1.5. Paper organization. This paper proceeds as follows. In section 2 we define a *basic* version of the MSOU problem and give some complexity bounds. We will prove in the rest of the paper that this problem is in NP. Then, in section 3 we define the MSOU problem in its most general form as a specialization of SOU, and we prove that it can be NP-reduced to the basic version. We prove some properties of singleton

context-free grammars in section 4, and in section 5 we use them to compact the representation of equations and solutions. We use a graph in order to describe the instantiation of some variable w.r.t. a given solution (section 6). Sometimes, we need to rewrite such graphs (section 7). Based on this graph, we prove that for any size-minimal solution we can represent the values of all variable instantiations using a polynomial-sized singleton grammar (Theorem 7.7). In section 8, we conclude the NP-completeness of MSOU and also of the corresponding matching problem.

2. Basic monadic second-order unification. In this section we present a simplification of the MSOU problem, called the *basic* MSOU problem. As we will see in section 3 (Proposition 3.1), general MSOU can be NP-reduced to this basic case; therefore this will not cause a loss of generality. The simplification consists in (1) considering only unary free variables (notice that, in the general case, the "monadic" restriction affects constants only, not variables) and (2) considering only the function symbols occurring in the equations and a unique (zero-ary) constant, called $\flat$. In this presentation we will limit the use of concepts and notation of the λ-calculus as much as possible. Moreover, we will use words to represent monadic second-order terms. This will make the use of context-free grammars in section 4 more comprehensible.

Let Σ be a finite set of unary function symbols, denoted by lowercase letters $f, g, \ldots$, and let $\mathcal{X}$ be an infinite and denumerable set of unary variables, denoted by uppercase letters $X, Y, \ldots$. Apart from these sets, we also consider a unique constant $\flat$.

Words of $(\Sigma \cup \mathcal{X})^*$ are denoted by lowercase letters $w, u, v, \ldots$, and ε is the empty word. The length of a word w is denoted by $|w|$. Concatenation is juxtaposition. The notation $v \preceq w$ means that the word v is a prefix of the word w.

Monadic terms, denoted by letters $s, t, \ldots$, are defined by the grammar $t ::= \flat \mid f(t) \mid X(t)$, where $f \in \Sigma$ and $X \in \mathcal{X}$. We remove parentheses and represent monadic terms, e.g., $f(X(g(Y(\flat))))$, as words, e.g., $f\,X\,g\,Y\,\flat$. Therefore, terms are redefined as words of $(\Sigma \cup \mathcal{X})^*\,\flat$. The size of a term $t = w\,\flat$, noted $|t|$, is defined by $|t| = |w|$.

Monadic functions, denoted by Greek letters $\varphi, \ldots$, may be of the form $\lambda x\,.\,w\,\flat$ or $\lambda x\,.\,w\,x$, where $w \in (\Sigma \cup \mathcal{X})^*$. In the first case we say that the function *does not use* the argument. In both cases, the size of the function is $|w|$, and x is said to be a *bound variable*, i.e., not *free*.

A *monadic substitution*, denoted by Greek letters $\sigma, \rho, \tau, \ldots$, is a mapping from a finite subset of variables to monadic functions. We represent these mappings as $\sigma = [X_1 \mapsto \varphi_1, \ldots, X_n \mapsto \varphi_n]$, where $Dom(\sigma) = \{X_1, \ldots, X_n\}$ is the *domain* of the substitution. We extend substitutions to functions from monadic terms to monadic terms recursively as follows:

$$\begin{aligned}
&\sigma(\flat) = \flat,\\
&\sigma(f\,w_1) = f\,\sigma(w_1),\\
&\sigma(X\,w_1) = w_2\,\flat \qquad \text{if } \sigma(X) = \lambda x\,.\,w_2\,\flat,\\
&\sigma(X\,w_1) = w_2\,\sigma(w_1) \quad \text{if } \sigma(X) = \lambda x\,.\,w_2\,x.
\end{aligned}$$

The size of a substitution is defined as $|\sigma| = \sum_{X \in Dom(\sigma)} |\sigma(X)|$. Given two substitutions σ and ρ, their composition is defined by $(\sigma \circ \rho)(t) = \sigma(\rho(t))$, for any term t, and is also a substitution; hence $Dom(\sigma \circ \rho)$ is finite. Given a set of variables V and a substitution σ, the restriction of σ to the domain V is denoted by $\sigma|_V$. Given a set of variables V, we say that a substitution σ is *more general* w.r.t. V than another substitution ρ, denoted $\sigma \preceq_V \rho$, if there exists a substitution τ such that $\rho(X) = \tau(\sigma(X))$

for all variables $X \in V$, i.e., $\rho = (\tau \circ \sigma)|_V$. (Usually, V will be the set of variables occurring in a set of equations; in this case, we do not mention V if it is clear from the context). This defines a preorder relation on substitutions. An equivalence relation can also be defined as $\sigma \approx_V \rho$ if $\sigma \preceq_V \rho$ and $\rho \preceq_V \sigma$. A substitution σ is said to be *ground* if $\sigma(X)$ does not contain (free occurrences of) variables for all $X \in Dom(\sigma)$. Notice that if σ and τ are ground, then $\sigma \approx_V \tau$ is equivalent to $\sigma|_V = \tau|_V$ (otherwise they are only equivalent modulo variable renaming). We say that a substitution σ *introduces* a constant a (or a variable X) if, for some $Y \in Dom(\sigma)$, $\sigma(Y)$ has an occurrence of a (or X).

DEFINITION 2.1. *A* basic monadic second-order unification problem *(basic MSOU problem) E is a finite set of pairs of monadic terms a.k.a.* monadic equations*, represented as $E = \{s_1 \stackrel{?}{=} t_1, \ldots, s_n \stackrel{?}{=} t_n\}$.*

The set of variables occurring in E is denoted as $FV(E)$. The *size* of E is the sum of the sizes of its terms s_i and t_i and is denoted as $|E|$. We denote the number of equations of E as $\#Eq(E)$.

DEFINITION 2.2. *A* unifier *of E is a monadic substitution σ, mapping variables of $FV(E)$ to monadic functions and solving all equations: $\sigma(s_i) = \sigma(t_i)$ for $i = 1, \ldots, n$. It is said to be* ground *if $\sigma(s_i)$ and $\sigma(t_i)$ do not contain free occurrences of variables for $i = 1, \ldots, n$.* Most general unifiers *are unifiers that are minimal w.r.t. $\preceq_{FV(E)}$.*

A solution *of E is a ground unifier. A solution σ of E is said to be* size-minimal *if $Dom(\sigma) = FV(E)$ and has minimal size among all solutions of E; i.e., it minimizes $\sum_{X \in FV(E)} |\sigma(X)|$.*

The problem E is said to be unifiable *if it has a unifier, and* solvable *if it has a ground unifier or solution.*

Example 4. Let f and g be unary function symbols and X and Y unary variables. Consider the following basic MSOU problem:

$$\{f\, g\, Y\, X\, \flat \stackrel{?}{=} X\, f\, g\, Y\, \flat\}.$$

It has infinitely many solutions, for instance, $\sigma_1 = [X \mapsto \lambda x\,.\,(f\, g)^n\, x, \quad Y \mapsto \lambda x\,.\,(f\, g)^m x]$ for any $n, m \geq 0$ or $\sigma_2 = [X \mapsto \lambda x\,.\,(f\, g)^{n+1}\, \flat, \quad Y \mapsto \lambda x\,.\,(f\, g)^n\, \flat]$ for any $n \geq 0$. Obviously σ_1 with $n = m = 0$ is a size-minimal solution. Observe also that, interpreting the problem as a WU equation, we can use σ_1 to get the corresponding solution for the word equation because the monadic functions of the solutions use their argument, whereas this is not the case for σ_2.

2.1. The exponent of periodicity bound. The following lemma will provide us with an upper bound on the number of iterations of subwords within solutions.

DEFINITION 2.3. *For a ground substitution σ, its* exponent of periodicity*, denoted as* $\mathrm{eop}(\sigma)$*, is the maximal number $n \in \mathbb{N}$, such that for words u, v, and w over Σ^*, where v is not empty, $\sigma(X) = \lambda y\,.\,u\, v^n\, w\, y$ or $\sigma(X) = \lambda y\,.\,u\, v^n\, w\, \flat$ for some $X \in Dom(\sigma)$.*

We know that any size-minimal ground unifier (i.e., solution) of a set of MSOU equations satisfies the following exponent of periodicity lemma [16, 8, 23, 22].

LEMMA 2.4 (see [22, Lemma 4.1]). *There exists a constant $\alpha \in \mathbb{R}^+$ such that for every basic MSOU problem $\langle \Sigma, E \rangle$ and every size-minimal solution σ we have $\mathrm{eop}(\sigma) \leq 2^{\alpha |E|}$.*

2.2. Some upper and lower complexity bounds. We show the relation of MSOU problems to WU. The NP-reduction of MSOU to WU (and its NP-hardness) allows us to translate any upper bound from WU to MSOU. It does not appear to be

possible to encode WU as an MSOU problem, which provides evidence that MSOU may be an easier problem than WU.

PROPOSITION 2.5. *MSOU is in PSPACE.*

Proof. MSOU is NP-reducible to solvability of basic MSOU problems (Proposition 3.1), and this in turn to WU: Given a basic MSOU problem E, we solve it using WU as follows. It is only necessary to search solutions where $\sigma(X)$, for $X \in FV(E)$, is of the form $\lambda x \,.\, a_1 \dots a_n \, x$ or of the form $\lambda x \,.\, a_1 \dots a_n \, \flat$. Thus, the first step is guessing, for every variable occurring in E, whether it uses its argument or not, i.e., whether it is of the first or second form. Then, we translate E into a set of word equations by first replacing every occurrence of $X\, s$ by $X \, \flat$, when $\sigma(X)$ does not use its argument, and then removing $\flat$ at the end of the terms and interpreting them as words. Now, we can apply an algorithm solving WU.

This nondeterministic reduction is correct, since if E is solvable as a basic MSOU problem, then the resulting word equations are solvable (for the convenient guessing). It is easy to see that the converse is also true.

A theorem of Plandowski [20] showing that WU is in PSPACE now implies that MSOU is in PSPACE. □

It is well known that MSOU is NP-hard [23]. We show that this also holds for monadic second-order matching. The proof gives a good feeling of what one can express in MSOU.

THEOREM 2.6. *Basic monadic second-order matching is NP-hard.*

Proof. We use the ONE-IN-THREE-SAT problem, which is known to be NP-complete [4]. An instance of the ONE-IN-THREE-SAT problem consists of the following: a set of propositional variables $p_1, \dots, p_n$ and m clauses $C_i = \{q_{i,1}, q_{i,2}, q_{i,3}\}$, where $q_{i,j} \in \{p_1, \dots, p_n\}$ for every $i = 1, \dots, m$ and $j = 1, 2, 3$. A solution is an assignment of the truth values *true* and *false* to the propositional variables, such that in every clause exactly one variable is assigned the value *true*.

We construct a basic MSOU problem where equations have ground right-hand sides and where $\Sigma = \{a, b, c\}$. For every $i = 1, \dots, n$ let X_i, Y_i be unary second-order variables. For $i = 1, \dots, n$, we use the equations

$$\begin{aligned} X_i \, Y_i \, b \flat &\stackrel{?}{=} a \, b \flat, \\ X_i \, Y_i \, c \flat &\stackrel{?}{=} a \, c \flat. \end{aligned}$$

These equations enforce that for all i either X_i is instantiated by $\lambda x \,.\, x$ or by $\lambda x \,.\, a \, x$, and similarly for Y_i, and that there are at most two possibilities for the instantiation of the pair X_i, Y_i for every i: The assignment $[X_i \mapsto \lambda x \,.\, a \, x, Y_i \mapsto \lambda x \,.\, x]$ is interpreted as *true*, and the assignment $[X_i \mapsto \lambda x \,.\, x, Y_i \mapsto \lambda x \,.\, a \, x]$ as *false*. Every clause $C = \{p_i, p_j, p_k\}$ is encoded as an equation

$$X_i \, X_j \, X_k \, b \flat \stackrel{?}{=} a \, b \flat.$$

Now it is obvious that the set of constructed equations has a unifier, if and only if the instance of ONE-IN-THREE-SAT is solvable. The equations form a monadic second-order matching problem and can be generated in linear time. Hence, the claim follows. □

3. General monadic second-order unification. In the rest of this paper we will prove the complexity estimation for *basic* MSOU problems. In this section we will argue that the restriction to "basic" does not compromise generality. The main claim is that there is a nondeterministic reduction from (general) MSOU problems to

basic MSOU problems that can be done in nondeterministic polynomial time. As a subcase of HOU, the definition of the problem in all its generality requires the use of the λ-calculus. However, we will limit its use to this section, which can be skipped by those readers not familiar with the λ-calculus.

We will use the standard notation and definitions of the simply typed λ-calculus, and we inherit the definitions of the previous section, unless we explicitly overwrite them here.

We consider only one (first-order) *base type* o and all the *second-order types* constructed from it, i.e., the ones described by the syntax $\tau ::= o \to o \mid o \to \tau$, with the usual convention that $\to$ is associative to the right. Hence, every type is o which has order one, or it is of the form $o \to o \to \cdots \to o$ and has order two.[1]

We consider a *signature* $\Sigma = \Sigma_0 \cup \Sigma_1$ of constants, denoted by $a, b, c, \ldots$, where constants of Σ_0 have type o and constants of Σ_1 have type $o \to o$. There is also a *set of variables* $\mathcal{X} = \bigcup_{i \geq 0} \mathcal{X}_i$, denoted by $x, y, z, \ldots$, where every set $\mathcal{X}_i$ contains infinitely and denumerable many variables with type $\underbrace{o \to \cdots \to o}_{i+1}$. Constants of Σ_0 and variables of $\mathcal{X}_0$ are first-order typed and are said to have arity zero, whereas those of Σ_i and $\mathcal{X}_i$, for $i > 0$, are second-order typed and have arity i.

Well-typed *terms* over the signature Σ and the set of variables $\mathcal{X}$ are built as usual in the simply typed λ-calculus:

(i) any constant $a \in \Sigma_i$ and any variable $x \in \mathcal{X}_i$ is a well-typed term of type $o \overset{i+1}{\to \cdots \to} o$,

(ii) if t is a well-typed term of type τ, and $x \in \mathcal{X}_0$, then $(\lambda x \,.\, t)$ is also a well-typed term of type $o \to \tau$, and

(iii) if s of type $o \to \tau$ and t of type o are well-typed terms, then $(s\, t)$ is also a well-typed term of type τ.

General second-order terms are defined using a signature $\Sigma = \bigcup_{i \geq 0} \Sigma_i$ and a set of variables $\mathcal{X} = \bigcup_{i \geq 0} \mathcal{X}_i$, where constants of Σ_i and variables of $\mathcal{X}_i$ have arity i. Therefore, monadic terms are second-order terms built without using constants of arity greater than one. Notice that there is no restriction on the arity of variables, whereas in basic MSOU we consider only unary variables.

Any term of type $\underbrace{o \to \cdots \to o}_{n+1}$ is said to have *arity* n. It is called of *first-order type* when $n = 0$, and of *second-order type* when $n > 0$. Hence, the arity of a term or of a symbol determines its type, and we will usually specify the arity instead of the type. When we say *normal form* we mean η-long β-reduced normal form, defined as usual. Since we do not consider third- or higher-order constants, first-order typed terms in normal form do not contain λ-abstractions, and second-order typed terms contain λ-abstractions only in outermost positions. The set of *free variables* of a term t is denoted by $FV(t)$. A term without occurrences of free variables is said to be *closed*. The *size* of a term t is denoted $|t|$ and defined as its number of symbols (variables and constants), when written in normal form.

Second-order substitutions are functions from terms to terms, defined as usual. The application of a substitution σ to a term t is written as $\sigma(t)$, where we implicitly assume that $\sigma(t)$ (after some β-reductions) is written in normal form. For any substitution σ, the set of variables x, such that $\sigma(x) \neq_{\beta\eta} x$, is finite and is called the *domain* of the substitution and denoted $Dom(\sigma)$. A substitution σ can be represented

[1] This also means that we do not allow symbols or expressions of third- or a higher-order type.

as $[x_1 \mapsto t_1, \ldots, x_n \mapsto t_n]$, where $x_i \in Dom(\sigma)$ and t_i has the same type as x_i and satisfies $t_i = \sigma(x_i)$.

An instance of the *(general) MSOU problem* is a pair $\langle \Sigma, E \rangle$, where $\Sigma = \Sigma_0 \cup \Sigma_1$ is a monadic signature and E is a *set of equations* $E = \{s_1 \stackrel{?}{=} t_1, \ldots, s_n \stackrel{?}{=} t_n\}$, where s_i and t_i are normalized first-order terms over Σ, i.e., terms not containing λ-abstractions.

Note that, in monadic signatures, closed second-order terms are of two forms: $\lambda x_1 . \cdots . \lambda x_n . (a_1 (\ldots (a_m x_i) \ldots))$ or $\lambda x_1 . \cdots . \lambda x_n . (a_1 (\ldots (a_m b) \ldots))$ for unary constants a_i and a zero-ary constant b. Since solutions σ map variables to closed terms, in the first case we say that $\sigma(x)$ *uses one* of its arguments, and if x is unary, we say that $\sigma(x)$ *uses* its argument, and in the second case we say that $\sigma(x)$ is constant or that it *ignores* its argument.

Unifiability of MSOU problems does not depend on the signature, as long as the symbols of the equations are in the signature. However, its solvability has some dependence on the signature; more precisely it depends on the existence of at least one first-order constant.

In MSOU, as in general SOU, we can prove that *for every unifiable set of equations E, and every most general unifier σ, all constants occurring in σ also occur in E.* The proof is by contradiction. If there is a most general unifier using constants not occurring in the equations, we can replace these constants by fresh variables, obtaining a more general unifier. The statement does not hold for variable occurrences in unifiers. Even if the set of equations is built from unary variables and unary constants, most general unifiers may introduce fresh n-ary variables with $n \geq 2$. For instance, the set of equations $\{(x\, a) \stackrel{?}{=} (y\, b)\}$ has only one most general second-order unifier $[x \mapsto \lambda x . ((z\, x)\, b), y \mapsto \lambda x . ((z\, a)\, x)]$ that introduces a binary variable z.

PROPOSITION 3.1. *Unifiability of MSOU problems is NP-reducible to solvability of basic MSOU problems.*

Proof. The reduction is done in three steps.

(i) First, we reduce unifiability of MSOU problems to solvability, provided that Σ_0 contains at least one constant. In other words, for any signature Σ, any set of equations E over Σ, and first-order constant b, $\langle \Sigma, E \rangle$ is unifiable, if and only if $\langle \Sigma \cup \{b\}, E \rangle$ is solvable.

For the *if* direction, assume given a solution σ. If $b \notin \Sigma$, then $b \notin E$ and we can replace b by a fresh first-order variable x_b everywhere in σ and obtain a (maybe nonground) unifier of $\langle \Sigma, E \rangle$. For the *only if* part, assume given a unifier σ. Then we can define a substitution ρ such that, for every $n \geq 0$, every n-ary variable $x \in FV(\sigma(E))$ is instantiated by $\lambda x_1 . \cdots . \lambda x_n . b$. Then $\rho \circ \sigma$ is a solution of $\langle \Sigma \cup \{b\}, E \rangle$.

(ii) Second, we prove that solvability of MSOU problems is reducible in polynomial time to solvability of MSOU problems with just one first-order constant.

Assume given an MSOU problem $\langle \Sigma, E \rangle$. If $\Sigma_0 = \emptyset$, then the problem is unsolvable. Otherwise, we reduce the problem as follows. We transform the signature Σ into a new signature $\Sigma' = \Sigma'_1 \cup \Sigma'_0$, where the set of unary constants is $\Sigma'_1 = \Sigma_1 \cup \Sigma_0$; i.e., the former zero-ary constants are unary ones in the new signature, and the set of zero-ary constants is $\Sigma'_0 = \{\flat\}$. We replace every first-order constant occurrence a in the equations E by $(a\, \flat)$, obtaining a set of equations E' over Σ'. We will see that any solution σ of $\langle \Sigma, E \rangle$ can be translated into a solution σ' of $\langle \Sigma', E' \rangle$, and vice versa.

Any solution σ of $\langle \Sigma, E \rangle$ can be translated into a solution of $\langle \Sigma', E' \rangle$ using the same transformation as for the equations. To show the other direction, let σ' be

a solution of $\langle \Sigma', E' \rangle$. Before retranslating σ' we transform it into σ'' as follows: For every x in $Dom(\sigma')$, we remove every occurrence of symbols $a \in \Sigma_0$ in $\sigma'(x)$ which is not of the form $(a\, \flat)$; i.e., we replace $(a\, s)$ by s when $s \neq \flat$, until this replacement is no longer applicable. The translation from E to E' ensures that in E' every occurrence of all x is in subterms of the form $((\ldots(x\, s_1)\ldots)\, s_n)$, where $s_i \neq \flat$. Looking at the different cases, the removal of symbols takes place only within instantiations of variables and does not conflict with the constants occurring in E. Hence, σ'' is a solution of $\langle \Sigma', E' \rangle$ and can be immediately retranslated to a solution of $\langle \Sigma, E \rangle$.

The translations of signature, set of equations, and solutions in either direction are polynomial.

(iii) Third, we prove that we can go a step further, assuming that all variables are unary: We show that solvability of MSOU, where $\Sigma_0 = \{\flat\}$, is nondeterministically reducible in polynomial time to solvability of MSOU with the same signature, and where all variables occurring in the equations are unary: $\mathcal{X}_n = \emptyset$ for all $n \neq 1$.

Given an MSOU problem $\langle \Sigma, E \rangle$, where $\Sigma_0 = \{\flat\}$, we consider substitutions ρ that instantiate every first-order variable $x \in FV(E)$ by $(x'\, \flat)$, where x' is a fresh unary variable, and every n-ary variable $y \in FV(E)$ (with $n \geq 2$) by either $\lambda x_1 . \cdots . \lambda x_n . (y'\, x_i)$, where $1 \leq i \leq n$, or $\lambda x_1 . \cdots . \lambda x_n . (y'\, \flat)$, where y' is a fresh unary variable, and the selection is nondeterministic. Obviously, if for some ρ as given above, $\langle \Sigma, \rho(E) \rangle$ is solvable, so is $\langle \Sigma, E \rangle$.

Conversely, if $\langle \Sigma, E \rangle$ is solvable, we prove that for some ρ satisfying the specified conditions, $\langle \Sigma, \rho(E) \rangle$ is also solvable. Mainly, we prove that there is some ρ as specified above and a substitution τ with $\sigma(x) = \tau \circ \rho(x)$ for all $x \in FV(E)$; thus τ solves $\langle \Sigma, \rho(E) \rangle$.

Since all constants have arity at most one and solutions are ground, instantiations $\sigma(x)$ of n-ary variables, for $n \geq 2$, use at most one of their arguments: $\sigma(x) = \lambda x_1 . \cdots . \lambda x_n . t$, where t has a unique occurrence of some x_i, or none. Therefore, we can take $\rho(x) = \lambda x_1 . \cdots . \lambda x_n . (x'\, x_i)$ or $\rho(x) = \lambda x_1 . \cdots . \lambda x_n . (x'\, \flat)$. Instantiations of first-order variables use at least the first-order constant $\flat$; therefore they can also be replaced by a fresh unary variable applied to this constant. It is obvious how to construct the solution τ of $\langle \Sigma, \rho(E) \rangle$ from σ.

Finally, note that we can compute the substitution ρ in nondeterministic polynomial time on the size of E because for any nonunary variable x, we can guess whether x uses one of its arguments and, in the positive case, which argument $\rho(x)$ uses. □

The following lemma states that if there is just one zero-ary constant in the signature, the set of size-minimal solutions is independent from the rest of the signature. Therefore, since we are dealing with size-minimal solutions of basic MSOU problems, in the next sections, we will not specify the signature.

LEMMA 3.2. *For any MSOU problem $\langle \Sigma, E \rangle$, where $\Sigma_0 = \{\flat\}$, every size-minimal solution σ contains only constants that also occur in E or are equal to $\flat$.*

Proof. Suppose that a size-minimal solution of $\langle \Sigma, E \rangle$ introduces a constant a that does not occur in E. Then, we could generate a solution with a strictly smaller size by replacing all subterms of the form $(a\, s)$ by $\flat$. This would contradict minimality. □

4. Singleton context-free grammars. In this section we prove some properties of context-free grammars. They will be used to *compactly* represent solutions of MSOU problems. In particular, we will use singleton context-free grammars that define languages with just one word.

A *context-free grammar (CFG)* is a 4-tuple (Σ, N, P, s), where Σ is an alphabet of *terminal* symbols, N is an alphabet of *nonterminal* symbols (contrary to the standard conventions and in order to avoid confusion between free variables (unknowns) and nonterminal symbols, all terminal and nonterminal symbols are denoted by lowercase letters), P is a finite set of rules, and $s \in N$ is the *start symbol*. In fact, we will not distinguish any particular start symbol, and we will represent a CFG as a 3-tuple (Σ, N, P). Moreover, we will use Chomsky grammars with at most two symbols on the right-hand sides of the rules.

DEFINITION 4.1. *We say that a CFG $G = (\Sigma, N, P)$* generates *a word $v \in \Sigma^*$ if there exists a nonterminal symbol $a \in N$ such that v belongs to the language defined by (Σ, N, P, a). In such a case, we also say that a* generates *v.*

We say that a CFG is singleton *if it is in Chomsky normal form, i.e., the right-hand sides of the productions consist of words of length at most* 2*, it is not recursive, and there exists just one production for each nonterminal symbol. Then, every nonterminal symbol $a \in N$ generates just one word, denoted w_a, and we say that a* generates *w_a. In general, for any sequence $\alpha \in (\Sigma \cup N)^*$, $w_\alpha \in \Sigma^*$ denotes the word generated by α.*

Plandowski [17, 18] defines singleton grammars, but he calls them *grammars defining set of words*. Note that so-called straight-line programs are an equivalent device [7]. Plandowski proves the following result.

THEOREM 4.2 (see [18, Theorem 33]). *The word equivalence problem for singleton CFGs is defined as follows: Given a singleton grammar and two nonterminal symbols a and b, decide whether $w_a = w_b$. This problem can be solved in polynomial worst-case time in the size of the grammar.*

Recent work [15] claims that this can be done in cubic time.

For nonrecursive grammars we define their depth as follows. The usage of both size and depth of the grammar is necessary for a good estimation, since they reflect balancing conditions for a singleton grammar seen as a tree. Using only a single measure leads to unsatisfactory upper bounds (see Remark 1 in section 8).

DEFINITION 4.3. *Let $G = (\Sigma, N, P)$ be a nonrecursive CFG. For any terminal symbol $a \in \Sigma$ we define $depth(a) = 0$, and for any nonterminal symbol $a \in N$ we define*

$$depth(a) = \max\{depth(b) + 1 \mid a \to \alpha \in P,\ b \text{ occurs in } \alpha\}.$$

We define the depth *of G as $depth(G) = \max\{depth(a) \mid a \in N\}$.*

Given a Chomsky CFG G, we define the size *of G, noted $|G|$, as the number of its rules.*

We say that $G' = (\Sigma', N', P')$ is an extension of $G = (\Sigma, N, P)$, denoted as $G' \supseteq G$, if and only if $\Sigma' \supseteq \Sigma$, $N' \supseteq N$, and $P' \supseteq P$, where we require only $\Sigma' = \Sigma$. We can extend a singleton grammar in order to generate concatenation, exponentiation, and prefixes and suffixes of words already generated by the grammar. We use these extension operations in the next sections to build the grammar defining some solution of the unification problem. The following three lemmas state how the size and the depth of the grammar are increased with these transformations. Since in the final step of this paper a grammar of polynomial size is guessed and checked in polynomial time, we only need the existence of polynomial-sized grammars. Thus we do not care about the algorithmic complexity of constructing these grammars.

LEMMA 4.4 (concatenation). *Let G be a singleton grammar generating the words $v_1, \ldots, v_n$ for $n \geq 1$. Then there exists a singleton grammar $G' \supseteq G$ that generates*

the word $v_1 \dots v_n$ and satisfies

$$\begin{array}{lcl} |G'| & \leq & |G| + n - 1, \\ \mathit{depth}(G') & \leq & \mathit{depth}(G) + \lceil \log n \rceil. \end{array}$$

Proof. Let a_i be the nonterminal symbol generating v_i, for any $i = 1, \dots, n$. We define G' by adding a set of rules to G of the form

$$b_{i,j} \to b_{i,\, \lfloor \frac{i+j}{2} \rfloor}\, b_{\lfloor \frac{i+j}{2} \rfloor + 1,\, j},$$

where $1 \leq i \leq j \leq n$ and $b_{i,i}$ is a_i. Then, $b_{1,n}$ generates $v_1 \dots v_n$, and to generate it we need only to add $n - 1$ of such rules. The depth is increased by at most $\lceil \log n \rceil$. □

LEMMA 4.5 (exponentiation). *Let G be a singleton grammar generating the word v. For any $n \geq 1$, there exists a singleton grammar $G' \supseteq G$ that generates the word v^n and satisfies*

$$\begin{array}{lcl} |G'| & \leq & |G| + 2 \lfloor \log n \rfloor, \\ \mathit{depth}(G') & \leq & \mathit{depth}(G) + \lfloor \log n \rfloor + 1. \end{array}$$

Proof. Let a be the nonterminal symbol generating v, $m = \lfloor \log n \rfloor$, and let $n = k_0 2^0 + k_1 2^1 + \dots + k_m 2^m$ be a binary representation satisfying $k_i \in \{0, 1\}$. We add the following set of rules to G:

$$\begin{array}{lcl} a_1 & \to & a\, a, \\ a_2 & \to & a_1\, a_1, \\ & \dots & \\ a_m & \to & a_{m-1}\, a_{m-1}, \end{array} \qquad \begin{array}{lcl} b_0 & \to & \begin{cases} a & \text{if } k_0 = 1, \\ \varepsilon & \text{if } k_0 = 0, \end{cases} \\ b_1 & \to & \begin{cases} a_1\, b_0 & \text{if } k_1 = 1, \\ b_0 & \text{if } k_1 = 0, \end{cases} \\ & \dots & \\ b_m & \to & \begin{cases} a_m\, b_{m-1} & \text{if } k_m = 1, \\ b_{m-1} & \text{if } k_m = 0. \end{cases} \end{array}$$

Then, the nonterminal symbol b_m generates v^n, and it is easy to see that this grammar satisfies the bounds stated by the lemma. □

LEMMA 4.6 (prefixes and suffixes). *Let G be a singleton grammar generating the word v. For any prefix or suffix v' of v, there exists a singleton grammar $G' \supseteq G$ that generates v' and satisfies*

$$\begin{array}{lcl} |G'| & \leq & |G| + \mathit{depth}(G), \\ \mathit{depth}(G') & = & \mathit{depth}(G). \end{array}$$

Proof. Let a be the nonterminal symbol generating v. By induction on $\mathit{depth}(a)$, we will prove a stronger result: For any prefix v' of w_a, there exists a grammar G' generating v' and satisfying $|G'| \leq |G| + \mathit{depth}(a)$ and $\mathit{depth}(G') = \mathit{depth}(G)$.

The base case is trivial since $\mathit{depth}(a) = 0$ implies that a is a terminal symbol, and $v' = v$ or v' is empty. For the induction case, assume that $v' \neq v$; otherwise we are done. Let $a \to \alpha$ be the rule for a. Note that $|\alpha| \leq 2$. There exists a prefix $\beta\, b$ of α, where b is a nonterminal, such that w_β is a prefix of v' and v' is a prefix of $w_{\beta\, b}$; i.e., $v' = w_\beta\, v''$, where v'' is a prefix of w_b. By induction hypothesis, there exists a grammar $G'' \supseteq G$ deriving v'' from some b' with the same depth as G and size $|G''| \leq |G| + \mathit{depth}(b) \leq |G| + \mathit{depth}(a) - 1$. We add $a' \to \beta\, b'$ to get the grammar G'

from G'' such that $w_{a'} = v'$. Notice that $|G'| = |G''| + 1$, and $depth(G') = depth(G'')$ because $depth(b') \leq depth(b)$ implies $depth(a') \leq depth(a)$.

For suffixes the proof is very similar. □

We illustrate Lemmas 4.4, 4.5, and 4.6 by means of Example 5.

Example 5. Let G be the grammar defined by the productions $\{c_1 \to c_2\, c_3$, $c_2 \to c_3\, c_4$, $c_3 \to ff$, $c_4 \to gg\}$. The words generated by the nonterminals c_1, c_2, c_3, and c_4 of G are $v_1 = ffggff$, $v_2 = ffgg$, $v_3 = ff$, and $v_4 = gg$, respectively.

(i) *Concatenation.* We first show how to build the word

$$v_1 v_2 v_3 v_4 = ffggffffggffgg$$

using the techniques of the proof of Lemma 4.4. Following the definitions of $b_{i,j} \to b_{i,\lfloor \frac{i+j}{2} \rfloor}\, b_{\lfloor \frac{i+j}{2} \rfloor + 1,\, j}$, and $b_{i,i} = c_i$, we extend G with the following rules:

$$\begin{array}{lcl} b_{1,4} & \to & b_{1,2}\, b_{3,4}, \\ b_{1,2} & \to & c_1\, c_2, \\ b_{3,4} & \to & c_3\, c_4. \end{array}$$

Then, $b_{1,4}$ generates $v_1 v_2 v_3 v_4$.

(ii) *Exponentiation.* Now we show how to build the word $(v_1)^5$ according to the techniques of the proof of Lemma 4.5. We have $5 = 1 \cdot 2^2 + 0 \cdot 2^1 + 1 \cdot 2^0$; hence we extend G with the following rules:

$$\begin{array}{lcllcl} a_1 & \to & c_1\, c_1, & b_0 & \to & c_1, \\ a_2 & \to & a_1\, a_1, & b_1 & \to & b_0, \\ & & & b_2 & \to & a_2\, b_1. \end{array}$$

Then b_2 generates $(v_1)^5$.

(iii) *Prefix.* Finally we show how to build the word prefix $v' = ffg$ of v_1 using the techniques of the proof of Lemma 4.6. We extend G with the following rules:

$$\begin{array}{lcl} c'_1 & \to & c'_2, \\ c'_2 & \to & c_3\, c'_4, \\ c'_4 & \to & g. \end{array}$$

Then c'_1 generates v'.

5. Compact representations. In this section we use singleton grammars to compact the representation of solutions of basic MSOU problems. We go a step further and also compact the representation of equations, allowing the use of nonterminal symbols of a singleton grammar to represent large words also in the equations.

DEFINITION 5.1. *Let Σ be a signature of unary symbols, and let $\mathcal{X}$ be a set of unary variables.*

A compact representation *of a basic MSOU problem E is a pair $\langle E', G\rangle$, where $G = \langle \Sigma, N, P\rangle$ is a singleton CFG and E' is a set of equations of the form $\{s_1 \stackrel{?}{=} t_1, \ldots, s_n \stackrel{?}{=} t_n\}$, where $s_i, t_i \in (\Sigma \cup \mathcal{X} \cup N)^* \flat$, for $i = 1, \ldots, n$, such that when replacing in E' every nonterminal symbol a by the word w_a that it generates, it results in the set of equations E.*

A compact representation *of a monadic substitution σ is a pair $\langle \sigma', G\rangle$, where $G = \langle \Sigma, N, P\rangle$ is a singleton CFG and σ' is a mapping from variables X to terms of the form $\lambda x\,.\,\alpha\flat$ or $\lambda x\,.\,\alpha\, x$, where $\alpha \in (\Sigma \cup N)^*$, such that, after replacing every nonterminal symbol by the word it represents, we obtain σ.*

We say that $\langle \tau, G' \rangle$ *is a* compacted solution *of* $\langle E, G \rangle$ *if the substitution represented by* $\langle \tau, G' \rangle$ *is a solution of the set of equations represented by* $\langle E, G \rangle$*, where* G' *is an extension of* G*.*

Notice that nonterminal symbols derive into sequences of unary function symbols, that we do not consider first-order variables, and that $\flat$ is the only constant. Words of $(\Sigma \cup \mathcal{X} \cup N)^*$ are denoted by Greek letters $\alpha, \beta, \ldots$.

Example 6. Let $\Sigma = \{f\}$ and $N := \{a, c, d\}$. Consider the compacted equations $\langle E, G \rangle$ defined by

$$\begin{array}{rcl} E & = & \{a\, X\, X\, f\, \flat \stackrel{?}{=} Y\, Y\, Y\, \flat\}, \\ G & = & \{a \to c\, c,\ c \to f\, f\}. \end{array}$$

Then, the pairs $\langle \sigma_1, G_1 \rangle$ and $\langle \sigma_2, G_2 \rangle$, defined by

$$\begin{array}{rcl} \sigma_1 & = & [X \mapsto \lambda x\,.\, c\, x,\ Y \mapsto \lambda x\,.\, d\, x], \\ G_1 & = & \{a \to c\, c,\ c \to f\, f,\ d \to c\, f\} \end{array} \quad \text{and} \quad \begin{array}{rcl} \sigma_2 & = & [X \mapsto \lambda x\,.\, e\, \flat,\ Y \mapsto \lambda x\,.\, a\, \flat], \\ G_2 & = & \{a \to c\, c,\ c \to f\, f,\ e \to \varepsilon\}, \end{array}$$

are compacted representations of solutions of $\langle E, G \rangle$. The first solution is not size-minimal. The second solution is size-minimal, but it is not a most general unifier. In fact, the second is an instantiation of the most general unifiers $[X \mapsto \lambda x\,.\, Z\, x,\ Y \mapsto \lambda x\,.\, a\, Z\, Z\, f\, \flat]$ and $[X \mapsto \lambda x\,.\, Z\, a\, Z\, a\, Z\, \flat, Y \mapsto \lambda x\,.\, a\, Z\, x]$.

We generalize the basic MSOU problem in the sense that, given some compacted equations $\langle E, G \rangle$, we will try to find a compacted solution $\langle \sigma, G' \rangle$. Moreover, the grammar G' used to represent the solution will be an extension of the grammar G given to represent the equations.

Notice that solvability of a set of monadic equations and solvability of compact equations are, w.r.t. decidability, equivalent problems. With respect to their complexity, we will prove that solvability of compact equations can be decided in NP-time. This implies that solvability of MSOU is also in NP (since $\langle E, \emptyset \rangle$ is a trivial compact representation of E).

Notice that the straightforward translation of a compacted set of equations into the set of monadic equations that they represent may exponentially increase the size of the equations. Using another translation, we can show that solvability of MSOU problems and solvability of compacted MSOU problems are polynomially equivalent.

PROPOSITION 5.2. *Given a compacted set of equations* $\langle E, G \rangle$*, there is a P-time translation into a basic MSOU problem* E'*, such that* $\langle E, G \rangle$ *is solvable if and only if* E' *is solvable.*

Proof. For every nonterminal a in G, define a fresh unary variable X_a. For every production $a \to b\, c$ of the grammar, where $a, b, c \in N$, define a set of two equations $E_a = \{X_a\, \flat \stackrel{?}{=} X_b\, X_c\, \flat,\ X_a\, f\, \flat \stackrel{?}{=} X_b\, X_c\, f\, \flat\}$, where $f \in \Sigma$ and $X_a, X_b, \ldots$ are fresh variables. This is similar for the other kinds of rules, where the right-hand sides are shorter. The terminal symbols are not translated. For instance, for $a \to b\, c$, where $a \in N$ and $b, c \in \Sigma$, $E_a = \{X_a\, \flat \stackrel{?}{=} b\, c\, \flat, X_a\, f\, \flat \stackrel{?}{=} b\, c\, f\, \flat\}$. Then, $E' = \hat{E} \cup \bigcup_{a \in N} E_a$, where $\hat{E}$ is the translation of the equations E by replacing nonterminals a with the corresponding unary variable X_a. The size of E' is smaller than $|E| + 12\,|G|$, and it can be constructed in polynomial time.

The equations in $\bigcup_{a \in N} E_a$ enforce that, for every nonterminal a, $\sigma(X_a)$ uses its argument, and therefore $\sigma(X_a) = \lambda x\,.\, w_a\, x$. Now it is easy to see that $\langle E, G \rangle$ is solvable if and only if E' is solvable. □

6. The graph of surface dependencies. In this section we define graphs of surface dependencies. The purpose of these graphs is to support constructing the compact representation of a minimal solution σ of a compacted set of equations and estimating the size of this representation. Later on this will be used to show that only a polynomial-sized representation has to be guessed in order to check solvability. Observe that we only impose a bound on the size of the representation and do not care about the complexity of finding such a representation. In our proof, we start from the compact representation $\langle E, G\rangle$ of some basic MSOU problem and a given solution σ. Then, we find a variable X whose instantiation can be compactly represented. This is done by extending the grammar to $G' \supseteq G$. Then, we repeat the process starting from the same equation with the variable already instantiated. Observe that G' (apart from the instantiation of the X) is able to generate all the words represented by G. This iteration describes a proof by induction, not the unification algorithm. It could be interpreted as a nondeterministic unification procedure, however, with the restriction of finding a size-minimal solution, and moreover, without a guarantee of being in NP.

There are cases in which for some variable X of the problem, its instantiation $\sigma(X)$ is immediately given or immediately constructible from the "surface" of the equations. We identify two such cases: when σ has a *small component* (Lemma 6.6) and when the graph contains a *cycle* (Lemma 6.12). We also identify three situations which ensure that any size-minimal solution has small components: when the graph has a constant equation (Lemma 6.7), when the graph has no edges (Lemma 6.8), and when there are strong divergences (Lemma 6.10). In the rest of the cases, it becomes necessary to rewrite the graph to obtain a new graph that describes the instantiation of some variable. This graph rewriting process will be described in section 7.

The graph of surface dependencies is defined only for *simplified* equations, where a simplified equation is defined as follows.

DEFINITION 6.1. *Given a compacted set of equations $\langle E, G\rangle$, we say that they are* simplified *if E does not contain equations of the following forms (symmetric cases omitted):*

(i) $a\,s \stackrel{?}{=} b\,t$, *where* $a, b \in \Sigma \cup N$,
(ii) $s \stackrel{?}{=} a\,b\,t$, *where* $a, b \in \Sigma \cup N$, *or*
(iii) $s \stackrel{?}{=} a\,t$, *where* $a \in N$ *and* $w_a = \varepsilon$.

Note that simplified equations are of the forms (symmetric cases omitted) $X\,s \stackrel{?}{=} a\,\flat$, $X\,s \stackrel{?}{=} a\,Y\,t$, $X\,s \stackrel{?}{=} \flat$ (flexible-rigid), or $X\,s \stackrel{?}{=} Y\,t$ (flexible-flexible), where a is a nonterminal. Note also that solvable equations without variables have the form $\alpha\,\flat \stackrel{?}{=} \beta\,\flat$, where α, β are in $(\Sigma \cup N)^*$, satisfy $w_\alpha = w_\beta$, and are not simplified.

We describe a simplification algorithm in the proof of the following lemma. This algorithm will be used as a subroutine in the proof of Theorem 7.7. Notice that it can increase the size of the associated grammar as stated in the lemma.

LEMMA 6.2 (simplification). *Given the solvable and compacted set of equations $\langle E, G\rangle$, there exists a simplified and compacted set of equations $\langle E', G'\rangle$ with the same solutions, such that*

$$\begin{aligned} |G'| &= |G| + \mathcal{O}(|E|(\mathit{depth}(G) + \log|E|)), \\ \mathit{depth}(G') &= \mathit{depth}(G) + \mathcal{O}(\log|E|), \end{aligned}$$

and the number of equations, number of variables, and number of occurrences of variables in E' are not greater than the corresponding numbers for E.

Proof. For all equations $s_i \stackrel{?}{=} t_i$ of E, let α_i, β_i be the longest prefixes of s_i and t_i, respectively, that do not contain variables or $\flat$; i.e., $s_i = \alpha_i\,s'_i$, and $t_i = \beta_i\,t'_i$, where

s'_i and t'_i have a variable or $\flat$ in the head. Let v_i be the word satisfying $w_{\alpha_i} = w_{\beta_i} v_i$ or $w_{\alpha_i} v_i = w_{\beta_i}$.

Using Lemma 4.4, construct an extension of the grammar with a nonterminal for the word $\alpha_1 \beta_1 \dots \alpha_n \beta_n$. For every $i = 1, \dots, n$, since v_i is a suffix of some prefix of this word, use Lemma 4.6 to prove that there exists another extension of the grammar that generates v_i. This last process will be repeated at most $2\,\#Eq(E)$ times to obtain a new grammar G'. This ensures that $depth(G') \leq depth(G) + \lceil \log |E| \rceil$ and $|G'| \leq |G| + |E| + 2\,\#Eq(E)\,(depth(G) + \lceil \log |E| \rceil)$. This implies the estimations given in the lemma.

Now, we construct E' from E as follows. For every $i = 1, \dots, n$,

(i) if $s'_i = t'_i = \flat$, then remove the equation from E;

(ii) if $w_{\alpha_i} = w_{\beta_i}$, then replace $s_i \stackrel{?}{=} t_i$ in E by $s'_i \stackrel{?}{=} t'_i$;

(iii) if w_{α_i} is a prefix of w_{β_i}, then replace $s \stackrel{?}{=} t$ in E by $s'_i \stackrel{?}{=} b\,t'_i$, where b is the nonterminal of G' generating v_i; and

(iv) proceed similarly if w_{β_i} is a prefix of w_{α_i}.

Notice that the case where neither w_{α_i} is a prefix of w_{β_i} nor w_{β_i} is a prefix of w_{α_i} is not possible for solvable equations. Notice also that, if we simplify equations one by one, generating a suffix of a prefix of α_i or of β_i each time, we would get a worse estimation. □

DEFINITION 6.3. *A* constant equation *is a simplified and compacted equation of the form* $X\,t \stackrel{?}{=} a\flat$ *or* $X\,t \stackrel{?}{=} \flat$, *where* $t \in (\Sigma \cup \mathcal{X} \cup N)^* \flat$ *is a compacted term and* $a \in N$ *is a nonterminal symbol.*

We define the graph of surface dependencies only for solvable, simplified, and compacted sets of equations.

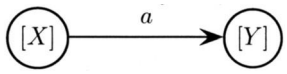
DEFINITION 6.4. *Let* $\langle E, G \rangle$ *be a solvable, simplified, and compacted set of equations. Let* $\approx$ *be the minimal equivalence relation satisfying* $X \approx Y$ *whenever* E *contains an equation of the form* $X\,s \stackrel{?}{=} Y\,t$. *This defines a partition on* $FV(E)$.

The graph of surface dependencies *of* $\langle E, G \rangle$ *is a labeled directed multigraph*[2] *defined as follows:*

Nodes: *The nodes are the* $\approx$*-equivalence classes of variables and the empty set* $\emptyset$.

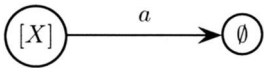
Edges: *There are two cases:*

(i) *For every equation of the form* $X\,s \stackrel{?}{=} a\,Y\,t$, *where* $X, Y \in \mathcal{X}$ *are variables and* $a \in N$ *is a nonterminal symbol, there is an edge*



Simplification yields that $w_a \neq \varepsilon$ *for the edge label* a.

(ii) *For every constant equation* $X\,s \stackrel{?}{=} a\flat$, *where* $X \in \mathcal{X}$ *and* $a \in N$, *there is an edge*



In the case of a constant equation $X\,s \stackrel{?}{=} \flat$, *we use* ε *as the label of the edge.*

The size *of a graph of surface dependencies* D, *denoted as* $|D|$, *is defined as its number of edges.*

Note that the node $\emptyset$ has no outgoing edges.

[2]There may be several edges, even labeled differently between two nodes.

6.1. Small components of solutions. We say that a solution of $\langle E, G\rangle$ has a small component if there exists a variable whose value is "small" enough to be described just as the prefix of some word defined by G. This will be helpful in the construction of a compact representation of a size-minimal solution for several reasons: It is a case where the instantiation of a variable is completely known, it can be constructed with only a small increase of the grammar, and it eases the definition and argumentation for the remaining cases.

We identify some classes of compacted equations that have a solution with a small component.

DEFINITION 6.5. *Given the simplified and compacted set of equations $\langle E, G\rangle$, a variable X occurring in E, and a solution σ, we say that X is a* small component *of σ if $\sigma(X) = \lambda x\,.\,v\,x$, or $\sigma(X) = \lambda x\,.\,v\,\flat$ and either $v = \varepsilon$ or there is a nonterminal a in G such that v is a prefix of w_a.*

LEMMA 6.6 (small component). *Let $\langle E, G\rangle$ be a simplified and compacted set of equations, and let σ be a solution of $\langle E, G\rangle$ with a small component X such that $\sigma(X) = \lambda x\,.\,v\,x$ or $\sigma(X) = \lambda x\,.\,v\,\flat$. Then, there exists a singleton CFG $G' \supseteq G$ generating v and satisfying*

$$\begin{aligned} |G'| &\leq |G| + \mathit{depth}(G), \\ \mathit{depth}(G') &= \mathit{depth}(G). \end{aligned}$$

Proof. The inequalities follow from Definition 6.5 and Lemma 4.6. □

This lemma is helpful in two ways: It allows us to eliminate variables from the problem and it restricts the cases where this elimination does not work (and it is necessary to rewrite the equations) to cases in which solutions do not have small components; i.e., they have only "large" instantiations. This will simplify the reasoning.

LEMMA 6.7. *All solutions of simplified and compacted sets of equations containing constant equations have at least one small component.*

Proof. Let $\langle E, G\rangle$ be a simplified and compacted set of equations, and let σ be a solution. Since σ solves a constant equation of the form $X\,s \stackrel{?}{=} a\,\flat$, it must instantiate X either with $\lambda x\,.\,v\,x$ or with $\lambda x\,.\,v\,\flat$ for some prefix v of w_a. Similar arguments hold for equations of the form $X\,s \stackrel{?}{=} \flat$. □

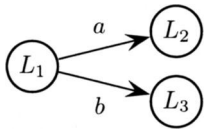
The following lemma describes the situation that reflects the difference between basic MSOU problems and WU when all equations are *flexible-flexible*. While in MSOU we can instantiate variables by terms not using their arguments, such as $\lambda x\,.\,\flat$, this is not possible when considering WU; hence the lemma does not hold for WU. This is the point that shows that our result is not straightforwardly transferable to WU.

LEMMA 6.8. *Let $\langle E, G\rangle$ be a simplified and compacted set of equations such that the graph of surface dependencies does not contain edges and such that $FV(E) \neq \emptyset$, and let σ be a size-minimal solution of $\langle E, G\rangle$. Then, for every variable $X \in FV(E)$, either $\sigma(X) = \lambda x\,.\,\flat$ or $\sigma(X) = \lambda x\,.\,x$. This also means that there is at least one small component in σ.*

Proof. If there are not edges, then all equations are of the form $X\,s \stackrel{?}{=} Y\,t$. The substitution σ, with $\sigma(X) = \lambda x\,.\,\flat$ for every variable $X \in FV(E)$, is a size-minimal solution; hence for every other size-minimal solution σ' and for every variable $X \in FV(E)$, only $\sigma'(X) = \lambda x\,.\,\flat$ or $\sigma'(X) = \lambda x\,.\,x$ is possible.[3] □

[3]We could make the solution with $\sigma'(X) = \lambda x\,.\,\flat$, for all variables, be the only size-minimal solution by changing the term size measure to make $\lambda x\,.\,\flat$ smaller than $\lambda x\,.\,x$. However, then the exponent of periodicity bound (see Lemma 2.4) must be adapted.

DEFINITION 6.9. *A dependence graph D is said to contain a* divergence $L_2 \overset{a}{\leftarrow} L_1 \overset{b}{\rightarrow} L_3$ *if it contains a subgraph of the following form (where L_1, L_2, and L_3 are not necessarily distinct nodes):*



If neither w_a is a prefix of w_b nor w_b is a prefix of w_a, then it is called a strong divergence *and otherwise a* weak divergence.

Strong divergences are easy to eliminate, whereas weak divergences require a more complex treatment, which will be done by rewriting the graph.

LEMMA 6.10. *Given a simplified and compacted set of equations, if its graph of surface dependencies contains a strong divergence, then every solution has small components.*

Proof. Given $\langle E, G\rangle$, let D be its graph of surface dependencies, and let σ be any of its solutions. Assume that D contains a strong divergence $L_2 \overset{a}{\leftarrow} L_1 \overset{b}{\rightarrow} L_3$. For every variable $X \in L_1$, let $v_X \in \Sigma^*$ be a word such that either $\sigma(X) = \lambda y\,.\,v_X\,y$ or $\sigma(X) = \lambda y\,.\,v_X\,\natural$. By definition of D, we have a pair of equations in E of the form $X_1 \cdots \overset{?}{=} a\,t_1$ and $X_2 \cdots \overset{?}{=} b\,t_2$, where $X_1, X_2 \in L_1$. Therefore, v_{X_1} is a prefix of $\sigma(w_a\,t_1)$, and v_{X_2} is a prefix of $\sigma(w_b\,t_2)$. Now, let $Y \in L_1$ be the variable such that v_Y is the shortest word of $\{v_X \mid X \in L_1\}$. By the equivalence relation and the dependence graph definitions, we have that v_Y is a prefix of both v_{X_1} and v_{X_2}, and thus a prefix of $\sigma(w_a\,t_1)$ and of $\sigma(w_b\,t_2)$. Since w_a is not a prefix of w_b, and vice versa, we have that v_Y is a proper prefix of both w_a and w_b. (Notice that v_Y is not necessarily the longest common prefix of w_a and w_b). Therefore, Y is a small component of σ. □

6.2. Cycles in the graph of dependencies. The cycles in the graph of surface dependencies describe the base of *some* exponentiation occurring in the instantiation of some variables. For instance, the solutions of the equation $X\,f\,\natural \overset{?}{=} f\,X\,\natural$ have the form $[X \mapsto \lambda y\,.\,f^n\,y]$ for some $n \geq 0$. The base of this power is described by a cycle in its graph of surface dependencies:

LEMMA 6.11. *Let E be a (noncompacted) set of equations with a cycle of the form*

$$\begin{array}{lcl} X_1 \cdots & \overset{?}{=} & w_1\,X_2 \cdots \\ X_2 \cdots & \overset{?}{=} & w_2\,X_3 \cdots \\ & \cdots & \\ X_m \cdots & \overset{?}{=} & w_m\,X_1 \cdots, \end{array}$$

where $w_i \in \Sigma^*$, for every $i = 1, \ldots, m$, and $w_1 \ldots w_m \neq \varepsilon$.

Then, for every solution σ of E, there is some variable X_k, with $1 \leq k \leq m$, such that $\sigma(X_k) = \lambda x \,.\, u\, x$, where u is a prefix of $(w_k \dots w_m\, w_1 \dots w_{k-1})^n$ for sufficiently large n.

Proof. The proof is by induction on the size of σ.

For any $i = 1, \dots, m$, if σ solves $X_i \cdots \stackrel{?}{=} w_i\, X_{i+1} \cdots$, then either $\sigma(X_i) = \lambda x \,.\, u_i\, x$ for some proper prefix u_i of w_i, or we have $\sigma(X_i) = \lambda x \,.\, w_i\, v_i\, x$ or $\sigma(X_i) = \lambda x \,.\, w_i\, v_i\, \flat$, for some word v_i. Therefore, there are two cases:

If, for some $k = 1, \dots, m$, we have the first situation that there is some X_k such that $\sigma(X_k) = \lambda x \,.\, u_k\, x$, where u_k is a prefix of w_k, then the claim of the lemma holds.

Otherwise, for every $i = 1, \dots, m$, we have $\sigma(X_i) = \lambda x \,.\, w_i\, v_i\, x$ or $\sigma(X_i) = \lambda x . w_i\, v_i\, \flat$. In this case we generate a new system by instantiating X_i by $\lambda x \,.\, w_i\, X'_i\, x$, where X'_i are fresh and different unary second-order variables. Then, the equations in the cycle become

$$\begin{array}{lcl} w_1\, X'_1 \cdots & \stackrel{?}{=} & w_1\, w_2\, X'_2 \cdots, \\ w_2\, X'_2 \cdots & \stackrel{?}{=} & w_2\, w_3\, X'_3 \cdots, \\ & \cdots & \\ w_m\, X'_m \cdots & \stackrel{?}{=} & w_m\, w_1\, X'_1 \cdots. \end{array}$$

Simplifying the equations, we obtain a new system of equations,

$$\begin{array}{lcl} X'_1 \cdots & \stackrel{?}{=} & w_2\, X'_2 \cdots, \\ X'_2 \cdots & \stackrel{?}{=} & w_3\, X'_3 \cdots, \\ & \cdots & \\ X'_m \cdots & \stackrel{?}{=} & w_1\, X'_1 \cdots. \end{array}$$

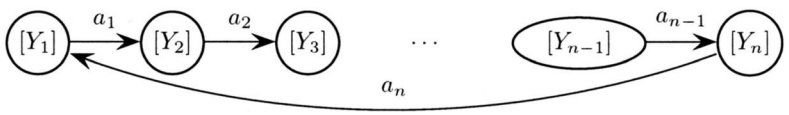
From the original solution σ we get a solution σ' of the new equations satisfying $\sigma'(X'_i) = \lambda x \,.\, v_i\, x$ or $\sigma(X'_i) = \lambda x \,.\, v_i\, \flat$, for all $i = 1, \dots, m$. Now the induction hypothesis applies since σ' is smaller than σ; hence there is a variable X'_k such that $\sigma'(X'_k) = \lambda x \,.\, v_k\, x$, where v_k is a prefix of $(w_{k+1} \dots w_m\, w_1 \dots w_k)^n$, for large enough n. Hence $\sigma(X_k) = \lambda x . w_k\, v_k\, x$, and the claim holds. □

LEMMA 6.12 (cycles). *Let $\langle E, G \rangle$ be a solvable, simplified, and compacted set of equations, with a graph of surface dependencies D with some cycle. Then, for every solution σ without small components, there exists a variable X such that $\sigma(X) = \lambda y \,.\, w\, y$ and w is generated by some grammar $G' \supseteq G$ satisfying*

$$\begin{array}{lcl} |G'| & = & |G| + \mathcal{O}(\mathit{depth}(G) + \#\mathit{Eq}(E) + \log \mathrm{eop}(\sigma)), \\ \mathit{depth}(G') & = & \mathit{depth}(G) + \mathcal{O}(\log \#\mathit{Eq}(E) + \log \mathrm{eop}(\sigma)). \end{array}$$

More precisely, the corresponding node $[X]$ is inside the cycle, and, for some $0 \leq n \leq \mathrm{eop}(\sigma)$ and some prefix v of w_α, we have $\sigma(X) = \lambda y \,.\, (w_\alpha)^n\, v\, y$, where $\alpha \in N^*$ is the sequence of labels of the edges completing the cycle from $[X]$.

Proof. Select a cycle in the graph D:



Therefore, there is a subset of equations in E of the form

$$\begin{array}{llll} Y_{1,m_1} \ldots \stackrel{?}{=} a_1\, Y_{2,1} \ldots; & Y_{2,1} \ldots \stackrel{?}{=} Y_{2,2} \ldots; & \cdots & Y_{2,m_2-1} \ldots \stackrel{?}{=} Y_{2,m_2} \ldots; \\ Y_{2,m_2} \ldots \stackrel{?}{=} a_2\, Y_{3,1} \ldots; & Y_{3,1} \ldots \stackrel{?}{=} Y_{3,2} \ldots; & \cdots & Y_{3,m_3-1} \ldots \stackrel{?}{=} Y_{3,m_3} \ldots; \\ \cdots & & & \\ Y_{n,m_n} \ldots \stackrel{?}{=} a_n\, Y_{1,1} \ldots; & Y_{1,1} \ldots \stackrel{?}{=} Y_{1,2} \ldots; & \cdots & Y_{1,m_1-1} \ldots \stackrel{?}{=} Y_{1,m_1} \ldots, \end{array}$$

where $\{Y_{i,1}, \ldots, Y_{i,m_i}\} \subseteq [Y_i]$ for $i = 1, \ldots, n$. Note that $w_{a_i} \neq \varepsilon$ for all i, since E is simplified.

Now, fix a solution σ and proceed as follows. Let E' be the set of equations represented by the compacted equations above. Notice that $w_{a_1} \cdots w_{a_n} \neq \varepsilon$, and E' fulfills the conditions of Lemma 6.11. The substitution σ also solves E', and applying Lemma 6.11, we get a variable $Y_{k,l}$ such that $\sigma(Y_{k,l}) = \lambda x.w_\alpha^n\, v\, x$, where $\alpha = a_k \cdots a_m\, a_1 \cdots a_{k-1}$ and v is a prefix of w_α. Moreover, we have $n \leq \mathrm{eop}(\sigma)$.

To prove the existence of G', we proceed by adding new rules to G. Note that all symbols labeling the edges of D are nonterminals in G. We construct a sequence of grammars $G \subseteq G_1 \subseteq G_2 \subseteq G_3 \subseteq G'$ such that G_1, apart from the words generated by G, also generates w_α, G_2 also generates v, G_3 also generates $(w_\alpha)^n$, and G' also generates $(w_\alpha)^n\, v$.

Since the length of α is at most $|D|$, by Lemma 4.4, we have

$$\begin{array}{lcl} |G_1| & \leq & |G| + |D| - 1, \\ \mathit{depth}(G_1) & \leq & \mathit{depth}(G) + \lceil \log |D| \rceil. \end{array}$$

By Lemma 4.6, we can define v with

$$\begin{array}{lcl} |G_2| & \leq & |G_1| + \mathit{depth}(G_1), \\ \mathit{depth}(G_2) & = & \mathit{depth}(G_1). \end{array}$$

By Lemma 4.5, we can define $(w_\alpha)^n$ with

$$\begin{array}{lcl} |G_3| & \leq & |G_2| + 2\, \lfloor \log \mathrm{eop}(\sigma) \rfloor, \\ \mathit{depth}(G_3) & \leq & \mathit{depth}(G_2) + \lceil \log \mathrm{eop}(\sigma) \rceil \end{array}$$

and, since we still need another rule to define $(w_\alpha)^n\, v$,

$$\begin{array}{lcl} |G'| & \leq & |G_3| + 1, \\ \mathit{depth}(G') & \leq & \mathit{depth}(G_3) + 1. \end{array}$$

The composition of all these inequalities results in the inequalities

$$\begin{array}{lcl} |G'| & \leq & |G| + \mathit{depth}(G) + |D| + \lceil \log |D| \rceil + 2\, \lfloor \log \mathrm{eop}(\sigma) \rfloor, \\ \mathit{depth}(G') & \leq & \mathit{depth}(G) + \lceil \log |D| \rceil + \lceil \log \mathrm{eop}(\sigma) \rceil + 1. \end{array}$$

In terms of O-notation, this reduces to

$$\begin{array}{lcl} |G'| & = & |G| + \mathcal{O}(\mathit{depth}(G) + |D| + \log \mathrm{eop}(\sigma)), \\ \mathit{depth}(G') & = & \mathit{depth}(G) + \mathcal{O}(\log |D| + \log \mathrm{eop}(\sigma)). \end{array}$$

And, since $|D| \leq \#Eq(E)$,

$$\begin{array}{lcl} |G'| & = & |G| + \mathcal{O}(\mathit{depth}(G) + \#Eq(E) + \log \mathrm{eop}(\sigma)), \\ \mathit{depth}(G') & = & \mathit{depth}(G) + \mathcal{O}(\log \#Eq(E) + \log \mathrm{eop}(\sigma)), \end{array}$$

as stated in the lemma. □

7. Rewriting the graph of dependencies. In the previous section we saw that Lemmas 6.6 and 6.12 both describe the instantiation $\sigma(X)$ of some variable and allow us to eliminate it during the construction of a compact representation of the solution σ. In other words, they describe parts of the solution, i.e., a substitution $\rho = [X \mapsto \sigma(X)]$ satisfying $\rho \preceq_{FV(E)} \sigma$.

In this section we will see that, when these two lemmas are not applicable, we can *rewrite* the set of equations (and its corresponding graph of dependencies) until one of the two lemmas becomes applicable. This rewriting process is done by *partially* instantiating some variables, i.e., applying a substitution ρ also satisfying $\rho \preceq_{FV(E)} \sigma$. The substitution has the form $\rho = [X \mapsto \lambda y \,.\, w\, X'\, y]$, where X' is a fresh variable and $w \in \Sigma^*$. Substitutions of such form, as well as the total instantiations of the form $\rho = [X \mapsto \lambda y \,.\, w\, y]$ and $\rho = [X \mapsto \lambda y \,.\, w\, \flat]$ described in Lemmas 6.6 and 6.12, are all called *partial instantiations*. Formally, we define partial instantiations as follows.

DEFINITION 7.1. *We say that a substitution ρ is a* partial instantiation *if it can be decomposed as $\rho = (\rho_1 \circ \cdots \circ \rho_n)|_{Dom(\rho)}$, where each ρ_i either has the form $\rho_i = [X_i \mapsto \lambda y \,.\, w_i\, X'_i\, y]$, $\rho_i = [X_i \mapsto \lambda y \,.\, y]$, or $\rho_i = [X_i \mapsto \lambda y \,.\, \flat]$, for some $X_i, X'_i \in \mathcal{X}_1$ and some $w_i \in \Sigma^*$.*

The following lemma states the preservation of some properties of partial instantiations of equations. Notice that some of these properties do not hold for arbitrary substitutions satisfying $\rho \preceq_{FV(E)} \sigma$.

LEMMA 7.2 (preservation). *For any (noncompacted) set of equations E, any solution σ, and any partial instantiation ρ, satisfying $\rho \preceq_{FV(E)} \sigma$, there exists a substitution σ' satisfying*

(i) $\sigma = (\sigma' \circ \rho)|_{FV(E)}$,
(ii) *σ' is a solution of $\rho(E)$,*
(iii) *if σ is a size-minimal solution of E, then σ' is also a size-minimal solution of $\rho(E)$,*
(iv) $\mathrm{eop}(\sigma) \geq \mathrm{eop}(\sigma')$,
(v) $|\,FV(E)| \geq |\,FV(\rho(E))|$, *and*
(vi) *the number of occurrences of variables in E is greater than or equal to the number of occurrences of variables in $\rho(E)$.*

Proof. The requirement $\rho \preceq_{FV(E)} \sigma$ ensures that there exists a substitution σ' such that $\sigma(X) = \sigma' \circ \rho(X)$ for any $X \in FV(E)$. The restriction of σ' to the domain $FV(\rho(E))$ also satisfies this property. Therefore, the required σ' always exists.

Since σ is a solution of E, for any variable $X \in FV(E)$, $\sigma(X)$ is a closed term. Moreover, since $\sigma = (\sigma' \circ \rho)|_{FV(E)}$, for any variable $X \in FV(E)$, $\sigma(X) = \sigma' \circ \rho(X)$. The same applies to any term containing only variables of E, hence to any side of any equation of E. Therefore, for any equation $\rho(s) \stackrel{?}{=} \rho(t)$ of $\rho(E)$, we have $\sigma'(\rho(s)) = \sigma(s) = \sigma(t) = \sigma'(\rho(t))$. Hence, σ' solves $\rho(E)$.

Minimality is proved by contradiction. Assume that σ' is not size-minimal. Let τ' be a size-minimal solution of $\rho(E)$. Obviously, $\tau' \circ \rho$ is a solution of E. Since τ' is size-smaller than σ', we have $\sum_{X \in FV(\rho(E))} |\tau'(X)| < \sum_{X \in FV(\rho(E))} |\sigma'(X)|$. Now, since ρ is a partial instantiation, we have

$$\sum_{X \in FV(E)} |\tau'(\rho(X))| = \sum_{X \in FV(E)} |\rho(X)| + \sum_{Y \in FV(\rho(E))} (|\tau'(Y)| - 1) \quad \text{and}$$

$$\sum_{X \in FV(E)} |\sigma'(\rho(X))| = \sum_{X \in FV(E)} |\rho(X)| + \sum_{Y \in FV(\rho(E))} (|\sigma'(Y)| - 1).$$

Therefore, $\sum_{X\in FV(E)} |\tau'(\rho(X))| < \sum_{X\in FV(E)} |\sigma'(\rho(X))| = \sum_{X\in FV(E)} \sigma(X)$, which contradicts the assumption that σ is size-minimal.

Let $X' \in Dom(\sigma')$ be a variable, and let v be a nonempty word, such that $\sigma'(X') = \lambda y\,.\,u\,v^{\mathrm{eop}(\sigma')}\,w\,\flat$ (or similarly replacing $\flat$ by y). Since $Dom(\sigma') = FV(\rho(E))$, either $X' \in FV(E)$ or, for some variable $Y \in FV(E)$, $\rho(Y)$ contains X. Hence, in both cases, there exists a variable $X \in FV(E) \subseteq Dom(\sigma)$ such that $\sigma(X)$ contains $v^{\mathrm{eop}(\sigma')}$. Therefore $\mathrm{eop}(\sigma)$ is at least $\mathrm{eop}(\sigma')$.

The requirement that ρ is a partial instantiation ensures that after applying this substitution the number of variables and the number of occurrences of variables in E do not increase. □

Now we deal with the following case: There are compacted sets of equations whose graph of surface dependencies does not have any cycle, and the focused solution does not have any small component; i.e., we deal with the case not covered by Lemmas 6.6 and 6.12. Since there are no cycles, the edges define a partial order $\succ$ on the nodes, with $N \succ N'$ if and only if $N \to N'$ is an edge. Hence we can speak of $\succ$-maximal nodes. Since there are size-minimal solutions without small components, Lemma 6.8 shows that these graphs contain at least one edge, Lemma 6.10 states that they do not contain strong divergences, and Lemma 6.7 shows that they do not contain any edge to the node labeled with $\emptyset$. There is a $\succ$-maximal node with at least one outgoing edge to other nodes and without any strong divergence. We will transform the equations, whose graph of dependencies contains such maximal nodes, in order to obtain a description of some variable instantiation. In fact, this transformation on the equations carries over to a graph transformation. An example of this graph transformation (or rewriting) is shown in Example 7.

DEFINITION 7.3. *Let $\langle E, G\rangle$ with $FV(E) \neq \emptyset$ be a simplified and compacted set of equations without cycles such that there is a solution without small components. Then the transformation rule $\langle E, G\rangle \Rightarrow \langle E', G'\rangle$ is defined as follows.*

Let D be the graph of surface dependencies of $\langle E, G\rangle$. Let $[X]$ be a $\succ$-maximal node in D with at least one outgoing edge. Let $\{a_1, \ldots, a_m\}$ be the set of all labels of the outgoing edges of $[X]$, where w_{a_1} is a prefix of w_{a_i}, for all $i = 1, \ldots, m$. For every $Y \in [X]$, let Y' be a fresh unary variable, and let ρ be the substitution that maps each $Y \in [X]$ to $\lambda y\,.\,w_{a_1}\,Y'\,y$. Then let $\langle E', G'\rangle$ be the simplification of $\langle \rho(E), G\rangle$.

If D' is the graph of surface dependencies of $\langle E', G'\rangle$, we write $D \Rightarrow D'$.

Notice that in the previous definition, since there are not any cycles and there are solutions without small components, by Lemma 6.8 there are edges, and hence there is a $\succ$-maximal node with some outgoing edge; by Lemmas 6.7 and 6.10 there are neither constant equations nor strong divergences. This allows us to assume that w_{a_1} is a prefix of w_{a_i} for $i = 1, \ldots, m$. Notice also that for all equations of the form $Y\,s \stackrel{?}{=} a\,Z\,t$, where $Y \in [X]$, the symbol a is the label of some outgoing edge of $[X]$. Finally, notice that the substitution ρ is a partial instantiation; hence Lemma 7.2 applies.

The transformation of $\langle E, G\rangle$ results in the compacted equations $\langle E', G'\rangle$ satisfying the following:

(i) The grammar G' is an extension of G such that for $i = 1, \ldots, m$, the nonterminal b_i generates the word v_i, which is defined by $w_{a_i} = w_{a_1}\,v_i$.

(ii) The set of equations E' is obtained from E by replacing all equations of the form $Y\,s \stackrel{?}{=} Z\,t$, where $Y, Z \in [X]$, by the equation $Y'\,\rho(s) \stackrel{?}{=} Z'\,\rho(t)$, and replacing every equation of the form $Y\,s \stackrel{?}{=} a_i\,Z\,t$, where $Y \in [X]$, by $Y'\,\rho(s) \stackrel{?}{=} b_i\,Z\,\rho(t)$.

Every solution σ without small components of E can be transformed into a solution of E' by defining it on the fresh variables Y' (see Lemma 7.5).

In the special case that $m = 2$, $w_{a_1} \neq w_{a_2}$, and $w_{a_1} \prec w_{a_2}$, the transformation on the graph of surface dependencies can be represented as a graph rewriting rule

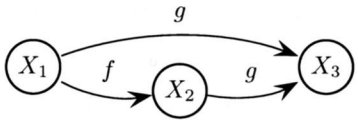
where b_2 is a new nonterminal of the grammar G', that generates a word satisfying $w_{a_2} = w_{a_1}\, w_{b_2}$.

Notice that in this rewriting process at least one arrow and also the node $[X]$ are removed. Note also that in the case $w_{a_1} = w_{a_2}$, the three nodes are merged into one node $[X'] \cup [Z_1] \cup [Z_2]$, thus removing more than one edge.

Example 7. Consider the following simplified and compacted set of equations and their set of solution components for $n \geq 0$:

$$\begin{array}{l} \Sigma = \{a, b, c, d, e\}, \\ N = \{f, g\}, \\ X_1\, c\flat \stackrel{?}{=} f\, X_2\, c\flat, \\ X_1\, d\flat \stackrel{?}{=} g\, X_3\, a\, b\, d\flat, \\ X_2\, e\flat \stackrel{?}{=} g\, X_3\, e\flat, \\ G\text{-rules: } \{f \to a\, b,\ g \to a\}. \end{array} \qquad \begin{array}{lcl} X_1 & \mapsto & \lambda x\,.\,(a\, b)^{n+2}\, x, \\ X_2 & \mapsto & \lambda x\,.\,(a\, b)^{n+1}\, x, \\ X_3 & \mapsto & \lambda x\,.\,b\,(a\, b)^{n}\, x, \end{array}$$

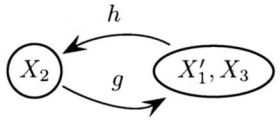
The graph of surface dependencies is



Applying the transformation rule to the only $\succ$-maximal node $[X_1]$, we get the following simplified and compacted set of equations E':

$$\begin{array}{l} \Sigma = \{a, b, c, d, e\}, \\ N' = \{f, g, h\}, \\ X_1'\, c\flat \stackrel{?}{=} h\, X_2\, c\flat, \\ X_1'\, d\flat \stackrel{?}{=} X_3\, a\, b\, d\flat, \\ X_2\, e\flat \stackrel{?}{=} g\, X_3\, e\flat, \\ G'\text{-rules: } \{f \to a\, b,\ g \to a,\ h \to b\}. \end{array}$$

The modified graph is as follows:



LEMMA 7.4 (rewriting). *Let $\langle E, G\rangle$ be a simplified and compacted set of equations, and let $\langle E, G\rangle \Rightarrow \langle E', G'\rangle$; then*

$$\begin{array}{lcl} |G'| & \leq & |G| + \#Eq(E)\ depth(G), \\ depth(G') & = & depth(G). \end{array}$$

Moreover, $|E'| \leq |E| + m$*, where* m *is the number of variable occurrences of* E*.*

Proof. Let m be the number of outgoing edges of the removed node. The new grammar G' extends G by defining $m-1$ suffixes of words defined by G. Therefore, according to Lemma 4.6, we can obtain such a grammar G' satisfying the upper bounds:

$$\begin{array}{lcl} |G'| & \leq & |G| + (m-1)\, depth(G), \\ depth(G') & = & depth(G). \end{array}$$

It is easy to check that $m \leq \#Eq(E)$.

Finally E' is obtained by replacing in E the variable occurrences of some variables Y (belonging to $[X]$) by $b\,Y'$ and then simplifying. This simplification only has to remove the same nonterminal symbol from the head of both sides of some equations; hence it does not increase the size of the grammar. Therefore, the rewriting increases the size of E at most by 1 for each variable occurrence in E. □

LEMMA 7.5. *For any simplified and compacted set of equations* $\langle E, G\rangle$ *without cycles in its graph of surface dependencies, any solution* σ *without small components, and any transformation* $\langle E, G\rangle \Rightarrow \langle E', G'\rangle$ *defined by the substitution* ρ*, there exists a substitution* σ' *such that*

(i) σ' *is a solution of* $\langle E', G'\rangle$*,*

(ii) σ' *satisfies* $\sigma = (\sigma' \circ \rho)|_{FV(E)}$*.*

Proof. If there are not any small components, then the substitution ρ satisfies $\rho \preceq_{FV(E)} \sigma$. Then the lemma is a direct consequence of Lemma 7.2. □

The previous lemma may be iterated: If σ' does not contain small components, and the graph of surface dependencies of $\langle E', G'\rangle$ does not contain cycles, we use it again to obtain a new solution σ'' of a new $\langle E'', G''\rangle$ and so on. By Lemma 7.6, this process cannot be repeated more than $\#Eq(E)$ times.

LEMMA 7.6. *Any graph rewriting sequence* $D \Rightarrow^* D'$ *has length at most* $|D|$*.*

Proof. This is clear, since in every transformation step at least one edge is removed. □

In Figure 7.1 we define an algorithm that, given the compacted set of equations $\langle E, G\rangle$ and a size-minimal solution σ, computes a polynomial-sized compacted solution $\langle \rho, G'\rangle$ representing σ. Note that the complexity of this algorithm is irrelevant; only the polynomial size of the obtained representation will be needed.

THEOREM 7.7 (compacted solution). *Given the initial compacted set of equations* $\langle E_0, G_0\rangle$ *and the size-minimal solution* σ_0*, the algorithm of Figure* 7.1 *computes a compacted solution* $\langle \rho, G'\rangle$ *representing* σ_0*.*

Moreover, the following inequalities hold:

$$\begin{array}{lcl} |G'| & \leq & |G_0| + \mathcal{O}(|E_0|^4\ depth(G_0) + |E_0|^6), \\ depth(G') & \leq & depth(G_0) + \mathcal{O}(|E_0|^2), \\ |\rho| & = & \mathcal{O}(|E_0|^3). \end{array}$$

Proof. The algorithm performs a sequence of transformations on the compacted equations $\langle E, G\rangle$, the compacted substitution $\langle \rho, G\rangle$, and the solution σ. These transformations are of four types: simplification (step 6), small components (step 9), cycles (step 16), and rewriting (step 23). First we show how many transformations of each type are performed and then how they modify some of the measures of the representations (number of equations, their size, etc.).

(i) *Termination*: Cycle and small component transformations remove a variable from E; therefore they cannot be executed more than $|E_0|$ times. According

Input: σ_0, $\langle E_0, G_0\rangle$

34. $\rho := \rho|_{FV(E_0)}$

FIG. 7.1. *Pseudocode of the algorithm to compute a representation ρ of a solution.*

to Lemma 7.6, rewriting sequences cannot be longer than $|D|$. The size $|D|$ of the graph of surface dependencies is bounded by the number of equations (we will see in the following that this measure is decreasing), hence by $|E_0|$. After every rewriting sequence we get a set of equations E with a cycle, or a solution σ with a small component. Therefore, there is a total number of at most $|E_0|^2$ rewriting steps. Finally, after every rewriting step we get a simplified set of equations. Therefore, we cannot perform more simplification steps than cycle elimination plus small component elimination steps, hence not more than $|E_0|$.

(ii) *Number of equations, variables, and occurrences of variables*: Simplifications preserve or decrease all these parameters, as well as the partial instantiations performed by the cycle and small component transformations, according to Lemma 7.2. Rewritings are composed by a partial instantiation followed by a simplification; therefore they also preserve or decrease these parameters.

(iii) *Size of the equations,* $|E|$: The size of E is preserved or decreases with simplifications, cycles, and small component steps. However, it can be increased in the number of occurrences of variables at every rewriting step (see Lemma 7.4). Since there are no more than $|E_0|^2$ rewriting steps and the increase is bounded by $|E_0|$, we have $|E| \leq |E_0| + |E_0|^3$ along the execution of the algorithm.

(iv) *Exponent of periodicity,* $\mathrm{eop}(\sigma)$: According to Lemma 7.2, the exponent of periodicity of the solution, after a partial instantiation like the ones we perform in the cycle, small component and rewriting steps, is preserved or decreases. Since by Lemma 2.4, $\mathrm{eop}(\sigma_0) \leq 2^{\alpha\,|E_0|}$ for the initial minimal solution σ_0, this bound holds along the execution of the algorithm.

(v) *Depth of the grammar,* $depth(G)$: There are the following possibilities:

$$\begin{array}{lcll}
depth(G') & = & depth(G) + \mathcal{O}(\log|E|) & \text{(simplification, Lemma 6.2),}\\
depth(G') & = & depth(G) & \text{(small component, Lemma 6.6),}\\
depth(G') & = & depth(G) + \mathcal{O}(\log \#Eq(E) & \\
 & & \quad + \log \mathrm{eop}(\sigma)) & \text{(cycle, Lemma 6.12),}\\
depth(G') & = & depth(G) & \text{(rewriting, Lemma 7.4).}
\end{array}$$

Since $\log \mathrm{eop}(\sigma) = \mathcal{O}(|E_0|)$ and the number of cycle steps as well as of simplifications is at most $|E_0|$, an upper bound is $depth(G) = depth(G_0) + \mathcal{O}(|E_0|^2)$.

(vi) *Size of the grammar,* $|G|$: There are the following possibilities:

$$\begin{array}{lcll}
|G'| & = & |G| + \mathcal{O}(|E|(depth(G) + \log|E|)) & \text{(simplification, Lemma 6.2),}\\
|G'| & \leq & |G| + depth(G) & \text{(small component, Lemma 6.6),}\\
|G'| & = & |G| + \mathcal{O}(depth(G) + \#Eq(E) & \\
 & & \quad + \log \mathrm{eop}(\sigma)) & \text{(cycles, Lemma 6.12),}\\
|G'| & \leq & |G| + \#Eq(E)\ depth(G) & \text{(rewriting, Lemma 7.4).}
\end{array}$$

We know that the maximal number of rewriting steps is $|E_0|^2$ and the maximal number of small component, simplification, and cycle steps is at most $|E_0|$. We also have $\log \mathrm{eop}(\sigma) = \mathcal{O}(|E_0|)$, $|E| = \mathcal{O}(|E_0|^3)$, and $\#Eq(E) = \mathcal{O}(|E_0|)$. Together with the upper bound on $depth(G)$, this gives an upper bound (simplification is responsible for the dominating terms):

$$\begin{array}{rcl}
|G'| & = & |G_0| + |E_0|\,\mathcal{O}(|E_0|^3(depth(G) + \log|E_0|^3)),\\
 & & \quad + |E_0|\,depth(G),\\
 & & \quad + |E_0|\,\mathcal{O}(depth(G) + |E_0|),\\
 & & \quad + 6|E_0|^2\,|E_0|\ depth(G),\\
 & = & |G_0| + \mathcal{O}(|E_0|^4\,depth(G_0) + |E_0|^6).
\end{array}$$

(vii) *Size of the compacted solution,* $|\rho|$: We have to represent the instantiation of at most $|E_0|$ variables, where the size of each instantiation is bounded by the number of rewriting steps. This gives $\mathcal{O}(|E_0|^3)$.

All the transformations are sound according to Lemma 7.2. Now, if the compacted equations are not simplified, we can always simplify them. If they are simplified, either there is a cycle, or a solution with small components, or we can rewrite the equations. □

8. Main results and some remarks. Theorem 7.7 states that, given a compact representation $\langle E, G\rangle$ of a set of equations, we can build a new singleton grammar G' of polynomial size defining all components of the compact representation of a size-minimal solution. The final step is to use Plandowski's theorem (Theorem 4.2) to check that the polynomial-sized guessed substitution is really a unifier.

MAIN THEOREM 8.1. *Solvability of compact representations of basic MSOU problems is NP-complete.*

Proof. Theorem 7.7 shows that for every compact representation $\langle E, G\rangle$ of a basic MSOU problem and every size-minimal solution σ, there is compacted solution $\langle \rho, G'\rangle$ that represents σ, where G' is a singleton grammar of polynomial size in $|E| + |G|$ and $|\rho|$ is also polynomial in $|E|$.

Thus we can guess a polynomial-sized singleton grammar G' and a compacted solution ρ as above, and then test whether $\langle \rho, G'\rangle$ is a solution of $\langle E, G\rangle$. We can replace every variable occurrence in E by its instantiation in ρ, then normalize both sides of each equation $s_i \stackrel{?}{=} t_i$, to obtain $s'_i \stackrel{?}{=} t'_i$, and, finally, extend G' to obtain G'' by Lemma 4.4, generating $s'_1 \# \cdots \# s'_n$ and $t'_1 \# \cdots \# t'_n$, where $\#$ is a new constant symbol. Then, the test for solvability is an equality test w.r.t. the singleton grammar G'', which can be performed in polynomial time by Plandowski's theorem (see Theorem 4.2). This shows that the problem is in NP. Together with the NP-hardness of the problem, which was proved in [22], this leads us to conclude that the problem is NP-complete. □

COROLLARY 8.2. *Monadic second-order unification is NP-complete.*

Proof. The proof follows from Theorem 8.1 and Proposition 3.1. □

COROLLARY 8.3. *Monadic second-order matching is NP-complete.*

Proof. The proof follows from Theorems 2.6 and 8.1. □

Remark 1. Theorem 7.7 clarifies the increase of the size of the grammar representing a size-minimal solution of some compacted equations, after instantiating N variables. This theorem fixes the increase w.r.t. the size of the equations, the logarithm of the upper bound on the exponent of periodicity, and the *depth* of the grammar. The question is then, *Could we avoid the use of the depth of the grammar?* The answer is no. For instance, Lemma 4.6 says that, if we want to define a prefix of some word defined by a grammar G, in the worst case, we can keep the depth, but we may need to increase the size of G' as $|G'| \leq |G| + \mathit{depth}(G)$. If we use only the size of the grammar to characterize it, then in the worst case we may be forced to duplicate the size of the grammar $|G'| \leq 2\,|G|$. Each time that we instantiate a variable, it can be necessary to define a new prefix; therefore, in the worst case, the size of the resulting grammar would be 2^N, being $N \leq |E|$ the number of variables.

The combined use of size and depth allows us to keep track of balancing conditions of singleton grammars as trees and also to provide tighter measures.

Remark 2. Our method computes a compact representation of a size-minimal solution. This means that every solvable MSOU problem has at least one solution that can be represented by a polynomial-sized grammar. Our method can easily be extended to compute a compact representation of any solution; however, there is no longer any size-bound. If one is interested in representing all solutions, then our method does not help, since singleton grammars do not support the representation of infinite sets of words; e.g., the representation of $\{(a\,b)^n \mid n \in \mathbb{N}\}$ is not possible. Note that there is already an investigation of a representation of sets of solutions using words with exponents for MSOU (see [2]).

9. Conclusions. In this paper we proved in Corollary 8.2 that monadic second-order unification (MSOU) is in NP using a result of Plandowski about context-free grammars [17, 18] and the exponential bound on the exponent of periodicity [23, 22]. These results, together with the NP-hardness of the problem [22], prove its NP-completeness. As we mention in the introduction, MSOU is a specialization of bounded second-order unification (BSOU) [22], a variant of second-order unification, where instantiations of second-order variables can use their argument a bounded number of times. During revision of this paper we were able to apply variants of this method to prove that BSOU [11] and stratified context unification [12] are also NP-complete.

THE SPECTRAL METHOD FOR GENERAL MIXTURE MODELS*

RAVINDRAN KANNAN†, HADI SALMASIAN‡, AND SANTOSH VEMPALA§

Abstract. We present an algorithm for learning a mixture of distributions based on spectral projection. We prove a general property of spectral projection for arbitrary mixtures and show that the resulting algorithm is efficient when the components of the mixture are logconcave distributions in $\Re^n$ whose means are separated. The separation required grows with k, the number of components, and $\log n$. This is the first result demonstrating the benefit of spectral projection for *general* Gaussians and widens the scope of this method. It improves substantially on previous results, which focus either on the special case of spherical Gaussians or require a separation that has a considerably larger dependence on n.

Key words. logconcave distributions, mixture models, principal component analysis, singular value decomposition

1. Introduction.

Mixture models are widely used for statistical estimation, unsupervised concept learning, and text and image classification [12, 17]. Roughly speaking, a finite mixture model is a weighted combination of a finite number of distributions of a known type. More precisely, the problem of learning or estimating a mixture model is formulated as follows. We assume that we get samples from a distribution F on $\Re^n$ which is a mixture (convex combination) of unknown distributions $F_1, F_2, \ldots, F_k$, with (unknown) mixing weights $w_1, w_2, \ldots, w_k > 0$, i.e., $F = \sum_{i=1}^k w_i F_i$, where $\sum_{i=1}^k w_i = 1$. The goal is to (a) classify the sample points according to the underlying distributions and (b) estimate essential parameters of the components such as the mean and covariance matrix of each component. This problem has been widely studied, particularly for the special case when each F_i is a Gaussian.

One algorithm that is often used is the expectation-maximization (EM) algorithm [5, 21]. It is quite general but does not have guarantees on efficiency and could even converge to an incorrect or suboptimal classification. A second known technique, from statistics, projects the sample points to a random low-dimensional subspace and then tries to find the right classification by exploiting the low dimensionality and exhaustively examining all possible classifications. The trouble is that two different densities may overlap after projection—the means of the projected densities may coincide (or get closer), making it hard to separate the samples.

In this paper, we investigate a learning method which is based on principal component analysis (PCA). The idea of this method is known as spectral projection, i.e., representation of data in the subspace spanned by its top k principal components. We present our results following a discussion of the relevant literature.

1.1. Recent theoretical work. There has been progress in recent years in finding algorithms with rigorous theoretical guarantees [3, 2, 4, 19], mostly for the important special case of learning mixtures of Gaussians. These algorithms assume a separation between the means of each pair of component distributions which depends on the variances of the two distributions and also on n and k. For a component F_i of the mixture let μ_i denote its mean and σ_i denote the maximum standard deviation along any direction in $\Re^n$ (see section 1.3). In order for the classification problem to have a well-defined (unique) solution with high probability, any two components i, j must be separated by $\sigma_i + \sigma_j$ times a logarithmic factor; if the separation is smaller than this, then the distributions may "overlap" significantly; namely, some of the samples have a good chance of coming from more than one component. Dasgupta [3] showed that if each mixing weight is $\Omega(1/k)$ and the variances are within a bounded range, then a separation of (the Ω^* notation suppresses logarithmic terms and error parameters)

$$|\mu_i - \mu_j| = (\sigma_i + \sigma_j)\Omega^*(n^{1/2})$$

is enough to efficiently learn the mixture.

Shortly thereafter, this result was improved by Dasgupta and Schulman [4] and Arora and Kannan [2], who reduced the separation required to

$$|\mu_i - \mu_j| = (\sigma_i + \sigma_j)\Omega^*(n^{1/4}).$$

In [4], the algorithm used is a variant of EM (and requires some technical assumptions on the variances), while the result of [2] works for general Gaussians using distance-based classification. The idea is that at this separation, it is possible to examine just the pairwise distances of the sample points and infer the right classification with high probability.

The dependence on n is critical; typically n represents the number of attributes and is much larger than k, the size of the model. Further, the underlying method used in these papers, namely, distance-based classification, inherently needs such a large separation that grows with n [2].

In [19], a spectral algorithm was used for the special case of spherical Gaussians, and the separation required was reduced to

$$|\mu_i - \mu_j| = (\sigma_i + \sigma_j)\Omega^*(k^{1/4}).$$

Since in several applications k is a constant which is much less than n, this result is a substantial improvement for the spherical case. The algorithm uses a projection of the sample onto the subspace spanned by the top k singular vectors of the distribution (i.e., the singular vectors of a matrix, each of whose rows is one of the independent and identically distributed (i.i.d) samples drawn according to the mixture), also called the SVD subspace. The idea there is that the SVD subspace of a mixture of spherical Gaussians *contains* the means of the k components. Hence, after projection onto this subspace the separation between the means is preserved. On the other hand, each component is still a Gaussian and the dimension is only k, and so the separation required is only a function of k. Further, the SVD subspace computed from a random sample is "close" to the means, and this is used in the algorithm.

1.2. New results. Given the success of the spectral method for spherical Gaussians, a natural question is whether it can be used for more general distributions, in particular for nonspherical Gaussians. At first sight, the method does not seem to

be applicable. The property that the SVD subspace of the distribution contains the means is clearly false for nonspherical Gaussians; e.g., see Figure 1. In fact, the SVD subspace can be orthogonal to the one spanned by the means, and so using spectral methods might seem hopeless.

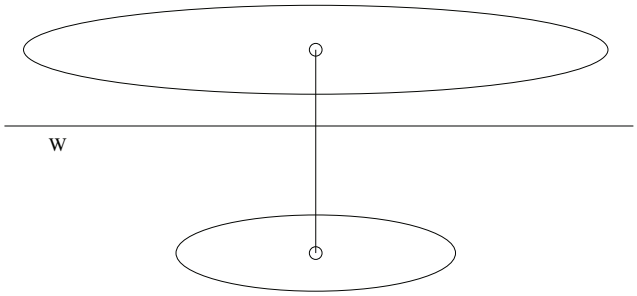

FIG. 1. *The SVD subspace W; the plane that minimizes the average squared distance and is represented by the horizontal line might miss the means of the components.*

The key insight of this paper is that while according to this (misleading) example the SVD subspace may not contain the means, it is always *close* (in an average sense) to the means of the distributions (Theorem 1). As a result, upon projection onto this subspace, the intermean distances are approximately preserved "on average." Moreover, this property is true for a mixture of *arbitrary* distributions.

It is then a reasonable idea to project the sample to the SVD subspace to reduce the dimensionality. To identify individual components in this subspace, we need them to remain nonoverlapping. If the mixture is arbitrary, then even though the means are separated on average, the samples could intermingle. To overcome this, we assume that the component distributions are logconcave.

A function $f : \Re^n \to \Re_+$ is logconcave if its logarithm is concave; i.e., for any two points $x, y \in \Re^n$ and any $\lambda \in [0, 1]$,

$$f(\lambda x + (1 - \lambda)y) \geq f(x)^{\lambda} f(y)^{1-\lambda}.$$

These functions have many useful properties; e.g., the product, minimum, and convolution of two logconcave functions are also logconcave [6, 11, 15]. Logconcave densities are a powerful generalization of Gaussians. Besides Gaussians, many other common probability measures, such as exponential families and the uniform measure over a convex set, are logconcave. So, for example, one component of the mixture could be a Gaussian while another is the uniform distribution over a cube. The following properties make these distributions suitable for our purpose: (a) the projection of a logconcave distribution remains logconcave; (b) the distance of a random point from the mean has an exponentially decreasing distribution.

In section 3, we give an iterative spectral algorithm that identifies one component of the mixture in each iteration. It should be emphasized that there are many possible alternatives for identifying the components *after* projection (e.g., the EM algorithm), and we expect they will also benefit from the enhancement provided by projection. For the postprojection algorithm presented here, we assume that each mixing weight is at least ε and the pairwise separation satisfies

$$|\mu_i - \mu_j| = (\sigma_i + \sigma_j)\Omega^*(k^{\frac{3}{2}}/\varepsilon^2).$$

More precisely, our algorithm requires only a lower bound ε, a probability of error δ, an upper bound k, and a sample set from an n-dimensional mixture distribution of size $\Omega(\frac{nk}{\varepsilon^3}\log^5(nk/\delta))$ which satisfies the given separation, and it classifies all but a fixed number with probability at least $1-\delta$. For a precise statement of our main result together with the exact form of the required separation, see Theorem 3. It is easy to see that it requires time polynomial in $n, \varepsilon, \log(\frac{1}{\delta})$. After classification, the means and covariance matrices of the components can be estimated efficiently. For the special case of Gaussians, $O(n\log^3(n/\delta)/\varepsilon^2)$ samples suffice. Table 1 presents a comparison of algorithms for learning mixtures (logarithmic terms are suppressed).

1.3. Notation. This section introduces the notation used throughout the paper. For readers' convenience, in Table 2 we provide a quick reference to some of our notation. A mixture F has k components $F_1, \ldots, F_k$. We denote their mixing weights by $w_1, \ldots, w_k$ and their means by $\mu_1, \ldots \mu_k$. The maximum variance of F_i in any direction is denoted by σ_i^2. For any subspace W, we denote the maximum variance of F_i along any direction in W by $\sigma_{i,W}^2$. Namely, we set

$$\sigma_i^2 = \max_{v\in\Re^n, ||v||=1} \left\{ \int_{\Re^n} |(x-\mu_i)\cdot v|^2 F_i(x)dx \right\}$$

and

$$\sigma_{i,W}^2 = \max_{v\in W, ||v||=1} \left\{ \int_{\Re^n} |(x-\mu_i)\cdot v|^2 F_i(x)dx \right\}.$$

Let S be a set of i.i.d. samples from F. One can think of S as being picked as follows: first, i is picked from $\{1, 2, \ldots, k\}$ with probability w_i (unknown to the algorithm); then a sample is picked from F_i. We can partition S as

$$S = S_1 \cup S_2 \cup \cdots \cup S_k,$$

where each S_i is from F_i (note: this partition of S is unknown to the algorithm). For each i, we denote by μ_i^S the sample mean, i.e.,

$$\mu_i^S = \frac{1}{|S_i|}\sum_{x\in S_i} x.$$

For a subspace V and a vector x, we write $d(x, V)$ for the orthogonal distance of x from V.

For any set of points S, we can form a matrix A whose rows are the points in S. The subspace spanned by the top k right singular vectors of A will be called the *SVD subspace* of S. The SVD subspace can be found efficiently (i.e., in polynomial time). For more on properties and applications of SVD subspaces, see [8].

For any subspace W, we denote the maximum variance of a set of sample points in $S = S_1 \cup \cdots \cup S_k$ which belong to S_i along any direction in W by $\hat{\sigma}_{i,W}^2(S)$. Namely, we set

$$\hat{\sigma}_{i,W}^2(S) = \max_{v \in \Re^n, ||v||=1} \left\{ \frac{1}{|S_i|} \sum_{x \in S_i} |(x - \mu_i^S) \cdot v|^2 \right\}.$$

If there is no ambiguity about the set S or the space W, we use a simplified notation such as $\hat{\sigma}_{i,W}^2$ or $\hat{\sigma}_i^2$.

2. The SVD subspace. In this section, we prove an important property of spectral projection. The theorem says that the SVD subspace of a sample is close to the means of the samples from each component of the mixture, where "close" is in terms of the sample variances. Note that the theorem holds for *any* mixture, but in the analysis of our algorithm, we will apply it only to mixtures of logconcave distributions. We prove that

$$\sum_{i=1}^{k} w_i d(\mu_i, W)^2 \leq k \sum_{i=1}^{k} w_i \sigma_i^2. \tag{1}$$

Here W is the SVD subspace of the entire distribution (subspace spanned by the top k principal components of the distribution). In Theorem 1 we state and prove a variation of this inequality for samples, but it can also be proved in a similar fashion.

THEOREM 1. *Let $S = S_1 \cup S_2 \cup \cdots \cup S_k$ be a sample from a mixture F with k components such that S_i is from the ith component F_i, and let W be the SVD subspace of S (see section 1.3). For each i, let μ_i^S be the mean of S_i and $\hat{\sigma}_{i,W}^2(S)$ be the maximum variance of S_i along any direction in W. Then*

$$\sum_{i=1}^{k} |S_i| d(\mu_i^S, W)^2 \leq k \sum_{i=1}^{k} |S_i| \hat{\sigma}_{i,W}^2(S).$$

Proof. We begin by stating a general lemma which follows immediately from the Pythagorean theorem.

LEMMA 2. *Given $p, p_1, \ldots, p_K \in \Re^n$, if $\mu_P = \frac{1}{K}\sum_{i=1}^K p_i$, then*

$$\sum_{i=1}^K |p_i - p|^2 = K|p - \mu_P|^2 + \sum_{i=1}^K |p_i - \mu_P|^2.$$

Lemma 2 is used in the proof of the following theorem.

Let M be the span of $\mu_1^S, \mu_2^S, \ldots, \mu_k^S$. For $x \in \Re^n$, write $\pi_M(x)$ for the projection of x onto M and $\pi_W(x)$ for the projection of x onto W.

Using Lemma 2 and the facts that μ_i^S is the average of $x \in S_i$ and $\mu_i^S \in M$, we write

$$\begin{aligned}\sum_{x\in S} |\pi_M(x)|^2 &= \sum_{i=1}^k \sum_{x\in S_i} |\pi_M(x) - \mu_i^S|^2 + \sum_{i=1}^k |S_i||\mu_i^S|^2 \\ &\geq \sum_{i=1}^k |S_i||\mu_i^S|^2 \\ &= \sum_{i=1}^k |S_i||\pi_W(\mu_i^S)|^2 + \sum_{i=1}^k |S_i| d(\mu_i^S, W)^2. \qquad (2)\end{aligned}$$

Let $\vec{e}_1, \ldots, \vec{e}_k$ be an orthonormal basis for W. Using Lemma 2 and the fact that the variance of S_i along any direction in the k-dimensional subspace W is at most $\hat{\sigma}_{i,W}^2(S)$, we have

$$\begin{aligned}\sum_{x\in S} |\pi_W(x)|^2 &= \sum_{i=1}^k \sum_{x\in S_i} |\pi_W(x - \mu_i^S)|^2 + \sum_{i=1}^k |S_i||\pi_W(\mu_i^S)|^2 \\ &\leq \sum_{i=1}^k \sum_{j=1}^k \sum_{x\in S_i} |\pi_W(x - \mu_i^S)\cdot \vec{e}_j|^2 + \sum_{i=1}^k |S_i||\pi_W(\mu_i^S)|^2 \\ &\leq k\sum_{i=1}^k |S_i|\hat{\sigma}_{i,W}^2(S) + \sum_{i=1}^k |S_i||\pi_W(\mu_i^S)|^2. \qquad (3)\end{aligned}$$

It is well known that the SVD subspace maximizes the sum of squared projections among all subspaces of rank at most k (alternatively, it minimizes the sum of squared distances to the subspace; see, e.g., [8]). From this, we get

$$\sum_{x\in S} |\pi_W(x)|^2 \geq \sum_{x\in S} |\pi_M(x)|^2.$$

Using this, the right-hand side (RHS) of (3) is at least the RHS of (2), and the theorem follows. ∎

Although we will apply Theorem 1 only for logconcave component distributions, it suggests a benefit for spectral projection more generally. Inequality (1) puts a lower bound on the average squared distance between component means after projection; if the means are well separated to begin with, they continue to be, in an average sense. On the other hand, the distance of a point from the mean of its distribution can shrink only upon projection, thus magnifying the ratio of intercomponent distance to intracomponent distance. This aspect is studied further along with empirical results in [20].

3. An iterative spectral algorithm. In this section, we describe the algorithm. It follows the method suggested by Theorem 1, namely, to project onto the SVD subspace and to try to identify components in that subspace. However, since pairwise distances are preserved only in an average sense, it is possible that some means are very close to each other in the projected subspace and we cannot separate the corresponding samples. To get around this, we will show that all "large" components remain well separated from the rest and there is at least one large component. We identify this component, filter it from the sample, and repeat. For technical reasons (see below), the samples used to compute the SVD are discarded. The input to the algorithm below is a set of N i.i.d. samples, a weight lower bound $0 < \varepsilon < 1$, a maximum probability of error δ, a lower bound k for the number of distributions, and a parameter $N_0 < N$.

ALGORITHM.

Repeat while there are samples left:

1. For a subset S of size N_0, find the k-dimensional SVD subspace W.
2. Discard S and project the rest, T, to the subspace W.
3. For each projected point p:
   --- Find the closest $\varepsilon N/2$ points. Let this set be $T(p)$ with mean $\mu(p)$.
   --- Form the matrix $A(p)$ whose rows are x-$\mu(p)$ for each x in $T(p)$. Compute the largest singular value $\sigma(p)$ of $A(p)$ (note: this is the maximum standard deviation of $T(p)$ over all directions in W).
4. Find a point p_0 for which $\sigma(p_0)$ is maximum. Let T_0 be the set of all points of T whose projection to W is within distance $\frac{2^8\sqrt{k}\log(\frac{Nk}{\delta})}{\varepsilon}\sigma(p)$ of p_0.
5. Label T_0 as one component; estimate its mean and covariance matrix.
6. Delete T_0 from T.

In step 3 of the algorithm, for any point p, the top singular value $\sigma(p)$ of $A(p)$ can also be expressed as follows:

$$\sigma(p)^2 = \max_{v \in W, |v|=1} \frac{1}{|T(p)|} \sum_{q \in T(p)} |q \cdot v|^2 - \left(\frac{1}{|T(p)|} \sum_{q \in T(p)} q \cdot v \right)^2.$$

This value is an estimate of the maximum variance of the entire subsample of the component to which p belongs.

There is a technical issue concerning independence. If we use the entire sample to compute the SVD subspace W, then the sample is not independent from W. So we use a subset S to compute the SVD subspace in each iteration and discard it. The rest of the sample, i.e., the part not used for SVD computation, is classified correctly with high probability. The size of the subset S in each iteration is N_0, where

$$N_0 = 100 \frac{n}{\varepsilon^2} \log^5 \frac{nk}{\delta}.$$

Let $0 < \varepsilon, \delta < 1$. Our main result is the following guarantee for the proposed algorithm.

THEOREM 3. *Suppose we have N i.i.d. samples from a mixture F of k logconcave distributions with mixing weights at least ε and the means of the components separated as follows:*

$$\forall\, i,j \quad |\mu_i - \mu_j| \geq 2^{11}(\sigma_i + \sigma_j)\left(\frac{k^{\frac{3}{2}}}{\varepsilon^2}\right)\log^2\left(\frac{Nk}{\delta}\right).$$

There exists an absolute constant C such that if $N > C\frac{kN_0}{\varepsilon}$, then the iterative spectral algorithm correctly classifies $N - kN_0$ samples with probability at least $1-\delta$ (a subset of kN_0 samples is used by the algorithm and discarded).

Remark. A crude upper bound of $C < 10^6$ can be obtained quite easily by tracing through the proof of Theorem 3. More careful estimates should yield a much smaller upper bound.

We will prove Theorem 3 in the next section. The following corollary of Theorem 3 provides a second guarantee for the algorithm in terms of estimating the means and covariances of the distributions.

COROLLARY 4. *Let $0 < \eta < 1$, and suppose we are given N i.i.d. samples from a mixture F of k logconcave distributions in $\Re^n$, with mixing weights at least ε and the means separated as stated in Theorem 3. For any $1 \leq i \leq k$, let μ_i be the mean and $A_i = \mathsf{E}_{F_i}\left((x-\mu_i)(x-\mu_i)^T\right)$ be the covariance matrix of F_i. If $N = \Omega^*(\frac{nk^2}{\delta^2\eta^2\varepsilon^3})$, then using the iterative spectral algorithm we can find approximations $\mu_1', \ldots, \mu_k'$ to the means and $A_1', \ldots, A_k'$ to the covariance matrices of the components $F_1, \ldots, F_k$ of the sample such that with probability at least $1-\delta$, for $1 \leq i \leq k$,*

$$|\mu_i - \mu_i'| \leq \eta\sigma_i \quad \text{and} \quad ||A_i - A_i'|| \leq \eta\sigma_i^2,$$

where $||\cdot||$ is the spectral norm of the matrix.

The proof of Corollary 4 is given in section 4.4.

4. Analysis.

4.1. Preliminaries. We begin with some properties of logconcave distributions, paraphrased from [13]. The proof of the first uses a theorem from [16] (see also Proposition 2.11 of [7]).

LEMMA 5. *Let $0 < \eta < 1$ and $y_1, \ldots, y_m$ be i.i.d. samples from a logconcave distribution G in $\Re^n$ whose mean is the origin. There is an absolute constant C such that for*

$$m > C\frac{n}{\eta^2}\log^5\left(\frac{n}{\eta\delta}\right)$$

with probability at least $1-\delta$, for any vector $v \in R^n$,

$$(1-\eta)\mathsf{E}_G((v^Ty)^2) \leq \frac{1}{m}\sum_{i=1}^{m}(v^Ty_i)^2 \leq (1+\eta)\mathsf{E}_G((v^Ty)^2).$$

The next lemma is an adaptation of Lemma 5.7 of [13].

LEMMA 6. *Let F be any logconcave distribution in $\Re^n$ with mean μ and second moment $\mathsf{E}_F(|X-\mu|^2) = R^2$. There is an absolute constant c such that, for any $t > 1$,*

$$\Pr(|X-\mu| > tR) < e^{1-t}.$$

Lemma 5.5 of [13] implies the following lemma.

LEMMA 7. *Let $f : \Re \to \Re_+$ be a logconcave density function with variance σ^2. Then*

$$\max_{\Re} f(x) \le \frac{1}{\sigma}.$$

4.2. Sample properties. Assume that $m > N_0$ and T is a set of m elements consisting of i.i.d. samples generated by the mixture F. Then there is a partition T as $T = T_1 \cup T_2 \cup \cdots \cup T_k$, where T_i is the set of samples from F_i.

LEMMA 8. *With probability at least $1 - \delta/4k$, for every $i \in \{1, 2, \ldots, k\}$ we have the following:*

(a) $w_i|T| - \frac{\varepsilon}{4}|T| \le |T_i| \le w_i|T| + \frac{\varepsilon}{4}|T|$.

(b) $|\mu_i - \mu_i^T| \le \frac{\sigma_i}{4}$.

(c) *For any subspace W, $\frac{7}{8}\sigma_{i,W} \le \hat{\sigma}^2_{i,W}(T) \le \frac{8}{7}\sigma^2_{i,W}$.*

Proof.

(a) A point $x \in T$ belongs to T_i with probability w_i. If $T = \{x_1, \ldots, x_m\}$, define a random variable $Y_j, 1 \le j \le m$, as follows:

$$Y_j = \begin{cases} 1 & \text{if } x_j \in T_i, \\ 0 & \text{otherwise.} \end{cases}$$

The Y_j's are Bernoulli variables and $\mathrm{E}(Y_j) = w_i$. Therefore by Chernoff's bound (see Theorem 4.1 of [14]) we have

$$\Pr\left(\frac{Y_1 + \cdots + Y_m}{m} - w_i > \frac{\varepsilon}{4}\right) < \left(\frac{e^{\frac{\varepsilon}{4w_i}}}{(1 + \frac{\varepsilon}{4w_i})^{(1+\frac{\varepsilon}{4w_i})}}\right)^{mw_i}. \tag{4}$$

Since $w_i \ge \varepsilon$, $\varepsilon = 4tw_i$ for some $t \le \frac{1}{4}$. The RHS of (4) equals $(\frac{e^t}{(1+t)^{(1+t)}})^{mw_i}$, and one can check that for $t \le \frac{1}{4}$ we have $\frac{e^t}{(1+t)^{(1+t)}} < e^{-\frac{t^2}{4}}$. Similarly we have

$$\Pr\left(\frac{Y_1 + \cdots + Y_m}{m} - w_i < -\frac{\varepsilon}{4}\right) < (e^{-\frac{t^2}{4}})^{mw_i}.$$

It follows that Lemma 8(a) fails for distribution F_i with probability at most $2e^{-\frac{t^2}{4}mw_i}$, which is equal to $2e^{-\frac{m\varepsilon^2}{64w_i}}$. Now Lemma 8(a) follows immediately from $m \ge N_0$.

(b) For any fixed $|T_i|$, the random variable $\mu_i^T = \frac{1}{|T_i|}\sum_{x \in T_i} x$ is a convolution of logconcave distributions and hence is also logconcave. Its variance is bounded from above by $n\sigma_i^2/|T_i|$. We apply Lemma 6 to the random variable μ_i^T. Now Lemma 8(b) follows from Lemma 8(a).

(c) The proof follows immediately from Lemma 5. ∎

In our proof, we would like to apply Theorem 1. However, the theorem holds for the sample S that is used to compute the SVD subspace. The next lemma derives a similar bound for an independent sample T that is not used in the SVD computation.

LEMMA 9. *Let W be the SVD subspace obtained in the algorithm, and suppose $T = T_1 \cup \cdots \cup T_k$ is the set of sample points not used for the SVD computation in the algorithm. Then we have*

$$\sum_{i=1}^{k} |T_i| d(\mu_i^S, W)^2 \le 2k \sum_{i=1}^{k} |T_i| \hat{\sigma}_i^2, \tag{5}$$

where $\hat{\sigma}_i^2 = \hat{\sigma}_{i,W}^2(T)$ is the maximum variance of T_i along any direction in W.

Proof. First, we apply Theorem 1 to S. Then, using Lemma 8(a), we can relate $|T_i|$ to $|S_i|$, and we have

$$\sum_{i=1}^{k} |T_i| d(\mu_i^S, W) \le \frac{3}{2} k \sum_{i=1}^{k} |T_i| \hat{\sigma}_{i,W}^2(S).$$

Next, Lemma 5 implies that

$$\hat{\sigma}_{i,W}^2(S) \le \frac{7}{6} \sigma_{i,W}^2.$$

Finally, we use the lower bound in Lemma 8(c) to get the desired inequality. ∎

4.3. Proof of Theorem 3. We will prove the following claim: With probability at least $1 - \frac{\delta}{2k}$, the algorithm identifies one component exactly in any one iteration. We will prove the claim for the first iteration, and it will follow inductively for all subsequent iterations. From now on, we assume that Lemma 8 holds. Note that this happens with probability at least $1 - \frac{\delta}{4k}$.

Let $T = T_1 \cup T_2 \cup \cdots \cup T_k$ be the partition of the current sample T according to the components F_i. For each i, recall that μ_i^T is the sample mean, and define $\hat{\mu}_i^T$ to be the projection of μ_i^T onto the subspace spanned by W. Similarly, $\hat{\mu}_i^S$ and $\hat{\mu}_i$ are the projections of μ_i^S and μ_i. For convenience, we write $\hat{\sigma}_{i,W}(T)^2$ as $\hat{\sigma}_i^2$. Let

$$\alpha = 2^{11} \frac{k^{\frac{3}{2}}}{\varepsilon^2} \log^2\left(\frac{Nk}{\delta}\right) \quad \text{and} \quad \beta = \frac{\varepsilon^3}{2^{14} k \log^2(\frac{Nk}{\delta})}.$$

We say that a component F_r is *large* if the following condition holds:

$$|T_r| \hat{\sigma}_r^2 \ge \beta \max_i |T_i| \hat{\sigma}_i^2. \tag{6}$$

Recall that $|T| > N_0$. The proof of Theorem 3 is based on the next two lemmas.

LEMMA 10. *For any large component F_r, for every $i \ne r$,*

$$|\hat{\mu}_i^T - \hat{\mu}_r^T| > \frac{\alpha}{5}(\sigma_i + \sigma_r).$$

Proof. For any $1 \le j \le r$, let $d_j = d(\mu_j^S, W)$. By (5),

$$|T_r| d_r^2 \le 2k \sum_i |T_i| \hat{\sigma}_i^2 \le \frac{2k^2}{\beta} |T_r| \hat{\sigma}_r^2. \tag{7}$$

Thus,

$$d_r^2 \le \frac{2k^2}{\beta} \hat{\sigma}_r^2 \le \frac{\alpha^2}{16} \hat{\sigma}_r^2. \tag{8}$$

Next, let

$$R = \left\{ i \ne r \,:\, |\hat{\mu}_i^S - \hat{\mu}_r^S| \le \frac{\alpha}{4}(\sigma_i + \sigma_r) \right\}.$$

Then we have

$$\begin{aligned} d_i = d(\mu_i^S, W) &= |\mu_i^S - \hat{\mu}_i^S| \\ &= |(\mu_i^S - \mu_i) + (\mu_i - \mu_r) + (\mu_r - \mu_r^S) + (\mu_r^S - \hat{\mu}_r^S) + (\hat{\mu}_r^S - \hat{\mu}_i^S)| \end{aligned}$$

and, by the triangle inequality,

$$\begin{aligned} d_i &\geq |\mu_i - \mu_r| - |(\mu_i^S - \mu_i) + (\mu_r - \mu_r^S) + (\mu_r^S - \hat{\mu}_r^S) + (\hat{\mu}_r^S - \hat{\mu}_i^S)| \\ &\geq |\mu_i - \mu_r| - |\mu_i - \mu_i^S| - |\mu_r - \mu_r^S| - d_r - |\hat{\mu}_i^S - \hat{\mu}_r^S|. \end{aligned}$$

Next, we use the inequality above to show that

$$d_i \geq \frac{\alpha}{3}\sigma_r. \tag{9}$$

To this end, we need inequalities given in (10), (11), and (12). By the separation assumed in Theorem 3, we have

$$|\mu_i - \mu_r| \geq \alpha(\sigma_i + \sigma_r). \tag{10}$$

From Lemma 8(b) we have

$$|\mu_i - \mu_i^S| \leq \frac{\sigma_i}{4} \qquad \text{and} \qquad |\mu_r - \mu_r^S| \leq \frac{\sigma_r}{4}. \tag{11}$$

Moreover, from (8) and Lemma 8(c) it follows that

$$d_r \leq \frac{\alpha}{4}\hat{\sigma}_r \leq \frac{2\alpha}{7}\sigma_{r,W} \leq \frac{2\alpha}{7}\sigma_r. \tag{12}$$

From these facts (9) follows immediately.

Next, from Lemma 8(c) and (9) it follows that

$$d_i \geq \frac{\alpha}{4}\hat{\sigma}_r.$$

Therefore, using (7) and Lemma 9,

$$\begin{aligned} \frac{2k^2}{\beta}|T_r|\hat{\sigma}_r^2 \geq 2k\sum_{i=1}^{k}|T_i|\hat{\sigma}_i^2 &\geq \sum_{i=1}^{k}|T_i|d_i^2 \\ &\geq \sum_{i\in R}|T_i|d_i^2 \geq \sum_{i\in R}|T_i|\frac{\alpha^2}{16}\hat{\sigma}_r^2. \end{aligned}$$

As a result,

$$\sum_{i\in R}|T_i| \leq \frac{32k^2}{\alpha^2\beta}|T_r| < \frac{\varepsilon}{2}|T|.$$

However, since each $|T_i| \geq \frac{\varepsilon}{2}|T|$ (by Lemma 8(a)), this implies that R is empty. Consequently, for any $i \neq r$ we have

$$|\hat{\mu}_i^S - \hat{\mu}_r^S| > \frac{\alpha}{4}(\sigma_i + \sigma_r). \tag{13}$$

To complete the proof of the lemma, we note that by Lemma 8(b), for any $1 \leq j \leq r$,

$$|\hat{\mu}_j^T - \hat{\mu}_j^S| \leq |\mu_j^T - \mu_j^S| \leq |\mu_j^T - \mu_j| + |\mu_j - \mu_j^S| \leq \frac{\sigma_j}{2}.$$

Therefore, by (13) and the triangle inequality,

$$\begin{aligned}|\hat{\mu}_i^T - \hat{\mu}_r^T| &= |(\hat{\mu}_i^T - \hat{\mu}_i^S) + (\hat{\mu}_i^S - \hat{\mu}_r^S) + (\hat{\mu}_r^S - \hat{\mu}_r^T)| \\ &\geq |\hat{\mu}_i^S - \hat{\mu}_r^S| - |\hat{\mu}_r^S - \hat{\mu}_r^T| - |\hat{\mu}_i^S - \hat{\mu}_i^T| \\ &\geq \frac{\alpha}{4}(\sigma_i + \sigma_r) - \frac{\sigma_i}{2} - \frac{\sigma_r}{2} \\ &> \frac{\alpha}{5}(\sigma_i + \sigma_r). \qquad \square\end{aligned}$$

LEMMA 11. *Let $p \in T_i$. With probability at least $1 - \frac{\delta}{4k}$,*

$$\sigma(p)^2 \leq 16k\hat{\sigma}_i^2 \log^2\left(\frac{Nk}{\delta}\right).$$

Further, if i is a large component, then

$$\sigma(p)^2 \geq \frac{w_i^2}{512}\hat{\sigma}_i^2.$$

Proof. Consider the samples in T_i after projection onto W. These points are i.i.d. samples from a logconcave distribution with maximum variance at most $k\sigma_i^2$. Fix a (projected) sample point p. By Lemma 6,

$$\Pr\left(|p - \hat{\mu}_i| > \frac{3}{2}\sqrt{k}\sigma_{i,W}\log\left(\frac{Nk}{\delta}\right)\right) < \frac{\delta}{8kN}. \tag{14}$$

Therefore, with probability at least $1 - \frac{\delta}{8k}$, every projected sample point from any F_i lies within distance at most $\frac{3}{2}\sqrt{k}\sigma_{i,W}\log(\frac{Nk}{\delta})$ of $\hat{\mu}_i$. Consequently, with probability at least $1 - \frac{\delta}{8k}$, any pair of projected samples from T_i are within $3\sqrt{k}\sigma_{i,W}\log(\frac{Nk}{\delta})$ of each other. Since by Lemma 8(a) $|T_i| > \frac{N\varepsilon}{2}$, it follows that elements of $T(p)$ lie within a ball of radius at most $3\sqrt{k}\sigma_{i,W}\log(\frac{Nk}{\delta})$ centered at p. From the definition of $\sigma(p)$, Lemma 2, and Lemma 8(c) it follows that

$$\sigma(p)^2 \leq \frac{1}{|T(p)|}\sum_{x \in T(p)}|x - p|^2 \leq 9k\sigma_{i,W}^2 \log^2\left(\frac{Nk}{\delta}\right) \leq 16k\hat{\sigma}_i^2 \log^2\left(\frac{Nk}{\delta}\right).$$

For the second inequality, note that by Lemma 10 the set $T(p)$ of samples used to compute $\sigma(p)$ are all from T_i. If v is the direction in W for which the distribution F_i has maximum variance, then Lemma 7 implies that for

$$H = \left\{x \in \Re^n : \mu^{T(p)} \cdot v - \frac{\varepsilon}{8}\sigma_{i,W} \leq v.x \leq \mu^{T(p)} \cdot v + \frac{\varepsilon}{8}\sigma_{i,W}\right\}$$

we have $F_i(H) \leq \frac{1}{\sigma_{i,W}} \times 2\frac{\varepsilon\sigma_{i,W}}{8} = \frac{\varepsilon}{4}$.

Now we apply a result which follows from VC-dimension techniques (see [10]). To make the paper self-contained, we will give a proof of this result in section 4.5. For any interval I along the direction v, let $H_I = \{x \in \Re^n : x \cdot v \in I\}$.

LEMMA 12. *Suppose $T = T_1 \cup T_2 \cup \cdots \cup T_k$ is a set of i.i.d. samples generated from the mixture F such that $|T| > N_0$. Fix $i \in \{1, \ldots, r\}$, and let I be any interval along the direction of v such that $F_i(H_I) \leq \frac{\varepsilon}{4}$. With probability at least $1 - \frac{\delta}{8k}$, we have*

$$\left|\frac{|T_i \cap H_I|}{|T_i|} - F_i(H_I)\right| \leq \frac{\varepsilon}{8}.$$

We now complete the proof of Lemma 11. From Lemma 12 we have

$$|T(p) \cap H| \leq \frac{3\varepsilon}{8}|T_i| \leq \frac{3}{4} \times \frac{\varepsilon|T_i|}{2} \leq \frac{3|T(p)|}{4}.$$

This means that at least $\frac{|T(p)|}{4}$ samples in $T(p)$ are out of the strip H; i.e., they are at least as far as $\frac{\varepsilon}{8}\sigma_{i,W}$ apart from $\mu^{T(p)}$ in the direction of v. Hence, using Lemma 8(c),

$$\begin{aligned}\sigma(p)^2 &\geq \frac{1}{|T(p)|}\left(\frac{1}{||v||^2}\sum_{x\in T(p)}(x\cdot v - \mu^{T(p)}\cdot v)^2\right)\\ &\geq \frac{1}{|T(p)|}\times\frac{|T(p)|}{4}\times\left(\frac{\varepsilon}{8}\sigma_{i,W}\right)^2\\ &\geq \frac{\varepsilon^2}{256}\sigma_{i,W}^2 \geq \frac{\varepsilon^2\hat{\sigma}_i^2}{512},\end{aligned}$$

which completes the proof. □

We continue with the proof of Theorem 3. First, note that from Lemma 8(a) it follows that in each iteration the size of the set of samples is at least $2N_0$. The algorithm uses N_0 samples for SVD computation, and the rest are classified. Since there are at least N_0 samples left, all of the necessary lemmas will be valid.

Suppose the point p_0 which maximizes $\sigma(p)$ in step 4 of the algorithm is actually from a large component F_r (i.e., one which satisfies (6)). By Lemma 6 and the first part of Lemma 11, we have

$$\frac{\alpha}{8}\sigma_r > 2^8\frac{\sqrt{k}}{\varepsilon}\sigma(p)\log\left(\frac{Nk}{\delta}\right) > 3\sqrt{k}\sigma_{r,W}\log\left(\frac{Nk}{\delta}\right). \tag{15}$$

It was shown that from (14) it follows that with probability $1-\frac{\delta}{8k}$, any pair of projected samples onto W from F_i are within $3\sqrt{k}\sigma_{i,W}\log(\frac{Nk}{\delta})$ of each other. This, together with (15), means that the output of an iteration contains T_r entirely. Moreover, from Lemma 10 and the above consequence of (14) it follows that the distance between any projected samples of F_r and F_i, $i \neq r$, is at least $\frac{\alpha}{8}\sigma_r$. This, together with (15), implies that the output of the iteration does not contain any samples from any F_i, $i \neq r$. Therefore the output of the iteration exactly classifies samples from one distribution.

Next, we will show that the point p_0 in step 4 of the algorithm must indeed be from a large component. Let r be the component for which $|T_r|\hat{\sigma}_r^2$ is maximum. Take any $p \in T_i$ for an i which is not large, i.e.,

$$|T_i|\hat{\sigma}_i^2 < \beta|T_r|\hat{\sigma}_r^2. \tag{16}$$

Therefore,

$$\hat{\sigma}_i^2 \leq \beta\frac{|T_r|}{|T_i|}\hat{\sigma}_r^2 \leq \frac{2\beta}{\varepsilon}\hat{\sigma}_r^2.$$

By Lemma 11,

$$\sigma(p)^2 < 16k\hat{\sigma}_i^2\log^2\left(\frac{Nk}{\delta}\right) \leq \frac{32k\beta}{\varepsilon}\hat{\sigma}_r^2\log^2\left(\frac{Nk}{\delta}\right) = \frac{\varepsilon^2}{512}\hat{\sigma}_r^2.$$

On the other hand, for any point $q \in T_r$,

$$\sigma(q)^2 \geq \frac{\varepsilon^2}{512}\hat{\sigma}_r^2 > \sigma(p)^2.$$

Hence the point p_0 chosen in step 4 of the algorithm will be from a large component. This completes the proof of Theorem 3.

4.4. Proof of Corollary 4. Assume $N > \frac{C'k^2}{\varepsilon^3\eta^2\delta^2}\log^5(\frac{nk}{\delta\eta})$, where C' is a large enough constant. We use our spectral algorithm to obtain a classification of $N - kN_0$ samples such as $T = T_1 \cup \cdots \cup T_k$. By Theorem 3, with probability at least $1-\delta$ the algorithm classifies the samples correctly. For any $1 \leq i \leq k$, set

$$\mu_i' = \mu_i^T = \frac{1}{|T_i|}\sum_{x\in T_i} x \quad \text{and} \quad A_i' = \frac{1}{|T_i|}\sum_{x\in T_i}(x-\mu_i')(x-\mu_i')^T.$$

From Lemma 8(a) it follows that with probability at least $1-\delta$, for every $1 \leq i \leq k$ we have $|T_i| > \frac{4n}{\eta^2}\log^2(\frac{2k}{\delta})$. Now the samples in T_i are i.i.d. and all generated from F_i. With a method analogous to the proof of Lemma 8(b) given below, we can prove that for any $1 \leq i \leq k$, with probability at least $1 - \frac{\delta}{2k}$ we have $|\mu_i - \mu_i'| < \frac{\eta}{2}\sigma_i$.

Finally, let G_i be the shifted logconcave distribution given by

$$G_i(x) = F_i(x + \mu_i).$$

Clearly the mean of G_i is located at the origin. Set

$$A_i'' = \frac{1}{|T_i|}\sum_{x\in T_i}(x-\mu_i)(x-\mu_i)^T.$$

Since $|T_i| = \Omega\Big(\frac{n}{(\frac{\delta^2\eta^2}{4k^2})}\log^5(\frac{n}{(\frac{\delta^2\eta^2}{4k^2})})\Big)$, Lemma 5 implies that for any $1 \leq i \leq k$, with probability at least $1 - \frac{\delta}{2k}$ for any vector $v \in \Re^n$ we have

$$\begin{aligned}|v^T A_i'' v| &= \left|\left(\frac{1}{|T_i|}\sum_{y\in T_i-\mu_i}(v^T y)^2\right) - \mathsf{E}_{G_i}((v^T y)^2)\right| \\ &\leq \frac{\eta}{2}\mathsf{E}_{G_i}((v^T y)^2) = \frac{\eta}{2}v^T A_i v,\end{aligned}$$

which implies that $||\sum_{x\in T_i}(x-\mu_i)(x-\mu_i)^T|| \leq \frac{\eta}{2}||A_i|| \leq \frac{\eta}{2}\sigma_i^2$. Next, a simple calculation shows that

$$A_i' = A_i'' - (\mu_i - \mu_i')(\mu_i - \mu_i')^T,$$

which, together with $|\mu_i - \mu_i'| < \frac{\eta}{2}\sigma_i$, implies that $||A_i' - A_i|| < \eta\sigma_i^2$.

4.5. Proof of Lemma 12. In this section we prove Lemma 12. Our notation will be the same as in the statement of the lemma. Let $\mathcal{L}_v$ be the line in the direction of v. Let $t = \lceil\frac{30}{\varepsilon}\rceil$. Choose a sequence of closed intervals $I_1, \ldots, I_t$ on $\mathcal{L}_v$ such that the following hold:

- For any $1 \leq j \leq t$, we have $F(H_{I_j}) = \frac{1}{t}$.
- $\mathcal{L}_v = I_1 \cup \cdots \cup I_t$.
- The interiors of $I_1, \ldots, I_t$ are disjoint.

For any $1 \le j \le t$, let r_j be the number of samples in T_i which belong to H_{I_j}. Using Chernoff's inequality one can see that

$$\Pr\left(\left|\frac{r_j}{|T_i|} - \frac{1}{t}\right| > \frac{1}{100t}\right) < 2e^{-\frac{|T_i|}{10^4 t}}.$$

From Lemma 8(a) it follows that with probability at least $1 - \frac{\delta}{8k}$, for any j we have $|\frac{r_j}{|T_i|} - \frac{1}{t}| < \frac{1}{100t}$. Next, we show that when this holds, the inequality of the statement of the lemma holds as well.

Let I be an interval such that $F_i(H_I) = l \le \frac{\varepsilon}{4}$. Suppose a, b are chosen such that $I_{a+1} \cup \cdots \cup I_{b-1} \subset I \subset I_a \cup \cdots \cup I_b$. Then $(b-a+1) > lt$ and $b-a-1 < lt$. Therefore

$$\begin{aligned}\frac{|T_i \cap H_I|}{|T_i|} &< \frac{r_a + \cdots + r_b}{|T_i|} < (b-a+1)\left(\frac{1}{t} + \frac{1}{100t}\right) < (lt+2)\left(\frac{101}{100t}\right)\\ &= l + \frac{l}{100} + \frac{101}{50t} < l + \frac{\varepsilon}{8}\end{aligned}$$

and, similarly,

$$\begin{aligned}\frac{|T_i \cap H_I|}{|T_i|} &> \frac{r_{a+1} + \cdots + r_{b-1}}{|T_i|} > (b-a-1)\left(\frac{1}{t} - \frac{1}{100t}\right) > (lt-2)\left(\frac{99}{100t}\right)\\ &= l - \frac{1}{100t} - \frac{99}{50t} > l - \frac{\varepsilon}{8}.\end{aligned}$$

5. Concluding remarks. In this paper we showed that assuming a mild separation for the means a PCA-based learning algorithm provably classifies samples from a mixture of logconcave distributions.

From the example in Figure 1, it is not hard to see that spectral projection requires a separation between means that grows with the largest variance of individual components. Following the preliminary version of our results [18, 9], Achlioptas and McSherry [1] have improved the polynomial dependence on k and ε using a more sophisticated algorithm *after* projection. It remains an open problem to learn (nonspherical) Gaussians at smaller separation. The near disjointness of Gaussian components (e.g., total variation distance nearly 1 for two Gaussians), and thus their learnability, is implied by the assumption that the distance between two means is of the order of the variance *in the direction of* the line joining the means. Spectral projection fails at such a small separation, and a different technique will have to be used.

On the other hand, the main technique used in this paper is fairly easy to implement and commonly used in practice for many applications. In [20], Vempala and Wang present empirical evidence and propose an explanation for why the method is effective for real data where the assumption that the components are Gaussian (or logconcave) might not be valid.

Finally, most guarantees for spectral methods assume that the data is generated from some restricted model such as a random model. Our algorithm is also for "random" data, but the distributions considered are more general. Spectral projection seem to be well suited for such models, and our result can be viewed as further evidence of this.

Acknowledgment. We thank the referees for patiently reading the original version of the paper and making several useful suggestions.

IMPROVED APPROXIMATION ALGORITHMS FOR BROADCAST SCHEDULING*

NIKHIL BANSAL†, DON COPPERSMITH‡, AND MAXIM SVIRIDENKO†

Abstract. We consider scheduling policies in a client-server system where the server delivers data by broadcasting it to the users. In thesimplest model of the problem, there is a single server that holds n pages of unit size. Multiple requests for these pages arrive over time. At each time slot the server broadcasts exactly one page which satisfies all of the outstanding requests for this page at that time. We consider the problem of minimizing the average response time of requests, where the response time of the request is the duration since the request is placed until the time it is satisfied. For the offline version of this problem we give an algorithm with an approximation ratio of $O(\log^2(n)/\log\log(n))$. More generally, for any $\epsilon > 0$, the algorithm achieves an average response time of $(2+\epsilon)\cdot \mathrm{OPT} + O(\log n \cdot \log_{(1+\epsilon)} n)$, which is useful when the optimum value is large. This substantially improves the previously best known approximation factor of $O(\sqrt{n})$ for the problem [N. Bansal, M. Charikar, S. Khanna, and J. Naor, *Proceedings of the Sixteenth Annual ACM-SIAM Symposium on Discrete Algorithms*, Vancouver, British Columbia, ACM, New York, SIAM, Philadelphia, 2005, pp. 215–221]. Our result is based on iteratively relaxing and rounding an auxiliary linear program derived from a natural linear programming relaxation of the problem.

Key words. LP rounding, approximation algorithm, broadcast scheduling

1. Introduction.

In a broadcast data dissemination system, we have a collection of data items at a broadcast server (typically a satellite). Users submit requests for these data items at various times and the server continuously transmits the data items. Whenever the server broadcasts a data item, it simultaneously satisfies all users waiting for that item. Broadcast systems have received a lot of attention recently. These systems exploit the fact that most requests are for a small common set of objects and they scale very well with increasing demand and number of users. Data broadcasting is actually being used in many commercial systems such as Intel Intercast system, Hughes DirecPC system [10], and the Airmedia system [1] to increase the bandwidth of the system. In fact broadcast is not unique to computer systems. There are several radio music channels where listeners submit the requests for songs, and then these songs eventually get played.

There has been a lot of research interest in various aspects of broadcast systems. In this paper we consider scheduling algorithms to improve the quality of service perceived by the users of the system. We focus on the average response time, which is one of the most commonly used measures of quality of service, defined as the average time a user waits until his request is satisfied.

Problem formulation. The setting and problem we study in this paper is formalized as follows: There is a collection of pages $P = \{1, \ldots, n\}$. Time is slotted and any page can be broadcast in a *single* time slot. At any time t, the broadcast server

receives $n_p(t)$ requests for page $p \in P$. We say that a request ρ for page p that arrives at time t is satisfied at time $c_p(t)$, if $c_p(t)$ is the first time after t when page p is transmitted by the broadcast server. The *response time* of the request ρ is defined to be the time that elapses from its arrival till the time it is satisfied, i.e., $c_p(t) - t$. We assume that request ρ arrives in the end of the time slot t and, therefore, cannot be satisfied in the time slot in which it arrived; i.e., the response time for any request is at least 1. Let T denote the last time when any request arrives.

We consider the average response time minimization problem, where we want to find a broadcast schedule that minimizes the average response time, defined to be $(\sum_{p\in P}\sum_{t=1}^{T} n_p(t)(c_p(t)-t))/(\sum_{p\in P}\sum_{t=1}^{T} n_p(t))$. In this paper we study the offline problem, where the request sequence is known in advance to the scheduling algorithm.

The problem can also be viewed as the response time minimization version of the minimum latency problem (aka traveling repairman problem) on a uniform metric space. In the classical minimum latency problem [5, 8, 16], we wish to find a tour on n points in a metric space which minimizes the average time a vertex is visited. This can be viewed as a request arriving at each vertex at time 0, and the goal is to satisfy the average response time of the requests. One can consider a stronger variant of the minimum latency problem when requests at vertices arrive over time, and, moreover, several requests might arrive at a vertex at different times. By associating each vertex with a page, and viewing every visit to a vertex as a transmission of the corresponding page, it can be seen that the problem considered in this paper is identical to the response time version of the latency problem for the uniform metric space.

Previous work. The average response time problem was shown to be NP hard by Erlebach and Hall [13]. Most of the previous algorithmic work has focused on resource augmentation where the server is given extra speed compared to the optimal algorithm. These results compare k-speed approximation algorithm against the performance of an optimal 1-speed algorithm, where a k-speed algorithm is one that allows a server to broadcast k pages in each time slot. Kalyanasundaram, Pruhs, and Velauthapillai [17] gave the first $\frac{1}{\alpha}$-speed, $\frac{1}{1-2\alpha}$-approximation algorithm for any fixed α, for $0 \le \alpha \le 1/3$. This guarantee was improved in a sequence of papers [14, 13, 15]. Gandhi et al. [14] gave a $\frac{1}{\alpha}$-speed, $\frac{1}{1-\alpha}$-approximation algorithm for any $\alpha \in (0, 1/2]$. Erlebach and Hall [13] gave a 6-speed 1-approximation algorithm for the problem, which was improved to a 4-speed, 1-approximation algorithm by [14]. Then, Gandhi et al. [15] gave a 2-speed, 1-approximation. Subsequently, Bansal et al. [2] gave an algorithm that achieves a constant approximation ratio for arbitrarily small extra speed up factor. Their algorithm achieves an additive approximation ratio of $O(1/\epsilon)$ with $(1+\epsilon)$-speed.[1]

When no extra speed is allowed, the problem seems to be considerably harder. Note that repeatedly transmitting the pages in the cyclic order $1, \ldots, n$ is an $O(n)$ approximation, as every request has a response time of at most n in the schedule above, and at least 1 in any schedule. Prior to our work, the only result with a guarantee better than the naive $O(n)$ was due to Bansal et al. [2]. Their algorithm produces a solution with an average response time of $\mathrm{OPT} + O(\sqrt{n})$, where OPT is the optimum average response time. We note that this is an additive $O(\sqrt{n})$ approximation, hence it directly implies an $O(\sqrt{n})$ multiplicative approximation (since OPT is at least 1). Alternately, the result can be viewed as an $O(\max(1, \sqrt{n}/\mathrm{OPT}))$ multiplicative

[1] Here $(1+\epsilon)$-speed means that the algorithm is allowed to transmit one extra page every $1/\epsilon$ time steps.

approximation. Furthermore, for any $\epsilon > 0$, the same algorithm achieves the $(1+\epsilon)$-speed, $O(1/\epsilon)$-additive approximation guarantee mentioned earlier.

In the online setting, a lower bound of $\Omega(\sqrt{n})$ without speedup and a lower bound of $\Omega(1/\epsilon)$ with a speedup factor of $(1+\epsilon)$ on the competitive ratio of any randomized online algorithm is known [2]. In [17, Lemma 7], an $\Omega(n)$ lower bound on the competitive ratio of deterministic algorithms is given. Edmonds and Pruhs [11] gave a $(4+\epsilon)$-speed, $O(1+1/\epsilon)$-competitive online algorithm. Later, they [12] showed that a natural algorithm, Longest Wait First, is 6-speed, $O(1)$-competitive. Recently, Robert and Schabanel have extended these results to the setting where jobs can have dependencies [19].

Other measures have also been studied in the broadcast setting. Bartal and Muthukrishnan [4] considered the problem of minimizing the maximum response time of a request and gave an $O(1)$-competitive algorithm. Charikar and Khuller [7] consider a generalization of the above problem where the goal is to minimize the maximum response time of a certain fraction of the requests. The profit maximization version of the problem has also been studied. Here each request also has a deadline and a profit which is obtained if this request is satisfied before its deadline. This problem was first studied by Bar-Noy et al. [3] (in a more general setting), who gave a 1/2-approximation algorithm for it. Later, Gandhi et al. [15] designed a 3/4-approximation algorithm for the problem by using the dependent randomized rounding technique. Recently, Chang et al. [6] showed that this problem is NP-hard even in the special case when all profits are equal to 1 (referred to as the throughput maximization problem).

Our results. Our main result is an $O(\log^2 n/\log\log n)$-approximation algorithm for minimizing average response time in the absence of extra speed. In fact the bound above follows from a more general guarantee of $(2+\gamma)\cdot \mathrm{OPT} + O(\log_{1+\gamma} n \cdot \log n)$, where $\gamma > 0$ is an arbitrary positive parameter and OPT denotes the value of the optimum solution. The bound $O(\log^2 n/\log\log n)$ follows by choosing $\gamma = \Theta(\log n)$. Setting γ arbitrarily close to 0 implies a guarantee of $(2+\gamma)\mathrm{OPT} + O(\log^2 n/\gamma)$, which could be more useful in cases when OPT is large. For example, this implies an $O(1)$ approximation when OPT is $\Omega(\log^2 n)$.

Organization. We begin by defining a natural integer programming formulation in section 1 and discuss some properties of its linear programming (LP) relaxation. Section 2 describes the high level idea of our algorithm, and we present the algorithm and its analysis in section 3. The analysis is split into two parts. For simplicity, we first show a guarantee of $3\cdot \mathrm{OPT} + O(\log^2(T+n))$, where T is the time horizon. Then, in section 3.5 we show how to remove the dependence on T, and show how to refine the guarantee further to obtain an $O(\log^2 n/\log\log n)$ approximation. Finally, in section 4 we give an example of a solution to the LP relaxation where every local rounding procedure (defined below) incurs a large gap. This essentially implies that techniques used prior to our work are unlikely to yield an approximation ratio better than $\Theta(\sqrt{n})$.

Preliminaries. We begin by considering an LP relaxation of a natural time-indexed integer linear program (ILP) for the response time minimization problem. This formulation is also the starting point of all previously known approximation algorithms for this problem [17, 14, 15, 2].[2]

Consider the following time-indexed integer programming formulation: For each page $p = 1, \ldots, n$ and each time t', there is a variable $y_{pt'}$ which indicates whether

[2]Strictly speaking, [17] considered a different LP formulation. However, it is equivalent [18] to the one considered in this paper.

page p was transmitted at time t'. In particular, $y_{pt'}$ is 1 if p is broadcast at time t' and 0 otherwise. We have another set of variables $x_{ptt'}$ indexed by a page p and two times t and t' such that $t' > t$. These are used to model the response of a request. In particular, $x_{ptt'} = 1$ if a request for page p that arrived at time t is satisfied at time $t' > t$ and 0 otherwise. Let n_{pt} denote the number of requests for page p that arrive at time t. The following integer program is an exact formulation of the problem:

$$\min \sum_{p} \sum_{t} \sum_{t'=t+1}^{T+n} (t' - t) \cdot n_{pt} \cdot x_{ptt'} \tag{1}$$

$$\text{subject to} \quad \sum_{p} y_{pt'} \leq 1 \quad \forall t', \tag{2}$$

$$\sum_{t'=t+1}^{T+n} x_{ptt'} \geq 1 \quad \forall p, t, \tag{3}$$

$$x_{ptt'} \leq y_{pt'} \quad \forall p, t, t' > t, \tag{4}$$

$$x_{ptt'} \in \{0, 1\} \quad \forall p, t, t', \tag{5}$$

$$y_{pt'} \in \{0, 1\} \quad \forall p, t'. \tag{6}$$

Here T denotes the last time when any request arrives. Observe that it suffices to define variables only until time $t = T + n$, as all of the requests can be satisfied by transmitting page p at time $T + p$ for $p = 1, \ldots, n$. The set of constraints (2) ensures that at most one page is transmitted in each time slot. The set of constraints (3) ensures that each request must be satisfied and, finally, the set of constraints (4) ensures that a request for page p can be satisfied at time t only if p is transmitted at time t. A request that arrives at time t and is satisfied at time t' contributes $(t' - t)$ to the objective function. Without loss of generality, it can be assumed that in any optimum solution the constraints (2) are satisfied with an equality and that for every p and t, the variable $x_{ptt'}$ is equal to 1 at the earliest time $t' > t$ such that $y_{pt'} = 1$.

As stated the size of the formulation is polynomial in the time horizon T which could be arbitrarily large. However, we can assume that the input size of the problem is at least T/n, since if there is a period of n consecutive time units when no page is requested, then we can split the problem into two disjoint instances.

Consider the linear program obtained by relaxing the integrality constraints on $x_{ptt'}$ and y_{pt}. This fractional relaxation may be viewed as broadcasting pages fractionally at each unit of time such that total fraction of all the pages broadcast in any unit of time is 1. A request for a page p arriving at a time t is considered completely satisfied at time t' if t' is the earliest time such that the total amount of page p broadcast during the interval $(t, t']$ is at least 1.

Let (x^*, y^*) be some optimum solution to the fractional relaxation of the program (1)–(6). It is easily seen that the value of variables (x^*) are completely determined by the values of variables (y^*). Since each page needs one unit of transmissions to be satisfied, we can assume that for each p and t, the variable $x^*_{ptt'}$ is greedily set equal to $y^*_{pt'}$ starting from $t' = t + 1$ until one unit of page p has been transmitted. Equivalently, for each page p, time t, and any time $\tau > t$,

$$\sum_{t'=\tau}^{\infty} x_{ptt'} = \max \left\{ 0, \left(1 - \sum_{t''=t+1}^{\tau-1} y_{pt''} \right) \right\}. \tag{7}$$

For each page p and time t, the solution (x^*, y^*) determines a (fractional) response time $r(p,t)$ for the request for p that arrives at time t. In particular, $r(p,t) = \sum_{t'>t}(t'-t)x^*_{ptt'}$. As $(t'-t)$ can be written as $\sum_{\tau=t+1}^{t'} 1$, we can rewrite $r(p,t) = \sum_{t'>t}\sum_{\tau=t+1}^{t'} x^*_{ptt'}$. By interchanging the order of summation, we get that $r(p,t) = \sum_{\tau>t}\sum_{t'\geq\tau} x^*_{ptt'}$. By (7), it follows that for each page p and time t we have

$$r(p,t) = \sum_{\tau>t} \max\left\{0, 1 - \sum_{t''=t+1}^{\tau-1} y_{pt''}\right\}. \tag{8}$$

The following is an extremely useful view of response times that we will use repeatedly.

LEMMA 1. *Consider a request for a page p that arrives at time t. For $\alpha \in (0,1]$, let $t(\alpha,p)$ denote the earliest time after t such that the cumulative amount of page p broadcast by the LP during the interval $[t+1, t(\alpha,p)]$ is at least α. Then $r(p,t) = \int_0^1 (t(\alpha,p)-t)d\alpha$.*

Equivalently, if we choose α uniformly at random in $(0,1]$ and transmit page p at time $t(\alpha,p)$, then the expected response time for this request is equal to the LP cost for this request.

Proof. Consider some time $\tau > t$. Since α is chosen uniformly at random in $(0,1]$, the probability that $t(\alpha,p) \geq \tau$ is exactly equal to the probability that $\alpha > \sum_{t''=t+1}^{\tau-1} y_{pt''}$, which is exactly equal to $\max\{0, 1 - \sum_{t''=t+1}^{\tau-1} y_{pt''}\}$. Now,

$$\begin{aligned}\int_0^1 (t(\alpha,p)-t)d\alpha &= \mathbb{E}_\alpha[t(\alpha,p)-t] \\ &= \sum_{\tau>t} \Pr[t(\alpha,p) \geq \tau] \\ &= \sum_{\tau>t} \max\left\{0, 1 - \sum_{t''=t+1}^{\tau-1} y_{pt''}\right\}\end{aligned}$$

which is exactly equal to $r(p,t)$ by (8), and hence the result follows. ∎

2. Algorithm overview and techniques. The algorithm begins by solving the LP relaxation of (1)–(6). Our high level approach is the same as the one introduced in [2]. We first produce a *tentative* schedule which has a good response time, but can violate the "capacity" constraints (2), by transmitting more than one page during certain time slots. However, this violation will be bounded as explained in condition 2 below. In particular, suppose this tentative schedule satisfies the following properties:

1. The total response time for this schedule is at most $c = O(1)$ times the cost of the LP relaxation.
2. The capacity constraints are satisfied approximately in the following sense. For any interval of time $(t,t']$, the total number of pages broadcast by the tentative schedule during $(t,t']$ is at most $t'-t+b$, for some b independent on the time interval $(t,t']$. We refer to this b as the *backlog* of the schedule.

In this case, the tentative schedule can be transformed into a valid schedule as follows: We transmit pages in the same order as the tentative schedule while ensuring that no page is transmitted at an earlier time than in the tentative schedule. It is not hard to see that the backlog property ensures that no page is transmitted more than b steps later than in the tentative schedule (see Lemma 8 for a formal proof). Thus, this

produces an integral solution with average response time $c \cdot \mathrm{OPT} + b$. The $O(\sqrt{n})$-approximation algorithm of [2] was based on obtaining a tentative solution with cost equal to the LP cost (i.e., $c = 1$) and backlog $O(\sqrt{n})$.

In this paper we will give a procedure to obtain a tentative schedule with $c = 2+\gamma$ and $b = O(\log_{1+\gamma}(T+n) \cdot \log(T+n))$, for any arbitrary $\gamma > 0$. By Lemma 11, this will imply the desired approximation guarantee of $(2+\gamma)\mathrm{OPT} + O(\log_{1+\gamma} n \cdot \log n)$. Our improved approximation is based on two new ideas: First, we relax a locality requirement (explained below) in the rounding procedure. Prior to our work, all algorithms were *local* in the following sense: Given a solution to the LP formulation, they produced a schedule (or a tentative schedule) that ensured that for every interval, if the LP solution transmits more than one unit of page p during this interval, then the rounded solution has at least one transmission of p during this interval. The main reason for enforcing this locality was that the response time for each request can be charged directly to its cost in the LP solution, which makes the analysis relatively simple. Interestingly, in section 4 we show that relaxing this locality requirement seems necessary to obtain approximation ratios better than $\Theta(\sqrt{n})$. In particular, we show that there exist LP solutions such that any rounding procedure that is local must have backlog at least $\Omega(\sqrt{n})$.

In our rounding procedure we relax the locality requirement so that it does not necessarily hold for all time intervals. In particular, for each page p we partition the time horizon, $1, \ldots, T+n$, into intervals $B(p,i)$ called blocks, where $B(p,i)$ refers to the ith block for page p. These intervals are small in the sense that the cumulative amount of page p transmitted by the LP during $B(p,i)$ is $O(\log(T+n))$. We require only that the rounding be local within each block $B(p,i)$. While this could lead to some requests (that lie at the interface of two blocks) to pay much more than their LP costs, our technique for constructing $B(p,i)$ ensures that the response times of these requests are not too much more.

The second part of the algorithm is to give a scheme to choose local schedules for each block $B(p,i)$ such that when the tentative schedule is constructed by merging these local schedules for all the pages, it satisfies the following two properties. First, the cost of the tentative schedule is bounded by a constant times the optimum, and second, the backlog of the tentative schedule is bounded by $O(\log^2(T+n))$. To do this, we solve a sequence of linear programs iteratively. We begin by defining a (different) linear program (LP') where the variables correspond to the possible local schedules that can be chosen for each block $B(p,i)$. LP' has the property that there is a feasible fractional solution where the backlog is 0 and the response time is only $O(1)$ times the optimum cost. Observe that a solution to LP' can be viewed as assigning a linear combination of local schedules to each block. Our novel step is to show that the number of constraints in LP' can be reduced in such a way that in any basic solution to this reduced linear program, at least a constant fraction of blocks gets assigned exactly one local schedule, and yet the backlog increases only by $O(\log(T+n))$. Since this linear program has fewer constraints, the objective function can only be better. Since at least a constant fraction of blocks gets assigned exactly one schedule, we can remove these blocks to obtain a smaller problem instance. This allows us to apply this procedure iteratively, where we successively relax the constraints. At each iteration, the problem size decreases geometrically, the backlog increases additively by $O(\log(T+n))$, and the objective function does not worsen. After $O(\log(T+n))$ iterations the procedure terminates and we obtain a tentative schedule with backlog $O(\log^2(T+n))$, and cost equal to $O(1)$ times the optimum cost. We now describe the

details.

3. Minimizing average response time. Our algorithm begins by solving the LP (1)–(6). Fix an optimum solution (x^*, y^*) to this LP, and let $r(p,t)$ denote the response time according to the LP solution for a request for page p at time t, that is $r(p,t) = \sum_{t'>t}(t'-t)x^*_{ptt'}$. Let $c(p,t,t')$ denote the cumulative amount of page p transmitted by the LP solution during the time interval $(t,t']$, that is $c(p,t,t') = \sum_{t''=t+1}^{t'} y^*_{pt''}$. In the rest of this paper we refer to the time interval $(t-1,t]$ for $t \geq 1$ as the *time slot* t. We now define the key concept of p-good time slots which will be used to form the blocks for each page.

3.1. Blocks and p-good time slots.

DEFINITION 2 (p-good time slot). *Let $r(p,t)$ denote the response times as determined by the solution to the LP* (1)–(6). *For a page p we say a time slot t is p-good if $r(p,t) \leq 2r(p,\tau)$ for all $\tau < t$ such that $c(p,\tau,t) \leq 1$.*

Intuitively, the LP response time for page p at a p-good time t is not much more than that at any other time τ, where τ is sufficiently close to t in the sense defined above. The following lemma shows that a p-good slots can be found in any interval of time that broadcasts a sufficient amount of page p.

LEMMA 3. *Any time interval $(t,t']$ such that $c(p,t,t') > \log(T+n)$ contains a p-good slot.*

Proof. For the sake of contradiction, suppose that none of the slots in the interval $(t,t']$ are p-good. Since t' is not p-good, there exists a $t_1 < t'$ such that $c(p,t_1,t') \leq 1$ and $r(p,t_1) > 2r(p,t')$. Note that t_1 lies in the interval (t,t') and, hence, is not p-good by our assumption. Thus there exists t_2 such that $c(p,t_2,t_1) \leq 1$ and $r(p,t_2) > 2r(p,t_1)$. Repeating the argument for $k = \log(T+n)$ steps, we obtain a sequence of slots $t < t_k < \cdots < t_2 < t_1 < t'$ such that $c(p,t_k,t') \leq \log(T+n)$ and $r(p,t_k) > 2^k r(p,t') = (T+n)\cdot r(p,t')$, which is impossible as the response time for any request is bounded between 1 and $(T+n)$. ∎

Lemma 3 implies that if t is a p-good slot, and such that $c(p,t,T+n) > \log(T+n)$, then there is another p-good slot $t' > t$ such that $c(p,t,t') \leq \log(T+n)$. Thus, for each p we can form a collection

$$G(p) = \{0 = t(p,0), t(p,1), t(p,2), \ldots, t(p,b_p) = (T+n)\}$$

of time slots such that the $t(p,i)$ is p-good for $1 \leq i \leq b_p - 1$ and $1 \leq c(p,t(p,i-1),t(p,i)) \leq 1 + \log(T+n)$ for all $1 \leq i \leq b_p - 1$. The last interval must be such that $1 \leq c(p,t(p,b_p-1),t(p,b_p)) \leq 2 + \log(T+n)$, and such a collection of slots can be formed by a simple iterative greedy strategy.

Indeed, let $t(p,s)$ be the current p-good point. Let $t(p,s,1)$ be the next p-good point. By Lemma 3 $c(p,t(p,s),t(p,s,1)) \leq \log(T+n)$. If $c(p,t(p,s),t(p,s,1)) \geq 1$, then $t(p,s+1) = t(p,s,1)$. Otherwise, let $t(p,s,2)$ be the next p-good point. By Lemma 3 $c(p,t(p,s,1),t(p,s,2)) \leq \log(T+n)$ and therefore $c(p,t(p,s),t(p,s,2)) \leq 1 + \log(T+n)$. If $c(p,t(p,s),t(p,s,2)) \geq 1$, then $t(p,s+1) = t(p,s,2)$. Otherwise, we define $t(p,s,3)$ and continue until we either define $t(p,s+1)$ or hit the end of the planning horizon. If the last interval produced by this greedy strategy has length smaller than 1, then we merge this interval and the second-last interval (this is why we have slack for the size of the last interval).

We call the time intervals $(0 = t(p,0), t(p,1)], (t(p,1), t(p,2)], \ldots, (t(p,b_p-1), t(p,b_p)]$, blocks for page p. Note that there are b_p blocks for page p. We will use $B(p,i) = (t(p,i-1), t(p,i)]$ to denote the ith block for page p. Let $\mathcal{B}_p$ denote the set

of all blocks for page p, and let $\mathcal{B} = \cup_p \mathcal{B}_p$ denote the set of all blocks. For a block $B(p,i)$, we define its *tail* to be the time slots t such that $c(p,t,t(p,i)) < 1$. That is, the cumulative amount of page p transmitted after time t until the end of the block in which t lies is less than 1. Obviously, there is a tail for each block $B(p,i)$ since $c(p,t(p,i-1),t(p,i)) \geq 1$. Note that if a request for page p arrives during the tail of a block, then it is not satisfied completely within that block by the LP solution.

Let us focus on a particular block, say $B(p,i)$. For $\alpha \in (0,1]$, $l = 0,1,2,\ldots$, and block $B(p,i)$, let $t(p,i,l,\alpha)$ denote the earliest time in $B(p,i)$ when an $l+\alpha$ amount of page p has been broadcast since the start of $B(p,i)$; i.e., an $(l+\alpha)$ amount of page p has been broadcast during $(t(p,i-1),t(p,i,l,\alpha)]$ (the time $t(p,i,l,\alpha)$ is defined only if block $B(p,i)$ transmits at least $l+\alpha$ amount of page p). For a given block $B(p,i)$ and $\alpha \in (0,1]$, let $C(p,i,\alpha)$ denote the set of all time slots $t(p,i,l,\alpha)$ for $l = 0,1,2,\ldots$.

Note that if we transmit page p at slots in $C(p,i,\alpha)$ for some $\alpha \in (0,1]$, then this is a local schedule for $B(p,i)$ (since we transmit page p whenever the LP transmits one unit of page p during any time interval contained in $B(p,i)$). We say that this local schedule is formed by choosing the *offset* α for block $B(p,i)$. We will only be interested in local schedules for blocks that are obtained by choosing some offset $\alpha(p,i)$ for each block $B(p,i)$ and transmitting page p at all time slots in $C(p,i,\alpha(p,i))$. Suppose we arbitrarily choose some offset $\alpha(p,i)$ for each block $B(p,i)$. We claim that the tentative schedule thus obtained satisfies each request. To see this, observe that each request for page p that arrives in $B(p,i)$ for $1 \leq i \leq b_p - 1$ (i.e., except for the last block for page p) is served within $B(p,i)$ or in $B(p,i+1)$. Finally, as there is at least one unit of page p broadcast in the LP solution after the arrival of the last request for page p (see comment after the definition of LP (1)–(6), all requests for page p that arrive during the last block $B(p,b_p)$ are served within $B(p,b_p)$.

The following lemma shows that if we construct a tentative schedule by choosing an offset independently at random for each block, then the expected total response time is not too high and all of the capacity constraints are satisfied at each time step in expectation.

LEMMA 4. *Suppose for each block $B(p,i) \in \mathcal{B}$, we choose the offset $\alpha(p,i)$ independently and uniformly at random in $[0,1]$. Then the tentative schedule thus obtained satisfies the following properties:*

1. *The expected number of pages transmitted at any time step t is exactly* 1.
2. *For each request, its expected response time is at most* 3 *times the cost incurred by it in the LP solution of* (1)–(6).

Proof. Consider a time t and suppose that $t \in B(p,i)$. Since we choose the offset $\alpha(p,i)$ uniformly at random in $(0,1]$, the probability that page p is transmitted at time t is exactly y^*_{pt}.

For any p, the blocks $B(p,i)$ partition the entire time interval $(0,T+n]$, and hence for each time t there is exactly one block for page p that contains t. Thus, the probability that page p is transmitted at time t in the tentative schedule is exactly y^*_{pt}. Summing up over all of the pages, we have that the expected number of pages transmitted at time t is exactly $\sum_p y^*_{pt}$ which is exactly 1 by constraints (2) in the LP. This proves the first part of the lemma.

Consider a particular block $B(p,i)$, and let ρ be a request for page p that arrives during $B(p,i)$. We say that request ρ is *early* if it does not arrive in the tail of $B(p,i)$, or, equivalently, that $c(p,t_\rho,t(p,i)) \geq 1$. Note that ρ is always served within $B(p,i)$ irrespective of the choice of $\alpha(p,i)$. Since $\alpha(p,i)$ is chosen uniformly at random in $(0,1]$, by Lemma 1 the expected response time for an early request is exactly $r(p,t)$.

Thus it suffices to focus on the contribution of requests that are not early. Consider a request ρ for page p that arrives at time $t_\rho \in B(p,i)$ such that $c(p,t_\rho,t(p,i)) < 1$. Since $\alpha(p,i)$ is chosen uniformly at random, with probability $c(p,t_\rho,t(p,i))$ this request is served in $B(p,i)$ and with probability $1-c(p,t_\rho,t(p,i))$ it is served in $B(p,i+1)$. Since $\alpha(p,i+1)$ is chosen uniformly at random in $(0,1]$ and is independent of $\alpha(p,i)$, it follows that conditioned on the event that ρ is served in $B(p,i+1)$, by Lemma 1 its expected response time is $(t(p,i)-t_\rho)+r(p,t(p,i))$. Thus the overall expected response time of ρ is

$$\begin{aligned}
&\left(\sum_{t''=t_\rho+1}^{t(p,i)} (t''-t_\rho)\cdot x^*_{pt_\rho t''}\right) + (1-c(p,t_\rho,t(p,i)))\cdot(t(p,i)-t_\rho+r(p,t(p,i)))\\
&= \left(\sum_{t''=t_\rho+1}^{t(p,i)} (t''-t_\rho)\cdot x^*_{pt_\rho t''}\right) + \left(\sum_{t''=t(p,i)+1}^{\infty} (t(p,i)-t_\rho)\cdot x^*_{pt_\rho t''}\right)\\
&\quad +(1-c(p,t_\rho,t(p,i)))\cdot r(p,t(p,i))\\
&\le \left(\sum_{t''=t_\rho+1}^{t(p,i)} (t''-t_\rho)\cdot x^*_{pt_\rho t''}\right) + \left(\sum_{t''=t(p,i)+1}^{\infty} (t''-t_\rho)\cdot x^*_{pt_\rho t''}\right)\\
&\quad +(1-c(p,t_\rho,t(p,i)))\cdot r(p,t(p,i))\\
&\le \left(\sum_{t''=t_\rho+1}^{\infty} (t''-t_\rho)\right)\cdot x^*_{pt_\rho t''} + r(p,t(p,i)) \le r(p,t_\rho)+2r(p,t_\rho) = 3r(p,t_\rho).
\end{aligned}$$

The first equality follows by observing that

$$\left(\sum_{t''=t(p,i)+1}^{\infty} x^*_{pt_\rho t''}\right) = 1-c(p,t_\rho,t(p,i)).$$

The final step follows as $t(p,i)$ is a p-good time slot; hence by definition $r(p,t(p,i)) \le 2r(p,t_\rho)$. □

The following lemma will allow us to consider discrete choices for the offsets $\alpha(p,i)$.

LEMMA 5. *Let $\varepsilon > 0$ be an arbitrary precision parameter. We can assume that $x_{ptt'}$ and y_{pt} are integral multiples of $\delta = \varepsilon/(T+n)^2$. This adds at most ε to the response time of each request.*

Proof. Given an arbitrary LP solution, we simply round down the values of y_{pt} to the closest multiple of δ and modify $x_{ptt'}$ accordingly. We also transmit $\delta\cdot T \le 1/n$ units of each page p at time $T+n+1$ to ensure that each request remains completely satisfied.

Observe that each $x_{ptt'}$ is reduced by at most δ. As the response time for a request for page p at time t is $\sum_{t'>t}(t'-t)x_{ptt'}$, the rounding adds at most $T\cdot T\cdot\delta \le \varepsilon$ to the response time of each request. □

Thus we can assume that all of the offsets $\alpha(p,i)$ are integral multiples of δ for $\delta = \varepsilon/(T+n)^2$. Henceforth, we will use $B(p,i,j)$ to denote the time slots in $C(p,i,\alpha=\delta j)$ (i.e., those obtained by choosing $\alpha(p,i)=\delta j$), where $j=0,\ldots,1/\delta-1$. We will call the set of time slots $B(p,i,j)$ a *block-offset*.

3.2. Auxiliary LP. Recall that our goal is to choose exactly one offset for each block in such a way that the total response time of the tentative schedule thus obtained is not too high, and the backlog is small. For this purpose we define the LP (9)–(12).

We have variables z_{pij} that correspond to choosing the offset j for block $B(p,i)$, or equivalently transmitting the page p at times in $B(p,i,j)$ during $B(p,i)$. The parameters $R(B(p,i,j))$ and $w(B(p,i,j),t)$ are defined below.

$$\min \sum_p \sum_i \sum_j R(B(p,i,j)) \cdot z_{pij} \tag{9}$$

$$\text{subject to} \quad \sum_j z_{pij} = 1 \quad \forall p,i, \tag{10}$$

$$\sum_p \sum_i \sum_j w(B(p,i,j),t) \cdot z_{pij} = 1 \quad \forall t, \tag{11}$$

$$z_{pij} \geq 0 \quad \forall p,i,j. \tag{12}$$

Here $w(B(p,i,j),t)$ is an indicator function: $w(B(p,i,j),t)$ is 1 if $t \in B(p,i,j)$ and 0 otherwise. Observe that the constraints (10) require that there is exactly one unit of offsets chosen for each block $B(p,i)$, and the constraints (11) require that for each time slot t the total amount of pages transmitted is exactly 1. Thus, this LP can be viewed as choosing a convex combination of local schedules for each block $B(p,i)$ such that certain global constraints are satisfied.

The objective function of minimizing the total response time is expressed in terms of the variables z_{pij} as follows: For each block $B(p,i)$ we associate a *block-offset response time* $R(B(p,i,j))$ which essentially accounts for the contribution of the block-offset $B(p,i,j)$ to the total response time. Observe that choosing an offset for block $B(p,i)$ can affect the response time of requests for page p that arrive in $B(p,i)$ and possibly the requests that arrive during the tail of $B(p,i-1)$. The block-offset response time $R(B(p,i,j))$ is computed as follows:

1. Let t' denote the earliest time in $B(p,i,j)$. Each request for page p in the tail of the previous block $B(p,i-1)$ contributes $t' - t(p,i-1)$ to $R(B(p,i,j))$. Note that this is the amount of time (restricted to time slots in $B(p,i)$) that any request in $B(p,i-1)$ might possibly have to wait until it is satisfied.
2. For a request ρ for page p that arrives at time t where $t \in B(p,i)$, we do the following. Let t' denote the earliest time such that $t' > t$ and $t' \in B(p,i,j)$. If such a t' does not exist, then we set $t' = t(p,i)$. Then the request ρ contributes exactly $t' - t$ to $R(B(p,i,j))$. Note that this quantity is the contribution to the response time of ρ restricted to the time slots in $B(p,i)$.

This definition of $R(B(p,i,j))$ ensures that for any tentative schedule obtained by choosing one offset for each block, i.e., for any setting of z_{pij} to 0 or 1 subject to the constraints (10), the total response time of this tentative schedule is no more than $\sum_{p,i,j} R(B(p,i,j)) \cdot z_{pij}$.

We next observe that the linear program above has a good fractional solution. In particular, Lemma 4 implies the following about the linear program defined by LP (9)–(12).

LEMMA 6. *There is a feasible solution to the LP* (9)–(12) *with cost no more than* 3 *times the cost of the optimum value of the LP* (1)–(6).

Proof. Consider the solution where $z_{pij} = \delta$ for all p,i and $0 \leq j \leq 1/\delta - 1$. This corresponds to choosing an offset uniformly at random for each block $B(p,i)$. Lemma 4 (part 1) implies that the constraints (11) are satisfied.

We now show that the cost of this solution is no more than 3 times the cost of LP (1)–(6). Consider an early request in $B(p,i)$. Since this request is completely served within $B(p,i)$ by Lemma 1, the contribution of this request to the objective function is exactly its response time. For a request for page p that arrives at time t in the tail of $B(p,i-1)$, its contribution to the objective function corresponding to $\sum_j z_{p,i-1,j} \cdot R(B(p,i-1,j))$ is exactly $\sum_{t''=t+1}^{t(p,i)}(t''-t)x^*_{ptt''} + (1-c(p,t,t(p,i))) \cdot (t(p,i)-t)$ which is at most $r(p,t)$. Similarly, the contribution to $\sum_j z_{p,i,j} \cdot R(B(p,i,j))$ is exactly $r(p,t(p,i-1))$ (by Lemma 1), which is at most $2r(p,t)$ by the definition of a p-good point and as t lies in tail of $B(p,i-1)$. □

Observe that a solution to the LP (9)–(12) satisfies the capacity constraints (11) exactly. Hence if this LP had an integral optimum solution, then the backlog of the tentative schedule implied by this solution would be 0; we would then have an exact schedule with cost at most 3 times the optimum. However, this LP in general could have a fractional optimum solutions. The rest of the algorithm will deal with obtaining an integral solution to the above LP by successively relaxing the capacity constraints (11) but still ensuring that the quality of the solution remains reasonably good.

3.3. The algorithm. The idea for our algorithm is the following: Suppose we relax the capacity constraints (11) in the auxiliary LP such that we require them only to hold for time intervals of integer size b' rather than for each time unit. That is, we require only that intervals of size b' contain exactly b' pages, but we do not care how these pages are transmitted during an interval. An important observation is that if this relaxed LP had an integral optimum solution, it would give a tentative schedule with backlog $2b'$ and cost at most 3 times the optimum (and we would obtain an approximation guarantee of $3 \cdot \mathrm{OPT} + 2b'$). Since this is too strong to hope for, we will show something weaker. We will show that for $b' = O(\log(T+n))$, there is an optimum solution to this LP where more than half of the blocks $B(p,i)$ have some z_{pij} set integrally to 1. Armed with this result, we will define a smaller problem instance by removing the blocks $B(p,i)$ that have some $z_{pij} = 1$. We then apply this procedure to this smaller problem by redefining the intervals and the LP suitably and relaxing the capacity constraints of the type (11). We repeat this for $O(\log(T+n))$ steps, until we obtain a problem where only a constant number of blocks remain which can be easily solved by trying all possibilities. At a high level, we add $O(\log(T+n))$ to the backlog at each iteration of this process, which will imply that in the end we obtain a tentative schedule with cost at most 3 times the optimum and backlog of $O(\log^2(T+n))$. We now make these arguments precise.

Before we can describe the algorithm to compute the tentative schedule formally, we need some notation. Let $I = (t_1, t_2]$ be a collection of time slots $t_1+1, \ldots, t_2$. We refer to I as an interval. The size of I denoted by $\mathrm{Size}(I)$ is defined as $t_2 - t_1$. The weight of an interval with respect to $B(p,i,j)$, which we denote by $w(B(p,i,j),I)$, is the cardinality of the set $B(p,i,j) \cap I$. That is, $w(B(p,i,j),I)$ is the number of time slots in the interval I that belong to $B(p,i,j)$.

Our algorithm will solve a sequence of LP's. At step k, some variables z_{pij} that were fractional (not 0 or 1) at the end of step $k-1$ get assigned to 1. A partial solution is an assignment where some z_{pij} are set to 1. For a partial solution obtained at the end of step k, and an interval I, let $\mathrm{Used}(I,k)$ denote the number of time slots in this interval used up by z_{pij} that are assigned integrally to 1, i.e., $\mathrm{Used}(I,k) = \sum_{p,i,j} w(B(p,i,j),I)$ such that $z_{pij} = 1$. We will use $\mathrm{Free}(I,k)$ to denote $\mathrm{Size}(I) - \mathrm{Used}(I,k)$.

We now describe the algorithm to compute the tentative schedule.

1. Initialize: We divide the time horizon from $1, \ldots, T+n$ into consecutive intervals of size $5\log(T+n)$. We call this collection of intervals $\mathcal{I}_0$. For all $I \in \mathcal{I}_0$, we define $\text{Used}(I,0) = 0$ and $\text{Free}(I,0) = \text{Size}(I) - \text{Used}(I,0) = \text{Size}(I)$. Let $\tilde{\mathcal{B}}_0$ be the set of all blocks $B(p,i)$, and let $\mathcal{S}_0 = \emptyset$.
2. Repeat the following for $k = 1, \ldots,$.
   - Consider the following linear program defined iteratively based on $\tilde{\mathcal{B}}_{k-1}$, $\mathcal{I}_{k-1}$, and $\text{Free}(I, k-1)$:

$$\min \sum_{B(p,i)\in\tilde{\mathcal{B}}_{k-1}} \sum_{j=0}^{1/\delta-1} R(B(p,i,j)) \cdot z_{pij} \tag{13}$$

$$\text{subject to} \quad \sum_{j=0}^{1/\delta-1} z_{pij} = 1 \qquad \forall p, i : B(p,i) \in \tilde{\mathcal{B}}_{k-1}, \tag{14}$$

$$\sum_{p\in P} \sum_{i=1}^{b_p} \sum_{j=0}^{1/\delta-1} w(B(p,i,j), I) \cdot z_{pij} = \text{Free}(I, k-1) \qquad \forall I \in \mathcal{I}_{k-1}, \tag{15}$$

$$z_{pij} \geq 0 \qquad \forall p, i, j. \tag{16}$$

     Note that for $k = 1$ this LP is similar to the LP defined by (9)–(12) except that the constraints in (11) are relaxed to hold only for intervals of size $5\log(T+n)$ rather than for each time unit.
   - Solve this LP and consider some basic solution. Let $\mathcal{P}$ denote the set of blocks $B(p,i)$ such that $z_{pij} = 1$ for some j. Let $\mathcal{S}$ denote the set of block-offset pairs $B(p,i,j)$ such that $z_{pij} = 1$.
   - Set $\tilde{\mathcal{B}}_k = \tilde{\mathcal{B}}_{k-1} \setminus \mathcal{P}$. These are precisely the blocks $B(p,i)$ for which z_{pij} is not equal to 1 for any j at the end of step k. Set $\mathcal{S}_k = \mathcal{S}_{k-1} \cup \mathcal{S}$. These are precisely the variables z_{pij} that are integrally set to 1 thus far by the end of step k. For each interval $I \in \mathcal{I}_{k-1}$, recompute

$$\text{Used}(I,k) = \text{Used}(I,k-1) + \sum_{p,i,j:B(p,i,j)\in\mathcal{S}} w(B(p,i,j), I).$$

     Note that $\sum_{p,i,j:B(p,i,j)\in\mathcal{S}} w(B(p,i,j), I)$ is exactly the number of pages that are assigned to be transmitted during interval I in step k. Set $\text{Free}(I,k) = \text{Size}(I) - \text{Used}(I,k)$. Essentially, $\text{Free}(I,k)$ denotes the number of free time slots in interval I at the end of step k.
   - Finally, we compute the set of intervals $\mathcal{I}_k$ by merging the intervals in $\mathcal{I}_{k-1}$ as follows: Initially $\mathcal{I}_k = \emptyset$. Starting from the leftmost interval in $\mathcal{I}_{k-1}$, merge intervals $I_1, I_2, \ldots, I_l \in \mathcal{I}_{k-1}$ greedily to form I until $\text{Free}(I_1,k) + \text{Free}(I_2,k) + \cdots +, \text{Free}(I_l,k)$ first exceeds $5\log(T+n)$. We set $\text{Free}(I,k) = \text{Free}(I_1,k) + \text{Free}(I_2,k) + \cdots +, \text{Free}(I_l,k)$ and $\text{Used}(I,k) = \text{Used}(I_1,k) + \text{Used}(I_2,k) + \cdots +, \text{Used}(I_l,k)$. By construction, we have that $5\log(T+n) \leq \text{Free}(I,k) \leq 10\log(T+n)$. Add I to $\mathcal{I}_k$ and remove $I_1, \ldots, I_l$ from $\mathcal{I}_{k-1}$ and repeat the process until the total free space in the intervals in $\mathcal{I}_{k-1}$ is less than $5\log(T+n)$; hence, we cannot form new intervals. In this case we just merge all of the remaining intervals in $\mathcal{I}_{k-1}$ into one interval and add this final interval to $\mathcal{I}_k$.

- If $|\mathcal{I}_k| = 1$, then the algorithm makes one more iteration and then stops. On this last iteration there is just one constraint of type (15) in the relaxed auxiliary LP. The optimal solution is integral and very easy to define. We choose the best offset for every remaining block; i.e., we define $z_{pij} = 1$ if $R(B(p,i,j)) = \min_s R(B(p,i,s))$ for block $B(p,i)$.

3.4. Analysis.

LEMMA 7. *At each iteration of step* 2 *in the previous algorithm, the number of blocks* $B(p,i)$ *that do not have any* z_{pij} *set to* 1 *decreases by a constant factor. In particular*

$$|\tilde{\mathcal{B}}_k| \leq 0.6 \cdot |\tilde{\mathcal{B}}_{k-1}| + 1.$$

Proof. The total number of nontrivial constraints (of types (14) and (15)) in the LP at step k is $|\mathcal{I}_{k-1}| + |\tilde{\mathcal{B}}_{k-1}|$. Consider a basic optimal solution of the LP at stage k. Let f_k be the number of nonzero variables that are set fractionally (strictly between 0 and 1), and let g_k denote the number of variables set to 1. Then, since we have a basic solution, we have that $f_k + g_k \leq |\mathcal{I}_{k-1}| + |\tilde{\mathcal{B}}_{k-1}|$. Now, consider the constraints of type (14); if in some block $B(p,i)$ there is no z_{pij} that is set to 1, then there must be at least 2 variables z_{pij} set fractionally, which implies that $f_k/2 + g_k \geq |\tilde{\mathcal{B}}_{k-1}|$. Combining these two facts implies that $g_k \geq |\tilde{\mathcal{B}}_{k-1}| - |\mathcal{I}_{k-1}|$. By definition, as $|\tilde{\mathcal{B}}_k| = |\tilde{\mathcal{B}}_{k-1}| - g_k$, this implies that $|\tilde{\mathcal{B}}_k| \leq |\mathcal{I}_{k-1}|$.

We now upper bound $|\mathcal{I}_{k-1}|$. Let Free_{k-1} denote the total free space at the end of iteration $k-1$, that is, $\sum_{I \in \mathcal{I}_{k-1}} \text{Free}(I, k-1)$. Since each interval, except probably the last one, has at least $5 \log(T+n)$ free spaces, we have that $|\mathcal{I}_{k-1}| \leq \lceil \text{Free}_{k-1}/(5 \log(T+n)) \rceil$. As for any block-offset $B(p,i,j)$ and interval I, the number of time slots $w(B(p,i,j), I)$ is at most $\log(T+n) + 2$, it follows from the constraints (14) and (15) that $\text{Free}_{k-1} \leq (\log(T+n) + 2)|\tilde{\mathcal{B}}_{k-1}| \leq 3 \log(T+n)|\tilde{\mathcal{B}}_{k-1}|$. This implies that

$$|\mathcal{I}_{k-1}| \leq \lceil 0.6 \cdot |\tilde{\mathcal{B}}_{k-1}| \rceil \leq 0.6 \cdot |\tilde{\mathcal{B}}_{k-1}| + 1. \qquad \square$$

As $|\tilde{\mathcal{B}}_0| \leq T+n$, by Lemma 7 we have that the algorithm stops after $\log(T+n) + \Theta(1)$ iterations. When our algorithm ends we obtain an assignment of zero-one values to variables z_{pij}. Since in every step of our algorithm we relaxed the LP from the previous step, the cost of this final integral solution is upper bounded by the optimal value of LP (9)–(12), which is at most 3 times the optimal value of LP (1)–(6) by Lemma 6. This solution also provides us with an integral tentative schedule since it gives us an assignment of pages to the time slots.

To actually obtain a proper schedule from this tentative schedule, we look at the pages transmitted in the tentative schedule at time 0 and greedily assign it to the next free slot after time t. Formally, we can view the process of constructing the feasible schedule from the tentative schedule as follows: There is a queue Q. Whenever a page p is tentatively scheduled at time t, we add p to the tail of Q at time t. At every time step, if Q is nonempty, we broadcast the page at the head of Q.

To complete the proof, we show that no page is delayed more than $O(\log^2(T+n))$ than its position in the tentative schedule. Thus it suffices to show that the queue length $Q(t)$ at time t in the above description is always bounded by $O(\log^2(T+n))$ at all times t.

LEMMA 8. *Let* $\text{Used}(t_1, t_2)$ *denote the pages transmitted during* $(t_1, t_2]$ *in the tentative schedule. The maximum queue length at any time is bounded by* $\max_{t_1 < t_2} (\text{Used}(t_1, t_2) - (t_2 - t_1))$.

Proof. Let t_2 be the time when the backlog in the queue is maximum, and let b denote this backlog. Consider the last time t_1 was before t_2 the queue was empty. Since t_1 was the last time when the queue was empty, it must be the case that exactly $t_2 - t_1$ pages were transmitted during the interval $(t_1, t_2]$, and hence b is exactly $\text{Used}(t_1, t_2) + t_2 - t_1$. This implies the desired result. ∎

LEMMA 9. *For every* t_1, t_2, $\text{Used}(t_1, t_2) - (t_2 - t_1) \leq 20 \log^2(T+n) + O(\log(T+n))$.

Proof. Consider the time interval $(t_1, t_2]$. If $\Lambda \leq \log(T+n) + \Theta(1)$ is the number of iterations of our algorithm, then there are at most 2Λ intervals $[a, b]$ generated by the algorithm which strictly overlap with t_1, i.e., either $a < t_1 < b$ or strictly overlap t_2, i.e., $a < t_2 < b$. The total number of pages assigned to these intervals by the tentative schedule is at most $2\Lambda \cdot 10 \log n \leq 20 \log^2(T+n) + O(\log(T+n))$.

All other intervals generated by our algorithm do not strictly overlap with t_1 and t_2. They are either completely inside $(t_1, t_2]$ or else lie completely outside $(t_1, t_2]$. We claim that by the constraints (15), the total number of pages assigned to the intervals completely contained in $(t_1, t_2]$ is upper bounded by $t_2 - t_1$. This follows from the fact that on each iteration we are allowed to use only time slots which were not occupied by the integral assignments from previous iterations and the total number of pages transmitted in every interval on each iteration is exactly the length of this interval minus the amount of free space which could be used on the next iteration. The lemma thus follows. ∎

Thus we have the following theorem.

THEOREM 10. *The above algorithm produces a broadcast schedule with average response time at most* $3 \cdot OPT + O(\log^2(T+n))$, *where* OPT *denotes the average response time of the optimum schedule.*

3.5. Improving the approximation guarantee further. We first remove the dependence on T in the approximation ratio. We do this by showing that at the expense of a small loss (a factor of $(1 + o(1))$) in the approximation ratio, the time horizon T can be assumed to be polynomially bounded in n.

LEMMA 11. *We are given an instance* I *of the broadcast scheduling problem with planning horizon of length* T *and* n *pages. Then we can define instances* $I_1, \ldots, I_s$ *such that each* I_i *has a time horizon of length at most* $2n^5$, *and the solutions to these satisfy the following properties:*

1. *Let* LP^* *and* LP_i *denote the optimal value to the LP* (1)–(6) *for* I *and* I_i, *respectively. Then,* $\sum_{i=1}^{s} LP_i \leq (1 + o(1)) LP^*$.
2. *Given any integral solutions* $IP_1, \ldots, IP_s$ *for* $I_1, \ldots, I_s$, *respectively, we can obtain another solution for* I *with cost* $(1 + o(1))(\sum_{i=1}^{s} IP_i)$.

It is easily seen that this lemma allows us to assume that $T = \text{poly}(n)$. In particular, we can apply this decomposition to the original instance I, obtain an $O(\log n)$ approximation to each of these instances, and then use the second property to obtain an integral solution to I.

Proof of Lemma 11. We describe a randomized decomposition procedure which satisfies the properties in expectation. Once we describe this procedure it will be immediately clear how this can be derandomized in polynomial time. We first split the original time interval $[1, T]$ into time intervals $T_1, \ldots, T_s$ as follows. Choose an integer $k = 1, \ldots, n^5$ uniformly at random, and let $T_1 = [1, k + n^5]$, and $T_i = (k + (i-1)n^5, k + in^5]$ for $i = 2, \ldots, s$. Let $V_i \subseteq T_i$ denote the interval consisting of the last n time steps of T_i for $i = 1, \ldots, s$. The instance I_i consists of two types of requests in I: those that arrive during $T_i \setminus V_i$ and those that arrive during V_i. We keep the requests

that arrive during $T_i \setminus V_i$ unchanged and move those that arrive during V_i to I_{i+1} by changing their arrival time to the beginning of T_{i+1} (thus I_i contains the requests that arrive during V_{i-1}). This completes the description of the instances. Note that there are only $O(n^5)$ possible decompositions, and hence the procedure can be easily derandomized by trying out all choices of k.

Consider an optimal solution (x, y) to LP (1)–(6) for I. Suppose we choose this solution for each I_i. Then response times for requests that arrive during $T_i \setminus V_i$ remain unchanged and it can only increase for those that arrive during V_i. To handle this, we modify the solution (x, y) as follows. Consider the first n^2 time slots of T_{i+1}, since there are n pages there must be at least some page p_{i+1} such that the amount of p_{i+1} transmitted by the LP during these slots is at least n. We remove $n-1$ units of page p_{i+1} from these slots and, for every page other than p_{i+1}, arbitrarily assign one unit of this page fractionally to the free space in the first n^2 slots. This can increase the response time of requests that arrive during T_{i+1} by at most n^2. Moreover, the response time of requests that arrive during V_i is at most $n^2 + n$. Since a request has a probability of at most $n/n^5 = 1/n^4$, over the random choices of k, of arriving in some V_i, the expected increase in the total response time of requests in V_i is at most $(n^2 + n)m/n^4 = o(m)$, where m is the total number of requests in the instance. Thus the average response time increases by at most $o(1)$. Similarly, for requests in the first n^2 slots of T_{i+1} the average response time increases by at most $n^2 m/n^3 = o(m)$ in expectation. This implies the first part of the lemma.

We now prove the second part of the lemma. Assume we are given an integral solution for each I_i. Since all requests in I_i arrive during $T_i \setminus V_i$ and $|V_i| = n$, we can assume that all the requests in I_i are satisfied during T_i. Consider the integral solution for I obtained by concatenating all of the schedules for I_i. When we consider this schedule for the instance I, the only difference is that the response time for requests that arrived during V_i can have an additional response time of n, since these requests were moved at most n steps in the future to obtain the instances I_i. Again, over the random choices of k, the probability that a request lies in some V_i is $1/n^4$ and hence the expected increase in the average response time is at most $n/n^4 = 1/n^3$. This proves the desired result. ∎

We next show how to obtain a more refined balance between the multiplicative and additive term in Theorem 10.

LEMMA 12. *For any $\gamma > 0$, there is algorithm that achieves an approximation guarantee of $(2+\gamma)OPT + O(\log_{1+\gamma}(T+n) \cdot \log(T+n))$ for minimizing the average response time. Choosing γ close to 0 implies a guarantee of $(2+\gamma) \cdot OPT + O(\log^2(T+n)/\gamma)$.*

Proof. For a fixed $\gamma > 0$, we modify the definition (see Definition 2) of a p-good point such that we call a time t to be p-good if $r(p,t) \leq (1+\gamma) r(p,\tau)$ for all τ, t such that $c(p,\tau,t) < 1$. With this modification, imitating Lemma 3, we can form blocks $B(p,i)$, where the amount of page p transmitted in a block is at most $\log_{1+\gamma}(T+n) + 2$. Moreover, Lemma 4 now gives us that the expected response time of the tentative schedule obtained is at most $(2+\gamma)$ times the optimum cost. Now repeat the algorithm in section 3.3 with intervals of size $5\log_{1+\gamma}(T+n)$ (instead of intervals of size $5\log(T+n)$). Again we have that the number of blocks reduces by more than a factor of half at each iteration while adding $O(\log_{1+\gamma}(T+n))$ to the backlog. Thus, there are $O(\log(T+n))$ iterations of step 2 of the algorithm, and it follows directly that the backlog of the tentative schedule thus constructed is at most $O(\log_{1+\gamma}(T+n) \cdot \log(T+n))$, which implies the desired guarantee. ∎

By Theorem 10, Lemma 11, and setting $\gamma = \log(T+n)$ in Lemma 12, we have the following theorem.

THEOREM 13. *There is a polynomial time algorithm that produces a broadcast schedule with average response time at most* $O((\log^2 n/\log\log n)OPT)$*, where OPT denotes the average response time of the optimum schedule.*

4. Bad instance for local rounding procedures. We show that any way of rounding the ILP (1)–(6) that gives a tentative schedule that is local is unlikely to achieve an approximation ratio better than $O(\sqrt{n})$. Recall that a local rounding procedure ensures that there is a transmission of page p in every time interval $[t_1, t_2]$, where the LP transmits at least one unit of page p. One consequence of having a local schedule is that if a page p is broadcast at time t, then the next broadcast of page p must be at some time t' such that the cumulative amount of page p transmitted by the LP solution during $(t, t']$ is no more than 1. We give an example of an LP solution for which every tentative schedule that is local has a backlog of $\Omega(\sqrt{n})$ at some time. This will imply that algorithmic techniques based on local tentative schedules are unlikely to yield an approximation guarantee better than $\Theta(\sqrt{n})$.

We construct a half integral LP solution as follows: Let H be the Hadamard matrix of order n, and J be the matrix of order n with all entries equal to 1. Consider the matrix $A = \frac{1}{2}(H+J)$. The matrix A is a $\{0,1\}$ matrix where each row A_i (except for the one with all 1's) contains exactly $n/2$ 1's. A well-known property (see, for example, [9, p. 17]) of A is that for any vector $x \in \{-1,+1\}^n$, there is a row with a discrepancy of at least $\sqrt{n}/2$. That is, for each vector $x \in \{-1,+1\}^n$, $|A_i x| \geq \sqrt{n}/2$ for some $1 \leq i \leq n$.

We view these A_i as subsets of $\{1,\ldots,n\}$. We also assume that n is a multiple of 4. Let n_i denote the number of $1's$ in A_i. Let $S_i = n_1 + \cdots + n_i$, and let $S_0 = 0$. The LP schedule is constructed as follows: The schedule transmits, in any particular order, 1/2 unit of each page in A_i during the interval $(S_{i-1}, S_{i-1} + n_i/2]$, and again during the interval $(S_{i-1} + n_i/2, S_i]$. For $j \in A_i$, we denote the time when it is transmitted (half unit) during $(S_{i-1}, S_{i-1} + n_i/2]$ its *odd* slot and its transmission during $(S_{i-1} + n_i/2, S_i]$ its *even* slot.

