\mathsf{OR}_{2,1}(q', q)$ in φ', m maps q to 1. Thus every x_i ($i \in I$) is mapped to 1 as well because of the constraints $\mathsf{OR}_{2,1}(q, x_i)$. Therefore, m satisfies φ, which is thus satisfiable. □

Appendix B. Proof of Lemma 20. Let (φ, A, q) be an instance of PQ-ABDUCTION$(L \cup \{\mathsf{F}\})$, and write

$$\varphi = \varphi_0 \wedge \bigwedge_{i \in I} \mathsf{F}(x_i),$$

where φ_0 is an L-formula.

First of all, if $q \in \{x_i \mid i \in I\}$, then the problem cannot have a solution; hence it can be reduced soundly and in constant time to the constant problem $(\varphi' = \mathsf{OR}_{3,1}(q, q, q), A' = \emptyset, q)$.

Thus we assume without loss of generality that $q \notin \{x_i \mid i \in I\}$. Let q' be a new variable (i.e., $q' \notin \mathit{Vars}(\varphi)$), write $I = \{i_1, \ldots, i_k\}$, and define the formula

$$\varphi' = \varphi_0 \wedge \mathsf{OR}_{k+2,1}(q, x_{i_1}, \ldots, x_{i_k}, q').$$

It is easily seen that φ' can be built in polynomial time from φ and that the relation $\mathsf{OR}_{k+2,1}$ is implemented by $\{\mathsf{OR}_{3,1}\}$ in the usual way. Now define A' to be $A \cup \{x_i \mid i \in I\}$. We show that the problem (φ', A', q') has a solution if and only if the problem (φ, A, q) has one.

(Solution of $(\varphi, A, q) \rightarrow$ solution of (φ', A', q').) Assume that E is a solution for the problem (φ, A, q), and define E' to be $E \cup \{\neg x_i \mid i \in I\}$. It is easily seen that every model of the formula $\varphi' \wedge \bigwedge E'$ satisfies $\varphi \wedge \bigwedge E$ as well, and thus that $\varphi' \wedge \bigwedge E' \wedge \mathsf{F}(q)$ is unsatisfiable since $\varphi \wedge \bigwedge E \wedge \mathsf{F}(q)$ is also. It follows that $\varphi' \wedge \bigwedge E' \wedge \mathsf{OR}_{k+1,1}(q, x_{i_1}, \ldots, x_{i_k})$ is unsatisfiable, and thus that $\varphi' \wedge \bigwedge E' \wedge \mathsf{F}(q')$ is unsatisfiable as well. Now let m be a model of $\varphi \wedge \bigwedge E$. Because of the clauses $\mathsf{F}(x_i)$ in φ we know that $\forall i \in I, m(x_i) = 0$, and it follows that adding $m(q') = 1$ to m we get a model of $\varphi' \wedge \bigwedge E'$. Thus E' is a solution for the problem (φ', A', q').

(Solution of $(\varphi', A', q') \rightarrow$ solution of (φ, A, q).) Let E' be a solution for the abduction problem (φ', A', q'). Define E to be $E' \backslash \{x_i, \neg x_i \mid i \in I, x_i \notin A\}$. First of all, we know that $\varphi' \wedge \bigwedge E' \wedge \mathsf{F}(q')$ is unsatisfiable. It follows that $\varphi_0 \wedge \mathsf{OR}_{k+1,1}(q, x_{i_1}, \ldots, x_{i_k}) \wedge \mathsf{F}(q') \wedge \bigwedge E'$ is unsatisfiable and thus that $\varphi_0 \wedge \mathsf{OR}_{k+1,1}(q, x_{i_1}, \ldots, x_{i_k}) \wedge \bigwedge E'$ is unsatisfiable since $q' \notin \mathit{Vars}(\varphi_0)$. Since $\varphi_0 \wedge \bigwedge E'$ is satisfiable (because so is $\varphi' \wedge \bigwedge E'$), we derive that (i) for no $i \in I$, E' contains x_i, and thus that every model of $\varphi \wedge \bigwedge E$ satisfies $\varphi_0 \wedge \bigwedge E'$ as well, and (ii) $\varphi_0 \wedge \bigwedge E' \wedge \mathsf{F}(q)$ is unsatisfiable, since otherwise any of its models would satisfy $\mathsf{F}(q)$, thus $\mathsf{OR}_{k+1,1}(q, x_{i_1}, \ldots, x_{i_k})$ and finally $\varphi_0 \wedge \mathsf{OR}_{k+1,1}(q, x_{i_1}, \ldots, x_{i_k}) \wedge \bigwedge E'$. Finally, by point (i) every model of $\varphi \wedge \bigwedge E \wedge \mathsf{F}(q)$ satisfies $\varphi_0 \wedge \bigwedge E' \wedge \mathsf{F}(q)$, and thus the latter is unsatisfiable by point (ii). On the other hand, since every model of $\varphi_0 \wedge \bigwedge E' \wedge \mathsf{OR}_{k,0}(x_{i_1}, \ldots, x_{i_k})$ satisfies $\varphi_0 \wedge \bigwedge E' \wedge \mathsf{OR}_{k+1,1}(q, x_{i_1}, \ldots, x_{i_k})$, which is shown to be unsatisfiable above, it is unsatisfiable too, and thus we know that any model of $\varphi_0 \wedge \bigwedge E'$ satisfies $\varphi_0 \wedge \bigwedge E' \wedge \bigwedge_{i \in I} \mathsf{F}(x_i)$ and, since there is at least one such model, that $\varphi \wedge \bigwedge E$ is satisfiable, which concludes the proof. □

Appendix C. Proof of Lemma 21. Let (φ, A, q) be an instance of PQ-ABDUCTION$(L \cup \{\mathsf{F}\})$, and write

$$\varphi = \varphi_0 \wedge \bigwedge_{i \in I} \mathsf{F}(x_i),$$

where φ_0 is an L-formula.

First of all, if $q \in \{x_i \mid i \in I\}$, then the problem cannot have a solution; hence it can be reduced soundly and in constant time to the constant problem $(\varphi' = \mathsf{SymOR}_{2,1}(q, q, q), A' = \emptyset, q)$.

Thus we assume without loss of generality that $q \notin \{x_i \mid i \in I\}$. Let q', β be two new variables (i.e., $q', \beta \notin \mathit{Vars}(\varphi)$), and define the formula

$$\varphi' = \varphi_0 \wedge \mathsf{SymOR}_{2,1}(\beta, q, q') \wedge \bigwedge_{i \in I} (x_i = \beta).$$

Moreover, let $A' = A \cup \{\beta\} \cup \bigcup \{x_i \mid i \in I\}$. We show that the abduction problem (φ, A, q) has a solution if and only if the problem (φ', A', q') has one. This will conclude the proof since replacing every x_i $(i \in I)$ with β and removing all the equalities in

φ', one gets an $L \cup \{\mathsf{SymOR}_{2,1}\}$-formula φ'', and it is easily seen that the abduction problems (φ', A, q') and (φ'', A, q') have the same solution (β and all the x_i's play the same role with respect to A and q').

(Solution of $(\varphi, A, q) \rightarrow$ solution of (φ', A', q').) Let E be a solution for (φ, A, q), and define E' to be $E \cup \{\neg\beta\} \cup \{\neg x_i \mid i \in I\}$. Let m be a model of $\varphi \wedge \bigwedge E$. Then m satisfies φ_0 and q, and it is easily seen that, adding $m(\beta) = 0$ and $m(q') = 1$ to m, one gets a model of $\varphi' \wedge \bigwedge E'$. Now $\varphi' \wedge \bigwedge E' \wedge \mathsf{F}(q)$ is unsatisfiable because every model of $\varphi' \wedge \bigwedge E'$ satisfies $\varphi \wedge \bigwedge E$, and $\varphi \wedge \bigwedge E \wedge \mathsf{F}(q)$ is unsatisfiable by assumption. We conclude that every model of $\varphi' \wedge \bigwedge E'$ maps q to 1, and since $(\neg\beta) \in E'$ we know that no model of $\varphi' \wedge \bigwedge E'$ satisfies $\mathsf{OR}_{2,1}(q, \beta)$ and thus, because of the relation $\mathsf{SymOR}_{2,1}(\beta, q, q')$, that every model m of $\varphi' \wedge \bigwedge E'$ satisfies $m(q') = 1$, which finishes to show that E' is a solution for (φ', A', q').

(Solution of $(\varphi', A', q') \rightarrow$ solution of (φ, A, q).) Let E' be a solution for (φ', A', q'), and let $E = E' \backslash (\{x_i, \neg x_i \mid i \in I, x_i \notin A\} \cup \{\beta, \neg\beta\})$. Since $\varphi' \wedge \bigwedge E' \wedge \mathsf{F}(q')$ is unsatisfiable and q' occurs only in the constraint $\mathsf{SymOR}_{2,1}(\beta, q, q')$, we know that $\varphi' \wedge \bigwedge E' \wedge \mathsf{OR}_{2,1}(q, \beta)$ is unsatisfiable. Indeed, otherwise there would be a model of $\varphi' \wedge \bigwedge E'$ satisfying $\mathsf{OR}_{2,1}(q, \beta) \wedge \mathsf{F}(q')$ (precisely, a model m of $\varphi' \wedge \mathsf{OR}_{2,1}(q, \beta)$ with $m(q')$ changed to 0). We conclude that every model of $\varphi' \wedge \bigwedge E'$ satisfies $\mathsf{T}(q) \wedge \mathsf{F}(\beta)$, and thus $\mathsf{F}(x_i)$ for every $i \in I$. Hence on one hand, every model of $\varphi' \wedge \bigwedge E'$ is a model of $\varphi \wedge \bigwedge E$, which is thus satisfiable. On the other hand, in order to obtain a contradiction, suppose that $\varphi \wedge \bigwedge E \wedge \mathsf{F}(q)$ is satisfiable and let m be a model. Then m satisfies $\mathsf{F}(x_i)$ for every $i \in I$, and thus satisfies $\varphi_0 \wedge \mathsf{F}(q) \wedge \bigwedge E'$. It is easily seen that, adding $m(\beta) = m(q') = 0$ to m, one gets a model of $\varphi' \wedge \bigwedge E' \wedge \mathsf{F}(q')$, which contradicts the fact that E' is a solution. □

Appendix D. Proof of Lemma 27. The first point is Schaefer's result [25]. The third and fifth ones are given in [7, Lemma 5.41].

(Second claim.) First remark that $L \cup \{\mathsf{T}\}$ is neither 0-valid nor 1-valid nor complementive. Thus by the first claim $L \cup \{\mathsf{T}\}$ can implement every Boolean relation. Consider the ternary relation $R = \{000, 100, 110\}$; since $L \cup \{\mathsf{T}\}$ can implement every Boolean relation there is an L-formula φ_0 over $V \cup \{x, y, z, t\}$ with

$$R(x, y, z) \equiv \exists V \ \exists t, \varphi_0 \wedge \mathsf{T}(t).$$

Note that we assume without loss of generality that there is only one constraint involving the relation T, since we can replace all the variables that are in the scope of such a constraint with t (noting that none involves any of x, y, z because $000 \in R$). By construction the 4-ary relation R' defined by $R'(x, y, z, t) = \exists V \varphi_0$ contains 0001, 1001, and 1101; moreover, since it is complementive (because so is L) it also contains 1110, 0110, and 0010. Now assume that there is another 4-ary vector $m = (m_x, m_y, m_z, m_t)$ in R'; then if $m_t = 1$, we should have $(m_x, m_y, m_z) \in R$, which is false by assumption. Now if $m_t = 0$, by complementivity of L we should have $(m_x \oplus 1, m_y \oplus 1, m_z \oplus 1, m_t \oplus 1) \in R'$ and thus $(m_x \oplus 1, m_y \oplus 1, m_z \oplus 1) \in R$, which is false as well. It is finally easily seen that the formula $\exists t R'(x, y, z, t)$ is logically equivalent to the formula $\mathsf{SymOR}_{2,1}(x, y, z)$, which concludes the proof.

(Fourth claim.) Since L is not Schaefer there are three relations R, R', and R'' in L that are, respectively, non–dual Horn, non-Horn, and nonaffine. Thus because of the closure properties given in the preliminaries there are two vectors $m_1 = 1^a 1^b 0^c 0^d, m_2 = 1^a 0^b 1^c 0^d \in R$ such that $m_1 \vee m_2 = 1^a 1^b 1^c 0^d \notin R$, where, e.g., 1^a indicates that the value 1 is repeated a times; by identifying the components of those vectors we can see that R implements some 4-ary relation R_0 with $1100, 1010 \in R_0$

and $1110 \notin R_0$. (Note that we can assume $a, b, c, d \neq 0$ since we can introduce auxiliary, unconstrained variables and check that the assumptions remain true.) In the same manner, the non-Horn relation R' implements some 4-ary relation R'_0 with $1100, 1010 \in R'_0$ and $1000 \notin R'_0$, and finally the 1-valid but nonaffine relation R'' satisfies $\exists m_1, m_2 \in R'', m_1 \oplus m_2 \oplus 1 \ldots 1 \notin R''$ [7, Lemma 4.10], from which we derive as before that R'' implements some 4-ary relation R''_0 with $1100, 1010 \in R''_0$ and $1001 \notin R''_0$. Now consider the ternary relation R_1 defined by

$$R_1(x, y, z) = \exists t, R_0(t, x, y, z) \wedge R'_0(t, x, y, z) \wedge R''_0(t, x, y, z) \wedge \mathsf{T}(t).$$

By construction, $111, 100, 010 \in R_1$ and $110, 000, 001 \notin R_1$. Now consider the ternary relation R''' defined by

$$R'''(x, y, z) = \exists t, u, R_1(t, x, y) \wedge R_1(t, z, u).$$

It is easily seen that $111, 110, 001, 000, 101 \in R'''$ and that $100 \notin R'''$. Observe that if $010 \in R'''$, then so does 011. Indeed, if $010 \in R'''$, then either $001 \in R_1$ or $101 \in R_1$, and since $001 \notin R_1$ we have $101 \in R_1$, and it is then easily seen that $011 \in R'''$. Therefore, there remain only two cases to discuss: either $011 \in R'''$, or both $011 \notin R'''$ and $010 \notin R'''$. In the first case we have

$$\mathsf{OR}_{3,1}(x, y, z) \exists u_1 R'''(x, u_1, u_1) \wedge R'''(u_1, y, z),$$

in the second

$$\mathsf{OR}_{3,1}(x, y, z) \exists u_1 \exists u_2 \exists u_3 \exists u_4 R'''(x, u_1, u_2) \wedge R'''(y, u_1, u_3) \wedge R'''(z, u_2, u_4).$$

We conclude that $L \cup \{\mathsf{T}\}$ implements $\mathsf{OR}_{3,1}$. Since L is 1-valid but not 0-valid, L implements T, and we finally deduce that L implements $\mathsf{OR}_{3,1}$. □

FULL CONSTRAINT SATISFACTION PROBLEMS*

TOMÁS FEDER† AND PAVOL HELL‡

Abstract. Feder and Vardi have conjectured that all constraint satisfaction problems to a fixed structure (constraint language) are polynomial or NP-complete. This so-called dichotomy conjecture remains open, although it has been proved in a number of special cases. Most recently, Bulatov has verified the conjecture for conservative structures, i.e., structures which contain all possible unary relations. We explore three different implications of Bulatov's result. First, the above dichotomy can be extended to so-called inclusive structures, corresponding to conservative constraint satisfaction problems in which each variable comes with its own domain. (This has also been independently observed by Bulatov.) We prove a more general version, extending the dichotomy to so-called three-inclusive structures, i.e., structures which contain, with any unary relation R, all unary relations R' for subsets $R' \subseteq R$ with at most three elements. For the constraint satisfaction problems in this generalization we must restrict the instances to so-called 1-full structures, in which each variable is involved in a unary constraint. This leads to our second focus, which is on restrictions to more general kinds of "full" input structures. For any set W of positive integers, we consider a restriction to W-full input structures, i.e., structures in which, for each $w \in W$, any w variables are involved in a w-ary constraint. We identify a class of structures (the so-called W-set-full structures) for which the restriction to W-full input structures does not change the complexity of the constraint satisfaction problem, and hence the family of these restricted problems also exhibits dichotomy. The general family of three-inclusive constraint satisfaction problems restricted to W-full input structures contains examples which we cannot seem to prove either polynomial or NP-complete. Nevertheless, we are able to use our result on the dichotomy for three-inclusive constraint satisfaction problems, to deduce the fact that all three-inclusive constraint satisfaction problems restricted to W-full input structures are NP-complete or "quasi-polynomial" (of order $n^{O(\log n)}$). Our third focus deals with bounding the number of occurrences of a variable, which we call the degree. We conjecture that the complexity classification of three-inclusive constraint satisfaction problems extends to the case where all degrees are bounded by three. Using previous results, we are able to verify this conjecture in a number of special cases. Conservative, inclusive, and three-inclusive constraint satisfaction problems can be viewed as problems in which each variable is restricted to a "list" of allowed values. This point of view of lists is frequently encountered in the study of graph colorings, graph homomorphisms, and graph partitions. Our results presented here, in all three areas, were strongly motivated by these results on graphs.

Key words. constraint satisfaction problems, dichotomy conjecture, conservative constraint satisfaction problems, full constraint satisfaction problems, graph homomorphisms, list homomorphisms, matrix partitions, bounded degrees, NP-complete problems, quasi-polynomial algorithms

1. Introduction.

A large class of problems in artificial intelligence and other areas of computer science can be viewed as *constraint satisfaction problems* [8, 31, 32, 33, 34, 40]. These include problems in machine vision, belief maintenance, scheduling, temporal reasoning, type reconstruction, graph theory, and satisfiability.

The standard formulation of the constraint satisfaction problem goes back to Montanari [36] in 1974. This framework has proved its value over the years by its wide-ranging applicability [8, 39]. The constraint satisfaction in its full generality is NP-complete. Thus constraint satisfaction problems have been studied under various

restrictions. The main model [20] considers constraint satisfaction problems with a fixed template determining the size of the domain and the set of allowed constraint types in an instance.

Formally, a *vocabulary* V is a set of pairs (R_i, ℓ_i), where the R_i are *relation names* and the ℓ_i are *relation arities*. A *structure* S *over the vocabulary* V consists of a set (called the *domain*) D, together with a collection of relations $R_i \subseteq D^{\ell_i}$, one ℓ_i-ary relation R_i for each pair (R_i, ℓ_i) in V. We say that the structure S is an *interpretation* of the vocabulary V and emphasize this, if necessary, by writing V^S instead of S. We also write the domains and relations as D^S and R_i^S, to indicate the structure in which they are being interpreted.

The *constraint satisfaction problem* $CSP(H)$ (or $CSP(V^H)$) for a fixed structure $H = V^H$ over a vocabulary V is given as follows. An *instance* of $CSP(H)$ is a structure V^G over the same vocabulary V. The *question* asked by $CSP(H)$ is whether or not there exists a *homomorphism* f of G to H, that is, a mapping $f : D^G \to D^H$ such that if $(x_1, \ldots, x_{\ell_i}) \in R_i^G$, then $(f(x_1), \ldots, f(x_{\ell_i})) \in R_i^H$ for all choices of $x_i \in D^G$ and $(R_i, \ell_i) \in V$. We shall speak of the elements x_i of D^G as *variables*, constrained by the relations R_i^G to be assigned suitable *values* $f(x_i)$ in D^H, as allowed by the constraints R_i^H.

This model was studied in its full generality by Feder and Vardi [20], who found evidence toward the following *dichotomy conjecture.*

Conjecture 1.1. *For each fixed structure H, the problem $CSP(H)$ is NP-complete or polynomial time solvable.*

(Recall that it is known that if P $\neq$ NP, there are problems in NP that are neither NP-complete nor polynomial [30].) This conjecture was supported by earlier classifications that exhibited dichotomies. Schaefer [38] classified the complexity of Boolean constraint satisfaction problems, i.e., problems $CSP(H)$ with a two-element domain $D^H = \{0, 1\}$. In essence, the polynomial cases consist of Horn or anti-Horn clauses, two-satisfiability, and linear equations modulo two. The remaining constraint satisfaction problems $CSP(H)$ for a two-element domain D^H are all NP-complete. Bulatov classified constraint satisfaction problems on a three-element domain [3]. Hell and Nešetřil [26] classified the complexity of constraint satisfaction problems $CSP(H)$ where $H = V^H$ is a graph (with loops allowed). In other words, V consists of one pair $(R, 2)$, and the relation R^H is symmetric. They showed that this so-called *H-coloring problem* is polynomial if H is bipartite or has a loop and is NP-complete otherwise. Such a result is not known for digraphs (structures V^H in which R^H is not necessarily symmetric) [1, 20]. In fact, Feder and Vardi [20] have shown that dichotomy for digraph H-coloring problems would imply the validity of the entire dichotomy conjecture.

For this paper, the most relevant special case where the conjecture has been proved is the following result. We say that a structure H is *conservative* if it contains a unary relation R for each subset R of the domain D^H. We shall denote the set of unary relation names (names R involved in pairs $(R, 1)$) of a vocabulary V by $\mathcal{U}(V)$, and also denote the set of the corresponding relations R^H in a structure $H = V^H$ by $\mathcal{U}(V^H)$ (or just $\mathcal{U}(H)$). (Thus the vocabulary V of a conservative structure V^H with $|D^H| = n$ has $|\mathcal{U}(V)| = 2^n$, and $\mathcal{U}(V^H)$ is precisely the power set of D^H.) Bulatov [2] proved that dichotomy holds for all conservative structures, i.e., that *for every conservative structure H, the problem $CSP(H)$ is NP-complete or polynomial time solvable.* His approach is based on tools and techniques of universal algebra [2, 3, 4, 5, 28, 29]. Problems $CSP(H)$, for conservative structures H, will be called

conservative constraint satisfaction problems.

An alternative interpretation of Bulatov's result is the following. Suppose H is a conservative structure; we may restrict $CSP(H)$ to those input structures G that contain each variable $v \in D^G$ in some unary relation. Such structures G will be called 1-*full*. The restriction of $CSP(H)$ to 1-full instances G will be denoted by $CSP_1(H)$. Since H is conservative this is not a real restriction, as there exists in $\mathcal{U}(V)$ a pair $(R, 1)$ with the corresponding unary relation R^H equal to D^H. Thus the relation R^G can be imposed an any variable in D^G without changing the problem, and so $CSP(H)$ and $CSP_1(H)$ are equivalent problems. On the other hand, $CSP_1(V^H)$ is easily seen to be equivalent to the following *list constraint satisfaction problem*. The *instance* is a structure V^G in which each variable $v \in D^G$ is equipped with a list $L(v) \subseteq D^H$, and the *question* is whether or not there exists a homomorphism f of G to H such that each $f(v)$ belongs to $L(v)$. List constraint satisfaction problems have been extensively studied in the case when H is a graph. The problem is polynomial if H is a so-called bi-arc graph and is NP-complete otherwise [12, 13, 14, 15, 16]. Let C be a fixed circle with two specified points p and q. A graph H (with loops allowed) is called a *bi-arc graph* if there exist pairs of arcs (N_x, S_x), $x \in V(H)$, with each N_x being an arc on C containing p but not q, and each S_x being an arc on C containing q but not p, so that for any $x, y \in V(H)$, not necessarily distinct, the following hold:

- either N_x intersects S_y and N_y intersects S_x, or N_x does not intersect S_y and N_y does not intersect S_x;
- N_x intersects S_y (and N_y intersects S_x) if and only if x and y are not adjacent in H.

This class of graphs conveniently generalizes both the class of interval graphs, and the class of (complements of) circular arc graphs of clique covering number two [14, 22].

List constraint satisfaction problems involving multiple binary relations were studied by Feder, Madelaine, and Stewart [19].

Let us say that a structure H is *inclusive* if for any $R \in \mathcal{U}(H)$ and any $R' \subseteq R$ we also have $R' \in \mathcal{U}(H)$. Note that each conservative structure is inclusive. It was independently observed by the present authors, and by Bulatov, that the above result for conservative structures H extends to all inclusive structures in the following sense. *For every inclusive structure H, the problem $CSP_1(H)$ is NP-complete or polynomial time solvable.* Since for conservative structures H the problems $CSP_1(H)$ and $CSP(H)$ are equivalent, this extends the original result of Bulatov [2]. It is easy to interpret this result as the dichotomy of a list constraint satisfaction problem where the variables range over multiple domains. In this context, Feder has previously classified a family of list problems involving multiple Boolean domains [10].

We prove in this paper a more general version of the dichotomy for inclusive structures. We say that a structure H is *three-inclusive* if for any $R \in \mathcal{U}(H)$ and all $R' \subseteq R$ with $|R'| \leq 3$ we also have $R' \in \mathcal{U}(H)$. Thus each inclusive (and hence each conservative) structure is also three-inclusive. We shall prove that *for any three-inclusive structure H, the problem $CSP_1(H)$ is NP-complete or polynomial time solvable.* Problems $CSP_1(H)$, for three-inclusive structures H, will be called *three-inclusive constraint satisfaction problems.*

Three-inclusive structures H are the main focus of this paper. Note that a structure H without unary relations is three-inclusive (in fact inclusive) and thus proving dichotomy for $CSP(H)$ would yield dichotomy for digraph H-coloring problems and hence the entire dichotomy conjecture. Therefore we restrict the instances G as well. The restriction $CSP_1(H)$ mentioned above is one natural way—restricting to 1-full

instances G amounts to assuming the inputs are equipped with lists, as described above. Thus requiring H to be three-inclusive and G to be 1-full gives the three-inclusive constraint satisfaction problem $CSP_1(H)$ that is the connecting thread of our paper. (We then consider further restrictions on both G and H.)

This suggests looking at other versions of "fullness." Let W be a set of positive integers such that $1 \in W$, and let V be a vocabulary which contains at least one pair (R, w) for each $w \in W$. We shall say that a structure $G = V^G$ is *W-full* if for each $w \in W$, and any distinct variables $x_1, x_2, \ldots, x_w$ in D^G, there exist a permutation σ of $\{1, 2, \ldots, w\}$ and a pair (R, w) in V, such that $(x_{\sigma(1)}, \ldots, x_{\sigma(k)}) \in R^G$. Note that the notion of a 1-full structure coincides with the notion of a W-full structure with $W = \{1\}$. We shall also focus on the next natural special case when $W = \{1, 2\}$; in this case we simply say that a W-full structure is *pairwise full* (remembering that, despite the suggestive name, it is assumed to be at the same time 1-full and 2-full). The problem $CSP_W(H)$ is the restriction of $CSP(H)$ to W-full instances G.

A W-full structure $G = V^G$ is *strictly W-full* if the above permutation σ and relation R are unique for each $w \in W, w \geq 2$, and any distinct variables $x_1, x_2, \ldots, x_w$ in D^G. The restriction of $CSP(H)$ to strictly W-full instances G will be denoted by $CSP^*_W(H)$. The notion of *strictly pairwise full* structure refers to, as would be expected, a strictly W-full structure with $W = \{1, 2\}$. A graph G (with loops allowed) can be viewed as a strictly pairwise full structure with two binary relations, corresponding to the edges and the nonedges of G. (To conform to the definition as given, we choose an arbitrary orientation of G, i.e., consider each edge uv of G as an oriented arc—either $\vec{uv}$ or $\vec{vu}$—and consider each nonedge in a similar manner.) Under this interpretation, the problems $CSP^*_{\{1,2\}}(H)$ have been studied as *list matrix partition problems* [6, 18, 17, 23, 27]. (The structures H are usually taken to be conservative structures with two binary relations whose union is $(D^H)^2$.)

After the work of Jeavons [28] and Jeavons, Cohen, and Gyssens [29], it is usual, when studying the complexity of $CSP(H)$, to consider the relations "definable in H" along with the relations of H. The properties of structures considered in this paper are somewhat fragile with respect to adding definable relations. Thus to convert a $CSP(H)$ problem to a full problem $CSP_W(H)$, one needs to add to H relations of the arities in W that hold for all tuples of elements in D. To convert a full problem $CSP_W(H)$ further to a strict problem $CSP^*_W(H)$ one needs to further add to H relations of each arity in W corresponding to intersection of relations of this arity in H.

This family of (strictly) full problems is not directly under the scope of the dichotomy conjecture, and many problems in this class resist attempts at classification [6, 18, 23]. Consider, for instance, the following problem: The vocabulary V consists of eight unary relation names U_i (in other words, V contains eight pairs $(U_i, 1)$) and three binary relation names R_0, R_1, R_2 (additional pairs $(R_0, 2), (R_1, 2), (R_2, 2)$ in V). Now consider the structure V^H with domain $D = D^H = \{0, 1, 2\}$, where the interpretations of the three binary relations are $R^H_j = D^2 - (j, j)$ for $j = 0, 1, 2$, and the eight unary relations correspond to the eight subsets of D. (Assume that U_7 is the relation name for which $U^H_7 = D^H$.) The complexity of $CSP^*_{\{1,2\}}(H)$ is not known. It will follow from Theorem 3.2 that the problem can be solved in quasi-polynomial time $n^{O(\log n)}$ (where $n = |D^G|$). We first illustrate the idea of the recursive algorithm from the proof of Theorem 3.2. For simplicity, we shall assume that the instance V^G has all variables only in the unary relation U^G_7 (having the lists D^H), which does not restrict them in any way. (It is easy to argue that this version is equivalent to the original problem.) Thus we want to solve the following combinatorial problem.

Given a complete graph G with edges colored $0, 1, 2$, can the vertices also be colored by $0, 1, 2$ so that there is no monochromatic edge (an edge of color i, both of whose endpoints are also colored i)?

For each vertex x of G we choose a *majority color* $m(x)$ from $0, 1, 2$, with the property that at least a third of the edges incident to x have color $m(x)$. Suppose G has n vertices. We reduce the problem for G to $n + 1$ subproblems as follows. In the first subproblem we assume no vertex x obtains its majority color. In the remaining n subproblems we assume, for each vertex x in turn, that (at least) x obtains its majority color. The first subproblem leaves us with two choices of color for each vertex, with all constraints expressible as clauses with two variables, and hence can be solved by a two-satisfiability algorithm. Each of the other n problems yields a vertex that has been colored, and hence can be removed from the graph; moreover, this implies, for all vertices y adjacent to x along edges of the color $m(x)$, that $m(x)$ is not a legal choice of color for y. In the general step, we have some vertices with lists (of allowed values) of size two and some with lists of size three; we define the majority color $m(x)$ to be the color of at least one-third of the edges from x to vertices with lists of size three. Therefore the time to solve a problem with p vertices with lists of size three is

$$T(p) \leq (1 + pT(2p/3)) \cdot T_2(n),$$

where $T_2(n)$ is the (polynomial) time to solve the two-satisfiability problem arising from n vertices. The recurrence implies that $T(n)$ is quasi-poynomial $n^{O(\log n)}$. Despite the simplicity of this algorithm we have not been able to find a polynomial time algorithm. We have, however, obtained an algorithm of time complexity $n^{O(\log n/\log\log n)}$ [18].

The analogous problem with colors $0, 1$ corresponds to the well-known graph problem of recognition of *split graphs*, which has a simple polynomial time algorithm [22] (cf. also [24, 27]). When there are more than three colors, the problem is easily seen to be NP-complete. (Our problem can be shown to be no easier than the so-called *stubborn problem* from [6], which also resists classification.)

We shall conclude, using the dichotomy of $CSP(H)$ for three-inclusive structures, that *for a three-inclusive structure H, each problem $CSP_W(H)$ (respectively, $CSP^*_W(H)$) is NP-complete or solvable in quasi-polynomial time $n^{O(\log n)}$.* Thus we obtain a new kind of dichotomy—not between problems that are NP-complete and those that are solvable in polynomial time, but between problems that are NP-complete and those that are solvable in quasi-polynomial time. For convenience and brevity we shall call such a result a *quasi-dichotomy*. Our interest in quasi-dichotomy is motivated by arguments similar to those for dichotomy. It is generally expected that no NP-complete problem admits a quasi-polynomial algorithm, and if one NP-complete problem admitted such an algorithm, then so would all others. The relationship between the dichotomy conjecture and quasi-dichotomies was previously studied in the case of list matrix partition problems by Feder, Hell, Klein, and Motwani [17].

Megiddo and Vishkin [35] studied a problem on tournaments that has a quasi-polynomial algorithm. The problem asks for a minimum size dominating set in a tournament on n vertices. A minimum size dominating set always has at most $\log n$ vertices, so the problem can be solved in time $n^{O(\log n)}$. Megiddo and Vishkin showed that the problem of solving a satisfiability instance with $\log^2 n$ variables and n clauses reduces to the dominating set problem in tournaments. Papadimitriou and Yannakakis [37] showed that the dominating set problem for tournaments is complete for

the class $LOGSNP$, with the containment of classes $LOGSNP \subseteq LOGNP$, and both classes reduce in polynomial time to problems in $NP[\log^2 n] \cap DSPACE(\log^2 n)$. Here $NP[\log^2 n]$ is the class of problems that can be solved in nondeterministic polynomial time with only $O(\log^2 n)$ bits of nondeterminism.

The classes $LOGNP$ and $LOGSNP$ are classes of problems in NP involving guessing only $\log n$ elements in an n-element input structure I. More formally, the classes are defined by setting $LOGNP_0$ to be defined by a formula $\{I : \exists S \in [n]^{\log n}\ \forall x \in [n]^p\ \exists y \in [n]^q\ \forall j \in [\log n]\phi(I, s_j, x, y, j)\}$ and setting $LOGSNP_0$ to be defined by a formula $\{I : \exists S \in [n]^{\log n}\ \forall x \in [n]^p\ \exists j \in [\log n]\phi(I, s_j, x, j)\}$, where the S in $LOGSNP_0$ means *strict*, I is an input relation, x, y are tuples of first order variables ranging over $[n] = \{1, \ldots, n\}$, and ϕ is a quantifier-free first order expression. We then define $LOGNP$ to be the class of all languages that can be polynomially reduced to a problem in $LOGNP_0$, and similarly for $LOGSNP$ and $LOGSNP_0$.

All our quasi-polynomial algorithms involve guessing $O(\log n)$ vertices and $O(\log n)$ additional bits of information (thus with $O(\log^2 n)$ bits of nondeterminism) and then solving a resulting problem in deterministic polynomial time. Our quasi-polynomial problems are thus in $NP[\log^2 n]$. However, some of these problems are complete for P and are thus unlikely to be in $DSPACE(\log^2 n)$.

We shall also observe that constraint satisfaction problems for three-inclusive H show an interesting structure when the degree of the variables, i.e., the number of occurrences of each variable, is bounded. With maximum degree two, Boolean constraint satisfaction can express matching and delta-matroid intersection [7, 9, 11], while with maximum degree three it is the same as with unbounded degree. Similar results on degree restrictions for the case of graphs can be found in [15, 21, 25].

We conjecture that every three-inclusive list constraint satisfaction problem that is NP-complete remains NP-complete when restricted to degree three instances. Using existing results we verify this conjecture in four particular families of three-inclusive list constraint satisfaction problems.

A structure V^H is *W-set-full* if it is three-inclusive and if for any $w \in W$ and any (not necessarily distinct) pairs $(S_1, 1), \ldots, (S_w, 1)$ in V such that each $|S_i^H| \leq 3$ for $1 \leq i \leq w$, there exists a pair (R, w) in V and a permutation σ on $\{1, \ldots, w\}$, such that $S^H_{\sigma(1)} \times \cdots \times S^H_{\sigma(w)} \subseteq R^H$. These W-set-full structures H define *W-set-full constraint satisfaction problems* $CSP_W(H)$ and $CSP^*_W(H)$, which will turn out to be equivalent to the corresponding constraint satisfaction problem $CSP_1(H)$ and hence exhibit dichotomy just like the three-inclusive constraint satisfaction problems. When $W = \{1, 2\}$, we call a W-set-full structure (and problem) *pairwise-set-full*.

The *degree of x in a tuple $t = (t_1, \ldots, t_k)$* is the number of t_i that are equal to x. The *degree of x in a relation R_i* is the sum of the degrees of x in the tuples in R_i. The *degree of x in a structure G* is the sum of the degrees of x in the relations R_i of arity $\ell_i \geq 2$ in G. The *degree of a structure G* is the maximum degree of the elements of D^G in G.

2. Three-inclusive constraint satisfaction problems. A *polymorphism* of a structure H with domain $D = D^H$ is a mapping $g : D^k \to D$ such that for all relations R_i^H and all tuples $(x_{1j}, \ldots, x_{\ell_i j}) \in R_i^H$, for $1 \leq j \leq k$, we have $(y_1, \ldots, y_{\ell_i}) \in R_i^H$ for $y_t = g(x_{t1}, \ldots, x_{tk})$. Jeavons [28] showed that the complexity of a constraint satisfaction problem $CSP(H)$ is characterized, up to polynomial time reductions, by the complete set of polymorphisms that H has.

Bulatov [2] classified conservative constraint satisfaction problems $CSP(H)$ as polynomial or NP-complete. The polynomial cases are characterized by the existence

of three polymorphisms of H, namely $g_1 : D^2 \to D$, $g_2 : D^3 \to D$, and $g_3 : D^3 \to D$, satisfying the following properties:

(1) g_1, g_2, g_3 are *conservative*; that is, $g_1(x, y) \in \{x, y\}$, $g_2(x, y, z) \in \{x, y, z\}$, and $g_3(x, y, z) \in \{x, y, z\}$ for all $x, y, z \in D$.

For each $a, b \in D$ with $a \neq b$, at least one of the following holds:

(2) g_1 is *commutative* on $\{a, b\}$; that is, $g_1(a, b) = g_1(b, a) \in \{a, b\}$;

(3) g_2 is *majority* on $\{a, b\}$; that is, $g_2(a, a, a) = g_2(a, a, b) = g_2(a, b, a) = g_2(b, a, a) = a$ and $g_2(b, b, b) = g_2(b, b, a) = g_2(b, a, b) = g_2(a, b, b) = b$; and

(4) g_3 is *minority* on $\{a, b\}$; that is, $g_3(a, a, a) = g_3(a, b, b) = g_3(b, a, b) = g_3(b, b, a) = a$ and $g_3(b, b, b) = g_3(b, a, a) = g_3(a, b, a) = g_3(a, a, b) = b$.

Using this classification, we can now prove dichotomy of three-inclusive constraint satisfaction problems $CSP_1(H)$.

THEOREM 2.1. *If H is three-inclusive, then the constraint satisfaction problem $CSP_1(H)$ is polynomial time solvable or NP-complete.*

Proof. Let H be a three-inclusive structure; we define three auxiliary structures H^*, H', H'' on the same domain $D^{H^*} = D^{H'} = D^{H''} = D^H = D$, as follows.

- The structure H^* is obtained from H by replacing each nonunary relation R_i of H by the relations $R_i^a = R_i \cap (T_1 \times \cdots \times T_{\ell_i})$ for each choice a of unary relations $T_1, \ldots, T_{\ell_i} \in \mathcal{U}(H)$.
- The structure H' is obtained from H by removing all unary relations $S \in \mathcal{U}(H)$ with $|S| > 3$, and replacing each nonunary relation R_i of H by the relations R_i^a for each choice a of unary relations of the new structure H' (thus all $|T_i| \leq 3$).
- The structure H'' is obtained from H' by adding all missing unary relations S, so that $\mathcal{U}(H'')$ is the power set of D.

We note that all these structures are three-inclusive and that H'' is conservative. (Also observe that the three structures are over different vocabularies.)

We first prove that $CSP_1(H)$ and $CSP(H^*)$ are polynomially equivalent problems. To reduce $CSP_1(H)$ to $CSP(H^*)$, we transform an instance G of $CSP_1(H)$ to an instance G^* of $CSP(H^*)$; the structure G^* is obtained from G in a way similar to how H^* is obtained from H. (Each nonunary relation R_i is replaced by the relations R_i^a.) It is easy to see that a homomorphism of G to H is also a homomorphism of G^* to H^*. On the other hand, it is also the case that a homomorphism of G^* to H^* is a homomorphism of G to H, since G is 1-full. Thus G has a solution in $CSP_1(H)$ if and only if G^* has a solution in $CSP(H^*)$. To reduce $CSP(H^*)$ to $CSP_1(H)$, we transform an instance G of $CSP(H^*)$ to an instance G' of $CSP_1(H)$ obtained from G as follows. If a variable x is not constrained in G (does not appear in any relation), we remove it. For each $(x_1, x_2, \ldots, x_{\ell_i}) \in R_i^a$ in G, we impose the constraint $(x_1, x_2, \ldots, x_{\ell_i}) \in R_i$ as well as the unary constraints $x_i \in T_i$, $i = 1, \ldots, \ell_i$, in G'. It follows that G' is 1-full, i.e., an instance of $CSP_1(H)$; it is again easy to check that G has a solution in $CSP(H^*)$ if and only if G' has a solution in $CSP_1(H)$.

Since H'' is conservative, we know by [2] that the problem $CSP(H'')$ is polynomial time solvable (if there are polymorphisms g_1, g_2, g_3 of H'' as described above) or NP-complete. If $CSP(H'')$ is polynomial, then the three polymorphisms g_1, g_2, g_3 of H'' are also polymorphisms of H', as all relations in H' are in H''. (In particular, $CSP(H')$ is also polynomial.) Moreover, in this case, g_1, g_2, g_3 are also polymorphisms of H^*, and hence $CSP(H^*)$ is also polynomial. Indeed, consider a relation R_i^a of H^*, where a is the choice of unary relations $T_1, T_2, \ldots, T_{\ell_i} \in \mathcal{U}(H)$. Suppose $x = (x_1, \ldots, x_{\ell_i})$, $y = (y_1, \ldots, y_{\ell_i})$, and $z = (z_1, \ldots, z_{\ell_i})$ are in R_i^a. Let a' be the choice

of unary relations $T'_1, T'_2, \ldots, T'_{\ell_i} \in \mathcal{U}(H)$, where each $T'_i = \{x_i, y_i, z_i\}$. Since each $T'_i \subseteq T_i$ and H is three-inclusive, each $T'_i \in \mathcal{U}(H)$ and hence also $T'_i \in \mathcal{U}(H')$. Thus x, y, z are also in $R_i^{a'}$, and, since g_1, g_2, g_3 are polymorphisms of H', we must also have $(g_1(x_1, y_1), \ldots, g_1(x_{\ell_i}, y_{\ell_i})) \in R_i^{a'}$, $(g_2(x_1, y_1, z_1), \ldots, g_2(x_{\ell_i}, y_{\ell_i}, z_{\ell_i})) \in R_i^{a'}$, and $(g_3(x_1, y_1, z_1), \ldots, g_3(x_{\ell_i}, y_{\ell_i}, z_{\ell_i})) \in R_i^{a'}$. Since $R_i^{a'} \subseteq R_i^a$, g_1, g_2, g_3 are also polymorphisms of H^*, whence $CSP(H^*)$ (and $CSP_1(H)$) is polynomial.

Suppose instead $CSP(H'')$ is NP-complete. We will reduce $CSP(H'')$ to $CSP(H')$ and then to $CSP(H^*)$, proving that $CSP(H^*)$ (and $CSP_1(H)$) is also NP-complete. Given an instance G of $CSP(H'')$, we may assume that each variable x is constrained by some nonunary relation of G. (If a variable x is only in unary relations of G, then either the intersection of all the subsets of H corresponding to these unary relations is empty, in which case there is no solution, or the intersection is nonempty, and assigning any value from the intersection to x allows us to remove x from consideration.) Thus each variable x of G occurs in some jth position in some R_i^a in H', where a is the choice of some unary relations $T_1, T_2, \ldots, T_{\ell_i}$ with $|T_j| \leq 3$. We form G_1 from G by replacing each unary relation T containing x which is in H'' but not in H' by the unary relation $T' = T \cap T_j$ for x. Note that T' is a relation of H', since $T' \subseteq T_j$. It is easy to see that G_1 has a solution for $CSP(H')$ if and only if G has a solution for $CSP(H'')$. Therefore $CSP(H')$ is NP-complete. The final reduction from $CSP(H')$ to $CSP(H^*)$ is trivial, as each instance G of $CSP(H')$ is also an instance of $CSP(H^*)$. Therefore $CSP(H^*)$ (and $CSP_1(H)$) is also NP-complete. □

Let us call a structure H *subunary* if each nonunary relation R_i of H is included in some product $T_1 \times T_2 \times \cdots \times T_{\ell_i}$ of unary relations $T_1, T_2, \ldots, T_{\ell_i} \in \mathcal{U}(H)$. The structure H^* in the above proof is subunary, and this was the only property used in the proof. Thus we have also proved the following fact.

COROLLARY 2.2. *If H is a subunary three-inclusive structure, then $CSP(H)$ is polynomial or NP-complete.*

The above proof also shows that two structures which differ only in their unary relations S with $|S| > 3$ have the same behavior for CSP_1.

COROLLARY 2.3. *If H and K are three-inclusive structures on the same domain $D^H = D^K$ with the same nonunary relations and the same unary relations S with $|S| \leq 3$, then $CSP_1(H)$ and $CSP_1(K)$ are both NP-complete or both polynomial.*

Proof. In the proof of Theorem 2.1, the problems $CSP_1(H)$ and $CSP_1(K)$ yield the same derived problems: $CSP(H') = CSP(K')$ and $CSP(H'') = CSP(K'')$. □

We can apply the theorem to the following *three-inclusive list H-coloring problem*, where H is a fixed graph (with loops allowed). *An instance* is a graph G, together with lists $L(v)$, $v \in V(G)$, of vertices of H, such that each $|L(v)| \leq 3$. The *question* is whether or not there exists a homomorphism f of G to H with each $f(v) \in L(v)$.

COROLLARY 2.4 (see [15]). *Each three-inclusive list H-coloring problem is NP-complete or polynomial time solvable.*

In fact, in [15] we classify exactly which three-inclusive list H-coloring problems are polynomial—they turn out to be the same bi-arc graphs defined above.

3. Restriction to pairwise full (and strictly pairwise full) instances. Our general goal is to study the restriction of three-inclusive constraint satisfaction problems to W-full instances. For simplicity we shall first state and prove our results in the special case where $W = \{1, 2\}$, i.e., for pairwise full instances G. The general case will be treated in the next section, mostly just by pointing out the extra effort required.

We begin by observing that each three-inclusive constraint satisfaction problem $CSP_1(H)$ can be viewed as the restricted problem $CSP_{\{1,2\}}(H')$, where H' is obtained from H by adding the binary relation $D^H \times D^H$ (and the binary relation $D^G \times D^G$ to any instance G, without changing the problem). We prove a strong converse to this observation; in particular, this will show that $CSP_{\{1,2\}}(H)$ and $CSP^*_{\{1,2\}}(H)$ enjoy dichotomy for pairwise-set-full structures H.

THEOREM 3.1. *Let H be a pairwise-set-full structure.*

The problems $CSP_{\{1,2\}}(H), CSP^*_{\{1,2\}}(H)$, and $CSP_1(H)$ are all polynomial or all NP-complete.

Proof. The problem $CSP_1(H)$ is polynomial or NP-complete by Theorem 2.1 because the pairwise-set-full structure H is by definition three-inclusive. Every instance of $CSP^*_{\{1,2\}}(H)$ is an instance of $CSP_{\{1,2\}}(H)$, and every instance of $CSP_{\{1,2\}}(H)$ is an instance of $CSP_1(H)$; thus if $CSP_1(H)$ is polynomial, then all three problems are polynomial.

If, on the other hand, $CSP_1(H)$ is NP-complete, then by Corollary 2.3 so is $CSP_1(K)$ where K is obtained from H by deleting all unary relations $S \in \mathcal{U}(H)$ with $|S| > 3$. Since each instance of $CSP_1(K)$ is 1-full, we can prove, along the lines of the first part of the proof of Theorem 2.1, that $CSP_1(K)$ is polynomially equivalent to $CSP_1(K')$ where K' is subunary. To simplify the notation, let us assume that K itself is subunary.

For every pair of variables x, y in an instance G of $CSP_1(K)$, we have x and y constrained by unary relations S^G and T^G, respectively, such that $|S^K|, |T^K| \leq 3$. Since H and hence also K are pairwise-set-full, there is a binary relation R^K such that $S^K \times T^K \subseteq R^K$. We may thus add the pair (x, y) to R^G without affecting the existence of a solution. Therefore, for every pair of variables x, y in this modified instance G', there exists a binary relation $R^{G'}$ such that $(x, y) \in R^{G'}$. Hence G' is an instance of $CSP_{\{1,2\}}(K)$ and also of $CSP_{\{1,2\}}(H)$, and thus $CSP_{\{1,2\}}(H)$ is NP-complete.

We can transform the instance G of $CSP_{\{1,2\}}(H)$ into an instance G' of $CSP^*_{\{1,2\}}(H)$, in which each pair (x, y) occurs in only one binary relation R_i, as one of $(x, y) \in R_i$ or $(y, x) \in R_i$. Let r be the number of binary relations in H. For the transformation we shall use an edge colored complete bipartite graph B with the following properties:

- B has s vertices in each part;
- each edge of B has one of $2r$ colors;
- between any $s/3$ vertices in one part of B and any $s/3$ vertices in the other part of B, there is an edge of each of the $2r$ colors.

Given B, we replace each variable x in the instance with s variables x_i. Two variables x and y are joined by some $k \leq 2r$ choices of binary relations out of the r binary relations with two possible choices of orientation (from x to y or from y to x) for these binary relations. We may thus join the x_i to the y_i with a bipartite graph obtained from B with edges of k colors, by replacing the remaining $2r - k$ colors with some of the k chosen colors. A variable x is constrained by a unary relation $S \subseteq D^H$ with $|S| \leq 3$, and since H is pairwise-set-full, there exists a binary relation R in H such that $S \times S \subseteq R$. We add the pairs (x_i, x_j) to R for all the copies x_i and x_j of x. We now have an instance G' of $CSP^*_{\{1,2\}}(H)$. In a solution, out of the s variables x_i, at least $s/3$ of them will have the same value from S, which can then be used as a value for the original variable x. The k binary relations involving x and y appear between the $s/3$ corresponding choices of x_i and the $s/3$ corresponding choices of y_i; a solution to G' gives a solution to G. This completes the reduction and shows that

$CSP^*_{\{1,2\}}(H)$ is NP-complete as well.

It remains to show that such a bipartite graph B exists for any r. (Note that we may choose s as large as we want.) Given a complete bipartite graph with s vertices on each side, assign a color out of $2r$ colors to each edge uniformly at random. The probability that two sets of size $s/3$ will miss one of the $2r$ colors is at most $2r(1-1/(2r))^{(s/3)^2}$, and the number of choices of such subsets is $\binom{s}{s/3}^2$; hence it suffices to choose s large enough so that $2r(1-1/(2r))^{(s/3)^2}\binom{s}{s/3}^2 < 1/2$ to guarantee that with probability at least $1/2$ the complete bipartite graph B will be assigned $2r$ edge colors with the desired property. (The quantity on the left is easily seen to converge to 0 with increasing s for any constant r.) □

Thus pairwise-set-full constraint satisfaction problems enjoy dichotomy when restricted to either the pairwise full or the strictly pairwise full instances G. We have not succeeded in obtaining a similar dichotomy for three-inclusive constraint satisfaction in general. We can, however, use Theorem 3.1 to obtain a quasi-dichotomy, because of the following result.

THEOREM 3.2. *Let H be a three-inclusive structure, and let $\mathcal{H}$ be the set of all pairwise-set-full structures H' with the same domain and the same nonunary relations as H, and such that each $S \in \mathcal{U}(H')$ with $|S| \le 3$ is also in $\mathcal{U}(H)$.*

If all $CSP_1(H')$ for $H' \in \mathcal{H}$ are polynomial, then both $CSP_{\{1,2\}}(H)$ and $CSP^*_{\{1,2\}}(H)$ are quasi-polynomial. If some $CSP_1(H')$ for $H' \in \mathcal{H}$ is NP-complete, then both $CSP_{\{1,2\}}(H)$ and $CSP^*_{\{1,2\}}(H)$ are NP-complete.

COROLLARY 3.3. *For each three-inclusive structure H, the problems $CSP_{\{1,2\}}(H)$ and $CSP^*_{\{1,2\}}(H)$ are both NP-complete or both quasi-polynomial.*

Proof. We shall focus on proving the theorem for $CSP_{\{1,2\}}(H)$; the proof for $CSP^*_{\{1,2\}}(H)$ is similar.

We shall transform $CSP_{\{1,2\}}(H)$ to problems $CSP_1(H')$ for $H' \in \mathcal{H}$ in such a way that if any of these problems is NP-complete, then so is $CSP_{\{1,2\}}(H)$. In the transformation, each instance G of $CSP_{\{1,2\}}(H)$ with n variables gives rise to $n^{O(\log n)}$ instances G' of problems $CSP_1(H')$, so that if all these problems are polynomial, then $CSP_{\{1,2\}}(H)$ is quasi-polynomial.

The problems $CSP_1(H')$ will have a pairwise-set-full structure H' obtained from H by repeatedly replacing certain unary relations S with all proper subsets $T \subset S$. In fact, each structure $H' \in \mathcal{H}'$ will be *strongly pairwise-set-full*, in the sense that it is three-inclusive and for any unary relations S_1, S_2 (not just those with $|S_i| \le 3$) there is a binary relation R with $S_1 \times S_2$ or $S_2 \times S_1$ contained in R.

To obtain these $n^{O(\log n)}$ instances G' (and the problems $CSP_1(H')$ to which they correspond), we proceed as follows. Let A and B be two subsets of D^H such that no binary relation of H contains $A \times B$ or $B \times A$. Since we want to make our structure strongly pairwise-set-full, we shall ensure that there is no $S \in \mathcal{U}(H)$ that contains A, or no $T \in \mathcal{U}(H)$ that contains B. (Later on, we shall keep ensuring this property for other pairs A, B of sets, on structures H' previously obtained from H.)

Let L be the set of variables (elements of D^G) which are in unary constraints S^G such that $A \subseteq S^H$, and let M be the set of variables (elements of D^G) in unary constraints T^G such that $B \subseteq T^H$. Let $\ell = |L|$, $m = |M|$, and let r again denote the number of binary relations in H. For every variable $v \in L$ there exists a binary relation R_i such that (v, w) or (w, v) is in R_i^G for at least $m/(2r)$ variables $w \in M$. We now transform the instance G of $CSP_{\{1,2\}}(H)$ (later on, the instance G' of the current $CSP_{\{1,2\}}(H')$) into $\ell + 1$ new problems. For each binary relation R_i we

choose variables $a_i, a_i' \in A$, $b_i, b_i' \in B$ so that $(a_i, b_i) \notin R_i^H, (b_i', a_i') \notin R_i^H$. In the first derived problem we change, for each variable $v \in L$, the unary constraint S^G to the unary constraint $S^G - a_i$ or $S^G - a_i'$, depending on whether R_i was chosen above for pairs (v, w) or (w, v). In the remaining ℓ derived problems, we change, for one variable $v \in L$, the constraint S^G to the constraint $\{a_i\}^G$ or $\{a_i'\}^G$, depending on whether R_i was chosen above for pairs (v, w) or (w, v). We also change, for all variables $w \in M$ such that (v, w) (respectively, (w, v)) is constrained by R_i^G, the constraint T^G to the constraint $T^G - b_i$ (respectively, $T^G - b_i'$). Recall that for each choice of v, the number of such variables w is at least $m/(2r)$. Thus an instance with $(|L|, |M|) = (\ell, m)$ has been replaced with one instance with $(|L|, |M|) = (0, m)$ and ℓ instances with $(|L|, |M|) = (\ell - 1, m(1 - 1/(2r)))$. Repeating this process $-\log m / \log(1 - 1/(2r)) = O(\log n)$ times, we obtain $n^{O(\log n)}$ instances that each have $\ell = 0$ or $m = 0$; that is, either no unary constraint contains A or no unary constraint contains B. The problem $CSP_{\{1,2\}}(H)$ is correspondingly replaced by problems $CSP_{\{1,2\}}(H')$. Note that no unary constraint in H' contains A or no unary constraint in H' contains B, and all the unary constraints in H' are subsets of unary constraints in H.

We repeat this process for each pair of sets (A, B) as above. In the end, we obtain $n^{O(\log n)}$ instances and corresponding structures H', such that H' is strongly pairwise-set-full. If all such $CSP_1(H')$ are polynomial, then we can solve each of these $n^{O(\log n)}$ resulting problems, obtaining a quasi-polynomial algorithm for $CSP_{\{1,2\}}(H)$. Otherwise, at least one such $CSP_1(H')$ is NP-complete. Let H'' be obtained from H' by removing all unary constraints $S^{H'}$ with $|S^{H'}| > 3$. By Corollary 2.3 the pairwise-set-full constraint satisfaction problem $CSP_1(H'')$ is also NP-complete; note that all the unary constraints of H'' are in $\mathcal{U}(H)$. By Theorem 3.1 the problem $CSP_{\{1,2\}}(H'')$ is also NP-complete, and its instances are also instances of the original problem $CSP_{\{1,2\}}(H)$; thus this problem is also NP-complete. □

Recall the list matrix partition problems $CSP_{1,2}^*(H)$ defined in the introduction and studied in [6, 17, 18, 24, 27]. We obtain the following corollaries. (The first corollary has been anticipated in [17].)

COROLLARY 3.4. *Each list matrix partition problem is NP-complete or quasi-polynomial.*

We call a list matrix partition problem $CSP_{1,2}^*(H)$ *three-inclusive* if the instances are graphs G with lists of size at most three.

COROLLARY 3.5. *Each three-inclusive list matrix partition problem is NP-complete or quasi-polynomial.*

The analogue of Corollary 2.3 follows from Theorems 3.1 and 3.2 by an application of Corollary 2.3.

COROLLARY 3.6. *If H and K are pairwise-set-full structures on the same domain $D^H = D^K$ with the same nonunary relations and the same unary relations S with $|S| \leq 3$, then $CSP_{\{1,2\}}(H)$ and $CSP_{\{1,2\}}(K)$ are both NP-complete or both polynomial.*

If H and K are three-inclusive structures on the same domain $D^H = D^K$ with the same nonunary relations and the same unary relations S with $|S| \leq 3$, then $CSP_{\{1,2\}}(H)$ and $CSP_{\{1,2\}}(K)$ are both NP-complete or both quasi-polynomial.

The same conclusions hold for the strict versions $CSP_{\{1,2\}}^*(H)$ and $CSP_{\{1,2\}}^*(K)$.

4. Restriction to W-full (and strictly W-full) instances. Theorems 3.1 and 3.2 generalize to W-full structures, and the proofs are similar. Here we briefly state the results and describe the additional effort required to prove them.

Here is the generalization of Theorem 3.1.

THEOREM 4.1. *Let H be a W-set-full structure.*

The problems $CSP_W(H)$, $CSP^*_W(H)$, and $CSP_1(H)$ are all polynomial or all NP-complete.

Proof. We prove the theorem for $W = \{1, w\}$ for a single $w \geq 2$. For general W we can carry out this proof for each value $w \in W$ with $w \geq 2$ in turn. Thus we assume $W = \{1, w\}$ and proceed as in Theorem 3.1. If $CSP_1(H)$ is polynomial, then trivially both $CSP^*_W(H)$ and $CSP_W(H)$ are polynomial. If $CSP_1(H)$ is NP-complete, then by Corollary 2.3 we may restrict $CSP_1(H)$ to three possible values in H per variable (using the unary relations) and still obtain an NP-complete problem. Again, for every collection of distinct variables $x_1, \ldots, x_w$ in D^G, where x_i has at most three possible values given by S^H_i, there exists a relation R^H and a permutation σ such that $S^H_{\sigma(1)} \times \cdots \times S^H_{\sigma(w)} \subseteq R^H$ (since H is W-set-full), so the instance G can be made W-full as before and thus becomes an instance of the W-set-full problem $CSP_W(H)$. Therefore $CSP_W(H)$ is also NP-complete.

It remains to enforce strictness to obtain an instance of $CSP^*_W(H)$. As in Theorem 3.1, we make s copies of each variable and use an auxiliary construction to define the relations on this enlarged set of variables. Specifically, we apply Lemma 4.2 below, with $t = w!r$ (corresponding to the $w!$ choices of permutations σ and r choices of relations R^H in the definition of strictly W-full structures). We then obtain an instance equivalent to G that is strictly W-full, whence $CSP^*_W(H)$ is also NP-complete. □

LEMMA 4.2. *Let K_{ws} be the structure with ws elements x_{ij}, $1 \leq i \leq w$, $1 \leq j \leq s$, and relation R consisting of all w^s tuples $(x_{1i_1}, \ldots, x_{wi_w})$. For every pair of integers $w \geq 2$ and $t \geq 1$, there exists an integer $s \geq 1$ and a coloring of the tuples in K_{ws} with t colors such that for every choice of w subsets $S_1, \ldots, S_w$ with $S_i \subseteq \{x_{i1}, \ldots, x_{is}\}$ and $|S_i| \geq s/3$, we have that $S_1 \times \cdots \times S_w$ contains tuples of all t colors.*

Proof. Assign a color out of t colors to each tuple uniformly at random. The probability that a choice of w sets S_i with $|S_i| \geq s/3$ will miss one of the t colors is at most $t(1 - 1/t)^{(s/3)^t}$ and the number of choices of such subsets is $\binom{s}{s/3}^t$, so it suffices to choose s large enough so that $t(1 - 1/t)^{(s/3)^w} \binom{s}{s/3}^w < 1/2$ to guarantee that with probability at least $1/2$ the structure K_{ws} will be assigned t tuple colors with the desired property. □

The generalization of Theorem 3.2 takes the following form.

THEOREM 4.3. *Let H be a three-inclusive structure, and let $\mathcal{H}$ be the set of all W-set-full structures H' that have the same nonunary relations as H and such that each $S \in \mathcal{U}(H')$ with $|S| \leq 3$ is also in $\mathcal{U}(H)$.*

If all $CSP_1(H')$ for $H' \in \mathcal{H}$ are polynomial, then both $CSP_W(H)$ and $CSP^*_W(H)$ are quasi-polynomial. If some $CSP_1(H')$ for $H' \in \mathcal{H}$ is NP-complete, then both $CSP_W(H)$ and $CSP^*_W(H)$ are NP-complete.

COROLLARY 4.4. *For each three-inclusive structure H, the problems $CSP_W(H)$ and $CSP^*_W(H)$ are both NP-complete or both quasi-polynomial.*

In the proof of Theorem 4.3 we shall again treat each $w \in W$ in turn; thus we shall assume that $W = \{1, w\}$.

Let G be a W-full structure, let $L_1, \ldots, L_w$ be (not necessarily disjoint) nonempty subsets of D^G, and let $\alpha = 1/(w!r)$, where r is the number of w-ary relations R^G_i. Say that a rooted tree T is a *select-tree* if the vertices of T at depth $1 \leq i \leq w$ correspond to the variables in L_i, with the root ρ at depth 0. For a w-ary relation R^G_i, a permutation σ of $\{1, \ldots, w\}$, and $0 < \beta < 1$, let an (R_i, σ, β)-*tree* be a select-tree T such that each path $(\rho, x_1, \ldots, x_w)$ in T has $(x_{\sigma(1)}, \ldots, x_{\sigma(w)}) \in R^G_i$ or has

$x_i = x_j$ for some $1 \le i < j \le w$, and each vertex of T at depth $0 \le i < w$ has at least $\beta|L_{i+1}|$ children.

LEMMA 4.5. *For every W-full structure G and sets $L_1, \ldots, L_w$ as above, there exist R_i and σ such that G has an (R_i, σ, β)-tree for $\beta = \alpha/(4w)$.*

Proof. Let $z = \ell_1 \cdots \ell_w$ for $\ell_i = |L_i|$. There exist a relation R_i^G and a permutation σ of $\{1, \ldots, w\}$ such that at least $\alpha z = z/(w!r)$ tuples $(x_1, \ldots, x_w)$ with $x_i \in L_i$ have $(x_{\sigma(1)}, \ldots, x_{\sigma(w)}) \in R_i^G$ or have $x_i = x_j$ for some $1 \le i < j \le w$. By Markov's inequality, there are at least $\beta\ell_1$ elements $x \in L_1$ such that the number of w-tuples $(x_1, \ldots, x_w)$ with $x = x_1$ and $x_i \in L_i$ having $(x_{\sigma(1)}, \ldots, x_{\sigma(w)}) \in R_i^G$, or having $x_i = x_j$ for some $1 \le i < j \le w$, is at least $\alpha'(z/\ell_1)$ for $\alpha' = (\alpha - \beta)/(1 - \beta)$, for any β with $0 < \beta < \alpha$. (Markov's inequality states that a nonnegative random variable X has value at most $tE(X)$ with probability at least $1 - \frac{1}{t}$ for each choice of $t > 1$.) By our special choice of β, we have $\alpha''(1 - 1/(2(w-1))) \ge (\alpha'' - \beta)/(1 - \beta)$ for each $\alpha'' \ge \alpha/2$. Thus repeatedly replacing α by α' a total of $w - 1$ times reduces α by a factor of at least $(1 - 1/(2(w-1)))^{w-1} \ge 1/2$, so that at any point in time the new value α'' satisfies $\alpha'' \ge \alpha/2$. We therefore obtain at least $\beta\ell_1$ children of the root, and for each chosen child x, we have z replaced with z/ℓ_1 and αz replaced with $\alpha'(z/\ell_1)$, giving again at least $\beta\ell_2$ children of x, and by induction, each vertex of T at depth $0 \le i < w$ has at least $\beta\ell_{i+1}$ children for $\beta = \alpha/(4w)$. □

Proof of Theorem 4.3. We again focus on proving the statement for $CSP_W(H)$, the proof for $CSP_W^*(H)$ being similar. We proceed as in Theorem 3.2. Assume H is a three-inclusive structure, and transform $CSP_W(H)$ to problems $CSP_1(H')$ for W-set-full structures $H' \in \mathcal{H}$ such that if any of these problems is NP-complete then $CSP_W(H)$ is also NP-complete. In the transformation, each instance G of $CSP_W(H)$ gives rise to $n^{O(\log n)}$ instances G' of the problems $CSP_1(H')$, so that if all these problems are polynomial, then $CSP_W(H)$ is quasi-polynomial. Recall that we assume $W = \{1, w\}$. The problems $CSP_1(H')$ will again have a W-set-full structure H' obtained from H by repeatedly replacing certain unary relations S with all proper subsets $T \subset S$.

To obtain these $n^{O(\log n)}$ instances G' (and the problems $CSP_1(H')$ to which they correspond), we shall ensure that if some elements $a_{ij\sigma} \in D^H$, one for each of the r w-ary relations R_i^H, $1 \le j \le w$, and each fixed permutation σ on $\{1, \ldots, w\}$, are such that $(a_{i\sigma(1)\sigma}, \ldots, a_{i\sigma(w)\sigma}) \notin R_i^H$, and we let $A_j = \{a_{ij\sigma} : 1 \le i \le r\}$, then for some $1 \le j \le w$ the unary constraints on the instances G' (and corresponding structures H', both described below) do not contain A_j. This will guarantee that we obtain a W-set-full problem.

Let L_j be the set of variables with unary constraints S^G such that $A_j \subseteq S^H$ for $1 \le j \le w$, and let $\ell_j = |L_j|$. By Lemma 4.5 G has an (R_i, σ, β)-tree T for $\beta = 1/(4w!wr)$. For every solution f to the instance G, there must exist a path $(\rho, x_1, \ldots, x_{t-1})$ in T with $1 \le t \le w$, with the tree vertices x_u corresponding to distinct elements of D^G, that gives to x_u value $a_{iu\sigma}$ for $1 \le u < t$, but does not give value $a_{it\sigma}$ to any child x_t of x_{t-1} corresponding to an element distinct from the elements for these x_u, $1 \le u < t$.

Since the number of such children of x_{t-1} is at least $\beta\ell_t$, and the solution f belongs to a family of solutions that assigns the values $a_{iu\sigma}$ for $1 \le u < t$ and removes the value $a_{it\sigma}$ from the lists of these children, we obtain a new instance with ℓ_t replaced by $(1-\beta)\ell_t$. This simplification can be performed at most $-\log(\ell_1 \cdots \ell_w)\log(1-\beta) \le -w \log n \log(1 - 1/(4w!wr)) = O(\log n)$ times, and the number of possible choices of paths $(\rho, x_1, \ldots, x_{t-1})$ for each iteration is at most $2\ell_1 \cdots \ell_w \le 2n^w = n^{O(1)}$, so we obtain $n^{O(\log n)}$ instances that have some $\ell_j = 0$, thus satisfying the condition for the

corresponding A_j.

We repeat this process for each tuple of sets $(A_1, \ldots, A_w)$ as above. In the end, we obtain $n^{O(\log n)}$ instances (and corresponding structures H') that satisfy the stated condition for each tuple $(A_1, \ldots, A_w)$. Thus for each resulting instance G' of $CSP_1(H')$, the structure H' is strongly W-set-full. If all such $CSP_1(H')$ are polynomial, then we can solve each of these $n^{O(\log n)}$ resulting problems. If one such $CSP_1(H')$ is NP-complete, then by Corollary 2.3 the W-set-full structure H'', obtained from H' by restricting all unary relations to subsets of size at most three, yields a problem $CSP_1(H'')$ that is also NP-complete, and all these subsets of size at most three are in the original structure H. By Theorem 4.1 the problem $CSP_W(H'')$ is NP-complete, and since the instances of $CSP_W(H'')$ are also instances of $CSP_W(H)$, the problem $CSP_W(H)$ is also NP-complete.

We also obtain the analogue of Corollary 3.6, which follows from Theorems 4.1 and 4.3 by an application of Corollary 2.3.

COROLLARY 4.6. *If H and K are W-set-full structures on the same domain $D^H = D^K$ with the same nonunary relations and the same unary relations S with $|S| \leq 3$, then $CSP_W(H)$ and $CSP_W(K)$ are both NP-complete or both polynomial.*

If H and K are three-inclusive structures on the same domain $D^H = D^K$ with the same nonunary relations and the same unary relations S with $|S| \leq 3$, then $CSP_W(H)$ and $CSP_W(K)$ are both NP-complete or both quasi-polynomial.

The same conclusions hold for the strict versions $CSP^*_W(H)$ and $CSP^*_W(K)$.

As in the proof of Theorem 4.1, every three-inclusive problem $CSP_W(H)$ can be transformed into a polynomially equivalent problem $CSP^*_W(H)$. However, it is not clear how to accomplish the converse transformation in general; so the latter family of problems may define a more general family, up to polynomial time equivalence. But the two families of problems are the same, up to quasi-polynomial time equivalence, since all problems considered are either quasi-polynomial (hence equivalent up to quasi-polynomial reductions) or NP-complete (hence equivalent up to polynomial reductions).

5. Bounded degree problems. Here we consider restricting the three-inclusive constraint satisfaction problems $CSP_1(H)$ to instances G with bounded degree. We are led to propose the following conjecture.

CONJECTURE 5.1. *Every three-inclusive list constraint satisfaction problem $CSP_1(H)$ that is NP-complete remains NP-complete when restricted to instances of degree three.*

We denote by $CSP^3_1(H)$ the restriction of $CSP_1(H)$ to instances of degree three. We now briefly explain four special cases in which the conjecture holds. All are based on existing results.

We shall say that a three-inclusive constraint satisfaction problem $CSP_1(H)$ *d-simulates* a three-inclusive constraint satisfaction problem $CSP_1(H')$ if for every relation $R_i^{H'}$, there is an instance G_i of $CSP_1(H)$ of degree at most d containing ℓ_i particular variables $x_1, \ldots, x_{\ell_i}$ of degree at most one, such that $(a_1, \ldots, a_{\ell_i}) \in R_i^{H'}$ if and only if there exists a homomorphism f of G_i to H such that each $f(x_i) = a_i$. If $CSP_1(H)$ d-simulates $CSP_1(H')$ with $d \leq 3$, then there is a polynomial reduction of the problem $CSP^3_1(H')$ to $CSP^3_1(H)$, obtained by substituting each occurrence of a relation $R_i^{H'}$ in an instance G' of $CSP^3_1(H')$ by a copy of the instance G_i corresponding to R_i, thus obtaining an instance G of $CSP^3_1(H)$. Therefore showing the conjecture for $CSP^3_1(H')$ implies the conjecture for $CSP^3_1(H)$.

In the first case, we focus on the case of *Boolean constraint satisfaction problems*,

i.e., $CSP_1(H)$, where D^H has two elements $(0,1)$. The theorem stated below was first proved by Dalmau and Ford [7] and by Feder and Ford [11], using a result of Feder [9]. We briefly explain the proof as it is the basis for the other cases.

THEOREM 5.2 (see [7, 11]). *Conjecture* 5.1 *holds for Boolean constraint satisfaction problems.*

Proof. In other words, we claim that if for a three-inclusive H with $D = D^H = \{0,1\}$ the problem $CSP_1(H)$ is NP-complete, then so is its restriction $CSP_1^3(H)$ to instances of degree three. It is shown in [9] that each NP-complete case of Boolean constraint satisfaction problems $CSP_1(H)$ 2-simulates the problem $CSP_1(H')$ which contains the ternary relation $D^3-\{(0,0,0)\}$ (corresponding to the disjunction $x\vee y\vee z$), the ternary relation $D^3-\{(1,1,1)\}$ (corresponding to the disjunction $\overline{x}\vee\overline{y}\vee\overline{z}$), and the binary relation $D^2-\{(1,0)\}$ (corresponding to the implication $x\to y$).

This simulation yields a reduction from the NP-complete problem of 3-satisfiability to the problem $CSP_1^3(H')$, as we may include a variable x in any number k of clauses by using k auxiliary variables $x_1, x_2, \ldots, x_k$ with implications $x_1 \to x_2, x_2 \to x_3, \ldots, x_{k-1} \to x_k, x_k \to x_1$. These implications involve two occurrences for each x_i, and the third occurrence of each of these k variables x_i that all take the same value can be used for the k occurrences of x in clauses $x \vee y \vee z$ or $\overline{x} \vee \overline{y} \vee \overline{z}$. □

In the second case, we focus on three-inclusive constraint satisfaction problems $CSP_1(H)$ in which all $S \in \mathcal{U}(H)$ have $|S| \leq 2$. These problems correspond to list constraint satisfaction problems with lists of size at most two, and we call these problems *small-list constraint satisfaction problems.*

THEOREM 5.3. *Conjecture* 5.1 *holds for small-list constraint satisfaction problems.*

Proof. It is shown in [10] that each NP-complete case of the small-list constraint satisfaction problems 2-simulates a problem $CSP_1(H')$ for a structure H' containing the unary relations $\{0_i, 1_i\}$, for $1 \leq i \leq r$, and the binary relations $(\{0_i,1_i\} \times \{0_j,1_j\}) - \{(1_i,0_j)\}$ (corresponding to the implications $x_i \to x_j$) or the binary relations $(\{0_i,1_i\} \times \{0_j,1_j\}) - \{(1_i,0_j),(0_i,1_j)\}$ (corresponding to the equalities $x_i = x_j$) for each $1 \leq i,j \leq r$, $i \neq j$. It is also shown in [10] that the problem $CSP_1(H)$ with $D^H = \{0,1\}$, obtained from $CSP_1(H')$ by identifying all sets $\{0_i,1_i\}$ with $\{0,1\}$, is NP-complete.

We may thus represent kr occurrences of a Boolean variable x, with k of these occurrences having unary relation $\{0_i,1_i\}$ for each $1 \leq i \leq r$, by a cycle of implications $x_i \to x_j$ or equalities $x_i = x_j$, as in the proof of Theorem 5.2, involving variables x_{ij} having unary relation $\{0_i,1_i\}$ for $1 \leq i \leq r$ and $1 \leq j \leq k$. This completes the reduction from the NP-complete problem $CSP_1(H)$ obtained by identifying all $\{0_i,1_i\}$ with $\{0,1\}$ to $CSP_1^3(H')$. □

The third case concerns list homomorphism problems for graphs (with loops allowed). The problem $CSP_1(H)$, where H is three-inclusive and consists of a single symmetric binary relation, will be called a *graph list homomorphism problem.* The following theorem has been proved in [15].

THEOREM 5.4 (see [15]). *If H is a bi-arc graph, then $CSP_1^3(H)$ is polynomial; otherwise, $CSP_1^3(H)$ is NP-complete.*

Since this classification agrees exactly with that for $CSP_1(H)$ from [14], we obtain the desired corollary.

COROLLARY 5.5. *Conjecture* 5.1 *holds for graph list homomorphism problems.*

The last case deals with N-free binary relations. A binary relation B is called *N-free* if $(x,z),(y,z),(y,t) \in B$ imply either $x = y$ or $z = t$. A *binary N-free constraint*

satisfaction problem is a three-inclusive problem $CSP_1(H)$ where $\mathcal{U}(H)$ contains all S with $|S| \leq 3$, all binary relations of H are N-free, and H has no relations of higher arity.

THEOREM 5.6. *Conjecture* 5.1 *holds for binary N-free constraint satisfaction problems.*

Proof. It is shown in [19] that each NP-complete binary N-free constraint satisfaction problem 3-simulates a problem $CSP_1(H)$ containing the relation $\{(1_A, 0_B, 0_C), (0_A, 1_B, 0_C), (0_A, 0_B, 1_C)\}$, with $|\{0_A, 1_A\}| = |\{0_B, 1_B\}| = |\{0_C, 1_C\}| = 2$.

This relation may further be used to 3-simulate a problem $CSP_1(H')$ that also contains the relation $\{(1_A, 0_B), (0_A, 1_B)\}$ (corresponding to the inequality $x_A \neq x_B$), by setting x_C to value 0_C, and similarly $\{(1_B, 0_C), (0_B, 1_C)\}$ (corresponding to the inequality $x_B \neq x_C$, and also contains the relation $\{(0_A, 0_C), (1_A, 1_C)\}$ (corresponding to the equality $x_A = x_C$), obtained by combining $x_A \neq x_B$ with $x_B \neq x_C$, and similarly the relation $\{(0_A, 0_B), (1_A, 1_B)\}$ (corresponding to the equality $x_A = x_B$). Thus we may set $x_{A1} = \cdots = x_{Ak} = x_{B1} \cdots x_{Bk} = x_{C1} \cdots x_{Ck}$ as a chain of equalities that uses only two of the three allowed occurrences of each variable. This allows us to identify the three unary relations $\{0_i, 1_i\}$ with a single unary relation $\{0, 1\}$, with k occurrences per variable, for the NP-complete Boolean constraint satisfaction problem one-in-three SAT, with relation $\{(1, 0, 0), (0, 1, 0), (0, 0, 1)\}$ (obtained from $\{(1_A, 0_B, 0_C), (0_A, 1_B, 0_C), (0_A, 0_B, 1_C)\}$ by the identification $x_A = x_B = x_C$). Thus $CSP_1^3(H')$ and $CSP_1^3(H)$, with degree at most three, are also NP-complete. ∎

Acknowledgment. We are grateful to the referees for guiding us to present these results more clearly.

RAPIDLY MIXING MARKOV CHAINS FOR SAMPLING CONTINGENCY TABLES WITH A CONSTANT NUMBER OF ROWS*

MARY CRYAN†, MARTIN DYER‡, LESLIE ANN GOLDBERG§, MARK JERRUM†, AND RUSSELL MARTIN¶

Abstract. We consider the problem of sampling almost uniformly from the set of contingency tables with given row and column sums, when the number of rows is a constant. Cryan and Dyer [*J. Comput. System Sci.*, 67 (2003), pp. 291–310] have recently given a *fully polynomial randomized approximation scheme* (fpras) for the related counting problem, which employs Markov chain methods indirectly. They leave open the question as to whether a natural Markov chain on such tables mixes rapidly. Here we show that the "2×2 heat-bath" Markov chain is rapidly mixing. We prove this by considering first a heat-bath chain operating on a larger window. Using techniques developed by Morris [*Random Walks in Convex Sets*, Ph.D. thesis, Department of Statistics, University of California, Berkeley, CA, 2000] and Morris and Sinclair [*SIAM J. Comput.*, 34 (2004), pp. 195–226] for the multidimensional knapsack problem, we show that this chain mixes rapidly. We then apply the comparison method of Diaconis and Saloff-Coste [*Ann. Appl. Probab.*, 3 (1993), pp. 696–730] to show that the 2×2 chain is also rapidly mixing.

Key words. contingency table, balanced almost-uniform permutation, strongly balanced permutation

1. Introduction. Given two vectors of positive integers, $r = (r_1, \ldots, r_m)$ and $c = (c_1, \ldots, c_n)$, an $m \times n$ matrix $[X[i,j]]$ of nonnegative integers is a *contingency table* with row sums r and column sums c if $\sum_{j=1}^{n} X[i,j] = r_i$ for every row i and $\sum_{i=1}^{m} X[i,j] = c_j$ for every column j. We write $\Sigma_{r,c}$ to denote the set of all contingency tables with row sums r and column sums c. We assume that $\sum_{i=1}^{m} r_i = \sum_{j=1}^{n} c_j$ (since otherwise $\Sigma_{r,c} = \emptyset$) and denote by N the common total, called the *table sum*.

In this paper, we consider the problem of sampling contingency tables almost uniformly at random. No technique currently exists for polynomial-time sampling when the row and column sums can be arbitrary. In this paper we consider a particular restriction, namely, the case in which the number of rows is a constant. We focus on the Markov chain Monte Carlo (MCMC) method for sampling, which has already been successfully used to sample contingency tables, for other restrictions of the problem (see [8, 15, 2, 11]). We prove that a natural Markov chain, which we refer to as $\mathcal{M}_{2\times 2}$, is rapidly mixing when the number of rows is constant.

Before we give details of previous work on the MCMC method for sampling contingency tables, we will first discuss recent work on approximate counting of con-

tingency tables, when the number of rows is constant. Cryan and Dyer [3] recently gave a *fully polynomial randomized approximation scheme* (fpras) for approximately counting contingency tables in this setting (i.e., for approximating $|\Sigma_{r,c}|$ with given r, c). It was previously shown by Dyer, Kannan, and Mount [12] that the problem of *exact* counting is $\sharp P$-complete, even when there are only two rows. (Barvinok [1] gave a polynomial-time algorithm to exactly count contingency tables when the number of rows and the number of columns is constant.) It is well known that for all *self-reducible* problems, finding an fpras for approximate counting is equivalent to finding a *fully polynomial almost uniform sampler* (fpaus) (see Jerrum, Valiant, and Vazirani [17]). Contingency tables are not known to be self-reducible—it is true that the existence of an fpaus for almost-uniform sampling of contingency tables does imply an fpras for approximately counting contingency tables (see, for example, [11]), but the other direction is not known to hold. It is shown in [3] that the fpras does imply a sampling algorithm, though this algorithm depends on ϵ^{-1} rather than on $\log \epsilon^{-1}$. Recently Dyer [10] developed an elegant dynamic programming technique for contingency tables with a constant number of rows. He applied this technique to design two algorithms: an fpaus for uniformly sampling contingency tables with a constant number of rows and an fpras for approximately counting the number of contingency tables when the number of rows is constant. The running times of his algorithms significantly improve on the results in [3].

The algorithm in [3] is a mixture of dynamic programming and volume estimation and uses Markov chain methods only indirectly. The sampling algorithm of [10] is based on dynamic programming, and samples are generated by a probabilistic traceback through the dynamic programming table. It does not use Markov chain methods at all. Therefore the question still remains as to whether the MCMC method can be applied *directly* to this problem. In addition to its intrinsic interest, this question is important for two reasons. First, previous research in this area has routinely adopted the MCMC approach. Second, the MCMC method is more convenient, and has been more widely applied, for practical applications of sampling.

We give here the first proof of rapid mixing for a natural Markov chain when the number of rows m is a constant. This Markov chain, which we refer to as $\mathcal{M}_{2\times 2}$, was introduced by Dyer and Greenhill [11]. During a step of the chain, a 2×2 subtable is selected uniformly at random and is updated randomly. The subtable is updated according to the "heat-bath" method. In particular, a new subtable is chosen from the conditional distribution (the uniform distribution, conditioned on the configuration outside of the subtable). In order to analyze $\mathcal{M}_{2\times 2}$, we first introduce an alternative heat-bath chain, $\mathcal{M}_{\mathrm{HB}}$, which randomly updates a larger subtable. In particular, for a constant d_m which will be defined later, it updates a subtable of size $m \times (2d_m + 1)$ (also following the "heat-bath" method of selecting a new subtable chosen uniformly at random, conditioned on the configuration outside of the subtable). We use the multicommodity flow technique of Sinclair [24] to analyze the mixing time of $\mathcal{M}_{\mathrm{HB}}$. Using techniques developed by Morris and Sinclair [20] (see also [19]), we show that this chain mixes in time polynomial in the number of columns and the logarithm of the table sum. In section 5 we compare $\mathcal{M}_{\mathrm{HB}}$ to $\mathcal{M}_{2\times 2}$ and hence show that $\mathcal{M}_{2\times 2}$ is also rapidly mixing. This is the first proof that any chain converges in polynomial time even when the number of columns, as well as the number of rows, is constant. Establishing mixing in this case is one step of our proof. (See Pak [22] for an approach to this problem not using MCMC.) We note further that our results provide an alternative (and very different) fpras for counting contingency tables to that of Cryan and Dyer [3].

We now review previous work on the MCMC method for sampling contingency tables.

Contingency tables are important in applied statistics, where they are used to summarize the results of tests and surveys. The conditional volume test of Diaconis and Efron [5] is perhaps the most soundly based method for performing tests of significance in such tables. The Diaconis–Efron test provides strong motivation for the problem of efficiently choosing a contingency table with given row and column sums uniformly at random. Other applications of counting and sampling contingency tables are discussed by Diaconis and Gangolli [6]. See also Mount [21] for additional information, and De Loera and Sturmfels [4] for the current limits of exact counting methods.

With the exception of [1, 3] (and a recent result of Dyer [10]), most previous work on sampling contingency tables applies the MCMC method, as described in the survey of Jerrum and Sinclair [16]. This method, which has been used to solve many different sampling problems, is based on a very simple idea. Suppose that we have a Markov chain on a finite set of discrete structures Ω, defined by the transition matrix P. If the Markov chain is *ergodic*, then it will converge to a unique stationary distribution ϖ on Ω, regardless of the initial state. This gives a nice method for sampling from the distribution ϖ: Starting in any state, we run the Markov chain for some "sufficiently long" number of steps. Then the final state is taken as a sample. The key issue with using the MCMC method is determining how long the chain takes to converge to its stationary distribution.

The first explicit definition of Markov chains for uniformly sampling contingency tables apparently occurs in the papers of Diaconis and Gangolli [6] and Diaconis and Saloff-Coste [8], although it is mentioned in [6] that this chain had already been used by practitioners. A single step of the chain is generated as follows: An ordered pair of rows i_1, i_2 is chosen uniformly at random from all rows of the table, and an ordered pair of columns j_1, j_2 is chosen uniformly at random from all columns, giving a 2×2 submatrix. The entries of the 2×2 submatrix are modified as follows:

$$X'[i_1, j_1] = X[i_1, j_1] + 1, \quad X'[i_1, j_2] = X[i_1, j_2] - 1,$$
$$X'[i_2, j_1] = X[i_2, j_1] - 1, \quad X'[i_2, j_2] = X[i_2, j_2] + 1.$$

If modifying the matrix results in a negative value for any $X'[i, j]$, the move is not carried out. Diaconis and Gangolli proved that this Markov chain is ergodic, and the stationary distribution of the chain is uniform on $\Sigma_{r,c}$. They did not attempt to bound the mixing time of the chain, but it is clear that the mixing time is not better than pseudopolynomial in the input. That is, the mixing time is at least a polynomial in N (rather than a polynomial in $\log N$). For a discussion of pseudopolynomial time and approximation algorithms, see Chapter 8 of [26].

Later Diaconis and Saloff-Coste [8] considered the case when the numbers of rows and columns are both constant and proved that, in this case, their chain converges in time quadratic in the table sum. Hernek [15] considered the case when the table has two rows and proved that the same chain mixes in time polynomial in the number of columns and the table sum. Chung, Graham, and Yau [2] showed that a slightly modified version of the Diaconis and Saloff-Coste chain converges in time polynomial in the table sum, the number of rows, and the number of columns, provided that all row and column sums are sufficiently large.

The first truly polynomial-time algorithm (polynomial in the number of rows, the number of columns, and the logarithm of the table sum) for sampling contingency

tables was given by Dyer, Kannan, and Mount [12]. They took a different approach to the sampling problem, considering $\Sigma_{r,c}$ as the set of integer points within a convex polytope. They used an existing algorithm for sampling continuously from a convex polytope, combined with a rounding procedure, to sample integer points from inside the polytope. For any input with row sums of size $\Omega(n^2m)$ and column sums of size $\Omega(nm^2)$, their algorithm converges to the uniform distribution on $\Sigma_{r,c}$ in time polynomial in the number of rows, the number of columns, and the logarithm of the table sum. Their result was later refined by Morris [18], who showed that the result also holds when the row sums are $\Omega(n^{3/2}m\log m)$ and the column sums are $\Omega(m^{3/2}n\log n)$.

Using different techniques, Dyer and Greenhill [11] considered the problem of sampling contingency tables when the table has only two rows. They considered the 2×2 heat-bath chain $\mathcal{M}_{2\times 2}$ and showed that for two-rowed tables, the chain converges to the uniform distribution on $\Sigma_{r,c}$ in time that is polynomial in the number of columns and the logarithm of the table sum.

Our paper can properly be viewed as extending Dyer and Greenhill's results to any constant number of rows. Thus, our main result is that $\mathcal{M}_{2\times 2}$ is rapidly mixing for any constant number of rows. First, however, in section 4, we examine $\mathcal{M}_{\mathrm{HB}}$. Theorem 7 shows that this chain is rapidly mixing. Theorem 8 of section 5 bounds the mixing time of the $\mathcal{M}_{2\times 2}$ in terms of the mixing time of $\mathcal{M}_{\mathrm{HB}}$. Combining the two theorems gives the main result.

2. Definitions. First, we define the Markov chain $\mathcal{M}_{2\times 2}$. The state space is $\Sigma_{r,c}$. Given a contingency table $X \in \Sigma_{r,c}$, a move is made as follows. With probability $1/2$, the chain stays at state X. With the remaining probability, a 2×2 submatrix is chosen as follows. A pair of rows i_1, i_2 is chosen uniformly at random, and a pair of columns j_1, j_2 is chosen uniformly at random. The submatrix $X[i_1, j_1], X[i_1, j_2], X[i_2, j_1], X[i_2, j_2]$ is then replaced with a submatrix chosen uniformly at random from the set of 2×2 matrices with row sums $X[i_1, j_1] + X[i_1, j_2]$ and $X[i_2, j_1] + X[i_2, j_2]$ and column sums $X[i_1, j_1] + X[i_2, j_1]$ and $X[i_1, j_2] + X[i_2, j_2]$.

The self-loop probability $1/2$ in the definition of $\mathcal{M}_{2\times 2}$ is introduced for a technical reason—it simplifies the comparison of $\mathcal{M}_{2\times 2}$ and $\mathcal{M}_{\mathrm{HB}}$ in section 5 by ensuring that the eigenvalues of the transition matrix of $\mathcal{M}_{2\times 2}$ are not negative.

Next we define the Markov chain $\mathcal{M}_{\mathrm{HB}}$. In section 4 we will define a constant d_m (which depends on m but not on n or on the input vectors r and c). The state space is $\Sigma_{r,c}$. Given a contingency table $X \in \Sigma_{r,c}$, a move is made as follows. With probability $3/4$, the chain stays at state X. With the remaining probability, an $m \times (2d_m + 1)$ submatrix is chosen as follows. A set of $2d_m + 1$ columns $j_1, \ldots, j_{2d_m+1}$ is chosen uniformly at random from all columns of the table. The submatrix involving these columns is then replaced with a submatrix chosen uniformly at random from the set of all $m \times (2d_m + 1)$ matrices with the same row and column sums as the chosen submatrix.

The self-loop probability $3/4$ in the definition of $\mathcal{M}_{\mathrm{HB}}$ is again introduced for a technical reason—it ensures that the eigenvalues of the transition matrix of $\mathcal{M}_{\mathrm{HB}}$ are all at least $1/2$, which is useful in the comparison of $\mathcal{M}_{2\times 2}$ and $\mathcal{M}_{\mathrm{HB}}$. It is not necessary to make the self-loop probability be $3/4$—anything greater than $1/2$ suffices.

3. Background. In this section we summarize the techniques that we will use to bound the mixing time of $\mathcal{M}_{\mathrm{HB}}$. Our analysis is carried out using the multicommodity flow approach of Sinclair [24] for bounding the mixing time of a Markov chain. Sinclair's result builds on some earlier work due to Diaconis and Stroock [9].

In this section, and throughout the rest of the paper, we will use $[n]$ to denote the set $\{1, \ldots, n\}$ when n is a positive integer. We will use w^i to denote the ith component of a multidimensional weight vector w.

The setting is familiar: We have a finite set Ω of discrete structures and a transition matrix P on the state space Ω. It is assumed that the Markov chain defined by P is *ergodic*; that is, it satisfies the properties of *irreducibility* and *aperiodicity* (see Grimmett and Stirzaker [13]). It is well known that any ergodic Markov chain has a unique *stationary distribution*; that is, there is a unique distribution ϖ on Ω such that $\varpi P = \varpi$. Furthermore, for any choice of initial state $x \in \Omega$ and any state $y \in \Omega$, $P^t(x, y) \to \varpi(y)$ as $t \to \infty$ (see Chapter 6 of Grimmett and Stirzaker [13] for details). Sinclair also assumes that the Markov chain is *reversible* with respect to its stationary distribution; that is, $\varpi(x)P(x, y) = \varpi(y)P(y, x)$ for all $x, y \in \Omega$.

For any start state x, we define the *variation distance* between the stationary distribution and a walk of length t by $\mathrm{V}(\varpi, P^t(x)) = (1/2)\sum_{y\in\Omega} |\varpi(y) - P^t(x, y)|$. For any $0 < \epsilon < 1$ and any start state x, let $\tau_x(\epsilon)$ be defined as $\tau_x(\epsilon) = \min\{t : \mathrm{V}(\varpi, P^t(x)) \le \epsilon\}$. The *mixing time* of the chain is given by the function $\tau(\epsilon)$, defined as $\tau(\epsilon) = \max\{\tau_x(\epsilon) : x \in \Omega\}$.

The multicommodity flow approach is defined in terms of a graph G_Ω defined by the Markov chain. The vertices of G_Ω are the elements of Ω, and the graph contains an edge $(u \to v)$ for every pair of states such that $P(u, v) > 0$. We call this graph the *Markov kernel*. For any $x, y \in \Omega$, a *unit flow* from x to y is a set $\mathcal{P}_{x,y}$ of simple directed paths of G_Ω from x to y, such that each path $p \in \mathcal{P}_{x,y}$ has a positive weight α_p, and the sum of the α_p over $p \in \mathcal{P}_{x,y}$ is 1. A *multicommodity flow* is a family of unit flows $\mathcal{F} = \{\mathcal{P}_{x,y} : x, y \in \Omega\}$ containing a unit flow for every pair of states from Ω. The important properties of a multicommodity flow are the maximum flow passing through any edge and the maximum length of a path in the flow. We define the length $\mathcal{L}(\mathcal{F})$ of the multicommodity flow $\mathcal{F}$ by $\mathcal{L}(\mathcal{F}) = \max_{x,y} \max\{|p| : p \in \mathcal{P}_{x,y}\}$, where $|p|$ denotes the length of p. For any edge e of G_Ω, we define $\mathcal{F}(e)$ to be the sum of the α_p weights over all p such that $e \in p$ and $p \in \mathcal{P}_{x,y}$ for some $x, y \in \Omega$.

The following theorem is an amalgamation of the results of Sinclair [24]. See also the closely connected work of Diaconis and Stroock [9]. Note that all logarithms in this paper are taken to be natural logarithms.

THEOREM 1 (Sinclair [24]). *Let P be the transition matrix of an ergodic, reversible Markov chain on Ω whose stationary distribution is the uniform distribution. Suppose that the eigenvalues of P are nonnegative. Let $\mathcal{F}$ be a multicommodity flow on the graph G_Ω. Then the mixing time of the chain is bounded above by*

$$\tau(\epsilon) \le |\Omega|^{-1}\mathcal{L}(\mathcal{F}) \max_e \frac{\mathcal{F}(e)}{P(e)}(\log|\Omega| + \log\epsilon^{-1}). \tag{1}$$

Two key ingredients of our analysis of $\mathcal{M}_{\mathrm{HB}}$ in section 4 are the "balanced almost-uniform permutations" and the "strongly balanced permutations" used by Morris and Sinclair [20] for their analysis of the multidimensional knapsack problem. We will use an interleaving of a balanced almost-uniform permutation and a strongly balanced permutation to spread flow between each pair of states $x, y \in \Sigma_{r,c}$. The main idea is this: Given x and y we will use a permutation π of the columns of x to define a path of contingency tables from x to y. We will route flow from x to y along this path. Actually, π will be chosen from a distribution, and the amount of flow routed along the path corresponding to π will be proportional to the probability with which π is generated.

We will use the following notation. If π is a permutation of the n columns of a contingency table, $\pi(i)$ will denote the original column (in $\{1,\ldots,n\}$) which gets put into position i by the permutation. Thus, $\pi\{1,\ldots,k\} = \{\pi(1),\ldots,\pi(k)\}$ denotes the set of original columns that get put into the first k positions by the permutation.

DEFINITION 2 (Morris and Sinclair [20, Definition 3.2]). *Let σ be a random variable taking values in S_n (i.e., σ is a permutation of $\{1,\ldots,n\}$) and let $\lambda \in \mathbb{R}$. Then σ is a λ-uniform permutation if*

$$\Pr[\sigma\{1,\ldots,k\} = U] \le \lambda \times \binom{n}{k}^{-1}$$

for every k with $k \in [n]$ and every $U \subseteq \{1,\ldots,n\}$ of cardinality k.

DEFINITION 3 (Morris and Sinclair [20, Definition 5.1]). *Let $w_1,\ldots,w_n \in \mathbb{R}^d$ be any d-dimensional* weights *satisfying $\sum_{j=1}^n w_j = 0$ (i.e., $\sum_{j=1}^n w_j^i = 0$ for every $i \in [d]$). A permutation σ of $1,\ldots,n$ is ℓ-balanced if*

$$\left|\sum_{j=1}^{k} w_{\sigma(j)}^i\right| \le \ell M_i$$

for all $i \in [d]$ and $k \in [n]$, where $M_i = \max_{1\le j\le n} |w_j^i|$.

Checking the definition above, we see that a balanced permutation is one in which the partial sums of the weights (in each dimension) do not vary too much, where the factor ℓ gives us a bound on this variation. Morris and Sinclair showed how to construct balanced almost-uniform permutations when d is constant. (See also Theorem 3.2 in [19].)

THEOREM 4 (Morris and Sinclair [20, Theorem 5.3]). *For every positive integer d, there exist a constant g_d and a polynomial function p_d such that for any set of weights $\{w_j\}_{j=1}^n$ in $\mathbb{R}^d$, there exists a g_d-balanced, $p_d(n)$-uniform permutation.*

The key points which we should keep in mind are (1) the distribution which Morris constructs is "nearly" uniform (and has a fair amount of entropy) and (2) the permutations satisfy some sort of balance property on multidimensional weights. Roughly, one should think of these weights as corresponding to the columns of our contingency tables—the multiple dimensions come from having multiple rows. Loosely speaking, the "balance" property of these permutations will be used to construct our multicommodity flow to generate a path (or a family of paths) of contingency tables to get from X to Y, each pair of tables along this path differing by a single move of $\mathcal{M}_{\mathrm{HB}}$.

Note that the construction of the g_d-balanced, $p_d(n)$-uniform permutation of Morris and Sinclair is carried out by induction on the number of dimensions d. It is clear from the construction that g_d will be no greater than $4^{d+1} - 1$, though it is not easy to see a way of obtaining a smaller constant. We mention this because g_m will appear in the exponent of n when we bound the mixing time of our Markov chains (where m is the number of rows).

The "almost uniform" property will help ensure that the flow $\mathcal{F}(e)$ through any edge in G_Ω will not be too large (cf. Theorem 1). As mentioned before, we actually use a combination of permutations, one of which is balanced and almost-uniform, and a second type called "strongly balanced."

DEFINITION 5 (Morris and Sinclair [20, Definition 5.4]). *Let $w_1,\ldots,w_n \in \mathbb{R}^d$ be any d-dimensional weights. Define $\mu = (\mu^1,\ldots,\mu^d)$ to be the vector of means of the w_j weights ($\mu^i = (\sum_{j=1}^n w_j^i)/n$ for all i). A permutation σ of $1,\ldots,n$ is*

strongly ℓ-balanced if for all $k \in [n]$ and all $i \in [d]$, there exists a set $S \subseteq [n]$ with $|S \oplus \{1, \ldots, k\}| < \ell$ such that $(\sum_{j=1}^{k} w^i_{\sigma(j)} - k\mu^i)$ and $(\sum_{j \in S} w^i_{\sigma(j)} - k\mu^i)$ have opposite signs (or either is 0).

The main difference between ordinary balance and "strong balance" is that the definition of ordinary balance requires that the prefix sum $\sum_{j=1}^{k} w^i_{\sigma(j)}$ should be "close" to $k\mu$ for every k. However, strong balance requires that for every prefix k and every row i, it should be possible to find a small number of columns so that removing those columns changes the sign of $(\sum_{j=1}^{k} w^i_{\sigma(j)} - k\mu^i)$.

Morris and Sinclair [20] adapted a result of Steinitz [25] (see also Grinberg and Sevast'yanov [14]) to show that the following theorem holds.

THEOREM 6 (Morris and Sinclair [20, Lemma 5.5]). *For any sequence $\{w_j\}_{j=1}^{n}$ in $\mathbb{R}^d$, there exists a strongly $16d^2$-balanced permutation.*

4. Analysis of the generalized chain. We fix $r = (r_1, \ldots, r_m)$, the list of row sums, and $c = (c_1, \ldots, c_n)$, the list of column sums, and let Ω be the state space $\Sigma_{r,c}$ of $m \times n$ contingency tables with these row and column sums. Recall that N denotes the table sum $\sum_{i=1}^{m} r_i$.

Recall that g_m is the constant of Theorem 4 for balanced almost-uniform permutations for columns of dimension m. Let $d_m = 2m(3g_m + 1) + 1 + 34m^3$. We use P_{HB} for the transition matrix of the Markov chain $\mathcal{M}_{\mathrm{HB}}$ which was defined in section 2.

In this section, our goal is to prove the following theorem.

THEOREM 7. *The mixing time τ_{HB} of $\mathcal{M}_{\mathrm{HB}}$ is bounded from above by a polynomial in n, $\log N$, and $\log \epsilon^{-1}$.*

In order to prove Theorem 7, we will show how to define a multicommodity flow $\mathcal{F}$ such that the total flow along any transition (ω, ω'') is at most $8fn^{2d_m+1}P_{\mathrm{HB}}(\omega, \omega'')$, where f is an expression that is at most $poly(n)\,|\Omega|$. We will also ensure that $\mathcal{L}(\mathcal{F})$ is bounded from above by a polynomial in n. Theorem 7 will then follow from (1) in Theorem 1. Constructing the flow $\mathcal{F}$ is done in a two-stage process. In subsection 4.1, we will define a multicommodity flow $\mathcal{F}^*$. Then in subsection 4.2, we will first prove that the total flow through any state ω is at most f. Finally, also in subsection 4.2, we will construct $\mathcal{F}$ by modifying $\mathcal{F}^*$.

In the first subsection we define the multicommodity flow we use in our application of Theorem 1. The construction uses the balanced, strongly balanced, and almost-uniform properties of permutations of (some of) the columns of the contingency tables.

The second subsection shows that, with the multicommodity flow we define, each edge of the graph G_Ω is not too congested, and each path length is small. Theorem 7 then follows from Theorem 1.

4.1. Defining the flow. The construction of $\mathcal{F}$ in this subsection uses the methods of Morris and Sinclair [20] introduced in section 3.

Let k be the index of the largest column sum c_k. Let X and Y be contingency tables in Ω. Let X_j denote the jth column of X. We show how to route a unit of flow from X to Y.

The rough idea is as follows. We first define the notion of a *column constrained table*, which is an $m \times n$ matrix that has the correct column sums for $\Sigma_{r,c}$ but may violate the row sum constraints. We will choose a permutation π from an appropriate distribution. The distribution from which π is chosen will be defined in terms of an interlacing of the random balanced permutation of Theorem 4 and the strongly balanced permutation of Theorem 6. π will be a permutation of most of the columns

of the table. The permutation π will define a path

$$Z_0 = X, \ldots, Z_{n'}$$

(for some $n' < n$) of column constrained tables, where each table Z_h contains the column Y_j for $j \in \pi\{1, \ldots, h\}$ and the column X_j for all other j (so at each point, we swap another column of X for the same column of Y). In subsection 4.1.1 we show that the balance properties of π ensure that for any Z_h, we can bring all the row sums below r_i by deleting a constant number of columns. Then in subsection 4.1.2 we will show how to use this fact to define a path

$$X = Z'_0, \ldots, Z'_{n'+1} = Y,$$

where each Z'_h is in $\Sigma_{r,c}$ and there is a transition in $\mathcal{M}_{\mathrm{HB}}$ from each Z'_h to Z'_{h+1}. The amount of flow that we will route along this path will be proportional to the probability with which π is chosen.

4.1.1. A first step toward building paths. We start building our path(s) from X to Y by first defining a path of column constrained tables $Z_0 = X, \ldots, Z_{n'}$ using an interlacing of the random balanced permutation of Theorem 4 and the strongly balanced permutation of Theorem 6. In subsection 4.1.2, we will show how to modify these columns, in a specific manner, to yield a new path of tables such that (i) the new tables are contingency tables (i.e., they satisfy the row sums as well as the column sums) and (ii) each successive pair along this path differs by a transition of $\mathcal{M}_{\mathrm{HB}}$.

Let R_i^X be the set of indices for the $3g_m + 1$ largest entries of row i of X.

Let R_i^Y be the set of indices for the $3g_m + 1$ largest entries of row i of Y.

Let $R = \left(\cup_i R_i^X\right) \cup \left(\cup_i R_i^Y\right) \cup \{k\}$ be the union of all the R_i^X and R_i^Y sets, together with the index k (which was defined earlier to be the index of the largest column sum).

The cardinality of R is at most $2m(3g_m + 1) + 1$.

The columns in R are "reserved" columns that we identify before permuting the columns. We do not permute these columns—we need them for something else. For every row i, define

$$M_i = \min\{\max\{X[i,j] : j \notin R\}, \max\{Y[i,j] : j \notin R\}\},$$
$$L_i = \{j : j \notin R, X[i,j] > M_i\} \cup \{j : j \notin R, Y[i,j] > M_i\}.$$

Note that by definition of M_i, we either have $\{j : j \notin R,\ X[i,j] > M_i\} = \emptyset$ or $\{j : j \notin R, Y[i,j] > M_i\} = \emptyset$, so each L_i corresponds to a set of columns of X *or* a set of columns of Y, but not both. Also from their definitions, we see that $M_i \le X[i,j]$ for all $j \in R_i^X$, and $M_i \le Y[i,j]$ for all $j \in R_i^Y$. Set $L = \cup_{i=1}^m L_i$ and $S = [n] - (L \cup R)$.

For every column $j \in [n] - R$, define the m-dimensional weight $w_j = Y_j - X_j$. Let μ be the m-dimensional vector representing the mean of the $w_{j \in [n]-R}$. Note that

$$\mu^i = \frac{\sum_{j \in [n]-R} Y[i,j] - X[i,j]}{n - |R|} = \frac{\sum_{j \in R} X[i,j] - Y[i,j]}{n - |R|}.$$

Let π_1 be a strongly $16m^2$-balanced permutation on the set of weights $\{w_j\}_{j \in L}$. This exists by Theorem 6. Let π_2 be a g_m-balanced $p_m(|S|)$-uniform permutation on $\{w_j\}_{j \in S}$. This exists by Theorem 4. π_2 is a random permutation. We interlace π_1 and π_2 in the same way as Morris and Sinclair [20] do to get a permutation π on $\{w_j\}_{j \in [n]-R}$. For the benefit of the reader, we restate the rule for performing

this interlacing: Suppose that $\pi(1), \pi(2), \ldots, \pi(h)$ have already been assigned and that $\pi\{1, 2, \ldots, h\} = \pi_1\{1, \ldots, h_1\} \cup \pi_2\{1, \ldots, h_2\}$. Then either $\frac{h_1}{h} \leq \frac{|L|}{|L|+|S|}$ or $\frac{h_2}{h} < \frac{|S|}{|L|+|S|}$. We define $\pi(h+1)$ by

$$\pi(h+1) = \begin{cases} \pi_1(h_1+1) & \text{if } \frac{h_1}{h} \leq \frac{|L|}{|L|+|S|}, \\ \pi_2(h_2+1) & \text{if } \frac{h_2}{h} < \frac{|S|}{|L|+|S|}. \end{cases}$$

This new permutation π satisfies inequalities (5.8) and (5.9) in Morris and Sinclair [20], reproduced as inequalities (2) and (3) below and proved in [20]. (See also inequalities (3.8) and (3.9) in [19].) These inequalities state that for every prefix h (h is the index of a column) and every dimension i (i is the index of a row), there exist sets of column indices $V_{i,h}$ and $W_{i,h}$ such that $V_{i,h}$ differs from $\{1, \ldots, h\}$ by at most $17m^2$ indices and $W_{i,h}$ differs from $\{1, \ldots, h\}$ by at most $17m^2$ indices, and

$$\sum_{j \in V_{i,h}} w^i_{\pi(j)} \leq (h-1)\mu^i + 3g_m M_i \quad \text{for every } i = 1, \ldots, m, \tag{2}$$

$$\sum_{j \in W_{i,h}} w^i_{\pi(j)} \geq (h-1)\mu^i - 3g_m M_i \quad \text{for every } i = 1, \ldots, m. \tag{3}$$

The sets $V_{i,h}$ and $W_{i,h}$ will play an important role for us later.

Now let $n' = n - |R|$. For the permutation π constructed above we define the path of tables $X = Z_0, Z_1, \ldots, Z_{n'}$ as follows: For every h, Z_h contains the columns X_j for $j \in R \cup \pi\{h+1, \ldots, n'\}$ and columns Y_j for $j \in \pi\{1, \ldots, h\}$. We see that $Z_{n'}$ differs from Y by at most $2m(3g_m + 1) + 1$ columns.

It is important to note that $Z_0, \ldots, Z_{n'}$ may not be contingency tables in $\Sigma_{r,c}$ since they need not satisfy the row constraints. Thus, we cannot use this path directly to define our flow from X to Y. Nevertheless, we may base our path on these tables. The important point is that π and, in particular, (2) and (3) will allow us to turn $Z_0, \ldots, Z_{n'}$ into a path of contingency tables. In the remainder of this subsection, we will show that we do not have to change too many columns to turn Z_h into a contingency table. Subsequently in subsection 4.1.2 we will show that if we are careful about how we map Z_h to a contingency table, the resulting collection of paths will have good congestion.

We introduce the notation $(J(X), J(Y))$ to denote a set containing columns from X and from Y: For sets of indices $J(X) \subseteq [n]$ and $J(Y) \subseteq [n]$, $(J(X), J(Y))$ contains the column X_j for each $j \in J(X)$ and the column Y_j for each $j \in J(Y)$. For any set of columns $(J(X), J(Y))$, we represent the "row sum" for row i by $row^i(J(X), J(Y))$, which has the value $\sum_{j \in J(X)} X[i,j] + \sum_{j \in J(Y)} Y[i,j]$.

Defining $J_h(X) = R \cup \pi\{h+1, \ldots, n'\}$ and $J_h(Y) = \pi\{1, \ldots, h\}$, we see that Z_h is the set of columns $(J_h(X), J_h(Y))$. Each of the Z_h tables is a column constrained table because, as previously noted, it is possible that some rows i may have $row^i(J_h(X), J_h(Y)) \neq r_i$. However, all the column sums are satisfied by Z_h.

Step 1. We show we can modify Z_h by "deleting" at most d_m columns (including all of the X_j columns for $j \in R$) to bring the row sum for every row i below $r_i(1-1/n)$. We also show a dual result—if we "add" at most d_m columns to Z_h this brings the row sum for every row i above $r_i(1+1/n)$. The "adding" causes some column indices to appear in both $J(X)$ and $J(Y)$; thus the resulting configuration isn't much like a contingency table, but the construction will be useful below. Let $V_{i,h}$ and $W_{i,h}$ be the sets of inequalities (2) and (3).

First, instead of considering Z_h, consider $(\pi([n'] - V_{i,h}), \pi(V_{i,h}))$. This set of columns is the result of starting with the contingency table X, removing X_j for every reserved column $j \in R$, and then adding the weights w_j for $j \in \pi(V_{i,h})$. By (2), we know that $|V_{i,h} \oplus \{1, \ldots, h\}| \leq 17m^2$ and

$$\begin{aligned} row^i(\pi([n'] - V_{i,h}), \pi(V_{i,h})) &\leq \left(r_i - \sum_{j \in R} X[i,j]\right) + (h-1)\mu^i + 3g_m M_i \\ &= \left(r_i - \sum_{j \in R} X[i,j]\right) + 3g_m M_i \\ &\quad + \frac{h-1}{n'}\left(\sum_{j \in R} X[i,j] - Y[i,j]\right) \\ &= r_i - \frac{n'-h+1}{n'}\left(\sum_{j \in R} X[i,j]\right) \\ &\quad - \frac{h-1}{n'}\left(\sum_{j \in R} Y[i,j]\right) + 3g_m M_i \\ &\leq r_i\Big(1 - \frac{1}{n}\Big), \qquad \text{(a)} \end{aligned}$$

where the last step follows because (i) we know that $M_i \leq X[i,j]$ for every $j \in R_i^X$, and $R_i^X \subseteq R$, $|R_i^X| = 3g_m + 1$. Also $\max_{j \in R_i^X} X[i,j] \geq r_i/n$. Thus $3g_m M_i + r_i/n \leq \sum_{j \in R} X[i,j]$; (ii) similarly, $3g_m M_i + r_i/n \leq \sum_{j \in R} Y[i,j]$; and (iii) the convex combination $((n'-h+1)\sum_{j \in R} X[i,j] + (h-1)\sum_{j \in R} Y[i,j])/n'$ is at least $3g_m M_i + r_i/n$.

Now suppose we also "delete" $\pi\{1, \ldots, h\} \oplus \pi\{V_{i,h}\}$ from $(\pi([n'] - V_{i,h}), \pi(V_{i,h}))$. Let $B_{i,h} = R \cup (\pi\{1, \ldots, h\} \oplus \pi\{V_{i,h}\})$.

Then

$$\begin{aligned} J_h(X) - B_{i,h} &= \pi\{h+1, \ldots, n'\} \cap \pi([n'] - V_{i,h}), \\ J_h(Y) - B_{i,h} &= \pi\{1, \ldots, h\} \cap \pi(V_{i,h}). \end{aligned}$$

By (a), we have $row^i(J_h(X) - B_{i,h}, J_h(Y) - B_{i,h}) \leq row^i(\pi([n'] - V_{i,h}), \pi(V_{i,h})) \leq r_i(1 - 1/n)$. Also, $|B_{i,h}| \leq 2m(3g_m + 1) + 1 + 17m^2$.

For the dual result, consider $(\pi([n'] - W_{i,h}) \cup R, \pi(W_{i,h}) \cup R)$. This set of columns is the result of starting with the contingency table X, adding the Y_j columns for $j \in R$, and then adding the weights w_j for $j \in \pi(W_{i,h})$. By (3), we know that $|W_{i,h} \oplus \{1, \ldots, h\}| \leq 17m^2$ and

$$\begin{aligned} row^i(\pi([n'] - W_{i,h}) \cup R, \pi(W_{i,h}) \cup R) &\geq \left(r_i + \sum_{j \in R} Y[i,j]\right) + (h-1)\mu^i - 3g_m M_i \\ &= \left(r_i + \sum_{j \in R} Y[i,j]\right) - 3g_m M_i \\ &\quad + \frac{h-1}{n'}\left(\sum_{j \in R} X[i,j] - Y[i,j]\right) \end{aligned}$$

$$= r_i + \frac{n' - h + 1}{n'}\left(\sum_{j \in R} Y[i,j]\right) + \frac{h-1}{n'}\left(\sum_{j \in R} X[i,j]\right) - 3g_m M_i$$
$$\geq r_i\Big(1 + \frac{1}{n}\Big), \qquad \text{(b)}$$

where the last step follows using (i) $3g_m M_i + r_i/n \leq \sum_{j \in R} X[i,j]$; (ii) $3g_m M_i + r_i/n \leq \sum_{j \in R} Y[i,j]$; and (iii) the convex combination property mentioned on the previous page.

Suppose we add $\pi\{1,\ldots,h\} \oplus \pi\{W_{i,h}\}$ to $(\pi([n'] - W_{i,h}) \cup R, \pi(W_{i,h}) \cup R)$.

Let $C_{i,h} = R \cup (\pi\{1,\ldots,h\} \oplus \pi\{W_{i,h}\})$.

Then

$$J_h(X) \cup C_{i,h} = \pi\{h+1,\ldots,n'\} \cup \pi([n'] - W_{i,h}) \cup R,$$
$$J_h(Y) \cup C_{i,h} = \pi\{1,\ldots,h\} \cup \pi(W_{i,h}) \cup R.$$

By (b), we have $row^i(J_h(X) \cup C_{i,h}, J_h(Y) \cup C_{i,h}) \geq row^i(\pi([n'] - W_{i,h}) \cup R, \pi(W_{i,h}) \cup R) \geq r_i(1 + 1/n)$. Also, $|C_{i,h}| \leq 2m(3g_m + 1) + 1 + 17m^2$.

Finally, define D_h to be a set of d_m column indices, including any column that is in $(\cup_i B_{i,h}) \cup (\cup_i C_{i,h})$. This is possible because $d_m = 2m(3g_m + 1) + 1 + 34m^3$. In addition to the set R (of size $2m(3g_m + 1) + 1$), each set $B_{i,h}$ contains up to $17m^2$ indices as does each set $C_{i,h}$.

Consider Z_h with all of the columns in D_h "deleted." This is the table

$$Z_h^* =_{def} (J_h(X) - D_h, J_h(Y) - D_h).$$

Since $B_{i,h} \subseteq D_h$ for every i, we have $row^i(J_h(X) - D_h, J_h(Y) - D_h) \leq r_i(1 - 1/n)$ for all i. Also define

$$\bar{Z}_h^* =_{def} (J_h(X) \cup D_h, J_h(Y) \cup D_h).$$

Since $C_{i,h} \subseteq D_h$ for every i, we have $row^i(J_h(X) \cup D_h, J_h(Y) \cup D_h) \geq r_i(1 + 1/n)$ for all i.

Note that D_h contains all of R, including the index k.

4.1.2. Going from Z_h to an element of Ω. Having defined the set D_h, we now show how to change Z_h into a contingency table. This is a crucial step, actually turning the tables $Z_0, \ldots, Z_{n'}$ into a path of elements of Ω that joins the two contingency tables X and Y. The most critical part in the construction of this multicommodity flow is to ensure that the flow on any edge $e \in G_\Omega$ is not too large. Therefore it will be important to prove that we do not map too many of the column constrained tables Z_h to any given element of Ω. We will see below that we will need to be careful in mapping column constrained tables which have large column sums for some of the "deleted" columns D_h.

Step 2. We now show how to convert Z_h into an element of Ω. We focus on the "deleted" columns D_h and show that by changing only the entries of the columns in D_h, we can obtain a contingency table $Z'_h \in \Sigma_{r,c}$. We also show a dual result: that if we define $\bar{Z}_h$ to be the set of columns which contains X_j for every Y_j column in Z_h

and contains Y_j for every X_j column in Z_h, we can show the same result for $\bar{Z}_h$ (we can construct a $\bar{Z}'_h$ in $\Sigma_{r,c}$ by changing at most d_m columns).

First let $\widehat{r}_i = row^i(J_h(X) - D_h, J_h(Y) - D_h)$, the partial row sum for row i of Z_h with the D_h columns removed. Define $s_i = r_i - \widehat{r}_i$ for all i, the sum for row i of the subtable that was removed from Z_h.

Note that $s_i \geq r_i/n$ for all i.

Let $N_h = \sum_{i=1}^{m} s_i = \sum_{j \in D_h} c_j$, by construction. We have two cases to consider.

Case 1. First suppose $N_h < 2(md_m)^2$. It is well known that whenever the total of the row sums equals the total of the column sums, there is at least one contingency table satisfying these row and column sums (see Diaconis and Gangolli [6]). For this case we choose *any* set of modified values $Z'_h[i,j]$ for $j \in D_h$ such that $\sum_{i=1}^{m} Z'_h[i,j] = c_j$ for all $j \in D_h$ and $\sum_{j \in D_h} Z'_h[i,j] = s_i$ for all $1 \leq i \leq m$. Note that because $N_h < 2(md_m)^2$ we have $s_i < 2(md_m)^2$ for all i and therefore $r_i < 2n(md_m)^2$ for all i.

Case 2. Alternatively, assume that $N_h \geq 2(md_m)^2$. As above, we are guaranteed that there is some set of $Z'_h[i,j]$ values for $j \in D_h$ that satisfy the row and column sums. But, for this case, we need something stronger—we show how we can modify the values of $Z_h[i,j]$ for the $j \in D_h$ columns in a *structured way* to obtain a subtable Z'_h satisfying the induced row sums s_i and the column sums c_j. Performing the modification in this carefully structured way allows us to ensure that the congestion on edges in G_Ω in our multicommodity flow is not too large, a point we return to following the definitions in the next paragraph.

By our previous definition of D_h, we already know that k is the index of the largest column sum c_j for $j \in D_h$. Let ℓ be the index of the biggest s_i value. For every $i \neq \ell$ and every $j \in D_h - \{k\}$, we define $a_{i,j}$ in terms of the overall row sums and the column sums:

$$a_{i,j} =_{def} \lfloor \min\{r_i, c_j\}/n(d_m)^2 \rfloor.$$

Since $Z_h[i,j]$ is either $X[i,j]$ or $Y[i,j]$, we know $Z_h[i,j] \leq \min\{r_i, c_j\}$. Therefore, for every $i \neq \ell$ and every $j \in D_h - \{k\}$, we can write

$$Z_h[i,j] = Q[i,j](a_{i,j} + 1) + R[i,j]$$

for nonnegative integers $Q[i,j], R[i,j]$, where $Q[i,j] < n(d_m)^2$ and $0 \leq R[i,j] \leq a_{i,j}$. $Q[i,j]$ and $R[i,j]$ are uniquely determined by $Z_h[i,j]$. We will show that by changing only the values of the $Q[i,j]$ to new values $Q'[i,j]$, we can obtain a subtable Z'_h satisfying the row sums s and the column sums. As promised, however, we first give the reason why we want to view the entries of Z_h in this way, focusing on the importance of changing only the $Q[i,j]$ terms to obtain the subtable Z'_h.

Our analysis of the flow we construct will rely on bounding the number of column constrained tables Z_h that can be transformed into the contingency table Z'_h. In particular, for each particular choice of D_h, we bound the number of tables Z_h that can be transformed into Z'_h. If the subtable sum N_h is less than $2(md_m)^2$, then $r_i < 2n(md_m)^2$ for every i and therefore, for every $j \in D_h$ and every row i, there are at most $2n(md_m)^2$ possible original values for $Z_h[i,j]$. On the other hand, when $N_h \geq 2(md_m)^2$, we do not have an upper bound on the original entries of the subtable. However, the method above for constructing the $Z'_h[i,j]$ values using $a_{i,j}$ gives an indirect upper bound for the number of Z_h that could be converted to Z'_h. For any true contingency table Z'_h and any selection of D_h columns which gives $N_h \geq 2(md_m)^2$, we can calculate $a_{i,j}$ for all $i \neq \ell$ and all $j \in D_h - \{k\}$. Then, for every row $i \neq \ell$

and every column j in $D_h - \{k\}$, we can find the original value of $R[i,j]$ using that $R[i,j] = Z'_h[i,j] \bmod (a_{i,j}+1)$. By the definition of $a_{i,j}$, there are at most $n(d_m)^2$ possible values for the original $Q[i,j]$, so there are only $(n(d_m)^2)^{(m-1)(d_m-1)}$ different ways of filling in the entire subtable on the $D_h - \{k\}$ columns. The fact that there are at most $poly(n)$ possible values for the original $Q[i,j]$ cells is the key that makes our analysis work in section 4.2.

We now return to our proof, since we still need to show that we can choose values $Q'[i,j]$ which ensure that the new $Z'_h[i,j]$ values will satisfy row sums s_i and column sums c_j. Recall our assumption that $N_h \geq 2(md_m)^2$. It is well known (see Dyer, Kanaan, and Mount [12]) that the row and column sums are satisfied by any integer matrix Z'_h which has $Z'_h[i,j] \geq 0$ for all i,j, where the $Z'[i,j]$ also satisfy the following inequalities:

$$\sum_{i \neq \ell} Z'_h[i,j] \leq c_j \quad \text{for every } j \in D_h - \{k\}, \tag{4}$$

$$\sum_{j \in D_h - \{k\}} Z'_h[i,j] \leq s_i \quad \text{for every } i \neq \ell, \tag{5}$$

$$\sum_{i \neq \ell} \sum_{j \in D_h - \{k\}} Z'_h[i,j] \geq N_h - s_\ell - c_k. \tag{6}$$

Now define $Q'[i,j]$ in terms of the induced row sums and the original column sums:

$$Q'[i,j] =_{def} \lfloor s_i c_j / N_h (a_{ij}+1) \rfloor$$

for all $i \neq \ell$ and all $j \in D_h - \{k\}$. For those values of i and j, we set $Z'_h[i,j] = Q'[i,j](a_{i,j}+1) + R[i,j]$. Note that $Q'[i,j] \geq 0$ for all i,j. We now prove that inequalities (4), (5), and (6) are satisfied for these $Z'[i,j]$.

Inequality (4):

$$\begin{aligned}
\sum_{i \neq \ell} Z'_h[i,j] &= \sum_{i \neq \ell} Q'[i,j](a_{i,j}+1) + \sum_{i \neq \ell} R[i,j] \\
&= \sum_{i \neq \ell} \lfloor s_i c_j / N_h (a_{ij}+1) \rfloor (a_{i,j}+1) + \sum_{i \neq \ell} R[i,j] \\
&\leq \sum_{i \neq \ell} s_i c_j / N_h + \sum_{i \neq \ell} R[i,j] \\
&\leq \sum_{i \neq \ell} s_i c_j / N_h + \sum_{i \neq \ell} a_{i,j} \\
&= c_j (1 - s_\ell / N_h) + \sum_{i \neq \ell} \lfloor \min\{r_i, c_j\} / n(d_m)^2 \rfloor \\
&\leq c_j (1 - s_\ell / N_h) + c_j (m-1) / n(d_m)^2 \\
&\leq c_j (1 - 1/m + 1/nd_m) \\
&\leq c_j.
\end{aligned}$$

The last two steps use the facts that (i) $s_\ell / N_h \geq 1/m$ (because s_ℓ is the largest row sum) and (ii) $d_m > m$.

Inequality (5): The early steps are similar to the proof for inequality (4). We get

$$\begin{aligned}\sum_{j\in D_h-\{k\}} Z'_h[i,j] &\le s_i(1-c_k/N_h) + \sum_{j\in D_h-\{k\}} \lfloor \min\{r_i,c_j\}/n(d_m)^2 \rfloor \\ &\le s_i(1-c_k/N_h) + (d_m-1)r_i/n(d_m)^2 \\ &\le s_i(1-1/d_m) + s_i/d_m \\ &\le s_i,\end{aligned}$$

where the second-to-last step uses the facts that (i) $c_k/N_h \ge 1/d_m$ (because c_k is the largest column sum in the subtable) and (ii) $s_i \ge r_i/n$.

Inequality (6):

$$\begin{aligned}\sum_{i\neq\ell}\sum_{j\in D_h-\{k\}} Z'_h[i,j] &= \sum_{i\neq\ell}\sum_{j\in D_h-\{k\}} Q'[i,j](a_{i,j}+1) + \sum_{i\neq\ell}\sum_{j\in D_h-\{k\}} R[i,j] \\ &= \sum_{i\neq\ell}\sum_{j\in D_h-\{k\}} \lfloor s_i c_j/N_h(a_{i,j}+1)\rfloor (a_{i,j}+1) + \sum_{i\neq\ell}\sum_{j\in D_h-\{k\}} R[i,j] \\ &\ge \sum_{i\neq\ell}\sum_{j\in D_h-\{k\}} s_i c_j/N_h - \sum_{i\neq\ell}\sum_{j\in D_h-\{k\}} (a_{i,j}+1) + \sum_{i\neq\ell}\sum_{j\in D_h-\{k\}} 0 \\ &= (N_h-s_\ell)(N_h-c_k)/N_h - \sum_{i\neq\ell}\sum_{j\in D_h-\{k\}} (a_{i,j}+1) \\ &= (N_h-s_\ell-c_k) + s_\ell c_k/N_h - \sum_{i\neq\ell}\sum_{j\in D_h-\{k\}} (a_{i,j}+1).\end{aligned}$$

Next, note that

$$\begin{aligned} s_\ell c_k/N_h &\ge N_h/(md_m), \\ \sum_{i\neq\ell}\sum_{j\in D_h-\{k\}} (a_{i,j}+1) &\le md_m + m(N_h-c_k)/n(d_m)^2 \le md_m + N_h/(nd_m m),\end{aligned}$$

by definition of the $a_{i,j}$ and because $d_m \ge m^2$. Therefore, to show that inequality (6) holds, it suffices to show

$$N_h/(md_m) \ge md_m + N_h/(nd_m m). \tag{7}$$

We note the following statements:

$$\begin{aligned} & N_h/(md_m) \ge md_m + N_h/(nd_m m) \\ \iff & N_h(1-1/n)/(md_m) \ge md_m \\ \Longleftarrow\ & N_h/2 \ge (md_m)^2 \quad \text{(using that } n\ge 2\text{)} \\ \iff & N_h \ge 2(md_m)^2.\end{aligned}$$

This last statement holds by our previous assumption on N_h; therefore inequality (7) holds, and hence (6) is true, as required.

Therefore, in parallel with our path of column constrained tables, we have a path $X = Z'_0, \ldots, Z'_h, \ldots, Z'_{n'}$ such that Z'_h differs from Z_h in only d_m columns and $Z'_0, Z'_1, \ldots$ are true contingency tables. We can add a final step to change $Z'_{n'}$ (using one step of the Markov chain) into Y. The amount of flow from X to Y that is routed

along this path is proportional to the probability that π is chosen. Since $n' \le n$, we see that the length of this path from X to Y is at most $n+1$.

Remember that the column constrained table Z_h contains exactly n columns and that $X_j \in Z_h \Leftrightarrow Y_j \notin Z_h$. Also, Z_h is the pair $(J_h(X), J_h(Y))$. Then if we define $\bar{Z}_h$ by the pair of sets $(J_h(Y), J_h(X))$, $\bar{Z}_h$ also contains exactly n columns and $X_j \in \bar{Z}_h \Leftrightarrow X_j \notin Z_h$. Now to calculate the row sums of $\bar{Z}_h$, consider $\bar{Z}_h$ with the columns of D_h removed. Then

$$\begin{aligned} row^i(J_h(Y) - D_h, J_h(X) - D_h) &= row^i(([n] - J_h(X)) - D_h, ([n] - J_h(Y)) - D_h) \\ &= row^i([n] - (J_h(X) \cup D_h), [n] - (J_h(Y) \cup D_h)) \\ &= 2r_i - row^i(J_h(X) \cup D_h, J_h(Y) \cup D_h) \\ &\le r_i(1 - 1/n) \end{aligned}$$

because we proved that $row^i(J_h(X) \cup D_h, J_h(Y) \cup D_h) \ge r_i(1 + 1/n)$ in Step 1.

Therefore, for $\bar{Z}_h$, there also exists a set of d_m columns (the same set of indices D_h) such that we can obtain a true contingency table $\bar{Z}'_h \in \Sigma_{r,c}$ by modifying these columns in the structured way described above.

4.2. Analysis of the multicommodity flow. Next we show that the flow through any state $Z' \in \Omega$ is at most $poly(n)\,|\Omega|$. (Remark: We actually bound all of the flow *except* that due to pairs (X, Y) where $Z' = Y$. The total flow for all such pairs is only $|\Omega|$. Hence showing a bound of the form $poly(n)\,|\Omega|$ for the flow between remaining pairs where $Z' \ne Y$ provides us a similar bound for the total flow through Z'.) We assume Z' occurs as Z'_h for some pairs of contingency tables (X, Y) and some values of h and $\pi\{1, \ldots, h\}$. Again, we write $\bar{Z}_h$ for the column constrained table with X_j for $j \in J_h(Y)$ and Y_j for $j \in J_h(X)$. We claim that if we are given Z'_h and

(1) $\bar{Z}'_h \in \Omega$, a true contingency table obtained by changing d_m of the columns of $\bar{Z}_h$;
(2) the value of h and the set $\pi\{1, \ldots, h\}$ of columns already changed from X to Y in Z_h;
(3) the set D_h of d_m columns of Z_h which were modified to obtain Z'_h (note that the columns of $\bar{Z}_h$ that were modified are also the columns in D_h);
(4) the index ℓ of the largest induced row sum s_ℓ for the subtable of Z_h on D_h and the index ℓ' of the largest induced row sum for the subtable of $\bar{Z}_h$ on D_h;
(5) two possibilities:
(i) If $N_h < 2(md_m)^2$, then we are given the original values of $Z_h[i, j]$ for all i, for all $j \in D_h$. Note we have $Z_h[i, j] \le 2(md_m)^2$;
(ii) Otherwise if $N_h \ge 2(md_m)^2$, we are given the original integers $Q[i, j]$ obtained from $Z_h[i, j]$ for every $i \ne \ell$ and every $j \in D_h - \{k\}$. Note we have $0 \le Q[i, j] < n(d_m)^2$;
(5′) two possibilities:
(i) If $N_h < 2(md_m)^2$, then we are given the original values of $\bar{Z}_h[i, j]$ for all i, for all $j \in D_h$. Note we have $\bar{Z}_h[i, j] \le 2(md_m)^2$;
(ii) Otherwise if $N_h \ge 2(md_m)^2$, we are given the original integers $\bar{Q}[i, j]$ obtained from $\bar{Z}_h[i, j]$ for every $i \ne \ell'$ and every $j \in D_h - \{k\}$. Note we have $0 \le \bar{Q}[i, j] < n(d_m)^2$;

then we can construct X and Y. We refer to the information in (1)–(5′) as an "encoding" (for X and Y at the element $Z' \in \Omega$).

First we concentrate on recovering Z_h. From (3) we know the submatrix D_h which has to be modified to obtain Z_h from Z'_h. Since we know the D_h columns, we can calculate N_h. If $N_h < 2(md_m)^2$, then the information in (5) tells us the original $Z_h[i,j]$ values for $j \in D_h$ and this gives us the entire column constrained table Z_h. If $N_h \geq 2(md_m)^2$, then we use (4) to identify ℓ. For every $i \neq \ell$ and $j \in D_h - \{k\}$ we calculate $a_{i,j}$ from r_i and c_j and we calculate $R[i,j] = Z'_h[i,j] \bmod (a_{i,j}+1)$. Finally, by (5) we have the original values of $Q[i,j]$ for all $i \neq \ell$ and all $j \in D_h - \{k\}$. Therefore we calculate $Z_h[i,j] = Q[i,j](a_{i,j}+1) + R[i,j]$. We can also calculate $Z_h[\ell,j]$ for $j \in D_h - \{k\}$ by subtracting the other values of $Z_h[i,j]$ (which we just calculated) from c_j. We still need to find the values $Z_h[i,k]$, but we defer this for the moment.

In a similar way, we use (3), (4), and (5′) to obtain all columns except column k of $\bar{Z}_h$ from $\bar{Z}'_h$ (given to us in (1)).

We now have all the columns except for column k of Z_h and $\bar{Z}_h$. Z_h contains column X_j for every $j \in J_h(X) = R \cup \pi\{h+1,\ldots,n'\}$ and contains column Y_j for every $j \in J_h(Y) = \pi\{1,\ldots,h\}$. $\bar{Z}_h$ contains column X_j for every $j \in J_h(Y) = [n] - J_h(X)$ and column Y_j for every $j \in J_h(X) = [n] - J_h(Y)$. By (2), we are given $\pi\{1,\ldots,h\}$. Then the contingency table X is the set of columns where

$$X_j = \begin{cases} \text{column } j \text{ of } Z_h \text{ for } j \in [n] - \pi\{1,\ldots,h\}, \\ \text{column } j \text{ of } \bar{Z}_h \text{ for } j \in \pi\{1,\ldots,h\}. \end{cases}$$

The contingency table Y is the set of columns where

$$Y_j = \begin{cases} \text{column } j \text{ of } Z_h \text{ for } j \in \pi\{1,\ldots,h\}, \\ \text{column } j \text{ of } \bar{Z}_h \text{ for } j \in [n] - \pi\{1,\ldots,h\}. \end{cases}$$

Thus for any $Z'_h \in \Omega$, we can construct all columns of X and Y except column k. Column k of each of these can then be recovered using the original r_i values. Thus, for any $Z'_h \in \Omega$, we can construct X and Y for any pair (X,Y) whose path passes through Z'_h, given the encoding (1)–(5′).

Now we bound the flow through our given Z'_h. Note that the flow through Z'_h is (bounded by) the number of possible choices for (1) and for (3)–(5′), times the amount of flow given by all possible choices for $\pi\{1,\ldots,h\}$ (given by (2)).

Since $\bar{Z}'_h \in \Omega$, there are $|\Omega|$ choices for (1).

There are $\binom{n}{d_m-1}$ possible D_h sets (choices for (3)), since D_h always contains k.

There are m^2 choices for (4).

Depending on the value of N_h, either there are at most $n(d_m)^2$ possible values for the original value of $Z_h[i,j]$ for $j \in D_h$ (obtained via $Q[i,j]$), or there are at most $2(md_m)^2$ possible values for the original value of $Z_h[i,j]$ for $j \in D_h$. Therefore there are at most $(2n(md_m)^2)^{md_m}$ possible sets of $Z_h[i,j]$ for (5). The same upper bound holds for (5′).

The total number of choices for (4)–(5′) is $m^2(2n(md_m)^2)^{2md_m}$. We will write this as $C_m n^{2md_m}$, where C_m is the constant $2^{2m(d_m)}m^2(md_m)^{4md_m}$.

Recall that we are shipping one unit of flow from X to Y for all ordered pairs $(X,Y) \in \Omega^2$, and we want to find an upper bound on the amount of flow that passes through a given element $Z' \in \Omega$. The portion of flow from X to Y passing through Z' is determined by the distribution on the choices of permutations in (2). The permutation π defines the sequence $Z_0,\ldots,Z_{n'}$ which, in turn, defines $Z'_0,\ldots,Z'_{n'}$. We want to know how much flow passes through Z'_h for the choices (1), (3)–(5′) of the

encoding. Therefore, we see the amount passing through Z'_h is bounded above by

$$|\Omega| C_m \binom{n}{d_m - 1} n^{2md_m} \sum_h \sum_{U:\ |U|=h} \Pr[\pi\{1,\dots,h\} = U],$$

where $\Pr[\pi\{1,\dots,h\} = U]$ is the probability that U is the set of the first h columns to be changed.

Therefore (as in [20]), we need to bound $\sum_h \sum_{U:\ |U|=h} \Pr[\pi\{1,\dots,h\} = U]$ for each particular possibility for parts 1, 3, 4, 5, and 5′ of the encoding. As explained before, these parts of the encoding determine Z_h and $\bar{Z}_h$ (apart from column k). Z_h and $\bar{Z}_h$ together give us the set $\{X_j, Y_j\}$ for any $j \neq k$, but they don't tell us which of the two columns is X_j and which is Y_j. The relevant parts of the encoding also determine D_h. For the given value of D_h, there are at most $2^{d_m - 1}$ possibilities for R (which must include column k), and we shall sum over all of them. We then upper bound the flow coming from all permutations $\pi\{1,\dots,h\}$ on the columns of $[n] - R$. There are at most $(2(n - |R|))^m \leq (2n)^m$ possibilities for the vector M giving the M_i values and we like likewise sum over all such choices. For each choice of (possible) values $\{M_i\}$ we can compute from Z_h and $\bar{Z}_h$ the set $L_i = \{j : j \notin R,\ X[i,j] > M_i\} \cup \{j : j \notin R,\ Y[i,j] > M_i\}$. Note that this gives us $S = [n] - (L \cup R)$ as well. By our remark on page 254, we know that each L_i consists solely of columns of X, or solely of columns of Y. Therefore there are only two possibilities for assigning all the L_i columns to X or Y (2^m choices for all of $L = \cup_i L_i$).

Let $h_2 = h - |\pi\{1,\dots,h\} \cap L|$. We bound the flow passing through Z'_h below. Note that the first summation is over all $(2(n - |R|))^m$ possibilities for M and all 2^m possible assignments of L.

$$\begin{aligned}
&|\Omega| C_m \binom{n}{d_m - 1} n^{2md_m} \sum_{R,M,L,h_2} \sum_{U \subseteq S:\ |U|=h_2} \Pr[\pi_2\{1,\dots,h_2\} = U] \\
&\leq |\Omega| C_m \binom{n}{d_m - 1} n^{2md_m} 2^{d_m - 1} (2n)^m 2^m n \sum_{U \subseteq S:\ |U|=h_2} \Pr[\pi_2\{1,\dots,h_2\} = U] \\
&\leq |\Omega| C_m \binom{n}{d_m - 1} n^{2md_m} 2^{d_m - 1} (2n)^m 2^m n \sum_{U \subseteq S:\ |U|=h_2} p_m(|S|) \Big/ \binom{|S|}{h_2} \\
&\leq |\Omega| C_m \binom{n}{d_m - 1} n^{2md_m} 2^{d_m - 1} (2n)^m 2^m n \binom{|S|}{h_2} p_m(|S|) \Big/ \binom{|S|}{h_2} \\
&\leq |\Omega| C_m \binom{n}{d_m - 1} n^{2md_m} 2^{d_m - 1} (2n)^m 2^m n p_m(|S|),
\end{aligned}$$

which is $poly(n)\,|\Omega|$.

Thus we know that the flow through any *state* is bounded by a quantity f which is at most $poly(n)\,|\Omega|$. In the application of Morris and Sinclair [20] this is already sufficient to prove polynomial time mixing, since the term $P(e)$ in the denominator of (1) is only polynomially small. However, for our heat-bath chain P_{HB}, this term may be exponentially small, and a further argument is required to establish rapid mixing.

To this end, let $e = (\omega, \omega')$ $(\omega, \omega' \in \Omega^2)$ be a (directed) transition of $\mathcal{M}_{\mathrm{HB}}$, with transition probability $P_{\mathrm{HB}}(e)$. Suppose that f_e units of flow are shipped along e in the multicommodity flow $\mathcal{F}^*$ defined above. We will construct a new flow $\mathcal{F}$ in which these f_e units are dispersed, travelling from ω to ω' via a "random destination" ω''.

Let B be the set of columns on which ω and ω' disagree and let W be the set of all size $m \times (2d_m + 1)$ heat-bath windows which include B. Let Ω'' be the set of all contingency tables ω'' such that

1. there is a $U \in W$ which contains all the columns on which ω and ω'' differ, and

2. there is a $U' \in W$ which contains all the columns on which ω' and ω'' differ.

For each $\omega'' \in \Omega''$, the flow $\mathcal{F}$ will route $f_e/|\Omega''|$ flow from ω to ω' via ω''. Note that this construction doubles the length of our flow paths, but no more. Hence, the length of the longest path in the new flow $\mathcal{F}$ is at most $2(n+1)$.

The quantity shipped through (ω, ω'') in $\mathcal{F}$ from the original transition e in the multicommodity flow $\mathcal{F}^*$ is $f_e/|\Omega''|$, which is at most $4f_e n^{2d_m+1} P_{\mathrm{HB}}(\omega, \omega'')$. To see this, let K be the (nonempty) set of columns on which ω and ω'' differ. For every heat-bath window U, let $\Omega_\omega(U)$ denote the set of contingency tables which agree with ω, except possibly on window U, and write

$$\begin{aligned} P_{\mathrm{HB}}(\omega, \omega'') &= \frac{1}{4} \sum_{U \supseteq K} \frac{1}{\binom{n}{2d_m+1}} \frac{1}{|\Omega_\omega(U)|} \\ &\geq \frac{1}{4} \sum_{U \supseteq K, U \in W} \frac{1}{\binom{n}{2d_m+1}} \frac{1}{|\Omega_\omega(U)|} \\ &\geq \frac{1}{4} \sum_{U \supseteq K, U \in W} \frac{1}{\binom{n}{2d_m+1}} \frac{1}{|\Omega''|} \\ &\geq \frac{1}{4} \frac{1}{\binom{n}{2d_m+1}} \frac{1}{|\Omega''|}, \end{aligned}$$

where the last inequality follows from the fact that $\omega'' \in \Omega''$, so there is at least one U in the summation.

We call the transition (ω, ω'') a *type* 1 transition and a transition (ω'', ω') a *type* 2 transition.

We can now give an upper bound for the total type 1 flow along the transition (ω, ω''). For each $e = (\omega, \omega')$, we ship at most $4f_e n^{2d_m+1} P_{\mathrm{HB}}(\omega, \omega'')$ flow. Let f be the bound from above on the *total* flow that leaves node ω in our original multicommodity flow $\mathcal{F}^*$ (so $f = \sum_e f_e$, where the sum is over transitions e which start at ω). Then the total amount routed via ω'' in $\mathcal{F}$ is at most $4fn^{2d_m+1} P_{\mathrm{HB}}(\omega, \omega'')$.

Using a symmetric argument, we can show that the total type 2 flow along the transition (ω'', ω') in $\mathcal{F}$ is at most $4fn^{2d_m+1} P_{\mathrm{HB}}(\omega'', \omega')$.

Thus, the total flow in $\mathcal{F}$ along transition (ω, ω'') is at most $8fn^{2d_m+1} P_{\mathrm{HB}}(\omega, \omega'')$. Using the fact that the longest flow-carrying path length is at most $2(n+1)$, this is now sufficient for the right-hand side of (1) to be polynomially bounded, since the (possibly small) $P_{\mathrm{HB}}(e)$ term cancels. This completes the proof of Theorem 7. □

5. Mixing of the 2×2 chain. Theorem 7 shows that the Markov chain $\mathcal{M}_{\mathrm{HB}}$ is rapidly mixing. In this section we use the comparison method of Diaconis and Saloff-Coste [7] to show that the 2×2 chain $\mathcal{M}_{2\times 2}$ is also rapidly mixing. We briefly describe the comparison method, in the context of contingency tables, adapted from [7]. For more details and other examples of applications of this method, see [7], Randall and Tetali [23], and Vigoda [27].

5.1. Setting up the comparison. Recall that P_{HB} denotes the transition matrix of the Markov chain $\mathcal{M}_{\mathrm{HB}}$ which was analyzed in section 4. Let $E(P_{\mathrm{HB}})$ be

the set of edges (excluding loops) in the Markov kernel of that chain. That is, $E(P_{\mathrm{HB}}) = \{(X,Y) : X \neq Y \text{ and } P_{\mathrm{HB}}(X,Y) > 0\}$. Let $P_{2\times 2}$ denote the transition matrix of $\mathcal{M}_{2\times 2}$ and let $E(P_{2\times 2})$ denote the edge-set of its Markov kernel.

For every $(X,Y) \in E(P_{\mathrm{HB}})$ we define a set of paths $\Gamma_{X,Y}$ where each $\gamma \in \Gamma_{X,Y}$ is a path $X = \eta_0, \eta_1, \ldots, \eta_k = Y$, such that $(\eta_i, \eta_{i+1}) \in E(P_{2\times 2})$ for all $i \in \{0, \ldots, k-1\}$. Let $|\gamma|$ denote the length (number of edges) of the path. We also define a *flow* $f_{X,Y}$, which is a function from $\Gamma_{X,Y}$ to the positive reals satisfying the condition

$$\sum_{\gamma \in \Gamma_{X,Y}} f_{X,Y}(\gamma) = 1. \tag{8}$$

It is important to note that this flow need be defined only for pairs $(X,Y) \in E(P_{\mathrm{HB}})$, not for all pairs (X,Y).

For each $(Z,Z') \in E(P_{2\times 2})$, define the quantity

$$A_{Z,Z'} = \frac{1}{P_{2\times 2}(Z,Z')} \sum_{(X,Y)\in E(P_{\mathrm{HB}})} \sum_{\substack{\gamma \in \Gamma_{X,Y} \text{ such} \\ \text{that } (Z,Z') \in \gamma}} |\gamma| f_{X,Y}(\gamma) P_{\mathrm{HB}}(X,Y).$$

We use the comparison theorem of Diaconis and Saloff-Coste, which says[1] that

$$\tau_{2\times 2}(\epsilon) \in O(\tau_{HB}(\epsilon) \log(|\Sigma_{r,c}|) \max_{(Z,Z')\in E(P_{2\times 2})} A_{Z,Z'}).$$

In our construction of the flow, we ensure that the length of each path $\gamma \in \Gamma_{X,Y}$ is bounded by a constant. Thus, the theorem of Diaconis and Saloff-Coste tells us that to establish rapid mixing, we need only define $f_{X,Y}$ for every $(X,Y) \in E(P_{\mathrm{HB}})$ such that (8) is satisfied and also, for all $(Z,Z') \in E(P_{2\times 2})$, the following is satisfied:

$$\frac{1}{P_{2\times 2}(Z,Z')} \sum_{(X,Y)\in E(P_{\mathrm{HB}})} \sum_{\substack{\gamma \in \Gamma_{X,Y} \text{ such} \\ \text{that } (Z,Z') \in \gamma}} f_{X,Y}(\gamma) P_{\mathrm{HB}}(X,Y) \leq poly(n). \tag{9}$$

It helps us to rework (9) before defining the flows. For $(X,Y) \in E(P_{\mathrm{HB}})$, let $\mathcal{W}(X,Y)$ be the set of all $m \times (2d_m + 1)$ "windows" such that X and Y agree outside of W, where a "window" is just a set of m rows and $2d_m + 1$ columns. Note that

$$P_{\mathrm{HB}}(X,Y) = \frac{1}{4} \sum_{W\in\mathcal{W}(X,Y)} \frac{1}{\binom{n}{2d_m+1}} \frac{1}{|\Omega_X(W)|},$$

where $\Omega_X(W)$ is the set of all contingency tables that agree with X outside of W. We may view $P_{\mathrm{HB}}(X,Y)$ as (a multiple of) the average of the quantities $1/|\Omega_X(W)|$ over all windows $W \in \mathcal{W}(X,Y)$. Therefore, there is some $W(X,Y) \in \mathcal{W}(X,Y)$ such that

$$P_{\mathrm{HB}}(X,Y) \leq \frac{1}{|\Omega_X(W(X,Y))|}. \tag{10}$$

[1]The statement of the theorem in this form is from Vigoda [27] and Randall and Tetali [23]. The derivation of Proposition 4 in [23] required the eigenvalues of P_{HB} to be at least $1/2$, which is why we added the self-loops to $\mathcal{M}_{\mathrm{HB}}$. (Actually, bounding the eigenvalues above zero by any amount suffices.) The comparison uses the fact that the eigenvalues of $P_{2\times 2}$ are positive since this method provides a lower bound for $1 - \lambda_1(P_{2\times 2})$ in terms of $1 - \lambda_1(P_{\mathrm{HB}})$, and in these situations those differences directly relate to mixing times.

The essential idea to keep in mind in what follows is that routing the unit flow $f_{X,Y}$ from X to Y is done using paths of contingency tables that differ from one another solely on (a 2×2 part of) this specially chosen window $W(X,Y)$ that satisfies (10).

For each $m \times (2d_m + 1)$ window W, let $E_W = \{(X,Y) : (X,Y) \in E(P_{HB}) \text{ and } W(X,Y) = W\}$. Later, when we define our flows, we do the following for every fixed window W: For every $(X,Y) \in E_W$, we define a flow $f_{X,Y}$ such that (8) is satisfied. We also ensure that for all $(Z,Z') \in E(P_{2\times 2})$, the following is satisfied:

$$\frac{1}{P_{2\times 2}(Z,Z')} \sum_{(X,Y)\in E_W} \sum_{\substack{\gamma\in\Gamma_{X,Y} \text{ such} \\ \text{that } (Z,Z')\in\gamma}} f_{X,Y}(\gamma) P_{\mathrm{HB}}(X,Y) \le poly(n). \tag{11}$$

Since there are only polynomially many windows W, by summing over all of them we see that (11) implies (9), and ensures rapid mixing of $\mathcal{M}_{2\times 2}$.

For each window W, section 5.2 shows how to define a flow $f^*_{X,Y}$ for every $(X,Y) \in E_W$ such that

$$\sum_{\gamma\in\Gamma_{X,Y}} f^*_{X,Y}(\gamma) = 1$$

and the total flow through any contingency table $Z \in \Sigma_{r,c}$ is in $O(|\Omega_X(W)|)$. At the end of section 5.1 we will define $f_{X,Y}$ by modifying $f^*_{X,Y}$. Let $f^*_{X,Y}(Z)$ denote the amount of flow passing through the contingency table Z in the flow $f^*_{X,Y}$. Let $f^*(Z) = \sum_{(X,Y)\in E_W} f^*_{X,Y}(Z)$. Similarly, let $f_{X,Y}(Z,Z')$ denote the amount of flow passing through the transition (Z,Z') in the flow $f_{X,Y}$. Let $f(Z,Z') = \sum_{(X,Y)\in E_W} f_{X,Y}(Z,Z')$. Our construction of $f_{X,Y}$ from $f^*_{X,Y}$ will ensure that for every $(Z,Z') \in E(P_{2\times 2})$, we have

$$f(Z,Z') \le 4 f^*(Z) P_{2\times 2}(Z,Z') \binom{n}{2}\binom{m}{2}. \tag{12}$$

Thus, the left-hand side of (11) is equal to

$$\begin{aligned}
&\frac{1}{P_{2\times 2}(Z,Z')} \sum_{(X,Y)\in E_W} \sum_{\substack{\gamma\in\Gamma_{X,Y} \text{ such} \\ \text{that } (Z,Z')\in\gamma}} f_{X,Y}(\gamma) P_{\mathrm{HB}}(X,Y) \\
&\le \frac{1}{P_{2\times 2}(Z,Z')} \sum_{(X,Y)\in E_W} \sum_{\substack{\gamma\in\Gamma_{X,Y} \text{ such} \\ \text{that } (Z,Z')\in\gamma}} f_{X,Y}(\gamma) \frac{1}{|\Omega_X(W)|} \qquad (13)\\
&= \frac{1}{P_{2\times 2}(Z,Z')} \cdot \frac{1}{|\Omega_X(W)|} \sum_{(X,Y)\in E_W} f_{X,Y}(Z,Z') \\
&= \frac{f(Z,Z')}{P_{2\times 2}(Z,Z')} \cdot \frac{1}{|\Omega_X(W)|} \\
&\le \frac{4 f^*(Z)\binom{n}{2}\binom{m}{2}}{|\Omega_X(W)|} \le poly(n). \qquad (14)
\end{aligned}$$

Inequality (13) comes from (10), where $\Omega_X(W) = \Omega_X(W(X,Y))$, and from our definition of E_W. The first inequality in (14) comes from (12) which we establish shortly, and the second inequality in (14) comes from the fact that $f^*(Z) \in$

$O(|\Omega_X(W)|)$, which is established in section 5.2. We will then have shown that (11) is satisfied, as required, and thus $\mathcal{M}_{2\times 2}$ is rapidly mixing on $\Sigma_{r,c}$.