Now, any local tentative schedule requires that if a page is transmitted in its odd slot at some time t, then the next transmission of this page must be no later than next odd slot for this page, and similarly for even slots. We first note that it suffices to consider *strictly* local schedules where each page in transmitted in the tentative schedule only during the odd slots or only during the even slots. Indeed, if some page is transmitted in both an odd slot and the adjacent even slot, then the number of transmissions of the page in the integral solution will be strictly more than those in the LP solution, leading to a backlog of at least 1. Repeating the instance k times (with completely disjoint set of pages) will imply a backlog of k. Thus it suffices to consider strictly local schedules.

A strict local schedule associates a vector $x \in \{-1,+1\}^n$, where the ith entry is -1 if page i is transmitted during odd slots and is 1 otherwise. As the number of pages transmitted by the tentative schedule during $(S_{i-1}, S_i]$ is exactly n_i, it is easy to see that $|A_i x|$ is exactly equal to the backlog at time $S_{i-1} + n_i/2$ or S_i, which implies the desired claim for strict tentative schedules.

5. Concluding remarks. In the offline setting, nothing more than NP-completeness is known for the problem. It would also be very interesting to construct nontrivial integrality gaps for the LP relaxation considered in this paper. Currently, the best

known integrality gap for the LP relaxation is 1.027 [2], and hence it is possible that an $O(1)$ approximation for the problem can be obtained using this LP.

Another very interesting problem would be to give an $O(1+\epsilon)$-speed, $O(1)$-competitive algorithm for the online version of the problem. Currently, no $O(1)$ competitive algorithm is known for the problem that uses a speed up of less than 4.

Acknowledgments. We thank Moses Charikar, Sanjeev Khanna, Tomasz Nowicki, Tracy Kimbrel, Seffi Naor, Kirk Pruhs, Baruch Schieber, and Grzegorz Swirszcz for helpful discussions.

GEOMETRIC COMPLEXITY THEORY II: TOWARDS EXPLICIT OBSTRUCTIONS FOR EMBEDDINGS AMONG CLASS VARIETIES*

KETAN D. MULMULEY† AND MILIND SOHONI‡

Dedicated to Sri Ramakrishna

Abstract. In [K. D. Mulmuley and M. Sohoni, *SIAM J. Comput.*, 31 (2001), pp. 496–526], henceforth referred to as Part I, we suggested an approach to the P vs. NP and related lower bound problems in complexity theory through geometric invariant theory. In particular, it reduces the arithmetic (characteristic zero) version of the $NP \not\subseteq P$ conjecture to the problem of showing that a variety associated with the complexity class NP cannot be embedded in a variety associated with the complexity class P. We shall call these *class varieties* associated with the complexity classes P and NP. This paper develops this approach further, reducing these lower bound problems—which are all nonexistence problems—to some existence problems: specifically to proving the existence of *obstructions* to such embeddings among class varieties. It gives two results towards explicit construction of such obstructions. The first result is a generalization of the Borel–Weil theorem to a class of orbit closures, which include class varieties. The second result is a weaker form of a conjectured analogue of the second fundamental theorem of invariant theory for the class variety associated with the complexity class NC. These results indicate that the fundamental lower bound problems in complexity theory are, in turn, intimately linked with explicit construction problems in algebraic geometry and representation theory. The results here were announced in [K. D. Mulmuley and M. Sohoni, in *Advances in Algebra and Geometry (Hyderabad,* 2001*)*, Hindustan Book Agency, New Delhi, India, 2003, pp. 239–261].

1. Main results.

We shall now state the results precisely. For the sake of completeness, we recall in section 2 the main results from Part I of this paper [26]. The rest of this paper is self-contained. All groups in this paper are algebraic, and the base field is $\mathbb{C}$.

Let G be a connected, reductive group, V its (finite dimensional) linear representation, and $P(V)$ the corresponding projective space. Let $\Delta_V[v]$ denote the projective closure of the G-orbit of v in $P(V)$. It is an almost-homogeneous space in the terminology of [1]. Let $R_V[v]$ be its homogeneous coordinate ring, $I_V[v]$ its ideal, and $R_V[v]_d$ the degree d component of $R_V[v]$.

In Part I, we reduced arithmetic (characteristic zero) implications of the lower bound problems in complexity theory, such as P vs. NP and NC vs. $P^{\#P}$, to instances of the following problem (section 2).

PROBLEM 1.1 (the orbit closure problem). *Given explicit points $f, g \in P(V)$, does $f \in \Delta_V[g]$? Equivalently, is $\Delta_V[f] \subseteq \Delta_V[g]$?*

*Received by the editors January 24, 2005; accepted for publication (in revised form) January 10, 2008; published electronically July 16, 2008.

The goal is to show that this is not the case in the problems under consideration.

The f's and g's here depend on the complexity classes in the lower bound problem under consideration. In the context of the P vs. NP problem, the point g will correspond to a judiciously chosen P-complete problem, and f to a judiciously chosen NP-complete problem. We call $\Delta_V[g]$ and $\Delta_V[f]$ the *class varieties* associated with the complexity classes P and NP (this terminology was not used in Part I). The orbit closure problem in this context is to show that the class variety associated with NP cannot be embedded in a class variety associated with P. We have oversimplified the story here. There is not just one class variety associated with a given complexity class, but a sequence of class varieties depending on the parameters of the lower bound problem under consideration. In the context of the P vs. NP problem, the goal is to show that a class variety for NP associated with a given set of parameters cannot be embedded in the class variety for P associated with the same set of parameters. This would imply that $P \neq NP$ in characteristic zero.

Class variety for the complexity class NC. We give an example of a class variety associated with the complexity class NC, the class of problems with efficient parallel algorithms. This occurs in the context of the NC vs. $P^{\#P}$ problem (section 2.1). Here we let g be the determinant function, which is a complete function for this class. Specifically, let Y be an $m \times m$ variable matrix, which can also be thought of as a variable l-vector, $l = m^2$. Let $V = \mathrm{Sym}^m(Y)$ be the space of homogeneous forms of degree m in the l variable entries of Y, with the natural action of $G = SL(Y) = SL_l(\mathbb{C})$. Let $g = \det(Y) \in P(V)$ be the determinant form, considered as a point in the projective space. Then $\Delta_V[g]$, the orbit closure of the determinant function, is the class variety associated with NC. This is a basic example of a class variety, which the reader may wish to keep in mind throughout this paper.

For arbitrary f and g, Problem 1.1 is hopeless. But f and g in the preceding lower bound problems can be chosen judiciously, like the determinant function, to have some special properties (cf. section 2 and Part I). To state these properties, we need a few definitions.

Given a point $v \in P(V)$, let $\hat{v} \in V$ denote a nonzero point on the line representing v; the exact choice of $\hat{v}$ will not matter. Let $G_v, G_{\hat{v}} \subseteq G$ denote the stabilizers of v and $\hat{v}$, respectively. We say that v is *characterized* by its stabilizer if $V^{G_{\hat{v}}}$, the set of points in V stabilized by $G_{\hat{v}}$, is equal to $\mathbb{C}v$, the line in V corresponding to v.

Following Mumford, Fogarty, and Kirwan [27] and Kempf [10], we say that v is *stable* if the orbit $G\hat{v} \subseteq V$ is closed, and *semistable* if the closure of this orbit does not contain zero. We say v belongs to the *null cone* if all homogeneous G-invariants of positive degree vanish at $\hat{v}$. We also define a more general notion of *partial stability* which also applies to points in the null cone. A stable point is also partially stable by definition. Now suppose v is not stable. Let S be any closed G-invariant subset of V not containing $\hat{v}$ and meeting the boundary of the orbit $G\hat{v}$. Kempf [10] associates with v and S a canonical parabolic subgroup $P = P[S, v] \subseteq G$, called its canonical destabilizing flag. Let L be its semisimple Levi subgroup. We say that v is *partially stable* with defect zero or, more specifically, (L, P)-stable if (1) the unipotent radical U of P is contained in G_v and (2) v is stable with respect to the restricted action of L on V. A more general notion of partial stability allowing nonzero defect is given later (Definition 7.1).

We say that v is *excellent* if

1. it is stable or partially stable with defect zero, and
2. it is characterized by its stabilizer.

If V is an irreducible representation $V_\lambda(G)$ of G, corresponding to a dominant weight λ, then the point in $P(V)$ corresponding to the highest weight vector of G is excellent. This is the simplest example of an excellent point. In this case, the stabilizer G_v is a parabolic subgroup $P = P_\lambda$ of G, and the orbit $Gv \cong G/P$ is closed. Hence $\Delta_V[v] \cong G/P$. The algebraic geometry of G/P has been intensively studied in the literature and is well understood by now; cf. [5, 13] for surveys.

For the lower bound problems under consideration, the points f and g can be chosen so that they are either excellent or almost excellent; the meaning of almost excellent is stated in section 2. For example, the determinant function above is excellent. In this paper, we shall develop an approach to the orbit closure problem specifically for such f and g. The goal is to understand the orbit closure problem by systematically extending the results for G/P to the (almost) excellent points that arise in this approach.

A natural approach to the orbit closure problem is the following. If f lies in $\Delta_V[g]$, then the embedding $\Delta_V[f] \hookrightarrow \Delta_V[g]$ is G-equivariant. This gives a degree preserving G-equivariant surjection from $R_V[g]$ to $R_V[f]$. Hence, if S is any irreducible representation of G, its multiplicity in $R_V[g]_d$ is greater than or equal to its multiplicity in $R_V[f]_d$, for all d.

DEFINITION 1.2. *We say that S is an* obstruction *for the pair (f, g) if, for some d,*

1. *it occurs in (a complete G-decomposition of) $R_V[f]_d$,*
2. *but not in $R_V[g]_d$.*

Existence of such an S implies that f cannot lie in $\Delta_V[g]$. In a lower bound problem, this S can be considered to be a "witness" to the computational hardness of f.

If S occurs in $R_V[g]_d$, then it is easy to show (Proposition 4.2) that its dual S^* contains a G_g-module isomorphic to $(\mathbb{C}g)^d$, the dth tensor power of $\mathbb{C}g$. Hence we are led to the following definition.

DEFINITION 1.3. *We say that S is a* strong obstruction *if, for some d,*

1. *it occurs in $R_V[f]_d$,*
2. *but its dual S^* does not contain a G_g-module isomorphic to $(\mathbb{C}g)^d$.*

A strong obstruction is also an obstruction.

For the (f, g)'s in the lower bound problems under consideration, strong obstructions are conjectured to exist in plenty (section 3). But to prove their existence it is necessary to construct them more or less explicitly. Otherwise, the proof technique cannot cross the natural proof barrier formulated in [28] that any technique for proving the $P \neq NP$ conjecture must cross. Explicit constructions have been used in the theory of computing earlier in different contexts. For example, explicit expanders, needed for efficient pseudorandom generation, have been constructed by Margulis [20], and Lubotzky, Phillips, and Sarnak [16]. The essential difference from the situation here is that proving existence of expanders is easy, whereas proving existence of obstructions is itself the main problem.

Hence, we are led to the following problem.

PROBLEM 1.4 (explicit construction of obstructions). *Given f and g as in Problem* 1.1*, explicitly construct a (strong) obstruction for the embedding $\Delta_V[f] \hookrightarrow \Delta_V[g]$.*

In the orbit closure problems under consideration, $H = G_g$ turns out to be a reductive subgroup of G. Hence, to solve Problem 1.4, we have to solve the following problems first.

PROBLEM 1.5 (subgroup restriction problem). *Let H be a reductive subgroup of*

a connected, reductive group G. Find an explicit decomposition of a given irreducible G-representation S as an H-module.

This arises in the context of the second condition in Definition 1.3 (with S^* in place of S).

Problem 1.5, with H equal to the stabilizer of the determinant function considered earlier, turns out to be equivalent to the Kronecker problem of finding an explicit decomposition of the tensor product of two irreducible representations of the symmetric group; cf. section 2. This is an outstanding problem in the representation theory of the symmetric group [19, 5]. Other specific instances of Problem 1.5 that arise in the lower bound problems under consideration (cf. section 2) include the well-known plethysm problem [19, 5], which is an outstanding problem in the representation theory of $GL_n(\mathbb{C})$.

PROBLEM 1.6 (problem in geometric invariant theory). *Let $v \in P(V)$ be an (almost) excellent point. Find an explicit decomposition of $R_V[v]_d$, for a given d, as a G-module.*

This is needed in the context of both conditions in Definition 1.2. For this, it is desirable to solve the following problem first.

PROBLEM 1.7 (SFT problem). *Let $v \in P(V)$ be an (almost) excellent point. Find an explicit set of generators for the ideal $I_V[v]$ of $\Delta_V[v]$ with good representation theoretic properties. (The short form SFT is explained below.)*

Problems 1.6 and 1.7 are intractable for general v's. Hence, specialization to almost excellent v's is necessary. Some additional reasonable restrictions may be necessary in these problems.

When $V = V_\lambda(G)$, v is the point corresponding to the highest weight vector of $V_\lambda(G)$, and $\Delta_V[v] \cong G/P$, the second fundamental theorem (SFT) of invariant theory for G/P [13] answers Problem 1.7. By the Borel–Weil theorem for G/P [5], $R_V[v]_d = V_{d\lambda}(G)^*$. This answers Problem 1.6.

What is desired is a generalization of these results for G/P to the class varieties $\Delta_V[v]$, for the (almost) excellent v's under consideration. Before we go any further, let us point out the main difference between G/P and the class varieties:

1. Luna and Vust [18] have assigned a complexity to orbit closures, which measures the complexity of their algebraic geometry. All orbit closures whose algebraic geometry has been well understood have low Luna–Vust complexity—close to zero. For example, the Luna–Vust complexity of G/P is zero. In contrast, the Luna–Vust complexity of a class variety can be polynomial in the number of parameters in the lower bound problem under consideration.
2. The analogue of the subgroup restriction problem (Problem 1.5), with H being the parabolic stabilizer P of the highest weight vector in $V_\lambda(G)$, is trivial. In contrast, the instances of Problem 1.5 in the context of the class varieties include the nontrivial Kronecker and plethysm problems.

This indicates that the algebraic geometry of class varieties is substantially more complex than that of G/P. For this reason, we cannot expect a full solution to Problems 1.6 and 1.7 until the outstanding Problem 1.5 in representation theory is resolved. Rather, our goal is to connect Problems 1.6 and 1.7 with the "easier" Problem 1.5 for the almost excellent v's under consideration. We prove two results in this direction.

Let us begin by considering a weaker form of Problem 1.6; i.e., we only ask which G-modules can occur in $R_V[v]$, without worrying about $R_V[v]_d$ for a specific d. This is addressed by the following result.

We call a G-module $V_\lambda(G)$ $G_{\hat{v}}$-admissible if it contains a $G_{\hat{v}}$-invariant (cf. Definition 4.1).

THEOREM 1.1 (Borel–Weil for orbit closures of partially stable points). *Let V be a (finite dimensional) linear representation of a connected, reductive G.*

(a) *If $v \in P(V)$ is stable, an irreducible G-module $V_\lambda(G)$ with weight λ can occur in $R_V[v]$ iff $V_\lambda(G)$ is $G_{\hat{v}}$-admissible.*

(b) *Suppose v is partially stable with defect zero, specifically (L, P)-stable, as defined above. Let $S_V[v]$ be the homogeneous coordinate ring of the projective closure in $P(V)$ of the L orbit of v. Then the G-module structure of $R_V[v]$ is completely determined by the L-module structure of $S_V[v]$. A weaker statement holds for a partially stable point of nonzero defect as defined in section 7.*

A precise statement of (b) is given in section 8. We actually prove a stronger result (Theorem 8.2) that specializes to the Borel–Weil theorem [11] when v corresponds to the highest weight vector of an irreducible representation $V = V_\lambda(G)$ of a semisimple G.

When the defect is nonzero, Theorem 1.1(b) does not tell precisely which irreducible G-modules occur in $R_V[v]$ if we only know which irreducible L-modules occur in $S_V[v]$ as a whole. But it gives good information on this and also on which irreducible G-modules occur in $R_V[v]_d$, for a given d, provided we know precisely which irreducible L-modules occur in every degree d-component $S_V[v]_d$; this is Problem 1.6 for a stable v, with L playing the role of G.

Now we turn to the actual Problem 1.6. For this, we have to understand Problem 1.7 first. We turn to this problem next.

Let v be an excellent point. We associate with it a representation-theoretic data $\Pi_v = \cup_d \Pi_v(d)$ (cf. Definitions 6.1 and 10.1). If v is stable, $\Pi_v(d)$ is just the set of all irreducible G-submodules of $\mathbb{C}[V]$ whose duals do not contain a G_v-submodule isomorphic $(\mathbb{C}v)^d$.

Then the ideal $I_V[v]$ contains all modules in Π_v (Proposition 4.2). Let $X(\Pi_v)$ be the variety (scheme) defined by the ideal generated by the modules in Π_v. It follows that $\Delta_V[v] \subseteq X(\Pi_v)$.

Now we ask the following question.

QUESTION 1.8. *Suppose v is excellent. Is $X(\Pi_v) = \Delta_V[v]$ as a variety or, more strongly, as a scheme?*

The scheme theoretic equality means that the ideal $I_V[v]$ of $\Delta_V[v]$ is generated by the modules in Π_v.

If v is stable, then G_v is reductive [2, 24]. Hence, the G-modules contained in Π_v are precisely determined once we know the answer to Problem 1.5, with $H = G_v$. This turns out to be so even for the partially stable v's that arise in the lower bound problems, by letting H be the reductive part of G_v. Hence, if the answer to Question 1.8 is yes, the algebraic geometry of $\Delta_V[v]$ is completely determined by the representation theory of the pair (G_v, G), and hence, Problems 1.6 and 1.7 are intimately related to Problem 1.5. Clearly, this can happen only for very special v's. The answer need not be yes even for a general excellent v.

When v corresponds to the highest weight vector of $V_\lambda(G)$, so that $\Delta_V[v] = G/P$, the answer to Question 1.8 is yes. This follows from the SFT for G/P [13] (cf. section 10.1).

We conjecture that the situation is similar for the class variety associated with the complexity class NC.

CONJECTURE 1.9 (SFT for the orbit closure of the determinant). *Let $\Delta_V[v]$ be*

the class variety associated with the complexity class NC—the orbit closure of the determinant function.

Then $X(\Pi_v) = \Delta_V[v]$ as a variety. (It would be interesting to know if this is so even as a scheme.)

This conjecture is expected because of the very special nature of the determinant function. We have already remarked that it is excellent. Furthermore, its stabilizer has an additional conjectural property called G-separability (Definition 6.3). For analogous conjectures for other almost excellent class varieties, one has to address complications caused by almost excellence instead of full excellence. This is possible and will be done elsewhere.

The following general result implies a weaker form of Conjecture 1.9 when v is the determinant function.

THEOREM 1.2 (SFT for the orbit of an excellent point). *Suppose V is a linear representation of a connected, reductive group G, and $v \in P(V)$ is an excellent point.*

(a) *Suppose v is stable. Furthermore, assume that the stabilizer $G_{\hat{v}}$ is G-separable (cf. Definition 6.3). Then the orbit $Gv \subseteq P(V)$ is determined by the representation-theoretic data Π_v within some G-invariant neighborhood U, i.e.,*

$$Gv = \Delta_V[v] \cap U = X(\Pi_v) \cap U,$$

as schemes.

(b) *A generalized result also holds for the G-orbit of a partially stable, excellent point with defect zero.*

This follows from a stronger result proved in section 6 (stable case) and section 11 (partially stable case).

When v corresponds to the highest weight vector in $V_\lambda(G)$, Theorem 1.2(b), after some strengthening (cf. section 10.1), becomes the second fundamental theorem for G/P [13]—hence the terminology.

The rest of this paper is organized as follows. In section 2, we describe how the orbit closure problem arises in complexity theory, and we summarize the relevant results from Part I. In section 3 we describe why obstructions should exist in the context of the orbit closure problems under consideration. In section 4 we prove some basic propositions based on the notion of admissibility. The stable case of Theorem 1.1 is proved in section 5. The stable case of Theorem 1.2 is proved in section 6. The stable cases illustrate the main ideas in this paper. The notion of partial stability is introduced in section 7. The partially stable case of Theorem 1.1 is proved in section 8. Its specialization in the context of complexity theory is given in section 9. The partially stable case of Theorem 1.2 is proved in section 11. Conjectural G-separability of the stabilizer of the determinant is proved in section 12 for a special case.

Notation. We let G denote a connected reductive group. An irreducible G-representation with highest weight λ will be denoted by $V_\lambda(G)$. We say that $V_\lambda(G)$ occurs in a G-module M, or that M contains $V_\lambda(G)$, if a complete decomposition of M into G-irreducibles contains a copy of $V_\lambda(G)$. We denote the dual of M by M^*. We always denote a Levi-decomposition of a parabolic subgroup $P \subseteq G$ in the form $P = TLU = KU$, where T is a torus, L is a semisimple Levi subgroup, $K = TL$ is a reductive Levi subgroup, and U is the unipotent radical. The root system of K is a subsystem of that of G. Hence a dominant weight of G can be assumed to be a dominant weight of K by restriction.

2. The orbit closure problem. In this section we describe the orbit closure problem that arises in complexity theory and the related results; cf. Part I for details and proofs.

Let $Y = [y_0, \cdots, y_{l-1}]$ denote a variable l-vector. For $k < l$, let $X = [y_1, \cdots, y_k]$ and $\bar{X} = [y_0, \cdots, y_k]$ be its subvectors of size k and $k+1$. Let $V = \mathrm{Sym}^m(Y) = \mathrm{Sym}^m((\mathbb{C}^l)^*)$ be the space of homogeneous forms of degree m in the l variable-entries of Y, with the natural action of $G = SL(Y) = SL_l(\mathbb{C})$, and $\hat{G} = GL(Y) = GL_l(\mathbb{C})$.

Let $W = \mathrm{Sym}^n(X)$, $n < m$, be the representation of $GL(X) = GL_k(\mathbb{C})$. We have a natural embedding $\phi : W \to V$, which maps any $w \in W$ to $y^{m-n}w$, where $y = y_0$ is used as the homogenizing variable. The image $\phi(W)$ is contained in $\bar{W} = \mathrm{Sym}^m(\bar{X})$, a representation of $GL(\bar{X}) = GL_{k+1}(\mathbb{C})$.

DEFINITION 2.1. *We say that $f = \phi(h)$ is partially stable with respect to the action of G (and also $\hat{G}$) if $h \in P(W)$ is stable with respect to the action of $SL_k(\mathbb{C})$.*

These are the only kinds of partially stable points that arise in the context of complexity theory. If the reader wishes, he may confine himself to only these kinds. When we introduce a more general definition of partial stability (section 7), it will turn out that f is partially stable with defect one. In contrast, the (L, P)-stable points in the introduction will turn out to be partially stable points with defect zero. Note that f in Definition 2.1 belongs to the null cone of the G-action—this follows easily from the Hilbert–Mumford criterion [27].

The orbit closure problems (Problem 1.1) that arise in complexity theory (cf. Part I) have the following form.

PROBLEM 2.2. *Given fixed forms $g \in P(V)$ and $h \in P(W) \overset{\phi}{\hookrightarrow} P(V)$, does $f = \phi(h)$ belong to $\Delta_V[g]$? That is, is $\Delta_V[f] \subseteq \Delta_V[g]$?*

The goal is to show that the specific f does not belong to $\Delta_V[g]$. The specific f and g depend on the lower bound problem under consideration and will be either excellent (cf. section 1) or almost excellent. The latter means that (1) the defect of partial stability may not be zero, but will be small, and (2) the point may not be fully characterized by the stabilizer, but almost (as explained in Part I).

The following are two instances of the orbit closure problem that arise in complexity theory.

2.1. Arithmetic version of the NC vs. $P^{\#P}$ conjecture. In concrete terms, this says that the permanent of an $n \times n$ matrix cannot be computed by an integral circuit of depth $\log^c n$, for any constant $c > 0$ [31].

The class varieties in this context are as follows. Let Y be an $m \times m$ variable matrix, which can also be thought of as a variable l-vector, $l = m^2$. Let X be its, say, principal bottom-right $n \times n$ submatrix, $n < m$, which can be thought of as a variable k-vector, $k = n^2$. We use any entry y of Y not in X as the homogenizing variable for embedding $W = \mathrm{Sym}^n(X)$ in $V = \mathrm{Sym}^m(Y)$. Let $g = \det(Y) \in P(V)$ be the determinant form (which will also be considered as a point in the projective space), and $f = \phi(h)$, where $h = \mathrm{perm}(X) \in P(W)$. Then $\Delta_V[g]$ is the class variety associated with NC, and $\Delta_V[f]$ is the class variety associated with $P^{\#P}$. These depend on the lower bound parameters n and m. If we wish to make these implicit, we should write $\Delta_V[f, n, m]$ and $\Delta_V[g, m]$ instead of $\Delta_V[f]$ and $\Delta_V[g]$.

It is conjectured in Part I that, if $m = 2^{O(\mathrm{polylog}_n)}$ and $n \to \infty$, then $f \notin \Delta_V[g]$; i.e., the class variety $\Delta_V[f, n, m]$ cannot be embedded in the class variety $\Delta_V[g, m]$. This implies the arithmetic form of the $NC \neq P^{\#P}$ conjecture.

The following result provides the connection with geometric invariant theory.

THEOREM 2.1 (cf. Part I). *The point $h = perm(X) \in P(W)$ is stable with respect to the action of $SL(X) = SL_k(\mathbb{C})$ on $P(W)$ (thinking of X as a k-vector). Hence the point $f = \phi(h) \in P(V)$ is partially stable (Definition 2.1) with respect to the action of $G = SL(Y) = SL_l(\mathbb{C})$, as well as $\hat{G} = GL(Y) = GL_l(\mathbb{C})$.*

Similarly, $g = \det(Y) \in P(V)$ is stable with respect to the action of G on $P(V)$, thinking of Y as an l-vector on which $SL_l(\mathbb{C})$ acts in the usual way.

Moreover, both $\mathrm{perm}(X) \in P(W)$ and $\det(Y) \in P(V)$ are characterized by their stabilizers. Hence, both h and g are excellent. But, in contrast, $f = \phi(h)$ is only almost excellent—because its defect of partial stability is one.

The stabilizer of $\det(Y)$ in $G = SL_{m^2}(\mathbb{C})$ consists of linear transformations of the form $Y \to AY^*B^{-1}$, thinking of Y as an $m \times m$ matrix, where Y^* is either Y or Y^T, $A, B \in GL_m(\mathbb{C})$. The stabilizer of $\mathrm{perm}(X)$ in $SL_{n^2}(\mathbb{C})$ is generated [22] by linear transformations of the form $X \to \lambda X \mu^{-1}$, thinking of X as an $n \times n$ matrix, where λ and μ are either diagonal or permutation matrices.

Let $H \subseteq G = SL_{m^2}(\mathbb{C})$ be the stabilizer of $\det(Y)$. Since $SL_m(\mathbb{C}) \times SL_m(\mathbb{C})$ is a subgroup of H, the subgroup restriction problem (Problem 1.5) in this context becomes the following problem.

PROBLEM 2.3 (Kronecker problem). *Given a partition λ of height at most m^2, find an explicit decomposition of $V_\lambda(G)$ as an $SL_m(\mathbb{C}) \times SL_m(\mathbb{C})$-module:*

$$V_\lambda(G) = \oplus_{\alpha,\beta} k^\lambda_{\alpha,\beta} V_\alpha(SL_m(\mathbb{C})) \otimes V_\beta(SL_m(\mathbb{C})),$$

where α, β range over partitions of height at most m.

The coefficients $k^\lambda_{\alpha,\beta}$'s here are the same as the Kronecker coefficients that arise in the internal product of Schur functions. The problem of decomposing the tensor product of two irreducible representations of the symmetric group S_m can be reduced to this problem [5]. This is one of the outstanding problems in the representation theory of symmetric groups.

2.2. Arithmetic (nonuniform) version of the $P \neq NP$ conjecture. This is a version of the usual $P \neq NP$ conjecture (the nonuniform version), which does not involve problems of positive characteristic and, hence, is addressed first.

Now h, g in the orbit closure problem (Problem 2.2) correspond to some integral functions that are NP-complete and P-complete, respectively. These functions have to be chosen judiciously, because most functions that arise in complexity theory, e.g., the one associated with the travelling salesman problem, do not have a nice stabilizer, as required in our approach. For a detailed definition of h and g, see Part I. We shall call $\Delta_V[f]$, $f = \phi(h)$, and $\Delta[g]$ for the specific h and g here the *class varieties* associated with the complexity classes NP and P. The conjecture that $NP \not\subseteq P$ in characteristic zero is then reduced to the problem of showing that the class variety $\Delta_V[f]$ associated with NP cannot be embedded in the class variety $\Delta_V[g]$ associated with P, for the parameters of the lower bound problem under consideration.

The following is an analogue of Theorem 2.1 in this context.

THEOREM 2.2. *The point $h \in P(W)$, for a suitable W, which corresponds to an NP-complete function as in* [26]*, is stable with respect to the action of $SL(W)$ on $P(W)$. Hence, the point $f = \phi(h)$ is partially stable.*

The h here is not completely characterized by its stabilizer, but almost so; cf. Part I. Hence it is almost excellent. The subgroup restriction problem, Problem 1.5, that arises for the stabilizer of h is essentially the well-known plethysm problem [5] in the theory of symmetric functions.

3. Why should obstructions exist? Before we go any further, we have to argue why obstructions should exist for the pairs (f, g) that arise in the lower bound problems under consideration.

Let us begin with an observation that for an orbit closure problem that arises in complexity theory, an obstruction for the pair (f, g) cannot exist if l is sufficiently larger than k. For example, let $(f, g) = (\phi(h), g)$, where $h = \text{perm}(X)$ and $g = \det(Y)$, as in section 2.1. Then there cannot be any obstruction for $m > n!$ or, for that matter, $m > 2^{cn}$ for a large enough constant c. This is because $\text{perm}(X)$ has a formula of size 2^{cn} for a large enough $c > 0$ [22] (the usual formula is of size $n!$), and hence $f \in \Delta_V[g]$, for $m > 2^{cn}$ (cf. Part I).

At the other extreme, when $l = k$, so that f is a stable point of V, it follows from the étale slice theorem [27, 17] that, if $f \in \Delta_V[g]$, then some conjugate of the stabilizer of f must be contained in the stabilizer of g (cf. Part I). This will not happen for our judiciously chosen f and g. For example, when f and g are the permanent and the determinant and $m = n$—in fact, in this case there are infinitely many obstructions to this containment (cf. Part I).

The goal is to understand the transition between these two extremes.

First, let us consider the arithmetic implication of the $P^{\#P} \neq NC$ conjecture. Let $g = \det(Y)$, $f = \phi(h)$, and $h = \text{perm}(X)$ as in section 2.1.

PROPOSITION 3.1. *Suppose $h = perm(X)$ cannot be approximated infinitesimally closely by a circuit of depth $O(\log^c n)$, where $c > 0$ is a constant, and $n \to \infty$. Suppose $X(\Pi_g) = \Delta_V[g]$ as varieties (cf. Conjecture* 1.9*). Then there exists a strong obstruction for the pair (f, g), for $m \leq 2^{\log^{c/2} n}$.*

Proof. It is proved in Part I that the hypothesis implies that $f \notin \Delta_V[g]$ if $m \leq 2^{\log^{c/2} n}$. Assuming $X(\Pi_g) = \Delta_V[g]$, this means $f \notin X(\Pi_g)$. Hence there exists a G-module $S \in \Pi_g$ which does not vanish on f, and hence on its orbit. So S occurs in $R_V[f]$. By the definition of Π_g, the dual S^* does not contain a G_g-module isomorphic to $(\mathbb{C}g)^d$. Hence S is a strong obstruction for the pair (f, g). □

Since $\text{perm}(X)$ is $\#P$-complete [31], it is not expected to have infinitesimally close approximations by circuits of $O(log^c(n))$ depth, for any constant $c > 0$. Hence, Proposition 3.1 leads to the following conjecture.

CONJECTURE 3.2. *There exist (infinitely many) strong obstructions for $(f, g) = (\phi(h), g)$, $g = \det(Y)$, $h = perm(X)$ if $m = 2^{\log^c n}$, c is a constant, and $n \to \infty$.*

In turn, this conjecture implies $f \notin \Delta_V[g]$ and, hence, the arithmetic implication of the $P^{\#P} \neq NC$ conjecture (section 2.1).

In the same vein, we also make the next conjecture.

CONJECTURE 3.3. *There exist (infinitely many) obstructions for $(f, g) = (\phi(h), g)$ that occur in the context of the P vs. NP problem if $m = poly(n)$ and $n \to \infty$, where n denotes the input size parameter and m denotes the circuit size parameter in the nonuniform version of the P vs. NP problem.*

This would imply $f \notin \Delta_V[g]$ and, hence, the arithmetic implication of the $P \neq NP$ conjecture in section 2.2. This conjecture is motivated by similar considerations as in Proposition 3.1. The g that occurs in the context of the P vs. NP problem is not fully characterized by its stabilizer. But it is still determined by its stabilizer to a large extent. Hence, similar considerations apply.

4. Admissibility. In this section, we introduce a basic notion of admissibility and study how it influences which G-modules may appear in the homogeneous coordinate ring $R_V[v]$ of the projective-orbit closure of a point $v \in P(V)$. The basic propositions proved here will be useful in the proofs of the main results.

DEFINITION 4.1. *Given a reductive subgroup $H \subseteq G$ and an H-module W, we say that a G-module M is (H, W)-admissible if some irreducible H-submodule of M occurs in W.*

We say that M is H-admissible if it is $(H, 1_H)$-admissible, where 1_H is the trivial H-module, i.e., if it contains a (nonzero) H-invariant.

For general H, not necessarily reductive, we say that M is H-admissible if M^* contains an H-invariant.

If H is reductive, M contains an H-invariant iff M^* does—this follows from Weyl's result on complete reducibility of a reductive group representation—and hence, the second and third statements are then equivalent.

Given a G-module S and a subgroup $H \subseteq G$, not necessarily reductive, we shall say that S has an H-coinvariant if S is H-admissible; i.e., the dual module S^* has an H-invariant (cf. Definition 4.1).

Let $h \in P(V)$ be any point, not necessarily stable. Let $\mathbb{C}h$ be the corresponding line in V. It is one-dimensional, i.e., a character, as a G_h-module, and trivial as a $G_{\hat{h}}$-module. Let $\check{\Delta}[h] = \check{\Delta}_V[h] \subseteq V$ denote the affine cone of the projective-orbit closure $\Delta[h]$. Its coordinate ring $\mathbb{C}[\check{\Delta}[h]]$ coincides with the homogeneous coordinate ring $R[h] = R_V[h]$ of $\Delta[h]$. Since the G-action is degree preserving, each homogeneous component $R[h]_d$ is a finite dimensional G-module.

PROPOSITION 4.2. *Let V be a linear representation of a reductive group G. Let $h \in P(V)$ be any point, not necessarily stable, with stabilizer $G_h \subseteq G$. Let S be any irreducible G-module occurring in $R[h]$—that is, in $R[h]_d$ for some d. Then the dual module S^* must contain a G_h-submodule isomorphic to $(\mathbb{C}h)^d$, and hence both S and S^* are $G_{\hat{h}}$-admissible. In particular, a G-module $S \subseteq \mathbb{C}[V]_d$ not satisfying this constraint belongs to the ideal $I_V[h]$.*

Similarly, given an algebraic subgroup $H \subseteq G$ and an H-module M, let $B = G \times_H M$ be the induced bundle [27] *with base space G/H and fiber M. Let N be any irreducible G-submodule of $\Gamma(G/H, B)$, the space of global sections of B. Then the G-module $Hom(N, M)$ must contain a nonzero H-invariant.*

Proof. Not all functions in S can vanish at $\hat{h}$: Otherwise, they will vanish identically on the G-orbit of $\hat{h}$ in V, and so also on its cone, since the functions in S are homogeneous. But the cone of the affine G-orbit of h is dense in $\check{\Delta}[h]$. Hence, it would follow that the functions in S vanish on $\check{\Delta}[h]$ identically, a contradiction.

Consider the G_h-equivariant map $\phi : S \to ((\mathbb{C}h)^*)^d = (\mathbb{C}h^d)^*$ that maps every function in S to its restriction on the line $\mathbb{C}h$. It follows that this evaluation map is nonzero. Hence the dual map ϕ injects the G_h-module $\mathbb{C}h^d$ into S^*.

The argument extends to the vector bundle B by considering instead the evaluation map $\phi : N \to M$ at the base point $e \in G/H$, which must be nonzero and H-equivariant; i.e., $\phi \in \mathrm{Hom}(N, M)^H$. ∎

5. Admissibility and stability. In this section we shall prove the first statement of Theorem 1.1 concerning stable points.

PROPOSITION 5.1. *Let $h \in P(V)$ be a point such that the stabilizer $H = G_{\hat{h}}$ of $\hat{h} \in V$ is reductive. Then every irreducible G-module occurring in $R[h]$ must be H-admissible; i.e., it must contain a nonzero H-invariant.*

If $G_{\hat{h}}$ is not reductive, this still holds if H is any reductive subgroup of $G_{\hat{h}}$.

Proof. If H is reductive, then Weyl's theorem on complete decomposibility of H-modules into irreducibles implies that the existence of an H-invariant is equivalent to the existence of an H-coinvariant. Hence this follows from Proposition 4.2. ∎

Conversely, we have the following proposition.

PROPOSITION 5.2. *Suppose $h \in P(V)$ is stable. Then every H-admissible, irreducible G-module occurs in $R[h]$.*

Proof. Since h is stable, the stabilizer $H = G_{\hat{h}}$ is reductive [3, 24], and the orbit $G\hat{h} \subseteq V$ is affine and isomorphic to G/H [27]. Moreover, an explicit G-module decomposition of the coordinate ring $\mathbb{C}[G\hat{h}] = \mathbb{C}[G/H]$ can be computed as follows. First, we recall (cf. [30, p. 48]) the algebraic version of the *Peter–Weyl theorem*:

$$\mathbb{C}[G] = \oplus_S S \otimes S^*, \tag{1}$$

where S ranges over all irreducible G-modules and S^* is the dual module. From this it follows that

$$\mathbb{C}[G/H] = \oplus_S S \otimes (S^*)^H, \tag{2}$$

where $(S^*)^H$ denotes the subspace of H-invariants in S^*. Since h is stable, the affine orbit $G\hat{h}$ is closed in V. So it is a closed G-subvariety of the cone $\check{\Delta}[h] \subseteq V$, which is also a G-variety. It follows that there is a G-equivariant surjection from $R[h]$ to $\mathbb{C}[G\hat{h}] = \mathbb{C}[G/H]$. Both $R[h]$ and $\mathbb{C}[G/H]$ have direct sum decompositions into finite dimensional G-modules. It follows that every irreducible G-module that occurs in $\mathbb{C}[G/H]$ must occur in $R[h]$. But by the Peter–Weyl theorem, i.e., (2), the irreducible G-modules that appear within $\mathbb{C}[G/H]$ are precisely the H-admissible ones. □

Proof of Theorem 1.1(a). Since $v \in P(V)$ is stable, $G_{\hat{v}}$ is reductive [3, 24]. Hence this follows from Propositions 5.1 and 5.2. □

6. SFT for the orbit of a stable, excellent point. In this section we prove Theorem 1.2 for stable points. To give its precise statement, we need a few definitions.

We associate with a stable point v representation-theoretic data Π_v and $\Sigma_v \subseteq \Pi_v$ as follows.

DEFINITION 6.1. *Suppose $v \in P(V)$ is stable.*

Let Σ_v be the set of all non–$G_{\hat{v}}$-admissible G-submodules of $\mathbb{C}[V]$—here $G_{\hat{v}}$ is necessarily reductive [3, 24].

Let $\Pi_v = \cup_d \Pi_v(d)$, where $\Pi_v(d)$ is the set of all irreducible G-submodules of $\mathbb{C}[V]$ whose duals do not contain a G_v-submodule isomorphic $(\mathbb{C}v)^d$—the dth tensor power of $\mathbb{C}v$.

Clearly $\Sigma_v \subseteq \Pi_v$. Basis elements (suitably chosen) of the G-submodules of Σ_v will be called *nonadmissible basis elements*.

PROPOSITION 6.2. *If v is stable, the G-modules in the representation-theoretic data Π_v, and hence Σ_v, associated with v are contained in $I_V[v]$.*

This follows from Proposition 4.2.

DEFINITION 6.3. *Given a reductive $H \subseteq G$, we say that a nontrivial, irreducible H-module L which occurs in some G-module is G-separable (from the trivial H-module) if there exists an irreducible non–H-admissible G-module M that contains L; we say it is strongly G-separable if there exist infinitely many such G-modules. We shall say that a subgroup $H \subseteq G$ is G-separable (strongly G-separable) if every nontrivial irreducible H-module which occurs in some G-module is G-separable (resp., strongly G-separable).*

For example, $SL_k(\mathbb{C}) \subseteq SL_n(\mathbb{C})$, $k > n/2$, and a semisimple $H \subseteq H \times H$ (diagonal embedding) are separable (Proposition 12.1). We conjecture that $SL_n(\mathbb{C}) \times SL_n(\mathbb{C}) \subseteq SL(\mathbb{C}^n \otimes \mathbb{C}^n) = SL_{n^2}(\mathbb{C})$ is separable and prove this for $n = 2$ (Proposition 12.6). We also conjecture that the stabilizers of the permanent, the determinant, and other functions that arise in our lower bound applications are G-separable; the stabilizer of

the determinant is very similar to the subgroup $SL_n(\mathbb{C}) \times SL_n(\mathbb{C}) \subseteq SL_{n^2}(\mathbb{C})$ above (cf. section 2.1).

A precise statement of Theorem 1.2 now reads as follows.

THEOREM 6.1. *Suppose V is a linear representation of a connected, reductive group G. Let $v \in P(V)$ be a stable point such that stabilizer $G_{\hat{v}}$ is G-separable (cf. Definition* 6.3*) and characterizes v.*

Then there exists a homogeneous G-invariant $\beta \in \mathbb{C}[V]$ not vanishing at v such that the ideal of Gv as a closed subvariety of the open neighborhood $U = P(V)_\beta = P(V) \setminus \{\beta = 0\}$ is generated by the nonadmissible basis elements in Σ_v—in fact, it is generated by the bases of less than $\operatorname{codim}(Gv, P(V))$ *irreducible, non–$G_{\hat{v}}$-admissible G-submodules of $\mathbb{C}[V]$.*

Remark. Since $\Sigma_v \subseteq \Pi_v$, this statement is slightly stronger than Theorem 1.2.

Theorem 6.1, in turn, follows from the following stronger result.

Let X be a nonsingular, affine G-variety, G a connected reductive group. Given a point $x \in X$, we shall denote by $[x] \subseteq X$ the subvariety consisting of all points in X whose stabilizers contain $H = G_x$, the stabilizer of x. Assume that x is a nonsingular point of $G \cdot [x]$; when the orbit $Gx \subseteq X$ is closed, this is automatically so, because of the étale slice theorem [17] (cf. the proof of Lemma 6.3). We shall denote by N_x (resp., $N_{[x]}$) the H-module that is an H-complement of the tangent space of $G \cdot x$ (resp., $G \cdot [x]$) at x in the total tangent space to X at x; it can be thought of as the "normal" space to $G \cdot x$ (resp., $G \cdot [x]$) at x. $N_{[x]}$ is the H-submodule of N_x consisting of all nontrivial H-submodules of N_x.

Given a G-invariant $\beta \in \mathbb{C}[X]$, we shall denote by $X(\beta)$ the G-variety obtained from X by removing the divisor $\{\beta = 0\}$.

We shall denote the codimension of a subvariety $Y \subseteq X$ by $\operatorname{codim}(Y, X)$. We say that an open subset $U \subseteq X$ is saturated if it is of the form $\psi^{-1}(U')$, where ψ is the projection from X to the quotient X/G and U' is an open subset of X/G.

Theorem 6.1 for stable points in $P(V)$ follows from the following result by letting $X = V$ and $x = \hat{v}$. When $v \in P(V)$ is characterized by the stabilizer $G_{\hat{v}}$, $[x] = \mathbb{C}v$. Passage from V to $P(V)$ is possible because the nonadmissible basis elements are homogeneous.

THEOREM 6.2. *Assume that G is a connected, reductive group, and X an affine, nonsingular, irreducible G-variety X. Let $x \in X$ be a point, with stabilizer $H = G_x$, whose orbit Gx is closed. Suppose every H-module L that appears in $N^*_{[x]}$ is G-separable (Definition* 6.3*). Then, for some G-invariant $\beta \in \mathbb{C}[X]$ not vanishing at x, and non–H-admissible, irreducible G-submodules $P_i \subseteq \mathbb{C}[X]$, $1 \le i \le r$, with $r < \operatorname{codim}(G \cdot [x], X)$, Spec$(\mathbb{C}[X]/J) \cap X(\beta) = G \cdot [x] \cap X(\beta)$, where J denotes the ideal generated by the P_i's.*

(Here we are identifying a variety with the corresponding reduced scheme supported by it.)

Proof. By Proposition 4.2, or rather its proof, the functions in every non–H-admissible P within $\mathbb{C}[X]$ must vanish on $G \cdot [x]$. We need to show that, for some G-invariant β not vanishing at x, the zero set of J within $X(\beta)$ equals $G \cdot [x] \cap X(\beta)$ scheme-theoretically.

Étale slice theorem (see [27, p. 198], [17]). Let x be a point of an affine, smooth, irreducible G-variety X, whose orbit $Gx \subseteq X$ is closed. Then there exists a smooth, affine H-variety $Y \subseteq X$ passing through x and a strongly étale map ψ from $G \times_H Y$ to a G-invariant neighborhood of $G \cdot x$ in X of the form $X(\alpha)$, for some G-invariant $\alpha \in \mathbb{C}[X]$.

Here $Z = G \times_H Y$ denotes the induced G-equivariant fiber bundle, with base G/H and fiber isomorphic to Y [27]. Strong étaleness of ψ means that the map ψ/G from the quotient Z/G to X/G is étale and that the induced natural map from Z to $X \times_{X/G} Z/G$, the G-variety obtained from X by base extension, is a G-isomorphism.

The slice theorem suggests that we prove our theorem in two steps. First, consider the case when X is a fiber bundle of the form $G \times_H Y$, where Y is a smooth affine variety, and then make a transition to the general case. Note that $H = G_x$ is reductive since $Gx \subseteq X$ is closed and hence affine [24].

We shall need the following proposition.

PROPOSITION 6.4. *Let V be a finite-dimensional irreducible G-module, G connected and reductive, with basis coordinate functions $V_1, \ldots, V_s$. Let $g \in V$ be a point with closed, affine orbit $Gg \subseteq V$. Further, let $I(g)$ be the ideal of Gg. Let J be an ideal of $\mathbb{C}[V]$ such that the following hold:*

(i) *The variety of J is precisely the orbit $O = Gg$.*

(ii) *The ideal J is itself G-invariant.*

(iii) *There are elements $w_1, \ldots, w_k \in J$ such that the tangent space TO_g of the orbit O at g consists of precisely the tangent vectors in TV_g annihilated by the differential forms dw_i's.*

Then $J = I(g)$; i.e., Spec$(\mathbb{C}[V]/J) = O$.

Suppose (i) *is replaced by the weaker condition:*

(i)′ *the variety of J contains the orbit $O = G \cdot g$.*

Then there exists a G-invariant neighborhood U_g of the orbit Gg such that the zero set of J restricted to U_g coincides with Gg scheme-theoretically.

Proof. The G-invariance of J and the connectedness of G imply that all associated primes of J must themselves be G-invariant. Since there are no proper G-invariant subsets of O, we conclude that there are no associated primes of J other than $I(g)$. Now (iii) may be used to apply the "Jacobian criterion" (Matsumura [21, Theorem 30.4]) locally. The G-invariance of J shows that (iii) holds at every point $y \in O$. The global assertion then follows. □

Given an H-module M, we denote by $\mathbb{C}[M]$ the H-module $\sum_{i \geq 0} \mathrm{Sym}^i(M^*)$, i.e., the space of polynomial functions on M. Let N denote the tangent space to Y at x; it is an H-module. Now we prove the theorem for the variety $G \times_H N$.

LEMMA 6.3. *The theorem holds when $X = G \times_H N$ and $x = (1_G, 0_N)$ is the base point on its null section G/H, with stabilizer $G_x = H$.*

Proof. In this case N can be identified with the normal space N_x at x to the orbit $G \cdot x = G/H$. Let $N = \sum_R R$ be an H-module decomposition of N into irreducibles. Then we can write $N_x = N_{[x]} + M_x$, where $\bar{N} = N_{[x]}$ is the sum of all nontrivial H-submodules R in this decomposition and M_x is the sum of all trivial H-submodules. The subvariety $G \cdot [x] = G \cdot M_x$, and the codimension of $G \cdot [x]$ is just the dimension of $N_{[x]}$.

For any H-submodule L of N_x, consider the induced bundle $F(L^*) : G \times_H L^* \to G/H$. Let $\mathcal{O}_{F(L^*)}$ be the sheaf of germs of sections of this bundle. Let $H^0(G/H, \mathcal{O}_{F(L^*)})$ be the G-module of its global sections. These global sections are regular functions on $G \times_H L$ that are linear on each fiber. Clearly $H^0(G/H, \mathcal{O}_{F(N^*_{[x]})})$ is a G-submodule of $H^0(G/H, \mathcal{O}_{F(N^*_x)})$, whose elements are regular functions on X linear on each fiber. Since G is connected, we can apply the Jacobian criterion (Proposition 6.4) and the transitivity of G-action. Hence it suffices to show that the sections in the non–H-admissible G-submodules of $H^0(G/H, \mathcal{O}_{F(N^*_{[x]})})$, when restricted to the fiber $N^*_{[x]}$ at x, span $N^*_{[x]}$; clearly the number r of such submodules is less than $\dim(N_{[x]}) = \mathrm{codim}(G \cdot [x], X)$.

Let $N_{[x]} = \oplus_R R$ be an H-module direct sum decomposition of $N_{[x]}$, where each R is an irreducible, nontrivial H-submodule. Then $N^*_{[x]} = \oplus_R R^*$, as an H-module, so we get a natural G-module decomposition

$$H^0(G/H, \mathcal{O}_{F(N^*_{[x]})}) = \oplus_R H^0(G/H, \mathcal{O}_{F(R^*)}).$$

Hence, it suffices to show that for each R in this decomposition, there exists a non–H-admissible G-submodule of $H^0(G/H, \mathcal{O}_{F(R^*)})$, whose sections, when restricted to the fiber R^* at x, span R^*.

Thus, let R be any such nontrivial, irreducible H-submodule in this decomposition and let $L = R^*$ be its dual. By the Peter–Weyl theorem (1)

$$H^0(G/H, \mathcal{O}_{F(L)}) = \oplus_Q Q \otimes Hom(Q, L)^H, \tag{3}$$

where Q ranges over all finite dimensional irreducible G-modules, and $Hom(Q, L)^H$ denotes the vector space of H-equivariant linear maps from Q to L. Thus the G-modules Q that appear in $H^0(G/H, \mathcal{O}_{F(L)})$ are precisely the ones that contain L. By our G-separability assumption, there exists a nonadmissible, irreducible G-module Q_L containing L. By (3), $H^0(G/H, \mathcal{O}_{F(L)})$ contains a copy of Q_L. Fix one such copy; we denote it by Q_L again. The restriction of Q_L to the fiber L of $F(L)$ at x is precisely L. Hence the basis elements of Q_L, when restricted to L, span L. □

For every R that appears in the H-module decomposition of $N_{[x]}$, let $Q_L \subseteq H^0(G/H, \mathcal{O}_{F(N^*_{[x]})})$, $L = R^*$, be a fixed copy as in the proof above. Let Φ be the set of such finitely many Q_Ls, each a non–H-admissible, irreducible G-module of regular functions on $G \times_H N$. The number r of Q_L's in Φ is less than $\operatorname{codim}(G \cdot [x], X)$. Since many R's in the H-module decomposition may be isomorphic, many Q_Ls in Φ may be isomorphic as G-modules. The proof above shows that the following lemma holds.

LEMMA 6.4. *The differentials of the basis elements of the non–H-admissible G-modules Q_L in Φ, when restricted to $N_{[x]}$, span the whole of $N_{[x]}$, and the zero set of the ideal generated by them coincides with $G \cdot [x] = G \cdot M_x$ scheme-theoretically. The number r of modules in Φ is less than codim$(G \cdot [x], G \times_H N)$.*

Now we turn to the general case. By the étale slice theorem, there exists an affine H-variety $Y \subseteq X$ passing through x and a strongly étale map ψ from $G \times_H Y$ to a G-invariant neighborhood of $G \cdot x$ in X of the form $X(\alpha)$, for some G-invariant $\alpha \in \mathbb{C}[X]$ not vanishing at x. Since $\mathbb{C}[X(\alpha)] = \mathbb{C}[X]_\alpha$, the ideal generated by non–H-admissible, irreducible G-submodules of $\mathbb{C}[X]$ within $\mathbb{C}[X(\alpha)]$ coincides with the one generated by non–H-admissible, irreducible G-submodules of $\mathbb{C}[X(\alpha)]$. Hence, in the statement of the theorem, we can replace X by $X(\alpha)$. Strong étaleness of ψ implies [27] that there is an analytic neighborhood $Y_{an} \subseteq N_x$ of x in N_x—called an analytic slice through x—such that $G \times_H Y_{an}$ is G-isomorphic to an analytic G-invariant neighborhood U of the orbit of x. However, there may not be an algebraic slice with this property, and this forces us into the analytic category in what follows. Since $U \simeq G \times_H Y_{an} \subseteq G \times_H N$, each Q_L corresponds to, and can be identified with, a G-module $Q_L(U)$ of analytic functions on U. By Lemma 6.4, the zero set of the $Q_L(U)$'s in Φ within U coincides, as a complex space [8], with $G \cdot [x] \cap U$. Our goal is to show that each $Q_L(U)$ can be approximated very closely within U by an isomorphic G-submodule of $\mathbb{C}[X]$. For this, we shall need the following results from complex function theory.

Cartan–Oka theorem (see [8]). Let A be a Stein space, and let B be its closed analytic subspace. Then every holomorphic function on B extends to a holomorphic function on A.

Let $\mathcal{O}_A$, $\mathcal{O}_B$ be the sheaves of germs of holomorphic functions on A and B, respectively, and let $\mathcal{I}_B$ be the sheaf of ideals of B. Then by Oka's theorem $\mathcal{I}_B$ is coherent, and since A is Stein, its higher cohomology $H^i(A, \mathcal{I}_B)$, $i > 0$, vanishes (Cartan's theorem B). Hence, this result follows from the long exact cohomology sequence associated with the exact sequence of sheaves

$$0 \to \mathcal{I}_B \to \mathcal{O}_A \to \mathcal{O}_B \to 0,$$

where we consider $\mathcal{O}_B$ as a sheaf on A via extension by zero.

We shall denote the ring of holomorphic functions on an analytic variety W by $\mathcal{O}(W)$.

LEMMA 6.5. *Let A be a Stein G-space, and let B be its closed analytic G-subspace, with G a connected reductive group. Let M be a finite dimensional G-submodule of $\mathcal{O}(B)$. Then there exists a G-equivariant extension map $\phi : M \to \mathcal{O}(A)$.*

Here, we say that ϕ is an extension map if, for any $s \in M$, the restriction of $\phi(s)$ to B coincides with s.

Proof. Fix a basis $s_1, \ldots, s_l$ of M. By the Cartan–Oka theorem, each s_i can be extended to a holomorphic function $\hat{s}_i$ on A. Let $\rho : M \to \mathcal{O}(A)$ be a linear map defined by setting $\rho(\sum_i b_i s_i) = \sum_i b_i \hat{s}_i$. Though ρ need not be G-equivariant, it may be converted into a G-equivariant map by Weyl's unitary trick [5]. Specifically, regard $Hom(M, \mathcal{O}(A))$ as a G-module in the natural way. Fix a maximal compact subgroup $E \subseteq G$. Let de denote the left-invariant Haar measure on E, and let

$$\phi = \int_E e(\rho) de.$$

Then ϕ is an E-equivariant extension. Since M is finite dimensional, it follows from the unitary trick that ϕ is G-equivariant as well. □

LEMMA 6.6. *Let W be a linear representation of connected, reductive G, V a linear space with trivial G action, and $D \subseteq V$ a ball around the origin. Let $A = W \times D$. Then the following hold:*

(1) *Any holomorphic function a on A has a unique power series expansion of the form*

$$a(w, v) = \sum_{i,j} a_i^j w^j v^i. \tag{4}$$

Here $i = (i_1, \cdots, i_r)$, $r = \dim(V)$, and $j = (j_1, \cdots, j_q)$, $q = \dim(W)$, are tuples of nonnegative integers, and $v^i = v_1^{i_1} \cdots v_r^{i_r}$ and $w^j = w_1^{j_1} \cdots w_q^{j_q}$, where $v_1, \ldots, v_r$ are the coordinates of V and $w_1, \ldots, w_q$ are the coordinates of W.

(2) *For any $k = (i, d)$, the map $\delta_k : \mathcal{O}(A) \to \mathbb{C}[W \times V] = \mathbb{C}[W] \otimes \mathbb{C}[V]$, which maps a to $\sum_{j : j_1 + \cdots + j_q = d} a_i^j w^j v^i$, is G-equivariant.*

Proof. The first statement follows because A is a proper Reinhardt domain in $W \times V$ (cf. [6, p. 20]).

Each $w_1^{j_1} \cdots w_q^{j_q}$ is a polynomial (regular) function on W and is contained in the finite dimensional G-submodule in $\mathbb{C}[W]$ of homogeneous forms of degree $d = j_1 + \cdots + j_q$. Since the G-action on D is trivial, it follows that each δ_k is G-equivariant. □

Let X be an affine, smooth G-variety, with G a connected reductive group. Let ψ be the projection from X to its quotient X/G. Let x be a point in X with closed orbit $Gx \subseteq X$ and $\bar{x} = \psi(x)$ its projection. Embed the affine variety X/G in a linear

space V, with $\bar{x}$ at its origin. Suppose $U_{\bar{x}}$ is a Stein neighborhood of $\bar{x}$ in X/G such that $U_{\bar{x}} = D \cap X/G$, where $D \subseteq V$ is a ball around $\bar{x}$. Let $U = \psi^{-1}(U_{\bar{x}})$.

LEMMA 6.7. *Let Q be a finite dimensional G-submodule of $\mathcal{O}(U)$. Then there exist G-equivariant linear maps $\rho_k : Q \to \mathbb{C}[X]$ such that any $s \in Q$ admits a power series expansion $s = \sum_{k=0}^{\infty} \rho_k(s)$ that converges everywhere in U.*

Proof. We can embed X G-equivariantly as a closed affine G-subvariety of some linear representation W of G [10, Lemma 1.1]. Let $A = W \times D$, which is Stein. It has a G-action, the action on D being trivial. Let $B \subseteq A$ be the closed analytic G-subspace consisting of points (x, u), with $x \in X$, $u \in U_{\bar{x}}$, and $\psi(x) = u$. It is isomorphic to U. So s corresponds to a holomorphic function on B, which we shall denote by s again. Thus we can regard $Q \subseteq \mathcal{O}(B)$.

By Lemma 6.5, there exists a G-equivariant extension map $\phi : Q \to \mathcal{O}(A)$. Let δ_k be the G-equivariant map of Lemma 6.6 applied to A. Finally, let $\alpha : \mathbb{C}[W \times V] \to \mathbb{C}[X]$ be the G-equivariant restriction map corresponding to the G-equivariant embedding $X \to W \times V$, which maps $x \in X$ to $(x, \psi(x))$. Let $\rho_k = \alpha \circ \delta_k \circ \phi$. Then $s \in Q$ has a G-equivariant power series expansion

$$s = \sum_k \rho_k(s)$$

that converges everywhere in U. ∎

Now we return to the proof of Theorem 6.2. Let ψ be the strongly étale map from $G \times_H Y_{an}$ to a G-invariant neighborhood U of the orbit $G \cdot x$. Here $Y_{an} \subseteq N_x$ is an analytic slice, and U is of the form $\psi^{-1}U_{\bar{x}}$, where $U_{\bar{x}}$ is an analytic neighborhood of $\bar{x} = \psi(x)$. We can assume that $U_{\bar{x}}$ is Stein, of the form $D \cap X/G$ as in Lemma 6.7, for a small enough ball D around $\bar{x}$ in $V \supseteq X/G$. Let $Q_L \in \Phi$ be the finitely many, irreducible, non–H-admissible G-submodules of the ring of regular functions on $G \times_H N$ as in Lemma 6.4; their number r is less than $\operatorname{codim}(G \cdot [x], G \times_H N) = \operatorname{codim}(G \cdot [x], X)$. We shall denote the restriction of Q_L to $G \times_H Y_{an}$ by Q_L again. It corresponds to a G-module of analytic functions on U, which we shall denote by $Q_L(U)$; the analytic functions in $Q_L(U)$, though, may not extend to the whole of X.

Now we come to the crux of the proof. The G-module $Q_L(U)$ is isomorphic to Q_L and, hence, finite dimensional. Hence we may apply Lemma 6.7. Let $\rho_k(L)$ denote the G-equivariant projection from $Q_L(U)$ to $\mathbb{C}[X]$ therein. Let $\tilde{\rho}_k(L) = \sum_{j \le k} \rho_j(L)$. When k is large enough, $\tilde{\rho}_k(L)(Q_L(U))$ will be a good approximation to $Q_L(U)$. Let $Q_L^k \subseteq \mathbb{C}[X]$ be the G-module that is the image of this G-equivariant projection $\tilde{\rho}_k$. Since $Q_L(U) \simeq Q_L$ is irreducible, Q_L^k is either zero or isomorphic to Q_L. When k is large enough, Q_L^k is isomorphic to Q_L—hence it is non–H-admissible and vanishes on $G \cdot [x]$.

Since U is G-isomorphic to $G \times_H Y_{an} \subseteq G \times_H N$, it follows from Lemma 6.4 that the differentials of the basis functions in all the $Q_L(U)$'s in Φ, when restricted to $N_{[x]}$, span the whole of $N^*_{[x]}$. We approximate each $Q_L(U)$ by $Q_L^k \subseteq \mathbb{C}[X]$ for a large enough k. When k is large enough, the differentials of the basis functions in Q_L^k, when restricted to $N_{[x]}$, will also span the whole of $N^*_{[x]}$. But each Q_L^k is a non–H-admissible, irreducible G-submodule of $\mathbb{C}[X]$. Thus it follows that the differentials of the basis functions of the non–H-admissible, irreducible G-submodules Q_L^k of $\mathbb{C}[X]$, for k large enough, span $N^*_{[x]}$. Because of the transitivity of the G-action, the same holds for all points in the orbit of x. Since G is connected, and all Q_L's are G-modules, it now follows from the Jacobian criterion (Proposition 6.4, or rather its proof) and the fact that $U \simeq G \times_H Y_{an}$, that the zero set of the basis functions of these Q_L^k's within U

coincides with $G \cdot [x] \cap U$ scheme-theoretically (i.e., as a complex space [8]). Since Q_L^k's are G-submodules of $\mathbb{C}[X]$, there exists a Zariski-open G-invariant neighborhood $U' \supseteq U$ such that the zero set of Q_L^k's within U' coincides with $G \cdot [x] \cap U'$ scheme-theoretically. It remains to show that U' can be chosen to be of the form $X(\beta)$, for some G-invariant β. The projection $\psi(U')$ into X/G is a constructible [9] set that contains $U_{\bar{x}}$. Hence $\psi(U')$ contains a Zariski-open affine neighborhood of the form $(X/G)_\alpha$ for some G-invariant α not vanishing at x. Its inverse $\psi^{-1}(X/G)_\alpha$ is of the form $X(\alpha)$ and has the required properties. □

Remark. Suppose every H-module that appears in $N^*_{[x]}$ is not G-separable, as assumed in Theorem 6.2. Then one can similarly prove a weaker assertion that, for some G-invariant analytic neighborhood U (as in the proof above) of Gx, $\mathrm{Spec}(\mathbb{C}[X]/J) \cap U$, as a complex space [7], is a subspace of $G \times_H \mathrm{Spec}(I)$, where $\mathrm{Spec}(I)$ is a subscheme of $N_{[x]}$ and $I \subseteq \mathbb{C}[N_{[x]}]$ is the ideal generated by the G-separable H-submodules of $\mathbb{C}[N_{[x]}]$.

7. Partial stability. Let V be a linear representation of G. Let $P = KU$ be a parabolic subgroup of G, and let R be a reductive subgroup of K.

DEFINITION 7.1. *We say that $v \in P(V)$ is (R, P)-stable (*partially stable*) if* (1) *it is stable with respect to the restricted action of R on V, and* (2) *$U \subseteq G_v \subseteq P$.*

Here $U \subseteq G_v$ implies that $U \subseteq G_{\hat{v}}$. The defect $\delta(v)$ of v is defined to be the difference between the ranks of the root systems of R and K. In our applications, the defect will be small—in fact, just one—and R will always be a semisimple Levi subgroup of a parabolic subgroup of K—so that the root system of R will always be a subsystem of that of K.

A stable point of V is (G, G)-stable. A point $v \in P(V)$ is (R, P)-stable iff it is an (R, K)-stable point of $P(Y)$, where $Y = V^U$ is the K-module of U-invariants in V.

Example 1. The simplest example of a partially stable point with defect zero is the point $v = v_\lambda \in P(V)$ that corresponds to the highest weight vector of an irreducible G-representation $V = V_\lambda(G)$. The stabilizer $P = G_v$ is parabolic, and v is clearly (L, P)-stable, where L is a semisimple Levi subgroup of P.

Example 2. Let $f = \phi(h)$ be as in Definition 2.1, with h stable. Then f is (R, P)-stable, with defect one, with respect to the action of G (as well as $\hat{G}$), where: P is a parabolic subgroup of G (resp., $\hat{G}$), whose elements transforms the variables in $\bar{X}$ to their linear combinations, thus preserving an appropriate flag $\mathbb{C}^{k+1} \subseteq \mathbb{C}^l$, and $R \simeq SL_k(\mathbb{C}) \times SL_{l-k-1}$ is naturally embedded in the semisimple Levi subgroup of P isomorphic to $SL_{k+1}(\mathbb{C}) \times SL_{l-k-1}(\mathbb{C})$.

DEFINITION 7.2. *Given dominant weights α and β of R and K, we shall say that $\alpha \lhd_R^K \beta$, or $\beta \rhd_R^K \alpha$, if $V_\alpha(R)$ occurs in $V_\beta(K)$, dropping the superscript or subscript whenever possible.*

In the definition of (R, P)-stability the group R will usually be such that

$$\tilde{L} \subseteq R \subseteq \tilde{K} \subseteq K, \tag{5}$$

for some parabolic subgroup $\tilde{P} = \tilde{T}\tilde{L}\tilde{U} = \tilde{K}\tilde{U}$ of K, as in Example 2. Then, using Littelmann's restriction rule [14], one can determine how any irreducible representation $V_\beta(K)$ explicitly decomposes as a $\tilde{K}$-module (and hence as an R-module). This, in turn, gives an explicit relationship between α and β in Definition 7.2.

In Example 2 above, $K \simeq GL_{1+k}(\mathbb{C}) \times GL_{l-1-k}$ and $R \simeq SL_k(\mathbb{C}) \times SL_{l-1-k}(\mathbb{C})$. In this case, Littelmann's restriction rule reduces to a variant of the well-known Pieri's branching rule [5], which gives an explicit decomposition of $V_\mu(GL_{1+k}(\mathbb{C}))$ as a $GL_k(\mathbb{C})$-module.

For a connected reductive group D, we shall denote by i_D the canonical involution of its dominant weights so that $V_\lambda(D)^* = V_{i_D\lambda}(D)$. Let $v \in P(V)$ be an (R,P)-stable point as above. Let W and Y be, respectively, the smallest K-submodule and R-submodule of V containing $\hat{v}$.

DEFINITION 7.3. *We say that a dominant weight β of G lies over a weight μ of R at v and degree d if*

1. *$V_\mu(R)$ and $V_{\beta'}(K)$ occur in $R_Y[v]_d$ and $R_W[v]_d$, respectively, where $\beta' = i_K(i_G\beta)$, and*
2. *$\mu \lhd_R^K \beta'$.*

We say that a dominant weight β of G lies over a weight μ of R at v if this is so at some d.

This definition does not depend on the choice of a Levi subgroup $K \supseteq R$ of P, because $U \subseteq G_v$. When the defect is zero and R satisfies (5), condition 2 just says that the weight β', restricted to R, is equal to μ. The number of β's lying over μ at a fixed d depends on the defect; it is small if the defect is small.

8. Borel–Weil for a partially stable point. In this section we shall prove Theorem 1.1(b) for partially stable points. Its precise statement is as follows.

THEOREM 8.1. *Suppose v is (R,P)-stable (cf. Definition 7.1). Then $V_\lambda(G)$ can occur in $R_V[v]$ only if λ lies over some $R_{\hat{v}}$-admissible dominant weight μ of R at v (cf. Definition 7.3). Conversely, for every $R_{\hat{v}}$-admissible dominant weight μ of R, $R_V[v]$ contains $V_\lambda(G)$ for some dominant weight λ of G lying over μ at v.*

This will follow from the following stronger result.

Suppose $v \in P(V)$ is partially stable, specifically (R,P)-stable, where $P = TLU = KU$ and $R \subseteq K$.

Let W and Y be, respectively, the smallest K-submodule and R-submodule of V containing $\hat{v}$. Let $\mathcal{O}(d)$ be the twisting sheaf on $P(V)$, and let $\mathcal{O}_{\Delta_V[v]}(d)$, $\mathcal{O}_{\Delta_W[v]}(d)$ be the corresponding invertible sheaves on $\Delta_V[v]$ and $\Delta_W[v]$, respectively. Let $\Gamma(\Delta_V[v], \mathcal{O}_{\Delta_V[v]}(d))$ and $\Gamma(\Delta_W[v], \mathcal{O}_{\Delta_W[v]}(d))$ be the G- and K-modules of their global sections. Clearly $R_V[v]_d \subseteq \Gamma(\Delta_V[v], \mathcal{O}_{\Delta_V[v]}(d))$ for all $d \geq 0$. We have an equality for all $d \geq 0$ iff $\Delta_V[v]$ is projectively normal (cf. Hartshorne [9, p. 126]). Similarly, $R_W[v]_d \subseteq \Gamma(\Delta_W[v], \mathcal{O}_{\Delta_W[v]}(d))$ for all $d \geq 0$, with equality if $\Delta_W[v]$ is projectively normal.

The following result shows that the G-module structure of $R_V[v]$ is ultimately related to the R-module structure of $R_Y[v]$. In turn, we already know which R-modules can occur in $R_Y[v]$ since $v \in P(Y)$ is stable with respect to the action of R (Theorem 1.1(a)).

THEOREM 8.2 (Borel–Weil for partially stable points). *Suppose $v \in P(V)$ is (R,P)-stable as above. Then*

1. *The G-module structure of $R_V[v]$ is equivalent to the K-module structure of $R_W[v]$: Specifically, the multiplicity of a G-module $V_\lambda(G)$ in $R_V[v]_d^*$ is equal to the multiplicity of the K-module $V_\lambda(K)$ in $R_W[v]_d^*$, where λ is regarded as a dominant weight of K by restriction. Moreover, a K-module $V_\alpha(K)$ can occur in $R_W[v]_d^*$ only if α is also a dominant weight of G.*
2. *The multiplicity of $V_\lambda(G)$ in the module $\Gamma(\Delta_V[v], \mathcal{O}_{\Delta_V[v]}(d))^*$ of global sections of $\mathcal{O}_{\Delta_V[v]}(d)$ is less than or equal to the multiplicity of $V_\lambda(K)$ in $\Gamma(\Delta_W[v], \mathcal{O}_{\Delta_W[v]}(d))^*$. If $\Delta_W[v]$ is projectively normal, then the two multiplicities are equal, for all λ and $d \geq 0$, and $\Delta_V[v]$ is also projectively normal.*
3. *A K-module $V_\beta(K)$ can occur in $R_W[v]_d$ only if, for some dominant weight $\alpha \lhd_R^K \beta$ of R, $V_\alpha(R)$ occurs in $R_Y[v]_d$. Conversely, for every R-module $V_\alpha(R)$*

occurring in $R_Y[v]_d$, there exists a dominant weight $\beta \rhd_R^K \alpha$ of K such that $V_\beta(K)$ occurs in $R_W[v]_d$.

4. *Finally, an R-module $V_\mu(R)$ occurs in $R_Y[v]$, i.e., in some $R_Y[v]_d$, iff it is $R_{\hat{v}}$-admissible.*

Remark 1. In the third statement, it is desirable that we have an explicit criterion for deciding if $\alpha \lhd_R^K \beta$. When R satisfies (5), such a criterion is given by Littlemann's rule as pointed out there.

Remark 2. When G is semisimple and simply connected and v corresponds to the highest weight vector in $V = V_\lambda(G)$, $\Delta_V[v] = G/P$ and $\Delta_W[v]$ is just the point v. Hence $\Gamma(\Delta_W[v], \mathcal{O}_{\Delta_W[v]}(d))^* = V_{d\lambda}(K)$, for $d \geq 0$. The second statement now implies that $\Gamma(\Delta_V[v], \mathcal{O}_{\Delta_V[v]}(d))^* = \Gamma(G/P, \mathcal{O}_{G/P}(d))^* = V_{d\lambda}(G)$ for $d \geq 0$, which is the Borel–Weil theorem [11].

We will first prove two propositions. For that we need the following lemma from representation theory.

LEMMA 8.3 (cf. [11, Theorem 5.104]). *Let $V_\lambda(G)$ be an irreducible representation of a connected reductive group G with highest weight λ. Let $P = KU \subseteq G$ be a parabolic subgroup. Then $V_\lambda(G)^U = V_\lambda(K)$; here $V_\lambda(G)^U$ is the subspace of U-invariants in $V_\lambda(G)$.*

Let $z \in P(V)$ be a point whose stabilizer $G_z \subseteq G$ contains U, so that the stabilizer $G_{\hat{z}} \subseteq G$ of $\hat{z} \in V$ also contains U. Let Z be the smallest K-submodule of V containing $\hat{z}$. Let i denote the embedding of Z in V. The following result shows that $R_Z[z]$ and $R_V[z]$ are closely related.

PROPOSITION 8.1. (a) *The multiplicity of an irreducible module $V_\lambda(G)$ in $R_V[z]_d^*$ is equal to the multiplicity of $V_\lambda(K)$ in $R_Z[z]_d^*$. Moreover, $V_\alpha(K)$ can occur in $R_Z[z]_d^*$ only if α is also a dominant weight of G.*

(b) *The multiplicity of $V_\lambda(G)$ in $\Gamma(\Delta_V[z], \mathcal{O}_{\Delta_V[z]}(d))^*$ is less than or equal to the multiplicity of $V_\lambda(K)$ in $\Gamma(\Delta_Z[z], \mathcal{O}_{\Delta_Z[z]}(d))^*$. If $\Delta_Z[z]$ is projectively normal, then the two multiplicities are equal for all λ and $d \geq 0$, and $\Delta_V[z]$ is also projectively normal.*

Proof. Since the stabilizer $G_{\hat{z}}$ contains U, and U is normalized by K, the stabilizer of every point in Z contains U; in other words, the action of U on Z is trivial. Thus Z can be considered a P-module. The embedding map $i : Z \to V$ is then P-equivariant. By restriction, we get a P-equivariant, closed embedding $i : \check{\Delta}_Z[z] \to \check{\Delta}_V[z]$, where $\check{\Delta}_V[z] \subseteq V$ and $\check{\Delta}_Z[z] \subseteq Z$ denote the affine cones of $\Delta_V[z]$ and $\Delta_Z[z]$. Hence, the corresponding surjection $i^* : R_V[z] \to R_Z[z]$ is P-equivariant. Since it is degree preserving, by restriction, we get a P-equivariant surjection $i^* : R_V[z]_d \to R_Z[z]_d$ for every d. Since the action of U on Z is trivial, we get the dual injection $i : (R_Z[z]_d)^* \to (R_V[z]_d^*)^U$.

Let M be any irreducible G-submodule of $R_V[z]_d$. Not all functions in M can vanish at z—otherwise, arguing as in the proof of Proposition 4.2, we can conclude that the functions in M vanish identically on the affine cone $\check{\Delta}_V[z]$, which is not possible. It follows that the restriction map i^* is nonzero on M. Thus $N = i^*(M)$ is a nonzero K-module, with trivial U-action. Dually, this means $i(N^*)$ is a nonzero K-submodule of $(M^*)^U$. If $M^* = V_\lambda(G)$, then $(M^*)^U = V_\lambda(K)$ (Lemma 8.3), and hence is irreducible. So $(M^*)^U \simeq i(N^*)$. Thus the injection $i : (R_Z[z]_d)^* \to (R_V[z]_d^*)^U$ is an isomorphism. Hence the multiplicity of $V_\lambda(G)$ in $R_V[z]_d^*$ is equal to the multiplicity of $V_\lambda(K)$ in $R_Z[z]_d^*$, and, moreover, $V_\alpha(K)$ can occur in $R_Z[z]_d^*$ only if α is also a dominant weight of G. This proves (a).

The proof of (b) is similar. The embedding map $i : Z \to V$ induces a P-equivariant

map $i^* : \Gamma(\Delta_V[z], \mathcal{O}_{\Delta_V[z]}(d))^* \to \Gamma(\Delta_Z[z], \mathcal{O}_{\Delta_Z[z]}(d))^*$, which need not be a surjection in general. Let M be any irreducible G-submodule of $\Gamma(\Delta_V[z], \mathcal{O}_{\Delta_V[z]}(d))$. One shows similarly that $N = i^*(M)$ is a nonzero K-submodule of $\Gamma(\Delta_Z[z], \mathcal{O}_{\Delta_Z[z]}(d))$, with trivial U-action, and $(M^*)^U \simeq i(N^*)$. This proves the first statement of (b).

If $\Delta_Z[z]$ is projectively normal, i.e., its homogeneous coordinate ring is integrally closed, then $\Gamma(\Delta_Z[z], \mathcal{O}_{\Delta_Z[z]}(d)) = R_Z[z]_d$, for $d \geq 0$ (cf. Hartshorne [9, p. 126]). Hence i^* is a surjection, for $d \geq 0$, since the restriction $i^* : R_V[z]_d \to R_Z[z]_d$ is surjective, and $R_V[z]_d \subseteq \Gamma(\Delta_V[z], \mathcal{O}_{\Delta_V[z]}(d))$. Now we prove equality of multiplicities as in (a). Since the multiplicity of every $V_\lambda(G)$ in $\Gamma(\Delta_V[z], \mathcal{O}_{\Delta_V[z]}(d))$ or $R_V[z]_d$ is now the same, both being equal to the multiplicity of $V_\lambda(K)$ in $\Gamma(\Delta_Z[z], \mathcal{O}_{\Delta_Z[z]}(d))^*$, it now follows that $\Gamma(\Delta_V[z], \mathcal{O}_{\Delta_V[z]}(d)) = R_V[z]_d$, for all $d \geq 0$. Hence $R_V[z]$ is integrally closed and $\Delta_V[z]$ is projectively normal (cf. Hartshorne [9, p. 126]). □

Now let W be any linear representation of a connected, reductive group K, and let $R \subseteq K$ be a reductive subgroup. Fix a point $y \in P(W)$. Let Y be the smallest R-submodule of W containing $\hat{y}$.

PROPOSITION 8.2. *An irreducible K-module $V_\beta(K)$ can occur within $R_W[y]_d$ only if an R-module $V_\alpha(R)$, with $\alpha \lhd_R^K \beta$, occurs within $R_Y[y]_d$. Conversely, if an R-module $V_\alpha(R)$ occurs in $R_Y[y]_d$, then there exists a K-module $V_\beta(K)$, with $\beta \rhd_R^K \alpha$, in $R_W[y]_d$.*

Proof. The embedding $r : Y \to W$ is R-equivariant. Hence, we have an R-equivariant, closed embedding $r : \check{\Delta}_Y[y] \to \check{\Delta}_W[y]$ of the affine cone of $\Delta_Y[y]$, and the corresponding R-equivariant surjection $r^* : R_W[y] \to R_Y[y]$. Since this surjection is degree preserving, by restriction, we get an R-equivariant surjection $r^* : R_W[y]_d \to R_Y[y]_d$ for each d.

Let $V_\beta(K)$ be any irreducible K-module in $R_W[y]_d$. Arguing as in the proof of Proposition 8.1, we can conclude that its image under r^* is nontrivial. The image can thus be identified with an R-submodule of $V_\beta(K)$. If an R-module $V_\alpha(R)$ occurs in this image, then by definition (cf. section 7), $\alpha \lhd \beta$. Conversely, for every R-module $V_\alpha(R)$ that appears in $R_Y[y]_d$, there is a K-module $V_\beta(K)$ in $R_W[y]_d$ whose image contains $V_\alpha(K)$, and hence we must have $\beta \rhd \alpha$. □

Proof of Theorem 8.2. The first and second statements follow from Proposition 8.1, letting $z = v$, $Z = W$. The third statement follows from Proposition 8.2. The fourth statement follows statement (a) of Theorem 1.1, since, by definition of partial stability, v is a stable point of Y with respect to the action of R. □

Proof of Theorem 8.1. Suppose $V_\lambda(G)$ occurs in $R_V[v]_d$; i.e., $V_{i_G\lambda}(G)$ occurs in $R_V[v]_d^*$. Then by the first statement of Theorem 8.2, $V_{i_G\lambda}(K)$ occurs in $R_W[v]_d^*$. That is, $V_{i_K(i_G\lambda)}(K)$ occurs in $R_W[v]$. It now follows from the third and fourth statements of Theorem 8.2 that λ lies over some $R_{\hat{v}}$-admissible weight μ of R.

Conversely, it follows from Theorem 8.2 similarly that, for every $R_{\hat{v}}$-admissible dominant weight μ of R, $R_V[v]$ contains $V_\lambda(G)$ for some dominant weight λ of G lying over μ at v. □

9. Application in complexity theory. We now specialize the Borel–Weil theorem for partially stable points (section 8) to the orbit closure problem that arises in complexity theory (section 2). We follow the notation of section 2. Now $V = \mathrm{Sym}^m(Y)$ is a linear representation of $G = SL(Y) = SL_l(\mathbb{C})$, and $W = \mathrm{Sym}^n(X)$ is a representation of $SL(X) = SL_k(\mathbb{C})$. Let $\hat{G} = GL_l(\mathbb{C})$. Let i^l denote the involution on the weights of $GL_l(\mathbb{C})$ so that $V_\lambda(GL_l(\mathbb{C}))^* = V_{i^l\lambda}(GL_l(\mathbb{C}))$, for a weight λ. Recall that every weight λ of $GL_l(\mathbb{C})$ or its dual $i^l(\lambda)$ corresponds to a Young diagram of height at most l. Every weight of $GL_l(\mathbb{C})$ that occurs in $\mathbb{C}[V]_d^* = \mathrm{Sym}^d(V) =$

$\mathrm{Sym}^d(\mathrm{Sym}^m(Y))$ corresponds to a Young diagram of size md—this will be used implicitly in what follows.

THEOREM 9.1. (a) *Suppose $g \in P(V)$ is stable with respect to the action of G. Then a Weyl module $V_\lambda(G)$ occurs in $\Delta_V[g]$ iff it is $G_{\hat{g}}$-admissible.*

(b) *Suppose $f \in P(V)$ is of the form $\phi(h)$, $h \in P(W)$. Then $V_\lambda(\hat{G})$ can occur in $R_V[f]_d$ only if* (1) *the weight $i^l(\lambda)$ corresponds to a Young diagram with md boxes and height at most $k+1$, and* (2) *$V_{\lambda'}(GL_{k+1}(\mathbb{C}))$, with $\lambda' = i^{k+1} \circ i^l(\lambda)$, contains some $SL_k(\mathbb{C})_{\hat{h}}$-admissible module $V_\mu(SL_k(\mathbb{C}))$, where we consider $SL_k(\mathbb{C})$ as a subgroup of $GL_{k+1}(\mathbb{C})$ in a natural way. This means μ and λ' are related by (a variant of) Pieri's branching rule.*

Conversely, for every $SL_k(\mathbb{C})_{\hat{h}}$-admissible module $V_\mu(SL_k(\mathbb{C}))$, there exist a d and λ satisfying (1) *and* (2) *above such that $V_\lambda(\hat{G})$ occurs in $R_V[g]_d$.*

Proof. (a) follows from Theorem 1.1(a).

(b) The point $f \in P(V)$ is partially stable with defect one with respect to the action of $\hat{G} = GL_l(\mathbb{C})$ on $P(V)$, specifically, (R,P)-stable, with R and P as specificed in section 2. Now we apply Theorem 8.2 for the action of $\hat{G}$ on $P(V)$. We will only clarify why the height of $i^l(\lambda)$ is at most $k+1$. The reductive Levi subgroup of P under consideration is $K \simeq GL_{k+1} \times GL_{l-k-1}$, and the subgroup $1 \times GL_{l-k-1}$, where 1 denotes the identity in GL_{k+1}, is contained in the stabilizer $K_{\hat{f}}$. Suppose $V_\lambda(G)$ occurs in $R_V[f]_d$. The irreducible K-submodule of V containing f is just $\bar{W} = \mathrm{Sym}^m(\bar{X})$ defined in section 2. Hence, by Theorem 8.2, $V_{i_K \circ i^l \lambda}(K)$ is a nonzero K-submodule of $R_{\bar{W}}[f]_d$, where i_K is the involution on the weights of K. By Proposition 5.1, $V_{i_K \circ i^l \lambda}(K)$ and, hence, $V_{i^l \lambda}(K)$ must be $K_{\hat{f}}$-admissible and, hence, $1 \times GL_{l-k-1}$-admissible. For any $V_\alpha(GL_l(\mathbb{C}))$, where α is a Young diagram of height $\leq l$, the K-module $V_\alpha(K)$, with the same weight, is equal to $V_{\alpha_1}(GL_{k+1}) \otimes V_{\alpha_2}(GL_{l-k-1})$, where α_1 consists of the first $k+1$ rows of α and α_2 consists of the remaining $l-k-1$ rows; here an empty row is treated as a row with zero length. Let $\alpha = i^l(\lambda)$. Then $V_{\alpha_2}(GL_{l-k-1})$ must be trivial since $V_\alpha(K)$ is $1 \times GL_{l-k-1}$-admissible; thus $\alpha_2 = 0$, and $\alpha_1 = \alpha$. It follows that the length of α is at most $k+1$. The number of boxes in $i^l(\lambda)$ must be md since every irreducible $\hat{G}$-representation occurring in $\mathbb{C}[V]_d^* = \mathrm{Sym}^d(\mathrm{Sym}^m(Y))$ has degree md.

The rest follows from Theorems 8.2 and 8.1; details are left to the reader. ∎

10. Representation theoretic data associated with a partially stable point. We extend the definition of the representation theoretic data (Definition 6.1) to the partially stable case and illustrate its significance with an application to G/P.

DEFINITION 10.1. *Suppose $v \in P(V)$ is (R,P) stable, $P = KU$. We say that a G-submodule $M \subseteq \mathbb{C}[V]_d$ is admissible, with respect to v and d, if $(M^*)^U$ is* (1) *$(K, Sym^d(W))$-admissible, where W is the smallest K-submodule of V containing $\hat{v}$, and* (2) *it is also $R_{\hat{v}}$-admissible. Let Σ_v be the set of all nonadmissible G-submodules of $\oplus_d \mathbb{C}[V]_d = \mathbb{C}[V]$.*

Let $\Sigma_v(d) \subseteq \mathbb{C}[V]_d$ be the union of nonadmissible G-submodules of $\mathbb{C}[V]_d$.

Basis elements of the G-submodules in Σ_v will be called *nonadmissible basis elements*. The following is a generalization of Proposition 6.2.

PROPOSITION 10.2. *Suppose v is (R,P)-stable. Then the G-modules in the representation-theoretic data Σ_v associated with v are contained in $I_V[v]$.*

Proof. Let $P = KU$. Fix any irreducible G-submodule $S \subseteq R_V[v]_d$. The result will follow if we show that every such S is admissible with respect to v and d (Definition 10.1). It follows from the first statement of Proposition 4.2 that S^* must contain

a $G_{\hat{v}}$-invariant. Since $U \subseteq G_{\hat{v}}$, this implies that $(S^*)^U$ contains an $R_{\hat{v}}$-invariant.

Let W be the smallest K-submodule of V containing $\hat{v}$. It remains to show that $(S^*)^U$ is $(K, \mathrm{Sym}^d(W))$-admissible. Since v, and hence $\hat{v}$, is stabilized by U, and U is normalized by K, W is also a P-module with trivial U-action. Let $\Phi = G \cdot W \subseteq V$. Consider the induced vector bundle $G \times_P W$ [27] with base space G/P and fiber W. Then Φ is the image of the natural G-equivariant map $\phi : G \times_P W \to V$ that maps (g, x), $g \in G$, $x \in W$, to $gx \in V$. We also have the associated map $\tilde{\phi} : G \times_P P(W) \to P(V)$. Since $\tilde{\phi}$ is proper, its image $\tilde{\Phi}$ is closed. The G-variety Φ is just the affine cone of $\tilde{\Phi}$, and is closed. $\Delta_V[v]$ is a closed G-subvariety of $\tilde{\Phi}$, and its affine cone $\check{\Delta}_V[v]$ is a closed G-subvariety of Φ. Hence, $R_V[v]$ is a G-summand of the homogeneous coordinate ring $R[\tilde{\Phi}]$ of $\tilde{\Phi}$. So every irreducible G-submodule of $R_V[v]$ can be thought of as an irreducible G-submodule of $R[\tilde{\Phi}]$. An element of $R[\tilde{\Phi}]_d$ is a regular function on Φ of degree d. Its pull-back via ϕ is a global section of the bundle $B = G \times_P (\mathrm{Sym}^d W)^*$. Hence, an irreducible G-submodule S of $R_V[v]_d$ corresponds to a nonzero irreducible G-submodule of $\Gamma(G/P, B)$. The second statement of Proposition 4.2 applied to B, in conjunction with Schur's lemma, implies that, given any such S, S^* must contain a P-submodule isomorphic to a P-submodule of $\mathrm{Sym}^d(W)$; i.e., $(S^*)^U$ must be $(K, \mathrm{Sym}^d(W))$-admissible. □

10.1. Example: G/P. Proposition 10.2 suggests we study to what extent the data Σ_v determines the ideal $I_V[v]$. In this section we shall show that for G/P the data Σ_v determines $I_v[v]$ completely. This observation was a starting point for Theorem 1.2 and Conjecture 1.9.

Let G be a simply connected, semisimple group G, and let $P \subseteq G$ be its parabolic subgroup, with Levi decomposition $P = KU$. Consider any embedding of G/P in $P(V)$, where $V = V_\lambda(G)$ is an irreducible G-representation and λ is a dominant weight lying in the interior of the face of the dominant Weyl chamber in correspondence [5] with P. Let $v \in P(V)$ correspond to its highest weight vector. Then G/P must actually be the orbit of v in $P(V)$ [5]; i.e., $\Delta_V[v] \simeq G/P$. Recall that v is (L, P)-stable, with defect zero, where L is the semisimple Levi subgroup of P (Example 1 in section 7).

Basis elements of $\Sigma_v(2)$ are equivalent to the Grassman–Plücker syzygies in the case of Grassmanian and, more generally, the quadratic straightening relations of the standard monomial theory [13] in the ideal of G/P.

PROPOSITION 10.3.

1. $\mathbb{C}[V]_d = V_{d\lambda}(G)^* \oplus \Sigma_v(d)$.
2. $R_V[v]_d = V_{d\lambda}(G)^*$.
3. *$I_V[v]$ is generated by the basis elements of $\Sigma_v(2)$, the nonadmissibility data of degree two.*

Remark. The second statement is one part of the Borel–Weil theorem (cf. section 8). Compare its proof here with the one based on Bruhat decomposition [11].

Proof. 1. Since $\mathbb{C}[V]_d^* \simeq \mathrm{Sym}^d(V_\lambda)$ contains a unique highest weight vector with weight $d\lambda$, its G-module decomposition is of the form

$$\mathbb{C}[V]_d^* = V_{d\lambda} + \sum_\mu V_\mu, \tag{6}$$

where each μ is some dominant weight smaller than $d\lambda$, in the usual ordering on the weights. Let $W = \mathbb{C}_\lambda$ be the one-dimensional representation (character) of P corresponding to the weight λ, so that $\mathrm{Sym}^d(W) = \mathbb{C}_{d\lambda}$. We want to show (cf. Definition 10.1) that each $V_\mu = V_\mu(G)$, $\mu \neq d\lambda$, is not admissible at v, i.e., V_μ^U is not

$(K, \mathbb{C}_{d\lambda})$-admissible, or, in other words, that V_μ, as a P-module, cannot contain $\mathbb{C}_{d\lambda}$ as a P-submodule (with trivial U-action): Otherwise let $w \in V_\mu$ be a basis vector of this one-dimensional module. Since w is invariant under the unipotent subgroup of P, it must be the highest weight vector of V_μ, and μ must belong to the interior of the face of the dominant Weyl chamber that corresponds to P [5]. Moreover, as a P-module, the line $\mathbb{C}w$ corresponding to w cannot be isomorphic to $\mathbb{C}_{d\lambda}$ unless $\mu = d\lambda$. Hence $V_\mu^* \subseteq \Sigma_v(d)$ (Definition 10.1). This proves Statement 1.

2. By Proposition 10.2, $\Sigma_v(d) \subseteq I_V[v]$, for all d. Hence, this follows from Statement 1 since $R_V[v]_d$ is clearly nonzero.

3. This is now a consequence of the second fundamental theorem for G/P in the standard monomial theory (cf. Theorem 7.5 in [13]), which states that the ideal $I_V[v]$ is generated by the functions in $\mathbb{C}[V]_2$ that vanish on $\Delta_V[v]$. By Statement 1, these are contained in $\Sigma_v(2) \subseteq I_V[v]$. □

11. SFT for the orbit of a partially stable, excellent point. Now we shall prove Theorem 1.2 for partially stable points with defect zero, by reducing it to the stable case that we have already proved. Let V be a linear representation of G. Let $P \subseteq G$ be a parabolic subgroup with Levi decomposition $P = KU = TLU$. We shall assume that the group R in the definition of (R, P)-stability satisfies the restriction in (5), as it does in our applications (cf. section 2).

A precise statement of Theorem 1.2 in the partially stable case is as follows.

THEOREM 11.1. *Let $V = V_\lambda(G)$. Let $v \in P(V)$ be an (R, P)-stable point with defect zero. Let W be the smallest K-submodule of V containing $\hat{v}$. Assume that* (1) *$L \subseteq R \subseteq K$, and* (2) *$R_{\hat{v}} \subseteq R$ is R-separable and characterizes v, considered as a point in $P(W)$. Then the orbit $Gv \subseteq P(V)$ is determined by the representation-theoretic data Σ_v (Definition* 10.1*) within some G-invariant neighborhood of the orbit. Specifically, there exists a G-invariant neighborhood $Z \subseteq P(V)$ such that Gv is a closed subvariety of Z and the zero set (scheme) in Z of the basis elements of the G-modules in Σ_v coincides with Gv.*

For example, suppose $W = \mathrm{Sym}^n(X)$ is embedded via ϕ in $V = \mathrm{Sym}^m(Y)$, as in section 2. Suppose that (1) f is a stable point in $P(W)$ with respect to the action of $R = SL(X) = SL_{n^2}(\mathbb{C})$, and (2) $R_{\hat{f}}$ characterizes f and is R-separable. Then $\phi(f)$ is a partially stable point of the type above.

Let $\Phi = G \cdot W \subseteq V$ as in the proof of Proposition 10.2. As we observed there, it is the image of the natural G-equivariant map $\phi : G \times_P W \to V$ that maps (g, x), $g \in G$, $x \in W$, to $gx \in V$, and we also have the associated map $\tilde{\phi} : G \times_P P(W) \to P(V)$. Since $\tilde{\phi}$ is proper, its image $\tilde{\Phi}$ is closed. The G-variety Φ is just the affine cone of $\tilde{\Phi}$. Let $R[\tilde{\Phi}]$ be the homogeneous coordinate ring of $\tilde{\Phi}$.

Our goal is to show that the orbit Gv of v is determined scheme-theoretically by the representation theoretic data within some G-invariant neighborhood of the orbit. Since Gv is contained in $\tilde{\Phi}$, our first goal is to understand the geometry of $\tilde{\Phi}$. Once this is done, we shall be able to reduce the present case to the stable case that has already been analyzed.

When v corresponds to the highest weight vector of $V = V_\lambda(G)$, $\tilde{\Phi} = \Delta_V[v] = G/P$. Hence we wish to generalize the results in section 10.1.

The geometry of $\tilde{\Phi}$. We say that $V_\alpha(G)$ is (K, U, W, d)-admissible if $(V_\alpha(G)^*)^U$ contains an irreducible K-submodule that also occurs in $\mathrm{Sym}^d(W)$, and that it is non–(K, U, W, d)-admissible otherwise.

PROPOSITION 11.1. *Every G-submodule in $R[\tilde{\Phi}]_d$ is (K,U,W,d)-admissible. Hence, every non–(K,U,W,d)-admissible G-submodule of $\mathbb{C}[V]_d$ belongs to the homogeneous ideal of $\tilde{\Phi}$.*

The proof is an easy modification of the proof of Proposition 10.2.

The following is a generalization of Proposition 10.3. Recall that W is a P-module with trivial U-action (cf. proof of Proposition 10.2).

PROPOSITION 11.2. (1) *As a G-module, $R[\tilde{\Phi}]_d$ is isomorphic to the space $\Gamma_d = \Gamma(G/P, Sym^d(W^*))$ of global sections of the vector bundle $G \times_P Sym^d(W^*)$.*

(2) *$\mathbb{C}[V]_d = \Gamma_d \oplus (\oplus_\beta V_\beta(G))$, where $V_\beta(G)^*$, for any β, cannot contain an irreducible K-submodule that also occurs in $Sym^d(W)$. In particular, each $V_\beta(G)$ is non–(K,U,W,d)-admissible and hence belongs to the ideal of $\tilde{\Phi}$.*

(3) *The ideal of $\tilde{\Phi}$ is generated (actually spanned) by non–(K,U,W,d)-admissible G-submodules of $\mathbb{C}[V]_d$.*

For the proof of this proposition we shall need a lemma. Let $P = KU = TLU$ be the Levi decomposition as above. We think of the root system of K as a subsystem of that of G. Let l be any linear functional l on the weight space of G with respect to which the usual ordering of the roots of G is defined; here it is assumed that l is irrational with respect to the weight lattice. Let

$$V_\lambda(G) = V_\lambda(K) \oplus \bigoplus_\mu V_\mu(K) \tag{7}$$

be a decomposition of $V_\lambda(G)$ as a K-module. Let v_β be the highest weight vector of $V_\beta(K)$ occurring in this decomposition with respect to l. Let $w_T(\beta) = w_T(v_\beta)$ denote its T-weight, i.e., the weight with respect to the central torus $T \subseteq K$.

The following is a complement to Lemma 8.3. Let ϕ be the projection of the dominant weights of G onto the largest face F of the dominant Weyl chamber that is orthogonal (in the Killing norm) to the simple roots of $\mathcal{K}$, the Lie algebra of K. Note that (1) $w_T(\alpha) = w_T(\phi(\alpha))$, for any dominant weight, since $w_T(\gamma) = 0$ for any simple root γ of K, and (2) $w_T(\phi(\alpha)) \neq w_T(\phi(\beta))$ if $\phi(\alpha) \neq \phi(\beta)$. Order the projected weights in F according to the restriction of l to F. This induces an order on the T-weights $w_T(\alpha)$'s.

LEMMA 11.2. *For every μ in (7), $w_T(\mu) = w_T(v_\mu)$ is less than $w_T(\lambda) = w_T(v_\lambda)$ for an appropriate l.*

Proof. Let W denote the Weyl group of G. For a simple root g, let W_g be the reflection in the hyperplane perpendicular to g.

The weights of $V_\lambda(G)$ are contained in the convex hull C of the conjugates of λ under the Weyl group elements [5]. Let A be the affine space, perpendicular to F, spanned by λ and $W_g(\lambda)$'s, where g ranges over the simple roots of $\mathcal{K}$. Its intersection with C is a face of C—call it L; it is the smallest face of C containing λ and $W_g(\lambda)$, for each simple root g of $\mathcal{K}$.

CLAIM 11.3. *The weight vectors of $V_\lambda(G)$, whose weights are contained in L, span the irreducible K-submodule $V_\lambda(K) \subseteq V_\lambda(G)$ with weight λ.*

Proof of the claim. Let $\mathcal{G}, \mathcal{K}$ denote the Lie algebras of G and K, and $U(\mathcal{G}), U(\mathcal{K})$ the corresponding universal enveloping algebras. We know that $V_\lambda(G)$ is spanned by αv_λ, where v_λ is the highest weight vector of $V_\lambda(G)$ and $\alpha \in U(\mathcal{G})$ ranges over all monomials in the negative roots of $\mathcal{G}$. If we order the roots appropriately, the Poincare–Birkoff–Witt theorem implies that α is of the form $\alpha_1\alpha_2$, where $\alpha_2 \in U(\mathcal{K})$ is a monomial in the negative roots of $\mathcal{K}$ and α_1 is a monomial in the remaining negative roots of $\mathcal{G}$. Then αv_λ is nonzero with weight in L iff $\alpha_1 = 1$. But $\alpha_2 v_\lambda$, as

α_2 ranges over all monomials in the negative roots of $\mathcal{K}$, clearly span $V_\lambda(K) \subseteq V_\lambda(G)$. This proves the claim.

It follows from the claim that no $\mu \neq \lambda$ in (7) can belong to L. We shall choose an irrational l such that the weights of $V_\lambda(G)$ within L have higher l-coordinates than the remaining weights of $V_\lambda(G)$; it clearly exists.

Consider the restriction of the linear function l to F. Then $l(\phi(\alpha))$ is higher than $l(\phi(\beta))$ for any weight β of $V_\lambda(G)$ not contained in L. Since no $\mu \neq \lambda$ in (7) can belong to L, the result follows. □

Proof of Proposition 11.2. Since w is P-stable, its stabilizer contains U. Since U is normalized by K, it follows that every point in W is also stabilized by U. By Lemma 8.3, $W = W_\lambda = V_\lambda(G)^U = V_\lambda(K)$.

The decomposition of $V = V_\lambda$ as a K-module is of the form

$$V = V_\lambda = W_\lambda \oplus \bigoplus_\mu W_\mu,$$

where, for each μ, $w_T(v_\mu) < w_T(v_\lambda)$ (Lemma 11.2). Let $W' = \bigoplus_\mu W_\mu$. By induction, and using the formula

$$\mathbb{C}[V]_d^* = \mathrm{Sym}^d(V) = \mathrm{Sym}^d(W_\lambda \oplus W') = \sum_{i+j=d} \mathrm{Sym}^i(W_\lambda) \otimes \mathrm{Sym}^j(W'),$$

it follows that $\mathbb{C}[V]_d^*$ has a K-module decomposition of the form

$$\mathbb{C}[V]_d^* = \mathrm{Sym}^d(V) = \mathrm{Sym}^d(W) \oplus W_d, \tag{8}$$

where the T-weight of the highest-weight-vector of each K-submodule of W_d is strictly smaller than the T-weight of the highest-weight-vector of each K-submodule in $\mathrm{Sym}^d(W)$. Hence no irreducible K-module can occur in both $\mathrm{Sym}^d(W)$ and W_d, considered as abstract K-modules; i.e., $\mathrm{Hom}(\mathrm{Sym}^d(W), W_d)^K = 0$.

Now consider a G-module decomposition

$$\mathbb{C}[V]_d^* \simeq \mathrm{Sym}^d(V_\lambda(G)) = \sum_\mu c_\mu^\lambda V_\mu(G), \tag{9}$$

where all $c_\mu^\lambda \geq 0$ and μ ranges over all dominant weights of G less than or equal to $d\lambda$. We do not know this decomposition explicitly; finding an explicit decomposition is a special case of the unsolved plethysm problem [5]. It follows from (9) that

$$\mathbb{C}[V]_d^{*U} \simeq \mathrm{Sym}^d(V_\lambda(G))^U = \sum_\mu c_\mu^\lambda V_\mu(G)^U = \sum_\mu c_\mu^\lambda V_\mu(K), \tag{10}$$

where the last step follows from Lemma 8.3. Since $W = V^U$, $\mathrm{Sym}^d(W)$ is a U-submodule of $\mathrm{Sym}^d(V)$. Hence it follows from (10) that each weight β of K that occurs in $\mathrm{Sym}^d(W)$ with nonzero multiplicity d^β also occurs as a weight of G in $\mathrm{Sym}^d(V)$ with multiplicity at least d^β. On the other hand, by the Borel–Weil theorem and Lemma 8.3 (cf. also Frobenius reciprocity [4]),

$$(\Gamma_d^*)^U = \mathrm{Sym}^d(W). \tag{11}$$

It follows that as a G-module,

$$\mathbb{C}[V]_d^* = \Gamma_d^* \oplus \bigoplus_\mu c_\mu V_\mu(G), \tag{12}$$

for suitable μ's. On the other hand, comparing this equation with (8), it follows that no $V_\mu(G)$ here can contain an irreducible K-submodule that also occurs in $\mathrm{Sym}^d(W)$. This proves the second statement of the proposition.

It remains to show that Γ_d is a G-submodule of $R[\Phi]_d$. By (11), $\Gamma_d^U = \mathrm{Sym}^d(W^*)$. Hence by the second statement, in conjunction with Lemma 8.3, this is equivalent to showing that $\mathrm{Sym}^d(W^*)$ is a K-submodule of $R[\Phi]_d^U$. This is clear, since we have the canonical U-equivariant embedding of W within Φ, the U-action on W being trivial. □

When $\tilde{\Phi} = G/P$, by the standard monomial theory, we know that nonadmissible basis elements of degree two generate the ideal of G/P (section 10.1). Analogously, in the context of Proposition 11.2, one can ask for a degree bound c such that the basis elements of non–(K, U, W, d)-admissible G-submodules of $\mathbb{C}[V]_d$, $d \le c$, generate the ideal of $\tilde{\Phi}$. This seeks an extension of the standard monomial theory to $\tilde{\Phi} = GW$.

Reduction to the stable case. Now we are ready to prove Theorem 11.1. Let $V = V_\lambda(G)$. Let v be an (R, P)-stable point with defect zero, as hypothesized, and let $W = V_\lambda(K)$ be the smallest K-submodule of V containing $\hat{v}$. Since $L \subseteq R \subseteq K$, K and R are both products of the form $LT(K)$ and $LT(R)$, respectively, where $T(K)$ and $T(R)$ are tori. Hence an irreducible K-module is also an irreducible R-module. In particular, W is an irreducible R-module with the action of the torus $T(R)$ being determined by a character; i.e., the action of $T(R)$ on $P(W)$ is trivial. Hence, any R-invariant subset of $P(W)$ is also K-invariant, and, in particular, $Rv = Kv \subseteq P(W)$.

The orbit $Gv \subseteq P(V)$ is contained in $\tilde{\Phi}$. By Proposition 11.2, the ideal of $\tilde{\Phi}$ is generated (actually spanned) by the non–(K, U, W, d)-admissible G-submodules of $\mathbb{C}[V]_d$. These submodules are contained in the nonadmissibility data Σ_v associated with v (cf. Definition 10.1). Let $\hat{\Sigma}_v$ be the set of remaining G-submodules of $\mathbb{C}[V]$ in Σ_v. A G-submodule $M \subseteq \mathbb{C}[V]_d$ belongs to $\hat{\Sigma}_v$ iff $(M^*)^U$ is not $R_{\tilde{v}}$-admissible. We shall show that there exists a G-invariant neighborhood Z of Gv in $\tilde{\Phi}$ such that Gv is a closed subvariety of Z and Gv is determined within Z by the data $\hat{\Sigma}_v$; i.e., the zero set of the (basis elements of) the G-modules in $\hat{\Sigma}_v$, restricted to Z, coincides with Gv scheme-theoretically.

Consider the G-equivariant map $\tilde{\phi} : G \times_P P(W) \to \tilde{\Phi}$.

Claim 11.4. *$\tilde{\phi}^{-1}(v)$ is a point.*

Proof of the claim. Suppose to the contrary. Then there exists $g \notin P$ and a $w \in P(W)$ such that $\phi(g, w) = v$, i.e., $gw = v$, and hence, $w = g^{-1}(v)$. Since v is (R, P)-stable, $U \subseteq G_v \subseteq P$ (Definition 7.1). Since $w \in P(W)$, and the U-action on W is trivial,

$$U \subseteq G_w = (G_v)^{g^{-1}} \subseteq P^{g^{-1}}.$$

Thus both P and $P^{g^{-1}}$ contain U. This implies that $P = P^{g^{-1}}$ (by Lemma 5.2.5(ii) in [30] and Corollary 11.17(iii) in [2]). Thus g^{-1} normalizes P. Since the normalizer of P is P itself (Theorem 11.16 in [2]), it follows that $g \in P$, a contradiction.

Let us denote the point $\phi^{-1}(v)$ by $\tilde{v}$. Since $\tilde{\phi}$ is surjective, to show that Gv is scheme-theoretically determined within a G-invariant neighborhood by the data $\hat{\Sigma}_v$, it suffices to show that $\tilde{\phi}^{-1}(Gv) = G \cdot \tilde{\phi}^{-1}(v) = G\tilde{v} \subseteq G \times_P P(W)$ is determined scheme-theoretically within some G-invariant neighborhood by the set $\tilde{\phi}^{-1}(\hat{\Sigma}_v)$ of the pull-backs of the G-modules in $\hat{\Sigma}_v$. But since $G_{\tilde{v}} = G_v \subseteq P$, the normal space to $G\tilde{v}$ can be identified with the normal space to its restriction to the slice $\tilde{\phi}^{-1}(P(W)) \simeq P(W)$, which in turn, corresponds to the normal space to the orbit $Rv = Kv \subseteq P(W)$. By the

Jacobian criterion (Proposition 6.4), it now suffices to show that the set $\tilde{\phi}^{-1}(\hat{\Sigma}_v)_{P(W)}$ of the restrictions of the modules in $\tilde{\phi}^{-1}(\hat{\Sigma}_v)$ to the fixed slice $\tilde{\phi}^{-1}(P(W)) \simeq P(W)$ of the bundle $G \times_P (W)$ determines the orbit of $Rv = Kv \subseteq P(W)$ within some K-invariant neighborhood of this orbit.

By Proposition 11.2, $R[\Phi]_d$ is isomorphic to the space $\Gamma_d = \Gamma(G/P, \mathrm{Sym}^d(W^*))$ of global sections of the bundle $G \times_P \mathrm{Sym}^d(W^*)$. By the Borel–Weil theorem and Lemma 8.3 (see also the Frobenius reciprocity in [4]), the set of restrictions of the modules in Γ_d to the slice $P(W)$ can be identified with Γ_d^U: If $M \in R[\Phi]$ and is isomorphic to $V_\lambda(G)$, then the restriction of $\tilde{\phi}^{-1}(M)$ to $P(W)$ corresponds to M^U, which is isomorphic to $V_\lambda(K)$ (Lemma 8.3). Hence, the restrictions of the modules in $\tilde{\phi}^{-1}(\hat{\Sigma}_v)$ to the slice $P(W)$ consists of precisely the K-modules in $\mathbb{C}[W]$ that do not contain any $R_{\hat{v}}$-invariant. Since K and R are of the form $LT(K)$, $LT(R)$, an irreducible K-module is also an irreducible R-module, and the subspace of $\mathbb{C}[W]$ spanned by non–$R_{\hat{v}}$-admisible K-submodules coincides with the subspace spanned by non–$R_{\hat{v}}$-admisible R-submodules. Thus, $\tilde{\phi}^{-1}(\hat{\Sigma}_v)_{P(W)}$ consists of precisely the non–$R_{\hat{v}}$-admisible R-modules in $\mathbb{C}[W]$. Since $v \in P(W)$ is stable with respect to the action of R on $P(W)$, we can now apply Theorem 6.1 for the stable case. It implies that $Rv \subseteq P(W)$ has an R-invariant, and hence, K-invariant, neighborhood Y such that Rv as a subvariety of Y is determined scheme-theoretically by $\tilde{\phi}^{-1}(\hat{\Sigma}_v)_{P(W)}$.

This shows that $\tilde{\phi}^{-1}(\hat{\Sigma}_v)_{P(W)}$ determines the orbit of $Rv = Kv \subseteq P(W)$ within a K-invariant neighborhood of the orbit.

This proves Theorem 11.1. □

12. *G*-separability. We now study the notion of G-separability (Definition 6.3), which is of interest in the context of Theorem 1.2.

PROPOSITION 12.1.

1. *A semisimple group H, embedded in $G = H \times H$ diagonally, is strongly G-separable.*
2. *$H = SL_k(\mathbb{C})$ is a strongly G-separable subgroup of $G = SL_n(\mathbb{C})$ if $k > (n+1)/2$.*
3. *$H = SL_k(\mathbb{C}) \times SL_l(\mathbb{C}) \subseteq G = SL_{k+l}(\mathbb{C})$, with natural embedding, is strongly G-separable.*

Remark. The last statement can be generalized to semisimple Levi subgroups of maximal parabolic subgroups of classical simple groups if one uses, instead of the decomposition formula in (13), Littelmann's restriction rule [14].

Proof. (1) By Schur's lemma, a G-module $V_\alpha(H) \otimes V_\beta(H)$, where $\otimes$ denotes the external tensor product here, is H-admissible iff $V_\beta(H) \simeq V_\alpha(H)^*$; i.e., $\beta = i_H(\alpha)$, where i_H is the involution on dominant H-weights (section 7). Any nontrivial representation $V_\lambda(H)$ occurs in the non–H-admissible G-module $V_\lambda(H) \otimes 1_H$, where 1_H denotes the trivial H-module. So H is clearly G-separable.

Strong G-separation follows from the following more general fact.

CLAIM 12.2. *$V_\lambda(H)$ occurs in the non–H-admissible G-module $V_\delta(H) \otimes V_\rho(H)$, $\delta = \lambda + \beta$ $\rho = i_H(\beta)$, for any dominant H-weight β.*

Proof of the claim. By Schur's lemma, this is equivalent to showing that

$$\begin{aligned} \mathrm{Hom}(V_\delta(H) \otimes V_\rho(H), V_\lambda(H)) &= V_{\lambda+\beta}(H)^* \otimes V_\rho(H)^* \otimes V_\lambda(H) \\ &= V_{\lambda+\beta}(H)^* \otimes V_\beta(H) \otimes V_\lambda(H) \end{aligned}$$

contains an H-invariant. By Schur's lemma again, this is equivalent to showing that $V_{\lambda+\beta}(H)$ occurs in $V_\beta(H) \otimes V_\lambda(H)$, which is clear.

(2) Consider a nontrivial $V_\lambda(SL_k(\mathbb{C}))$, where λ is a Young diagram of height h less than k. We shall exhibit a non–H-admissible $V_\mu(SL_n(\mathbb{C}))$ containing it. If h is greater than $n-k$, we let $\mu = \lambda$. Otherwise, let μ be a Young diagram obtained by adding $n-k-h+1$ boxes to the first column of λ. Its height is $n-k+1 < k$. By Pieri's branching rule, it is easy to see that $V_\mu(SL_n(\mathbb{C}))$ contains $V_\lambda(SL_k(C))$ but not the trivial representation of $SL_k(\mathbb{C})$. More generally, if μ' is a Young diagram obtained by appropriately extending, i.e., adding boxes to the first $n-k$ rows of μ, then $V_{\mu'}(SL_n(\mathbb{C}))$ contains $V_\lambda(SL_k(C))$ but not the trivial representation of $SL_k(\mathbb{C})$. There are infinitely many such μ's. So $SL_k(\mathbb{C})$ is strongly separable.

(3) Assume that $k \geq l$, the other case being similar. Consider a nontrivial H-module $L = V_\alpha(SL_k(\mathbb{C})) \otimes V_\beta(SL_l(\mathbb{C}))$, where α and β correspond to Young diagrams of height less than k and l, respectively. We shall exhibit a non–H-admissible G-module $V_\lambda(G)$ containing it. We identify α and β with the partitions: $\alpha = (\alpha_1, \alpha_2, \ldots)$, where α_i denotes the length of the ith row of the corresponding Young diagram, and $\beta = (\beta_1, \beta_2, \ldots)$. We proceed by cases.

Case 1. Either α does not correspond to a rectangular Young diagram of height l, or β is not trivial.

Let $\lambda = \alpha + \beta = (\alpha_1 + \beta_1, \ldots)$. Note that the height of λ is less than k. We have [5]

$$V_\lambda(GL_{l+k}(\mathbb{C})) = \sum_{\rho,\delta} N^\lambda_{\rho,\delta} V_\rho(GL_k(\mathbb{C})) \otimes V_\delta(GL_l(\mathbb{C})), \tag{13}$$

where $N^\lambda_{\rho,\delta}$ denotes the Littlewood–Richardson coefficient. From this it easily follows that $V_\lambda(SL_{k+l}(\mathbb{C}))$ contains the representation $V_\alpha(SL_k(\mathbb{C})) \otimes V_\beta(SL_l(\mathbb{C}))$ of $SL_k(\mathbb{C}) \times SL_l(\mathbb{C})$. But it cannot contain the trivial H-representation: If $\rho \neq 0$ and δ (possibly zero) correspond to rectangular Young diagrams with height k and l, respectively—so that $V_\rho(SL_k(\mathbb{C}))$ and $V_\delta(SL_l(\mathbb{C}))$ are trivial—then $N^\lambda_{\rho,\delta}$ is easily seen to be zero; otherwise the height of λ will be at least k. On the other hand, if $\rho = 0$, then $\lambda = \delta$. Since the height of β is less than l, the definition of λ then implies that $\alpha = \delta$ and $\beta = 0$; a contradiction.

More generally, let α' be any Young diagram obtained from α by adding columns of length k. Let $\lambda' = \alpha' + \beta$. Then $V_{\lambda'}(SL_{k+l}(\mathbb{C}))$ also contains $V_\alpha(SL_k(\mathbb{C})) \otimes V_\beta(SL_l(\mathbb{C}))$ but not the trivial representation of $SL_k(\mathbb{C}) \times SL_l(\mathbb{C})$. Moreover, there are infinitely many such λ's.

Case 2. α is rectangular of height l and width w, and $\beta = 0$.

We can assume that $k > l$; otherwise $V_\alpha(SL_k(\mathbb{C}))$ too will be trivial. For any integer $r \geq 0$, let λ be the Young diagram whose first r columns are of height k, the $(r+1)$st column is of length $l+1$, the columns numbered $r+2, \ldots, r+w$ are of height l, and the column numbered $r+w+1$ is of height $l-1$. Then it follows from (13) that $V_\lambda(GL_{l+k}(\mathbb{C}))$ contains $V_\rho(GL_k(\mathbb{C})) \otimes V_\delta(GL_l(\mathbb{C}))$, where ρ is obtained from α by adding to its left r columns of length k, and δ consists of a single column of height l. Clearly $V_\rho(GL_k(\mathbb{C})) \otimes V_\delta(GL_l(\mathbb{C}))$ is isomorphic to $V_\alpha(SL_k(\mathbb{C})) \otimes V_\beta(SL_l(\mathbb{C}))$ as an $SL_k(\mathbb{C}) \times SL_l(\mathbb{C})$-module. But it does not contain the trivial $SL_k(\mathbb{C}) \times SL_l(\mathbb{C})$-module; this too follows from (13). Moreover, there are infinitely many such λ.

This proves strong G-separability of H. □

For us, it is important to know if the stabilizers of the points that arise in the context of complexity theory are separable (cf. section 2). The connected component of the stabilizer of $\det(Y)$ in $SL_{n^2}(\mathbb{C})$, where Y is an $n \times n$ matrix, contains $SL_n(\mathbb{C}) \times$

$SL_n(\mathbb{C}) \subseteq SL(Y) = SL_{n^2}(\mathbb{C})$ (section 2.1). Regarding this subgroup we make the following conjecture.

CONJECTURE 12.3. *$SL_n(\mathbb{C}) \times SL_n(C)$ is a strongly separable subgroup of $SL_{n^2}(\mathbb{C})$.*

Here the embedding corresponds to the natural embedding $SL(V) \otimes SL(V) \subseteq SL(V \otimes V)$, $V = C^n$. Specifically, letting $V_\lambda(n)$ denote $V_\lambda(SL_n(\mathbb{C}))$ in what follows, the conjecture can be reformulated as follows.

CONJECTURE 12.4. *For every nontrivial Weyl module $V_\lambda(n) \otimes V_\mu(n)$ of $SL_n(\mathbb{C}) \times SL_n(\mathbb{C})$, such that $|\lambda| = |\mu| \pmod n$, there exist (infinitely many) Weyl modules $V_\rho(n^2)$ of $SL_{n^2}(\mathbb{C})$ whose decomposition as an $SL_n(\mathbb{C}) \times SL_n(\mathbb{C})$-module contains $V_\lambda(n) \otimes V_\mu(n)$ but not the trivial $SL_n(\mathbb{C}) \times SL_n(\mathbb{C})$-module.*

The restriction $|\lambda| = |\mu| \pmod n$ is required to ensure (cf. Definition 6.3) that $V_\lambda(n) \otimes V_\mu(n)$ occurs in some representation of $SL_{n^2}(\mathbb{C})$; cf. (14) below.

The conjecture can be reformulated in terms of the symmetric group as follows. Let $\hat{V}_\gamma(n^2)$ be a Weyl module of $GL_{n^2}(\mathbb{C})$. Embed $GL_n(\mathbb{C}) \times GL_n(\mathbb{C}) = GL(\mathbb{C}^n) \times GL(\mathbb{C}^n)$ in $GL(\mathbb{C}^n \otimes \mathbb{C}^n) = GL_{n^2}(\mathbb{C})$. The decomposition of $\hat{V}_\gamma(n^2)$ as a $GL_n(\mathbb{C}) \times GL_n(\mathbb{C})$-module is of the form

$$\hat{V}_\gamma(n^2) = \sum_{\alpha,\beta} c_{\alpha,\beta,\gamma} \hat{V}_\alpha(n) \otimes \hat{V}_\beta(n); \tag{14}$$

here $c_{\alpha,\beta,\gamma}$ can be nonzero only if $|\alpha| = |\beta| = |\gamma|$. To get the decomposition of $\hat{V}_\gamma$ as an $SL_n(\mathbb{C}) \times SL_n(\mathbb{C})$-module, we reduce the Young diagrams occurring on the right-hand side by removing columns of length n. This does not change their sizes modulo n; this explains the restriction $|\lambda| = |\mu| \pmod n$ in the conjecture. By Littlewood's symmetry conditions [5], the coefficients $c_{\alpha,\beta,\gamma}$ do not depend on the ordering of α, β, and γ.

Given a Young diagram δ, $|\delta| = m$, let W_δ denote the corresponding irreducible representation, the Specht module, of the symmetric group S_m. Then the coefficient $c_{\alpha,\beta,\gamma}$ occurring in the preceding decomposition is the same as the one occurring in the decomposition of the tensor product $W_\alpha \otimes W_\beta$ as an S_m-module,

$$W_\alpha \otimes W_\beta = \sum_\gamma c_{\alpha,\beta,\gamma} W_\gamma,$$

where $m = |\alpha| = |\beta|$; cf. [5].

For any λ of height less than n and $m = |\lambda| \pmod n$, let $\lambda(m)$ be the unique Young diagram of size m obtained by adding to α columns of length n. Then the preceding conjecture is equivalent to saying the following:

For every nontrivial pair of Young diagrams (λ, μ) of height less than n, and such that $|\lambda| = |\mu| \pmod n$, there exist an $m = |\lambda| = |\mu| \pmod n$, $m \geq n$, and a ρ of size m such that W_ρ occurs in the decomposition of $W_{\lambda(m)} \otimes W_{\mu(m)}$ as an S_m-module, but not in the decomposition of $W_\delta \otimes W_\delta$, where δ is the rectangular Young diagram of height n and size m.

If $|\lambda| = |\mu| \neq 0 \pmod n$, the last restriction is vacuous, because no such δ exists, and hence we have the following proposition.

PROPOSITION 12.5. *If $|\lambda| = |\mu| \neq 0 \pmod n$, Conjecture 12.4 holds.*

So, let us assume that $|\lambda| = |\mu| = 0 \pmod n$ in what follows.

PROPOSITION 12.6. *Conjecture 12.4 holds for $n = 2$.*

The main difficulty in extending the proof below to $n > 2$ is that an explicit decomposition of the tensor product of two arbitrary Specht modules is not yet known.

Proof. We need to show that for every nontrivial pair of (λ, μ) of row-shaped Young diagrams, with $|\lambda|$ and $|\mu|$ even, there exist an even m and a ρ of size m such that W_ρ occurs in the decomposition of $W_{\lambda(m)} \otimes W_{\mu(m)}$ as an S_m-module, but not in the decomposition of $W_\delta \otimes W_\delta$, where δ is the rectangular Young diagram of height 2 and width $m/2$. We shall show that there exists such a ρ for every large enough $m \geq 4(|\lambda| + |\mu|)$. Fix such an m.

Given a Young diagram γ, we shall let γ_i denote the number of boxes in its ith row from the top. We assume that the topmost row has the highest length in the diagram. We shall denote $\lambda(m)$ and $\mu(m)$ by $\bar{\lambda}$ and $\bar{\mu}$, respectively. Since λ and μ are row shaped, we shall let λ and μ denote the lengths of their row as well. Since $|\bar{\lambda}| = |\bar{\mu}| = m$, $\bar{\lambda}_2 - \bar{\lambda}_1 = \lambda$, and $\bar{\mu}_2 - \bar{\mu}_1 = \mu$, we have $\bar{\lambda}_2 = m/2 - \lambda/2$ and $\bar{\mu}_2 = m/2 - \mu/2$. Since $\bar{\lambda}$, $\bar{\mu}$, and δ have two rows, we can use the decomposition formula of Remmel and Whitehead [29].

First, we shall try to find a required ρ with two rows. Let (a, b), $a \geq b$, denote the two-row Young diagram with the top row of length a and the bottom row of length b. Suppose we are given Young diagrams $(k, h), (r, l), (d, c)$ of size m. Because of Littlewood's symmetry conditions we can assume that $l \leq h \leq c$. With this condition, the formula in [29, Theorem 3.3] says that

$$c_{(r,l),(k,h),(d,c)} = (1 + w - v)\chi(w \geq v), \tag{15}$$

where $w = \lfloor (l + h - c)/2 \rfloor$, $v = \max(0, \lceil (l + h + c - m)/2 \rceil)$, and the function χ is one if $w \geq v$ and zero otherwise.

By Littlewood's symmetry condition, $c_{\delta,\delta,\rho} = c_{\rho,\delta,\delta}$. Applying the preceding formula with $(r, l) = \rho$ and $(k, h) = (d, c) = \delta = (m/2, m/2)$, we conclude that this coefficient is nonzero iff $\lfloor \rho_2/2 \rfloor \geq \lceil \rho_2/2 \rceil$. That is, iff ρ_2 is even. So we need to find a ρ, with ρ_2 odd, such that $c_{\bar{\lambda},\bar{\mu},\rho}$ is nonzero. Because of symmetry, we can assume that $\bar{\lambda}_2 \leq \bar{\mu}_2$. We will try to find ρ such that

$$\rho_2 \leq \bar{\lambda}_2. \tag{16}$$

Then setting $(k, h) = \rho$, $(r, l) = \bar{\lambda}$, and $(d, c) = \bar{\mu}$ in (15), we conclude that $c_{\bar{\lambda},\bar{\mu},\rho} = c_{\rho,\bar{\lambda},\bar{\mu}}$ is nonzero iff

$$\lfloor (\rho_2 + \bar{\lambda}_2 - \bar{\mu}_2)/2 \rfloor \geq \max(0, \lceil (\rho_2 + \bar{\lambda}_2 + \bar{\mu}_2 - m)/2 \rceil), \tag{17}$$

i.e., iff

$$\lfloor (\rho_2 - \lambda/2 + \mu/2)/2 \rfloor \geq \max(0, \lceil (\rho_2 - \lambda/2 - \mu/2)/2 \rceil). \tag{18}$$

We now proceed by cases.

Case 1. $\mu \neq 0$.

In this case the condition in (18) can be satisfied if

$$\rho_2 \geq (\lambda + \mu)/2 \tag{19}$$

and $\mu \geq 2$, which holds since μ is nonzero and even. But there are many odd ρ_2's such that (16) and (19) are satisfied if, say, $m \geq 4(\lambda + \mu)$.

Case 2. $\mu = 0$, and $\lambda/2$ is odd.

In this case, (18) is satisfied if we let $\rho_2 = \lambda/2$, which is nonzero—otherwise (λ, μ) will be trivial—and odd, as required. Since m is large enough, (16) is also satisfied.

It remains to consider the following case.

Case 3. $\mu = 0$, and $\lambda/2$ is even.

In this case, the required two-row ρ does not exist. So we shall find an appropriate $\rho = (\rho_1, \rho_2, \rho_3, \rho_4)$ with four rows such that $\rho_3 = \rho_4$.

Given Young diagrams (k, h), (m, l), (d, c, a, a) (entries in nonincreasing order) with m boxes such that $a > 0$ and $\lceil (h+1)/2 \rceil \leq h - c$, the Remmel–Whitehead formula [29, Theorem 3.1] says that

$$c_{(k,h),(m,l),(d,c,a,a)} = \sum_{r=h-c}^{\min(l, \lfloor \frac{l-a+h-c}{2} \rfloor)} 1 - \sum_{r=\max(a, l+h+a-m-1)}^{\min(l, \lfloor \frac{h-1}{2} \rfloor, \lfloor \frac{l+h+a+c-m-1}{2} \rfloor)} 1. \tag{20}$$

We will set $(k, h) = (m, l) = \delta = (m/2, m/2)$ and $(d, c, a, a) = \rho = (\rho_1, \rho_2, \rho_3, \rho_4)$ in this formula. For the formula to be applicable, we need to ensure that

$$\lceil \lceil (h+1)/2 \rceil = (m/2+1)/2 \rceil \leq h - c = m/2 - \rho_2. \tag{21}$$

If, in addition,

$$\rho_2 + \rho_3 < m/2, \tag{22}$$

we get that

$$\begin{aligned} c_{\delta,\delta,\rho} &= \sum_{\frac{m}{2}-\rho_2}^{\lfloor \frac{(m-\rho_3-\rho_2)}{2} \rfloor} 1 - \sum_{r=\rho_3}^{\lfloor \frac{\rho_3+\rho_2-1}{2} \rfloor} 1 \\ &= \left\lfloor \frac{(m-\rho_3-\rho_2)}{2} \right\rfloor - \left(\frac{m}{2} - \rho_2\right) + \rho_3 - \left\lfloor \frac{\rho_3+\rho_2-1}{2} \right\rfloor, \\ &= \left\lfloor \frac{\rho_2-\rho_3}{2} \right\rfloor - \left\lfloor \frac{\rho_2-\rho_3-1}{2} \right\rfloor, \end{aligned}$$

which is 1 if $\rho_2 - \rho_3$ is even, and zero otherwise.

So we need to find a ρ with $\rho_2 - \rho_3$ odd, satisfying (21) and (22), such that $c_{\bar{\mu},\bar{\lambda},\rho}$ is nonzero. Since $\mu = 0$, we have $\bar{\mu}_1 = \bar{\mu}_2 = m/2$. Also, recall that $\bar{\lambda}_2 = m/2 - \lambda/2$. Set $(k, h) = \bar{\mu} = (m/2, m/2)$, $(m, l) = \bar{\lambda}$, and $(d, c, a, a) = \rho$ in (20). We shall choose a four-row ρ, with nonzero ρ_3, such that $\rho_2 - \rho_3$ is odd, ρ_2 and ρ_3 are sufficiently larger than λ, and also such that the difference between $m/2$ and $\rho_2 + \rho_3$ is sufficiently larger than λ. This is possible if m is large enough compared to λ. In this case, the upper index of the first sum in (20) becomes $\lfloor \frac{\bar{\lambda}_2 - \rho_3 + m/2 - \rho_2}{2} \rfloor$, and the lower index is $m/2 - \rho_2$. So the contribution of the first term is $\lfloor \frac{\rho_2 - \rho_3 - \lambda/2}{2} \rfloor$. Since λ is nonzero, the lower index of the second sum in (20) is equal to $\frac{\lambda}{2} - 1 + \rho_3$. The upper index, assuming that m is large enough and $m/2 - \rho_2 - \rho_3$ is sufficiently larger than λ, becomes $\lfloor \frac{-\lambda/2 + \rho_2 + \rho_3 - 1}{2} \rfloor$. Assuming that ρ_2 and ρ_3 are sufficiently larger than λ, it is larger than the lower index. Hence the second term becomes

$$\frac{\lambda}{2} - 1 + \rho_3 - \left\lfloor \frac{-\lambda/2 + \rho_2 + \rho_3 - 1}{2} \right\rfloor = \frac{\lambda}{2} - 1 + \left\lfloor \frac{\lambda/2 - \rho_2 + \rho_3 + 1}{2} \right\rfloor.$$

Thus

$$c_{\bar{\mu},\bar{\lambda},\rho} = \left\lfloor \frac{\rho_2 - \rho_3 - \lambda/2}{2} \right\rfloor + \frac{\lambda}{2} - 1 + \left\lfloor \frac{\lambda/2 - \rho_2 + \rho_3 + 1}{2} \right\rfloor = \frac{\lambda}{2} - 1.$$

This is nonzero, since $\lambda/2$, being nonzero and even, is at least two. So we can choose a ρ, with $\rho_2 - \rho_3$ odd, and subject to the preceding conditions, as required. ∎

Acknowledgments. We are grateful to Madhav Nori for his guidance and encouragement during the course of this work, and to C. S. Seshadri and Burt Totaro for helpful discussions.

FAULT-TOLERANT QUANTUM COMPUTATION WITH CONSTANT ERROR RATE*

DORIT AHARONOV† AND MICHAEL BEN-OR†

Abstract. This paper shows that quantum computation can be made fault-tolerant against errors and inaccuracies when η, the probability for an error in a qubit or a gate, is smaller than a constant threshold η_c. This result improves on Shor's result [*Proceedings of the 37th Symposium on the Foundations of Computer Science*, IEEE, Los Alamitos, CA, 1996, pp. 56–65], which shows how to perform fault-tolerant quantum computation when the error rate η decays polylogarithmically with the size of the computation, an assumption which is physically unreasonable. The cost of making the quantum circuit fault-tolerant in our construction is polylogarithmic in time and space. Our result holds for a very general local noise model, which includes probabilistic errors, decoherence, amplitude damping, depolarization, and systematic inaccuracies in the gates. Moreover, we allow exponentially decaying correlations between the errors both in space and in time. Fault-tolerant computation can be performed with any universal set of gates. The result also holds for quantum particles with $p > 2$ states, namely, p-qudits, and is also generalized to one-dimensional quantum computers with only nearest-neighbor interactions. No measurements, or classical operations, are required during the quantum computation. We estimate the threshold of our construction to be $\eta_c \simeq 10^{-6}$, in the best case. By this we show that local noise is in principle not an obstacle for scalable quantum computation. The main ingredient of our proof is the computation on states encoded by a quantum error correcting code (QECC). To this end we introduce a special class of Calderbank–Shor–Steane (CSS) codes, called polynomial codes (the quantum analogue of Reed–Solomon codes). Their nice algebraic structure allows all of the encoded gates to be transversal. We also provide another version of the proof which uses more general CSS codes, but its encoded gates are slightly less elegant. To achieve fault tolerance, we encode the quantum circuit by another circuit by using one of these QECCs. This step is repeated polyloglog many times, each step slightly improving the effective error rate, to achieve the desired reliability. The resulting circuit exhibits a hierarchical structure, and for the analysis of its robustness we borrow terminology from Khalfin and Tsirelson [*Found. Phys.*, 22 (1992), pp. 879–948] and Gács [*Advances in Computing Research: A Research Annual: Randomness and Computation*, JAI Press, Greenwich, CT, 1989]. The paper is to a large extent self-contained. In particular, we provide simpler proofs for many of the known results we use, such as the fact that it suffices to correct for bit-flips and phase-flips, the correctness of CSS codes, and the fact that two-qubit gates are universal, together with their extensions to higher-dimensional particles. We also provide full proofs of the universality of the sets of gates we use (the proof of universality was missing in Shor's paper). This paper thus provides a self-contained and complete proof of universal fault-tolerant quantum computation in the presence of local noise.

Key words. quantum computation, quantum fault tolerance, noise and decoherence, quantum error correction, concatenated codes, density matrices, polynomial codes, quantum Reed–Solomon codes, universal set of gates

1. Introduction. The area of quantum algorithms has witnessed remarkable discoveries over the past decade, the most remarkable of which is Shor's groundbreaking discovery of a polynomial quantum algorithm for factoring [82]. These results indicate a possibility that quantum computers exhibit exponential speedups over classical computers. It is yet unclear whether and how large scale quantum computers will be physically realizable (see [68] for possible implementation schemes). However, as in any physical system, quantum computers will *in principle* be subjected to noise, such as decoherence [103, 93, 94], and inaccuracies. Without error corrections, the effect of noise will accumulate and ruin the entire computation [97, 30, 71, 65, 66, 20]. Thus, the question of whether quantum computation can be protected against noise cannot be separated from the subject of quantum computational complexity.

One cannot hope to achieve fault tolerance of any computational model, be it quantum or classical, unless the noise model is restricted in some way. In this paper we adopt the assumption that the noise is *local*. Roughly, it means that the noise is independent between the different components of the system. This seems to be a fairly natural assumption to work with from a physical point of view and is often assumed in the classical case. We characterize the amount of noise by a parameter η which we call the *error rate*. The most basic variant of local noise with error rate η is called *independent probabilistic noise* and is defined as the following process: Each gate undergoes an arbitrary error with independent probability η, and in addition, for every time step, the qubits that do not participate in any gate undergo errors, too, each with independent probability η. Local noise can be defined much more generally, to include decoherence, systematic errors, and other kinds of physical processes. We will deal with these later in this paper, but for a first reading it is best to keep in mind the simplest local noise model of independent probabilistic noise.

This paper settles the question of whether quantum computation preserves its computational power in the presence of local noise. We give a positive answer to this question, for a very wide variety of cases under the title of local noise. To do this, we show how to simulate an unreliable quantum circuit by one that is robust to local noise of error rate η, as long as η is below a certain (constant) threshold. The overhead is only polylogarithmic in both space and time. By this we show that, in principle, local noise is not an obstacle against the physical realization of quantum computers. We do not attempt here to optimize the threshold value but rather to achieve a systematic and simple mathematical structure and as general a proof as possible. In the rest of the introduction, we state and explain the result in more detail, describe its context and limitations, and provide an outline of the proof.

1.1. Background on quantum error correction and fault tolerance. The analogue question of protecting classical computation from errors was already studied by von Neumann in 1956, when he showed that classical computation can be made robust to noise with constant error probability per gate [67]. This was done by using computation on redundant information, encoded by a repetition code.

The similar question for quantum computation, however, is far more complicated. Even the simpler question of transmitting quantum information reliably over a noisy channel poses a lot of conceptual obstacles in comparison with its classical analogue, and, in fact, scientists were skeptical about this possibility [97, 62]. There were several valid reasons for these concerns. First, the fact that quantum states cannot be cloned [99] implies that straightforward redundancy techniques cannot help. Second, Hilbert space is continuous, and this implies that it may be difficult to distinguish between bona fide quantum information and a state with a small error. Third, and

possibly the most difficult problem, is the fact that quantum noise can cause occasional *measurements* of the quantum state by the environment which lead to a collapse of the quantum state—a process which seems to cause irreversible damage to the quantum information. Finally, it seems that, in order to correct the error, one must measure the state to figure out what error had occurred. It seems impossible to perform such a measurement without collapsing the state and losing the quantum information.

These pessimistic beliefs were disputed and replaced with cautious optimism with the discoveries of the first examples of quantum error correcting codes (QECCs), encoding one qubit by nine [83] or seven [88] qubits and allowing for the correction of one faulty qubit. The main ingredients that allowed this discovery are as follows: (1) Despite the seemingly infinitely versatile set of possible quantum errors, all quantum errors on one qubit can actually be written as combinations of two errors (called *bit-flip* and *phase-flip*). It is thus sufficient to correct for these two errors. This discretization of the errors allowed turning to classical techniques of error correction. (2) In order to discover the error that had occurred, it suffices to perform a partial measurement on the state, which does not necessarily collapse the part of the state carrying the important information.

Immediately after this discovery, Calderbank and Shor [28], and independently Steane [89], presented a general construction of a large class of good quantum error correcting codes,[1] now called Calderbank–Shor–Steane (CSS) codes, which are based on known classical error correcting codes. These results were followed by the development of a whole theory for quantum error correction, including the important definition of stabilizer codes, and with many examples of QECCs (see, e.g., [68, 87] for more information and references). The theory of QECCs shows that, in principle, quantum information can be transmitted over a noisy channel in a reliable and efficient way.

The existence of QECCs is not in itself sufficient to ensure the possibility of quantum computation in the presence of noise. The reason is as follows. To compute in the presence of noise, one might try to encode the quantum state by using a QECC. In order to prevent the accumulation of errors, one must perform error corrections frequently, in between the computational steps. However, when dealing with noisy computation we are faced with several new problems that do not exist when dealing with the problem of transmitting information over noisy channels. First, in the information transmission setting, one assumes that the encoding and decoding processes are error-free. In the case of noisy computation, on the other hand, the error correction procedure itself is done in the presence of noise. It can thus introduce additional errors into the state and quite possibly cause more harm than help. A second problem is that the process of computation involves interactions between different qubits. If a gate is applied on two qubits, where one of them is faulty, it is likely that at the end of the operation the two qubits are faulty, or, in other words, the gate has caused the *propagation* of the error from a faulty qubit to an error-free qubit. One must therefore be able to compute on encoded states by using procedures and error corrections which do not allow the errors to propagate too much. Such procedures which limit the propagation of errors are called *fault-tolerant.*

In [84], Shor showed how to design fault-tolerant procedures for a universal set of quantum gates.[2] These procedures are applied to states encoded by a code from

[1] Good codes are codes which have a nonzero asymptotic transmission rate, in the presence of a constant error rate per bit.

[2] A set of gates is universal if an arbitrary unitary transformation can be constructed by using only gates from the set.

a certain class of CSS codes. In order to use these fault-tolerant constructions so as to improve the reliability of the quantum circuit, one would first encode the qubits in the original circuit by using the CSS quantum error correcting code and then apply fault-tolerant computation and fault-tolerant error corrections on these encoded states alternately. Shor showed that the resulting quantum circuit performs the desired computation reliably when the error rate, or the fault probability at each time step, per qubit or gate, decays polylogarithmically with the size of the quantum circuit. This result is a major improvement over the performances of quantum circuits without error corrections, in which the error probability is required to decay as one over the size of the circuit in order for the computation to succeed [21].

Nevertheless, the assumption that Shor used, namely, that the error probability decays polylogarithmically with the size of the computer, is a physically unrealistic assumption. We would like to assume that the resources required for applying one elementary operation are fixed and independent of the input size and, in particular, that the probability for a fault in each computer element, as well as the inaccuracy in each gate, is a constant number independent on the number of computer components.

1.2. Results. In this paper we improve on Shor's result and show how to perform fault-tolerant quantum computation in a more realistic model of computation, in which the error rate η is a fixed parameter, independent of the size of the computation.

THEOREM 1 (the threshold result, roughly). *There exists a threshold $\eta_0 > 0$ such that the following holds. Let $\epsilon > 0$. If Q is a quantum circuit operating on n input qubits for t time steps using s two- and one-qubit gates, there exists a quantum circuit Q' with depth, size, and width overheads which are polylogarithmic in n, s, t, and $1/\epsilon$ such that, in the presence of local noise of error rate $\eta < \eta_0$, Q' computes a function which is within ϵ total variation distance from the function computed by Q.*

The locality assumption is at the core of our threshold result. Our methods cannot handle errors which hit large sets of qubits chosen by an adversary. Within this realm of local noise, our fault tolerance result holds for a very general noise model. Our first threshold theorem (Theorem 12) is devoted to proving the threshold result for the independent probabilistic noise model. We use it as a basis to prove several other versions of the threshold theorem. Section 8 extends the result to work with what we call general local noise (Theorem 13). This version allows us to include in the noise model also decoherence, amplitude and phase damping, depolarization, systematic inaccuracies in the gates, leakage errors (of some sort—not disappearance of particles), and more. In fact, our result seems to apply to almost any conceivable quantum process as long as it is local. Later on, we generalize Theorem 12 in another direction (section 10) and show that our construction is reliable even when the probabilistic noise model allows correlations in space and time, as long as these correlations decay exponentially in some well defined sense.

We further generalize the threshold result by considering not only generalizations of the noise model but also different constraints to which the quantum system may be subjected. In particular, Theorem 14 shows that fault tolerance against general local noise can be achieved with any universal set of gates (not necessarily with the set of gates that we show how to encode fault tolerantly). This may be important in the likely scenario in which the set of gates implementable in the laboratory is different than the one we use in our constructions. Furthermore, in various implementation schemes only nearest-neighbor gates are available. Theorem 15 shows that fault tolerance can be achieved even when the particles of the quantum computer are

set on a one-, two-, or three-dimensional grid, and only nearest-neighbor interactions are allowed.

The various versions of the threshold theorem lead to different values of the threshold.

1.3. Assumptions on the architecture of the quantum system. It might be helpful to make explicit various issues related to the requirements from the physical realization of the quantum computer in order for our fault tolerance scheme to work.

- *Redundancy in the input.* We always assume that the input is given to the quantum circuit in many copies. This redundancy requirement is unavoidable if we want to achieve robustness to noise, because otherwise we would have negligible probability that we even start the computation correctly. This is also assumed in the classical scenario [67].
- *Redundancy in the output.* The output of the circuit is also given in a redundant way. In order to interpret the output string, one needs to calculate a certain majority function of the many output bits, which are all equal in the ideal case but not in the presence of errors.
- *Noise on wires vs. noise on gates.* In some quantum systems, the noise and decoherence on the wires are negligible. In other words, errors occur only while the qubits participate in a gate. In this paper we do not make such an assumption, and we assume that the wires are noisy, too. If one is dealing with a quantum system with noisy wires, then one must bear in mind that, in order to achieve fault tolerance, the quantum system must satisfy two important requirements.
  1. *Parallelism.* It is required that gates on different qubits can be applied in parallel, so that many gates can be applied at the same time step. It can be shown that, without parallelism, fault tolerance is impossible when wires are noisy, since error corrections cannot be applied fast enough to prevent accumulation of errors [5].
  2. *A supply of fresh qubits.* Another requirement is that fresh or clean qubits namely, qubits in the state $|0\rangle$, are available at any time and not just in the beginning. In other words, it must be possible to *restart* a qubit, namely, initialize it to the state $|0\rangle$, in the middle of the computation. Once again, without this assumption, reliable quantum computation is impossible because there is no way to discard entropy which accumulates rapidly in the circuit due to noise [7].
- *Intermediate measurements.* One might imagine cases in which measurements can be applied during the quantum computation, and so parts of the intermediate computation (e.g., computations inside the error correction procedure) can be performed by a classical computer. Moreover, in some cases it is also reasonable to assume that classical computations can be performed infinitely fast. This would be the case if the time it takes to perform a classical operation is negligible in comparison to the time it takes to perform a quantum gate. Of course, such cases are significantly simpler to handle than the general case. The reason is that, to a very large accuracy, classical computation can be assumed to be error-free, and so intermediate computations, such as parts of the error correction, can then be assumed to be error-free. In this paper we do not require this assumption. Measurements in the middle of the computation are not necessary in order to achieve fault tolerance. Though allowing intermediate measurements simplifies the situation considerably, we

make an effort to show that fault tolerance can be achieved without using classical operations or measurements. We do this because of two reasons. One is purely theoretical: One would like to know that measurements and classical operations are not essential and that the quantum model is complete in the sense that it can be made fault-tolerant within itself. Even more importantly, the assumption on the infinitely fast classical computation breaks down at some point and does not scale with the size of the input. One should certainly try to avoid such an assumption when attempting to prove a threshold theorem that holds asymptotically. The other reason we make an effort to avoid intermediate measurements is practical: In some suggestions for physical realizations of quantum computers (such as the NMR-based quantum computation—see [68]), it is very difficult to perform intermediate measurements during the quantum computation, and therefore everything should be done within the quantum computation model, without the help of classical computers.

- *Different sets of gates.* Our main fault-tolerant construction (Theorem 12) uses very specific universal sets of gates (see subsections 4.2 and 5.2 for the definitions). Nevertheless, one can actually convert the fault-tolerant circuit into one that uses any universal set of gates. This is proved and explained in section 9. Again, this is important for practical purposes, because the set of gates that is implementable in the laboratory might be entirely different than the ones that are easy to implement fault-tolerantly.
- *Nearest-neighbor interactions.* In some implementation schemes, interaction is limited to nearest-neighbor particles. We show that this is not a restriction in terms of fault tolerance: Resilience to noise can be achieved even under very restricted geometrical conditions, namely, that qubits are arranged in a one-dimensional lattice and gates are allowed only between nearest neighbors.

We summarize the division of our threshold theorems with respect to their assumptions on the architecture of the system. All of our theorems allow noise on the wires and thus assume parallelism and a constant supply of fresh qubits. Also, all of our theorems work without the assumption of intermediate measurements. Our first two versions of the threshold result, Theorems 12 and 13, and also section 10, are concerned with quantum systems subject to the following two assumptions on their architecture: First, a gate can be applied on any set of particles, regardless of their physical location. In other words, qubits that participate in a gate need not be nearest neighbors. Second, the final realization of the quantum circuit may consist of gates taken out of two particular sets, which we call $\mathcal{G}_1$ or $\mathcal{G}_2$. The other versions of our theorem release these assumptions. Theorem 15 shows that nearest-neighbor interactions suffice, and Theorem 14 allows the use of arbitrary universal sets of gates, including sets that contain only two-qubit gates.

1.4. Proof overview. We outline here the proof of our first threshold result, Theorem 12, which holds for the simplest noise model of independent probabilistic errors. The extensions to other cases build upon this case and do not require much more innovation.

1.4.1. Ingredients for the construction. There are several ingredients that are required in the proof.

1. A quantum error correcting code. To this end we define a new type of a quantum error correcting code (QECC) called *polynomial quantum error correcting code*. This is the quantum analogue of the Reed–Solomon code [64],

and it is a special case of CSS codes over large fields. We draw intuition here from Ben-Or, Goldwasser, and Wigderson [24], who used Reed–Solomon codes to achieve classical fault-tolerant distributed computation. An alternative version of the proof uses the general class of CSS code that Shor used in [84].

2. To compute on states encoded by QECCs, we need fault-tolerant maintenance procedures. First, we require a fault-tolerant way to perform error correction, which would allow us to correct errors in encoded states without introducing too many new errors. Second, we need a zero-state preparation procedure, namely, a procedure which prepares a state that encodes $|0\rangle$ (and uses fresh qubits for this purpose). These encoded zero states will be used as ancilla states for error correction as well as for computation. Both of these procedures can be performed in many different ways (e.g., [4]). Here we choose to work with the nice idea used by Steane for error correction [89]. Finally, we need a fault-tolerant decoding procedure which would allow us to read the logical value of the encoded state. This is not difficult to design.
3. To perform the actual computation, we need a universal set of gates which can be performed fault-tolerantly on encoded states. Each gate g needs to be replaced by an *encoded gate*, which takes the encoding of a state $|\alpha\rangle$ to the encoding of $g|\alpha\rangle$. Most importantly, the encoded gates need to be applied fault-tolerantly, i.e., without letting the errors propagate too much. Here is where the reason we chose to work with polynomial codes becomes apparent. Due to their algebraic structure, these codes exhibit the following very nice property: The entire universal set of quantum gates can be performed in a manner which is called *transversal*, or *bitwise*. This term refers to the application of the encoded gate g simply by applying g on each of the qubits in the code word individually (see Figure 1.1).
   This means that the set of encoded gates is extremely simple. Unfortunately, some complication cannot be avoided. The transversal operations in the case of polynomial codes indeed perform the desired computation, but in some cases they cause the degree of the polynomials involved in the code to increase (to see why this might happen, consider the case in which two polynomials are multiplied). To avoid accumulation of this effect, we perform a fairly simple procedure called *degree reduction*. This procedure, too, can be applied transversally, except it requires the help of ancilla zero states. Overall, we get a set of fault-tolerant procedures which possesses a nice algebraic structure. We also provide fault-tolerant procedures for the alternative codes we use, namely, the more general CSS codes that are used in Shor's scheme. Our constructions are based on those used by Shor [84], adapted to our re-

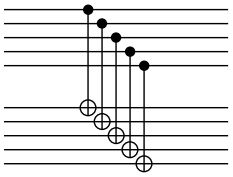

FIG. 1.1. *Encoded* CNOT *gate on two logical qubits encoded by five qubits each. Five* CNOT *gates are applied, where the ith gate is applied from the ith qubit in the first block to the ith qubit in the second block.*

quirement of no measurements during the computation. The fault-tolerant application of the Toffoli gate in this case does not possess as nice an algebraic structure as the procedures we design for polynomial codes.

4. We next need to show that the set of gates which we use is indeed universal, so that arbitrary quantum computations can be performed using our scheme. A known result due to Solovay [85] and Kitaev [50, 52] implies that it suffices for this purpose to show that the set of gates in question generates a dense subset in the group of unitary matrices. We use algebraic and field theoretical tools, and employ a few known group theoretical results, to prove that both sets of gates we use indeed satisfy this density requirement. In the case of polynomial codes, the proof is fairly involved. We note that a proof of the universality of the set of gates used by Shor was missing in [84].

1.4.2. The fault-tolerant circuit. We now want to combine all of the above ingredients to construct a fault-tolerant circuit from a given circuit M_0 which is not protected against errors. We want to make the circuit reliable against a constant error rate η, independent of the size of the computer n.

The first step of the idea is already present in Shor's original fault-tolerant result (except for using different codes and fault-tolerant procedures): Compute on states encoded by a QECC. We use a QECC that encodes one qubit into, say, m qubits. The circuit M_1 which computes on encoded states is defined as a *simulation* of M_0. A qubit in M_0 transforms to a block of m qubits in M_1, and each gate in M_0 transforms to a fault-tolerant procedure in M_1 applied on the corresponding blocks. Note that procedures might take more than one time step to perform. Thus, a time step in M_0 is mapped to a time interval in M_1, which is called a *working period*. In order to prevent accumulation of errors, at the beginning of each working period an error correction is applied on each block. The working period now consists of two stages: a correction stage and a computation stage. To be precise, the initialization and output stages in M_1 require some special attention, in order to encode the redundant input, and also decode the output states into a redundant classical output. We do not elaborate on this part here.

The idea is therefore to apply alternately computation stages and correction stages, hoping that during the computation stage the damage that accumulated is still small enough so that the corrections are able to handle it. We will soon argue that if the error rate is below a certain threshold, the reliability of M_1 is better than that of M_0. Let us assume this for the moment. In any case, we need to reduce the effective error rate of the final circuit to something which is inverse polynomially small, which would guarantee that with high probability there is effectively no error in the entire computation. Some thought would lead the reader to the conclusion that, regardless of how we choose the QECC in the above scheme, it seems impossible to achieve an improvement from a constant error rate to an effective error rate that is inverse polynomial.

Our solution is fairly simple to state. The crucial point here is that the new circuit M_1 might not be reliable enough for our purposes, but it suffices that it is even *slightly* more reliable than the original circuit. If this is the case, we can continue to improve the reliability by repeating the same process as we did for the original circuit, but starting from the new, more reliable circuit M_1. We do this for several levels; let us denote the number of levels by r, so the final circuit is M_r. How many levels are needed? It turns out that the improvement in the error rate is doubly exponential in the number of levels, and so it suffices that r is taken to be polyloglog in the

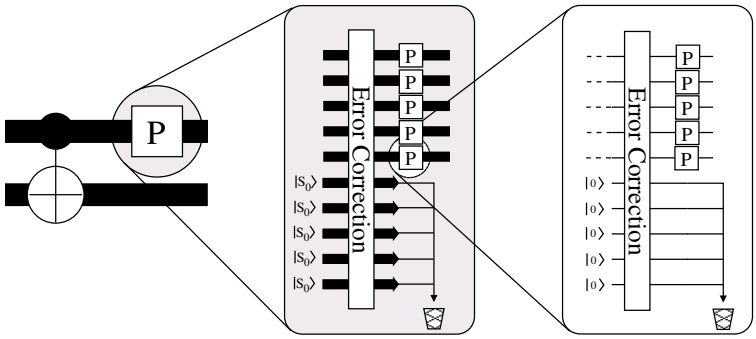

FIG. 1.2. *This figure shows the two-level simulation of a two-gate circuit. When looking at it at the coarsest resolution, we see the circuit on the left. The gates we see are those gates which* M_0 *consists of, namely, a* CNOT *followed by a one-qubit gate. By increasing the resolution a bit, we see the next level circuit* M_1*. The figure shows only part of it, namely, the second gate in* M_0 *transformed in* M_1 *to its encoded version. This includes an error correction of that block (with the help of an ancilla), followed by a transversal application of the one-qubit gate. By increasing the resolution yet one last time, we get to see the actual physical circuit, namely,* M_2*. Here we show only the encoding of one one-qubit gate in* M_1*.*

parameters of M_0.

The resulting circuit M_r exhibits a hierarchical structure resembling the one in Figure 1.2.

Each qubit in the original circuit transforms to a block of qubits in the next level, and they in their turn transform to a block of blocks in the second simulation, and so on. A gate in the original circuit transforms to a procedure in the next level, which transforms to a larger procedure containing smaller procedures in the next level, and so on. The final circuit computes in all of the levels: The largest procedures, computing on the largest (highest-level) blocks, correspond to operations on qubits in the original circuit. The smaller procedures, operating on smaller blocks, correspond to computation in lower levels. Note that each level simulates the error corrections in the previous level and adds error corrections in the current level. The final circuit, thus, includes error corrections of all of the levels, where during the computation of error corrections of larger blocks, smaller blocks of lower levels are being corrected. The lower the level, the more often error corrections of this level are applied, which is in correspondence with the fact that smaller blocks are more likely to be quickly damaged. This is the source of the advantage of using recursive simulations, rather than one step of simulation, as is done in Shor's scheme [84].

One other way to understand this is that the hierarchical structure takes advantage of a very important fact, namely, that the errors are located *randomly*. It is easy to see that the resulting QECC, namely, a concatenation of the QECC for r levels, can correct very few (less than a fraction of n) errors if their locations are chosen by an adversary, but as long as their locations are random, all is fine.

We note that the final circuit in one of our constructions (the one that uses polynomial codes) is made of p-qudits rather than qubits. This circuit can be easily converted to one that works with qubits by replacing each qudit by the appropriate number of qubits and each gate by a sequence of gates on these qubits. The analysis of robustness of this final circuit follows exactly the lines of section 9.

1.4.3. New reliability and the threshold value. We now want to argue that the reliability of the simulating circuit M_1 is larger than that of the original circuit

M_0, as long as the error rate is below a certain threshold. In other words, we want to explain why, below a certain threshold error rate, we should expect some improvement in reliability from one level of simulation to the next.

In the original circuit, the occurrence of one fault may cause the failure of the computation. In contrast, suppose that one fault occurs in each procedure of the simulating circuit. If the fault-tolerant procedures allow this fault to propagate to, say, at most one error in each block, then these faults would have no effect on the correctness of the simulation since they would be corrected during the error correcting stages. In other words, if in each encoded gate and the preceding error correction procedure the number of faults is such that they can cause only less than the correctable number of errors, then the error corrections will prevent the errors from accumulating. (In fact, this argument needs to be made much more carefully (see Lemma 9), but for the sake of the introduction here it suffices.) The *effective* error rate of M_1 is thus, roughly, the probability for more than the correctable number of faults to occur in one procedure.

Just for the sake of illustration, let us consider an example in which our QECC corrects one error but not two and a fault-tolerant procedure allows one fault to propagate to at most one error in each of the final blocks. We now estimate the effective error rate in a slightly incorrect way, but which demonstrates the idea. In this case, the effective error rate is the probability for more than one fault to occur in one procedure. In other words, we need to consider all ways in which two or more faults can occur in one procedure. This is a combinatorial calculation, which behaves approximately like

$$\eta_{\text{eff}} \approx \left(\begin{array}{c} A \\ 2 \end{array} \right) \eta^2,$$

where A is the number of locations an error can possibly occur during the application of one procedure. Now observe that, for η_{eff} to be strictly smaller than η, we get the requirement $\eta < \frac{1}{\binom{A}{2}}$. Thus, if η is below a certain threshold that depends on A, we gain an improvement in the reliability of the circuit. This is the origin for the *threshold* in the threshold theorem. See section 12 for estimations of the values in our construction.

1.4.4. The proof. The analysis of the scheme turns out to be quite complicated. To do this, we borrow terminology used by Khalfin and Tsirelson [49] and Gács [42] to analyze self-correcting classical cellular automata. First, we distinguish between two notions which we have been using so far as if they are the same: the *error* in the state of the qubits, i.e., the set of qubits which have errors, and the actual *faults*, namely, the occasions where noise operators were applied. We use the term *fault path* to denote the list of locations, namely, points in time and space, where faults had occurred (in a specific run of the computation).

We then define the notion of sparse errors and sparse fault paths. Naturally, due to the hierarchical structure of this scheme, these notions are defined recursively. A block in the lowest level is said to be k-close to its correct state if it does not have more than k errors, and a higher level block is "k-close" to its correct state if it does not contain more than k blocks of the previous level which are far from their correct state. If all of the blocks of the highest level are k-close to being correct, we say that the set of errors, or the deviation, is *k-sparse*.

Which set of faults does not cause the state to be too far from correct in the above metric? The answer is recursive, too: A computation of the lowest-level procedure

is said to be undamaged if not too many faults occurred in it. Computations of higher-level procedures are not damaged if they do not contain too many lower-level procedures which are damaged. A fault path will be called *sparse* if the computations of all of the highest-level procedures are not damaged.

The proof of the threshold result is done by showing that the probability for "bad" faults, i.e., the probability for the set of faults not to be sparse, decays as a double exponential with the number of levels r. Thus, bad faults are negligible, if the error rate is below the threshold. This is the easy part. The more complicated task is to show that the "good" faults are indeed good; i.e., if the set of faults is sparse enough, then the set of errors is also kept sparse until the end of the computation. This part is done by using a double induction on the number of levels r.

1.5. Related work and the state of the art in quantum fault tolerance. A preliminary version of the threshold result (for independent probabilistic errors) was published in the proceedings version of this paper [3]. Different variants of the threshold result for probabilistic noise were independently discovered at about the same time (1996) by Knill, Laflamme, and Zurek [56, 57, 58], who used Steane's seven-qubit QECC, and by Kitaev [50], who used toric codes. All of these works are based on the same idea of applying one scheme recursively to get a hierarchical structure and achieve approximately the same estimated threshold value of 10^{-6}.

An important unique contribution of our work is that our proof does not require intermediate measurements and classical operations during the quantum computation: Our fault-tolerant circuits use only quantum gates and, thus, work entirely within the framework of the quantum model. All works on fault tolerance we are aware of (other than the current paper) work under the assumption that intermediate measurements are allowed, and, moreover, classical computation can be performed infinitely fast. This makes the problem significantly easier, because under these assumptions large parts of the computation can be assumed to be error-free.

Our proof, as well as the proof of Kitaev [50], requires using a QECC that corrects two errors. It turns out that our construction works for a QECC that corrects one error, but a different analysis is required. An idea of how to perform this analysis was suggested in [56, 57, 58], by using the notion of overlapping rectangles. This idea was recently made into a proof by Aliferis, Gottesman, and Preskill [14]. A different proof was independently given by Reichardt [78].

Since the discovery of the threshold result mentioned above, intensive scientific effort was put into generalizing, simplifying, and improving the fault-tolerant networks. This effort started with the important work by Gottesman [45, 44] showing that fault tolerance can be achieved with any stabilizer code and with the works of Preskill [73, 74] and of Steane [90, 91]; it continued with a long line of works which we will not attempt to survey here for lack of space. The main goal of this line of work is practical: that of improving the threshold and making it realistic.

We mention a few main lines of developments. The first is that of developing the usage of ancilla state distillation, also known as *ancilla factories*. In the basic fault-tolerant schemes, one initiates the computation with states encoding 0, and the preparation of these states can be thought of as a separate process. Steane [90], Gottesman and Chuang [48], and finally Bravyi and Kitaev [27] have each shown how to use more and more cleverly designed ancillary states to significantly simplify the main computational process and improve the threshold.

The creation of ancilla states of high fidelity is the bottleneck in the threshold calculations in the above-mentioned schemes. In a breakthrough work, Knill [54] has

suggested to use concatenation of quantum error *detection* (rather than correction) codes, for the distillation of ancilla states. If an error is detected, the ancilla state can be discarded, without affecting the ongoing computation. The overhead in the number of qubits is large, but numerical estimations [54] of the threshold of this scheme revealed a value of up to several percent. Reichardt [76] and independently Aliferis, Gottesman, and Preskill [15] provide a rigorous proof of a much worse threshold than the estimated one, but still the best rigorously proven today: 10^{-3}. It is left open to close the gap between the numerics and the theoretical work.

Completely different methods to achieve fault tolerance were also explored. The first idea in this context is the beautiful idea of Kitaev, of achieving fault tolerance in the different model of topological quantum computation with anyons [51]. In this model of computation, the information is protected by topological means, and no concatenation is required.

Another interesting development along nonstandard lines is that of using subsystem codes [59]. These are a generalization of quantum error correcting codes. Aliferis and Cross [13] recently showed how to use subsystem codes due to Bacon [16], to get a threshold of $1.9 \cdot 10^{-4}$.

So far, we have discussed only methods which did not take into consideration geometrical restrictions on the system. Another issue which is explored in this paper is that of fault-tolerant quantum computation with nearest-neighbor interactions between qubits in one-, two, or three-dimensional systems. We prove a threshold result under such assumptions in section 11. This was proved independently also by Gottesman in [47]. In contrast to [47], our proof of generalization to low dimensions is very simple (see section 11), since one only has to keep track of the error propagation in one level, and the general threshold theorem (section 7) takes care of the rest. Both results provide very small values of the threshold. The lower bound on the threshold value in the case of $1D$ was improved recently to 10^{-6} in [92]. In two dimensions, better results are known. Svore, Divincenzo, and Terhal [95] have proved a threshold in $2D$ which is of the order of 10^{-5}, and Raussendorf and Harrington [75] have provided a scheme in which topological codes are used, in which the simulated threshold is of the order of 10^{-3}.

All of the above works consider the case of probabilistic noise only. Yet another different line of work in the area of fault tolerance is the study of the limitations and applicability of the threshold result in the presence of more general noise models. This direction is explored quite thoroughly in the current paper, where we prove the threshold result for a general local noise model (section 8) and, moreover, (slightly) relax the locality requirement to allow exponentially decaying correlations in the noise process (section 10). Following the preliminary version of this work [4], and based on similar methods, Terhal and Burkard [96], and recently Aliferis, Gottesman, and Preskill [14], proved threshold results in the presence of non-Markovian noise. The most recent development in this context [9] shows that fault tolerance can be achieved even in the presence of correlations which decay *polynomially* in space.

We also mention here an alternative approach to fault tolerance which has attracted interest, namely, "decoherence-free subspaces" (DFSs) [41, 102, 63, 101, 55]. A DFS is a subspace of the Hilbert space, which, under certain assumptions on the noise, is completely unaffected by the noise process. The computation is then performed entirely within this subspace [17, 18]. The DFS method might indeed be very useful in the presence of special types of noise, such as collective decoherence (see references above), and can thus deal with various correlated noise processes. However, we note that the assumptions on the noise made in the DFS model are quite

restrictive and, in particular, do not allow local noise. If one wants to correct for local noise, these methods must be combined with the standard methods of fault tolerance presented in this paper.

Finally, since the publication of the preliminary version of this paper [3], polynomial codes have found several applications in other areas of quantum computation such as secure multiparty computation [36] and quantum secret sharing [33]. Nonbinary codes were defined independently also by Chuang, Leung, and Yamamoto [31] and Knill [53]. Fault tolerance with higher-dimensional particles was discussed also in [46].

1.6. Conclusions and open problems. This paper implies that quantum computation can in theory be carried out in the presence of noise, as long as the noise satisfies a fairly reasonable assumption, namely, locality, and as long as the error rate in the system can be decreased below a certain constant value. Within this locality assumption, our results holds for a very general noise model. Moreover, our result holds for quantum systems with fairly limited constraints, such as no classical computation and subject to geometrical restrictions. Thus, this paper provides a thorough and general solution to the problem of quantum computation in the presence of local noise.

The value of the threshold is of utmost importance to the practicality of the theorem. We did not attempt to optimize the threshold value in our fault tolerance scheme, and our estimated threshold of $\approx 10^{-6}$ (see section 12) is far from being practical, according to the state of the art in experimental systems. As mentioned in subsection 1.5, since the preliminary publication of this work there have been many improvements. The best current rigorous results give a threshold value of approximately 10^{-3}, whereas computer simulations of the best constructions say that the threshold value is of the order of one to several percent. Providing rigorous proofs for the latter is a challenge. Any improvement in the threshold value is significant, as it brings quantum computation closer to being practical. We note that one should be careful in interpreting these numbers, since the threshold depends on many parameters; see section 12 and subsection 1.3 for further discussion of this matter.

Another parameter which is crucial for practical purposes is the space efficiency of the fault-tolerant construction, namely, the overhead in the number of qubits. Once again, we have not attempted to optimize this parameter. This parameter has achieved significantly less attention in the literature than the threshold value. See [77, 54] for some discussion of this matter.

It is of course desirable to save time as well. Our scheme requires a polylogarithmic blowup in the depth of the circuit. In the original version of this paper [3, 4] we conjectured that it might be possible to use a quantum analogue of multilinear codes [86], to reduce the multiplicative factor of $O(\log(n))$ to a factor of $O(\log(\log(n))$. Recently, Ahn [10] indeed achieved fault tolerance with this improved depth overhead, by using clever combinatorial considerations for toric codes. An open question is whether it is possible to reduce the time cost to a constant, as in the classical case. We conjecture that the answer is negative.

Another important open problem is to further relax the assumptions on the noise model and to make them as realistic as possible. This is a natural continuation of the work presented in sections 8 and 10 of the current paper and in several papers of the past few years [96, 14, 9].

The results achieved in this work shed light on a very interesting question, regarding the transition from quantum to classical physics [103]. Traditionally, this transition is viewed as a gradual transition (but see [49]). The threshold result suggests that in some cases this transition can actually be viewed as a *phase transition*,

occurring at a critical error rate, above which the system abruptly loses its ability to entangle large sets of particles. This is supported by the result of this paper, showing that at a very small error rate quantum systems can maintain their quantum nature, together with another result of ours [5], showing that at very high error rates quantum computers can be simulated efficiently by a classical Turing machine. In [2] one of us formalized this phase transition idea and provided a physical explanation for this computational difference between high and low error rates, by showing that in fault-tolerant circuits a phase transition in a certain property of entanglement called *entanglement length* occurs at a critical error rate. This draws a natural connection between the transition from quantum to classical and the notion of entanglement. The connection between the quantum-classical transition, entanglement, and quantum phase transitions has since become an active field of research (see, e.g., [69, 70]). We believe that the physical realization of fault-tolerant quantum computers might enable far better understanding of this fundamental question.

1.7. Organization of paper and instructions as to how to read it. Section 2 starts with a rigorous definition of the model of quantum circuits which we use, namely, quantum circuits with mixed states. We define the basic noise model, of independent probabilistic errors, and its various generalizations. Section 3 provides the definitions of quantum error correcting codes in general and the particular QECC codes we use in this paper. Section 4 describes how to apply fault-tolerant procedures for polynomial codes. Section 5 describes how to apply fault-tolerant gates on states encoded by CSS QECC. Section 6 proves the universality of the sets of gates defined in the previous two sections. Section 7 proves the threshold result for independent probabilistic noise. This is the main result of the paper. Section 8 generalizes the threshold result to general local noise. In section 9 we generalize our result to circuits which use any universal set of gates and not necessarily the set of gates for which we have constructed fault-tolerant procedures. In section 10 we relax the assumption of independence and explain how to deal with exponentially decaying correlations in the noise. Section 11 proves the threshold result for quantum circuits with restricted geometry, i.e., one-dimensional quantum circuits. In section 12 we discuss the estimation of the threshold values in various cases.

Many readers would be satisfied with understanding the main ingredients of the proof of the threshold result, for the simplest noise model of independent probabilistic noise, and for one type of QECC, either general CSS codes or polynomial codes. Such readers might also be less interested in the details of the proof that the set of gates we use is universal. The relevant chapters for those readers are sections 2.8, 2.9, 3, 4 (or 5), and 7. In general, the paper is written in a very modular way, so the readers can skip to the interesting parts.

Each section starts with a short overview. A reader who is interested in a more detailed overview than the one provided in the introduction, but still not in all of the details, can read only these overviews.

2. The model of noisy quantum circuits.

2.1. Overview. This section provides the necessary definitions for this paper. For more details on the quantum computation model consult [68]; for more on quantum mechanics consult [34, 79, 72].

The standard model [38, 39, 100] of quantum circuits with unitary gates allows only unitary operations on qubits. However, noisy quantum systems are not isolated from other quantum systems, usually referred to as the environment. Their inter-

actions with the environment are unitary, but, when restricting the system to the quantum computer alone, the operation on the system is no longer unitary, and the state of the quantum circuit is no longer a vector in the Hilbert space. It is indeed possible to stay within the unitary model with pure states, by keeping track of the state of the environment. However, this environment is not part of the computer, and it is assumed that we have no control or information on its state. We find it more elegant to follow the framework of the physicists and to work within the model of quantum circuits with mixed states defined by Aharonov, Kitaev, and Nisan [6]. In this model, the state of the set of qubits is always defined: It is a probability distribution over pure states, i.e., a *mixed state*. It is described by a *density matrix* (see below). The quantum gates in this model are not necessarily unitary: Any physically allowed operator on qubits is a quantum gate. In particular, this model allows an operation which adds a blank qubit to the system, discards a qubit, or applies a measurement in some basis. The model of quantum circuits with mixed states is equivalent in computational power to the standard model of quantum circuits [6] but seems more adequate for the study of noisy quantum computation. Since noise is a dynamical process which depends on time, the circuits we consider are leveled; i.e., gates are applied at discrete time steps.

To include noise in our model, we add noise operators which act in between the time steps of the circuit. The simplest model for noise is the independent probabilistic noise. After every time step, we consider the sets of qubits that interacted in the previous time step. Each such set undergoes a fault (i.e., an arbitrary quantum operation) with independent probability η, and η is referred to as the *error rate*. A qubit that did not participate in a gate undergoes the same process on its own.

The probabilistic noise process can be generalized to a more realistic model of noise, which is the following process. After each time step, each set of qubits participating in the same gate goes through a physical operator which is at most η-far from the identity (in some operator metric discussed below). This model includes, apart from probabilistic errors, also decoherence, amplitude and phase damping, systematic inaccuracies in the gates, and more (see [68] for an explanation of these terms). Two important assumptions were made in this definition: independence between different faults in space, i.e., locality, and independence in time, which is called the Markovian assumption. We remain within this framework until the end of the paper, and only in section 10 do we relax it to allow also exponentially decaying correlations in both time and space.

We note that all definitions here use qubits, namely, two-state particles, but can trivially be extended to any finite-dimensional particles, namely, to *qudits*.

2.2. Pure states. A quantum physical system in a *pure state* is described by a unit vector in a Hilbert space, i.e., a vector space with an inner product. In the *Dirac* notation a pure state is denoted by $|\alpha\rangle$. The physical system which corresponds to a quantum circuit consists of n quantum two-state particles, called qubits. The Hilbert space of a qubit is a two-dimensional complex space and is denoted by $\mathcal{H}_2$. We choose an orthonormal basis for this space and denote its vectors by $|0\rangle$ and $|1\rangle$. The Hilbert space of n qubits is the n-fold tensor product of $\mathcal{H}_2$, namely, $\mathcal{H}_2 \otimes \cdots \otimes \mathcal{H}_2$, its dimension is 2^n, and it is isomorphic to $\mathcal{C}^{2^n}$. As a basis for this space we choose all possible tensor products of the basis vectors of the individual qubits $|i_1\rangle \otimes |i_2\rangle \otimes \cdots \otimes |i_n\rangle$, where i_j is either 0 or 1. We often use the notation $|i_1, i_2, \ldots, i_n\rangle$ or $|i\rangle$ for brevity. A pure state $|\alpha\rangle \in \mathcal{H}_2^n$ is a *superposition* of the basis states: $|\alpha\rangle = \sum_{i=1}^{2^n} c_i|i\rangle$, with $\sum_{i=1}^{2^n} |c_i|^2 = 1$. The transposed-complex conjugate of $|\alpha\rangle$ is denoted by $\langle\alpha|$. The

inner product between $|\alpha\rangle$ and $|\beta\rangle$ is denoted by $\langle\alpha|\beta\rangle$.

2.3. Mixed states and density matrices. In general, a quantum system is not in a pure state but in a *mixed state*, namely, a probability distribution, or a *mixture* of pure states, denoted by $\{\alpha\} = \{p_k, |\alpha_k\rangle\}$. This means that the system is with probability p_k in the pure state $|\alpha_k\rangle$. This description is not unique, as different mixtures might represent the same physical system. An equivalent unique description uses *density matrices*. A density matrix ρ on $\mathcal{H}_2^n$ is an Hermitian (i.e., $\rho = \rho^\dagger$) semipositive-definite matrix, of dimension $2^n \times 2^n$, with trace $\mathrm{Tr}(\rho) = 1$. A pure state $|\alpha\rangle = \sum_i c_i|i\rangle$ is represented by the density matrix $\rho_{|\alpha\rangle} = |\alpha\rangle\langle\alpha|$ (by definition, $\rho(i,j) = \langle i|\rho|j\rangle$). A mixture $\{\alpha\} = \{p_s, |\alpha_s\rangle\}$ is associated with the density matrix $\rho_{\{\alpha\}} = \sum_s p_s|\alpha_s\rangle\langle\alpha_s|$. This association is not one-to-one, but it is *onto* the density matrices, because any density matrix describes the mixture of its eigenvectors, with the probabilities being the corresponding eigenvalues.

Given a density matrix of n qubits, one can assign a density matrix to a subsystem A of $m < n$ qubits. We say that the rest of the system, represented by the Hilbert space $\mathcal{G} = \mathbf{C}^{2^{n-m}}$, is *traced out* and denote the new matrix by $\rho|_A$. We have $\rho|_A(i,j) = \sum_{k=1}^{2^{n-m}} \rho(ik, jk)$, and k runs over a basis for $\mathcal{G}$. In words, this means averaging over $\mathcal{G}$. The new density matrix $\rho|_A$ is called the *reduced* density matrix to A. If the state of the qubits which are traced out is in tensor product with the state of the other qubits, then discarding the qubits means simply erasing their state. However, if the state of the discarded qubits is not in tensor product with the rest, the reduced density matrix is always a mixed state.

2.4. Measurements. A quantum system can be *measured*, or observed. The measurement is a probabilistic process which, given a density matrix, yields a pair: a classical output and the associated density matrix. In this paper we will use only a measurement of one qubit in the computational basis. Let P_0 (P_1) be a projection on the subspace spanned by all states in which the measured qubit is 0 (1). For a given density matrix ρ, the classical output is $m \in \{0,1\}$ with probability $\Pr(m) = \mathrm{Tr}(P_m\rho)$. Given the outcome m, the resulting state of the quantum system after the measurement is equal to $\Pr(m)^{-1}P_m\rho P_m$ (this has the same meaning as a conditional probability distribution). Any measurement thus defines a probability distribution over the possible outputs.

2.5. Quantum operators and quantum gates. To define the possible transformations on density matrices, we consider linear operators on operators (sometimes called *superoperators*). A superoperator is called *positive* if it sends positive-semidefinite Hermitian matrices to positive-semidefinite Hermitian matrices. Superoperators can be extended to operate on larger spaces by taking a tensor product with the identity operator. A superoperator is a *completely positive map* if all of its extensions are positive. For a superoperator to be physically permissible, it must take density matrices to density matrices. Thus, it must be a completely positive map which is trace-preserving. It turns out that any superoperator which satisfies these conditions is indeed physically permissible, as it takes density matrices to density matrices [60, 61]. Thus quantum superoperators are defined as follows.

DEFINITION 1. *A* permissible superoperator T *from k to ℓ qubits is a trace-preserving, completely positive, linear map from density matrices on k qubits to density matrices on ℓ qubits. Its action on a density matrix ρ is denoted as follows:* $\rho \longmapsto T \circ \rho$.

Linear operations on mixed states preserve the probabilistic interpretation of the

mixture: $T \circ \rho = T \circ (\sum_s p_s |\alpha_s\rangle\langle\alpha_s|) = \sum_s p_s T \circ (|\alpha_s\rangle\langle\alpha_s|)$.

A very important example of a quantum superoperator is the superoperator corresponding to the standard unitary transformation $|\alpha\rangle \mapsto U|\alpha\rangle$, which sends a quantum state $\rho = |\alpha\rangle\langle\alpha|$ to the state $U\rho U^\dagger$.

Another important superoperator is to discard a set of qubits. This operation corresponds to tracing out the discarded qubits. In this paper, a discarding qubit gate will always be applied to qubits which ideally (if no error occurred) are in tensor product with the rest of the system.

One more useful quantum superoperator is the one which adds a blank qubit to the system $V_0 : |\xi\rangle \mapsto |\xi\rangle \otimes |0\rangle : \mathbf{C}^{2^n} \to \mathbf{C}^{2^{n+1}}$. This is described by the superoperator $T : \rho \mapsto \rho \otimes |0\rangle\langle 0|$.

A lemma by Choi [29] and Hellwig and Kraus [60, 61] asserts that any permissible superoperator from k to l qubits can be described as a combination of the above three operations: Add $k + l$ blank qubits, apply a unitary transformation on the $2k + l$ qubits, and then trace out $2k$ qubits. One can think of this as the definition of a permissible superoperator. We define a quantum gate to be the most general quantum operator.

DEFINITION 2. *A quantum gate from k to ℓ qubits is a permissible superoperator from k to ℓ qubits.*

In this paper we will use only three types of quantum gates: discard or add qubits and, of course, unitary gates. However, quantum noise will be allowed to be an arbitrary permissible superoperator (with the required restrictions as explained below).

We mention here that it is possible to describe a measurement as a superoperator. For this, we replace the classical result of a measurement $m \in \{0, 1\}$ by the density matrix $|m\rangle\langle m|$ in an appropriate Hilbert space $\mathcal{M}$. We then present the measurement as a superoperator T:

$$T\rho \;=\; \sum_m (P_m \rho P_m) \otimes \Big(|m\rangle\langle m|\Big). \tag{2.1}$$

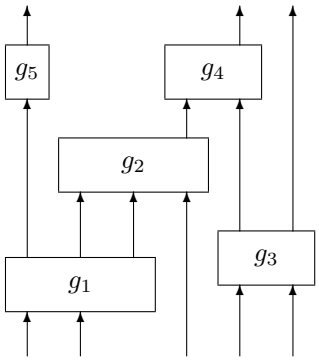
2.6. The trace metric on density operators. A useful metric on density matrices is the *trace* metric. It is induced from the *trace norm* for general Hermitian operators. The trace norm on Hermitian matrices is half the sum of the absolute values of the eigenvalues. $\|\rho\| = \frac{1}{2}\sum_i |\lambda_i|$. We thus have that $0 \le \|\rho_1 - \rho_2\| \le 1$. It was shown in [6] that the trace distance between two matrices equals the measurable distance between them in the following sense. Consider the two probability distributions D_1, D_2 which one gets when applying the same measurement to the two density matrices. Each such measurement thus induces some statistical difference between the outcomes, quantified by the total variation distance between the two distributions.[3] The trace distance is exactly the maximum over all possible measurements of half the total variation distance.

2.7. Quantum circuits with mixed states. We now define a quantum circuit.

DEFINITION 3. *Let $\mathcal{G}$ be a family of quantum gates.* A quantum circuit that uses gates from $\mathcal{G}$ *is a directed acyclic graph. Each node v in the graph is labeled by a gate $g_v \in \mathcal{G}$ from k_v to ℓ_v qubits. The in-degree and out-degree of v are equal k_v and ℓ_v, respectively.*

[3] The total variation distance between two probability distributions D_1, D_2 is defined to be $\sum_j |D_1(j) - D_2(j)|$.

Here is a schematic example of such a circuit.



The circuit operates on a density matrix as follows.

DEFINITION 4 (final density matrix). *Let Q be a quantum circuit. Choose a topological sort for Q: $g_t, \ldots, g_1$, where g_j are the gates used in the circuit. The final density matrix for an initial density matrix ρ is $Q \circ \rho = g_t \circ \cdots \circ g_2 \circ g_1 \circ \rho$.*

It is easy to see that $Q \circ \rho$ is well defined and does not depend on the topological sort of the circuit (see [6] for a detailed proof). At the end of the computation, the r output qubits are measured, and the classical outcome, which is a string of r bits, is the output of the circuit. For an input string i, the probability for an output string j is $\langle j|(Q \circ |i\rangle\langle i|)|j\rangle$.

2.8. Quantum circuits with independent probabilistic noise. To introduce noise to the quantum circuits, we consider leveled quantum circuits, where each level corresponds to one time step. Let us denote by T the number of time steps in the quantum circuit. The gates are then applied at integer times from 1 to T. We recall that, due to the input gate, qubits can be input to the circuit at different time steps. Faults occur in between time steps. We define a *location* (namely, a possible place where a fault can occur) as follows.

DEFINITION 5. *A set $(b_1, b_2, \ldots, b_\ell, t)$ is a* location *in the quantum circuit Q if the qubits $b_1, \ldots, b_\ell$ participate in the same gate in Q at time step t, and no other qubit participates in that gate. For this matter, the absence of a gate is viewed as the identity gate on one qubit, so if a qubit b does not participate in any gate at time t, then (b, t) is a location in Q as well.*

We will need the following terminology for our analysis of fault tolerance.

DEFINITION 6 (fault path). *The list of locations where faults had occurred (in a specific run of the computation) is called a fault path.*

DEFINITION 7 (error rate). *In the independent probabilistic noise model, each location is faulty with independent probability η, and this probability is called the error rate of the circuit.*

Each fault path $\mathcal{F}$ is thus assigned a probability $\Pr(\mathcal{F})$, which is a function of the number of locations in $\mathcal{F}$, the total number of locations in the circuit, and η.

The fault path does not determine the exact faults that occur in the circuit. In our model, once the fault path is chosen, an adversary chooses the exact noise superoperators applied on the faulty locations. That is, given a fault path, the adversary chooses T permissible superoperators; each one is applied on the faulty locations of time t in the fault path. We denote this choice of superoperators by $\mathcal{E}(\mathcal{F}) = (\mathcal{E}_T, \ldots, \mathcal{E}_2, \mathcal{E}_1)$, where $\mathcal{E}_t$ is a permissible superoperator applied by the noise process on the faulty locations of time step t.

We can now define the model precisely.

DEFINITION 8 (the independent probabilistic noise model). *Let Q be a leveled quantum circuit of T time steps. Let $\mathcal{E}(\mathcal{F})$ be a function from fault paths on Q to T-tuples of superoperators (as above). The noisy quantum circuit is denoted by $Q^{\mathcal{E}}$ and is defined as follows. We first define the final density matrix for a given choice of a fault path to be the result of applying the noise superoperators in between the time steps: $Q^{\mathcal{E}}(\mathcal{F}) \circ \rho = \mathcal{E}_t \circ g_t \circ \cdots \circ \mathcal{E}_2 \circ g_2 \circ \mathcal{E}_1 \circ g_1 \circ \rho$. The final density matrix of the circuit $Q^{\mathcal{E}} \circ \rho$ is defined as a weighted average over the final density matrices for each fault path:*

$$Q^{\mathcal{E}} \circ \rho = \sum_{\mathcal{F}} Pr(\mathcal{F}) Q^{\mathcal{E}}(\mathcal{F}) \circ \rho. \tag{2.2}$$

We say that a noisy quantum computer computes a function f with error ϵ in the presence of error rate η if $Q^{\mathcal{E}}$ defined above computes the function f with an error probability at most ϵ for any adversarial choice of faults $\mathcal{E}$.

This model includes, for example, probabilistic measurements of individual qubits, as well as the depolarization model in which each qubit is randomly replaced by a completely random qubit, i.e., a qubit in the identity density matrix.

2.9. Quantum circuits with general local noise. Most of the paper uses only the independent probabilistic noise model defined above. However, in section 8 we extend the threshold result to hold for a much more general noise model. In the general noise model, we replace the probabilistic faults which occur with probability η in each location with a different noise operator which is applied at each and every location in the quantum circuit, after every time step. The only restriction on the noise operator applied at a specific location is that it is within η distance to the identity. Thus, in between time steps, a *noise operator* of the following form operates on *all* of the qubits (here we give an example for the noise operator after time step t):

$$\mathcal{E}(t) = \mathcal{E}_{A_{1,t}}(t) \otimes \mathcal{E}_{A_{2,t}}(t) \otimes \cdots \otimes \mathcal{E}_{A_{l_t,t}}(t). \tag{2.3}$$

$A_{i,t}$ runs over all possible locations at time t, and for each one of them,

$$\|\mathcal{E}_{A_{i,t}}(t) - I\| \leq \eta. \tag{2.4}$$

The norm we use here is the *diamond norm* on superoperators [50, 6]. The exact definition of the diamond norm is not needed in this paper. We merely use the following properties (see [6]):

1. $\|T\rho\| \leq \|T\|\|\rho\|$.
2. $\|TR\| \leq \|T\|\|R\|$.
3. $\|T \otimes R\| = \|T\|\|R\|$.
4. The norm of any permissible superoperator T is equal to 1.

This defines the general local noise model with error rate η.

An interesting example of such a noise process is a restricted version of the independent probabilistic noise model. Suppose for each one of the superoperators in the product (2.3) we write

$$\mathcal{E}_{A_{i,t}}(t) = \left(1 - \frac{\eta}{2}\right) I_{A_{i,t}} + \frac{\eta}{2} \mathcal{E}'_{A_{i,t}}(t), \tag{2.5}$$

where $\mathcal{E}'_{A_{i,t}}(t)$ is some permissible superoperator. This operator is within η distance from the identity, and so this satisfies the conditions of local noise (2.3), (2.4) with error rate η. It is easy to see that this gives a restricted version of the independent noise model with error rate $\eta/2$, because the operator $\mathcal{E}_{A_{i,t}}$ can be interpreted as if the operator $\mathcal{E}'_{A_{i,t}}(t)$ is applied with probability $\eta/2$, and otherwise nothing is done to the qubit. Note that we do not get the independent probabilistic model in its full generality because (2.3) implies that the noise operator on the faulty locations of each time step is a tensor product of operators, one on each location.

This gives a very general error model, under the locality restriction. The model includes many physical sources for noise and errors, such as decoherence, systematic inaccuracies in the gates, amplitude and phase damping, and more (for explanations of these terms, see [43, 68]). As for leakage errors, this is a term that can mean one of two things. The first is that the state of the particle, due to noise, leaves the subspace spanned by computational states. This can be easily taken care of by defining the computational space to include all possible states of the particle, and so this is included implicitly in our discussion (allowing, as we do, higher-dimensional particles). The other meaning of leakage errors is the disappearance of a particle. We do not deal with this source of errors in this paper.

The general local noise model can be further relaxed to allow exponentially decaying correlations in time and space, but we delay the exact definition to section 10 where we deal with such correlations.

3. Quantum error correcting codes.

3.1. Overview of QECC, CSS codes, and polynomial codes. We will use here only QECCs which encode one qubit into, say, m qubits, and we call the set of m qubits a *block*. By linearity, if $|0\rangle$ is encoded by $|S_0\rangle$ and $|1\rangle$ by $|S_1\rangle$, then $a|0\rangle + b|1\rangle$ is encoded by $a|S_0\rangle + b|S_0\rangle$. It follows that such a quantum code is a two-dimensional subspace in the Hilbert space of m qubits. We note that we slightly abuse language here, confusing between the code space and the map encoding the states into this subspace. The exact meaning should be clear from the context. The state of the encoded qubit is sometimes called the *logical* state. The code is said to correct q errors if the logical state is recoverable given that not more than q errors occurred in the block. Roughly speaking, we say that no more than q errors occurred if the density matrix of the remaining $m - q$ qubits did not change.

There is a big difference between classical ECCs and QECCs, in that, for QECCs, not only basis states but also quantum superpositions should be recoverable after an error occurred. The codes we use here are CSS codes [28], and their construction is based on two ideas that enable the protection of superpositions.

1. Despite the fact that quantum operations are extremely versatile and can be continuous, the most general fault or quantum operation on a qubit can be described as (loosely speaking) a linear combination of four simple operations: the identity, i.e., no error at all, a bit-flip ($|0\rangle \leftrightarrow |1\rangle$), a phase-flip ($|0\rangle \longmapsto |0\rangle, |1\rangle \longmapsto -|1\rangle$), or both a bit-flip and a phase-flip. Thus correcting for these three errors suffice. This important fact was first proved by Bennett et al. [22], by using a beautiful group symmetry argument and a notion called *twirl*. We give here a simple proof based on an idea by Steane [89].
2. In order to correct bit-flips, one can use the analogue of classical error correcting codes. To correct phase-flips, one observes that phase-flips are actually bit-flips in the Fourier basis. One can therefore correct bit-flips in the Fourier transform basis, and this will translate to correcting phase-flips in the correct

basis. To correct general errors, one would first correct bit-flips and then correct bit-flips in the Fourier transformed basis, which translates to correcting phase-flips in the original basis.

CSS codes [28, 89] were first presented for qubits, that is, over the field F_2. We give here a proof for the fact that CSS codes are quantum codes, which is simpler than the original proof [28], and generalize it to the field F_p for any prime[4] $p > 2$.

Next, we define a new class of quantum codes, which are called *polynomial codes*. The idea underlying their construction is based on a theorem by Schumacher and Nielsen [80] which asserts that a quantum state can be corrected only if no information about the state has leaked to the environment through the noise process. More precisely, if the reduced density matrix on any t qubits does not depend on the logical qubit, then there exists a unitary operation which recovers the original state even if the environment interacted with t qubits, i.e., t errors occurred. This is reminiscent of the situation in classical secret-sharing schemes [81] and hints at the following possibility: We should divide the "secret," i.e., the logical qudit, among many parties (i.e., physical qudits) such that no t parties share any information about the secret. We adopt Shamir's secret-sharing scheme [81] which suggested to use random polynomials, evaluated at different points in a field of p elements, as a way to divide a secret among m parties. A random polynomial of degree d is chosen, and then each party gets the evaluation of the polynomial at a different point in the field F_p. The secret is the value of the polynomial at 0. To adopt this scheme to the quantum setting, we simply replace the random polynomial by a superposition of all polynomials of the appropriate degree to get a QECC. The result is the quantum analogue of Reed–Solomon codes [64]. It turns out that polynomial codes are a special case of CSS codes over a large field F_p.

The remainder of the section assumes basic knowledge in classical error correcting codes, which can be found in [64].

3.2. Quantum codes. A quantum code is a subspace of some dimension, say, k, in the Hilbert space of $m > k$ qubits. A word in the code is any vector in the subspace or, more generally, any density matrix ρ supported on the subspace. We say that a density matrix ρ' on m qubits is a word with q errors in the qubits $b_1, \ldots, b_q$, if ρ' can be written as $\mathcal{E}(b_1, \ldots, b_q) \circ \rho$, where ρ a word in the code, and $\mathcal{E}(b_1, \ldots, b_q)$ is some permissible superoperator on the q qubits. A quantum circuit $\mathcal{R}$ is said to correct an error $\mathcal{E}(b_1, \ldots, b_q)$ on ρ if

$$\mathcal{R} \circ \mathcal{E}(b_1, \ldots, b_q) \circ \rho = \rho. \tag{3.1}$$

We can now define a quantum error correcting code which corrects q errors.

DEFINITION 9 (QECC). *An $[[m, k, q]]$ quantum error correcting code is a subspace of dimension 2^k in the Hilbert space of m qubits such that the following holds. Let $\{|\alpha_i\rangle\}_{i=1}^k$ be a basis for C. There exists a quantum circuit $\mathcal{R}$, called an error correction procedure, such that for any i, j and $\mathcal{E}(b_1, \ldots, b_q)$*

$$\mathcal{R} \circ \mathcal{E}(b_1, \ldots b_q) \circ |\alpha_i\rangle\langle\alpha_j| = |\alpha_i\rangle\langle\alpha_j|.$$

Note that, from linearity, the last requirement implies the correction of any word in the code and not just the basis states. Note that $\mathcal{R}$ may (and, in fact, has to) use extra qubits during its application, but at the end all ancillary qubits are discarded, and the original state should be recovered.

[4] In fact, the results in this paper can be extended to work over any field, but we do not provide the details here.

3.3. From general errors to bit-flips and phase-flips. We now prove that it suffices to correct bit-flips and phase-flips in order to correct for general errors. To do this, we use the linearity of quantum operators. We recall the definition of the Pauli operators (slightly modified for simplicity here):

$$\mathcal{I} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix},\ \sigma_x = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix},\ \sigma_y = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix},\ \sigma_z = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}. \tag{3.2}$$

σ_x is called a bit-flip, since it takes $|0\rangle$ to $|1\rangle$ and $|1\rangle$ to $|0\rangle$. σ_z is called a phase-flip, as it multiplies $|1\rangle$ by a minus sign, while leaving $|0\rangle$ as is. σ_y is a combination of the two, since $\sigma_y = \sigma_z\sigma_x$. Let us define a *Pauli error* on a qubit as the application of one of the nontrivial Pauli matrices on that qubit. We note that the Pauli operators form a basis for the matrices on one qubit.

We proceed to many qubits. Consider all possible strings e of length m in the alphabet $\mathcal{I}, X, Y, Z$. The set of 4^m matrices:

$$\sigma_e = \sigma_{e_m} \otimes \cdots \sigma_{e_1}, \quad e \in \{\mathcal{I}, X, Y, Z\}^m, \tag{3.3}$$

form a basis for the linear operators on the Hilbert space of m qubits. We call it the Pauli basis. It is easy to check that this is an orthonormal basis with respect to the inner product $(V, U) = \frac{1}{2^m}\mathrm{tr}(VU^\dagger)$ for $2^m \times 2^m$ matrices.

DEFINITION 10. *We say that σ_e, for $e \in \{\mathcal{I}, X, Y, Z\}^m$, is a Pauli error of length q, if the string e has at most q coordinates that are not the identity.*

Before we show that it suffices to correct Pauli errors, we need two definitions.

DEFINITION 11. *We say that $\mathcal{R}$ corrects Pauli errors of length q in C if for any two basis states in the code, $|\alpha\rangle$ and $|\alpha'\rangle$, and any Pauli error of length q, σ_e, we have*

$$\mathcal{R} \circ \sigma_e|\alpha\rangle\langle\alpha'|\sigma_e^\dagger = |\alpha\rangle\langle\alpha'|. \tag{3.4}$$

DEFINITION 12. *We say that $\mathcal{R}$ detects Pauli errors of length q in C if for any two basis states of the code, $|\alpha\rangle$ and $|\alpha'\rangle$, and any two different Pauli errors of length q, $\sigma_e \neq \sigma_{e'}$,*

$$\mathcal{R} \circ \sigma_e|\alpha\rangle\langle\alpha'|\sigma_{e'}^\dagger = 0. \tag{3.5}$$

The reason for the fact that such $\mathcal{R}$ is said to detect errors is the following. Suppose $\mathcal{R}$ first writes down e on an ancilla $\mathcal{R} \circ \sigma_e|\alpha\rangle = |\alpha\rangle \otimes |e\rangle$. Then for two different errors the two ancilla states are orthogonal, and thus when discarding the ancilla qubits we get zero. If $\mathcal{R}$ does not write e on an ancillary register, but instead e can be discovered from the extra information written on the ancilla qubits, then discarding the ancilla register would result similarly in 0 for two different errors. In this paper we use error correcting procedures which not only correct but also detect the errors. We can now prove the following.

THEOREM 2. *Let C be a quantum code, and let $\mathcal{R}$ correct and detect any Pauli error of length q in C. Then R corrects any general error on any q qubits in C.*

Proof. We recall (section 2) that any permissible noise operator $\mathcal{E}$ on q qubits can be written as a combination of three operators: adding $2q$ blank qubits, applying a unitary transformation on the $3q$ qubits, and then discarding $2q$ qubits. We write the error operator as $\mathcal{E} = \mathcal{T} \circ \mathcal{L}$, where $\mathcal{T}$ is the discarding qubits operator. In the most general case, $\mathcal{L}$ is the following operation on q qubits. For all $0 \leq i \leq 2^q - 1$,

$$\mathcal{L} : |i\rangle \longmapsto |0^{2q}\rangle|i\rangle \longmapsto \sum_{j=0}^{2^q-1} |A_{i,j}\rangle \otimes |j\rangle, \tag{3.6}$$

where all of the coefficients are put into the vectors $|A_i^j\rangle$ which are states of $2q$ qubits (these vectors are not necessarily unit vectors). Observe that $\mathcal{L}$ can be presented as a multiplication of the state of the right register of q qubits by

$$\sum_{i,j} |A_{i,j}\rangle \otimes |j\rangle\langle i|. \tag{3.7}$$

The above object can be viewed as a $2^q \times 2^q$ matrix, whose entries are not real numbers but operators. In particular, each entry is a tensor product with a 2^{2q}-dimensional vector $|A_{i,j}\rangle$.

We would like to present this object in terms of the Pauli basis. This is easy to do by recalling that the Pauli basis is orthonormal. Define A to be the matrix whose entries are the vectors $|A_{i,j}\rangle$. We get that the object in (3.7) is equal to

$$\sum_{e \in \{\mathcal{I},X,Y,Z\}^q} |A_e\rangle \otimes \sigma_e,$$

where $|A_e\rangle = (A, \sigma_e) = \frac{1}{2^q}\mathrm{tr}(A\sigma_e^\dagger)$ ($A\sigma_e^\dagger$ is a matrix of vectors, the trace of which is a vector).

We thus have that

$$\mathcal{L} = \sum_{e,e'} |A_e\rangle\langle A_{e'}| \otimes \sigma_e \cdot \sigma_{e'}^\dagger. \tag{3.8}$$

We can now see that $\mathcal{R}$ indeed corrects for the error $\mathcal{E} = \mathcal{T} \circ \mathcal{L}$, by the following:

$$\begin{aligned} \mathcal{R} \circ \mathcal{E} \circ |\alpha\rangle\langle\alpha'| &= \mathcal{R} \circ \mathcal{T} \circ \sum_{e,e'} |A_e\rangle\langle A_{e'}| \otimes \sigma_e |\alpha\rangle\langle\alpha'| \sigma_{e'}^\dagger \\ &= \left(\mathcal{T} \circ \sum_e |A_e\rangle\langle A_e| \right) \otimes |\alpha\rangle\langle\alpha'| = |\alpha\rangle\langle\alpha'|, \end{aligned} \tag{3.9}$$

where in the second equality we have used the fact that $\mathcal{T}$ commutes with $\mathcal{R}$ because they operate on different qubits and that $\mathcal{R}$ corrects and detects errors. In the last equality we used the fact that $\mathcal{T} \circ \sum_e |A_e\rangle\langle A_e| = c$ does not depend on $|\alpha\rangle, |\alpha'\rangle$. By choosing $|\alpha\rangle = |\alpha'\rangle$, we have that $\mathrm{Tr}(\mathcal{R} \circ \mathcal{E} \circ |\alpha\rangle\langle\alpha|) = \mathrm{Tr}(c|\alpha\rangle\langle\alpha|) = c$, but on the other hand $\mathcal{R} \circ \mathcal{E}$ is trace-preserving, so $c = 1$. □

3.4. Calderbank–Shor–Steane codes. We give here the definition of CSS codes, which is a slight modification (and simplification) of the definition from [28] but gives the same codes. A linear code of length m and dimension k is a subspace of dimension k in F_2^m, where F_2^m is the m-dimensional vector space over the field F_2 of two elements. Let C_1, C_2 be two linear codes of length m such that $\{0\} \subset C_2 \subset C_1 \subset F_2^m$, and let us define a quantum code by taking the superpositions of all words in a coset of C_2 in C_1 to be one basis word in the code. We have

$$\forall a \in C_1/C_2 : |S_a\rangle = \frac{1}{\sqrt{2^{\dim(C_2)}}} \sum_{w \in C_2} |w + a\rangle. \tag{3.10}$$

Note that $|S_a\rangle$ is well defined and does not depend on the representative of the coset since if $(a_1 - a_2) \in C_2$, then $|S_{a_1}\rangle = |S_{a_2}\rangle$. Also, for different cosets the vectors are orthogonal. Thus, this defines a basis for a subspace of dimension $2^{\dim(C_1)-\dim(C_2)}$.

This is our quantum code. Note that the support of $|S_a\rangle$ are words in the code C_1. We see that bit-flips can be corrected by using classical error correction techniques for the code C_1 (that is, the classical error correction is performed unitarily, adding ancillary qubits).

Before we discuss how to correct phase-flips, let us define a very important quantum gate on one qubit, called the *Hadamard* gate, or the Fourier transform over F_2:

$$H = H^{-1} = \begin{pmatrix} \frac{1}{\sqrt{2}} & \frac{1}{\sqrt{2}} \\ \frac{1}{\sqrt{2}} & -\frac{1}{\sqrt{2}} \end{pmatrix}. \tag{3.11}$$

Observe that

$$H\sigma_z H^{-1} = \sigma_x. \tag{3.12}$$

This means that a phase-flip transforms to a bit-flip in the Fourier transform basis. By applying the Hadamard gate on each qubit in $|S_a\rangle$, we get the state:

$$\begin{aligned} |C_a\rangle &= H \otimes H \otimes \cdots \otimes H |S_a\rangle = \frac{1}{\sqrt{2^{m+\dim(C_2)}}} \sum_{b=0}^{2^m-1} \sum_{w \in C_2} (-1)^{(w+a)\cdot b} |b\rangle \\ &= \frac{1}{\sqrt{2^{m-\dim(C_2)}}} \sum_{b \in C_2^\perp} (-1)^{a\cdot b} |b\rangle, \end{aligned} \tag{3.13}$$

which is a superposition of words in the perpendicular subspace $C_2^\perp$. Thus, to correct phase-flips, one transforms to the Fourier basis and corrects bit-flips in the code $C_2^\perp$. These observations led to the following theorem due to Calderbank and Shor [28]. We give here a simple proof of this theorem, based on Theorem 2.

THEOREM 3 (CSS codes). *Let C_1 and $C_2^\perp$ be linear codes over F_2, of length m, such that $0 \subset C_2 \subset C_1 \subset F_2^m$, and such that $C_2^\perp, C_1$ correct q errors. Then the subspace spanned by $|S_a\rangle$ for all $a \in C_1/C_2$ is a $[[m, 2^{\dim(c_1)-\dim(C_2)}, q]]$ QECC. The error correction procedure $\mathcal{R}$ is constructed by correcting bit-flips with respect to C_1 in the S-basis, rotating to the C-basis by applying Hadamard on each coordinate, correcting with respect to $C_2^\perp$, and rotating back to the S-basis.*

Proof. We define the procedure $\mathcal{R}_{C_1}$ to be a unitary embedding of m qubits into the space of $2m$ qubits, by

$$\mathcal{R}_{C_1} |i\rangle = |w(i)\rangle \otimes |e(i)\rangle \tag{3.14}$$

for each $i \in F_2^m$, where $w(i) \in C_1$ is a string of minimal distance to i, and $e(i) \in \{0,1\}^m$ satisfies $w(i) + e(i) = i$. Since this is a one-to-one transformation, it is a unitary embedding, and therefore it is a permissible superoperator. Let $e_b \in \{0,1\}^m$ have at most q 1′s in it. Let $\mathcal{E}_b$ be an error operator which is the corresponding tensor product of bit-flips (σ_x) and identities. In the coordinates where e_b is 0, $\mathcal{E}_b$ has the identity, and in the coordinates where it is 1, $\mathcal{E}_b$ has a bit-flip. Then for any $|\alpha\rangle, |\alpha'\rangle$ supported on C_1, we have

$$R_{C_1} \circ \mathcal{E}_b \circ |\alpha\rangle\langle\alpha'| = |\alpha\rangle\langle\alpha'| \otimes |e_b\rangle\langle e_b|. \tag{3.15}$$

$\mathcal{R}_{C_2^\perp}$ is defined similarly:

$$\mathcal{R}_{C_2^\perp} |j\rangle = |w(j)\rangle \otimes |e(j)\rangle, \tag{3.16}$$

where $w(j) \in C_2^\perp$ is a string of minimal distance to j, and $e(j) \in \{0,1\}^m$ satisfies $w(j) + e(j) = j$. Let $e_f \in \{0,1\}^m$ have at most q 1′s. Let $\mathcal{E}_f$ be the error operator which is the corresponding tensor product of phase-flips (σ_z) and identities. Then for any $|\beta\rangle, |\beta'\rangle$ supported on $C_2^\perp$, we have

$$R_{C_2^\perp} \circ \mathcal{E}_f \circ |\beta\rangle\langle\beta'| = |\beta\rangle\langle\beta'| \otimes |e_f\rangle\langle e_f|. \tag{3.17}$$

Denote by $\mathcal{H}$ the operator that applies the Hadamard gate H on every qubit: $\mathcal{H} = H \otimes H \otimes \cdots \otimes H$. We claim that the operator

$$\mathcal{R} = \mathcal{T}_f \circ \mathcal{T}_b \circ \mathcal{H} \circ \mathcal{R}_{C_2^\perp} \circ \mathcal{H} \circ \mathcal{R}_{C_1} \tag{3.18}$$

is the desired error correcting procedures. $\mathcal{T}_f, \mathcal{T}_b$ are the operators discarding the qubits added for $\mathcal{R}_{C_2^\perp}, \mathcal{R}_{C_1}$, respectively.

By Theorem 2, it is enough to show that this procedure corrects and detects q Pauli errors. To show that it corrects q Pauli errors, write the error vector e in two parts e_b and e_f as follows: e_b is 1 in the coordinates where σ_x or σ_y occurred and 0 elsewhere. e_f is 1 in the coordinates where σ_z or σ_y occurred and 0 elsewhere. We can therefore write the error operator $\mathcal{E}$ as a product of two operators $\mathcal{E} = \mathcal{E}_f \circ \mathcal{E}_b$, by using the fact that $\sigma_y = \sigma_z \sigma_x$. We now have

$$\mathcal{R} \circ \mathcal{E} \circ |\alpha\rangle\langle\alpha'| = \mathcal{T}_f \circ \mathcal{T}_b \circ \mathcal{H} \circ \mathcal{R}_{C_2^\perp} \circ \mathcal{H} \circ \mathcal{R}_{C_1} \circ \mathcal{E}_f \circ \mathcal{E}_b \circ |\alpha\rangle\langle\alpha'|. \tag{3.19}$$

We would like to start developing the expression above by applying $\mathcal{R}_{C_1}$, but the phase errors stand in the way. For this, note that for any string $|i\rangle$ we have

$$\mathcal{R}_{C_1} \mathcal{E}_f |i\rangle = \mathcal{E}_f R_{C_1} |w(i)\rangle \otimes \mathcal{E}_f |e(i)\rangle.$$

This means that

$$R_{C_1} \mathcal{E}_f = (\mathcal{E}_f \otimes \mathcal{E}_f) R_{C_1}. \tag{3.20}$$

We apply (3.20) as well as (3.15), to the right-hand side of (3.19). We get

$$\mathcal{R} \circ \mathcal{E} \circ |\alpha\rangle\langle\alpha'| = \mathcal{T}_f \circ \mathcal{H} \circ \mathcal{R}_{C_2^\perp} \circ \mathcal{H} \circ \mathcal{E}_f \circ |\alpha\rangle\langle\alpha'| \otimes \mathcal{T}_b \circ \mathcal{E}_f \circ |e_b\rangle\langle e_b|, \tag{3.21}$$

where we have used the fact that $\mathcal{T}_b$ commutes with all operators except R_{C_1}. Since $\mathcal{E}_f$ is trace-preserving, we can now apply $\mathcal{T}_b$ and get a scalar which is exactly 1. We proceed with

$$\begin{aligned} &\mathcal{T}_f \circ \mathcal{H} \circ \mathcal{R}_{C_2^\perp} \circ \mathcal{H} \circ \mathcal{E}_f \circ |\alpha\rangle\langle\alpha'| \\ &= \mathcal{T}_f \circ \mathcal{H} \circ \mathcal{R}_{C_2^\perp} \circ (\mathcal{H} \circ \mathcal{E}_f \circ \mathcal{H}) \circ (\mathcal{H} \circ |\alpha\rangle\langle\alpha'|) \\ &= \mathcal{T}_f \circ \mathcal{H} \circ (\mathcal{H} \circ |\alpha\rangle\langle\alpha'|) \otimes |e_f\rangle\langle e_f| = |\alpha\rangle\langle\alpha'|. \end{aligned} \tag{3.22}$$

We thus see that $\mathcal{R}$ indeed corrects q Pauli errors. It is left to show that $\mathcal{R}$ also detects q Pauli errors. To show that

$$\mathcal{R} \circ \sigma_e |\alpha\rangle\langle\alpha'| \sigma_{e'}^\dagger = 0,$$

we observe that if $e \neq e'$, then either $e_b \neq e_b'$ or $e_f \neq e_f'$. We can repeat the previous argument. If $e_b \neq e_b'$, we get zero due to $\mathcal{T}_b \circ |e_b\rangle\langle e_b'| = 0$. Otherwise, we have $e_f \neq e_f'$, and we get zero because $\mathcal{T}_f \circ |e_f\rangle\langle e_f'| = 0$. □

3.5. CSS codes over F_p. The theory of quantum error corrections can be generalized to quantum computers which are composed of quantum particles of $p > 2$ states, called qudits. If we want to stress the dimensionality of the particles, we call them p-qudits. To generalize the notion of bit-flips and phase-flips to p-qudits, define the following two matrices:

- B : $B|a\rangle = |(a+1) \text{mod p}\rangle$,
- P : $P|a\rangle = w^a|a\rangle$,

where $w = e^{\frac{2\pi i}{p}}$. The analogue of Pauli matrices are combinations of powers of these matrices, i.e., the p^2 matrices:

$$B^c P^{c'} \quad \forall c, c' \in F_p. \tag{3.23}$$

Just as we did in the case of Pauli matrices, we can consider the p^{2m} m-fold tensor products of such matrices and show that they form a basis for matrices on m p-qudits. This basis is orthonormal, with respect to the inner product $(U, V) = \frac{1}{p^m}\text{tr}(UB^\dagger)$.

Like in the case of qubits, errors of type B transform to errors of type P and vice versa, via the analogue of the Hadamard, namely, the appropriate Fourier transform. In fact, there are several possible analogues of the Hadamard matrix for the case of F_p. Let $w = e^{2\pi i/p}$ and $w_l = w^l$. Then we define the lth Fourier transform over F_p to be

$$W(w_l) : |a\rangle \longmapsto \frac{1}{\sqrt{p}} \sum_{b \in F} w^{lab}|b\rangle. \tag{3.24}$$

It can be easily checked that

$$\forall c \in F_p, \quad W(w_l)P^c W(w_l)^{-1} = B^{c\ell^{-1}}, \quad W(w_l)B^c W(w_l)^{-1} = P^{c\ell}. \tag{3.25}$$

We can now define CSS codes over F_p in a very similar way as it is done for F_2. We first fix a choice of inner product over F_p^m with which we work: We choose the coefficients c_i in the bilinear form $\vec{a} \cdot \vec{b} = \sum_{i=1}^m c_i a_i b_i$. This fixes what we mean by the orthogonal code $C_2^\perp$. The statements and proofs of Theorems 2 and 3 are generalized to F_p by using the above definition of the generalized bit-flip B and the generalized phase-flip P, where F_2^m is replaced by F_p^m and the Hadamard gate on the ith qubit is replaced by the Fourier transform $W(w_{c_i})$ over the ith qudit.

3.6. Polynomial quantum codes. We define polynomial codes over the field F_p, for p a prime. We set d to be an upper bound on the degree of the polynomials used in the code and m to be the length of the code. Let $m < p$ be the number of elements in the field F_p with which we will be working. Set $\alpha_1, \ldots, \alpha_m$ to be m distinct nonzero elements of the field F_p. We consider the set of polynomials over F_p of degree at most d:

$$V_d = \{f(\cdot) \in F_p[x], \deg(f) \leq d\}, \tag{3.26}$$

where $F_p[x]$ is the field of polynomials with coefficients in F_p. Define the following classical codes:

$$\begin{aligned} C_1 &= \{(f(\alpha_1), \ldots, f(\alpha_m))|f(\cdot) \in V_d\} \subset F_p^m, \\ C_2 &= \{(f(\alpha_1), \ldots, f(\alpha_m))|f(\cdot) \in V_d, f(0) = 0\} \subset C_1. \end{aligned} \tag{3.27}$$

We can now define the quantum code:

$$\forall a \in F_p, \quad |S_a\rangle = \frac{1}{\sqrt{p^d}} \sum_{f(\cdot)\in V_d, f(0)=a} |f(\alpha_1), \ldots, f(\alpha_m)\rangle = \frac{1}{\sqrt{p^d}} \sum_{w\in C_2} |w + \vec{a}\rangle, \tag{3.28}$$

where $\vec{a}$ is the vector of length m with a at each coordinate. Since C_2 has p different cosets in C_1, the dimension of the code is p, and the code encodes exactly one p-qudit. We prove the following theorem.

THEOREM 4. *A polynomial code of degree d with length m over F_p is a* $[[m, p, \min\{\lfloor \frac{m-d-1}{2} \rfloor, \lfloor \frac{d}{2} \rfloor\}]]$ QECC.

Proof. Two different words in C_1 agree on at most d coordinates, and thus C_1 is a linear code of distance $m-d$. It can thus correct and detect $\lfloor (m-d-1)/2 \rfloor$ errors. $C_2^\perp$ (under any choice of the inner product in which the coefficients are nonzero) is a linear code of minimal distance $\geq d+1$. This is true since the projection on any d coordinates of the code C_2 contains all possible strings of length d, and therefore the only vector of length d orthogonal to all of the vectors is the 0 vector. Thus, $C_2^\perp$ corrects and detects $\lfloor d/2 \rfloor$ errors. Theorem 4 follows from Theorem 3 for F_p. □

We call the polynomial code which uses polynomials of degree $m-d-1$ (the codegree of d) the *dual code* of the code which uses polynomials of degree d. By the above lemma, the two codes correct the same number of errors.

4. Fault-tolerant gates for polynomial codes.

4.1. Overview. In this section we define $\mathcal{G}_1$ (subsection 4.2), the universal set of gates with which we work when computing with polynomial codes. We note that our set of gates involves only one- and two-qudit gates. We show how to apply the gates in $\mathcal{G}_1$ on encoded states, in a fault-tolerant manner. Our fault-tolerant procedures will all have what we call *spread* 1. This notion will be defined shortly (subsubsection 4.3.4), but roughly it means that one fault in a procedure can cause at most one error in the final state of the procedure. We augment the fault-tolerant gates by fault-tolerant procedures for error correction, zero-state preparation and decoding (a zero-state preparation procedure prepares a state $|S_0\rangle$, and a decoding procedure takes $|S_a\rangle$ to m copies of a). These procedures also have spread 1. This section thus proves the following theorem.

THEOREM 5. *For any gate in $\mathcal{G}_1$, there exists a fault-tolerant procedure with spread* 1 *that computes the gate on states encoded by a quantum polynomial code. There exist also fault-tolerant error correction, decoding, and zero-state preparation procedures for this code, which all have spread* 1. *Moreover, all of these procedures use only gates from $\mathcal{G}_1$ and in particular do not use measurements.*

The requirement that the procedures use only gates from $\mathcal{G}_1$ is imposed so that the scheme can be applied recursively, as we will do in section 7.

In an ideal situation, all gates can be applied transversally, as in Figure 1.1, in which case it is clear that one fault can propagate to at most one error in each block. Unfortunately, we do not know of any universal set of gates and any code in which all gates can be applied transversally in the simple way depicted by Figure 1.1. It is here that the advantage of polynomial codes comes into play. Due to the algebraic properties of polynomials, all of the gates in $\mathcal{G}_1$ can be applied essentially transversally: The gates are applied either transversally or by first preparing some states of the form $|S_0\rangle$ and then applying some operations transversally on the computational blocks and the ancilla blocks together.

To achieve this nice property, we observe that in the case of polynomial codes the transversal application of the gates always achieves the correct result, except for one problem: Instead of getting the final state as a superposition of polynomials with degree d, for some gates we end up with the correct logical dit, except that it is encoded with polynomials of a different degree. This can be illustrated if one considers gates which involve multiplication of polynomials, such as the generalized Toffoli gate, where the degree d becomes $2d$. Likewise, the Fourier transform gate takes d to the codegree $m-d-1$. To get back into the code that uses polynomials of degree d, we make use of a procedure called *degree reduction*. In the classical case, degree reduction was used by Ben-Or, Goldwasser, and Wigderson [24] to achieve fault-tolerant classical distributed computation. These techniques can be adapted to the quantum case, as was done in the original version of this paper [3, 4]. Here, however, we present a much simpler construction that reduces the degree by teleportation between states of different degrees. This technique, which was used in [8, 36], is based on ideas in [48].

In order for the above ideas to work, it must be that, even after the degree has changed, the state is still inside a QECC so that errors can be corrected. For this reason we work with codes of length $m = 3d + 1$ such that the quantum polynomial code of twice the degree (which is equal to the codegree) corrects the same number of errors (see Theorem 4).

It is therefore the case that, for polynomial codes, all fault-tolerant procedures can be applied in a remarkably simple manner, namely, transversally with the help of ancilla zero states.

We start with the definition of the set of gates $\mathcal{G}_1$ and continue to general definitions related to encoded gates and to fault-tolerant procedures, such as transversal and semitransversal operations and the spread of errors inside an encoded gate. We then proceed to the description of fault-tolerant encoded gates and finally to fault-tolerant error correction, zero-state preparation, and decoding procedures. We note that much work is put into making these final three procedures measurement-free. At the end of this section we remark about how to simplify procedures when measurements and classical computations can be used.

4.2. The set of gates for polynomial codes $\mathcal{G}_1$. We fix $m = 3d + 1$ in the polynomial codes we use. We work with the following set of gates, which we denote by $\mathcal{G}_1$:

1. $\mathsf{NOT}_p(c)$: $\forall\ c \in F_p$, $|a\rangle \longmapsto |a + c\rangle$ (also denoted B^c).
2. CNOT_p: $|a, b\rangle \longmapsto |a, a + b\rangle$.
3. CNOT_p^{-1}: $|a, b\rangle \longmapsto |a, a - b\rangle$.
4. SWAP: $|a\rangle|b\rangle \longmapsto |b\rangle|a\rangle$.
5. Multiplication by a constant: $0 \neq c \in F_p$: $|a\rangle \longmapsto |ac\rangle$.
6. P^c (generalized phase): $\forall c \in F_p\ |a\rangle \longmapsto w^{ca}|a\rangle$, for $w = e^{2\pi i/p}$.
7. Generalized controlled phase of order c: $\forall c \in F_p\ |a\rangle|b\rangle \longmapsto (w)^{abc}|a\rangle|b\rangle$.
8. $W(c)$ (generalized Fourier transform (of order c)): $|a\rangle \longmapsto \frac{1}{\sqrt{p}} \sum_{b \in F_p} w^{abc}|b\rangle \forall 0 < l < p$.
9. Generalized Toffoli: $|a\rangle|b\rangle|c\rangle \longmapsto |a\rangle|b\rangle|c + ab\rangle$.
10. Adding a qudit in the state $|0\rangle$.
11. Discarding a qudit.

All of the additions and multiplications are in F_p (i.e., modulo p). We will often denote $\mathsf{NOT}_p(1)$ simply by NOT_p. We note that, if the characteristic of the field we work with is not 2, we can replace the generalized Toffoli gate in the above construction

with the following gate:

- Squaring gate: $|a\rangle|b\rangle \longmapsto |a\rangle|b + a^2/2\rangle$.

We get a set of gates which consists of two-qudit gates without any three-qudit gate involved. In either case, the set is proved to be universal in section 6. This set is by no means a minimal set for universality, but the fault-tolerant procedures become simpler and shorter if we have a larger repertoire of fault-tolerant gates that we can use.

4.3. Fault-tolerant procedures—general definitions.

4.3.1. Encoded gates. Say we have a unitary gate g which is applied on the state $|\alpha\rangle$ in the original circuit. We now want to apply the corresponding gate to the state encoding $|\alpha\rangle$. We denote the encoding of $|\alpha\rangle$ by $\phi(|\alpha\rangle)$.

DEFINITION 13. *A sequence of gates Q is said to encode a gate g for the code C, and is denoted by $\Phi(g)$, if, for any superposition $|\alpha\rangle$,*

$$\Phi(g)\phi(|\alpha\rangle) = \phi(g|\alpha\rangle).$$

4.3.2. Transversal and semitransversal gates. The way to apply a gate which is the simplest and which allows the least propagation of errors is the transversal application.

DEFINITION 14. *Consider a gate g on, say, k qudits (k is between 1 and 3 in this paper's case). Consider k blocks of m qudits each. Let us label the qudits in each block from 1 to m (from left to right). We say that the gate g is applied* transversally *on $1, 2$, or 3 encoded blocks if, in order to apply $\Phi(g)$ on k encoded blocks, it suffices to apply the gate g m times, each time on all qudits labeled by the same label.*

We will sometimes need to modify the above transversal construction by just a little bit. Instead of applying the same gate on the set of ith qudits, independent of i, we allow ourselves to apply a gate which depends on the index i. The structure of the circuit remains the same, as in Figure 1.1. We call this way of encoding a gate *semitransversal*. In both cases, it is clear that one fault of a gate during the procedure can affect at most one qubit in each block at the end of the procedure. We now make these notions slightly more precise.

4.3.3. Errors versus faults. To analyze the propagation of errors in our fault-tolerant procedures, we need to make an important distinction between *errors*, which are the actual deviations of the quantum state from being correct, and *faults*, which are the events that occur that cause the qubits to have errors. Let us start by defining what we mean by errors. This requires some definition since the state of one qudit is not well defined in the quantum model, and so we cannot consider one qudit and say that it is "correct" or not.

DEFINITION 15 (deviation). *Consider a density matrix ρ' of a set of qudits B. We say that ρ' is deviated from the correct matrix ρ on the set of qudits $A \subseteq B$ if $\rho'|_{B-A} = \rho|_{B-A}$.*

This definition coincides with the more operative notion of errors which we used in the discussion about error correction in section 3.

CLAIM 1. *Let ρ be a (correct) density matrix of a pure state on a set of qudits B. The matrix ρ' is deviated from ρ on a set of qudits A if and only if there exists a permissible quantum operator on the set A which takes ρ to ρ'.*

Proof. For one direction, suppose that the deviation in ρ' is confined to the set of qudits A. Consider a *purification* of ρ', namely, a state $|\psi'\rangle$ of the set of qudits B plus extra qudits C, such that $|\psi'\rangle\langle\psi'||_B = \rho'$. Such a state exists by, e.g., [68, page 110].

Note that reducing the matrices $|\psi\rangle\langle\psi| \otimes |0\rangle_C\langle 0|_C$, $|\psi'\rangle\langle\psi'|$ to the set of qudits $B - A$ results in the same matrix. By standard results (see, e.g., [68, page 111, Exercise 2.81]), there is a unitary matrix U acting on $C \cup A$ which takes $|\psi\rangle \otimes |0\rangle_C$ to $|\psi'\rangle$. Thus, to get from ρ to ρ', we add the qudits in C in the state $|0\rangle_C$, apply U on $A \cup C$, and discard C. We have designed a permissible operator on A that takes ρ to ρ'. The other direction of the claim is trivial. □

The above claim relates the notions of deviation and error operators. Thus, if ρ is the density matrix of the correct state (which is always a pure state in our construction), we can loosely say that the set of qudits A are the faulty qudits or that the *errors* occurred on the qudits in A. We note that the set A is not uniquely defined. In the rest of the paper, however, in every place where we assume something about the deviation set A, it suffices to choose an arbitrary set of qudits that satisfies the relevant assumption and continue from there.

We will use the above correspondence between error operators and deviations many times in the paper. The way we do this is that we prove, say, that the deviation from the correct state at some stage in our construction is confined to some set of qudits. This implies, by Claim 1, that one can view the density matrix as if an error operator was applied on the deviated qudits, and so all of the results about quantum error correction apply. From now on, therefore, we can talk only about deviation.

The notion of a fault is completely different from the notion of error or deviation. To understand this difference, recall subsection 2.8, where the notions of "locations" and "fault paths" were defined. A *fault* in the circuit is thus the noise operator which is applied at a certain location that appears in the fault path.

We will analyze the effect of faults occurring at certain locations, on the resulting errors in the final states.

4.3.4. Spread. In order to analyze how faults in the circuit affect the errors in the final state, we define the notion of a "spread" of a circuit or a procedure. In most cases, a very simple consideration is required: It is clear that a fault in a location $(q_1, \ldots, q_l, t)$ can affect a qubit q' at time $t' > t$ only if there is a path in the circuit from $(q_1, \ldots, q_l, t)$ to (q', t'). In other words, if we know the correct propagation of some density matrix in the circuit, an additional fault at a certain location can cause a deviation from that correct propagation only in locations affected by the location of the fault via such a path in the circuit. For transversal procedures, it is thus easy to see that one fault can affect at most one qudit in each block. We say that the spread of the procedure is 1.

Unfortunately, for the error correction, zero-state preparation, and decoding procedures, a more careful analysis is required, because the circuit itself is far from being transversal. In such a case one needs to actually take into account the computation performed by the circuit, in order to bound the propagation of errors. It is sufficient for our purposes that the error propagation is limited only when the total number of errors is small. For example, we cannot hope to control the number of errors in the output if the number of errors in the input to an error correction procedure is large.

Definition 16. *We consider procedures that compute on states encoded by a QECC which can correct q errors. We say that the procedure has* spread 1 *if the following holds. Consider a fault path with k faulty locations in this procedure. Suppose that the input state to the procedure is deviated on a set of qudits which has at most f qudits in each of the blocks on which the procedure works. We require that, as long as $f + k \leq q - 1$, adding one additional faulty location to the fault path increases the final*

deviation in each one of the relevant blocks by at most 1 *(while leaving the number of errors in the other blocks unchanged).*

Except for sections 9 and 11, all of our procedures have spread equal to 1. However, there are cases in which more complicated situations arise, where the propagation of errors is confined to a small number of qudits but larger than 1. For example, such is the case when we introduce geometrical constraints to the system, which cause more propagation of errors. The above definition can be generalized to spread equal to ℓ.

DEFINITION 17. *We consider procedures that compute on states encoded by a QECC which can correct q errors. We say that the procedure has* spread ℓ *if the following holds. Consider a fault path with k faulty locations in this procedure. Suppose that the input state to the procedure is deviated on a set of qudits which has at most f qudits in each of the blocks on which the procedure works. We require that, as long as $(f+k)\ell \leq q-\ell$, adding one additional faulty location to the fault path increases the final deviation in each one of the relevant blocks by at most ℓ (while leaving the number of errors in the other blocks unchanged).*

The proofs of section 7, showing that our general hierarchical scheme (without exact specification of the code being used) is fault-tolerant, are done for the more general case of spread ℓ. This does not impose any additional difficulty in the proof. For a first reading, it is perhaps simpler to keep the definition of spread 1 in mind.

4.3.5. Issues related to ancillas. In some of the procedures, we will use ancilla qudits as extra working space. At the end of the procedure these qudits will be discarded, in order to get exactly the state we need. As was explained in subsection 2.5, we will always discard qudits which are (in an ideal noiseless situation) in tensor product with the rest of the system. In this case the operation of discarding qudits means simply erasing their state, and the resulting state is a pure state. This is necessary if we want to apply unitary operations on the encoded states. We will describe a procedure by specifying what it does to basic states of the code. It is easy to see that if for any input basis state the ancilla qubits at the end of the procedure are in a tensor product with the rest of the qubits, and their state does not depend on the input basis state, i.e.,

$$|S_a\rangle \longmapsto |S_{g(a)}\rangle \otimes |A\rangle, \tag{4.1}$$

where A is independent of a, then for any input superposition for the procedure the ancilla qubits are in tensor product with the rest of the qudits, and thus they can be discarded simply by erasing them.

4.4. Transversal and semitransversal gates for polynomial codes. We begin with the simplest cases.

LEMMA 1. *The first seven gates:* $\mathsf{NOT}_p(c), \mathsf{CNOT}_p, \mathsf{CNOT}_p^{-1}, \mathsf{SWAP}$*, multiplication by a constant, generalized phase, and generalized controlled phase, can all be applied in a transversal or semitransversal manner.*

Proof. It is easy to check that the first five gates, namely, $\mathsf{NOT}_p(c)$, CNOT_p, CNOT_p^{-1}, SWAP, and multiplication by a constant different than zero, can be applied transversally by applying the gate on corresponding qudits from the different blocks. We give here just one example, for the $\mathsf{NOT}_p(c)$ gate:

$$|S_a\rangle = \sum_{w\in C_2} |a+w_1\rangle\otimes\cdots\otimes|a+w_m\rangle \longmapsto \sum_{w\in C_2} |a+c+w_1\rangle\otimes\cdots\otimes|a+c+w_m\rangle = |S_{a+c}\rangle. \tag{4.2}$$

The other four gates are similar. The generalized phase is just slightly more complicated. It can be applied semitransversally. Define c_l as the interpolation coefficients such that

$$\forall\ f \in F[x],\ \deg(f) \le m-1, f(0) = \sum_{i=1}^{m} c_i f(\alpha_i). \tag{4.3}$$

We apply on the lth qudit the gate $|a\rangle \longmapsto w^{c_l a}|a\rangle$. This achieves the desired operation because

$$\begin{aligned} |S_a\rangle &= \frac{1}{\sqrt{p^d}} \sum_{f\in V, f(0)=a} |f(\alpha_1), \ldots, f(\alpha_m)\rangle \\ &\longmapsto \frac{1}{\sqrt{p^d}} \sum_{f\in V, f(0)=a} \Pi_{i=1}^{m} w^{c_l f(\alpha_l)} |f(\alpha_1), \ldots, f(\alpha_m)\rangle \\ &= \frac{1}{\sqrt{p^d}} \sum_{f\in V, f(0)=a} w^a |f(\alpha_1), \ldots, f(\alpha_m)\rangle = w^a |S_a\rangle. \end{aligned} \tag{4.4}$$

Finally, the generalized controlled phase of order c can also be applied semitransversally, by using the same idea. On the lth coordinate we apply the generalized controlled phase of order $c \cdot c_l$. We get

(4.5)

$$\begin{aligned} |S_a\rangle|S_b\rangle &= \frac{1}{p^d} \sum_{f\in V, f(0)=a} |f(\alpha_1), \ldots, f(\alpha_m)\rangle \sum_{g\in V, g(0)=b} |g(\alpha_1), \ldots, g(\alpha_m)\rangle \\ &\longmapsto \frac{1}{p^d} \sum_{f,g\in V, f(0)=a, g(0)=b} \Pi_{i=1}^{m} w^{cc_l f(\alpha_l) g(\alpha_l)} |f(\alpha_1), \ldots, f(\alpha_m)\rangle |g(\alpha_1), \ldots, g(\alpha_m)\rangle. \end{aligned}$$

Since f, g are both of degree at most d, the product of the two polynomials is of degree at most $2d$, and the interpolation applies. If we denote $f \cdot g = h$, we get $\Pi_{i=1}^{m} w^{cc_l f(\alpha_l) g(\alpha_l)} = w^{c\sum_l c_l h(\alpha_l)} = w^{ch(0)} = w^{cf(0)g(0)} = w^{abc}$, as we wanted. ∎

4.5. Rotation to the dual code. The remaining two gates, namely, the generalized Fourier transform and the generalized Toffoli (or the squaring gate), are not as simple, since the transversal application changes the degree of the polynomials involved. To this end we add a superscript d or $2d$ denoting the degree of the polynomials used in the code, as in $|S_a^d\rangle$ or $|S_b^{2d}\rangle$. We start by showing the effect of a semitransversal Fourier transform on a state encoded by using degree d' polynomials. Denote by $w_l = w^{c_l}, l = 1, \ldots, m$, for c_l the interpolation coefficients, as in the proof of Lemma 1. Recall that in our notation

$$W(c_l) : |a\rangle \longmapsto \frac{1}{\sqrt{p}} \sum_{b\in F_p} w_l^{ab} |b\rangle. \tag{4.6}$$

We apply $W(c_l)$ to the lth qudit for all $1 \le l \le m$.

$$|S_a^{d'}\rangle \longmapsto W(c_1) \otimes W(c_2) \otimes \cdots \otimes W(c_m) |S_a^{d'}\rangle. \tag{4.7}$$

Claim 2 (rotation to the dual code). *The transformation of* (4.7) *performs the generalized Fourier transform, except it moves the word to the dual code, namely, the*

polynomial code with the codegree $m-d'-1$*:*

$$|S_a^{d'}\rangle \longmapsto \frac{1}{\sqrt{p}} \sum_{b\in F_p} w^{ab} |S_b^{m-d'-1}\rangle.$$

Proof. Let us denote the final state of the transformation by $|\alpha\rangle$:

$$|S_a^{d'}\rangle = \frac{1}{\sqrt{p^d}} \sum_{f\in V, f(0)=a} |f(\alpha_1),\dots,f(\alpha_m)\rangle \tag{4.8}$$

$$\longmapsto |\alpha\rangle = \frac{1}{\sqrt{p^{d+m}}} \sum_{b_1,b_2,\dots,b_m\in F} \sum_{f\in V, f(0)=a} w^{\sum_{l=1}^m c_l f(\alpha_l) b_l} |b_1,\dots,b_m\rangle.$$

For each string $b_1,\dots,b_m \in F_p$, associate the unique polynomial $b(x)$ which satisfies $b(\alpha_l)=b_l$ and has degree $\deg(b)\le m-1$. The exponent of w in (4.8) can be written in a much simpler form when $b(x)$ is of degree $\deg(b)\le m-d'-1$. For such $b(x)$, the polynomial $h(x)=b(x)f(x)$ is of degree $\deg(h)\le m-1$ so

$$\sum_{l=1}^m c_l f(\alpha_l) b(\alpha_l) = \sum_{l=1}^m c_l h(\alpha_l) = h(0) = f(0)b(0). \tag{4.9}$$

Hence, the sum over all b with $\deg(b)\le m-d-1$ in (4.8) gives

$$\frac{1}{\sqrt{p^{d+m}}} \sum_{b_1,b_2,\dots,b_m\in F,\deg\ b(x)\le m-d-1} \sum_{f\in V, f(0)=a} w^{b(0)f(0)} |b_1,\dots,b_m\rangle \tag{4.10}$$

$$= \frac{1}{\sqrt{p^{m-d}}} \sum_{b_1,b_2,\dots,b_m\in F,\deg\ b(x)\le m-d-1} w^{b(0)a} |b_1,\dots,b_m\rangle$$

$$= \frac{1}{\sqrt{p}} \sum_{b\in F_p} w^{ab} \frac{1}{\sqrt{p^{m-d-1}}} \sum_{b_1,b_2,\dots,b_m\in F,\deg\ b(x)\le m-d-1, b(0)=b} |b_1,\dots,b_m\rangle$$

$$= \frac{1}{\sqrt{p}} \sum_{b\in F_p} w^{ab} |S_b^{m-d'-1}\rangle.$$

Now we claim that the sum over the rest of the b's must vanish. The reason is that the norm of the above vector is 1. Now $|\alpha\rangle$ can be written as a sum of two vectors: the contribution from b's with $\deg(b)\le m-d-1$ and that from the rest of the b's. The two are orthogonal, since different $|b\rangle$'s are orthogonal. Hence, the squared norm of $|\alpha\rangle$, which is 1 (because the operation is unitary and we started with a norm one vector), is the sum of the squared norms of the contribution of $\deg(b)\le m-d-1$, which is also 1, and the norm of the orthogonal vector. Thus, the norm of the sum over b's with $\deg(b) > m-d'-1$ must vanish. ∎

4.6. Degree reduction and degree increase.

DEFINITION 18. *A* degree reduction *is a procedure which takes a state* $|S_a^{d'}\rangle$ *and returns the state* $|S_a^d\rangle$*, for* $d' > d$*.* Degree increase *is defined similarly, except we require that* $d' < d$*.*

To construct these procedures, we need to have at our disposal a *zero-state preparation* procedure, namely, a fault-tolerant procedure which generates the state $|S_0^d\rangle$. In fact, we will need a zero-state preparation procedure also for the polynomial code of degree $2d = m-d-1$, so that we have the states $|S_0^{m-d-1}\rangle$ available, too. We

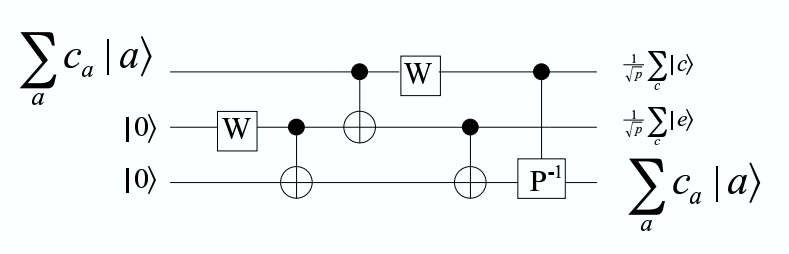


FIG. 4.1. *Teleportation of a general state of the topmost p-qudit to the bottommost one.*

will see how to perform these procedures in subsection 4.13, and for now we merely assume that we have them at our disposal.

The degree increase is derived by using teleportation. The idea is to apply teleportation from a state encoded with polynomials of degree d to a state encoded with polynomials of degree $2d$. We first recall how teleportation works for p-qudits (see Figure 4.1) and then consider its encoded version.

The first qudit is in a general state $\sum_{a\in F_p} c_a|a\rangle$, and the other two qudits are in the state $|0\rangle$. The first step is transforming the last two qudits to the analogue of an EPR pair for F_p: We apply the generalized Fourier transform W on the second qudit and then a CNOT_p^{-1} from the second qudit to the third one. This gives the state

$$\frac{1}{\sqrt{p}} \sum_{a,b\in F_p} c_a|a\rangle|b\rangle|-b\rangle.$$

We then apply CNOT_p from the first qudit to the second, which gives

$$\frac{1}{\sqrt{p}} \sum_{a,b\in F_p} c_a|a\rangle|b+a\rangle|-b\rangle.$$

Next, we apply a generalized Fourier transform on the first qudit to get

$$\frac{1}{p} \sum_{a,b,c\in F_p} c_a w^{ac}|c\rangle|b+a\rangle|-b\rangle.$$

We then apply CNOT_p from the second qudit to the third:

$$\frac{1}{p} \sum_{a,b,c\in F_p} c_a w^{ac}|c\rangle|b+a\rangle|a\rangle.$$

Finally, we apply a generalized controlled phase of order -1 from the first qudit to the third, to get

$$\frac{1}{p} \sum_{a,b,c\in F_p} c_a|c\rangle|b+a\rangle|a\rangle = \frac{1}{p} \sum_{a,e,c\in F_p} c_a|c\rangle|e\rangle|a\rangle = \frac{1}{\sqrt{p}} \sum_{c\in F_p} \otimes \frac{1}{\sqrt{p}} \sum_{e\in F_p} \otimes|c\rangle|e\rangle \otimes \sum_a c_a|a\rangle,$$

which is the desired teleportation.

The degree increase is basically an encoding of the above circuit, by using the correct choice of degrees for each block. We work on three blocks of qudits. The first

block is a general state of one qudit encoded by using polynomial codes of degree d. The second block is initially in the state $|S_0^d\rangle$, and the last block is in the state $|S_0^{2d}\rangle$. All of the gates in the teleportation are now applied transversally, except for the generalized Fourier transform which is applied semitransversally, as in Claim 2. We thus see that, after applying the first two gates in the teleportation circuit transversally, we get that the last two blocks are in the state

$$\frac{1}{\sqrt{p}} \sum_b |S_b^{2d}\rangle |S_{-b}^{2d}\rangle.$$

The next gate, which is the encoded CNOT_p, is now applied from a word in the code of degree d to that of degree $2d$. It is easy to check that this does not matter to the correctness of this gate. After the next step, namely, the semitransversal generalized Fourier transform, Claim 2 implies that all blocks are encoded by using degree $2d$ polynomials, and so the correctness follows from the correctness of the teleportation circuit.

The construction we have shown for degree increase does not work for degree reduction, since, for example, the first CNOT_p does not work correctly if the target state is of a smaller degree than that of the control state. To bypass this problem, we can instead perform a degree increase in the dual code. This is done as follows. We start with a state of degree $2d$. We first apply the semitransversal generalized Fourier transform (4.7). This takes us to the dual code (of degree d), by Claim 2. We now apply a degree increase, to get the same state encoded by using polynomials of degree $2d$. Finally, we apply the reverse of the transformation in (4.7), which achieves the desired result, again, by Claim 2.

4.7. Fault-tolerant Fourier transform. To achieve the generalized Fourier transform of order 1, we simply apply the transformation of (4.7). By Claim 2, this yields the desired state but in the wrong degree. Applying a degree reduction solves the problem. To achieve a generalized Fourier transform $W(c)$ of order $c \neq 1$, we use w^c instead of w everywhere in subsection 4.5.

4.8. Fault-tolerant generalized Toffoli and squaring. To apply the generalized Toffoli gate on $|S_a\rangle|S_b\rangle|S_c\rangle$, we first increase the degree of the third register to $2d$. We now apply the general Toffoli gate transversally on the m coordinates, which gives $|S_a\rangle|S_b\rangle|S_{ab+c}^{2d}\rangle$, as is easy to check. We now apply a degree reduction on the third register, and this achieves the desired result. The squaring gate is applied in exactly the same manner.

4.9. Remaining gates. The fault-tolerant version of the gate that adds a qubit in the state $|0\rangle$ is simply the zero-state preparation procedure. We will see how to perform this procedure in subsection 4.13. The fault-tolerant gate that discards a qudit can obviously be done transversally by discarding all of the qudits in the block. This completes our description of fault-tolerant procedures for the set $\mathcal{G}_1$.

4.10. Fault-tolerant error correction. Our construction of the error correction procedure is based on the simplest known quantum error correcting technique, namely, Steane's error correction [90]. Once again, we assume here that we have at our disposal a fault-tolerant zero-state preparation procedure, which we will show later.

The error correction procedure is composed of two stages: The first stage detects and corrects dit-flips (faults of type B), by using classical error correction techniques for the code C_1. The second stage applies on each coordinate the generalized Fourier

transform (4.7). We then correct dit-flips by using classical error correction techniques for the code C_2. Finally, we rotate back by applying the inverse of the generalized Fourier transform on each coordinate. By subsections 3.5 and 3.6 this achieves the desired error correction. It is therefore sufficient to describe how to correct dit-flips fault-tolerantly.

Let us first describe one part of the error correction procedure. Generate an ancilla block in the state $|S_0^{2d}\rangle$, by using the fault-tolerant zero-state preparation procedure. Apply a generalized Fourier transform semitransversally, as in (4.7), on the ancilla block. Its state is now $\frac{1}{\sqrt{p}}\sum_{a\in F_p}|S_a^d\rangle$. Then apply CNOT_p transversally from the block we would like to correct to the ancilla blocks. Now observe that there is a classical circuit that, given any string from the ancilla block, can output the value of e_i, the ith dit of the error vector on the original block, as long as the number of faults is at most q, the number of errors that C_1 corrects. To see this, note that, for any $w \in C_2, w' \in C_1$, and e a word in F_p^m, the transversal CNOT_p takes

$$|w+e\rangle|w'\rangle \mapsto |w+e\rangle|w'+e\rangle,$$

and we can find e by finding the closest word in C_1 to the string $w'+e$.

To correct dit-flips, we repeat the above procedure m times: Generate m ancilla states, rotate them to the dual code, apply CNOT_p transversally from the computational block to each one of the ancilla blocks, and then apply on the ith ancilla block a circuit that outputs $p-r$, where B^r is the dit-flip that occurred on the ith coordinate. Finally, apply a CNOT_p from this output dit into the ith coordinate of the computation block.

By ignoring the zero-state preparation procedures in the above construction for now, it is easy to see that one fault in the above procedure can affect only one qudit in the final block.

4.11. Error correction which projects any word into the code. We would like to insert here one important modification, which is not necessary for the fault-tolerant error correction but will become crucial when applying the error corrections in the recursive scheme. This is the requirement that the error correction takes any word to some word in the code, regardless of the number of faults in the original state. This requirement applies, of course, only if during the error correction there are no faults.

Roughly, this is done by checking whether too many errors occurred and, if so, replacing the entire block by another block which is initialized in the state $|S_0\rangle$. However, we should be careful to keep the procedure fault-tolerant. We do this in the following way: Before starting the correction procedure, we generate another ancilla state $|S_0\rangle$, by using the state preparation procedure. When computing the value of e_i in the error correction procedure, we also compute whether the total number of faults is at most q and write the answer on another qudit. Let us call this an *indication bit*. The CNOT which checks if the ith dit is wrong and if so applies NOT on the i*th* qubit is replaced by a generalized Toffoli gate which takes as an input also the ith indication bit and also checks if the number of faults is at most q. We then swap the ith qudit with the ith qudit of the state $|S_0\rangle$, conditioned that the ith indication bit indicates that the number of faults is larger than q. Such a conditional swap can be achieved by a small circuit which uses only the classical gates from $\mathcal{G}_1$.

To see that this procedure indeed takes any word to some word in the code, observe that this is true if no fault occurs during the procedure itself. Since the procedure is performed fault-tolerantly, the final state will differ from a word in the code only in the qubits affected by an error.

4.12. More issues regarding ancillas. In subsection 4.3.5 we required that, in all of our procedures, the state of the ancilla qudits that are discarded at the end of a procedure is in tensor product with and independent of the state of the computer (in a noiseless situation). This requirement was imposed so that the ancilla states are in tensor product with the state of the computer even if this state is a superposition of the basis states and not only in a basis state like in our analysis. This requirement can be released in two cases: the zero-state preparation and the decoding procedures.

The zero-state preparation procedure is supposed to get as an output one basis state. Thus, we can release the above requirement about ancilla qudits and demand only that the ancilla state is in tensor product with the computational qubits at the end of the procedure. This requirement can also be released in the decoding procedure, since once we decode a state in our scheme, we do not use it any more. Hence, we should check only that it gives the correct answer when measured.

4.13. Fault-tolerant zero-state preparation. We need to show how to generate $|S_0\rangle$ with spread 1. By Definition 16, we need to check the propagation of errors only under the assumption that the total number of errors in the input string, plus the number of faults during the procedure, is at most q, the number of errors that the codes can correct. In this case, we can assume that the number of faults is at most q, since the zero-state preparation has no input. The construction is based on one basic design, which is essentially concatenated with itself, up to some modifications.

4.13.1. Zero-state preparation resilient to one fault. Assume for a moment that $q = 1$, so that we only have to make sure that the spread of the state preparation procedure is 1 if there is one fault in the procedure. In this situation, our state preparation procedure is the following construction. Let $\mathcal{Q}$ be some quantum circuit that generates $|S_0\rangle$ from $|0^m\rangle$, without any fault-tolerant requirement. We start with $5m$ blank qubits and apply $\mathcal{Q}$ on the first, second, third, fourth, and fifth m-tuples of qubits. We now apply a circuit that is very similar to the error correction circuit: It attempts to detect errors with respect to the code containing one word, namely, $|S_0\rangle$. To detect dit-flips in the first block, we apply CNOT_p transversally from the first block to the second one and then perform some computation on the qudits of the second block to assess the number of dit-flips. This time, we do not attempt to infer the exact error vector, or to correct the state, but just to decide whether we accept the state or not. To do this, we copy each dit in the block to m different dits. The circuit we apply on the second block gets as an input the ith copy of these dits, namely, a string in F_p^m, and outputs whether its distance from the code C_2 is more than 1 or not. The output bit is called the *dit-flips indication bit*. We perform m independent calculations to get m such indication bits.

We use the third block to detect phase-flips. We would like to follow a similar construction as for the detection of dit-flips. The difference is that we first rotate both the first block and the third block to the dual code, as in (4.7). After we apply CNOT_p from the first to the third block, we detect errors by using the third block, except that the error detection is done with respect to the code C_1 for polynomials with the codegree. Unfortunately, this scheme requires some modification. The problem is that if one fault occurred in the generation of the third block, such that after its rotation this block contains many phase-flips, these phase-flips will propagate through the CNOT_p gates to the first block but will not be detected. To prevent this, before we apply the above construction, we use the fourth block to detect for dit-flips of the third block. This is done just as the above dit-flip detection with the first and second blocks. This initial check creates m additional indication bits. We condition each of

the CNOT_p gates from the first to the third block on the relevant additional indication bit—hence instead of applying a transversal CNOT_p, we in fact apply generalized Toffoli gates transversally. After the application of the Toffoli gates, we rotate the first block back to the dual of the dual code, namely, to the original code. We now compute from the third block m phase-flip indication bits, independently, exactly as we have computed the dit-flip indication bits before.

In fact, we need to insert one last modification in this construction. We would like to be able to bound the total number of dit-flips and phase-flips, and not just each of them separately, so that we can bound the deviation. Hence, instead of the two separate indication bits, we actually calculate one indication bit, as follows. The circuit gets as an input two strings in F_p^m. It checks whether there exists one coordinate such that it suffices to change this coordinate in both strings, in some way (including leaving it as is), to put the first string in C_2 and the second string in C_1 (with the codegree). If there is no such coordinate, this bit is turned to 1.

Finally, we apply transversally the following three-qudit transformation, on the ith dit of the first block, the ith indication bit, and the ith dit of the fifth block. The transformation swaps the ith dits of the first and fifth blocks, conditioned that the indication bit is 1 (namely, more than one error was detected). This three-qudit transformation can be constructed from classical gates in $\mathcal{G}_1$.

CLAIM 3. *If exactly one fault in the above construction occurred, then the final state has at most one error.*

Proof. By subsections 3.5 and 3.3 we can treat the error as if it is a linear combination of dit-flips and phase-flips. Let us first consider the case of a fault occurring in one of the non-fault-tolerant circuits preparing the states $|S_0\rangle$. If the fault occurs in the fifth circuit, nothing happens, since no swap occurs. If the fault occurs in the first circuit, it could be that this fault propagated to more than one qudit in $|S_0\rangle$. If there is more than one coordinate in which either a dit-flip or a phase-flip occurred, the remainder of the circuit, which is fault-free, will detect it. Hence, all indication bits would indicate that the first and fifth blocks should be swapped. If the fault propagated to at most one qudit, this would not cause a swap, but this is OK since there will only be one error in the final state.

A similar argument applies if the fault occurs in the second block. If there is more than one faulty qudit in the $|S_0\rangle$ state of this block, this will result in swapping the first block with the correct state (the fifth block). If there is one error, this will not cause a swap but can only cause one error in the final state.

What about the third block? If the $|S_0\rangle$ state of the third block has more than one dit-flip, these will be detected in the dit-flip preliminary detection of the third block, and the conditioning on the additional indication dits will prevent them from propagating. Hence, we can assume that there is at most one dit-flip in this state. One such dit-flip can propagate from the third block to the first block through the CNOT_p gates, after the rotation, but can cause at most one error. Now let us add phase-flips. After the rotation of the third block, these transform to dit-flips. If there are at least 2 of them, a swap will occur and no error will be caused in the final block. If there is at most one such dit-flip, it has no affect at all since it does not propagate through the CNOT_p gates. Overall, we have seen that one fault of any kind in the third block can cause at most one error in the final block.

Similar arguments apply to show that one fault in the fourth block can cause at most one error. If the fourth $|S_0\rangle$ state has more than one dit-flip, nothing will happen due to the additional indication bits. But even if it has at most one dit-flip, this does not propagate through the CNOT_p gates from the third to the fourth block,

and so the dit-flips have no effect. As for the phase-flips, these can propagate to the third block, and the argument proceeds as in the case of the third block.

The next case is a fault that occurs during the CNOT_p and rotation gates. Since these are applied transversally, one fault can affect only exactly one qudit in each block. Let us see how these errors propagate through the remaining fault-free circuit. As for the propagation of a dit-flip, since one dit-flip cannot cause the indication bits to turn into 1, we have that all indications bits will be zero. As for a phase-flip, this does not propagate at all through the remaining gates. Hence, as no swap will occur, the final state will have at most one error.

A more subtle case is the case in which the fault occurred during the copying of the bits of the second (or third, or fourth) block. Suppose a fault occurred while copying the ith bit. It could be that the ith indication dit is flipped and/or had a phase flip, and, possibly, the ith dit in the second block is flipped, too, and/or suffers from a phase-flip. Let us first consider just the dit-flips and concentrate on a dit-flip in the copied dit itself. The problem is that in this case the remaining copied dits will all be wrong! Fortunately, this does not pose a problem. This affects exactly one dit in the input string of each circuit that computes an indication bit. Because of the fact that the indication bits turn to 1 only if they see more than one error, all indication dits (except, possibly, for the one in which the fault actually occurred) will still be 0. So in this case no swap occurs, except for possibly in one qudit, and the state, which was error-free to begin with, will have at most one error. An extra phase-flip in the same location of the dit-flip, if one occurred, does not change this analysis. A phase-flip in the copied qudit itself does not propagate via the CNOT_p gates to the target dit. Hence, by the end of the copying stage, the error will still be confined to the qudits where the fault had occurred, namely, one qudit in the second or third or fourth block, and one indication bit. So once again, at most one qudit will be swapped. Note that if just a phase-flip occurred in the indication bit, this does not affect the final state at all because it does not propagate through the SWAP gates.

Finally, a fault in the circuit calculating one of the indication bits, or a fault in one of the three-qudit circuits, can cause only one error since the remainder of the circuit is transversal. □

4.13.2. Zero-state preparation resilient to q faults. Let us now consider the case of $q > 1$. The above construction does not work any more, even for $q = 2$, since two faults can ruin completely both the first and the last block, which are constructed in a non-fault-tolerant way. Instead, we apply the above construction in a way that is sort of concatenated. For $q = 2$, we concatenate it once with itself, in the following way: We first apply the above construction five times, to get five $|S_0\rangle$ states—we call these states the first-level states. We then apply the above construction once more, except for two changes. The first change is that, instead of applying the original non-fault-tolerant circuit to construct the five $|S_0\rangle$ states, we use the five first-level states that we have generated. The second change is that we set the threshold of the indication bits in the second-level construction to be 2 instead of 1; namely, we only flip the indication bit to 1 if more than *two* errors were detected.

To increase q to any value, we simply apply the above concatenation q times, each time by using as input states the final states from the previous level of concatenation and increasing the threshold for the indication bits by 1. Overall, the scheme that allows for q faults, denoted by Q_q, uses 5^q $|S_0\rangle$ states.

CLAIM 4. *If $k \leq q$ faults occur during the application of Q_q, the final output block will have at most k errors.*

Proof. We prove this by induction. The case of $q = 1$ was essentially given in Claim 3, where it was shown that if $k = 1$, then the final block will have at most one error. It is obvious that if $k = 0$, the state will have no error. Now assume for q, and prove for $q + 1$. We divide this proof into two cases.

In the first case, in each one of the five q-level blocks that are used to generate the final block, there are at most q faults. In this case we can apply the induction. Let $x_1, \ldots, x_5$ be the number of faults occurring in the five circuits generating the q-level blocks, respectively. By induction, the number of errors in the final states is at most $x_1, \ldots, x_5$, respectively. If x is the number of faults occurring in the final part of the circuit, we have that $x_1 + \cdots + x_5 + x = k$. The next step in the circuit involves CNOT_p gates, which do not increase the number of errors in each block beyond k. The next step is the copying of each dit m times and computation of the indication bits. Recall that, at this step, the threshold for the indication bit to flip is for the number of errors it sees to be larger than $q + 1$. However, the calculation of each indication bit gets as an input two strings, such that the union of their errors is confined to at most $k \leq q + 1$ qudits, and so, unless the calculation itself involves a fault, the indication bit will remain 0. Hence, in this stage, too, one fault can propagate only to one error. The remainder of the circuit is transversal. This means that the total number of faults in the final $q + 1$-level block is at most k.

In the other case, $q + 1$ faults occurred during the generation of one of the five q-level blocks which are input to the final $(q + 1)$ level. In this case, the remainder of the circuit is fault-free. We consider five subcases: The faulty block is the first, second, third, fourth, or fifth $|S_0\rangle$s. Suppose first that it is the first block. Then either the final state of the faulty block has more than $q+1$ errors, and then the entire block will be swapped with the fifth block and the final state will be error-free, or the final state of the first block has $q + 1$ errors or less, in which case it will not be swapped, but still the number of errors is at most $k = q + 1$. A similar argument works if the faulty block is the second block. Suppose that there are x dit-flips, and suppose that y phase-flips have propagated to the first block. If $x + y > q + 1$, there will be a swap. Otherwise, this will cause at most $k = q + 1$ errors. Suppose that the faulty block is either the third or the fourth block. Observe that phase-flips before the rotation become dit-flips, and these do not propagate from the third block to the first block. Either there are more than $q + 1$ of these phase-flips, and they cause a SWAP, or they do not affect the final state. Hence, we need consider only the effect of the at most $q + 1$ dit-flips, which after the rotation become phase-flips, and can propagate to at most $q + 1$ errors in the final state. Finally, if the faulty block is the fifth block, the final state will not be swapped, so there will not be errors at all. ∎

This implies that the zero-state preparation procedure has spread 1.

4.14. A fault-tolerant decoding procedure. A decoding procedure applies

$$|S_a\rangle \longmapsto |A_a\rangle|\vec{a}\rangle, \tag{4.11}$$

where the state $|A_a\rangle$ is an ancillary state which depends on a. (We can discard this state at the end of the procedure; we will see that, whenever the decoding procedure is applied, the state encodes a well-defined logical bit a.) To apply this transformation, we compute a independently m times from the state $|S_a\rangle$. To do this, we add m^2 blank qubits and copy each qudit from $|S_a\rangle$ m times to m different blank qudits, by using m CNOT_p gates. We get m "copies" of $|S_a\rangle$. These are, of course, not real copies of $|S_a\rangle$, since they are entangled. However, each word in the classical code is copied m times. On each copy of the word we apply the quantum analogue of the

classical computation that computes what is the logical bit that the word encodes. The answer, which is a if no error occurred, is written on another blank qubit. For this computation we use the classical gates in $\mathcal{G}_1$. We might need some extra blank qudits as working space. The computation of a is done in the shortest way possible, regardless of whether it is fault-tolerant. An error in this computation can affect only the one copy of a which it computes. A fault in the first stage of copying the qubits m times can affect only one qubit in each of the copies, and, if the number of errors in S_a plus the number of faults in the first stage is smaller than the number of errors correctable by the code, these faults have no effect. One fault in the second stage of the procedure, during the computation of one of the a's, can affect only the correctness of that a.

Remark 1. We remark regarding the significantly simpler version of the error correction, decoding, and zero-state preparation procedures, in case measurements and classical computation are allowed.

In the error correction procedure, no repetition is required, and one ancilla state is needed for either dit-flips or phase-flips. This saved a factor of m in the construction.

The simplification is most notable in the case of the zero-state preparation procedure. In this case, we can omit the entire concatenated construction. We use the circuit as in the case of $q = 1$ and simplify it further as follows. Observe that, after the CNOT_p gates from the computational block to the ancilla blocks it suffices to measure every qudit in the ancilla blocks and perform the calculation of the error vector classically, without copying the dits first. Hence, the construction is transversal except for the classical computation which does not introduce errors, and the spread is 1.

Finally, in the decoding procedure we can omit the copying of the dits.

5. Fault-tolerant gates for CSS codes over F_2. In this section we give an alternative construction to the one using polynomial codes. Here we use a restricted class of CSS codes, which were used by Shor in [84]. Shor showed how to apply a universal set of gates (which we denote by $\mathcal{G}_2$) on states encoded by such codes. It turns out that almost all of the gates in $\mathcal{G}_2$ can be applied transversally. The only complicated procedure is the Toffoli gate. We repeat the constructions of Shor for the simple gates for completeness. As for the Toffoli gate, we essentially use Shor's construction, except that we adopt it to our framework in which no measurements are allowed, which requires some extra work.

5.1. Some restrictions on the CSS codes. In the following, we will put some restrictions on the CSS codes which we will use. This is done in order to be able to apply several gates transversally, as will be seen shortly. We start with C_1, a punctured doubly even self-dual code, and set $C_2 = C_1^{\perp}$. A punctured self-dual code is a code which is obtained from a self-dual code C' (namely, a code for which $C' = C'^{\perp}$) by deleting one coordinate. We also require that C' is a doubly even code; i.e., the weight of each word in the code is divisible by 4. To see that in this case $C_2 = C_1^{\perp} \subset C_1$, as in the definitions of CSS codes, observe that if $v \perp C_1$, then $v0 \perp C'$, so $v0 \in C'^{\perp} = C'$, so $v \in C_1$. We will denote that $C_1 = C$ and $C_2 = C^{\perp}$.

We now claim that there are only two cosets of $C^{\perp}$ in C. If the length of C is m, then $\dim(C'^{\perp}) = \dim(C') = (m+1)/2$. Hence $\dim(C) = (m+1)/2$ as well, since $|C| = |C'|$, because no two words in C' are mapped to the same word in C by the punctuation. Hence, $\dim(C^{\perp}) = m - (m+1)/2 = (m-1)/2$, and so $\dim(C) - \dim(C^{\perp}) = 1$. Observe that C includes the all-one vector: $\vec{1} \in C$. This is true since $1^{m+1} \in C'^{\perp}$, because C' is even, and since C' is self-dual, $1^{m+1} \in C'$. Hence $1^m \in C$. Observe also that the length m must be odd due to the above considerations.

This implies that $\vec{1} \notin C^{\perp}$. The two code words in our quantum code can thus be written as

$$|S_{\vec{0}}\rangle = \sum_{w \in C^{\perp}} |w\rangle, \tag{5.1}$$
$$|S_{\vec{1}}\rangle = \sum_{w \in C^{\perp}} |w + \vec{1}\rangle.$$

$|S_{\vec{0}}\rangle$ and $|S_{\vec{1}}\rangle$ can be thought of as encoding $|0\rangle$ and $|1\rangle$, respectively. We will make use of the fact that $\vec{a} \cdot \vec{b} \bmod 2 = ab$, for $a, b \in 0, 1$, and that $\vec{a} + \vec{b} = \overrightarrow{a+b}$. This fact allows us to shift easily between operations on vectors and operations on the bits they represent. We will therefore usually omit the vectors in the notations of $|S_{\vec{0}}\rangle$ and $|S_{\vec{1}}\rangle$, unless there is ambiguity.

5.2. The set of gates for CSS codes $\mathcal{G}_2$. We work with the following set of gates, which we denote by $\mathcal{G}_2$:

1. NOT: $|a\rangle \longmapsto |1 - a\rangle$.
2. CNOT: $|a, b\rangle \longmapsto |a, a + b\rangle$.
3. Phase: $|a\rangle \longmapsto i^a |a\rangle$.
4. SWAP: $|a\rangle|b\rangle \longmapsto |b\rangle|a\rangle$.
5. Controlled phase: $|a\rangle|b\rangle \longmapsto (-1)^{ab}|a\rangle|b\rangle$.
6. Hadamard: $|a\rangle \longmapsto \frac{1}{\sqrt{2}} \sum_b (-1)^{ab} |b\rangle$.
7. Toffoli gate: $|a, b, c\rangle \longmapsto |a, b, c + ab\rangle$.
8. Adding a qubit in the state $|0\rangle$.
9. Discarding a qubit.

All of the additions and multiplications above are in F_2 (i.e., modulo 2). Section 6 shows that this set of gates is universal. We remark here once again that, like the set $\mathcal{G}_1$, the set $\mathcal{G}_2$ is by no means a minimal universal set of gates, but the fault-tolerant procedures become simpler and shorter if we have a larger repertoire of fault-tolerant gates that we can use. The following theorem shows how to perform gates from $\mathcal{G}_2$ on encoded states fault-tolerantly.

THEOREM 6. *Fix a CSS code that satisfies the restrictions of subsection* 5.1. *For any gate in $\mathcal{G}_2$, there exists a fault-tolerant procedure with spread* 1 *that computes the gate on states encoded by the code. There exist also fault-tolerant error correction, decoding, and zero-state preparation procedures for this code, which all have spread* 1. *Moreover, all of these procedures use only gates from $\mathcal{G}_2$ and in particular do not use measurements.*

The constructions of the error correcting, decoding, and zero-state preparation procedures follows exactly the construction of section 4. It remains to show the constructions of the computational gates.

5.3. Transversal gates. In the following we omit overall normalization factors, since all vectors are known to be unit vectors. We also set $a, b \in C/C^{\perp}$. We start with the NOT gate:

$$\begin{aligned} |S_a\rangle &= \sum_{w \in C^{\perp}} |a_1 + w_1\rangle \otimes \cdots \otimes |a_m + w_m\rangle \\ &\longmapsto \sum_{w \in C^{\perp}} |a_1 + 1 + w_1\rangle \otimes \cdots \otimes |a_m + 1 + w_m\rangle = |S_{a+\vec{1}}\rangle. \end{aligned} \tag{5.2}$$

For CNOT,

(5.3)
$$\begin{aligned}|S_a\rangle|S_b\rangle &= \sum_{w\in C^\perp} |a_1+w_1\rangle\otimes\cdots\otimes|a_m+w_m\rangle \sum_{w'\in C^\perp} |b_1+w'_1\rangle\otimes\cdots\otimes|b_m+w'_m\rangle\\ &\longmapsto \sum_{w\in C^\perp} |a_1+w_1\rangle\otimes\cdots\otimes|a_m+w_m\rangle \sum_{w'\in C^\perp} |a_1+b_1+w_1+w'_1\rangle\otimes\cdots\\ &\quad\otimes|a_m+b_m+w_m+w'_m\rangle\\ &= |S_a\rangle|S_{a+b}\rangle,\end{aligned}$$

where the last equality follows from the fact that $C^\perp$ is a linear subspace, and therefore summing over $w+w'$ for a fixed w in the code is equivalent to summing over w'. For the phase gate, apply the gate $|a\rangle \longmapsto i^a|a\rangle$ three times on each coordinate. This gives

(5.4)
$$|S_a\rangle = \sum_{w\in C^\perp} |a_1+w_1\rangle\otimes\cdots\otimes|a_m+w_m\rangle \longmapsto \sum_{w\in C^\perp} i^{3(\sum_k a_k+w_k)}|a_1+w_1\rangle\otimes\cdots\otimes|a_m+w_m\rangle.$$

This is the desired result, because of the following fact. Since C is obtained from a doubly even self-dual code C' by deleting one coordinate, it is easy to see that $C^\perp \subset C$ are exactly those words in which the deleted coordinate was 0. Thus, all words in $C^\perp$ have weight which is divisible by 4, and all words in C but not in $C^\perp$ have weight which is 3 mod 4.

For the encoded controlled phase gate,

$$|S_{\vec a}\rangle|S_{\vec b}\rangle = \sum_{w,w'\in C^\perp} |\vec a+w\rangle|\vec b+w'\rangle \longmapsto \sum_{w,w'\in C^\perp} (-1)^{(\vec a+w)\cdot(\vec b+w')}|\vec a+w\rangle|\vec b+w'\rangle. \tag{5.5}$$

Now $(\vec a+w)\cdot(\vec b+w') = \vec a\cdot\vec b \bmod 2$. This is true since $\vec a\in C$ and $w'\in C^\perp$ so $\vec a\cdot w' = 0 \bmod 2$, and likewise $w\cdot\vec b = w\cdot w' = 0 \bmod 2$. Moreover, $\vec a\cdot\vec b \bmod 2$ is equal to ab, and so the final state is indeed the desired state. Finally, for the Hadamard gate,

$$\begin{aligned}|S_a\rangle &= \sum_{w\in C^\perp} |a_1+w_1\rangle\otimes\cdots\otimes|a_m+w_m\rangle \longmapsto \sum_{x\in F_2^m}\sum_{w\in C^\perp} (-1)^{(a+w)\cdot x}|x\rangle\\ &= \sum_{x\in C}(-1)^{a\cdot x}|x\rangle = \sum_{b\in C/C^\perp}\sum_{w\in C^\perp}(-1)^{a\cdot(b+w)}|b+w\rangle = \sum_b (-1)^{a\cdot b}|S_b\rangle.\end{aligned} \tag{5.6}$$

It remains to show how to apply the Toffoli gate on encoded states.

5.4. The fault-tolerant Toffoli gate. To apply the Toffoli gate, we roughly follow Shor's scheme, where we construct an ancillary state denoted by $|A_0\rangle$ and use it to obtain the Toffoli gate. The main difference from Shor's scheme is in the construction of the ancillary state, which is not completely straightforward if one wants to avoid using measurements.

Our constructions of encoded gates for polynomial codes, which we discussed in section 4, is much simpler than the construction we get for the Toffoli gate. First, for the Toffoli gate we need not only zero-state preparations but also the preparation of a three-block ancilla state. Second, the subsequent operations given the ancilla state are not transversal as in the case of the polynomial codes. The work of [48]

shows how to encode a universal set of gates by procedures which consist of ancilla state preparation followed by transversal operations (namely, teleportation). This, however, is done by assuming measurements and classical computation.

5.4.1. Construction of the ancilla state $|A_0\rangle$. Define the ancilla state

$$|A_0\rangle = \frac{1}{2}\sum_{a,b}|S_aS_bS_{ab}\rangle. \tag{5.7}$$

We also define

$$|A_1\rangle = \frac{1}{2}\sum_{a,b}|S_aS_bS_{1-ab}\rangle, \tag{5.8}$$

which is easily convertible to $|A_0\rangle$ by applying NOT on the third block. Note that the state

$$\frac{1}{\sqrt{2}}(|A_0\rangle + |A_1\rangle) = \frac{1}{2\sqrt{2}}(|S_0\rangle + |S_1\rangle)(|S_0\rangle + |S_1\rangle)(|S_0\rangle + |S_1\rangle) \tag{5.9}$$

is easy to construct by preparing three zero states $|S_0\rangle$ and then applying an encoded Hadamard on each block. In order to convert this state to $|A_0\rangle$, we use states of the form

$$|S_{cat}\rangle = \frac{1}{\sqrt{2}}(|S_0\rangle^m + |S_1\rangle^m), \tag{5.10}$$

which we call encoded cat states. An encoded cat state can be achieved by applying m zero-state preparation procedures to get $|S_0\rangle^m$, followed by an encoded Hadamard on the first block, and then CNOT gates from the first block to all other blocks.

We will also make use of the transformation

$$|S_a\rangle^m|A_b\rangle \longmapsto (-1)^{ab}|S_a\rangle^m|A_b\rangle \tag{5.11}$$

for bits a, b. The transformation (5.11) is performed by applying

$$|S_a\rangle|b\rangle|c\rangle|d\rangle \longmapsto (-1)^{a(bc+d)}|S_a\rangle|b\rangle|c\rangle|d\rangle \tag{5.12}$$

on the ith block in the encoded cat state and the ith bit in each of the three blocks of $|A_0\rangle + |A_1\rangle$. By applying this transformation for $1 \le i \le m$ we get

$$|S_a\rangle^m|S_b\rangle|S_c\rangle|S_d\rangle \longmapsto (-1)^{a(bc+d)}|S_a\rangle^m|S_b\rangle|S_c\rangle|S_d\rangle, \tag{5.13}$$

which is exactly the desired transformation of (5.11). Note that transformation (5.12) need not be fault-tolerant. We do not care if one fault ruins the entire block $|S_a\rangle$.

Let us start with the state

$$\frac{1}{\sqrt{2^{r+1}}}(|S_0\rangle^m + |S_1\rangle^m)^r(|A_0\rangle + |A_1\rangle), \tag{5.14}$$

where r will be chosen soon. Now apply transformation (5.11) between each one of the r encoded cat states and the last register, and between every two subsequent applications of transformation (5.11), perform an error correction on the last register.

The reason for the error corrections will become clear shortly. The resulting state would then be

$$\frac{1}{\sqrt{2^{r+1}}}(|S_0\rangle^m + |S_1\rangle^m)^r|A_0\rangle + \frac{1}{\sqrt{2^{r+1}}}(|S_0\rangle^m - |S_1\rangle^m)^r|A_1\rangle. \tag{5.15}$$

We would now like to "measure" (without any measurement) the r cat states, in order to decide (essentially, by taking majority over the r "measurement" results) whether the cat states are in their plus or minus states. If the answer is "plus," we would know that the state of the final three registers is $|A_0\rangle$, the desired state, and if "minus," we would know it is $|A_1\rangle$, in which case we could apply NOT on the third block to get $|A_0\rangle$.

We can now explain why the error corrections were added in between the different applications of transformation (5.11) that led to the state of (5.15): Transformation (5.11) is derived by m applications of transformation (5.13). Hence, a single error in the last register can cause a flip of sign in the encoded cat state, from "plus" to "minus" or vice versa. If this single error is not corrected, the signs will be wrong in all of the remaining cat states, too.

To apply the measurement of the sign of one encoded cat state in a fault-tolerant manner, we observe that applying encoded Hadamard gates on all m blocks in one encoded cat state results in

$$\begin{aligned}
&\frac{1}{\sqrt{2}}(|S_0\rangle^m + |S_1\rangle^m) \longmapsto \frac{1}{\sqrt{2^{m-1}}} \sum_{i=0, i\cdot\vec{1}=0}^{2^m} |S_{i_1}\rangle|S_{i_2}\rangle \dots |S_{i_m}\rangle, \\
&\frac{1}{\sqrt{2}}(|S_0\rangle^m - |S_1\rangle^m) \longmapsto \frac{1}{\sqrt{2^{m-1}}} \sum_{i=0, i\cdot\vec{1}=1}^{2^m} |S_{i_1}\rangle|S_{i_2}\rangle \dots |S_{i_m}\rangle.
\end{aligned} \tag{5.16}$$

This means that the answer plus or minus is determined by the parity of the strings in the sum. To compute the parity fault-tolerantly, we apply a fault-tolerant decoding procedure on each block, to get a string of m (ideally equal) bits. We then compute the parity transversally: We consider all of the first bits in the blocks (there are m of them) and compute their parity, by using a quantum circuit made of Toffoli, CNOT, and NOT gates. Likewise, we consider all of the second bits and compute their parity, and so on. For each encoded cat state, we therefore get m parity bits. We compare the parity bits of the different encoded cat states transversally by applying m majority votes of the form:

$$|a_1, a_2, \dots, a_r, b\rangle \longmapsto |a_1, a_2, \dots, a_r, b + maj(a_i)\rangle. \tag{5.17}$$

Each such majority vote can be constructed once again from Toffoli, CNOT, and NOT gates, since they are universal for classical computations. Finally, we apply CNOT transversally from the result of the majority vote to the qubits in the third block of $|A_0\rangle$.

It is left to see that the spread of this procedure is 1. We will consider errors at different stages of the procedure. The construction of an encoded cat state allows one fault to propagate to one error since it is composed of the state preparation procedure and CNOTs applied transversally. This is true also for the construction of the state $\frac{1}{\sqrt{2}}(|A_0\rangle + |A_1\rangle)$ because we used only the fault-tolerant state preparation procedure and the transversal Hadamard gate. A more subtle consideration is required for

transformation (5.11). An error during this transformation can cause a whole block in one of the cat states in the state (5.13) to be affected, together with one qubit in each one of the last three blocks. However, one such block can ruin the parity bits of only one encoded cat state. As long as the number of faulty parity bits is less than $r/2$, the majority vote will still give the correct parity. An error in the parity computations or in the majority vote cannot affect more than one qubit in $|A_0\rangle$, since they are done transversally.

We choose r to be $2k_0+1$, where $k_0 = \lfloor q/2 \rfloor$. The reason is that, in our proof, we will distinguish between cases with at most k_0 faults in a rectangle, which we treat as the good case, and other cases which will be shown to be rare. Hence, we would like to be able to tolerate $\lfloor q/2 \rfloor$ faults in a rectangle. Choosing $r = 2k_0 + 1$ will do the trick.

5.4.2. Construction of Toffoli gate given $|A_0\rangle$. The construction of the Toffoli gate given $|A\rangle$ follows Shor's scheme almost exactly, with minor changes due to the fact that measurements are replaced by CNOT gates to additional blank qubits. Also, classical conditioning on the results of the measurements is replaced by unitary gates on the computation qubits and extra blank qubits carrying the results of the measurements. Here is how this is done. We will first generate "half" a Toffoli gate:

$$|S_a\rangle|S_b\rangle|S_0\rangle \longmapsto |S_a\rangle|S_b\rangle|S_{ab}\rangle. \tag{5.18}$$

A Toffoli gate can be generated from transformation (5.18) in the following way. We start with the three blocks on which we want to apply Toffoli: $|S_a\rangle|S_b\rangle|S_c\rangle$. Then we generate $|S_0\rangle$ on an extra block, by using the zero-state preparation procedure. We then apply transformation (5.18) on the first two blocks and the newly generated $|S_0\rangle$. Then we apply an encoded CNOT from our original third block $|S_c\rangle$ to the new block. We finally apply an encoded Hadamard on the original third block. This gives the overall transformation:

$$|S_a\rangle|S_b\rangle|S_c\rangle|S_0\rangle \longmapsto \frac{1}{\sqrt{2}}|S_a S_b S_{c+ab}\rangle(|S_0\rangle + (-1)^c|S_1\rangle). \tag{5.19}$$

Note that if the fourth block was not there, we would be done, because the operation on the first three blocks is exactly the Toffoli gate. We next decode the fourth block. Hence, we would like to apply the operation

$$|S_a\rangle|S_b\rangle|S_c\rangle \longmapsto (-1)^{ab+c}|S_a\rangle|S_b\rangle|S_c\rangle \tag{5.20}$$

on the first three blocks, conditioned that the decoded qubits are 1.

This can be applied transversally, in the following way. First, apply a controlled phase on $|S_c\rangle$ and the decoded qubits, in a transversal manner. This will give the factor $(-1)^c$. To apply $|S_a\rangle|S_b\rangle \longmapsto (-1)^{ab}|S_a\rangle|S_b\rangle$ conditioned on the decoded qubits, apply transversally the operation: $|a\rangle|b\rangle|d\rangle \longmapsto (-1)^{abd}|a\rangle|b\rangle|d\rangle$, where $|d\rangle$ is a decoded qubit. This achieves the correct transformation since we know that the controlled phase can be applied transversally. This operation can be applied by adding a blank qubit $|a\rangle|b\rangle|0\rangle|d\rangle$ and applying a Toffoli gate on the first three qubits, followed by a controlled phase on the last two qubits, and then by a Toffoli gate again on the first three qubits.

It is left to show how to construct transformation (5.18) on two blocks B_1 and B_2. This is done by generating the ancilla state $|A_0\rangle$ as before. Now apply an encoded

CNOT from the first block of $|A_0\rangle$ to the first block B_1 and from the second block of $|A\rangle$ to the second block B_2. This achieves the transformation

$$|S_c\rangle|S_d\rangle|A_0\rangle \longmapsto \sum_{a,b} |S_{a+c}\rangle|S_{b+d}\rangle|S_a\rangle|S_b\rangle|S_{ab}\rangle. \tag{5.21}$$

We note that the last three blocks have a strong connection to the Toffoli gate. More precisely, we note that projecting the above sum on the subspace where the first two blocks are $|S_0\rangle|S_0\rangle$ implies that $a = c, b = d$, and the gate which is achieved on the last three blocks is exactly the desired Toffoli gate. If the first two blocks are the state $|S_0\rangle|S_1\rangle$, this implies that $a = c, b = \neg d$, and so the gate which is achieved is the encoded version of $|c, d\rangle \mapsto |c, \neg d, c\neg d\rangle$. Similarly for the two other possibilities we get the encoded versions of $|c, d\rangle \mapsto |\neg c, d, \neg cd\rangle$ and $|c, d\rangle \mapsto |\neg c, \neg d, \neg c\neg d\rangle$, respectively.

To adjust for these deviations from the Toffoli gate, we apply decoding procedures to the first two blocks and then apply the following corrections transversally on the five blocks:

$$\begin{aligned}
&|0,0\rangle|a,b,c\rangle \longmapsto |0,0\rangle|a,b,c\rangle,\\
&|0,1\rangle|a,b,c\rangle \longmapsto |0,1\rangle\mathsf{NOT}(2)\mathsf{CNOT}(1,3)|a,b,c\rangle,\\
&|1,0\rangle|a,b,c\rangle \longmapsto |1,0\rangle\mathsf{NOT}(1)\mathsf{CNOT}(2,3)|a,b,c\rangle,\\
&|1,1\rangle|a,b,c\rangle \longmapsto |1,1\rangle\mathsf{NOT}(1)\mathsf{NOT}(2)\mathsf{NOT}(3)\mathsf{CNOT}(1,3)\mathsf{CNOT}(2,3)|a,b,c\rangle.
\end{aligned} \tag{5.22}$$

It is easy to check that this achieves the desired corrections. The transformation in (5.22) is a reversible transformation on five qubits and can therefore be constructed by a constant number of classical gates from the set $\mathcal{G}_2$.

The spread of this procedure is 1, since we use the decoding procedure which has spread 1 and everything else is done transversally.

6. Universality of the sets of gates $\mathcal{G}_1$ and $\mathcal{G}_2$. In this section we prove the universality of the sets of gates we use. Roughly, a set of gates is said to be universal if the subgroup generated by the set of gates is dense in the group of unitary operations on n qubits $U(2^n)$ (for p-qudits the group is $U(p^n)$). A beautiful theorem by Kitaev [50, 52] and Solovay and Yao [85] implies that if a set $\mathcal{G}$ is universal, then any quantum circuit that uses arbitrary gates with constant fan-in can be replaced by one that uses only gates from $\mathcal{G}$, such that the overhead in time and space of the new circuit is only polylogarithmic. This theorem gives meaning to the notion of universality, since it implies that restricting the computation to a universal gate set implies only polylogarithmic overhead, and thus one can regard such a set as sufficient for quantum computation.

Our proof of universality of the set $\mathcal{G}_2$, used for CSS codes, is a simple reduction to a set of gates shown to be universal by Kitaev [50]. A similar result was achieved independently by Boykin et al. [26]. The proof that the set of gates $\mathcal{G}_1$ used for polynomial codes is universal is much more complicated. It is based on geometrical arguments on the special unitary group $SU(n)$, together with some basic facts from the theory of finite fields.

We start with a detailed discussion of the notion of universality. We then proceed to prove some geometrical lemmas that we will use in our universality proofs, and, finally, we prove the universality of the gate sets $\mathcal{G}_1$ and $\mathcal{G}_2$.

6.1. Universal sets of gates—basic results.

DEFINITION 19. *Let $p \geq 2$. A set of gates $\mathcal{G}$ on $k \geq 2$ p-qudits is said to be universal if it is closed under inversion and $\mathcal{G} \cup \{e^{i2\pi\theta} I\}_{real\ \theta}$ generates a dense subset in $U(p^k)$.*

The inclusion of the scalars of the form $e^{2\pi i\theta}$ (which are of absolute value 1 and are sometimes called *phases*) does not have any physical effect, since multiplying a gate by such a phase does not change the resulting density matrix.

The fact that this definition indeed captures the notion of universality is summarized by the following theorem.

THEOREM 7. *Consider $\epsilon > 0$, a quantum circuit Q that uses arbitrary gates (of constant fan-in), and a universal set of gates $\mathcal{G}$. The circuit Q can be translated to a circuit Q_ϵ that uses only gates from $\mathcal{G}$ such that the following three conditions hold:*

1. *Q_ϵ computes a function that approximates the function computed by Q to within total variation distance ϵ.*
2. *Q_ϵ is only polylogarithmically larger and deeper than Q.*
3. *The description of Q_ϵ can be efficiently computed given the description of Q.*

The proof of this theorem is well known for the case of qubits, and we extend it here for the case of p-qudits. The proof is based on two results. The first result, known as the Solovay–Kitaev theorem, states that "density implies efficiency": If a set operating on some Hilbert space is universal, then it can be used to approximate any unitary matrix on the same space exponentially rapidly. Moreover, the sequence of gates from $\mathcal{G}$ that achieves the approximation can be found efficiently.

THEOREM 8 (see Kitaev [50, 52] and Solovay [85]). *Let $\mathcal{G}$ be a universal set of gates over $U(p^k)$ for some integers $p, k \geq 2$. Then there exists a Turing machine A that, given a matrix $M \in U(p^k)$ and $\epsilon > 0$, outputs a sequence of gates $g_1, \ldots, g_\ell \in \mathcal{G}$ such that $\|M - g_\ell \cdot g_{\ell-1} \ldots g_1\| < \epsilon$, and both ℓ and the running time of A are polynomial in $\log(1/\epsilon)$.*

The proof of this beautiful and fundamental theorem uses Lie groups and Lie algebras and is beyond the scope of this paper.

To complete the proof of Theorem 7 we need another fact: An operation on any number of qubits (qudits) can be achieved by using gates that operate on only two qubits (qudits). This was proved for the case of qubits by DiVincenzo [40], a proof which was simplified by Barenco et al. [19]. We give here a proof for the general case of qudits, by using similar ideas to those used by Deutsch [39] and Barenco et al. [19].

THEOREM 9. *Let $\mathcal{G}$ be a universal set of gates on $k \geq 2$ p-qudits. Consider the Hilbert space of $m > k$ p-qudits. Then the set of gates achieved by extending the gates in $\mathcal{G}$ to operate on m p-qudits generates a dense subset of $U(p^m)$.*

Proof. We define a generalized Toffoli gate on m qudits $T_m(Q)$ to be a gate which applies Q on the mth qudit conditioned that the first $m-1$ qudits are in the state $p-1$ (see Figure 6.1).

The conditioned Q can be applied on the rth qudit, instead of the mth one, in which case we denote the gate by $T_{m,r}(Q)$.

CLAIM 5. *The set of gates $T_{m,r}(Q)$ can be approximated to within an arbitrary accuracy by using the extensions of gates from G to m qudits.*

Proof. We first show in Figure 6.2 an explicit sequence of generalized Toffoli gates on $m-1$ qudits, $T_{m-1}(Q)$'s, which achieves $T_m(Q)$.

We denote that $V = Q^{\frac{1}{p}}$, and $\oplus$ denotes here the $\mathsf{NOT}_p = \mathsf{NOT}_p(1)$ operation. It is easy to check that the above circuit indeed gives the desired controlled Q, by considering what happens to the basis states, in two cases: All first $m-2$ qudits

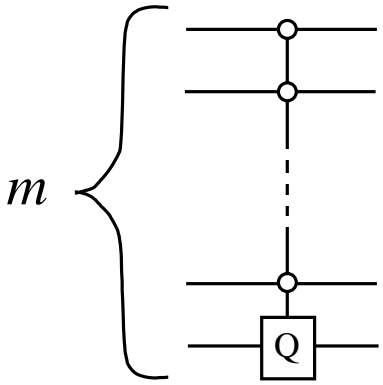

FIG. 6.1. *The controlled operation in F_2 is replaced here by conditioning the application of Q on the fact that the first $m-1$ qudits are in the state $p-1$. Note the difference from the usual conditioning, which for the case of $m=2$ would give CNOT_p. To distinguish it from the standard kind of conditioning, we denote this controlling operation by an empty circle.*

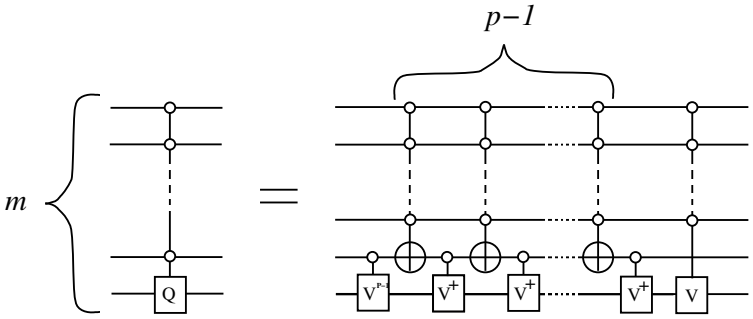

FIG. 6.2. *The gate $T_m(Q)$ can be written as a sequence of gates of the form $T_{m-1}(Q)$. After the first controlled V^{p-1}, we apply $T_{m-1}(\mathsf{NOT}_p)$, followed by a controlled $V^\dagger$, and repeat this pair of gates $p-1$ times. At the end we apply V controlled on the first $p-2$ qudits.*

are equal to $p-1$, or not. By using the above scheme recursively we can construct a circuit which uses k-qudit gates of the form of $T_k(Q)$ and achieves $T_m(Q)$ for any $m > k$ and any one-qudit Q. Since the set $\mathcal{G}$ is universal, the gates of the form $T_k(Q)$ can be approximated. Note that the recursion starts with two-qudit gates, which is the reason why we require $k \geq 2$. The construction is similar for $T_{m,r}(Q)$. □

The gate $T_m(Q)$ can be seen as applying Q on the subspace spanned by the last p basis vectors while applying identity on the rest. The next step is to construct a generalization of the above gate, i.e., a gate which applies $Q \in U(p)$ on the subspace spanned by any p basis vectors $|i_1\rangle, \ldots, |i_p\rangle$ while applying identity on the rest of the basis vectors. Denote this matrix by $T_m(Q, i_1, \ldots, i_p)$. We note that since $\mathcal{G}$ is universal, it can be used to approximate any one-qudit gate, so we are also allowed to use in our construction NOT_p gates.

CLAIM 6. *The gate $T_m(Q, i_1, \ldots, i_p)$ can be constructed by using gates of the form $T_{m,r}(Q)$ together with NOT_p gates.*

Proof. Consider the set of gates $\{T_{m,r}(Q)\}$, where Q runs over all permutation matrices on the Hilbert space of one qudit and r runs over all m qudits. We first prove that this set, augmented with NOT_p gates, generates all permutation matrices

on m qudits. To prove this, it suffices to construct all matrices of the form $\tau_{i,j}$ for two strings $i, j \in \{0, p-1\}^m$ that differ in only one coordinate. The matrix $\tau_{i,j}$ is defined to be the transformation that switches the two basis vectors $|i\rangle, |j\rangle$ and $\tau_{i,j}|k\rangle = |k\rangle$ for any $k \neq i, j$. Let the coordinate on which i, j disagree be the rth coordinate, and let this coordinate be equal to a in the string i and to b in the string j. To construct $\tau_{i,j}$, apply NOT_p gates on all of the coordinates except the rth coordinate, so that all of these coordinates in both strings become equal to $p-1$. Now apply $T_{m,r}(Q)$, with Q on the rth coordinate being the matrix which permutes $|a\rangle$ and $|b\rangle$, leaving the rest of the basis vectors untouched. Then reverse all of the NOT_p gates on all of the coordinates but the rth one. This gives $\tau_{i,j}$ and therefore all permutations on basis vectors. The general $T_m(Q, i_1, \ldots, i_p)$ for any Q can now be achieved by first permuting the basis vectors $i_1, \ldots, i_p$ to the last p vectors, applying $T_m(Q)$, and then permuting back. □

The last step is to use $T_m(Q, i_1, \ldots, i_p)$ to construct a general $p^m \times p^m$ unitary matrix U. Let us denote the p^m eigenvectors of U by $|\psi_j\rangle$ with corresponding eigenvalues $e^{i\theta_j}$. U is specified by $U|\psi_j\rangle = e^{i\theta_j}|\psi_j\rangle$. Define

$$U_k|\psi_j\rangle = \begin{cases} |\psi_j\rangle & \text{if } k \neq j, \\ e^{i\theta_k}|\psi_k\rangle & \text{if } k = j. \end{cases} \tag{6.1}$$

Then $U = \Pi_{k=1}^{p^m} U_k$. It is left to show how to construct U_k. For this we will show how to construct a transformation R with the following properties: R takes $|\psi_k\rangle$ to $\lambda|(p-1)^m\rangle$ for some complex number λ of absolute value 1. We don't care what R does to the rest of the vectors. Given such an R, we can use it to construct U_k as follows. We first apply R. We then apply the generalized Toffoli gate which takes $|(p-1)^m\rangle$ to $e^{i\theta_k}|(p-1)^m\rangle$ and does nothing to the rest of the basis states. Then we apply R^{-1} which takes $\lambda|(p-1)^m\rangle$ to $|\psi_k\rangle$. This indeed achieves U_k, as can be easily checked.

To construct R, and similarly R^{-1}, we do the following. We start with $|\psi_k\rangle$, and we first make the coefficient in front of $|0^m\rangle$ zero, by a rotation in the plane spanned by $|0^m\rangle$ and $|(p-1)^m\rangle$. This is a special case of the $T_m(Q, i_1, \ldots, i_p)$ which we have constructed before. Thus, the weight of $|0^m\rangle$ has been shifted to $|(p-1)^m\rangle$. In the same way, the weights in front of all basis vectors, one by one, can be shifted to $|(p-1)^m\rangle$, and this achieves R. □

6.2. Useful lemmas for proving universality. We proceed to state two geometrical lemmas. These will be used in the proofs of universality of the sets of gates $\mathcal{G}_1$ and $\mathcal{G}_2$. These lemmas are due to Kitaev, who used them for proving universality of the set of gates in [50].

LEMMA 2. *Let $n \geq 3$. Let $|\alpha\rangle \in \mathcal{C}^n$. Let H be the subgroup in $SU(n)$ which fixes $|\alpha\rangle$, and let $V \in U(n)$ be a matrix which does not leave the subspace spanned by $|\alpha\rangle$ invariant. Then the subgroup generated by the subgroups H and $V^{-1}HV$ is dense in $SU(n)$.*

The proof of this lemma can be found in the solution of Problem 8.11 in [52].

LEMMA 3. *Let U_1 and U_2 be two noncommuting matrices in $SU(2)$ such that their eigenvalues are not integer roots of unity. The subgroup generated by U_1, U_2 is dense in $SU(2)$.*

Proof. If x is an element of $SU(2)$ not of finite order, then the closed subgroup generated by x is connected and of dimension 1. The closed group generated by both U_1 and U_2 is thus connected and is noncommutative. Any connected noncommutative subgroup of $SU(2)$ is *all* of $SU(2)$. □

6.3. Universality of the set of gates $\mathcal{G}_1$ for polynomial codes. We would now like to show that the set of gates for polynomial codes $\mathcal{G}_1$ is universal.

THEOREM 10. *Consider p-qudits for a prime $p > 3$. The set of gates $\mathcal{G}_1$ together with all phase factors is universal for $U(p^5)$.*

Let us first show that we have at our disposal all classical gates on two qudits. Let F be a finite field of characteristic p for some prime p and size $q = p^r$ for some r. Consider the basic classical reversible gates on F-valued registers, including addition and multiplication by a nonzero constant, reversible addition, $[a, b] \to [a, a + b]$, and Toffoli $[a, b, c] \to [a, b, c + ab]$. For a characteristic different than 2, we also consider the second basic set, which is the above set of gates but with the Toffoli gate replaced by the squaring gate: $[a, b] \to [a, b + a^2/2]$. We claim the following.

LEMMA 4 (folklore). *Both sets of basic reversible gates, applied on $k \geq 3$ qudits, generate the full permutation group S_{q^k}. In both cases an ancillary register in the state 0 is added to the system.*

Proof. We start with the first set of basic gates. Denote by G_k the group generated by the basic gates on k registers. For a function $g : F^{k-1} \to F$ we define the permutation $\pi_g : F^k \to F^k$ by

$$\pi_g([a_1, \ldots, a_k]) = [a_1 + g(a_2, \ldots, a_k), a_2, \ldots, a_k].$$

The coordinate to which g is added is called the target coordinate. The main result of Ben-Or and Cleve [23] is that, for $k \geq 3$ and any such function g, $\pi_g \in G_k$.

We now use functions of the form π_g to generate all of S_{q^k}. First, recall that any permutation on S_{q^k} can be written as a product of transpositions of the form $\tau_{i,j}$ for $i, j \in F^k$ such that the string i differs from the string j in only one coordinate ($\tau_{i,j}$ leaves all other coordinates unchanged). It thus suffices to generate $\tau_{i,j}$ from functions of the form π_g. To do this, we add one ancillary dit in the state 0. Let us assume that the coordinate in which the strings i, j differ is the rth one. Define $g : F^k \to F$ to be the function that takes a string s to the value of the rth coordinate in $\tau_{i,j}(s)$. We have that $\pi_g([a_0, a_1, \ldots, a_k]) = [a_0 + g(a_1, \ldots, a_k), a_1, \ldots, a_k]$, which operates on an ancillary coordinate (a_0) plus the k original coordinates, is at our disposal.

To achieve $\tau_{i,j}$, we apply π_g. This is followed by π'_g, which we define to be $\pi'_g([a_0, a_1, \ldots, a_k]) = [a_0, a_1, a_{r-1}, a_r - g(a_1, \ldots, a_{r-1}, a_0, a_{r+1}, \ldots, a_k), a_{r+1}, \ldots, a_k]$. We note that

$$[a_1, \ldots, a_k] \to [a_1 - g(a_2, \ldots, a_k), a_2, \ldots, a_k]$$

is in G_k, by applying π_g $q - 1$ times. Hence, by renaming coordinates, π'_g is also at our disposal. By the definition of g we have that $\pi'_g \pi_g [0, a_1, \ldots, a_k] = [g[a_1, \ldots, a_k], a_1, \ldots, a_{r-1}, 0, a_{r+1}, \ldots, a_k]$ which is the desired transposition up to swapping the coordinates.

The proof for the second set of basic reversible gates is similar by using the fact that in this case $\pi_g \in G_k$ for any $k \geq 2$, which was also proved in [23]. ∎

Remark 2. In fact, the same result can be proved without the ancillary qudit, by using results from Coppersmith and Grossman [35]. We do not give details here.

Since $\mathcal{G}_1$ contains all basic gates, this implies that we have at our disposal all classical gates on three (and therefore also on two) qudits. Next, we prove an analogue for F_p of the well-known fact that one-qubit gates and classical two-qubit gates are universal for qubits [19].

LEMMA 5. *The group G generated by the set of gates consisting of all one-qudit gates $SU(C^p)$ and all classical two-qudit gates is the special unitary group on two qudits $SU(C^{p^2})$.*

Proof. We will use the fact that the lemma we are trying to prove is already known for the case of $p = 2$. Let S be the two-dimensional subspace in C^p spanned by the first two basis vectors $|0\rangle$ and $|1\rangle$. Clearly, $SU(S)$ is in $U(C^p)$. Let S_ℓ be the two-dimensional subspace in the Hilbert space of the ℓth qudit, for $\ell \in \{0, 1\}$, and let $A = S_1 \otimes S_2$. Since we have at our disposal all classical gates, we also have all permutations of basis vectors of A. We can use the fact that A is isomorphic to the Hilbert space of two qubits, and Lemma 5 for the case of qubits, and so this implies that $SU(A)$ can be generated. We now augment A by one computational basis state at a time to get the entire space.

Consider $|i_1\rangle, \ldots, |i_{p^2-2}\rangle$ to be a sequence of computational basis vectors which completes the basis of A, $|00\rangle, |10\rangle, |01\rangle, |11\rangle$, to a basis for C^{p^2}. Define $A_j = A \oplus |i_1\rangle \oplus \cdots \oplus |i_j\rangle$. We prove by induction on j that we can generate $SU(A_j)$. Suppose that we can generate $SU(A_{j-1})$. The classical gate which permutes $|i_j\rangle$ and $|i_{j-1}\rangle$, leaving all other states unchanged, is at our disposal. This gate is in $SU(A_j)$ and does not leave the subspace spanned by $|i_j\rangle$ invariant. Hence, we can apply Lemma 2 to get all of $SU(A_j)$. ∎

Lemma 5 implies that it would suffice to show that all one-qudit gates are at our disposal. Denote by Q the one-qudit matrix of the form

$$Q = \begin{pmatrix} w & & & \\ & 1 & & \\ & & \ddots & \\ & & & 1 \end{pmatrix}, \tag{6.2}$$

which applies a phase factor of w on the state $|0\rangle$.

LEMMA 6. *Q and Q^{-1} are in the subgroup generated by $\mathcal{G}_1$ on three qudits.*

Proof. We will generate $Q \otimes I \otimes I$, which applies the following transformation:

$$\begin{aligned} |0\rangle|a\rangle|b\rangle &\longmapsto w|0\rangle|a\rangle|b\rangle, \\ |j\rangle|a\rangle|b\rangle &\longmapsto |j\rangle|a\rangle|b\rangle, \quad j \neq 0. \end{aligned} \tag{6.3}$$

To achieve this transformation, we view this gate as applying multiplication by w of the second qudit, conditioned that the first qudit is 0. Recall that in our notation P is a one-qudit gate that applies a phase shift $P|a\rangle = w^a|a\rangle$, and B is a one-qudit gate that applies a bit shift $B|a\rangle = |a + 1 \bmod \mathrm{p}\rangle$. Both B and P are in our repertoire. Denote by $\Lambda(B)$ the controlled B, which applies B on the second qudit, conditioned that the first qudit is 0, and applies the identity on the second qudit if the state of the first qudit is anything but 0. $\Lambda(B)$ is also at our disposal by Lemma 4. Now consider the commutator

$$P^{-1} \cdot \Lambda(B)^{-1} \cdot P \cdot \Lambda(B), \tag{6.4}$$

where the P's are applied to the second qudit. This is exactly the gate we want, since, if the first qudit is 0, the matrix which is applied on the second qudit is $P^{-1} \cdot B^{-1} \cdot P \cdot B = wI$. If the first qudit is in a basic state which is not $|0\rangle$, the matrix which is applied on the second qudit is the identity. ∎

We now consider the two commutator matrices in $\langle \mathcal{G}_1 \rangle$, the group generated by $\mathcal{G}_1$:

$$X = HQH^{-1}Q^{-1}, \quad Y = HQ^{-1}H^{-1}Q, \tag{6.5}$$

where H is the generalized Fourier transform. We also define the two-dimensional subspace S:

$$S = span\left\{ |0\rangle, \sum_{b\in F_p, b\neq 0} |b\rangle \right\}. \tag{6.6}$$

The claim is that X and Y operate as the identity on the orthogonal subspace to S.

LEMMA 7. *X and Y operate as the identity on $S_i^{\perp}$.*

Proof. It is easy to write down explicitly the matrix elements of $X = HQH^{-1}Q^{-1}$ and $Y = HQ^{-1}H^{-1}Q$:

$$X_{ab} = \begin{cases} \delta_{ab} + \frac{1}{p}(w-1) & \text{if } b \neq 0, \\ (\delta_{ab} + \frac{1}{p}(w-1))w^{-1} & \text{if } b = 0, \end{cases} \tag{6.7}$$

$$Y_{ab} = \begin{cases} \delta_{ab} + \frac{1}{p}(w^{-1}-1) & \text{if } b \neq 0, \\ (\delta_{ab} + \frac{1}{p}(w^{-1}-1))w & \text{if } b = 0. \end{cases}$$

To see that X and Y operate as the identity on the subspace orthogonal to S, consider the matrices $X - I$ and $Y - I$, which satisfy (6.7) if we subtract δ_{ab} from each term. We show that the orthogonal vectors to S are all in the kernel of $X - I$ and $Y - I$. A vector v orthogonal to S satisfies

$$v_0 = 0, \quad \sum_{b,b\neq 0} v_b = 0, \tag{6.8}$$

and thus

$$\sum_{b\in F_p} (X-I)_{ab} v_b = \frac{1}{p}(w-1)\sum_{b\neq 0} v_b = 0, \tag{6.9}$$

$$\sum_{b\in F_p} (Y-I)_{ab} v_b = \frac{1}{p}(w^{-1}-1)\sum_{b\neq 0} v_b = 0. \qquad \square$$

We denote by X' and Y' the two matrices confined to S. We claim that these matrices generate a dense subgroup in the group of 2×2 unitary matrices $U(2)$ operating on S. We will want to use Lemma 3, and the main effort is to prove that the eigenvalues of X' and Y' are not integer roots of unity. The proof of this fact is based on some basic results regarding cyclotomic fields and Galois fields, which can be found in [98].

LEMMA 8. *For $p > 3$, the eigenvalues of X' and Y' are not integer roots of unity.*

Proof. The subspace S is spanned by the orthonormal basis vectors $|0\rangle$ and $|\alpha\rangle = \frac{1}{\sqrt{p-1}} \sum_{b\in F_p, b\neq 0} |b\rangle$. By (6.7) and a little algebra we get

$$X'|0\rangle = \left(1 + \frac{1}{p}(w-1)\right) w^{-1}|0\rangle + \frac{\sqrt{p-1}}{p}(w-1)|\alpha\rangle, \tag{6.10}$$

$$X'|\alpha\rangle = \frac{\sqrt{p-1}}{p}(w-1)w^{-1}|0\rangle + \left(1 + \frac{p-1}{p}(w-1)\right)|\alpha\rangle,$$

and for Y we get the transformation

$$Y'|0\rangle = \left(1 + \frac{1}{p}(w^{-1}-1)\right) w|0\rangle + \frac{\sqrt{p-1}}{p}(w^{-1}-1)|\alpha\rangle, \tag{6.11}$$

$$Y'|\alpha\rangle = \frac{\sqrt{p-1}}{p}(w^{-1}-1)w|0\rangle + \left(1 + \frac{p-1}{p}(w^{-1}-1)\right)|\alpha\rangle.$$

It is easy to verify that X', and similarly Y', have determinant 1. The characteristic polynomial for X' is $\lambda^2 - \mathrm{Tr}(X')\lambda + \mathrm{Det}(X')$, which amounts to

$$f(\lambda) = \lambda^2 - \frac{2 + (p-1)(w + w^{-1})}{p}\lambda + 1. \tag{6.12}$$

Y' has exactly the same characteristic polynomial. We want to show that the roots of this polynomial are not integer roots of unity. Let us assume that one of the roots of the above polynomial is a primitive nth root of unity, denoted by ζ_n, for some integer n. The other solution is the complex conjugate of ζ_n, and we have

$$\frac{2 + (p-1)(w + w^{-1})}{p} = \zeta_n + \zeta_n^{-1}. \tag{6.13}$$

We will first prove that $n = p$ or $2p$. Denote by $Q(w)$ and $Q(\zeta_n)$ the Galois extensions of the field of rationals obtained by adjoining w and ζ_n, respectively, to the field of rationals Q. Also, denote by $Q(w)^+$ the maximal real subfield of $Q(w)$ obtained by extending Q by $w + w^{-1}$, and similarly denote the maximal real subfield of $Q(\zeta_n)$ by $Q(\zeta_n)^+$. By (6.13), $Q(\zeta_n)^+ = Q(w)^+$.

The degree of the extension $\deg(Q(w)/Q(w)^+)$ is exactly 2, since w is a root of the minimal two degree polynomial $x^2 - (w + w^{-1})x + 1$ over the field $Q(w)^+$. Similarly, $\deg(Q(\zeta_n)/Q(\zeta_n)^+) = 2$. On the other hand, $\deg(Q(w)/Q) = p - 1$ and $\deg(Q(\zeta_n)/Q) = \phi(n)$, by Theorem 2.5 in [98]. Now, for three fields, F_1, F_2, and F_3 such that F_3 extends F_2 which extends F_1, we have $\deg(F_3/F_1) = \deg(F_3/F_2)\deg(F_2/F_1)$. It follows that

$$\deg(Q(w)^+/Q) = \frac{p-1}{2}, \quad \deg(Q(\zeta_n)^+/Q) = \frac{\phi(n)}{2}. \tag{6.14}$$

But $Q(w)^+ = Q(\zeta_n)^+$, which implies that the degrees of extensions are equal, so $\phi(n) = p - 1$.

Now if $p > 3$, then $w + w^{-1} \notin Q$, since $\deg(Q(w + w^{-1})/Q) = (p-1)/2 > 1$. Since $w + w^{-1} \in Q(w) \cap Q(\zeta_n)$, we have $Q \neq Q(w) \cap Q(\zeta_n)$. If p and n were relatively prime, we would have $Q = Q(w) \cap Q(\zeta_n)$ (by Proposition 2.4 in [98]), and so p must divide n, say, $n = p^r m$, with m coprime to p. This implies that

$$\phi(n) = p^{r-1}(p-1)\phi(m). \tag{6.15}$$

Since, as we have seen before, $\phi(n) = p - 1$, we have $p^{r-1}\phi(m) = 1$. We deduce that $r = 1$ and $\phi(m) = 1$. This can be satisfied only if $m = 1$ or $m = 2$, namely, $n = p$ or $n = 2p$.

In the first case of $p = n$ we get

$$\frac{1 + (p-1)\cos(2\pi/p)}{p} = \cos(2k\pi/p), \tag{6.16}$$

where we have set $\xi_n = e^{2\pi i k/n}$. If $p > 3$, (6.16) is not satisfied by any integer k, since the left-hand side is a convex combination of $\cos(2\pi/p)$ and 1, and no real part of a pth root of unity lies between these two points.

In the second case of $p = 2n$, we get

$$\frac{1 + (p-1)\cos(2\pi/p)}{p} = \cos(k\pi/p). \tag{6.17}$$

Ruling this out is similar to ruling out (6.16), except that we have to show that the case of $k = 1$ does not hold, namely, $\frac{1+(p-1)\cos(2\pi/p)}{p} \neq \cos(\pi/p)$. This is true because the cosine function is a concave function. The lemma follows. □

We can now show that we have at our disposal all one-qudit gates.

CLAIM 7. *For $p > 3$, the set $\mathcal{G}_1$ operating on three qudits generates all one-qudit gates.*

Proof. Since we are allowed to operate on three qudits, we can generate Q by Lemma 6. We can thus generate X and Y. It is easy to see that, if $w \neq \pm 1$ or, equivalently, $p \neq 2$, the off-diagonal terms of $X'Y' - Y'X'$ are not zero, and so X' and Y' do not commute. We can therefore apply Lemma 3, by using the fact that the eigenvalues are not roots of unity, by Lemma 8. We thus have a dense subset of the special unitary group $SU(2)$ on all subspaces S. We now want to augment the subspace S by one basis vector at a time, to get the entire $SU(p)$ group. To do this, we define $S_0 = S$ and, for $p > j \geq 1$, $S_j = S \oplus |1\rangle \oplus \cdots \oplus |j\rangle$. We have seen that we can generate $SU(S_0)$. Assume by induction that we can generate $SU(S_{j-1})$, and let us see that we can generate $SU(S_j)$. Let $|\gamma\rangle$ be the state orthogonal to S_{j-1} inside S_j. If we set $|\delta\rangle = \ sum_{k=j+1}^{p-1} |k\rangle$, then it is easy to check that $|\gamma\rangle$ is a nontrivial combination of $|\delta\rangle$ and $|j\rangle$. We have at our disposal a classical gate which exchanges $|0\rangle$ and $|j\rangle$. Moreover, this gate is in $SU(S_j)$. This gate does not leave the subspace spanned by $|\gamma\rangle$ invariant. Hence we can apply Lemma 2 and get all of $SU(S_j)$. Since $SU(S_{p-1}) = SU(p)$, the claim is proved. ∎

The proof of Theorem 10 now follows easily.

Proof of Theorem 10. We have shown that we have at our disposal all one-qudit gates. Lemma 4 shows that, by working on five qudits, we also have in our repertoire all classical gates on three qudits and, in particular, all classical gates on two qudits which act trivially on the third qudit. Lemma 5 implies that we can generate all two-qudit gates. The theorem follows from Theorem 9, which shows that these matrices can be used to construct all matrices on five qudits $U(p^5)$. ∎

6.4. Universality of the set of gates $\mathcal{G}_2$ used for CSS codes. The set of gates used for CSS codes is shown here to be universal. The theorem is based on an argument by Kitaev [50] which is given here for completeness.

THEOREM 11. *The set of gates $\mathcal{G}_2$ together with all phase factors is universal for $U(2^5)$.*

Proof. We denote by P the gate that takes $|1\rangle$ to $i|1\rangle$ and does nothing to $|0\rangle$. $\Lambda(P)$ is the controlled P, namely, the gate which applies P on a second qubit only if the first qubit is $|1\rangle$ and does nothing otherwise. The proof is based on a result by Kitaev [50], which asserts that the set of gates $\{\Lambda(P), H\}$ is universal. Since the Hadamard gate H is already in our set $\mathcal{G}_\in$, we need only to show how to construct $\Lambda(P)$ from our set of gates. We will denote by $T_{a_1,\ldots,a_k}$ a generalized Toffoli on the k qubits $a_1, \ldots, a_k$. This gate applies NOT on the kth qubit conditioned that the first $k-1$ qubits are in the state $|1\rangle$. We first construct $T_{1,2,4,5}$ out of five qubits. This can be done by using three-qubit Toffoli gates as follows:

$$
\begin{aligned}
a, b, c, d, e \quad &\overset{T_{1,2,3}}{\longmapsto} \\
a, b, c + ab, d, e \quad &\overset{T_{3,4,5}}{\longmapsto} \\
a, b, c + ab, d, e + cd + abd \quad &\overset{T_{1,2,3}}{\longmapsto} \\
a, b, c, d, e + cd + abd \quad &\overset{T_{3,4,5}}{\longmapsto} \\
a, b, c, d, e + abd,
\end{aligned}
\tag{6.18}
$$

which is exactly $T_{1,2,4,5}$. Define $X = P_4^3 T_{1,2,3,4} P_4 T_{1,2,3,4}$, where P_4 applies the gate P to the fourth qubit. X takes $|1110\rangle \longmapsto i|1110\rangle$, $|1111\rangle \longmapsto -i|1111\rangle$ and does nothing

to the other basis states. X^2 is the three-qubit gate which gives $|111\rangle \longmapsto -|111\rangle$ and identity on the rest of the basis vectors, tensored with identity on the fourth qubit. Now, to construct $\Lambda(P)$, we apply $P_3^3 T_{1,2,3} P_3 T_{1,2,3}$ followed by X^2. The first sequence of gates gives $|110\rangle \longmapsto i|110\rangle, |111\rangle \longmapsto -i|111\rangle$ and identity on the rest. By applying X^2 we get $\Lambda(P)$ tensored with identity on the third qubit. The theorem now follows from Kitaev [50].

We now provide Kitaev's argument which uses Lemmas 2 and 3 to show that $\Lambda(P)$ and the Hadamard gate are universal. Denote that

$$X_1 = H_1 \Lambda(P)_{1,2} H_1, \qquad X_2 = H_2 \Lambda(P)_{2,1}^{-1} H_2. \tag{6.19}$$

Define $Y_1 = X_1 X_2^{-1}$ and $Y_2 = X_2 X_1^{-1}$. Note that Y_1 and Y_2 both operate as the identity on the two states $|00\rangle$ and $|\eta\rangle = |01\rangle + |10\rangle + |11\rangle$. Denote by L the subspace orthogonal to $|00\rangle$ and $|\eta\rangle$. Then $Y_1\ Y_2 \in SU(L)$. Y_1, and Y_2 do not commute, and their eigenvalues are $\frac{1}{4}(1 \pm \sqrt{15})$. Hence, by Lemma 3 they generate a dense subgroup in $SU(L)$. Now add to Y_1, Y_2 also the gate $\Lambda(P)$ itself. This gate fixes $|00\rangle$ but does not stabilize the space $|\eta\rangle$. We can use Lemma 2 to show that the set $\{Y_1, Y_2, \Lambda(P)\}$ generates a dense subgroup in $SU(L \oplus |\eta\rangle)$. Finally, add H_1 to the set $Y_1, Y_2, \Lambda(P)$. We have seen that $Y_1, Y_2, \Lambda(P)$ generates a dense set in the subgroup that fixes $|00\rangle$, while H_1 is not in this subgroup. Hence, $H_1, Y_1, Y_2, \Lambda(P)$ (which are all gates generated by H and $\Lambda(P)$) generate a dense subgroup of $SU(L \oplus |\eta\rangle \oplus |00\rangle) = SU(4)$. Together with all phase factors, we get the unitary group on two qubits. □

7. Fault tolerance for independent probabilistic noise. In this section we prove our main result: the threshold theorem for fault tolerance in the presence of probabilistic noise with a constant error rate. To do this we use the ingredients we have developed in the previous sections: quantum error correcting codes and fault-tolerant procedures on states encoded by these codes. The construction is based on a simulation of an unreliable circuit M_0 by another circuit M_1, which computes the same function. The new circuit M_1 is deeper and requires more space than M_0 but only by a constant factor. The advantage is that, under certain conditions on the error rate, M_1 is more reliable than the original circuit M_0. In such a case, the simulation can be applied recursively, each time achieving further improvement in the effective error rate. The final quantum circuit M_r, which is only polylogarithmically larger and deeper than M_0, can be shown to be fault-tolerant against a constant error rate. To analyze the propagation of errors in M_r, we define the notion of sparse errors and sparse fault paths, by using hierarchical definitions that fit the hierarchical structure of the construction. The threshold theorem is proved in two parts. First, we show that sparse fault paths are good, meaning that they cause sparse errors which do not affect the final result. Second, we show that nonsparse fault paths are rare, as long as the error rate is below a certain threshold.

For this section, we use the terminology of qubits. Everything works in exactly the same way if the particles are qudits instead, as is required in the scheme which uses the polynomial codes. In this case, the final circuit will of course consist of p-qudits, where p is some finite dimension.[5]

[5]One can of course apply our construction, which uses polynomial codes, such that the final circuit is implemented with qubits. For this, we simply replace each p-qudit in the final circuit with $\lceil \log(p) \rceil$ qubits. The proof that the new circuit is fault-tolerant follows similar ideas as in section 9.

7.1. Quantum computation codes. In order to compute on encoded states, we need a quantum code accompanied with a universal set of gates which can be applied fault-tolerantly (namely, with small spread) on states encoded by C. The code should also be accompanied with fault-tolerant decoding, zero-state preparation, and error correction procedures. We define the following.

DEFINITION 20. *A quantum code is called a quantum computation code with spread* 1 *if it is accompanied with a universal set of gates G with fault-tolerant procedures and with fault-tolerant zero-state preparation, decoding, and correction procedures, all with spread* 1. *Moreover, we require that*

(1) *all procedures use only gates from G, and*

(2) *the correction procedure takes any density matrix to some word in the code.*

The first restriction in the definition of a quantum computation code allows us to use this code in a recursive construction. The second restriction is required for a more subtle reason, as will become clear in the proof of Lemma 9.

Theorem 5 implies that the polynomial QECC accompanied by the set of gates $\mathcal{G}_1$ is a quantum computation code with spread 1. Theorem 6 implies the same for CSS codes over F_2 restricted as in section 5.1, with the set of gates $\mathcal{G}_2$.

In our proof of fault tolerance, we will be interested not in the spread of one procedure but in the spread of a *sequence* of two procedures, namely, an encoded gate preceded by an error correction (this will be referred to as a rectangle). For the case of procedures of spread 1, this does not matter, since by augmenting two such procedures one after the other, the resulting circuit consisting of the pair of procedures also has spread 1.

Unfortunately, this does not hold for the case in which the spread of the procedures we augment is larger than 1. In fact, if the spread of the procedures is ℓ', the spread of a circuit consisting of two of them one after the other might be ℓ'^2. We take this into account in our definition of a quantum computation code which uses procedures of spread larger than 1. A quantum computation code with spread ℓ is defined as in Definition 20, except that we require that the spread of the decoding and zero-state preparation procedure, as well as the spread of a sequence of an encoded gate preceded by an error correction procedure, be ℓ.

Obviously, we must require that the number of errors that the code can correct q be larger than the spread of the code, so that we can tolerate at least one fault in a rectangle. In fact, we require more than that for our proof to work: We need $2\ell \leq q$, as will be seen in Lemma 9.

7.2. Recursive simulations. From now on, fix a quantum computation code C. It encodes one qubit on m qubits, it corrects q errors, and it is accompanied with a universal set of gates $\mathcal{G}$ which can be performed fault-tolerantly. We will fix m to be a constant which does not grow with n. Let M_0 be a quantum circuit using gates from $\mathcal{G}$. We simulate M_0 by a more reliable circuit M_1, as follows. Each qubit is replaced by a block of qubits. Each time step in M_0 transforms in M_1 to a working period, which consists of two stages. In the first stage, an error correction procedure is applied on each block. At the second stage, each gate which operated in the simulated time step in M_0 is replaced in M_1 by its procedure, operating on the corresponding blocks.

The input of M_1 is the input to M_0, where each input bit is duplicated m times. Before any computation is done on this input, we apply in M_1 a zero-state preparation procedure, then apply CNOT_p transversally from the given input string $|a^m\rangle$ to the encoded state $|S_0\rangle$, and discard the m initial dits. At the end of the computation we will again use redundancy: For each block, we apply a decoding procedure which

decodes the state to m copies of the logical bit, and the output of M_1 is defined as the majority of the bits in each block.

The above mapping, denoted by $M_1 = \phi(M_0)$, constitutes one level of the simulation. The mapping ϕ is then applied once again, this time on M_1, to give M_2. We repeat this r levels to get $M_r = \phi^r(M_0)$, an r-simulating circuit of M_0. The number of levels r is $O(\text{polyloglog}(V(M_0)))$, where $V(M_0)$ is the volume of M_0, i.e., the number of locations in M_0 (see Definition 5 of the term *location*). The output of M_r is defined by taking recursive majority on the outputs. This means that first we take the majority in each block of size m, then we take the majority, of m such majority bits, and so on for r levels, to give one output bit.

7.3. Blocks and rectangles. The recursive simulations induce a definition of s-blocks: Every qubit transforms to a block of m qubits in the next level, and this block transforms to m blocks of m qubits, and so on. One qubit in M_{r-s} thus transforms to m^s qubits in M_r. This set of qubits in M_r is called an s-block. This induces a division of the qubits in M_r to s-blocks, and this division is a refinement of the division to $s+1$-blocks. A 0-block in M_r is simply a qubit. In the same way, one can define s-working periods. Each time step in M_0 transforms to w time steps in M_1, and an s-working period is the time interval in M_r which corresponds to one time step in M_{r-s}.

The recursive simulation induces a partition of the set of locations in M_r to generalized rectangles. An r-rectangle in M_r is the set of locations which originated from one location in M_0. This is best explained by an example: Consider a CNOT gate which is applied in M_0 at time t on qubits q_1, q_2. The location $((q_1, q_2), t)$ in M_0 transforms in M_1 to error correction procedures on both blocks, followed by the procedure of the CNOT gate. The set of locations in these three procedures is the 1-rectangle in M_1 which originated from the location $((q_1, q_2), t)$ in M_0. More generally, an s-rectangle in M_r is the set of points in M_r which originated from one location in M_{r-s}. Note that the partition to s-rectangles is a refinement of the partition to $(s+1)$-rectangles. A 0-rectangle in M_r is just one location.

7.4. Sparse errors and sparse faults. In a noiseless scenario, the state of M_r at the end of each r-working period encodes the state of M_0 at the end of the corresponding time step. However, we assume that errors occur in M_r, and we want to analyze those. In order to analyze the propagation of errors in M_r, we need to distinguish between the actual faults that occur during the computation and the errors that are caused in the state. First, we focus on the errors in the states and define a distance between encoded states. The hierarchy of blocks requires a recursive definition.

DEFINITION 21. *Let B be the set of qubits in n r-blocks. An (r,k)-sparse set of qubits A in B is a set of qubits in which, for every r-block in B, there are at most k $(r-1)$-blocks such that the set A in these blocks is not $(r-1,k)$ sparse. A $(0,k)$-sparse set of qubits A is an empty set of qubits.*

Two density matrices ρ_1 and ρ_2 of the set of qubits B are said to be (r,k)-deviated if there exists an (r,k)-sparse set of qubits $A \subseteq B$, with $\rho_1|_{B-A} = \rho_2|_{B-A}$. The deviation satisfies the triangle inequality since the union of two sets which are (r,l_1)- and (r,l_2)-sparse, respectively, is (r,l_1+l_2)-sparse, by induction on r.

We will see that a computation is successful if the error at the end of each r-working period is sparse enough. The question is which fault paths keep the errors sparse. We will show in Lemma 9 that this is guaranteed if the fault path is sparse.

DEFINITION 22. *A set of locations in an r-rectangle is said to be (r,k)-sparse if there are no more than k $(r-1)$-rectangles in which the set is not $(r-1,k)$-sparse. A $(0,k)$-sparse set in a 0-rectangle is an empty set. A fault path in M_r is (r,k)-sparse if, in each r-rectangle, the set is (r,k)-sparse.*

7.5. The good part: Sparse fault paths keep the error sparse. We claim that if the fault path is sparse enough, then the error corrections keep the deviation small. The number of effective errors at any given level is thus constantly maintained below the dangerous zone. This is true at all levels, and indeed we prove it by induction on the level index r.

LEMMA 9. *Let C be a computation code that corrects q errors, with spread ℓ. Let M_r be the r-simulation of M_0 by C. Consider a computation subjected to an (r,k)-sparse fault path with $2k\ell \le q$. At the end of each r-working period the error is $(r,q/2)$-sparse.*

A condition of the form $k\ell \le q$ is natural, since k faults can indeed propagate to $k\ell$ errors if the spread is ℓ, and so we have to require that $k\ell \le q$ for the error correction to work. Our condition is in fact more restrictive, having the additional factor of 2, for technical reasons that will become apparent in the proof.

Proof. It is instructive to first prove this lemma for $r = 1$. This is done by induction on the time step t. For $t = 0$ the deviation is zero. Suppose that the density matrix at the end of the tth working period is $(1,q/2)$-deviated from the correct density matrix. If no errors occur during the tth working period, the error corrections would have corrected the state to $\phi(\rho(t))$, and the procedures would have taken it to the correct state $\phi(\rho(t+1))$. However, k faults did occur in each rectangle. We will use the fact that the rectangle has spread ℓ. Let us add the k faults to the fault path in the rectangle one by one. While adding the ith fault, we have $(q/2 + (i-1))\ell \le q - \ell$, because $i \le k$, and $2k\ell \le q$. Hence, this satisfies the requirement in Definition 17, and so we can deduce that each of the faults we add increases the deviation in the state at the end of the rectangle by at most ℓ qubits in each block. Thus, we have in each block at most $k\ell$ qubits which are affected by the faults, and the final deviation is at most $k\ell \le q/2$. This proves the theorem for $r = 1$.

For general r, we prove two assertions together, by using induction on r. The first assertion implies the desired result.

1. Consider n r-blocks, in a density matrix ρ_r which is $(r,q/2)$-deviated from $\phi^r(\rho_0)$, where ρ_0 is a density matrix of n qubits. At the end of an r-working period which r-simulates the operation of g_0 on ρ_0, with an (r,k)-sparse set of faults, the density matrix is $(r,q/2)$-deviated from $\phi^r(g_0 \circ \rho_0)$.
2. Consider n r-blocks in the state ρ_r such that x of the blocks are in an arbitrary density matrix and y of them are in a density matrix which is $(r,q/2)$-deviated from some word in the code $\phi^r(\rho_0)$. Consider an r-working period which r-simulates the operation g_0 with an (r,k)-sparse set of faults, applied on ρ_r. We claim that at the end of the r-working period the state is the same as if we started with the y blocks as they are and the x blocks corrected to some word in the code. More precisely, at the end of the r-working period the density matrix is $(r,q/2)$-deviated from $\phi^r(g_0 \circ \rho_0')$, where ρ_0' is a density matrix of n qubits which when reduced to the qubits corresponding to the y good blocks is equal to ρ_0.

For $r = 1$ the proof of the first assertion is as before. The second assertion is true because of a similar argument, using the second requirement in the definition of a quantum computation code (Definition 20), namely, that the error correction

procedure takes any density matrix to a word in the code. Let us now assume both claims for r and prove each of the claims for $r+1$.

Proof of Assertion 1. We consider an $(r+1)$-working period operating on ρ_{r+1}, $(r+1)$-simulating the procedure encoding g_0 on ρ_0. The $(r+1)$-simulation working period can be seen as an r-simulation of one working period in M_1 which 1-simulates some computation in M_1, consisting of an error correction procedure followed by an encoded gate.

Consider for a moment the 1-simulation circuit. We know that this circuit has spread ℓ. By using the fact that $k\ell + q/2 \leq q$, we know that if at most k faults occurred in this 1-simulation, and if the input state is $(1, q/2)$-deviated from being correct, then the output state is at most $(1, q/2)$-deviated from the correct state, namely, from $\phi(g_0(\rho_0))$.

We now turn back to the r-simulation of this circuit, namely, to our $(r+1)$-working period. We now assume a wrong assumption: The state at the end of each r-working period (in our $(r+1)$-working period) is $(r, q/2)$-deviated from some word in the code. This means that the $q/2$ problematic input blocks are $(r, q/2)$-deviated from some word in the code and, moreover, that at the end of each of the problematic r-rectangles the state of these blocks is $(r, q/2)$-deviated from some word in the code. In this case the proof of the first assertion follows easily from our first induction assumption, as follows.

Let w be the number of r-working periods in the $(r+1)$-working period. By the induction assumption on the first assertion, we have that at the end of each one of the r-working periods the matrix is $(r, q/2)$-deviated from what it is supposed to be by the computation we are r-simulating, namely, by the 1-simulation with spread ℓ. After w applications of this induction assumption, we get that the matrix at the end is $(r, q/2)$-deviated from a matrix $\phi^r(\rho_1)$, where ρ_1 is $(1, q/2)$-deviated from $g_0(\rho_0)$. This implies that the final density matrix is $(r+1, q/2)$-deviated from the correct matrix $\phi^{r+1}(g_0(\rho_0))$.

To release the wrong assumption, we use the induction hypothesis on the second assertion. We claim that nothing changes in the above argument if we apply, before each r-working period, an error correction procedure on each r-block, which has an (r, k)-sparse set of faults. By the induction assumption on the first assertion, for blocks which are $(r, q/2)$-deviated from some word in the code, this will remain the case after this error correction. Consider a block which is not $(r, q/2)$-deviated from some word in the code. Then the error correction will indeed change it to a block which is $(r, q/2)$-deviated from some word in the code. If the next r-rectangle that operates on that block is bad (namely, the fault path in this r-rectangle is not (r, k)-sparse), then the fact that we have added the correction does not change anything in the argument, since the faults can be chosen adversarially to ruin the entire block. If the next r-rectangle is good (namely, the fault path in it is (r, k)-sparse), then by the induction assumption on the second assertion this correction will happen in any case, and thus does not matter. Hence, the above argument goes through.

Proof of Assertion 2. The proof follows almost exactly the same argument as for the first assertion. We consider again an r-simulation of a 1-simulation. The first stage of the 1-simulation we consider here is a 1-error correction which takes any word to some word in the code, and so it is supposed to take the 1-blocks corresponding to the y-blocks to their state $\phi(\rho_0)$ and the x-blocks to some state. Hence, the 1-simulation is supposed to take the state to $\phi(\rho_0')$ as in the assertion. The remainder of the procedure is supposed to apply $\phi(g_0)$ to this state. Once again impose the wrong assumption as in the proof of the first assertion, and use the fact that the

spread of the 1-circuit is ℓ. By the induction assumption on the first assertion, we have that, at the end of each one of the r-working periods in the r-simulation of the above 1-simulation, the matrix is $(r, q/2)$-deviated from what it is supposed to be. We get that, under this assumption, the final matrix would be $(r, q/2)$-deviated from a matrix $\phi^r(\rho_1)$, where ρ_1 is $(1, q/2)$-deviated from $\phi(\rho')$. This implies that the final matrix is $(r+1, q/2)$-deviated from $\phi^r(\rho'_0)$. The relaxation of the wrong assumption is done exactly as before. □

This lemma implies that, if the faults are sufficiently sparse, the level of deviation can be kept below a certain value for the entire computation, and so at the end of the computation the set of errors is sparse. We need to show that in this case the recursive majority of the output bits indeed gives the correct answer.

LEMMA 10. *Let $2q+1 \leq m$. Let the final density matrix of M_r be $(r, q/2)$-deviated from the correct one. Consider the distribution on n bit strings which is obtained by measuring the output and taking recursive majority on each r-block. This distribution is equal to the output distribution of M_0.*

Proof. Let ρ_r be the correct final density matrix of M_r. Let ρ'_r be the final density matrix which is $(r, q/2)$-deviated from ρ_r. This remains true if we apply a measurement of all of the qubits and also if we discard certain r-blocks which do not correspond to the output of the computation. We can thus assume that ρ_r and ρ'_r are the density matrices of the output qubits, that they are mixtures of basis states, and that ρ'_r is $(r, q/2)$-deviated from ρ_r.

Note that, due to the reading procedure, the correct density matrix ρ_r is in the subspace which is spanned by basis states in which all of the coordinates in one r-block are equal, i.e., are of the form $|i_1^{m^r}, i_2^{m^r}, \ldots, i_n^{m^r}\rangle$. We have to show that, when we measure the qubits as a density matrix which is $(r, q/2)$-deviated from such a matrix, and we take the recursive majority, we get the correct distribution.

The matrix ρ_r can be written as $\{p_i, |\alpha_i\rangle\}$, where $|\alpha_i\rangle = |i_1^{m^r}, i_2^{m^r}, \ldots, i_n^{m^r}\rangle$. All qubits in an r-block are equal, since the matrix is correct. The probability that the recursive majority string is i is exactly p_i. ρ'_r can be written as $\{q_j, |\beta_j\rangle\}$, where $|\beta_j\rangle$ are basis vectors. Let A be a subset of qubits such that $\rho_r|_A = \rho'_r|_A$ and A contains all of the qubits on which ρ_r operates, except an $(r, q/2)$-sparse set. We know that the reduced density matrix of ρ'_r to A is the same as that of ρ_r, and so we have that ρ'_r is supported only by $|\beta_j\rangle$ such that their restrictions to qubits in A are strings which agree on all qubits in each r-block. Moreover, we have

$$\sum_{j, \beta_j|_A = \alpha_i|_A} q_j = p_i. \tag{7.1}$$

It is easy to see that the recursive majority string for $|\beta_j\rangle$ in the above sum is the same as that of $|\alpha_i\rangle$ and therefore is equal to i. Hence, we have that the probability for the recursive majority to be i in ρ'_r is p_i, and this completes the proof. □

7.6. The bad part: Nonsparse fault paths are rare below the threshold. Let us first analyze the improvement in the effective error rate when going from M_0 to M_1. By Lemma 9 we know that, as long as the number of faults k in each rectangle in M_1 satisfies $k \leq q/2\ell$ (where q is the number of errors the code corrects and ℓ is the spread of the code), then the computation at the end is correct. Therefore, the probability for more faults than $q/2\ell$ in one rectangle is a good definition of the effective error rate: If no such event happened, than there is no error. We can easily upper bound this probability from above. We set $k_0 = \lfloor q/2\ell \rfloor$ and denote by A the

number of locations in the largest rectangle in any simulation using C. Then

$$\eta_{\text{eff}} = \binom{A}{k_0+1} \eta^{k_0+1} \tag{7.2}$$

is an upper bound on the probability for more than k_0 faults in one rectangle. We refer to this bound as the effective error rate of the new circuit M_1 (we have obviously overestimated the effective error rate in this definition, but we do not attempt to optimize our analysis here).

DEFINITION 23 (the threshold). *We define the threshold η_c to be the error rate for which $\eta_{\text{eff}} = \eta$:*

$$\eta_c = \frac{1}{\binom{A}{k_0+1}^{1/k_0}}. \tag{7.3}$$

The following claim justifies the term *threshold*.

CLAIM 8. *Suppose that $k_0 \geq 1$. For any η below the threshold $\eta < \eta_c$, we have that the effective error rate is strictly smaller than the actual error rate: $\eta_{\text{eff}} < \eta$.*

Proof. Note that $x = \eta/\eta_c < 1$.

$$\eta_{\text{eff}} = \binom{A}{k_0+1} \eta^{k_0+1} = \binom{A}{k_0+1} \eta_c^{k_0+1} x^{k_0+1} = \eta_c x^{k_0+1} = \eta x^{k_0} < \eta. \qquad \square$$

We now show that, below the threshold, bad (namely, nonsparse) fault paths are rare.

LEMMA 11. *If $\eta < \eta_c$, $\exists \delta > 0$ such that the probability $P(r)$ for the fault path restricted to an r-rectangle to be (r, k_0)-sparse is larger than $1 - \eta^{(1+\delta)^r}$.*

Proof. Let δ be such that

$$\binom{A}{k_0+1} \eta^{k_0+1} < \eta^{1+\delta}. \tag{7.4}$$

Such a δ exists for η below the threshold, by Claim 8.

The proof of the lemma follows by induction on r. The probability for a 0-rectangle, i.e., one location, to have faults which are $(0, k_0)$-sparse, namely, the probability that in this location a fault did not occur, is $1 - \eta$.

Assume for r, and let us prove for $r+1$. For the faults in an $(r+1)$-rectangle not to be $(r+1, k_0)$-sparse, there must be at least $k_0 + 1$ r-rectangles in which the fault path is not (r, k_0)-sparse. So

$$P(r+1) \geq 1 - \binom{A}{k_0+1} (1 - P(r))^{k_0+1} > 1 - \eta^{(1+\delta)^{r+1}},$$

by using the induction assumption and the fact that $\eta^{(1+\delta)^r} < \eta < \eta_c$, and hence (7.4) can be applied with $\eta^{(1+\delta)^r}$ instead of η. $\square$

We can now prove the threshold theorem.

THEOREM 12 (the threshold theorem for probabilistic noise). *Let $\epsilon > 0$. Let C be a computation code using a set of gates $\mathcal{G}$. There exist a constant threshold $\eta_c > 0$ and constants c_1, c_2, c_3 such that the following holds. Let Q be a quantum circuit, with n input qubits (qudits), which operates t time steps, uses s gates from $\mathcal{G}$, and has v locations. There exists a quantum circuit Q' which operates on $n \cdot O(\log^{c_1}(\frac{v}{\epsilon}))$ qubits*

(qudits), for time $t \cdot O(\log^{c_2}(\frac{v}{\epsilon}))$*, and uses* $v \cdot O(\log^{c_3}(\frac{v}{\epsilon}))$ *gates from* $\mathcal{G}$ *such that, in the presence of probabilistic noise with error rate* $\eta < \eta_c$*,* Q' *computes a function which is within* ϵ *total variation distance to that computed by* Q*.*

Proof. We set M_0 to be equal to Q. Let $k_0 = \lfloor q/2\ell \rfloor$ as before. We set δ to be as in (7.4). We choose r such that $v\eta^{(1+\delta)^r} < \epsilon$. We then define Q' to be M_r generated according to the above scheme. By Lemma 11, we have that the probability for a fault path to be bad, i.e., not (r, k_0)-sparse, is smaller than ϵ. By Lemmas 9 and 10, the (r, k_0)-sparse fault paths give correct outputs. The resulting function (or distribution) is thus within ϵ total variation distance from correct.

As for the overhead, the number of qubits in Q' is nm^r, the number of time steps is tw^r, where w is the largest number of time steps in one rectangle, and the number of gates is vA^r. The proof follows from our choice of r, which turns out to be some constant times $\log\log(\epsilon/v)$. ∎

8. The threshold result for general noise. So far, we have dealt only with probabilistic faults. Actually, the circuit generated by the above recursive scheme is robust also against general local noise. This makes the applicability of the result much wider.

We prove this by writing the noise operator on each qubit as the identity plus a small error term. By expanding the error terms in powers of η, we get a sum of terms, each corresponding to a different fault path. The threshold result for general noise is again proved by dividing the faults into good and bad parts. First, we show that the bad part is negligible, i.e., that the norm of the sum of all terms which correspond to nonsparse fault paths is small. The proof that the good faults are indeed good, i.e., that the error in the terms corresponding to sparse fault paths is sparse, is based on the proof for probabilistic errors, together with some linearity considerations.

The threshold one gets in this case is slightly worse.

8.1. Fault paths in the case of general noise. The notion of fault paths is less clear in the case of general noise. To define fault paths, write the final density matrix of the noisy circuit as follows:

$$\rho(t) = \mathcal{E}(t) \cdot \mathcal{L}(t) \cdot \mathcal{E}(t-1) \cdot \mathcal{L}(t-1) \ldots \mathcal{E}(0) \cdot \mathcal{L}(0)\rho(0). \tag{8.1}$$

In the above equation, $\mathcal{E}(t)$ is the noise operator operating at time t, and $\mathcal{L}(t)$ is the computation operator at time t. According to our noise model (2.3), $\mathcal{E}(t)$ can be written as a tensor product of operators, operating on the possible locations of faults at time t, $A_{i,t}$. Each such operator can be written as a sum of two operators, by using (2.4):

$$\mathcal{E}_{A_{i,t}}(t) = (1-\eta)I + \mathcal{E}'_{A_{i,t}}(t), \quad \|\mathcal{E}'_{A_{i,t}}(t)\| \le 2\eta. \tag{8.2}$$

We can replace all of the error operators in (8.1) by the products of operators of the form (8.2). We get:

$$\begin{aligned}\rho(t) = {} & \left(\otimes_{A_{i,t}}((1-\eta)I + \mathcal{E}'_{A_{i,t}})\right) \cdot \mathcal{L}(t) \cdot \left(\otimes_{A_{i,t-1}}((1-\eta)I + \mathcal{E}'_{A_{i,t-1}})\right) \cdot \mathcal{L}(t-1) \\ & \ldots \left(\otimes_{A_{i,0}}((1-\eta)I + \mathcal{E}'_{A_{i,t-1}})\right) \mathcal{L}(0)\rho(0).\end{aligned} \tag{8.3}$$

We can open up the brackets in the above expression. We get a sum of terms, where in each term, for each set of qubits $A_{i,t}$ at time t, we operate either $(1-\eta)I$ or $\mathcal{E}'_{A_{i,t}}(t)$. Thus, each term in the sum corresponds to a certain fault path. More

precisely, a fault path is a subset of the locations $\{A_{i,t}\}_{i,t}$, and the term in the sum which corresponds to this fault path is exactly the term in which we apply $\mathcal{E}'_{A_{i,t}}(t)$ on all locations in the fault path and apply $(1-\eta)I$ on the rest. As was done in the probabilistic case, we can now divide the above sum (8.3) into two parts: the sum over the *good* fault paths and the sum over the *bad* fault paths. We define the good fault paths to be those which are (r, k_0)-sparse, and the bad ones are all of the rest. We write

$$\rho(t) = \mathcal{L}_g \cdot \rho(0) + \mathcal{L}_b \cdot \rho(0). \tag{8.4}$$

We will treat each part separately.

8.2. The bad part: Nonsparse fault paths are negligible below the threshold. We show that the trace norm of the *bad* part is negligible, when η is below the threshold for general noise.

DEFINITION 24. *The threshold for general noise $\eta'_c > 0$ is defined to be the error rate η such that*

$$e \begin{pmatrix} A \\ k_0+1 \end{pmatrix} (2\eta)^{k_0+1} = 2\eta, \tag{8.5}$$

where, as before, $k_0 = \lfloor q/2\ell \rfloor$, q is the number of errors which the code corrects, ℓ is the spread of the code, and A is the maximal number of locations in a rectangle. The threshold for general noise for the code C is thus

$$\eta'_c = \frac{1}{2} e^{-k_0} \begin{pmatrix} A \\ k_0+1 \end{pmatrix}^{-k_0}. \tag{8.6}$$

Note that there is a slight difference from the threshold in the case of probabilistic noise. A factor of 2 is added to η, and the factor of e is added to the whole definition. These differences are due to the fact that the norm of the good operators in the general noise case is not smaller than 1 but can also be slightly larger than 1. η'_c is thus taken to be smaller than the threshold for probabilistic noise η_c.

We now prove that the contribution of the bad fault paths is indeed small.

LEMMA 12. *Let $\eta \langle \eta'_c, \epsilon \rangle 0$. Let M_0 use v locations. Let $r = \text{polyloglog}(\frac{v}{\epsilon})$. Then in M_r*

$$\|\mathcal{L}_b\| \leq \epsilon, \quad \|\mathcal{L}_g\| \leq 1 + \epsilon.$$

Proof. We shall rewrite the sum over all fault paths, by collecting together all of the operations according to in which r-rectangles they were done. In other words, we order the r-rectangles in some topological order, and then apply all of the operators that belong to one rectangle, before we start with a different rectangle. We now open up the operators corresponding to one r-rectangle, by using (8.2). We denote by $\mathcal{L}_b(i)$ the sum over all operators on the ith r-rectangle that correspond to errors on a bad fault path in this rectangle. Similarly, $\mathcal{L}_g(i)$ is the sum over all operators on the ith rectangle that correspond to good fault paths. If there are v procedures, we can write

$$\rho(t) = (\mathcal{L}_g(v) + \mathcal{L}_b(v)) \cdot (\mathcal{L}_g(v-1) + \mathcal{L}_b(v-1)) \ldots (\mathcal{L}_g(1) + \mathcal{L}_b(1))\rho(0) \tag{8.7}$$

for $\rho(0)$ being the initial density matrix. We first prove that

$$\forall 1 \leq i \leq v, \quad \|\mathcal{L}_b(i)\| \leq (2\eta)^{(1+\delta)^r}, \quad \|\mathcal{L}_g(i)\| \leq 1 + (2\eta)^{(1+\delta)^r}, \tag{8.8}$$

where δ is defined by

$$e\begin{pmatrix} A \\ k_0+1 \end{pmatrix}(2\eta)^{k_0+1} < (2\eta)^{1+\delta}. \tag{8.9}$$

Such a δ exists because η is below the threshold defined in (8.6). The proof of inequality (8.8) for $\eta < \eta_c'$ follows the lines of Lemma 11.

We use induction on r. It is useful to add the superscript r and denote by $\mathcal{L}_b^r(i)$ the sum over all bad fault paths in an r-rectangle. For $r = 0$, a 0-rectangle is simply one location. Hence $\mathcal{L}_b^0(i)$, which is the sum over all *bad* fault paths in this location, consists of only one term: the gate applied in this location (which could be the identity) followed by one noise operator. By (8.2), and the properties of the norm on superoperators in section 2.9, $\|\mathcal{L}_b^0(i)\| \le 2\eta$ and $\|\mathcal{L}_g^0(i)\| \le 1 + 2\eta$.

We now assume for r and prove for $r+1$. For the faults in an $(r+1)$-rectangle *not* to be $(r+1, k_0)$-sparse, there must be at least k_0+1 r-rectangles in which the fault is not (r, k_0)-sparse. So by the induction assumption on both $\mathcal{L}_b(i)$ and $\mathcal{L}_g(i)$

$$\begin{aligned} \|\mathcal{L}_b^{r+1}(i)\| &\le \begin{pmatrix} A \\ k+1 \end{pmatrix}((2\eta)^{(1+\delta)^r})^{k+1}(1+(2\eta)^{(1+\delta)^r})^{A-k-1} \\ &\le e\begin{pmatrix} A \\ k+1 \end{pmatrix}((2\eta)^{(1+\delta)^r})^{k+1}, \end{aligned} \tag{8.10}$$

where we have used the fact that $(1+(2\eta)^{(1+\delta)^r})^{A-k-1} < e$, since $(2\eta)^{(1+\delta)^r} < 2\eta$ and $2\eta A \le 1$. The right-hand side is $\le (2\eta)^{(1+\delta)^{r+1}}$ by using the fact that $(2\eta)^{(1+\delta)^r} < 2\eta$ and the fact that the threshold condition of (8.6) is satisfied for $\eta < \eta_c'$. This proves the induction step for $\mathcal{L}_b(i)$. By using $\|\mathcal{L}_g(i) + \mathcal{L}_b(i)\| = 1$ we can prove the induction step also for $\mathcal{L}_g(i)$. To prove the statement, we consider bad fault paths, i.e., at least one r-rectangle is bad. If there are v rectangles, we have

$$\|\mathcal{L}_b\| \le v \cdot (1 + (2\eta)^{(1+\delta)^r})^{v-1}(2\eta)^{(1+\delta)^r}. \tag{8.11}$$

Setting $r = \text{polyloglog}(\frac{v}{\epsilon})$ gives the desired result. ∎

8.3. The good part: Sparse fault paths give almost correct outputs.

LEMMA 13. *Let $\eta < \eta_c', \epsilon > 0$. Let M_0 have v locations. Let P_i be the probability to measure the string i in M_0 (operating without noise). Let $r = \text{polyloglog}(\frac{v}{\epsilon})$, as in Lemma* 12*, and let M_r be defined as before. We consider the operator $\mathcal{L}_g$ as in* (8.4)*, and $\rho(0)$ as the input density matrix of M_r. Then*

$$\left|\sum_{j \mapsto i}[\mathcal{L}_g \cdot \rho(0)]_{j,j} - P_i\right| \le \epsilon,$$

where $j \mapsto i$ means that taking recursive majority on the string j results in the string i.

Proof. The measurement of the output qubits of any density matrix of nm^r qubits induces some probability distribution over n-bit strings by taking the recursive majority. For any density matrix ρ which is $(r, q/2)$-deviated from the correct final density matrix of M_r, this probability distribution is the same one as the output distribution of M_0. In other words, the probability for each n-bit string is the same as that of M_0.

Since $\mathcal{L}_g$ corresponds to sparse fault paths, we would now like to apply Lemma 9 to show that $\mathcal{L}_g\rho(0)$ is $(r, q/2)$-deviated from the correct final matrix. However,

since we are dealing with general noise, the matrix $\mathcal{L}_g\rho(0)$ is not necessarily a density matrix or even a positive-semidefinite matrix. This is because the operators $\mathcal{E}'_{A_{i,t}}$ that it involves are not necessarily completely positive.

To bypass this technical issue, we recall that

$$\mathcal{E}'_{A_{i,t}} = \mathcal{E}_{A_{i,t}} - (1-\eta)I, \tag{8.12}$$

which is a weighted sum of physically admissible operators ($\mathcal{E}_{A_{i,t}}$ and I). Hence, we can write $\mathcal{L}_g$ as a weighted sum of (r, k_0)-sparse fault paths that *do* correspond to physically admissible operators:

$$\mathcal{L}_g \cdot \rho(0) = \sum_f \lambda_f \mathcal{L}_f \cdot \rho(0), \tag{8.13}$$

where each term in the above sum $\mathcal{L}_f \cdot \rho(0)$ corresponds to an evolution of the initial density matrix subject to physically admissible faults operating in a set of locations which is (r, k_0)-sparse. Lemma 9 thus applies to each term in the sum. We get that each density matrix $\mathcal{L}_f \cdot \rho(0)$ is $(r, q/2)$-deviated from correct. This means that

$$\sum_{j\mapsto i}[\mathcal{L}_g \cdot \rho(0)]_{j,j} = \sum_f \lambda_f \sum_{j\mapsto i}[\mathcal{L}_f \cdot \rho(0)]_{j,j} = \left(\sum_f \lambda_f\right) P_i. \tag{8.14}$$

However, by using (8.13), we have

$$\left|\sum_f \lambda_f - 1\right| = |\operatorname{Tr}(\mathcal{L}_g\cdot\rho(0)) - 1| = |\operatorname{Tr}((\mathcal{L}_g+\mathcal{L}_b)\cdot\rho(0)) - 1 - \operatorname{Tr}(\mathcal{L}_b\cdot\rho(0))| = |\operatorname{Tr}(\mathcal{L}_b\cdot\rho(0))|. \tag{8.15}$$

By using Property 1 of the superoperator norm (section 2) and Lemma 12, we have

$$|\operatorname{Tr}(\mathcal{L}_b \cdot \rho(0))| \le \|\mathcal{L}_b\|\|\rho(0)\| \le \epsilon, \tag{8.16}$$

which completes the proof. □

8.4. The threshold theorem for general noise. We can now prove the threshold result for general noise.

THEOREM 13 (the threshold theorem for general noise). *Let $\epsilon > 0$. Let C be a computation code with gates $\mathcal{G}$. There exist a threshold $\eta'_c > 0$ and constants c_1, c_2, c_3 such that the following holds. Let Q be a quantum circuit, operating on n qubits for t time steps, which uses s gates from $\mathcal{G}$, and has v locations. There exists a quantum circuit Q' which operates on $n\log^{c_1}(\frac{v}{\epsilon})$ qubits, for time $t\log^{c_2}(\frac{v}{\epsilon})$, and uses $v\log^{c_3}(\frac{v}{\epsilon})$ gates from $\mathcal{G}$ such that, in the presence of general noise with error rate $\eta < \eta'_c$, Q' computes a function which is within ϵ total variation distance from that computed by Q.*

Proof. We construct Q' to be the r-simulation of Q, where r is chosen such that the requirements of Lemma 12 are satisfied with $\epsilon' = \epsilon/2$. We now estimate the total variation distance between the output distribution of Q' (after taking recursive majority) and that of Q. As before, we denote the probability to measure i at the

output of Q by P_i. The total variation distance is then

(8.17)
$$\frac{1}{2}\sum_i \left| \sum_{j\mapsto i} \rho(t)_{j,j} - P_i \right| = \frac{1}{2}\sum_i \left| \sum_{j\mapsto i} ([\mathcal{L}_b \cdot \rho(0)]_{j,j} + [\mathcal{L}_g \cdot \rho(0)]_{j,j}) - P_i \right|$$
$$\leq \frac{1}{2}\left(\sum_i \left| \sum_{j\mapsto i} [\mathcal{L}_b \cdot \rho(0)]_{j,j} \right| + \sum_i \left| \sum_{j\mapsto i} [\mathcal{L}_g \cdot \rho(0)]_{j,j} - P_i \right| \right).$$

Lemma 13 implies that the second term is at most ϵ'. The first term is bounded from above by the trace norm of $\mathcal{L}_b \cdot \rho(0)$ and hence, by Lemma 7.6, by ϵ'. The sum of the two gives $2\epsilon' = \epsilon$. □

9. Fault tolerance with any universal set of gates. So far, the reliable circuits which we have constructed can use only universal set of gates associated with a quantum computation code, such as the sets $\mathcal{G}_1$ and $\mathcal{G}_2$. This is an undesirable situation, both theoretically and practically. Theoretically, we would like to be able to show that the fault-tolerance result is robust, meaning that fault-tolerant quantum computation can be performed regardless of the universal set of gates which we use. Practically, it is likely that the sets of gates $\mathcal{G}_1$ or $\mathcal{G}_2$ are difficult to implement in the laboratory. We would like to be able to implement fault-tolerant quantum computation by using the gates that are most readily available to us. Indeed, in this section we provide the desired generalization and show that the threshold result holds for any universal set of gates $\mathcal{G}$. In other words, starting from a quantum circuit which uses an arbitrary universal set of gates $\mathcal{K}$, we can implement it fault-tolerantly with any universal set of gates $\mathcal{G}$ of our choice. We require only that $\mathcal{G}$ contains a gate which discards a qubit (qudit) and a gate which adds a blank qubit (qudit) to the circuit.

The idea of the proof is that we design the final circuit in three stages: We start from the original circuit which uses gates from $\mathcal{K}$ and simulate it by a circuit which uses one of the sets of gates for which a quantum computation code exists, e.g., $\mathcal{G}_1$. We then apply our fault-tolerant construction and get a circuit M_r which uses once again gates from the same set associated with the computation code, say, $\mathcal{G}_1$. Finally, we replace every gate g in M_r by a sequence of gates from $\mathcal{G}$ which approximates the gate g to within a constant μ. The final circuit is denoted M'_r. We now prove that this construction works, if μ is chosen correctly.

In the following, we assume that we use the fault-tolerant construction with the set of gates $\mathcal{G}_1$. The discussion can be easily changed to use the gate set $\mathcal{G}_2$.

DEFINITION 25. *For any gate g in $\mathcal{G}_1$, consider the smallest circuit (in terms of number of locations) that uses gates from $\mathcal{G}$ and approximates g to within accuracy μ. Denote this circuit by $Q(g,\mu)$. Let $S(\mu)$ be the maximum number of locations in $Q(g,\mu)$ taken over all g in $\mathcal{G}_1$.*

CLAIM 9. *Fix a gate $g \in \mathcal{G}_1$. Consider the superoperator $Q'(g,\mu)$ which corresponds to applying the circuit $Q(g,\mu)$ in the presence of general noise of error rate η. We claim that, if $\eta < 1/2S(\mu)$, $\|g - Q'(g,\mu)\| \leq 3S(\mu)\eta + \mu$.*

Proof. By the definition of $Q(g,\mu)$, it suffices to prove that $\|Q(g,\mu) - Q'(g,\mu)\| \leq 3S(\mu)\eta$. We write down the superoperator corresponding to $Q'(g,\mu)$, as is done in

(8.3). By using the triangle inequality, and (2.4), we have

$$\begin{aligned}\|Q(g,\mu)-Q'(g,\mu)\| &\le S(\mu)(2\eta)(1-\eta)^{S(\mu)-1} \\ &\quad + \binom{S(\mu)}{2}(2\eta)^2(1-\eta)^{S(\mu)-2}+\cdots+(2\eta)^{S(\mu)} \\ &= (1+\eta)^{S(\mu)}-(1-\eta)^{S(\mu)}.\end{aligned} \tag{9.1}$$

Simple combinatorics now implies the result, taking into account that $S(\mu)\eta \le 0.5$. ∎

We view the circuit M'_r as composed of generalized locations, where each generalized location corresponds to the set of locations arising from the approximation of one gate in M_r. Let us compare M'_r in the presence of noise, viewed in this resolution of generalized locations, to the circuit M_r operating without noise. Claim 9 implies that at each generalized location the error in M'_r, compared to the correct gate in M_r, is at most $3S(\mu)\eta+\mu$. We would like to apply our result from section 8, and so we need to require that $3S(\mu)\eta+\mu<\eta'_c$, the threshold for general noise. By optimizing for μ we get the following definition for the threshold:

$$\eta''_c = \min\left\{\max_{\mu<\eta'_c}\frac{\eta'_c-\mu}{3S(\mu)}, \frac{1}{2S(\mu)}\right\}. \tag{9.2}$$

If η is smaller than this threshold, then Claim 9 applies, and we get that the effective error rate $\eta_{\text{eff}} = 3S(\mu)\eta+\mu$ is indeed below the threshold for general noise. This allows us to prove the threshold theorem by using any universal set of gates in the presence of general noise.

THEOREM 14 (the threshold result in full generality). *Let $\epsilon>0$. Let $\mathcal{K}$ and $\mathcal{G}$ be two universal sets of quantum gates. There exist a constant $\eta''_c>0$ and constants c_1,c_2,c_3 such that the following holds. Given any quantum circuit Q with n input qubits, which operates for t time steps, uses s gates from $\mathcal{K}$, and has v locations, there exists a corresponding quantum circuit Q' which operates on $nO(\log^{c_1}(\frac{v}{\epsilon}))$ qubits, for time $tO(\log^{c_2}(\frac{v}{\epsilon}))$, and uses $vO(\log^{c_3}(\frac{v}{\epsilon}))$ gates from $\mathcal{G}$ such that, in the presence of general noise with error rate $\eta<\eta''_c$, Q' computes a function which is within ϵ total variation distance from the function computed by Q.*

Proof. We first approximate Q by a circuit M_0 which uses only gates from the set of gates $\mathcal{G}_1$ of a computation code C. Our new circuit M_0 computes the same function as Q up to total variation distance $\epsilon/2$. We do this by approximating every one of the s gates in Q by a sequence of gates from $\mathcal{G}$ that approximates the gate to within ϵ/s. Due to the Kitaev–Solovay theorem (see section 6), the number of gates required to replace each gate in Q is $\text{polylog}(s/\epsilon)$.

We now construct M_r, the r-simulation of M_0, which again uses gates from $\mathcal{G}_1$. This is done as in section 7, except that the choice of r is taken to suit the error rate $\eta_{\text{eff}} = 3S(\mu_0)\eta+\mu_0$.

To construct Q', we replace each location in M_r by a circuit of $S(\mu_0)$ locations, by using gates from $\mathcal{G}$ that approximate the gate performed in the location to within μ_0.

We would now like to prove that the final circuit is fault-tolerant against general noise of error rate $\eta<\eta''_c$ by using essentially the same lines as in section 8. To be able to apply this proof, we do the following. We group the locations in the final circuit M'_r to groups of $S(\mu_0)$ locations, where each group corresponds to the location from which it originated in M_r. Consider the superoperator $\mathcal{L}$ associated with the application of the gates and noise operators in one generalized location corresponding

to the gate g. By Claim 9, $\|\mathcal{L}-g\| \leq \eta_{\text{eff}}$. Hence, $\|g^{-1}\mathcal{L}-I\| \leq \eta_{\text{eff}}$. We can therefore consider an equivalent circuit to M'_r, where for each generalized location, described by a superoperator $\mathcal{L}$ which consists of a sequence of gates and noise operators, we instead put the gate g followed by a noise operator $g^{-1}\mathcal{L}$. The proof now follows from the proof of Theorem 13, by using $\ell = S(\mu_0)$ for the spread of the procedures. □

The threshold value we get for arbitrary sets of gates (9.2) is of course worse than the threshold values for the fault-tolerant constructions that use gates of computation codes. The value of the threshold depends on the exact set of gates $\mathcal{G}$, because it depends on the number of gates required to approximate the gates of the computation code.

10. Robustness against exponentially decaying correlations. We would now like to show how the above results hold also in the case of exponentially decaying correlations between the noise processes, in both space and time.

10.1. Adding correlations to the noise model. Two very important assumptions were made when introducing our general model of noise.

- Locality: No correlations between environments of different qubits, except through the gates.
- The Markovian assumption: The environment is renewed at each time step, and hence no correlations between the environments at different time steps.

Both of these assumptions can be slightly released, to allow exponentially decaying correlations in both space and time, while the results of this paper still hold.

To add exponentially decaying correlations to the probabilistic noise model, we generalize it in the following way. Instead of considering independent probabilities for error in each location, we require that the probability for a fault path which contains k locations is bounded by some constant times the probability for the same fault path in the independent errors model:

$$\Pr(\text{fault path with } k \text{ errors}) \leq c\eta^k(1-\eta)^{v-k}, \tag{10.1}$$

where v is the number of locations in the circuit. Then an adversary chooses a noise operator which operates on all of the qubits in the fault path, without any restrictions. The most general case is as follows. The adversary adds some blank qubits, which are called the environment, at the beginning of the computation. At each time step, the adversary can operate a general operator on the environment and the set of qubits in the fault path at that time step. This model allows correlations in space, since the noise operator need not be of the form of a tensor product of operators on different locations. Correlations in time appear because the environment that the adversary added in is not renewed at each time step, so noise operators of different time steps are correlated. Note that the independent probabilistic noise process is a special case of this process.

10.2. Proof of the threshold theorem with exponentially decaying correlations. We observe that all of the lemmas that we have used in order to prove the threshold theorem for probabilistic noise hold in this case, except for one step which fails. It is the step that shows that bad fault paths are rare, in the case of probabilistic noise (Lemma 11). The proof of this lemma relies on the independence of faults. We observe that the proof of Lemma 11 is actually a union bound. In this section we show that the same threshold as is used for probabilistic noise (Definition 23) guarantees that the bad fault paths are rare also in the presence of probabilistic noise with exponentially decaying correlations.

We use a union bound argument, as follows. Consider fault paths in v r-rectangles. If a fault path is bad, there must be at least one r-rectangle in which it is bad, namely, not (r, k_0)-sparse. Let us concentrate on this r-rectangle. We first count the number of bad fault paths in this r-rectangle that have a minimal number of faulty locations. To do this, denote by F_j the number of minimal fault paths in a j-rectangle. We have

$$F_1 \leq \begin{pmatrix} A \\ k_0+1 \end{pmatrix} \tag{10.2}$$

and

$$F_{j+1} \leq \begin{pmatrix} A \\ k_0+1 \end{pmatrix} F_j^{k_0+1}. \tag{10.3}$$

We can solve the recursion to get

$$F_r \leq \begin{pmatrix} A \\ k_0+1 \end{pmatrix}^{\frac{(k_0+1)^r-1}{k_0}}. \tag{10.4}$$

A minimal bad fault path contains exactly $(k_0+1)^r$ locations. Now, v r-rectangles contain vA^r locations. We can bound the number of bad fault paths in v r-rectangles, that consist of $(k_0+1)^r + i$ locations, as follows. We first choose one r-rectangle (this gives a factor of v). In this rectangle we pick one of the possible minimal bad fault paths (this gives a factor of F_r). We can then choose the rest of the locations arbitrarily. This gives that the number of bad fault paths in v r-rectangles consisting of $(k_0+1)^r + i$ locations is at most

$$v \begin{pmatrix} A \\ k_0+1 \end{pmatrix}^{\frac{(k_0+1)^r-1}{k_0}} \begin{pmatrix} vA^r - (k_0+1)^r \\ i \end{pmatrix}. \tag{10.5}$$

By using (10.1), we have that the overall probability of the bad fault paths is at most

(10.6)

$$\begin{aligned} &\sum_{i=0}^{vA^r-(k_0+1)^r} v \binom{A}{k_0+1}^{\frac{(k_0+1)^r-1}{k_0}} \binom{vA^r-(k_0+1)^r}{i} c\eta^{(k_0+1)^r+i}(1-\eta)^{vA^r-(k_0+1)^r-i} \\ &\leq cv \left(\binom{A}{k_0+1}^{\frac{1}{k_0}} \eta \right)^{(k_0+1)^r} \sum_{i=0}^{vA^r-(k_0+1)^r} \binom{vA^r-(k_0+1)^r}{i} \eta^i (1-\eta)^{vA^r-(k_0+1)^r-i} \\ &= cv \left(\binom{A}{k_0+1}^{\frac{1}{k_0}} \eta \right)^{(k_0+1)^r}. \end{aligned}$$

The expression above decays exponentially fast to zero with r, if η is strictly below the threshold for probabilistic noise (Definition 23). This completes the proof. □

11. Fault tolerance in a *d*-dimensional quantum computer. We now proceed to our final generalization of the threshold theorem. So far, we allowed a gate to operate on any set of qubits, regardless of the actual location of these qubits in space. Here we consider quantum systems with geometrical constraints: The qubits

are embedded in space, in a one-, two-, or three-dimensional grid, and gates can be applied only to nearest-neighbor qubits. In the case of dimensionality higher than 1, and gates of more than two qubits, we also require that all qubits in a gate lie on the same line. We show that the threshold result holds in full generality for d-dimensional quantum computers, for any $d \geq 1$.

In physical systems with geometrical constraints, discarding and adding qubits is a questionable process, unless we allow empty spots. To avoid this complication, we replace these two operations by one gate called RESTART, which is constructed by discarding a qubit and then adding a blank qubit instead of the discarded qubit. This allows us to remove entropy out of the system while maintaining the geometrical structure. Since the gates are restricted to operate on nearest neighbors, we also need to require that the set of gates we use contains the SWAP gate, so that, when we want to apply a gate on qubits that are not nearest neighbors, we can bring them closer together.

THEOREM 15 (threshold theorem for d-dimensional circuits). *Let $\epsilon > 0$. Let $d \geq 1$. Let $\mathcal{G}'$ and $\mathcal{G}''$ be two universal sets of quantum gates. There exist a threshold $\eta_c''' > 0$ and constants c_1, c_2, c_3 such that the following holds. Let Q' be a d-dimensional quantum circuit, with n input qubits, which operates t time steps, uses s gates from $\mathcal{G}'$, and has v locations. There exists a d-dimensional quantum circuit Q'' which operates on $nO(\log^{c_1}(\frac{v}{\epsilon}))$ qubits, for time $tO(\log^{c_2}(\frac{v}{\epsilon}))$, and uses $vO(\log^{c_3}(\frac{v}{\epsilon}))$ gates from $\mathcal{G}'' \cup \{\mathsf{SWAP}, \mathsf{RESTART}\}$ such that, in the presence of general noise with error rate $\eta < \eta_c'''$, Q'' computes a function which is ϵ-close to that computed by Q'.*

Proof. To prove the theorem, we need to modify the fault-tolerant procedures so that they apply gates on nearest neighbors only and also all of the qubits remain in the circuit throughout the computation.

Here is how one level of the simulation is done. We first pick a preferred direction, and each qubit will be extended to an array of qubits lying in that direction. The simulation will "stretch" the simulated circuit only in the preferred direction, by a constant factor. Let a be the maximal number of ancilla qubits used in any of the procedures of the computation code $\mathcal{G}$. Let m be the size of the block. A qubit in Q' will be replaced by $m + a$ qubits, placed in a line along the preferred direction. The ancilla qubits will serve as a working space, but we will also SWAP computational qubits with ancilla qubits, in order to bring computation qubits closer and operate gates on them.

The fault-tolerant procedures are thus modified as follows. First, instead of adding ancilla qubits during the procedure, we use only the ancilla qubits that are already there and apply a RESTART gate on an ancilla qubit one step before we use it in the procedure. Also, any gate g in the original procedure that operates on qubits that are far apart is replaced by a sequence of SWAP gates which bring the qubits that g operates on to nearest neighbor sites, followed by g, followed by another sequence of SWAP gates which bring the qubits back to their original sites. Since the simulated circuit Q' applies gates only on nearest neighbors, say, on $s \in \{1, 2, 3\}$ qubits in a row, the number of SWAP gates used in the above modification per gate g is at most $2(s-1)(m+a)$, i.e., a constant. This means that the modified procedure is larger than the original one by a constant factor (both in time and in space).

The claim is that the procedure is still fault-tolerant. This might seem strange since the SWAP gates operate on many qubits and seem to help in the propagation of errors. However, note that a SWAP gate which operates on a faulty qubit and an unaffected qubit does not propagate the error to the two qubits but keeps it confined to the original qubit, which is now in a new site. Hence, a SWAP gate which is not

faulty does not cause a propagation of error. If a fault does occur in a SWAP gate, then the two qubits participating in it are contaminated. If the fault occurred before the application of the gate g, then one of the qubits the gate g operates on is faulty, and hence this also causes the contamination of all of the qubits on which g operates (in the worst case). So an error in a SWAP gate is equivalent to an error in all of the original sites of the qubits participating in the gate and also the final site of the other qubit participating in the SWAP gate. This adds a factor of 2 at most to the original spread of the procedure. All other aspects of the theorem remain the same. □

12. Threshold estimations. Finally, it is left to estimate the exact threshold value for fault-tolerant quantum computation. However, there is not one such value: This value depends on many things such as which variants of the threshold theorem we use (probabilistic noise, general local noise, d-dimensional circuits) as well as the choice of the computation code and, mainly, the exact assumptions we make on the quantum system, most importantly, whether we allow classical computation in the middle of the quantum process or not. Since our results are mainly proofs of existence, where we have not attempted to optimize the threshold, we do not attempt to provide exact values of the threshold in all of these cases. Nevertheless, we give here a rough estimation of the threshold value in one of the simpler cases: the case of probabilistic independent noise, with no geometrical constraints on the system, and under the assumption that infinitely fast classical operations are allowed during the computation.

To estimate this threshold, we examine the formula for the threshold value in the case of independent probabilistic noise with no geometrical constraints, which is given by Definition 23. The threshold value depends on two parameters: A, the number of locations in the biggest rectangle in the simulation, and $k_0 = \lfloor q/2\ell \rfloor$, where we recall that q is the number of errors that the code can correct, and ℓ is its spread, which is 1 in both our constructions. We use polynomial codes of degree $d = 4$, i.e., length $m = 13$, so that $q = 2$, and so $k_0 = 1$. The threshold in our case is thus $\binom{A}{2}^{-1}$.

The parameter A, the size of the largest rectangle, is estimated by counting the number of locations where quantum (rather than classical) gates and qubits are involved. The bottleneck in our construction using polynomial codes, namely, the largest rectangle, is the one corresponding to applying transversal operation on two blocks, preceded by error correction on both of these blocks. The reason for this is as follows. First, we need to consider only two-qubit encoded gates because we use the squaring gate instead of the Toffoli gate in the set $\mathcal{G}_1$ (see subsection 4.2). Second, one might think that the largest rectangle involves the ancilla state preparation for the degree reduction as well. However, to avoid such large rectangles, we consider each step in the ancilla preparation as a rectangle of its own.

It remains to estimate the size of the above rectangle. For each error correction we need two zero-state preparations, and so altogether we need four zero-state preparations plus transversal operations. Since we use $q = 2$, every zero-state preparation requires 25 preliminary zero-state preparations (not done fault-tolerantly) plus transversal operations. We estimate the size of the rectangle in this case to be of the order of 10^3 locations, which implies a threshold of the order of $\simeq 10^{-6}$.

The threshold value in other cases, and under different sets of assumptions on the noise and on the constraints of the quantum system, can be estimated by using (8.6), (9.2), and the definition of η_c''' as is defined in section 11, where the estimation of the parameters involved should depend on the assumptions being used.

Acknowledgments. We thank Peter Shor for discussions about his result, Thomas Beth for helping to construct the fault-tolerant Toffoli gate without measurements for the CSS codes, Richard Cleve for asking the question of nearest neighbors and suggesting the solution, Noam Nisan for a fruitful discussion regarding the correct model to use, and Prasad Gospel, Denis Gaitsgori, Erez Lapid, and Bob Solovay for helpful discussions regarding the proofs of universality. We are grateful to Hoi-Kwong Lo for correcting an error in the definition of polynomial codes. Finally, we thank Alesha Kitaev for a very helpful remark regarding the generalization to the general noise model and Daniel Gottesman for very helpful remarks and corrections regarding the final draft of this paper.

MITOTIC CLASSES IN INDUCTIVE INFERENCE*

SANJAY JAIN† AND FRANK STEPHAN‡

Abstract. For the natural notion of splitting classes into two disjoint subclasses via a recursive classifier working on texts, the question of how these splittings can look in the case of learnable classes is addressed. Here the strength of the classes is compared using the strong and weak reducibility from intrinsic complexity. It is shown that, for explanatorily learnable classes, the complete classes are also mitotic with respect to weak and strong reducibility, respectively. But there is a weakly complete class that cannot be split into two classes which are of the same complexity with respect to strong reducibility. It is shown that, for complete classes for behaviorally correct learning, one-half of each splitting is complete for this learning notion as well. Furthermore, it is shown that explanatorily learnable and recursively enumerable classes always have a splitting into two incomparable classes; this gives an inductive inference counterpart of the Sacks splitting theorem from recursion theory.

Key words. recursion theory, inductive inference, mitotic classes, reducibilities

1. Introduction.

A well-known observation is that infinite sets can be split into two parts of the same cardinality as the original set, while finite sets cannot be split in such a way; for example, the integers can be split into the sets of the even and odd numbers, while splitting a set of five elements would result in subsets of unequal sizes. In this sense, infinite sets are better than finite ones. The corresponding question in complexity and recursion theory is the following: Which sets can be split into two sets of the same complexity as the original set [1, 9, 10, 15]?

Ambos-Spies [1] defined one of the variants of mitoticity using many-one reducibilities. Here a set A is many-one reducible to a set B iff there is a recursive function f such that $A(x) = B(f(x))$. That is, one translates every input x for A into an input $f(x)$ for B, takes the solution provided by B (in the set or in its complement), and then copies this to obtain the solution for A. Similarly one also considers complexity-theoretic counterparts of many-one reductions; for example, one can translate an instance (G_1, G_2) of the graph-isomorphism problem into an instance ϕ of the satisfiability problem in polynomial time, where G_1 is isomorphic to G_2 iff ϕ is satisfiable. Here, one can choose the reduction such that one not only tests membership, but can also translate a solution of ϕ into an isomorphism between G_1 and G_2 whenever such a solution exists for ϕ. Indeed, NP-complete problems are characterized as those into which every NP problem can be translated. This general method of reducing problems and translating solutions (although here the translation of the solution is just the identity) occurs quite frequently in other fields of mathematics. In inductive inference, intrinsic complexity is based on the notion of reducing one learning problem $\mathcal{L}$ to another problem $\mathcal{H}$: First an operator translates a text T for a set L in $\mathcal{L}$ into a text $\Theta(T)$ for a set H in $\mathcal{H}$, and then another operator translates a solution E,

which is a sequence converging to an index e of H, into a solution for L given as a sequence converging to an index e' of L. Before explaining this in more detail, some terminology is necessary to make it precise.

- A partial recursive function is a partial function computed by a Turing machine, where the machine does not halt on inputs on which the function is undefined. A recursively enumerable set is the domain (or, equivalently, the range) of a partial recursive function. There is an acceptable numbering $W_0, W_1, W_2, \ldots$ of all recursively enumerable sets [16, section II.5]; this numbering will be kept fixed from now on.
- A general recursive operator Θ is a mapping from total functions to total functions such that there is a recursively enumerable set E of triples which satisfies the following: For every total function f and every x, y, $\Theta(f)(x) = y$ iff there is an n such that $(f(0)f(1)\ldots f(n), x, y) \in E$.
- A language is a recursively enumerable subset of the natural numbers.
- A class $\mathcal{L}$ is a set of languages. A family $L_0, L_1, L_2, \ldots$ is an indexing for $\mathcal{L}$ iff $\{(e, x) : x \in L_e\}$ is recursively enumerable and $\mathcal{L} = \{L_0, L_1, L_2, \ldots\}$.
- A text T (see [11]) is a mapping from the set $\mathbb{N}$ of natural numbers to $\mathbb{N} \cup \{\#\}$. Content of a text T, content(T), is the set $\{T(n) \mid n \in \mathbb{N} \wedge T(n) \in \mathbb{N}\}$. T is a text for L iff content$(T) = L$. $T[n]$ denotes the first n elements of the sequence T, that is, $T[n] = T(0)\,T(1)\ldots T(n-1)$. Furthermore, content$(T[n])$ denotes the set of natural numbers occurring in $T(0)\,T(1)\ldots T(n-1)$. As an example, $T = \#\#3\#\#8\#8\#\#7\#9\#^\infty$ is a text for the set $\{3, 7, 8, 9\}$, $T(0) = \#$, $T(2) = 3$, and $T[6] = \#\#3\#\#8$.
- A learner is a general recursive operator (see [22]) which translates T into another sequence E. The learner converges on T iff there is a single e such that $E(n) = e$ for almost all n—in this case one says that the learner converges on T to e. The learner explanatorily learns (see [5, 11]) T iff it converges on T to some index e such that W_e = content(T). A learner explanatorily learns L iff it explanatorily learns every text for L. A learner explanatorily learns $\mathcal{L}$ iff it explanatorily learns every $L \in \mathcal{L}$. Note that, in some cases, learning algorithms can also be described such that they use the indices from a given indexing for $\mathcal{L}$; such indices can always be translated into indices of the acceptable numbering $W_0, W_1, \ldots$ of all recursively enumerable sets.
- A classifier [21] is a general recursive operator which translates texts to sequences over $\{0, 1\}$. A classifier C converges on a text T to a iff $C(T[n]) = a$ for almost all n.
- For the learning criteria considered in this paper, one can assume without loss of generality [17] that the learner M computes $E(n)$ from input $T[n]$. $M(T[n])$ denotes this hypothesis. A similar convention holds for classifiers.