We finish this section by showing how to construct $f_{X,Y}$ given the flow $f^*_{X,Y}$, thereby establishing (12). The method is similar to (but simpler than) the one that we used at the end of section 4.2.

Recall that $E(P_{2\times 2})$ excludes self-transitions of the form (Z, Z). Thus, for each $(Z, Z'') \in E(P_{2\times 2})$, there is a *unique* 2×2 window $U(Z, Z'')$ on which Z and Z'' disagree. Let $\Omega_Z(U(Z, Z''))$ denote the set of all contingency tables that agree with Z (and Z'') everywhere outside of the 2×2 window $U(Z, Z'')$. Let $f^*_{X,Y}(Z, Z'')$ be the flow that passes through (Z, Z'') in $f^*_{X,Y}$. For each $Z' \in \Omega_Z(U(Z, Z''))$, some of this flow is allocated to the path Z, Z', Z''. In particular, $f^*_{X,Y}(Z, Z'')/|\Omega_Z(U(Z, Z''))|$ flow is sent this way.

Now $f_{X,Y}(Z, Z') \le 2\sum_{Z''\in U(Z,Z')} \frac{f^*_{X,Y}(Z,Z'')}{|\Omega_Z(U(Z,Z''))|}$, where the first "2" comes from the fact that we must consider paths Z, Z', Z'' above, and also paths that end in edge Z, Z'. The right-hand side is at most

$$2\frac{f^*_{X,Y}(Z)}{|\Omega_Z(U(Z, Z'))|} \le 4f^*_{X,Y}(Z)P_{2\times 2}(Z, Z')\binom{n}{2}\binom{m}{2};$$

thus (12) holds.

By considering all $m \times (2d_m + 1)$-sized windows which contain the two columns on which Z and Z' differ, we can see that for each $(Z, Z') \in E(P_{2\times 2})$, we have

$$A_{Z,Z'} \le C\binom{n}{2}\binom{n-2}{2d_m - 1},$$

where the constant C accounts for the maximum length of any (X, Y) path for $(X, Y) \in E(P_{\mathrm{HB}})$, and the constant factors arising in the bound for the flow $f^*(Z)$ over a single $m \times (2d_m + 1)$ window W. Therefore, we have the following theorem.

THEOREM 8.

$$\tau_{\mathcal{M}_{2\times 2}}(\epsilon) \in O(\tau_{\mathcal{M}_{\mathrm{HB}}}(\epsilon)\log(|\Sigma_{r,c}|)n^{2d_m+1}).$$

5.2. Defining $f^*(X, Y)$. In this section we define a flow $f^*_{X,Y}$ for every $(X, Y) \in E_W$ such that $\sum_{\gamma\in\Gamma_{X,Y}} f^*_{X,Y}(\gamma) = 1$ and the total flow through any contingency table Z, due to pairs in E_W, is in $O(|\Omega_X(W)|)$.

Throughout this entire section, we therefore focus on some fixed $m \times (2d_m + 1)$-sized window W of the larger $m \times n$ table. Without loss of generality (and to make our notation simpler in what follows), we assume that W includes the first $2d_m + 1$ columns of the table. This window W has induced row sums ρ_i (for $i \in [m]$) and induced column sums ζ_j (for $j \in [2d_m + 1]$). For convenience we also set $\delta = 2d_m + 1$.

Let $\rho = (\rho_1, \ldots, \rho_m)$, $\zeta = (\zeta_1, \ldots, \zeta_\delta)$ be the lists of induced row and column sums. Let $\Sigma_{\rho,\zeta}$ denote the set of $m \times \delta$ contingency tables with rows sums ρ and column sums ζ, and let N_W denote the table sum. Let $\Upsilon, \Psi \in \Sigma_{\rho,\zeta}$. We show how to route a unit of flow between Υ and Ψ using a path of contingency tables that differ by moves of $\mathcal{M}_{2\times 2}$. This flow lifts in the obvious fashion to transitions $(X, Y) \in E(P_{\mathrm{HB}})$, giving us the flow $f^*_{X,Y}$ required in the previous section. In other words, we simply use the exact same sequence of 2×2 transitions on the window $W(X, Y)$, keeping everything outside this window fixed (where X and Y agree anyway).

If $N_W < (2m\delta)^2$, then $|\Sigma_{\rho,\zeta}| \in O(1)$; thus it does not really matter how we route flow between Υ and Ψ. For example, it suffices to fix each square in the contingency

table in lexicographic order. Each path in the resulting flow is of length $O(1)$, and there are $O(1)$ pairs (Υ, Ψ) of contingency tables, so the desired bound is easily established. This is similar to, but simpler than, what we do later in section 5.2.3. Thus, from now on we assume $N_W \geq (2m\delta)^2$ and show how to construct a flow between Υ and Ψ in $\Sigma_{\rho,\zeta}$.

Without loss of generality we may assume that the row totals are sorted into nondescending order and that the column totals are also sorted into nondescending order. Therefore ρ_m is the largest row sum and ζ_δ is the largest column sum.

As we did in section 4.1.2, we view the space $\Sigma_{\rho,\zeta}$ of contingency tables as the $(m-1)(\delta-1)$-dimensional space of integer matrices Φ that satisfy $\Phi[i,j] \geq 0$ for all $i \in [m-1]$ and all $j \in [\delta-1]$, and also satisfy the following inequalities (see Dyer, Kannan, and Mount [12]):

$$\sum_{i=1}^{m-1} \Phi[i,j] \leq \zeta_j \quad \text{for every } j \in [\delta-1], \tag{15}$$

$$\sum_{j=1}^{\delta-1} \Phi[i,j] \leq \rho_i \quad \text{for every } i \in [m-1], \tag{16}$$

$$\sum_{i=1}^{m-1} \sum_{j=1}^{\delta-1} \Phi[i,j] \geq N_W - \rho_m - \zeta_\delta. \tag{17}$$

Let

$$\alpha_{i,j} = \left\lfloor \frac{\min\{\rho_i, \zeta_j\}}{m^2\delta^2} \right\rfloor \tag{18}$$

for all $i \in [m-1]$, $j \in [\delta-1]$.

Note that

$$\begin{aligned} \max_{j \in [\delta-1]} \alpha_{i,j} &= \alpha_{i,\delta-1} \text{ for all } i; \\ \max_{i \in [m-1]} \alpha_{i,j} &= \alpha_{m-1,j} \text{ for all } j; \\ \max_{i \in [m-1], j \in [\delta-1]} \alpha_{i,j} &= \alpha_{m-1,\delta-1}. \end{aligned}$$

For any contingency table $\Phi \in \Sigma_{\rho,\zeta}$, and any $i \in [m-1]$, $j \in [\delta-1]$, we can write

$$\Phi[i,j] = Q[i,j](\alpha_{i,j}+1) + R[i,j]$$

for a unique integer $R[i,j]$ satisfying $0 \leq R[i,j] \leq \alpha_{i,j}$, and a unique integer $Q[i,j]$.

For all $i \in [m-1]$, $j \in [\delta-1]$ we define

$$Q^*[i,j] = \left\lfloor \frac{\rho_i \zeta_j}{N_W(\alpha_{i,j}+1)} \right\rfloor. \tag{19}$$

Let $\Upsilon, \Psi \in \Sigma_{\rho,\zeta}$. We are almost ready to start building a path from Υ to Ψ that uses transitions of $\mathcal{M}_{2\times 2}$. We use the following lemma.

LEMMA 9. *Let $\Phi^*[i,j]$ be defined by*

$$\Phi^*[i,j] = Q^*[i,j](\alpha_{i,j}+1) + R[i,j]$$

for any nonnegative integers $R[i,j] \le \alpha_{i,j}$, *for all* $i \in [m-1]$, $j \in [\delta-1]$. *Also, we set*

$$\Phi^*[i,\delta] = \rho_i - \sum_{j=1}^{\delta-1} \Phi^*[i,j] \qquad \text{for } i \in [m-1],$$

$$\Phi^*[m,j] = \zeta_j - \sum_{i=1}^{m-1} \Phi^*[i,j] \qquad \text{for } j \in [\delta-1],$$

$$\text{and} \quad \Phi^*[m,\delta] = \zeta_\delta - \sum_{i=1}^{m-1} \Phi^*[i,\delta].$$

Then the following hold.

(i) $\Phi^* \in \Sigma_{\rho,\zeta}$.

(ii) *Under the assumption that* $N_W \ge (2m\delta)^2$, *we have the following:*

$$\Phi^*[i,\delta] \ge (\alpha_{i,\delta-1}+1) \text{ for all } i \in [m-1],$$
$$\Phi^*[m,j] \ge (\alpha_{m-1,j}+1) \text{ for all } j \in [\delta-1],$$
$$\Phi^*[m,\delta] \ge 2(\alpha_{m-1,\delta-1}+1).$$

Proof. (i) It suffices to show that the inequalities (15), (16), and (17) hold for the defined values of $\Phi^*[i,j]$ with $i \in [m-1]$ and $j \in [\delta-1]$. (Then the definitions of $\Phi^*[i,\delta]$, $\Phi^*[m,j]$, and $\Phi^*[m,\delta]$ are such that the entire $m \times \delta$ table satisfies the row and column sums ρ and ζ, respectively.)

This proof is analogous to that given in Case 2 in section 4.1.2 when we showed that inequalities (4), (5), and (6) held there, so we do not repeat that proof here.

(ii) By definition,

$$\begin{aligned}
\Phi^*[i,\delta] &= \rho_i - \sum_{j=1}^{\delta-1} \Phi^*[i,j] \\
&= \rho_i - \sum_{j=1}^{\delta-1} \left(\left\lfloor \frac{\rho_i \zeta_j}{N_W(\alpha_{i,j}+1)} \right\rfloor (\alpha_{i,j}+1) + R[i,j] \right) \\
&\ge \rho_i - \sum_{j=1}^{\delta-1} \left(\frac{\rho_i \zeta_j}{N_W} + \alpha_{i,j} \right) \\
&= \frac{\rho_i \zeta_\delta}{N_W} - \sum_{j=1}^{\delta-1} \alpha_{i,j} \\
&\ge \frac{\rho_i \zeta_\delta}{N_W} - \frac{\delta \rho_i}{m^2\delta^2} \\
&\ge \frac{\rho_i}{\delta} - \frac{\rho_i}{m^2\delta} \\
&\ge \frac{\rho_i}{m\delta} \\
&\ge 2\alpha_{i,\delta-1}.
\end{aligned}$$

Then, if $\alpha_{i,\delta-1} \ge 1$, we automatically have $\Phi^*[i,\delta] \ge (\alpha_{i,\delta-1}+1)$. However, if $\alpha_{i,\delta-1} = 0$, then $\alpha_{i,j} = 0$ for all $j \in [\delta-1]$, and there are two subcases to consider.

The first subcase is when $\rho_i\zeta_\delta < N_W$. Then $\rho_i\zeta_j < N_W$ for all $j \in [\delta-1]$, and $\Phi^*[i,j] = 0$ for all $j \in [\delta-1]$. Therefore $\Phi^*[i,\delta] = \rho_i \geq 1$. If $\rho_i\zeta_\delta \geq N_W$, then the fourth line of the derivation above (with $\alpha_{i,j} = 0$) gives $\Phi^*[i,\delta] \geq \rho_i\zeta_\delta/N_W \geq 1$. So in either subcase we have $\Phi^*[i,\delta] \geq 1 = (\alpha_{i,\delta-1}+1)$.

Using a similar argument we conclude that

$$\Phi^*[m,j] \geq (\alpha_{m-1,j}+1).$$

By definition

$$\begin{aligned}
\Phi^*[m,\delta] &= \zeta_\delta - \sum_{i=1}^{m-1} \Phi^*[i,\delta] \\
&= \zeta_\delta - \sum_{i=1}^{m-1} \left(\rho_i - \sum_{j=1}^{\delta-1} \Phi^*[i,j] \right) \\
&= (\rho_m + \zeta_\delta - N_W) + \sum_{i=1}^{m-1}\sum_{j=1}^{\delta-1} \left(\left\lfloor \frac{\rho_i\zeta_j}{N_W(\alpha_{i,j}+1)} \right\rfloor (\alpha_{i,j}+1) + R[i,j] \right) \\
&\geq (\rho_m + \zeta_\delta - N_W) + \sum_{i=1}^{m-1}\sum_{j=1}^{\delta-1} \left(\left\lfloor \frac{\rho_i\zeta_j}{N_W(\alpha_{i,j}+1)} \right\rfloor (\alpha_{i,j}+1) \right) \\
&\geq (\rho_m + \zeta_\delta - N_W) + \sum_{i=1}^{m-1}\sum_{j=1}^{\delta-1} \left(\frac{\rho_i\zeta_j}{N_W} - (\alpha_{i,j}+1) \right) \\
&= \frac{\rho_m\zeta_\delta}{N_W} - \sum_{i=1}^{m-1}\sum_{j=1}^{\delta-1} (\alpha_{i,j}+1) \\
&\geq \frac{\rho_m\zeta_\delta}{N_W} - \frac{m(N_W-\zeta_\delta)}{m^2\delta^2} - (m-1)(\delta-1) \\
&\geq \frac{N_W}{m\delta} - \frac{N_W}{m\delta^2} - (m-1)(\delta-1) \\
&\geq \frac{N_W}{4m\delta} + \left(\frac{N_W}{2m\delta} - \frac{N_W}{m\delta^2} \right) + \left(\frac{N_W}{4m\delta} - (m-1)(\delta-1) \right) \\
&\geq \frac{2\zeta_{\delta-1}}{4m\delta} + 0 + (\delta+m-1) \\
&\geq 2\alpha_{m-1,\delta-1} + 2,
\end{aligned}$$

as required. □

DEFINITION 10. *If Φ is a contingency table such that $Q[i,j] = Q^*[i,j]$ for every $i \in [m-1]$, $j \in [\delta-1]$, then we say that Φ belongs to the* inner domain *of $\Sigma_{\rho,\zeta}$.*

Now we consider a pair $\Upsilon, \Psi \in \Sigma_{\rho,\delta}$. For every $i \in [m-1]$, $j \in [\delta-1]$, we write

$$\Upsilon[i,j] = Q_\Upsilon[i,j](\alpha_{i,j}+1) + R_\Upsilon[i,j]$$

for the unique integer $R_\Upsilon[i,j]$ that satisfies $0 \leq R_\Upsilon[i,j] \leq \alpha_{i,j}$.

Similarly, for every $i \in [m-1]$, $j \in [\delta-1]$, we write

$$\Psi[i,j] = Q_\Psi[i,j](\alpha_{i,j}+1) + R_\Psi[i,j]$$

for the unique $R_\Psi[i,j]$ satisfying $0 \leq R_\Psi[i,j] \leq \alpha_{i,j}$.

The routing from Υ to Ψ proceeds in two stages. In the first phase, we route flow from Υ to the table Υ^* in the inner domain of $\Sigma_{\rho,\zeta}$ such that $\Upsilon^*[i,j] = Q^*[i,j](\alpha_{i,j}+1) + R_\Upsilon[i,j]$ holds for every $i \in [m-1]$, $j \in [\delta-1]$. Note that $\Upsilon^* \in \Sigma_{\rho,\zeta}$ using the previous lemma.

By defining a similar path between Ψ and Ψ^* and then reversing all the edges, we can route flow from some Ψ^* in the inner domain of $\Sigma_{\rho,\zeta}$ to Ψ such that $\Psi^*[i,j] = Q^*[i,j](\alpha_{i,j}+1) + R_\Psi[i,j]$ holds for every $i \in [m-1]$, $j \in [\delta-1]$. Similarly, we also have $\Psi^* \in \Sigma_{\rho,\zeta}$.

In the second phase of the routing we show how to route flow from Υ^* to Ψ^* by changing the $R_\Upsilon[i,j]$ to the $R_\Psi[i,j]$ values.

5.2.1. Phase 1. We show how to route Υ to Υ^* in the inner domain of $\Sigma_{\rho,\zeta}$, by changing only $Q[i,j]$ values at any step. For our analysis, we define the following metric on pairs $\Phi, \Phi' \in \Sigma_{\rho,\zeta}$:

$$
\begin{aligned}
d(\Phi,\Phi') &= d_1(\Phi,\Phi') + d_2(\Phi,\Phi') + d_3(\Phi,\Phi') + d_4(\Phi,\Phi'), \qquad \text{where} \\
d_1(\Phi,\Phi') &= \sum_{i=1}^{m-1}\sum_{j=1}^{\delta-1} |\Phi[i,j] - \Phi'[i,j]| \\
d_2(\Phi,\Phi') &= \frac{N_W+1}{3N_W}\left(\sum_{i=1}^{m-1} |\Phi[i,\delta] - \Phi'[i,\delta]|\right) \\
d_3(\Phi,\Phi') &= \frac{N_W+1}{3N_W}\left(\sum_{j=1}^{\delta-1} |\Phi[m,j] - \Phi'[m,j]|\right) \\
d_4(\Phi,\Phi') &= \frac{N_W+1}{3N_W}|\Phi[m,\delta] - \Phi'[m,\delta]|.
\end{aligned}
$$

This metric is used to show that the path we construct is moving us closer to Υ^* and that the length of this path from Υ to Υ^* is bounded by a constant.

We route Υ to Υ^* as a series of moves. Let Υ' denote some interim contingency table on the path from Υ to Υ^*. We choose our next move on this path from amongst four cases.

Case (a). Suppose that $\Upsilon'[m,\delta] < (\alpha_{m-1,\delta-1}+1)$. Then we perform a move to make $\Upsilon'[m,\delta]$ bigger (because we need to "leave room" for our other cases).

We now show there is at least one $\ell \in [m-1]$ such that $\Upsilon'[\ell,\delta] \geq \Upsilon^*[\ell,\delta] + (\alpha_{\ell,\delta-1}+1)$.

Note that by Lemma 9, in this case $\Upsilon'[m,\delta] < \Upsilon^*[m,\delta] - (\alpha_{m-1,\delta-1}+1)$. Suppose (for contradiction) that there is no ℓ as described above, so that

$$\Upsilon'[i,\delta] < \Upsilon^*[i,\delta] + (\alpha_{i,\delta-1}+1) \quad \text{for } i \in [m-1].$$

By definition

$$
\begin{aligned}
\Upsilon^*[i,\delta] &= \rho_i - \left(\sum_{j=1}^{\delta-1} \Upsilon^*[i,j]\right) \\
&= \rho_i - \left(\sum_{j=1}^{\delta-1} \left(\left\lfloor \frac{\rho_i \zeta_j}{N_W(\alpha_{i,j}+1)} \right\rfloor (\alpha_{i,j}+1) + R_\Upsilon[i,j]\right)\right).
\end{aligned}
$$

Now

$$\begin{aligned}\Upsilon'[m,\delta] &= \zeta_\delta - \left(\sum_{i=1}^{m-1}\Upsilon'[i,\delta]\right)\\ &> \zeta_\delta - \sum_{i=1}^{m-1}\left(\rho_i - \left(\sum_{j=1}^{\delta-1}\Upsilon^*[i,j]\right) + (\alpha_{i,\delta-1}+1)\right)\\ &= (\zeta_\delta + \rho_m - N_W) + \sum_{i=1}^{m-1}\left(\left(\sum_{j=1}^{\delta-1}\Upsilon^*[i,j]\right) - (\alpha_{i,\delta-1}+1)\right). \qquad (20)\end{aligned}$$

We expand $\sum_{i=1}^{m-1}((\sum_{j=1}^{\delta-1}\Upsilon^*[i,j]) - (\alpha_{i,\delta-1}+1))$ as

$$\begin{aligned}&\sum_{i=1}^{m-1}\left(\sum_{j=1}^{\delta-1}\left(\left\lfloor\frac{\rho_i\zeta_j}{N_W(\alpha_{i,j}+1)}\right\rfloor(\alpha_{i,j}+1) + R_\Upsilon[i,j]\right) - (\alpha_{i,\delta-1}+1)\right)\\ &\geq \sum_{i=1}^{m-1}\left(\sum_{j=1}^{\delta-1}\left(\frac{\rho_i\zeta_j}{N_W} - (\alpha_{i,j}+1)\right) - (\alpha_{i,\delta-1}+1)\right)\\ &= (N_W - \rho_m - \zeta_\delta) + \frac{\rho_m\zeta_\delta}{N_W} - \sum_{i=1}^{m-1}\sum_{j=1}^{\delta-1}(\alpha_{i,j}+1) - \sum_{i=1}^{m-1}(\alpha_{i,\delta-1}+1)\\ &\geq (N_W - \rho_m - \zeta_\delta) + \frac{\rho_m\zeta_\delta}{N_W} - \frac{m(N_W-\zeta_\delta)}{m^2\delta^2} - (m-1)(\delta-1) - \frac{m\zeta_{\delta-1}}{m^2\delta^2} - (m-1)\\ &\geq (N_W - \rho_m - \zeta_\delta) + \frac{N_W}{m\delta} - \frac{N_W}{m\delta^2} - m\delta + \delta\\ &\geq (N_W - \rho_m - \zeta_\delta) + \frac{N_W}{2m\delta} - m\delta + \delta\\ &\geq (N_W - \rho_m - \zeta_\delta) + \frac{N_W}{4m\delta} + \delta\\ &\geq (N_W - \rho_m - \zeta_\delta) + (\alpha_{m-1,\delta-1}+1), \qquad (21)\end{aligned}$$

where the second-to-last line follows since $N_W \geq (2m\delta)^2$, and the last line follows from the definition of $\alpha_{i,j}$ and because $\delta \geq m \geq 2$.

Combining (20) and (21), we have a contradiction to our original assumption that $\Upsilon'[m,\delta] < (\alpha_{m-1,\delta-1}+1)$. Therefore it must be that $\Upsilon'[\ell,\delta] \geq \Upsilon^*[\ell,\delta] + (\alpha_{\ell,\delta-1}+1)$ for some $\ell \in [m-1]$.

Similarly, there must be some $k \in [\delta-1]$ such that $\Upsilon'[m,k] \geq \Upsilon^*[m,k] + (\alpha_{m-1,k}+1)$.

In this case we add the transition $(\Upsilon' \to \Upsilon'')$ to our path from Υ to Υ^*, where Υ'' is identical to Υ' except for the following entries:

$$\begin{aligned}\Upsilon''[\ell,k] &= \Upsilon'[\ell,k] + (\alpha_{\ell,k}+1), \quad \Upsilon''[\ell,\delta] = \Upsilon'[\ell,\delta] - (\alpha_{\ell,k}+1),\\ \Upsilon''[m,k] &= \Upsilon'[m,k] - (\alpha_{\ell,k}+1), \quad \Upsilon''[m,\delta] = \Upsilon'[m,\delta] + (\alpha_{\ell,k}+1).\end{aligned}$$

Now we show that $d(\Upsilon'', \Upsilon^*) < d(\Upsilon', \Upsilon^*)$:

$$d_1(\Upsilon'', \Upsilon^*) = \sum_{i=1}^{m-1}\sum_{j=1}^{\delta-1} |\Upsilon''[i,j] - \Upsilon^*[i,j]| \leq d_1(\Upsilon', \Upsilon^*) + (\alpha_{\ell,k}+1),$$

$$d_2(\Upsilon'', \Upsilon^*) = \frac{N_W+1}{3N_W}\left(\sum_{i=1}^{m-1} |\Upsilon''[i,\delta] - \Upsilon^*[i,\delta]|\right) = d_2(\Upsilon', \Upsilon^*) - \frac{N_W+1}{3N_W}(\alpha_{\ell,k}+1),$$

$$d_3(\Upsilon'', \Upsilon^*) = \frac{N_W+1}{3N_W}\left(\sum_{j=1}^{\delta-1} |\Upsilon''[m,j] - \Upsilon^*[m,j]|\right) = d_3(\Upsilon', \Upsilon^*) - \frac{N_W+1}{3N_W}(\alpha_{\ell,k}+1),$$

$$d_4(\Upsilon'', \Upsilon^*) = \frac{N_W+1}{3N_W}|\Upsilon''[m,\delta] - \Upsilon^*[m,\delta]| = d_4(\Upsilon', \Upsilon^*) - \frac{N_W+1}{3N_W}(\alpha_{\ell,k}+1).$$

The equation for d_4 follows from Lemma 9.

Thus $d(\Upsilon'', \Upsilon^*) \leq d(\Upsilon', \Upsilon^*) + (\alpha_{\ell,k}+1) - (\alpha_{\ell,k}+1)(N_W+1)/N_W \leq d(\Upsilon', \Upsilon^*) - (\alpha_{\ell,k}+1)/N_W < d(\Upsilon', \Upsilon^*)$.

Case (b). We execute (b) whenever Case (a) does not hold and when *either* $\Upsilon'[\ell,\delta] < \Upsilon^*[\ell,\delta]$ for some $\ell \in [m-1]$ *or* $\Upsilon'[m,j] < \Upsilon^*[m,j]$ for some $j \in [\delta-1]$. Without loss of generality, assume the former. If this is the case, then there must be at least one $k \in [\delta-1]$ such that $\Upsilon'[\ell,k] > \Upsilon^*[\ell,k]$. Since we change only $Q[i,j]$ values during our routing, we know that $\Upsilon'[\ell,k] \geq \Upsilon^*[\ell,k] + (\alpha_{\ell,k}+1)$. Also, since we are not in Case (a), we know that $\Upsilon'[m,\delta] \geq (\alpha_{m-1,\delta-1}+1) \geq (\alpha_{\ell,k}+1)$.

In this case we add the transition $(\Upsilon' \to \Upsilon'')$ in our path from Υ to Υ^*, where Υ'' is identical to Υ' except for the following entries:

$$\Upsilon''[\ell,k] = \Upsilon'[\ell,k] - (\alpha_{\ell,k}+1), \quad \Upsilon''[\ell,\delta] = \Upsilon'[\ell,\delta] + (\alpha_{\ell,k}+1),$$
$$\Upsilon''[m,k] = \Upsilon'[m,k] + (\alpha_{\ell,k}+1), \quad \Upsilon''[m,\delta] = \Upsilon'[m,\delta] - (\alpha_{\ell,k}+1).$$

Now we show that $d(\Upsilon'', \Upsilon^*) < d(\Upsilon', \Upsilon^*)$:

$$d_1(\Upsilon'', \Upsilon^*) = \sum_{i=1}^{m-1}\sum_{j=1}^{\delta-1} |\Upsilon''[i,j] - \Upsilon^*[i,j]| = d_1(\Upsilon', \Upsilon^*) - (\alpha_{\ell,k}+1),$$

$$d_2(\Upsilon'', \Upsilon^*) = \frac{N_W+1}{3N_W}\left(\sum_{i=1}^{m-1} |\Upsilon''[i,\delta] - \Upsilon^*[i,\delta]|\right) \leq d_2(\Upsilon', \Upsilon^*) + \frac{N_W+1}{3N_W}(\alpha_{\ell,k}-1),$$

$$d_3(\Upsilon'', \Upsilon^*) = \frac{N_W+1}{3N_W}\left(\sum_{j=1}^{\delta-1} |\Upsilon''[m,j] - \Upsilon^*[m,j]|\right) \leq d_3(\Upsilon', \Upsilon^*) + \frac{N_W+1}{3N_W}(\alpha_{\ell,k}+1),$$

$$d_4(\Upsilon'', \Upsilon^*) = \frac{N_W+1}{3N_W}|\Upsilon''[m,\delta] - \Upsilon^*[m,\delta]| \leq d_4(\Upsilon', \Upsilon^*) + \frac{N_W+1}{3N_W}(\alpha_{\ell,k}+1),$$

where the expression for $d_2(\Upsilon'', \Upsilon^*)$ follows because $\Upsilon'[\ell,\delta] \leq \Upsilon^*[\ell,\delta] - 1$.

Therefore $d(\Upsilon'', \Upsilon^*) \leq d(\Upsilon', \Upsilon^*) - (\alpha_{\ell,k}+1) + (\alpha_{\ell,k}+1)(N_W+1)/N_W - 2(N_W+1)/3N_W$. This is at most $d(\Upsilon', \Upsilon^*) + (\alpha_{\ell,k}+1)/N_W - 2(N_W+1)/3N_W$. Then because $\alpha_{\ell,k} \leq N_W/(\delta m)^2$, we have $d(\Upsilon'', \Upsilon^*) \leq d(\Upsilon', \Upsilon^*) + 1/(m\delta)^2 + 1/3N_W - 2/3$, and using $N_W \geq (2\delta m)^2$, we obtain $d(\Upsilon'', \Upsilon^*) < d(\Upsilon', \Upsilon^*)$.

Case (c). We execute (c) when Cases (a)–(b) do not hold and *either* $\Upsilon'[\ell,\delta] > \Upsilon^*[\ell,\delta]$ for some $\ell \in [m-1]$ *or* $\Upsilon'[m,j] > \Upsilon^*[m,j]$ for some $j \in [\delta-1]$. Assume the former without loss of generality. Then there must exist some $k \in [\delta-1]$ such

that $\Upsilon'[\ell,k] < \Upsilon^*[\ell,k]$, and since we can only change the $\Upsilon[\ell,k]$ values by factors of $(\alpha_{\ell,k}+1)$, we have $\Upsilon'[\ell,k] \le \Upsilon^*[\ell,k] + (\alpha_{\ell,k}+1)$. Note that since $\Upsilon'[\ell,\delta] > \Upsilon^*[\ell,\delta]$ and using part (ii) of Lemma 9, we know $\Upsilon'[\ell,\delta] \ge (\alpha_{\ell,\delta-1}+1) \ge (\alpha_{\ell,k}+1)$. Because Case (b) does not hold, we know $\Upsilon'[m,k] \ge \Upsilon^*[m,k]$, and, from part (ii) of Lemma 9, this is at least $(\alpha_{m-1,k}+1) \ge (\alpha_{\ell,k}+1)$.

Therefore we can perform the transition $(\Upsilon' \to \Upsilon'')$, where Υ'' is identical to Υ' except for the following entries:

$$\begin{aligned}\Upsilon''[\ell,k] &= \Upsilon'[\ell,k] + (\alpha_{\ell,k}+1), \quad & \Upsilon''[\ell,\delta] &= \Upsilon'[\ell,\delta] - (\alpha_{\ell,k}+1),\\ \Upsilon''[m,k] &= \Upsilon'[m,k] - (\alpha_{\ell,k}+1), \quad & \Upsilon''[m,\delta] &= \Upsilon'[m,\delta] + (\alpha_{\ell,k}+1).\end{aligned}$$

As before, we now show that $d(\Upsilon'',\Upsilon^*) < d(\Upsilon',\Upsilon^*)$:

$$\begin{aligned}
d_1(\Upsilon'',\Upsilon^*) &= \sum_{i=1}^{m-1}\sum_{j=1}^{\delta-1} |\Upsilon''[i,j] - \Upsilon^*[i,j]| = && d_1(\Upsilon',\Upsilon^*) - (\alpha_{\ell,k}+1),\\
d_2(\Upsilon'',\Upsilon^*) &= \frac{N_W+1}{3N_W}\sum_{i=1}^{m-1} |\Upsilon''[i,\delta] - \Upsilon^*[i,\delta]| \le && d_2(\Upsilon',\Upsilon^*) + \frac{N_W+1}{3N_W}(\alpha_{\ell,k}-1),\\
d_3(\Upsilon'',\Upsilon^*) &= \frac{N_W+1}{3N_W}\sum_{j=1}^{\delta-1} |\Upsilon''[m,j] - \Upsilon^*[m,j]| \le && d_3(\Upsilon',\Upsilon^*) + \frac{N_W+1}{3N_W}(\alpha_{\ell,k}+1),\\
d_4(\Upsilon'',\Upsilon^*) &= \frac{N_W+1}{3N_W}|\Upsilon''[m,\delta] - \Upsilon^*[m,\delta]| \le && d_4(\Upsilon',\Upsilon^*) + \frac{N_W+1}{3N_W}(\alpha_{\ell,k}+1),
\end{aligned}$$

where the bound on $d_2(\Upsilon'',\Upsilon^*)$ follows, using that $\Upsilon'[\ell,\delta] \ge \Upsilon^*[\ell,\delta]+1$.

Case (d). This is the case when $\Upsilon'[i,\delta] = \Upsilon^*[i,\delta]$ for all $i \in [m-1]$, and $\Upsilon'[m,j] = \Upsilon^*[m,j]$ for all $j \in [\delta-1]$ (so neither Case (b) nor (c) holds), but $\Upsilon'[\ell,k] \ne \Upsilon^*[\ell,k]$ for some $\ell \in [m-1], k \in [\delta-1]$. We also assume Case (a) does not hold; otherwise we would not consider Case (d). In this case we will specify *two* transitions of $\mathcal{M}_{2\times 2}$, $\Upsilon' \to \Upsilon''$ and $\Upsilon'' \to \Upsilon'''$, so that $d(\Upsilon''',\Upsilon^*) < d(\Upsilon',\Upsilon^*)$.

Assume without loss of generality that $\Upsilon'[\ell,k] > \Upsilon^*[\ell,k]$. Hence, there must be some $k' \in [\delta-1]$ such that $\Upsilon'[\ell,k'] < \Upsilon^*[\ell,k']$.

Now because we change only $Q[i,j]$ values on the path from Υ to Υ^*, $\Upsilon'[\ell,k] > \Upsilon^*[\ell,k]$ implies $\Upsilon'[\ell,k] \ge \Upsilon^*[\ell,k] + (\alpha_{\ell,k}+1)$, and $\Upsilon'[\ell,k'] \le \Upsilon^*[\ell,k'] + (\alpha_{\ell,k'}+1)$.

By Lemma 9 and $\Upsilon'[m,\delta] = \Upsilon^*[m,\delta]$ we know $\Upsilon'[m,\delta] \ge (\alpha_{\ell,k}+1)$. Therefore we can perform the transition $(\Upsilon' \to \Upsilon'')$, where Υ'' is identical to Υ' except for the following entries:

$$\begin{aligned}\Upsilon''[\ell,k] &= \Upsilon'[\ell,k] - (\alpha_{\ell,k}+1), \quad & \Upsilon''[\ell,\delta] &= \Upsilon'[\ell,\delta] + (\alpha_{\ell,k}+1),\\ \Upsilon''[m,k] &= \Upsilon'[m,k] + (\alpha_{\ell,k}+1), \quad & \Upsilon''[m,\delta] &= \Upsilon'[m,\delta] - (\alpha_{\ell,k}+1).\end{aligned}$$

By Lemma 9 we also know $\Upsilon'[\ell,\delta] \ge (\alpha_{\ell,k'}+1)$ and $\Upsilon'[m,k'] \ge (\alpha_{\ell,k'}+1)$. Then we can perform the transition $(\Upsilon'' \to \Upsilon''')$ by changing the following entries:

$$\begin{aligned}\Upsilon'''[\ell,k'] &= \Upsilon''[\ell,k'] + (\alpha_{\ell,k'}+1), \quad & \Upsilon'''[\ell,\delta] &= \Upsilon''[\ell,\delta] - (\alpha_{\ell,k'}+1),\\ \Upsilon'''[m,k'] &= \Upsilon''[m,k'] - (\alpha_{\ell,k'}+1), \quad & \Upsilon'''[m,\delta] &= \Upsilon''[m,\delta] + (\alpha_{\ell,k'}+1).\end{aligned}$$

Finally we show that $d(\Upsilon''', \Upsilon^*) < d(\Upsilon', \Upsilon^*)$.

$$\begin{aligned}
d_1(\Upsilon''', \Upsilon^*) &= d_1(\Upsilon', \Upsilon^*) - (\alpha_{\ell,k} + \alpha_{\ell,k'} + 2),\\
d_2(\Upsilon''', \Upsilon^*) &= d_2(\Upsilon', \Upsilon^*) + \tfrac{N_W+1}{3N_W}|\alpha_{\ell,k} - \alpha_{\ell,k'}|,\\
d_3(\Upsilon''', \Upsilon^*) &= d_3(\Upsilon', \Upsilon^*) + \tfrac{N_W+1}{3N_W}(\alpha_{\ell,k} + \alpha_{\ell,k'} + 2),\\
d_4(\Upsilon''', \Upsilon^*) &= d_4(\Upsilon', \Upsilon^*) + \tfrac{N_W+1}{3N_W}|\alpha_{\ell,k} - \alpha_{\ell,k'}|.
\end{aligned}$$

Therefore

$$\begin{aligned}
d(\Upsilon''', \Upsilon^*) &= d(\Upsilon', \Upsilon^*) - (2/3 - 1/3N_W)(\alpha_{\ell,k} + \alpha_{\ell,k'} + 2)\\
&\quad + (2/3 + 2/3N_W)|\alpha_{\ell,k} - \alpha_{\ell,k'}|\\
&\le d(\Upsilon', \Upsilon^*) - (2/3 - 1/3N_W)(\alpha_{\ell,k} + \alpha_{\ell,k'} + 2)\\
&\quad + (2/3 + 2/3N_W)(\alpha_{\ell,k} + \alpha_{\ell,k'})\\
&\le d(\Upsilon', \Upsilon^*) + (\alpha_{\ell,k} + \alpha_{\ell,k'})/N_W - (2 - 1/N_W)(2/3)\\
&\le d(\Upsilon', \Upsilon^*) + 2/m^2\delta^2 - (2/3)\\
&< d(\Upsilon', \Upsilon^*).
\end{aligned}$$

By a repeated application of these cases, we construct a path joining Υ to some Υ^* that is in the inner domain of $\Sigma_{\rho,\zeta}$. As mentioned, we can also construct such a path joining Ψ to some Ψ^* in the inner domain, and then reverse all of the edges. Following a brief analysis of the flow for this first phase in the next section, we show how to join pairs of elements in the inner domain.

5.2.2. Analysis of flow for Phase 1. The definition of $\alpha_{i,j}$ defines an equivalence class on the set $\Sigma_{\rho,\zeta}$, where $\Phi \equiv \Phi'$ if and only if $\Phi[i,j] = \Phi'[i,j] \bmod (\alpha_{i,j}+1)$ for every $i \in [m-1]$, $j \in [\delta - 1]$ (i.e., all the remainders $R[i,j]$ and $R'[i,j]$ are the same).

Note that by definition of the $\alpha_{i,j}$ values, and since $\Phi[i,j] \le \{\rho_i, \zeta_j\}$ for all $i \in [m-1]$, $j \in [\delta-1]$ for every $\Phi \in \Sigma_{\rho,\zeta}$, any equivalence class contains at most $(m^2\delta^2)^{m\delta}$ contingency tables (there are at most $m^2\delta^2$ choices for each $Q[i,j]$ with $i \in [m-1]$, $j \in [\delta-1]$). Therefore each equivalence class contains a constant number of contingency tables.

The routing scheme given in Cases (a)–(d) defines a path $\Upsilon = \Phi_0, \Phi_1, \ldots, \Phi_t = \Upsilon^*$ from Υ to Υ^* for every $\Upsilon \in \Sigma_{\rho,\zeta}$. We know Φ_h lies in the same equivalence class as Υ and Υ^* for every h. By our analysis of Cases (a)–(d), we know that for every $h \ge 0$, either $d(\Phi_{h+1}, \Upsilon^*) < d(\Phi_h, \Upsilon^*)$ or $d(\Phi_{h+2}, \Upsilon^*) < d(\Phi_h, \Upsilon^*)$. This means we can define a subsequence of the path $\{\Phi_h\}$ such that (i) the subsequence contains at least every second element of $\{\Phi_h\}$ and (ii) no contingency table ever appears twice in the subsequence. Thus the length of the path from Υ to Υ^* is at most $2(m^2\delta^2)^{m\delta}$.

To analyze the amount of flow from Phase 1 that may pass through $\Phi \in \Sigma_{\rho,\zeta}$, we rely on the fact that for any $\Upsilon \in \Sigma_{\rho,\zeta}$ the path from Υ to Υ^* lies in the equivalence class of Υ. Therefore, for any fixed Ψ, there are at most $(m^2\delta^2)^{m\delta}$ different contingency tables Υ that may pass through Φ on the way to Υ^*. Also, by our bound on the length of the path, we know that for any fixed Ψ and Υ, Φ may occur at most $(m^2\delta^2)^{m\delta}$ times on the path from Υ to Υ^*.

Putting all of this information together, we see that for any fixed Ψ, the flow through any Φ during Phase 1 is at most $(m^2\delta^2)^{2m\delta}$. This implies that the total flow through Φ during Phase 1 is at most $|\Sigma_{\rho,\zeta}|\,(m^2\delta^2)^{2m\delta}$.

5.2.3. Phase 2. In this phase we describe how to route Υ^* to Ψ^*, i.e., route flow between any pair of elements in the inner domain of $\Sigma_{\rho,\zeta}$. We know that

$$\Upsilon^*[i,j] = Q^*[i,j](\alpha_{i,j}+1) + R_\Upsilon[i,j],$$
$$\Psi^*[i,j] = Q^*[i,j](\alpha_{i,j}+1) + R_\Psi[i,j]$$

for all $i \in [m-1]$, $j \in [m-1]$, where $Q^*[i,j]$ was defined in (19).

In this phase we route Υ^* to Ψ^* in $(m-1)(\delta-1)$ steps, by "fixing" one remainder at a time. The key to this approach is part (i) of Lemma 9, which shows that for *any* remainders $R[i,j]$ satisfying $R[i,j] \le \alpha_{i,j}$ for $i \in [m-1]$, $j \in [\delta-1]$, if Φ is defined by

$$\Phi[i,j] = Q^*[i,j](\alpha_{i,j}+1) + R[i,j]$$

for $i \in [m-1]$, $j \in [\delta-1]$, then $\Phi \in \Sigma_{\rho,\zeta}$ (where $\Phi[m,j]$ and $\Phi[i,\delta]$ are defined as in Lemma 9 to satisfy the row and column sums).

Suppose we order the "boxes" of the $m \times \delta$ contingency tables in lexicographic order: $(1,1),(1,2),\ldots,(1,\delta-1),(2,1),\ldots,(m-1,1),\ldots,(m-1,\delta-1)$. Letting $h = (h_1,h_2)$ denote any point in this lexicographic order, we use h^+ to denote the successor to h in this ordering.

Then we can define a series of tables

$$\Upsilon^* = \Phi_{(1,1)}, \Phi_{(1,2)}, \ldots, \Phi_h, \ldots, \Phi_{(m-1,\delta-1)} = \Psi^*$$

by

$$\Phi_h[i,j] = \begin{cases} \Psi^*[i,j] & \text{if } (i,j) \le h \text{ (and } i \ne m \text{ and } j \ne \delta), \\ \Upsilon^*[i,j] & \text{if } (i,j) \ge h^+ \text{ (and } i \ne m \text{ and } j \ne \delta), \\ \rho_i - \sum_{j=1}^{\delta-1} \Phi_h[i,j] & \text{if } j = \delta, \\ \zeta_j - \sum_{i=1}^{m-1} \Phi_h[i,j] & \text{if } i = m. \end{cases}$$

By part (i) of Lemma 9 we know that $\Phi_h \in \Sigma_{\rho,\zeta}$ for all h, and therefore $\Phi_h \to \Phi_{h^+}$ is a transition of $\mathcal{M}_{2\times 2}$. ("Fixing" the (i,j) remainder, i.e., changing $R_\Upsilon[i,j]$ into $R_\Psi[i,j]$, uses a transition of $\mathcal{M}_{2\times 2}$ that involves the four "boxes" (i,j), (i,δ), (m,j), and (m,δ).)

Note that if we define a dual table $\bar{\Phi}_h$ by

$$\bar{\Phi}_h[i,j] = \begin{cases} \Upsilon^*[i,j] & \text{if } (i,j) \le h \text{ (and } i \ne m \text{ and } j \ne \delta), \\ \Psi^*[i,j] & \text{if } (i,j) \ge h^+ \text{ (and } i \ne m \text{ and } j \ne \delta), \\ \rho_i - \sum_{j=1}^{\delta-1} \bar{\Phi}_h[i,j] & \text{if } j = \delta, \\ \zeta_j - \sum_{i=1}^{m-1} \bar{\Phi}_h[i,j] & \text{if } i = m, \end{cases}$$

then Lemma 9(i) also tells us that $\bar{\Phi}_h \in \Sigma_{\rho,\zeta}$.

Therefore we have a path of length $(m-1)(\delta-1)$ connecting Υ^* to Ψ^* in $\Sigma_{\rho,\zeta}$.

5.2.4. Analysis of flow for Phase 2. We bound the amount of flow from Phase 2 that can pass through any $\Phi \in \Sigma_{\rho,\zeta}$. Similar to section 4.2, we do this using an encoding. Suppose that we are given

(1) a pair of indices $h = (h_1, h_2)$ specifying that Φ occurs as Φ_h on the path from Υ^* to Ψ^* during phase 2;
(2) the dual contingency table $\bar{\Phi}_h$;
(3) the integers $Q_\Upsilon[i,j]$ for all $i \in [m]$, $j \in [\delta]$;
(4) the integers $Q_\Psi[i,j]$ for all $i \in [m]$, $j \in [\delta]$.

Then we can construct the original pair of tables Υ and Ψ exactly. The information in (1) and (2) first allows us to reconstruct Υ^* and Ψ^*. Then using Υ^*, we may reconstruct $R_\Upsilon[i,j]$ for all i,j since we know (or may compute) $Q^*[i,j]$. Knowing $R_\Upsilon[i,j]$, together with the information in (3), we can find Υ exactly, and in a like manner we can reconstruct Ψ. There are at most $(m^2\delta^2)^{m\delta}$ possible values for the $Q_\Upsilon[i,j]$, and the same number for the $Q_\Psi[i,j]$.

Therefore, for any $\Phi \in \Sigma_{\rho,\zeta}$, the total amount of flow that may pass through Φ during Phase 2 is at most $(m\delta)(m^2\delta^2)^{2m\delta}|\Sigma_{\rho,\zeta}|$.

5.2.5. Finishing up. Combining Phases 1 and 2, the length of any (Υ, Ψ)-path is at most $4(m\delta)^{2m\delta} + (m-1)(\delta-1)$. The total amount of flow that can pass through any $\Phi \in \Sigma_{\rho,\zeta}$ is at most $|\Sigma_{\rho,\zeta}|(2(m\delta)^{4m\delta} + m\delta(m^2\delta^2)^{2m\delta})$.

This establishes the condition on the flow f^* that was cited in section 5.1. As explained in that section we can alter this flow to get the new flow f, letting us establish Theorem 8, proving rapid mixing of $\mathcal{M}_{2\times 2}$ on the set of $m \times n$ contingency tables $\Sigma_{r,c}$.

ERRATUM: DISTRIBUTED ANONYMOUS MOBILE ROBOTS: FORMATION OF GEOMETRIC PATTERNS*

ICHIRO SUZUKI† AND MASAFUMI YAMASHITA‡

Abstract. In this note we make a minor correction to a scheme for robots to broadcast their private information. All major results of the paper [I. Suzuki and M. Yamashita, *SIAM J. Comput.*, 28 (1999), pp. 1347–1363] hold with this correction.

Key words. anonymous robots, broadcast

AMS subject classification. 68Q99

DOI. 10.1137/050631562

1. Correction. Algorithms $\psi_{f-point(2)}$ in section 3 and $\psi_{getview}$ in section 4 of [1] use the following technique for all robots r_i to simultaneously "broadcast" to the other robots a privately chosen directed line ℓ_i (e.g., the positive x-axis of its local coordinate system Z_i). As outlined in the paragraph that follows the proof of Theorem 3.4, the basic idea is that each r_i moves repeatedly along ℓ_i in a fixed direction each time it becomes active until, for each $j \neq i$, it has seen r_j at two or more distinct locations. Robot r_i can then figure out ℓ_j based on two distinct locations that r_j has occupied. In an effort to ensure at the same time that r_j has also seen r_i at two or more distinct locations (so that it can figure out ℓ_i), we made an incorrect claim that if r_i has observed r_j at three or more distinct locations, then r_j has observed r_i at two or more distinct locations. This claim must be replaced by the following.

PROPOSITION 1. *For any integer $m \geq 1$, if r_i has seen r_j at $2m$ distinct locations in the time interval $[0, t]$, then r_j has seen r_i at m or more distinct locations in $[0, t)$.*

Proof. Suppose r_i becomes active at times t_1 and t_2, $t_1 < t_2$, and observes r_j at two distinct locations. Since r_j occupies distinct locations at t_1 and t_2, r_j must become active in $[t_1, t_2)$ and observe r_i at a location on the line segment $\overline{p_1 p_2}$, where p_1 and p_2 are the locations of r_i on line ℓ_i at t_1 and t_2, respectively. This means that r_j observes r_i at a distinct location each time r_i observes r_j at two distinct locations, since r_i moves along ℓ_i in a fixed direction each time it becomes active. □

Therefore, to ensure that r_j has seen r_i at two distinct locations, r_i must continue to move along ℓ_i until it has seen r_j at four or more distinct locations. However, if we allow r_i to simply stop moving as soon as it has observed r_j at four or more distinct locations, then r_j may not be able to observe r_i at four or more distinct locations. This means that r_j may never finish the broadcast.

Fortunately, broadcasting a line is usually a preliminary step that precedes a main task. In the case of $\psi_{f-point(2)}$, the ultimate goal of r_i and r_j is to move to the midpoint p of their initial positions. (Because of the way ℓ_i and ℓ_j are chosen in $\psi_{f-point(2)}$, both r_i and r_j can compute p from ℓ_i and ℓ_j.) Note that when r_i has seen r_j at four or more distinct locations, r_i knows not only ℓ_j, but also that r_j knows ℓ_i (because by Proposition 1 r_j has seen r_i at two or more distinct locations). Thus r_i

†EECS, University of Wisconsin-Milwaukee, Milwaukee, WI 53201 (suzuki@cs.uwm.edu).
‡Department of Computer Science and Communications Engineering, Kyushu University, Fukuoka 812-8581, Japan (mak@csce.kyushu-u.ac.jp).

can now safely quit broadcasting ℓ_i and move to (or toward) p, regardless of whether r_j has seen r_i at four or more distinct locations. By moving to a point not on ℓ_i, r_i effectively "announces" to r_j that it now knows ℓ_j. Robot r_j eventually observes r_i at a location not on ℓ_i and learns that it can quit broadcasting ℓ_j as well and proceed to p.

Based on the above discussion, r_i can use the following scheme to broadcast ℓ_i to all other robots:

1. r_i moves along ℓ_i in a fixed direction each time it becomes active until, for each $j \neq i$, either
   (a) it has seen r_j at four or more distinct locations, or
   (b) it observes that r_j is at a location not on ℓ_j. (Note that r_i knows ℓ_j by the time this case occurs.)
2. Then it moves to a point not on ℓ_i.

Algorithm $\psi_{f-point(2)}$, the proof of Theorem 3.3, and the paragraph that follows the proof of Theorem 3.4 should be revised accordingly.

Algorithm $\psi_{getview}$ must be modified using a similar idea. In $\psi_{getview}$, each robot r_i, initially located at the origin o_i of its local coordinate system Z_i, broadcasts three lines: its x-axis, y-axis, and line L_i through o_i in direction $f(d_i)$, where d_i is the minimum distance between any two initial positions of the robots, and for $x > 0$, $f(x) = (1 - 1/2^x) \times 90^\circ$ is a monotonically increasing function with range $(0^\circ, 90^\circ)$. (This function replaces $f(x) = (1 - 1/2^x) \times 360^\circ$ used in the paper. Both $f(d_i)$ and d_i are measured in terms of Z_i.) Note that the orientations of the three lines are all distinct.

Each robot r_i first broadcasts its x-axis by moving along it in the positive direction. When r_i knows that all other robots know r_i's x-axis and its orientation, i.e., for each $j \neq i$, either

(a) r_i has seen r_j at four or more distinct locations, or
(b) r_i observes that r_j has changed the direction of its motion (r_i knows the x-axis of r_j by the time this occurs),

it returns straight to o_i and starts broadcasting its y-axis by moving along it in the positive direction (thereby changing its direction of motion and announcing to others that it now knows the x-axes of all other robots). Eventually all robots finish broadcasting their x-axes and start broadcasting their y-axes. r_i ends the broadcast of its y-axis when it knows that all other robots know its y-axis and its orientation, returns straight to o_i, and starts broadcasting line L_i by moving in direction $f(d_i)$ (thereby changing its direction of motion again, announcing to others that it knows the y-axes of all other robots). Eventually all robots r_j start broadcasting their lines L_j. Once again, r_i terminates this broadcast when it knows that all other robots know L_i, and returns to its initial position o_i. By returning to o_i, r_i announces to others that it has finished the broadcast of L_i.

DOMINATING SETS IN PLANAR GRAPHS: BRANCH-WIDTH AND EXPONENTIAL SPEED-UP*

FEDOR V. FOMIN† AND DIMITRIOS M. THILIKOS‡

Abstract. We introduce a new approach to design parameterized algorithms on planar graphs which builds on the seminal results of Robertson and Seymour on graph minors. Graph minors provide a list of powerful theoretical results and tools. However, the widespread opinion in the graph algorithms community about this theory is that it is of mainly theoretical importance. In this paper we show how deep min-max and duality theorems from graph minors can be used to obtain exponential speed-up to many known practical algorithms for different domination problems. Our use of branch-width instead of the usual tree-width allows us to obtain much faster algorithms. By using this approach, we show that the k-dominating set problem on planar graphs can be solved in time $O(2^{15.13\sqrt{k}} + n^3)$.

Key words. branch-width, tree-width, dominating set, planar graph, fixed-parameter algorithm

1. Introduction.

DOMINATING SET is a classic NP-complete graph problem which fits into the broader class of *domination* and *covering* problems on which hundreds of papers have been written. (The book of Haynes, Hedetniemi, and Slater [32] is a nice source for further references on the dominating set problem.) The problem PLANAR DOMINATING SET asks, given a planar graph G and a positive k, whether G has a dominating set of size at most k. It is well known that the PLANAR DOMINATING SET (as well as several variants of it) is NP-complete. In this paper we design exact *fixed-parameter* algorithms (which run fast provided that the parameter k is small). The theory of fixed-parameter algorithms and parameterized complexity has been thoroughly developed over the past few years; see, e.g., [1, 3, 4, 8, 12, 13, 21, 23, 24].

The last six years have seen dramatic developments and improvements to the design of subexponential algorithms with running times of $2^{O(\sqrt{k})}n^{O(1)}$ for different planar graph problems; see, e.g., [1, 4, 8, 9, 13, 14, 22, 31, 35]. For example, the first algorithm for the PLANAR DOMINATING SET appeared in [2], with running time $O(8^k n)$. The first algorithm with a *sublinear* exponent was given by Alber et al. in [1] and its running time was $O(2^{69.98\sqrt{k}}n)$. A time $O(2^{49.88\sqrt{k}}n)$ algorithm was obtained in [4], and Kanj and Perković [35] announced an algorithm of running time $O(2^{27\sqrt{k}}n)$.

A common method for solving PLANAR DOMINATING SET is to prove that every planar graph with a dominating set of size at most k has tree-width at most $c\sqrt{k}$, where c is a constant. With some work (sometimes very technical) a tree decomposition of width at most $c\sqrt{k} + O(1)$ is constructed, and standard dynamic programming techniques on graphs of bounded tree-width are implemented. Currently, the fastest

dynamic programming algorithm for a dominating set on graphs of tree-width at most t runs in $O(2^{2t}n)$ steps and was given by Alber et al. in [1]. This implies an $O(2^{2c\sqrt{k}}n)$ step algorithm for the Planar Dominating Set. Let

$$c_{\rm tw} = \min\{c \mid \text{if } G \text{ is planar and dominated by } k \text{ vertices, then } \mathbf{tw}(G) \leq c\sqrt{k} + O(1)\}.$$

The challenge in this approach is that a small bound for $c_{\rm tw}$ is required for most practical applications. The first bound for $c_{\rm tw}$ appeared in [1] and was $c_{\rm tw} < 6\sqrt{34} = 34.98$, while the next improvement was given by Kanj and Perković in [35], who proved that $c_{\rm tw} < 16.5$.

The main tool of this paper is the branch-width of a graph. Branch-width was introduced by Robertson and Seymour in their graph minors series of papers several years after tree-width. These parameters are rather close, but surprisingly many theorems of the graph minors series are easier to prove when one uses branch-width instead of tree-width. Nice examples of the use of branch-width in proof techniques can be found in [38] and [39]. Another powerful property of branch-width is that it can be naturally generalized for hypergraphs and matroids. A good example of generalization of Robertson and Seymour theory for matroids by using branch-width is the paper by Geelen, Gerards, and Whittle [29]. Algorithms for problems expressible in monadic second-order logic on matroids of bounded branch-width are discussed by Hliněný [34]. Alekhnovich and Razborov [5] use branch-width of hypergraphs to design algorithms for SAT.

From a practical point of view, branch-width is also promising. For some problems, branch-width is more suitable for actual implementations. Cook and Seymour [10, 11] used branch decompositions to solve the ring routing problem, related to the design of reliable cost-effective SONET networks and to solving TSP (see also [7, 19]). In theory, there is not a big difference between tree-width and branch-width based algorithms. However in practice, branch-width is sometimes easier to use. The question due to Bodlaender (private communication) is the following: Are there examples where the constant factors for branch-width algorithms are significantly smaller than for their tree-width counterparts? This paper is partially motivated[1] by this question.

Our results. In this paper we introduce a new approach for solving the Planar Dominating Set problem. Our approach is based on branch-width and provides an algorithm of running time $O(2^{15.13\sqrt{k}} + n^3)$, which is a significant step toward a practical algorithm. Instead of constructing a tree decomposition and proving that the width of the obtained tree decomposition is upper bounded by $c\sqrt{k}$, we prove a combinatorial result relating the branch-width with the domination number of a planar graph. The proof of the combinatorial bounds is complicated and is based on nice properties of branch-width, which follow from deep results of the graph minors series.

Our proof is not constructive, in the sense that it cannot be turned into a polynomial algorithm that *constructs* the corresponding branch decomposition. Fortunately, there is a well-known algorithm due to Seymour and Thomas for computing an optimal branch decomposition of a planar graph in $O(n^4)$ steps. We stress that this algorithm does not have the so-called enormous hidden constants and is really practical.

[1] One of the challenges that appeared during the workshop "Optimization Problems, Graph Classes and Width Parameters" (Centre de Recerca Matemàtica, Bellaterra, Spain, November 15–17, 2001), was the following question: *Is it possible, using bounded branch-width instead of bounded tree-width, to obtain more efficient solutions for* Planar Dominating Set *and other parameterized problems?*

(We refer to the work of Hicks [33] on implementations of the Seymour and Thomas algorithm; see also [30] for a recent algorithm that runs in $O(n^3)$ steps.)

Our main combinatorial result is that for every planar graph G with a dominating set of size $\leq k$, the branch-width of G is at most $3\sqrt{4.5}\sqrt{k} < 6.364\sqrt{k}$. We combine this bound with the following algorithmic results: (i) the algorithm of Seymour and Thomas for planar branch-width, (ii) the results of Alber, Fellows, and Niedermeier [3] on a linear problem kernel for Planar Dominating Set, and (iii) a new dynamic programming algorithm for solving the dominating set problem on graphs of bounded branch-width (see subsection 4.2). As a result, we obtain an algorithm of running time $O(2^{15.13\sqrt{k}} + n^3)$.

According to Robertson and Seymour [36], for any graph G with at least three edges, the tree-width of G is always bounded by $\frac{3}{2}$ times its branch-width. This result, in combination with our bound, implies that $c_{\mathrm{tw}} < 9.546$. To our knowledge, this gives an improvement on any other bound for the tree-width of planar graphs dominated by k vertices.

Organization of the paper. In section 2, we give basic definitions and state some known theorems. We also present how a theorem of Robertson, Seymour, and Thomas can be directly used to prove that every planar graph with a dominating set of size $\leq k$ has branch-width at most $\leq 12\sqrt{k} + 9$. This observation (combined with the results discussed in section 4) already implies an algorithm for the Planar Dominating Set problem with running time $O(2^{28.56\sqrt{k}} + n^3)$, where n is the number of vertices of G. This is already a strong improvement (for large k) on the result of Alber et al. in [1] and is close to the running time $O(2^{27\sqrt{k}}n)$ of the algorithm of Kanj and Perković in [35].

Section 3 is devoted to the proof of Theorem 3.22, the main combinatorial result of the paper. The proof of this result is complicated, and we split it into several parts. In subsection 3.1, we give technical results about branch decompositions. These results are based on the powerful theorem of Robertson and Seymour on the branch-width of dual graphs. We emphasize that these results are crucial for our proof. In subsection 3.2, we define the notion of the *extension* of a graph and prove that the branch-width of an extension is at most three times the branch-width of the original graph. In section 3.3 we introduce the notion of *nicely dominated graphs*, which is a suitable "normalization" of the structure of the dominated planar graphs. In subsection 3.4, we explain how nicely dominated graphs can be gradually decomposed into simpler ones so that the branch-width of the original graph is bounded by the branch-width of some "enhanced version" of the simpler ones. In subsection 3.5 we introduce the *prime nicely dominated graphs* as those that are "the simplest possible" with respect to the decomposition of subsection 3.4. In subsection 3.6, we prove that any prime nicely dominated graph G is "contained" in the extension of a simpler planar graph denoted as $\mathbf{red}(G)$. In subsection 3.7 we use this fact along with the results of subsections 3.2, 3.4, and 3.6 to prove that $\mathbf{bw}(G) \leq 3 \cdot \mathbf{bw}(\mathbf{red}(G))$. By its construction, all the vertices of $\mathbf{red}(G)$ are vertices of the dominating set D. The result follows because, according to [28], $\mathbf{bw}(\mathbf{red}(G)) \leq \sqrt{4.5 \cdot |D|}$.

Section 4 contains discussions on algorithmic consequences of the combinatorial result. Subsection 4.1 describes the general algorithmic scheme that we follow. Subsection 4.2 contains a dynamic programming algorithm for the solving dominating set problem on graphs of branch-width $\leq \ell$ and m edges, in time $O(3^{1.5\cdot\ell}m)$.

In section 5 we discuss the optimality of our results (subsection 5.1) and provide some concluding remarks and open problems (subsection 5.2).

2. Definitions and preliminary results. Let G be a graph with vertex set $V(G)$ and edge set $E(G)$. For every nonempty $W \subseteq V(G)$, the subgraph of G induced by W is denoted by $G[W]$. A vertex $v \in V(G)$ of a connected graph G is called a *cut vertex* if the graph $G - \{v\}$ is not connected. A connected graph on at least three vertices without a cut vertex is called 2-*connected*. Maximal 2-connected subgraphs of a graph G or induced edges whose two endpoints are cut vertices are called 2-*connected components*.

Let Σ be a sphere. By Σ-*plane* graph G we mean a planar graph G with the vertex set $V(G)$ and the edge set $E(G)$ drawn in Σ. To simplify notations, we usually do not distinguish between a vertex of the graph and the point of Σ used in the drawing to represent the vertex, or between an edge and the open line segment representing it. If $\Delta \subseteq \Sigma$, then $\overline{\Delta}$ denotes the *closure* of Δ, and the boundary of Δ is $\widehat{\Delta} = \overline{\Delta} \cap \overline{\Sigma - \Delta}$. We denote the set of the faces of the drawing by $R(G)$. (Every face is an open set.) An edge e (a vertex v) is incident to a face r if $e \subseteq \bar{r}$ ($v \subseteq \bar{r}$). We do not distinguish between a boundary of a face and the subgraph of the drawing induced by edges incident to the face. The *length* of a face r is the number of edges incident to r. $\Delta \subseteq \Sigma$ is an open disc if it is homeomorphic to $\{(x, y) : x^2 + y^2 < 1\}$. Let C be a cycle in a Σ-plane graph G. By the Jordan curve theorem, C bounds exactly two discs. For a vertex $x \in V(G)$, we call a disc Δ bounded by C x-*avoiding* if $x \notin \overline{\Delta}$. We call a face $r \in R(G)$ *square face* if $\widehat{r}$ is a cycle of length four.

A set $D \subseteq V(G)$ is a *dominating set* in a graph G if every vertex in $V(G) - D$ is adjacent to a vertex in D. Graph G is D-*dominated* if D is a dominating set in G.

For a hypergraph $\mathcal{G}$ we denote by $V(\mathcal{G})$ its vertex (ground) set and by $E(\mathcal{G})$ the set of its hyperedges. A *branch decomposition* of a hypergraph $\mathcal{G}$ is a pair (T, τ), where T is a tree with vertices of degree one or three and τ is a bijection from $E(\mathcal{G})$ to the set of leaves of T. The *order function* $\omega : E(T) \to 2^{V(\mathcal{G})}$ of a branch decomposition maps every edge e of T to a subset of vertices $\omega(e) \subseteq V(\mathcal{G})$ as follows. The set $\omega(e)$ consists of all vertices $v \in V(\mathcal{G})$ such that there exist edges $f_1, f_2 \in E(\mathcal{G})$ with $v \in f_1 \cap f_2$, and such that the leaves $\tau(f_1)$, $\tau(f_2)$ are in different components of $T - \{e\}$.

The *width* of (T, τ) is equal to $\max_{e \in E(T)} |\omega(e)|$, and the *branch-width* of $\mathcal{G}$, $\mathbf{bw}(\mathcal{G})$, is the minimum width over all branch decompositions of $\mathcal{G}$.

Given an edge $e = \{x, y\}$ of a graph G, the graph G/e is obtained from G by contracting the edge e; that is, to get G/e we identify the vertices x and y and remove all loops and duplicate edges. A graph H obtained by a sequence of edge contractions is said to be a *contraction* of G. H is a *minor* of G if H is a subgraph of a contraction of G. We use the notation $H \preceq G$ (resp., $H \preceq_c G$) when H is a minor (a contraction) of G. It is well known that $H \preceq G$ or $H \preceq_c G$ implies $\mathbf{bw}(H) \leq \mathbf{bw}(G)$. Moreover, the fact that G has a dominating set of size k and $H \preceq_c G$ imply that H has a dominating set of size $\leq k$ (which is not true for $H \preceq G$).

For planar graphs the branch-width can be bounded in terms of the domination number by making use of the following result of Robertson, Seymour, and Thomas (Theorems 4.3 in [36] and 6.3 in [38]).

THEOREM 2.1 (see [38]). *Let $k \geq 1$ be an integer. Every planar graph with no (k, k)-grid as a minor has branch-width $\leq 4k - 3$.*

To give an idea on how results from graph minors can be used on the study of dominating sets in planar graphs, we present the following simple consequence of Theorem 2.1.

LEMMA 2.2. *Let G be a planar graph with a dominating set of size $\leq k$. Then $\mathbf{bw}(G) \leq 12\sqrt{k} + 9$.*

Proof. Suppose that $\mathbf{bw}(G) > 12\sqrt{k}+9$. By Theorem 2.1, there exists a sequence of edge contractions or edge/vertex removals reducing G to a (ρ,ρ)-grid where $\rho = 3\sqrt{k}+3$. We apply to G only the contractions from this sequence and call the resulting graph J. J contains a (ρ,ρ)-grid as a subgraph. As $J \preceq_c G$, J also has a dominating set D of size $\leq k$. A vertex in D cannot dominate more than nine internal vertices of the (ρ,ρ)-grid. Therefore, $k \geq (\rho-2)^2/9$, which implies $\rho \leq 3\sqrt{k}+2 = \rho-1$, a contradiction. □

In the remaining part of the paper we show how the above upper bound for the branch-width of a planar graph in terms of its dominating set number can be strongly improved. Our results will use as a basic ingredient the following theorem, which is a direct consequence of the Robertson and Seymour min-max Theorem 4.3 in [36] relating tangles and branch-width and Theorem 6.6 in [37] establishing relations between tangles of dual graphs. Since the result is not mentioned explicitly in the articles of Robertson and Seymour, we provide here a short explanation of how it can be derived.

We denote as K_2^2 the graph consisting of two vertices connected by a double edge. Notice that K_2^2 is a dual of itself; therefore, if G contains K_2^2 as a minor, then its dual G^* also contains K_2^2 as a minor.

THEOREM 2.3. *Let G be a Σ-plane graph that contains K_2^2 as a minor and let G^d be its dual. Then $\mathbf{bw}(G) = \mathbf{bw}(G^d)$.*

Proof. A *separation* of a graph G is a pair (A,B) of subgraphs with $A \cup B = G$ and $E(A \cap B) = \emptyset$, and its *order* is $|V(A \cap B)|$. A *tangle of order* $\theta \geq 1$ is a set $\mathcal{T}$ of separations of G, each of order less than θ, such that

1. for every separation (A,B) of G of order less than θ, $\mathcal{T}$ contains one of (A,B) and (B,A);
2. if $(A_1,B_1),(A_2,B_2),(A_3,B_3) \in \mathcal{T}$, then $A_1 \cup A_2 \cup A_3 \neq G$; and
3. if $(A,B) \in \mathcal{T}$, then $V(A) \neq V(G)$.

The *tangle number* $\theta(G)$ of G is the maximum order of tangles in G. By the result of Robertson and Seymour [36, Theorem 4.3], for any graph G of branch-width at least two, $\theta(G) = \mathbf{bw}(G)$. Since $\mathbf{bw}(K_2^2) = 2$ and $K_2^2 \preceq G$, we have that $\theta(G) = \mathbf{bw}(G)$. By similar arguments, $\theta(G^d) = \mathbf{bw}(G^d)$.

Let G be a graph 2-cell embedded in a connected surface Σ. A subset of Σ meeting the drawing only at vertices of G is called *G-normal*. The *length* of a G-normal arc is the number of vertices it meets. A tangle $\mathcal{T}$ of order θ is *respectful* if, for every homeomorphic to a circle G-normal arc N in Σ of length less than θ, there is a closed disk $\Delta \subseteq \Sigma$ with $\widehat{\Delta} = N$ such that the separation $(G \cap \Delta, G \cap \overline{\Sigma - \Delta}) \in \mathcal{T}$. By the first tangle property, every tangle $\mathcal{T}$ of a graph embedded in a *sphere* is respectful.

By [37, Theorem 6.6], for every 2-cell embedded graph G on a connected surface Σ, G has a respectful tangle of order θ if and only if its dual G^d does. This implies that $\theta(G) = \theta(G^d)$ and the theorem follows. □

For our bounds, we need an upper bound on the size of branch-width of a planar graph in terms of its size. The best published bound for the branch-width that we were able to find in the literature is $\mathbf{bw}(G) \leq 4\sqrt{|V(G)|} - 3$ which follows directly from Theorem 2.1. An improvement of this inequality can be found in [28]. This proof is based on a relation between slopes and majorities, the two notions introduced by Robertson and Seymour in [36] and Alon, Seymour, and Thomas in [6], respectively.

THEOREM 2.4 (see [28]). *For any planar graph G, $\mathbf{bw}(G) \leq \sqrt{4.5 \cdot |V(G)|}$.*

3. Bounding branch-width of *D*-dominated planar graphs. This section is devoted to the proof of the main combinatorial result of this paper: The branch-

width of any planar graph with a dominating set of size k is at most $3\sqrt{4.5}\sqrt{k}$. The idea of the proof is to show that for every planar graph G with a dominating set of size k there is a graph H on at most k vertices such that $\mathbf{bw}(G) \leq 3 \cdot \mathbf{bw}(H)$. Then Theorem 2.4 will do the rest of the job.

The construction of the graph H and the proof of $\mathbf{bw}(G) \leq 3 \cdot \mathbf{bw}(H)$ is not direct. First we prove that every planar graph with a dominating set D is a minor of some graph with a nice structure. We call these "structured" graphs nicely D-dominated. For a nicely D-dominated planar graph G we show how to define a graph $\mathbf{red}(G)$ on $|D|$ vertices. The most complicated part of the proof is the proof that $\mathbf{bw}(G) \leq 3 \cdot \mathbf{bw}(\mathbf{red}(G))$ (clearly this implies the main combinatorial result). The proof of this inequality is based on a more general result about isomorphism of special hypergraphs obtained from G and $\mathbf{red}(G)$ (Lemma 3.16) and the structural properties of nicely D-dominated graphs.

3.1. Auxiliary results. In this section we obtain some useful technical results about branch-width.

LEMMA 3.1. *Let $\mathcal{G}_1$ and $\mathcal{G}_2$ be hypergraphs with one hyperedge in common, i.e., $V(\mathcal{G}_1) \cap V(\mathcal{G}_2) = f$ and $\{f\} = E(\mathcal{G}_1) \cap E(\mathcal{G}_2)$. Then $\mathbf{bw}(\mathcal{G}_1 \cup \mathcal{G}_2) \leq \max\{\mathbf{bw}(\mathcal{G}_1), \mathbf{bw}(\mathcal{G}_2), |f|\}$. Moreover, if every vertex $v \in f$ has degree ≥ 2 in at least one of the hypergraphs (i.e., v is contained in at least two edges in $\mathcal{G}_1$ or in at least two edges in $\mathcal{G}_2$), then $\mathbf{bw}(\mathcal{G}_1 \cup \mathcal{G}_2) = \max\{\mathbf{bw}(\mathcal{G}_1), \mathbf{bw}(\mathcal{G}_2)\}$.*

Proof. Clearly, $\mathbf{bw}(\mathcal{G}_1 \cup \mathcal{G}_2) \geq \max\{\mathbf{bw}(\mathcal{G}_1), \mathbf{bw}(\mathcal{G}_2)\}$.

For $i = 1, 2$, let (T_i, τ_i) be a branch decomposition of $\mathcal{G}_i$ of width $\leq k$ and let $e_i = \{x_i, y_i\}$ be the edge of T_i having as endpoint the leaf $\tau_i(f) = x_i$. We construct tree T as follows. First we remove the vertices x_i and add edge $\{y_1, y_2\}$. Then we subdivide $\{y_1, y_2\}$ by introducing a new vertex y. Finally we add vertex x and make it adjacent to y.

We set $\tau(f) = x$. For any other edge $g \in E(\mathcal{G}_1) \cup E(\mathcal{G}_2)$ we set $\tau(g) = \tau_1(g)$ if $g \in E(\mathcal{G}_1)$ and $\tau(g) = \tau_2(g)$ otherwise.

Because $|\omega(\{y_1, y\})| = |\omega(\{y_2, y\})| = |\omega(\{x, y\})| \leq |f|$ and for any other edge of T, its order is equal to the order of the corresponding edge in one of the T_i's, we have that (T, τ) is a branch decomposition of width $\leq \max\{k, |f|\}$.

If every vertex v of f has degree ≥ 2 in one of the hypergraphs, then $|f| \leq \max\{|\omega(e_1)|, |\omega(e_2)|\} \leq k$. Thus in this case, (T, τ) is a branch decomposition of width $\leq k$. □

Let G be a connected Σ-plane graph with all vertices of degree at least two. For a vertex x of G and a pair (z, y) of two of its neighbors, we call (z, y) a *pair of consecutive neighbors of x* if edges $\{x, z\}$, $\{x, y\}$ appear consecutively in the cyclic ordering of the edges incident to x. (Notice that if x has only two neighbors y and z, then both (y, z) and (z, y) are pairs of consecutive neighbors of x.)

LEMMA 3.2. *Let G be a planar graph. Then G is the minor of a planar 2-connected graph H such that $\mathbf{bw}(H) = \max\{\mathbf{bw}(G), 2\}$.*

Proof. We use induction on the number of vertices in G. Every graph on at most three vertices is the minor of a complete graph on three vertices, which is 2-connected and has branch-width two. Suppose that the lemma is correct for every planar graph on at most n vertices.

Let G be a graph on $n + 1$ vertices.

Case A. *G is 2-connected.* In this case the lemma trivially holds.

Case B. *G is connected (but not 2-connected).* Then G has a cut vertex x. Let $V_1, V_2, \ldots, V_k$ be the vertex sets of the connected components of $G - \{x\}$. Let G_1 be

the subgraph of G induced by $V_1 \cup \{x\}$ and let G_2 be the subgraph of G induced by $V_2 \cup V_3 \cup \cdots \cup V_k \cup \{x\}$.

By the induction assumption, there are 2-connected planar graphs H_i, $i = 1, 2$, such that $\mathbf{bw}(H_i) = \max\{\mathbf{bw}(G_i), 2\}$, and $G_i \prec H_i$.

Planar graphs H_1 and H_2 have only one common vertex x, and thus the graph $H_1 \cup H_2$ is also planar. Let H be a Σ-plane graph which is a drawing of $H_1 \cup H_2$. Let a and b be two consecutive neighbors of x in H (i.e., vertices such that the edges $\{a, x\}$, $\{b, x\}$ are incident to the same face), where $a \in V(H_1)$ and $b \in V(H_2)$. We denote by H' the graph obtained from H by drawing the edge $\{a, b\}$ so that it does not intersect other edges of H (this is possible because $\{a, x\}$, $\{b, x\}$ are incident to the same face). Let us remark that H' is 2-connected and contains H (and therefore G) as a minor.

The complete graph K on three vertices $\{a, b, x\}$ has one common edge $\{a, b\}$ with H_1. The degrees of a and x in K are two, and at least two in H_1 (H_1 is 2-connected). By Lemma 3.1, we have that

$$\mathbf{bw}(H_1 \cup K) = \max\{\mathbf{bw}(H_1), 2\} = \max\{\mathbf{bw}(G_1), 2\}.$$

By applying Lemma 3.1, for $H_1 \cup K$ and H_2, we arrive at

$$\mathbf{bw}(H') = \mathbf{bw}(H_1 \cup H_2 \cup K) = \max\{\mathbf{bw}(G_1), \mathbf{bw}(G_2), 2\} \leq \max\{\mathbf{bw}(G), 2\}.$$

Since G is the minor of H', we have that $\mathbf{bw}(H') = \max\{\mathbf{bw}(G), 2\}$.

Case C. *G is not connected.* Let F be the graph obtained from G by adding an edge connecting two connected components. By making use of Lemma 3.1, it is easy to show that $\mathbf{bw}(F) \leq \max\{\mathbf{bw}(G), 2\}$, and this case can be reduced to Case B. □

A graph G is *weakly triangulated* if all its faces are of length two or three. A graph is $(2, 3)$-regular if all its vertices have degree two or three. Notice that the dual of a weakly triangulated graph is $(2, 3)$-regular and vice versa.

LEMMA 3.3. *Every 2-connected Σ-plane graph G has a weak triangulation H such that $\mathbf{bw}(H) = \mathbf{bw}(G)$.*

Proof. Because G is 2-connected every face of G is bounded by a cycle. Suppose that there is a face r of G bounded by a cycle $C = (x_0, \ldots, x_{s-1}), s \geq 4$. We show that there are vertices x_i and x_j that are not adjacent in C such that the graph G' obtained from G by adding the edge $\{x_i, x_j\}$ has $\mathbf{bw}(G') = \mathbf{bw}(G)$. By applying this argument recursively, one obtains a weak triangulation of G of the same branch-width.

If there are vertices x_i and x_j that are adjacent in G and are not adjacent in C, then we can draw a chord joining x_i and x_j in r. Because G is 2-connected it holds that $\mathbf{bw}(G) \geq 2$ and, therefore, the addition of multiple edges does not increase the branch-width. Suppose now that the cycle C is chordless. Let (T, τ) be a branch decomposition of G and let ω be its order function. Every edge f of T corresponds to the partition of $E(G)$ into two sets. One of these sets contains at least $\lceil |C|/2 \rceil \geq 2$ edges of C. By induction on the number of edges in G, it is easy to show that there is always an edge f of T such that for the corresponding partition (E_1, E_2) of $E(G)$, the set E_1 contains exactly two edges of C. Let e_1, e_2 be such edges. Because C is chordless and its length is at least four, we have that $\omega(f)$ contains at least two vertices, say x_i and x_j, of C that are not adjacent. Then adding edge $\{x_i, x_j\}$ does not increase the branch-width. (The decomposition can be obtained from T by subdividing f and adding the leaf corresponding to $\{x_i, x_j\}$ to the vertex subdividing f.) □

In the next lemma we use powerful duality results of Robertson and Seymour. Moreover, the implications of these results play the crucial role in our proof.

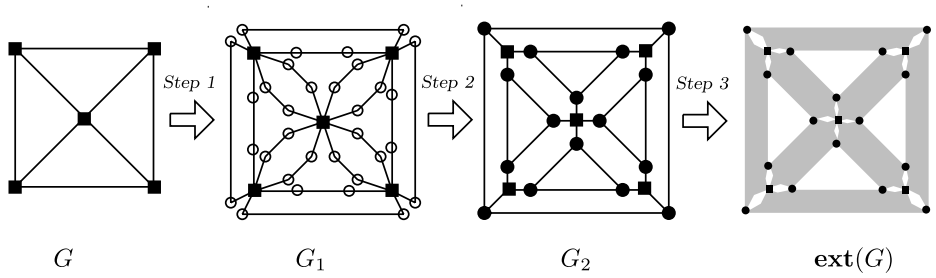

FIG. 1. *The steps* 1, 2, *and* 3 *of the definition of the function* **ext**.

LEMMA 3.4. *Every* 2*-connected* Σ*-plane graph* G *is the contraction of a* $(2,3)$*-regular* Σ*-plane graph* H *such that* $\mathbf{bw}(H) = \mathbf{bw}(G)$.

Proof. Let G^d be the dual graph of G. By Theorem 2.3, $\mathbf{bw}(G^d) = \mathbf{bw}(G)$ (the dual of a 2-connected graph is 2-connected, and any 2-connected graph contains K_2^2 as a minor). By Lemma 3.3, there is a weak triangulation H^d of G^d such that $\mathbf{bw}(H^d) = \mathbf{bw}(G^d)$. The dual of H^d, which we denote by H, contains G as a contraction (each edge removal in a planar graph corresponds to an edge contraction in its dual and vice versa). Applying Theorem 2.3 the second time, we obtain that $\mathbf{bw}(H) = \mathbf{bw}(H^d)$. Hence, $\mathbf{bw}(H) = \mathbf{bw}(G)$. Since H^d is weakly triangulated, we have that H is $(2,3)$-regular. □

3.2. Extensions of Σ-plane graphs. Let G be a connected Σ-plane graph where all the vertices have degree at least two. We define the *exension* of G, $\mathbf{ext}(G)$, as the hypergraph obtained from G by making use of the following three steps (see Figure 1 for an example).

Step 1. For each edge $e \in E(G)$, duplicate e and then subdivide each of its two copies twice. That way, each edge $e = \{x, y\}$ of G is replaced by a cycle denoted as $C_{x,y} = (x, x^+_{x,y}, y^-_{x,y}, y, y^+_{x,y}, x^-_{x,y}, x)$ (indexed in clockwise order). Let G_1 be the resulting graph.

Step 2. For each vertex $x \in V(G)$ and each pair (y, z) of consecutive neighbors of x (in G), identify the edges $\{x, x^-_{x,y}\}$ and $\{x, x^+_{x,z}\}$ in G_1. Let G_2 be the resulting graph.

Step 3. The hypergraph $\mathbf{ext}(G)$ is defined by setting $\mathbf{ext}(G) = (V(G_2), \{C_{x,y} \mid \{x, y\} \in E(G)\})$.

From the above construction, if $\mathcal{H} = \mathbf{ext}(G)$, then there exists a bijection $\theta : E(G) \to E(\mathcal{H})$ mapping each edge $e = \{x, y\}$ to the hyperedge formed by the vertices of $C_{x,y}$. See Figure 1 for an example of the definition of **ext**.

LEMMA 3.5. *For any* $(2,3)$*-regular* Σ*-plane graph* G, $\mathbf{bw}(\mathbf{ext}(G)) \leq 3 \cdot \mathbf{bw}(G)$.

Proof. Let (T, τ) be a branch decomposition of G of width $\leq k$. By the definition of $\mathbf{ext}(G)$, there is a bijection $\theta : E(G) \to E(\mathbf{ext}(G))$ defining which edge of G is replaced by which hyperedge of $\mathbf{ext}(G)$. Let L be the set of leaves in T. For $\mathbf{ext}(G)$ we define a branch decomposition (T, τ') with a bijection $\tau' : E(\mathbf{ext}(G)) \to L$ such that $\tau'(t) = \theta(\tau(t))$. We use the notations ω and ω' for the order functions of (T, τ) and (T, τ'), respectively.

We claim that (T, τ') is a branch decomposition of $\mathbf{ext}(G)$ of width $\leq 3k$. To prove the claim we show that for any $f \in E(T), |\omega'(f)| \leq 3 \cdot |\omega(f)|$. In other words, we need to show that it is possible to define a function σ_f mapping each vertex $v \in \omega(f)$ to a set of three vertices of $\omega'(f)$ such that every vertex $y \in \omega'(f)$ is contained in $\sigma_f(x)$ for some $x \in \omega(f)$.

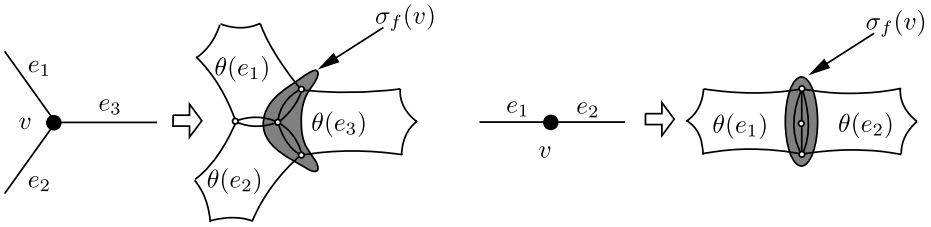

FIG. 2. *The construction of the value of $\sigma_f(v)$ in the proof of Lemma* 3.5.

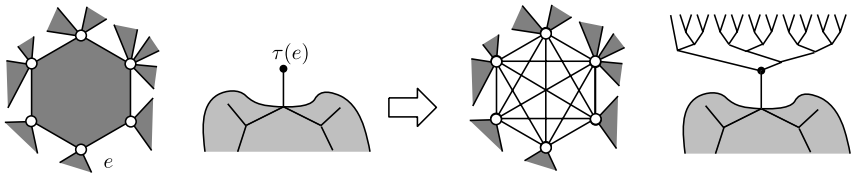

FIG. 3. *The construction of the branch decomposition of $\mathbf{cl}_E(H)$ in the proof of Lemma* 3.6.

Let T_1 and T_2 be the components of $T - \{f\}$. We construct σ_f by distinguishing two cases.

• *The degree of v is three in G.* We can assume that two of its incident edges, say e_1, e_2, are images of leaves of T_1 and one, say e_3, is an image of a leaf in T_2. We define $\sigma_f(v) = (\theta(e_1) \cap \theta(e_3)) \cup (\theta(e_2) \cap \theta(e_3))$. (This process is illustrated in the left half of Figure 2.)

• *The degree of v is two in G.* We can assume that one of its incident edges, say e_1, is an image of some leaf of T_1 and the other, say e_2, is an image of a leaf in T_2. We define $\sigma_f(v) = \theta(e_1) \cap \theta(e_2)$ (this is illustrated in the right half of Figure 2).

Note that in both cases $|\sigma_f(v)| = 3$. Suppose now that y is a vertex in $\omega'(f)$. Then y should be an endpoint of at least two hyperedges α and β of $\mathbf{ext}(G)$ and without loss of generality we assume that $\tau'(\alpha)$ is a leaf of T_1 and $\tau'(\beta)$ is a leaf of T_2. By the definition of τ', this means that $\tau(\theta^{-1}(\alpha))$ is a leaf of T_1 and $\tau(\theta^{-1}(\beta))$ is a leaf of T_2. By the construction of $\mathbf{ext}(G)$, $\theta^{-1}(\alpha)$ and $\theta^{-1}(\beta)$ have a vertex x in common; therefore $x \in \omega(f)$. From the definition of σ_f, we get that $y \in \sigma_f(x)$. This proves the relation $|\omega'(f)| \leq 3 \cdot |\omega(f)|$, and the lemma follows. □

Let $\mathcal{H}$ be a planar hypergraph and let $E \subseteq E(\mathcal{H})$. We set $\mathbf{cl}_E(\mathcal{H}) = (V(\mathcal{H}), E_{\mathcal{H}})$, where $E_{\mathcal{H}} = E(\mathcal{H}) - E \cup \{\{x, y\} \subseteq V(\mathcal{H}) \mid \exists_{e \in E(\mathcal{H})} : \{x, y\} \in e\}$ (in other words, we replace each hyperedge $e \in E$ by a clique formed by connecting each pair of endpoints of e).

LEMMA 3.6. *Let $\mathcal{H}$ be a hypergraph with every vertex of degree at least two. Then for any $E \subseteq E(\mathcal{H})$, $\mathbf{bw}(\mathbf{cl}_E(\mathcal{H})) \leq \mathbf{bw}(\mathcal{H})$.*

Proof. If (T, τ) is a branch decomposition of $\mathcal{H}$, then we construct a branch decomposition of $\mathbf{cl}_E(\mathcal{H})$ by identifying each leaf t where $\tau(t) \in E$ with the root of a binary tree T_t that has $\binom{|\tau(t)|}{2}$ leaves. The leaves of T_t are mapped to the edges of the clique made up by pairs of endpoints in $\tau(t)$ (see also Figure 3). □

LEMMA 3.7. *Let G and H be connected Σ-plane graphs with all vertices of minimum degree at least two and such that $G \preceq H$. Then $\mathbf{bw}(\mathbf{ext}(G)) \leq \mathbf{bw}(\mathbf{ext}(H))$.*

Proof. Let E' (resp., E'') be the set of edges that one should contract (resp., remove) in H in order to obtain G (clearly, we can assume that $E' \cap E'' = \emptyset$). Let

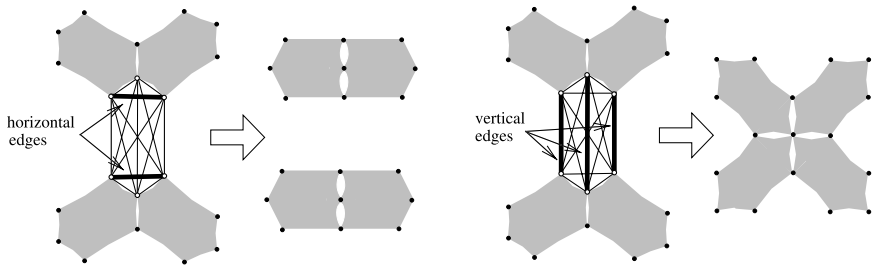

FIG. 4. *The construction of the branch decomposition of* $\mathbf{cl}_E(H)$ *in the proof of Lemma* 3.7.

θ be the bijection mapping edges of G to hyperedges of $\mathbf{ext}(G)$. If we prove that $\mathbf{ext}(G)$ is a minor of $\mathbf{cl}_{\theta(E'\cup E'')}(\mathbf{ext}(H))$, then the result will follow from Lemma 3.6. To see this, for each $e = \{x, y\} \in E'$, we separate the edges of the clique replacing $\theta(e) = (x, x^+_{x,y}, y^-_{x,y}, y, y^+_{x,y}, x^-_{x,y}, x)$ into two categories: We call $\{x^+_{x,y}, y^-_{x,y}\}$, $\{x, y\}$, and $\{y^+_{x,y}, x^-_{x,y}\}$ *horizontal* and we call the rest *unimportant*. Moreover, for any edge $e = \{x, y\} \in E''$, we separate the edges of the clique replacing $\theta(e) = (x, x^+_{x,y}, y^-_{x,y}, y, y^+_{x,y}, x^-_{x,y}, x)$ into two categories: We call $\{x^+_{x,y}, x^-_{x,y}\}$ and $\{y^+_{x,y}, y^-_{x,y}\}$ *vertical* and the rest *useless*. To obtain $\mathbf{ext}(G)$ from $\mathbf{cl}_{E'}(\mathbf{ext}(H))$ we first remove the useless and the unimportant edges and then contract all the horizontal and vertical ones (see Figure 4). □

We are ready to state the main property of **ext**.

LEMMA 3.8. *Let* G *be a connected* Σ*-plane graph with all vertices of degree at least two. Then* $\mathbf{bw}(\mathbf{ext}(G)) \leq 3 \cdot \mathbf{bw}(G)$.

Proof. The branch-width of G is at least two, and by Lemma 3.2, G is the minor of a 2-connected Σ-plane graph G' such that $\mathbf{bw}(G') = \mathbf{bw}(G)$. By Lemma 3.4, G' is the contraction of a $(2, 3)$-regular Σ-plane graph H where $\mathbf{bw}(H) \leq \mathbf{bw}(G')$. Notice that G is a minor of H and both G and H are Σ-plane and connected and have all vertices of degree at least two. By Lemma 3.7, $\mathbf{bw}(\mathbf{ext}(G)) \leq \mathbf{bw}(\mathbf{ext}(H))$. Note also that H is $(2, 3)$-regular. By Lemma 3.5, $\mathbf{bw}(\mathbf{ext}(H)) \leq 3 \cdot \mathbf{bw}(H)$, and the result follows. □

3.3. Nicely *D*-dominated Σ-plane graphs. An important tool spanning all of our proofs is the concept of unique D-domination. We call a D-dominated graph G *uniquely dominated* if there is no path of length < 3 connecting two vertices of D. Let us remark that this implies that each vertex $x \in V(G) - D$ has exactly one neighbor in D (i.e., is uniquely dominated).

We call a multiple edge $\{a, b\}$ represented by lines $l_1, l_2, \ldots, l_r$ of a D-dominated Σ-plane graph G *exceptional* if

- $a, b \notin D$;
- a and b are both adjacent to the same vertex in D;
- for any i, j, $i \neq j$, each of the open discs bounded by $l_i \cup l_j$ contains at least one vertex of D.

For example, all the multiple edges in the graphs in Figure 5 are exceptional.

LEMMA 3.9. *For every 2-connected* D*-dominated* Σ*-plane graph* G *without multiple edges, there exists a* Σ*-plane graph* H *such that the following hold:*

(a) G *is a minor of* H.
(b) H *is uniquely* D*-dominated.*
(c) *All multiple edges of* H *are exceptional.*

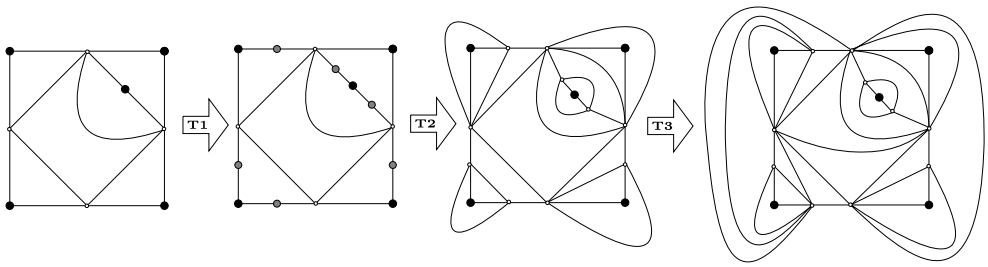

FIG. 5. *Example of the transformations* **T1**, **T2**, *and* **T3** *in the proof of Lemma* 3.9.

(d) *For any face r of H, $\widehat{r}$ is either a triangle or a square.*
(e) *If the distance between vertices $x, y \in D$ in H is three, then there exist at least two distinct (x, y)-paths in H of length three.*
(f) *If a (closed) face r of H contains a vertex of D, then $\widehat{r}$ is a triangle.*
(g) *Every square face of H contains two edges $e_i, i = 1, 2$, without common vertices such that for each $i = 1, 2$, there exists a vertex $x_i \in D$ adjacent to both endpoints of e_i.*
(h) *If $x, y \in D$, then every two distinct (x, y)-paths of H of length three are internally disjoint.*

Proof. We construct a graph H, satisfying properties (a)–(f), by applying, one after the other, on G the following transformations:

• **T1**. As long as there exists in G a vertex x with more than one neighbor y in D, subdivide the edge $\{x, y\}$.

We call the resulting graph G_1.

As G_1 does not have multiple edges, properties (a), (c) are trivially satisfied. Moreover, notice that, if G_1 is not uniquely dominated, then **T1** can be further applied. Therefore, (b) holds for G_1. For an example of the application of **T1**, see the first step of Figure 5.

• **T2**. As long as G_1 has a face r bounded by a cycle $\widehat{r} = (x_0, \ldots, x_{q-1}), q \geq 4$, and such that $x_i \in D$ for some $i, 0 \leq i \leq q-1$, add in G_1 the edge $\{x_{i-1}, x_{i+1}\}$ (indices are taken modulo q).

We call the resulting graph G_2.

Notice that the vertices of $\widehat{r}$ are distinct because G_2 is 2-connected. Clearly, G_2 satisfies property (a). Recall now that G_1 satisfies property (b). Therefore, if some vertex $x_i \in \widehat{r}$ is in D, then its neighbors x_{i-1} and x_{i+1} (the indices are taken modulo q) are not in D. Therefore, property (b) holds also for G_2. Notice that, if **T2** creates a multiple edge, then this can be only an exceptional multiple edge. Therefore, (c) holds for G_2. For an example of the application of **T2**, see the second step of Figure 5.

Finally note that none of the vertices of D is in a face of G_2 of length ≥ 4.

We call a square face that satisfies property (g) *solid*.

• **T3**. As long as G_2 has a face r that is not a solid square and such that $\widehat{r} = (x_0, \ldots, x_{q-1}), r \geq 4$, choose an edge in $\{\{x_1, x_3\}, \{x_0, x_2\}\}$ that is not already present in G_2 and add it to G_2.

We call the resulting graph G_3.

The above transformation can always be applied because it is impossible that both $\{x_1, x_3\}$ and $\{x_0, x_2\}$ are in the planar graph G_3. Therefore, property (c) is an invariant of **T3**. Clearly, G_3 satisfies property (a). Property (b) is an invariant of **T3** as the added edge has no endpoints in D. We have that all the faces of G_3 are either

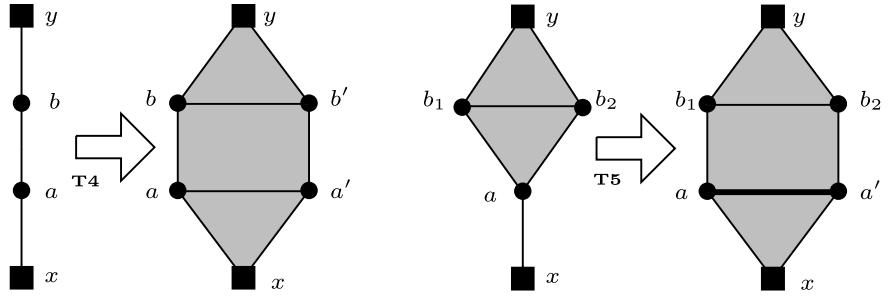

FIG. 6. *The transformations* **T4** *and* **T5** *in the proof of Lemma* 3.6.

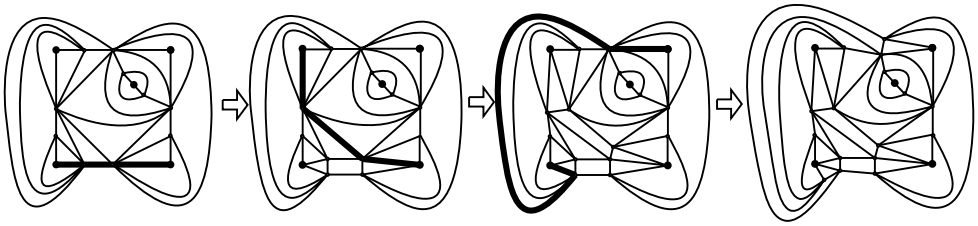

FIG. 7. *Example of the transformation* **T4** *in the proof of Lemma* 3.6.

triangles or solid squares and therefore G_3 also satisfies (d) and (g). For an example of the application of **T3**, see the third step of Figure 5.

• **T4**. As long as G_3 has a *unique* (x, y)-path $P = (x, a, b, y)$, where $x, y \in D$, apply the first transformation of Figure 6 on P.

We call the resulting graph G_4.

It is easy to verify that properties (a)–(d) are invariants of **T4**. Also, it is easy to see that the transformation of Figure 6 creates square faces with property (g) and does not alter property (g) for square faces that already have been created. Moreover, G_4 satisfies (e) because each time we apply the transformation of Figure 6 the number of pairs in D connected by unique paths decreases. Finally, none of the square faces appearing (because of **T4**) contains a vertex in D. Thus (f) holds. For an example of the application of **T4**, see Figure 7.

In order to give the transformation that enforces property (h) we need some definitions. Observe that if property (h) does not hold for G_4, this implies the existence of some pair of paths $P_i = (x, a, b_i, y), i = 1, 2$. We call the graph O defined by this pair an (h)-obstacle and we define its (h)-disc as the x-avoiding closed disc Δ_O bounded by the cycle (a, b_1, y, b_2, a). An (h)-obstacle is *minimal* if no (x, y)-path has vertices contained in its (h)-disc. Notice that if G_4 has an (h)-obstacle it also has a minimal (h)-obstacle and vice versa. We call an (h)-obstacle *hollow* if its (h)-disc contains no neighbor of a except b_1 and b_2. Notice that a hollow (h)-obstacle is always minimal. We claim that in any hollow (h)-disc, vertices b_1 and b_2 are adjacent. Indeed, by property (b), a is not adjacent to y in G_4. Therefore b_1, a, b_2 are in a face of G_4 that, from property (g), cannot be a square face (otherwise, property (b) would be violated). Therefore, (b_1, a, b_2) is a triangle and the claim follows.

• **T5**. As long as G_4 has a hollow (h)-obstacle O, apply the second transformation of Figure 6 on edge $\{a, x\}$ and the face bounded by (b_1, b_2, a).

We call the resulting graph G_5.

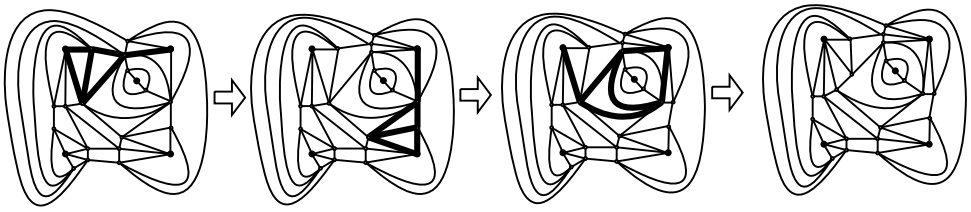

FIG. 8. *Example of the transformation* **T5** *in the proof of Lemma* 3.6.

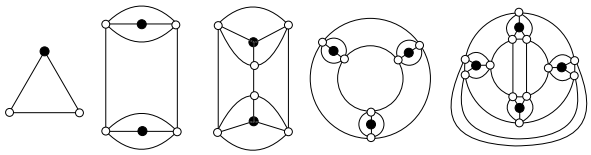

FIG. 9. *Simple examples of nicely* D*-dominated* Σ*-plane graphs.*

Notice that after **T5** none of the properties (a)–(g) is altered by the application of **T5** (the arguments are the same as those used for the previous transformations). Moreover, each time the second transformation of Figure 6 is applied, the number of hollow (h)-obstacles decreases and no new nonhollow (h)-obstacles appear. For an example of the application of **T5**, see Figure 8. To finish the proof, we show that **T5** is able to eliminate all the (h)-obstacles. It remains to prove the following claim.

Claim. If a 2-connected D-dominated Σ-plane graph satisfies properties (b)–(g) and contains a minimal (h)-obstacle, then it also contains a hollow (h)-obstacle.

Proof of claim. Let $O = (P_1, P_2)$ be a minimal nonhollow (h)-obstacle with (h)-disc Δ_O and let $\mathcal{O}$ be the set containing O along with of all the minimal (h)-obstacles that contain the edge $\{a, x\}$ and whose (h)-disc is a subset of Δ_O. If $O_1, O_2 \in \mathcal{O}$ and $\Delta_{O_1} \subset \Delta_{O_2}$, then we say that $O_1 < O_2$ (clearly, for any $O' \in \mathcal{O} - \{O\}$, $O' < O$). Let us remark that relation "$<$" is a partial order on $\mathcal{O}$ and that all its minimal elements are hollow (h)-obstacles. The claim follows and thus **T5** is able to enforce property (h). □

Let G be a connected D-dominated Σ-plane graph satisfying properties (b)–(h) of Lemma 3.9. We call such graphs *nicely* D-dominated Σ-plane graphs. For example, the graphs of Figure 9 and the last graph in Figure 8 are nicely D-dominated Σ-plane graphs (see also Figure 10 and all the graphs of Figure 11).

Given a nicely D-dominated Σ-plane graph G, we define $\mathcal{T}(G)$ as the set of all the triangles (cycles of length three) containing a vertex of D. By property (f), for every face r with $\widehat{r} \cap D \neq \emptyset$, $\widehat{r} \in \mathcal{T}(G)$. (The inverse is not always correct; i.e., not every triangle in $\mathcal{T}(G)$ bounds a face.) We call the triangles in $\mathcal{T}(G)$ D-triangles.

We also define $\mathcal{C}(G)$ as the set of all cycles consisting of two distinct paths of length three connecting two vertices of D (these are indeed cycles because of property (h) of nicely dominated graphs). Thus each cycle C in $\mathcal{C}(G)$ is of length six and is the union of two length-three paths connecting its two dominating vertices.

We call the cycles in $\mathcal{C}(G)$ *D-hexagons*. The *poles* of a cycle $C \in \mathcal{C}(G)$ are the vertices in $D \cap C$. We call a D-triangle T (D-hexagon C) *empty* if one of the open discs bounded in Σ by T (C) does not contain vertices of G. Notice that all empty

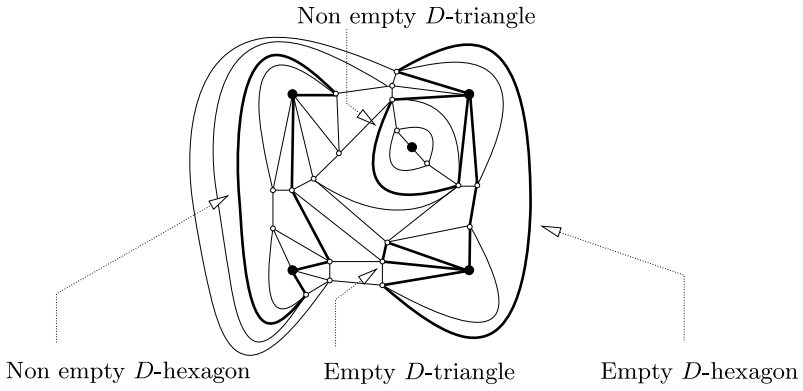

FIG. 10. *D-triangles and D-hexagons of the last graph of Figure* 8.

D-triangles are boundaries of faces of G. For some examples of the above definitions see Figure 10.

3.4. Decomposing nicely D-dominated Σ-planar graphs. In this subsection we show how nicely D-dominated planar graphs can be simplified. The idea is based on the structure imposed by properties (b)–(h): Any nicely D-dominated planar graph can be seen as the result of gluing together two simpler structures of the same type. This is described by the following two lemmata.

LEMMA 3.10. *Let G be a nicely D-dominated Σ-plane graph G and let $T \in \mathcal{T}(G)$ be a nonempty D-triangle bounding the closed discs Δ_1, Δ_2. Let also G_i, $i = 1, 2$, be the subgraph of G containing all vertices and edges included in Δ_i. Then $G_i, i = 1, 2$, is a nicely D_i-dominated graph for some $D_i \subseteq D$ and G_i has fewer vertices than G.*

Proof. Let $D_i = D \cap \Delta_i, i = 1, 2$. Clearly, $D_i \subseteq D$. Moreover, as T is nonempty, we have that $|V(G_i)| < |V(G)|$. Let us verify that properties (b)–(h) hold for $G_i, i = 1, 2$. First of all we observe that, by the construction of G_i, two vertices in G_i are adjacent if and only if they are adjacent in G. We will refer to this fact saying that G_i *preserves the adjacency of* G. (Note that since G can have multiple edges, G_i is not necessary an induced subgraph of G.)

To prove property (b), we show first that G_i is D_i-dominated. For the sake of contradiction, suppose that there exists a vertex $a \in V(G_i)$ that is not dominated by D_i. As property (b) holds for G, there exists a vertex $w \in D - D_i$ so that a is uniquely dominated by w in G. This means that $w \in \Sigma - \Delta_i$ and $a \in \Delta_i$. Therefore, a is a vertex of T. Because T is a D-triangle, there is some $x \in D \cap T$. Since a is adjacent in G_i to x and $x \neq w$, we have a contradiction to the property (b) on G. Now it remains to prove that G_i is uniquely D'-dominated and that this is a direct consequence of the fact that G_i preserves the adjacency of G.

For property (c), let $e = \{v, u\}$ be some multiple edge in G_i represented by edges $l_1, \ldots, l_r$, and suppose that x is the dominating vertex of T. As e is an exceptional multiple edge in G and because of property (b), none of its endpoints is in D and also $x \notin e$. Let Δ_l, Δ_l^* be the two closed discs defined by some pair l_h, l_j of edges representing e. By the definition of G_i, $l_h \cup l_j \subseteq \Delta_i$, therefore one, say Δ_l, of Δ_l, Δ_l^* includes T. As $x \notin e$, we have that $x \notin \hat{\Delta}_l$ and $\Delta_l - \hat{\Delta}_l$ contains some vertex of D. Observe now that $\Delta_l^* \subseteq \Delta_i$. Therefore, if $\Delta_l^* - \hat{\Delta}_l^*$ does not contain vertices of D in G_i, then the same holds also for G, which is a contradiction as e is exceptional in G. It remains now to prove that v and u are adjacent to the same vertex of D in G_i.

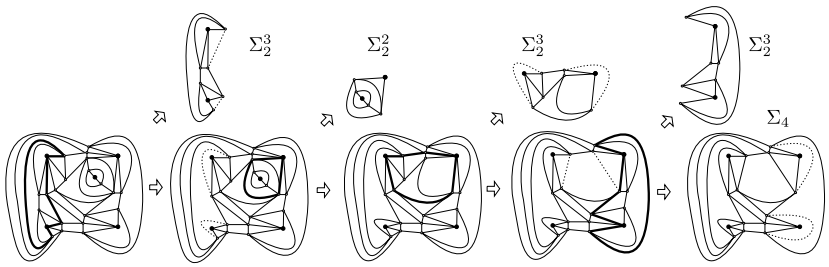

FIG. 11. *Examples of the application of Lemmata* 3.10 *and* 3.11.

Indeed, this is the case for G, and we let w be this vertex. If $w \notin \Delta_i$, then both v, u should be vertices of T, which contradicts property (b). Therefore, $w \in V(G_i)$ and property (c) holds for G_i.

For (d), we stress that all the faces of G_i that are in Δ_i are also the faces of G. Therefore, property (d) holds for all these faces. Also, it holds for the unique new face $r = \Sigma - \Delta_i$ of G_i because $\widehat{r}$ is a triangle.

For property (e), let x, y be two vertices in D_i of distance three in G_i. Let P_i^1 and P_i^2 be two internally disjoint paths connecting x and y in G (these paths exist because of properties (e) and (h) in G). Notice that (e) holds if we prove that both P_i^j, $j = 1, 2$, are paths of G_i, $i = 1, 2$, as well. Suppose to the contrary that one, say $P_i^1 = (x, a, b, y)$, of P_i^j, $j = 1, 2$, is not a path in G_i. This means that at least one of a, b is in $(\Sigma - \Delta_i) \cap V(G)$. It follows that two nonconsecutive vertices of P_i^1 are vertices of T. Therefore, the distance between x and y in G is at most two, a contradiction to property (b) for G.

Suppose now that (f) does not hold for G_i. As (d) holds for G_i we have that there exists a square in G_i containing a vertex of D. As G_i preserves the adjacency of G, this square also should exist in G, a contradiction to (f) for G.

To prove (g), suppose that (a, b, c, d) is a square of G_i. As G_i preserves the adjacency of G, (a, b, c, d) is also a square of G; therefore we may assume that there are vertices $z, w \in D$ where (z, a, b) and (w, c, d) are triangles of G. It is enough to prove that $\{z, a\}, \{z, b\}, \{w, c\}$, and $\{w, d\}$ are edges of G_i. Suppose to the contrary that one of them, say $\{a, z\}$, is not an edge of G_i. As G_i preserves the adjacency of G, this means that $z \notin V(G_i)$. In other words, we have that (z, a, b) is a triangle of G where $z \in (\Sigma - \Delta_i) \cap V(G)$ and $\{a, b\} \in \Delta_i \cap V(G)$. If this is true, then a, b should be vertices of T; therefore the distance in G between z and the dominating vertex belonging in T is at most two, a contradiction to property (b).

Finally, if there exist two paths violating (h) in G_i the same also should happen in G as G_i preserves the adjacency of G. □

For an example of the application of Lemma 3.10, see the second step of Figure 11.

LEMMA 3.11. *Let G be a nicely D-dominated Σ-plane graph G and let $C = (x, a, b, y, c, d, x)$ be a nonempty D-hexagon with poles x, y bounding the closed discs Δ_1, Δ_2. Let also $G_i, i = 1, 2$, be the graph containing all the edges and vertices included in Δ_i and extended by adding the edges $\{b, c\}$ and $\{a, d\}$ (edges $\{b, c\}$ and $\{a, d\}$ are placed outside D_i to ensure planarity of G_i). Then $G_i, i = 1, 2$, is a nicely D_i-dominated graph for some $D_i \subseteq D$ and $G_i, i = 1, 2$, has fewer vertices than G.*

Proof. Let G_i^- be a graph where $V(G_i^-) = \Delta_i \cap V(G)$ and $E(G_i^-) = \{e \in E(G) \mid e$ is included in $\Delta_i\}$; i.e. G_i^-, contains all edges and vertices included in Δ_i. Set $D_i = D \cap \Delta_i, i = 1, 2$. Therefore, G_i can be seen as the graph with $V(G_i) = V(G_i^-)$

and $E(G_i) = E(G_i^-) \cup \{\{b,c\} \cup \{a,d\}\}$. As in the proof of Lemma 3.10, we will say that G_i^- preserves the adjacency of G in the sense that two vertices in G_i^- are adjacent if and only if they are adjacent in G. We also have that $D_i \subseteq D$ and $|V(G_i)| < |V(G)|$.

Let us verify properties (b)–(h) for G_i, $i = 1, 2$.

To prove (b) we first claim that G_i is D_i-dominated. If some vertex $\alpha \in V(G_i) - D_i$ is not dominated by D_i, then it is dominated by some vertex $w \in D - D_i$ (property (b) for G). This means that $w \in \Sigma - \Delta_i$ implying $\alpha \in C$. Thus $\alpha \in \{a,b,c,d\}$. But this means that the distance between $w, x \in D$ or the distance between $w, y \in D$ in G is ≤ 2, which also violates (b) for G. Therefore G_i is D_i-dominated. Clearly, as G_i preserves the adjacency of G, G_i should be uniquely dominated and (b) holds for G_i.

For property (c), we will first prove that it holds for G_i^-. Let $e = \{v, u\}$ be some multiple edge in G_i^- represented by edges $l_1, \ldots, l_r$. As e is an exceptional multiple edge in G and because of property (b), none of its endpoints is in D and also $x, y \notin e$. Let Δ_l, Δ_l^* be the two closed discs defined by some pair l_h, l_j of edges representing e. By the definition of G_i^-, $l_h \cup l_j \subseteq \Delta_i$, therefore one of Δ_l, Δ_l^*, say Δ_l, includes C. As $x, y \notin e$, we have that $x, y \notin \hat{\Delta}_l$ and $\Delta_l - \hat{\Delta}_l$ contains some vertex of D. Observe now that $\Delta_l^* \subseteq \Delta_i$. Therefore, if $\Delta_l^* - \hat{\Delta}_l^*$ does not contain vertices of D, then the same holds also for G, which is a contradiction, as e is exceptional in G. It remains now to prove that v and u are adjacent to the same vertex of D in G_i^-. Since this holds for G, we have that there exists a vertex $w \in D$ such that $\{u, w\}, \{v, w\} \in E(G)$. If $w \notin \Delta_i$, then both v, u should be vertices of C, which contradicts property (b). Therefore, $w \in V(G_i^-)$ and property (c) holds for G_i^-. If now the addition of any, say $\{b, c\}$, of $\{b, c\}$, $\{a, d\}$ creates a multiple edge, then $\{b, c\}$ should already be an edge in G_i^-. Suppose then that $l_{\text{old}}, l_{\text{new}}$ are two lines in G_i, representing $\{b, c\}$, and l_{new} is the newly added one. As $l_{\text{new}} \not\subseteq D_i$ and $l_{\text{old}} \subseteq D_i$, it follows that the one of the open discs defined by $l_{\text{old}} \cup l_{\text{new}}$ contains y and the other contains x. Therefore, (c) holds also for G_i.

Notice that all the faces of G_i that are included in Δ_i are also faces of G_i. The boundaries of the new faces are the cycles (y, a, b), (a, b, c, d), and (x, c, b) that are all either triangles or squares. Therefore, (d) holds for G_i.

If property (e) holds for G_i^-, then it also holds for G_i. Let P be a (w, v)-path in G_i^- of length three. Property (e) holds trivially for G_i^- if $\{w, v\} = \{x, y\}$. So suppose that it is violated for some pair $\{w, v\} \neq \{x, y\}$. Because (e) holds for G, we can find a $\{w, v\}$-path $P' = (w, \alpha, \beta, v)$ of length three in G that is not a path in G_i^-. As $\{w, v\} \neq \{x, y\}$, only one, say α, of α, β can be outside Δ_i. This means that w and β are vertices of C. Since $\beta \in \{a, b, c, d\}$, we have that v is adjacent in G to a vertex in $\{a, b, c, d\}$. This contradicts property (b) for G, as it implies the existence of a path of length ≤ 2 connecting $v \in D$ and one of the vertices $x, y \in D$.

It is easy to verify (f) for the new faces (x, a, d), (a, b, c, d), and (y, c, d) of G_i. Suppose now that (f) is violated for some face of G_i that is also a face of G. As (d) holds for G_i, we have that there exists a square in G_i containing a vertex of G_i. As G_i preserves the adjacency of G, this square should exist also in G, a contradiction to (f) for G.

Property (g) is trivial for the new square face of G_i bounded by (a, b, c, d). Let us prove that (g) also holds for all the square faces of G_i^-. Let $\widehat{r} = (\alpha, \beta, \gamma, \delta)$ be the boundary of some square face r of G_i^-. As G_i^- preserves the adjacency of G, $(\alpha, \beta, \gamma, \delta)$ is also the boundary of some square face of G. Therefore, we may assume that there are vertices $z, w \in D$ where (z, α, β) and (w, γ, δ) are triangles of G. It is

enough to prove that $\{z,\alpha\},\{z,\beta\},\{w,\gamma\}$, and $\{w,\delta\}$ are all edges of G_i^-. Suppose, to the contrary, that one of them, say $\{a,z\}$, is not an edge of G_i^-. As G_i^- preserves the adjacency of G, this means that $z \notin V(G_i^-)$. In other words, we have that (z,α,β) is a triangle of G, where $z \in (\Sigma - \Delta_i) \cap V(G)$ and $\{\alpha,\beta\} \in \Delta_i \cap V(G)$. Then α,β should be vertices of C different from x and y. Therefore, either z,x or z,y are at distance at most two in G, contradicting property (b).

For (h), we observe that no path of length three in G_i connecting two vertices of D can use the edges $\{a,d\}$ and $\{b,c\}$ in G_i. Indeed, if this is possible for one, say $\{a,d\}$, of the edges $\{a,d\}$ and $\{b,c\}$, then such a path would have extremes in distance two from x, a contradiction to property (b) for G_i. Therefore, if there exist two paths violating (h) in G_i, they should be paths of G_i^- and also paths of G as G_i^- preserves the adjacency of G, a contradiction to property (b). □

For an example of the application of Lemma 3.10, see steps 1, 3, and 4 of Figure 11.

3.5. Prime *D*-dominated Σ-plane graphs. A nicely D-dominated Σ-plane graph G is a *prime D-dominated Σ-plane graph* (or just *prime*) if all its D-triangles and D-hexagons are empty. For example, all the graphs in Figure 9 are prime.

LEMMA 3.12. *Let G be a prime D-dominated Σ-plane graph. If G contains two vertices $x,y \in D$ connected by three paths of length three, then $V(P_1) \cup V(P_2) \cup V(P_3) = V(G)$.*

Proof. By property (h), the paths $P_i, i = 1,2,3$, are mutually internally disjoint. Then $\Sigma - (P_1 \cup P_2 \cup P_3)$ contains three connected components that are open discs. We call them $\Delta_{1,2}$, $\Delta_{2,3}$, and $\Delta_{1,3}$ assuming that they do not contain vertices of P_3, P_1, and P_2, respectively. Let i,j,h be any three distinct indices of $\{1,2,3\}$. As $P_i \cup P_j$ forms an empty D-hexagon, all the vertices of G should be contained in one, say Δ, of the closed discs bounded by the cycle $P_i \cup P_j$. Notice that P_h should be entirely included in $\overline{\Delta}_{i,j}$ because of its internal vertices. Therefore, $\Delta = \overline{\Delta}_{i,j}$ and thus $V(G) = V(G) \cap \overline{\Delta}_{i,j}$. Resuming, we have that $V(G) = V(G) \cap (\overline{\Delta}_{1,2} \cap \overline{\Delta}_{2,3} \cap \overline{\Delta}_{1,3})$ and the lemma follows as $\overline{\Delta}_{1,2} \cap \overline{\Delta}_{2,3} \cap \overline{\Delta}_{1,3}$ contains exactly the vertices of the paths $P_i, i = 1,2,3$. □

The graph Σ_2^3 of Figure 11 is a graph satisfying the conditions of Lemma 3.12.

Let us recall that $\mathcal{C}(G)$ is the set of all cycles consisting of two distinct paths of length three connecting two vertices of D. For a nicely D-dominated Σ-plane graph G, we define its *reduced* graph, $\mathbf{red}(G)$, as the graph with vertex set D and where two vertices $x,y \in D$ are adjacent in $\mathbf{red}(G)$ if and only if the distance between x and y in G is three. Let us stress that $\mathbf{red}(G)$ is a connected graph. The main idea of our proof is that $\mathbf{red}(G)$ expresses a "good" part of the structure of a nicely D-dominated graph G.

An important relation of a prime graph and its reduced graph is provided by the following lemma.

LEMMA 3.13. *Let G be a prime D-dominated Σ-plane graph with $|D| \geq 3$. Then the mapping*

$$\phi : E(\mathbf{red}(G)) \to \mathcal{C}(G), \text{ where } \phi(e) = C \text{ if and only if the endpoints of } e \text{ are in } D \cap C,$$

is a bijection.

Proof. Clearly, any D-hexagon C with poles x and y implies the existence of a (x,y)-path in G and therefore C is the image of $\{x,y\} \in E(\mathbf{red}(G))$. In order to show that ϕ is a bijection, we have to show that for every $e = \{x,y\} \in E(\mathbf{red}(G))$, there exists a *unique* D-hexagon C with poles x and y. By the definition of $\mathbf{red}(G)$, x and y are within distance three in G. By properties (e) and (h) of nicely

D-dominated Σ-plane graphs, there are at least two internally disjoint paths connecting x and y. Suppose to the contrary that G has at least three (x,y)-paths P_1, P_2, P_3. As $|D| \geq 3$, G contains vertices that are not in $V(P_1) \cup V(P_2) \cup V(P_3)$, a contradiction to Lemma 3.12. □

Let G be a prime D-dominated Σ-plane graph with $|D| \geq 3$ and let ϕ be the bijection defined in Lemma 3.13. For every edge $e = \{x,y\} \in E(\mathbf{red}(G))$, we choose a vertex $w \in D - \{x\} - \{y\}$ and define $\Delta(e)$ as the w-avoiding open disc bounded by $\phi(e)$ (because G is prime, the definition does not depend on the choice of w). Observe that for any two different $e_1, e_2 \in E(\mathbf{red}(G))$, it holds that $\Delta(e_1) \cap \Delta(e_2) = \emptyset$.

Some of the properties of prime D-dominated Σ-plane graphs are given by the next two lemmata.

LEMMA 3.14. *Let G be a prime D-dominated Σ-plane graph with $|D| \geq 2$. For any D-triangle $T = (x,a,b)$ with $x \in D$, the edges $\{x,a\}$ and $\{x,b\}$ are also the edges of some D-hexagon of G with poles x and $y \in D$. Moreover, if $|D| \geq 3$, the edge $\{a,b\}$ is in $\Delta(\{x,y\})$.*

Proof. Because G is a prime graph, one of the open discs bounded by T is a face of G. Let r_x, $\widehat{r}_x = T = (x,a,b)$, be such a face. Let r, $r \neq r_x$, be the (unique) face incident to $\{a,b\}$, i.e., $\{a,b\} \subseteq \widehat{r}$. By (d), r is either a triangle or a square face.

We claim that it is a square face. Suppose to the contrary that $\widehat{r} = (a,b,c)$. Then, from property (b), $c \notin D$. Let $y \in D$ be the unique vertex dominating c. We distinguish two cases:

Case 1. $x = y$. In this case all vertices in $V(G) - \{x,a,b,c\}$ are covered (in Σ) by four open discs bounded by triangles $(x,a,b), (x,a,c), (x,b,c)$, and (a,b,c). Since G is prime, all D-triangles $(x,a,b), (x,a,c), (x,b,c)$ are empty. Therefore, all vertices in $V(G) - \{x,a,b,c\}$ are in the x-avoiding open disc Δ bounded by (a,b,c). As $\Delta = r$ is a face of G, we have that $V(G) - \{x,a,b,c\} = \emptyset$, a contradiction to the fact that $|D| \geq 2$.

Case 2. $x \neq y$. Then G contains the paths (x,a,c,y) and (x,b,c,y), a contradiction to property (h), and the claim holds.

As r is a square face, we assume that $\widehat{r} = (a,b,c,d)$. Property (g), together with the fact that a, b are adjacent to x, implies that either all vertices a,b,c,d are adjacent to x, or there is $y \in D$, $y \neq x$, that is adjacent to c and d.

We claim that the first case is impossible. Indeed, if a,b,c,d are adjacent to x, then all the vertices in $V(G) - \{x,a,b,c,d\}$ should be included in the five open discs bounded by triangles $(x,a,b), (x,a,c), (x,b,d)$, (c,d,x) and square (a,b,c,d). Four discs bounded by D-triangles are faces of G (G is prime); thus all the vertices of $V(G) - \{x,a,b,c,d\}$ are in the x-avoiding open disc r bounded by (a,b,c,d). Because r is a face of G, we conclude that $V(G) - \{x,a,b,c,d\} = \emptyset$. Since by property (b), $a,b,c,d \notin D$, we have a contradiction to the fact that $|D| \geq 2$, and the claim holds.

Therefore, there is $y \in D$, $y \neq x$, and y is adjacent to c and d. Because (y,c,d) is a D-triangle in a prime graph, one of the discs r_y bounded by (y,c,d) is the face of G. Hence $C = (x,a,c,y,d,b,x)$ is a D-hexagon containing edges $\{x,a\}$ and $\{x,b\}$, as required. Notice now that $\Delta = r_x \cup \{a,b\} \cup r \cup \{c,d\} \cup r_y$ is one of the open discs bounded by C (here an edge represents an open set). As $V(G) \cap \Delta = \emptyset$, we have that $\Delta(\{x,y\}) = \Delta$ and thus the edge $\{a,b\}$ is contained in $\Delta(\{x,y\})$. □

LEMMA 3.15. *Let G be a prime D-dominated Σ-plane graph with $|D| \geq 2$. Then the endpoints of each edge of G are the vertices of some D-hexagon.*

Proof. Let $e = \{x,y\}$ be an edge of G.

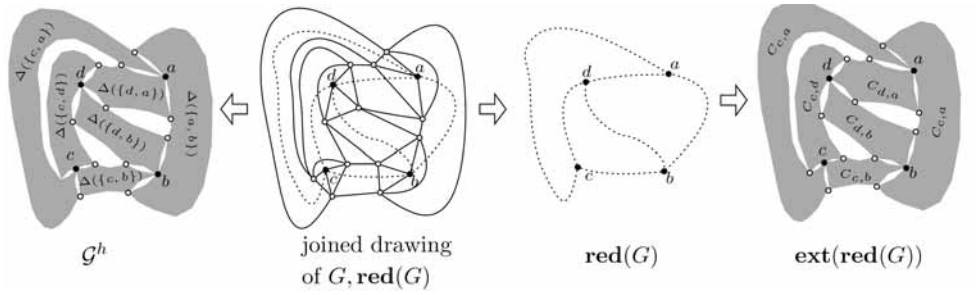

FIG. 12. *An example of the proof of Lemma* 3.17.

Case 1. $\{x, y\} \cap D = \{x\}$ (by property (b), $|\{x, y\} \cap D| \leq 1$). Let r be the face of G incident to $e = \{x, y\}$. From property (f), r is a D-triangle and the result follows from Lemma 3.14.

Case 2. $\{x, y\} \cap D = \emptyset$. Let d_x and d_y be the vertices of D-dominating x and y, respectively. If $d_x = d_y$, then e is incident to the D-triangle (d_x, x, y), and the result follows from Lemma 3.14. Suppose now that $d_x \neq d_y$. Then (d_x, x, y, d_y) is the path connecting two vertices in D. From property (e), $\{x, y\}$ belongs to the union of two distinct paths connecting d_x and d_y. Therefore, $\{x, y\}$ should be an edge of some D-hexagon and the lemma follows. □

3.6. On the structure of nicely D-dominated Σ-plane graphs. For a given nicely D-dominated Σ-plane graph G, we define hypergraph $\mathcal{G}^*$ with the vertex set $V(\mathcal{G}^*) = V(G)$ and edge set $E(\mathcal{G}^*) = E(G) \cup \mathcal{T}(G) \cup \mathcal{C}(G)$; i.e., $\mathcal{G}^*$ is obtained from G by adding all D-triangles and D-hexagons as hyperedges. We also define hypergraph $\mathcal{G}^h$ with the vertex set $V(\mathcal{G}^h) = V(G)$ and the edge set $E(\mathcal{G}^h) = \mathcal{C}(G)$; i.e., $\mathcal{G}^h$ has the vertices of G as vertices and each of its hyperedges contains the vertices of some D-hexagon of G. Observe that $\mathcal{G}^h$ can be obtained from $\mathcal{G}^*$ by removing all the (hyper)edges of size two and three.

LEMMA 3.16. *For any prime D-dominated Σ-plane graph G with $|D| \geq 2$,* $\mathbf{bw}(\mathcal{G}^*) \leq \max\{\mathbf{bw}(\mathcal{G}^h), 3\}$.

Proof. By Lemmata 3.14 and 3.15, we have that for each hyperedge in $\mathcal{G}^*$ there exists some D-hexagon containing all its endpoints. In other words, each hyperedge of $\mathcal{G}^*$ is a subset of some hyperedge of $\mathcal{G}^h$. By applying Lemma 3.1 recursively for every hyperedge f of $\mathcal{G}^*$ that is an edge or a triangle, we arrive at $\mathbf{bw}(\mathcal{G}^*) \leq \max\{\mathbf{bw}(\mathcal{G}^h), 3\}$. □

The following structural result will serve as a base for the recursive application of Lemmata 3.10 and 3.11 in the proof of Lemma 3.21.

LEMMA 3.17. *Let G be a prime D-dominated Σ-plane graph with $|D| \geq 3$. Then* $\mathbf{red}(G)$ *is a connected Σ-plane graph, all vertices of G have degree at least two, and* $\mathcal{G}^h$ *is isomorphic to* $\mathbf{ext}(\mathbf{red}(G))$.

Proof. We define the *joined drawing of G and* $\mathbf{red}(G)$ *in* Σ as follows:

Take a drawing of G on Σ and draw the vertices of $\mathbf{red}(G)$ identically to the vertices of G. For each edge $e_i = \{x, y\} \in E(\mathbf{red}(G))$ we draw $\{x, y\}$ as an I-arc connecting x and y and contained in $\Delta(e_i)$.

For an example of joined drawing, see the second drawing of Figure 12. The following three auxiliary propositions are used in the proof of the lemma.

PROPOSITION 3.18. *If G is a prime D-dominated Σ-plane graph, then* $\mathbf{red}(G)$ *is a Σ-plane graph.*

To prove the proposition, let us take the joined drawing of G and $\mathbf{red}(G)$ in Σ. Observe that, for any pair of edges $e_i, e_i \in E(\mathbf{red}(G))$, $\Delta(e_i) \cap \Delta(e_i) = \emptyset$. Therefore, if in this drawing we delete all the points that are not points of vertices or edges of $\mathbf{red}(G)$, what remains is a planar drawing of $\mathbf{red}(G)$.

PROPOSITION 3.19. *Let G be a prime D-dominated Σ-plane graph where $|D| \geq 3$ and let ϕ be the bijection defined in Lemma* 3.13. *In the joined drawing of G and $\mathbf{red}(G)$ in Σ, for any vertex $x \in D$, of degree at least three, two edges $\{x, y\}$ and $\{x, z\}$ are consecutive if and only if the D-hexagons $\phi(\{x, y\})$ and $\phi(\{x, z\})$ have exactly one edge in common. In the special case where $x \in D$ has degree two, the D-hexagons $\phi(\{x, y\})$ and $\phi(\{x, z\})$ have exactly two edges in common.*

In fact, let $\phi(\{x, y\})$ and $\phi(\{x, z\})$ be two hexagons sharing only x as a common vertex. By property (f), all faces of G incident to x are bordered by triangles that in turn are cyclically ordered according to the cyclic ordering of their edges incident to x. This ordering contains one triangle from $\phi(\{x, y\})$ and one from $\phi(\{x, z\})$. The removal of these triangles from the cyclic ordering breaks it into two nonempty subintervals, such that each of the subintervals contains one of the triangles T_1 and T_2. By Lemma 3.14, each of T_1, T_2 is a part of some D-hexagon $\phi(\{x, z_1\})$ and $\phi(\{x, z_2\})$, respectively, and this implies that the edges $\{x, y\}$ and $\{x, z\}$ cannot be consecutive in $\mathbf{red}(G)$. The inverse direction follows directly by the definition of the joined drawing of G and $\mathbf{red}(G)$.

PROPOSITION 3.20. *Let G be a prime D-dominated Σ-plane graph where $|D| \geq 3$. Then all vertices of $\mathbf{red}(G)$ have degree at least two.*

In fact, let $x \in D$ be a vertex of G incident to a face r. By property (f) of Lemma 3.9, the boundary of r is a triangle $\widehat{r} = (x, a_1, a_2)$. By Lemma 3.14, the edges $\{x, a_1\}$ and $\{x, a_2\}$ are also the edges of some D-hexagon with poles x and y. We distinguish the following cases:

Case 1. x has a neighbor a_3, distinct from a_1 and a_2. We choose a_3 so that a_2 and a_3 are consecutive in the cyclic ordering of the neighbors of x. Note also that the unique face whose boundary contains x, a_2, and a_3 should be a triangle (otherwise we have a contradiction to property (f)). By Lemma 3.14, the edges $\{x, a_2\}$ and $\{x, a_3\}$ are contained in some D-hexagon with poles x and w. Clearly $w \neq y$ (otherwise x and y are connected by three internally disjoint paths), and from Lemma 3.12 we have that $|D| = 2$, a contradiction. We conclude that $\{x, w\}$ is an edge of $\mathbf{red}(G)$, different from $\{x, y\}$.

Case 2. The only neighbors of x are the vertices a_1 and a_2. From property (f), $e = \{a_1, a_2\}$ is an exceptional edge; i.e., there are two lines l_1 and l_2, representing e, whose extremes are a_1 and a_2. Let T^1, T^2 be the triangles containing x and lines l_1 and l_2, respectively. For $i = 1, 2$, we apply Lemma 3.14 for T^i and derive that both $\{x, a_i\}, i = 1, 2$, belong to some D-hexagon C^i of G with poles x and y_i. Moreover, as $|D| \geq 3$, the line l_i is contained in $\Delta(\{x, y_i\})$. Therefore, for the case $y_1 = y_2$ we have that both lines l_1, l_2 are in $\Delta(\{x, y_i\})$, which is impossible. So, x has two neighbors in $\mathbf{red}(G)$, which completes the proof of Proposition 3.20.

Now we are in position to prove Lemma 3.17.

By Proposition 3.18, G is a Σ-plane graph. By Proposition 3.20, all vertices of $\mathbf{red}(G)$ have degree at least two. Therefore, the three transformation steps of **ext** can be applied on $\mathbf{red}(G)$. Consider now the joint drawing of G and $\mathbf{red}(G)$ in Σ. For each edge $e = \{x, y\} \in E(\mathbf{red}(G))$, we use the notation $\phi(x, y) = (x, x^+_{x,y}, y^-_{x,y}, y, x^+_{x,y}, x^-_{x,y}, x)$ (the ordering is clockwise). Apply Steps 1 and 2 of the definition of **ext** on $\mathbf{red}(G)$. During Step 2, identify vertices $x^-_{x,y}$, $x^+_{x,z}$ with the

vertices of G that are denoted in the same way. This is possible because of Proposition 3.19 and because the graph G_2 created after Step 2 has exactly the same vertex set as the graph G. Let us recall that there exists a bijection $\theta : E(G) \to E(\mathbf{ext}(G))$ mapping each edge $e = \{x, y\}$ to the hyperedge formed by the vertices of $C_{x,y}$. Moreover, for any edge $e = \{x, y\} \in E(\mathbf{red}(G))$, the cycle $\theta(x, y) = C_{x,y}$ is identical to the D-hexagon $\phi(x, y)$. Notice now that the application of Step 3 of the definition of **red** on G_2 ignores the edges of G_2 and adds as edges all the cycles $\phi(e), e \in E(\mathbf{red}(G))$. As these cycles are exactly those added toward constructing $\mathcal{G}^h$, the graph $\mathcal{G}^h$ is also identical to the result of Step 3. Thus $\mathcal{G}^h$ is isomorphic to $\mathbf{ext}(\mathbf{red}(G))$. □

3.7. Main combinatorial result.

LEMMA 3.21. *For any nicely D-dominated Σ-plane graph G,* $\mathbf{bw}(G) \leq 3 \cdot \sqrt{4.5 \cdot |D|}$.

Proof. For $|D| = 1$, $G - D$ is outerplanar. It is well known that the branch-width of an outerplanar graph is at most two, implying $\mathbf{bw}(G) \leq 3$.

Suppose that $|D| \geq 2$. Clearly, $\mathbf{bw}(G) \leq \mathbf{bw}(\mathcal{G}^*)$, and to prove the lemma we show that $\mathbf{bw}(\mathcal{G}^*) \leq 3 \cdot \sqrt{4.5 \cdot |D|}$.

Prime case. We first examine the special case where G is a prime D-dominated Σ-plane graph. There are two subcases:

• If $|D| = 2$, then we set $D = \{x, y\}$. If there are only two (x, y)-paths in G, then $G = \Sigma_2^2$. If there are three (x, y)-paths in G, then $G = \Sigma_2^3$ (see Figure 9). Moreover, G cannot contain more than three (x, y)-paths; otherwise it would not be prime. Therefore, $|V(G)| \leq 8$ and thus $\mathbf{bw}(\mathcal{G}^*) \leq 8 \leq 3 \cdot \sqrt{4.5 \cdot 2} = 9$.

• Suppose now that G is a prime D-dominated Σ-plane graph and $|D| \geq 3$. By Theorem 2.4, $\mathbf{bw}(\mathbf{red}(G)) \leq \sqrt{4.5 \cdot |D|}$. By Lemma 3.17, all the vertices $\mathbf{red}(G)$ have degree ≥ 2. Therefore, we can apply Lemma 3.8 on $\mathbf{red}(G)$ (recall that $\mathbf{red}(G)$ is connected) and get $\mathbf{bw}(\mathbf{ext}(\mathbf{red}(G))) \leq 3 \cdot \mathbf{bw}(\mathbf{red}(G))$. By Lemma 3.17, $\mathbf{bw}(\mathcal{G}^h) = \mathbf{bw}(\mathbf{ext}(\mathbf{red}(G)))$ and by Lemma 3.16, $\mathbf{bw}(\mathcal{G}^*) \leq \max\{\mathbf{bw}(\mathcal{G}^h), 3\}$. Resuming, we conclude that if G is prime, then $\mathbf{bw}(\mathcal{G}^*) \leq 3 \cdot \sqrt{4.5 \cdot |D|}$.

General case. Suppose that G is a nicely D-dominated Σ-plane graph. We use induction on the number of vertices of G. If $|V(G)| = 3$, then G is a triangle (the graph Σ_1 of Figure 9) and $\mathbf{bw}(\mathcal{G}^*) = 3 \leq 3 \cdot \sqrt{4.5}$. Suppose that $\mathbf{bw}(\mathcal{G}^*) \leq 3 \cdot \sqrt{4.5 \cdot |D|}$ for every nicely D-dominated graph on $< n$ vertices. Let G be a nicely D-dominated Σ-plane graph where $|V(G)| = n$ and let q be a nonempty D-triangle or D-hexagon (if q does not exist, then the induction step follows by the prime case above). By Lemmata 3.10 and 3.11, we have that if Δ_1, Δ_2 are the discs bounded by q, then, for $i = 1, 2$, $G_i = G[V(G) \cap \Delta_i]$ is a subgraph of a nicely D_i-dominated Σ-plane graph for some $D_i \subseteq D$, $i = 1, 2$, and that $|V(G_i)| < n$ (we use the expression "subgraph" in order to capture the case when q is a D-hexagon). Applying the induction hypothesis, we get that $\mathbf{bw}(G_i^*) \leq 3 \cdot \sqrt{4.5 \cdot |D_i|}, i = 1, 2$. Notice also that $\mathcal{G}^* = \mathcal{G}_1^* \cup \mathcal{G}_2^*$ and that $V(\mathcal{G}_1^*) \cap V(\mathcal{G}_2^*) = q \in E(\mathcal{G}_1^*) \cap E(\mathcal{G}_2^*)$. Therefore, we can apply Lemma 3.1 and we get $\mathbf{bw}(\mathcal{G}^*) \leq 3 \cdot \sqrt{4.5 \cdot |D_i|}$ (recall that $|q| \leq 6$). □

For an example of the induction of the general case in the proof of Lemma 3.21, see Figure 11.

The following is the main combinatorial result of this paper.

THEOREM 3.22. *Let G be a D-dominated Σ-plane graph. Then* $\mathbf{bw}(G) \leq 3\sqrt{4.5 \cdot |D|}$.

Proof. If the branch-width of G is at most one, the theorem is trivial. Suppose that $\mathbf{bw}(G) \geq 2$. Then removing multiple edges does not decrease the branch-width of G, and we can assume that G is simple.

Let A be the set of cut vertices of G. Let G_i be the 2-connected components of G, $D_i = D \cap V(G_i)$, and $A_i = A \cap V(G_i)$, $1 \leq i \leq r$. Let also N_i be the vertices of G_i that are not dominated by D_i, $1 \leq i \leq r$.

Note also that each vertex of N_i is dominated in G by some vertex from $V(G) - V(G_i)$. Moreover, a vertex from $V(G) - V(G_i)$ cannot dominate more than one vertex in G_i. Therefore, $|N_i| \leq |D - D_i|$. Thus for $D'_i = N_i \cup D_i$, we have that G_i is D'_i-dominated and $|D'_i| \leq |D|$.

Consider now two cases for the graph $G_i, 1 \leq i \leq r$.

Case 1. G_i is a D'_i-dominated 2-connected planar graph. We take a drawing of this graph in a sphere Σ and apply Lemma 3.9. In this way, we construct a nicely D'_i-dominated Σ-plane graph H_i containing (property (a)) G_i as a minor. By Lemma 3.21, $\mathbf{bw}(H_i) \leq 3 \cdot \sqrt{4.5 \cdot |D'_i|}$. Since G_i is a minor of H_i, we have that $\mathbf{bw}(G_i) \leq 3\sqrt{4.5 \cdot |D'_i|} \leq 3\sqrt{4.5 \cdot |D|}$.

Case 2. G_i is an induced edge. Clearly, in this case, $\mathbf{bw}(G_i) \leq 3\sqrt{4.5 \cdot |D|}$.

Each graph G_i can be treated as a hypergraph with the ground set $V(G_i)$ and the edge set $E(G) \cup \{\{v\} \mid v \in V(G)\}$. As hypergraphs, graphs G_i have at most one edge (edge consisting of one vertex) in common, and by applying Lemma 3.1 recursively we obtain that $\mathbf{bw}(G) \leq \max\{1, \max_{1 \leq i \leq r} \mathbf{bw}(G_i)\} \leq 3\sqrt{4.5 \cdot |D|}$. □

4. Algorithmic consequences. In this section we discuss an algorithm that, given a planar graph G on n vertices and an integer k, decides whether G has a dominating set of size at most k.

4.1. The general algorithm. The algorithm runs in $O(2^{12.75\sqrt{k}} + n^3)$ steps and works in three phases as follows.

Phase 1. We use the known reduction of Planar Dominating Set problem to a linear problem kernel as a preprocessing procedure. Alber, Fellows, and Niedermeier [3] designed a procedure that, for a given integer k and planar graph G on n vertices, outputs a planar graph H on $\leq 335k$ vertices such that G has a dominating set of size $\leq k$ if and only if H has a dominating set of size $\leq k$. Later, Chen, Fernau, Kanj, and Xia [9] improved this result, providing a reduction to a kernel of a size $\leq 67k$. Each of the aforementioned reductions can be performed in $O(n^3)$ steps.

Phase 2. We compute an optimal branch decomposition of the graph H. For this step, one can use the algorithms due to Seymour and Thomas (algorithms 7.3 and 9.1 of sections 7 and 9 in [39]—for an implementation, see the work of Hicks in [33]). These algorithms need $O(n^2)$ steps for checking and $O(n^4)$ steps for constructing the branch decomposition for graphs on n vertices. We stress that there are no *large hidden constants* in the running time of these algorithms, which is important for practical applications. Thus a branch decomposition of H can be constructed in $O(k^4)$ steps. Check whether $\mathbf{bw}(H) \leq (3\sqrt{4.5})\sqrt{k} < 6.364\sqrt{k}$. If the answer is "no," then by Theorem 3.22 we conclude that there is no dominating set of size k in G. If the answer is "yes," then we proceed with the next phase.

Phase 3. Here we use a dynamic programming approach to solve the Planar Dominating Set problem on graph H. Alber et al. [1] suggested a dynamic programming algorithm based on the so-called monotonicity property of the domination problem. For a graph G on n vertices with a given tree decomposition of width ℓ, the algorithm of Alber et al. can be implemented in $O(2^{2\ell}n)$ steps. There is a well known transformation due to Robertson and Seymour [36] that, given a branch decomposition of width $\leq \ell$ of a graph with m edges, constructs a tree decomposition of width $\leq (3/2)\ell$ in $O(m^2)$ steps. Thus the result of Alber et al. immediately implies that

the DOMINATING SET problem on graphs with n vertices and m edges and of branch-width $\leq \ell$ can be solved in $O(2^{3\ell}n + m^2)$ steps. Notice now that for planar graphs $m = O(n)$. This phase requires $O(2^{3\cdot 3\sqrt{4.5\cdot k}}k+k^2)$ steps. As $3\cdot 3\sqrt{4.5} < 19.1$, we obtain an $O(2^{19.1\sqrt{k}}+n^3)$-step algorithm that finds in planar graph on n vertices a dominating set of size at most k, or reports that no such dominating set exists. However, in the next subsection (Theorem 4.1) we construct a dynamic programming algorithm solving the DOMINATING SET problem on graphs of branch-width $\leq \ell$ in $O(3^{1.5\ell}m)$ steps, where m is the number of edges in a graph. Because $(1.5\cdot\log_2 3)\cdot 3\sqrt{4.5} < 15.13$ and $m = O(k)$, we can reduce the cost of this phase to $O(2^{15.13\sqrt{k}})$ steps and conclude with a time $O(2^{15.13\sqrt{k}} + n^3)$ algorithm.

4.2. Dynamic programming on graphs of bounded branch-width. Let (T', τ) be a branch decomposition of a graph G with m edges and let $\omega' : E(T') \to 2^{V(G)}$ be the order function of (T', τ). We choose an edge $\{x, y\}$ in T', put a new vertex v of degree two on this edge, and make v adjacent to a new vertex r. By choosing r as a root in the new tree $T = T' \cup \{v, r\}$, we turn T into a rooted tree. For every edge of $f \in E(T) \cap E(T')$ we put $\omega(f) = \omega'(f)$. Also we put $\omega(\{x, v\}) = \omega(\{v, y\}) = \omega'(\{x, y\})$ and $\omega(\{r, v\}) = \emptyset$.

For an edge f of T we define E_f (V_f) as the set of edges (vertices) that are "below" f, i.e., the set of all edges (vertices) g such that every path containing g and $\{v, r\}$ in T contains f. With this notation, $E(T) = E_{\{v,r\}}$ and $V(T) = V_{\{v,r\}}$. Every edge f of T that is not incident to a leaf has two children that are the edges of E_f incident to f. We also denote by G_f the subgraph of G formed by edges of G corresponding to the leaves of V_f.

For every edge f of T we color the vertices of $\omega(f)$ in three colors:

black (represented by 1, meaning that the vertex is in the dominating set),

white (represented by 0, meaning that the vertex is dominated at the current step of the algorithm and is not in the dominating set), and

grey (represented by $\hat{0}$, meaning that at the current step of the algorithm we still have not decided to color this vertex white or black).

For every edge f of T we use mapping

$$A_f \colon \{0, \hat{0}, 1\}^{|\omega(f)|} \to \mathbb{N} \cup \{+\infty\}.$$

For a coloring $c \in \{0, \hat{0}, 1\}^{|\omega(f)|}$, the value $A_f(c)$ stores the minimum cardinality of a set $D_f \subseteq V(G_f)$ such that every nongrey vertex of G_f is dominated by a vertex from D_f and all black vertices are in D_f. More formally, $A_f(c)$ stores the minimum cardinality of a set $D_f(c)$ such that

- every vertex of $V(G_f) \setminus \omega(f)$ is adjacent to a vertex of $D_f(c)$,
- for every vertex $u \in \omega(f)$, $c(u) = 1 \Rightarrow u \in D_f(c)$ and $c(u) = 0 \Rightarrow (u \notin D_f(c)$ and u is adjacent to a vertex from $D_f(c))$.

We put $A_f(c) = +\infty$ if there is no such set $D_f(c)$. Because $\omega(\{r, v\}) = \emptyset$ and $G_{\{r,v\}} = G$, we have that $A_{\{r,v\}}(c)$ is the smallest size of a dominating set in G.

Let f be a nonleaf edge of T and let f_1, f_2 be the children of f. Define $X_1 = \omega(f) - \omega(f_2)$, $X_2 = \omega(f) - \omega(f_1)$, $X_3 = \omega(f) \cap (\omega(f_1) \cap \omega(f_2))$, and $X_4 = (\omega(f_1) \cup \omega(f_2)) - \omega(f)$.

Notice that $X_i \cap X_j \neq \emptyset$, $1 \leq i \neq j \leq 4$, and

$$\omega(f) = X_1 \cup X_2 \cup X_3. \tag{1}$$

Notice now that by the definition of ω it is impossible that a vertex belongs in exactly one of $\omega(f), \omega(f_1), \omega(f_2)$. Therefore, condition $u \in X_4$ implies that $u \in \omega(f_1) \cap \omega(f_2)$.

Hence

$$\omega(f_1) = X_1 \cup X_3 \cup X_4, \tag{2}$$

and

$$\omega(f_2) = X_2 \cup X_3 \cup X_4. \tag{3}$$

We say that a coloring c of $\omega(f)$ is *formed* from coloring c_1 of $\omega(f_1)$ and coloring c_2 of $\omega(f_2)$ if the following hold:

- **[F1]** For every $u \in X_1$, $c(u) = c_1(u)$.
- **[F2]** For every $u \in X_2$, $c(u) = c_2(u)$.
- **[F3]** For every $u \in X_3$, $(c(u) \in \{\hat{0}, 1\} \Rightarrow c(u) = c_1(u) = c_2(u))$ and $(c(u) = 0 \Rightarrow [c_1(u), c_2(u) \in \{\hat{0}, 0\} \wedge (c_1(u) = 0 \vee c_2(u) = 0)])$. (The color 1 ($\hat{0}$) can appear only if both colors in c_1 and c_2 are 1 ($\hat{0}$). The color 0 appears when both colors in c_1, c_2 are not 1 and at least one of them is 0.)
- **[F4]** For every $u \in X_4, (c_1(u) = c_2(u) = 1) \vee (c_1(u) = c_2(u) = 0) \vee (c_1(u) = 0 \wedge c_2(u) = \hat{0}) \vee (c_1(u) = \hat{0} \wedge c_2(u) = 0)$. This property says that every vertex u of $\omega(f_1)$ and $\omega(f_2)$ that does not appear in $\omega(f)$ (and hence does not appear further) should be finally colored either by 1 (if both colors of u in c_1 and c_2 are 1) or 0 (0 can appear if both colors of u in c_1 and c_2 are not 1 and at least one color is 0).

Notice that every coloring of f is formed from some colorings of its children f_1 and f_2. We start computations of values $A_f(c)$ from leaves of T. For every leaf f, $|\omega(f)| \leq 1$, and the number of colorings of $\omega(f)$ is at most three. Thus all possible values of $A_f(c)$ can be computed in $O(m)$ steps.