As an example, the class $\mathcal{D}$ of all finite sets is explanatorily learnable. The following learner explanatorily learns $\mathcal{D}$: On every finite sequence σ it outputs a canonical index for content(σ), so $M(\#\#3\#\#8\#8)$ outputs an index for $\{3, 8\}$. Then it is easy to see that M converges on every text for a finite set to the canonical index for this set. An example for a nonexplanatorily learnable class was obtained by Gold [11] who showed that $\mathcal{D} \cup \{L\}$ is not explanatorily learnable for any infinite set L. Let $\mathcal{D}_{even}$ and $\mathcal{D}_{odd}$ be the classes of finite sets with an even and odd number of elements, respectively. Then one can easily construct a classifier which separates $\mathcal{D}_{odd}$ from $\mathcal{D}_{even}$ by defining that $M(\sigma) = 1$ if content(σ) has an even number of elements and $M(\sigma) = 0$ otherwise.

Freivalds, Kinber, and Smith [6] consider reductions between learnability prob-

lems for function classes. Jain and Sharma [13] carried this idea over to the field of learning languages from positive data and formalized the following two reducibilities for learnability problems. The main difference between these two reducibilities is that Θ can be one-to-many in the case of the weak reducibility, as different texts for the same language can be mapped to texts for different languages, while for the strong reducibility this is not allowed, at least for languages in the given class.

- A class $\mathcal{L}$ is weakly reducible to $\mathcal{H}$ iff there are general recursive operators Θ and Ψ such that
  - whenever T is a text for a language in $\mathcal{L}$, $\Theta(T)$ is a text for a language in $\mathcal{H}$;
  - whenever E is a sequence which converges to an index e with $W_e = \text{content}(\Theta(T))$ for some text T of a language in $\mathcal{L}$, $\Psi(E)$ is a sequence converging to an e' with $W_{e'} = \text{content}(T)$.

  One writes $\mathcal{L} \leq_{weak} \mathcal{H}$ in this case.
- A class $\mathcal{L}$ is strongly reducible to $\mathcal{H}$ iff there are general recursive operators Θ, Ψ as above with the following additional constraint. Whenever T, T' are texts for the same language in $\mathcal{L}$, $\Theta(T), \Theta(T')$ are texts for the same language in $\mathcal{H}$. One writes $\mathcal{L} \leq_{strong} \mathcal{H}$ in this case. Furthermore, $\Theta(L)$ denotes the language content$(\Theta(T))$, where T is a text for L.

For example, the class $\{\{x\} : x \in \mathbb{N}\}$ of all singleton sets is strongly reducible to $\mathcal{D}$, but $\mathcal{D}$ is not weakly reducible to the class of all singleton sets [13]. Furthermore, $\mathcal{D}_{even}$ and $\mathcal{D}_{odd}$ are strongly reducible to each other by the same mapping (Θ, Ψ). The operator Θ translates every text for a set D to a text for $\{0\} \cup \{d+1 : d \in D\}$; the operator Ψ translates an index e, in a sequence of hypotheses, to an index $g(e)$ of the set $W_{g(e)} = \{x : x+1 \in W_e\}$.

Jain, Kinber, Sharma, and Wiehagen investigated these concepts in several papers [12, 13, 14]. They found that there are complete classes with respect to $\leq_{weak}$ and $\leq_{strong}$. Here a class $\mathcal{H}$ is complete with respect to $\leq_{weak}$ ($\leq_{strong}$) iff $\mathcal{H}$ can be explanatorily learned and for every explanatorily learnable class $\mathcal{L}$ it holds that $\mathcal{L} \leq_{weak} \mathcal{H}$ ($\mathcal{L} \leq_{strong} \mathcal{H}$). If $\sqsubset$ is a recursive dense linear ordering on $\mathbb{N}$ without least and greatest element (which makes $\mathbb{N}$ an order-isomorphic copy of the rationals), then

$$\mathcal{Q} = \{\, \{y \in \mathbb{N} \mid y \sqsubseteq x\} \mid x \in \mathbb{N}\}$$

is a class which is complete for both $\leq_{weak}$ and $\leq_{strong}$ (see [12]). The following classes are complete for $\leq_{weak}$ but not for $\leq_{strong}$ (see [13]):

$$\mathcal{I} = \{\, \{0, 1, \ldots, x\} \mid x \in \mathbb{N}\},$$
$$\mathcal{CS} = \{\, \mathbb{N} - \{x\} \mid x \in \mathbb{N}\}.$$

If one looks at $\mathcal{CS}$, one can easily see that it is the disjoint union of two classes of equivalent intrinsic complexity, namely, the class $\{\, \mathbb{N}-\{x\} \mid x \text{ is even}\}$ and $\{\, \mathbb{N}-\{x\} \mid x$ is odd$\}$. All three classes can be translated into each other, and a classifier can witness the splitting: If T is a text for a member of $\mathcal{CS}$, then the classifier converges in the limit to the remainder of x divided by 2 for the unique $x \notin \text{content}(T)$. This type of splitting can be formalized to the notion of a mitotic class.

DEFINITION 1. *Two infinite classes $\mathcal{L}_0$ and $\mathcal{L}_1$ are called a* splitting *of a class $\mathcal{L}$ iff $\mathcal{L}_0 \cup \mathcal{L}_1 = \mathcal{L}$, $\mathcal{L}_0 \cap \mathcal{L}_1 = \emptyset$, and there exists a classifier C such that, for all $a \in \{0,1\}$ and for all texts T with content$(T) \in \mathcal{L}_a$, C converges on T to a.*

A class $\mathcal{L}$ is strongly mitotic (weakly mitotic) *iff there is a splitting $\mathcal{L}_0, \mathcal{L}_1$ of $\mathcal{L}$ such that $\mathcal{L} \equiv_{strong} \mathcal{L}_0 \equiv_{strong} \mathcal{L}_1$ ($\mathcal{L} \equiv_{weak} \mathcal{L}_0 \equiv_{weak} \mathcal{L}_1$).*

The study of such notions is motivated by recursion theory [16, 22] where a recursively enumerable set is called mitotic iff it is the disjoint union of two other recursively enumerable sets which have the same Turing degree. The importance of this notion is reflected by Ladner's result that a recursively enumerable set is mitotic iff it is autoreducible, that is, iff there is an oracle Turing machine M such that $A(x) = M^{A\cup\{x\}}(x)$ for all x [15]. Furthermore the notion had been carried over to complexity theory where it is still an important research topic [1, 9, 10]. Thus, we feel it is interesting to explore this notion in the context of inductive inference too. The results show some interesting properties related to mitoticity. In particular, classes complete for explanatory learning with respect to $\leq_{strong}$ ($\leq_{weak}$) are strongly (weakly) mitotic. Thus, nonmitotic classes cannot be complete.

Although intrinsic complexity is not the exact counterpart of Turing degrees in recursion theory, it is the only type of complexity which is defined via reducibilities and not via measures such as counting mind changes or the size of long-term memory in inductive inference. Therefore, from the viewpoint of inductive inference, the above defined version of mitotic classes is reasonable. Indeed, there are some obvious parallels: In recursion theory, any recursively enumerable cylinder is mitotic, where a cylinder A is a set of the form $\{(x,y) \mid x \in B, y \in \mathbb{N}\}$ for some set $B \subseteq \mathbb{N}$. A corresponding cylindrification of a class $\mathcal{L}$ would be the class

$$\{\,\{(x,y) \mid y \in L\} \mid x \in \mathbb{N}, L \in \mathcal{L}\}.$$

It can easily be seen that this class is strongly mitotic and thus also weakly mitotic. Indeed, two constraints are placed in Definition 1 in order to be as near to the original definition of mitoticity in recursion theory as possible:

- In the recursion theoretic setting, if A is split into two recursively enumerable sets A_0, A_1 with $A_0 \equiv_T A_1$, then $A \equiv_T A_0 \equiv_T A_1$. Thus, in the definition of mitoticity for learning theory, it is required that all three classes, class $\mathcal{L}$ and its two halves $\mathcal{L}_1$ and $\mathcal{L}_2$, have the same intrinsic complexity degree.
- If A is recursively enumerable and mitotic and split into A_0, A_1, then there is a partial recursive function with domain A mapping the elements of A_a to a for all $a \in \{0,1\}$. For mitotic classes of languages, the corresponding function is a classifier which works correctly on all texts for the languages in the class. It is not required that the classifier converges on every text, as then many naturally strongly mitotic classes, such as $\mathcal{CS}$, would no longer be mitotic. This has a parallel in recursion theory: if one splits a maximal set (as defined in Remark 8 below) into two recursively enumerable sets A_0 and A_1, which are both not recursive, then the sets A_0 and A_1 are recursively inseparable.

Besides the reducibilities $\leq_{weak}$ and $\leq_{strong}$ considered here, other reducibilities have also been considered [12, 13]. This paper deals only with $\leq_{weak}$ and $\leq_{strong}$, as these two are the most natural and representative.

One emphasis of the current work is on the search for natural classes which split or do not split. Therefore it is always required that the class under consideration is learnable (under the criterion in consideration). Furthermore, one tries to show properties for complete classes, recursively enumerable classes, and indexed families. Angluin [2] defined that $\{L_0, L_1, L_2, \ldots\}$ is an indexed family iff the function $e, x \mapsto L_e(x)$ is recursive. For indexed families $\{L_0, L_1, L_2, \ldots\}$ one can assume, without loss of generality, that $L_n \neq L_m$ whenever $n \neq m$. A learner for this family is called exact iff it converges on every text for L_n to n.

In this paper, it is shown that classes complete for explanatory learning with respect to $\leq_{strong}$ ($\leq_{weak}$) are strongly (weakly) mitotic. Furthermore, there are classes

complete for explanatory learning with respect to $\leq_{weak}$ which are not strongly mitotic. Similar phenomena are studied for behaviorally correct learning. A counterpart to the Sacks splitting theorem is that every infinite recursively enumerable explanatory learnable class has a splitting into two incomparable subclasses. The relations between autoreducibility and mitoticity are also investigated. However, in contrast to the situation in complexity theory, these two notions turn out to be different.

The following remark is important for several proofs.

Remark 2. One says that a learner M or a classifier C converges on T to a value a iff $M(T[n]) = a$ or $C(T[n]) = a$ for almost all n, respectively. But it does not matter—in the framework of inductive inference—how fast this convergence is; the machine can be slowed down by starting with an arbitrary guess and later repeating hypotheses, if needed. Similarly, if one translates one text of a language L into a text of a language H, it is not important how fast the symbols of H show up in the translated text; it is only important that they show up eventually. Therefore the translator can put into the translated text a pause symbol, #, until more data are available or certain simulated computations have terminated.

Therefore, learners, operators translating texts, and classifiers can be made primitive recursive by the just mentioned delaying techniques. Thus one can have recursive enumerations $\Theta_0, \Theta_1, \Theta_2, \ldots$ of translators from texts to texts, $M_0, M_1, M_2, \ldots$ of learners, and $C_0, C_1, C_2, \ldots$ of classifiers such that, for every given translator, learner or classifier, this list contains an equivalent one. These lists can be used in proofs where diagonalizations are needed.

Given a text T and a number n, one denotes by $\Theta(T[n])$ the initial part $\Theta(T)[m]$ for the largest $m \leq n$ such that $\Theta(T)[m]$ is produced without accessing any datum in T beyond the nth position. Note that, for every m, there is an n such that $\Theta(T[n])$ extends $\Theta(T)[m]$ and $\Theta(T[n])$ can be computed from $T[n]$.

2. Complete classes. The two main results are that classes which are complete for $\leq_{strong}$ are strongly mitotic and classes which are complete for $\leq_{weak}$ are weakly mitotic. This stands in contrast to the situation in recursion theory where some Turing-complete recursively enumerable sets are not mitotic [15]. Note that certain classes which are complete only for $\leq_{weak}$ fail to be strongly mitotic; thus the main results cannot be improved.

THEOREM 3. *Every class which is complete for $\leq_{strong}$ is also strongly mitotic.*

Proof. Let $\mathcal{L}$ and $\mathcal{H}$ be any classes which are complete for $\leq_{strong}$. Then the class $\mathcal{K}$ consisting of the sets $I = \{1, 3, 5, 7, \ldots\}$, $J = \{0\} \cup I$, $\{2x + 3 : x \in H\}$, and $J \cup \{2x+2 : x \in H\}$ for every $H \in \mathcal{H}$ is also complete for $\leq_{strong}$. Since $\mathcal{L}$ is complete for $\leq_{strong}$, there is a translation Θ which maps languages in $\mathcal{K}$ to languages in $\mathcal{L}$ such that proper inclusion is preserved [14]. Thus there is some $e \in \Theta(J) - \Theta(I)$. As $\mathcal{H}$ is complete for $\leq_{strong}$, the subclasses $\{\Theta(\{2x + 3 : x \in H\}) : H \in \mathcal{H}\}$ and $\{\Theta(J \cup \{2x + 2 : x \in H\}) : H \in \mathcal{H}\}$ of $\mathcal{L}$ are also complete for $\leq_{strong}$. All members of the first class do not contain e, while all members of the second class contain e as an element. It follows that the subclasses $\mathcal{L}_0 = \{L \in \mathcal{L} : e \notin L\}$ and $\mathcal{L}_1 = \{L \in \mathcal{L} : e \in L\}$ are disjoint and complete for $\leq_{strong}$. Thus $\mathcal{L}$ can be classified by a classifier C, which conjectures 1 if e has shown up in the text so far and 0 otherwise. Therefore, $\mathcal{L}$ is strongly mitotic. ∎

The following notion is used to formulate Proposition 6 which is a central ingredient of Theorem 7. Furthermore, learners with certain properties are needed.

DEFINITION 4. *For any sequence T of symbols, let all(T) be the length of the*

shortest prefix of T containing all symbols which show up in T; that is, let

$$all(T) = \sup\{n+1 : content(T[n]) \subset content(T)\}.$$

Note that $all(T) < \infty$ iff $content(T)$ is a finite set.

The following remark combines some ideas of Blum and Blum [4] and Fulk [8].

Remark 5. Let $\mathcal{L}$ be an explanatorily learnable class. Then there is an explanatory learner M for $\mathcal{L}$ with the following properties:

- M is prudent [17]; that is, whenever M outputs an index e on some input data, then M explanatorily learns W_e.
- M is order independent [4]; that is, for every set L, either M diverges on all texts for L or M converges on all texts for L to the same index.
- For every text T and index e, if $M(T[n]) = e$ for infinitely many n, then $M(T[n]) = e$ for almost all n.

PROPOSITION 6. *Suppose $\mathcal{I} \leq_{weak} \mathcal{L}$ and M is a explanatory learner for $\mathcal{L}$ which satisfies the conditions in Remark* 5. *Then there is a reduction (Θ, Ψ) from $\mathcal{I}$ to $\mathcal{L}$ such that, for all texts T for a language in $\mathcal{I}$, M converges on $\Theta(T)$ to an index $e > all(T)$.*

Proof. Assume that (Θ'', Ψ'') witnesses that $\mathcal{I} \leq_{weak} \mathcal{L}$. Now a reduction (Θ', Ψ') from $\mathcal{I}$ to $\mathcal{I}$ is constructed such that Θ can be taken to be the composition of Θ' and Θ''.

The key idea for this is the following: One constructs (Θ', Ψ') from $\mathcal{I}$ to $\mathcal{I}$ such that, for every text T of a set in $\mathcal{I}$, M converges on $\Theta''(\Theta'(T))$ to an index $e > \text{all}(T)$. Note that $\text{all}(T)$ is finite for all texts for members of $\mathcal{I}$. By Remark 2, assume without loss of generality that Θ'' is primitive recursive. The idea is that Θ' translates a text T for $I_n = \{0, 1, \ldots, n\}$ to a text for $I_{2^n(1+2m)}$ for some m; Ψ' translates any sequence converging to an index of the set $I_{2^n(1+2m)}$ into a sequence converging to an index of I_n.

Given a sequence E of indices, $\Psi'(E)(s)$ is computed as follows. Let k be the least number such that $W_{E(s),s} \subseteq I_k$. Choose m, n such that $2^n(1+2m) = k$ and output the canonical index for I_n. It is easy to see that this translation works whenever E converges to an index of some set in $\mathcal{I}$.

CONSTRUCTION OF Θ'. The construction of Θ' is more involved. For the construction, the special properties of M from Remark 5 are important. The most adequate way to describe $\Theta'(T)$ is to build longer and longer finite prefixes $\tau_0, \tau_1, \tau_2, \ldots$ of this target $\Theta'(T)$. The construction starts with $\tau_0 = 0\#$, and, in stage s, the extension τ_{s+1} of τ_s is defined according to the first case which applies:

Case 1. $M(\Theta''(\tau_s)) \leq \text{all}(T[s])$. Then let τ_{s+1} be the first extension of τ_s found such that $M(\Theta''(\tau_{s+1})) \neq M(\Theta''(\tau_s))$.

Case 2. Case 1 does not hold, but $\text{content}(\tau_s) \neq I_{2^n(1+2m)}$ for all m, where n is the least number with $\text{content}(T[s]) \subseteq I_n$. Then let $\tau_{s+1} = \tau_s a$ for the least nonelement a of $\text{content}(\tau_s)$.

Case 3. Cases 1 and 2 do not hold. Then $\tau_{s+1} = \tau_s\#$.

Here $\Theta''(\tau_s)$ and $\Theta''(\tau_{s+1})$ are defined as in Remark 2 and can be computed from τ_s and τ_{s+1}, respectively.

VERIFICATION. For the verification, assume that a set $I_n = \{0, 1, 2, \ldots, n\} \in \mathcal{I}$ and a text T for I_n are given.

First note that, in Case 1 of the construction, the extension τ_{s+1} of τ_s can always be found. To see this, note that there are two texts T_1, T_2 extending τ_s for different sets in $\mathcal{I}$. It follows that $\Theta''(T_1)$ and $\Theta''(T_2)$ are texts of different sets and thus M

converges on them to different indices. Thus one can take a sufficiently long prefix of one of T_1, T_2 in order to get the desired τ_{s+1}.

Second, it can be shown by induction that $|\tau_s| > s$ at all stages s; this guarantees that Θ' is indeed a general recursive operator.

Third, one shows that M does not converge on $\Theta''(\Theta'(T))$ to any index less than or equal to all(T). By Case 1 in the construction, M cannot converge on $\Theta''(\Theta'(T))$ to an index $e \leq \text{all}(T)$. Thus, by Remark 5, there is a stage s_0 such that Case 1 of the construction is never taken after stage s_0 and content$(T[s_0]) = I_n$.

Fourth, one shows that $\Theta'(T)$ is a text for some language in $\mathcal{I}$. There is a least m such that content$(\tau_{s_0}) \subseteq I_{2^n(1+2m)}$. For all stages $s > s_0$, if content$(\tau_s) \subset I_{2^n(1+2m)}$, then τ_{s+1} is chosen by Case 2; else τ_{s+1} is chosen by Case 3. One can easily see that the resulting text $\Theta'(T) = \lim_{s\to\infty} \tau_s$ is a text for $I_{2^n(1+2m)}$. Indeed, $\Theta'(T) = \tau_{s_1}\#^\infty$ for $s_1 = s_0 + 2^n(1+2m) + 2$.

Thus it follows that Θ' maps every text of a set I_n to a text for some set $I_{2^n(1+2m)}$, as desired. So, for all texts T of sets in $\mathcal{I}$, M converges on $\Theta''(\Theta'(T))$ to some index $e > \text{all}(T)$. □

THEOREM 7. *Let $\mathcal{L}$ be an explanatorily learnable class which is complete for $\leq_{weak}$. Then $\mathcal{L}$ is weakly mitotic.*

Proof. Let $I_n = \{0, 1, \ldots, n\}$. By Proposition 6 there is a reduction (Θ, Ψ) from $\mathcal{I}$ to $\mathcal{L}$ and a learner M such that M satisfies the conditions outlined in Remark 5 and, for every text T of a member of $\mathcal{I}$, M converges on $\Theta(T)$ to an index $e > \text{all}(T)$. For this reason, using oracle K for the halting problem, one can check, for every index e, whether there is a text T for a language in $\mathcal{I}$ such that M on $\Theta(T)$ converges to e. This can be seen as follows: One can assume, without loss of generality, that, besides $\#$, no data item in a text is repeated. Also, among the texts for sets in $\mathcal{I}$, only the texts of the sets $\{0\}$, $\{0,1\}$, $\{0,1,2\}$, $\ldots$, $\{0,1,2,\ldots,e\}$ can satisfy all$(T) \leq e$. Thus, one has just to check the behavior of the given explanatory learner M for the class $\mathcal{L}$ on the texts $\Theta(T')$, for T' in the class

$$\mathcal{T}_e = \{T' \mid T' \in \{0, 1, \ldots, e, \#\}^e \cdot \#^\infty \wedge \text{content}(T) \in \mathcal{I}\}.$$

Now, define a classifier C such that on a text T, the nth guess of C is 1 iff there is an odd number $m \leq M(T[n])$ and a text $T'' \in \mathcal{T}_{M(T[n])}$ for I_m such that $M(\Theta(T'')[n]) = M(T[n])$.

For the verification that C is a classifier, assume that M converges on T to some index e. Then C converges on T to 1 iff there is an odd number m and a text T' for I_m in $\mathcal{T}_e$ such that M converges on the texts T and $\Theta(T')$ to the same number. Otherwise C converges on T to 0. If M does not converge on T, then T is not a text for a set in $\mathcal{L}$, and the behavior of C on T is irrelevant. Thus C is a classifier which splits $\mathcal{L}$ into two classes $\mathcal{L}_0$ and $\mathcal{L}_1$. These classes $\mathcal{L}_0$ and $\mathcal{L}_1$ contain the images of repetition-free texts of sets in the classes $\{I_0, I_2, I_4, \ldots\}$ and $\{I_1, I_3, I_5, \ldots\}$, respectively. Thus both classes are complete for $\leq_{weak}$, and the splitting of $\mathcal{L}$ into $\mathcal{L}_0$ and $\mathcal{L}_1$ witnesses that $\mathcal{L}$ is weakly mitotic. □

As several proofs use known properties of the maximal sets, the following remark summarizes some of these properties.

Remark 8. A set A is *maximal* (see [16]) iff (a) A is recursively enumerable, (b) A has an infinite complement, and (c) every recursively enumerable set B satisfies that either $B - A$ is finite or the complement of $A \cup B$ is finite.

A maximal set is dense simple; that is, if $a_0, a_1, a_2, \ldots$ gives the complement in the ascending order and f is a recursive function, then $f(a_n) < a_{n+1}$ for almost all n.

For any partial recursive function ψ and any maximal set A, the following statements hold.

- $\psi(x)$ is defined either for almost all $x \in \overline{A}$ or for only finitely many $x \in \overline{A}$.
- The set $\{x \notin A \mid \psi(x) \in A\}$ either is finite or contains almost all elements of $\overline{A}$.
- If, for every x, there is some $y > x$ such that $y \notin A$, $\psi(y)$ is defined, $\psi(y) > x$, and $\psi(y) \notin A$, then $\psi(z)$ is defined and $\psi(z) = z$ for almost all $z \in \overline{A}$.

These basic facts about the maximal sets will be used in several proofs. Odifreddi [16, pp. 288–294] provides more information on the maximal sets including the proof of their existence by Friedberg [7].

THEOREM 9. *There exists an indexed family $\{L_0, L_1, L_2, \ldots\}$ which is weakly mitotic and complete for $\leq_{weak}$, but not strongly mitotic.*

Proof. Let A be a maximal set with complement $\{a_0, a_1, \ldots\}$, where $a_n < a_{n+1}$ for all n. Now let $\mathcal{L}$ consist of the sets

- $\{x, x+1, x+2, \ldots, x+y\}$ for all $x \in A$ and $y \in \mathbb{N}$,
- $\{x, x+1, x+2, \ldots\}$ for all $x \notin A$.

As A is recursively enumerable, $\mathcal{L}$ can be represented as an indexed family. Explanatory learnability is also clear as the learner, on input σ, first determines $x = \min(\text{content}(\sigma))$ and then conjectures content(σ) if $x \in A_{|\sigma|}$, and conjectures $\{x, x+1, x+2, \ldots\}$ otherwise. Without loss of generality, it can be assumed that $a_0 > 0$ and thus $\mathcal{L}$ is a superclass of $\mathcal{I}$ and therefore complete for $\leq_{weak}$. By Theorem 7, $\mathcal{L}$ is weakly mitotic.

Let $\mathcal{L}_0$ and $\mathcal{L}_1$ be two disjoint classes with union $\mathcal{L}$. Without loss of generality, $\{a_0, a_0+1, a_0+2, \ldots\} \in \mathcal{L}_1$. Assume now by way of contradiction that $\mathcal{L} \leq_{strong} \mathcal{L}_0$ as witnessed by (Θ, Ψ). As Θ has to preserve the proper subset relation on the content of the texts while translating, every text of a set of the form $\{a_n, a_n+1, a_n+2, \ldots\}$ has to be translated into a text for a set of the form $\{a_m, a_m+1, a_m+2, \ldots\}$ (to preserve the property that translation of $\{a_n, a_n+1, a_n+2, \ldots\}$ has infinitely many subsets in the class).

Now consider the function f which outputs, on input x, the first element found to be in the range of the image $\Theta(\sigma)$ for some σ with $x = \min(\text{content}(\sigma))$. The function f is recursive, but by Remark 8 and A being a maximal set, the relation $f(a_n) < a_{n+1}$ holds for almost all n. It follows that, if n is sufficiently large, then some text of $\{a_n, a_n+1, a_n+2, \ldots\}$ is translated to a text of one of the sets $\{a_k, a_k+1, a_k+2, \ldots\}$ with $k \leq n$. Now fix a text T for $\{a_n, a_n+1, a_n+2, \ldots\}$. One can then inductively define a sequence of strings $\sigma_n, \sigma_{n-1}, \ldots, \sigma_0$ such that each sequence $\sigma_n\sigma_{n-1}\ldots\sigma_m T$ is a text for $\{a_m, a_m+1, a_m+2, \ldots\}$ and

$$\text{content}(\Theta(\sigma_n\sigma_{n-1}\ldots\sigma_m\sigma_{m-1})) \not\subseteq \text{content}(\Theta(\sigma_n\sigma_{n-1}\ldots\sigma_m T))$$

for each $m \leq n$. As Θ maps texts of infinite sets in $\mathcal{L}$ to texts of infinite sets in $\mathcal{L}$, one can conclude that

$$\text{content}(\Theta(\sigma_n\sigma_{n-1}\ldots\sigma_m T)) = \{a_m, a_m+1, a_m+2, \ldots\}.$$

Thus, for every m, some text of the set $\{a_m, a_m+1, a_m+2, \ldots\}$ is mapped to a text for the same set, contradicting the assumption that Θ does not have $\{a_0, a_0+1, a_0+2, \ldots\}$ in its range. Therefore $\mathcal{L}$ is not strongly mitotic. □

3. Incomplete learnable classes. Finite classes are not mitotic, and thus every nonempty class has a subclass which is not mitotic. For infinite classes, one can get

that the corresponding subclass is also infinite. The proof is a standard application of Ramsey's theorem: Given classifiers $C_0, C_1, C_2, \ldots$, one selects a subclass $\{H_0, H_1, H_2, \ldots\}$ of $\{L_0, L_1, L_2, \ldots\}$ such that each classifier C_n classifies $H_n, H_{n+1}, H_{n+2}, \ldots$ in the same way. The class $\{H_0, H_1, H_2, \ldots\}$ may not be an indexed family but may be a very thin class in the sense that the indices of H_n with respect to $L_0, L_1, L_2, \ldots$ are growing very fast. Alternatively, one can also take the $H_0, H_1, H_2, \ldots$ such that, for a given enumeration of primitive recursive operators, the text $\Theta_n(T_m)$ of the ascending text T_m of H_m is not a text for any H_k with $k > \max(\{n, m\})$. The latter method gives the following result.

THEOREM 10. *Every infinite class $\mathcal{L}$ has an infinite subclass $\mathcal{H}$ such that $\mathcal{H}$ is not weakly reducible to any proper subclass of $\mathcal{H}$. In particular, $\mathcal{H}$ is not weakly mitotic.*

There is an easier example of a class which is not weakly mitotic. It is even an indexed family consisting only of finite sets.

Example 11. Assume that $\{L_0, L_1, L_2, \ldots\}$ is given as $L_0 = \{0, 1\}$ and $L_n = \{n\}$ for all $n \in \mathbb{N} - \{0\}$. Then $\{L_0, L_1, L_2, \ldots\}$ is not weakly mitotic.

Proof. Given any splitting $\mathcal{L}_0, \mathcal{L}_1$ of $\{L_0, L_1, L_2, \ldots\}$, one of these classes, say $\mathcal{L}_0$, contains at most one of the sets L_0, L_1. Then, for any given reduction (Θ, Ψ) from $\{L_0, L_1, L_2, \ldots\}$ to $\mathcal{L}_0$, $\Theta(\sigma)$ produces some string of nonempty content for some $\sigma \in 1\#^*$. Thus there are texts T_0, T_1 extending σ for L_0 and L_1, respectively, such that $\Theta(T_0)$ and $\Theta(T_1)$ are texts for different sets in $\mathcal{L}_0$ with a nonempty intersection. However, such sets do not exist, by choice of $\mathcal{L}_0$. □

Note that the class

$$\{\{0, 1, 2\}, \{1, 2\}, \{2\}, \{3\}, \{4\}, \{5\}, \ldots, \{n\}, \ldots\}$$

compared with the class from Example 11 has the following slight improvement. For any splitting $\mathcal{L}_0, \mathcal{L}_1$ of the class, one half of the splitting contains an ascending chain of two or three sets, while the other half contains only disjoint sets. Thus the two halves are not equivalent with respect to $\leq_{weak}$.

As these two examples show, it is more adequate to study the splitting of more restrictive classes like the inclusion-free classes. A special case of such classes are the finitely learnable classes. Here a class is finitely learnable [11] iff there is a learner which, on every text for a language to be learned, outputs only one hypothesis, which must be correct. For technical reasons, the learner keeps outputting a special symbol denoting the absence of a reasonable conjecture until it outputs its only hypothesis.

THEOREM 12. $\{L_0, L_1, L_2, \ldots\} \equiv_{strong} \{H_0, H_1, H_2, \ldots\}$ *whenever both classes are infinite indexed families which are finitely learnable. In particular, every such class is strongly mitotic.*

Proof. As $\{L_0, L_1, L_2, \ldots\}$ and $\{H_0, H_1, H_2, \ldots\}$ are infinite, one can without loss of generality assume that the underlying enumerations are one-to-one. Furthermore, they have exact finite learners M and N, respectively, which use the corresponding indexing. Now one translates $\{L_0, L_1, L_2, \ldots\}$ to $\{H_0, H_1, H_2, \ldots\}$ by mapping L_n to H_n; thus Ψ is the identity mapping, where in the domain the n stands for H_n and in the range the n stands for L_n. $\Theta(T) = \#^k T_n$, where k is the least number such that M outputs a hypothesis n on input $T[k]$ (that is, the first position where M conjectures a hypothesis) and T_n is the ascending text of H_n. This completes the proof of the first statement.

Given now an infinite finitely learnable class $\{L_0, L_1, L_2, \ldots\}$, one can split it into $\{L_0, L_2, L_4, \ldots\}$ and $\{L_1, L_3, L_5, \ldots\}$, which are the subclasses of languages with even and odd index, respectively. Both classes are also infinite indexed families which are

finitely learnable. Thus they are all equivalent by the above result. Furthermore, a classifier for splitting can be obtained by simulating the exact finite learner M for $\{L_0, L_1, L_2, \ldots\}$ on the input text, and then converging to 0 if the (only) grammar output by M on the input text is even and to 1 if the (only) grammar output by M on the input text is odd. □

4. Further splitting theorems. Another question is whether classes can be split into incomparable classes. So one would ask whether there is a parallel result to the Sacks splitting theorem [20]: Every recursively enumerable but nonrecursive set A is the disjoint union of two recursively enumerable sets A_0 and A_1 such that the Turing degrees of A_0 and A_1 are incomparable and strictly below that of A. The next example shows that there are classes where every splitting is of this form; thus these classes are not weakly mitotic. Furthermore, splittings exist, so the result is not making use of a pathological diagonalization against all classifiers.

Example 13. Let A be a maximal set. If $a \notin A$, then let $L_a = \{a\}$; else let $L_a = A$. Then $\{L_0, L_1, L_2, \ldots\}$ is recursively enumerable and finitely learnable, but any splitting $\mathcal{L}_0, \mathcal{L}_1$ of $\{L_0, L_1, L_2, \ldots\}$ satisfies $\mathcal{L}_0 \not\leq_{weak} \mathcal{L}_1$ and $\mathcal{L}_1 \not\leq_{weak} \mathcal{L}_0$.

Proof. Let $T_0, T_1, T_2, \ldots$ be a recursive enumeration of recursive texts for $L_0, L_1, L_2, \ldots$, respectively. Let $F(a)$ be the cardinality of $\{b < a \mid b \notin A\}$. It is easy to see that one can split $\{L_0, L_1, L_2, \ldots\}$ into $\{L_a \mid a \in A \vee F(a) \text{ is even}\}$ and $\{L_a \mid a \notin A \wedge F(a) \text{ is odd}\}$. Thus this class has a splitting; in fact there are infinitely many of them. Furthermore, $\{L_0, L_1, L_2, \ldots\}$ is finitely learnable by outputting an index for L_a for the first a occurring in a given text.

Assume now by way of contradiction that there is a splitting $\mathcal{L}_0, \mathcal{L}_1$ with $\mathcal{L}_0 \leq_{weak} \mathcal{L}_1$ via a reduction (Θ, Ψ). Now one defines the partial recursive function f which outputs on input a the first number occurring in $\Theta(T_a)$; if there occurs no number, then $f(a)$ is undefined. As $\mathcal{L}_0$ is infinite, there are infinitely many $a \notin A$ with $L_a \in \mathcal{L}_0$. For all but one of these, $\Theta(T_a)$ has to be a text for some set $L_b \neq A$ in $\mathcal{L}_1$. Then $L_b = \{b\}$ and $f(a) = b \notin A$ for these a's. It follows that, for every x, there is an $a > x$ with $a \notin A \wedge f(a) \notin A \wedge f(a) > x$. Then, by Remark 8, $f(a) = a$ for almost all $a \notin A$. As infinitely many of these a's belong to an $L_a \in \mathcal{L}_0$, one has that $\Theta(T_a)$ is a text for L_a and Θ translates some text for a set in $\mathcal{L}_0$ into a text for a set in $\mathcal{L}_0$ and not into a text for a set in $\mathcal{L}_1$. Thus $\mathcal{L}_0 \not\leq_{weak} \mathcal{L}_1$. By symmetry of the argument, $\mathcal{L}_1 \not\leq_{weak} \mathcal{L}_0$. □

While Example 13 showed that there are classes for which every splitting is a Sacks splitting, the next result shows that every explanatorily learnable recursively enumerable class has a Sacks splitting; but it might also have other splittings.

THEOREM 14. *Every infinite recursively enumerable and explanatorily learnable class $\{L_0, L_1, L_2, \ldots\}$ has a splitting into two infinite subclasses $\mathcal{L}_0, \mathcal{L}_1$ such that $\mathcal{L}_0 \not\leq_{weak} \mathcal{L}_1$ and $\mathcal{L}_1 \not\leq_{weak} \mathcal{L}_0$.*

Proof. Let M be a explanatory learner for $\{L_0, L_1, L_2, \ldots\}$ which satisfies the three conditions from Remark 5. Now one defines the following function F from $\mathbb{N}$ to $\{0, 1\}$, inductively using the oracle K for the halting problem.

Let $\Theta_0, \Theta_1, \Theta_2, \ldots$ be the enumeration of operators as given in Remark 2. Let T_n be a text for L_n, constructed effectively from n (as $\{L_0, L_1, L_2, \ldots\}$ is recursively enumerable, this can be done). Let U be the set of all minimal indices of languages in $\{L_0, L_1, L_2, \ldots\}$; that is, $n \in U$ iff for all $m < n$, $L_m \neq L_n$. Note that one can decide U relative to K, since $L_m = L_n$ iff M converges to the same index on both T_m and T_n. Let $F^*(n, a)$ be the number of $k \in U$ satisfying $k < n$ and $F(k) = a$. Note that $F^*(n, a)$ can be computed using oracle K (assuming F can be computed relative to

K, as will be shown later).

The value of $F(n)$ is defined by using the case below, with higher priority (reflected by the least number), for which the corresponding condition is true.

- Case with priority 0: $n \notin U$. Then there is an $m < n$ such that $L_m = L_n$. Let $F(n) = F(m)$ for the least such m.
- Case with priority $4e + 1$: There is an $m < n$ such that (a) M converges on $\Theta_e(T_m)$ and T_n to the same value; (b) $F(m) = 0$; and (c) there are no $i, j < n$ such that $F(i) = 0$, $F(j) = 0$, and M converges on $\Theta_e(T_i)$ to the same value as on T_j. Then let $F(n) = 0$.
- Case with priority $4e + 2$: There is an $m < n$ such that (a) M converges on $\Theta_e(T_m)$ and T_n to the same value; (b) $F(m) = 1$; and (c) there are no $i, j < n$ such that $F(i) = 1$, $F(j) = 1$, and M converges on $\Theta_e(T_i)$ to the same value as on T_j. Then let $F(n) = 1$.
- Case with priority $4e + 3$: $F^*(m, 0) < F^*(m, 1) + e$ for all $m \leq n$. Then let $F(n) = 0$.
- Case with priority $4e + 4$: $F^*(m, 1) < F^*(m, 0) + e$ for all $m \leq n$. Then let $F(n) = 1$.

More precisely, when defining $F(n)$ one searches for the least number k such that the case with priority k applies, and then defines F as described in that case. Note that the conditions for the cases with priorities $4e + 3$ and $4e + 4$ apply for all $e > n$, and thus there is always some case which applies.

Next it is shown that $F \leq_T K$. As M converges on T_m, for every m, the test whether the condition of the case with priority 0 applies for computing $F(n)$ (and the corresponding computation of $F(n)$) can be done relative to K: $L_m = L_n$ iff M converges to the same value on both T_m and T_n. For the test whether the condition of the case with priority $4e + 1$ applies, it needs to be checked whether M converges to the same value on both $\Theta_e(T_m)$ and T_n. This can be done using oracle K as follows. First compute the value d to which M converges on T_n. Then, as M satisfies the constraints in Remark 5, M on $\Theta_e(T_m)$ either converges to d or outputs d only finitely often. Thus one can check, using the oracle K, whether M converges on $\Theta_e(T_m)$ to d. Similarly, one can check, for any two numbers i and $j < n$, whether M converges to the same value on $\Theta_e(T_i)$ and T_j. Thus, one can test, using oracle K, whether the case with priority $4e + 1$ applies. Similarly, one can test whether the case with priority $4e + 2$ applies. The tests for the cases with priorities $4e + 3$ and $4e + 4$ are obviously doable relative to K as $U \leq_T K$ and the conditions refer only to statistics of previous values of F at places where the argument is in U.

So F can be computed in the limit. Having an approximation F_s to F, one defines a classifier C as $C(\sigma) = F_{|\sigma|}(m)$ for the least m such that $m = |\sigma| \vee M(T_m[|\sigma|]) = M(\sigma)$. Assume now that a text T of a language in $\{L_0, L_1, L_2, \ldots\}$ is given and n is the least index such that $L_n = \text{content}(T)$. Then, for all sufficiently large s, $C(T[s]) = F_s(n)$ (as M converges on T and T_n to the same index of L_n, but, for $m < n$, M converges on T_m to an index for the language L_m which is not equal to L_n). Thus C converges on T to $F(n)$.

Clearly the case with priority 0 is applied for computing $F(n)$ iff $n \notin U$ (this happens for infinitely many n). Now it is shown by induction that the case with priority $4e + c > 0$ (where $c \in \{1, 2, 3, 4\}$) applies for computing only finitely many $F(n)$. Assume by induction that, for some ℓ, all cases with priorities k strictly between 0 and $4e + c$ do not apply for computation of $F(n)$, $n \geq \ell$, and the case with priority $4e + c$ applies for computing $F(\ell)$. Now one makes a case-distinction depending on

which of the priorities $4e + c$ is applied for computing $F(\ell)$.

In the case of priority $4e+1$, for $n = \ell$, there is an $m < n$ such that (a) $F(m) = 0$, (b) $F(n) = 0$, and (c) M converges on $\Theta_e(T_m)$ and T_n to the same value. Now let $i = m$ and $j = \ell$. Then, for $n > \ell$, these values i, j are below n and ensure that the case with priority $4e + 1$ does not apply. So $n = \ell$ is the maximal n where $F(n)$ is defined according to this case.

In the case of priority $4e+3$, consider the set $\{n_0, n_1, n_2, \ldots, n_k\}$ of the least $k+1$ elements of $U \cap \{\ell, \ell + 1, \ell + 2, \ldots\}$, where $k = e + F^*(\ell, 1) - F^*(\ell, 0)$. One can now prove by induction for $u = 0, 1, 2, \ldots$ that

- for n_u with $u < k$, the case with priority $4e + 3$ applies and $F(n_u) = 0$;
- for n_u with $u \leq k$, $F^*(n_u, 0) = F^*(\ell, 0) + u$ and $F^*(n_u, 1) = F^*(\ell, 1)$.

Thus, $F^*(n_k, 0) = F^*(n_k, 1) + e$, and for $n \geq n_k$ the case with priority $4e + 3$ does not apply for computing $F(n)$.

The other two cases of priority $4e+2$ and $4e+4$ are symmetric to the two previous cases. Thus, one can conclude that there are only finitely many n where the case with priority $4e+c$ applies in the computation of $F(n)$. This completes the inductive step.

Let $\{L_0, L_1, L_2, \ldots\}$ be split into two classes as $\mathcal{L}_a = \{L_i : F(i) = a\}$. Now assume by way of contradiction that there is a reduction (Θ_e, Ψ) witnessing that $\mathcal{L}_0 \leq_{weak} \mathcal{L}_1$. Let ℓ be so large that the cases with priorities $1, 2, \ldots, 4e$ are not used to define any $F(n)$ with $n \geq \ell$. Due to the case with priority $4\ell + 7$, there is an $\ell' \in U$ with $F^*(\ell', 0) \geq F^*(\ell', 1) + \ell + 1$; note that $\ell' > \ell$. So more sets in $\mathcal{L}_0$ than in $\mathcal{L}_1$ have an index below ℓ'. Thus, there is an $m \leq \ell'$ such that $L_m \in \mathcal{L}_0$ and $\Theta_e(T_m)$ is not the text of any of the sets $L_0, L_1, \ldots, L_{\ell'}$. Let n be the minimal index of content$(\Theta_e(T_m))$; this index exists as Θ_e maps texts of languages in $\mathcal{L}_0$ to texts of languages in $\mathcal{L}_1$. It follows from the construction that either $F(n) = F(m) = 0$ and $L_n \in \mathcal{L}_0$ or there are $i, j < n$ with $F(i) = F(j) = 0$, $L_i, L_j \in \mathcal{L}_0$, and $\Theta_e(T_i)$ being a text for L_j. This contradicts the assumption that (Θ_e, Ψ) reduces $\mathcal{L}_0$ to $\mathcal{L}_1$. Hence $\mathcal{L}_0 \not\leq_{weak} \mathcal{L}_1$. Similarly one can show that $\mathcal{L}_1 \not\leq_{weak} \mathcal{L}_0$. □

For this reason, one cannot give a recursively enumerable class where all splittings $\mathcal{L}_0, \mathcal{L}_1$ satisfy either $\mathcal{L}_0 \leq_{strong} \mathcal{L}_1$ or $\mathcal{L}_1 \leq_{strong} \mathcal{L}_0$. Furthermore, complete classes have comparable splittings like before as they are mitotic and have even equivalent splittings. The next example gives a class where halves of some splittings are comparable but are never equivalent.

Example 15. Let A be a maximal set. For all $a \in \mathbb{N}$ and $b \in \{0, 1, 2\}$, let $L_{3a+b} = \{3a + b\}$ if $a \notin A$ and $L_{3a+b} = \{3c + b \mid c \in A\}$ if $a \in A$. Then $\{L_0, L_1, L_2, \ldots\}$ is not weakly mitotic as no halves of any splitting are equivalent with respect to $\leq_{weak}$, but $\{L_0, L_1, L_2, \ldots\}$ has a splitting $\mathcal{L}_0, \mathcal{L}_1$ with $\mathcal{L}_0 \leq_{strong} \mathcal{L}_1$.

Proof. If one takes the splitting $\mathcal{L}_0 = \{L_0, L_3, L_6, \ldots\}$ and $\mathcal{L}_1 = \{L_1, L_2, L_4, L_5, L_7, L_8, \ldots\}$, then it is easy to see that $\mathcal{L}_0 \leq_{strong} \mathcal{L}_1$ via (Θ, Ψ) such that Θ is based on translating every datum $3x$ to $3x + 1$ and Ψ is based on transforming every index e into an index for $\{3x \mid 3x + 1 \in W_e\}$. The details are left to the reader.

Given now a further splitting $\mathcal{L}_2, \mathcal{L}_3$ of $\{L_0, L_1, L_2, \ldots\}$, one of these two classes, say $\mathcal{L}_2$, must contain at least two of the sets $L_{3a}, L_{3a+1}, L_{3a+2}$ for infinitely many $a \notin A$. Assume by way of contradiction that (Θ, Ψ) would witness $\mathcal{L}_2 \leq_{weak} \mathcal{L}_3$. Now one defines the following functions f_b for $b = 0, 1, 2$ by letting $f_b(a)$ be the number x such that $3x$ or $3x + 1$ or $3x + 2$ occurs earliest in the text $\Theta((3a + b)^\infty)$. Now choose two different $b, b' \in \{0, 1, 2\}$ such that there are infinitely many $a \in \mathbb{N} - A$ with $L_{3a+b}, L_{3a+b'} \in \mathcal{L}_2$. Then one knows that, for every bound c, there are infinitely many $a \in \mathbb{N} - A$ such that $L_{3a+b} \in \mathcal{L}_2$ and $\Theta((3a+b)^\infty)$ is a text for some language in

$\mathcal{L}_3 - \{L_0, L_1, L_2, \ldots, L_c\}$. It follows by Remark 8 that $f_b(a) = a$ for almost all $a \notin A$. The same applies to $f_{b'}$. So there is an $a \notin A$ such that $L_{3a+b}, L_{3a+b'}$ are both in $\mathcal{L}_2$ and that Θ maps texts of both languages to texts of the sets L_{3a}, L_{3a+1}, or L_{3a+2}. As only one of these sets can be in $\mathcal{L}_3$, Θ has to map texts of different languages to texts of the same language, a contradiction. Thus $\mathcal{L}_2 \not\leq_{weak} \mathcal{L}_3$ and the class cannot be weakly mitotic. □

While in recursion theory a splitting A_0, A_1 of a recursively enumerable set A satisfies $A_0 \equiv_T A_1 \Rightarrow A_0 \equiv_T A$, the next example shows that the corresponding connection does not hold in inductive inference. The proof is very similar to Example 15 and is thus omitted.

Example 16. Let A be a maximal set. For all $a \in \mathbb{N}$ and $b \in \{0, 1\}$, let $L_{2a+b} = \{2a + b\}$ if $a \notin A$ and $L_{2a+b} = \{2c + b \mid c \in A\}$ if $a \in A$. Then $\{L_0, L_1, L_2, \ldots\}$ is not weakly mitotic, but the halves of the splitting $\{L_0, L_2, L_4, \ldots\}, \{L_1, L_3, L_5, \ldots\}$ are equivalent with respect to $\leq_{strong}$.

5. Beyond explanatory learning. One could, besides classes which are complete for explanatory learning, also consider classes which are complete for behaviorally correct learning [3, 5, 18] with respect to $\leq_{strong}$. Note that such a class $\mathcal{L}$ may no longer be explanatorily learnable, but $\mathcal{L}$ satisfies the following two properties:

- The class $\mathcal{L}$ is behaviorally correct learnable; that is, there is a learner which outputs, on every text T for a language in $\mathcal{L}$, an infinite sequence $e_0, e_1, e_2, \ldots$ of hypotheses such that $W_{e_n} = \text{content}(T)$ for almost all n.
- Every behaviorally correct learnable class $\mathcal{H}$ satisfies $\mathcal{H} \leq_{strong} \mathcal{L}$.

Note that the reduction $\leq_{strong}$ considered in this paper is always the same as defined for explanatory learning; reducibilities more adapted to behaviorally correct learning have also been studied [12, 13]. Completeness with respect to $\leq_{weak}$ is not considered in this section, so "complete" means "complete for $\leq_{strong}$" in this section.

It is easy to show that such complete classes exist. Consider as an example the class $\mathcal{L}$ of all sets $\{x\} \cup \{x + y + 1 \mid y \in L\}$, where the xth learner behaviorally correct learns the set L. So given any behaviorally correct learnable class and an index x of its learner, the translation $L \mapsto \{x\} \cup \{x + y + 1 \mid y \in L\}$ would translate all the sets behaviorally correct learned by this learner into sets in $\mathcal{L}$.

In the following let $\mathcal{L}$ be any class which is complete for behaviorally correct learning with respect to $\leq_{strong}$. Note that methods similar to those in Theorem 3 show that $\mathcal{L}$ is strongly mitotic. The next result shows that for any splitting $\mathcal{L}_0, \mathcal{L}_1$ of $\mathcal{L}$, one of these two classes is complete for behaviorally correct learning as well and therefore this class cannot be split into two incomparable subclasses.

THEOREM 17. *If $\mathcal{L}_0, \mathcal{L}_1$ are a splitting of a class which is complete for behaviorally correct learning with respect to $\leq_{strong}$, then either $\mathcal{L}_0 \equiv_{strong} \mathcal{L}_0 \cup \mathcal{L}_1$ or $\mathcal{L}_1 \equiv_{strong} \mathcal{L}_0 \cup \mathcal{L}_1$.*

Proof. First the theorem is shown for a special class $\mathcal{S}$ defined below. Let $\mathcal{H}$ be a class which is complete for behaviorally correct learning with respect to $\leq_{strong}$. Furthermore, let $C_0, C_1, \ldots$ be a list of all primitive recursive classifiers. One builds, for each x, a sequence $\tau_{x,0}, \tau_{x,1}, \ldots$ starting with $\tau_{x,0} = x$ as follows. If $\tau_{x,y}$ has been defined, then one takes $\tau_{x,y+1}$ to be the first extension of $\tau_{x,y}$ found, if any, such that

$$\{x, x + 1, x + 2, \ldots, x + y\} \subseteq \text{content}(\tau_{x,y+1}) \subseteq \{x, x + 1, x + 2, \ldots\}$$

and $C_x(\tau_{x,y+1}) \neq C_x(\tau_{x,y})$.

In the case that the above process terminates at some y, that is, if $\tau_{x,y+1}$ does not exist, then let $z = \max(\text{content}(\tau_{x,y}))$ and place in $\mathcal{S}$ the set

$$\{x, x+1, x+2, \ldots, z\} \cup \{z+u+1 \mid u \in H\},$$

for each $H \in \mathcal{H}$.

On the other hand, if the process does not terminate at any y, then $T = \lim_{y\in\mathbb{N}} \tau_{x,y}$ is a text for $\{x, x+1, x+2, \ldots\}$ on which C_x does not converge; in this case, one places the set

$$\{x, x+1, x+2, \ldots\}$$

into $\mathcal{S}$. Note that, in this case, C_x does not split $\mathcal{S}$ into two subclasses, as it diverges on a text for $\{x, x+1, x+2, \ldots\}$.

Now it is shown that $\mathcal{S}$ is behaviorally correct learnable. Suppose M is a behaviorally correct learner for $\mathcal{H}$. The new learner N for $\mathcal{S}$ works as follows. On input $T[n]$, it determines $x_n = \min(\text{content}(T[n]))$, $y_n =$ largest value of y such that $\tau_{x_n,y}$ is defined within n steps in the process given above, and $z_n = \max(\text{content}(\tau_{x_n,y_n}))$. The learner N then constructs a new string η, where it replaces every u in $T[n]$ by $u - z_n - 1$ if $u > z_n$, and by $\#$ if $u < z_n$. Then N conjectures the following set:

$$W_{N(\sigma)} = \begin{cases} \{x_n, x_n+1, x_n+2, \ldots, z_n\} & \\ \quad \cup\ \{u + z_n + 1 \mid u \in W_{M(\eta)}\} & \text{if } \tau_{x_n,y_n+1} \text{ does not get defined;} \\ \{x_n, x_n+1, x_n+2, \ldots\} & \text{if } \tau_{x_n,y_n+1} \text{ is defined.} \end{cases}$$

Note that the definition above is valid, as $\{x_n, x_n+1, x_n+2, \ldots, z_n\} \cup \{u+z_n+1 \mid u \in W_{M(\eta)}\} \subseteq \{x_n, x_n+1, x_n+2, \ldots\}$, and thus one can always switch to the second case when τ_{x_n,y_n+1} is defined. The verification that N indeed behaviorally correct learns $\mathcal{S}$ is straightforward; therefore the verification is omitted.

Now consider any classifier C_x which converges on every text for a language in $\mathcal{S}$. Then there is a maximal y such that $\tau_{x,y}$ is defined (since otherwise C_x does not converge on $T = \bigcup_{y\in\mathbb{N}} \tau_{x,y}$, which is a text for the language in $\mathcal{S}$). Let $z = \max(\text{content}(\tau_{x,y}))$. Therefore, the class $\mathcal{H}$ is strongly reducible to the subclass

$$\{\, \{x, x+1, x+2, \ldots, z\} \cup \{z+u+1 \mid u \in H\} \mid H \in \mathcal{H}\}$$

of $\mathcal{S}$. Furthermore, every set in this subclass has a text starting with $\tau_{x,y}$ and C_x converges on all such texts to $C_x(\tau_{x,y})$. Therefore this complete class is contained in one member of the splitting of $\mathcal{S}$ defined by C_x. Thus, one of these members is complete for behaviorally correct learning with respect to $\leq_{strong}$.

After dealing with this special class $\mathcal{S}$, consider any splitting $\mathcal{L}_0, \mathcal{L}_1$ of a class $\mathcal{L}$ which is complete for behaviorally correct learning with respect to $\leq_{strong}$. There is a reduction (Θ, Γ) from $\mathcal{S}$ to $\mathcal{L}_0 \cup \mathcal{L}_1$ due to completeness. Let C be the classifier which splits $\mathcal{L}$ into $\mathcal{L}_0, \mathcal{L}_1$. Let $\mathcal{S}_a$ consist of those L in $\mathcal{S}$ which are mapped to $\mathcal{L}_a$ by Θ. Note that this splitting of $\mathcal{S}$ can be effectively obtained by using Θ and C. As one of $\mathcal{S}_0$, $\mathcal{S}_1$ is complete for behaviorally correct learning (by the proof above), one of $\mathcal{L}_0$, $\mathcal{L}_1$ is complete for behaviorally correct learning with respect to $\leq_{strong}$. ∎

As just seen, any splitting $\mathcal{L}_0, \mathcal{L}_1$ of a class which is complete for behaviorally correct learning satisfies either $\mathcal{L}_0 \equiv_{strong} \mathcal{L}_1$ or $\mathcal{L}_0 <_{strong} \mathcal{L}_1$ or $\mathcal{L}_1 <_{strong} \mathcal{L}_0$. As the class is strongly mitotic, it can happen that the two halves of a splitting are

equivalent (although this is not always the case). The next result gives a class where the two halves of a splitting are always comparable but never equivalent.

THEOREM 18. *There is a recursively enumerable and behaviorally correct learnable class, which is not weakly mitotic, such that every splitting $\mathcal{L}_0, \mathcal{L}_1$ of the class satisfies either $\mathcal{L}_0 \leq_{strong} \mathcal{L}_1$ or $\mathcal{L}_1 \leq_{strong} \mathcal{L}_0$, but not $\mathcal{L}_0 \equiv_{weak} \mathcal{L}_1$.*

Proof. A minor modification of the construction of Post's simple set [19] gives the following: There is a recursive partition of the odd natural numbers into sets $I_0, I_1, I_2, \ldots$ and a recursively enumerable set L_1 of odd natural numbers such that (a) $1 \in L_1$, (b) $I_n \not\subseteq L_1$ for all n, and (c) L_1 intersects every recursively enumerable set which contains infinitely many odd natural numbers.

For $n \neq 1$, if n is even, then let $L_n = \{n\}$; else let $L_n = L_1 \cup \{n\}$.

Clearly $\{L_0, L_1, L_2, \ldots\}$ is behaviorally correct learnable: On input σ, the learner conjectures content(σ) if σ does not contain an odd number; otherwise it conjectures content(σ) $\cup L_1$.

Let $\mathcal{L}_0, \mathcal{L}_1$ be a splitting of $\{L_0, L_1, L_2, \ldots\}$. L_1 is in one of these classes, say in $\mathcal{L}_1$. Let C be the classifier witnessing the split. Then there is a stabilizing sequence σ for C on L_1, such that content(σ) $\subseteq L_1$ and $C(\tau) = 1$ for all extensions τ of σ with content(τ) $\subseteq L_1$. Let T be a text of L_1. Now for every $a \in L_1$ and every n, $C(\sigma a T[n]) = 1$. Since L_1 is simple, it follows that the set

$$D = \{a \mid a \text{ is odd and } \exists n\,[M(\sigma a T[n]) = 0]\}$$

is finite and thus $L_a \in \mathcal{L}_1$ for all odd $a \notin D$. Let n be such that $D \cap I_m = \emptyset$ for all $m \geq n$. Let $a_0, a_1, a_2, \ldots$ be an ascending enumeration of all even numbers plus members of D. Note that $\mathcal{L}_0 \subseteq \{L_{a_0}, L_{a_1}, L_{a_2}, \ldots\}$.

Let $b_m = \min(I_{n+m} - L_1)$—note that b_m is well defined since $I_{n+m} \not\subseteq L_1$ for all m. Note that $L_1 \cup \{b_m\}$ is in $\mathcal{L}_1$ for all m.

Now it is shown that $\mathcal{L}_0 \leq_{strong} \mathcal{L}_1$. Let Θ be an operator which maps texts for L_{a_m} to texts for $L_1 \cup \{b_m\}$. Note that such a Θ can easily be constructed. For Ψ, given a sequence E, one can determine, in the limit, the grammar e to which E converges (if any), and then determine, in the limit, the m such that e is a grammar for $L_1 \cup \{b_m\}$ (if there is any such m). Thus, one can construct a sequence which converges to a grammar for L_{a_m}, whenever such an m as above exists.

On the other hand, if an operator translates texts of sets in $\mathcal{L}_1$ into texts of sets in $\mathcal{L}_0$, then it has to map some text T of L_1 to some text of some L_{a_m}. There is an initial segment σ of T such that a_m appears on the output when σ is fed into the operator. There is only the set L_{a_m} in $\mathcal{L}_0$ containing a_m, but infinitely many sets in $\mathcal{L}_1$ that have a text starting with σ. Therefore the translation maps some texts of different sets in $\mathcal{L}_1$ to texts of L_{a_m}. Thus, the translation cannot be used for a weak reduction from $\mathcal{L}_1$ to $\mathcal{L}_0$. Hence $\mathcal{L}_1 \not\leq_{weak} \mathcal{L}_0$. □

6. Autoreducibility. Trakhtenbrot [23] defined that a set A is autoreducible iff one can reduce A to A such that $A(x)$ is obtained by accessing A only at places different from x. Ladner [15] showed that a recursively enumerable set is mitotic iff it is autoreducible. Ambos-Spies pointed out this result to the authors and asked whether the same holds in the setting of inductive inference. Unfortunately, this characterization fails for both of the major variants of autoreducibility. These variants are the ones corresponding to strong and weak reducibility.

DEFINITION 19. *A class $\mathcal{L}$ is strongly (weakly) autoreducible iff there is a strong (weak) reduction (Θ, Ψ) from $\mathcal{L}$ to $\mathcal{L}$ such that, for all sets $L \in \mathcal{L}$ and all texts T for L, $\Theta(T)$ is a text for a language in $\mathcal{L} - \{L\}$.*

Example 20. Let A be a maximal set and let $\mathcal{L}$ contain the following sets:

- $\{3x\}, \{3x+1\}, \{3x+2\}$ for all $x \notin A$;
- $\{3y : y \in A\}$, $\{3y+1 : y \in A\}$, $\{3y+2 : y \in A\}$.

Then the class $\mathcal{L}$ is neither strongly mitotic nor weakly mitotic. But $\mathcal{L}$ is autoreducible via some (Θ, Ψ) where Θ maps any text T to a text T' such that all elements of the form $3y$ in T have the form $3y+1$ in T', all elements of the form $3y+1$ in T have the form $3y+2$ in T', and all elements of the form $3y+2$ have the form $3y$ in T'.

So even the implication "strongly autoreducible $\Rightarrow$ weakly mitotic" fails. The remaining question is whether at least the converse direction is true in inductive inference. This is still unknown, but there is some preliminary result on sets which are complete for $\leq_{weak}$.

THEOREM 21. *If a class $\mathcal{L}$ is complete for $\leq_{weak}$, then it is weakly autoreducible.*

Proof. Let $\mathcal{L}$ be complete for $\leq_{weak}$ and let M be an explanatory learner for $\mathcal{L}$ which satisfies the conditions from Remark 5. As $\mathcal{L}$ is complete for $\leq_{weak}$, by Proposition 6, there is a reduction (Θ, Ψ) from the class $\mathcal{I}$ to $\mathcal{L}$ such that, for any set $I_x = \{0, 1, \ldots, x\} \in \mathcal{I}$ and any text T for I_x, $\Theta(T)$ is a text for a set on which M does not converge to an index less than or equal to x. Now, an autoreduction (Θ', Ψ') is constructed.

For this, one first defines Θ'' as follows and then concatenates it with Θ. The operator Θ'' translates every text T for a set L into a text for $I_{2^n(1+2m)}$, where m, n are chosen such that n is the value to which M converges on T and m is so large that all the elements put into $\Theta''(T)$, when following intermediate hypotheses of M on T, are contained in the set $I_{2^n(1+2m)}$. It is easy to verify that this can be done. Then Θ' is given as $\Theta'(T) = \Theta(\Theta''(T))$. The sequence $\Theta'(T)$ is a text for a set in $\mathcal{L}$ with the additional property that M converges on it to an index larger than $2^n(1+2m)$; this index is therefore different from n and $\text{content}(\Theta'(T)) \neq \text{content}(T)$.

The reverse operator Ψ' can easily be generated from Ψ. If E converges to an index for $\text{content}(\Theta'(T))$, then $\Psi(E)$ converges to some index for $I_{2^n(1+2m)}$. The number $2^n(1+2m)$ can be determined in the limit from this index by enumerating the corresponding finite set; thus Ψ' can translate E via $\Psi(E)$ to a sequence which converges to n. ∎

Example 22. The class $\mathcal{L}$ from Theorem 9 is complete for $\leq_{weak}$ and weakly autoreducible but not strongly autoreducible.

Proof. Let $\mathcal{L}$ and $a_0, a_1, a_2, \ldots$ be as in Theorem 9. Assume that (Θ, Ψ) witness that $\mathcal{L}$ is strongly autoreducible. Then Θ has to preserve inclusions and therefore map infinite sets in $\mathcal{L}$ to infinite sets. So, $\text{content}(\Theta(a_0\,(a_0+1)\,(a_0+2)\,\ldots))$ is an infinite set in $\mathcal{L}$ different from $\{a_0, a_0+1, a_0+2, \ldots\}$. By induction, one can show that

$$\text{content}(\Theta(a_n\,(a_n+1)\,(a_n+2)\,\ldots)) \subseteq \{a_{n+1}, a_{n+1}+1, a_{n+1}+2, \ldots\} \quad \text{and}$$
$$\text{content}(\Theta(a_n\,(a_n+1)\,(a_n+2)\,\ldots)) \subset \{a_n, a_n+1, a_n+2, \ldots\}.$$

But in Theorem 9 it was shown that no recursive operator has these properties. That $\mathcal{L}$ is complete for $\leq_{weak}$ was shown in Theorem 9, and that $\mathcal{L}$ is weakly autoreducible follows from Theorem 21. ∎

Acknowledgment. We would like to thank the anonymous referees for several helpful comments.

ON MONOTONE FORMULA COMPOSITION OF PERFECT ZERO-KNOWLEDGE LANGUAGES*

ALFREDO DE SANTIS†, GIOVANNI DI CRESCENZO‡, GIUSEPPE PERSIANO†, AND MOTI YUNG§

Abstract. We investigate structural properties of interactive perfect zero-knowledge (PZK) proofs. Specifically, we look into the closure properties of PZK languages under monotone boolean formula composition. This gives rise to new protocol techniques. We show that interactive PZK for random self-reducible (RSR) (and for co-RSR) languages is closed under monotone boolean formula composition. Namely, we present PZK proofs for monotone boolean formulae whose atoms are statements about membership in a PZK language which is RSR (or whose complement is RSR). We also discuss extensions, recent applications, and generalizations of the techniques.

Key words. zero knowledge, interactive proofs, random self-reducible languages

1. Introduction.

A *zero-knowledge proof*, as introduced by Goldwasser, Micali, and Rackoff [42], is a proof procedure with the remarkable property of yielding nothing but the validity of the assertion. In [38] it was then shown that, under the assumption that one-way functions exist, all NP statements have computational zero-knowledge proofs, namely, proofs that are zero knowledge with respect to computationally bounded adversaries. Perfect zero-knowledge (PZK) proofs [42] are those proofs that are zero knowledge even with respect to a computationally unbounded adversary. The notion is important from both a practical and a theoretical perspective. We next review the practical and theoretical motivations of our work.

Practical motivations. PZK proof systems find their main application in the design of identification schemes, as first noted in [31]. An identification scheme is a protocol for two parties, called the user and the system, by which the user identifies himself to the system in a secure way; that is, a third party listening to the conversation cannot later impersonate the user. Typically, the user is trying to log into a system and has to identify himself as a legitimate user before the system grants him access. Identification schemes rely on the fact that certain PZK proofs are also "proofs of possession of knowledge of a witness" [31, 54, 3, 28] (a notion alluded to in [42, 32]).

In some applications it is desirable that the identity of the specific user trying to get access be kept secret from the system. For example, an investment firm accessing a stock market database would prefer not to reveal its identity to the database manager;

knowing which firm is interested in the stock of a given company is usually valuable information. At the same time, the system must make sure that the person trying to get access is a legitimate user (i.e., a subscriber to the service). The following "multifaceted identification scheme" is a possible solution to the above problem. As a concrete example, consider a system where user i knows a square root of x_i modulo an integer n which is the product of two primes. A user can identify himself as being a member of the group by proving that he knows a witness to the statement $(x_1 \in \mathrm{QR}_n) \vee (x_2 \in \mathrm{QR}_n) \vee \cdots \vee (x_m \in \mathrm{QR}_n)$ without disclosing his identity which is related to the specific x_i for which he knows a square root (QR_n is the set of elements of Z_n^* that admit a square root modulo n). On the other hand, at some other times user i can prove its individual (as opposed to group) identity by proving possession of a witness (square root) to the specific disjunct $(x_i \in \mathrm{QR}_n)$ associated with him. Other similar applications may employ a more complicated sharing of witnesses according to some given structure (typically called an access structure [44]), thus needing proof systems for general formulae (not just simply disjunction). In [24], a communication-efficient multifaceted identification scheme based on quadratic residuosity is presented.

Recently, the dual problem—consisting in hiding which record is accessed and not the identity of the user—has also been studied (see, e.g., [19]).

Theoretical motivations. From a theoretical prospective, PZK (as well as the related, less stringent notion of statistical ZK (SZK)) has been the subject of a number of early investigations. In [38] PZK proofs were given for the language of graph isomorphism as well as of graph nonisomorphism (which was the first language not known to be in NP shown to have an interactive proof). In [33, 2] it was proved that a complement of any SZK language has a 2-round proof system, and in [2] it was shown that any language with an SZK proof system also has a 2-round proof system. The round complexity and prover-power for SZK and PZK were studied in [5, 6, 7]. The honest verifier versus dishonest verifier and the private coin versus public coin problems have been studied, e.g., in [6, 49]. As PZK proofs do not depend on the properties of assumed hard problems (such as one-way functions) but only on the input language, they constitute a clean context for studying the intrinsic structural properties of the notion of a zero-knowledge proof and knowledge complexity of languages [42, 41, 40].

We remark that PZK/SZK proofs also motivated the useful notion of computationally sound proofs (in conjunction with the idea of zero-knowledge arguments) [17, 18, 47] and inspired the recent work on program checking and testing [14, 11].

PZK proofs are also the basic schemes used as preprocessing of further zero-knowledge proof systems; for example, in the noninteractive scenario [12, 13] and its applications (e.g., [48, 29, 28, 4]).

Given its practical use, its influence, and the complexity-theoretic investigations concerning PZK/SZK, we observe that relatively very few languages are known to be PZK. This, in turn, implies that only very few general protocol techniques are available for designing and utilizing the notion. Besides the proofs for quadratic residuosity and quadratic nonresiduosity given in the original paper [42], PZK proofs were given in [38, 34, 54, 37, 16, 25] and in [12, 22, 27] for the noninteractive zero-knowledge case. In [54] it was noted that all these languages have certain relations to random self-reducibility properties—either positively by claiming that the input is randomly reducible (by a group action) to some structure (e.g., one graph isomorphic to another), or negatively by claiming that the input is not reducible (e.g., a graph

is not isomorphic to another). This corresponds to the membership problem of a complement of an RSR language; see, e.g., [54]. All of their proof systems rely on certain algebraic properties associated with the random self-reducibility property.

The results of this paper suggest new protocol construction techniques, prove that a large class of logically constructible languages over atomic languages which are in PZK are themselves in PZK, and show that PZK is a larger class than previously known.

Summary of results. We prove that PZK for RSR languages (see [54]) is closed under monotone formula composition, thus extending the work of [42, 38] on PZK. More precisely, we present PZK proofs for all *monotone boolean formulae* whose atoms are statements about membership in an RSR language.

Let us give a concrete example. Fix an RSR language L (say graph isomorphism) and consider the following scenario. The prover and the verifier get as common input a monotone formula ϕ on m variables and strings $x_1, \ldots, x_m$. The prover wishes to convince the verifier that $\phi(\chi_1, \ldots, \chi_m)$ is true where $\chi_i = 1$ if $x_i \in L$ and $\chi_i = 0$ otherwise. We show that this can be done in PZK (and the interaction takes time polynomial in the size of ϕ and all the x_i's).

The above results are also shown for languages whose complement is RSR (such as nonisomorphism, nonresiduosity). Moreover, we prove that *threshold formulae* over membership statements for RSR languages and threshold formulae over *negated* membership statements for RSR languages also have PZK proofs.

Finally, we also show closure properties for a specific class of *nonmonotone* formulae.

Results in this paper for the special case of graph isomorphism and graph nonisomorphism languages have appeared in [26].

2. Notation and terminology. Given a boolean formula $\phi(v_1, \ldots, v_m)$, each truth assignment $t : \{v_1, \ldots, v_m\} \to \{0, 1\}$ naturally defines the validity t_ϕ of the formula ϕ under t. For convenience we assume that, scanning the formula from left to right, the variables $v_1, \ldots, v_m$ appear in this order. A *monotone formula* ϕ over the variables $v_1, \ldots, v_m$ is a boolean formula where each boolean operator is either an OR or an AND with two inputs and one output. A *threshold formula* is a boolean formula where each boolean operator computes a threshold function, where a threshold function $T_{k,m}$ takes m boolean values as input and outputs 1 if and only if at least k out of the m boolean values are 1. In this paper we will consider the following classes of boolean formulae: MON, the class of monotone formulae; T, the class of threshold formulae; and OR, the class of formulae that can be written as $((\phi) \vee (\neg\psi))$, where ϕ, ψ are monotone formulae.

Let L be a language, and let χ_L denote the indicator function for the language L (i.e., $\chi_L(x) = 1$ if and only if $x \in L$). Also, let B_m be a class of boolean formulae over m variables, $B = \cup_{m \geq 1} B_m$, and let $\vec{x} = (x_1, \ldots, x_m)$ be an m-tuple of binary strings. We define the language

$$CL(B; L) = \{(\phi; \vec{x}) \,|\, \text{for some } m > 0,\ \phi \in B_m; \phi(\chi_L(x_1), \ldots, \chi_L(x_m)) = 1\}.$$

We define the *size* of $(\phi, \vec{x})$ as the sum of the lengths of $\vec{x}$ and ϕ, according to their standard encoding (see, e.g., [35]).

Let us give a concrete example. Consider the language ISO of pairs of isomorphic graphs. Let ϕ be the monotone formula $(v_1 \wedge v_2) \vee (v_3 \wedge v_4)$, and let $\mathcal{G} = ((G_{10},$

$G_{11}), \ldots, (G_{40}, G_{41}))$ be a quadruple of pairs of graphs. Then, the pair $(\phi, \mathcal{G})$ belongs to the language CL(MON; ISO) if and only if the following statement is true:

$$((G_{10} \approx G_{11}) \wedge (G_{20} \approx G_{21})) \vee ((G_{30} \approx G_{31}) \wedge (G_{40} \approx G_{41})),$$

where the symbol $\approx$ denotes graph isomorphism.

By $\overline{L}$ we denote the complement of a language L. The symbol $\oplus$ denotes the (bitwise) xor logical operator. If $\vec{x} = (x_1, \ldots, x_l)$ and $\vec{y} = (y_1, \ldots, y_m)$ are sequences, by $\vec{x} \circ \vec{y}$ we denote the sequence $(x_1, \ldots, x_l, y_1, \ldots, y_m)$. If π_1 and π_2 are permutations, by $\pi_1 \circ \pi_2$ we denote the permutation obtained as a composition of π_1 and π_2, where π_2 is applied first.

Read-once formulae. Throughout this paper we will only consider read-once formulae, that is, formulae where each variable appears at most once. This is, however, without loss of generality, as we can always have a read-once formula which is still in the language by a small change in the representation (and length extension). Suppose that ϕ is a formula on m variables $v_1, \ldots, v_m$ and that v_i appears l_i times. By giving each variable a different name each time it appears, we construct a formula ϕ' on $m' = \sum_{i=1}^{m} l_i$ variables such that

$$\phi(v_1, \ldots, v_m) = \phi'(\underbrace{v_1, \ldots, v_1}_{l_1}, \ldots, \underbrace{v_m, \ldots, v_m}_{l_m}).$$

From this it follows that

$$(\phi, (x_1, \ldots, x_m)) \in \text{CL(MON;L)} \text{ if and only if } (\phi', (\underbrace{x_1, \ldots, x_1}_{l_1}, \ldots, \underbrace{x_m, \ldots, x_m}_{l_m})) \in \text{CL(MON;L)}.$$

2.1. Zero-knowledge proof systems.

DEFINITION 1. *Let* P*, the* prover*, be a probabilistic Turing machine, and let* V*, the* verifier*, be a probabilistic polynomial-time machine.* P *and* V *share the same input and can communicate with each other. By* $\text{P} \leftrightarrow \text{V}(x)$ *we denote* V*'s output after interacting with* P *on input* x*. A pair* (P,V) *constitutes an* interactive proof system *for the language* L *if the following hold:*

1. *(Completeness) If* $x \in L$*, then*

$$\Pr(\text{P} \leftrightarrow \text{V}(x) = \text{ACCEPT}) \geq 2/3.$$

2. *(Soundness) If* $x \notin L$*, then for all probabilistic Turing machines* P^*

$$\Pr(\text{P}^* \leftrightarrow \text{V}(x) = \text{ACCEPT}) \leq 1/2.$$

For simplicity, the above definition considers a constant error in the completeness and soundness requirements. Any protocol satisfying such definition can be easily transformed into a protocol with exponentially small error by using the standard technique of multiple independent repetitions. We define *View* $_{\text{V}}(x)$, V's view of the interaction with P on input x, as the random variable that assigns to pairs $(R; \textit{Trans})$ the probability that R is the portion of V's random tape used during the execution of the protocol and that *Trans* is the transcript of a conversation between P and V on input x given that V uses random string R.

DEFINITION 2. *An interactive proof system* (P,V) *for L is a* PZK proof system *for L (in short, a PZK proof system) if for each probabilistic polynomial-time machine* V^* *there exists a probabilistic machine S_{V^*} (called the simulator) running in expected polynomial time such that for all $x \in L$ the probability spaces $View_{V^*}(x)$ and $S_{V^*}(x)$ coincide.*

We denote by PZK the class of languages that have a PZK proof system.

3. Random self-reducible languages. The class of random self-reducible languages was introduced in [54, 1] and has since been referred to as RSR.

DEFINITION 3. *A* relation *is a subset of* $\{0,1\}^* \times \{0,1\}^*$.

Let $\mathcal{N}$ be a BPP language. A family of relations $\mathcal{R} = \{\mathcal{R}_x\}_{x \in \mathcal{N}}$ is a polynomial-time family of relations *if for an* instance z *and a* witness w *it is possible to check in time polynomial in $|x|$ whether $(z,w) \in \mathcal{R}_x$.*

DEFINITION 4. *A family of sets $\{\mathcal{S}_x\}_{x \in \mathcal{N}}$ is* efficiently samplable *if and only if there exists an algorithm running in expected polynomial time that, on input $x \in \mathcal{N}$, outputs a uniformly randomly chosen element of $\mathcal{S}_x$.*

DEFINITION 5 (RSR languages). *Let $\mathcal{N}$ be a BPP language and $\{\mathcal{S}_x\}_{x \in \mathcal{N}}$ be an efficiently samplable family of sets. Let $\{\mathcal{R}_x\}_{x \in \mathcal{N}}$ be a family of polynomial-time relations and define the* domain *of $\mathcal{R}_x$, $\mathrm{dom}_{\mathcal{R}}(x)$, as the set $\{z \mid \exists w$ such that $(z,w) \in \mathcal{R}_x\}$. If $(z,w) \in \mathcal{R}_x$, then we say that w is an x-*witness *for z. The language $L_{\mathcal{R}} = \{(x,z) | x \in \mathcal{N}$ and $z \in \mathrm{dom}_{\mathcal{R}}(x)\}$ is* RSR *if the following conditions hold:*

1. *There exists a polynomial-time algorithm $Sample_{\mathcal{R}}$ that, on input $(x,z) \in L_{\mathcal{R}}$ and $r \in \mathcal{S}_x$, outputs $y \in \mathrm{dom}_{\mathcal{R}}(x)$, and, if r is chosen at random from $\mathcal{S}_x$, then y is uniformly distributed over* $\mathrm{dom}_{\mathcal{R}}(x)$.
2. *There exists an algorithm that on input*
   2.1. *x, z, y, r such that $Sample_{\mathcal{R}}(x,z,r) = y$ and*
   2.2. *an x-witness for y*

   outputs an x-witness for z.
3. *There exists an algorithm $Generate_{\mathcal{R}}$ that, on input x, outputs in expected polynomial time a pair $(z,w) \in \mathcal{R}_x$ with z uniformly distributed over the domain of $\mathcal{R}_x$ and w uniformly distributed over all x-witnesses for z.*
4. *There exists a polynomial-time* reconstructing *algorithm $A_{\mathcal{R}}$ that, on input x, z, u, y and r', r'', satisfying $y = Sample_{\mathcal{R}}(x,z,r')$ and $u = Sample_{\mathcal{R}}(x,z,r'')$, returns r such that $y = Sample_{\mathcal{R}}(x,u,r)$. Moreover, if r'' is uniformly distributed over $\mathcal{S}_x$, then so is r.*

Remark 1 (the properties for RSR languages). Conditions 1 and 2 in the above definition for RSR languages are also contained in the definition given in [54]. Our results in section 4 use only conditions 1–3. In section 5 we show a protocol for monotone formulae over co-RSR languages that also uses condition 4 (which is, however, satisfied by all known RSR languages), and then in Remark 4 we briefly discuss a different construction that does not use this condition but results in a somewhat less efficient protocol.

Remark 2 (expected polynomial time versus strict polynomial time). Notice that we require only that the algorithm $Generate_{\mathcal{R}}$ and the algorithms to sample from the families $\{\mathcal{S}_x\}$ stop in expected polynomial time. We can use any of the known standard techniques and change the strategy of the verifier in order to keep the running time strictly bounded by a polynomial. This comes at the expense of increasing the soundness probability by a constant factor, and the zero-knowledge property of the protocol is not affected because we do not modify the prover's strategy.

We define the class co-RSR as the class of languages L such that $\overline{L} \in$ RSR.

Let us now give a few examples of RSR languages.

Square roots. Let $\mathcal{N}$ be the set of all positive integers x, and let $\mathcal{S}_x$ be the set Z_x^*. The relation Square_x is defined as $\text{Square}_x = \{(z,w)|w \in Z_x^* \text{ and } w^2 \equiv z \bmod x\}$. If $(z,w) \in \text{Square}_x$, then we say that z is a *square modulo* x and w is a *square root of* z *modulo* x. The language $L_{\text{Square}} = \{(x,z)|z \text{ is a square modulo } x\}$ is RSR. Indeed, conditions 1–4 of Definition 5 are satisfied.

1. Consider algorithm $Sample_{\text{Square}}$ that on input (x,z,r) outputs $y = zr^2 \bmod x$. If z is a square modulo x and r is chosen at random in Z_x^*, then y is a random square modulo x.
2. To see that condition 2 is met, we observe that, if x, y, z, and r are such that $y = zr^2 \bmod x$ and s is a square root of y modulo x, then $w = sr^{-1} \bmod x$ is a square root of z modulo x.
3. Algorithm $Generate_{\text{Square}}$ on input x chooses s at random from Z_x^*, sets $y = s^2 \bmod x$, and outputs (y,s).
4. The reconstructing algorithm takes as input values x, z, u, y, r', r'' satisfying $y = z(r')^2 \bmod x$ and $u = z(r'')^2 \bmod x$, and returns $r = r' \cdot (r'')^{-1} \bmod x$. It is easily verified that $y = ur^2 \bmod x$ and that r is uniformly distributed in Z_x^* if r' and r'' also are.

Graph isomorphism. We say that two graphs G and H on the same set V of vertices are *isomorphic* if there exists a permutation π of V such that (u,v) is an edge of G if and only if $(\pi(u), \pi(v))$ is an edge of H. In this case we write $H = \pi(G)$. Let $\mathcal{N}$ be the set of all graphs G. For a graph $G = (\text{V}, E)$, let $\mathcal{S}_G$ be the set of all permutations of V. The relation ISO_G is defined as $\text{ISO}_G = \{(H,\pi)|\pi(G) = H\}$. We next show that the language $L_{\text{ISO}} = \{(G,H)|G \text{ and } H \text{ are isomorphic}\}$ is RSR.

1. Algorithm $Sample_{\text{ISO}}(G,H,\pi)$ outputs the graph $M = \pi(H)$. When π is chosen uniformly over all permutations of V and G and H are isomorphic, the graph M is uniformly distributed over the set of graphs isomorphic to G.
2. To see that condition 2 is met, we observe that if $Sample_{\text{ISO}}(G,H,\pi) = M$ and τ is such that $M = \tau(G)$ (that is, τ is a G-witness for M), then $\pi^{-1} \circ \tau$ is a G-witness for H.
3. Algorithm $Generate_{\text{ISO}}(G)$ randomly selects a permutation τ of the vertices of G and outputs $M = \tau(G)$ and τ.
4. The *reconstructing* algorithm $A_{\mathcal{R}}$, on input G, H, M, L, π, and τ that satisfy $M = \pi(H)$ and $L = \tau(H)$, constructs the isomorphism μ such that $M = \mu(L)$ as $\mu = \pi \circ \tau^{-1}$. It is easily verified that μ is uniformly distributed over the set of all permutations of V if π and τ also are.

Discrete logarithm. Let $\mathcal{N}$ be the set of pairs (p,g), where p is a prime and g is an element of Z_p, and let $\mathcal{S}_{(p,g)}$ be the set Z_{p-1}. Define the relation $\text{SUB}_{(p,g)}$ as $\text{SUB}_{(p,g)} = \{(z,w)|z = g^w \bmod p\}$. If $(z,w) \in \text{SUB}_{(p,g)}$, then we say that z belongs to the *subgroup* of Z_p generated by g and that w is the (p,g)-*logarithm* of z. The language L_{SUB} defined as $L_{\text{SUB}} = \{((p,g),z)|\exists w \text{ such that } z = g^w \bmod p\}$ is RSR.

1. Algorithm $Sample_{\text{SUB}}$ on input $((p,g),z,r)$ outputs $y = g^r z \bmod p$. If z belongs to the subgroup of Z_p generated by g and r is a random element of Z_{p-1}, then y is a random element of the subgroup of Z_p generated by g.
2. Condition 2 is seen to be satisfied by observing that if s is the (p,g)-logarithm of y and $((p,g),z,r)$ are such that $Sample_{\text{SUB}}((p,g),z,r) = y$, then $z \equiv g^{s-r} \bmod p$ and thus $(s-r) \bmod (p-1)$ is the (p,g)-logarithm of z.
3. Algorithm $Generate_{\text{SUB}}$ on input (p,g) picks an element s at random from Z_{p-1}, sets $y = g^s \bmod p$, and outputs the pair (y,s).

4. The reconstructing algorithm $A_{\mathcal{R}}$ is defined as follows. On input x, z, y, u, r', r'' such that $y = zg^{r'} \bmod p$ and $u = zg^{r''} \bmod p$, it outputs $r = (r' - r'') \bmod (p-1)$. Simple algebra gives $y = ug^r \bmod p$, and we note that r is uniformly distributed over Z_{p-1} if r' and r'' also are.

Decisional Diffie–Hellman. Using the same definitions for the discrete logarithm problem, we define the relation $\mathrm{DDH}_{(p,g)}$ as consisting of the pairs $((z_a, z_b, z_c), (a, b, c))$ such that $z_a = g^a \bmod p, z_b = g^b \bmod p, z_c = g^c \bmod p$, and $c = ab \bmod (p-1)$. If $((z_a, z_b, z_c), (a, b, c)) \in \mathrm{DDH}_{(p,g)}$, then we say that $z = (z_a, z_b, z_c)$ is a *Diffie–Hellman triple* with respect to (p, g). The language L_{DDH} defined as $L_{\mathrm{DDH}} = \{((p, g), z) | z$ is a Diffie–Hellman triple with respect to $(p, g)\}$ is RSR.

1. Algorithm $Sample_{\mathrm{DDH}}$ on input $((p, g), (z_a, z_b, z_c), (r, s))$ outputs the triple $y = (y_a, y_b, y_c)$ defined as $y_a = g^r z_a \bmod p$, $y_b = g^s z_b \bmod p$, and $y_c = g^{rs} z_a^s z_b^r z_c \bmod p$. If z is a Diffie–Hellman triple with respect to (p, g) and r, s are random and independent elements of Z_{p-1}, then y is a random Diffie–Hellman triple with respect to (p, g).
2. Condition 2 is seen to be satisfied by observing that if a, b, c are the discrete logarithms of z_a, z_b, z_c, respectively, with $c = ab \bmod (p-1)$, and $Sample_{\mathrm{DDH}}((p, g), (z_a, z_b, z_c), (r, s)) = (y_a, y_b, y_c)$, then the discrete logarithms of y_a, y_b, y_c, respectively, are $a + r \bmod (p-1)$, $b + s \bmod (p-1)$, and $(a + r)(b + s) \bmod (p-1)$.
3. Algorithm $Generate_{\mathrm{DDH}}$ on input (p, g) picks elements a, b at random from Z_{p-1}; sets $y_a = g^a \bmod p$, $y_b = g^b \bmod p$, and $y_c = g^{ab} \bmod p$; and outputs the triple (y_a, y_b, y_c).
4. The reconstructing algorithm $A_{\mathcal{R}}$ is defined as follows. On input $p, g, z = (z_a, z_b, z_c)$, $y = (y_a, y_b, y_c)$, $u = (u_a, u_b, u_c)$, (r', s'), (r'', s'') such that $y_a = g^{r'} z_a \bmod p$, $y_b = g^{s'} z_b \bmod p$, $y_c = g^{r's'} z_a^{s'} z_b^{r'} z_c \bmod p$, and $u_a = g^{r''} z_a \bmod p$, $u_b = g^{s''} z_b \bmod p$, $u_c = g^{r''s''} z_a^{s''} z_b^{r''} z_c \bmod p$, it returns r, s such that $r = (r' - r'') \bmod (p-1)$ and $s = (s' - s'') \bmod (p-1)$. Simple algebra gives $y_a = g^r u_a \bmod p$, $y_b = g^s u_b \bmod p$, and $y_c = g^{rs} u_a^r u_b^s u_c \bmod p$, and we note that r, s are uniformly distributed over Z_{p-1} if r', s' and r'', s'' also are.

The following lemma gives a useful property of algorithm *Sample*.

LEMMA 6. *Let $L_{\mathcal{R}}$ be an RSR language and let $(x, z) \notin L_{\mathcal{R}}$. Then, for all $r \in \mathcal{S}_x$, $Sample_{\mathcal{R}}(x, z, r) \notin \mathrm{dom}_{\mathcal{R}}(x)$.*

Proof. Suppose there exists an r such that $y = Sample_{\mathcal{R}}(x, z, r) \in \mathrm{dom}_{\mathcal{R}}(x)$, and let w be such that $(y, w) \in \mathcal{R}_x$. By property 2 of the RSR languages, knowing x, z, y, r, and w, it is possible to compute an x-witness for z. This would imply that $(x, z) \in L_{\mathcal{R}}$, a contradiction. □

In [54], extending the protocol for quadratic residuosity of [42] and graph isomorphism of [38], it was proved that all RSR languages have PZK proof systems.

THEOREM 7 (Tompa and Woll [54]). *All RSR languages have a PZK proof system.*

4. Monotone formulae over RSR languages. In this section we prove that the language of all true monotone formulae whose atoms are statements about membership in an RSR language have a PZK proof system.

Before describing the proof system in its full generality we sketch an example for the simple cases of OR and AND of two statements about graph isomorphisms. These two simple proof systems will constitute the building block of our proof systems for general monotone formulae.

OR OF TWO GRAPH ISOMORPHISMS. We now briefly describe a zero-knowledge proof system for proving that at least one of two pairs of graphs (A_0, A_1) and (B_0, B_1) consists of two isomorphic graphs.

The prover randomly picks bits c_1 and c_2 and permutations τ_A and τ_B, constructs graphs $A = \tau_A(A_{c_1})$ and $B = \tau_B(B_{c_2})$, and sends the pair (A, B) to the verifier. The verifier picks a random bit b and sends it to the prover. The prover responds by sending random bits b_1 and b_2 such that $b = b_1 \oplus b_2$ and isomorphisms π_A and π_B such that $A = \pi_A(A_{b_1})$ and $B = \pi_B(B_{b_2})$.

For the completeness property, suppose that A_0 and A_1 are isomorphic. The prover sets $b_1 = b \oplus c_2$, $b_2 = c_2$, and $\pi_B = \tau_B$. Isomorphism π_A instead is computed in the following way. If b_1 is equal to c_1, then isomorphism π_A is set equal to τ_A. If b_1 is not equal to c_1, then, since A_0 and A_1 are isomorphic, there exists isomorphism μ such that $A_{c_1} = \mu(A_{b_1})$. Therefore isomorphism $\pi_A = \tau_A \circ \mu$ is such that $A = \pi_A(A_{b_1})$.

On the other hand, suppose A_0 and A_1 and B_0 and B_1 are not isomorphic. Then no matter how graphs A and B are constructed there exists at most one b_1 such that A is isomorphic to A_{b_1} and at most one b_2 such that B is isomorphic to A_{b_2}. Therefore there exists at most one value of b (namely, $b = b_1 \oplus b_2$) for which the prover can convince the verifier.

For the zero-knowledge property we consider a simulator that picks c_1 and c_2 at random and then simulates the exchange of messages until it happens that $b = c_1 \oplus c_2$. Since the value $c_1 \oplus c_2$ is independent from the pair of graphs (A, B), the simulator has probability $1/2$ of succeeding, and it can be verified that, when it succeeds, it produces a perfect simulation. Thus, on average the simulation has to be repeated two times.

AND OF TWO GRAPH ISOMORPHISMS. Suppose now that we wish to prove that A_0 is isomorphic to A_1 and B_0 is isomorphic to B_1. Obviously, we could prove the two statements sequentially using the proof system of [38]: first prove that A_0 is isomorphic to A_1 and then prove that B_0 is isomorphic to B_1. Instead we propose to perform the two proofs in parallel in the following way: the prover presents the verifier with two graphs A and B; the verifier picks *one* random bit c; and the prover shows isomorphism between A and A_c and B and B_c. As is immediately seen, completeness, soundness, and zero knowledge continue to hold.

The general case. Let us introduce a bit of notation. For the rest of this section, we let L be an RSR language. The *value* $Val(c_1, \ldots, c_m; \phi) \in \{0, 1, \perp\}$ of a formula ϕ with m variables with respect to the m-tuple $(c_1, \ldots, c_m) \in \{0,1\}^m$ is defined recursively in the following way. (Recall that we consider only read-once formulae.) If ϕ consists of a single variable v, then $Val(a; v) = a$. Else, suppose that $\phi = \phi_1 \wedge \phi_2$ and let $v_1, \ldots, v_{m_1}$ be the variables in ϕ_1 and $v_{m_1+1}, \ldots, v_m$ be the variables in ϕ_2. If $Val(c_1, \ldots, c_{m_1}; \phi_1) = Val(c_{m_1+1}, \ldots, c_m; \phi_2) = b \in \{0, 1, \perp\}$, then $Val(c_1, \ldots, c_m; \phi) = b$. If, instead, $Val(c_1, \ldots, c_{m_1}; \phi_1) \neq Val(c_{m_1+1}, \ldots, c_m; \phi_2)$, then $Val(c_1, \ldots, c_m; \phi)$ is set equal to $\perp$. On the other hand, suppose that $\phi = \phi_1 \vee \phi_2$. If $Val(c_1, \ldots, c_{m_1}; \phi_1)$ and $Val(c_{m_1+1}, \ldots, c_m; \phi_2)$ are both different from $\perp$, then $Val(c_1, \ldots, c_m; \phi) = Val(c_1, \ldots, c_{m_1}; \phi_1) \oplus Val(c_{m_1+1}, \ldots, c_m; \phi_2)$; otherwise we set $Val(c_1, \ldots, c_m; \phi) = \perp$. For example, $Val(c_1, c_2; v_1 \vee v_2) = c_1 \oplus c_2$ for $c_1, c_2 \in \{0, 1\}$. The above definition is depicted in Table 1.

If $Val(c_1, \ldots, c_m; \phi) \neq \perp$, then we say that the sequence of bits $(c_1, \ldots, c_m)$ is *well formed* with respect to ϕ. The following fact can be easily proved by induction on the length of the sequences.

FACT 8. *If $\vec{a} = (a_1, \ldots, a_m)$ and $\vec{c} = (c_1, \ldots, c_m)$ are two well-formed sequences with respect to ϕ, then so is sequence $\vec{b} = (a_1 \oplus c_1, \ldots, a_m \oplus c_m)$. Moreover, the number*

TABLE 1

Value of ϕ_1	Value of ϕ_2	Value of $\phi_1 \vee \phi_2$	Value of $\phi_1 \wedge \phi_2$
0	0	0	0
0	1	1	$\perp$
0	$\perp$	$\perp$	$\perp$
1	0	1	$\perp$
1	1	0	1
1	$\perp$	$\perp$	$\perp$

of sequences $\vec{a}$ such that $Val(\vec{a};\phi) = 0$ is equal to the number of sequences $\vec{a}$ such that $Val(\vec{a};\phi) = 1$.

DEFINITION 9 (opening). *Let ϕ be a monotone formula, and let $\mathcal{I} = ((x_1, z_1), \ldots, (x_m, z_m))$ be an m-tuple of pairs. We say that the m-tuple of quadruples $R = ((c_1, r_1, s_1, t_1), \ldots, (c_m, r_m, s_m, t_m))$ is a $(\phi, \mathcal{I})$-*opening as $b \in \{0,1\}$ with auxiliary sequence $S = ((s_1, t_1) \ldots, (s_m, t_m))$ of the m-tuple $Y = (y_1, \ldots, y_m)$ *if and only if*

1. *$r_i \in \mathcal{S}_{x_i}$, $c_i \in \{0,1\}$, and $(s_i, t_i) \in \mathcal{R}_{x_i}$ for $i = 1, \ldots, m$;*
2. *$Val(c_1, \ldots, c_m; \phi) = b$;*
3. *if $c_i = 0$, then $y_i = Sample_{\mathcal{R}}(x_i, z_i, r_i)$;*
4. *if $c_i = 1$, then $y_i = Sample_{\mathcal{R}}(x_i, s_i, r_i)$.*

Whenever ϕ and $\mathcal{I}$ are clear from the context we will simply say "opening" instead of $(\phi, \mathcal{I})$-opening.

The following two lemmas summarize the properties of the concept of an opening that we will exploit for the construction of our proof system. If $(\phi, \mathcal{I}) \in$ CL(MON;L), then every m-tuple that can be opened as 0 can also be opened as 1 and vice versa. If instead $(\phi, \mathcal{I}) \notin$ CL(MON;L), then if an m-tuple can be opened as 0, it cannot be opened as 1 and vice versa.

LEMMA 10. *Let ϕ be a formula with m variables and $\mathcal{I}$ be an m-tuple of pairs such that $(\phi, \mathcal{I}) \in$ CL(MON;L). Let Y be an m-tuple, and let R be a $(\phi, \mathcal{I})$-opening of Y as $b \in \{0,1\}$. Then, there exists a $(\phi, \mathcal{I})$-opening R' of Y as $1 - b$.*

Proof. The proof proceeds by induction on the number m of variables of ϕ.

Suppose that $m = 1$ and let $Y = (y)$ and $\mathcal{I} = ((x, z))$. As $(\phi, ((x, z))) \in$ CL(MON;L), it must be the case that $z \in \mathrm{dom}_{\mathcal{R}}(x)$. By property 1 of the RSR languages, it follows that, for any $s, y \in \mathrm{dom}_{\mathcal{R}}(x)$, there exists r such that $y = Sample_{\mathcal{R}}(x, s, r)$. Therefore if y can be opened as 0 (i.e., $y = Sample_{\mathcal{R}}(x, z, r)$ for some r), then $y \in \mathrm{dom}_{\mathcal{R}}(x)$, and, thus, it can also be opened as a 1: pick any $s \in \mathrm{dom}_{\mathcal{R}}(x)$ along with an x-witness t for s and r' such that $y = Sample_{\mathcal{R}}(x, s, r')$ and construct opening $R' = (1, r', s, t)$. Similarly, if y can be opened as 1, then it can also be opened as 0.

Suppose now that $m \geq 2$ and $\phi = \phi_1 \vee \phi_2$ and let R be a $(\phi, \mathcal{I})$-opening of Y as 0. We construct a $(\phi, \mathcal{I})$-opening of Y as 1. Let m_1 be the number of variables of ϕ_1 and split $\mathcal{I}$ in $\mathcal{I}_1 = ((x_1, z_1), \ldots, (x_{m_1}, z_{m_1}))$ and $\mathcal{I}_2 = ((x_{m_1+1}, z_{m_1+1}), \ldots, (x_m, z_m))$ and Y in $Y_1 = (y_1, \ldots, y_{m_1})$ and $Y_2 = (y_{m_1+1}, \ldots, y_m)$. As $(\phi, \mathcal{I}) \in$ CL(MON;L), it must be the case that at least one of $(\phi_1, \mathcal{I}_1)$ and $(\phi_2, \mathcal{I}_2)$, say $(\phi_1, \mathcal{I}_1)$, belongs to CL(MON;L). Let $a \in \{0,1\}$ be such that Y_2 can be $(\phi_2, \mathcal{I}_2)$-opened as a. (Such an a exists, for otherwise Y cannot be $(\phi, \mathcal{I})$-opened as 0.) Let R_2 be such an opening and let R_1 be a $(\phi_1, \mathcal{I}_1)$-opening of Y_1 as $1 \oplus a$. (Such an opening exists by the inductive hypothesis.) Then, as can be readily verified, $R_1 \circ R_2$ is a $(\phi, \mathcal{I})$-opening of Y as 1. If

Y can be $(\phi, \mathcal{I})$-opened as 1, a $(\phi, \mathcal{I})$-opening of Y as 0 is constructed in a similar way.

The case where $m \geq 2$ and $\phi = \phi_1 \wedge \phi_2$ is proved similarly. □

LEMMA 11. *Let ϕ be a formula with m variables and $\mathcal{I}$ be an m-tuple of pairs such that $(\phi, \mathcal{I}) \notin$ CL(MON;L). Then for each m-tuple Y there is at most one bit $b \in \{0, 1\}$ for which there exists a $(\phi, \mathcal{I})$-opening of Y as b.*

Proof. We proceed by induction on m.

Suppose $m = 1$ and let $Y = (y)$ and $\mathcal{I} = ((x, z))$. Since $(\phi, \mathcal{I}) \notin$ CL(MON;L), it follows that $(x, z) \notin L_{\mathcal{R}}$. If Y can be opened as 1, then $y \in \text{dom}_{\mathcal{R}}(x)$. By Lemma 6, for all $r \in \mathcal{S}_x$, it holds that $Sample_{\mathcal{R}}(x, z, r) \notin \text{dom}_{\mathcal{R}}(x)$, and thus Y cannot be $(\phi, \mathcal{I})$-opened as 0. If Y can be opened as 0, then there is $r \in \mathcal{S}_x$ such that $y = Sample_{\mathcal{R}}(x, z, r)$. Since $(x, z) \notin L_{\mathcal{R}}$, by Lemma 6, $y \notin \text{dom}_{\mathcal{R}}(x)$, and thus y cannot be opened as 1.

Suppose now that $m \geq 2$ and that $\phi = \phi_1 \vee \phi_2$. Moreover, let Y be an m-tuple that can be $(\phi, \mathcal{I})$-opened as 0. Let m_1 be the number of variables of ϕ_1 and split $\mathcal{I}$ in $\mathcal{I}_1 = ((x_1, z_1), \ldots, (x_{m_1}, z_{m_1}))$ and $\mathcal{I}_2 = ((x_{m_1+1}, z_{m_1+1}), \ldots, (x_m, z_m))$ and Y in $Y_1 = (y_1, \ldots, y_{m_1})$ and $Y_2 = (y_{m_1+1}, \ldots, y_m)$. As $(\phi, \mathcal{I}) \notin$ CL(MON;L), neither $(\phi_1, \mathcal{I}_1)$ nor $(\phi_2, \mathcal{I}_2)$ belongs to CL(MON;L). Suppose now that Y can be $(\phi, \mathcal{I})$-opened as both 0 and 1. This implies that at least one of Y_1 and Y_2 can be opened as both a 0 and a 1, which contradicts the inductive hypothesis.

The case $\phi = \phi_1 \wedge \phi_2$ is similar. □

The properties of the opening suggest the following simple interactive proof system (P,V) for CL(MON;L) (a formal description is found in Figure 2). Let $(\phi, \mathcal{I})$ be the input to the proof system. The prover chooses an m-tuple Y that can be $(\phi, \mathcal{I})$-opened as 0 and sends it to the verifier. The verifier picks a bit b at random and sends it to the prover. The prover then shows an opening of Y as b and sends it to the verifier. The verifier accepts if the prover complies with his request. Completeness follows from Lemma 10 and soundness from Lemma 11. To guarantee zero knowledge, we have the prover pick Y using the procedure *Construct-Opening* found in Figure 1.

The following lemma can be easily proved by induction on the length of Y.

LEMMA 12. *Let (Y, R) be a pair output by Construct-Opening on input $(\phi, \mathcal{I}, a)$. Then Y can be $(\phi, \mathcal{I})$-opened as a, and R is a $(\phi, \mathcal{I})$-opening of Y as a.*

In Figure 2, we formally describe proof system (P,V).

THEOREM 13. *The pair* (P,V) *is an interactive proof system for* CL(MON;L).

Proof. First observe that the verification step V.2 can be performed in polynomial time because both $Sample_{\mathcal{R}}$ and $\mathcal{R}$ are polynomial time.

Completeness. From Lemma 10, it follows that if $(\phi, \mathcal{I}) \in$ CL(MON;L), then the prover can always provide V with the requested opening of Y.

Soundness. Suppose that $(\phi, \mathcal{I}) \notin$ CL(MON;L). Let Y' be the m-tuple given to the verifier by prover P* and suppose that Y' can be opened as b. (If Y' cannot be opened at all, then the verifier will never accept.) With probability 1/2 the verifier asks the prover to open Y as $1 - b$, and the prover will not be able to satisfy the verifier's request. (See Lemma 11.) Therefore, the prover has probability at most 1/2 to make the verifier accept $(\phi, \mathcal{I})$. □

4.1. The simulator for (P,V). In this section we exhibit a simulator for (P,V). The simulator uses procedure *Construct-Opening* described in Figure 1 that on input $(\phi, \mathcal{I}, a)$ outputs a pair (Y, R) such that R is a $(\phi, \mathcal{I})$-opening as a of Y.

In the next lemma we prove that for (Y, R) output by procedure *Construct-Opening* on input $(\phi, \mathcal{I}, a)$ we have that

1. Y is independent from a given ϕ and $\mathcal{I}$;

Procedure *Construct-Opening*$(\phi, \mathcal{I}, a)$
Input:

- ϕ is a monotone formula, and let m be the number of variables of ϕ;
- $\mathcal{I} = ((x_1, z_1), \ldots, (x_m, z_m))$;
- $a \in \{0, 1\}$.

1. If ϕ consists of one variable v_1, then
   run $Generate_{\mathcal{R}}(x_1)$ obtaining (s_1, t_1);
   randomly choose $r_1 \in \mathcal{S}_{x_1}$;
   if $a = 0$, then set $y_1 = Sample_{\mathcal{R}}(x_1, z_1, r_1)$;
   if $a = 1$, then set $y_1 = Sample_{\mathcal{R}}(x_1, s_1, r_1)$;
   return$((y_1), (a, r_1, s_1, t_1))$;
2. If $\phi = \phi_1 \vee \phi_2$, then
   let m_1 be the number of variables of ϕ_1;
   let $\mathcal{I}_1 = ((x_1, z_1), \ldots, (x_{m_1}, z_{m_1}))$ and let $\mathcal{I}_2 = ((x_{m_1+1}, z_{m_1+1}), \ldots, (x_m, z_m))$;
   randomly choose $b \in \{0, 1\}$;
   obtain (Y_1, R_1) by running *Construct-Opening* on input $(\phi_1, \mathcal{I}_1, b)$;
   obtain (Y_2, R_2) by running *Construct-Opening* on input $(\phi_2, \mathcal{I}_2, a \oplus b)$;
   return$(Y_1 \circ Y_2, R_1 \circ R_2)$.
3. If $\phi = \phi_1 \wedge \phi_2$, then
   let m_1 be the number of variables of ϕ_1;
   let $\mathcal{I}_1 = ((x_1, z_1), \ldots, (x_{m_1}, z_{m_1}))$ and let $\mathcal{I}_2 = ((x_{m_1+1}, z_{m_1+1}), \ldots, (x_m, z_m))$;
   obtain (Y_1, R_1) by running *Construct-Opening* on input $(\phi_1, \mathcal{I}_1, a)$;
   obtain (Y_2, R_2) by running *Construct-Opening* on input $(\phi_2, \mathcal{I}_2, a)$;
   return$(Y_1 \circ Y_2, R_1 \circ R_2)$.

FIG. 1. *The procedure Construct-Opening.*

The Proof System (P,V).
Input: $(\phi, \mathcal{I}) \in$ CL(MON;L).

P.1 Obtain (Y, R) by running *Construct-Opening* on input $(\phi, \mathcal{I}, 0)$ and let S be the auxiliary sequence.
Send (Y, S) to V.
V.1 Randomly select $b \in \{0, 1\}$. Send b to P.
P.2 Select a $(\phi, \mathcal{I})$-opening R_b of Y as b according to the distribution induced on its second output by procedure *Construct-Opening* on input $(\phi, \mathcal{I}, b)$ conditioned on Y being the first element of the output pair and S being the auxiliary sequence.
Send R_b to V.
V.2 Verify that R_b is a $(\phi, \mathcal{I})$-opening of Y as b.

FIG. 2. *The proof system* (P,V) *for* CL(MON;L).

2. the auxiliary sequence S is independent from a given ϕ, $\mathcal{I}$, and Y.

LEMMA 14. *Let* $(\phi,\mathcal{I}) \in \mathrm{CL(MON;L)}$ *and denote by* $\mathrm{Prob}(Y,S,\phi,\mathcal{I},a)$ *the probability that Construct-Opening*$(\phi,\mathcal{I},a)$ *outputs the sequence* Y *and a* $(\phi,\mathcal{I})$*-opening* R *of* Y *as* a *with auxiliary sequence* S*. Then, for each* Y *and* S *we have*

$$\mathrm{Prob}(Y,S,\phi,\mathcal{I},0) = \mathrm{Prob}(Y,S,\phi,\mathcal{I},1).$$

Proof. The proof proceeds by induction on the number m of pairs of $\mathcal{I}$.

Base case: $m = 1$. In this case we have $\mathcal{I} = ((x,z))$, $Y = (y)$, and $S = (s,t)$.

First of all, observe that, independently of a, S is produced by running procedure *Generate*$_{\mathcal{R}}$. Moreover, since $(\phi,\mathcal{I}) \in \mathrm{CL(MON;L)}$, it must be the case that $z \in \mathrm{dom}_{\mathcal{R}}(x)$.

If $a = 0$, then y is the output of *Sample*$_{\mathcal{R}}$ on input x, z, and a random $r \in \mathcal{S}_x$ and thus, by property 1 of RSR languages and since $z \in \mathrm{dom}_{\mathcal{R}}(x)$, y is uniformly distributed over $\mathrm{dom}_{\mathcal{R}}(x)$.

Similarly, if $a = 1$, then y is the output of *Sample*$_{\mathcal{R}}$ on input x, s, and a random $r \in \mathcal{S}_x$. By property 1 of RSR languages and since $s \in \mathrm{dom}_{\mathcal{R}}(x)$, y is uniformly distributed over $\mathrm{dom}_{\mathcal{R}}(x)$. Therefore, independently from the values of a and s, y is a random element of $\mathrm{dom}_{\mathcal{R}}(x)$.

Finally, we observe that, by property 1 of RSR languages, given y, z, and s all belonging to $\mathrm{dom}_{\mathcal{R}}(x)$, there exist (the same number of) r' and r'' such that $y = \mathit{Sample}(x,z,r')$ and $y = \mathit{Sample}(x,s,r'')$.

Induction step: $m > 1$. Suppose that $\phi = \phi_1 \vee \phi_2$ and denote by m_1 the number of variables of ϕ_1 and let $\mathcal{I}_1 = ((x_1,z_1),\ldots,(x_{m_1},z_{m_1}))$ and $\mathcal{I}_2 = ((x_{m_1+1},z_{m_1+1}), \ldots,(x_m,z_m))$. Write $Y = (y_1,\ldots,y_m)$ and $S = ((s_1,t_1),\ldots,(s_m,t_m))$ and set $Y_1 = (y_1,\ldots,y_{m_1})$, $S_1 = ((s_1,t_1),\ldots,(s_{m_1},t_{m_1}))$, and $Y_2 = (y_{m_1+1},\ldots,y_m)$, $S_2 = ((s_{m_1+1},t_{m_1+1}),\ldots,(s_m,t_m))$. Then, we have

$$\begin{aligned}\mathrm{Prob}(Y,S,\phi,\mathcal{I},0) = \quad & \mathrm{Prob}(b=0 \text{ at step 2 of } \textit{Construct-Opening}) \\ & \cdot\mathrm{Prob}(Y_1,S_1,\phi_1,\mathcal{I}_1,0)\cdot\mathrm{Prob}(Y_2,S_2,\phi_2,\mathcal{I}_2,0) \\ + \quad & \mathrm{Prob}(b=1 \text{ at step 2 of } \textit{Construct-Opening}) \\ & \cdot\mathrm{Prob}(Y_1,S_1,\phi_1,\mathcal{I}_1,1)\cdot\mathrm{Prob}(Y_2,S_2,\phi_2,\mathcal{I}_2,1)\end{aligned}$$

and

$$\begin{aligned}\mathrm{Prob}(Y,S,\phi,\mathcal{I},1) = \quad & \mathrm{Prob}(b=0 \text{ at step 2 of } \textit{Construct-Opening}) \\ & \cdot\mathrm{Prob}(Y_1,S_1,\phi_1,\mathcal{I}_1,1)\cdot\mathrm{Prob}(Y_2,S_2,\phi_2,\mathcal{I}_2,0) \\ + \quad & \mathrm{Prob}(b=1 \text{ at step 2 of } \textit{Construct-Opening}) \\ & \cdot\mathrm{Prob}(Y_1,S_1,\phi_1,\mathcal{I}_1,0)\cdot\mathrm{Prob}(Y_2,S_2,\phi_2,\mathcal{I}_2,1).\end{aligned}$$

Since $(\phi,\mathcal{I}) \in \mathrm{CL(MON;L)}$ and $\phi = \phi_1 \vee \phi_2$, we can assume without loss of generality that $(\phi_1,\mathcal{I}_1) \in \mathrm{CL(MON;L)}$. Therefore, by the inductive hypothesis we have

$$\mathrm{Prob}(Y_1,S_1,\phi_1,\mathcal{I}_1,0) = \mathrm{Prob}(Y_1,S_1,\phi_1,\mathcal{I}_1,1)$$

from which the lemma follows.

The case $\phi = \phi_1 \wedge \phi_2$ is proved similarly. □

In Figure 3, we present a simulator S_{V^*} for each verifier V^*. In the formal description of S_{V^*}, we say that a random tape of appropriate length is picked for V^*. By this we mean that S_{V^*} picks $p(n)$ random bits for an input of length n, where $p(n)$ is a polynomial that upper bounds the number of steps performed by V^* on inputs of length n.

The simulator S_{V^*}
Input: $(\phi, \mathcal{I}) \in$ CL(MON;L).

1. Randomly choose a string *Random* of appropriate length and write it on the random tape of the verifier V^*.
2. Randomly choose $a \in \{0,1\}$ and run procedure *Construct-Opening* on input $(\phi, \mathcal{I}, a)$ obtaining (Y, R). Let S be the auxiliary sequence of R.
   Send (Y, S) to V^*.
3. Receive string σ from V^*, and let b be its first bit.
   If $a = b$, then **Output**$(Random; Y, S, b, R)$ and STOP; else Goto 1.

FIG. 3. *The simulator* S_{V^*}

LEMMA 15. *Assume* $(\phi, \mathcal{I}) \in$ CL(MON;L) *and let* V^* *be a verifier. Then, the simulator* S_{V^*} *runs in expected polynomial time. Moreover, the probability spaces* $S_{V^*}(\phi, \mathcal{I})$ *of the output by* S_{V^*} *on input* $(\phi, \mathcal{I})$ *and the probability space of* V^**'s view,* $View_{V^*}(\phi, \mathcal{I})$*, on input* $(\phi, \mathcal{I})$ *are identical.*

Proof. Since $Sample_{\mathcal{R}}$ is polynomial time, $Generate_{\mathcal{R}}$ is expected polynomial time, and $\mathcal{S}_x$ is efficiently samplable, *Construct-Opening* can be executed in expected polynomial time.

Observe that since $(\phi, \mathcal{I}) \in$ CL(MON;L), by Lemma 14, (Y, S) is independent from a. Therefore the probability that $b \neq a$ is exactly $1/2$; thus S_{V^*} runs in expected polynomial time.

The simulator produces strings of the form $(Random; Y, S, b, R)$, where *Random* is a string of bits, Y is an m-tuple, S is the auxiliary sequence of R, $b \in \{0,1\}$, and R is a random opening of Y as b, conditioned on S. Obviously, *Random* has the same distribution in both spaces.

In the output of S_{V^*} on input $(\phi, \mathcal{I})$, (Y, S) is picked according to the probability induced by *Construct-Opening* on input $(\phi, \mathcal{I}, 0)$ with probability $1/2$, and with probability $1/2$ according to the probability induced by *Construct-Opening* on input $(\phi, \mathcal{I}, 1)$. Therefore, by Lemma 14, (Y, S) is picked according to the probability induced by *Construct-Opening* on input $(\phi, \mathcal{I}, 0)$ which is exactly the distribution of (Y, S) in the view of V^*.

The bit b is, in both spaces, the output of V^* on input $(\phi, \mathcal{I})$ and (Y, S) computed using *Random* as source of random bits. Finally, R is in both spaces an opening of Y as b picked according to the distribution induced on R by *Construct-Opening* on input $(\phi, \mathcal{I}, b)$ conditioned on Y being the first element of the output pair and S being the auxiliary sequence. □

Thus, we obtain the following theorem.

THEOREM 16. *Let* L *be an RSR language. Then* CL(MON;L) $\in$ *PZK.*

Remark 3 (the properties of RSR languages used). Notice that the results of this section use only properties 1, 2, and 3 of the definition of RSR languages.

5. Monotone formulae over co-RSR languages. In this section we prove that the language of all true monotone formulae whose atoms are statements about membership in a co-RSR language has a PZK proof system.

We start from the following simple observation. De Morgan's law specifies a simple transformation DM by which it is possible to transform any monotone formula

ϕ into a monotone formula $\psi = DM(\phi)$ of essentially the same size and such that ϕ being evaluated with atoms $(x_i \in \bar{L})$ is equivalent to $\neg\psi$ being evaluated with atoms $(x_i \in L)$. In other words, proving that a monotone formula over a co-RSR language is true is equivalent to proving that a monotone formula over an RSR language is false. This can be done using the concept of opening in the following way.

Suppose the prover wants to prove that $(\phi, \mathcal{I}) \in \mathrm{CL}(\mathrm{MON}; \bar{\mathrm{L}})$, where L is an RSR language. The verifier first constructs formula $\psi = DM(\phi)$, runs procedure *Construct-Opening* on input $\psi, \mathcal{I}$ and a randomly selected bit c, obtains a pair (Y, R), and sends Y to the prover. The prover then has to guess the value of c. Completeness and soundness follow directly from Lemmas 11 and 14, and zero knowledge with respect to a honest verifier can also be easily argued.

In the formal description of the proof system, we denote by *co-Construct-Opening* the procedure that, on input $(\phi, \mathcal{I}, a)$, first constructs $\psi = DM(\phi)$ and then runs *Construct-Opening* on input $(\psi, \mathcal{I}, a)$. Also, we will say that the m-tuple of quadruples $R = ((c_1, r_1, s_1, t_1), \ldots, (c_m, r_m, s_m, t_m))$ is a $(\phi, \mathcal{I})$-*co-opening* as $b \in \{0, 1\}$ of the m-tuple $Y = (y_1, \ldots, y_m)$ if and only if R is a $(DM(\phi), \mathcal{I})$-opening as b of Y. From the discussion above and from the properties of an opening, it follows that if $(\phi, \mathcal{I}) \in \mathrm{CL}(\mathrm{MON}; \bar{\mathrm{L}})$, then any tuple Y which can be opened as a 0 cannot be opened as a 1 and vice versa. On the other hand, if $(\phi, \mathcal{I}) \notin \mathrm{CL}(\mathrm{MON}; \bar{\mathrm{L}})$, then any tuple Y which can be opened as a 0 can also be opened as a 1 and vice versa.

Next we observe that, as a direct consequence of De Morgan's law, the procedure *co-Construct-Opening* can be obtained by swapping the roles of $\vee$ and $\wedge$ in the definition of *Construct-Opening*. Similarly, we define the *co-Val* of a sequence $(c_1, \ldots, c_m)$ with respect to a formula ϕ as the *Val* of $(c_1, \ldots, c_m)$ with respect to $DM(\phi)$. We also say that $(c_1, \ldots, c_m)$ is *co-well-formed* with respect to ϕ if *co-Val*$(c_1, \ldots, c_m; \phi) \neq \perp$, and, analogously to Fact 8, we obtain the following fact.

FACT 17. *If $\vec{a} = (a_1, \ldots, a_m)$ and $\vec{c} = (c_1, \ldots, c_m)$ are two co-well-formed sequences with respect to ϕ, then so is sequence $\vec{b} = (a_1 \oplus c_1, \ldots, a_m \oplus c_m)$. Moreover, the number of sequences $\vec{a}$ such that co-Val$(\vec{a}; \phi) = 0$ is equal to the number of sequences $\vec{a}$ such that co-Val$(\vec{a}; \phi) = 1$.*

5.1. Zero knowledge. Designing a zero-knowledge proof system (and not just an honest-verifier zero-knowledge system) requires some extra care. Following the suggestion of [42], we have the verifier give a "proof that he knows the value of c." Only after receiving such a "proof" does the prover give the verifier his guess for c. At the base of our construction is the notion of similarity that can be informally presented as follows. We say that the pair (u_0, u_1) is *similar* to the pair (x, z) if one of the elements of (u_0, u_1) is obtained by running $Sample_{\mathcal{R}}$ on input (x, s, r'), and the other is obtained by running $Sample_{\mathcal{R}}$ on input (x, z, r''), where $s \in \mathrm{dom}_{\mathcal{R}}(x)$ and $r', r'' \in \mathcal{S}_x$. The fact that pair (u_0, u_1) is similar to pair (x, z) can be proved by giving $s \in \mathrm{dom}_{\mathcal{R}}(x)$, an x-witness for s, and the random strings r', r'' used by $Sample_{\mathcal{R}}$ to generate (u_0, u_1). The following definition extends the concept of similarity to m-tuples of pairs with respect to a formula.

DEFINITION 18. *Let ϕ be a formula with m variables. We say that the m-tuple of pairs $\mathcal{H} = ((u_{10}, u_{11}), \ldots, (u_{m0}, u_{m1}))$ is* similar to the m-tuple of pairs $\mathcal{I} = ((x_1, z_1), \ldots, (x_m, z_m))$ with respect to ϕ *if and only if, for $i = 1, \ldots, m$, there exist $(s_i, t_i) \in \mathcal{R}_{x_i}$, $r'_i, r''_i \in \mathcal{S}_{x_i}$, and $a_i \in \{0, 1\}$ such that*

- *if $a_i = 0$, then $u_{i0} = Sample_{\mathcal{R}}(x_i, z_i, r'_i)$ and $u_{i1} = Sample_{\mathcal{R}}(x_i, s_i, r''_i)$;*
- *if $a_i = 1$, then $u_{i0} = Sample_{\mathcal{R}}(x_i, s_i, r'_i)$ and $u_{i1} = Sample_{\mathcal{R}}(x_i, z_i, r''_i)$;*
- *co-Val$(a_1, \ldots, a_m; \phi) \in \{0, 1\}$.*

If $\mathcal{H}$ is similar to $\mathcal{I}$ with respect to ϕ, we say that the vector $W = (w_1, \ldots, w_m)$, where $w_i = (s_i, t_i, r'_i, r''_i, a_i)$ for $i = 1, \ldots, m$, is a witness of the similarity of $\mathcal{H}$ *to* $\mathcal{I}$.

In the following whenever the formula ϕ is clear from the context, we will simply say "similar."

In Figure 4, we present the procedure *Construct-Similar* that can be used to construct similar tuples. We summarize the properties of *Construct-Similar* in the following lemma, whose proof is simple.

Procedure *Construct-Similar*$(\phi, \mathcal{I}, S, a)$.
Input:

- ϕ is a monotone formula on m variables;
- $\mathcal{I} = ((x_1, z_1), \ldots, (x_m, z_m))$;
- $S = ((s_1, t_1), \ldots, (s_m, t_m))$;
- $a \in \{0, 1\}$.

1. If ϕ consists of one literal v_1, then
   randomly choose $r', r'' \in \mathcal{S}_{x_1}$;
   if $a = 0$, then set $u_0 = \mathit{Sample}_{\mathcal{R}}(x_1, z_1, r')$ and $u_1 = \mathit{Sample}_{\mathcal{R}}(x_1, s_1, r'')$;
   if $a = 1$, then set $u_0 = \mathit{Sample}_{\mathcal{R}}(x_1, s_1, r')$ and $u_1 = \mathit{Sample}_{\mathcal{R}}(x_1, z_1, r'')$;
   return$((u_0, u_1), (s_1, t_1, r', r'', a))$.
2. If $\phi = \phi_1 \wedge \phi_2$, then
   let m_1 be the number of variables of ϕ_1;
   let $\mathcal{I}_1 = ((x_1, z_1), \ldots, (x_{m_1}, z_{m_1}))$ and $\mathcal{I}_2 = ((x_{m_1+1}, z_{m_1+1}), \ldots, (x_m, z_m))$;
   let $S_1 = ((s_1, t_1), \ldots, (s_{m_1}, t_{m_1}))$ and $S_2 = ((s_{m_1+1}, t_{m_1+1}), \ldots, (s_m, t_m))$;
   randomly choose $\tilde{a} \in \{0, 1\}$;
   obtain $(\mathcal{H}_1, W_1)$ by running *Construct-Similar* on input $(\phi_1, \mathcal{I}_1, S_1, \tilde{a})$;
   obtain $(\mathcal{H}_2, W_2)$ by running *Construct-Similar* on input $(\phi_2, \mathcal{I}_2, S_2, \tilde{a} \oplus a)$;
   return$(\mathcal{H}_1 \circ \mathcal{H}_2, W_1 \circ W_2)$.
3. If $\phi = \phi_1 \vee \phi_2$, then
   let m_1 be the number of variables of ϕ_1;
   let $\mathcal{I}_1 = ((x_1, z_1), \ldots, (x_{m_1}, z_{m_1}))$ and $\mathcal{I}_2 = ((x_{m_1+1}, z_{m_1+1}), \ldots, (x_m, z_m))$;
   let $S_1 = ((s_1, t_1), \ldots, (s_{m_1}, t_{m_1}))$ and $S_2 = ((s_{m_1+1}, t_{m_1+1}), \ldots, (s_m, t_m))$;
   obtain $(\mathcal{H}_1, W_1)$ by running *Construct-Similar* on input $(\phi_1, \mathcal{I}_1, S_1, a)$;
   obtain $(\mathcal{H}_2, W_2)$ by running *Construct-Similar* on input $(\phi_2, \mathcal{I}_2, S_2, a)$;
   return$(\mathcal{H}_1 \circ \mathcal{H}_2, W_1 \circ W_2)$.

FIG. 4. *The procedure Construct-Similar.*

LEMMA 19. *Let ϕ be a formula over m variables, let $(s_i, t_i) \in \mathcal{R}_{x_i}$ for $i = 1, \ldots, m$, and let $\mathcal{I} = ((x_1, z_1), \ldots, (x_m, z_m))$ and $S = ((s_1, t_1), \ldots, (s_m, t_m))$. Procedure Construct-Similar on input $\phi, \mathcal{I}, S$ and $a \in \{0, 1\}$ outputs in expected polynomial time an m-tuple $\mathcal{H} = ((u_{10}, u_{11}), \ldots, (u_{m0}, u_{m1}))$ similar to $\mathcal{I}$ along with*

a witness of similarity $W = ((s_1, t_1, r'_1, r''_1, a_1), \ldots, (s_m, t_m, r'_m, r''_m, a_m))$ *such that co-Val*$(a_1, \ldots, a_m; \phi) = a$. *Moreover, the ith pair* (u_{i0}, u_{i1}) *of the m-tuple* $\mathcal{H}$ *is constructed by running Sample*$_{\mathcal{R}}$ *twice: on input* x_i, z_i *and* $r'_i \in \mathcal{S}_{x_i}$ *and on input* x_i, s_i *and* $r''_i \in \mathcal{S}_{x_i}$.

An informal presentation. The zero-knowledge proof system for proving that $(\phi, \mathcal{I}) \in \mathrm{CL}(\mathrm{MON}; \overline{\mathrm{L}})$ can be informally presented in the following way. The verifier V randomly selects a bit c, computes an m-tuple $Y = (y_1, \ldots, y_m)$ that can be $(\phi, \mathcal{I})$-co-opened as c, and sends it to the prover P. The prover has to guess the value of c. By the definition of co-opening and the properties of an opening, we have that if $(\phi, \mathcal{I}) \in \mathrm{CL}(\mathrm{MON}; \overline{\mathrm{L}})$, then the prover has a way of guessing what c is; if instead $(\phi, \mathcal{I}) \notin \mathrm{CL}(\mathrm{MON}; \overline{\mathrm{L}})$, then he can guess the value of c with probability at most $1/2$. However, to ensure the zero-knowledge property, before the prover sends his guess for c, the prover and the verifier perform the following protocol $l(|Y|)$ times in parallel, where $l(\cdot)$ is a polynomial to be specified later. V computes an m-tuple of pairs $\mathcal{H} = ((u_{10}, u_{11}), \ldots, (u_{m0}, u_{m1}))$ that is similar to $\mathcal{I}$ with respect to ϕ and has the following additional property: there exists a sequence $(b_1, \ldots, b_m)$ such that *co-Val*$(b_1, \ldots, b_m; \phi) \in \{0, 1\}$, and, for $i = 1, \ldots, m$, there exists $r_{y_i} \in \mathcal{S}_{x_i}$ such that $y_i = \mathit{Sample}_{\mathcal{R}}(x_i, u_{ib_i}, r_{y_i})$. The prover receives $\mathcal{H}$ and chooses at random to see either a witness of similarity of $\mathcal{H}$ to $\mathcal{I}$ or the sequence $(b_1, \ldots, b_m, r_1, \ldots, r_m)$. If his request is satisfied by the verifier, the prover gives his guess for the bit c.

A formal description of the proof system (P,V) is found in Figure 5.

V *runs in probabilistic polynomial time.* Let us now show that the verifier's program can be executed in probabilistic polynomial time.

At step V.0 the verifier constructs the m-tuple Y by running the procedure *co-Construct-Opening*. As seen from the description of *Construct-Opening* in Figure 1, by De Morgan's law and by the discussion in Remark 2, procedure co-Construct-Opening runs in polynomial time and returns the m-tuple Y and a $(\phi, \mathcal{I})$-co-opening $R = ((c_1, r_1, s_1, t_1), \ldots, (c_m, r_m, s_m, t_m))$ of Y. The m-tuples Y and R are such that, for each $i = 1, \ldots, m$, the element y_i is obtained by running $\mathit{Sample}_{\mathcal{R}}$ either on input x_i, z_i and $r_i \in \mathcal{S}_{x_i}$ or on input x_i, s_i and $r_i \in \mathcal{S}_{x_i}$.

At step V.1, the verifier executes procedure *Construct-Similar* on input $\phi, \mathcal{I}$, the m-tuple $S = ((s_1, r_1), \ldots, (s_m, r_m))$, and a random bit a (see Figure 4 for a formal description of procedure *Construct-Similar*). By Lemma 19, procedure *Construct-Similar* runs in polynomial time and outputs an m-tuple $\mathcal{H}$ similar to $\mathcal{I}$ along with a witness of similarity

$$W = ((s_1, t_1, r'_1, r''_1, a_1), \ldots, (s_m, t_m, r'_m, r''_m, a_m))$$

of $\mathcal{H}$ to $\mathcal{I}$.

Step V.2 is the only nontrivial step of V's program that remains to be specified. If $d = 0$, then it is enough for V to send the witness of similarity W to P obtained by running *Construct-Similar* at step V.1. Let us now examine the case $d = 1$. In this case the verifier sets $b_i = a_i \oplus c_i$. Now observe that, since the sequences $(a_1, \ldots, a_m)$ and $(c_1, \ldots, c_m)$ are, by construction, co-well-formed with respect to ϕ, by Fact 17 so is the sequence $(b_1, \ldots, b_m)$, and thus the first verification of step P.2 in the case $d = 1$ is always successfully passed. Moreover, this setting allows the verifier to use algorithm $A_{\mathcal{R}}$ to compute r_{y_i} such that $y_i = \mathit{Sample}_{\mathcal{R}}(x_i, u_{ib_i}, r_{y_i})$, for $i = 1, \ldots, m$, as follows. First, suppose that $a_i = 1$ (the case $a_i = 0$ is similar) and thus $u_{i0} = \mathit{Sample}_{\mathcal{R}}(x_i, s_i, r'_i)$ and $u_{i1} = \mathit{Sample}_{\mathcal{R}}(x_i, z_i, r''_i)$ (see step 1 in the procedure *Construct-Similar*). If $c_i = 0$, we have $y_i = \mathit{Sample}_{\mathcal{R}}(x_i, z_i, r_i)$ and $b_i = 1$.

The Proof System (P,V).
Input: $(\phi, \mathcal{I}) \in \mathrm{CL}(\mathrm{MON}; \overline{\mathrm{L}})$

V.0 Uniformly select $c \in \{0,1\}$;
run procedure *co-Construct-Opening* on input $(\phi, \mathcal{I}, c)$ obtaining (Y, R);
write R as $R = ((c_1, r_1, s_1, t_1), \ldots, (c_m, r_m, s_m, t_m))$ and Y as $Y = (y_1, \ldots, y_m)$ and set $S = ((s_1, t_1), \ldots, (s_m, t_m))$;
send (Y, S) to P.

P↔V Perform $l(|Y|)$ parallel and independent executions of the following protocol.
begin

V.1 Uniformly select $a \in \{0,1\}$;
run procedure *Construct-Similar* on input $(\phi, \mathcal{I}, S, a)$ obtaining $(\mathcal{H}, W)$;
write $\mathcal{H}$ as $\mathcal{H} = ((u_{10}, u_{11}), \ldots, (u_{m0}, u_{m1}))$;
write W as $W = ((s_1, t_1, r'_1, r''_1, a_1), \ldots, (s_m, t_m, r'_m, r''_m, a_m))$;
send $\mathcal{H}$ to P.

P.1 Uniformly select $d \in \{0,1\}$ and send d to V.

V.2 If $d = 0$, then send W to P;
if $d = 1$, then
for $i = 1, \ldots, m$
set $b_i = a_i \oplus c_i$;
use algorithm $A_{\mathcal{R}}$ to compute r_{y_i} such that $y_i = \mathit{Sample}_{\mathcal{R}}(x_i, u_{ib_i}, r_{y_i})$;
send $T = (b_1, r_{y_1}, \ldots, b_m, r_{y_m})$ to P.

P.2 If $d = 0$, then check that W is a witness of similarity of $\mathcal{H}$ to $\mathcal{I}$;
if $d = 1$, then
check that $\mathit{co\text{-}Val}(b_1, \ldots, b_m; \phi) \in \{0,1\}$;
check that $y_i = \mathit{Sample}_{\mathcal{R}}(x_i, u_{ib_i}, r_{y_i})$ for $i = 1, \ldots, m$.

end

P.3 If any of the verifications of the $l(|Y|)$ parallel executions is not satisfied, then STOP;
else compute $c' \in \{0,1\}$ such that Y can be $(\phi, \mathcal{I})$-co-opened as c'.
Send c' to V.

V.3 Verify that $c = c'$. If not, reject.

FIG. 5. *The proof system* (P,V) *for* $\mathrm{CL}(\mathrm{MON}; \overline{\mathrm{L}})$.

By the first part of property 4 of the RSR languages, the verifier can compute in polynomial time r_{y_i} such that $y_i = \mathit{Sample}_{\mathcal{R}}(x_i, u_{i1}, r_{y_i})$. On the other hand, if $c_i = 1$, we have $y_i = \mathit{Sample}_{\mathcal{R}}(x_i, s_i, r_i)$ (see step 1 of procedure *Construct-Opening*) and $b_i = 0$. Again, by property 4 of the RSR languages the verifier can compute r_{y_i} such that $y_i = \mathit{Sample}_{\mathcal{R}}(x_i, u_{i0}, r_{y_i})$.

Completeness and soundness. The completeness property is easily proved and follows directly from Lemma 11 and from the discussion above.

For the soundness we assume that $(\phi, \mathcal{I}) \notin \mathrm{CL}(\mathrm{MON}; \overline{\mathrm{L}})$. Under this assumption, we prove that the distribution of all that the prover sees (that is, the pair (Y, S), the $\mathcal{H}$'s, and the verifier's answers in the $l(n)$ execution of the subprotocol) is independent

from that of bit c. Thus, the probability that the prover correctly guesses the value of c by seeing V's answers to his challenges is at most $1/2$.

We start with pair (Y, S); the following lemma directly implies that the distribution of such a pair is independent from that of bit c when $(\phi, \mathcal{I}) \notin \mathrm{CL}(\mathrm{MON}; \bar{\mathrm{L}})$.

LEMMA 20. *Let* $(\phi, \mathcal{I}) \notin \mathrm{CL}(\mathrm{MON}; \bar{\mathrm{L}})$ *and denote by* $\mathrm{Prob}(S, Y, \phi, \mathcal{I}, a)$ *the probability that co-Construct-Opening outputs the sequence* Y *and a* $(\phi, \mathcal{I})$*-opening* R *of* Y *as a with auxiliary sequence* S*. Then, for each* Y *and* S *we have*

$$\mathrm{Prob}(S, Y, \phi, \mathcal{I}, 0) = \mathrm{Prob}(S, Y, \phi, \mathcal{I}, 1).$$

Proof. Observe that $(\phi, \mathcal{I}) \notin \mathrm{CL}(\mathrm{MON}; \bar{\mathrm{L}})$ implies $(DM(\phi), \mathcal{I}) \in \mathrm{CL}(\mathrm{MON};\mathrm{L})$. The lemma thus follows from Lemma 14. □

For the jth parallel execution we denote by $\mathcal{H}^j$ the value sent by the verifier to the prover at step V.1, by d^j the bit sent by the prover to the verifier at step P.1, and by A^j the answer sent by the verifier at step V.2 for $j \in \{1, \ldots, l(|Y|)\}$.

We now see that when $(\phi, \mathcal{I}) \notin \mathrm{CL}(\mathrm{MON}; \bar{\mathrm{L}})$, the distribution of tuple $\vec{\mathcal{H}} = (\mathcal{H}^1, \ldots, \mathcal{H}^{l(|Y|)})$, conditioned by the value of pair (Y, S), is independent from that of bit c.

LEMMA 21. *We let* $(\phi, \mathcal{I}) \notin \mathrm{CL}(\mathrm{MON}; \bar{\mathrm{L}})$ *and denote by* $\mathrm{Prob}(\vec{\mathcal{H}} \mid S, Y, \phi, \mathcal{I}, c)$ *the probability that Construct-Similar outputs the sequence* $\vec{\mathcal{H}}$ *given that co-Construct-Opening*$(\phi, \mathcal{I}, c)$ *returns* (Y, S) *with* S *as the auxiliary sequence in* R*. Then, for each* $\vec{\mathcal{H}}$ *we have that*

$$\mathrm{Prob}(\vec{\mathcal{H}} \mid S, Y, \phi, \mathcal{I}, 0) = \mathrm{Prob}(\vec{\mathcal{H}} \mid S, Y, \phi, \mathcal{I}, 1).$$

Proof. Note that $\vec{\mathcal{H}} = \mathcal{H}^1, \ldots, \mathcal{H}^{l(|Y|)}$. The lemma follows by observing that each $\mathcal{H}^j$ is generated as the first component of a pair returned by an independent execution of algorithm *Construct-Similar* on input $\phi, \mathcal{I}, S$ and a random and independent bit a, where we use the fact that the distribution of S is independent from that of c, as implied by Lemma 20. □

We now prove that, for $j = 1, \ldots, l(|Y|)$, the distribution of the answer A^j, conditioned on the values $Y, S, \vec{\mathcal{H}}$, $\vec{d} = (d^1, \ldots, d^{l(|Y|)})$, and $A^1, \ldots, A^{j-1}$, is independent from that of bit c. To this purpose, we distinguish two cases, according to the value of bit d^j.

First, consider the case $d^j = 0$. In this case A^j is generated as the second component W^j of the pair returned by an independent execution of algorithm *Construct-Similar* on input $\phi, \mathcal{I}, S$ and a random bit a. Here we can again use the fact that the distribution of S is independent from that of c, as implied by Lemma 20. Therefore, in this case, the distribution of A^j, conditioned on the values of $Y, S, \vec{\mathcal{H}}, \vec{d}, A^1, \ldots, A^{j-1}$, is independent from that of c.

The rest of the proof for the soundness property refers only to the case $d^j = 1$. In this case A^j is equal to sequence $T^j = (b_1^j, r_{y_1}, \ldots, b_m^j, r_{y_m})$. We first note that, even with further conditioning of the values of $b_1^j, \ldots, b_m^j$, each r_{y_i} is, by property 4 of the RSR languages, distributed as a random and independent value r such that $y_i = \mathit{Sample}(x_i, u_{iq}, r)$ for $q = b_i^j$. Therefore, to conclude the proof for this case, it is enough to prove that the distribution of sequence $(b_1^j, \ldots, b_m^j)$, conditioned on $Y, S, \vec{\mathcal{H}}, \vec{d}, A^1, \ldots, A^{j-1}$, is independent from c. We start the proof of this latter fact with some definitions.

DEFINITION 22. *Let $c \in \{0,1\}$, and let (Y,R) be the output of co-Construct-Opening on input $(\phi,\mathcal{I},c)$, where $Y=(y_1,\ldots,y_m)$, $R=((a_1,r_1,s_1,t_1),\ldots,(a_m,r_m,s_m,t_m))$, and $S=((s_1,t_1),\ldots,(s_m,t_m))$ denotes the auxiliary sequence. Also, let $\mathcal{H}=((u_{01},u_{11}),\ldots,(u_{0m},u_{1m}))$ be the first component of the pair returned by algorithm Construct-Similar on input $(\phi,\mathcal{I},S,a)$. Let sequence $(e_1,\ldots,e_m)\in\{0,1\}^m$ be co-well-formed with respect to ϕ; we say that $(e_1,\ldots,e_m)$ is*

- $(\phi,\mathcal{I},S,Y)$-consistent *if there exist $e\in\{0,1\}$ and $r_i\in\mathcal{S}_{x_i}$, for $i=1,\ldots,m$, such that the tuple $((e_1,r_1,s_1,t_1),\ldots,(e_m,r_m,s_m,t_m))$ is a $(\phi,\mathcal{I})$-co-opening of Y as e;*
- $(\phi,\mathcal{I},S,\mathcal{H})$-consistent *if there exist $e\in\{0,1\}$ and $r'_i,r''_i\in\mathcal{S}_{x_i}$, for $i=1,\ldots,m$, such that $\mathcal{H}$ is similar to $\mathcal{I}$ with respect to ϕ, and W is a witness of the similarity of $\mathcal{H}$ to $\mathcal{I}$, where $W=(w_1,\ldots,w_m)$, $w_i=(s_i,t_i,r'_i,r''_i,e_i)$, for $i=1,\ldots,m$, and co-Val$(e_1,\ldots,e_m)=e$;*
- $(\phi,\mathcal{I},S,Y,\mathcal{H})$-consistent *if there exists $e\in\{0,1\}$ such that co-Val$(e_1,\ldots,e_m)=e$, and, for $i=1,\ldots,m$, there exists r_{y_i} such that $y_i=$ Sample$_{\mathcal{R}}(x_i,u_{ie_i},r_{y_i})$.*

For any formula ϕ, and given $\mathcal{I},S,Y$, we denote by $\mathrm{Seq}(\phi,\mathcal{I},S,Y)$ *the set of sequences $(e_1,\ldots,e_m)$ that are $(\phi,\mathcal{I},S,Y)$-consistent; moreover, for any $j\in\{1,\ldots,l(|Y|)\}$, all $c\in\{0,1\}$, and given $\mathcal{H}^j$, we denote by* $\mathrm{Seq}(\phi,\mathcal{I},S,Y,\mathcal{H}^j)$ *(resp.,* $\mathrm{Seq}(\phi,\mathcal{I},S,\mathcal{H}^j)$*) the set of sequences $(e_1,\ldots,e_m)$ that are $(\phi,\mathcal{I},S,Y,\mathcal{H}^j)$-consistent (resp., $(\phi,\mathcal{I},S,\mathcal{H}^j)$-consistent).*

We will use the above definitions for the following three facts. First, we note that we can rephrase the analysis done while proving that V runs in polynomial time in step V.2 (in the case $d^j=1$) as follows.

FACT 23. *Let $j\in\{1,\ldots,l(|Y|)$ be such that $d_j=1$. If $(\phi,\mathcal{I})\notin\mathrm{CL}(\mathrm{MON};\bar{\mathrm{L}})$, then for any m-tuple $\vec{b}=(b_1,\ldots,b_m)\in\mathrm{Seq}(\phi,\mathcal{I},S,Y,\mathcal{H}^j)$, and any m-tuple $\vec{c}=(c_1,\ldots,c_m)\in\mathrm{Seq}(\phi,\mathcal{I},S,Y)$, there exists an m-tuple $\vec{a}=(a_1,\ldots,a_m)\in\mathrm{Seq}(\phi,\mathcal{I},S,\mathcal{H}^j)$ such that $a_i=b_i\oplus c_i$ for $i=1,\ldots,m$.*

Recall that by $\vec{c}=(c_1,\ldots,c_m)$ we denote the sequence of bits obtained from the output R returned by the execution of algorithm *co-Construct-Opening* in step V.0. We then note that, by definition of *co-Construct-Opening*, $\vec{c}$ is co-well-formed with respect to ϕ, and, by definition of step V.0, $\vec{c}\in\mathrm{Seq}(\phi,\mathcal{I},S,Y)$. For $c=0,1$, define $\mathrm{Seq}(\phi,\mathcal{I},S,Y,c)=\{\vec{c}\,|\,\vec{c}\in\mathrm{Seq}(\phi,\mathcal{I},S,Y),\text{co-Val}(\vec{c})=c\}$. Moreover, for $r=0,1,2$, define $\mathrm{Prob}_r[\,\vec{e}\,|\,tr,c,\ldots\,]$ as the probability that tuple $\vec{e}$ is computed by V during round V.r of the protocol, conditioned on the values $tr=(Y,S,\vec{\mathcal{H}},\vec{d},A^1,\ldots,A^{j-1})$, and by bit c chosen by V in step V.0. We now prove a useful fact about the distribution of sequence $\vec{c}$ with respect to the value of bit c chosen by V in step V.0.

FACT 24. *If $(\phi,\mathcal{I})\notin\mathrm{CL}(\mathrm{MON};\bar{\mathrm{L}})$, then*

$$\sum_{\vec{c}\in\,\mathrm{Seq}(\phi,\mathcal{I},S,Y,0)}\mathrm{Prob}_0[\,\vec{c}\,|\,tr,0\,]=\sum_{\vec{c}\in\,\mathrm{Seq}(\phi,\mathcal{I},S,Y,1)}\mathrm{Prob}_0[\,\vec{c}\,|\,tr,1\,].$$

Proof. As a first claim, we note that each tuple $\vec{c}$ co-well-formed with respect to ϕ has the same probability of being returned by algorithm *co-Construct-Opening* on input ϕ and a randomly chosen bit c. (This can be proved by simple induction over formula ϕ.) Using Fact 17, we note a second claim, stating that for any formula ϕ, the number of tuples $\vec{c}$ that can be returned by algorithm *co-Construct-Opening*, on input formula ϕ and c, is the same for both values of bit c.

Now, assume $(\phi,\mathcal{I})\notin\mathrm{CL}(\mathrm{MON};\bar{\mathrm{L}})$. By induction over formula ϕ, we can extend the above second claim to prove a third claim, saying that the number of tuples $\vec{c}$

belonging to set $\mathrm{Seq}(\phi, \mathcal{I}, S, Y, c)$ is the same for both values of bit c.

Specifically, the base case directly follows as an application of Lemma 10.

For the induction case, first consider the case $\phi = \phi_1 \vee \phi_2$, where ϕ_1 has m_1 variables. Then the claim follows by observing that the number of sequences $\vec{c}$ in $\mathrm{Seq}(\phi, \mathcal{I}, S, Y, c)$ is the product of the number of sequences $(c_1, \ldots, c_{m_1})$ in $\mathrm{Seq}(\phi_1, \mathcal{I}, S, Y, c)$ times the number of sequences $(c_{m_1+1}, \ldots, c_m)$ in $\mathrm{Seq}(\phi_2, \mathcal{I}, S, Y, c)$, and by applying the inductive hypothesis to both ϕ_1, ϕ_2, since our assumption implies that $(\phi_j, \mathcal{I}_j) \notin \mathrm{CL}(\mathrm{MON}; \bar{\mathrm{L}})$ for $j = 1, 2$.

Now, consider the case $\phi = \phi_1 \wedge \phi_2$, where ϕ_1 has m_1 variables. If $(\phi_j, \mathcal{I}_j) \notin \mathrm{CL}(\mathrm{MON}; \bar{\mathrm{L}})$ for $j = 1, 2$, then the claim follows similarly as for the previous case. Therefore, assume that $(\phi_1, \mathcal{I}_1) \notin \mathrm{CL}(\mathrm{MON}; \bar{\mathrm{L}})$ and $(\phi_2, \mathcal{I}_2) \in \mathrm{CL}(\mathrm{MON}; \bar{\mathrm{L}})$ (the symmetric case being proved similarly). Note that Lemma 11 implies that, after conditioning on Y, there exists exactly one bit c_2 such that *co-Val*$(c_{m_1+1}, \ldots, c_m; \phi_2) = c_2$. Then the claim follows by applying the inductive hypothesis to ϕ_1 and by observing that the number of sequences $\vec{c}$ in $\mathrm{Seq}(\phi, \mathcal{I}, S, Y, c)$ is the product of the number of sequences $(c_1, \ldots, c_{m_1})$ in $\mathrm{Seq}(\phi_1, \mathcal{I}, S, Y, c \oplus c_2)$ times the number of sequences $(c_{m_1+1}, \ldots, c_m)$ in $\mathrm{Seq}(\phi_2, \mathcal{I}, S, Y, c_2)$, where we note that the latter number does not depend on c.

Then the fact follows by combining the first and third claims. □

Now, consider the jth execution of algorithm *Construct-Similar* in step V.2 while running the jth parallel iteration, and recall that we denote by $\vec{a} = (a_1, \ldots, a_m)$ the sequence of bits obtained from the output W returned by this execution. Here, we note that, by the definition of *Construct-Similar*, $\vec{a}$ is co-well-formed with respect to ϕ, and, moreover, using simple induction over formula ϕ, we obtain that $\vec{a} \in \mathrm{Seq}(\phi, \mathcal{I}, S, \mathcal{H}^j)$. For any subformula ψ of ϕ satisfying $(\psi, \mathcal{I}_\psi) \in \mathrm{CL}(\mathrm{MON}; \bar{\mathrm{L}})$ and having leaves $i_1, \ldots, i_k$, we denote as $\mathcal{H}^j_\psi = ((u_{i_1,0}, u_{i_1,1}), \ldots, (u_{i_k,0}, u_{i_k,1}))$ the subsequence of $\mathcal{H}^j$, where each pair $(u_{i_j,0}, u_{i_j,1})$ is computed at step 1 of procedure *Construct-Similar* in correspondence to literal v_{i_j}. Note that an execution of algorithm *Construct-Similar* returning $\mathcal{H}^j$ implicitly defines a witness of similarity of $\mathcal{H}^j_\psi$ to $\mathcal{I}_\psi$, containing sequence $(a_{i_1}, \ldots, a_{i_k})$ such that *co-Val*$(a_{i_1}, \ldots, a_{i_k})$ is equal to a bit that we denote as $a_{\mathcal{H}^j,\psi}$. In the following fact we characterize set $\mathrm{Seq}(\phi, \mathcal{I}, S, \mathcal{H}^j)$ and the distribution of sequence $\vec{a}$ computed by V in step V.1.

FACT 25. *Let $j = 1, \ldots, l(|Y|)$ be such that $d_j = 1$; the following holds. Set $\mathrm{Seq}(\phi, \mathcal{I}, S, \mathcal{H}^j)$ is equal to the set of sequences $\vec{a}$ that are co-well-formed with respect to ϕ and such that for each subformula ψ of ϕ satisfying $(\psi, \mathcal{I}_\psi) \in \mathrm{CL}(\mathrm{MON}; \bar{\mathrm{L}})$ and having leaves $i_1, \ldots, i_k$, it holds that co-Val$(a_{i_1}, \ldots, a_{i_k}; \psi) = a_{\mathcal{H}^j,\psi}$. Moreover, the distribution of sequence $\vec{a}$ computed at step* V.1 *is uniform over set* $\mathrm{Seq}(\phi, \mathcal{I}, S, \mathcal{H}^j)$.

Proof. The definition of algorithm *Construct-Similar* already implies that set $\mathrm{Seq}(\phi, \mathcal{I}, S, \mathcal{H}^j)$ includes all co-well-formed sequences $\vec{a}$ satisfying *co-Val*$(a_{i_1}, \ldots, a_{i_k}; \psi) = a_{\mathcal{H}^j,\psi}$ for each subformula ψ of ϕ with leaves $i_1, \ldots, i_k$ and such that $(\psi, \mathcal{I}_\psi) \in \mathrm{CL}(\mathrm{MON}; \bar{\mathrm{L}})$. Now, consider all sequences $(a_1, \ldots, a_m)$ in $\mathrm{Seq}(\phi, \mathcal{I}, S, \mathcal{H}^j)$. By Definition 22, there exists a witness of the similarity between $\mathcal{H}^j$ and $\mathcal{I}$, and *co-Val*$(a_1, \ldots, a_m) \in \{0, 1\}$. This implies that for each subformula ψ of ϕ such that $(\psi, \mathcal{I}_\psi) \in \mathrm{CL}(\mathrm{MON}; \bar{\mathrm{L}})$, it holds that *co-Val*$(a_{i_1}, \ldots, a_{i_k})$ is equal to a bit that we denote as $a'_{\mathcal{H}^j,\psi}$. By Lemma 11, this bit is unique; that is, we have that $a'_{\mathcal{H}^j,\psi} = a_{\mathcal{H}^j,\psi}$. The claim on the distribution of sequence $\vec{a}$ follows by combining Fact 17 with the above characterization. □

We can now use the above facts to prove that the distribution of tuple $\vec{b}$ computed by V in step V.2, even conditioned over the view of P so far, is independent from bit

c chosen by V in step V.0. Specifically, for all $\vec{b} \in \mathrm{Seq}(\phi, \mathcal{I}, S, Y, \mathcal{H}^j)$, we have that

$$\begin{aligned}
\mathrm{Prob}_2[\,\vec{b}\,|\,tr, c\,] &= \sum_{\vec{c}} \mathrm{Prob}_0[\,\vec{c}\,|\,tr, c\,] \cdot \mathrm{Prob}_2[\,\vec{b}\,|\,tr, c, \vec{c}\,] \\
&= \sum_{\vec{c} \in \mathrm{Seq}(\phi,\mathcal{I},S,Y,c)} \mathrm{Prob}_0[\,\vec{c}\,|\,tr, c\,] \cdot \mathrm{Prob}_2[\,\vec{b}\,|\,tr, c, \vec{c}\,] \\
&= \sum_{\vec{c} \in \mathrm{Seq}(\phi,\mathcal{I},S,Y,c)} \mathrm{Prob}_0[\,\vec{c}\,|\,tr, c\,] \cdot \mathrm{Prob}_1[\,(b_1 \oplus c_1, \ldots, b_m \oplus c_m)\,|\,tr, c, \vec{c}\,] \\
&= \mathrm{Prob}_1[\,\vec{a}\,|\,tr\,] \cdot \sum_{\vec{c} \in \mathrm{Seq}(\phi,\mathcal{I},S,Y,c)} \mathrm{Prob}_0[\,\vec{c}\,|\,tr, c\,],
\end{aligned}$$

where the second equality follows from the fact that $\mathrm{Prob}_0[\,\vec{c}\,|\,tr, c\,] = 0$ when $\vec{c} \notin \mathrm{Seq}(\phi, \mathcal{I}, S, Y, c)$; the third equality follows from the fact that $\mathrm{Prob}_2[\,\vec{b}\,|\,tr, c, \vec{c}\,] = 0$ when $\vec{a} \neq (b_1 \oplus c_1, \ldots, b_m \oplus c_m)$ and from Fact 23; and the fourth equality follows by the definition of *Construct-Similar*, implying that the probability that tuple $(b_1 \oplus c_1, \ldots, b_m \oplus c_m)$ in $\mathrm{Seq}(\phi, \mathcal{I}, S, \mathcal{H}^j)$ is computed in step V.1 does not depend on the value of c or $\vec{c}$, as proved in Fact 25. Finally, we observe that even the factor $\sum_{\vec{c} \in \mathrm{Seq}(\phi,\mathcal{I},S,Y,c)} \mathrm{Prob}_0[\,\vec{c}\,|\,tr, c\,]$ does not depend on the value of c, as proved in Fact 24, and therefore neither does the value $\mathrm{Prob}_2[\,\vec{b}\,|\,tr, c\,]$. We obtain that from P's point of view, the distribution of sequence $\vec{b}$, even when conditioned from the transcript of the protocol so far, is independent from bit c chosen by V at step V.0. As discussed before, this implies the soundness property.

The simulator. Now we exhibit a simulator to prove the zero-knowledge property. The idea is to have the simulator run the protocol twice so as to get from the verifier both the witness of similarity and the two sequences $(b_1, \ldots, b_m)$ and $(r_{y_1}, \ldots, r_{y_m})$. As we shall prove next, this allows the simulator to compute the bit c. We give a formal description of the simulator in Figure 6.

LEMMA 26. *The simulator S_{V^*} runs in expected polynomial time.*

Proof. All the steps of S_{V^*} can be executed in probabilistic polynomial time except possibly step 7. For a random tape *Rand*, a formula ϕ, and a sequence $\mathcal{I}$, we denote by $\mathit{Good}(\mathit{Rand}, \phi, \mathcal{I})$ the set of l-bit sequences $(d_1, \ldots, d_l)$ for which V^* provides a correct answer and by $G = G(\mathit{Rand}, \phi, \mathcal{I})$ its size. Obviously, we have $0 \leq G \leq 2^l$. We distinguish three cases.

1. $G = 0$. In this case the simulator stops at step 6 for all values of $(d_1, \ldots, d_l)$.
2. $G = 1$. If $D \notin \mathit{Good}(\mathit{Rand}, \phi, \mathcal{I})$, then the simulator stops at step 6.
   If $D \in \mathit{Good}(\mathit{Rand}, \phi, \mathcal{I})$, which happens with probability 2^{-l}, then the simulator has to compute c such that Y can be co-opened as c.
   Therefore, if we let $l = l(|\phi| + |\mathcal{I}|)$, where $l(\cdot)$ is a polynomial such that the length of a $(\phi, \mathcal{I})$-co-opening of a sequence Y is at most $l(|\phi| + |\mathcal{I}|)$, and thus such a co-opening can be computed in time $O(\mathit{poly}(|\phi| + |\mathcal{I}|) \cdot 2^{l(|\phi|+|\mathcal{I}|)})$, the contribution of this case to the expected running time of the simulator is polynomial.
3. $G > 1$. The expected number of executions of step 7(a) is upper bounded by the probability that D is good (which equals $G/2^l$) times the expected number of trials until a good D' different from D is found (which equals $2^l/(G-1)$), for a total of $G/(G-1) \leq 2$. ∎

We now show that S_{V^*} is indeed a simulator for (P,V). Clearly, the random tape *Rand* and the sequence of bits $d_1, \ldots, d_m$ have the same distribution in the output of

The simulator S_{V^*}.
Input: $(\phi, \mathcal{I}) \in \mathrm{CL}(\mathrm{MON}; \overline{\mathrm{L}})$, where ϕ is a formula with m variables.

1. Uniformly choose a string *Rand* (of appropriate length) and write it on the random tape of the verifier V^*.
2. Receive (Y, S) from V^* and denote $l(|Y|)$ simply by l.
3. Receive $\mathcal{H}_1, \ldots, \mathcal{H}_l$ from V^*.
4. Uniformly choose $D = (d_1, \ldots, d_l) \in \{0,1\}^l$. Send D to V^*.
5. Receive $mes = mes_1 \circ \ldots \circ mes_l$ from V^*.
6. If, for some i, mes_i is not a correct answer, then
   Output:$(Rand; Y, \mathcal{H}_1, \ldots, \mathcal{H}_l D, mes)$ and STOP.
7. Execute the following two steps (a) and (b) in parallel and continue to step 8 as soon as one of the two steps completes.
   (a) Repeatedly try to "extract" c from V^*
      (i) Rewind V^* to the state just after step V^*.1.
      (ii) Randomly choose sequence $D' = (d'_1, \ldots, d'_l)$.
      If $D = D'$, then go to step 7(a)(i) else send D' to V^*.
      (iii) Receive $mes' = mes'_1 \circ \cdots \circ mes'_l$ from V^*.
      (iv) If for some $j \in \{1, \ldots, l\}$, mes'_j is not a correct answer, then go to step 7(a)(i)
      (v) Let j be any index such that $d_j \neq d'_j$.
      (vi) If $d_j = 0$, then
         write mes_j as $mes_j = ((s_1, t_1, r'_1, r''_1, a_1), \ldots, (s_m, t_m, r'_m, r''_m, a_m))$;
         write mes'_j as $mes'_j = ((b_1, r_{y_1}), \ldots, (b_m, r_{y_m}))$;
      else
         write mes'_j as $mes'_j = ((s_1, t_1, r'_1, r''_1, a_1), \ldots, (s_m, t_m, r'_m, r''_m, a_m))$;
         write mes_j as $mes_j = ((b_1, r_{y_1}), \ldots, (b_m, r_{y_m}))$.
      (vii) Compute c as $c = co\text{-}Val(a_1 \oplus b_1, \ldots, a_m \oplus b_m; \phi)$.
   (b) Run an exhaustive search algorithm for computing bit c such that Y can be co-opened as c.
8. **Output:** $(Rand; Y, \mathcal{H}_1, \ldots, \mathcal{H}_l, D, mes, c)$ and STOP.

FIG. 6. *The simulator for verifier* V^*.

S_{V^*} as in the view of V^*. The next lemma shows that the bit c computed at step 7(a) is such that Y can be co-opened as c.

LEMMA 27. *Let* $W = ((s_1, t_1, r'_1, r''_1, a_1), \ldots, (s_m, t_m, r'_m, r''_m, a_m))$ *be a witness of the similarity of the* m*-tuple* $\mathcal{H} = ((u_{10}, u_{11}), \ldots, (u_{m0}, u_{m1}))$ *to the* m*-tuple* $\mathcal{I} = ((x_1, z_1), \ldots, (x_m, z_m))$*, let* $(b_1, \ldots, b_m)$ *be a well-formed sequence with respect to the formula* ϕ*, and let* $Y = (y_1, \ldots, y_m)$ *be a sequence.*

Then there exists a polynomial-time algorithm that, on input W *and* $r_i \in \mathcal{S}_{x_i}$ *such that* $y_i = Sample_{\mathcal{R}}(x_i, u_{ib_i}, r_i)$ *for* $i = 1, \ldots, m$*, computes a* $(\phi, \mathcal{I})$*-co-opening of* Y *as* $c = co\text{-}Val(a_1 \oplus b_1, \ldots, a_m \oplus b_m; \phi)$.

Proof. Let $c_i \stackrel{\text{def}}{=} a_i \oplus b_i$. We show that it is possible to compute in polynomial time, for $i = 1, \ldots, m$, r_{y_i} such that if $c_i = 0$, then $y_i = Sample_{\mathcal{R}}(x_i, z_i, r_{y_i})$, and if $c_i = 1$, then $y_i = Sample_{\mathcal{R}}(x_i, s_i, r_{y_i})$. The sequence $((c_1, r_{y_1}), \ldots, (c_m, r_{y_m}))$ is a co-opening of Y as c.

We consider only the case $c_i = 0$, the case $c_i = 1$ being similar. Assume $a_i = 0$ and $b_i = 0$. Then we have $u_{i0} = \mathit{Sample}_{\mathcal{R}}(x_i, z_i, r'_i)$, $u_{i1} = \mathit{Sample}_{\mathcal{R}}(x_i, s_i, r''_i)$, and $y_i = \mathit{Sample}_{\mathcal{R}}(x_i, u_{i0}, r_i)$. Using property 4 of RSR languages we have that it is possible to compute in polynomial time r_{y_i} such that $y_i = \mathit{Sample}_{\mathcal{R}}(x_i, z_i, r_{y_i})$. If instead $a_i = 1$ and $b_i = 1$, we have that $u_{i0} = \mathit{Sample}_{\mathcal{R}}(x_i, s_i, r'_i)$, $u_{i1} = \mathit{Sample}_{\mathcal{R}}(x_i, z_i, r''_i)$, and $y_i = \mathit{Sample}_{\mathcal{R}}(x_i, u_{i1}, r_i)$. Again by property 4 of the RSR languages it follows that it is possible to compute in polynomial time r_{y_i} such that $y_i = \mathit{Sample}_{\mathcal{R}}(x_i, z_i, r_{y_i})$. □

LEMMA 28. *The probability distributions* $S_{\mathrm{V}^*}(\phi, \mathcal{I})$ *and* $\mathit{View}_{\mathrm{V}^*}(\phi, \mathcal{I})$ *are identical for all* $(\phi, \mathcal{I}) \in \mathrm{CL}(\mathrm{MON}; \bar{\mathrm{L}})$.

Proof. Both distributions consist of a random *Rand*, sequences Y and $\mathcal{H}_1, \ldots, \mathcal{H}_l$ (obtained for both distributions by applying V^* to *Rand* and $(\phi, \mathcal{I})$), a random sequence $D = d_1, \ldots, d_l$, and, in case $D \in \mathit{Good}(\mathit{Rand}, \phi, \mathcal{I})$, messages from the verifier (obtained for both distributions by applying V^* to *Rand*, D, and $(\phi, \mathcal{I})$), and a bit c. By Lemma 11, c is the only value for which Y can be $(\phi, \mathcal{I})$-co-opened as c. □

We have thus proved the following theorem.

THEOREM 29. *Let L be an RSR language. Then,* $\mathrm{CL}(\mathrm{MON}; \bar{\mathrm{L}}) \in PZK$.

Remark 4 (a variation on the protocol for monotone formulae over co-RSR languages). Next we show that it is possible to design a zero-knowledge proof system for any monotone formula over co-RSR languages, which, although being less efficient than the one already presented, does not use condition 4 in the definition of RSR languages.

The only variation from the protocol described in Figure 5 is in the subprotocol in which the verifier gives a "proof that he knows what c is." Here, the verifier considers the NP statement "there exist a string R and a bit c such that (Y, R) is a $(\phi, \mathcal{I})$-co-opening as c of Y." Using standard polynomial-time reductions (see [35]), this statement can be reduced in polynomial time to a statement about the Hamiltonicity of graph G. We can assume without loss of generality that the used reduction is witness-preserving (i.e., there exists an efficient algorithm that, on input a witness R for the former statement, allows us to compute a witness π for the latter), since so are many such reductions in the literature. Now, the verifier will compute a witness π for the latter statement and prove its knowledge using a parallel execution of a modification of the zero-knowledge proof system for graph Hamiltonicity given in [10]. The modification is the following. Recall that the protocol in [10] uses a bit commitment scheme based on one-way functions to encode an isomorphic copy of the input graph G. We propose instead to use the procedure *co-Construct-Opening* as a bit commitment scheme: to commit to a bit b run *co-Construct-Opening* on input $\phi, \mathcal{I}$ and b. The commitment scheme described has the following properties. If $(\phi, \mathcal{I}) \in \mathrm{CL}(\mathrm{MON}, \bar{\mathrm{L}})$, the verifier is information theoretically bound to the committed bit; this allows us to extract the bit c and thus to prove the zero-knowledge property. On the other hand, if $(\phi, \mathcal{I}) \notin \mathrm{CL}(\mathrm{MON}, \bar{\mathrm{L}})$, the committed bit is perfectly hidden to the prover, and thus soundness can be easily proved.

The described technique is based on ideas that first appeared in [45].

6. Threshold formulae over RSR languages. In this section we give a PZK proof system for the language $\mathrm{CL}(T; L)$ of all true threshold formulae whose atoms are statements about membership in an RSR language L. As MON is a subset of T, the results in this section subsume the one in section 4. However, we note that the proof system presented here is more complicated than that presented in section 4. On the other hand, the threshold function has polynomial-size monotone boolean formulae (see [55]), and thus we could use the proof system of section 4 for the monotone

formula of size $O(n^{5.3})$ for the threshold function on n arguments given by Valiant in [55]. We show, however, a much more efficient construction that is constructive. (Valiant's proof that the threshold function has a monotone formula does not provide an effective construction.)

6.1. Threshold schemes. In the construction of our proof system we will use the notion of *threshold scheme*, introduced by Shamir [52] and Blackley [9]. A (k, m)-threshold scheme is an efficient probabilistic algorithm that, on input a datum D, outputs m *pieces* $sh_1, \ldots, sh_m$, such that

- knowledge of any k or more pieces sh_i makes D easily computable;
- knowledge of any $k-1$ or fewer pieces sh_i leaves D completely undetermined (i.e., all its possible values are equally likely).

Shamir [52] shows how to construct such threshold schemes using interpolation of polynomials in the following way. Let $(\mathcal{E}, +, \cdot)$ be a finite field with more than m elements and let $D \in \mathcal{E}$ be the value to be shared; we will consider $\mathcal{E} = \mathrm{GF}(2^l)$ (which we identify with $\{0, 1, \ldots, 2^l - 1\}$). Choose at random $a_1, \ldots, a_{k-1} \in \mathcal{E}$, construct the polynomial $q(x) = D + a_1 \cdot x + \cdots + a_{k-1} \cdot x^{k-1}$, and output $sh_i = q(i) \in \mathcal{E}$ (all operations are performed in $\mathcal{E}$) for $i = 1, \ldots, m$.

We say that a sequence $(sh_1, \ldots, sh_m)$ is a (k, m)-*sequence of admissible shares* (we will simply call it a *sequence of admissible shares* when k and m are clear from the context) if there exists a polynomial $q(x) = a_0 + a_1 x + \cdots + a_{k-1} x^{k-1}$ with coefficients in $\mathcal{E}$, such that $sh_i = q(i)$ for $i = 1, \ldots, m$. We say that a sequence $(sh_1, \ldots, sh_m)$ is a (k, m)-*sequence of admissible shares* for D if there exists a polynomial $q(x) = a_0 + a_1 x + \cdots + a_{k-1} x^{k-1}$ with coefficients in $\mathcal{E}$, such that $a_0 = D$ and $sh_i = q(i)$ for $i = 1, \ldots, m$.

Now we recall some facts about threshold schemes that will be important for the construction of our proof system. Let $I \subseteq \{1, \ldots, m\}$ and suppose $|I| < k$. Given D and a sequence $(sh_i | i \in I)$ of values, it is always possible to efficiently generate values sh_i, $i \notin I$, such that $(sh_1, \ldots, sh_m)$ is a sequence of admissible shares for D and the sh_i's for $i \notin I$ are uniformly distributed among the sh_i's such that $(sh_1, \ldots, sh_m)$ is a sequence of admissible shares for D. If $|I| \geq k$, then a sequence $(sh_i | i \in I)$ of values uniquely determines at most one value D and values sh_i for $i \notin I$ such that $(sh_1, \ldots, sh_m)$ is a sequence of admissible shares for D. Also, for $|I| < k$, given a sequence $(sh_i | i \in I)$ of values, if the values sh_i for $i \notin I$ are chosen with uniform distribution among the sh_i's such that $(sh_1, \ldots, sh_m)$ is a sequence of admissible shares, then D is uniformly distributed in $\mathcal{E}$.

6.2. The construction. The construction of a proof system for $\mathrm{CL}(T; L)$ is based on an ad hoc modification of the concepts of value and opening and will be obtained as for the proof system for monotone formulae over RSR languages.

The *value* $t\text{-}Val(sh_1, \ldots, sh_m; \phi) \in \mathcal{E} \cup \{\perp\}$ of an m-tuple $(sh_1, \ldots, sh_m) \in \mathcal{E}^m$ with respect to a threshold formula ϕ with m variables is defined recursively in the following way. If ϕ consists of a single variable v_i, then $t\text{-}Val(sh_i; v_i) = sh_i$. Otherwise, assume ϕ is a threshold formula $T_{k,n}$, over subformulae $\phi_1, \ldots, \phi_n$ for some integers k, n; also, let $m_0 = 0$, let m_i be the number of variables in $\phi_1, \ldots, \phi_i$, for $i = 1, \ldots, n$, and let $s_i = t\text{-}Val(sh_{m_{i-1}+1}, \ldots, sh_{m_i}, \phi_i)$. Then it holds that $t\text{-}Val(sh_1, \ldots, sh_m; \phi)$ is equal to $D \in \mathcal{E}$ if $(s_1, \ldots, s_n)$ is a $(n - k + 1, n)$-sequence of admissible shares for D, or equal to $\perp$ otherwise. Now we can define the notion of threshold-opening.

DEFINITION 30 (threshold-opening). *Let ϕ be a threshold formula, let $D \in \mathrm{GF}(2^l)$, and let $\mathcal{I} = ((x_1, z_1), \ldots, (x_m, z_m))$ be an m-tuple of pairs.*

We say that

$$R = (((c_{11}, r_{11}, s_{11}, t_{11}), \ldots, (c_{1l}, r_{1l}, s_{1l}, t_{1l})), \ldots, ((c_{m1}, r_{m1}, s_{m1}, t_{m1}), \ldots, (c_{ml}, r_{ml}, s_{ml}, t_{ml})))$$

is a $(\phi, \mathcal{I})$*-threshold-opening as* D *of* $Y = ((y_{11}, \ldots, y_{1l}), \ldots, (y_{m1}, \ldots, y_{ml}))$ *if and only if the following hold:*

1. $r_{i,j} \in \mathcal{S}_{x_i}$, $c_{i,j} \in \{0,1\}$, *and* $(s_{i,j}, t_{i,j}) \in \mathcal{R}_{x_i}$ *for* $i = 1, \ldots, m$ *and* $j = 1, \ldots, l$;
2. $t\text{-}Val(sh_1, \ldots, sh_m, \phi) = D$, *where* $sh_i = c_{i1} \circ \cdots \circ c_{il}$;
3. *if* $c_{i,j} = 0$, *then* $y_{ij} = Sample_{\mathcal{R}}(x_i, z_i, r_{ij})$;
4. *if* $c_{i,j} = 1$, *then* $y_{ij} = Sample_{\mathcal{R}}(x_i, s_i, r_{ij})$.

Using the above properties of threshold schemes and the properties of RSR languages, one can see that if $(\phi, \mathcal{I}) \in \mathrm{CL}(T; L)$, then any m-tuple $\vec{Y}$ can be threshold-opened as a sequence of admissible shares of D for all $D \in \{0,1\}^l$. Moreover, if $(\phi, \mathcal{I}) \notin \mathrm{CL}(T; L)$, then any m-tuple can be threshold-opened as a sequence of admissible shares for at most one D.

Therefore, similarly as before, we have the following two lemmas describing the properties of the concept of threshold-opening.

LEMMA 31. *Let* $(\phi, \mathcal{I}) \in \mathrm{CL}(T; L)$, *let* $D, D' \in \{0,1\}^l$, *let* Y *be a tuple, and let* R *be a* $(\phi, \mathcal{I})$*-threshold-opening as* D *of the* m*-tuple* Y. *Then, there exists a tuple* R' *that is a* $(\phi, \mathcal{I})$*-threshold-opening as* D' *of* Y.

LEMMA 32. *Let* $(\phi, \mathcal{I}) \notin \mathrm{CL}(T; L)$ *and let* Y *be a tuple. Then, there exists at most one element* D *for which there exists a* $(\phi, \mathcal{I})$*-threshold-opening as* D *of* Y.

Similarly to procedure *Construct-Opening*, we can design a procedure *Threshold-Construct-Opening* that on input $(\phi, \mathcal{I}, a)$ with $a \in \{0,1\}$ outputs a sequence Y and a $(\phi, \mathcal{I})$-threshold-opening as a of the m-tuple Y. Moreover, if $(\phi, \mathcal{I}) \in \mathrm{CL}(T; L)$, the distribution induced on Y is independent of a.

A PZK proof system (P,V) for language $\mathrm{CL}(T; L)$ follows from the above two properties and can be found in Figure 7.

The Proof System (P,V).
Input:$(\phi, \mathcal{I}) \in \mathrm{CL}(T; L)$.

- P.1 Obtain (Y, R) by running *Threshold-Construct-Opening* on input $\phi, \mathcal{I}$ and 0. Send Y to V.
- V.1 Randomly select $b \in \{0,1\}$. Send b to P.
- P.2 Randomly select a $(\phi, \mathcal{I})$-threshold-opening R of Y as $D' = b$ according to the distribution induced by procedure *Threshold-Construct-Opening* on its second output conditioned on Y being the first element of the output pair. Send R to V.
- V.2 Verify that R is a $(\phi, \mathcal{I})$-threshold-opening of Y as b.

FIG. 7. *The proof system* (P,V) *for* $\mathrm{CL}(T; L)$.

The completeness of (P,V) follows from Lemma 31 and the soundness from Lemma 32. The simulator is designed analogously to the one in section 4.1, using procedure *Threshold-Construct-Opening*.

THEOREM 33. *Let* L *be an RSR language. The above protocol* (P,V) *is a PZK proof system for* $\mathrm{CL}(T; L)$.

6.3. Threshold formulae over co-RSR languages. Similarly to what we did for the monotone formulae, we can obtain a proof system for threshold formulae over co-RSR languages using DeMorgan's law and observing that a threshold formula over statements $x_i \notin L$ is equivalent to the negation of a threshold formula $x_i \in L$ with a (k, n)-threshold becoming an $(n - k + 1, n)$-threshold.

7. Nonmonotone formulae over RSR languages. In this section we prove that a class of nonmonotone formulae over RSR languages is in PZK. Specifically, we consider the language CL(OR;L), where L is an RSR language. Recall that such language is defined as the set of all tuples $((\phi, \mathcal{I}_\phi), (\psi, \mathcal{I}_\psi))$, where ϕ and ψ are monotone formulae, such that at least one of ϕ, ψ is true, and the atoms of ϕ (resp., ψ) are statements about membership in an RSR language L (resp., nonmembership in L). That is, $(\phi, \mathcal{I}_\phi) \in \mathrm{CL}(\mathrm{MON}; \mathrm{L})$ or $(\psi, \mathcal{I}_\psi) \in \mathrm{CL}(\mathrm{MON}; \bar{\mathrm{L}})$.

Before explaining the proof system in its generality, we briefly discuss an example relative to graph isomorphism.

A simple example. Let us consider the following proof system for proving that, given two pairs of graphs (A_0, A_1) and (B_0, B_1), A_0 is isomorphic to A_1 or B_0 is not isomorphic to B_1. The verifier picks a random bit b and encodes it by constructing and sending the prover graph B isomorphic to B_b. The prover then constructs and sends the verifier a graph A. Then the verifier reveals b by giving an isomorphism between B and B_b. Finally, the verifier accepts if the prover shows an isomorphism between A and A_b.

For the completeness, first consider the case in which A_0 and A_1 are isomorphic. Then A can be constructed isomorphic to A_0, and then, no matter what the value of b is, the prover can always exhibit an isomorphism between A and A_b. Suppose instead that A_0 and A_1 are not isomorphic and thus B_0 and B_1 are not isomorphic either. Then, B is isomorphic to exactly one of B_0 and B_1, and thus the prover can compute the value of b and construct A isomorphic to A_b.

For the soundness, observe that if A_0 and A_1 are not isomorphic, then A is isomorphic to exactly one of the two. Moreover, since B_0 and B_1 are isomorphic, the prover does not learn the value of b until after A has been given to the verifier. Therefore, the verifier accepts with probability at most 1/2.

Finally, it is also easy to argue that the proof system described is honest-verifier zero-knowledge. Indeed the simulator, after receiving graph B from the verifier, picks a random $\hat{b}$ and constructs A isomorphic to $A_{\hat{b}}$. Then if $b = \hat{b}$, the simulation is completed by giving the isomorphism between A_b and A. If instead $b \neq \hat{b}$, then the simulation is started again from scratch. Since b and $\hat{b}$ are uniformly distributed (and independent), the simulation will have to be repeated on average two times. To make it zero-knowledge, we need to augment it as we have done in section 5.

The general case. The construction of a proof system for CL(OR;L) is based on the concepts of value, co-value, opening, and co-opening.

Now we informally describe our proof system (P,V) for CL(OR;L). Let $((\phi, \mathcal{I}_\phi), (\psi, \mathcal{I}_\psi))$ be the input to (P,V). The first three rounds are precisely the first three rounds of protocol (P,V) in section 5 (i.e., steps labeled as V.0, V.1, P.1, V.2, P.2), when run on input the formula ψ and the m-tuple $\mathcal{I}_\psi$. That is, V sends a pair (Y_ψ, S) to P and proves that he knows a $(\psi, \mathcal{I}_\psi)$-co-opening of Y_ψ and that S has been correctly constructed. The fourth step of our proof system is the following: P checks that V knows a $(\psi, \mathcal{I}_\psi)$-co-opening of Y and that S has been correctly constructed. If this check is not satisfied, he stops. Otherwise, he computes whether the formula ψ is true. If it is, he computes the bit b such that Y_ψ can be $(\psi, \mathcal{I}_\psi)$-co-opened as b,

and then he sets $a = b$. If the formula ψ is false, he picks the value of a at random from $\{0, 1\}$. Then he sends an m-tuple Y_ϕ to V that can be $(\phi, \mathcal{I}_\phi)$-opened as a. Now, V reveals the bit b that he chose in his first step and the $(\psi, \mathcal{I}_\psi)$-co-opening of Y_ψ as b to P. Finally P computes and sends to V a $(\phi, \mathcal{I}_\phi)$-opening of Y_ϕ as bit b, and V verifies that he receives a $(\phi, \mathcal{I}_\phi)$-opening of Y_ϕ as b.

The following theorem holds.

THEOREM 34. *Let L be an RSR language; then the language* CL(OR;L) *is in PZK.*

Proof. We show that the above protocol (P,V) is a PZK proof system for CL(OR;L).

Completeness. Suppose that $((\phi, \mathcal{I}_\phi), (\psi, \mathcal{I}_\psi)) \in$ CL(OR;L).

In the first case $(\psi, \mathcal{I}_\psi) \in$ CL(MON; $\bar{\text{L}}$). Then, by the properties of a co-opening, the prover can always find exactly one bit b such that Y_ψ can be $(\psi, \mathcal{I}_\psi)$-co-opened as b and pick a equal to the bit b chosen by V. Also, as in section 5.1, one can show that V can always perform the "proof of knowledge" in polynomial time. Then we have that P can compute an m-tuple Y_ϕ such that Y_ϕ can be $(\phi, \mathcal{I}_\phi)$-opened as b, and he can later reveal an opening for Y_ϕ.

Assume now that $(\phi, \mathcal{I}_\phi) \in$ CL(MON; L). Then, by Lemma 10, the m-tuple Y_ϕ can be opened both as 0 and as 1, and P can compute a $(\phi, \mathcal{I}_\phi)$-opening as the bit b sent by V. In both cases V's verifications are satisfied with probability 1.

Soundness. Suppose that $((\phi, \mathcal{I}_\phi), (\psi, \mathcal{I}_\psi)) \notin$ CL(OR; L). In this case, the m-tuple Y_ψ sent by the verifier can be $(\psi, \mathcal{I}_\psi)$-co-opened both as 0 and as 1. Moreover, observe that, using an argument similar to the one used for proving the soundness of the proof system of section 5, it can be shown that no information about b is revealed by the verifier in his proof of knowledge. Also, by Lemma 11 any m-tuple Y_ϕ can be $(\phi, \mathcal{I}_\phi)$-opened as at most one bit a. Thus the probability that bit a is equal to the bit b chosen by the verifier is at most $1/2$. Thus the verifications of the verifier are satisfied with probability at most $1/2$.

Perfect zero knowledge. Now we only sketch a simulator S_{V^*} for (P,V) as the simulator is based on the same strategy as the simulator for the proof system of section 5. The verifier is run twice, and from the answers of the verifier it is possible to reconstruct the bit b. Finally, once b has been extracted, the simulator uses the procedure *Construct-Opening* to compute an m-tuple Y_ϕ that can be $(\phi, \mathcal{I}_\phi)$-opened as b along with an opening. □

8. Conclusions, recent works, and open problems. We have shown closure properties under composition of (polynomial-size) monotone formulae and some classes of nonmonotone formulae for the class PZK when restricted to RSR languages. In the context of PZK, even for this set of languages, showing closure with respect to any boolean formula, or, more generally, any boolean circuit, is still open.

Related works include closure results in [22, 23] for PZK proofs on quadratic residuosity in the noninteractive model, as well as some closure techniques in [20] for witness hiding and witness indistinguishable proofs over a class of languages containing RSR languages.

We notice that the techniques of this paper have played an important role in some recent results. Specifically, closure under some clustering-based type of composition has been considered in [25] based on the techniques herein. Restricted to the class SZK of statistical zero-knowledge proofs (see [42] for definitions), our techniques were also applied recently in [51] as probability amplification techniques for proving some closure properties over general SZK statements proved to an honest verifier (the techniques can, in turn, be applied to achieve monotone formula com-

position of the resulting general SZK proofs constructed there using results in [49]). Furthermore, our techniques were used to augment the set of known languages having other types of PZK protocols [30], such as PZK proofs of decision power or PZK and result-indistinguishable transfers of decision.

Acknowledgments. We would like to thank Erez Petrank for very useful discussions, and Mihir Bellare, Oded Goldreich, and Johan Håstad for their remarks, corrections, and valuable suggestions on early manuscripts. Finally, we thank the referees for their careful reading of the manuscript and for several suggestions that have significantly improved the presentation of our results.

NETWORK FAILURE DETECTION AND GRAPH CONNECTIVITY*

JON KLEINBERG†, MARK SANDLER‡, AND ALEKSANDRS SLIVKINS§

Abstract. We consider a model for monitoring the connectivity of a network subject to node or edge failures. In particular, we are concerned with detecting (ϵ, k)-*failures*: events in which an adversary deletes up to k network elements (nodes or edges), after which there are two sets of nodes A and B, each at least an ϵ fraction of the network, that are disconnected from one another. We say that a set D of nodes is an (ϵ, k)-detection set if, for any (ϵ, k)-failure of the network, some two nodes in D are no longer able to communicate; in this way, D "witnesses" any such failure. Recent results show that for any graph G, there is an (ϵ, k)-detection set of size bounded by a polynomial in k and ϵ, independent of the size of G. In this paper, we expose some relationships between bounds on detection sets and the edge-connectivity λ and node-connectivity κ of the underlying graph. Specifically, we show that detection set bounds can be made considerably stronger when parameterized by these connectivity values. We show that for an adversary that can delete $k\lambda$ edges, there is always a detection set of size $O(\frac{k}{\epsilon}\log\frac{1}{\epsilon})$ which can be found by random sampling. Moreover, an (ϵ, λ)-detection set of minimum size (which is at most $\frac{1}{\epsilon}$) can be computed in polynomial time. A crucial point is that these bounds are independent not just of the size of G but also of the value of λ. Extending these bounds to node failures is much more challenging. The most technically difficult result of this paper is that a random sample of $O(\frac{1}{\epsilon}\log\frac{1}{\epsilon})$ nodes is a detection set for adversaries that can delete a number of nodes up to κ, the node-connectivity. For the case of edge-failures we use VC-dimension techniques and the cactus representation of all minimum edge-cuts of a graph; for node failures, we develop a novel approach for working with the much more complex set of all minimum node-cuts of a graph.

Key words. network failures, detection sets, connectivity, minimal cuts, cactus representation, VC-dimension

1. Introduction.

Monitoring network connectivity. As links or nodes fail in a network, it is important to maintain information about basic properties such as connectivity. For large, unstructured networks, this is often done by recourse to sampling and other approximate measurements; performing such measurements in a robust and accurate way is an active research topic (e.g., [4, 5, 19, 21, 20]). A general problem here is to minimize the cost of network monitoring and measurement, in terms of communication, computation, and resource usage.

Here we consider a model proposed by the first author for monitoring network connectivity [16]. We are given a connected node graph G on n nodes, and we want to detect "failure events" in which at most k network elements (nodes or edges) are deleted, after which there are two sets of nodes A and B, each of size $\geq \epsilon n$, such that no node in A has a path to any node in B. We will call such a pair of sets *separated*,

*Received by the editors July 20, 2007; accepted for publication April 2, 2008; published electronically August 6, 2008. and we will call such an event an (ϵ, k)-*failure*. (To reflect the fact that the k node or edge failures can be arbitrary, we will sometimes speak of them as being selected by an adversary.)

To detect such failures, we consider the strategy of placing "detectors" at a subset D of the nodes of G. Now, if we find that two detectors are unable to communicate—either because there is no path between them, or because one has been deleted—we can record a fault in the network. We would like our set D to have the property that *whenever* an (ϵ, k)-failure occurs, some two detectors are unable to communicate; we will refer to such a set D as an (ϵ, k)-*detection set.* Note the nature of this condition: D must detect all possible (ϵ, k)-failures, so we imagine D as being chosen *before* the adversary selects a set of k network elements to delete. The emphasis in [16] was on finding a bound on the number of nodes that must be randomly selected from a graph G in order to obtain an (ϵ, k)-detection set with high probability. Improvements to these bounds were obtained by [7].[1]

In this paper, we adopt a somewhat different approach to this issue, by exposing some interesting and nontrivial connections between the size of the smallest detection set for a graph G and the values of its edge- and node-connectivity. (The edge-connectivity of G, denoted $\lambda(G)$, is the smallest number of edges that must be deleted in order to disconnect G. The node-connectivity of G, denoted $\kappa(G)$, is the analogous quantity for node deletions.) We show that stronger bounds on detection set size can be obtained if we parameterize these bounds by the connectivity values λ and κ, and, for some cases, we use this relationship with connectivity to provide the first *per-instance* guarantees for detection sets.

Because our results are different depending on whether the adversary is deleting edges or nodes, we consider these two cases separately.

Detection sets for edge failures. We begin with adversaries that can delete up to k edges; as such, we will be concerned with (ϵ, k)-*edge-failures*, which are (ϵ, k)-failures in which only edges are deleted. It is known that a random set of $O(\frac{k}{\epsilon} \log \frac{1}{\epsilon})$ nodes is an (ϵ, k)-detection set for edge-failures with high probability [16], and that every graph contains an (ϵ, k)-detection set for edge-failures of size $O(\frac{k}{\epsilon})$ [7]; note that both bounds are independent of the size of the graph G. It is not difficult to show that both bounds are tight, and so there is no prospect of obtaining an improvement that applies to all graphs. However, it makes sense to ask whether better bounds are possible in terms of natural parameters of the graph G.

An obvious parameter to consider here is the edge-connectivity λ; indeed, there can be no (ϵ, k)-edge-failures in G if $k < \lambda$. Our first main result establishes that λ is indeed a natural way to parameterize the problem; we show that every graph G has an (ϵ, λ)-detection set for edge-failures of size at most $\frac{1}{\epsilon}$. Note that there is no leading constant in this bound and that it is independent not just of the size of G but also of the value of λ. Extending this result, we show further that an (ϵ, λ)-detection set for edge-failures of *minimum* size for a graph G can be computed in polynomial time. The algorithms used to establish these results are based on the cactus representation of all minimum edge-cuts of G [6, 9].

Given that strong bounds are possible for detecting an adversary that can delete one minimum cut's worth of edges, it is natural to ask what can be said about an adversary capable of deleting a number of edges equal to k times the size of a minimum cut. We show that a random set of $O(\frac{k}{\epsilon} \log \frac{1}{\epsilon})$ nodes is a $(k\lambda, \epsilon)$-detection set for edge-

[1] Following the publication of the conference version of this paper, further improvements have been obtained in [8].

failures with high probability. This is essentially a factor of λ times stronger than the bounds of [7, 16], which did not take edge-connectivity into account. Our proof of this result uses a VC-dimension argument in the style of [16]; the bound on the VC-dimension is obtained using a result of Mader [18, 10] that extends results of Lovász [17] and of Cherkasskij [3] (also see [10]) on edge-disjoint paths in graphs.

Detection sets for node failures. We now consider adversaries that can delete up to k nodes. By analogy with our results for edge-failures, we consider the size of detection sets in terms of the node-connectivity κ. Our main result here is that every graph G (with $\kappa = O(\epsilon^2 n)$) has an (ϵ, κ)-detection set for node-failures of size $O(\frac{1}{\epsilon})$; moreover, a random set of $O(\frac{1}{\epsilon} \log \frac{1}{\epsilon})$ nodes forms an (ϵ, κ)-detection set for node-failures with high probability. Again, note that these bounds are independent not just of the size of G but also of the value of κ. Extending our results to adversaries that delete $k\kappa$ nodes for $k > 1$ is a very interesting and apparently difficult open question.