Then we compute the values of the corresponding functions in bottom-up fashion. The main observation here is that if f_1 and f_2 are the children of f, then the vertex sets $\omega(f_1)$, $\omega(f_2)$ "separate" subgraphs G_1 and G_2; thus the value $A_f(c)$ can be obtained from the information on colorings of $\omega(f_1)$ and $\omega(f_2)$. More precisely, let $\#_1(X_i, c)$, $1 \leq i \leq 4$, be the number of vertices in X_i colored by color 1 in coloring c. For a coloring c we assign

$$A_f(c) = \min\{A_{f_1}(c_1) + A_{f_2}(c_2) - \#_1(X_3, c_1) - \#_1(X_4, c_1) | c_1, c_2 \text{ form } c\}. \tag{4}$$

(Every 1 from X_3 and X_4 is counted in $A_{f_1}(c_1) + A_{f_2}(c_2)$ twice, and $X_3 \cap X_4 = \emptyset$.) The number of steps to compute the minimum in (4) is given by

$$O\Big(\sum_c |\{c_1, c_2\} \colon c_1, c_2 \text{ form } c|\Big).$$

Let $x_i = |X_i|$, $1 \leq i \leq 4$. For a fixed coloring c of $\omega(f)$, let p be the number of vertices of X_3 colored with 0. By [F3], every 0 of a vertex $u \in X_3$ can be "formed" in three ways, from $\hat{0}$ and 0, or from 0 and 0, or from 0 and $\hat{0}$. By [F4], a color of $u \in X_4$ can be obtained in four ways: 1 can be obtained from 1 and 1; 0 can be obtained either from 0 and 0, or from 0 and $\hat{0}$, or from $\hat{0}$ and 0. Then by [F1]–[F4], the number of colorings that form a fixed coloring c with exactly p vertices of X_3 of color 0 is equal to $3^p 4^{x_4}$. Every vertex of $\omega(f) = X_1 \cup X_2 \cup X_3$ can be colored in one of the three colors. The number of operations needed to estimate (4) for all possible colorings of $\omega(f)$ is

$$\sum_{p=0}^{x_3} 3^{x_1+x_2} \cdot 2^{x_3-p} \cdot 3^p \binom{x_3}{p} 4^{x_4} = 3^{x_1+x_2} 5^{x_3} 4^{x_4}.$$

The obtained bound can be reduced by using the trick due to Alber et al. [1]. The trick is based on the following observation. If for some coloring c of f we replace a color of a vertex u from $\hat{0}$ to 0, then for the new coloring c', $A_f(c) \leq A_f(c')$. Thus in (4) we can replace "c_1, c_2 form c" with "c_1 and c_2 satisfies **[F1]**, **[F2]**, **[F3′]**, and **[F4′]**," where **[F3′]** and **[F4′]** are as follows:

[F3′] For every $u \in X_3$, $(c(u) \in \{\hat{0}, 1\} \Rightarrow c(u) = c_1(u) = c_2(u))$ and $(c(u) = 0 \Rightarrow [c_1(u), c_2(u) \in \{\hat{0}, 0\} \wedge (c_1(u) \neq c_2(u))])$.

[F4′] For every $u \in X_4$, $(c_1(u) = c_2(u) = 1) \vee [c_1(u), c_2(u) \in \{\hat{0}, 0\} \wedge (c_1(u) \neq c_2(u))]$.

The purpose of properties **[F3′]** and **[F4′]** is to reduce the search space from all coloring forming c to the smaller set of colorings. Thus the number of steps for evaluating $A_f(c)$ is bounded by

$$\sum_{p=0}^{x_3} 3^{x_1+x_2} \cdot 2^{x_3-p} \cdot 2^p \binom{x_3}{p} 3^{x_4} = 3^{x_1+x_2} 4^{x_3} 3^{x_4}.$$

Let ℓ be the branch-width of G. By (1), (2), and (3),

$$\begin{aligned} x_1 + x_2 + x_3 &\leq \ell, \\ x_1 + x_3 + x_4 &\leq \ell, \\ x_2 + x_3 + x_4 &\leq \ell. \end{aligned} \tag{5}$$

The maximum value of the linear function $x_1 + x_2 + x_4 + x_3 \cdot \log_3 4$ subject to constraints (5) is $\frac{3\log_4 3}{2}\ell$. (This is because the value of the corresponding linear program achieves maximum in $x_1 = x_2 = x_4 = 0.5\ell$, $x_3 = 0$.) Thus

$$3^{x_1+x_2} 4^{x_3} 3^{x_4} \leq 4^{\frac{3\log_4 3}{2}\ell} = 3^{\frac{3\ell}{2}}.$$

It is easy to check that the number of edges in T is $O(m)$ and the number of steps needed to evaluate $A_{\{r,v\}}(c)$ is $O(3^{\frac{3\ell}{2}} m)$. Summarizing, we get the following theorem.

THEOREM 4.1. *For a graph G on m edges and given a branch decomposition of width $\leq \ell$, the dominating set of G can be computed in $O(3^{\frac{3\ell}{2}} m)$ time.*

5. Concluding remarks and open problems. We start this section with a discussion on the optimality of our results. We then give a presentation on several open problems and results that were motivated by this work.

5.1. Can Theorem 3.22 be improved? We have proved that for any planar graph with a dominating set of size $\leq k$, $\mathbf{bw}(G) \leq 3\sqrt{4.5 \cdot k} < 6.364\sqrt{k}$. The first of the multiplicative factors 3 follows from our results on the structure of planar graphs with a given dominating set in section 3. The second factor $\sqrt{4.5} \approx 2.121$ follows from [28] and is the bound on branch-width of planar graphs (Theorem 2.4). Any improvement to any of these two factors immediately implies an improvement to the time analysis of our fixed-parameter algorithm for a dominating set. However, our approach cannot be strongly improved because the upper bound of Theorem 3.22 is not far from the optimal.

LEMMA 5.1. *There exist planar graphs with a dominating set of size $\leq k$ and with branch-width $> 3\sqrt{k}$.*

Proof. Let G be a $(3n+2, 3n+2)$-grid for any $n \geq 1$. Let V' be the vertices of G of degree < 4. Let also V'' be the set of all vertices adjacent to V' in G. We define D as the unique $S \subseteq V(G) - V' - V''$, where $|S| = n^2$ and such that the

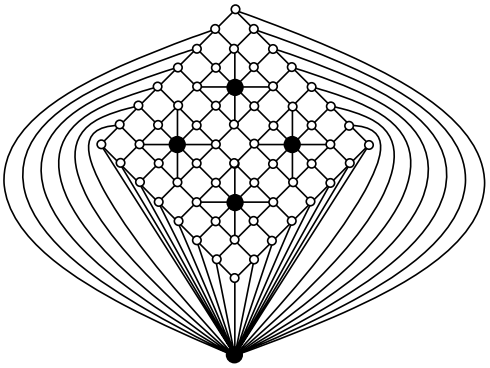

FIG. 13. *An example of the proof of Lemma* 5.1.

distance in G of all pairs $v, u \in D$ in G is a multiple of three. Then for any vertex $v \in D$, and for any possible cycle (square) (v, x, y, z, v) add the edge $\{x, z\}$. The construction is completed by connecting all the vertices in V' with a new vertex v_{new} (see Figure 13). We call the resulting graph J_n. Clearly, $D \cup \{v_{\text{new}}\}$ is a dominating set of J_n of size $k = n^2 + 1 \geq 2$. As the $(3n + 2, 3n + 2)$-grid is a subgraph of J_n we have that $\mathbf{bw}(J_n) \geq 3n + 2 \geq 3\sqrt{k-1} + 2 > 3\sqrt{k}$ (from [36], the (ρ, ρ)-grid has branch-width ρ). □

5.2. Open problems and extensions of our results. A (k, r)-*center* in a graph G is a set of at most k vertices, which we call centers, such that any vertex of G is within distance at most r from some center. Extending the results of section 4, [13] gives an algorithm that outputs, if it exists, a (k, r)-center of a planar graph in $r^{O(r\sqrt{k})} + n^{O(1)}$ steps (according to [13], the same result also holds for map graphs). The constants hidden in the first O-notation are based on an extension of Lemma 2.2, bounding the branch-width of any planar graph containing a (k, r)-center by $4(2r + 1)\sqrt{k} + O(r)$. We conjecture that this bound (and subsequently the running time of the algorithm in [13]) can be improved to $(2r + 1)\sqrt{4.5 \cdot k}$. We also suspect that a proof of this conjecture could be based on the same steps as those we used for Theorem 3.22.

An approach similar to the one of section 4 has been applied for a wide number of problems related to the PLANAR DOMINATING SET problem. In this way, our upper bound improves the algorithm complexity analysis for a series of problems when their inputs are restricted to planar graphs. As a sample we mention the following: INDEPENDENT DOMINATING SET, PERFECT DOMINATING SET, PERFECT CODE, WEIGHTED DOMINATING SET, TOTAL DOMINATING SET, EDGE DOMINATING SET, FACE COVER, VERTEX FEEDBACK SET, VERTEX COVER, MINIMUM MAXIMAL MATCHING, CLIQUE TRANSVERSAL SET, DISJOINT CYCLES, and DIGRAPH KERNEL (see [17] for details and extensions to more general graph classes). However, in all of the aforementioned problems, the time analysis is based on algorithms and combinatorial bounds for tree-width. It is an interesting problem whether better speed-up is possible using branch-width instead of tree-width, as we did in this paper. To our knowledge, not much progress has been noted so far on the design of algorithms on graphs of bounded branch-width (see [11, 13, 20]).

It appears that the planarity is not a limit for the existence of bounds like the one in Theorem 3.22. In [27], it was proved that for any D-dominated graph G,

$\mathbf{bw}(G) \leq 3(\sqrt{4.5}+2\sqrt{2 \cdot \mathbf{eg}(G)})\sqrt{|D| + 6 \cdot \mathbf{eg}(G)} = O(\sqrt{|D| \cdot \mathbf{eg}(G)}+\mathbf{eg}(G))$, where $\mathbf{eg}(G)$ is the Euler genus of G. The proof of this bound uses Theorem 3.22 as a basic ingredient. As a consequence of [27], most of the applications mentioned in the previous paragraph also can be extended for graphs of bounded genus. For discussions on the limits of this approach, see [26].

Finally, the idea behind Lemma 2.2 offers a mechanism for proving similar bounds for a wide family of parameters. This is the general family of *bidimensional parameters* introduced in [12] that unified the framework where the algorithmic paradigm of section 4 can be applied. Recent research on bidimensionality extends to several results such as [14, 15, 16, 18].

Acknowledgments. We are grateful to Hans Bodlaender, Ton Kloks, and Robin Thomas for answering our questions.

BETWEEN O(nm) AND O(n^α)*

DIETER KRATSCH† AND JEREMY SPINRAD‡

Abstract. This paper uses periodic matrix multiplication to improve the time complexities for a number of graph problems. The time for finding an asteroidal triple is reduced from O(nm) to O($n^{2.82}$), and the time for finding a star cutset, a two-pair, and a dominating pair is reduced from O(nm) to O($n^{2.79}$). It is also shown that each of these problems is at least as hard as one of three basic graph problems for which the best known algorithms run in times O(nm) and O(n^α). We note that the fast matrix multiplication algorithms do not seem to be practical because of the enormous constants needed to achieve the asymptotic time bounds. These results are important theoretically for breaking the n^3 barrier rather than giving efficient algorithms for a user.

Key words. algorithms, graphs, reductions, AT-free graphs, two-pair, star cutset, dominating pair

1. Introduction. We will describe a method which takes an undirected graph $G = (V, E)$ as input and finds for all vertices $x \in V$ the connected components of $G - \mathrm{N}[x]$. Here $\mathrm{N}(x) = \{y \in V : \ (x, y) \in E\}$ denotes the open neighborhood, and $\mathrm{N}[x] = \mathrm{N}(x) \cup \{x\}$ denotes the neighborhood. We will call the set of connected components for $G - \mathrm{N}[x]$ for all $x \in V$ the *neighborhood-deleted components* of G. Clearly, the neighborhood-deleted components can be found in O(nm) time by simply computing for each x the components of $G - \mathrm{N}[x]$ using breadth-first search. Our algorithm will use fast matrix multiplication to reduce the time complexity on dense graphs to O($n^{2.79}$). The computation of the neighborhood-deleted components is the bottleneck step for a number of apparently unrelated algorithms on graphs. Thus we improve the best known running time for a collection of graph problems. We describe some of these applications below.

Three vertices x, y, z are an *asteroidal triple* in a graph if they are pairwise nonadjacent and between any two of them there is a path avoiding the neighborhood of the third. This concept was introduced by Lekkerkerker and Boland [18] to characterize interval graphs. It was also used by Gallai in his study of comparability graphs [14, 10]. Graphs without asteroidal triple, called *AT-free graphs*, were first studied as a separate class of graphs by Corneil, Olariu, and Stewart [6]. Many interesting properties and characterizations of AT-free graphs have been discovered [7, 19], and these are now recognized as an important graph class. It is not hard to see that x, y, z form an asteroidal triple iff x and y are in the same component of $G - \mathrm{N}[z]$, x and z are in the same component of $G - \mathrm{N}[y]$, and y and z are in the same component of $G - \mathrm{N}[x]$. Thus, the running time of algorithms for recognizing AT-free graphs was given as O(n^3). Early efforts to establish a linear time recognition algorithm for

AT-free graphs were dismissed after Spinrad showed that recognizing AT-free graphs is at least as hard as recognizing a triangle [21] (see our Theorem 5.1). We note that triangle recognition is a fundamental and well-studied graph problem and that its best known algorithm on dense graphs has running time O(n^α).[1] Using Gallai's concept of the knotting graph, Köhler [15] obtained a recognition algorithm for AT-free graphs with running time O($n^{2.82}$) plus the time to compute the neighborhood-deleted components. Thus we reduce the time bound for recognizing AT-free graphs to O($n^{2.82}$). It remains an interesting open question whether there is a recognition algorithm for AT-free graphs with running time O(n^β) such that $\alpha \leq \beta < 2.82$.

A *two-pair* in a graph is a pair of vertices x, y such that every chordless path between x and y has length two. Hayward [12] showed that every weakly chordal graph is either a clique or has a two-pair. Two-pairs are fundamental for recognition and optimization algorithms on weakly chordal graphs; they are also used as a tool for showing perfection in graph classes. We show that the neighborhood-deleted components can be used to reduce the time complexity of finding a two-pair in a graph.

Similar results can be obtained for problems on *dominating pairs*, *star cutsets*, and *extremities*; these terms will be defined in section 3.

We note that an earlier version of this paper [16] also gave an algorithm which used periodic matrix multiplication to improve the running time of an algorithm for finding a clique cutset in a graph. Since that time, we have discovered an improved algorithm for finding a minimal fill in a graph [17], which leads to a simpler algorithm achieving the same time bound for the clique cutset problem.

The problems solved in this paper all make use of fast matrix multiplication to beat bounds of O(nm). It is natural to ask whether these problems can be solved even faster (perhaps in linear time), or solved efficiently without using matrix multiplication. Motivated by the reduction from triangle recognition to AT-free graph recognition (Theorem 5.1), we show that each of the abovementioned problems is as hard as one of the following three basic graph problems:

- *determining whether a graph has a triangle*;
- *determining whether a graph has a simplicial vertex*, i.e., a vertex x such that N(x) is a clique;
- *determining whether a graph has a dominated vertex*, i.e., a vertex x such that for some y, N(x) $\subset$ N[y].

This gives evidence that significant improvements over our results, e.g., solving any of our problems in time o(n^α), or solving any of our problems in O($n^{3-\epsilon}$), $\epsilon > 0$, time without using matrix multiplication, would require a major breakthrough (such as, e.g., a faster algorithm for finding a triangle).

2. Neighborhood-deleted components. Before presenting our algorithm for finding the neighborhood-deleted components of G, we introduce some notation. Let $G = (V, E)$ be a graph. For $A \subseteq V$, we denote by $G[A]$ the subgraph of G induced by A. We write $G - A$ instead of $G[V - A]$. We denote by N(A) the set of all neighbors of A, i.e., N(A) = $\bigcup_{a \in A}$ N(a). A connected component C of a graph G is a maximal subset of vertices of G such that $G[C]$ is connected, thus components are vertex sets. We also call $B \subseteq V$ a *connected subset* of a graph $G = (V, E)$ if $G[B]$ is a connected graph. For standard graph theory notation we refer to [2, 11].

[1] α denotes the best known exponent of an algorithm to multiply two binary n by n matrices. Currently $\alpha = 2.376...$ [5].

To understand the motivation of several steps of our algorithm, we first discuss its fundamental idea. Suppose we have found a partition of $V - \mathrm{N}[v]$ into connected subsets of $G - \mathrm{N}[v]$ for all $v \in V$; initially we might have a partition into singletons. We can perform a single matrix multiplication and get all subset pairs which are joined by at least one edge when using a vertex-subset incidence matrix, as we will show later. However, if this is done from the initial condition, each $G - \mathrm{N}[v]$ may have $\Theta(n)$ components, and we would be performing matrix multiplication on two $\Theta(n)$ by $\Theta(n)$ matrices, which is too expensive.

Therefore, we want to reduce the number of initial connected subsets for each $G - \mathrm{N}[v]$. To do this, for each pair v, w we want to find a large enough set of edges $(u, w) \in E$ with $u \in \mathrm{N}(w) - \mathrm{N}[v]$ such that after using these edges only for merging connected subsets, w is guaranteed to be in a large component of $G - \mathrm{N}[v]$. The difficulty lies in finding $\mathrm{N}(w) - \mathrm{N}[v]$ without stepping through $\mathrm{N}[v]$ and $\mathrm{N}(w)$. Instead, we will use matrix multiplication to determine regions of a suitable matrix which contain at least one vertex of $\mathrm{N}(w) - \mathrm{N}[v]$, thus avoiding the $\mathrm{O}(n)$ expense of identifying $\mathrm{N}(w) - \mathrm{N}[v]$.

We now make the outline above more specific. We want to select a function $f(n)$, and for each pair of vertices v, w we will find either all vertices of $\mathrm{N}(w) - \mathrm{N}[v]$ if $|\mathrm{N}(w) - \mathrm{N}[v]| < f(n)$, or $f(n)$ vertices from $\mathrm{N}(w) - \mathrm{N}[v]$ otherwise. Let $\mathrm{MM}(i, j, k)$ be the time of an algorithm which multiplies an i by j matrix and a j by k matrix.

LEMMA 2.1. *Let G be a graph with n vertices, and let $f(n)$, $g(n)$ be functions of n. There is an $\mathrm{O}((n/g(n))\mathrm{MM}(n, g(n), n) + n^2 f(n) g(n))$ time algorithm to find for all pairs of vertices v, w of G a set $S_{v,w}$ such that $S_{v,w} \subseteq \mathrm{N}(w) - \mathrm{N}[v]$ and $|S_{v,w}| = \min\{f(n), |\mathrm{N}(w) - \mathrm{N}[v]|\}$.*

Proof. We describe the procedure to search for vertices of $\mathrm{N}(w) - \mathrm{N}[v]$ for all pairs v, w. Partition V into subsets of size $g(n)$ (possibly one subset will be of smaller size). Let S be a set of $g(n)$ vertices. For each vertex v in G, count the number of neighbors of v in S. Create an n by $g(n)$ binary matrix M_S with a row for each vertex of G and a column for each vertex of S, with $M_S[v, j] = 1$ iff vertex v of G is adjacent to the jth vertex of S. Let M'_S be the result of multiplying M_S by its transpose; thus $M'_S[v, w] = |\mathrm{N}(v) \cap \mathrm{N}(w) \cap S|$. Determine for each pair v, w whether there is any vertex of $\mathrm{N}(w) - \mathrm{N}[v]$ in S using $M'_S[v, w]$ and the number of neighbors of w in S; store this information for each set S.

Let v, w be a pair of vertices. Consider each set S in turn until we have found $f(n)$ vertices from $\mathrm{N}(w) - \mathrm{N}[v]$ or considered all sets S. If there is at least one vertex of $\mathrm{N}(w) - \mathrm{N}[v]$ in S, look at every $s \in S$, and add each vertex $s \in S$ to $S_{v,w}$ (initially empty) if $(s, w) \in E$, $(s, v) \notin E$, and $s \neq v$. At the end of this procedure for each pair of vertices v, w, clearly the set $S_{v,w}$ has $\min\{f(n), |\mathrm{N}(w) - \mathrm{N}[v]|\}$ vertices and $S_{v,w} \subseteq \mathrm{N}(w) - \mathrm{N}[v]$.

We now analyze the running time of the procedure. We first analyze the time needed to find whether $\mathrm{N}(w) - \mathrm{N}[v]$ is empty for all pairs of vertices v, w. The number of neighbors of a vertex v in S can be computed in $\mathrm{O}(|S|)$ time, so all these values, for all v and all S, can be computed in time $\mathrm{O}(n^2)$. The dominant cost of the procedure is finding the matrices M'_S for each S. Each of these $n/g(n)$ matrices is the result of multiplying an n by $g(n)$ matrix by a $g(n)$ by n matrix, giving us the first term in the statement of the theorem.

It takes time $\mathrm{O}(n^3/g(n))$ to determine for which sets S $\mathrm{N}(v) \cap \mathrm{N}(w) \cap S \neq \emptyset$. Since $n^3/g(n)$ is the size of the output matrices of $n/g(n)$ matrix multiplications as above, this term can be ignored with respect to order notation complexity of the algorithm. Then some of these sets S are checked to find actual vertices of $\mathrm{N}(w) - \mathrm{N}[v]$.

For each pair v, w, at most $f(n)$ sets are checked, taking O($g(n)$) time for a set; thus, the total time is O($n^2 f(n)g(n)$). □

LEMMA 2.2. *Let G be a graph with n vertices, and let $f(n)$ and $g(n)$ be functions of n. There is an* O($n/g(n)$MM$(n, g(n), n) + n^2 f(n)g(n) +$ MM$(n^2/f(n), n, n)$) *time algorithm to compute the neighborhood-deleted components of G.*

Proof. In phase 1 of our algorithm the procedure of Lemma 2.1 is used to compute the sets $S_{v,w}$. In phase 2, initial connected subsets for all $G - \mathrm{N}[v]$ are created as follows. For each v, start with each vertex of $G - \mathrm{N}[v]$ in its own connected subset and label each connected subset by the corresponding v. For each x in $S_{v,w}$, unify those connected subsets of $G - \mathrm{N}[v]$ containing x and w. At the end of phase 2, suppose that some connected subset C of $G - \mathrm{N}[v]$ contains fewer than $f(n)$ vertices. Then $|\mathrm{N}(c) - \mathrm{N}[v]| < f(n)$ and $\mathrm{N}(c) - \mathrm{N}[v] = S_{v,c}$ for every vertex c of C. Thus, there is no edge joining (a vertex of) C and a vertex of $V - (C \cup \mathrm{N}[v])$, and C is a connected component of $G - \mathrm{N}[v]$.

For the remainder, the algorithm treats only connected subsets of size at least $f(n)$. In phase 3, create a directed graph D with 3 levels of vertices as follows. At the first level of D, create a vertex for each connected subset of size at least $f(n)$ found in phase 2. At the second and third levels of D, create a vertex for each vertex in G. Add an edge from C at the first level to x at the second level if x is in C. Add an edge from x at the second level to y at the third level if x is adjacent to y. Now there is an edge joining a connected subset C and a vertex u in G iff there is a path from C in the first level of D to the copy of u in the third level of D. Let M_{CtoG} be a binary matrix with a row for each connected subset and a column for each vertex of G, with $M_{CtoG}[C, u] = 1$ iff $(u, v) \notin E$ (here v is the vertex that C is labeled with) and there is an edge joining C and u in G. Computing M_{CtoG} involves multiplying an $n^2/f(n)$ by n matrix representing the edges between the first two levels of D and an n by n matrix representing the edges between the second and third levels of D.

Recall that C is a connected subset of $G - \mathrm{N}[v]$ for some specific vertex v and that C is labeled by v. In phase 4, for every vertex u and every connected subset C, if there is an edge joining u and C in G, then unify C and the connected subset containing u in $G - \mathrm{N}[v]$. Since each vertex u is compared to $n^2/f(n)$ connected subsets there are $n^3/f(n)$ such operations; the cost of performing these union and find operations is dominated by the time for performing the matrix multiplication in phase 3. Therefore, the running time of the algorithm is O($n/g(n)$MM$(n, g(n), n) + n^2 f(n)g(n) +$ MM$(n^2/f(n), n, n)$). □

THEOREM 2.3. *The neighborhood-deleted components of G can be computed in* O($n^{2.79}$) *time.*

Proof. Let $f(n) = n^{.575}$, $g(n) = n^{.2125}$. It is clear that $n^2 f(n)g(n)$ is O($n^{2.79}$) for these values. It is known that MM$(n, g(n), n))$ is O($n^{2+o(1)}$) whenever $g(n) < n^{.294}$ [13, 4], so the $n/g(n)$ multiplications of n by $g(n)$ and $g(n)$ by n matrices take O($n^{2.79}$) time. The best algorithm for multiplying rectangular matrices of the form $n^2/f(n)$ by n and n by n is given in [13].

The time complexity from [13, p. 273] is somewhat complex to state. For chosen values of q, the exponent of MM$(n, n^{1.425}, n)$ is at most $(1/\log q)\log(2.425^{2.45}(q + 2)^{3.425}/3.425^{3.425})$. Using $q = 7$, as suggested on page 280 of [13], this works out to approximately 2.787, implying that the overall cost of the algorithm for computing neighborhood-deleted components is O($n^{2.79}$). □

3. Algorithmic consequences. We show that the neighborhood-deleted components of G can be used to solve a variety of well-known graph problems.

Our first application is recognition of AT-free graphs.

The *knotting graph* $\mathrm{K}(G)$ is defined as follows. For each vertex v of G and each connected component i of $\overline{G}[\mathrm{N}(v)]$ (i.e., the complement of the graph induced by $\mathrm{N}(v)$), there is a vertex v_i of $\mathrm{K}(G)$. If (u, v) is an edge of G, $\mathrm{K}(G)$ has an edge between the copy of u corresponding to the connected component containing v in $\overline{G}[\mathrm{N}(u)]$ and the copy of v corresponding to the connected component containing u in $\overline{G}[\mathrm{N}(v)]$.

Knotting graphs were first defined by Gallai [10], who showed that G is a comparability graph iff $\mathrm{K}(G)$ is bipartite.

COROLLARY 3.1. *AT-free graphs can be recognized in* $\mathrm{O}(n^{2.82})$ *time.*

Proof. Köhler [15] showed that you can recognize AT-free graphs in $\mathrm{O}(n^{2.82})$ time plus the time to compute a graph known as the knotting graph. Components of $\overline{G}[N(v)]$ correspond exactly to neighborhood-deleted components caused by deletion of neighbors of v in $\overline{G}$. Therefore, we can compute $\mathrm{K}(G)$ by finding neighborhood-deleted components in $\overline{G}$, and using our earlier theorem knotting graphs can be constructed in $\mathrm{O}(n^{2.79})$ time. □

An *extremity* of a graph is a vertex v such that $G - \mathrm{N}[v]$ is connected. Thus, knowing the neighborhood-deleted components, we can easily identify the extremities.

COROLLARY 3.2. *All extremities of a graph can be listed in time* $\mathrm{O}(n^{2.79})$.

A *star cutset* in a graph is a set S of vertices such that $G - S$ is disconnected, and there is a vertex s in S which is adjacent to every other vertex in S. Chvátal showed that a minimal imperfect graph cannot have a star cutset [3], and generalizations of this star cutset lemma played a crucial role in resolving the strong perfect graph conjecture. Since the generalizations, called skew partitions, can only be found using algorithms with incredibly high time complexity [8], algorithms can be simplified greatly on classes which can be decomposed using the simpler star cutset decomposition. Chvátal also gave a lemma which showed that star cutsets can be found in polynomial time; a star cutset corresponds either to a pair of neighbors x, y such that $\mathrm{N}(x)$ is a subset of $\mathrm{N}[y]$, or to a nonextremity.

COROLLARY 3.3. *It is possible to determine whether a graph has a star cutset in* $\mathrm{O}(n^{2.79})$ *time.*

Proof. Since we can determine all neighborhood containments $\mathrm{N}(x) \subseteq \mathrm{N}[y]$ for all pairs x, y in a graph from a single matrix multiplication, the time complexity of finding a star cutset is dominated by the time needed to find whether the graph has a nonextremity. □

A *dominating pair* in a graph is a pair x, y of vertices such that for every path P from x to y and every vertex z of G, z is adjacent to at least one vertex of P.

COROLLARY 3.4. *It is possible to determine whether* x, y *is a dominating pair in* $\mathrm{O}(n^{2.79})$ *time.*

Proof. The vertices x, y are a dominating pair exactly when x and y are not in the same connected component of $G - \mathrm{N}[z]$ for any z. □

The following theorem needs a more sophisticated use of the neighborhood-deleted components.

THEOREM 3.5. *All dominating pairs of* G *can be listed in* $\mathrm{O}(n^{2.79})$ *time.*

Proof. First, we note that all adjacent dominating pairs can be determined in $\mathrm{O}(n^2)$ time given the square of the adjacency matrix. The number of vertices adjacent to x or y for neighbors x, y is equal to $a(x, y) = |\mathrm{N}(x)| + |\mathrm{N}(y)| - A^2[x, y]$; the latter term is equal to the number of common neighbors of x and y. Neighbors x and y form a dominating pair iff $a(x, y) = n$.

In the remainder of this proof, we show how to determine whether nonadjacent vertices are dominating pairs.

Construct a graph G' with a vertex w for each vertex of G, and a vertex c for each component of all $G - \mathrm{N}[v]$. Add an edge from c to w iff w is in component c. Determining whether w and x are in a common component (and thus are not a dominating pair) is equivalent to asking whether there is a path from w to x of length 2 in this graph, which can be solved by matrix multiplication. However, if the number of components is large, then the cost of these multiplications is too high; we will reduce the number by solving the problem in a different way for components with a small number of vertices.

We will not optimize this step, since it takes less time than the bottleneck step of computing the components. For any component c with fewer than $n^{0.7}$ vertices, we step through all pairs of vertices w, x in c, and mark w, c in a matrix to indicate that these cannot form a dominating pair. On each vertex we spend at most $n^{1.7}$ time marking other vertices during this step (at most $n^{0.7}$ time for each $G - \mathrm{N}[v]$), so the time spent eliminating vertex pairs as candidates because they are in a common small component is $\mathrm{O}(n^{2.7})$. Vertices corresponding to components with fewer than $n^{0.7}$ vertices are then removed from G'.

Testing whether vertices are in a common large component is equivalent to testing for paths of length 2 in G', and can be solved using matrix multiplication of an n by $n^{1.3}$ matrix by an $n^{1.3}$ by n matrix, which takes $\mathrm{o}(n^{2.7})$ time.

Therefore, the bottleneck step for determining whether a graph has a dominating pair is the computation of neighborhood-deleted components of G, and this also takes $\mathrm{O}(n^{2.79})$ time. □

4. Two-pairs. A more sophisticated algorithm based on our fast algorithm for finding neighborhood-deleted components is an improved algorithm to list all two-pairs of a graph. The current best algorithm for finding either a single two-pair, or all two-pairs, in a graph is based on the following observation [1]: v, w is a two-pair of G iff $\mathrm{N}(w) \cap \mathrm{N}(v) = \mathrm{N}(C) \cap \mathrm{N}(v)$, where C is the connected component of $G - \mathrm{N}(v)$ containing w. This gave an $\mathrm{O}(nm)$ algorithm for finding all two-pairs of G.

Suppose that all neighborhood-deleted components of G are known. It is not hard to identify for all vertices v a subset of vertices S_v such that v, w form a two-pair implies $w \in S_v$. We call a vertex w a *candidate* for v if w has the maximum number of common neighbors with v from any vertex in the component of $G - \mathrm{N}[v]$ containing w. The number of common neighbors $|\mathrm{N}(v) \cap \mathrm{N}(w)|$ for each pair of vertices v, w can be determined from the square of the adjacency matrix of G. It is also not hard to see that if two vertices w, x in the same component are candidates, then v, w is a two-pair iff v, x is a two-pair. Assuming that we know the number of common neighbors of each pair of vertices (which takes $\mathrm{O}(n^\alpha)$ time), it takes $\mathrm{O}(n^2)$ time to find all candidates; simply step through each neighborhood-deleted component C of v and choose the vertex of C which has the most common neighbors with v. We may limit our further search to one candidate for each component of $G - \mathrm{N}[v]$. If the number of components is too large, the time complexity can become too large. Therefore, we must once again use balancing, finding the candidates in large components using one form of matrix multiplication, and using a different technique for small components.

THEOREM 4.1. *There is an* $\mathrm{O}(n^{2.79})$ *algorithm to list all two-pairs in* G.

Proof. Recall that each component C is associated with a vertex v, such that C is a connected component of $G - \mathrm{N}(v)$.

Let $f(n)$ be a function to be fixed later. For a candidate w in a small component

C of $G-\mathrm{N}[v]$, i.e., $|C| < f(n)$, test as follows whether v, w is a two-pair of G. Compute $|\mathrm{N}(w) \cap \mathrm{N}(w') \cap C|$ for all vertices $w' \in C$. This takes $\mathrm{O}(|C|^2)$ time for a component C. To test whether v, w is a two-pair of G, for each $w' \in C$ calculate the number of common neighbors of w and w' in $\mathrm{N}(v)$ (which is $|\mathrm{N}(w) \cap \mathrm{N}(w')| - |\mathrm{N}(w) \cap \mathrm{N}(w') \cap C|$). If there is a $w' \in C$ such that $|\mathrm{N}(v) \cap \mathrm{N}(w')| > |\mathrm{N}(w) \cap \mathrm{N}(w') \cap \mathrm{N}(v)|$, then v, w is not a two-pair of G, otherwise v, w is a two-pair of G.

To test candidates from large components C, i.e., $|C| \geq f(n)$, set up the following digraph D. At level 1 of D, make a copy of each vertex of G. At level 2, make a second copy of each vertex of G, with an edge from x at level 1 to y at level 2 in D iff x is adjacent to y in G. At level 3 of D, create a vertex for each component of size at least $f(n)$. Add an edge from a vertex at level 2 to a component at level 3 in D iff the vertex belongs to the component. Perform a single multiplication of an n by n matrix representing the edges between levels 1 and 2 of D by an n by $n^2/f(n)$ matrix representing the edges between levels 2 and 3 of D. (Note that there are at most $n/f(n)$ large components.) The resulting matrix tells you which vertices have a neighbor in component C for each component C; for a vertex u which is not in C, entry $[u, C]$ of the result matrix is nonzero iff u has an edge to a vertex in C. Create a matrix E by changing every nonzero value of the result matrix to 1.

Perform another matrix multiplication, multiplying the adjacency matrix of G with E. Entry v, C of this matrix tells you how many neighbors of v have an edge to component C, i.e., $|\mathrm{N}(v) \cap \mathrm{N}(C)|$.

Finally v, w is a two-pair in G for a candidate w belonging to a component C of $G - \mathrm{N}[v]$ iff $|\mathrm{N}(v) \cap \mathrm{N}(w)| = |\mathrm{N}(C) \cap \mathrm{N}(v)|$.

The total time for testing candidates from large components is $\mathrm{O}(n^{3.376}/f(n))$. The time for testing candidates from small components is the sum of the squares of the component sizes. Maximizing the sum of squares given a fixed sum of numbers is achieved by making the numbers as large as possible; thus the time spent on small components can be bounded by making each component size $f(n)$, taking time $f^2(n)$ on $n^2/f(n)$ components, for an overall bound of $\mathrm{O}(n^2 f(n))$. By choosing $f(n)$ from a particular range ($f(n) = n^{0.6}$ is one possible value), the time for finding all two-pairs given the components is smaller than the time to compute the neighborhood-deleted components of G. Hence all two-pairs of a graph can be listed in $\mathrm{O}(n^{2.79})$ time. □

5. Reductions. The problems solved in this paper all make use of fast matrix multiplication algorithms to beat bounds of $\mathrm{O}(nm)$. It is natural to ask whether these problems can be solved even faster (perhaps in linear time), or solved efficiently without using matrix multiplication. In this section, we give evidence that finding an $o(n^\alpha)$ time algorithm for solving any of the problems solved in this paper by using fast matrix multiplication, or solving them efficiently without using matrix multiplication in time $O(n^{3-\epsilon})$ for some $\epsilon > 0$, would require a major breakthrough. We do this by showing that certain simple, famous problems currently solved most efficiently by matrix multiplication can be reduced to our problems. This still leaves open the question as to whether the time complexity for any of these problems can be reduced to the time for performing a single matrix multiplication of n by n matrices.

Our first basic problem which can be solved using matrix multiplication is recognizing triangle-free graphs. It is easy to see that G has a triangle iff there is a pair of vertices x, y joined by both a path of length 2 and a path of length 1. Therefore, it is easy to determine whether a graph is triangle-free in $\mathrm{O}(n^2)$ time if we are given both the adjacency matrix and the square of the adjacency matrix. There is no known algorithm which solves the problem in $\mathrm{O}(n^{3-\epsilon})$ time for some $\epsilon > 0$ without using

matrix multiplication.

Our second basic problem which can be solved using matrix multiplication is determining whether there is a pair of vertices x, y such that $N(x) \subset N[y]$; we call this the problem of determining whether a graph has a dominated vertex. It is not hard to see that the dominated vertex problem can be solved using matrix multiplication; $N(x)$ is a subset of $N[y]$ iff the number of paths of length 1 or 2 from x to y is equal to the degree of x.

Our third basic problem is the problem of determining whether a graph has a simplicial vertex. This can be solved easily in $O(n^2)$ time if the cube of the adjacency matrix is given, since v is simplicial iff the number of paths of length 3 from v to v is equal to $|N(v)|(|N(v)| - 1)$.

Although no faster algorithm is known to solve the second and third problems, these are not as well studied as triangle-free recognition. For each of the problems Π solved in the previous sections of the paper, we will show that there is an $O(n^2)$ time reduction which takes a graph G as input and produces a graph G' with $O(n)$ vertices as output, where either G has a triangle iff G' has property Π, G has a dominated vertex iff G' has property Π, or G has a simplicial vertex iff G' has property Π. This will show that faster algorithms to solve problem Π may be hard to find, since they would imply faster algorithms for one of our fundamental problems.

THEOREM 5.1 (see [21]). *Testing whether a graph with $2n$ vertices has an asteroidal triple is at least as hard as testing whether a graph with n vertices has a triangle.*

Proof. We reduce the triangle finding problem to the asteroidal triple finding problem.

Let G be a graph with n vertices. Create a graph G' as follows. Create n vertices corresponding to vertices of G, where x and y are adjacent in G' iff x and y are nonadjacent in G. Add n new vertices, where each new vertex has degree $2n-2$, and new vertex i is nonadjacent only to the vertex of G' corresponding to the ith vertex of G; we will call this new vertex i'.

Suppose that G has a triangle x, y, z. Then x, y, z are pairwise nonadjacent in G', and the paths x, y', z; x, z', y; y, x', z show that G' has an asteroidal triple. Suppose that G' has an asteroidal triple. Since each new vertex (i.e., the vertices labeled v') of G' is nonadjacent only to one vertex of G', the independent vertices of this asteroidal triple in G' must correspond to a triangle in G. □

THEOREM 5.2. *Determining whether a graph with $3n+4$ vertices has a dominating pair (or whether a particular pair of vertices b, z is a dominating pair of a graph with $3n+4$ vertices) is at least as hard as determining whether a graph with n vertices has a triangle.*

Proof. Let G be a graph with n vertices. Create a graph G' with vertices x_1, x_2, x_3 for each x in G, and vertices b, c, y, z. Add edges from b to c, y to z, c to x_1 for all x, and x_3 to y for all x. For all $v, w \in V$, add edges (v_1, w_1), (v_2, w_2), and (v_3, w_3). Add edges between v_1 and w_2, v_2 and w_3 if v and w are adjacent in G and from v_1 and w_3 iff v and w are distinct and nonadjacent in G.

Suppose that G has an independent set v, w, x. Then the path b, c, v_1, x_3, y, z avoids all neighbors of w_2, so b, z is not a dominating pair. Suppose that b, z is not a dominating pair. Since any path from b to z which uses vertices of all 3 indices is a dominating path, there must be some path from b to z which uses an edge (v_1, x_3) such that there is a vertex w_2 being nonadjacent to v_1 and to x_3. Hence there is an independent set v, w, x in G.

Therefore, G has an independent set of size 3 iff b, z is not a dominating pair in G'. It is clear that if there is a dominating pair in G', then b, z is a dominating pair, so G' has a dominating pair iff G has no independent set of size 3. □

We note that it is easy to find a dominating pair in linear time in a graph which is known to have no asteroidal triples [7]. Since the above reductions show that neither AT-free recognition nor dominating pair recognition can be solved in linear time without a major breakthrough, it is an interesting open question as to whether there is a robust linear time algorithm for finding a dominating pair in an AT-free graph. Robust is used here in the sense of [20]; a robust linear time algorithm must take an arbitrary (i.e., not necessarily AT-free) graph, and should in linear time either find a dominating pair or answer that the graph is not AT-free. The difference from other algorithms is that if the input graph is not AT-free but has a dominating pair, such an algorithm is allowed to answer either that G has a dominating pair or that G is not AT-free.

THEOREM 5.3. *Identifying all extremities in a graph on $3n$ vertices is at least as hard as determining whether a graph with n vertices has a triangle.*

Proof. We reduce the triangle recognition problem to the question of identifying all extremities.

Let G be a graph with n vertices. Create 3 copies x_1, x_2, x_3 in G' for every x in G. Add edges from x_1 to y_2 and from x_2 to y_3 iff x is nonadjacent to y in G, or if $x = y$. Add edges from x_1 to y_3 iff x and y are adjacent in G. Add edges (x_1, y_1), (x_2, y_2), and (x_3, y_3) for all x, y.

We will show that x is in some triangle of G iff x_2 is an extremity of G'. Note that vertices of $G' - \mathrm{N}[x_2]$ correspond to u_1 and u_3 such that u is adjacent to x in G.

Suppose that x, y, z form a triangle in G. Since there is an edge from y_1 to z_3, and vertices with each index 1 and 3 form a clique, x_2 is an extremity of G'.

Suppose that x is not part of a triangle in G. Then there is no edge between vertices with index 1 and vertices with index 3 in $G' - \mathrm{N}[x_2]$; any such edge between neighbors of x would be a triangle in G. Therefore, x_2 is a nonextremity of G'. □

We note that the important special case of determining whether a graph has a nonextremity can be solved more efficiently than recognizing triangle-free graphs remains open.

THEOREM 5.4. *Testing whether a graph with $4n + 6$ vertices has a two-pair is at least as hard as testing whether a graph with n vertices has a dominated vertex.*

Proof. Let G be a graph with n vertices; we will assume that G has at least one edge, or finding a dominated vertex is trivial. Create a graph G' as follows. For each vertex x of G, create vertices x_1, x_2, x_3, x_4 in G'. G' will consist of two disconnected subgraphs, one containing each x_1 and x_2, the other containing x_3 and x_4. The two disconnected subgraphs of G' are constructed similarly, but differ in one detail.

Add an edge from x_1 to y_2 iff x and y are adjacent in G. Similarly, add an edge from x_3 to y_4 iff x and y are adjacent in G.

Add a vertex w_1 which is adjacent to every vertex x_1, and a vertex z_2 adjacent to every vertex y_2. Add a vertex v adjacent only to w_1 and z_2. Similarly, add a vertex w_3 which is adjacent to every vertex x_3, a z_4 which is adjacent to every vertex y_4, and a vertex u which is adjacent only to w_3 and x_4.

The constructions of the two subgraphs differ only in that we now add edges from x_3 to x_4 for every x in G; i.e., the two copies of a vertex are made adjacent in one subgraph, but not the other. Intuitively, one subgraph translates nonadjacent pairs $\mathrm{N}(x) \subset \mathrm{N}[y]$ into two-pairs, while the other translates adjacent pairs with the

property into two-pairs.

Suppose that G has a dominated vertex x, i.e., that $\mathrm{N}(x) \subset \mathrm{N}[y]$. If x and y are nonadjacent, then every neighbor of x_1 is a neighbor of y_1 in G', so x_1,y_1 form a two-pair in G'. If x and y are adjacent, then every neighbor of x_3 is adjacent to y_3, and x_3,y_3 forms a two-pair of G'.

Suppose that G' has a two-pair b', c'. Neither b' nor c' can be w_1; w_1 is adjacent to every vertex x_1, has a path w_1, v, z_2, y_2 to every vertex y_2, is adjacent to v, and has a path of length 3 to z_2 using any edge (x_1, y_2). Symmetrically, neither b' nor c' can be z_2, and similar arguments show that neither b' nor c' can be v, u, w_3, or z_4. It is also impossible to have $b' = x_1$, $c' = y_2$, since either x_1 is adjacent to y_2 or there is a chordless path x_1, w, v, z, y_2 between the vertices; the same reasoning shows that we cannot have $b' = x_3$, $c' = y_4$. Thus, we assume without loss of generality that the two-pair is of the form x_1, y_1 or x_3, x_4.

Suppose that $b' = x_1$ and $c' = y_1$. If there is a vertex i adjacent to x but not y and a vertex j adjacent to y but not x, then the path x_1, i_2, z_2, j_2, y_1 contradicts the assumption that x_1, y_2 is a two-pair. Similarly, two-pairs x_3, y_3 must correspond to dominated vertices, or we get a path from x_3 to y_3 using i_4, z_4, j_4.

Therefore, G' has a two-pair iff G has a dominated vertex. □

THEOREM 5.5. *Testing whether a graph on $8n + 2$ vertices has a star cutset is at least as hard as testing whether a graph G with n vertices has a dominated vertex.*

Proof. Let G be a connected graph with n vertices, such that all vertices have degree at least 2.

Our construction is similar to that of the previous theorem, in that we create two subgraphs, one to deal with adjacent pairs such that $\mathrm{N}(x) \subset \mathrm{N}[y]$, and the other when x and y are nonadjacent. In this construction, the two subgraphs are connected by a complete join between the vertex sets, rather than being disconnected. We give the construction for the first subgraph before discussing the modification for the second subgraph.

The first subgraph is created as follows. Create four vertices x_1, x_2, x_3, x_4 of G' for each vertex x of G. Add an edge from x_1 to y_2 in G' iff x and y are adjacent in G. Add an edge from x_2 to x_3 and from x_3 to x_4 for each x in G. Add edges (x_4, y_4) for every x, y. Add a single vertex w, with edges from w to x_1 for all x.

The second subgraph is created in the same fashion as the first, except that x_1 is adjacent to x_2 in the second subgraph. The entire graph G' is formed by adding all edges between the first and second subgraphs.

Suppose that $\mathrm{N}(x) \subset \mathrm{N}[y]$ in G. If x and y are nonadjacent, then G' contains the star cutset $\{y_1\} \cup \mathrm{N}(x_1)$. If x and y are adjacent, then G' contains the star cutset consisting of the copies of $\{y_1\} \cup \mathrm{N}(x_1)$ from the second subgraph. This is because if we exclude x_2 and y_2, x_1's neighborhood is contained in y_1's neighborhood in both subgraphs. If x and y are nonadjacent, then x_1 is not adjacent to either x_2 or y_2 in the first subgraph, so we get neighborhood containment, while if x is adjacent to y, then the copy of y_1 in the second subgraph is adjacent to both x_2 and y_2, and thus its neighborhood contains that of the corresponding x_1.

Suppose that G' has a star cutset. Then by Chvátal's theorem [3] G' has either a vertex which is dominated by a neighbor, or a nonextremity. It is not hard to see that no vertex can dominate a neighbor in G', so G' must contain a vertex v such that $G - \mathrm{N}[v]$ is disconnected. One cannot disconnect G' by removing neighbors of a vertex with index 3 or 4; all remaining vertices clearly have a path to w. One cannot disconnect G' by removing w, since all remaining vertices can reach a vertex

with index 4, and these vertices form a clique. G' cannot become disconnected by removing any vertex x_2; all remaining vertices with index 2 remain connected since they have paths to level 4, and all remaining vertices with index 1 remain connected through w. Since x_1 remains in $G' - \mathrm{N}[x_2]$ and has an edge to some y_2, $G' - \mathrm{N}[x_2]$ is connected.

Therefore, we can assume that G' can be disconnected by removing all neighbors of some vertex x_1. If there is no vertex y such that $\mathrm{N}[x] \subseteq \mathrm{N}(y)$, then every vertex of $G' - \mathrm{N}[x_1]$ has a path to a vertex with index 4 (any v_2 is adjacent to v_3 and v_3 to v_4, and any y_1 has an edge to some z_2 which is nonadjacent to x_1, and we can reach z_4 from z_2); since vertices with index 4 form a clique, $G' - \mathrm{N}[x_1]$ is connected. Therefore, if G' has a star cutset, G has a dominated vertex. □

In the conference version of this paper, we presented an algorithm using periodic matrix multiplication to determine whether a graph has a clique cutset. Since that time, we devised a new algorithm to find a minimal fill and a clique cutset in a graph. These algorithms became sufficiently different from the techniques used here (they were based on an implementation of Tarjan's LEX-M algorithm, and were unrelated to neighborhood-deleted components) so that the algorithms were put in a separate paper [17]. However, the evidence that the problem requires the use of matrix multiplication seems to be much more closely related to this paper than the algorithmic work in the other paper; we feel that it is more consistent to talk about difficulty of the clique cutset problem here.

THEOREM 5.6. *Determining whether a graph on $4n + 2$ vertices has a clique cutset is at least as hard as determining whether an n vertex graph has a simplicial vertex.*

Proof. Let $G = (V, E)$ be a connected n vertex graph. Create a graph $G' = (V', E')$ as follows. For every x in G, create vertices x_1, x_2, x_3, x_4 in G'. Add edges from x_1 to x_2 and from x_3 to x_4 for every x in G. Add edges (x_1, y_3) and (x_2, y_3) to G' iff x is adjacent to y in G. Add adjacent vertices b and z, and edges (b, x_1) and (x_4, z) for all x. Add edges (x_3, y_3) iff x and y are adjacent in G. Note that $\mathrm{N}_{G'}[x_1] = \mathrm{N}_{G'}[x_2] \cup \{b\}$ for each x in G.

Suppose that G has a simplicial vertex v. Then $K' = \{v_1\} \cup \{w_3 : (v, w) \in E\}$ is a clique, and a cutset since $\{v_2\}$ is a component of $G' - K'$.

Suppose that G' has a clique cutset. It is clear that no clique cutset contains one or more of the vertices b,z, or any x_4; the only cliques involving these vertices correspond to edges, and it is easy to see that removing any adjacent vertex pair cannot disconnect G'. Any $K' \subseteq \{x_2, x_3 : x \in V\}$ is not a cutset, since each remaining vertex w_2 would have an edge to w_1 and thus a path to b, while each remaining vertex w_3 has an edge to w_4 and thus to z. Therefore, any clique cutset contains a vertex v_1. The only vertex which could not have a path to b if neighbors of v_1 are removed is v_2, and this will have a path to b unless all w_3 adjacent to v_1 are removed. Therefore, the only possible clique cutset in G' corresponds to a simplicial vertex v and its neighbors in G. Thus G has a simplicial vertex. □

It would be nice if we could show that all these problems were at least as hard as a single problem, of which the most natural would seem to be determining whether a graph has a triangle, which would be used as general evidence of difficulty. Although we were not able to show that determining whether a graph has a simplicial vertex is as hard as recognizing triangle-free graphs, the following theorem is an attempt to show a relationship between triangle-free recognition and finding simplicial vertices.

THEOREM 5.7. *The problem of counting the number of simplicial vertices in a*

graph with $3n + 2$ vertices is at least as hard as determining whether a graph on n vertices has a triangle.

Proof. Let G be a graph on n vertices, none of which is isolated. Create three vertices x_1, x_2, x_3 for each vertex x in G. Add edges (w_1, x_2) and (w_2, x_3) iff w is adjacent to x in G, and add an edge (w_1, x_3) iff w is nonadjacent to x in G, or $w = x$. Add edges (w_1, x_1) and (w_3, x_3) for all vertices w, x of G. Add adjacent vertices b and z, where b is adjacent to all vertices x_1 of G' and z is adjacent to all vertices x_3.

Suppose that v is contained in a triangle v, w, x of G. Then v_2 is not simplicial in G', since w_1 is nonadjacent to x_3.

Suppose that v is not contained in a triangle of G. Then v_2 is simplicial in G', since all neighbors w_1 of v_2 are adjacent to all neighbors x_3 of v_2, and vertices of the same index form a clique.

No vertex x_1 is simplicial in G', since b and v_2 are nonadjacent for any neighbor v_2 of x_1. Similarly, no x_3 is simplicial in G', and clearly b and z are nonsimplicial.

Therefore, the number of simplicial vertices in G' is equal to the number of vertices which are not contained in a triangle of G', and G is triangle-free iff G' has n simplicial vertices. □

The final reduction is related to comments received about clique cutset decomposition. Some researchers seem to feel that clique cutsets are so closely tied to minimal elimination orderings that fast algorithms to compute a minimal elimination ordering would give fast algorithms for finding a clique cutset. The following reduction shows that beyond a certain speed, faster minimal elimination orderings are not the only issue in finding a clique cutset.

THEOREM 5.8. *Finding a clique cutset in a graph with $2n+2$ vertices is at least as hard as finding a simplicial vertex in an n vertex graph, even if a minimal elimination ordering is given as part of the input.*

Proof. Let G be an arbitrary graph. Let G' be a graph with two copies x_1, x_2 of each x in G, plus two nonadjacent vertices y, z such that y and z are adjacent to every vertex x_2. Let X_1 be the set of vertices of G' with index 1, and let X_2 be the vertices with index 2. v_1 is adjacent to w_2 iff v is adjacent to w in G, and v_2 is adjacent to w_2 iff v is adjacent to w in G. A minimal elimination ordering of G' can be formed by adding edges between every pair of vertices from X_2 (all fill edges (v, w) are unique chords of 4-cycles v, y, w, z in G'), and y, z, X_1, X_2 is a minimal elimination ordering of G'.

The only possible clique cutset of G' is the set of all neighbors of x_1 such that x is simplicial in G. We know a minimal elimination ordering of G', but any algorithm for finding a clique cutset in G' given this minimal elimination ordering would give a fast algorithm for finding a simplicial vertex in G. □

6. Comments on reductions. We begin this section by summarizing the results of the previous section.

Problems as hard as triangle-free graph recognition:

(1) Recognizing AT-free graphs.
(2) Determining whether a graph has a dominating pair.
(3) Determining whether a specific vertex pair u, v is a dominating pair.
(4) Identifying all extremities in a graph.
(5) Counting the number of simplicial vertices.

Problems as hard as testing for a dominated vertex:

(1) Determining whether a graph has a two-pair.
(2) Determining whether a graph has a star cutset.

Problems as hard as testing for a simplicial vertex:

(1) Determining whether a graph has a clique cutset.

Ideally, we would have a single problem P, and show that all these problems are as hard as problem P. Since triangle-free graph recognition seems more fundamental than the other problems, we might try to show that all the problems above are as hard as triangle-free graph recognition. We now explain why we believe it would be very difficult to show that all these problems were as difficult as determining whether a graph has a triangle. Fundamentally, this deals with incomparability of proof sizes with respect to the question of whether a graph does/does not satisfy a particular property.

Let us consider certificates which prove whether a graph does/does not have each of the properties in question. The measurements size of the certificate and time to verify that a property holds are often used interchangeably in the literature; we will phrase the issues in terms of size of the certificate.

There is a certificate of constant size which shows that a graph has a triangle. No deterministic certificate of size $o(n^{2.376})$ is known for showing that a graph has no triangle. We note that although there is a randomized $O(n^2)$ certificate showing that a graph has no triangle (one provides the square of the adjacency matrix, and multiply by random n-vectors to verify that the results are the same for your proposed A^2 times the vector and A times (A times the vector)) [9], this involves producing the square of the matrix as part of your certificate.

For each problem P, Certsize(P) will be a pair, consisting of the best times known for a deterministic certificate for yes instances of P and a deterministic certificate for no instances of P. Thus, Certsize(triangle-free) = ($O(1)$,$O(n^{2.376})$). We will order the pair so that the smaller of these two values comes first in the ordered pair.

Let us consider Certsize(P) for other problems P which were considered in this paper. For simplicity, we limit ourselves to the decision problems, as opposed to counting and enumeration problems.

There is a certificate of size $O(n)$ that a graph has an asteroidal triple (the paths between each pair of vertices in the triple), but no $o(n^{2.376})$ certificate is known for showing that a graph has no asteroidal triple. Thus Certsize(AT-free) = ($O(n)$,$\Omega(n^{3.376})$).

There is a certificate of size $O(n)$ showing that x, y is not a dominating pair; it is only necessary to check that a path from x to y has no neighbors of z. There is no known certificate of size $o(n^{2.376})$ proving that x, y is a dominating pair. For showing that G has no dominating pair, we do not know of any certificate of either yes or no of size $o(n^{2.376})$. Thus, Certsize(xy-dominating pair) = ($O(n)$,$\Omega(n^{2.376})$), while Certsize(Exists dominating pair) = ($\Omega(n^{2.376})$,$\Omega(n^{2.376})$).

For all these problems P, Certsize(triangle-free) $\leq$ Certsize(P), in the sense that both the first and second values of the ordered pair Certsize(triangle-free) were less than or equal to the corresponding values for Certsize(P). In all of these cases, we were able to find a reduction showing that these problems were as hard as recognizing triangle-free graphs.

We now consider some of the problems which we chose to reduce from existence of a dominated vertex or existence of a simplicial vertex rather than triangle-free recognition. First, let us examine the "basic" problems themselves with respect to certificate size.

There is a certificate of size $O(n)$ showing that G has a dominated vertex; given x and y, it takes only $O(n)$ time to verify that $N(x) \subset N[y]$. There is also an $O(n^2)$

certificate showing that a graph has no dominated vertex; for each x, y, give a neighbor of x but not y and a neighbor of y but not x. Thus, Certsize(dominated vertex) = (O(n),O(n^2)).

There is a certificate of size O(n^2) that G contains a simplicial vertex (the simplicial vertex plus the list of all edges between its neighbors) and a certificate of size O(n^2) that G has no simplicial vertex (a pair of nonadjacent neighbors of each vertex). Thus, Certsize(simplicial vertex) = (O(n^2),O(n^2)).

The star cutset problem also has certificates of both yes and no of size O(n^2). One certificate is obvious; to verify that G has a star cutset, we verify that a set is a star and that the vertices not in the cutset induce a disconnected graph. Verifying that the graph has no star cutset uses Chvátal's theorem on star cutsets being either nonextremities or neighbors such that one neighborhood dominates the other; we give vertices in $\mathrm{N}[x] - \mathrm{N}[y]$ and $\mathrm{N}[y] - \mathrm{N}[x]$ for each pair of adjacent vertices x, y, and we show that each vertex is an extremity by providing a spanning tree for $G - \mathrm{N}[v]$ for each v. Thus, Certsize(star cutset) = (O(n^2),O(n^2)).

Showing that x, y form a two-pair can be done in O(n^2) time, by showing that there is no path from x to y in $G - (\mathrm{N}(x) \cap \mathrm{N}(y))$. An O($n^2$) certificate that a graph has no two-pair can also be given, though since it is more involved we will simply outline it here. For each v, one can provide an O(n) certificate that v is not part of a two-pair. A spanning tree is given for each connected component of $G - \mathrm{N}(v)$. For each nonneighbor w of v, give an edge from some x in the same component as w to a nonneighbor of w which is adjacent to both x and v. It is not difficult to argue that such an x exists iff v, w is not a two-pair. Therefore, Certsize(two-pair) = (O(n^2),O(n^2)).

Similarly, Certsize(clique cutset) = (O(n^2),O(n^2)), though this is not obvious unless you are familiar with an algorithm such as that of [24] for constructing a clique cutset.

In all these cases, Certsize(triangle-free) is incomparable with Certsize(P), in the sense that the first value in the pair was smaller for Certsize(triangle-free), while the second value was smaller for Certsize(P).

These observations about certificate sizes made us realize that it would be very difficult to find an O(n^2) reduction from triangle-free graph recognition to the problems of finding a clique cutset, star cutset, or a two-pair in a graph. Suppose that such a reduction existed for one of these problems; for example, assume that there was an O(n^2) reduction which took an n vertex graph G and produced an O(n) vertex graph G' such that G contains a triangle iff G' contains a two-pair. Any such reduction would give us an O(n^2) proof that a graph contains no triangle, since this would be equivalent to proving that G' has no two-pair, and we gave a simple proof of this fact above. Therefore, finding a reduction from recognizing two-pair free graphs would involve a major breakthrough, and the same would be true if two-pair was replaced by clique cutset or star cutset.

Therefore, for each of our problems solved, we either showed the problem was as hard as triangle-free recognition or are able to show using certificate sizes that such a reduction is likely to be difficult to find.

We were left with the problem of showing difficulty of the problems star cutset and existence of a two-pair. We introduce as a new concept the problems of being as hard as finding a simplicial vertex or as hard as finding a dominated vertex. There seems to be no particular reason to prefer one over the other as a basic problem for evidence of difficulty. We also would like to raise the general issue of which problems

that have $O(n^2)$ yes and no certificates, but can be solved using matrix multiplication, are appropriate to use as evidence of difficulty of beating matrix multiplication.

Finally, we would like to note that we also believe it will be difficult to find reductions in either direction between triangle-free recognition and dominated vertex/simplicial vertex existence. We explain above why we believe that reducing triangle-free recognition to the other problems is hard. However, reductions in the other direction may also prove to be difficult, since there is a constant size certificate that a graph contains a triangle. Suppose we had a reduction from G to G' such that G contains a two-pair iff G' is triangle-free. It would be possible to show that G has no two-pair by showing a triangle in G', although it is impossible to prove that G has no two-pair in constant time. Thus, any such reduction cannot be "local"; by this, we mean that there must be vertex pairs x, y of G' such that adjacency between x and y in G' cannot be determined from G in constant time. Such transformations cannot be ruled out but would necessarily be more complex than those that generally come to mind when the term reduction is used, and reductions in this direction will not be as simple as the reduction used in this paper.

It might be possible, however, to find reductions in one or both directions between finding a dominated vertex and finding a simplicial vertex. It might also be possible to find reductions from one of these problems to such problems as finding an asteroidal triple for which we chose a reduction from triangle-free recognition. In our opinion, it is perhaps too soon to consider such reductions; while it seems to be generally agreed upon that recognizing triangle-free graphs in less time than matrix multiplication is hard, we would like to find a community consensus on fundamental hard problems with short certificates before producing too many reductions which might not convince other researchers of the hardness of a problem.

Acknowledgment. We would like to thank one of the referees for a particularly careful reading of the manuscript, leading to a number of improvements in the paper.

CERTIFYING ALGORITHMS FOR RECOGNIZING INTERVAL GRAPHS AND PERMUTATION GRAPHS*

DIETER KRATSCH†, ROSS M. MCCONNELL‡, KURT MEHLHORN§, AND JEREMY P. SPINRAD¶

Abstract. A *certifying algorithm* for a problem is an algorithm that provides a certificate with each answer that it produces. The certificate is a piece of evidence that proves that the answer has not been compromised by a bug in the implementation. We give linear-time certifying algorithms for recognition of interval graphs and permutation graphs, and for a few other related problems. Previous algorithms fail to provide supporting evidence when they claim that the input graph is not a member of the class. We show that our certificates of nonmembership can be authenticated in $O(|V|)$ time.

Key words. certificates, certifying algorithms, interval graphs, permutation graphs

DOI. 10.1137/S0097539703437855

1. Introduction.

A recognition algorithm is an algorithm that decides whether some given input (graph, geometrical object, picture, etc.) has a certain property. Such an algorithm *accepts* the input if it has the property or *rejects* it if it does not. A *certifying algorithm* for a decision problem is an algorithm that provides a certificate with each answer that it produces. The certificate is a piece of evidence that proves that the answer has not been compromised by a bug in the implementation.

We give linear-time certifying algorithms for recognition of interval graphs and permutation graphs. Previous algorithms fail to provide supporting evidence of nonmembership. We show that our certificates of nonmembership can be authenticated in $O(n)$ time, where n is the number of vertices.

A familiar example of a certifying recognition algorithm is a recognition algorithm for bipartite graphs that computes a 2-coloring for bipartite input graphs and an odd cycle for nonbipartite input graphs. A more complex example is the linear-time planarity test which is part of the library of efficient data structures and algorithms (LEDA) system [19, section 8.7]. It computes a planar embedding for planar input graphs and a *Kuratowski subgraph* (a subdivision of K_5 or $K_{3,3}$) for nonplanar input graphs.

Certifying versions of recognition algorithms are highly desirable in practice; see [28, 20, 21] and [19, section 2.14] for general discussions on result checking. Consider a planarity testing algorithm that produces a planar embedding if the graph is planar, and simply declares it nonplanar otherwise. Though the algorithm may have been proven correct, the implementation may contain bugs. When the algorithm

declares a graph nonplanar, there is no way to check whether it did so because of a bug.

Given the reluctance of practitioners to assume on faith that a program is bug-free, it is surprising that the theory community has often ignored the question of requiring an algorithm to certify its output, even in cases when the existence of adequate certificates is well known.

An *authentication algorithm* is an algorithm that check the validity of the certificate. In contrast to the case of an algorithm that solves the problem from scratch, an authentication algorithm may reject the certificate if it is invalid, leaving open the answer to the original problem. However, it must be the case that the authentication algorithm provides a correct answer to the original problem if the certificate is valid, and never declares an incorrect answer to the problem due to an invalid certificate. The certificate has practical value when the algorithm for solving the problem from scratch is difficult but the authentication algorithm is trivial.

For instance, in the case of planarity testing, the authentication algorithm cycles through the edges of the Kuratowski subgraph, verifying that they are, in fact, present in the graph and form a Kuratowski subgraph as claimed. Though planarity testing in linear time is a complicated problem, checking a Kuratowski subgraph is a trivial task, especially if the edges are supplied in a convenient order by the certificate.

The notion of a certifying algorithm is related to the concept of run-time checking. Typically, run-time checking has been applied to very small fragments of code; for example, a program to calculate square roots might check at run-time that the square of the result equals the input value. An attempt to create a corresponding model of run-time checking for more complex algorithms is given in [28] with motivations which are very similar to our own. The authors conceive of a method for checking whether a (possibly complex) program that computes a function has produced a correct output. Their model does not require an algorithm to provide supporting evidence with its answer, but subsequent calls to it are allowed in order to present it with nondeterministically generated challenges after it has already returned a solution. If it has answered incorrectly, it can pass with only a certain probability of success. Confidence in the answer to within any desired probability can be attained through a sufficiently large set of challenges.

An important distinction between run-time checking and certifying algorithms is that run-time checking is generally conceived as being separate from the process of producing the output, while certifying algorithms produce proofs of correctness together with their output.

To clarify the difference between these two approaches, let us consider two valid, but opposing, views on proofs of output correctness. One can take the view that it is desirable to have a mechanism that uses as little information as possible in verifying the correctness of the output, preferably only the standard format of the solution. This approach has the advantage of enabling a user to check, using a single program, the correctness of the output of any program that has been designed to solve the problem.

Papers such as [1] have devised clever mechanisms of this form for verifying that the output of any program that solves a diverse set of problems, including such problems as graph isomorphism and equivalence search, is correct. If such a mechanism exists, one can take the position that there is no reason for the creator of the program to work on a technique for verifying that the output is correct, since any errors will be caught in a separate checking phase.

We instead want to shift the burden of creating proof of correctness to the software

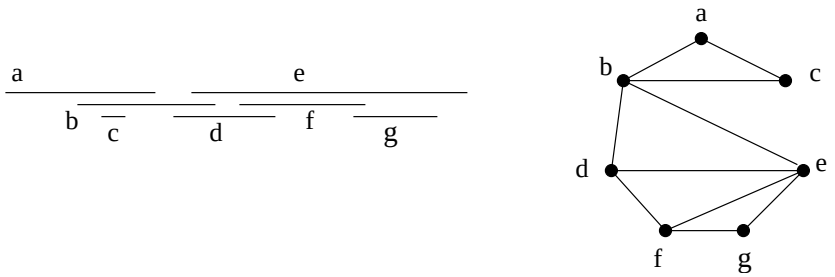

FIG. 1. *An interval graph is the intersection graph of a set of intervals on a line. The graph has one vertex for each of the intervals, and two vertices are adjacent if the corresponding intervals intersect.*

engineering phase as part of the design of the algorithm for solving the problem upon which to base the program. In finding the solution to the problem, the algorithm often goes through steps that can be used to create a simple certificate of correctness of the output. We believe that it should be part of the routine process of algorithm design to look for this certificate, and provide one wherever possible, rather than leaving this to a separate checking phase.

An interval graph is the intersection graph of intervals on a line (see Figure 1). That is, each vertex corresponds to an associated interval, and two vertices are adjacent iff the corresponding intervals intersect. The intervals constitute an *interval model* of the graph. Interval graphs have applications in molecular biology and scheduling.

Several linear-time recognition algorithms for interval graphs are known [2, 4, 9, 11, 12, 13, 18]. These graphs come up in the context of a variety of problems in scheduling and molecular biology; see [8, 24] for surveys. When a graph is an interval graph, these algorithms produce a certificate in the form of an interval model. When a graph is not an interval graph, none of these algorithms provides a certificate. However, the existence of certificates of rejection in the form of a forbidden substructure characterization is also well known. We extend the linear-time algorithm of Korte and Möhring [13] so that it also produces a certificate when a graph is not an interval graph; see section 5.

A permutation graph is the graph of inversions in a permutation. That is, each vertex corresponds to an element of the ground set of a permutation, and two vertices are adjacent iff the permutation reverses the relative order of the two corresponding elements (see Figure 2). If a graph is a permutation graph, we may show this by giving a *permutation model*, which consists of two linear orderings $(v_1, v_2, \ldots, v_n)$ and $(v_{\pi(1)}, v_{\pi(2)}, \ldots, v_{\pi(n)})$ of the vertices, such that two vertices v_i and v_j are adjacent iff v_i is before v_j in exactly one of the orderings.

The only previous linear-time algorithm for recognizing permutation graphs is given in [18]. This algorithm produces a permutation model if the graph is a member of the class, and presents its failure to produce such a model as the only evidence that a graph is not a member of the class. We give a linear-time algorithm that produces a certificate also in the case of nonmembership; see section 6. The algorithm is based on the following connection to comparability graphs. A graph G is a permutation graph iff G and its complement $\overline{G}$ are comparability graphs.

A dag is *transitive* if, whenever (a, b) and (b, c) are directed edges of the dag, (a, c) is also a directed edge. A transitive dag is a graphical representation of a

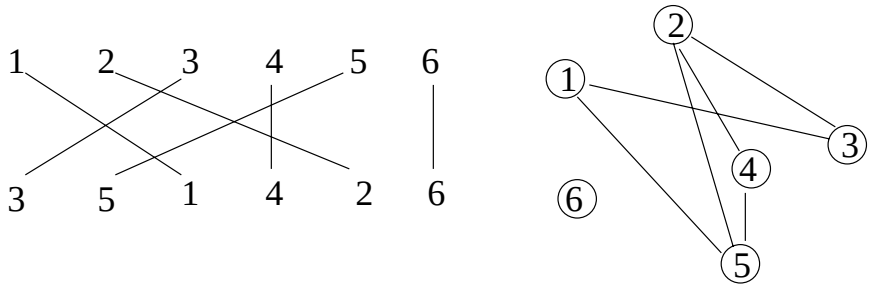

FIG. 2. *When a permutation acts on a sequence of elements, the corresponding permutation graph has one vertex for each of the elements. Two vertices are adjacent if the permutation swaps the relative order of the two elements.*

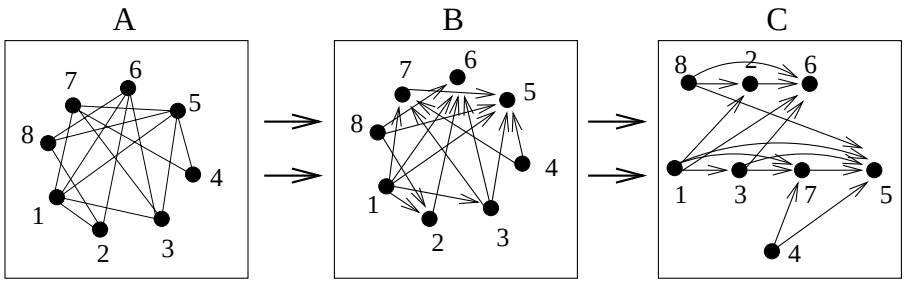

FIG. 3. *A comparability graph is a graph whose edges can be oriented so that the resulting digraph is acyclic and transitive. Part A depicts a comparability graph, part B is a transitive orientation, and part C is a redrawing of part B that makes it easy to see that the result is transitive.*

partial order (poset) relation. A graph is a *comparability graph* if orientations can be assigned to its edges so that the resulting digraph is a transitive dag (see Figure 3). Such an orientation is called a *transitive orientation*. A transitive orientation of a comparability graph can be found in linear time [18].

Gallai gave a forbidden substructure characterization of comparability graphs [7]. Since a graph G is a permutation graph iff G and $\overline{G}$ are comparability graphs, this forbidden structure in G or in $\overline{G}$ serves as a certificate that a graph is not a comparability graph. We do not know how to obtain this certificate in linear time for noncomparability graphs; no linear-time recognition algorithm is known. However, we show that when G is not a permutation graph, we may produce this certificate for G or for $\overline{G}$ in linear time. The algorithm fails to give a linear-time certifying algorithm for comparability graphs only because we cannot control whether the algorithm will find the certificate in G or in $\overline{G}$ when both G and $\overline{G}$ fail to be comparability graphs.

Certifying algorithms also exist for optimization problems; linear programming duality is a prime example. Primal and dual optimal solutions of a linear program certify each other. A *proper coloring* of a graph is a coloring of the vertices such that no adjacent vertices have the same color, and it is *minimum* if there is no proper coloring that uses fewer colors. A linear-time algorithm is known for finding a maximum clique and a minimum proper coloring of a comparability graph [18]. In a comparability graph, the size of the maximum clique is always the same as the minimum number of colors in a proper coloring. Since the vertices of a clique must all be colored differently in any proper coloring, the clique is a certificate of minimality of the coloring, and the coloring is a certificate that the clique is of maximum size. We give an algorithm that

provides a certificate that the input graph is not a comparability graph whenever this algorithm fails to find the desired coloring and clique.

2. Preliminaries. We consider only finite, undirected, and simple graphs. Let $G = (V, E)$ be a graph. We let n denote the number of vertices and m denote the number of edges.

For $W \subseteq V$ we denote by $G[W]$ the subgraph of G induced by W and we write $G - W$ instead of $G[V - W]$. The neighborhood of v is $N(v) = \{u \in V | uv \in E\}$ and $N[v] = N(v) \cup \{v\}$. If G is a directed graph, $N^-(v) = \{u \in V | (u, v) \in E\}$ and $N^+(v) = \{u \in V | (v, u) \in E\}$.

If $P = (v_1, v_2, \ldots, v_k)$ is a path, $u \in N(v_1)$, and $w \in N(v_k)$, then uP denotes the path $(u, v_1, v_2, \ldots, v_k)$, and Pw denotes the path $(v_1, v_2, \ldots, v_k, w)$. A P_4 is an induced subgraph on four vertices that is a path.

For an arc $e = (a, b)$, let its *transpose* e^T denote (b, a).

2.1. Representation of graphs. Analysis of the running time of an algorithm requires an agreement between the user and the designer of an algorithm about an appropriate format for the input data. No graph algorithm can claim an $O(n + m)$ running time if the input is provided in the form of an adjacency matrix, so a consensus has arisen that it is reasonable to require that the input be an adjacency list representation of the graph. If the user must spend $\Theta(n^2)$ time converting an adjacency matrix representation to this form before giving it as an input to the graph algorithm, this cost is not attributed to the running time of the graph algorithm.

Let us view a graph as an abstract data type that supports the following queries, possibly in addition to other queries:

- `Neighbors(`x`):` Given a vertex x, find its neighbors.
- `Adjacency(`x, y`):` Given two vertices, x and y, determine whether they are adjacent.

Algorithm texts usually contain a discussion of the trade-offs in space and time bounds for these two operations that arise in choosing an adjacency matrix representation or an adjacency list representation of a graph. The list of neighbors of a vertex in an adjacency list representation is typically unordered. This gives an extremely poor time bound for the `Adjacency` operation ($\Theta(n)$ in the worst case as opposed to $O(1)$ for the adjacency matrix).

This can easily be remedied by assuming that the adjacency lists are represented by a standard representation of an ordered set, such as a sorted array or a balanced binary search tree. This improves the time for the `Adjacency` query from $\Theta(n)$ in the worst case to $O(\log n)$, without increasing the space requirements or the time bound for the `Neighbors` operation. Moreover, it is possible to convert the unsorted variant to the sorted variant in $O(n + m)$ time by labeling the vertices with identifiers from 1 to n and then radix sorting the set of all edges according to the identifiers of their endpoints.

The only disadvantages to adopting this *ordered adjacency list representation* as a standard representation for sparse graphs seem to be cases where the data type must also support dynamic graph operations such as insertion of edges or contraction of vertices. Maintaining the sorted variant of the data structure can add an $O(\log n)$ factor to the cost of such operations. However, most graph algorithms deal with static graphs, and in the cases where the costs of these dynamic operations are an issue, an algorithm can ignore the ordering in the input data and neglect to maintain the invariant that it remain ordered as it executes.

Why has this ordered adjacency list representation not been adopted as a standard representation over the seemingly less desirable unordered one? This is probably because any algorithm that makes repeated use of the `Adjacency` query can produce the ordered representation from the unordered one in linear time before beginning work on the problem. Since a graph algorithm is assumed to run in $\Omega(n+m)$ time, the issue has been deemed inconsequential to the analysis of running times.

The possibility of graph algorithms that run in sublinear time, however, requires a reexamination of this issue. In contrast to algorithms that solve a problem on a graph from scratch, it is often the case that authentication algorithms can run in sublinear time.

An example of this occurs in connection with the class of *cographs*, which are the class of graphs that have no induced subgraph that is a P_4. That is, they have no induced subgraph that consists of exactly three edges forming a path (v_1, v_2, v_3, v_4) on four vertices. It takes $O(n+m)$ time to determine whether a given graph G is a cograph without the aid of a certificate [5]. However, given a legitimate P_4 that has been pointed out by a distrusted source, it takes $O(n)$ time to verify it on an unordered adjacency list representation, and $O(\log n)$ time on the ordered representation, since the `Adjacency` query takes $O(\log n)$ time. We therefore have a case where the choice of an unordered adjacency list representation versus an ordered one makes a difference in the analysis of the time bound of an algorithm.

We think that an ordered adjacency list representation would be a reasonable alternative to the unsorted one as a general-purpose representation of sparse graphs. In any case, there are compelling reasons to use the ordered representation when analyzing sublinear algorithms, and we will assume this representation throughout the paper. To be specific, since we deal only with problems involving static graphs, let us assume that each adjacency list is implemented as a sorted array of neighbors.

Before leaving this topic, we should mention that although the `Adjacency` operation takes $O(\log n)$ time, we can improve this to $O(1)$ by supplying what amounts to a certificate of the answer to the `Adjacency` query. If the answer to `Adjacency`(x, y) is `true`, the certificate consists of the location of the edge in the data structure, and if the answer is `false`, the certificate consists of the location where it would appear if it occurred. In either case, the user can check the result in $O(1)$ time. The certificate of a `false` answer cannot be made to work in this way on an unordered adjacency list representation.

Given this, it is easy to see that verifying the presence of a P_4 in a graph can be improved to $O(1)$ by building a certificate out of a collection of "subcertificates" for individual `Adjacency` queries on all pairs of elements of $\{v_1, v_2, v_3, v_4\}$. The same technique is useful for checking any induced subgraph that has been pointed out as a certificate of an answer to a graph problem.

3. What constitutes a certificate. Since software that generates a certificate could have a bug, a proposed certificate must be authenticated by verifying that it does, in fact, prove the result. For instance, if an odd cycle in a graph is presented as a certificate that the graph is not bipartite, authentication consists of verifying that it is a cycle, it has odd length, and that the claimed edges occur in the graph. The cycle can be given as a sequence of pointers to its edges in the input data structure, and takes $O(n)$ time for the user to authenticate, which is better than the $O(n+m)$ bound for checking whether a graph is bipartite.

A good certificate has an authentication algorithm that is conceptually simpler than algorithms for the original problem, or has a better time bound, or has both. If

the authentication step is simple and efficient enough, it may be possible to perform the check by visual inspection.

When the certificate is checked automatically, determining reliability of the implementation of the authentication algorithm is an obvious goal. Otherwise, consider the following scenario. The implementations of the certifying algorithm and of the authentication algorithm are both faulty. The certifying algorithm produces both an erroneous answer to the decision problem and an erroneous certificate, while the faulty authentication algorithm then claims that the certificate proves the given answer. The user is led to believe an erroneous conclusion.

A certificate is *sublinear* if its authentication algorithm has a tighter time bound than a linear one. For instance, for a problem where arbitrary graphs can be given as input, a certificate with an $O(n)$ authentication algorithm is sublinear, since this bound is never worse than linear and is often better. A certificate is *strong* (with respect to current algorithmic knowledge) if its authentication algorithm has a better time bound than that of the current fastest algorithm that solves the problem without a certificate. It is *weak* if it takes the same time to authenticate as it does to solve the original problem without the certificate, but may have other advantages such as greatly simplifying the task conceptually.

One of the anonymous referees has inquired about the possibility of certifying algorithms or authentication algorithms that require asymptotically more time or space than a noncertifying algorithm. Given the importance of software reliability in some industrial settings, the advantages of using these algorithms might outweigh the extra costs. We have not yet found interesting examples to support this, however.

Some of these notions are related to concepts that come up in the theory of NP-completeness. The class NP of decision problems are those for which, whenever the answer is *true*, this answer can be confirmed in polynomial time if one is supplied an appropriate certificate. The question of whether this is always possible without a certificate is the famous question of whether P = NP. The notion of a certificate and the time bound that it makes possible provides a precise mathematical definition of the class NP.

A certifying algorithm that returns a strong or sublinear certificate can be distinguished on objective mathematical grounds from a noncertifying algorithm. To be able to claim that certifying algorithms are a formal class of algorithms, we could require all certifying algorithms to produce sublinear certificates. Unfortunately, this restriction excludes many algorithms that produce certificates that are clearly useful in practice.

In addition, though sublinear certificates appear to be common, if the rejection certificate is sublinear, the acceptance certificate often fails to be sublinear, and if the acceptance certificate is sublinear, the rejection certificate often fails to be sublinear. For instance, the problem of recognizing bipartite graphs has a sublinear rejection certificate (an odd cycle) and a weak acceptance certificate (a 2-coloring). Recognizing connected graphs has a sublinear acceptance certificate (a spanning tree) and a weak rejection certificate (a cut $\{V', V - V'\}$ that has no edges across it). Directed acyclic graphs have a weak acceptance certificate (a topological sort) and a sublinear rejection certificate (a directed cycle). A similar phenomenon is seen in interval graphs and permutation graphs where the rejection certificate can be checked in $O(n)$ time, whereas the acceptance certificate is an $O(n)$ representation of G that defines the graph class and that requires $O(n + m)$ time to verify that it faithfully represents G.

What constitutes a weak certificate lacks the formal criteria that define sublinear or strong certificates. A weak certificate has value if it dramatically simplifies the task of solving the problem, without necessarily yielding a better time bound. There is no satisfactory formal measure of the conceptual difficulty of an algorithm, though differences are often obvious.

The value of proposed weak certificates must therefore be debated on a case-by-case basis in much the way that the ill-defined notion of "significance" of any new mathematical result is debated and evaluated through the peer-review process. The certificates in our examples were recognized previously as having theoretical relationships to the problems in question, independently of their use in algorithm design or error checking.

We would therefore describe certifying algorithms as embodying an algorithm-design philosophy, rather than a formal class of algorithms. We show through examples that the approach has been largely overlooked by both algorithm designers and software engineers, and we argue that it can have significant economic impact when algorithms are implemented. Moreover, in the case of graph algorithms, there is an extensive literature on forbidden subgraph characterizations of graph classes that promises to be a rich source of potential certificates for future work on certifying variants of existing graph algorithms.

3.1. Proofs of correctness of authentication algorithms. An interesting question raised by one of the anonymous referees of this paper is what relevance the simplicity of the proof of the authentication algorithm should have. Suppose the input is x, the correct output is $y = f(x)$, and the certificate, w, proves that $y = f(x)$. The proof that the authentication algorithm accepts only valid triples (x, y, w) should be trivial. The proof that the existence of such a triple proves that $y = f(x)$ does not need to be easy for the certificate to be useful.

Consider the question of deciding whether a graph is planar. A noncertifying algorithm for solving this problem inputs a graph G and outputs a bit $y = f(G)$ that is equal to 1 iff the graph is connected and planar. A certifying algorithm for planarity testing implemented in the LEDA package returns a Kuratowski subgraph when the input graph is nonplanar. A Kuratowski subgraph K is difficult to find, but easy to check once it is pointed out. Therefore, the proof that the authentication algorithm accepts only valid triples $(G, 0, K)$ is trivial. However, that K proves that $f(G) = 0$ is also easy to understand. It is not necessary for a user to understand why such a K appears in every nonplanar graph in order to understand that it proves that such an instance of a graph is nonplanar and that the program has answered truthfully.

What happens when G is planar gives a better illustration of the point raised by the referee. In this case, LEDA returns a *planar combinatorial embedding*. The validity of a planar combinatorial embedding is also easy to authenticate once it is pointed out, but it is more difficult to explain why it proves that the graph is planar.

For simplicity, assume for the moment that G is connected. Each undirected edge uv of G can be viewed as consisting of two directed edges (u, v) and (v, u); let $twin((u, v)) = (v, u)$. A planar embedding of G induces a cyclic order on the directed edges directed out of each vertex. Let $\pi_v((u, v))$ be the permutation of the edges that maps in clockwise order each edge out of a vertex to the next edge out of the vertex. Clearly, π_v has one cycle for each vertex. Given π_v, let $\pi_f((u, v)) = \pi_v(twin((u, v))$; it is easy to see that this is a permutation that maps each edge to the next edge about the face that lies immediately to the left of the edge. Therefore, π_f has a cycle for each face.

An abstraction of this is a *combinatorial embedding* of G, which consists of an *arbitrary* cyclic order π_v of the directed edges emanating from each vertex, but which may or may not correspond to the cyclic orders induced by any embedding of G in the plane. This nevertheless defines a second permutation $\pi_f((u,v)) = \pi_v(twin((u,v)))$ as before. By a well-known theorem of Euler, a combinatorial embedding is planar iff $2c - m - n - f = 0$, where f is the number of cycles π_f, c is the number of connected components of G, m is the number of edges, and n is the number of vertices.

To present this certificate, it is necessary only to give π_v as a cyclic order of edges out of each vertex and a pointer from each directed edge (u,v) to its twin (v,u). An authentication algorithm must verify that π_v induces a cyclic order on the edges directed out of each vertex, count the cycles in π_v and π_f, and verify that Euler's relation applies.

Though this test is simple, the proof that it implies that G is planar is not easy to explain to an unsophisticated programmer or user. (See [14] for a typical proof.) The usefulness of the certificate lies in the fact that Euler's formula applies to all instances of the problem and has received the thorough scrutiny of many experts. A person who trusts the theorem does not need to understand its proof in order to make use of the certificate. The certificate is useful because it allows trust in a well-known theorem to be substituted for trust in a program of dubious origin.

3.2. Preconditions and postconditions. One can imagine programs where different subproblems are solved by procedures that produce certificates, and where the program contains embedded code to authenticate each certificate before proceeding.

Suppose that an $O(\log n)$ binary search procedure is asked to search a sorted array of integers for an element i, and that the procedure returns with the answer that i does not occur in the array. It could be the case that the array was not correctly sorted, causing the binary search procedure to falsely declare that i does not occur in it, even though the binary search procedure is correctly implemented. Checking for this error would take $O(n)$ time, which would obviate the advantages of using a binary search procedure instead of a linear search.

Instead of this, we could define the binary search procedure as one that has a precondition that the input array be sorted *and a postcondition that its answer is correct whenever the precondition is met.* An error has occurred in the binary search procedure only if the precondition is met and the returned answer is incorrect.

Let us formally define an *error* in the binary search procedure to be a circumstance where the precondition is met but the returned value is incorrect. As in the case of all certifying algorithms, the question of whether a procedure has erred in some circumstance is separated from the question of whether it contains bugs. The binary search procedure can provide a certificate that it has not erred by returning either the index where i occurs, or else the index where i would occur if it is absent in the array. If the procedure claims that i occurs, the authentication algorithm checks the location to make sure that it is there. If the procedure claims that i does not occur, the authentication algorithm checks the location to make sure that the element at that position is smaller than i and the element at the next position is larger i. (Trivial special cases occur when the index is the last in the array.)

Though this example is trivial, it illustrates the possibility of designing certificates that show that *either* the returned value is correct *or* that the preconditions were not met, without distinguishing which of these cases occurred. This exonerates a procedure as the ultimate source of an error.

As a nontrivial example of such a certificate, the transitive orientation algorithm of [18] finds a transitive orientation of a comparability graph in $O(n+m)$ time. If a graph is given to the procedure that is not a comparability graph, then no transitive orientation exists, and the procedure produces an orientation in $O(n+m)$ time that is not transitive, without recognizing this. Various nonlinear bounds for checking whether an orientation is transitive are known, such as $O(nm)$, $O(m^{3/2})$, and the time to multiply two $n \times n$ matrices, $O(n^{2.376})$. These are the best bounds for recognizing comparability graphs.

However, it is reasonable to view as a precondition the requirement that the input to the transitive orientation algorithm be a comparability graph, since the orientation is meaningless if this is not the case. Below, we show how to provide a certificate, called an *orientation tree*, that shows that either the precondition has not been met or the returned orientation is transitive. This certificate is quite simple to check in $O(n+m)$ time.

4. Chordal bipartite graphs. A *chord* in a simple cycle is an edge that is not an edge of the cycle, but whose endpoints are both vertices in the cycle. In a bipartite graph, every cycle is even, so every cycle has length at least four. A graph is *chordal bipartite* if it has no chordless cycle of length greater than four.

Chordal bipartite graphs provide an easy introduction to techniques that we will use to produce certifying algorithms. Lubiw [16] gives an $O(n+m\log^2 n)$ noncertifying algorithm for recognizing them. We show how to modify it to obtain a certifying algorithm.

If M is a matrix, let $M_{i,j}$ denote the element in row i, column j. The rows of a matrix M are in *lexical order* if they are sorted in dictionary order. That is, whenever $\{i, i+1\}$ are a consecutive pair of rows and j is the first column where the rows differ, then $M_{i+1,j} > M_{i,j}$. The columns are in lexical order if, as rows, they are in lexical order in the transpose of the matrix.

A bipartite graph G with bipartition U, W can be represented with a Boolean *bipartite adjacency matrix* A, which has one row i for each element of $u_i \in U$, one column for each element $w_i \in W$, and for each pair $\{u_i, w_j\}$, $A_{i,j} = 1$ if $u_i w_j$ is an edge of G, and $A_{i,j} = 0$ otherwise.

Given a graph G, Lubiw's algorithm tests whether G is bipartite, and, if so, finds a bipartition and a *doubly lexical ordering* of the resulting bipartite adjacency matrix. A doubly lexical ordering of a matrix is a permutation of the rows and columns such that the resulting matrix passes the following two tests:

1. When the order of the columns is reversed, the rows are in lexical order.
2. When the order of the rows is reversed, the columns are in lexical order.

Every matrix has a doubly lexical ordering, so this is not a test of whether G is chordal bipartite. Lubiw's algorithm then searches this doubly lexical matrix A for a configuration called a *Gamma* (Γ). A Γ is a pair (h, i) of rows and a pair (j, k) of columns such that $h < i$, $j < k$, $A_{h,j} = A_{h,k} = A_{i,j} = 1$, and $A_{i,k} = 0$.

The critical theorem is that a bipartite graph is chordal bipartite iff a doubly lexical ordering of its bipartite adjacency matrix has no Γ. Lubiw's algorithm for finding the doubly lexical ordering and testing for Γ's uses a sparse representation of A and takes $O(n+m\log^2 n)$, which gives this bound for recognition of chordal bipartite graphs. The bound for finding the doubly lexical ordering has been improved to $O(n+m\log n)$ by Paige and Tarjan [22], and to $O(n^2)$ by Spinrad [26], and these give bounds of $O(n+m\log n)$ and $O(n^2)$, respectively, for recognizing chordal bipartite graphs.

Though its proof of correctness is not obvious, Lubiw's algorithm for searching for a Γ with respect to given orderings of the bipartition classes is trivial to program and runs in $O(n+m)$ time. Therefore, a doubly lexical ordering is a strong certificate that a graph is chordal bipartite. The certificate is represented by a bipartition of the vertices and two orderings of the bipartition classes. The authentication algorithm verifies that each of the two bipartition classes is an independent set and that the graph has no Γ with respect to the given orderings of the bipartition classes. All of this takes $O(n+m)$ time. The doubly lexical ordering is therefore a strong certificate, but not a sublinear one.

When a graph is not chordal bipartite, the same certificate can be used to show this, so it is a strong certificate for this case also. However, with some additional effort, we can obtain a sublinear certificate. Note that this precludes verifying the correctness of a doubly lexical ordering, which requires $\Theta(n+m)$ time.

Lubiw [16] proves that when a Γ occurs in a doubly lexical ordering, it is part of a chordless cycle that has at least six vertices. To find such a cycle, let $\{(a,b),(b,c),(c,d)\}$ be the Γ, and remove $N(b)\cup\{b\}\cup N(c)\cup\{c\}-\{a,d\}$ from the graph. Since the Γ is part of a chordless cycle, there exists a path from a to d in this induced subgraph. Using breadth-first search (BFS) starting at a, we may find a shortest path P from a to d in this induced subgraph. Since $\{(a,b),(b,c),(c,d)\}$ is a P_4 and all members of P other than a and d are nonneighbors of b and c, the union of P and the $\{(a,b),(b,c),(c,d)\}$ is a chordless cycle of length at least six. This chordless cycle can be returned as a certificate that the input graph is not chordal bipartite.

On first inspection, this does not seem like a sublinear certificate. To verify that the returned cycle C is indeed chordless, a skeptical user must spend $O(n+m)$ time in the worst case to verify that the cycle has no chords. The key to an $O(n)$ authentication algorithm is the observation that its purpose is to verify that the graph has a chordless cycle and to not verify that C is an example of one.

An $O(n)$ authentication algorithm first verifies that C is a cycle in G of size greater than four. It then selects any four consecutive vertices (u,x,y,w) on the cycle and verifies that x and y have no neighbors on C other than the ones that are supposed to have. That is, it verifies that x has no neighbors on C other than u and y, and y has no neighbors on C other than x and w, and that u and w are nonadjacent. If these tests fail, the certificate is ruled faulty. Otherwise, even if C still has undetected chords, the existence of a path from u to w that avoids the neighborhoods of x and y proves the existence of a shortest such path, P. The union of (u,x,y,w) and such a shortest path is a chordless cycle of length greater than four. Therefore, the user may be certain that the graph has a chordless cycle based on this authentication algorithm, even though the algorithm does not fully verify that C is itself chordless.

5. Interval graphs. An undirected graph is *chordal* if it has no chordless cycle of length at least four. Three independent vertices x,y,z of a graph G are an *asteroidal triple* (AT) of G if, between each pair of these vertices, there is a path that contains no neighbors of the third. A graph is said to be *AT-free* if it has no AT. For more information on these and other graph classes we refer the reader to [3, 8]. We will rely on the following well-known theorem.

THEOREM 5.1 (see [15]). *A graph is an interval graph iff it is chordal and AT-free.*

A graph is chordal iff it has a *perfect elimination ordering*, which is an ordering $(v_1,v_2,\ldots,v_n)$ of the vertices such that for each v_i, $N(v_i)\cap\{v_{i+1},v_{i+2},\ldots,v_n\}$ is a clique [6]. A perfect elimination ordering of a chordal graph can be found in

linear time by the lexicographical BFS (LexBFS) algorithm [25, 8]. A modification of this algorithm points out a chordless cycle of length at least four as a certificate of nonmembership [27]. Hence, this is a linear-time certifying recognition algorithm for chordal graphs.

5.1. The certificates. When the graph is an interval graph, we produce an interval model, just as the prior algorithms do. For the authentication step, it is easy to check whether this model corresponds to the input graph in time that is linear in the size of the input graph. The basic trick is to work left-to-right through the model, generating edges implied by the model and rejecting the certificate immediately if the number of edges exceeds the number of edges in the graph. Otherwise, when finished, verify that the generated edges are the same as those in the graph by labeling the vertices with identifiers from 1 to n, and then radix sorting the set of all edges of G according to the identifiers of their endpoints. Since authentication takes linear time, the interval model is a weak certificate.

When the graph is not an interval graph, Theorem 5.1 provides the basis of our certificate: we produce either a chordless cycle or an AT. Despite initial appearances, these can be turned into sublinear certificates. For the AT, we accomplish this by returning not only the triple, but for each pair in the triple, the sequence of edges of a simple path between them that avoids the neighborhood of the third. The sequence of edges may be given by pointers to the corresponding edge structures in the user-supplied data. Given the triple, it is easy to find these three paths in linear time. The authentication algorithm must verify that each proposed path is, in fact, a path, that its edges occur in G, and that no neighbors of the third vertex occur on it. If each path is given by pointers to edges in the input structure in the order in which they occur on the path, this is accomplished in $O(n)$ time by marking the neighbors of each vertex in the triple. This is a sublinear certificate because $O(n)$ is a better bound than $O(n + m)$.

As in the case of chordal bipartite graphs, a chordless cycle can be used to verify in $O(n)$ time that such a cycle exists, without fully verifying that the given cycle is an example of one. The authentication algorithm is the same as in the chordal bipartite case, except that when (u, x, y, w) are consecutive vertices, the certificate is not rejected if u and w are adjacent.

5.2. Generating the certificates. For our certifying algorithm, we use the linear-time algorithm of Korte and Möhring [13] as a subroutine. Though this is not a certifying algorithm, it produces a certificate in the form of an interval representation in the case where the graph is an interval graph.

Suppose the input graph is not an interval graph. Using the algorithm of [27], we return a chordless cycle if the graph is not chordal.

It remains to show how to produce a certificate in the case where the graph is chordal, but not an interval graph. Henceforth, we will assume that this case applies.

The algorithm of Korte and Möhring produces a perfect elimination ordering $(v_1, v_2, \ldots, v_n)$, and incrementally decides whether the subgraph induced by the vertices $\{v_n, \ldots, v_i\}$ is an interval graph. Since we now assume that the graph is not an interval graph, it fails when considering a particular vertex v_{i-1}. The subgraph induced by the vertices $\{v_n, \ldots, v_i\}$ is an interval graph and the subgraph induced by $\{v_n, \ldots, v_i, v_{i-1}\}$ is not.

In the remainder of this section, we use G to denote the subgraph induced by $\{v_n, \ldots, v_i\}$ and we let $x = v_{i-1}$. The graph $G + x$ is a chordal graph, but not an interval graph, and hence it must contain an AT by Theorem 5.1. The neighbors of x

form a clique in G since $(v_1, v_2, \ldots, v_n)$ is a perfect elimination ordering of the input graph.

The Korte–Möhring algorithm provides an interval model of G. We may assume without loss of generality that all endpoints in the interval model of G are pairwise distinct, since, when they are not, they can be perturbed to make this true without altering the represented graph. Let us then number the endpoints in left-to-right order, and for each vertex, let $l(v)$ and $r(v)$ denote the numbers of the left and right endpoints of the interval corresponding to v. This gives a "normalized" interval model where $I(v) = [l(v), r(v)]$ is the interval that corresponds to v, all endpoints are distinct, and $l()$ and $r()$ are integer-valued functions from $V(G)$ to $\{1, 2, \ldots, 2n\}$.

LEMMA 5.2. *Let G be an interval graph such that $G' = G + x$ is not an interval graph and $N(x)$ is a clique. Then x is a member of every AT of G'.*

Proof. Suppose $\{a, b, c\}$ is an AT of G' and $x \notin \{a, b, c\}$. There is a path P from a to b in G' that avoids the neighborhood of c. If P contains x, then, since the neighborhood of x is a clique, x's predecessor and successor on P must be adjacent, and x can be spliced out of P to yield a path in G. Thus, there is a path in G from a to b that avoids the neighborhood of c. By symmetry among the members of $\{a, b, c\}$, $\{a, b, c\}$ is an AT of G, contradicting the assumption that G is an interval graph. □

DEFINITION 5.3. *Let us say that interval $[x_1, x_2]$* precedes *interval $[y_1, y_2]$ iff $x_1 < y_1$ and $x_2 < y_2$. Let P be a path in G. Let the* rightward extent *$R(P)$ of P denote* $\texttt{max}\ \{r(u) | u$ *is a vertex on $P\}$, and let the* leftward extent *$L(P)$ of P denote* $\texttt{min}\ \{l(w) | w$ *is a vertex in $P\}$. Let $D(x) = \bigcap\{I(v) | v \in N(x)\}$ be the intersection of the intervals representing the neighbors of x. Then $D(x) \neq \emptyset$ since the neighbors of x form a clique.*

Since an AT is an independent set, in any AT $\{x, y, z\}$ of G', one of $I(y)$ and $I(z)$ precedes the other, and if $I(y)$ precedes $I(z)$, then $r(y) < l(z)$.

LEMMA 5.4. *Let $\{x, y, z\}$ be an AT in G', where $I(y)$ precedes $I(z)$. Then*

$$r(y) < l(D(x)) < r(D(x)) < l(z).$$

Proof. Assume otherwise, say, $l(D(x)) < r(y)$, and consider any path P from z to $v \in N(x)$ avoiding $N(y)$. Then $v \notin N(y)$. Together with $l(v) \leq l(D(x))$, this implies $r(v) < l(y)$. Since $r(y) < l(z)$, P must contain a neighbor of y, a contradiction. □

DEFINITION 5.5. *If $r(y) < l(D(x))$, then let $R(y) =$* $\texttt{min}\ \{R(P) | P$ *is a path from y to a neighbor of $x\}$. That is, $R(y)$ is the minimum rightward extent of any path from y to a neighbor of x. Similarly, if $r(D(x)) < l(z)$, then let $L(z) =$* $\texttt{max}\ \{L(P) | P$ *is a path from z to a neighbor of $x\}$. That is, $L(z)$ is the maximum leftward extent of any path from z to a neighbor of x.*

LEMMA 5.6. *If $r(y) < l(D(x)) < r(D(x)) < l(z)$, then $\{x, y, z\}$ is an AT in G' iff y and z are in the same component of $G - N(x)$ and $[r(y), R(y)]$ precedes $[L(z), l(z)]$.*

Proof. If $\{x, y, z\}$ is an AT in G', then y and z are in the same component of $G - N(x)$, since there is a path of G' that avoids the neighborhood of x. There is a path from y to x in G' that avoids the neighborhood of z, and hence a path to a neighbor of x in G that contains no neighbor of z. Since $r(y) < l(z)$, the intervals of all vertices on this path have their right endpoint to the left of $l(z)$. Therefore, $R(y) < l(z)$. By mirror symmetry, $r(y) < L(z)$.

If $\{x, y, z\}$ is not an AT in G', then since $\{x, y, z\}$ is an independent set, every path of G' between some pair of the vertices contains a neighbor of the third. If every path between y and z contains a neighbor of x, then y and z are in different components of $G - N(x)$. If all paths from y to a neighbor of x contain a neighbor of

z, then the rightward extent of all such paths is greater than $l(z)$, and $R(y) > l(z)$. By mirror symmetry, $r(y) < L(z)$. □

Lemma 5.6 gives the strategy of our approach for finding an AT in G'. Removing the intervals corresponding to $N(x)$ from the interval model of G gives an interval model of $G - N(x)$. We look for a component whose intervals span $[l(D(x)), r(D(x))]$. For each y in the component such that $r(y) < l(D(x))$ we compute $R(y)$, and for each z in the component such that $r(D(x)) < l(z)$ we compute $L(z)$. We then look for a pair $[r(y), R(y)]$, $[L(z), l(z)]$, such that $[r(y), R(y)]$ precedes $[L(z), l(z)]$, using Lemma 5.7, which we give first.

LEMMA 5.7. *Given two sets $\mathcal{X}$ and $\mathcal{Y}$ of intervals, where the right endpoints of $\mathcal{X}$ are given in ascending order and the left endpoints of $\mathcal{Y}$ are given in descending order, it takes $O(|\mathcal{X}| + |\mathcal{Y}|)$ time to either determine that no interval in $\mathcal{X}$ precedes any interval in $\mathcal{Y}$, or else return $a \in \mathcal{X}$ and $b \in \mathcal{Y}$ such that a precedes b.*

Proof. As a base case, if $\mathcal{X}$ or $\mathcal{Y}$ is empty, there is no such pair. Otherwise, select $u \in \mathcal{X}$ that minimizes $r(u)$, and select $w \in \mathcal{Y}$ that maximizes $l(w)$. If $l(u) < l(w)$ and $r(u) < r(w)$, then return (u, w) as (a, b). Otherwise, if $l(u) \geq l(w)$, then u is not a candidate for a since its left endpoint does not lie to the left of any left endpoint in $\mathcal{Y}$. Let $\mathcal{X} := \mathcal{X} - \{u\}$. By mirror symmetry, if $r(u) \geq r(w)$, then w is not a candidate for b, so let $\mathcal{Y} := \mathcal{Y} - \{w\}$. By induction on the size of $|\mathcal{X}| + |\mathcal{Y}|$, a recursive call on the new $\mathcal{X}$ and $\mathcal{Y}$ solves the original problem. Because of the way the data are sorted, it takes $O(1)$ time to select u and w and to prepare the recursive call, in which $|\mathcal{X}| + |\mathcal{Y}|$ has been reduced by at least 1. □

To use Lemma 5.7, we let $\mathcal{X} = \{[r(y), R(y)] | r(y) < l(D(x))\}$ and let $\mathcal{Y} = \{[L(z), l(z)] | r(D(x)) < l(z)\}$. Since $r()$ and $l()$ are integer functions from 1 to $2n$, sorting the endpoints as required by the lemma takes $O(n)$ time.

Therefore, by Lemmas 5.6 and 5.7, the problem of finding an AT reduces in linear time to computing $R(y)$ at each y such that $r(y) < l(D(x))$ and $L(z)$ at each z such that $r(D(x)) < l(z)$. We give the procedure for $R()$, and by mirror symmetry, this gives the procedure for $L()$.

DEFINITION 5.8. *A path P in G is* increasing *if, whenever u is earlier than v on P, $r(u) < r(v)$. Let D_r be the orientation of $G - N(x)$, where (u, v) is an arc in D_r iff uv is an edge in $G - N(x)$ and $r(u) < r(v)$.*

Our strategy for computing $R()$ is to find a way to restrict our attention to increasing paths from y to $N(x)$, which allows us to work in D_r rather than in G. Since D_r is a dag, this simplifies the problem.

LEMMA 5.9. *If there is a path P from u to v with rightmost extent $R(P) = r(v)$, then there is an increasing path P' from u to v such that $R(P') = R(P)$.*

Proof. If $u = v$, P is vacuously increasing. Suppose P has length greater than 0 and the lemma is true for shorter paths. Let w be the first vertex on P with $r(w) > r(u)$. $R(P) = r(v)$ implies $r(u) < r(v)$, so w exists. Then $I(u)$ and $I(w)$ intersect, and hence u and w are neighbors. By induction, there is an increasing path P'' from w to v and $P' = uP''$ satisfies the lemma. □

LEMMA 5.10. *Let $r(y) < l(D(x))$ and let P be a path in G from y to a neighbor v of x. Then there is a path $P'v$ from y to v such that $R(P'v) \leq R(P)$ and P' is increasing.*

Proof. If $R(P) = r(v)$, then the claim follows from Lemma 5.9. Otherwise, let w be the first vertex on P such that $I(w)$ intersects $D(x)$, and let P'' be the portion of P from y to w. Since $R(P'') = r(w)$, there is an increasing path P' from y to w, and since $I(w)$ intersects $D(x)$, w and v are adjacent. □

LEMMA 5.11. *It takes linear time to compute $R(y)$ for every $y \in V(G)$ such that $r(y) < l(D(x))$.*

Proof. By Lemma 5.10, we need only consider *well-behaved* paths in G that consist of a directed path in D_r, followed by a single edge of G to a neighbor of x. For any such well-behaved path P, $R(P)$ is the maximum of the last two values of $r()$ on the path. For each $y \in V(G) - N(x)$, let $R_i(y) = \texttt{min}\{R(P)|P$ is a well-behaved path of length at most $i\}$, or ∞ if there is no such path. The value of $R_1(y)$ is trivial to compute at all nodes in $V - N(x)$ in linear time. Let $(u_p, u_{p-1}, \ldots, u_1)$ be a topological sort of D_r. Then $R_i(u_i) = \texttt{min}\ \{R_1(u_i)\} \cup \{R_j(u_j)|(u_i, u_j)$ is an arc of $D_r\}$. This may be computed by induction on i in linear time. For any $y = u_k$ such that $r(y) < l(D(x))$, $R(y) = R_k(u_k)$, since y has at most $k - 1$ successors in D_r. □

5.3. Comparison with the original Korte–Möhring algorithm. One of the anonymous referees has asked for a clarification of why the Korte–Möhring algorithm is not already a certifying algorithm, producing a sublinear certificate of rejection, just as ours does.

Answering this question requires more details about how the algorithm works. The Korte–Möhring algorithm paper [13] defines a *modified PQ tree* (*MPQ tree*) for an interval graph G, which gives a way of representing implicitly all possible interval representations of G. Vertices of G are associated with nodes of the MPQ tree; details about this representation are given in the paper.

As described above, the Korte–Möhring algorithm works by induction on a perfect elimination order $(v_1, v_2, \ldots, v_n)$. Let G_i denote the subgraph of G induced by $\{v_n, v_{n-1}, \ldots, v_i\}$, and let T_i be its MPQ tree. At each step $i - 1$ it produces the MPQ tree T_{i-1} of G_{i-1} from the MPQ tree T_i of G_i, unless G_{i-1} fails to be an interval graph, in which case it rejects G_{i-1}, and hence G is not an interval graph.

At each step, recognizing whether G_{i-1} is an interval graph is trivial, since this is the case iff the neighbors of v_{i-1} in G_i have a certain relationship to T_i that is quite easy to check in $O(n)$ time. If G is not an interval graph, the test will fail at some step $i - 1$.

Since it is possible to verify that G is not an interval graph in $O(n)$ time using T_i and v_{i-1}, the referee has suggested that (T_i, V_{i-1}) be returned as a sublinear certificate of rejection.

Though compelling, this idea has the subtle flaw that it violates the principle that it must not be possible for an authentication algorithm to be induced to make a false declaration by an erroneous or counterfeit certificate. It must either declare a correct answer to the original problem, or it must correctly declare that the claimed certificate contains an error and fails to show what it claims to show. Showing that (T_i, v_{i-1}) fails the simple $O(n)$ test demonstrates only that *either* G_{i-1} is not an interval graph, *or* that T_i is not the correct MPQ tree for G_i, *or* that T_i is the correct MPQ tree for G_i but that $(v_1, v_2, \ldots, v_n)$ is not a perfect elimination order. In fact, the authors make clear that an additional requirement for the algorithm to work is for $(v_1, v_2, \ldots, v_n)$ to be a special case of a perfect elimination order produced by the LexBFS algorithm.

Therefore, in addition to verifying that (T_i, v_{i-1}) fails to have the required simple relationship to T_i, it is also necessary to verify that T_i is the correct MPQ tree for G_i and that $(v_1, v_2, \ldots, v_n)$ is a LexBFS order.

A necessary step in checking that T_i is the correct MPQ tree for G_i is to check that an interval model it implies correctly reflects every edge of G_i. Otherwise, it leaves open the possibility that T_i is the MPQ tree for some interval graph $G_i' \neq G_i$.

The authentication algorithm will falsely declare that G_{i-1} is not an interval graph if $G'_i + v_{i-1}$ is not an interval graph, but $G_i + v_{i-1}$ is. There is little hope of finding a sublinear algorithm for checking whether a given interval model faithfully represents a given graph G, though this is easily accomplished in linear time. The claim that it is a sublinear certificate cannot be made, given what is currently known, and there are reasons to believe that this will not change in the future.

Whether (T_i, v_{i-1}) is useful as a weak certificate depends on the question of whether it clearly simplifies conceptually the task of verifying that G is not an interval graph. In constructing T_i, checking whether T_j and v_{j-1} satisfy the required test for $j > i$ is quite simple, but updating T_j to produce T_{j-1} when it passes this test is considerably more complicated. Though it takes linear time, the problem of checking that an interval model $\mathcal{I}_i$ implied by the MPQ tree T_i faithfully represents G_i is a fairly simple task. However, once this has been accomplished, one must still verify that T_i is the correct MPQ tree for $\mathcal{I}_i$. This problem is one of the main subjects of a forthcoming paper [17]; it is shown there that it can be solved in $O(n)$ time. The algorithm is quite involved, though it is possible that a simpler algorithm could accomplish the task in $O(n + m)$ time. As for verifying the LexBFS order, there is an algorithm for checking whether an order is a perfect elimination order [8], but we do not know of an algorithm for verifying a LexBFS order other than rerunning the LexBFS algorithm that produced it. An interesting question is whether the interval representation could help.

In summary, the usefulness of (T_i, v_{i-1}) in simplifying the problem significantly without leaving open the possibility of giving erroneous output has not been demonstrated. If this is accomplished, it appears unlikely that the resulting authentication will compete in simplicity with the one for checking a given AT or given chordless cycle, or that it will be sublinear.

6. Comparability graphs. Let us consider an undirected graph G to be a special case of a digraph, namely, the symmetric digraph where if (x, y) is a directed arc, then so is (y, x). The undirected edge xy is just the pair $\{(x, y), (y, x)\}$. Finding a transitive orientation of an undirected graph G amounts to deleting one arc from each symmetric pair so that the remaining arcs form a transitive digraph.

Suppose (a, b) and (b, c) are arcs of G and (a, c) is not. Any orientation of G where both (a, b) and (b, c) appear must fail to be transitive, due to the forced absence of (a, c) in the orientation. Then (b, c) is *incompatible* with (a, b), as is (b, a), since a transitive orientation must be antisymmetric. We may represent the incompatibility relation with an *incompatibility graph* whose vertices are the arcs of G and whose (undirected) edges are the incompatible pairs of arcs of G. (See Figure 4.)

We show in section 6.3 that the following is an immediate corollary of a result from [7, 8].

THEOREM 6.1. *An undirected graph G is a comparability graph iff its incompatibility graph is bipartite.*

The following is a consequence of Theorem 6.18, which we give in section 6.3, and gives a sublinear certificate that a graph is not a comparability graph, since it can be checked in $O(n)$ time.

THEOREM 6.2. *When G fails to be a comparability graph, its incompatibility graph has an odd cycle of length $O(n)$.*

A linear-time algorithm for finding a transitive orientation of a comparability graph is given in [18]. This transitive orientation algorithm represents the orientation it assigns to the edges implicitly by giving a linear extension (topological sort) of the

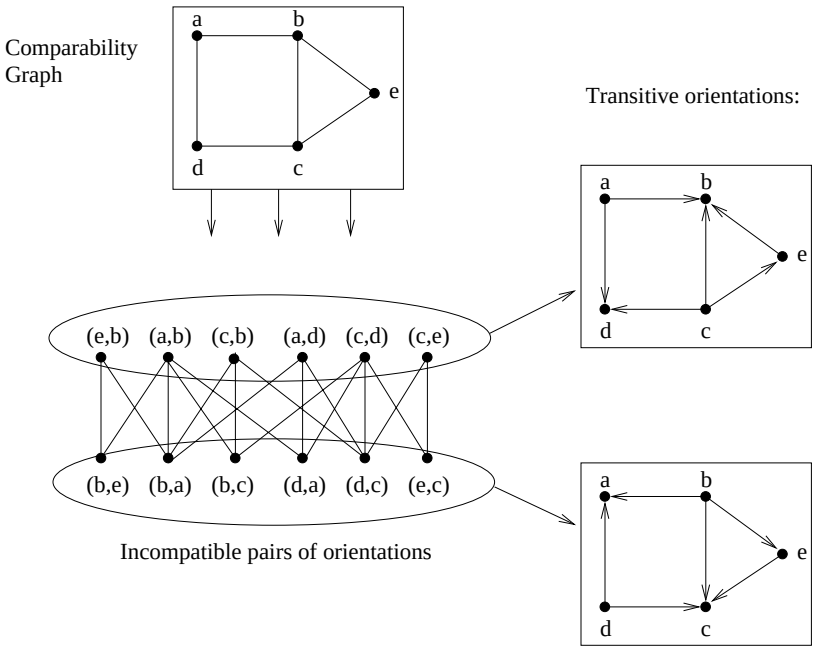

FIG. 4. *The incompatibility graph of a graph. There is one vertex for each directed edge, and two are adjacent if one is the transpose of the other, or if they are of the form* $\{(a,b),(b,c)\}$ *and* (a,c) *is not an edge. Two adjacent edges cannot appear in a transitive orientation. Therefore, a transitive orientation must be an independent set in the incompatibility graph. Reversing the direction of the edges in a transitive orientation yields a new transitive orientation. From this observation, it is easy to see that the incompatibility graph of a comparability graph is bipartite.*

orientation that it produces. This allows it to be applied to $\overline{G}$ in time linear in the size of G.

When the transitive orientation algorithm is asked to provide a transitive orientation of a graph G that is not a comparability graph, it produces an acyclic orientation of the graph, which it represents with a linear extension. This orientation must contain an incompatible pair, namely, a pair $\{(a,b),(b,c)\}$ of directed edges in series such that ac is not an edge of G, and hence (a,c) is not a directed edge in the orientation. No general linear-time algorithm for finding an incompatible pair in a dag is known. Because of this, no linear-time algorithm is known for recognizing comparability graphs, even though a linear-time algorithm for transitively orienting them is available.

We prove the following lemma in section 6.3.

LEMMA 6.3. *Given an incompatible pair in the orientation of a graph* G *produced by the transitive orientation algorithm of* [18]*, it takes* $O(n+m)$ *time to find an odd cycle of length* $O(n)$ *in* G*'s incompatibility graph, and given an incompatible pair in an orientation of* $\overline{G}$ *by the algorithm, it takes* $O(n+m)$ *time to find an odd cycle of length at* $O(n)$ *in* $\overline{G}$*'s incompatibility graph.*

6.1. Minimum proper coloring and maximum clique. The algorithm of [18] for finding a minimum proper coloring and maximum clique in a comparability graph proceeds as follows. Given an arbitrary input graph G, it finds an acyclic orientation that will be transitive if the input is a comparability graph. It then labels each vertex

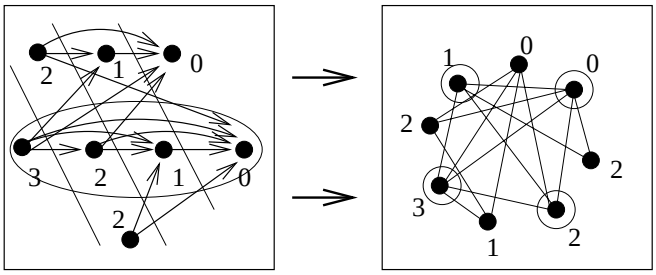

FIG. 5. *Finding a maximum clique and minimum proper coloring in a comparability graph. The color of each vertex is the length of the longest directed path originating in a transitive orientation. A longest path is a clique. Since the size of a clique is a lower bound on the number of colors in a proper coloring, the coloring is a certificate that the clique is of maximum size and the clique is a certificate that the proper coloring is a minimum one.*

with the length of the longest directed path originating at the vertex in the resulting directed acyclic graph. This labeling is easily accomplished in $O(n + m)$ time by labeling each vertex as it finishes during a depth-first search of the graph. (See Figure 5.) Each neighbor of the vertex is already labeled at that point, so the vertex can be labeled with one plus the maximum of the labels of its neighbors. This is a proper coloring, since for any edge xy of G, the label of one of x and y will exceed the other's by at least 1.

If the longest path is a clique, then the coloring is a minimum one and the path is a maximum clique. This is because the size of a clique is a lower bound on the number of colors needed, and since the clique has the same number of vertices as the number of colors used, the coloring serves as a certificate that the clique is a maximum one and the clique serves as a certificate that the coloring is a minimum one. These are weak certificates, since it takes $O(n+m)$ time for a user to verify that the coloring is a proper one and that the path is a clique.

If G is not a comparability graph, the algorithm still assigns an acyclic orientation, which allows the vertices to be colored as before, and finds a maximum-length directed path P. If P is a clique in G, then it is a maximum clique and the coloring is a minimum proper coloring, so these may be returned as each other's certificate just as in the case where G is a comparability graph. If P is not a clique in G, then there exist two consecutive arcs (a, b) and (b, c) on P such that (a, c) is not an edge, and these are easy to find in linear time. Since (a, b) and (b, c) are an incompatible pair, an odd cycle in the incompatibility graph may then be found in $O(n+m)$ time, by Lemma 6.3. As pointed out above, this is a sublinear certificate that G is not a comparability graph.

6.2. Permutation graphs. In [18], it is shown that the transitive orientation algorithm given there gives rise to a linear-time bound for recognizing permutation graphs. The algorithm is based on the following characterization of permutation graphs.

THEOREM 6.4 (see [23, 8]). *An undirected graph G is a permutation graph iff G and its complement $\overline{G}$ are both comparability graphs.*

When G is a permutation graph, the algorithm finds a topological sort of a transitive orientation D of G and a topological sort of a transitive orientation D' of $\overline{G}$. $D \cup D'$ is a *tournament* (an orientation of a complete graph) and acyclic. It then finds the unique topological sort of $D \cup D'$ to yield a linear ordering of V, and the unique

topological sort of $D^T \cup D'$ to give a second linear arrangement of V. By results from [23, 8], these two linear arrangements are a permutation model of G.

When G is not a permutation graph, the procedure in [18] produces a faulty permutation model of G. Success or failure of an authentication algorithm on the permutation model it produces provides the basis for deciding whether the graph is a permutation graph in that algorithm. The procedure is not a certifying algorithm, since the permutation model could also have been faulty due to a bug in the implementation.

A linear-time authentication algorithm for a proposed permutation model is given in [18]. The permutation model is therefore a weak certificate.

The algorithm for recognizing permutation graphs given in [18] uses the transitive orientation algorithm to find linear extensions of orientations D and D' of G and of $\overline{G}$. Since it provides a certificate if G is a permutation graph, we will assume in the remainder of the paper that G is not. In this case, at least one of D and D' has an incompatible pair.

We now describe how to find an incompatible pair in D or D' in time linear in the size of G, given G and linear extensions π and τ of D and of D'. This constitutes proof that the implementation of the transitive orientation algorithm failed to produce an orientation of G or of $\overline{G}$ that is transitive. However, it is not a certificate that G is not a permutation graph, since the failure could be due to a bug in the implementation of the algorithm.

LEMMA 6.5. *Let G be a graph, and let D and D' be acyclic orientations of G and $\overline{G}$. Then $D \cup D'$ and $D^T \cup D'$ are both acyclic iff D and D' are each transitive.*

Proof. Since $D \cup D'$ is a tournament, then if it has a cycle, it has a three-cycle. Suppose there is a directed three-cycle $(x, y), (y, z), (z, x)$ in $D \cup D'$. Since D and D' are both acyclic, one of these arcs belongs to D and another belongs to D'. Suppose without loss of generality that $(x, y), (y, z)$ belong to D. Then since $(x, z) \notin D$, D is not transitive. An identical argument applies if $D^T \cup D'$ contains a directed three-cycle.

Next, suppose that one (or both) of D and D' fails to be transitive. Assume without loss of generality that D fails to be transitive. Then there exists an incompatible pair $\{(a, b), (b, c)\}$. Therefore (a, c) is not an arc of D, and since D is acyclic, (c, a) is not an arc of D. Therefore, (a, c) or (c, a) is an arc of D'; if (a, c) is an arc of D', then $\{a, b, c\}$ induces a three-cycle in $D^T \cup D'$, and if (c, a) is an arc of D', then $\{a, b, c\}$ induces a three-cycle in $D \cup D'$. □

LEMMA 6.6. *Let G, D, and D' be as in Lemma 6.5. Given a three-cycle in $D \cup D'$ or $D^T \cup D'$, it takes $O(1)$ time to return an incompatible pair in D or in D'.*

Proof. Suppose the three-cycle occurs in $D \cup D'$. Since each of D and D' is acyclic, two of the arcs of the cycle occur in one of D and D' and give an incompatible pair in it. □

Let $p(x)$ be the number of predecessors of $x \in V$ in $D \cup D'$. This is just $|N^-(x)|$ in D plus $|N^-(x)|$ in D'.

LEMMA 6.7. *If for each $i \in \{0, 1, \ldots, n-1\}$ there exists $x \in V$ such that $p(x) = i$, then $D \cup D'$ is acyclic.*

Proof. (By induction on i.) Suppose $D \cup D'$ has n vertices and satisfies the conditions of the lemma. The claim is immediate if $n = 1$. Suppose $n > 1$ and the claim holds for $n-1$. There is a vertex s in $D \cup D'$ such that $p(s) = n-1$. Since every other vertex is a predecessor of s, no directed cycle of $D \cup D'$ contains s. However, removal of s leaves an induced subgraph of $D \cup D'$ on $n - 1$ vertices that satisfies

the condition of the lemma, so by the induction hypothesis, there can be no directed cycle that excludes s. □

LEMMA 6.8. *Let G, D, and D' be as in Lemma 6.5, and let π and τ be topological sorts of D and D', respectively. Given G, π, and τ, it takes $O(n+m)$ time to find a three-cycle in $D \cup D'$ or else determine that $D \cup D'$ is acyclic.*

Proof. In $O(n)$ time, we may label the elements of V with their position numbers in π and in τ. In $O(n+m)$ time, we can then label every $x \in V$ with the value of $|N^-(x)|$ in D by counting, for each vertex, the neighbors in G with earlier position numbers. To find $N^-(x)$ in D' we cannot do this directly in linear time, since D' is an orientation of $\overline{G}$, which might not have $O(n+m)$ size. Instead, let $i(x)$ be the number of predecessors of x in τ; $i(x)$ is just the position number of x in τ, minus one. Let $q(x)$ denote the number of neighbors of x in G that have earlier position numbers in τ. We can then compute $|N^-(x)|$ in D' as $i(x) - q(x)$. It takes $O(n+m)$ time to compute $q(x)$ for all $x \in V$, and hence $O(n+m)$ time to label each $x \in V$ with $|N^-(x)|$ in D'.

If the condition of Lemma 6.7 holds, then $D \cup D'$ is acyclic. Otherwise, there exist $x, y \in V$ such that $p(x) = p(y)$. Without loss of generality, suppose that $(x, y) \in D \cup D'$. Since y has x as a predecessor, and x and y have the same number of predecessors, then in $D \cup D'$, x must have a predecessor z that y does not have. In $O(n)$ time, we may list the predecessors of x in D and in D', do the same for y, and compare these two lists to find such a z. Then (x, y), (y, z), (z, x) is a three-cycle. □

By symmetry, Lemma 6.8 also applies to $D^T \cup D'$. The linear time bound for finding the incompatible pair now follows by Lemma 6.6.

6.3. Proof of Theorem 6.1, Theorem 6.2, and Lemma 6.3. In this subsection, we give a linear-time algorithm to find an odd cycle of length $O(n)$ in the incompatibility graph of G, given an incompatible pair in the orientation assigned to it by the transitive orientation algorithm. We show how to apply the algorithm to $\overline{G}$ in time linear in the size of G.

Let Γ be the relation on arcs, where $(u, w)\Gamma(x, y)$ if $u = x$ and w and y are nonadjacent or $w = y$ and u and x are nonadjacent. (This accepted term has nothing to do with the Γ's defined in section 4.) When $(u, w)\Gamma(x, y)$, any transitive orientation that contains one of the arcs must also contain the other. Let $G = (V, E)$ be an arbitrary undirected graph, and let A_G be its directed arcs. Let Γ_G be the graph (A_G, Γ) whose vertices are the arcs of G and whose edges are the pairs of elements in Γ.

DEFINITION 6.9. *A* transposed path *is a path in Γ_G between an arc (x, y) of G and its transpose (y, x).*

The following is well known.

THEOREM 6.10 (see [7, 8]). *An undirected graph G is a comparability graph iff it has no transposed path.*

LEMMA 6.11. *If there is a transposed path of length at most k in Γ_G, then there is an odd cycle in G's incompatibility graph of length at most $k+1$.*

Proof. Note that $e_1 \Gamma e_2$ iff $e_1 \neq e_2^T$ and $e_1 e_2^T$ is an edge of the incompatibility graph. A path $(e_0, e_1, \ldots, e_k)$ in Γ_G can be turned into a path in Γ_G by replacing each edge of odd index with its transpose. An odd-length path from e_0 to e_0^T in Γ maps to an odd-length cycle from e_0 to e_0 in the incompatibility graph, and an even-length path from e_0 to e_0^T in Γ maps to an even-length path from e_0 to e_0^T in the incompatibility graph, which, together with the edge (e_0^T, e_0), defines an odd cycle in the incompatibility graph. □

Proof of Theorem 6.1. The proof is immediate from Lemma 6.11.

Re-expressing Theorem 6.10 as Theorem 6.1 makes it immediately obvious to a user that the certificate proves that G has no transitive orientation. Since a skeptical user can check an edge of the incompatibility graph in $O(1)$ time, an odd cycle of size $O(n)$ in the incompatibility graph is a sublinear certificate that G is not a comparability graph if the odd cycle has size $O(n)$. However, Γ_G is useful for explaining the algorithm to generate the certificate. The constructive proof of Lemma 6.11 shows how to convert a transposed path to an odd cycle of the incompatibility graph in time proportional to the length of the transposed path.

A *module* of an undirected graph $G = (V, E)$ is a set X of vertices such that for each vertex $y \in V - X$, either every element of X is a neighbor of y or no member of X is a neighbor of y. V, the empty set, and the singleton subsets $\{\{x\}|x \in V\}$ are *trivial modules*. G is *prime* if it has only trivial modules. A set of vertices in G is a module iff it is a module in $\overline{G}$, and hence G is prime iff its complement is prime.

The problem of verifying that G is a comparability graph reduces in linear time to the problem of verifying that a set of prime induced subgraphs is a set of comparability graphs [7, 18]. A transposed path in an induced subgraph is also a transposed path in G. Therefore, when G or $\overline{G}$ is not a comparability graph, producing a transposed path in G or in $\overline{G}$ reduces in linear time to the same problem in the special case where G is prime.

THEOREM 6.12 (see [7, 8]). *Let G be a prime undirected graph. If G is not a comparability graph, then Γ_G has one connected component. Otherwise, Γ_G has two components, where one component contains the transposes of the arcs in the other component.*

We show how to modify the transitive orientation algorithm of [18] so that it creates a record that allows us to find a path of length $O(n)$ in Γ_G between any two arcs that are included in its orientation of a prime graph G.

The transitive orientation algorithm of [18] begins with a partition $\mathcal{P} = \{\{v\}, V - \{v\}\}$ of the vertices V of a prime graph G, where v is a selected *initial lone vertex*. In a process called *vertex partitioning*, it iteratively refines the partition using the following step, until $\mathcal{P}$ is the partition of V into one-element subsets:

- Select a vertex x as a *pivot*, and a partition class Y that does not contain x. Split Y into two classes, $Y_a = Y \cap N(x)$ of vertices that are *adjacent* to x and $Y_n = Y - N(x)$ of vertices that are *nonadjacent* to x. Let $\mathcal{P} := (\mathcal{P} - \{Y\}) \cup \{Y_a, Y_n\}$.

Figure 6 gives an example. Performing the first pivot on the initial lone vertex v splits $V - \{v\}$ into nonneighbors $\{c, f, g\}$ and neighbors $\{a, e, w\}$. Performing a pivot on w then splits the class $\{c, f, g\}$ into neighbors $\{c, f\}$ and nonneighbor $\{g\}$. Performing a pivot on $\{f\}$ then splits $\{a, e, w\}$ into nonneighbor $\{a\}$ and neighbors $\{e, w\}$, etc. Since G is prime, any partition class of size greater than one fails to be a module, so it is always possible to find a pivot that will split it. The vertex partitioning procedure halts when all partition classes are of size 1.

During the partitioning, a linear arrangement of the partition classes is maintained, so that when a set Y is split into two sets, Y_n and Y_a, these two sets occupy consecutive places at the former position of Y, with Y_a placed farther than Y_n from the partition class that contains the pivot. Initially, the lone vertex $\{v\}$ is placed first. For example, in Figure 6, when v splits $\{a, c, e, f, g, w\}$, it is in a class that *precedes* $\{a, c, e, f, g, w\}$, so the neighbors $\{a, e, w\}$ are placed *after* the nonneighbors, $\{c, f, g\}$. In the next step, when w then splits $\{c, f, g\}$, w is in a class that *follows* $\{c, f, g\}$, so

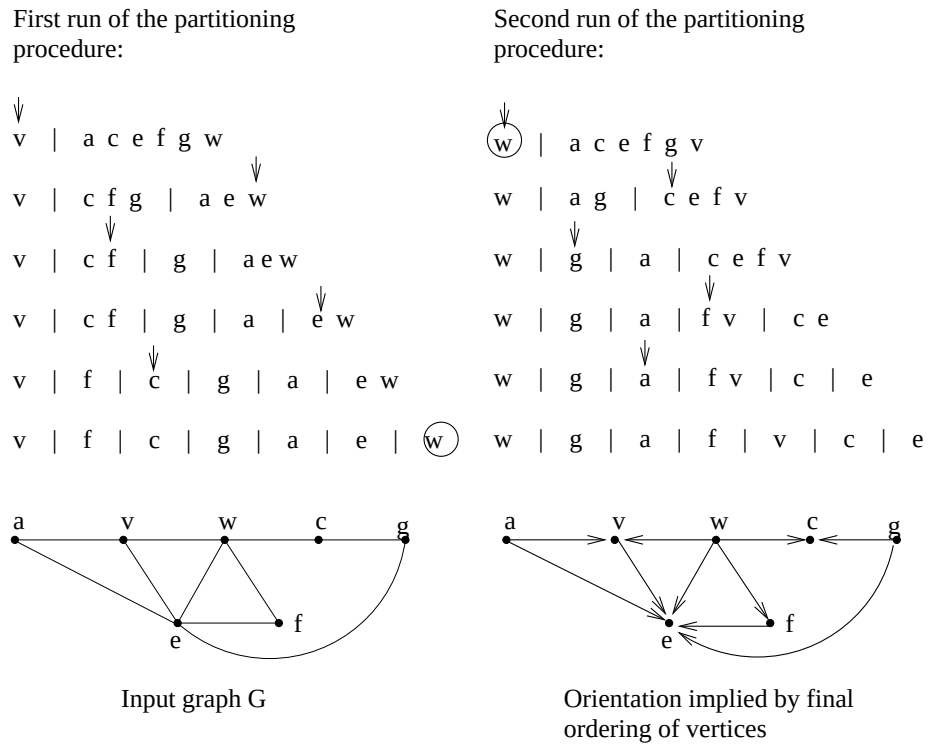

FIG. 6. *The transitive orientation algorithm of* [18] *performs two vertex partition refinements on a prime comparability graph in order to find a linear ordering of the vertices that gives a topological sort of a transitive orientation of the graph. The final ordering given by the second partition,* (w, g, a, f, v, e, c) *in this example, is the topological sort, which gives implicitly the transitive orientation of the graph. Arrows indicate pivot vertices that are used for the next refinement of the partition.*

the neighbors $\{c, f\}$ are placed before the nonneighbor $\{g\}$ in the ordering.

It is shown in [18] that if the initial lone vertex v is a source or sink in a transitive orientation of G, then the final ordering of vertices will be a topological sort of that transitive orientation. Moreover, it is shown that if v is an arbitrary vertex, then the rightmost vertex in the final ordering must be a source or sink in a transitive orientation of G. (The reasons will become apparent below.) Therefore, the procedure is run twice, once starting with arbitrary initial lone vertex v to identify a source/sink w, and once starting with w as the initial lone vertex to find a topological sort of the transitive orientation. Since the topological sort implies the orientations of the edges, this gives the transitive orientation if G is a comparability graph. In the illustration, the ordering (w, g, a, f, v, c, e) produced by the second run of the vertex partitioning gives the transitive orientation depicted in the graph at the bottom.

Let us now examine what happens when G is not a comparability graph. The procedure still produces an ordering of the vertices. Since G has no transitive orientation, this orientation must contain a pair (a, b) and (b, c) of directed edges such that (a, c) is not an edge, namely, an incompatible pair. An incompatible pair does not serve as a certificate that G is not a comparability graph, since it shows only that either G is not a comparability graph or the implementation of the transitive orientation algorithm has a bug.

We therefore seek a mechanism to turn an incompatible pair into a certificate

that G is not a comparability graph.

To accomplish this, we define a *parent* relation on the directed arcs of G that results from the vertex partitioning procedure. Suppose a set Y is split into Y_n and Y_a by a pivot vertex x. Let (y, z) be an arc from Y_n to Y_a. By the definition of Y_n and Y_a, xy is not an edge of G, and xz is, so $(y, z)\Gamma_G(x, z)$ and $(z, y)\Gamma_G(z, x)$. Let (x, z) be the *parent* of (y, z), and let (z, x) be the *parent* of (z, y).

LEMMA 6.13. *If arc a_1 is the parent of arc a_2, then $a_1\Gamma_G a_2$.*

Clearly, every arc has a unique parent except those that are incident to the initial lone vertex, which have no parents. At a given point in the partition refinement, let us say that a directed arc is *protected* if both of its endpoints are currently within a single partition class, and *exposed* if its endpoints are in two different partition classes. The parent relation is acyclic, since the parent is always exposed earlier than the child. All arcs are assigned a parent except those that are incident to the initial lone vertex, so the parent relation arising from one run of the vertex partitioning procedure defines a forest of rooted trees on the arcs of G, and the roots of these trees are the arcs incident to the initial lone vertex.

Let P_1 be the parent relation arising from the first run of the vertex partitioning procedure, which begins with partition $\{\{v\}, V - \{v\}\}$ and discovers a source/sink w. Let P_2 be the parent relation arising from the partition $\{\{w\}, V - \{w\}\}$. The arcs incident to v are the tree roots in P_1, and the arcs incident to w are the tree roots in P_2. Therefore, the only arcs that fail to have parents in both P_1 and P_2 are (v, w) and (w, v). Moreover, since w is in the rightmost class after every pivot during the first run of the partitioning procedure, every time it is in a class that is split by a pivot, it is in the class that contains neighbors of the pivot. Since it is a neighbor of the pivot, the parent of each edge incident to w that gets exposed by the pivot is also incident to w.

Therefore, all arcs incident to w lie in the two trees of P_1 that are rooted at (v, w) and (w, v). Let P_1' be the restriction of P_1 to arcs incident to w; that is, P_1' is two trees rooted at (v, w) and (w, v) that span the arcs incident to w.

It follows that $P_1' \cup P_2$ consists of exactly two trees $T_{(v,w)}$ and $T_{(w,v)}$ that are rooted at (v, w) and (w, v) and that span all directed arcs of G. Whenever a_1 and a_2 are arcs of G where a_1 is a parent of a_2, $a_1\Gamma_G a_2$. By Lemma 6.13, any transitive orientation of G that contains (v, w) must contain every arc in $T_{(v,w)}$ and any transitive orientation of G that contains (w, v) must contain every arc in $T_{(w,v)}$. The arcs spanned by the two trees are the two transitive orientations of G if G has a transitive orientation. Let us therefore call $T_{(v,w)}$ and $T_{(w,v)}$ the *orientation trees*.

Figure 7 depicts one of the two orientation trees produced by the two runs of the vertex partitioning algorithm in Figure 6. Each node is labeled with two vertices and represents the arc from the first vertex label to the second. (The other orientation tree is identical except that the directions of all of the edges are reversed.) The parent relation on arcs determined by the second run (P_2) is shown with solid edges; the parent relation on edges incident to w determined by the first run (P_1') are shown with dashed edges.

Given a parent arc a_1 and child arc a_2, it is easy to check in $O(1)$ time that $a_1\Gamma_G a_2$. Performing this on all parent-child pairs allows a user to confirm in $O(n + m)$ time that *if* G has a transitive orientation, then it must be the orientation consisting of the nodes of one of the two trees. It therefore serves as a certificate either that the precondition that G was a comparability graph was violated or that the orientation is transitive, without identifying which of these two cases occurred. In either case, it exonerates an implementation of the transitive orientation algorithm of providing a

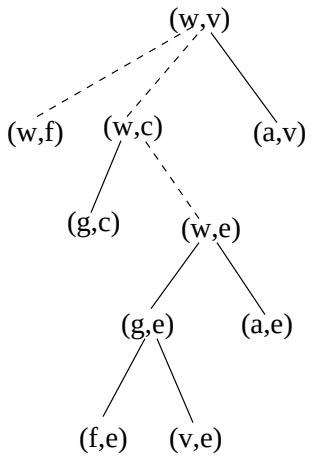

FIG. 7. *The orientation tree defined by the two runs of the vertex partitioning procedure shown in Figure* 6. *Solid edges depict the parent relation implied by the second run of the partitioning procedure and form a forest of trees rooted at arcs incident to* w. *Dashed edges give the parents of edges incident to* w *that are implied by the first run of the partitioning procedure. Together, these edges link this forest together into a tree rooted at* (w, v).

nontransitive orientation of a comparability graph.

In contrast to a simple transitive orientation, the orientation trees contain information that allows us to find a transposed path if G is not a comparability graph. In this case, each of the trees must contain two edges (a, b) and (b, c) that form an incompatible pair, which implies that ac is not an edge of G, and $(b, a)\Gamma_G(b, c)$.

Suppose without loss of generality that (a, b) and (b, c) occur within $T_{(v,w)}$. To document that G is not a comparability graph, we may find the least common ancestor (d, e) of (a, b) and (b, c) in $T_{(v,w)}$. Let $P_{(a,b)}$ be the path from (a, b) to (d, e) and $P_{(b,c)}$ be the path from (b, c) to (d, e) in $T_{(v,w)}$. $P_{(a,b)} \cup P_{(b,c)}$ defines a path in Γ_G from (a, b) to (b, c). Taking these together with $(b, a)\Gamma_G(b, c)$, we get a transposed path from (a, b) to (b, a)—a certificate that G is not a comparability graph.

For instance, suppose edge ae is removed from the graph of Figure 6. The resulting graph is no longer a comparability graph, but it is easy to see that the removal of this particular edge does not affect any of the steps of either of the two runs of the vertex partitioning procedure. Therefore, the transitive orientation algorithm still produces the topological sort (w, g, a, f, v, c, e) of an orientation that contains the incompatible pair $((a, v), (v, c))$. The least common ancestor of (a, v) and (v, e) in the orientation tree of Figure 7 is (w, v). The union of the paths from (a, v) and (v, c) to this least common ancestor forms the path $((v, e), (g, e), (w, e), (w, c), (w, v), (a, v))$ which, together with $((e, v)\Gamma_G(a, v))$, is a transposed path $((v, e), (g, e), (w, e), (w, c), (w, v), (a, v), (e, v))$ from (v, e) to (e, v). A skeptic can check each of the links of this path once they are pointed out and conclude that the graph is not, in fact, a comparability graph.

$T_{(v,w)}$ and $T_{(w,v)}$ have size $O(m)$; we now show how to construct them in $O(m)$ time. For this, we modify the vertex partitioning procedure to produce the data structure pictured on the right side of Figure 8. The construction is illustrated for the run of the vertex partitioning procedure, where w is the initial lone vertex; the data structure, where v is the initial lone vertex, is constructed in the same way. The data structure is a tree whose nodes represent subsets of V. The root of the tree is V, its children are $\{w\}$ and $V - \{w\}$ if w is the initial lone vertex, and the remaining

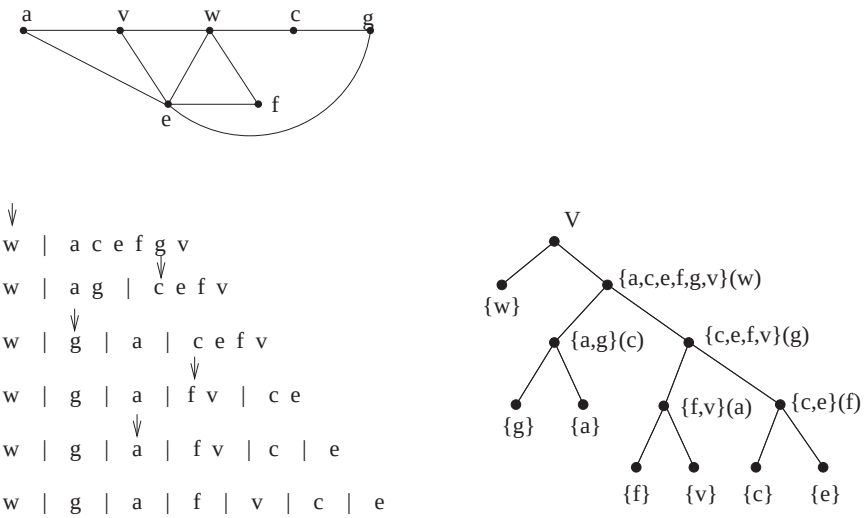

FIG. 8. *The Hasse diagram of a run of the vertex partitioning procedure. If a set Y is split into two sets Y_n and Y_a by a pivot, Y_n and Y_a are its children. In the figure, each set is labeled with its members, as well as the pivot that split it if it is an internal node. For the data structure, it is not necessary to label internal nodes with their members, so the data structure requires $O(n)$ space.*

nodes are the remaining sets that appear at some point during the vertex partitioning procedure. When a partition class Y is split into Y_n and Y_a by a pivot x, Y_n and Y_a are the children of Y. In other words, the tree is the Hasse diagram of the subset relation on the partition classes that appear at some point during the refinement. Let us refer to it as the *Hasse diagram* of the run of the partition refinement algorithm.

Each node is labeled with the identity of the pivot, in parentheses, that caused it to split into its two children during the refinement. For instance, when $\{c, e, f, v\}$ is split into $\{f, v\}$ and $\{c, e\}$ by pivot g, $\{f, v\}$ and $\{c, e\}$ become the children of $\{c, e, f, v\}$, and $\{c, e, f, v\}$ is labeled with the pivot (g) that split it.

To represent this tree with a data structure, we label each leaf with its sole member, and label each internal node only with the pivot that caused it to split, but not with a list of members. The members of the set X represented by an internal node can be found in $O(|X|)$ time by visiting its leaf descendants, which is just as efficient as labeling the node explicitly with the members of X. This allows each internal node to take $O(1)$ space, so the data structure for the Hasse diagram takes $O(n)$ space. The time to construct it does not affect the $O(n + m)$ time to run the vertex partitioning procedure, since it requires creating two children of size $O(1)$ each time a partition class is split by the procedure.

LEMMA 6.14. *Suppose (a, b) is an arc of G. Let Y be the least common ancestor of $\{a\}$ and $\{b\}$ in the Hasse diagram.*

- *If $Y = V$, then (a, b) has no parent.*
- *Otherwise, let c be the pivot that split Y into nonneighbors Y_n and neighbors Y_a of c. Then if $a \in Y_n$ and $b \in Y_a$, then (c, b) is the parent of (a, b), and if $b \in Y_a$ and $a \in Y_n$, then (a, c) is the parent of (a, b).*

Proof. The proof is immediate from the definition of the parent function. □

COROLLARY 6.15. *Given the Hasse diagram and a set A of arcs of G, it takes $O(|A| + n)$ time to find the parents of the members of A.*

Proof. Numbering the leaves from 1 to n in left-to-right order allows one to find, for any two vertices, which is earlier on the leaf order in $O(1)$ time. By the off-line least common ancestors algorithm of Harel and Tarjan [10], given k pairs of nodes in a rooted tree with $O(n)$ nodes, it takes $O(k+n)$ time to find the least common ancestor of each of the k pairs. By the rule for ordering partition classes, for an arc (a,b) with a least common ancestor split by pivot c, $a \in Y_n$ if a is in between b and c in this order, and $b \in Y_n$ otherwise. In the former case, (c,b) is the parent and, in the latter case, (a,c) is the parent. □

COROLLARY 6.16. *It takes $O(n+m)$ time to find the two orientation trees implied by the transitive orientation algorithm.*

Proof. It takes $O(n+m)$ time to get the parents of all arcs not incident to the lone initial vertex w in the parent relation defined by the second run of the partitioning procedure by Corollary 6.15, and it takes $O(n)$ time to get the parents of arcs incident to w, but not v in the first run. The union of these two sets of parent pointers is formed by the two orientation trees. □

Since the arcs of G are nodes of the orientation trees, these trees have $\Theta(m)$ nodes. However, we can now state the following.

COROLLARY 6.17. *The orientation trees have height $O(n)$.*

Proof. Recall that an arc is *exposed* during partitioning at the point when its endpoints are separated into two different partition classes. Each time a partition class splits, the number of partition classes increases by one, and this number is initially equal to one when the initial lone vertex is separated from V and equal to n when the partitioning procedure terminates. Therefore, classes are split at most $n-1$ times. When a split of a class exposes an arc, this means that the parent of the arc was exposed by an earlier split. Therefore, there is no chain longer than $n-1$ in the parent relation implied by one run of the partitioning procedure.

Each path from an arc of G to the arc (w,v) or (v,w) that is the root of the orientation tree follows zero or more parent pointers defined by the second run of the partitioning procedure to arrive at an arc incident to w, followed by zero or more parent pointers defined by the first run of the partitioning procedure, through arcs incident to w, to arrive at (w,v) or (v,w). The height of the tree is therefore at most $2n-2$. □

THEOREM 6.18. *Given an incompatible pair $((a,b),(b,c))$ in the orientation of a graph G produced by the transitive orientation algorithm, it takes $O(n+m)$ time to find an odd cycle of length $O(n)$ in G's incompatibility graph.*

Proof. It takes $O(n+m)$ time to find the orientation tree that contains (a,b) and (b,c) by Corollary 6.16. It takes $O(n)$ time to find the path from (a,b) to (b,c) in this tree by Corollary 6.17. By Lemma 6.13, this path, together with $(b,c)\Gamma_G(b,a)$, is a transposed path from (a,b) to (b,a). The constructive proof of Lemma 6.11 shows how to turn this into an odd cycle of the incompatibility graph of size $O(n)$. □

Proof of Theorem 6.2. The proof is immediate from Theorem 6.18 and Lemma 6.11.

Note that we do not claim an $O(n+m)$ certifying algorithm for recognizing comparability graphs, and no such bound is known for recognizing them, with or without a certificate. The bottleneck for recognition of comparability graphs is finding an incompatible pair in the orientation produced by the algorithm of [18]. It is noteworthy, however, that this gives a certifying algorithm for recognizing comparability graphs that is as fast as any currently known, and that produces a sublinear certificate of rejection.

LEMMA 6.19 (see [18]). *Given a graph G with n vertices and m edges, it takes*

$O(n+m)$ time to find an ordering of the vertices that is a topological sort of a transitive orientation of $\overline{G}$ if $\overline{G}$ is a comparability graph.

The algorithm works by symmetry in the roles of edges and nonedges. It performs the pivots exactly as it does for orienting G, but reverses the roles of the set Y_n of nonneighbors and the set Y_a of neighbors of the pivot. The only effect of this is that it reverses the relative order of Y_n and Y_a when we replace Y with these two sets in the ordering of partition classes. This trick is used in [18] to get linear-time recognition of permutation graphs.

However, one difficulty we now face in producing a certificate that $\overline{G}$ is not a comparability graph in this time bound is that the number of arcs in G, hence the number of nodes of its orientation trees, is $\Theta(n^2 - m)$, which does not conform to our desired $O(n + m)$ time bound. We cannot construct the orientation trees for $\overline{G}$ and stay within our time bound.

Fortunately, given an incompatible pair $((a, b), (b, c))$, the construction of Theorem 6.18 requires us only to find the paths from (a, b) and (b, c) to their least common ancestor in the orientation tree, not the whole orientation tree. These paths have length $O(n)$ by Corollary 6.17.

LEMMA 6.20. *Given an incompatible pair $((a, b), (b, c))$ in the orientation of $\overline{G}$ produced by the algorithm of Lemma* 6.19*, it takes $O(n)$ time to find an odd cycle of size $O(n)$ in the incompatibility graph of $\overline{G}$.*

Proof. Creation of the Hasse diagram is not affected by the modification of the partitioning algorithm for Lemma 6.19. To find the parent of an arc (a, b) of $\overline{G}$ in one run of the partitioning algorithm, mark the ancestors of a in the Hasse diagram. This takes $O(n)$ time. Search upward from b until a marked node is encountered. This is the least common ancestor A_1 of $\{a\}$ and $\{b\}$ in the Hasse diagram. Suppose by induction that the least common ancestor A_k in the Hasse diagram has been found for $\{x\}$ and $\{y\}$, where (x, y) is some ancestor of (a, b) in the parent relation. Let z be the pivot label of this ancestor. Search upward from z until a marked node of the Hasse diagram is encountered. This is the least common ancestor A_{k+1} in the Hasse diagram of the parent of (x, y) in T_1. Since this A_{k+1} is higher in the Hasse diagram than any other least common ancestor found so far, the search upward from z uses a different set of edges of the Hasse diagram from those used by previous upward searches. The cost of this search can be charged to the edges traversed during the search. The cost of finding all ancestors in the Hasse diagram is $O(n)$, and the length of the path is $O(n)$. □

Acknowledgments. The authors would like to thank the two anonymous referees for generous observations, questions, and comments that we have made ample use of in the paper.

LOWER BOUNDS FOR ON-LINE GRAPH PROBLEMS WITH APPLICATION TO ON-LINE CIRCUIT AND OPTICAL ROUTING*

YAIR BARTAL†, AMOS FIAT‡, AND STEFANO LEONARDI§

Abstract. We present lower bounds on the competitive ratio of randomized algorithms for a wide class of on-line graph optimization problems, and we apply such results to on-line virtual circuit and optical routing problems. Lund and Yannakakis [*The approximation of maximum subgraph problems*, in Proceedings of the 20th International Colloquium on Automata, Languages and Programming, 1993, pp. 40–51] give inapproximability results for the problem of finding the largest vertex induced subgraph satisfying any nontrivial, hereditary property π—e.g., independent set, planar, acyclic, bipartite. We consider the on-line version of this family of problems, where some graph G is fixed and some subgraph H of G is presented on-line, vertex by vertex. The on-line algorithm must choose a subset of the vertices of H, choosing or rejecting a vertex when it is presented, whose vertex induced subgraph satisfies property π. Furthermore, we study the on-line version of graph coloring whose off-line version has also been shown to be inapproximable [C. Lund and M. Yannakakis, *On the hardness of approximating minimization problems*, in Proceedings of the 25th ACM Symposium on Theory of Computing, 1993], on-line max edge-disjoint paths, and on-line path coloring problems. Irrespective of the time complexity, we show an $\Omega(n^\epsilon)$ lower bound on the competitive ratio of randomized on-line algorithms for any of these problems. As a consequence, we obtain an $\Omega(n^\epsilon)$ lower bound on the competitive ratio of randomized on-line algorithms for virtual circuit routing on general networks, in contrast to the known results for some specific networks. Similar lower bounds are obtained for on-line optical routing as well.

1. Introduction.

1.1. On-line graph problems.

On-line graph optimization problems have been previously considered in several works: the problem of obtaining a maximal on-line matching in a bipartite graph is considered in [KVV90], the on-line coloring of a three colorable graph is studied in [V90], the problem of coloring an inductive graph is studied in [I90], and randomized lower bounds for on-line graph coloring are given in [HS92].

In all the previous papers, vertices and/or edges arrive on-line, and the on-line algorithm has to make some relevant decision when this happens. The adversary has total freedom to decide what graph will be presented, and in what order the edges/vertices will arrive.

In this paper, we consider a different model, where the graph presented by the

adversary is a subgraph of some (larger) graph that is *known in advance* to the on-line algorithm. Upper bounds that hold for the models of [KVV90, V90, I90, HS92] clearly also hold for the model where the presented graph is a subgraph of some known graph. Lower bounds do not. Lower bounds for the unknown graph model can be trivially translated into our model simply by considering a much larger graph that contains all possible subgraphs. However, the large graph is now exponentially larger than the subgraph, which implies that the lower bound is exponentially smaller.

The motivation for this model is not only theoretical. It allows one to capture problems such as on-line routing in networks. We effectively translate routing problems onto graph problems on a graph related to the original network. It is reasonable to assume that the on-line routing algorithm does not know anything about future communication requests. It is not reasonable to assume that it does not know anything about the routing network itself.

We consider a large set of on-line graph optimization problems. Some of the problems are benefit problems (e.g., find the largest subgraph satisfying a property), and others are cost problems (e.g., color a graph with as few colors as possible).

The graph optimization problems that we consider are listed below. For each such problem we first give the off-line version and then give the on-line variant. The performance of an algorithm for an on-line problem is measured by its *competitive ratio* [ST85]. The competitive ratio for benefit problems is defined as the worst case ratio between the optimal off-line benefit and the on-line benefit. For cost problems the competitive ratio is defined as the worst case ratio between the on-line cost and the optimal off-line cost.

Off-line induced subgraph. Let π be a graph property that is *nontrivial* (i.e., true for infinitely many graphs and false for infinitely many graphs) and *hereditary* (i.e., if a graph G satisfies it, then also any vertex induced subgraph of G satisfies it). Given a graph $G = (V, E)$, find the subset of V of maximum cardinality whose vertex induced subgraph satisfies π.

Such problems include complete graph, independent set, k-colorable, planar, outerplanar, bipartite, complete bipartite, acyclic, degree-constrained, interval, circular-arc, circle graph, chordal, perfect, etc.

Lund and Yannakakis [LY93a] give inapproximability results for this family of problems. Note that in on-line computation, time complexity is not considered, and thus our results do not follow from [LY93a].

On-line induced subgraph. The graph $G = (V, E)$ is known to the on-line algorithm. Vertices $v \in V$ are presented in arbitrary order. The adversary may choose to stop the sequence at any time. The on-line algorithm has to decide whether to accept v or not. The induced graph of the accepted vertices must satisfy property π. The benefit of the on-line algorithm is the cardinality of the set of accepted vertices.

We define the *on-line independent set* problem as the on-line induced subgraph problem for the hereditary property $\pi =$ *independent set*.

Off-line graph coloring. Given a graph $G = (V, E)$, color its vertices with as few colors as possible so that no two adjacent nodes receive the same color.

Lund and Yannakakis [LY93b] also prove inapproximability results for minimum graph coloring.

On-line graph coloring. The graph $G = (V, E)$ is known to the algorithm. At every step, a new vertex $v \in V$ is presented to the on-line algorithm and assigned a color. The adversary may choose to stop the sequence at any time. The coloring must be valid. The cost of the on-line algorithm is given by the number of colors used.

The on-line graph coloring problem has been studied extensively, and determin-

istic and randomized algorithms have been proposed, but only in the setting where the graph is unknown [I90, V90, HS92].

Off-line edge-disjoint paths. The instance is a graph $G = (V, E)$ and a collection $\mathcal{C} = \{(s_1, t_1), \ldots, (s_k, t_k)\}$ of k pairs of vertices. We say that a set of pairs $\{(s_{i_j}, t_{i_j})\}_{j=1}^{m}$ is *consistent* if there exist edge-disjoint paths $\{p_{i_j}\}_{j=1}^{m}$, where p_{i_ℓ} connects s_{i_ℓ} to t_{i_ℓ}. The problem is to find a maximum cardinality consistent subset of $\mathcal{C}$.

On-line edge-disjoint paths. The graph G is known to the algorithm, and at every step the adversary presents a pair of vertices to the on-line algorithm. The on-line algorithm may accept or reject this pair, and for every accepted pair must commit to a route connecting the two vertices, but the set of all accepted pairs must be consistent. The benefit of the on-line algorithm is here defined as the cardinality of the set of accepted pairs.

A variation of this problem is the edge-disjoint fixed paths problem, where an entire path, rather than just its endpoints, is given. The goal is to accept a maximal set of pairwise nonoverlapping paths.

Off-line path coloring. Given a graph $G = (V, E)$ and a collection $\mathcal{C} = \{(s_1, t_1), \ldots, (s_k, t_k)\}$ of k pairs of vertices in G, what is the minimum number of consistent sets of pairs so that their union gives $\mathcal{C}$? This is equivalent to minimizing the number of colors required to color paths between the k endpoints (s_i, t_i) so that no edge is contained in two paths colored with the same color.

On-line path coloring. The graph $G = (V, E)$ is known to the on-line algorithm, and at every step the adversary presents a pair of vertices. The on-line algorithm chooses a color for the two vertices and commits to a route connecting the two vertices. The set of pairs accepted with the same color has to be consistent. The on-line cost is the number of colors used.

For all of the problems above we prove a lower bound of $\Omega(n^\epsilon)$ on the competitive ratio of any on-line algorithm, for some $\epsilon > 0$. This is fairly easy to show for deterministic algorithms; our main contribution is showing that this holds even for randomized on-line algorithms against an oblivious adversary (cf. [BBKTW90]).[1]

We complement these lower bounds results by presenting an algorithm for the on-line induced subgraph problem that achieves a competitive ratio of $O(\frac{n}{\sqrt{\alpha}})$, given a black-box $O(\frac{n}{\alpha})$-approximation algorithm for the induced subgraph problem, and an $O(\frac{n}{\sqrt{\alpha}})$-competitive algorithm for graph coloring if an $O(\frac{n}{\alpha})$-approximation algorithm for independent sets is available.

1.2. Virtual circuit routing problems. The benefit or throughput version of the virtual circuit routing problem is where communication requests require the assignment of a specified bandwidth on a path that connects a transmitter to a receiver, for a given duration and offering a given benefit. Each call can be either accepted and scheduled, observing the bandwidth constraints on all links, or rejected. Following [GG92], we call this problem the *call control* problem.

[1] In a recent paper Kaplan and Szegedy [KS98] pointed out an error in our original proof of Lemma 10 (presented as the proof of an analogous claim in [BFL96]) and gave a corrected version. A correct proof of Lemma 10, along slightly different lines from those in [KS98], is also presented in this paper.

In the conference version of this paper [BFL96] we showed that similar lower bounds also hold in the context of benefit problems for the on-line independent set and the on-line edge-disjoint paths problems when the use of *preemption* is allowed to the randomized algorithm. This means that the on-line algorithm is allowed to discard a previously chosen element (a vertex or a pair) but cannot later change its mind again. These results can be viewed in the on-line version of that report (see [BFL96]).

[GGKMY93] considered the call control problem when the algorithm is allowed to preempt previously accepted calls. They give deterministic preemptive algorithms with a competitive ratio of $O(\log n)$ for a line network, and show that no deterministic algorithm can achieve a better ratio. [BCK+95] studied a preemptive algorithm for a single link and a line topology when the benefit of a call is proportional to the bandwidth duration product. Lower bounds for randomized preemptive algorithms for a single link were given in [CI95]. The authors show an $\Omega\left(\sqrt{\frac{\log \mu}{\log \log \mu}}\right)$ lower bound, where μ is either the ratio between the maximum and the minimum duration or the ratio between the maximum and the minimum benefit of a call.

Nonpreemptive call control was first considered in [AAP93]. They gave throughput competitive algorithms, $O(\log n)$ competitive, for arbitrary networks (not requiring preemption), if every call request bandwidth was for no more than a logarithmic fraction of the minimal link capacity. They also prove an $\Omega(n)$ lower bound on the competitive ratio of deterministic on-line algorithms on general networks if calls may request arbitrary bandwidth.

[ABFR94] considered randomized nonpreemptive algorithms for call control, on tree networks, getting a competitive ratio of $O(\log n)$ when all edge capacities are 1, all bandwidth requests are 1, all durations are infinite, and all benefits are 1. [ABFR94] also showed that problem parameters such as variable bandwidth, call benefit, and call duration can be dealt with by a randomized algorithm at the expense of logarithmic factors in the competitive ratio.

The call control problem when all links have capacity 1, all calls require bandwidth 1, duration is infinite, and all call benefits are 1 is thus a central problem to be considered. This problem is equivalent to the edge-disjoint paths graph problem stated above. Thus, any lower bound on the competitive ratio for edge-disjoint paths is a lower bound for the call control problem. Similarly, an upper bound on the competitive ratio for edge-disjoint paths gives an upper bound on the more general problem using the techniques of [ABFR94].

[AGLR94] give a randomized call control algorithm for the mesh, with a competitive ratio of $O(\log^2 n)$ and an $O(\log D)$ competitive algorithm for trees, where D is the diameter of the tree. In a later paper, [KT95] gave an $O(\log n)$ competitive randomized call control algorithm for the mesh, and extended this result to more general "densely embedded nearly Euclidean" planar graphs. The issue of the variance of randomized on-line algorithms was considered in [LMPR98]. The authors propose randomized on-line competitive algorithms for trees and meshes that both achieve optimal competitive ratio and produce a solution concentrated with good probability around the expectation.

We show an $\Omega(n^{\epsilon})$ lower bound on the competitive ratio of nonpreemptive randomized on-line algorithms for general networks. We give specific networks where this occurs, including a network of degree $\Omega(\log n)$.

1.3. Routing problems in optical networks. In optical networks the bandwidth available on any link is split into many channels, each at a different wavelength. Each transmission is associated with exactly one wavelength that must be available on all links forming a path from the transmitter to the receiver.

The routing problem on optical networks varies considerably, depending on the network model considered. There are a number of models, differing in the nature of network switches.

The basic classification is into the following types:

- Nonreconfigurable networks—also called passive or *switchless* networks—

where a wavelength originating from a transmitting node will always follow a fixed pattern. There may be "switches" that mix and match incoming wavelengths to outgoing links, but these cannot be changed during the operation of the network.

- Reconfigurable networks, which use two different types of switches:
  - elementary switches, which can direct signals coming along one of the input lines to one or more output links, but which cannot differentiate between wavelengths when performing the switch;
  - generalized switches, which are capable of splitting the incoming stream based upon the wavelength.

In all models, the key restriction is that if more than one data item is transmitted along an edge on the same wavelength (color), then they are all unusable.

Optical routing was considered in [RU94, ABC$^+$94, BH93, P92]. Most of that work focuses on the question of how many wavelengths are required to accommodate a given communication traffic.

We consider a number of on-line optical routing problems on both *reconfigurable* optical networks, where all vertices are generalized switches, and *switchless* optical networks. We consider benefit problems, where calls can be accepted or rejected, analogous to the call control problem, and coloring problems, whose goal is to minimize the number of wavelengths (colors) used.

On-line routing in reconfigurable optical networks—benefit version. Calls are presented one-by-one, and calls can be either accepted or rejected. Every accepted call is assigned with a wavelength and can be routed using the generalized switches along a path to be chosen. All calls transmitted along the same wavelength cannot share an edge. If only one wavelength is available, this problem is identical to on-line edge-disjoint paths.

On-line routing in reconfigurable optical networks—coloring version. Calls are presented one-by-one, and all calls have to be accepted and assigned a wavelength and a path linking source to destination. The goal is to minimize the number of wavelengths used, in order to preserve the rule that no two calls on *the same wavelength* can share an edge. The problem is identical to on-line path coloring.

In the switchless cases described below, the routing decisions are very restricted. What does have to be decided is the wavelength to be assigned to any call so that calls do not interfere with one another. Switchless optical networks are modeled as directed acyclic graphs in order to prevent self-interference of transmissions.

Off-line routing in switchless optical networks—benefit version. Consider a directed graph $D = (V, E)$ and a collection $\mathcal{C} = \{(s_1, t_1), \ldots, (s_k, t_k)\}$ of k pairs of vertices. Denote by $R(v)$ the set of vertices of V reachable from v in D via a directed path. We say that two pairs (s_i, t_i), (s_j, t_j) of terminal vertices are *noninterfering* if $t_j \notin R(s_i)$ and $t_i \notin R(s_j)$. The problem on a single wavelength consists of finding a maximum cardinality pairwise noninterfering subset of $\mathcal{C}$.

On-line routing in switchless optical networks—benefit version. The graph D is known to the algorithm. At every step a pair is communicated to the on-line algorithm, which can either accept or reject it; the set of accepted pairs should be pairwise noninterfering. The benefit of the on-line algorithm is the cardinality of the set of accepted calls.

Off-line routing in switchless optical networks—coloring version. Given a directed graph $D = (V, E)$ and a collection $\mathcal{C} = \{(s_i, t_i), \ldots, (s_k, t_k)\}$ of pairs of vertices, what is the minimum number of pairwise noninterfering sets of pairs so that their union

gives $\mathcal{C}$? This can be seen minimizing the number of colors necessary to color the pairs in $\mathcal{C}$, where two pairs with the same color must be noninterfering.

On-line routing in switchless optical networks—coloring version. The on-line algorithm knows some graph D. At each step a new pair of vertices is chosen by the adversary and assigned a color by the on-line algorithm. The on-line algorithm assigns a color so that the pair is noninterfering with all pairs previously assigned with the same color. The on-line cost is the number of colors used.

We show for all these on-line optical routing problems an $\Omega(n^{\epsilon})$ lower bound on the competitive ratio of randomized algorithms.

The results for reconfigurable networks are directly derived from the analogous results for on-line edge-disjoint paths and on-line path coloring.

The results for switchless networks are derived by showing that an independent set is a subproblem of routing in switchless optical networks (benefit version), and that graph coloring is a subproblem of routing in optical switchless networks (coloring version).

1.4. Structure of the paper. In section 2 we give formal definitions of competitive analysis and explain the use of Yao's lemma [Y77] for lower bounds for on-line randomized algorithms.

Section 3 deals with the on-line induced subgraph problem. In section 3.1 we present the lower bound for randomized algorithms for the on-line induced subgraph problem. Finally, section 3.2 gives upper bounds for the on-line induced subgraph problem. We then show in section 4 how the lower bounds for on-line independent sets can be transformed into a lower bound for on-line edge-disjoint paths (and thus for call control).

Section 5 deals with the on-line graph coloring problem. The lower bound for the problem is presented in section 5.1, and upper bounds are presented in section 5.2. The lower bound for on-line graph coloring is then transformed into a lower bound for on-line path coloring in section 6.

Section 7 deals with optical routing. The section contains all the lower bound results that follow from the results in the previous sections. Finally, in section 8 we present the lower bounds for the on-line edge-disjoint fixed paths problem.

2. Competitive analysis of randomized on-line algorithms. We consider problems that consist of a set of request sequences and a set of possible corresponding answers. Given a specific request sequence, an algorithm for the problem must provide an answer in response to each of the requests in the sequence. If the algorithm is on-line, it must base its answer for a particular request upon only the requests presented prior to the current request and the current request itself. A randomized algorithm may use coin tosses to decide upon its answers. An objective function is defined that maps request/answer sequences into the nonnegative reals.

Let A be an algorithm, and let σ be a request sequence. The value of the objective function of algorithm A associated with σ is denoted by $\mathrm{A}(\sigma)$.

Problems are divided into *cost* problems and *benefit* problems.

Cost problems. In the case of cost problems, $\mathrm{A}(\sigma)$ denotes the *cost* of algorithm A, and the goal of the algorithm is to minimize its cost. If A is randomized, the goal is to minimize its expected cost over its coin tosses, $\mathrm{E}[\mathrm{A}(\sigma)]$.

Let ON be an on-line algorithm (possibly randomized) and OPT be an optimal algorithm for some problem.

We say that ON is ρ-competitive [ST85] for a cost problem (against an oblivious

adversary (cf. [BBKTW90])) if there exists a constant a so that for every sequence σ,

$$\mathrm{E}[\mathrm{ON}(\sigma)] \leq \rho \cdot \mathrm{OPT}(\sigma) + a.$$

The value ρ is called the competitive ratio of the algorithm.

Benefit problems. In the case of benefit problems, $\mathrm{A}(\sigma)$ denotes the *benefit* of algorithm A, and the goal of the algorithm is to maximize its benefit. If A is randomized, the goal is to maximize its expected benefit over its coin tosses, $\mathrm{E}[\mathrm{A}(\sigma)]$.

Let ON be an on-line algorithm (possibly randomized) and OPT be an optimal algorithm for some problem.

We say that ON is ρ-competitive for a benefit problem (against an oblivious adversary) if there exists a constant a so that for every sequence σ,

$$\mathrm{OPT}(\sigma) \leq \rho \cdot (\mathrm{E}[\mathrm{ON}(\sigma)] + a).$$

The value ρ is called the competitive ratio of the algorithm.

2.1. Lower bounds using the minimax principle. Lower bounds for on-line randomized algorithms can be proved using Yao's lemma based on the *von Neumann minimax principle* (see [Y77]) applied to on-line algorithms. We need consider only the case where the sequences are finite and the number of deterministic algorithms is finite.

In [BE97] it is shown that in this case the following corollaries can be derived from Yao's lemma.

COROLLARY 1. *Given a cost problem, the following three statements are equivalent:*

1. *ρ is a lower bound on the competitive ratio of randomized on-line algorithms.*
2. *For every constant $a \geq 0$, there exists a probability distribution over request sequences σ such that $\mathrm{OPT}(\sigma) \geq a$ and for any deterministic on-line algorithm*
$$\mathrm{E}\left[\frac{\mathrm{ON}(\sigma)}{\mathrm{OPT}(\sigma)}\right] \geq \rho.$$
3. *For every constant $a \geq 0$, there exists a probability distribution over request sequences σ such that $\mathrm{OPT}(\sigma) \geq a$ and for any deterministic on-line algorithm*
$$\frac{\mathrm{E}[\mathrm{ON}(\sigma)]}{\mathrm{E}[\mathrm{OPT}(\sigma)]} \geq \rho.$$

COROLLARY 2. *Given a benefit problem, the following three statements are equivalent:*

1. *ρ is a lower bound on the competitive ratio of randomized on-line algorithms.*
2. *For every constant $a \geq 0$, there exists a probability distribution over request sequences σ such that $\mathrm{OPT}(\sigma) \geq a$ and for any deterministic on-line algorithm*
$$\mathrm{E}\left[\frac{\mathrm{ON}(\sigma)}{\mathrm{OPT}(\sigma)}\right] \leq \frac{1}{\rho}.$$
3. *For every constant $a \geq 0$, there exists a probability distribution over request sequences σ such that $\mathrm{OPT}(\sigma) \geq a$ and for any deterministic on-line algorithm*
$$\frac{\mathrm{E}[\mathrm{OPT}(\sigma)]}{\mathrm{E}[\mathrm{ON}(\sigma)]} \geq \rho.$$

Note that the expectation in the above corollaries is over the probability distribution on the input sequences.

In the remainder of the paper we sometime slightly abuse notation by using "input sequence from the probability distribution D" in place of the more accurate "input sequence having nonzero probability according to probability distribution D."

In this paper we give lower bounds based on statement 3 in the above corollaries.

3. The on-line induced subgraph problem. In this section we give lower and upper bounds on the competitive ratio of randomized algorithms for the on-line induced subgraph problem.

We start with some properties concerning induced subgraph problems, which will be used later in our proofs.

A graph property π is *hereditary* if, when satisfied for a given graph G, it is also satisfied for any vertex induced subgraph of G. Property π is *nontrivial* if it is satisfied for infinitely many graphs and not satisfied for infinitely many graphs.

Given a graph $G = (V, E)$ and a nontrivial hereditary property π, the induced subgraph problem consists of finding the maximum cardinality induced subgraph satisfying the property π. Any graph H that does not satisfy a hereditary property π is called a *forbidden graph* for π. Observe that any graph G that has H as an induced subgraph does not satisfy π.

For any hereditary property there exists a set of "minimal" forbidden graphs, i.e., forbidden graphs for which every induced proper subgraph satisfies the property. For instance, a K_5 (a clique of 5 vertices) is a minimal forbidden graph for planarity, and a K_2 is a minimal forbidden graph for an independent set.

Given a nontrivial hereditary property π, there is a complementary property π^c that is satisfied for a graph G if and only if π is satisfied for the complemented graph G^c (the graph that contains an edge if and only if G does not contain that edge). The complementary property is also a nontrivial hereditary property. Ramsey's theorem implies that any nontrivial hereditary property is satisfied by all independent sets or by all cliques [LY93a]. Thus, as observed in [LY93a], it is possible to restrict our attention to hereditary nontrivial graph properties that are satisfied for all independent sets.

The graph instances for our lower bounds are based on an application of the following variant of Lemma 9 in [LY93a].

LEMMA 3 (Lund and Yannakakis). *Given any graph H, there exist constants M and α such that for all $n > M$ there exists a graph G on n vertices such that any induced subgraph of G on at least $l = \alpha \log n$ vertices contains H as an induced subgraph.*

Observe that if the graph H of the lemma is a K_c, then G can be a K_n and $l = c$.

Let the graph H of Lemma 3 be a forbidden graph for a nontrivial, hereditary, property π. We base our lower bound constructions on a graph $G = (V, E)$ of n vertices, whose existence is guaranteed by Lemma 3 applied with the specific graph H.

On the basis of this graph G, we build the instance $\tilde{G}$ for the lower bound for the on-line induced subgraph problem.

Recall that in the on-line version of the induced subgraph problem we assume that the graph $\tilde{G}$, from which the adversary draws vertices, is known to the on-line algorithm.

The graph $\tilde{G}$ is built recursively. The vertex set of $\tilde{G}$ is V. In fact, $\tilde{G}$ is simply the graph G with some edges removed. We remove edges so that the "clever" adversary can choose vertices carefully while avoiding including the forbidden graph H as an

induced subgraph of the solution, whereas the on-line algorithm cannot do so well.

We next need to define sequences of requests to the vertices in $\tilde{G}$. Recall that at every step a new vertex is presented to the on-line algorithm, which must decide whether to choose to include it or choose to reject it.

The lower bounds are based on Yao's lemma (see section 2). We recursively define a probability distribution on request sequences in $\tilde{G}$ so that the ratio between the expected benefit of an optimal off-line algorithm and the expected benefit of any deterministic on-line algorithm is $\Omega(n^\epsilon)$.

Section 3.1 describes the graph construction, the definition of the probability distribution, and the analysis of the lower bound on the competitive ratio. In section 3.2 we give upper bounds for the on-line induced subgraph problem.

3.1. Lower bound for randomized algorithms for on-line induced subgraph. Let π be a hereditary nontrivial graph property. Let $G = (V, E)$ be a graph of n vertices such that every induced subgraph of at least $l = \alpha \log n$ vertices is a forbidden graph for property π. As mentioned before, the existence of such a graph for a large enough value of n is given by Lemma 3. For clarity of exposition, we assume that n is a power of 4.

We consider a sequence of $\log_4 n$ partitions of the vertices of $V = \{v_1, v_2, \ldots, v_n\}$. The level 0 partition,

$$P_0 = \{V_0^1 = \{v_1\}, V_0^2 = \{v_2\}, \ldots, V_0^n = \{v_n\}\},$$

consists of n disjoint singleton sets of vertices from V. The level i partition, $0 < i \leq \log_4 n$,

$$P_i = \{V_i^1, V_i^2, \ldots, V_i^{n/4^i}\},$$

is a partition of the vertices of V, where

$$V_i^j = \cup_{k=1}^4 V_{i-1}^{4(j-1)+k}.$$

As a shorthand notation we may use the definition $V_{i-1}^{4(j-1)+k} = V_{i-1,j}^k$, for $1 \leq i \leq \log_4 n$, $1 \leq j \leq n/4^i$, $1 \leq k \leq 4$. Note that $V_{\log_4 n}^1 = V$. Note too that the set $V_i^j = \{v_{(j-1)4^i+1}, \ldots, v_{j \cdot 4^i}\}$.

We now describe the construction of $\tilde{G}$ recursively. The vertex set of $\tilde{G}$ is V. The graph $\tilde{G}$ can be viewed as the graph G with some edges removed.

For all $0 \leq i \leq \log_4 n$ and all $V_i^j \in P_i$ we define graphs $\tilde{G}_i(V_i^j)$ with vertex set equal to V_i^j. The final graph is $\tilde{G} = \tilde{G}_{\log_4 n}(V)$. The graph $\tilde{G}_0(V_0^j)$ is simply the single vertex v_j and has no edges.

The graph $\tilde{G}_i(V_i^j)$, $i > 0$, $j = 1, \ldots, n/4^i$, is constructed from four graphs $\tilde{G}_{i-1,j}^k = \tilde{G}_{i-1}(V_{i-1,j}^k)$, for $k = 1, 2, 3, 4$.

The set of edges of $\tilde{G}_i(V_i^j)$ (see Figure 1) is recursively defined as the union of the set of edges in $\tilde{G}_{i-1,j}^1, \ldots, \tilde{G}_{i-1,j}^4$ and three new sets of edges:

- E^{12}—edges (u, w), $u \in V_{i-1,j}^1$, $w \in V_{i-1,j}^2$, if and only if $(u, w) \in E$;
- E^{13}—edges (u, w), $u \in V_{i-1,j}^1$, $w \in V_{i-1,j}^3$, if and only if $(u, w) \in E$;
- E^{24}—edges (u, w), $u \in V_{i-1,j}^2$, $w \in V_{i-1,j}^4$, if and only if $(u, w) \in E$.

Graph $\tilde{G}_i(V_i^j)$ has $n(i) = 4^i$ vertices.

Note that in general it is not true that the graphs $\tilde{G}_i(V_i^j)$, $V_i^j \in P_i$, are isomorphic. This will be true if $G = K_n$.

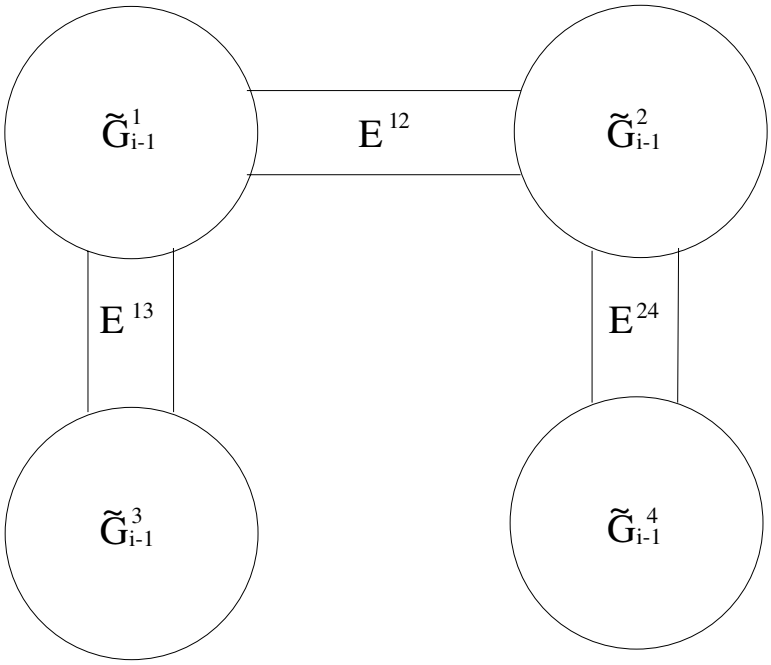

FIG. 1. *The construction of graph* $\tilde{G}_i(V_i^j)$.

We say that two graphs of level $i-1$ connected by edges are *adjacent*. (Observe that in the case that $G = K_n$ a vertex of a graph is connected to all the vertices of an adjacent graph).

We say that $H \subseteq V$ induces a subgraph of G, with respect to $\tilde{G}_i(V_i^j)$, of size m if the following condition holds: There exist m different vertices $\{u_1, u_2, \ldots, u_m\} \subseteq H \cap V_i^j$ such that, for all $1 \leq l, k \leq m$, if $(u_l, u_k) \in E$, then (u_l, u_k) is an edge of $\tilde{G}_i(V_i^j)$.

For a set $H \subseteq V$ and for any $0 \leq i \leq \log_4 n$, $1 \leq j \leq n/4^i$, we define

$$s(\tilde{G}_i(V_i^j), H) = \max\{m | H \text{ induces a subgraph of } G, \text{ with respect to } \tilde{G}_i(V_i^j), \text{ of size } m\};$$

i.e., $s(\tilde{G}_i(V_i^j), H)$ is the size of the largest vertex induced subgraph of $G(V_i^j)$ that is also a vertex induced subgraph of $\tilde{G}_i$ and whose vertices all belong to H. Note that H may contain other vertices not in V_i^j.

Assume that H induces a subgraph I_1 of G with respect to $\tilde{G}^1_{i-1,j}$, and that H also induces a subgraph I_2 of G with respect to $\tilde{G}^2_{i-1,j}$; then H induces a subgraph of G of size $|I_1| + |I_2|$ with respect to $\tilde{G}_i(V_i^j)$. This follows since $H \cap V_i^j \supseteq H \cap V^1_{i-1,j} \cup H \cap V^2_{i-1,j}$, and $\tilde{G}_i^j$ contains all the edges of $\tilde{G}^1_{i-1,j}$ and $\tilde{G}^2_{i-1,j}$ and all the edges between $V^1_{i-1,j}$ and $V^2_{i-1,j}$ that belong to E. A similar argument can be made for the subgraphs induced by H with respect to the pair of graphs $\tilde{G}^1_{i-1,j}$, $\tilde{G}^3_{i-1,j}$, respectively, and likewise for the pair $\tilde{G}^2_{i-1,j}$, $\tilde{G}^4_{i-1,j}$.

To summarize the argument above, the purpose of the edges E^{12}, E^{13}, and E^{24} is to ensure that for all $H \subseteq V$, $1 \le i \le \log_4 n$, and $1 \le j \le n/4^i$

$$\begin{aligned} s(\tilde{G}_i(V_i^j), H) \ge \max\{ & s(\tilde{G}^1_{i-1,j}, H) + s(\tilde{G}^2_{i-1,j}, H), \\ & s(\tilde{G}^3_{i-1,j}, H) + s(\tilde{G}^1_{i-1,j}, H), \\ & s(\tilde{G}^2_{i-1,j}, H) + s(\tilde{G}^4_{i-1,j}, H)\}. \end{aligned}$$

We will now define the probability distribution on the request sequences of vertices of $\tilde{G}$. We will prove for any on-line algorithm ON a lower bound on the ratio ρ between the expected optimal off-line benefit $\mathrm{E}[|OPT(\sigma)|]$ and the expected on-line benefit $\mathrm{E}[|ON(\sigma)|]$. We remark that for our distribution over sequences, the off-line benefit is independent of the choice of sequence.

The probability distribution over the sequences will be a uniform distribution over a set of sequences of vertices. The set of sequences is defined recursively as follows. The set of sequences for the graph $\tilde{G}_0(u)$, $u \in V$, consists of the single sequence $\langle u \rangle$. Let $S(V_i^j)$ denote the set of sequences over V_i^j, $0 \le i \le \log_4 n$, $V_i^j \in P_i$. Also, let $\|$ denote the concatenation operator on sequences.

Given $S(V^1_{i-1,j})$, $S(V^2_{i-1,j})$, $S(V^3_{i-1,j})$, and $S(V^4_{i-1,j})$, $1 \le i \le \log_4 n$, we define the set $S(V_i^j)$ as the result of the following process:

$$S_{12} = \{x \| y \mid x \in S(V^1_{i-1,j}), y \in S(V^2_{i-1,j})\},$$

$$S_{123} = \{x \| y | x \in S_{12}, y \in S(V^3_{i-1,j})\}, \tag{1}$$

$$S_{124} = \{x \| y | x \in S_{12}, y \in S(V^4_{i-1,j})\}, \tag{2}$$

$$S(V_i^j) = S_{123} \cup S_{124}.$$

Claim 4. *In any outcome of the above process (to generate $S(V_i^j)$), $|S_{123}| = |S_{124}|$.*

Proof. From step (1) above we have that $|S_{123}| = |S_{12}| \cdot |S(V^3_{i-1,j})|$, and from step (2) $|S_{124}| = |S_{12}| \cdot |S(V^4_{i-1,j})|$. For any two sets $V^k_{i-1,j}$, $V^\ell_{i-1,j}$, $1 \le k < \ell \le 4$, we can find a mapping $f(u) \mapsto w$, $u \in V^k_{i-1,j}$, $w \in V^\ell_{i-1,j}$, such that both sets and their recursive partitions into subsets are isomorphic under f. Specifically, $f(v_t) = v_{t+(\ell-k)4^{i-1}}$ will be such a mapping. Thus, $|S(V^3_{i-1,j})| = |S(V^4_{i-1,j})|$, and it now follows that $|S_{123}| = |S_{124}|$. ∎

Define the probability distribution $U(S)$, where S is a set of sequences to be the uniform distribution over S. Let $T \subset V$; the notation $\sigma|T$ denotes the sequence derived from σ by removing all elements in $V - T$. Let $T' \subseteq T \subseteq V$, where $S(T)$ and $S(T')$ are defined (i.e., $T = V_i^j$ and $T' = V_{i'}^{j'}$ for some i, j, i', j'). Define the restriction of $S(T)$ to T', i.e., $S(T|T') = \{\sigma|T' | \sigma \in S(T)\}$. $U(S(T|T'))$ is a distribution over $S(T')$.

Claim 5. *$U(S(V_i^j|V^k_{i-1,j})) = U(S(V^k_{i-1,j}))$ for $k = 1, \ldots, 4$.*

Proof. Every sequence in $S(V^k_{i-1,j})$ appears as a subsequence of the same number of sequences in $S(V_i^j)$. ∎

Let A be any algorithm (on-line or off-line), and let σ be a sequence of vertices from V. Let $A(\sigma)$ denote the set of vertices chosen by the algorithm. ($A(\sigma)$ induces a subgraph of $\tilde{G}(V)$ satisfying property π.)

Lemma 6. *For any $0 \le i \le \log_4 n$, $1 \le j \le n/4^i$, and any sequence $\sigma \in S(V_i^j)$, $|\mathrm{OPT}(\sigma)| \ge 2^i$.*

Proof. Given any sequence $\sigma \in S(V_i^j)$, we will prove by induction on i that the set of vertices in σ contains a subset of vertices $I(\sigma) \subseteq V_i^j$, $|I(\sigma)| = 2^i$, where $I(\sigma)$ is an independent set in $\tilde{G}_i(V_i^j)$. (And thus $I(\sigma)$ obeys property π—OPT *can* choose all vertices in $I(\sigma)$ giving $|\mathrm{OPT}(\sigma)| \geq 2^i$.)

The claim is clearly true for $i = 0$. Assume that the inductive hypothesis holds for $i-1$: Let τ be any sequence in $S(V_{i-1}^\ell)$, $1 \leq \ell \leq n/4^{i-1}$. The set of vertices in τ contain a subset of vertices $I(\tau) \subseteq V_{i-1}^\ell$, $|I(\tau)| \geq 2^{i-1}$, where $I(\tau)$ is an independent set in $\tilde{G}_{i-1}(V_{i-1}^\ell)$.

Without loss of generality, assume that $\sigma \in S_{123}$ from the construction. By construction (of S_{123}) there are disjoint subsequences of σ, $\tau_2 \in S(V_{i-1,j}^2)$ and $\tau_3 \in S(V_{i-1,j}^3)$. By the inductive hypothesis, there exist $I(\tau_2) \subseteq V_{i-1,j}^2$, $I(\tau_3) \subseteq V_{i-1,j}^3$, $|I(\tau_2)| = 2^{i-1}$, and $|I(\tau_3)| = 2^{i-1}$, where $I(\tau_2)$ is an independent set in $\tilde{G}_{i-1}(V_{i-1,j}^2)$, and $I(\tau_3)$ is an independent set in $\tilde{G}_{i-1}(V_{i-1,j}^3)$.

Letting $I(\sigma) = I(\tau_2) \cup I(\tau_3)$, we claim that $I(\sigma)$ is an independent set in $\tilde{G}_i(V_i^j)$; this follows because there are no edges in $\tilde{G}_i(V_i^j)$ between the sets $V_{i-1,j}^2$ and $V_{i-1,j}^3$.

It is also true that $|I(\sigma)| = |I(\tau_2)| + |I(\tau_3)| = 2^i$.

If $\sigma \in S_{124}$, then the same argument works, with $V_{i-1,j}^1$ taking the place of $V_{i-1,j}^2$ and $V_{i-1,j}^4$ taking the place of $V_{i-1,j}^3$. □

Let $E_{x \in_R D}[r(x)]$ denote the expectation of the random variable $r(x)$, where x is chosen from the distribution D.

Claim 7. *Given an online algorithm ON, a subset $T \subseteq V$, and sequences τ', τ'' of vertices from $V - T$, then for any sequence τ of vertices from T there is an online algorithm $ON^{\tau'}$ such that*

$$ON(\tau' \| \tau \| \tau'') \cap T = ON^{\tau'}(\tau).$$

Proof. $ON^{\tau'}$ emulates the execution of ON as follows. For any τ, $ON^{\tau'}$ accepts τ_ℓ if and only if ON would accept τ_ℓ after seeing the input sequence $\tau' \| \langle \tau_1, \tau_2, \ldots, \tau_\ell \rangle$. Note that any vertices accepted in τ' or τ'' are not in T, and therefore

$$ON(\tau' \| \tau \| \tau'') \cap T = ON^{\tau'}(\tau). \qquad \square$$

Example. Let ON be an online algorithm, and assume that $\sigma \in S_{123}$ from the construction. By construction (of S_{123}), σ is the concatenation of three disjoint subsequences: $\tau_1 \in S(V_{i-1,j}^1)$, $\tau_2 \in S(V_{i-1,j}^2)$, and $\tau_3 \in S(V_{i-1,j}^3)$. We have $ON(\tau_1) = ON(\sigma) \cap V_{i-1,j}^1$, $ON^{\tau_1}(\tau_2) = ON(\sigma) \cap V_{i-1,j}^2$, and $ON^{\tau_1 \| \tau_2}(\tau_3) = ON(\sigma) \cap V_{i-1,j}^3$.

Lemma 8. *For any deterministic online algorithm ON and a sequence of vertices from V_i^j, $0 \leq i \leq \log_4 n$, $1 \leq j \leq n/4^i$, the following hold:*

$$(3)\quad E_{\sigma \in_R U(S(V_i^j))}[|ON(\sigma) \cap V_{i-1,j}^1|] = E_{\tau_1 \in_R U(S(V_{i-1,j}^1))}[|ON(\tau_1)|],$$

$$(4)\quad E_{\sigma \in_R U(S(V_i^j))}[|ON(\sigma) \cap V_{i-1,j}^2|] = E_{\tau_1 \in_R U(S(V_{i-1,j}^1))} E_{\tau_2 \in_R U(S(V_{i-1,j}^2))}[|ON^{\tau_1}(\tau_2)|],$$

$$(5)\quad E_{\sigma \in_R U(S(V_i^j))}[|ON(\sigma) \cap V_{i-1,j}^3|] = \frac{1}{2} E_{\tau_1 \in_R U(S(V_{i-1,j}^1))} E_{\tau_2 \in_R U(S(V_{i-1,j}^2))} E_{\tau_3 \in_R U(S(V_{i-1,j}^3))}[|ON^{\tau_1 \| \tau_2}(\tau_3)|],$$

$$(6)\quad E_{\sigma \in_R U(S(V_i^j))}[|ON(\sigma) \cap V_{i-1,j}^4|] = \frac{1}{2} E_{\tau_1 \in_R U(S(V_{i-1,j}^1))} E_{\tau_2 \in_R U(S(V_{i-1,j}^2))} E_{\tau_4 \in_R U(S(V_{i-1,j}^4))}[|ON^{\tau_1 \| \tau_2}(\tau_4)|].$$

Proof. Let $\sigma = \tau_1\|\tau_2\|\tau'$, where $\tau_1 \in S(V^1_{i-1,j})$, $\tau_2 \in S(V^2_{i-1,j})$, and $\tau' \in S(V^3_{i-1,j}) \cup S(V^4_{i-1,j})$.

To prove (3) above we have

$$E_{\sigma\in_R U(S(V_i^j))}[|ON(\sigma)\cap V^1_{i-1,j}|] \tag{7}$$
$$= \frac{\sum_{\sigma\in S(V_i^j)}|ON(\sigma)\cap V^1_{i-1,j}|}{|S(V_i^j)|}$$
$$= \frac{\sum_{\tau_1\|\tau_2\|\tau'\in S(V_i^j)}|ON(\tau_1\|\tau_2\|\tau')\cap V^1_{i-1,j}|}{|S(V_i^j)|} \tag{8}$$
$$= \frac{\sum_{\tau_1\|\tau_2\|\tau'\in S(V_i^j)}|ON(\tau_1)|}{|S(V_i^j)|} \tag{9}$$
$$= \frac{|S(V^2_{i-1,j})|\cdot(|S(V^3_{i-1,j})|+|S(V^4_{i-1,j})|)\cdot\sum_{\tau_1\in S(V^1_{i-1,j})}|ON(\tau_1)|}{|S(V^1_{i-1,j})|\cdot|S(V^2_{i-1,j})|\cdot(|S(V^3_{i-1,j})|+|S(V^4_{i-1,j})|)} \tag{10}$$
$$= E_{\tau_1\in_R U((V^1_{i-1,j}))}|ON(\tau_1)|. \tag{11}$$

Equation (7) follows from the definition of the expectation. In (8) we substitute $\tau_1\|\tau_2\|\tau'$ for σ. As $\tau_2\cap V^1_{i-1,j} = \tau'\cap V^1_{i-1,j} = \emptyset$, we get that $ON(\tau_1\|\tau_2\|\tau')\cap V^1_{i-1,j} = ON(\tau_1)$, giving (9). Using that

$$|S(V_i^j)| = |S(V^1_{i-1,j})|\cdot|S(V^2_{i-1,j})|\cdot(|S(V^3_{i-1,j})|+|S(V^4_{i-1,j})|),$$

we derive (10) and (11).

To prove (4) above we have

$$E_{\sigma\in_R U(S(V_i^j))}[|ON(\sigma)\cap V^2_{i-1,j}|] \tag{12}$$
$$= \frac{\sum_{\sigma\in S(V_i^j)}|ON(\sigma)\cap V^2_{i-1,j}|}{|S(V_i^j)|}$$
$$= \frac{\sum_{\tau_1\|\tau_2\|\tau'\in S(V_i^j)}|ON(\tau_1\|\tau_2\|\tau')\cap V^2_{i-1,j}|}{|S(V_i^j)|} \tag{13}$$
$$= \frac{\sum_{\tau_1\|\tau_2\|\tau'\in S(V_i^j)}|ON^{\tau_1}(\tau_2)|}{|S(V_i^j)|} \tag{14}$$
$$= \frac{(|S(V^3_{i-1,j})|+|S(V^4_{i-1,j})|)\cdot\sum_{\tau_1\in S(V^1_{i-1,j}),\tau_2\in S(V^2_{i-1,j})}|ON^{\tau_1}(\tau_2)|}{|S(V^1_{i-1,j})|\cdot|S(V^2_{i-1,j})|\cdot(|S(V^3_{i-1,j})|+|S(V^4_{i-1,j})|)} \tag{15}$$
$$= E_{\tau_1\in_R U(S(V^1_{i-1,j}))}E_{\tau_2\in_R U(S(V^2_{i-1,j}))}|ON^{\tau_1}(\tau_2)|.$$

We derive (12) by definition of the expectation, (13) substitutes $\tau_1\|\tau_2\|\tau'$ for σ, and using Claim 7, we get (14). Next, we note that

$$\sum_{\tau_1\|\tau_2\|\tau'\in S(V_i^j)} f(\tau_1,\tau_2) = (|S(V^3_{i-1,j})|+|S(V^4_{i-1,j})|)\sum_{\tau_1\in V^1_{i-1,j},\tau_2\in V^2_{i-1,j}} f(\tau_1,\tau_2).$$

Our final simplification (15) follows from the definition of the expectation.

Next we prove (5). Equation (6) is analogous and can be derived similarly. We have

$$E_{\sigma\in_R U(S(V_i^j))}[|ON(\sigma)\cap V_{i-1,j}^3|] \tag{16}$$

$$= \frac{\sum_{\sigma\in S(V_i^j)}|ON(\sigma)\cap V_{i-1,j}^3|}{|S(V_i^j)|}$$

$$= \frac{\sum_{\tau_1\|\tau_2\|\tau'\in S(V_i^j)}|ON(\tau_1\|\tau_2\|\tau')\cap V_{i-1,j}^3|}{|S(V_i^j)|} \tag{17}$$

$$= \frac{\sum_{\tau_1\in S(V_{i-1,j}^1),\tau_2\in S(V_{i-1,j}^2),\tau_3\in S(V_{i-1,j}^3)}|ON^{\tau_1\|\tau_2}(\tau_3)|}{|S(V_{i-1,j}^1)|\cdot|S(V_{i-1,j}^2)|\cdot(|S(V_{i-1,j}^3)|+|S(V_{i-1,j}^4)|)} \tag{18}$$

$$= \frac{1}{2}\frac{\sum_{\tau_1\in S(V_{i-1,j}^1),\tau_2\in S(V_{i-1,j}^2),\tau_3\in S(V_{i-1,j}^3)}|ON^{\tau_1\|\tau_2}(\tau_3)|}{|S(V_{i-1,j}^1)|\cdot|S(V_{i-1,j}^2)|\cdot|S(V_{i-1,j}^3)|} \tag{19}$$

$$= \frac{1}{2}E_{\tau_1\in_R U(S(V_{i-1,j}^1))}E_{\tau_2\in_R U(S(V_{i-1,j}^2))}E_{\tau_3\in_R U(S(V_{i-1,j}^3))}[|ON^{\tau_1\|\tau_2}(\tau_3)|]. \tag{20}$$

We derive (16) by definition of the expectation, (17) substitutes $\tau_1\|\tau_2\|\tau'$ for σ, by noting that $ON(\tau_1\|\tau_2\|\tau')\cap V_{i-1,j}^3$ is empty when $\tau'\in S(V_{i-1,j}^4)$, and using Claim 7, we get (18). Equation (19) follows from Claim 4. Our final simplification (20) follows from the definition of the expectation. □

Given an on-line algorithm ON, define $s_i^j(\sigma, ON)$ to be $s(\tilde{G}_i(V_i^j), ON(\sigma))$, the size of the largest subgraph of G induced by $ON(\sigma)$ with respect to $\tilde{G}_i(V_i^j)$. Likewise define $s_{i-1,j}^k(\sigma, ON)$ to be $s(\tilde{G}_{i-1}(V_{i-1,j}^k), ON(\sigma))$, for $k = 1, 2, 3, 4$.

CLAIM 9. *For any deterministic on-line algorithm ON defined on sequences of vertices from V_i^j, $0 \le i \le \log_4 n$, $1 \le j \le n/4^i$, and for any $\tau_1 \in S(V_{i-1,j}^1), \tau_2 \in S(V_{i-1,j}^2), \tau_3 \in S(V_{i-1,j}^3), \tau_4 \in S(V_{i-1,j}^4)$ the following hold:*

$$s_{i-1,j}^2(\tau_2, ON^{\tau_1}) = s_{i-1,j}^2(\tau_1\|\tau_2, ON), \tag{21}$$

$$s_{i-1,j}^3(\tau_3, ON^{\tau_1\|\tau_2}) = s_{i-1,j}^3(\tau_1\|\tau_2\|\tau_3, ON), \tag{22}$$

$$s_{i-1,j}^4(\tau_4, ON^{\tau_1\|\tau_2}) = s_{i-1,j}^4(\tau_1\|\tau_2\|\tau_4, ON). \tag{23}$$

Proof. The proof follows from the definitions of ON^τ and s_i^j. □

LEMMA 10. *For any $0 \le i \le \log_4 n$, $1 \le j \le n/4^i$, the expected benefit of any deterministic on-line algorithm over the distribution $U(S(V_i^j))$ satisfies*

$$E_{\sigma\in_R U(S(V_i^j))}[|ON(\sigma)|] \le \left(\frac{3}{2}\right)^i E_{\sigma\in_R U(S(V_i^j))}[s_i^j(\sigma, ON)].$$

Proof. We prove the claim by induction on i. Consider an algorithm ON. The claim holds for $i = 0$, and any $1 \le j \le n$ (V_0^j is a single vertex). We assume by induction that the claim holds for all probability distributions $U(S(V_{i-1}^j))$, $1 \le j \le n/4^{i-1}$, which means in particular that it holds for the probability distributions $U(S(V_{i-1,j}^k))$, $1 \le j \le n/4^i$, $k = 1, 2, 3, 4$.

We prove the claim as follows:

$$
\begin{aligned}
&E_{\sigma\in_R U(S(V_i^j))}[|ON(\sigma)|]\\
&\quad= E_{\sigma\in_R U(S(V_i^j))}[|ON(\sigma)\cap V_{i-1,j}^1|]\\
&\qquad+E_{\sigma\in_R U(S(V_i^j))}[|ON(\sigma)\cap V_{i-1,j}^2|]\\
&\qquad+E_{\sigma\in_R U(S(V_i^j))}[|ON(\sigma)\cap V_{i-1,j}^3|]\\
&\qquad+E_{\sigma\in_R U(S(V_i^j))}[|ON(\sigma)\cap V_{i-1,j}^4|]\\
&\quad= E_{\tau_1\in_R U(S(V_{i-1,j}^1))}[|ON(\tau_1)|]\\
&\qquad+E_{\tau_1\in_R U(S(V_{i-1,j}^1))}E_{\tau_2\in_R U(S(V_{i-1,j}^2))}[|ON^{\tau_1}(\tau_2)|]\\
&\qquad+\frac{1}{2}E_{\tau_1\in_R U(S(V_{i-1,j}^1))}E_{\tau_2\in_R U(S(V_{i-1,j}^2))}E_{\tau_3\in_R U(S(V_{i-1,j}^3))}[|ON^{\tau_1\|\tau_2}(\tau_3)|]\\
&\qquad+\frac{1}{2}E_{\tau_1\in_R U(S(V_{i-1,j}^1))}E_{\tau_2\in_R U(S(V_{i-1,j}^2))}E_{\tau_4\in_R U(S(V_{i-1,j}^4))}[|ON^{\tau_1\|\tau_2}(\tau_4)|].
\end{aligned}
\tag{24}
$$

By the inductive hypothesis we get that (24) is at most

$$
\left(\frac{3}{2}\right)^{i-1}\left\{\begin{array}{l}
E_{\tau_1\in_R U(S(V_{i-1,j}^1))}[s_{i-1,j}^1(\tau_1,ON)]\\
\quad+E_{\tau_1\in_R U(S(V_{i-1,j}^1))}E_{\tau_2\in_R U(S(V_{i-1,j}^2))}[s_{i-1,j}^2(\tau_2,ON^{\tau_1})]\\
\quad+\frac{1}{2}E_{\tau_1\in_R U(S(V_{i-1,j}^1))}E_{\tau_2\in_R U(S(V_{i-1,j}^2))}E_{\tau_3\in_R U(S(V_{i-1,j}^3))}[s_{i-1,j}^3(\tau_3,ON^{\tau_1\|\tau_2})]\\
\quad+\frac{1}{2}E_{\tau_1\in_R U(S(V_{i-1,j}^1))}E_{\tau_2\in_R U(S(V_{i-1,j}^2))}E_{\tau_4\in_R U(S(V_{i-1,j}^4))}[s_{i-1,j}^4(\tau_4,ON^{\tau_1\|\tau_2})]
\end{array}\right\}.
\tag{25}
$$

We have

$$
\begin{aligned}
&E_{\tau_1\in_R U(S(V_{i-1,j}^1))}[s_{i-1,j}^1(\tau_1,ON)]\\
&\quad=\frac{1}{2}E_{\tau_1\in_R U(S(V_{i-1,j}^1))}E_{\tau_2\in_R U(S(V_{i-1,j}^2))}E_{\tau_3\in_R U(S(V_{i-1,j}^3))}[s_{i-1,j}^1(\tau_1,ON)]\\
&\qquad+\frac{1}{2}E_{\tau_1\in_R U(S(V_{i-1,j}^1))}E_{\tau_2\in_R U(S(V_{i-1,j}^2))}[s_{i-1,j}^1(\tau_1,ON)],\\
&E_{\tau_1\in_R U(S(V_{i-1,j}^1))}E_{\tau_2\in_R U(S(V_{i-1,j}^2))}[s_{i-1,j}^2(\tau_2,ON^{\tau_1})]\\
&\quad=\frac{1}{2}E_{\tau_1\in_R U(S(V_{i-1,j}^1))}E_{\tau_2\in_R U(S(V_{i-1,j}^2))}[s_{i-1,j}^2(\tau_2,ON^{\tau_1})]\\
&\qquad+\frac{1}{2}E_{\tau_1\in_R U(S(V_{i-1,j}^1))}E_{\tau_2\in_R U(S(V_{i-1,j}^2))}E_{\tau_4\in_R U(S(V_{i-1,j}^4))}[s_{i-1,j}^2(\tau_2,ON^{\tau_1})].
\end{aligned}
$$

Thus, we get that (25) is equal to

$$
\left(\frac{3}{2}\right)^{i-1}\frac{1}{2}\left\{\begin{array}{l}
E_{\tau_1\in_R U(S(V_{i-1,j}^1))}E_{\tau_2\in_R U(S(V_{i-1,j}^2))}E_{\tau_3\in_R U(S(V_{i-1,j}^3))}\\
\qquad\cdot[s_{i-1,j}^1(\tau_1,ON)+s_{i-1,j}^3(\tau_3,ON^{\tau_1\|\tau_2})]\\
+E_{\tau_1\in_R U(S(V_{i-1,j}^1))}E_{\tau_2\in_R U(S(V_{i-1,j}^2))}E_{\tau_4\in_R U(S(V_{i-1,j}^4))}\\
\qquad\cdot[s_{i-1,j}^2(\tau_2,ON^{\tau_1})+s_{i-1,j}^4(\tau_4,ON^{\tau_1\|\tau_2})]\\
+E_{\tau_1\in_R U(S(V_{i-1,j}^1))}E_{\tau_2\in_R U(S(V_{i-1,j}^2))}[s_{i-1,j}^1(\tau_1,ON)+s_{i-1,j}^2(\tau_2,ON^{\tau_1})]
\end{array}\right\}.
\tag{26}
$$

Using Claim 9, we get that (26) is equal to

$$\left(\left(\frac{3}{2}\right)^{i-1}\cdot\frac{1}{2}\right)\cdot$$

$$\left\{\begin{array}{l} E_{\tau_1\in_R U(S(V^1_{i-1,j}))}E_{\tau_2\in_R U(S(V^2_{i-1,j}))}E_{\tau_3\in_R U(S(V^3_{i-1,j}))}[s^1_{i-1,j}(\tau_1\|\tau_2\|\tau_3,ON) \\ \qquad\qquad + s^3_{i-1,j}(\tau_1\|\tau_2\|\tau_3,ON)] \\ + E_{\tau_1\in_R U(S(V^1_{i-1,j}))}E_{\tau_2\in_R U(S(V^2_{i-1,j}))}E_{\tau_4\in_R U(S(V^4_{i-1,j}))}[s^2_{i-1,j}(\tau_1\|\tau_2\|\tau_4,ON) \\ \qquad\qquad + s^4_{i-1,j}(\tau_1\|\tau_2\|\tau_4,ON)] \\ + E_{\tau_1\in_R U(S(V^1_{i-1,j}))}E_{\tau_2\in_R U(S(V^2_{i-1,j}))}[s^1_{i-1,j}(\tau_1\|\tau_2,ON)+s^2_{i-1,j}(\tau_1\|\tau_2,ON)] \end{array}\right\}.$$

We now have

$$\begin{aligned} &E_{\sigma\in_R U(S(V^j_i))}[s^j_i(\sigma,ON)] \\ &\geq \frac{1}{2}E_{\tau_1\in_R U(S(V^1_{i-1,j}))}E_{\tau_2\in_R U(S(V^2_{i-1,j}))}E_{\tau_3\in_R U(S(V^3_{i-1,j}))} \\ &\qquad\cdot[s^1_{i-1,j}(\tau_1\|\tau_2\|\tau_3,ON)+s^3_{i-1,j}(\tau_1\|\tau_2\|\tau_3,ON)] \\ &\quad+\frac{1}{2}E_{\tau_1\in_R U(S(V^1_{i-1,j}))}E_{\tau_2\in_R U(S(V^2_{i-1,j}))}E_{\tau_4\in_R U(S(V^4_{i-1,j}))} \\ &\qquad\cdot[s^2_{i-1,j}(\tau_1\|\tau_2\|\tau_4,ON)+s^4_{i-1,j}(\tau_1\|\tau_2\|\tau_4,ON)] \end{aligned} \tag{27}$$

and

$$\begin{aligned} &E_{\sigma\in_R U(S(V^j_i))}[s^j_i(\sigma,ON)] \\ &\geq E_{\tau_1\in_R U(S(V^1_{i-1,j}))}E_{\tau_2\in_R U(S(V^2_{i-1,j}))}[s^1_{i-1,j}(\tau_1\|\tau_2,ON)+s^2_{i-1,j}(\tau_1\|\tau_2,ON)]. \end{aligned} \tag{28}$$

The lemma follows from (27) and (28). □

We then conclude with the following result.

THEOREM 11. *Any randomized algorithm for the on-line induced subgraph problem has competitive ratio* $\Omega(n^{1-\log_4 3-o(1)})$. *For a hereditary property having a* K_c *as forbidden graph the competitive ratio is* $\Omega(n^{1-\log_4 3})$.

Proof. By Lemmas 6 and 10 we have the following. For any $0 \leq i \leq \log_4 n$, $1 \leq j \leq n/4^i$, and any sequence $\sigma \in S(V^j_i)$, $|\mathrm{OPT}(\sigma)| \geq 2^i$. For any $0 \leq i \leq \log_4 n$, $1 \leq j \leq n/4^i$, the expected benefit of any deterministic on-line algorithm over the distribution $U(S(V^j_i))$ satisfies

$$E_{\sigma\in_R U(S(V^j_i))}[|ON(\sigma)|] \leq \left(\frac{3}{2}\right)^i E_{\sigma\in_R U(S(V^j_i))}[s^j_i(\sigma,ON)].$$

The ratio $\rho(i,j)$ between the expected optimal benefit and the expected on-line benefit for the probability distribution on the input sequences $U(S(V^j_i))$, $1 \leq i \leq \log_4 n$, $1 \leq j \leq n/4^i$, is

$$\begin{aligned} \rho(i,j) &= \frac{E_{\sigma\in_R U(S(V^j_i))}[|\mathrm{OPT}(\sigma)|]}{E_{\sigma\in_R U(S(V^j_i))}[|\mathrm{ON}(\sigma)|]} && \geq \frac{2^i}{\left(\frac{3}{2}\right)^i \mathrm{E}_{\sigma\in_R U(S(V^j_i))}[s^j_i(\sigma,ON)]} \\ &\geq \frac{4^i}{3^i E_{\sigma\in_R U(S(V^j_i))}[s^j_i(\sigma,ON)]} && = \frac{n(i)}{3^{\log_4 n(i)} E_{\sigma\in_R U(S(V^j_i))}[s^j_i(\sigma,ON)]} \\ &= \frac{n(i)}{n(i)^{\log_4 3} E_{\sigma\in_R U(S(V^j_i))}[s^j_i(\sigma,ON)]} && = \frac{n(i)^{1-\log_4 3}}{E_{\sigma\in_R U(S(V^j_i))}[s^j_i(\sigma,ON)]}. \end{aligned}$$

From Lemma 3 it follows that $E_{\sigma \in_R U(S(V_i^j))}[s_i^j(\sigma, ON)] < l = \alpha \log n$. Therefore, for $i = \log_4 n$, we obtain the $\Omega(n^{1-\log_4 3-o(1)})$ lower bound on the competitive ratio. If the forbidden graph is a K_c and G is a K_n, then $l = c$ and we get an $\Omega(n^{1-\log_4 3})$ lower bound. □

3.2. Upper bounds for the on-line induced subgraph problem. In this section we give upper bounds for the on-line induced subgraph problem. The upper bounds are based on algorithms that compute an approximate solution for the off-line maximum induced subgraph problem.

We present a randomized algorithm based on the "classify and randomly select" method of [ABFR94].

Let $G = (V, E)$ be the graph that we assume is known to the on-line algorithm. The algorithm requires a preprocessing phase in which a collection of k solutions $I_1, I_2, \ldots, I_k$ of the induced subgraph problem for the graph G are computed, as follows.

Let $G_1 = G$, and $G_{i+1} = G_i - I_i$ be the result of the operation that removes from G_i all vertices in I_i and all the incident edges.

I_i is the set of vertices forming the solution of the induced subgraph problem returned by applying the $\frac{n}{\alpha}$-approximation algorithm to the graph G_i. The process of computing solutions is continued until $|I_{k+1}| \leq \sqrt{\alpha}$. Let $\overline{I} = V - \{I_1 \cup I_2 \cup \cdots \cup I_k\}$ be the set of vertices of G_{k+1}.

Finally, the algorithm performs the following random choice.

Toss a fair coin:

1. If heads, choose at random with equal probability one of the sets $I_1, I_2, \ldots, I_k$, and then accept only presented vertices that belong to that set.
2. If tails, then greedily accept vertices from $\overline{I}$.

THEOREM 12. *Suppose that there is some $\frac{n}{\alpha}$-approximation algorithm for the induced subgraph problem and that there exists an $O(\frac{n}{\sqrt{\alpha}})$-competitive randomized algorithm for the on-line version of the problem. If the original algorithm is polynomial, so is the on-line algorithm.*

Proof. First observe that k is at most $\frac{n}{\sqrt{\alpha}}$. Next, observe that the optimal solution over the set $\overline{I}$ is at most $\frac{n}{\sqrt{\alpha}}$, as the solution produced by the $\frac{n}{\alpha}$-approximation algorithm applied to the graph induced by $\overline{I}$ has size not bigger than $\sqrt{\alpha}$.

Let $\mathrm{OPT}(I)$ be the size of the optimal solution in the subgraph of I induced by the vertices in I presented. Then

$$\mathrm{OPT} \leq \sum_{i=1}^{k} \mathrm{OPT}(I_i) + \mathrm{OPT}(\overline{I}).$$

The expected number of vertices accepted by the on-line algorithm is

$$\begin{aligned} \mathrm{ON} &\geq \frac{1}{2}\left(\frac{1}{k}\sum_{i=1}^{k} \mathrm{OPT}(I_i) + 1\right) \\ &\geq \frac{\sqrt{\alpha}}{2n}\left(\sum_{i=1}^{k} \mathrm{OPT}(I_i) + \mathrm{OPT}(\overline{I})\right) \geq \frac{\sqrt{\alpha}}{2n}\mathrm{OPT}. \end{aligned}$$ □

The current best known polynomial time algorithms have an approximation ratio of $O(\frac{n}{\log n})$ for the induced subgraph problem [Hal94], and $O(\frac{n}{(\log n)^2})$ for the indepen-

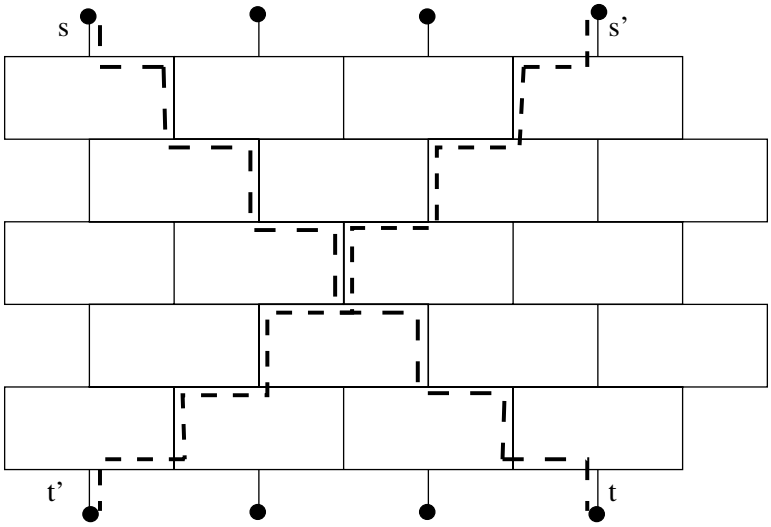

FIG. 2. *The brick wall network.*

dent set [BH92]. In particular, using the optimal (nonpolynomial time) algorithm for the problem (e.g., $\alpha = n$), we obtain the following result.

COROLLARY 13. *There exists an $O(\sqrt{n})$-competitive randomized algorithm for the on-line induced subgraph problem.*

4. On-line edge-disjoint paths. In this section we present $\Omega(n^\epsilon)$ lower bounds on the competitive ratio of nonpreemptive randomized algorithms for on-line edge-disjoint paths. As a consequence (see section 1.2), we obtain an $\Omega(n^\epsilon)$ lower bound for on-line call control. For this reason, in the following we refer to pairs of vertices as calls.

The lower bounds are derived from the lower bounds for the on-line induced subgraph problem presented in section 3 when the hereditary property is an independent set. Recall that the forbidden graph of Lemma 3 for an independent set can be a K_2, and thus the proofs of section 3 can be carried out with the graph G of n vertices being a K_n.

We say two calls are *consistent* if they can be connected with two edge-disjoint paths; otherwise they are *inconsistent*.

The lower bounds for on-line edge-disjoint paths we derive are obtained by embedding the graph $\tilde{G}$ and all input sequences used in the lower bounds proof for the on-line independent set within a network W with the following two properties:

1. Every vertex u in $\tilde{G}$ corresponds to one call $(s(u), t(u))$ in W.
2. Two vertices u, v in $\tilde{G}$ are not adjacent if and only if the two corresponding calls $(s(u), t(u))$, $(s(v), t(v))$ in W are consistent.

The network constructions we will present are based on the *brick wall* network. A brick wall means a portion of the hexagonal lattice as indicated in Figure 2. A brick wall of height h and width w consists of h horizontal paths with w edges between consecutive pairs of them.

We restrict our attention to calls from top vertices to bottom vertices of the brick wall. Top and bottom vertices of the network are numbered from left to right. We can easily observe in Figure 2 the following property.

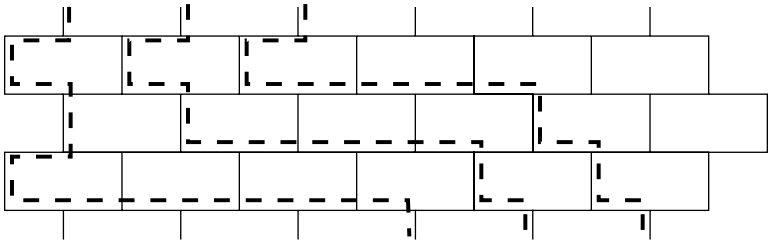

FIG. 3. *Three consistent calls in a brick wall of height* 3.

LEMMA 14. *Let $c = (s, t)$ and $c' = (s', t')$ be two top-to-bottom calls in W with $s < s'$. The calls c and c' are consistent if and only if $t < t'$.*

The following lemma gives a bound on the maximum number of top-to-bottom calls that can be routed in a brick wall network.

LEMMA 15. *Let h be the height of the brick wall, and let w be its width. Any set of up to $\ell = \min(h, w)$ pairwise consistent top-to-bottom calls can be routed in a brick wall network of height h and width w.*

Proof. Consider a set of pairwise consistent top-to-bottom calls. A feasible routing of the set of calls is as follows. Consider the calls from left to right. Assign at each call the leftmost available path that does not intersect a path assigned to any previous considered call. Figure 3 gives an example for a set of three calls in a brick wall of height 3. □

In section 4.1 we present a lower bound on the competitive ratio of nonpreemptive algorithms for on-line edge-disjoint paths, obtained by embedding the on-line independent set lower bounds of section 3 in a network of $O(n^{\frac{3}{2}})$ vertices. This result is then improved using a more complicated embedding in a network of $O(n^{\log_4 6})$ vertices.

4.1. A lower bound for on-line edge-disjoint paths. In this section we present the embedding in a brick wall W of the graph $\tilde{G}$ used in the lower bound for nonpreemptive randomized algorithms for on-line independent sets presented in section 3.

Let n be the number of vertices in $\tilde{G}$. The number of vertices at both top and bottom rows of W (indicated with dots in Figure 2) is n. The largest independent set in the graph $\tilde{G}$ of n vertices of the randomized lower bound for an on-line independent set has size $\sqrt{n}$. By setting the height of W to $\sqrt{n}$, we can ensure, by Lemma 15, that the optimal solution can be consistently routed. Thus, the number of vertices of the network W is $N = O(n^{\frac{3}{2}})$.

We associate every vertex $u \in \tilde{G}$ with a top-to-bottom call $(s(u), t(u))$ in W. The mapping will be such that two vertices are adjacent in $\tilde{G}$ if and only if the two calls are inconsistent. Each of the top and bottom vertices will appear in exactly one call.

Figure 4 shows how such embedding can be done at the ith level. For each of the four graphs of level $i-1$, $\tilde{G}^1_{i-1}$, $\tilde{G}^2_{i-1}$, $\tilde{G}^3_{i-1}$, and $\tilde{G}^4_{i-1}$ that make up $\tilde{G}_i$, a slice of the brick wall is reserved. The mapping of vertices to calls observes the same rules as for the embedding in the nonpreemptive lower bound of the previous subsection.

Observe in Figure 4 that the slices associated with adjacent graphs of Figure 1 intersect, while the slices associated with nonadjacent graphs are disjoint.

Since W has $N = n^{\frac{3}{2}}$ vertices, from Theorem 11 we get the following theorem.

THEOREM 16. *Any nonpreemptive randomized algorithm for the on-line edge-disjoint paths problem (and hence for call control) on general networks of N vertices has competitive ratio $\Omega(N^{\frac{2}{3}(1-\log_4 3)})$.*

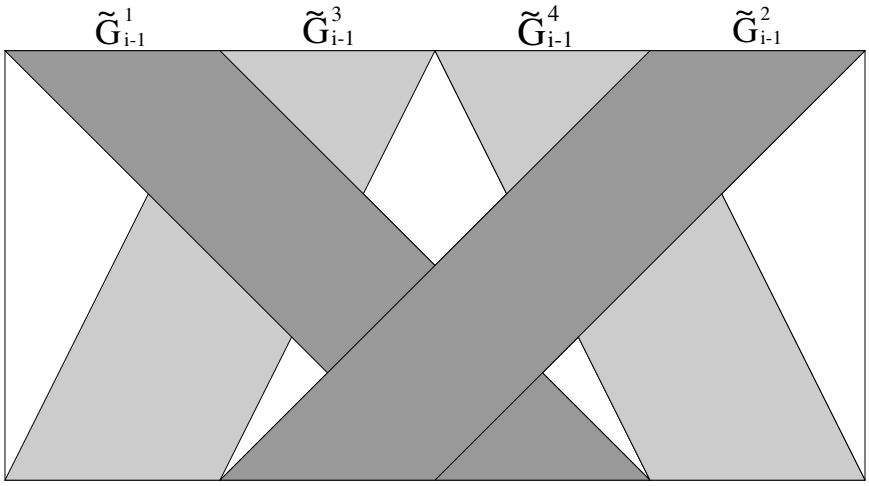

FIG. 4. *The mapping of the sequence in the graph $\tilde{G}_i$ on the brick wall.*

In the next section we will present a better lower bound for preemptive randomized algorithms.

4.2. Better results for on-line edge-disjoint paths. In this section we present an improved randomized lower bound for nonpreemptive on-line edge-disjoint paths.

As for the lower bounds for on-line edge-disjoint paths described in the previous subsections, the lower bound is obtained by embedding the lower bound for an on-line independent set (section 3) on a particular network. The transformation associates a call with every vertex in the instance of the on-line independent set lower bound.

Let $n(i)$ denote the number of vertices in the i-level graph of the on-line independent set lower bound. We describe a network construction with $N(i) = O(n(i)^{\log_4 6})$ nodes.

The construction is built recursively. The network is associated with a set of calls, only some of which can be routed consistently. The construction of a certain i-level network is composed of $(i-1)$-level networks.

The network H_i has 4^i input nodes and 3^i output nodes.

H_0 is the network having a single vertex, representing both one input and one output of the network.

The network H_i (Figure 5) is recursively composed of four instances of $(i-1)$-level networks, H^1_{i-1}, H^2_{i-1}, H^3_{i-1}, H^4_{i-1}, and one brick-wall network of width $4 \cdot 3^{i-1}$ and height 2^i.

The input of H_i is formed by the union of the sets of inputs for the four $(i-1)$-level networks.

The outputs of $H^1_{i-1}, H^2_{i-1}, H^3_{i-1}$, and H^4_{i-1} are directed into the appropriate four slices of the brick wall network, *while maintaining the respective order of the outputs within a slice.* The slices are chosen to intersect in such a way that the calls associated with H^1_{i-1} intersect with those associated with H^2_{i-1} and H^3_{i-1}, and the calls associated with H^2_{i-1} intersect with H^4_{i-1}.

We now describe in detail the transformation from the instance of the independent set lower bound to the network described above.

Let $\tilde{G}_i$ denote the i-level graph of the independent set lower bound. Recall that the graph $\tilde{G}_i$ is recursively composed of four $(i-1)$-level graphs, $\tilde{G}^1_{i-1}, \tilde{G}^2_{i-1}, \tilde{G}^3_{i-1}, \tilde{G}^4_{i-1}$.

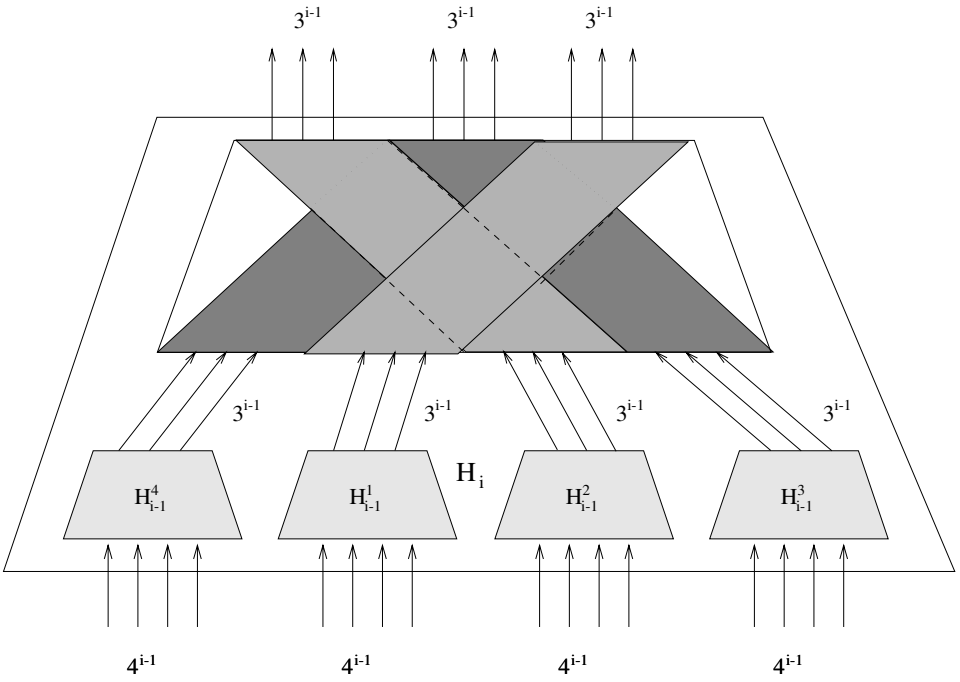

FIG. 5. *The construction of the network H_i.*

With each vertex v of $\tilde{G}_i$ we associate a corresponding call in the network H_i recursively.

If $v \in \tilde{G}^j_{i-1}$, then v is recursively associated with a call in H^j_{i-1} $(1 \le j \le 4)$.

For $i = 0$, the single vertex of $\tilde{G}_0$ is associated with the degenerate call (u, u), where u is the single vertex of H_0.

Let $v \in \tilde{G}^j_{i-1}$. Consider the associated call $c_{i-1}(v) = (s_{i-1}(v), t_{i-1}(v))$ in H^j_{i-1}. We define the associated call in H_i as the call $c_i(v) = (s_i(v), t_i(v))$, where $s_i(v) = s_{i-1}(v)$ and $t_i(v)$ is the output in the slice of the brick wall contained in H_i corresponding to the input on which $t_{i-1}(v)$ is directed.

LEMMA 17.

1. *Two nodes v_1, v_2 of $\tilde{G}_i$ are adjacent if and only if $c_i(v_1), c_i(v_2)$ are inconsistent in H_i.*
2. *Given an independent set T in $\tilde{G}_i$, all calls in the set $C(T) = \{c_i(v); v \in T\}$ can be routed consistently in H_i.*

Proof. The proof is by induction on i. For $i = 0$ the claims are trivial.

Assume that the claim holds for $i-1$. First we prove the first part of the lemma. Let us consider first the case in which two nodes v_1 and v_2 are in the same $(i-1)$-level graph. The corresponding calls $c_{i-1}(v_1)$ and $c_{i-1}(v_2)$ in the associated $(i-1)$-level network enter the brick wall of H_i in the same slice, and the order between $t_{i-1}(v_1)$ and $t_{i-1}(v_2)$ is maintained between $t_i(v_1)$ and $t_i(v_2)$. Therefore, $c_i(v_1)$ and $c_i(v_2)$ are consistent if and only if $c_{i-1}(v_1)$ and $c_{i-1}(v_2)$ are consistent, and thus the claim holds for the inductive hypothesis.

We are left to consider pairs of nodes in different $(i-1)$-level graphs.

Let v_1 and v_2 be nodes from two different $(i-1)$-level graphs, with the exception of $\tilde{G}^3_{i-1}$ and $\tilde{G}^4_{i-1}$ which are never presented together in the on-line independent set lower bound. Therefore $c_{i-1}(v_1)$ and $c_{i-1}(v_2)$ enter the brick wall of network H_i in

two different slices. It follows that the two calls $c_i(v_1)$ and $c_i(v_2)$ are inconsistent if and only if the two corresponding slices are intersecting and thus if and only if the two graphs are nonadjacent. This ends the proof of the first part of the lemma.

Now we turn to the second part of the lemma. We will prove the claim by induction on the level i of the network construction. For level i the independent set T is of size at most 2^i. For $i = 0$ there is only one call, and the claim is obvious.

Consider $i > 0$. The vertices of T can be partitioned into two subsets T_1 and T_2, belonging to two nonadjacent level $(i-1)$ graphs (each of size at most 2^{i-1}). Notice that the two nonadjacent graphs are either $\tilde{G}^1_{i-1}$ and $\tilde{G}^4_{i-1}$ or $\tilde{G}^2_{i-1}$ and $\tilde{G}^3_{i-1}$.

Therefore, without loss of generality, we can assume that T_1 belongs to $\tilde{G}^1_{i-1}$ and T_2 belongs to $\tilde{G}^4_{i-1}$, and thus for every vertex $v \in T_1$, $c_{i-1}(v)$ belongs to H^1_{i-1}, and for every vertex $v \in T_2$, $c_{i-1}(v)$ belongs to H^4_{i-1}.

By induction, the set of calls $\{c_{i-1}(v); v \in T_1\}$ can be routed consistently through H^1_{i-1}, and the set of calls $\{c_{i-1}(v); v \in T_2\}$ can be routed consistently through H^4_{i-1}.

The output vertices of these calls in H^1_{i-1} and H^4_{i-1} are all distinct, and so are the input vertices in the brick wall of H_i into which these calls are directed. Since the slices of the brick wall associated with H^1_{i-1} and H^4_{i-1} are nonintersecting, and since for each slice the order of the corresponding outputs in the brick wall of H_i is maintained, we have that every pair of calls in $C(T)$ can be routed consistently through the brick wall of H_i.

Since the number of such calls is at most 2^i, and thus at most the height of the brick wall of H_i, all calls in $C(T)$ can be routed consistently.

The case in which T_1 belongs to $\tilde{G}^2_{i-1}$ and T_2 belongs to $\tilde{G}^3_{i-1}$ can be similarly proved. □

The next lemma gives a bound on the number of vertices in an i-level network.

CLAIM 18. *The number of vertices/edges in H_i is $N(i) = O(6^i)$.*

Proof. Let α be some constant such that a brick wall of height h and width w has at most αhw vertices/edges. We show by induction on i that $N(i) \le 4\alpha \cdot 6^i$. For $i = 0$ the claim is clearly satisfied. Assume that $N(i-1) \le \alpha \cdot 6^{i-1}$. Since H_i is composed of four H_{i-1} networks and a brick wall of width $4 \cdot 3^{i-1}$ and height 2^i, we obtain

$$N(i) \le 4\alpha \cdot 3^{i-1} \cdot 2^i + 4 \cdot 4\alpha \cdot 6^{i-1} \le 4\alpha \cdot 6^i. \qquad \square$$

Using the network construction described, we derive from Theorem 11 the following result.

THEOREM 19. *Any randomized nonpreemptive algorithm for on-line edge-disjoint paths (and thus for call control) on general networks of N vertices has competitive ratio $\Omega(N^{\frac{1-\log_4 3}{\log_4 6}})$.*

4.3. Lower bounds for networks of high degree. The brick wall network has degree 3. However, we prove the following theorem, which extends any lower bound for on-line edge-disjoint paths to networks of minimum degree δ.

THEOREM 20. *Given an $\Omega(f(N))$ lower bound on the competitive ratio of nonpreemptive algorithms for on-line edge-disjoint paths (and thus for on-line call control) on networks of N vertices, there exists an $\Omega(f(\frac{N}{\delta}))$ lower bound for the problem on networks of minimum degree δ.*

Proof. We transform the network H of N vertices on which the lower bound is achieved into a network H' of minimum degree δ as follows. To every vertex corresponds a clique of size δ in the new network, and to every edge of H corresponds a single edge between two arbitrary vertices in the two associated cliques.

Let us consider the input sequence σ for the $\Omega(f(n))$ lower bound in H. We transform σ into an input sequence σ' for H' by replacing every call in σ formed by two vertices with a call formed by two arbitrary vertices in the two associated cliques. Under this transformation, any solution for σ' in H' corresponds to a solution for σ in H with equal size. Since H' has more vertices than H by a factor δ, the $\Omega(f(N))$ lower bound in the network H with input sequence σ yields an $\Omega(f(\frac{N}{\delta}))$ lower bound in H' with input sequence σ'. □

5. The on-line graph coloring problem. In this section we will consider the on-line graph coloring problem. We present a lower bound of $\Omega(n^\epsilon)$ on the competitive ratio of randomized on-line algorithms. We recall that in our model the algorithm knows the graph $G = (V, E)$ from which the instance of the problem is drawn.

Vertices of V are presented over time. Each time a new vertex is communicated, the algorithm must answer with a color for the vertex. The goal is to color the set of vertices presented with as few colors as possible, so that any two adjacent vertices have different colors.

In section 5.1 we present an $\Omega(n^\epsilon)$ lower bound for the on-line graph coloring problem, and in section 5.2 we give upper bounds for the problem.

5.1. Lower bounds for on-line graph coloring. The structure of the graph G from which the input sequence is chosen is recursive. Given a set of vertices $V = \{v_0, v_1, \ldots, v_{n-1}\}$, where n is a power of 5, we define subsets $V_i^j \subset V$, $|V_i^j| = 5^i$,

$$V_i^j = \{v_{j5^i}, v_{j5^i+1}, \ldots, v_{(j+1)5^i-1}\},$$

for all $0 \le i \le \log_5 n$, $0 \le j \le n/5^i - 1$. We also define the graphs $G_i^j = (V_i^j, E_i^j)$, $0 \le i \le \log_5 n$, $0 \le j \le n/5^i - 1$, where E_i^j is the set of edges in $E_{i-1}^{5j} \cup E_{i-1}^{5j+1} \cup \cdots \cup E_{i-1}^{5j+4}$, to which we add all edges between V_{i-1}^{5j+k} and $V_{i-1}^{5j+((k+1) \bmod 5)}$, $0 \le k \le 4$. The recursive construction of G_i^j is given pictorially in Figure 6.

Note that $V_{\log_5 n}^0 = V$, and we set $G = G_{\log_5 n}^0$ for all $0 \le i \le \log_5 n$ and $0 \le j \le n/5^i - 1$; G_i^j is a vertex induced subgraph of G.

As in section 3.1 we define a probability distribution on the request sequences of G. For any on-line vertex coloring algorithm ON we give a lower bound on the ratio between the number of different colors required by the online algorithm and the optimal number of colors (which is constant for all sequences with nonzero probability in the distribution).

The probability distribution over the sequences will be a uniform distribution over a set of sequences of vertices. The set of sequences is defined recursively as follows. The set of sequences for the graph G_0^j, $0 \le j \le n-1$, consists of the single sequence $\langle v_j \rangle$. Let $S(V_i^j)$ denote the set of sequences over V_i^j, $0 \le i \le \log_5 n$, $0 \le j \le n/5^i - 1$. Also, let $\|$ denote the concatenation operator on sequences.

Given $S(V_{i-1}^{5j})$, $S(V_{i-1}^{5j+1})$, $S(V_{i-1}^{5j+2})$, $S(V_{i-1}^{5j+3})$, and $S(V_{i-1}^{5j+4})$, $1 \le i \le \log_5 n$, $0 \le j \le n/5^i - 1$, we define the set $S(V_i^j)$ as the result of the following process:

Set

$$S_{023} = \{x\|y\|z | x \in S(V_{i-1}^{5j}), y \in S(V_{i-1}^{5j+2}), z \in S(V_{i-1}^{5j+3})\},$$

$$S_{0231} = \{x\|y | x \in S_{023}, y \in S(V_{i-1}^{5j+1})\}, \tag{29}$$

$$S_{0234} = \{x\|y | x \in S_{023}, y \in S(V_{i-1}^{5j+4})\}, \tag{30}$$

$$S(V_i^j) = S_{0231} \cup S_{0234}.$$

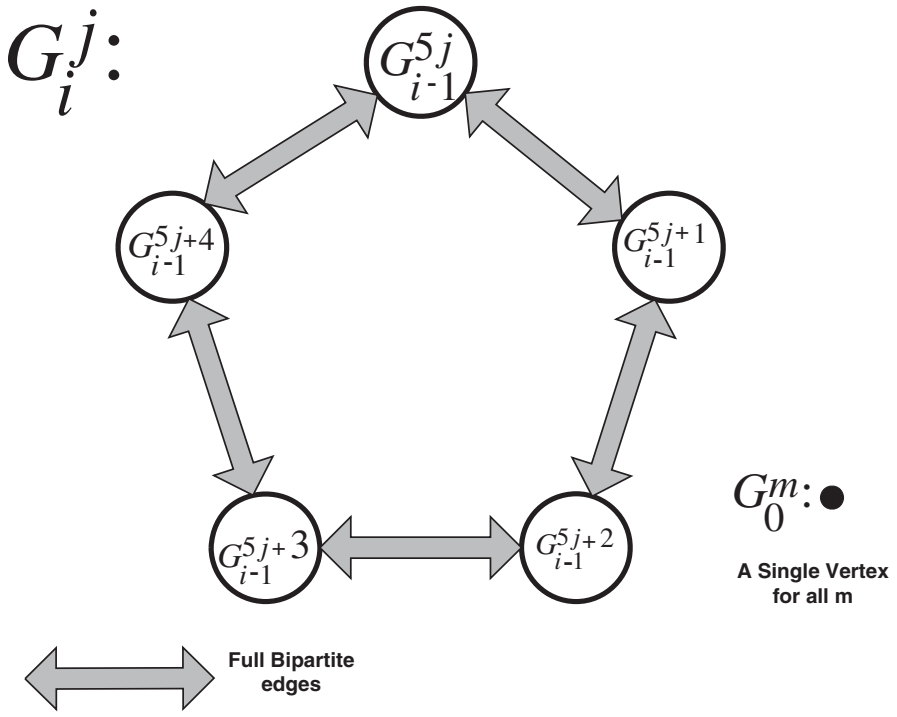

FIG. 6. *The recursive definition of* G_i.

CLAIM 21. *In any outcome of the above process (to generate* $S(V_i^j)$*),* $|S_{0231}| = |S_{0234}|$.

Proof. From step (29) above we have that $|S_{0231}| = |S_{023}| \cdot |S(V_{i-1}^{5j+1})|$, and by step (30) above we have $|S_{0234}| = |S_{023}| \cdot |S(V_{i-1}^{5j+4})|$. For any two sets V_{i-1}^{5j+k}, $V_{i-1}^{5j+\ell}$, $0 \le k < \ell \le 4$, we can find a mapping $f(u) \mapsto w$, $u \in V_{i-1}^{5j+k}$, $w \in V_{i-1}^{5j+\ell}$, such that both sets and their recursive partition into subsets are isomorphic under f. Specifically, $f(v_t) = v_{t+(\ell-k)5^{i-1}}$ will be such a mapping. Thus, $|S(V_{i-1}^{5j+1})| = |S(V_{i-1}^{5j+4})|$, and it now follows that $|S_{0231}| = |S_{0234}|$. □

CLAIM 22. $U(S(V_i^j | V_{i-1}^{5j+k})) = U(S(V_{i-1}^{5j+k}))$ *for* $k = 0, \ldots, 4$.

Proof. Every sequence in $S(V_{i-1}^{5j+k})$ appears as a subsequence of the same number of sequences in $S(V_i^j)$. □

Given a sequence σ of vertices from V, let $T(\sigma)$ denote the set of vertices in σ. For any algorithm A (online or offline) and any sequence of vertices σ from V, let $A^C(\sigma) : T(\sigma) \mapsto Z^+$ denote the function mapping vertices of $T(\sigma)$ onto colors.[2] Let $A^\#(\sigma)$ denote the number of different colors used by A to color the vertices of $T(\sigma)$:

$$A^\#(\sigma) = |\{A^C(\sigma)(u) : u \in T(\sigma)\}|.$$

Given a sequence σ of vertices from V and a set $V' \subset V$, we let $A(\sigma, V')$ denote

[2]For online algorithms, the function $A^C(\sigma)$ cannot depend on yet unseen parts of σ; i.e., if $\sigma = \langle \sigma_1, \sigma_2, \ldots, \sigma_{|\sigma|} \rangle$, $A^C(\sigma)(\sigma_i)$ cannot depend on the suffix $\langle \sigma_{i+1}, \ldots, \sigma_{|\sigma|} \rangle$.

the set of colors assigned by $A^C(\sigma)$ to the vertices of $V' \cap T(\sigma)$,

$$A(\sigma, V') = \{A^C(\sigma)(u) : u \in V' \cap T(\sigma)\}.$$

We also define

$$A^{\#}(\sigma, V') = |A(\sigma, V')|.$$

For example, $A^{\#}(\sigma, V) = A^{\#}(\sigma, T(\sigma)) = A^{\#}(\sigma)$.

LEMMA 23. *For any $0 \le i \le \log_5 n$, $0 \le j \le n/5^i - 1$, and any sequence $\sigma \in S(V_i^j)$, $\mathrm{OPT}^{\#}(\sigma) \le 2^i$.*

Proof. Given any sequence $\sigma \in S(V_i^j)$, we will prove by induction on i that the number of colors used to color the vertices of σ is no more than 2^i. For $i = 0$, σ is a single vertex and can be colored with one color.

For $i \ge 1$, $\sigma \in V_i^j$, either $\sigma \in S_{0231}$ or $\sigma \in S_{0234}$, as defined in (29) and (30). If $\sigma \in S_{0231}$, then we can use the same set of 2^{i-1} colors to color both the vertices in V_{i-1}^{5j} and V_{i-1}^{5j+2}; likewise, we can use the same set of 2^{i-1} colors to color the vertices in V_{i-1}^{5j+1} and in V_{i-1}^{5j+3}. Thus, if $\sigma \in S_{0231}$, then we can color the vertices of V_i^j with 2^i colors. A similar argument works for the case where $\sigma \in S_{0234}$. ∎

Let $E_{x \in_R D}[r(x)]$ denote the expectation of the random variable $r(x)$, where x is chosen from the distribution D.

Let $T \subset V$, the notation $\sigma|T$ denotes the sequence derived from σ by removing all elements in $V - T$.

CLAIM 24. *Given an online algorithm ON, for any sequences of vertices τ, τ', and τ'' from V, such that $T(\tau)$, $T(\tau')$, and $T(\tau'')$ are pairwise disjoint, there is an online algorithm $ON^{\tau'}$ such that*

$$\begin{aligned} ON^C(\tau' \| \tau \| \tau'')(u) &= {ON^{\tau'}}^C(\tau)(u) \quad \textit{for all} \ \ u \in T(\tau), \\ ON(\tau' \| \tau \| \tau'', T(\tau)) &= ON^{\tau'}(\tau, T(\tau)), \\ ON^{\#}(\tau' \| \tau \| \tau'', T(\tau)) &= {ON^{\tau'}}^{\#}(\tau, T(\tau)). \end{aligned}$$

Proof. Let $\tau = \tau_1, \tau_2, \ldots, \tau_{|\tau|}$. $ON^{\tau'}$ emulates the execution of ON as follows: $ON^{\tau'}$ colors vertex τ_ℓ, $1 \le \ell \le |\tau|$, with the same color that ON would have given τ_ℓ after coloring $\tau' \| \langle \tau_1, \tau_2, \ldots, \tau_{\ell-1} \rangle$. Thus,

$${ON^{\tau'}}^C(\tau)(\tau_\ell) = ON^C(\tau' \| \tau)(\tau_\ell). \qquad ∎$$

LEMMA 25. *For any deterministic online algorithm ON defined on sequences of vertices from V_i^j, $0 \le i \le \log_5 n$, $0 \le j \le n/5^i - 1$, the following hold:*

(31)
$$E_{\sigma \in_R U(S(V_i^j))}[ON^{\#}(\sigma, V_{i-1}^{5j})] = E_{\tau_0 \in_R U(S(V_{i-1}^{5j}))}[ON^{\#}(\tau_0)],$$

(32)
$$E_{\sigma \in_R U(S(V_i^j))}[ON^{\#}(\sigma, V_{i-1}^{5j+2})] = E_{\tau_0 \in_R U(S(V_{i-1}^{5j}))} E_{\tau_2 \in_R U(S(V_{i-1}^{5j+2}))}[{ON^{\tau_0}}^{\#}(\tau_2)],$$

(33)
$$\begin{aligned} &E_{\sigma \in_R U(S(V_i^j))}[ON^{\#}(\sigma, V_{i-1}^{5j+3})] \\ &= E_{\tau_0 \in_R U(S(V_{i-1}^{5j}))} E_{\tau_2 \in_R U(S(V_{i-1}^{5j+2}))} E_{\tau_3 \in_R U(S(V_{i-1}^{5j+3}))}[{ON^{\tau_0 \| \tau_2}}^{\#}(\tau_3)], \end{aligned}$$

(34)
$$E_{\sigma\in_R U(S(V_i^j))}[ON^{\#}(\sigma, V_{i-1}^{5j+1})]$$
$$= \frac{1}{2} E_{\tau_0\in_R U(S(V_{i-1}^{5j}))} E_{\tau_2\in_R U(S(V_{i-1}^{5j+2}))} E_{\tau_3\in_R U(S(V_{i-1}^{5j+3}))} E_{\tau_1\in_R U(S(V_{i-1}^{5j+1}))} [ON^{\tau_0\|\tau_2\|\tau_3\#}(\tau_1)],$$
(35)
$$E_{\sigma\in_R U(S(V_i^j))}[ON^{\#}(\sigma, V_{i-1}^{5j+4})]$$
$$= \frac{1}{2} E_{\tau_0\in_R U(S(V_{i-1}^{5j}))} E_{\tau_2\in_R U(S(V_{i-1}^{5j+2}))} E_{\tau_3\in_R U(S(V_{i-1}^{5j+3}))} E_{\tau_4\in_R U(S(V_{i-1}^{5j+4}))} [ON^{\tau_0\|\tau_2\|\tau_3\#}(\tau_4)].$$

Proof. The proof follows from Claim 24 and follows arguments similar to those made in Lemma 8. □

CLAIM 26. *For any function f such that*

$$f : \{\tau_0 \times \tau_2 \times \tau_3 | \tau_k \in S(V_{i-1}^{5j+k}), k = 0, 2, 3\} \mapsto Z^+$$

we have

$$\begin{aligned} &E_{\sigma\in S_{0231}}[f(\tau_0, \tau_2, \tau_3)] \\ &\quad = E_{\sigma\in S_{0234}}[f(\tau_0, \tau_2, \tau_3)] \\ &\quad = E_{\tau_0\|\tau_2\|\tau_3\|\tau'\in U(S(V_i^j)), \tau_k\in S(V_{i-1}^{5j+k}), k=0,2,3}[f(\tau_0, \tau_2, \tau_3)]. \end{aligned}$$

For any function f such that

$$f : \{\tau' | \tau' \in S(V_{i-1}^{5j+1})\} \mapsto Z^+$$

we have

$$E_{\sigma\in S_{0231}}[f(\tau')] = 2\ E_{\tau_0\|\tau_2\|\tau_3\|\tau'\in U(S(V_i^j)), \tau_k\in S(V_{i-1}^{5j+k}), k=0,2,3}[f(\tau')].$$

For any function f such that

$$f : \{\tau' | \tau' \in S(V_{i-1}^{5j+4})\} \mapsto Z^+$$

we have

$$E_{\sigma\in S_{0234}}[f(\tau')] = 2\ E_{\tau_0\|\tau_2\|\tau_3\|\tau'\in U(S(V_i^j)), \tau_k\in S(V_{i-1}^{5j+k}), k=0,2,3}[f(\tau')].$$

Proof. We have

$$\begin{aligned} E_{\sigma\in S_{0231}}[f(\tau_0, \tau_2, \tau_3)] &= \frac{\sum_{\tau_0\|\tau_2\|\tau_3\|\tau_1\in S_{0231}} f(\tau_0, \tau_2, \tau_3)}{|S_{0231}|} \\ &= \frac{|S(V_{i-1}^{5j+1})| \cdot \sum_{\tau_0\|\tau_2\|\tau_3\in S_{023}} f(\tau_0, \tau_2, \tau_3)}{|S_{023}| \cdot |S(V_{i-1}^{5j+1})|} \\ &= \frac{\sum_{\tau_0\|\tau_2\|\tau_3\in S_{023}} f(\tau_0, \tau_2, \tau_3)}{|S_{023}|} \\ &= \frac{|S(V_{i-1}^{5j+1}) \cup S(V_{i-1}^{5j+4})|}{|S(V_{i-1}^{5j+1}) \cup S(V_{i-1}^{5j+4})|} \cdot \frac{\sum_{\tau_0\|\tau_2\|\tau_3\in S_{023}} f(\tau_0, \tau_2, \tau_3)}{|S_{023}|} \\ &= \frac{\sum_{\tau_0\|\tau_2\|\tau_3\|\tau'\in S(V_i^j)} f(\tau_0, \tau_2, \tau_3)}{|S(V_i^j)|} \\ &= E_{\tau_0\|\tau_2\|\tau_3\|\tau'\in S(V_i^j)}[f(\tau_0, \tau_2, \tau_3)]. \end{aligned}$$

Similar arguments prove the other claims. ∎

LEMMA 27. *For any $1 \le i \le \log_5 n$, $0 \le j \le n/5^i - 1$, and any deterministic online algorithm ON defined over sequences from V_i^j,*

$$E_{\sigma \in_R U(S(V_i^j))}[ON^{\#}(\sigma)] \ge \left(\frac{5}{2}\right)^i.$$

Proof. We prove the claim by induction on i. The claim holds for $i = 0$ and any $1 \le j \le n$ (V_0^j is a single vertex). We assume by induction the claim holds for all probability distributions $U(S(V_{i-1}^{\ell}))$, $0 \le \ell \le n/5^{i-1} - 1$, which means in particular that it holds for the probability distributions $U(S(V_{i-1}^{5j+k}))$, $0 \le j \le n/5^i - 1$, $0 \le k \le 4$.

From Claim 21 we have that $|S_{0231}| = |S_{0234}|$ and so

$$E_{\sigma \in S(V_i^j)}[ON^{\#}(\sigma)] = (1/2)E_{\sigma \in S_{0231}}[ON^{\#}(\sigma)] + (1/2)E_{\sigma \in S_{0234}}[ON^{\#}(\sigma)]. \tag{36}$$

The set of colors used to color V_i^j is the union of the sets of colors used to color V_i^{5j+k}, $0 \le k \le 4$. For $\sigma \in S(V_i^j)$, where $\sigma \in S_{0231}$ as described in the construction of $S(V_i^j)$, we have $\sigma = \tau_0 \| \tau_2 \| \tau_3 \| \tau_1$, where $\tau_k \in S(V_{i-1}^{5j+k})$, $k = 0, 1, 2, 3$. For $\sigma \in S(V_i^j)$, where $\sigma \in S_{0234}$ as described in the construction of $S(V_i^j)$, we have $\sigma = \tau_0 \| \tau_2 \| \tau_3 \| \tau_4$, where $\tau_k \in S(V_{i-1}^{5j+k})$, $k = 0, 2, 3, 4$.

From (31), (32), (33), (34), and (35) we can now derive the following:

(37)
$$E_{\sigma \in S_{0231}}[ON^{\#}(\sigma)] \ge E_{\sigma \in S_{0231}} \left[\begin{array}{l} ON^{\#}(\sigma, T(\tau_0)) + ON^{\#}(\sigma, T(\tau_2)) \\ + ON^{\#}(\sigma, T(\tau_3)) + ON^{\#}(\sigma, T(\tau_1)) \\ - |ON(\sigma, T(\tau_0)) \cap (ON(\sigma, T(\tau_2)) \cup ON(\sigma, T(\tau_3)))| \\ - |ON(\sigma, T(\tau_1)) \cap ON(\sigma, T(\tau_3))| \end{array} \right],$$

(38)
$$E_{\sigma \in S_{0234}}[ON^{\#}(\sigma)] \ge E_{\sigma \in S_{0234}} \left[\begin{array}{l} ON^{\#}(\sigma, T(\tau_0)) + ON^{\#}(\sigma, T(\tau_2)) \\ + ON^{\#}(\sigma, T(\tau_3)) + ON^{\#}(\sigma, T(\tau_4)) \\ - |ON(\sigma, T(\tau_0)) \cap (ON(\sigma, T(\tau_2)) \cup ON(\sigma, T(\tau_3)))| \\ - |ON(\sigma, T(\tau_4)) \cap ON(\sigma, T(\tau_2))| \end{array} \right].$$

Now,

$$\begin{aligned} |ON(\sigma, T(\tau_0)) \cap (ON(\sigma, T(\tau_2)) \cup ON(\sigma, T(\tau_3)))| = & \; |ON(\sigma, T(\tau_0)) \cap ON(\sigma, T(\tau_2))| \\ & + |ON(\sigma, T(\tau_0)) \cap ON(\sigma, T(\tau_3))| \\ & - |ON(\sigma, T(\tau_2)) \cap ON(\sigma, T(\tau_3))| \\ = & \; |ON(\sigma, T(\tau_0)) \cap ON(\sigma, T(\tau_2))| \\ & + |ON(\sigma, T(\tau_0)) \cap ON(\sigma, T(\tau_3))|, \end{aligned} \tag{39}$$

because the colors used for V_{i-1}^{5j+2} and V_{i-1}^{5j+3} must be distinct.

By substituting (37) and (38) into (36) and making use of the equalities in (39), we obtain

$$
\begin{aligned}
(40)\quad E_{\sigma\in S(V_i^j)}[ON^{\#}(\sigma)] \geq\ & (1/2)E_{\sigma\in S_{0231}}\begin{bmatrix} ON^{\#}(\sigma,T(\tau_0))+ON^{\#}(\sigma,T(\tau_2)) \\ +ON^{\#}(\sigma,T(\tau_3))+ON^{\#}(\sigma,T(\tau_1)) \end{bmatrix} \\
& +(1/2)E_{\sigma\in S_{0234}}\left[ON^{\#}(\sigma,T(\tau_4))\right] \\
& +(1/2)E_{\sigma\in S_{0234}}\begin{bmatrix} ON^{\#}(\sigma,T(\tau_0)) \\ -\,|ON(\sigma,T(\tau_0))\cap ON(\sigma,T(\tau_2))| \\ -\,|ON(\sigma,T(\tau_0))\cap ON(\sigma,T(\tau_3))| \end{bmatrix} \\
& +(1/2)E_{\sigma\in S_{0234}}\begin{bmatrix} ON^{\#}(\sigma,T(\tau_2)) \\ -\,|ON(\sigma,T(\tau_4))\cap ON(\sigma,T(\tau_2))| \end{bmatrix} \\
& -(1/2)E_{\sigma\in S_{0231}}\left[|ON(\sigma,T(\tau_0))\cap ON(\sigma,T(\tau_2))|\right] \\
& +(1/2)E_{\sigma\in S_{0234}}\left[ON^{\#}(\sigma,T(\tau_3))\right] \\
& -(1/2)E_{\sigma\in S_{0231}}\begin{bmatrix} |ON(\sigma,T(\tau_0))\cap ON(\sigma,T(\tau_3))| \\ +\,|ON(\sigma,T(\tau_1))\cap ON(\sigma,T(\tau_3))| \end{bmatrix}.
\end{aligned}
$$

The following equations are derived from Claim 26 and by observing that the colors assigned to vertices V_{i-1}^{5j+k} must be distinct from the colors assigned to vertices $V_{i-1}^{5j+(k+1)\bmod 5}$, $k=0,\ldots,4$:

$$
(41)\qquad E_{\sigma\in S_{0234}}\left[\begin{array}{l} ON^{\#}(\sigma,T(\tau_0)) \\ -\,|ON(\sigma,T(\tau_0))\cap ON(\sigma,T(\tau_2))| \\ -\,|ON(\sigma,T(\tau_0))\cap ON(\sigma,T(\tau_3))| \end{array}\right] \geq 0,
$$

$$
\begin{aligned}
(42)\qquad & E_{\sigma\in S_{0234}}\left[\begin{array}{l} ON^{\#}(\sigma,T(\tau_2)) \\ -\,|ON(\sigma,T(\tau_4))\cap ON(\sigma,T(\tau_2))| \end{array}\right] \\
& -E_{\sigma\in S_{0231}}\left[\ |ON(\sigma,T(\tau_0))\cap ON(\sigma,T(\tau_2))|\ \right] \\
& =E_{\sigma\in S_{0234}}\left[\begin{array}{l} ON^{\#}(\sigma,T(\tau_2)) \\ -\,|ON(\sigma,T(\tau_4))\cap ON(\sigma,T(\tau_2))| \\ -\,|ON(\sigma,T(\tau_0))\cap ON(\sigma,T(\tau_2))| \end{array}\right] \geq 0,
\end{aligned}
$$

$$
\begin{aligned}
(43)\qquad & E_{\sigma\in S_{0234}}\left[\ ON^{\#}(\sigma,T(\tau_3))\ \right] \\
& -E_{\sigma\in S_{0231}}\left[\begin{array}{l} |ON(\sigma,T(\tau_0))\cap ON(\sigma,T(\tau_3))| \\ +\,|ON(\sigma,T(\tau_1))\cap ON(\sigma,T(\tau_3))| \end{array}\right] \\
& =E_{\sigma\in S_{0234}}\left[\begin{array}{l} ON^{\#}(\sigma,T(\tau_3)) \\ -\,|ON(\sigma,T(\tau_0))\cap ON(\sigma,T(\tau_3))| \\ -\,|ON(\sigma,T(\tau_1))\cap ON(\sigma,T(\tau_3))| \end{array}\right] \geq 0.
\end{aligned}
$$

Using (41), (42), (43) and Claim 26, we derive the following from (40):

$$
\begin{aligned}
(44)\quad E_{\sigma\in S(V_i^j)}[ON^{\#}(\sigma)] \geq\ & (1/2)E_{\sigma\in S_{0231}}\left[\begin{array}{l} ON^{\#}(\sigma,T(\tau_0))+ON^{\#}(\sigma,T(\tau_2)) \\ +ON^{\#}(\sigma,T(\tau_3))+ON^{\#}(\sigma,T(\tau_1)) \end{array}\right] \\
& +(1/2)E_{\sigma\in S_{0234}}\left[\ ON^{\#}(\sigma,T(\tau_4))\ \right] \\
=\ & (1/2)E_{\sigma\in S(V_i^j)}\left[\begin{array}{l} ON^{\#}(\sigma,T(\tau_0))+ON^{\#}(\sigma,T(\tau_2)) \\ +ON^{\#}(\sigma,T(\tau_3)) \end{array}\right] \\
& +E_{\sigma\in S(V_i^j)}\left[\ ON^{\#}(\sigma,T(\tau_1))+ON^{\#}(\sigma,T(\tau_4))\ \right].
\end{aligned}
$$

Now, observe that for every $\sigma = \tau_0 \| \tau_2 \| \tau_3 \| \tau_1 \in U(S(V_i^j))$, $\tau_k \in U(S(V_{i-1}^{5j+k}))$, $k =, 0, 2, 3, 1$, we have

$$T(\sigma) \cap V_{i-1}^{5j+k} = T(\tau_k),$$

and for every $\sigma = \tau_0 \| \tau_2 \| \tau_3 \| \tau_4 \in U(S(V_i^j))$, $\tau_k \in U(S(V_{i-1}^{5j+k}))$, $k =, 0, 2, 3, 4$,

$$T(\sigma) \cap V_{i-1}^{5j+k} = T(\tau_k).$$

The two relations above allow us to apply Lemma 25 to (44), to obtain

(45)

$$\begin{aligned} & E_{\sigma \in S(V_i^j)}[ON^{\#}(\sigma)] \\ & \geq \left(\frac{1}{2}\right) \begin{bmatrix} E_{\tau_0 \in_R U(S(V_{i-1}^{5j+k}))}[ON^{\#}(\tau_0)] \\ + E_{\tau_0 \in_R U(S(V_{i-1}^{5j+k}))} E_{\tau_2 \in_R U(S(V_{i-1}^{5j+2}))}[ON^{\tau_0 \#}(\tau_2)] \\ + E_{\tau_0 \in_R U(S(V_{i-1}^{5j+k}))} E_{\tau_2 \in_R U(S(V_{i-1}^{5j+2}))} E_{\tau_3 \in_R U(S(V_{i-1}^{5j+3}))}[ON^{\tau_0 \| \tau_2 \#}(\tau_3)] \\ + E_{\tau_0 \in_R U(S(V_{i-1}^{5j+k}))} E_{\tau_2 \in_R U(S(V_{i-1}^{5j+2}))} E_{\tau_3 \in_R U(S(V_{i-1}^{5j+3}))} E_{\tau_1 \in_R U(S(V_{i-1}^{5j+1}))} \\ \quad \cdot [ON^{\tau_0 \| \tau_2 \| \tau_3 \#}(\tau_1)] \\ + E_{\tau_0 \in_R U(S(V_{i-1}^{5j+k}))} E_{\tau_2 \in_R U(S(V_{i-1}^{5j+2}))} E_{\tau_3 \in_R U(S(V_{i-1}^{5j+3}))} E_{\tau_4 \in_R U(S(V_{i-1}^{5j+4}))} \\ \quad \cdot [ON^{\tau_0 \| \tau_2 \| \tau_3 \#}(\tau_4)] \end{bmatrix}. \end{aligned}$$

By the inductive hypothesis we get that (45) is at least

$$\begin{aligned} E_{\sigma \in S(V_i^j)}[ON^{\#}(\sigma)] &\geq \frac{5}{2} \left(\frac{5}{2}\right)^{i-1} \\ &= \left(\frac{5}{2}\right)^{i}, \end{aligned}$$

thus proving the lemma. □

We then conclude with the following result.

THEOREM 28. *Any randomized algorithm for the on-line vertex coloring problem has a competitive ratio of* $\Omega(n^{1-\log_5 4})$.

Proof. By Lemmas 23 and 27 we have the following. For any $0 \leq i \leq \log_5 n$, $0 \leq j \leq n/5^i - 1$, and any sequence $\sigma \in S(V_i^j)$, $\mathrm{OPT}^{\#}(\sigma) = 2^i$. For any $0 \leq i \leq \log_5 n$ and $0 \leq j \leq n/5^i - 1$, the number of colors required by any deterministic on-line algorithm over the distribution $U(S(V_i^j))$ satisfies

$$E_{\sigma \in_R U(S(V_i^j))}[ON^{\#}(\sigma)] \geq \left(\frac{5}{2}\right)^{i}.$$

The ratio $\rho(i, j)$ between the expected on-line number of colors and the expected optimal number of colors and for the probability distribution on the input sequences $U(S(V_i^j))$, $0 \leq i \leq \log_5 n$, $0 \leq j \leq n/5^i - 1$, is

$$\begin{aligned} \rho(i, j) &= \frac{E_{\sigma \in_R U(S(V_i^j))}[\mathrm{ON}^{\#}(\sigma)]}{E_{\sigma \in_R U(S(V_i^j))}[\mathrm{OPT}^{\#}(\sigma)]} \\ &\geq \frac{\left(\frac{5}{2}\right)^{i}}{2^i} \qquad (46) \\ &= \left(\frac{5}{4}\right)^{i}. \end{aligned}$$

For $i = \log_5 n$ we obtain that for any online algorithm the ratio $\rho(\log_5 n, 0)$ for sequences drawn from the probability distribution $U(S(V^0_{\log_5 n}))$ is

$$\begin{aligned}\rho(\log_5 n, 0) &\geq \frac{n}{4^{\log_5 n}} \\ &= n^{1-\log_5 4}.\end{aligned}$$

Using Yao's lemma (Lemma 1) yields the claimed result. □

5.2. Upper bounds for on-line graph coloring. Using techniques similar to those in section 3.2, we show that off-line algorithms for maximum independent sets can also be used to obtain deterministic on-line graph coloring algorithms.

Let $G = (V, E)$ be the graph that we assume is known to the on-line algorithm. The algorithm requires a preprocessing phase similar to the algorithm presented in section 3.2 for an on-line induced subgraph. A collection of k independent sets $I_1, I_2, \ldots, I_k$ of the graph G are computed as follows:

Let $G_1 = G$, and $G_{i+1} = G_i - I_i$ be the result of the operation that removes from G_i all the vertices of the independent set I_i and all the incident edges.

In particular, I_i is the set of vertices forming the solution of the independent set problem returned by applying the $\frac{n}{\alpha}$-approximate algorithm to the graph G_i. The process of computing solutions is continued until $|I_{k+1}| \leq \sqrt{\alpha}$. Let $\overline{I} = V - \{I_1 \cup I_2 \cup \cdots \cup I_k\}$ be the set of vertices of G_{k+1}.

The algorithm colors every presented vertex v as follows:

1. If there exist $i \leq k$ such that $v \in I_i$, assign color i to vertex v.
2. Otherwise, if $v \in \overline{I}$, assign the first color $j > k$ not used for any previously presented vertex $u \in \overline{I}$, $(u, v) \in E$.

THEOREM 29. *Given an $\frac{n}{\alpha}$-approximation (deterministic) algorithm for a maximum independent set, there exists a (deterministic) $O(\frac{n}{\sqrt{\alpha}})$-competitive algorithm for on-line minimum graph coloring. If the original algorithm is polynomial and deterministic, so is the on-line algorithm.*

Proof. First note that k is at most $\frac{n}{\sqrt{\alpha}}$. Next, observe that the maximum size of an independent set in $\overline{I}$ is at most $\frac{n}{\sqrt{\alpha}}$, since the size of the solution of the $\frac{n}{\alpha}$-approximate algorithm applied to the graph induced by $\overline{I}$ is less than $\sqrt{\alpha}$. Let $\overline{I}'$ be the subset of $\overline{I}$ presented in the sequence.

If the sequence is not empty, the number of colors of the optimal solution is at least the size of $\overline{I}'$ divided by the size of a maximum independent set in $\overline{I}'$. Therefore

$$\mathrm{OPT} \geq \max\left\{1, \frac{\sqrt{\alpha}}{n}|\overline{I}'|\right\}.$$

The number of colors used by the on-line algorithm is bounded by

$$\mathrm{ON} \leq k + |\overline{I}'| \leq 2\frac{n}{\sqrt{\alpha}}\mathrm{OPT},$$

thus proving the theorem. □

Using the optimal (nonpolynomial time) algorithm for a maximum independent set (e.g., $\alpha = n$) we obtain the following.

COROLLARY 30. *There exists a deterministic $O(\sqrt{n})$-competitive algorithm for the on-line graph coloring problem.*

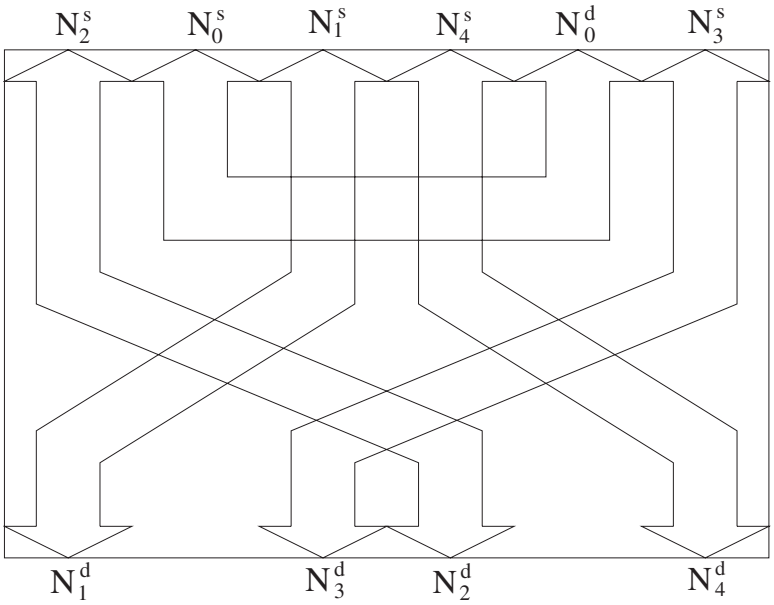

FIG. 7. *The mapping on the brick wall of a sequence of graph* G_i^j.

6. Lower bound for on-line path coloring. In this section we derive an $\Omega(n^\epsilon)$ competitive randomized lower bound for on-line path coloring. In the on-line path coloring problem, a pair of vertices of the network is presented at every step. The algorithm must reply with a color before the pairs following in the sequence are known. The coloring must obey the constraint that any collection of pairs assigned the same color can be connected with edge-disjoint paths.

The lower bound for on-line path coloring is obtained by transforming every sequence of vertices in the graph G (see Figure 6) used for the graph coloring lower bound into a sequence of pairs in the brick wall W shown in Figure 7. We say that two pairs are *consistent* if they can be connected through edge-disjoint paths; otherwise they are *inconsistent*. To derive the result it is sufficient to show that the embedding satisfies the two following properties:

1. Any two adjacent vertices of G are mapped to two inconsistent pairs.
2. Every independent set of G is mapped to a collection of mutually consistent pairs.

Consider a graph G_i^j, $i = 1, \ldots, \log_5 n$, $j = 0, \ldots, n/5^i - 1$, as defined in section 5. G_i^j is formed of five graphs G_{i-1}^{5j+k}, $k = 0, \ldots, 4$. The embedding, described in Figure 7, associates a top-to-bottom call in the brick wall of level i to each vertex of graph G_{i-1}^{5j+k}, $k = 1, \ldots, 4$, and a top-to-top call to every vertex of graph G_{i-1}^{5j}. More precisely, the vertices of G^i are recursively associated with calls from vertices N_i^s to vertices N_i^d. Property 1 then immediately follows, since every two adjacent vertices are mapped to inconsistent pairs.

It is also rather simple to see that property 2 holds if the brick wall of level i has height 2^i and width 6^i. Every sequence of $S(V_i^j)$ contains an independent set of size at most 2^i. The independent set is formed of vertices from at most two nonadjacent sets of vertices of G_i^j, e.g., V_{i-1}^{5j+1} and V_{i-1}^{5j+3} or V_{i-1}^{5j} and V_{i-1}^{5j+2}. If all vertices of the independent set are mapped to top-to-bottom calls, as in the case when they belong to

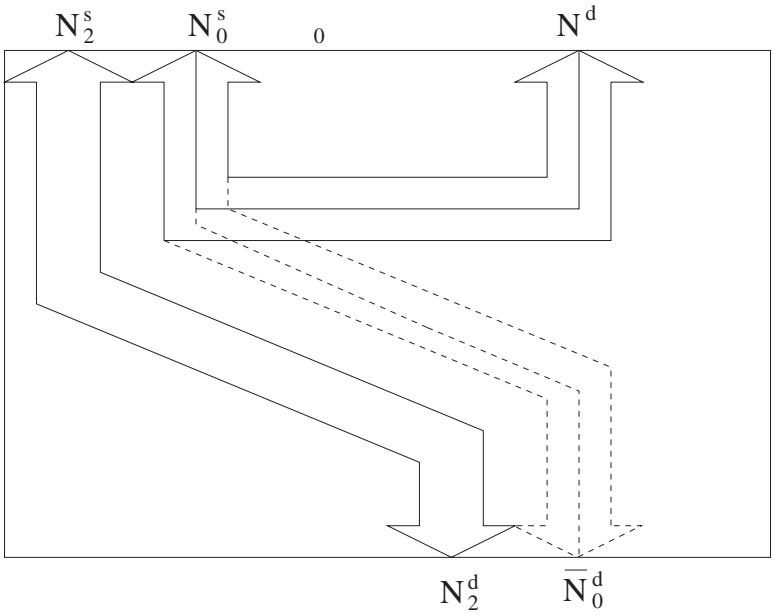

FIG. 8. *The routing of top-to-top calls.*

V_{i-1}^{5j+1} and V_{i-1}^{5j+3}, by Lemma 15, the associated pairs are mutually consistent in a brick wall of height 2^i. Alternatively, consider the case of an independent set containing vertices of V_{i-1}^{5j} mapped to top-to-top calls, and vertices mapped to top-to-bottom calls, for instance, of set V_{i-1}^{5j+2}.

For the sake of the analysis, assume for the moment that every vertex of V_{i-1}^{5j} is mapped, as shown in Figure 8, to two top-to-bottom calls, rather than one top-to-top call. The first call is from a vertex of N_0^s to a vertex of $\overline{N}_0^d$, while the second call is from a vertex of $\overline{N}_0^s$ to a vertex of N_0^d. (Observe that the vertices of $\overline{N}_0^d$ and $\overline{N}_0^s$ are not endpoints of other calls of the sequence.) By Lemma 15, a collection of calls from N_0^s to $\overline{N}_0^d$ and from N_2^s to N_2^d associated with an independent set G of size at most 2^i can be consistently routed.

Consider also the edge-disjoint paths connecting pairs, associated with vertices of V_{i-1}^{5j} in the independent set, formed of a vertex in $\overline{N}_0^s$ and a vertex in N_0^d . A set of edge-disjoint paths connecting the top-to-top pairs associated with vertices of V_{i-1}^{5j} is then obtained as follows: For every vertex of the independent set, let x be the intersection of the two paths connecting the associated pairs from N_0^s to $\overline{N}_0^d$ and from $\overline{N}_0^s$ to N_0^d. The path from N_0^s to N_0^d is then formed, as shown in Figure 8, by the segment between the vertex of N_0^s and x, followed by the segment between x and the vertex of N_0^d. Every such path is disjoint from any other path from N_0^s to N_0^d and from N_2^s to N_2^d connecting pairs associated with vertices of the independent set. Property 2 is then proved.

Let n be the number of vertices of graph G. Every input sequence for the graph $G = G_{\log_5 n}^0$ is therefore mapped in a brick wall W of size $N = 6^i \times 2^i$. We then conclude with the following theorem.

THEOREM 31. *Any randomized algorithm for on-line path coloring on general*

networks of N vertices has competitive ratio $\Omega(N^{\frac{\log 5}{\log 12}\log_5 4})$.

Proof. The theorem follows from Theorem 28 and by observing that any input sequence of vertices of the graph G of n vertices can be mapped into a brick wall of $N = n^{\frac{\log 12}{\log 5}}$ vertices. □

7. Lower bounds for optical networks. As pointed out in the introduction, a lower bound for on-line edge-disjoint paths is also a lower bound for on-line routing in reconfigurable networks (benefit version), and a lower bound for on-line path coloring is also a lower bound for on-line routing in reconfigurable networks (coloring version). Therefore, from Theorems 19 and 31, we derive the following two corollaries.

COROLLARY 32. *Any nonpreemptive randomized algorithm for on-line routing in reconfigurable optical networks (benefit version) on general networks of N vertices has competitive ratio* $\Omega(N^{\frac{1-\log_4 3}{\log_4 6}})$.

COROLLARY 33. *Any randomized algorithm for on-line routing in reconfigurable optical networks (coloring version) on general networks of N vertices has competitive ratio* $\Omega(N^{\frac{2}{3}(1-\log_4 3)})$.

In what follows we present a simple result (Lemma 36) that allows us to reduce maximum independent sets to routing in switchless optical networks (benefit version) and minimum graph coloring to routing in switchless optical networks (coloring version). This reduction is from a graph of n vertices to a network of $O(n)$ vertices. Therefore, from Theorems 11 and 28 we respectively derive the following two corollaries.

COROLLARY 34. *Any nonpreemptive randomized algorithm for on-line routing in switchless optical networks (benefit version) on general networks of N vertices has competitive ratio* $\Omega(N^{1-\log_4 3})$.

COROLLARY 35. *Any randomized algorithm for on-line routing in switchless optical networks (coloring version) on general networks of N vertices has competitive ratio* $\Omega(N^{1-\log_4 3})$.

The required reductions are derived from the following lemma.

LEMMA 36. *For any undirected graph $G = (V, E)$ there exist a directed network $D' = (V', E')$ and a one-to-one mapping from vertices v in G to calls $(s(v), t(v))$ in D' so that two vertices $v_i, v_j \in V$ are adjacent if and only if the two corresponding calls $(s(v_i), t(v_i))$, $(s(v_j), t(v_j))$ are conflicting.*

Proof. Let n be the number of vertices of $V = \{v_1, \ldots, v_n\}$. D' is a bipartite graph whose set of vertices V' is formed by the union of two sets of n vertices, $S = \{s_1, \ldots, s_n\}$ and $T = \{t_1, \ldots, t_n\}$. The one-to-one mapping is defined by $s(v_i) = s_i$ and $t(v_i) = t_i$, $i = 1, \ldots, n$. The set of directed edges of D' is $E' = \{(s(v), t(v)) | v \in V\} \cup \{(s(v_i), t(v_j)) | (v_i, v_j) \in E\}$.

For any two vertices $v_i, v_j \in V$ consider the two calls $(s(v_i), t(v_i))$ and $(s(v_j), t(v_j))$ in D'. If v_i and v_j are adjacent in E, then the bipartite graph D' contains the two edges $(s(v_i), t(v_j))$ and $(s(v_j), t(v_i))$. Therefore, $t(v_j) \in R(s(v_i))$ and $t(v_i) \in R(s(v_j))$, implying that the two calls are interfering. For the other direction, if v_i and v_j are nonadjacent, then $t(v_j) \notin R(s(v_i))$ and $t(v_j) \notin R(s(v_i))$. Since the graph D' is bipartite, with all edges directed from S to T, it follows that $u_2 \notin R(v_1)$ and $u_1 \notin R(v_2)$, implying that the two calls are noninterfering. □

8. Lower bounds for on-line edge-disjoint fixed paths. In this section we present tight lower bounds for on-line edge-disjoint fixed paths, an $\Omega(\sqrt{n})$ lower bound for *meshes* and an $\Omega(n)$ lower bound for *general networks*. We use the terminology of call control.

We make use of Yao's lemma (see section 2) and establish a lower bound for any deterministic algorithm on a given probability distribution. First we describe the probability distribution we use in proving the lower bounds.

The generic call c_i of an input sequence is specified by a path p_i connecting endpoints s_i and t_i. Two calls c_i and c_j from the input sequence are said to be *inconsistent* if p_i and p_j intersect on at least one edge ($p_i \cap p_j \neq \emptyset$), and *consistent* otherwise ($p_i \cap p_j = \emptyset$).

Every input sequence having nonzero probability is formed of $2k$ calls presented in k steps according to the following probability distribution:

1. At step j, $j = 1, \ldots, k$, two inconsistent calls c_j^1 and c_j^2 are presented.
2. Toss a fair coin.
   - If heads, all the calls presented later will be consistent with c_j^1 and inconsistent with c_j^2.
   - If tails, all the calls presented later will be consistent with c_j^2 and inconsistent with c_j^1.

LEMMA 37. *Any nonpreemptive randomized algorithm for on-line edge-disjoint fixed paths has competitive ratio $\Omega(k)$ on the probability distribution of k steps described above.*

Proof. There is a maximal set of k mutually consistent calls. This set is formed by selecting for every step of the sequence the call that is consistent with all the calls presented in the future. The claim then follows by proving an $O(1)$ upper bound on the expected on-line benefit.

Let $p(i)$ be the probability that an on-line algorithm has accepted i calls, $i \geq 1$, at some point along the execution of the algorithm. We prove by induction on i that $p(i) \leq \frac{1}{2^{i-1}}$. For the base of the induction, $p(1) \leq 1$. Assume $p(i-1) \leq \frac{1}{2^{i-2}}$, $i \geq 2$. Let A_i, $i \geq 2$, be the event "The algorithm is able to accept one additional call after having already accepted $i-1$ calls." Let c be the $(i-1)$th call accepted by the algorithm. The probability of event A_i is $p(A_i) \leq 1/2$ since, with probability $1/2$, all the calls presented after c are inconsistent with c itself. We then have $p(i) \leq p(A_i)p(i-1) \leq \frac{1}{2^{i-1}}$. Let $p(=i)$ be the probability that the on-line algorithm has accepted exactly i calls along its execution. We clearly have $p(=i) \leq p(i)$. Therefore, the expected on-line benefit is bounded by $E[\mathrm{ON}] \leq \sum_{i=1}^{k} ip(=i) \leq \sum_{i=1}^{k} i\frac{1}{2^{i-1}} = O(1)$. ∎

We will present in the following two sections the embedding of the probability distribution described in this section on a mesh topology and a general network. The obvious goal is to have k as large as possible with respect to the size of the network. In the two following subsections we will implement the probability distribution on specific networks to provide lower bounds on mesh topologies and general networks.

8.1. Lower bound on meshes. Consider a two-dimensional $\sqrt{n} \times \sqrt{n}$ mesh. Let the set of nodes be $\{(u,v) | 1 \leq u \leq \sqrt{n}, 1 \leq v \leq \sqrt{n}\}$. Every vertex is denoted with a pair; the first item is the row index, and the second item is the column index.

For our construction we use a network (see Figure 9, where the row index increases from top to bottom, the column index from left to right) derived from a two-dimensional mesh via the two following operations:

1. Remove all vertices (u,v) with $v > u$, and the adjacent edges.
2. Insert the edges $\{((u,v),(u-1,v+1)) | 3 \leq u \leq \sqrt{n}, 1 \leq v \leq \sqrt{n}-1\}$.

Such network can always be embedded in a mesh of size $2\sqrt{n} \times 2\sqrt{n}$.

We prove that any instance drawn from the probability distribution for the $\Omega(k)$ lower bound of the previous section can be implemented on this network with $k =$

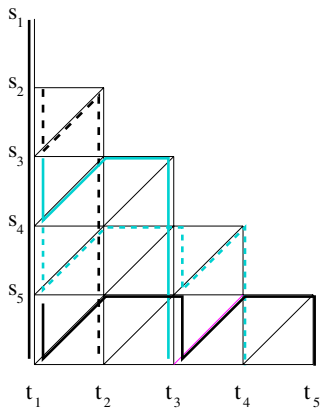

FIG. 9. *The network for the lower bound on meshes.*

$\frac{\sqrt{n}-1}{2}$. This is done by presenting a sequence of $\sqrt{n}-1$ calls; the path of each call is chosen in order to make it consistent or inconsistent with any other previous call in the sequence, as required from the outcome of the coin tosses.

Call c_i in the sequence is defined by a pair of vertices (s_i, t_i) and by a path p_i that connects s_i to t_i. Let $C_i = \{j : j < i, p_i \cap p_j = \emptyset\}$ be the set of previous calls in the input sequence from the probability distribution that are consistent with c_i, and let $I_i = \{j : j < i, p_i \cap p_j \neq \emptyset\}$ be the set of previous calls that are inconsistent with c_i.

Call c_i of the sequence, $i = 1, \ldots, \sqrt{k}-1$, is defined as follows:

- $s_i = (i, 1)$;
- $t_i = (\sqrt{n}, i)$;
- p_i is formed by the following sets of edges:
  1. $E_i^1 = \{((i,j),(i,j+1)) | j \in C_i\}$;
  2. $E_i^2 = \{((i,j),(i+1,j)) \text{ and } ((i+1,j),(i,j+1)) | j \in I_i\}$;
  3. $E_i^3 = \{((j,i),(j+1,i)) | i \leq j \leq \sqrt{n}-1\}$.

Observe that the set of edges forming p_i, i.e., $E_i^1 \cup E_i^2 \cup E_i^3$, is actually a path from s_i to t_i. For $j = 1, \ldots, i-1$, vertex (i,j) is connected to vertex $(i, j+1)$, either directly if $j \in C_i$ or through the two-edge path formed by $((i,j),(i+1,j))$ and $((i+1,j),(i,j+1))$ if $j \in I_i$. For $j = i, \ldots, \sqrt{n}-1$, vertex (j,i) is directly connected to vertex $(j+1,i)$. Moreover, the first vertex of the path is $s_i = (i,1)$, and the last vertex is $(\sqrt{n}, i)$.

Figure 9 shows a network with a sequence of five calls and the relative paths, where c_1 and c_3 are inconsistent and c_2 and c_4 consistent with respect to following calls.

LEMMA 38. *Let c_j and c_i, $j < i$, be two calls in the sequence. Calls p_i and p_j do not intersect if and only if $j \in C_i$.*

Proof. First we show that if $j \in I_i$, then c_i and c_j intersect in one edge, namely $((i,j),(i+1,j))$. In fact, this edge always belongs to p_j, while it belongs to p_i only if c_j is inconsistent with c_i.

Next, we show that if $j \in C_i$, then p_i and p_j do not intersect in any edge. For any h, all edges in $E_h^1 \cup E_h^2$ are either between two vertices in row h or connect a vertex in row h to a vertex in row $h+1$. Hence, the set $E_i^1 \cup E_i^2$ does not intersect with the set $E_j^1 \cup E_j^2$.

Since all edges in p_j have endpoints of column at most j, and all edges in E_i^3 have endpoints of column $i > j$, the two sets do not intersect.

It remains to show that the edges in E_j^3 do not intersect with the edges in $E_i^1 \cup E_i^2$. This follows since every edge of E_j^3 has both endpoints on column j, whereas since $j \in C_i$, no edge in $E_i^1 \cup E_i^2$ has both endpoints on column j. □

We then conclude with the following theorem.

THEOREM 39. *Any nonpreemptive randomized algorithm for on-line edge-disjoint with fixed paths on meshes of n nodes has competitive ratio* $\Omega(\sqrt{n})$.

8.2. Lower bound on general networks. We prove an $\Omega(n)$ lower bound on the competitive ratio of randomized algorithms for the on-line edge-disjoint fixed paths problem in general networks by showing that the probability distribution at the basis of Lemma 37 can be constructed for a sequence of $\Omega(n)$ steps, in a complete graph with $O(n)$ vertices.

Let n be a *prime number*, and let $V \cup V'$ with $V = \{v(0), \ldots, v(n-1)\}$ and $V' = \{v'(0), \ldots, v'(n-1)\}$ be the set of vertices of a complete graph G.

We define

$$n_h^l = (h \cdot l) \bmod n,$$

with $h = 1, \ldots, \lfloor \frac{n-1}{2} \rfloor$ and $l = 1, \ldots, n$.

The two following lemmas follow from simple algebraic properties of prime numbers.

LEMMA 40. *Let* (h, l) *and* (h', l') *be such that* $h, h' \in \{1, \ldots, \frac{n-1}{2}\}$, $h \neq h'$, *and* $l, l' \in \{1, \ldots, n-1\}$. *Then,* $\{n_h^l, n_h^{l+1}\} \neq \{n_{h'}^{l'}, n_{h'}^{l'+1}\}$.

LEMMA 41. *For any integer* $h = 1, \ldots, \frac{n-1}{2}$ *it holds that*

$$\{n_h^l | l = 0, \ldots, n-1\} = \{0, 1, \ldots, n-1\}.$$

Let c_i be the ith call of the sequence, let $C_i = \{j : j < i, p_i \cap p_j = \emptyset\}$ be the set of previous calls that are consistent with c_i, and let $I_i = \{j : j < i, p_i \cap p_j \neq \emptyset\}$ be the set of previous calls that are inconsistent with c_i.

With every pair of calls c_i, c_j, $i = 1, \ldots, j-1$, $j = 1, \ldots, k$, two values s_{ij} and s'_{ij} are associated, $s_{ij} \in \{0, \ldots, n-2\}$ and $s'_{ij} \in \{0. \ldots, n-1\}$.

The idea behind the construction presented in the remainder of this section is the following. The generic path p_i associated with call c_i crosses all vertices of set V in the sequence $v(n_i^0), \ldots, v(n_i^{n-1})$. (By Lemma 41 such a sequence spans the set V.) Consider two calls c_i and c_j, $i < j$, with associated values s_{ij} and s'_{ij}. By Lemma 41, there exist two integer values q and r such that $n_i^q = n_j^r = s_{ij}$. In our construction, path p_i always contains edges $(v(s_{ij}), v'(s'_{ij}))$ and $(v'(s'_{ij}), v(n_i^{q+1}))$. If $c_i \in C_j$, then path p_j must not share any edge with p_i. In this case vertex $v(s_{ij})$ is followed by $v(n_j^{r+1})$ in p_j. Otherwise, if $c_i \in I_j$, then path p_j contains edges $(v(s_{ij}), v'(s'_{ij}))$ and $(v'(s'_{ij}), v(n_j^{r+1}))$, the first of which is common with p_i.

To ensure that two consistent calls do not share any edge we use Lemma 40, which states that two integers between 0 and $n-1$ are adjacent only in one sequence; furthermore, the association of values s_{ij} and s'_{ij} with any pair of calls c_i, c_j is to guarantee that any edge between a vertex in V and a vertex in V', included in some path p_i and dedicated to the possible intersection with path p_j, does not appear in any other path.

Values s_{ij} and s'_{ij} are assigned to any pair of calls c_i, c_j, $i < j$, in order of increasing j, and for a fixed j in order of increasing i. Let $n_i^q = n_j^r = s_{ij}$.

Consider a pair x, y, $x < y \leq j$, for which the values s_{xy} and s'_{xy} have been assigned prior to the assignment for i, j. Let l and m be integers such that $n_x^l = n_y^m = s_{xy}$. The conditions on the assignment for c_i, c_j are as follows:

1. Assign value s_{ij} different from s_{xy} with $y = i$, $y = j$, or $x = i$.
2. Assign value s'_{ij} different from s'_{xy} if $\{s_{xy}, n_x^{l+1}, n_y^{m+1}\} \cap \{s_{ij}, n_i^{q+1}, n_j^{r+1}\} \neq \emptyset$ for any previously assigned pair xy.

LEMMA 42. *There exists a sequence of $k = \Omega(n)$ calls such that for every pair c_i, c_j, $i < j$, values s_{ij} and s'_{ij} can be assigned obeying conditions* 1 *and* 2.

Proof. We prove that there exists a value $k = \Omega(n)$ such that, in the worst case, at least one possibility to assign values s_{ij} and s'_{ij} is left for any pair of calls c_i, c_j with $i < j \leq k$.

Denote by x, y any pair considered before i, j in the designed order. Then either $x < y < j$ or $y = j$ and $x < i$.

Following condition 1, we can bound the number of pairs such that $y = i$, $y = j$, or $x = i$ by $(i-1) + (j-1) + (j-i) \leq 2(k-2)$. Therefore, if $n > 2(k-2)$, at least one possibility is left for assigning s_{ij}.

Following condition 2, we would like to bound the number of pairs c_x, c_y for which one of the three values in $\{s_{ij}, n_i^{q+1}, n_j^{r+1}\}$ appears in $\{s_{xy}, n_x^{l+1}, n_y^{m+1}\}$.

For fixed $h < k$, each of the values in $\{s_{ij}, n_i^{q+1}, n_j^{r+1}\}$ is equal to n_h^d for some integer d. By condition 1 there could be either one y for which $s_{hy} = n_h^d$ or one x such that $s_{xh} = n_h^d$. Similarly, there could be either one y for which $s_{hy} = n_h^{d-1}$ or one x such that $s_{xh} = n_h^{d-1}$. Thus we get that h can be involved in at most six pairs for which the above restriction holds.

Hence, if $n > 6(k-1)$, there is still a possibility left for assigning s'_{ij}.

The above observations show that by setting $k = n/6$, values s_{ij} and s'_{ij} can be assigned to each pair of calls c_i, c_j. ∎

In the following we formally define call c_i, $i = 1, \ldots, k$. The endpoints s_i, t_i of call c_i are

- $s_i = v(n_i^0)$,
- $t_i = v(n_i^{n-1})$.

Path p_i associated with call c_i contains the following set of edges:

1. $(v(n_i^l), v(n_i^{l+1}))$, for any $l \in \{1, \ldots, n-1\}$ such that
   (a) For all $j < i$, $n_i^l \neq s_{ji}$ and for all $j > i$, $n_i^l \neq s_{ij}$.
   (b) There exists $j < i$ such that $n_i^l = s_{ji}$ and $j \in C_i$.
2. $(v(n_i^l), v'(s'_{ij}))$ and $(v'(s'_{ij}), v(n_i^{l+1}))$, for any $l \in \{1, \ldots, n-1\}$ such that there exists $j > i$ for which $s_{ij} = n_i^l$.
3. $(v(n_i^l), v'(s'_{ji}))$ and $(v'(s'_{ji}), v(n_i^{l+1}))$, for any $l \in \{1, \ldots, n-1\}$ such that there exists $j < i$ for which $s_{ji} = n_i^l$ and $j \in I_i$.

LEMMA 43. *Let c_i, c_j, with $i < j$ be two calls in the sequence. p_i and p_j do not intersect if and only if $i \in C_j$.*

Proof. First we prove that, for any $i \in I_j$, the paths p_i and p_j intersect. Then the edge $(v(s_{ij}), v'(s'_{ij}))$ is in p_i by rule 2 and in p_j by rule 3.

We now turn to proving that if $c_i \in C_j$, then the two paths p_i and p_j do not intersect. Lemma 40 ensures that the edges between two vertices in V (rule 1) cannot be shared by two paths.

Edges in p_i connecting vertices of V to vertices of V' are either (by rule 2) of the form $(v(s_{ih}), v'(s'_{ih}))$ or $(v'(s'_{ih}), v(n_i^{d+1}))$ for some $h > i$ and d such that $s_{ih} = n_i^d$, or (by rule 3) $(v(s_{hi}), v'(s'_{hi}))$ or $(v'(s'_{hi}), v(n_i^{d+1}))$ for some $h < i$ and d such that

$s_{hi} = n_i^d$ (by rule 3). Thus, one endpoint of each such edge is a vertex $v'(s'_{xy})$, and the other one has index in $\{s_{xy}, n_x^{l+1}, n_y^{m+1}\}$ for a pair in which one of x, y is equal to i and $n_x^l = n_y^m = s_{xy}$. A similar statement holds for path p_j. By condition 2 of the assignment procedure for s'_{ij}, such edges cannot appear in more than one path, and hence the claim follows. □

We conclude with the following theorem.

THEOREM 44. *Any nonpreemptive randomized algorithm for on-line edge-disjoint fixed paths in a network of n nodes has competitive ratio* $\Omega(n)$.

Acknowledgments. The authors would like to thank Yossi Azar, Anna Karlin, and Alberto Marchetti-Spaccamela. We also thank Allan Borodin, Ran El-Yaniv, Haim Kaplan, Mario Szegedy, and two anonymous referees for very helpful comments and for helping us avoiding errors.

EFFICIENT BUNDLE SORTING*

YOSSI MATIAS†, ERAN SEGAL‡, AND JEFFREY SCOTT VITTER§

Abstract. Many data sets to be sorted consist of a limited number of distinct keys. Sorting such data sets can be thought of as bundling together identical keys and having the bundles placed in order; we therefore denote this as *bundle sorting*. We describe an efficient algorithm for bundle sorting in external memory, which requires at most $c(N/B)\log_{M/B} k$ disk accesses, where N is the number of keys, M is the size of internal memory, k is the number of distinct keys, B is the transfer block size, and $2 < c < 4$. For moderately sized k, this bound circumvents the $\Theta((N/B)\log_{M/B}(N/B))$ I/O lower bound known for general sorting. We show that our algorithm is optimal by proving a matching lower bound for bundle sorting. The improved running time of bundle sorting over general sorting can be significant in practice, as demonstrated by experimentation. An important feature of the new algorithm is that it is executed "in-place," requiring no additional disk space.

1. Introduction.

Sorting is a frequent operation in many applications. It is used not only to produce sorted output, but also in many sort-based algorithms such as grouping with aggregation, duplicate removal, and sort-merge join, as well as set operations including union, intersect, and except [Gra93, IBM95]. In this paper, we identify a common external memory sorting problem, present an algorithm to solve it while circumventing the lower bound for general sorting for this problem, prove a matching lower bound for our algorithm, and demonstrate the improved performance through experiments.

External merge sort is the most commonly used algorithm for large-scale sorting. It has a run formation phase, which produces sorted runs, and a merge phase, which merges the runs into sorted output. Its running time, as in most external memory algorithms, is dominated by the number of input/outputs (I/Os) performed, which is $O((N/B)\log_{M/B}(N/B))$, where N is the number of keys, M is the size of internal memory, and B is the transfer block size. It was shown in [AV88] (see also [Vit99]) that there is a matching lower bound within a constant factor.

The number of passes over the sequence performed by sorting algorithms is $\lceil \log_{M/B}(N/B) \rceil$ in the worst case. When the available memory is large enough compared to the size of the sequence, the sorting can be performed in one or two passes over the sequence (see [ADADC+97] and references therein). However, there are many

settings in which the available memory is moderate, at best. For instance, in multithreading and multiuser environments, an application, process, or thread which may execute a sorting program might be allocated only a small fraction of the machine memory. Such settings may be relevant to anything from low-end servers to high-end decision support systems. For moderate size memory, $\log_{M/B}(N/B)$ may become large enough to imply a significant number of passes over the data. As an example, consider the setting $N = 256$ GB, $B = 128$ kB, and $M = 16$ MB. Then we have $\log_{M/B}(N/B) = 3$, and the number of I/Os per disk block required by merge sort is at least 6. For smaller memory allocations, the I/O costs will be even greater.

Our contributions. Data sets that are to be sorted often consist of keys taken from a bounded universe. This fact is well exploited in main memory algorithms such as counting sort and radix sort, which are substantially more efficient than general sort. In this paper we consider the extent to which a limit, k, on the number of distinct keys can be exploited to obtain more effective sorting algorithms in external memory on massive data sets, where the attention is primarily given to the number of I/Os. Sorting such data sets can be thought of as bundling together identical keys and having the bundles placed in order; we therefore denote this as *bundle sorting*. It is similar to partial sorting, which was identified by Knuth [Knu73] as an important problem. While many algorithms are given for partial sorting in main memory, to the best of our knowledge, there exist no efficient algorithms for solving the problem in external memory. As we shall see, bundle sorting can be substantially more efficient than general sorting.

A key feature of bundle sorting is that the number of I/Os performed per disk block depends solely on the number k of distinct keys. Hence, in sorting applications in which the number of distinct keys is constant, the number of I/Os performed per disk block remains constant for any data set size. In contrast, merge sort or other general sorting algorithms will perform more I/Os per disk block as the size of the data set increases. In settings in which the size of the data set is large this can be significant. In the example given earlier, six I/Os per data block are needed to sort in the worst case. For some constant $k < 100$, bundle sorting performs only two I/Os per disk block, and for some constant $k < 10000$, only four I/Os per disk block, regardless of the size of the data set.

The algorithm that we present requires at most $3 \log_{M/B} k$ passes over the sequence. It performs the sorting in-place, meaning that the input data set can be permuted as needed without using any additional working space in external memory. When the number k of distinct keys is less than N/B, our bundle sorting algorithm circumvents the lower bound for general sorting. The lower bound for general sorting is derived by a lower bound for permuting the input sequence, which is an easier problem than general sorting. In contrast to general sorting, bundle sorting is not harder than permuting; rather than requiring that a particular key be moved to a specific location, it is required that the key be moved to a location within a specified range, which belongs to its bundle. This so-called bundle-permutation consists of a set of permutations, and implementing bundle-permutation can be done more efficiently than implementing a particular permutation.

For cases in which $k \ll N/B$, the improvement in the running time of bundle sorting over general sorting algorithms can be significant in practical sorting settings, as supported by our experimentation done on U.S. Census data and on synthetic data. In fact, the number of passes over the sequence executed by our algorithm does not depend at all on the size of the sequence, in contrast to general sorting algorithms.

To complement the algorithmic component, we prove a matching lower bound

for bundle sorting. In particular, we show that the number of I/Os required in the worst case to sort N keys consisting of k distinct key values is $\Omega((N/B)\log_{M/B} k)$. This lower bound is realized by proving lower bounds on two problems that are both easier than bundle sorting, and the combination of the lower bounds gives the desired result. The first special case is bundle-permutation, and the second is a type of matrix transposition. Bundle-permutation is the special case of bundle sorting in which we know the distribution of key values beforehand, and thus it is easier than bundle sorting for much the same reason that permuting is easier than general sorting. The other special case of bundle sorting is a type of matrix transposition, in which we transpose a $k \times N/k$ matrix, but the final order of the elements in each row is not important. This problem is a special case of bundle sorting of N keys consisting of exactly N/k records for each of k different keys and is thus easier than bundle sorting. Interestingly, these two problems, when combined, capture the difficulty of bundle sorting.

Our bundle sorting algorithm is based on a simple observation: If the available memory, M, is at least kB, then we can sort the data in three passes over the sequence, as follows. In the first pass, we count the size of each bundle. After this pass we know the range of blocks in which each bundle will reside upon termination of the bundle sorting. The first block from each such range is loaded to main memory. The loaded blocks are scanned concurrently, while swapping keys so that each block is filled only with keys belonging to its bundle. Whenever a block is fully scanned (i.e., it contains only keys belonging to its bundle), it is written back to disk, and the next block in its range is loaded. In this phase, each block is loaded exactly once (except for at most k blocks in which the ranges begin), and the total number of accesses over the input sequence in the entire algorithm is hence 3. Whenever memory is insubstantial to hold the k blocks in memory, we group bundles together into M/B superbundles, implementing the algorithm to sort the superbundles to M/B subsequences and reiterate within each subsequence, incurring a total of $\log_{M/B} k$ iterations over the sequence to complete the bundle sorting.

There are many applications and settings in which bundle sorting may be applied, resulting in a significant speed-up in performance. For instance, any application that requires partial sorting or partitioning of a data set into value independent buckets can take advantage of bundle sorting since the number of buckets (k in bundle sorting) is small, thus making bundle sorting very appealing. Another example would be *accelerating sort join computation for suitable data sets*: Consider a join operation between two large relations, each having a moderate number of distinct keys; then our bundle sorting algorithm can be used in a sort join computation, with performance improvement over the use of general sort algorithm.

Finally, we consider a more performance-sensitive model that, rather than just counting the number of I/Os as a measurement for performance, differentiates between a sequential I/O and a random I/O and assigns a reduced cost for sequential I/Os. We study the tradeoffs that occur when we apply bundle sorting in this model, and show a simple adaptation of bundle sorting that results in an optimal performance. In this sense, we also present a slightly different algorithm for bundle sorting, which is more suitable for sequential I/Os.

The rest of the paper is organized as follows. In section 2 we explore related work. In section 3 we describe the external memory model in which we will analyze our algorithm and prove the lower bound. Section 4 presents our algorithm for bundle sorting along with the performance analysis. In section 5 we prove the lower bound for external bundle sorting. In section 6 we consider a more performance-sensitive

model, which takes into account a reduced cost for sequential I/Os and shows the modifications in our bundle sorting algorithm required to achieve an optimal algorithm in that model. Section 7 describes the experiments we conducted, and section 8 is our conclusions.

2. Related work. External memory sorting is an extensively researched area. Many efficient in-memory sorting algorithms have been adapted for sorting in external memory, such as merge sort, and much of the recent research in external memory sorting has been dedicated to improving the run time performance. Over the years, numerous authors have reported the performance of their sorting algorithms and implementations (cf. [Aga96, BBW86, BGK90]). We note a recent paper [ADADC+97] that shows external sorting of 6 GB of data in under one minute on a network of workstations. For the problem of bundle sorting where $k < N/B$ we note that our algorithm will reduce the number of I/Os that all these algorithms perform and hence can be utilized in benchmarks. We also consider a more performance-sensitive model of external memory, in which rather than just counting the I/Os for determining the performance, there is a reduced cost for sequential I/Os compared to random access I/Os. We study the tradeoffs there, and show the adaptation in our bundle sorting algorithm to arrive at an optimal algorithm in that model. We also note that another recent paper [ZL98] shows in detail how to improve the merge phase of the external merge sort algorithm, a phase that is completely avoided by using our in-place algorithm.