We note the distinction, raised by Gupta [13] (see section 1.4.2 of [7]), between *strong* and *weak* detection sets for node-failures. A strong detection set D has the property that, after any (ϵ, k)-node-failure, two nodes of D lie in different connected components. A weak detection set D' has the property that, after any (ϵ, k)-node-failure, two nodes of D lie in different connected components *or* an element of D has been deleted. Either of these definitions arguably forms a plausible definition of network failure detection. Improving a bound of [16], Fakcharoenphol showed that a random set of $O(\frac{k}{\epsilon} \log k \log \frac{1}{\epsilon})$ nodes is a strong (ϵ, k)-detection set for node-failures [7], and Gupta showed that every graph has a weak (ϵ, k)-detection set for node-failures of size $O(\frac{k}{\epsilon})$. As we note in section 4, weak detection appears to be a more useful notion when the problem is parameterized by node-connectivity; in particular, our main result is about weak detection sets. Henceforth, we will assume that all detection sets for node-failures are weak unless otherwise specified.

Our analysis for node-failures is significantly more complicated than for edge-failures, and this is not surprising; not only is no analogue of the cactus representation known for min-node-cuts, but this appears to be intrinsic due to the $\#P$-completeness of even counting the number of min-node-cuts [2]. Indeed, given the lack of tractable representations for min-node-cuts, we believe that our analysis develops some useful properties of their structure. We begin by constructing a detection set of minimum size for adversaries that can delete *shredders* [2, 15]—min-node-cuts whose deletion produces at least three components. The construction of the detection set then proceeds by greedily isolating a maximal collection of relatively balanced min-node-cuts that produce just two components, and whose "small sides" are disjoint; the small side of each such cut is required to have at least $\frac{\epsilon n}{10}$ nodes. We then show that by placing detectors so that one lies on the small side of each of these cuts, there is no way for a min-node-cut producing two components of size at least ϵn each to avoid being detected.

Further discussion. A simple calculation based on Karger's algorithm gives an upper bound of $O(\frac{k}{\epsilon} \log n)$ on a random sample of nodes that forms an $(\epsilon, k\lambda)$-detection set for edge-failures.[2] However, our goal in this paper is to find bounds that do not depend on the size of the graph.

Following [16], we can extend our results to a model in which the nodes of the network G are partitioned into two sets—a set V_0 of *end nodes* and a set V_1 of *internal*

[2]Note that no such simple bound is available for the case of node-failures, which is yet another evidence of its difficulty.

nodes. We assume that we are allowed only to place detectors at end nodes, and correspondingly are interested only in monitoring the connectivity of the end nodes. Specifically, we redefine (ϵ, k)-failures as failures of $\leq k$ network elements, after which two disjoint subsets of V_0, each of size $\geq \epsilon|V_0|$, are separated from each other. We can show that the bounds obtained above carry over to this more general setting; we omit further discussion of the generalization from this version of the paper.

Our work is similar in spirit to some of the work on vertex connectivity and augmentation thereof, e.g., [14, 2, 15, 12]. The actual technical issues are quite different, however, since we are interested only in balanced cuts. In general one could view our work here as integrating notions from edge- and node-connectivity with the problem of balanced separators of graphs—two topics that have traditionally been approached separately due to their great differences in tractability.

Notation. In this paper all graphs are assumed undirected; our standard notation for a graph is $G = (V, E)$. An edge(node)-cut is a set X of edges (nodes) such that $G \setminus X$ is disconnected.

A min-edge(node)-cut is an edge(node)-cut of minimum size. This size is also known as edge(node)-*connectivity* and is denoted by λ and κ, respectively. We will write *min-cut* when it is clear whether we are talking about edge-cuts or node-cuts. A set of nodes is *tight* if it is a union of some (but not all) components of a min-cut. A cut X is called ϵ-*balanced* if there are two sets of vertices of size $\geq \epsilon n$ that are disconnected from one another in $G \setminus X$. An ϵ-balanced cut of $\leq k$ edges(nodes) is called an (ϵ, k)-cut.

If sets X, Y have a nonempty intersection, we say X *meets* Y. To help clarify the notation in places, we will sometimes write $X + Y$ to denote the union of disjoint sets X and Y, and $X - Y$ to denote the difference of sets X and Y for which $Y \subseteq X$.

2. Detection sets for edge failures. In this section we present our results on edge-failures. For edge-failures that correspond to min-edge-cuts, our algorithms are based on the *cactus representation* of all min-cuts in a graph [6, 9]. We include a self-contained review of the relevant definitions and facts. Our result for the general edge-failure proof uses a VC-dimension argument in the style of [16]; the bound on the VC-dimension is obtained using a result of Mader [18, 10] on edge-disjoint paths in graphs.

Throughout the section, all cuts are edge-cuts, and all detection sets are for edge-failures. Let D be a set of nodes, representing the locations of our detectors. We say that D *detects* a cut X if some pair of detectors is separated in $G \setminus X$. We call D an (ϵ, k)-*detection set* if it detects every (ϵ, k)-edge-cut.

In section 2.1 we review the cactus representation. Section 2.2 is on min-edge-cuts: we construct a smallest (ϵ, λ)-detection set and prove that it has size $\leq \frac{1}{\epsilon}$. Section 2.3 is on general edge-failures: we prove that a set of $O(\frac{k}{\lambda\epsilon} \log \frac{1}{\epsilon})$ randomly sampled nodes is an (ϵ, k)-detection set with high probability.

2.1. Review: Cactus representation. Edges will be viewed as cycles of length 2; cycles of length 3 or more are called *proper*. A *cactus* is a connected graph such that any two of its cycles have at most one vertex in common. An arbitrary cactus can be obtained starting from a cycle and recursively adding new cycles that share a single vertex with the existing graph. In a cactus, some edges are contained in a proper cycle (*cycle edges*), and some are not (*path edges*). Each cycle edge has capacity $\frac{1}{2}$, and each path edge has capacity 1. It follows that min-cuts of a cactus have capacity 1. We can characterize them as follows.

FACT 2.1. *Consider a cactus T. Then* (a) *each path edge is a min-cut,* (b) *any pair of cycle edges from the same cycle is a min-cut, and* (c) *there are no other min-cuts.*

Proof. Clearly any cut in T has capacity at least 1. For part (a), let uv be a path edge. If there exists a uv-path p not containing the edge uv, then $p + uv$ is a cycle, contradicting the definition of a path edge. Therefore u and v are separated in $T - uv$. So uv is a cut in T, hence a min-cut.

For part (b), let e_1, e_2 be cycle edges from the same cycle C. $e_1 + e_2$ splits C into two arcs; call them C_1 and C_2. Suppose C_1 and C_2 are connected in $T - e_1 - e_2$. Then there exist vertices $u \in C_1$, $v \in C_2$ such that there is a uv-path p that does not intersect with C except for the endpoints. Let C' be the uv-arc of C that contains e_1. Then $p + C'$ is a cycle in T that shares ≥ 2 vertices with C, which is a contradiction. So C_1 and C_2 are not connected in $T - e_1 - e_2$. Therefore $e_1 + e_2$ is a cut in T, hence a min-cut.

For part (c), suppose X is a min-cut of T that is neither a path edge nor a pair of cycle edges from the same cycle. Since the capacity of X is ≤ 1, it consists of one or two cycle edges. Thus there is a (proper) cycle C such that X contains exactly one edge $uv \in C$. Since X is a min-cut, it must separate u and v. However, they are connected by $C - uv$, which is a contradiction. □

In a cactus, nodes of degree one will be called *leaves*, nodes of degree two that are contained in a cycle will be called *cycle nodes*, and all other nodes will be called *branch nodes*.

FACT 2.2. *Let v be a branch node of a cactus T. Then the cycles that contain v are pairwise disconnected in $T - v$.*

Proof. Let C, C' be cycles that contain v. Let uv, $u'v$ be edges in C, C', respectively, Suppose u and u' are connected in $T - v$; i.e., there is a uu'-path p not containing v. Then $p + uv + vu'$ is a cycle that shares ≥ 2 vertices with C (and C'), a contradiction. Thus C and C' are disconnected in $T - v$. □

Consider a branch node v of a cactus T. It connects two or more cycles. By Fact 2.2, the removal of v splits T into two or more connected components (v-*components*). Each v-component X is tight: for some cycle C containing v, it is obtained by removing any edge of C that is adjacent to v.

FACT 2.3. *Suppose S is a tight set in cactus T, and v is a branch node. Then*

(a) *if $v \in S$, then S contains at least one v-component;*
(c) *if $v \notin S$, then S is contained in a v-component;*
(c) *for any v-component X of T, either $X \subset S$, or $S \subset X$, or $X \subset V - S$, or $V - S \subset X$.*

Proof. For part (a), let S be a component of a min-cut C. By Fact 2.1 C is contained in a cycle, so $C \subset T[X + v]$ for some v-component X. Therefore if Y is any other v-component, then $Y + v$ is connected in $T \setminus C$. $Y \subset S$ follows since $v \in S$ and S is connected in $T \setminus C$.

For part (a), suppose S meets two v-components. Then they are connected in $T - v$ (via S), a contradiction.

For part (c), suppose X meets both S and $V - S$. Then by part (b) if $v \in S$, then $V - S \subset X$; else we have $S \subset X$. □

Let G be a weighted graph on n vertices. A *cactus-pair* of G is a pair (T, π) where T is a cactus and π is a mapping from $V(G)$ to $V(T)$ such that if M is a tight set in T, then $\pi^{-1}(M)$ is a tight set in G. For each tight set M of T, say that (T, π) *represents* the min-cut C of G such that $\pi^{-1}(M)$ is a C-component. A *cactus representation*

of G is a cactus-pair of G that represents all min-cuts of G. Dinits, Karzanov, and Lomonosov [6] proved that every capacitated graph has a cactus representation of size $O(n)$. Further results show that a cactus representation of size $O(n)$ can be efficiently constructed. See the introduction of [9] for a discussion.

2.2. Detection sets for min-edge-cuts. Here we are interested only in ϵ-balanced min-cuts, and so the cactus representation is too general for our purposes. This motivates the following definitions.

DEFINITION 2.4. *Let an* ϵ-cactus-pair *be a cactus-pair that represents all* ϵ-*balanced min-cuts. Let an* ϵ-cactus *be the cactus in such a cactus-pair (if the mapping is clear). A subset* S *of vertices of a cactus is* heavy *if* $|\pi^{-1}(S)| \geq \epsilon n$. *Call a cactus-pair* reduced *if every* v*-component is heavy.*

A reduced ϵ-cactus-pair can be efficiently computed from a standard cactus representation by consecutively applying the following reduction.

LEMMA 2.5. *Suppose* T *is an* ϵ*-cactus,* v *is a branch node, and* X *is a* v*-component that is not heavy. Let* T' *be* T *with* X *contracted into* v. *Then* T' *is also an* ϵ*-cactus.*

Proof. For each ϵ-balanced min-cut C of G there is a min-cut C' of T that represents it. By Fact 2.3(c) there is a component S of C' such that $X \subset S$ or $S \subset X$. Since S is heavy and X is not, it must be the case that X is a proper subset of S. Then $v \in S$, so C' is a min-cut in T', too. Therefore T' represents C. □

Let G be a capacitated graph. Let (T, π) be a reduced ϵ-cactus-pair of G. We will characterize (ϵ, λ)-detection sets of minimum size in terms of T.

Let a *subcycle* be a set of consecutive cycle nodes of a (proper) cycle in T. Consider the nondegenerate case when there is at least one branch node. Then the weight $|\pi^{-1}(\cdot)|$ of each leaf and each subcycle is at most $(1-\epsilon)n$. Let a *canonical subcactus* be a set of nodes of T that contains each leaf, has an element in every heavy subcycle, and contains no branch nodes. Let $D \subset V(G)$ be a set of detectors (not necessarily an (ϵ, λ)-detection set). Say D is T*-canonical* if $\pi(D)$ is a canonical subcactus and at most one detector is mapped to each node of T. The following two lemmas show that any smallest (ϵ, λ)-detection set is in fact a smallest T-canonical set.

Call $S \subset V$ *heavy* if $|S| \geq \epsilon n$, and *balanced* if both S and $V \setminus S$ are heavy. Call $S' \subset V(T)$ *balanced* if $\pi^{-1}(S')$ is balanced. For each balanced tight set S of G let $\pi'(S)$ be a (balanced) tight set S' of T such that $S = \pi^{-1}(S')$.

LEMMA 2.6. *Any smallest* (ϵ, λ)*-detection set is* T*-canonical.*

Proof. Let D be a smallest (ϵ, λ)-detection set. Call elements of D *detectors*. We need to show that (1) at most one detector is mapped to each node of T, (2) there is a detector mapped to each leaf and each heavy subcycle of T, and (3) no detectors are mapped to branch nodes of T. (See Figure 1.) Let us prove these three statements in order.

(1) Suppose two detectors d_1, d_2 map to a node v of T. To obtain a contradiction it suffices to show an (ϵ, λ)-detection set smaller than D. We claim that $D - d_1$ is also an (ϵ, λ)-detection set. Suppose not. Then there is a balanced tight set S of G that contains $D - d_1$. Obviously $d_1 \notin S$. Let $S' = \pi'(S)$. Since $d_2 \in S$, $v = \pi(d_2) \in S'$, and thus $d_1 \in S$, too, a contradiction.

(2) There is a detector mapped to each heavy tight set of T, in particular, to each leaf and each heavy subcycle.

(3) Suppose a detector d is mapped to a branch node v of T. By analogy with (1), we claim that $D - d$ is also an (ϵ, λ)-detection set. For suppose not. Then $D - d$ is disjoint with some balanced tight set S. Let $S' = \pi'(S)$. Since D is an (ϵ, λ)-detection

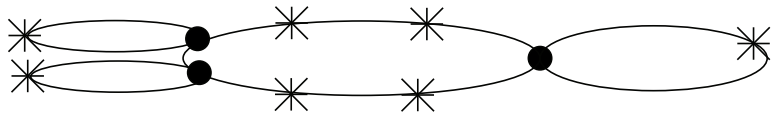

FIG. 1. *An ϵ-cactus with detectors. Branch nodes are denoted by "•", detectors by "*". In the central cycle, there are three subcycles between the branch nodes. The smallest of them is not heavy, and hence does not contain a detector. The other two are big enough so that they need two detectors each. Each of the three smaller cycles is heavy (even without its branch node), since otherwise it would have been contracted.*

set, $d \in S$, and thus $v \in S'$. Therefore by Fact 2.3(a) S' contains some v-component S''. Since T is reduced, S'' is heavy, so there is a detector mapped to it. Thus S contains a detector other than d, a contradiction. □

LEMMA 2.7. *Any T-canonical set is an (ϵ, λ)-detection set.*

Proof. Suppose $D \subset V$ and $\pi(D)$ meets each leaf and each heavy subcycle of T. We need to prove that $\pi(D)$ meets each heavy tight set of T. To show this we claim that any heavy tight set S of T contains a leaf or a heavy subcycle.

We will use induction on the size of S. The base case corresponds to an S that consists of one vertex, say v. By Fact 2.3(a) v cannot be a branch node. So either v is a leaf or it is a heavy subcycle consisting of a single cycle node.

For the induction step, note that if S contains a branch node v, then by Fact 2.3(a) S contains some (heavy) v-components S', to which the induction hypothesis applies. If S does not contain any branch nodes, then it lies within a single cycle, so S is a (heavy) subcycle. The claim follows. □

THEOREM 2.8. *A smallest (ϵ, λ)-detection set is of size at most $\frac{1}{\epsilon}$. There is a polynomial-time algorithm to construct it.*

Proof. Let (T, π) be a reduced ϵ-cactus-pair of G. We have seen that smallest (ϵ, λ)-detection sets are (mapped to) smallest canonical subcacti of T. Therefore it suffices to compute a smallest canonical subcactus of T.

Let S be a subset of a proper cycle C in T. Call S a C-detection set if S does not contain any branch nodes and every heavy subcycle of C contains an element of S. By definition, if there are no heavy subcycles in C, then an empty set is a C-detection set. Obviously, a subset of T is a canonical subcactus if and only if it is a union of leaves of T and (disjoint) C-detection sets, one for each proper cycle of T. Therefore to compute a smallest canonical subcactus of T it suffices to construct a smallest C-detection set for each proper cycle C of T.

The construction is as follows. Assuming T consists of more than one cycle, C contains one or more branch nodes. Assuming C contains cycle nodes, pick any branch node v_b followed by a cycle node v. Start with v. In the iterative step, start with a cycle node and move clockwise along C till a heavy subcycle is detected (call this subcycle *selected*) or a branch node is reached. Start a new step with the next cycle node. Stop when v_b is reached. Let S be the set of the last nodes (clockwise) of selected subcycles.

Obviously S is a C-detection set. S is a smallest such set by the following observation. Let S' be a C-detection set. Let $v \in C$ be a branch node or an element of S'. Let v' be the next node clockwise. Let C' be the smallest heavy subcycle starting with v' if it exists. Let w be the last node of C'. Then C' contains at least one element of S. The observation is that $S' - C' + w$ is a C-detection set with the same or smaller number of elements. Consecutively applying this observation, we can transform S' to

S without increasing the number of detectors.

Our construction puts one detector into each leaf of T and each selected sub cycle. Since leaves of T are heavy and selected subcycles are heavy and disjoint, our construction covers at least ϵn weight with each detector. Since the total weight of (nodes of) T is n, the total number of detectors is at most $\frac{1}{\epsilon}$. □

2.3. Smaller detection sets for edge-failures. A set S of nodes is *k-edge-separable* if there exists a set Z of $\leq k$ edges such that S is a union of components of $G \setminus Z$. Let $\mathcal{F}$ be the family of all k-edge-separable sets. We say that $A \subseteq V$ is *shattered* by $\mathcal{F}$ if for all $B \subseteq A$ there exists an $F \in \mathcal{F}$ such that $B = A \cap F$. The *VC-dimension* of $\mathcal{F}$ is defined to be the maximum cardinality of a subset of V that is shattered by $\mathcal{F}$.

In [16], it was shown that one can connect the VC-dimension d of $\mathcal{F}$ with (ϵ, k)-detection sets via the notion of an *ϵ-net*, which is a set that meets each $F \in \mathcal{F}$ of size $\geq \epsilon n$. Specifically, a theorem by [1] says that a set of $O(\frac{d}{\epsilon} \log \frac{1}{\epsilon} + \frac{1}{\epsilon} \log \frac{1}{\delta})$ randomly sampled nodes is an ϵ-net for $\mathcal{F}$ with probability at least $1 - \delta$.[3] Moreover, it is easy to show [16] that an ϵ-net for $\mathcal{F}$ is an (ϵ, k)-detection set.

In [16], it was shown that the VC-dimension of $\mathcal{F}$ is at most $2k + 1$, yielding a bound of $O(\frac{k}{\epsilon} \log \frac{1}{\epsilon})$ on the size of an (ϵ, k)-detection set. In this section, we strengthen the VC-dimension bound on $\mathcal{F}$ to $O(\frac{k}{\lambda})$. Therefore, we obtain the following theorem.

THEOREM 2.9. *A set of $O(\frac{k}{\lambda\epsilon} \log \frac{1}{\epsilon})$ randomly sampled nodes is an (ϵ, k)-detection set with high probability.*

We now turn to the new bound on the VC-dimension; to prove it, we will use the following theorem by Mader [18] on edge-disjoint paths between elements of a given set of vertices. Let R be a subset of V of size r. Let $d(R)$ be the number of edges leaving R. Let $q(R)$ be the number of components C of $G - R$ for which $d(C)$ is odd. Let an *R-path* be a path connecting distinct elements of R.

THEOREM 2.10 (Mader [18]). *The maximal number of edge-disjoint R-paths is $\frac{1}{2} \min(\sum d(V_i) - q(\cup V_i))$, where the minimum is taken over all collections of disjoint subsets of vertices $V_1, V_2, \ldots, V_r$ such that $|V_i \cap R| = 1$.*

COROLLARY 2.11. *There are $\Omega(r\lambda)$ edge-disjoint R-paths.*

Proof. Consider a collection of disjoint subsets of vertices $V_1, V_2, \ldots, V_r$ such that $|V_i \cap R| = 1$. Let $d = \sum d(V_i)$, $q = q(\cup V_i)$. By the above theorem it suffices to prove that $d - q = \Omega(r\lambda)$.

Note that $d \geq r\lambda$ since $d(V_i) \geq \lambda$. Let $C_1 \ldots C_q$ be the components C of $G - \cup V_i$ such that $d(C)$ is odd. All edges exiting each C_i are to $\cup V_i$. So $d \geq d(\cup V_i) \geq \sum d(C_i) \geq q\lambda$. If $r \geq q$, then $d - q \geq r\lambda - q \geq r(\lambda - 1)$. If $r < q$, then $d - q \geq q\lambda - q \geq r(\lambda - 1)$. Therefore $d - q = \Omega(r\lambda)$. □

The following is a well-known application of the probabilistic method.

LEMMA 2.12. *Let (R, F) be a multigraph on R. Then there exists a partition of R into sets R_1, R_2 such that there are at least $\frac{1}{2}|F|$ edges between R_1 and R_2.*

LEMMA 2.13. *The VC-dimension of $\mathcal{F}$ is $O(\frac{k}{\lambda})$.*

Proof. Let R be a subset of V of size r. By Corollary 2.11 there exists a family $\mathcal{P}$ of $\Omega(rc)$ edge-disjoint R-paths. Let (R, F) be a multigraph on R such that there is a 1-1 correspondence between uv-paths in $\mathcal{P}$ and edges $uv \in F$. By Lemma 2.12 there exists a partition of R into sets R_1, R_2 such that (in the original graph) there

[3] Both [16] and [7] used a slightly weaker theorem, with a corresponding bound of $O(\frac{d}{\epsilon} \log \frac{d}{\epsilon} + \frac{1}{\epsilon} \log \frac{1}{\delta})$.

are $\Omega(r\lambda)$ edge-disjoint paths between R_1 and R_2. We can choose $r = \Theta(\frac{k}{\lambda})$ so that there is guaranteed to be a family $\mathcal{P}'$ of (at least) $k+1$ edge-disjoint paths between R_1 and R_2.

We claim that R cannot be shattered by $\mathcal{F}$. Suppose not. Then there exists $X \in \mathcal{F}$ such that $X \cap R = R_1$. X is a union of components of some cut Z of k or fewer edges. Z is disjoint with (at least) one path $p \in \mathcal{P}'$. The ends of p are in the same Z-component, so they are either both in X, or both not in X. In both cases this contradicts $X \cap R = R_1$. Thus, the claim is proved, and it follows that the VC-dimension of $\mathcal{F}$ is $r = O(\frac{k}{\lambda})$. □

3. Detection sets for node failures. The main theorem of this section (Theorem 3.6) is that for $\kappa < O(\epsilon^2 n)$ a set of $O(\frac{1}{\epsilon}\log\frac{1}{\epsilon})$ randomly sampled nodes is a weak (ϵ,κ)-detection set with high probability. We rely on a special case of ϵ-shredders, which is a corollary of our result on *strong* detection thereof (Theorem 3.1). We also present a partial result (Theorem 3.15) on extending strong detection sets for ϵ-shredders to those for general (ϵ,κ)-cuts.

Before we proceed, let us review the definitions. In this section all cuts are node-cuts, and all detection sets are for node failures. A cut X is called *two-way* if $G \setminus X$ has exactly two connected components, called the *sides* of X. A *shredder* is a min-cut with three or more components. An *ϵ-shredder* is an ϵ-balanced shredder. A set D of nodes *strongly detects* a cut X if some pair of detectors is separated in $G \setminus X$. If D either meets or strongly detects X, we say D *weakly* detects X. D detects (is a detection set for) a family of cuts if it detects every cut in the family.

The rest of this section is organized as follows. In section 3.1 we show how to find a strong detection sets for ϵ-shredders. In section 3.2 we use shredders to get a detection set for two-way ϵ-balanced min-cuts. In section 3.3 we combine these two results and obtain the main theorem. Finally, in section 3.4 we present our partial result on strong detection sets.

3.1. Strong detection sets for shredders. It is a well-known fact that there can be exponentially many min-cuts. Furthermore, even *counting* min-cuts is #P-complete [2]. However, there can be only $O(n)$ shredders [15], with a polynomial-time enumeration algorithm [2]. We start by stating the main result of this subsection.

THEOREM 3.1. *Suppose $\kappa < \epsilon n$. Then a set of $O(\frac{1}{\epsilon}\log\frac{1}{\epsilon\delta})$ randomly sampled nodes is a strong detection set for ϵ-shredders with probability at least $1-\delta$. Moreover, a* smallest *strong detection set for ϵ-shredders has size $\le \frac{1}{\epsilon}$ and can be constructed in polynomial time.*

Before we prove this theorem we need to establish some basic facts about min-cuts. For a cut X the connected components of $G \setminus X$ are also called *X-components*. Let S, T be min-cuts. Say *S meshes T* if S meets at least two T-components. By [2, Lemma 4.3(1)], if S meshes T, then T meets every S-component. Thus meshing is a symmetric relation. If S meshes T (and T meshes S), the two cuts are *meshing*. Else S and T are *nonmeshing*.

LEMMA 3.2 (see [2, Lemma 4.3(2)]). *If min-cuts S and T are meshing, then there is a component Q of either S or T such that Q contains $V - S - T$.*

COROLLARY 3.3. *If $\kappa < \epsilon n$, then any two ϵ-shredders are nonmeshing.*

LEMMA 3.4. *Let S and T be nonmeshing shredders. Let C be the S-component that meets T. Then C contains all T-components but one, call it C'. Moreover, C' contains $V - S - C$, i.e., all S-components other than C.*

Proof. Pick any $v \in S - T$. By minimality of S, v has edges to each S-component (else, $S - v$ is a cut). Thus, $V - S - C + \{v\}$ is connected. Since $T \subset S \cup C$, $V - T - C$

is connected and hence lies in a T-component C'. So all other T-components are contained in C and $V - S - C \subset V - T - C \subset C'$. □

For a family $\mathcal{F}$ of ϵ-shredders, we call a component of a shredder an *$\mathcal{F}$-head* if it meets at least one shredder in $\mathcal{F}$. Now, suppose we have an (ϵ, k)-detection set for shredders, and S is an ϵ-shredder with an $\mathcal{F}$-head H. Then there exists $T \in \mathcal{F}$ that meets H; so by Lemma 3.4, H contains all T-components but one and hence contains a detector. This gives the following lemma.

LEMMA 3.5. *Let $\mathcal{F}$ be a family of ϵ-shredders, with $\kappa < \epsilon n$, and let S be an ϵ-shredder with an $\mathcal{F}$-head H. Then any detection set for $\mathcal{F}$ meets H.*

Proof of Theorem 3.1. Let $\mathcal{F}_0$ be the family of all ϵ-shredders. Start with $\mathcal{F} = \mathcal{F}_0$. While there exists an ϵ-shredder $S \in \mathcal{F}$ with two or more $\mathcal{F}$-heads, delete S from $\mathcal{F}$. Let $\mathcal{F}_1$ be the resulting family of shredders. By Lemma 3.5 any strong detection set for $\mathcal{F}_1$ is a strong detection set for $\mathcal{F}_0$.

Let $S \in \mathcal{F}_1$. Let the *head* H of S be the (single) $\mathcal{F}_1$-head of S. Let the *tail* of S be $V - S - H$. Note that by Lemma 3.4 for any $S, T \in \mathcal{F}_1$ the tail of S is contained in the head of T (and vice versa). In particular, tails are pairwise disjoint. Since each head contains someone else's tail, a set D of nodes is a detection set for $\mathcal{F}_1$ if and only if D meets the tail of each $S \in \mathcal{F}_1$. Therefore, a smallest detection set for $\mathcal{F}_1$ has size $|\mathcal{F}_1|$. Since tails are of size $\geq \epsilon n$ each, $|\mathcal{F}_1| \leq \frac{1}{\epsilon}$. The random sampling result follows by a simple probabilistic computation. □

3.2. Detecting two-way min-cuts. In this subsection we construct a weak detection set for two-way (ϵ, κ)-cuts. First we give a nonefficient deterministic construction. We consider $(\frac{\epsilon}{10}, \kappa)$-cuts and use a greedy-type algorithm to construct a "maximal" family of two-way $(\frac{\epsilon}{10}, \kappa)$-cuts with sides A_i and B_i such that $A_i \subseteq B_j$ for all $i \neq j$. In particular A_i's are pairwise disjoint, so there are at most $\frac{10}{\epsilon}$ of them. It turns out that, if $\kappa < O(\epsilon^2 n)$, then putting a detector into each A_i suffices. More precisely we show (Theorem 3.8) that these detectors together with any weak detection set for shredders give a weak (ϵ, κ)-detection set. Then a simple probabilistic argument yields a randomized result stated below.

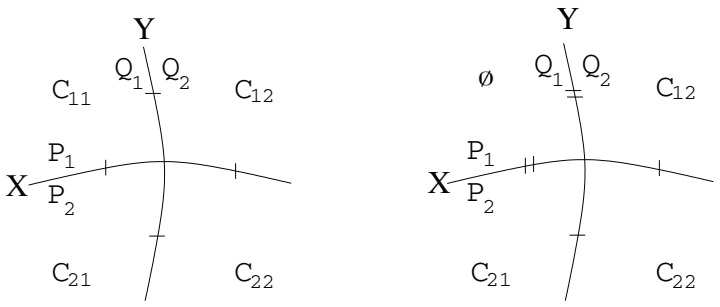
THEOREM 3.6. *Suppose $\kappa < \frac{\epsilon^2 n}{20}$. Then a set of $O(\frac{1}{\epsilon} \log \frac{1}{\epsilon\delta})$ randomly sampled nodes is a weak (ϵ, κ)-detection set with probability at least $1 - \delta$.*

We start with some notation and a simple but very useful lemma about crossing min-cuts. Let S be a set of nodes. Call S *connected* if the subgraph of G induced by S is connected. Else say S is *disconnected*. Say a cut X *preserves* S if X is disjoint with S and S lies in one component of $G \setminus X$. Note that a connected set of nodes is preserved by X if and only if it is disjoint with X. $N(S)$ denotes the set of neighbors of S, i.e., the set of all nodes in $V - S$ that have an edge to S. Note that if $V - S - N(S)$ is nonempty, then $N(S)$ is a cut.

Say two-way min-cuts X and Y are *strongly crossing* if each side of X meets each side of Y. Say X and Y are *weakly crossing* if X meets both sides of Y and vice versa.[4] It is easy to see that strong crossing implies weak crossing, but not the other way round.

To formulate the promised lemma, we will use the following notation. The sides of X and Y are, respectively, P_1, P_2 and Q_1, Q_2. Their intersections ("quarters") are $C_{ij} = P_i \cap Q_j$. Also let $X_i = Q_i \cap X$, $Y_i = P_i \cap Y$, and $X \cap Y = S$.

[4]Note that if X meets both sides of Y, say at v_1 and v_2, respectively, then Y meets both sides of X. Indeed, for the sake of contradiction suppose Y does not meet a side P_1 of X. Then, since any node in X has at least one edge to P_1 and P_1 is connected, there is a v_1v_2-path in G/Y, a contradiction.



(a) X and Y are strongly crossing (b) X and Y are weakly crossing

FIG. 2. *Two applications of the two-quarter lemma.*

LEMMA 3.7 (the two-quarters lemma). *Suppose two-way min-cuts X and Y are weakly crossing so that the two quarters C_{21} and C_{12} are nonempty. Then*

(a) $|X_1| = |Y_1|$ *and* $|Y_2| = |X_2|$,

(b) C_{21} *and* C_{12} *are tight, with* $N(C_{ij}) = Y_j + X_i + S$,

(c) $V - C_{21} - N(C_{21})$ *is connected, same for* C_{12}.

Proof. $T = X_1 + Y_2 + S$ and $U = X_2 + Y_1 + S$ separate C_{21} and C_{12}, respectively, from the rest of the graph. It follows that $Y_2 \geq X_2$ (else $|T| < |X|$), $X_1 \geq Y_1$ (else $|T| < |Y|$), $X_2 \geq Y_2$ (else $|U| < |Y|$), and $Y_1 \geq X_1$ (else $|U| < |X|$). Therefore $|X_1| = |Y_1|$ and $|X_2| = |Y_2|$, so U and T are min-cuts and C_{12} and C_{21} are tight. Finally, $V - C_{21} - N(C_{21})$ is connected as a union of two connected sets (Q_1 and P_2) with a nonempty intersection (C_{12}). ∎

This lemma is similar to the result of Jordán [14] on intersecting tight sets. Note that if X and Y are strongly crossing, our lemma yields $|X_1| = |X_2| = |Y_1| = |Y_2|$ (Figure 2(a)). We will also use it for $\frac{\epsilon}{10}$-balanced min-cuts that are crossing weakly but not strongly. Then one of the "quarters," say C_{11}, is empty, so, assuming $\kappa < \frac{\epsilon n}{10}$, C_{21} and C_{12} are not (Figure 2(b)).

Now we are ready to describe the construction.

CONSTRUCTION.

1. Let $\mathcal{F}$ denote the family of all $\frac{\epsilon}{10}$-balanced two-way min-cuts, and let $\mathcal{A}(\mathcal{F})$ denote the family of the sides of all $F \in \mathcal{F}$. Stop if $\mathcal{F}$ is empty.
2. Choose any inclusionwise minimal component A_0 from $\mathcal{A}(\mathcal{F})$, let $X_0 = N(A_0)$ be the corresponding cut, and let B_0 be the second component of X_0. Put detectors in A_0 and B_0.
3. Delete from $\mathcal{F}$ all cuts which do not preserve A_0. For $X \in \mathcal{F}$, let $A(X)$ be the side of X that *does not* contain A_0.
4. Start with the first iteration. For the ith iteration choose a cut $X_i \in \mathcal{F}$ so that $A(X_i)$ does not contain any other $A(X)$ for $X \in \mathcal{F}$. Let $A_i = A(X_i)$. Let B_i be the other side of X_i. (See Figure 3.)
5. Put a detector into A_i. Remove from $\mathcal{F}$ all cuts which do not preserve $A_0 \cup A_1 \cup \cdots \cup A_i$. Stop if $\mathcal{F}$ is empty; else iterate.

By construction all A_i's are pairwise disjoint, and each $A_i \geq \frac{\epsilon}{10}$. Therefore our algorithm will terminate after at most $\frac{10}{\epsilon}$ steps after putting at most $\frac{10}{\epsilon}$ detectors. Denote this set of detectors by $\mathcal{D}_2$. Let $\mathcal{D}_1$ be any weak detection set for shredders, $\mathcal{D} = \mathcal{D}_1 \cup \mathcal{D}_2$.

THEOREM 3.8. *Suppose $\kappa \leq \frac{\epsilon^2}{20} n$. Then any ϵ-balanced two-way min-cut is weakly detected by $\mathcal{D}$.*

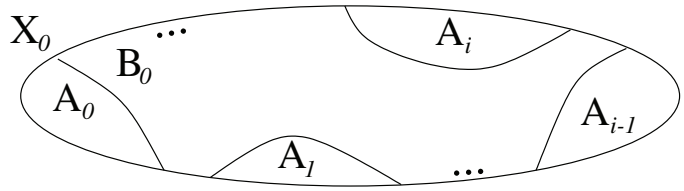


FIG. 3. *Partitioning of the graph after the ith iteration of the algorithm.*

Let us start with some simple properties of the construction.

LEMMA 3.9. *For all $i \neq j$, $A_j \subseteq B_i$. In particular, X_i is disjoint with A_j.*

Proof. We will prove that, for any $i \neq j$, X_i is disjoint with A_j (which would immediately imply $A_j \subseteq B_i$). If $j < i$, then by construction X_i is disjoint with all A_j for $j \leq i$ and $A_j \subseteq B_i$. On the other hand, if $j > i$, then B_j contains A_i, and, supposing $A_j \cap X_i \neq \emptyset$, then $v \in A_j \cap X_i$ has at least one edge to A_i and thus to B_j. Thus A_j and B_j are not separated, a contradiction. ∎

COROLLARY 3.10. *Each B_i contains at least one detector.*

LEMMA 3.11. *If a tight set $A \subset A_i$ is of size $\geq \frac{\epsilon n}{10}$, then the cut $N(A)$ is a shredder.*

Proof. Suppose not. Then $N(A)$ is a two-way $(\frac{\epsilon}{10}, \kappa)$-cut preserving B_i and hence $\bigcup_{j=0}^{i-1} A_j$. Thus $N(A)$ was not deleted from $\mathcal{F}$ until iteration i, so it should have been chosen instead of X_i, a contradiction. ∎

In what follows we assume $\kappa \leq \frac{\epsilon^2}{20} n$. The next lemma shows how $\mathcal{D}_1$ (a detection set for shredders) helps to detect two-way min-cuts.

LEMMA 3.12. *Let Y be an $\frac{\epsilon}{10}$-balanced two-way min-cut with sides C and D. Suppose D contains a set W of size at least $\frac{\epsilon n}{10}$ such that $N(W)$ is a shredder. Then $D + Y$ contains at least one detector from $\mathcal{D}_1$.*

Proof. The shredder $Z = N(W)$ is $\frac{\epsilon}{10}$-balanced, so it is weakly detected by $\mathcal{D}_1$. Since Y is a cut, there are no edges between W and C; i.e., Z lies in $D + Y$. It follows that C is connected in $G \setminus Z$, and hence lies in a single connected component thereof. Thus at least one detector from $\mathcal{D}_1$ is not in C, so it is in $D + Y$. ∎

Now we are ready to sketch the proof of Theorem 3.8; the details are in the next subsection.

Proof sketch of Theorem 3.8. Let Y be an ϵ-balanced two-way min-cut with sides C and D. We need to show that $\mathcal{D}$ meets Y or both sides thereof. For the sake of contradiction suppose it is not so. Then without loss of generality $\mathcal{D} \subset C$, which implies that C meets every A_i and B_i. Clearly then $A_i \not\subseteq D + Y$, for every i. Also note that by Lemma 3.12 D cannot contain disconnected tight sets larger than $\frac{\epsilon n}{10}$.

There are now three cases to consider, depending on the relation of Y to the sets X_i. First, suppose Y does not strongly cross any X_i. We show that $N(D \setminus \cup X_i)$ is a two-way $\frac{\epsilon}{10}$-balanced cut that was not excluded from $\mathcal{F}$ (see Figure 4(a)), and this contradicts the stopping condition of the algorithm. If Y strongly crosses exactly one X_i, then we replace Y by the cut $Y' = N(D \cap B_i)$ (see Figure 4(b)). Y' does not strongly cross any X_i, so we apply the argument from the case above to show that Y' is detected. Therefore there is at least one detector in set D, which contradicts our assumption. Finally, if neither of these two cases applies, then Y strongly crosses at least two sets among $\{X_i\}$, say X_i and X_j. An argument using the two-quarters lemma then shows that X_i and X_j partition Y into the same subsets (see Figure 4c). We then prove that X_i and X_j cut off a large connected subset D' of D such that

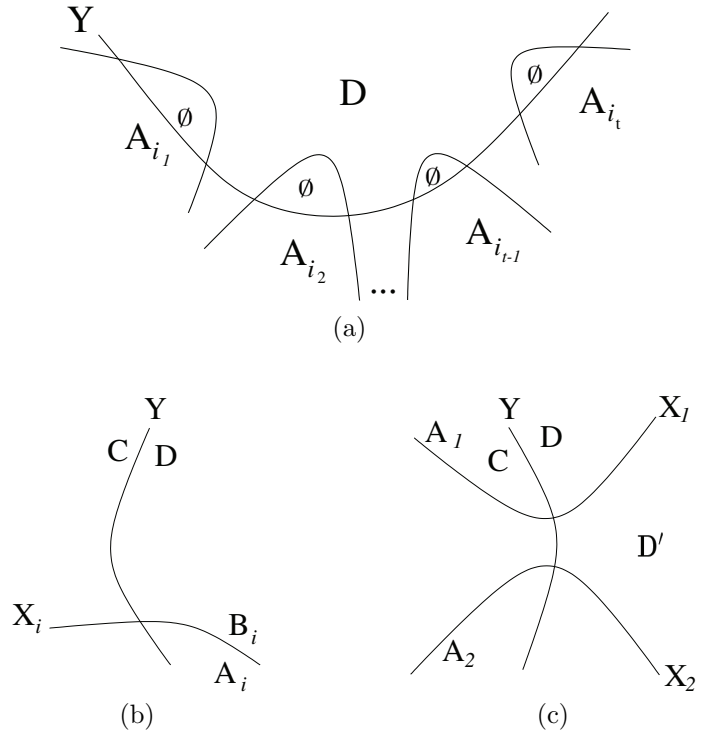

FIG. 4. *Three different options of how Y can interact with X_i's. For* (c) *we prove that the portion of Y between cuts X_1 and X_2 shrinks to an empty set, and $X_1 \cap Y = X_2 \cap Y$.*

$N(D')$ is a two-way $(\frac{\epsilon}{10}, \kappa)$-cut not deleted from $\mathcal{F}$, which thus violates the stopping condition. □

3.3. Full proof of Theorem 3.8.

LEMMA 3.13. *Suppose Y is ϵ-balanced and A_i meets D. Then either there is a detector in $D + Y$ or the following conditions hold:*

(a) *Y strongly crosses X_i, and*

(b) *$N(D \cap B_i)$ is a two-way $\frac{8\epsilon}{10}$-balanced min-cut.*

Proof. Suppose there is no detector in $D + Y$. Since A_i and B_i each contain a detector, they meet C. Now we can invoke the two-quarters lemma to quarters $B_i \cap C$ and $A_i \cap D$ and conclude that $A_i \cap D$ is tight. We claim that $|B_i \cap D| \geq \frac{8\epsilon}{10}\, n$. Indeed, otherwise $|A_i \cap D| \geq \frac{\epsilon n}{10}$; thus, by Lemma 3.12, $N(A_i \cap D)$ is a two-way cut, which contradicts Lemma 3.11. The claim is proved.

This proves (a) and shows that $N(B_i \cap D)$ is an $\frac{8\epsilon}{10}$-balanced cut. To complete (b), note that $B_i \cap D$ is tight by the two-quarters lemma; thus, by Lemma 3.12, $N(B_i \cap D)$ is two-way. □

Let Y be an ϵ-balanced two-way min-cut with sides C and D. We need to show that $\mathcal{D}$ meets Y or both sides thereof. For the sake of contradiction suppose it is not so. Then without loss of generality $\mathcal{D} \subset C$, which implies that C meets every A_i and B_i. Clearly then $A_i \not\subseteq D + Y$, for every i. Also note that, by Lemma 3.12, D cannot contain disconnected tight sets larger than $\frac{\epsilon n}{10}$. There are three possible cases which we prove separately: (1) cut Y does not strongly cross any X_i, (2) cut Y strongly crosses exactly one X_i, and (3) cut Y strongly crosses at least two X_i's.

Case 1. Cut Y does not strongly cross any X_i.

To reuse this proof for the second case, we will assume that Y is only $\frac{8\epsilon}{10}$-balanced, rather than ϵ-balanced,

Since we assumed that X_i does not strongly cross Y, by Lemma 3.13 we have that all A_i's are disjoint with D. Using this fact, we show that each X_i excises a small piece of size at most κ from D, and finally we show that $D \setminus \cup X_i$ is large, tight, and connected and preserves $\cup A_i$; thus our algorithm could have made at least one more step.

Let $X_{i_1}, X_{i_2}, \ldots, X_{i_t}$ be all cuts which are intersecting with D. Let $D_j = D - D \cap \bigcup_{h=1}^{j} X_{i_h}$, $Y_j = N(D_j)$, and $C_j = V - Y_j - D_j$. First,

$$|D_j| \geq |D| - \sum_{h=1}^{j} |X_{i_h}| \geq \frac{8\epsilon}{10}\, n - \kappa \frac{10}{\epsilon} \geq \frac{3\epsilon}{10}\, n.$$

The last transition is because $\kappa \leq \frac{\epsilon^2}{20} n$.

We will prove by induction that each D_j is tight and connected and that corresponding cut $Y_j = N(D_j)$ is two-way for every $0 \leq j \leq t$.

Suppose we did that; then D_t by its construction is disjoint with any X_i, and thus all A_i's are disjoint with Y_t and hence lie in $V - D_t - Y_t$. Therefore Y_t preserves $\bigcup A_i$ (because Y_t is a two-way cut). On the other hand, $|D_t| \geq \frac{2\epsilon}{10}\, n$ and $|C_t| \geq |C| \geq \epsilon N$. So Y_t is a $\frac{2\epsilon}{10}$-balanced two-way min-cut and preserves $\bigcup A_i$; thus our algorithm could have made one more step, and so we come to a contradiction.

Now we have to prove our claim. Clearly D_0 is tight and connected, and $N(D_0) = Y$ is two-way by our definition of Y and D. Supposing the claim holds for D_{j-1}, we now prove it for D_j. We have

$$D_j = D_{j-1} - D_{j-1} \cap X_{i_j} = B_{i_j} \cap D_{j-1}.$$

If D_j is disjoint with X_{i_j} then $D_j = D_{j-1}$ and we are immediately done. Otherwise, Y_{j-1} weakly crosses X_{i_j}. (Indeed, D_{j-1} is not preserved by X_{i_j}. Moreover, C_{j-1} contains C and hence meets both A_{i_j} and B_{i_j}. It follows that C_{j-1} is not preserved by X_{i_j}.) But then we satisfy conditions of the two-quarters lemma, where $A_{i_j} \cap C_{j-1}$ and $B_{i_j} \cap D_{j-1}$ is not empty, and thus $D_j = B_{i_j} \cap D_{j-1}$ is tight. Therefore, by Lemma 3.12, D_j is connected and $N(D_j)$ is a two-way cut. This proves the claim.

Case 2. Cut Y strongly crosses exactly one X_i.

Indeed, consider set $D' = D \cap B_i$. By Lemma 3.13 and our assumption that there were no detectors in $D + Y$, it has size at least $\frac{8\epsilon}{10}\, n$ and is tight, and corresponding cut $Y' = D \cap X_i + X_i \cap Y + Y \cap B_i$ is a two-way min-cut.

Since $D' \subseteq D$ and only one A_i meets D (and it does not meet with D' by our construction), no A_i meets with D'. Therefore, by Lemma 3.13, Y' does not strongly cross any X_i, and thus by the case (1) Y' is detected by $\mathcal{D}$. This proves that there is at least one detector in $Y' + D'$, and by construction $Y' + D' \subseteq D + Y$; therefore there is at least one detector in $D + Y$, a contradiction.

Case 3. Cut Y strongly crosses at least two X_i's. We need to prove that either $D + Y$ contains at least one detector from $\mathcal{D}$ (thus contradicting our assumption), or we could have done one more iteration of the construction in section 3.2. Without loss of generality, Y strongly crosses X_1 and X_2 (see Figure 4(c)).

First we prove that each of the triples (A_1, X_1, B_1) and (A_2, X_2, B_2) partitions set Y into the same subsets.

CLAIM 3.14. *$X_1 \cap Y = X_2 \cap Y$, $A_1 \cap Y = B_2 \cap Y$, and $B_1 \cap Y = A_2 \cap Y$.*

Proof. Note that $Y = Y \cap A_i + Y \cap X_i + Y \cap B_i$. Since $A_1 \subseteq B_2$, we have that $Y \cap A_1 \subseteq Y \cap B_2$, and analogously $Y \cap A_2 \subseteq Y \cap B_1$, but by the two-quarters lemma we have $|Y \cap A_1| = |Y \cap B_1|$ and $|Y \cap A_2| = |Y \cap B_2|$ and thus $Y \cap A_1 = Y \cap B_2$ and $Y \cap A_2 = Y \cap B_1$. Thus $X_1 \cap Y = X_2 \cap Y$. ∎

We will prove that either there is a leftover part D' in D, which could have been used for the next step of the algorithm, or Y is detected.

For each $i = 1, 2$, since X_i strongly crosses Y, set D is partitioned by X_i into three nonempty parts $D'_i = D \cap B_i$, $D''_i = D \cap A_i$, and $D'''_i = D \cap X_i$. Now, by Lemma 3.13 and our assumption that $\mathcal{D} \cap (D + Y) = \emptyset$, we conclude that D'_i is tight, its cardinality is at least $\frac{8\epsilon}{10} n$, and $N(D'_i)$ is two-way min-cut.

Consider $D' = D'_1 \cap D'_2$. We claim that the corresponding cut $Z = N(D')$ is a two-way $(\frac{\epsilon}{10}, \kappa)$-cut that preserves $\cup A_i$. This contradicts the stopping condition of the algorithm: it could have made one more iteration. Therefore it remains to prove the claim.

First, D' is tight by the two-quarters lemma applied to cuts $N(D'_1)$ and $N(D'_2)$. Its size is

$$|D'| = |D'_1 \cap D'_2| = |D - (D''_1 + D'''_1) \cup (D''_2 + D'''_2)| \geq \epsilon n - 2\left(\frac{\epsilon n}{10} + \kappa\right) \geq \frac{6\epsilon}{10} n,$$

so Z is $\frac{\epsilon}{10}$-balanced, and, moreover, D' is connected (this is by Lemma 3.12 and the assumption that $\mathcal{D}$ is disjoint with $Y + D$). Since $Z = (X_1 \cup X_2) \cap (D \cup Y)$, we conclude that (1) Z is two-way, since $V - D' - Z$ is connected as a union of three nondisjoint connected subsets C, A_1, and A_2, and (2) Z is disjoint with $\cup A_i$ by Lemma 3.9.

To prove that Z preserves $\cup A_i$ it remains to show that all A_i's are disjoint with D'. Indeed, suppose some A_i meets D'. It cannot be properly contained in D, and hence not in D'. So, since A_i is connected, it meets Z, a contradiction. The claim is proved. This completes the proof of Theorem 3.8. ∎

3.4. Strong detection sets. We present a partial result on extending strong detection sets for ϵ-shredders to those for general (ϵ, κ)-cuts. Essentially, we show that it suffices to have a strong (ϵ, κ)-detection set D' for some subgraph $G' = (V, E')$ of G of the same connectivity κ. In particular, we can without loss of generality assume that G is *minimally* k-connected.

THEOREM 3.15. *Suppose $\kappa < \epsilon n$ and we have a strong (ϵ, κ)-detection set D' for a κ-connected subgraph $G' = (V, E')$ of G. Then we can use D' to construct a strong (ϵ, κ)-detection set for G. Specifically, for a high-probability result it suffices to add $O(\frac{1}{\epsilon} \log \frac{1}{\epsilon})$ randomly sampled detectors. Alternatively, it suffices to add at most $\frac{2}{\epsilon}$ detectors, and there is a polynomial-time algorithm to construct them.*

Proof. Let D'' be a smallest detection set for ϵ-shredders of G. Let S be an (ϵ, κ)-cut G. Then S is an (ϵ, κ)-cut in G' such that each S-component in G is a union of S-components in G'. Obviously, if S-components are the same in G and in G', then D' detects S. Therefore, if $D' \cup D''$ does not detect S, then S is a two-way (ϵ, κ)-cut in G but a shredder in G'. Call such cuts *evil*. Therefore it suffices to detect all evil cuts.

For an evil cut S, the two components of S in G are called *S-shores*. We need to put a detector in each S-shore. For the rest of the proof we can forget about G. We operate (only) on G' and treat S-shores as unions of components of S in G'. The proof is similar to that of Theorem 3.1.

Evil cuts are ϵ-shredders in G', so there are at most n of them and they can be efficiently listed. Let $\mathcal{F}_0$ be the family of *all* evil cuts. Start with $\mathcal{F} = \mathcal{F}_0$. While

there exists $S \in \mathcal{F}$ such that each S-shore contains an $\mathcal{F}$-head of S, delete S from $\mathcal{F}$ (because by Lemma 3.5 S is detected by D'). Let $\mathcal{F}_1$ be the resulting family of evil cuts. Clearly if D is a detection set for $\mathcal{F}_1$, then $D \cup D'$ is a detection set for $\mathcal{F}_0$.

Say $H \subset V$ is a *head* of S if H is an $\mathcal{F}_1$-head of S. Let the *tail shore* of $S \in \mathcal{F}_1$ be the S-shore that does not contain any heads of S (such a shore exists by construction of $\mathcal{F}_1$). Observe that for any two $S, T \in \mathcal{F}_1$ the tail shore of T is contained in a head of S (and vice versa). Why? T meets exactly one component of S, say H (so H is a head). By Lemma 3.4 H contains all T-components but one, call it C. C meets S; thus C is a head. Therefore, the tail shore of T is contained in H.

By the observation above, the tail shores of cuts in $\mathcal{F}_1$ are pairwise disjoint, and, moreover (assuming $\mathcal{F}_1$ consists of at least two cuts), putting a detector in each of these shores strongly detects $\mathcal{F}_1$. Since the tail shores have size $\geq \epsilon n$ each, $|\mathcal{F}_1| \leq \frac{1}{\epsilon}$. Therefore we need $\frac{1}{\epsilon}$ detectors for F_0, which together with D'' is at most $\frac{2}{\epsilon}$ detectors.

For the random sampling result note that it suffices to augment D' by a hitting set for the tail shores of $\mathcal{F}_1$ and the tails of ϵ-shredders of G, as defined in the proof of Theorem 3.1. □

4. Extensions and further directions. There are a number of natural questions left open by this work. One is to investigate whether an (ϵ, κ)-detection set for node failures of minimum size can be computed in polynomial time for a given graph G; this would parallel the per-instance result we obtain for edge failures. We note that section 3.1 provides such an optimality result for node failures when the adversary is restricted to deleting a shredder.

We believe it would be interesting to extend our results on node failures to obtain bounds for strong detection sets. In fact, our bounds for shredders apply already to the case of strong detection, and in Theorem 3.15 we provide a further step in this direction, proving that we can without loss of generality assume that G is *minimally* k-connected.

It would clearly be interesting to obtain results on detection sets with respect to adversaries that can delete a number of nodes equal to a constant times the node-connectivity, by analogy with our results for edge-connectivity. To obtain detection set bounds here that are independent of the value of κ, it is not difficult to see that we need to focus on weak detection; indeed, there exist graphs in which we would need at least $k - \kappa$ nodes in any strong (ϵ, k)-detection set for node failures.

Finally, the problem of deciding whether a given set D is an (ϵ, k)-detection set provides another clear connection to the problem of balanced separators in graphs: indeed, deciding whether the empty set is an (ϵ, k)-detection set is coNP-complete because of its equivalence to a balanced separator problem. On the other hand, using techniques from [11, 22], we can obtain a polynomial-time algorithm for deciding whether D is an (ϵ, k)-detection set for node failures when $k = \kappa$; this is nontrivial due to the fact that there can be exponentially many min-node-cuts.

Acknowledgment. It is our pleasure to acknowledge the contribution of Laszlo Lovász; discussions with him about the prospect of parameterizing detection sets by the minimum cut size provided a portion of the motivation for this work and also led to the results described in section 2.3.

RESOLUTION IS NOT AUTOMATIZABLE UNLESS W[P] IS TRACTABLE*

MICHAEL ALEKHNOVICH† AND ALEXANDER A. RAZBOROV‡

Abstract. We show that neither resolution nor tree-like resolution is automatizable unless the class **W[P]** from the hierarchy of parameterized problems is fixed-parameter tractable by randomized algorithms with one-sided error.

Key words. proof complexity, resolution, automatizability

AMS subject classifications. 03F20, 03D15

DOI. 10.1137/06066850X

1. Introduction.

Analysis of the usefulness of proof search heuristics and automated theorem proving procedures based on a proof system P amounts (on the theoretical level) to the following two basic questions:

Question 1. Which theorems in principle possess efficient P-proofs?

Question 2. How can one find the optimal (or, at least, a nearly optimal) proof of a given theorem in P?

Traditional proof complexity mostly dealt, and still deals, with the first question. However, there has been a growing interest in the second one, too. An additional motivation for studying the complexity of finding optimal proofs comes from deep connections with efficient interpolation theorems; we refer the reader to the surveys [9, 19, 22] for more details. These surveys also serve as a good starting point for learning more about propositional proof complexity in general.

One convenient framework for the theoretical study of Question 2 was proposed by Bonet, Pitassi, and Raz in [13]. Namely, they called a proof system P *automatizable* if there exists a deterministic algorithm A which, given a tautology τ, returns its P-proof in time polynomial *in the size of the shortest P-proof of τ*. The definition of a quasi-automatizable proof system is given in the same way, but we only require algorithm A to run in time which is quasi-polynomial (in the same parameter).

One advantage of this definition is that it allows us to completely disregard the first basic question on the *existence* of efficient P-proofs and to indeed concentrate on *finding* efficient proofs *provided* they exist. In particular, the notion of automatizability makes perfect sense for those (weak) proof systems for which hard tautologies are already known. Moreover, the weaker our system is, the more likely it seems to be automatizable. One possible explanation of this phenomenon comes from the connection between automatizability and efficient interpolation (every automatizable proof system has efficient interpolation, and the property of having efficient interpolation is indeed antimonotone w.r.t. the strength of the system). Anyway, given

this connection, the results from [20, 13] imply that extended Frege and TC^0-Frege proof systems, respectively, are not automatizable under some widely believed cryptographic assumptions. Bonet et al. [11] extended the latter result to bounded-depth Frege but under a much stronger assumption.

In this paper we are primarily interested in the automatizability of resolution and tree-like resolution. It is worth noting that both systems possess efficient interpolation, and therefore their nonautomatizability cannot be proved via techniques similar to those in [20, 13, 11]. Nonetheless, [18] proved that it is **NP**-hard to find the shortest resolution refutation. Alekhnovich et al. [3] proved that if $\mathbf{P} \neq \mathbf{NP}$, then the length of the shortest resolution refutation cannot be approximated to within a constant factor (both for general and tree-like resolution). Under the stronger assumption $\mathbf{NP} \not\subseteq \mathbf{QP}$, they were able to improve the ratio from an arbitrary constant to $2^{\log^{1-\epsilon} n}$ (later, Dinur and Safra [16] obtained a better probabilistically checkable proofs (PCP) characterization of **NP** that allows one to prove the same bound for arbitrary $\epsilon \to 0$ modulo $\mathbf{P} \neq \mathbf{NP}$).

In the opposite direction, Beame and Pitassi [8] observed that tree-like resolution is quasi-automatizable. Thus, it is unlikely to show that this system is not automatizable modulo $\mathbf{P} \neq \mathbf{NP}$, because it would imply quasi-polynomial algorithms for **NP** (in case of general resolution this goal seems also tricky at the moment because there is only one[1] known example [12] for which the proof search algorithm of [10] requires more than quasi-polynomial time). Therefore, any result establishing nonautomatizability of tree-like resolution needs to be formulated within a complexity framework in which the asymptotics $n^{O(1)}$ and $n^{\log n}$ are essentially different.

One natural example of such a framework is *parameterized complexity* introduced by Downey and Fellows (see [17]) in which algorithms working in times $f(k)n^{O(1)}$ and n^k are considered different from the point of view of effectiveness (here k is an integer input parameter that should be thought of as an "arbitrarily large" constant). In this paper we prove that neither resolution nor tree-like resolution is automatizable unless the class $\mathbf{W}[\mathbf{P}]$ (lying very high in the hierarchy of parameterized problems) is fixed-parameter tractable by a randomized algorithm with one-sided error (Theorem 2.7). Our proof goes by a reduction from the optimization problem MINIMUM MONOTONE CIRCUIT SATISFYING ASSIGNMENT (MMCSA) whose decision version is complete for the class $\mathbf{W}[\mathbf{P}]$. An alternative hardness assumption is that there is no *deterministic* fixed-parameter algorithm which *approximates* MMCSA within any constant factor (Theorem 2.5). It is worth noting in this connection that we were able to relate to each other the hardness of finding *exact* and *approximate* solutions for MMCSA without using the PCP theorem (see the proof of Theorem 2.7 given in section 4). This result can be interesting on its own.

The paper is organized as follows. Section 2 contains necessary preliminaries and definitions. In section 3 we present our core reduction from MMCSA to automatizability of resolution, and in section 4 we use (sometimes nontrivial) self-improving techniques to prove our main results, Theorems 2.5 and 2.7. The paper is concluded with some open problems in section 5.

1.1. Recent developments. Since the preliminary version of this paper was released, the following related developments have occurred.

Atserias and Bonet [6] studied a slightly different variant of automatizability that they called *weak automatizability*. Using their techniques, they were also able

[1] See, however, section 1.1.

to produce more examples of poly-size tautologies for which the width-based proof search algorithm from [10] requires more than quasi-polynomial time. In the opposite direction, Alekhnovich and Razborov [4] introduced an enhancement of that algorithm which they called BWBATP (branch-width based automated theorem prover). This algorithm performs better than the width-based algorithm for several important classes of tautologies, and for at least one such class it even achieves complete (that is, polynomial) automatization. Finally, quite unexpectedly our techniques turned out to be useful in the totally different area of computational learning, where they inspired a number of strong hardness results for the so-called model of proper learning [2].

2. Preliminaries and main results.

2.1. Resolution and automatizability. Let x be a Boolean variable, i.e., a variable that ranges over the set $\{0,1\}$. A *literal* of x is either x (denoted sometimes as x^1) or $\bar{x}$ (denoted sometimes as x^0). A *clause* is a disjunction of literals. A *CNF* (conjunctive normal form) is a conjunction of pairwise different clauses.

Let $f(x_1,\dots,x_n)$ be an arbitrary function (possibly, partial) from $\{0,1\}^n$ to some finite domain D. An *assignment to* f is a mapping $\alpha : \{x_1,\dots,x_n\} \to \{0,1\}$. A *restriction of* f is a mapping $\rho : \{x_1,\dots,x_n\} \to \{0,1,\star\}$. We denote by $|\rho|$ the number of assigned variables, $|\rho| \stackrel{\text{def}}{=} |\rho^{-1}(\{0,1\})|$. The *restriction of a function* f *or CNF* τ *by* ρ, denoted by $f|_\rho$ [$\tau|_\rho$], is the function [CNF] obtained from f [τ, respectively] by setting the value of each $x \in \rho^{-1}(\{0,1\})$ to $\rho(x)$, and leaving each $x \in \rho^{-1}(\star)$ as a variable.

The general definition of a propositional proof system was given in the seminal paper [15]. But since we are interested only in resolution (which is one of the simplest and most widely studied concrete systems), we prefer to skip this general definition. *Resolution* operates with clauses and has one rule of inference called *resolution rule*:

$$\frac{A \vee x \qquad B \vee \bar{x}}{A \vee B}.$$

A resolution proof is *tree-like* if its underlying graph is a tree. A *resolution refutation* of a CNF τ is a resolution proof of the empty clause from the clauses appearing in τ.

The *size* of a resolution proof is the overall number of clauses in it. For an unsatisfiable CNF τ, $S(\tau)$ [$S_T(\tau)$] is the minimal size of its resolution refutation (tree-like resolution refutation, respectively). Clearly, $S(\tau) \le S_T(\tau)$.

The *width* $w(C)$ *of a clause* C is the number of literals in C. The *width* $w(\tau)$ *of a set of clauses* τ (in particular, the width of a resolution proof) is the maximal width of a clause appearing in this set. For a CNF τ, let $n(\tau)$ be the overall number of distinct variables appearing in it, and let $|\tau|$ be the overall number of occurrences of variables in τ, i.e., $|\tau| \stackrel{\text{def}}{=} \sum_{C\in\tau} w(C)$. For an unsatisfiable CNF τ, $w(\tau \vdash \emptyset)$ will denote the minimal width of its resolution refutation.

For a nonnegative integer n, let $[n] \stackrel{\text{def}}{=} \{1,2,\dots,n\}$, and let $[n]^k \stackrel{\text{def}}{=} \{\, I \subseteq [n] \mid |I| = k \,\}$.

We will recall the general definition of automatizability from [13] for the special cases of resolution and tree-like resolution.

DEFINITION 2.1. *Resolution (tree-like resolution) is* (quasi-)automatizable *if there exists a deterministic algorithm* A *which, given an unsatisfiable CNF* τ*, returns its resolution refutation (tree-like resolution refutation, respectively) in time which is (quasi-)polynomial in* $|\tau| + S(\tau)$ *(*$|\tau| + S_T(\tau)$*, respectively).*

Remark 1. Note that we do not require that all clauses from τ must necessarily appear in the refutation, and therefore, we cannot a priori expect the inequality $n(\tau) \cdot S(\tau) \geq |\tau|$. This is why we must introduce the term $|\tau|$ into the bound on the running time of A when adapting the general definition of automatizability from [13] to the case of resolution.

2.2. Parameterized complexity and the MMCSA problem. We refer the reader to [17] for a good general introduction to the topic of parameterized complexity.

DEFINITION 2.2 (see [17, Definition 2.4]). *The class* **FPT** (fixed-parameter tractable) *of parameterized problems consists of all languages $L \subseteq \Sigma^* \times \mathbb{N}$ for which there exists an algorithm Φ, a constant c, and a recursive function $f : \mathbb{N} \longrightarrow \mathbb{N}$ such that*

1. *the running time of $\Phi(\langle x, k\rangle)$ is at most $f(k) \cdot |x|^c$;*
2. *$\langle x, k\rangle \in L$ iff $\Phi(\langle x, k\rangle) = 1$.*

Thus, an algorithm is considered to be feasible if it works in time polynomial in $n \stackrel{\text{def}}{=} |x|$ and $f(k)$, where k should be thought of as much smaller than n, and f is an arbitrarily large (recursive) function. A similar feasibility requirement arises in the theory of polynomial-time approximation schemes (PTAS) for **NP**-hard problems: assume that we have an algorithm that approximates a given problem within arbitrary error $\epsilon > 0$ working in time $n^{O(1/\epsilon)}$. Is it possible to get rid of $1/\epsilon$ in the exponent and do it in time $f(1/\epsilon)n^{O(1)}$? (The algorithms which obey the latter bound on the running time are called EPTAS, efficient polynomial-time approximation schemes.)

It turns out that this question is tightly related to the fixed-parameter tractability. Namely, the existence of EPTAS for a given problem implies an *exact* algorithm for the corresponding fixed-parameter version (see [7, 14]).

To study the complexity of parameterized problems, the following *parameterized reduction* (that preserve the property of being in **FPT**) is used.

DEFINITION 2.3 (see [17, Definition 9.3]). *A parameterized problem $L \subseteq \Sigma^* \times \mathbb{N}$* reduces *to another parameterized problem $L' \subseteq \Sigma^* \times \mathbb{N}$ if there exist (arbitrary!) functions $f, g : \mathbb{N} \longrightarrow \mathbb{N}$, and a function $h : \Sigma^* \times \mathbb{N} \longrightarrow \Sigma^*$ such that $h(x, k)$ is computable in time $f(k)|x|^{O(1)}$, and $\langle x, k\rangle \in L$ iff $\langle h(x, k), g(k)\rangle \in L'$.*

For any integer t, the parameterized problem WEIGHTED t-NORMALIZED SATISFIABILITY is defined by restricting the ordinary SATISFIABILITY to a certain class of Boolean formulas depending on t (we omit the exact definition since it is a little bit technical and not needed for our results), and the parameter k bounds the Hamming weight of the satisfying assignment we are searching for. The complexity class $\mathbf{W[t]}$ consists of all problems that can be reduced to WEIGHTED t-NORMALIZED SATISFIABILITY via parameterized reduction, and the class $\mathbf{W[P]}$ (where P stands for polynomial) includes all problems reducible to WEIGHTED CIRCUIT SATISFIABILITY described as follows:

WEIGHTED CIRCUIT SATISFIABILITY:
Instance: A circuit C.
Parameter: A positive integer k.
Question: Does C have a satisfying assignment of Hamming weight (defined as the number of ones) k?

These definitions lead to the following *parameterized hierarchy*, in which every inclusion is believed to be strict:

$$\mathbf{FPT} \subseteq \mathbf{W[1]} \subseteq \mathbf{W[2]} \cdots \subseteq \mathbf{W[P]}.$$

In our paper we construct a randomized parameterized reduction from the automatizability of resolution to the following optimization problem (MMCSA in what follows) that was introduced in [3].

Monotone minimum circuit satisfying assignment:
Instance: A monotone circuit C in n variables over the basis $\{\wedge, \vee\}$.
Solution: An assignment $a \in \{0,1\}^n$ such that $C(a) = 1$.
Objective function: $k(a)$, defined as its Hamming weight.

By $k(C)$ we will denote the minimal value $k(a)$ of a solution a for an instance C of MMCSA.

The following easy observation was made in [3] ("self-improvement").

PROPOSITION 2.4. *For every fixed integer $d > 0$ there exists a polynomial-time computable function π which maps monotone circuits into monotone circuits and such that $k(\pi(C)) = k(C)^d$ for all C.*

Our first result can be now formulated as follows.

THEOREM 2.5. *If either resolution or tree-like resolution is automatizable, then for any fixed $\epsilon > 0$ there exists an algorithm Φ receiving as inputs monotone circuits C which runs in time $\exp\left(k(C)^{O(1)}\right) \cdot |C|^{O(1)}$ and approximates the value of $k(C)$ to within a factor $(1+\epsilon)$.*

The decision version of MMCSA was considered in [17] (under the name WEIGHTED MONOTONE CIRCUIT SATISFIABILITY) in the context of parameterized complexity and was shown to be complete in the class **W[P]**.

In order to formulate our second (and main) result, we need to introduce the obvious hybrid of the classes **R** and **FPT**.

DEFINITION 2.6. *The class* **FPR** *(fixed-parameter randomized) of parameterized problems consists of all languages $L \subseteq \Sigma^* \times \mathbb{N}$ for which there exists a probabilistic algorithm Φ, a constant c, and a recursive function $f : \mathbb{N} \longrightarrow \mathbb{N}$ such that*

1. *the running time of $\Phi(\langle x, k\rangle)$ is at most $f(k) \cdot |x|^c$;*
2. *if $\langle x, k\rangle \in L$, then $\mathbf{P}[\Phi(\langle x, k\rangle) = 1] \geq 1/2$;*
3. *if $\langle x, k\rangle \notin L$, then $\mathbf{P}[\Phi(\langle x, k\rangle) = 1] = 0$.*

Then we have the following.

THEOREM 2.7. *If either resolution or tree-like resolution is automatizable, then* **W[P]** $\subseteq$ *co-*__FPR__.

3. Main reduction from MMCSA to automatizability of resolution. This section is entirely devoted to the proof of the following technical lemma.

LEMMA 3.1. *There exists a polynomial-time computable function τ which maps any pair $\langle C, 1^m\rangle$, where C is a monotone circuit and m is an integer, to an unsatisfiable CNF $\tau(C, m)$ such that*

$$S_T(\tau(C,m)) \leq |C| \cdot m^{O(\min\{k(C),\ \log m\})}$$

and

$$S(\tau(C,m)) \geq m^{\Omega(\min\{k(C),\ \log m\})}. \tag{1}$$

We begin the proof of Lemma 3.1 by describing CNFs, which form the main building block $\tau(C, m)$, and establishing their necessary properties. From now on fix a monotone circuit C in n variables $p_1, \ldots, p_n$. Let $\mathcal{A} \subseteq \{0,1\}^m$. We will call vectors from $\mathcal{A}$ (usually represented as columns) *admissible* and call a 0-1 matrix with m rows $\mathcal{A}$-*admissible* if all its columns are so. Consider the following combinatorial principle

$\mathcal{P}_{C,\mathcal{A}}$ (that may be true or false, depending on the choice of C and $\mathcal{A}$):

$\mathcal{P}_{C,\mathcal{A}}$: *every* $(m \times n)$ 0-1 $\mathcal{A}$*-admissible matrix* $A = (a_{ij})$ *contains a row* $i \in [m]$ *such that* $C(a_{i1}, a_{i2}, \ldots, a_{in}) = 1$.

Let us formulate one sufficient condition for $\mathcal{P}_{C,\mathcal{A}}$ to be true (regardless of proof complexity considerations).

DEFINITION 3.2. *$d_1(\mathcal{A})$ is the maximal d such that for every d vectors from $\mathcal{A}$ there exists a position $i \in [m]$ in which all these vectors have* 1.

$d_1(\mathcal{A})$ can also be easily characterized in terms of minimum covers. Namely, if we associate with every

$$\begin{pmatrix} a_1 \\ \vdots \\ a_m \end{pmatrix} \in \mathcal{A}$$

the subset $\{\, i \in [m] \mid a_i = 0 \,\}$ of $[m]$, then $d_1(\mathcal{A}) + 1$ is exactly the minimal number of such sets needed to cover the whole $[m]$.

LEMMA 3.3. *If $k(C) \le d_1(\mathcal{A})$, then $\mathcal{P}_{C,\mathcal{A}}$ is true.*

Proof. Let A be an $(m \times n)$ 0-1 $\mathcal{A}$-admissible matrix. Let $a = (a_1, \ldots, a_n)$ be such that $C(a_1, \ldots, a_n) = 1$ and $k(a) = k(C)$. Let

$$\mathcal{A}_0 \stackrel{\text{def}}{=} \left\{ \left(\begin{array}{c} a_{1j} \\ \vdots \\ a_{mj} \end{array} \right) \middle| \; a_j = 1 \right\}$$

be the set of all columns in A corresponding to those positions j for which $a_j = 1$. Since $|\mathcal{A}_0| \le k(a) = k(C) \le d_1(\mathcal{A})$, there exists $i \in [m]$ such that $a_{ij} = 1$ whenever $a_j = 1$. This means $a_{ij} \ge a_j$ for all $j \in [n]$ and implies $C(a_{i1}, \ldots, a_{in}) = 1$ since C is monotone. □

The proof of Lemma 3.3 suggests that if C and $\mathcal{A}$ with the property $k(C) \le d_1(\mathcal{A})$ are "generic enough," then the optimal propositional proof of the principle $\mathcal{P}_{C,\mathcal{A}}$ should exhaustively search through all $|\mathcal{A}|^{k(C)}$ possible placements of admissible vectors to the columns $\{\, j \mid a_j = 1 \,\}$ and thus have size roughly $|\mathcal{A}|^{k(C)}$. Our task is to find an encoding of (the negation of) $\mathcal{P}_{C,\mathcal{A}}$ as a CNF so that we can prove tight upper and lower bounds on $S_T(\tau(C, \mathcal{A}))$ and $S(\tau(C, \mathcal{A}))$ of (roughly) this order. This encoding is somewhat technical and involves several auxiliary functions (see Definition 3.4 below). In order to convey why we need all of these, let us briefly discuss two "naive" attempts at a simpler proof.

Attempt 1 (no encoding at all). Suppose that we simply enumerate elements of $\mathcal{A}$ by binary strings of length $\log |\mathcal{A}|$ and introduce propositional variables expressing their bits. The main problem with this encoding is that it does not behave well with respect to (random) restrictions. The standard width-reducing argument from [8] that we use in part (c) of Lemma 3.8 below assumes a "reasonably uniform" distribution on the set of those restrictions that "reasonably preserve" the complexity of the tautology. But with the straightforward encoding, any restriction of propositional variables used for enumerating the set $\mathcal{A}$ results in shrinking this set and completely destroys its useful properties.

We circumvent this in a standard way by using "excessive encodings" $F_1, \ldots, F_n : \{0,1\}^s \longrightarrow \mathcal{A}$, where $F_i(x_1, \ldots, x_s)$ are surjective and remain so after restricting not too many variables (Definition 3.5). It is worth noting that even if we may have assumed in our definition of $\tau(C, \mathcal{A})$ that $F_1 = F_2 = \cdots = F_n$, this property will *not*

be invariant under restrictions (and this is why it is more convenient not to make this assumption).

Attempt 2 (same encoding for $\mathcal{A}$ and C). The naive encoding of the circuit C (that is, by propositional variables z_{iv} encoding the intermediate result of the computation by the circuit C at the gate v when its input is the ith row of A) suffers from the same drawback as above, which is that we do not want the values of z_{iv} to be exposed by a random restriction. But why do we not apply to the variables z_{iv} just the same excessive encodings we used above for the elements of $\mathcal{A}$?

It turns out that with this "lighter" version our lower bounds already go through, and the upper bound holds for *general* resolution (in particular, the reader interested in only this case can safely assume this simplification). In the tree-like case, however, the upper bound becomes problematic. Namely, when formalizing the proof of Lemma 3.3, we need to prove the fact $C(a_{i_1}, \dots, a_{i_n}) = 1$, and the natural way of doing this in *tree-like* resolution assumes full access to clauses of the form $(z_{i,v_1} \wedge \dots \wedge z_{i,v_\mu} \supset z_{i,v})$ (cf. the proof of part (a) of Lemma 3.8). This is not a problem if the variables $z_{i,v}$ are not encoded, but if we encode them in a nontrivial way, then we no longer will have a resolution proof.

In order to balance between these two conflicting requirements, we introduce a more sophisticated encoding scheme that intuitively looks as follows. Imagine that we have many independent copies $C_1, \dots, C_r$ of the circuit C; indices $c \in \{1, 2, \dots, r\}$ will be called *controls*. The (unencoded!) variables $z^c_{i,v}$ will again express the protocol of computing the value $C_c(a_{i_1}, \dots, a_{i_n})$. But for every individual row $i \in [m]$, our axioms will require this protocol to be valid only for *one* of these r circuits (say, C_{c_i}), and the values c_i *are* excessively encoded by surjective mappings $f_1, \dots, f_m : \{0,1\}^s \longrightarrow [r]$ in the same way as we did with the elements of $\mathcal{A}$.

In order to not obstruct the proof with irrelevant details, we will define our CNFs $\tau(C, \mathcal{A}, \vec{F}, \vec{f})$ and establish their necessary properties in a situation which is more general than what will be actually needed for completing the proof of Lemma 3.1. If the reader prefers, he/she may think during the course of the proof that $\mathcal{A}$ is an arbitrary set of vectors such that $d_1(\mathcal{A}) \geq \Omega(\log m)$ and (see Definition 3.6) $d_0(\mathcal{A}) \geq \Omega(\log m)$. Furthermore, $r = \log m$, $s = O(\log m)$, and F_j, f_i will be $(\log m)$-surjective in the sense of Definition 3.5.

DEFINITION 3.4. *Let $C(p_1, \dots, p_n)$ be a monotone circuit, $\mathcal{A} \subseteq \{0,1\}^m$ be a set of vectors, and $F_1, \dots, F_n : \{0,1\}^s \longrightarrow \mathcal{A}$, $f_1, \dots, f_m : \{0,1\}^s \longrightarrow [r]$ be surjective functions, where f_is are possibly partial. For every $j \in [n]$ and $\nu \in [s]$ we introduce a propositional variable x^ν_j, for every $i \in [m]$ and $\nu \in [s]$ introduce a variable y^ν_i, and for every $i \in [m]$, every $c \in [r]$ (elements of this set will be sometimes referred to as* controls*), and every vertex v of the circuit C introduce a variable z^c_{iv}.*

For $j \in [n]$ and $\vec{a} \in \mathcal{A}$, let us denote by $[Column_j = \vec{a}]$ the predicate $F_j(x^1_j, \dots, x^s_j) = \vec{a}$. Likewise, for $i \in [m]$ and $c \in [r]$, let $[Control_i = c]$ denote the predicate "$f_i(y^1_i, \dots, y^s_i)$ is defined and $f_i(y^1_i, \dots, y^s_i) = c$."

The CNF $\tau(C, \mathcal{A}, \vec{F}, \vec{f})$ consists of all clauses that result from the expansion of the following Boolean predicates as CNFs:

$$(y^1_i, \dots, y^s_i) \in dom(f_i) \text{ for all } i \in [m]; \tag{2}$$

$$\left.\begin{array}{c} ([Column_j = \vec{a}] \wedge [Control_i = c]) \supset z^c_{i,p_j} \\ \text{for all } \vec{a} \in \mathcal{A},\ i \in [m] \text{ such that } a_i = 1 \text{ and all } j \in [n],\ c \in [r]; \end{array}\right\} \tag{3}$$

$$\left.\begin{array}{c} \big([\mathit{Control}_i = c] \wedge (z^c_{i,v'} * z^c_{i,v''})\big) \supset z^c_{iv} \\ \text{for all } i \in [m],\ c \in [r] \text{ and all internal nodes } v \\ \text{corresponding to the instruction } v \leftarrow v' * v'',\ * \in \{\wedge, \vee\}; \end{array}\right\} \tag{4}$$

$$[\mathit{Control}_i = c] \supset \bar{z}_{i,v_{\mathrm{fin}}},\ \text{where } v_{\mathrm{fin}} \text{ is the output node of } C. \tag{5}$$

It is easy to see that $\tau(C, \mathcal{A}, \vec{F}, \vec{f})$ is unsatisfiable (for arbitrary surjective $\vec{F}, \vec{f}$) iff $P_{C,\mathcal{A}}$ is true. Also, as we already mentioned, the only thing we need from $\vec{F}, \vec{f}$ is that they remain surjective after restricting a few variables.

DEFINITION 3.5. *We say that an onto (possibly partial) function $g : \{0,1\}^s \longrightarrow D$ is* r-surjective *if for any restriction ρ with $|\rho| \le r$ the function $g|_\rho$ is still onto.*

Finally, for the lower bound we need a notion dual to $d_1(\mathcal{A})$.

DEFINITION 3.6. *$d_0(\mathcal{A})$ is the maximal d such that for every d positions $i_1, \ldots, i_d \in [m]$ there exists $\vec{a} \in \mathcal{A}$ such that $a_{i_1} = \cdots = a_{i_d} = 0$.*

Now we are ready to formulate our main technical lemma that provides upper and lower bounds on the size of optimal resolution refutations of $\tau(C, \mathcal{A}, \vec{F}, \vec{f})$. Like many similar proofs in the area, the lower bound is naturally split into two fairly independent parts. The first part provides lower bounds on $w(\tau(C, \mathcal{A}, \vec{F}, \vec{f}) \vdash \emptyset)$, but for technical reasons we need a slightly stronger statement based on a modified notion of width.

DEFINITION 3.7. *For a clause D in the variables of the CNF $\tau(C, \mathcal{A}, \vec{F}, \vec{f})$, let $w_x(D), w_y(D)$, and $w_c(D)$ ($c \in [r]$) be the numbers of x-variables, y-variables, and z-variables of the form $z^c_{i,v}$, respectively, appearing in D. We define the* controlled width $\widetilde{w}(D)$ *as*

$$\widetilde{w}(D) \stackrel{\mathrm{def}}{=} w_x(D) + w_y(D) + r \cdot \min_{c \in [r]} w_c(D).$$

The minimal controlled width $\widetilde{w}(\tau(C, \mathcal{A}, \vec{F}, \vec{f}) \vdash \emptyset)$ *is defined similarly to the minimal refutation width.*

Clearly, $\widetilde{w}(D) \le w(D)$ for any clause D, and thus $\widetilde{w}(\tau(C, \mathcal{A}, \vec{F}, \vec{f}) \vdash \emptyset) \le w(\tau(C, \mathcal{A}, \vec{F}, \vec{f}) \vdash \emptyset)$.

LEMMA 3.8. *Let C be a monotone circuit in n variables, let $\mathcal{A} \subseteq \{0,1\}^m$, and let $F_1, \ldots, F_n : \{0,1\}^s \longrightarrow \mathcal{A}$, $f_1, \ldots, f_m : \{0,1\}^s \longrightarrow [r]$ be r-surjective functions, where the f_i's are possibly partial and m, r, s are arbitrary integer parameters. Then the following bounds hold:*

(a) (*cf. Lemma* 3.3). *If $k(C) \le d_1(\mathcal{A})$, then $S_T(\tau(C, \mathcal{A}, \vec{F}, \vec{f})) \le O(|C| \cdot 2^{s(k(C)+1)})$.*

(b) $\widetilde{w}(\tau(C, \mathcal{A}, \vec{F}, \vec{f}) \vdash \emptyset) \ge \frac{r}{2} \cdot \min\{k(C), d_0(\mathcal{A})\}$.

(c) $S(\tau(C, \mathcal{A}, \vec{F}, \vec{f})) \ge \exp(\Omega(\frac{r^2}{s} \cdot \min\{k(C), d_0(\mathcal{A})\}))$.

Proof of Lemma 3.8.

Part (a). We show this part by formalizing the proof of Lemma 3.3. Let $k \stackrel{\mathrm{def}}{=} k(C)$ and $a_1, \ldots, a_n$ be such that $C(a_1, \ldots, a_n) = 1$ and $k(a) = k$. Assume for simplicity

that $a_1 = \cdots = a_k = 1,\ a_{k+1} = \cdots = a_n = 0$. Fix arbitrary admissible vectors

$$\vec{a}_1 \stackrel{\text{def}}{=} \begin{pmatrix} a_{i1} \\ \vdots \\ a_{m1} \end{pmatrix}, \ldots, \vec{a}_k \stackrel{\text{def}}{=} \begin{pmatrix} a_{ik} \\ \vdots \\ a_{mk} \end{pmatrix}$$

and, using the inequality $d_1(\mathcal{A}) \geq k$, pick up an arbitrary $i \in [m]$ (depending in general on $\vec{a}_1, \ldots, \vec{a}_k$) such that $a_{i1} = a_{i2} = \cdots = a_{ik} = 1$. We want to infer from $\tau(C, \mathcal{A}, \vec{F}, \vec{f})$ all clauses in the CNF expansion of

$$[\mathrm{Column}_1 \neq \vec{a}_1] \vee \cdots \vee [\mathrm{Column}_k \neq \vec{a}_k] \vee [\mathrm{Control}_i \neq c] \tag{6}$$

for all $c \in [r]$. It is fairly obvious how to do this efficiently in general resolution. Namely, let V be the set of all nodes of the circuit C that are evaluated to 1 by the assignment $(1^k, 0^{n-k})$. Then we may proceed by induction on the construction of C and subsequently infer

$$([\mathrm{Column}_1 = \vec{a}_1] \wedge \cdots \wedge [\mathrm{Column}_k = \vec{a}_k] \wedge [\mathrm{Control}_i = c]) \supset z^c_{iv}$$

for all $v \in V$ until we reach v_{fin}.

In order to get a *tree-like* proof, however, we should employ a dual (top-down) strategy. Namely, enumerate the set V in some order which is consistent with the topology of C: $V = \langle v_1 = p_1, v_2 = p_2, \ldots, v_k = p_k, v_{k+1}, v_{k+2}, \ldots, v_t = v_{\mathrm{fin}} \rangle$; all wires between vertices in V go from left to right. Then, by a reverse induction on $\mu = t, t-1, \ldots, k$ we infer (all clauses in the CNF expansion of) $[\mathrm{Control}_i = c] \supset (\bar{z}^c_{i,v_1} \vee \cdots \vee \bar{z}^c_{i,v_\mu})$. For $\mu = t$ this is (a weakening of) (5), and for the inductive step we resolve with the appropriate axiom in (4). When we descend to $[\mathrm{Control}_i = c] \supset \left(\bar{z}^c_{i,p_1} \vee \cdots \vee \bar{z}^c_{i,p_k}\right)$, we consecutively resolve with the corresponding axioms (3) to get rid of $\bar{z}^c_{i,p_j}$ and arrive at (6). Clearly, this resolution inference of every individual clause in (6) is tree-like and has size $O(|C|)$.

Finally, for every $i \in [m]$, every clause in the variables $\{\, y^\nu_i \mid 1 \leq \nu \leq s \,\}$ appears in one of the CNFs resulting from the predicate $\{\, [\mathrm{Control}_i \neq c] \mid c \in [r] \,\}$ or the predicates in (2), and every clause in the variables $\left\{\, x^\nu_j \mid 1 \leq \nu \leq s \,\right\}$ appears in one of $[\mathrm{Column}_j \neq \vec{a}_j]$. This gives us an obvious tree-like refutation of the set of clauses (2), (6) that has size $O(2^{s(k+1)})$. Combining this refutation with previously constructed inferences of (6) from $\tau(C, \mathcal{A}, \vec{F}, \vec{f})$, we get the desired upper bound.

Part (b). We follow the general strategy proposed in [10]. Note that every one of the axioms (2)–(5) "belongs" to a uniquely defined row; let Row_i be the set of axioms in $\tau(C, \mathcal{A}, \vec{F}, \vec{f})$ that correspond to the row i. For a clause D, let $\mu(D)$ be the smallest cardinality of $I \subseteq [m]$ such that $\cup\{\, \mathrm{Row}_i \mid i \in I \,\}$ (semantically) implies D. $\mu(D)$ is subadditive, that is, $\mu(D) \leq \mu(D_1) + \mu(D_2)$ whenever D is obtained from D_1, D_2 via a single application of the resolution rule. It is also obvious that $\mu(A) = 1$ for any axiom $A \in \tau(C, \mathcal{A}, \vec{F}, \vec{f})$.

We claim that $\mu(\emptyset) > d_0(\mathcal{A})$. Indeed, fix any $I \subseteq [m]$ with $|I| \leq d_0(\mathcal{A})$. We need to construct an assignment that satisfies all axioms in $\cup\{\, \mathrm{Row}_i \mid i \in I \,\}$. Pick $\vec{a}$ accordingly to Definition 3.6 in such a way that for all $i \in I (a_i = 0)$. Assign every x^ν_j to α^ν_j, where $\alpha^1_j, \ldots, \alpha^s_j$ is an arbitrary vector such that $F_j(\alpha^1_j, \ldots, \alpha^s_j) = \vec{a}$; assign y^ν_i in an arbitrary way with the only requirement that they satisfy (2), and assign all z-variables to 0. This assignment will satisfy all axioms in $\cup\{\, \mathrm{Row}_i \mid i \in I \,\}$, which proves $\mu(\emptyset) > d_0(\mathcal{A})$.

Thus, any resolution refutation of $\tau(C, \mathcal{A}, \vec{F}, \vec{f})$ must contain a clause D with $\frac{1}{2}d_0(\mathcal{A}) \le \mu(D) \le d_0(\mathcal{A})$, and we need only show that this implies $\widetilde{w}(D) \ge \frac{r}{2} \cdot \min\{k(C), d_0(\mathcal{A})\}$. Fix $I \subseteq [m]$ such that $\cup\{\mathrm{Row}_i \mid i \in I\}$ semantically implies D and $|I|$ is minimal with this property; $\frac{1}{2}d_0(\mathcal{A}) \le |I| \le d_0(\mathcal{A})$.

If for every $i \in I$ at least one of the following two events is true, then we are done:

1. the clause D contains at least r variables among $\{y_i^\nu \mid \nu \in [s]\}$;
2. for every control $c \in [r]$ the clause D contains at least one variable among $\{z_{iv}^c \mid v \text{ is a node}\}$.

Indeed, if h is the number of indices i for which 1 is true, then $w_y(D) \ge rh$. For those $i \in I$ for which 1 does not hold, we apply 2 to conclude $\min_{c\in[r]} w_c(D) \ge (|I| - h)$, and altogether we have $\widetilde{w}(D) \ge w_y(D) + r \cdot \min_{c\in[r]} w_c(D) \ge r \cdot |I| \ge \frac{r}{2}d_0(\mathcal{A})$.

Thus, suppose that for some $i_0 \in I$ neither of these two is true. In particular, there exists a control $c_0 \in [r]$ such that no variable of the form $z_{i_0,v}^{c_0}$ appears in D. Fix an arbitrary assignment α that satisfies all axioms in $\{\mathrm{Row}_i \mid i \in I \setminus \{i_0\}\}$ and falsifies D (such an assignment exists due to the minimality of $|I|$).

Let J_0 consist of those $j \in [n]$ for which the clause D contains at least r variables from $\{x_j^\nu \mid \nu \in [s]\}$. If $|J_0| \ge k(C)$, we are also done. If this is not the case, we will show how to alter the assignment α so that it will satisfy all axioms in $\cup\{\mathrm{Row}_i \mid i \in I\}$ (including Row_{i_0}) but still will falsify D, and this will give us the contradiction.

According to Definition 3.6, there exists $\vec{a} \in \mathcal{A}$ such that $a_i = 0$ for all $i \in I$. We alter α as follows.

Step 1. Using that F_j is r-surjective, we change for every $j \notin J_0$ the values of the variables $\{x_j^\nu \mid \nu \in [s]\}$ not appearing in D in such a way that $F_j(x_j^1, \dots, x_j^s) = \vec{a}$.

Step 2. Using the fact that f_{i_0} is r-surjective, we change the values of variables $\{y_{i_0}^\nu \mid \nu \in [s]\}$ not appearing in D in such a way that $f_{i_0}(y_{i_0}^1, \dots, y_{i_0}^s) = c_0$. Finally, we reassign every $z_{i_0,v}^{c_0}$ to the value computed by the node v on the characteristic vector of the set J_0. Note that $z_{i_0,p_j}^{c_0}$ is set to 1 for $j \in J_0$, whereas $z_{i_0,v_{\mathrm{fin}}}^{c_0}$ is set to 0 since $|J_0| < k(C)$.

We claim that this altered assignment α' satisfies all axioms in $\cup\{\mathrm{Row}_i \mid i \in I\}$. Indeed, we made sure in our construction that it satisfies all axioms in Row_{i_0} of types (2), (4), (5), and for $i \in I \setminus \{i_0\}$ axioms of these types are satisfied since we have not touched any variable appearing in them. Thus, we have only to check the axiom (3). If $j \in J_0$ and $i \ne i_0$, this axiom has not been touched, and if $j \notin J_0$, it becomes satisfied because of the first step in our construction of α', and due to the condition $a_i = 0$ ($i \in I$). Finally, if $j \in J_0$ and $i = i_0$, the axiom (3) gets satisfied during the second step (in which we set $z_{i_0,p_j}^{c_0}$ to 1).

But α' also falsifies D since we have not touched variables appearing in it. This contradiction with the fact that $\{\mathrm{Row}_i \mid i \in I\}$ implies that D completes the proof of part (b).

Part (c). We apply the standard argument of width-reducing restrictions (cf. [8]). For doing this we observe that the CNFs of the form $\tau(C, \mathcal{A}, \vec{F}, \vec{f})$ behave well with respect to certain restrictions. Namely, let $d \le r$ and $R \subseteq [r]$ be an arbitrary set of controls. Denote by $\mathcal{R}_{d,R}$ the set of all restrictions that arbitrarily assign to a Boolean value d variables in every one of the groups $\{x_j^\nu \mid \nu \in [s]\}, \{y_i^\nu \mid \nu \in [s]\}$ with $j \in [n], i \in [m]$ as well as all the variables z_{iv}^c with $c \notin R$. Then it is easy to see that for $\rho \in \mathcal{R}_{d,R}$, every nontrivial clause in $\tau(C, \mathcal{A}, \vec{F}, \vec{f})|_\rho$, after a suitable re-enumeration of variables and controls, contains a subclause from $\tau(C, \mathcal{A}, \vec{F}|_\rho, (\vec{f}|_\rho)|_R)$ (the *partial* function $(f_i|_\rho)|_R$ is obtained from $f_i|_\rho$ by restricting its domain to $\{y_i \mid f_i|_\rho(y_i) \in R\}$ and range to R).

Pick now $\boldsymbol{\rho}$ uniformly at random from $\mathcal{R}_{r/2,\boldsymbol{R}}$, where $\boldsymbol{R}$ is picked at random from $[r]^{r/2}$. Then $F_j|_{\boldsymbol{\rho}}, (f_i|_{\boldsymbol{\rho}})|_{\boldsymbol{R}}$ will be $(r/2)$-surjective. Therefore, by the already proven part (b), for every refutation P of $\tau(C, \mathcal{A}, \vec{F}, \vec{f})$, $\boldsymbol{\rho}(P)$ will contain a clause of controlled width

$$\Omega\left(r \cdot \min\{k(C), d_0(\mathcal{A})\}\right) \tag{7}$$

with probability 1.

It is easy to see, however, that every clause D whose controlled width $\widetilde{w}(D)$ is that large is killed (that is, set to 1 and hence removed from the proof) by $\boldsymbol{\rho}$ with probability

$$1 - \exp\left(-\Omega\left(\frac{r^2}{s} \cdot \min\{k(C), d_0(\mathcal{A})\}\right)\right).$$

Indeed, according to Definition 3.7, either $w_x(D)$ or $w_y(D)$ or $r \cdot \min_{c\in[r]} w_c(D)$ is bounded from below by a quantity of the form (7). Let $w_{x,j}(D)$ be the number of variables in the corresponding group that appear in D so that $w_x(D) = \sum_{j\in[n]} w_{x,j}(D)$. Then the probability that D is not killed by variables in the jth group is $\exp\big(-\Omega\big(\frac{r\cdot w_{x,j}(D)}{s}\big)\big)$, and these events are independent so the probabilities of survival multiply to $\exp\big(-\Omega\big(\frac{r\cdot w_{x,j}(D)}{s}\big)\big)$. The case when $w_y(D)$ is large is treated in exactly the same way, and the case when $r \cdot \min_{c\in[r]} w_c(D)$ is large is even simpler since for *every* choice of $\boldsymbol{R}$, the number of assigned z-variables is at least $\frac{r}{2} \cdot \min_{c\in[r]} w_c(D)$ (and $s \geq r$).

Therefore, the size of P must be at least $\exp\big(\Omega\big(\frac{r^2}{s} \cdot \min\{k(C), d_0(\mathcal{A})\}\big)\big)$ since otherwise a random restriction $\boldsymbol{\rho}$ would have killed all such clauses with nonzero probability, which is impossible.

Lemma 3.8 is completely proved. □

Proof of Lemma 3.1. Our construction of $\tau(C, m)$ proceeds in polynomial time as follows.

1. Let p be the smallest prime greater than or equal to m. Since $m \leq p \leq 2m$, both bounds in Lemma 3.1 remain unchanged if we replace m by p or vice versa. Therefore, w.l.o.g. we may assume from the beginning that m itself is a prime. Let P_m be the $(m \times m)$ 0-1 *Paley matrix* given by $a_{ij} = 1$ iff $j \neq i$ and $(j-i)$ is a quadratic residue mod m. Let $\mathcal{A} \subseteq \{0,1\}^m$ consist of all columns of P_m. Then $|\mathcal{A}| = m$ and $d_0(\mathcal{A}), d_1(\mathcal{A}) \geq \frac{1}{4}\log m$ (see, e.g., [5]).

2. Fix any $\mathbb{F}_2$-linear code $L \subseteq \{0,1\}^{h\lceil\log m\rceil}$ of dimension $\lceil\log m\rceil$ that is computable (as a language) in time $m^{O(1)}$ and has minimal distance $\geq \lceil\log m\rceil$ ($h > 0$ is an absolute constant). Consider the linear mapping $G : \{0,1\}^{h\lceil\log m\rceil} \longrightarrow \{0,1\}^{\lceil\log m\rceil}$ dual to the inclusion $L \to \{0,1\}^{h\lceil\log m\rceil}$ (that is, we fix in L an arbitrary basis $x_1, \ldots, x_{\lceil\log m\rceil}$ and let $G(y) \stackrel{\text{def}}{=} (\langle x_1, y\rangle, \ldots, \langle x_{\lceil\log m\rceil}, y\rangle)$). By linear duality, the fact that L has minimal distance $\geq \lceil\log m\rceil$ is equivalent to $\lceil\log m\rceil$-surjectivity of G. Set $r \stackrel{\text{def}}{=} \lceil\log m\rceil$ and $s \stackrel{\text{def}}{=} h\lceil\log m\rceil$. Consider arbitrary (polynomial-time computable) surjective mappings $\Pi : \{0,1\}^{\lceil\log m\rceil} \longrightarrow \mathcal{A}$, $\pi : \{0,1\}^{\lceil\log m\rceil} \longrightarrow [r]$ and let $F_j \stackrel{\text{def}}{=} \Pi \cdot G, f_i \stackrel{\text{def}}{=} \pi \cdot G$ for all i, j.

3. Construct $\tau(C, \mathcal{A}, \vec{F}, \vec{f})$. Note that the size of this CNF is polynomial in $|C|, m, 2^s$, which is polynomial in $|C|, m$ due to our choice of parameters.

At this point, Lemma 3.8(c) already implies (1) for $\tau(C, \mathcal{A}, \vec{F}, \vec{f})$. The only remaining problem is that a priori we do not have the condition $k(C) \leq d_1(\mathcal{A})$ needed for part (a) of Lemma 3.8. We circumvent this by a trick similar to one used in [3].

Namely, let τ_m be a fixed unsatisfiable (polynomial-time constructible) CNF with $S(\tau_m), S_T(\tau_m) = m^{\theta(\log m)}$ (for example, one can take a Tseitin tautology with $\theta((\log m)^2)$ variables) and such that its set of variables is disjoint from the set of variables of $\tau(C, \mathcal{A}, \vec{F}, \vec{f})$. We finally set $\tau(C, m) \stackrel{\text{def}}{=} \tau(C, \mathcal{A}, \vec{F}, \vec{f}) \wedge \tau_m$.

Since both $\tau(C, \mathcal{A}, \vec{F}, \vec{f})$ and τ_m satisfy the lower bound (1), the weak feasible disjunction property (see, e.g., [21] and the literature cited therein) for resolution implies that $\tau(C, m)$ satisfies this bound, too. If $k(C) \le \frac{1}{4}\log m$ then, since $d_1(\mathcal{A}) \ge \frac{1}{4}\log m$, we can apply Lemma 3.8(a) to get the required upper bound $S_T(\tau(C, m)) \le |C| \cdot m^{O(k(C))}$. If, on the other hand, $k(C) \ge \frac{1}{4}\log m$, the required upper bound $S_T(\tau(C, m)) \le m^{O(\log m)}$ simply follows from the upper bound for τ_m. This completes the proof of Lemma 3.1. □

4. Self-improvement. In this section we complete the proof of Theorems 2.5 and 2.7 by combining Lemma 3.1 with a (nontrivial) self-improvement technique. First, we need to get rid of the dummy parameter m in the statement of Lemma 3.1.

LEMMA 4.1. *If either resolution or tree-like resolution is automatizable, then there exists an absolute constant $h > 1$ and an algorithm Φ working on pairs $\langle C, k\rangle$, where C is a monotone circuit and k is an integer such that*

1. *the running time of $\Phi(\langle C, k\rangle)$ is at most $\exp(O(k^2)) \cdot |C|^{O(1)}$;*
2. *if $k(C) \le k$, then $\Phi(\langle C, k\rangle) = 1$;*
3. *if $k(C) \ge hk$, then $\Phi(\langle C, k\rangle) = 0$.*

Proof. Combining the reduction in Lemma 3.1 with an automatizing algorithm for either resolution or tree-like resolution, we get an integer-valued function $S(C, m)$ computable in time $\left(|C| \cdot m^{\min\{k(C),\ \log m\}}\right)^{h_0}$ and such that

$$m^{\epsilon \cdot \min\{k(C),\ \log m\}} \le S(C, m) \le \left(|C| \cdot m^{\min\{k(C),\ \log m\}}\right)^{h_1}$$

for some absolute constants $\epsilon, h_0, h_1 > 0$. Set the constant h in the statement in such a way that

$$h^2 > \frac{h_1}{\epsilon}(h + 1). \tag{8}$$

Our algorithm Φ works as follows. We set

$$m \stackrel{\text{def}}{=} 2^{h \cdot \max\{k,\ \log |C|/k\}}.$$

Φ simulates $\left(|C| \cdot m^k\right)^{h_0}$ steps in the computation of $S(C, m)$, outputs 1 if the computation halts within this time, and its result $S(C, m)$ satisfies the inequality $S(C, m) \le \left(|C| \cdot m^k\right)^{h_1}$ and outputs 0 in all other cases.

Our choice of m ensures that $m^k \le \exp(O(k^2)) \cdot |C|^{O(1)}$, which implies property 1.

Since $\log m \ge hk \ge k$, under the assumption $k(C) \le k$ the limitations we have imposed on the running time and the output value of the algorithm Φ are less stringent than the bounds known of the underlying algorithm computing $S(C, m)$. This observation implies property 2.

Finally, using again the inequality $\log m \ge hk$, $k(C) \ge hk$ implies that $S(C, m) \ge m^{\epsilon hk}$, and elementary calculations show that, along with (8), this gives us $S(C, m) > \left(|C| \cdot m^k\right)^{h_1}$. Thus, if $k(C) \ge hk$, the algorithm Φ outputs the value 0.

Lemma 4.1 is proved. □

Proof of Theorem 2.5. First, we extract from Lemma 4.1 an algorithm which meets the bound on the running time and achieves the ratio of approximation h. For that we consecutively run the algorithm Φ from that lemma on the inputs $\langle C, 1\rangle, \ldots, \langle C, k\rangle, \ldots$ and output the first value k for which we get the answer 0.

Combining this algorithm with the self-improving reduction from Proposition 2.4 (for $d = \lceil \frac{1}{\epsilon} \ln h \rceil$), we get an approximating algorithm with the required properties. □

In the established terminology, what we have seen so far under the assumption of automatizability of (tree-like) resolution is a polynomial-time approximation scheme (PTAS) for MMCSA in the context of parameterized complexity (the latter referring to the term $\exp\left(k(C)^{O(1)}\right)$ in the bound on the running time). Unfortunately, our PTAS is not efficient (see the discussion in section 2.2), as the reduction from Proposition 2.4 blows up the size of the circuit. The task of converting an arbitrary PTAS into an EPTAS seems to be hopeless in general even in the context of parameterized complexity (where it appears to be easier). We nonetheless can perform it (in the latter context) for the specific problem MMCSA using a much trickier self-improvement construction. This construction (that completes the proof of our main theorem, Theorem 2.7) might be of independent interest, and its idea is roughly as follows.

We need to improve the approximation ratio of the algorithm Φ in Theorem 2.5 from (say) 2 to (say) $(1 + \frac{1}{\sqrt{k}})$, and the straightforward way of doing this is by iteratively applying Proposition 2.4 (say) $d = \sqrt{k}$ times. The corresponding reduction will map any circuit $C(x_1, \ldots, x_n)$ into an n-ary tree of C-gates, and of depth d, and the resulting increase in size is too costly to us. What we basically show is that we can circumvent this by replacing the tree with a *random* directed acyclic graph (DAG) of the same depth d and of width polynomial in n.

Proof of Theorem 2.7. Let C be a monotone circuit in n variables and k be an integer such that

$$10 \le k \le \epsilon(\log n / \log\log n)^2 \tag{9}$$

for a sufficiently small constant $\epsilon > 0$ (we will remark later how to get rid of this condition). Our goal is to construct in polynomial time a randomized monotone circuit $\boldsymbol{\pi}(C, k)$ and an integer $\alpha(k)$ (deterministically depending only on k) such that α is recursive and the following conditions hold:

$$k(C) \le k \implies \mathbf{P}[k(\boldsymbol{\pi}(C,k)) \le \alpha(k)] = 1; \tag{10}$$

$$k(C) \ge k+1 \implies \mathbf{P}[k(\boldsymbol{\pi}(C,k)) \ge 2\alpha(k)] \ge 1/2. \tag{11}$$

First, we apply to C the reduction from Proposition 2.4 with $d = 2$ that maps the range $[k, k+1]$ to $[k^2, k^2 + 2k + 1]$. Redenoting k^2 back to k, we may assume w.l.o.g. that in (11) we have the stronger premise

$$k(C) \ge k + 2\sqrt{k} \implies \mathbf{P}[k(\boldsymbol{\pi}(C,k)) \ge 2\alpha(k)] \ge 1/2. \tag{12}$$

Now comes our main reduction. Let N, d be two parameters (to be specified later). The randomized circuit $\boldsymbol{\pi}(C, N, d)$ in (nN) variables consists of d layers. Each layer consists of N independent copies of the circuit C (see Figure 1); thus, it has (nN) inputs and N outputs. We connect input nodes at the $(i+1)$st level to output nodes at the ith level at random. Finally, we pick up an arbitrary output node at the last dth level and declare it to be the output of the whole circuit $\boldsymbol{\pi}(C, N, d)$.

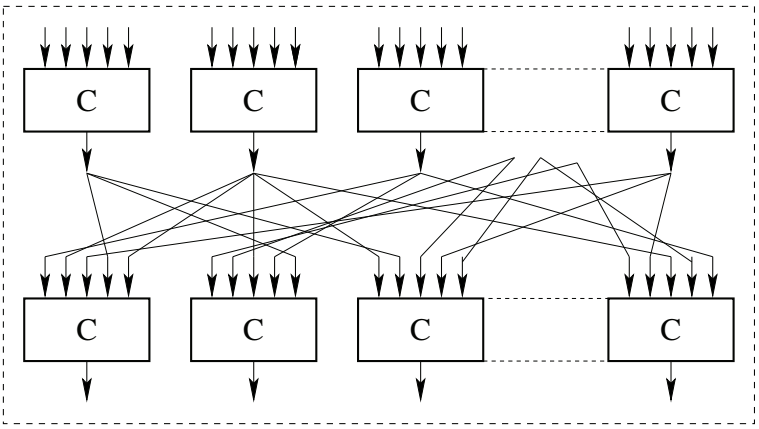

FIG. 1. *One layer of* $\boldsymbol{\pi}(C, N, d)$.

Clearly, this construction is polynomial in $|C|, N, d$. Also, an obvious induction on d shows that

$$k(\boldsymbol{\pi}(C, N, d)) \le k(C)^d \tag{13}$$

with probability 1. In order to get a lower bound on $k(\boldsymbol{\pi}(C, N, d))$, we need the following easy lemma. It is of course yet another version of the well-known fact that a random (bipartite) graph makes an extremely good expander.

LEMMA 4.2. *Let* $\boldsymbol{\chi} : [N] \times [n] \longrightarrow [N]$ *be a randomly chosen function, and let* k, a *be any parameters. Then* $\mathbf{P}\big[\exists V \in [N]^k (|\boldsymbol{\chi}(V \times [n])| \le kn - a)\big] \le N^k \cdot (\frac{4k^2n^2}{N})^a$.

Proof of Lemma 4.2. This event takes place iff there exist $V \in [N]^k$ and disjoint $D_1, \dots, D_r \subseteq V \times [n]$ such that $|D_1|, \dots, |D_r| \ge 2$, $\sum_{i=1}^r (|D_i| - 1) = a$, and $\boldsymbol{\chi}|_{D_i} =$ const for all $i \in [r]$. Since the two first properties imply $\sum_{i=1}^r |D_i| \le 2a$, the overall number of all choices of $\langle V, D_1, \dots, D_r \rangle$ does not exceed $N^k \cdot (2kn)^{2a}$. On the other hand, for every fixed choice, we have

$$\mathbf{P}[\boldsymbol{\chi}|_{D_1} = \text{const}, \dots, \boldsymbol{\chi}|_{D_r} = \text{const}] = \frac{N^r}{N^{(\sum_{i=1}^r |D_i|)}} = N^{-a}.$$

Lemma 4.2 follows. □

Now we can complete the description of our reduction. Namely, we set $N \stackrel{\text{def}}{=} n^3$, $d \stackrel{\text{def}}{=} \sqrt{k}$ and let $\boldsymbol{\pi}(C, k) = \boldsymbol{\pi}(C, n^3, \sqrt{k})$, $\alpha(k) \stackrel{\text{def}}{=} k^{\sqrt{k}}$.

Equation (10) follows from (13).

In order to check (12), denote by $\boldsymbol{\chi_i} : [N] \times [n] \longrightarrow [N]$ the function used for connecting input nodes at the $(i+1)$st level of $\boldsymbol{\pi}(C, n^3, \sqrt{k})$ to the output nodes at the ith level. Let $k_i \stackrel{\text{def}}{=} (k + \sqrt{k})^{d-i}$. Let us call $\boldsymbol{\pi}(C, N, d)$ *bad* if for at least one of these functions $\boldsymbol{\chi_i}$ there exists a set V of circuits at the $(i+1)$st level such that $|V| = k_{i+1}$ and $|\boldsymbol{\chi_i}(V \times [n])| \le k_{i+1}(n - \sqrt{k})$. Using Lemma 4.2 and (9), we get the

bound

$$\begin{aligned}\mathbf{P}[\boldsymbol{\pi}(C,N,d) \text{ is bad}] &\le \sum_{i=1}^{d-1} N^{k_{i+1}} \cdot \left(\frac{4k_{i+1}^2 n^2}{N}\right)^{\sqrt{k}\cdot k_{i+1}} \\ &= \sum_{i=1}^{d-1} \left(\frac{4k_{i+1}^2}{n^{1-3/\sqrt{k}}}\right)^{\sqrt{k}\cdot k_{i+1}} \\ &\le \sum_{i=1}^{d-1} \left(\frac{1}{3}\right)^{\sqrt{k}\cdot k_{i+1}} \le \frac{1}{2}.\end{aligned}$$

On the other hand, it is easy to see by induction on $i = d, \dots, 1$ that if $k(C) \ge k + 2\sqrt{k}$ and $\boldsymbol{\pi}(C,N,d)$ is good, then every satisfying assignment a should satisfy at least k_i output nodes at the ith level. Indeed, the base $i = d$ is obvious ($k_d = 1$). For the inductive step, assume that a satisfies the output nodes of a set V of circuits at the $(i+1)$st level, $|V| = k_{i+1}$. Then at least $(k + 2\sqrt{k}) \cdot k_{i+1}$ *input* nodes to these circuits should be satisfied. Since $\boldsymbol{\chi_i}$ is good, there are at most $\sqrt{k} \cdot k_{i+1}$ collisions between the $(k + 2\sqrt{k}) \cdot k_{i+1}$ wires leading to these input nodes from the ith level. Therefore, at least $(k + 2\sqrt{k}) \cdot k_{i+1} - \sqrt{k} \cdot k_{i+1} = k_i$ output nodes at the ith level should be satisfied.

In particular, at the first level we will have $\ge (k + \sqrt{k})^{d-1}$ satisfied circuits and $\ge (k + 2\sqrt{k}) \cdot (k + \sqrt{k})^{\sqrt{k}-1} > 2\alpha(k)$ satisfied input nodes. This completes the proof that our probabilistic reduction $\boldsymbol{\pi}(C,k)$ has the properties (10), (12) (and, as we already remarked, improving (12) to (11) takes one more easy step).

Now we finish the proof of Theorem 2.7. Suppose that either resolution or tree-like resolution is automatizable. Since WEIGHTED MONOTONE CIRCUIT SATISFIABILITY is **W[P]**-complete (see [17, Chapter 13]), we have only to show that the language $\{\, \langle C,k\rangle \mid k(C) \le k \,\}$ is in co-**FPR**. Given an input $\langle C,k\rangle$ we check condition (9). If it is violated, we apply a straightforward brute-force algorithm with running time $O(|C|\cdot n^k) \le |C|\cdot f(k)\cdot n^9$ for some recursive f. Otherwise we simply combine our probabilistic reduction $\langle \boldsymbol{\pi}, \alpha\rangle$ with the deterministic algorithm for deciding whether $k(\boldsymbol{\pi}(C,k)) \le \alpha(k)$ or $k(\boldsymbol{\pi}(C,k)) \ge 2\alpha(k)$ provided by Theorem 2.5. Theorem 2.7 is completely proved. □

5. Open problems. The main problem left open by this paper is whether general resolution is quasi-automatizable. Since the width algorithm by Ben-Sasson and Wigderson [10] finds a resolution refutation of any unsatisfiable CNF τ in time $n^{O(w(\tau\vdash\emptyset))}$, a negative solution to this problem must involve a construction of a broad and "tractable" family of CNF τ for which $S(\tau)$ is much smaller than $2^{w(\tau\vdash\emptyset)}$. Such families are not so easy to come by (e.g., our techniques involve showing the *opposite* in the proof of Lemma 3.8(c)), although some progress toward this goal was reported in [6].

As we already mentioned in section 1.1, the same paper [6] also proposed an interesting notion of weak automatizability. Namely, a proof system P is *weakly automatizable* if there exists any automatizable proof system that polynomially simulates P. Is resolution *weakly* automatizable (under any reasonable complexity assumptions in the case of a negative answer)? Paper [6] showed that this is equivalent to another important open question in proof complexity, namely, if the system $Res(2)$ has the feasible interpolation property (for definitions, see, e.g., [22]).

We were not able to derandomize the proof of Lemma 4.2. In the terminology of [1], we need explicit constructions of $(N \times N)$ 0-1 matrices that would be $(k, n, n - O(1))$-expanders for $n \geq N^{\Omega(1)}$ and an arbitrary function $k = k(N)$ tending to infinity. Explicit constructions based on Ramanujan graphs seem to give only $(k, n, n - k^{\epsilon})$-expanders for any *fixed* ϵ which is not sufficient for our purposes. Can we weaken the hardness assumption in Theorem 2.7 to $\mathbf{W[P]} \neq \mathbf{FPT}$ by an explicit construction of better expanders (or by using any other means)?

Acknowledgment. The second author is greatly indebted to all three anonymous referees of the journal version of this paper for their constructive criticism and many useful remarks and suggestions.

PRESERVATION UNDER EXTENSIONS ON WELL-BEHAVED FINITE STRUCTURES*

ALBERT ATSERIAS†, ANUJ DAWAR‡, AND MARTIN GROHE§

Abstract. A class of relational structures is said to have the extension preservation property if every first-order sentence that is preserved under extensions on the class is equivalent to an existential sentence. The class of all finite structures does not have the extension preservation property. We study the property on classes of finite structures that are better behaved. We show that the property holds for classes of acyclic structures, structures of bounded degree, and more generally structures that are *wide* in a sense that we will make precise. We also show that the preservation property holds for the class of structures of treewidth at most k, for any k. In contrast, we show that the property fails for the class of planar graphs.

Key words. finite model theory, first-order logic, bounded treewidth, planar graphs, Gaifman locality

1. Introduction.

The subject of model theory is concerned with the relationship between syntactic and semantic properties of logic. Among classical results in the subject are preservation theorems which relate syntactic restrictions on first-order logic with structural properties of the classes of structures defined. A key example is the Łoś–Tarski theorem, which asserts that a first-order formula is preserved under extensions on all structures if and only if it is logically equivalent to an existential formula (see [13]). One direction of this result is easy, namely, that any formula that is purely existential is preserved under extensions, and this holds for any class of structures. The other direction, going from the semantic restriction to the syntactic restriction, makes key use of the compactness of first-order logic and hence of infinite structures.

In the early development of finite model theory, when it was realized that finite structures are the ones that are interesting from the point of view of studying computation, it was observed that most classical preservation theorems from model theory fail when only finite structures are allowed. In particular, the Łoś–Tarski theorem fails on finite structures [16, 12]. These results suggest that the class of finite structures is not well behaved from the point of view of model theory. However, when one considers the computational structures that arise in practice and are used as interpretations for logical languages (for instance, program models interpreting specifications or databases interpreting queries), in many cases they are not only finite but also satisfy other structural restrictions as well. This motivates the study of not just the

class of finite structures, but that of well-behaved subclasses of this class as well. Note that classical model theory, in most of its more advanced parts, also considers restricted classes of structures such as stable, simple, and o-minimal structures, and specific structures that are of interest in other areas of mathematics.

There are certain restrictions on finite structures that have proved especially useful in modern graph structure theory and also from an algorithmic point of view. For instance, many intractable computational problems become tractable when restricted to planar graphs or structures of bounded treewidth [4]. This is also the case in relation to evaluation of logical formulas [9]. A common generalization of classes of bounded treewidth and planar graphs are classes of structures that exclude a minor, which have also been extensively studied.

A study of preservation properties for such restricted classes of finite structures was initiated in [1]. There, the focus was on the homomorphism preservation theorem, whose status on the class of finite structures was open. It was shown that this preservation property holds for any class of structures of bounded degree or treewidth or that excludes some minor (and has certain other closure properties). In the present paper, we investigate the Łoś–Tarski extension preservation property on these classes of finite structures. Note that the failure of the property on the class of all finite structures does not imply its failure on subclasses. If one considers the nontrivial direction of the preservation theorem on a class $\mathcal{C}$, it says that any sentence φ that is preserved under extensions *on* $\mathcal{C}$ is equivalent *on* $\mathcal{C}$ to an existential sentence. Thus, restricting to a subclass $\mathcal{C}'$ of $\mathcal{C}$ weakens both the hypothesis and the conclusion of the statement.

We show that the extension preservation theorem holds for any class of finite structures closed under substructures and disjoint unions that is also *wide* in the sense that any sufficiently large structure in the class contains a large number of elements that are far apart. This includes, for instance, any class of structures of bounded degree. While classes of structures of bounded treewidth are not wide, they are nearly so in that they can be made wide by removing a small number of elements. We use this property and show that it implies the extension preservation theorem for the class $\mathcal{T}_k$—the class of structures of treewidth k or less (note that this is not as general as saying that the property holds for all classes of bounded treewidth). Finally, although all classes defined by excluded minors are known to be *almost wide* in the same sense as $\mathcal{T}_k$ is, we show that the construction does not extend to them. We provide a counterexample to the extension preservation property for the class of planar graphs and, indeed, even for the class of planar graphs of treewidth at most four. This contrasts with the results obtained for the homomorphism preservation property in [1] as this property was shown to hold for all classes excluding a graph minor and closed under substructures and disjoint unions.

The main methodology in establishing the preservation property for a class of structures $\mathcal{C}$ is to show an upper bound on the size of a minimal model of a first-order sentence φ that is preserved under extensions on $\mathcal{C}$. The way we do this is to show that for any sufficiently large model $\mathbf{A}$ of φ, there is a proper substructure of $\mathbf{A}$ and an extension of $\mathbf{A}$ that cannot be distinguished by φ. In section 3 we establish this for the relatively simple case of acyclic structures by means of a Hanf locality argument. Section 4 contains the main combinatorial argument for wide structures which uses Gaifman locality and an iterated construction of the substructure of $\mathbf{A}$. In section 5, the combinatorial argument is adapted to the classes $\mathcal{T}_k$. Finally, in section 6 we discuss the existence of a counterexample in the case of planar graphs. We begin in section 2 with some background and definitions.

2. Preliminaries. We use standard notation and terminology from finite model theory (see [5]). Some particular definitions and notation are explained in this section.

2.1. Relational structures. A *relational vocabulary* σ is a finite set of *relation symbols*, each with a specified *arity*. A *σ-structure* $\mathbf{A}$ consists of a *universe* A, or *domain*, and an *interpretation* which associates to each relation symbol $R \in \sigma$ of some arity r a relation $R^{\mathbf{A}} \subseteq A^r$. A *graph* is a structure $\mathbf{G} = (V, E)$, where E is a binary relation that is symmetric and antireflexive. Thus, our graphs are undirected, loopless, and without parallel edges.

A σ-structure $\mathbf{B}$ is called a *substructure* of $\mathbf{A}$ if $B \subseteq A$ and $R^{\mathbf{B}} \subseteq R^{\mathbf{A}}$ for every $R \in \sigma$. It is called an *induced substructure* if $R^{\mathbf{B}} = R^{\mathbf{A}} \cap B^r$ for every $R \in \sigma$ of arity r. Notice the analogy with the graph-theoretical concept of *subgraph* and *induced subgraph*. A substructure $\mathbf{B}$ of $\mathbf{A}$ is proper if $\mathbf{A} \neq \mathbf{B}$. If $\mathbf{A}$ is an induced substructure of $\mathbf{B}$, we say that $\mathbf{B}$ is an *extension* of $\mathbf{A}$. If $\mathbf{A}$ is a proper induced substructure, then $\mathbf{B}$ is a proper extension. If $\mathbf{B}$ is the disjoint union of $\mathbf{A}$ with another σ-structure, we say that $\mathbf{B}$ is a *disjoint extension* of $\mathbf{A}$. If $S \subseteq A$ is a subset of the universe of $\mathbf{A}$, then $\mathbf{A} \cap S$ denotes the *induced substructure generated by* S; in other words, the universe of $\mathbf{A} \cap S$ is S, and the interpretation in $\mathbf{A} \cap S$ of the r-ary relation symbol R is $R^{\mathbf{A}} \cap S^r$.

The *Gaifman graph* of a σ-structure $\mathbf{A}$, denoted by $\mathcal{G}(\mathbf{A})$, is the (undirected) graph whose set of nodes is the universe of $\mathbf{A}$, and whose set of edges consists of all pairs (a, a') of distinct elements of A such that a and a' appear together in some tuple of a relation in $\mathbf{A}$. The *degree* of a structure is the degree of its Gaifman graph, that is, the maximum number of neighbors of nodes of the Gaifman graph.

2.2. Neighborhoods and treewidth. Let $\mathbf{G} = (V, E)$ be a graph. Moreover, let $u \in V$ be a node and let $d \geq 0$ be an integer. The *d-neighborhood* of u in $\mathbf{G}$, denoted by $N_d^{\mathbf{G}}(u)$, is defined inductively as follows:

1. $N_0^{\mathbf{G}}(u) = \{u\}$;
2. $N_{d+1}^{\mathbf{G}}(u) = N_d^{\mathbf{G}}(u) \cup \{v \in V : (v, w) \in E \text{ for some } w \in N_d^{\mathbf{G}}(u)\}$.

If $\mathbf{A}$ is a σ-structure, a is a point in $\mathbf{A}$, and $\mathbf{G}$ is the Gaifman graph of $\mathbf{A}$, we let $N_d^{\mathbf{A}}(a)$ denote the d-neighborhood of a in $\mathbf{G}$. Where it causes no confusion, we also write $N_d^{\mathbf{A}}(a)$ for the substructure of $\mathbf{A}$ generated by this set.

A *tree* is an acyclic connected graph. A *tree-decomposition* of $\mathbf{G} = (V, E)$ is a pair (T, L) where T is a tree and $L : T \to \wp(V)$ is a labeling of the nodes of T by sets of vertices of $\mathbf{G}$ such that

1. for every edge $\{u, v\} \in E$, there is a node t of T such that $\{u, v\} \subseteq L(t)$;
2. for every $u \in V$, the set $\{t \in T : u \in L(t)\}$ forms a connected subtree of T.

The *width* of a tree-decomposition (T, L) is $\max_{t \in T} |L(t)| - 1$. The *treewidth* of $\mathbf{G}$ is the smallest k for which $\mathbf{G}$ has a tree-decomposition of width k. The *treewidth* of a σ-structure is the treewidth of its Gaifman graph. Note that trees have treewidth one.

2.3. First-order logic, monadic second-order logic, and types. Let σ be a relational vocabulary. The *atomic formulas* of σ are those of the form $R(x_1, \ldots, x_r)$, where $R \in \sigma$ is a relation symbol of arity r, and $x_1, \ldots, x_r$ are first-order variables that are not necessarily distinct. Formulas of the form $x = y$ are also atomic.

The collection of *first-order formulas* is obtained by closing the atomic formulas under negation, conjunction, disjunction, and universal and existential first-order quantification. The collection of *existential* first-order formulas is obtained by closing the atomic formulas and the negated atomic formulas under conjunction, disjunction,

and existential quantification. The semantics of first-order logic is standard.

The collection of *monadic second-order formulas* is obtained by closing the atomic formulas under negation, conjunction, disjunction, universal and existential first-order quantification, and universal and existential second-order quantification over sets. The semantics of monadic second-order logic is also standard.

The quantifier rank of a formula, be it first-order or monadic second-order, is the depth of nesting of quantifiers in the formula.

Let $\mathbf{A}$ be a σ-structure, and let $a_1, \ldots, a_n$ be points in $\mathbf{A}$. If $\varphi(x_1, \ldots, x_n)$ is a formula with free variables $x_1, \ldots, x_n$, we use the notation $\mathbf{A} \models \varphi(a_1, \ldots, a_n)$ to denote the fact that φ is true in $\mathbf{A}$ when x_i is interpreted by a_i. If m is an integer, the first-order m-type of $a_1, \ldots, a_n$ in $\mathbf{A}$ is the collection of all first-order formulas $\varphi(x_1, \ldots, x_n)$ of quantifier rank at most m, up to logical equivalence, for which $\mathbf{A} \models \varphi(a_1, \ldots, a_n)$. The monadic second-order m-type of $a_1, \ldots, a_n$ in $\mathbf{A}$ is the collection of all monadic second-order formulas $\varphi(x_1, \ldots, x_n)$ of quantifier rank at most m, up to logical equivalence, for which $\mathbf{A} \models \varphi(a_1, \ldots, a_n)$. In this definition, by quantifier rank of a monadic second-order formula we mean the *total* quantifier rank, which means that we include both first-order and second-order quantifiers in the count. We note that some definitions of monadic second-order type in the literature distinguish between first-order and second-order quantifier rank [14], but we do not need this refinement.

2.4. Preservation under extensions and minimal models. Let $\mathcal{C}$ be a class of finite σ-structures that is closed under induced substructures. Let φ be a first-order sentence. We say that φ is *preserved under extensions* on $\mathcal{C}$ if whenever $\mathbf{A}$ and $\mathbf{B}$ are structures in $\mathcal{C}$ such that $\mathbf{B}$ is an extension of $\mathbf{A}$, then $\mathbf{A} \models \varphi$ implies $\mathbf{B} \models \varphi$. We say that $\mathbf{A}$ is a *minimal model* of φ if $\mathbf{A} \models \varphi$ and every proper induced substructure $\mathbf{A}'$ of $\mathbf{A}$ is such that $\mathbf{A}' \not\models \varphi$. The following lemma states that the existential sentences are precisely those that have finitely many minimal models. Its proof is part of folklore.

LEMMA 2.1. *Let $\mathcal{C}$ be a class of finite σ-structures that is closed under induced substructures. Let φ be a first-order sentence that is preserved under extensions on $\mathcal{C}$. Then the following are equivalent:*

1. *φ is equivalent on $\mathcal{C}$ to an existential sentence.*
2. *φ has finitely many minimal models in $\mathcal{C}$.*

In the rest of the paper, we use several times the implication from item 2 to item 1. Just for completeness, this is proved by taking the disjunction of the existential closure of the atomic types of each of the finitely many minimal models.

3. Acyclic structures. We begin with the simple case of acyclic structures, by which we mean structures whose Gaifman graph is acyclic. We show that any class of such structures satisfying certain closure properties admits the extension preservation property. Note that for structures whose Gaifman graphs are acyclic, there is no loss of generality in assuming that the vocabulary σ consists of unary and binary relations only.

The proof makes heavy use of a technique known as Hanf locality, for which we provide the necessary background first.

Let $\mathbf{A}$ and $\mathbf{B}$ be structures. If $\mathbf{a} \in A^m, \mathbf{b} \in B^m$ are m-tuples, we write $(\mathbf{A}, \mathbf{a}) \equiv^m (\mathbf{B}, \mathbf{b})$ to denote that the first-order m-type of $\mathbf{a}$ in $\mathbf{A}$ is the same as the first-order m-type of $\mathbf{b}$ in $\mathbf{B}$. In particular $\mathbf{A} \equiv^m \mathbf{B}$ denotes that the structures $\mathbf{A}$ and $\mathbf{B}$ are not distinguished by any first-order sentence of quantifier rank m or less. The equivalence relation $\equiv^m$ is characterized by Ehrenfeucht–Fraïssé games (see, for instance, [5]). These can be used to show that the relation is a congruence with respect to disjoint

union with a multiplicity threshold of m. A precise statement of this useful property is given in the following lemma. We write $\mathbf{A} \oplus \mathbf{B}$ to denote the disjoint union of the structures $\mathbf{A}$ and $\mathbf{B}$ and $n\mathbf{A}$ to denote the disjoint union of n copies of $\mathbf{A}$ (see [5, Prop. 2.3.10]).

LEMMA 3.1. *Let $\mathbf{A}_1$, $\mathbf{A}_2$, $\mathbf{B}_1$, and $\mathbf{B}_2$ be structures, and let m, n, and n' be integers.*

1. *If $\mathbf{A}_1 \equiv^m \mathbf{B}_1$ and $\mathbf{A}_2 \equiv^m \mathbf{B}_2$, then $\mathbf{A}_1 \oplus \mathbf{A}_2 \equiv^m \mathbf{B}_1 \oplus \mathbf{B}_2$.*
2. *If $n, n' \geq m$ and $\mathbf{A} \equiv^m \mathbf{B}$, then $n\mathbf{A} \equiv^m n'\mathbf{B}$.*

A useful sufficient condition for the $\equiv^m$ equivalence of structures is provided by Hanf locality. The *Hanf type* of radius r of a structure $\mathbf{A}$ is the multiset of isomorphism types of r-neighborhoods of elements in $\mathbf{A}$. We say that two structures $\mathbf{A}$ and $\mathbf{B}$ are *Hanf equivalent* with radius r and threshold q, written $\mathbf{A} \simeq_{r,q} \mathbf{B}$, if, for every $a \in A$, *either* the number of occurrences of the isomorphism type of $N_r^{\mathbf{A}}(a)$ in the Hanf type of $\mathbf{A}$ is the same as that in the Hanf type of $\mathbf{B}$ *or* it is at least q, and conversely for every element $b \in B$. This allows us to state the following (for a proof see, for instance, [14, Thm. 4.24]).

THEOREM 3.2 (Hanf locality). *For every vocabulary σ and every m there are r and q such that for any pair of σ-structures $\mathbf{A}$ and $\mathbf{B}$ if $\mathbf{A} \simeq_{r,q} \mathbf{B}$, then $\mathbf{A} \equiv^m \mathbf{B}$.*

As a first step towards the main result of this section, we establish a useful property of connected, acyclic structures with degree at most 2. These are structures whose Gaifman graph consists of a simple path. This is a very restricted class of structures. In particular, any class of such structures is wide, in the sense of Theorem 4.3 below. Thus, on any class of such structures, the extension preservation property holds by virtue of Theorem 4.3. However, the property in Lemma 3.3 provides a useful stepping stone in our proof for all acyclic structures and also serves as a useful warm-up for the proof in section 4.

LEMMA 3.3. *For every vocabulary σ and every $m > 0$ there is a p such that if $\mathbf{A}$ is a σ-structure whose Gaifman graph is connected, acyclic, and of degree at most 2 and $|A| > p$, then there is a disjoint extension $\mathbf{B}$ of $\mathbf{A}$ and a proper substructure $\mathbf{A}'$ of $\mathbf{A}$ such that $\mathbf{A}' \equiv^m \mathbf{B}$.*

Proof. Given m, let r and q be obtained from Theorem 3.2. We first consider the $2r$-neighborhoods of elements of $\mathbf{A}$, returning later to consider r-neighborhoods when we wish to establish the Hanf types of the structures we construct. Clearly, the $2r$-neighborhood type of an element determines its r-neighborhood type. Also note that among σ-structures whose degree is bounded (by 2) there are only finitely many isomorphism types of $2r$-neighborhoods. Let n be the number of such types, let $l = 2r(n+1)+1$, and let $p = nl(q+l)$.

For t the isomorphism type of a $2r$-neighborhood in $\mathbf{A}$, we say that t is *frequent* if there are at least $q+l$ elements in $\mathbf{A}$ whose type is t. Since there are at most n types, the number of occurrences of elements whose type is not frequent is less than $n(q+l)$. Thus, in a path of length p there must be a sequence of l consecutive elements of frequent type. Let $a_1, \ldots, a_l$ be such a sequence. Among the $2rn+1$ central elements of the sequence $a_{r+1}, \ldots, a_{(2n+1)r+1}$ there must be a pair a_i, a_j which have the same type and such that $j - i > 2r$. Let $\mathbf{C}$ be the substructure of $\mathbf{A}$ generated by the elements $a_{i+1}, \ldots, a_j$. We define $\mathbf{B}$ to be $\mathbf{A} \oplus \mathbf{C}$ and $\mathbf{A}'$ to be the substructure of $\mathbf{A}$ generated by $A \setminus C$.

Our aim is to prove $\mathbf{A}' \equiv^m \mathbf{B}$ by showing that $\mathbf{A}' \simeq_{r,q} \mathbf{B}$. We do this by considering how the Hanf type changes in going from $\mathbf{A}$ to $\mathbf{A}'$ and also how it changes in going from $\mathbf{A}$ to $\mathbf{B}$. So, for t the isomorphism type of an r-neighborhood in $\mathbf{A}$, we

say that t is *rare* if there are fewer than q elements in $\mathbf{A}$ whose type is t. Write D for the set of elements $\{a_{i-r+1}, \ldots, a_i, a_{j+1}, \ldots, a_{j+r}\}$. That is, D consists of the r elements that occur immediately before C and the r elements that occur immediately after C in the sequence $a_1, \ldots, a_l$. For any element $a \in \mathbf{A}$ that is not in $C \cup D$, $N_r^{\mathbf{A}}(a) = N_r^{\mathbf{A}'}(a)$. For any element a of $C \cup D$, the multiplicity of the type t of $N_r^{\mathbf{A}}(a)$ may decrease in going from $\mathbf{A}$ to $\mathbf{A}'$. However, t occurs at least $q + l$ times in $\mathbf{A}$ and this multiplicity cannot decrease by more than l as $|C \cup D| \leq l$. Thus, t is not rare in $\mathbf{A}'$. Clearly the elements of D may have types in $\mathbf{A}'$ that are different from their types in $\mathbf{A}$, and therefore the multiplicities of these types may increase.

Similarly, for any element $a \in A$, $N_r^{\mathbf{A}}(a) = N_r^{\mathbf{B}}(a)$, thus any type t that occurs in $\mathbf{A}$ has at least the same multiplicity in $\mathbf{B}$. Let $C' = \{a'_{i+1}, \ldots, a'_j\}$ denote the elements in the new disjoint copy of $\mathbf{C}$. If $a'_k \in C'$ is such that $i + r < k \leq j - r$, then the r-neighborhood of a'_k is isomorphic to $N_r^{\mathbf{A}}(a_k)$. Since the type of a_k is frequent, adding to its multiplicity is not significant. Thus, we only need to consider the types of the elements in $D' = \{a'_{i+1}, \ldots, a'_{i+r+1}, a'_{j-r+1}, \ldots, a'_j\}$. For these elements, the types of their r-neighborhoods in $\mathbf{B}$ may be new and result in an increase of the multiplicities of these types over their occurrences in $\mathbf{A}$. Thus, to establish our result that $\mathbf{A}' \simeq_{r,q} \mathbf{B}$ it suffices to show that there is a bijection $f : D \to D'$ such that for all $a \in D$, $N_r^{\mathbf{A}'}(a) \cong N_r^{\mathbf{B}}(f(a))$. By construction, there is an isomorphism $h : N_{2r}^{\mathbf{A}}(a_i) \to N_{2r}^{\mathbf{A}}(a_j)$ and therefore in particular, for $-r \leq k \leq r$, $N_r^{\mathbf{A}}(a_{i+k}) \cong N_r^{\mathbf{A}}(a_{j+k})$. We can now define the desired bijection f as follows: for $1 \leq k \leq r$, $f(a_{i-k+1}) = a'_{j-k+1}$ and $f(a_{j+k}) = a'_{i+k}$. □

We now use the above lemma to obtain a similar result for connected acyclic structures without a bound on the degree. This is done by reducing the case of general degree to those with degree at most 2 by means of an appropriate translation. For the vocabulary σ, there are only finitely many first-order m-types of σ-structures. Let $\tau_1, \ldots, \tau_n$ be an enumeration of the possible types of a in $\mathbf{A}$, where $\mathbf{A}$ is a connected, acyclic structure and $a \in A$. We refer to a as *the distinguished element* of $(\mathbf{A}, a)$. We define a new vocabulary σ' which has the same binary relations as σ and a unary relation T_i for each τ_i.

Let $\mathbf{A}$ be a σ'-structure that is connected, acyclic, and of degree at most 2 with the property that for each $a \in A$ there is a unique i such that $T_i(a)$. We construct from $\mathbf{A}$ a σ-structure $\tilde{\mathbf{A}}$ as follows: each element $a \in A$ with $T_i(a)$ is replaced by a structure $\mathbf{T}_a$ of type τ_i. Moreover, for any binary relation R, $(b, c) \in R^{\tilde{\mathbf{A}}}$ if and only if *either* b and c are in the same structure $\mathbf{T}_a$ and $(b, c) \in R^{\mathbf{T}_a}$ *or* b is the distinguished element of $\mathbf{T}_a$, c is the distinguished element of $\mathbf{T}_{a'}$, and $(a, a') \in R^{\mathbf{A}}$. The structure $\tilde{\mathbf{A}}$ is not uniquely determined by $\mathbf{A}$ as there are, in general, many structures of type τ_i. However, the following lemma is easily established along the lines of Lemma 3.1.

LEMMA 3.4. *Let* $\mathbf{A}$ *and* $\mathbf{B}$ *be connected, acyclic structures of degree at most* 2 *with the property that for each element there is a unique* i *such that* T_i *holds, and let* m *be an integer. If* $\mathbf{A} \equiv^m \mathbf{B}$, *then* $\tilde{\mathbf{A}} \equiv^m \tilde{\mathbf{B}}$.

We will call a structure of the form $\tilde{\mathbf{A}}$ a σ-companion of $\mathbf{A}$.

LEMMA 3.5. *For every vocabulary* σ *and every* $m > 0$ *there is a* p *such that if* $\mathbf{A}$ *is a structure whose Gaifman graph is connected and acyclic and which contains a path with more than* p *elements, then there is a disjoint extension* $\mathbf{B}$ *of* $\mathbf{A}$ *and a proper substructure* $\mathbf{A}'$ *of* $\mathbf{A}$ *such that* $\mathbf{A}' \equiv^m \mathbf{B}$.

Proof. Let σ' be the vocabulary, as above, with a unary relation for each m-type of σ-structures, and let p be as in Lemma 3.3 for the vocabulary σ'. Let $a_1, \ldots, a_p$ be the path of length p in $\mathbf{A}$. For each i, let S_i be the set of elements that are reachable

(in the Gaifman graph of $\mathbf{A}$) from a_i without going through a_j for any $j \neq i$, and let $\mathbf{S}_i$ be the substructure generated by S_i. We define the σ'-structure $s\mathbf{A}$ as follows. The universe of $s\mathbf{A}$ is $\{a_1, \ldots, a_p\}$; $T_k(a_i)$ holds if and only if a_i has type τ_k in $\mathbf{S}_i$; and $(a_i, a_j) \in R^{s\mathbf{A}}$ if and only if $(a_i, a_j) \in R^{\mathbf{A}}$. Then it is easily seen that $\mathbf{A}$ is a σ-companion of $s\mathbf{A}$ (which is defined, since the Gaifman graph of $\mathbf{A}$ is acyclic).

Let $s\mathbf{A}'$ and $s\mathbf{B}$ be the structures obtained from $s\mathbf{A}$ by Lemma 3.3. We obtain $\mathbf{A}'$ as a σ-companion of $s\mathbf{A}'$ by replacing each element a_i by the structure $(\mathbf{S}_i, a_i)$. This ensures that $\mathbf{A}'$ is a substructure of $\mathbf{A}$. Similarly, we obtain $\mathbf{B}$ as a σ-companion of $s\mathbf{B}$, ensuring that $\mathbf{B}$ is a disjoint extension of $\mathbf{A}$. Since $s\mathbf{A}' \equiv^m s\mathbf{B}$ by Lemma 3.3, we also have $\mathbf{A}' \equiv^m \mathbf{B}$ by Lemma 3.4. □

Note that in both Lemmas 3.3 and 3.5 $\mathbf{B}$ is not only a disjoint extension of $\mathbf{A}$, it is in fact also the disjoint union of $\mathbf{A}$ with a substructure of $\mathbf{A}$.

In order to prove the main theorem of this section, we need one further composition property of acyclic structures along the lines of the properties in Lemma 3.1. In order to define it, we introduce some further notation. Given an acyclic structure $\mathbf{A}$ and an element $a \in A$, for every neighbor b of a let S_b be the set of elements in A which are reachable from b (in the Gaifman graph) without going through a and let $\mathrm{tp}_a(b)$ denote the first-order m-type of b in $\mathbf{S}_b$. We define the *child-type* of b with respect to a to be the pair $(\mathrm{at}(a,b), \mathrm{tp}_a(b))$, where $\mathrm{at}(a,b)$ is the atomic type of the pair (a,b). Finally, we define the *child-type* of an element a, written $\mathrm{ct}^{\mathbf{A}}(a)$, to be the multiset of the child-types of its neighbors with respect to a. Write $(\mathbf{A}, a) \sim_m (\mathbf{B}, b)$ to denote that every type *either* occurs the same number of times in $\mathrm{ct}^{\mathbf{A}}(a)$ as it does in $\mathrm{ct}^{\mathbf{B}}(b)$ *or* occurs at least m times in both. The following lemma is now a straightforward application of games.

LEMMA 3.6. *If* $(\mathbf{A}, a) \sim_m (\mathbf{B}, b)$*, then* $(\mathbf{A}, a) \equiv_m (\mathbf{B}, b)$.

We are now ready for the main theorem of this section.

THEOREM 3.7. *Let* $\mathcal{C}$ *be a class of acyclic finite structures, closed under substructures and disjoint unions. Then, on* $\mathcal{C}$*, every first-order sentence that is preserved under extensions is equivalent to an existential sentence.*

Proof. Let φ be such a sentence of quantifier rank m. We aim to show that there is an N such that if $\mathbf{A}$ in $\mathcal{C}$ is a model of φ with more than N elements, then $\mathbf{A}$ is not minimal. Let p be as in Lemma 3.5, let n be the number of distinct first-order m-types of connected structures in $\mathcal{C}$, and let q be the number of distinct types of the form $(\mathrm{at}(a,b), \mathrm{tp}_a(b))$, where a and b are neighbors in a structure in $\mathcal{C}$. Let $N = mn(qm)^p$.

Now, suppose $\mathbf{A}$ is a minimal model of φ in $\mathcal{C}$ with more than N elements. We consider three cases.

Case 1. $\mathbf{A}$ has more than mn distinct connected components. Then there must be some collection of more than m such components that have the same first-order m-type. Consider the structure $\mathbf{A}'$ obtained by removing one of these components. By Lemma 3.1 $\mathbf{A}' \equiv^m \mathbf{A}$, contradicting the minimality of $\mathbf{A}$.

If $\mathbf{A}$ has mn or fewer connected components, one of these components must have at least $(qm)^p$ elements. Call this component $\mathbf{C}$ the large component.

Case 2. The large component of $\mathbf{A}$ has a node of degree greater than qm. Call this node a. The type $\mathrm{ct}^{\mathbf{A}}(a)$ must contain a type with more than m occurrences. Let b be a neighbor of a that has this child-type with respect to a. Let $\mathbf{A}'$ be the substructure of $\mathbf{A}$ obtained by removing all elements in S_b. By Lemma 3.6, we have $\mathbf{A}' \equiv^m \mathbf{A}$, again contradicting the minimality of $\mathbf{A}$.

Case 3. If $\mathbf{C}$ does not contain a node of degree greater than qm, it must contain a path of length p. Thus, by Lemma 3.5, there is a proper substructure $\mathbf{C}'$ of $\mathbf{C}$ and a

disjoint extension $\mathbf{D}$ of $\mathbf{C}$ such that $\mathbf{C}' \equiv^m \mathbf{D}$. Let $\mathbf{A}'$ be the structure obtained from $\mathbf{A}$ by replacing $\mathbf{C}$ by $\mathbf{C}'$ and let $\mathbf{B}$ be the structure obtained from $\mathbf{A}$ by replacing $\mathbf{C}$ by $\mathbf{D}$. Then, by Lemma 3.1, $\mathbf{A}' \equiv^m \mathbf{B}$. Note also that $\mathbf{A}'$ and $\mathbf{B}$ are in $\mathcal{C}$ since it is closed under substructures and disjoint unions. Since φ is preserved under extensions on $\mathcal{C}$, $\mathbf{B} \models \varphi$, and hence $\mathbf{A}' \models \varphi$, again contradicting the minimality of $\mathbf{A}$. □

4. Wide structures. This section will focus on classes of structures that are *wide*, meaning that large enough structures contain many points that are pairwise far apart from each other. It was shown in [1] that the homomorphism preservation theorem holds for any wide class of structures. Here we aim to establish the analogous result for the extension preservation property.

DEFINITION 4.1. *A set of elements B in a σ-structure $\mathbf{A}$ is* d-scattered *if for every pair of distinct $a, b \in B$ we have $N_d^{\mathbf{A}}(a) \cap N_d^{\mathbf{A}}(b) = \emptyset$.*

We say that a class of finite σ-structures $\mathcal{C}$ is wide *if for every d and m there exists an N such that every structure in $\mathcal{C}$ of size at least N contains a d-scattered set of size m.*

The canonical example of a wide class of structures is the collection of all structures of degree bounded by a constant. More generally, any class of structures whose maximum degree is bounded by $n^{o(1)}$, where n is the number of elements of the structure, is wide.

Unfortunately, the techniques and arguments of section 3 based on Hanf locality will not be enough for our current purpose. Instead, we will have to resort to Gaifman locality, for which we provide the necessary background first.

For every integer $r \geq 0$, let $\delta(x, y) \leq r$ denote the first-order formula expressing that the distance between x and y in the Gaifman graph is at most r. Let $\delta(x, y) > r$ denote the negation of this formula. Note that the quantifier rank of $\delta(x, y) \leq r$ is bounded by r. A *basic local sentence* is a sentence of the form

$$(\exists x_1) \cdots (\exists x_n) \left(\bigwedge_{i \neq j} \delta(x_i, x_j) > 2r \wedge \bigwedge_i \psi^{N_r(x_i)}(x_i) \right), \tag{4.1}$$

where ψ is a first-order formula with one free variable. Here, $\psi^{N_r(x_i)}(x_i)$ stands for the relativization of ψ to $N_r(x_i)$; that is, the subformulas of ψ of the form $(\exists x)(\theta)$ are replaced by $(\exists x)(\delta(x, x_i) \leq r \wedge \theta)$, and the subformulas of the form $(\forall x)(\theta)$ are replaced by $(\forall x)(\delta(x, x_i) \leq r \rightarrow \theta)$. The *locality radius* of a basic local sentence is r. Its *width* is n. Its *local quantifier rank* is the quantifier rank of ψ. We will use the fact that basic local sentences are preserved under disjoint extensions. Note, however, that they may not be preserved under plain extensions since in that case the neighborhoods can grow.

The main result about basic local sentences is that they form a building block for first-order logic. This is known as Gaifman's theorem (for a proof, see, for example, [5, Thm. 2.5.1]).

THEOREM 4.2 (Gaifman locality). *Every first-order sentence is equivalent to a Boolean combination of basic local sentences.*

The following theorem contains the main technical construction of the paper.

THEOREM 4.3. *Let $\mathcal{C}$ be a class of finite σ-structures that is wide and closed under substructures and disjoint unions. Then, on $\mathcal{C}$, every first-order sentence that is preserved under extensions is equivalent to an existential sentence.*

Proof. Let φ be a first-order sentence that is preserved under extensions on $\mathcal{C}$.

By Gaifman's theorem we may assume that $\varphi = \bigvee_{i\in I} \tau_i$, with

$$\tau_i = \bigwedge_{j\in J_i} \theta^i_j \wedge \bigwedge_{k\in K_i} \neg\theta^i_k, \tag{4.2}$$

where each θ^i_h is a basic local sentence. Now we define a list of parameters that we need in the proof (the reader may skip this list now and use it to look up the values when they are needed):

- r is the maximum of the locality radii of all θ^i_h;
- s is the sum of all widths of all θ^i_h;
- m is the maximum of the local quantifier ranks of all θ^i_h;
- ℓ is the number of disjuncts in φ, so $\ell = |I|$;
- $n = (\ell + 2)s$;
- $M = m + 3r + 3$;
- $d = 2(r + 1)(\ell + 1)s + 6r + 2$;
- q is the number of monadic second-order M-types with one free variable;
- N is such that every structure in $\mathcal{C}$ of size at least N contains a $(4dq+2r+1)$-scattered set of size $(n-1)q + s + \ell s + 1$.

Our goal is to show that the minimal models of φ have size less than N. Suppose on the contrary that $\mathbf{A}$ is a minimal model of φ of size at least N. We define the *type* of a point $a \in A$ to be its monadic second-order M-type in $\mathbf{A} \cap N^{\mathbf{A}}_d(a)$. In other words, the type of a is the collection of all monadic second-order formulas $\psi(x)$ of quantifier rank at most M, up to logical equivalence, for which $\mathbf{A} \cap N^{\mathbf{A}}_d(a) \models \psi(a)$. We say that a realizes its type. The reason we consider monadic second-order types, instead of first-order types, will become clear later in the proof. Let $t_1, \ldots, t_q$ be all possible types. We need a couple of definitions. Let C be a subset of A and t a type. We say that t is *covered by* C if for all realizations a of t we have $N^{\mathbf{A}}_d(a) \subseteq C$. We say that t is *free over* C if there are at least n realizations $a_1, \ldots, a_n$ of t such that $N^{\mathbf{A}}_d(a_i)$ and $N^{\mathbf{A}}_d(a_j)$ are pairwise disjoint and do not intersect C.

Claim 4.4. *There exist a radius $e \leq 2dq$ and a set D of at most $(n-1)q$ points in A such that each type is either covered by $N^{\mathbf{A}}_e(D)$ or free over $N^{\mathbf{A}}_e(D)$.*

Proof. We define D and e inductively. Let $D_0 = \emptyset$ and $e_0 = 0$. Suppose now that D_i and e_i are already defined. Let $C = N^{\mathbf{A}}_{e_i}(D_i)$. If all types are either covered by C or free over C, then let $D = D_i$ and $e = e_i$. Otherwise, let j be minimal such that type t_j is neither covered by C nor free over C. We define a set E inductively as follows. Let $E_0 = \emptyset$. Suppose now that E_t is already defined. If there is no realization of t_j outside $N^{\mathbf{A}}_{2d}(C \cup E_t)$, then let $E = E_t$ and we are done with the construction of E. Otherwise, let a_{t+1} be a realization of t_j outside $N^{\mathbf{A}}_{2d}(C \cup E_t)$ and let $E_{t+1} = E_t \cup \{a_{t+1}\}$. Note that this iteration cannot continue beyond $n-1$ steps since otherwise t_j would be free over C. This means that the iteration stops, and when it does $|E| \leq n-1$ and t_j is covered by any set that contains $N^{\mathbf{A}}_{2d}(C \cup E)$, and in particular by $N^{\mathbf{A}}_{e_i+2d}(D_i \cup E)$. Let $D_{i+1} = D_i \cup E$ and $e_{i+1} = e_i + 2d$. The construction stops after at most q steps because at each step one new type is covered and remains covered for the rest of the construction. This shows that $|D| \leq (n-1)q$ and $e \leq 2dq$, which proves the claim. ∎

In the following, we fix e and D according to Claim 4.4. We say that a type t is *frequent* if it is not covered by $N^{\mathbf{A}}_e(D)$. Otherwise we say that t is *rare*.

We shall build a finite sequence of sets $S_0 \subseteq S_1 \subseteq \cdots \subseteq S_p \subseteq A$, with $p \leq \ell$, so that the last set S_p in the sequence will be such that the substructure of $\mathbf{A}$ induced by S_p is a proper substructure of $\mathbf{A}$ that satisfies φ. This will contradict the minimality

of $\mathbf{A}$ and will prove the theorem. The sequence S_i is constructed inductively together with a second sequence of sets $C_0 \subseteq C_1 \subseteq \cdots \subseteq C_p \subseteq A$ called the *centers*, and a sequence of sets of indices $I_0 \subseteq I_1 \subseteq \cdots \subseteq I_p \subseteq I$ (recall that φ is the disjunction of the formulas τ_i from (4.2) for $i \in I$). Moreover, the following conditions will be preserved by the inductive construction for every $i < p$.

(a) $S_i \subseteq N_r^{\mathbf{A}}(C_i)$.
(b) $|C_i| \leq is$.
(c) No disjoint extension of $\mathbf{A} \cap S_i$ satisfies $\bigvee_{j \in I_i} \tau_j$.
(d) $N_e^{\mathbf{A}}(D)$ and $N_d^{\mathbf{A}}(C_i)$ are disjoint.
(e) $|I_i| = i$.

Observe that it is a direct consequence of property (d) that the type of each $a \in C_i$ is frequent.

Let $S_0 = C_0 = I_0 = \emptyset$, and let us assume that S_i, C_i, and I_i have already been defined with the properties above. We construct S_{i+1}, C_{i+1}, and I_{i+1}. Let $\mathbf{B}$ be the disjoint union of $\mathbf{A}$ with a copy of $\mathbf{A} \cap S_i$.

(4.3) Since $\mathbf{B}$ is an extension of $\mathbf{A}$, it satisfies φ.

Therefore, there exists an $i' \in I$ such that $\mathbf{B}$ satisfies $\tau_{i'}$. By property (c), since the extension is disjoint, we know that $i' \notin I_i$. Let $I_{i+1} = I_i \cup \{i'\}$. For the rest of the proof, the index i' will be fixed so we drop any reference to it. For example, we will write τ instead of $\tau_{i'}$ and θ_h instead of $\theta_h^{i'}$. Recall that

$$\tau = \bigwedge_{j \in J} \theta_j \wedge \bigwedge_{k \in K} \neg \theta_k.$$

Since $\mathbf{B}$ satisfies τ, in particular it satisfies the positive requirements: $\mathbf{B} \models \bigwedge_{j \in J} \theta_j$. Let W_j be a minimal set of witnesses in $\mathbf{B}$ for the outermost existential quantifiers in θ_j, and let $W = \bigcup_{j \in J} W_j$. We have $|W| \leq s$. Some of these witnesses may be in $\mathbf{A}$ and some may be in the new copy of $\mathbf{A} \cap S_i$ in $\mathbf{B}$. Let $W_A \cup W_B = W$ be such a partition, with W_A being the witnesses in A. The following claim shows that W_A can be chosen far from C_i. This will be needed later.

CLAIM 4.5. *There is a set W of witnesses such that $N_{r+1}^{\mathbf{A}}(C_i) \cap N_r^{\mathbf{A}}(W_A) = \emptyset$.*

Proof. Fix a set W of witnesses so that the number of points b in W_A for which $N_{r+1}^{\mathbf{A}}(C_i)$ and $N_r^{\mathbf{A}}(b)$ are not disjoint is minimal. Suppose that this number is not zero, and let $b \in W_A$ with $N_{r+1}^{\mathbf{A}}(C_i) \cap N_r^{\mathbf{A}}(b) \neq \emptyset$. Let $a \in C_i$ be such that $N_{r+1}^{\mathbf{A}}(a) \cap N_r^{\mathbf{A}}(b) \neq \emptyset$. Then $N_r^{\mathbf{A}}(b) \subseteq N_{3r+1}^{\mathbf{A}}(a) \subseteq N_d^{\mathbf{A}}(a)$. By property (d), the type t of a is frequent. So let a' be a realization of t such that $N_{r+1}^{\mathbf{A}}(W \cup C_i)$ and $N_{3r+1}^{\mathbf{A}}(a')$ are disjoint. Such an a' exists because t is frequent and thus, by Claim 4.4, is free over $N_e^{\mathbf{A}}(D)$ and thus has

$$n > (\ell + 1)s \geq |W \cup C_i|$$

realizations whose d-neighborhoods are pairwise disjoint and disjoint from $N_e^{\mathbf{A}}(D)$.

The goal now is to find a b' such that $N_r^{\mathbf{A}}(b') \subseteq N_{3r+1}^{\mathbf{A}}(a') \subseteq N_d^{\mathbf{A}}(a')$ and such that b and b' have the same first-order m-type on $\mathbf{A} \cap N_r^{\mathbf{A}}(b)$ and $\mathbf{A} \cap N_r^{\mathbf{A}}(b')$, respectively. If we achieve this, then b' can replace b as a witness in W_A, and since $N_{r+1}^{\mathbf{A}}(W \cup C_i)$ and $N_{3r+1}^{\mathbf{A}}(a')$ are disjoint, so are $N_{r+1}^{\mathbf{A}}(C_i)$ and $N_r^{\mathbf{A}}(b')$. This will contradict the minimality of W.

In order to find b' as above, let T be the first-order m-type of b on $\mathbf{A} \cap N_r^{\mathbf{A}}(b)$,

and let $\xi(x)$ be the following first-order formula:

$$(\exists y)\left((\forall z)(\delta(y,z)\leq r\rightarrow\delta(x,z)\leq 3r+1)\wedge\bigwedge_{\chi\in T}\chi^{N_r(y)}(y)\right).$$

Note that the conjunction is finite because the first-order m-type T contains finitely many formulas up to logical equivalence, and that the quantifier rank of this formula is bounded by $3r+3+m\leq M$. Also $N_d^{\mathbf{A}}(a)\models\xi(a)$ because b can serve as a witness for y. Therefore, since a and a' have the same monadic second-order M-type and hence the same first-order M-type in $N_d^{\mathbf{A}}(a)$ and $N_d^{\mathbf{A}}(a')$, also $N_d^{\mathbf{A}}(a')\models\xi(a')$. Note here that we are not yet using the full power of monadic second-order type, only the fact that it contains the first-order type as a subset. Let b' be the witness to y in $N_d^{\mathbf{A}}(a')\models\xi(a')$, completing the proof. □

In the following, we fix a set W of witnesses such that $N_{r+1}^{\mathbf{A}}(C_i)\cap N_r^{\mathbf{A}}(W_A)=\emptyset$. We let $\mathbf{C}$ be the substructure of $\mathbf{A}$ induced by $N_e^{\mathbf{A}}(D)\cup N_r^{\mathbf{A}}(W_A)\cup S_i$. We claim that $\mathbf{C}$ satisfies the positive requirements of τ.

Claim 4.6. *$\mathbf{C}$ is a substructure of $\mathbf{A}$ such that $\mathbf{C}\models\bigwedge_{j\in J}\theta_j$.*

Proof. It is obvious that $\mathbf{C}$ is a substructure of $\mathbf{A}$. The point, however, is that $\mathbf{C}$ is in fact the disjoint union of the substructure induced by $N_e^{\mathbf{A}}(D)\cup N_r^{\mathbf{A}}(W_A)$ and the substructure induced by S_i. This is because $S_i\subseteq N_r^{\mathbf{A}}(C_i)$ and $N_{r+1}^{\mathbf{A}}(C_i)$ is disjoint from $N_e^{\mathbf{A}}(D)$ by property (d) and also disjoint from $N_r^{\mathbf{A}}(W_A)$ by Claim 4.5. It follows that the witnesses from $\mathbf{B}$ in W_B can also be found in $\mathbf{C}$. Obviously, also the witnesses from $\mathbf{B}$ in W_A can be found in $\mathbf{C}$. This proves that $\mathbf{C}$ satisfies the positive requirements of τ. □

Consider φ on $\mathbf{C}$. If $\mathbf{C}$ is a model of φ, let $S_p=N_e^{\mathbf{A}}(D)\cup N_r^{\mathbf{A}}(W_A)\cup S_i$ and we are done. Notice that $\mathbf{C}$ is a proper substructure of $\mathbf{A}$ because $\mathbf{A}$ contains $(n-1)q+s+\ell s+1$ points that are $(4dq+2r+1)$-scattered, but $S_p\subseteq N_{2dq+r}^{\mathbf{A}}(D\cup W_A\cup C_i)$ and

$$|D\cup W_A\cup C_i|\leq(n-1)q+s+\ell s.$$

If $\mathbf{C}$ is not a model of φ, it cannot satisfy τ. However, by Claim 4.6, $\mathbf{C}$ satisfies the positive requirements $\bigwedge_{j\in J}\theta_j$. Therefore, $\mathbf{C}$ does not satisfy $\bigwedge_{k\in K}\neg\theta_k$. Let $k\in K$ such that $\mathbf{C}\models\theta_k$. In the next claim we find a substructure of $\mathbf{A}$ that extends $\mathbf{A}\cap S_i$ and forces all its disjoint extensions to satisfy θ_k.

Claim 4.7. *There exist $C_{i+1}\supseteq C_i$ and $S_{i+1}\supseteq S_i$ as required by conditions* (a)–(d).

Proof. Suppose that

$$\theta_k=(\exists x_1)\dots(\exists x_{s'})\left(\bigwedge_{i\neq j}\delta(x_i,x_j)>2r'\wedge\bigwedge_i\psi^{N_{r'}(x_i)}(x_i)\right)$$

for some $r'\leq r, s'\leq s$, and some formula ψ of quantifier rank $m'\leq m$. Without loss of generality we may assume that $m'=m$, and in order to simplify the notation, we will assume that $r'=r$ and $s'=s$. It will suffice to replace r by r' and s by s' in the appropriate places.

We have $\mathbf{C}\models\theta_k$. Let $V=\{a_1,\dots,a_s\}$ be a set of witnesses for the outermost existential quantifiers in θ_k. Then $N_r^{\mathbf{C}}(a_i)\cap N_r^{\mathbf{C}}(a_j)=\emptyset$ for all $i\neq j$ and $\mathbf{C}\cap N_r^{\mathbf{C}}(a_i)\models\psi^{N_r(x_i)}(a_i)$ for all i. Necessarily, the type t of some $a\in V$ is frequent. Otherwise

$N_r^{\mathbf{A}}(V) \subseteq N_e^{\mathbf{A}}(D) \subseteq A$, so $\mathbf{A} \models \theta_k$, and thus $\mathbf{B} \models \theta_k$, because $\mathbf{B}$ is a disjoint extension of $\mathbf{A}$. However, this is impossible because $\mathbf{B} \models \tau$.

So let $a \in V$ have frequent type t. Let Z be a set of s realizations of t such that

(i) $N_d^{\mathbf{A}}(b) \cap N_d^{\mathbf{A}}(b') = \emptyset$ for every pair of distinct $b, b' \in Z$,
(ii) $N_e^{\mathbf{A}}(D) \cap N_d^{\mathbf{A}}(Z) = \emptyset$,
(iii) $N_{r+1}^{\mathbf{A}}(C_i) \cap N_r^{\mathbf{A}}(Z) = \emptyset$.

Such a set Z exists because t is frequent, $n = (\ell+2)s$, and $|C_i| \leq \ell s$ by property (b).

Now, let $F = N_r^{\mathbf{C}}(a)$. Remember that $\mathbf{C} \cap F \models \psi^{N_r(x)}(a)$. As $F \subseteq N_r^{\mathbf{A}}(a)$, it follows that $\mathbf{A} \cap F \models \psi^{N_r(x)}(a)$. Let X be a set variable, and let $\psi^{N_r(x)\cap X}(X, x)$ denote the simultaneous relativization of $\psi(x)$ to $N_r(x)$ and X, that is, the formula obtained from ψ by replacing each subformula of the form $(\exists z)\xi$ by $(\exists z)(\delta(x, z) \leq r \wedge X(z) \wedge \xi)$, and similarly for universally quantified subformulas. Observe that the quantifier rank of $\psi^{N_r(x)\cap X}(X, x)$ is at most $m+r \leq M-1$, where we take r as an upper bound for the quantifier rank of the formula expressing $\delta(x, z) \leq r$. Moreover, $\mathbf{A} \models \psi^{N_r(x)\cap X}(F, a)$ and hence $\mathbf{A} \models \exists X \psi^{N_r(x)\cap X}(a)$.

Next comes the place where we use the full power of monadic second-order types. Since every $b \in Z$ has the same monadic second-order M-type as a, we have $\mathbf{A} \models \exists X \psi^{N_r(x_i)\cap X}(b)$. Thus there is a set $F_b \subseteq N_r^{\mathbf{A}}(b)$ such that $\mathbf{A} \models \psi^{N_r(x_i)\cap X}(F_b, b)$. It follows that

$$\mathbf{A} \cap F_b \models \psi^{N_r(x)}(b).$$

Define $C_{i+1} = C_i \cup Z$ and

$$S_{i+1} = S_i \cup \bigcup_{b \in Z} F_b.$$

Let us prove that C_{i+1} and S_{i+1} satisfy the properties (a), (b), (c), and (d). Property (a) is clear since $F_b \subseteq N_r^{\mathbf{A}}(b)$. For property (b) we have $|C_{i+1}| = |C_i| + s \leq (i+1)s$. Property (d) is satisfied by (ii) in our choice of Z.

Finally, for property (c) we argue as follows. First note that $\mathbf{A} \cap S_{i+1}$ is a disjoint extension of $\mathbf{A} \cap S_i$ because $N_{r+1}^{\mathbf{A}}(C_i) \cap N_r^{\mathbf{A}}(Z) = \emptyset$ by (iii) and $S_i \subseteq N_r^{\mathbf{A}}(C_i)$ by (a). Therefore, no disjoint extension of $\mathbf{A} \cap S_{i+1}$ satisfies τ_j for any $j \in I_i$. It remains to show that no disjoint extension of $\mathbf{A} \cap S_{i+1}$ satisfies τ. However, this is clear from the construction because every disjoint extension of $\mathbf{A} \cap S_{i+1}$ contains witnesses for the outermost existential quantifiers in θ_k, namely, the elements of the set Z. Suppose that $Z = \{b_1, \ldots, b_s\}$. Note that b_i have pairwise distance $> 2r$ by (i), and we have $\mathbf{A} \cap S_{i+1} \models \psi^{N_r(x_i)}(b_i)$, because $N^{\mathbf{A}\cap S_{i+1}}(b_i) = F_{b_i}$ and $\mathbf{A} \cap F_{b_i} \models \psi^{N_r(x_i)}(b_i)$. □

Note that I_{i+1} is constructed to satisfy property (e) as well. This completes the definition of the inductive construction. All that remains to be shown is that the construction stops in at most ℓ steps. Because suppose for contradiction that we have constructed S_ℓ, C_ℓ, and I_ℓ satisfying (a)–(e). Then $I_\ell = I$ by (e), and by (c) no disjoint extension of $\mathbf{A} \cap S_\ell$ satisfies $\varphi = \bigvee_{i \in I} \tau_i$. However,

(4.4) the disjoint union $\mathbf{B}$ of $\mathbf{A} \cap S_\ell$ with $\mathbf{A}$ is an extension of $\mathbf{A}$ and hence does satisfy φ.

This is a contradiction. □

As a direct application of Theorem 4.3, let us consider the class $\mathcal{D}_r$ of all finite σ-structures of degree bounded by r. This class is both wide and closed under substructures and disjoint unions. To see the wideness, note that when the degree of

every node is at most r, for any element a, $N_d(a)$ contains at most r^d elements. Thus, if a structure has size greater than $m(r^d)$, it must contain a d-scattered set of m elements.

THEOREM 4.8. *Let r be an integer. Then, on $\mathcal{D}_r$, every first-order sentence that is preserved under extensions is equivalent to an existential sentence.*

In the following section we show how the argument of Theorem 4.3 can be extended, in some cases, to classes of structures that are *almost wide*.

5. Bounded treewidth structures. The class of structures of bounded degree provide a canonical example of a wide class. On the other hand, acyclic structures (which we considered in section 3) are not wide. Indeed, in an arbitrarily large tree of height 1 all pairs of nodes are at distance at most 2 from each other and there is therefore no large d-scattered set for any $d > 2$, yet the tree may be arbitrarily large. However, in such a structure, the removal of just one element, the root, creates a large scattered set. This motivates the definition below.

DEFINITION 5.1. *A class of finite σ-structures $\mathcal{C}$ is* almost wide *if there is a k such that for every d and m there exists an N such that every structure $\mathbf{A}$ of size at least N in $\mathcal{C}$ contains a set B with at most k elements such that $\mathbf{A} - B$ contains a d-scattered set of size m.*

It was shown in [1] that the homomorphism preservation property holds for almost wide classes of structures which are closed under substructures and disjoint unions. It was also established that any class of graphs that excludes a minor is almost wide.

It is not the case that the extension preservation property holds for all almost wide classes. This can be seen in the next section, where we show, in particular, that it fails for the class of planar graphs. It turns out that the requirement that an almost wide class be closed under substructures and disjoint unions is not sufficient to guarantee the extension preservation property. Nevertheless, closure under unions *over a set of bottlenecks* suffices, a notion we make more precise later. In this section we show that this yields the preservation under extensions property for some particularly interesting almost wide classes. To be precise, we show that the property holds for the class $\mathcal{T}_k$ of all finite σ-structures of treewidth less than k. In other words, we aim to prove the following result.

THEOREM 5.2. *Let k be an integer. Then, on $\mathcal{T}_k$, every first-order sentence that is preserved under extensions is equivalent to an existential sentence.*

The proof of this result requires three ingredients. The first ingredient is a generalization of the disjoint union operation on structures by allowing some nonempty intersection. Let $\mathbf{A}$ and $\mathbf{B}$ be σ-structures, and let $C \subseteq A \cap B$ be such that $\mathbf{A}\cap C = \mathbf{B}\cap C$. The *union of* $\mathbf{A}$ *and* $\mathbf{B}$ *through* C, denoted by $\mathbf{A} \oplus_C \mathbf{B}$, is a new σ-structure defined as follows. The universe of $\mathbf{D} = \mathbf{A} \oplus_C \mathbf{B}$ is $A' \cup B' \cup C$, where A' is a disjoint copy of $A - C$ and B' is a disjoint copy of $B - C$. The relations of $\mathbf{D}$ are defined in the obvious way: If $a_1, \ldots, a_r$ are points in A and $a'_1, \ldots, a'_r$ are the corresponding points in $A' \cup C$, then $(a'_1, \ldots, a'_r) \in R^{\mathbf{D}}$ if and only if $(a_1, \ldots, a_r) \in R^{\mathbf{A}}$. Similarly, if $b_1, \ldots, b_r$ are points in B and $b'_1, \ldots, b'_r$ are the corresponding points in $B' \cup C$, then $(b'_1, \ldots, b'_r) \in R^{\mathbf{D}}$ if and only if $(b_1, \ldots, b_r) \in R^{\mathbf{B}}$. Observe that this construction is precisely the disjoint union of $\mathbf{A}$ and $\mathbf{B}$ when $C = \emptyset$.

The next lemma is a straightforward generalization of the obvious fact that $\mathcal{T}_k$ is closed under disjoint unions. The lemma states, roughly, that $\mathcal{T}_k$ is closed under unions through *subsets of bags of tree-decompositions*.

LEMMA 5.3. *Let k be an integer. Let $\mathbf{A}$ and $\mathbf{B}$ be two σ-structures, let $C \subseteq A \cap B$ be such that $\mathbf{A}\cap C = \mathbf{B}\cap C$, and let (T, L) and (T', L') be tree-decompositions of width k*

of $\mathbf{A}$ *and* $\mathbf{B}$*, respectively. Then, if there exists nodes* $u \in T$ *and* $u' \in T'$ *such that* $C \subseteq L(u) \cap L'(u')$*, then the union of* $\mathbf{A}$ *and* $\mathbf{B}$ *through* C *has treewidth at most* k*.*

Proof. The tree-decomposition of the union is $(T'', L \cup L')$, where $T'' = T \cup T'$ with a new tree edge joining u and u'. □

The second ingredient is the fact that the class of structures of treewidth less than k is almost wide, in the sense of Definition 5.1 that there exists a small set of vertices whose removal produces a large scattered set. Such a set is henceforth called a *bottleneck*. This was proved in [1], but here we state the stronger claim that the bottleneck can be found in a single bag of a tree-decomposition. The proof is the same as in [1] and is sketched here for completeness.

LEMMA 5.4. *For every* k*, and for every* d *and* m*, there exists an* N *such that if* $\mathbf{A}$ *is a* σ*-structure of size at least* N *and* (T, L) *is a tree-decomposition of* $\mathbf{A}$ *of width* k*, then there exist* $u \in T$ *and* $K \subseteq L(u)$ *such that* $\mathbf{A} - K$ *contains a* d*-scattered set of size* m*.*

Proof sketch. Let $p = (m-1)(2d+1)+1$, $M = k!(p-1)^k$, and $N = k(m-1)^M$ and suppose that $\mathbf{A}$ is a structure with more than N elements. Let (T, L) be a tree decomposition of $\mathbf{A}$ such that $L(u)$ has size at most k for all $u \in T$. Note that T has size at least $N/k+1$. Furthermore, suppose T has a node u of degree at least m. But then it is easy to see that taking $K = L(u)$ gives a graph with at least m distinct connected components and therefore a scattered set of size m. On the other hand, if every node of T has degree less than m, then T must have a path with length greater than M. By the sunflower lemma of Erdös and Rado [7], it follows that we can find p distinct nodes $u_1, \ldots, u_p \in T$ and a set $K \subseteq A$ such that for $i \neq j$, $L(u_i) \cap L(u_j) = K$. It can then be shown that $\mathbf{A} - K$ must contain a d-scattered set of size m. □

The third ingredient in the proof is a first-order bi-interpretation between an almost wide structure and a wide structure. From now on we focus on graphs; the construction extends easily to the general case. Let $P_1, \ldots, P_k, Q_1, \ldots, Q_k$ be unary relation symbols and $\sigma = \{E, P_1, \ldots, P_k, Q_1, \ldots, Q_k\}$. For every graph $\mathbf{G} = (V, E^{\mathbf{G}})$ and every tuple $\mathbf{a} = (a_1, \ldots, a_k) \in V^k$ we define a σ-structure $\mathbf{A} = \mathbf{A}(\mathbf{G}, \mathbf{a})$ as follows:

1. $A = V$.
2. $E^{\mathbf{A}} = E^{\mathbf{G}} - \{(a,b) \in A^2 : \{a,b\} \cap \{a_1, \ldots, a_k\} \neq \emptyset\}$.
3. $P_i^{\mathbf{A}} = \{a_i\}$.
4. $Q_i^{\mathbf{A}} = \{b \in A : (a_i, b) \in E^{\mathbf{G}}\}$.

Let us call a σ-structure $\mathbf{A}$ *derived* if $E^{\mathbf{A}}$ is a symmetric and antireflexive binary relation, and there are elements $a_1, \ldots, a_k \in A$ such that $P_i^{\mathbf{A}} = \{a_i\}$ for $1 \leq i \leq k$ and a_i is isolated in the graph underlying $\mathbf{A}$; that is, for $1 \leq i \leq k$ there is no b such that $(a_i, b) \in E^{\mathbf{A}}$. Note that for every derived structure $\mathbf{A}$ there is a unique graph $\mathbf{G}(\mathbf{A})$ and a unique k-tuple $\mathbf{a}(\mathbf{A})$ of vertices of $\mathbf{G}(\mathbf{A})$ such that

$$\mathbf{A} = \mathbf{A}(\mathbf{G}(\mathbf{A}), \mathbf{a}(\mathbf{A})).$$

The point behind the construction of $\mathbf{A} = \mathbf{A}(\mathbf{G}, \mathbf{a})$ is that if $K = \{a_1, \ldots, a_k\}$ is a bottleneck of $\mathbf{G}$ in the sense that $\mathbf{G} - K$ contains a large scattered set, then $\mathbf{A}$ itself has a large scattered set and maintains all the information needed to reconstruct $\mathbf{G}$. Indeed, $\mathbf{G}(\mathbf{A})$ is first-order interpretable in $\mathbf{A}$, and thus we get the following lemma.

LEMMA 5.5. *For every first-order sentence* φ *of vocabulary* $\{E\}$ *there is a sentence* $\tilde{\varphi}$ *of vocabulary* σ *such that for all* σ*-structures* $\mathbf{A}$ *we have the following:*

1. *If* $\mathbf{A} \models \tilde{\varphi}$*, then* $\mathbf{A}$ *is derived.*
2. *If* $\mathbf{A}$ *is derived, then* $\mathbf{A} \models \tilde{\varphi}$ *if and only if* $\mathbf{G}(\mathbf{A}) \models \varphi$*.*

This follows at once from a standard result on syntactical interpretations (cf., for example, Theorem VIII.2.2 of [6]).

Equipped with these three ingredients, we are ready for the main argument.

Proof of Theorem 5.2. Let φ be a first-order sentence that is preserved under extensions in $\mathcal{T}_k$. It suffices to show that φ has finitely many minimal models. Let $\mathbf{G} = (V, E^{\mathbf{G}})$ be a graph in $\mathcal{T}_k$ that is a minimal model of φ. Suppose for contradiction that $\mathbf{G}$ is very large. Let (T, L) be a tree-decomposition of width k of $\mathbf{G}$, and let $K = \{b_1, \ldots, b_k\} \subseteq V$ be a bottleneck; that is, a set such that $\mathbf{G} - K$ contains a large scattered set. By Lemma 5.4 we may assume that $K \subseteq L(u)$ for some $u \in T$. Let $\mathbf{A} = \mathbf{A}(\mathbf{G}, \mathbf{b})$, where $\mathbf{b} = (b_1, \ldots, b_k)$. The idea is to work with $\mathbf{A}$ and $\tilde{\varphi}$ instead of $\mathbf{G}$ and φ and proceed as in the proof of Theorem 4.3. The difference is that $\tilde{\varphi}$ is *not* preserved under extensions. However, preservation under extensions is used only twice in the proof of section 4 (in (4.3) and (4.4)), both times to prove that the disjoint union $\mathbf{B}$ of the structure $\mathbf{A}$ with $\mathbf{A} \cap S_i$ is a model of φ. Claim 5.6 shows that in both cases, $\mathbf{B}$ is a model of $\tilde{\varphi}$.

Claim 5.6. *Let $C \subseteq A$ such that the type of each $a \in C$ is frequent. Let $S \subseteq N_r(C)$ and let $\mathbf{B}$ be the disjoint union of $\mathbf{A}$ with a disjoint copy of $\mathbf{A} \cap S$. Then $\mathbf{B}$ is derived, $\mathbf{G}$ is an induced subgraph of $\mathbf{G}(\mathbf{B})$, and $\mathbf{G}(\mathbf{B})$ belongs to $\mathcal{T}_k$.*

Proof. The bottleneck points are not in C as their type is not frequent and therefore not in $N_r(C)$ as they are isolated in $\mathbf{A}$. Thus, note that $\mathbf{B}$ is derived because the bottleneck points are not in S. Let $\mathbf{H} = \mathbf{G}(\mathbf{B})$. Clearly, $\mathbf{G}$ is an induced subgraph of $\mathbf{H}$. Thus all we have to prove is that $\mathbf{H}$ belongs to $\mathcal{T}_k$. Let $\mathbf{A}' = \mathbf{A} \cap (S \cup K)$, where K is the bottleneck of $\mathbf{G}$. Again, $\mathbf{A}'$ is derived. Let $\mathbf{G}' = \mathbf{G}(\mathbf{A}')$. Clearly, $\mathbf{G}'$ is an induced subgraph of $\mathbf{G}$. In particular, $\mathbf{G}'$ is in $\mathcal{T}_k$ so it has a tree-decomposition of width k. More importantly, since $K \subseteq L(u)$, we can assume as well that K is a subset of some bag of the tree-decomposition of $\mathbf{G}'$. These two facts together imply that the union of $\mathbf{G}$ and $\mathbf{G}'$ through K, which is precisely $\mathbf{H}$, is in $\mathcal{T}_k$ by Lemma 5.3. ∎

This then shows that the $\mathbf{B}$ in (4.3) and (4.4) is a model of $\tilde{\varphi}$. The proof proceeds until we construct a structure $\mathbf{C}$ that satisfies $\tilde{\varphi}$ and is a proper substructure of $\mathbf{A}$. We claim that $\mathbf{C}$ is derived. This is because all bottleneck points have rare type, so they belong to D. Let $\mathbf{H} = \mathbf{G}(\mathbf{C})$. Note now that $\mathbf{H}$ is the union of two subgraphs $\mathbf{G}_1$ and $\mathbf{G}_2$ of $\mathbf{G}$ through the bottleneck K. Again K is a subset of a bag of the tree-decompositions of $\mathbf{G}_1$ and $\mathbf{G}_2$, so $\mathbf{H}$ belongs to $\mathcal{T}_k$ by Lemma 5.3. Moreover $\mathbf{H}$ is a proper induced subgraph of $\mathbf{G}$ and $\mathbf{H} \models \varphi$ by Lemma 5.5. This contradicts the minimality of $\mathbf{G}$, which concludes the proof. ∎

This completes the proof of Theorem 5.2. ∎

Note that this does not imply that the existential preservation theorem holds on all classes of bounded treewidth. Indeed, we show in the next section that it fails, in particular, for the class of planar graphs of treewidth 4.

6. Counterexample for planar graphs. The aim of this section is to show that the preservation-under-extensions property fails on the class of planar graphs. Let us focus first on the class of planar graphs whose vertices are colored either black or white. Later we show how to remove the colors. The vocabulary contains a binary relation symbol E for the edge relation, and a unary relation symbol P for the color. Let φ be the following first-order sentence:

$$\begin{aligned}
\varphi &= (\exists x)(\exists y)\big(x \neq y \wedge P(x) \wedge P(y) \wedge (\varphi_1(x,y) \rightarrow \varphi_2(x,y))\big),\\
\varphi_1(x,y) &= (\forall z)\big(z \neq x \wedge z \neq y \rightarrow \neg P(z) \wedge E(x,z) \wedge E(y,z)\big),\\
\varphi_2(x,y) &= (\forall u)\big(u \neq x \wedge u \neq y\\
&\qquad \rightarrow (\exists v)(\exists w)\big(v \neq w \wedge \neg P(v) \wedge \neg P(w) \wedge E(u,v) \wedge E(u,w)\big)\big).
\end{aligned}$$

We claim that φ is preserved under extensions on the class of black/white-colored

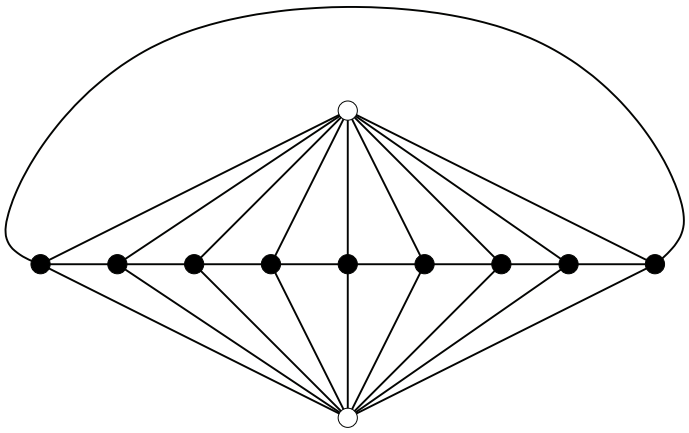

FIG. 1. $\mathbf{G}_9$.

planar graphs. Before we prove this we need a technical gadget. For every $n \geq 3$, let $\mathbf{G}_n$ be the black/white-colored planar graph displayed in Figure 1, where the number of black vertices is exactly n.

It is not hard to see that $\mathbf{G}_n$ does not have any planar proper extension in which all other vertices are adjacent to both white vertices. Let us state this as follows.

LEMMA 6.1. *Let $n \geq 3$, and let $\mathbf{H}$ be a black/white-colored planar graph that is a proper extension of $\mathbf{G}_n$. Then no vertex in $\mathbf{H} - \mathbf{G}_n$ is adjacent to both white vertices in $\mathbf{G}_n$.*

Proof. Let u be a vertex in $\mathbf{H} - \mathbf{G}_n$. Suppose that u is adjacent to both white vertices in $\mathbf{G}_n$. Then $\mathbf{H}$ contains a $\mathbf{K}_5$ minor by contracting one of the edges connecting u to a white vertex in $\mathbf{G}_n$, and by contracting all but two of the edges in $\mathbf{G}_n$ that do not have a white endpoint. This contradicts the planarity of $\mathbf{H}$. □

Now we are ready to show that φ is preserved under extensions on the class of black/white-colored planar graphs.

LEMMA 6.2. *Let $\mathbf{G}$ and $\mathbf{H}$ be black/white-colored planar graphs such that $\mathbf{H}$ is a proper extension of $\mathbf{G}$. If $\mathbf{G}$ is a model of φ, so is $\mathbf{H}$.*

Proof. Suppose that $\mathbf{G}$ is a model of φ, so let a and b be two different white vertices in $\mathbf{G}$. If $\mathbf{G} \not\models \varphi_1(a, b)$, then clearly $\mathbf{H} \not\models \varphi_1(a, b)$ because $\mathbf{G}$ is an induced substructure of $\mathbf{H}$. In this case, $\mathbf{H}$ is also a model of φ and we are done. Otherwise, since $\mathbf{G} \models \varphi$ and $\mathbf{G} \models \varphi_1(a, b)$, we have $\mathbf{G} \models \varphi_2(a, b)$. This means that every vertex in $\mathbf{G} - \{a, b\}$ is adjacent to at least two other black vertices. It follows that $\mathbf{G}$ contains some $\mathbf{G}_n$ as a (not necessarily induced) subgraph with a and b as white vertices. Here $n \geq 3$. It follows then by Lemma 6.1 that some vertex in $\mathbf{H} - \mathbf{G}_n$ fails to be connected to both a and b. But then $\mathbf{H} \not\models \varphi_1(a, b)$ so $\mathbf{H}$ is a model of φ again. □

To complete the argument we need to show that φ is not equivalent to an existential sentence on the class of black/white-colored graphs.

LEMMA 6.3. *There is no existential sentence equivalent to φ on all black/white-colored planar graphs.*

Proof. By virtue of Lemma 2.1, we only need to show that φ has infinitely many minimal models among planar graphs. It is easily seen that for all n, $\mathbf{G}_n$ is a minimal model of φ. Indeed, if we remove at least one of the white vertices from $\mathbf{G}_n$, we would not have witnesses for the two outermost existential quantifiers in φ, and if we remove at least one of the black vertices, then φ_1 remains true while φ_2 fails. □

This shows that the preservation-under-extensions property fails for the class of black/white-colored planar graphs. Removing the colors is easy. It suffices to replace each occurrence of $P(x)$ by a formula $\varphi_3(x)$ stating that x is attached to a 4×4-grid that is otherwise disconnected from the rest of the graph. One point to note is that a node without such a grid attached in a graph $\mathbf{G}$ may have a grid in an extension of $\mathbf{G}$. However, this would mean that φ_1 would fail in the extension and thus φ would necessarily be true. Thus, the formula is still preserved under extensions. This shows then that the preservation-under-extensions property fails for the class of planar graphs.

Note further that for any n, the treewidth of $\mathbf{G}_n$ is at most 4. This implies that the existential preservation theorem fails, even for the class $\mathcal{P}$ of planar graphs of treewidth at most 4. Indeed, the sentence φ is preserved under extensions on $\mathcal{P}$ since it is preserved under extensions on all planar graphs. However, φ still has infinitely many minimal models in this class as each $\mathbf{G}_n$ is in $\mathcal{P}$.

7. Conclusions. We have established the extension preservation theorem for a number of interesting classes of finite structures. These include all wide classes—such as any class of structures of bounded degree—and some almost wide classes, such as $\mathcal{T}_k$, the class of all structures of treewidth less than k. The situation for the extension preservation theorem is quite different from that established for the homomorphism preservation theorem in [1]. In particular, the former fails on the class of planar, while the latter holds on all classes that exclude a graph minor. Indeed, the methods of proof used here to establish the extension preservation property are rather different from those used in [1]. It should also be noted that Rossman [15] recently established that the homomorphism preservation theorem holds for the class of all finite structures; compare this with the known failure of the extension preservation theorem for the same class.

A number of recent results in finite model theory [1, 2, 3, 8, 10, 11] indicate that classes of structures such as trees or structures of bounded treewidth, planar graphs, and graphs of bounded genus, graphs with excluded minors, and graphs of bounded degree are well behaved in various ways related to their first-order model theory (in a broad sense). So far, no serious attempt has been made to identify general criteria connecting the different results. The locality of first-order logic always appears to play a crucial role, and the notion of *wideness* formally introduced here seems to be a good structural counterpart. But there is more to it than this simple observation; for example, the result of this paper holds on graphs of bounded degree, but not on planar graphs, whereas for the algorithmic results of [3] it is the other way round. The order invariance result of [2] has so far eluded all efforts to extend it beyond acyclic structures.