In the general framework of external memory algorithms, Aggarwal and Vitter showed a lower bound of $\Omega((N/B)\log_{M/B}(N/B))$ on the number of I/Os needed in the worst case for sorting [AV88, Vit99]. In contrast, since our algorithm relies on the number k of distinct keys for its performance, we are able to circumvent this lower bound when $k \ll N/B$. Moreover, we prove a matching lower bound for bundle sorting, which shows that our algorithm is optimal.

Finally, sorting is used not only to produce sorted output, but also in many sort-based algorithms such as grouping with aggregation, duplicate removal, and sort-merge join, as well as set operations including union, intersect, and except [Gra93, IBM95]. In many of these cases the number of distinct keys is relatively small, and hence bundle sorting can be used for improved performance. We identify important applications for bundle sorting, but note that since sorting is such a common procedure, there are probably many more applications for bundle sorting that we did not consider.

3. External memory model. In our main bundle sorting algorithm and in the lower bound that we prove, we use the external memory model from Aggarwal and Vitter [AV88] (see also [Vit99]). The model is as follows. We assume that there is a single central processing unit, and we model secondary storage as a generalized random-access magnetic disk. (For completeness, the model is also extended to the case in which the disk has some parallel capabilities.) The parameters are

$$\begin{aligned} N &= \#\text{ records to sort,} \\ M &= \#\text{ records that can fit into internal memory,} \\ B &= \#\text{ records transferred in a single block,} \\ D &= \#\text{ blocks that can be transferred concurrently,} \end{aligned}$$

where $1 \le B \le M/2$, $M < N$, and $1 \le D \le \lfloor M/B \rfloor$. For brevity we consider only the case of $D = 1$, which corresponds to a single conventional disk.

The parameters N, M, and B are referred to as the *file size*, *memory size*, and *transfer block size*, respectively. Each block transfer is allowed to access any contiguous group of B records on the disk. We will consider the case where $D = 1$, meaning that there is no disk parallelism. Performance in this model is measured by the number of I/O accesses performed where the cost of all I/Os is identical. In section 6 we consider a more performance-sensitive model in which we differentiate between costs of sequential and random-access I/Os and assign a reduced cost for sequential I/Os.

4. External bundle sorting algorithm. In this section we present our bundle sorting algorithm, which sorts in-place a sequence that resides on disk and contains k distinct keys. We start by defining the bundle sorting problem:

Input: *A sequence of keys* $\{a_1, a_2, \ldots, a_n\}$ *from an ordered universe* U *of size* k.

Output: *A permutation* $\{a'_1, a'_2, \ldots, a'_n\}$ *of the input sequence such that* $a'_1 \leq a'_2 \leq \cdots \leq a'_n$.

In our algorithm, it will be easy, and with negligible overhead, to compute and use an order-preserving mapping from U to $\{1, \ldots, k\}$; we discuss the implementation details of this function in section 4.2. This enables us to consider the problem at hand as an integer sorting problem in which the keys are taken from $\{1, \ldots, k\}$. Hence, we assume that $U = \{1, \ldots, k\}$.

We use the external memory model from section 3, where performance is determined by the number of I/Os performed. Our goal is to minimize the number of disk I/Os. In section 6 we consider a more performance-sensitive model in which rather than simply counting I/Os as a measurement of performance, we differentiate between a sequential I/O and a random I/O and assign a reduced cost to sequential I/Os. We show the necessary modifications to the bundle sorting presented in this section required to achieve an optimum in that model.

4.1. $\{1, \ldots, k\}$ integer sorting. We start by presenting "one-pass sorting"—a procedure that sorts a sequence into $\mu = \lfloor M/B \rfloor$ distinct keys. It will be used by our bundle sorting algorithm to perform one iteration that sorts a chunk of data blocks into μ ranges of keys.

The general idea is this: Initially we perform one pass on the sequence, loading one block of size B at a time, in which we count the number of appearances of each of the μ distinct keys in the sequence. Next, we keep in memory μ blocks and a pointer for each block, where each block is of size B. Using the count pass, we initialize the μ blocks, where the ith block is loaded from the exact location in the sequence where keys of type i will start residing in the sorted sequence. We set each block pointer to point to the first key in its block. When the algorithm runs, the ith block pointer is advanced as long as it encounters keys of type i. When a block pointer is "stuck" on a key of type j, it waits for the jth block pointer until it too is stuck (this will happen since a block pointer yields only to keys of its block), in which case a swap is performed and at least one of the two block pointers may continue to advance. When any of the μ block pointers reaches the end of its block, we write that block back to disk to the exact location from which it was loaded, and load the next contiguous block from disk into memory (and of course set its block pointer again to the first key in the block). We finish with each of the μ blocks upon crossing the boundaries of the next adjacent block. The algorithm terminates when all blocks are done with. The following is a pseudocode of the algorithm. See also Figure 1.

ONE-PASS SORTING ALGORITHM.

procedure one-pass-sort $(sequence, k, M, B)$

for $i = 0$ to $\lfloor M/B \rfloor$

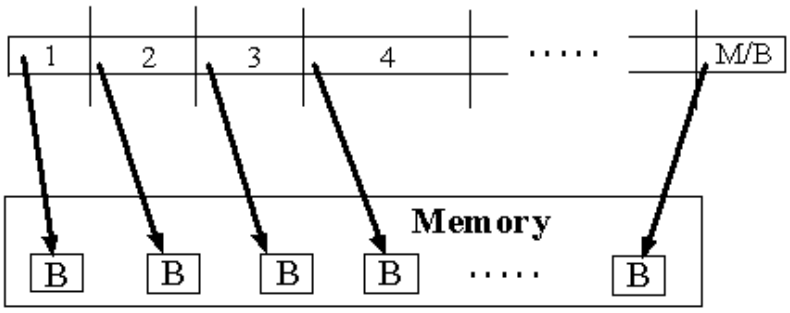

FIG. 1. *Initialization of the M/B blocks in the One-pass sorting algorithm. After the counting pass, we know where the sorted blocks reside, and load blocks from these locations. Swaps are performed in memory. When any of the blocks is full, we write it to disk to the location from which it was loaded, and load the next block from disk.*

```
        current_block = ith block of sequence
        for j = 0 to B of current_block
            Count[sequence[i · B + j]]++
    Count[k + 1] = M
    for i = 1 to k
        μ[i] = block at position Count[i] from sequence
        μ_block_pointer[i] = 0
        μ_global_pointer[i] = Count[i]
    blocks_done = 0
    while blocks_done < k
        for i = 1 to k
            if μ_global_pointer[i] < Count[i + 1]
                while μ_block_pointer[i] < B and μ[i][μ_block_pointer[i]] = i
                    μ_block_pointer[i]++
                    μ_global_pointer[i]++
                stuck[i] = (μ_block_pointer[i] < B and μ_global_pointer[i] < Count[i + 1])
                stuck_value = μ[i][μ_block_pointer[i]]
                if stuck[i] and stuck[stuck_value] then
                    swap μ[i][μ_block_pointer[i]] with
                    μ[stuck_value][μ_block_pointer[stuck_value]]
                if μ_block_pointer[i] = B
                    Write μ[i] as a block to the location from which it was loaded
                    μ[i] = block at position μ_global_pointer[i] from sequence
                    μ_block_pointer[i] = 0
                if μ_global_pointer[i] = Count[i + 1]
                    blocks_done++;
```

LEMMA 4.1. *Let S be a sequence of N keys from $\{1, \ldots, \mu\}$, let B be the transfer block size, and let M be the available memory such that $M \geq \mu B$. Then the sequence can be sorted in-place using the procedure "one-pass sorting" with a total of $\lceil 3N/B + 2M/B \rceil$ I/Os.*

Proof. We first show that the algorithm indeed sorts the input sequence. The algorithm allocates one pointer in memory for each of the μ distinct keys, and the ith

such pointer writes only contiguous blocks of records whose keys consist solely of the ith key. Thus, to show that the sequence is sorted by "one-pass sorting," it suffices to show that the algorithm terminates and that, upon termination, the ith pointer writes its blocks in a physical location that precedes the blocks written by any j pointer for $j > i$. The ordering between the pointers is ensured by setting the contiguous block of the ith pointer to write to the exact location where keys of its type should reside in the sorted sequence. This location is derived from the first pass in which we count the number of appearances of each of the μ distinct keys. Termination is guaranteed, since at each step at least one of the pointers encounters keys of its type, or a swap will be performed and at least one of the pointers can proceed. Note that such a swap will always be possible, since if the ith pointer is "stuck" on a key of type j, then the jth pointer will necessarily get stuck at some step. Since at each step one of the keys is written and there are N keys, the algorithm will terminate.

For computing the number of I/Os, note that the first counting pass reads each block once and thus requires $\lceil N/B \rceil$ I/Os. All the μ pointers combined read and write each block once, adding another $\lceil 2N/B \rceil$ I/Os. Finally, if the number of appearances of each distinct key is not an exact multiple of B, then every pair of consecutive pointers may overlap by one block at the boundaries, thus requiring an additional $\lceil 2M/B \rceil$ I/Os. □

We now present the complete integer sorting algorithm. We assume that the sequence contains keys in the range $1, \ldots, k$, where k is the number of distinct keys. In section 4.2 we discuss the adaptation needed if the k distinct keys are not from this integer range. We use the above one-pass sorting procedure. The general idea is this: We initially perform one sorting iteration in which we sort the sequence into $k' = \lfloor M/B \rfloor$ keys. We select a mapping function f such that for all $1 \le i \le k$ we have $f(i) = \lceil ik'/k \rceil$, and we apply f to every key when the key is examined. This ensures that we are actually in the range of $1, \ldots, k'$. Moreover, it will create sorted buckets on disk such that the number of distinct keys in each of the buckets is roughly k/k'. We repeat this procedure recursively for each of the sorted blocks obtained in this iteration until the whole sequence is sorted. Each sorting iteration is done by calling the procedure for one-pass sorting. We give a pseudocode of the algorithm below, followed by an analysis of its performance.

THE INTEGER SORTING ALGORITHM.

```
procedure sort (sequence, k, M, B)
    k' = max(⌊M/B⌋, 2)      // compute k'
    if (k > 2) then
        call one-pass sorting (sequence, k', M, B)
        for i = 1 to k'
            bucket = the ith bucket sorted
            call sort (bucket, ⌈k/k'⌉, M, B)
```

THEOREM 4.1. *Let S be a sequence of N keys from $\{1, \ldots, k\}$, let M be the available memory, and let B be the transfer block size. A sequence residing on disk can be sorted in-place using the bundle sorting algorithm, while the number of I/Os is at most*

$$\left\lceil \frac{3N}{B} \log_{\lfloor M/B \rfloor} k \right\rceil + 4k \left\lfloor \frac{M}{B} \right\rfloor.$$

Proof. We first show that bundle sorting results in a sorting of the input sequence. Since we map each key i to $\lceil ik'/k \rceil$, it follows from the correctness of the one-pass

sorting that, after the first call to one-pass sorting, the sequence will be sorted such that for all i, keys in the range $\{\lceil (i-1)k'/k \rceil + 1, \ldots, \lceil ik'/k \rceil\}$ precede all keys greater than $\lceil ik'/k \rceil$. Each of the resulting range of keys is then recursively sorted. After at most $\log_{\lfloor M/B \rfloor} k$ recursive iterations, the number of distinct keys will be less than k', in which case the one-pass sorting will result in a full sorting of the sequence.

For the number of I/Os, we can view the bundle sorting algorithm as proceeding in levels of recursion, where at the first level of recursion bundle sorting is applied once, at the second level it is applied k' times, and at the ith level it is applied k'^{i-1} times. The total number of levels of recursion is $\log_{\lfloor M/B \rfloor} k$. Even though at the ith recursive level bundle sorting is applied k'^{i-1} times, each application is given a disjoint sequence shorter than N as input, and all applications of bundle sorting at the same recursive level cover the N input sequence exactly once. Thus, the counting pass of all applications at the same recursive level will still require $\lceil N/B \rceil$ I/Os, and all such applications will result in a read and write of each block, incurring an additional $\lceil 2N/B \rceil$ I/Os. Finally, since in general the number of distinct keys will not be a multiple of B, there might be an overlap of at most one block between every pair of consecutive pointers in one-pass sorting. Thus, we require an additional $2\lfloor M/B \rfloor$ I/Os for each application of one-pass sorting. One-pass sorting is called once for the first level of recursion, k' for the second level, and k'^{i-1} for the ith level, and thus the total number of times that one-pass sorting is called is $\frac{k'^{1+log_{k'} k}-1}{k'-1} = \frac{k'k-1}{k'-1} \leq 2k$. Hence, we add an additional $4k\lfloor M/B \rfloor$ I/Os, which results in the desired bound on the number of I/Os. ∎

4.2. General bundle sorting. In section 4.1 we assumed that the input was in the range $1, \ldots, k$, where k is the number of distinct keys in the sequence. We now discuss how to construct a mapping function when the input is not in this range.

In the simple case where the input is from a universe that is not ordered (i.e., the sorting is done just to cluster keys together), we can simply select any universal hash function as our mapping function. This ensures that the number of distinct keys that will be distributed to each bucket is fairly equal and that our algorithm performs without any loss of performance.

For the general case we assume that the input is from an ordered universe U and consists of k distinct keys. We show how to construct a mapping function from U to $1, \ldots, k$. More specifically, we need a way to map the keys into the range $[1, M/B]$ at every application of the one-pass sorting procedure. A solution to this mapping is to build an M/B-ary tree, whose leaves are the k distinct keys in sorted order and each internal node stores the minimum and the maximum values of its M/B children. Each application of one-pass sorting in integer sorting corresponds to an internal node in the tree (starting from the root) along with its children, and so the tree provides the appropriate mapping. This is because in each run of one-pass sorting the keys are within the range of the minimum and maximum values stored in the corresponding internal node, and the mapping into $1, \ldots, M/B$ is done according to the ranges of the internal node's children.

Constructing the sorted leaves can be done via count sort, in which we are given a sequence of size N with k distinct keys and we need to produce a sorted list of the k distinct keys and their counts. An easy way to do count sort is via merge sort, in which identical keys are combined together (and their counts summed) whenever they appear together. In each merge sort pass, the output run will never be longer than k/B blocks. Initially, the runs contain at most M/B blocks. After $\log_{M/B}(k/B)$ passes, the runs will be of length at most k/B blocks, and after that point the number

of runs decreases geometrically, and the running time is thus linear in the number of I/Os. The rest of the tree can be computed in at most one extra scan of the leaves-array and lower order postprocessing. We can show the following.

LEMMA 4.2 (see [WVI98]). *A sequence of size N consisting of k distinct keys can be count-sorted, using a memory of size M and block transfer size B, within an I/O bound of*

$$\frac{2N}{B}\log_{M/B}\frac{k}{B}.$$

An interesting observation is that by adding a count to each leaf representing its frequency in the sequence, and a count to each internal node which is the sum of the counts of its children, we can eliminate the count phase of the one-pass sorting procedure in the integer sorting algorithm. Thus, the general bundle sorting algorithm is as follows. Initially, we use count sort and produce the tree. We now traverse the tree, and on each internal node we call one-pass sorting, where the mapping function is simply the ranges of values of the node's M/B children. By combining Theorem 4.1 and Lemma 4.2 we can prove the bound for general bundle sorting.

THEOREM 4.2. *Let S be a sequence of size N, which consists of k distinct keys; let M be the available memory; and let B be the transfer block size. Then we can in-place sort S using the bundle sorting algorithm, while the number of I/Os is at most*

$$\frac{2N}{B}\left(\log_{\lfloor M/B\rfloor} k + \log_{\lfloor M/B\rfloor}\frac{k}{B}\right).$$

For all $k < B^2$, this bound would be better than the bound for integer sorting. Note that we can traverse the tree in either BFS (breadth first search) or DFS (depth first search). If we choose BFS, the sorting will be done concurrently, and we get an algorithm that gradually refines the sort. If we choose DFS, we get fully sorted items quickly, while the rest of the items are left completely unsorted. The overhead we incur by using the mapping will be in memory, where we now have to perform a search over the M/B children of the internal node that we are traversing in order to determine the mapping of each key into the range $1,\ldots,M/B$. Using a simple binary search over the ranges, the overhead will be an additional $\log_2(M/B)$ memory operations per key.

5. Lower bound for external bundle sorting. In this section we present a lower bound for the I/O complexity of bundle sorting. We let k be the number of distinct keys, M be the available memory, N be the size of the sequence, and B be the transfer block size. We then differentiate between the following two cases:

1. $k/B = B^{\Omega(1)}$ or $M/B = B^{\Omega(1)}$. We prove the lower bound for this case by proving a lower bound on bundle permutation, which is an easier problem than bundle sorting.
2. $k/B = B^{o(1)}$ and $M/B = B^{o(1)}$. We prove the lower bound for this case by proving a lower bound on a special case of matrix transposition, which is easier than bundle sorting.

Lower bound using bundle-permutation. We assume that $k/B = B^{\Omega(1)}$ or $M/B = B^{\Omega(1)}$ and use a similar approach as in the lower bound for general sorting of Aggarwal and Vitter [AV88] (see also [Vit99]). They proved the lower bound on the problem of computing an arbitrary permutation, which is easier than sorting. Bundle sorting is not necessarily harder than computing an arbitrary permutation, since

the output sequence may consist of one out of a set of permutations, denoted as a bundle-permutation. A *bundle-permutation* is an equivalence class of permutations, where two permutations can be in the same class if one can be obtained from the other by permuting within bundles. Computing a permutation from an arbitrary bundle-permutation, which we will refer to as the bundle-permutation problem, is easier than bundle sorting.

LEMMA 5.1. *Under the assumption that $k/B = B^{\Omega(1)}$ or $M/B = B^{\Omega(1)}$, the number of I/Os required in the worst case for sorting N data items of k distinct keys, using a memory of size M and block transfer size B, is*

$$\Omega\left(\frac{N}{B}\log_{M/B} k\right).$$

Proof. Given a sequence of N data items consisting of k bundles of sizes $\alpha_1, \alpha_2, \ldots, \alpha_k$, the number of distinct bundle-permutations is

$$\frac{N!}{\alpha_1! \cdot \alpha_2! \cdot \cdots \cdot \alpha_k!} \geq \frac{N!}{\left(\left(\frac{N}{k}\right)!\right)^k};$$

the inequality is obtained using a convexity argument.

For the bundle-permutation problem, for each $t \geq 0$ we measure the number of distinct orderings that are realizable by at least one sequence of t I/Os. The value of t for which the number of distinct orderings first exceeds the minimum orderings needed to be considered is a lower bound on the worst-case number of I/Os needed for the bundle-permutation problem and thus on the bundle sorting on disks.

Initially, the number of different permutations defined is 1. We consider the effect of an output operation. There can be at most $N/B + t - 1$ full blocks before the tth output, and hence the tth output changes the number of permutations generated by at most a multiplicative factor of $N/B+t$, which can be bounded trivially by $N \log N$.

For an input operation, we consider a block of B records input from a specific block on disk. The B data keys in the block can intersperse among the M keys in the internal memory in at most $\binom{M}{B}$ ways, so that the number of realizable orderings increases by a factor of $\binom{M}{B}$. If the block has never before resided in internal memory, the number of realizable orderings increases by an extra factor of $B!$, since the keys in the block can be permuted among themselves. This extra contribution can occur only once for each of the N/B original blocks. Hence, the number of distinct orderings that can be realized by some sequence of t I/Os is at most

$$(B!)^{N/B}\left(N \log N \binom{M}{B}\right)^t.$$

We want to find the minimum t for which the number of realizable orderings exceeds the minimum orderings required. Hence we have

$$(B!)^{N/B}\left(N \log N \binom{M}{B}\right)^t \geq \frac{N!}{\left(\left(\frac{N}{k}\right)!\right)^k}.$$

Taking the logarithm and applying Stirling's formula, with some algebraic manipulations, we get

$$t\left(\log N + B \log \frac{M}{B}\right) = \Omega\left(N \log \frac{k}{B}\right).$$

By solving for t, we get

$$\text{number of IOs} = \Omega\left(\frac{N}{B}\log_{M/B}\frac{k}{B}\right).$$

Recall that we assume either $k/B = B^{\Omega(1)}$ or $M/B = B^{\Omega(1)}$. In either case, it is easy to see that $\log_{M/B}(k/B) = \Theta(\log_{M/B} k)$, which gives us the desired bound. □

Lower bound using a special case of matrix transposition. We now assume that $k/B = B^{o(1)}$ and $M/B = B^{o(1)}$ (the case not handled earlier) and prove a lower bound on a special case of matrix transposition, which is easier than bundle sorting. Our proof proceeds under the normal assumption that the records are treated indivisibly and that no compression of any sort is utilized.

LEMMA 5.2. *Under the assumption that $k/B = B^{o(1)}$ and $M/B = B^{o(1)}$, the number of I/Os required in the worst case for sorting N data items of k distinct keys, using a memory of size M block transfer size B, is*

$$\Omega\left(\frac{N}{B}\log_{M/B} k\right).$$

Proof. Consider the problem of transposing a $k \times N/k$ matrix, in which the final order of the elements in each row is not important. More specifically, let us assume that the elements of the matrix are originally in column-major order. The problem is to convert the matrix into row-major order, but the place in a row to which the element goes can be arbitrary, as long as it is transferred to the proper row. Each element that ends up in row i can be thought of as having the same key i. This problem is a special case of sorting N keys consisting of exactly N/k records for each of the k distinct keys. Hence, this problem is easier than bundle sorting. We now prove a lower bound for this problem of

$$\Omega\left(\frac{N}{B}\log_{M/B}\min(k, B)\right)$$

I/Os. Under our assumption that $k/B = B^{o(1)}$, this proves the desired bound for bundle sorting.

We can assume that $k \le N/B$, since otherwise bundle sorting can be executed by using any general sorting algorithm. We assume, without loss of generality, by the assumption of the indivisibility of records, that there is always exactly one copy of each record, and it is either on disk or in memory but not in both. At time t, let X_{ij} for $1 \le i \le k$ and $1 \le j \le N/B$ be the number of elements in the jth block on disk that need to end up on the ith row of the transposed matrix. At time t, let Y_i be the number of elements currently in internal memory that need to go on the ith row in the transposed matrix. We use the potential function $f(x) = x \log x$ for all $x \ge 0$. Its value at $x = 0$ is $f(0) = 0$. We define the overall potential function POT to be

$$POT = \sum_{i,j} f(X_{ij}) + \sum_i f(Y_i).$$

When the algorithm terminates, we have $Y_i = 0$ for all i, and the final value of potential POT is

$$\frac{N}{B}(B \log B) + 0 = N \log B.$$

If $k < B$, the initial potential is

$$\frac{N}{B} k \left(\frac{B}{k} \log \frac{B}{k} \right) = N \log \frac{B}{k},$$

and the initial potential is 0 otherwise (if $k \geq B$).

Note that our potential function satisfies

$$f(a+b) = (a+b)\log(a+b) \geq f(a) + f(b)$$

for all $a, b \geq 0$. Consider an output operation that writes a complete block of size B from memory to disk. If we write x_i records that need to go to the ith row and there are y_i such records in memory, then the change in potential is $\sum_i \big(f(x_i) + f(y_i) - f(x_i + y_i)\big) \leq 0$. Hence, output operations can only decrease the potential, and thus we need to consider only how much an input operation increases the potential.

If we read during an input operation a complete block of B records that contains x_i records that need to go to the ith row and there are y_i such records already in memory, then the change in the potential is

$$\sum_{1 \leq i \leq k} \left(f(x_i + y_i) - f(x_i) - f(y_i) \right).$$

By a convexity argument, this quantity is maximized when $x_i = B/k$ and $y_i = (M-B)/k$ for each $1 \leq i \leq k$, in which case the change in potential is bounded by $B \log(M/B)$.

We get a lower bound on the number of read operations by dividing the difference of the initial and final potentials by the bound on the maximum change in potential per read. For $k < B$, we get the I/O bound

$$\frac{N \log B - N \log \frac{B}{k}}{B \log \frac{M}{B}} = \frac{N}{B} \log_{M/B} k.$$

For $k \geq B$, we get the I/O bound

$$\frac{N \log B - 0}{B \log \frac{M}{B}} = \frac{N}{B} \log_{M/B} B.$$

We have thus proved a lower bound of $\Omega((N/B) \log_{M/B} \min(k, B))$ I/Os. Under our assumption that $k/B = B^{o(1)}$, this gives us an I/O lower bound for this case of bundle sorting of

$$\Omega \left(\frac{N}{B} \log_{M/B} k \right). \qquad \square$$

Theorem 5.1 for the lower bound of bundle sorting follows from Lemmas 5.1 and 5.2, since together they cover all possibilities for k, M, and B.

THEOREM 5.1. *The number of I/Os required in the worst case for sorting N data items of k distinct keys, using a memory of size M and block transfer size B, is*

$$\Omega \left(\frac{N}{B} \log_{M/B} k \right).$$

6. The disk latency model. In this section we consider the necessary modifications in the external bundle sorting algorithm in order to achieve an optimum number of I/Os in a more performance-sensitive model, as in [FFM98]. In this model, we differentiate between two types of I/Os: sequential I/Os and random I/Os, where there is a reduced cost for sequential I/Os. We start by presenting the model, followed by the modifications necessary in the bundle sorting, as presented in section 4.2. We also provide an additional, slightly different integer sorting algorithm that, depending on the setting, may enhance performance by up to 33% in this model for the integer sorting problem.

6.1. The model. The only difference between this model and the external memory model presented in section 3 is that we now differentiate between costs of two types of I/O: sequential and random I/Os. We define ℓ to be the latency to move the disk read/write head to a new position during a random seek. We define r to be the cost of reading a block of size B into internal memory once the read/write head is positioned at the start of the block.

The parameters N, M, and B, as before, are referred to as the *file size*, *memory size*, and *transfer block size*, respectively, and they satisfy $1 \leq B \leq M/2$ and $M < N$. We will consider the case where $D = 1$, meaning that there is no disk parallelism. It should be clear, from the above parameters, that the cost of a random I/O that loads one transfer block into memory is $\ell + r$, and the cost of a sequential I/O is simply r.

6.2. Optimal bundle sorting in the disk latency model. The modification for bundle sorting is based on the observation that in the worst-case scenario of the algorithm as described in section 4.2, every I/O in the sorting pass can be a random I/O. This is because we are loading $\lfloor M/B \rfloor$ blocks from disk into $\lfloor M/B \rfloor$ buckets, and in the worst case they may be written back in a round robin fashion resulting solely in random I/Os. However, if we decide to read more blocks into each bucket, we will increase the total number of I/Os, which will result in the worst case with sequential I/Os in addition to random I/Os.

Let α be the number of blocks that we load into each bucket, where clearly, $1 \leq \alpha \leq (M/2B)$. Thus, in each call to one-pass sorting of bundle sorting we sort into $\lfloor M/(\alpha B) \rfloor$ distinct keys, resulting in a total of $\log_{M/(\alpha B)} k$ passes over the sequence. However, we are now sure that at least $(\alpha - 1)/\alpha$ of the I/Os are sequential. We differentiate between the I/Os required in the external count sort, in which we perform only sequential I/Os, and the sorting pass, in which we also have random I/Os. Using Theorem 4.2, the performance is now

$$\frac{2N}{B}\left(\frac{1}{\alpha}(\ell + \alpha r)\log_{M/\alpha B} k + r \log_{M/B} \frac{k}{B}\right)$$

I/Os, and the optimal value of α can be determined via an optimization procedure. In section 7 we show experimentally how the execution time varies in this model as we change α.

7. Experiments. We conducted several experiments with various data sets and settings, while changing the size of the data sets N, the available memory M, the transfer block size B, and the number of distinct items k. The data sets were generated by the IBM test data generator (http://www.almaden.ibm.com/cs/quest), or taken from the U.S. Census data, and the following experiments were executed on both data sources. In all our experiments, the records consisted of 10-byte keys in 100-byte records. All experiments were run on a Pentium2, 300 MHz, 128 MB RAM machine.

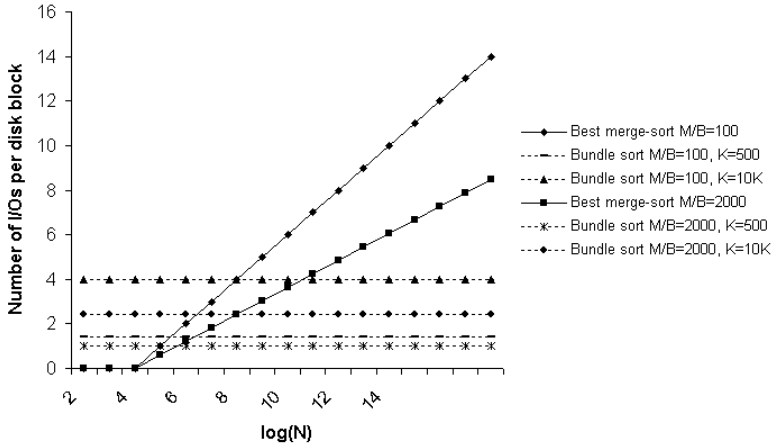

FIG. 2. *Bundle sorting versus regular sorting (best merge sort, for instance). The x-axis is the size of the data set drawn on a log scale. The y-axis is the number of I/Os performed per block of input. As can be seen, in contrast to merge sort, the number of I/Os per block in bundle sorting remains the same for a constant k as N increases.*

We first demonstrate an important feature of bundle sorting: As long as the number k of distinct keys remains constant, it performs the same number of I/O accesses per disk block with no dependence on the size of the data set. This is in contrast to general sort algorithms such as merge sort, which require more I/Os per disk block as the size of the data set increases. See Figure 2. The parameter B was set to 10 kB, and we tested for a memory of 1 MB and a memory of 20 MB. In both these cases merge sort, as expected, increased the number of I/Os per disk block as the size of the data set increased. In contrast, bundle sort performed a constant number of I/O accesses per disk block. As N increases, the improvement in performance becomes significant, demonstrating the advantages of bundle sorting. For instance, even when $k = 10000$ and the available memory is 20 MB, the break-even point occurs at $N = 1$ GB. As N increases, bundle sorting will perform better. If $k \leq 500$, then in the setting above, the break-even point occurs at $N = 10$ MB, making bundle sorting most appealing.

The next experiments demonstrate the performance of bundle sort as a function of k. See Figure 3. We set N at a fixed size of 1 GB and B at 10 kB. We ran the tests with a memory of 1 MB and 20 MB and counted the number of I/Os. We let k vary over a wide range of values from 2 to 10^9 ($k \leq N$ is always true). Since merge sort does not depend on the number of distinct keys, it performed the same number of I/O accesses per disk block in all these settings. In all these runs, as long as $k \leq N/B$, bundle sort performed better. When k is small the difference in performance is significant.

As for the disk-latency model, we show the optimal α values for various settings. Recall that in this model we attribute different costs to sequential and random I/Os. See Figure 4. We measured α for different ratios between ℓ, the cost of moving the disk reader to a random location (the latency), and r, the cost of reading a transfer block of size B. Parameter α also depends on the relation between M and B, so we plot M/B on the x-axis of the graph. As can be seen, when the ratio is 1, the optimal algorithm is exactly our bundle sorting algorithm, which counts only I/Os (hence it

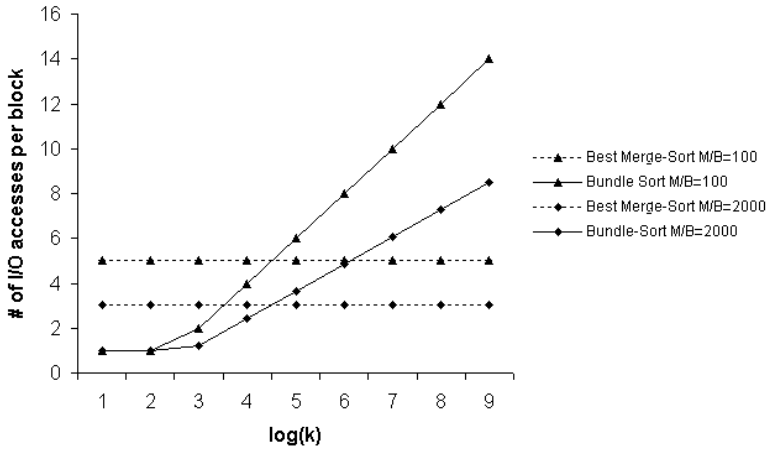

FIG. 3. *Bundle sorting versus regular sorting (best merge sort, for instance). The x-axis is the number of distinct keys (k) in the sequence drawn on a log scale. The y-axis is the number of I/Os per disk block. As can be seen, for $k \leq N/B$, bundle sorting performs better than merge sort, and the difference is large as k is smaller.*

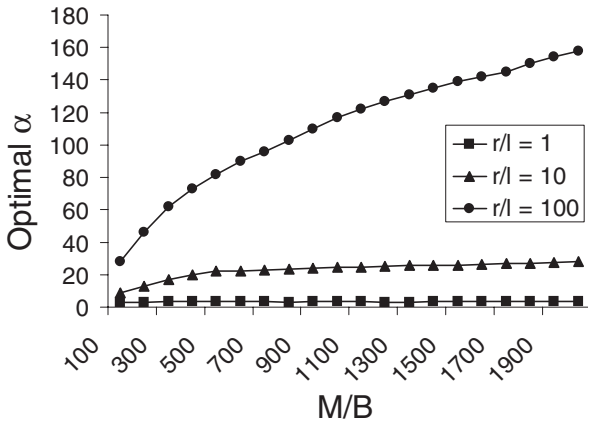

FIG. 4. *Optimum bundle sorting in the disk latency model—resolving α as a function of r, ℓ, and M/B.*

assumes that the cost of a random and a sequential I/O are equivalent). As this ratio increases, α increases, calling for a larger adaptation of our algorithm. Also affecting α, but in a more moderate way, is M/B. As this ratio increases, the optimum is achieved for a larger α.

8. Conclusions. We considered the sorting problem for large data sets with a moderate number of distinct keys, which we denote as bundle sorting, and identified it as a problem that is inherently easier than general sorting. We presented a simple in-place sorting algorithm for external memory, which may provide significant improvement over current sorting techniques. We also provided a matching lower bound, indicating that our solution is optimal.

Sorting is a fundamental problem, and any improvement in its solution may have

many applications. For instance, consider the sort join algorithm that computes join queries by first sorting the two relations that are to be joined, after which the join can be done efficiently in only one pass on both relations. Clearly, if the relations are large and their keys are taken from a universe of moderate size, then bundle sorting could provide more efficient execution than general sort.

It is interesting to note that the nature of the sorting algorithm is such that after the ith pass over the data set, the sequence is fully sorted into $(\lfloor M/B \rfloor)^i$ keys. In effect, the sequence is gradually sorted, where after each pass a further refinement is achieved, until finally the sequence is sorted. We can take advantage of this feature and use it in applications that benefit from quick, rough estimates that are gradually refined as we perform additional passes over the sequence. For instance, we could use it to produce intermediate join estimates, while refining the estimates by additional passes over the sequence. We can estimate the join after each iteration over the data set, improving the estimate after each such pass, and arrive at the final join after bundle sorting has completely finished.

The bundle sorting algorithm can be adapted efficiently and in a most straightforward way in the parallel disk model (PDM) described in [Vit99]. We now assume, in the external memory model, that $D > 1$, meaning that we can transfer D blocks into memory concurrently. This is like having D independent parallel disks. Assume that the data to be stored is initially located on one of the disks. In the first step we sort the data into exactly D buckets, writing each bucket into a distinct disk. Next, we sort, in parallel on each of the disks, the data set that was partitioned into each of the disks. Except for the initial partitioning step, we make full utilization of the parallel disks, thus enhancing performance by a factor of nearly D over all the bounds given in this paper. Note that extending bundle sorting to fit the PDM model was straightforward because of its top-down nature. Bundle sorting can also be utilized to enhance the performance of general sorting when the available working space is substantially smaller than the input set.

Bundle sorting is a fully in-place algorithm, which in effect causes the available memory to be doubled as compared to non–in-place algorithms. The performance gain from this feature can be significant. For instance, even if $M/B = 1000$, the performance gain is 10% and can be much higher for a smaller ratio. In some cases, an in-place sorting algorithm can avoid the use of high cost memory such as virtual memory.

We considered the disk latency model, which is a more performance-sensitive model where we differentiate between two types of I/Os—sequential and random I/Os—with a reduced cost for sequential I/Os. This model can be more realistic for performance analysis, and we have shown the necessary adaptation in the bundle sorting algorithm to arrive at an optimal solution in this model.

We have shown experimentation with real and synthetic data sets, which demonstrates that the theoretical analysis gives an accurate prediction of the actual performance.

APPROXIMATION ALGORITHMS FOR METRIC FACILITY LOCATION PROBLEMS*

MOHAMMAD MAHDIAN†, YINYU YE‡, AND JIAWEI ZHANG§

Abstract. In this paper we present a 1.52-approximation algorithm for the metric uncapacitated facility location problem, and a 2-approximation algorithm for the metric capacitated facility location problem with soft capacities. Both these algorithms improve the best previously known approximation factor for the corresponding problem, and our soft-capacitated facility location algorithm achieves the integrality gap of the standard linear programming relaxation of the problem. Furthermore, we will show, using a result of Thorup, that our algorithms can be implemented in quasi-linear time.

Key words. approximation algorithms, facility location problem, greedy method, linear programming

1. Introduction.

Variants of the facility location problem (FLP) have been studied extensively in the operations research and management science literatures and have received considerable attention in the area of approximation algorithms (see [21] for a survey). In the metric uncapacitated facility location problem (UFLP), which is the most basic FLP, we are given a set $\mathcal{F}$ of *facilities*, a set $\mathcal{C}$ of *cities* (i.e., clients), a cost f_i for opening facility $i \in \mathcal{F}$, and a connection cost c_{ij} for connecting client j to facility i. The objective is to open a subset of the facilities in $\mathcal{F}$ and connect each city to an open facility so that the total cost, that is the cost of opening facilities and connecting the clients, is minimized. We assume that the connection costs form a metric, meaning that they are symmetric and satisfy the triangle inequality.

Since the first constant factor approximation algorithm due to Shmoys, Tardos, and Aardal [22], a large number of approximation algorithms have been proposed for UFLP [23, 12, 25, 14, 2, 4, 6, 8, 15]. Table 1 shows a summary of these results. Prior to this work, the best known approximation factor for UFLP was 1.58, given by Sviridenko [23], which was achieved using linear programming (LP) rounding. Guha and Khuller [8] proved that it is impossible to get an approximation guarantee of 1.463 for UFLP, unless $\mathbf{NP} \subseteq \mathrm{DTIME}[n^{O(\log \log n)}]$. In this paper, we give a 1.52-approximation algorithm for UFLP, which can be implemented in quasi-linear time, using a result of Thorup [24]. Our algorithm combines the greedy algorithm of Jain, Mahdian, and Saberi [13] and Jain et al. [12] with the idea of cost scaling, and is analyzed using a factor-revealing linear program.

The growing interest in UFLP is not only due to its applications in a large number of settings [7], but also due to the fact that UFLP is one of the most basic models

among discrete location problems. The insights gained in dealing with UFLP may also apply to more complicated location models, and in many cases the latter can be reduced directly to UFLP.

In the second part of this paper, we give a 2-approximation algorithm for the soft-capacitated facility location problem (SCFLP) by reducing it to UFLP. SCFLP is similar to UFLP, except that there is a capacity u_i associated with each facility i, which means that if we want this facility to serve x cities, we have to open it $\lceil x/u_i \rceil$ times at a cost of $f_i\lceil x/u_i \rceil$. This problem is also known in the operations research literature as the facility location problem with integer decision variables (see [3] and [20]). Chudak and Shmoys [5] gave a 3-approximation algorithm for SCFLP with uniform capacities (i.e., $u_i = u$ for all $i \in \mathcal{F}$) using LP rounding. For nonuniform capacities, Jain and Vazirani [14] showed how to reduce this problem to UFLP, and by solving UFLP through a primal-dual algorithm, they obtained a 4-approximation. Arya et al. [2] proposed a local search algorithm that achieves an approximation ratio of 3.72. Following the approach of Jain and Vazirani [14], Jain and coworkers [13, 12] showed that SCFLP can be approximated within a factor of 3. This was the best previously known algorithm for this problem. We improve this factor to 2, achieving the integrality gap of the natural LP relaxation of the problem. The main idea of our algorithm is to consider algorithms and reductions that have separate (not necessarily equal) approximation factors for the facility and connection costs. We will define the concept of *bifactor* approximate reduction in this paper, and show how it can be used to get an approximation factor of 2 for SCFLP. The idea of using bifactor approximation algorithms and reductions can be used to improve the approximation factor of several other problems.

The rest of this paper is organized as follows: In section 2 the necessary definitions and notation are presented. In section 3, we present the algorithm for UFLP and its underlying intuition, and we prove the upper bound of 1.52 on the approximation factor of the algorithm. In section 4 we present a lemma on the approximability of the linear-cost FLP. In section 5 we define the concept of a bifactor approximate reduction between facility location problems. Using bifactor reductions to the linear-cost FLP and the lemma proved in section 4, we present algorithms for SCFLP and the concave SCFLP. Concluding remarks are given in section 6.

2. Preliminaries. In this paper, we will define reductions between various FLPs. Many such problems can be considered as special cases of the *universal FLP*, as defined below. This problem was first defined in [9] and further studied in [17].

DEFINITION 1. *In the* metric universal FLP*, we are given a set $\mathcal{C}$ of n_c cities, a set $\mathcal{F}$ of n_f facilities, a connection cost c_{ij} between city j and facility i for every $i \in \mathcal{F}, j \in \mathcal{C}$, and a facility cost function $f_i : \{0, \ldots, n_c\} \mapsto \mathcal{R}^+$ for every $i \in \mathcal{F}$. Connection costs are symmetric and obey the triangle inequality. The value of $f_i(k)$ equals the cost of opening facility i if it is used to serve k cities. A solution to the problem is a function $\phi : \mathcal{C} \to \mathcal{F}$ assigning each city to a facility. The* facility cost F_ϕ *of the solution ϕ is defined as $\sum_{i \in \mathcal{F}} f_i(|\{j : \phi(j) = i\}|)$, i.e., the total cost for opening facilities. The* connection cost *(or service cost) C_ϕ of ϕ is $\sum_{j \in \mathcal{C}} c_{\phi(j),j}$, i.e., the total cost of opening each city to its assigned facility. The objective is to find a solution ϕ that minimizes the sum $F_\phi + C_\phi$.*

For the metric universal FLP, we distinguish two models by how the connection costs are given. In the distance oracle model, the connection costs are explicitly given by a matrix (c_{ij}) for any $i \in \mathcal{F}$ and $j \in \mathcal{C}$. In the sparse graph model, $\mathcal{C}$ and $\mathcal{F}$ are nodes of an undirected graph (which may not be complete) in which the cost of each edge is given, and the connection cost between a facility i and a client j is implicitly given by the shortest distance between i and j.

Now we can define the uncapacitated and soft-capacitated FLPs as special cases of the universal FLP, as follows.

DEFINITION 2. *The* metric uncapacitated facility location problem (UFLP) *is a special case of the universal FLP in which all facility cost functions are of the following form: for each $i \in \mathcal{F}$, $f_i(k) = 0$ if $k = 0$, and $f_i(k) = f_i$ if $k > 0$, where f_i is a constant which is called the facility cost of i.*

DEFINITION 3. *The* metric soft-capacitated facility location problem (SCFLP) *is a special case of the universal FLP in which all facility cost functions are of the form $f_i(k) = f_i\lceil k/u_i \rceil$, where f_i and u_i are constants for every $i \in \mathcal{F}$, and u_i is called the capacity of facility i.*

The algorithms presented in this paper build upon an earlier approximation algorithm of Jain and coworkers [13, 12], which is sketched below. We call this algorithm the JMS algorithm.

THE JMS ALGORITHM.

1. At the beginning, all cities are *unconnected*, all facilities are *unopened*, and the *budget* of every city j, denoted by B_j, is initialized to 0. At every moment, each city j offers some money from its budget to each *unopened* facility i. The amount of this offer is equal to $\max(B_j - c_{ij}, 0)$ if j is unconnected, and $\max(c_{i'j} - c_{ij}, 0)$ if it is connected to some other facility i'.
2. While there is an unconnected city, increase the budget of each *unconnected* city at the same rate, until one of the following events occurs:
   (a) For some unopened facility i, the total offer that it receives from cities is equal to the cost of opening i. In this case, we open facility i, and for every city j (connected or unconnected) which has a nonzero offer to i, we connect j to i.
   (b) For some unconnected city j, and some facility i that is already open, the budget of j is equal to the connection cost c_{ij}. In this case, we connect j to i.

The analysis of the JMS algorithm has the feature that allows the approximation factor for the facility cost to be different from the approximation factor for the connection cost, and gives a way to compute the tradeoff between these two factors. The following definition captures this notion.

DEFINITION 4. *An algorithm is called a (γ_f, γ_c)-approximation algorithm for the universal FLP if, for every instance $\mathcal{I}$ of the universal FLP and for* every *solution*

SOL for $\mathcal{I}$ with facility cost F_{SOL} and connection cost C_{SOL}, the cost of the solution found by the algorithm is at most $\gamma_f F_{SOL} + \gamma_c C_{SOL}$.

Recall the following theorem of Jain and coworkers [13, 12] on the approximation factor of the JMS algorithm.

THEOREM A (see [13, 12]). *Let $\gamma_f \geq 1$ be fixed and $\gamma_c := \sup_k\{z_k\}$, where z_k is the solution of the following optimization program, referred to as the factor-revealing LP:*

$$\text{(LP1)} \quad \text{maximize } \frac{\sum_{i=1}^{k} \alpha_i - \gamma_f f}{\sum_{i=1}^{k} d_i}$$

$$\text{(1)} \quad \text{subject to } \forall\, 1 \leq i < k: \ \alpha_i \leq \alpha_{i+1},$$

$$\text{(2)} \quad \forall\, 1 \leq j < i < k: \ r_{j,i} \geq r_{j,i+1},$$

$$\text{(3)} \quad \forall\, 1 \leq j < i \leq k: \ \alpha_i \leq r_{j,i} + d_i + d_j,$$

$$\text{(4)} \quad \forall\, 1 \leq i \leq k: \ \sum_{j=1}^{i-1} \max(r_{j,i} - d_j, 0) + \sum_{j=i}^{k} \max(\alpha_i - d_j, 0) \leq f,$$

$$\text{(5)} \quad \forall\, 1 \leq j \leq i \leq k: \ \alpha_j, d_j, f, r_{j,i} \geq 0.$$

Then the JMS algorithm is a (γ_f, γ_c)-approximation algorithm for UFLP. Furthermore, for $\gamma_f = 1$ we have $\gamma_c \leq 2$.

3. The uncapacitated facility location algorithm.

3.1. Description of the algorithm. We use the JMS algorithm to solve the UFLP with an improved approximation factor. Our algorithm has two phases. In the *first* phase, we scale up the opening costs of all facilities by a factor of δ (which is a constant that will be fixed later) and then run the JMS algorithm to find a solution. The technique of cost scaling has been previously used by Charikar and Guha [4] for the FLP in order to take advantage of the asymmetry between the performance of the algorithm with respect to the facility and that with respect to the connection costs.

Here we give a different intuitive reason: Intuitively, the facilities that are opened by the JMS algorithm with the scaled-up facility costs are those that are very economical, because we weigh the facility cost more than the connection cost in the objective function. Therefore, we open these facilities in the first phase of the algorithm.

One important property of the JMS algorithm is that it finds a solution in which there is no unopened facility that one can open to decrease the cost (without closing any other facility). This is because for each city j and facility i, j offers to i the amount that it would save in the connection cost if it gets its service from i. This is, in fact, the main advantage of the JMS algorithm over a previous algorithm of Mahdian et al. [16].

However, the facility costs have been scaled up in the first phase of our algorithm. Therefore, it is possible that the total cost (in terms of the original cost) can be reduced more by opening an unopened facility and by reconnecting each city to its closest open facility. This motivates the second phase of our algorithm.

In the *second* phase of the algorithm, we decrease the scaling factor δ at rate 1, so that at time t the cost of facility i has reduced to $(\delta - t)f_i$. If at any point during this process a facility could be opened without increasing the total cost (i.e., if the opening cost of the facility equals the total amount that cities can save by switching their "service provider" to that facility), then we open the facility and connect each

city to its closest open facility. We stop when the scaling factor becomes 1. This is equivalent to a greedy procedure introduced by Guha and Khuller [8] and Charikar and Guha [4]. In this procedure, in each iteration we pick a facility u of opening cost f_u such that if by opening u the total connection cost decreases from C to C'_u, the ratio $(C - C'_u - f_u)/f_u$ is maximized. If this ratio is positive, then we open the facility u and iterate; otherwise we stop. It is not hard to see that the second phase of our algorithm is equivalent to the Charikar–Guha–Khuller procedure: in the second phase of our algorithm, the first facility u that is opened corresponds to the minimum value of t, or the maximum value of $\delta - t$, for which we have $(\delta - t)f_u = C - C'_u$. In other words, our algorithm picks the facility u for which the value of $(C - C'_u)/f_u$ is maximized, and stops when this value becomes less than or equal to 1 for all u. This is the same as what the Charikar–Guha–Khuller procedure does. The original analysis of our algorithm in [18] was based on a lemma by Charikar and Guha [4]. Here we give an alternative analysis of our algorithm that uses only a single factor-revealing LP.

We call our two-phase algorithm Algorithm A. In the remainder of this section, we analyze Algorithm A and prove that it always outputs a solution to the UFLP of cost at most 1.52 times the optimum. The analysis is divided into three parts. First, in section 3.2, we derive the factor-revealing linear program whose solution gives the approximation ratio of our algorithm. Next, in section 3.3, we analyze this linear program, and compute its solution in terms of the approximation factors of the JMS algorithm. This gives the following result.

THEOREM 1. *Let (γ_f, γ_c) be a pair obtained from the factor-revealing linear program* (LP1). *Then for every $\delta \geq 1$, Algorithm A is a $(\gamma_f + \ln(\delta) + \epsilon, 1 + \frac{\gamma_c - 1}{\delta})$-approximation algorithm for the UFLP.*

Finally, we analyze the factor-revealing linear program (1) and show that the JMS algorithm is a $(1.11, 1.78)$-approximation algorithm for the UFLP. This, together with the above theorem for $\delta = 1.504$, implies that Algorithm A is a 1.52-approximation algorithm for the UFLP. We will show in section 3.4 that this algorithm can be implemented in quasi-linear time, both for the distance oracle model and for the sparse graph model.

3.2. Deriving the factor-revealing LP. Recall that the JMS algorithm, in addition to finding a solution for the scaled instance, outputs the *share* of each city in the total cost of the solution. Let α_j denote the share of city j in the total cost. In other words, α_j is the value of the variable B_j at the end of the JMS algorithm. Therefore the total cost of the solution is $\sum_j \alpha_j$. Consider an arbitrary collection $\mathcal{S}$ consisting of a single facility $f_{\mathcal{S}}$ and k cities. Let δf (f in the original instance) denote the opening cost of facility $f_{\mathcal{S}}$; α_j denote the share of city j in the total cost (where cities are ordered such that $\alpha_1 \leq \cdots \leq \alpha_k$); d_j denote the connection cost between city j and facility $f_{\mathcal{S}}$; and $r_{j,i}$ $(i > j)$ denote the connection cost between city j and the facility that it is connected to at time α_i, right before city i gets connected for the first time (or if cities i and j get connected at the same time, define $r_{j,i} = \alpha_i = \alpha_j$). The main step in the analysis of the JMS algorithm is to prove that for any such collection $\mathcal{S}$, the δf, d_j, α_j, and $r_{j,i}$ values constitute a feasible solution to the program (LP1), where f is now replaced with δf since the facility costs have been scaled up by δ.

We implement and analyze the second phase as the following. Instead of decreasing the scaling factor continuously from δ to 1, we decrease it discretely in L steps, where L is a constant. Let δ_i denote the value of the scaling factor in the ith step. Therefore, $\delta = \delta_1 > \delta_2 > \cdots > \delta_L = 1$. We will fix the value of the δ_i's later. After decreasing the scaling factor from δ_{i-1} to δ_i, we consider facilities in an *arbitrary* or-

der, and open those that can be opened without increasing the total cost. We denote this modified algorithm by A_L. Clearly, if L is sufficiently large (depending on the instance), the algorithm A_L computes the same solution as Algorithm A.

In order to analyze the above algorithm, we need to add extra variables and inequalities to the inequalities in the factor-revealing program (LP1) given in Theorem A. Let $r_{j,k+i}$ denote the connection cost that city j in $\mathcal{S}$ pays after we change the scaling factor to δ_i and process all facilities as described above. (Thus, $r_{j,k+1}$ is the connection cost of city j after the first phase.) Therefore, by the description of the algorithm, we have

$$\forall\, 1 \le i \le L: \ \sum_{j=1}^{k} \max(r_{j,k+i} - d_j, 0) \le \delta_i f.$$

This is because if the above inequality is violated and if $f_{\mathcal{S}}$ is not open, we could open $f_{\mathcal{S}}$ and decrease the total cost. If $f_{\mathcal{S}}$ is open, then $r_{j,k+i} \le d_j$ for all j, and the inequality holds.

Now, we compute the share of the city j in the total cost of the solution that algorithm A_L finds. In the first phase of the algorithm, the share of city j in the total cost is α_j. Of this amount, $r_{j,k+1}$ is spent on the connection cost, and $\alpha_j - r_{j,k+1}$ is spent on the facility costs. However, since the facility costs are scaled up by a factor of δ in the first phase, therefore the share of city j in the *facility costs* in the original instance is equal to $(\alpha_j - r_{j,k+1})/\delta$. After we reduce the scaling factor from δ_i to δ_{i+1} $(i = 1, \ldots, L-1)$, the connection cost of city j is reduced from $r_{j,k+i}$ to $r_{j,k+i+1}$. Therefore, in this step, the share of city j in the facility costs is $r_{j,k+i} - r_{j,k+i+1}$ with respect to the scaled instance, or $(r_{j,k+i} - r_{j,k+i+1})/\delta_{i+1}$ with respect to the original instance. Thus, at the end of the algorithm, the total share of city j in the facility costs is

$$\frac{\alpha_j - r_{j,k+1}}{\delta} + \sum_{i=1}^{L-1} \frac{r_{j,k+i} - r_{j,k+i+1}}{\delta_{i+1}}.$$

We also know that the final amount that city j pays for the connection cost is $r_{j,k+L}$. Therefore, the share of the city j in the total cost of the solution is

$$\frac{\alpha_j - r_{j,k+1}}{\delta} + \sum_{i=1}^{L-1} \frac{r_{j,k+i} - r_{j,k+i+1}}{\delta_{i+1}} + r_{j,k+L+1} = \frac{\alpha_j}{\delta} + \sum_{i=1}^{L-1} \left(\frac{1}{\delta_{i+1}} - \frac{1}{\delta_i} \right) r_{j,k+i}. \tag{6}$$

This, together with a *dual fitting* argument similar to [12], implies the following.

THEOREM 2. *Let (ξ_f, ξ_c) be such that $\xi_f \ge 1$ and ξ_c is an upper bound on the solution of the following maximization program for every k:*

$$\text{(LP2)} \quad \text{maximize} \ \frac{\sum_{j=1}^{k} \left(\frac{\alpha_j}{\delta} + \sum_{i=1}^{L-1} \left(\frac{1}{\delta_{i+1}} - \frac{1}{\delta_i} \right) r_{j,k+i} \right) - \xi_f f}{\sum_{i=1}^{k} d_i}$$

$$\text{subject to } \forall\, 1 \le i < k: \ \alpha_i \le \alpha_{i+1}, \tag{7}$$

$$\forall\, 1 \le j < i < k: \ r_{j,i} \ge r_{j,i+1}, \tag{8}$$

$$\forall\, 1 \le j < i \le k: \ \alpha_i \le r_{j,i} + d_i + d_j, \tag{9}$$

$$\forall\, 1 \le i \le k: \ \sum_{j=1}^{i-1} \max(r_{j,i} - d_j, 0) + \sum_{j=i}^{k} \max(\alpha_i - d_j, 0) \le \delta f, \tag{10}$$

$$\forall\, 1 \le i \le L: \quad \sum_{j=1}^{k} \max(r_{j,k+i} - d_j, 0) \le \delta_i f, \tag{11}$$

$$\forall\, 1 \le j \le i \le k: \quad \alpha_j, d_j, f, r_{j,i} \ge 0. \tag{12}$$

Then, algorithm A_L is a (ξ_f, ξ_c)-approximation algorithm for UFLP.

3.3. Analyzing the factor-revealing LP. In the following theorem, we analyze the factor-revealing linear program (LP2) and prove Theorem 1. In order to do this, we need to set the values of the δ_i's. Here, for simplicity of computations, we set δ_i to $\delta^{\frac{L-i}{L-1}}$; however, it is easy to observe that any choice of δ_i's such that $\delta = \delta_1 > \delta_2 > \cdots > \delta_L = 1$ and the limit of $\max_i(\delta_i - \delta_{i+1})$ as L tends to infinity is zero will also work.

THEOREM 3. *Let (γ_f, γ_c) be a pair given by the maximization program* (LP1) *in Theorem* A, *and $\delta \ge 1$ be an arbitrary number. Then for every ϵ, if L is a sufficiently large constant, algorithm A_L is a $(\gamma_f + \ln(\delta) + \epsilon, 1 + \frac{\gamma_c - 1}{\delta})$-approximation algorithm for the UFLP.*

Proof. Since the inequalities of the factor-revealing program (7) are a superset of the inequalities of the factor-revealing program (1), by Theorem A and the definition of (γ_f, γ_c), we have

$$\sum_{j=1}^{k} \alpha_j \le \gamma_f \delta f + \gamma_c \sum_{j=1}^{k} d_j. \tag{13}$$

By inequality (11), for every $i = 1, \ldots, L$ we have

$$\sum_{j=1}^{k} r_{j,k+i} \le \sum_{j=1}^{k} \max(r_{j,k+i} - d_j, 0) + \sum_{j=1}^{k} d_j \le \delta_i f + \sum_{j=1}^{k} d_j. \tag{14}$$

Therefore,

$$\begin{aligned}
&\sum_{j=1}^{k} \left(\frac{\alpha_j}{\delta} + \sum_{i=1}^{L-1} \left(\frac{1}{\delta_{i+1}} - \frac{1}{\delta_i} \right) r_{j,k+i} \right) \\
&\quad = \frac{1}{\delta} \left(\sum_{j=1}^{k} \alpha_j \right) + \sum_{i=1}^{L-1} \left(\left(\frac{1}{\delta_{i+1}} - \frac{1}{\delta_i} \right) \sum_{j=1}^{k} r_{j,k+i} \right) \\
&\quad \le \frac{1}{\delta} \left(\gamma_f \delta f + \gamma_c \sum_{j=1}^{k} d_j \right) + \sum_{i=1}^{L-1} \left(\left(\frac{1}{\delta_{i+1}} - \frac{1}{\delta_i} \right) \left(\delta_i f + \sum_{j=1}^{k} d_j \right) \right) \\
&\quad = \gamma_f f + \frac{\gamma_c}{\delta} \sum_{j=1}^{k} d_j + \sum_{i=1}^{L-1} \left(\frac{\delta_i}{\delta_{i+1}} - 1 \right) f + \left(\frac{1}{\delta_L} - \frac{1}{\delta_1} \right) \sum_{j=1}^{k} d_j \\
&\quad = \left(\gamma_f + (L-1)(\delta^{1/(L-1)} - 1) \right) f + \left(\frac{\gamma_c}{\delta} + 1 - \frac{1}{\delta} \right) \sum_{j=1}^{k} d_j.
\end{aligned}$$

This, together with Theorem 2, shows that A_L is a $(\gamma_f + (L-1)(\delta^{1/(L-1)} - 1), 1 + \frac{\gamma_c - 1}{\delta})$-approximation algorithm for the UFLP. The fact that the limit of $(L-1)(\delta^{1/(L-1)} - 1)$ as L tends to infinity is $\ln(\delta)$ completes the proof. ∎

We observe that the proof of Theorem 3 goes through as long as the limit of $\sum_{i=1}^{L-1}(\frac{\delta_i}{\delta_{i+1}}-1)$ as L tends to infinity is $\ln(\delta)$. This condition holds if we choose the δ_i's such that $\delta=\delta_1>\delta_2>\cdots>\delta_L=1$ and the limit of $\max_i(\delta_i-\delta_{i+1})$ as L tends to infinity is zero. It can be seen as follows. Let $x_i=\frac{\delta_i}{\delta_{i+1}}-1>0$. Then, for $i=1,2,\ldots,L-1$,

$$x_i-o(x_i)\le \ln\left(\frac{\delta_i}{\delta_{i+1}}\right)\le x_i.$$

It follows that

$$\sum_{i=1}^{L-1} x_i\left(1-\frac{o(x_i)}{x_i}\right)\le \ln(\delta)\le \sum_{i=1}^{L-1} x_i.$$

Since $\lim_{L\to\infty}\frac{o(x_i)}{x_i}=\lim_{x_i\to 0}\frac{o(x_i)}{x_i}=0$, we conclude that $\lim_{L\to\infty}\sum_{i=1}^{L-1}x_i=\ln(\delta)$.

Now we analyze the factor-revealing linear program (LP1) and show that the JMS algorithm is a $(1.11, 1.78)$-approximation algorithm.

LEMMA 4. *Let $\gamma_f=1.11$. Then for every k, the solution of the factor-revealing linear program* (LP1) *is at most* 1.78.

Proof. For the proof, see the appendix. □

Remark 1. Numerical computations using CPLEX show that $z_{500}\approx 1.7743$ and therefore $\gamma_c>1.774$ for $\gamma_f=1.11$. Thus, the estimate provided by the above lemma for the value of γ_c is close to its actual value.

3.4. Running time. The above analysis of Algorithm A, together with a recent result of Thorup [24], enables us to prove the following result.

COROLLARY 5. *For every $\epsilon>0$, there is a quasi-linear time $(1.52+\epsilon)$-approximation algorithm for the UFLP, both in the distance oracle model and in the sparse graph model.*

Proof sketch. We use the algorithm A_L for a large constant L. Thorup [24] shows that for every $\epsilon>0$, the JMS algorithm can be implemented in quasi-linear time (in both the distance oracle and the sparse graph models) with an approximation factor of $1.61+\epsilon$. It is straightforward to see that his argument actually implies the stronger conclusion that the quasi-linear algorithm is a $(\gamma_f+\epsilon,\gamma_c+\epsilon)$-approximation, where (γ_f,γ_c) are given by Theorem A. This shows that the first phase of algorithm A_L can be implemented in quasi-linear time. The second phase consists of a constant number of rounds. Therefore, we need to show only that each of these rounds can be implemented in quasi-linear time. This is easy to see in the distance oracle model. In the sparse graph model, we can use the exact same argument as that used by Thorup in the proof of Lemma 5.1 of [24]. □

4. The linear-cost FLP. The *linear-cost FLP* is a special case of the universal FLP in which the facility costs are of the form

$$f_i(k)=\begin{cases}0, & k=0,\\ a_ik+b_i, & k>0,\end{cases}$$

where a_i and b_i are nonnegative values for each $i\in\mathcal{F}$. a_i and b_i are called the marginal (or incremental) and setup costs, respectively, of facility i.

We denote an instance of the linear-cost FLP with marginal costs (a_i), setup costs (b_i), and connection costs (c_{ij}) by $LFLP(a,b,c)$. Clearly, the regular UFLP is

a special case of the linear-cost FLP with $a_i = 0$, i.e., $LFLP(0, b, c)$. Furthermore, it is straightforward to see that $LFLP(a, b, c)$ is equivalent to an instance of the regular UFLP in which the marginal costs are added to the connection costs. More precisely, let $\bar{c}_{ij} = c_{ij} + a_i$ for $i \in \mathcal{F}$ and $j \in \mathcal{C}$, and consider an instance of UFLP with facility costs (b_i) and connection costs $(\bar{c}_{ij})$. We denote this instance by $UFLP(b, c + a)$. It is easy to see that $LFLP(a, b, c)$ is equivalent to $UFLP(b, c + a)$. Thus, the linear-cost FLP can be solved using any algorithm for UFLP, and the overall approximation ratio will be the same. However, for applications in the next section, we need bifactor approximation factors of the algorithm (as defined in Definition 4).

It is not necessarily true that applying a (γ_f, γ_c)-approximation algorithm for UFLP on the instance $UFLP(b, a + c)$ will give a (γ_f, γ_c)-approximate solution for $LFLP(a, b, c)$. However, we will show that the JMS algorithm has this property. The following lemma generalizes Theorem A for the linear-cost FLP.

LEMMA 6. *Let (γ_f, γ_c) be a pair obtained from the factor-revealing LP in Theorem* A. *Then applying the JMS algorithm on the instance $UFLP(b, a + c)$ will give a (γ_f, γ_c)-approximate solution for $LFLP(a, b, c)$.*

Proof. Let SOL be an arbitrary solution for $LFLP(a, b, c)$, which can also be viewed as a solution for $UFLP(b, \bar{c})$ for $\bar{c} = c + a$. Consider a facility f that is open in SOL and the set of clients connected to it in SOL. Let k denote the number of these clients, $f(k) = ak + b$ (for $k > 0$) be the facility cost function of f, and $\bar{d}_j$ denote the connection cost between client j and the facility f in the instance $UFLP(b, a + c)$. Therefore, $d_j = \bar{d}_j - a$ is the corresponding connection cost in the original instance $LFLP(a, b, c)$. Recall the definition of α_j and $r_{j,i}$ in the factor-revealing linear program of Theorem A. By inequality (3) we also know that $\alpha_i \leq r_{j,i} + \bar{d}_j + \bar{d}_i$. We strengthen this inequality as follows.

CLAIM 7. $\alpha_i \leq r_{j,i} + d_j + d_i$.

Proof. The claim is true if $\alpha_i = \alpha_j$, since it happens only if $r_{j,i} = \alpha_j$. Otherwise, consider clients i and $j(< i)$ at time $t = \alpha_i - \epsilon$. Let s be the facility to which j is assigned at time t. By the triangle inequality, we have

$$\bar{c}_{si} = c_{si} + a_s \leq c_{sj} + d_i + d_j + a_s = \bar{c}_{sj} + d_i + d_j \leq r_{j,i} + d_i + d_j.$$

On the other hand, $\alpha_i \leq \bar{c}_{si}$ since otherwise i could have connected to facility s at a time earlier than t. □

Also, by inequality (4), we know that

$$\sum_{j=1}^{i-1} \max(r_{j,i} - \bar{d}_j, 0) + \sum_{j=i}^{k} \max(\alpha_i - \bar{d}_j, 0) \leq b.$$

Notice that $\max(a - x, 0) \geq \max(a, 0) - x$ if $x \geq 0$. Therefore, we have

$$\sum_{j=1}^{i-1} \max(r_{j,i} - d_j, 0) + \sum_{j=i}^{k} \max(\alpha_i - d_j, 0) \leq b + ka. \tag{15}$$

Claim 7 and inequality (15) show that the values α_j, $r_{j,i}$, d_j, a, and b constitute a feasible solution of the following optimization program:

$$\text{maximize } \frac{\sum_{i=1}^{k} \alpha_i - \gamma_f(ak + b)}{\sum_{i=1}^{k} d_i}$$

$$\begin{aligned}
\text{subject to } & \forall\, 1 \le i < k:\ \alpha_i \le \alpha_{i+1},\\
& \forall\, 1 \le j < i < k:\ r_{j,i} \ge r_{j,i+1},\\
& \forall\, 1 \le j < i \le k:\ \alpha_i \le r_{j,i} + d_i + d_j,\\
& \forall\, 1 \le i \le k:\ \sum_{j=1}^{i-1} \max(r_{j,i} - d_j, 0) + \sum_{j=i}^{k} \max(\alpha_i - d_j, 0) \le b + ka,\\
& \forall\, 1 \le j \le i \le k:\ \alpha_j, d_j, a, b, r_{j,i} \ge 0.
\end{aligned}$$

However, it is clear that the above optimization program and the factor-revealing linear program in Theorem A are equivalent. This completes the proof of this lemma. □

The above lemma and Theorem A give us the following corollary, which will be used in the next section.

COROLLARY 8. *There is a* $(1, 2)$*-approximation algorithm for the linear-cost FLP.*

It is worth mentioning that Algorithm A can also be generalized for the linear-cost FLP. The only trick is to scale up both a and b in the first phase by a factor of δ, and scale them both down in the second phase. The rest of the proof is almost the same as the proof of Lemma 6.

5. The SCFLP. In this section we will show how the SCFLP can be reduced to the linear-cost FLP. In section 5.1 we define the concept of reduction between FLPs. We will use this concept in sections 5.2 and 5.3 to obtain approximation algorithms for SCFLP and a generalization of SCFLP and the concave-cost FLP.

5.1. Reduction between FLPs.

DEFINITION 5. *A reduction from an FLP* $\mathcal{A}$ *to another FLP* $\mathcal{B}$ *is a polynomial-time procedure* R *that maps every instance* $\mathcal{I}$ *of* $\mathcal{A}$ *to an instance* $R(\mathcal{I})$ *of* $\mathcal{B}$*. This procedure is called a* (σ_f, σ_c)*-reduction if the following conditions hold:*

1. *For any instance* $\mathcal{I}$ *of* $\mathcal{A}$ *and any feasible solution for* $\mathcal{I}$ *with facility cost* $F^*_{\mathcal{A}}$ *and connection cost* $C^*_{\mathcal{A}}$*, there is a corresponding solution for the instance* $R(\mathcal{I})$ *with facility cost* $F^*_{\mathcal{B}} \le \sigma_f F^*_{\mathcal{A}}$ *and connection cost* $C^*_{\mathcal{B}} \le \sigma_c C^*_{\mathcal{A}}$*.*
2. *For any feasible solution for the instance* $R(\mathcal{I})$*, there is a corresponding feasible solution for* $\mathcal{I}$ *whose total cost is at most as much as the total cost of the original solution for* $R(\mathcal{I})$*. In other words, cost of the instance* $R(\mathcal{I})$ *is an overestimate of cost of the instance* $\mathcal{I}$*.*

THEOREM 9. *If there is a* (σ_f, σ_c)*-reduction from an FLP* $\mathcal{A}$ *to another FLP* $\mathcal{B}$*, and a* (γ_f, γ_c)*-approximation algorithm for* $\mathcal{B}$*, then there is a* $(\gamma_f\sigma_f, \gamma_c\sigma_c)$*-approximation algorithm for* $\mathcal{A}$*.*

Proof. On an instance $\mathcal{I}$ of the problem $\mathcal{A}$, we compute $R(\mathcal{I})$, run the (γ_f, γ_c)-approximation algorithm for $\mathcal{B}$ on $R(\mathcal{I})$, and output the corresponding solution for $\mathcal{I}$. In order to see why this is a $(\gamma_f\sigma_f, \gamma_c\sigma_c)$-approximation algorithm for $\mathcal{A}$, let SOL denote an arbitrary solution for $\mathcal{I}$, ALG denote the solution that the above algorithm finds, and $F^*_{\mathcal{P}}$ and $C^*_{\mathcal{P}}$ ($F^{ALG}_{\mathcal{P}}$ and $C^{ALG}_{\mathcal{P}}$, respectively) denote the facility and connection costs of SOL (ALG, respectively) when viewed as a solution for the problem $\mathcal{P}$ ($\mathcal{P} = \mathcal{A}, \mathcal{B}$). By the definition of (σ_f, σ_c)-reductions and (γ_f, γ_c)-approximation algorithms, we have

$$F^{ALG}_{\mathcal{A}} + C^{ALG}_{\mathcal{A}} \le F^{ALG}_{\mathcal{B}} + C^{ALG}_{\mathcal{B}} \le \gamma_f F^*_{\mathcal{B}} + \gamma_c C^*_{\mathcal{B}} \le \gamma_f\sigma_f F^*_{\mathcal{A}} + \gamma_c\sigma_c C^*_{\mathcal{A}},$$

which completes the proof of the lemma. □

We will see examples of reductions in the rest of this paper.

5.2. The SCFLP. In this subsection, we give a 2-approximation algorithm for the soft-capacitated FLP by reducing it to the linear-cost FLP.

THEOREM 10. *There is a* 2*-approximation algorithm for the SCFLP.*

Proof. We use the following reduction. Construct an instance of the linear-cost FLP, where we have the same sets of facilities and clients. The connection costs remain the same. However, the facility cost of the ith facility is $(1 + \frac{k-1}{u_i})f_i$ if $k \geq 1$ and 0 if $k = 0$. Note that, for every $k \geq 1$, $\lceil \frac{k}{u_i} \rceil \leq 1 + \frac{k-1}{u_i} \leq 2 \cdot \lceil \frac{k}{u_i} \rceil$. Therefore, it is easy to see that this reduction is a $(2, 1)$-reduction. By Corollary 8, there is a $(1, 2)$-approximation algorithm for the linear-cost FLP, which together with Theorem 9 completes the proof. □

Furthermore, we now illustrate that the following natural LP formulation of the SCFLP has an integrality gap of 2. This means that we cannot obtain a better approximation ratio using this LP relaxation as the lower bound.

$$\begin{aligned}
\text{minimize } & \sum_{i \in \mathcal{F}} f_i y_i + \sum_{i \in \mathcal{F}} \sum_{j \in \mathcal{C}} c_{ij} x_{ij} \\
\text{subject to } & \forall\, i \in \mathcal{F}, j \in \mathcal{C} :\ x_{ij} \leq y_i, \\
& \forall\, i \in \mathcal{F} :\ \sum_{j \in \mathcal{C}} x_{ij} \leq u_i y_i, \\
& \forall\, j \in \mathcal{C} :\ \sum_{i \in \mathcal{F}} x_{ij} = 1, \\
& \forall\, i \in \mathcal{F}, j \in \mathcal{C} :\ x_{ij} \in \{0, 1\}, \qquad (16) \\
& \forall\, i \in \mathcal{F} :\ y_i \text{ is a nonnegative integer.} \qquad (17)
\end{aligned}$$

In a natural linear program relaxation, we replace the constraints (16) and (17) by $x_{ij} \geq 0$ and $y_i \geq 0$. Here we see that even if we relax only constraint (17), the integrality gap is 2. Consider an instance of the SCFLP that consists of only one potential facility i and $k \geq 2$ clients. Assume that the capacity of facility i is $k - 1$, the facility cost is 1, and all connection costs are 0. It is clear that the optimal integral solution has cost 2. However, after relaxing constraint (17), the optimal fractional solution has cost $1 + \frac{1}{k-1}$. Therefore, the integrality gap between the integer program and its relaxation is $\frac{2(k-1)}{k}$, which tends to 2 as k tends to infinity.

5.3. The concave SCFLP. In this subsection, we consider a common generalization of the SCFLP and the concave-cost FLP. This problem, which we refer to as the *concave SCFLP*, is the same as the SCFLP except that if $r \geq 0$ copies of facility i are open, then the facility cost is $g_i(r)a_i$, where $g_i(r)$ is a given concave increasing function of r. In other words, the concave SCFLP is a special case of the universal FLP in which the facility cost functions are of the form $f_i(x) = a_i g_i(\lceil x/u_i \rceil)$ for constants a_i, u_i and a concave increasing function g_i. It is also a special case of the so-called staircase cost FLP [11]. On the other hand, it is a common generalization of the SCFLP (when $g_i(r) = r$) and the concave-cost FLP (when $u_i = 1$ for all i). The concave-cost FLP is a special case of the universal FLP in which facility cost functions are required to be concave and increasing (see [9]). The main result of this subsection is the following.

THEOREM 11. *The concave SCFLP is* $(\max_{i \in \mathcal{F}} \frac{g_i(2)}{g_i(1)}, 1)$*-reducible to the linear-cost FLP.*

The above theorem is established by the following lemmas, which show the reductions between the concave SCFLP, the concave-cost FLP, and the linear-cost FLP. Notice that $\max_{i\in\mathcal{F}} \frac{g_i(2)}{g_i(1)} \le 2$.

LEMMA 12. *The concave soft-capacitated FLP is* $(\max_{i\in\mathcal{F}} \frac{g_i(2)}{g_i(1)}, 1)$ *reducible to the concave-cost FLP.*

Proof. Given an instance $\mathcal{I}$ of the concave SCFLP, where the facility cost function of the facility i is $f_i(k) = g_i(\lceil k/u_i \rceil)a_i$, we construct an instance $R(\mathcal{I})$ of the concave-cost FLP as follows. We have the same sets of facilities and clients and the same connection costs as in $\mathcal{I}$. The facility cost function of the ith facility is given by

$$f_i'(k) = \begin{cases} \left(g_i(r) + (g_i(r+1) - g_i(r))(\frac{k-1}{u_i} - r + 1)\right) a_i & \text{if } k > 0,\ r := \lceil k/u_i \rceil, \\ 0 & \text{if } k = 0. \end{cases}$$

Concavity of g_i implies that the above function is also concave, and therefore $R(\mathcal{I})$ is an instance of the concave-cost FLP. Also, it is easy to see from the above definition that

$$g_i(\lceil k/u_i \rceil)a_i \le f_i'(k) \le g_i(\lceil k/u_i \rceil + 1)a_i.$$

By the concavity of the function g_i, we have $\frac{g_i(r+1)}{g_i(r)} \le \frac{g_i(2)}{g_i(1)}$ for every $r \ge 1$. Therefore, for every facility i and number k,

$$f_i(k) \le f_i'(k) \le \frac{g_i(2)}{g_i(1)} f_i(k).$$

This completes the proof of the lemma. ∎

Now, we will show a simple $(1,1)$-reduction from the concave-cost FLP to the linear-cost FLP. This, together with the above lemma, reduces the concave SCFLP to the linear-cost FLP.

LEMMA 13. *There is a* $(1,1)$*-reduction from the concave-cost FLP to the linear-cost FLP.*

Proof. Given an instance $\mathcal{I}$ of concave-cost FLP, we construct an instance $R(\mathcal{I})$ of linear-cost FLP as follows: Corresponding to each facility i in $\mathcal{I}$ with facility cost function $f_i(k)$, we put n copies of this facility in $R(\mathcal{I})$ (where n is the number of clients) and let the facility cost function of the lth copy be

$$f_i^{(l)}(k) = \begin{cases} f_i(l) + (f_i(l) - f_i(l-1))(k-l) & \text{if } k > 0, \\ 0 & \text{if } k = 0. \end{cases}$$

In other words, the facility cost function is the line that passes through the points $(l-1, f(l-1))$ and $(l, f(l))$. The set of clients and the connection costs between clients and facilities are unchanged. We prove that this reduction is a $(1,1)$-reduction.

For any feasible solution SOL for $\mathcal{I}$, we can construct a feasible solution SOL' for $R(\mathcal{I})$ as follows. If a facility i is open and k clients are connected to it in SOL, we open the kth copy of the corresponding facility in $R(\mathcal{I})$ and connect the clients to it. Since $f_i(k) = f_i^{(k)}(k)$, the facility and connection costs of SOL' are the same as those of SOL.

Conversely, consider an arbitrary feasible solution SOL for $R(\mathcal{I})$. We construct a solution SOL' for $\mathcal{I}$ as follows. For any facility i, if at least one of the copies of i

is open in SOL, we open i and connect to it all clients that were served by a copy of i in SOL. We show that this does not increase the total cost of the solution as follows. Assume that the l_1th, l_2th, ..., and l_sth copies of i were open in SOL, serving $k_1, k_2, \ldots,$ and k_s clients, respectively. By the concavity of f_i and the fact that $f_i^{(l)}(k) \geq f_i^{(k)}(k) = f_i(k)$ for every l, we have

$$f_i(k_1 + \cdots + k_s) \leq f_i(k_1) + \cdots + f_i(k_s) \leq f_i^{(l_1)}(k_1) + \cdots + f_i^{(l_s)}(k_s).$$

This shows that the facility cost of SOL' is at most the facility cost of SOL. □

6. Conclusion. We have obtained the best approximation ratios for two well-studied facility location problems, 1.52 for the UFLP and 2 for the SCFLP, respectively. The approximation ratio for the UFLP almost matches the lower bound of 1.463, and the approximation ratio for the SCFLP achieves the integrality gap of the standard LP relaxation of the problem. An interesting open question in this area is how to close the gap between 1.52 and 1.463 for the UFLP.

Although the performance guarantee of our algorithm for the UFLP is very close to the lower bound of 1.463, it would be nice to show that the bound of 1.52 is actually tight. In [12], it was shown that a solution to the factor-revealing linear program for the JMS algorithm provides a tight bound on the performance guarantee of the JMS algorithm. It is reasonable to expect that a solution to linear program (LP2) may also be used to construct a tight example for our 1.52-approximation algorithm. However, we were unsuccessful in constructing such an example.

Our results (Theorem 1 and Lemma 4) for the UFLP and/or the idea of bifactor reduction have been used to get the currently best known approximations ratios for several multilevel FLPs [1, 26]. Since the UFLP is the most basic FLP, we expect to see more applications of our results.

Appendix. Proof of Lemma 4.

Proof. By doubling a feasible solution of the factor-revealing program (LP1) (as in the proof of Lemma 12 in [13]), it is easy to show that for every k, $z_k \leq z_{2k}$. Therefore, without loss of generality, we can assume that k is sufficiently large.

Consider a feasible solution of the factor-revealing linear program. Let $x_{j,i} := \max(r_{j,i} - d_j, 0)$. Inequality (4) of the factor-revealing linear program implies that for every $i \leq i'$,

$$(i' - i + 1)\alpha_i - f \leq \sum_{j=i}^{i'} d_j - \sum_{j=1}^{i-1} x_{j,i}. \tag{18}$$

Now, we define l_i as follows:

$$l_i = \begin{cases} p_2 k & \text{if } i \leq p_1 k, \\ k & \text{if } i > p_1 k, \end{cases}$$

where p_1 and p_2 are two constants with $p_1 < p_2$ that will be fixed later. Consider inequality (18) for every $i \leq p_2 k$ and $i' = l_i$:

$$(l_i - i + 1)\alpha_i - f \leq \sum_{j=i}^{l_i} d_j - \sum_{j=1}^{i-1} x_{j,i}. \tag{19}$$

For every $i = 1, \ldots, k$, we define θ_i as follows. Here p_3 and p_4 are two constants with $p_1 < p_3 < 1 - p_3 < p_2$ and $p_4 \leq 1 - p_2$ that will be fixed later.

$$\theta_i = \begin{cases} \frac{1}{l_i - i + 1} & \text{if } i \leq p_3 k, \\ \frac{1}{(1-p_3)k} & \text{if } p_3 k < i \leq (1-p_3)k, \\ \frac{p_4 k}{(k-i)(k-i+1)} & \text{if } (1-p_3)k < i \leq p_2 k, \\ 0 & \text{if } i > p_2 k. \end{cases} \tag{20}$$

By multiplying both sides of inequality (19) by θ_i and adding up this inequality for $i = 1, \ldots, p_1 k$, $i = p_1 k + 1, \ldots, p_3 k$, $i = p_3 k + 1 \ldots, (1 - p_3)k$, and $i = (1 - p_3)k + 1, \ldots, p_2 k$, we get the following inequalities:

$$\sum_{i=1}^{p_1 k} \alpha_i - \left(\sum_{i=1}^{p_1 k} \theta_i \right) f \leq \sum_{i=1}^{p_1 k} \sum_{j=i}^{p_2 k} \frac{d_j}{p_2 k - i + 1} - \sum_{i=1}^{p_1 k} \sum_{j=1}^{i-1} \frac{\max(r_{j,i} - d_j, 0)}{p_2 k - i + 1}, \tag{21}$$

$$\sum_{i=p_1 k+1}^{p_3 k} \alpha_i - \left(\sum_{i=p_1 k+1}^{p_3 k} \theta_i \right) f \leq \sum_{i=p_1 k+1}^{p_3 k} \sum_{j=i}^{k} \frac{d_j}{k - i + 1} - \sum_{i=p_1 k+1}^{p_3 k} \sum_{j=1}^{i-1} \frac{\max(r_{j,i} - d_j, 0)}{k - i + 1}, \tag{22}$$

$$\begin{aligned} &\sum_{i=p_3 k+1}^{(1-p_3)k} \frac{k - i + 1}{(1-p_3)k} \alpha_i - \left(\sum_{i=p_3 k+1}^{(1-p_3)k} \theta_i \right) f \\ &\quad \leq \sum_{i=p_3 k+1}^{(1-p_3)k} \sum_{j=i}^{k} \frac{d_j}{(1-p_3)k} - \sum_{i=p_3 k+1}^{(1-p_3)k} \sum_{j=1}^{i-1} \frac{\max(r_{j,i} - d_j, 0)}{(1-p_3)k}, \end{aligned} \tag{23}$$

$$\begin{aligned} \sum_{i=(1-p_3)k+1}^{p_2 k} \frac{p_4 k}{k - i} \alpha_i - \left(\sum_{i=(1-p_3)k+1}^{p_2 k} \theta_i \right) f \leq &\sum_{i=(1-p_3)k+1}^{p_2 k} \sum_{j=i}^{k} \frac{p_4 k d_j}{(k-i)(k-i+1)} \\ &- \sum_{i=(1-p_3)k+1}^{p_2 k} \sum_{j=1}^{i-1} \frac{p_4 k \max(r_{j,i} - d_j, 0)}{(k-i)(k-i+1)}. \end{aligned} \tag{24}$$

We define $s_i := \max_{l \geq i}(\alpha_l - d_l)$. Using this definition and inequalities (2) and (3) of the factor-revealing linear program (LP1), we obtain

$$\forall i : \ r_{j,i} \geq s_i - d_j \Longrightarrow \forall i : \ \max(r_{j,i} - d_j, 0) \geq \max(s_i - 2d_j, 0), \tag{25}$$

$$\forall i : \ \alpha_i \leq s_i + d_i, \tag{26}$$

$$s_1 \geq s_2 \geq \cdots \geq s_k \ (\geq 0). \tag{27}$$

We assume $s_k \geq 0$ here because, if instead $\alpha_k < d_k$, we can always set α_k equal to d_k without violating any constraint in the factor-revealing (LP1) and increase z_k.

Inequality (26) and $p_4 \le 1 - p_2$ imply

$$\sum_{i=p_3k+1}^{(1-p_3)k} \left(1 - \frac{k-i+1}{(1-p_3)k}\right)\alpha_i + \sum_{i=(1-p_3)k+1}^{p_2k} \left(1 - \frac{p_4k}{k-i}\right)\alpha_i + \sum_{i=p_2k+1}^{k} \alpha_i$$
$$\le \sum_{i=p_3k+1}^{(1-p_3)k} \frac{i-p_3k-1}{(1-p_3)k}(s_i+d_i) + \sum_{i=(1-p_3)k+1}^{p_2k} \left(1 - \frac{p_4k}{k-i}\right)(s_i+d_i) + \sum_{i=p_2k+1}^{k} (s_i+d_i). \tag{28}$$

Let $\zeta := \sum_{i=1}^{k} \theta_i$. Thus,

$$\begin{aligned}\zeta &= \sum_{i=1}^{p_1k} \frac{1}{p_2k-i+1} + \sum_{i=p_1k+1}^{p_3k} \frac{1}{k-i+1} + \sum_{i=p_3k+1}^{(1-p_3)k} \frac{1}{(1-p_3)k} \\ &\quad + \sum_{i=(1-p_3)k+1}^{p_2k} \left(\frac{p_4k}{k-i} - \frac{p_4k}{k-i+1}\right) \\ &= \ln\left(\frac{p_2}{p_2-p_1}\right) + \ln\left(\frac{1-p_1}{1-p_3}\right) + \frac{1-2p_3}{1-p_3} + \frac{p_4}{1-p_2} - \frac{p_4}{p_3} + o(1). \end{aligned} \tag{29}$$

By adding the inequalities (21), (22), (23), (24), (28) and using (25), (27), and the fact that $\max(x,0) \ge \delta x$ for every $0 \le \delta \le 1$, we obtain

$$\begin{aligned}&\sum_{i=1}^{k} \alpha_i - \zeta f \\ &\le \sum_{i=1}^{p_1k}\sum_{j=i}^{p_2k} \frac{d_j}{p_2k-i+1} - \sum_{i=1}^{p_1k}\sum_{j=1}^{i-1} \frac{s_i-2d_j}{2(p_2k-i+1)} \\ &\quad + \sum_{i=p_1k+1}^{p_3k}\sum_{j=i}^{k} \frac{d_j}{k-i+1} - \sum_{i=p_1k+1}^{p_3k}\sum_{j=1}^{i-1} \frac{s_i-2d_j}{k-i+1} \\ &\quad + \sum_{i=p_3k+1}^{(1-p_3)k}\sum_{j=i}^{k} \frac{d_j}{(1-p_3)k} - \sum_{i=p_3k+1}^{(1-p_3)k}\sum_{j=1}^{i-1} \frac{s_i-2d_j}{(1-p_3)k} \\ &\quad + \sum_{i=(1-p_3)k+1}^{p_2k}\sum_{j=i}^{k} \frac{p_4kd_j}{(k-i)(k-i+1)} - \sum_{i=(1-p_3)k+1}^{p_2k}\sum_{j=1}^{i-1} \frac{p_4k\max(s_{p_2k+1}-2d_j,0)}{(k-i)(k-i+1)} \\ &\quad + \sum_{i=p_3k+1}^{(1-p_3)k} \frac{i-p_3k-1}{(1-p_3)k}(s_i+d_i) \\ &\quad + \sum_{i=(1-p_3)k+1}^{p_2k} \left(1 - \frac{p_4k}{k-i}\right)(s_i+d_i) + \sum_{i=p_2k+1}^{k} (s_{p_2k+1}+d_i) \\ &= \sum_{j=1}^{p_2k}\sum_{i=1}^{\min(j,p_1k)} \frac{d_j}{p_2k-i+1} - \sum_{i=1}^{p_1k} \frac{i-1}{2(p_2k-i+1)}s_i + \sum_{j=1}^{p_1k}\sum_{i=j+1}^{p_1k} \frac{d_j}{p_2k-i+1} \end{aligned}$$

&\quad+\sum_{j=(1-p_3)k+1}^{p_2k}\left(1-\frac{p_4k}{k-j}\right)s_j+(1-p_2)ks_{p_2k+1}.
\end{aligned}
\tag{30}
$$

Let us denote the coefficients of d_j in the above expression by λ_j. Therefore, we have

$$
\begin{aligned}
&\sum_{i=1}^{k}\alpha_i-\zeta f\\
&\quad\le \sum_{j=1}^{k}\lambda_j d_j-\sum_{j=1}^{p_1k}\frac{j-1}{2(p_2k-j+1)}s_j-\sum_{j=p_1k+1}^{p_3k}\frac{j-1}{k-j+1}s_j-\sum_{j=p_3k+1}^{(1-p_3)k}\frac{p_3k}{(1-p_3)k}s_j\\
&\qquad+\sum_{j=(1-p_3)k+1}^{p_2k}\left(1-\frac{p_4k}{k-j}\right)s_j+\left(1-p_2-(1-2p_3)\left(\frac{p_4}{1-p_2}-\frac{p_4}{p_3}\right)\right)ks_{p_2k+1}\\
&\qquad-\left(\frac{p_4}{1-p_2}-\frac{p_4}{p_3}\right)\sum_{j=1}^{p_3k}\max(s_{p_2k+1}-2d_j,0),
\end{aligned}
\tag{31}
$$

where

$$\lambda_j := \begin{cases} \ln\left(\frac{p_2}{p_2-p_1}\right) + 2\ln\left(\frac{1-p_1}{1-p_3}\right) + \frac{2(1-2p_3)}{1-p_3} + o(1) \\ \qquad\qquad \text{if } 1 \le j \le p_1 k, \\ \ln\left(\frac{p_2}{p_2-p_1}\right) + \ln\left(\frac{1-p_1}{1-p_3}\right) + \frac{2(1-2p_3)}{1-p_3} + \mathrm{H}_{k-j} - \mathrm{H}_{(1-p_3)k} + o(1) \\ \qquad\qquad \text{if } p_1 k < j \le p_3 k, \\ \ln\left(\frac{p_2}{p_2-p_1}\right) + \ln\left(\frac{1-p_1}{1-p_3}\right) + \frac{2(1-2p_3)}{1-p_3} + \frac{2p_4}{1-p_2} - \frac{2p_4}{p_3} + o(1) \\ \qquad\qquad \text{if } p_3 k < j \le (1-p_3)k, \\ \ln\left(\frac{p_2}{p_2-p_1}\right) + \ln\left(\frac{1-p_1}{1-p_3}\right) + \frac{1-2p_3}{1-p_3} + 1 - \frac{p_4}{p_3} + o(1) \\ \qquad\qquad \text{if } (1-p_3)k < j \le p_2 k, \\ \ln\left(\frac{1-p_1}{1-p_3}\right) + \frac{1-2p_3}{1-p_3} + 1 + \frac{p_4}{1-p_2} - \frac{p_4}{p_3} + o(1) \\ \qquad\qquad \text{if } p_2 k < j \le k. \end{cases}$$

For every $j \le p_3 k$, we have

(32)
$$\lambda_{(1-p_3)k} - \lambda_j \le \frac{2p_4}{1-p_2} - \frac{2p_4}{p_3} \Rightarrow \delta_j := (\lambda_{(1-p_3)k} - \lambda_j) \Big/ \left(\frac{2p_4}{1-p_2} - \frac{2p_4}{p_3}\right) \le 1.$$

Also, if we choose p_1, p_2, p_3, p_4 in such a way that

$$\ln\left(\frac{1-p_1}{1-p_3}\right) < \frac{2p_4}{1-p_2} - \frac{2p_4}{p_3}, \tag{33}$$

then for every $j \le p_3 k$, $\lambda_j \le \lambda_{(1-p_3)k}$ and therefore $\delta_j \ge 0$. Then, since $0 \le \delta_j \le 1$, we can replace $\max(s_{p_2k+1} - 2d_j, 0)$ by $\delta_j(s_{p_2k+1} - 2d_j)$ in (31). This gives us

$$\begin{aligned} &\sum_{i=1}^{k} \alpha_i - \zeta f \\ &\le \sum_{j=1}^{k} \lambda_j d_j - \sum_{j=1}^{p_1 k} \frac{j-1}{2(p_2 k - j + 1)} s_j - \sum_{j=p_1k+1}^{p_3 k} \frac{j-1}{k-j+1} s_j - \sum_{j=p_3k+1}^{(1-p_3)k} \frac{p_3 k}{(1-p_3)k} s_j \\ &\quad + \sum_{j=(1-p_3)k+1}^{p_2 k} \left(1 - \frac{p_4 k}{k-j}\right) s_j + \left(1 - p_2 - (1-2p_3)\left(\frac{p_4}{1-p_2} - \frac{p_4}{p_3}\right)\right) k s_{p_2k+1} \\ &\quad - \frac{1}{2} \sum_{j=1}^{p_3 k} (\lambda_{(1-p_3)k} - \lambda_j)(s_{p_2k+1} - 2d_j). \end{aligned} \tag{34}$$

Let μ_j denote the coefficient of s_j in the above expression. Therefore the above inequality can be written as

$$\sum_{i=1}^{k} \alpha_i - \zeta f \le \lambda_{(1-p_3)k} \sum_{j=1}^{(1-p_3)k} d_j + \sum_{j=(1-p_3)k+1}^{k} \lambda_j d_j + \sum_{j=1}^{p_2 k+1} \mu_j s_j, \tag{35}$$

where

$$\mu_j = \begin{cases} -\dfrac{j-1}{2(p_2k-j+1)} & \text{if } 1 \le j \le p_1k, \\ -\dfrac{j-1}{k-j+1} & \text{if } p_1k < j \le p_3k, \\ -\dfrac{p_3}{1-p_3} & \text{if } p_3k < j \le (1-p_3)k, \\ 1-\dfrac{p_4k}{k-j} & \text{if } (1-p_3)k < j \le p_2k, \end{cases} \tag{36}$$

and

(37)

$$\begin{aligned} &\mu_{p_2k+1} \\ &= \left(1-p_2-(1-2p_3)\left(\frac{p_4}{1-p_2}-\frac{p_4}{p_3}\right)\right)k - \frac{1}{2}\lambda_{(1-p_3)k}p_3k + \frac{1}{2}\sum_{j=1}^{p_3k}\lambda_j \\ &= \left(1-p_2-(1-2p_3)\left(\frac{p_4}{1-p_2}-\frac{p_4}{p_3}\right)\right)k - \frac{1}{2}\lambda_{(1-p_3)k}p_3k \\ &\quad + \frac{p_1k}{2}\left(\ln\left(\frac{p_2}{p_2-p_1}\right)+2\ln\left(\frac{1-p_1}{1-p_3}\right)+\frac{2(1-2p_3)}{1-p_3}+o(1)\right) \\ &\quad + \frac{(p_3-p_1)k}{2}\left(\ln\left(\frac{p_2}{p_2-p_1}\right)+\ln\left(\frac{1-p_1}{1-p_3}\right)+\frac{2(1-2p_3)}{1-p_3}+o(1)\right) \\ &\quad + \frac{1}{2}\sum_{j=p_1k+1}^{p_3k}\sum_{i=(1-p_3)k+1}^{k-j}\frac{1}{i} \\ &= \left(\ln\left(\frac{1-p_1}{1-p_3}\right)+2-2p_2-p_3+p_1-2(1-p_3)\left(\frac{p_4}{1-p_2}-\frac{p_4}{p_3}\right)+o(1)\right)\frac{k}{2}. \end{aligned}$$

Now, if we pick p_1, p_2, p_3, p_4 in such a way that $\lambda_j \le \gamma$ for every $j \ge (1-p_3)k$, i.e.,

$$\ln\left(\frac{p_2}{p_2-p_1}\right)+\ln\left(\frac{1-p_1}{1-p_3}\right)+\frac{2(1-2p_3)}{1-p_3}+\frac{2p_4}{1-p_2}-\frac{2p_4}{p_3} < \gamma, \tag{38}$$

$$\ln\left(\frac{p_2}{p_2-p_1}\right)+\ln\left(\frac{1-p_1}{1-p_3}\right)+\frac{1-2p_3}{1-p_3}+1-\frac{p_4}{p_3} < \gamma, \tag{39}$$

and

$$\ln\left(\frac{1-p_1}{1-p_3}\right)+\frac{1-2p_3}{1-p_3}+1+\frac{p_4}{1-p_2}-\frac{p_4}{p_3} < \gamma, \tag{40}$$

then the term $\lambda_{(1-p_3)k}\sum_{j=1}^{(1-p_3)k} d_j + \sum_{j=(1-p_3)k+1}^{k}\lambda_j d_j$ on the right-hand side of (35) is at most $\gamma\sum_{j=1}^{k} d_j$. Also, if for every $i \le p_2k+1$ we have

$$\mu_1+\mu_2+\cdots+\mu_i \le 0, \tag{41}$$

then by inequality (27) we have $\sum_{j=1}^{p_2k+1} \mu_j s_j \le 0$. Therefore, if p_1, p_2, p_3, p_4 are chosen in such a way that, in addition to the above inequalities, we have

$$\ln\left(\frac{p_2}{p_2-p_1}\right)+\ln\left(\frac{1-p_1}{1-p_3}\right)+\frac{1-2p_3}{1-p_3}+\frac{p_4}{1-p_2}-\frac{p_4}{p_3}<1.11, \tag{42}$$

then inequality (35) can be written as

$$\sum_{i=1}^{k}\alpha_i - 1.11f \le \gamma\sum_{j=1}^{k} d_j, \tag{43}$$

which shows that the solution of the maximization program (LP1) is at most γ. From (36), it is clear that $\mu_j \le 0$ for every $j \le (1-p_3)k$ and $\mu_j \ge 0$ for every $(1-p_3)k \le j \le p_2k$. Therefore, it is enough to check inequality (41) for $i = p_2k$ and $i = p_2k+1$. We have

$$\begin{aligned}
\sum_{j=1}^{p_2k}\mu_j &= -\sum_{j=1}^{p_1k}\frac{p_2k-p_2k+j-1}{2(p_2k-j+1)} - \sum_{j=p_1k+1}^{p_3k}\frac{k-k+j-1}{k-j+1} - \frac{p_3(1-2p_3)k}{1-p_3} \\
&\quad + (p_2-1+p_3)k - \sum_{j=(1-p_3)k+1}^{p_2k}\frac{p_4k}{k-j} \\
&= -\frac{p_2k}{2}(\mathrm{H}_{p_2k}-\mathrm{H}_{(p_2-p_1)k}) + \frac{p_1k}{2} - k(\mathrm{H}_{(1-p_1)k}-\mathrm{H}_{(1-p_3)k}) + (p_3-p_1)k \\
&\quad - \frac{p_3(1-2p_3)k}{1-p_3} + (p_2-1+p_3)k - p_4k(\mathrm{H}_{p_3k}-\mathrm{H}_{(1-p_2)k}) \\
&= \left(-\frac{p_1}{2}+p_2+2p_3-1-\frac{p_2}{2}\ln\left(\frac{p_2}{p_2-p_1}\right)-\ln\left(\frac{1-p_1}{1-p_3}\right)-\frac{p_3(1-2p_3)}{1-p_3}\right. \\
&\quad \left. - p_4\ln\left(\frac{p_3}{1-p_2}\right)+o(1)\right)k.
\end{aligned} \tag{44}$$

Therefore, inequality (41) is equivalent to the following two inequalities:

$$-\frac{p_1}{2}+p_2+2p_3-1-\frac{p_2}{2}\ln\left(\frac{p_2}{p_2-p_1}\right)-\ln\left(\frac{1-p_1}{1-p_3}\right)-\frac{p_3(1-2p_3)}{1-p_3}-p_4\ln\left(\frac{p_3}{1-p_2}\right)<0, \tag{45}$$

$$\begin{aligned}
&-\frac{p_1}{2}+p_2+2p_3-1-\frac{p_2}{2}\ln\left(\frac{p_2}{p_2-p_1}\right)-\ln\left(\frac{1-p_1}{1-p_3}\right)-\frac{p_3(1-2p_3)}{1-p_3}-p_4\ln\left(\frac{p_3}{1-p_2}\right) \\
&\quad +\frac{1}{2}\ln\left(\frac{1-p_1}{1-p_3}\right)+1-p_2-\frac{p_3}{2}+\frac{p_1}{2}-(1-p_3)\left(\frac{p_4}{1-p_2}-\frac{p_4}{p_3}\right)<0.
\end{aligned} \tag{46}$$

Now, it is enough to observe that if we let $p_1 = 0.225$, $p_2 = 0.791$, $p_3 = 0.30499$, $p_4 = 0.06984$, and $\gamma = 1.7764$, then $p_1 < p_3 < 1-p_3 < p_2$ and $p_4 < 1-p_2$, as specified earlier, and inequalities (33), (38), (39), (40), (42), (45), and (46) are all satisfied. Therefore, the solution of the optimization program (LP1) is at most $1.7764 < 1.78$. □

Acknowledgments. We would like to thank Asaf Levin for pointing out that our analysis of the 2-approximation algorithm for the SCFLP is tight. We also want

to mention that an idea for deriving better approximation factors for the UFLP using the $(1, 2)$ bifactor guarantee was independently proposed earlier by Kamal Jain in a private communication to the first author, and by the last two authors. We thank the anonymous referees for their helpful suggestions that significantly improved the exposition of our paper.

AN UNCONDITIONAL LOWER BOUND ON THE TIME-APPROXIMATION TRADE-OFF FOR THE DISTRIBUTED MINIMUM SPANNING TREE PROBLEM*

MICHAEL ELKIN†

Abstract. The design of distributed approximation protocols is a relatively new and rapidly developing area of research. However, so far, little progress has been made in the study of the *hardness* of distributed approximation. In this paper we initiate the systematic study of this subject and show strong unconditional *lower bounds* on the *time-approximation trade-off* of the distributed *minimum spanning tree* problem, and show some of its variants.

Key words. minimum spanning tree, distributed algorithms, hardness of approximation

1. Introduction.

1.1. Distributed computing. Consider a synchronous network of processors with unbounded computational power, modeled by an undirected n-vertex graph. The initial knowledge of the processors (henceforth, vertices) is very limited. Specifically, each of them has its own *local* perspective of the network (henceforth, graph), which is confined to its immediate neighborhood. The vertices, however, have to compute some *global* function of the graph, such as its *minimum spanning tree* (henceforth, *MST*).

To this end, distributed algorithms (henceforth, *protocols*) are designed. There are several measures of efficiency of protocols, but in this paper we restrict our attention to the running time, defined as the worst-case number of rounds of distributed communication. On each round of communication at most B bits can be sent through each edge, where B is a parameter of the model. The running time efficiency measure of protocols naturally gives rise to a complexity measure of problems, called the time complexity.

The design of efficient protocols for this model, as well as proving lower bounds on their efficiency, is a lively area of study known as locality-sensitive distributed computing (henceforth, *distributed computing*); see [31] and references therein.

1.2. Distributed approximation and hardness of approximation. While traditionally the research in the area of distributed computing concentrated on designing protocols that solve the problem at hand *exactly*, some of the more recent research focuses on providing *approximate* solutions for various distributed problems. Most notably, several approximation protocols were recently devised for the minimum dominating set problem [22, 9, 25, 35], for the minimum edge-coloring problem [33, 20, 5], for the maximum matching problem [15, 21, 7], and for the distance estimation problem [10, 14]. Another relevant important direction is the study of distributed

algorithms for finding approximate solutions for positive linear programs initiated by Papadimitriou and Yannakakis in [34] and continued with the works of Bartal, Byers, and Raz [4] and Kuhn and Wattenhofer [26]. Recently Moscibroda and Wattenhofer [30] and Grandoni et al. [19] used techniques based on linear programming for developing distributed approximation algorithms for several natural problems.

However, the situation with lower bounds on approximability of distributed problems is by far less satisfactory. Specifically, the existing results on hardness of distributed approximation can be divided into two categories.

First, there are inapproximability results that are based on lower bounds on the time required for the *exact* solution of certain problems, and on integrality of the objective functions of these problems. For example, there is a fundamental result due to Linial [27] saying that 3-coloring an n-vertex ring requires $\Omega(\log^* n)$ time. In particular, it implies that any 3/2-approximation protocol for vertex-coloring problem requires $\Omega(\log^* n)$ time.

Second, there are inapproximability results that assume that the vertices are computationally limited, e.g., are allowed to perform at most polynomial in n number of operations. Obviously, under this assumption any NP-hardness inapproximability result immediately gives rise to an analogous result in the distributed model.

Note, however, that results of this sort are just somewhat different semantic interpretations of already known lower bounds, and as such, they provide no new insights that were not provided by the original lower bounds. Moreover, we believe that the study of the role of *locality* in distributed computing should be conducted in the cleanest possible model, and, consequently, restricting the computational power of the vertices is obstructive to the goals of this study (see [27, 31]).

To summarize, while sophisticated distributed approximation protocols were developed for various problems, so far no real progress has been made in the study of the *hardness of distributed approximation*. In this paper we initiate the systematic study of this subject. Specifically, we study the inapproximability of the distributed *MST* problem and show strong unconditional *lower bounds* on the *time-approximation trade-offs* for this problem and some of its variants.

1.3. Distributed *MST* problem. The (distributed) *MST* problem is one of the most important problems in the area of distributed computing and has been the subject of extensive research [16, 8, 18, 1, 17, 23, 32, 28, 11].

The most time-efficient protocol known for this problem was devised in [11], and its running time is $O(\mu(G,\omega) \cdot \log^3 n + \sqrt{\frac{n \log^* n}{B}} \log n)$, where $\mu(G,\omega)$ stands for the *MST*-radius of the weighted graph $(G = (V,E),\omega)$, $\omega : E \to R^+$. The definition of the *MST*-radius $\mu(G,\omega)$ is somewhat involved (see [11]), but for the rest of this discussion it is sufficient to keep in mind that for any graph (G,ω), $\mu(G,\omega) \leq \Lambda(G) \leq n$, where $\Lambda(G)$ stands for the *unweighted* diameter of the graph G.

On the negative side, Peleg and Rubinovich [32] have shown a lower bound of $\Omega(\frac{\sqrt{n}}{B})$ on the time complexity of the *MST* problem restricted to graphs of small diameter (at most $O(n^\delta)$ for an arbitrarily small positive $\delta > 0$).

In this paper we show that *approximating* the *MST* problem within a ratio H on graphs of small diameter requires $T = \Omega(\sqrt{\frac{n}{H \cdot B}})$ time. (The result applies to graphs of diameter $\Omega(n^\delta)$ for an arbitrarily small constant $\delta > 0$, exactly like the result of [32]; see section 2 for the formal definitions of the notions of *approximation* and *randomization* in this context.) In other words, we derive an unconditional lower bound on the time-approximation trade-off for the *MST* problem, specifically, $T^2 \cdot H =$

$\Omega(\frac{n}{B})$. Substituting $H = O(1)$ into this formula shows that approximating the *MST* problem within any constant factor requires $\Omega(\sqrt{\frac{n}{B}})$ time, improving the lower bound of [32] by a factor of $\sqrt{B}$ (recall that the lower bound of [32] applies only for the exact solution of the *MST* problem).

Moreover, our lower bound implies that for any $0 < \epsilon < 1$, approximating the *MST* problem within a factor of $\left(\frac{n}{B}\right)^{1-\epsilon}$ requires $\Omega\left(\left(\frac{n}{B}\right)^{\epsilon/2}\right)$ time. The latter means, in particular, that the $\left(\frac{n}{B}\right)^{1-\epsilon}$-approximate *MST* problem is *not a local* problem, i.e., cannot be solved in time polylogarithmic in n. This lower bound, like all the other lower bounds that we prove in this paper, applies even to *randomized* protocols. We also remark that our lower bounds, as well as the lower bounds of [32, 28], apply to the scenario when the vertices have their own distinct identity numbers at the beginning of computation.

1.4. Additional results. One direction of recent research on the distributed *MST* problem was to refine the lower bound of Peleg and Rubinovich [32] that applies to the *exact* computation of the *MST* on graphs G with diameter $\Lambda(G) = O(n^\delta)$, $0 < \delta < 1/2$, and to prove similar lower bounds for the *MST* problem restricted to graphs of even smaller diameter. Specifically, Peleg and Rubinovich themselves [32] have shown a lower bound of $\Omega(\frac{\sqrt{n}}{B \cdot \log n})$ for the *MST* problem restricted to graphs G of diameter $\Lambda(G) = O(\log n)$, and Lotker, Patt-Shamir, and Peleg [28] have shown lower bounds of $\Omega(\frac{n^{1/3}}{B})$ (resp., $\Omega(\frac{n^{1/4}}{\sqrt{B}})$) for the *MST* problem restricted to graphs of diameter $\Lambda(G) \leq 4$ (resp., $\Lambda(G) \leq 3$). For graphs of diameter $\Lambda(G) \leq 2$ (resp., $\Lambda(G) = 1$) upper bounds of $O(\log n)$ (resp., $O(\log \log n)$) were shown in [28] (resp., [29]). Recall that all the aforementioned lower bounds apply only to the exact *MST* problem.

In addition to the lower bound on the time-approximation trade-off for the general variant of the *MST* problem, in this paper we also show a lower bound on the time-approximation trade-off for the *MST* problem restricted to graphs of diameter $\Lambda(G) \leq \Lambda$, for $\Lambda = 3$ and all even Λ in the range $4 \leq \Lambda = O(\log n)$. Specifically, denoting the running time of an approximation protocol by T, and its approximation ratio by H, we show that $T^{2+\frac{2}{\Lambda-2}} \cdot H = \Omega(\frac{n}{\Lambda \cdot B})$.

Note that this result improves all the previous lower bounds for the exact computation of the *MST*. Specifically, it improves the result of [32] for $\Lambda = O(\log n)$ by a factor of $\sqrt{B \cdot \log n}$, and the results of [28] for $\Lambda = 4$ (resp., $\Lambda = 3$) by a factor of $B^{2/3}$ (resp., $B^{1/4}$). Moreover, our result gives rise to a lower bound of $\Omega((\frac{n}{B})^{1/2-\epsilon})$ for the exact computation (or even approximation within any constant factor) of the *MST* on graphs of constant diameter $O(1/\epsilon)$, significantly improving the previously best-known lower bound of $\Omega(\frac{n^{1/3}}{B})$. Table 1.1 summarizes the previously known lower bounds on the time complexity of the *MST* problem restricted to graphs of diameter at most Λ, parameterized by Λ, along with our improved lower bounds on this problem.

On the positive side, we devise an H-approximation protocol for the *MST* problem with running time $O(\Lambda(G) + \frac{\omega_{max}}{H-1} \cdot \log^* n)$, where ω_{max} is the ratio between the maximal and the minimal weight of an edge in the input graph (G, ω). It follows that the approximate *MST* problem becomes easy when ω_{max} is small (our lower bounds on the H-approximate *MST* problem apply for $\omega_{max} = \Omega(\sqrt{n} \cdot H^{3/2})$). Finally, our techniques enable us to derive some similar upper and lower bounds on the time-

TABLE 1.1

The summary of previously known and new lower bounds on the MST problem restricted to graphs of diameter at most Λ.

Diameter Λ	Previous lower bound on the exact computation	New lower bound on the exact computation	Lower bound on the time-approximation trade-off
n^{δ}, $0 < \delta < 1/2$	$\Omega(\frac{\sqrt{n}}{B})$ [32]	$\Omega(\sqrt{\frac{n}{B}})$	$T^2 \cdot H = \Omega(\frac{n}{B})$
$\Theta(\log n)$	$\Omega(\frac{\sqrt{n}}{B \cdot \log n})$ [32]	$\Omega(\sqrt{\frac{n}{B \cdot \log n}})$	$T^2 \cdot H = \Omega(\frac{n}{B \cdot \log n})$
Constant (at least 3)	$\Omega(\frac{n^{1/3}}{B})$ [28]	$\Omega((\frac{n}{B})^{\frac{1}{2} - \frac{1}{2\Lambda - 2}})$	$T^{2 + \frac{2}{\Lambda - 2}} \cdot H = \Omega(\frac{n}{B \cdot \Lambda})$
4	$\Omega(\frac{n^{1/3}}{B})$ [28]	$\Omega((\frac{n}{B})^{1/3})$	$T^3 \cdot H = \Omega(\frac{n}{B})$
3	$\Omega(\frac{n^{1/4}}{\sqrt{B}})$ [28]	$\Omega((\frac{n}{B})^{1/4})$	$T^4 \cdot H = \Omega(\frac{n}{B})$

approximation trade-off of the *shortest-path tree* problem, but they are omitted for the sake of brevity.

Structure of the paper. Our main result (the lower bound of $T^2 \cdot H = \Omega(\frac{n}{B})$ on the time-approximation trade-off for the general variant of the *MST* problem) is proved in section 3. In section 4 we present the extensions of this result to the *MST* problem restricted to graphs of diameter smaller than n^{δ}. In section 5 we generalize our lower bounds even further and show that they apply for $\omega_{max} = \Omega(\sqrt{n} \cdot H^{3/2})$. In section 6 we describe our approximation protocol for the *MST* problem.

Related work. Our line of research was continued in a recent work of Kuhn, Moscibroda, and Wattenhofer [24], who proved remarkable lower bounds on time-approximation trade-offs for several problems, including the *maximum dominating set* and *maximum matching*. See also the recent survey [13] and references therein.

2. Preliminaries. For an undirected graph $G = (V, E)$, a *spanning tree* is an acyclic connected subgraph $\tau = (V, E')$, $E' \subseteq E$. For a weighted graph $(G = (V, E), \omega)$ with a nonnegative weight function $\omega : E \rightarrow \mathtt{R}^+$, an *MST* is a spanning tree $\tau = (V, E')$ with minimum weight $\omega(\tau) = \sum_{e \in E'} \omega(e)$.

An H-approximate *MST* τ for a graph (G, ω) is a spanning tree of weight that is at most H times greater than the weight of the *MST* of the graph (G, ω). A protocol Π is said to be an *H-approximation* for the *MST* problem if for every input graph (G, ω) it outputs an H-approximate *MST* τ.

In a *distributed* exact (resp., H-approximate) *MST* problem, at the beginning of computation each vertex v knows its own identity number, the identity numbers of all its neighbors, and the weights of the edges adjacent to v. Let E_v denote the set of these edges. A correct protocol Π must guarantee that at the end of computation every vertex v will know which edges of E_v end up belonging to the computed exact (resp., H-approximate) *MST*. Formally, the output sets K_v of different vertices v should satisfy (1) that for every $v \in V$, $K_v \subseteq E_v$; (2) $\bigcup_{v \in V} K_v = T$, where T is the exact (resp., H-approximate) *MST* tree; and (3) for every edge $e = (v, w) \in E$, either ($e \in K_v$ and $e \in K_w$) or ($e \notin K_v$ and $e \notin K_w$).

Our lower bounds apply to *randomized* protocols with bounded worst-case running time. In other words, these protocols necessarily terminate within specified time bounds, but they are allowed to err with some constant probability $0 \leq q < 1/2$. Two possible types of error are allowed. First, a protocol may produce a subgraph of the input graph (G, ω) that is not an H-approximate *MST* of (G, ω). This subgraph may contain cycles or multiple connectivity components. Second, the protocol may return $\perp$, indicating that it failed to compute the correct answer.

For a pair of vertices $u, w \in V$, we denote by $dist_G(u, w)$ the *unweighted* distance between u and w in the graph $G = (V, E)$.

3. A lower bound on the time-approximation trade-off. In this section we show a lower bound on the trade-off between the possible approximation ratio for the *MST* problem and the running time of a distributed protocol that may achieve this approximation ratio.

3.1. Preliminaries, overview, and discussion. We start with describing the family of graphs that will be used in the proof of our lower bounds. For a sufficiently large positive integer n, let Γ, m, and p be positive integer parameters that satisfy $p \leq \log n$ and $(m+1)\Gamma + \frac{(m+1)^{1+1/p}-1}{(m+1)^{1/p}-1} = n$. Note that $n = \Theta(\Gamma \cdot m)$. Let $d = (m+1)^{1/p}$ (assume that d is integer; nonintegrality issues affect only lower-order terms of our results, and are, therefore, ignored).

Consider a family $\mathcal{G}$ of graphs that contains one unweighted n-vertex graph $G_n = (V_n, E_n)$ for infinitely many positive integers n. The vertex set V_n is comprised of Γ vertex-disjoint paths $P_1, P_2, \ldots, P_\Gamma$ with $m+1$ vertices each, and a d-regular tree τ of depth p with its own vertex set $V(\tau)$ (that is disjoint from $\bigcup_{i=1}^{\Gamma} V(P_i)$). Observe that $|V(\tau)| = 1 + d + \cdots + d^p = \frac{d^{p+1}-1}{d-1} = \frac{(m+1)^{1+1/p}-1}{(m+1)^{1/p}-1}$. Let rt denote the root of τ, i.e., the only vertex that had degree d in τ; all the other vertices have either d children and a parent, or they have only a parent. The latter vertices are called *leaves* of τ. Let $s = z_0, z_1, \ldots, z_m = r$ denote the leaves of τ. The edge set of the graph G_n consists of the edge set $E(\tau)$ of the tree τ, the edge set $\bigcup_{j=1}^{\Gamma} E(P_j)$ of the Γ paths $P_1, P_2, \ldots, P_\Gamma$, and $m+1$ stars S_i, $i \in \{0, 1, \ldots, m\}$. Let $P_j = (v_j^{(0)}, v_j^{(1)}, \ldots, v_j^{(m)})$, $j \in \{1, 2, \ldots, \Gamma\}$, denote the vertices of the path P_j, $j \in \{1, 2, \ldots, \Gamma\}$. Then the edge set of the star S_i, for $i \in \{0, 1, \ldots, m\}$, is the set $\{(z_i, v_j^{(i)}) \mid j \in \{1, 2, \ldots, \Gamma\}\}$. (See Figure 3.1.)

A family $\mathcal{G}^\omega$ of *weighted* graphs contains 2^Γ n-vertex graphs for each n such that $G_n \in \mathcal{G}$. Each of these 2^Γ graphs has the vertex set V_n and the edge set E_n, but the weights of edges are different for at least one edge in any two distinct graphs of $\mathcal{G}^\omega$. The edges of the paths $P_1, P_2, \ldots, P_\Gamma$, as well as the edges of the tree τ, are all of weight zero in all the 2^Γ graphs. The edges of the stars S_i for $i \in \{1, 2, \ldots, m-1\}$ are all of weight infinity in all the 2^Γ graphs. All the edges of the star S_m have unit weight in all the 2^Γ graphs. Each of the Γ edges of the star S_0 may have weight zero or infinity. This induces 2^Γ different n-vertex graphs in $\mathcal{G}^\omega$.

The family $\mathcal{G}$ of unweighted graphs generalizes the family (that we refer to as $\mathcal{G}''$) of unweighted graphs that was used in [28] to prove a lower bound of $\Omega(n^{1/3}/B)$ on the number of rounds that are required for a distributed protocol to compute exact *MST* on graphs of diameter 4. However, the choice of weights above is inherently different from the one used in [28], and this difference will be discussed below.

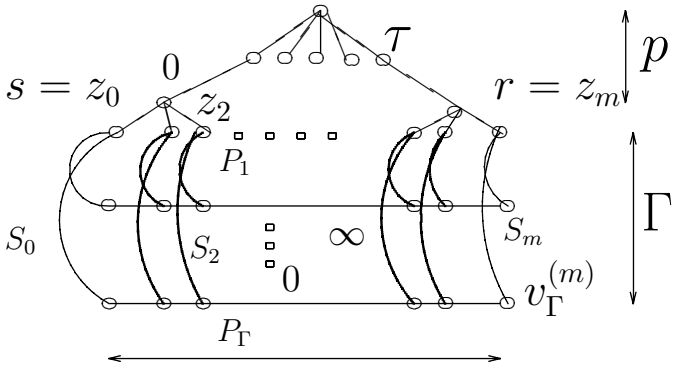

FIG. 3.1. *The family $\mathcal{G}$. The edges of the tree τ and of the paths $P_1, \ldots, P_\Gamma$ have weight zero. The edges of the "internal" stars $S_1, \ldots, S_{m-1}$ have infinite weights. The edges of the rightmost star S_m have unit weights, and the edges of the leftmost star S_0 have weights zero or one, depending on the particular graph.*

Consider the *MST* problem restricted to the family $\mathcal{G}^\omega$ of graphs. We will show that for any $1 \leq H = o(n/B)$, *any* distributed protocol that, given a graph $G \in \mathcal{G}^\omega$ constructs an H-approximate *MST* for G, requires $\Omega((\frac{n}{p \cdot B \cdot H})^{\frac{1}{2} - \frac{1}{2(2p+1)}})$ rounds.

This proof is done by a reduction from a problem of distributed delivery of information throughout the graphs of family $\mathcal{G}$. The problem, referred by us as the CORRUPTEDMAIL problem, generalizes the mailing problem of [32, 28] in two senses. First, the family $\mathcal{G}$ of graphs is somewhat more general than the corresponding families $\mathcal{G}'$ and $\mathcal{G}''$ in [32, 28], and this enables us to get lower bounds that are parameterized on the diameter. Second, the mailing problem of [32, 28] requires exact delivery of all the input bits, whereas our CORRUPTEDMAIL problem allows the protocol to make a restricted number of *one-sided errors* (i.e., some zero input bits might be delivered as ones, but not vice versa). This modification is geared toward capturing the situation when the (oracle) protocol for the *MST* problem (its existence is assumed by the reduction) does not compute the exact *MST*, as it is assumed in [32, 28], but rather provides the reduction to some (possibly very loose) approximation of it.

For a bit string $\chi \in \{0,1\}^\Gamma$ and an index $j \in \{1, 2, \ldots, \Gamma\}$, let χ_j denote the jth bit of χ. The *Hamming weight* of χ, denoted $||\chi||$, is the number of indices $j \in \{1, 2, \ldots, \Gamma\}$ such that $\chi_j = 1$. For two bit strings $\chi, \chi' \in \{0,1\}^\Gamma$, the string χ' is said to *dominate* χ if for each $j \in \{1, 2, \ldots, \Gamma\}$, $\chi_j = 1$ implies $\chi'_j = 1$. Consider some mapping $\phi : \{0,1\}^\Gamma \to \{0,1\}^\Gamma$, and suppose $\phi(\chi) = \chi'$. The mapping ϕ is said to make an error of the *first* (resp., *second*) *type* in the jth position if $\chi_j = 0$ and $\chi'_j = 1$ (resp., $\chi_j = 1$ and $\chi'_j = 0$).

Let α and β, $0 < \alpha < \beta < 1$, be two additional parameters of the construction that will be fixed later. The CORRUPTEDMAIL(α, β) problem is defined on unweighted graphs $G_n \in \mathcal{G}$. Recall that for each graph $G \in \mathcal{G}$, there are two designated vertices s and r, $s, r \in V_n$. The input to this problem is a bit string $\chi \in \{0,1\}^\Gamma$ of length Γ with Hamming weight $||\chi|| = \alpha\Gamma$. The input is provided to the vertex s only. The output, returned by the vertex r, is a string $\chi' \in \{0,1\}^\Gamma$ of Hamming weight at most $\beta\Gamma$, and it is required that the output string χ' dominate the input string χ. As the parameters α and β are fixed throughout this and the next sections, we will refer to the CORRUPTEDMAIL(α, β) problem as the CORRUPTEDMAIL problem.

Observe, however, that the restriction that χ' should dominate χ guarantees that the errors that are done throughout the delivery of the bit string χ are *one-sided* (i.e., all the errors are of the first type). This is in contrast to the usual setting of error-correcting codes, where a two-sided error is allowed. One of the crucial properties required for a reduction from the CorruptedMail problem to the approximate *MST* problem to work is that approximating the *MST* with sufficiently small factor causes only one-sided errors in the delivery of the bit string χ. In our reduction, the latter is ensured by an appropriate choice of the weights of the edges in $\mathcal{G}^{\omega}$. This is the essential difference between our choice of weights of edges for $\mathcal{G}^{\omega}$ and the choices of weights of edges in analogous families of graphs in [32] and [28].

We remark that allowing a symmetric two-sided error in the CorruptedMail problem, and using error-correcting codes (possibly with list-decoding) directly would also lead to a proof of hardness of distributed approximation of the *MST* problem within some small constant factor (smaller than 2, to the best of our knowledge). The bottleneck in this case is the fact that corrupting a bit string χ that has Hamming weight $\alpha\Gamma$ in at least $\alpha\Gamma$ arbitrary positions in an arbitrary way may make the string almost indistinguishable from a string that is drawn out of the uniform distribution over all the strings of Hamming weight at most $2\alpha\Gamma$, even from an information-theoretic point of view. However, this is not the case when only a one-sided error is allowed. Then, as we will show, one can allow $(\beta-\alpha)\Gamma$ corrupted positions for $1 > \beta \gg \alpha > 0$, and still the corrupted string χ' will carry on a significant amount of information (roughly, $\Gamma \cdot \alpha \cdot \log(1/\beta)$ bits for sufficiently small positive $\alpha > 0$; note that the amount of information carried by χ is $\Gamma \cdot \mathit{Entropy}(\alpha) = \Gamma \cdot (\alpha \log(1/\alpha) + (1-\alpha)\log(1/(1-\alpha)))$). This way, we are able to prove hardness of distributed approximation of the *MST* problem within a factor of, roughly, $1/\alpha$, for an arbitrarily small $\alpha > 0$.

As we mentioned, to ensure a one-sided error of the reduction, an appropriate setting of the weights of edges of graphs in $\mathcal{G}^{\omega}$ is required. The setting that we described has, however, the drawback of a very high ratio, denoted ω_{max}, between the largest weight of an edge and the smallest one. Specifically, this ratio is $\Theta(n^2)$. If one wants to prove a similar lower bound for instances of the *MST* problem with smaller ω_{max} ratios, it is no longer possible to guarantee a one-sided error in the delivery of the bit string χ in the reduction. Nevertheless, as we will show in section 5, controlling the ratio between n^2 and ω_{max} also controls the number of errors of the second type. In this case we get into a situation when the delivery may suffer an *asymmetric two-sided error*, with a huge possible number of errors of the first type (specifically, $(\beta-\alpha)\Gamma$ for some $1 > \beta \gg \alpha > 0$) and a reasonably small number of errors of the second type (specifically, some constant fraction of $\alpha\Gamma$). We will show that this way one can achieve the same lower bound on time-approximation trade-off as in the case that $\omega_{max} = \Theta(n^2)$ (that is, $T^2 \cdot H = \Omega(n/B)$), but with $\omega_{max} = \sqrt{n} \cdot H^{3/2}$, which is significantly smaller than n^2 for $H(n) = o(n)$. We remark that one cannot expect to achieve such a trade-off with $\omega_{max} = o(\frac{\sqrt{nH/B}}{\log^* n})$. This is because, as we will show in section 6, one can approximate the *MST* on an n-vertex graph G within a ratio of $O(\omega_{max}/T')$ in $O(T' \log^* n + \Lambda(G))$ rounds. For $\omega_{max} = o(\frac{\sqrt{nH/B}}{\log^* n})$, the approximation ratio is $H = O(\omega_{max}/T') = o(\frac{\sqrt{nH/B}}{T' \log^* n})$. The number of rounds is $T = T' \log^* n = o(\sqrt{nH/B})$, i.e., $T^2 H = o(\sqrt{n/B})$, contradicting our lower bound.

3.2. A lower bound for the CorruptedMail problem. In this section we prove a lower bound on the time complexity of the CorruptedMail problem.

For $0 < \alpha < \beta < 1$, let

$$l(\alpha,\beta) = (\beta-\alpha)\log(\beta-\alpha) - (1-\alpha)\log(1-\alpha) - \beta\log\beta\ . \tag{1}$$

Lemma 3.1. *For any α, β, $0 < \alpha < \beta < 1$,*

$$l(\alpha,\beta) \geq \alpha \cdot \log(1/\beta). \tag{2}$$

Proof. Let $f(\alpha,\beta) = l(\alpha,\beta) + \alpha \cdot \log\beta$. It is easy to verify that for a fixed β, $0 < \beta < 1$, it holds that $f(0,\beta) = 0$. Also,

$$\frac{\partial f}{\partial\alpha}(\alpha,\beta) \ = \ \frac{\partial l}{\partial\alpha}(\alpha,\beta) + \log\beta \ = \ \log\left(\frac{\beta-\beta\alpha}{\beta-\alpha}\right) \ > \ 0$$

for any α, β in the range $0 < \alpha < \beta < 1$, and $\frac{\partial f}{\partial\alpha}(0,\beta) = 0$ for any β, $0 < \beta < 1$. Hence,

$$f(\alpha,\beta) = f(0,\beta) + \int_0^\alpha \frac{\partial f}{\partial\alpha}(x,\beta)dx \ \geq \ 0$$

for any α, β in the same range. □

In the following lemma the Ω-notation hides a universal constant.

Lemma 3.2. *For any deterministic protocol Π for the* CorruptedMail(α,β) *problem, its set of all possible outputs $\{\Pi(\chi) \mid \chi \in \{0,1\}^\Gamma, ||\chi|| = \alpha\Gamma\}$ contains at least $\Omega(2^{l(\alpha,\beta)\Gamma})$ elements.*

Proof. Let $\mathcal{A} = \{\chi \in \{0,1\}^\Gamma \mid ||\chi|| = \alpha\cdot\Gamma\}$ be the set of all possible bit strings that may serve as input for the vertex s. Let $\Upsilon = \{\chi' \in \{0,1\}^\Gamma \mid ||\chi'|| \leq \beta\cdot\Gamma\}$ be the set of all possible bit strings that may be returned by the vertex r. Consider the bipartite graph $(\mathcal{A}, \Upsilon, E(\mathcal{A},\Upsilon))$ with $\mathcal{A}$ serving as the set of the left-hand vertices, Υ serving as the set of the right-hand vertices, and $E(\mathcal{A},\Upsilon) = \{(\chi,\chi') \mid \chi \in \mathcal{A}, \chi' \in \Upsilon \text{ s.t. } \chi' \text{ dominates } \chi\}$. Observe that $|\mathcal{A}| = \binom{\Gamma}{\alpha\Gamma} = \frac{\Gamma!}{(\alpha\Gamma)!((1-\alpha)\Gamma)!}$. Consider some bit string $\chi' \in \Upsilon$. The number of the bit strings $\chi \in \mathcal{A}$ that are dominated by χ' is at most $D = \binom{\beta\Gamma}{\alpha\Gamma} = \frac{(\beta\Gamma)!}{((\beta-\alpha)\Gamma)!(\alpha\Gamma)!}$.

A subset $\Upsilon' \subseteq \Upsilon$ is said to *dominate* the set $\mathcal{A}$ if for each bit string $\chi \in \mathcal{A}$ there exists a bit string $\chi' \in \Upsilon'$ that dominates χ. As each bit string $\chi' \in \Upsilon$ may dominate at most D bit strings of $\mathcal{A}$, it follows that any subset $\Upsilon' \subseteq \Upsilon$ that dominates $\mathcal{A}$ has cardinality at least

$$|\Upsilon'| \geq \frac{|\mathcal{A}|}{D} = \frac{\Gamma!((\beta-\alpha)\Gamma)!}{((1-\alpha)\Gamma)!(\beta\Gamma)!}\ .$$

Using the Stirling formula to approximate the factorials, we get

$$|\Upsilon'| \ \geq \ \left(\frac{(\beta-\alpha)^{\beta-\alpha}}{(1-\alpha)^{1-\alpha}\beta^\beta}\right)^\Gamma \cdot \sqrt{\frac{\beta-\alpha}{(1-\alpha)\beta}} \cdot (1-o(1))\ .$$

For β and α such that $\beta - \alpha > 0$ is at least some constant, it follows that $|\Upsilon'| = \Omega\big(\big(\frac{(\beta-\alpha)^{\beta-\alpha}}{(1-\alpha)^{1-\alpha}\beta^\beta}\big)^\Gamma\big)$.

Let $h(\alpha,\beta) = \frac{(\beta-\alpha)^{\beta-\alpha}}{(1-\alpha)^{1-\alpha}\beta^{\beta}}$, and note that $l(\alpha,\beta) = \log h(\alpha,\beta)$. It follows that $|\Upsilon'| = \Omega(2^{l(\alpha,\beta)\Gamma})$ for any subset $\Upsilon' \subseteq \Upsilon$ of bit strings that dominate $\mathcal{A}$. □

We next show that for any protocol Π with worst-case running time at most t for t in a certain range, its set of possible outputs (over all possible inputs) is at most exponential in t. To argue this we use the determinism of the protocol and the fact that the vertex r that returns the output could not get "too much" information about the input. It will follow that the running time t of a protocol Π cannot be too small, unless the protocol Π is incorrect. To prove an upper bound on the size of the set of possible outputs of any correct protocol, we show that the set of all possible *configurations* of the vertex r is relatively small as a function of t.

For some fixed sufficiently large n, consider again a graph $G = (V,E) = G_n \in \mathcal{G}$ that was described in section 3.1. Intuitively, we next argue that information can be delivered through G_n from s to r in a quite slow rate. A similar statement was proved in [32, 28] regarding somewhat different families of graphs $\mathcal{G}'$ and $\mathcal{G}''$.

Our proof has a similar structure to that of [32], but as the structure of the family $\mathcal{G}$ is somewhat more complicated than that of $\mathcal{G}'$ or $\mathcal{G}''$, the proof requires a more delicate argument. Basically, all three proofs (due to [32, 28] and this paper) construct a sequence of low-capacity cuts and argue that each bit has to cross all these cuts. As the cuts have low capacities, no cut can be crossed by "many" bits simultaneously, implying a lower bound on the number of rounds of distributed computation. However, while the choice of the cuts and the proof that they have low capacity are rather straightforward in [32, 28], it is somewhat more involved in our case.

We first need a few definitions. For a rooted tree (τ', rt'), let the *ancestor-descendent* (resp., *parent-child*) relation, denoted $AD(\tau', rt')$ (resp., $PC(\tau', rt')$), be the set of pairs of distinct vertices $(u,w) \in V(\tau') \times V(\tau')$ such that the vertex u is an ancestor (resp., parent) of the vertex w in the tree (τ', rt'). For a vertex $u \in V(\tau')$, let $par_{(\tau',rt')}(u)$ denote the *parent* of u in the rooted tree (τ', rt').

Recall that the graph $G = G_n$ contains as a subgraph the d-regular rooted tree (τ, rt) of height p, with $m+1$ leaves $s = z_0, z_1, \ldots, z_m = r$. For $i \in \{0,1,2,\ldots,m\}$, let $\tau(i)$ denote the connected subtree of τ with minimal number of vertices, such that its set of leaves, $Leaves(\tau(i))$, is equal to $\{z_i, z_{i+1}, \ldots, z_m\}$. Let the *root* of $\tau(i)$, denoted $rt(\tau(i))$, be the closest vertex of $\tau(i)$ to the root rt of the tree τ.

Observe that for a pair of vertices $x, y \in V(\tau(i))$ such that x is an ancestor of y in the rooted tree (τ, rt), x is an ancestor of y in the rooted tree $(\tau(i), rt(\tau(i)))$ as well; i.e., $(x,y) \in AD(\tau, rt)$ and $x, y \in V(\tau(i))$ imply that $(x,y) \in AD(\tau(i), rt(\tau(i)))$. Also, $AD(\tau(i), rt(\tau(i))) \subseteq AD(\tau, rt)$ for each $i \in \{0,1,\ldots,m\}$. Note that both statements are true for the parent-child relation PC as well.

Let Cut_i denote the subset of edges of $E(\tau)$ that are in the cut between $V(\tau(i))$ and the rest of $V(\tau)$ for $i \in \{1,2,\ldots,m\}$. We next argue that the size of this cut is never greater than $p \cdot d$.

LEMMA 3.3. *For $i \in \{1,2,\ldots,m\}$, $|Cut_i| \leq p \cdot d$.*

Proof. Fix an index $i \in \{1,2,\ldots,m\}$. Let $L_j = \{(u,w) \in Cut_i \cap AD(\tau, rt) \mid dist_\tau(rt,u) = j\}$, for $j \in \{0,1,\ldots,p-1\}$, be the *jth layer* of the edge set Cut_i. Note that $Cut_i = \bigcup_{j=0}^{p-1} L_j$. It remains to argue that $|L_j| \leq d$ for $j \in \{0,1,\ldots,p-1\}$.

To this end, we will show that for any pair of edges $e_1 = (u_1, w_1), e_2 = (u_2, w_2) \in L_j$ (assume, without loss of generality, that $u_1 = par_{(\tau,rt)}(w_1)$ and $u_2 = par_{(\tau,rt)}(w_2)$), u_1 is equal to u_2. It will follow that all the edges of L_j share a common endpoint, and, furthermore, this endpoint is a parent of all the other endpoints of these edges. As every vertex has at most d children in the tree τ, this would imply $|L_j| \leq d$.

Consider a pair of edges e_1, e_2 as above. First, suppose $u_1 \notin V(\tau(i))$, $w_1 \in V(\tau(i))$. As the parent-child relation in $\tau(i)$ is a subset of the parent-child relation in τ, it follows that $w_1 = rt(\tau(i))$. In this case it is easy to see that (u_1, w_1) is the only edge in L_j, and consequently, $e_1 = e_2$, and $|L_j| = 1$.

It remains to consider the case when $u_1, u_2 \in V(\tau(i))$ and $w_1, w_2 \in V(\tau) \setminus V(\tau(i))$. However, in this case $u_1 \neq u_2$ and $u_1, u_2 \in V(\tau(i))$ imply that either all the descendents of u_1 or all the descendents of u_2 belong to $V(\tau(i))$, and both of them contradict $w_1, w_2 \in V(\tau) \setminus V(\tau(i))$. □

We define the *tail* sets, $T_0, T_1, \ldots, T_m$ as follows. The tail set T_0 contains the entire vertex set V of G except the vertex s, i.e., $T_0 = V \setminus \{s\}$. For $i \in \{1, 2, \ldots, m\}$, $T_i = \{v_j^{(i')} \mid j \in \{1, 2, \ldots, \Gamma\}, i' \in \{i, i+1, \ldots, m\}\} \cup V(\tau(i))$. It will be more convenient to view the vertex sets T_i as sequences of vertices. The order of the vertices in these sequences can be arbitrary, and for simplicity we will assume that the vertices are ordered as a monotone increasing sequence of their (distinct) identity numbers.

Consider some protocol Π for the CorruptedMail problem, and consider an execution φ_χ of this protocol on some input bit string χ. Let the *state* of the vertex v at the beginning of round t during the execution φ_χ of the protocol Π, denoted $\sigma(v, t, \chi)$, be the $deg(v)$-tuple of sequences of messages that the vertex v received on its incoming links. For the vertex s, the state of s also includes the input string χ. Other vertices receive no input in the CorruptedMail problem.

For some subset $U = (u_1, u_2, \ldots, u_\ell) \subseteq V$ of vertices, let the *configuration* of U in the execution φ_χ at the beginning of round t, denoted $C(U, t, \chi)$, be the sequence of states $(\sigma(u_1, t, \chi), \sigma(u_2, t, \chi), \ldots, \sigma(u_\ell, t, \chi))$. Let $\mathcal{C}(U, t)$ denote the collection of all possible configurations of the subset U at the beginning of round t over all possible executions φ_χ (i.e., for all possible legal input bit strings χ; given a bit string, the execution φ_χ is fixed). Let $\rho(U, t)$ denote the cardinality of $\mathcal{C}(U, t)$. We remark that our proof does not attempt to analyze the actual sets of configurations, but rather only the cardinalities of those sets.

In what follows let us assume that the rounds are indexed starting from 0 and not from 1. Obviously, this may affect the lower bounds by at most an additive term of 1. At the beginning of round $t = 0$, i.e., at the beginning of the execution of the protocol, all the vertices except s are in some fixed initial state, that is, independent of the input bit string χ. Hence, $\rho(T_0, 0) = \rho(V \setminus \{s\}, 0) = 1$. We next prove an upper bound on the number of configurations of the tail set T_t after a relatively small number of rounds $t \leq m - 1$.

Lemma 3.4. *For $t \in \{0, 1, \ldots, m-1\}$, $\rho(T_t, t) \leq (2^{B+1} - 1)^{t \cdot p \cdot d}$.*

Remark. To provide some intuition for the proof of Lemma 3.4, we illustrate its central idea on a simple example. Consider a path $P = (v_0, v_1, \ldots, v_n)$ with the vertex v_0 serving as a sender, and v_n serving as a receiver, that is, $s = v_0$, $r = v_n$. Also, let $T_i = \{v_{i+1}, v_{i+2}, \ldots, v_n\}$ be the tail sets, for $i \in \{0, 1, \ldots, n-1\}$.

Suppose we are given a configuration C of the vertices of T_i at the beginning of round i. This configuration uniquely determines the messages sent on round i by the vertices of T_i, and, in particular, by the vertex v_{i+1}. Hence, the unique configuration of T_0 at the beginning of round 0 (note that $T_0 = V \setminus \{s\}$, and s is the only vertex that receives input) determines the unique configuration of T_1 at the beginning of round 1. This is because the only link that connects T_1 to $V \setminus T_1$ is the edge (v_1, v_2), but the message sent by the vertex v_1 over this link on round 0 is determined by the

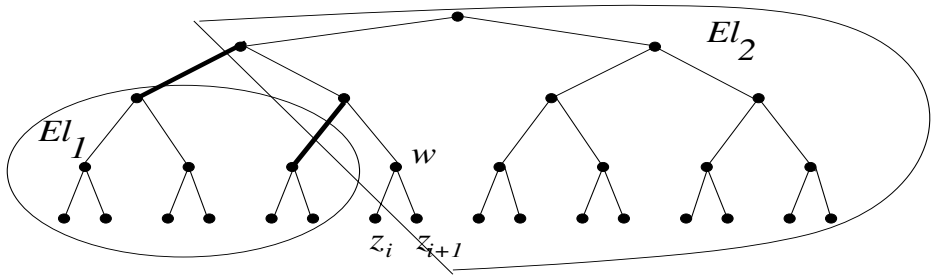

FIG. 3.2. *The sets $V(\tau) \setminus V(\tau(i))$ and $V(\tau(i+1))$ are depicted by ellipses El_1 and El_2, respectively. Edges of $E_{i,i+1}$ are depicted by thick solid lines. Note that, somewhat surprisingly, the edge (z_i, w) does not belong to $E_{i,i+1}$ because $z_i \in V(\tau(i))$.*

configuration of T_0 at the beginning of round 0, and this configuration is independent of the bit string χ that the sender s accepts as input.

Applying this consideration inductively we conclude that the configuration of the tail set $T_{n-1} = \{r\} = \{v_n\}$ at the beginning of round $n-1$ is uniquely determined by the initial configuration of the vertices of the set $T_0 = V \setminus \{s\}$ and is independent of the input string χ.

For a more elaborate example consider the graph $H = P \cup S$, where P is the n-vertex path that we have just discussed, and $S = \{(v_0, v_i) \mid i \in \{2, 3, \ldots, n\}\}$ is the star rooted at v_0. The tail sets are left unchanged.

In this graph the unique configuration of the vertices of T_0 at the beginning of round 0 branches into roughly $2^{B(n-2)}$ possible configurations of the vertices of T_1 at the beginning of round 1, because the vertices of T_1 could receive up to $B(n-2)$ different bits from the vertex v_0 on this round, and each distinct combination of these bits may determine a new configuration of the vertices of T_1. Repeating this argument we derive that there are roughly $2^{B(n-2)} \cdot 2^{B(n-3)}$ possible configurations of T_2 at the beginning of round 2, and, ultimately, at most $2^{O(B \cdot n^2)}$ possible configurations of the tail set $T_{n-1} = \{r\}$ at the beginning of round $n-1$. In other words, intuitively, at most $O(Bn^2)$ bits could have been delivered through this network in $n-1$ rounds.

Proof. The proof is by induction on t. The induction base was argued above. We next prove the induction step. Observe that $T_0 \supseteq T_1 \supseteq \cdots \supseteq T_m$. Suppose we are given a configuration $C \in \mathcal{C}(T_i, i)$. Note that C uniquely determines the messages that are sent at round i by vertices of T_i. Therefore, the only messages that are not yet determined are those that are sent by the vertices of $V \setminus T_i$ to the vertices of T_{i+1}. Denote this set of edges by $E_{i,i+1}$. Observe that the edges of the paths $P_1, P_2, \ldots, P_\Gamma$ do not belong to $\bigcup_{i=0}^{m-1} E_{i,i+1}$. It follows that $E_{i,i+1} \subseteq E(\tau)$ for $i \in \{0, 1, \ldots, m-1\}$. For $i = 0$, clearly, $E_{0,1} = \{(z_0, par_{(\tau,rt)}(z_0))\}$. More generally, $E_{i,i+1}$ is a subset of edges of $E(\tau)$ that are incident both to $V(\tau(i+1))$ and to $V \setminus V(\tau(i))$, $i \in \{0, 1, \ldots, m-1\}$. See Figure 3.2 for an illustration.

Note that $E_{i,i+1} \subseteq Cut_{i+1}$ for $i \in \{0, 1, \ldots, m-1\}$. Hence, by Lemma 3.3, $|E_{i,i+1}| \leq p \cdot d$ for $i \in \{0, 1, \ldots, m-1\}$. In other words for $i \in \{0, 1, \ldots, m-1\}$, there are at most $p \cdot d$ edges that are incident to the tail set T_{i+1}, such that given a configuration C in $\mathcal{C}(T_i, i)$ of the vertices of T_i at the beginning of round i, the messages that are sent over these edges at round i are not determined by this configuration.

Recall that at most B bits can be delivered through an edge in each round. Therefore, the number of possible messages that may be sent through an edge in a

given direction in one round is at most $\sum_{\ell=0}^{B} 2^\ell = 2^{B+1} - 1$. (In this summation, the case $\ell = 0$ reflects the possibility of transmitting nothing through a certain edge on a certain round.)

Observe that there is only one relevant direction of sending messages in our case, that is, towards the vertices of the tail set T_{i+1}. Hence, the number of possible messages that may be sent through at most $p \cdot d$ edges in one round is at most $(2^{B+1}-1)^{p \cdot d}$. It follows that for $i \in \{0, 1, \ldots, m-1\}$, $\rho(T_{i+1}, i+1) \leq (2^{B+1}-1)^{p \cdot d} \cdot \rho(T_i, i)$. Along with $\rho(T_0, 0) = 1$, this implies the statement of the lemma. □

Note that the proof argument that counts the number of configurations holds when each vertex knows its unique identity number at the beginning of computation.

In the following lemma and its proof, the asymptotic Ω- and O-notations hide universal constants.

LEMMA 3.5. *The deterministic complexity of the* CORRUPTEDMAIL *problem is* $\Omega(\min\{m, \frac{\Gamma}{p \cdot B \cdot m^{1/p}} \cdot \alpha \cdot \log(\frac{1}{\beta})\})$.

Proof. Consider a protocol Π for the CORRUPTEDMAIL problem, and let t denote its worst-case running time on inputs of fixed size Γ. By Lemma 3.4, it follows that if $t \leq m-1$, then $\rho(T_t, t) \leq (2^{B+1}-1)^{t \cdot p \cdot d}$. On the other hand, observe that the number of possible configurations of the vertex r upon the termination of the protocol Π is at least the cardinality of some subset $\Upsilon' \subseteq \Upsilon$ of a subset of bit strings that dominates $\mathcal{A}$. By Lemma 3.2, $|\Upsilon'| = \Omega(2^{l(\alpha,\beta)\Gamma})$. It follows that the (worst-case) running time t of the protocol Π for the CORRUPTEDMAIL problem is either at least $t \geq m$ rounds, or it satisfies the following inequality

$$\Omega(2^{l(\alpha,\beta)\Gamma}) = |\Upsilon'| \leq \rho(\{r\}, t) \leq \rho(T_t, t) \leq (2^{B+1}-1)^{t \cdot p \cdot d} \ . \tag{3}$$

(The inequality $\rho(\{r\}, t) \leq \rho(T_t, t)$ follows from the fact that $r \in T_t$ for $t \in \{0, 1, \ldots, m\}$.) Hence, $\Omega(l(\alpha,\beta)\Gamma) - O(1) \leq t \cdot p \cdot d \cdot B$; i.e., $t = \Omega(l(\alpha,\beta) \cdot \Gamma/(p \cdot d \cdot B))$. In other words, in both cases $t = \Omega(\min\{m, (l(\alpha,\beta) \cdot \Gamma)/(p \cdot d \cdot B)\})$. Recall that $n = O(\Gamma m)$ and $d = (m+1)^{1/p}$. Hence,

$$t = \Omega\left(\min\left\{m, l(\alpha,\beta)\frac{n}{p \cdot m^{1+1/p} \cdot B}\right\}\right). \tag{4}$$

By Lemma 3.1, for $\alpha > 0$ it holds that $l(\alpha,\beta) \geq \alpha \cdot \log(1/\beta)$. Set β to be a constant between 0 and 1, and the lemma follows. □

Finally, set $m = \left(\frac{n \cdot \alpha}{p \cdot B}\right)^{\frac{1}{2} - \frac{1}{2(2p+1)}}$. It follows that

$$t = \Omega\left(\left(\frac{n \cdot \alpha}{p \cdot B}\right)^{\frac{1}{2} - \frac{1}{2(2p+1)}}\right). \tag{5}$$

It follows that any deterministic protocol Π that solves the CORRUPTEDMAIL problem on *every* input bit string χ requires $\Omega\left(\left(\frac{n \cdot \alpha}{p \cdot B}\right)^{\frac{1}{2} - \frac{1}{2(2p+1)}}\right)$ rounds in the worst case.

Henceforth, the term "randomized protocol" will be used as a shortcut for "randomized protocol that succeeds with at least some constant probability on every input."

LEMMA 3.6. *Any randomized protocol* Π *for the* CORRUPTEDMAIL *problem requires* $\Omega\left(\left(\frac{n \cdot \alpha}{p \cdot B}\right)^{\frac{1}{2} - \frac{1}{2(2p+1)}}\right)$ *rounds.*

Proof. Consider a deterministic protocol Π' that accepts as input a string drawn at random from the uniform distribution over the bit strings χ of Hamming weight

$\alpha\Gamma$. For such a protocol to succeed with at least a constant probability q in $t \leq m-1$ rounds, the number of configurations of the vertex r at the end of the protocol has to be at least the size of a subset $\Upsilon'' \subseteq \Upsilon$ that dominates at least a fraction q of the set $\mathcal{A}$. However, by the same considerations as above, such a subset Υ'' must have cardinality at least $q|\mathcal{A}|/D$. In other words, for protocol Π', $\rho(T_t, t) \geq \rho(\{r\}, t) \geq q|\mathcal{A}|/D = \Omega(2^{l(\alpha,\beta)\Gamma})$. In other words, up to lower-order terms, the same lower bound (5) applies also to a protocol Π' as above. By Yao's minimax theorem [37], any randomized protocol that succeeds with probability at least q on *every* input of the CorruptedMail problem requires at least as many rounds as required by a deterministic protocol Π' that succeeds with the same probability on the uniform distribution of inputs. Hence, the lower bound (5) applies to randomized protocols as well. □

3.3. Reduction to the approximate *MST* problem. In this section we describe the reduction from the CorruptedMail(α, β) problem on the family $\mathcal{G}$ of unweighted graphs to the $\frac{\beta}{\alpha}$-approximate *MST* problem on the family $\mathcal{G}^\omega$ of weighted graphs (see the beginning of section 3 for the definition of this family).

The protocol Π_{Corr} for the CorruptedMail(α, β) problem proceeds in the following way. Given an instance (G, χ), $G \in \mathcal{G}$, $\chi \in \mathcal{A}$, of the CorruptedMail problem, the vertex s computes the weights of edges $(s, v_j^{(0)})$, $j \in \{1, 2, \ldots, \Gamma\}$, in the following way. If $\chi_j = 0$, then the weight of the edge $(s, v_j^{(0)})$ is set to zero; otherwise it is set to infinity. All the other weights of edges are set by their endpoints to the values that are determined by the definition of the family $\mathcal{G}^\omega$. (Recall that there is no freedom in setting other weights, and the only difference between two distinct n-vertex graphs from $\mathcal{G}^\omega$ is the setting of the weights of the edges of the star S_0.) This setting of weights is performed locally by every vertex and requires no distributed computation.

Next, the vertices invoke a $\frac{\beta}{\alpha}$-approximation protocol Π for the obtained instance $G(\chi)$ of the *MST* problem. Upon the termination of the protocol, each vertex v knows which edges among the edges that are incident to v belong to the approximate *MST* tree τ_0 for $G(\chi)$ that was constructed by the protocol. The vertex r calculates the output bit string $\chi' \in \{0,1\}^\Gamma$ in the following way. For each index $j \in \{1, 2, \ldots, \Gamma\}$, if the edge $(r, v_j^{(m)})$ belongs to the tree τ_0, the vertex r sets $\chi'_j = 1$. Otherwise, it sets $\chi'_j = 0$. Finally, the vertex r returns the bit string χ'.

Observe that whenever the construction of the approximate *MST* tree τ_0 is completed, the computation of the bit string χ' is performed locally by the vertex r and requires no distributed computation. It follows that the running time of the obtained protocol Π_{Corr} for the CorruptedMail(α, β) problem is precisely equal to the running time of the $\frac{\beta}{\alpha}$-approximation protocol Π for the *MST* problem.

We next argue that the reduction is correct, i.e., that the protocol Π_{Corr} solves correctly the CorruptedMail(α, β) problem, assuming that the protocol Π is a $\frac{\beta}{\alpha}$-approximation protocol for the *MST* problem.

Lemma 3.7. *For each $\chi \in \mathcal{A}$, if τ_0 is a $\frac{\beta}{\alpha}$-approximate MST for the graph $G(\chi)$, then the bit string χ' that is returned by the protocol Π_{Corr} has Hamming weight at most $\beta \cdot \Gamma$, and, furthermore, the bit string χ' dominates the input bit string χ.*

Proof. Consider a bit string $\chi \in \{0,1\}^\Gamma$ of Hamming weight $||\chi|| = \alpha\Gamma$. By construction, precisely $\alpha\Gamma$ edges of the star S_0 have weight ∞ in $G(\chi)$. Therefore, the exact *MST* contains all the edges of the paths $P_1, P_2, \ldots, P_\Gamma$ and of the tree τ, as all of them have weight zero, and it contains $(1-\alpha)\Gamma$ edges of weight zero that belong

to the star S_0. In addition, for each index $j \in \{1, 2, \ldots, \Gamma\}$ such that $\omega(s, v_j^{(0)}) = \infty$, it contains the edge $(r, v_j^{(m)})$. Recall that the latter edge has unit weight. Also, note that $\omega(s, v_j^{(0)}) = \infty$ implies that $\chi_j = 1$. As $||\chi|| = \alpha\Gamma$, it follows that exactly $\alpha\Gamma$ edges of the star S_0 have weight ∞. Hence, exactly $\alpha\Gamma$ edges of the star S_m belong to the *MST*, implying that its weight is $\alpha\Gamma$.

Consider a $\frac{\beta}{\alpha}$-approximate *MST* τ_0. By definition of approximate *MST*, its weight is at most $\beta\Gamma$. Hence, in particular, it contains at most $\beta\Gamma$ edges of the star S_m, implying that $||\chi'|| \leq \beta\Gamma$. Consider an index $j \in \{1, 2, \ldots, \Gamma\}$ such that $\chi_j = 1$. It follows that the weight of the edge $(s, v_j^{(0)})$ in $G(\chi)$ is ∞. As no edge with infinite weight may belong to τ_0 (as its weight is at most $\beta\Gamma$), it follows that neither $(s, v_j^{(0)})$ nor $(z_i, v_j^{(i)})$ for some $i \in \{1, 2, \ldots, m-1\}$ may belong to the tree τ_0. It follows that the edge $(r, v_j^{(m)})$ belongs to τ_0, as otherwise the vertex s would not be connected in τ_0 to the vertices of the path P_j. The latter would imply that τ_0 is not a spanning tree of the graph $G(\chi)$, contradicting the assumption that it is an approximate *MST* for $G(\chi)$. Hence, the edge $(r, v_j^{(m)})$ belongs to the tree τ_0. Hence, the bit χ'_j is set to 1 by the reduction. It follows that the output bit string χ' dominates the input bit string χ and that $||\chi'|| \leq \beta\Gamma$. □

Therefore, if Π is a $\frac{\beta}{\alpha}$-approximation protocol for *MST* on the family $\mathcal{G}^\omega$ of weighted graphs, then Π_{Corr} is a protocol for the CorruptedMail(α, β) problem on the family $\mathcal{G}$ of unweighted graphs, with the same running time. Recall that any (deterministic or randomized) protocol for the CorruptedMail(α, β) problem on the family $\mathcal{G}$ of graphs requires $t = \Omega\big(\big(\frac{n \cdot \alpha}{p \cdot B}\big)^{\frac{1}{2} - \frac{1}{2(2p+1)}}\big)$ rounds. Observe that all the graphs in the family $\mathcal{G}^\omega$ have the same unweighted diameter $2p+2$. The next theorem follows.

Theorem 3.8. *Any randomized H-approximation protocol for the MST problem on graphs of diameter at most Λ for $\Lambda \in \{4, 6, 8, \ldots\}$ requires $T = \Omega\big(\big(\frac{n}{H \cdot \Lambda \cdot B}\big)^{\frac{1}{2} - \frac{1}{2(\Lambda-1)}}\big)$ rounds of distributed computation; i.e., $T^{2 + \frac{2}{\Lambda-2}} \cdot H = \Omega\left(\frac{n}{\Lambda \cdot B}\right)$.*

In particular, for any $\epsilon > 0$, approximation of *MST* on graphs with constant diameter $\Lambda \geq 4$ within a factor of $\big(\frac{n}{B}\big)^{1-\epsilon}$ requires at least $\Omega(\big(\frac{n}{B}\big)^{\epsilon(\frac{1}{2} - \frac{1}{2\Lambda-2})})$ rounds of distributed computation.

We remark that in addition to being the first result on the hardness of distributed approximation, Theorem 3.8 also implies a lower bound of $\Omega((n/B)^{1/2-\epsilon})$ on the time complexity of the exact computation (or even approximation within any constant factor) of the *MST* problem restricted to graphs with constant diameter $O(1/\epsilon)$. Previously, the best-known lower bound on exact computation of *MST* on graphs with constant diameter was $\Omega(n^{1/3}/B)$ due to [28]. However, the lower bound of [28] is stronger in the sense that it requires the protocol to work only on graphs of diameter at most 4. Substituting $\Lambda = 4$ in our result yields an improvement, by a factor of $B^{2/3}$, in the result of [28].

By substituting $\Lambda = \log \frac{n}{H \cdot B}$, we get the following.

Corollary 3.9. *Any randomized H-approximation protocol for the MST problem on graphs of diameter $\Lambda = O(\log n)$ requires $T = \Omega(\sqrt{\frac{n}{H \cdot B \cdot \log n}})$ rounds of distributed computation; i.e., $T^2 \cdot H = \Omega(\frac{n}{B \cdot \log n})$.*

A lower bound of $\Omega(\frac{\sqrt{n}}{B \log n})$ on the running time of a protocol that computes the *MST* exactly on graphs of diameter at most $O(\log n)$ was shown in [32]. Our

lower bound (Corollary 3.9) shows, in particular, a stronger (by a factor of $\sqrt{B \log n}$) lower bound on the running time of a protocol that computes the *MST* exactly or *approximates* it within *any constant factor* on graphs with diameters in the same range.

4. Dependence on the diameter. In this section we show that if the diameter is $\Omega(n^\epsilon)$ for some constant $\epsilon > 0$, then the lower bound of Corollary 3.9 can be strengthened by a factor of $\sqrt{\log n}$.

To this end, consider the following family $\tilde{\mathcal{G}}$ of unweighted graphs that contains one n-vertex graph $\tilde{G}_n$ for infinitely many positive integers n. Fix some n such that $\tilde{G}_n \in \tilde{\mathcal{G}}$, and denote $\tilde{G} = \tilde{G}_n$. The vertex set $\tilde{V}$ of the graph $\tilde{G}$ consists of Γ paths $P_1, P_2, \ldots, P_\Gamma$, each of length m^2 (as in the definition of the family $\mathcal{G}$, Γ and m are sufficiently large positive integers that will be fixed later on); i.e., for $j \in \{1, 2, \ldots, \Gamma\}$, $P_j = (v_j^{(0)}, v_j^{(1)}, \ldots, v_j^{(m^2)})$. In addition, the vertex set $\tilde{V}$ contains a path P^τ (in the family $\tilde{\mathcal{G}}$ the path P^τ plays a role that is analogous to the one that the tree τ plays in the family $\mathcal{G}$) of length m; i.e., $P^\tau = (s = z_0, z_1, \ldots, z_m = r)$. The edge set $\tilde{E}$ of the graph $\tilde{G}$ contains, in addition to the paths $P_1, P_2, \ldots, P_\Gamma$ and the path P^τ, the stars $S_0, S_1, \ldots, S_m$, where $S_i = \{(z_i, v_j^{(i \cdot m)}) \mid j \in \{1, 2, \ldots, \Gamma\}\}$ for $i \in \{0, 1, \ldots, m\}$. This completes the description of the family $\tilde{\mathcal{G}}$ of unweighted graphs. This family is a slight generalization of the family $\mathcal{G}'$ of unweighted graphs that was introduced in [32]. Specifically, in [32], $\Gamma = m^2$. Observe that the the diameter of the graph G is $\Omega(m)$.

Consider the CorruptedMail(α, β) problem on family $\tilde{\mathcal{G}}$ of unweighted graphs. We next argue that it requires $\Omega(\min\{m, \Gamma/B\})$ rounds of distributed computation. The proof proceeds similarly to the proof of the analogous fact for the family $\mathcal{G}$ of unweighted graphs (see section 3.2), but it is simpler because the graphs of the family $\tilde{\mathcal{G}}$ have a simpler structure than the graphs of family $\mathcal{G}$. The *tails* sets are $T_0 = \tilde{V} \setminus \{s\}$, $T_i = \{v_j^{(i)}, v_j^{(i+1)}, \ldots, v_j^{(m^2)} \mid j \in \{1, 2, \ldots, \Gamma\}\} \cup \{z_{i'} \mid i' \in \{\lfloor i/m \rfloor, \lfloor i/m \rfloor + 1, \ldots, m\}\}$, $i \in \{1, 2, \ldots, m\}$. As in Lemma 3.4, $T_0 \supseteq T_1 \supseteq \cdots \supseteq T_m$, and let $\tilde{E}_{i,i+1}$ be the set of edges that connect one of the vertices of $\tilde{V} \setminus T_i$ with one of the vertices of T_{i+1}. It is easy to see that $|E_{i,i+1}| \leq 1$ for $i \in \{0, 1, \ldots, m^2 - 1\}$. (Recall that the proof of an analogous upper bound, $|E_{i,i+1}| \leq p \cdot m^{1/p}$, for a graph $G \in \mathcal{G}$ is somewhat more complicated.) Now, a lemma that is analogous to Lemma 3.4 follows.

Lemma 4.1. *For $t \in \{0, 1, \ldots, m^2 - 1\}$, $\rho(T_t, t) \leq (2^{B+1} - 1)^t$.*

Exactly the same argument as the one that works for family $\mathcal{G}$ shows that any deterministic protocol for the CorruptedMail(α, β) problem on family $\tilde{\mathcal{G}}$ either runs for at least $t \geq m^2 - 1$ rounds or has a running time t that satisfies the inequality $\rho(\{r\}, t) \geq |\Upsilon'| = \Omega(2^{l(\alpha,\beta)\Gamma})$ (see inequality (3)). Hence,

$$(2^{B+1} - 1)^t \geq \rho(T_t, t) \geq \rho(\{r\}, t) = \Omega(2^{l(\alpha,\beta)\Gamma}) \ .$$

It follows that $t = \Omega(\min\{m^2, l(\alpha, \beta)\Gamma/B\})$. An argument analogous to the one that was presented above for the CorruptedMail(α, β) problem on the family $\mathcal{G}$ shows that the same (up to a constant factor) lower bound applies to any *randomized* protocol for the CorruptedMail(α, β) problem on the family $\tilde{\mathcal{G}}$ as well.

Finally, for the reduction to the *MST* problem, one needs to introduce the family $\tilde{\mathcal{G}}^\omega$ of weighted graphs. The choice of weights of edges is analogous to the choice of weights for family $\mathcal{G}^\omega$, and is different from the one suggested in [32], since it is geared toward guaranteeing that the delivery will suffer from only a *one-sided error*, as was

discussed above. Specifically, the edges of the paths $P_1, P_2, \ldots, P_\Gamma$, as well as the edges of the path P^τ, all have weight zero. The edges of the stars $S_1, S_2, \ldots, S_{m-1}$ all have weight ∞. The edges of the star S_m all have unit weights, and, finally, each edge of the star S_0 may weigh either 0 or ∞, so that exactly $\alpha\Gamma$ of them have weight ∞.

The reduction from the CorruptedMail(α, β) problem on family $\tilde{\mathcal{G}}$ to the $\frac{\beta}{\alpha}$-approximate *MST* problem on family $\tilde{\mathcal{G}}^\omega$ is identical to the reduction between these problems on families of graphs $\mathcal{G}$ and $\mathcal{G}^\omega$, respectively. The latter reduction was described in section 3.3. The analysis of the reduction, described in section 3.3, applies here as well. It follows that any randomized protocol for the *MST* problem on the family $\tilde{\mathcal{G}}^\omega$ of weighted graphs requires $t = \Omega(\min\{m^2, l(\alpha,\beta)\Gamma/B\})$ rounds. By (1), $t = \Omega(\min\{m^2, \alpha\cdot\Gamma/B\})$. Substitute $m = \sqrt{\alpha\cdot\Gamma/B}$, set $H = 1/\alpha$, and observe that the number of vertices n in $\tilde{G}$ is $O(\Gamma\cdot m^2)$. The diameter Λ of the graphs from the family $\mathcal{G}$ is $m+2 = O\big(\big(\frac{n}{HB}\big)^{\frac{1}{4}}\big)$. It is easy to see that by replacing the path P^τ with k paths $P_1^\tau, P_2^\tau, \ldots, P_k^\tau$ of decreasing lengths $m, m^{1/2}, m^{1/4}, \ldots, m^{1/2^k}$ we obtain a similar lower bound for graphs of diameter $\Lambda = O\big(\big(\frac{n}{HB}\big)^{\frac{1}{2^{k+2}}}\big)$. We conclude with the following theorem.

Theorem 4.2. *For any constant $\delta > 0$, any randomized H-approximation protocol for the MST problem on graphs of diameter at most $O(n^\delta)$ requires $T = \Omega(\sqrt{\frac{n}{H\cdot B}})$ rounds of distributed computation; i.e., $T^2\cdot H = \Omega(\sqrt{\frac{n}{B}})$. In particular, for any $\epsilon > 0$, an $\big(\frac{n}{B}\big)^{1-\epsilon}$-approximation requires $\Omega(\big(\frac{n}{B}\big)^{\frac{\epsilon}{2}})$ rounds.*

In particular, this improves the result of [32] by a factor of $\sqrt{B}$. Specifically, [32] has shown a lower bound of $\Omega(\sqrt{n}/B)$ on the number of rounds required for the exact computation of the *MST*, while our result gives a stronger (by a factor of $\sqrt{B}$) lower bound on the number of rounds required to approximate the *MST* within any constant approximation factor.

Similarly, our technique enables us to get a lower bound on the time-approximation trade-off for the *MST* problem on graphs of diameter 3. This is done by replacing the tree τ in the family $\mathcal{G}$ of unweighted graphs with a clique of size $m+1$. The clique consists of original "leaves" $s = z_0, z_1, \ldots, z_m = r$. The obtained family generalizes the family $\mathcal{G}''$ due to [28]. In [28] the family $\mathcal{G}''$ proved a lower bound of $\Omega(n^{1/4}/B)$ on the number of rounds required for exact computation of the *MST* on graphs of diameter 3. In construction of [28], $\Gamma = m^3$.

The tail sets are defined exactly as for the family $\mathcal{G}$, except that $\tau(i) = \{z_i, z_{i+1}, \ldots, z_m\}$ for $i \in \{1, 2, \ldots, m\}$. It is easy to see that the edge sets $E_{i,i+1}$ are of cardinality $O(m^2)$ for each index i, implying that $\rho(T_t, t) \le (2^{B+1}-1)^{t\cdot m^2}$, for each $t \in \{0, 1, \ldots, m-1\}$. The rest of the proof is identical to that described above, and it yields a lower bound of $\Omega(\min\{m, \frac{\Gamma\cdot\alpha}{m^2\cdot B}\})$ on the number of rounds required for any randomized protocol for a $\frac{\beta}{\alpha}$-approximate *MST* on graphs of diameter 3. Substitute $m = (n\cdot\alpha/B)^{1/4}$, $H = 1/\alpha$, and observe that the number of vertices n is $O(\Gamma\cdot m)$. The next theorem follows.

Theorem 4.3. *Any randomized H-approximation protocol for the MST problem on graphs of diameter at most 3 requires $T = \Omega(\big(\frac{n}{H\cdot B}\big)^{\frac{1}{4}})$ rounds of distributed computation; i.e., $T^4\cdot H = \Omega(\frac{n}{B})$. In particular, for any $\epsilon > 0$, $\big(\frac{n}{B}\big)^{1-\epsilon}$-approximation requires $\Omega(\big(\frac{n}{B}\big)^{\frac{\epsilon}{4}})$ rounds.*

In particular, this improves the lower bound of [28] for exact computation of the *MST* on graphs of diameter 3 by a factor of $B^{1/4}$.

Observe that our time-approximation trade-off cannot be generalized further to

graphs of diameter at most 2, as there is a protocol for exact computation of the *MST* in $O(\log n)$ rounds on graphs of diameters 1 and 2 (due to [36, 28, 29]).

5. Dependence on ω_{max}: Asymmetric two-sided error. Observe that in the lower bounds that we described in the previous sections, the ratio ω_{max} between the maximum weight of an edge in a graph and the minimum weight is infinity. Actually, the weights ∞ and 0 were introduced for clarity of presentation, and one can carry on the proof if $\omega_{max} = O(n^2)$. However, allowing ω_{max} to get even smaller than that disables the reduction from the CorruptedMail problem to the *MST* problem. Specifically, it can happen that a protocol for the *MST* problem will produce a $\frac{\beta}{\alpha}$-approximate *MST* τ_0, and this tree τ_0 will induce (through the reduction) an output bit string χ' for the CorruptedMail problem that will not dominate the input bit string χ. This is due to the fact that now some edges of "infinite" weight can be taken into the approximate *MST* τ_0, while still keeping a relatively small total weight of τ_0. However, fortunately, if ω_{max} is at least $\frac{\sqrt{n}}{\alpha^{3/2}}$, the number of errors of the second type (i.e., indices j such that $\chi_j = 1$ and $\chi'_j = 0$) is small. This enables us to prove a time-approximation trade-off similar to that of Theorem 3.8 for ω_{max} that is much smaller than n^2 (specifically, $\Omega(\frac{\sqrt{n}}{\alpha^{3/2}})$). As was already mentioned, due to our upper bound on the distributed approximation of *MST* (section 6), such a trade-off becomes impossible for $\omega_{max} = o(\sqrt{n \cdot H/B}/\log^* n) = o(\sqrt{n/(B \cdot \alpha)} \cdot \log^* n)$.

The proof utilizes the following observation that may be interesting in its own right. Consider a bit string χ of length Γ of Hamming weight $\alpha\Gamma$. Suppose that an adversary is allowed to introduce into χ a *huge* number of corruptions of the first type (i.e., to change from 0 to 1 at most $(\beta-\alpha-\epsilon)\Gamma$ positions for some constant arbitrarily small positive α and ϵ and constant $\beta < 1$ that is arbitrarily close to 1), and it is allowed to introduce a reasonable number of corruptions of the second type (i.e., to change from 1 to 0 at most a constant fraction of $\varrho \cdot \alpha\Gamma$ of positions for some universal constant $0 < \varrho < 1 - 2\epsilon$). Then the obtained bit string χ' still carries on a significant fraction of the entropy that was carried on by the original bit string χ!

To capture this intuition, we introduce the AsymMail (asymmetrically corrupted mail) problem. This problem generalizes the CorruptedMail problem that was discussed in the previous sections. The AsymMail(α, β) problem is defined on the same family $\mathcal{G}$ of unweighted graphs as the CorruptedMail(α, β) problem. The vertex s accepts as input a bit string χ of Hamming weight $\alpha\Gamma$, and the vertex r outputs a bit string χ' of Hamming weight at most $\beta\Gamma$. It is required that for each index $j \in \{1, 2, \ldots, \Gamma\}$ such that $\chi_j = 1$, $\chi'_j = 1$ as well, *except for* $\frac{\alpha}{10}\Gamma$ *indices* j. For a pair of bit strings $\chi, \chi' \in \{0,1\}^\Gamma$ that satisfy the above condition, we will say that the bit string χ' *almost dominates* the bit string χ.

Consider a bipartite graphs $(\mathcal{A}, \Upsilon, E(\mathcal{A}, \Upsilon))$, with $E(\mathcal{A}, \Upsilon) = \{(\chi, \chi') \mid \chi \in \mathcal{A}, \chi' \in \Upsilon, \chi' \text{ almost dominates } \chi\}$. Fix some bit string $\chi' \in \Upsilon$ with Hamming weight $\lambda\Gamma$, $\frac{9}{10}\alpha \le \lambda \le \beta$. The number of the bit strings $\chi \in \mathcal{A}$ that are almost dominated by χ' is at most

$$D = \sum_y \binom{\lambda\Gamma}{(\alpha - y)\Gamma} \cdot \binom{(1-\lambda)\Gamma}{y\Gamma}, \tag{6}$$

where the index y runs over $y \in \{0, 1/\Gamma, 2/\Gamma, \ldots, \alpha/10\}$ (the last index y of this sum is the biggest multiple of $1/\Gamma$ that is smaller than or equal to $\alpha/10$).

The expression $\binom{\lambda\Gamma}{(\alpha-y)\Gamma}\binom{(1-\lambda)\Gamma}{y\Gamma}$ is a monotone increasing function of y whenever

$0 \leq y \leq \alpha(1-\lambda)$. To ensure that y is in this range in (6), it is sufficient to fix $\beta = 3/4$ (or, actually, any other constant smaller than $9/10$). For this choice of β,

$$D \;\leq\; (\alpha/10)\Gamma \cdot \binom{\lambda\Gamma}{(9\alpha/10)\Gamma}\binom{(1-\lambda)\Gamma}{(\alpha/10)\Gamma}\;. \tag{7}$$

Let $g(\lambda)$ denote the logarithm of base 2 of the right-hand side expression in (7). This function has a positive derivative for $\lambda < 9/10$. Hence, setting $\lambda = \beta < 9/10$ maximizes this expression. It follows that

$$D \;\leq\; (\alpha/10)\Gamma \cdot \binom{\beta\Gamma}{(9\alpha/10)\Gamma}\binom{(1-\beta)\Gamma}{(\alpha/10)\Gamma}\;.$$

A subset $\Upsilon' \subseteq \Upsilon$ is said to *almost dominate* the set $\mathcal{A}$ if for each bit string $\chi \in \mathcal{A}$ there exists a bit string $\chi' \in \Upsilon'$ that almost dominates χ.

It follows that any subset $\Upsilon' \subseteq \Upsilon$ that almost dominates $\mathcal{A}$ has cardinality at least

$$|\Upsilon'| \;\geq\; (|\mathcal{A}|/D) \;\geq\; \frac{\binom{\Gamma}{\alpha\Gamma}}{(\alpha/10)\Gamma\binom{\beta\Gamma}{(9\alpha/10)\Gamma}\binom{(1-\beta)\Gamma}{(\alpha/10)\Gamma}}\;.$$

The factor $(\alpha/10)\Gamma$ affects only lower-order terms of the lower bound, and, therefore, can be ignored. Using the Stirling formula, and analyzing the logarithm $\hat{l}(\alpha,\beta)$ of the right-hand side expression, we get $|\Upsilon'| \geq 2^{\hat{l}(\alpha,\beta)\Gamma}$, with $\hat{l}(\alpha,\beta) = \hat{l}(0,\beta) + \frac{\partial \hat{l}}{\partial \alpha}(\alpha,\beta)\cdot\alpha + o(\alpha) = \alpha(\frac{9}{10}\log(\frac{1}{\beta}\cdot\frac{9}{10}) + \frac{1}{10}\log(\frac{1}{1-\beta}\cdot\frac{1}{10})) + o(\alpha)$.

Consider $f(q) = q\cdot\log(\frac{1}{\beta}\cdot q) + (1-q)\cdot\log\frac{1-q}{1-\beta}$. Note that $f(1) = \lim_{q\to 1} f(q) = \log\frac{1}{\beta}$, and that $f'(q) = c\cdot\log\left(\frac{q}{1-q}\cdot\frac{1-\beta}{\beta}\right)$ for some universal positive constant $c > 0$. Hence, $f'(q) > 0$ whenever $q > \beta$. As we set $q = 9/10$ and $\beta = 3/4$, it follows that $f(9/10) < \log 1/\beta$. Recall that $l(\alpha,\beta) = \alpha\cdot\log 1/\beta + o(\alpha)$ and that $\hat{l}(\alpha,\beta) < l(\alpha,\beta)$ is consistent with the intuition that the entropy of the corrupted bit string when two-sided errors are allowed is smaller than the entropy of the corrupted bit string when only one-sided errors are allowed.

Now, exactly the same argument that counts the number of possible configurations of the vertices of the graph $G \in \mathcal{G}$ shows the following lemma.

LEMMA 5.1. *Any protocol for the* AsymMail(α,β) *problem on a family $\mathcal{G}$ of graphs requires* $\Omega(\min\{m, \hat{l}(\alpha,\beta)\frac{\Gamma}{p\cdot m^{1/p}\cdot B}\})$ *rounds.*

Recalling that $n = O(\Gamma\cdot m)$ and setting $m = (\frac{n\cdot\alpha}{p\cdot B})^{\frac{1}{2}-\frac{1}{2(2p+1)}}$, we see that a lower bound of $\Omega(m) = \Omega((\frac{n\cdot\alpha}{p\cdot B})^{\frac{1}{2}-\frac{1}{2(2p+1)}})$ follows (this lower bound is only by a constant factor smaller than the analogous lower bound (5) for the CorruptedMail problem).

We next describe the reduction from the AsymMail problem to the approximate *MST* problem with "small" ω_{max}. Consider the family $\mathcal{G}^{\omega m}$ of weighted graphs. This family is constructed out of the family $\mathcal{G}^{\omega}$ of weighted graphs by the following mapping ψ. Given a graph $G = (V,E) \in \mathcal{G}^{\omega}$, the mapping ψ constructs a graph in $\mathcal{G}^{\omega m}$ with the same vertex set and the same edge set, but with slightly different edge weights. Let ω_1, $\omega_2 > 1$ be two positive integer parameters to be fixed later. For an edge $e \in E$, the new weight $\omega'(e)$ is determined by

$$\omega'(e) = \begin{cases} 1, & \omega(e) = 0, \\ \omega_1, & \omega(e) = 1, \\ \omega_1\cdot\omega_2, & \omega(e) = \infty. \end{cases} \tag{8}$$

Consider the same reduction that was described in section 3.3 that, given an instance of the CorruptedMail problem, produces an instance of the *MST* problem. Consider a composition of this reduction with the mapping ψ. Let $\alpha > 0$ be at most a small positive constant, and let β' satisfy $\alpha < \beta' < \frac{100}{101}(\beta - \alpha)$. We obtain a reduction from the AsymMail(α, β) problem to the $\frac{\beta'}{\alpha}$-approximate *MST* problem on graphs with $\omega_{max} = \omega_1 \cdot \omega_2$.

Consider a weighted graph $G(\chi) \in \mathcal{G}^{\omega m}$ that is formed by the reduction. Recall that χ is the input bit string of the AsymMail problem, and its Hamming weight is $\alpha \cdot \Gamma$. It follows that precisely $\alpha \cdot \Gamma$ edges of the star S_0 have weight $\omega_1 \cdot \omega_2$ (this is the analogue of ∞), and all remaining $(1-\alpha) \cdot \Gamma$ edges of this star have unit weights. It is easy to see that the *MST* of $G(\chi)$ contains all the edges of unit weight, and, in addition, precisely $\alpha \cdot \Gamma$ edges of weight ω_1 of the star S_m.

It follows that the weight of the *MST*, $\omega'(MST) = \alpha\Gamma \cdot \omega_1 + (n-1-\alpha\Gamma)$. Consider the $\frac{\beta'}{\alpha}$-approximate *MST* τ_0 that is returned by the oracle approximation protocol for *MST* (its existence is assumed by the reduction). By definition, $\omega'(MST) \leq \omega'(\tau_0) \leq \frac{\beta'}{\alpha} \cdot (\alpha\Gamma \cdot \omega_1 + (n-1-\alpha\Gamma))$. Consider some index $j \in \{1, 2, \ldots, \Gamma\}$ such that $\chi_j = 1$, and suppose that $\chi'_j = 0$. As $\chi_j = 1$, the weight of the edge $(s, v_j^{(0)})$ is $\omega_1 \cdot \omega_2$. As $\chi'_j = 0$, the edge $(r, v_j^{(m)})$ does not belong to the tree τ_0. As τ_0 is a spanning tree of $G(\chi)$, it follows that at least one edge from the set $HE_j = \{(z_i, v_j^{(i)}) \mid i \in \{0, 1, \ldots, m-1\}\}$ belongs to the tree τ_0 (*HE* stands for "heavy edges"). Observe that for each edge $e \in HE_j$, $\omega'(e) = \omega_1 \cdot \omega_2$. Note also that for two distinct indices $j \neq j'$, $j, j' \in \{1, 2, \ldots, \Gamma\}$, $HE_j \cap HE_{j'} = \emptyset$. It follows that if there are q indices j such that $\chi_j = 1$ and $\chi'_j = 0$, then at least q edges of weight $\omega_1 \cdot \omega_2$ belong to approximate *MST* τ_0; i.e., $q \cdot \omega_1\omega_2 \leq \beta'\Gamma \cdot \omega_1 + \frac{\beta'}{\alpha}(n-1-\alpha\Gamma)$. As we allow at most $\alpha\Gamma/10$ errors of the second type, we impose the following condition on ω_1 and ω_2:

$$\left(\frac{\alpha}{10}\Gamma + 1\right)\omega_1 \cdot \omega_2 > \beta' \cdot \Gamma \cdot \omega_1 + \frac{\beta'}{\alpha}(n-1-\alpha\Gamma)\ . \tag{9}$$

Consider some index $j \in \{1, 2, \ldots, \Gamma\}$ such that $\chi_j = 0$, and suppose that $\chi'_j = 1$. As $\chi_j = 0$, $\omega'(s, v_j^{(0)}) = 1$. As $\chi'_j = 1$, the edge $(r, v_j^{(m)})$ belongs to the tree τ_0. Recall that $\omega'((r, v_j^{(m)})) = \omega_1$. It follows that $\omega'(\tau_0) \geq \omega_1 \cdot (||\chi'|| - ||\chi||) = \omega_1 \cdot (||\chi'|| - \alpha\Gamma)$; i.e., $\omega_1 \cdot (||\chi'|| - \alpha\Gamma) \leq \omega'(\tau_0) \leq \beta'\Gamma \cdot \omega_1 + \frac{\beta'}{\alpha}(n-1-\alpha\Gamma)$. We next impose the following condition on ω_1:

$$\Gamma \cdot \omega_1 \geq 100\frac{n}{\alpha}\ . \tag{10}$$

Then $\beta' \cdot (\Gamma\omega_1 + \frac{n-1-\alpha\Gamma}{\alpha}) \leq \beta' \cdot (\Gamma\omega_1 + \frac{n}{\alpha}) \leq \frac{101}{100}\beta'\Gamma \cdot \omega_1$. It follows that $||\chi'|| - \alpha\Gamma \leq \frac{101}{100}\beta'\Gamma$. Recall that $\beta' < \frac{100}{101}(\beta - \alpha)$. Hence, $||\chi'|| \leq (\frac{101}{100}\beta' + \alpha)\Gamma < \beta\Gamma$. Hence, under conditions (9) and (10), the output bit string χ' almost dominates the input bit string χ. It follows that under these conditions, the AsymMail(α, β) problem reduces to a $\frac{\beta'}{\alpha}$-approximate *MST* problem for any $\beta' < \frac{100}{101}(\beta - \alpha)$.

Conditions (9) and (10) determine how large ω_1 and ω_2 should be for this reduction to work. Inequality (10) means that $\omega_1 \geq 100\frac{n}{\Gamma \cdot \alpha}$, and to satisfy (9), it is enough to ensure that $\frac{\alpha}{10}\Gamma \cdot \omega_1 \cdot \omega_2 > \beta'\frac{101}{100}\Gamma\omega_1$. The latter implies that $\omega_2 > \frac{\beta'}{\alpha} \cdot \frac{101}{10}$. Hence, $\omega_{max} = \omega_1 \cdot \omega_2 > 1010 \cdot \beta' \cdot \frac{n}{\Gamma \cdot \alpha^2}$. As β' is a fixed constant ($\beta' < 1$), it follows that $\omega_{max} = \Theta(\frac{n}{\Gamma \cdot \alpha^2})$ is enough. Combining this with the lower bound on the AsymMail(α, β) problem (Lemma 5.1) implies that approximating *MST*

within a ratio of $\Theta(\frac{1}{\alpha})$ on graphs of diameter $2p+2$ with $\omega_{max} = \Theta(\frac{n}{\Gamma \cdot \alpha^2})$ requires $\Omega(\min\{m, \hat{l}(\alpha,\beta)\frac{\Gamma}{p \cdot m^{1/p} \cdot B}\})$ rounds for some constant $\beta < 1$.

Recall that $n = O(\Gamma \cdot m)$. Set $H = \frac{1}{\alpha}$, and $m = \left(\frac{n \cdot \alpha}{p \cdot B}\right)^{\frac{1}{2} - \frac{1}{2(2p+1)}}$. We conclude with the following.

THEOREM 5.2. *Any randomized H-approximation protocol for the MST problem on graphs of diameter at most Λ for $\Lambda \in \{4, 6, \dots\}$ with $\omega_{max} = \Theta\left(\left(\frac{n}{\Lambda \cdot B}\right)^{\frac{1}{2} - \frac{1}{2(\Lambda-1)}} \cdot H^{\frac{3}{2} + \frac{1}{2(\Lambda-1)}}\right)$ requires at least $T = \Omega\left(\left(\frac{n}{\Lambda \cdot H \cdot B}\right)^{\frac{1}{2} - \frac{1}{2(\Lambda-1)}}\right)$ rounds; i.e., $T^{2 + \frac{2}{\Lambda-2}} \cdot H = \Omega(\frac{n}{\Lambda \cdot B})$. In particular, for $\Lambda = \Theta(\log n)$, $\omega_{max} = \Theta\left(\left(\frac{n}{B \cdot \log n}\right)^{\frac{1}{2}} \cdot H^{3/2}\right)$, and $T^2 \cdot H = \Omega\left(\frac{n}{B \cdot \log n}\right)$.*

By setting m to be smaller than $\left(\frac{n}{HpB}\right)^{\frac{1}{2} - \frac{1}{2(2p+1)}}$, one can get a smaller lower bound on T but with $\omega_{max} = \Theta(mH^2)$. Also, as for the case of unbounded ω_{max}, the factor $\log n$ in the denominator can be eliminated if one allows a bigger diameter (specifically, $O(n^\delta)$ for any constant positive $\delta > 0$). Also, this way one can get a lower bound for approximate *MST* on graphs with diameter 3 (Theorem 5.2 applies as is) by considering the ASYMMAIL(α, β) problem on the family $\mathcal{G}''$ of graphs (see Theorem 4.3 and the discussion that precedes it).

We remark that one cannot expect to get $\omega_{max} = o\left(\sqrt{\frac{n \cdot H}{B}} / \log^* n\right)$ in Theorem 5.2. This is because by Theorem 6.4, there exists an $O(\frac{\omega_{max}}{T'})$-approximation protocol for the *MST* problem with running time $O(\Lambda(G) + T' \log^* n)$. For ω_{max} as above, the approximation ratio is $H = O(\frac{\omega_{max}}{T'}) = o(\sqrt{\frac{n}{B}} \frac{1}{\log^* n} \cdot \frac{\sqrt{H}}{T'})$; i.e., $T' = o(\sqrt{\frac{n}{BH}} \frac{1}{\log^* n})$, and the running time of the protocol is $T = O(\Lambda(G)) + o(\sqrt{\frac{n}{BH}}) = o(\sqrt{\frac{n}{BH}})$ (assuming that $\Lambda(G) = o(\sqrt{\frac{n}{BH}})$; indeed, the lower bounds apply for a small diameter, and the upper bound apply for an arbitrarily large diameter). This protocol provides an H-approximation for the *MST* problem. Hence, $T^2 \cdot H = o(\sqrt{n/B})$, contradicting the stronger (by a factor of $\log n$) version of Theorem 5.2 (that applies for $\Lambda(G) = O(n^\delta)$ for any constant $\delta > 0$).

6. An upper bound. In this section we devise a distributed protocol for the approximate *MST* problem. Our protocol runs in $O(\Lambda(G) + n^\epsilon \cdot \log^* n)$ rounds and constructs an $O(\frac{\omega_{max}}{n^\epsilon})$-approximate *MST*, where ω_{max} is the ratio between the weights of the heaviest and the lightest edges in the graph G, and ϵ is any fixed number between zero and one. Note that the approximation ratio of $O(\omega_{max})$ is trivial.

Throughout this section we assume that $B = \log n$. Hence, the protocol can be used whenever $B = \Omega(\log n)$, and its running time will be the same. Also, obviously it can be adapted to the case $B = o(\log n)$ incurring an overhead of $O(\frac{\log n}{B}) = O(\log n)$. Also, we assume that the weights of edges are scaled between 1 and ω_{max}.

Consider an *MST* τ_0 of the graph G. A connected subtree of τ_0 is called a *fragment* of τ_0. When the *MST* τ_0 can be understood from the context, such a fragment will be called an *MST fragment*. A *k-MST forest* $\mathcal{F}$ of a graph $G = (V, E)$ is a collection of vertex-disjoint trees that satisfy the following properties:

1. $\bigcup_{T \in \mathcal{F}} V(T) = V$, $\bigcup_{T \in \mathcal{F}} E(T) \subseteq E$.
2. $|V(T)| = \Omega(k)$, $\Lambda(T) = O(k)$.
3. There exists an *MST* τ_0 for the graph G, such that each tree $T \in \mathcal{F}$ is its fragment.

The notion of a *k-MST* forest is related to the notion of the (σ, ρ) spanning forest of [23]. Trees $T \in \mathcal{F}$ of a (σ, ρ) spanning forest $\mathcal{F}$ have to satisfy properties 1 and 2 with $|V(T)| \geq \sigma$ and $\Lambda(T) \leq \rho$, but may not satisfy property 3. It was demonstrated

in [23] that a k-*MST* forest of an n-vertex graph G can be constructed in $O(k \cdot \log^* n)$ rounds of distributed computation.

The first step of our n^ϵ-approximation protocol for the *MST* problem is to construct an n^ϵ-*MST* forest $\mathcal{F}$. This requires $O(n^\epsilon \cdot \log^* n)$ rounds. The second step is to construct a breath first search (BFS) spanning tree τ of the entire graph, rooted at some arbitrary vertex $rt = rt(\tau)$. This requires $O(\Lambda(G))$ rounds. After the construction of the tree τ, each vertex v in the graph knows its unweighted distance to the root rt, $dist_\tau(rt, v)$. At the third step of the protocol, convergecasts are conducted in parallel over the spanning trees of the fragments $T \in \mathcal{F}$ of the n^ϵ-*MST* forest $\mathcal{F}$. Throughout the convergecast over a fragment T, the root of the fragment T learns the identity of the vertex $v \in V(T)$ that is closest in τ to the root rt of τ. The draws are broken arbitrarily. The fourth step involves broadcasts over the spanning trees of the fragments of the identities of these chosen vertices. Both convergecasts and broadcasts are done in parallel (recall that the fragments are vertex disjoint) and require $O(\max\{\Lambda(T) \mid T \in \mathcal{F}\})$ rounds. As $\mathcal{F}$ is an n^ϵ-*MST* forest, it follows that $\Lambda(T) = O(n^\epsilon)$ for every tree $T \in \mathcal{F}$. Hence, these steps require $O(n^\epsilon)$ rounds. After the broadcasts are done, the fifth step occurs. On the fifth step in each fragment $T \in \mathcal{F}$, the chosen vertex $v \in V(T)$ inserts the edge $e_v = (par_{(\tau, rt(\tau))}(v), v)$ into the tree τ_0 that the protocol constructs. It also informs the parent of the vertex v in τ, $par_{(\tau, rt(\tau))}(v)$, that it was chosen, and the parent inserts the edge e_v into τ_0 as well. In addition, each vertex w in the graph inserts into the tree τ_0 the edges of the k-*MST* forest $\mathcal{F}$ that are incident to w. Observe that the fifth step requires only one round of distributed computation (for sending the messages by the chosen vertices to their parents in τ).

This completes the description of the protocol. It follows from our discussion that its running time is $O(\Lambda(G) + n^\epsilon \cdot \log^* n)$. We next argue that it is indeed an $O(\frac{\omega_{max}}{n^\epsilon})$-approximation protocol for the *MST* problem.

LEMMA 6.1. *The subgraph τ_0 that is constructed by the protocol is acyclic.*

Proof. Suppose for contradiction that there is a cycle $((u_0, w_0), P_0, (u_1, w_1), P_1, \ldots, (u_{t-1}, w_{t-1}), P_{t-1})$, where P_i is a path in some fragment T_i between w_i and $u_{((i+1) \bmod t)}$, and $(u_i, w_i) \in E(\tau)$, $i \in \{0, 1, \ldots, t-1\}$ (where τ is the BFS spanning tree of the graph). Fragments may appear more than once. (Observe that the cycle cannot be contained entirely in one fragment, because for each fragment $T \in \mathcal{F}$, the edges of τ_0 with both endpoints in T all belong to the spanning tree of T.) It follows that $|dist_\tau(rt, u_i) - dist_\tau(rt, w_i)| = 1$ for $i \in \{0, 1, \ldots, t-1\}$.

Assume, without loss of generality that $dist_\tau(rt, w_0) - dist_\tau(rt, u_0) = 1$; i.e., $u_0 = par_{(\tau, rt)}(w_0)$. Then $u_1 = par_{(\tau, rt)}(w_1)$, because otherwise both edges $(u_0, w_0), (u_1, w_1)$ connect vertices of the same fragment (the vertices w_0 and u_1) to their parents in the BFS tree τ. However, at most one such edge is inserted into the tree τ_0 for each fragment in the approximation protocol. It follows that $u_i = par_{(\tau, rt)}(w_i)$ for $i \in \{0, 1, \ldots, t-1\}$. Hence,

$$dist_\tau(rt, u_0) > dist_\tau(rt, w_0) \geq dist_\tau(rt, u_1) > \cdots \geq \cdots > dist_\tau(rt, w_{t-1}) \geq dist_\tau(rt, u_0) .$$

This is a contradiction, implying that the subgraph τ_0 is acyclic. □

LEMMA 6.2. *The subgraph τ_0 is connected, and it is spanning all the vertices of the graph G.*

Proof. The second assertion follows directly from the observation that the edge set of the tree τ_0 contains the edge set of the n^ϵ-*MST* forest $\mathcal{F}$, and from the definition of a k-*MST* forest.

For the first assertion, consider some pair of vertices u and w in V. Let T_u and T_w be the pair of fragments of the n^ϵ-*MST* forest $\mathcal{F}$ such that $u \in T_u$, $w \in T_w$. If $T_u = T_w$, then u and w are connected in τ_0, because the subgraph τ_0 contains a spanning tree of each fragment T of the n^ϵ-*MST* forest $\mathcal{F}$, and, in particular, of $T_u = T_w$. Otherwise, let $u_0 \in T_u$ (resp., $w_0 \in T_w$) be the closest vertex in T_u (resp., T_w) to $rt = rt(\tau)$ (in terms of the unweighted distance). To prove that there is a path between u and w in τ_0, it suffices to prove that there is a path between u_0 and w_0. We prove this by induction on $dist_\tau(rt, u_0) + dist_\tau(rt, w_0)$.

The induction base is the case when the sum is 0, i.e., $u_0 = w_0 = rt$, and then the assertion is obvious.

For the induction step, consider the parent $v = par_{(\tau,rt)}(u_0)$ of the vertex u_0 in the BFS tree τ. Observe that $dist_\tau(rt, v) = dist_\tau(rt, u_0) - 1 < dist_\tau(rt, u_0)$, and that the edge $e = (u_0, v)$ belongs to τ_0. Thus, it suffices to prove that there is a path between v and w_0 in τ_0. Let T_v be the fragment of $\mathcal{F}$ that contains the vertex v, and let v_0 be the vertex that was chosen by the convergecast on this fragment. It follows that $dist_\tau(rt, v_0) \leq dist_\tau(rt, v) < dist_\tau(rt, u_0)$, and, thus, the induction hypothesis is applicable to the pair of vertices, v_0 and w_0. As the fragment T_v is connected, the lemma follows. □

It follows from Lemmas 6.1 and 6.2 that τ_0 is a spanning tree of the graph G.

LEMMA 6.3. *The tree τ_0 is a $(1 + O(\frac{\omega_{max}}{n^\epsilon}))$-approximate MST of the graph G.*

Proof. Let $\omega : E \to R^+$ denote the weight function that is associated with the graph G, and let $\omega(MST)$ denote the weight of the *MST*. Observe that the weight of the n^ϵ-*MST* forest $\mathcal{F}$ is at most $\omega(MST)$, and that the convergecast and broadcast procedures insert into τ_0 at most $O(n^{1-\epsilon})$ additional edges. Hence, $\omega(\tau_0) = O(n^{1-\epsilon} \cdot \omega_{max}) + \omega(MST)$. Thus,

$$\frac{\omega(\tau_0)}{\omega(MST)} = 1 + O\left(\frac{n^{1-\epsilon} \cdot \omega_{max}}{\omega(MST)}\right) .$$

Recall that by our assumption, all the weights are scaled between 1 and ω_{max}. Hence, $\omega(MST) \geq n - 1$. It follows that $\omega(\tau_0)/\omega(MST) = O(\omega_{max}/n^\epsilon)$. □

To conclude, we have the following.

THEOREM 6.4. *For any $0 < \epsilon < 1$, there exists a protocol that constructs an H-approximate MST for an n-vertex weighted graph (G, ω) in $O(\Lambda(G) + n^\epsilon \cdot \log^* n)$ rounds with $H = 1 + O(\frac{\omega_{max}}{n^\epsilon})$. Let $T = n^\epsilon \cdot \log^* n$. Then $T \cdot H = O(\omega_{max} \cdot \log^* n)$.*

Note that for graphs with small ω_{max} (e.g., constant, or polylogarithmic in n) this protocol provides an approximation ratio that is arbitrarily close to 1, and the running time of the protocol is arbitrarily close to $O(\Lambda(G))$.

7. Discussion. In this paper we presented a lower bound on the time-approximation trade-off of the distributed *MST* problem. While this is one of the most fundamental problems in the area of distributed computing, there are many other important distributed problems whose approximation behavior is yet to be explored. In our opinion, it would be of particular interest to establish lower bounds on time-approximation trade-offs of such problems as maximum dominating set and maximum matching. Interrelating the complexities of these problems via distributed reductions appears to be an even greater challenge.

TOWARD A TOPOLOGICAL CHARACTERIZATION OF ASYNCHRONOUS COMPLEXITY*

GUNNAR HOEST† AND NIR SHAVIT‡

Abstract. This paper introduces the use of topological models and methods, formerly used to analyze computability, as tools for the quantification and classification of *asynchronous complexity*. We present the first *asynchronous complexity theorem*, applied to decision tasks in the iterated immediate snapshot (IIS) model of Borowsky and Gafni. We do so by introducing a novel form of topological tool called the *nonuniform chromatic subdivision*. Building on the framework of Herlihy and Shavit's topological computability model, our theorem states that the time complexity of any asynchronous algorithm is directly proportional to the level of nonuniform chromatic subdivisions necessary to allow a simplicial map from a task's input complex to its output complex. To show the power of our theorem, we use it to derive a new tight bound on the time to achieve n process approximate agreement in the IIS model: $\lceil \log_d \frac{\max\_input - \min\_input}{\epsilon} \rceil$, where $d = 3$ for two processes and $d = 2$ for three or more. This closes an intriguing gap between the known upper and lower bounds implied by the work of Aspnes and Herlihy. More than the new bounds themselves, the importance of our asynchronous complexity theorem is that the algorithms and lower bounds it allows us to derive are intuitive and simple, with topological proofs that require no mention of concurrency at all.

1. Introduction.

In the 21st century, computers are progressively being used as coordination devices in asynchronous, distributed systems. Unfortunately, the standard, Turing notions of computability and complexity are not sufficient for evaluating the behavior of such systems. In the last few years, techniques of modeling and analysis based on classical algebraic topology [3, 12, 14, 18, 20, 21, 22, 24, 25, 26, 32] in conjunction with distributed simulation methods [9, 10, 11, 12] have brought about significant progress in our understanding of computability problems in an asynchronous distributed setting. We feel the time is ripe to extend these techniques to address *asynchronous complexity*.

This paper studies asynchronous shared memory solutions to the class of problems called *decision tasks*, input/output problems in which N processes start with input values and, after communicating, halt with private output values. We focus on the *iterated immediate snapshot* (IIS) memory model introduced by Borowsky and Gafni [12] as part of their new simplified proof of the asynchronous computability theorem [26]. The model is a restriction of atomic snapshot memory that guarantees that processes' scan operations return views that contain nondecreasing sets of the

participating processes' inputs. Though it is not a realistic computation model (no machine supports such operations) we believe it is a good first candidate for topological modeling since it has a particularly nice geometric representation and hence easily lends itself to topological analysis.

1.1. Historical background and related work. Let us begin by giving a brief account of previous work on computability problems in fault-prone, asynchronous, distributed systems, applications of algebraic topology to asynchronous computability problems, simulation techniques, and also on characterizing the *Approximate Agreement* task.

In 1985, a fundamental paper by Fischer, Lynch, and Paterson [17] demonstrated that traditional Turing computability theory is not sufficient for analyzing computability problems in asynchronous, distributed systems. In particular, it showed that the well-known *Consensus* task, in which each participating process has a private input value drawn from some set S, and every nonfaulty process must decide on the same output value equal to the input of some process, cannot be solved in a message passing system even if only one process may fail by halting. Later, it was also shown that the message passing and shared memory models are equivalent [4], so this result carries over to shared memory systems as well. This fundamental discovery led to the creation of a highly active research area, which is surveyed in a recent book by Lynch [29].

In 1988, Biran, Moran, and Zaks [7] provided a breakthrough result by introducing a graph-theoretic framework that allows a complete characterization of the types of tasks that can be solved in a message passing or shared memory system in the presence of a single failure. However, this framework proved hard to extend to more than one failure, and even the problem of characterizing the solvability of specific tasks such as *Renaming* [5] and *Set Agreement* [13] for any number of processes remains unsolved.

In 1993, three research teams working independently—Borowsky and Gafni [10], Saks and Zaharoglou [32], and Herlihy and Shavit [24]—derived impossibility results for solving the Set Agreement task in the read-write shared memory model. The paper of Borowsky and Gafni introduced a powerful new simulation technique for proving solvability and unsolvability results in asynchronous, distributed systems. The technique allows N-process protocols to be executed by fewer processes in a resilient way and has been proven correct by Borowsky, Gafni, Lynch, and Rajsbaum [9]. The paper by Saks and Zaharoglou [32] constructed an elegant topological structure that captures the knowledge of the processors of the state of the system, allowing them to prove the impossibility of wait-free k-set agreement using point-set topology. The proof exposes an interesting relation between set agreement and the Brouwer fixed point theorem for the k-dimensional ball.

The paper of Herlihy and Shavit [24, 26] introduced a new formalism based on tools from classical, algebraic topology for reasoning about computations in asynchronous, distributed systems in which any number of processes may fail. Their framework consisted of modeling tasks and protocols using algebraic structures called *simplicial complexes* and then applying standard homology theory to reason about them. Herlihy and Shavit extended this framework by providing the *asynchronous computability theorem*, which states a condition that is necessary and sufficient for a task to be solvable by a wait-free protocol in shared memory [26], and showed applications of this theorem to tasks such as Set Agreement and Renaming. Borowsky [8] generalized this solvability condition to a model consisting of regular shared memory augmented with set-consensus objects, under more general resiliency requirements.

In 1993, Chaudhuri, Herlihy, Lynch, and Tuttle [14] also used topological and geometric arguments to prove tight bounds on solving the Set Agreement problem in the *synchronous* message passing model where an arbitrary number of processes may fail.

In 1994, Herlihy and Rajsbaum derived further impossibility results for Set Agreement by applying classical homology theory [20]. Moreover, in a unifying paper in 1995, Herlihy and Rajsbaum provided a common, general framework for describing a wide collection of impossibility results by using chain maps and chain complexes [22]. At the same time, Attiya and Rajsbaum reproved several impossibility results using purely combinatorial tools [3].

In 1995, Gafni and Koutsopias presented a reduction from the classical contractibility problem of algebraic topology to show that it is undecidable whether a certain class of 3-process tasks is wait-free solvable in the shared memory model [18]. This work was then generalized by Herlihy and Rajsbaum to arbitrary numbers of processes and failures in a variety of computational models [21]. More recently, Havlicek showed that, while undecidability holds in the general case, the problem of solvability is in fact decidable for a relatively large class of tasks [19]. Another recent paper by Herlihy, Rajsbaum, and Tuttle [23] introduces the use of pseudospheres as a means for unifying the synchronous, semisynchronous, and asynchronous message passing computation models.

The immediate snapshot (IS) object was introduced by Borowsky and Gafni in 1993 [11]. It is the basic building block of the iterated immediate snapshot (IIS) model, first implicitly used by Herlihy and Shavit [24, 25] and more recently formulated as a computation model by Borowsky and Gafni [12] as part of their new, simplified proof of the asynchronous computability theorem of Herlihy and Shavit [26]. This work also shows that the IIS model is computationally equivalent to standard shared memory models by providing a wait-free implementation of IIS from shared memory, and vice versa. It is not clear, however, whether these implementations are optimal from a complexity-theoretic viewpoint.

The *Approximate Agreement* problem is a weakening of the *Consensus* problem in which each process has a real valued input, and in any execution, nonfaulty processes with inputs in a range $[\min\_input, \max\_input]$ (the range changes from one execution to the next based on the input set of participating processes) must agree on output values within that range that are at most $\epsilon > 0$ apart. The problem was first introduced in 1986 by Dolev, Lynch, Pinter, Stark, and Weihl [15] in a paper showing that this task can be solved in both the synchronous and asynchronous message passing models even when assuming a Byzantine failure model (in which processes may exhibit arbitrary, even malicious, behavior). The paper also provided matching upper and lower bounds for solving the task in these settings. These results were extended to various failure models by Fekete [16], who also showed optimality in terms of the number of rounds of communication used.

In 1994, Attiya, Lynch, and Shavit published a paper giving an $\Omega(\log N)$ step complexity lower bound, together with a matching $O(\log N)$ upper bound, for solving in a wait-free manner N-process Approximate Agreement in "normal" (synchronous and failure-free) executions using single-writer, multireader shared memory [6]. These results were part of a proof that, in certain settings, wait-free algorithms are inherently *slower* than non–wait-free algorithms.

This work was extended by Schenk [33], who showed matching upper and lower bounds for solving the task in the asynchronous single-writer, multireader shared memory model where the magnitudes of the inputs are bounded from above.

Finally, in 1994, Aspnes and Herlihy [2] showed a $\lceil \log_3 \frac{\max\_input - \min\_input}{\epsilon} \rceil$ lower bound, together with a $\lceil \log_2 \frac{\max\_input - \min\_input}{\epsilon} \rceil$ upper bound on the time complexity (the number of steps taken by a process) for solving Approximate Agreement using wait-free protocols in the asynchronous single-writer, multireader shared memory model.

1.2. The asynchronous complexity theorem. This paper introduces a new theorem that for the first time provides a topological characterization of complexity for asynchronous computation. We introduce the *nonuniform iterated immediate snapshot (NIIS) model*, a refinement of the IIS model that allows better modeling of complexity. Keeping in style with Herlihy and Shavit's topological computability framework [26], our theorem states that the worst case time complexity for solving a decision task in the NIIS model is equivalent to the minimal number of nonuniform chromatic subdivisions of the task's input complex necessary to allow a simplicial map from the subdivided input complex to the output complex. The theorem implies an algorithm if one is given a subdivision and a mapping.

The nonuniform chromatic subdivisions we introduce (see Figure 13) are a looser and more general form of standard chromatic subdivisions [26]. Unlike the iterated standard chromatic subdivisions used in the computability work of [26, 12], they allow individual simplexes in a complex to be subdivided a different number of times, while ensuring that the subdivision of the complex as a whole remains consistent. Nonuniformity is a necessary property when analyzing complexity since it allows the level of subdivision of input simplexes to differ from one simplex to the next. This allows one to model a world in which different numbers of steps are taken on different input sets. If one used only uniform subdivisions, one could talk only about the complexity of the most highly subdivided simplex. This would make the complexity theorem useless, since, for example, for the Approximate Agreement problem, Aspnes and Herlihy [2] show that for any k one can find a set of inputs that will require time k in the worst case.

The power of our theorem lies in its ability to allow one to reason about the complexity of problems in a purely geometric setting. As we show, the subdivisions of a complex are a clean and higher level way of thinking about the multitude of different length executions of a concurrent protocol. We found this geometric representation helpful and believe that it will prove to be an invaluable tool for designing and analyzing concurrent algorithms. For technical reasons, in order to avoid the need to deal with infinite size complexes, we restrict our problem space to decision tasks with finite (yet not necessarily bounded) input and output domains.

We provide an example application of Theorem 4.2. In section 5, we use our topological framework to show tight upper and lower bounds on the time to solve the Approximate Agreement problem in a wait-free manner in the NIIS model. We close the gap implied by the work of Aspnes and Herlihy [2], proving matching upper and lower bounds of $\lceil \log_d \frac{\max\_input - \min\_input}{\epsilon} \rceil$, where $d = 3$ for two processes and $d = 2$ for three or more.

Apart from the theorem itself, its proof provides two additional contributions to the asynchronous computability literature.

- The upper bound proof of Herlihy and Shavit's asynchronous computability theorem [26] and related papers by Borowsky and Gafni [11, 12] all rely on the fact that the standard chromatic subdivision [25, 26] is indeed a subdivision in the topological sense. We provide the first formal proof of this fact.
- In 1997, Borowsky and Gafni provided a simulation of atomic snapshot mem-

ory from IIS memory [12]. They showed that based on this simulation, if one is given a proof of an asynchronous computability theorem for the IIS model (which they called Proposition 3.1), it will imply one for the general read-write model. The hope was that the proof of their Proposition 3.1 would be constructive and therefore significantly simpler than the nonconstructive proof in [24, 26]. The proof of our asynchronous complexity theorem in section 4 provides a constructive proof of computability for the NIIS model, and since IIS is a subset of NIIS, it provides the first known proof of Proposition 3.1 of [12].

1.3. Organization. The paper is organized as follows. Section 2 provides a formal definition of decision tasks. It also contains a thorough description of our model of computation, together with the complexity measures we use for analyzing protocols in this model. Section 3 contains a collection of necessary definitions and results from algebraic topology, as well as a description of how we model decision tasks and NIIS protocols topologically. It also contains definitions of the standard chromatic subdivision and the nonuniform chromatic subdivision. Section 4 contains a statement and proof of our main theorem. Section 5 contains an application of our asynchronous complexity theorem to the Approximate Agreement task. Finally, section 6 summarizes our results and also gives some directions for further research.

2. Model. In order to develop a useful and applicable complexity theory for asynchronous, distributed computer systems, we need to define some reasonable model of such systems. This model must be detailed enough so as to accurately and faithfully capture the inherent complexity of solving tasks in real distributed systems yet be simple enough so as to easily lend itself to some practical form of complexity analysis. The model we consider in this paper consists of a class of one-shot distributed problems, called *decision tasks*, together with a novel model of computation, a type of shared memory called the *nonuniform iterated immediate snapshot (NIIS) model*. This section contains a detailed description of these fundamental concepts. It also contains the complexity measures that will be used to analyze the complexity of solving decision tasks in the NIIS model.

2.1. Informal synopsis. We begin with an informal synopsis of our model, which largely follows that of Herlihy and Shavit [24, 25, 26]. Some fixed number $N = n+1$ of sequential threads of control, called *processes*, communicate by asynchronously accessing shared memory in order to solve *decision tasks*. In such a task, each process starts with a private *input* value and halts with a private *output* value. For example, in the well-known *Binary Consensus* task, the processes have binary inputs and must agree on some process's input [17]. A *protocol* is a distributed program that solves a decision task in such a system. A protocol is *wait-free* if it guarantees that every nonfaulty process will halt in a finite number of steps, independent of the progress of the other processes. The *time complexity* of solving a decision task in this model on a given input set is the supremum of the number of accesses to shared memory made by any process on that input set.

2.2. Decision tasks. In this section, we define decision tasks more precisely. This class of tasks is intended to provide a simplified model of reactive systems, such as databases, file systems, or automated teller machines. An input value represents information entering the system from the surrounding environment, such as a character typed at a keyboard, a message from another computer, or a signal from a sensor. An output value models an effect on the outside world, such as an irrevocable

decision to commit a transaction, to dispense cash, or to launch a missile. Informally speaking, a decision task is a relation between vectors of input values and vectors of output values. We define this more precisely below.

Let D_I and D_O be two finite data types, possibly identical, called the *input data type* and the *output data type*, respectively. We first define the concept of an input vector.

DEFINITION 2.1. *An $n+1$-process* input vector $\vec{I}$ *is an $n+1$-dimensional vector, indexed by $\{0,\ldots,n\}$, each component of which is either an object of type D_I or the distinguished value $\perp$, with the additional requirement that at least one component of $\vec{I}$ must be different from $\perp$.*

The definition of output vectors is similar to that of input vectors.

DEFINITION 2.2. *An $n+1$-process* output vector $\vec{O}$ *is an $n+1$-dimensional vector, indexed by $\{0,\ldots,n\}$, each component of which is either an object of type D_O or the distinguished value $\perp$.*

When it is clear from the context, we omit mentioning the number of processes in specifying input and output vectors. We denote the ith component of an input vector $\vec{I}$ by $\vec{I}[i]$, and, similarly, we denote the ith component of an output vector $\vec{O}$ by $\vec{O}[i]$. In the remainder of the paper, unless stated otherwise, we will assume that i and j are index values in the set $\{0,\ldots,n\}$. These index values will be used both for specifying vector elements and also for indexing processes. We will use the terms "one-dimensional array" ("array" for short) and "vector" interchangeably.

We are often concerned with executions that are prefixes of a given execution.

DEFINITION 2.3. *Vector $\vec{U}$ is a* prefix *of $\vec{V}$ if, for $0 \le i \le n$, either $\vec{U}[i] = \vec{V}[i]$ or $\vec{U}[i] = \perp$.*

If a prefix has an entry distinct from $\perp$, then it agrees with the corresponding entry in the original.

DEFINITION 2.4. *A set V of vectors is* prefix-closed *if for all $\vec{V} \in V$, every prefix $\vec{U}$ of $\vec{V}$ is in V.*

In this paper, we will consider only sets of input and output vectors that are finite and prefix-closed.

DEFINITION 2.5. *An* input set *is a finite, prefix-closed set of input vectors. An* output set *is a finite, prefix-closed set of output vectors.*

Next, we define the notion of a task specification map, which maps each element of the input set to a subset of the output set. Our definition is similar to that of Havlicek [19].

DEFINITION 2.6. *Let I and O be input and output sets, respectively. A* task specification map *relating the two sets is a relation $\gamma \subseteq I \times O$ such that the following conditions hold:*

- *For all $\vec{I} \in I$, there exists a vector $\vec{O} \in O$ such that $(\vec{I}, \vec{O}) \in \gamma$.*
- *For all $(\vec{I}, \vec{O}) \in \gamma$, and for all i, $\vec{I}[i] = \perp$ if and only if $\vec{O}[i] = \perp$.*

Note that the above definition requires that in defining the task, every participating process must have a defined output. This is the specification of the task and does not model its solvability in any given computation model.

As a convenient notation, we denote the set of vectors $\vec{O}$ in O such that $(\vec{I}, \vec{O}) \in \gamma$ by $\gamma(\vec{I})$. For a given input vector $\vec{I}$, the set of vectors $\gamma(\vec{I})$ simply represents the set of legitimate output vectors for the set of inputs specified by $\vec{I}$. This set will generally contain more than one allowable output vector.

DEFINITION 2.7. *A* decision task *$\mathcal{D} = \langle I, O, \gamma \rangle$ is a tuple consisting of a set I of input vectors, a set O of output vectors, and a task specification map γ relating these two sets.*

We note that, by definition, decision tasks are inherently *one-shot* in the sense that all processes have a single input and must decide on a single output exactly once. Not all entries in a given input vector need contain an input value; some may contain the special value $\perp$, indicating that some processes do not receive an input value. We formalize this notion of participation in the definition below.

DEFINITION 2.8. *For any input vector $\vec{I}$, if the ith component is not $\perp$, then i* participates *in $\vec{I}$. Otherwise, we say that i does not participate in $\vec{I}$. Moreover, we define the* participating set *in $\vec{I}$ to be the set of participating indexes.*

As noted by Herlihy and Shavit [24, 25, 26], the reason for incorporating an explicit notion of participating indexes in our formalism for decision tasks is that it is convenient for capturing the intuitive notion of "order of actions in time" through the use of participating processes. For example, it allows us to distinguish between tasks such as *Unique-Id* and *Fetch-And-Increment*, which have the same sets of input and output vectors, have the same $\gamma(\mathcal{I})$ when all processes participate, but have quite different task specification maps when subsets of participating processes are taken into account.

$\vec{I}$	$\gamma(\vec{I})$
$(0,\perp,\perp)$	$(0,\perp,\perp),(1,\perp,\perp),(2,\perp,\perp)$
$(\perp,0,\perp)$	$(\perp,0,\perp),(\perp,1,\perp),(\perp,2,\perp)$
$(\perp,\perp,0)$	$(\perp,\perp,0),(\perp,\perp,1),(\perp,\perp,2)$
$(0,0,\perp)$	$(0,1,\perp),(1,0,\perp),(0,2,\perp),(0,2,\perp),(2,1,\perp),(1,2,\perp)$
$(0,\perp,0)$	$(0,\perp,1),(1,\perp,0),(0,\perp,2),(0,\perp,2),(2,\perp,1),(1,\perp,2)$
$(\perp,0,0)$	$(\perp,0,1),(\perp,1,0),(\perp,0,2),(\perp,0,2),(\perp,2,1),(\perp,1,2)$
$(0,0,0)$	$(0,1,2),(0,2,1),(1,0,2),(1,2,0),(2,0,1),(2,1,0)$

FIG. 1. *The Unique-Id task.*

$\vec{I}$	$\gamma(\vec{I})$
$(0,\perp,\perp)$	$(0,\perp,\perp)$
$(\perp,0,\perp)$	$(\perp,0,\perp)$
$(\perp,\perp,0)$	$(\perp,\perp,0)$
$(0,0,\perp)$	$(0,1,\perp),(1,0,\perp)$
$(0,\perp,0)$	$(0,\perp,1),(1,\perp,0)$
$(\perp,0,0)$	$(\perp,0,1),(\perp,1,0)$
$(0,0,0)$	$(0,1,2),(0,2,1),(1,0,2),(1,2,0),(2,0,1),(2,1,0)$

FIG. 2. *The Fetch-And-Increment task.*

EXAMPLE 2.9. *The $n+1$-process* Unique-Id *task is defined as follows: each participating process $i \in \{0,\ldots,n\}$ has an input $x_i = 0$ and chooses an output $y_i \in \{0,\ldots,n\}$ such that for any pair of processes $i \neq j$, $y_i \neq y_j$.*

EXAMPLE 2.10. *In the* Fetch-And-Increment *problem, each participating process $i \in \{0,\ldots,n\}$ has an input $x_i = 0$ and chooses a unique output $y_i \in \{0,\ldots,n\}$ such that* (1) *for some participating process i, $y_i = 0$, and* (2) *for $1 \leq k \leq n$, if $y_i = k$, then for some $j \neq i$, $y_j = k-1$.*

The tables in Figures 1 and 2, taken from [26], show the task specifications for *Unique-Id* and *Fetch-And-Increment* for three processes. Notice that *Unique-Id* allows identifiers to be assigned statically, while *Fetch-And-Increment* effectively requires

that they be assigned dynamically in increasing order. The first task has a trivial wait-free solution: statically preassign the values 0, 1, and 2 to the three processes. The second has no solution in read-write memory if one or more processes can fail.

2.3. Modeling objects, processes, and protocols. We formally model objects, processes, and protocols using a simplified form of the Input/Output (I/O) automaton formalism of Lynch and Tuttle [28]. An *I/O automaton* is a nondeterministic automaton with a finite or infinite set of *states*, a set of *input actions*, a set of *output actions*, and a transition relation given by a set of *steps*, each defining a state transition following a given action. An *execution* of an I/O automaton is an alternating sequence of states and enabled actions, starting from some initial state. An *execution fragment* is a subsequence of consecutive states and actions occurring in an execution. For simplicity we will use the term execution to mean either execution or execution fragment, the appropriate term being clear from the context. An automaton *history* is the subsequence of actions occurring in an execution. Automata can be composed by identifying input and output actions in the natural way (details can be found in [28]).

An *object* X is an automaton with input action $call(i, v, X, D)$ and output action $return(i, v, X, D)$, where i is a process id, v is a value, X an object, and D a data type. An action on object X by process i is said to occur on X's ith "port." A *process* i is an automaton with output actions $call(i, v, X, D)$, and $decide(i, v)$ and input actions $return(i, v, X, D)$ and $start(i, v)$. An *operation* is a *matching* pair of *call* and *return* actions, that is, having the same type, name, and process id. From here on we will abuse this notation for the sake of clarity by dropping unnecessary parameters and denoting others using subscripts.

A *protocol* $\mathcal{P} = \{0, \ldots, n; M\}$ is the automaton composed by identifying in the obvious way the actions for processes $0, \ldots, n$ and the memory M. A process i is said to *participate* in an execution of a protocol if the execution contains a $start(v)_i$ action. The set of participating processes is called the execution's *participating set*. Note that this definition of the participating set matches our earlier definition of a participating set of input vectors. To capture the notion that a process represents a single thread of control, a protocol execution is *well formed* if every process history (the projection of the history onto the actions of i) has a unique *start* action (generated externally to the protocol) which precedes any *call* or *return* actions, alternates matching *call* and *return* actions, and has at most one *decide* action. We restrict our attention to well-formed executions.

2.4. Solvability. We are interested in solvability in the face of arbitrary fail-stop failures [17] (such failures also model processes being arbitrarily delayed or halted). To capture the notion of processes having fail-stop failures, we add to the process automaton a unique $fail(i)$ event. A process's execution is thus a sequence of actions ending in either a *decide* or a *fail* action. If the execution ended in a *fail* action the process is said to be *faulty*. An execution is *t-faulty* if up to t processes become faulty.

DEFINITION 2.11. *A protocol* solves *a decision task in an execution if the following condition holds. Let* $\{i | i \in U\}$ *be the processes that have start actions, and let* $\{u_i | i \in U\}$ *be their arguments. Let* $\{j | j \in V\}$, $V \subseteq U$, *be the processes that execute decide actions, and let* $\{v_j | j \in V\}$ *be their output values. Let* $\vec{I}$ *be the input vector with* u_i *in component* i, *and* $\perp$ *elsewhere, and let* $\vec{O}$ *be the corresponding output vector for the* v_j. *We require that*

1. *no process takes an infinite number of steps without a decide or fail action, and*
2. $\vec{O}$ *is a prefix of some vector in* $\Delta(\vec{I})$.

Informally, the second condition implies that if a protocol solves a task in an execution, the outputs of the nonfaulty processes in any prefix of the execution are consistent with the allowable outputs of the possibly larger set of inputs to the execution as a whole. A protocol for N processes *wait-free solves* a decision task if it solves it in every t-faulty execution where $0 \leq t < N$. We will call such a protocol *wait-free* and henceforth use the term *solves* to mean *wait-free solves.*[1]

2.5. One-shot IS. Our memory model is based on Borowsky and Gafni's *IS object* [11], a model that has proven to be a useful building block for the construction and analysis of protocols in many asynchronous, distributed systems [11, 12, 24, 25, 26, 31].

Informally, an $n+1$-process IS object consists of a shared $n+1$-dimensional memory array and supports a single type of operation, called *writeread*. Each *writeread* operation writes a value to a single shared memory array cell, and returns a "snapshot" view of the entire array in the state immediately following the write—hence the name "immediate snapshot." A *writeread* operation by process i writes its value to the ith cell of the memory array.

Formally, we can specify IS objects as I/O automata [28]. Let D be any data type, and define $\vartheta(D)$ to be the data type $(D \cup \{\perp\})^{n+1}$, the set of all $n+1$-arrays each of whose cells contains either an element of D or $\perp$. We index the elements of $\vartheta(D)$ using the numbers in $\{0, \ldots, n\}$ and define $\vartheta^k(D)$ for $k \geq 2$ as $\vartheta(\vartheta^{k-1}(D))$, that is, a recursively growing vector of vectors. An IS automaton for $n+1$-processes and data type D called IS_x is defined as in Figure 3. We refer to such an object as an IS_D^{n+1} object. When the data type and number of processes are clear from the context, we usually omit the subscripts and superscripts above.

In Figure 3, the operation *writeread*$(v, S)_{i,x}$ by process i on IS_x writes the value v to the ith cell of *memory* and subsequently returns a snapshot S. The idea of the automaton specification is to capture the notion of an update of a memory array location followed immediately by a snapshot view of the entire array. Using a style similar to that of the atomic snapshot memory specification of [1], we record the history of invocations and responses using interface variables and allow the combined "write and snapshot" operation itself to occur via an internal automaton transition at some point between the invocation and associated response. Figure 4 shows a stylized diagram of the IS object IS_x.

For all i, the *inv_writeread*$(v)_{i,x}$ action simply writes the input value v to the ith cell of the *input_value* array of IS_x. This array provides temporary storage for inputs to the IS_D^{n+1} object. At the same time, the flag *"inv"* is written to the ith cell of the *interface* array, which indicates an input by process i. The *update*$(\mathcal{U})$ action is the internal transition that periodically copies a set of values corresponding to the indexes in $\mathcal{U}$ from the *input_value* array to the *memory* array. The set $\mathcal{U}$ must be a subset of the indexes i with the property that *interface*$[i] = inv$; in other words, these are operations that have been invoked by participating processes and have not yet been updated in memory. Additionally, a copy of the *memory* array is written to the ith cell of the *return_value* array for each $i \in \mathcal{U}$. This corresponds to an IS view being collected. Finally, the flag *"ret"* is written to the ith cell of the *interface* array for each $i \in \mathcal{U}$, indicating that a response value to the invocation by process i is available.

[1] Note that we use the standard notion of *wait-free* protocols [27] and not the more restrictive notion of *bounded wait-free* protocols [27] even though, given that we consider deterministic algorithms and that in our discussion the input space is finite, one could actually place a bound on the length of any wait-free execution.

IS_D^{n+1} *object named* IS_x

Signature
Inputs:
$inv\_writeread(v)_{i,x}$, $v \in D$, $i \in \{0, \ldots, n\}$.
Internals:
$update(\mathcal{U})$, $\mathcal{U} \subseteq \{0, \ldots, n\}$.
Outputs:
$ret\_writeread(S)_{i,x}$, $S \in \vartheta(D)$, $i \in \{0, \ldots, n\}$.
State
memory $\in \vartheta(D)$, initially $(\perp, \ldots, \perp)$.
input_value $\in \vartheta(D)$, initially $(\perp, \ldots, \perp)$.
return_value $\in \vartheta^2(D)$, initially $(\perp, \ldots, \perp)$.
interface $\in \{inv, ret, \perp\}^{n+1}$, initially $(\perp, \ldots, \perp)$.

Pre: $interface[i] = ret$
$return\_value[i] = S$
Eff: $interface[i] := \perp$

FIG. 3. *I/O automaton for an* IS_D^{n+1} *object with name* IS_x.

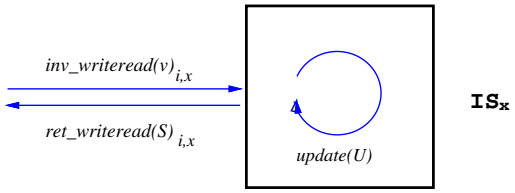

FIG. 4. *Diagram of* IS_x.

The $ret\_writeread(S)_{i,x}$ output action provides a response to a previous invocation by process i. Its only effect on the IS object is to reset the value $interface[i]$ to $\perp$, thereby preventing more than one response to an invocation. The $ret\_writeread(S)_{i,x}$ action can occur only after a return value has been written to the ith cell of the *return_value* array and the flag *"ret"* has been written to the corresponding cell in the *interface* array.

In the remainder of this section, we will state and prove a few basic properties about IS objects. These properties will be useful later, when we prove the correctness of a topological framework for analyzing the complexity of protocols in models of computation that include multiple IS objects.

In this paper we will consider only a restricted class of executions of IS_x, called *one-shot executions*, in which each object has at most one invocation and at most one response by any process.

LEMMA 2.12. *For any two distinct actions* $update(\mathcal{U})$ *and* $update(\mathcal{U}')$ *in a one-shot execution* α *of* IS_x, *the index sets* $\mathcal{U}$ *and* $\mathcal{U}'$ *are disjoint.*

Proof. Suppose without loss of generality that $\mathcal{U}$ occurs before $\mathcal{U}'$, and suppose $i \in \mathcal{U}$. Immediately after the action *update*($\mathcal{U}$), *interface[i]* is equal to *"ret."* Since we are considering a one-shot execution, *interface[i]* will not return to the value *"inv"* for the remainder of the execution. Hence, the precondition of the *update*($\mathcal{U}'$) action guarantees that $i \notin \mathcal{U}'$. □

We can now define what we mean by concurrent operations of IS_x.

DEFINITION 2.13. *Two operations writeread*$(v_i, S_i)_{i,x}$ *and writeread*$(v_j, S_j)_{j,x}$ *in a one-shot execution* α *of* IS_x *are concurrent if there exists an action update*($\mathcal{U}$) *in* α *such that* $i, j \in \mathcal{U}$.

The proof of the following lemma is immediate by construction.

LEMMA 2.14. *Consider any operation writeread*$(v_i, S_i)_{i,x}$ *in a one-shot execution* α *of* IS_x. *Then* $S_i[i] = v_i$.

The value returned by a *ret_writeread*$(S)_{i,x}$ action is a one-dimensional array of type $\vartheta(D)$. In the following lemma, we prove that IS_x exhibits the property that the set of snapshots returned in a one-shot execution can be totally ordered by the prefix relation defined in Definition 2.3.

LEMMA 2.15. *Consider any two writeread operations in a one-shot execution* α, *writeread*$(v_i, S_i)_{i,x}$ *and writeread*$(v_j, S_j)_{j,x}$. *Either* S_i *is a prefix of* S_j *or* S_j *is a prefix of* S_i.

Proof. Suppose the values v_i and v_j are written to *memory* by the actions *update*($\mathcal{U}_i$) and *update*($\mathcal{U}_j$), respectively.

If these actions are the same, that is, if $\mathcal{U}_i = \mathcal{U}_j$, the two operations *writeread*$(v_i, S_i)_{i,x}$ and *writeread*$(v_j, S_j)_{j,x}$ are concurrent. In this case, the value of *memory* that is copied to *return_value[i]* is identical to the value copied to *return_value[j]*, since both are copied by the same *update*($\mathcal{U}_i$) action. It follows that $S_i = S_j$. Now suppose $\mathcal{U}_i \neq \mathcal{U}_j$, and suppose *update*($\mathcal{U}_i$) occurs after *update*($\mathcal{U}_j$). Since no *memory* cells are ever reset, it follows that the *memory* version that is written to *return_value[j]* during *update*($\mathcal{U}_j$) is a prefix of the version that is written to *return_value[i]* during *update*($\mathcal{U}_i$). Hence S_j is a prefix of S_i. The case where *update*($\mathcal{U}_j$) occurs after *update*($\mathcal{U}_i$) is similar, and in this case we have that S_i is a prefix of S_j. The lemma follows. □

The next lemma concerns what is referred to in [11] as the *immediacy* property of *IS* objects. If a value written to *memory* by an invocation by process j is contained in a snapshot of an operation by process i, then the snapshot returned to process j is a prefix of that returned to process i. This corresponds to the informal notion of a *writeread* operation by j happening *before* a writeread operation by i.

LEMMA 2.16. *Consider any two writeread operations in a one-shot execution* α, *writeread*$(v_i, S_i)_{i,x}$ *and writeread*$(v_j, S_j)_{j,x}$. *If* $S_i[j] \neq \perp$, *then* S_j *is a prefix of* S_i.

Proof. Suppose the values v_i and v_j are written to *memory* by the actions *update*($\mathcal{U}_i$) and *update*($\mathcal{U}_j$), respectively, and suppose $S_i[j] \neq \perp$. This implies that either v_j was written to *memory* during *update*($\mathcal{U}_i$), in which case $\mathcal{U}_i = \mathcal{U}_j$, or the action *update*($\mathcal{U}_j$) occurred before *update*($\mathcal{U}_i$). In either case, we have that S_j must be a prefix of S_i. □

2.6. The NIIS model. Our *nonuniform iterated immediate snapshot (NIIS) model* is a variant of the iterated immediate snapshot (IIS) model, first used implicitly by Herlihy and Shavit [25, 26], and later formulated as a computation model by Borowsky and Gafni [12].

The IIS model assumes a bounded sequence $IS_D^{n+1}, IS_{\vartheta(D)}^{n+1}, IS_{\vartheta^2(D)}^{n+1}, \ldots, IS_{\vartheta^{k-1}(D)}^{n+1}$ of IS objects, denoted by $IS_1, IS_2, IS_3, \ldots, IS_k$, where $k > 0$. On a high level, the IIS

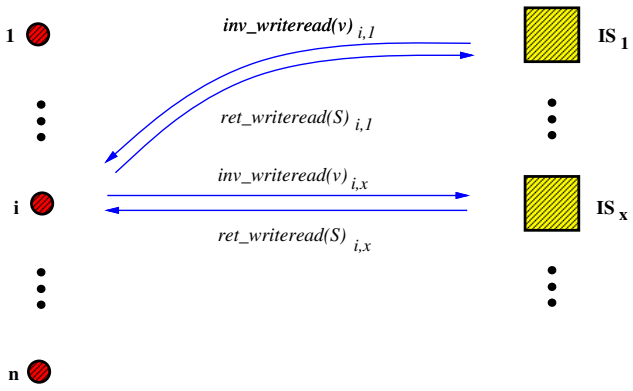

FIG. 5. *Diagram of the NIIS model.*

model has each participating process proceed in accessing IS objects in ascending order in the sequence. On each object it executes a *writeread(v)*$_{i,1}$ action, with v equal to its *local_state*. The response from each object, consisting of an IS of its shared memory vector, is provided as input to the next object accessed in the sequence, until k objects have been accessed. Once a process has received an output from the kth IS object, it applies a decision map δ to this value to create its returned decision value. We note that there is no loss of generality in assuming a "full information model" where the input to one *writeread* operation is the response by the previous one.

We generalize the IIS model by introducing the *NIIS model*. Unlike IIS, the NIIS model assumes an unbounded sequence $IS_D^{n+1}, IS_{\vartheta(D)}^{n+1}, IS_{\vartheta^2(D)}^{n+1}, \ldots$ of IS objects, denoted $IS_1, IS_2, IS_3, \ldots$. A stylized interconnection diagram of the k-shot IIS model is given in Figure 5. The number of IS objects accessed by any two distinct processes in a given execution need not be the same, and, moreover, the number of objects accessed by any fixed process may vary from execution to execution. The motivation behind this is to be able to model complexity more accurately. In a given execution it may be the case that the necessary amount of computation will vary from process to process, from input value to input value, and indeed from execution to execution. This cannot be captured by a uniform model such as IIS in which every execution of a given protocol will involve the same number of steps.

The only significant difference between a protocol $\mathcal{P}_{(n,\tau,\delta)}$ in the NIIS model and a protocol in the IIS model is that after each complete *writeread* operation, each process checks whether it has reached a final state by applying the predicate τ to the *local_state* variable. If τ returns `true`, the process executes a *decide(S)*$_i$ action and halts. Otherwise, it accesses the next IS object as in the IIS model, and so on. In fact, any protocol in the IIS model is equivalent to a protocol $\mathcal{P}_{(n,\tau,\delta)}$ in the NIIS model, in which the predicate τ simply checks whether the *local_state* variable is of type $\vartheta^k(D)$.

Notice that, unlike the IIS model, the NIIS model permits unbounded length executions (assuming an unbounded number of IS objects) for some choices of the termination predicate map τ. However, we will consider only protocols for which τ is chosen such that the entire system does not have any infinite executions.

Each protocol in the NIIS model is fully characterized by the maximum number $n+1$ of processes that can participate, a predicate function $\tau : \bigcup_{l=0}^{\infty} \vartheta^l(D) \to \{\texttt{true}, \texttt{false}\}$, which each process applies to its *local_state* variable after each com-

FIG. 6. *I/O automaton for process i running NIIS protocol.*

plete *writeread* operation to determine whether or not to decide, and a decision map $\delta : \bigcup_{l=0}^{\infty} \vartheta^l(D) \to D_O$, where D_O is an arbitrary data type, which we call the protocol's *output data type*. We refer to the protocol obtained by fixing these parameters as $\mathcal{P}_{(n,\tau,\delta)}$.

We specify each IS object as in Figure 3, and each process i as in Figure 6. The protocol can then be specified by composing the automata for the processes and the automata for IS objects by matching up invocations and responses from consecutive IS objects in the natural way. The resulting protocol automaton is denoted by $\mathcal{P}_{(n,\tau,\delta)} = \{0, 1, \ldots, n; IS_1, IS_2, \ldots\}$.

For any execution α of $\mathcal{P}_{(n,\tau,\delta)}$, the processes' input values can conveniently be represented using an $n+1$-dimensional *input vector* $\vec{I}$, as specified in the previous section, with input data type D. The ith entry of $\vec{I}$ is the input of process i. Similarly, the processes' output values in α can be represented using an $n+1$-dimensional *output vector* $\vec{O}$. The ith entry of $\vec{O}$ is the output of process i.

It should be noted that the notions of participating processes and sets defined for executions and input vectors are consistent; a process i participates in an execution α if and only if the index i participates in the input vector $\vec{I}$ corresponding to α. Therefore, when the meaning is clear from the context, we usually omit qualifying a participating set with an execution or input vector.

We note that we have added $fail_i$ actions to the protocol to achieve the stopping failure property. We note that by construction if α is an execution of $\mathcal{P}_{(n,\tau,\delta)}$ that contains a $fail_i$ action, then α contains no actions locally controlled by i ($inv\_writeread(v)_{i,x}$ or $decide(S)_i$) after the $fail_i$ action.

2.7. Complexity measures for the IIS and NIIS models. We now define the complexity measures to be used for analyzing the performance of protocols in the NIIS model. Since the IIS model is equivalent to a special case of the NIIS model, these measures also apply directly to the IIS model.

Let $\mathcal{P}_{(n,\tau,\delta)}$ be a protocol in the NIIS model solving a given decision task $\mathcal{D}$, let $\vec{I}$ be an input vector, and let α be any execution of $\mathcal{P}_{(n,\tau,\delta)}$ that corresponds to $\vec{I}$. For all i, let t_i be the number of IS objects accessed by process i in α. We first define the time complexity of the execution α.

DEFINITION 2.17. *The time complexity of α, denoted t_α, is $\max_i t_i$, the maximum number of IS objects accessed by any process.*

We note that t_α is well defined, since the number of processes $n+1$ is finite. Moreover, by definition of the max function, t_α is an integer value. We use the definition given above to define the time complexity of the protocol $\mathcal{P}$ on the input vector $\vec{I}$.

DEFINITION 2.18. *The time complexity of $\mathcal{P}_{(n,\tau,\delta)}$ on $\vec{I}$, denoted $t_{\vec{I}}$, is the supremum of the set $\{t_\alpha \mid t_\alpha$ is an execution corresponding to $\vec{I}\}$.*

Finally, we define the complexity of a protocol $\mathcal{P}_{(n,\tau,\delta)}$ on an input set I.

DEFINITION 2.19. *The time complexity of $\mathcal{P}_{(n,\tau,\delta)}$ on I, denoted t_I, is the supremum of the set $\{t_{\vec{I}} \mid \vec{I} \in I\}$.*

The reason for preferring these simple, discrete complexity measures over other, more elaborate, measures such as real time, for instance, is the highly regular structure of the IIS and NIIS models. We make the assumption that each access to an IS object takes the same amount of time and do not worry about breaking up the time required to complete each access to an IS object into subparts. Instead, we group the time spent on invocation, response, and on local computation at the IS object. This assumption is somewhat strong, as the presence of asynchrony in our model will tend to introduce varying delays for each access to an object. However, we believe that, as a first step toward a complexity theory, this assumption is justifiable, as it allows for complexity measures that are simple and easy to apply, and that have a particularly nice topological representation, as we will see in section 4.

3. A topological framework. In this section we first introduce some known tools from the field of algebraic topology and show how they may be used to model decision tasks and protocols in the NIIS model of computation. We then introduce a new tool for analyzing complexity in this setting, called the nonuniform iterated chromatic subdivision.

3.1. Basic topological definitions and concepts. This section introduces the basic topological definitions and concepts that we shall need for modeling decision tasks and wait-free protocols in the NIIS model. Some of these definitions are fairly standard and are mainly taken from popular textbooks on algebraic topology [30, 34], while others are due to Herlihy and Shavit [24, 25, 26]. The statements and proofs related to subdivisions are novel to this work. Some of the figures used in this section are also adopted from Herlihy and Shavit's work [24, 25, 26].

A *vertex* $\vec{v}$ is a point in a Euclidean space $\mathbb{R}^l$. A set $\{\vec{v}_0, \ldots, \vec{v}_n\}$ of vertexes is *geometrically independent* if and only if the set of vectors $\{\vec{v}_i - \vec{v}_0\}_{i=1}^n$ is linearly independent. Clearly, for a set of $n+1$ vertexes to be geometrically independent, $l \geq n$. We can now define the concept of a geometric simplex, or simplex for short.

DEFINITION 3.1. *Let $\{\vec{v}_0, \ldots, \vec{v}_n\}$ be a geometrically independent set of vertexes in $\mathbb{R}^l$. We define the n-simplex S spanned by $\vec{v}_0, \ldots, \vec{v}_n$ to be the set of all points x*

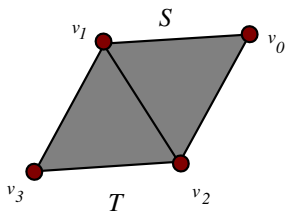

FIG. 7. *Example of a pure, two-dimensional simplicial complex.*

such that $x = \sum_{i=0}^{n} t_i \vec{v}_i$, *where* $\sum_{i=0}^{n} t_i = 1$ *and* $t_i \geq 0$ *for all* i.

For example, a 0-simplex is a vertex, a 1-simplex a line segment, a 2-simplex a solid triangle, and a 3-simplex a solid tetrahedron. For simplicity, we often denote the simplex spanned by a set $\{\vec{v}_0, \ldots, \vec{v}_n\}$ of geometrically independent vertexes as $(\vec{v}_0, \ldots, \vec{v}_n)$. The number n is called the *dimension* of the simplex S and is often denoted by $\dim(S)$. For clarity, we will sometimes include the number n as an explicit superscript when referring to a simplex; that is, we will write S^n to refer to the simplex spanned by the vertexes in $\{\vec{v}_0, \ldots, \vec{v}_n\}$.

Any simplex T spanned by a subset of $\{\vec{v}_0, \ldots, \vec{v}_n\}$ is called a *face* of S. The faces of S different from S itself are called the *proper* faces of S. The simplex spanned by the vertexes $\{\vec{v}_0, \vec{v}_1\}$ is a proper face of the 2-simplex S spanned by $\{\vec{v}_0, \vec{v}_1, \vec{v}_2\}$ in Figure 7.

The union of the proper faces of S is called the *boundary* of S and is denoted $Bd(S)$. The interior of S, denoted $\mathrm{Int}(S)$, is defined by the set equation $\mathrm{Int}(S) = S - Bd(S)$. For any set of points, the point

$$\vec{b} = \sum_{i=0}^{n} (\vec{v}_i/(n+1))$$

is their *barycenter*. The *barycenter* of a simplex S is the barycenter of its vertexes. In particular, if S is a vertex, then $\vec{b} = S$.

We will use a vertex to model the state of a single process, and a simplex to model consistent states of all the processes involved in solving a decision task or in running a protocol in the NIIS model. To model a collection of such states we need the concept of a geometric, simplicial complex, or complex for short, which is defined below.

DEFINITION 3.2. *A geometric simplicial complex* $\mathcal{K}$ *in the Euclidean space* $\mathbb{R}^l$ *is a collection of geometric simplexes in* $\mathbb{R}^l$ *such that*

- *every face* T *of every simplex* S *in* $\mathcal{K}$ *is contained in* $\mathcal{K}$, *and*
- *the intersection* U *of any two simplexes* S, T *in* K *is contained in* $\mathcal{K}$.

In this paper we will consider only finite complexes. The *dimension* of a complex $\mathcal{K}$, often denoted by $\dim(\mathcal{K})$, is the highest dimension of any of its simplexes and is also sometimes indicated explicitly by a superscript. An n-dimensional complex (or n-complex) is *pure* if every simplex is a face of some n-simplex. All complexes considered in this paper are pure unless stated otherwise. A simplex S in $\mathcal{K}$ with dimension $\dim(S) = \dim(\mathcal{K})$ is called a *maximal* simplex.

Given a simplex S, let $\mathcal{S}$ denote the complex of all faces of S, and let $\dot{\mathcal{S}}$ denote the complex consisting of all proper faces of S. We note that, since $\dot{\mathcal{S}}$ contains all faces

of S except S itself, $\dim(\dot{\mathcal{S}}) = \dim(S) - 1$. An example of a pure, two-dimensional simplicial complex, which we call $\mathcal{K}$, is shown in Figure 7. This complex equals the union of $\mathcal{S}$ and $\mathcal{T}$, where S is the 2-simplex spanned by $\{\vec{v}_0, \vec{v}_1, \vec{v}_2\}$, and T is the 2-simplex spanned by $\{\vec{v}_0, \vec{v}_1, \vec{v}_3\}$. Both S and T are maximal simplexes in this example.

If $\mathcal{L}$ is a subcollection of simplexes in $\mathcal{K}$ that is closed under containment and intersection, where $\dim(\mathcal{L}) \leq \dim(\mathcal{K})$, then $\mathcal{L}$ is a complex in its own right. It is called a *subcomplex* of $\mathcal{K}$. For example, the complex $\dot{\mathcal{S}}$ of faces of S is a subcomplex of $\mathcal{K}$ in Figure 7.

One subcomplex of a complex $\mathcal{K}$ of particular interest is the subcomplex of all simplexes in $\mathcal{K}$ of dimension at most p, where p is some integer between 0 and $\dim(\mathcal{K})$. We call this subcomplex the pth *skeleton* of a $\mathcal{K}$, denoted $skel^p(\mathcal{K})$. The elements of the collection $skel^0(\mathcal{K})$ are called the 0-*simplexes* of $\mathcal{K}$. The 0-skeleton of the complex $\mathcal{K}$ in Figure 7 is the collection of 0-simplexes $\{(\vec{v}_0), (\vec{v}_1), (\vec{v}_2), (\vec{v}_3)\}$. Similarly, the 1-skeleton of $\mathcal{K}$ is the union of the 0-skeleton described above and the collection $\{(\vec{v}_0, \vec{v}_1), (\vec{v}_0, \vec{v}_2), (\vec{v}_1, \vec{v}_2), (\vec{v}_1, \vec{v}_3), (\vec{v}_2, \vec{v}_3)\}$.

Let $|\mathcal{K}|$ be the subset $\bigcup_{S \in \mathcal{K}} S$ of $\mathbb{R}^l$ that is the union of the simplexes of $\mathcal{K}$. Giving each simplex its natural topology as a subspace of $\mathbb{R}^l$, we topologize $|\mathcal{K}|$ by declaring a subset A of $|\mathcal{K}|$ to be closed if and only if $A \cap S$ is closed for all $S \in \mathcal{K}$. This space is called the *polytope* of $\mathcal{K}$. Conversely, $\mathcal{K}$ is called a *triangulation* of $|\mathcal{K}|$.

In practice, the geometric representations we have given for simplexes and complexes are not always convenient, since the analytic geometry involved can get quite involved. Therefore, we introduce the notions of *abstract simplexes* and *abstract complexes*.

DEFINITION 3.3. *An abstract simplex S is a finite, nonempty set.*

The *dimension* of S is its cardinality. Each nonempty subset T of S is called a *face* of S. Each element of S is called a *vertex* of S. There is a close relationship between geometric simplexes and abstract simplexes. Any geometrically independent set of vectors $\{\vec{v}_0, \ldots, \vec{v}_n\}$ not only spans a geometric simplex; it also forms an abstract simplex.

DEFINITION 3.4. *An abstract complex $\mathcal{K}_a$ is a collection of abstract simplexes, such that if S is in $\mathcal{K}_a$, so is any face of S.*

Most concepts defined for geometric complexes immediately carry over to abstract complexes; the *dimension* of $\mathcal{K}_a$, often denoted by $\dim(\mathcal{K}_a)$, is the highest dimension of any of its simplexes. An n-dimensional abstract complex (or n-complex) is *pure* if every simplex is a face of some n-simplex. If $\mathcal{L}_a$ is a subcollection of $\mathcal{K}_a$ that is itself an abstract complex, then $\mathcal{L}_a$ is called a *subcomplex* of $\mathcal{K}_a$.

DEFINITION 3.5. *Let $\mathcal{K}$ be a geometric complex, and let V be the vertex set of $\mathcal{K}$. Let $\mathcal{K}_a$ be the abstract complex of all subsets S of V such that S spans a simplex in $\mathcal{K}$. Then $\mathcal{K}_a$ is called the* vertex scheme *of $\mathcal{K}$.*

DEFINITION 3.6. *Two abstract complexes $\mathcal{K}_a$ and $\mathcal{L}_a$ are* isomorphic *if there is a bijective correspondence ψ between their vertex sets such that a set S of vertexes is in $\mathcal{K}_a$ if and only if $\psi(S) \in \mathcal{L}_a$. The bijective correspondence ψ is called an* isomorphism.

THEOREM 3.7. *Every abstract complex $\mathcal{K}_a$ is isomorphic to the vertex scheme of some geometric complex $\mathcal{K}$ in $\mathbb{R}^{2\dim(\mathcal{K}_a)+1}$.*

We will not prove this theorem here. For a proof, see any standard textbook on algebraic topology [30, 34]. In the rest of this paper, for convenience, we will often use abstract and geometric representations of simplexes and complexes interchangeably.

We now define a way of "adding" simplexes, known as *starring*.

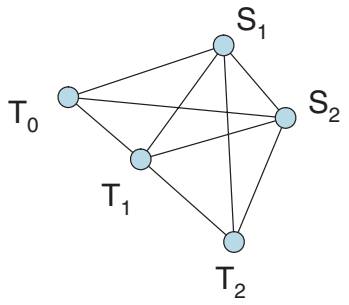

FIG. 8. *The star of two complexes S and T.*

DEFINITION 3.8. *Let $S = (s_0, \ldots, s_p)$ and $T = (t_0, \ldots, t_q)$ be simplexes whose combined sets of vertexes are affinely independent. Then the* star *of S and T, denoted $S \star T$, is the simplex $(s_0, \ldots, s_p, t_0, \ldots, t_q)$.*

We may extend the notion of starring to complexes as well.

DEFINITION 3.9. *Let $\mathcal{K}$ and $\mathcal{L}$ be simplicial complexes, not necessarily of the same dimension. Then the* star *of $\mathcal{K}$ and $\mathcal{L}$, denoted $\mathcal{K} \star \mathcal{L}$, is the collection of simplexes $\mathcal{K} \cup \mathcal{L} \cup \{S \star T \mid S \in \mathcal{K}, T \in \mathcal{L}\}$.*

The star of two complexes $\mathcal{K}$ and $\mathcal{L}$ is a complex in its own right [30]. Figure 8 shows a complex consisting of two 3-simplexes and all their faces resulting from starring the complex S which includes the 1-simplex (s_0, s_1) and all its faces, and the complex T consisting of the two 1-simplexes (t_0, t_1) and (t_1, t_2) and all their faces.

The remainder of this section, however, which introduces a number of important topological concepts, such as simplicial maps, subdivisions, and carriers, is set in the context of geometric complexes.

We first define the notions of simplicial vertex maps and simplicial maps from one complex into another.

DEFINITION 3.10. *Let $\mathcal{K}$ and $\mathcal{L}$ be complexes, possibly of different dimensions, and let $\mu : skel^0(\mathcal{K}) \to skel^0(\mathcal{L})$ be a function mapping vertexes to vertexes. Suppose that whenever the vertexes $\vec{v}_0, \ldots, \vec{v}_n$ of $\mathcal{K}$ span a simplex of $\mathcal{K}$, the vertexes $\mu(\vec{v}_0), \ldots, \mu(\vec{v}_n)$ span a simplex of $\mathcal{L}$. Then μ is called a simplicial vertex map from $\mathcal{K}$ to $\mathcal{L}$. μ can be extended to a continuous map $\mu_* : |\mathcal{K}| \to |\mathcal{L}|$ such that*

$$x = \sum_{i=0}^{n} t_i \vec{v}_i \Rightarrow \mu_*(x) = \sum_{i=0}^{n} t_i \mu_*(\vec{v}_i).$$

This continuous extension is called a simplicial map from $\mathcal{K}$ to $\mathcal{L}$.

For simplicity, we henceforth refer to the simplicial vertex map μ as the simplicial map, without actual reference to the continuous extension μ_*, which is less relevant for our purposes. As a further abuse of notation, we usually write $\mu : \mathcal{K} \to \mathcal{L}$ when we refer to the simplicial vertex map, glossing over the fact that this map is in fact defined only on the vertexes of $\mathcal{K}$, and that the image of the map is a subset of the vertex set of $\mathcal{L}$. Henceforth, unless stated otherwise, all maps between complexes are assumed to be simplicial. An example of a simplicial map is given in Figure 9.

We note that a simplex and its image under a simplicial map need not have the same dimension. A simplicial map $\mu : \mathcal{K} \to \mathcal{L}$ is *noncollapsing* if it preserves dimension; that is, for all $S \in \mathcal{K}$: $\dim(\mu(S)) = \dim(S)$.

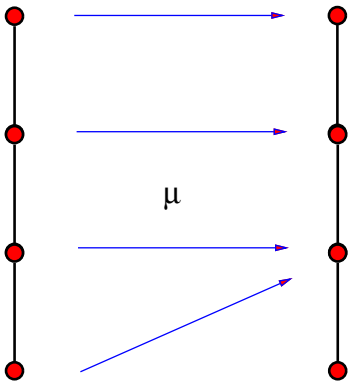

FIG. 9. *Example of a simplicial map between two complexes.*

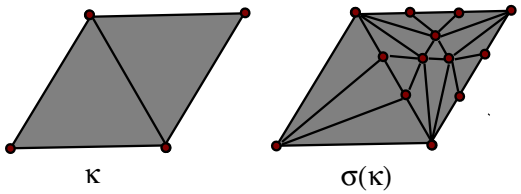

FIG. 10. *Example of a pure, two-dimensional simplicial complex and a subdivision of it.*

DEFINITION 3.11. *A* coloring *of an n-dimensional complex $\mathcal{K}$ is a noncollapsing simplicial map $\chi : \mathcal{K} \to \mathcal{S}$, where S is an n-simplex.*

Intuitively, a coloring corresponds to a labeling of the vertexes of the complex such that no two neighboring vertexes (connected by a 1-simplex) have the same label. A *chromatic complex* $(\mathcal{K}, \chi)$ is a complex $\mathcal{K}$ together with a coloring χ of $\mathcal{K}$. When it is clear from the context, we specify the chromatic complex $(\mathcal{K}, \chi)$ simply as the complex $\mathcal{K}$, omitting explicit mention of the coloring χ.

DEFINITION 3.12. *Let $(\mathcal{K}, \chi_{\mathcal{K}})$ and $(\mathcal{L}, \chi_{\mathcal{L}})$ be chromatic complexes, and let $\mu : \mathcal{K} \to \mathcal{L}$ be a simplicial map. We say that μ is* chromatic *if, for every vertex $\vec{v} \in \mathcal{K}$, $\chi_{\mathcal{K}}(\vec{v}) = \chi_{\mathcal{L}}(\mu(\vec{v}))$.*

In other words, μ is chromatic if it maps each vertex in $\mathcal{K}$ to a vertex in $\mathcal{L}$ of the same color. All the simplicial maps we consider in this paper are chromatic. We can now define the concepts of a *subdivision* of a complex and the *carrier* of a simplex in a subdivision.

DEFINITION 3.13. *Let $\mathcal{K}$ be a complex in $\mathbb{R}^l$. A complex $\sigma(\mathcal{K})$ is said to be a* subdivision *of $\mathcal{K}$ if the following two conditions hold:*

- *Each simplex in $\sigma(\mathcal{K})$ is contained in a simplex in $\mathcal{K}$.*
- *Each simplex of $\mathcal{K}$ equals the union of finitely many simplexes in $\sigma(\mathcal{K})$.*

An example of a complex and its subdivision is given in Figure 10.

DEFINITION 3.14. *If S is a simplex of $\sigma(\mathcal{K})$, the* carrier *of S, denoted carrier(S), is the unique smallest $T \in \mathcal{K}$ such that $S \subset T$.*

The concept of a carrier of a simplex is illustrated in Figure 11. The original

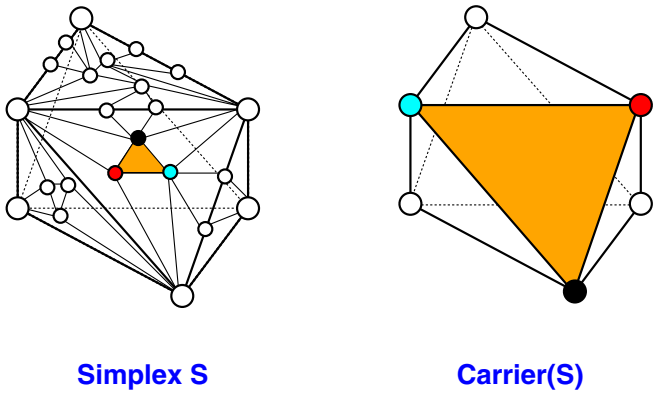

FIG. 11. *The carrier of a simplex.*

complex is shown on the right, and the subdivided complex is shown on the left. A simplex S in the subdivision and the corresponding carrier $carrier(S)$ in the original complex are highlighted in the figure.

A *chromatic subdivision* of $(\mathcal{K}, \chi_{\mathcal{K}})$ is a chromatic complex $(\sigma(\mathcal{K}), \chi_{\sigma(\mathcal{K})})$ such that $\sigma(\mathcal{K})$ is a subdivision of $\mathcal{K}$, and for all S in $\sigma(\mathcal{K})$, $\chi_{\sigma(\mathcal{K})}(S) \subseteq \chi_{\mathcal{K}}(carrier(S))$. A simplicial map $\mu : \sigma_1(\mathcal{K}) \to \sigma_2(\mathcal{K})$ between chromatic subdivisions of $\mathcal{K}$ is *carrier preserving* if for all $S \in \sigma_1(\mathcal{K})$, $carrier(S) = carrier(\mu(S))$. All subdivisions we consider in this paper will be chromatic, unless explicitly stated otherwise.

3.2. Topological modeling of decision tasks. Earlier in this section, we defined the notion of a decision task in terms of input and output vectors. That definition was intended to help the reader understand what a decision task is, but it lacks the mathematical structure necessary to prove interesting results. We now reformulate this definition in terms of simplicial complexes. To illustrate our constructions, we will first explain on a high level how to topologically model tasks, specifically the well-known Unique-Id task of Example 2.9. We will then provide detailed topological definitions of decision tasks.

We represent all possible input vectors to a task as a simplicial complex. In the case of the *Unique-Id* task, there is a (unique) $n+1$-dimensional input vector $\vec{I} = [0, \ldots, 0]$ represented as a simplex S, with dimension $0 \leq \dim(S) \leq n$. The dimension of S equals the number of non-$\perp$ elements in the vector.

From here on, each vertex $\vec{v}$ in a simplex S will be labeled with a process id and an input value. We will use $ids(S)$ to denote a simplex S's set of process ids (similarly for a complex), and $vals(S)$ to denote the multiset of values in S (similarly for a complex). If $\vec{J}$ is a prefix of $\vec{I}$, then the simplex corresponding to $\vec{J}$ is a face of S. The set I of input vectors is thus modeled as a complex $\mathcal{I}$ of input simplexes, called the *input complex*. For the *Unique-Id* task each vertex in $\vec{I}$ is labeled $\langle i, v_i \rangle$, where $\vec{I}[i] = v_i = 0$.

Similarly, the set O of output vectors is modeled as a complex $\mathcal{O}$ of output simplexes, called the *output complex*. In the *Unique-Id* task we represent each $n+1$-dimensional output vector $\vec{O} = [x_1, \ldots, x_n]$, where for all i, j, either $x_i = \perp$ or $0 \leq x_i \leq n$ and $(x_i = x_j) \Rightarrow (x_i = \perp)$, as a simplex T, with dimension $0 \leq \dim(T) \leq n$. Each vertex $\vec{v}$ in T is labeled with a process id and an output value $\langle i, v_i \rangle$, where $\vec{O}[i] = v_i$. As before, if $\vec{P}$ is a prefix of $\vec{O}$, then the simplex corresponding to $\vec{P}$ is a face of T.

A *topological task specification map* Γ maps the input complex to the output complex in a way that captures the input/output vector relation γ of a given task. The *Unique-Id* task induces a topological task specification map Γ in the natural way, mapping each input simplex $S \in \mathcal{I}$ to a set $\Gamma(S)$ of output simplexes in $\mathcal{O}$, with the property that for all $T \in \Gamma(S)$, the set $vals(T)$ contains no non-$\perp$ duplicates.

We can now give an alternative, topological representation of the *Unique-Id* decision task by simply specifying it as a tuple $\mathcal{D} = \langle \mathcal{I}, \mathcal{O}, \Gamma \rangle$ consisting of an input complex $\mathcal{I}$, an output complex $\mathcal{O}$, and a topological task specification map Γ.

This topological representation gives an alternative interpretation of the notion of "similar" system states. The processes corresponding to vertexes on the common boundary of the two simplexes cannot distinguish between the two global output sets based on their own output values. Unlike graph-theoretic models (e.g., [7]), simplicial complexes capture in a natural way the notion of the *degree* of similarity between the two global output sets: it is the dimension of the intersection of the two 2-simplexes.

We now give a formal procedure for how to specify a given decision task $\mathcal{D} = \langle I, O, \gamma \rangle$ topologically. We first construct a representation using abstract simplexes and complexes. It then follows from Theorem 3.7 that there exists a representation using geometric simplexes and complexes for which the vertex scheme is isomorphic to the abstract representation. There are standard ways of constructing such geometric complexes [30], but we choose not to get into the details of these constructions in this paper.

DEFINITION 3.15. *Let $\vec{I} \in I$ be an input vector. The* input simplex *corresponding to $\vec{I}$, denoted $S(\vec{I})$, is the abstract simplex $(\langle i_0, v_{i_0} \rangle, \ldots, \langle i_m, v_{i_m} \rangle)$, where $v_{i_j} = \vec{I}[i_j]$, and where for all i_j, $i_0 \leq i_j \leq i_m$, $i_j \in \{0, \ldots, n\} \wedge \vec{I}[i_j] \neq \perp$, and for all i, $(\vec{I}[i] = \perp) \Rightarrow (i \notin \{i_0, \ldots, i_m\})$.*

DEFINITION 3.16. *Let $\vec{O} \in O$ be an output vector. The* output simplex *corresponding to $\vec{O}$, denoted $T(\vec{O})$, is the abstract simplex $(\langle i_0, v_{i_1} \rangle, \ldots, \langle i_m, v_{i_m} \rangle)$, where $v_{i_j} = \vec{O}[i_j]$, and where for all i_j, $i_0 \leq i_j \leq i_m$, $i_j \in \{0, \ldots, n\} \wedge \vec{O}[i_j] \neq \perp$, and for all i, $(\vec{O}[i] = \perp) \Rightarrow (i \notin \{i_0, \ldots, i_m\})$.*

In other words, the vertexes in an input/output simplex correspond exactly to the non-$\perp$ values of the input/output vectors. Having defined input and output simplexes, we can define input and output complexes.

DEFINITION 3.17. *The* input complex *corresponding to I, denoted $\mathcal{I}$, is the collection of input simplexes $S(\vec{I})$ corresponding to the input vectors of I.*

DEFINITION 3.18. *The* output complex *corresponding to O, denoted $\mathcal{O}$, is the collection of output simplexes $T(\vec{O})$ corresponding to the output vectors of O.*

Definitions 3.17 and 3.18 make sense topologically due to the following lemma which follows from the fact that the sets of input and output vectors we consider are prefix-closed (see Definition 2.5).

LEMMA 3.19. *Given a set I of input vectors (alternatively a set O of output vectors), the corresponding input complex $\mathcal{I}$ (output complex $\mathcal{O}$), as defined in Definition* 3.17*, is an abstract, chromatic complex.*

Given a pair of (abstract) input and output complexes, we may apply Theorem 3.7 to construct a corresponding pair of geometric chromatic input and output complexes by embedding the abstract complexes in $\mathbb{R}^{2n+1}$. As discussed in section 3.1, we will

thus work with both interchangeably in the remainder of this paper.

We now construct a topological equivalent of the task specification map $\gamma \subseteq I \times O$.

DEFINITION 3.20. *The* topological task specification map *corresponding to* γ*, denoted* $\Gamma \subseteq \mathcal{I} \times \mathcal{O}$*, is defined as follows:*

$$(S(\vec{I}), T(\vec{O})) \in \Gamma \iff (\vec{I}, \vec{O}) \in \gamma.$$

As a convenient notation, for all $S(\vec{I}) \in \mathcal{I}$, we denote the set of simplexes $T(\vec{O})$ in $\mathcal{O}$ such that $(S(\vec{I}), T(\vec{O})) \in \Gamma$ by $\Gamma(S(\vec{I}))$. Usually, we simply refer to a topological task specification map as a "task specification map." We now prove that task specifications are id-preserving; if a process i has an input value, it must also have an output value, and vice versa.

LEMMA 3.21. *For all* $S(\vec{I}) \in \mathcal{I}$*, and all* $T(\vec{O}) \in \Gamma(S(\vec{I}))$*,* $ids(T) = ids(S)$.

Proof. Let $S(\vec{I})$ be any simplex in $\mathcal{I}$, and let $T(\vec{O}) \in \Gamma(S(\vec{I}))$. Then $\vec{O} \in \gamma(\vec{I})$ by Definition 3.20. Suppose $i \notin ids(S(\vec{I}))$. Then $\vec{I}[i] = \perp$ by Definition 3.15, and hence by Definition 2.6, $\vec{O}[i] = \perp$. It follows from Definition 3.16 that $i \notin ids(T(\vec{O}))$. Now suppose $i \notin ids(T(\vec{O}))$. Then $\vec{O}[i] = \perp$ by Definition 3.16, and hence by Definition 2.6, $\vec{I}[i] = \perp$. It follows from Definition 3.15 that $i \notin ids(S(\vec{I}))$. ∎

A schematic illustration of a topological decision task specification is given in Figure 12.

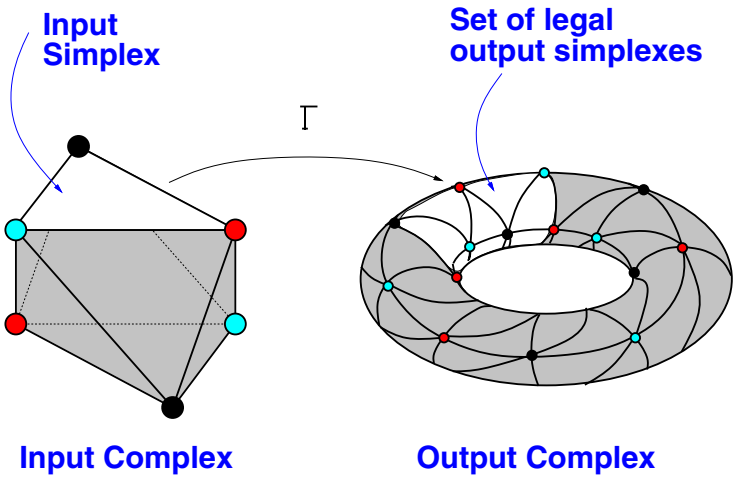

FIG. 12. *A decision task.*

DEFINITION 3.22. *Given a decision task* $\mathcal{D} = \langle I, O, \gamma \rangle$*, the corresponding* topological representation *of the task, denoted* $\mathcal{D} = \langle \mathcal{I}, \mathcal{O}, \Gamma \rangle$*, consists of an input complex* $\mathcal{I}$ *corresponding to* I*, an output complex* $\mathcal{O}$ *corresponding to* O*, and a task specification map* Γ *corresponding to* γ.

In the remainder of this paper, we will specify decision tasks using Definitions 2.7 and 3.22 interchangeably. A set of inputs or outputs may thus be specified as either a vector or a simplex, the vertexes of which are labeled with process ids and values.

3.3. Topological modeling of NIIS protocols. We model protocols in the NIIS model in much the same way that we model decision tasks. As discussed in section 2, the sets of inputs and outputs for any execution α of a protocol $\mathcal{P}_{(n,\tau,\delta)}$

in the NIIS model can be modeled using $n + 1$ process input and output vectors. We denote the sets of input vectors and output vectors of a protocol by I and O, respectively. We are interested only in protocols that solve decision tasks, so we may assume that the set I of possible input vectors to a protocol is prefix-closed. The following lemma states that for any protocol in the NIIS model, the set O of possible output vectors from all executions of the protocol must necessarily be prefix-closed. Recall from section 2.6 that we are considering only the set of fair (and hence finite) executions of a protocol here.

LEMMA 3.23. *Let O be the set of possible output vectors of a protocol $\mathcal{P}_{(n,\tau,\delta)}$ in the NIIS model, with a corresponding set of input vectors I. Then O is prefix-closed.*

Proof. Let $\vec{O}$ be an output vector produced by the execution α_O, and let $\vec{P}$ be a prefix of $\vec{O}$. We construct an execution α_P as follows: For each i such that $\vec{O}[i] = v_i \neq \perp = \vec{P}[i]$, replace the action *decide(S)*$_i$ (S is the output value returned by that action) in α_O with a *fail*$_i$ action, meaning that process i fail-stopped before deciding. Clearly, the execution thus obtained is a possible execution of $\mathcal{P}_{(n,\tau,\delta)}$, and its output vector is $\vec{P}$. Hence $\vec{P}$ is in O, and O is prefix-closed. □

Given that both the set of input vectors I and the set of output vectors O associated with a protocol $\mathcal{P}_{(n,\tau,\delta)}$ are prefix-closed sets of vectors, we can construct corresponding input and output complexes, denoted $\mathcal{I}$ and $\mathcal{P}_{(n,\tau,\delta)}(\mathcal{I})$, respectively. These complexes are constructed in the same way as the complexes corresponding to input and output sets of vectors for decision tasks, and the proofs that they are indeed chromatic complexes are also identical. The output complex $\mathcal{P}_{(n,\tau,\delta)}(\mathcal{I})$ is called a *protocol complex*.

Let $\mathcal{J}$ be a subcomplex of the input complex $\mathcal{I}$. The set of possible outputs when the protocol is given inputs corresponding to simplexes in $\mathcal{J}$ is denoted $\mathcal{P}_{(n,\tau,\delta)}(\mathcal{J})$.

LEMMA 3.24. *Let $\mathcal{J}$ be a subcomplex of $\mathcal{I}$. Then $\mathcal{P}_{(n,\tau,\delta)}(\mathcal{J})$ is a subcomplex of $\mathcal{P}_{(n,\tau,\delta)}(\mathcal{I})$.*

Proof. It suffices to show that $\mathcal{P}_{(n,\tau,\delta)}(\mathcal{J})$ is a complex, since $\mathcal{P}_{(n,\tau,\delta)}(\mathcal{J})$ is clearly a subset of $\mathcal{P}_{(n,\tau,\delta)}(\mathcal{I})$. Consider the set of vectors J corresponding to the subcomplex $\mathcal{J}$ as the set of input vectors to the protocol $\mathcal{P}_{(n,\tau,\delta)}$. This set is prefix-closed since $\mathcal{J}$ is a complex and hence is closed under containment. Hence the set P of output vectors given input vectors in J is prefix-closed by Lemma 3.23. It follows that the complex corresponding to $\mathcal{P}_{(n,\tau,\delta)}$ with input complex $\mathcal{J}$, denoted $\mathcal{P}_{(n,\tau,\delta)}(\mathcal{J})$, is by construction a complex and hence a subcomplex of $\mathcal{P}_{(n,\tau,\delta)}(\mathcal{I})$. □

In the remainder of this paper, we will specify protocols in NIIS using both its formal specification from section 2.6 as well as protocol complexes as described in this section interchangeably. A set of inputs or outputs may thus be specified as either a vector or a simplex, the vertexes of which are labeled with process ids and values.

3.4. Subdivisions. The standard chromatic subdivision was introduced by Herlihy and Shavit as part of their work on asynchronous computability [24, 25, 26]. It is essentially a chromatic generalization of the standard barycentric subdivision from classical algebraic topology [30, 34]. In this section, we will present a complete, formal definition of the standard chromatic subdivision, together with a proof that it is, in the topological sense, a chromatic subdivision of a given complex. As noted earlier, such a proof also provides the necessary formal basis for the use of the standard chromatic subdivision in [12, 26]. We note that our definition is somewhat different from that of Herlihy and Shavit [24, 25, 26], as it is based on an explicit, inductive, geometric construction. We also introduce the concept of a *nonuniform chromatic subdivision*, a generalization of the standard chromatic subdivision, in which the different simplexes

of a complex are not necessarily subdivided the same number of times. Informally, a nonuniform chromatic subdivision of level 1 of a complex $\mathcal{K}$, denoted by $\widetilde{\mathcal{X}}^1(\mathcal{K})$, is constructed by choosing, for each n-simplex in $\mathcal{K}$, a *single* face of the simplex (a face can be of any dimension and can also be the whole simplex) to which we apply the standard chromatic subdivision. We then induce the subdivision onto the rest of the simplex. The subdivisions of any two intersecting simplexes must be such that they agree on their shared face. Examples can be seen in Figure 13. Its right-hand side shows a valid nonuniform chromatic subdivision of a complex where, for example, the simplex (b, c, d)'s subdivision is the result of subdividing the 1-face (c, d) once and then inducing this subdivision onto the rest of the simplex. The left-hand side structure is not a legal subdivision, since the subdivision of the simplex (b, c, d) does not agree with that of the simplex (a, b, d) on the shared face (b, d). This structure is not even a simplicial complex, since it contains an object that is not a simplex (the cross-hatched region in Figure 13). A kth level nonuniform chromatic subdivision of a complex $\mathcal{K}$, denoted by $\widetilde{\mathcal{X}}^k(\mathcal{K})$, is generated by repeating this process k times, where only simplexes in faces that were subdivided in round $k-1$ can be subdivided in phase k. The complex on the right-hand side of Figure 13 is an example of a nonuniform chromatic subdivision of level 2, since the face (a, d) is subdivided twice.

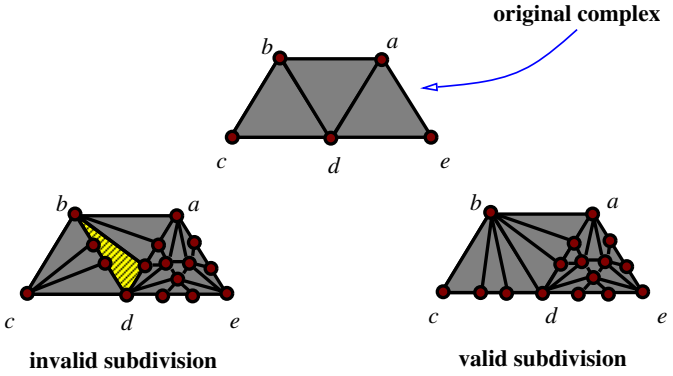

FIG. 13. *Valid and invalid nonuniform subdivisions.*

Later in this section we will show that the nonuniform chromatic subdivisions correspond in a natural way to the set of protocol complexes in the NIIS model of computation. As an execution in the NIIS model unfolds, some processes continue to step through IIS objects while others fail or decide. For a given input simplex, each transition through an IIS object by a subset of processes will correspond to a subdivision of the face corresponding to their respective vertexes. The other faces of the simplex, ones corresponding to the remaining processes, are not subdivided further, corresponding to the idea that the respective processes have either failed or decided. In the input complex, input simplexes sharing the same face have compatible subdivisions. As it turns out, each nonuniform standard chromatic subdivision is equal to some NIIS protocol complex (up to isomorphism).

3.4.1. The standard chromatic subdivision. In this section we provide our definition of the *standard chromatic subdivision* and prove that this definition does indeed specify a chromatic subdivision of a given complex.

Let $\mathcal{K}$ be a pure, n-dimensional, chromatic geometric complex, where the colors are the numbers in $0, \ldots, n$. Label each vertex $\vec{v}$ in $\mathcal{K}$ with $\langle i, v_i \rangle$, where i is the color

(process id) of $\vec{v}$ denoted also as $id(\vec{v})$, and v_i is a value (denoted also as $val(\vec{v})$) in some set D_I chosen such that no two vertexes in $\mathcal{K}$ have the same label. Note that two adjacent vertexes may have the same values if they have different colors. We define the standard chromatic subdivision of $\mathcal{K}$ by inductively defining a sequence of subdivisions $\mathcal{L}_p$ of the skeletons of $\mathcal{K}$, $0 \leq p \leq n$, as follows. We begin with the following auxiliary definition of the *containment conditions* among labeled vertexes.

DEFINITION 3.25. *For any set of simplexes $T = (\vec{t_0}, \ldots, \vec{t_r})$ in a complex $\mathcal{K}$ with labels $\langle i, S_i \rangle$, where S_i is the vertex scheme of some subset of simplexes in $\mathcal{K}$, define the* containment conditions *on the labels of T for any $1 \leq i, j \leq r$, $i \neq j$, as follows:*

C1. $id(\vec{t_i}) \neq id(\vec{t_j})$.

C2. $id(\vec{t_i}) \in ids(val(\vec{t_i}))$.

C3. $val(\vec{t_i})$ *is a face of* $val(\vec{t_j})$ *or vice versa.*

C4. $id(\vec{t_j}) \in ids(val(\vec{t_i})) \Rightarrow val(\vec{t_j})$ *is a face of* $val(\vec{t_i})$.

Condition C1 simply states that the given simplex is chromatic; that is, vertexes are colored with different ids. The remaining three conditions, which we will elaborate on shortly, will be used to capture the relation among the values written and read by a collection of *writeread* operations. In a nutshell, if one thinks of the $id(\vec{t_i})$ as the value written and the $ids(val(\vec{t_i}))$ as the IS value returned, then conditions C2, C3, and C4 correspond to the properties in Lemmas 2.14, 2.15, and 2.16.

We inductively define $\mathcal{L}_p$. Let $\mathcal{L}_0 = skel^0(\mathcal{K})$. Inductively assume that $\mathcal{L}_{p-1}$ is a chromatic subdivision of the $p-1$-skeleton of $\mathcal{K}$ where each vertex $\vec{v}$ in $\mathcal{L}_{p-1}$ is labeled $\langle i, S_i \rangle$, and where S_i is the vertex scheme of some simplex in $skel^{p-1}(\mathcal{K})$. We further assume that the labels $\langle i, S_i \rangle$ are such that any $T = (\vec{t_0}, \ldots, \vec{t_r})$, where $r \leq p-1$, is a simplex in $\mathcal{L}_{p-1}$ if and only if $ids(T) \subseteq ids(carrier(T))$ and for all $1 \leq i, j \leq r$, $i \neq j$, the labels of T meet the containment conditions of Definition 3.25.

Figure 14 describes a simplex (S_0, S_1, S_2) whose $\mathcal{L}_0$ subdivision includes the black vertexes. It has been subdivided by $\mathcal{L}_1$, causing each simplex in $\mathcal{L}_0$ to be split in three by the two new vertexes in grey. Note that each of these pairs of vertexes has a different *id* but the same value field which represents the vertex scheme of its carrier $\mathcal{L}_0$ simplex. The reader can check that the labels of these vertexes meet the four containment conditions of Definition 3.25. If we think of the value fields of vertexes as representations of the return value of an IS *writeread* operation, then the four conditions capture the nature of two process executions in the IIS model. For any two processes, say, 0 and 1, there are three possible outcomes of passing through an IIS object, represented by the three simplexes of the subdivided $(\langle 0, 0 \rangle, \langle 1, 1 \rangle)$ simplex: 0 reads only itself and 1 reads both, 1 reads only itself and 0 reads both, or they both read each other.

Based on $\mathcal{L}_{p-1}$ we can now complete the definition of $\mathcal{L}_p$. Let $S = (\vec{s_0}, \ldots, \vec{s_p})$ be a p-simplex in $\mathcal{K}$. The set $Bd(S)$ is the polytope of a subcomplex of the $p-1$-skeleton of $\mathcal{K}$, and hence of a subcomplex of $\mathcal{L}_{p-1}$, which we denote $\mathcal{L}_{Bd(S)}$. Let $\vec{b}$ be the barycenter of S, and let δ be some positive real number such that $0 < \delta < 1/p$. For each $1 \leq i \leq p$, define $\vec{m_i}$ to be the point $(1+\delta)\vec{b} - \delta\vec{s_i}$. These points are called the *midpoints* of S. Figure 14 shows the barycenter and midpoints of a 2-simplex. We can now label $\vec{m_i}$ with $\langle i, S \rangle$, S here being the vertex scheme of the geometric simplex S. Let M_S be the set of midpoints of S. We define $\mathcal{L}_S$ to be the union of $\mathcal{L}_{Bd(S)}$ and all the faces of all chromatic p-simplexes $T = (\vec{t_0}, \ldots, \vec{t_p})$, such that for all $1 \leq i, j \leq p : i \neq j$, $\vec{t_i} \in skel^0(\mathcal{L}_{Bd(S)}) \cup M_S$, and the four containment conditions of Definition 3.25 hold. $\mathcal{L}_p$ is thus the complex consisting of the union of the complexes $\mathcal{L}_S$, as S ranges over all the p-simplexes of $\mathcal{K}$.

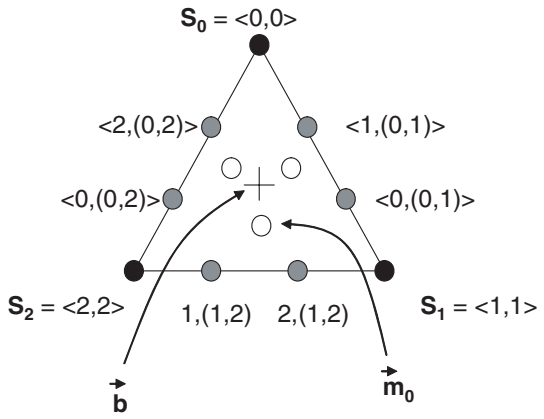

FIG. 14. *Example of the inductive step in the construction of the standard chromatic subdivision (for the sake of brevity, labels of simplexes slightly abuse notation).*

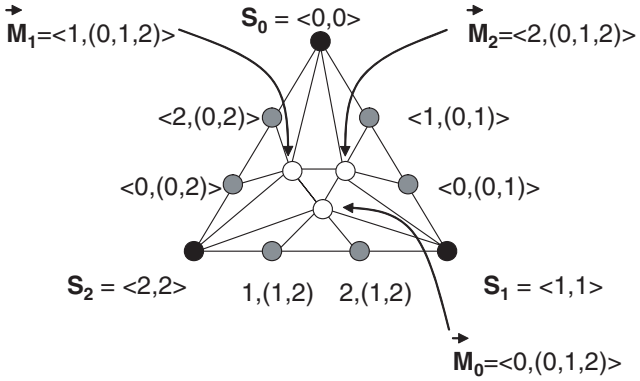

FIG. 15. *Example of the standard chromatic subdivision of a* 2*-simplex.*

Figure 15 describes a single subdivision $\mathcal{L}_p$ of a 2-simplex. Think of the value fields of vertexes as representations of the return values of an IS *writeread* operation by any one of three processes 1, 2, or 3. The complex captures all the possible outputs of executions in the IIS model. Each 2-simplex represents one such execution. A simplex with a face belonging to the boundary, such as the simplex $(\langle 1,1\rangle, \langle 2,(1,2)\rangle, \langle 0,(0,1,2)\rangle)$ in the lower right-hand corner of Figure 15, represents an execution where process 1 executed a *writeread* reading of only itself, process 2 performed a *writeread* and read itself, and process 1, and finally process 0 performed a *writeread* and read all three. The middle simplex (m_0, m_1, m_2) corresponds to an execution where all three processes were concurrent and read each other's written value. The three containment conditions C2, C3, and C4 on the labels of the vertexes guarantee the properties of the IIS model as they are captured in Lemmas 2.14, 2.15, and 2.16: *writeread* operations are by different processes, $writeread_i$ returns i's written value, the returned snapshot by one process must include the values returned by the other, and finally, if i read j, then the value returned by j cannot contain an input that i did not read.

We now prove that this structure makes sense mathematically, that is, that it is in fact a subdivision of the p-skeleton of $\mathcal{K}$.

LEMMA 3.26. *For all $0 \leq p \leq n$, $\mathcal{L}_p$ is a chromatic subdivision of $skel^p(\mathcal{K})$.*

Proof. We argue by induction. The case $p = 0$ is trivial. So suppose $p > 0$, and suppose the claim holds for $\mathcal{L}_0, \ldots, \mathcal{L}_{p-1}$. We will first prove that $\mathcal{L}_p$ is a chromatic simplicial complex. To that end, we prove the following auxiliary lemma.

LEMMA 3.27. *For all p-simplexes S in $\mathcal{K}$, $\mathcal{L}_S$ is a chromatic complex.*

Proof. We must show that $\mathcal{L}_S$ is closed under containment and intersection. Let U be a simplex in $\mathcal{L}_S$, and let V be a face of U, where $0 \leq \dim(V) \leq \dim(U) < p$. If U is in $\mathcal{L}_{Bd(S)}$, then so is V, since $\mathcal{L}_{Bd(S)}$ is a complex (since $\mathcal{L}_p$ is a subdivision and hence a complex by assumption). Hence V is in $\mathcal{L}_S$. Suppose U is not contained in $\mathcal{L}_{Bd(S)}$. Then U must be the face of a p-simplex T as described above. By definition of $\mathcal{L}_S$, all the faces of T, and hence all faces of U, must be in $\mathcal{L}_S$. It follows that $\mathcal{L}_S$ is closed under containment.

Let U, V be simplexes in $\mathcal{L}_S$, and suppose their intersection, denoted by W, is nonempty. If U, V are both in $\mathcal{L}_{Bd(S)}$, it follows immediately that V^r is in $\mathcal{L}_{Bd(S)}$ and hence in L_S. Similarly, if U is in $\mathcal{L}_{Bd(S)}$ but V is not, then $W = U \cap V = U \cap (V \cap |\mathcal{L}_{Bd(S)}|)$. Note that $V \cap |\mathcal{L}_{Bd(S)}|$ is a simplex in $\mathcal{L}_{Bd(S)}$, since all the containment conditions of Definition 3.25 are satisfied. Hence it follows that W is in $\mathcal{L}_{Bd(S)}$, and hence in $\mathcal{L}_S$. If neither U nor V is in $\mathcal{L}_{Bd(S)}$, then since all faces of U and V are in $\mathcal{L}_S$, then so is W. It follows that $\mathcal{L}_S$ is closed under intersection, and hence is a complex. That $\mathcal{L}_S$ is chromatic follows from the fact that we include only chromatic simplexes in $\mathcal{L}_S$ in our construction (note that $\mathcal{L}_{p-1}$ and hence $\mathcal{L}_{Bd(S)}$ are chromatic by assumption). □

Notice that for all distinct p-simplexes S, T we have that $|\mathcal{L}_S| \cap |\mathcal{L}_T| = S \cap T$, which is a simplex in $skel^{p-1}(\mathcal{K})$ and hence is the polytope of a subcomplex of $\mathcal{L}_{p-1}$ and hence of both $\mathcal{L}_S$ and $\mathcal{L}_T$. It follows that $\mathcal{L}_p$ is a simplicial complex [30]. It remains to show that $\mathcal{L}_p$ is a chromatic subdivision. To this end, we must first show that every simplex in $\mathcal{L}_p$ is contained in some simplex in $skel^p(\mathcal{K})$ and that every simplex in $skel^p(\mathcal{K})$ is the union of finitely many simplexes in $\mathcal{L}_p$. Now, it is clear from our construction that any simplex T_q in $\mathcal{L}_p$ is contained in some simplex S in $skel^p(\mathcal{K})$. Also, since for all simplexes S in $skel^p(\mathcal{K})$, the set of midpoints is finite, and $\mathcal{L}_{p-1}$ is a subdivision of $skel^{p-1}(\mathcal{K})$ by assumption, it follows that S is the union of finitely many simplexes in $\mathcal{L}_p$. Hence $\mathcal{L}_p$ is a subdivision. This subdivision is chromatic, since $\mathcal{L}_{p-1}$ is chromatic by assumption, since the colors used to color the midpoints of any simplex S are exactly the colors used to color S, and since any simplex in $\mathcal{L}_p$ including midpoints must satisfy the requirement that no two vertexes have the same color (id). □

We are now ready to give our definition of the standard chromatic subdivision of a complex $\mathcal{K}$.

DEFINITION 3.28. *The* standard chromatic subdivision *of $\mathcal{K}$, denoted $\mathcal{X}(\mathcal{K})$, is the complex $\mathcal{L}_n$.*

An example of a complex and its standard chromatic subdivision is given in Figure 16. As one can see, the subdivision of a simplex as seen in Figure 15 is applied to all the simplexes in the complex $\mathcal{K}$. Applying the standard chromatic subdivision k times, where $k > 1$, yields a subdivision $\mathcal{X}^k(\mathcal{K}) = \mathcal{X}^{k-1}(\mathcal{X}(\mathcal{K}))$, which we call the kth iterated standard chromatic subdivision [24, 25, 26]. Since the standard chromatic subdivision of a complex is again a complex, and a chromatic subdivision of a chromatic subdivision of $\mathcal{K}$ is itself a chromatic subdivision of $\mathcal{K}$, $\mathcal{X}^k(\mathcal{K})$ is a chromatic subdivision of $\mathcal{K}$. The number k is called the *level* of the subdivision.

The following is the vertex scheme representation of the standard chromatic subdivision. This particularly compact formulation of the standard chromatic subdivision

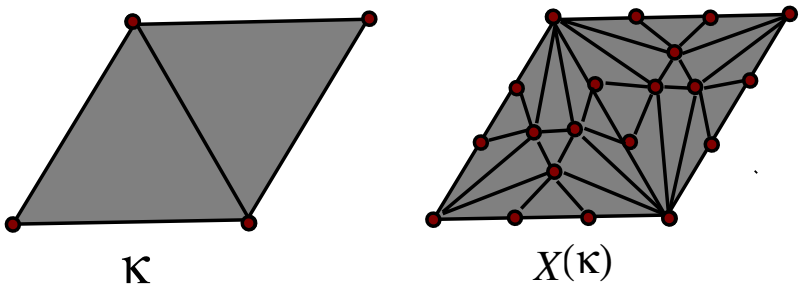

FIG. 16. *Example of a two-dimensional complex and its standard chromatic subdivision.*

is equivalent to the definition of Herlihy and Shavit [24, 25, 26].

LEMMA 3.29. *Let $\mathcal{K}$ be a pure, chromatic complex of dimension n. The vertex scheme of $\mathcal{X}(\mathcal{K})$ is the closure under containment of the set of all n-simplexes of the form $S = (\langle 0, S_0\rangle, \ldots, \langle n, S_n\rangle)$, where for all i, S_i is the vertex scheme of some face of a simplex S in $\mathcal{K}$, and the following conditions hold for all $i \neq j$:*

- *$i \in ids(S_i)$.*
- *S_i is a face of S_j or vice versa.*
- *If $j \in ids(S_i)$, then S_j is a face of S_i.*

Furthermore, any abstract complex $\mathcal{L}$ with a vertex scheme meeting the above criteria has a realization as a geometric standard chromatic subdivision $\mathcal{X}(\mathcal{K}) = \mathcal{L}$ of the complex $\mathcal{K}$ induced by all vertexes $\langle i, S_i\rangle$ where $\dim(S_i) = 0$.

As before, the above three conditions have the exact same role as containment conditions C2, C3, and C4 of Definition 3.25.

Proof. We argue that the vertex scheme of $\mathcal{X}(\mathcal{K})$ meets the above properties by induction on k, where $0 \leq k \leq n$. It is immediate that the simplexes of $\mathcal{X}(\mathcal{K})$ lying in the subdivision $\mathcal{L}_0$ of $skel^0(\mathcal{K})$ are of this form (each such simplex is a vertex of $\mathcal{K}$ labeled with a process id and a value), and the three requirements of the lemma are all satisfied trivially.

Now suppose the claim holds for $0, \ldots, k-1$. Consider a simplex T lying in the subdivision $\mathcal{L}_k$ of $skel^k(\mathcal{K})$ and not in $\mathcal{L}_{k-1}$. Then $T = U \star V$, where U is a simplex in $\mathcal{L}_{k-1}$, and V is a simplex, each vertex of which is one of the midpoints in M_S, where $S = carrier(T)$. By assumption, V is nontrivial, meaning that there is at least one vertex in V. However, U may be trivial. For each vertex $\vec{v}$ in V, $val(\vec{v}) = S$, the vertex scheme of S. Hence, for i, j in $ids(V)$, since $ids(V) \subseteq ids(S)$, all the containment conditions of Definition 3.25 are met. For i, j in $ids(U)$, the conditions are satisfied by induction. Now suppose i is in $ids(U)$, while j is in $ids(V)$. Notice that $S_i = carrier(U)$, and $S_j = carrier(V) = S$.

The first condition follows by induction (for i) and since $ids(V) \subseteq ids(S) = vals(V)$ (for j). Since $carrier(U)$ is a face of S, it follows that S_i is a proper face of S, and hence of S_j, which equals the vertex scheme of S, and so the second condition is satisfied. It is clear that i is in $ids(S_j)$, since S_j equals the vertex scheme of S, and i is in $ids(carrier(U))$, which is a subset of $ids(S)$. That S_i is a face of S_j has already been established. It follows that, since $\mathcal{X}(\mathcal{K})$ is chromatic, $ids(U) \cap ids(V) = \emptyset$,

$ids(S_i) \subseteq ids(carrier(U))$, and j is not in $ids(carrier(U))$, j cannot be in $ids(S_i)$. It follows that the third condition is satisfied.

We now show that any abstract complex $\mathcal{L}$ with a vertex scheme meeting the above criteria has a realization as a geometric standard chromatic subdivision $\mathcal{X}(\mathcal{K}) = \mathcal{L}$ of the complex $\mathcal{K}$ induced by all vertexes with 0-dimensional labels, that is, $\langle i, S_i \rangle$ where $\dim(S_i) = 0$. We argue by induction on k, $0 \leq k \leq n$, the size of the set S_i in the label of any vertex $\langle i, S_i \rangle$ in $\mathcal{L}$. It is immediate that the vertexes with zero-dimensional labels meet the criteria since the first condition of Lemma 3.29 implies condition C2 and all other conditions of Definition 3.28 are satisfied trivially. These vertexes form $skel^0(\mathcal{K})$.

Now suppose the claim holds for $0, \ldots, k-1$. Consider the set of k-simplexes T_j, all having vertexes $\langle i, S_i \rangle$ out of the same subset of k ids in $\mathcal{L}$. By definition each simplex has at least one vertex whose label $\langle i, S_i \rangle$ has $\dim(S_i) = k$. By the induction hypothesis the realization of this set includes k complexes, each with a proper subset using $k-1$ of these ids, and each a geometric complex meeting the requirements of the geometric standard chromatic subdivision. These complexes which inductively form $skel^{k-1}$ meet each other at $k-2$-dimensional boundaries, and their union (topological sum [30]) is a complex that is a $k-1$-dimensional sphere (for example, three one-dimensional complexes, each a subdivision using two unique ids, form a one-dimensional sphere, i.e., a circle). Let $\vec{b}$ be the barycenter of this sphere, and let v_i, $0 \leq i \leq k$, be the set of vertexes in the sphere with zero-dimensional labels. Now, in the set of simplexes T_j there are by the definition of Lemma 3.29 k vertexes with k-dimensional labels. If we choose each of them as a midpoint $\vec{m_i}$ at some distance $(1+\delta)\vec{b} - \delta\vec{v_i}$, from the barycenter $\vec{b}$ where $0 \leq \delta \leq 1/k$, then the simplexes T_j defined by the conditions of Lemma 3.29 form the interior of a simplex bounded by the $k-1$-dimensional sphere and fit the conditions of Lemma 3.26, implying that the above realization of $\mathcal{L}$ is a geometric standard chromatic subdivision of the complex $\mathcal{K}$ induced by the vertexes with zero-dimensional labels in $\mathcal{L}$. □

In the remainder of this paper, we will usually work with this description of the standard chromatic subdivision, and we refer to it as $\mathcal{X}(\mathcal{K})$. Whenever the distinction between the geometric and abstract representations of $\mathcal{X}(\mathcal{K})$ is significant, it will be mentioned explicitly.

3.4.2. The nonuniform chromatic subdivision. In this section, we define the *nonuniform chromatic subdivision* and prove that this definition does indeed specify a chromatic subdivision of a given complex. We will give a recursive definition of the *nonuniform chromatic subdivision* which we denote as $\widetilde{\mathcal{X}}^k(\mathcal{K})$, $k \geq 0$. We note that unlike $\mathcal{X}^k(\mathcal{K})$, $\widetilde{\mathcal{X}}^k(\mathcal{K})$ is a procedure and not a function, and so $\widetilde{\mathcal{X}}^k(\widetilde{\mathcal{X}}(\mathcal{K})) \neq \widetilde{\mathcal{X}}(\widetilde{\mathcal{X}}^k(\mathcal{K}))$.

DEFINITION 3.30. *Let $\mathcal{K}$ be a pure n-dimensional chromatic complex, where the colors are the numbers in $0, \ldots, n$. A k-level nonuniform chromatic subdivision of a complex $\mathcal{K}$ by $\widetilde{\mathcal{X}}^k(\mathcal{K})$ for $k \geq 0$ is defined as follows.*

If $\dim(\mathcal{K}) = 0$, then for all $k \geq 0$, $\widetilde{\mathcal{X}}^k(\mathcal{K})$ is $\mathcal{K}$ itself. Now suppose $\dim(\mathcal{K}) > 0$. Then $\widetilde{\mathcal{X}}^0(\mathcal{K})$ is $\mathcal{K}$ itself. For $k > 0$, $\widetilde{\mathcal{X}}^k(\mathcal{K})$ is given by the following procedure: Partition the vertexes of $\mathcal{K}$ into two disjoint sets, A and B, where $\mathcal{A}$ is nonempty. Let $\mathcal{A}$ and $\mathcal{B}$ be the pure subcomplexes of $\mathcal{K}$ induced (respectively) by the vertexes in A and the vertexes in B. The subdivision $\widetilde{\mathcal{X}}^k(\mathcal{K})$ is the complex consisting of all simplexes in $\mathcal{B}$, all simplexes in $\widetilde{\mathcal{X}}^{k-1}(\mathcal{X}(\mathcal{A}))$, and all simplexes of the form $S \star T$, where S is a simplex in $\widetilde{\mathcal{X}}^{k-1}(\mathcal{X}(\mathcal{A}))$, T is a simplex in $\mathcal{B}$, and $carrier(S) \star T$ is a simplex in $\mathcal{K}$.

We note that in the above definition, when we say induced subcomplexes $\mathcal{A}$ and $\mathcal{B}$, we mean that a simplex S in $\mathcal{K}$ is in $\mathcal{A}$ if the vertexes spanning S are all in A, and it is in $\mathcal{B}$ if its spanning vertexes are all in $\mathcal{B}$. Since $\mathcal{K}$ is pure, so are $\mathcal{A}$ and $\mathcal{B}$.

Informally speaking, a nonuniform chromatic subdivision of level k is one in which there is some simplex in $\mathcal{K}$ which is subdivided k times but no simplex that is subdivided more than k times. Note that the k-level standard chromatic subdivision is a special case of the k-level nonuniform chromatic subdivision. Hence for all $k \geq 0$, there exists some nonuniform chromatic subdivision of level k.

Our definition of nonuniform chromatic subdivisions is designed to model protocol complexes of the NIIS model. The main difference between IIS and NIIS protocols is that in NIIS, some processes may decide after passing through fewer IS objects than others. This is captured by the recursive definition that splits vertexes into two groups A and B. At any level of the recursion, the vertexes in $\mathcal{A}$ can be thought of as corresponding to processes that continue computing given their current local state, while the vertexes in $\mathcal{B}$ correspond to processes that decide.

To better understand our construction, let us jump slightly ahead of ourselves and consider how the protocol complex of any NIIS protocol with input complex $\mathcal{I}$ in some subset of processes accesses one IS object and is captured by a nonuniform chromatic subdivision $\widetilde{\mathcal{X}}^1(\mathcal{I})$ up to isomorphism.

Consider any vertex $\vec{v}$ in $\mathcal{I}$. It is labeled with $\langle i, v_i \rangle$, where i is a process id and v_i represents an input value to process i. According to the specification of NIIS protocols in section 2.6, process i will (provided it does not fail), upon having received the input v_i, execute either an *inv_writeread(v)*$_{i,1}$ action or a *decide(S)*$_i$ action, depending on whether τ(*local_state*) evaluates to true or not. In this way, the predicate map τ induces a partition of the vertexes of $\mathcal{I}$ into two disjoint sets A and B. We now construct complexes $\mathcal{A}$ and $\mathcal{B}$ as in Definition 3.30; that is, a simplex T in $\mathcal{I}$ is in $\mathcal{A}$ if and only if all its vertexes are in A, and it is in $\mathcal{B}$ if and only if all its vertexes are in B.

The vertexes in A correspond to processes that, based on their input values, execute an *inv_writeread(v)*$_{i,1}$ action with the object IS_1. The protocol complex on $\mathcal{A}$ equals $\mathcal{X}(\mathcal{A})$ up to isomorphism. In any execution α of the protocol, some of the participating, nonfailing processes decide on their input values (corresponding to vertexes in B), while some decide on the snapshots they receive from the object IS_1 (corresponding to vertexes in the protocol complex of $\mathcal{A}$). It follows that the protocol complex on $\mathcal{I}$ contains every simplex in $\mathcal{B}$, every simplex in $\mathcal{X}(\mathcal{A})$, and every simplex of the form $S \star T$, where S is in $\mathcal{X}(\mathcal{A})$, T is in $\mathcal{B}$, and $carrier(S) \star T$ is in $\mathcal{I}$.

Note that the structure of the recursion of $\widetilde{\mathcal{X}}^k$ is such that $\widetilde{\mathcal{X}}^{k-1}(\mathcal{X}(\mathcal{A}))$ is applied and not $\mathcal{X}(\widetilde{\mathcal{X}}^{k-1}(\mathcal{A}))$. This guarantees that we model a situation in which the subset of processes with nodes A in $\mathcal{K}$ go through the first IS object, and only a subset of these can then go through the next IS object, and so on. It is never the case that a node corresponding to a process that has stopped passing through earlier IS objects is later subdivided.

An example of a level 1 nonuniform chromatic subdivision of a 2-complex $\mathcal{K}$ is given in Figure 17, and an example of a level 2 nonuniform chromatic subdivision of a slightly bigger 2-complex $\mathcal{L}$ is given in Figure 18. Note that in Figure 18 the complex $\mathcal{A}$ for the second level of recursion is isomorphic to the complex $\mathcal{A}$ for the first level of recursion in Figure 17.

An example of a chromatic subdivision that does *not* satisfy Definition 3.30 is given in Figure 19. It is not a nonuniform chromatic subdivision because the vertex

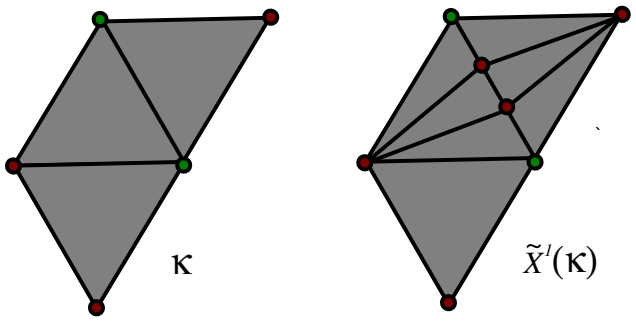

FIG. 17. *Example of level* 1 *nonuniform chromatic subdivision of a* 2*-complex.*

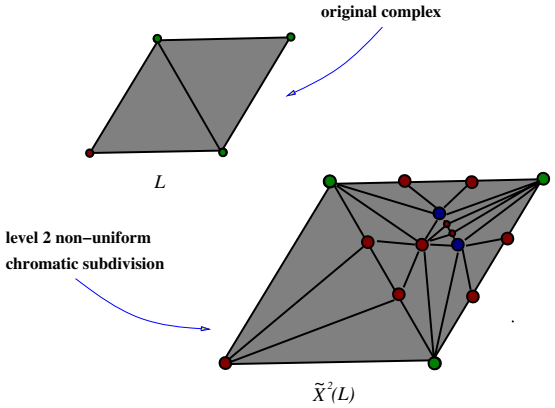

FIG. 18. *Example of level* 2 *nonuniform chromatic subdivision of a* 2*-complex.*

b is part of the $\mathcal{B}$ complex at the first level of recursion (that is, it is not part of the subcomplex that is subdivided further), while in the next level of recursion, the edge between d (which is in the $\mathcal{A}$ complex at the first level of recursion, and hence is to be subdivided further) and b is subdivided, meaning that b is in the $\mathcal{A}$ complex at the second level of recursion, which is clearly impossible, since the carrier of any vertex in the $\mathcal{A}$ complex at the second level must be a simplex in the $\mathcal{A}$ complex at the first level of recursion. Informally, this simply means that, if a vertex is not to be part of the complex to be further subdivided at the first level, it cannot be part of the complex to be further subdivided at the second level.