CLOSEST SUBSTRING PROBLEMS WITH SMALL DISTANCES*

DÁNIEL MARX†

Abstract. We study two pattern matching problems that are motivated by applications in computational biology. In the CLOSEST SUBSTRING problem k strings $s_1, \ldots, s_k$ are given, and the task is to find a string s of length L such that each string s_i has a consecutive substring of length L whose distance is at most d from s. We present two algorithms that aim to be efficient for small fixed values of d and k: for some functions f and g, the algorithms have running time $f(d) \cdot n^{O(\log d)}$ and $g(d,k) \cdot n^{O(\log \log k)}$, respectively. The second algorithm is based on connections with the extremal combinatorics of hypergraphs. The CLOSEST SUBSTRING problem is also investigated from the parameterized complexity point of view. Answering an open question from [P. A. Evans, A. D. Smith, and H. T. Wareham, *Theoret. Comput. Sci.*, 306 (2003), pp. 407–430, M. R. Fellows, J. Gramm, and R. Niedermeier, *Combinatorica*, 26 (2006), pp. 141–167, J. Gramm, J. Guo, and R. Niedermeier, *Lecture Notes in Comput. Sci.* 2751, Springer, Berlin, 2003, pp. 195–209, J. Gramm, R. Niedermeier, and P. Rossmanith, *Algorithmica*, 37 (2003), pp. 25–42], we show that the problem is W[1]-hard even if both d and k are parameters. It follows as a consequence of this hardness result that our algorithms are optimal in the sense that the exponent of n in the running time cannot be improved to $o(\log d)$ or to $o(\log \log k)$ (modulo some complexity-theoretic assumptions). CONSENSUS PATTERNS is the variant of the problem where, instead of the requirement that each s_i has a substring that is of distance at most d from s, we have to select the substrings in such a way that the average of these k distances is at most δ. By giving an $f(\delta) \cdot n^9$ time algorithm, we show that the problem is fixed-parameter tractable. This answers an open question from [M. R. Fellows, J. Gramm, and R. Niedermeier, *Combinatorica*, 26 (2006), pp. 141–167].

1. Introduction.

Computational biology applications provide a steady source of interesting stringology problems. In this paper we investigate two pattern matching problems that received considerable attention lately. Finding similar regions in multiple DNA, RNA, or protein sequences plays an important role in many applications, for example, in locating binding sites [27] and in finding conserved regions in unaligned sequences [24, 28, 34]. This task can be formalized the following way. Given k strings $s_1, \ldots, s_k$ over an alphabet Σ and an integer L, the task is to find a pattern that appears (possibly with some errors) in each string s_i. More precisely, we have to find a length L string s and a length L substring s_i' of each s_i such that s is "close" to every s_i'. We investigate two variants of the problem that differ in how closeness is defined. In the CLOSEST SUBSTRING problem the goal is to find a string s such that the Hamming-distance of s is at most d from every s_i'. An equally natural optimization goal is to minimize the sum of the distances of s from the substrings s_i': in the CONSENSUS PATTERNS problem we have to find a string s such that this sum is at most D. An equivalent way of formulating this problem is to require that the average distance is at most $\delta := D/k$.

The CLOSEST SUBSTRING problem is NP-hard even in the special case when $\Sigma = \{0, 1\}$ and every string s_i has length L [18]. This means that most likely there are only exponential-time algorithms for the problem. However, an exponential-time algorithm can still be efficient if the exponential dependence is restricted to parameters that are typically small in practice (for example, the size of the alphabet or the maximum number of mismatches that we allow) and the running time depends polynomially on all the other parameters (such as the lengths of the strings and length of the pattern). Parameterized complexity is the systematic study of problem parameters with the goal of restricting the exponential increase of the running time to as few parameters of the instance as possible.

1.1. Parameterized complexity. In classical complexity theory, the running time of an algorithm is usually expressed as a function of the input size. Parameterized complexity provides a more refined, two-dimensional analysis of the running time: the goal is to study how the different parameters of the input instance affect the running time. We assume that every input instance has an integer number k associated to it, which will be called the *parameter.* For example, in the case of (the decision version of) MAXIMUM CLIQUE, we can associate to each instance the size of the clique that has to be found. When evaluating an algorithm for a parameterized problem we take into account both the input size n and the parameter k, and we try to express the running time as a function of n and k. The goal is to develop algorithms that run in *uniformly polynomial time*: the running time is $f(k) \cdot n^c$, where c is a constant and f is a (possibly exponential) function depending only on k. We call a parameterized problem *fixed-parameter tractable (FPT)* if such an algorithm exists. This means that the exponential increase of the running time can be restricted to the parameter k. It turns out that several NP-hard problems are fixed-parameter tractable, for example, MINIMUM VERTEX COVER, LONGEST PATH, and DISJOINT TRIANGLES. Therefore, for small values of k, the $f(k)$ term is just a constant factor in the running time, and the algorithms for these problems can be efficient even for large values of n. This has to be contrasted with algorithms that have a running time such as n^k: in this case the algorithm becomes practically useless for large values of n even if k is as small as 10. Analogously to NP-completeness in classical complexity, the theory of W[1]-hardness can be used to show that a problem is unlikely to be fixed-parameter tractable, which means that for every algorithm the parameter has to appear in the exponent of n. For example, for MAXIMUM CLIQUE and MINIMUM DOMINATING SET the running time of the best known algorithms is $n^{\Omega(k)}$, and the W[1]-hardness of these problems tells us that it is unlikely that an algorithm with a running time, say, $O(2^k \cdot n)$ can be found.

For a particular problem, there are many possible parameters that can be defined. For example, in the case of the MAXIMUM CLIQUE problem, the maximum degree of the graph, the genus of the graph, or the treewidth of the graph are also natural choices for the parameter. Different applications might suggest different parameters: whether a particular choice of parameter is relevant to an application depends on whether it can be assumed that this parameter is typically "small" in practice. The theory can be extended in a straightforward way to the case when there is more than one parameter: if there are two parameters k_1 and k_2, then the goal is to develop algorithms with a running time $f(k_1, k_2) \cdot n^c$. For more details, see section 2 and [12, 16].

1.2. Previous work on CLOSEST SUBSTRING. The NP-completeness of CLOSEST SUBSTRING was first shown by Frances and Litman [18] by considering an equiv-

alent problem in coding theory. Li, Ma, and Wang [30] presented a polynomial-time approximation scheme, but the running time of their approximation algorithm is prohibitive. Heuristic approaches for the problem are discussed in [6, 31, 32, 26]; see also the references therein.

Under the standard complexity-theoretic assumptions, the NP-completeness of Closest Substring means that any exact algorithm has to run in exponential time. However, there can be great qualitative differences between exponential-time algorithms: for example, it can be a crucial difference whether the running time is exponential in the length of the strings or in the number of the strings. This question was investigated in the framework of parameterized complexity by several papers. Formally, the following problem is studied:

Closest Substring

Input:
k strings $s_1, \ldots, s_k$ over an alphabet Σ and integers d and L.

Parameters:
k, $|\Sigma|$, d, L

Task:
Find a string s of length L such that for every $1 \leq i \leq k$, the string s_i has a length L consecutive substring s'_i with $d(s, s'_i) \leq d$.

The Hamming-distance of two strings w_1 and w_2 (i.e., the number of positions where they differ) is denoted by $d(w_1, w_2)$. The string s in the solution is called the *center string*. Observe that for a given center string s, it is easy to check in polynomial time whether the substrings s'_i exist: we have to try every length L consecutive substring of the strings s_i. Therefore, the real difficulty of the problem lies in finding the best center string s. We will denote by n the size of the input, which is an upper bound on the total length of the strings. In the following, "substring" will always mean consecutive substring (and not an arbitrary subsequence of the symbols).

The problem can be solved in polynomial time if k, d, or L is fixed to a constant. For every fixed value of L, the problem can be solved in polynomial time by enumerating all the $|\Sigma|^L = O(n^L)$ possible center strings. If d is a fixed constant, then the problem can be solved in polynomial time by making a guess at s'_1 (at most n possibilities) and then trying every center string s that is of distance at most d from s'_1 (at most $(|\Sigma|L)^d = O(n^{2d})$ possibilities). For fixed values of k, the problem can be solved in polynomial time as follows. First, we guess the k substrings s'_k (at most n^k possibilities). Now we have to find a center string s that is of distance at most d from each s'_i. This can be done by dynamic programming in $O(n^k)$ time or by applying the linear-time algorithm of Gramm, Niedermeier, and Rossmanith [21] for Closest String that is based on integer linear programming. Therefore, for fixed values of L, d, or k, the problem can be solved in polynomial time. However, the algorithms described above are not uniformly polynomial: the exponent of n increases as we consider greater fixed values. The parameterized complexity analysis of the problem can reveal whether it is possible to remove these parameters from the exponent of n and obtain algorithms with a running time such as $f(k) \cdot n^c$.

In [14] and [13] it is shown that the problem is W[1]-hard even if all three of k, d, and L are parameters. Therefore, if the size of the alphabet Σ is not bounded in the input, then we cannot hope for an efficient exact algorithm for the problem. Fortunately, in the computational biology applications the strings are typically DNA

TABLE 1.1

d, k, L	FPT	FPT	W[1]-hard

or protein sequences, hence the number of different symbols is a small constant (4 or 20). Therefore, we will focus on the case when the size of Σ is a parameter. Restricting $|\Sigma|$ only does not make the problem tractable, since CLOSEST SUBSTRING is NP-hard even if the alphabet is binary. On the other hand, if $|\Sigma|$ and L are both parameters, then the problem becomes fixed-parameter tractable: we can enumerate and check all the $|\Sigma|^L$ possible center strings. However, if the strings are long (which is often the case in practical applications), then it makes much more sense to assume that the number of strings k or the distance constraint d are parameters. In [14] it is shown that CLOSEST SUBSTRING is W[1]-hard with parameter k, even if the alphabet is binary. However, the complexity of the problem with parameter d or with combined parameters d, k remained an open question.

1.3. New results for CLOSEST SUBSTRING**.** We show that the problem is W[1]-hard with combined parameters k and d, even if the alphabet is binary. This resolves an open question asked in [13, 14, 20, 21]. Therefore, even in the binary case, there is no $f(k,d) \cdot n^c$ algorithm for CLOSEST SUBSTRING (unless FPT = W[1]); the exponential increase cannot be restricted to the parameters k and d. This completes the parameterized complexity analysis of CLOSEST SUBSTRING (see Table 1.1; the results of this paper are marked with an asterisk.)

As a first step of the reduction, we introduce a technical problem called SET BALANCING, and prove W[1]-hardness for this problem. This part of the proof contains most of the new combinatorial ideas. The SET BALANCING problem is reduced to CLOSEST SUBSTRING by a reduction very similar to the one presented in [14].

We present two exact algorithms for the CLOSEST SUBSTRING problem. These algorithms can be efficient if d, or both d and k, are small (say, $o(\log n)$). The first algorithm runs in $|\Sigma|^{d(\log d+2)} n^{O(\log d)}$ time. Notice that this algorithm is not uniformly polynomial, but only the logarithm of the parameter appears in the exponent of n. Therefore, the algorithm might be efficient for small values of d. The second algorithm has running time $|\Sigma|^d \cdot 2^{kd} \cdot d^{O(d \log\log k)} \cdot n^{O(\log\log k)}$. Here the parameter k appears in the exponent of n, but $\log\log k$ is a very slowly growing function. This algorithm is based on defining certain hypergraphs and enumerating all the places where one hypergraph appears in the other. Using some results from extremal combinatorics, we develop techniques that can speed up the search for hypergraphs. It turns out that if hypergraph H has bounded fractional edge cover number, then we can enumerate in uniformly polynomial time all the places where H appears in some larger hypergraph G. This result might be of independent interest.

Notice that the running times of our two algorithms are incomparable. Assume

that $|\Sigma| = 2$. If $d = \log n$ and $k = \sqrt{n}$, then the running time of the first algorithm is $n^{O(\log\log n)} \cdot n^{O(\log\log n)} = n^{O(\log\log n)}$, while the second algorithm needs at least $2^{kd} = 2^{\sqrt{n}\log n} = n^{\sqrt{n}}$ steps, which can be much larger. On the other hand, if $d = k = \log\log n$, then the first algorithm runs in something like $n^{O(\log\log\log n)}$ time, while the running time of the second algorithm is dominated by the $n^{O(\log\log k)}$ factor, which is only $n^{O(\log\log\log\log n)}$.

Our W[1]-hardness proof combined with some recent results on subexponential algorithms shows that the two exact algorithms are in some sense best possible. The exponents are optimal: we show that if there is an $f_1(k, d, |\Sigma|) \cdot n^{o(\log d)}$ or an $f_2(k, d, |\Sigma|) \cdot n^{o(\log\log k)}$ algorithm for Closest Substring, then n-variable 3-Sat can be solved in $2^{o(n)}$ time. It is widely believed that 3-Sat does not have subexponential-time algorithms; this conjecture is called the Exponential Time Hypothesis (cf. [25, 35]).

1.4. Relation to approximability. Li, Ma, and Wang [30] studied the optimization version of Closest Substring, where the task is to find the smallest d that makes the problem feasible. They presented a *polynomial-time approximation scheme (PTAS)* for the problem: for every $\epsilon > 0$, there is an $n^{O(1/\epsilon^4)}$ time algorithm that produces a solution that is at most $(1+\epsilon)$-times worse than the optimum. This PTAS was improved to $n^{O(\log(1/\epsilon)/\epsilon^2)}$ time by Andoni, Indyk, and Pătraşcu [2] using an idea from an earlier version of this paper. However, such a PTAS becomes practically useless for large n, even if we ask for an error bound of, say, 20%. As pointed out in [11], there are numerous approximation schemes in the literature where the degree of the algorithm increases very rapidly as we decrease ϵ: having $O(n^{1,000,000})$ or worse for 20% error is not uncommon. Clearly, such approximation schemes do not yield efficient approximation algorithms. Nevertheless, these results show that there are no theoretical limitations on the approximation ratio that can be achieved.

An *efficient PTAS (EPTAS)* is an approximation scheme that produces a $(1+\epsilon)$-approximation in $f(\epsilon) \cdot n^c$ time for some constant c. If $f(\epsilon)$ is, e.g., $2^{1/\epsilon}$, then such an approximation scheme can be practical even for $\epsilon = 0.1$ and large n. A standard consequence of W[1]-hardness is that there is no EPTAS for the optimization version of the problem [7, 4]. Hence our hardness result shows that the approximation schemes of [30] and [2] for Closest Substring cannot be improved to an EPTAS.

1.5. Previous work on Consensus Patterns. The Consensus Patterns problem is the same as Closest Substring, but instead of minimizing the maximum distance between the center string and the substrings s'_i, now the goal is to minimize the sum of the distances. Similarly to Closest Substring, the problem is NP-complete and admits a PTAS [29]. Heuristic algorithms for Consensus Patterns and some generalizations are given in, e.g., [31, 23, 17, 33, 5].

We will study the decision version of the problem:

Consensus Patterns

Input:
k strings $s_1, \ldots, s_k$ over an alphabet Σ and integers D and L.

Parameters:
k, $|\Sigma|$, D, L

Task:
Find a string s of length L, and a length L consecutive substring s'_i of s_i for every $1 \leq i \leq k$ such that $\sum_{i=1}^{k} d(s, s'_i) \leq D$ holds.

TABLE 1.2
Complexity of CONSENSUS PATTERNS *with different parameterizations. Asterisk denotes the new results of this paper.*

Parameters	$\|\Sigma\|$ is constant	$\|\Sigma\|$ is parameter	$\|\Sigma\|$ is unbounded
δ	FPT (*)	FPT (*)	W[1]-hard
D	FPT (*)	FPT (*)	W[1]-hard
k	W[1]-hard	W[1]-hard	W[1]-hard
L	FPT	FPT	W[1]-hard
k, L	FPT	FPT	W[1]-hard
D, k, L	FPT	FPT	W[1]-hard

The string s in the solution is called the *median string*. Similarly to CLOSEST SUBSTRING, the problem is fixed-parameter tractable if both $|\Sigma|$ and L are parameters: we can enumerate and test every possible median string. Fellows, Gramm, and Niedermeier [14] showed that their hardness results for CLOSEST SUBSTRING can be adapted for CONSENSUS PATTERNS. Thus the problem is W[1]-hard with combined parameters L, k, D in the unbounded alphabet case, and W[1]-hard with parameter k in the binary alphabet case. The complexity of the problem in the binary alphabet case with parameter D or combined parameters k and D remained open.

Notice that if $D < k$, then the problem can be solved in polynomial time. To see this, observe that $\sum_{i=1}^{k} d(s, s'_i) \leq D < k$ is only possible if $d(s, s'_i) = 0$ for at least one i. This means that the median string is a substring of some s_i, thus a solution can be found by trying every length L substring of the input strings. Therefore, we can assume that $D \geq k$ holds in the problem instance. It follows that the complexity of CONSENSUS PATTERNS is the same with parameter D and with combined parameters k, D.

1.6. New results for CONSENSUS PATTERNS. We define and investigate the new parameter $\delta := D/k$, which is the average error that is allowed between the median string and the substrings s'_i. Parameterization by δ (and not by k) is relevant for applications where we want to find a solution with small average error, but the number of strings is allowed to be large.

By presenting an algorithm with running time $\delta^{O(\delta)} \cdot |\Sigma|^{\delta} \cdot n^9$, we show that CONSENSUS PATTERNS is fixed-parameter tractable if both $|\Sigma|$ and δ are parameters. The algorithm uses similar hypergraph techniques as the $f(k, d, |\Sigma|) \cdot n^{O(\log \log k)}$ time algorithm for CLOSEST SUBSTRING. However, a subtle difference in the combinatorics of the two problems allows us to replace the $O(\log \log k)$ term in the exponent of n with a constant.

Since parameter δ is not greater than parameter D, it follows trivially that the problem is fixed-parameter tractable with combined parameters $|\Sigma|$ and D. This settles another open question from [14]. The results for CONSENSUS PATTERNS are summarized in Table 1.2, with an asterisk marking the results of this paper.

1.7. Organization. The paper is organized as follows. Section 2 briefly reviews the most important notions of parameterized complexity. The first algorithm for CLOSEST SUBSTRING is presented in section 3. In section 4 we discuss techniques for finding one hypergraph in another. In section 5 we present the second algorithm

for Closest Substring. This section introduces a new hypergraph property called *half-covering,* which plays an important role in the algorithm. The algorithm for Consensus Patterns is presented in section 6. We define the Set Balancing problem in section 7 and prove that it is W[1]-hard. In section 8 the Set Balancing problem is used to show that Closest Substring is W[1]-hard with combined parameters d and k. We conclude the paper with a summary in section 9.

Algorithm 1 (section 3) and Algorithm 2 (sections 4 and 5) for the Closest Substring problem are independent from each other. The algorithm for Consensus Patterns (section 6) is very similar to the algorithm in section 5, but is presented in a self-contained way. The algorithm of section 6 is also based on the hypergraph techniques developed in section 4.

The hardness results in sections 7 and 8 are independent from the algorithms; the reductions can be understood without the preceding sections. However, the combinatorics of the reduction in section 7 has subtle connections with the half-covering property discussed in section 5. In some sense, section 5 explains why the reduction in section 7 has to be done that way.

2. Parameterized complexity. We follow [16] for the standard definitions of parameterized complexity. Let Σ be a finite alphabet. A decision problem is represented by a set $Q \subseteq \Sigma^*$ of strings over Σ. A *parameterization* of a problem is a polynomial-time computable function $\kappa : \Sigma^* \to \mathbb{N}$. A *parameterized decision problem* is a pair (Q, κ), where $Q \subseteq \Sigma^*$ is an arbitrary decision problem and κ is a parameterization. Intuitively, we can imagine a parameterized problem as a decision problem where each input instance $x \in \Sigma^*$ has a positive integer $\kappa(x)$ associated with it. A parameterized problem (Q, κ) is FPT if there is an algorithm that decides whether $x \in Q$ in time $f(\kappa(x)) \cdot |x|^c$ for some constant c and computable function f. An algorithm with such a running time is called an *fpt-time algorithm* or simply *fpt-algorithm.*

Many NP-hard problems were investigated in the parameterized complexity literature, with the goal of identifying fixed-parameter tractable problems. There is a powerful toolbox of techniques for designing fpt-algorithms: kernelization, bounded search trees, color coding, well-quasi ordering—just to name some of the more important ones. On the other hand, certain problems resisted every attempt at obtaining fpt-algorithms. Analogously to NP-completeness in classical complexity, the theory of W[1]-hardness can be used to give strong evidence that certain problems are unlikely to be fixed-parameter tractable. We omit the somewhat technical definition of the complexity class W[1]; see [12, 16] for details. Here it will be sufficient to know that there are several problems, including Maximum Clique, that were proved to be W[1]-hard. Furthermore, we also expect that there is no $n^{o(k)}$ (or even $f(k) \cdot n^{o(k)}$) algorithm for Maximum Clique: recently it was shown that if there exists an $f(k) \cdot n^{o(k)}$ algorithm for n-vertex Maximum Clique, then n-variable 3-Sat can be solved in time $2^{o(n)}$ (see [8] and [15]).

To prove that a parameterized problem (Q', κ') is W[1]-hard, we have to present a parameterized reduction from a known W[1]-hard problem (Q, κ) to (Q', κ'). A *parameterized reduction* from problem (Q, κ) to problem (Q', κ') is a function that transforms a problem instance x of Q into a problem instance x' of Q' in such a way that

1. $x' \in Q'$ if and only if $x \in Q$,
2. $\kappa'(x)$ can be bounded by a function of $\kappa(x)$, and
3. the transformation can be computed in time $f(\kappa(k)) \cdot |x|^c$ for some constant c and function $f(k)$.

It is easy to see that if there is a parameterized reduction from (Q, κ) to (Q', κ'), and (Q', κ') is fixed-parameter tractable, then it follows that (Q, κ) is fixed-parameter tractable as well. The most important difference between parameterized reductions and classical polynomial-time many-to-one reductions is the second requirement: in most NP-completeness proofs the new parameter is not a function of the old parameter. Therefore, finding parameterized reductions is usually more difficult and the constructions have a somewhat different flavor than classical reductions.

There are many possible parameters that can be defined for a particular problem; different parameters can be relevant in different applications. Usually, the parameter is either some property of the solution we seek (number of vertices, quality of the solution, etc.) or describes some aspect of the input structure (degree/genus/treewidth of the input graph, number of variables/clauses in the input formula, etc.). The complexity of the problem can be different with different parameters. Observe that if parameter k_1 is never greater than parameter k_2, then the problem cannot be easier with parameter k_1 than with k_2: an $f(k_1) \cdot n^c$ time algorithm implies the existence of an $f(k_2) \cdot n^c$ time algorithm.

In some cases we want to investigate the complexity of the problem by considering two or more parameters at the same time; i.e., we assume that both parameter k_1 and parameter k_2 are typically small in applications. The problem is fixed-parameter tractable with combined parameters k_1 and k_2 if there is an algorithm with running time $f(k_1, k_2) \cdot n^{O(1)}$. For a particular problem, we can investigate several different combinations of parameters. In general, if we increase the set of parameters, then we cannot make the problem harder: for example, if the problem is fixed-parameter tractable with parameter k_1, then clearly it is fixed-parameter tractable with combined parameters k_1 and k_2.

3. Finding generators. In this section we present an algorithm for Closest Substring that has running time proportional to roughly $n^{\log d}$. The algorithm is based on the following observation: if all the strings $s'_1, \ldots, s'_k$ agree at some position p in the solution, then we can safely assume that the same symbol appears at the pth position of the center string s. However, if we look at only a subset of the strings s'_1, $\ldots$, s'_k, then it is possible that they all agree at some position, but the center string contains a different symbol at this position. We will be interested in sets of strings that do not have this problem.

Definition 3.1. *Let $G = \{g_1, g_2, \ldots, g_\ell\}$ be a set of length L strings. We say that G is a* generator *of the length L string s if whenever every g_i has the same character at some position p, then string s has this character at position p. The* size *of the generator is ℓ, the number of strings in G. The* conflict size *of the generator is the number of those positions where not all of the strings g_i have the same character.*

As we have argued above, it can be assumed that the strings $s'_1, \ldots, s'_k$ of a solution form a generator of the center string s. Furthermore, these strings have a subset of size at most $\log d + 2$ that is also a generator.

Lemma 3.2. *If an instance of* Closest Substring *is solvable, then there is a solution s that has a generator G having the following properties:*

1. *each string in G is a substring of some s_i,*
2. *G has size at most $\log d + 2$,*
3. *the conflict size of G is at most $d(\log d + 2)$.*

Proof. Let $s, s'_1, \ldots, s'_k$ be a solution such that $\sum_{i=1}^{k} d(s, s'_i)$ is minimal. We prove by induction that for every j we can select a subset G_j of j strings from $\{s'_1, \ldots, s'_k\}$ such that there are less than $(d+1)/2^{j-1}$ *bad positions* where the strings in G_j all

CLOSEST SUBSTRING-1$(k, L, d, (s_1, \ldots, s_k))$

7. There is no solution, STOP.

FIG. 3.1. *Algorithm* 1 *for* CLOSEST SUBSTRING.

agree, but this common character is different from the character in s at this position. The lemma follows from $j = \lceil \log(d+1) \rceil + 1 \leq \log d + 2$: the set G_j has no bad positions, hence it is a generator of s. Furthermore, each string in G_j is at distance at most d from s, thus the conflict size of G_j can be at most $d(\log d + 2)$.

For the case $j = 1$ we can set $G_1 = \{s'_1\}$, since s'_1 differs from s at not more than d positions. Now assume that the statement is true for some j. Let P be the set of bad positions, where the j strings in G_j agree, but they differ from s. We claim that there is some string s'_t in the solution and a subset $P' \subseteq P$ with $|P'| > |P|/2$ such that s'_t differs from all the strings in G_j at every position of P'. If this is true, then we add s'_t to the set G_j to obtain G_{j+1}. Only the positions in $P \setminus P'$ are bad for the set G_{j+1}: for every position p in P', the strings cannot all agree at p, since s'_t do not agree with the other strings at this position. Thus there are at most $|P \setminus P'| < |P|/2 < (d+1)/2^j$ bad positions, completing the induction.

Assume that there is no such string s'_t. In this case we modify the center string s the following way: for every position $p \in P$, let the character at position p be the same as in string s'_1. Denote by s^* the new center string. We show that $d(s^*, s'_i) \leq d(s, s'_i) \leq d$ for every $1 \leq i \leq k$, hence s^* is also a solution. By assumption, every string s'_i in the solution agrees with s'_1 on at least $|P|/2$ positions of P. Therefore, if we replace s with s^*, the distance of s'_i from the center string decreases on at least $|P|/2$ positions, and the distance can increase only on the remaining at most $|P|/2$ positions. Therefore, $d(s^*, s'_i) \leq d(s, s'_i)$ follows. Furthermore, $d(s^*, s'_1) = d(s, s'_1) - |P|$ implies $\sum_{i=1}^{k} d(s^*, s'_i) < \sum_{i=1}^{k} d(s, s'_i)$, which contradicts the minimality of s. □

We note that Lemma 3.2 (appearing in an earlier version of this paper) was used by Andoni, Indyk, and Pătraşcu [2] to improve the running time of the PTAS of Li, Ma, and Wang [30] to $n^{O(\log(1/\epsilon)/\epsilon^2)}$ time.

Our algorithm first creates a set S containing all the length L substrings of s_1, $\ldots$, s_k. For every subset $G \subseteq S$ of $\log d + 2$ strings, we check whether G generates a center string s that solves the problem. Since $|S| \leq n$, there are at most $n^{\log d + 2}$ possibilities to try. By Lemma 3.2 we have to consider only those generators whose conflict size is at most $d(\log d + 2)$, hence at most $|\Sigma|^{d(\log d+2)}$ possible center strings have to be tested for each G.

THEOREM 3.3. CLOSEST SUBSTRING *can be solved in time* $|\Sigma|^{d(\log d+2)} n^{\log d + O(1)}$.

Proof. The algorithm is presented in pseudocode in Figure 3.1. Let S be the set of all length L substrings in s_1, $\ldots$, s_k, clearly $|S| \leq n$ (recall that n is the total length of the input). If there is a solution s, then Lemma 3.2 ensures that there is a subset $G \subseteq S$ of size at most $\log d + 2$ that generates s. We test every size $\log d + 2$ subset of S to see whether it can generate a solution. First, by Lemma 3.2 we can restrict our attention to those G where the strings in G agree on all but at

most $d(\log d + 2)$ positions. If such a G generates a string s, then the characters of s are determined everywhere except on the conflicting positions of G. Therefore, G can be the generator of at most $|\Sigma|^{d(\log d+2)}$ different strings. We try all the possible combinations of assigning characters on the conflicting positions of G and check for each resulting string s whether it is true for every $1 \le i \le k$ that there is a substring s_i' of s_i such that $d(s, s_i') \le d$. This method will eventually find a solution, if one exists.

We try $O(n^{\log d+2})$ different subsets G (line 2), and each G can generate at most $|\Sigma|^{d(\log d+2)}$ different center strings s (line 4). It can be checked in polynomial time whether a center string s is a solution (line 5), hence the total running time is $|\Sigma|^{d(\log d+2)} n^{\log d+O(1)}$. □

We remark here that the algorithm can be made slightly more efficient: it is sufficient to check those generators where the $\log d + 2$ strings come from different strings s_i. However, this observation does not improve the asymptotics of the running time, and we did not want to complicate the notation to accommodate this improvement.

4. Finding hypergraphs. Let us recall some standard definitions concerning hypergraphs. A *hypergraph* $H(V_H, E_H)$ consists of a set of *vertices* V_H and a collection of *edges* E_H, where each edge is a subset of V_H. Let $H(V_H, E_H)$ and $G(V_G, E_G)$ be two hypergraphs. We say that H *appears at* $V' \subseteq V_G$ *as partial hypergraph* if there is a bijection π between the elements of V_H and V' such that for every edge $E \in E_H$ we have that $\pi(E)$ is an edge of G (where the mapping π is extended to the edges the obvious way). For example, if H has the edges $\{1, 2\}$, $\{2, 3\}$, and G has the edges $\{a, b\}$, $\{b, c\}$, $\{c, d\}$, then H appears as a partial hypergraph at $\{a, b, c\}$ and at $\{b, c, d\}$. We say that H *appears at* $V' \subseteq V_G$ *as subhypergraph* if there is such a bijection π where for every $E \in E_H$, there is an edge $E' \in E_G$ with $\pi(E) = E' \cap V'$. For example, let the edges of H be $\{1, 2\}$, $\{2, 3\}$, and let the edges of G be $\{a, c, d\}$, $\{b, c, d\}$. Now H does not appear in G as partial hypergraph, but H appears as subhypergraph at $\{a, b, c\}$ and at $\{a, b, d\}$. If H appears at some $V' \subseteq V_G$ as partial hypergraph, then it appears there as subhypergraph as well.

A *stable set* in $H(V_H, E_H)$ is a subset $S \subseteq V_H$ such that every edge of H contains at most one element from S. The *stable number* $\alpha(H)$ is the size of the largest stable set in H. A *fractional stable set* is an assignment ϕ: $V_H \to [0, 1]$ such that $\sum_{v \in E} \phi(v) \le 1$ for every edge E of H. The *fractional stable number* $\alpha^*(H)$ is the maximum of $\sum_{v \in V_H} \phi(v)$ taken over all fractional stable sets ϕ. The incidence vector of a stable set is a fractional stable set, hence $\alpha^*(H) \ge \alpha(H)$.

An *edge cover* of H is a subset $E' \subseteq E_H$ such that each vertex of V_H is contained in at least one edge of E'. The *edge cover number* $\rho(H)$ is the size of the smallest edge cover in H. (The hypergraphs considered in this paper do not have isolated vertices, hence every hypergraph has an edge cover.) A *fractional edge cover* is an assignment ψ: $E_H \to [0, 1]$ such that $\sum_{E: v \in E} \psi(E) \ge 1$ for every vertex v. The *fractional cover number* $\rho^*(H)$ is the minimum of $\sum_{E \in E_H} \psi(E)$ taken over all fractional edge covers ψ, clearly $\rho^*(H) \le \rho(H)$. It follows from the duality theorem of linear programming that $\alpha^*(H) = \rho^*(H)$ for every hypergraph H with no isolated vertices.

Friedgut and Kahn [19] determined the maximum number of times a hypergraph $H(V_H, E_H)$ can appear as partial hypergraph in a hypergraph G with m edges. That is, we are interested in the maximum number of different subsets $V' \subseteq V_G$ where H can appear in G. A trivial upper bound is $m^{|E_H|}$: if we fix $\pi(E) \in E_G$ for each edge $E \in E_H$, then this uniquely determines $\pi(V_H)$. This trivial bound can be improved to $m^{\rho(H)}$: if edges $E_1, E_2, \ldots, E_{\rho(H)}$ cover every vertex of V_H, then by fixing $\pi(E_1)$,

$\pi(E_2), \ldots, \pi(E_{\rho(H)})$ the set $\pi(V_H)$ is determined. The result of Friedgut and Kahn says that ρ can be replaced with the (possibly smaller) ρ^*.

THEOREM 4.1 (see [19]). *Let H be a hypergraph with fractional cover number $\rho^*(H)$, and let G be a hypergraph with m edges. There are at most $|V_H|^{|V_H|} \cdot m^{\rho^*(H)}$ different subsets $V' \subseteq V_G$ such that H appears in G at V' as partial hypergraph. Furthermore, for every H and sufficiently large m, there is a hypergraph with m edges where H appears $m^{\rho^*(H)}$ times.*

We remark here that Theorem 4.1 was proved for the special case of graphs in the first published paper of Alon [1].

To appreciate the strength of Theorem 4.1, it is worth pointing out that $\rho^*(H)$ can be much smaller than $\rho(H)$, hence the upper bound can be much stronger than $m^{\rho(H)}$. For example, consider the hypergraph where the vertices correspond to the k-element subsets of $\{1, 2, \ldots, n\}$, and edge E_i $(1 \leq i \leq n)$ contains those vertices that correspond to sets containing i. Now $\rho = n - k + 1$: if we select less than $n - k + 1$ edges, then there is a k-element set that is not covered by the less than $n - k + 1$ elements corresponding to the edges. On the other hand, we can construct a fractional edge cover of total weight n/k by assigning weight $1/k$ to each edge. This is a fractional edge cover, since each vertex is contained in exactly k edges. Therefore, the ratio $\rho/\rho^* = (n - k + 1)/(n/k)$ can be arbitrarily large.

Theorem 4.1 does not remain valid if we replace "partial hypergraph" with "subhypergraph." For example, let H contain only one edge $\{1, 2\}$, and let G have one edge E of size ℓ. Now H appears at each of the $\binom{\ell}{2}$ two element subsets of E as subhypergraph. However, if we bound the size of the edges in G, then we can state a subhypergraph analog of Theorem 4.1.

COROLLARY 4.2. *Let H be a hypergraph with fractional cover number $\rho^*(H)$, and let G be a hypergraph with m edges, each of size at most ℓ. Hypergraph H can appear in G as subhypergraph at most $|V_H|^{|V_H|} \cdot \ell^{|V_H|\rho^*(H)} \cdot m^{\rho^*(H)}$ times.*

Proof. Let $G'(V_G, E_{G'})$ be a hypergraph over V_G where $E' \in E_{G'}$ if and only if $|E'| \leq |V_H|$ and E' is a subset of some edge $E \in E_G$. An edge of G contributes at most $\ell^{|V_H|}$ edges to G', hence G' has at most $\ell^{|V_H|} \cdot m$ edges. If H appears as subhypergraph at $V' \subseteq V_G$ in G, then H appears as partial hypergraph at V' in G'. By Theorem 4.1, hypergraph H can appear at most $|V_H|^{|V_H|} \cdot \ell^{|V_H|\rho^*(H)} \cdot m^{\rho^*(H)}$ times in G' as partial hypergraph, proving the lemma. □

Given hypergraphs $H(V_H, E_H)$ and $G(V_G, E_G)$, we would like to find all the places $V' \subseteq V_G$ in G where H appears as subhypergraph. If there are t such places, then obviously we cannot enumerate all of them in less than t steps. Therefore, our aim is to find an algorithm with running time polynomial in the upper bound $|V_H|^{|V_H|} \cdot \ell^{|V_H|\rho^*(H)} \cdot m^{\rho^*(H)}$ on t given by Corollary 4.2. The proof of Theorem 4.1 is not algorithmic (it is based on Shearer's Lemma [10], which is proved by entropy arguments), hence it does not directly imply an efficient way of enumerating all the places where H appears. However, in Theorem 4.3, we show that there is a very simple algorithm for enumerating all these places. Corollary 4.2 is used to bound the running time of the algorithm. This result might be useful in other applications as well.

THEOREM 4.3. *Let $H(V_H, E_H)$ be a hypergraph with fractional cover number $\rho^*(H)$, and let $G(V_H, E_H)$ be a hypergraph where each edge has size at most ℓ. There is an algorithm that enumerates in time $|V_H|^{O(V_H)} \cdot \ell^{|V_H|\rho^*(H)+1} \cdot |E_G|^{\rho^*(H)+1} \cdot |V_G|^2$ every subset $V' \subseteq V_G$ where H appears in G as subhypergraph.*

Proof. Let $V_H = \{1, 2, \ldots, r\}$. For each $1 \leq i \leq r$, let $H_i(V_i, E_i)$ be the subhy-

FIG. 4.1. *Algorithm for enumerating all the places where hypergraph H appears in G as subhypergraph.*

pergraph of H induced by $V_i = \{1, 2, \ldots, i\}$; that is, if E is an edge of H, then $E \cap V_i$ is an edge of H_i. For each $i = 1, 2, \ldots, r$, we find all the places where H_i appears in G as subhypergraph. Since $H = H_r$ this method will solve the problem.

For $i = 1$ the problem is trivial, since V_i has only one vertex. Assume now that we have a list L_i of all the i-element subsets of V_G where H_i appears as subhypergraph. The important observation is that if H_{i+1} appears as subhypergraph at some $(i+1)$-element subset $V' \subseteq V_G$, then V' has an i-element subset $V'' \in L_i$ where H_i appears as subhypergraph. Thus for each set $X \in L_i$, we try all the $|V_G \setminus X|$ different ways of extending X to an $(i+1)$-element set X', and check whether H_{i+1} appears at X' as subhypergraph. This can be checked by trying all the $(i+1)!$ possible bijections π between V_{i+1} and X', and by checking for each edge E of H_{i+1} whether there is an edge E' in G with $\pi(E) = E' \cap X'$.

The structure of the algorithm is presented in Figure 4.1. Let us make a rough estimate of the running time. The loop in step 2 consists of $|V_H| - 1$ iterations. Notice first that $\rho^*(H_i) \leq \rho^*(H)$, since a fractional edge cover of H can be used to obtain a fractional edge cover of H_i. Therefore, by Corollary 4.2, each list L_i has size at most $|V_H|^{|V_H|} \cdot \ell^{|V_H|\rho^*(H)} \cdot |E_G|^{\rho^*(H)}$, which bounds the maximum number of times the loop in step 3 is iterated. When we determine the list L_{i+1}, we have to check for at most $|L_i| \cdot |V_G|$ different sets X' of size $i+1$ whether H_{i+1} appears at X' as subhypergraph (step 4). Adding duplicate entries into the list L_{i+1} should be avoided; otherwise we would not have the bound on the size of L_i claimed above. Therefore, in step 6, we check whether X' is already in L_i. If the list L_i is implemented as a trie structure, then the test in step 6 can be performed in time $O(|V_H| \cdot |V_G|)$. The trie structure can increase the time required to enumerate the list L_i by a factor of $|V_H|$. Checking one X' requires us to test $(i+1)!$ different bijections π (step 7). Testing a bijection π means that for each $E \in E_{i+1}$ (step 8), it has to be checked whether there is a corresponding $E' \in E_G$ (step 9) such that $E' \cap X' = E$ (step 10). Hypergraph H has at most $2^{|V_H|}$ edges, hence the loop of step 8 is iterated at most $2^{|V_H|}$ times. If the edges of G are represented as lists of vertices, then the check in step 10 can be implemented in $O(\ell)$ time. Adding a new element into the trie structure (step 13)

can be done in $O(|V_H| \cdot |V_G|)$ time.

The dominating part of the running time comes from steps 7–13, which are repeated $|V_H|^{O(V_H)} \cdot \ell^{|V_H|\rho^*(H)} \cdot |E_G|^{\rho^*(H)} \cdot |V_G|$ times. The loop in steps 7–12 takes $O(|V_H|! \cdot 2^{|V_H|} \cdot |E_G| \cdot \ell) = |V_H|^{O(V_H)} \cdot |E_G| \cdot \ell$ time, while step 13 takes $O(|V_H| \cdot |V_G|)$ time. Therefore, the total running time can be bounded by $|V_H|^{O(V_H)} \cdot \ell^{|V_H|\rho^*(H)+1} \cdot |E_G|^{\rho^*(H)+1} \cdot |V_G|^2$. □

We can use a similar technique to find all the places where H appears in G as partial hypergraph. This result is not used in this paper, but might be useful in some other applications.

COROLLARY 4.4. *Let $H(V_H, E_H)$ be a hypergraph with fractional cover number $\rho^*(H)$, and let $G(V_G, E_G)$ be an arbitrary hypergraph. There is an algorithm that enumerates in time $|V_H|^{O(|V_H|\rho^*(H))} \cdot |E_G|^{\rho^*(H)+1} \cdot |V_G|^2$ all the subsets $V' \subseteq V_G$ where H appears in G as partial hypergraph.*

Proof. We can throw away from G every edge larger than $|V_H|$ without changing the problem. Now Theorem 4.3 can be used to find in time $|V_H|^{O(|V_H|\rho^*(H))} \cdot |E_G|^{\rho^*(H)+1} \cdot |V_G|^2$ the list L of all the subsets $V' \subseteq V_G$ where H appears in G as subhypergraph. If H appears at V' as partial hypergraph, then this is only possible if H appears at V' as subhypergraph. Therefore, the algorithm returns a list that is a superset of the expected result. Let us modify step 10 of the algorithm of Theorem 4.3 such that in iteration $i = r - 1$ it tests $\pi(E) = E'$ instead of $\pi(E) = E' \cap X'$. This ensures that L_r contains only those positions where H appears as partial hypergraph. □

5. Half-covering and the CLOSEST SUBSTRING problem. The following hypergraph property plays a crucial role in our second algorithm for the CLOSEST SUBSTRING problem.

DEFINITION 5.1. *We say that a hypergraph $H(V, E)$ has the* half-covering *property if for every nonempty subset $Y \subseteq V$ there is an edge $X \in E$ with $|X \cap Y| > |Y|/2$.*

Theorem 4.3 says that finding a hypergraph H is easy if H has small fractional cover number. In our algorithm for the CLOSEST SUBSTRING problem (described later in this section), we have to find hypergraphs satisfying the half-covering property. The following combinatorial lemma shows that such hypergraphs have small fractional cover number, hence they are easy to find.

LEMMA 5.2. *If $H(V, E)$ is a hypergraph with m edges satisfying the half-covering property, then the fractional cover number ρ^* of H is $O(\log \log m)$.*

Proof. The fractional cover number equals the fractional stable number, thus there is a function ϕ: $V \to [0, 1]$ such that $\sum_{v \in X} \phi(v) \leq 1$ holds for every edge $X \in E$, and $\sum_{v \in V} \phi(v) = \rho^*$. The lemma is proved by a probabilistic argument: we show that if a random subset $Y \subseteq V$ is selected such that the probability of selecting a vertex v is proportional to $\phi(v)$, then with nonzero probability no edge covers more than half of Y, unless the number of edges is double exponential in ρ^*. The idea is to show that for each edge X, the expected size of Y is ρ^* times the expected size of $Y \cap X$, hence the Chernoff Bound can be used to show that there is only a small probability that X covers more than half of Y. However, the straightforward application of this idea gives only an exponential lower bound on the number of edges. To improve the bound to double exponential, we have to restrict our attention to a suitable subset T of vertices, and scale the probabilities appropriately.

Let $v_1, v_2, \ldots, v_{|V|}$ be an ordering of the vertices by nonincreasing value of $\phi(v_i)$. First, we give a bound on the sum of the largest $\phi(v_i)$'s.

PROPOSITION 5.3. $\sum_{j=1}^{i} \phi(v_j) \leq -4 \log_2 \phi(v_i) + 4$ *holds for every* $1 \leq i \leq |V|$.

Proof. The proof is by induction on i. Since $\phi(v_1) \le 1$, the claim is trivial for $i = 1$. For an arbitrary $i > 1$, let $i' \le i$ be the smallest value such that $\phi(v_{i'}) \le 2\phi(v_i)$. By assumption, there is an edge X of H that covers more than half of the set $S = \{v_{i'}, \dots, v_i\}$. Every weight in S is at least $\phi(v_i)$, hence X can cover at most $1/\phi(v_i)$ elements of S. Thus $|S| \le 2/\phi(v_i)$, and $\sum_{j=i'}^{i} \phi(v_j) \le 4$ follows from the fact that $\phi(v_j) \le 2\phi(v_i)$ for $i' \le j \le i$. If $i' = 1$, then we are done. Otherwise $\sum_{j=1}^{i'-1} \phi(v_j) \le -4\log_2 \phi(v_{i'-1}) + 4 < -4(\log_2 \phi(v_i) + 1) + 4$ follows from the induction hypothesis and from $\phi(v_{i'-1}) > 2\phi(v_i)$. Therefore, $\sum_{j=1}^{i} \phi(v_j) = \sum_{j=1}^{i'-1} \phi(v_j) + \sum_{j=i'}^{i} \phi(v_j) \le -4\log_2 \phi(v_i) + 4$, what we had to show. □

In the rest of the proof, we assume that ρ^* is sufficiently large, say $\rho^* \ge 100$. Let i be the largest value such that $\sum_{j=i}^{|V|} \phi(v_j) \ge \rho^*/2$. By the definition of i, $\sum_{j=i+1}^{|V|} \phi(v_j) < \rho^*/2$, hence $\sum_{j=1}^{i} \phi(v_j) \ge \rho^*/2$. Thus by Proposition 5.3, the weight of v_i (and every v_j with $j \ge i$) is at most $2^{-(\rho^*/2-4)/4} \le 2^{-\rho^*/10}$ (assuming that ρ^* is sufficiently large). Define $T := \{v_i, \dots, v_{|V|}\}$, and let us select a random subset $Y \subseteq T$: independently each vertex $v_j \in T$ is selected into Y with probability $p(v_j) := 2^{\rho^*/10} \cdot \phi(v_j) \le 1$. We show that if H does not have $2^{2^{\Omega(\rho^*)}}$ edges, then with nonzero probability every edge of H covers at most half of Y, contradicting the assumption that H satisfies the half-covering property.

The size of Y is the sum of $|T|$ independent 0-1 random variables. The expected value of this sum is $\mu = \sum_{j=i}^{|V|} p(v_j) = 2^{\rho^*/10} \cdot \sum_{j=i}^{|V|} \phi(v_j) \ge 2^{\rho^*/10} \cdot \rho^*/2$. We show that with nonzero probability $|Y| \ge \mu/2$, but $|X \cap Y| \le \mu/4$ for every edge X. To bound the probability of the bad events, we use the following form of the Chernoff Bound.

THEOREM 5.4 (see [3]). *Let $X_1, X_2, \dots, X_n$ be independent 0-1 random variables with $\Pr[X_i = 1] = p_i$. Denote $X = \sum_{i=1}^{n} X_i$ and $\mu = \mathrm{E}[X]$. Then*

$$\Pr[X \le (1-\beta)\mu] \le \exp(-\beta^2\mu/2) \quad \text{for } 0 < \beta \le 1,$$
$$\Pr[X \ge (1+\beta)\mu] \le \begin{cases} \exp(-\beta^2\mu/3) \text{ for } 0 < \beta \le 1, \\ \exp(-\beta^2\mu/(2+\beta)) \text{ for } \beta > 1. \end{cases}$$

Thus by setting $\beta = \frac{1}{2}$, the probability that Y is too small can be bounded as

$$\Pr[|Y| \le \mu/2] \le \exp(-\mu/8).$$

For each edge X, the random variable $|X \cap Y|$ is the sum of $|X \cap T|$ independent 0-1 random variables. The expected value of this sum is $\mu_X = \sum_{v \in X \cap T} p(v) = 2^{\rho^*/10} \cdot \sum_{v \in X \cap T} \phi(v) \le 2^{\rho^*/10} \le \mu/(\rho^*/2)$, where the first inequality follows from the fact that ϕ is a fractional stable set, hence the total weight X can cover is at most 1. Notice that if ρ^* is sufficiently large, then the expected size of $X \cap Y$ is much smaller than the expected size of Y. We want to bound the probability that $|X \cap Y|$ is at least $\mu/4$. Setting $\beta = (\mu/4)/\mu_X - 1 \ge \rho^*/8 - 1$, the Chernoff bound gives

$$\begin{aligned} \Pr\big[|X \cap Y| \ge \mu/4\big] &= \Pr\big[|X \cap Y| \ge (1+\beta)\mu_X\big] \le \exp(-\beta^2\mu_X/(2+\beta)) \\ &\le \exp(-\beta^2\mu_X/(2\beta)) = \exp(-\mu/8 + \mu_X/2) \le \exp(-\mu/16). \end{aligned}$$

Here we assumed that ρ^* is sufficiently large such that $\beta \ge 2$ (second inequality) and $\mu_X/2 \le \mu/16$ (third inequality) hold. If H has m edges, then the probability that $|Y| \le \mu/2$ holds or an edge X covers at least $\mu/4$ vertices of Y is at most

$$\exp(-\mu/8) + m \cdot \exp(-\mu/16) \le (m+1)\exp(-2^{\rho^*/10} \cdot \rho^*/32) \le m \cdot 2^{-2^{\Omega(\rho^*)}}. \tag{5.1}$$

If H satisfies the half-covering property, then for every Y there has to be at least one edge that covers more than half of Y. Therefore, the upper bound (5.1) cannot be smaller than 1. This is only possible if m is $2^{2^{\Omega(\rho^*)}}$, and it follows that $\rho^* = O(\log\log m)$, what we had to show. □

The following example shows that the bound $O(\log\log m)$ is tight in Lemma 5.2. Fix an integer r, and consider the 2^r-1 vertices $V := \{1,2,\ldots,2^r-1\}$. We construct a hypergraph that has not more than 2^{2^r} edges and its fractional cover number is at least $r/2$. Given a finite nonempty set F of positive integers, define $\mathrm{up}(F)$ to be the largest $\lceil(|F|+1)/2\rceil$ elements of this set. For every nonempty subset X of V, add the edge $\mathrm{up}(X)$ to the set system. This results in not more than $2^{2^r-1}-1$ edges. (There will be lots of parallel edges, but let us not worry about that.) Clearly, the set system satisfies the half-covering property: for every set Y, the set $\mathrm{up}(Y)$ covers more than half of Y.

We claim that the fractional cover number of the hypergraph is at least $r/2$. This can be proved by presenting a fractional stable set of weight $r/2$. Let the weight of v_1 be $1/2$, the weight of v_2 and v_3 be $1/4$, the weight of v_4, v_5, v_6, v_7 be $1/8$, and so on. It is easy to see that the total weight assigned is exactly $r/2$. Furthermore, observe that the weight of v_t is at most $1/(t+1)$ (there is equality if t is of the form 2^k-1; otherwise v_t is strictly smaller). To show that this weight assignment is indeed a fractional stable set, suppose that the vertices covered by some edge have total weight of more than 1. Let this edge be $\mathrm{up}(X)$ for some subset X of V. Let t be the smallest element in $\mathrm{up}(X)$. Vertex v_t has weight of at most $1/(t+1)$, and if t is the smallest element in $\mathrm{up}(X)$, then $\mathrm{up}(X)$ contains at most $t+1$ elements. Therefore, the total weight of the vertices covered by this edge is at most $(t+1)/(t+1)=1$. We remark that the W[1]-hardness proof in section 7 is essentially based on this example (see the construction of the enforcer systems in the proof of Proposition 7.2).

Now we are ready to prove the main result of this section.

THEOREM 5.5. CLOSEST SUBSTRING *can be solved in time* $|\Sigma|^d \cdot 2^{kd} \cdot d^{O(d\log\log k)} \cdot n^{O(\log\log k)}$.

Proof. Let us fix the first substring $s_1' \in s_1$ of the solution. We will repeat the following algorithm for each possible choice of s_1'. Since there are at most n possibilities for choosing s_1', the running time of the algorithm presented below has to be multiplied by a factor of n, which is dominated by the $n^{O(\log\log k)}$ term.

The center string s can differ on at most d positions from s_1'. Therefore, if we can find the set P of these positions, then the problem can be solved by trying all the $|\Sigma|^{|P|} \le |\Sigma|^d$ possible assignments on the positions in P. We show how to enumerate efficiently all the possible sets P.

We construct a hypergraph G over the vertex set $\{1,\ldots,L\}$. The edges of the hypergraph describe the possible substrings in the solution. If w is a length L substring of some string s_i and the distance of w is at most $2d$ from s_1', then we add an edge E to G such that $p \in E$ if and only if the pth character of w differs from the pth character of s_1'. Clearly, G has at most n edges, each of size at most $2d$. If $(s, s_1', \ldots, s_k')$ is a solution, then let H be the partial hypergraph of G that contains only the $k-1$ edges corresponding to the $k-1$ substrings $s_2', \ldots, s_k'$. (Note that the distance of s_1' and s_i' is at most $2d$, hence G indeed contains the corresponding edges.) Denote by P the set of at most d positions where s and s_1' differ. Let H_0 be the subhypergraph of H induced by P: the vertex set of H_0 is P, and for each edge E of H there is an edge $E \cap P$ in H_0. Hypergraph H_0 is subhypergraph of H and H is partial hypergraph of G, thus H_0 appears in G at P as subhypergraph.

CLOSEST SUBSTRING-2$(k, L, d, (s_1, \ldots, s_k))$
1. **for** each substring s'_1 of s_1 having length L **do**
2. Construct the hypergraph G on $\{1, \ldots, L\}$
3. **for** every hypergraph H_0 having $\leq d$ vertices and $\leq k$ edges **do**
4. **if** H_0 has the half-covering property **then**
5. **for** every place P where H_0 appears in G as subhypergraph **do** (Algorithm FIND-SUBHYPERGRAPH of Theorem 4.3)
6. **for** every string s that differs from s'_1 only at P **do**
7. **if** $\max_{i=1}^{k} \min_{\{s'_i \text{ is a substring of } s_i\}} d(s, s'_i) \leq d$ **then**
8. s is a solution, STOP.
9. There is no solution, STOP.

FIG. 5.1. *Algorithm* 2 *for* CLOSEST SUBSTRING.

We say that a solution is *minimal* if $\sum_{i=1}^{k} d(s, s'_i)$ is minimal. In Proposition 5.6, we show that if the solution $(s, s'_1, \ldots, s'_k)$ is minimal, then H_0 has the half-covering property. Therefore, we can enumerate all the possible P's by considering every hypergraph H_0 on at most d vertices that has the half-covering property (there are only a constant number of them), and for each such H_0, we enumerate all the places in G where H_0 appears as subhypergraph. Lemma 5.2 ensures that every H_0 considered has small fractional cover number. By Lemma 4.3, this means that we can enumerate efficiently all the places P where H_0 appears in G as subhypergraph. As discussed above, for each such P we can check whether there is a solution where the center string s differs from s'_1 only on P. By repeating this method for every hypergraph H_0 having the half-covering property, we eventually find a solution, if one exists.

PROPOSITION 5.6. *For every minimal solution* $(s, s'_1, \ldots, s'_k)$*, the corresponding hypergraph* H_0 *has the half-covering property.*

Proof. To see that H_0 has the half-covering property, assume that for some $Y \subseteq P$, every edge of H_0 covers at most half of Y. We show that in this case the solution is not minimal. Modify s such that it is the same as s'_1 on every position of Y; let s^* be the new center string. Clearly, $d(s^*, s'_1) = d(s, s'_1) - |Y|$. Furthermore, we show that this modification does not increase the distance for any i, that is, $d(s^*, s'_i) \leq d(s, s'_i)$ for every i. It follows that s^* is also a good center string, contradicting the minimality of the solution.

Let E_i be the edge of H_0 corresponding to the substring s'_i. This means that s'_1 and s'_i differ on $Y \cap E_i$, and they are the same on $Y \setminus E_i$. Therefore, $d(s^*, s'_i) \leq d(s, s'_i) + |Y \cap E_i| - |Y \setminus E_i|$. By assumption, E_i can cover at most half of Y, hence $d(s^*, s'_i) \leq d(s, s'_i)$, as required. □

The overall algorithm is presented in Figure 5.1. There are at most n different possibilities for the string s'_1 in step 1. The construction of the hypergraph G in step 2 takes polynomial time. There are not more than 2^{kd} different hypergraphs on at most d vertices having at most k edges, since there are at most 2^d possibilities for each edge. Therefore, the loop in step 3 is iterated at most 2^{kd} times. In step 4 the half-covering property can be tested by complete enumeration: we have to test for at most 2^d different subsets whether there is an edge that covers more than half of it. If H_0 satisfies the half-covering property, then by Lemma 5.2 its fractional cover number is at most $O(\log \log k)$. Therefore, by Theorem 4.3, step 5 takes $d^{O(d \log \log k)} \cdot n^{O(\log \log k)}$ time. If H_0 appears at P in G as subhypergraph, then in step 6 we have to try at most

$|\Sigma|^d$ possible center strings. Testing each center string can be done in polynomial time (step 7). Therefore, the total running time is $n \cdot 2^{kd} \cdot d^{O(d \log\log k)} \cdot n^{O(\log\log k)} \cdot |\Sigma|^d$. □

6. Algorithm for Consensus Patterns. The aim of this section is to show that the problem Consensus Patterns is fixed-parameter tractable in the bounded alphabet case if the parameter is $\delta := D/k$, the average distance. The algorithm is very similar to the algorithm of Theorem 5.5. The crucial difference is that here we can obtain a constant bound on the fractional cover number of the small hypergraphs H_0, instead of the weaker $O(\log\log k)$ bound coming from the half-covering property. This means that the exponent of n in the running time of the Find-Subhypergraph algorithm of Theorem 4.3 is a constant and we obtain a uniformly polynomial algorithm.

Theorem 6.1. Consensus Patterns *can be solved in time* $\delta^{O(\delta)} \cdot |\Sigma|^\delta \cdot n^9$.

Proof. If $\{s, s'_1, \ldots, s'_k\}$ is a solution for an instance of Consensus Patterns, then $d(s, s'_i) \leq \delta$ for at least one i. Therefore, if there is a solution for the instance, then it can be found by considering every string s_0 that is a length L substring of some s_i, and by checking for each such s_0 whether there is a solution with $d(s, s_0) \leq \delta$. Below we describe how to perform this check for a particular s_0. There are at most n possibilities for s_0, hence the total running time is at most n times greater than for a single s_0. We will assume that $\delta \geq 2$; otherwise it is easy to check every possible s with $d(s, s_0) \leq \delta$.

We construct a hypergraph G over the vertex set $\{1, \ldots, L\}$. If w is a length L substring of some string s_i, then we add an edge E to G such that $p \in E$ if and only if the pth character of w differs from the pth character of s_0. (Note that, unlike in the proof of Theorem 5.5, the hypergraph G can have edges larger than $2d$.) If $(s, s'_1, \ldots, s'_k)$ is a solution, then let H be the partial hypergraph of G that contains only the k edges corresponding to the k substrings $s'_1, \ldots, s'_k$.

Let $(s, s_1, \ldots, s_k)$ be a minimal solution; that is, $\sum_{i=1}^k d(s, s'_i)$ is as small as possible. Denote by P the set of positions where s and s_0 differ. Let H_0 be the subhypergraph of H induced by P: the vertex set of H_0 is P, and for each edge E of H there is an edge $E \cap P$ in H_0. Hypergraph H_0 is subhypergraph of H and H is partial hypergraph of G, thus H_0 appears in G at P as subhypergraph.

We follow the same path as in the proof of Theorem 5.5. It can be shown that the fractional cover number of H_0 is at most 2 (see the proof of Proposition 6.2 below). Therefore, we can find all the possible places P by enumerating every suitable hypergraph H_0, and by using Theorem 4.3 to enumerate all the places where H_0 appears in G as subhypergraph. The problem is that there can be large edges in G, and the algorithm of Theorem 4.3 can be used only if the size of the edges is bounded by the parameter. However, we argue that the same technique works even if the large edges are thrown away from G.

Remove every edge of size greater than 20δ from G (resp., H), let G^* (resp., H^*) be the resulting hypergraph, and let H_0^* be the subhypergraph of H^* induced by P. It is clear that H_0^* is a subhypergraph of G^*. Furthermore, the fractional edge cover number of H_0^* can be bounded by a constant.

Proposition 6.2. *For every minimal solution* $(s, s'_1, \ldots, s'_k)$*, the corresponding hypergraph* H_0^* *has fractional cover number at most* $5/2$.

Proof. We claim that every element of P is covered by at least $k/2$ edges of H_0. Assume that only $k' < k/2$ edges of H_0 cover some $p \in P$. This means that only k' of the strings $s'_1, \ldots, s'_k$ differ from s_0 at position p. Let us change position p of the median string s: let this character be the same as the character at position p of

CONSENSUS PATTERNS$(k, L, \delta, (s_1, \ldots, s_k))$
1. **for** each substring s_0 of $s_1, \ldots, s_k$ having length L **do**
2. Construct the hypergraph G^* on $\{1, \ldots, L\}$
3. **for** every hypergraph H_0^{**} having $\leq \delta$ vertices and $\leq 200 \ln \delta$ edges **do**
4. **if** every vertex of H_0^{**} is covered by at least $1/5$ part of the edges **then**
5. **for** every place P where H_0^{**} appears in G^* as subhypergraph **do** (Algorithm FIND-SUBHYPERGRAPH of Theorem 4.3)
6. **for** every string s that differs from s_0 only at P **do**
7. **if** $\sum_{i=1}^{k} \min_{\{s_i' \text{ is a substring of } s_i\}} d(s, s_i') \leq \delta k$ **then**
8. s is solution, STOP
9. There is no solution, STOP

FIG. 6.1. *Algorithm for* CONSENSUS PATTERNS.

s_0. Now $d(s, s_i')$ decreases for $k - k' > k/2$ values of i, and it increases for at most $k' < k/2$ values of i. Therefore, $\sum_{i=1}^{k} d(s, s_i')$ strictly decreases, contradicting the minimality of s. This shows that every vertex of H_0 is covered by at least $k/2$ of the k edges, hence the fractional cover number of H_0 is at most 2.

From $d(s, s_0) \leq \delta$ and $\sum_{i=1}^{k} d(s, s_i') \leq D = k\delta$, it follows that $\sum_{i=1}^{k} d(s_0, s_i') \leq 2k\delta$. Therefore, the total size of the edges in H is at most $2k\delta$, which means that there are at most $2k/20 \leq k/10$ edges in H that have size greater than 20δ. Each element of P is covered by at least $k/2$ edges of H_0, hence even if the edges greater than 20δ are thrown away, there remain at least $k/2 - k/10 = 2k/5$ edges in H_0^* to cover each element. Therefore, if we set the weight of each edge to $(5/2) \cdot (1/k)$, then we obtain a fractional edge cover with total weight $5/2$. □

Proposition 6.2 shows that we can find all the possible places P by enumerating every hypergraph H_0^* on δ vertices having fractional cover number at most $5/2$, and then enumerating every place in G^* where H_0^* appears. To reduce the number of hypergraphs H_0^* that has to be considered, we show that it is sufficient to restrict our attention to hypergraphs having $O(\log \delta)$ edges.

PROPOSITION 6.3. *Assume $\delta \geq 2$. If $(s, s_1', \ldots, s_k')$ is a minimal solution and H_0^* is the corresponding hypergraph, then it is possible to select $200 \ln \delta$ edges of H_0^* in such a way that if we delete all the other edges, then the resulting hypergraph H_0^{**} has fractional cover number at most 5.*

Proof. Let $k' \leq k$ be the number of edges of H_0^*. Let us select each edge of H_0^* independently with probability $(150 \ln \delta)/k'$. The expected number of selected edges is $150 \ln \delta$; from Theorem 5.4 ($\beta = 1/3$) it follows that the probability of selecting more than $200 \ln \delta$ edges is at most $\exp((-150 \ln \delta)/27) < 1/\delta^2$. We have seen in Proposition 6.2 that each vertex of H_0^* is covered by at least $2k/5$ edges, thus the expected number of edges that cover a given vertex of H_0^{**} is at least $60(k/k') \ln \delta \geq 60 \ln \delta$. Furthermore, by Theorem 5.4 ($\beta = 1/3$) the probability that a given vertex of H_0^{**} is covered by less than $40 \ln \delta$ edges is at most $\exp(-60 \ln \delta/18) \leq 1/\delta^3$. Therefore, with probability at least $1 - 1/\delta^2 - \delta \cdot 1/\delta^3 > 0$, we select a maximum of $200 \ln \delta$ edges and each vertex is covered by at least $40 \ln \delta$ edges. This means that the fractional cover number of H_0^{**} is at most 5: setting the weight of each edge to $1/(40 \ln \delta)$ gives a fractional edge cover. □

The overall algorithm is presented in Figure 6.1. There are at most n different possibilities for the string s_0 in step 1. The rest of the algorithm checks whether there is a solution where the median string differs from s_0 on at most δ positions. The

construction of the hypergraph G^* can be done in $O(Ln)$ time in step 2. Since we try to find solutions with $d(s_0, s) \leq \delta$, it can be assumed that H_0^{**} has at most δ vertices. There are not more than $2^{O(\delta \ln \delta)} = \delta^{O(\delta)}$ different hypergraphs on at most δ vertices having at most $200 \ln \delta$ edges, since there are at most 2^δ possibilities for each edge. Therefore, the loop in step 3 is iterated at most $2^{O(\delta \ln \delta)}$ times. The test in step 4 is trivial. Since the fractional cover number of H_0^{**} is at most 5 and every edge of G^* has size at most 20δ, step 5 takes $\delta^{O(\delta)} \cdot n^6 L^2$ time. If H_0^{**} appears at P in G^* as subhypergraph, then in step 6 we have to try at most $|\Sigma|^\delta$ possible median strings. Testing each median string can be done in $O(Ln)$ time (step 7). Therefore, the total running time is $\delta^{O(\delta)} \cdot |\Sigma|^\delta \cdot n^9$. □

7. Set balancing. In this section we introduce a new problem called Set Balancing. The problem is somewhat technical and it is not motivated by practical applications. However, as we will see it in section 8, the problem is useful in proving the W[1]-hardness of Closest Substring.

Set Balancing

Input:
A collection of m set systems $\mathscr{S}_i = \{S_{i,1}, \ldots, S_{i,|\mathscr{S}_i|}\}$ $(1 \leq i \leq m)$ over the same ground set A and a positive integer d. The size of each set $S_{i,j}$ is at most ℓ, and there is an integer weight $w_{i,j}$ associated to each set $S_{i,j}$.

Parameters:
m, d, ℓ

Task:
Find a set $X \subseteq A$ of size at most d and select a set $S_{i,a_i} \in \mathscr{S}_i$ for every $1 \leq i \leq m$ in such a way that

$$|X \triangle S_{i,a_i}| \leq w_{i,a_i} \tag{7.1}$$

holds for every $1 \leq i \leq m$.

Here $X \triangle S_{i,a_i}$ denotes the symmetric difference $(X \setminus S_{i,a_i}) \cup (S_{i,a_i} \setminus X)$. We have to select a set X and a set from each set system in such a way that the balancing requirement (7.1) is satisfied: every selected set is close to X. The weight $w_{i,j}$ of each set $S_{i,j}$ prescribes the maximum distance of X from this set. The smaller the weight, the more restrictive the requirement. The distance is measured by symmetric difference; therefore, adding an element outside $S_{i,j}$ to X can be compensated by adding an element from $S_{i,j}$ to X. If (7.1) holds for some set S_{i,a_i}, then we say that S_{i,a_i} is *balanced*, or X *balances* S_{i,a_i}.

It can be assumed that the weight of each set is at most $\ell + d$; otherwise the requirement would be automatically satisfied for every possible X. If a set appears in multiple set systems, then it can have different weights in the different systems.

In this section we show that Set Balancing is W[1]-hard even when all of m, d, and ℓ are parameters. It is not very difficult to show that the problem is W[1]-hard if we consider the variant of the problem where the size of X has to be *exactly* d. However, the proof becomes significantly more complicated if we have only the requirement $|X| \leq d$. Intuitively, now the problem is that we have to ensure that the reduction does not construct instances that can be solved by a "small" X, since such an X could be found with an exhaustive search. An easy way to ensure that X is

large would be to have a set that can be balanced only by selecting d elements from this set. However, this would reduce the search space to the d-element subsets of this set, and the problem would be easy, since there are at most $\binom{\ell}{d}$ such sets. The main combinatorial challenge in the proof is to ensure that there are no small solutions, but there are lots of possible sets that could form a solution. It should be the combined effect of several set systems that prevent $|X|$ from being small. Furthermore, each set in a set system should be useful for many possible solutions, since the set systems cannot be too large.

THEOREM 7.1. SET BALANCING *is* W[1]*-hard with combined parameters* m*,* d*, and* ℓ*.*

Proof. The proof is by reduction from the MAXIMUM CLIQUE problem. Assume that a graph $G(V, E)$ is given with n vertices and e edges; the task is to find a clique of size t. It can be assumed that $n = 2^{2^C}$ for some integer C: we can ensure that the number of vertices has this form by adding at most $|V|^2$ isolated vertices. Furthermore, we can assume that $C \geq t$ (i.e., $n \geq 2^{2^t}$): if $n < 2^{2^t}$, then MAXIMUM CLIQUE can be solved directly in time $O((2^{2^t})^t \cdot n)$ by enumerating every set of size t.

The ground set A of the constructed instance of SET BALANCING is partitioned into t groups $A_0, \ldots, A_{t-1}$. The group A_i is further partitioned into 2^i blocks $A_{i,1}$, $\ldots$, $A_{i,2^i}$; the total number of blocks is $2^t - 1$. The block $A_{i,j}$ contains $n^{1/2^i} = 2^{2^{C-i}}$ elements. Set $d := 2^t - 1$. Later we will argue that it is sufficient to restrict our attention to solutions where X contains exactly one element from each block $A_{i,j}$. Let us call such a solution a *standard solution*. We construct the set systems in such a way that there is one-to-one correspondence between the standard solutions and the size t cliques of G. In a standard solution X contains exactly 2^i elements from group A_i, and there are $(n^{1/2^i})^{2^i} = n$ different possibilities for selecting these 2^i elements from the blocks of A_i. Let $X_{i,1}, \ldots, X_{i,n}$ be these n different 2^i-element sets. These n possibilities will correspond to the choice of the ith vertex of the clique.

The set systems are of two types: the verifier systems and the enforcer systems. The role of the verifier systems is to ensure that every standard solution corresponds to a clique of size t, while the enforcer systems ensure that there are only standard solutions.

For each $0 \leq i_1 < i_2 \leq t-1$ the verifier system $\mathscr{S}_{i_1,i_2}$ ensures that the i_1th and the i_2th vertices of the clique are adjacent. The set system $\mathscr{S}_{i_1,i_2}$ contains $2e$ sets of size $2^{i_1} + 2^{i_2}$ each. If vertices u and v are adjacent in G, then $X_{i_1,u} \cup X_{i_2,v}$ is in $\mathscr{S}_{i_1,i_2}$. The weight of every set in $\mathscr{S}_{i_1,i_2}$ is $(2^t - 1) - (2^{i_1} + 2^{i_2})$.

PROPOSITION 7.2. *There is a standard solution if and only if* G *has a size* t *clique.*

Proof. Assume that $v_0, \ldots, v_{t-1}$ is a clique in G. Let

$$X = \bigcup_{i=0}^{t-1} X_{i,v_i}.$$

The size of X is $\sum_{i=0}^{t-1} 2^i = 2^t - 1$. Select the set $X_{i_1,v_{i_1}} \cup X_{i_2,v_{i_2}}$ from the verifier system $\mathscr{S}_{i_1,i_2}$. This set is balanced by X: it is a size $2^{i_1} + 2^{i_2}$ subset of X having weight $(2^t - 1) - (2^{i_1} + 2^{i_2})$.

To prove the other direction, assume now that there is a standard solution X. In a standard solution, $X \cap A_i$ is a 2^i-element set X_{i,v_i} for some v_i. We claim that these v_i's form a size t clique in G.

Suppose that for some $i_1 < i_2$ vertices v_{i_1} and v_{i_2} are not connected by an edge (including the possibility $v_{i_1} = v_{i_2}$). Consider the set $S \in \mathscr{S}_{i_1,i_2}$ selected in the solution. The size of X is $2^t - 1$ in a standard solution, thus the set X contains at least $2^t - 1 - (2^{i_1} + 2^{i_2})$ elements outside the set S. Therefore, S can be balanced only if all the $2^{i_1} + 2^{i_2}$ elements of S are in X. Assume that the set S selected from $\mathscr{S}_{i_1,i_2}$ is $X_{i_1,u} \cup X_{i_2,v}$. Now $X_{i_1,u} \cup X_{i_2,v} \subseteq X$, which means that $u = v_{i_1}$ and $v = v_{i_2}$. By construction, if $X_{i_1,u} \cup X_{i_2,v}$ is in $\mathscr{S}_{i_1,i_2}$, then u and v are adjacent, hence v_{i_1} and v_{i_2} are indeed neighbors. □

The job of the enforcer systems is to ensure that every solution of weight at most $d = 2^t - 1$ is standard. The $2^t - 1$ blocks $A_{i,j}$ are indexed by two indices i and j. In the following, it will be more convenient to index the blocks by a single variable. Let $B_1, \ldots, B_{2^t-1}$ be an ordering of the blocks such that B_1 is the only block of group A_0, the blocks B_2, B_3 are the blocks of A_1, the next four blocks after that are the blocks of A_2, etc.

A naive way of constructing the enforcer set systems would be to have for each block B_i a corresponding set system $\mathscr{S}_i$ that contains $|B_i|$ one-element sets: there is one set of weight $2^t - 2$ for each element of B_i. This ensures that if a solution contains at least one element from every block other than B_i (i.e., it contains at least $2^t - 2$ elements outside B_i), then it has to contain an element of B_i as well (otherwise the symmetric difference is at least $2^t - 1$). The problem with this construction is that every set of $\mathscr{S}_i$ is balanced by the solution $X = \emptyset$, hence such systems cannot ensure that every solution is standard.

There are $2^{2^t-1} - 1$ enforcer set systems: there is a set system $\mathscr{S}_F$ corresponding to each nonempty subset F of $\{1, 2, \ldots, 2^t - 1\}$. The job of $\mathscr{S}_F$ is to rule out the possibility that a solution X contains no elements from the blocks indexed by F, but X contains at least one element from every other block. Clearly, these systems will ensure that no block is empty in a solution, hence every solution of weight $2^t - 1$ is standard. One possible way of constructing the system $\mathscr{S}_F$ is to have one set of size $|F|$ and weight $2^t - 1 - |F|$ for each possible way of selecting one element from each block indexed by F. Clearly, this makes it impossible to have at least one element in each of the $2^t - 1 - |F|$ blocks outside F, but none in F. Now the problem is that the size of $\mathscr{S}_F$ can be too large, in particular when $F = \{1, 2, \ldots, 2^t - 1\}$. We use a somewhat more complicated construction to keep the size of the systems small.

Recall the definition of $\mathrm{up}(F)$ from section 5: given a finite set F of positive integers, $\mathrm{up}(F)$ is defined to be the largest $\lceil (|F| + 1)/2 \rceil$ elements of this set. The enforcer system corresponding to F is defined as

$$\mathscr{S}_F = \prod_{p \in \mathrm{up}(F)} B_p. \tag{7.2}$$

That is, we consider the blocks indexed by the upper half of F, and put into $\mathscr{S}_F$ all the possible combinations of selecting one element from each block. Let the weight of each set in $\mathscr{S}_F$ be $2^t - 1 - |\mathrm{up}(F)|$. Notice that it is possible that $\mathrm{up}(F_1) = \mathrm{up}(F_2)$ for some $F_1 \neq F_2$, which means that for such F_1 and F_2 the systems $\mathscr{S}_{F_1}$ and $\mathscr{S}_{F_2}$ are in fact the same. However, we do not care about that.

We have to verify that these set systems are not too large; i.e., they can be constructed in uniformly polynomial time.

PROPOSITION 7.3. *For every nonempty $F \subseteq \{1, 2, \ldots, 2^t - 1\}$, the enforcer system $\mathscr{S}_F$ contains at most n^2 sets.*

Proof. Let x be the smallest element of $\mathrm{up}(F)$, and assume that $2^p \leq x < 2^{p+1}$

for some integer p. There is one block of size n, there are 2 blocks of size $n^{1/2}$, ..., there are 2^i blocks of size $n^{1/2^i}$, hence the size of B_{2^p} is $n^{1/2^p}$. The size of the blocks is decreasing, thus all the sets in the product (7.2) are of size at most $n^{1/2^p}$. If the smallest element of $\mathrm{up}(F)$ is x, then it can contain at most $x+1$ elements. This means that we take the direct product of at most $x+1$ sets of size at most $n^{1/2^p}$ each. Therefore, the total number of sets in $\mathscr{S}_F$ is at most $(n^{1/2^p})^{x+1} \leq (n^{1/2^p})^{2^{p+1}} = n^2$. □

The following proposition completes the proof of the first direction: if the solution is standard, then we can select a set from each enforcer system. Together with Proposition 7.2, it follows that if there is a clique of size t, then there is a (standard) solution for the constructed instance of Set Balancing.

Proposition 7.4. *If X is a standard solution, then each $\mathscr{S}_F$ contains a set that is balanced by X.*

Proof. For the enforcer system $\mathscr{S}_F$, let us select the set

$$S_F = X \cap \bigcup_{p \in \mathrm{up}(F)} B_p.$$

That is, S_F contains those elements of X that belong to the blocks indexed by $\mathrm{up}(F)$. The set S_F is a size $|\mathrm{up}(F)|$ subset of X. Therefore, $|X \triangle S_F| = 2^t - 1 - |\mathrm{up}(F)|$, which is exactly the weight of the selected set. Thus S_F is balanced. □

On the other hand, if there is a solution for the constructed instance of Set Balancing with $|X| \leq d = 2^t - 1$, then this solution has to be standard, and by Proposition 7.2 there is a clique of size t in G. This completes the proof of the second direction.

Proposition 7.5. *If $|X| \leq 2^t - 1$, then X contains exactly one element from each block.*

Proof. Assume first that X does not contain elements from some of the blocks. Let F contain the indices of those blocks that are disjoint from X. This means that X contains at least one element from each block not in F, hence $|X| \geq 2^t - 1 - |F|$. Assume that some set S is selected from $\mathscr{S}_F$ in the solution. This set contains elements only from blocks indexed by $\mathrm{up}(F) \subseteq F$, hence S is disjoint from X. Thus $|X \triangle S| = |X| + |S| \geq 2^t - 1 - |F| + |\mathrm{up}(F)| > 2^t - 1 - |\mathrm{up}(F)|$, which means that S is not balanced (here we used $|F| - |\mathrm{up}(F)| < |\mathrm{up}(F)|$). Therefore, each block contains at least one element of X. Since there are $2^t - 1$ blocks, this is only possible if each block contains exactly one element of X. □

The distance $d = 2^t - 1$ is a function of the original parameter t. The number m of the constructed set systems is $\binom{t}{2} + 2^{2^t - 1} - 1$, which is also a function of t. Each set in the constructed systems has size at most $\ell := 2^t - 1$. We have seen that the size of each set system is polynomial in n, hence the reduction is a correct parameterized reduction. □

8. Hardness of Closest Substring. In this section we show that Closest Substring is W[1]-hard with combined parameters k and d. The reduction is very similar to the reduction presented in [14], where it is proved that problem is W[1]-hard with parameter k only. As in that reduction, the main technical trick is that each string s_i is divided into blocks and we ensure that the string s'_i is one of these blocks in every solution. However, here the reduction is from Set Balancing, and not from Maximum Clique. This allows us to construct an instance of Closest Substring where the distance parameter d is bounded by a constant.

THEOREM 8.1. CLOSEST SUBSTRING *is* W[1]*-hard with parameters* d *and* k*, even if* $\Sigma = \{0, 1\}$.

Proof. The reduction is from the SET BALANCING problem, whose W[1]-hardness was shown in section 7. Assume that m set systems $\mathscr{S}_i = \{S_{i,1}, \ldots, S_{i,|\mathscr{S}_i|}\}$ and an integer d are given. Let $0 \leq w_{i,j} \leq d + \ell$ be the weight of $S_{i,j}$ in $\mathscr{S}_i$, and assume that each set has size at most ℓ. We construct an instance of CLOSEST SUBSTRING with distance parameter $d' := d + \ell$, where $d' + 1$ strings $s_{i,1}, s_{i,2}, \ldots, s_{i,d'+1}$ correspond to each set system $\mathscr{S}_i$, and there is one additional string s_0 called the *template string*. Thus there are $k := (d' + 1)m + 1$ strings in total.

Set $L := 6d' + 3d'(3d' + 1) + |A| + d' - d + 2d'm(d' + 1)$, where A is the common ground set of the set systems. The template string s_0 has length L, hence $s'_0 = s_0$ in every solution. The string $s_{i,j}$ is the concatenation of *blocks* $B_{i,j,1}, \ldots, B_{i,j,|\mathscr{S}_i|}$ of the same length L, and each block corresponds to a set in $\mathscr{S}_i$. We will ensure that in a solution the substring $s'_{i,j}$ is one complete block from $s_{i,j}$. Therefore, selecting $s'_{i,j}$ from $s_{i,j}$ in the constructed CLOSEST SUBSTRING instance plays the same role as selecting a set S_i from $\mathscr{S}_i$ in SET BALANCING.

Each block $B_{i,j,k}$ of the string $S_{i,j}$ is the concatenation of four parts: the front tag, the core, the complete tag, and the back tag. The *front tag* is the same in every block: $1^{3d'}(10^{3d'})^{3d'}1^{3d'}$. The *core* corresponds to the ground set A in the SET BALANCING problem. The length of the core is $|A|$, and the pth character of the core in block $B_{i,j,k}$ is 1 if and only if the set $S_{i,k} \in \mathscr{S}_i$ contains the pth element of A. The *complete tag* is $1^{d'-d}$ in every block. The *back tag* is the concatenation of $m(d' + 1)$ segments $C_{i,j}$ $(1 \leq i \leq m, 1 \leq j \leq d' + 1)$ (the order in which these segments are concatenated will not be important). The length of each segment is $2d'$. In block $B_{i,j,k}$ of string $s_{i,j}$ the back tag contains 1's only in segment $C_{i,j}$: there is 1 on the first $d' - w_{i,k} \geq 0$ positions of $C_{i,j}$; the rest of $C_{i,j}$ is 0. This completes the description of the strings $s_{i,j}$. Notice that the blocks $B_{i,j_1,k}$ and $B_{i,j_2,k}$ differ only in the back tag. The length L template string s_0 is similar to the blocks defined above: it has the same front tag as all the other blocks, but its core, complete tag, and back tag contain only 0's.

The first direction of the proof is shown in the following proposition.

PROPOSITION 8.2. *If the* SET BALANCING *instance has a solution, then the constructed instance of* CLOSEST SUBSTRING *also has a solution.*

Proof. Let $X \subseteq A$ and $S_{1,a_1} \in \mathscr{S}_1, \ldots, S_{m,a_m} \in \mathscr{S}_m$ be a solution of SET BALANCING. Let the center string s be the concatenation of the front tag, the incidence vector of X, the string $1^{d'-d}$, and the string $0^{2d'm(d'+1)}$. The distance of s and s_0 is $|X| + d' - d \leq d'$: the distance is $|X|$ on the core and $d' - d$ on the complete tag. Furthermore, we claim that the block B_{i,j,a_i} in string $s_{i,j}$ is at distance at most d' from s. If we can show this, then it follows that CLOSEST SUBSTRING has a solution.

The front tag of B_{i,j,a_i} is the same as the front tag of s. In the core the distance is the symmetric difference of X and S_{i,a_i}. The complete tag is the same in s and B_{i,j,a_i}. The back tag of s is all 0, while the back tag of B_{i,j,a_i} contains $d' - w_{i,k}$ characters 1 (in the segment $C_{i,j}$). Therefore,

$$d(s, B_{i,j,a_i}) = |X \triangle S_{i,a_i}| + d' - w_{i,k} \leq d',$$

where the inequality follows from the fact that X balances the set S_{i,a_i}, that is, $|X \triangle S_{i,a_i}| \leq w_{i,k}$. ∎

To prove the reverse direction, first we show that each substring $s'_{i,j}$ has to be a complete block of the string $s_{i,j}$. By the triangle inequality, $d(s_0, s'_{i,j}) = d(s'_0, s'_{i,j}) \leq$

$d(s'_0, s) + d(s, s'_{i,j}) \leq 2d'$ has to hold in every solution. We show that $d(s_0, s'_{i,j}) \leq 2d'$ implies that $s'_{i,j}$ is a complete block.

PROPOSITION 8.3. *If $d(s_0, s'_{i,j}) \leq 2d'$ for some substring $s'_{i,j}$ of $s_{i,j}$, then $s'_{i,j}$ is the block $B_{i,j,b}$ for some b.*

Proof. Assume that $s'_{i,j}$ starts on the pth character of some block $B_{i,j,b}$. This means that $s'_{i,j}$ contains the last $L - p + 1$ characters from $B_{i,j,b}$ and the first $p - 1$ characters from the next block $B_{i,j,b+1}$. We show that if $p \neq 1$, then $d(s_0, s'_{i,j}) > 2d'$. Denote by $f = 6d' + 3d'(3d' + 1)$ the length of the front tag. Assume first that $3d' < p \leq L - f$. In this case the first $3d'$ characters of $B_{i,j,b+1}$ (all of them are 1's) are aligned with characters $L+1-p, \ldots, L+3d'-p$ of s_0 (all of them are 0's), hence $d(s_0, s'_{i,j}) > 2d'$ follows. Assume now that $L - f < p \leq L - 3d'$; a similar argument shows that the last $3d'$ characters in the front tag of $B_{i,j,b+1}$ cause $3d'$ mismatches. If $1 < p \leq 3d'$, then the 1's in the $(10^{3d'})^{3d'}$ part of the front tag are not aligned, which increases the difference to more than $2d'$. The same thing happens if $L - 3d' < p \leq L$ holds. This concludes the proof that $p = 1$; that is, the string $s'_{i,j}$ is one complete block $B_{i,j,b}$. □

Since the template string and each block begins with the front tag, it cannot hurt if the center string also begins with the front tag.

PROPOSITION 8.4. *If there is a solution for the constructed instance of* CLOSEST SUBSTRING*, then there is such a solution where the front tag of the center string s is the same as the front tag of s_0.*

It can be assumed that the back tag of the center string s contains only 0's.

PROPOSITION 8.5. *If there is a solution for the constructed instance of* CLOSEST SUBSTRING*, then there is such a solution where the back tag of the center string s contains only 0's.*

Proof. Let s be the center string of a solution. Since the back tag of s_0 contains only 0's, in the back tag of s at most d' characters can be 1. This means that with the exception of at most d' segments, the segments of the back tag contain only 0's. Thus for every $1 \leq i \leq m$, there is a $1 \leq x_i \leq d' + 1$ such that segment C_{i,x_i} of the back tag of s contains only 0's. Let s^* be the same as s but with the back tag set to 0's. It is clear that $d(s^*, s_0) \leq d(s, s_0) \leq d'$: the back tag of s_0 is empty, hence setting the back tag to 0 cannot increase the distance.

We claim that a block can be selected from each string $s_{i,j}$ in such a way that the distance of each selected block is at most d' from s^*. For the string s_{i,x_i} we can select the same s'_{i,x_i} as before: the back tag of s'_{i,x_i} contains 1's only in segment C_{i,x_i}, but s does not contain any 1's in C_{i,x_i}. This means that setting to 0 the back tag of s does not increase the distance between s and s'_{i,x_i}. Assume that s'_{i,x_i} is block $B_{i,x_i,t}$ for some t. For every $j \neq x_i$, select block $B_{i,j,t}$ from the string $s_{i,j}$. The only difference between blocks $B_{i,x_i,t}$ and $B_{i,j,t}$ is in the back tag: they have the same number of 1's in the back tag, but in different segments. However, s^* has only 0's in the back tag, hence $d(B_{i,j,t}, s^*) = d(B_{i,x_i,t}, s^*) \leq d'$. Therefore, s^* and the selected blocks form a solution where the back tag of the center string s^* contains only 0's. □

We can assume that the complete tag is $1^{d'-d}$ in s.

PROPOSITION 8.6. *If there is a solution for the constructed instance of* CLOSEST SUBSTRING*, then there is such a solution where the complete tag of the center string s contains only 1's.*

Proof. Let s be a solution where the number of 0's in the complete tag of the center string is minimal. Assume first that there is a 1 in the core of s. In this case replace this 1 with a 0, and set one of the 0's in the complete tag to 1. This modification

does not change the difference of s from s_0. Furthermore, it does not increase the distance of s from $s'_{i,j}$: replacing the 0 with a 1 in the complete tag decreases the distance, while replacing the 1 with 0 in the core may or may not increase the distance. Therefore, the new center string contradicts the minimality of s.

Assume now that the core of s contains only 0's. We have already seen that the front tag of s is the same as the front tag of s_0 (Proposition 8.4), and the back tag contains only 0's (Proposition 8.5). Therefore, s differs from s_0 only in the complete tag. This means that in the complete tag of s we can replace every 0 with 1: the distance between s and s_0 increases only to $d'-d$, while the distance decreases between s and every string $s'_{i,j}$. □

The proofs of Propositions 8.4–8.6 are independent in the sense that we can assume that there is a solution where the center string s satisfies all three requirements at the same time. Assuming that s is of this form, it is not difficult to prove the converse of Proposition 8.2.

PROPOSITION 8.7. *If there is a solution for the constructed instance of* CLOSEST SUBSTRING*, then there is a solution for the* SET BALANCING *problem.*

Proof. Consider a solution where the complete tag of s contains only 1's, and the back tag of s contains only 0's. Define the set $X \subseteq A$ based on the core of s: let an element of A be in X if and only if the corresponding character is 1 in the core of s. The string s differs from the template string s_0 at $|X|$ positions in the core and at $d'-d$ positions in the complete tag. Since $d(s,s_0) \leq d'$, it follows that $|X| \leq d$.

We claim that for every $1 \leq i \leq s$, a set can be selected from $\mathscr{S}_i$ that is balanced by X. Assume that $s'_{i,1}$ is the block $B_{i,1,t}$ of $s_{i,1}$ for some t. We show that $S_{i,t} \in \mathscr{S}_i$ is balanced by X. Let us determine the distance $d(B_{i,1,t}, s)$, which is by assumption at most d'. In the core, the two strings differ on the symmetric difference of $S_{i,t}$ and X. The strings do not differ on the complete tag, but they differ on every position of the back tag where $B_{i,1,t}$ is 1. There are exactly $d'-w_{i,t}$ such positions, hence

$$d(s, s'_{i,j}) = |X \triangle S_{i,k}| + d' - w_{i,t} \leq d',$$

which means that $|X \triangle S_{i,t}| \leq w_{i,t}$ and the set $S_{i,t}$ is balanced. □

Propositions 8.2 and 8.7 together prove the correctness of the reduction. □

Putting together Theorems 7.1 and 8.1 gives a two-step reduction from MAXIMUM CLIQUE to CLOSEST SUBSTRING. Let us follow how the parameters depend on each other during this reduction. If an instance of MAXIMUM CLIQUE is given with parameter t, then Theorem 7.1 constructs an instance of SET BALANCING with the following parameters:

$$\begin{aligned} d &:= 2^t - 1, \\ m &:= \binom{t}{2} + 2^{2^{t-1}} - 1 = 2^{2^{O(t)}}, \\ \ell &:= 2^{t-1}. \end{aligned}$$

Theorem 8.1 transforms this instance into an instance of CLOSEST SUBSTRING with the following parameters:

$$\begin{aligned} k &:= (d+\ell+1)m + 1 = 2^{2^{O(t)}}, \\ d' &:= d + \ell = 2^{O(t)}. \end{aligned}$$

Theorem 3.3 gives an $|\Sigma|^{d(\log d+2)}n^{\log d+O(1)}$ time algorithm for CLOSEST SUBSTRING and Theorem 5.5 gives an algorithm with running time $2^{kd} \cdot d^{O(d \log\log k)}$.

$n^{O(\log\log k)} \cdot |\Sigma|^d$. We argue that in some sense these algorithms are best possible: the exponent of n cannot be improved to $o(\log d)$ or to $o(\log\log k)$ (modulo some complexity-theoretic assumptions).

Assume that there is an $f_1(k,d)\cdot n^{o(\log d)}$ time algorithm for Closest Substring. We can construct an algorithm for Maximum Clique by reducing it to Closest Substring and using our assumed algorithm for the latter problem. The running time of this algorithm for finding a size t clique is $f_1(k,d) \cdot n^{o(\log d)} = f_1(2^{2^{O(t)}}, 2^t) \cdot n^{o(\log 2^t)} = f_1'(t) \cdot n^{o(t)}$ (it can be assumed that the running time of the reduction to Closest Substring is dominated by the time required to solve the Closest Substring instance.) By a result of [9], the existence of an $f_1'(t) \cdot n^{o(t)}$ algorithm for Maximum Clique would imply that n-variable 3-Sat can be solved in $2^{o(n)}$ time; i.e., the Exponential Time Hypothesis would be violated. Therefore, it is highly unlikely that there is an algorithm for Closest Substring with $o(\log d)$ in the exponent.

Corollary 8.8. *There is no $f_1(k,d) \cdot n^{o(\log d)}$ time algorithm for* Closest Substring*, unless n-variable* 3-Sat *can be solved in time $2^{o(n)}$.*

Similarly, an $f_2(k,d) \cdot n^{o(\log\log k)}$ time algorithm for Closest Substring would imply that there is an $f_2(2^{2^{O(t)}}, 2^t) \cdot n^{o(\log\log 2^{2^{O(t)}})} = f_2'(t) \cdot n^{o(t)}$ algorithm for Maximum Clique.

Corollary 8.9. *There is no $f_2(k,d) \cdot n^{o(\log\log k)}$ time algorithm for* Closest Substring*, unless n-variable* 3-Sat *can be solved in time $2^{o(n)}$.*

In our reduction from Maximum Clique to Closest Substring, the blow-up of the parameters is unusually large: double exponential. It might seem that with some more careful construction we could give a simpler reduction, where the parameters of the constructed instance are smaller. However, the connection with subexponential algorithms shows that the double exponential increase cannot be avoided, i.e., it is a necessary part of any reduction from Maximum Clique to Closest Substring. Assume that there is an $f(t) \cdot n^c$ time parameterized reduction where $d = g_1(t)$ and $k = g_2(t) = 2^{2^{o(t)}}$. This reduction and the $h(k,d) \cdot n^{O(\log\log k)}$ time algorithm of Theorem 5.5 would give an algorithm for Maximum Clique with running time

$$\begin{aligned} &f(t)n^c + h(g_1(t), g_2(t)) \cdot (f(t)n^c)^{O(\log\log g_2(t))} \\ &\qquad = h'(t) \cdot n^{O(\log\log 2^{2^{o(t)}})} = h'(t) \cdot n^{o(t)}, \end{aligned}$$

which is not possible, unless 3-Sat has subexponential algorithms.

Cesati and Trevisan [7] and Bazgan [4] have shown that if a problem is W[1]-hard, then the corresponding optimization problem cannot have an EPTAS (i.e., a PTAS with running time $f(\epsilon) \cdot n^c$), unless FPT = W[1]. Let us recall the argument here. Assume that there is an approximation scheme with running time $f(\epsilon) \cdot n^c$ for Closest Substring. Running the algorithm with $\epsilon = 1/2k$ decides whether there is a solution with $d \le k$: if there is such a solution, then the approximation scheme always produces a solution with d at most $(1+\epsilon)k < k+1$. This would imply an $f(1/2k)\cdot n^c$ algorithm for Closest Substring, and it would follow that the problem is fixed-parameter tractable, which is not possible, unless FPT = W[1].

We can push this argument a bit further: it can be shown that there is no PTAS with running time $f(\epsilon) \cdot n^{o(\log 1/\epsilon)}$. The same reasoning as in the previous paragraph shows that such a PTAS would imply an $f(1/2k) \cdot n^{o(\log 2k)}$ algorithm for Closest Substring. In Corollary 8.8, we have seen that this is not possible, unless there are subexponential algorithms for 3-Sat.

COROLLARY 8.10. *There is no* $f(\epsilon) \cdot n^{o(\log 1/\epsilon)}$ *time PTAS for* CLOSEST SUBSTRING*, unless* n*-variable* 3-SAT *can be solved in time* $2^{o(n)}$.

The lower bound of Corollary 8.10 does not match the known approximation schemes for the problem. Using a different approach, Andoni, Indyk, and Pătraşcu [2] proved an essentially tight lower bound. However, in a strict technical sense, their lower bound is not directly comparable with Corollary 8.10.

9. Conclusions. We have presented algorithms and complexity results for two string matching problems, CLOSEST SUBSTRING and CONSENSUS PATTERNS. We have proved that CLOSEST SUBSTRING parameterized by the distance parameter d and by the number of strings k is W[1]-hard, even if the alphabet is binary. This improves the previous result of [14], where it is proved that the problem is W[1]-hard with parameter k only (and binary alphabet). Our hardness result also improves [20], where it is proved that DISTINGUISHING SUBSTRING SELECTION (a generalization of CLOSEST SUBSTRING) is W[1]-hard with parameters k and d (again with binary alphabet). In our reduction we used some of the techniques from these results, but new ideas were also required. In particular, we had to ensure that in the constructed instance of CLOSEST SUBSTRING there is no solution where the center string is very close to some substring. This is easy to ensure if d is unbounded, or if we can use the additional features of DISTINGUISHING SUBSTRING SELECTION. However, if d is a parameter, then we have to develop new combinatorial machinery to make sure that no solution can be close to some substring.

The W[1]-hardness of a problem is usually interpreted as evidence that the problem is unlikely to be fixed-parameter tractable; that is, the parameter has to appear in the exponent of n. Furthermore, using recent connections with subexponential algorithms, we can even give a lower bound on the exponent of n. Our reduction for CLOSEST SUBSTRING is "weak" in the sense that the parameters are significantly increased (exponentially and double exponentially). Therefore, we obtain only weak lower bounds on the exponent of n: all we can show is that the exponent cannot be $o(\log d)$ or $o(\log \log k)$. However, it turned out that these bounds are tight: we presented two algorithms where the exponent of n is $O(\log d)$ and $O(\log \log k)$, respectively. The second algorithm is based on some surprising connections with the extremal combinatorics of hypergraphs. We have introduced and investigated the half-covering property, which played an important role in the algorithm. Furthermore, we have shown that all the copies of hypergraph H in hypergraph G can be efficiently found if H has small fractional cover number. This result might be useful in some other applications as well. More generally, the fractional cover number and Shearer's lemma (which is the main combinatorial idea behind Theorem 4.1 and hence behind Theorem 4.3) can be useful algorithmic tools in other contexts; see [22].

The same hypergraph techniques can be used in the case of the CONSENSUS PATTERNS problem. However, the combinatorial structure of this problem is slightly different, and this slight difference allows us to obtain a uniformly polynomial time algorithm with running time $f(|\Sigma|, \delta) \cdot n^9$. Therefore, in the constant alphabet case the problem is fixed-parameter tractable with parameter δ (and also with the larger parameter D). This resolves another open question from [14].

The algorithms of Theorems 5.5 and 6.1 are based on the same idea: we want to enumerate all the "small" places P in a large hypergraph G that are "well-covered" in a certain sense. Our algorithms do this in a somewhat cumbersome way: first every small well-covered hypergraph is enumerated, and then for each such H, the algorithm enumerates all the places where H appears in G. It might be possible to do this in

a more direct and elegant way. What we need is an algorithm that enumerates every maximal subset of vertices having the property that it can be fractionally covered by weight k with the running time being something like $n^{O(k)}$. Developing such an algorithm could improve the running time of our algorithms, and, more importantly, would give us more insight into the nature of fractional edge covers.

Our results present an example where parameterized complexity and subexponential algorithms are closely connected. First, a weak parameterized reduction might be the sign that some kind of subexponential algorithm is possible for the problem. On the other hand, a parameterized reduction can be used to show the optimality of a subexponential algorithm. It is possible that this interplay between parameterized complexity and subexponential algorithms appears in the case of some other problems as well.

Acknowledgments. I'm grateful to Mike Fellows for directing my attention to this problem and to Ildi Schlotter for reading the manuscript.

APPROXIMATION ALGORITHMS FOR DATA PLACEMENT PROBLEMS*

IVAN BAEV†, RAJMOHAN RAJARAMAN‡, AND CHAITANYA SWAMY§

Abstract. We develop approximation algorithms for the problem of placing replicated data in arbitrary networks, where the nodes may both issue requests for data objects and have capacity for storing data objects so as to minimize the average data-access cost. We introduce the *data placement problem* to model this problem. We have a set of caches $\mathcal{F}$, a set of clients $\mathcal{D}$, and a set of data objects $\mathcal{O}$. Each cache i can store at most u_i data objects. Each client $j \in \mathcal{D}$ has demand d_j for a specific data object $o(j) \in \mathcal{O}$ and has to be assigned to a cache that stores that object. Storing an object o in cache i incurs a storage cost of f_i^o, and assigning client j to cache i incurs an access cost of $d_j c_{ij}$. The goal is to find a placement of the data objects to caches respecting the capacity constraints, and an assignment of clients to caches so as to minimize the total storage and client access costs. We present a 10-approximation algorithm for this problem. Our algorithm is based on rounding an optimal solution to a natural linear-programming relaxation of the problem. One of the main technical challenges encountered during rounding is to preserve the cache capacities while incurring only a constant-factor increase in the solution cost. We also introduce the *connected data placement problem* to capture settings where write-requests are also issued for data objects, so that one requires a mechanism to maintain consistency of data. We model this by requiring that all caches containing a given object be connected by a Steiner tree to a root for that object, which issues a multicast message upon a write to (any copy of) that object. The total cost now includes the cost of these Steiner trees. We devise a 14-approximation algorithm for this problem. We show that our algorithms can be adapted to handle two variants of the problem: (a) a k-median variant, where there is a specified bound on the number of caches that may contain a given object, and (b) a generalization where objects have lengths and the total length of the objects stored in any cache must not exceed its capacity.

1. Introduction.

Consider a distributed network, some of whose nodes need to periodically access certain data objects, and some of whose nodes have storage capacity and may serve as caches to store data objects thereby reducing the cost of accessing data objects. For example, one could have a network of distributed caches and/or processors in a large-scale information system or computing environment. A powerful paradigm for improving performance, which has been explored in several studies [10, 5, 2, 28], is cooperative caching, wherein the caches cooperate in making

storage decisions and in serving each other's requests. (Cooperation is of course likely to be the default mode under centralized control, where all the network nodes are under the control of a single entity, e.g., as in an organization's local area network.) Clearly, cooperation has the potential to improve system performance by reducing average access cost and improving storage-space utilization. A basic problem that arises in such a cooperative setup is the following: given a cost function specifying the cost of accessing an object stored at one location from another, and the access pattern of each node for each object, determine a placement or mapping of the data objects to caches so as to minimize the average cost of accessing the data objects.

We abstract this problem via the following mathematical formulation, which we call the *data placement problem*. We are given a set of caches $\mathcal{F}$, a set of data objects $\mathcal{O}$, and a set of clients $\mathcal{D}$. Each cache $i \in \mathcal{F}$ has a capacity u_i that limits the total number of data objects that may be stored in the cache. Each client $j \in \mathcal{D}$ has demand d_j for a specific data object $o(j) \in \mathcal{O}$ and has to be assigned to a cache that stores that object. Storing an object o in cache i incurs a *storage cost* of f_i^o, and assigning client j to cache i incurs an *access cost* of $d_j c_{ij}$ proportional to the "distance" c_{ij} between i and j. The storage costs could be used to model the cost of realizing a placement; e.g., the cost f_i^o might represent the cost of expunging some items from the cache in order to free up storage space. The data placement problem seeks a placement of the data objects to caches that respects the cache capacities, and an assignment of clients to caches so as to minimize the total storage and client access costs. More precisely, we want to determine a set of objects $\mathcal{O}(i) \subseteq \mathcal{O}$ to place in each cache $i \in \mathcal{F}$ satisfying $|\mathcal{O}(i)| \leq u_i$ and assign each client j to a cache $i(j)$ that stores object $o(j)$ (i.e., $o(j) \in \mathcal{O}(i(j))$) so as to minimize $\sum_{i \in \mathcal{F}} \sum_{o \in \mathcal{O}(i)} f_i^o + \sum_{j \in \mathcal{D}} d_j c_{i(j)j}$. As in several previous studies, especially on facility location [5, 2, 37, 34, 7, 6], we assume that the caches and clients are located in a common metric space, so the distances c_{ij} form a metric.

More generally, each object $o \in \mathcal{O}$ may have a *length* l_o, and the capacity u_i of cache $i \in \mathcal{F}$ now bounds the total length of data objects that may be stored in the cache. The access cost of an object is weighted by its length, so if client j is assigned to cache i, it incurs an access cost of $d_j l_{o(j)} c_{ij}$. Unless otherwise stated, we will use the data placement problem to denote the problem with unit (or, equivalently, uniform) object lengths.

The data placement problem can also be motivated from a facility-location perspective. In a typical facility-location setting, we are given a set of facilities with facility-opening costs and a set of clients with demands, and we want to open facilities and assign clients to open facilities so as to minimize the sum of the facility-opening costs and client-assignment costs. In various such applications, the clients are differentiated according to the kind of service they require, and in order to satisfy a client we need to assign (the demand of) the client to a facility where the service required by it has been "installed" (so that the facility can provide this service). The data placement problem can be used to abstract such settings, wherein the caches represent facilities and the objects correspond to the different services required by the clients; the storage cost models the cost of installing service at a given facility, and the cache capacity imposes a restriction on the *number of services* that may be installed at a facility. Shmoys, Swamy, and Levi [35] and Ravi and Sinha [33] introduced problems closely related to the data placement problem, motivated by such facility-location applications.

The data placement problem is a generalization of the metric *uncapacitated facility location* (UFL) problem and, hence, is *APX*-hard. Moreover, as we show in section 6

by a reduction from metric UFL, the problem (with uniform object lengths) remains *APX*-hard even when there are no storage costs.

Our results and techniques. Our main result (section 3) is a 10-approximation algorithm for the data placement problem. The algorithm we present here is an improvement over the approximation algorithm described in [3]. For the benefit of the reader, in section 1.1 we briefly sketch the differences between this algorithm and the one in [3].

Our algorithm is based on rounding an optimal solution to a natural linear-programming (LP) relaxation of the problem. Observe that the placement problem for each individual object is a UFL instance; however, these instances are coupled due to the cache-capacity constraints, which is what makes the problem hard. One of the main technical challenges faced in the rounding is to preserve the cache capacities while losing only a constant factor in the approximation ratio. Despite the similarity with UFL, hard capacities make it quite difficult to apply the standard rounding ideas underlying the design of approximation algorithms for UFL. All LP-based algorithms for UFL either employ filtering [26, 37] or use the dual to bound the solution cost [8, 18, 17, 6]. Filtering typically involves blowing up the LP variables, thereby violating the cache capacities, and the dual of the LP relaxation of the data placement problem contains negative variables (corresponding to the primal capacity constraints), which presents a serious obstacle to using the dual to bound the solution cost. Instead, we use the techniques developed by Charikar et al. [7] for the k-median problem.

Our algorithm proceeds in two phases. In the first phase, we build upon a clustering method introduced by Charikar et al. (Step 1 in [7]) and round the LP solution to a *half-integral* solution. In the second phase of our algorithm, we use the Shmoys–Tardos–Aardal clustering method [37] *without any filtering* to cluster the demand-nodes for each object and obtain a solution with the property that for every object o and cache i, there is at most one demand-node for o that is served by i. The key observation that allows us to do away with the problematic filtering step is that, in a half-integral solution, the distance between a client and any cache serving it fractionally is already bounded relative to its access cost in the half-integral solution. Once we have the aforementioned property, we can view the fractional solution as a feasible flow to a minimum-cost flow problem with integral capacities. By the integrality property of flows one can now extract an integer solution of no greater cost. This algorithm and its analysis are described in section 3.

The formulation of the data placement problem appears most suitable for applications where objects are rarely written. In a setting where write-requests are issued for data objects, one needs to have a separate mechanism to maintain consistency among the replicas of an object. In section 4, we formulate the *connected data placement problem*, which incorporates this aspect of data management (which is not captured by the data placement problem). As proposed by Krick, Räcke, and Westermann [22] in the context of another caching problem, we model this by requiring that, for every object o, all caches containing o be connected via a Steiner tree T_o to a root r_o. When a write-request is issued for object o, the root initiates an update of all the copies of object o using the tree T_o as a multicast tree. The objective is to minimize the total cost incurred in storing and accessing objects and building the Steiner trees, that is, to minimize $\sum_{i\in\mathcal{F}}\sum_{o\in\mathcal{O}(i)} f_i^o + \sum_{j\in\mathcal{D}} d_j c_{i(j)j} + \sum_{o\in\mathcal{O}} M_o \sum_{e\in T_o} c_e$, where the M_os are input scaling parameters. This generalizes the *connected facility location* problem [14, 39, 15] for which the best known guarantee is 8.55 [39]. We present a 14-approximation algorithm for this problem. One noteworthy feature here is the ease

with which one can interface the algorithm developed in section 3 (which handles the data placement part of the problem) with the rounding ideas proposed in [32, 14] to handle the connectivity aspect of the problem.

In section 5, we consider a couple of extensions. First, we consider the k-median variant, where, for every object o, there is a bound of k_o on the number of caches that may store object o. Our rounding algorithm is versatile and extends easily with minimal changes to this variant, yielding the same approximation guarantee. Second, we consider the data placement problem with arbitrary object lengths. It is easy to show (see section 6) via a reduction from the PARTITION problem that with arbitrary object lengths, it is *NP*-complete to even decide if there exists a feasible solution; hence, no approximation ratio is achievable in polynomial time unless $P = NP$. We can modify our algorithm to obtain a bicriteria approximation guarantee in this setting: we return a placement of cost at most 10 times the optimal where the total length of objects stored in a cache may exceed its capacity by the maximum object length. We conclude in section 6 with a couple of hardness results about the data placement problem with (i) no storage costs, and (ii) nonuniform object lengths.

Related work. The problem of data management in a distributed network has been extensively studied. Dowdy and Foster [10] initiated the study of cooperative caching in the context of allocating files in a distributed network, and this problem has since received much attention. We limit ourselves to an overview of the work in models that most closely resemble our model; the reader is referred to the surveys [10, 12] for a more detailed discussion.

Various works [5, 1, 2] have considered an *online* version of our problem, both with and without cache capacities, where read- and write-requests arrive online and have to be taken care of on the fly. The competitive ratios achievable in the online setting are, not surprisingly, weaker than the approximation ratios achievable in the offline setting. Awerbuch, Bartal, and Fiat [1] gave a randomized algorithm with competitive ratio $\text{polylog}(\sum_{i\in\mathcal{F}} u_i)$ for the uniform metric, whereas in [2] they give a $\text{polylog}(\max_{ij} c_{ij})$-competitive algorithm for arbitrary metrics, but require a $\text{polylog}(\max_{ij} c_{ij})$-factor blow-up in the cache capacities. Various studies have incorporated routing information into the caching problem, for instance, by having intermediate nodes cache copies of an object when the object is being routed [16, 31, 41], or by considering the problem of minimizing network congestion due to routing of requests [27, 28]. In contrast, we abstract away routing concerns by assuming that the c_{ij}-values, which determine the access costs, are given to us as input.

The *offline* data placement problem that we consider was first studied for hierarchical networks, or, equivalently, when the access costs form an ultrametric (a more restricted class of metrics). Leff, Wolf, and Yu [23] considered ultrametrics derived from a star, Korupolu, Plaxton, and Rajaraman [20] gave exact and approximation algorithms for general ultrametrics, and Korupolu and Dahlin [19] evaluated the practical performance of several placement algorithms for ultrametrics. Independent of [3], Meyerson, Munagala, and Plotkin [29] considered a generalization of our problem (called the page placement problem), where a cache also has a client capacity limiting the number of clients that may be assigned to it. They gave a constant approximation, but with a logarithmic violation of both the client capacities and the object capacities. Subsequently, Guha and Munagala [13] obtained a constant-factor approximation where the capacities are violated by only a constant factor. Fleischer et al. [11] considered a maximization version of the data placement problem with similar client-capacity constraints that limit the total demand that may be assigned to a cache. They give a $(1 - \frac{1}{e} - \epsilon)$-approximation algorithm, for any $\epsilon > 0$, and show

that no better guarantee is achievable unless $NP \subseteq \mathrm{DTIME}\left[n^{O(\log \log n)}\right]$.

As mentioned earlier, the data placement problem can also be motivated from a facility-location perspective, where caches correspond to facilities and the objects correspond to the different *services* required by clients. Shmoys, Swamy, and Levi [35] formulated a closely related problem in this context called *facility location with service installation costs (FLSIC)*. Using the terminology of the data placement problem, in FLSIC the caches (facilities) are uncapacitated, but one has to pay a location-dependent cache-setup (facility-opening) cost to "build" a cache at a location before storing any data object at that cache. Independently, Ravi and Sinha [33] proposed the multicommodity facility-location problem giving a similar motivation. Shmoys, Swamy, and Levi [35] give a 6-approximation algorithm for FLSIC under a certain assumption on the service installation costs.

The data placement problem (without storage costs) and FLSIC have also been studied for the special case of the *directed* line-metric under the names of *broadcast scheduling* [4] and the *joint replenishment problem* [24], respectively. In both problems, both the clients and the caches correspond to points on the timeline. In broadcast scheduling, the objects correspond to pages. A client corresponds to a request for a page, a cache corresponds to a page-broadcast, and a request at time t must be assigned to a broadcast of that page at some time $t' > t$. At most c pages may be broadcast at any time; the goal is to minimize the average response time of the requests. The best-known approximation factor for this problem is $O\left(\frac{\log^2 |\mathcal{O}|}{\log \log |\mathcal{O}|}\right)$ due to Bansal, Coppersmith, and Sviridenko [4]. In the joint replenishment problem, the objects are items. Demands for items occur at various points of time, and one has to determine which items to order at which times, so that all demand can be met by orders that are placed at earlier points of time. Placing an order for a subset of items incurs a joint ordering cost to start the order and an item-dependent cost, and each demand gets charged the cost incurred to hold the inventory for that demand. Levi, Roundy, and Shmoys [24] gave a 2-approximation algorithm for this problem.

The data placement problem is a generalization of UFL, which corresponds to the special case with only one object. There is a large body of literature that deals with designing approximation algorithms for metric UFL; see [34] for a survey of this and earlier work. The first constant approximation guarantee for UFL was obtained by Shmoys, Tardos, and Aardal [37] via an LP-rounding algorithm, and the current state-of-the-art is a 1.5-approximation algorithm due to Byrka [6]. For the closely related *k-median problem*, the first constant-factor approximation algorithm was given by Charikar et al. [7] using LP rounding. As mentioned earlier, the clustering method developed by them plays a key role in our algorithm.

Finally, we remark that the presence of cache capacities might suggest a similarity to the capacitated facility location (CFL) problem, but this resemblance is only superficial. The capacities in our problem limit the number of objects that may be assigned to a cache, but there is *no bound* on the demand (or number) of clients requesting a given object, or total demand, that may be assigned to a cache. (The data placement problem may be viewed as a collection of *UFL instances*, one for each object, that are coupled due to the cache-capacity constraints.) In particular, as our algorithm shows, the integrality gap of the natural LP relaxation for our problem is at most a constant, whereas there is no known LP relaxation of CFL with constant integrality gap. Moreover, the local search algorithms in [21, 9, 30, 42] do not directly apply, and it is not clear if they can be adapted to our problem.

1.1. Relationship with the work of [3] and [38]. This work is a merger of two earlier papers: an extended abstract of Baev and Rajaraman [3] and an unpublished manuscript of Swamy [38]. In order to place our work in proper bibliographic context, and for the benefit of the reader, we include a brief comparison of our work with [3] and [38].

The data placement problem that we consider was introduced by Baev and Rajaraman [3]. (In their model, each client j has demand d_{jo} for every object $o \in \mathcal{O}$; this easily reduces to the model considered here since one can create a colocated copy $j^{(o)}$ of client j with demand d_{jo} for every object o.) They gave a 20.5-approximation algorithm for this problem, which is based on rounding an optimal solution to the same LP relaxation of the problem that we consider. The 10-approximation algorithm described in this paper is from [38] and is based on an improved rounding procedure for the same LP. We briefly describe the main differences between the two algorithms.

As described earlier, our algorithm proceeds in two phases. The first phase of our algorithm, where we round the LP solution to a *half-integral* solution, is identical to the first half (steps 1–3) of the algorithm in [3]. From here on the two algorithms proceed along different tracks. In both algorithms, the goal is to modify the previously obtained half-integral solution into one that has the property that for every object o and cache i, there is at most one demand-node for o that is served by i, so that one can then set up a minimum-cost flow problem to round the half-integral solution to an integral one. In the second phase of our algorithm, we use the Shmoys–Tardos–Aardal clustering method [37] (without filtering) to obtain a solution with the above property. In contrast, the Baev–Rajaraman algorithm dovetails the rounding procedure of [7] (creating 1-level trees that are used to cluster the clients) to obtain a solution with the aforementioned property. By adopting a different clustering approach that better exploits half-integrality, we obtain a simpler algorithm that also yields a much better approximation guarantee.

The connected data placement problem was introduced by Swamy [38], and the 14-approximation algorithm that we present for this problem was described therein.

2. An LP relaxation. We can express the data placement problem as an integer program and relax the integrality constraints to get a linear program. Throughout we will use i to index the caches in $\mathcal{F}$, j to index the clients in $\mathcal{D}$, and o to index the objects in $\mathcal{O}$.

$$\text{(P)} \qquad \min \quad \sum_i \sum_o f_i^o y_i^o + \sum_j \sum_i d_j c_{ij} x_{ij}$$

$$\text{subject to} \qquad \sum_i x_{ij} \geq 1 \qquad \forall j,$$

$$x_{ij} \leq y_i^{o(j)} \qquad \forall i, j,$$

$$\text{(1)} \qquad \sum_o y_i^o \leq u_i \qquad \forall i,$$

$$x_{ij}, y_i^o \geq 0 \qquad \forall i, j, o.$$

Variable y_i^o indicates if object o is stored in cache i, and x_{ij} indicates if client j is assigned to cache i. The first and second constraints say that each client must be assigned to a cache and if client j is assigned to cache i, then object $o(j)$ must be

stored in cache i. The third constraint states that the total length of items stored in any cache i is at most its capacity u_i. An integer solution corresponds exactly to a solution to our problem. We let G_o denote the set of clients that demand object o, i.e., $G_o = \{j : o(j) = o\}$.

3. The rounding procedure. Let (x, y) denote the optimal solution to (P) and OPT be its value. We will round this to an integer solution losing a factor of at most 10. We use the terms access cost and assignment cost interchangeably.

3.1. Overview of the algorithm. We first give a high level description of the algorithm. Suppose for a moment that the optimal solution (x, y) satisfies the following property: for any cache i and object o, there is *at most one* client $j \in G_o$ such that $x_{ij} > 0$ $(*)$. We can then set up the following min-cost flow problem: create a bipartite graph with vertex set $\mathcal{D} \cup \mathcal{F}$ and edges (i, j) for every i, j such that $x_{ij} > 0$ with cost $f_i^{o(j)} + d_j c_{ij}$ and capacity 1; client j has a demand of 1, and cache i has capacity u_i. The LP solution translates to a feasible fractional flow in this graph of cost at most OPT. *Note that property* $(*)$ *is crucial for this.* Conversely an integer flow yields an integer solution to (P) of cost equal to the flow cost. Therefore by the integrality property of flows (given integer capacities) we can round (x, y) to an integer solution of no greater cost. Of course, the LP solution need not have property $(*)$, so our goal will be (loosely speaking) to transform (x, y) to a solution that has property $(*)$ without increasing the cost by much. One of the major challenges encountered is to do this transformation *without violating the cache capacities*, while increasing the cost by only a constant factor.

Roughly speaking we want to do the following: for each object o, cluster the clients in G_o around certain "centers" (also clients in G_o) such that (a) every client k is mapped to a "nearby" cluster center j whose LP assignment cost is less than that of k, and (b) the facilities serving the cluster centers in the fractional solution (x, y) are disjoint. Thus, the modified instance where the demand of a client is moved to the center of its cluster has a fractional solution, namely, the solution induced by (x, y), that satisfies $(*)$ and has cost at most OPT. Furthermore, given a solution to the modified instance we can obtain a solution to the original instance losing a small additive factor. This clustering idea lies at the core of most algorithms for facility location; however, the necessity of preserving cache capacities renders many of the known clustering methods [37, 8, 25] unsuitable for our purposes. For example, one option is to use the decomposition method of Shmoys, Tardos, and Aardal [37] that produces precisely such a clustering. The problem, however, is that [37] uses filtering which involves blowing up the x_{ij} and y_i^o values and thus violating the cache capacities. Chudak and Shmoys [8] and Levi, Shmoys, and Swamy [25] use similar clustering ideas but without filtering, using the dual solution to bound (portions of) the cost. The difficulty here in bounding the cost using the dual solution is that there are terms with negative coefficients in the dual objective function that correspond to the primal capacity constraints (1). Although [40, 25] showed that it is possible to overcome this difficulty in certain cases, the situation here looks more complicated, and it is not clear how to use their techniques.

Instead, we use the clustering technique of Charikar et al. [7] developed for the k-median problem. Our algorithm proceeds in two phases. In the first phase (section 3.2), we extract a modified instance and a fractional solution to this instance from the LP solution, and round this to a *half-integral* solution $(\hat{x}, \hat{y})$, that is, each $\hat{x}_{ij}, \hat{y}_i \in \left\{0, \frac{1}{2}, 1\right\}$, losing a factor of 3. Further, any solution here will give a solution

to the original instance while increasing the cost by at most $4 \cdot OPT$. We do this by first transferring demands to certain well-separated centers (Step I) exactly as in the demand-consolidation step of [7], so as to ensure that each center has its own private set of caches that serve it to an extent of at least half. This allows us to set up a minimum-cost flow problem (Step II) with half-integral capacities with a one-one correspondence between solutions and flows, and thereby round the fractional solution on the centers to a half-integral solution.

In phase two (section 3.3), we observe that we can now use the clustering method in [37] on the half-integral solution $(\hat{x}, \hat{y})$ *without any filtering* (Step III) since such a solution is essentially already filtered: if client j is assigned to i and i' in $\hat{x}$, then $c_{ij}, c_{i'j} \leq 2(c_{ij}\hat{x}_{ij} + c_{i'j}\hat{x}_{i'j})$. This clustering satisfies the requirements (a) and (b) mentioned above. Thus, one can obtain an integer solution for the new cluster centers by solving a suitable min-cost flow problem. This is essentially what we do, but we set up the min-cost flow problem more carefully (Step IV) so as to lose only a factor of 2 in converting $(\hat{x}, \hat{y})$ to an integer solution (for the modified instance extracted in phase 1). So overall we get an approximation ratio of $4 + 2 \times 3 = 10$ (Theorem 3.5).

We now describe each of these steps in detail. Let $\bar{C}_j = \sum_i c_{ij} x_{ij}$ denote the cost incurred by the LP solution to assign one unit of demand of client j.

3.2. Obtaining a half-integral solution $(\hat{x}, \hat{y})$.

Step I: *Consolidating demands around centers.* We first consider every object o separately and consolidate (or cluster) the demand of clients in G_o at certain clients, which we call *cluster centers*. We do not modify the fractional solution (x, y) but modify only the demands so that for some clients j, the demand d_j is "moved" to a "nearby" center k. We assume every client has a nonzero demand.

Set $d'_j \leftarrow 0$ for every j. Consider the clients in G_o in increasing order of $\bar{C}_j$. For each client j, if there exists a client k (including j) such that $d'_k > 0$ and $c_{jk} < 4\max(\bar{C}_j, \bar{C}_k) = 4\bar{C}_j$, set $d'_k \leftarrow d'_k + d_j$; otherwise set $d'_j \leftarrow d_j$. We do this for every object o. Let $D_o = \{j \in G_o : d'_j > 0\}$ and $D = \bigcup_o D_o$. Each client in D is a cluster center. Let $OPT' = \sum_{i,s} f_i^o y_i^o + \sum_{j \in D, i} d'_j c_{ij} x_{ij}$ denote the cost of (x, y) for the modified instance consisting of the cluster centers. Since the demand of each client $k \notin D$ moves a distance of at most $4\bar{C}_k$, it is clear that any solution to the modified instance yields a solution for client-set $\mathcal{D}$ incurring an additive factor of at most $4\sum_{k \notin D} d_k \bar{C}_k \leq 4 \cdot OPT$. We obtain the following lemma.

LEMMA 3.1. *The following hold:* (i) *if* $j, k \in D_o$, *then* $c_{jk} \geq 4\max(\bar{C}_j, \bar{C}_k)$; (ii) $OPT' \leq OPT$; *and* (iii) *any solution* (x', y') *to the modified instance can be converted to a solution to the original instance incurring an additional cost of at most* $4 \cdot OPT$.

From now on we will focus on the modified instance with client-set D and modified demands d'_j. At the very end we will use the above lemma to translate an integer solution to the modified instance to an integer solution to the original instance.

Step II: *Transforming to a half-integral solution.* We define the cluster of a client $j \in D_o$ to consist of all clients $k \in G_o$ whose demand d_k was moved to j, and a set of facilities F_j. F_j consists of all facilities i to which j is fractionally assigned such that j is the center in D_o closest to i; that is, $F_j = \{i : x_{ij} > 0 \text{ and } c_{ij} = \min_{k \in D_o} c_{ik}\}$, with ties broken arbitrarily. Let $F'_j \subseteq F_j = \{i \in F_j : c_{ij} \leq 2\bar{C}_j\}$. Define γ_j to be $\min_{i \notin F_j : x_{ij} > 0} c_{ij}$. Clearly the sets F_j for $j \in D_o$ are disjoint. By property (i) of Lemma 3.1, we have that F_j contains all the facilities i such that $x_{ij} > 0$ and $c_{ij} \leq 2\bar{C}_j$. So $\sum_{i \in F'_j} x_{ij} = \sum_{i : c_{ij} \leq 2\bar{C}_j} x_{ij} \geq \frac{1}{2}$, where the last inequality follows from Markov's inequality.

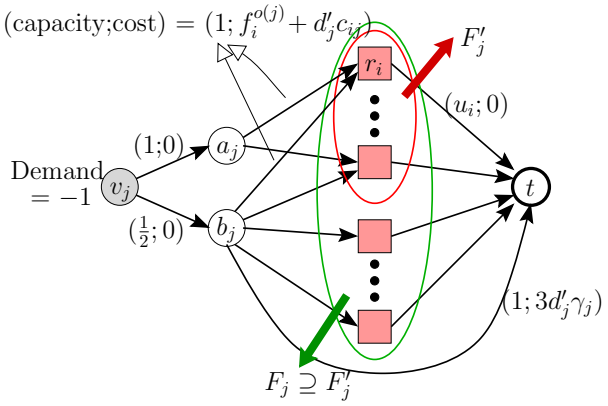

FIG. 3.1. *The min-cost flow network constructed in Step* II. *The tuple labeling an edge gives the (capacity;cost) for the edge.*

In the half-integral solution $(\hat{x}, \hat{y})$, we will store object o only at caches that lie in some set F_j for $j \in D_o$. To obtain $(\hat{x}, \hat{y})$, we set up a min-cost flow problem. We create a sink t and a node r_i for every cache i in $\bigcup_{j \in D} F_j$ with an outgoing edge (r_i, t) of capacity u_i and cost 0 (see Figure 3.1). For each client $j \in D$ we create three nodes v_j, a_j, and b_j. Node v_j has demand -1 (i.e., the net outgoing flow should be 1) to denote the requirement that j must be assigned to a cache. We add edges (v_j, a_j) with capacity 1 and cost 0, and (v_j, b_j) with capacity $\frac{1}{2}$ and cost 0. Node a_j represents the option that j is assigned to a facility in F'_j, so we add edges (a_j, r_i) to every $i \in F'_j$ with capacity 1 and cost $f_i^{o(j)} + d'_j c_{ij}$. Notice that setting the capacity of (v_j, b_j) to $\frac{1}{2}$ forces j to be assigned to an extent of at least $\frac{1}{2}$ to facilities in F'_j. Node b_j signifies that j is assigned either to a facility in F_j or to some other facility. To encode this, we add edges (b_j, r_i) to every $i \in F_j$ with capacity 1 and cost $f_i^{o(j)} + d'_j c_{ij}$, and an edge (b_j, t) with capacity 1 and cost $3d'_j\gamma_j$ (since, as we show later, there is always a facility at distance at most $3\gamma_j$ from j that is at least half-open). Figure 3.1 shows the portion of the min-cost flow instance corresponding to client j.

Since all edge capacities are $\frac{1}{2}$ or 1, the network has a half-integral min-cost flow. Given such a flow, we obtain $(\hat{x}, \hat{y})$ as follows. We initialize all $\hat{x}_{ij}$, $\hat{y}_i^o$ to 0. Consider object o. For every $j \in D_o$ and cache $i \in F'_j$, we set $\hat{y}_i^o = \hat{x}_{ij} =$ flow along (a_j, r_i) + flow along (b_j, r_i). For every $i \in F_j \setminus F'_j$, we set $\hat{y}_i^o$ and $\hat{x}_{ij}$ equal to the flow along edge (b_j, r_i). Observe that there is at least one cache $i \in F'_j$ such that $\hat{x}_{ij} > 0$; we call the cache in F'_j closest to j with $\hat{x}_{ij} > 0$ the *primary cache* of j. Note that since the sets F_j (and hence F'_j) for $j \in D_o$ are disjoint, every client in D_o has a unique primary cache i. Let i' be the cache nearest to j, other than its primary cache, with $\hat{y}_{i'}^o > 0$. If edge (b_j, t) carries positive flow (so no edge (b_j, r_i) carries any flow implying that $\hat{y}_i^o = 0$ for every $i \in F_j \setminus F'_j$), we set $\hat{x}_{i'j} =$ flow on $(b_j, t) = \frac{1}{2}$. We do this for every object o. If a client j is assigned to a cache other than its primary cache, we call the other cache the *secondary cache* of j. It is easy to verify that $(\hat{x}, \hat{y})$ is a feasible solution to (P), where the client-set is D. The following lemma shows that the cost of $(\hat{x}, \hat{y})$ is at most $3 \cdot OPT$.

LEMMA 3.2. *The cost of* $(\hat{x}, \hat{y})$, *that is,* $\sum_{i,o} f_i^o \hat{y}_i^o + \sum_{j \in D, i} d'_j c_{ij} \hat{x}_{ij}$, *is at most* $3 \cdot OPT' \leq 3 \cdot OPT$.

Proof. First we show that (x, y) induces a flow of cost at most $3 \cdot OPT'$, so the cost

of the min-cost flow is no greater. Then we show that the cost of $(\hat{x}, \hat{y})$ is bounded by the cost of the min-cost flow.

Consider the following flow: each edge (v_j, a_j) has flow $\sum_{i \in F'_j} x_{ij}$, (v_j, b_j) has flow $1 - \sum_{i \in F'_j} x_{ij}$, and (b_j, t) has flow $1 - \sum_{i \in F_j} x_{ij}$; every edge (a_j, r_i) or (b_j, r_i) has flow x_{ij}; the flow on (r_i, t) is $\sum_o \sum_{j \in D_o : i \in F_j} x_{ij}$. It is easy to see that this is a feasible flow. The cost of this flow is

$$\sum_{o, j \in D_o} \left(\sum_{i \in F_j} (d'_j c_{ij} + f_i^o) x_{ij} + 3 d'_j \gamma_j \left(1 - \sum_{i \in F_j} x_{ij} \right) \right)$$

$$\leq \sum_{i,o} f_i^o y_i^o + \sum_j d'_j \left(\sum_{i \in F_j} c_{ij} x_{ij} + 3\gamma_j \left(1 - \sum_{i \in F_j} x_{ij} \right) \right).$$

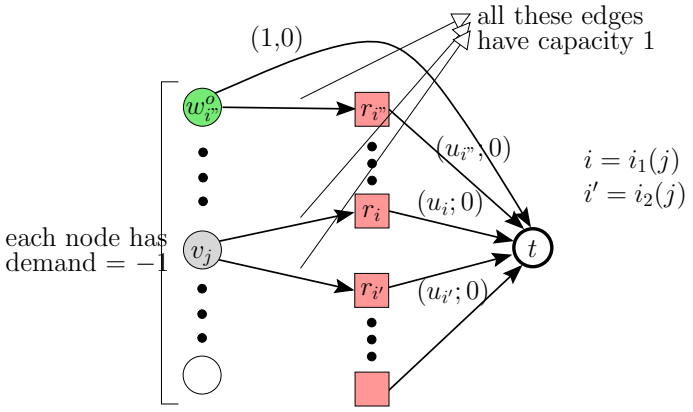
We have $OPT' = \sum_{i,o} f_i^o y_i^o + \sum_j d'_j \bar{C}_j$. For any $j \in D$, $\bar{C}_j = \sum_{i \in F_j} c_{ij} x_{ij} + \sum_{i \notin F_j} c_{ij} x_{ij} \geq \sum_{i \in F_j} c_{ij} x_{ij} + \gamma_j (1 - \sum_{i \in F_j} x_{ij})$ since γ_j was defined as $\min_{i \notin F_j : x_{ij} > 0} c_{ij}$. This shows that the cost of the constructed flow, and hence of the min-cost flow, is at most $3 \cdot OPT'$.

Now consider the solution $(\hat{x}, \hat{y})$ induced by the half-integral min-cost flow. By construction, the quantity $\sum_{i,o} f_i^o \hat{y}_i^o + \sum_{j \in D, i \in F_j} d'_j c_{ij} \hat{x}_{ij}$ is exactly equal to the total cost of the flow on edges (a_j, r_i) and (b_j, r_i). For any $j \in D$ the remaining cost $\sum_{i \notin F_j} d'_j c_{ij} \hat{x}_{ij}$ is equal to $d'_j c_{i'j} \cdot (\text{flow on } (b_j, t))$, where i' is the secondary cache of j. So it suffices to show that $c_{i'j} \leq 3\gamma_j$. Let $\gamma_j = c_{i''j}$, where $i'' \notin F_j$ and $x_{i''j} > 0$. Let k be the center in D_o nearest to i'' and let ℓ be the primary cache of k. Then, $c_{i'j} \leq c_{\ell j}$ and $4 \max(\bar{C}_j, \bar{C}_k) \leq c_{jk} \leq c_{i''j} + c_{i''k} \leq 2\gamma_j$. Also $c_{\ell k} \leq 2\bar{C}_k$ since $\ell \in F'_k$. Combining the inequalities we get that $c_{i'j} \leq 3\gamma_j$ which completes the proof of the lemma. ∎

3.3. Converting $(\hat{x}, \hat{y})$ to an integer solution $(\tilde{x}, \tilde{y})$. Define $\hat{C}_j = \sum_i c_{ij} \hat{x}_{ij}$ for $j \in D$. Let $i_1(j)$ denote the primary cache of j. For convenience, we will say that every client $j \in D$ has both a primary cache $i_1(j)$ and a secondary cache i' with $\hat{x}_{i_1(j)j} = \hat{x}_{i'j} = \frac{1}{2}$, with the understanding that if j does not have a secondary cache, then i' is a copy of $i_1(j)$, so effectively $\hat{x}_{i_1(j)j} = 1$. We denote the secondary cache by $i_2(j)$. Then we have $\hat{C}_j = \frac{1}{2}(c_{i_1(j)j} + c_{i_2(j)j})$, $c_{i_1(j)j} \leq \hat{C}_j$, and $c_{i_1(j)j} \leq c_{i_2(j)j} \leq 2\hat{C}_j$. Notice that $i_1(j)$ and $i_2(j)$ are the (one or) two caches with $\hat{y}_i^{o(j)} > 0$ that are nearest to j. Let $L_o = \{i : \hat{y}_i^o > 0\}$ and $L = \bigcup_o L_o$.

Step III: *Clustering.* First for every object o we cluster the clients in D_o as follows: pick $j \in D_o$ with smallest $\hat{C}_j$. Remove every client $k \in D_o$ such that both j and k are (fractionally) assigned to a cache $i \in L_o$, and recurse on the remaining set of clients until no client in D_o is left. Let D'_o be the set of clients picked for object o and let $D' = \bigcup_o D'_o$; D' denotes the *new cluster centers*. It is clear that for any cache in L_o at most one client in D'_o is assigned to it. Observe that for every client $k \in D_o \setminus D'_o$ there is some $j \in D'_o$ such that $\hat{C}_j \leq \hat{C}_k$ and $\hat{x}_{ij}, \hat{x}_{ik} > 0$ for some $i \in L_o$, implying that $c_{jk} \leq 4\hat{C}_k$. We call j the *center* of k and denote it by $\mathsf{ctr}(k)$.

Now for every client $k \in D \setminus D'$ we can move its demand d'_k to $j = \mathsf{ctr}(k)$. The resulting instance with client-set D' (and the new demands) satisfies the property $(*)$ mentioned in section 3.1. Hence, one can set up a min-cost flow problem as mentioned in section 3.1 to get an integer solution to the instance with client-set D', which translates to a solution with client-set D (and the original demands d'_j).



cost of (v_j, r_i) is $f_i^{o(j)} + d'_j c_{ij} + \sum_{k \in A_j} d'_k c_{ik}$
cost of $(v_j, r_{i'})$ is $f_{i'}^{o(j)} + d'_j c_{i'j} + \sum_{k \in A_j} d'_k c_{i'k} + \sum_{k \in B_j} d'_k (c_{i'k} - c_{i_2(k)k})$
cost of $(w^o_{i''}, r_{i''})$ is $f^o_{i''} + \sum_{k \in B^o_{i''}} d'_k (c_{i''k} - c_{i_2(k)k})$

FIG. 3.2. *The min-cost flow network constructed in Step* IV. *The tuple labeling an edge gives the (capacity;cost) for the edge.*

Doing this naively, we lose an additive factor of (at most) $4 \sum_{k \in D} d'_k \hat{C}_k$ in translating the demands back from D' to D. We will set up the min-cost flow network more carefully so that we lose only a multiplicative factor of 2 in rounding $(\hat{x}, \hat{y})$ to an integer solution for the client-set D. We want to capture the following observation: suppose the demand of a client $k \in D_o$ is moved to $j = \mathsf{ctr}(k)$. Let $\hat{x}_{ik} = \hat{x}_{i'k} = \frac{1}{2}$ and $\hat{x}_{ij} = \hat{x}_{i''j} = \frac{1}{2}$. The per-unit-demand assignment cost of k is at most $\frac{1}{2}(c_{ik} + c_{i''k}) \leq c_{ik} + \hat{C}_j \leq 3\hat{C}_k$ (since $c_{i''k} \leq c_{i''j} + c_{ij} + c_{ik}$), which is much less than the naive bound of $4\hat{C}_k + \hat{C}_j$.

Step IV: *The min-cost flow network.* Fix $o \in \mathcal{O}$ and consider a client $j \in D'_o$. We will maintain two sets A_j and B_j for j. Let $i = i_1(j)$ and $i' = i_2(j)$ be the primary and secondary caches of j. We define $A_j = \{k \in D_o : \mathsf{ctr}(k) = j\}$ and $B_j = \{k \in D_o : \mathsf{ctr}(k) \neq j \text{ and } i' = i_1(k)\}$. Also, for every cache $i \in L_o$ such that $\hat{x}_{ij} = 0$ *for every* $j \in D'_o$, we define $B^o_i = \{k \in D_o : i = i_1(k)\}$ (which is either empty or a singleton). Note that all the sets A_j, B_j, and B^o_i are subsets of $D_o \setminus D'_o$.

We create a sink t, and a node r_i for every $i \in L$ for which $\hat{x}_{ij} > 0$ for some $j \in D'$, or $B^o_i \neq \phi$ for some o (see Figure 3.2). We have an edge (r_i, t) of capacity u_i and cost 0. For every client $j \in D'$ we create a node v_j. Further, for every $i \in L, o \in \mathcal{O}$ with $B^o_i \neq \phi$ we create a node w^o_i. The nodes v_j and w^o_i all have demand -1. For every node v_j we have edges (v_j, r_i) to every i with $\hat{x}_{ij} > 0$, and we have edges (w^o_i, r_i), (w^o_i, t) for every node w^o_i. All these edges have capacity 1. The cost of these edges is set as follows. Consider a node v_j and let $i = i_1(j), i' = i_2(j)$. We set the cost of (v_j, r_i) to $f_i^{o(j)} + d'_j c_{ij} + \sum_{k \in A_j} d'_k c_{ik}$ and the cost of $(v_j, r_{i'})$ to $f_{i'}^{o(j)} + d'_j c_{i'j} + \sum_{k \in A_j} d'_k c_{i'k} + \sum_{k \in B_j} d'_k (c_{i'k} - c_{i_2(k)k})$. We set the cost of (w^o_i, r_i) to $f^o_i + \sum_{k \in B^o_i} d'_k (c_{ik} - c_{i_2(k)k})$ and the cost of (w^o_i, t) to 0; see Figure 3.2.

Since all capacities are integer, there is an integer min-cost flow. We map this to an integer solution $(\tilde{x}, \tilde{y})$ to the instance with client-set D. Set $\tilde{x}_{ij}, \tilde{y}_i \leftarrow 0$ for all i, j. Consider object o. First, for every $j \in D'_o$ and $i \in \{i_1(j), i_2(j)\}$, we set

$\tilde{x}_{ij}$ = flow on edge (v_j, r_i). For every client $k \in B_j$ we set $\tilde{x}_{i_2(j)k} = \tilde{x}_{i_2(j)j}$, and for every $k \in B_i^o$ we set $\tilde{x}_{ik}$ = flow on (w_i^o, r_i). Next, for every $j \in D'_o$ and every $k \in A_j$ that has not yet been assigned (i.e., $\sum_i \tilde{x}_{ik} = 0$), we set $\tilde{x}_{ik} = \tilde{x}_{ij}$ for $i \in \{i_1(j), i_2(j)\}$. Finally, set $\tilde{y}_i^o = \max_{j \in D_o} \tilde{x}_{ij}$. We do this for every o. Observe that $\tilde{y}_i^o = 1$ for at most one facility from F'_j for every client $j \in D_o$. This will be useful in section 4. It is easy to see that $(\tilde{x}, \tilde{y})$ is a feasible integer solution. We now bound its cost.

LEMMA 3.3. *The cost of the min-cost flow in the network is at most twice the cost of* $(\hat{x}, \hat{y})$.

Proof. We exhibit a fractional flow of cost at most the claimed cost. The fractional flow is obtained by setting the flow on every edge (v_j, r_i) to $\hat{x}_{ij}$, and the flow on (w_i^o, t) and (w_i^o, r_i) to $\max_{k \in B_i^o} \hat{x}_{ik} = \frac{1}{2}$, where the equality follows since every $k \in B_i^o$ is assigned to an extent of $\frac{1}{2}$ to $i_2(k) \neq i$. The flow on the edges (r_i, t) is set accordingly to $\sum_o \big(\sum_{j \in D'_o} \hat{x}_{ij} + \max_{k \in B_i^o} \hat{x}_{ik}\big)$. This is a feasible flow since, for every i, o, either $B_i^o = \phi$ and there is exactly one $j \in D'_o$ such that $\hat{x}_{ij} > 0$, or $B_i^o \neq \phi$ and $\hat{x}_{ij} = 0$ for every $j \in D'_o$. So $\sum_{j \in D'_o} \hat{x}_{ij} + \max_{k \in B_i^o} \hat{x}_{ik}$ is at most y_i^o.

The cost of an edge (v_j, r_i) or (w_i^o, r_i) consists of a storage component ($f_i^{o(j)}$ or f_i^o) and an assignment component that can be attributed to various clients. We call the contribution of the storage components to the flow cost the *flow storage cost*, and the contribution of the assignment components the *flow assignment cost*. The flow storage cost is $\sum_{i,o} f_i^o \big(\sum_{j \in D'_o} \hat{x}_{ij} + \max_{k \in B_i^o} \hat{x}_{ik}\big) \leq \sum_{i,o} f_i^o y_i^o$ by the above reasoning. To evaluate the flow assignment cost we consider the contribution of each client to the assignment components separately. Fix an object o. First consider $j \in D'_o$ with $i = i_1(j)$, $i' = i_2(j)$. Client j figures only in the assignment component of (v_j, r_i) and $(v_j, r_{i'})$, and its contribution is $d'_j(c_{ij}\hat{x}_{ij} + c_{i'j}\hat{x}_{i'j}) = d'_j \hat{C}_j$. A client $k \in D_o \setminus D'_o$ is in exactly one set A_j, where $j = \mathsf{ctr}(k)$, and may possibly also lie in one of the sets $B_{j'}$ or $B_{i''}^o$. Let $i = i_1(j)$ and $i' = i_2(j)$.

1. If k does not lie in any set $B_{j'}$ or $B_{i''}^o$, then it must be that $\hat{x}_{i_1(k)j} > 0$. Client k contributes only to the assignment component of edges (v_j, r_i) and $(v_j, r_{i'})$, and this contribution is $d'_k(c_{ik}\hat{x}_{ij} + c_{i'k}\hat{x}_{i'j}) \leq d'_k(c_{i_1(k)k} + \hat{C}_j) \leq 2d'_k \hat{C}_k$ since $\hat{x}_{ij} = \hat{x}_{i'j} = \frac{1}{2}$ and $c_{ik} + c_{i'k} \leq 2c_{i_1(k)k} + c_{ij} + c_{i'j}$.

2. Now suppose k is also in one of the sets $B_{j'}$ or $B_{i''}^o$, so that it also contributes to the assignment component of an edge $(v_{j'}, r_{i_1(k)})$ or an edge $(w_{i''}^o, r_{i''})$. The contribution in both cases is $\frac{d'_k}{2}(c_{i_1(k)k} - c_{i_2(k)k})$ since we must have $x_{i_1(k)j'} = \frac{1}{2} = x_{i''k}$. Adding the contributions to edges (v_j, r_i) and $(v_j, r_{i'})$, the total contribution is $\frac{d'_k}{2}(c_{ik} + c_{i'k} + c_{i_1(k)k} - c_{i_2(k)k}) \leq d'_k(\hat{C}_k + \hat{C}_j) \leq 2d'_k \hat{C}_k$ since $c_{ik} + c_{i'k} \leq 2c_{i_2(k)k} + c_{ij} + c_{i'j}$.

So the flow assignment cost is at most $2\sum_{j \in D} d'_j \hat{C}_j$. Thus the total flow cost is at most $\sum_{i,o} f_i^o \hat{y}_i^o + 2\sum_{j \in D} d'_j \hat{C}_j$, which is at most twice the cost of $(\hat{x}, \hat{y})$. ∎

LEMMA 3.4. *The cost of the integer solution* $(\tilde{x}, \tilde{y})$ *is at most the cost of the min-cost integer flow.*

Proof. Observe that, for any o, $\sum_i f_i^o \tilde{y}_i^o = \sum_{i, j \in D'_o} f_i^o \tilde{x}_{ij} + \sum_{\text{nodes } w_i^o} f_i^o$ (flow on (w_i^o, r_i)). So the total storage cost is $\sum_{e=(v_j, r_i)} f_i^{o(j)}$ (flow on e) $+ \sum_{e=(w_i^o, r_i)} f_i^o$ (flow on e) which is just the flow storage cost.

We will bound the assignment cost of a client by the contribution it makes to the flow assignment cost. Fix object o. Consider $j \in D'_o$. Let $i = i_1(j)$ and $i' = i_2(j)$. At most one of the edges (v_j, r_i), $(v_j, r_{i'})$ carries nonzero flow, and we set $\tilde{x}_{ij}, \tilde{x}_{i'j}$ equal to the flow on the corresponding edge. So the assignment cost of j is

$d'_j(c_{ij}(\text{flow on } (v_j, r_i)) + c_{i'j}(\text{flow on } (v_j, r_{i'})))$, which is also the contribution of j to the assignment flow cost. The same argument holds for $k \in A_j$ if k is assigned to one of i or i'. The remaining case is when $k \in A_j$, and k is not assigned to i or i', but is assigned to $i'' = i_1(k)$ either because $k \in B_{j'}$ where $i'' = i_2(j')$ and $(v_{j'}, r_{i''})$ has nonzero flow, or because $k \in B^o_{i''}$ and $(w^o_{i''}, r_{i''})$ carries nonzero flow. The assignment cost of k is $d'_k c_{i''k}$. The contribution of k to the assignment flow cost is at least $d'_k(c_{i''k} - c_{i_2(k)k}) + d'_k \min(c_{ik}, c_{i'k})$ since $k \in A_j$. This is at least $d'_k c_{i''k}$ since both $c_{ik}, c_{i'k}$ are at least $c_{i_2(k)}$. So the assignment cost of $(\tilde{x}, \tilde{y})$ is bounded by the flow assignment cost. This completes the proof. ∎

Combining Lemmas 3.1–3.4, we obtain that $(\tilde{x}, \tilde{y})$ yields an integer solution to the original instance of cost at most $10 \cdot OPT$. Thus, we obtain the following theorem.

THEOREM 3.5. *There is a* 10*-approximation algorithm for the data placement problem.*

4. The connected data placement problem. The formulation of the data placement problem seems most suitable for applications where objects are rarely written. In the presence of write-requests, one needs to have a mechanism that ensures that all the copies of a data object replicated in the various caches are consistent, and this requires that a write-request updates all the replicas of the data object. One way of modeling this, as proposed by Krick, Räcke, and Westermann [22], is to insist that all caches containing the same data object be interconnected via a Steiner tree, which would serve as a multicast tree that is used to update all copies of an object when a write-request is issued for it.

This gives rise to the *connected data placement problem*. We assume that there is a root $r_o \in \mathcal{D} \cup \mathcal{F}$ for each object o that issues the multicast message when a write-request is issued for o, and require that all caches containing object o be connected to r_o. Thus, our goal is to find a placement $\{\mathcal{O}(i)\}_{i \in \mathcal{F}}$ of objects to caches respecting the cache-capacity constraints, assign each client j to a cache $i(j)$ containing the object $o(j)$, and, for each object o, connect the caches storing object o to r_o via a Steiner tree T_o, so as to minimize

$$\sum_{i \in \mathcal{F}} \sum_{o \in \mathcal{O}(i)} f^o_i + \sum_{j \in \mathcal{D}} d_j c_{i(j)j} + \sum_{o \in \mathcal{O}} M_o \sum_{e \in T_o} c_e.$$

Here $M_o \geq 1$ is an input scaling parameter; e.g., it might denote the total number of write-requests for object o.

The LP relaxation (P) is modified as follows. We introduce variables $z^o_e \geq 0$ for each object o, and each edge e (of the complete graph on $\mathcal{D} \cup \mathcal{F}$) that indicates (in the integer program) if edge e is part of the tree T_o. The objective function includes the additional term $\sum_o M_o \sum_e c_e z^o_e$. For each object o, set $S \subseteq \mathcal{D} \cup \mathcal{F}$ such that $r_o \notin S$, and client $j \in G_o$, we add the constraint $\sum_{e \in \delta(S)} z^o_e \geq \sum_{i \in S} x_{ij}$, where $\delta(S) = \{e = (u, v) : |S \cap \{u, v\}| = 1\}$. Although this LP has an exponential number of constraints, it can be solved efficiently via the ellipsoid method.

Observe that the connected data placement is a generalization of the *connected facility location* problem [14, 39, 15] (which is the special case with only one object) for which the best-known approximation guarantee is 8.55 [39]. However, due to the presence of cache capacities, it is not clear how to apply the primal-dual technique in [39] or the random-sampling idea in [15]. We show that the LP-rounding technique proposed in [32, 14] to handle such connectivity requirements can be overlaid almost directly on top of our rounding procedure from section 3, to round an optimal solution to the above LP losing a factor of at most 14.

We briefly sketch the main steps. Let (x, y, z) be an optimal fractional solution, and let $\bar{C}_j = \sum_i c_{ij} x_{ij}$. We slightly modify the demand-consolidation step (Step I) of our rounding procedure: we now move the demand of client k to client j (where $d'_j > 0,\ \bar{C}_j \le \bar{C}_k$) if $c_{jk} < 8\max(\bar{C}_j, \bar{C}_k)$. Recall that $F'_j = \{i : x_{ij} > 0,\ c_{ij} \le 2\bar{C}_j\}$ and that the sets F'_j are disjoint for clients in D_o. Due to the above change, we lose an additive factor of $8\sum_j d_j \bar{C}_j$ in translating a solution for client-set $D = \bigcup_o D_o$ to a solution for $\mathcal{D}$. More importantly, for any two facilities $i \in F'_j$ and $i' \in F'_k$, where $j, k \in D_o,\ j \ne k$, we now have that $c_{ii'} \ge 4\max(\bar{C}_j, \bar{C}_k)$. The rest of the rounding process in section 3 is unchanged. Thus, the sum of the storage costs and access costs is at most $14\big(\sum_{i,o} f_i^o y_i^o + \sum_{j,i} d_j c_{ij} x_{ij}\big)$.

For each object o, we build the tree T_o as follows. We contract the sets F'_j for $j \in D_o$ into supernodes and build a minimum spanning tree (MST) T'_o connecting these to r_o, and then connect the caches storing object o to T'_o. To bound the cost of T'_o, notice that $2z^o$ yields a fractional Steiner tree on the supernodes and r_o, since for any set S containing a supernode F'_j and not containing r_o, we have $\sum_{e\in\delta(S)} z_e^o \ge \sum_{i\in F'_j} x_{ij} \ge \frac{1}{2}$. Thus, we get $c(T'_o) \le 4\sum_e z_e^o$ since it is well known that the cost of the MST is at most twice the cost of a fractional solution for the Steiner tree LP. Observe that an edge e of T'_o joining F'_j and F'_k has $c_e \ge 4\max(\bar{C}_j, \bar{C}_k)$. Let i be a facility on which object o is stored. Notice there is a *unique* client $j \in D_o$ such that $i \in F'_j$. To connect i to T'_o, we add the edge (i, j) and add edges joining j to every cache in F'_j that has an edge incident to it in T'_o. We do this for every cache on which o is stored. Let δ_j denote the degree of the supernode F'_j in the tree T'_o. The cost of adding these extra edges is at most $\sum_{j\in D_o}(1+\delta_j)2\bar{C}_j \le 2\sum_{j\in D_o}\delta_j \cdot 2\bar{C}_j \le 2c(T'_o)$. Thus, $c(T_o) \le 3c(T'_o) \le 12\sum_e z_e^o$, and the total cost incurred is at most $14\sum_{i,o} f_i^o y_i^o + 14\sum_{j,i} d_j c_{ij} x_{ij} + 12\sum_o M_o \sum_e z_e^o$, yielding a 14-approximation algorithm.

THEOREM 4.1. *There is a* 14*-approximation algorithm for the connected data placement problem.*

5. Extensions.

The k-median variant. We can easily adapt our techniques to handle an extension of the data placement problem where additionally, for every object o, there is a bound of k_o on the number of caches that can store object o. This adds the constraints $\sum_i y_i^o \le k_o$ for all o to (P). We need to modify the min-cost flow network construction slightly in Steps II and IV of section 3. In Step II, we remove the edges (b_j, t). Instead, for every object o, we add a node p_o with demand $|D_o| - k_o$ and edges (b_j, p_o) for $j \in D_o$ of capacity $\frac{1}{2}$ and cost $3\gamma_j$. We also add an edge (p_o, t) with capacity k_o and cost 0. The effect of these changes is to limit the total flow on edges (a_j, r_i) and (b_j, r_i), where $j \in D_o$, to at most k_o so that at most k_o caches store object o (half-integrally). The half-integral solution $(\hat{x}, \hat{y})$ is obtained as before with p_o now playing the role of t. It is easy to see that $(\hat{x}, \hat{y})$ is feasible and Lemma 3.2 still holds. Similarly, in Step IV, we remove the edges (w_i^o, t). For every o, we add a node p_o with demand $|\{i : B_i^o \ne \phi\}| - (k_o - |D'_o|)$, add edges (w_i^o, p_o) with capacity 1 and cost 0, and add edge (p_o, t) with capacity $k_o - |D'_o|$ and cost 0. This limits the total flow on edges (v_j, r_i), where $j \in D'_o$, and (w_i^o, r_i) to at most k_o. The integer solution $(\tilde{x}, \tilde{y})$ is obtained as before, and Lemmas 3.3 and 3.4 still hold. So we get the following theorem.

THEOREM 5.1. *There is a* 10*-approximation algorithm for the data placement problem with a priori bounds on the number of caches that may store an object.*

Nonuniform object lengths. We can obtain a bicriteria approximation algorithm for the setting where each object o has a nonuniform length l_o and the total length of the objects stored in any cache must not exceed its capacity. Constraint (1) of (P) now reads $\sum_o l_o y_o^i \leq u_i$. As mentioned in the introduction, no approximation ratio is achievable in polynomial time in this case, unless $P = NP$ (see Theorem 6.2). We show the following theorem.

THEOREM 5.2. *For the data placement problem with arbitrary object lengths, one can compute in polynomial time a placement of cost at most* $10 \cdot OPT$ *where the cache capacities are violated by an additive amount of at most* $\max_o l_o$.

Proof. We need only modify Steps II and IV above. Instead of formulating a min-cost flow problem to take care of cache capacities, we will now construct an instance of the *generalized assignment problem* (GAP) [36]. In Step II, each node a_j, b_j of the min-cost flow network represents a job, and each node r_i and the sink t represent a machine. Each machine r_i has processing-time capacity $2u_i$, and the sink t has 0 capacity. An edge (a_j, r_i) or (b_j, r_i) denotes that job a_j or b_j has processing time $l_{o(j)}$ on machine r_i. Its assignment cost for machine r_i is $f_i^{o(j)} + d'_j l_{o(j)} c_{ij}$, which is simply a modification of the cost of the corresponding edge in the flow network that takes into account the length $l_{o(j)}$. Job b_j also has processing time 0 and assignment cost $3d'_j l_{o(j)} \gamma_j$ on machine t, corresponding to the edge (b_j, t). All other processing times (corresponding to nonedges) are infinity. It is not hard to see that $(2x, 2y)$ induces a feasible solution to this GAP instance of cost at most $6 \cdot OPT'$. Hence, by [36], there exists an integer solution $(2\hat{x}, 2\hat{y})$ of no greater cost, where $\sum_o l_o \cdot 2\hat{y}_i^o \leq 2u_i + \max_o l_o$ for every $i \in \mathcal{F}$. Thus, $(\hat{x}, \hat{y})$ yields a half-integral solution of cost at most $3 \cdot OPT'$, where the cache capacities are violated by at most $\frac{1}{2} \max_o l_o$.

Similarly, in Step IV, we have a job for each node v_j and each node w_i^o, and a machine for each node r_i and the sink t. Each machine r_i has capacity $u_i + \frac{1}{2} \max_o l_o$, and machine t has 0 capacity. As before, an edge (v_j, r_i) or (w_i^o, r_i) represents that the corresponding job has processing time $l_{o(j)}$ or l_o, respectively, on machine r_i. The assignment cost is the cost of the corresponding edge in the flow network modified (as above) to incorporate object lengths by multiplying the terms not involving the storage cost by the object length ($l_{o(j)}$ in case of job v_j, and l_o in case of job w_i^o). For example, corresponding to the edge $(v_j, r_{i'})$, where $i' = i_2(j)$, we set the assignment cost of job v_j on a machine $r_{i'}$ to be $f_{i'}^{o(j)} + l_{o(j)} \big(d'_j c_{i'j} + \sum_{k \in A_j} d'_k c_{i'k} + \sum_{k \in B_j} d'_k (c_{i'k} - c_{i_2(k)k}) \big)$ (note that $o(k) = o(j)$ for all $k \in A_j \cup B_j$). Edge (w_i^o, t) denotes that job w_i^o has 0 processing time and 0 assignment cost on machine t. All job-machine processing times corresponding to nonedges are infinity. As in Lemma 3.3, $(\hat{x}, \hat{y})$ induces a half-integral feasible solution of cost at most twice the cost of $(\hat{x}, \hat{y})$. Using the algorithm in [36] directly, one can obtain an integer solution of no greater cost where the load of every machine r_i is at most $u_i + \frac{3}{2} \max_o l_o$. A more careful analysis that exploits the half-integrality of the solution shows that the violation in the capacity of r_i is in fact at most $\frac{1}{2} \max_o l_o$, and the load of r_i is at most $u_i + \max_o l_o$. As in Lemma 3.4 and Theorem 3.5, this yields an integer solution of cost at most $10 \cdot OPT$. ∎

We observe that for the connected versions of the above extensions, one obtains the same guarantees as for the connected data placement problem. We simply use the algorithms described above (with the modification to Step I specified in section 4) to handle the data-placement part of the problem; then we apply the rounding method of section 4 to build the Steiner trees. The analysis from section 4 still applies, since it is still true that for any cache i on which an object o is stored, there is a unique client $j \in D_o$ such that $i \in F'_j$.

THEOREM 5.3. *There is a* 14*-approximation algorithm for the connected version of the following data placement problems:*

(i) *the placement problem with a priori bounds on the number of caches that may store a data object;*

(ii) *the placement problem with arbitrary object lengths; here we obtain a bicriteria guarantee where the cache capacities may be violated by an additive amount of at most* $\max_o l_o$.

6. Hardness results. In this section, we establish two hardness results. It is clear that the data placement problem with storage costs is *APX*-hard, since it is a generalization of metric UFL. We show that the data placement problem is *APX*-hard even when there are no storage costs. Our second result is that for the data placement problem with arbitrary object lengths, it is *NP*-complete to even decide if there exists a feasible solution; hence, one cannot achieve any approximation ratio in polynomial time unless $P = NP$.

THEOREM 6.1. *The data placement problem is* APX*-hard even when there are no storage costs.*

Proof. We give a reduction from metric UFL. In the unit-demand version of metric UFL (which is still *APX*-hard), we are given a set of n facilities F with facility-opening costs $\{f_i\}_{i\in\mathcal{F}}$, a client-set D, and distances/assignment costs $\{C_{ij}\}$ that form a metric. The goal is to open a subset of the facilities and assign each client to an open facility, so as to minimize the sum of the facility-opening and client-assignment costs.

Given such a UFL instance, we construct the following instance of the data placement problem. We let $\mathcal{F} = F \cup \{\Gamma\}$ be the set of caches, and $\mathcal{D} = D \cup F'$ be the set of clients, where F' is a copy of F; i.e., for every $i \in F$, we create a unique client $\sigma(i) \in F'$. There are $|F| + 1$ data objects $o_0, o_1, \ldots, o_n$. Each client $j \in D$ has unit demand for object o_0. Each client $\sigma(i) \in F'$ has demand f_i/M for object o_i, where M is some large number such that $M \gg \max_{i,j} C_{ij}$. Each cache $i \in F$ has unit capacity, and cache Γ has capacity $n + 1 = |F| + 1$. We define the distances c_{ij} for $i \in \mathcal{F}$ and $j \in \mathcal{D}$; all other distances are equal to the shortest-path distances in the bipartite graph $(\mathcal{F} \cup \mathcal{D}, \{(i, j) : i \in \mathcal{F},\ j \in D \cup \{\sigma(i)\}\})$ with these c_{ij}'s as the edge weights. For every $i \in F$, we set $c_{ij} = C_{ij}$ if $j \in D \subseteq \mathcal{D}'$, and 0 if $j = \sigma(i)$; for $i = \Gamma$ and every $j \in \mathcal{D}$, we set $c_{ij} = M$. It is easy to see that the c_{ij}'s form a metric.

We show that this is an approximation-preserving reduction by arguing that any UFL solution translates to a data placement solution of no greater cost and vice versa. Consider a UFL solution that opens the facilities in $S \subseteq F$ (and assigns each client to the nearest facility in S). We map this to the data placement solution, where each cache in S stores object o_0, each cache $i \in F \setminus S$ stores object o_i, and cache Γ stores the objects o_i for $i \in S$. Clearly, the total access cost incurred for object o_0 is equal to the client-assignment cost of the UFL solution, the total access cost incurred for the objects o_i, where $i \in S$, is $\sum_i f_i$, and the access cost for all other objects is 0. So the cost of this data placement solution is exactly the cost of the UFL solution.

Conversely, suppose we have a data placement solution. We may assume that object o_0 is stored in some cache in F; otherwise we can improve the solution cost by storing o_0 in some cache $i \in F$ (and moving the object stored in i to Γ if necessary). Let $S \subseteq F$ be the set of caches that store o_0. We open the facilities corresponding to S (and assign each client to the nearest facility in S). Since $M \gg \max_{i,j} C_{ij}$, the client-assignment cost in the UFL solution is at most the total access cost for o_0. For each cache $i \in S$, the access cost for object o_i is at least $f_i/M \cdot M = f_i$ (since the distance from i to any other cache is at least M), so the facility-opening cost of the

UFL solution is at most the access cost for the objects o_i, where $i \in S$. Thus, the cost of the UFL solution is at most that of the data placement solution. □

THEOREM 6.2. *It is NP-complete to decide if there exists a feasible solution to an instance of the data placement problem with arbitrary object lengths. Consequently, there is no polynomial-time approximation algorithm for this problem unless* $P = NP$.

Proof. Membership in *NP* is immediate. The *NP*-hardness proof follows from an easy reduction from the PARTITION problem. Let $a_1, \ldots, a_m$ be an instance of the PARTITION problem with $A = \sum_i a_i/2$. In the data placement instance, we have two caches with capacity A, m objects with lengths $a_1, \ldots, a_m$, and m clients, each of which has unit demand for a unique object. (The distances and the locations of the clients and the caches are not important.) Clearly, any feasible solution to the data placement problem yields a solution to the PARTITION problem, and vice versa. The *NP*-completeness result follows. □

FASTER ALGORITHMS FOR MINIMUM CYCLE BASIS IN DIRECTED GRAPHS*

RAMESH HARIHARAN†, TELIKEPALLI KAVITHA‡, AND KURT MEHLHORN§

Abstract. We consider the problem of computing a minimum cycle basis in a directed graph. The input to this problem is a directed graph G whose edges have nonnegative weights. A cycle in this graph is actually a cycle in the underlying undirected graph with edges traversable in both directions. A $\{-1, 0, 1\}$ edge incidence vector is associated with each cycle: edges traversed by the cycle in the right direction get 1 and edges traversed in the opposite direction get -1. The vector space over $\mathbb{Q}$ generated by these vectors is the cycle space of G. A set of cycles is called a cycle basis of G if it forms a basis for this vector space. We seek a cycle basis where the sum of weights of the cycles is minimum. The current fastest algorithm for computing a minimum cycle basis in a directed graph with m edges and n vertices runs in $\tilde{O}(m^{\omega+1}n)$ time, where $\omega < 2.376$ is the exponent of matrix multiplication. We present an $O(m^3n + m^2n^2 \log n)$ algorithm. We obtain our algorithm by using fast matrix multiplication over rings and an efficient extension of Dijkstra's algorithm to compute a shortest cycle in G whose dot product with a function on its edge set is nonzero. We also present a simple $O(m^2n + mn^2 \log n)$ Monte Carlo algorithm. The problem of computing a minimum cycle basis in an *undirected* graph has been well studied. In this problem a $\{0, 1\}$ edge incidence vector is associated with each cycle and the vector space over $\mathbb{Z}_2$ generated by these vectors is the cycle space of the graph. The fastest known algorithm for computing a minimum cycle basis in an undirected graph runs in $O(m^2n + mn^2 \log n)$ time and our randomized algorithm for directed graphs matches this running time.

Key words. cycle basis, fast matrix multiplication, randomization, shortest paths

1. Introduction.

Let $G = (V, E)$ be a directed graph with m edges and n vertices. A *cycle* in G is actually a cycle in the underlying undirected graph, i.e., edges are traversable in both directions. Associated with each cycle is a $\{-1, 0, 1\}$ edge incidence vector: edges traversed by the cycle in the right direction get 1, edges traversed in the opposite direction get -1, and edges not in the cycle at all get 0.[1] The vector space over $\mathbb{Q}$ generated by these vectors is the *cycle space* of G. A set of cycles is called a *cycle basis* if it forms a basis for this vector space. When G is connected, the cycle space has dimension $d = m - n + 1$.

We assume that there is a weight function $w : E \to \mathbb{R}^{\geq 0}$, i.e., the edges of G have nonnegative weights assigned to them. The weight of a cycle basis is the sum of the weights of its cycles. A *minimum cycle basis* of G is a cycle basis of minimum weight. We consider the problem of computing a minimum cycle basis in a given digraph.

[1]Formally, the incidence vector is determined only up to a factor ± 1 as either direction (clockwise or counterclockwise) could be chosen to traverse a cycle.

A related problem pertains to undirected graphs, where we associate a $\{0,1\}$ edge incidence vector with each cycle; edges in the cycle get 1 and others get 0. Unlike directed graphs where the cycle space is defined over $\mathbb{Q}$, cycle spaces in undirected graphs are defined as vector spaces over $\mathbb{Z}_2$. The minimum cycle basis problem in an undirected graph G asks for the cycle basis of minimum weight in G.

The different possible settings for the minimum cycle basis problem are (i) the minimum cycle basis problem in undirected graphs, (ii) the minimum cycle basis problem in directed graphs (where the directions on the cycles are ignored), and (iii) the minimum *directed cycle* basis problem in directed graphs, where the cycle basis has to consist of cycles that traverse edges only along the direction of the edge.

We first compare problems (i) and (ii) and then discuss problem (iii). Problems (i) and (ii) are essentially different, since the first problem deals with computing a minimum weight spanning set of cycles that is linearly independent over $\mathbb{Z}_2$ while the second problem needs to compute a minimum weight spanning set of cycles that is linearly independent over $\mathbb{Q}$. Transforming cycles in a cycle basis of a directed graph by replacing both -1 and 1 by 1 does not necessarily yield a basis for the underlying undirected graph, since the given cycle basis could be linearly independent over $\mathbb{Q}$ but linearly dependent over $\mathbb{Z}_2$. In addition, lifting a minimum cycle basis of the underlying undirected graph by putting back directions does not necessarily yield a *minimum* cycle basis for the directed graph. Examples of both phenomena were presented in [22], which we include in section 2. Thus, one cannot find a minimum cycle basis for a directed graph by simply working with the underlying undirected graph.

A *directed cycle* basis is a spanning set of cycles where the incidence vector of each cycle in this basis is a vector in $\{0,1\}^m$, that is, each edge in a cycle here is traversed in the right direction. Note that a directed graph need not admit a directed cycle basis. Berge [2] studied the question of when a directed graph G admits such a cycle basis. He showed that if G is strongly connected, then G admits a directed cycle basis. Conversely, he showed that if G admits a directed cycle basis, then each maximal weakly connected induced subgraph of G with no cut vertex has to be strongly connected or a single arc.

Efficient algorithms for computing minimum cycle bases in the above settings have several applications. The minimum cycle basis problem is a special case of the *null space problem*. The null space problem is defined as follows: given a field $\mathbb{F}$ and an $n \times m$ matrix A with $n \leq m$, rank r, and entries in $\mathbb{F}$, find a matrix with the fewest nonzeros, whose columns span the null space of A. The null space problem was studied by Coleman and Pothen [6, 7], and this problem is NP-hard in general. The minimum cycle basis problem in undirected graphs with unit weights on the edges arises when the underlying field is $\mathbb{Z}_2$ and A is the $\{0,1\}$ vertex-edge incidence matrix of an undirected graph $G(V,E)$. The null vectors of this A are the vectors $(x_e)_{e\in E} \in \mathbb{Z}_2^{|E|}$ such that for each $v \in V$ we have $\sum_{e\in\delta(v)} x_e = 0 \pmod 2$, where $\delta(v)$ is the set of edges incident on v. Note that the set of such vectors $(x_e)_{e\in E}$ is the cycle space of G, and a solution to the null space problem is a minimum cycle basis of G.

Similarly, the minimum cycle basis problem in directed graphs with unit weights on the edges is an instance of the null space problem when the underlying field is $\mathbb{Q}$ and A is the $\{-1,0,1\}$ vertex-edge incidence matrix of a directed graph $G(V,E)$. The null vectors of such an A are the vectors $(x_e)_{e\in E} \in \mathbb{Q}^{|E|}$ such that for each $v \in V$ we have $\sum_{e\in\delta^+(v)} x_e - \sum_{e\in\delta^-(v)} x_e = 0$, where $\delta^+(v)$ and $\delta^-(v)$ are the set of edges leaving v and entering v, respectively. It is easy to see that the set of such vectors $(x_e)_{e\in E}$ is the cycle space of G. The minimum cycle basis of G is a solution to this

null space problem. Indeed, assume that B is a minimum solution to the null space problem. We may assume that the entries of B are integral, as multiplication by a suitable constant makes all entries integral and does not change the number of nonzero entries. So assume that B contains a column C whose entries are not in $\{0, \pm 1\}$. Since C belongs to the null space of the vertex-edge incidence matrix A, C decomposes into a set of simple cycles C_1 to C_k. Each C_i uses a subset (not necessarily proper) of the edges of C and $B \setminus C \cup C_i$ is a basis for some i. We conclude that there exists a solution with $0, \pm 1$ entries to this null space problem, which implies that a minimum cycle basis of the directed graph G is a solution to this null space problem.

Some of the applications of minimum cycle bases arise from the above characterization of minimum cycle bases as the solutions of the null space problem in graphs. The cycle analysis of electrical networks [9] corresponding to Kirchoff's law is such an example. Applications of minimum cycle bases have also been shown in structural engineering [5], chemistry and biochemistry [11, 19], and surface reconstruction from point clouds [23]. The minimum directed cycle basis has applications in metabolic flux analysis [12]. A cycle basis of minimum weight in a directed graph whose $d \times m$ cycle-edge incidence matrix satisfies the constraint that all its regular $d \times d$ submatrices have determinant ± 1 has been found to be very useful in cyclic timetabling [20, 21]. Books by Deo [10] and Bollobás [4] have in-depth coverage of cycle bases.

Horton [15] designed the first polynomial time algorithm to compute a minimum cycle basis in an undirected graph and there are now several polynomial time algorithms for this problem [3, 9, 13, 18], the fastest running in $O(m^2n + mn^2 \log n)$ time [18]. Gleiss, Leydold, and Stadler [12] used Berge's characterization of directed cycle bases and showed that a generalization of Horton's minimum cycle basis algorithm in undirected graphs computes a minimum directed cycle basis in strongly connected directed graphs. The first polynomial time algorithm for computing a minimum cycle basis in a directed graph had a running time of $\tilde{O}(m^4n)$ [17]. Liebchen and Rizzi [22] gave an $\tilde{O}(m^{\omega+1}n)$ algorithm for this problem, where $\omega < 2.376$ [8] is the exponent of matrix multiplication; this was the fastest deterministic algorithm so far for this problem in directed graphs.

In this paper we present an $O(m^3n + m^2n^2 \log n)$ deterministic algorithm and an $O(m^2n + mn^2 \log n)$ Monte Carlo algorithm to compute a minimum cycle basis in a directed graph G with m edges, n vertices, and nonnegative edge weights. The running time of our deterministic algorithm is m times the running time of the fastest algorithm for computing minimum cycle bases in undirected graphs, we leave it as a challenge to close the gap. The increased complexity seems to stem from the larger base field. Arithmetic in $\mathbb{Z}_2$ suffices for undirected graphs. For directed graphs, the base field is $\mathbb{Q}$, which seems to necessitate the handling of large numbers. Also, the computation of a shortest cycle that has a nonzero dot product with a given vector seems more difficult in directed graphs than in undirected graphs.

The framework used in our algorithms was introduced by de Pina [9] and was also used in [3, 18, 17]: we compute cycles C_i and supporting vectors N_i so that each C_i is a shortest cycle *not* orthogonal to its corresponding N_i, and each N_i is orthogonal to all previous C_j, $j < i$. This collection of cycles C_i is known to be a minimum cycle basis. Our algorithms for computing the C_i's and N_i's rest on two ideas.

First, we show how to compute the vectors N_i efficiently using fast matrix multiplication and inversion. Our basic algorithm updates all vectors N_j with $j > i$ in iteration i, which results in an $\tilde{O}(m^4)$ algorithm. The improvement rests on an idea already used in [18] to delay the update of vectors with higher index and to perform these updates in bulk using matrix multiplication and inversion. However, this creates

a problem since the numbers involved in the arithmetic get very large. We show two approaches to solving this problem, leading to an $O(m^2n + mn^2 \log n)$ randomized algorithm and an $O(m^3n + m^2n^2 \log n)$ deterministic algorithm. In the randomized algorithm we work over a finite field $\mathbb{Z}_p$ for a small prime p, which ensures that the numbers involved here do not get large. We show that we compute a minimum cycle basis with a probability of at least $3/4$ when p is a prime chosen uniformly at random from a set of d^2 small primes. In the deterministic algorithm, we could run into intermediate numbers whose bit size is $\tilde{\Theta}(m^2)$ when we use fast matrix inversion algorithms. This makes the running time of our algorithm $\tilde{\Theta}(m^{\omega+2})$, which is worse than the original iterative algorithm. We circumvent the problem by working over a suitable ring $\mathbb{Z}_R$. The important point is that there is no fixed R over which we work during the entire algorithm: whenever we perform the matrix multiplication and inversion, we determine a suitable R so that the inverse of the matrix that we seek to invert exists in $\mathbb{Z}_R$. This leads us to the vectors $N_i \bmod R$, and the number R will be large enough so that we can easily recover the original vectors N_i from $N_i \bmod R$. The total time needed now is $\tilde{O}(m^{\omega+1})$.

The second key step in our algorithm is a subroutine to compute a shortest cycle whose dot product with a given vector N_i is nonzero modulo a small number p. We present an $O(mn + n^2 \log n)$ algorithm to compute such a cycle C_p. This algorithm is obtained by computing two types of paths between each adjacent pair of vertices. The first path is a shortest path between these two vertices and the second is a shortest path whose residue class is different from the residue class of the first path. Thus this yields an $O(m^2n + mn^2 \log n)$ algorithm over $\mathbb{Z}_p$ for computing the d cycles. For the deterministic algorithm, the computation of each cycle can be reduced via the Chinese remainder theorem to computing a shortest cycle C_p whose inner product with N_i is nonzero modulo p for some $p \in \{p_1, \ldots, p_d\}$, which is a collection of small primes. This procedure is repeated for each $p \in \{p_1, \ldots, p_d\}$ yielding $O(m^2n+mn^2 \log n)$ time for each C_i and thus $O(m^3n + m^2n^2 \log n)$ time overall for all of the d cycles.

Organization of this paper. In section 2 we discuss some preliminaries and describe the examples from [22] that were mentioned in section 1. Our framework is given in section 3, and we present a simple deterministic algorithm from [17] that follows from this framework. Section 4 lays the approach for a faster scheme and shows the problem of large numbers that such an approach runs into. Section 5 describes the deterministic algorithm that overcomes this problem, and section 6 gives a randomized algorithm. Section 7 describes the subroutine for computing the required cycles.

2. Preliminaries. We are given a digraph $G = (V, E)$, where $|V| = n$ and $|E| = m$. Without loss of generality, the underlying undirected graph of G is connected. Then $d = m - n + 1$ is the dimension[2] of the cycle space of G. So a minimum cycle basis of G consists of d cycles $C_1, \ldots, C_d$. We describe cycles by their incidence vectors in $\{-1, 0, +1\}^m$.

A cycle basis of a directed graph need not project onto an undirected cycle

[2]Fix any spanning tree of G. For a nontree edge e, the fundamental cycle F_e induced by e consists of e plus the tree path connecting its endpoints. This set of cycles is clearly independent as every nontree edge is contained in a single cycle. We need to show that it spans all cycles. Consider any cycle $C = (x_e)_{e \in E}$ and define the sum $S = \sum_{e \text{ is a nontree edge}} x_e F_e$, in which every fundamental cycle is multiplied with the multiplicity of its defining edge in C. The vector S is in the cycle space and so is $Z = S - C$. The entries of Z corresponding to nontree edges are zero (by the definition of S) and Z satisfies the flow conservation constraints. Hence the entries of Z corresponding to tree edges must also be zero. Thus $Z = 0$ and the fundamental cycles form a basis. The number of fundamental cycles is exactly $m - n + 1$.

basis. Consider the following three 4-cycles in the directed graph in Figure 2.1: $C_1 = (e_1, e_2, e_3, e_4)$, $C_2 = (e_1, e_6, e_3, e_5)$, and $C_3 = (e_2, e_5, e_4, e_6)$ given by the vectors $(1, 1, 1, 1, 0, 0), (1, 0, -1, 0, -1, -1)$, and $(0, 1, 0, -1, -1, 1)$. It is easy to see that these vectors are linearly independent over $\mathbb{Q}$. Hence they form a cycle basis for the directed K_4. But in the underlying undirected graph, each of these cycles is equal to the sum modulo 2 of the other two, so C_1, C_2, C_3 do not form a cycle basis for the undirected K_4.

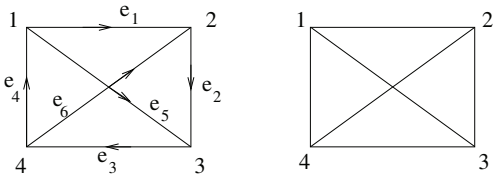

FIG. 2.1. *Directed K_4 and the underlying undirected graph.*

Further, there are directed weighted graphs in which the minimum cycle basis has lower weight than any cycle basis of the underlying undirected graph; such an example was given in [22]. Consider the generalized Petersen graph $P_{7,2}$ in Figure 2.2.

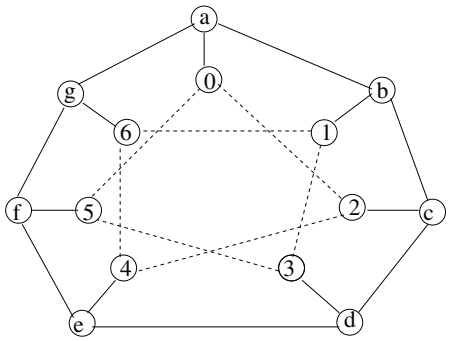

FIG. 2.2. *The generalized Petersen graph $P_{7,2}$.*

Call an edge (u, v) an *inner edge* if $\{u, v\} \subset \{0, 1, \ldots, 6\}$. Similarly call an edge (u, v) an *outer edge* if $\{u, v\} \subset \{a, \ldots, g\}$. The seven edges that remain are called *spokes*. Assign weight two to the seven inner edges and weight three to the outer edges and spokes. The shortest cycle in this graph has a weight of 14 and there are precisely eight cycles having a weight of 14, namely the cycle C_I consisting of only inner edges, and the seven cycles using one inner edge, two spokes, and two outer edges. Use C_i, $0 \leq i \leq 6$, to denote the cycle using the inner edge connecting i and $i + 2 \bmod 7$. Every other cycle has a length of at least 15.

Every edge of $P_{7,2}$ belongs to precisely two of the eight cycles with a weight of 14. Therefore in the undirected case, these $8 = m - n + 1$ cycles are not independent over $\mathbb{Z}_2$. Thus in the undirected case, every cycle basis has a weight of at least 113. In the directed case, these 8 cycles under any orientation of edges are linearly independent.[3] So there is a directed cycle basis of weight 112.

[3]Direct the inner edges clockwise, the spokes outward, and the outer edges counterclockwise. Then all eight cycles use their inner and outer edges in the forward direction. Assume $\alpha_I C_I + \sum_{0 \leq i \leq 6} \alpha_i C_i = 0$. The edge $(i, i + 2 \bmod 7)$ is used only by C_I and C_i, and hence we must have $\alpha_i = -\alpha_I$ for all i. But then the outer edges do not cancel out.

We will assume for the rest of this paper that the edges in $E = \{e_1, \ldots, e_m\}$ are ordered so that edges e_{d+1} to e_m form the edges of a spanning tree T of the underlying undirected graph. This means that the first d coordinates, of each of $C_1, \ldots, C_d$, correspond to edges outside the tree T, and the last $n-1$ coordinates are the edges of T. This will be important in our proofs in section 3. We can also assume that there are no multiple edges in G. It is easy to see that whenever there are two edges from u to v, the heavier edge (call it a) can be deleted from E, and the least weight cycle (call it $C(a)$) that contains the edge a can be added to the minimum cycle basis computed on $(V, E \setminus \{a\})$. The cycle $C(a)$ consists of the edge a and the shortest path between u and v in the underlying undirected graph. All such cycles can be computed by an all-pairs-shortest-paths computation in the underlying undirected graph of G, which takes $\tilde{O}(mn)$ time. So we will assume from now on that $m \leq n^2$.

3. Framework and a simple algorithm. We begin with a structural characterization of a minimum cycle basis. This characterization uses auxiliary rational vectors $N_1, \ldots, N_d$ which serve as a scaffold for proving properties of $C_1, \ldots, C_d$, as described below. We use $\langle v_1, v_2 \rangle$ to denote the standard inner product or dot product of the vectors v_1 and v_2.

THEOREM 3.1. *Cycles $C_1, \ldots, C_d$ form a minimum cycle basis if there are vectors $N_1, \ldots, N_d$ in $\mathbb{Q}^m$ such that for all i, $1 \leq i \leq d$:*

1. *Prefix orthogonality: $\langle N_i, C_j \rangle = 0$ for all j, $1 \leq j < i$.*
2. *Nonorthogonality: $\langle N_i, C_i \rangle \neq 0$.*
3. *Shortness: C_i is a shortest cycle with $\langle N_i, C_i \rangle \neq 0$.*

Proof. First, we show that $C_1, \ldots, C_d$ is a cycle basis of G by showing that these are linearly independent over $\mathbb{Q}$ (recall that any set of d linearly independent cycles is a cycle basis). Suppose it is not. Then a rational linear combination of a subset of these cycles yields 0. Let the cycle with the largest index in this subset be C_i. By properties 1 and 2 of the theorem, taking the dot product of this linear combination with N_i yields a nonzero value on one side of this linear combination and a 0 on the other side, a contradiction.

Second, we show that $C_1, \ldots, C_d$ is a minimum cycle basis of G. Suppose it is not. Then consider the smallest $i \geq 1$ such that $C_1, \ldots, C_i$ are not in any minimum cycle basis. Then $C_1, \ldots, C_{i-1}$ belong to some minimum cycle basis; call this basis $\mathcal{K}$ (in the event that $i = 1$, let $\mathcal{K}$ be any minimum cycle basis). We will exhibit a cycle $K \in \mathcal{K}$ such that (i) $\langle N_i, K \rangle \neq 0$ and (ii) K can be written as a rational linear combination of C_i along with cycles in $\mathcal{K}/\{K\}$. Demonstrating such a cycle $K \in \mathcal{K}$ is easy: since $\mathcal{K}$ is a basis not containing C_i, the cycle C_i must be a rational linear combination of cycles in $\mathcal{K}$. At least one of these cycles $K \in \mathcal{K}$ satisfies $\langle N_i, K \rangle \neq 0$, because $\langle N_i, C_i \rangle \neq 0$ by property 2 in the theorem. Therefore (i) holds. Further, (ii) follows by rewriting the above linear combination to switch the sides of C_i and K.

Property 1 of the theorem and condition (i) ensure that the cycle K is not one of $C_1, \ldots, C_{i-1}$. Condition (ii) implies that $\mathcal{K}/\{K\} \cup \{C_i\}$ is a cycle basis. Property 3 of the theorem and condition (i) imply that C_i has weight at most that of K and therefore $\mathcal{K}/\{K\} \cup \{C_i\}$ is also a minimum cycle basis. $C_1, \ldots, C_i$ belong to this minimum cycle basis, a contradiction. ∎

We present a simple deterministic algorithm from [17] that computes N_i's and C_i's satisfying the criteria in Theorem 3.1.

The algorithm deterministic-MCB.

1. Initialize the vectors $N_1, \ldots, N_d$ of $\mathbb{Q}^m$ to the first d vectors $e_1, \ldots, e_d$ of the standard basis of $\mathbb{Q}^m$.
   (The vector e_i has 1 in the ith position and 0's elsewhere.)

2. For $i = 1$ to d do
   - compute C_i to be a shortest cycle such that $\langle C_i, N_i \rangle \neq 0$,
   - for $j = i + 1$ to d do

$$\text{update } N_j \text{ as: } N_j = N_j - N_i \frac{\langle C_i, N_j \rangle}{\langle C_i, N_i \rangle},$$

$$\text{normalize } N_j \text{ as: } N_j = N_j \frac{\langle C_i, N_i \rangle}{\langle C_{i-1}, N_{i-1} \rangle}.$$

(We take $\langle C_0, N_0 \rangle = 1$.)

The above algorithm needs the vector N_i in the ith iteration to compute the cycle C_i. Instead of computing N_i from scratch in the ith iteration, it obtains N_i by update and normalization steps through iterations 1 to $i-1$. We describe how to compute a shortest cycle C_i such that $\langle C_i, N_i \rangle \neq 0$ in section 7. Let us now show that the N_i's obey the prefix orthogonality property. Lemma 3.2, proved in [17], shows this and more.

LEMMA 3.2. *For any i, at the end of iteration $i-1$, the vectors $N_i, \ldots, N_d$ are orthogonal to $C_1, \ldots, C_{i-1}$, and, moreover, for any j with $i \leq j \leq d$, $N_j = \langle N_{i-1}, C_{i-1} \rangle (x_{j,1}, \ldots, x_{j,i-1}, 0, \ldots, 0, 1, 0, \ldots, 0)$, where 1 occurs in the jth coordinate and the vector $\mathbf{x} = (x_{j,1}, \ldots, x_{j,i-1})$ is the unique solution to the set of equations:*

$$\begin{pmatrix} \tilde{C}_1^T \\ \vdots \\ \tilde{C}_{i-1}^T \end{pmatrix} \mathbf{x} = \begin{pmatrix} -c_{1j} \\ \vdots \\ -c_{(i-1)j} \end{pmatrix}. \tag{3.1}$$

Here $\tilde{C}_k$, $1 \leq k < i$, is the restriction of C_k to its first $i-1$ coordinates and c_{kj} is the jth coordinate of C_k.

Proof. The claim is certainly true after the 0th iteration, that is, at the beginning of the algorithm. So consider the ith iteration and assume that the claim is true at the end of iteration $i-1$. In iteration i, we determine C_i with $\langle C_i, N_i \rangle \neq 0$ and then update the N_j's for all j with $i+1 \leq j \leq n$. Consider any j with $i+1 \leq j \leq n$ and use N_j' to denote the updated value of N_j.