LEMMA 3.31. *Any nonuniform chromatic subdivision* $\widetilde{\mathcal{X}}^k(\mathcal{K})$ *is a chromatic subdivision of* $\mathcal{K}$*.*

Proof. We first note that $\widetilde{\mathcal{X}}^k(\mathcal{K})$ is well defined, since each recursive step lowers the level of subdivision by 1, and $\widetilde{\mathcal{X}}^0(\mathcal{K})$ is defined for all $\mathcal{K}$. We will prove that $\widetilde{\mathcal{X}}^k(\mathcal{K})$ is a chromatic subdivision by induction on k.

The case where $k = 0$ is trivial, since $\widetilde{\mathcal{X}}^0(\mathcal{K}) = \mathcal{K}$. Now suppose that $k > 0$, and that for $0 \leq l \leq k-1$, and any complex $\mathcal{K}$, $\widetilde{\mathcal{X}}^l(\mathcal{K})$ is a chromatic subdivision of $\mathcal{K}$.

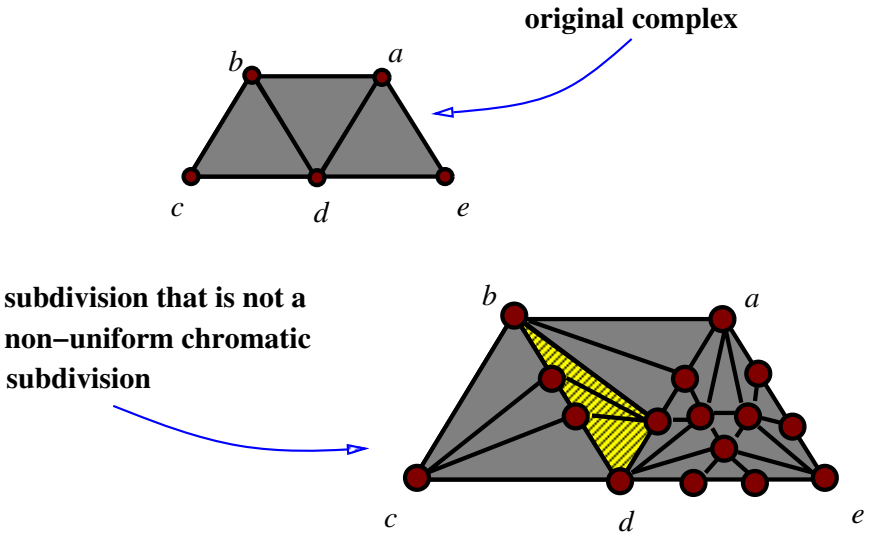

FIG. 19. *Example of a subdivision that is* not *a nonuniform chromatic subdivision.*

If $B = \emptyset$, the result follows by induction and by Lemma 3.26. So suppose that B is nonempty.

We first show that $\widetilde{\mathcal{X}}^k(\mathcal{K})$ is closed under containment. Let U be a simplex in $\widetilde{\mathcal{X}}^k(\mathcal{K})$, and let V be a face of U. If U is in $\mathcal{B}$, then so is V, since $\mathcal{B}$ is a complex. Hence V is in $\widetilde{\mathcal{X}}^k(\mathcal{K})$. Similarly, if U is in $\widetilde{\mathcal{X}}^{k-1}(\mathcal{X}(\mathcal{A}))$, then so is V, since $\widetilde{\mathcal{X}}^{k-1}(\mathcal{X}(\mathcal{A}))$ is a complex by our induction hypothesis. Now suppose $U = S \star T$ for some S in $\widetilde{\mathcal{X}}^{k-1}(\mathcal{X}(\mathcal{A}))$, T in $\mathcal{B}$. Then $S \cap V$ is in $\widetilde{\mathcal{X}}^{k-1}(\mathcal{X}(\mathcal{A}))$, and $T \cap V$ is in $\mathcal{B}$. It follows that $V = (S \cap V) \star (T \cap V)$, where $carrier(S \cap V) \star (T \cap V)$ is a simplex in $\mathcal{K}$. By Definition 3.30, V is in $\widetilde{\mathcal{X}}^k(\mathcal{K})$. It follows that $\widetilde{\mathcal{X}}^k(\mathcal{K})$ is closed under containment.

Let U, V be simplexes in $\widetilde{\mathcal{X}}^k(\mathcal{K})$, and let W be their intersection. If both U, V are in $\mathcal{B}$, then so is W, since $\mathcal{B}$ is closed under intersection. Similarly, if both U and V are in $\widetilde{\mathcal{X}}^{k-1}(\mathcal{X}(\mathcal{A}))$, then so is W, since $\widetilde{\mathcal{X}}^{k-1}(\mathcal{X}(\mathcal{A}))$ is closed under intersection. If U is in $\mathcal{B}$ and V is in $\widetilde{\mathcal{X}}^{k-1}(\mathcal{X}(\mathcal{A}))$, or vice versa, then $U \cap V = \emptyset$, and so containment under intersection holds vacuously. We now consider the case where either U or V is not contained in either complex; that is, suppose $U = S \star T$ for some S in $\widetilde{\mathcal{X}}^{k-1}(\mathcal{X}(\mathcal{A}))$, T in $\mathcal{B}$, and $V = X \star Y$ for some X in $\widetilde{\mathcal{X}}^{k-1}(\mathcal{X}(\mathcal{A}))$, Y in $\mathcal{B}$. Now, $U \cap V = (S \star T) \cap (X \star Y)$, and $(S \star T) \cap (X \star Y) = (S \cap X) \star (T \cap Y)$ [30]. If $S \cap X = \emptyset$ or $T \cap Y = \emptyset$, then since the remaining nonempty intersecting pair of subsets is completely in $\mathcal{B}$ or completely in $\widetilde{\mathcal{X}}^{k-1}(\mathcal{X}(\mathcal{A}))$, it follows that W is also. So suppose now that S, T, X, Y, and the intersections $S \cap X$ and $Y \cap T$ are all nonempty. Since $carrier(S \cap X)$ is a face of both $carrier(S)$ and $carrier(X)$, it follows that $carrier(S \cap X) \star T$ and $carrier(S \cap X) \star Y$ are simplexes in $\mathcal{K}$, and so is their intersection $carrier(S \cap X) \star (T \cap Y)$, since $\mathcal{K}$ is a complex. It follows that W is in $\widetilde{\mathcal{X}}^k(\mathcal{K})$. This concludes the proof that $\widetilde{\mathcal{X}}^k(\mathcal{K})$ is a complex. That it is a chromatic complex follows directly from Lemma 3.26.

We now prove that $\widetilde{\mathcal{X}}^k(\mathcal{K})$ is a chromatic subdivision. Given is a simplex U in $\widetilde{\mathcal{X}}^k(\mathcal{K})$. If U is in $\mathcal{B}$, then U is clearly contained in a simplex in $\mathcal{K}$, namely, itself, and the colors of U are contained in the set of colors of its carrier. If U is in $\widetilde{\mathcal{X}}^{k-1}(\mathcal{X}(\mathcal{A}))$, it follows by induction and Lemma 3.26 that U is contained in some some simplex

carrier(U) in $\mathcal{A}$, and hence in $\mathcal{K}$, and that the colors of U are a subset of the colors of its carrier. Now suppose $U = S \star T$, where *carrier*$(S) \star T$ is in $\mathcal{K}$. Then U is contained in *carrier*$(S) \star T$, and the colors of U are a subset of the colors of *carrier*$(S) \star T$. Now consider any simplex U in $\mathcal{K}$. We can decompose it into two disjoint faces S and T, such that $S \in \mathcal{A}$ and $T \in \mathcal{B}$. The simplex S is subdivided according to $\widetilde{\mathcal{X}}^{k-1}(\mathcal{X}(\mathcal{A}))$, which by induction and Lemma 3.26 consists of finitely many simplexes. The simplex T is not subdivided at all. It follows that the subdivision $\widetilde{\mathcal{X}}^{k}(\mathcal{K})$ subdivides U into finitely many simplexes (those in $\widetilde{\mathcal{X}}^{k-1}(\mathcal{X}(\mathcal{S})) \star T$). This completes the proof that $\widetilde{\mathcal{X}}^{k}(\mathcal{K})$ is a chromatic subdivision. □

A nonuniform subdivision $\widetilde{\mathcal{X}}^{k}(\mathcal{K})$ of a complex induces a nonuniform chromatic subdivision of any subcomplex $\mathcal{L}$ of $\mathcal{K}$. The level of the induced subdivision of $\mathcal{L}$ may vary from subcomplex to subcomplex. We slightly abuse our notation to be able to define the effect of $\widetilde{\mathcal{X}}^{k}(\mathcal{K})$ on the restricted subcomplex $\mathcal{L}$.

DEFINITION 3.32. *Let $\mathcal{K}$ be a chromatic complex, let $\mathcal{L}$ be a subcomplex or simplex of $\mathcal{K}$, and let $\widetilde{\mathcal{X}}^{k}(\mathcal{K})$ be a nonuniform iterated chromatic subdivision of $\mathcal{K}$. We denote its restriction to simplexes in $\mathcal{L}$ by $\widetilde{\mathcal{X}}^{k}(\mathcal{L}/\mathcal{K})$. The* level *of subdivision $k_{\mathcal{L}}$ is the maximal level of subdivision of $\widetilde{\mathcal{X}}^{k}(\mathcal{L}/\mathcal{K})$.*

It is clear that for any subcomplex or simplex $\mathcal{L}$ of $\mathcal{K}$, $k_{\mathcal{L}} \leq k$.

4. The asynchronous complexity theorem. The strength and usefulness of the NIIS model of computation comes from the fact that each of its associated protocol complexes has a nice, recursive structure. In fact, it turns out that any protocol complex of NIIS is equal to some nonuniform iterated chromatic subdivision of the input complex, and vice versa. This is the essence of our main theorem, which we state and prove in this section.

The level of subdivision necessary for the existence of a simplicial map from the input to the output complex of a decision task that agrees with the task specification can be interpreted as a topological measure of the task's time complexity. The following definition introduces the concept of *mappability*, which is a useful construct for reasoning about this topological measure.

DEFINITION 4.1. *Given a decision task $\mathcal{D} = \langle \mathcal{I}, \mathcal{O}, \Gamma \rangle$ and a nonnegative integer k, we say that $\widetilde{\mathcal{X}}^{k}(\mathcal{I})$ is a* mappable *subdivision of the input complex and k is a* mappable *level of subdivision if there exists some chromatic simplicial map μ from $\widetilde{\mathcal{X}}^{k}(\mathcal{I})$ to $\mathcal{O}$ such that for all T in $\widetilde{\mathcal{X}}^{k}(\mathcal{I})$, $\mu(T) \in \Gamma($*carrier*$(T))$.*

This definition extends naturally to individual simplexes as the map induces different levels of subdivision on the individual simplexes in accordance with the idea that, in order to solve a decision task, some processes may have to do more computational work than others, and some inputs may require more computation than others. We can now state our main theorem.

THEOREM 4.2 (time complexity). *A decision task $\mathcal{D} = \langle \mathcal{I}, \mathcal{O}, \Gamma \rangle$ has a wait-free solution protocol in the NIIS model with worst case time complexity k_S on inputs $S \in \mathcal{I}$ if and only if there is a mappable nonuniform iterated chromatic subdivision $\widetilde{\mathcal{X}}^{k}(\mathcal{I})$ with level k_S on S.*

Keeping in style with Herlihy and Shavit [24, 25, 26], the theorem simply states that solvability of a decision task $\mathcal{D} = \langle \mathcal{I}, \mathcal{O}, \Gamma \rangle$ in the NIIS model is equivalent to the existence of a chromatic simplicial map μ from some nonuniform chromatic subdivision $\widetilde{\mathcal{X}}^{k}(\mathcal{I})$ to $\mathcal{O}$ that agrees with the task specification Γ; that is, for all T in $\widetilde{\mathcal{X}}^{k}(\mathcal{I})$, $\mu(T^m) \in \Gamma($*carrier*$(T))$. The minimum possible level k_S is a lower bound on the worst case time complexity of solving this task with inputs in S in the NIIS model.

As noted in the introduction, the theorem directly implies Proposition 3.1 of [12]. In [12], Borowsky and Gafni provided a simulation of atomic snapshot memory from IIS memory and showed that, based on this simulation, if one is given a constructive proof of an asynchronous computability theorem for the IIS model (which they called Proposition 3.1), it will imply one for the general read-write model. The proof we are about to present provides a constructive proof of computability for the NIIS model, and since IIS is a subset of NIIS, it provides the first known proof of Proposition 3.1 of [12].

Our theorem immediately provides a solution algorithm for a task given the subdivision and simplicial mapping. Simply run the protocol of Figure 6. Since each process can locally store the subdivision and mapping, the termination predicate map τ just needs to test if the *local_state* variable is equal to some node v in the subdivision and if so return $\mu(v)$.

In the remainder of this section, we will give the proof of our asynchronous time complexity theorem. We begin by proving a lemma about the protocol complex of a protocol in the IIS model with only one available IS object.

LEMMA 4.3. *Let $\mathcal{A}$ be an input complex in the IIS model with a single IS object. The corresponding protocol complex is isomorphic to $\mathcal{X}(\mathcal{A})$.*

Proof. We will construct an isomorphism Ψ from the abstract complex $\mathcal{P}_{(n,\tau,\delta)}(\mathcal{A})$ to the abstract complex (vertex scheme) $\mathcal{X}(A)$, as specified by Lemma 3.29. Let $\vec{v} = \langle i, S_i\rangle$ be any vertex in $\mathcal{P}_{(n,\tau,\delta)}(\mathcal{A})$. Then $\Psi(\vec{v}) = \langle i, T_i\rangle$, where T_i is the simplex in $\mathcal{A}$ such that for all j, $S_i[j] = v_j$ if and only if $\langle j, v_j\rangle \in T_i$. Notice that this isomorphism is chromatic; that is, the id of a vertex equals the id of its image under Ψ.

By Lemma 3.29, we must show that a set of vertexes $\vec{v}_0, \ldots, \vec{v}_m$ in $skel^0(\mathcal{P}_{(n,\tau,\delta)}(\mathcal{A}))$, where $m \leq n$, forms a simplex in $\mathcal{P}_{(n,\tau,\delta)}(\mathcal{A})$ if and only if the set of vertexes $\Psi(\vec{v}_0)$, $\ldots, \Psi(\vec{v}_m)$ in $skel^0(\mathcal{X}(\mathcal{A}))$ forms a simplex in $\mathcal{X}(\mathcal{A})$. Suppose without loss of generality that for all i, where $0 \leq i \leq m$, $\vec{v}_i = \langle i, S_i\rangle$, where $S_i \in \vartheta(D_I)$, and D_I is the input data type (that is, the id of the ith vertex is i).

Suppose that the vertexes $\vec{v}_0, \ldots, \vec{v}_m$ do form a simplex V in $\mathcal{P}_{(n,\tau,\delta)}(\mathcal{A})$. This output simplex corresponds to some execution α in the one-shot IS model, with corresponding input simplex U in $\mathcal{A}$. Each vertex in U is labeled with a process id i and an input value $v_i \in D_I$. Notice that $\dim(V) \leq \dim(U)$, since some participating processes may not decide, that is, they may fail (execute a $fail_i$ action) before executing a *decide* action.

From Lemma 2.14, we have that, for any vertex $\vec{v}_i = \langle i, S_i\rangle$ in V, $S_i[i] = v_i$. This implies that $\langle i, v_i\rangle$ is in T_i. From Lemma 2.15, we have that, for any two vertexes $\vec{v}_i = \langle i, S_i\rangle$ and $\vec{v}_j = \langle j, S_j\rangle$ in V, either S_i is a prefix of S_j or vice versa. Suppose without loss of generality that S_j is a prefix of S_i. Then for all x, where $0 \leq x \leq n$, if $S_i[x] = \perp$, then $S_j[x] = \perp$, and if $S_j[x] \neq \perp$, then $S_i[x] = S_j[x]$. It follows that if $\langle x, v_x\rangle$ is in T_j, it is also in T_i, and if x is not in $ids(T_i)$, then it is also not in $ids(T_j)$. This implies that T_j is a face of T_i. From Lemma 2.16, it follows that, if $S_i[j] = v_j$, then S_j is a prefix of S_i. This means that, if $\langle j, v_j\rangle$ is in T_i, then T_j is a face of T_i.

Now suppose that the vertexes $\Psi(\vec{v}_0), \ldots, \Psi(\vec{v}_m)$ in $skel^0(\mathcal{X}(\mathcal{A}))$ form a simplex V in $\mathcal{X}(\mathcal{A})$. We will construct an execution α with corresponding output simplex U such that $\Psi(U) = V$. Let $W = carrier(V)$. Partition the set $ids(V)$ into a collection of nonempty *concurrency classes* of process ids, $\mathcal{C}_1, \ldots, \mathcal{C}_k$ for some $k \geq 0$, such that any two process indexes i, j are in the same concurrency class if and only if $T_i = T_j$.

We can define a total order $\prec$ on this collection of concurrency classes as follows. Let $\mathcal{C}_x, \mathcal{C}_y$ be distinct concurrency classes. Then $\mathcal{C}_x \cap \mathcal{C}_y = \emptyset$. Since both classes are nonempty, we can pick an element from each, say, $i \in \mathcal{C}_x$ and $j \in \mathcal{C}_y$. By assumption,

$T_i \neq T_j$. Then by Lemma 3.29, either T_i is a face of T_j or T_j is a face of T_i. In the first case, let $\mathcal{C}_x \prec \mathcal{C}_y$, and in the second case, let $\mathcal{C}_y \prec \mathcal{C}_x$. Thus $\prec$ is a total order of the concurrency classes.

Now use this ordered partition of the participating processes in α to define a second partition $\mathcal{C}'_1, \ldots, \mathcal{C}'_k$ of the set $ids(W)$ as follows. For each concurrency class $\mathcal{C}$ of $ids(V)$, define a concurrency class $\mathcal{C}'$ of $ids(W)$ as follows. $\mathcal{C}'$ is the union of $\mathcal{C}$ and all $i \in ids(W) - ids(V)$ such that $\mathcal{C}$ is the least concurrency class (as determined by $\prec$) such that for all $j \in \mathcal{C}$, $i \in T_j$. Note that this is a partition of all $ids(W)$ since $W = carrier(V)$. This partition gives us a new collection of concurrency classes $\mathcal{C}'_1, \ldots, \mathcal{C}'_k$.

We are now ready to construct α. First position $update_{\mathcal{C}'_i}$ actions in increasing order according to the $\prec$ ordering. For each concurrency class $\mathcal{C}'_x$, position the *inv_writeread(v)*$_{i,1}$ actions of all i such that $i \in \mathcal{C}'_x$ immediately before the $update_{\mathcal{C}'_x}$ action (their internal ordering does not matter). Similarly, position the *ret_writeread(v)*$_{i,1}$ and *decide(S)*$_i$ actions of all i such that $i \in \mathcal{C}_x$ and $i \in ids(V)$ immediately after the $update_{\mathcal{C}'_x}$ action, but before the *inv_writeread(v)*$_{i,1}$ actions associated with the next concurrency class $\mathcal{C}'_y$. Processes i whose indexes are not in $ids(W)$ do not participate and hence take no steps in α. Processes i whose indexes are in some concurrency class $\mathcal{C}'_x$ but not in $ids(V)$ do not execute a *ret_writeread(v)*$_{i,1}$ action; instead, they execute a $fail_i$ action after the $update_{\mathcal{C}'_x}$ action, but before the *inv_writeread(v)*$_{i,1}$ actions associated with the next concurrency class $\mathcal{C}'_y$. Recall that earlier concurrency classes could not have included i since by construction $\mathcal{C}'_x$ is the least class including i. By construction, each deciding process i decides S_i in α, as required. The lemma follows. □

We now consider the protocol complex of a protocol in NIIS with time complexity 1 on the input complex $\mathcal{I}$; that is, some processes access a single IS object, while some decide based only on their own inputs. We will show that, if δ is trivial, which we denote by $\delta = 1$, then this protocol complex is indeed a nonuniform chromatic subdivision.

LEMMA 4.4. *For all $k \geq 0$, the protocol complex $\mathcal{P}_{(n,\tau,1)}(\mathcal{I})$ of any protocol in the NIIS model, with time complexity k on inputs in $\mathcal{I}$, is equal to some nonuniform chromatic subdivision $\widetilde{\mathcal{X}}^k(\mathcal{I})$ up to isomorphism.*

Proof. We use induction on the time complexity k. The result holds for $k = 0$ trivially. Now suppose $k > 0$ and that the result holds for $1, \ldots, k-1$. Consider the protocol complex $\mathcal{P}_{(n,\tau,1)}(\mathcal{I})$ of any protocol in the NIIS model with time complexity k on inputs in $\mathcal{I}$.

Any vertex $\vec{v}$ in $\mathcal{I}$ is labeled with $\langle i, v_i \rangle$, where i is a process id and v_i represents an input value to process i. According to the specification of NIIS protocols in section 2.6, any nonfailing process i will, upon having received the input v_i, execute either an *inv_writeread(v)*$_{i,1}$ action or a *decide(S)*$_i$ action, depending on whether $\tau(local\_state)$ evaluates to true or not. In this way, the predicate map τ induces a partition of the vertexes of $\mathcal{I}$ into two disjoint sets A and B. Since the time complexity of $\mathcal{P}_{(n,\tau,1)}$ on inputs in $\mathcal{I}$ is k, the set A must be nonempty. We now construct complexes $\mathcal{A}$ and $\mathcal{B}$ as in Definition 3.30; that is, a simplex T in $\mathcal{I}$ is in $\mathcal{A}$ if and only if all its vertexes are in A, and it is in $\mathcal{B}$ if and only if all its vertexes are in B.

The vertexes in A correspond to processes that, based on their input values, execute an *inv_writeread(v)*$_{i,1}$ action with the object IS_1. By Lemma 4.3, the output protocol complex on inputs in $\mathcal{A}$ after the first IS access equals $\mathcal{X}(\mathcal{A})$ up to isomorphism. The final protocol complex $\mathcal{P}_{(n,\tau,1)}(\mathcal{A})$ is given by applying $\mathcal{X}(\mathcal{A})$ as an input complex to the protocol. Since the complexity of the protocol on inputs in $\mathcal{I}$, and hence

on inputs in $\mathcal{A}$, is k, the complexity of the protocol on inputs in $\mathcal{X}(\mathcal{A})$ must be $k-1$. It follows by induction that the protocol complex $\mathcal{P}_{(n,\tau,1)}(\mathcal{A})$ equals some nonuniform chromatic subdivision $\widetilde{\mathcal{X}}^{k-1}(\mathcal{X}(\mathcal{A}))$ of $\mathcal{X}(\mathcal{A})$ up to isomorphism. A simplex U is in $\mathcal{P}_{(n,\tau,1)}(\mathcal{I})$ if and only if it corresponds to a valid set of outputs of an execution α of the protocol. In any execution α of the protocol, some of the participating, nonfailing processes decide on their input values (corresponding to vertexes in B), while some decide on the returned snapshots they receive from some IS object. It follows that $\mathcal{P}_{(n,\tau,1)}(\mathcal{I})$ contains any simplex in $\mathcal{B}$, any simplex in $\mathcal{P}_{(n,\tau,1)}(\mathcal{A}) = \widetilde{\mathcal{X}}^{k-1}(\mathcal{X}(\mathcal{A}))$, and any simplex of the form $S \star T$, where S is in $\widetilde{\mathcal{X}}^{k-1}(\mathcal{X}(\mathcal{A}))$, T is in $\mathcal{B}$, and $carrier(S) \star T$ is in $\mathcal{I}$. It follows from Definition 3.30 that the protocol complex $\mathcal{P}_{(n,\tau,1)}(\mathcal{I})$ equals some nonuniform chromatic subdivision $\widetilde{\mathcal{X}}^{k}(\mathcal{I})$ of $\mathcal{I}$ up to isomorphism. □

We must also prove that, for any mappable nonuniform chromatic subdivision $\widetilde{\mathcal{X}}^{k}(\mathcal{I})$ of an input complex $\mathcal{I}$, there is a matching protocol $\mathcal{P}_{(n,\tau,1)}$ in the NIIS model.

LEMMA 4.5. *For any mappable nonuniform chromatic subdivision $\widetilde{\mathcal{X}}^{k}(\mathcal{I})$ of an input complex $\mathcal{I}$, there is a matching protocol $\mathcal{P}_{(n,\tau,1)}$ in the NIIS model such that the protocol complex $\mathcal{P}_{(n,\tau,1)}(\mathcal{I}) = \widetilde{\mathcal{X}}^{k}(\mathcal{I})$ up to isomorphism.*

Proof. Given is a vertex $\vec{v}$ in $\mathcal{I}$. The definition of the subdivision $\widetilde{\mathcal{X}}^{k}(\mathcal{I})$ induces a sequence of nonuniform chromatic subdivisions $\mathcal{I}, \widetilde{\mathcal{X}}^{1}(\mathcal{I}), \ldots, \widetilde{\mathcal{X}}^{k}(\mathcal{I})$ and corresponding sequences $\mathcal{A}_0, \ldots, \mathcal{A}_{k-1}$ and $\mathcal{B}_0, \ldots, \mathcal{B}_{k-1}$ of complexes, the former sequence specifying the subcomplex to be subdivided further at each level of recursion.

In order to construct a protocol for $n+1$ processes, we must specify the function $\tau : \bigcup_{l=0}^{k} \vartheta^l(D) \to \{\texttt{true}, \texttt{false}\}$ and the decision map $\delta : \bigcup_{l=0}^{k} \vartheta^l(D) \to D_O$. We specify τ to be `true` for all values v such that there is a vertex $\vec{v}$ in one of the complexes $\mathcal{A}_0, \ldots, \mathcal{A}_{k-1}$ with $val(\vec{v}) = v$. For all other values v, τ evaluates to `false`. This definition is well formed, since for all p, where $0 \le p \le k$, it follows from Definitions 3.28 and 3.30 that there are no two vertexes in $\widetilde{\mathcal{X}}^{p}(\mathcal{I})$ with the same process-value label pair, and for all p, q, where $0 \le p, q \le k$ and $p \ne q$, $\mathcal{B}_p$ and $\mathcal{B}_q$ have no vertexes with common labels (process id *and* value label). This concludes the proof. □

We now give the proof of Theorem 4.2.

Proof of Theorem 4.2. Let $\mathcal{D} = \langle \mathcal{I}, \mathcal{O}, \Gamma \rangle$ be a decision task. Lemma 4.4 states that any protocol complex $\mathcal{P}_{(n,\tau,1)}(\mathcal{I})$, with worst case complexity k_S on input S, corresponds to a nonuniform chromatic subdivision $\widetilde{\mathcal{X}}^{k}(\mathcal{I}^n)$ with level k_S on S. Suppose now the decision map δ is not trivial. Then, if $\mathcal{P}_{(n,\tau,\delta)}$ solves $\mathcal{D} = \langle \mathcal{I}, \mathcal{O}, \Gamma \rangle$, $\mu = \delta$ is a simplicial map from $\widetilde{\mathcal{X}}^{k}(\mathcal{I}^n)$ to $\mathcal{O}$ that is in correspondence with Γ, so $\widetilde{\mathcal{X}}^{k}(\mathcal{I}^n)$ is mappable.

Lemma 4.5 states that any mappable nonuniform chromatic subdivision $\widetilde{\mathcal{X}}^{k}(\mathcal{I}^n)$ with level k_S on S is equal to the protocol complex $\mathcal{P}_{(n,\tau,1)}(\mathcal{I})$ (where δ is trivial) of a protocol in the NIIS model with worst case complexity k_S on input S. If there is a simplicial map μ from $\widetilde{\mathcal{X}}^{k}(\mathcal{I}^n)$ to $\mathcal{O}$ that is consistent with Γ, then by setting $\delta = \mu$, we have a protocol $\mathcal{P}_{(n,\tau,\delta)}$ solving $\mathcal{D} = \langle \mathcal{I}, \mathcal{O}, \Gamma \rangle$ with complexity k_S on input S. The theorem follows. □

5. Approximate Agreement. As an application of Theorem 4.2, we analyze the well-known *Approximate Agreement* [15] task, defined as follows: each process $i \in \{0, \ldots, n\}$ has an input x_i taken from some finite subset of the reals and chooses a unique output y_i such that, for some predetermined $\epsilon \ge 0$, (1) $\max_i y_i - \min_i y_i < \epsilon$, and (2) for all i, $y_i \in [\min_i x_i, \max_i x_i]$.

This problem, which at first glance may seem similar to Consensus, is in fact quite different and is solvable in the read-write memory model. (If ϵ were 0 this problem

would be equivalent to Consensus and hence not solvable.) Aspnes and Herlihy [2] proved a lower bound on Approximate Agreement in the read-write memory model that implies a worst case time complexity of $\lceil \log_3 \frac{\max_i x_i - \min_i x_i}{\epsilon} \rceil$ and an upper bound of $\lceil \log_2 \frac{\max_i x_i - \min_i x_i}{\epsilon} \rceil$ in the NIIS model. We will show that this $\log_2$ versus $\log_3$ gap is not simply a technical fluke.

DEFINITION 5.1. *Let V be some finite subsequence of values from $\mathbb{R}$, at most ϵ apart from its successor. The finite $n+1$-process* Approximate Agreement *task is the tuple $\mathcal{D} = \langle I, O, \gamma \rangle$:*

- $I = \{[x_0, \ldots, x_n] \mid x_i \in V \cup \{\perp\}\}$.
- $O = \{[y_0, \ldots, y_n] \mid y_i \in V \cup \{\perp\}, (y_i, y_j \neq \perp) \Rightarrow |y_i - y_j| \leq \epsilon\}$.
- $\gamma = \{(\vec{I}, \vec{O}) \mid \vec{O}[i] \in [\min_i \vec{I}[i], \max_i \vec{I}[i]] \cup \{\perp\}\}$.

Define an input vector $\vec{I}$ to be *nontrivial* if the $\max_i x_i$ and $\min_i x_i$ are at least ϵ apart and each belongs to at least one other disjoint input vector. We can now state the complexity bounds for the Approximate Agreement problem.

THEOREM 5.2. *Given $\epsilon > 0$, there is a protocol $\mathcal{P}_{(n,\tau,\delta)}$ solving* Approximate Agreement *for any nontrivial input vector $\vec{I}$ with complexity $\lceil \log_d \frac{\max_i \vec{I}[i] - \min_i \vec{I}[i]}{\epsilon} \rceil$, where $d = 3$ if the size of the participating set of $\vec{I}$ is 2, and $d = 2$ if the size of the participating set of $\vec{I}$ is 3 or more. Moreover, this protocol is optimal for $\vec{I}$.*

We note that in many cases, for trivial input vectors one can "statically" predefine the outputs for each input value so that no access to an *IS* object is necessary.

Our proof structure will be as follows. The upper bound will follow by showing a subdivision and simplicial map and then applying Theorem 4.2. The lower bound proof will follow from a geometric observation regarding the structure of any NIIS subdivided complex for approximate agreement.

We first restate the description of the Approximate Agreement task using our topological framework.

- $\mathcal{I}$ is the closure under containment of the collection of all simplexes of the form $(\langle 0, x_0 \rangle, \ldots, \langle n, x_n \rangle)$.
- $\mathcal{O}$ is the closure under containment of the collection of all simplexes of the form $(\langle 0, y_0 \rangle, \ldots, \langle n, y_n \rangle)$, where for all i, j, $y_i \in V$ and $|y_i - y_j| \leq \epsilon$.
- $\Gamma = \{(S, T) \mid \mathit{vals}(T) \subseteq [\min \mathit{vals}(S), \max \mathit{vals}(S)]\}$.

Note that the size of the participating set for the input vector corresponding to a simplex S in $\mathcal{I}$ equals $\dim(S) + 1$.

To understand our proof approach, consider Figure 20, which shows the subdivisions induced by a three process protocol. In [2], the lower bound for any $n+1$-process algorithm is derived from a "bad" execution in which only the two processes P and Q with inputs farthest apart participate. Cast in our model, processes P and Q have inputs p and q (the corners of the input simplex in Figure 20). Because there are other simplexes adjacent to the input 1-simplex $(\langle P, p \rangle, \langle Q, q \rangle)$ that share only the input value p and, respectively, q, μ must map $\langle P, p \rangle$ to output value p and $\langle Q, q \rangle$ to output value q. An execution in the NIIS model corresponds to a sequence of chromatic subdivisions of the edge $(\langle P, p \rangle, \langle Q, q \rangle)$ (a path of 1-simplexes) from which there is a simplicial map to a path in the output complex. In the end of the execution, the vertexes of each 1-simplex along this edge must be mapped to an output 1-simplex with values less than ϵ apart. Each subdivision, corresponding to an NIIS execution step, introduces two new vertexes and splits the edge $(\langle P, p \rangle, \langle Q, q \rangle)$ in three. This implies that reaching a distance of ϵ or less along the path of simplexes in the subdivision of $(\langle P, p \rangle, \langle Q, q \rangle)$ requires at least $\log_3(\text{distance}(p, q)/\epsilon)$. This is the bound of [2].

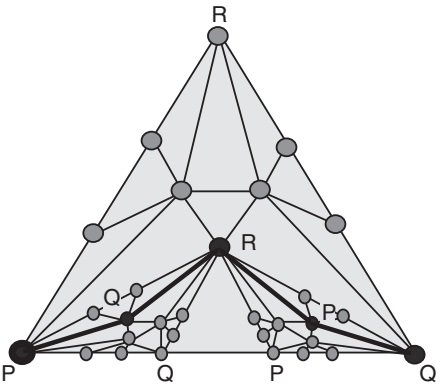

FIG. 20. *Simplex subdivided by an Approximate Agreement protocol.*

However, if one considers executions in which three processes participate, this proof does not work. Consider the first round of subdivision of the simplex for three processors. There is a path (a sequence of adjoining 1-simplexes) between the two endpoints P and Q, along which only a single vertex is introduced by the subdivision. This is the path of length two through the central vertex marked R in Figure 20 (it is not marked since its simplexes are further subdivided in the figure). So the maximum distance is cut by at most a half in the first subdivision. In the next step of subdivision, even though each of the original 1-simplexes (P, R) and (R, Q) of $\widetilde{\mathcal{X}}(S)$ can be subdivided into three simplexes, there is still a path (highlighted in the figure) from P to Q along which only a single node was added connecting P and R (and, respectively, R and Q). In general, after k subdivisions, there is always a path that was divided only 2^k times—hence the lower bound of $\log_2(\text{distance}(p, q)/\epsilon)$. Our upper bounds follow directly from Theorem 4.2 by specifying the proper subdivision and map. The thing to note about the proof we will present for Theorem 5.2 is that it will not involve any mention of the actual executions; all we need to do is argue about the topology of the inputs and outputs and then apply Theorem 4.2.

Proof. Theorem 5.2 states that, given $\epsilon > 0$, there is a protocol $\mathcal{P}_{(n,\tau,\delta)}$ solving Approximate Agreement with complexity $\left\lceil \log_d \frac{\max vals(S) - \min vals(S)}{\epsilon} \right\rceil$ on any input simplex S, where $d = 3$ if $\dim(S) = 1$ and $d = 2$ if $\dim(S) \geq 1$. Moreover, this protocol is optimal on each input simplex S.

We first establish the lower bound. Let $\mathcal{P}_{(n,\tau,\delta)}$ be a protocol that solves Approximate Agreement with worst case complexity k_S on S, where S is any simplex of dimension $n \geq \dim(S) > 0$. Let $D(S) = \max_{\vec{v},\vec{u} \in S}(val(\vec{v}) - val(\vec{u}))$ and let $D(\widetilde{\mathcal{X}}^k(\mathcal{I}))$ equal $\max_{S \in \widetilde{\mathcal{X}}^k(\mathcal{I})} D(S)$. Then Theorem 4.2 states that there is some mappable nonuniform chromatic subdivision $\widetilde{\mathcal{X}}^k(\mathcal{I})$, with level k_S on S. We will show that $k_S \geq \left\lceil \log_d \frac{D(S)}{\epsilon} \right\rceil$. The proof uses the following lemma.

LEMMA 5.3. *Let $l \leq k$. Label the vertexes of $\widetilde{\mathcal{X}}^l(S/\mathcal{I})$ with real numbers in a way that agrees with the initial value labeling of S, and let l_S be the level of $\widetilde{\mathcal{X}}^l(S/\mathcal{I})$. Then*

$$D(\widetilde{\mathcal{X}}^l(S/\mathcal{I})) \geq \frac{D(S)}{d^{l_S}}.$$

Proof. Suppose without loss of generality that $l = l_S$. We first give the proof for the case of two participating processes and $d = 3$. By definition of $D(S)$, there

is a 1-simplex $U = (\vec{u_0}, \vec{u_1})$ in $\mathcal{S}$ such that $D(U) = D(S)$. The complex $\widetilde{\mathcal{X}}^l(U)$ contains at most 3^l 1-simplexes, denoted $U_1, \ldots, U_M$, where $M \leq 3^l$. These form a continuous path from $\vec{u}_0$ to $\vec{u}_1$, the endpoints of which are labeled with $val(\vec{u}_0)$ and $val(\vec{u}_1)$, respectively. So the best we can do is cut $D(U)$ into 3^l pieces. The triangle inequality tells us that $D(U) \leq \sum_{i=1}^{M} D(U_i) \leq M \max_i D(U_i) \leq 3^l \max_i D(U_i)$. Hence $\max_i D(U_i) \geq D(U)/3^l = D(S)/3^l$. The lemma follows, since $\max_i D(U_i) \leq D(\widetilde{\mathcal{X}}^l(S/\mathcal{I}))$.

We now prove the case where the size of the participating set is greater than 2 (and hence $\dim(S)$ is greater than 1) and $d = 2$. We argue by induction on l. The case $l = 0$ is trivial. Now suppose the claim is true for $l - 1$. By definition of $D(\widetilde{\mathcal{X}}^{l-1}(S/\mathcal{I}))$, there is a 1-simplex $U = (\vec{u_0}, \vec{u_1})$ in $\widetilde{\mathcal{X}}^{l-1}(S/\mathcal{I})$ such that $D(U) = D(\widetilde{\mathcal{X}}^{l-1}(S/\mathcal{I}))$. U is a face of some 2-simplex $U' = (\vec{u_0}, \vec{u_1}, \vec{u}_2)$. Suppose first that the next level of nonuniform chromatic subdivision does not subdivide U completely. Then there is some 1-simplex T in the level l nonuniform subdivision of U' with $D(T) \geq D(U)/2$. Since $D(U) = D(\widetilde{\mathcal{X}}^{l-1}(S/\mathcal{I}))$ and $D(T) \leq D(\widetilde{\mathcal{X}}^{l}(S/\mathcal{I}))$, the lemma follows by induction. Suppose instead that the next level of subdivision does subdivide U' completely. Then the level l subdivision has an internal vertex $\vec{m}_2$, colored with $id(\vec{u}_2)$, and two neighboring 1-simplexes $T_0 = (\vec{u}_0, \vec{m}_2)$ and $T_1 = (\vec{m}_2, \vec{u}_1)$. The triangle inequality then tells us that $D(U) \leq D(T_0) + D(T_1) \leq 2 \max_i D(T_i)$, where $i \in \{0, 1\}$. It follows that $D(\widetilde{\mathcal{X}}^{l}(S/\mathcal{I})) \geq D(\widetilde{\mathcal{X}}^{l-1}(S/\mathcal{I}))/2$. The lemma follows by induction. □

Suppose now that there exists a chromatic simplicial map $\mu : \widetilde{\mathcal{X}}^k(\mathcal{I}) \to \mathcal{O}$ such that, for all simplexes T in $\widetilde{\mathcal{X}}^k(\mathcal{I})$, $\mu(T) \in \Gamma(carrier(T))$. We can associate this map with a labeling of the vertexes in $\widetilde{\mathcal{X}}^k(\mathcal{I})$ as follows. Label each vertex $\vec{v}$ in $\widetilde{\mathcal{X}}^k(\mathcal{I})$ with $val(\mu(\vec{v}))$. This labeling agrees with the input value labeling of $\mathcal{I}$, since for any vertex $\vec{v}$, the task specification requires that for any simplex S_0 that contains $\vec{v}$, it must be the case that $\mu(\vec{v})$ is in the range of S_0. Based on the nontriviality assumption, choose two neighboring simplexes S_0 and S_1 containing $\vec{v}$ such that the intersection of the ranges of S_0 and S_1 is $val(\vec{v})$. It follows that $\mu(\vec{v}) = val(\vec{v})$. Now let T be any simplex in $\widetilde{\mathcal{X}}^k(\mathcal{I})$. By definition of μ, $\mu(T)$ is a simplex in $\mathcal{O}$, and hence $D(\mu(T)) < \epsilon$. It follows that $D(T) = D(\mu(T)) < \epsilon$ and hence that $D(\widetilde{\mathcal{X}}^k(\mathcal{I})) < \epsilon$. Clearly, for any input simplex S, it follows that the labels on $\widetilde{\mathcal{X}}^k(S/\mathcal{I})$ have range less than ϵ. The previous lemma then states that $\epsilon > D(\widetilde{\mathcal{X}}^k(S/\mathcal{I})) \geq \frac{D(S)}{d^{k_S}}$. We conclude that

$$k_S \geq \left\lceil \log_d \frac{D(S)}{\epsilon} \right\rceil .$$

To prove the upper bound, we construct a mappable nonuniform chromatic subdivision $\widetilde{\mathcal{X}}^k(\mathcal{I})$ of the input complex with level $k_S = \left\lceil \log_d \frac{D(S)}{\epsilon} \right\rceil$ on each input simplex S, according to Definition 3.30. As argued above, the requirement that the subdivision be mappable is equivalent to saying that there is a vertex labeling of $\widetilde{\mathcal{X}}^k(\mathcal{I})$ that agrees with the initial value labeling of $\mathcal{I}$ with the additional property that $D(\widetilde{\mathcal{X}}^k(\mathcal{I})) < \epsilon$.

Apply $\widetilde{\mathcal{X}}^k$ to $\mathcal{I}$ where for every input n-simplex $S \in \mathcal{I}$, and construct $\widetilde{\mathcal{X}}^k(S/\mathcal{I})$ by repeatedly applying the procedure $\widetilde{\mathcal{X}}^k$ (as specified by Definition 3.30) for each level of subdivision $l \leq k$. For each level, split the vertexes into two sets so that a vertex $\vec{v}$ is in A if there is another adjacent vertex $\vec{u}$ such that $val(\vec{v}) - val(\vec{u}) > \epsilon$; otherwise it is in B. Before applying the next level of subdivision to $\mathcal{X}(\mathcal{A})$, we relabel all new vertexes in $\mathcal{X}(\mathcal{A})$ (those not in $skel^0(\mathcal{A})$) as follows: If the dimension of $\mathcal{A}$ is 1,

label the new vertexes in $\mathcal{X}(\mathcal{A})$ with $(2\min val(\mathcal{A})+\max val(\mathcal{A}))/3$ and $(\min val(\mathcal{A})+2\max val(\mathcal{A}))/3$, respectively. This cuts the distance between the vertexes with values apart in 3. Otherwise, label the new vertexes with $(\min val(\mathcal{A})+\max val(\mathcal{A}))/2$. This cuts the distance between the values furthest apart in 2.

It is clear from this construction that, at each level of recursion, for all simplexes S in $\mathcal{I}$ we have that, if $D(\widetilde{\mathcal{X}}^l(S)) > \epsilon$, then either $D(\widetilde{\mathcal{X}}^{l+1}(S)) = D(\widetilde{\mathcal{X}}^l(S))/d$ or $D(\widetilde{\mathcal{X}}^{l+1}(S)) < \epsilon$. It follows that the level k_S of $\widetilde{\mathcal{X}}^k(\mathcal{I})$ on S is $\lceil \log_d \frac{D(S)}{\epsilon} \rceil$, where $d = 3$ if $\dim(S) = 1$, and $d = 2$ if $\dim(S) > 1$. We conclude from Theorem 4.2 that there is a wait-free protocol that solves Approximate Agreement with worst case time complexity $\lceil \log_d \frac{D(S)}{\epsilon} \rceil$ on input S, where $d = 3$ for two participating processes and $d = 2$ for three or more. □

6. Conclusion and directions for further research. This paper extended the topological framework of Herlihy and Shavit [24, 25, 26] to obtain a complete characterization of the complexity of solving decision tasks in the NIIS model, a generalization of Borowsky and Gafni's IIS model [12]. The main difference between the proof of Theorem 4.2 and Herlihy and Shavit's proof of their asynchronous computability theorem is that our proof rests on the ability to explicitly construct a protocol complex for the NIIS model and to show that this complex is indeed equal to a nonuniform chromatic subdivision. Since nonuniform chromatic subdivisions have a recursive structure, they are well suited for arguing about complexity; the level of recursion of a mappable nonuniform chromatic subdivision of a task's input complex *is* the complexity of the corresponding wait-free NIIS solution protocol.

We have applied Theorem 4.2 to tighten the upper and lower bounds on solving the *Approximate Agreement* task implied by the work of Aspnes and Herlihy [2]. The intuition behind this result as well as its formal proof are based on simple, geometric, and topological arguments about the level of nonuniform chromatic subdivision that is necessary and sufficient for mappability. We believe this is an excellent example of how Theorem 4.2 exposes subtle properties of protocols in asynchronous shared memory systems and how it allows us to reason formally about them without having to argue directly about concurrent executions.

We believe it is possible to extend our existing topological framework to develop a characterization of *work complexity*, the total number of steps taken by all processors in a computation. As was the case for time complexity, a mappable nonuniform chromatic subdivision of an input complex does contain the information necessary to describe work complexity, and the question is really how to quantify and measure it using a simple topological invariant.

Another possible direction is to try to extend the framework to other models of computation, such as the atomic snapshot model, the single-writer multireader model, or even the multiwriter multireader model. Our choice of the NIIS model was motivated by the fact that its protocol complex is highly structured and corresponds to a nonuniform chromatic subdivision, as the proof of Theorem 4.2 shows. Other, less restricted, models, such as atomic snapshots, do not have this property, and so in order to prove a result similar to Theorem 4.2 in any of these models, one would need to identify some invariant, recursive substructure that one can model topologically with reasonable ease.

An alternative approach would be to use simulation techniques to relate the NIIS model to other models of computation, thereby obtaining an indirect characterization of the complexity of solving decision tasks in these models. Currently, however, the best known wait-free simulation of a single IS object using atomic snapshots re-

quires $O(N)$ accesses to shared memory by each process, where N is the number of processes. There is thus an important open problem in finding an *optimal*, wait-free implementation of NIIS using atomic snapshot, and vice versa.

Acknowledgments. We wish to thank Nancy Lynch for her comments on initial drafts of this paper. We also thank the anonymous referees for their careful reading of the manuscript and for providing an abundance of constructive comments.

COVERING PROBLEMS WITH HARD CAPACITIES*

JULIA CHUZHOY† AND JOSEPH (SEFFI) NAOR‡

Abstract. We consider the classical vertex cover and set cover problems with *hard* capacity constraints. This means that a set (vertex) can cover only a limited number of its elements (adjacent edges), and the number of available copies of each set (vertex) is bounded. This is a natural generalization of the classical problems which also captures resource limitations in practical scenarios.

We obtain the following results. For the unweighted vertex cover problem with hard capacities we give a 3-approximation algorithm that is based on randomized rounding with alterations. We prove that the weighted version is at least as hard as the set cover problem, yielding an interesting separation between the approximability of weighted and unweighted versions of a "natural" graph problem. A logarithmic approximation factor for both the set cover and the weighted vertex cover problem with hard capacities follows from the work of Wolsey [*Combinatorica*, 2 (1982), pp. 385–393] on submodular set cover. We provide here a simple and intuitive proof for this bound.

Key words. vertex cover, set cover, hard capacities, submodular set cover

1. Introduction.

The *set cover* problem is the following. Let $E = \{1, \ldots, n\}$ be a ground set of elements, and let $\mathcal{S}$ be a collection of sets defined over E. Each $S \in \mathcal{S}$ has a nonnegative *cost* $w(S)$ associated with it. A *cover* is a collection of sets such that their union is E. The goal is to find a cover of minimum cost. The set cover problem is a classic NP-hard problem that has been studied extensively in the literature, and the best approximation factor achievable for it is $\Theta(\log n)$ [9, 11, 20, 22].

We consider in this paper the set cover problem with *capacity* constraints, or the *capacitated set cover* problem. We assume that each set $S \in \mathcal{S}$ has a *capacity* $k(S)$ associated with it, meaning that it can cover at most $k(S)$ elements.

Generally, capacitated covering problems come in two flavors. In the case of *soft* capacities, an unbounded number of copies of each covering object is available. In the case of *hard* capacities, which is considered in this paper, each covering object (set S) has a bound (denoted by $m(S)$) on the number of available copies. Thus, a cover $\mathcal{C}$ is a multiset of input sets that can cover all the elements, while $\mathcal{C}$ contains at most $m(S)$ copies of each $S \in \mathcal{S}$, and each copy covers at most $k(S)$ elements.

The capacitated (multi-)set cover problem is a natural generalization of a basic and well-studied problem that captures practical scenarios where resource limitations are present.

A special case of the capacitated set cover problem that we consider is the *capacitated vertex cover* problem, defined as follows. An undirected graph $G = (V, E)$ is

given, and each vertex $v \in V$ is associated with a *cost* $w(v)$, a *capacity* $k(v)$, and a *multiplicity* $m(v)$ (we assume that no parallel edges are present). The goal is to find a minimum cost multiset U of vertices that cover all the edges such that, for each vertex $v \in V$, at most $m(v)$ copies appear in U, and each copy covers at most $k(v)$ edges adjacent to v. The capacitated vertex cover problem generalizes the well-known vertex cover problem, probably one of the most studied problems (see [19] for an overview) in the area of approximation algorithms. The best currently known approximation factor for vertex cover is $2 - \frac{\log\log|V|}{2\log|V|}$ [3, 18].

The capacitated vertex cover problem was first introduced by Guha et al. [17]. They considered the version of the problem with *soft* capacities, a special case where the number of available copies of each vertex is unbounded. A straightforward rounding of a linear programming relaxation of the problem gives a 4-approximate solution. Guha et al. [17] show a 2-approximation primal-dual algorithm, and they also give a 3-approximation for the case where each edge $e \in E$ has an (unsplittable) demand $d(e)$. (Gandhi et al. [13] provide further results on the capacitated vertex cover problem with soft capacities.) Guha et al. [17] motivate the study of the vertex cover problem with soft capacities by an application in glycobiology. The problem emerged in the redesign of known drugs involving glycoproteins and can be represented as an instance of the capacitated vertex cover problem.

Two other closely related capacitated covering problems are *capacitated facility location* and *capacitated k-median*. In both problems, the input consists of a set of facilities and a set of clients. For each facility and each client, there is a distance that defines the cost of assigning the client to the facility. Each facility f has a capacity k_f and a number of available copies m_f. Each client i has a demand d_i. The goal is to open facilities and to assign all the clients to them. In the facility location problem, each facility f has a cost w_f. Any number of facilities can be opened, as long as the number of copies of any facility f does not exceed m_f. The cost of a solution is the total cost of the open facilities plus the assignment costs of the clients. In the k-median problem, we are given a bound k on the number of facilities. A solution must contain at most k facilities, and the cost of the solution is the sum of the assignments costs of the clients to the facilities. The capacitated set cover problem is a special case of facility location with hard capacities, where all the distances are either 0 or ∞ (note that this distance function is not a metric). Bar-Ilan, Kortsarz, and Peleg [2] gave an $O(\log n + \log M)$-approximation for the facility location with hard capacities, where M is the value of the maximum input parameter.

Prior work. There is extensive research on the set cover problem, and the reader is referred to the surveys in [15, 7, 1, 26, 19]. The set cover problem is known to be $\Omega(\log n)$ hard to approximate [11, 23]. A greedy heuristic gives an $O(\log n)$-approximation [9, 22] for the set cover problem.

Wolsey [30] considered the *submodular set cover* problem. Let f be an integer valued function defined over all subsets of a finite set of elements E. Function f is called *nondecreasing* if $f(S) \leq f(T)$ for all $S \subseteq T \subseteq E$, and *submodular* if $f(S) + f(T) \geq f(S \cap T) + f(S \cup T)$ for all $S, T \subseteq E$. The input to the submodular set cover problem is a family $\mathcal{S}$ of subsets of E together with a nonnegative cost function. There is a nonnegative nondecreasing submodular function f defined over all collections of the input sets. The goal is to find a minimum cost collection $\mathcal{P}$ of sets such that $f(\mathcal{P}) = f(\mathcal{S})$. The special case where $f(\mathcal{S}) = |\cup_{S \in \mathcal{S}} S|$ for each set $S \in \mathcal{S}$ is the classical set cover problem.

Consider the capacitated set cover problem. We can assume without loss of generality that the multiplicities of all the sets are unit, as is the case in the submodular

set cover problem, by viewing each one of the $m(S)$ copies of each set $S \in \mathcal{S}$ as a distinct set. For any family $\mathcal{A}$ of input sets, define $f(\mathcal{A})$ to be the maximum number of elements that $\mathcal{A}$ can cover (given the capacity constraints). It is not hard to see that f is a nondecreasing nonnegative submodular function. Wolsey [30] showed using dual fitting that the approximation factor of a greedy heuristic for the submodular set cover problem is $1 + O(\log f_{\max})$, where $f_{\max} = \max_{S \in \mathcal{S}} f(\{S\})$.

Metric facility location is a well-studied special case of the facility location problem, where the distance function defined on the clients is a metric. Many heuristics, as well as approximation algorithms with bounded performance guarantees, were developed for this version [6, 25, 27, 29]. For the metric facility location problem with hard capacities, Pál, Tardos, and Wexler [28] gave a $(9 + \epsilon)$-approximation using local search. This result has been improved to $(8 + \epsilon)$-approximation by Mahdian and Pál [24], and the best currently known approximation is $(6 + \epsilon)$, due to Zhang, Chen, and Ye [31] and Garg, Khandekar, and Pandit [16]. Unlike the facility location problem, it is not known whether the capacitated k-median problem has a constant approximation, even if the capacities are soft. Bartal, Charikar, and Raz [4] show a constant factor bicriteria approximation for the soft capacities version, where the number of open facilities k is exceeded by at most a constant. Chuzhoy and Rabani [8] provide a different constant factor bicriteria approximation for the same problem. In their algorithm, the capacities are violated by at most a constant factor, while the number of open facilities is guaranteed to be at most k.

1.1. Our contribution. Our first result is a randomized 3-approximation algorithm for the unweighted capacitated vertex cover problem in simple graphs (i.e., with no parallel edges). Our algorithm uses randomized rounding with *alterations*. The first rounding step in our algorithm applies randomized rounding where the probabilities are derived from a solution to a linear programming relaxation of the problem. However, the rounding may not yield a feasible cover, and therefore we need to add more vertices to the cover. This is done in the alteration step. Our analysis uses a charging scheme to bound the number of vertices that are added to the cover in this step. We also prove that the more general version where edges have unsplittable demands is not approximable in the presence of hard capacities. Contrast this with the 3-approximation algorithm of Guha et al. [17] for this case (with soft capacities).

We next consider the weighted capacitated vertex cover problem and prove that it is set cover hard. This means that the best approximation factor that can be achieved for this problem is $\Omega(\log n)$. Our hardness proof holds even for the case of $\{0, 1\}$ weights and unit multiplicity. Interestingly, we are not aware of any other "natural" graph problem where there is a logarithmic separation between the approximability of weighted and unweighted versions. (However, there are several examples of problems where the unweighted version is polynomially solvable, while the weighted version is NP-hard.)

We leave open the version of the capacitated vertex cover problem where the graph is unweighted, yet there are parallel edges. Our constant-factor approximation algorithm is not applicable to this version of the problem. Following our work, Gandhi et al. [12] obtained a 2-approximation for the unweighted vertex cover with hard capacities, using a modification of our algorithm.

We proceed to consider the capacitated set cover problem. As already noted, it follows from Wolsey's work [30] that a natural greedy heuristic achieves an approximation factor of $O(\log n)$ for this problem. We note that the integrality gap of the natural linear programming relaxation of the problem is unbounded, similar to the

case of facility location with hard capacities [28]. Indeed, Wolsey uses a different linear programming formulation (see section 6 for a formulation of the linear program). We consider the same greedy heuristic as Wolsey and provide a direct combinatorial proof of the approximation factor of this heuristic. We believe that our proof is simple and intuitive. We note that the main obstacle in applying the "standard" (set cover) charging scheme in the presence of hard capacities is that it is not clear how to "charge" the sets in the optimal solution for the sets in the solution computed by the greedy algorithm. Since there are hard capacities, the assignment of elements to sets in the cover is dynamic, and, moreover, elements may be covered and uncovered several times during the iterations of the algorithm.

The paper is organized as follows. In section 3, we show a 3-approximation algorithm for unweighted capacitated vertex cover. In section 4.1 we show that the weighted capacitated vertex cover problem is at least as hard as the set cover problem, even in the case where $m(v) = 1$ for all $v \in V$. In section 4.2 we consider the version where edges have unsplittable demands, and show that this version is not approximable in the presence of hard capacities. In section 5 we provide a description of the greedy algorithm for the set cover problem with hard capacities, and give a simple proof that the algorithm achieves an $O(\log n)$-approximation, implying an $O(\log |V|)$-approximation for the weighted capacitated vertex cover problem. In section 6 we discuss extensions of the algorithm to more general covering problems, such as submodular set cover and multiset multicover.

2. Preliminaries. A set cover instance with hard capacities contains a ground set of elements $E = \{1, \ldots, n\}$ and a collection of sets $\mathcal{S}$ defined over E. Each set $S \in \mathcal{S}$ is associated with a nonnegative cost $w(S)$, a capacity $k(S)$ that bounds the number of elements it can cover, and a bound $m(S)$ on the number of available copies of S. Let $\mathcal{P}$ be a multiset of sets from $\mathcal{S}$. Then $C \subseteq \mathcal{P} \times E$ is called a *partial cover* iff for each $(S, e) \in C$, $e \in S$. We say that element $e \in E$ is covered by S in C if $(S, e) \in C$. Without loss of generality we can assume that each element $e \in E$ is covered in C at most once. Cover C is *feasible* if $\mathcal{P}$ contains at most $m(S)$ copies of each $S \in \mathcal{S}$, and each copy covers at most $k(S)$ elements. The *value* of C, i.e., the number of elements it covers, is denoted by $|C|$. Given a multiset $\mathcal{P}$, denote by $f(\mathcal{P})$ the maximal value of a feasible (partial) cover $C \subseteq \mathcal{P} \times E$. The cost of C is defined to be the sum of the costs of the sets belonging to $\mathcal{P}$. We start by showing that when $\mathcal{P}$ is fixed, a feasible cover $C \subseteq \mathcal{P} \times E$ of value $f(\mathcal{P})$ can be computed in polynomial time.

LEMMA 2.1. *Given an instance of set cover with hard capacities and a multiset $\mathcal{P}$ of sets from $\mathcal{S}$, a cover C of value $f(\mathcal{P})$ can be computed in polynomial time. In particular, whether $\mathcal{P}$ defines a feasible solution to the set cover problem can be established.*

Proof. For each $S \in \mathcal{S}$, let $m^{\mathcal{P}}(S)$ denote the number of copies of S that appear in $\mathcal{P}$. We build the following directed network. Let $G = (L, R, E')$ be the directed incidence graph of $\mathcal{P}$ and E; i.e., L contains a vertex for each copy of each set in $\mathcal{P}$: $L = \{v_i(S) |\ S \in \mathcal{S}, 1 \le i \le m^{\mathcal{P}}(S)\}$, $R = E$. For each $v_i(S) \in L$, $e \in R$, there is an edge $(v_i(S), e) \in E'$ of capacity 1 iff $e \in S$. Add a source vertex s and an edge $(s, v_i(S))$ of capacity $k(S)$ for each $S \in \mathcal{S}, 1 \le i \le m^{\mathcal{P}}(S)$. Add a sink vertex t and an edge (e, t) of capacity 1 for each $e \in E$.

Consider the maximum flow in this network. The value of the flow is at least $f(\mathcal{P})$, since the optimal cover defines a feasible flow in the network. Also, the maximum flow in the network is integral, and thus it induces a feasible partial cover of the same value.

Clearly, $\mathcal{P}$ is a feasible solution to the set cover problem iff $f(\mathcal{P}) = |E|$ and for each $S \in \mathcal{S}$, $m^{\mathcal{P}}(S) \leq m(S)$. □

Since vertex cover with hard capacities is a special case of set cover with hard capacities (where each vertex $v \in V$ can be viewed as a set whose elements are the edges adjacent to v), all the above definitions, as well as Lemma 2.1, can also be applied to the vertex cover problem.

3. Vertex cover with hard capacities. In this section, we show a randomized 3-approximation algorithm for the unweighted capacitated vertex cover problem. Our starting point is the following linear programming relaxation of the problem. For $v \in V$, let $x(v)$ be a variable indicating the number of copies of v that belong to the cover. For $e = (u, v) \in E$, let $y(e, v)$ be a variable indicating whether vertex v covers edge e. Denote by (x, y) a solution to (UVC). For each $v \in V$, $N(v)$ denotes the set of edges adjacent to v.

$$
\begin{array}{lll}
\text{(UVC)} & \min \quad \displaystyle\sum_{v \in V} x(v) & \\
& \text{s.t.} & \\
(1) & y(e,u) + y(e,v) = 1 & \text{for all } e = (u,v) \in E, \\
(2) & y(e,v) \leq x(v) & \text{for all } e \in E,\ v \in e, \\
(3) & \displaystyle\sum_{e \in N(v)} y(e,v) \leq k(v) \cdot x(v) & \text{for all } v \in V, \\
& x(v), y(e,v) \ \geq \ 0 & \text{for all } v \in V,\ e \in E, \\
& x(v) \ \leq \ m(v) & \text{for all } v \in V.
\end{array}
$$

LEMMA 3.1. *Let (x, y) be a feasible solution to* (UVC)*, where x is integral. Then there exists a feasible solution (x, y') to* (UVC)*, where y' is integral. Moreover, this solution can be computed in polynomial time (given x).*

Proof. Let U be the multiset of vertices defined by x; i.e., for each vertex $v \in V$, there are exactly $x(v)$ copies of v in U. We use Lemma 2.1 to compute an (integral) cover y' of the edges by vertices in U. Note that y induces a fractional flow of value $|E|$ in the network constructed in the proof of Lemma 2.1. Thus, $f(U) = |E|$, and therefore, in y', all the edges are covered. □

3.1. A simple 8-approximation algorithm. In this section we show a simple 8-approximation algorithm for the special case of unit multiplicities (i.e., for each vertex exactly one copy is available). The description and the analysis of the algorithm are presented in an informal way. The goal is to give an intuitive explanation of the ideas behind the algorithm. The next section contains a formal description and analysis of a modified (and more complicated) version of the algorithm, which achieves a 3-approximation for the general version (with arbitrary multiplicities).

Let (x, y) be a fractional optimal solution to (UVC). We will find a feasible solution (x', y'), where x' is integral and the expected cost is at most 8 times the cost of the original solution (x, y). By Lemma 3.1, (x', y') can be converted into an integral solution of the same cost. The algorithm consists of three steps.

Step 1 (*setting it up*). We define $U = \left\{v \mid x_v \geq \frac{1}{2}\right\}$. Note that each edge $e \in E$ has at least one endpoint in U. Let $\overline{U} = V \setminus U$, and let E' denote all the edges with one endpoint in $\overline{U}$. Thus, we have two types of edges: edges with both endpoints in

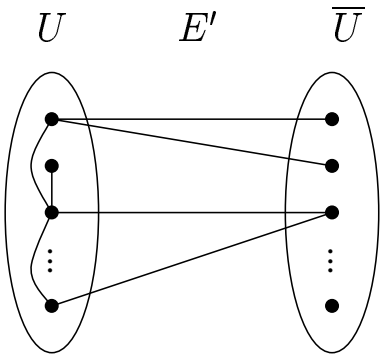

FIG. 3.1. *The sets U and $\overline{U}$.*

U, and edges with one endpoint in U and one endpoint in $\overline{U}$. Figure 3.1 shows the partition of the input graph vertices into sets U, $\overline{U}$, and the types of edges present in the graph.

For each vertex $u \in U$, let $N'(u)$ denote the set of edges in E' incident to u. Set $\ell(u) = \sum_{e \in N'(u)} y(e,u)$ and $r(u) = \sum_{e=(u,v) \in N'(u)} y(e,v) = |N'(u)| - \ell(u)$. Note that the value of $\ell(u)$ denotes the total contribution of u to the coverage of edges in $N'(u)$ (or the "budget" of u), and $r(u)$ denotes the total contribution of vertices in $\overline{U}$ to the coverage of these edges (or the "deficit" of u). The idea is to choose a small subset of vertices $I \subseteq \overline{U}$ such that each $u \in U$ can receive a contribution of at least $r(u)$ from the vertices in I for covering the edges in $N'(u)$. The coverage of the edges with both endpoints in U remains the same as in the linear programming solution. The construction of set I is performed in two steps: randomized rounding and then alterations.

Step 2 (*randomized rounding*). Each vertex $v \in \overline{U}$ is chosen randomly and independently into I with probability $2x_v$. Consider some edge $e = (u,v)$ with $u \in U$, $v \in I$. We set the contribution of v to the coverage of e to be $z(e,v) = \frac{y(e,v)}{x(v)}$. Note that since $y(e,v) \leq x(v)$ is required in (UVC), $z(e,v) \leq 1$, and it follows from constraint (3) that the capacity of v is not exceeded. If vertex $u \in U$ receives a contribution of at least $r(u)$ from the vertices in I, then the budget of u is sufficient to complete the fractional cover of all the edges adjacent to u. However, it is still possible that some vertices $u \in U$ receive a contribution smaller than $r(u)$. This is corrected in the next step.

Step 3 (*alterations*). We denote by P the vertices in U that are in "deficit," i.e.,

$$P = \left\{ u \in U \mid \sum_{e=(v,u) \in E', v \in I} z(e,v) < r(u) \right\}.$$

We proceed iteratively. In each iteration, a new vertex v that fractionally covers some edges adjacent to vertices in P is added to I. Then set P is updated. We continue until P becomes an empty set. The cost of the newly added vertices is charged to the vertices in P.

An iteration is performed as follows. (See Figure 3.2.) Let u be some vertex in P. Then there is at least one edge $e = (v,u) \in E'$, where $v \notin I$. Add v to I. For each edge $e' = (v,w)$, where $w \in P$, $w \neq u$, set the contribution of v to the coverage of e' to be $z(e',v) = \frac{y(e',v)}{x(v)}$. The contribution of v to the coverage of e is defined to

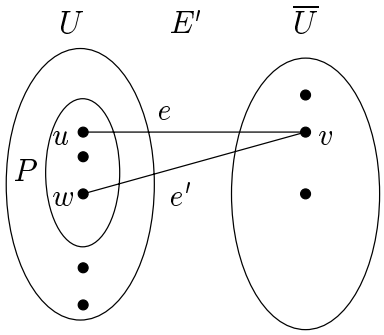

FIG. 3.2. *A Step* 3 *iteration.*

be the minimum between 1 and the remaining capacity of v (which must be at least $y(e,v)$). The cost of v is charged to the vertices in P as follows. Each $w \in P$, $w \neq u$ such that $e' = (w,v) \in E$, pays $z(e',v)$, which is exactly the contribution of v to the coverage of edge e'. The remaining cost is charged to u.

Observe that at the end of this procedure, the cost charged to each vertex $u \in P$ is at most $r(u)+1$. Let i be the last iteration when u belongs to P. In each iteration, u is charged with the amount which is bounded by the contribution it receives in this iteration. Once the total contribution exceeds $r(u)$, u is removed from P. So at the beginning of iteration i, the total amount charged to u does not exceed $r(u)$, and u pays at most 1 in iteration i.

Analysis. The cost of the algorithm is divided into three parts.

1. The cost incurred in Step 1 is at most $2\sum_{u\in U} x(u)$.
2. The expected cost of randomized rounding is at most $2\sum_{u\in \overline{U}} x_u$.
3. The expected cost of Step 3 is bounded as follows. Consider some $u \in U$.
   - If $r(u) \leq 2$, then u pays at most $r(u)+1 = 3$ for Step 3.
   - Assume that $r(u) > 2$. In this case the probability that u belongs to P after Step 2 is at most $\frac{2}{r(u)}$ (this follows from a simple application of the Chebyshev inequality; since the next section contains a similar proof, we omit the proof here). Therefore, the expected cost incurred by u is at most $\frac{2}{r(u)} \cdot (r(u)+1) \leq 3$.

   In total, the expected cost of Step 3 is at most $3|U| \leq 6\sum_{u\in U} x(u)$.

Summing up over the three steps, the expected cost of the solution is bounded by

$$8 \cdot \sum_{u\in U} x(u) + 2\sum_{v\in\overline{U}} x(v) \leq 8 \cdot \sum_{v\in V} x(v).$$

3.2. A 3-approximation algorithm. In this section we show a randomized 3-approximation algorithm for vertex cover with hard capacities and arbitrary multiplicities. The algorithm is based on the ideas presented in the previous section. Consider a fractional optimal solution (x,y) to (UVC). We show how to round this solution, obtaining a feasible solution (x',y'), where x' is integral. By Lemma 3.1, x' induces an integral capacitated vertex cover. As before, the rounding algorithm consists of three major steps.

Step 1 (*setting it up*). We need the following definitions.

- Define $U = \{u \mid x(u) \geq \frac{1}{3}\}$ and $\overline{U} = V \setminus U$. Let U' be the multiset of vertices, where for each $u \in U$ there are $\lceil x(u) \rceil$ copies of u in U'.

- Define E' to be the set of edges with one endpoint in U and the other endpoint in $\overline{U}$.
- For each $u \in V$, $N'(u) = E' \cap N(u)$.
- For each $u \in U$, define: $\ell(u) = \sum_{e \in N'(u)} y(e,u)$ and $r(u) = \sum_{e=(u,v) \in N'(u)} y(e,v) = |N'(u)| - \ell(u)$.
  Note that the value of $\ell(u)$ denotes the total contribution of u to the coverage of edges in $N'(u)$, and $r(u)$ denotes the total contribution of vertices in $\overline{U}$ to the coverage of these edges.
- For each $u \in U$, define $\epsilon(u) = \frac{\lceil x(u) \rceil}{x(u)} - 1$ and $h(u) = (1 - 2\epsilon(u))r(u)$. The meaning of these variables is explained below.

The constraints of (UVC) guarantee that each edge $e = (u,v) \in E$ has at least one endpoint in U: Since $y(e,u) + y(e,v) = 1$, $y(e,u) \le x(u)$, and $y(e,v) \le x(v)$, it follows that either $x(u) \ge \frac{1}{3}$ or $x(v) \ge \frac{1}{3}$ must hold.

Consider a vertex $u \in U$. Let (u,v) be some edge such that $v \in \overline{U}$. Since $y(e,v) \le x(v) < \frac{1}{3}$, it follows that $x(u) \ge y(e,u) > \frac{2}{3}$. It also follows that for each $u \in U$, $\ell(u) \ge 2r(u)$, since $y(e,u) \ge 2y(e,v)$ for each $(u,v) \in N'(u)$.

Our cover is going to contain the vertices of U' together with a subset $I \subseteq \overline{U}$, such that $U' \cup I$ can fractionally cover all the edges. (By Lemma 3.1, $U' \cup I$ is also an integral feasible vertex cover.)

First, we round up $x(u)$ to be equal to $\lceil x(u) \rceil$ for each vertex $u \in U$. As a result, u can increase its contribution to the coverage of the edges belonging to $N'(u)$ by a factor of $\lceil x(u) \rceil / x(u)$; i.e., now it can contribute $\frac{\lceil x(u) \rceil}{x(u)} l(u)$ to the coverage of $N'(u)$. By the definition of $\epsilon(u)$, the new contribution of u is at least $\ell(u)(1+\epsilon(u)) \ge \ell(u) + 2r(u)\epsilon(u)$. If $\epsilon(u) \ge \frac{1}{2}$, then this is enough to complete the coverage of $N'(u)$. Therefore, assume that $\epsilon(u) < \frac{1}{2}$. To complete the fractional cover, we need an additional coverage of value $(1 - 2\epsilon(u))r(u) = h(u)$ from vertices belonging to $\overline{U}$, since $\ell(u) + r(u)$ suffices to cover $N'(u)$. Our goal in the next two steps is to find $I \subseteq \overline{U}$ such that for each $u \in U$, the vertices from I can contribute at least $h(u)$ to the coverage of $N'(u)$.

Step 2 (*randomized rounding*). Each vertex $v \in \overline{U}$ is independently chosen to be in I with probability equal to $3x(v)$. Note that for each $v \in \overline{U}$, we add at most one copy of v to I. For each vertex $v \in I$, for each $e \in N'(v)$, define a new cover of edge e by vertex v: $z(e,v) = \frac{y(e,v)}{x(v)}$.

Step 3 (*alterations*). In this step we start with a feasible fractional solution (x', y') and iteratively alter it until x' becomes integral, while maintaining feasibility of (x', y'). We denote by P the vertices in U that are in "deficit," i.e.,

$$P = \left\{ u \in U \mid \sum_{e=(v,u) \in E', v \in I} z(e,v) < h(u) \right\}.$$

Our initial feasible solution (x', y') for (UVC) is defined as follows: If $v \in U$, then $x'(v) = \lceil x(v) \rceil$. If $v \in I$, then $x'(v) = 1$. Otherwise $x'(v) = x(v)$. For $e = (u,v)$, $y'(e,v)$ and $y'(e,u)$ are defined as follows:

- If $u, v \in U$, then $y'(e,u) = y(e,u)$ and $y'(e,v) = y(e,v)$.
- If $u \in U \setminus P$: if $v \in I$, then $y'(e,v) = z(e,v)$; else $y'(e,v) = 0$. Set $y'(e,u) = 1 - y'(e,v)$. Note that since $u \notin P$, it has enough capacity to complete the cover of $N'(u)$.
- If $u \in P$: if $v \in I$, then $y'(e,v) = z(e,v)$ and $y'(e,u) = 1 - z(e,v)$. (Note that $y'(e,u) \le y(e,u)$, since $z(e,v) \ge y(e,v)$.) Else $(v \notin I)$; set $y'(e,u) = y(e,u)$

and $y'(e,v) = y(e,v)$.

It is easy to see that (x', y') is a feasible solution for (UVC). We now show how to get rid of P by adding new vertices to I. We charge the cost of the new vertices added to I to the vertices of P.

PROCEDURE ELIMINATE. While $P \neq \emptyset$:

1. Let $u \in P$, $e = (u,v) \in E'$, such that $v \in \overline{U} \setminus I$ (there must be at least one such v). Let $P' = \{w \in P \mid w \neq u,\ e' = (w,v) \in E'\}$.
2. Add v to I (set $x'(v) = 1$).

   Update the cover: For each $w \in P'$, where $e' = (v,w) \in E'$, set $y'(e',v) := z(e',v) = \frac{y(e',v)}{x(v)}$. Set $y'(e',w) := 1 - y'(e',v)$. Note that the value of $y'(e',w)$ can only decrease. Set $y'(e,v)$ to be the minimum between 1 and the remaining capacity of v (which must be at least $y(e,v)$). Set $y'(e,u) = 1 - y'(e,v)$.

   Update the set P: For each $w \in P$ for which $\sum_{e=(w,a):a\in I} y'(e,a) \geq h(w)$, remove w from P. Update the cover of $N'(w)$ as follows. For each $e = (b,w) \in E'$ such that $b \notin I$, set $y'(e,b) = 0$ and $y'(e,w) = 1$. Note that w has enough capacity to cover all such edges.

It is easy to see that feasibility is maintained after each iteration. The number of iterations of Procedure Eliminate is bounded by $|\overline{U}|$, since $|I|$ is increased by one in each iteration. At the end, when P becomes empty, for each v with $x'(v) < 1$, we set $x'(v) = 0$. In the final solution, for each $v \in U \cup I$, $x(v) = 1$, and for all other vertices v, $x(v) = 0$. The next theorem follows from the discussion.

THEOREM 3.2. *The algorithm computes a feasible solution (x', y') to* (UVC)*, where x' is integral.*

To obtain an integral capacitated vertex cover, we apply Lemma 3.1 to the solution (x', y').

3.3. Analysis. The analysis of the rounding is divided into two parts.

Charging scheme for Step 3. We show that we can charge the cost of adding vertices to I in Procedure Eliminate to the vertices in P, such that each $u \in P$ pays at most $h(u)+1$. Consider an iteration of Procedure Eliminate. We charge the vertices of $P' \cup \{u\}$ for adding v to I. Each $w \in P'$, where $e' = (w,v) \in E'$, pays $z(e',v)$ (which is exactly the contribution of v to the cover of e'). Vertex u pays the remaining cost (if any remains), which is also at most the contribution of v to the cover of the edge (u,v). We now bound the total amount charged to $a \in P$. While a is still in P, at each iteration it pays at most the amount of coverage that edges in $N'(a)$ get from the newly added vertex v. Once the coverage of $N'(a)$ coming from vertices in I exceeds $h(a)$, a is removed from P. Therefore, in total a pays at most $h(a) + 1$.

Bounding the cost. We now bound the total cost of the solution produced.

CLAIM 3.3. *Let $u \in U$ such that $r(u) \geq \frac{3}{4(1+\epsilon(u))^2}$. Then, the probability that $u \in P$ after Step* 2 *is at most $\frac{3}{4(1+\epsilon(u))^2 r(u)}$.*

Proof. Consider $e = (u,v) \in N'(u)$. We define the random variable

$$t_e = \begin{cases} z(e,v), & v \in I, \\ 0 & \text{otherwise.} \end{cases}$$

Variables t_e are independent since there are no parallel edges in the graph. Note that

- $u \in P$ iff $\sum_{e\in N'(u)} t_e < h(u)$;

- the expectation of $\sum_{e\in N'(u)} t(e)$ is

$$\begin{aligned}\mu &= \mathbf{Exp}\left[\sum_{e\in N'(u)} t_e\right]\\ &= \sum_{e=(v,u)\in N'(u)} 3z(e,v)\cdot x(v)\\ &= 3r(u);\end{aligned}$$

- the variance of $\sum_{e\in N'(u)} t(e)$ is

$$\begin{aligned}\sigma^2 &= \mathbf{Var}\left[\sum_{e\in N'(u)} t_e\right]\\ &= \sum_{e=(u,v)\in N'(u)} z^2(e,v)\cdot 3x(v)\cdot(1-3x(v))\\ &\le \mu.\end{aligned}$$

When applying Chebyshev's inequality to the random variable $\sum_{e\in N'(u)} t_e$, it follows that

$$\begin{aligned}&\mathbf{Prob}\left[\sum_{e\in N'(u)} t_e < h(u)\right]\\ &\le \mathbf{Prob}\left[\left|\sum_{e\in N'(u)} t_e - \mu\right| \ \ge\ \mu - r(u)(1-2\epsilon(u))\right]\\ &= \mathbf{Prob}\left[\left|\sum_{e\in N'(u)} t_e - \mu\right| \ \ge\ 2r(u)(1+\epsilon(u))\right]\\ &\le \frac{\sigma^2}{4r^2(u)(1+\epsilon(u))^2}\\ &\le \frac{3}{4r(u)(1+\epsilon(u))^2}. \qquad \square\end{aligned}$$

We are now ready to compute the expected cost of the solution.

- For $v\in\overline{U}$, the expected cost we pay in Step 2 is $3x(v)$.
- For $u\in U$, where $N'(u)=\emptyset$ or $\epsilon(u)\ge\frac{1}{2}$, we pay at most $3x(u)$ in Step 1, and we do not pay in Step 3.
- For $u\in U$, where $N'(u)\neq\emptyset$ and $\epsilon(u)<\frac{1}{2}$, for the sake of convenience, denote $k=\lceil x(u)\rceil$, $\epsilon=\epsilon(u)$, $x=x(u)$. Consider the following two cases:
  - If $r(u)\ge\frac{3}{4(1+\epsilon)^2}$, then in Step 1 we pay k for the copies of u we use. In Step 3, we pay at most $h(u)+1$ with probability at most $\frac{3}{4r(u)(1+\epsilon)^2}$.

Thus, the expected cost is bounded by

$$\begin{aligned} k + (h(u)+1) \cdot \frac{3}{4r(u)(1+\epsilon)^2} &= k + ((1-2\epsilon)r(u)+1)\,\frac{3}{4r(u)(1+\epsilon)^2} \\ &= k + \frac{3(1-2\epsilon)}{4(1+\epsilon)^2} + \frac{3}{4r(u)(1+\epsilon)^2} \\ &\le k + 1 + \frac{3(1-2\epsilon)}{4(1+\epsilon)^2}. \end{aligned}$$

– If $r(u) < \frac{3}{4(1+\epsilon)^2}$, then in Step 1 we pay k for the copies of u, and at most $h(u)+1$ in Step 3. In total we pay

$$\begin{aligned} k + 1 + h(u) &= k + 1 + (1-2\epsilon)r(u) \\ &\le k + 1 + \frac{3(1-2\epsilon)}{4(1+\epsilon)^2}. \end{aligned}$$

In both cases it suffices to prove that

$$k + 1 + \frac{3(1-2\epsilon)}{4(1+\epsilon)^2} \le 3x.$$

Since $x = \frac{k}{1+\epsilon}$, this is equivalent to showing that

$$k + 1 + \frac{3(1-2\epsilon)}{4(1+\epsilon)^2} \le \frac{3k}{1+\epsilon}.$$

Claim 3.4. *For any $k \ge 1$, $0 \le \epsilon < \frac{1}{2}$, the following inequality holds:*

$$k + 1 + \frac{3(1-2\epsilon)}{4(1+\epsilon)^2} \le \frac{3k}{1+\epsilon}.$$

Proof. The claim is equivalent to

$$k\left(1 - \frac{3}{1+\epsilon}\right) + 1 + \frac{3(1-2\epsilon)}{4(1+\epsilon)^2} \le 0.$$

Note that $1 - \frac{3}{1+\epsilon} < 0$ for $\epsilon < \frac{1}{2}$. Therefore, the left-hand side is maximized when $k = 1$, and it is enough to prove that

$$2 - \frac{3}{1+\epsilon} + \frac{3(1-2\epsilon)}{4(1+\epsilon)^2} \le 0.$$

This is equivalent to

$$8\epsilon^2 - 2\epsilon - 1 \le 0,$$

which holds for all ϵ, $0 \le \epsilon \le \frac{1}{2}$. ∎

4. Hardness results.

4.1. Weighted vertex cover. We show that the capacitated vertex cover with arbitrary weights is at least as hard to approximate as the set cover problem. Given an instance of the set cover problem, let $G = (L, R, E')$ be its bipartite incidence graph, where $L = \mathcal{S}$, $R = E$, $(S, e) \in E'$ iff $e \in S$. For each vertex v in the graph, let $\delta(v)$ denote its degree. For each $v \in L$, define $w(v)$ to be the weight of the corresponding set, and $k(v) = \delta(v)$. For each $v \in R$, define $w(v) = 0$ and $k(v) = \delta(v) - 1$. For each vertex v in the graph, define the multiplicity to be $m(v) = 1$. Given a solution to the set cover instance, the solution to the capacitated vertex cover consists of all the vertices of R and the vertices from L corresponding to the sets in the set cover. The set vertices can cover all their adjacent edges. Since each element is covered in the set cover solution, for each $v \in R$, at least one of its adjacent edges is covered by a set vertex, and thus v has enough capacity to cover the remaining edges. The converse is also true. Given a feasible solution to the vertex cover problem, we can find a feasible solution to the set cover problem of the same cost. The solution to the set cover problem consists of the sets corresponding to the vertices of L that participate in the solution of the vertex cover instance.

4.2. Vertex cover with unsplittable demands. We assume that each edge e has a demand $d(e)$ that must be supplied by one of its endpoints. For each $v \in V$, the sum of the demands of the adjacent edges that v supplies must not exceed the capacity $k(v)$. It is impossible to approximate this problem, since, given a problem instance, it is NP-hard to answer the question of whether V (the set of all the vertices in the problem instance) is a feasible vertex cover, even if the demands are given in unary. The reduction is from the 3-partition problem, which is defined as follows. We are given a bound $B \in Z^+$ and a collection of $3m$ numbers, $a_1, \ldots, a_{3m}$, such that $\sum_{i=1}^{3m} a_i = mB$, and for each $i : 1 \le i \le 3m$, $B/4 < a_i < B/2$. The question is whether the numbers can be partitioned into m sets, such that the sum of numbers in each set is B. Note that if such a partition exists, each set will contain exactly three numbers. This problem is NP-hard in the strong sense (i.e., it is NP-hard even if the numbers are given in unary) [14].

The reduction proceeds as follows. We have $3m$ vertices $v_1, \ldots, v_{3m}$ representing the $3m$ numbers. The capacity of vertex v_i, $1 \le i \le 3m$, is $(m-1)a_i$. We also have m vertices $u_1, \ldots, u_m$ representing the sets, and the capacity of each such vertex is B. Thus, the set of vertices is $V = \{v_i \mid 1 \le i \le 3m\} \cup \{u_j \mid 1 \le j \le m\}$. For each v_i, u_j: $1 \le i \le 3m$, $1 \le j \le m$, there is an edge between the two vertices with demand a_i. Suppose there is a valid partition of the $3m$ numbers into m sets $S_1, \ldots, S_m$. Then for each vertex u_j, $1 \le j \le m$, and for each vertex v_i, $1 \le i \le 3m$, such that $a_i \in S_j$, vertex u_j covers the edge connecting u_j and a_i. As the sum of the numbers in each S_j is exactly B, the capacity of u_j is enough to cover all these edges. Now for each vertex v_i, $1 \le i \le 3m$, one of the edges adjacent to this vertex is covered by one of the vertices $u_1, \ldots, u_m$, and therefore the capacity of v_i is sufficient to cover the remaining $(m-1)$ edges.

The converse direction is also true. Suppose that the set V of vertices can cover all the edges. We show a valid partition of the input elements into m sets $S_1, \ldots, S_m$. Note that each vertex v_i, $1 \le i \le 3m$, has enough capacity to cover only $(m-1)$ of its adjacent edges. Therefore, at least one edge adjacent to v_i is covered by some u_j, $1 \le j \le m$. Set S_j contains all such elements a_i for which vertex u_j covers the edge that connects it with v_i. As the capacities of the vertices u_j, $1 \le j \le m$, are B, the elements in each set sum up also to at most B. Thus, a solution to the capacitated vertex cover problem defines a solution to the 3-partition problem.

5. Set cover with hard capacities. In this section we consider the set cover problem with hard capacities. For the sake of simplicity, we assume that for each set $S \in \mathcal{S}$, only one copy is available, i.e., $m(S) = 1$. If this is not the case, we can view each available copy of each set as a distinct set. Note that the input size remains polynomial, as at most n copies of each set are needed. Thus, given two families $\mathcal{A}, \mathcal{B} \subset \mathcal{S}$ of sets, their union is now defined as usual: $\mathcal{A} \cup \mathcal{B} = \{S \mid S \in \mathcal{A} \text{ or } S \in \mathcal{B}\}$.

We need the following notation. Let $\mathcal{T} \subseteq \mathcal{S}$ be a collection of sets, and let $f(\mathcal{T})$ denote the maximum number of elements that the sets belonging to $\mathcal{T}$ can cover without violating the capacity constraints. Note that $f(\mathcal{T})$ can be computed using Lemma 2.1. For $S \in \mathcal{S}$, define $f_{\mathcal{T}}(S) = f(\mathcal{T} \cup \{S\}) - f(\mathcal{T})$ (i.e., $f_{\mathcal{T}}(S)$ is the increase in the number of elements that can be covered when S is added to set family $\mathcal{T}$). Consider the following greedy algorithm for the set cover problem with hard capacities.

Algorithm Greedy Cover.

1. Initially, $\mathcal{P} = \emptyset$.
2. While $\mathcal{P}$ is not a feasible capacitated set cover:
   (a) Let $S = \arg\min_{S:\ f_{\mathcal{P}}(S)>0} \frac{w(S)}{f_{\mathcal{P}}(S)}$.
   (b) Add S to $\mathcal{P}$.

Wolsey [30] showed using the *dual fitting* technique that Algorithm Greedy Cover achieves an approximation factor of $O(\log(\max_S |S|))$. We show a simpler and a more intuitive charging scheme that proves the same result.

Let $\mathcal{T} \subseteq \mathcal{S}$ be a collection of sets, and let $C \subseteq \mathcal{T} \times E$ be a feasible partial cover. Denote by $|C|$ the number of elements covered by C. We can assume without loss of generality that no element is covered by more than one set in $\mathcal{T}$. For each $\mathcal{T}' \subseteq \mathcal{T}$, we denote by $C_{\mathcal{T}'}$ the projection of C on $\mathcal{T}'$, and by $f_C(\mathcal{T}')$ the number of elements covered by sets belonging to $\mathcal{T}'$ in C. We need the following lemma.

Lemma 5.1. *Consider an instance of the set cover problem with hard capacities. Let $\mathcal{T}$ be a feasible cover, and let $\mathcal{T}_1, \mathcal{T}_2$ be a partition of $\mathcal{T}$ into two disjoint subsets. Then, there is a feasible cover $C \subseteq \mathcal{T} \times E$ such that all the elements are covered in C and $f_C(\mathcal{T}_1) = f(\mathcal{T}_1)$.*

Proof. Let $C \subseteq \mathcal{T} \times E$ be a feasible cover, where each element $e \in E$ is covered by some $S \in \mathcal{T}$, and assume that $f_C(\mathcal{T}_1) < f(\mathcal{T}_1)$. Let $C' \subseteq \mathcal{T}_1 \times E$ be a feasible partial cover, where $f_{C'}(\mathcal{T}_1) = f(\mathcal{T}_1)$. Since C' is a partial cover, some elements may not be covered in C'. We gradually change the cover C, while maintaining its feasibility, until the lemma is satisfied. Perform the following procedure:

While $f_C(\mathcal{T}_1) < f(\mathcal{T}_1)$:

1. Let $S \in \mathcal{T}_1$ be a set such that S covers fewer elements in C than it does in C'. There is at least one such set, since $f_C(\mathcal{T}_1) < f(\mathcal{T}_1)$.
2. Let $e \in E$ be an element covered by S in C' but covered by some $T \neq S$ in C. (Note that T can belong to either $\mathcal{T}_1$ or $\mathcal{T}_2$.)
3. Change C so that e is covered by S; i.e., remove (T, e) and add (S, e) to C.

It is clear that we can perform the procedure and maintain a feasible cover C, while $f_C(\mathcal{T}_1) < f(\mathcal{T}_1)$. Once a pair $(S, e) \in C'$ is added to C, it remains there until the end of the procedure. Thus, the number of iterations is bounded by $|C'|$ and is therefore finite. Upon termination of the procedure, we have a cover C that satisfies the conditions of the lemma. ∎

We now proceed with analyzing Algorithm Greedy Cover. Denote the solution computed by Algorithm Greedy Cover by $\mathcal{P} = \{S_1, S_2, \ldots, S_k\}$, and assume that the sets are added to the solution by the algorithm in this order. For each i, $0 \le i \le k$, let $\mathcal{P}_i = \{S_1, S_2, \ldots, S_i\}$ be the solution at the end of iteration i. Let OPT be an optimal solution. We "replay" the algorithm, while charging the costs of the sets added to $\mathcal{P}$ by Algorithm Greedy Cover to the sets in OPT.

Start with $\mathcal{P}_0 = \emptyset$. For each $S \in OPT$, let $a_0(S)$ be the number of elements covered by S in OPT (assuming every element is covered by exactly one set in OPT). For each iteration i of Algorithm Greedy Cover, new values $a_i(S)$ of sets in $OPT \setminus \mathcal{P}_i$ are defined. The following invariant holds throughout the analysis: we can cover all the elements by the sets in $OPT \cup \mathcal{P}_i$, even if the capacities of sets $S \in OPT \setminus \mathcal{P}_i$ are restricted to be $a_i(S)$.

The invariant is clearly true for $\mathcal{P}_0$ and a_0. Consider iteration i of Algorithm Greedy Cover. We add set S_i to the solution. Since the invariant holds for $\mathcal{P}_{i-1}$, a_{i-1}, the collection of sets $\mathcal{P}_i \cup OPT$ is a feasible cover, even if we restrict the capacities of sets $S \in OPT \setminus \mathcal{P}_i$ to be $a_{i-1}(S)$. By Lemma 5.1, there is a feasible cover $C \subseteq (\mathcal{P}_i \cup OPT) \times E$, where the sets in $\mathcal{P}_i$ cover exactly $f(\mathcal{P}_i)$ elements and each set $S \in OPT \setminus \mathcal{P}_i$ covers at most $a_{i-1}(S)$ elements. For each $S \in OPT \setminus \mathcal{P}_i$, define $a_i(S)$ to be the number of elements covered by S in C. Note that $a_i(S) \le a_{i-1}(S)$.

If $S_i \in OPT$, we do not charge any sets for its cost, since OPT also pays for it. Otherwise, suppose $f_{\mathcal{P}_{i-1}}(S_i) = n_i$. The number of elements covered by sets in $OPT \setminus \mathcal{P}_i$ in C is $\sum_{S \in OPT \setminus \mathcal{P}_i} a_{i-1}(S) - n_i$. Therefore, $\sum_{S \in OPT \setminus \mathcal{P}_i} (a_{i-1}(S) - a_i(S)) = n_i$. We charge each $S \in OPT \setminus \mathcal{P}_i$ with $\frac{w(S_i)}{n_i} \cdot (a_{i-1}(S) - a_i(S))$. Note that the total cost charged to the sets in OPT in this iteration is exactly $w(S_i)$.

We now bound the cost charged to each $S \in OPT$. If $S \in \mathcal{P}$, let j denote the last iteration before S is added to $\mathcal{P}$ (i.e., S is added to $\mathcal{P}$ at iteration $j+1$). Otherwise, let j be the first iteration after which $a_j = 0$ (note that the equality holds for the last iteration). For each $i < j$, at the beginning of iteration i, $f_{\mathcal{P}_{i-1}}(S) \ge a_{i-1}(S)$. This follows from the way the value of $a_{i-1}(S)$ is determined. Since Algorithm Greedy Cover chooses a set other than S in this iteration, $\frac{w(S_i)}{n_i} \le \frac{w(S)}{a_{i-1}(S)}$. Therefore, the total value charged to S is

$$\sum_{i=1}^{j} (a_{i-1}(S) - a_i(S)) \frac{w(S_i)}{n_i} \le w(S) \sum_{i=1}^{j} \frac{(a_{i-1}(S) - a_i(S))}{a_{i-1}(S)}.$$

Observe that for each $i : 1 \le i \le j$, the term $\frac{a_{i-1}(S) - a_i(S)}{a_{i-1}(S)}$ can be written as

$$\sum_{\ell = a_i(S)+1}^{a_{i-1}(S)} \frac{1}{a_{i-1}(S)} \le \sum_{\ell = a_i(S)+1}^{a_{i-1}(S)} \frac{1}{\ell}.$$

Thus, the value charged to S is bounded by $w(S)H(|S|)$, and the total cost of the solution is at most $OPT(1 + \ln(\max_S |S|))$.

6. Extensions.

6.1. Submodular set cover. Recall the *submodular set cover* problem. Let f be an integer valued function defined over all subsets of a finite set E of elements.

Function f is called *nondecreasing* if $f(S) \leq f(T)$ for all $S \subseteq T \subseteq E$, and *submodular* if $f(S) + f(T) \geq f(S \cap T) + f(S \cup T)$ for all $S, T \subseteq E$. The input to the submodular set cover problem is a family $\mathcal{S}$ of subsets of E, together with a nonnegative cost function. There is a nondecreasing nonnegative integer valued submodular function f defined over all collections of the input sets. The goal is to find a minimum cost collection $\mathcal{P} \subset \mathcal{S}$ of sets such that $f(\mathcal{P}) = f(\mathcal{S})$.

It is not hard to show that the natural linear programs for the set cover problem with hard capacities, as well as the more general submodular set cover problem, have an unbounded integrality gap. We note that Algorithm Greedy Cover can be applied to the general submodular set cover problem as well. Indeed, Wolsey [30] showed using the dual fitting technique that Algorithm Greedy Cover achieves a $1 + O(\log(f_{\max}))$-approximation for this problem, where $f_{\max} = \max_{S \in \mathcal{S}} f(\{S\})$. For the sake of completeness, we describe Wolsey's linear program (SSC) below. As before, for $\mathcal{T} \subseteq \mathcal{S}$ and $S \in \mathcal{S}$, $f_{\mathcal{T}}(S) = f(\mathcal{T} \cup \{S\}) - f(\mathcal{T})$. For each set $S \in \mathcal{S}$, there is an indicator variable $x(S)$ showing whether S is in the solution. The goal is to minimize the solution cost, i.e., $\sum_{S \in \mathcal{S}} w(S)x(S)$.

Consider now some collection of input sets $\mathcal{T} \subset \mathcal{S}$, and suppose $f(\mathcal{S}) - f(\mathcal{T}) > 0$. Let $\mathcal{P}$ denote any feasible solution and $\mathcal{P}' = \mathcal{P} \setminus \mathcal{T}$. As $f(\mathcal{S}) - f(\mathcal{T}) > 0$, some sets in $\mathcal{S} \setminus \mathcal{T}$ must be in the solution; i.e., $\mathcal{P}'$ is nonempty. Moreover, $f(\mathcal{P}' \cup \mathcal{T}) - f(\mathcal{T}) \geq f(\mathcal{S}) - f(\mathcal{T})$. Note that, due to the submodularity of f, $\sum_{S \in \mathcal{P}'} (f(\{S\} \cup \mathcal{T}) - f(\mathcal{T})) \geq f(\mathcal{P}' \cup \mathcal{T}) - f(\mathcal{T})$, and therefore $\sum_{S \in \mathcal{P}'} f_{\mathcal{T}}(S) \geq f(\mathcal{S}) - f(\mathcal{T})$ must hold. This condition is expressed by the set of constraints (1).

$$
\begin{array}{lll}
\text{(SSC)} & \min & \displaystyle\sum_{S \in \mathcal{S}} w(S)x(S) \\
& \text{s.t.} & \\
\text{(1)} & \displaystyle\sum_{S \notin \mathcal{T}} f_{\mathcal{T}}(S)x(S) \geq f(\mathcal{S}) - f(\mathcal{T}) & \text{for all } \mathcal{T} \subseteq \mathcal{S}, \\
& x(S) \geq 0 & \text{for all } S \in \mathcal{S}.
\end{array}
$$

We show that our analysis of Algorithm Greedy Cover can be extended to prove a similar approximation guarantee for the submodular set cover problem.

Denote by $\mathcal{P} = \{S_1, S_2, \ldots, S_k\}$ the solution computed by Algorithm Greedy Cover, and assume that the sets are added to the solution by the algorithm in this order. For each i, $0 \leq i \leq k$, let $\mathcal{P}_i = \{S_1, S_2, \ldots, S_i\}$ be the solution at the end of iteration i. Let OPT be an optimal solution. Choose an arbitrary ordering of sets in OPT such that the sets in $\mathcal{P} \cap OPT$ appear at the beginning, in the same order in which they are added to the solution by Algorithm Greedy Cover. For each j, let $\mathcal{T}_j$ denote the first j sets in OPT.

Consider some iteration i of the algorithm. Let $S \in OPT$, and assume that S is the jth set in OPT. Define

$$a_i(S) = f(\mathcal{T}_j \cup \mathcal{P}_i) - f(\mathcal{T}_{j-1} \cup \mathcal{P}_i).$$

If $S_i \in OPT$, then we do not have to charge its cost to sets in OPT. Otherwise, each set $S \in OPT \setminus \mathcal{P}_i$ is charged with $\frac{w(S_i)}{f(\mathcal{P}_i) - f(\mathcal{P}_{i-1})}(a_{i-1}(S) - a_i(S))$.

Observe that the amount charged in iteration i to sets in $OPT \setminus S_i$ is at least $w(S_i)$. This is true, since

$$\begin{aligned}\sum_{S\in OPT\setminus\mathcal{P}_i}(a_{i-1}(S)-a_i(S)) &= \sum_j (f(\mathcal{T}_j\cup\mathcal{P}_{i-1})-f(\mathcal{T}_{j-1}\cup\mathcal{P}_{i-1}))\\ &\quad -\sum_j (f(\mathcal{T}_j\cup\mathcal{P}_i)-f(\mathcal{T}_{j-1}\cup\mathcal{P}_i))\\ &= f(OPT\cup\mathcal{P}_{i-1})-f(\mathcal{P}_{i-1})-f(OPT\cup\mathcal{P}_i)+f(\mathcal{P}_i)\\ &= f(OPT)-f(OPT)+f(\mathcal{P}_i)-f(\mathcal{P}_{i-1})\\ &= f(\mathcal{P}_i)-f(\mathcal{P}_{i-1}).\end{aligned}$$

Observe also that at the beginning of iteration $i+1$, for each $S\in OPT\setminus\mathcal{P}_i$, $f(\{S\})\geq a_i(S)$. Since $f(\{S\})\geq f(\{S\}\cup\mathcal{P}_i)-f(\mathcal{P}_i)$ (due to the submodularity of f), it is enough to show that

$$f(\{S\}\cup\mathcal{P}_i)-f(\mathcal{P}_i)\geq f(\mathcal{T}_j\cup\mathcal{P}_i)-f(\mathcal{T}_{j-1}\cup\mathcal{P}_i).$$

Rearranging the sides, this is equivalent to

$$f(\{S\}\cup\mathcal{P}_i)+f(\mathcal{T}_{j-1}\cup\mathcal{P}_i)\geq f(\mathcal{T}_j\cup\mathcal{P}_i)+f(\mathcal{P}_i),$$

which holds by the submodularity of f.

Using the same reasoning as in the case of the proof of the set cover with hard capacities, the total amount charged to any $S\in OPT$ is at most $w(S)H(|S|)$, and the total cost of the solution is bounded by $OPT(1+\ln(\max_S f(\{S\})))$.

6.2. Multiset multicover. An interesting special case of the submodular set cover problem is the multiset multicover problem. In this problem, the input sets are actually multisets; i.e., an element $e\in E$ can appear in $S_j\in\mathcal{S}$ more than once, and the elements have splittable demands. An integer programming formulation of the multiset multicover problem with unbounded set capacities is the following: $\min\{w^Tx \mid Ax\geq d, 0\leq x\leq b, x\in Z\}$. The constraints $x\leq b$ are called multiplicity constraints, and they generally make covering problems much harder, as the natural linear programming relaxation has an unbounded integrality gap. Dobson [10] gives a combinatorial greedy $H(\max_{1\leq j\leq m}\sum_{1\leq i\leq n}A_{ij})$-approximation algorithm, where $H(t)$ is the tth harmonic number. This is a logarithmic approximation factor for the case where A is a $\{0,1\}$ matrix (set multicover), but can be as bad as a polynomial approximation bound in the general case (multiset multicover). Recently, Carr et al. [5] gave a p-approximation algorithm, where p denotes the maximum number of variables in any constraint. Their algorithm is based on a linear relaxation in the spirit of (SSC). Using similar ideas for strengthening the linear program, Kolliopoulos and Young [21] obtained an $O(\log n)$-approximation.

We can assume again that the multiplicities of the sets are unit, by viewing each copy of each set as a distinct set. We can then define, for each collection $\mathcal{T}$ of input sets, $f(\mathcal{T})$ to be the maximum number of elements that can be covered by $\mathcal{T}$ (with the capacity constraints). It is not hard to see that f is a nonnegative nondecreasing submodular function, and thus the algorithm of Wolsey and our analysis hold for this case.

Notice that the number of sets now is not necessarily polynomial, as the initial set multiplicities $m(S)$ for $S\in\mathcal{S}$ are not necessarily polynomial in the input size. However, the function $f(\mathcal{T})$ can still be computed in polynomial time. Thus, Algorithm Greedy Cover can be implemented to run in polynomial time, achieving an approximation ratio of $O(\log(\max_{S\in\mathcal{S}}|S|))$.

Acknowledgments. We would like to thank the anonymous referee for pointing out the reduction in section 4.2.

PROPERTIES OF NP-COMPLETE SETS*

CHRISTIAN GLAßER†, A. PAVAN‡, ALAN L. SELMAN§, AND SAMIK SENGUPTA§

Abstract. We study several properties of sets that are complete for NP. We prove that if L is an NP-complete set and $S \not\supseteq L$ is a p-selective sparse set, then $L - S$ is $\leq_m^p$-hard for NP. We demonstrate the existence of a sparse set $S \in \mathrm{DTIME}(2^{2^n})$ such that for every $L \in \mathrm{NP} - \mathrm{P}$, $L - S$ is not $\leq_m^p$-hard for NP. Moreover, we prove for every $L \in \mathrm{NP} - \mathrm{P}$ that there exists a sparse $S \in \mathrm{EXP}$ such that $L - S$ is not $\leq_m^p$-hard for NP. Hence, removing sparse information in P from a complete set leaves the set complete, while removing sparse information in EXP from a complete set may destroy its completeness. Previously, these properties were known only for exponential time complexity classes. We use hypotheses about pseudorandom generators and secure one-way permutations to derive consequences for longstanding open questions about whether NP-complete sets are immune. For example, assuming that pseudorandom generators and secure one-way permutations exist, it follows easily that NP-complete sets are not p-immune. Assuming only that secure one-way permutations exist, we prove that no NP-complete set is $\mathrm{DTIME}(2^{n^\epsilon})$-immune. Also, using these hypotheses we show that no NP-complete set is quasi-polynomial-close to P. We introduce a strong but reasonable hypothesis and infer from it that disjoint Turing-complete sets for NP are not closed under union. Our hypothesis asserts the existence of a UP-machine M that accepts 0^* such that for some $0 < \epsilon < 1$, no 2^{n^ϵ} time-bounded machine can correctly compute infinitely many accepting computations of M. We show that if $\mathrm{UP} \cap \mathrm{coUP}$ contains $\mathrm{DTIME}(2^{n^\epsilon})$-bi-immune sets, then this hypothesis is true.

Key words. NP-completeness, robustness, immunity, one-way permutations, disjoint unions

1. Introduction.

This paper continues the long tradition of investigating the structure of complete sets under various kinds of reductions. Concerning the most interesting complexity class, NP, almost every question has remained open. While researchers have always been interested primarily in the structure of complete sets for NP, for the most part, success, where there has been any, has come from studying the exponential time classes. In this paper we focus entirely on the complexity class NP.

The first topic we study concerns the question, How robust are complete sets? Schöning [Sch86] raised the following question: If a small amount of information is removed from a complete set, does the set remain hard? Tang, Fu, and Liu [TFL93] proved the existence of a sparse set S such that for every $\leq_m^p$-complete set L for EXP, $L - S$ is not hard. Their proof depends on the fact that for any exponential time computable set B and any exponential time complete set A, there exists a length-increasing, one-one reduction from B to A [Ber76]. We do not know that about NP. Buhrman, Hoene, and Torenvliet [BHT98] proved that $L - S$ still remains hard for EXP if S is any p-selective sparse set.

Here we prove these results unconditionally for sets that are NP-complete. We prove that if L is an NP-complete set and $S \not\supseteq L$ is a p-selective sparse set, then $L - S$ is $\leq_m^p$-hard for NP. We use the left-set technique of Ogiwara and Watanabe [OW91] to prove this result, and we use this technique elsewhere in the paper also. We demonstrate the existence of a sparse set $S \in \mathrm{DTIME}(2^{2^n})$ such that for every $L \in \mathrm{NP} - \mathrm{P}$, $L - S$ is not $\leq_m^p$-hard for NP. Moreover, we prove for every $L \in \mathrm{NP} - \mathrm{P}$ that there exists a sparse $S \in \mathrm{EXP}$ such that $L - S$ is not $\leq_m^p$-hard for NP. Hence, removing sparse information in P from a complete set leaves the set complete, while removing sparse information in EXP from a complete set may destroy its completeness.

In the fourth section of this paper we build on results of Agrawal [Agr02], who demonstrated that pseudorandom generators can be used to prove structural theorems on complete degrees. We use hypotheses about pseudorandom generators to answer the longstanding open question of whether NP-complete sets can be immune. Assuming the existence of pseudorandom generators and secure one-way permutations, we prove easily that no NP-complete set is p-immune. (This too is a well-known property of the EXP-complete sets.) Assuming only that secure one-way permutations exist, we prove that no NP-complete set is $\mathrm{DTIME}(2^{n^\epsilon})$-immune. Also, we use this hypothesis to show that no NP-complete set is quasi-polynomial-close to P. It is already known [Ogi91, Fu93] that no NP-complete set is p-close to a set in P unless P = NP.

The fifth section studies the question of whether the union of disjoint Turing-complete sets for NP is Turing-complete. Here is the background. If A and B are two disjoint computably enumerable (c.e.) sets, then $A \leq_T A \cup B$, $B \leq_T A \cup B$, and it follows that if either A or B is Turing-complete for the c.e. sets, then so is $A \cup B$ [Sho76]. The proofs are straightforward: To demonstrate that $A \leq_T A \cup B$, on input x, ask whether $x \in A \cup B$. If not, then $x \notin A$. Otherwise, simultaneously enumerate A and B until x is output. The proof suggests that these properties may not hold for $\leq_T^p$-complete sets for NP. In particular Selman [Sel88] raised the question of whether the union of two disjoint $\leq_T^p$-complete sets for NP is $\leq_T^p$-complete. It is unlikely that $A \leq_T^p A \cup B$ for every two disjoint sets A and B in NP; if this holds, then $\mathrm{NP} \cap \mathrm{coNP} = \mathrm{P}$: Take $A \in \mathrm{NP} \cap \mathrm{coNP}$; then $\overline{A} \in \mathrm{NP} \cap \mathrm{coNP}$ as well, and $A \leq_T^p (A \cup \overline{A}) \implies A \in \mathrm{P}$.

First, we will prove that if UEE $\neq$ EE, then there exist two disjoint languages A and B in NP such that $A \not\leq_T^p A \cup B$. Second, we introduce the following reasonable but strong hypothesis: There is a UP-machine M that accepts 0^* such that for some $0 < \epsilon < 1$, no 2^{n^ϵ} time-bounded machine can correctly compute infinitely many accepting computations of M. This hypothesis is similar to hypotheses used in several earlier papers [FFNR96, HRW97, FPS01, PS01]. We prove, assuming this hypothesis, that there exist disjoint Turing-complete sets for NP whose union is not Turing-complete. Also, we show that if UP $\cap$ coUP contains $\mathrm{DTIME}(2^{n^\epsilon})$-bi-immune sets, then this hypothesis is true. Finally, we make several observations about the question of whether the union of two disjoint NP-complete sets is NP-complete. It would be difficult to obtain results about these questions without introducing hypotheses about complexity classes, because there are oracles relative to which the answers to these questions are both positive and negative. Proofs that would settle these questions would not relativize to all oracles.

2. Preliminaries. We use standard notation and assume familiarity with standard resource-bounded reducibilities. Given a complexity class $\mathcal{C}$ and a reducibility $\leq_r$, a set A is $\leq_r$-*hard* for $\mathcal{C}$ if for every set $L \in \mathcal{C}$, $L \leq_r A$. The set A is $\leq_r$-*complete* if, in addition, $A \in \mathcal{C}$. We use the phrase "NP-complete" to mean $\leq_m^p$-complete for NP.

A set S is *sparse* if there exists a polynomial p such that for all positive integers n, $\|S \cap \Sigma^n\| \leq p(n)$. We use polynomial-time invertible pairing functions $\langle \cdot, \cdot \rangle : \Sigma^* \times \Sigma^* \to \Sigma^*$.

A set S is *p-selective* [Sel79] if there is a polynomial-time-computable function $f : \Sigma^* \times \Sigma^* \to \Sigma^*$ such that for all words x and y, (i) $f(x, y) = x$ or $f(x, y) = y$ and (ii) $x \in A$ or $y \in A$ implies $f(x, y) \in A$.

A set L is *immune* to a complexity class $\mathcal{C}$, or *$\mathcal{C}$-immune*, if L is infinite and no infinite subset of L belongs to C. A set L is *bi-immune* to a complexity class $\mathcal{C}$, or *$\mathcal{C}$-bi-immune*, if both L and $\overline{L}$ are $\mathcal{C}$-immune.

3. Robustness. In this section we consider the following question: If L is NP-complete and S is a sparse set, then does $L - S$ remain complete? This question was studied for exponential time complexity classes by Tang, Fu, and Liu [TFL93] and by Buhrman, Hoene, and Torenvliet [BHT98]. The basic result [TFL93] is that there exists a subexponential-time computable sparse set S such that for every $\leq_m^p$-complete set L for EXP, $L - S$ is not EXP-complete. On the other hand, for any p-selective sparse set S, $L - S$ still remains hard [BHT98]. The theorems of Tang, Fu, and Liu depend on the fact that for any exponential-time computable set B and any exponential-time complete set A, there exists a length-increasing, one-one reduction from B to A [BH77]. We do not know that about NP. Nevertheless, here we prove the analogues of these results for NP. Observe that our first result, Theorem 3.1, holds unconditionally.

THEOREM 3.1. *Let L be an* NP*-complete set, and let S be a p-selective sparse set such that $L \not\subseteq S$. Then $L - S$ is $\leq_m^p$-hard for* NP.

Proof. Note that $L - S \neq \emptyset$. If $L - S$ is finite, then L is sparse as well. Since L is $\leq_m^p$-complete for NP, NP = P [Mah82]. Therefore, $L - S$ is also NP-complete. So we assume that $L - S$ is infinite in the rest of the proof.

We use the left set technique of Ogiwara and Watanabe [OW91]. Assume that M is a nondeterministic machine that accepts L. Let T_x be the computation tree of M on any string x. Without loss of generality, assume that T_x is a complete binary tree, and let d be the depth of T_x. Given two nodes u and v in T_x, we say that $u < v$ if the path from the root to u lies to the left of the path from the root to v, and $u \leq v$ if either $u < v$ or u lies on the path from the root to v. Let

$$\begin{aligned}\text{Left}(L) = \{\langle x, u\rangle \mid \exists v, u \leq v, u, v \in T_x, \text{ an accepting} \\ \text{computation of } M \text{ on } x \text{ passes through } v\}.\end{aligned}$$

Since L is NP-complete and Left(L) is in NP, Left$(L) \leq_m^p L$ via some $f \in$ PF. When it is understood that $v \in T_x$, we will write v as an abbreviation for $\langle x, v\rangle$ and $f(v)$ as an abbreviation for $f(\langle x, v\rangle)$. Given x of length n, the length of every node of T_x is bounded by a polynomial in n. Since f is polynomial-time computable, the length of $f(v)$, where $v \in T_x$, is bounded by $p(n)$ for some polynomial $p(\cdot)$. We call $f(v)$ the *label* of v. Since S is sparse, there is a polynomial bound $q(n)$ on the number of strings in S of length at most $p(n)$. Let $g(\cdot, \cdot)$ be the selector function for S. Consider the following total preorder [Tod91] on some $Q \subseteq \Sigma^{\leq p(n)}$:

$$\begin{aligned}x \leq_g y \iff & \exists z_1, z_2, \ldots, z_m \in Q, \\ & g(x, z_1) = x, g(z_1, z_2) = z_1, \ldots, \\ & g(z_{m-1}, z_m) = z_{m-1}, g(z_m, y) = z_m.\end{aligned}$$

Observe that if $x \leq_g y$ and $y \in S$, then $x \in S$ also. Given the selector g, the strings in Q can be ordered by $\leq_g$ in time polynomial in the sum of the lengths of

the strings in Q. Therefore, if $\|Q\|$ is polynomial in n, then the strings in Q can be ordered by $\leq_g$ in time polynomial in n as well.

We first make a few simple observations.

Observation 1. If $u < v$, and w is a descendant of u, then $w < v$.

Observation 2. Let v be the left most node of T_x at some level. Then

$$x \in L \Leftrightarrow v \in \text{Left}(L) \Leftrightarrow f(v) \in L.$$

Observation 3. Let $X = \{x_1, x_2, \dots\} \subseteq \Sigma^{\leq p(n)}$ be a set of more than $q(n)$ distinct strings. Then there exists a procedure that runs in time polynomial in n and outputs $x_i \notin S, i \leq q(n) + 1$.

Proof. Order the first $q(n) + 1$ strings in X by $\leq_g$ and output a highest string as x_i. Since there can be at most $q(n)$ strings of length $\leq p(n)$ in S, x_i cannot be in S. □

We now define a reduction from L to $L - S$. Before we give the formal algorithm, we present the idea behind the reduction. At any time during the reduction our reduction maintains a list of nodes in T_x and a node called *special*. Given x, we perform a breadth first search on T_x. If at any level of the search we find two nodes u and v such that $f(u) = f(v)$, then we do an Ogiwara–Watanabe pruning. If at any stage more than $q(n)$ nodes remain after the pruning, then we can find the left most node *special* such that $f(special)$ is not S. The list contains all the nodes that are to the left of *special*. At this point, we would like stop the search and output $f(special)$. However, it is possible that the rightmost accepting computation passes through a node in the list and so *special* is not in $Left(L)$; thus the reduction is wrong. Thus before we output $f(special)$, we have to verify that the rightmost accepting computation does not pass through a node in the list. However, it is not clear that this can be done in polynomial time.

To get around this, we further expand the nodes in the list and do an Ogiwara–Watanabe pruning again. This process may redefine the node *special*. We stop the search when every node in the list is a leaf node. If any of the leaf nodes is an accepting node, then we know that x is in L, and we output a fixed string not in $L - S$. Otherwise, we output $f(special)$ and argue that the rightmost accepting computation (if it exists) must either pass through *special* or it lies to the right of it.

Now we give a formal description of the reduction.

On input x, $|x| = n$, the reduction traverses T_x in stages. During stage k, the reduction maintains a list $\texttt{list}_k$ of nodes in T_x at level k. The reduction procedure has a variable called "`special`" which holds some node of T_x. At stage 1, $\texttt{list}_1$ contains the root of T_x, and the value of `special` is undefined. Now we define stage $k > 1$.

Step 1 Let $\texttt{list}_{k-1} = \langle v_1, v_2, \dots, v_t \rangle$.

Step 2 Let $u'_1 < u'_2 < \cdots < u'_{2t}$ be the children of nodes in $\texttt{list}_{k-1}$. This ordering is possible since all nodes in $\texttt{list}_{k-1}$ are at depth $k - 1$ of the tree T_x, and therefore $u'_1, \dots, u'_t$ are at level k. Put all these nodes in $\texttt{list}_k$.

Step 3: Pruning If there exist two nodes u'_i and u'_l, $i < l$, in $\texttt{list}_k$ such that $f(u'_i) = f(u'_l)$, then remove $u'_i, \dots, u'_{l-1}$ from $\texttt{list}_k$. Now let $u_1 < \cdots < u_m$ be the nodes in $\texttt{list}_k$, where every u_i has distinct labels. If $m \leq q(n)$, go to the next stage.

Step 4 It must be the case that $m > q(n)$. Therefore, by Observation 3, there must be some $j \leq q(n) + 1$ such that $f(u_j) \notin S$. Set $\texttt{special} = u_j$.

Step 5 If `special` is the leftmost node of T_x at level k, then output `special` and halt.

Step 6 Otherwise, place $u_1, \ldots, u_{j-1}$ in $\texttt{list}_k$ and go to the next stage.

The following algorithm h defines the reduction from L to $L - S$:

```
for k = 1 to d
    run stage k
if any stage halts and outputs v, then
    output f(v)
else /* list_d contains some leaf nodes of T_x */
    if any of the leaf nodes is an accepting computation
        of M on x, then output a predetermined fixed
        string w ∈ L − S
    else
        output f(special)
    endif
endif
```

We prove that the above reduction is correct by the following series of claims.

CLAIM 3.2. *For any $k < d$, if stage k outputs a string v, then*

$$x \in L \Leftrightarrow f(v) \in L - S.$$

Proof. If stage k outputs v, then v is the leftmost node of T_x at level k and $f(v) \notin S$. By Observation 2, the claim follows. □

From now assume that for no k, stage k halts in Step 5. First we make some observations.

Observation 4. During stage $k \geq 1$, $\|\texttt{list}_k\| \leq q(n)$.

Proof. For any stage k, assume that $\texttt{list}_{k-1}$ has $t \leq q(n)$ nodes. The number of nodes in $\texttt{list}_k$ before pruning is at most $2t$. After the pruning step, every $v \in \texttt{list}_k$ has a different label. If there are $\leq q(n)$ nodes in $\texttt{list}_k$, then the procedure goes to the next stage. Otherwise, the node u_j, where $j \leq q(n) + 1$, has a label outside S. Since we assume that stage k does not halt in Step 5, the procedure goes to stage k with $\|\texttt{list}_k\| = j - 1 \leq q(n)$. □

Observation 5. Suppose $\texttt{special} = v$ at the end of stage k. Then for $l \geq k$, for all $u \in \texttt{list}_l$, $u < v$.

Proof. At the end of stage k, let $v = \texttt{special} = u_j$. After Step 6, $\texttt{list}_k$ is a subset of $\{u_1, \ldots, u_{j-1}\}$. Thus for all $u \in \texttt{list}_k$, $u < v$. Note that in any subsequent stage $l > k$, the nodes that belong to $\texttt{list}_l$ are the descendants of nodes in $\texttt{list}_k$. By Observation 1, we obtain the proof. □

Observation 6. No node that is pruned in Step 3 can be on the path containing the rightmost accepting computation.

Proof. If $x \notin L$, no node in T_x is on the path containing any accepting computation. Therefore, let us assume that $x \in L$. If two nodes u'_i and u'_l at the same depth have the identical label w, then $f(u'_i) \in \text{Left}(L) \iff f(u'_l) \in \text{Left}(L)$. Therefore, if any u'_k at the same depth is on the path of the rightmost accepting computation, then either $k < i$ or $k \geq l$. Since only the nodes $u'_i, \ldots, u'_{l-1}$ are pruned, u'_k cannot be pruned. □

CLAIM 3.3. *Assume that $x \in L$ and stage $k \geq 1$ does not halt in Step 5. If $\exists v \in \texttt{list}_k$ that is on the path containing the rightmost accepting computation, then either $\exists u \in \texttt{list}_{k+1}$ that is on the path containing the rightmost accepting computation or* $\texttt{special} \in \text{Left}(L)$.

Proof. Since there is a node v in $\texttt{list}_k$ that is on the path containing the rightmost accepting computation, let u'_r be the node that is generated at Step 2 of stage $k+1$ that

is on the path containing the rightmost accepting computation. By Observation 6, u'_r cannot get pruned in Step 3, and therefore it is in $\texttt{list}_k$ at Step 4. Let us denote this node by u_r. If a node u_j is assigned `special` in Step 4, then either $j \leq r$, in which case $\texttt{special} \in \text{Left}(L)$, or $r < j$, and therefore u_r is in $\texttt{list}_{k+1}$ after Step 6. □

CLAIM 3.4. *If, for every k, stage k does not halt in Step 5, then $x \in L$ if and only if $\texttt{list}_d$ contains a leaf node that is an accepting computation or* $\texttt{special} \in \text{Left}(L)$.

Proof. Note that if x is not in L, then no leaf node can be accepting, and no node of T_x can be in $\text{Left}(L)$. Therefore, the *if* direction is trivial. We show the *only if* direction. We prove the following by induction on the number of stages: If $x \in L$, then after stage k, either the rightmost accepting computation passes through a node in $\texttt{list}_k$ or $\texttt{special} \in \text{Left}(L)$.

After stage 1, $\texttt{list}_1$ contains the root of the tree. Thus the claim is true after stage 1. Assume that the claim is true after stage $k-1$. Thus either the rightmost accepting computation passes through a node in $\texttt{list}_{k-1}$ or $\texttt{special} \in \text{Left}(L)$. We consider two cases.

Case 1. The rightmost accepting computation passes through a node in $\texttt{list}_{k-1}$. By Claim 3.3, either there is a node in $\texttt{list}_k$ that is on the path of the rightmost accepting computation, or the node that is assigned `special` during stage k is in $\text{Left}(L)$.

Case 2. $\texttt{special} \in \text{Left}(L)$. Let s be the node that is currently assigned to `special`. It suffices to show that if a node u is assigned to `special` at stage k, then u will also be in $\text{Left}(L)$. By Observation 5, for every node $v \in \texttt{list}_{k-1}$, $v < s$. Since u is a descendant of some node v in $\texttt{list}_{k-1}$, $u < s$ as well. Therefore, $s \in \text{Left}(L) \implies u \in \text{Left}(L)$.

Therefore, after stage k, $k \geq 1$, the rightmost accepting computation of M either passes through a node in $\texttt{list}_k$ or $\texttt{special} \in \text{Left}(L)$. When $k = d$, this implies that either the rightmost accepting computation is a node in $\texttt{list}_d$ or $\texttt{special} \in \text{Left}(L)$. This completes the proof. □

The correctness of the reduction now follows.

CLAIM 3.5. *The reduction $h(\cdot)$ is correct, and it runs in polynomial time.*

Proof. If the reduction halts at Step 5 during any stage, then by Claim 3.2 $x \in L \Leftrightarrow h(x) \in L - S$. Assume that no stage halts in Step 5. Assume $x \in L$. By Claim 3.4, either $\texttt{list}_d$ contains an accepting leaf or $\texttt{special} \in \text{Left}(L)$. If $\texttt{list}_d$ contains an accepting computation, then $h(x) = w \in L - S$. Otherwise, if $\texttt{special} \in \text{Left}(L)$, then $f(\texttt{special}) \in L$. However, by the definition of `special`, $f(\texttt{special}) \notin S$. Therefore, $f(\texttt{special}) \in L - S$. On the other hand, if $x \notin L$, then no node of T_x can be in $\text{Left}(L)$, and so, in particular, $\texttt{special} \notin \text{Left}(L)$. Therefore, $h(x) = f(\texttt{special}) \notin L$.

By Observation 4, the number of nodes in $\texttt{list}_k$ for any $k \geq 1$ is bounded by $q(n)$. Therefore, the number of nodes visited by the reduction is at most $d \times 2q(n)$. Since d is bounded above by the running time of M on x, the total time required by the reduction is at most polynomial in n. □

Therefore, $L \leq^p_m L - S$. So $L - S$ is $\leq^p_m$-hard for NP. □

COROLLARY 3.6. *Let L be a $\leq^p_m$-complete set for* NP*, and let $S \in$ P be sparse. Then $L - S$ is $\leq^p_m$-complete for* NP.

Observe that the reduction h that is constructed in the proof of Theorem 3.1 actually satisfies the following property:

$$x \in L \implies h(x) \in L - S,$$
$$x \notin L \implies h(x) \in \overline{L}.$$

So for any $S' \subseteq S$ it holds that $L \leq_m^p L - S'$ via h. This shows the following generalization of Theorem 3.1.

THEOREM 3.7. *Let L be a $\leq_m^p$-complete set of* NP*, and let S be a subset of a sparse p-selective set. Then $L - S$ is $\leq_m^p$-hard for* NP.

In contrast to the theorem we just proved, in Theorem 3.9, we construct a sparse set $S \in \mathrm{DTIME}(2^{2^n})$ such that for any set $L \in \mathrm{NP} - \mathrm{P}$, $L - S$ is not $\leq_m^p$-hard for NP. Again, as in Theorem 3.1, we cannot assert that $L - S \in \mathrm{NP}$. In Corollary 3.10, we obtain that for every $L \in \mathrm{NP} - \mathrm{P}$, there is a sparse $S \in \mathrm{EXP}$ such that $L - S$ is not $\leq_m^p$-hard for NP.

The following lemma shows a collapse to P for a restricted form of truth-table reduction from $\overline{\mathrm{SAT}}$ to a sublogarithmically dense set. In other words, we show that if $\overline{\mathrm{SAT}}$ disjunctively reduces to some sublogarithmically dense set where the reduction machine makes logarithmically many nonadaptive queries, then NP = P. We exploit this strong consequence in Theorem 3.9.

LEMMA 3.8. *If there exist $f \in \mathrm{FP}$, $S \subseteq \Sigma^*$, and a real number $\alpha < 1$ such that*

1. *for all $n \geq 0$, $\|S^{\leq n}\| \leq O(\log^\alpha n)$ and*
2. *for all x, $f(x)$ is a set of words such that $\|f(x)\| \leq O(\log |x|)$ and*

$$x \in \mathrm{SAT} \Leftrightarrow f(x) \cap S = \emptyset,$$

then P = NP.

Proof. Assume f, S, and α exist. Let

$$\mathrm{LeftSAT} \stackrel{df}{=} \{\langle x, z\rangle \mid \text{formula } x \text{ has a satisfying assignment } y \geq z\}.$$

Note that for a formula x with n variables, $\langle x, 0^n\rangle \in \mathrm{LeftSAT} \iff x \in \mathrm{SAT}$. Also, LeftSAT is in NP. Let us assume that $\mathrm{LeftSAT} \leq_m^p \mathrm{SAT}$ via reduction $g \in \mathrm{PF}$. Let $h(w) \stackrel{df}{=} f(g(w))$, and let $p(\cdot)$ be the computation time of h. Therefore, by assumption, for all w, $h(w)$ is a set of words such that $\|h(w)\| \leq O(\log |w|)$ and

$$w \in \mathrm{LeftSAT} \Leftrightarrow g(w) \in \mathrm{SAT} \Leftrightarrow h(w) \cap S = \emptyset.$$

Therefore, for every $S' \subseteq S$, and for all x, y,

$$\langle x, y\rangle \in \mathrm{LeftSAT} \implies h(\langle x, y\rangle) \cap S' = \emptyset.$$

Choose constants c and d such that $\|S^{\leq n}\| \leq c \log^\alpha n$ and $\|h(w)\| \leq d \log |w|$. Below we describe a *nondeterministic* polynomial-time-bounded algorithm that accepts SAT. We will see that this algorithm can be simulated in *deterministic* polynomial time. The input is a formula x.

```
1   S' := ∅
2   n := number of variables in x
3   if 1^n satisfies x, then accept x
    /* Otherwise, ⟨x, 1^n⟩ ∉ LeftSAT, and so h(⟨x, 1^n⟩) ∩ S ≠ ∅. */
4   choose some s ∈ h(⟨x, 1^n⟩) nondeterministically
5   S' := S' ∪ {s}
6   for i = 1 to c log^α p(|x| + n)
7       if h(⟨x, 0^n⟩) ∩ S' ≠ ∅, then reject
        /* At this point, h(⟨x, 0^n⟩) ∩ S' = ∅ and h(⟨x, 1^n⟩) ∩ S' ≠ ∅. */
8       Use binary search to determine a word y ∈ Σ^n − {1^n}
        such that h(⟨x, y⟩) ∩ S' = ∅ and h(⟨x, y + 1⟩) ∩ S' ≠ ∅.
```

9 if y satisfies x, then accept
10 choose some $s \in h(\langle x, y\rangle)$ nondeterministically
11 $S' := S' \cup \{s\}$
12 increment i
13 reject

We argue that the algorithm runs in nondeterministic polynomial time. The loop in steps 6–12 runs at most $c \log^\alpha p(|x| + n)$ times, and the binary search takes at most $O(n)$ steps for a formula of n variables. Therefore, the running time is bounded by a polynomial in $(n + |x|)$.

We argue that the algorithm accepts SAT. The algorithm accepts only if we find a satisfying assignment (step 3 or step 9). So all unsatisfiable formulas are rejected. We now show that all satisfiable formulas are accepted by at least one computation path.

Let x be a satisfiable formula; we describe an accepting computation path. On this path, S' will always be a subset of S. If x is accepted in step 3, then we are done. Otherwise, $\langle x, 1^n\rangle \notin$ LeftSAT, and therefore $h(\langle x, 1^n\rangle) \cap S \neq \emptyset$. So in step 4 at least one computation path chooses some $s \in S$.

Since $x \in$ SAT, $\langle x, 0^n\rangle \in$ LeftSAT. Hence $h(\langle x, 0^n\rangle) \cap S = \emptyset$. Since $S' \subseteq S$, it follows that $h(\langle x, 0^n\rangle) \cap S' = \emptyset$. Therefore, if $x \in$ SAT, the nondeterministic path that makes the correct choice for s in step 4 cannot reject x in step 7. Now we have

$$h(\langle x, 0^n\rangle) \cap S' = \emptyset \quad \text{and} \quad h(\langle x, 1^n\rangle) \cap S' \neq \emptyset.$$

Therefore, there must be some y as required by the algorithm, which can be obtained by binary search as follows. Initially, the algorithm considers the interval $[0^n, 1^n]$ and chooses the middle element 10^{n-1}. If $h(\langle x, 10^{n-1}\rangle) \cap S' \neq \emptyset$, then we proceed with the interval $[0^n, 10^{n-1}]$. Otherwise, we proceed with the interval $[10^{n-1}, 1^n]$. By continuing this procedure, we obtain intervals $[a, b]$ of decreasing size such that $a < b$ and

$$h(\langle x, a\rangle) \cap S' = \emptyset \quad \text{and} \quad h(\langle x, b\rangle) \cap S' \neq \emptyset.$$

If we accept in step 9, then we are done. Otherwise, we can argue as follows: By step 8, we have $h(\langle x, y + 1\rangle) \cap S' \neq \emptyset$ and therefore $h(\langle x, y + 1\rangle) \cap S \neq \emptyset$. Hence $\langle x, y + 1\rangle \notin$ LeftSAT. Together with the fact that y does not satisfy x in step 9, we obtain $\langle x, y\rangle \notin$ LeftSAT. Therefore, $h(\langle x, y\rangle) \cap S \neq \emptyset$. On the other hand, $h(\langle x, y\rangle) \cap S' = \emptyset$. Therefore, the correct nondeterministic path can choose an $s \in S - S'$ and continues with the next iteration of the loop. Along this path, S' is always a subset of $S \cap \Sigma^{\leq p(|x|+n)}$. By assumption,

$$\|S^{\leq p(|x|+n)}\| \leq c \cdot \log^\alpha p(|x| + n).$$

We enter the loop with $\|S'\| = 1$, and in each iteration we add a new element to S'. Hence at the beginning of the $(c \cdot \log^\alpha p(|x| + n))$th iteration it holds that $S' = S \cap \Sigma^{\leq p(|x|+n)}$. Now consider this iteration at step 8. Elements of $h(\langle x, y\rangle)$ and elements of $h(\langle x, y + 1\rangle)$ are of length $\leq p(|x| + n)$. So in this iteration we obtain a word y such that

$$h(\langle x, y\rangle) \cap S = \emptyset$$

and

$$h(\langle x, y + 1\rangle) \cap S \neq \emptyset.$$

It follows that $\langle x, y\rangle \in \text{LeftSAT}$ and $\langle x, y+1\rangle \notin \text{LeftSAT}$. So y is the lexicographically largest satisfying assignment of x. Therefore, we accept in step 9. It follows that our algorithm accepts SAT.

We argue that the algorithm can be simulated in deterministic polynomial time. Clearly, each path of the nondeterministic computation is polynomially bounded. We estimate the total number of paths as follows. Each path has at most

$$c \cdot \log^{\alpha} p(|x| + n) + 1$$

nondeterministic choices, where $\alpha < 1$. Each such nondeterministic choice guesses an $s \in h(\langle x, y\rangle)$ for some $y \in \Sigma^n$. By assumption, $\|h(\langle x, y\rangle)\| \leq d \cdot \log(|x| + n)$. Hence the total number of paths is

$$\begin{aligned}
&(d \cdot \log(|x| + n))^{c \cdot \log^{\alpha} p(|x|+n)+1} \\
&\leq 2^{O(\log\log(|x|+n)) \cdot O(\log^{\alpha}(|x|+n))} \\
&\leq 2^{O(\log^{1-\alpha}(|x|+n)) \cdot O(\log^{\alpha}(|x|+n))} \\
&\leq 2^{O(\log(|x|+n))} \\
&\leq (|x| + n)^{O(1)}.
\end{aligned}$$

Hence there is only a polynomial number of nondeterministic paths. Therefore, the algorithm can be simulated in deterministic polynomial time. □

THEOREM 3.9. *There exists a sparse* $S \in \text{DTIME}(2^{2^n})$ *such that for every* $L \in \text{NP} - \text{P}$, $L - S$ *is not* $\leq_m^p$*-hard for* NP.

Proof. Let $\{N_i\}_{i\geq 0}$ be an enumeration of all nondeterministic polynomial-time-bounded Turing machines such that for all i, the running time of N_i is bounded by the polynomial $p_i(n) = n^i + i$. Similarly, let $\{f_j\}_{j\geq 0}$ be an enumeration of all polynomial-time computable functions such that for all j, the running time of f_j is bounded by the polynomial $p_j(n) = n^j + j$. We use a polynomial-time computable and polynomial-time invertible pairing function $\langle\cdot,\cdot\rangle$ such that $r = \langle i, j\rangle$ implies $i \leq r$ and $j \leq r$.

A *requirement* is a natural number r. If $r = \langle i, j\rangle$, then we interpret this as the requirement that $L(N_i)$ does not many-one reduce to $L(N_i) - S$ via reduction function f_j.

Let $t(m) = 2^{2^m}$. We describe a decision algorithm for S. Let w be the input and let $n = |w|$.

```
1   if |w| < 4, then reject
2   n := |w|, m := greatest number such that t(m) ≤ n
3   for k = 1 to m
4       S_k := ∅, L_k := ∅
5       for r = 1 to k
6           if r ∉ L_1 ∪ L_2 ∪ ··· ∪ L_{k−1}, then
7               determine i and j such that r = ⟨i, j⟩,
8               for all z ∈ Σ^{<t(k+2)} in increasing lexicographic order
9                   y := f_j(z)
10                  if t(k) ≤ |y| < t(k + 1) and N_i(z) accepts, then
11                      S_k := {y}
12                      L_k := {r}
13                      exit the loops for z and r, and consider next k
14                  endif
15              increment z
```

16 endif
17 increment r
18 increment k
19 accept if and only if $S_m = \{w\}$

The algorithm works in stages $1, \ldots, m$, where m is the greatest natural number such that $t(m) \leq n$. In stage k, we construct a set S_k such that $\|S_k\| \leq 1$ and

$$S_k = \{w \in S \mid t(k) \leq |w| < t(k+1)\}.$$

Hence S can be written as $S_1 \cup S_2 \cup \cdots$. The input w is accepted if and only if it belongs to S_m. The aim of stage k is to satisfy a requirement $r \in \{1, \ldots, k\}$ that has not been satisfied so far (i.e., $r \notin L_1 \cup \cdots \cup L_{k-1}$). If more than one requirement is satisfiable, then we choose the smallest one. Requirement $r = \langle i, j \rangle$ is satisfied by placing a string y into S_k and therefore into S such that $f_j(z) = y$ for a suitable $z \in L(N_i)$. This makes sure that $L(N_i)$ does not many-one reduce to $L(N_i) - S$ via reduction f_j.

Whenever we refer to (the value of) a program variable without mentioning the time when we consider this variable, then we mean the value of the variable when the algorithm stops. Variables L_k represent sets of requirements. If requirement i is satisfied in stage k, then i is added to the set L_k. The algorithm ensures that $\|L_k\| \leq 1$ for every k.

We observe that S is sparse. For all inputs of length $\geq t(k)$ the algorithm constructs the same sets $S_1, S_2, \ldots, S_m$ and $L_1, L_2, \ldots, L_m$. Therefore, it is unambiguous to refer to S_k and L_k. Moreover, it is immediately clear that any S_k contains at most one word, and this word, if it exists, has a length that belongs to the interval $[t(k), t(k+1))$. By the definition of $t(k)$, for every $n \geq 4$,

$$t(\lfloor \log \log n \rfloor) \leq n < t(\lfloor \log \log n \rfloor + 1).$$

Hence on input of some word of length $n \geq 4$, we have

$$m = \lfloor \log \log n \rfloor \tag{1}$$

in step 2. So the algorithm computes singletons $S_1, S_2, \ldots, S_m$ such that $S^{\leq n} \subseteq S_1 \cup S_2 \cup \cdots \cup S_m$. It follows that

$$\|S^{\leq n}\| \leq \lfloor \log \log n \rfloor. \tag{2}$$

In particular, S is sparse.

We observe that $S \in \mathbf{DTIME}(2^{2^n})$. Note that in step 10, $|z| < t(m+2) = t(m)^4 \leq n^4$ and $i \leq r \leq m = \lfloor \log \log n \rfloor$. So a single path of the nondeterministic computation $N_i(z)$ has length

$$\leq n^{4i} + i \leq 2^{O(\log^2 n)}.$$

Hence the simulation of the complete computation takes

$$2^{2^{O(\log^2 n)}} \cdot 2^{O(\log^2 n)} = 2^{2^{O(\log^2 n)}}$$

steps. Similarly, step 9 takes $2^{O(\log^2 n)}$ steps. So the loop at steps 8–15 takes at most

$$2^{n^4} \cdot 2^{2^{O(\log^2 n)}} = 2^{2^{O(\log^2 n)}}$$

steps. The loops 5–17 and 3–18 multiply this number of steps at most by factor

$$m^2 \leq \lfloor \log \log n \rfloor^2.$$

Therefore, the overall running time is $2^{2^{O(\log^2 n)}}$. This shows

$$S \in \mathrm{DTIME}(2^{2^{O(\log^2 n)}}) \subseteq \mathrm{DTIME}(2^{2^n}).$$

We observe that no $L - S$ is many-one hard. Let $L \in \mathrm{NP} - \mathrm{P}$ and choose a machine N_i such that $L = L(N_i)$. Assume that $L - S$ is $\leq_m^p$-hard for NP. Therefore, there exists j such that $L \leq_m^p L - S$ via reduction function f_j. We consider two cases and show that both cases lead to contradiction. This will complete the proof.

Case 1. Assume there exists an $e \geq 1$ such that for all $x \in L^{\geq e}$, $|f_j(x)| < \sqrt{|x|}$. Using Lemma 3.8, we show that this implies $L \in \mathrm{P}$, thereby obtaining a contradiction.

Consider an arbitrary formula x. Let $s_0 \stackrel{df}{=} x$, and let $s_{l+1} \stackrel{df}{=} f_j(s_l)$ for $l \geq 0$. By assumption, for all $y \in L^{\geq e}$ it holds that

$$y \in L \iff f_j(y) \notin S \wedge f_j(y) \in L. \tag{3}$$

Hence

$$x \in L \iff s_1 \notin S \wedge s_1 \in L. \tag{4}$$

If $|s_1| \geq e$, we use equivalence (3) for $y = s_1$. We obtain

$$s_1 \in L \iff s_2 \notin S \wedge s_2 \in L. \tag{5}$$

By equivalences (5) and (4), we have

$$x \in L \iff s_1 \notin S \wedge s_2 \notin S \wedge s_2 \in L. \tag{6}$$

Now we use equivalence (3) again, this time for $y = s_2$. We proceed in this way until we reach an s_k such that either $|s_k| < e$ or $|s_k| \geq \sqrt{|s_{k-1}|}$. The following equivalence holds:

$$x \in L \iff \bigwedge_{l=1}^{k} s_l \notin S \wedge s_k \in L. \tag{7}$$

Note that if $|s_k| < e$, then it is easy to verify whether s_k belongs to L. So in polynomial time we can determine a string s which is defined as follows. If $s_k \in L^{<e}$, then let s be a fixed element from $\overline{S}$. Otherwise, let s be a fixed element from S. We show

$$x \in L \iff \{s_1, \ldots, s_k, s\} \cap S = \emptyset. \tag{8}$$

"⇒" Assume $x \in L$. Therefore, $s_1, \ldots, s_k \in L$. If $|x| < e$, then $k = 0$, $s \in \overline{S}$, and we are done. Otherwise, $|x| \geq e$ and $k \geq 1$. If $|s_k| < e$, then, by equivalence (7), $s \in \overline{S}$. So from equivalence (7) it follows that $\{s_1, \ldots, s_k, s\} \cap S = \emptyset$, and we are done. We show that the remaining case, i.e., $|s_k| \geq e$, is impossible. Since the algorithm terminated, it must be the case that $|s_k| \geq \sqrt{|s_{k-1}|}$. However, since $x \in L$, $s_k \in L$ by equivalence (7). By our assumption, it cannot happen that $s_k \in L^{\geq e}$ and $|s_k| \geq \sqrt{|s_{k-1}|}$. Therefore, $|s_k| < e$.

"⇐" Assume $\{s_1, \ldots, s_k, s\} \cap S = \emptyset$. Hence $s \in \overline{S}$ and therefore $s_k \in L^{<e}$. From equivalence (7) we obtain $x \in L$. This shows equivalence (8).

For $1 \leq l \leq k-1$ it holds that $|s_l| < \sqrt{|s_{l-1}|}$. Therefore, $k \leq |x|$, and so the strings s and s_i can be constructed in polynomial time in $|x|$. Let $g \in \mathrm{FP}$ be the function that on input x computes the set $\{s_1, \ldots, s_k, s\}$. So for all x,

$$x \in L \Leftrightarrow g(x) \cap S = \emptyset. \tag{9}$$

Observe that for all x,

$$\|g(x)\| \leq \lfloor \log \log |x| \rfloor + 1.$$

By assumption, $L - S$ is many-one hard for NP. So there exists a reduction function $h \in \mathrm{FP}$ such that $\mathrm{SAT} \leq_m^p L - S$ via h. By (9), for all x,

$$\begin{aligned} x \in \mathrm{SAT} &\Leftrightarrow h(x) \in L \wedge h(x) \notin S \\ &\Leftrightarrow (g(h(x)) \cup \{h(x)\}) \cap S = \emptyset. \end{aligned}$$

With $h'(x) \stackrel{df}{=} g(h(x)) \cup \{h(x)\}$ it holds that for all x,

$$x \in \mathrm{SAT} \Leftrightarrow h'(x) \cap S = \emptyset. \tag{10}$$

Clearly, h' belongs to FP and for all x,

$$\|h'(x)\| \leq \lfloor \log \log |h(x)| \rfloor + 2 \leq \lfloor \log \log |x| \rfloor + c \tag{11}$$

for a suitable constant c. By (2), (10), and (11), we satisfy the assumptions of Lemma 3.8 (take h', S, and $\alpha = 1/2$). It follows that $L \in \mathrm{P}$. This contradicts our assumption.

Case 2. Assume there exist infinitely many $x \in L$ such that $|f_j(x)| \geq \sqrt{|x|}$. We show that in this case L does not many-one reduce to $L - S$ via f_j. This will give us the necessary contradiction.

Recall that $L = L(N_i)$. Let $\bar{r} \stackrel{df}{=} \langle i, j \rangle$. Since every nonempty L_k contains a unique requirement, we can choose a number $m' \geq \bar{r}$ such that for all $k \geq m'$,

$$L_k \cap \{0, \ldots, \bar{r} - 1\} = \emptyset. \tag{12}$$

Note that for infinitely many strings $x \in L$, $|f_j(x)| \geq \sqrt{|x|}$. Therefore, we can choose some string $\bar{z} \in L$ such that

$$\sqrt{|\bar{z}|} \geq t(m') \tag{13}$$

and

$$|f_j(\bar{z})| \geq \sqrt{|\bar{z}|}. \tag{14}$$

Let $w \stackrel{df}{=} f_j(\bar{z})$ and $n \stackrel{df}{=} |w|$. Let $\bar{m}$ be such that $t(\bar{m}) \leq n < t(\bar{m}+1)$. By the choice of $\bar{z}$, $|\bar{z}| < t(\bar{m}+2)$. We will show that if $\bar{r}$ is not in $L_1 \cup \cdots \cup L_{\bar{m}-1}$, then $L_{\bar{m}} = \{\bar{r}\}$.

Consider the algorithm on input w. By the choice of $\bar{m}$, $t(\bar{m}) \leq |w| = n < t(\bar{m}+1)$. Therefore, by the choice of m in step 2 of the algorithm, $m = \bar{m}$. Consider step 6 when $k = \bar{m}$ and $r = \bar{r}$. We note that as a consequence of (12), for any $k \geq \bar{m} \geq m'$, $L_k \cap \{0, \ldots, \bar{r} - 1\} = \emptyset$. Therefore, the loop (steps 5–17) cannot exit with some $r < \bar{r}$. On the other hand, for $\bar{r}$, the condition in step 6 must be true, since we assumed that

$\bar{r} \notin L_1 \cup \cdots \cup L_{\bar{m}-1}$. Therefore, we reach step 7. By the choice of $\bar{m}$, $|\bar{z}| \leq t(\bar{m}+2)$. Therefore, either we reach step 9 such that $z = \bar{z}$ or $\bar{r}$ is put in $L_{\bar{m}}$ with some other z and $S_{\bar{m}} = \{f_j(z)\}$. If $z = \bar{z}$, then after step 9, $y = f_j(\bar{z}) = w$ and therefore $|y| = n$. Therefore, it must hold in step 10 that $t(\bar{m}) \leq |y| < t(\bar{m}+1)$. Moreover, $N_i(\bar{z})$ accepts since $\bar{z} \in L$. Therefore, we reach steps 11 and 12, where we obtain that $L_{\bar{m}} = \{\bar{r}\}$. As a consequence,

$$\bar{r} \notin L_1 \cup \cdots \cup L_{\bar{m}-1} \implies \bar{r} \in L_{\bar{m}}.$$

It follows that $\bar{r} \in L_1 \cup L_2 \cup \cdots \cup L_{\bar{m}}$. Let k, $1 \leq k \leq \bar{m}$, be such that $L_k = \{\bar{r}\}$. Let $S_k = \{y\}$. By steps 9 and 10, there exists a $z \in L$ such that $y = f_j(z)$. From $y \in S$ it follows that $y \notin L - S$. Therefore, L does not many-one reduce to $L - S$ via reduction function f_j. This contradicts our assumption. □

COROLLARY 3.10. *For every* $L \in \mathrm{NP} - \mathrm{P}$ *there exists a sparse* $S \in \mathrm{EXP}$ *such that* $L - S$ *is not* $\leq_m^p$*-hard for* NP.

Proof. Choose i such that $L = L(N_i)$. We recycle the proof of Theorem 3.9. Here we have to do only the diagonalization against the machine N_i. So we interpret r as the requirement that L does not many-one reduce to $L - S$ via reduction function f_r. We modify the algorithm in the proof of Theorem 3.9 by replacing step 7 with "`j := r`."

Analogously to the proof of Theorem 3.9 we observe that S is sparse. Because we modified the algorithm, now S belongs to EXP. This is seen as follows: Again in step 10,

$$|z| < t(m+2) = t(m)^4 \leq n^4.$$

But now i is a constant. So a single path of the nondeterministic computation $N_i(z)$ now has length $\leq n^{4i} + i$. Hence the simulation of the complete computation takes the following number of steps:

$$2^{n^{4i}+i} \cdot (n^{4i} + i) \leq 2^{n^{O(1)}}.$$

Note that

$$j = r \leq m \leq \lfloor \log \log n \rfloor.$$

So step 9 takes

$$n^{4j} + j \leq 2^{O(\log^2 n)} \leq 2^{O(n)}$$

steps. Therefore, the loop at steps 8–15 takes at most

$$2^{n^4} \cdot 2^{n^{O(1)}} = 2^{n^{O(1)}}$$

steps. The loops 5–17 and 3–18 multiply this number of steps at most by factor

$$m^2 \leq \lfloor \log \log n \rfloor^2.$$

Therefore, the overall running-time remains $2^{n^{O(1)}}$. This shows $S \in \mathrm{EXP}$.

Analogously to the proof of Theorem 3.9 we argue that $L - S$ is not $\leq_m^p$-hard for NP. Here we have to define $\bar{r} \stackrel{df}{=} j$ in Case 2. □

In view of Corollary 3.10 we would like to minimize the complexity of S. For this it suffices to consider $L = \mathrm{SAT}$: Given a sparse set S such that $\mathrm{SAT} - S$ is not $\leq_m^p$-hard for NP, for every $L \in \mathrm{NP}$ it is easy to describe a sparse set S' such that $S' \leq_m^p S$ and $L - S'$ is not $\leq_m^p$-hard for NP. Let $f \in \mathrm{PF}$ be the one-one function that reduces L to SAT. Then $S' = \{x \mid f(x) \in S\}$ is sparse and $L - S'$ reduces to $\mathrm{SAT} - S$ via f. So $L - S'$ cannot be $\leq_m^p$-hard for NP.

4. Immunity and closeness. Agrawal [Agr02] demonstrated that pseudorandom generators can be used to prove structural theorems on complete degrees of NP. Here we build on his results and show that hypotheses about pseudorandom generators and secure one-way permutations answer the longstanding open question of whether NP-complete sets can be immune. Also, using these hypotheses we show that no NP-complete set is quasi-polynomial-close to P.

It is well known that no EXP-complete set is p-immune. To see this, consider $L \in \text{EXP}$ that is $\leq_m^p$-complete. Then $0^* \leq_m^p L$ via some length-increasing reduction f. Since f is length-increasing, $\{f(0^n) \,|\, n \geq 0\}$ is an infinite subset of L. However, while for any EXP-complete set L and any $A \in \text{EXP}$, there is a length-increasing reduction from A to L [BH77], this is not known to hold for NP.

We begin with the following definitions. In particular it is important to distinguish pseudorandom generators, as defined by Nisan and Wigderson [NW94], for derandomization purposes, from cryptographic pseudorandom generators [Yao82, BM84].

DEFINITION 4.1. *A function $G = \{G_n\}_n$, $G_n : \Sigma^{=n} \mapsto \Sigma^{=m(n)}$, is an* $s(n)$-secure cryptographic pseudorandom generator *(*crypto-prg *for short) if G is computable in polynomial time in the input length, $m(n) > n$ and for every $\delta(\cdot)$ such that $\delta(n) < 1$, for every $t(\cdot)$ such that $t(n) \leq \delta(n) \cdot s(n)$, and for every circuit C of size $t(n)$, for all sufficiently large n,*

$$\left| \Pr_{x \in \Sigma^{=m(n)}}[C(x) = 1] - \Pr_{y \in \Sigma^{=n}}[C(G_n(y)) = 1] \right| \leq \delta(n).$$

DEFINITION 4.2. *A function $G = \{G_n\}_n$, $G_n : \Sigma^{=l} \mapsto \Sigma^{=n}$, is a* pseudorandom generator *(*prg *for short) if $l = O(\log n)$, G is computable in time polynomial in n, and for any linear-size circuit C,*

$$\left| \Pr_{x \in \Sigma^{=n}}[C(x) = 1] - \Pr_{y \in \Sigma^{=l}}[C(G_n(y)) = 1] \right| \leq \frac{1}{n}.$$

DEFINITION 4.3. *A function $f = \{f_n\}_n$, $f_n : \Sigma^{=n} \mapsto \Sigma^{=m(n)}$, is* $s(n)$-secure *if for every $\delta(\cdot)$ such that $\delta(n) < 1$, for every $t(\cdot)$ such that $t(n) \leq \delta(n) \cdot s(n)$, and for every nonuniform circuit family $\{C_n\}_n$ of size $t(n)$, for all sufficiently large n,*

$$\Pr_{x \in \Sigma^{=n}}[C_n(x) = f_n(x)] \leq \frac{1}{2^{m(n)}} + \delta(n).$$

Hypothesis A. Pseudorandom generators exist.