N_j is updated by subtracting a scalar multiple of N_i from it. Since N_j and N_i are orthogonal to C_l for $l < i$ by induction hypothesis, N_j' is orthogonal to C_l. The update step also guarantees orthogonality to C_i. Indeed,

$$\langle C_i, N_j' \rangle = \langle C_i, N_j \rangle - \langle C_i, N_i \rangle \frac{\langle C_i, N_j \rangle}{\langle C_i, N_i \rangle} = 0.$$

By induction hypothesis, N_j is of the form $(t_{j,1}, \ldots, t_{j,i-1}, 0, \ldots, t_{j,j}, 0, \ldots)$, where $t_{j,j} = \langle C_{i-1}, N_{i-1} \rangle$ and N_i has nonzero entries only in its first i coordinates. So N_j' has the form $(t'_{j,1}, \ldots, t'_{j,i}, 0, \ldots, t_{j,j}, 0, \ldots)$. After normalization, the jth coordinate of N_j' is

$$t_{j,j} \frac{\langle N_i, C_i \rangle}{\langle N_{i-1}, C_{i-1} \rangle} = \langle N_{i-1}, C_{i-1} \rangle \frac{\langle N_i, C_i \rangle}{\langle N_{i-1}, C_{i-1} \rangle} = \langle N_i, C_i \rangle.$$

Hence N_j' has the form

$$N_j' = \langle N_i, C_i \rangle (u_{j,1}, \ldots, u_{j,i}, 0, \ldots, 1, 0, \ldots, 0).$$

Since N'_j is orthogonal to $C_1, \ldots, C_i$ and $\langle N_i, C_i \rangle \neq 0$, $(u_{j,1}, \ldots, u_{j,i})$ is a solution to the following set of equations:

$$\begin{pmatrix} \tilde{C}_1^T \\ \vdots \\ \tilde{C}_i^T \end{pmatrix} \mathbf{x} = \begin{pmatrix} -c_{1j} \\ \vdots \\ -c_{ij} \end{pmatrix}, \tag{3.2}$$

where $\tilde{C}_k$, for $k = 1, \ldots, i$, is the restriction of the vector C_k to its first i coordinates and c_{kj} is the jth coordinate of the vector C_k. We show that the matrix of $\tilde{C}_k$'s is nonsingular, hence $(u_{j,1}, \ldots, u_{j,i})$ is the unique solution of (3.2). The proof of the nonsingularity of this matrix mimics the argument in Theorem 3.1. Consider any linear combination of the rows adding to the zero vector:

$$\sum_{k=1}^{i} \alpha_k \tilde{C}_k = \mathbf{0}. \tag{3.3}$$

Assume that one of the α_k's is nonzero and consider the largest ℓ such that $\alpha_\ell \neq 0$. We take the inner product of both sides of (3.3) with $\tilde{N}_\ell$, where $\tilde{N}_\ell$ is the restriction of the vector N_ℓ to its first i coordinates. Note that $\tilde{N}_\ell$ has all of the nonzero entries of N_ℓ since $\ell \leq i$ and only the first ℓ entries of N_ℓ may be nonzero. So $\langle \tilde{C}_k, \tilde{N}_\ell \rangle = \langle C_k, N_\ell \rangle$ for all $k \leq \ell$. Hence the left-hand side is $\sum_{k=1}^{\ell} \alpha_k \langle C_k, N_\ell \rangle = \alpha_\ell \langle C_\ell, N_\ell \rangle$ since $\langle C_k, N_\ell \rangle = 0$ for each k with $k < \ell$. Since α_ℓ and $\langle C_\ell, N_\ell \rangle$ are nonzero while the right-hand side is zero, we get a contradiction. Thus all of the α_k's in (3.3) are zero and so the matrix with $\tilde{C}_k$'s as its rows is nonsingular and the proof is complete. □

Remark. Note that the ith coordinate of N_i is nonzero. This readily implies that there is at least one cycle that has nonzero dot product with N_i, namely the fundamental cycle F_{e_i} formed by the edge e_i and the path in the spanning tree T connecting its endpoints. The dot product $\langle F_{e_i}, N_i \rangle$ is equal to the ith coordinate of N_i, which is nonzero.

We next give an alternative characterization of these N_j's. This characterization helps us in bounding the running time of the algorithm deterministic-MCB. Let M denote the $(i-1) \times (i-1)$ matrix of $\tilde{C}_k$'s in (3.1), and let b_j denote the column vector of $-c_{kj}$'s on the right. We claim that solving $M\mathbf{x} = \det(M) \cdot b_j$ leads to the same vectors N_j for all j with $i \leq j \leq d$. We first show the following claim.

LEMMA 3.3. $\langle N_{i-1}, C_{i-1} \rangle = \det(M)$.

Proof. Let X be the $(i-1) \times (i-1)$ matrix with its kth column equal to N_k truncated to its first $i-1$ coordinates. We know from Lemma 3.2 that X is an upper triangular matrix with $X[k,k] = \langle N_{k-1}, C_{k-1} \rangle$. So $\det(X) = \prod_{k=1}^{i-1} \langle N_{k-1}, C_{k-1} \rangle$. The product MX has $\langle C_j, N_k \rangle$ as its (j,k)th element, so it is a lower triangular matrix by prefix orthogonality. Hence $\det(MX)$ is the product of its diagonal values, i.e, $\det(MX) = \prod_{k=1}^{i-1} \langle N_k, C_k \rangle$. Since $\det(M) \cdot \det(X) = \det(MX)$, $\langle N_0, C_0 \rangle = 1$, and $\langle N_k, C_k \rangle \neq 0$ for all k, the lemma follows. □

We know by Lemma 3.2 that $(x_{j,1}, \ldots, x_{j,i-1})$ is the unique solution to $M\mathbf{x} = b_j$. In the ith iteration of the algorithm, we could have directly computed the vector $N_i = \langle N_{i-1}, C_{i-1} \rangle (x_{i,1}, \ldots, x_{i,i-1}, 1, 0, \ldots)$, which is $\det(M)(x_{i,1}, \ldots, x_{i,i-1}, 1, 0, \ldots)$ (by Lemma 3.3), by solving the set of equations $M\mathbf{x} = \det(M) b_i$ and appending $(\det(M), 0, \ldots, 0)$ to $\mathbf{x}$. However, such an algorithm would be slower—it would take time $\tilde{\Theta}(m^{\omega+2})$, where $\omega < 2.376$ is the exponent of matrix multiplication. The updates and normalizations in the algorithm deterministic-MCB achieve the same result in a more efficient manner.

Let us now bound the running time of the ith iteration of deterministic-MCB. We will show in section 7 that a shortest cycle C_i such that $\langle C_i, N_i\rangle \neq 0$ can be computed in $O(m^2n+mn^2\log n)$ time. Let us look at bounding the time taken for the update and normalization steps. We take $O(m)$ arithmetic steps for updating and scaling each N_j since each N_j has m coordinates. Thus the total number of arithmetic operations in the ith iteration is $O((d-i)m) = O(md)$ over all j, $i+1 \leq j \leq d$. We next estimate the cost of the arithmetic. The coordinates of N_j are determined by the system $M\mathbf{x} = \det(M)b_j$ and hence are given by Cramer's rule. Fact 1 below shows that each entry in N_j is bounded by $d^{d/2}$. Thus we pay $\tilde{O}(d)$ time per arithmetic operation. Thus the running time of the ith iteration is $\tilde{O}(m^3)$, and hence the running time of deterministic-MCB is $\tilde{O}(m^4)$.

FACT 1. *Since M is a $\pm 1, 0$ matrix of size $(i-1)\times(i-1)$ and b_j is a $\pm 1, 0$ vector, all determinants used in Cramer's rule in solving $M\mathbf{x} = \det(M)b_j$ are bounded by $i^{i/2}$ using Hadamard's inequality. Therefore, the absolute value of each entry in N_j in the ith iteration, where $j \geq i$, is bounded by $i^{i/2}$.*

4. A faster scheme. The update and normalization steps form the bottleneck in the algorithm deterministic-MCB. We will reduce their cost from $\tilde{O}(m^4)$ to $\tilde{O}(m^{\omega+1})$.

- First, we delay updates until after several new cycles have been computed. For instance, we update $N_{\lfloor d/2\rfloor+1}, \ldots, N_d$ not after each new cycle but in bulk after *all* of $C_1, C_2, \ldots, C_{\lfloor d/2\rfloor}$ are computed.
- Second, we use a fast matrix multiplication method to do the updates for all of $N_{\lfloor d/2\rfloor+1}, \ldots, N_d$ together, and not individually as before.

The scheme. The faster deterministic algorithm starts with the same configuration for the N_i's as before, i.e., N_i is initialized to the ith unit vector, $1 \leq i \leq d$. It then executes three steps. First, it computes $C_1, \ldots, C_{\lfloor d/2\rfloor}$ and $N_1, \ldots, N_{\lfloor d/2\rfloor}$ recursively, leaving $N_{\lfloor d/2\rfloor+1}, \ldots, N_d$ at their initial values. Second, it runs a bulk update step in which $N_{\lfloor d/2\rfloor+1}, \ldots, N_d$ are modified so that they become orthogonal to $C_1, \ldots, C_{\lfloor d/2\rfloor}$. And third, $C_{\lfloor d/2\rfloor+1}, \ldots, C_d$ are computed recursively modifying $N_{\lfloor d/2\rfloor+1}, \ldots, N_d$ in the process.

A crucial point to note about the second recursive call is that it modifies $N_{\lfloor d/2\rfloor+1}$, $\ldots, N_d$ while ignoring $C_1, \ldots, C_{\lfloor d/2\rfloor}$ and $N_1, \ldots, N_{\lfloor d/2\rfloor}$; how then does it retain the orthogonality of $N_{\lfloor d/2\rfloor+1}, \ldots, N_d$ with $C_1, \ldots, C_{\lfloor d/2\rfloor}$ that we achieved in the bulk update step? The trick lies in the fact that whenever we update any N_j in $\{N_{\lfloor d/2\rfloor+1}, \ldots, N_d\}$ in the second recursive call, we do it as $N_j = \sum_{k=\lfloor d/2\rfloor+1}^{d} \alpha_k N_k$, where $\alpha_k \in \mathbb{Q}$. That is, the updated N_j is obtained as a rational linear combination of $N_{\lfloor d/2\rfloor+1}, \ldots, N_d$. Since the bulk update step prior to the second recursive call ensures that $N_{\lfloor d/2\rfloor+1}, \ldots, N_d$ are all orthogonal to $C_1, \ldots, C_{\lfloor d/2\rfloor}$ at the beginning of this step, the updated N_j's remain orthogonal to $C_1, \ldots, C_{\lfloor d/2\rfloor}$. This property allows the second recursive call to work strictly in the bottom half of the data without looking at the top half.

The base case for the recursion is a subproblem of size 1 (let this subproblem involve C_ℓ, N_ℓ) in which case the algorithm simply retains N_ℓ as it is and computes C_ℓ using the algorithm in section 7. With regards to time complexity, the bulk update step will be shown to take $O(md^{\omega-1})$ arithmetic operations.

We describe the bulk update procedure in the recursive call that computes the cycles $C_\ell, \ldots, C_h$ for some h and ℓ with $h > \ell$. This recursive call works with the vectors $N_\ell, \ldots, N_h$: all of these vectors are already orthogonal to $C_1, \ldots, C_{\ell-1}$. The recursive call runs as follows:

1. Compute the cycles $C_\ell, \ldots, C_{mid}$, where $mid = \lceil (\ell + h)/2 \rceil - 1$, using the vectors $N_\ell, \ldots, N_{mid}$ recursively.
2. Modify $N_{mid+1}, \ldots, N_h$, which are untouched by the first step, to make them orthogonal to $C_\ell, \ldots, C_{mid}$.
3. Compute $C_{mid+1}, \ldots, C_h$ using these $N_{mid+1}, \ldots, N_h$ recursively.

Step 2 is the bulk update step. We wish to update each N_j, $mid + 1 \leq j \leq h$, to a rational linear combination of $N_\ell, \ldots, N_{mid}$ and N_j as follows:[4]

$$N_j = \frac{\langle N_{mid}, C_{mid} \rangle}{\langle N_{\ell-1}, C_{\ell-1} \rangle} N_j + \sum_{t=\ell}^{mid} \alpha_{tj} N_t,$$

where the α_{tj}'s are to be determined in a way which ensures that N_j becomes orthogonal to $C_\ell, \ldots, C_{mid}$. That is, for all i, j, where $\ell \leq i \leq mid$ and $mid + 1 \leq j \leq h$, we want

$$\frac{\langle N_{mid}, C_{mid} \rangle}{\langle N_{\ell-1}, C_{\ell-1} \rangle} \langle C_i, N_j \rangle + \sum_{t=\ell}^{mid} \alpha_{tj} \langle C_i, N_t \rangle = 0. \tag{4.1}$$

Rewriting the above relations in matrix form, we get

$$A \cdot \mathcal{N}_d \cdot D = -A \cdot \mathcal{N}_u \cdot X, \tag{4.2}$$

where (let $k = mid - \ell + 1$)

- A is a $k * m$ matrix, the ith row of which is $C_{\ell+i-1}$,
- $\mathcal{N}_d$ is an $m * (h - k)$ matrix, the jth column of which is N_{mid+j},
- D is an $(h - k) * (h - k)$ scalar matrix with $\langle N_{mid}, C_{mid} \rangle / \langle N_{\ell-1}, C_{\ell-1} \rangle$ in the diagonal,
- $\mathcal{N}_u$ is an $m * k$ matrix, the tth column of which is $N_{\ell+t-1}$, and
- X is the $k * (h - k)$ matrix of variables α_{tj}, with t indexing the rows and j indexing the columns.

To compute the α_{tj}'s, we solve for $X = -(A \cdot \mathcal{N}_u)^{-1} \cdot A \cdot \mathcal{N}_d \cdot D$. Using fast matrix multiplication, we can compute $A \cdot \mathcal{N}_u$ and $A \cdot \mathcal{N}_d$ in $O(mk^{\omega-1})$ time by splitting the matrices into d/k square blocks and using fast matrix multiplication to multiply the blocks. Multiplying each element of $A \cdot \mathcal{N}_d$ with the scalar $\langle N_{mid}, C_{mid} \rangle / \langle N_{\ell-1}, C_{\ell-1} \rangle$ gives us $A \cdot \mathcal{N}_d \cdot D$. Thus we compute the matrix $A \cdot \mathcal{N}_d \cdot D$ with $O(mk^{\omega-1})$ arithmetic operations. Next, we find the inverse of $A \cdot \mathcal{N}_u$ with $O(k^\omega)$ arithmetic operations (this inverse exists because $A \cdot \mathcal{N}_u$ is a lower triangular matrix whose diagonal entries are $\langle C_i, N_i \rangle \neq 0$). Then we multiply $(A \cdot \mathcal{N}_u)^{-1}$ with $A \cdot \mathcal{N}_d \cdot D$ using $O(k^\omega)$ arithmetic operations. Thus we obtain X. Finally, we obtain $N_{mid+1}, \ldots, N_d$ from X using the product $\mathcal{N}_u \cdot X$, which we can compute in $O(mk^{\omega-1})$ arithmetic operations, and adding $\mathcal{N}_d \cdot D$ to $\mathcal{N}_u \cdot X$. The total number of arithmetic operations required for the bulk update step is thus $O(mk^{\omega-1})$.

The total number of arithmetic operations required for the bulk update step is $O(mk^{\omega-1})$; however, each arithmetic operation is quite expensive since we deal with large numbers here. In this algorithm, the entries in $(A \cdot \mathcal{N}_u)^{-1}$ could be very large. The elements in $A \cdot \mathcal{N}_u$ have values up to $d^{\Theta(d)}$, which would result in the entries in $(A \cdot \mathcal{N}_u)^{-1}$ being as large as $d^{\Theta(d^2)}$. So each arithmetic operation then costs us

[4] Note that the coefficient $\langle N_{mid}, C_{mid} \rangle / \langle N_{\ell-1}, C_{\ell-1} \rangle$ for N_j is chosen so that the updated vector N_j here is exactly the same vector N_j that we would have obtained at this stage using the algorithm deterministic-MCB (section 3).

up to $\tilde{\Theta}(d^2)$ time, and the overall time for the outermost bulk update step would be $\tilde{\Theta}(m^{\omega+2})$ time, which makes this approach slower than the algorithm deterministic-MCB.

5. A fast deterministic algorithm. In the approach described in the previous section, we saw that entries in the matrix $(A \cdot \mathcal{N}_u)^{-1}$ (refer to (4.2)) could be as large as $d^{\Theta(d^2)}$. Thus we were not able to use the faster scheme for updating the vectors N_j, since each arithmetic operation could cost us up to $\tilde{\Theta}(d^2)$ time. But observe that the α_{tj}'s are just *intermediate* numbers in our computation. That is, they are the coefficients in

$$\sum_{t=\ell}^{mid} \alpha_{tj} N_t + \frac{\langle N_{mid}, C_{mid}\rangle}{\langle N_{\ell-1}, C_{\ell-1}\rangle} N_j.$$

Our final aim is to determine the updated coordinates of N_j which are at most $d^{d/2}$ (see Fact 1), since we know $N_j = (y_1, \ldots, y_{mid}, 0, \ldots, 0, \langle N_{mid}, C_{mid}\rangle, 0, \ldots, 0)$, where $\mathbf{y} = (y_1, \ldots, y_{mid})$ is the solution to the linear system: $M\mathbf{y} = \det(M) b_j$; M is the $mid \times mid$ matrix of $C_1, \ldots, C_{mid}$ truncated to the their first mid coordinates, and b_j is the column vector of negated j coordinates of $C_1, \ldots, C_{mid}$.

Since the final coordinates are bounded by $d^{d/2}$ while the intermediate values could be much larger, this suggests the use of modular arithmetic here. We could work over the finite fields $\mathbb{Z}_{p_1}, \mathbb{Z}_{p_2}, \ldots, \mathbb{Z}_{p_s}$ where $p_1, \ldots, p_s$ are small primes (say, in the range d to d^2) and try to retrieve N_j from $N_j \bmod p_1, \ldots, N_j \bmod p_s$, which is possible (by the Chinese remainder theorem) if $s \approx d/2$. Arithmetic in $\mathbb{Z}_p$ takes $O(1)$ time and we thus spend $O(s \cdot mk^{\omega-1})$ time for the update step now. However, if it is the case that some p is a divisor of some $\langle N_i, C_i\rangle$ where $\ell \le i \le mid$, then we cannot invert $A \cdot \mathcal{N}_u$ in the field $\mathbb{Z}_p$. Since each number $\langle N_i, C_i\rangle$ could be as large as $d^{d/2}$, it could be a multiple of up to $\Theta(d)$ primes which are in the range $d, \ldots, d^2$. So in order to be able to determine d primes which are relatively prime to each of $\langle N_\ell, C_\ell\rangle, \ldots, \langle N_{mid}, C_{mid}\rangle$, we might in the worst case have to test about $(mid - \ell + 1) \cdot d = kd$ primes. Testing kd primes for divisibility with respect to k d-bit numbers costs us $k^2 d^2$ time. We cannot afford so much time per update step.

Another idea is to work over just one finite field $\mathbb{Z}_q$ where q is a large prime. If $q > d^{d/2}$, then q can never be a divisor of any $\langle N_i, C_i\rangle$, so we can carry out all of our arithmetic in $\mathbb{Z}_q$ since the matrix $A \cdot \mathcal{N}_u$ will be nonsingular in $\mathbb{Z}_q$. Arithmetic in $\mathbb{Z}_q$ costs us $\tilde{\Theta}(d)$ time if $q \approx d^d$. Then our update step takes $\tilde{O}(m^2 k^{\omega-1})$ time, which will result in a total time of $\tilde{O}(m^{\omega+1})$ for all of the update steps, which is our goal. But computing such a large prime q is a difficult problem.

The solution is to work over a suitable ring instead of over a field; recall that fast matrix multiplication algorithms work over rings. Let us do the above computation modulo a large integer R, say, $R \approx d^d$. Then intermediate numbers do not grow more than R and we can retrieve N_j directly from $N_j \bmod R$, because R is much larger than any coordinate of N_j.

What properties of R do we need? The integer R must be relatively prime to the numbers: $\langle N_\ell, C_\ell\rangle$, $\langle N_{\ell+1}, C_{\ell+1}\rangle, \ldots, \langle N_{mid}, C_{mid}\rangle$ so that the triangular matrix $A \cdot \mathcal{N}_u$ which has these elements along the diagonal is invertible in $\mathbb{Z}_R$. And R must also be relatively prime to $\langle N_{\ell-1}, C_{\ell-1}\rangle$ so that $\langle N_{mid}, C_{mid}\rangle / \langle N_{\ell-1}, C_{\ell-1}\rangle$ is defined in $\mathbb{Z}_R$. Once we determine such an R, we will work in $\mathbb{Z}_R$. We stress the point that such an R is a number used only in this particular bulk update step—in another bulk update step of another recursive call, we need to compute another such large integer.

It is easy to see that the number R determined below is a large number that is relatively prime to $\langle N_{\ell-1}, C_{\ell-1}\rangle$, $\langle N_\ell, C_\ell\rangle, \langle N_{\ell+1}, C_{\ell+1}\rangle, \ldots,$ and $\langle N_{mid}, C_{mid}\rangle$ by doing the following.

1. Right at the beginning of the algorithm, compute d^2 primes $p_1, \ldots, p_{d^2}$, where each of these primes is at least d. Then form the d products: $P_1 = p_1 \cdots p_d$, $P_2 = p_1 \cdots p_{2d}$, $P_3 = p_1 \cdots p_{3d}$, $\ldots$, $P_d = p_1 \cdots p_{d^2}$.
2. Then during our current update step, compute the product
$$\mathcal{L} = \langle N_{\ell-1}, C_{\ell-1}\rangle\langle N_\ell, C_\ell\rangle \cdots \langle N_{mid}, C_{mid}\rangle.$$
3. By doing a binary search on $P_1, \ldots, P_d$, determine the smallest $s \geq 0$ such that P_{s+1} does not divide $\mathcal{L}$.
4. Determine a $p \in \{p_{sd+1}, \ldots, p_{sd+d}\}$ that does not divide $\mathcal{L}$. Let $R = p^d$.

Cost of computing R. The value of $\pi(r)$, the number of primes less than r, is given by $r/6\log r \leq \pi(r) \leq 8r/\log r$ [1]. So all the primes $p_1, \ldots, p_{d^2}$ are $\tilde{O}(d^2)$, and computing them takes $\tilde{O}(d^2)$ time using a sieving algorithm. The products $P_1, \ldots, P_d$ are computed just once in a preprocessing step. We will always perform arithmetic on large integers using Schönhage–Strassen multiplication, so that it takes $\tilde{O}(d)$ time to multiply two d-bit numbers. Whenever we perform a sequence of multiplications, we will use a tree so that d numbers (each of bit size $\tilde{O}(d)$) can be multiplied in $\tilde{O}(d^2)$ time. So computing $P_1, \ldots, P_d$ takes $\tilde{O}(d^3)$ preprocessing time.

In the update step, we compute $\mathcal{L}$, which takes $\tilde{O}(d^2)$ time. The product $P_{s+1} = p_{sd+1} \cdots p_{sd+d}$ is found in $\tilde{O}(d^2)$ time by binary search in the set $\{P_1, \ldots, P_d\}$. Determine a p in the set $\{p_{sd+1}, \ldots, p_{sd+d}\}$ that does not divide $\mathcal{L}$ by testing which of the two products $p_{sd+1} \cdots p_{sd+\lfloor d/2\rfloor}$ or $p_{sd+\lfloor d/2\rfloor+1} \cdots p_{sd+d}$ does not divide $\mathcal{L}$, and recurse on the product that does not divide $\mathcal{L}$. Thus R can be computed in $\tilde{O}(d^2)$ time.

Computation in $\mathbb{Z}_R$. We need to invert the matrix $A \cdot \mathcal{N}_u$ in the ring $\mathbb{Z}_R$. Recall that this matrix is lower triangular. Computing the inverse of a lower triangular matrix is easy. If

$$A \cdot \mathcal{N}_u = \begin{pmatrix} W & 0 \\ Y & Z \end{pmatrix}, \text{ then we have } (A \cdot \mathcal{N}_u)^{-1} = \begin{pmatrix} W^{-1} & 0 \\ -Z^{-1}YW^{-1} & Z^{-1} \end{pmatrix}.$$

Hence to invert $A \cdot \mathcal{N}_u$ in $\mathbb{Z}_R$ we need the multiplicative inverses of only its diagonal elements: $\langle C_\ell, N_\ell\rangle, \ldots, \langle C_{mid}, N_{mid}\rangle$ in $\mathbb{Z}_R$. Using Euclid's greatest common divisor (gcd) algorithm, each inverse can be computed in $\tilde{O}(d^2)$ time, since each of the numbers involved here and R have bit size $\tilde{O}(d)$. The matrix $A \cdot \mathcal{N}_u$ is inverted via fast matrix multiplication, and once we compute $(A \cdot \mathcal{N}_u)^{-1}$, the matrix X, that consists of all the coordinates α_{tj} that we need (see (4.1)), can be easily computed in $\mathbb{Z}_R$ as $-(A \cdot \mathcal{N}_u)^{-1} \cdot A \cdot \mathcal{N}_d \cdot D$ by fast matrix multiplication. Then we determine all N_j mod R for $mid + 1 \leq j \leq h$ from $\mathcal{N}_u \cdot X + \mathcal{N}_d \cdot D$. It follows from the analysis presented in section 4 that the time required for all of these operations is $\tilde{O}(m^2k^{\omega-1})$ since each number is now bounded by d^d.

Retrieving the actual N_j. Each entry of N_j can have absolute value at most $d^{d/2}$ (from Fact 1). The number R is much larger than this, $R > d^d$. So if any coordinate, say, n_l in N_j mod R, is larger than $d^{d/2}$, then we can retrieve the original n_l as $n_l - R$. Thus we can retrieve N_j from N_j mod R in $O(d^2)$ time. The time complexity for the update step, which includes matrix operations, gcd computations, and other arithmetic, is $\tilde{O}(m^2k^{\omega-1} + d^2k)$ or $\tilde{O}(m^2k^{\omega-1})$. Thus our recurrence becomes

(assuming Lemma 7.4 from section 7, which shows that the base case $T(1)$ takes $O(m^2n + mn^2 \log n)$ time)

$$T(k) = \begin{cases} 2T(k/2) + \tilde{O}(m^2k^{\omega-1}) & \text{if } k > 1, \\ m^2n + mn^2 \log n & \text{if } k = 1. \end{cases}$$

The recurrence solves to $T(k) = O(k(m^2n + mn^2 \log n) + k^{\omega-1}m^2 \cdot \text{poly}(\log m))$, and hence $T(d) = O(m^3n + m^2n^2 \log n) + \tilde{O}(m^{\omega+1})$, which is $O(m^3n + m^2n^2 \log n)$, because $m \leq n^2$ implies $\tilde{O}(m^{\omega+1})$ is always $o(m^3n)$. Thus we have shown the following theorem.

THEOREM 5.1. *A minimum cycle basis in a weighted directed graph with m edges and n vertices and nonnegative edge weights can be computed in $O(m^3n + m^2n^2 \log n)$ time.*

6. Faster arithmetic via randomization. Suppose we could perform each arithmetic operation in $O(1)$ time; then our recurrence relation for $T(k)$, $k > 1$ will be given by:

$$T(k) = 2T(k/2) + O(mk^{\omega-1}).$$

We would also like to show that $T(1)$ is $O(mn + n^2 \log n)$. Then this yields a running time of $O(n^2d \log n + nmd + m^\omega)$ or $O(m^2n + mn^2 \log n)$, since m^ω is $o(m^2n)$. Such a running time matches the complexity of minimum cycle basis computation in undirected graphs.

Now we will show that we *can* perform each arithmetic operation in $O(1)$ time. This will require working modulo a randomly chosen prime p. We will perform all arithmetic over the finite field $\mathbb{Z}_p$ and not over the rationals. The danger now is that the results of working in this field could be different from those obtained by working over rationals. Fortunately, the following theorem claims that the results remain the same, provided the prime p chosen satisfies certain properties. In the description below, let C_i, N_i denote the results obtained by the fast deterministic algorithm working over the rationals, and let C_i', N_i' be the counterparts obtained by the fast deterministic algorithm working over $\mathbb{Z}_p$.

THEOREM 6.1. *If $\langle C_i, N_i \rangle \neq 0 \pmod p$ for all i, $1 \leq i \leq d$, then $C_i' = C_i$ and $N_i' = N_i \pmod p$.*

Proof. Recall that the fast deterministic algorithm has a recursive structure. We use an inductive argument that mimics this recursion. At the very beginning, $N_i' = N_i \pmod p$ for all i, $1 \leq i \leq d$, as the N_i's are $\{0,1\}$ vectors. Each recursive subproblem (when working with rationals) then takes a contiguous subset $N_\ell, N_{\ell+1}, \ldots, N_h$ and computes $C_\ell, C_{\ell+1}, \ldots, C_h$ using only $N_\ell, N_{\ell+1}, \ldots, N_h$, modifying the latter in the process. We claim that if this recursive subproblem began with $N_\ell', N_{\ell+1}', \ldots, N_h'$ instead of $N_\ell, N_{\ell+1}, \ldots, N_h$, where

$$N_\ell' = N_\ell \pmod p,\ N_{\ell+1}' = N_{\ell+1} \pmod p, \ldots, N_h' = N_h \pmod p,$$

and subsequently worked modulo p, then it would still produce the same cycles $C_\ell, \ldots, C_h$ and in addition, after modification, the relations $N_\ell' = N_\ell \pmod p$, $N_{\ell+1}' = N_{\ell+1} \pmod p, \ldots, N_h' = N_h \pmod p$ will continue to hold. We will use induction on $\ell - h + 1$ to prove this claim. We will explicitly show the base case when $\ell - h + 1 = 1$. We will then assume that the claim is true for all recursive subproblems with $1 \leq \ell - h + 1 < t$ and then prove it for $\ell - h + 1 = t$.

Consider a subproblem of size 1 ($\ell - h + 1 = 1$, i.e., $\ell = h$). When working over rationals, N_ℓ does not change and C_ℓ is defined as the shortest cycle such that $\langle C_\ell, N_\ell \rangle \neq 0$. When working (mod p), N'_ℓ does not change and C'_ℓ is defined as the shortest cycle such that $\langle C'_\ell, N'_\ell \rangle \neq 0 \pmod{p}$. Assuming $N'_\ell = N_\ell \pmod{p}$ at the beginning of this subproblem, and given that p satisfies $\langle C_\ell, N_\ell \rangle \neq 0 \pmod{p}$, it follows that $C'_\ell = C_\ell$. This shows the base case.

Next, consider the three-step process used in the fast deterministic algorithm. First, consider the first recursive step which computes $C_\ell, \ldots, C_{mid}$. By the induction hypothesis, at the end of this step, we have $C'_\ell = C_\ell, \ldots, C'_{mid} = C_{mid}$ and $N'_\ell = N_\ell \pmod{p}, \ldots, N'_{mid} = N_{mid} \pmod{p}$. The vectors $N'_{mid+1}, \ldots, N'_h$ are untouched by this step and by virtue of the initial assignment, stay identical to $N_{mid+1}, \ldots, N_h$. Second, consider the bulk update step. This step modifies $N'_{mid+1} \ldots N'_h$ as a function of $N'_\ell, \ldots, N'_{mid}$ and $C'_\ell, \ldots, C'_{mid}$. Since $N'_\ell = N_\ell \pmod{p}, \ldots, N'_{mid} = N_{mid} \pmod{p}$ and $C'_1 = C_1, \ldots, C'_{mid} = C_{mid}$, it follows that $N'_{mid+1} = N_{mid+1} \pmod{p}, \ldots, N'_h = N_h \pmod{p}$ after the bulk update step. This sets up the necessary initial condition for the second recursive step which computes $C'_{mid+1}, \ldots, C'_h$ from $N'_{mid+1}, \ldots, N'_h$ alone. Applying the induction hypothesis again proves the theorem. ∎

Selecting the number p. It remains to show how p is chosen. Consider a pool of d^2 primes, each of which is bigger than d^2, and suppose we choose a prime at random from this pool. Lemma 6.3 shows that it satisfies the conditions of Theorem 6.1 with probability of at least 3/4. Let us first make the following definition.

DEFINITION 6.2. *Call a prime p* good *if $\langle C_i, N_i \rangle \neq 0 \pmod{p}$ for each $i \in \{1, \ldots, d\}$. Call a prime p* bad *if it is not good.*

LEMMA 6.3. *Let P be a set of d^2 primes, each of which is at least d^2. Then at least 3/4th of the set P is good.*

Proof. We will use Lemma 3.3 here. Lemma 3.3 shows that for all $1 \leq j \leq d$, $\langle C_j, N_j \rangle = \det(M)$, where M is the $j \times j$ matrix of $\tilde{C}_k$'s on the right-hand side of (3.1). Hadamard's inequality tells us that the absolute value of $\det(M)$ is at most $d^{d/2}$, since the entries in M are $0, \pm 1$. Hence for all $1 \leq i \leq d$, we have $0 \neq |\langle C_i, N_i \rangle| \leq d^{d/2}$. Since each prime in P is at least d^2, at most $d/4$ elements in P can be divisors of $\langle C_i, N_i \rangle$. So the number of primes in P that can divide at least one of $\langle C_1, N_1 \rangle, \langle C_2, N_2 \rangle, \ldots, \langle C_d, N_d \rangle$ is at most $d^2/4$. Hence the fraction of bad primes in P is at most $d^2/4d^2 \leq 1/4$. ∎

We now need to show how to compute the pool P of d^2 primes, each bigger than d^2. As mentioned earlier, the value of $\pi(r)$, the number of primes less than r, is given by $r/6 \log r \leq \pi(r) \leq 8r/\log r$. So the elements in P can be bounded by $100d^2 \log d$. Using sieving, we can compute the set of primes in the first $100d^2 \log d$ numbers in $O(d^2 \log^2 d)$ time. So the set P can be determined in $O(d^2 \log^2 d) = O(m^2 \log^2 n)$ time. Note that this term does not appear in the final complexity of $O(m^2 n + mn^2 \log n)$ because it is completely dominated by the $m^2 n$ term.

Arithmetic modulo p. Under the assumption that arithmetic on $O(\log m)$ bits takes unit time, it follows that addition, subtraction, and multiplication in $\mathbb{Z}_p$ can be implemented in unit time since p is $O(d^2 \log d) = O(m^2 \log m)$. However, we also need to implement division efficiently. Once p is chosen, we will compute the multiplicative inverses of all elements in $\mathbb{Z}_p^*$ by the extended Euclid's gcd algorithm by solving $ax = 1 (\mathrm{mod} p)$ for each $a \in \mathbb{Z}_p^*$. This takes time $O(\log p)$ for each element and hence $O(p \log p) = O(d^2 \log^2 d)$ for all of the elements. Thereafter, division in $\mathbb{Z}_p$ gets implemented as multiplication with the inverse of the divisor. The $O(d^2 \log^2 d)$

term does not appear in the final complexity of $O(m^2n + mn^2 \log n)$ because it is completely dominated by the m^2n term.

Lemma 7.3, proved in section 7, shows that $T(1)$, the time taken to compute the shortest C_i such that $\langle C_i, N_i \rangle \neq 0 (\bmod p)$, is $O(mn + mn^2 \log n)$. Hence Theorem 6.4 follows from the recurrence relation for $T(\cdot)$ (refer to the beginning of this section).

THEOREM 6.4. *A minimum cycle basis in a directed graph with n vertices and m edges, with nonnegative weights on its edges, can be computed with a probability of at least $3/4$ in $O(m^2n + mn^2 \log n)$ time.*

7. Computing nonorthogonal shortest cycles. Now we come to the second key routine required by our algorithm—given a directed graph G with nonnegative edge weights, compute a shortest cycle in G whose dot product with a given vector $N_i \in \mathbb{Z}^m$ is nonzero. We will first consider the problem of computing a shortest cycle C_p such that $\langle C_p, N_i \rangle \neq 0 \pmod p$ for a number $p = O(d^2 \log d)$. Recall that C_p can traverse edges of G in both forward and reverse directions; the vector representation of C_p has a 1 for every forward edge in the cycle, a -1 for every reverse edge, and a 0 for edges not present at all in the cycle. This vector representation is used for computing dot products with N_i. The weight of C_p itself is simply the sum of the weights of the edges in the cycle. We show how to compute C_p in $O(mn + n^2 \log n)$ time.

Definitions. To compute shortest paths and cycles, we will work with the undirected version of G. Directions will be used only to compute the *residue class* of a path or cycle, i.e., the dot product between the vector representation of this path or cycle and N_i modulo p. Let p_{uv} denote a shortest path between vertices u and v and let f_{uv} denote its length and r_{uv} its residue class. Let s_{uv} be the length of a shortest path, if any, between u and v in a residue class distinct from r_{uv}. Observe that the value of s_{uv} is independent of the choice of p_{uv}.

We will show how to compute f_{uv} and s_{uv} for all pairs of vertices u, v in $O(mn + n^2 \log n)$ time. As is standard, we will also compute paths realizing these lengths in addition to computing the lengths themselves. The following claim tells us how these paths can be used to compute a shortest nonorthogonal cycle—simply take each edge uv and combine it with s_{vu} to get a cycle. The shortest of all these cycles having a nonzero residue class is our required cycle.

LEMMA 7.1. *Let $C = u_0u_1 \dots u_ku_0$ be a shortest cycle whose residue class is nonzero modulo p and whose shortest edge is u_0u_1. Then the path $u_1u_2 \dots u_ku_0$ has a residue class different from the residue class of the edge u_1u_0, the length of the path $u_1u_2 \dots u_ku_0$ equals $s_{u_1u_0}$, and the length of the edge u_0u_1 equals $f_{u_1u_0}$.*

Proof. First, we show that the path $u_1u_2 \dots u_ku_0$ and the edge u_1u_0 have different residue classes. Let x denote the residue class of the path, and let y denote the residue class of the edge u_0u_1. Since C is in a nonzero residue class, $x + y \not\equiv 0 \pmod p$, so $x \not\equiv -y \pmod p$. Since the incidence vector corresponding to u_1u_0 is the negation of the incidence vector corresponding to u_0u_1, the residue class of the edge u_1u_0 is $-y$. Thus the claim follows.

Now, if the length of u_1u_0 is strictly greater than $f_{u_1u_0}$, then consider any shortest path π between u_1 and u_0 (which, of course, has length $f_{u_1u_0}$). Combining π with u_1u_0 yields a cycle and combining π with $u_1u_2 \dots u_ku_0$ yields another cycle. These cycles are in distinct residue classes and are shorter than C. This contradicts the definition of C. Therefore, the edge u_1u_0 has length $f_{u_1u_0}$.

Since $u_1u_2 \dots u_ku_0$ has a different residue class from the edge u_1u_0, the length of $u_1u_2 \dots u_ku_0$ cannot be smaller than $s_{u_1u_0}$, by the very definition of $s_{u_1u_0}$. Suppose,

for a contradiction, that the length $u_1u_2 \dots u_ku_0$ is strictly larger than $s_{u_1u_0}$. Then combining the path between u_1 and u_0 which realizes the length $s_{u_1u_0}$ along with the edge u_1u_0 yields a cycle which is shorter than C and which has a nonzero residue class modulo p. This contradicts the definition of C. The lemma follows. ∎

Computing f_{uv} and s_{uv}. We first find any one shortest path (among possibly many) between each pair of vertices u and v by Dijkstra's algorithm; this gives us p_{uv}, f_{uv}, and r_{uv} for each pair u, v. The time taken is $O(mn+n^2 \log n)$. For each pair u, v, we now need to find a shortest path between u, v with a residue class distinct from r_{uv}; the length of this path will be s_{uv}. Use q_{uv} to denote any such path. We show how a modified Dijkstra search can compute these paths in $O(mn + n^2 \log n)$ time. The following lemma shows the key prefix property of the q_{uv} paths needed for a Dijkstra-type algorithm.

LEMMA 7.2. *For any u and v, the path q_{uv} can be chosen from the set $\{p_{uw} \circ wv,\ q_{uw} \circ wv\ :\ wv \in E\}$. Here $p \circ e$ denotes the path p extended by the edge e.*

Proof. Consider any path π between u and v that realizes the value s_{uv}, i.e., it has length s_{uv} and residue class distinct from r_{uv}. Let w be the penultimate vertex on this path, and let π' be the prefix path from u to w. Clearly, π cannot be shorter than $p_{uw} \circ wv$. Hence, if the residue class of $p_{uw} \circ wv$ is distinct from r_{uv}, then we are done. So assume that $p_{uw} \circ wv$ has residue class r_{uv}. Then π' must have a residue class distinct from p_{uw} and hence q_{uw} exists. Also, the length of π' must be at least the length of q_{uw}, and the residue class of $q_{uw} \circ wv$ is distinct from the residue class of $p_{uw} \circ wv$ and hence distinct from r_{uv}. Thus $q_{uw} \circ wv$ realizes s_{uv}. ∎

We now show how to compute the s_{uv}'s for any fixed u in time $O(m + n \log n)$ with a Dijkstra-type algorithm. Repeating this for every source gives the result. The algorithm differs from Dijkstra's shortest path algorithm only in the initialization and update steps, which we describe below. We use the notation key_{uv} to denote the key used to organize the priority heap; key_{uv} will finally equal s_{uv}.

Initialization. We set key_{uv} to the minimal length of any path $p_{uw} \circ wv$ with residue class distinct from r_{uv}. If there is no such path, then we set it to ∞.

The update step. Suppose we have just removed w from the priority queue. We consider the u-w path of length key_{uw} which was responsible for the current key value of w. For each edge wv incident on w, we extend this path via the edge wv. We update key_{uv} to the length of this path provided its residue class is different from r_{uv}.

Correctness. We need to show that key_{uv} is set to s_{uv} in the course of the algorithm (note that one does not need to worry about the residue class since any path that updates key_{uv} in the course of the algorithm has residue class different from r_{uv}). This follows immediately from Lemma 7.2. If s_{uv} is realized by the path $p_{uw} \circ wv$ for some neighbor w, then key_{uv} is set to s_{uv} in the initialization step. If s_{uv} is realized by the path $q_{uw} \circ wv$ for some neighbor w, then key_{uv} is set to s_{uv} in the update step. This completes the proof of correctness. Thus we have given an $O(mn+n^2 \log n)$ algorithm to compute the s_{uv}'s for all $u, v \in V$. We have thus shown the following lemma.

LEMMA 7.3. *A shortest cycle C_p in G, whose dot product with N_i is nonzero modulo p, can be computed in $O(mn + n^2 \log n)$ time.*

We now consider the complexity of computing a shortest cycle C_i whose dot product with N_i is nonzero, instead of the condition that the dot product is nonzero modulo p. But any cycle C_i which satisfies $\langle C_i, N_i \rangle \neq 0$ satisfies $\langle C_i, N_i \rangle \neq 0 \pmod{p}$ for some $p \in \{p_1, \dots, p_{d/2}\}$, where $p_1, \dots, p_{d/2}$ are distinct primes, each of which is at least d. This follows from the isomorphism of the ring $\mathbb{Z}_{\prod p_i}$ to the ring $\mathbb{Z}_{p_1} \times$

$\mathbb{Z}_{p_2} \times \cdots \times \mathbb{Z}_{p_{d/2}}$. So any nonzero element whose absolute value is less than $\prod_{i=1}^{d/2} p_i$ is mapped to a tuple of its residues that is not the zero vector.

We have $|\langle C_i, N_i \rangle| \leq d^{d/2}$ (from Lemma 3.3 and Hadamard's inequality). Thus $|\langle C_i, N_i \rangle| < \prod_{i=1}^{d/2} p_i$. So if $\langle C_i, N_i \rangle$ is nonzero, then it is a nonzero element in $\mathbb{Z}_{\prod p_i}$, and so it satisfies $\langle C_i, N_i \rangle \neq 0 \pmod{p}$ for some p in $\{p_1, \ldots, p_{d/2}\}$. Thus a shortest cycle C_i such that $\langle C_i, N_i \rangle \neq 0$ is the shortest among all the cycles C_p, $p \in \{p_1, \ldots, p_{d/2}\}$, where C_p is a shortest cycle such that $\langle C_p, N_i \rangle \neq 0 \pmod{p}$. Hence, by Lemma 7.3, the time taken to compute C is $O(d \cdot (mn + n^2 \log n))$ or $O(m^2 n + mn^2 \log n)$. Thus we have shown Lemma 7.4.

LEMMA 7.4. *A shortest cycle C_i in G, whose dot product with N_i is nonzero, can be computed in $O(m^2 n + mn^2 \log n)$ time.*

8. Conclusions. We considered the minimum cycle basis problem in directed graphs with nonnegative edge weights. We presented an $O(m^3 n + m^2 n^2 \log n)$ deterministic algorithm and an $O(m^2 n + mn^2 \log n)$ randomized algorithm for this problem, where m is the number of edges and n is the number of vertices. These algorithms use the framework of computing cycles $C_1, \ldots, C_d$ and their supporting vectors $N_1, \ldots, N_d$ using fast matrix multiplication. However, this approach leads to large intermediate numbers and the cost of arithmetic becomes high. We overcome this problem in the randomized algorithm by working over a finite field $\mathbb{Z}_p$ for a small random prime p and by working over suitable rings $\mathbb{Z}_R$ in the deterministic algorithm. We also presented an efficient algorithm, based on Dijkstra's algorithm, to compute a shortest cycle whose dot product with a function on its edge set is nonzero.

LINEAR EQUATIONS MODULO 2 AND THE L_1 DIAMETER OF CONVEX BODIES*

SUBHASH KHOT† AND ASSAF NAOR†

Abstract. We design a randomized polynomial time algorithm which, given a 3-tensor of real numbers $A = \{a_{ijk}\}_{i,j,k=1}^n$ such that for all $i,j,k \in \{1,\ldots,n\}$ we have $a_{ijk} = a_{ikj} = a_{kji} = a_{jik} = a_{kij} = a_{jki}$ and $a_{iik} = a_{ijj} = a_{iji} = 0$, computes a number $\mathrm{Alg}(A)$ which satisfies with probability at least $\frac{1}{2}$, $\Omega(\sqrt{\frac{\log n}{n}}t) \cdot \max_{x\in\{-1,1\}^n} \sum_{i,j,k=1}^n a_{ijk}x_ix_jx_k \le \mathrm{Alg}(A) \le \max_{x\in\{-1,1\}^n} \sum_{i,j,k=1}^n a_{ijk}x_ix_jx_k$. On the other hand, we show via a simple reduction from a result of Håstad and Venkatesh [*Random Structures Algorithms*, 25 (2004), pp. 117–149] that under the assumption $NP \not\subseteq DTIME(n^{(\log n)^{O(1)}})$, for every $\epsilon > 0$ there is no algorithm that approximates $\max_{x\in\{-1,1\}^n} \sum_{i,j,k=1}^n a_{ijk}x_ix_jx_k$ within a factor of $2^{(\log n)^{1-\epsilon}}$ in time $2^{(\log n)^{O(1)}}$. Our algorithm is based on a reduction to the problem of computing the diameter of a convex body in $\mathbb{R}^n$ with respect to the L_1 norm. We show that it is possible to do so up to a multiplicative error of $O(\sqrt{\frac{n}{\log n}})$, while no randomized polynomial time algorithm can achieve accuracy $o(\sqrt{\frac{n}{\log n}})$. This resolves a question posed by Brieden et al. in [*Mathematika*, 48 (2001), pp. 63–105]. We apply our new algorithm to improve the algorithm of Håstad and Venkatesh for the Max-E3-Lin-2 problem. Given an overdetermined system $\mathcal{E}$ of N linear equations modulo 2 in $n \le N$ Boolean variables such that in each equation only three distinct variables appear, the goal is to approximate in polynomial time the maximum number of satisfiable equations in $\mathcal{E}$ minus $\frac{N}{2}$ (i.e., we subtract the expected number of satisfied equations in a random assignment). Håstad and Venkatesh obtained an algorithm which approximates this value up to a factor of $O(\sqrt{N})$. We obtain an $O(\sqrt{\frac{n}{\log n}})$ approximation algorithm. By relating this problem to the refutation problem for random $3-CNF$ formulas, we give evidence that obtaining a significant improvement over this approximation factor is likely to be difficult.

1. Introduction.

A function $f : \{-1,1\}^n \to \mathbb{R}$ has Fourier expansion $f(x) = \sum_{S\subseteq\{1,\ldots,n\}} \widehat{f}(S) \prod_{i\in S} x_i$. Assume that f has a succinct representation in phase space; i.e., only polynomially many of the Fourier coefficients $\widehat{f}(S)$ are nonzero. Can we then compute in polynomial time a good approximation of the maximum of f over the discrete cube $\{-1,1\}^n$? In other words, if we are given polynomially many Fourier coefficients, is there a way to approximate $\max_{x\in\{-1,1\}^n} f(x)$ while looking only at the values of f on a tiny part of the cube? As we shall see below, under widely believed complexity assumptions the answer to this question is generally negative. But, under some additional structural information on the support of the Fourier transform it is possible to achieve this goal, and when this occurs such phenomena have powerful algorithmic applications. Currently our understanding of this fundamental problem is far from satisfactory, and the purpose of the present paper is to investigate cases which have previously eluded researchers. As a result, we uncover new connections

to problems in algorithmic convex geometry and combinatorial optimization.

The Fourier maximization problem described above has been investigated extensively in the quadratic case, partly due to its connections to various graph partitioning problems. In [3] it has been shown that a classical inequality of Grothendieck can be used to give a constant factor approximation algorithm for computing the maximum of functions $f : \{-1,1\}^n \times \{-1,1\}^m \to \mathbb{R}$ which have the form $f(x,y) = \sum_{i=1}^n \sum_{j=1}^m a_{ij} x_i y_j$. This algorithm has various applications, including an algorithmic version of Szemerédi's regularity lemma. In the nonbipartite case, several researchers [27, 25, 12] have discovered an algorithm which computes up to a factor $O(\log n)$ the maximum of functions $f : \{-1,1\}^n \to \mathbb{R}$ which have the form $f(x) = \sum_{i,j=1}^n a_{ij} x_i x_j$, where the matrix (a_{ij}) is assumed to be symmetric and vanish on the diagonal. This result was shown in [12] to imply the best-known approximation algorithms for graphing partitioning problems such as MAXCUTGAIN and correlation clustering. In [2] the structure of the "Fourier support graph," i.e., the pairs $\{i,j\} \in \{1,\ldots,n\}$ for which $a_{ij} \neq 0$, was taken into account. It was shown there that there exists an approximation algorithm which approximates the maximum of f up to a factor $O(\log \vartheta) = O(\log \chi)$, where ϑ is the Lovász theta function of the complement of the Fourier support graph and χ is the chromatic number of this graph. We refer to [2] for more information on this topic, as well as its connection to the evaluation of ground states of spin glasses.

Negative results on the performance of the above mentioned algorithms as well as complexity lower bounds were obtained in [3, 2, 5, 24, 1]. In particular, it was shown in [2] that the semidefinite relaxation that was used in the $O(\log n)$ algorithm discussed above had integrality gap $\Omega(\log n)$. Moreover, in [5] it was shown that unless $NP \subseteq DTIME(n^{O((\log n)^3)})$ there is no polynomial time algorithm which approximates the maximum of $\sum_{i,j=1}^n a_{ij} x_i x_j$ on $\{-1,1\}^n$ up to a factor smaller than $(\log n)^\gamma$, where γ is a universal constant. It was also shown in [5] that under the assumption of the existence of sufficiently strong PCPs it is also NP-hard to approximate this problem to within a factor of $O(\log n)$.

The motivation for the present paper is to study the case of functions whose Fourier expansion is supported on the third level. Specifically, given a 3-tensor of real numbers $A = \{a_{ijk}\}_{i,j,k=1}^n$ such that for all $i,j,k \in \{1,\ldots,n\}$ we have $a_{ijk} = a_{ikj} = a_{kji} = a_{jik} = a_{kij} = a_{jki}$ and $a_{iik} = a_{ijj} = a_{iji} = 0$, we wish to approximate the maximum of the function $f : \{-1,1\}^n \to \mathbb{R}$ given by $f(x) = \sum_{i,j,k=1}^n a_{ijk} x_i x_j x_k$. Despite being a modest goal, this problem has eluded researchers for some time, as the "obvious" semidefinite programming approach that was previously applied to the quadratic case does not generalize to the degree-3 case. As we shall see below, this issue reflects a major difference from the quadratic case: Unless $NP \subseteq DTIME(n^{(\log n)^{O(1)}})$, for every $\epsilon > 0$ there is no algorithm that approximates the maximum of f within a factor of $2^{(\log n)^{1-\epsilon}}$ in time $2^{(\log n)^{O(1)}}$. On the other hand, we will derive here a polynomial time algorithm which approximates the maximum of f to within a factor of $O(\sqrt{\frac{n}{\log n}})$. This algorithm is based on a novel connection between this problem and the problem of efficient computation of the diameter of convex bodies under the ℓ_1^n norm, which is the main new insight of the present paper. We shall now describe our new approach and its application to a fundamental problem in combinatorial optimization: the Max-E3-Lin-2 problem.

We associate with every 3-tensor A as above a convex body $K_A \subseteq \mathbb{R}^n$. The body K_A admits a polynomial time solution to the weak optimization problem for linear functionals (see [19, 18] for the relevant background on convex optimization).

Moreover, we show that the ℓ_1^n diameter of K_A, i.e., $\mathrm{diam}_1(K_A) := \max_{a,b\in K_A} \|a-b\|_1$, is within a constant factor of $\max_{x_i\in\{-1,1\}} \sum_{i,j,k=1}^n a_{ijk}x_ix_jx_k$. This step is crucially based on an application of Grothendieck's inequality. We therefore reduce the level-3 Fourier maximization problem to the following question: Given a convex body $K \subseteq \mathbb{R}^n$ with a weak optimization oracle, approximate in oracle-polynomial time its ℓ_1^n diameter $\mathrm{diam}_1(K)$.

Such problems have been studied extensively in the literature, though mostly in the context of the Euclidean ℓ_2^n diameter (see, for example, [6, 8, 18, 10, 9, 31] and the references therein). In particular, a famous result of Bárány and Füredi states that no deterministic polynomial time algorithm can approximate the ℓ_2^n diameter of convex bodies up to a factor of $o(\sqrt{\frac{n}{\log n}})$. In the paper [10] of Brieden et al. it is shown that unlike the case of volume computation, randomization does not help when it comes to approximating the Euclidean diameter of convex bodies: The same lower bound holds also for the accuracy of randomized oracle-polynomial time algorithms. The paper [10] also studies the case of the ℓ_1^n diameter, or more generally the ℓ_p^n diameter, i.e., $\mathrm{diam}_p(K) := \max_{a,b\in K_A} \|a-b\|_p$. It is shown there that there is an oracle-polynomial time algorithm which approximates $\mathrm{diam}_1(K)$ to within a factor of $O(\sqrt{n})$, and no polynomial time algorithm can achieve accuracy better than $O(\frac{\sqrt{n}}{\log n})$. When $1 < p \le 2$ it is shown in [10] that $\mathrm{diam}_p(K)$ can be approximated within a factor $O(\frac{\sqrt{n}}{(\log n)^{(p-1)/p}})$, and no polynomial time algorithm can achieve accuracy better than $O_p(\sqrt{\frac{n}{\log n}})$. These bounds coincide only when $p = 2$, and the question of closing the gap in the remaining cases was raised in [10] (see also [9]). Here we resolve this problem by showing that the accuracy threshold for randomized oracle-polynomial algorithms that compute $\mathrm{diam}_p(K)$ is $\Theta(\sqrt{\frac{n}{\log n}})$ for all $1 \le p \le 2$. Our improved accuracy lower bound when $p = 1$ is a slight variant of the argument in [10]. The main issue is obtaining an improved approximation algorithm—our approach is different from the polyhedral approximation of the ℓ_p^n ball that was used in [10] (though we believe that the construction of [10] is of independent interest).

We apply the results described above to obtain a significant improvement to the Max-E3-Lin-2 algorithm of Håstad and Venkatesh [22]. This fundamental problem is described as follows. Consider a system $\mathcal{E}$ of N linear equations modulo 2 in n Boolean variables $z_1, \ldots, z_n$ such that in each equation only three distinct variables appear. We assume throughout that $N \ge n$ (thus avoiding degenerate cases). Let $\mathrm{MAXSAT}(\mathcal{E})$ be the maximum number of equations in $\mathcal{E}$ that can be satisfied simultaneously. A random assignment of these variables satisfies in expectation $\frac{N}{2}$ equations, so in the Max-E3-Lin-2 problem it is natural to ask for an approximation algorithm to $\mathrm{MAXSAT}(\mathcal{E}) - \frac{N}{2}$. This problem was studied extensively by Håstad and Venkatesh in [22], where the best known upper and lower bounds were obtained. In particular, using the powerful methods of Håstad [21] they show that unless $NP \subseteq DTIME(n^{(\log n)^{O(1)}})$, for every $\epsilon > 0$ there is no algorithm that approximates $\mathrm{MAXSAT}(\mathcal{E}) - \frac{N}{2}$ within a factor of $2^{(\log n)^{1-\epsilon}}$ in time $2^{(\log n)^{O(1)}}$. Moreover, they design a randomized polynomial time algorithm which approximates $\mathrm{MAXSAT}(\mathcal{E}) - \frac{N}{2}$ to within a factor of $O(\sqrt{N})$.

Let $\mathcal{E}$ be a system of linear equations as above. Write $a_{ijk}(\mathcal{E}) = 1$ if the equation $z_i + z_j + z_k = 0$ is in the system $\mathcal{E}$. Similarly write $a_{ijk}(\mathcal{E}) = -1$ if the equation $z_i + z_j + z_k = 1$ is in $\mathcal{E}$. Finally, write $a_{ijk}(\mathcal{E}) = 0$ if no equation in $\mathcal{E}$ corresponds to $z_i + z_j + z_k$. Assume that the assignment $(z_1, \ldots, z_k)$ satisfies m of the equations in

$\mathcal{E}$. Then $\sum_{i,j,k=1}^{n} a_{ijk}(\mathcal{E})(-1)^{z_i+z_j+z_k} = m - (N-m) = 2\left(m - \frac{N}{2}\right)$. It follows that

$$\max_{x_i\in\{-1,1\}} \sum_{i,j,k=1}^{n} a_{ijk}(\mathcal{E}) x_i x_j x_k = \max_{z_i\in\{0,1\}} \sum_{i,j,k=1}^{n} a_{ijk}(\mathcal{E})(-1)^{z_i+z_j+z_k} = 2\left(\mathrm{MAXSAT}(\mathcal{E}) - \frac{N}{2}\right).$$

Thus our algorithm yields an $O(\sqrt{\frac{n}{\log n}})$ approximation to the Max-E3-Lin-2 problem. Note that when $N = \Theta(n)$ our improvement over the Håstad–Venkatesh algorithm is only logarithmic, but typically N can be as large as $\Theta(N^3)$. The above reasoning also allows us to apply the Håstad–Venkatesh hardness result for Max-E3-Lin-2 that was described above to the level-3 Fourier maximization problem. In particular it follows that this problem is computationally much harder than the quadratic case, in which an $O(\log n)$ approximation is possible. Finally, our reasoning comes full circle to shed light on the problem of approximating the ℓ_1^n diameter $\mathrm{diam}_1(K)$. While the proof in [10] is essentially an "entropy argument" showing that there are simply too many convex bodies to allow an approximation factor better than $O(\sqrt{n})$, our reduction produces a concrete family of convex bodies for which computing the ℓ_1^n diameter within a factor of $2^{(\log n)^{1-\epsilon}}$ is hard.

2. A new algorithm for Max-E3-Lin-2. As described in the reduction that was presented in the introduction, our new algorithm for Max-E3-Lin-2 will follow from the more general algorithm for approximating the maximum of functions whose Fourier transform is supported on subsets of size 3. So, from now on let $\{a_{ijk}\}_{i,j,k=1}^{n}$ be real numbers such that for all $i,j,k \in \{1,\dots,n\}$ we have $a_{ijk} = a_{ikj} = a_{kji} = a_{jik} = a_{kij} = a_{jki}$ and $a_{iik} = a_{ijj} = a_{jii} = 0$. Our first lemma reduces the problem of maximizing $\sum_{i,j,k=1}^{n} a_{ijk}x_ix_jx_k$ to the analogous tripartite case. Note that such a result *is false* in the quadratic case. Indeed, Theorem 3.5 in [2] implies that the gap between $\max_{x_i\in\{-1,1\}} \sum_{i,j=1}^{n} a_{ij}x_ix_j$ and $\max_{x_i,y_j\in\{-1,1\}} \sum_{i,j=1}^{n} a_{ij}x_iy_j$ can be as large as $\Omega(\frac{n}{\log n})$. The key "trick" which allows us to prove that this cannot happen in the level-3 case is identity (1) below.

LEMMA 2.1. *The following inequalities hold true:*

$$\frac{1}{10} \max_{x_i,y_j,z_k\in\{-1,1\}} \sum_{i,j,k=1}^{n} a_{ijk}x_iy_jz_k \le \max_{x_i\in\{-1,1\}} \sum_{i,j,k=1}^{n} a_{ijk}x_ix_jx_k \le \max_{x_i,y_j,z_k\in\{-1,1\}} \sum_{i,j,k=1}^{n} a_{ijk}x_iy_jz_k.$$

Proof. Define

$$M = \max_{x_i,y_j,z_k\in\{-1,1\}} \sum_{i,j,k=1}^{n} a_{ijk}x_iy_jz_k$$

and

$$m = \max_{x_i\in\{-1,1\}} \sum_{i,j,k=1}^{n} a_{ijk}x_ix_jx_k.$$

Clearly $m \le M$, so we need to show that $M \le 10m$. To see this observe first that $\sum_{i,j,k=1}^n a_{ijk}x_ix_jx_k$ is linear in x_i for each i. This implies that

$$m = \max_{|x_i|\le 1} \sum_{i,j,k=1}^n a_{ijk}x_ix_jx_k.$$

Moreover, since $\sum_{i,j,k=1}^n a_{ijk}x_ix_jx_k$ changes sign if we replace x_i by $-x_i$ for each i, we see that

$$m = \max_{|x_i|\le 1} \left| \sum_{i,j,k=1}^n a_{ijk}x_ix_jx_k \right|.$$

Now, for each $i,j,k \in \{1,\ldots,n\}$ we have the identity

$$\begin{aligned}(1)\quad & 2x_iy_jy_k + 2x_jy_iy_k + 2x_ky_iy_j \\ &= (x_i+y_i)(x_j+y_j)(x_k+y_k) + (x_i-y_i)(x_j-y_j)(x_k-y_k) - 2x_ix_jx_k - 2y_iy_jy_k.\end{aligned}$$

Multiplying this identity by a_{ijk}, summing over all $i,j,k \in \{1,\ldots,n\}$, and using the symmetries of the coefficients a_{ijk}, we see that

$$\begin{aligned}6\sum_{i,j,k=1}^n a_{ijk}x_iy_jy_k &= 8\sum_{i,j,k=1}^n a_{ijk}\frac{x_i+y_i}{2}\cdot\frac{x_j+y_j}{2}\cdot\frac{x_k+y_k}{2} \\ &\quad + 8\sum_{i,j,k=1}^n a_{ijk}\frac{x_i-y_i}{2}\cdot\frac{x_j-y_j}{2}\cdot\frac{x_k-y_k}{2} \\ &\quad - 2\sum_{i,j,k=1}^n a_{ijk}x_ix_jx_k - 2\sum_{i,j,k=1}^n a_{ijk}y_iy_jy_k.\end{aligned}$$

It follows that

$$M' := \max_{x_i,y_j\in\{-1,1\}} \left| \sum_{i,j,k=1}^n a_{ijk}x_iy_jy_k \right| \le \frac{20}{6}m = \frac{10}{3}m.$$

As before, because $\sum_{i,j,k=1}^n a_{ijk}x_iy_jy_k$ is linear in each of the variables x_i and y_j, we have the identity

$$M' = \max_{|x_i|,|y_j|\le 1} \left| \sum_{i,j,k=1}^n a_{ijk}x_iy_jy_k \right|.$$

Now, consider the identity

$$y_jz_k + y_kz_j = (y_j+z_j)(y_k+z_k) - y_jy_k - z_jz_k.$$

Multiplying by $a_{ijk}x_i$ and summing up, we get the identity

$$\begin{aligned}2\sum_{i,j,k=1}^n a_{ijk}x_iy_jz_k &= 4\sum_{i,j,k=1}^n a_{ijk}x_i\cdot\frac{y_j+z_j}{2}\cdot\frac{y_k+z_k}{2} - \sum_{i,j,k=1}^n a_{ijk}x_iy_jy_k \\ &\quad - \sum_{i,j,k=1}^n a_{ijk}x_iz_jz_k \le 6M' \le 20m.\end{aligned}$$

It follows that $M \leq 10m$, as required. □

Let $(\ell_2^n)_\infty^n$ denote the space of $\vec{v} = (v_1, \ldots, v_n) \in (\mathbb{R}^n)^n$, equipped with the norm

$$\|\vec{v}\|_{(\ell_2^n)_\infty^n} := \max_{1 \leq j \leq n} \|v_j\|_2.$$

Similarly we let $(\ell_2^n)_1^n$ denote the space of $\vec{v} = (v_1, \ldots, v_n) \in (\mathbb{R}^n)^n$, equipped with the norm

$$\|\vec{v}\|_{(\ell_2^n)_1^n} := \sum_{j=1}^n \|v_j\|_2.$$

Any $n \times n$ matrix $B = (b_{ij}) \in M_n(\mathbb{R})$ can be tensorized with the identity to yield an operator $B \otimes I : (\ell_2^n)_\infty^n \to (\ell_2^n)_1^n$ given by

$$((B \otimes I)\vec{v})_i := \sum_{j=1}^n b_{ij} v_j.$$

The operator norm of $B \otimes I$ is given by

$$\begin{aligned}
\|B \otimes I\|_{(\ell_2^n)_\infty^n \to (\ell_2^n)_1^n} &= \max \left\{ \sum_{i=1}^n \left\| \sum_{j=1}^n b_{ij} v_j \right\|_2 : \max_{1 \leq j \leq n} \|v_j\|_2 \leq 1 \right\} \\
&= \max \left\{ \sum_{i=1}^n \left\langle \sum_{j=1}^n b_{ij} v_j, u_i \right\rangle : \max_{1 \leq j \leq n} \|v_j\|_2 \leq 1 \ \wedge \ \max_{1 \leq i \leq n} \|u_i\|_2 \leq 1 \right\} \\
&= \max_{\|u_i\|_2, \|v_j\|_2 \leq 1} \sum_{i,j=1}^n b_{ij} \langle u_i, v_j \rangle . \qquad (2)
\end{aligned}$$

By Lemma 2.1, our goal is to approximate the value

$$\mathrm{Opt}(A) := \max_{x_i, y_j, z_k \in \{-1,1\}} \sum_{i,j,k=1}^n a_{ijk} x_i y_j z_k.$$

For every $x \in \{-1,1\}^n$, define an $n \times n$ matrix $A(x) \in M_n(\mathbb{R})$ by

$$A(x)_{jk} = \sum_{i=1}^n a_{ijk} x_i.$$

Since for each $x \in \mathbb{R}^n$ we have

$$\|A(x) \otimes I\|_{(\ell_2^n)_\infty^n \to (\ell_2^n)_1^n} \geq \max_{|y_j|, |z_k| \leq 1} \sum_{j,k=1}^n A(x)_{ij} y_j z_k,$$

it follows that $\mathrm{Opt}(A) \leq \max_{x \in \{-1,1\}^n} \|A(x) \otimes I\|_{(\ell_2^n)_\infty^n \to (\ell_2^n)_1^n}$. On the other hand, using (2), Grothendieck's inequality (see the discussion in [3]) says that

$$\begin{aligned}
\max_{x \in \{-1,1\}^n} \|A(x) \otimes I\|_{(\ell_2^n)_\infty^n \to (\ell_2^n)_1^n} &\leq \max_{x \in \{-1,1\}^n} K_G \max_{y, x \in \{-1,1\}^n} \sum_{j,k=1}^n A(x)_{jk} y_j z_k \\
&= K_G \cdot \mathrm{Opt}(A),
\end{aligned}$$

where $K_G \leq 2$ is Grothendieck's constant. It therefore suffices to approximate the value of

$$\max_{x\in\{-1,1\}^n} \|A(x)\otimes I\|_{(\ell_2^n)_\infty^n\to(\ell_2^n)_1^n}.$$

Define a norm $\|\cdot\|_A$ on $\mathbb{R}^n$ by $\|x\|_A := \|A(x)\otimes I\|_{(\ell_2^n)_\infty^n\to(\ell_2^n)_1^n}$. Then the unit ball $B_A := \{x\in\mathbb{R}^n : \|x\|_A \leq 1\}$ is a centrally symmetric convex body. Denote by $K_A = B_A^\circ$ the polar of B_A, i.e.,

$$K_A = \{y\in\mathbb{R}^n : \forall x\in B_A,\ \langle x,y\rangle \leq 1\}.$$

Then

$$\begin{aligned}\max_{x\in\{-1,1\}^n} \|A(x)\otimes I\|_{(\ell_2^n)_\infty^n\to(\ell_2^n)_1^n} &= \max_{\|x\|_\infty\leq 1}\|x\|_A = \max_{\|x\|_\infty\leq 1}\max_{y\in K_A}\langle x,y\rangle\\ &= \max_{y\in K_A}\max_{\|x\|_\infty\leq 1}\langle x,y\rangle = \max_{y\in K_A}\|y\|_1 = \frac{1}{2}\mathrm{diam}_1(K_A).\end{aligned}$$

We have thus reduced our original problem to approximating $\mathrm{diam}_1(K_A)$ in polynomial time. Note that (2) implies that the computation of $\|x\|_A$ is a semidefinite program. Therefore by the theory of Grötschel, Lovász, and Schrijver [19] it follows that linear functionals can be optimized on B_A in polynomial time. As shown in [19], this property is preserved under polarity; i.e., linear functionals can be optimized on $B_A^\circ = K_A$ in polynomial time. We have therefore reduced the problem of approximating $\max_{x_i\in\{-1,1\}}\sum_{i,j,k=1}^n a_{ijk}x_ix_jx_k$ to the problem of approximating $\mathrm{diam}_1(K)$ in oracle-polynomial time, where K is a centrally symmetric convex body with a weak optimization oracle. This problem is resolved in section 3, thus proving the following theorem, which is our main result.

THEOREM 2.2. *There is a randomized polynomial time algorithm which, given a 3-tensor $A = \{a_{ijk}\}_{i,j,k=1}^n$ such that for all $i,j,k\in\{1,\ldots,n\}$ we have $a_{ijk} = a_{ikj} = a_{kji} = a_{jik} = a_{kij} = a_{jki}$ and $a_{iik} = a_{ijj} = a_{iji} = 0$, computes a number $\mathrm{Alg}(A)$, which satisfies with probability at least $\frac{1}{2}$*

$$\max_{x\in\{-1,1\}^n}\sum_{i,j,k=1}^n a_{ijk}x_ix_jx_k \leq \mathrm{Alg}(A) \leq O\left(\sqrt{\frac{n}{\log n}}\right)\max_{x\in\{-1,1\}^n}\sum_{i,j,k=1}^n a_{ijk}x_ix_jx_k.$$

3. An approximation algorithm for the L_1 diameter. The main result of this section is the following theorem, which settles a problem posed by Brieden et al. in [10].

THEOREM 3.1. *Let $K\subseteq\mathbb{R}^n$ be a convex body with a weak optimization oracle. Then there exists a randomized algorithm which computes in oracle-polynomial time a number $\mathrm{Alg}(K)$ such that with probability at least $\frac{1}{2}$*

$$\frac{1}{2}\sqrt{\frac{\log n}{n}}\cdot\mathrm{diam}_1(K) \leq \mathrm{Alg}(K) \leq \mathrm{diam}_1(K).$$

On the other hand, no randomized oracle-polynomial time algorithm can compute $\mathrm{diam}_1(K)$ with accuracy $o(\sqrt{\frac{n}{\log n}})$.

Since we will be using Theorem 3.1 only when K is 0-symmetric, i.e., $K = -K$, we will prove it under this assumption. This is only for the sake of simplifying the

notation—identical arguments work in the general case. Our starting point is the following distributional inequality.

LEMMA 3.2. *For every $\delta \in (0, \frac{1}{2})$ there is a constant $c(\delta) > 0$ with the following property. Fix $a = (a_1, \ldots, a_n) \in \mathbb{R}^n$ and let $\epsilon_1, \ldots, \epsilon_n$ be independently and identically distributed (i.i.d.) symmetric Bernoulli random variables. Then*

$$\Pr\left(\sum_{j=1}^n a_j \epsilon_j \geq \sqrt{\frac{\delta \log n}{n}} \cdot \|a\|_1\right) \geq \frac{c(\delta)}{n^\delta}.$$

Proof. Write $X = \sum_{j=1}^n a_j \epsilon_j$. Assume first that

$$\frac{4\|a\|_2^2 \sqrt{n}}{\|a\|_1^2} > \frac{1}{12 n^\delta}. \tag{3}$$

The classical Paley–Zygmund inequality [28, 23, 4] states that for every $\theta \in (0,1)$ we have

$$\Pr\left(X^2 \geq \theta \mathbb{E}X^2\right) \geq (1-\theta)^2 \cdot \frac{\left(\mathbb{E}X^2\right)^2}{\mathbb{E}X^4} \geq \frac{(1-\theta)^2}{9}, \tag{4}$$

where we used the well-known (and easy) fact that $\mathbb{E}X^4 \leq 9\left(\mathbb{E}X^2\right)^2$.

The inclusion of events $\{X^2 \geq \theta\} \subseteq \{X \geq \sqrt{\theta}\} \cup \{-X \geq \sqrt{\theta}\}$, and the fact that X is symmetric, implies that $\Pr(X \geq \sqrt{\theta}) \geq \frac{1}{2}\Pr(X^2 \geq \theta)$. Since $\delta < \frac{1}{2}$ there is $n_0(\delta) \in \mathbb{N}$ such that for every $n \geq n_0(\delta)$ we have $\frac{48\delta \log n}{n^{\frac{1}{2}-\delta}} < \frac{1}{2}$. For such n we deduce that

$$\Pr\left(\sum_{j=1}^n a_j \epsilon_j \geq \sqrt{\frac{\delta \log n}{n}} \cdot \|a\|_1\right) \geq \frac{1}{2}\Pr\left(X^2 \geq \frac{\delta \log n}{n}\|a\|_1^2\right)$$
$$\overset{(3)}{\geq} \frac{1}{2}\Pr\left(X^2 \geq \frac{48\delta \log n}{n^{\frac{1}{2}-\delta}} \cdot \mathbb{E}X^2\right) \overset{(4)}{\geq} \frac{1}{72}.$$

Hence Lemma 3.2 holds assuming (3) and $n \geq n_0(\delta)$. By adjusting $c(\delta)$, the required result holds also when $n \leq n_0(\delta)$, so it remains to deal with the case

$$\frac{4\|a\|_2^2 \sqrt{n}}{\|a\|_1^2} \leq \frac{1}{12 n^\delta}. \tag{5}$$

Assuming (5), we define $S := \{j \in \{1, \ldots, n\} : \ |a_j| < \frac{2\|a\|_2^2}{\|a\|_1}\}$. Then

$$\|a\|_1 = \sum_{j \notin S} |a_j| + \sum_{j \in S} |a_j| \leq \frac{\|a\|_1}{2\|a\|_2^2} \sum_{j \notin S} a_j^2 + \sqrt{|S| \sum_{j \in S} a_j^2} \leq \frac{\|a\|_1}{2} + \sqrt{n \sum_{j \in S} a_j^2}.$$

Hence,

$$\sqrt{\sum_{j \in S} a_j^2} \geq \frac{\|a\|_1}{2\sqrt{n}}. \tag{6}$$

Write $Y = \sum_{j \in S} a_j \epsilon_j$ and $Z = X - Y$. For every $t \in \mathbb{R}$ we have $\{Y \geq 2t\} \subseteq \{Y + Z \geq t\} \cup \{Y - Z \geq t\}$. Since $Y + Z$ and $Y - Z$ have the same distribution as

X, it follows that $\Pr(X \geq t) \geq \frac{1}{2}\Pr(Y \geq 2t)$. Let g be a standard Gaussian random variable. By the Berry–Esseen inequality (see [20]; the constant we use below follows from [30]), we know that

$$\begin{aligned}\Pr(Y \geq 2t) &= \Pr\left(\frac{Y}{\sqrt{\mathbb{E}Y^2}} \geq \frac{2t}{\sqrt{\mathbb{E}Y^2}}\right) \geq \Pr\left(\frac{Y}{\sqrt{\mathbb{E}Y^2}} \geq \frac{t\sqrt{n}}{\|a\|_1}\right) \\ &\geq \Pr\left(g \geq \frac{t\sqrt{n}}{\|a\|_1}\right) - \max_{j\in S}\frac{|a_j|}{\sqrt{\sum_{k\in S} a_k^2}} \overset{(6)}{\geq} \frac{1}{\sqrt{2\pi}}\exp\left(-\frac{t^2 n}{\|a\|_1^2}\right) - \frac{4\|a\|_2^2\sqrt{n}}{\|a\|_1^2}.\end{aligned}$$

Plugging $t = \sqrt{\frac{\delta \log n}{n}} \cdot \|a\|_1$ into the equation, we get that

$$\Pr\left(\sum_{j=1}^n a_j\epsilon_j \geq \sqrt{\frac{\delta\log n}{n}}\cdot\|a\|_1\right) \geq \frac{1}{2}\Pr(Y \geq 2t) \geq \frac{1}{6n^\delta} - \frac{4\|a\|_2^2\sqrt{n}}{\|a\|_1^2} \overset{(5)}{\geq} \frac{1}{12n^\delta},$$

as required. □

Proof of Theorem 3.1. Let $\{\epsilon_{ij} : i \in \{1,\ldots,m\},\ j \in \{1,\ldots,n\}\}$ be i.i.d. symmetric Bernoulli random variables. Compute the number

$$\mathrm{Alg}(K) := 2\max_{1\leq i\leq m}\max_{a\in K}\sum_{j=1}^n a_j\epsilon_{ij}.$$

Then $\mathrm{Alg}(K) \leq 2\max_{a\in K}\|a\|_1 = \mathrm{diam}_1(K)$. Moreover, M can be computed using $O(m)$ oracle calls. Now, fix $a \in K$ such that $\|a\|_1 = \frac{1}{2}\mathrm{diam}_1(K)$. Using Lemma 3.2, we see that there exists a universal constant $c > 0$ for which

$$\begin{aligned}&\Pr\left(\mathrm{Alg}(K) > \frac{1}{2}\sqrt{\frac{\log n}{n}}\cdot\mathrm{diam}_1(K)\right) \\ &= 1 - \Pr\left(\bigcap_{i=1}^m\left\{\sum_{j=1}^n a_j\epsilon_{ij} < \frac{1}{2}\sqrt{\frac{\log n}{n}}\cdot\|a\|_1\right\}\right) \\ &\geq 1 - \left(1 - \frac{c}{\sqrt[4]{n}}\right)^m \\ &\geq 1 - \exp\left(-\frac{cm}{\sqrt[4]{n}}\right).\end{aligned}$$

Choosing $m = \left\lceil \frac{\sqrt[4]{n}}{c}\right\rceil$, we see that with probability at least $\frac{1}{2}$

$$\frac{1}{2}\sqrt{\frac{\log n}{n}}\cdot\mathrm{diam}_1(K) \leq \mathrm{Alg}(K) \leq \mathrm{diam}_1(K),$$

as required.

The algorithmic lower bound in Theorem 3.1 is essentially already contained in [10]—the authors simply overlooked an easy stronger upper bound on the volume of polytopes inscribed in the cube $[-1,1]^n$. In Proposition 1.10 in [10] the authors prove that for every 0-symmetric polytope $P \subseteq [-1,1]^n$ with at most $2k$ vertices, where $20\log_2\left(\frac{k}{n}+1\right) \leq n \leq k$,

$$(\mathrm{vol}(P))^{1/n} \leq O(1)\sqrt{1+\log n}\cdot\sqrt{\frac{\log\left(\frac{k}{n}+1\right)}{n}}. \tag{7}$$

The term $\sqrt{1+\log n}$ in (7) is precisely the reason that the lower bound in [10] for the accuracy of randomized algorithms which compute $\mathrm{diam}_1(K)$ was $\Omega(\frac{\sqrt{n}}{\log n})$ instead of $O(\sqrt{\frac{n}{\log n}})$. This term can be removed as follows.

Let B_2^n be the standard unit Euclidean ball of ℓ_2^n. Write $P = \mathrm{conv}\{\pm v_1, \ldots, \pm v_k\}$, where $v_i \in [-1,1]^n$. Then $\frac{v_i}{\sqrt{n}} \in B_2^n$, and by the results of [6, 11, 17] we deduce that

$$\left(\frac{\mathrm{vol}\left(\frac{1}{\sqrt{n}}P\right)}{\mathrm{vol}\,(B_2^n)}\right)^{1/n} \leq O(1)\sqrt{\frac{\log\left(\frac{k}{n}+1\right)}{n}}.$$

Since $(\mathrm{vol}\,(B_2^n))^{1/n} = \Theta(\frac{1}{\sqrt{n}})$ it follows that

$$(\mathrm{vol}(P))^{1/n} \leq O(1)\sqrt{\frac{\log\left(\frac{k}{n}+1\right)}{n}}. \qquad \square$$

3.1. The case of the L_p diameter, $1 < p < 2$. Fix $p \in (1,2)$, and define $q = \frac{p}{p-1} > 2$. Let $h_1, \ldots, h_n$ be i.i.d. random variables whose density is $\frac{q}{2\Gamma(1/q)}e^{-|t|^q}$. Let H be the random vector $(h_1, \ldots, h_n) \in \mathbb{R}^n$. Then the random variables $H/\|H\|_q$ and $\|H\|_q$ are independent [29] (see [7] for more information on this phenomenon). The following lemma is analogous to Lemma 3.2.

LEMMA 3.3. *There exist universal constants $\delta, c_1, c_2 > 0$ such that for every $a = (a_1, \ldots, a_n) \in \mathbb{R}^n$ we have*

$$\Pr\left(\left\langle \frac{H}{\|H\|_q}, a\right\rangle \geq \sqrt{\frac{\delta \log n}{n}} \cdot \|a\|_p\right) \geq \frac{c_1}{n^{c_2}}.$$

Proof. The random variable $\|H\|_q$ has density $\frac{q}{\Gamma(n/q)}u^{n-1}e^{-u^q}$ for $u > 0$ (see, for example, [26]). Hence for every $t \in (0,1)$ we have

$$\begin{aligned}\mathbb{E}e^{t\|H\|_q^q} &= \frac{q}{\Gamma(n/q)}\int_0^\infty e^{tu^q}\cdot u^{n-1}e^{-u^q}du \\ &= \frac{q}{\Gamma(n/q)}\int_0^\infty u^{n-1}e^{-[(1-t)^{1/q}u]^q}du = \frac{1}{(1-t)^{n/q}}.\end{aligned}$$

Since $q \geq 2$ it follows that

$$\begin{aligned}\Pr\left(\|H\|_q \geq n^{1/q}\right) &\leq e^{-n\left(1-\frac{1}{e}\right)}\mathbb{E}e^{\left(1-\frac{1}{e}\right)\|H\|_q^q} = e^{-n\left(1-\frac{1}{e}-\frac{1}{q}\right)} \\ &\leq e^{-n\left(\frac{1}{2}-\frac{1}{e}\right)} \leq e^{-n/8}.\end{aligned} \tag{8}$$

Using the independence of $H/\|H\|_q$ and $\|H\|_q$, we deduce that

$$\begin{aligned}
&\Pr\left(\left\langle \frac{H}{\|H\|_q}, a\right\rangle \geq \sqrt{\frac{\delta\log n}{n}}\cdot\|a\|_p\right)\\
&\geq \Pr\left(\left\langle \frac{H}{\|H\|_q}, a\right\rangle \geq \sqrt{\frac{\delta\log n}{n}}\cdot\|a\|_p\right)\Pr\left(\|H\|_q \leq n^{1/q}\right)\\
&= \Pr\left(\left\langle \frac{H}{\|H\|_q}, a\right\rangle \geq \sqrt{\frac{\delta\log n}{n}}\cdot\|a\|_p \ \wedge\ \|H\|_q \leq n^{1/q}\right)\\
&\geq \Pr\left(\langle H, a\rangle \geq n^{1/q}\sqrt{\frac{\delta\log n}{n}}\cdot\|a\|_p \ \wedge\ \|H\|_q \leq n^{1/q}\right)\\
&\geq 1-\Pr\left(\langle H, a\rangle < n^{1/q}\sqrt{\frac{\delta\log n}{n}}\cdot\|a\|_p\right)-\Pr\left(\|H\|_q > n^{1/q}\right)\\
&\overset{(8)}{\geq} \Pr\left(\langle H, a\rangle \geq n^{1/q}\sqrt{\frac{\delta\log n}{n}}\cdot\|a\|_p\right)-e^{-n/8}. \qquad (9)
\end{aligned}$$

As in the proof of Lemma 3.2 we write $X=\sum_{j=1}^n a_j h_j$. Let

$$S := \left\{ j\in\{1,\ldots,n\} :\ |a_j| \leq \frac{2^{\frac{1}{2-p}}\|a\|_2^{\frac{2}{2-p}}}{\|a\|_p^{\frac{p}{2-p}}}\right\}.$$

Then, using the definition of S and Hölder's inequality, we see that

$$\begin{aligned}
\|a\|_p^p = \sum_{j\notin S}|a_j|^p + \sum_{j\in S}|a_j|^p &\leq \frac{\|a\|_p^p}{2\|a\|_2^2}\sum_{j\notin S}a_j^2 + |S|^{\frac{2-p}{2}}\left(\sum_{j\in S}a_j^2\right)^{\frac{p}{2}}\\
&\leq \frac{\|a\|_p^p}{2} + n^{\frac{2-p}{2}}\left(\sum_{j\in S}a_j^2\right)^{\frac{p}{2}}.
\end{aligned}$$

It follows that

$$\sqrt{\sum_{j\in S}a_j^2} \geq \frac{\|a\|_p}{2^{\frac{1}{p}}n^{\frac{1}{p}-\frac{1}{2}}}. \qquad (10)$$

Set $Y:=\sum_{j\in S}a_j h_j$, and note that

$$\sqrt{\mathbb{E}Y^2} = \sqrt{\sum_{j\in S}a_j^2\mathbb{E}h_j^2} = \Omega(1)\sqrt{\sum_{j\in S}a_j^2} \overset{(10)}{\geq} c\frac{\|a\|_p}{n^{\frac{1}{p}-\frac{1}{2}}}, \qquad (11)$$

where $c>0$ is a universal constant. Using the Berry–Esseen inequality as in the proof

of Lemma 3.2, we see that

(12)
$$\Pr\left(\sum_{j=1}^{n} a_j h_j \geq n^{\frac{1}{q}}\sqrt{\frac{\delta\log n}{n}}\cdot\|a\|_p\right) \geq \frac{1}{2}\Pr\left(\frac{Y}{\sqrt{\mathbb{E}Y^2}} \geq 2cn^{1-\frac{1}{p}}\sqrt{\frac{\delta\log n}{n}}\cdot n^{\frac{1}{p}-\frac{1}{2}}\right)$$
$$\geq \frac{1}{6n^{4c^2\delta}} - \max_{j\in S}\frac{|a_j|}{\sqrt{\sum_{k\in S}a_k^2}}\cdot\mathbb{E}|h_1|^3 = \frac{1}{6n^{4c^2\delta}} - O\left(n^{\frac{1}{p}-\frac{1}{2}}\left(\frac{\|a\|_2}{\|a\|_p}\right)^{\frac{2}{2-p}}\right) \geq \frac{1}{12n^{4c^2\delta}},$$

provided that

$$n^{\frac{1}{p}-\frac{1}{2}}\left(\frac{\|a\|_2}{\|a\|_p}\right)^{\frac{2}{2-p}} \leq \frac{\tilde{c}}{n^{4c^2\delta}} \tag{13}$$

for some small enough constant $\tilde{c}$. But, assuming that (13) fails, and that δ is small enough and n is large enough, we may apply the Paley–Zygmund inequality to conclude that

$$\Pr\left(\sum_{j=1}^{n} a_j h_j \geq n^{\frac{1}{q}}\sqrt{\frac{\delta\log n}{n}}\cdot\|a\|_p\right) \geq \Pr\left(X^2 \geq \frac{\tilde{c}^{2-p}\delta\log n}{n^{2-\frac{p}{2}-\frac{1}{p}-8c^2\delta}}\cdot\mathbb{E}X^2\right)$$
$$\geq \Pr\left(X^2 \geq \frac{\delta\log n}{n^{\frac{1}{2}-8c^2\delta}}\cdot\mathbb{E}X^2\right) \geq \Omega(1), \tag{14}$$

where we used the fact that $p \in (1,2)$ and the easy bound $\sqrt[4]{\mathbb{E}X^4} = O(\sqrt{\mathbb{E}X^2})$. Combining (12) and (14) with (9) yields the required result. □

Now, arguing as in the proof of Theorem 3.1, given a 0-symmetric convex body $K \subseteq \mathbb{R}^n$ with a weak optimization oracle, we select m i.i.d. copies of H, $H_1, \ldots, H_m$, and define

$$\mathrm{Alg}(K) := 2\max_{1\leq i\leq m}\max_{a\in K}\left\langle\frac{H_i}{\|H_i\|_q}, a\right\rangle.$$

Arguing as in the proof of Theorem 3.1, with Lemma 3.2 replaced by Lemma 3.3, we see that for $m = \mathrm{poly}(n)$, with constant probability

$$\Omega(1)\sqrt{\frac{\log n}{n}}\cdot\mathrm{diam}_p(K) \leq \mathrm{Alg}(K) \leq \mathrm{diam}_p(K).$$

4. Discussion and open problems. We end this paper with some remarks and directions for future research.

• We assumed throughout that $a_{iik} = a_{ijj} = a_{iji} = 0$. This restriction, which also appeared in [2] as the condition that the Fourier support graph does not have self loops, is necessary since otherwise if $P \neq NP$, then there is no polynomial time algorithm that evaluates the maximum of $\sum_{i,j,k=1}^{n} a_{ijk}x_ix_jx_k$ over $x \in \{-1,1\}^n$ up to any factor (even one that grows with n arbitrarily fast)—see the discussion in Remark 3.2 in [2].

• It would be very interesting to investigate the maximization problem of $\sum_{i,j,k=1}^{n} a_{ijk}x_ix_jx_k$ in terms of the combinatorial structure of the Fourier support *hypergraph* given by $\{\{i,j,k\} : \ a_{ijk} \neq 0\}$. The results of [2] suggest that it might

be possible to achieve a better approximation guarantee in the presence of additional structural information of this type.

• A natural question that arises from our results is to study the maximization problem for

$$\sum_{\substack{S\subseteq\{1,\ldots,n\}\\|S|=k}} a_S \prod_{j\in S} x_j$$

when $k \geq 4$. Our methods do not immediately give good bounds in this case—it is quite easy to get an $O(n^{\frac{k}{2}-1}/(\log n)^{\frac{k}{2}-1})$ approximation algorithm for odd k by iterating our approach, and it would be desirable to get improved bounds. Such improvements, beyond their intrinsic interest, might have implications for the problem of refutation of random $k-CNF$ formulas [16, 15, 14] (see [13] for motivation of such questions). The connection between these two problems is explained in the following theorem.

THEOREM 4.1. *Suppose for every $\ell \in \{1,\ldots,k\}$ there is a deterministic polynomial time algorithm that approximates*

$$\max_{x_1,x_2,\ldots,x_n\in\{-1,1\}} \sum_{\substack{S\subseteq\{1,\ldots,n\}\\|S|=\ell}} a_S \prod_{j\in S} x_j$$

within factor $f(n)$. Then there is a polynomial time refutation procedure that refutes with high probability a random k-CNF formula with $2^{4k+1}nf(n)^2$ clauses.

Remark 1. Note that for $\ell = 1$ there is a (trivial) exact algorithm, and for $\ell = 2$ the result of [27, 25, 12] gives an $O(\log n)$-approximation. Therefore, as long as $f(n) \geq O(\log n)$, the hypothesis in Theorem 4.1 is required to hold only for $3 \leq \ell \leq k$.

The best known refutation procedure for random $3-CNF$ formulas works when they have $O(n^{3/2})$ clauses [16]. This can be viewed as evidence that obtaining an improvement over our approximation factor to $o(n^{1/4})$ is likely to be difficult.

Before proving Theorem 4.1 we shall introduce some notation. Let -1 represent logical TRUE and 1 represent logical FALSE. Let $\phi = \{C_1, C_2, \ldots, C_m\}$ be a k-CNF formula on variables $x := \{x_1, x_2, \ldots, x_n\}$. Let the set of indices of variables in the clause C_i be denoted as S_i, so that $|S_i| = k$. Define $\{\sigma_{ij} : 1 \leq i \leq m,\ j \in S_i\}$ as follows: $\sigma_{ij} = 1$ if x_j appears in clause C_i unnegated and $\sigma_{ij} = -1$ if x_j appears in clause C_i negated. Consider the expression

$$1 - \frac{1}{2^k} \prod_{j\in S_i} (1 + \sigma_{ij} x_j)\,.$$

For any $\{-1,1\}$-assignment to variables, this expression evaluates to 1 if the clause C_i is satisfied and to 0 if the clause C_i is not satisfied. Therefore, the fraction of satisfied clauses is

$$\frac{1}{m}\sum_{i=1}^{m}\left(1 - \frac{1}{2^k}\prod_{j\in S_i}(1+\sigma_{ij}x_j)\right). \tag{15}$$

For notational convenience, think of S_i as an ordered k-tuple of indices, and for $T \subseteq \{1,\ldots,k\}$, let $S_i[T]$ denote the subset of S_i given by the coordinates in T. With

this notation (15) can be rewritten as

$$1 - \frac{1}{2^k} - \frac{1}{m}\sum_{i=1}^{m} \sum_{\emptyset \neq T \subseteq \{1,\ldots,k\}} \prod_{j \in S_i[T]} \sigma_{ij} x_j = 1 - \frac{1}{2^k} + \sum_{\emptyset \neq T \subseteq \{1,\ldots,k\}} \Gamma_T(x), \tag{16}$$

where

$$\Gamma_T(x) := -\frac{1}{m}\sum_{i=1}^{m} \prod_{j \in S_i[T]} \sigma_{ij} x_j. \tag{17}$$

LEMMA 4.2. *If ϕ is satisfiable, then there exists a $\{-1,1\}$ assignment to variables of ϕ and a nonempty set $T \subseteq \{1,\ldots k\}$ such that $\Gamma_T(x) \geq \frac{1}{2^k(2^k-1)}$. In other words,*

$$\exists\, \emptyset \neq T \subseteq \{1,\ldots,k\}, \qquad \max_{x \in \{-1,1\}^n} \Gamma_T(x) \geq \frac{1}{2^k(2^k-1)}.$$

Proof. Since ϕ is satisfiable, there is an assignment x that satisfies every clause. For this assignment, the expression (16) has value 1. Thus, for some $T \subseteq [k], T \neq \emptyset$, it must be the case that $\Gamma_T(x) \geq \frac{1}{2^k(2^k-1)}$. ∎

LEMMA 4.3. *Let ϕ be a random k-CNF formula with $m \geq 2^{4k+1} n f(n)^2$ clauses. Then with probability $1 - 2^{-\Omega(n)}$ over the choice of the formula, for every $\{-1,1\}$-assignment to variables and every nonempty $T \subseteq \{1,\ldots,k\}$ we have $\Gamma_T(x) \leq \frac{1}{2^k f(n)}$. In other words,*

$$\forall \emptyset \neq T \subseteq \{1,\ldots,k\}, \qquad \max_{x \in \{-1,1\}^n} \Gamma_T(x) \leq \frac{1}{2^k f(n)}.$$

Proof. Fix any $\{-1,1\}$-assignment to the variables and a nonempty set $T \subseteq \{1,\ldots,k\}$. We will show that with probability $1 - e^{-n}$ over the choice of ϕ we have $\Gamma_T(x) \leq \frac{1}{2^k f(n)}$. Taking the union bound over all possible $\{-1,1\}$-assignments to variables and all choices for T implies the statement of the lemma.

Note that when ϕ is random, the signs σ_{ij} are random and independent, and therefore an inspection of the definition (17) shows that $\Gamma_T(x)$ is an average of m independent Bernoulli random variables. By the Chernoff bound,

$$\Pr\left[\Gamma_T(x) \geq \frac{1}{2^k f(n)}\right] \;\leq\; \exp\left(-\frac{1}{2} \cdot \frac{m}{(2^k f(n))^2}\right) \leq e^{-n}. \qquad \blacksquare$$

Proof of Theorem 4.1. The refutation procedure is very simple. Given a formula ϕ, use the $f(n)$-approximation algorithm to compute, for every nonempty $T \subseteq \{1,\ldots,k\}$, a number $\mathrm{Alg}(\Gamma_T)$ such that

$$\frac{1}{f(n)}\left(\max_{x \in \{-1,1\}^n} \Gamma_T(x)\right) \leq \mathrm{Alg}(\Gamma_T) \leq \max_{x \in \{-1,1\}^n} \Gamma_T(x).$$

If there is some $T \neq \emptyset$ for which $\mathrm{Alg}(\Gamma_T) \geq \frac{1}{2^k(2^k-1)f(n)}$, then say YES. Otherwise, say NO. Lemma 4.2 shows that this procedure always says YES if ϕ is satisfiable. Lemma 4.3 shows that the procedure says NO on a $1 - 2^{-\Omega(n)}$ fraction of random formulas. ∎

Abstract. We prove semilogarithmic inapproximability for a maximization problem called *unique coverage*: given a collection of sets, find a subcollection that maximizes the number of elements covered exactly once. Specifically, assuming that NP $\not\subseteq$ BPTIME(2^{n^ε}) for an arbitrary $\varepsilon > 0$, we prove $O(1/\log^\sigma n)$ inapproximability for some constant $\sigma = \sigma(\varepsilon)$. We also prove $O(1/\log^{1/3-\varepsilon} n)$ inapproximability for any $\varepsilon > 0$, assuming that refuting random instances of 3SAT is hard on average; and we prove $O(1/\log n)$ inapproximability under a plausible hypothesis concerning the hardness of another problem, balanced bipartite independent set. We establish an $\Omega(1/\log n)$-approximation algorithm, even for a more general (budgeted) setting, and obtain an $\Omega(1/\log B)$-approximation algorithm when every set has at most B elements. We also show that our inapproximability results extend to envy-free pricing, an important problem in computational economics. We describe how the (budgeted) unique coverage problem, motivated by real-world applications, has close connections to other theoretical problems, including max cut, maximum coverage, and radio broadcasting.

Key words. unique coverage, hardness of approximation, wireless networks

1. Introduction.

In this paper we consider the approximability of the following natural maximization analogue of the set cover problem:

> **Unique coverage problem.** Given a universe $U = \{e_1, \ldots, e_n\}$ of elements, and given a collection $\mathcal{S} = \{S_1, \ldots, S_m\}$ of subsets of U, find a subcollection $\mathcal{S}' \subseteq \mathcal{S}$ to maximize the number of elements that are *uniquely covered*, i.e., appear in exactly one set of $\mathcal{S}'$.

We also consider a generalized form of this problem that is useful for several applications (detailed in section 2):

> **Budgeted unique coverage problem.** Given a universe $U = \{e_1, \ldots, e_n\}$ of elements, a profit p_i for each element e_i, a collection $\mathcal{S} = \{S_1, \ldots, S_m\}$ of subsets of U, a cost c_i of each subset S_i, and a budget B, find a subcollection $\mathcal{S}' \subseteq \mathcal{S}$, whose total cost is at most the budget B, to maximize the total profit of elements that are *uniquely covered*, i.e., appear in exactly one set of $\mathcal{S}'$.

Motivation. Logarithmic inapproximability for minimization problems is by now commonplace, starting in 1993 with a result for the celebrated set cover problem

[42], which has since been improved to the optimal constant [18] and to assume just $P \neq NP$ [47], and has been used to prove other tight (not necessarily logarithmic) inapproximability results for a variety of minimization problems; see, e.g., [34, 25, 13]. In contrast, for maximization problems, $\log n$ inapproximability seems more difficult, and relatively few results are known. The only three such results of which we are aware are $(1+\varepsilon)/\ln n$ inapproximability for domatic number unless $NP \subseteq DTIME(n^{O(\log \log n)})$ [21]; $1/\log^{1/2-\varepsilon} n$ inapproximability for the maximum edge-disjoint paths problems unless $NP \subseteq ZPTIME(n^{\text{polylog } n})$ [5, 6, 48]; and $1/\log^{1-\varepsilon} n$ inapproximability for the maximum edge-disjoint cycles problems unless $NP \subseteq ZPTIME(n^{\text{polylog } n})$ [38]. Although these problems are interesting, they are rather specific, and we lack a central maximization problem analogous to set cover to serve as a basis for further reduction to many other maximization problems.

The unique coverage problem defined above is a natural maximization version of set cover which was brought to our attention from its applications in wireless networks. In one (simplified) application, we have a certain budget to build/place some transmitters at a subset of some specified set of possible locations. Our goal is to maximize the clients that are "covered" by (i.e., are within the range of) exactly one transmitter; these are the clients that receive signal without interference; see section 2.1 for details. Another closely related application is the radio broadcast problem, in which a message (starting from one node of the network) is to be sent to all the nodes in the network in rounds. In each round, some of the nodes that have already received the message send it to their neighbors, and a node receives a message only if it receives it from exactly one of its neighbors. The goal is to find the minimum number of rounds to broadcast the message to all the nodes; see section 2.5 for details. Therefore, every single round of a radio broadcast can be seen as a unique coverage problem. These applications and others are studied in more detail in section 2.

Known results. To the best of our knowledge, there is no explicit study in the literature of the unique coverage problem and its budgeted version. However, the closely related radio broadcast problem has been studied extensively in the past, and implicitly includes an $\Omega(1/\log n)$-approximation algorithm for the basic (unbudgeted) unique coverage problem; see section 2.5 for details.

Concurrently and independently of our work, Guruswami and Trevisan [28] study the so-called 1-in-k SAT problem, which includes the unique coverage problem (but not its budgeted version) as a special case. In particular, they show that there is an approximation algorithm that achieves an approximation ratio of $1/e$ on satisfiable instances (in which all items can be covered by mutually disjoint sets).

Our results. On the positive side, we give an $\Omega(1/\log n)$-approximation for the budgeted unique coverage problem. We also show that if each set has a bound B on the ratio between the maximum profit of a set (where the profit of a set is the sum of profits of its elements) and the minimum profit of an element, then budgeted unique coverage has an $\Omega(1/\log B)$-approximation. Section 4 proves these results.

The main focus of this paper is proving the following inapproximability results. We show that it is hard to approximate the unique coverage problem within a factor of $\Omega(1/\log^{\sigma} n)$ for some constant σ depending on ε, assuming that $NP \not\subseteq BPTIME(2^{n^{\varepsilon}})$ for some constant $\varepsilon > 0$. This inapproximability can be strengthened to $\Omega(1/\log^{1/3-\varepsilon} n)$ (for any constant $\varepsilon > 0$) under the assumption that refuting random instances of 3SAT is hard on average (hardness of R3SAT as in [19]). The inapproximability can be further strengthened to $1/(\varepsilon \log n)$ for some constant $\varepsilon > 0$ under a plausible hardness

hypothesis about a problem called balanced bipartite independent set; see Hypothesis 3.22. Section 3 proves all of these results.

Our hardness results have other implications regarding the hardness of some well-studied problems. In particular, for the problem of unlimited-supply single-minded (envy-free) pricing, a recent result [27] proves an $\Omega(1/\log n)$-approximation, but no inapproximability result better than APX-hardness is known. As we show in section 2.2, our hardness results for the unique coverage problem imply the same hardness-of-approximation bounds for this version of envy-free pricing. For the radio broadcast problem, as we discuss in section 2.5, there is essentially a gap of $\Omega(\log n)$ between the approximation and inapproximability factors ($O(\log^2 n)$ vs. $\Omega(\log n)$). We believe that our technique to prove hardness of unique coverage may shed some light on how to obtain a hardness of approximation beyond $\Omega(\log n)$ for this problem.

More generally, there are many maximization problems for which the best known approximation factor is $\Omega(1/\log n)$—see, e.g., [27, 9, 43]—and it is not known whether an $\Omega(1)$-factor approximation is possible. Often (as indeed is the case with unique coverage) these problems naturally decompose into $\Theta(\log n)$ subproblems, where at least an $\Omega(1/\log n)$ fraction of the optimum's value comes from one of these subproblems. In isolation, each subproblem can be approximated up to a constant factor, leading to an $\Omega(1/\log n)$-approximation algorithm for the whole problem. It may appear that this isolation approach is too naïve to give the best possible approximation, and that by a clever combination of the subproblems, it should be possible to get an $\Omega(1)$-approximation algorithm. Our hardness results show to the contrary that such intelligent combination can be hard, in the sense that the naïve isolation approach cannot be substantially improved, and suggest how one might obtain better hardness results for these problems.

2. Applications and related problems.

2.1. Wireless networks. Our original motivation for the budgeted unique coverage problem is a real-world application arising in wireless networks.[1] We are given a map of the densities of mobile clients throughout a service region (e.g., the plane with obstacles). We are also given a collection of candidate locations for wireless base stations, each with a specified building cost and a specified coverage region (typically a cone or a disk, possibly obstructed by obstacles). This collection may include multiple options for base stations at the same location, e.g., different powers and different orientations of antennas. The goal is to choose a set of base stations and options to build, subject to a budget on the total building cost, in order to maximize the density of served clients.

The difficult aspect of this problem (and what distinguishes it from maximum coverage—see section 2.4) is interference between base stations. In the simplest form, there is a limit k on the number of base stations that a mobile client can reasonably hear without conflict between the signals; any client within range of more than k base stations cannot communicate because of interference and thus is not serviced. More generally, a mobile client's reception is better when it is within range of fewer base stations, and our goal is to maximize total reception. To capture these desires, the instance specifies the *satisfaction* s_i of a client within range of exactly i base stations,

[1] The application arises in the context of cellular networks at Bell Labs. The problem we consider here is a somewhat simplified theoretical formulation of this application. In the real application, the interference patterns are more complicated, but this problem seems to be the cleanest theoretical formulation.

such that $s_0 = 0$ and $s_1 \geq s_2 \geq s_3 \geq \cdots \geq 0$. The goal is to choose a set of base stations and options, again subject to the budget constraint, in order to maximize the total satisfaction weighted by client densities.

When all s_i's are equal, we just have the maximum coverage problem (section 2.4). When $s_1 = 1$ and $s_i = 0$ for all $i \neq 1$, this problem can be formulated as a budgeted unique coverage problem, by standard discretization of the density map. More generally, for any assignment of s_i's, the problem can be formulated as a generalization of budgeted unique coverage, the *budgeted low-coverage problem*. In this problem, we are also given satisfaction factors s_i for an element being covered exactly i times, zero for $i = 0$ and nonincreasing for $i > 0$, and the goal is to maximize the total satisfaction, i.e., the sum over all elements of the product of the element's profit (here, density) and its satisfaction factor (the appropriate s_i). We show that our approximation algorithms for the budgeted unique coverage problem apply more generally to the budgeted low-coverage problem, yielding an $\Omega(1/\log n)$-approximation where n is the total number of options for base stations.

While similar problems about base-station placement have been considered before, very few works consider maximization forms of the problem, which is the focus of this paper. Lev-Tov and Peleg [41] consider the following very specialized form of the problem: base stations are unit disks in the plane, and the goal is to maximize the number of uniquely receiving clients. For this problem they give an $n^{O(\sqrt{n})}$-time algorithm, where n is the number of candidate disks. In the application of interest, we believe that it is more natural to allow clients to be covered more than once but reduce (or eliminate) the satisfaction of these clients; this removal of an artificial constraint may enable substantially better solutions to the problem. Other work [31, 22, 8] solves the problem of assigning powers to base stations such that, when each client prefers a unique base station, we do not violate the capacities of the base stations, provided the number of clients is at most the total capacity of the network.

2.2. Envy-free pricing. Fundamental to "fair" equilibrium pricing in economics is the notion of envy-free pricing [49, 26]. This concept has recently received attention in computer science [1, 27] in the new trend toward an algorithmic understanding of economic game theory; see, e.g., [14, 15] for related work.

The following version of envy-free pricing was considered in [27]. A single seller prices m different items, $I_1, \ldots, I_m$, each with a specified quantity (limited or unlimited *supply*). Each of n buyers b_i $(1 \leq i \leq n)$ wishes to purchase a subset of items (a *bundle*), and the seller knows the maximum price that each buyer is willing to pay for each bundle (the *valuation*). A buyer's *utility* is the difference between the valuation and the price of the bundle (sum of the prices of the items in the bundle) as sold to the buyer. The seller must choose the item prices, price p_i for item I_i, and which bundles are sold to which buyers in such a way that is *envy-free*: each buyer should be sold a bundle that has the maximum utility among all bundles. The goal is to maximize the seller's *profit*, i.e., the total price of the sold bundles.

Among other results, Guruswami et al. [27] give an $\Omega(1/(\log n + \log m))$-approximation algorithm for the unlimited-supply *single-minded* bidder problem, where each buyer b_i considers only one particular bundle B_i and buys it if the cost is less than the valuation. They also give a constant-factor hardness-of-approximation result for this problem, via a reduction from max-cut. Single-minded bidders were considered before in the context of combinatorial auctions and mechanism design [7, 45, 40]. The unlimited-supply assumption in combination with single-mindedness simplifies the problem, as the notion of *envy* does not play a role in this case. The general version

of the envy-free pricing problem is of course at least as difficult as this special case.

We now show that unlimited-supply single-minded (envy-free) pricing is as hard to approximate as the unique coverage problem. The reduction is as follows. Each set S_i in the collection (for the instance of unique coverage) maps to an item I_i (for the instance of envy-free pricing). Each element e_i of the universe U maps to a buyer b_i. Buyer b_i has a valuation of 1 for one bundle, B_i, namely, the set of items I_j that correspond to sets S_j containing the element e_i. In this context, every price assignment is envy-free, because we have unlimited supply for each item so the seller can always sell each buyer its desired bundle (if the buyer wants). Because the valuations are all 1, we can assume that all prices are between 0 and 1. By randomized rounding (see Lemma A.1), we can assume that all prices are either 0 or 1, at a loss of a constant factor in profit. In this case, each buyer b_i will buy its bundle precisely if at most one item is priced at 1, and the rest of the items are priced at 0. If all items in a bundle are priced at 0, then the seller makes no profit; if exactly one item is priced at 1 and the rest are priced at 0, then the seller profits by 1. Thus the effective goal is to assign prices of 0 or 1 in order to maximize the number of bundles for which exactly one item is priced at 1, which is identical to the original unique coverage problem.

Therefore our hardness-of-approximation results apply to unlimited-supply single-minded (envy-free) pricing and establish semilogarithmic inapproximability.

2.3. Max-cut. Recall the max-cut problem: given a graph G, find a cut $(S, \overline{S})$, where $S \subseteq V(G)$ and $\overline{S} = V(G) - S$, that maximizes the number of edges with one endpoint in S and the other endpoint in $\overline{S}$. The max-cut problem can be seen to be equivalent to a special case of the unique coverage problem in which every element is in exactly two sets. Simply view every vertex as a set and every edge as an element.

Max-cut is 0.878567-approximable [24], 0.941177-inapproximable assuming P $\neq$ NP [29], and 0.878568-inapproximable assuming the unique games conjecture [33]. From these results one can immediately obtain constant-factor hardness for unique coverage, but in this paper we show that unique coverage is in fact much harder.

2.4. Maximum coverage. Our budgeted unique coverage problem is also closely related to the *budgeted maximum coverage* variation of set cover: given a collection of subsets S of a universe U, where each element in U has a specified weight and each subset has a specified cost, and given a budget B, find a subcollection $S' \subseteq S$ of sets, whose total cost is at most B, in order to maximize the total weight of elements covered by S'. For this problem, there is a $(1 - 1/e)$-approximation [30, 34], and this is the best constant approximation ratio possible unless P = NP [18, 34].

At first glance, one might expect the greedy $(1 - 1/e)$-approximation algorithm to work for unique coverage as well: the only difference between the two problems is whether we count elements that are covered (contained in at least one set) or uniquely covered (contained in exactly one set). Of course, we show that the (in)approximability of the two problems is quite different. Indeed, a natural class of greedy algorithms can be very bad for unique coverage. Consider the collection of sets $S_i = \{i, k+1, k+2, \ldots, n\}$ for $i = 1, 2, \ldots, k$, with an infinite budget B. Consider a greedy algorithm that repeatedly chooses a set to add to the cover, according to some (arbitrary) rule, with one of two stopping conditions: either when the budget is exhausted, or when the number of uniquely covered elements goes down. Then the approximation ratio is $\Theta(1/n)$ with the first stopping condition if $k = 2$, and with the second stopping condition if $k = n - 2$.

2.5. Radio broadcast. The unique coverage problem is closely related to a single "round" of the *radio broadcast* problem [10]. This problem considers a *radio network*, i.e., a network of processors (nodes) that communicate synchronously in rounds. In each round, a node can either transmit to all of its neighbors in an undirected graph (representing the communicability between pairs of nodes) or not transmit. A node receives a message if exactly one of its neighbors transmits a message in the round; otherwise the messages are lost because of radio interference. In the radio broadcast problem, initially one node has a message, and the goal is to propagate this message to all nodes in the network.

Radio broadcast is one of the most important communication primitives in radio networks, and the problem has been studied extensively in the literature. In summary, the current best algorithms for approximating the minimum number of rounds are a (multiplicative) $O(\log^2 n)$-approximation [12, 10, 36, 35] and an additive $O(\log^2 n)$-approximation [23]. Alon et al. [3] show that, even for graphs with diameter 3, $\Omega(\log^2 n)$ rounds can be necessary. The problem has also been considered in the context of distributed algorithms [39, 37] and low-energy ad-hoc wireless networks [4]. Elkin and Kortsarz prove a lower bound of inapproximability of a (multiplicative) $\Omega(\log n)$ [16] and an additive $\Omega(\log^2 n)$ [17] assuming NP $\not\subseteq$ BPTIME($n^{O(\log\log n)}$).

The unique coverage problem (but not the budgeted version) can be considered as a single round of a greedy algorithm for the radio broadcast problem, which maximizes the number of nodes that receive the message in each step. Specifically, consider the bipartite subgraph where one side consists of all nodes that currently have the message and the other side consists of all nodes that do not yet have the message. In one round of the greedy algorithm, the goal is to find a subset of nodes in the first side to transmit in order to maximize the number of nodes in the second side that (uniquely) receive the message. This problem is equivalent to unique coverage, viewing nodes on the first side as sets and the nodes on the second side as elements of the universe.

One implication of the radio broadcasting work on unique coverage is an implicit $\Omega(1/\log n)$-approximation algorithm for the (unbudgeted) unique coverage problem. Namely, there is a randomized broadcasting algorithm that, in each round, guarantees transmission to an $\Omega(1/\log r)$ fraction of the r neighbors of nodes that currently have the message. Because r is an obvious upper bound on the number of successful transmissions of the message, this result is an $\Omega(1/\log r) = \Omega(1/\log n)$-approximation in this special case; see, e.g., [10].

To avoid the possibility of misunderstanding, let us point out that the known hardness-of-approximation results for radio broadcast [16, 17] do not give (neither explicitly nor implicitly) any useful hardness-of-approximation result for the unique coverage problem (not even a constant factor). Likewise, our hardness-of-approximation results for the unique coverage problem do not by themselves imply any new hardness-of-approximation results for radio broadcast. However, they do introduce a component that may be useful in future hardness-of-approximation results for the radio broadcast problem, as they show that the greedy broadcast policy might need to lose a semilogarithmic factor already in a single round (a fact not used in [16, 17]).

3. Inapproximability. In this section we prove that it is hard to approximate unique coverage within a factor of $\Omega(1/\log^c n)$ for some constant c, $0 < c \leq 1$. Our main result is a general reduction from a variation of the balanced bipartite independent set (BBIS) problem (defined below) to the unique coverage problem. From this reduction and the known hardness results for BBIS, we can derive an $O(1/\log^c n)$ hardness for unique coverage. Under a plausible assumption about the hardness of BBIS, this bound can be improved to $O(1/\log n)$.

We consider the natural graph-theoretic model of the unique coverage problem. Define the bipartite graph $H(V \cup W, F)$ with a vertex $v_i \in V$ for every set $S_i \in \mathcal{S}$ and a vertex $w_j \in W$ for every element $e_j \in U$, and with an edge $f = (v_i, w_j) \in F$ precisely if $e_j \in S_i$. Then the unique coverage problem asks to find a subset $V' \subseteq V$ such that the subgraph induced by $V' \cup W$ has the maximum number of degree-1 vertices in W. We call the degree-1 vertices *uniquely covered* by the vertices in V'.

DEFINITION 3.1. *Given a bipartite graph $G(A \cup B, E)$ with $|A| = |B| = n$, the BBIS problem asks to find the largest value of k such that there are sets $\tilde{A} \subseteq A$ and $\tilde{B} \subseteq B$ with $|\tilde{A}| = |\tilde{B}| = k$ where the subgraph $\tilde{G}$ of G induced by $\tilde{A} \cup \tilde{B}$ is an independent set.*

As detailed below, this problem has known hardness results (see [19, 32]). In order to prove hardness of the unique coverage problem, we define a variation of BBIS. Then we give a reduction from this variation of BBIS. Before stating the main result, we need to define what we mean by an (a, b)-BIS (bipartite independent set). Let $G(A \cup B, E)$ be a given a bipartite graph. If the subgraph $\tilde{G}$ induced by $\tilde{A} \subseteq A$ and $\tilde{B} \subseteq B$, with $|\tilde{A}| = a$ and $|\tilde{B}'| = b$, is an independent set, then we call it an (a, b)-*BIS*.

DEFINITION 3.2. *Given bipartite graph $G(A \cup B, E)$ with $|A| = |B| = n$, and given parameters γ, γ', δ, and δ' satisfying $0 < \gamma' < \gamma \leq 1$ and $0 \leq \delta < \delta' \leq 1$, the* BBIS$(\gamma, \gamma', \delta, \delta')$ *problem is to distinguish between two cases:*

1. Yes instance: *G has an $(n^{\gamma}, n/\log^{\delta} n)$-BIS.*
2. No instance: *G has no $(n^{\gamma'}, n/\log^{\delta'} n)$-BIS.*

The main theorem of this section is the following.

THEOREM 3.3. *There is a polynomial-time probabilistic reduction from BBIS to the unique coverage problem with the following properties. Given a bipartite graph $G(A \cup B, E)$ with $|A| = |B| = n$ and given constants γ, γ', δ, and δ' satisfying $0 < \gamma' < \gamma \leq 1$ and $0 \leq \delta < \delta' \leq 1$, the algorithm constructs in randomized polynomial time an instance $H(V \cup W, F)$ of unique coverage with $|W| = \Theta((\gamma - \gamma')n \log n)$ and $|V| = n$ satisfying the following two properties:*

1. *If G is a Yes instance of* BBIS$(\gamma, \gamma', \delta, \delta')$*, then H has a solution of size $\Omega((\gamma - \gamma')n \log^{1-\delta} n)$.*
2. *If G is a No instance of* BBIS$(\gamma, \gamma', \delta, \delta')$*, then H has no solution of size $O((\gamma - \gamma')n \log^{1-\delta'} n)$.*

COROLLARY 3.4. *Assuming that* BBIS$(\gamma, \gamma', \delta, \delta')$ *is hard for constants $\gamma, \gamma', \delta, \delta'$, we get a hardness of approximation within a factor of $\Omega(1/\log^{\delta'-\delta} n)$ for unique coverage.*

This theorem is proved in section 3.1. Next we show how the known hardness results for BBIS can be used to derive explicit hardness results for unique coverage. In particular, the following theorems follow from Theorem 3.3.

THEOREM 3.5. *Let $\varepsilon > 0$ be an arbitrarily small constant. Assuming that* NP $\not\subseteq$ BPTIME$(2^{n^{\varepsilon}})$*, it is hard to approximate the unique coverage problem within a factor of $\Omega(1/\log^{\sigma} n)$ for some constant $\sigma = \sigma(\varepsilon)$.*

Feige [19] makes the following hypothesis about average-case hardness of 3SAT.

> **R3SAT hardness hypothesis [19]:** Let ϕ be a 3SAT formula with n variables and $m = \Delta n$ clauses where every clause is generated independently at random by selecting three literals independently at random. For arbitrary large constant Δ, there is no polynomial-time algorithm that accepts if ϕ is satisfiable and refutes at least half of the times for those formulas that are not satisfiable.

Under this hypothesis, we can prove the same hardness result with an explicit value for σ.

THEOREM 3.6. *Assuming R3SAT hardness hypothesis, unique coverage is hard to approximate within a factor of* $\Omega(1/\log^{1/3-\sigma} n)$ *for an arbitrarily small constant* $\sigma > 0$.

Under a stronger (yet plausible) hardness assumption, explained in section 3.2, we close the gap between the approximation factor and the hardness of approximation, up to the constant multiplicative factor, by proving an $O(1/\log n)$-hardness result for unique coverage.

THEOREM 3.7. *Assuming a specific hardness of factor* $\Omega(n^{\varepsilon})$ *for BBIS for some constant* $\varepsilon > 0$ *(Hypothesis* 3.22*), it is hard to approximate the unique coverage problem within a factor of* $\Omega(1/\log n)$ *where the constant in the* Ω *term depends on* ε.

Theorems 3.5 to 3.7 are proved in section 3.2.

3.1. Reduction from BBIS to unique coverage and proof of Theorem 3.3.

Construction. Consider an instance of BBIS$(\gamma, \gamma', \delta, \delta')$: a bipartite graph $G(A \cup B, E)$ with $|A| = |B| = n$, and constants γ, γ', δ, and δ' with $0 < \gamma' < \gamma \leq 1$ and $0 \leq \delta < \delta' \leq 1$. We construct a graph $H(V \cup W, F)$ as an instance of unique coverage as follows.

First we construct a random graph $G'(A' \cup B', E')$ where A' is a copy of A and B' is a copy of B. For every $a \in A'$ and $b \in B'$ we place the edge (a, b) in E' with probability $1/n^{\gamma}$. So the expected degree of every vertex in G' is $n^{1-\gamma}$.

Now to construct H, let V be a copy of A. Then with $\gamma'' = \frac{\gamma - \gamma'}{7}$, create $p = \gamma'' \log n$ copies of B, named $W_1, \ldots, W_p$. We define a bipartite graph $H_i(V \cup W_i, F_i)$, for every $1 \leq i \leq p$, and at the end $H = \bigcup_{i=1}^{p} H_i$. Note that $|V| = n$ and $|W| = pn$. The set of edges F_i (in H_i) consists of the union of two edge sets: (i) the edges of the random graph G' induced on the vertices $V \cup W_i$ (V as A' and W_i as B'), plus (ii) the edges of another random graph G_i, where G_i is defined recursively as follows. Initially, G_1 is G induced on $V \cup W_1$. For every $i \geq 2$, G_i is obtained from G_{i-1} by deleting every edge independently with probability $\frac{1}{2}$. The edges of G' in H_i are called *type*-1 *edges* and the rest of the edges of H_i (which come from G_i) are called *type*-2 *edges* of H_i. In a solution to $V' \subseteq V$ for instance H, we say a vertex of W is uniquely covered by a type-1 (type-2) edge if that vertex is adjacent to exactly one vertex of V' and that edge is a type-1 (type-2) edge.

Proof overview. Here is the general idea of the proof. Intuitively, the balanced independent sets in G relate to the elements that will be uniquely covered by type-1 edges in H. The removal of edges (randomly) from G_i to G_{i+1} is to ensure that not too many vertices are uniquely covered by type-2 edges. More specifically, we will show that the number of vertices uniquely covered by type-2 edges (edges that were originally in G) in this instance is $O(n)$. So let us focus on the vertices uniquely covered by type-1 edges (i.e., edges from the random graph G' in each H_i).

First suppose that G is a Yes instance; i.e., it has an $(n^{\gamma}, \frac{n}{\log^{\delta} n})$-BIS, say $A^* \cup B^*$ (with $A^* \subseteq A$ and $B^* \subseteq B$). Because the expected degree of every vertex in G' is $n^{1-\gamma}$, the expected number of type-1 edges coming out of A^* (in G') is n, and because these edges are selected at random, we expect a fraction of $1/e$ of the vertices in B' (in G') and in particular a fraction of $1/e$ of the vertices in B^* to have degree 1. This implies that the type-1 edges in each H_i uniquely cover a linear number of vertices of B^* (at least in expectation); i.e., it gives a solution of size $\Omega(\frac{n}{\log^{\delta} n})$ in H_i. Because

$H = \bigcup_{i=1}^{p} H_i$ and $p = \gamma'' \log n$, we have a total of $\Omega(\gamma'' n \log^{1-\delta} n)$ vertices uniquely covered by type-1 edges.

Now suppose that G is a No instance; i.e., it has no $(n^{\gamma'}, n/\log^{\delta'} n)$-BIS. We will show that although we delete edges to construct G_i from G_{i-1}, the last (and most sparse) graph G_p will not have "too large" a bipartite independent set with high probability. This property will be used to show that, in every graph H_i, the number of vertices uniquely covered by type-1 edges in any solution of H is at most $O(n/\log^{\delta'} n)$ with high probability. Thus, the total number of vertices uniquely covered in H (by type-1 or type-2 edges) in any solution is at most $O(\gamma'' n \log^{1-\delta'} n + n)$ with high probability. Because $\delta' \leq 1$, this creates a hardness gap of $\Omega(1/\log^{\delta'-\delta} n)$.

Now we give the details of the proof of Theorem 3.3. We use the following simplified version of the Chernoff bound.

LEMMA 3.8 (Chernoff bound). *For independent* 0/1 *random variables* $X_1, \ldots, X_n$, $X = \sum_{i=1}^{n} X_i$, $\mu = E[X]$, *and any* $0 < \delta < 1$, *we have*

$$\Pr[|X - E[X]| > \delta\mu] \leq e^{-\delta^2 \mu/3}.$$

LEMMA 3.9. *For every selection of vertices* $V' \subseteq V$ *as a solution for instance* H, *the number of vertices uniquely covered by type-2 edges in any solution to* H *is* $O(n)$ *with high probability.*

Proof. Let $b \in B$ be an arbitrary vertex (in G) and assume that $w_1, \ldots, w_p$ are its corresponding vertices in $W_1, \ldots, W_p$. Consider any subset $V' \subseteq V$. Assuming that V' is a solution to unique coverage, we compute the probability that exactly i vertices out of $w_1, \ldots, w_p$ are uniquely covered by type-2 edges (of the vertices of V'). Assume that j is the first index for which w_j is uniquely covered by a type-2 edge, and $w_j, \ldots, w_{j+i-1}$ are the copies that are uniquely covered by a type-2 edge. Because every edge is deleted with probability $\frac{1}{2}$ from G_t to G_{t+1} (for $1 \leq t < p$), the probability that a single edge survives i rounds is 2^{-i}. Let X_b be the number of copies of b (from $w_1, \ldots, w_p$) that are uniquely covered by a type-2 edge (by the vertices of V') and define $X = \sum_{b \in B} X_b$. Therefore,

$$\mathrm{E}[X] = \sum_{b \in B} \mathrm{E}[X_b] = n \sum_{i=1}^{p} \frac{i}{2^i} \leq 3n.$$

Using the Chernoff bound (Lemma 3.8), we obtain

$$\Pr[X \geq 6n] \leq e^{-4n}.$$

Because there are 2^n subsets V', a union bound shows that the probability that, for at least one of those sets, the number of vertices in W that are uniquely covered by type-2 edges is $\geq 6n$ is at most $2^n \cdot e^{-4n} \leq e^{-\Omega(n)}$. This completes the proof of the lemma. ∎

Completeness. Suppose that G is a Yes instance; i.e., it has a $(n^{\gamma}, n/\log^{\delta} n)$-BIS, say, $A^* \cup B^*$ where $A^* \subseteq A$ and $B^* \subseteq B$. Assume that V' and W_i' are the subsets of vertices in H_i and A'' and B'' are the subsets of vertices in G' corresponding to A^* and B^*, respectively. Because G_i is obtained from G by deleting edges, there are no type-2 edges in $V' \cup W_i'$ in H_i (for any $1 \leq i \leq p$). Therefore, every vertex $w \in W_i'$ (for all values of $1 \leq i \leq p$) has degree 1 if and only if the corresponding vertex $w \in B''$ (in G') has degree 1. For every $w \in B''$, let X_w be a 0/1 random variable that is 1

if and only if $w \in B''$ has degree 1 (and so w is uniquely covered by a type-1 edge in H_i for all $1 \le i \le p$). With $X = \sum_{w \in B''} X_w$,

$$\begin{aligned}\mathrm{E}[X] &= \sum_{w \in B''} \Pr[X_w = 1] \\ &= |B''| \cdot \binom{|A''|}{1} \cdot \frac{1}{n^\gamma} \left(1 - \frac{1}{n^\gamma}\right)^{|A''|-1} \\ &\ge \frac{|B''|}{e} \ge \frac{n}{e \log^\delta n}.\end{aligned}$$

A simple application of the Chernoff bound shows that $\Pr[X \le \frac{n}{6 \log^\delta n}] \le e^{-\Omega(n/\log^\delta n)}$. Therefore, if we select the subset of vertices in V (in H) corresponding to A^* (in G), then, with high probability, there are at least $p \cdot \frac{n}{6 \log^\delta n} = \Omega(\gamma'' n \log^{1-\delta} n)$ vertices in W uniquely covered (by type-1 edges). Thus, we have proved the following.

COROLLARY 3.10. *If G is a Yes instance, then, with high probability, H has a unique cover of size $\Omega(\gamma'' n \log^{1-\delta} n)$.*

Soundness. Suppose that G is a No instance; i.e., it has no $(n^{\gamma'}, n/\log^{\delta'} n)$-BIS. Our goal is to show that, with high probability, every solution to unique coverage for H has size $O(\gamma'' n \log^{1-\delta'} n)$. Because by Lemma 3.9 the number of vertices uniquely covered by type-2 edges is $O(n)$, we only need to prove that, with high probability, the number of vertices uniquely covered by type-1 edges is at most $O(\gamma'' n \log^{1-\delta'} n)$.

Consider any solution to unique coverage for H. By construction of the H_i's, it is easy to see that, for every vertex $b \in B$ (in G), if the corresponding vertex in W_i is uniquely covered by a type-1 edge in H_i, then all the corresponding vertices of b in the W_j's, for $i \le j \le p$, are also uniquely covered by a type-1 edge. Therefore, if we prove that the number of vertices uniquely covered by type-1 edges in H_p is upper bounded (with high probability) by $O(n/\log^{\delta'} n)$, then because $p = \gamma'' \log n$, we obtain the claimed upper bound for the total number of vertices uniquely covered by type-1 edges.

Suppose that $V' \subseteq V$ and $W' \subseteq W_p$ are such that all the vertices in W' are uniquely covered by V', and the edges that cover them are all type-1 edges. It is easy to see that $V' \cup W'$ must be a bipartite independent set in G_p (otherwise there is some type-2 edge incident to some vertex $w \in W'$ and therefore w is not uniquely covered).

LEMMA 3.11. *If $V' \cup W'$ (with $V' \subseteq V$ and $W' \subseteq W_p$) is a bipartite independent set in G_p, then with high probability, either $|V'| < n^{(\gamma+\gamma')/2}$ or $|W'| < 2n/\log^{\delta'} n$; i.e., G_p has no $(n^{(\gamma+\gamma')/2}, 2n/\log^{\delta'} n)$-BIS.*

Proof. Suppose that $V' \subseteq V$ and $W' \subseteq W_p$ satisfy $|V'| = n^{(\gamma+\gamma')/2}$ and $|W'| = 2n/\log^{\delta'} n$. Partition V' into $q = n^{(\gamma-\gamma')/2}$ subsets $V'_1, \ldots, V'_q$, each of size $n^{\gamma'}$. Let A^*_i and B^* $(1 \le i \le q)$ be the subset of vertices of A and B (in G) corresponding to V'_i and W', respectively. Consider the subgraph of G induced by $A^*_i \cup B^*$. Because $|A^*_i| = n^{\gamma'}$, $|B^*| = 2n/\log^{\delta'} n$, and because G has no $(n^{\gamma'}, n/\log^{\delta'} n)$-BIS, it follows that at least $n/\log^{\delta'} n$ vertices in B^* must be connected to the vertices in A^*_i. Therefore, the total number of edges in the subgraph induced by $B^* \cup \bigcup_{i=1}^q A^*_i$ is at least $q \cdot n/\log^{\delta'} n = \Omega(n^{1+(\gamma-\gamma')/2}/\log^{\delta'} n)$. Because $G_1 = G$, $V' \cup W'$ forms an independent set in G_p only if all of these $\Omega(n^{1+(\gamma-\gamma')/2}/\log^{\delta'} n)$ edges are deleted while G_p is created. Because in creating G_{i+1} from G_i, edges are deleted with probability $\frac{1}{2}$, we

have

$$\Pr[V' \cup W' \text{ is an independent set in } G_p] \le (1-2^{-p})^{\Omega(n^{1+(\gamma-\gamma')/2}/\log^{\delta'} n)}. \tag{3.1}$$

The number of such subsets $V' \cup W'$ is

$$\binom{n}{n^{(\gamma+\gamma')/2}}\binom{n}{2n/\log^{\delta'} n}. \tag{3.2}$$

Thus, using (3.1) and (3.2), the expected number of bipartite independent sets $V' \cup W'$ with $|V'| = n^{(\gamma'+\gamma)/2}$ and $|W'| = 2n/\log^{\delta'} n$ in G_p is at most

$$\begin{aligned}
&(1-2^{-p})^{\Omega(n^{1+(\gamma-\gamma')/2}/\log^{\delta'} n)}\binom{n}{n^{(\gamma+\gamma')/2}}\binom{n}{2n/\log^{\delta'} n}\\
&\le (1-n^{-(\gamma-\gamma')/7})^{\Omega(n^{1+(\gamma-\gamma')/2}/\log^{\delta'} n)} \cdot \left(\frac{en}{n^{(\gamma+\gamma')/2}}\right)^{n^{(\gamma+\gamma')/2}} \cdot \left(\frac{en}{2n/\log^{\delta'} n}\right)^{2n/\log^{\delta'} n}\\
&\le e^{-\Omega(n^{1+(\gamma-\gamma')/2-(\gamma-\gamma')/7}/\log^{\delta'} n)} \cdot e^{O(n^{(\gamma+\gamma')/2}\log n)} \cdot e^{O(n\log\log n/\log^{\delta'} n)}\\
&\le e^{-\Omega(n^{1+(\gamma-\gamma')/3})} \cdot e^{O(n/\log^{\delta'/2} n)}\\
&\le e^{-\Omega(n^{1+(\gamma-\gamma')/3})}.
\end{aligned}$$

Therefore, with probability $1 - e^{-\Omega(n^{1+(\gamma-\gamma')/3})}$, for every bipartite independent set $V' \cup W'$ of G_p, either $|V'| < n^{(\gamma+\gamma')/2}$ or $|W'| < 2n/\log^{\delta'} n$; i.e., G_p has no $(n^{(\gamma+\gamma')/2}, 2n/\log^{\delta'} n)$-BIS. ∎

LEMMA 3.12. *With high probability, for every selection of vertices $V' \subseteq V$ as a solution to instance H, for every H_i ($1 \le i \le p$), the number of vertices uniquely covered by type-1 edges is at most $O(n/\log^{\delta'} n)$.*

Proof. Let $V' \subseteq V$ be any fixed solution to instance H. Clearly, for every vertex uniquely covered by a type-1 edge in W_i, its corresponding copy is also uniquely covered (by a type-1 edge) in W_j for every $i \le j \le p$. So let us focus on the number of vertices uniquely covered by type-1 edges in H_p. If $W'_p \subseteq W_p$ is the set of vertices uniquely covered by type-1 edges in H_p (by V'), then $V' \cup W'_p$ is a $(|V'|, |W'_p|)$-BIS in G_p. We are going to use Lemma 3.11 to prove that, with high probability (for all possible choices of V'), the size of W'_p is small.

First consider the case that $|V'| \ge n^{(\gamma+\gamma')/2}$ and V', W'_p form a $(|V'|, |W'_p|)$-BIS in G_p. By Lemma 3.11, the probability that $V' \ge n^{(\gamma+\gamma')/2}$ and $|W'_p| \ge 2n/\log^{\delta'} n$ is at most $e^{-\Omega(n^{1+(\gamma-\gamma')/3})}$. The number of solutions to H (i.e., subsets V') that satisfy the bound on V' is clearly at most 2^n. Thus, the probability that there is a solution V' such that $V' \ge n^{(\gamma+\gamma')/2}$ and $|W'_p| \ge 2n/\log^{\delta'} n$ and V', W'_p forms a $(|V'|, |W'_p|)$-BIS in G_p is at most

$$2^n \cdot e^{-\Omega(n^{1+(\gamma-\gamma')/3})} = e^{-\Omega(n^{1+(\gamma-\gamma')/3})}. \tag{3.3}$$

Now consider the case that $|V'| < n^{(\gamma+\gamma')/2}$ (and of course $|W'_p| \le n$). In this case, we show that, with high probability, $|W'_p| \le O(n^{1-(\gamma-\gamma')/3})$, which is clearly $O(n/\log^{\delta'} n)$. Consider an arbitrary vertex $w \in W'_p$ and let X_w be a 0/1 random variable that is 1 if and only if w is incident to exactly one type-1 edge. With

$X = \sum_{w \in W'_p} X_w$,

$$\begin{aligned}
\mathrm{E}[X] &= \sum_{w \in W'_p} \Pr[X_w = 1] \\
&= \sum_{w \in W'_p} \binom{|V'|}{1} \cdot \frac{1}{n^\gamma} \left(1 - \frac{1}{n^\gamma}\right)^{|V'|-1} \\
&< n \cdot n^{(\gamma+\gamma')/2} \cdot \frac{1}{n^\gamma} \\
&\leq n^{1-(\gamma-\gamma')/2}.
\end{aligned}$$

Using the Chernoff bound,

$$\Pr[X \geq n^{1-(\gamma-\gamma')/3}] \leq e^{-\Omega(n^{1-(\gamma-\gamma')/6})}.$$

The number of solutions V' such that $|V'| < n^{(\gamma+\gamma')/2}$ is at most $\binom{n}{n^{(\gamma+\gamma')/2}} \leq \left(\frac{en}{n^{(\gamma+\gamma')/2}}\right)^{n^{(\gamma+\gamma')/2}} \leq e^{O(n^{(\gamma+\gamma')/2} \cdot \log n)}$. Thus, the probability that there is a solution V' such that $|V'| < n^{(\gamma+\gamma')/2}$ and $|W'_p| > O(n^{1-(\gamma-\gamma')/3})$ and V', W'_p forms a $(|V'|, |W'_p|)$-BIS in G_p is at most

$$e^{O(n^{(\gamma+\gamma')/2} \cdot \log n)} \cdot e^{-\Omega(n^{1-(\gamma-\gamma')/6})} \leq e^{-\Omega(n^{1-(\gamma-\gamma')/6})}, \tag{3.4}$$

since $1 > \frac{2\gamma}{3} + \frac{\gamma'}{3}$.

Therefore, using (3.3) and (3.4), with high probability over all possible solutions V', $|W'_p| \leq O(n/\log^{\delta'} n)$ as wanted. □

COROLLARY 3.13. *If G is a No instance, then, with high probability, every solution to unique coverage for H has size at most $O(\gamma'' n \log^{1-\delta'} n)$.*

Proof. From Lemma 3.12 and because $p = \gamma'' \log n$, it follows that, with high probability, the number of vertices uniquely covered by type-1 edges is at most $O(\gamma'' n \log^{1-\delta'} n)$. Combining this bound with Lemma 3.9 shows that if G is a No instance (i.e., has no $(n^{\gamma'}, n/\log^{\delta'} n)$-BIS), then the size of any solution to unique coverage for H is at most $O(\gamma'' n \log^{1-\delta'} n)$. □

Proof of Theorem 3.3. The proof follows easily from Corollaries 3.10 and 3.13 and the assumption that $BBIS(\gamma, \gamma', \delta, \delta')$ is hard. □

3.2. Proving specific hardness results for unique coverage. In this subsection we prove Theorems 3.5, 3.6, and 3.7. In order to prove these theorems, we will prove some hardness results for BBIS$(\gamma, \gamma', \delta, \delta')$ and then combine them with Theorem 3.3.

Recently, two hardness results for BBIS were proved by Feige [19] and Khot [32] under different complexity assumptions. Feige [19] proved a constant factor hardness result for BBIS under the R3SAT hardness hypothesis (for more details see [19]).

THEOREM 3.14 (see [19]). *For every $\varepsilon > 0$ and a given bipartite graph $G(A \cup B, E)$ with $|A| = |B| = n$, deciding between the following two cases is hard, under the complexity assumption that refuting random instances of 3SAT is hard on average:*

1. *G has a BBIS of size at least $(\frac{1}{4} - \varepsilon)n$.*
2. *Every BBIS of G has size smaller than $(\frac{1}{8} + \varepsilon)n$.*

More recently, Khot [32] proved a similar result, for some (unspecified) constants α and β instead of $(\frac{1}{4}-\varepsilon)$ and $(\frac{1}{8}+\varepsilon)$, respectively, but under a more plausible assumption that NP problems do not have subexponential-time algorithms. More specifically, he proved the following PCP (probabilistically checkable proof) theorem.

THEOREM 3.15 (see [32]). *For every $\varepsilon > 0$ an integer $d = O(\frac{1}{\varepsilon}\log(\frac{1}{\varepsilon}))$ exists such that there is a PCP verifier for SAT instances of size n such that the following hold:*

1. *The proof Π for the verifier has size 2^{n^ε}.*
2. *The verifier queries a set Q of size d bits from Π.*
3. *Every query bit is uniformly distributed over Π.*
4. *Completeness: If SAT is a Yes instance, Π is a correct proof, and Π_0 is the set of 0-bits in the proof (it contains half the bits from the proof), then*

$$\Pr[Q \subseteq \Pi_0] \geq \left(1 - O\left(\frac{1}{d}\right)\right)\frac{1}{2^{d-1}},$$

   where the probability is taken over the random tests of the verifier.
5. *Soundness: If SAT is a No instance and Π_* is any set of half the bits from Π, then*

$$\Pr[Q \subseteq \Pi_*] = \frac{1}{2^d} \pm O\left(\frac{1}{2^{20d}}\right).$$

A direct application of Theorem 3.15 implies the following (see [32]).[2]

THEOREM 3.16. *Let $\varepsilon > 0$ be an arbitrary constant and $d = O(\frac{1}{\varepsilon}\log(\frac{1}{\varepsilon}))$. Consider an instance Φ of SAT with n variables. Let $\alpha = \frac{3}{4}\frac{1}{2^{d-1}}$ and $\beta = (1-\frac{1}{2^{5d}})\alpha$. We can construct a bipartite graph $G(A \cup B, E)$ as an instance of BBIS from the PCP verifier of Theorem 3.15 with $|A| = |B| = N$ where $N = 2^{n^\varepsilon}$ such that the following hold:*

1. Yes instance: *If Φ is a Yes instance, then G has a BBIS of size αN.*
2. No instance: *If Φ is a No instance, then no BBIS of G has size βN.*

COROLLARY 3.17. *Assuming that* NP $\not\subseteq$ BPTIME(2^{n^ε}), *it is hard to distinguish between the Yes and No cases in the above theorem.*

In order to get a hardness for BBIS$(\gamma, \gamma', \delta, \delta')$, we need a stronger version of Theorem 3.16. For this, we boost the gap in Theorem 3.16 using the standard technique of graph products (see, for example, [20, 11]). Note that Theorem 1.2 in [32] amplifies the gap in Theorem 3.16 using the same technique. However, we require a gap which is asymmetric with respect to the sizes of sets selected on different parts; i.e., the bipartite independent set is not necessarily balanced. In particular, the gap created on one side (say A) is polynomial, whereas the gap created on the other side (that is, B) is polylogarithmic. Our proof is very similar to that of Theorem 1.2 in [32]. We need the following definition for our proof.

DEFINITION 3.18. *For a bipartite graph $G(A \cup B, E)$ and integers $K_A, K_B \geq 2$ the bipartite graph $G^{(K_A,K_B)}$ is defined as follows:*

1. *The vertex set of G^{K_A,K_B} is $A' \cup B'$, where $A' \cap B' = \emptyset$, $A' = A^{K_A}$, and $B' = B^{K_B}$; i.e., A' and B' are the sets of all K_A-tuples from A and all K_B-tuples from B, respectively.*
2. *Two vertices $(a_1, \ldots, a_{K_A}) \in A'$ and $(b_1, \ldots, b_{K_B}) \in B'$ are adjacent in $G^{(K_A,K_B)}$ if and only if $\exists i, j$, $1 \leq i \leq K_A$, $1 \leq j \leq K_B$, $(a_i, b_j) \in E$.*

[2] Khot defines the bi-clique problem and proves this theorem for bi-clique.

Suppose that $G(A \cup B, E)$ is a bipartite graph with $|A| = |B| = N$, $0 < \alpha < 1$ is a constant, and K_A, K_B are integers such that

$$\frac{1}{\alpha^{K_A}}, \frac{1}{\alpha^{K_B}} \in O(N). \tag{3.5}$$

Let $G^*(A^* \cup B^*, E^*)$ be a random subgraph of $G^{K_A,K_B}(A' \cup B', E')$ with $|A^*| = |B^*| = M$, where $M = N^3$ and every vertex of G^{K_A,K_B} is selected uniformly at random but with different probabilities for A' and B'.

LEMMA 3.19. *If $G(A \cup B, E)$ has a BBIS of size αN, then, with high probability, G^* has a $(\frac{1}{2}\alpha^{K_A}M, \frac{1}{2}\alpha^{K_B}M)$-BIS.*

Proof. Let $A_I \subseteq A$ and $B_I \subseteq B$ be subsets that form a BBIS of size αN in G. Clearly, the subgraph of G^{K_A,K_B} induced on $A_I^{K_A} \cup B_I^{K_B}$ is an independent set. Because the vertices of G^* are selected randomly, each vertex of A^* belongs to $A_I^{K_A}$ with probability α^{K_A}. Also, each vertex of B^* belongs to $B_I^{K_B}$ with probability α^{K_B}. Therefore, $\mathrm{E}[|A^* \cap A_I^{K_A}|] = \alpha^{K_A}|A^*|$ and $\mathrm{E}[B^* \cap B_I^{K_B}] = \alpha^{K_B}|B^*|$. Using the Chernoff bound and (3.5),

$$\Pr\left[|A^* \cap A_I^{K_A}| \leq \frac{1}{2}\alpha^{K_A}|A^*|\right] \leq 2^{-\Omega(N^2)}.$$

Similarly, with high probability, $|B^* \cap B_I^{K_B}| \geq \frac{1}{2}\alpha^{K_B}|B^*|$. Therefore, with high probability, G^* has a $(\frac{1}{2}\alpha^{K_A}|A^*|, \frac{1}{2}\alpha^{K_B}|B^*|)$-BIS. ∎

LEMMA 3.20. *If $G(A \cup B, E)$ has no BBIS of size βN, then, with high probability, G^* does not have any $(2\beta^{K_A}M, 2\beta^{K_B}M)$-BIS.*

Proof. First, note that every maximal bipartite independent set of G^{K_A,K_B} is of the form $A_I^{K_A} \cup B_I^{K_B}$, where $A_I \cup B_I$ is a bipartite independent set in G. Consider a fixed maximal bipartite independent set of G^{K_A,K_B}, say $A_I^{K_A} \cup B_I^{K_B}$. Either $|A_I^{K_A}| < \beta^{K_A}N^{K_A}$ or $|B_I^{K_B}| < \beta^{K_B}N^{K_B}$. Without loss of generality, assume $|A_I^{K_A}| < \beta^{K_A}N^{K_A}$. Because the elements in A^* and B^* are selected uniformly randomly, $\mathrm{E}[|A^* \cap A_I^{K_A}|] < \beta^{K_A}|A^*|$. Using the Chernoff bound,

$$\Pr\left[|A^* \cap A_I^{K_A}| \geq 2\beta^{K_A}|A^*|\right] \leq 2^{-\Omega(N^2)}.$$

An almost identical argument applies if $|B_I^{K_B}| < \beta^{K_B}N^{K_B}$. Because there are at most $2^{O(N)}$ possible maximal bipartite independent sets in G, using union bound, the probability of having a $(2\beta^{K_A}|A^*|, 2\beta^{K_B}|B^*|)$-BIS in G^* is $o(1)$. ∎

Let Φ be an instance of SAT and let $\varepsilon > 0$ be an arbitrary small constant. Define d, α, β, and $G(A \cup B, E)$ as in Theorem 3.16, with $|A| = |B| = N$. Also let $M = N^3$, $K_A = -\frac{(1-\gamma)\log M}{\log \alpha}$, and $K_B = -\frac{\delta \log\log M}{\log \alpha}$, for some constants $0 < \gamma, \delta < 1$ such that $1/\alpha^{K_A} \in O(N)$. Construct the graph G^{K_A,K_B} and the random subgraph of it $G^*(A^* \cup B^*, E^*)$, where $|A^*| = |B^*| = M$, as explained above. By Theorem 3.16 and Lemmas 3.19 and 3.20 we have the following:

1. If Φ is a Yes instance, then, by Theorem 3.16, G has a BBIS of size αN. So, by Lemma 3.19, with high probability, G^* has a $(\frac{1}{2}\alpha^{K_A}M, \frac{1}{2}\alpha^{K_B}M)$-BIS. By definition of K_A and K_B, this is a $(\frac{M^\gamma}{2}, \frac{M}{2\log^\delta M})$-BIS in G^*.
2. If Φ is a No instance, then, by Theorem 3.16, G has no BBIS of size βN. So, by Lemma 3.20, with high probability, G^* has no $(2\beta^{K_A}M, 2\beta^{K_B}M)$-BIS. With $\ell = \log_\alpha(\beta/\alpha)$, $\gamma' = \gamma - \ell(1-\gamma)$, and $\delta' = \delta(1+\ell)$, this means that, with high probability, G^* has no $(2M^{\gamma'}, \frac{2M}{\log^{\delta'} M})$-BIS.

Therefore, we have proved the following amplified version of Theorem 3.16.

THEOREM 3.21. *Let $G(A \cup B, E)$ be a given bipartite graph with $|A| = |B| = n$, together with an arbitrary small constant $\varepsilon > 0$, and $d = O(\frac{1}{\varepsilon}\log(\frac{1}{\varepsilon}))$, $\alpha = \frac{3}{4}\frac{1}{2^{d-1}}$, $\beta = (1 - \frac{1}{2^{5d}})\alpha$. Furthermore, let $0 < \gamma' < \gamma \leq 1$ and $0 \leq \delta < \delta' \leq 1$ be such that δ is any constant and with $\ell = \log_\alpha(\beta/\alpha)$: $\gamma' = \gamma - \ell(1-\gamma)$, and $\delta' = \delta(1+\ell)$. Then it is hard to distinguish between the following two cases unless* NP $\subseteq$ BPTIME(2^{n^ε})*:*

1. *G has a $(\frac{n^\gamma}{2}, \frac{n}{2\log^\delta n})$-BIS.*
2. *G has no $(2n^{\gamma'}, \frac{2n}{\log^{\delta'} n})$-BIS.*

Proof of Theorem 3.5. Given a bipartite graph $G(A \cup B, E)$ with $|A| = |B| = n$ as an instance of bipartite independent set and parameters ε, α, β, δ, γ, δ', and γ' as in Theorem 3.21 we construct $H(V \cup W, F)$ as explained in the proof of Theorem 3.3. We choose $\delta = \frac{1}{1+\ell}$, where $\ell = \log_\alpha(\beta/\alpha)$. Therefore $\delta' = 1$ and by Corollaries 3.10 and 3.13 unless NP $\subseteq$ BPTIME(2^{n^ε}) it is hard to approximate unique coverage within a factor of $\Omega(1/\log^{\delta'-\delta} n)$. Because $\delta' - \delta = \frac{\ell}{1+\ell}$ and ℓ is a function of ε, this completes the proof of the theorem. ∎

Proof of Theorem 3.6. If our starting point to prove Theorem 3.21 is Theorem 3.14 instead of Theorem 3.16, then we have $\alpha = \frac{1}{4} - \varepsilon$ and $\beta = \frac{1}{8} + \varepsilon$, and $\ell = \frac{1}{2} + \varepsilon'$, where $\varepsilon' = \varepsilon'(\varepsilon)$ is a constant. Then the same argument as in the proof of Theorem 3.5 proves a hardness of $O(1/\log^{\frac{1/2+\varepsilon'}{1+1/2+\varepsilon'}} n)$ which is $O(1/\log^{\frac{1}{3}-\sigma} n)$ for some $\sigma = \sigma(\varepsilon)$. ∎

We now turn to the proof of Theorem 3.7. It is based on the following hypothesis.

HYPOTHESIS 3.22. *Given a bipartite graph $G(A \cup B, E)$ with size $|A| = |B| = n$ as an instance of BBIS and for absolute constants $1 \geq \gamma > \gamma' > 0$ it is hard to distinguish the following two cases:*

1. *G has an $(n^\gamma, \Omega(n))$-BIS.*
2. *G has no $(n^{\gamma'}, n/\log n)$-BIS.*

Now we show how Hypothesis 3.22 would imply an $O(1/\log n)$-hardness for unique coverage.

Proof of Theorem 3.7. Given a bipartite graph $G(A \cup B, E)$ with size $|A| = |B| = n$ and $1 \geq \gamma > \gamma' > 0$ we construct $H(V \cup W, F)$, the instance of unique coverage, as in the reduction of Theorem 3.3.

1. If G has an $(n^\gamma, \Omega(n))$-BIS, then H has a unique coverage of size $\Omega((\gamma - \gamma')n\log^{1-\delta} n)$ with $\delta = 0$, which is $\Omega(n \log n)$.
2. If G has no $(n^{\gamma'}, n/\log n)$-BIS, then every unique coverage solution for H has size at most $O((\gamma - \gamma')n\log^{1-\delta'} n)$ with $\delta' = 1$, which is $O(n)$.

This implies that, assuming Hypothesis 3.22, it is hard to distinguish between the two cases above, and hence hard to approximate unique coverage within a factor of $\Omega(1/\log n)$. ∎

The authors suspect that Hypothesis 3.22 will be difficult to refute in the near future. The BBIS problem appears to be at least as hard to approximate as maximum independent set in general graphs. (This is not a theorem, but merely an empirical observation concerning currently known approximation algorithms.) For the latter problem, despite extensive work, no known polynomial-time algorithm can distinguish between graphs with independent sets of size $\Omega(n/k)$ and graphs with no independent set of size $n^{1/k}$, where k is some sufficiently large constant. It is plausible (though not certain) that any refutation of Hypothesis 3.22 would lead to major improvements in the approximation ratio for maximum independent sets in general graphs.

4. Approximation algorithms.

4.1. $\Omega(1/\log m)$-approximation. In this section we develop our main logarithmic approximation algorithm.

THEOREM 4.1. *There is an $\Omega(1/\log\rho) = \Omega(1/\log m)$-approximation algorithm for the budgeted unique coverage problem, where ρ is one more than the ratio of the maximum number of sets in which an element appears over the minimum number of sets in which an element appears.*

Proof. First we find an $(1-1/e)$-approximate solution $\mathcal{S}'$ to the maximum coverage problem with the same universe, profits, sets, costs, and budget [34]. Because the total profit of uniquely covered elements is always at most the total profit of all covered elements, the optimum solution value OPT to the unique coverage problem must be at most the optimum solution value to the maximum coverage problem. Thus the total profit of covered elements in $\mathcal{S}'$ is within an $1-1/e$ factor of an upper bound on OPT. Symbolically, if $p(S)$ denotes the total profit of elements in set S and $\bigcup\mathcal{S}'$ denotes the union $\bigcup_{S\in\mathcal{S}'} S$, then $p(\bigcup\mathcal{S}') \geq (1-1/e)\,\mathrm{OPT}$.

We cluster the elements in $\bigcup\mathcal{S}'$ into $\lg\rho$ groups as follows: an element is in *group* i if it is covered by between 2^i and $2^{i+1}-1$ sets. The group i^* with the most total profit must have at least a $1/\lg\rho$ fraction of $p(\bigcup\mathcal{S}') \geq (1-1/e)\,\mathrm{OPT}$. Now we randomly discard sets from $\mathcal{S}'$, keeping a set with probability $1/2^{i^*}$. We claim that, in expectation, the resulting collection $\mathcal{S}''$ uniquely covers a constant fraction of the elements in group i^*, which is $\Omega(\mathrm{OPT}/\log\rho)$.

Fix an element x in group i^*, and suppose that it was covered d times in $\mathcal{S}'$, $2^{i^*} \leq d \leq 2^{i^*+1}-1$. The probability that x is covered exactly once by $\mathcal{S}''$ is $(d/2^{i^*})(1-1/2^{i^*})^{d-1}$. (There is a factor of d for the choice of which set covers x, a $1/2^{i^*}$ probability that this set is kept, and a $1-1/2^{i^*}$ probability that each of the $d-1$ other sets is discarded.) By our bounds on d, the probability that x is covered exactly once by $\mathcal{S}''$ is at least $(1-1/2^{i^*})^{2^{i^*+1}} \geq 1/e^2$.

The expected total profit of elements covered exactly once by $\mathcal{S}''$ is at least $\sum\{p_x/e^2 \mid x \text{ in group } i^*\}$, which is $1/e^2$ times the total profit of elements in group i^*, which we argued is at least $(1-1/e)\,\mathrm{OPT}/\lg\rho$. Therefore the expected profit of our randomized solution is at least $(1/e^2 - 1/e^3)\,\mathrm{OPT}/\lg\rho = \Omega(\mathrm{OPT}/\log\rho)$.

We can derandomize this algorithm by the standard method of conditional expectation [44]. For each set in $\mathcal{S}'$, we decide whether to keep it in $\mathcal{S}''$ by trying both options, and choosing the option that maximizes the conditional expectation of the total profit of elements in group i^* uniquely covered by $\mathcal{S}''$. The conditional expectations can be computed easily in polynomial time according to the analysis above. ∎

The approximate solution computed by this algorithm is not only within an $\Omega(1/\log m)$ factor of the optimal unique coverage, but also within an $\Omega(1/\log m)$ of the optimal maximum coverage. As a consequence, we also obtain an $\Omega(1/\log m)$-approximation for the more general problem of budgeted low-coverage described in section 2.1.

4.2. Approximation with bounded set size. In this section we consider the unique coverage problem with a bound B on the maximum set size, or more generally, the budgeted unique coverage problem with a bound B on the ratio between the maximum profit of a set and the minimum profit of an element (recall that the profit of a set is the sum of profits of its elements). In both cases we obtain an approximation ratio of $\Omega(1/\log B)$. In particular, $B \leq n$, so this algorithm is an $\Omega(1/\log n)$-approximation.

THEOREM 4.2. *There is an $\Omega(1/\log B)$-approximation algorithm for instances of the budgeted unique coverage problem in which the minimum element profit is* 1 *and the total profit of every set is at most B.*

Proof. As before, we first find an $(1-1/e)$-approximate solution $\mathcal{S}'$ to the maximum coverage problem with the same universe, profits, sets, costs, and budget [34]. As argued in the proof of Theorem 4.1, $p(\bigcup \mathcal{S}') \geq (1-1/e)\,\mathrm{OPT}$, where $p(S)$ denotes the total profit of elements in set S, $\bigcup \mathcal{S}'$ denotes the union $\bigcup_{S\in\mathcal{S}'} S$, and OPT denotes the optimum solution value to the unique coverage problem.

We modify $\mathcal{S}'$ to be minimal by removing any sets that do not uniquely cover any elements. Thus the set of covered elements remains the same, so the same upper bound on OPT holds. Let X be the set of elements covered by exactly one set of $\mathcal{S}'$. Because $\mathcal{S}'$ is minimal, each set must uniquely cover at least one element in X, so $|X| \geq |\mathcal{S}'|$. Because every element has profit at least 1, $p(X) \geq |X| \geq |\mathcal{S}'|$.

If $p(\bigcup \mathcal{S}') \leq 2|\mathcal{S}'| \leq 2p(X)$, then $\mathcal{S}'$ is already an $\Omega(1)$-approximate solution to the budgeted unique coverage problem. If $p(\bigcup \mathcal{S}') > 2|\mathcal{S}'|$, then we claim that the total profit of elements covered at most B times by $\mathcal{S}'$ is at least $p(\bigcup \mathcal{S}')/2$. Otherwise, the elements covered more than B times by $\mathcal{S}'$ would be at least $p(\bigcup \mathcal{S}')/2$, and thus the total profit of the sets would satisfy $\sum_{S\in\mathcal{S}'} p(S) > Bp(\bigcup \mathcal{S}')/2 > B|\mathcal{S}'|$, contradicting that every set in $\mathcal{S}$ (and thus $\mathcal{S}'$) has total profit at most B. Now we apply Theorem 4.1 above to the elements covered at most B times by $\mathcal{S}'$, for which $\rho \leq B$. Thus we obtain an $\Omega(1/\log B)$-approximation for this subproblem, whose optimal solution value is at least $(1-1/e)\,\mathrm{OPT}/2$. ∎

We note that, when every set has cardinality at most $B = 3$ and every element appears in exactly two sets ($\rho = 1$), the unique coverage problem is APX-hard even in this restricted case [46, 2].

Appendix. Randomized rounding for envy-free pricing. In this section we prove the necessary lemma about randomized rounding needed in section 2.2 for the reduction from unique coverage to unlimited-supply single-minded envy-free pricing.

LEMMA A.1. *In the setting of single-minded envy-free pricing, suppose all valuations are* 1. *Then there is a price assignment that uses prices of just* 0 *and* 1 *and whose profit is within a constant factor of optimal.*

Proof. Consider the optimal assignment of prices p_i to items I_i. If any price p_i is larger than 1, we set it to 1 at no cost. Now we round by setting the new price p_i' of item I_i to 1 with probability $\frac{1}{2}p_i$ and to 0 otherwise. We claim that if $u_i = \sum_{I_j\in B_i} p_j < 1$ (i.e., the optimal solution profits u_i from buyer b_i), then the probability that the seller profits 1 from buyer b_i is at least $\frac{1}{2e}u_i$.

The probability that the seller profits 1 from buyer b_i, who desires bundle B_i, is $\sum_{I_j\in B_i} \frac{1}{2}p_j \prod_{I_j\neq I_k\in B_i}(1-\frac{1}{2}p_k)$. This quantity can be rewritten as $\prod_{I_k\in B_i}(1-\frac{1}{2}p_k)\sum_{I_j\in B_i}\frac{1}{2}p_j/(1-\frac{1}{2}p_j)$. Because $\sum_{I_j\in B_i} p_j \leq \frac{1}{2}$, it is easy to show that the quantity is minimized when all of the p_j's, $I_j \in B_i$, are equal. Thus the probability of profit from b_i is at least $(1-\frac{1}{2}u_i/|B_i|)^{|B_i|}\frac{1}{2}u_i/(1-\frac{1}{2}u_i|B_i|)$. Because $1-x \geq e^{-2x}$ for $0 \leq x \leq \frac{1}{2}$, this probability is at least $e^{-u_i}\frac{1}{2}u_i \geq e^{-1}\frac{1}{2}u_i$, as claimed.

Thus the expected total profit in the modified solution is at least $\sum_i \frac{1}{2e}u_i/e$, which is $\frac{1}{2e}$ times the profit of the optimal solution. We can derandomize this algorithm by the standard method of conditional expectation [44]; see the proof of Theorem 4.1. ∎

Acknowledgments. We thank David Abusch-Magder, who mentioned to us a real-world application in wireless networks at Bell Labs, of which unique coverage is

a natural simplification. We also thank David Karger for initial discussions about the problem. The third author also thanks Nikhil Bansal, Venkatesan Guruswami, Jason Hartline, Kamal Jain, and Kunal Talwar for fruitful discussions. Finally, we thank the anonymous referees for their helpful comments.

APPROXIMATION ALGORITHM AND PERFECT SAMPLER FOR CLOSED JACKSON NETWORKS WITH SINGLE SERVERS*

S. KIJIMA† AND T. MATSUI‡

Abstract. In this paper, we propose the first fully polynomial-time randomized approximation scheme (FPRAS) for closed Jackson networks with single servers. Our algorithm is based on the Markov chain Monte Carlo (MCMC) method, and our scheme returns an approximate solution, for which the size of error satisfies a given error rate. We propose two Markov chains: one is for approximate sampling, and the other is for perfect sampling based on the monotone coupling from the past algorithm.

1. Introduction. In this paper, we propose the first fully polynomial-time randomized approximation scheme for basic queueing networks, called closed Jackson networks with single servers. Our scheme is based on the Markov chain Monte Carlo (MCMC) method and returns an approximate value of the normalizing constant of the steady-state distribution of the numbers of customers at nodes. The complexity of our algorithm is bounded by a polynomial of n and the logarithm of K where n is the number of nodes and K is the number of customers in a network. Thus our scheme is a polynomial-time approximation scheme. We propose two Markov chains, both of which are rapidly mixing. One is for approximate sampling, while the other is for perfect sampling based on the coupling from the past (CFTP) algorithm.

The Jackson network, proposed by Jackson in 1957 [13], is one of the basic models in queueing network theory and is of considerable importance. The Jackson network consists of a set of nodes, each of which has one or more servers. In the network, customers receive a service from a server at a node according to an exponentially distributed service time, move stochastically to a next node after the service, and wait their turn in a line on a first-come-first-served (FCFS) basis. It is well known that the steady-state distribution of customers in a Jackson network is a product form [13, 11, 10].

We say a network is closed if no customers leave or enter the network. By computing the normalizing constant of the product form solution of a given closed queueing network, we can evaluate useful parameters such as network throughput and rates of utilization of stations [10]. Buzen's algorithm [5], which computes the normalizing constant of closed queueing networks, is well known. However, Buzen's algorithm runs in pseudopolynomial time that depends on K, the number of customers in a closed network, and not on the logarithm of K. To deal with networks where the

number of customers as well as the server capacities are very large, we need a weakly polynomial-time (approximation) algorithm.

The MCMC method is practical for computing the normalizing constant of a distribution. Chen and O'Cinneide [6] proposed a randomized algorithm based on MCMC, but their algorithm runs in weakly polynomial time only in some very special cases. Ozawa [23] proposed a perfect sampler for closed Jackson networks with single servers, and his chain mixes in pseudopolynomial time.

When we construct a randomized approximation algorithm based on MCMC, we need to consider the accuracy of the obtained value. For any given ε and δ with $0 < \varepsilon, \delta < 1$, a fully polynomial-time randomized approximation scheme (FPRAS) provides an algorithm which finds an approximate solution Z satisfying

$$\Pr[|Z - A| \leq \varepsilon A] \geq 1 - \delta$$

where A is the exact solution, and whose running time is bounded by a polynomial of the input size of the instance (the number of nodes n and *logarithm* of the number of customers K), ε^{-1}, and $\ln(\delta^{-1})$ [15].

In many practical situations, each node of a network has a single server. In this paper, we are concerned with a closed Jackson network with single servers. We propose an FPRAS based on MCMC for calculating the normalizing constant. We make use of a Markov chain which has the product form solution of a given closed Jackson network as a unique stationary distribution and show that the chain mixes in $\mathrm{O}(n^2 \ln K)$, where n is the number of nodes and K is the number of customers in the closed Jackson network. Here we note that the chain is not a simulation of customers' movements in a queueing network, but just has a unique stationary distribution which is the same as the product form solution for the given network.

We also propose a second Markov chain and show that this chain is *monotone* and rapidly $\mathrm{O}(n^3 \ln K)$ mixing. An ordinary sampling via Markov chain is an approximate sampler, whereas Propp and Wilson [24] devised the monotone CFTP algorithm which realizes a perfect (exact) sampling from stationary distribution in probabilistically finite time by ingeniously simulating the chain (see also [12, 18, 21]). Our chain provides an efficient perfect sampler based on monotone CFTP. One of the great advantages of utilizing perfect sampling is that we need not be concerned with the error rate ε. Another is that a perfect sampler becomes faster than any approximate sampler based on a Markov chain when we need a sample which accurately follows a particular distribution.

2. Closed Jackson networks. We denote the set of real numbers (nonnegative, positive real numbers) by $\mathbb{R}$ ($\mathbb{R}_+$, $\mathbb{R}_{++}$), and the set of integers (nonnegative, positive integers) by $\mathbb{Z}$ ($\mathbb{Z}_+$, $\mathbb{Z}_{++}$), respectively. A closed Jackson network with single servers is a queueing network model satisfying the following:

(i) The network has $n \in \mathbb{Z}_{++}$ nodes. Each node contains exactly one server; thus at most one customer can receive a service on a node at a time.

(ii) In each node, customers are served one by one on an FCFS basis. The servicing time on node $i \in \{1, \ldots, n\}$ is exponentially distributed with mean $1/\mu_i \in \mathbb{R}_{++}$.

(iii) Once served in node $i \in \{1, \ldots, n\}$, a customer goes to node $j \in \{1, \ldots, n\}$ with probability $W_{ij} \in \mathbb{R}_+$. We assume that the matrix $W = (W_{ij})$ of transition probabilities of customers is irreducible and aperiodic, and thus ergodic.

(iv) No customers leave or enter the network. Thus, there are always $K \in \mathbb{Z}_{++}$ customers in the network.

In queueing network theory, it is well known that a closed Jackson network has a *product form solution* as a steady-state distribution of customers in a network. Let us consider the set of nonnegative integer points

$$\Xi(K) \stackrel{\text{def.}}{=} \left\{ \boldsymbol{x} = (x_1, x_2, \ldots, x_n) \in \mathbb{Z}_+^n \;\middle|\; \sum_{i=1}^n x_i = K \right\}$$

contained in an $n-1$-dimensional simplex. Clearly, a state of customers in the network with K customers is represented by $\boldsymbol{x} = (x_1, x_2, \ldots, x_n) \in \Xi(K)$. We abbreviate $\Xi(K)$ to Ξ when doing so causes no confusion. Since matrix W of the transition probabilities of customers is ergodic, 1 is an eigenvalue and its corresponding eigenvector is unique, excluding a constant factor. Let $\theta \in \mathbb{R}_{++}^n$ be an eigenvector for W corresponding to the eigenvalue 1, i.e., $\theta W = \theta$. The steady-state distribution $J : \Xi \to \mathbb{R}_{++}$ for the closed Jackson network is a product form defined by

$$J(\boldsymbol{x}) = \frac{1}{G(K)} \prod_{i=1}^n \alpha_i^{x_i} \left(\equiv \frac{1}{G(K)} \prod_{i=1}^n \left(\frac{\theta_i}{\mu_i} \right)^{x_i} \right), \tag{2.1}$$

where $\alpha_i \stackrel{\text{def.}}{=} \theta_i/\mu_i$ and $G(K) \stackrel{\text{def.}}{=} \sum_{\boldsymbol{x} \in \Xi(K)} \prod_{i=1}^n \alpha_i^{x_i}$ is the normalizing constant [13].

3. Randomized approximation scheme. In the following we consider a closed Jackson network with n nodes, K customers, and parameters $\alpha_1, \alpha_2, \ldots, \alpha_n \in \mathbb{Z}_{++}$ which has the product form solution (2.1) for any $\boldsymbol{x} \in \Xi(K)$.

3.1. Rapidly mixing Markov chain. Now we propose a new Markov chain $\mathcal{M}_{\mathrm{A}}(K)$ with state space $\Xi(K)$. A transition of $\mathcal{M}_{\mathrm{A}}(K)$ from a current state $X \in \Xi(K)$ to a next state X' is defined as follows. First, we choose a pair of distinct indices (nodes) $\{j_1, j_2\} \subseteq \{1, \ldots, n\}$ uniformly at random. Next, put $k = X_{j_1} + X_{j_2}$, and choose $l \in \{0, 1, \ldots, k\}$ with probability

$$\frac{\alpha_{j_1}^l \alpha_{j_2}^{k-l}}{\sum_{s=0}^k \alpha_{j_1}^s \alpha_{j_2}^{k-s}} \quad \left(= \frac{\alpha_{j_1}^l \alpha_{j_2}^{k-l} \prod_{j \notin \{j_1, j_2\}} \alpha_j^{X_j}}{\sum_{s=0}^k \alpha_{j_1}^s \alpha_{j_2}^{k-s} \prod_{j \notin \{j_1, j_2\}} \alpha_j^{X_j}} \right) \tag{3.1}$$

and set

$$X_i' = \begin{cases} l & (\text{for } i = j_1), \\ k - l & (\text{for } i = j_2), \\ X_i & (\text{otherwise}). \end{cases}$$

The Markov chain $\mathcal{M}_{\mathrm{A}}(K)$ is irreducible and aperiodic, so ergodic, and hence has a unique stationary distribution. Also, $\mathcal{M}_{\mathrm{A}}(K)$ satisfies the detailed balance equation, and thus the stationary distribution is the product form solution $J(\boldsymbol{x})$.

Given a pair of probability distributions ν_1 and ν_2 on a finite state space Ω, the *total variation distance* between ν_1 and ν_2 is defined by $\mathrm{d}_{\mathrm{TV}}(\nu_1, \nu_2) \stackrel{\text{def.}}{=} \frac{1}{2} \sum_{x \in \Omega} |\nu_1(x) - \nu_2(x)|$. The *mixing time* of an ergodic Markov chain is defined by

$$\tau(\varepsilon) \stackrel{\text{def.}}{=} \max_{x \in \Xi} \{ \min\{ t \mid \forall s \geq t,\ \mathrm{d}_{\mathrm{TV}}(\pi, P_x^s) \leq \varepsilon \} \} \qquad (0 < \forall \varepsilon < 1),$$

where π is the stationary distribution and P_x^s is the probability distribution of the chain at time period $s \geq 0$ with initial state x at time period 0. In the following, we discuss the mixing time of $\mathcal{M}_{\mathrm{A}}(K)$.

0	$\alpha_i^0\alpha_j^k/A$	$\alpha_i^1\alpha_j^{k-1}/A$	$\cdots$	$\alpha_i^k\alpha_j^0/A$	1
0	$\alpha_i^0\alpha_j^{k+1}/A'$	$\alpha_i^1\alpha_j^k/A'$	$\alpha_i^2\alpha_j^{k-1}/A'$	$\cdots$ $\alpha_i^{k+1}\alpha_j^0/A'$	1

FIG. 3.1. *Alternating inequalities for a pair of indices (i,j) and a nonnegative integer k. In the figure, $A \stackrel{\text{def.}}{=} \sum_{s=0}^{k} \alpha_i^s \alpha_j^{k-s}$ and $A' \stackrel{\text{def.}}{=} \sum_{s=0}^{k+1} \alpha_i^s \alpha_j^{k+1-s}$ are normalizing constants.*

Here, we consider the cumulative distribution function $g_{ij}^k : \{0,1,\dots,k\} \to \mathbb{R}_+$ of the transition probability (3.1) after a pair of indices is chosen, defined by

$$g_{ij}^k(l) \stackrel{\text{def.}}{=} \frac{\sum_{s=0}^{l} \alpha_i^s \alpha_j^{k-s}}{A_{ij}^k} = \begin{cases} \frac{\alpha_i^{l+1} - \alpha_j^{l+1}}{\alpha_i^{k+1} - \alpha_j^{k+1}} \cdot \alpha_j^{k-l} & (\alpha_i \neq \alpha_j), \\ \frac{l}{k+1} & (\alpha_i = \alpha_j) \end{cases}$$

for $l \in \{0,1,\dots,k\}$, where $A_{ij}^k \stackrel{\text{def.}}{=} \sum_{s=0}^{k} \alpha_i^s \alpha_j^{k-s}$ is a normalizing constant. We also define $g_{ij}^k(-1) \stackrel{\text{def.}}{=} 0$ for convenience. We can simulate the Markov chain $\mathcal{M}_{\mathrm{A}}(K)$ efficiently by using the function g_{ij}^k as follows. First, choose a pair $\{i,j\}$ of indices with the probability $2/(n(n-1))$. Next, put $k = X_i + X_j$, generate a uniformly random real number $\Lambda \in [0,1)$, choose a unique integer l satisfying $g_{ij}^k(l-1) \leq \Lambda < g_{ij}^k(l)$, and set $X_i' = l$ and $X_j' = k - l$, keeping the value of the other indices. We can execute a transition of $\mathcal{M}_{\mathrm{A}}$ efficiently by employing an ordinary binary search technique.

The following lemma gives a property of functions g_{ij}^k, which plays a key role in this paper.

LEMMA 3.1. *The function g_{ij}^k satisfies the following* "alternating inequalities"*:*

$$g_{ij}^{k+1}(l) \leq g_{ij}^k(l) \leq g_{ij}^{k+1}(l+1) \quad \forall k \in \{1,\dots,K\},\ \forall l \in \{1,\dots,k\}. \tag{3.2}$$

Figure 3.1 is an illustration of inequalities (3.2) for a fixed k.

Proof. First, we prove the former inequality $g_{ij}^{k+1}(l) \leq g_{ij}^k(l)$ as follows:

$$\begin{aligned} \frac{g_{ij}^k(l)}{g_{ij}^{k+1}(l)} &= \frac{\sum_{s=0}^{l} \alpha_i^s \alpha_j^{k-s}}{A_{ij}^k} \cdot \frac{A_{ij}^{k+1}}{\sum_{s=0}^{l} \alpha_i^s \alpha_j^{k+1-s}} \\ &= \frac{A_{ij}^{k+1}}{\alpha_j A_{ij}^k} = \frac{\sum_{s=0}^{k+1} \alpha_i^s \alpha_j^{k+1-s}}{\alpha_j \sum_{s=0}^{k} \alpha_i^s \alpha_j^{k-s}} = \frac{\sum_{s=0}^{k+1} \alpha_i^s \alpha_j^{k+1-s}}{\sum_{s=0}^{k} \alpha_i^s \alpha_j^{k+1-s}} \geq 1. \end{aligned}$$

Next, we prove the latter inequality $g_{ij}^k(l) \leq g_{ij}^{k+1}(l+1)$ as follows (see, the appendix for details):

$$\begin{aligned} \frac{g_{ij}^{k+1}(l+1)}{g_{ij}^k(l)} &= \frac{\left(\sum_{s=0}^{k} \alpha_i^s \alpha_j^{k-s}\right)\left(\sum_{s=0}^{l} \alpha_i^s \alpha_j^{k+1-s} + \alpha_i^{l+1}\alpha_j^{k-l}\right)}{\left(\sum_{s=0}^{k} \alpha_i^s \alpha_j^{k+1-s} + \alpha_i^{k+1}\right)\left(\sum_{s=0}^{l} \alpha_i^s \alpha_j^{k-s}\right)} \\ &= \frac{\left(\alpha_i^{l+1}\alpha_j^{k-l}\right)^{-1} \alpha_j \left(\sum_{s=0}^{k} \alpha_i^s \alpha_j^{k-s}\right)\left(\sum_{s=0}^{l} \alpha_i^s \alpha_j^{k-s}\right) + \sum_{s=0}^{k} \alpha_i^s \alpha_j^{k-s}}{\left(\alpha_i^{l+1}\alpha_j^{k-l}\right)^{-1} \alpha_j \left(\sum_{s=0}^{k} \alpha_i^s \alpha_j^{k-s}\right)\left(\sum_{s=0}^{l} \alpha_i^s \alpha_j^{k-s}\right) + \sum_{s=k-l}^{k} \alpha_i^s \alpha_j^{k-s}} \geq 1. \end{aligned}$$

Thus we obtain the claim. ∎

The above alternating inequalities imply the following.

THEOREM 3.2. *For $0 < \forall\varepsilon < 1$, the mixing time $\tau(\varepsilon)$ of Markov chain $\mathcal{M}_{\mathrm{A}}(K)$ satisfies*

$$\tau(\varepsilon) \leq \frac{n(n-1)}{2} \ln(K\varepsilon^{-1}).$$

Proof. Let $G = (\Xi, \mathcal{E})$ be an undirected simple graph with vertex set Ξ and edge set $\mathcal{E}$ defined as follows. A pair of vertices $\{\boldsymbol{x}, \boldsymbol{y}\}$ is an edge of G if and only if $(1/2)\sum_{i=1}^{n} |x_i - y_i| = 1$. Clearly the graph G is connected. We define the length $l_{\mathrm{A}}(e)$ of every edge $e \in \mathcal{E}$ by $l_{\mathrm{A}}(e) \stackrel{\text{def.}}{=} 1$. For each pair $(\boldsymbol{x}, \boldsymbol{y}) \in \Xi^2$, we define the distance $d_{\mathrm{A}}(\boldsymbol{x}, \boldsymbol{y})$ by the length of the shortest path between $\boldsymbol{x}$ and $\boldsymbol{y}$ on G with respect to l_{A}. Clearly, the diameter of G, defined by $\max_{\boldsymbol{x},\boldsymbol{y}\in\Xi}\{d_{\mathrm{A}}(\boldsymbol{x}, \boldsymbol{y})\}$, is bounded by K.

We define a joint process $(X, Y) \mapsto (X', Y')$ for any pair $\{X, Y\} \in \mathcal{E}$ as follows. Pick a distinct pair of indices $\{i_1, i_2\}$ uniformly at random. Then set $k_X = X_{i_1} + X_{i_2}$ and $k_Y = Y_{i_1} + Y_{i_2}$, generate a uniform random number $\Lambda \in [0, 1)$, choose l_X and l_Y satisfying $g_{i_1 i_2}^{k_X}(l_X - 1) \leq \Lambda < g_{i_1 i_2}^{k_X}(l_X)$ and $g_{i_1 i_2}^{k_Y}(l_Y - 1) \leq \Lambda < g_{i_1 i_2}^{k_Y}(l_Y)$, and set $X'_{i_1} = l_X$, $X'_{i_2} = k_X - l_X$, $Y'_{i_1} = l_Y$, and $Y'_{i_2} = k_Y - l_Y$. Now we show that

$$\forall\{X, Y\} \in \mathcal{E},\ \mathrm{E}[d_{\mathrm{A}}(Y', Y')] \leq \beta \cdot d_{\mathrm{A}}(X, Y),\ \text{where } \beta = 1 - \frac{2}{n(n-1)}.$$

Since $\{X, Y\} \in \mathcal{E}$, there exists a distinct pair of indices $\{j_1, j_2\}$ satisfying $|X_j - Y_j| = 1$ for $j \in \{j_1, j_2\}$, and $|X_j - Y_j| = 0$ for $j \notin \{j_1, j_2\}$. We will consider the following three cases.

Case 1. When neither index j_1 nor j_2 is chosen, i.e., $\{i_1, i_2\} \cap \{j_1, j_2\} = \emptyset$, we put $k = X_{i_1} + X_{i_2}$, and it is easy to see that $\Pr(X'_{i_1} = l) = \Pr(Y'_{i_1} = l)$ for any $l \in \{0, \ldots, k\}$ since $Y_{i_1} + Y_{i_2} = k$. Thus $X'_{i_1} = Y'_{i_1}$ and $X'_{i_2} = Y'_{i_2}$ hold. Hence $d_{\mathrm{A}}(X', Y') = d_{\mathrm{A}}(X, Y)$.

Case 2. When both indices j_1 and j_2 are chosen, i.e., $\{i_1, i_2\} = \{j_1, j_2\}$, in the same way as Case 1, both $X'_{i_1} = Y'_{i_1}$ and $X'_{i_2} = Y'_{i_2}$ hold. Hence $d_{\mathrm{A}}(X', Y') = 0$.

Case 3. When exactly one of j_1 and j_2 is chosen, i.e., $|\{i_1, i_2\} \cap \{j_1, j_2\}| = 1$, without loss of generality, we can assume that $i_1 = j_1$ and that $X_{i_1} = Y_{i_1} + 1$. Let $k + 1 = X_{i_1} + X_{i_2}$. Then $Y_{i_1} + Y_{i_2} = k$ obviously. We parameterize the transition of Markov chain $\mathcal{M}_{\mathrm{A}}(K)$ with a uniformly random number $\Lambda \in [0, 1)$ by using the functions $g_{i_1 i_2}^{k+1}$ and $g_{i_1 i_2}^{k}$. Set $X_{i_1} = l_1$ such that $g_{i_1 i_2}^{k+1}(l_1 - 1) \leq \Lambda < g_{i_1 i_2}^{k+1}(l_1)$ and $Y_{i_1} = l_2$ such that $g_{i_1 i_2}^{k}(l_2 - 1) \leq \Lambda < g_{i_1 i_2}^{k}(l_2)$ for the common random number Λ. From Lemma 3.1, the alternating inequalities hold, and thus we can see that $l_1 = l_2$ or $l_1 = l_2 + 1$. In either case, we can set $[X'_{i_1} = Y'_{i_1} + 1$ and $X'_{i_2} = Y'_{i_2}]$ or $[X'_{i_1} = Y'_{i_1}$ and $X'_{i_2} = Y'_{i_2} + 1]$. Hence $d_{\mathrm{A}}(X', Y') = d_{\mathrm{A}}(X, Y)$.

Considering that Case 2 occurs with probability $2/(n(n-1))$, we obtain that

$$\mathrm{E}[d_{\mathrm{A}}(X', Y')] \leq \left(1 - \frac{2}{n(n-1)}\right) d_{\mathrm{A}}(X, Y).$$

Since the diameter of G is bounded by K, the path coupling theorem (see Theorem 3.3 described below) implies that the mixing time $\tau(\varepsilon)$ of $\mathcal{M}_{\mathrm{A}}(K)$ satisfies

$$\tau(\varepsilon) \leq \frac{n(n-1)}{2} \ln(K\varepsilon^{-1}). \qquad \square$$

The path coupling theorem proposed by Bubley and Dyer [4] is a useful technique for bounding the mixing time (see also [1, 3, 7, 22]).

THEOREM 3.3 (path coupling theorem [4]). *Let $\mathcal{M}$ be a finite ergodic Markov chain with state space Ω. Let $H = (\Omega, \mathcal{F})$ be a connected undirected graph with vertex set Ω and edge set $\mathcal{F} \subseteq \binom{\Omega}{2}$. Let $l : \mathcal{F} \to \mathbb{R}_{++}$ be a positive length defined on the edge set. For any pair of vertices $\{x, y\}$ of H, the distance between x and y, denoted by $d(x, y)$ and/or $d(y, x)$, is the length of a shortest path between x and y, where the length of a path is the sum of the lengths of edges in the path. Suppose that there exists a joint process $(X, Y) \mapsto (X', Y')$ with respect to $\mathcal{M}$ whose marginals are a faithful copy of $\mathcal{M}$ and satisfying*

$$0 < \exists\beta < 1,\ \forall\{X, Y\} \in \mathcal{F},\ \mathrm{E}[d(X', Y')] \le \beta d(X, Y).$$

Then the mixing time $\tau(\varepsilon)$ of the Markov chain $\mathcal{M}$ satisfies $\tau(\varepsilon) \le (1-\beta)^{-1} \ln(\varepsilon^{-1} D/d)$, where $d \stackrel{\text{def.}}{=} \min\{d(x, y) \mid \forall x, \forall y \in \Omega,\ x \ne y\}$ and $D \stackrel{\text{def.}}{=} \max\{d(x, y) \mid \forall x, \forall y \in \Omega\}$.

The above theorem differs from the original theorem in [4] in that the integrality of the edge lengths is not assumed. We dropped the integrality and introduced the minimum distance d. Theorem 3.3 can be proved by slightly modifying the original proof.

3.2. Monte Carlo integration. In this section, we give an FPRAS for calculating the normalizing constant $G(K)$ of product form solution for a closed Jackson network. Our approximation scheme is a standard Jerrum–Sinclair-type recursive algorithm [16, 15] but we need to exercise caution at some points.

Here we suppose that $K \ge 1$. We arrange the indices (nodes in the network) satisfying the following condition.

Condition 1. $\alpha_1 = \max_i \alpha_i$.

We define a set $\Xi'(K) \subset \Xi(K)$ by $\Xi'(K) \stackrel{\text{def.}}{=} \left\{\boldsymbol{x} \in \Xi(K) \mid x_1 \ge \left\lceil \frac{K}{n} \right\rceil\right\}$ and $G'(K) \stackrel{\text{def.}}{=} \sum_{\boldsymbol{x} \in \Xi'(K)} \prod_{i=1}^{n} \alpha_i^{x_i}$. It is not difficult to see that Condition 1 implies $G'(K)/G(K) \ge 1/n$.

Considering that α_i ($\forall i \in \{1, 2, \ldots, n\}$) is independent of K, it is easy to see that

$$\begin{aligned} G'(K) &= \sum_{\boldsymbol{x} \in \Xi'(K)} \left(\alpha_1^{\lceil K/n \rceil} \cdot \left(\prod_{i=2}^{n} \alpha_i^{x_i} \right) \cdot \alpha_1^{x_1 - \lceil K/n \rceil} \right) \\ &= \sum_{\boldsymbol{x} \in \Xi(K - \lceil K/n \rceil)} \left(\alpha_1^{\lceil K/n \rceil} \cdot \left(\prod_{i=2}^{n} \alpha_i^{x_i} \right) \cdot \alpha_1^{x_1} \right) \\ &= \alpha_1^{\lceil K/n \rceil} \cdot G(K - \lceil K/n \rceil). \end{aligned}$$

Thus, we can compute $G(K)$ by

$$G(K) = \frac{G(K)}{G'(K)} \cdot \alpha_1^{\lceil K/n \rceil} \cdot G(K - \lceil K/n \rceil)$$

if we know the value of $G(K)/G'(K)$ and $G(K - \lceil K/n \rceil)$. By applying the above equation recursively, $G(0) = 1$ implies that

$$G(K) = G(0) \prod_{j=1}^{R} \frac{G(K_{j-1})}{G(K_j)} = \prod_{j=1}^{R} \left(\alpha_1^{K_{j-1} - K_j} \cdot \frac{G(K_{j-1})}{G'(K_{j-1})} \right) = \alpha_1^K \prod_{j=0}^{R-1} \frac{G(K_j)}{G'(K_j)},$$

where we define $K_0 \stackrel{\text{def.}}{=} K$, and $K_j \stackrel{\text{def.}}{=} K_{j-1} - \left\lceil \frac{K_{j-1}}{n} \right\rceil$ for $j = 1, 2, \ldots, R$ while $K_j \ge 0$, and let $R \in \mathbb{Z}_{++}$ be the minimum index satisfying $K_R = 0$.

LEMMA 3.4. *The number of recursions R satisfies that $R \leq n \ln K + 1$ for any $K \in \mathbb{Z}_{++}$.*

We give a proof of Lemma 3.4 in the appendix. Since we already have an approximate sampler via the Markov chain $\mathcal{M}_{\mathrm{A}}(K)$, we only need to estimate $G(K_j)/G'(K_j)$ for $j \in \{0, 1, \ldots, R-1\}$ by the Monte Carlo method. The whole algorithm is as follows.

ALGORITHM 1 (randomize approximation scheme with approximate sampler).

Step 1. *Set $j = 1$, $K' = K$.*
While $K' \geq 1$,
do→
Generate Q_{A} samples, each of which is obtained by simulating $\mathcal{M}_{\mathrm{A}}(K')$ for $T_{\mathrm{A}}(K')$ steps.
Let U_j be the number of samples $\boldsymbol{x}$ which satisfy $x_1 \geq K'/n$.
Set $Z_j := (U_j + 1)/(Q_{\mathrm{A}} + 1)$.
Set $K' := K' - \left\lceil \frac{K'}{n} \right\rceil$ and set $j := j + 1$.
←od
Step 2. *Set $Z := \alpha_1^K \prod_j (1/Z_j)$. Output Z.*

Our algorithm generates Q_{A} samples by simulating $\mathcal{M}_{\mathrm{A}}(K_j)$ for $T_{\mathrm{A}}(K_j)$ steps for each sample. By setting $Q_{\mathrm{A}} = 144nR^2\varepsilon^{-2}\ln(2R/\delta)$ and $T_{\mathrm{A}}(K') = \left\lceil \frac{n(n-1)}{2} \ln \frac{6nRK'}{\varepsilon} \right\rceil$, we obtain the following theorem.

THEOREM 3.5. *If we set $Q_{\mathrm{A}} = 144nR^2\varepsilon^{-2}\ln(2R/\delta)$ and $T_{\mathrm{A}}(K') = \left\lceil \frac{n(n-1)}{2} \ln \frac{6nRK'}{\varepsilon} \right\rceil$, then our randomized approximation scheme (Algorithm 1) returns Z satisfying*

$$\Pr\left[|Z - G(K)| \leq \varepsilon G(K)\right] \geq 1 - \delta.$$

In our proof of the above theorem, we need the following modified Chernoff bound [17].

LEMMA 3.6. *Let X_i $(1 \leq i \leq M)$ be independently and identically distributed (i.i.d.) random variables such that $X_i = 1$ with probability p, and $X_i = 0$ with probability $1 - p$. Let $U = \sum_{i=1}^{M} X_i$ and $0 < \lambda < 1$. If $M \geq (4 + 2\sqrt{3})/p\lambda$, then the inequality*

$$\Pr\left[\left|\frac{U+1}{M+1} - p\right| \geq \lambda p\right] \leq 2\mathrm{e}^{-\frac{1}{4}\lambda^2 Mp}$$

holds.

Also we can estimate the error of bias.