Hypothesis B. There is a secure one-way permutation. Technically, there is a permutation $\pi \in \text{PF}$ and $0 < \epsilon < 1$ such that π^{-1} is 2^{n^ϵ}-secure.

Hypothesis B implies the existence of cryptographic pseudorandom generators [Yao82]. Agrawal [Agr02] showed that if Hypothesis B holds, then every $\leq_m^p$-complete set for NP is hard also for one-one, length-increasing, nonuniform reductions. The following theorem is implicit in the proof of his result.

THEOREM 4.4. *If Hypotheses A and B hold, then every set A that is $\leq_m^p$-hard for* NP *is hard for* NP *under length-increasing reductions.*

By Theorem 4.4, Hypotheses A and B imply that for every NP-complete set A, there is a length-increasing reduction f from 0^* to A. This immediately implies that the set

$$\{f(0^n) \,|\, n \geq 0\}$$

is an infinite subset of A that belongs to P; i.e., A cannot be p-immune.

THEOREM 4.5. *If Hypotheses A and B hold, then no* $\leq_m^p$*-complete set for* NP *can be p-immune.*

We consider immunity with respect to classes that are larger than P. Similar questions have been studied for EXP. For example, Homer and Wang [HW94] showed that EXP-complete sets have dense UP subsets.

THEOREM 4.6. *Let* $\mathcal{C} \subseteq$ NP *be a complexity class closed under* $\leq_m^p$*-reductions such that for some* $\epsilon > 0$*, there is a tally set* $T \in \mathcal{C}$ *that is not in* DTIME(2^{n^ϵ})*. Then no* $\leq_m^p$*-complete set for* NP *is* $\mathcal{C}$*-immune.*

COROLLARY 4.7. *If there is a tally set in* UP *that is not in* DTIME(2^{n^ϵ})*, then no* $\leq_m^p$*-complete set for* NP *is* UP*-immune.*

Proof of Theorem 4.6. Let T be a tally set in $\mathcal{C}$ that does not belong to DTIME(2^{n^ϵ}). We will show that no NP-complete set is $\mathcal{C}$-immune.

Let L be an NP-complete set, and let $k > 0$ such that $L \in$ DTIME(2^{n^k}). Let f be a $\leq_m^p$-reduction from T to L. We claim that the set

$$X = \{f(0^n) \,|\, 0^n \in T \text{ and } |f(0^n)| > n^{\epsilon/k}\}$$

is infinite. Assume otherwise: Then, for all but finitely many n, $0^n \in T \implies |f(0^n)| \leq n^{\epsilon/k}$. Consider the following algorithm that accepts a finite variation of T: On input 0^n, if $|f(0^n)| \leq n^{\epsilon/k}$, then accept 0^n if and only if $f(0^n) \in L$. Otherwise, reject 0^n. This algorithm takes time at most $2^{|f(0^n)|^k} \leq 2^{(n^{\epsilon/k})^k} = 2^{n^\epsilon}$. This contradicts the assumption that $T \notin$ DTIME(2^{n^ϵ}). Therefore, X is infinite. Also, $X \subseteq f(T) \subseteq L$. Now we will show that $X \leq_m^p T$. Since T belongs to $\mathcal{C}$ and $\mathcal{C}$ is closed under $\leq_m^p$-reductions, that will demonstrate that L is not $\mathcal{C}$-immune.

To see that $X \leq_m^p T$, we apply the following reduction: On input $y, |y| = m$, determine whether $f(0^i) = y$ for some $i < m^{k/\epsilon}$. If there is such an i, then output the first such 0^i. Otherwise, $y \notin X$. In this case, output some fixed string not in T. We need to show that $y \in X$ if and only if the output of this reduction belongs to T. If $y \in X$, then there exists i such that $i < m^{k/\epsilon}$, $0^i \in T$, and $f(0^i) = y$. Let 0^{i_0} be the output of the reduction. In this case, $y = f(0^i) = f(0^{i_0})$. Now recall that f is a reduction from T to L. For this reason, $0^i \in T$ if and only if $0^{i_0} \in T$. The converse case, that $y \notin X$, is straightforward. □

Agrawal [Agr02] defined a function $g \in$ PF to be γ*-sparsely many-one* on $S \subseteq \{0,1\}^n$ if

$$\forall x \in S,\ \|g^{-1}(g(x)) \cap \{0,1\}^n\| \leq \frac{2^n}{2^{n^\gamma}}.$$

Here $g^{-1}(z) = \{x \,|\, g(x) = z\}$. The function g is *sparsely many-one* on $S \subseteq \{0,1\}^n$ if it is γ-sparsely many-one on $S \subseteq \{0,1\}^n$ for some $\gamma > 0$.

Given a 2^{n^ϵ}-secure one-way permutation, Goldreich and Levin [GL89] construct a 2^{n^α}-secure crypto-prg, $0 < \alpha < \epsilon$. This crypto-prg G is defined only on strings of even length; i.e., G is a partial function. However, Agrawal [Agr02] notes that G can be extended to be total, and the security remains the same. This crypto-prg has a nice property; namely, it is a one-one function.

Let S be any set in NP and L be any NP-complete language. Let $S' = G(S)$. Since S' is in NP, there is a many-one reduction f from S' to L. Let $h \stackrel{def}{=} f \circ G$. Since G is one-one, h is a many-one reduction from S to L.

LEMMA 4.8 (see [Agr02]). *For every* n*,* $h \stackrel{def}{=} f \circ G$ *is a* $\alpha/2$*-sparsely many-one on* $S \cap \Sigma^{=n}$*, where* α *is the security parameter of* G*.*

LEMMA 4.9. *Let f be a γ-sparsely many-one function on $S = 0^* \times \Sigma^* \cap \{0,1\}^n$ for every n, and let $l = n^{2/\gamma}$. Then, for sufficiently large n,*

$$\|\{w \in 0^n \times \Sigma^{=l} \mid |f(w)| > n\}\| \geq \frac{3}{4}2^l.$$

Proof. Let $S_n = 0^n \times \Sigma^{=l}$. Every string in S_n has length $m = n + l$. For every $w \in S_n$, there are at most $\frac{2^m}{2^{m^\gamma}}$ strings of length m that can map to $f(w)$. Therefore, $\|f(S_n)\| \geq 2^l/(\frac{2^m}{2^{m^\gamma}})$. Taking $l = n^{\frac{2}{\gamma}}$, we obtain that at least $\frac{3}{4}$ of the strings in S_n have image of length $> n$. □

THEOREM 4.10. *If Hypothesis B holds, then for every $\epsilon > 0$, no $\leq_m^p$-complete set for* NP *can be* DTIME(2^{n^ϵ})*-immune.*

Proof. The hypothesis implies the existence of a 2^{n^ϵ}-secure one-way permutation. Let G be the 2^{n^α}-secure crypto-prg, $0 < \alpha < \epsilon$, constructed from this secure one-way function. Let $S = 0^* \times \Sigma^*$, and let $S' = G(S)$. Since L is NP-complete $S' \leq_m^p L$ via f. Thus $S \leq_m^p L$ via $h = f \circ G$. By Lemma 4.8, h is $\alpha/2$-sparsely many-one on $S \cap \Sigma^{=n}$ for every n. For any n, take $l = n^{4/\alpha}$. Then, by Lemma 4.9, we know that for large enough n, at least $\frac{3}{4}$ of the strings in $0^n \times \Sigma^{=l}$ map via h to a string of length $> n$.

Let $k = \frac{4}{\epsilon\alpha}$. Assume G maps strings of length n to strings of length n^r, $r > 0$. It is well known that from G we can construct a crypto-prg G' that expands n bits to n^k bits [Gol01, p. 115]. Thus for any string w of length n^ϵ, $G'(w)$ is of length $l = n^{4/\alpha}$. Consider the following circuit that on input $(0^n, y), |y| = l$ accepts if and only if $|h(0^n, y)| > n$. This circuit accepts at least $\frac{3}{4}$ of the inputs $(0^n, y), |y| = l$, if the input is chosen according to uniform distribution. Therefore, there must be some $w, |w| = n^\epsilon$, such that this circuit accepts $G'(w)$. Therefore, for this w, $|h(0^n, G'(w))| > n$. Now, the following DTIME(2^{n^ϵ})-algorithm outputs infinitely many strings of L:

Input 0^n
Let $m = n^\epsilon$
for $w \in \Sigma^{=m}$
  If $|h(0^n, G'(w))| > n$, then output $h(G'(w))$ □

4.1. Closeness. In general, Yesha [Yes83] considered two sets A and B to be close if the census of their symmetric difference, $A\Delta B$, is a slowly increasing function. For example, A and B are *p-close* if there is a polynomial p such that for every n, $\|(A\Delta B)^{=n}\| \leq p(n)$. Ogiwara [Ogi91] and Fu [Fu93] observed that if A is NP-complete, then A is not p-close to any set $B \in$ P, unless P = NP. Define A and B to be *quasi-polynomial-close* if there exists a constant k such that for every n, $\|(A\Delta B)^{=n}\| \leq 2^{\log^k n}$. We show that if Hypothesis B holds, then no NP-complete set is quasi-polynomial-close to a set in P. We show unconditionally that if L is paddable and quasi-polynomial-close to a set in P, then L belongs to BPP. As a corollary, if Hypothesis A holds, then no paddable NP-complete set is quasi-polynomial-close to a set in P.

We recall the following definitions and recall that all known, natural NP-complete sets are paddable [BH77].

DEFINITION 4.11. *A set A is* paddable *if there exists $p(\cdot,\cdot)$, a polynomial-time computable, polynomial-time invertible (i.e., there is a $g \in$ PF such that for all x and y, $g(p(x,y)) = \langle x, y\rangle$) function, such that for all a and x,*

$$a \in A \iff p(a,x) \in A.$$

Recall that a set A is *p-isomorphic* to B if there exists f, a polynomial-time computable, polynomial-time invertible permutation on Σ^*, such that $A \leq_m^p B$ via f.

Mahaney and Young [MY85] proved that two paddable sets are many-one equivalent if and only if they are p-isomorphic.

THEOREM 4.12. *If L is paddable and quasi-polynomial-close to a set in* P*, then* $L \in$ BPP.

Proof. Assume that L is a paddable set and there is a set $B \in$ P such that L is quasi-polynomial-close to B. Let $p(\cdot,\cdot)$ be a padding function for L. Given a string x, $|x| = n$, consider the following set:

$$P_x = \{p(x,y) \,|\, |x| = |y|\}.$$

Let q be a polynomial such that all strings in P_x have length $\leq q(n)$. Let k be a constant such that $\|(L \Delta B)^{\leq q(n)}\| \leq 2^{\log^k n}$. Note that $\|P_x\| = 2^n$.

If $x \in L$, then $P_x \subseteq L$. Therefore, at least $2^n - 2^{\log^k n}$ strings from P_x belong to B. On the other hand, if $x \notin L$, then $P_x \cap L = \emptyset$, and so at least $2^n - 2^{\log^k n}$ strings from P_x are not in B. Therefore,

$$x \in L \Rightarrow \Pr_{y \in \Sigma^n}[p(x,y) \in B] \geq 1 - \frac{2^{\log^k n}}{2^n},$$

$$x \notin L \Rightarrow \Pr_{y \in \Sigma^n}[p(x,y) \in B] \leq \frac{2^{\log^k n}}{2^n}.$$

Therefore, $L \in$ BPP. □

COROLLARY 4.13. *If* SAT *is quasi-polynomial-close to a set in* P*, then* NP = RP.

This follows immediately from the result of Ko [Ko82] that NP $\subseteq$ BPP implies NP = RP. Hypothesis A implies that BPP = P. Therefore, we have the following corollaries.

COROLLARY 4.14. *If Hypothesis A holds, then no paddable set $L \notin$ P can be quasi-polynomial-close to any set in* P.

COROLLARY 4.15. *If Hypothesis A holds, then no set p-isomorphic to* SAT *can be quasi-polynomial-close to any set in* P*, unless* P = NP.

Next we are interested primarily in Theorems 4.16 and 4.18 and their immediate consequence, Corollary 4.19. Theorem 4.16 follows directly from the statement of Hypothesis B.

THEOREM 4.16. *Hypothesis B implies that*

$$\text{NP} \not\subseteq \bigcup_{k>0} \text{DTIME}(2^{\log^k n}).$$

Proof. Hypothesis B asserts the existence of a 2^{n^ϵ}-secure one-way permutation π for some $0 < \epsilon < 1$. No 2^{n^ϵ}-size circuit can compute the inverse of π. So the set

$$B = \{\langle y, i\rangle \,|\, i\text{th bit of } \pi^{-1}(y) = 0\}$$

belongs to NP and cannot have a quasi-polynomial-size family of circuits. However, if $B \in \text{DTIME}(2^{\log^k n})$ for some $k > 0$, then B has a family of circuits of size $(2^{\log^k n})^2 < 2^{\log^{2k} n}$, which is a contradiction. □

We require the following proposition, which follows from Homer and Longpré's study of Ogiwara–Watanabe pruning [HL94].

PROPOSITION 4.17. *If there exists a set S that has a quasi-polynomially bounded census function and that is $\leq^p_{btt}$-hard for* NP*, then* NP $\subseteq \bigcup_{k>0} \text{DTIME}(2^{\log^k n})$.

THEOREM 4.18. *If* NP $\not\subseteq \bigcup_{k>0} \mathrm{DTIME}(2^{\log^k n})$, *then no* NP*-complete set is quasi-polynomial-close to a set in* P.

Proof. Assume there exists an NP-complete A that is quasi-polynomial-close to some $B \in \mathrm{P}$. Let $S \stackrel{df}{=} A \Delta B$. So S has a quasi-polynomially bounded census function. $A \leq^p_{1-tt} S$, and therefore S is $\leq^p_{1-tt}$-hard for NP. By Proposition 4.17, $\mathrm{NP} \subseteq \bigcup_{k>0} \mathrm{DTIME}(2^{\log^k n})$. □

As an immediate consequence, we have the following corollary, which has a stronger consequence than Corollary 4.15.

COROLLARY 4.19. *If Hypothesis B holds, then no* NP*-complete set is quasi-polynomial-close to any set in* P.

It is interesting to note that Corollary 4.19 has a short proof that does not depend on Theorems 4.16 and 4.18. We present that proof now.

Proof. We begin as the proof of Theorem 4.16 begins: Hypothesis B asserts the existence of a 2^{n^ϵ}-secure one-way permutation π. No 2^{n^ϵ}-size circuit can compute the inverse of π. So the set $B = \{\langle y, i\rangle \mid i\text{th bit of } \pi^{-1}(y) = 0\}$ belongs to NP and cannot have a quasi-polynomial-size family of circuits.

Let us assume that L is an NP-complete set such that there is some set $S \in \mathrm{P}$ and some $k > 0$ such that for every n, $\|L \Delta S\| \leq 2^{\log^k n}$. This implies that $L \in \mathrm{P}/(2^{\log^k n})$, where the advice for any length n is the set of strings in $L \Delta S$. On an input x, accept x if and only if $x \in S$ and x is not in the advice set or $x \notin S$ and x belong to the advice set.

Therefore, L has a family of quasi-polynomial-size circuits. Since L is NP-complete, it follows that every set in NP has a quasi-polynomial-size family of circuits. By the above discussion, this contradicts Hypothesis B. □

Finally, we state another consequence of Theorem 4.18, which has the same conclusion as Corollary 4.19. Buhrman and Homer [BH92] proved that NP-complete sets do not have circuits of quasi-polynomial size unless the exponential hierarchy collapses to $\mathrm{NEXP}^{\mathrm{NP}}$, the second level.

COROLLARY 4.20. *If the exponential hierarchy does not collapse to its second level, then no* NP*-complete set is quasi-polynomial-close to any set in* P.

5. Disjoint pairs. Recall that if $\mathrm{NP} \cap \mathrm{coNP} \neq \mathrm{P}$, then there exist disjoint sets A and B in NP such that $A \not\leq^p_T A \cup B$. Our first result derives the same consequence under the assumption that UEE $\neq$ EE.

THEOREM 5.1. *If* UEE $\neq$ EE, *then there exist two disjoint sets* A *and* B *in* UP *such that* $A \not\leq^p_T A \cup B$.

Proof. Beigel et al. [BBFG91] showed that if NEE $\neq$ EE, then there exists a language in $\mathrm{NP} - \mathrm{P}$ for which search does not reduce to decision. Their proof also shows that if UEE $\neq$ EE, then there exists a language S in $\mathrm{UP} - \mathrm{P}$ for which search does not reduce to decision. Let M be an unambiguous Turing machine that accepts S, and for every word $x \in S$, let a_x be the unique accepting computation of M on x. Let p be a polynomial such that for all $x \in S$, $|a_x| = p(|x|)$. Define

$$A = \{\langle x, y\rangle \mid x \in S, |y| = p(|x|), \text{ and } y \leq a_x\}$$

and

$$B = \{\langle x, y\rangle \mid x \in S, |y| = p(|x|), \text{ and } y > a_x\}.$$

Both A and B belong to UP and are disjoint. Let

$$A \cup B = S' = \{\langle x, y\rangle \mid x \in S \text{ and } |y| = p(|x|)\}.$$

Note that S' is many-one reducible to S. Now assume $A \leq_T^p S'$. Since S' is many-one reducible to S, it follows that $A \leq_T^p S$. However, we can compute the witness a_x for $x \in S$ by using a binary search algorithm with oracle A. Therefore, replacing A with S, we see that search reduces to decision for S, contradicting our choice of S. □

Next we study the question of whether there exist two disjoint Turing complete sets for NP whose union is not Turing complete. We consider the following hypothesis.

UP-machine hypothesis. There is a UP-machine M that accepts 0^* such that for some $0 < \epsilon < 1$, no 2^{n^ϵ} time-bounded machine can correctly compute infinitely many accepting computations of M.

The UP-machine hypothesis and its variant, the NP-machine hypothesis (obtained by replacing the UP-machine with an NP-machine), have been studied previously and shown to have several believable consequences. For example, Pavan and Selman [PS02] showed that the UP-machine hypothesis implies the existence of a Turing complete language for NP that is not truth-table complete, and the NP-machine hypothesis implies the existence of a Turing complete language for NP that is not many-one complete. Hitchcock and Pavan [HP04] showed that the NP-machine hypothesis implies AM = NP, $\mathrm{BPP}^{\mathrm{NP}} = \mathrm{P}^{\mathrm{NP}}$, and NEXP $\not\subseteq$ P/*poly*. Hemaspaandra, Rothe, and Wechsung [HRW97] showed several equivalent characterizations of variants of the NP- and UP-machine hypotheses. Fenner et al. [FFNR96] studied the infinite-often version of the NP-machine hypothesis.

Hitchcock and Pavan showed that if UE ∩ coUE is not included in $\mathrm{DTIME}(2^{2^{\epsilon n}})$ infinitely often, then the UP-machine hypothesis holds. They also related this hypothesis to the question of UE ∩ coUE having high circuit complexity: Let K be the standard complete set for EXP. If UE ∩ coUE does not have K-oracle circuits of size $2^{\epsilon n}$ infinitely often, then the UP-machine hypothesis holds. They also showed that these hypotheses are weaker than some hypotheses used in the context of uniform derandomization.

We show that if UP ∩ coUP has bi-immune languages, then the UP-machine hypothesis holds.

THEOREM 5.2. *If there is a* $\mathrm{DTIME}(2^{n^\epsilon})$*-bi-immune language in* UP ∩ coUP*, then the* UP*-machine hypothesis is true.*

Proof. Let $L \in$ UP ∩ coUP be the $\mathrm{DTIME}(2^{n^\epsilon})$-bi-immune set, and let N and N' be the UP-machines for L and $\overline{L}$. Consider the following machine M that accepts 0^*: On input 0^n, M guesses an accepting computation of N and of N' on 0^n, and accept 0^n if either guess is right. Note that for every 0^n, exactly one of the guesses will be correct, and therefore $L(M) = 0^*$. If there is a 2^{n^ϵ} time-bounded machine T that can correctly compute infinitely many accepting computation of M, then either $X = \{0^i \mid T(0^i)$ outputs an accepting computation of $N\}$ or $X' = \{0^i \mid T(0^i)$ outputs an accepting computation of $N'\}$ is an infinite subset of L or $\overline{L}$, contradicting the bi-immunity of L. □

THEOREM 5.3. *If the* UP*-machine hypothesis is true, then there exist two disjoint Turing complete sets for* NP *whose union is not Turing complete.*

Proof. Let a_n be the accepting computation of M on 0^n. Let $p(n)$ be the polynomial that bounds $|a_n|$. Note that a deterministic machine can verify in polynomial time whether a string of length $p(n)$ is an accepting path of M. Consider the following sets:

$$A = \{\langle x, a_m + 1\rangle \mid |x| = n, x \in \mathrm{SAT}, m = (2n)^{1/\epsilon}\} \\ \oplus \{\langle 0^n, i\rangle \mid i \leq p(n), \text{ bit } i \text{ of } a_n = 1\}$$

and

$$B = \{\langle x, a_m - 1\rangle \,\big|\, |x| = n, x \in \text{SAT}, m = (2n)^{1/\epsilon}\} \oplus \{\langle 0^n, i\rangle \,\big|\, i \le p(n), \text{ bit } i \text{ of } a_n = 0\}.$$

It is easy to see that both A and B are Turing-complete for NP. They can be made disjoint by choosing an appropriate pairing function. Note that

$$A \cup B = \{\langle x, a\rangle \,\big|\, |x| = n, x \in \text{SAT}, a = a_m - 1 \text{ or } a_m + 1, m = (2n)^{1/\epsilon}\} \oplus \{\langle 0^n, i\rangle \,\big|\, i \le p(n)\}.$$

Assume that $A \cup B$ is Turing complete for NP. Since the set $\{\langle 0^n, i\rangle \,\big|\, i \le p(n)\}$ is in P, the following set is Turing complete:

$$C = \{\langle x, a\rangle \,\big|\, |x| = n, x \in \text{SAT}, a = a_m - 1 \text{ or } a_m + 1, m = (2n)^{1/\epsilon}\}.$$

Consider the set

$$S = \{\langle 0^n, i\rangle \,\big|\, \text{ bit } i \text{ of } a_n = 1\}.$$

Since $S \in$ NP, $S \le_T^p C$ via some oracle Turing machine U.

We describe the following procedure $\mathcal{A}$:

1. input 0^n.
2. Simulate U on strings $\langle 0^n, i\rangle$, where $1 \le i \le p(n)$.
3. Let $q = \langle x, y\rangle$ be a query that is generated. If $y \ne a_t + 1$ or $y \ne a_t - 1$ for some t, then continue the simulation with answer "No."
4. Else, $q = \langle x, y\rangle$, $|x| = t^\epsilon/2$, and $y = a_t + 1$ or $y = a_t - 1$.
5. If $t \ge n^\epsilon$, then output "Unsuccessful," print a_t, and Halt.
6. Otherwise, check whether $x \in$ SAT; this takes at most $2^{|x|} \le 2^{n^{\epsilon^2}/2}$ time. Answer the query appropriately and continue the simulation of U.

Now we consider two cases.

CLAIM 5.4. *If $\mathcal{A}(0^n)$ does not output "Unsuccessful" for infinitely many n, then there is a 2^{n^ϵ}-time bounded machine that correctly outputs infinitely many accepting computations of M.*

Proof. Assume $\mathcal{A}(0^n)$ does not output "Unsuccessful." This implies that $\mathcal{A}$ is able to decide membership of $\langle 0^n, i\rangle$, $1 \le i \le p(n)$, in S. Therefore, $\mathcal{A}$ can compute a_n. The most expensive step of the above procedure is step 6, where $\mathcal{A}$ decides the membership of x in SAT. However, this occurs only if $|x| \le n^{\epsilon^2}/2$ and hence takes at most $2^{n^{\epsilon^2}/2}$ time. Thus the total time is bounded by $O(p(n) \times q(n) \times 2^{n^{\epsilon^2}/2})$, where $q(n)$ is the running time of U on $\langle 0^n, i\rangle$. Since $\epsilon < 1$, this is bounded by 2^{n^ϵ}. □

CLAIM 5.5. *If $\mathcal{A}(0^n)$ outputs "Unsuccessful" for all but finitely many n, then there is a 2^{n^ϵ}-time bounded machine that outputs infinitely many accepting computations of M.*

Proof. If $\mathcal{A}(0^n)$ is unsuccessful, then it outputs a string a_t such that $t \ge n^\epsilon$. Hence, if $\mathcal{A}(0^n)$ is unsuccessful for all but finitely many strings, then for infinitely many t there exists an n, where $n \le t^{1/\epsilon}$, and $\mathcal{A}(0^n)$ outputs a_t. Thus the following procedure computes infinitely many accepting computations of M:

input 0^t
for $i = 1$ to $t^{1/\epsilon}$ do
  if $\mathcal{A}(0^j)$ outputs a_t
    output a_t and halt.
  endif
end for

Note that $\mathcal{A}(0^i)$ runs in time $O(p(i) \times q(i) \times 2^{i^{\epsilon^2}/2})$. Thus the total running time of the above procedure is $O(2^{t^\epsilon})$. □

Claims 5.4 and 5.5 show that if C is Turing complete for NP, then there is a 2^{n^ϵ}-time bounded Turing machine that computes infinitely many accepting computations of M. This contradicts the UP-machine hypothesis, and therefore $A \cup B$ cannot be Turing complete for NP. □

5.1. Many-one complete languages. Here we consider the analogous questions for many-one reductions. We first show under two different hypotheses that there exist disjoint sets A and B in NP such that $A \not\leq_m^p A \cup B$. Also we study the question for NP-complete sets. One of our results will show a relation between our question and propositional proof systems. We refer the reader to Glasser et al. [GSS04] for definitions about proof systems and reductions between disjoint NP-pairs.

THEOREM 5.6. *If* $\mathrm{P} \neq \mathrm{NP} \cap \mathrm{coNP}$*, then there exist disjoint* $A, B \in \mathrm{NP}$ *such that*
1. A *and* B *are many-one equivalent and*
2. $A \not\leq_m^p A \cup B$.

Proof. Let $b \in \{0,1\}$, and let $L \in \mathrm{NP} \cap \mathrm{coNP} - \mathrm{P}$. Define

$$A = \{bw \,|\, b = \chi_L(w)\}$$

and

$$B = \{bw \,|\, b \neq \chi_L(w)\}.$$

Both A and B belong to $\mathrm{NP} \cap \mathrm{coNP} - \mathrm{P}$. Note that $A \cup B = \{0,1\} \circ \Sigma^*$. However, note that $A \leq_m^p B$ via $f(bw) = \bar{b}w$, and the same reduction reduces B to A. Also note that $w \to 1w$ reduces L to A, and hence A cannot be in P. Therefore, $A \not\leq_m^p A \cup B$. □

THEOREM 5.7. *If* $\mathrm{UE} \neq \mathrm{E}$*, then there exist disjoint sets* A *and* B *in* NP *such that* $A \not\leq_m^p A \cup B$.

Proof. Hemaspaandra et al. [HNOS96] showed that if $\mathrm{NE} \neq \mathrm{E}$, then there exists a language S in NP for which search does not reduce to decision nonadaptively. Essentially the same proof shows that if $\mathrm{UE} \neq \mathrm{E}$, then there exists a language S in UP for which search does not reduce to decision nonadaptively. Since $S \in \mathrm{UP}$, for each $x \in S$, there is a unique witness v_x, where $|v_x| = p(|x|)$, for some polynomial p. Define

$$A = \{\langle x, i\rangle \,|\, x \in S, i \leq p(|x|), \text{ and the } i\text{th bit of the witness } v_x \text{ of } x \text{ is } 0\}$$

and

$$B = \{\langle x, i\rangle \,|\, x \in S, i \leq p(|x|), \text{ and the } i\text{th bit of the witness } v_x \text{ of } x \text{ is } 1\}.$$

It is clear that both A and B are in NP and are disjoint. Then

$$A \cup B = S' = \{\langle x, i\rangle \,|\, x \in S, i \leq p(|x|)\}.$$

Observe that $S' \leq_m^p S$. Assume $A \leq_m^p S'$; then $A \leq_m^p S$. Therefore, we can compute the ith bit of the witness of x by making one query to S. This implies that search nonadaptively reduces to decision for S, which is a contradiction. □

Two disjoint sets A and B are P-*separable* if there is a set $S \in \mathrm{P}$ such that $A \subseteq S \subseteq \overline{B}$. Otherwise, they are P-*inseparable*. Let us say that (A, B) is a *disjoint* NP-*pair* if A and B are disjoint sets that belong to NP. If (A, B) is a disjoint NP-pair such that A and B are P-separable, then $A \leq_m^p A \cup B$ follows easily: On input x, the reduction outputs x if $x \in S$ and outputs some fixed string $w \notin A \cup B$ if $x \notin S$. This observation might lead one to conjecture that $A \cup B$ is not $\leq_m^p$-complete if A and B are disjoint, P-inseparable, $\leq_m^p$-complete NP sets. The following theorem shows that this would be false, assuming $\mathrm{P} \neq \mathrm{UP}$.

THEOREM 5.8. *If* $\mathrm{P} \neq \mathrm{UP}$*, then there exist disjoint* NP*-complete sets* A *and* B *such that*

1. (A, B) *is* P*-inseparable and*
2. $A \cup B$ *is many-one complete for* NP.

Proof. Under the assumption that $\mathrm{P} \neq \mathrm{UP}$, Grollmann and Selman [GS88] constructed a P-inseparable disjoint NP-pair (A', B') such that A' and B' are NP complete. Let

$$A \stackrel{df}{=} 0A' \cup 1\mathrm{SAT}$$

and

$$B \stackrel{df}{=} 0B'.$$

Therefore, $A \cap B = \emptyset$. Also, $\mathrm{SAT} \leq_m^p A \cup B$ via $f(\phi) = 1\phi$. Therefore, $A \cup B$ is NP complete. If (A, B) is P-separable, then so is (A', B'). □

Similar arguments show that in Theorem 5.8, we can use hypothesis $\mathrm{P} \neq \mathrm{NP} \cap \mathrm{coNP}$ instead of $\mathrm{P} \neq \mathrm{UP}$: If $\mathrm{P} \neq \mathrm{NP} \cap \mathrm{coNP}$, then there exist sets A and B with the same properties as in Theorem 5.8.

We learn from the next theorem that if there exist disjoint NP-complete sets whose union is not NP-complete, then this happens already for paddable NP-complete sets.

THEOREM 5.9. *The following are equivalent:*

1. *There exist an* NP*-complete set* A *and a set* $B \in \mathrm{NP}$ *such that* $A \cap B = \emptyset$ *and* $A \cup B$ *is not* NP*-complete.*
2. *There exist disjoint,* NP*-complete sets* A *and* B *such that* $A \cup B$ *is not* NP*-complete.*
3. *There exist paddable, disjoint,* NP*-complete sets* A *and* B *such that* $A \cup B$ *is not* NP*-complete.*
4. *For every paddable* NP*-complete set* A*, there is a paddable* NP*-complete set* B *such that* $A \cap B = \emptyset$ *and* $A \cup B$ *is not* NP*-complete. Furthermore, there is a polynomial-time-computable permutation* π *on* Σ^* *such that*
   a. *for all* x, $\pi(\pi(x)) = x$ *and*
   b. $A \leq_m^p B$ *and* $B \leq_m^p A$*, both via* π.
5. *For every* NP*-complete set* A*, there is a set* $B \in \mathrm{NP}$ *such that* $A \cap B = \emptyset$ *and* $A \cup B$ *is not* NP*-complete.*

By Theorem 5.9, if there exist disjoint, NP-complete sets whose union is not complete, then there is a set B in NP that is disjoint from SAT such that $\mathrm{SAT} \cup B$ is not NP-complete. Moreover, in that case, there exists such a set B so that B is p-isomorphic to SAT. It is even the case that SAT and B are $\leq_m^p$-reducible to one another via the same polynomial-time computable permutation.

Proof. $1 \Rightarrow 2$: Let $A' \stackrel{df}{=} 0A \cup 1B$ and $B' \stackrel{df}{=} 1A \cup 0B$. Since A is NP-complete, both sets A' and B' are NP-complete. However, $A' \cup B' = \{0,1\} \cdot (A \cup B)$, and hence is not NP-complete.

$2 \Rightarrow 3$: Choose A and B according to item 2. Let $A' \stackrel{df}{=} A \times \Sigma^*$ and $B' \stackrel{df}{=} B \times \Sigma^*$. A' and B' are disjoint, paddable, and NP-complete. $A' \cup B' = (A \cup B) \times \Sigma^*$. Hence $A' \cup B' \leq_m^p A \cup B$, and therefore $A' \cup B'$ is not NP-complete.

$3 \Rightarrow 4$: Choose A and B according to item 3. We may assume that there exists a polynomial-time computable permutation π on Σ^* such that

- for all x, $\pi(\pi(x)) = x$ and
- $A \leq_m^p B$ and $B \leq_m^p A$, both via π.

Otherwise, we use $0A \cup 1B$ and $1A \cup 0B$ instead of A and B; and π is the permutation on Σ^* that flips the first bit.

Let A' be any paddable NP-complete set. So A' and A are paddable and many-one equivalent. Therefore, A' and A are p-isomorphic; i.e., there exists f, a polynomial-time computable, polynomial-time invertible permutation on Σ^*, such that $A' \leq_m^p A$ via f.

Let $B' \stackrel{df}{=} f^{-1}(B)$. $B' \leq_m^p B$ via f and, therefore B' and B are p-isomorphic. It follows that B' is paddable and NP-complete. $A' \cap B' = \emptyset$, since $A \cap B = \emptyset$. Moreover, $A' \cup B' \leq_m^p A \cup B$ via f, and hence $A' \cup B'$ is not NP-complete. Let $\pi'(x) \stackrel{df}{=} f^{-1}(\pi(f(x)))$. So π' is a polynomial-time computable permutation on Σ^*. For all x,

$$\pi'(\pi'(x)) = f^{-1}(\pi(f(f^{-1}(\pi(f(x)))))) = x.$$

Moreover, for all x,

$$x \in A' \iff f(x) \in A \iff \pi(f(x)) \in B \iff \pi'(x) \in B'.$$

Therefore, $A' \leq_m^p B'$ via π', and analogously, $B' \leq_m^p A'$ via π'.

$4 \Rightarrow 1$: The proof follows immediately, since SAT is paddable and NP-complete.

$1 \Rightarrow 5$: Choose A and B according to item 1, and let A' be an arbitrary NP-complete set. Let $f \in \mathrm{PF}$ such that $A' \leq_m^p A$ via f. $B' \stackrel{df}{=} \{x \mid f(x) \in B\}$. Clearly, $B' \in \mathrm{NP}$ and $A' \cap B' = \emptyset$, since $A \cap B = \emptyset$. For all x,

$$x \in A' \cup B' \Leftrightarrow f(x) \in A \vee f(x) \in B \Leftrightarrow f(x) \in A \cup B.$$

So $A' \cup B' \leq_m^p A \cup B$ via f and, therefore $A' \cup B'$ is not NP-complete.

$5 \Rightarrow 1$: The proof is trivial. □

Next we state relations between our question and propositional proof systems [CR79]. The recent paper of Glasser et al. [GSSZ03] contains definitions of the relevant concepts: propositional proof systems (pps), optimal pps for a pps f, the canonical disjoint NP-pair $(\mathrm{SAT}^*, \mathrm{REF}_f)$ of f, and reductions between disjoint NP-pairs. If a propositional proof system f is optimal, then Razborov [Raz94] has shown that the canonical disjoint NP-pair of f is $\leq_m^{pp}$-complete. Therefore, it is natural to ask, for any proof system f, whether the union $\mathrm{SAT}^* \cup \mathrm{REF}_f$ of the canonical pair is complete for NP. However, this always holds. It holds for trivial reasons, because SAT reduces to $\mathrm{SAT}^* \cup \mathrm{REF}_f$ by mapping every x to (x, ϵ). Since x does not have a proof of size 0, we never map to REF_f. However, $x \in \mathrm{SAT} \Leftrightarrow (x, \epsilon) \in \mathrm{SAT}^*$. Nevertheless, it is interesting to inquire, as we do in the following theorem, whether some perturbation of the canonical proof system might yield disjoint sets in NP whose union is not complete.

THEOREM 5.10. *Assume* P $\neq$ NP *and there exist disjoint sets* A *and* B *in* NP *such that* A *is* NP*-complete but* $A \cup B$ *is not* NP*-complete. Then there exists a pps* f *and a set* $X \in$ P *such that*

1. $\mathrm{SAT}^* \cap X$ *is* NP*-complete and*
2. $(\mathrm{SAT}^* \cap X) \cup (\mathrm{REF}_f \cap X)$ *is not* NP*-complete.*

Proof. If NP = coNP, then $\overline{\mathrm{SAT}}$ has a polynomially bounded pps f. Let p be the bound, and let $X \stackrel{df}{=} \{(x, y) \,\big|\, y = 0^p(|x|)\}$. Clearly, $\mathrm{SAT}^* \cap X$ is NP-complete. Observe that

$$(\mathrm{SAT}^* \cap X) \cup (\mathrm{REF}_f \cap X) = X.$$

Since the latter set is in P and P $\neq$ NP, it cannot be NP-complete. So in this case we are done.

From now on, let us assume that NP $\neq$ coNP. By Theorem 5.9, there exists $B' \in$ NP such that $B' \subseteq \overline{\mathrm{SAT}}$ and $\mathrm{SAT} \cup B'$ is not NP-complete. Let $C \in$ P and p be a polynomial such that for all x,

$$x \in B' \iff \exists y \in \Sigma^{p(|x|)}[(x, y) \in C].$$

Choose a polynomial-time-computable, polynomial-time-invertible pairing function $\langle \cdot, \cdot \rangle$ such that for all x and y, $|\langle x, y \rangle| = 2|xy|$. Define the following pps:

$$f(z) \stackrel{df}{=} \begin{cases} x & \text{if } z = \langle x, y \rangle,\ |y| = p(|x|), \text{ and } (x, y) \in C, \\ x & \text{if } z = \left\langle x, 0^{2^{2^{|x|}}} \right\rangle \text{ and } x \in \overline{\mathrm{SAT}}, \\ \text{false} & \text{otherwise.} \end{cases}$$

Observe that f is a pps. Define

$$X \stackrel{df}{=} \{(x, 0^m) \,\big|\, m = 2(|x| + p(|x|))\}.$$

$X \in$ P. Let $\mathrm{SAT}' \stackrel{df}{=} \mathrm{SAT}^* \cap X$ and $\mathrm{REF}' \stackrel{df}{=} \mathrm{REF}_f \cap X$. $\mathrm{SAT}' \in$ NP and $\mathrm{REF}' \in$ NP. Moreover, SAT' is NP-complete.

It remains to show that $\mathrm{SAT}' \cup \mathrm{REF}'$ is not NP-complete. Let α be a fixed element in $\overline{\mathrm{SAT} \cup B'}$. (Such an element exists, because otherwise NP = coNP.) We show $\mathrm{SAT}' \cup \mathrm{REF}' \leq_m^p \mathrm{SAT} \cup B'$ via the following reduction function:

$$h(x, y) \stackrel{df}{=} \begin{cases} x & \text{if } (x, y) \in X, \\ \alpha & \text{otherwise.} \end{cases}$$

Assume $(x, y) \in \mathrm{SAT}' \cup \mathrm{REF}'$. Hence $(x, y) \in X$ and therefore $y = 0^{2(|x|+p(|x|))}$ and $h(x, y) = x$. If $(x, y) \in \mathrm{SAT}'$, then $h(x, y) = x \in \mathrm{SAT}$. If $(x, y) \in \mathrm{REF}'$, then there exists $z \in \Sigma^{\leq 2(|x|+p(|x|))}$ such that $f(z) = x$. By the definition of f, there exists $z \in \Sigma^{2(|x|+p(|x|))}$ such that $z = \langle x, y \rangle$, $|y| = p(|x|)$, and $(x, y) \in C$. Hence $h(x, y) = x \in B'$.

Now assume $(x, y) \notin \mathrm{SAT}' \cup \mathrm{REF}'$. If $(x, y) \notin X$, then $h(x, y) = \alpha \notin \mathrm{SAT} \cup B'$, and we are done. Otherwise, $(x, y) \in X$. First, $h(x, y) = x \notin \mathrm{SAT}$, since $(x, y) \notin \mathrm{SAT}'$. Second, if $x \in B'$, then there exists $y \in \Sigma^{p(|x|)}$ such that $(x, y) \in C$. Therefore, if $x \in B'$, then there exists $z \in \Sigma^{\leq 2(|x|+p(|x|))}$ such that $f(z) = x$. The latter is not possible, since $(x, y) \notin \mathrm{REF}'$. It follows that $h(x, y) = x \notin B'$.

This shows $\mathrm{SAT}' \cup \mathrm{REF}' \leq_m^p \mathrm{SAT} \cup B'$ via h. Hence, $\mathrm{SAT}' \cup \mathrm{REF}'$ is not NP-complete. □

In Theorem 5.11 we show that if there are sets A and B belonging to NP such that $A \cap B = \emptyset$ and $A \cup B$ is not NP-complete, then (A, B) cannot be a $\leq_{sm}^{pp}$-complete disjoint NP-pair.

THEOREM 5.11. *If (A, B) is a $\leq_{sm}^{pp}$-complete disjoint* NP*-pair, then A, B, and $A \cup B$ are* NP*-complete.*

Proof. Since the disjoint NP-pair $(\mathrm{SAT}, \{z \wedge \bar{z}\})$ $\leq_{sm}^{pp}$-reduces to (A, B), $\mathrm{SAT} \leq_m^p A$; i.e., A is NP-complete. Similarly, B is NP-complete as well. Assume that $(\mathrm{SAT}, \{z \wedge \bar{z}\})$ $\leq_{sm}^{pp}$-reduces to (A, B) via some reduction function f. Let

$$f'(x) \stackrel{df}{=} \begin{cases} f(x) & \text{if } x \neq z \wedge \bar{z}, \\ f(y \wedge z \wedge \bar{z}) & \text{if } x = z \wedge \bar{z}. \end{cases}$$

We obtain $f'(\mathrm{SAT}) \subseteq A \cup B$ and $f'(\overline{\mathrm{SAT}}) \subseteq \overline{A \cup B}$. Hence $A \cup B$ is NP-complete. □

According to the comments after Theorem 5.8, the converse of Theorem 5.11 does not hold if either $\mathrm{P} \neq \mathrm{UP}$ or $\mathrm{P} \neq \mathrm{NP} \cap \mathrm{coNP}$. Since we know that there exists a $\leq_{sm}^{pp}$-complete disjoint NP-pair if and only if there is a $\leq_m^{pp}$-complete disjoint NP-pair [GSS04], we obtain the following corollary.

COROLLARY 5.12. *If $\leq_m^{pp}$-complete disjoint NP-pairs exist, then there is a $\leq_m^{pp}$-complete disjoint NP-pair such that both components and their union are* NP*-complete.*

5.2. Relativizations. We have been considering the following questions:

1. Do there exist disjoint sets A and B in NP such that both A and B are $\leq_T^p$-complete but $A \cup B$ is not $\leq_T^p$-complete?
2. Do there exist disjoint sets A and B in NP such that both A and B are NP-complete but $A \cup B$ is not NP-complete?

We observe here that there exist oracles relative to which both of these questions have both "yes" and "no" answers. This implies that resolving these questions would require nonrelativizable techniques.

PROPOSITION 5.13. *If the union of every two disjoint $\leq_T^p$-complete sets for* NP *is $\leq_T^p$-complete for* NP*, then* $\mathrm{P} \neq \mathrm{NP} \implies \mathrm{NP} \neq \mathrm{coNP}$.

Proof. Let us assume that $\mathrm{NP} = \mathrm{coNP}$. Then $\mathrm{SAT} \cup \overline{\mathrm{SAT}} = \Sigma^*$, which is $\leq_T^p$-complete if and only if $\mathrm{P} = \mathrm{NP}$. □

Therefore, relative to an oracle for which $\mathrm{P} \neq \mathrm{NP} = \mathrm{coNP}$ holds [BGS75], the answer to question 1 is "yes." Also, it is obvious that relative to an oracle for which $\mathrm{P} = \mathrm{NP}$, the answer to this question is "no" [BGS75].

Now we consider question 2.

PROPOSITION 5.14. *If the union of every two disjoint* NP*-complete sets is* NP*-complete, then* $\mathrm{NP} \neq \mathrm{coNP}$.

Therefore, an oracle relative to which $\mathrm{NP} = \mathrm{coNP}$ holds will answer "yes" to question 2. We learned already that if A and B are disjoint, NP-complete, P-separable sets, then $A \cup B$ is NP-complete. Homer and Selman [HS92] construct an oracle relative to which all disjoint NP-pairs are P-separable, yet $\mathrm{P} \neq \mathrm{NP}$. Therefore, relative to this oracle, the answer to question 2 is "no." Indeed, relative to this oracle, the answer to question 1 is "no" also.

Acknowledgments. The authors are appreciative of enlightening conversation with M. Agrawal. The authors thank H. Buhrman for informing them of his work on

quasi-polynomial density and thank M. Ogiwara for informing them of his results on polynomial closeness. Also, we received helpful suggestions from L. Hemaspaandra.

THE DIRECTED STEINER NETWORK PROBLEM IS TRACTABLE FOR A CONSTANT NUMBER OF TERMINALS*

JON FELDMAN† AND MATTHIAS RUHL‡

Abstract. We consider the DIRECTED STEINER NETWORK problem, also called the POINT-TO-POINT CONNECTION problem. Given a directed graph G and p pairs $\{(s_1, t_1), \ldots, (s_p, t_p)\}$ of nodes in the graph, one has to find the smallest subgraph H of G that contains paths from s_i to t_i for all i. The problem is NP-hard for general p, since the DIRECTED STEINER TREE problem is a special case. Until now, the complexity was unknown for constant $p \geq 3$. We prove that the problem is polynomially solvable if p is any constant number, even if nodes and edges in G are weighted and the goal is to minimize the total weight of the subgraph H. In addition, we give an efficient algorithm for the STRONGLY CONNECTED STEINER SUBGRAPH problem for any constant p, where given a directed graph and p nodes in the graph, one has to compute the smallest strongly connected subgraph containing the p nodes.

1. Introduction.

The Steiner problem is one of the classic problems in computational geometry and theoretical computer science and is fundamental to the study of network design. The basic problem is the following: Given a set of points, what is the most efficient way to connect them? The first combinatorial formulation of a Steiner problem was the classic STEINER TREE problem, independently due to Hakimi [Hak71] and Levin [Lev71]. This was followed by extensive research on different variants of Steiner problems in the last 30 years.

In this paper we address one of the most general Steiner problems, the DIRECTED STEINER NETWORK problem, also called the POINT-TO-POINT CONNECTION problem.

DIRECTED STEINER NETWORK (p-DSN). *Given a directed graph $G = (V, E)$, with weights on the edges and p pairs of nodes in the graph $\{(s_1, t_1), \ldots, (s_p, t_p)\}$, find the minimum weight subgraph H of G that contains paths from s_i to t_i for $1 \leq i \leq p$.*

When p is arbitrary, this problem is NP-hard, since it generalizes STEINER TREE. The case $p = 2$ was solved in 1992 by Li, McCormick, and Simchi-Levi [LMS92]. However, when p is a fixed quantity greater than two, the question of whether there exists a polynomial-time algorithm for p-DSN was open until now.

In this paper we give the first polynomial-time algorithm for the case where p is any fixed constant, resolving this open question. In fact, the difficulty of the p-DSN problem is contained within a special case of p-DSN for strongly connected components:

STRONGLY CONNECTED STEINER SUBGRAPH (p-SCSS). *Given a directed graph*

$G = (V, E)$ and p terminal vertices $\{s_1, \ldots, s_p\}$ in V, find the smallest strongly connected subgraph H of G that contains $s_1, \ldots, s_p$.

In this paper we also give the first polynomial-time algorithm for p-SCSS for any constant p and use it as a subroutine in our algorithm for p-DSN.

1.1. Previous results.

Constant number of terminals. When $p = 1$, there is only one terminal pair (s, t); thus the solution to p-DSN is simply the shortest path from s to t. Finding a shortest path in a directed graph is a well-known problem solvable in polynomial time [CLRS01].

When all s_i are the same node, the p-DSN problem becomes the Directed Steiner Tree problem. This is solvable using an algorithm due to Dreyfus and Wagner [DW71] (and discovered independently by Levin [Lev71]). This algorithm exploits the fact that a solution to the Directed Steiner Tree problem can be described by the topology of the solution tree, i.e., the relative order in which the paths to the terminals diverge. Since the solution is always a tree, once two paths diverge, they never meet again; this makes the number of different topologies independent of the size of the graph. In contrast, topologies of solutions to the p-DSN problem can be arbitrary dags, which makes enumerating topologies infeasible.

When $p = 2$, the p-DSN problem becomes more difficult but still admits a reasonably simple solution. To motivate the solution for the general case, we present a solution for $p = 2$ in section 2. This problem was first solved by Li, McCormick, and Simchi-Levi [LMS92], who called the problem the Point-to-Point Connection problem. The running time of their algorithm is $\mathcal{O}(n^5)$. They also state the case for all $p \geq 3$ as an interesting open question.

Natu and Fang [NF95, NF97] improved the running time for the case where $p = 2$ first to $\mathcal{O}(n^4)$, and then to $\mathcal{O}(mn+n^2 \log n)$. They also propose an algorithm for $p = 3$ and conjecture that a variant of their algorithm works for all constant p. However, the conference version of the present paper [FR99] gives a counterexample to the correctness of their algorithm for $p = 3$, and thus to their conjecture.

Arbitrary number of terminals. There has been some work on the approximability of p-DSN for arbitrary p. The best positive result obtained so far is by Charikar et al. [CCC+98], who achieve an approximation ratio of $\mathcal{O}(p^{2/3} \log^{1/3} p)$ for any p. On the negative side, Dodis and Khanna [DK99] prove that p-DSN is $\Omega(2^{\log^{1-\varepsilon} p})$-hard; that is, unless $P = NP$, no algorithm exists for p-DSN that has an approximation ratio of $o(2^{\log^{1-\varepsilon} p})$.

The method of Charikar et al. [CCC+98] seems to be fundamentally different from what we use for the fixed-parameter version. Their algorithm is based on greedily finding low-cost "bunches" of vertices that connect a certain subset of the terminal pairs. A bunch has a simple structure; it consists of a path from a node u to a node v, and shortest paths from each of the sources to u and from v to each of the terminals. In this paper, we show structural properties of optimal solutions of p-DSN that are more complex than these bunches. These properties also exist for arbitrary p (but unfortunately cannot easily be found in polynomial time). It is our hope that the ideas presented here can be used to obtain a better approximation ratio for an arbitrary number of terminals.

1.2. Applications. Algorithms for Steiner problems are fundamental tools used for designing networks [MW84]. When many points in a network need to be connected and there is a cost associated with connecting them, the minimum Steiner tree between

the points represents the cheapest way of building the network. Examples of such networks include transportation, communication, or shipping. Leung, Magnanti, and Singhal [LMS90] discuss these applications in more detail.

Until recently, the directed version of the Steiner problem was of mostly theoretical interest, since networks were usually symmetric. However, with the increasing diversity of network links such as satellite and radio, link costs are becoming less symmetric [Ram96]. Therefore, the proper model for designing some types of networks is one where the underlying graph is directed [SRV97].

The problem of multicast tree generation is one example of the use of directed Steiner problems in network design that has received some attention recently [Ram96, SRV97]. A multicast tree is used for point-to-multipoint communication in high-bandwidth applications. For example, in video-conferencing, a single source must be broadcast to many different destinations. The routes taken to each destination are encoded in the multicast tree. Finding a low-cost multicast tree makes for more efficient use of resources. Ramanathan [Ram96] uses the DIRECTED STEINER TREE problem to find low-cost multicast trees.

1.3. Our contributions. In this paper, we give an exact algorithm for p-DSN for any constant p with a running time of $\mathcal{O}(mn^{4p-2} + n^{4p-1} \log n)$, where $n = |V|$ and $m = |E|$. (Throughout this paper, we will assume that the input graphs are connected, so that we have $m \geq n - 1$.) We also give an exact algorithm for p-SCSS for any constant p with a running time of $\mathcal{O}(mn^{2p-3} + n^{2p-2} \log n)$. If the input graphs are unweighted, these bounds can be slightly improved. For details on running times, see section 6.

For clarity, we present an algorithm for a version of p-DSN where there are no weights and the goal is to minimize the number of *nodes* in the subgraph H. Section 5.2 shows how to generalize our algorithm to weights and edge-minimization through simple modifications.

Our algorithm for p-DSN can best be understood in terms of a game, where a player moves tokens around the graph. Initially, p tokens are placed on the starting nodes $s_1, \ldots, s_p$, one token per node. The player is then allowed to make certain types of moves with the tokens, and his goal is to perform a series of these moves to get the tokens to their respective destinations $t_1, \ldots, t_p$ (the token from s_1 to t_1, the token from s_2 to t_2, etc.).

Every possible move has a cost associated with it: the number of nodes that are visited by the moving tokens. We define the moves carefully so that the lowest cost move sequence to get the tokens from $s_1, \ldots, s_p$ to $t_1, \ldots, t_p$ will visit only nodes from an optimal subgraph H and will visit each node in H exactly once. The difficulty of the construction is to ensure that such a sequence exists for every optimal H. For $p = 2$ this is easy to do, since the two involved paths can share vertices only in a very restricted manner. However, for $p \geq 3$ the relationships between the paths become significantly more complex. Critical to our argument is a structural lemma analyzing how these paths may overlap.

1.4. Outline of the paper. In section 2, we give a simple algorithm that solves p-SCSS for $p = 2$, while also defining the token game in more detail. We generalize this approach to any constant p and state the algorithm solving p-SCSS in section 3, making use of a token game similar to the one described above. The correctness proof is given in sections 3.4 and 4.

Using the algorithm for p-SCSS, in section 5 we then give the algorithm for the p-DSN problem and prove its correctness. We analyze the running times of our

algorithms in section 6, and conclude the paper in section 7 by summarizing our results and discussing possible future research directions.

2. A solution for 2-SCSS. We begin by solving unweighted 2-SCSS, the problem of finding a minimum (in terms of the number of nodes) strongly connected subgraph H of a graph $G = (V, E)$ that includes two specified nodes s and t. This is equivalent to finding the smallest H that contains paths from s to t and from t to s. Considering this simple problem allows us to introduce the notation and methodology used in the following sections. The algorithm described here is similar to the one given by Natu and Fang [NF97].

Figure 1 illustrates some of the difficulties of this problem. Let s, t be our terminals. The optimal subgraph consists of the six nodes $s, x_7, x_8, x_9, x_{10}, t$. The paths from s to t and t to s share vertex x_7 and the vertex sequence $x_8 \to x_9 \to x_{10}$. Note that the optimal subgraph includes neither the shortest path from s to t nor the shortest path from t to s.

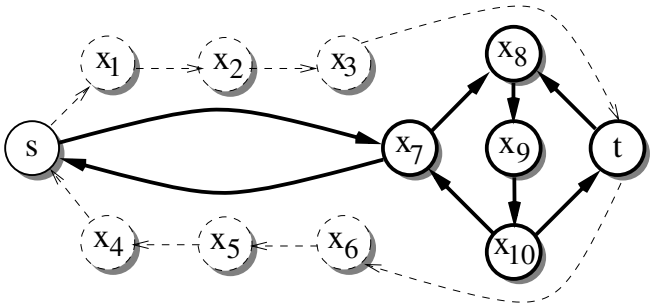

FIG. 1. *A sample graph for 2-SCSS, with terminals s and t. The optimal subgraph is in solid lines.*

2.1. The token game. To compute the optimal subgraph H, we will place two tokens, called f and b, on vertex s. We then move the tokens along edges, f moving forward along edges, and b moving backward along edges, until they both reach t. Then the set of nodes visited during the sequence of moves will contain paths $s \rightsquigarrow t$ and $t \rightsquigarrow s$.

To find the smallest subgraph H containing those paths, we will charge for the moves. The cost of a move will be the number of new vertices entered by the tokens during that move. Clearly we can never find a move sequence that gets both tokens from s to t with a total cost lower than $|H| - 1$, the size of the optimal solution H minus 1 (since we never charge for s). In fact, we will show that the lowest cost move sequence to get the tokens from s to t will have cost exactly $|H| - 1$, and thus corresponds to an optimal solution.

The three kinds of moves we allow are given below. The notation $\langle x, y \rangle$ refers to the situation where token f is on vertex x, and token b is on vertex y. The expression "$\langle x_1, y_1 \rangle \xrightarrow{c} \langle x_2, y_2 \rangle$" means that it is legal to move token f from x_1 to x_2 and token b from y_1 to y_2 (at the same time), and that this move has cost c. We want to find a move sequence from $\langle s, s \rangle$ to $\langle t, t \rangle$ with minimal cost.

(i) *Token f moving forward*: For every edge $(u, v) \in E$ and all $x \in V$, we allow
  (a) the move $\langle u, x \rangle \xrightarrow{1} \langle v, x \rangle$ and
  (b) the move $\langle u, v \rangle \xrightarrow{0} \langle v, v \rangle$.

(ii) *Token b moving backward*: For every edge $(u, v) \in E$ and all $x \in V$, we allow
  (a) the move $\langle x, v\rangle \xrightarrow{1} \langle x, u\rangle$ and
  (b) the move $\langle u, v\rangle \xrightarrow{0} \langle u, u\rangle$.

(iii) *Tokens switching places*: For every pair of vertices $a, b \in V$ for which there is a path from a to b in G, we allow the move $\langle a, b\rangle \xrightarrow{c} \langle b, a\rangle$, where c is the length of the shortest path from a to b in G. By length we mean the number of vertices besides a and b on that path.

Type (i) and (ii) moves allow the tokens f and b to move forward along a single edge and backward along an edge, respectively. Usually the cost is 1, accounting for the new vertex that the token visits. Only in the case where a token reaches a vertex with a token already on it, the cost is 0, since no "new" vertices are visited.

Type (iii) moves allow the two tokens to switch places. We call this type of move a "flip" and say that the vertices on the shortest path from a to b are *implicitly* traversed by the tokens. The cost c of the move accounts for all of these vertices.

Let us return to the example in Figure 1 to see how these moves are used. The lowest cost way to move both tokens from s to t is the following (we use subscripts to denote the type of the move):

$$\langle s, s\rangle \xrightarrow[\text{(i)}]{1} \langle x_7, s\rangle \xrightarrow[\text{(ii)}]{0} \langle x_7, x_7\rangle \xrightarrow[\text{(i)}]{1} \langle x_8, x_7\rangle$$
$$\xrightarrow[\text{(ii)}]{1} \langle x_8, x_{10}\rangle \xrightarrow[\text{(iii)}]{1} \langle x_{10}, x_8\rangle \xrightarrow[\text{(ii)}]{1} \langle x_{10}, t\rangle \xrightarrow[\text{(i)}]{0} \langle t, t\rangle.$$

The weight of this sequence is 5, which is $|H| - 1$, and the nodes visited by the tokens are exactly the nodes in the optimal solution H.

2.2. The algorithm. Let us phrase the preceding discussion in an algorithmic form. To compute H, we first construct a "game-graph" $\widetilde{G}$. The nodes of the graph correspond to token positions $\langle x, y\rangle$, the edges to legal moves between positions. In our case, the nodes are just $V \times V$, and the edges are the ones given above as legal moves.

The solution H is found by computing a lowest cost path from $\langle s, s\rangle$ to $\langle t, t\rangle$ in $\widetilde{G}$. The graph H then consists of all the vertices from V that are mentioned along that path, including the vertices that are implied by type (iii) moves.

Running time. Clearly, this game-graph can be computed in polynomial time. First, we perform an all-pairs-shortest-paths computation on G to obtain the information we need to set up the type (iii) moves. This takes time $\mathcal{O}(mn)$ using breadth-first search, where n and m are the number of vertices and edges in the original graph G. Then, we add to $\widetilde{G}$ all the edges corresponding to legal moves one at a time. The number of vertices in $\widetilde{G}$ is $\mathcal{O}(n^2)$. The number of type (i) and type (ii) edges in $\widetilde{G}$ is $\mathcal{O}(mn)$, since there are a type (i) and a type (ii) move for every edge and vertex combination in G. The number of type (iii) edges is $\mathcal{O}(n^2)$, making the total time to compute $\widetilde{G}$ equal to $\mathcal{O}(mn + n^2)$.

Now we just have to perform a single-source-shortest-paths computation from $\langle s, s\rangle$ to obtain H. Since we now have weights on the type (iii) edges, we cannot use breadth-first search. For a simple implementation, we could use Dijkstra's algorithm (which has a running time of $\mathcal{O}(|\widetilde{V}|^2)$) and achieve a running time of $\mathcal{O}(n^4)$. Using Fibonacci heaps [FT87], which allow single-source shortest paths in time $\mathcal{O}(|\widetilde{E}| + |\widetilde{V}| \log |\widetilde{V}|)$, we achieve a running time of $\mathcal{O}(mn + n^2 \log n)$.

As an aside, this algorithm can also be used to solve 2-DSN. Given a graph G and two node-pairs (s_1, t_1), (s_2, t_2), add two nodes s, t and edges $s \to s_1$, $t_1 \to t$, $t \to s_2$, $t_2 \to s$ to the graph and solve 2-SCSS for the two terminals s, t. The solution for this problem is also an optimal solution for the original 2-DSN problem (if we omit s and t). This leads to a running time of $\mathcal{O}(mn + n^2 \log n)$ for 2-DSN, which is the same as the running time obtained by Natu and Fang [NF95].

In fact, we can do a little better for unweighted graphs G by using more advanced shortest-paths algorithms. For a more detailed analysis, see section 6.

2.3. Correctness. The proof that our algorithm actually solves 2-SCSS can be split into two claims. We provide a proof here that motivates the techniques used in the general case. An alternate proof can be found in [NF95, NF97].

CLAIM 2.1. *If there is a legal move sequence from $\langle s, s\rangle$ to $\langle t, t\rangle$ with cost c, then there is a subgraph H of G of size $\leq c + 1$ that contains paths $s \rightsquigarrow t$ and $t \rightsquigarrow s$.*

Proof. If we follow a move sequence from $\langle s, s\rangle$ to $\langle t, t\rangle$, then f and b trace out paths $s \rightsquigarrow t$ and $t \rightsquigarrow s$, and this becomes our solution H. Moreover, the tokens traverse at most $c + 1$ vertices, since each vertex (except s) that we visit adds one to the cost of the move sequence. ∎

CLAIM 2.2. *Let H^* be an optimal subgraph containing paths $s \rightsquigarrow t$ and $t \rightsquigarrow s$. Then there exists a move sequence from $\langle s, s\rangle$ to $\langle t, t\rangle$ with total cost $|H^*| - 1$.*

Proof. We prove the claim by constructing a move sequence $\langle s, s\rangle \rightsquigarrow \langle t, t\rangle$, using H^* to tell us how to move the tokens.

When moving the tokens from $\langle s, s\rangle$ to $\langle t, t\rangle$, we "pay" each time we reach a new vertex in H^*. In order to achieve total cost $|H^*| - 1$ we must make sure that we pay only once for each vertex in H^*. To ensure this, we enforce one rule: After a token moves off a vertex, no other token will ever move to that vertex again. We say that a vertex becomes "dead" once a token moves from it, so that tokens are allowed to move only to vertices in H^* that are "alive." Note that the notion of dead and alive vertices is used only for the analysis; the algorithm itself never explicitly keeps track of them.

As we construct the move sequence, we maintain the invariant that there exist paths of "alive" vertices in H^* from the position of token f to t, and from t to the position of token b. This will ensure that we do not have to violate our rule to proceed with the sequence. When we reach $\langle t, t\rangle$, we will have constructed a legal move sequence and paid for each vertex in $|H^*|$ at most once. This will immediately imply the claim.

We construct the sequence in a greedy fashion. We start at position $\langle s, s\rangle$, and perform the following steps:

(a) *Move token f with type* (i) *moves.* Choose some path of alive vertices in H^* from the position of token f to t. We move token f forward along edges in that path (killing vertices along the way) using type (i) moves, until we reach t, or we reach a node x where moving token f would leave token b stranded; i.e., all paths of alive vertices from t to the position of token b go through x. We cannot move token f off of x; otherwise we would kill x and lose our invariant that there is a path of alive vertices from t to the position of token b (see Figure 2).

(b) *Move token b with type* (ii) *moves.* Choose some path of alive vertices from t to the position of token b and move the token b backward along edges of that path toward t using type (ii) moves. We proceed until we reach t, x, or some node $y \neq x$ that would leave the token f stranded if we killed it (all paths from x to t go through y).

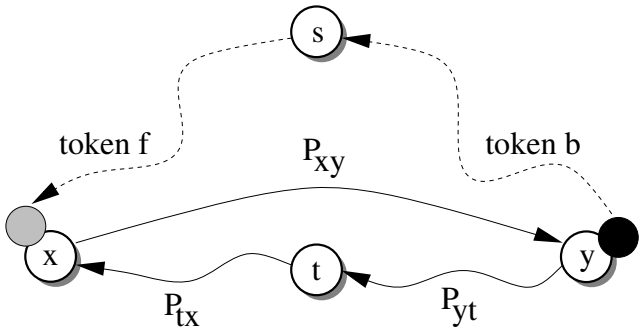

FIG. 2. *Deadlock in the construction of an optimal move sequence. Token f has moved forward onto node x, and token b has moved backward onto node y. All paths from x to t go through y, and all paths from t to y go through x. Therefore, moving either one of the tokens individually would leave the other token stranded. We resolve this deadlock using a flip: a type* (iii) *move exchanging the positions of the tokens.*

If the tokens are both on t, we are done. If the tokens are now on the same node x, go back to step (a). Note that in both these cases the last move of token b is free. If token b reaches some node $y \neq x$, we have a "deadlock" (see Figure 2).

(c) *Resolve the deadlock with a flip: A type* (iii) *move.* To resolve the deadlock, we will use a type (iii) move. We know that all paths from x to t go through y; thus there must be two disjoint simple paths P_{xy} and P_{yt} in H^* (see Figure 2). Likewise, since all paths from t to y go through x, there must be a simple path P_{tx}. Path P_{tx} must also be disjoint from P_{xy}, since if it were not, token b would be able to get from y to t without going through x.
We apply the type (iii) move $\langle x, y\rangle \rightarrow \langle y, x\rangle$. The cost of the move is at most the size of P_{xy} (not including x and y), and we kill only nodes on P_{xy}. Since P_{xy} is disjoint from both P_{tx} and P_{yt}, we maintain our invariant that there are paths of "alive" vertices from the position of token f to t and from t to the position of token b. We continue with step (a).

We never move a token onto a dead vertex, and each step maintains the invariant that there are paths of alive vertices from the position of token f to t and from t to the position of token b. Therefore both tokens reach t, and we pay only once for each vertex we visit. Since we visit only vertices in H^* and do not pay for s, it must be the case that the cost of the move sequence is at most $|H^*| - 1$. □

This claim immediately implies that the shortest path in $\widetilde{G}$ will correspond to an optimal solution, since by Claim 2.1 and the minimality of H^* there are no paths in $\widetilde{G}$ of length less than $|H^*| - 1$.

The token movements for the $p = 2$ case essentially describe the way in which paths are shared in the optimal solution. Path sharing for $p \geq 3$ is more complex, and thus we will need a richer set of token moves and a more involved proof.

3. Strongly connected Steiner subgraphs. In this section we give an algorithm for p-SCSS that is a generalization of the algorithm for 2-SCSS given in the previous section.

Again, we will use token movements to trace out the solution H. The way the tokens move is motivated by the following observation. Consider any strongly connected H containing $\{s_1, \ldots, s_p\}$. This H will contain paths from each $s_1, \ldots, s_{p-1}$ to

s_p, and these paths can be chosen to form an in-tree rooted at s_p; we will call this tree the *forward tree*. The graph H will also contain paths from s_p to each $s_1, \ldots, s_{p-1}$, forming an out-tree that we call the *backward tree*. Moreover, every H that is the union of two such trees is a feasible solution to our p-SCSS instance.

For ease of notation, we set $q := p - 1$ for the remainder of this section and let $r := s_p$, as s_p plays the special role of "root" in the two trees.

3.1. Token moves for *p*-SCSS. To trace out the two trees, we will have q "F-tokens" moving forward along edges in the forward tree from $\{s_1, \ldots, s_q\}$ to r, and q "B-tokens" moving backward along edges from $\{s_1, \ldots, s_q\}$ to r. Given a set of legal moves, we will again look for the lowest cost move sequence that moves all tokens to r. This will then correspond to the smallest subgraph containing paths $s_i \rightsquigarrow r$ and $r \rightsquigarrow s_i$ for all $i \leq q$, which is the graph we are looking for.

Since both sets of tokens trace out a tree, once two tokens of the same kind reach a vertex, they will travel the same way to the root. In that case, we will simply merge them into one token. It is therefore enough to describe the positions of the tokens by a pair of sets $\langle F, B \rangle$, where F and B are the sets of nodes currently occupied by the F- and B-tokens, respectively.

Again, we have three types of legal token moves. Type (i) moves correspond to F-tokens moving forward along an edge, and type (ii) moves correspond to B-tokens moving backward along an edge. We do not charge for entering a vertex if another token is already on it.

Since there are at most q tokens of each type, the possible token positions for a particular type are the subsets of V of size at most q. For the following, let $\mathcal{P}_q(V)$ be the set of subsets of V of size at most q.

(i) *Single moves for F-tokens*: For every edge $(u, v) \in E$ and all token sets $F \in \mathcal{P}_q(V)$, $B \in \mathcal{P}_q(V)$ such that $u \in F$, the following is a legal move:

$$\langle F, B \rangle \xrightarrow{c} \langle (F \setminus \{u\}) \cup \{v\}, B \rangle,$$

where the cost c of the move is 1 if $v \notin F \cup B$, and 0 otherwise.

(ii) *Single moves for B-tokens*: For every edge $(u, v) \in E$ and all token sets $F \in \mathcal{P}_q(V)$, $B \in \mathcal{P}_q(V)$, such that $v \in B$, the following is a legal move:

$$\langle F, B \rangle \xrightarrow{c} \langle F, (B \setminus \{v\}) \cup \{u\} \rangle,$$

where the cost c of the move is 1 if $u \notin F \cup B$, and 0 otherwise.

Type (iii) moves allow tokens to pass each other, similar to the type (iii) moves in the previous section, except that this time the "flip" is more complex (see Figure 3). We have two "outer" tokens, f and b, trying to pass each other. Between f and b there are other F-tokens moving forward and trying to pass b, and B-tokens moving backward and trying to pass f. These tokens, sitting on node sets F' and B', are "picked up" during the flip.

(iii) *Flipping*: For every pair of vertices f, b and vertex sets F, B, $F' \subset F$, $B' \subset B$, such that

- $f \in F$, $F \in \mathcal{P}_q(V)$,
- $b \in B$, $B \in \mathcal{P}_q(V)$, and
- there is a path in G from $f \rightsquigarrow b$ going through all vertices in $F' \cup B'$,

the following is a legal token move:

$$\langle F, B \rangle \overset{|M|}{\rightarrow} \langle (F \setminus (\{f\} \cup F')) \cup \{b\}, (B \setminus (\{b\} \cup B')) \cup \{f\} \rangle,$$

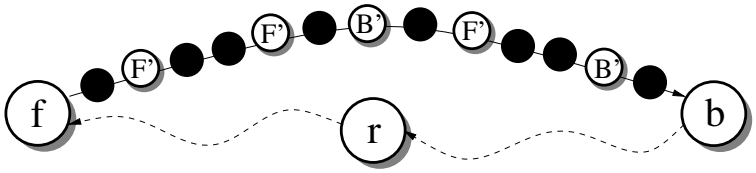

FIG. 3. *Flipping f and b, with tokens F' and B' that need to be "picked up." The black nodes are the set M.*

where M is the set of vertices on a shortest path from f to b in G going through all vertices in $F' \cup B'$, excluding f, b, and the vertices in $F' \cup B'$.

3.2. The algorithm for p-SCSS. We can now state the algorithm for p-SCSS:

1. Construct a game-graph $\widetilde{G} = (\widetilde{V}, \widetilde{E})$ from $G = (V, E)$. Set $\widetilde{V} := \mathcal{P}_q(V) \times \mathcal{P}_q(V)$, the possible positions of the token sets, and $\widetilde{E} :=$ all legal token moves defined above.
2. Find a shortest path P in $\widetilde{G}$ from $\langle \{s_1, \ldots, s_q\}, \{s_1, \ldots, s_q\} \rangle$ to $\langle \{r\}, \{r\} \rangle$.
3. Let H be the union of $\{s_1, \ldots, s_q, r\}$ and all nodes given by P (including those in sets M for type (iii) moves).

The difficult part of constructing the game-graph $\widetilde{G}$ is computing the costs for the type (iii) moves that flip f and b. We need to know the size of the shortest path between f to b in G going through all vertices in $F' \cup B'$. Note that we do not require this path to be simple. Thus, if we knew the order in which the vertices in F' and B' occurred on the path, computing the shortest path becomes easy: It is just the union of the shortest paths between consecutive nodes in that order. Since the number of tokens in $F' \cup B'$ is bounded by $2(q-1)$, which is a constant, we can simply try all possible permutations of the nodes in $F' \cup B'$.

The total running time of the algorithm is $\mathcal{O}(mn^{2p-3} + n^{2p-2} \log n)$. For more details on the running time, see section 6.

3.3. An example. As an example we look at how the token game works on the graph in Figure 4. Our terminals are s_1, s_2, s_3, s_4, s_5, and so we set s_5 to be the root vertex and put a forward and a backward token on each of the other terminals (Figure 4(a)). In Figures 4(b)–(i) we see the following move sequence:

$$
\begin{aligned}
&\langle \{s_1, s_2, s_3, s_4\}, \{s_1, s_2, s_3, s_4\} \rangle \\
&\xrightarrow[\text{(i)}]{1} \langle \{s_1, s_2, s_3, x_3\}, \{s_1, s_2, s_3, s_4\} \rangle \\
&\xrightarrow[\text{(ii)}]{0} \langle \{s_1, s_2, s_3, x_3\}, \{s_1, s_2, s_3\} \rangle \xrightarrow[\text{(iii)}]{2} \langle \{s_2\}, \{x_3\} \rangle \\
&\xrightarrow[\text{(i)}]{1} \langle \{x_5\}, \{x_3\} \rangle \xrightarrow[\text{(ii)}]{1} \langle \{x_5\}, \{x_4\} \rangle \xrightarrow[\text{(iii)}]{0} \langle \{x_4\}, \{x_5\} \rangle \\
&\xrightarrow[\text{(i)}]{1} \langle \{s_5\}, \{x_5\} \rangle \xrightarrow[\text{(ii)}]{0} \langle \{s_5\}, \{s_5\} \rangle.
\end{aligned}
$$

The total cost of the moves is 6 and therefore equal to $|H| - q = 10 - 4 = 6$, as expected. The solution $\{s_1, s_2, s_3, s_4, s_5, x_1, x_2, x_3, x_4, x_5\}$ (Figure 4(j)) is made up of the terminals $\{s_1, s_2, s_3, s_4, s_5\}$, the nodes $\{x_3, x_4, x_5\}$ mentioned in the sequence of moves, and the nodes $\{x_1, x_2\}$ in the set M for the first type (iii) move. This is optimal.

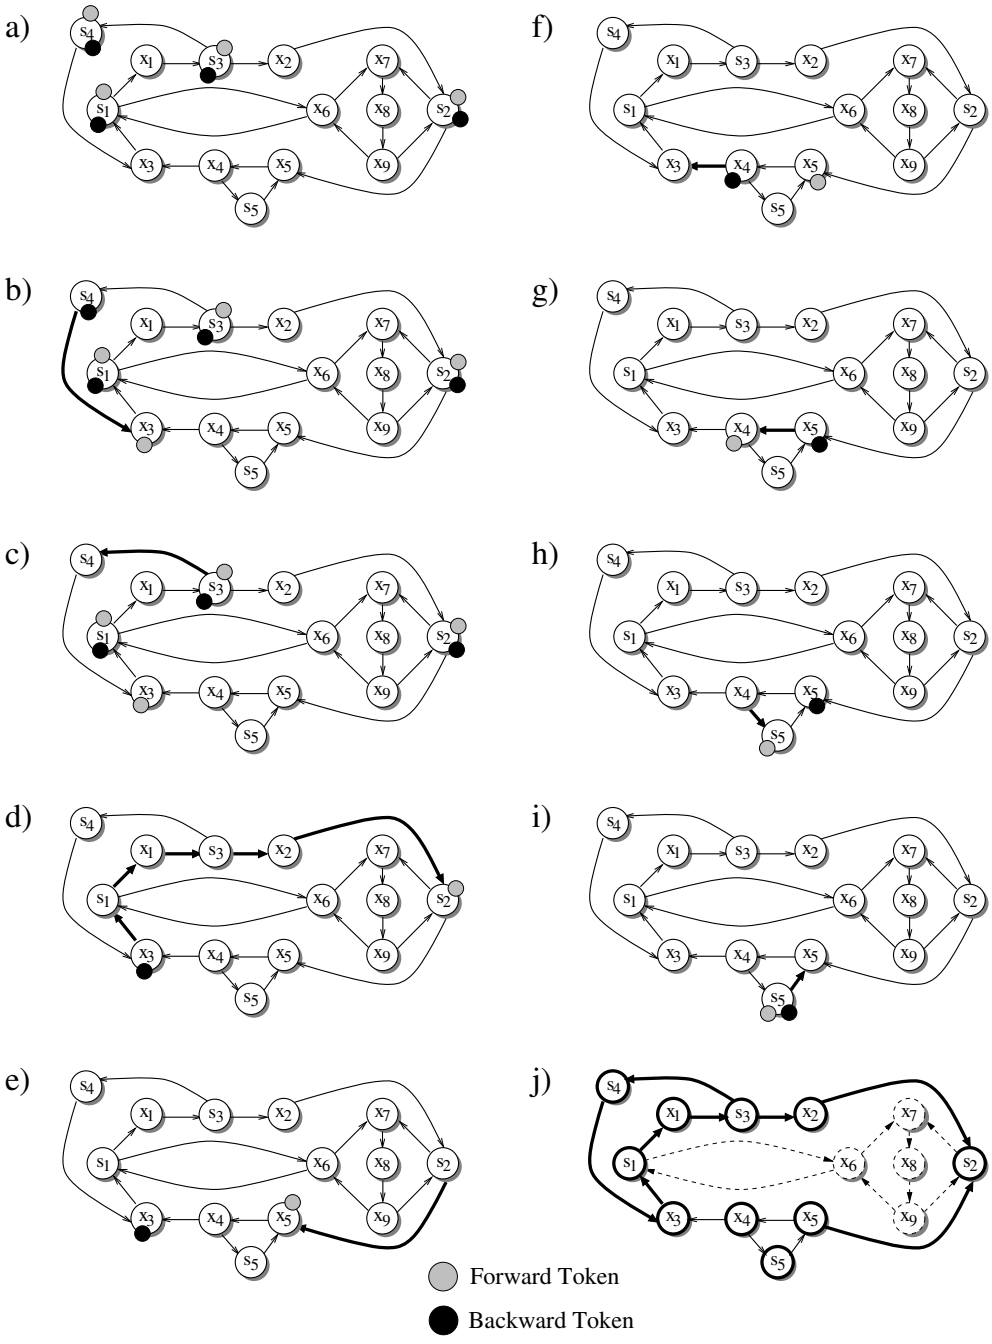

FIG. 4. *An example for the p-SCSS algorithm. Bold lines indicate the path of the previous token move.*

3.4. Correctness of the *p*-SCSS algorithm. The correctness proof for our p-SCSS algorithm can be split into the same two parts we used for 2-SCSS.

LEMMA 3.1. *Suppose there is a move sequence from* $\langle\{s_1,\ldots,s_q\},\{s_1,\ldots,s_q\}\rangle$ *to* $\langle\{r\},\{r\}\rangle$ *with total cost* c*. Then there exists a solution* H *to this* p-SCSS *instance of*

size $\leq c + q$. *Moreover, given the move sequence, it is easy to construct such an* H.

Proof. This follows directly from the definition of the moves. The cost of any move sequence is an upper bound on the number of vertices traversed by that sequence. Given the constructive nature of the moves, it is also easy to actually find H. ∎

Together with the following, much more involved lemma, the correctness of the algorithm is proved.

LEMMA 3.2. *Suppose* $H^* = (V^*, E^*)$ *is any minimal feasible solution. Then there is a move sequence from* $\langle \{s_1, \ldots, s_q\}, \{s_1, \ldots, s_q\} \rangle$ *to* $\langle \{r\}, \{r\} \rangle$ *with weight equal to* $|H^*| - q$.

Proof. To prove this lemma, we will effectively construct such a move sequence, where all intermediate positions of the tokens will be in H^*.

When moving the F- and B-tokens from $\{s_1, \ldots, s_q\}$ to r, we "pay" each time we reach a new vertex. To account for each move and achieve a total cost of $|H^*| - q$, we will use the same method as for 2-SCSS. We enforce the same rule: Once a token moves off a vertex, no other token will ever move to that vertex again. As before, we say that a vertex becomes "dead" once a token moves from it, so that tokens are allowed to move only to vertices in H^* that are "alive." This also ensures that our move sequence will be finite, since no token can return to a vertex it has already visited.

We say that a token t *requires* a vertex $v \in V^*$ if all legal paths for t to get to r pass through v. By "legal paths" we mean paths that are within H^*, go in the appropriate direction for the token t, and do not include any dead vertices. We will sometimes speak of tokens requiring tokens; in this case we mean that the first token requires the vertex on which the second token is sitting. Note that the requirement relation among tokens moving in the same direction is transitive; i.e., if f_1 requires f_2, and f_2 requires x, then f_1 also requires x.

We will construct our move sequence in a greedy fashion. That is, we will move tokens toward r using type (i) and (ii) moves, until each token sits on a vertex that is required by some other token to get to r. In this case we cannot apply any more type (i) or (ii) moves—doing so would leave some other token stranded as it is not allowed to move onto the now dead vertex.

In this case we need to use a type (iii) move to resolve the deadlock. Showing that this is always possible is the core of the correctness proof, the "flip lemma" shown in section 4. To state this lemma and see how it implies the correctness of the algorithm, we have to introduce some additional notation.

Let the "F_0-tokens" be the F-tokens that are not required by any other F-token. Similarly, let the "B_0-tokens" be the B-tokens that are not required by any other B-token. Note that since the requirements among the F-tokens are not cyclic, there will be at least one F_0-token and, similarly, at least one B_0-token.

LEMMA 3.3 (the flip lemma). *Suppose every token is required by some other token. Then there is an* F_0*-token* f *and a* B_0*-token* b *such that*

- f *requires* b*, and no other* F_0*-token requires* b*,*
- b *requires* f*, and no other* B_0*-token requires* f*.*

We will prove this lemma in the next section. Let us now see how it concludes the proof of Lemma 3.2.

Let f and b be chosen according to the flip lemma. Fix any simple path from f to r that uses only live vertices. Call P the portion of this path between f and b, and Q the portion between b and r (see Figure 5). By definition, P and Q are disjoint.

CLAIM 3.4. *All tokens that require a vertex on* P *are on* P *themselves.*

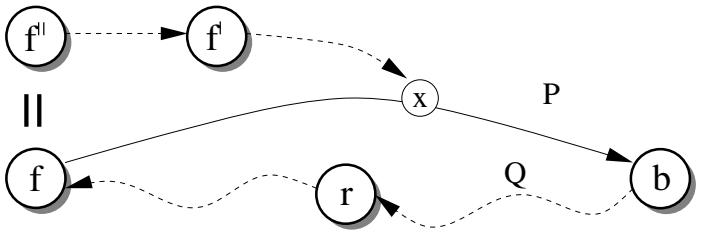

FIG. 5. *Showing Claim* 3.4*, that all tokens that require a vertex on* P *are on* P *themselves.*

Proof. We prove the claim for F-tokens; a symmetric argument applies to B-tokens. Suppose some F-token $f' \neq f$ requires a vertex x on P. Every path $x \rightsquigarrow r$ must include b; otherwise f could move to x and then to r, without visiting b. Therefore, f' also requires b (see Figure 5). The token f' cannot be an F_0-token, since the flip lemma tells us that f is the only F_0-token that requires b. Note that due to transitivity, every F-token is either an F_0-token or required by some F_0-token, so f' must be required by some F_0-token f''. By transitivity, f'' requires b, and thus $f'' = f$, by the flip lemma.

Since $f = f''$ requires f', the token f' is either on P or Q. If f' is on Q, then x is also on Q, since f' requires x. This contradicts the fact that P and Q are disjoint, and thus f' must be on P. □

Let F' be the set of F-tokens that are on the path P, and let B' be the set of B-tokens on P. We can apply a type (iii) move that switches f and b and picks up F' and B' along the way. All vertices on P become dead. No token is stranded, since by Claim 3.4, all tokens that required a vertex on P were on P and therefore were picked up by the flip.

We have shown, pending the flip lemma, that each step of the construction of our move sequence preserves paths of "alive" vertices from the F-tokens to r and from r to the B-tokens, and never moves a token onto a dead vertex. This shows that we can always continue the construction of our move sequence until all tokens reach r, and that the cost of the move sequence will be no more than $|H^*| - q$. □

4. The flip lemma. To complete the proof of correctness, it remains to prove Lemma 3.3, the flip lemma. We prove the flip lemma by making a graph out of the requirement relationships between the F_0- and B_0-tokens. We show that there is a two-cycle in this graph, consisting of an F_0- and a B_0-token, that does not have any other incoming requirements. This proves the lemma.

During the discussion, keep in mind that transitivity holds only among requirements for the same type of token; if an F-token f requires a node (or a token) x and some F-token f' requires f, then f' requires x. However, if some B-token b requires f, it is not necessarily the case that b also requires x, since b is moving backward along edges.

4.1. Proof of Lemma 3.3 (the flip lemma). Let $G_{req} = (V_{req}, E_{req})$ be a new directed graph, whose nodes are the F_0- and B_0-tokens. The edges in E_{req} correspond to requirements: G_{req} has an edge $x \to y$ if and only if the token x requires the token y.

This graph has a lot of structure. First of all, G_{req} is bipartite, since no two F_0-tokens (and no two B_0-tokens) have a requirement relationship (by the definition of an F_0- and a B_0-token). For the remainder of the discussion, we will use f to denote a node on the F_0 side of the bipartition and b to denote a node on the B_0 side.

By assumption (every token is required by some other token) and by definition (an F_0-token is not required by any F-token), we know that every F_0-token is required by at least one B-token. We know that either that B-token is a B_0-token, or there is another B_0-token that requires that B-token. Therefore, by transitivity for B-tokens, every F_0-token is required by at least one B_0-token. By symmetry, every B_0-token is required by at least one F_0-token. Therefore, every node in G_{req} has at least one incoming edge.

We want to find a two-cycle in G_{req} with no incoming edges, since the two tokens in such a cycle would require each other but would not be required by any other token, proving the lemma. We can view G_{req} as a dag (directed acyclic graph) of strongly connected components and sort the strongly connected components topologically. Let C be the first component in that ordering. This means that no token outside of C requires any token in C. Furthermore, C cannot consist of only one node, since then that token would be required by no other token, in contradiction to our assumption that every token is required by at least one token.

We will now prove that C cannot consist of more than two nodes. This gives us the desired two-cycle and shows the flip lemma. The proof rests on the observation that G_{req} satisfies a kind of transitivity, which we call the *projection* property. After showing his property, we prove the claim by contradiction by applying the projection property across the requirement graph.

CLAIM 4.1 (projection). *Suppose for three nodes f_1, f_2, b_1 ($f_1 \neq f_2$) in G_{req} we have edges $f_1 \to b_1$ and $b_1 \to f_2$ in G_{req}. Then the following holds: All nodes b that have an edge $b \to f_1$ also have an edge $b \to f_2$.*

Proof. By definition of F_0, there is a legal path in H^* from f_1 to r avoiding f_2. Since f_1 requires b_1, this path goes through b_1. Therefore, there is a path P_1 from f_1 to b_1 avoiding f_2 (see Figure 6).

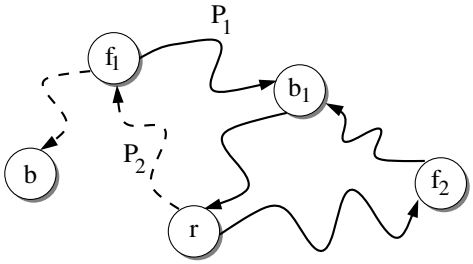

FIG. 6. *Proving the projection property in G_{req}. The solid lines are paths in H^* corresponding to edges $f_1 \to b_1$ and $b_1 \to f_2$ in G_{req}; the dashed line corresponds to the edge $b \to f_1$.*

Suppose that some node b in G_{req} has an edge $b \to f_1$. We show that $b \to f_2$ is also in G_{req} by contradiction. If $b \to f_2$ is not in the requirement graph, then there is a legal path in H^* from r to b avoiding f_2. Since b requires f_1, this path goes through f_1. Therefore, there is a path P_2 in H^* from r to f_1 avoiding f_2. Combining P_2 and P_1, we obtain a path from r to b_1 that does not visit f_2, in contradiction to $b_1 \to f_2$ being in G_{req}. ∎

A symmetric property holds by exchanging f's and b's; i.e., for any triple f_1, b_1, b_2 ($b_1 \neq b_2$), if there are edges $b_1 \to f_1$ and $f_1 \to b_2$ in G_{req}, then for every node f in G_{req}, if there is an edge $f \to b_1$, then there must also be an edge $f \to b_2$.

The projection property has a profound effect on the structure of G_{req}. In fact, it shows that if there is a path in G_{req} from a node b to a node f, then there is an edge

from b to f. To see this, consider the last four nodes on the path from b to f in G_{req}, $b'' \to f' \to b' \to f$. By projection, there must be an edge $b'' \to f$. This shortens the length of the path by 2. This argument can be repeated along the path until it shows that there must be an edge $b \to f$.

A symmetric argument (using the symmetric projection property) shows that if there is a path in G_{req} from a node f to a node b, then there is an edge from f to b. We further conclude that every strongly connected component in G_{req} is a complete bipartite graph (every pair of nodes on opposite sides of the bipartition is connected in both directions). Now we are ready to finish the flip lemma.

CLAIM 4.2. *No strongly connected component C of G_{req} has more than two nodes.*

Proof. We prove the claim by contradiction. Assume that a strongly connected component C in G_{req} has at least three elements. Either there are two F_0 nodes in C, or two B_0 nodes in C. We assume (without loss of generality) that there are two F_0 nodes (a symmetric argument shows the other case). Since C is a complete bipartite graph, there must be a complete bipartite subgraph of C consisting of nodes f_1, b_1, f_2.

We turn back to H^* to show that this structure cannot exist. Since b_1 requires both f_1 and f_2, there is a legal path in H^* from r to b_1 that visits both f_1 and f_2 (solid lines in Figure 7). Without loss of generality assume that f_1 is the first node on that path, so that there is a path P_1 from r to f_1 that avoids f_2. Since f_1 requires b_1, but f_1 does not require f_2, there must also be a path P_2 from f_1 to b_1 that avoids f_2 (dashed lines in Figure 7). Combining P_1 and P_2, we obtain a legal path in H^* from r to b_1 that avoids f_2, in contradiction to the fact that b_1 requires f_2.

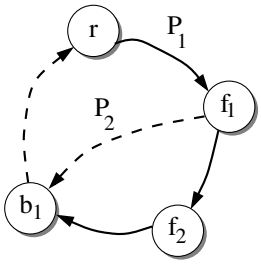

FIG. 7. *Components with more than two elements are impossible.*

This contradiction shows that C cannot have more than two nodes. This shows the claim and thereby the flip lemma. ∎

5. The directed Steiner network problem. In this section we show how to apply the algorithm developed in the previous sections to solve the DIRECTED STEINER NETWORK problem (p-DSN), for any constant p.

p-DSN (unweighted, node-minimizing). *Given a directed graph $G = (V, E)$ and p pairs of nodes in the graph $\{(s_1, t_1), \ldots, (s_p, t_p)\}$, find the subgraph H of G with the smallest number of nodes that contains paths from s_i to t_i for $1 \le i \le p$.*

We use the same general model of a token game, but now we have tokens moving from each source s_i to its destination t_i. This time, we have no backward moving tokens, and also tokens do *not* merge when they reach the same node. We describe the positions of the tokens by a p-tuple $\langle f_1, f_2, \ldots, f_p \rangle$. We have two kinds of moves for the tokens. The first kind of move allows a single token to move one step along an edge.

(i) For each edge (u, v) we include the moves $\langle —, u, — \rangle \xrightarrow{c} \langle —, v, — \rangle$, meaning that one token moves from u to v, and all others remain where they are. The cost c of the move is 0 if v already has a token on it, and 1 otherwise.

Using only type (i) token moves, it is easy to see that we can exactly trace out any dag. But since the optimal solution to p-DSN may contain cycles (or other more complex strongly connected components), we need to define additional token moves so as not to overcount.

Consider the optimal solution to p-DSN and contract every strongly connected component to a single node; the resulting graph is a dag (see Figure 8). Now imagine a single token moving through this graph along a path to its destination; for each strongly connected component it encounters along the way, it has an entrance point and an exit point. A particular strongly connected component in this decomposition has some number $k \leq p$ such entrance/exit point pairs.

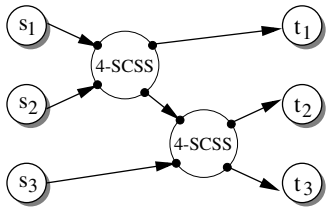

FIG. 8. *A solution to* p-DSN *is a dag of strongly connected components.*

Using this intuition, we define a special token move that allows a group of k tokens ($k \leq p$) to move from any k or fewer specific entrance points to any k or fewer specific exit points in a strongly connected component (if such a component exists). The cost of the move will be (roughly) the size of the smallest component containing these special entrance/exit points. This cost can be computed using our algorithm for SCSS from section 3.

Formally, our token moves are defined as follows.

(ii) For all $k \leq p$ and for every set of k node-pairs $\{(f_1, x_1), (f_2, x_2), \ldots, (f_k, x_k)\}$ for which there is a strongly connected subgraph of G containing the f_i and x_i for all $1 \leq i \leq k$, we allow the move

$$(— f_1 — f_2 — \cdots — f_k —)$$
$$\xrightarrow{c} (— x_1 — x_2 — \cdots — x_k —).$$

The cost c of this move is the size of the smallest strongly connected component containing the vertices $\{f_1, f_2, \ldots, f_k, x_1, x_2, \ldots, x_k\}$ minus the size of the set $\{f_1, \ldots, f_k\}$. We can use the algorithm developed in section 3 to compute this cost.

Similar in structure to our algorithm for p-SCSS in section 3, the algorithm for p-DSN consists of the following steps.

1. Compute the game-graph $\mathcal{G}$, where the vertices in $\mathcal{G}$ are p-tuples of vertices in the input graph G, and edges are included for each legal token move (type (i) or (ii)).
2. Find the minimum-weight path P in $\mathcal{G}$ from $\langle s_1, \ldots, s_p \rangle$ to $\langle t_1, \ldots, t_p \rangle$.
3. Output the subgraph H of G induced by P, i.e., the subgraph containing

- all vertices of G explicitly "mentioned" by vertices in P, and
- for all type (ii) moves used in P, all the vertices making up the smallest strongly connected component containing the f_i's and x_i's used to define that move.

5.1. Correctness. As for the previous algorithms, it is easy to see that for any move sequence from $\langle s_1, \ldots, s_p \rangle$ to $\langle t_1, \ldots, t_p \rangle$ of cost c, there is a feasible solution H of size at most $c + |\{s_1, \ldots, s_p\}|$. It is also easy to find this H, given the move sequence. The following lemma then implies the correctness of the algorithm.

LEMMA 5.1. *Let H^* be a minimum size subgraph of G that contains paths $s_i \rightsquigarrow t_i$ for all $i \in \{1, \ldots, p\}$. Then there is a legal sequence of token moves from $\langle s_1, \ldots, s_p \rangle$ to $\langle t_1, \ldots, t_p \rangle$ with cost $|H^*| - |\{s_1, \ldots, s_p\}|$.*

Proof. We again give a constructive proof. We start with tokens $f_1, \ldots, f_p$ at $s_1, \ldots, s_p$ and move them to their respective destinations $t_1, \ldots, t_p$.

Regard each strongly connected component in H^* as a single node and topologically sort this dag of strongly connected components. Let $C_1, \ldots, C_m$ be the resulting order of strongly connected components. We now consider each component in order and move each token in the component either to its destination (if its destination is in the component) or to some later component in the ordering on a path to its destination. After doing so, all nodes in the component are dead. This ensures that we pay only once for every node.

For each component C_i containing some k tokens ($k \leq p$), we perform the following moves. We execute (a) and (b) if C_i consists of more than one node, and only (b) if C_i consists of a single node.

(a) We apply a type (ii) move. For each token f_ℓ in C_i we define a node x_ℓ in C_i to which it moves. For tokens f_ℓ whose destination t_ℓ is in C_i, we set x_ℓ to that destination. For all other tokens f_ℓ we choose any legal path to its destination t_ℓ and let x_ℓ be the last node of that path that is in C_i. Using a type (ii) move we simultaneously move all the tokens f_ℓ to their respective x_ℓ.

(b) We apply a type (i) move for each token f_ℓ in C_i that is not yet at its destination t_ℓ. We move along one edge of a path to t_ℓ into a new component C_j ($j > i$). □

5.2. Weights and edges. The algorithms provided for p-DSN and p-SCSS can easily be modified to handle weighted nodes: Just make the cost of a move the total weight of the unoccupied nodes entered during the move instead of just their number.

It is also easy to minimize the total edge weight in H by reducing it to the weighted-node case. To do this, we give every vertex in G weight 0 and replace every edge e by a new vertex having the weight of e. We connect this new vertex to the two vertices incident to e. Naturally, it is also possible to combine vertex weights and edge weights.

6. Runtime analysis. In this section we provide the running time analysis for our algorithms solving p-SCSS (from section 3) and p-DSN (from section 5).

The aim of this section is mainly to give an idea as to how the running time is distributed over the different parts of the algorithms (game-graph construction and shortest-path computation).

6.1. The p-SCSS algorithm. The algorithm consists of two parts: the generation of the game-graph $\widetilde{G}$ from the input $G = (V, E)$ and the computation of a shortest path from $\langle \{s_1, \ldots, s_q\}, \{s_1, \ldots, s_q\} \rangle$ to $\langle \{r\}, \{r\} \rangle$ in $\widetilde{G}$.

The size of the game-graph $\widetilde{G}$. In the following, n and m are always the number of vertices and edges, respectively, of the input graph G. Recall that we assume that G is connected, and thus $m \geq n-1$. The number of vertices in the game-graph $\widetilde{G}$ is

$$|\mathcal{P}_q(V) \times \mathcal{P}_q(V)| = \left(\sum_{i=0}^{q} \binom{n}{i}\right)^2 = \mathcal{O}(n^{2q}).$$

The number of type (i) edges can be computed as follows. If we fix an edge $(u,v) \in E$, then there are $|\mathcal{P}_{q-1}(V \setminus \{u\})|$ choices for F and $|\mathcal{P}_q(V)|$ choices for B, and thus the total number of type (i) edges is

$$m \cdot |\mathcal{P}_{q-1}(V \setminus \{u\})| \cdot |\mathcal{P}_q(V)| = \mathcal{O}(m \cdot n^{q-1} \cdot n^q) = \mathcal{O}(mn^{2q-1}).$$

By symmetry, the number of type (ii) edges is the same.

For the type (iii) edges, we can also obtain an upper bound on their number by multiplying the number of choices for f and b ($\mathcal{O}(n)$ each), F and B ($\mathcal{O}(n^{q-1})$ each), and F' and B' ($\mathcal{O}(2^{q-1})$ each after choosing F and B). This yields a bound of $\mathcal{O}(n^{2q})$. Since $m \geq n-1$, the total number of edges is $\mathcal{O}(mn^{2q-1})$. The number of edges in $\widetilde{G}$ therefore is not much larger than the number of nodes.

Constructing the edge weights of the game-graph $\widetilde{G}$. Computing the edge weights takes constant time for type (i) and (ii) edges but is slightly more expensive for type (iii) edges. We need to compute, for each type (iii) edge, the length of a shortest path from a node f to a node b going through at most $2q-2$ specific intermediate nodes (the ones in $F' \cup B'$). Since this path does not have to be simple, it will be the union of the shortest paths between the consecutive intermediate vertices. Since there are only a constant number of intermediate vertices, we can guess their order.

More formally, we run an all-pairs-shortest-paths algorithm on the input graph G; this takes time at most $\mathcal{O}(n^2 \log n + mn)$. Now, for each type (iii) edge, we go through all possible sequences in which the vertices in $F' \cup B'$ could appear on the path. For each sequence, we add together the shortest path distances for consecutive vertices to compute the total cost of the best path for that sequence. The shortest path length among all sequences is kept as the weight of the type (iii) edge. There are $\mathcal{O}((2q-2)!)$ possible sequences of the vertices in $F' \cup B'$, and adding together the distances takes time $\mathcal{O}(2q)$. So as long as p (and therefore q) is constant, the time to compute the weight of a type (iii) edge is also constant.

To summarize, we spend a constant amount of time to compute the weight of each edge in the graph, which leads to a total time of $\mathcal{O}(mn^{2q-1})$ for the game-graph construction—subsuming the time for the all-pairs-shortest-path computation. Note that this bound also holds for the case where the original graph has arbitrary weights.

Computing the shortest path in the game-graph $\widetilde{G}$. The second part of the algorithm is to compute a single-source-shortest-path query in the game-graph $\widetilde{G} = (\widetilde{V}, \widetilde{E})$. Since all known shortest-paths algorithms might have to look at every edge, this step will dominate the running time of the algorithm. There exist a variety of different shortest-paths algorithms [AMO93], and the best one to use for a given graph depends on n, m, and C, where C is the largest weight in the graph if all weights are positive integers. For the case where the input graph G is weighted with positive real numbers, we want an algorithm that does not depend on C. Thus, the best choice is to use Fibonacci heaps [FT87], which allow us to compute single-source shortest paths in time $\mathcal{O}(|\widetilde{E}| + |\widetilde{V}| \log |\widetilde{V}|)$, and the total running time of our algorithm is

$$\mathcal{O}(n^{2q} + mn^{2q-1} + n^{2q} \log n) = \mathcal{O}(mn^{2p-3} + n^{2p-2} \log n).$$

If the input graph has no weights, as is the case for most of this paper, the weights in the game-graph will be positive integers bounded by n. So, we can use an algorithm of Ahuja et al. [AMOT90] that performs a shortest-path query in time $\mathcal{O}(|\widetilde{E}| + |\widetilde{V}|\sqrt{\log(|\widetilde{V}|C)})$, where C is the largest weight in the game-graph. Therefore the running time for the unweighted p-SCSS algorithm is

$$\mathcal{O}(mn^{2q-1} + n^{2q}\sqrt{\log n}) = \mathcal{O}(mn^{2p-3} + n^{2p-2}\sqrt{\log n}).$$

6.2. The *p*-DSN algorithm. For this algorithm, the game-graph $\mathcal{G}$ consists of $\mathcal{O}(n^p)$ nodes and can therefore have up to $\mathcal{O}(n^{2p})$ edges. This means that the final shortest-path computation will take time at most $\mathcal{O}(n^{2p})$, using Dijkstra's algorithm. We are deliberately rough with this calculation since it turns out that for the p-DSN algorithm, the time to construct the game-graph actually overshadows this shortest-path computation.

The most time-consuming part of the game-graph construction is to determine the weights of the type (ii) edges. Obviously, it would be very inefficient (though still polynomial) to call our k-SCSS algorithm for every type (ii) edge in the game-graph. Fortunately, a simple observation makes it possible to avoid that.

Solving the instances of k-SCSS *efficiently.* Every instance of k-SCSS that we wish to solve constructs a game-graph from the same underlying graph G. Furthermore, this game-graph does not depend on which vertices are terminals but only on G and the number k. This is because the game-graph describes legal token moves, which are independent of the starting positions of the tokens and their goals. Therefore, all instances of k-SCSS that operate on the same underlying graph G and have the same number of terminals use the same game-graph. Let us call this game-graph $\widetilde{G}_k$.

We need to solve instances of k-SCSS for all $k \leq 2p$. But, notice that $\widetilde{G}_k$ is a subgraph of $\widetilde{G}_{2p}$ if $k \leq 2p$. Moreover, there are no edges from this subgraph $\widetilde{G}_k$ to any other vertices in $\widetilde{G}_{2p}$, since all other vertices $\langle F, B\rangle$ in $\widetilde{G}_{2p}$ have more than k nodes in either F or B. Thus, we need only construct a single game-graph $\widetilde{G}_{2p}$ to determine all the weights of the type (ii) edges. However, we need to perform several different shortest-path computations on this graph for the different terminal sets.

Fortunately, all these computations have something in common. Solving a k-SCSS instance requires computing a shortest path in $\widetilde{G}_{2p}$, to a node of the form $\langle\{r\}, \{r\}\rangle$. This suggests the following strategy: Run n single-destination shortest-path computations, one for each possible destination $\langle\{r\}, \{r\}\rangle$ $(r \in V)$. Now the weights of type (ii) edges can then be computed in constant time by looking up the appropriate shortest path length.

The number of nodes in $\widetilde{G}_{2p}$ is $\mathcal{O}(n^{4p-2})$, and the number of edges is $\mathcal{O}(mn^{4p-3})$. Using Fibonacci heaps to perform each of the n shortest-path computations, we obtain a running time of $\mathcal{O}(mn^{4p-2} + n^{4p-1}\log n)$. In the unweighted case, the maximum weight in $\widetilde{G}_{2p}$ is again at most n. Thus, we use the algorithm of Ahuja et al. [AMOT90] and obtain a running time of $\mathcal{O}(mn^{4p-2} + n^{4p-1}\sqrt{\log n})$.

7. Conclusion. We have developed a polynomial time algorithm that computes the smallest subgraph containing paths between $p = O(1)$ pairs of nodes in a directed graph. It is an interesting open question whether p-DSN is fixed-parameter tractable, i.e., whether there is an algorithm whose running time is $O(n^k)$ for some k that does not depend on the constant p. We also wonder whether the tools developed to obtain our result can be used to construct improved approximation algorithms for arbitrary p, or for the closely related Directed Steiner Tree and Minimum Equivalent Digraph problems.

Acknowledgments. We would like to thank David Karger for helpful suggestions and Andras Frank for asking about the 2-SCSS problem, which started our research on this topic. We are grateful to Marshall Bern, Yevgeniy Dodis, John Dunagan, and Matt Levine for their comments on a previous version of this paper. We also thank the anonymous reviewers for their helpful comments.

TIME-SPACE LOWER BOUNDS FOR THE POLYNOMIAL-TIME HIERARCHY ON RANDOMIZED MACHINES*

SCOTT DIEHL† AND DIETER VAN MELKEBEEK†

Abstract. We establish the first polynomial-strength time-space lower bounds for problems in the linear-time hierarchy on randomized machines with two-sided error. We show that for any integer $\ell > 1$ and constant $c < \ell$, there exists a positive constant d such that QSAT_ℓ cannot be computed by such machines in time n^c and space n^d, where QSAT_ℓ denotes the problem of deciding the validity of a quantified Boolean formula with at most $\ell - 1$ quantifier alternations. Moreover, d approaches $1/2$ from below as c approaches 1 from above for $\ell = 2$, and d approaches 1 from below as c approaches 1 from above for $\ell \geq 3$. In fact, we establish the stronger result that for any constants $a \leq 1$ and $c < 1 + (\ell - 1)a$, there exists a positive constant d such that linear-time alternating machines using space n^a and $\ell - 1$ alternations cannot be simulated by randomized machines with two-sided error running in time n^c and space n^d, where d approaches $a/2$ from below as c approaches 1 from above for $\ell = 2$, and d approaches a from below as c approaches 1 from above for $\ell \geq 3$. Corresponding to $\ell = 1$, we prove that there exists a positive constant d such that the set of Boolean tautologies cannot be decided by a randomized machine with one-sided error in time $n^{1.759}$ and space n^d. As a corollary, this gives the same lower bound for satisfiability on deterministic machines, improving on the previously best known such result.

Key words. time-space lower bounds, randomized algorithms, polynomial-time hierarchy, satisfiability

1. Introduction.

Satisfiability, the problem of deciding if a propositional formula has at least one satisfying assignment, is among the most fundamental NP-complete problems. Proving lower bounds for satisfiability remains an open problem of paramount importance to the field of computational complexity. Although it is widely conjectured that any deterministic algorithm requires exponential time to solve satisfiability, a proof of this belief seems far out of reach. The trivial linear-time lower bound, which follows from the observation that the machine must look at its entire input formula in the worst case, is the state-of-the-art bound for random-access machines. Despite several decades of effort, there has been no success in proving superlinear time lower bounds for satisfiability.

A few years ago, Fortnow [8] established nontrivial time lower bounds for satisfiability on machines which are restricted to using a small amount of workspace. Fortnow's technique has its roots in earlier work by Kannan [14] and has been further developed in recent years [17, 19, 24]. For example, for machines using a subpolynomial amount of space, Fortnow and van Melkebeek [9] derived a time lower bound of $n^{\phi - o(1)}$, where $\phi \approx 1.618$ denotes the golden ratio. Recently, Williams [24] improved this lower bound to $n^{1.732}$, and we can further boost it to $n^{1.759}$ as a corollary to one of our results.

However, the main focus of this paper is not on lower bounds for deterministic machines, but rather on lower bounds for *randomized machines with two-sided error* (bounded away from 1/2). While it is conjectured that satisfiability requires exponential time even on such machines, proving lower bounds in the presence of randomness becomes a more difficult task than in the deterministic setting. No nontrivial lower bounds for satisfiability have been established on randomized random-access machines with two-sided error, even when the workspace of such machines is restricted to be logarithmic. In fact, previous to this work, no nontrivial time-space lower bounds have been shown for any complete problems in the polynomial-time hierarchy on randomized random-access machines with two-sided error.

1.1. Results. In this paper, we establish such time-space lower bounds. We consider the problem QSAT_ℓ of deciding the validity of a given quantified Boolean formula with at most $\ell-1$ quantifier alternations (beginning with existential). For any integer $\ell \geq 1$, QSAT_ℓ is complete for the ℓth level of the polynomial-time hierarchy. These problems are generalizations of satisfiability—for $\ell = 1$, QSAT_ℓ is precisely the satisfiability problem. Time-space lower bounds for QSAT_ℓ have been previously considered for deterministic machines. For example, Fortnow and van Melkebeek show an $n^{\ell-o(1)}$ time lower bound for deterministic machines solving QSAT_ℓ in subpolynomial space, for $\ell \geq 2$. We match these bounds for randomized machines running in subpolynomial space, and a more careful analysis yields lower bounds for small polynomial space bounds.

THEOREM 1 (main theorem). *For any integer $\ell \geq 2$ and constant $c < \ell$, there exists a positive constant d such that QSAT_ℓ cannot be solved by randomized random-access machines with two-sided error running in time n^c and space n^d. Moreover, d approaches 1/2 from below as c approaches 1 from above for $\ell = 2$, and d approaches 1 from below as c approaches 1 from above for $\ell \geq 3$.*

The randomized machines in Theorem 1 and in the rest of this paper refer to the natural coin flip model, in which the machine has one-way read-only access to a tape with random bits. Viola [23] recently extended Theorem 1 to the model in which the randomized machines have two-way access to the random bit tape, although his approach yields weaker lower bounds and works only for $\ell \geq 3$.

We note that Theorem 1 establishes the first polynomial-strength time-space lower bounds for problems in the polynomial-time hierarchy on two-sided error randomized machines. By time-space lower bounds of "polynomial strength" we mean time lower bounds of the form $\Omega(n^c)$ for some constant $c > 1$ under nontrivial space upper bounds. Previous works establish randomized time-space lower bounds, but either they consider problems believed not to be in the polynomial-time hierarchy, or the time lower bounds involved are only slightly superlinear. Allender et al.'s [1] time-space lower bounds for problems in the counting hierarchy on probabilistic machines with unbounded error fall within the first category. On the other hand, Beame et al.'s [3] nonuniform time-space lower bound for a binary quadratic form problem in P falls within the second category.

Because of the tight connection between QSAT_ℓ and the ℓth level of the linear-time hierarchy, Theorem 1 can be stated equivalently as a time-space lower bound for simulations of the ℓth level of the linear-time hierarchy on randomized machines with two-sided error. In fact, we can strengthen Theorem 1 and establish time-space lower bounds for simulations of linear-time alternating machines which use only space n^a for constant $a \leq 1$.

THEOREM 2. *For any integer $\ell \geq 2$ and any constants $a \leq 1$ and $c < 1 + (\ell - 1)a$, there exists a positive constant d such that linear-time alternating machines*

using space n^a and $\ell - 1$ alternations cannot be simulated by randomized random-access machines with two-sided error running in time n^c and space n^d. Moreover, d approaches $a/2$ from below as c approaches 1 from above for $\ell = 2$, and d approaches a from below as c approaches 1 from above for $\ell \geq 3$.

Note that when $a = 1$, the space restriction on the alternating machines disappears and Theorem 2 becomes Theorem 1.

The $\ell \geq 2$ restriction in Theorem 1 implies that it does not give any bounds for the first level of the polynomial-time hierarchy, i.e., for satisfiability or its complement, tautology, the problem of deciding if a propositional formula is true under all assignments. However, we are able to strengthen the known lower bounds for tautology on randomized machines with *one-sided error*. Previously, Fortnow and van Melkebeek showed a lower bound of $n^{\sqrt{2}-o(1)}$ for the tautology problem on nondeterministic machines using subpolynomial space. Since randomized machines with one-sided error (on the "yes" side) are special cases of nondeterministic machines, these bounds also apply to this setting. Using ideas from the proof of our main result, we manage to take advantage of the extra structure provided by the randomized machine and improve the known lower bounds for tautology on randomized machines with one-sided error.

THEOREM 3. *There exists a positive constant d such that tautology cannot be solved by randomized random-access machines with one-sided error running in time $n^{1.759}$ and space n^d.*

Notice that the lower bound of Theorem 3 applies to deterministic machines as a special case. Therefore, by the closure of deterministic classes under complement, Theorem 3 implies the improved lower bound for satisfiability on deterministic machines mentioned earlier.

COROLLARY 4. *There exists a positive constant d such that satisfiability cannot be solved by deterministic random-access machines running in time $n^{1.759}$ and space n^d.*

1.2. Techniques. Our proofs follow the paradigm of indirect diagonalization. This technique establishes a desired separation by contradiction—assuming the separation does not hold, we derive a sequence of progressively unlikely inclusions of complexity classes until we reach one that contradicts a known diagonalization result. Kannan [14] used the paradigm "avant la lettre" to investigate the relationship between deterministic linear time and nondeterministic linear time. All of the recent work on time-space lower bounds for satisfiability and problems higher up in the polynomial-time hierarchy [8, 17, 9, 19, 24] follow it as well. Allender et al. [1] employed the technique to establish time-space lower bounds for problems in the counting hierarchy.

At first glance, it might seem that current techniques from space-bounded derandomization let us derive time-space lower bounds on randomized machines as immediate corollaries to time-space lower bounds on deterministic machines. In particular, assuming that we can solve satisfiability on a randomized machine in logarithmic space and time n^c, Nisan's deterministic simulation [21] yields a deterministic algorithm for satisfiability that runs in polylogarithmic space and polynomial time. However, even for $c = 1$, the degree of the latter polynomial is far too large for this simulation to yield a contradiction with known time-space lower bounds for deterministic machines. Thus, we need a more delicate approach for the randomized setting.

The critical ingredient in this approach is a time- and space-efficient simulation of randomized computations in the second level of the polynomial-time hierarchy with very few guess bits. The latter follows from a careful combination of Nisan's partial space-bounded derandomization [20], deterministic amplification by a random walk on an expander [5, 13], and a version of Lautemann's proof that randomized machines

with two-sided error can be simulated by an alternating machine at a polynomial time-overhead [15]. It gives us (i) an unconditional way to speed up small-space randomized computations with two-sided error in higher levels of the polynomial-time hierarchy, and (ii) a conditional efficient complementation of computations within the ℓth level of the polynomial-time hierarchy for $\ell \geq 2$. The condition on the latter is the hypothesis of the indirect diagonalization argument that the ℓth level of the linear-time hierarchy can be simulated by randomized machines with two-sided error that run in time n^c and small space. Combining that hypothesis with (i) and (ii), we conclude that computations in the ℓth level of the polynomial-time hierarchy that run in time T (where T is some sufficiently large polynomial) can be complemented in time $g(T)$, where g is some function depending on c. For sufficiently small values of c, $g(T)$ becomes $o(T)$, which yields a contradiction with a known diagonalization result. For somewhat larger values of c, we do not obtain a contradiction right away but we obtain a more efficient complementation within the ℓth level of the polynomial-time hierarchy for larger polynomials T. We then run the argument again using the new efficient complementation in step (ii), yielding an even more efficient complementation. This allows us to rule out larger values of c and further improve the efficiency of complementation. Bootstrapping this way leads to Theorem 1.

A careful analysis shows that we can handle space bounds of the form n^d, where d is a positive constant depending on c. For $\ell = 2$, the above argument yields a constant d approaching $1/2$ from below when c approaches 1 from above. For $\ell \geq 3$, we achieve a better value of d for such small values of c by deriving a more efficient simulation of randomized computations in the *third* level of the polynomial-time hierarchy.[1] This follows by exploiting the structure of the second-level simulation described above and adding an alternation to reduce the time overhead. The savings in time are more substantial for large values of d. When c approaches 1 from above, the modified argument can handle values of d approaching 1 from below. For larger values of c, the cost of the additional alternation obviates the savings in running time and makes the earlier argument the better one. By paying close attention to the space used by the simulations involved, we obtain the strengthening given in Theorem 2.

For our tautology lower bounds, we extend Williams' recent lower bounds for deterministic machines [24] to nondeterministic machines with few guess bits and add a new component to the argument. The proof in [24] contains two ingredients. The first one is a bootstrapping argument similar to the one we just described. Instead of yielding more and more efficient complementations within the ℓth level of the polynomial-time hierarchy for some fixed ℓ at larger and larger polynomial time bounds T, it gives more and more efficient complementations of linear time within higher and higher levels of the polynomial-time hierarchy. The second ingredient is an improved starting point for the bootstrapping argument. This involves using the hypothesis to obtain a—conditional—better speedup of small-space deterministic computations in the second level of the polynomial-time hierarchy. To obtain the quantitative improvement stated in Corollary 4, we take the idea of exploiting the hypothesis of the indirect diagonalization argument further and show how to improve the conditional speedup of small-space deterministic computations in higher levels of the polynomial-time hierarchy. In order to establish the lower bounds on randomized machines with one-sided error (as in Theorem 3), we show that the above argument extends from deterministic machines to nondeterministic machines that use few guess

[1] Viola [23] independently obtained the same simulation using a somewhat more complicated argument.

bits. We exploit Nisan's partial derandomization again, this time to transform one-sided error randomized machines into equivalent nondeterministic machines with few guess bits at a marginal cost in time and space.

1.3. Organization. Section 2 introduces the notation and the machine models we use for this paper. Additionally, we state some useful complexity results which are fundamental to our techniques.

In section 3, we describe the general framework of our proofs. This includes a tight connection between QSAT_ℓ and linear time on an alternating machine with $\ell - 1$ alternations, which allows us to focus on proving lower bounds for the latter from there on. We also describe the paradigm of indirect diagonalization, which our lower bound proofs follow, and give a concrete example.

Section 4 shows how we can leverage Nisan's space-bounded derandomization, deterministic amplification, and Lautemann's proof that randomized machines with two-sided error can be simulated by alternating machines with one alternation at a polynomial time-overhead. Specifically, we obtain simulations of space-bounded randomized machines by alternating machines which use few guess bits and only marginally more time and space than the randomized machine. We exploit these simulations in section 5 to establish the lower bounds given by Theorem 1.

Section 6 contains our other results. Specifically, we show the more general time-space lower bounds for space-bounded linear-time alternating machines given by Theorem 2, as well as the time-space lower bounds for tautology on randomized machines with one-sided error given by Theorem 3.

Finally, we conclude in section 7 by discussing some open problems that remain directions for further research. We also include an appendix in which we prove some results regarding the running time of Nisan's generator and of deterministic amplification based on a random walk on the Gabber–Galil expander. We could not find these results in the literature and they may be of independent interest.

2. Preliminaries. While much of the notation we use is standard [2, 22], we introduce some conventions and additional notation in this section. We also state a few results which we use throughout the rest of the paper.

2.1. Machine model. Our lower bounds are robust with respect to the choice of machine model. In particular, they hold for random-access machines. We refer to [19] for the details of the specific model we use for our derivations.

We adopt the convention that the time and space bounds of these machines are constructible functions from natural numbers to natural numbers which are at least logarithmic, and refer to them as time and space functions. We often discuss "subpolynomial" space functions, which refer to space functions in $n^{o(1)}$. Our results ultimately apply to computations with polynomial time and space bounds, which certainly meet the required constructibility conditions. Note that machines running in sublinear time or sublogarithmic space trivially cannot solve problems like satisfiability, where the answer can depend on the entire input.

2.2. Notation. We introduce some additional terminology to represent randomized computation. In particular, we use the notation $\mathrm{BPTISP}[T, S]$ to refer to the class of languages recognized by randomized machines using time T and space S with error bounded by $\frac{1}{3}$ on both sides. Similarly, $\mathrm{RTISP}[T, S]$ refers to randomized machines with one-sided error on the membership side bounded by $\frac{1}{2}$.

As is standard, we assume that the random bits are presented to such machines on a one-way read-only worktape. If the machine wishes to reread random bits, it

must copy them down onto a worktape at the cost of space, as opposed to the more powerful model which has two-way access to the random tape. Except where stated otherwise, our results about randomized machines hold only for the former machine model.

Our arguments involve alternating computations in which the numbers of bits guessed at each stage are bounded by explicitly given small functions. To this end, we use the following notation to describe such computations.

DEFINITION 5. *Given a complexity class $\mathcal{C}$ and a function f, we define the class $\exists^f\mathcal{C}$ to be the set of languages that can be described as*

$$\{x|\exists y \in \{0,1\}^{O(f(|x|))} P(x,y)\},$$

where P is a predicate accepting a language in the class $\mathcal{C}$ when its complexity is measured in terms of $|x|$ (not $|x|+|y|$). We analogously define $\forall^f\mathcal{C}$.

For example, $\exists^f\text{DTIME}[n]$ and $\forall^f\text{DTIME}[n]$ are subsets of NP and coNP for $f(n) = n^{O(1)}$. The requirement that the complexity of P be measured in terms of $|x|$ allows us to express the running times in terms of the original input length, which is a more natural convention for our arguments.

A subtlety arises when we consider space-bounded classes $\mathcal{C}$. Computations corresponding to $\exists^f\mathcal{C}$ and $\forall^f\mathcal{C}$ explicitly write down their guess bits y and then run a space-bounded machine on the combined input consisting of the original input x and the guess bits y. Thus, the space-bounded machine effectively has two-way access to the guess bits y. For example, although machines corresponding to $\exists^n\text{DTISP}[n, n^{o(1)}]$ and to $\text{NTISP}[n, n^{o(1)}]$ both use only a subpolynomial amount of space to verify their guesses, they do not necessarily have the same computational power. This is because the former machines have two-way access to the guess bits, which are written down on a separate tape that does not count towards its space bound, whereas the latter machines have only one-way access to these bits and do not have enough space to write them down on their worktape.

2.3. Speedup of space-bounded computations. We also make use of the standard divide-and-conquer approach for speeding up space-bounded computations by introducing alternations. This technique is described in detail in [19]. By splitting up the computation tableau of a $\text{DTISP}[T,S]$ computation into $B \geq 1$ equal-sized blocks, we obtain

$$\text{DTISP}[T,S] \subseteq \exists^{BS}\forall^{\log B}\text{DTISP}[T/B,S] \subseteq \Sigma_2\text{TIME}[BS + T/B]. \tag{1}$$

By the closure of DTISP under complement, this inclusion can also be stated for the Π-side of the polynomial-time hierarchy, which will be more convenient to use in some of our arguments. If we choose B to optimize the running time of the resulting Π_2-computation, the result is a square-root speedup for small space bounds S:

$$\text{DTISP}[T,S] \subseteq \forall^{\sqrt{TS}}\exists^{\log T}\text{DTISP}[\sqrt{TS},S] \subseteq \Pi_2\text{TIME}[\sqrt{TS}]. \tag{2}$$

Recursively applying (1) while exploiting DTISP's closure under complementation to conserve alternations yields

$$\begin{aligned}\text{DTISP}[T,S] &\subseteq \underbrace{\forall^{BS}\exists^{BS}\cdots\overline{Q}^{BS}}_{k-1}\ Q^{\log B}\text{DTISP}[T/B^{k-1}+BS,S] \\ &\subseteq \Pi_k\text{TIME}[T/B^{k-1}+BS]\end{aligned} \tag{3}$$

for any integer $k \geq 2$, where $Q = \exists$ if k is even and $Q = \forall$ otherwise, and $\overline{Q}$ denotes the quantifier complementary to Q. Choosing B to optimize the resulting running time, (3) achieves a kth-root speedup for small space bounds S:

$$\mathrm{DTISP}[T,S] \subseteq \underbrace{\forall^{(TS^{k-1})^{1/k}}\exists^{(TS^{k-1})^{1/k}}\cdots\overline{Q}^{(TS^{k-1})^{1/k}}}_{k-1} Q^{\log(T/S)}\mathrm{DTISP}[(TS^{k-1})^{1/k},S]$$

$$\subseteq \Pi_k\mathrm{TIME}[(TS^{k-1})^{1/k}]. \tag{4}$$

2.4. Diagonalization results. Finally, we need a standard diagonalization result from which we can derive contradictions. The following lemma states that we cannot speed up the computation of every language in $\Sigma_\ell\mathrm{TIME}[T]$ by switching to Π_ℓ.

LEMMA 6 (folklore). *Let ℓ be a positive integer and T a time function. Then*

$$\Sigma_\ell\mathrm{TIME}[T] \not\subseteq \Pi_\ell\mathrm{TIME}[o(T)].$$

Our lower bounds for space-bounded alternating linear time require a stronger diagonalization result which is both time- and space-sensitive.

LEMMA 7 (see [9]). *Let T be a time function and S a space function. Then for any integer $\ell > 0$,*

$$\Sigma_\ell\mathrm{TISP}[T,S] \not\subseteq \Pi_\ell\mathrm{TISP}[o(T),o(S)].$$

3. Earlier techniques. We now outline some of the techniques common to many time-space lower bound arguments. We also use them for our results.

3.1. Alternating linear time versus QSAT_ℓ. The first such result involves a tight connection between QSAT_ℓ and linear time on an alternating Turing machine with ℓ alternating stages, $\Sigma_\ell\mathrm{TIME}[n]$. At the first level, we know that satisfiability can be solved in nondeterministic quasilinear time, so that time-space lower bounds for satisfiability imply the same lower bounds for $\mathrm{NTIME}[n]$ up to polylogarithmic factors. Conversely, Fortnow and van Melkebeek [9] show that a sufficient strengthening of the Cook–Levin theorem gives a reduction from $\mathrm{NTIME}[n]$ to satisfiability which is efficient in both time *and* space, showing that if satisfiability can be solved in time n^c and space n^d, then $\mathrm{NTIME}[n]$ can be solved in time $n^c\,\mathrm{polylog}(n)$ and space $n^d\,\mathrm{polylog}(n)$. Thus, time-space lower bounds for $\mathrm{NTIME}[n]$ and for satisfiability are equivalent up to polylogarithmic factors.

At higher levels of the polynomial-time hierarchy, we know that QSAT_ℓ can be solved in quasilinear time on a machine which makes $\ell - 1$ alternations, so that time-space lower bounds for QSAT_ℓ imply the same lower bounds for $\Sigma_\ell\mathrm{TIME}[n]$ up to polylogarithmic factors. Conversely, just as the Cook–Levin theorem generalizes from NP to higher levels of the polynomial-time hierarchy and shows that QSAT_ℓ is complete for Σ_ℓ^p, the reductions given by Fortnow and van Melkebeek [9] generalize to give time- and space-efficient reductions from $\Sigma_\ell\mathrm{TIME}[n]$ to QSAT_ℓ.

THEOREM 8. *For any integer $\ell \geq 1$ and constants $c, d > 0$, if*

$$\mathrm{QSAT}_\ell \in \mathrm{DTISP}[n^c, n^d],$$

then

$$\Sigma_\ell\mathrm{TIME}[n] \subseteq \mathrm{DTISP}[n^c\,\mathrm{polylog}(n), n^d\,\mathrm{polylog}(n)].$$

This also holds if we replace DTISP *with* BPTISP *or* RTISP.

This establishes the equivalence of time-space lower bounds for $\Sigma_\ell\text{TIME}[n]$ and QSAT_ℓ up to polylogarithmic factors. In particular, polynomial-strength time-space lower bounds for $\Sigma_\ell\text{TIME}[n]$ on randomized machines yield essentially the same lower bounds for QSAT_ℓ. With this in mind, we focus on proving lower bounds for $\Sigma_\ell\text{TIME}[n]$ for the rest of the paper. We include a proof of Theorem 8 here for completeness.

Proof. Let L be a language decided by a random-access linear-time alternating Turing machine which makes $\ell - 1$ alternations, beginning in an existential stage. For such an L, let P be the predicate recognized by a random-access linear-time nondeterministic machine so that the condition $x \in L$ can be written as

$$(\exists y_1 \in \{0,1\}^{rn})(\forall y_2 \in \{0,1\}^{rn}) \cdots (Q y_{\ell-1} \in \{0,1\}^{rn}) R(x, y_1, y_2, \ldots, y_{\ell-1}),$$

where r is some constant, and $Q = \forall$, $R = P$ if ℓ is odd, and $Q = \exists$, $R = \neg P$ otherwise. All that remains to represent the acceptance condition of L as a quantified Boolean formula is to reduce P to satisfiability. The original Cook–Levin reduction produces a formula of quadratic size, which is too large for our purposes. However, Cook [6] shows how to leverage the oblivious simulations of Hennie and Stearns [12] to obtain a formula of quasilinear size. More precisely, we can construct a formula φ depending only on P and n such that φ

(i) has size $O(n \operatorname{polylog}(n))$ where each bit can be constructed in time $O(\operatorname{polylog}(n))$ and space $O(\log(n))$,

(ii) involves the bits of $x, y_1, \ldots, y_{\ell-1}$ input to P as well as $O(n \log n)$ additional Boolean variables z, and

(iii) is satisfiable in z on input $x, y_1, \ldots, y_{\ell-1}$ if and only if P accepts $x, y_1, \ldots, y_{\ell-1}$.

Defining $\varphi' \doteq \varphi$ if ℓ is odd and $\varphi' \doteq \neg\varphi$ otherwise, this shows that the Σ_ℓ-formula,

$$\psi \doteq \exists y_1 \forall y_2 \cdots Q y_{\ell-1} \overline{Q} z \, \varphi',$$

is in QSAT_ℓ if and only if $x \in L$. The size of ψ is only $O(n \log n)$ more than φ—the log factor is required to write down the bit indices of the quantified variables. The easy nature of these extensions to φ endows ψ with the same constructibility properties as φ.

In the case that $\text{QSAT}_\ell \in \text{DTISP}[n^c, n^d]$, let M be a deterministic machine deciding QSAT_ℓ in time $O(n^c)$ and space $O(n^d)$. We simulate M on input ψ to decide L. However, computing ψ and writing down the result on a worktape requires too much space. Instead, when M needs a bit of ψ, the simulation computes this bit from scratch. As φ is of size $O(n \operatorname{polylog}(n))$, M runs for time $O(n^c \operatorname{polylog}(n))$ and space $O(n^d \operatorname{polylog}(n))$ on input ψ. Computing the bits of ψ on the fly adds a multiplicative overhead of $O(\operatorname{polylog}(n))$ to the time and an additive overhead of $O(\log n)$ to the space. Thus, this deterministic simulation decides L in the desired time and space bounds.

The cases for BPTISP and RTISP follow from the same argument. □

3.2. Indirect diagonalization. We set out to prove Theorem 1, i.e., that $\Sigma_\ell\text{TIME}[n] \not\subseteq \text{BPTISP}[t, s]$ for certain interesting values of t and s. To accomplish this, we follow the same general technique that is used to prove all previous time-space lower bounds for nondeterministic linear time, namely indirect diagonalization. This paradigm follows three basic steps:

1. Assume the inclusion that we wish to show does not hold. In our case, assume that $\Sigma_\ell\text{TIME}[n] \subseteq \text{BPTISP}[t, s]$.

2. Using the hypothesis, derive inclusions of complexity classes which are increasingly unlikely.

3. Eventually, one of these inclusions contradicts a known diagonalization result, proving the desired result.

There is a myriad of ways to derive new inclusions from the hypothesis in step 2, with different approaches yielding different results. Often, the inclusions derived in step 2 are obtained by a combination of two opposing processes. These can be loosely thought of as deriving a speedup at the cost of adding alternations, and removing alternations at the cost of a small slowdown. The main intuition that guides how we apply these processes is that we wish the speedup gained by introducing alternations to outweigh the cost of eliminating them, so that overall we obtain a contradiction to Lemma 6 (or Lemma 7).

The former process, deriving a speedup, involves simulating a space-bounded machine of the type for which we are attempting to derive a lower bound (i.e., deterministic or randomized) in significantly less time. We must pay a price to achieve this task, and we choose to pay in the currency of alternations. Specifically, we introduce a small number of alternations to the computation and carry out a fast simulation on an alternating machine. In the deterministic setting, such a simulation yields an inclusion resembling

$$\mathrm{DTISP}[T, S] \subseteq \Pi_\ell \mathrm{TIME}[f(T, S)],$$

for $\ell \geq 1$ and $f(T, S) \ll T$ when $S \ll T$. Note that the Π_2-simulation of a DTISP-computation given by (2) is an example of this process.

In the other direction, the process of removing alternations involves the task of simulating an alternating machine by another alternating machine which makes fewer alternations and runs for only slightly more time. In many cases, this is accomplished by deriving a statement such as

$$\Sigma_\ell \mathrm{TIME}[T] \subseteq \Pi_\ell \mathrm{TIME}[g(T)],$$

for a small function g. When g is polynomial, such an inclusion results in a collapse of the polynomial-time hierarchy to the ℓth level, and we refer to it as an *efficient complementation*. Note that a complementation can be derived unconditionally by using an exhaustive search in lieu of an alternating step, but in this case g will be exponential in T. In our arguments, we can derive an efficient complementation which is conditional on the hypothesis of step 1, from which more efficient complementations are derived in an inductive fashion in step 2.

Notice that by Lemma 6, a complementation with $g(T) = o(T)$ is not just unlikely but impossible. Deriving such an impossibly efficient complementation provides the desired inclusion to arrive at a contradiction in step 3. In the following section, we give an example of how to accomplish this end via an appropriate combination of a speedup and an efficient complementation.

3.3. A concrete example. We step through an instantiation of the indirect diagonalization paradigm and prove the result of [17] that satisfiability cannot be solved by deterministic random-access machines running in time n^c and space $n^{o(1)}$ for constants $c < \sqrt{2}$. The first step is to assume that

$$\mathrm{NTIME}[n] \subseteq \mathrm{DTISP}[n^c, n^{o(1)}]. \tag{5}$$

This allows a simulation of $\mathrm{NTIME}[T]$ by $\mathrm{DTISP}[T^c, T^{o(1)}]$ for some polynomial T. The speedup given by the inclusion (2) then yields a square-root speedup at the cost

of two alternations. The net result is

$$\mathrm{NTIME}[T] \subseteq \mathrm{DTISP}[T^c, T^{o(1)}] \subseteq \Pi_2\mathrm{TIME}[T^{c/2+o(1)}], \tag{6}$$

which represents a speedup of NTIME$[T]$ for $c < 2$ by using one more alternating stage. To contradict Lemma 6, we need to arrive at such a speedup which uses just a universal stage. Therefore, we use an efficient complementation to remove the inner existential stage from the Π_2-speedup represented by (6). Note that hypothesis (5) gives a simulation of NTIME$[n]$ by a deterministic machine, and since any deterministic machine is trivially a conondeterministic machine, we have

$$\mathrm{NTIME}[n] \subseteq \mathrm{coNTIME}[n^c]. \tag{7}$$

In order to use this efficient complementation to remove an alternation, we write

$$\Pi_2\mathrm{TIME}[T^{c/2+o(1)}] = \forall^{T^{c/2+o(1)}} \underbrace{\mathrm{NTIME}[T^{c/2+o(1)}]}_{(\alpha)}.$$

Note that (α) represents a nondeterministic computation which takes an input of size $n + T^{c/2+o(1)}$ and runs in time $T^{c/2+o(1)}$. For $T(n) \geq n^{2/c}$, the running time is at least linear in the input size, so that (7) gives a conondeterministic simulation of (α) running in time $T^{c^2/2+o(1)}$. By merging the resulting adjacent universal stages, we obtain

$$\mathrm{NTIME}[T] \subseteq \forall^{T^{c/2+o(1)}}\mathrm{coNTIME}[T^{c^2/2+o(1)}] = \mathrm{coNTIME}[T^{c^2/2+o(1)}].$$

When $c^2/2 < 1$, we can see this process has delivered a net speedup of nondeterministic time T on conondeterministic machines, which is a contradiction to Lemma 6. This proves the desired result.

4. Lautemann's proof and derandomization. We now adopt the techniques of the previous section to prove Theorem 1, beginning with the case $\ell = 2$. By way of Theorem 8 and the indirect diagonalization paradigm, we seek to derive a contradiction from the assumption

$$\Sigma_2\mathrm{TIME}[n] \subseteq \mathrm{BPTISP}[t, s] \tag{8}$$

for some interesting functions t and s. The known proofs that BPP (the class of languages recognized by polynomial-time randomized machines with two-sided error) lies in the second level of the polynomial-time hierarchy provide a simulation of randomized machines with two-sided error by Π_2-machines with a polynomial overhead in time. Combined with hypothesis (8), this immediately gives us one of the ingredients we need to carry through the program from the previous section, namely the efficient complementation of Σ_2TIME$[n]$.

Assuming the Π_2-simulation is sufficiently time and space efficient, we can also use it for the other ingredient we need, namely the speedup. This is because the divide-and-conquer strategy for DTISP-computations from section 2.3 applies to Σ_kTISP-computations as well. However, it turns out that the known Π_2-simulations of randomized two-sided error machines are not time- and space-efficient enough to obtain any lower bounds this way. Moreover, in order to achieve the quantitative strength of our lower bounds, we need to save alternations by applying the speedup as in (1) to the final deterministic phase of the simulation as opposed to the Π_2-simulations as a whole. For that approach to yield an overall speedup, we need the number of

guess bits in the alternating phases of the simulation to be small—otherwise, the time needed for the guesses would obviate the speedup obtained in the final deterministic phase. The known simulations use too many guess bits from that perspective. Therefore, in this section, we develop a new Π_2-simulation of randomized machines with two-sided error that meets all the above efficiency requirements.

We start by analyzing Lautemann's proof that any language L in BPP is also in $\Sigma_2^p \cap \Pi_2^p$. The proof assumes a randomized algorithm using R random bits to decide L with error ϵ. When ϵ is small enough in comparison to R, there is a $v \geq 1$ so that membership of x in L can be characterized by the existence of v shifts of the set of random strings accepting x which together cover the universe of all random strings. If $x \in L$, the set of random strings accepting x is large enough to guarantee that such shifts exist as long as $\epsilon^v < 2^{-R}$. On the other hand, if $x \notin L$, the set of accepting random strings is small enough so that v shifts cannot cover the universe of random strings as long as $\epsilon < \frac{1}{v}$. For such ϵ and v, these complementary conditions are expressed by a Σ_2^p predicate. Since BPP is closed under complement, this shows that BPP $\subseteq \Sigma_2^p \cap \Pi_2^p$. Specifically, we are interested in the Π_2^p-side of the inclusion.

THEOREM 9 (Lautemann [15]). *Let L be a language recognized by a randomized machine M that runs in time T and space S and that uses R random bits with error bounded on both sides by ϵ. Then for any $v \geq 1$ such that $\epsilon < \min(2^{-R/v}, \frac{1}{v})$, we have that*

$$L \in \forall^{vR}\exists^{R}\mathrm{DTISP}[vT, S + \log v]. \tag{9}$$

In Lautemann's proof that BPP $\subseteq \Sigma_2^p \cap \Pi_2^p$, one starts from an algorithm deciding $L \in$ BPP that has error less than the reciprocal of the number R' of random bits it uses. Such an error probability can be achieved from a standard BPP algorithm deciding L that uses R random bits by taking the majority vote of $O(\log R)$ independent trials, which results in $R' = O(R \log R)$. For $\epsilon < \frac{1}{R'}$, choosing $v = R'$ satisfies the conditions of Lemma 9. This shows that if L can be decided by a BPTISP$[T, S]$ machine using R random bits, then

$$L \in \forall^{(R \log R)^2}\exists^{R \log R}\mathrm{DTISP}[RT \log R, S]. \tag{10}$$

We can further reduce the number of guess bits in the alternating stages of the simulation by using more efficient methods of amplification. With such methods, the error can be made as small as 2^{-R} while using only $O(R)$ random bits. Specifically, the algorithm runs $O(R)$ trials, which are obtained from the labels of vertices on a random walk of length $O(R)$ in an easily constructible expander graph, and accepts if a majority of these trials accept. For our purposes, we choose the Gabber–Galil family of expanders [10], a construction based on the Margulis family [18] where the vertices are connected via simple affine transformations on the labels. The easy form of the edge relations ensures that the walk is efficiently computable in time $O(R^2)$ and space $O(R)$.

THEOREM 10 (see [5, 13]). *Let M be a randomized machine with constant error bounded away from $\frac{1}{2}$ that runs in time T and space S and that uses R random bits. Then M can be simulated by another randomized machine M' that runs in time $O(RT)$ and space $O(R + S)$, while using only $O(R)$ random bits to achieve error 2^{-R}.*

When an algorithm has been amplified as in Theorem 10, $v = O(1)$ shifts suffice for Theorem 9. This shows that if L can be decided by a BPTISP$[T, S]$ machine using R random bits, then

$$L \in \forall^{R}\exists^{R}\mathrm{DTISP}[RT, R + S]. \tag{11}$$

The efficiency of this simulation depends on the number of random bits R for all the criteria we mentioned: the number of bits guessed in the alternating stages, the multiplicative time overhead, and the additive space overhead for the final deterministic stage are all $O(R)$. Since R can be as large as T, we need an additional ingredient to do better. That ingredient exploits the fact that we are dealing with *space-bounded* BPP-computations. In that setting, we know of techniques to reduce the number of random bits without increasing the time or space by much, which in turn increases the efficiency of the Π_2-simulation in (11). The means by which we achieve the needed reduction in randomness is the space-bounded derandomization of Nisan [20]. We state a version here and leave the proof to Appendix A (where we also present a brief overview of Theorem 10).

THEOREM 11. *Any randomized machine M running in time T and space S with error ϵ can be simulated by another randomized machine that runs in time $O(T\,\mathrm{polylog}(T))$ and space $O(S\log T)$ and that uses only $O(S\log T)$ random bits. The error of the simulation is $\epsilon + 2^{-S}$, and is one-sided if M has one-sided error.*

Note that we do not apply Theorem 11 to deterministically simulate the randomized machine. Instead, we use it to reduce the randomness required by a BPTISP$[T,S]$ machine to $O(S\log T)$. If we subsequently efficiently amplify using Theorem 10, then the overhead of the alternating simulation given by Theorem 9 becomes acceptable for polynomial T and small S. More precisely, we have the following lemma.

THEOREM 12.

$$\mathrm{BPTISP}[T,S] \subseteq \forall^{S\log T}\exists^{S\log T}\mathrm{DTISP}[TS\,\mathrm{polylog}(T), S\log T]. \tag{12}$$

Proof. Let M be the randomized time T, space S machine for recognizing $L \in \mathrm{BPTISP}[T,S]$. By the derandomization of Theorem 11, we obtain a simulation using $R \doteq O(S\log T)$ random bits, time $O(T\,\mathrm{polylog}(T))$, and space $O(S\log T)$, with error $\frac{1}{3} + 2^{-S}$. Theorem 10 gives a machine deciding L with error 2^{-R} while using $O(R)$ random bits. The time increases to $O(TS\,\mathrm{polylog}(T))$, while the space is still $O(S\log T)$. Applying Theorem 9 for $v = O(1)$ yields the desired alternating simulation of M. □

We point out that using the instantiation of Theorem 9 given by (10) instead of (11) in the proof of Theorem 12 yields a simulation similar to (12). The main difference is that the initial universal phase takes time $O((S\log T)^2)$ rather than $O(S\log T)$. This version is still efficient enough to yield time-space lower bounds as in Theorem 1, but the dependence of the space parameter d on c becomes worse.

4.1. Speedup. Theorem 12 has the desired nice properties that allow us to derive a speedup for BPTISP. The simulation spends only time $O(S\log T)$ in its alternating phases, which is small when S is small. In this case, the running time is dominated by the final deterministic computation, so that a speedup of this final stage results in a speedup of the computation as a whole. Since the final deterministic computation of the simulation given by (12) is space bounded, we can achieve this by applying the speedup of (1) or (3). For example, applying (1) adds two alternations, and by merging adjacent existential stages we obtain a simulation given by

$$\begin{aligned}\mathrm{BPTISP}[T,S] &\subseteq \forall^{S\log T}\exists^{S\log T}\exists^{BS\log T}\forall^{\log B}\mathrm{DTISP}[TS\,\mathrm{polylog}(T)/B, S\log T]\\ &= \forall^{S\log T}\exists^{BS\log T}\forall^{\log B}\mathrm{DTISP}[TS\,\mathrm{polylog}(T)/B, S\log T].\end{aligned}$$

Choosing B to optimize the running time of this simulation up to a $\mathrm{polylog}(T)$ factor, we get

$$\mathrm{BPTISP}[T,S] \subseteq \forall^{S\log T}\exists^{\sqrt{T}S}\forall^{\log T}\mathrm{DTISP}[\sqrt{T}S\,\mathrm{polylog}(T), S\log T]. \tag{13}$$

For small S, we obtain a speedup for space-bounded randomized machines similar to that which (2) gives for deterministic machines. However, the simulation uses three alternations rather than two to realize the same speedup by a square root.

4.2. Complementation. We also use Theorem 12 to derive an efficient complementation under the hypothesis of the indirect diagonalization argument. Note that hypothesis (8) gives a simulation of Σ_2 by BPTISP, which can be simulated in turn by the Π_2-machine given by Theorem 12. Thus, we derive

$$\Sigma_2\text{TIME}[n] \subseteq \forall^{s\log t}\exists^{s\log t}\text{DTISP}[ts\,\text{polylog}(t), s\log t], \tag{14}$$

which gives the desired complementation for small enough t and s. For example, when t is polynomial, say $t = n^c$ and s is subpolynomial, (14) becomes

$$\Sigma_2\text{TIME}[n] \subseteq \forall^{n^{o(1)}}\exists^{n^{o(1)}}\text{DTISP}[n^{c+o(1)}, n^{o(1)}] \subseteq \Pi_2\text{TIME}[n^{c+o(1)}]. \tag{15}$$

Thus, we can see that when s is small, this complementation allows us to eliminate alternations at a cost little more than raising the running time to the power of c. In this manner, (15) can be used analogously to the complementation (7) in the deterministic case of section 3.3.

We note that the bottleneck causing our lower bounds for QSAT_ℓ to hold only for $\ell \geq 2$ arises right here. In the case $\ell = 1$, the hypothesis becomes $\text{NTIME}[n] \subseteq \text{BPTISP}[t, s]$; combining with Theorem 12 as above, we obtain $\text{NTIME}[n] \subseteq \Pi_2\text{TIME}[ts\,\text{polylog}(t)]$, which is trivial and does not represent an efficient complementation.

4.3. Higher levels of the hierarchy. The previous discussion in this section developed techniques towards proving lower bounds for $\Sigma_2\text{TIME}[n]$. These readily generalize to higher levels, where hypothesis (8) becomes

$$\Sigma_\ell\text{TIME}[n] \subseteq \text{BPTISP}[t, s] \tag{16}$$

for $\ell \geq 3$. Theorem 12 then allows for an efficient simulation of $\Sigma_\ell\text{TIME}[n]$ by a Π_2-machine, which can be used to eliminate alternations. This allows us to establish Theorem 1 for values of $c < \ell$, where d approaches some small value depending on ℓ from below as c approaches 1 from above.

For $\ell \geq 3$, we can get a better dependence of d on c when c approaches 1. In this setting, a Π_3-simulation of BPTISP suffices to achieve an efficient complementation. The ability to use an additional alternation allows us to achieve a more time-efficient simulation than the one given by Theorem 12. Specifically, we add an alternation to the latter Π_2-simulation and eliminate the time blowup incurred by running the $O(S\log T)$ trials required by the amplification of Theorem 10. Rather than deterministically simulate all of these trials, we use the power of alternation to efficiently verify that a majority of these trials accept.

LEMMA 13. *Let M be a randomized machine with constant error bounded away from $\frac{1}{2}$ that runs in time T and space S and that uses R random bits. Then M can be simulated by another randomized machine M' that uses $O(R)$ random bits to achieve error 2^{-R}. Furthermore, the acceptance of M' on input x and random string r can be decided in*

$$\exists^R\forall^{\log R}\text{DTISP}[T + R\,\text{polylog}(R), R + S].$$

We defer the proof to Appendix B. Notice that the final deterministic stage of the simulation represented by (12) can be replaced with the Σ_2-verification given by

Lemma 13. Merging the resulting adjacent existential phases results in a simulation using one more alternation but running in less time.

THEOREM 14.

$$\text{BPTISP}[T, S] \subseteq \forall^{S \log T} \exists^{S \log T} \forall^{\log S} \text{DTISP}[T \operatorname{polylog}(T), S \log T]. \tag{17}$$

As in sections 4.1 and 4.2, Theorem 14 admits a speedup of BPTISP to Π_4 as well as an efficient complementation of Σ_3. When $t = n^c$ and $s = n^d$ in (16), the latter eliminates alternations essentially at the cost of raising the running time to the power of c. For values of c close to 1, this cost is small enough to alleviate the effects of the extra alternation in (17). In this case, the better dependence of the running time of the simulation on the space parameter allows us to derive contradictions for larger values of d than we can by using Theorem 12. On the other hand, for larger values of c, the extra alternation in (17) has a greater impact and eventually prevents us from reaching a contradiction. In this case, switching to the more alternation-efficient simulation given by Theorem 12 allows us to derive a contradiction for such larger values of c. However, we must restrict d to smaller values in order to counteract the worse dependence of (12) on the space bound. Therefore, to derive Theorem 1, we focus on using Theorem 12 to obtain the bounds for large values of c first and then show how Theorem 14 yields the larger values of d when c is small.

5. Main result. We now use the techniques discussed in the previous sections to formulate an indirect diagonalization argument for the case $\ell = 2$ of Theorem 1. For clarity, we present the following exposition in terms of subpolynomial space bounds and generalize these techniques to polynomial space bounds in the subsequent formal proof. Thus, to obtain a lower bound for $\Sigma_2\text{TIME}[n]$, we start with the assumption (8) for $t = n^c$ and $s = n^{o(1)}$, i.e.,

$$\Sigma_2\text{TIME}[n] \subseteq \text{BPTISP}[n^c, n^{o(1)}].$$

Consider a $\Sigma_2\text{TIME}[T]$ computation for some time function $T(n) = n^{O(1)}$. We adopt the approach outlined in section 3.3, namely speeding up $\Sigma_2\text{TIME}[T]$ at the cost of adding alternations and then removing these alternations via an efficient complementation to arrive at a $\Pi_2\text{TIME}[o(T)]$ computation. The hypothesis gives a simulation of $\Sigma_2\text{TIME}[T]$ in $\text{BPTISP}[T^c, T^{o(1)}]$. We then apply the square-root speedup of (13) to obtain a simulation in Π_3:

$$\begin{aligned}\Sigma_2\text{TIME}[T] &\subseteq \text{BPTISP}[T^c, T^{o(1)}] \\ &\subseteq \forall^{T^{o(1)}} \underbrace{\exists^{T^{\frac{c}{2}+o(1)}} \forall^{\log T} \text{DTISP}[T^{c/2+o(1)}, T^{o(1)}]}_{(\alpha)}.\end{aligned}$$

We have arrived at a simulation which makes one more alternation than we started with. To balance the number of alternations, we eliminate one alternation. Notice that the stages of the computation indicated by (α) can be seen as a computation in Σ_2 taking input of size $n + T^{o(1)}$ and running in time $T^{\frac{c}{2}+o(1)}$. When T is large enough, this running time is at least linear in the input size, and we can pad (15) to allow us to switch (α) to Π_2. Merging the resulting adjacent universal stages yields the desired Π_2-simulation:

$$\Sigma_2\text{TIME}[T] \subseteq \Pi_2\text{TIME}[T^{\frac{c^2}{2}+o(1)}]. \tag{18}$$

For $c < \sqrt{2}$, this results in a net speedup which is a contradiction to Lemma 6. Thus, we have derived a lower bound of $n^{\sqrt{2}-o(1)}$ for QSAT_2 on subpolynomial-space randomized machines. However, we can do better by observing what (18) represents for values of c that do not immediately contradict Lemma 6. Specifically, (18) gives a complementation of Σ_2 of the same form as (15), but has an exponent cost of $c^2/2$ rather than c. Thus, we have derived a *more efficient* complementation for sufficiently large polynomial time bounds T when $c < 2$.