THEOREM 3.7. *If we set $Q_{\mathrm{A}} = 144nR^2\varepsilon^{-2}\ln(2R/\delta)$ and $T_{\mathrm{A}}(K') = \left\lceil \frac{n(n-1)}{2} \ln \frac{6nRK'}{\varepsilon} \right\rceil$, then the bias of the expectation of the obtained approximate solution is bounded as follows:*

$$\frac{|\mathrm{E}[Z] - G(K)|}{G(K)} \leq \frac{\varepsilon}{4} + R\mathrm{e}^{-120R^2\varepsilon^{-2}\ln(2R/\delta)} \leq \left(\frac{1}{4} + \frac{1}{10^{36}}\right)\varepsilon.$$

Proofs of the above results are given in the appendix.

4. Perfect sampler.

4.1. Monotone coupling from the past. Here we briefly review CFTP [24]. Suppose that we have an ergodic Markov chain $\mathcal{M}$ with a finite state space Ω and a transition matrix P. The transition rule of the Markov chain $X \mapsto X'$ can be described by a deterministic function $\phi : \Omega \times [0, 1) \to \Omega$, called an *update function*, as

follows. Given a random number Λ uniformly distributed over $[0,1)$, update function ϕ satisfies that $\Pr(\phi(x,\Lambda)=y)=P(x,y)$ for any $x,y\in\Omega$. We can realize the Markov chain by setting $X'=\phi(X,\Lambda)$. Clearly, update functions corresponding to the given transition matrix P are not unique. The result of transitions of the chain from the time t_1 to t_2 ($t_1<t_2$) with a sequence of random numbers $\boldsymbol{\lambda}=(\lambda[t_1],\lambda[t_1+1],\dots,\lambda[t_2-1])\in[0,1)^{t_2-t_1}$ is denoted by $\Phi_{t_1}^{t_2}(x,\boldsymbol{\lambda}):\Omega\times[0,1)^{t_2-t_1}\to\Omega$, where $\Phi_{t_1}^{t_2}(x,\boldsymbol{\lambda})\stackrel{\text{def.}}{=}\phi(\phi(\cdots\phi(x,\lambda[t_1]),\dots,\lambda[t_2-2]),\lambda[t_2-1])$. We say that a sequence $\boldsymbol{\lambda}\in[0,1)^{|T|}$ satisfies the *coalescence condition*, when $\exists y\in\Omega$, $\forall x\in\Omega$, $y=\Phi_T^0(x,\boldsymbol{\lambda})$.

Suppose that there exists a partial order "$\succeq$" on the set of states Ω. A transition rule expressed by a deterministic update function ϕ is called *monotone* (with respect to "$\succeq$") if $\forall\lambda\in[0,1)$, $\forall x,\forall y\in\Omega$, $x\succeq y\Rightarrow\phi(x,\lambda)\succeq\phi(y,\lambda)$. We also say that a chain is *monotone* if the chain has a *monotone* update function. Here we suppose that there exists a unique pair of states $(x_{\max},x_{\min})$ in a partially ordered set $(\Omega,\succeq)$, satisfying $x_{\max}\succeq x\succeq x_{\min}$ $\forall x\in\Omega$.

With these preparations, a standard monotone CFTP algorithm is expressed as follows.

ALGORITHM 2 (monotone CFTP algorithm [24]).

Step 1. *Set the starting time period $T:=-1$ to go back, and set $\boldsymbol{\lambda}$ to be the empty sequence.*

Step 2. *Generate random real numbers $\lambda[T],\lambda[T+1],\dots,\lambda[\lceil T/2\rceil-1]\in[0,1)$, and insert them to the head of $\boldsymbol{\lambda}$ in order, i.e., put $\boldsymbol{\lambda}:=(\lambda[T],\lambda[T+1],\dots,\lambda[-1])$.*

Step 3. *Start two chains from $x_{\max}$ and $x_{\min}$, respectively, at time period T, and run each chain to time period 0 according to the update function ϕ with the sequence of numbers in $\boldsymbol{\lambda}$. (Here we note that every chain uses the common sequence $\boldsymbol{\lambda}$.)*

Step 4. [*Coalescence check.*] *The state obtained at time period 0 is denoted by $\Phi_T^0(x,\boldsymbol{\lambda})$.*

(a) *If $\exists y\in\Omega$, $y=\Phi_T^0(x_{\max},\boldsymbol{\lambda})=\Phi_T^0(x_{\min},\boldsymbol{\lambda})$, then return y.*

(b) *Else, update the starting time period $T:=2T$, and go to Step 2.*

THEOREM 4.1 (monotone CFTP theorem [24]). *Suppose that a Markov chain defined by an update function ϕ is monotone with respect to a partially ordered set of states $(\Omega,\succeq)$, and $\exists x_{\max},\exists x_{\min}\in\Omega$, $\forall x\in\Omega$, $x_{\max}\succeq x\succeq x_{\min}$. Then the monotone CFTP algorithm (Algorithm 2) terminates with probability 1, and the obtained value is a realization of a random variable exactly distributed according to the stationary distribution.*

Theorem 4.1 says that Algorithm 2 is a (probabilistically) finite time algorithm for infinite time simulation.

4.2. Monotone Markov chain. In this section we propose a new Markov chain $\mathcal{M}_{\mathrm{P}}$ for a given Jackson network. The transition rule of $\mathcal{M}_{\mathrm{P}}$ is defined by the following *update function* $\phi:\Xi\times[1,n)\to\Xi$. For a current state $X\in\Xi$, the next state $X'=\phi(X,\lambda)\in\Xi$ with respect to a random number $\lambda\in[1,n)$ is defined by

$$X_i'=\begin{cases} l & (\text{for } i=\lfloor\lambda\rfloor),\\ k-l & (\text{for } i=\lfloor\lambda\rfloor+1),\\ X_i & (\text{otherwise}),\end{cases}$$

where $k=X_{\lfloor\lambda\rfloor}+X_{\lfloor\lambda\rfloor+1}$ and $l\in\{0,1,\dots,k\}$ satisfies

$$g^k_{\lfloor\lambda\rfloor(\lfloor\lambda\rfloor+1)}(l-1)\le\lambda-\lfloor\lambda\rfloor<g^k_{\lfloor\lambda\rfloor(\lfloor\lambda\rfloor+1)}(l).$$

Our chain $\mathcal{M}_{\mathrm{P}}$ is a modification of $\mathcal{M}_{\mathrm{A}}$, obtained by restricting ourselves to choosing only a consecutive pair of indices. Clearly, $\mathcal{M}_{\mathrm{P}}$ is ergodic. The chain has a unique stationary distribution $J(\boldsymbol{x})$ defined in section 2.

In the following, we show the monotonicity of $\mathcal{M}_{\mathrm{P}}$. Here we introduce a partial order "$\succeq$" on Ξ. For any state $\boldsymbol{x} \in \Xi$, we define *cumulative sum vector* $c_{\boldsymbol{x}} = (c_{\boldsymbol{x}}(0), c_{\boldsymbol{x}}(1), \ldots, c_{\boldsymbol{x}}(n)) \in \mathbb{Z}_+^{n+1}$ by

$$c_{\boldsymbol{x}}(i) \stackrel{\text{def.}}{=} \begin{cases} 0 & (\text{for } i = 0), \\ \sum_{j=1}^{i} x_j & (\text{for } i \in \{1, 2, \ldots, n\}). \end{cases}$$

For any pair of states $\boldsymbol{x}, \boldsymbol{y} \in \Xi$, we say $\boldsymbol{x} \succeq \boldsymbol{y}$ if and only if $c_{\boldsymbol{x}} \geq c_{\boldsymbol{y}}$. Next, we define two special states $x_{\max}, x_{\min} \in \Xi(K)$ by $x_{\max} \stackrel{\text{def.}}{=} (K, 0, \ldots, 0)$ and $x_{\min} \stackrel{\text{def.}}{=} (0, \ldots, 0, K)$. Then we can see easily that $\forall \boldsymbol{x} \in \Xi(K)$, $x_{\max} \succeq \boldsymbol{x} \succeq x_{\min}$.

THEOREM 4.2. *Markov chain $\mathcal{M}_{\mathrm{P}}$ is monotone on the partially ordered set $(\Xi(K), \succeq)$, i.e., $\forall \lambda \in [1, n)$, $\forall X, \forall Y \in \Xi(K)$, $X \succeq Y \Rightarrow \phi(X, \lambda) \succeq \phi(Y, \lambda)$.*

Outline of proof (a detailed proof appears in the appendix). We say that a state $X \in \Xi$ *covers* $Y \in \Xi$ (at j), denoted by $X \cdot\!\succ Y$ (or $X \cdot\!\succ_j Y$), when

$$X_i - Y_i = \begin{cases} +1 & (\text{for } i = j), \\ -1 & (\text{for } i = j + 1), \\ 0 & (\text{otherwise}). \end{cases}$$

We show that if a pair of states $X, Y \in \Xi$ satisfies $X \cdot\!\succ_j Y$, then $\forall \lambda \in [1, n)$, $\phi(X, \lambda) \succeq \phi(Y, \lambda)$. We denote $\phi(X, \lambda)$ by X' and $\phi(Y, \lambda)$ by Y' for simplicity. For any index $i \neq \lfloor \lambda \rfloor$, it is easy to see that $c_X(i) = c_{X'}(i)$ and $c_Y(i) = c_{Y'}(i)$, and so $c_{X'}(i) - c_{Y'}(i) = c_X(i) - c_Y(i) \geq 0$ since $X \succeq Y$. We can show that $c_{X'}(\lfloor \lambda \rfloor) \geq c_{Y'}(\lfloor \lambda \rfloor)$ by considering the following three cases:

Case 1. $[\lfloor \lambda \rfloor \neq j - 1$ and $\lfloor \lambda \rfloor \neq j + 1]$.

Case 2. $[\lfloor \lambda \rfloor = j - 1]$.

Case 3. $[\lfloor \lambda \rfloor = j + 1]$.

For any pair of states X, Y satisfying $X \succeq Y$, it is easy to see that there exists a sequence of states $Z_1, Z_2, \ldots, Z_r$ with an appropriate length that satisfies $X = Z_1 \cdot\!\succ Z_2 \cdot\!\succ \cdots \cdot\!\succ Z_r = Y$. Then, by applying the above property repeatedly, we obtain $\phi(X, \lambda) = \phi(Z_1, \lambda) \succeq \phi(Z_2, \lambda) \succeq \cdots \succeq \phi(Z_r, \lambda) = \phi(Y, \lambda)$.

Since $\mathcal{M}_{\mathrm{P}}$ is a monotone chain, we can design a perfect sampler based on monotone CFTP. We could also employ Wilson's read-once algorithm [25] and Fill's interruptible algorithm [8, 9], each of which also gives a perfect sampler.

4.3. Expected running time. Here, we assume a condition which gives the expected polynomial-time monotone CFTP algorithm.

Condition 2. Parameters are arranged in nonincreasing order, i.e., $\alpha_1 \geq \alpha_2 \geq \cdots \geq \alpha_n$.

THEOREM 4.3. *Under Condition* 2*, the expected running time of our perfect sampler is bounded by* $\mathrm{O}(n^3 \ln K)$*, where n is the number of nodes and K is the number of customers in a closed Jackson network.*

We can show Theorem 4.3 by estimating the expectation of *coalescence time* $T_* \in \mathbb{Z}_{++}$ defined by $T_* \stackrel{\text{def.}}{=} \min\{t > 0 \mid \exists y \in \Xi,\ \forall x \in \Xi,\ y = \Phi_{-t}^0(x, \boldsymbol{\Lambda})\}$. Note that T_* is a random variable.

Outline of proof. Let $G = (\Xi, \mathcal{E})$ be the graph defined in the proof of Theorem 3.2 in section 3. For each edge $e = \{X, Y\} \in \mathcal{E}$, there exists a unique pair of indices $j_1, j_2 \in \{1, 2, \ldots, n\}$ called a *supporting pair* of e satisfying

$$|X_j - Y_j| = \begin{cases} 1 & (\text{for } j \in \{j_1, j_2\}), \\ 0 & (\text{otherwise}). \end{cases}$$

We define the length of $l_{\mathrm{P}}(e)$ of an edge $e = \{X, Y\} \in \mathcal{E}$ by $l_{\mathrm{P}}(e) \stackrel{\text{def.}}{=} (1/(n-1)) \sum_{i=1}^{j^*-1} (n-i)$, where $j^* = \max\{j_1, j_2\} \geq 2$ and $\{j_1, j_2\}$ is the supporting pair of e. Note that $1 \leq \min_{e \in \mathcal{E}} l_{\mathrm{P}}(e) \leq \max_{e \in \mathcal{E}} l_{\mathrm{P}}(e) \leq n/2$. For each pair $X, Y \in \Xi$, we define the distance $d_{\mathrm{P}}(X, Y)$ to be the length of a shortest path between X and Y on G. Clearly, the length between $x_{\max}$ and $x_{\min}$ is bounded by Kn. Here we denote $X' = \phi(X, \lambda)$ and $Y' = \phi(Y, \Lambda)$ with the uniform real random number $\Lambda \in [1, n)$; then Condition 2 implies

$$\mathrm{E}[d_{\mathrm{P}}(X', Y')] \leq \left(1 - \frac{1}{n(n-1)^2}\right) d_{\mathrm{P}}(X, Y)$$

for any pair $\{X, Y\} \in \mathcal{E}$, and we can prove the claim.

A detailed proof appears in the appendix.

5. Concluding remarks. We proposed FPRAS for closed Jackson networks with single servers. Our scheme is based on MCMC, and we made use of two rapidly mixing Markov chains. One is for approximate sampling, while the other is for perfect sampling. Though we omit the details here, we can also construct an FPRAS using the perfect sampler in the same way as we did with the approximate sampler. It is also possible to show that it suffices to take $36nR^2\varepsilon^{-2} \ln(2R/\delta)$ samples in each iteration. In [19], we discussed a class of functions which satisfies alternating inequalities and showed that this class contains all logarithmic separable concave functions.

We plan to extend our FPRAS to closed Jackson networks with multiple servers [20]. We also hope to extend it to closed BCMP networks [2].

Appendix. Proofs.

LEMMA 3.1. *The function g_{ij}^k satisfies the following* "alternating inequalities"*:*

$$g_{ij}^{k+1}(l) \leq g_{ij}^k(l) \leq g_{ij}^{k+1}(l+1) \quad \forall k \in \{1, \ldots, K\},\ \forall l \in \{1, \ldots, k\}.$$

Proof. First, we prove the former inequality $g_{ij}^{k+1}(l) \leq g_{ij}^k(l)$ as follows:

$$\frac{g_{ij}^k(l)}{g_{ij}^{k+1}(l)} = \frac{\sum_{s=0}^{l} \alpha_i^s \alpha_j^{k-s}}{A_{ij}^k} \frac{A_{ij}^{k+1}}{\sum_{s=0}^{l} \alpha_i^s \alpha_j^{k+1-s}} = \frac{A_{ij}^{k+1}}{\alpha_j A_{ij}^k}$$
$$= \frac{\sum_{s=0}^{k+1} \alpha_i^s \alpha_j^{k+1-s}}{\alpha_j \sum_{s=0}^{k} \alpha_i^s \alpha_j^{k-s}} = \frac{\sum_{s=0}^{k+1} \alpha_i^s \alpha_j^{k+1-s}}{\sum_{s=0}^{k} \alpha_i^s \alpha_j^{k+1-s}} \geq 1.$$

Next, we prove the latter inequality $g_{ij}^k(l) \leq g_{ij}^{k+1}(l+1)$ as follows:

$$\frac{g_{ij}^{k+1}(l+1)}{g_{ij}^k(l)} = \frac{A_{ij}^k}{A_{ij}^{k+1}} \frac{\sum_{s=0}^{l+1} \alpha_i^s \alpha_j^{k+1-s}}{\sum_{s=0}^{l} \alpha_i^s \alpha_j^{k-s}} = \frac{\left(\sum_{s=0}^{k} \alpha_i^s \alpha_j^{k-s}\right)\left(\sum_{s=0}^{l+1} \alpha_i^s \alpha_j^{k+1-s}\right)}{\left(\sum_{s=0}^{k+1} \alpha_i^s \alpha_j^{k+1-s}\right)\left(\sum_{s=0}^{l} \alpha_i^s \alpha_j^{k-s}\right)}$$

$$
\begin{aligned}
&= \frac{\left(\sum_{s=0}^{k} \alpha_i^s \alpha_j^{k-s}\right)\left(\sum_{s=0}^{l} \alpha_i^s \alpha_j^{k+1-s} + \alpha_i^{l+1}\alpha_j^{k-l}\right)}{\left(\sum_{s=0}^{k} \alpha_i^s \alpha_j^{k+1-s} + \alpha_i^{k+1}\right)\left(\sum_{s=0}^{l} \alpha_i^s \alpha_j^{k-s}\right)} \\
&= \frac{\left(\sum_{s=0}^{k} \alpha_i^s \alpha_j^{k-s}\right)\left(\alpha_j \sum_{s=0}^{l} \alpha_i^s \alpha_j^{k-s}\right) + \alpha_i^{l+1}\alpha_j^{k-l}\left(\sum_{s=0}^{k} \alpha_i^s \alpha_j^{k-s}\right)}{\left(\alpha_j \sum_{s=0}^{k} \alpha_i^s \alpha_j^{k-s}\right)\left(\sum_{s=0}^{l} \alpha_i^s \alpha_j^{k-s}\right) + \alpha_i^{k+1}\left(\sum_{s=0}^{l} \alpha_i^s \alpha_j^{k-s}\right)} \\
&= \frac{\left(\alpha_i^{l+1}\alpha_j^{k-l}\right)^{-1}\alpha_j\left(\sum_{s=0}^{k} \alpha_i^s \alpha_j^{k-s}\right)\left(\sum_{s=0}^{l} \alpha_i^s \alpha_j^{k-s}\right) + \sum_{s=0}^{k} \alpha_i^s \alpha_j^{k-s}}{\left(\alpha_i^{l+1}\alpha_j^{k-l}\right)^{-1}\alpha_j\left(\sum_{s=0}^{k} \alpha_i^s \alpha_j^{k-s}\right)\left(\sum_{s=0}^{l} \alpha_i^s \alpha_j^{k-s}\right) + \alpha_i^{k-l}\alpha_j^{l-k}\sum_{s=0}^{l} \alpha_i^s \alpha_j^{k-s}} \\
&= \frac{\left(\alpha_i^{l+1}\alpha_j^{k-l}\right)^{-1}\alpha_j\left(\sum_{s=0}^{k} \alpha_i^s \alpha_j^{k-s}\right)\left(\sum_{s=0}^{l} \alpha_i^s \alpha_j^{k-s}\right) + \sum_{s=0}^{k} \alpha_i^s \alpha_j^{k-s}}{\left(\alpha_i^{l+1}\alpha_j^{k-l}\right)^{-1}\alpha_j\left(\sum_{s=0}^{k} \alpha_i^s \alpha_j^{k-s}\right)\left(\sum_{s=0}^{l} \alpha_i^s \alpha_j^{k-s}\right) + \sum_{s=k-l}^{k} \alpha_i^s \alpha_j^{k-s}} \geq 1.
\end{aligned}
$$

Thus we obtain the claim. □

LEMMA 3.4. *The number of recursions R satisfies that $R \leq n \ln K + 1$ for any $K \in \mathbb{Z}_{++}$.*

Proof. If $n = 1$, then $R = 1$; hence we obtain the claim. If $n \geq 2$ and $K = 1, 2$, then $R = 1, 2$, respectively; hence we also obtain the claim. In the following, we consider the case $n \geq 2$ and $K \geq 3$. We define R' by

$$
R' \stackrel{\text{def.}}{=} \min\left\{ r \;\middle|\; K\left(\frac{n-1}{n}\right)^r < 1 \right\}.
$$

Then clearly $R \leq R'$, since $K' - \lceil K'/n \rceil \leq K'(n-1)/n$ for any $K' \in \mathbb{Z}_{++}$. Thus it is enough to show that

$$
K\left(\frac{n-1}{n}\right)^{n \ln K} \leq 1.
$$

Considering $\ln K > 0$,

$$
\left(\frac{n-1}{n}\right)^{n \ln K} = \left(\left(1 - \frac{1}{n}\right)^n\right)^{\ln K} \leq \left(\frac{1}{\mathrm{e}}\right)^{\ln K} = 1/K.
$$

Thus we obtain the claim. □

THEOREM 3.5. *If we set $Q_{\mathrm{A}} = 144nR^2\varepsilon^{-2}\ln(2R/\delta)$ and $T_{\mathrm{A}}(K') = \left\lceil \frac{n(n-1)}{2} \ln \frac{6nRK'}{\varepsilon} \right\rceil$, then our randomized approximation scheme (Algorithm 1) returns Z satisfying*

$$
\Pr\left[|Z - G(K)| \leq \varepsilon G(K)\right] \geq 1 - \delta.
$$

Proof. In the following, we denote $\omega_j \stackrel{\text{def.}}{=} G'(K_j)/G(K_j)$ and $\widehat{\omega}_j \stackrel{\text{def.}}{=} \mathrm{E}[U_j/Q_{\mathrm{A}}]$ for $j \in \{1, 2, \ldots, R\}$, for simplicity.

(i) We show that $1 \leq \forall j \leq R$, the inequality $\widehat{\omega}_j \geq 1/n - \varepsilon/(6nR)$ holds. By the hypothesis of the theorem, $|\omega_j - \widehat{\omega}_j| \leq \varepsilon/(6nR)$. Since $\omega_j \geq 1/n$, we can see that $\widehat{\omega}_j \geq \omega_j - \varepsilon/(6nR) \geq 1/n - \varepsilon/(6nR)$ for $1 \leq j \leq R$.

(ii) We show that $|\omega_j - \widehat{\omega}_j| \leq \frac{\varepsilon\widehat{\omega}_j}{6R-\varepsilon}$. By using the result of (i), we have

$$
|\omega_j - \widehat{\omega}_j| \leq \frac{\varepsilon}{6nR} = \frac{\varepsilon}{6nR} \cdot \frac{1}{\widehat{\omega}_j} \cdot \widehat{\omega}_j \leq \frac{\varepsilon}{6nR} \cdot \frac{\widehat{\omega}_j}{\left(\frac{1}{n} - \frac{\varepsilon}{6nR}\right)} = \frac{\varepsilon}{6R - \varepsilon} \cdot \widehat{\omega}_j.
$$

(iii) We show that $\Pr[|Z_j - \widehat{\omega}_j| > (\varepsilon/(6R-\varepsilon))] \le \delta/R$. By employing the modified Chernoff bound in Lemma 3.6, we have

$$\Pr\left[\left|\tfrac{U+1}{M+1} - p\right| \ge \lambda p\right] \le 2\mathrm{e}^{-\frac{1}{4}\lambda^2 Mp}.$$

By substituting the parameters $\lambda = \varepsilon/(6R-\varepsilon)$ and $p = \widehat{\omega}_j \ge 1/n - \varepsilon/(6nR)$, clearly $Q_{\mathrm{A}} \ge (4+2\sqrt{3})/(p\lambda)$ holds. We put $M = Q_{\mathrm{A}} = 144nR^2\varepsilon^{-2}\ln(2R/\delta)$ and $U = U_j$. Then we obtain that $Z_j = \frac{U_j+1}{Q_{\mathrm{A}}+1}$ satisfies

$$\begin{aligned}\Pr\left[|Z_j - \widehat{\omega}_j| > \frac{\varepsilon}{6R-\varepsilon}\widehat{\omega}_j\right] &\le 2\mathrm{e}^{-\left(\frac{\varepsilon}{6R-\varepsilon}\right)^2 \frac{1}{4} 144nR^2\varepsilon^{-2}\left(\ln\frac{2R}{\delta}\right)\widehat{\omega}_j} \\ &\le 2\mathrm{e}^{-\left(\frac{\varepsilon}{6R-\varepsilon}\right)^2 36nR^2\varepsilon^{-2}\left(\ln\frac{2R}{\delta}\right)\left(\frac{6R-\varepsilon}{6nR}\right)} \le 2\mathrm{e}^{-\left(\frac{6R}{6R-\varepsilon}\right)\left(\ln\frac{2R}{\delta}\right)} \le 2\mathrm{e}^{-\left(\ln\frac{2R}{\delta}\right)} = \frac{\delta}{R}.\end{aligned}$$

(iv) We show that $|(Z_1\cdots Z_R)^{-1} - (\omega_1\cdots\omega_R)^{-1}| \le \varepsilon(\omega_1\cdots\omega_R)^{-1}$ with probability higher than $1-\delta$. By using the result of (ii), we obtain that

$$\frac{6R-2\varepsilon}{6R-\varepsilon}\cdot\widehat{\omega}_j \le \omega_j \le \frac{6R}{6R-\varepsilon}\cdot\widehat{\omega}_j. \tag{A.1}$$

From the result of (iii), we obtain that

$$\frac{6R-\varepsilon}{6R}\cdot Z_j \le \widehat{\omega}_j \le \frac{6R-\varepsilon}{6R-2\varepsilon}\cdot Z_j, \tag{A.2}$$

with probability higher than $1-\delta/R$. By combining (A.1) and (A.2), and considering $Z_j > 0$, the pair of ω_j and Z_j satisfy that

$$\frac{6R-2\varepsilon}{6R} \le \frac{\omega_j}{Z_j} \le \frac{6R}{6R-2\varepsilon} \quad \text{with probability higher than } 1-\delta/R.$$

The above inequality holds for each $1 \le j \le R$ and each Z_j follows i.i.d.; thus with probability higher than $1-\delta$, the inequalities

$$\left(1-\frac{\varepsilon}{3R}\right)^R \le \frac{\omega_1\cdots\omega_R}{Z_1\cdots Z_R} \le \left(\frac{1}{1-\frac{\varepsilon}{3R}}\right)^R \tag{A.3}$$

hold. The right-hand side of inequality (A.3) satisfies

$$\left(\frac{1}{1-\frac{\varepsilon}{3R}}\right)^R = \left(1+\frac{\varepsilon}{3R-\varepsilon}\right)^R \le \left(1+\frac{\varepsilon}{3R-1}\right)^R \le \mathrm{e}^{\frac{R}{3R-1}\varepsilon} \le \mathrm{e}^{\frac{1}{2}\varepsilon} \le 1+\varepsilon.$$

The left-hand side satisfies

$$\left(1-\frac{\varepsilon}{3R}\right)^R = \left(\frac{1}{1-\frac{\varepsilon}{3R}}\right)^{-R} \ge \frac{1}{1+\varepsilon} \ge 1-\varepsilon.$$

Thus, inequality (A.3) is transformed into

$$1-\varepsilon \le \frac{\omega_1\cdots\omega_R}{Z_1\cdots Z_R} \le 1+\varepsilon$$

accordingly. Then we have the result that with probability higher than $1-\delta$,

$$|(Z_1\cdots Z_R)^{-1} - (\omega_1\cdots\omega_R)^{-1}| \le \varepsilon(\omega_1\cdots\omega_R)^{-1}.$$

(v) Since $\alpha_1^K(\omega_1 \cdots \omega_R)^{-1} = G(K)$ and $\alpha_1^K(Z_1 \cdots Z_R)^{-1} = Z$, we obtain the desired result that

$$\Pr\left[|Z - G(K)| \le \varepsilon G(K)\right] \ge 1 - \delta. \qquad \square$$

LEMMA 3.6. *Let X_i $(1 \le i \le M)$ be i.i.d. random variables such that $X_i = 1$ with probability p, and $X_i = 0$ with probability $1 - p$. Let $U = \sum_{i=1}^{M} X_i$ and $0 < \lambda < 1$. If $M \ge (4 + 2\sqrt{3})/p\lambda$, then*

1. $\Pr\left[p - \frac{U+1}{M+1} \ge \lambda p\right] \le \mathrm{e}^{-\frac{1}{2}\lambda^2 Mp}$,
2. $\Pr\left[\frac{U+1}{M+1} - p \ge \lambda p\right] \le \mathrm{e}^{-\frac{1}{4}\lambda^2 Mp}$, *and*
3. $\Pr\left[\left|\frac{U+1}{M+1} - p\right| \ge \lambda p\right] \le 2\mathrm{e}^{-\frac{1}{4}\lambda^2 Mp}$

hold.

Proof. 1. If $p - \frac{U+1}{M+1} \ge \lambda p$, then $p - \frac{U}{M} \ge \lambda p$. This implies that

$$\Pr\left[p - \frac{U+1}{M+1} \ge \lambda p\right] \le \Pr\left[p - \frac{U}{M} \ge \lambda p\right] \le \mathrm{e}^{-\frac{1}{2}\lambda^2 Mp},$$

where the last inequality is obtained by a Chernoff bound.

2. By using a Chernoff bound, the condition $M \ge (4 + 2\sqrt{3})/p\lambda$ implies that

$$\begin{aligned}\Pr\left[\frac{U+1}{M+1} - p \ge \lambda p\right] &\le \Pr\left[\frac{U}{M} + \frac{1}{M} - p \ge \lambda p\right] = \Pr\left[\frac{U}{M} - p \ge \left(\lambda - \frac{1}{Mp}\right)p\right] \\ &\le \mathrm{e}^{-\frac{1}{3}\left(\lambda - \frac{1}{Mp}\right)^2 Mp} = \mathrm{e}^{-\frac{1}{3}\left(1 - \frac{1}{Mp\lambda}\right)^2 \lambda^2 Mp} \le \mathrm{e}^{-\frac{1}{4}\lambda^2 Mp}.\end{aligned}$$

3. By using the result of 1 and 2, clearly we have

$$\begin{aligned}\Pr\left[\left|\frac{U+1}{M+1} - p\right| \ge \lambda p\right] &= \Pr\left[p - \frac{U+1}{M+1} \ge \lambda p\right] + \Pr\left[\frac{U+1}{M+1} - p \ge \lambda p\right] \\ &\le \mathrm{e}^{-\frac{1}{2}\lambda^2 Mp} + \mathrm{e}^{-\frac{1}{4}\lambda^2 Mp} \le 2\mathrm{e}^{-\frac{1}{4}\lambda^2 Mp}. \qquad \square\end{aligned}$$

THEOREM 3.7. *If we set $Q_{\mathrm{A}} = 144nR^2\varepsilon^{-2}\ln(2R/\delta)$ and $T_{\mathrm{A}}(K') = \lceil \frac{n(n-1)}{2}\ln(\frac{6nRT'}{\varepsilon})\rceil$, then the bias of the expectation of the approximate solution Z obtained by Algorithm 1 is bounded as follows:*

$$\frac{|\mathrm{E}[Z] - G(K)|}{G(K)} \le \frac{\varepsilon}{4} + R\mathrm{e}^{-120R^2\varepsilon^{-2}\ln(2R/\delta)} \le \left(\frac{1}{4} + \frac{1}{10^{36}}\right)\varepsilon.$$

Proof. Since $Z_1, \ldots, Z_R$ are independent, the equalities

$$\mathrm{E}[Z] = \alpha_1^K \mathrm{E}\left[\prod_{i=1}^{R} \frac{1}{Z_i}\right] = \alpha_1^K \prod_{i=1}^{R} \mathrm{E}\left[\frac{1}{Z_i}\right]$$

hold. Now, we have

$$\begin{aligned}\mathrm{E}\left[\frac{1}{Z_i}\right] &= \sum_{U_i=0}^{Q_{\mathrm{A}}} \frac{Q_{\mathrm{A}}+1}{U_i+1}\binom{Q_{\mathrm{A}}}{U_i}\widehat{\omega_i}^{U_i}(1-\widehat{\omega_i})^{Q_{\mathrm{A}}-U_i} \\ &= \frac{1}{\widehat{\omega_i}}\sum_{U_i=0}^{Q_{\mathrm{A}}}\binom{Q_{\mathrm{A}}+1}{U_i+1}\widehat{\omega_i}^{U_i+1}(1-\widehat{\omega_i})^{Q_{\mathrm{A}}-U_i} \\ &= \frac{1}{\widehat{\omega_i}}\left\{1 - (1-\widehat{\omega_i})^{Q_{\mathrm{A}}+1}\right\}.\end{aligned}$$

Let $\gamma_i \overset{\text{def.}}{=} (1-\widehat{\omega}_i)^{Q_{\mathrm{A}}+1}$; then the equality

$$\mathrm{E}[Z] = \alpha_1^K \prod_{i=1}^{R} \frac{1}{\widehat{\omega}_i}(1-\gamma_i) \tag{A.4}$$

holds, where we note that $0 \le \gamma_i < 1$. From (A.4), $|G(K) - \mathrm{E}[Z]|$ satisfies

$$\begin{aligned}
|G(K) - \mathrm{E}[Z]| &= \left| \alpha_1^K \prod_{i=1}^{R} \tfrac{1}{\omega_i} - \alpha_1^K \prod_{i=1}^{R} \tfrac{1}{\widehat{\omega}_i}(1-\gamma_i) \right| \\
&= \alpha_1^K \left| \prod_{i=1}^{R} \frac{1}{\omega_i}(1-\gamma_i) + \left(\prod_{i=1}^{R} \frac{1}{\omega_i} \right) \left\{ 1 - \prod_{i=1}^{R}(1-\gamma_i) \right\} - \prod_{i=1}^{R} \frac{1}{\widehat{\omega}_i}(1-\gamma_i) \right| \\
&\le \alpha_1^K \left| \prod_{i=1}^{R} \frac{1}{\omega_i} - \prod_{i=1}^{R} \frac{1}{\widehat{\omega}_i} \right| \prod_{i=1}^{R}(1-\gamma_i) + \alpha_1^K \left(\prod_{i=1}^{R} \frac{1}{\omega_i} \right) \left\{ 1 - \prod_{i=1}^{R}(1-\gamma_i) \right\} \\
&\le \alpha_1^K \left(\prod_{i=1}^{R} \frac{1}{\omega_i} \right) \left| 1 - \prod_{i=1}^{R} \frac{\omega_i}{\widehat{\omega}_i} \right| + \alpha_1^K \left(\prod_{i=1}^{R} \frac{1}{\omega_i} \right) \left\{ 1 - \prod_{i=1}^{R}(1-\gamma_i) \right\} \\
&= G(K) \left| 1 - \prod_{i=1}^{R} \frac{\omega_i}{\widehat{\omega}_i} \right| + G(K) \left\{ 1 - \prod_{i=1}^{R}(1-\gamma_i) \right\}.
\end{aligned}$$

If $1 - \prod_{i=1}^{R}(\omega_i/\widehat{\omega}_i) \le 0$, we have that

$$\begin{aligned}
\left| 1 - \prod_{i=1}^{R} \frac{\omega_i}{\widehat{\omega}_i} \right| &= \prod_{i=1}^{R} \frac{\omega_i}{\widehat{\omega}_i} - 1 \le \left(1 + \frac{\varepsilon}{6R-\varepsilon} \right)^R - 1 = 1 + \sum_{k=1}^{R} \binom{R}{k} \left(\frac{\varepsilon}{6R-\varepsilon} \right)^k - 1 \\
&\le \sum_{k=1}^{R} \left(\frac{R}{6R-\varepsilon} \right)^k \varepsilon^k \le \varepsilon \sum_{k=1}^{R} \left(\frac{1}{5} \right)^k \le \varepsilon \sum_{k=1}^{\infty} \left(\frac{1}{5} \right)^k \le \frac{\varepsilon}{4},
\end{aligned}$$

since $R \ge 1 \ge \varepsilon$. Otherwise, $1 - \prod_{i=1}^{R}(\omega_i/\widehat{\omega}_i) > 0$ implies that

$$\left| 1 - \prod_{i=1}^{R} \frac{\omega_i}{\widehat{\omega}_i} \right| = 1 - \prod_{i=1}^{R} \frac{\omega_i}{\widehat{\omega}_i} \le 1 - \left(1 - \frac{\varepsilon}{6R-\varepsilon} \right)^R \le \left(1 + \frac{\varepsilon}{6R-\varepsilon} \right)^R - 1 \le \frac{\varepsilon}{4}.$$

Thus

$$|G(K) - \mathrm{E}[Z]| \le \frac{\varepsilon}{4} G(K) + G(K) \left\{ 1 - \prod_{i=1}^{R}(1-\gamma_i) \right\}.$$

Since $0 \le \gamma_i < 1$ $(\forall i)$, it is easy to show that $1 - \prod_{i=1}^{R}(1-\gamma_i) \le \sum_{i=1}^{R} \gamma_i$ by induction on R. Accordingly, we have

$$\begin{aligned}
1 - \prod_{i=1}^{R}(1-\gamma_i) &\le \sum_{i=1}^{R} \gamma_i = \sum_{i=1}^{R} (1-\widehat{\omega}_i)^{Q_{\mathrm{A}}+1} \le R \left\{ 1 - \left(\frac{1}{n} - \frac{\varepsilon}{6nR} \right) \right\}^{Q_{\mathrm{A}}} \\
&= R \left\{ 1 - \left(\frac{1 - \frac{\varepsilon}{6R}}{n} \right) \right\}^{Q_{\mathrm{A}}} \le R \left(1 - \frac{5}{6n} \right)^{Q_{\mathrm{A}}} \le R \left(1 - \frac{5}{6n} \right)^{144nR^2\varepsilon^{-2}\ln(2R/\delta)} \\
&\le R \left(\mathrm{e}^{-1} \right)^{\frac{5}{6n} 144nR^2\varepsilon^{-2}\ln(2R/\delta)} = \mathrm{e}^{-120R^2\varepsilon^{-2}\ln(2R/\delta)}.
\end{aligned}$$

Hence the bias is bounded as follows

$$|G(K) - \mathrm{E}[Z]| \le \frac{\varepsilon}{4} G(K) + R\mathrm{e}^{-120R^2\varepsilon^{-2}\ln(2R/\delta)} G(K)$$
$$\le G(K)\left(\frac{\varepsilon}{4} + R\mathrm{e}^{-120R^2\varepsilon^{-2}\ln(2R/\delta)}\right). \qquad \square$$

THEOREM 4.2. *Markov chain $\mathcal{M}_{\mathrm{P}}$ is monotone on the partially ordered set $(\Xi(K), \succeq)$, i.e., $\forall\lambda \in [1,n)$, $\forall X, \forall Y \in \Xi(K)$, $X \succeq Y \Rightarrow \phi(X,\lambda) \succeq \phi(Y,\lambda)$.*

Proof. We say that a state $X \in \Xi$ *covers* $Y \in \Xi$ (at j), denoted by $X \cdot\succ Y$ (or $X \cdot\succ_j Y$), when

$$X_i - Y_i = \begin{cases} +1 & (\text{for } i = j), \\ -1 & (\text{for } i = j+1), \\ 0 & (\text{otherwise}). \end{cases}$$

We show that if a pair of states $X, Y \in \Xi$ satisfies $X \cdot\succ_j Y$, then $\forall\lambda \in [1,n)$, $\phi(X,\lambda) \succeq \phi(Y,\lambda)$. We denote $\phi(X,\lambda)$ by X' and $\phi(Y,\lambda)$ by Y' for simplicity. For any index $i \neq \lfloor\lambda\rfloor$, it is easy to see that $c_X(i) = c_{X'}(i)$ and $c_Y(i) = c_{Y'}(i)$, and so $c_{X'}(i) - c_{Y'}(i) = c_X(i) - c_Y(i) \ge 0$ since $X \succeq Y$. In the following, we show that $c_{X'}(\lfloor\lambda\rfloor) \ge c_{Y'}(\lfloor\lambda\rfloor)$.

Case 1. In the case that $\lfloor\lambda\rfloor \neq j-1$ and $\lfloor\lambda\rfloor \neq j+1$, if we put $k = X_{\lfloor\lambda\rfloor} + X_{\lfloor\lambda\rfloor+1}$, then it is easy to see that $Y_{\lfloor\lambda\rfloor} + Y_{\lfloor\lambda\rfloor+1} = k$. Accordingly, $X'_{\lfloor\lambda\rfloor} = Y'_{\lfloor\lambda\rfloor} = l$, where l satisfies

$$g^k_{\lfloor\lambda\rfloor(\lfloor\lambda\rfloor+1)}(l-1) \le \lambda - \lfloor\lambda\rfloor < g^k_{\lfloor\lambda\rfloor(\lfloor\lambda\rfloor+1)}(l),$$

and hence $c_{X'}(\lfloor\lambda\rfloor) = c_{Y'}(\lfloor\lambda\rfloor)$.

Case 2. Consider the case that $\lfloor\lambda\rfloor = j-1$. Let $k+1 = X_{j-1} + X_j$. Then $Y_{j-1} + Y_j = k$, since $X \cdot\succ_j Y$. From the definition of the cumulative sum vector,

$$\begin{aligned} c_{X'}(\lfloor\lambda\rfloor) - c_{Y'}(\lfloor\lambda\rfloor) &= c_{X'}(j-1) - c_{Y'}(j-1) \\ &= c_{X'}(j-2) + X'_{j-1} - c_{Y'}(j-2) - Y'_{j-1} \\ &= c_X(j-2) + X'_{j-1} - c_Y(j-2) - Y'_{j-1} \\ &= X'_{j-1} - Y'_{j-1}. \end{aligned}$$

Thus, it is enough to show that $X'_{j-1} \ge Y'_{j-1}$. Now suppose that $l \in \{0,1,\ldots,k\}$ satisfies $g^k_{(j-1)j}(l-1) \le \lambda - \lfloor\lambda\rfloor < g^k_{(j-1)j}(l)$ for λ. Then $g^{k+1}_{(j-1)j}(l-1) \le \lambda - \lfloor\lambda\rfloor < g^{k+1}_{(j-1)j}(l+1)$, since the alternating inequalities imply that $g^{k+1}_{(j-1)j}(l-1) \le g^k_{(j-1)j}(l-1) < g^{k+1}_{(j-1)j}(l) \le g^{k+1}_{(j-1)j}(l+1)$. Thus we have that if $Y'_{j-1} = l$, then $X'_{j-1} = l$ or $l+1$. In other words,

$$\begin{pmatrix} X'_{j-1} \\ Y'_{j-1} \end{pmatrix} \in \left\{ \begin{pmatrix} 0 \\ 0 \end{pmatrix}, \begin{pmatrix} 1 \\ 0 \end{pmatrix}, \begin{pmatrix} 1 \\ 1 \end{pmatrix}, \begin{pmatrix} 2 \\ 1 \end{pmatrix}, \ldots, \begin{pmatrix} k \\ k \end{pmatrix}, \begin{pmatrix} k+1 \\ k \end{pmatrix} \right\}$$

and $X'_{j-1} \ge Y'_{j-1}$ in all cases. Accordingly, we have that $c_{X'}(\lfloor\lambda\rfloor) \ge c_{Y'}(\lfloor\lambda\rfloor)$.

Case 3. Consider the case that $\lfloor\lambda\rfloor = j+1$. We can show $c_{X'}(\lfloor\lambda\rfloor) \ge c_{Y'}(\lfloor\lambda\rfloor)$ in a similar way to Case 2.

For any pair of states X, Y satisfying $X \succeq Y$, it is easy to see that there exists a sequence of states $Z_1, Z_2, \ldots, Z_r$ with appropriate length satisfying $X = Z_1 \cdot\succ Z_2 \cdot\succ \cdots \cdot\succ Z_r = Y$. Then applying the above claim repeatedly, we obtain that $\phi(X,\lambda) = \phi(Z_1,\lambda) \succeq \phi(Z_2,\lambda) \succeq \cdots \succeq \phi(Z_r,\lambda) = \phi(Y,\lambda)$. $\square$

THEOREM 4.3. *Under Condition* 2*, the expected running time of our perfect sampler is bounded by* $\mathrm{O}(n^3 \ln K)$*, where* n *is the number of nodes and* K *is the number of customers in a closed Jackson network.*

To show the above theorem, we need the following three lemmas.

LEMMA A.1. *Under Condition* 2*, the mixing rate* τ*, defined by* $\tau \stackrel{\text{def.}}{=} \tau(1/\mathrm{e})$*, of our Markov chain* $\mathcal{M}_{\mathrm{P}}$ *satisfies*

$$\tau \le n(n-1)^2(1+\ln Kn).$$

Proof. Let $G = (\Xi, \mathcal{E})$ be an undirected simple graph with vertex set Ξ and edge set $\mathcal{E}$ defined as follows. A pair of vertices $\{X, Y\}$ is an edge if and only if $(1/2)\sum_{i=1}^{n} |X_i - Y_i| = 1$. Clearly, the graph G is connected. For each edge $e = \{X, Y\} \in \mathcal{E}$, there exists a unique pair of indices $j_1, j_2 \in \{1, \dots, n\}$, called a *supporting pair* of e, satisfying

$$|X_i - Y_i| = \begin{cases} 1 & (i \in \{j_1, j_2\}), \\ 0 & (\text{otherwise}). \end{cases}$$

We define the length $l_{\mathrm{P}}(e)$ of an edge $e = \{X, Y\} \in \mathcal{E}$ by $l_{\mathrm{P}}(e) \stackrel{\text{def.}}{=} (1/(n-1)) \sum_{i=1}^{j^*-1} (n-i)$, where $j^* = \max\{j_1, j_2\} \ge 2$ and $\{j_1, j_2\}$ is the supporting pair of e. Note that $1 \le \min_{e \in \mathcal{E}} l_{\mathrm{P}}(e) \le \max_{e \in \mathcal{E}} l_{\mathrm{P}}(e) \le n/2$. For each pair $X, Y \in \Xi$, we define the distance $d(X, Y)$ to be the length of a shortest path between X and Y on G. Clearly, the diameter of G, i.e., $\max_{(X,Y) \in \Xi^2} d(X, Y)$, is bounded by $Kn/2$, since $d(X, Y) \le (n/2)\sum_{i=1}^{n} (1/2)|X_i - Y_i| \le (n/2)K$ for any $(X, Y) \in \Xi^2$. The definition of edge length implies that for any edge $\{X, Y\} \in \mathcal{E}$, $d(X, Y) = l_{\mathrm{P}}(\{X, Y\})$.

We define a joint process $(X, Y) \to (X', Y')$ as $(X, Y) \to (\phi(X, \Lambda), \phi(Y, \Lambda))$ with a uniform real random number $\Lambda \in [1, n)$ and the update function ϕ defined in subsection 3.2. Now we show that

$$\mathrm{E}[d(X', Y')] \le \beta \cdot d(X, Y), \text{ where } \beta = 1 - 1/(n(n-1)^2), \tag{A.5}$$

for any pair $\{X, Y\} \in \mathcal{E}$. In the following, we denote the supporting pair of $\{X, Y\}$ by $\{j_1, j_2\}$. Without loss of generality, we can assume that $j_1 < j_2$ and $X_{j_2} + 1 = Y_{j_2}$.

Case 1. When $\lfloor \Lambda \rfloor = j_2 - 1$, we will show that

$$\mathrm{E}[d(X', Y') \mid \lfloor \Lambda \rfloor = j_2 - 1] \le d(X, Y) - (1/2)(n - j_2 + 1)/(n-1).$$

In the case $j_1 = j_2 - 1$, $X' = Y'$ with conditional probability 1. Hence $d(X', Y') = 0$. In the following, we consider the case $j_1 < j_2 - 1$. Put $k' = X_{j_2-1} + X_{j_2}$ and $k'' = Y_{j_2-1} + Y_{j_2}$. Since $X_{j_2} + 1 = Y_{j_2}$, $k' + 1 = k''$ holds. From the definition of the update function of our Markov chain, we have the following:

$$\begin{aligned} X'_{j_2-1} = l &\Leftrightarrow [g^{k'}_{(j_2-1)j_2}(l-1) \le \Lambda - \lfloor \Lambda \rfloor < g^{k'}_{(j_2-1)j_2}(l)], \\ Y'_{j_2-1} = l &\Leftrightarrow [g^{k'+1}_{(j_2-1)j_2}(l-1) \le \Lambda - \lfloor \Lambda \rfloor < g^{k'+1}_{(j_2-1)j_2}(l)]. \end{aligned}$$

Now, the alternating inequalities

$$\begin{aligned} 0 &< g^{k'+1}_{(j_2-1)j_2}(0) = g^{k'}_{(j_2-1)j_2}(0) \le g^{k'+1}_{(j_2-1)j_2}(1) \le g^{k'}_{(j_2-1)j_2}(1) \le \cdots \\ &\le g^{k'+1}_{(j_2-1)j_2}(k') \le g^{k'}_{(j_2-1)j_2}(k') = g^{k'+1}_{(j_2-1)j_2}(k'+1) = 1 \end{aligned}$$

hold. Thus we have

$$\begin{pmatrix} X'_{j_2-1} \\ Y'_{j_2-1} \end{pmatrix} \in \left\{ \begin{pmatrix} 0 \\ 0 \end{pmatrix}, \begin{pmatrix} 0 \\ 1 \end{pmatrix}, \begin{pmatrix} 1 \\ 1 \end{pmatrix}, \begin{pmatrix} 1 \\ 2 \end{pmatrix}, \ldots, \begin{pmatrix} k' \\ k' \end{pmatrix}, \begin{pmatrix} k' \\ k'+1 \end{pmatrix} \right\}.$$

If $X'_{j_2-1} = Y'_{j_2-1}$, the supporting pair of $\{X', Y'\}$ is $\{j_1, j_2\}$ and so $d(X', Y') = d(X, Y)$. If $X'_{j_2-1} \neq Y'_{j_2-1}$, the supporting pair of $\{X', Y'\}$ is $\{j_1, j_2 - 1\}$ and so $d(X', Y') = d(X, Y) - (n - j_2 + 1)/(n-1)$.

Lemma A.2 (proved later) implies that if $\alpha_{j_2-1} \geq \alpha_{j_2}$, then

$$\begin{aligned} &\Pr[X'_{j_2-1} \neq Y'_{j_2-1} \mid \lfloor \Lambda \rfloor = j_2 - 1] - \Pr[X'_{j_2-1} = Y'_{j_2-1} \mid \lfloor \Lambda \rfloor = j_2 - 1] \\ &= \sum_{l=0}^{k'} \left(g^{k'}_{(j_2-1),j_2}(l) - g^{k'+1}_{(j_2-1),j_2}(l) \right) \\ &\quad - \sum_{l=1}^{k'} \left(g^{k'+1}_{(j_2-1),j_2}(l) - g^{k'}_{(j_2-1),j_2}(l-1) \right) - g^{k'+1}_{(j_2-1),j_2}(0) \geq 0. \end{aligned}$$

Hence

$$\begin{aligned} \Pr[X'_{j_2-1} = Y'_{j_2-1} \mid \lfloor \Lambda \rfloor = j_2 - 1] &\leq (1/2), \\ \Pr[X'_{j_2-1} \neq Y'_{j_2-1} \mid \lfloor \Lambda \rfloor = j_2 - 1] &\geq (1/2). \end{aligned}$$

Thus we obtain that

$$\begin{aligned} \mathrm{E}[d(X', Y') | \lfloor \Lambda \rfloor = j_2 - 1] &\leq (1/2) d(X, Y) + (1/2)(d(X, Y) - (n - j_2 + 1)/(n-1)) \\ &= d(X, Y) - (1/2)(n - j_2 + 1)/(n-1). \end{aligned}$$

Case 2. When $\lfloor \Lambda \rfloor = j_2$, we can show that $\mathrm{E}[d(X', Y') | \lfloor \Lambda \rfloor = j_2] \leq d(X, Y) + (1/2)(n - j_2)/(n-1)$ in a similar way to Case 1.

Case 3. When $\lfloor \Lambda \rfloor \neq j_2 - 1$ and $\lfloor \Lambda \rfloor \neq j_2$, it is easy to see that the supporting pair $\{j'_1, j'_2\}$ of $\{X', Y'\}$ satisfies $j_2 = \max\{j'_1, j'_2\}$. Thus $d(X, Y) = d(X', Y')$.

The probability of appearance of Case 1 is equal to $1/(n-1)$, and that of Case 2 is less than or equal to $1/(n-1)$. From the above,

$$\begin{aligned} \mathrm{E}[d(X', Y')] &\leq d(X, Y) - \frac{1}{n-1} \cdot \frac{1}{2} \cdot \frac{n - j_2 + 1}{n-1} + \frac{1}{n-1} \cdot \frac{1}{2} \cdot \frac{n - j_2}{n-1} \\ &= d(X, Y) - \frac{1}{2(n-1)^2} \\ &\leq \left(1 - \frac{1}{2(n-1)^2} \cdot \frac{1}{\max_{\{X,Y\} \in \mathcal{E}} \{d(X, Y)\}} \right) d(X, Y) \\ &= \left(1 - \frac{1}{n(n-1)^2} \right) d(X, Y). \end{aligned}$$

Since the diameter of G is bounded by $Kn/2$, Theorem 3.3 implies that the mixing rate τ satisfies $\tau \leq n(n-1)^2(1 + \ln(Kn/2))$. □

Lemma A.2. *When $\alpha_i \geq \alpha_j > 0$, the inequality*

$$\sum_{l=0}^{k} \left(g^k_{ij}(l) - g^{k+1}_{ij}(l) \right) - \sum_{l=1}^{k} \left(g^{k+1}_{ij}(l) - g^k_{ij}(l-1) \right) - g^{k+1}_{ij}(0) \geq 0$$

holds.

Proof. We can transform the left-hand side as

$$\begin{aligned}
&\sum_{l=0}^{k}\left(g_{ij}^{k}(l)-g_{ij}^{k+1}(l)\right)-\sum_{l=1}^{k}\left(g_{ij}^{k+1}(l)-g_{ij}^{k}(l-1)\right)-g_{ij}^{k+1}(0)\\
&=\sum_{l=0}^{k}\left(g_{ij}^{k}(l)-g_{ij}^{k+1}(l)\right)-\sum_{l=0}^{k-1}\left(g_{ij}^{k+1}(k-l)-g_{ij}^{k}(k-l-1)\right)-g_{ij}^{k+1}(0)\\
&=\sum_{l=0}^{k-1}\left(g_{ij}^{k}(l)-g_{ij}^{k+1}(l)-g_{ij}^{k+1}(k-l)+g_{ij}^{k}(k-l-1)\right)+1-g_{ij}^{k+1}(k)-g_{ij}^{k+1}(0),
\end{aligned}$$

and we can see that

$$\begin{aligned}
1-g_{ij}^{k+1}(k)-g_{ij}^{k+1}(0)&=1-\frac{\sum_{s=0}^{k}\alpha_i^s\alpha_j^{k+1-s}}{\sum_{s=0}^{k+1}\alpha_i^s\alpha_j^{k+1-s}}-\frac{\sum_{s=0}^{0}\alpha_i^s\alpha_j^{k+1-s}}{\sum_{s=0}^{k+1}\alpha_i^s\alpha_j^{k+1-s}}\\
&=\frac{\alpha_i^{k+1}}{\sum_{s=0}^{k+1}\alpha_i^s\alpha_j^{k+1-s}}-\frac{\alpha_j^{k+1}}{\sum_{s=0}^{k+1}\alpha_i^s\alpha_j^{k+1-s}}\geq 0,
\end{aligned}$$

since $\alpha_i \geq \alpha_j$ (Condition 2). Thus it is sufficient to show that

$$g_{ij}^{k}(l)-g_{ij}^{k+1}(l)-g_{ij}^{k+1}(k-l)+g_{ij}^{k}(k-l-1)\geq 0 \quad \text{for any } l\ (0\leq l\leq k-1).$$

By transforming the left-hand side, we can see that

$$\begin{aligned}
&g_{ij}^{k}(l)-g_{ij}^{k+1}(l)-g_{ij}^{k+1}(k-l)+g_{ij}^{k}(k-l-1)\\
&=g_{ij}^{k}(l)-g_{ij}^{k+1}(l)-\frac{\sum_{s=0}^{k-l}\alpha_i^s\alpha_j^{k+1-s}}{\sum_{s=0}^{k+1}\alpha_i^s\alpha_j^{k+1-s}}+\frac{\sum_{s=0}^{k-l-1}\alpha_i^s\alpha_j^{k-s}}{\sum_{s=0}^{k}\alpha_i^s\alpha_j^{k-s}}\\
&=g_{ij}^{k}(l)-g_{ij}^{k+1}(l)-\left(1-\frac{\sum_{s=k-l+1}^{k+1}\alpha_i^s\alpha_j^{k+1-s}}{\sum_{s=0}^{k+1}\alpha_i^s\alpha_j^{k+1-s}}\right)+\left(1-\frac{\sum_{s=k-l}^{k}\alpha_i^s\alpha_j^{k-s}}{\sum_{s=0}^{k}\alpha_i^s\alpha_j^{k-s}}\right)\\
&=\frac{\sum_{s=0}^{l}\alpha_i^s\alpha_j^{k-s}}{A_{ij}^{k}}-\frac{\sum_{s=0}^{l}\alpha_i^s\alpha_j^{k+1-s}}{A_{ij}^{k+1}}+\frac{\sum_{s=k-l+1}^{k+1}\alpha_i^s\alpha_j^{k+1-s}}{A_{ij}^{k+1}}-\frac{\sum_{s=k-l}^{k}\alpha_i^s\alpha_j^{k-s}}{A_{ij}^{k}}\\
&=\frac{\sum_{s=0}^{l}\alpha_i^s\alpha_j^{k-s}}{A_{ij}^{k}}-\frac{\sum_{s=0}^{l}\alpha_i^s\alpha_j^{k+1-s}}{A_{ij}^{k+1}}+\frac{\sum_{s=0}^{l}\alpha_i^{k+1-s}\alpha_j^s}{A_{ij}^{k+1}}-\frac{\sum_{s=0}^{l}\alpha_i^{k-s}\alpha_j^s}{A_{ij}^{k}}\\
&=\left(\frac{1}{A_{ij}^{k}}-\frac{\alpha_j}{A_{ij}^{k+1}}\right)\sum_{s=0}^{l}\alpha_i^s\alpha_j^{k-s}+\left(\frac{\alpha_i}{A_{ij}^{k+1}}-\frac{1}{A_{ij}^{k}}\right)\sum_{s=0}^{l}\alpha_i^{k-s}\alpha_j^s\\
&=\frac{\sum_{s=0}^{l}\alpha_i^s\alpha_j^{k-s}}{A_{ij}^{k}A_{ij}^{k+1}}\left(\sum_{s=0}^{k+1}\alpha_i^s\alpha_j^{k+1-s}-\sum_{s=0}^{k}\alpha_i^s\alpha_j^{k+1-s}\right)\\
&\quad+\frac{\sum_{s=0}^{l}\alpha_i^{k-s}\alpha_j^s}{A_{ij}^{k}A_{ij}^{k+1}}\left(\sum_{s=1}^{k+1}\alpha_i^s\alpha_j^{k+1-s}-\sum_{s=0}^{k+1}\alpha_i^s\alpha_j^{k+1-s}\right)\\
&=\frac{1}{A_{ij}^{k}A_{ij}^{k+1}}\left(\alpha_i^{k+1}\sum_{s=0}^{l}\alpha_i^s\alpha_j^{k-s}-\alpha_j^{k+1}\sum_{s=0}^{l}\alpha_i^{k-s}\alpha_j^s\right)
\end{aligned}$$

$$= \frac{1}{A_{ij}^k A_{ij}^{k+1}} \sum_{s=0}^{l} \left(\alpha_i^{k+1+s} \alpha_j^{k-s} - \alpha_i^{k-s} \alpha_j^{k+1+s} \right)$$
$$= \frac{1}{A_{ij}^k A_{ij}^{k+1}} \sum_{s=0}^{l} \left(\alpha_i^{k-s} \alpha_j^{k-s} \left(\alpha_i^{2s+1} - \alpha_j^{2s+1} \right) \right) \geq 0,$$

since $\alpha_i \geq \alpha_j$ (Condition 2). Thus we obtain the claim. ∎

Next we estimate the expectation of the coalescence time of $\mathcal{M}_{\mathrm{P}}$.

LEMMA A.3. *Under Condition* 2*, the coalescence time* T_* *of* $\mathcal{M}_{\mathrm{P}}$ *satisfies* $\mathrm{E}[T_*] = \mathrm{O}(n^3 \ln Kn)$.

Proof. Let $G = (\Xi, \mathcal{E})$ be the undirected graph and $d(X, Y)$ $\forall X, \forall Y \in \Xi$ be the metric on G, both of which are defined in the proof of Lemma A.1. We define $D \stackrel{\text{def.}}{=} d(x_{\max}, x_{\min})$ and $\tau_0 \stackrel{\text{def.}}{=} n(n-1)^2(1 + \ln D)$. By using inequality (A.5) obtained in the proof of Lemma A.1, we have

$$\begin{aligned}
\Pr[T_* > \tau_0] &= \Pr\left[\Phi_{-\tau_0}^0(x_{\max}, \mathbf{\Lambda}) \neq \Phi_{-\tau_0}^0(x_{\min}, \mathbf{\Lambda})\right] = \Pr\left[\Phi_0^{\tau_0}(x_{\max}, \mathbf{\Lambda}) \neq \Phi_0^{\tau_0}(x_{\min}, \mathbf{\Lambda})\right] \\
&\leq \sum_{(X,Y) \in \Xi^2} d(X, Y) \Pr\left[X = \Phi_0^{\tau_0}(x_{\max}, \mathbf{\Lambda}), Y = \Phi_0^{\tau_0}(x_{\min}, \mathbf{\Lambda})\right] \\
&= \mathrm{E}\left[d\left(\Phi_0^{\tau_0}(x_{\max}, \mathbf{\Lambda}), \Phi_0^{\tau_0}(x_{\min}, \mathbf{\Lambda})\right)\right] \leq \left(1 - \frac{1}{n(n-1)^2}\right)^{\tau_0} d(x_{\max}, x_{\min}) \\
&= \left(1 - \frac{1}{n(n-1)^2}\right)^{n(n-1)^2(1+\ln D)} D \leq \mathrm{e}^{-1} \mathrm{e}^{-\ln D} D = \frac{1}{\mathrm{e}}.
\end{aligned}$$

By the *submultiplicativity* of coalescence time (see [24]), for any $k \in \mathbb{Z}_+$, the inequality $\Pr[T_* > k\tau_0] \leq (\Pr[T_* > \tau_0])^k \leq (1/\mathrm{e})^k$ holds. Thus

$$\begin{aligned}
\mathrm{E}[T_*] &= \sum_{t=0}^{\infty} t \Pr[T_* = t] \leq \tau_0 + \tau_0 \Pr[T_* > \tau_0] + \tau_0 \Pr[T_* > 2\tau_0] + \cdots \\
&\leq \tau_0 + \tau_0/\mathrm{e} + \tau_0/\mathrm{e}^2 + \cdots = \tau_0/(1 - 1/\mathrm{e}) \leq 2\tau_0.
\end{aligned}$$

Clearly $D \leq Kn$. Then we obtain the result that $\mathrm{E}[T_*] = \mathrm{O}(n^3 \ln Kn)$. ∎

Proof of Theorem 4.3. Let T_* be the coalescence time of our chain. Clearly T_* is a random variable. Put $m = \lceil \log_2 T_* \rceil$. Algorithm 2 terminates when we set the starting time period $T = -2^m$ to the $(m+1)$st iteration. Then the total number of simulated transitions is bounded by $2(2^0 + 2^1 + 2^2 + \cdots + 2^K) < 2 \cdot 2 \cdot 2^m \leq 8T_*$, since we need to execute two chains from both $x_{\max}$ and $x_{\min}$. Thus the expectation of total number of transitions of $\mathcal{M}$ is bounded by $\mathrm{O}(\mathrm{E}[8T_*]) = \mathrm{O}(n^3 \ln(Kn))$. ∎

APPROXIMATION ALGORITHMS FOR BICLUSTERING PROBLEMS*

LUSHENG WANG†, YU LIN‡, AND XIAOWEN LIU†

Abstract. One of the main goals in the analysis of microarray data is to identify groups of genes and groups of experimental conditions (including environments, individuals, and tissues) that exhibit similar expression patterns. This is the so-called biclustering problem. In this paper, we consider two variations of the biclustering problem: the *consensus submatrix problem* and the *bottleneck submatrix problem*. The input of the problems contains an $m \times n$ matrix A and integers l and k. The *consensus submatrix problem* is to find an $l \times k$ submatrix with $l < m$ and $k < n$ and a consensus vector such that the sum of distances between the rows in the submatrix and the consensus vector is minimized. The *bottleneck submatrix problem* is to find an $l \times k$ submatrix with $l < m$ and $k < n$, an integer d and a center vector such that the distance between every row in the submatrix and the vector is at most d and d is minimized. We show that both problems are NP-hard and give randomized approximation algorithms for special cases of the two problems. Using standard techniques, we can derandomize the algorithms to get polynomial time approximation schemes for the two problems. To the best of our knowledge, this is the first time that approximation algorithms with guaranteed ratios are presented for microarray data analysis.

1. Introduction.

In the past few years, microarray techniques have been widely used in biological research. Microarray techniques have helped to illuminate mechanisms of diseases, identify disease subphenotypes, predict disease progression, assign functions to previously unannotated genes, group genes into functional pathways, and predict activities of new compounds [1]. Microarray data analysis is an important problem in computational biology [2]. For this large-scale data, classifying genes into different groups under certain conditions is a first step to gain more sophisticated knowledge of different biological pathways or functions. Several clustering or classification techniques such as k-means [3, 4], self-organizing maps [5, 6], hierarchical clustering [7, 8, 9], principal component analysis, and singular value decomposition [10, 11, 12] have been extensively applied to identify groups of similarly expressed genes and conditions from gene expression data.

It is known that many activation patterns are common to a group of genes only under specific experimental conditions. We should expect subsets of genes to be coregulated and coexpressed only under certain experimental conditions, but to behave almost independently under other conditions, according to our general understanding of cellular processes [22, 23, 24]. The fact is that we need to discover local patterns in the microarray matrix. The basic model for biclustering is as follows: given an

$m \times n$ matrix A, where each element $a_{i,j} \in \{0, 1\}$, the problem here is to find an $l \times k$ submatrix with all elements identical to 1 such that $l \times k$ is maximized.

Let $\Sigma = \{\pi_1, \pi_2, \ldots, \pi_{|\Sigma|}\}$ be a fixed size alphabet of symbols. A vector over Σ is a sequence of symbols in Σ. Let A be an $m \times n$ matrix, where each row corresponds to a gene and each column corresponds to a condition. Each element $a_{i,j}$ in A represents the expression level of gene i under condition j. Such a matrix A is defined by its set of m rows, $X = \{x_1, x_2, \ldots, x_m\}$, and its set of n columns, $Y = \{y_1, y_2, \ldots, y_n\}$. Let $P = \{p_1, \ldots, p_l\}$ be a subset of $\{1, 2, \ldots, m\}$ indicating rows in X and $Q = \{q_1, \ldots, q_k\}$ be a subset of $\{1, 2, \ldots, n\}$ indicating columns in Y. The $l \times k$ submatrix $A_{P,Q}$ induced by the pair (P, Q) contains the elements $a_{i,j}$, where $i \in P$ and $j \in Q$. We treat each row in the matrix or submatrix as a vector over Σ. Define $x_i|^Q = a_{i,q_1} a_{i,q_2} \ldots a_{i,q_k}$. Let p and p' be two vectors of the same length over Σ. We use $d(p, p')$ to denote the number of mismatches between the two vectors. Throughout this paper, we will study the following two problems:

1. *The consensus submatrix problem*: Given an $m \times n$ matrix A, and integers l and k, find a subset P of l rows, a subset Q of k columns in matrix A, and a consensus vector z of length k such that the consensus score $\sum_{i=1}^{l} d(x_{p_i}|^Q, z)$ is minimized.
2. *The bottleneck submatrix problem*: Given an $m \times n$ matrix A, and integers l and k, find a subset P of l rows, a subset Q of k, columns in matrix A, a center vector z of length k, and an integer d such that for every $p_i \in P$, $d(x_{p_i}|^Q, z) \leq d$ and the bottleneck score d is minimized.

In some applications, the number of conditions/samples ranges from 50 to 550 and the number of genes is about a few thousand. The interesting submatrices (biclusters) may contain tens of conditions/samples. In this case, we have $k = \Omega(n)$. In practice, there are errors in the microarray data. In [22, 29], the input matrix contains 12.3% missing values (see Data Preparation in [22]). In the $l \times k$ submatrix, if we assume that 12.3% values are missing, then the total consensus score $\sum_{i=1}^{l} d(x_{p_i}|^Q, z)$ is $\Omega(lk)$ and the bottleneck score d is $\Omega(k)$. Moreover, the expression levels of coregulated and coexpressed genes in the submatrices are not 100% numerically identical. Therefore, in some cases we can assume that for the consensus submatrix problem $\sum_{i=1}^{l} d(x_{p_i}|^Q, z) = \Omega(lk)$ and for the bottleneck submatrix problem $d = \Omega(k)$.

Throughout this paper, we assume that for the consensus submatrix problem $\sum_{i=1}^{l} d(x_{p_i}|^Q, z) = \Omega(lk)$ and for the bottleneck submatrix problem $d = \Omega(k)$. Moreover, we further assume that $k = \Omega(n)$.

1.1. Real examples. Here we present a few real examples to show that our assumptions on d and k are reasonable in some real applications.

Example 1. The first paper using the biclustering approach for microarray data analysis is [22]. In this paper, the authors analyze the human data originated from [29]. There are $4,026$ genes and 96 conditions with 12.3% missing values in the input matrix. (For more on microarray data errors, see [13, 14, 15, 16, 17, 18, 19, 20].) For the interesting submatrices, the number of conditions ranges from 13 to 96 (most of them > 20). (See the caption of Figure 5 in [22].) Here the assumption that $k = \Omega(n)$ does hold. Moreover, with 12.3% missing values (thus $\sum_{i=1}^{l} d(x_{p_i}|^Q, z) = \Omega(lk)$ and $d = \Omega(k)$), they can still find some biologically interesting submatrices.

Example 2. Koyutürk, Szpankowski, and Grama study a dataset containing 84 samples for human breast cancer [28]. They obtain a biologically interesting submatrix containing 62 samples and 141 genes. Figure 1 shows the submatrix after binary quantization. From Figure 1, we can see that in the gray (red in the color version)

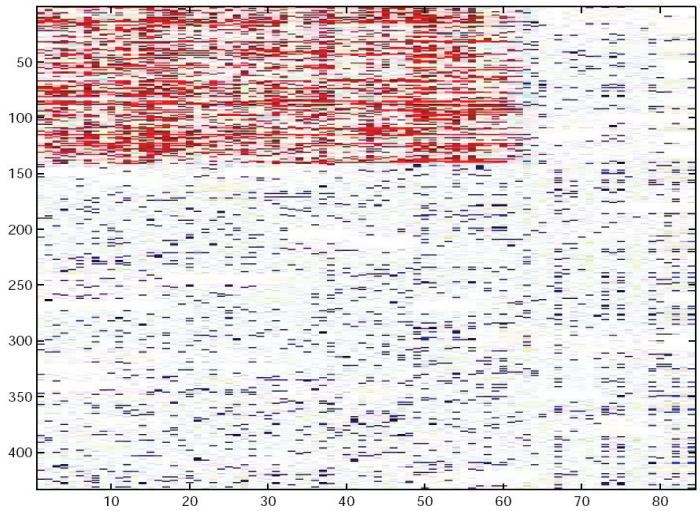

FIG. 1. *The interesting submatrix originally from* [*M. Koyutürk, W. Szpankowski, and A. Grama, Biclustering gene-feature matrices for statistically significant dense patterns, in Proceedings of the* 2004 *Annual IEEE Bioinformatics Conference,* 2004*, pp.* 480–484]. ©2004 *IEEE.*

submatrix, there are still quite a lot of dark and white (blue and white in the color version) dots indicating that the expression levels of genes are not completely identical. (This may be caused by the performance of genes or by data errors.) Based on Figure 1, it is easy to see that there are at least 10% errors. Again, this example shows that our assumptions on d and k are reasonable in some applications.

1.2. Relations to previous work. The basic model for biclustering is to find a submatrix $A_{P,Q}$ with all elements identical to a constant value [23]:

$$a_{i,j} = \mu \quad \text{for all} \quad i \in P, j \in Q.$$

If the submatrix is error free, both the consensus score and the bottleneck score are clearly 0 for the new problems that we propose in the paper.

In practice, it is interesting to find submatrices such that all elements in a row have the same constant value [21, 24]. That is,

$$a_{i,j} = c_i \text{ for } \quad j \in Q.$$

In this case, all the columns in the submatrix are identical. Again, it is clear that both the consensus score and the bottleneck score are 0 if the submatrix is error-free.

For the additive model [22, 23], we are interested in submatrices satisfying

$$a_{i,j} = a_{i',j} + c(i,i') \quad \text{for all} \quad i,i' \in P, \quad j \in Q. \tag{1}$$

That is, for two elements $a_{i,j}$ and $a_{i',j}$ in row i and row i', the difference is a constant $c(i',i)$.

Now we will show that our model can also handle the additive model. Let r be a row in the error-free submatrix. We construct a new matrix A' as follows:

$$a'_{i,j} = a_{i,j} - a_{r,j} \quad \text{for all} \quad i \in X, \quad j \in Y.$$

Then, the error-free submatrix is converted into a new submatrix $A'_{P,Q}$ with the element

$$\begin{aligned} a'_{i,j} &= a_{i,j} - a_{r,j} \\ &= c(i,r) \quad \text{for all} \;\; i \in P, \;\; j \in Q. \end{aligned}$$

That is, in the resulting submatrix, all elements in a row have the same value. Thus, the additive model degenerates to the second case. Therefore, our models can also handle the additive model by trying all rows in A as row r.

Cheng and Church were the first to use the biclustering approach for microarray data analysis [22]. They introduced the *mean squared residue score* H to measure the coherence of the rows and columns in the submatrix.

$$H(P,Q) = \frac{1}{|P||Q|} \sum_{i \in P, j \in Q} (a_{i,j} - a_{i,Q} - a_{P,j} + a_{P,Q})^2,$$

where

$$a_{i,Q} = \frac{1}{|Q|} \sum_{j \in Q} a_{i,j}, \quad a_{P,j} = \frac{1}{|P|} \sum_{i \in P} a_{i,j}, \quad \text{and} \quad a_{P,Q} = \frac{1}{|P||Q|} \sum_{i \in P, j \in Q} (a_{i,j}).$$

Clearly, the H score is 0 for the first two cases if the submatrix is error free. We can show that for the additive model, the H score is also 0 if the submatrix is error free.

In this paper, we design randomized approximation algorithms for both problems. We have a new idea to randomly select $\Theta(\log m)$ columns in the optimal set of columns $Q_{opt} \subseteq Y$ when Q_{opt} is not known. For the bottleneck submatrix problem, we use linear programming and randomized rounding to successfully select a good approximation Q of Q_{opt} and set the letters for the center vector at the columns in Q. Using standard techniques, we can derandomize the randomized algorithms to get polynomial time approximation schemes (PTAS) for the two problems. To the best of our knowledge, this is the first time that approximation algorithms with guaranteed ratios have been presented for microarray analysis.

The paper is organized as follows. In section 2, we prove that both problems are NP-hard. In section 3, we give the algorithm for the consensus submatrix problem. The algorithm for the bottleneck submatrix problem is given in section 4.

2. NP-hardness result. In this section, we will show that both the consensus submatrix problem and the bottleneck submatrix problem are NP-hard. The reduction is from the maximum edge biclique problem. The maximum edge biclique problem was proved to be NP-hard in [25]. A biclique is a complete bipartite subgraph, where every vertex of the first set is connected to every vertex of the second set.

The maximum edge biclique problem. Given a bipartite graph $G = (V_1 \cup V_2, E)$ and a positive integer t, does G contain a biclique with t edges?

THEOREM 1. *The consensus submatrix problem and the bottleneck submatrix problem are NP-hard.*

Proof. We use a reduction from the maximum edge biclique problem. Given a graph $G = (V_1 \cup V_2, E)$ and a positive integer t, where $|V_1| = m$, $|V_2| = n$, we construct an $m \times n$ matrix $A = \{a_{i,j}\}$ as follows: $a_{i,j} = 1$ if and only if $(v_1(i), v_2(j)) \in E$, and otherwise $a_{i,j} = 0$. After constructing A, we get a new matrix A' of size $2m \times n$ by

adding m rows, each containing n 1's, to A. Thus, for an element $a'_{i,j}$ in A', $a'_{i,j} = a_{i,j}$ if $1 \leq i \leq m$. Otherwise, $a'_{i,j} = 1$. (Here we need A' to ensure that every element in the consensus/center vector is 1.)

The input of both the consensus submatrix and the bottleneck submatrix problems contains the matrix A' and two integers $l+m$ and k with $t = l \times k$. The number of pairs for l and k is at most t^2.

It is easy to see that there exists an $l \times k$ biclique for the maximum edge biclique problem if and only if there is a size $l \times k$ submatrix of A in which every element is 1.

Now, we want to show that there is an $l \times k$ submatrix of A such that every element is 1 if and only if there is an $(l+m) \times k$ submatrix of A' such that every element is 1.

(if) Given an $l \times k$ submatrix of A such that every element is 1, we can obtain an $(l+m) \times k$ submatrix of A' such that every element is 1 by adding the m newly added rows with every element being 1 in A'.

(only if) Consider an $(l+m) \times k$ submatrix of A' such that every element is 1. There are at least l rows in the $(l+m) \times k$ submatrix that are also in A since there are m newly added rows in A'. Thus, we can select l rows in the $(l+m) \times k$ submatrix that are also in A. In this way, we get an $l \times k$ submatrix of A such that every element is 1.

Obviously, every element in the $(l+m) \times k$ submatrix of A' is 1 if and only if both the consensus score and the bottleneck score for the submatrix are 0 and every element in the consensus/center vector is 1. □

The proof also suggests that it is NP-hard to decide whether the score is 0 in both problems. Therefore, there is no approximation algorithm with *any* guaranteed ratio for both problems when the optimal score is 0.

3. The consensus submatrix problem. In this section, we will present the randomized approximation algorithm for the consensus submatrix problem. Let P_{opt}, Q_{opt}, and z_{opt} be the set of rows, the set of columns, and the consensus vector of an optimal solution. The optimal consensus score is H_{opt}. By assumption, $H_{opt} = \Omega(kl)$, i.e., there is a constant c' such that $H_{opt} \times c' = kl$. Again, by assumption, $k = \Omega(n)$, i.e., there is a constant c such that $k \times c = n$.

Before we present the algorithm, we first introduce the basic ideas of the algorithm. By enumerating all size k subsets of Y and all length k vectors, we can find Q_{opt} and z_{opt} at some moment. It is easy to see that if we know exactly Q_{opt} and z_{opt}, then we can find the corresponding P_{opt} in polynomial time to minimize the consensus score. However, this straightforward approach costs exponential time. Here we use a random sampling technique to randomly select $\Theta(\log m)$ columns in Q_{opt}, and enumerate all possible vectors of length $\Theta(\log m)$ for those columns. (If $n < \Theta(\log m)$, we will select all the n columns and the running time is still polynomial in terms of the input size.) At some point, we know $\Theta(\log m)$ bits of z_{opt} and we can use the partial z_{opt} to select the l rows which are closest to z_{opt} in those $\Theta(\log m)$ bits. After that we can construct a consensus vector z as follows. For each column, choose the (majority) letter that appears the most in each of the l letters in the l selected rows. Then for each of the n columns, we can calculate the number of mismatches between the majority letter and the l letters in the l selected rows. By selecting the best k columns, we can get a good solution.

The remaining difficulty is how to randomly select $\Theta(\log m)$ columns in Q_{opt} while Q_{opt} is unknown. Our new idea is to randomly select a set B of $\lceil (c+1)(\frac{4 \log m}{\epsilon^2} + 1) \rceil$ columns from A and enumerate all size $\lceil \frac{4 \log m}{\epsilon^2} \rceil$ subsets of B in time $O(m^{\frac{4(c+1)}{\epsilon^2}})$,

Algorithm 1 for the Consensus Submatrix Problem

Input: an $m \times n$ matrix A, integers l and k, and a number $\epsilon > 0$.

Output: a size l subset P of rows, a size k subset Q of columns and a length k consensus vector z.

Step 1: Randomly and independently select a set B of $\lceil (c+1)(\frac{4\log m}{\epsilon^2}+1)\rceil$ columns from A. (If $n < \lceil (c+1)(\frac{4\log m}{\epsilon^2}+1)\rceil$, we will select all the n columns and the running time is still polynomial in terms of the input size.)

(1.1) **for** every size $\lceil \frac{4\log m}{\epsilon^2}\rceil$ subset R of B **do**

(1.2) **for** every $z|^R \in \Sigma^{|R|}$ **do**

(a) Select the best l rows $P = \{p_1, \ldots, p_l\}$ that minimize $d(z|^R, x_i|^R)$.

(b) **for** each column j **do**

Compute $f(j) = \sum_{i=1}^{l} d(s_j, a_{p_i,j})$, where s_j is the majority element of the l rows in P in column j.

Select the best k columns $Q = \{q_1, \ldots, q_k\}$ with minimum value $f(j)$ and let $z(Q) = s_{q_1} s_{q_2} \ldots s_{q_k}$.

(c) Calculate $H = \sum_{i=1}^{l} d(x_{p_i}|^Q, z)$ of this solution.

Step 2: Output P, Q and z with minimum H.

FIG. 2. *Algorithm* 1.

which is polynomial in terms of the input size $O(mn)$. We can show that with high probability, we can get a set of $\lceil \frac{4\log m}{\epsilon^2}\rceil$ columns randomly selected from Q_{opt}.

Now we describe the complete algorithm in Figure 2.

The following lemma, originally from [26], will be used in our proofs.

LEMMA 1. *Let $X_1, X_2, \ldots, X_n$ be n independent random* 0-1 *variables, where X_i takes* 1 *with probability p_i, $0 < p_i < 1$. Let $X = \sum_{i=1}^{n} X_i$ and $\mu = E[X]$. Then for any $0 < \epsilon \le 1$,*

$$\mathbf{Pr}(X > \mu + \epsilon\, n) < \exp\left(-\frac{1}{3} n\epsilon^2\right),$$

$$\mathbf{Pr}(X < \mu - \epsilon\, n) \le \exp\left(-\frac{1}{2} n\epsilon^2\right).$$

LEMMA 2. *With probability at most $m^{-\frac{2}{\epsilon^2 c^2 (c+1)}}$, no subset R of size $\lceil \frac{4\log m}{\epsilon^2}\rceil$ used in Step* 1 *of Algorithm* 1 *satisfies $R \subseteq Q_{opt}$.*

Proof. Obviously, if the subset B in Step 1 of Algorithm 1 contains at least $\lceil \frac{4\log m}{\epsilon^2}\rceil$ columns in Q_{opt}, there is a size $\lceil \frac{4\log m}{\epsilon^2}\rceil$ subset $R \subseteq Q_{opt}$. Now we consider the probability that the subset B contains less than $\lceil \frac{4\log m}{\epsilon^2}\rceil$ columns in Q_{opt}. Let b be the number of columns in B that are also in Q_{opt}. Recall that $k \times c = n$. If we randomly select a column, the probability that the column is in Q_{opt} is $\frac{1}{c}$. Let μ be the expected number of columns in B that are in Q_{opt}. We have $\mu = \frac{|B|}{c} = \frac{1}{c}\lceil (c+1)(\frac{4\log m}{\epsilon^2}+1)\rceil$. Let $X_1, X_2, \ldots, X_{|B|}$ be $|B|$ independent random 0/1 variables, where $X_i = 1$ with probability $\frac{1}{c}$ indicating that the selected column is in Q_{opt}. Thus,

$$b = \sum_{i=1}^{|B|} X_i \tag{2}$$

and

$$\mu = E\left(\sum_{i=1}^{|B|} X_i\right) = \frac{1}{c}\left\lceil (c+1)\left(\frac{4\log m}{\epsilon^2}+1\right)\right\rceil. \tag{3}$$

From the algorithm,

$$|B| = \left\lceil (c+1)\left(\frac{4\log m}{\epsilon^2}+1\right)\right\rceil. \tag{4}$$

Based on Lemma 1, we have

$$\begin{aligned}
\mathbf{Pr}\left(b < \left\lceil \frac{4\log m}{\epsilon^2}\right\rceil\right) &\le \mathbf{Pr}\left(b < \frac{4\log m}{\epsilon^2}+1\right)\\
&\le \mathbf{Pr}\left(b < \left(\frac{1}{c}-\frac{1}{c(c+1)}\right)\left\lceil (c+1)\left(\frac{4\log m}{\epsilon^2}+1\right)\right\rceil\right)\\
&= \mathbf{Pr}\left(\sum_{i=1}^{|B|} X_i < \mu - \frac{1}{c(c+1)}|B|\right) \quad \text{(from (2), (3), and (4))}\\
&\le \exp\left(-\frac{1}{2c^2(c+1)^2}|B|\right)\\
&\le \exp\left(-\frac{1}{2c^2(c+1)^2}(c+1)\left(\frac{4\log m}{\epsilon^2}\right)\right)\\
&= \exp\left(-\frac{2\log m}{\epsilon^2 c^2(c+1)}\right) = m^{-\frac{2}{\epsilon^2 c^2(c+1)}}.
\end{aligned}$$

Therefore, with probability at most $m^{-\frac{2}{\epsilon^2 c^2(c+1)}}$, no subset R of size $\lceil \frac{4\log m}{\epsilon^2}\rceil$ used in Step 1 of Algorithm 1 satisfies $R \subseteq Q_{opt}$. □

LEMMA 3. *Assume* $|R| = \lceil \frac{4\log m}{\epsilon^2}\rceil$ *and* $R \subseteq Q_{opt}$. *Let* $\rho = \frac{k}{|R|}$. *With probability at most* m^{-1}, *there is a row* x_i *in* X *satisfying*

$$\frac{d(z_{opt}, x_i|^{Q_{opt}}) - \epsilon k}{\rho} > d(z_{opt}|^R, x_i|^R). \tag{5}$$

With probability at most $m^{-\frac{1}{3}}$, *there is a row* x_i *in* X *satisfying*

$$d(z_{opt}|^R, x_i|^R) > \frac{d(z_{opt}, x_i|^{Q_{opt}}) + \epsilon k}{\rho}. \tag{6}$$

Proof. We will calculate $\mathbf{Pr}(d(z_{opt}|^R, x_i|^R) < \frac{d(z_{opt}, x_i|^{Q_{opt}})-\epsilon k}{\rho})$ first. From Algorithm 1, R is a subset of B, a set of randomly independently selected columns. Thus, R is also a set of randomly independently selected columns. Therefore, we can treat $d(z_{opt}|^R, x_i|^R)$ as the sum of $|R|$ independent random 0/1 variables $\sum_{j=1}^{|R|} X_j$. As $R \subseteq Q_{opt}$, $X_j = 1$ indicates a mismatch between z_{opt} and x_i at the jth position in R. Clearly $E[d(z_{opt}|^R, x_i|^R)] = d(z_{opt}, x_i|^{Q_{opt}})/\rho$. From Lemma 1, we have

$$\begin{aligned}
&\mathbf{Pr}\left(d(z_{opt}|^R, x_i|^R) < \frac{d(z_{opt}, x_i|^{Q_{opt}}) - \epsilon k}{\rho}\right)\\
&= \mathbf{Pr}(d(z_{opt}|^R, x_i|^R) < E[d(z_{opt}|^R, x_i|^R)] - \epsilon|R|)\\
&\le \exp\left(-\frac{1}{2}\epsilon^2|R|\right) \le m^{-2},
\end{aligned}$$

where the last inequality is due to the setting $|R| = \lceil \frac{4 \log m}{\epsilon^2} \rceil$ in Step 1 of Algorithm 1. Considering all the m x_i's, the probability that an $x_i \in X$ satisfies (5) is at most $m \times m^{-2} = m^{-1}$.

Similarly, we have

$$\mathbf{Pr}\left(d(z_{opt}|^R, x_i|^R) > \frac{d(z_{opt}, x_i|^{Q_{opt}}) + \epsilon k}{\rho} \right) < m^{-\frac{4}{3}}.$$

Considering all the m x_i's, the probability that an $x_i \in X$ satisfies (6) is at most $m \times m^{-\frac{4}{3}} = m^{-\frac{1}{3}}$. □

LEMMA 4. *When $R \subseteq Q_{opt}$ and $z|^R = z_{opt}|^R$, with probability at most $2m^{-\frac{1}{3}}$, the set of rows $P = \{p_1, \ldots, p_l\}$ selected in Step* 1(a) *of Algorithm* 1 *satisfies $\sum_{i=1}^{l} d(z_{opt}, x_{p_i}|^{Q_{opt}}) > H_{opt} + 2\epsilon kl$.*

Proof. Let $P_{opt} = \{p_1^*, \ldots, p_l^*\}$ be the l rows in the optimal solution; we have

$$\sum_{i=1}^{l} d(z_{opt}, x_{p_i^*}|^{Q_{opt}}) = H_{opt}. \tag{7}$$

From Lemma 3, with probability at most m^{-1}, a row $x_{p_i} \in \{p_1, p_2, \ldots, p_l\}$ satisfies

$$\sum_{i=1}^{l} d(z_{opt}|^R, x_{p_i}|^R) < \sum_{i=1}^{l} \frac{d(z_{opt}, x_{p_i}|^{Q_{opt}}) - \epsilon k}{\rho}. \tag{8}$$

Again from Lemma 3, with probability at most $m^{-\frac{1}{3}}$, a row $x_{p_i^*} \in \{p_1^*, p_2^*, \ldots, p_l^*\}$ satisfies

$$\sum_{i=1}^{l} d(z_{opt}|^R, x_{p_i^*}|^R) > \sum_{i=1}^{l} \frac{d(z_{opt}, x_{p_i^*}|^{Q_{opt}}) + \epsilon k}{\rho}. \tag{9}$$

By trying all length $|R|$ vectors in Step 1 of Algorithm 1, we can assume that we know $z_{opt}|^R$. In Step 1(a), we select the best set $P = \{p_1, \ldots, p_l\}$ with minimum $d(z_{opt}|^R, x_i|^R)$. Thus, for any $R \subseteq Q_{opt}$, we have

$$\sum_{i=1}^{l} d(z_{opt}|^R, x_{p_i}|^R) \leq \sum_{i=1}^{l} d(z_{opt}|^R, x_{p_i^*}|^R). \tag{10}$$

From (8), (9), and (10), if $R \subseteq Q_{opt}$ and $z|^R = z_{opt}|^R$, with probability at most $m^{-1} + m^{-\frac{1}{3}} \leq 2m^{-\frac{1}{3}}$, there exists a set of rows $P = \{p_1, \ldots, p_l\}$ obtained in Step 1(a) of Algorithm 1 such that

$$\begin{aligned} \sum_{i=1}^{l} d(z_{opt}, x_{p_i}|^{Q_{opt}}) &> \sum_{i=1}^{l} (d(z_{opt}, x_{p_i^*}|^{Q_{opt}}) + 2\epsilon k) \\ &= H_{opt} + 2\epsilon kl. \end{aligned}$$

The last inequality is from (7). □

THEOREM 2. *For any $\delta > 0$, with probability at least $1 - m^{-\frac{8c'^2}{\delta^2 c^2 (c+1)}} - 2m^{-\frac{1}{3}}$, Algorithm* 1 *outputs a solution with consensus score at most $(1+\delta)H_{opt}$ in $O(nm^{O(\frac{1}{\delta^2})})$ time.*

Proof. When $R \subseteq Q_{opt}$ and $z|^R = z_{opt}|^R$, in Step 1(b), we can construct a Q and $z(Q)$ such that

$$\sum_{i=1}^{l} d(z(Q), x_{p_i}|^Q) \leq \sum_{i=1}^{l} d(z_{opt}, x_{p_i}|^{Q_{opt}}). \tag{11}$$

From Lemma 2, we know that with probability at most $m^{-\frac{2}{\epsilon^2 c^2 (c+1)}}$, there is no subset R with size $\lceil \frac{4 \log m}{\epsilon^2} \rceil$ in Step 1 of Algorithm 1 such that $R \subseteq Q_{opt}$. Combining with Lemma 4, we know that with probability at most $m^{-\frac{2}{\epsilon^2 c^2 (c+1)}} + 2m^{-\frac{1}{3}}$, in the execution of Algorithm 1, any set of rows $P = \{p_1, \ldots, p_l\}$ obtained in Step 1(a) satisfies

$$\sum_{i=1}^{l} d(z_{opt}, x_{p_i}|^{Q_{opt}}) > H_{opt} + 2\epsilon kl.$$

In other words, with probability at least $1 - m^{-\frac{2}{\epsilon^2 c^2 (c+1)}} - 2m^{-\frac{1}{3}}$, in the execution of Algorithm 1, we can get a set of rows $P = \{p_1, \ldots, p_l\}$ in Step 1(a) that satisfies $\sum_{i=1}^{l} d(z_{opt}, x_{p_i}|^{Q_{opt}}) \leq H_{opt} + 2\epsilon kl$.

From (11), we have

$$\sum_{i=1}^{l} d(z(Q), x_{p_i}|^Q) \leq \sum_{i=1}^{l} d(z_{opt}, x_{p_i}|^{Q_{opt}}) \leq H_{opt} + 2\epsilon kl.$$

Recall that $H_{opt} \times c' = kl$. Set $\epsilon = \frac{\delta}{2c'}$. So with probability at least $1 - m^{-\frac{8c'^2}{\delta^2 c^2 (c+1)}} - 2m^{-\frac{1}{3}}$, Algorithm 1 outputs a solution with consensus score at most $(1+\delta)H_{opt}$.

For the time complexity, Step 1(a), Step 1(b), and Step 1(c) take $O(mn)$ time. Step 1.1 is repeated $O(2^{\frac{4(c+1)\log m}{\epsilon^2}}) = O(m^{O(\frac{1}{\epsilon^2})}) = O(m^{O(\frac{1}{\delta^2})})$ times. Step 1.2 is repeated $O(m^{O(\frac{\log |\Sigma|}{\epsilon^2})}) = O(m^{O(\frac{1}{\delta^2})})$ times as $\epsilon = \frac{\delta}{2c'}$ and $|\Sigma|$ is a fixed constant. Thus, the total running time is $O(nm^{O(\frac{1}{\delta^2})})$. ∎

THEOREM 3. *There exists a PTAS for the consensus submatrix problem.*

Proof. Algorithm 1 can be derandomized by the standard method. For instance, instead of randomly and independently choosing $\Theta(\log m)$ columns from the n columns in Step 1, we can pick the vertices encountered on a random walk of length $\Theta(\log m)$ on a constant degree expander [27]. Obviously, the number of such random walks on a constant degree expander is polynomial in terms of m. Thus, by enumerating all random walks of length $\Theta(\log m)$, we have a polynomial time deterministic algorithm. (Also see [30].) ∎

4. The bottleneck submatrix problem. In this section, we present the randomized approximation algorithm for the bottleneck submatrix problem. Let P_{opt}, Q_{opt}, and z_{opt} be the set of rows, the set of columns, and the center vector of an optimal solution. The optimal bottleneck score is d_{opt}. By assumption, $d_{opt} = \Omega(k)$ and $k = \Omega(n)$, i.e., there are constants c'' and c such that $d_{opt} \times c'' = k$ and $k \times c = n$.

Similar to Algorithm 1, we can use a random sampling technique to know $\Theta(\log m)$ bits of z_{opt}. Then we can use the partial z_{opt} to select the l rows which are closest to z_{opt} in those $\Theta(\log m)$ bits as in Step 1(a) of Algorithm 1. From Lemma 3, we know that using $\Theta(\log m)$ bits in R, we can get a good estimation of $d(z_{opt}, x_i|^{Q_{opt}})$ for each

x_i in X. Thus, if we can correctly select Q_{opt} from the n given columns, then we can get a good approximation solution. However, Step 1(b) in Algorithm 1 does not work for the bottleneck score in selecting a good approximation of Q_{opt}. Thus, we use the linear programming and randomized rounding technique to select k columns in the matrix.

Linear programming formulation. Given a set of rows $P = \{p_1, \ldots, p_l\}$, we want to find a set of k columns Q and a vector z such that the bottleneck score is minimized. This problem is equivalent to the following optimization problem:

$$\begin{cases} \min d; \\ d(z, x_{p_i}|^Q) \le d, \quad i = 1, 2, \ldots, l, \quad Q \subseteq Y, \quad |Q| = k, z \in \Sigma^k. \end{cases} \tag{12}$$

Let $\Sigma = \{\pi_1, \pi_2, \ldots, \pi_{|\Sigma|}\}$. We introduce 0/1 variable $y_{i,j}$ $(i = 1, 2, \ldots, n, j = 1, 2, \ldots, |\Sigma|)$ to indicate the membership of column i in Q and the corresponding bit of z. We have $y_{i,j} = 1$ if and only if column i is in Q and the corresponding bit in z is π_j. For any $a, b \in \Sigma$, $\chi(a, b) = 0$ if $a = b$ and $\chi(a, b) = 1$ if $a \ne b$. We can formulate (12) as 0/1 integer linear programming:

$$\begin{cases} \min d; \\ \displaystyle\sum_{i=1}^{n} \sum_{j=1}^{|\Sigma|} y_{i,j} = k, \\ \displaystyle\sum_{j=1}^{|\Sigma|} y_{i,j} \le 1, \quad i = 1, 2, \ldots, n, \\ \displaystyle\sum_{i=1}^{n} \sum_{j=1}^{|\Sigma|} \chi(\pi_j, x_{p_s,i}) y_{i,j} \le d, \quad s = 1, 2, \ldots, l. \end{cases} \tag{13}$$

Here $y_{i,j}$ is used to achieve two tasks: (1) to decide whether column i is selected and (2) if column i is selected, to choose the letter in the center vector z on this column.

We can obtain a fraction solution $y_{i,j} = \overline{y_{i,j}} (i = 1, 2, \ldots, n, j = 1, 2, \ldots, |\Sigma|)$ for (13) in polynomial time. After we get the fraction solution, we do randomized rounding to get an integer solution.

Randomized rounding. Given a fraction solution $y_{i,j} = \overline{y_{i,j}}$ $(i = 1, 2, \ldots, n, j = 1, 2, \ldots, |\Sigma|)$ with cost $\overline{d}$, for each $1 \le i \le n, 1 \le j \le |\Sigma|$, we randomly select column i to Q with probability $\sum_{j=1}^{|\Sigma|} \overline{y_{i,j}}$ and randomly set the bit of z in this column according to the distribution $\overline{y_{i,j}}$ for $j = 1, 2, \ldots, |\Sigma|$. In terms of programming, we can generate a random number ρ in (0,1) for every column i. If $\rho < \sum_{j=1}^{|\Sigma|} \overline{y_{i,j}}$, we select this column into Q and let the bit of z corresponding to this column be π_t if and only if $\sum_{j=1}^{t-1} \overline{y_{i,j}} \le \rho < \sum_{j=1}^{t} \overline{y_{i,j}}$. If $\rho \ge \sum_{j=1}^{|\Sigma|} \overline{y_{i,j}}$, this column is not selected. Hence we get a 0/1 integer solution $y' = \{y'_{1,1}, \ldots, y'_{1,|\Sigma|}, \ldots, y'_{n,1}, \ldots, y'_{n,|\Sigma|}\}$.

In this randomized rounding process, we have to do two things: (1) select k' columns, where $k' \ge k - \delta d_{opt}$, and (2) get the integral value for each $y_{i,j}$ such that the distance (restricted on the k' selected columns) between any row in P and the center vector thus obtained is at most γd_{opt}. Here $\delta > 0$ and $\gamma > 0$ are two parameters used to control the errors.

LEMMA 5. *When* $\frac{n\gamma^2}{3(cc')^2} \ge 2 \log m$, *for any* $\gamma, \delta > 0$, *with probability at most* $\exp(-\frac{n\delta^2}{2(cc')^2}) + m^{-1}$, *the integer solution* $y' = \{y'_{1,1}, \ldots, y'_{1,|\Sigma|}, \ldots, y'_{n,1}, \ldots, y'_{n,|\Sigma|}\}$

violates at least one of the following inequalities,

$$\sum_{i=1}^{n}\left(\sum_{j=1}^{|\Sigma|} y'_{i,j}\right) > k - \delta d_{opt}, \tag{14}$$

and for every row $x_{p_s}(s = 1, 2, \ldots, l)$*,*

$$\sum_{i=1}^{n}\left(\sum_{j=1}^{|\Sigma|} \chi(\pi_j, x_{p_s,i}) y'_{i,j}\right) < \overline{d} + \gamma d_{opt}. \tag{15}$$

Proof. From $k \times c = n$ and $d_{opt} \times c'' = k$, we have $d_{opt} \times cc'' = n$. For each $1 \le i \le n$, the randomized rounding process ensures that at most one $y'_{i,a} = 1$ for $\pi_a \in \Sigma$. Since the rounding is independent for different i's, $(\sum_{j=1}^{|\Sigma|} y'_{i,j})$'s are independent 0/1 random variables for $1 \le i \le n$, and $(\sum_{j=1}^{|\Sigma|} \chi(\pi_j, x_{p_s,i}) y'_{i,j})$'s are independent 0/1 random variables for $1 \le i \le n$ in every row x_{p_s}. It is easy to see that

$$E\left(\sum_{i=1}^{n}\left(\sum_{j=1}^{|\Sigma|} y'_{i,j}\right)\right) = k,$$

and for every row $x_{p_s}(s = 1, 2, \ldots, l)$,

$$E\left(\sum_{i=1}^{n}\left(\sum_{j=1}^{|\Sigma|} \chi(\pi_j, x_{p_s,i}) y'_{i,j}\right)\right) \le \overline{d}.$$

From Lemma 1, we have

$$\begin{aligned}\mathbf{Pr}\left(\sum_{i=1}^{n}\left(\sum_{j=1}^{|\Sigma|} y'_{i,j}\right) < k - \delta d_{opt}\right) &= \mathbf{Pr}\left(\sum_{i=1}^{n}\left(\sum_{j=1}^{|\Sigma|} y'_{i,j}\right) < E\left(\sum_{i=1}^{n}\left(\sum_{j=1}^{|\Sigma|} y'_{i,j}\right)\right) - \frac{\delta n}{cc''}\right) \\ &\le \exp\left(-\frac{n\delta^2}{2(cc'')^2}\right),\end{aligned}$$

and for every row $x_{p_s}(s = 1, 2, \ldots, l)$,

$$\begin{aligned}&\mathbf{Pr}\left(\sum_{i=1}^{n}\left(\sum_{j=1}^{|\Sigma|} \chi(\pi_j, x_{p_s,i}) y'_{i,j}\right) > \overline{d} + \gamma d_{opt}\right) \\ &\le \mathbf{Pr}\left(\sum_{i=1}^{n}\left(\sum_{j=1}^{|\Sigma|} \chi(\pi_j, x_{p_s,i}) y'_{i,j}\right) > E\left(\sum_{i=1}^{n}\left(\sum_{j=1}^{|\Sigma|} \chi(\pi_j, x_{p_s,i}) y'_{i,j}\right)\right) + \frac{\gamma}{cc''} n\right) \\ &< \exp\left(-\frac{n\gamma^2}{3(cc'')^2}\right).\end{aligned}$$

Considering all l rows in P, the probability that at least one row in P satisfies $\sum_{i=1}^{n}(\sum_{j=1}^{|\Sigma|} \chi(\pi_j, x_{p_s,i}) y'_{i,j}) > \overline{d} + \gamma d_{opt}$ is at most $l \times \exp(-\frac{n\gamma^2}{3(cc'')^2}) \le m \times \exp(-\frac{n\gamma^2}{3(cc'')^2})$. Thus, with probability at most $\exp(-\frac{n\delta^2}{2(cc'')^2}) + m \times \exp(-\frac{n\gamma^2}{3(cc'')^2})$, the integer solution $y' = \{y'_{1,1}, \ldots, y'_{1,|\Sigma|}, \ldots, y'_{n,1}, \ldots, y'_{n,|\Sigma|}\}$ violates at least one of (14) and (15). When $\frac{n\gamma^2}{3(cc'')^2} \ge 2 \log m$, we get the desired probability. ∎

Algorithm 2 for the Bottleneck Submatrix Problem

Input: a matrix $A \in \Sigma^{m\times n}$, integers l, k, a row $z \in \Sigma^n$ and numbers $\epsilon > 0$, and $\gamma > 0$.

Output: a size l subset P of rows, a size k subset Q of columns and a length k center vector z.

if $\frac{n\gamma^2}{3(cc'')^2} \le 2\log m$ **then**

try all size k subset Q of the n columns and all center vectors of length k to solve the problem.

if $\frac{n\gamma^2}{3(cc'')^2} > 2\log m$ **then**

Step 1: randomly and independently select a set B of $\lceil \frac{4(c+1)\log m}{\epsilon^2} \rceil$ columns from A.

for every $\lceil \frac{4\log m}{\epsilon^2} \rceil$ size subset R of B **do**

for every $z|^R \in \Sigma^{|R|}$ **do**

(a) Select the best l rows $P = \{p_1, \ldots, p_l\}$ that minimize $d(z|^R, x_i|^R)$.

(b) Solve the optimization problem (12) by linear programming and randomized rounding to get Q and z.

Step 2: Output P,Q and z with minimum bottleneck score d.

FIG. 3. *Algorithm* 2.

When $\frac{n\gamma^2}{3(cc'')^2} < 2\log m$, we try all subsets of X with size k and all length k vectors in polynomial time and get the best solution.

From Lemma 5, we know that in the randomized rounding process, with high probability, we selected k' columns in Q, where $(1-\epsilon)k \le k'$. Our aim is to exactly select k columns. If $k' > k$, we can arbitrarily delete $k'-k$ columns from Q and obtain the set of k columns $Q' \subseteq Q$. If $k' < k$, we can arbitrarily select $k-k'$ columns outside Q and add them to Q to get a set of k columns $Q' \supset Q$. By doing so, the extra error introduced is at most ϵk. Since $d = \Omega(n)$, the error ϵk is small and we still can get a PTAS.

Now we describe the complete algorithm in Figure 3.

Similar to Lemma 4, we have the following lemma.

LEMMA 6. *When $R \subseteq Q_{opt}$ and $z|^R = z_{opt}|^R$, with probability at most $2m^{-\frac{1}{3}}$, the set of rows $P = \{p_1, \ldots, p_l\}$ obtained in Step* 1(a) *of Algorithm* 2 *satisfies $d(z_{opt}, x_{p_i}|^{Q_{opt}}) > d_{opt} + 2\epsilon k$ for some row $x_{p_i}(1 \le i \le l)$.*

Proof. Let $P_{opt} = \{p_1^*, \ldots, p_l^*\}$ be the l rows in the optimal solution. We have

$$\max_{p_i^* \in P_{opt}} d(z_{opt}, x_{p_i^*}|^{Q_{opt}}) = d_{opt}. \tag{16}$$

From Lemma 3, with probability at most m^{-1}, a row $x_{p_i} \in \{p_1, p_2, \ldots, p_l\}$ satisfies

$$d(z_{opt}|^R, x_{p_i}|^R) < \frac{d(z_{opt}, x_{p_i}|^{Q_{opt}}) - \epsilon k}{\rho}. \tag{17}$$

Again from Lemma 3, with probability at most $m^{-\frac{1}{3}}$, a row $x_{p_i^*} \in \{p_1^*, p_2^*, \ldots, p_l^*\}$ satisfies

$$d(z_{opt}|^R, x_{p_i^*}|^R) > \frac{d(z_{opt}, x_{p_i^*}|^{Q_{opt}}) + \epsilon k}{\rho}. \tag{18}$$

By trying all length $|R|$ vectors in Step 1 of Algorithm 2, we can assume that we know $z_{opt}|^R$. In Step 1(a), we select the best set $P = \{p_1, \ldots, p_l\}$ with minimum $d(z_{opt}|^R, x_i|^R)$. Thus, for any $R \subseteq Q_{opt}$, for every $p_i \in P$, we have

$$d(z_{opt}|^R, x_{p_i}|^R) \leq \max_{p_i^* \in P_{opt}} d(z_{opt}|^R, x_{p_i^*}|^R). \tag{19}$$

From (17), (18), and (19), if $R \subseteq Q_{opt}$ and $z|^R = z_{opt}|^R$, with probability at most $m^{-1} + m^{-\frac{1}{3}} \leq 2m^{-\frac{1}{3}}$, there exists a set of rows $P = \{p_1, \ldots, p_l\}$ obtained in Step 1(a) of Algorithm 2 such that for some row $x_{p_i} (1 \leq i \leq l)$,

$$\begin{aligned} d(z_{opt}, x_{p_i}|^{Q_{opt}}) &> \max_{p_i^* \in P_{opt}} d(z_{opt}, x_{p_i^*}|^{Q_{opt}}) + 2\epsilon k \\ &= d_{opt} + 2\epsilon k. \end{aligned}$$

The last inequality is from (16). ∎

From Lemmas 2, 5, and 6, we have the following theorem.

THEOREM 4. *With probability at least* $1 - m^{-\frac{2}{\epsilon^2 c^2 (c+1)}} - 2m^{-\frac{1}{3}} - \exp(-\frac{n\delta^2}{2(cc'')^2}) - m^{-1}$, *Algorithm* 2 *runs in time* $O(n^{O(1)} m^{O(\frac{1}{\epsilon^2} + \frac{1}{\gamma^2})})$ *and obtains a solution with the bottleneck score at most* $(1 + 2c''\epsilon + \gamma + \delta) d_{opt}$ *for any fixed* $\epsilon,\ \gamma,\ \delta > 0$.

Proof. From Lemma 2, we know that with probability at most $m^{-\frac{2}{\epsilon^2 c^2 (c+1)}}$, there is no subset R with size $\lceil \frac{4 \log m}{\epsilon^2} \rceil$ in Step 1 of Algorithm 2 such that $R \subseteq Q_{opt}$. Combining with Lemma 6, we know that with probability at most $m^{-\frac{8c''^2}{\epsilon'^2 c^2 (c+1)}} + 2m^{-\frac{1}{3}}$, in the execution of Algorithm 2, for any set of rows $P = \{p_1, \ldots, p_l\}$ obtained in Step 1(a), problem (12) has a solution $Q = Q_{opt}$ and $z = z_{opt}$ with the bottleneck score $d_P > (1 + 2c''\epsilon) d_{opt}$ as $k = 2c'' d_{opt}$. In Step 1(b), we can get a fraction solution $y_{i,j} = \overline{y_{i,j}}$ $(i = 1, 2, \ldots, n, j = 1, 2, \ldots, |\Sigma|)$ with cost $\overline{d} < d_P$. Thus, with probability at most $m^{-\frac{8c''^2}{\epsilon'^2 c^2 (c+1)}} + 2m^{-\frac{1}{3}}$,

$$\overline{d} > (1 + 2c''\epsilon) d_{opt}. \tag{20}$$

From Lemma 5, when $\frac{n\gamma^2}{3(cc'')^2} \geq 2 \log m$, we know that with probability at most $\exp(-\frac{n\delta^2}{2(cc'')^2}) + m^{-1}$, the integer solution $y' = \{y'_{1,1}, \ldots, y'_{1,|\Sigma|}, \ldots, y'_{n,1}, \ \ldots, y'_{n,|\Sigma|}\}$ violates at least one of (14) and (15). Thus the bottleneck score

$$d' > (\delta + \gamma) d_{opt} + \overline{d}. \tag{21}$$

From (20) and (21), when $\frac{n\gamma^2}{3(cc'')^2} \geq 2 \log m$, with probability at most $m^{-\frac{2}{\epsilon^2 c^2 (c+1)}} + 2m^{-\frac{1}{3}} + \exp(-\frac{n\delta^2}{2(cc'')^2}) + m^{-1}$,

$$d' > (1 + 2c''\epsilon + \gamma + \delta) d_{opt}.$$

In other words, when $\frac{n\gamma^2}{3(cc'')^2} \geq 2 \log m$, with probability at least $1 - m^{-\frac{2}{\epsilon^2 c^2 (c+1)}} - 2m^{-\frac{1}{3}} - \exp(-\frac{n\delta^2}{2(cc'')^2}) - m^{-1}$, in the execution of Algorithm 2, we can get a solution in Step 1(b) with the bottleneck score at most $(1 + 2c''\epsilon + \gamma + \delta) d_{opt}$.

For the time complexity, Step 1(a), Step 1(b), and Step 1(c) take $O((mn|\Sigma|)^{O(1)})$ time. Step 1 is repeated at most $O(m^{O(\frac{\log |\Sigma|}{\epsilon^2})}) = O(m^{O(\frac{1}{\epsilon^2})})$ times. Thus, the total time required is $O(n^{O(1)} m^{O(\frac{1}{\epsilon^2})})$.

When $\frac{n\gamma^2}{3(cc')^2} < 2\log m$, we can solve the problem in $O(n^{O(1)}m^{O(\frac{1}{\gamma^2})})$ time by enumerating all possible sets Q and all possible center vectors z. □

THEOREM 5. *There exists a PTAS for the bottleneck submatrix problem.*

Proof. For Step 1(b), we can use the technique in [26] to derandomize it. The derandomization of the random sampling step is the same as in Algorithm 1. □

5. Conclusion. We have designed PTASs for both the consensus submatrix and the bottleneck submatrix problems. To the best of our knowledge, this is the first time that approximation algorithms with guaranteed performance ratios have been presented for microarray data analysis. It is important to point out that the running time here is very high and the algorithms may not work in practice.

Acknowledgment. We thank the referees for their helpful suggestions.

A DETERMINISTIC SUBEXPONENTIAL ALGORITHM FOR SOLVING PARITY GAMES*

MARCIN JURDZIŃSKI†, MIKE PATERSON†, AND URI ZWICK‡

Abstract. The existence of polynomial-time algorithms for the solution of parity games is a major open problem. The fastest known algorithms for the problem are *randomized* algorithms that run in subexponential time. These algorithms are all ultimately based on the randomized subexponential simplex algorithms of Kalai and of Matoušek, Sharir, and Welzl. Randomness seems to play an essential role in these algorithms. We use a completely different, and elementary, approach to obtain a *deterministic* subexponential algorithm for the solution of parity games. The new algorithm, like the existing randomized subexponential algorithms, uses only polynomial space, and it is almost as fast as the randomized subexponential algorithms mentioned above.

1. Introduction.

A parity game [11, 15] is played on a directed graph (V, E) by two players, *Even* and *Odd*, who move a token from vertex to vertex along the edges of the graph so that an infinite path is formed. A partition (V_0, V_1) is given of the set V of vertices: player Even moves if the token is at a vertex of V_0, and player Odd moves if the token is at a vertex of V_1. Finally, a priority function $p : V \to \mathbb{N}$ is given. The players compete for the parity of the highest priority occurring infinitely often: player Even wins if $\limsup_{i\to\infty} p(v_i)$ is even, while player Odd wins if it is odd, where $v_0, v_1, v_2, \ldots$ is the infinite path formed by the players.

The algorithmic problem of solving parity games is, given a parity game $G = (V_0, V_1, E, p)$ and an initial vertex $v_0 \in V$, to determine whether player Even has a winning strategy in the game if the token is initially placed on vertex v_0. Algorithms for solving parity games [33, 20, 32, 15, 2] usually compute the winning sets win_0 and win_1, i.e., the sets of vertices from which players Even and Odd, respectively, have a winning strategy. By the determinacy theorem for parity games [11, 15] the winning sets win_0 and win_1 form a partition of the set of vertices V. None of these algorithms is known to run in polynomial time and the existence of a polynomial-time algorithm for the solution of parity games is a long-standing open problem [12, 15].

The original motivation for the study of parity games comes from the area of formal verification of systems by temporal logic model checking [5, 15]. The problem of solving parity games is polynomial-time equivalent to the nonemptiness problem of ω-automata on infinite trees with Rabin-chain acceptance conditions [12], and to the model checking problem of the modal μ-calculus (modal fixpoint logic) which is a formalism of great expressiveness and succinctness in formal specification and

validation [10, 15]. The model checking problem is a fundamental algorithmic problem in automated hardware and software verification [10, 5].

Another important motivation to study the problem of solving parity games is its intriguing complexity theoretic status: the problem is known to be in NP ∩ co-NP [12] and even in UP ∩ co-UP [19] but, as mentioned, despite considerable efforts of the community [12, 20, 32, 15, 2, 28] no polynomial-time algorithm has been found so far. (The complexity class UP, a.k.a. unambiguous NP, is defined to contain all problems that can be recognized by an unambiguous nondeterministic polynomial-time Turing machine. A Turing machine is unambiguous if for every input it has at most one accepting computation. Clearly, the inclusions P ⊆ UP ⊆ NP hold.) Moreover, parity games are polynomial-time reducible to mean payoff games [34], simple stochastic games [6], and discounted payoff games [6, 34]. A stochastic generalization of parity games was also studied [9, 3]. The problems of solving all those games are in UP ∩ co-UP as well [19, 3]. Condon has shown that simple stochastic games are complete (with respect to log-space reductions) in the class of log-space randomized alternating Turing machines [6].

The task of solving parity, mean payoff, discounted payoff, and simple stochastic games can be also viewed as a search problem: given a game graph, compute optimal strategies for both players. The value functions used in strategy improvement algorithms [7, 25, 32, 2] witness membership of all those optimal strategies search problems in PLS (i.e., the class of polynomial local search problems) [17]. On the other hand, the problem of computing optimal strategies in simple stochastic games can be reduced in polynomial time to solving a P-matrix linear complementarity problem [14, 31, 21], and to finding a Brouwer fixpoint [18], and hence it is also in PPAD (see [29] for a definition of PPAD). It follows that there are polynomial-time reductions from the problems of computing optimal strategies in parity, mean payoff, discounted payoff, and simple stochastic games to the problem of finding Nash equilibria in bimatrix games [8, 4].

Let $n = |V|$ and $m = |E|$ be the numbers of vertices and edges of a parity game graph and let d be the number of different priorities assigned to vertices by the priority function $p : V \to \mathbb{N}$. For parity games with a small number of priorities, more specifically if $d = O(n^{1/2})$, the progress-measure lifting algorithm [20] gave, until recently, the best time complexity of $O(dm(2n/d)^{d/2})$. This has been improved by Schewe [30] to $O(m(\kappa n/d)^{d/3})$, where $\kappa \leq (2e)^{3/2}$. If $d = \Omega(n^{(1/2)+\varepsilon})$, then the randomized algorithm of Björklund, Sandberg, and Vorobyov [2] has a better (expected) running-time bound of $n^{O(\sqrt{n/\log n})}$.

The main contribution of this paper is a *deterministic* algorithm for solving parity games which achieves roughly the same complexity as the randomized algorithm of Björklund, Sandberg, and Vorobyov [2]: the complexity of our algorithm is $n^{O(\sqrt{n/\log n})}$ if the out-degree of all vertices is bounded, and is $n^{O(\sqrt{n})}$ otherwise. The new algorithm uses only polynomial space.

The randomized algorithm of Björklund, Sandberg, and Vorobyov [2] is based on the randomized algorithm of Ludwig [25] for simple stochastic games, which in turn is inspired by the subexponential randomized simplex algorithms for linear programming and LP-type problems by Kalai [23] and by Matoušek, Sharir, and Welzl [26]. For games with out-degree two these algorithms are instantiations of the Random-Facet algorithm for finding the unique sink in an acyclic unique sink orientation (AUSO) of a hypercube [13]. The nodes of a hypercube correspond to positional strategies for one of the players, and the orientation of an edge connecting two positional strategies

that differ at exactly one vertex is determined by which of the two strategies has a better value when the opponent plays a best-response strategy [7, 25, 32, 2].

In contrast, our deterministic algorithm for parity games is obtained by a modification of a more elementary algorithm of McNaughton and Zielonka for parity games [33, 15]. The methods we use are thus very different from those of Ludwig and Björklund et al. Our method is applicable, so it seems, only to parity games, while the randomized algorithms for finding the unique sink in an AUSO [13] and for solving an LP-type problem [26] can be applied to a number of problems, including computing the values of parity, mean payoff, discounted payoff, and simple stochastic games [2, 1, 16].

The recent improvement of the complexity of solving parity games with a small number of priorities due to Schewe [30] was inspired by the preliminary version of this paper published at SODA'06 [22]. Schewe refined our technique of searching and removing dominions while running the classical recursive algorithm [27, 33]: instead of a brute-force search he used a modification of the progress measure lifting algorithm [20].

2. Definitions. A *parity game* $G = (V_0, V_1, E, p)$ is composed of two disjoint sets of vertices V_0 and V_1, a set of directed edges $E \subseteq V \times V$, where $V = V_0 \cup V_1$, and a *priority* function $p : V_0 \cup V_1 \to \mathbb{N}$, defined on its vertices. Every vertex $u \in V$ has at least one outgoing edge $(u, v) \in E$. The game is played by two players: *Even*, also referred to as Player 0, and *Odd*, also referred to as Player 1.

The game starts at some vertex $v_0 \in V$. The players construct an infinite path (a play) as follows. Let u be the last vertex added so far to the path. If $u \in V_0$, then Player 0 chooses an edge $(u, v) \in E$. Otherwise, if $u \in V_1$, then Player 1 chooses an edge $(u, v) \in E$. In either case, vertex v is added to the path, and a new edge is then chosen by either Player 0 or Player 1. As each vertex has at least one outgoing edge, the path constructed can always be continued.

Let $v_0, v_1, v_2, \ldots$ be the infinite path constructed by the two players, and let $p(v_0), p(v_1), p(v_2), \ldots$ be the sequence of the priorities of the vertices on the path. Player 0 wins the play if the largest priority seen infinitely many times is even, and Player 1 wins otherwise. Observe that removing an arbitrary finite prefix of a play in a parity game does not change the winner; we refer to this property of parity games as *prefix independence*.

A *strategy* for Player i in a game G specifies, for every finite path $v_0, v_1, \ldots, v_k$ in G that ends in a vertex $v_k \in V_i$, an edge $(v_k, v_{k+1}) \in E$. A strategy is said to be a *positional* strategy if the edge $(v_k, v_{k+1}) \in E$ chosen depends only on v_k, the last vertex visited. A strategy for Player i is said to be a *winning* strategy if using this strategy ensures a win for Player i, no matter which strategy is used by the other player. The determinacy theorem for parity games [11, 15] says that for every parity game G and every start vertex v_0, either Player 0 has a winning strategy or Player 1 has a winning strategy. (This claim is not immediate as the games considered are infinite.) Furthermore, if a player has a winning strategy from a vertex in a parity game, then she also has a winning positional strategy from this vertex.

In the parity game G illustrated in Figure 2.1, the initial vertex is labeled a, *Even*'s vertices are represented as squares (even number of sides), and *Odd*'s as triangles. The numbers within the vertices show priorities. Note that each player's vertices may have both even and odd parities. As an example of a play in G, if each player were to choose the double-headed arrow out of each of their vertices, then the infinite path formed would be $a, d, b, e, d, b, e, \ldots$, and the largest priority seen infinitely often would be 4 at vertex e. So *Even* would win this play.

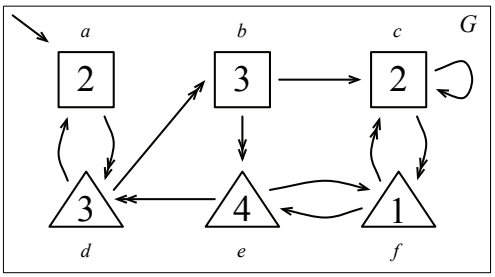

FIG. 2.1. *A parity game G. Double-headed arrows show a positional strategy for each player.*

The winning set for Player i, denoted by $win_i(G)$, is the set of vertices of the game from which Player i has a winning strategy. By the determinacy theorem for parity games [11, 15] we have that $win_0(G) \cup win_1(G) = V$.

3. Overview of the new algorithm. The previously known deterministic algorithm [33, 15] on which our improvement is built will be described fully in section 5. It has a recursive structure: solving a game with n vertices may require two recursive calls to smaller games. In the worst case, each of these games may have $n-1$ vertices, resulting in a running time satisfying the recurrence $T(n) \leq 2T(n-1)+O(n^2)$, which yields $T(n) = O(2^n)$. We offer no improvement in the first of the two recursive calls, but we do take advantage of a special feature of the second of these.

We introduce the notion of a *dominion*. An i-dominion, as the name suggests, is a set of vertices D *ruled* by Player i, in the sense that Player i can win from every vertex of D, without leaving D and without allowing the other player to leave D. One example of an i-dominion would be the whole of $win_i(G)$, but there may well be other "i-closed" subsets of $win_i(G)$ which are i-dominions. Although finding i-dominions can be just as hard as finding $win_i(G)$, we show that searching for small enough dominions is feasible, though taking time exponential in the size of dominion sought.

The significance of dominions for our algorithm depends on two properties. First, every i-dominion found can be easily removed at small cost, leaving a smaller game to be solved. Second, the second of the recursive calls is to a game resulting from the removal of a dominion. Therefore, if we look for and then remove all small dominions before entering the recursive calls, we can be sure that the second recursive call is to a substantially reduced game. The corresponding recurrence is then of the form $T(n) \leq T(n-1) + T(n-\ell) + O(n^\ell)$ for some $\ell = \ell(n)$.

With an appropriate choice of $\ell(n)$ to achieve a balance between the time to search for dominions of size up to ℓ and the savings from avoidance of the worst cases of the second recursive call, we achieve our subexponential algorithm with running time $n^{O(\sqrt{n})}$.

In the next section we prepare for the algorithms by introducing some key notions (*i-closed* and *reachability* set) and proving some of their properties. Lemmas 4.5 and 4.6 lay the foundation for the exponential algorithm. They show that we can begin to solve a game G by considering the set A of vertices with highest priority which Player i (say) would like the play to visit infinitely often, and identifying the set A^* from which Player i can guarantee to reach A at least once. From Lemma 4.6, we see that by first solving the smaller game G' based on vertices in $V(G) \setminus A^*$ we can identify a subset U of the winning set of the opponent of Player i, say Player j, in G.

By Lemma 4.5 we then know that the set U^*, from which Player j can guarantee to reach U at least once, is also included in the winning set of Player j in G. Moreover, Lemma 4.5 establishes that the winning set of Player i in G is equal to her winning set in the smaller game based on vertices in $V(G) \setminus U^*$, and hence the task of solving the game G is reduced to the task of solving the smaller game. For an illustration, see Figure 5.2, where $A^* = \mathit{reach}_i(A)$, $U = W'_j$, and $U^* = \mathit{reach}_j(W'_j)$.

After giving details of the exponential algorithm in section 5, we show in section 6 how to find dominions. In sections 7 and 8 we integrate this search-and-remove process into our new algorithm and analyze the resulting running time.

4. Preliminaries. The results presented in this section are well known [15] and form the basis of algorithms by McNaughton [27] and Zielonka [33]. We include our detailed exposition of them here in order to fix the terminology and to make the paper self-contained.

A set $B \subseteq V$ is said to be *i-closed*, where $i \in \{0,1\}$, if for every $u \in B$ the following hold:

- if $u \in V_i$, then there is some $(u,v) \in E$, such that $v \in B$; and
- if $u \in V_{\neg i}$, then for every $(u,v) \in E$, we have $v \in B$.

(We use $\neg i$ for the element $(1-i)$ in $\{0,1\}$.) In other words, a set B is i-closed if Player i can always choose to stay in B while Player $\neg i$ cannot escape from it, i.e., B is a "trap" for Player $\neg i$.

LEMMA 4.1. *For each $i \in \{0,1\}$, the set $\mathit{win}_i(G)$ is i-closed.*

Proof. The proof is straightforward from the definitions and prefix independence of parity games. □

Let $A \subseteq V$ be an arbitrary set. The *i-reachability set* of A, denoted $\mathit{reach}_i(A)$, contains all vertices in A and all vertices from which Player i has a strategy to enter the set A at least once; we call such a strategy an *i-reachability strategy to* set A. (See Figure 4.1 for a simple example.)

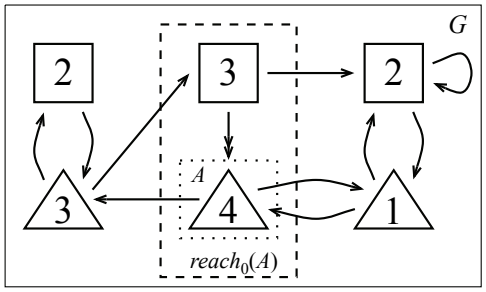

FIG. 4.1. *The 0-reachability set of A and a positional 0-reachability strategy to set A.*

LEMMA 4.2. *For every set $A \subseteq V$ and $i \in \{0,1\}$, the set $V \setminus \mathit{reach}_i(A)$ is $(\neg i)$-closed.*

Proof. Let $u \in V \setminus \mathit{reach}_i(A)$. Recall that every vertex has at least one outgoing edge; hence if $u \in V_{\neg i}$, then there must be an edge $(u,v) \in E$ from vertex u into the set $V \setminus \mathit{reach}_i(A)$, i.e., such that $v \notin \mathit{reach}_i(A)$, since otherwise vertex u would be in $\mathit{reach}_i(A)$. Similarly, if $u \in V_i$, then all edges from vertex u must go into the set $V \setminus \mathit{reach}_i(A)$. Therefore, the set $V \setminus \mathit{reach}_i(A)$ is $(\neg i)$-closed. □

LEMMA 4.3. *For every set $A \subseteq V$ and $i \in \{0,1\}$, the set $\mathrm{reach}_i(A)$ can be computed in $O(m)$ time, where $m = |E|$ is the number of edges in the game.*

Proof. The vertices of A are in $reach_i(A)$ so we initialize $B \leftarrow A$. We then iteratively add to B every vertex of V_i that has at least one edge going into B, and every vertex of $V_{\neg i}$ all of whose edges go into B. We stop when no new vertices can be added to B.

Some care is needed to keep the time in $O(m)$. One method is to maintain an adjacency list giving, for each vertex, the *incoming* edges together with a count of the number of outgoing edges. At each step we take an edge (u, v) entering B and delete it (from the list of edges entering v and from the count of edges leaving u): if $u \in B$, then nothing more is done; otherwise, if $u \in V_i$, then u is added to B; otherwise (when $u \in V_{\neg i} \setminus B$), if there are no other edges from u, then u is added to B.

It is easy to see that this process can be performed in $O(m)$ time, and that when it ends we have $B = reach_i(A)$, as required. □

If $B \subseteq V$ is such that for every vertex $u \in V \setminus B$ there is an edge (u, v) with $v \in V \setminus B$, then the *subgame* $G \setminus B$ is the game obtained from G by removing the vertices of B and all the edges that touch them. We will only be using B's for which $V \setminus B$ is an i-closed set for some i. In such cases $G \setminus B$ is always well-defined. The next lemmas show some useful properties of subgames.

LEMMA 4.4. *Let G' be a subgame of G and let $i \in \{0, 1\}$. If V', the vertex set of G', is i-closed in G, then $win_i(G') \subseteq win_i(G)$.*

Proof. A winning strategy for Player i from the set $win_i(G')$ in the subgame G' is also winning for her from the same set in the original game G. Player $\neg i$ cannot escape to $V \setminus V'$, since the set V' is i-closed in G. □

The following lemma implies that if we know an arbitrary nonempty subset U of the winning set of a player, say Player j, in a game G, then computing the winning sets of both players in G can be reduced to computing their winning sets in the smaller game $G \setminus reach_j(U)$.

LEMMA 4.5. *Let G be a parity game, let $i \in \{ 0, 1 \}$ and $j = \neg i$. If $U \subseteq win_j(G)$ and $U^* = reach_j(U)$, then $win_j(G) = U^* \cup win_j(G \setminus U^*)$ and $win_i(G) = win_i(G \setminus U^*)$.*

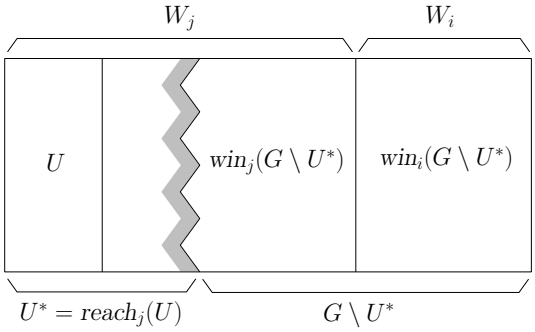

FIG. 4.2. *Diagram illustrating Lemma* 4.5.

Proof. Let $W_j = U^* \cup win_j(G \setminus U^*)$ and $W_i = win_i(G \setminus U^*)$; see Figure 4.2. Since (W_i, W_j) is a partition of V, it suffices to show that $W_i \subseteq win_i(G)$ and $W_j \subseteq win_j(G)$. By Lemma 4.2, $V \setminus U^*$, the vertex set of $G \setminus U^*$, is i-closed. The first inclusion then follows from Lemma 4.4.

To show the second inclusion, we exhibit a strategy for Player j that is winning for her from the set W_j in the game G. By the assumption that $U \subseteq win_j(G)$, there is a strategy σ for Player j in the game G which is winning for her from all vertices in U. Let τ be a winning strategy for Player j from the set $win_j(G \setminus U^*)$ in the

subgame $G \setminus U^*$. A strategy π for Player j in the game G is made by composing strategies τ and σ in the following way: if the play so far is contained in the set $win_j(G \setminus U^*)$, then follow strategy τ; otherwise use the j-reachability strategy to the set U and "restart" the play following the strategy σ thenceforth. The strategy π is well-defined because, by Lemma 4.1, Player i can escape from $win_j(G \setminus U^*)$ only into the set U^*. By prefix independence of parity games, the strategy π is a winning strategy for Player j, because if it ever switches from following τ to following σ, then an infinite suffix of the play is winning for Player j. □

The next lemma complements Lemma 4.5 by providing an algorithmic method which either finds a nonempty subset of the winning set of a player, say Player j, in a parity game G, or (if it returns an empty set) concludes that Player $\neg j$ can win from every vertex in G.

LEMMA 4.6. *Let G be a parity game. Let $d = d(G)$ be the highest priority and let $A = A_d(G)$ be the set of vertices of highest priority. Let $i = d \bmod 2$ and $j = \neg i$. Let $G' = G \setminus reach_i(A)$. Then we have $win_j(G') \subseteq win_j(G)$. Also, if $win_j(G') = \emptyset$, then $win_i(G) = V(G)$, i.e., Player i wins from every vertex of G.*

(As an example, consider Figures 4.1 and 4.3, with $i = 0$ and $j = 1$.)

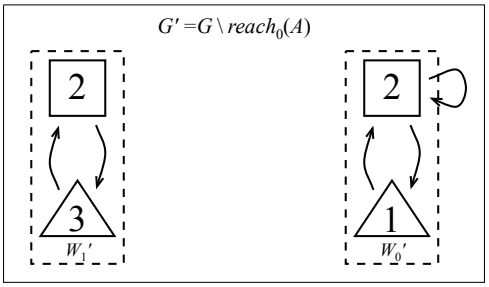

FIG. 4.3. *The game $G' = G \setminus reach_0(A)$ and winning sets $W'_i = win_i(G')$ for $i = 0, 1$.*

Proof. That $win_j(G') \subseteq win_j(G)$ follows from Lemmas 4.2 and 4.4.

Suppose now that $win_j(G') = \emptyset$. Let τ be a winning strategy for Player i from $win_i(G')$ (which, by determinacy, is equal to $V \setminus reach_i(A)$) in the subgame G'. We construct a strategy π for Player i in the following way: if a play so far is contained in the set $win_i(G')$, then follow strategy τ; otherwise the current vertex is in $reach_i(A)$ so follow the i-reachability strategy to the set A; moreover, each time the play reenters the set $win_i(G')$ "restart" the play and follow strategy τ, etc. If a play following the strategy π visits $reach_i(A)$ (and hence A) infinitely often, then it is winning for Player i because $i = d \bmod 2$. Otherwise, it has an infinite suffix played according to strategy τ, and hence it is winning for Player i by prefix independence of parity games. □

5. An exponential algorithm. A simple exponential-time algorithm for the solution of parity games is given in Figure 5.1. This algorithm originates from the work of McNaughton [27] and was first presented for parity games by Zielonka [33, 15]. Algorithm **win**(G) receives a parity game G and returns the pair of winning sets $(win_0(G), win_1(G))$ for the two players.

Algorithm **win**(G) is based on Lemmas 4.5 and 4.6. It starts by letting d be the largest priority in G and by letting A be the set of vertices having this highest priority. Let $i = d \bmod 2$ be the index of the player associated with the highest priority, and

```
algorithm win(G)
if V(G) = ∅ then return (∅, ∅)
d ← d(G) ; A ← A_d(G)
i ← d mod 2 ; j ← ¬i
(W'_0, W'_1) ← win(G \ reach_i(A))
if W'_j = ∅ then
   (W_i, W_j) ← (V(G), ∅)
else
   (W''_0, W''_1) ← win(G \ reach_j(W'_j))
   (W_i, W_j) ← (W''_i, V(G) \ W''_i)
endif
return (W_0, W_1)
```

FIG. 5.1. *An exponential algorithm for solving parity games.*

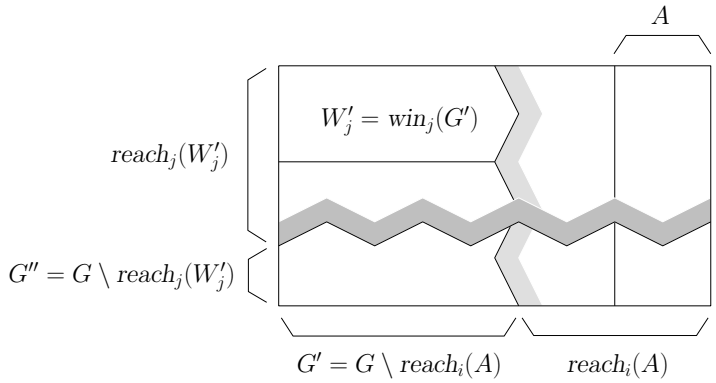

FIG. 5.2. *A game G and its subgames $G' = G \setminus reach_i(A)$ and $G'' = G \setminus reach_j(W'_j)$.*

let $j = \neg i$ be the index of the other player. The algorithm first finds the winning sets (W'_0, W'_1) of the smaller game $G' = G \setminus reach_i(A)$, using a recursive call; see Figure 5.2. By Lemma 4.6, if $W'_j = \emptyset$, then Player i wins from all vertices of G and we are done. Otherwise, again by Lemma 4.6, we know that $W'_j \subseteq win_j(G)$. The algorithm then finds the winning sets (W''_0, W''_1) of the smaller game $G'' = G \setminus reach_j(W'_j)$ by a second recursive call. By Lemma 4.5, we then know that $win_i(G) = W''_i$ and $win_j(G) = reach_j(W'_j) \cup W''_j = V(G) \setminus W''_i$.

A small detailed illustration of the main steps of the algorithm is given in Figures 4.1, 4.3, 5.3, and 5.4.

THEOREM 5.1. *Algorithm* $\mathbf{win}(G)$ *correctly finds the winning sets of the parity game G. Its running time is $O(2^n)$, where $n = |V(G)|$ is the number of vertices in G.*

Proof. The correctness of the algorithm follows from Lemmas 4.5 and 4.6, as argued above. Let $T(n)$ be the maximum running time of algorithm $\mathbf{win}(G)$ for a game on at most n vertices. Algorithm $\mathbf{win}(G)$ makes two recursive calls $\mathbf{win}(G')$ and $\mathbf{win}(G'')$ on games with at most $n-1$ vertices. Other than that, it performs only $O(n^2)$ operations. (The most time-consuming operations are the computations of the sets $reach_i(A)$ and $reach_j(W'_j)$.) Thus $T(n) \leq 2T(n-1) + O(n^2)$. It is easy to see then that $T(n) = O(2^n)$. □

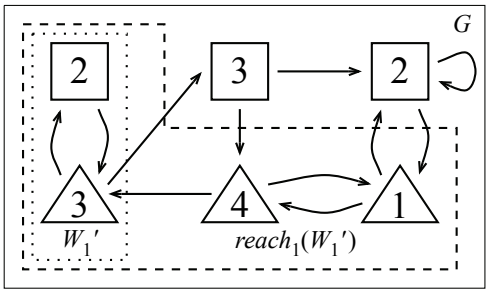

FIG. 5.3. *The* 1*-reachability set of* W_1'.

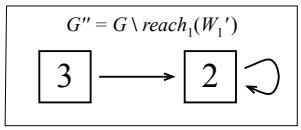

FIG. 5.4. *The game* $G'' = G \setminus reach_1(W_1')$.

6. Finding small dominions. A set $D \subseteq V(G)$ is said to be an *i-dominion* if Player i can win from every vertex of D without ever leaving D. Note, in particular, that an i-dominion must be i-closed. A set $D \subseteq V(G)$ is said to be a *dominion* if it is either a 0-dominion or a 1-dominion. By prefix independence of parity games, the winning set $win_i(G)$ of Player i is an i-dominion.

LEMMA 6.1. *Let* G *be a parity game on* n *vertices and let* $\ell \leq n/3$. *There is an* $O(n^\ell)$*-time algorithm that finds a nonempty dominion in* G *of size at most* ℓ, *or determines that no such dominion exists.*

Proof. If $\ell \leq n/3$, then, for all $j \leq \ell$, we have that $\binom{n}{j}/\binom{n}{j-1} > 2$. The number $\sum_{j=1}^{\ell}\binom{n}{j}$ of subsets of V of size at most ℓ is therefore at most $2\binom{n}{\ell}$. For each such subset U we check, in $O(\ell^2)$ time, whether it is 0-closed or 1-closed. If both tests fail, then U is clearly not a dominion. If U is i-closed, for some $i \in \{0,1\}$, we form the game $G[U]$, which is the game G restricted to U. This is well-defined since U is i-closed. We now apply the exponential algorithm of the previous section to $G[U]$ and find out, in $O(2^\ell)$ time, whether Player i can win from all the vertices of $G[U]$. If so, then U is an i-dominion; otherwise it is not. The total running time of the algorithm is therefore $O(\binom{n}{\ell}2^\ell) = O(n^\ell)$, as required. ∎

In a game with bounded out-degrees we can find small dominions even faster. For simplicity, the lemma below and the analysis in section 8 are stated for games in which the out-degree of every vertex is exactly two. Note, however, that for every constant b, every game on n vertices with out-degrees at most b can be easily converted into an equivalent game on at most $n(b-1)$ vertices with out-degrees exactly two, by replacing each higher-degree vertex by a binary tree.

LEMMA 6.2. *Let* G *be a parity game on* n *vertices in which the out-degree of each vertex is two. There is an* $O(n2^\ell \ell \log \ell)$*-time algorithm that finds a nonempty dominion in* G *of size at most* ℓ, *or determines that no such dominion exists.*

Proof. Assume, without loss of generality, that the vertices of G are numbered from 1 to n. Let $u \in V$ be a vertex of G and let (u, v_0) and (u, v_1) be the two edges emanating from v, where $v_0 \leq v_1$. We say that (u, v_0) is the 0th outgoing edge of v, while (u, v_1) is the 1st outgoing edge of v.

The algorithm generates at most $O(n2^\ell)$ 0-closed sets of size at most ℓ that are candidates for being 0-dominions. For every vertex $v \in V$ and a binary sequence $\langle a_1, \ldots, a_\ell \rangle \in \{0,1\}^\ell$, construct a set $U \subset V$ as follows. Start with $U = \{v\}$ and $r = 1$. Vertices added to U are initially unmarked. As long as there is still an unmarked vertex in U, pick the smallest such vertex $u \in U$ and mark it. If $u \in V_0$, then add the endpoint of the a_rth outgoing edge of u to U, if it is not already there,

and increment r. If $u \in V_1$, then add the endpoints of both the outgoing edges of u to U. If at some stage $|U| > \ell$, then discard the set U and restart the construction with the next binary sequence.

If the process above ends with $|U| \leq \ell$, then a 0-closed set of size at most ℓ has been found. Furthermore, for every vertex $u \in U \cap V_0$, one of the outgoing edges of u was selected. This corresponds to a suggested strategy for Player 0 in the game $G[U]$. Our algorithm therefore considers by exhaustive search all 0-closed sets of at most ℓ vertices, and for each set considers all possible positional strategies for Player 0.

Using an algorithm of King, Kupferman, and Vardi [24] we can check, in $O(\ell \log \ell)$ time, whether a given U and proposed strategy is indeed a winning strategy for Player 0 from all the vertices of U. Thus, if there is a 0-dominion of size at most ℓ in G, then the algorithm will find one. Finding 1-dominions of size at most ℓ can be done in an analogous manner. □

The algorithm described in Lemma 6.1 finds some i-dominion D if there is a dominion of size at most ℓ. We denote this algorithm by **dominion**(G, ℓ), and suppose that it returns either the pair (D, i) if successful, or $(\emptyset, -1)$ if not.

7. The new subexponential algorithm. The new algorithm for solving parity games is given in Figure 7.1. The algorithm **new-win** starts by trying to find a dominion of size at most ℓ, where $\ell = \lceil \sqrt{2n} \rceil$ (and $\ell = \lceil \sqrt{n \log n} \rceil$ for games with bounded out-degree) is a parameter chosen to minimize the running time of the whole algorithm. If such a small i-dominion is found, then it is easy to remove it, as well as its i-reachability set, from the game and recurse on what is left over. If no small

```
algorithm new-win(G)
if V(G) = ∅ then return (∅, ∅)
n ← |V(G)| ; ℓ ← ⌈√(2n)⌉
(D, i) ← dominion(G, ℓ); j ← ¬i
if D = ∅ then
    (W_0, W_1) ← old-win(G)
else
    (W'_0, W'_1) ← new-win(G \ reach_i(D))
    (W_j, W_i) ← (W'_j, V(G) \ W'_j)
endif
return(W_0, W_1)
```

```
algorithm old-win(G)
d ← d(G) ; A ← A_d(G)
i ← d mod 2 ; j ← ¬i
(W'_0, W'_1) ← new-win(G \ reach_i(A))
if W'_j = ∅ then
    (W_i, W_j) ← (V(G), ∅)
else
    (W''_0, W''_1) ← new-win(G \ reach_j(W'_j))
    (W_i, W_j) ← (W''_i, V(G) \ W''_i)
endif
return (W_0, W_1)
```

FIG. 7.1. *The new subexponential algorithm for solving parity games.*

dominion is found, then **new-win**(G) simply calls algorithm **old-win**(G), which is almost identical to the exponential algorithm **win**(G) of section 5. The only difference between **old-win**(G) and **win**(G) is that the recursive calls are made to **new-win**(G) and not to **win**(G).

THEOREM 7.1. *Algorithm* **new-win**(G) *correctly finds the winning sets of a parity game G. Its running time on a game with n vertices is $n^{O(\sqrt{n})}$.*

Proof. The correctness of the algorithm is immediate. We next analyze its running time. Let $T(n)$ be the maximum running time of **new-win**(G) on a game with at most n vertices.

Algorithm **new-win**(G) tries to find dominions of size at most $\ell = \lceil \sqrt{2n} \rceil$. By Lemma 6.1 this takes $O(n^\ell)$ time. If a nonempty dominion is found, then the algorithm simply proceeds on the remaining game, which has at most $n-1$ vertices, and the remaining running time is therefore at most $T(n-1)$. Otherwise, a call to **old-win**(G) is made. This results in a call to **new-win**$(G \setminus \mathit{reach}_i(A))$, which takes at most $T(n-1)$ time. If the set W'_j returned by the call is empty, then we are done. Otherwise, $W'_j = \mathit{win}_j(G \setminus \mathit{reach}_i(A))$, and this is equal to $\mathit{win}_j(G)$ by Lemma 4.5. Therefore W'_j is a j-dominion of G. We are in the case that there is no small dominion in G, so we know that $|W'_j| > \ell$, and therefore the second recursive call **new-win**$(G \setminus \mathit{reach}_j(W'_j))$ takes at most $T(n-\ell)$ time. Thus we get

$$T(n) \;\le\; O(n^\ell) + T(n-1) + T(n-\ell).$$

This recurrence relation, with $\ell = \lceil \sqrt{2n} \rceil$, is analyzed in Theorem 8.1, where it is shown that $T(n) = n^{O(\sqrt{n})}$. ∎

A slightly better bound is achieved for graphs with out-degree two.

THEOREM 7.2. *Consider the algorithm* **new-win**(G) *in which the variable ℓ is set to $\lceil \sqrt{n \log n} \rceil$. If the game G has n vertices and the out-degree of each of them is two, then the running time of the modified algorithm is $n^{O(\sqrt{n/\log n})}$.*

Proof. Note that if $\ell = \lceil \sqrt{n \log n} \rceil$, then $O(n 2^\ell \ell \log \ell) = n^{O(\sqrt{n/\log n})}$. Therefore, by Lemma 6.2 and by the analysis in the proof of the previous theorem, the time complexity $T(n)$ satisfies the following recurrence:

$$T(n) \;\le\; n^{O(\sqrt{n/\log n})} + T(n-1) + T(n-\ell).$$

The recurrence is analyzed in the following section in Theorem 8.2, where we show that $T(n) = n^{O(\sqrt{n/\log n})}$. ∎

8. Solving the recurrence relations. In this section we analyze the recurrence relations used in the previous section to bound the running time of the new algorithm.

We start by analyzing the recurrence relation used to bound the running time of the algorithm for game graphs with arbitrary out-degrees.

THEOREM 8.1. *If $T(n)$ is a positive function such that, for every $n > 3$,*

$$T(n) \;\le\; O(n^\ell) + T(n-1) + T(n-\ell),$$

where $\ell = \lceil \sqrt{2n} \rceil$, then $T(n) = n^{O(\sqrt{n})}$.

Proof. For every integer n we construct a binary tree $\mathcal{T}_n$ in the following way. The root of $\mathcal{T}_n$ is labeled by n. A node labeled by a number $k > 3$ has two children: a left child labeled by $k-1$ and a right child labeled by $k - \lceil \sqrt{2k} \rceil$. Nodes labeled by the numbers 1, 2, and 3 are leaves. A node labeled by k has a cost of $k^{O(\sqrt{2k})}$

associated with it. It is easy to see that the sum of the costs of the nodes of $\mathcal{T}_n$ is an upper bound on $T(n)$.

Clearly, the length of every path in $\mathcal{T}_n$ from the root to a leaf is at most n. We say that such a path makes a *right turn* when it descends from a vertex to its right child. We next claim that each such path makes at most $\lfloor\sqrt{2n}\rfloor$ right turns. This follows immediately from the observation that the function $f(n) = n - \lceil\sqrt{2n}\rceil$ can be iterated on n at most $\lfloor\sqrt{2n}\rfloor$ times before reaching the value of 3 or less. This observation can be proved by induction, based on the fact that if $\frac{1}{2}j^2 < n \leq \frac{1}{2}(j+1)^2$, then $n - \lceil\sqrt{2n}\rceil \leq \frac{1}{2}j^2$. (Initially we have $j = \lfloor\sqrt{2n}\rfloor$ and finally, with $1 \leq n \leq 3$, we have $j \geq 1$.)

As each leaf of $\mathcal{T}_n$ is determined by the positions of the right turns on the path leading to it from the root, we get that the number of leaves in $\mathcal{T}_n$ is at most $\binom{n}{\lfloor\sqrt{2n}\rfloor}$. The total number of nodes in $\mathcal{T}_n$ is therefore at most $2\binom{n}{\lfloor\sqrt{2n}\rfloor}$. As the cost of each node is at most $n^{O(\sqrt{2n})}$, we immediately get that

$$T(n) \;\leq\; 2\binom{n}{\lfloor\sqrt{2n}\rfloor} n^{O(\sqrt{2n})} \;=\; n^{O(\sqrt{n})}\,,$$

as claimed. □

A more careful analysis, in which the $O(n^\ell)$ term in the recurrence relation is replaced by $O\left(\binom{n}{\ell}2^\ell\right)$, can be used to show that $T(n) = O((cn)^{\sqrt{n/2}})$, for some constant $c > 0$, and that the choice $\ell = \lceil\sqrt{2n}\,\rceil$ is essentially optimal.

The running time of the algorithm for graphs with out-degree two satisfies a tighter recurrence relation, which is analyzed similarly in the next theorem.

THEOREM 8.2. *If $T(n)$ is a positive function such that, for every $n > 3$,*

$$T(n) \leq n^{O(\sqrt{n/\log n}\,)} + T(n-1) + T(n-\ell),$$

where $\ell = \lceil\sqrt{n \log n}\,\rceil$, then $T(n) = n^{O(\sqrt{n/\log n}\,)}$.

Proof. The proof is similar to the proof of Theorem 8.1. For every integer n we again construct a tree $\mathcal{T}_n$. A node labeled by a number $k > 2$ now has a left child labeled by $k-1$ and a right child labeled by $k - \lceil\sqrt{k \log k}\,\rceil$. The cost of a node labeled by k is now $k^{O(k/\log k)}$. Every root-to-leaf path in $\mathcal{T}_n$ is again of length at most n, and it can now make at most $O(\sqrt{n/\log n})$ right turns. Thus, the number of nodes in $\mathcal{T}_n$ is at most $n^{O(\sqrt{n/\log n})}$. As the cost of each node is also $n^{O(\sqrt{n/\log n})}$, we get that $T(n) = n^{O(\sqrt{n/\log n})}$, as claimed. □

9. Concluding remarks. We have obtained the first deterministic subexponential algorithm for solving parity games. Our algorithm does not seem to extend in an obvious way to the solution of the more general mean payoff games and simple stochastic games. On the other hand, the techniques that we have introduced in this paper have recently inspired a notable improvement in the running-time complexity of parity games with a small number of priorities [30].

Acknowledgments. We thank a SODA'06 referee for suggestions that resulted in a significant simplification of the proofs of Theorems 8.1 and 8.2, and the journal referees whose comments helped us improve the presentation.

LINEAR-TIME ALGORITHMS FOR DOMINATORS AND OTHER PATH-EVALUATION PROBLEMS*

ADAM L. BUCHSBAUM†, LOUKAS GEORGIADIS‡, HAIM KAPLAN§, ANNE ROGERS¶, ROBERT E. TARJAN‖, AND JEFFERY R. WESTBROOK**

Abstract. We present linear-time algorithms for the classic problem of finding dominators in a flowgraph, and for several other problems whose solutions require evaluating a function defined on paths in a tree. Although all these problems had linear-time solutions previously, our algorithms are simpler, in some cases substantially. Our improvements come from three new ideas: a refined analysis of path compression that gives a linear bound if the compressions favor certain nodes; replacement of random-access table look-up by a radix sort; and a more careful partitioning of a tree into easily managed parts. In addition to finding dominators, our algorithms find nearest common ancestors off-line, verify and construct minimum spanning trees, do interval analysis of a flowgraph, and build the component tree of a weighted tree. Our algorithms do not require the power of a random-access machine; they run in linear time on a pointer machine. The genesis of our work was the discovery of a subtle error in the analysis of a previous allegedly linear-time algorithm for finding dominators. That algorithm was an attempt to simplify a more complicated algorithm, which itself was intended to correct errors in a yet earlier algorithm. Our work provides a systematic study of the subtleties in the dominators problem, the techniques needed to solve it in linear time, and the range of application of the resulting methods. We have tried to make our techniques as simple and as general as possible and to understand exactly how earlier approaches to the dominators problem were either incorrect or overly complicated.

Key words. dominators, flowgraphs, pointer machine, random-access machine, set union, path compression, nearest common ancestors, minimum spanning trees, interval analysis, component tree, data structures, analysis of algorithms

1. Introduction.

The story of this paper begins with the publication in 1979 [43] of an almost-linear-time algorithm for the problem of finding immediate domina-

*Received by the editors May 30, 2007; accepted for publication (in revised form) July 18, 2008; published electronically November 12, 2008. This work is partially covered by the extended abstracts *Linear-time pointer-machine algorithms for least common ancestors, MST verification, and dominators*, in Proceedings of the 30th ACM Symposium on Theory of Computing, 1998, pp. 279–288, and *Finding dominators revisited*, in Proceedings of the 15th ACM-SIAM Symposium on Discrete Algorithms, 2004, pp. 862–871. tors in a flowgraph. Computing dominators is a fundamental problem in the theory of directed graphs and is a crucial first step in global optimizations of computer code. Although versions of the 1979 dominators algorithm are very fast in practice [34] and are widely used, the question remained of whether dominators could be computed in linear time, in either the random-access-machine (RAM) model or the less powerful pointer-machine model. Harel [37] claimed to have a linear-time RAM algorithm, but Alstrup et al. [10] found problems in his work. They developed a correct but very complicated algorithm that uses powerful bit-manipulation techniques. Buchsbaum et al. [16] claimed to present a simpler linear-time algorithm, but Georgiadis and Tarjan [32] found a flaw in their analysis, which, when corrected, results in a nonlinear-time bound. They also presented a way to repair and modify the algorithm so that it does indeed run in linear time, on a pointer machine. Buchsbaum et al. [16, Corrig.] gave a different fix for the RAM model.

Our paper addresses the question of exactly what techniques are needed to compute dominators in linear time and explores the range of application of these techniques. We clarify and extend the conference papers [15, 32] to provide not only a linear-time algorithm for finding dominators but linear-time algorithms for a variety of related problems as well. We avoid the use of bit-manipulation techniques, so that all our algorithms can run on a pointer machine. We describe the techniques needed (in different combinations) to obtain these results as well as the key difficulties in the dominators problem.

2. Overview. We study six problems—off-line computation of nearest common ancestors (NCAs), verification and construction of minimum spanning trees (MSTs), interval analysis of flowgraphs, finding dominators in flowgraphs, and building the component tree of a weighted tree—that directly or indirectly require the evaluation of a function defined on paths in a tree. Each of these problems has a linear-time algorithm on a RAM. Some of these algorithms are quite complicated, and the fastest pointer-machine algorithms are slower by an inverse-Ackermann-function factor.[1] (See Table 2.1.)

TABLE 2.1

Time bounds, where n is the number of vertices, m is either the number of edges/arcs for graph problems or the number of NCA queries for the NCA problem, and $\alpha(m, n)$ is the standard functional inverse of the Ackermann function.

Problem	Previous pointer-machine bound		Previous RAM bound	
Off-line NCAs	$O(m\alpha(m, n) + n)$	[3]	$O(n + m)$	[38, 52]
MST verification	$O(m\alpha(m, n) + n)$	[58]	$O(n + m)$	[22, 40]
MST construction	$O(m\alpha(m, n) + n)$	[18]	$O(n + m)$	[26, 39]
Interval analysis	$O(m\alpha(m, n) + n)$	[57]	$O(n + m)$	[29, 57]
Dominators	$O(m\alpha(m, n) + n)$	[43]	$O(n + m)$	[10, 16]
Component trees	$O(m\alpha(m, n) + n)$		$O(n + m)$	[62]

A pointer machine [59] allows binary comparisons and arithmetic operations on data, dereferencing of pointers, and equality tests on pointers. It does not permit pointer arithmetic or tests on pointers other than testing for equality and is thus less powerful than the RAM model [2]. Pointer machines are powerful enough to simulate

[1] We use Tarjan's definition [56]. Let $A(i, j)$ for $i, j \geq 1$ be defined by $A(1, j) = 2^j$ for $j \geq 1$; $A(i, 1) = A(i-1, 2)$ for $i \geq 2$; and $A(i, j) = A(i-1, A(i, j-1))$ for $i, j \geq 2$. Then $\alpha(m, n) = \min\{i \geq 1 : A(i, \lfloor m/n \rfloor) > \log n\}$.

functional programming languages like LISP and ML. Pointer machine algorithms can be simpler than RAM algorithms in that they avoid the use of table look-up and more complicated bit-manipulation techniques. Thus pointer machine algorithms may have a conceptual, if not a practical, advantage over RAM algorithms.

We develop linear-time algorithms for all six problems that are simpler than the previous algorithms, in some cases substantially. We extract the commonalities among the problems and develop a set of techniques that in various combinations give our efficient algorithms. We do not use table look-up or any bit-manipulation techniques, so all our algorithms can run on a pointer machine.

Our improvements come mainly from three new ideas. The first is a refined analysis of path compression. Path compression is a well-known technique first used to speed up the standard disjoint-set-union (DSU) data structure [56] and later extended to speed up the evaluation of functions defined on paths in trees [58]. Our applications use either the DSU structure or path evaluation for the function *minimum* or *maximum*, or both. We show that, under a certain restriction on the compressions, which is satisfied by our applications, compression takes constant rather than inverse-Ackermann amortized time.

The second new idea is to replace the table-based methods of the RAM algorithms with radix sorting. Each of the RAM algorithms precomputes answers to small subproblems, stores the answers in a table, and looks up the answers by random access. If the size of the subproblems is small enough, the total size of all distinct subproblems and the total time to solve them are linear (or even sublinear) in the size of the original problem. Our alternative approach is to construct an encoding of each subproblem, group isomorphic subproblems together using a radix sort, solve one instance of each group of isomorphic subproblems, and transfer its solution to the isomorphic subproblems.

The third new idea is to change the partitioning strategy. In order to reduce the original problem to a collection of small subproblems, the RAM algorithms partition a tree corresponding to the original problem into small subtrees. For some of the problems, partitioning the entire tree into subtrees produces serious technical complications, especially for computing dominators. Instead, for all but one of the problems we partition only the bottom part of the tree into small subtrees. For NCAs and MSTs, this technique together with our refined analysis of path compression suffices to yield a linear-time algorithm. For interval analysis and finding dominators, we also partition the remainder of the tree into a set of maximal disjoint paths. Only one of our applications, building a component tree, relies on the original idea of partitioning the entire tree into small subtrees.

The remainder of our paper proceeds as follows. Section 3 formally defines the problems we consider and reviews previous work. Section 4 discusses DSU and computing path minima on trees, and gives a refined analysis of path compression. Section 5 discusses the use of radix sorting to solve a graph problem for a collection of many small instances. Sections 6 through 10 discuss our applications: NCAs, MSTs, flowgraph interval analysis, finding dominators, and building a component tree, respectively. Section 11 contains concluding remarks. Our paper is a significantly revised and improved combination of two conference papers [15, 32], including new results in sections 8 and 10.

3. Problem definitions and previous work. Throughout this paper we denote the base-two logarithm by log. We assume $n \geq 2$ throughout.

3.1. Nearest common ancestors.

PROBLEM 3.1 (off-line nearest common ancestors). *Given an n-node tree T rooted at node r and a set P of m node pairs, find, for each pair $\{v, w\}$ in P, the nearest common ancestor of v and w in T, denoted by $nca(v, w)$.*

The fastest previous pointer-machine algorithm is that of Aho, Hopcroft, and Ullman (AHU) [3], which runs in $O(n + m\alpha(m + n, n))$ time. The AHU algorithm uses a DSU data structure; it runs in $O(n + m)$ time on a RAM if this structure is implemented using the DSU algorithm of Gabow and Tarjan [29] for the special case in which the set of unions is known in advance. The first linear-time RAM algorithm was actually given by Harel and Tarjan [38]. Other linear-time RAM algorithms were given by Schieber and Vishkin [52], Bender and Farach-Colton [12], and Alstrup et al. [9].

There are several variants of the NCAs problem of increasing difficulty. For each but the last, there is a nonconstant-factor gap between the running time of the fastest RAM and pointer-machine algorithms.

- *Static on-line.* T is given a priori but P is given on-line: each NCA query must be answered before the next one is known.
- *Linking roots.* T is given dynamically. Specifically, T is initially a forest of singleton nodes. Interspersed with the on-line NCA queries are on-line $link(v, w)$ operations, each of which is given a pair of distinct roots v and w in the current forest and connects them by making v the parent of w.
- *Adding leaves.* Like linking roots, only v is any node other than w and w is a singleton.
- *General linking.* Like linking roots, only v can be any node that is not a descendant of w.
- *Linking and cutting.* Like general linking, but with additional interspersed $cut(v)$ operations, each of which is given a nonroot node and makes it a root by disconnecting it from its parent.

Harel and Tarjan [38] showed that the static on-line problem (and thus each more general variant) takes $\Omega(\log \log n)$ time on a pointer machine for each query, in the worst case. Alstrup and Thorup [7] gave a matching $O(n + m \log \log n)$-time pointer-machine algorithm for general linking, which is also optimal for the static on-line, linking roots, and adding leaves variants. Earlier, Tsakalidis and van Leeuwen [63] gave such an algorithm for the static on-line variant, and a modified version of van Leeuwen's earlier algorithm [64] has the same bound for linking roots. The fastest known pointer-machine algorithm for linking and cutting is the $O(n + m \log n)$-time algorithm of Sleator and Tarjan [53]; Harel and Tarjan [38] conjectured that this is asymptotically optimal, which in the cell-probe model follows from a result of Pătraşcu and Demaine [47]. On a RAM, the fastest known algorithms take $\Theta(n + m)$ time for the static on-line [38, 52] and adding leaves [27] variants, $O(n + m\alpha(m + n, n))$ time for linking roots [38] and general linking [27], and $O(n + m \log n)$ time for linking and cutting [53]. All these algorithms use $O(n + m)$ space. For a more thorough survey of previous work see Alstrup et al. [9].

3.2. Verification and construction of MSTs.

PROBLEM 3.2 (MST construction). *Given an undirected, connected graph $G = (V, E)$ whose edges have real-valued weights, find a spanning tree of minimum total edge weight (an MST) of G.*

PROBLEM 3.3 (MST verification). *Given an undirected, connected graph $G = (V, E)$ whose edges have real-valued weights and a spanning tree T of G, determine whether T is an MST of G.*

In both problems, we denote by n and m the numbers of vertices and edges, respectively. Since G is connected and $n \geq 2$, $m \geq n-1$ implies $n = O(m)$.

MST construction has perhaps the longest and richest history of any network optimization problem; Graham and Hell [35] and Chazelle [18] provide excellent surveys. A sequence of faster and faster algorithms culminated in the randomized linear-time algorithm of Karger, Klein, and Tarjan [39]. This algorithm requires a RAM, but only for a computation equivalent to MST verification. It is also *comparison-based*: the only operations it does on edge weights are binary comparisons. Previously, Fredman and Willard [26] developed a linear-time RAM algorithm that is not comparison-based. Subsequently, Chazelle [18] developed a deterministic, comparison-based $O(m\alpha(m,n))$-time pointer-machine algorithm, and Pettie and Ramachandran [49] developed a deterministic, comparison-based pointer-machine algorithm that runs in minimum time to within a constant factor. Getting an asymptotically tight bound on the running time of this algorithm remains an open problem.

Although it remains open whether there is a comparison-based, deterministic linear-time MST construction algorithm, even for a RAM, such algorithms do exist for MST verification. Tarjan [58] gave a comparison-based, deterministic $O(m\alpha(m,n))$-time pointer-machine algorithm for verification. Komlós [41] showed how to do MST verification in $O(m)$ comparisons, without providing an efficient way to determine which comparisons to do. Dixon, Rauch, and Tarjan [22] combined Tarjan's algorithm, Komlós's bound, and the tree partitioning technique of Gabow and Tarjan [29] to produce a comparison-based, deterministic linear-time RAM algorithm. King later gave a simplified algorithm [40].

3.3. Interval analysis of flowgraphs. A *flowgraph* $G = (V, E, r)$ is a directed graph with a distinguished *root vertex* r such that every vertex is reachable from r. A *depth-first spanning tree* D of G is a spanning tree rooted at r defined by some depth-first search (DFS) of G, with the vertices numbered from 1 to n in preorder with respect to the DFS (the order in which the search first visits them). We identify vertices by their preorder number. We denote by n and m the number of vertices and arcs of G, respectively.

PROBLEM 3.4 (interval analysis). *Given a flowgraph G and a depth-first spanning tree D of G, compute, for each vertex v, its* head $h(v)$*, defined by*

$$h(v) = \max\{u : u \textit{ is a proper ancestor of } v \textit{ in } D \textit{ and there is a path from } v \textit{ to } u \textit{ in } G \textit{ containing only descendants of } u\},$$
or null if this set is empty.

The heads define a forest called the *interval forest* H, in which the parent of a vertex is its head. If v is any vertex, the descendants of v in H induce a strongly connected subgraph of G, which is called an *interval*; these intervals impose a hierarchy on the loop structure of G. Interval analysis has been used in global flow analysis of computer programs [4], in testing flowgraph reducibility [60], and in the construction of two maximally edge-disjoint spanning trees of a flowgraph [57]. Tarjan [57] gave an $O(m\alpha(m,n))$-time pointer-machine algorithm for interval analysis using DSU. The Gabow–Tarjan DSU algorithm [29] reduces the running time of this algorithm to $O(m)$ on a RAM.

3.4. Finding dominators. Let $G = (V, E, r)$ be a flowgraph. We denote by n and m the number of vertices and arcs of G, respectively. Vertex v *dominates* vertex

w if every path from r to w contains v, and v is the *immediate dominator* of w if every vertex that dominates w also dominates v. The dominators define a tree rooted at r, the *dominator tree* T, such that v dominates w if and only if v is an ancestor of w in T: for any vertex $v \neq r$, the immediate dominator of v is its parent in T.

PROBLEM 3.5 (finding dominators). *Given a flowgraph $G = (V, E, r)$, compute the immediate dominator of every vertex other than r.*

Finding dominators in flowgraphs is an elegant problem in graph theory with fundamental applications in global flow analysis and program optimization [1, 19, 24, 45] and additional applications in VLSI design [11], theoretical biology [5, 6], and constraint programming [51]. Lengauer and Tarjan [43] gave a practical $O(m\alpha(m, n))$-time pointer-machine algorithm, capping a sequence of previous improvements [1, 45, 50, 55]. Harel [37] claimed a linear-time RAM algorithm, but Alstrup et al. [10] found problems with some of his arguments and developed a corrected algorithm, which uses powerful bit-manipulation-based data structures. Buchsbaum et al. [16] proposed a simpler algorithm, but Georgiadis and Tarjan [32] gave a counterexample to their linear-time analysis and presented a way to repair and modify the algorithm so that it runs in linear time on a pointer machine; Buchsbaum et al. [16, Corrig.] gave a different resolution that results in a linear-time algorithm for a RAM.

3.5. Building a component tree. Let T be a tree and let L be a list of the edges of T. The *Kruskal tree* of T with respect to L is a tree representing the connected components formed by deleting the edges of T and adding them back one at a time in the order of their occurrence in L. Specifically, K contains $2n-1$ nodes. Its leaves are the nodes of T. Each internal node is a component formed by adding an edge (v, w) back to T; its children are the two components that combine to form it.

PROBLEM 3.6 (component-tree construction). *Given an n-node tree T and a list L of its edges, build the corresponding Kruskal tree.*

Compressed component trees (formed by adding edges a group at a time rather than one at a time) have been used in shortest-path algorithms [48, 62]. It is straightforward to build a component tree or a compressed component tree in $O(n\alpha(n, n))$ time on a pointer machine using DSU. The Gabow–Tarjan DSU algorithm [29] improves this algorithm to $O(n)$ time on a RAM, as described by Thorup [62].

4. Path compression on balanced trees.

4.1. DSU via path compression and balanced unions. The *disjoint set union* (DSU) problem calls for the maintenance of a dynamic partition of a universe U, initially consisting of singleton sets. Each set has a unique *designated element*; the designated element of a singleton set is its only element. Two operations are allowed:

- *unite*(v, w): Form the union of the sets whose designated elements are v and w, with v being the designated element of the new set.
- *find*(v): Return the designated element of the set containing element v.

There are alternative, equivalent formulations of the DSU problem. In one [59, 56], each set is accessed by a label, rather than by a designated element. In another [61], sets have labels but can be accessed by *any* element. In yet another [61], each set is accessed by a *canonical element*, which in the case of a *unite*(v, w) operation can be freely chosen by the implementation to be either v or w. Our formulation more closely matches our uses. We denote by n the total number of elements and by m the total number of finds.

The standard solution to the DSU problem [56, 61] represents the sets by rooted trees in a forest. Each tree represents a set, whose elements are the nodes of the tree.

Each node has a pointer to its parent and a bit indicating whether it is a root; the root points to the designated element of the set. To provide constant-time access to the root from the designated node, the latter is either the root itself or a child of the root. With this representation, to perform *unite*(v, w), find the roots of the trees containing v and w, link them together by making one root the parent of the other, and make v a child of the new root if it is not that root or a child of that root already. To perform *find*(v), follow parent pointers until reaching a root, reach the designated element of the set in at most one more step, and return this element. A unite operation takes $O(1)$ time. A find takes time proportional to the number of nodes on the find path. A sequence of intermixed unite and find operations thus takes $O(n + s)$ time, where s is the total number of nodes on find paths.

One way to reduce s is to use *path compression*: after a find, make the root the parent of every other node on the find path. Another way to reduce s is to do *balanced unions*. There are two well-known balanced-union rules. In the first, *union-by-size*, each root stores the number of its descendants. To perform *unite*(v, w), make the root of the larger tree the parent of the root of the smaller, making either the parent of the other in case of a tie. In the second, *union-by-rank*, each root has a nonnegative integer *rank*, initially zero. To perform *unite*(v, w), make the root of higher rank the parent of the root of lower rank; in case of a tie, make either root the parent of the other and add one to the rank of the remaining root. Both of these union rules produce *balanced* trees. More specifically, let F be the forest built by doing all the unite operations and none of the finds. We call F the *reference forest*. F is *balanced* or, more precisely, *c-balanced* if for a constant $c > 1$ the number of nodes of height h in F is $O(n/c^h)$ for every h. Both union-by-size and union-by-rank produce 2-balanced forests. Furthermore, since only roots must maintain sizes or ranks, these fields obviate the need for separate bits to indicate which nodes are roots.

For any sequence of unions and finds such that the unions build a balanced forest and the finds use path compression, the total running time is $O(n+m\alpha(m+n, n))$: the analysis of path compression by Tarjan and van Leeuwen [61] applies if the reference forest is balanced. We seek a linear time bound, which we can obtain for sequences of finds that are suitably restricted. Before obtaining this bound, we discuss a more general use of path compression and balanced union: to find minima on paths in dynamic trees.

4.2. Finding minima on paths. The *dynamic path-minimum problem* calls for the maintenance of a forest of rooted trees, each initially a one-node tree, whose arcs, which are directed from parent to child, have real values. The trees are subject to three operations:

- *link*(v, w, x): Nodes v and w are the roots of different trees in F, and x is a real number. Make v the parent of w by adding arc (v, w) to F, with value x.
- *findroot*(v): Return the root of the tree in F containing the node v.
- *eval*(v): Return the minimum value of an arc on the path to v from the root of the tree containing it.

We shall denote by n the total number of nodes and by m the total number of *findroot* and *eval* operations. Variants of this problem include omitting the *findroot* operation, replacing minimum by maximum, and requiring the *eval* operation to return an arc of minimum value rather than just the minimum value. The two solutions to be described are easily modified to handle these variants. We call a data structure that solves the dynamic path-minimum problem a *link-eval structure*.

Tarjan [58] considered this problem and developed two data structures to solve it: a simple one [58, sec. 2], which uses path compression on the forest defined by the links, and a sophisticated one [58, sec. 5], which uses path compression on a balanced forest related to the one defined by the links. Tarjan's simple link-eval structure uses a compressed version of F, represented by parent pointers, with the nodes rather than the arcs storing values. Each root has value infinity. Perform *link*(v, w, x) by making v the parent of w and giving w the value x. Perform *findroot*(v) by following parent pointers from v to the root of the tree containing it, compressing this path, and returning the root. Perform *eval*(v) by following parent pointers from v to the root of the tree containing it, compressing this path, and returning the value of v. To compress a path $v_0, v_1, \ldots, v_k$ with v_i the parent of v_{i+1} for $0 \leq i < k$, repeat the following step for each i from 2 through k: replace the parent of v_i by v_0, and replace the value of v_i by the value of v_{i-1} if the latter is smaller. Compression preserves the results of *findroot* and *eval* operations while making tree paths shorter.

If the final forest F is balanced, then this simple link-eval structure takes $O(n + m\alpha(m + n, n))$ time to perform a sequence of operations [58]: the effect of a compression on the structure of a tree is the same whether the compression is due to a *findroot* or an *eval*. In our MST application the final forest is actually balanced. Our application to finding dominators requires Tarjan's sophisticated link-eval structure.

4.3. Delayed linking with balancing. Tarjan's sophisticated structure delays the effect of some of the links so that they can be done in a way that makes the resulting forest balanced. Since our analysis requires some knowledge of the inner workings of this structure, we describe it here. We streamline the structure slightly, and we add to it the ability to do *findroot* operations, which were not supported by the original. We also describe (in section 4.4) a variant that uses linking-by-rank; the original uses linking-by-size.

We represent the forest F defined by the link operations by a *shadow forest* R. Each tree in F corresponds to a tree in R with the same vertices and the same root. Each tree T in R is partitioned into one or more subtrees $S_0, S_1, \ldots, S_k$, such that the root of S_i is the parent of the root of S_{i+1} for $0 \leq i < k$, and the root of S_0 is the root of T. We call the roots of the subtrees $S_0, S_1, \ldots, S_k$ (including the root of S_0) *subroots*. We represent R by a set of parent pointers that are defined for nodes that are not subroots and, for each subroot, a pointer to its child that is a subroot, if any. (Each subroot has a null parent pointer; the deepest subroot has a null child pointer.) Since parents are needed only for nodes that are not subroots and child pointers are required only for subroots, we can use a single pointer per node to store both kinds of pointers, if we mark each node to indicate whether it is a subroot. We shall use *shp*(v) to denote the parent of v in its subtree and *shc*(v) to denote the child of v that is a subroot, if there is one; *shp*$(v) =$ *null* if v is a subroot, and *shc*$(v) =$ *null* if v is a subroot without a child that is a subroot.

With each node v we store a value $b(v)$. We manipulate the trees of R and the node values to preserve two related invariants:

(i) *eval*$(v) = \min\{b(u) : u$ is an ancestor in R of v in the same subtree$\}$;
(ii) $b($*shc*$(v)) \leq b(v)$ if *shc*$(v) \neq$ *null*.

To help keep evaluation paths short, we use both path compression and a variant of union-by-size. We denote by *size*(v) the number of descendants of v in R and by *subsize*(v) the number of descendants of v in the same subtree as v. For convenience, we let *size*(*null*) $= 0$. Then *subsize*$(v) =$ *size*(v) if v is not a subroot, and *subsize*$(v) =$

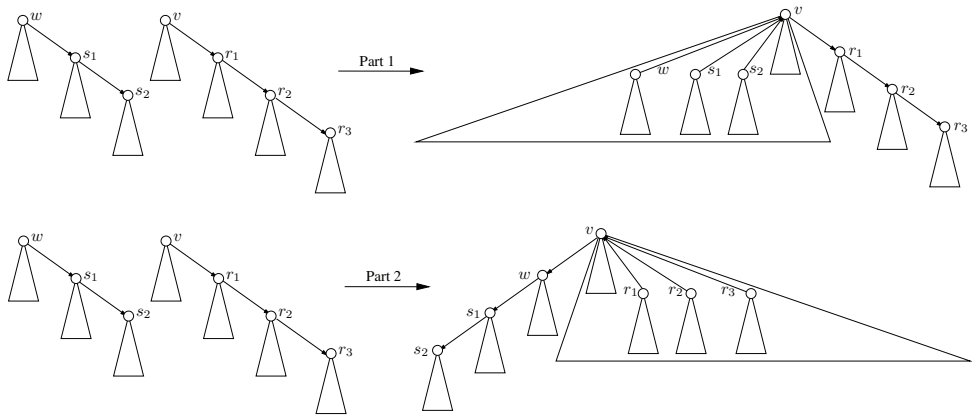

FIG. 4.1. *Linking by size: Part* 1, *size*$(v) \geq$ *size*(w), *and Part* 2, *size*$(v) <$ *size*(w).

size(v) − *size*(*shc*(v)) if v is a subroot. We maintain sizes but only for subroots, which allows us to compute the subsize of a subroot in constant time.

To initialize the structure, make each node v a singleton tree (*shp*(v) = *shc*(v) = *null*), with $b(v) = \infty$ and *size*$(v) = 1$. To perform *eval*(v), return $b(v)$ if *shp*(v) = *null*; otherwise, compress the path to v from the subroot of the subtree containing it (exactly as in the simple link-eval structure of section 4.2), and then return $\min\{b(v), b(shp(v))\}$. Perform *link*(v, w, x) as follows. First, set $b(w)$ (previously infinity) equal to x. Next, if *size*$(v) \geq$ *size*(w), perform Part 1 below; otherwise, perform Part 2 below and, if necessary, Part 3. (See Figures 4.1 and 4.2.)

Part 1 (*size*$(v) \geq$ *size*(w)). Combine the subtree rooted at v with all the subtrees in the tree rooted at w by setting *shp*$(u) = v$ and $b(u) = \min\{b(u), x\}$ for each subroot u of a subtree in the tree rooted at w. Find such subroots by following *shc* pointers from w. (In Figure 4.1 (Part 1), the successive values of u are w, s_1, s_2.) This step effects a compression to v from the deepest subroot descendant of w. The updates to the b-values maintain (i) and (ii).

Part 2 (*size*$(v) <$ *size*(w)). Combine all the subtrees in the tree rooted at v by setting *shp*$(u) = v$ for each subroot $u \neq v$ of a subtree in the tree rooted at v. (In Figure 4.1 (Part 2), the successive values of u are r_1, r_2, r_3.) This step effects a compression to v from the deepest subroot descendant of v. Then set *shc*$(v) = w$. This may cause violations of invariants (i) and (ii).

Part 3. In order to restore (i) and (ii) after Part 2, repeat the following step until it no longer applies. Let s_0 = *shc*(v) and s_1 = *shc*(s_0). (In the first iteration, $s_0 = w$.) If $s_1 \neq$ *null* and $x < b(s_1)$, compare the subsizes of s_0 and s_1. If the former is not smaller, combine the subtrees with subroots s_0 and s_1, making s_0 the new subroot, by simultaneously setting *shp*$(s_1) = s_0$ and *shc*(s_0) = *shc*(s_1). If the former is smaller, combine the subtrees with subroots s_0 and s_1, making s_1 the new subroot, by simultaneously setting *shp*$(s_0) = s_1$, *shc*$(v) = s_1$, $b(s_1) = x$, and *size*(s_1) = *size*(s_0). Once this step no longer applies, (i) and (ii) are restored.

Complete the linking by setting *size*(v) = *size*(v) + *size*(w). We call this linking method *linking-by-size*.

The method must keep track of which nodes are subroots. Nodes that are not subroots can be marked as such by, e.g., setting their sizes to zero, since sizes are maintained only for subroots. We have omitted this updating from Parts 1, 2, and 3.

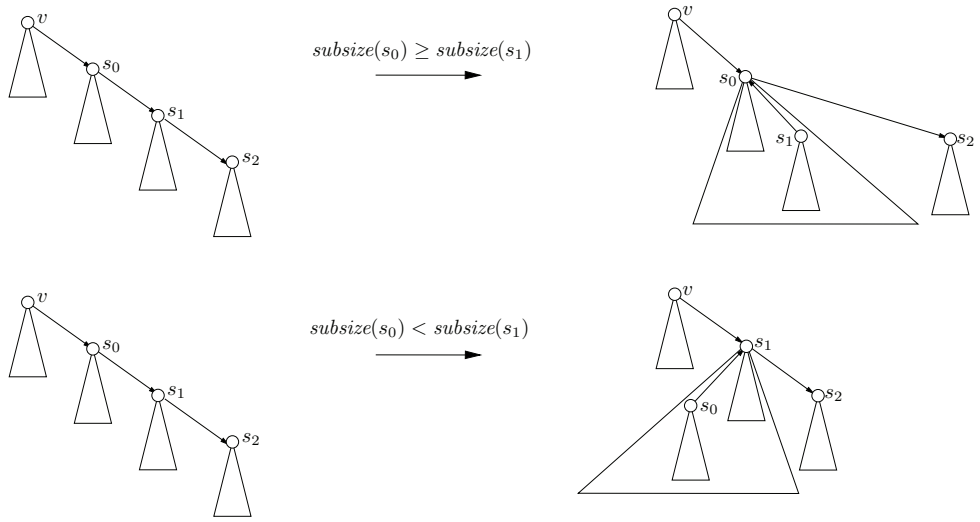

FIG. 4.2. *Linking by size: Part* 3.

This version of the data structure differs from the original [58] only in the placement of Part 3 of the link operation. In the original, Part 3 is done before Parts 1 and 2 to restore (i) and (ii), whether or not $size(v) \geq size(w)$. Delaying Part 3 allows it to be avoided entirely if $size(v) \geq size(w)$; in this case Part 1 alone suffices to restore (i) and (ii).

This structure does not support *findroot* (because an *eval* operation reaches only a subroot, not a root), but we can easily extend it to do so. To each subroot that is not a root, we add a pointer to its deepest subroot descendant; to each deepest subroot, we add a pointer to the root of its tree. Then a root is reachable from any subroot descendant in at most two steps. To perform *findroot*(v), compress the path to v from the subroot of its subtree; then follow at most two pointers to reach a root, and return this root. Operation *findroot* has the same asymptotic complexity as *eval*. The running time of a link operation increases by at most a constant factor because of the extra pointer updates needed.

In the sophisticated link-eval structure, path compression is performed on the subtrees, not on the trees. The next lemma implies that these subtrees are balanced.

LEMMA 4.1. *Consider a shadow forest built using linking-by-size. If u is a tree node such that $shp(u)$ and $shp(shp(u))$ are both nonnull, then $subsize(shp(shp(u))) \geq 2 \cdot subsize(u)$.*

Proof. A node u can be assigned a parent $shp(u)$ in Part 1, 2, or 3 of a link operation. If this occurs in Part 3, $subsize(shp(u)) \geq 2 \cdot subsize(u)$ after u gets its parent. Once this happens, $subsize(u)$ stays the same and $subsize(shp(u))$ can only increase. Thus when $shp(u)$ gets a parent, $subsize(shp(shp(u))) \geq subsize(shp(u)) \geq 2 \cdot subsize(u)$, and this inequality persists. Regardless of when u gets a parent $shp(u)$, if $shp(u)$ gets its parent in Part 3, then $subsize(shp(shp(u))) \geq 2 \cdot subsize(shp(u)) \geq 2 \cdot subsize(u)$ when this happens, and this inequality persists. Suppose then that both u and $shp(u)$ get their parents in Part 1 or 2. When u gets its parent, $size(shp(u)) \geq 2 \cdot subsize(u)$. Subsequently, $size(shp(u))$ cannot decrease until $shp(u)$ gets its parent, at which time $subsize(shp(shp(u))) \geq size(shp(u)) \geq 2 \cdot subsize(u)$. This inequality persists. ∎

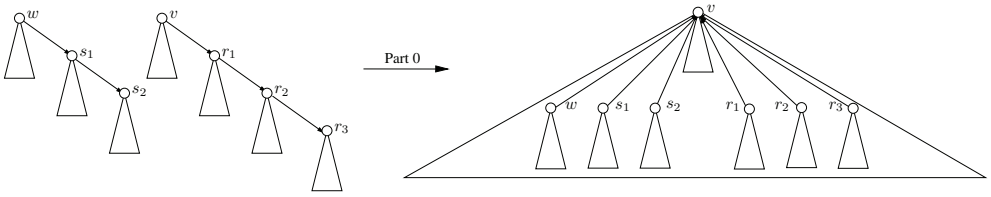

FIG. 4.3. *Linking by rank: Part* 0, *maxrank*(v) = *maxrank*(w).

COROLLARY 4.2. *The subtrees in any shadow forest built using linking-by-size are* $\sqrt{2}$*-balanced.*

4.4. Linking by rank. An alternative to using linking-by-size in the sophisticated link-eval structure is to use linking-by-rank. In place of a size, every node has a nonnegative integer *rank*, initially zero. The ranks satisfy the following invariant:

(iii) *rank*(*shp*(v)) > *rank*(v).

We explicitly maintain ranks only for subroots. If v is a virtual tree root (i.e., in F), we denote by *maxrank*(v) the maximum rank of a subroot descendant. With each virtual tree root v, we store *maxrank*(v) (in addition to *rank*(v)).

Perform *link*(v, w, x) as follows. First, set $b(w) = x$. Then compare *maxrank*(v) to *maxrank*(w). We split the rest of the operation into the following parts.

Part 0. If *maxrank*(v) = *maxrank*(w), set *rank*(v) = *maxrank*(v)+1, *maxrank*(v) = *maxrank*$(v) + 1$, and combine all the subtrees in the trees rooted at v and w into a single subtree rooted at v by setting *shp*$(u) = v$ for each subroot $u \neq v$, setting *shc*(v) = *null*, and setting $b(u) = \min\{b(u), b(w)\}$ if u was a descendant of w. (See Figure 4.3.)

Part 1. If *maxrank*(v) > *maxrank*(w), set *rank*$(v) = \max\{$*rank*(v), *maxrank*$(w) + 1\}$, and combine the subtree rooted at v with all the subtrees in the tree rooted at w by setting *shp*$(u) = v$ and $b(u) = \min\{b(u), b(w)\}$ for each subroot descendant u of w.

Part 2. If *maxrank*(v) < *maxrank*(w), combine all the subtrees in the tree rooted at v into a single subtree, unless *shc*(v) = *null*, by setting *rank*(v) = *maxrank*$(v) + 1$, *maxrank*(v)=*maxrank*(w), and, for each subroot $u \neq v$, *shp*$(u) = v$. Then set *shc*$(v) = w$. This may cause violations of invariants (i) and (ii).

Part 3. To restore (i) and (ii) after Part 2, repeat the following step until it no longer applies. Let s_0 = *shc*(v) and s_1 = *shc*(s_0). If $s_1 \neq$ *null* and $x < b(s_1)$, compare *rank*(s_0) to *rank*(s_1), and if *rank*(s_0) = *rank*(s_1), simultaneously set *shp*$(s_1) = s_0$, *shc*(s_0) = *shc*(s_1), *rank*(s_0) = *rank*$(s_0) + 1$, and *maxrank*$(v) = \max\{$*maxrank*(v), *rank*$(s_0) + 1\}$; if *rank*(s_0) > *rank*(s_1), simultaneously set *shp*$(s_1) = s_0$ and *shc*(s_0) = *shc*(s_1); if *rank*(s_0) < *rank*(s_1), simultaneously set *shp*$(s_0) = s_1$, *shc*$(v) = s_1$, and $b(s_1) = x$.

Parts 1, 2, and 3 of linking-by-rank correspond to Parts 1, 2, and 3 of linking-by-size; Part 0 handles the case of equal *maxranks*, in which all subtrees of both trees are combined. (We could add a corresponding Part 0 to linking-by-size, but this is unnecessary.) As does linking-by-size, linking-by-rank produces balanced forests, as we now show. For a node u, let *subsize*(u) be the number of descendants of u in its subtree.

LEMMA 4.3. *In any shadow forest built using linking-by-rank, any node* u *has* *subsize*$(u) \geq 2^{(rank(u)-1)/2}$.

Proof. To obtain this result we actually need to prove something stronger. Suppose we perform a sequence of link-by-rank operations. We track the states of nodes,

their ranks, and their subsizes as the links take place. Each node is in one of two states: *normal* or *special*. The following invariants will hold:

(a) a *normal node* u has $subsize(u) \geq 2^{rank(u)/2}$;

(b) a *special node* u has $subsize(u) \geq 2^{(rank(u)-1)/2}$;

(c) a *special root* u has a normal subroot descendant of rank at least $rank(u)$.

Initially all nodes are normal; since all initial ranks are zero, (a), (b), and (c) hold initially. We need to determine the effect of each part of an operation $link(v, w, x)$.

If $maxrank(v) = maxrank(w)$, we make v normal after the link; all other nodes retain their states. This preserves (a), (b), and (c); the only question is whether v satisfies (a), since it gains one in rank and can change from special to normal. Before the link, both the tree rooted at v and the tree rooted at w have a subroot of rank $maxrank(v)$. Since each of these nodes has subsize at least $2^{(maxrank(v)-1)/2}$ before the link by (a) and (b), after the link $subsize(v) \geq 2 \cdot 2^{(rank(v)-2)/2} = 2^{rank(v)/2}$. Hence (a) holds for v after the link.

If $maxrank(v) > maxrank(w)$ and $rank(v)$ does not change as a result of the link, all nodes retain their states. The link preserves (a), (b), and (c), because no node increases in rank. If $rank(v)$ does change because of the link (becoming one greater than the old value of $maxrank(w)$), we make v special. Node v now satisfies (b), because before the link w had a normal subroot descendant u of rank $maxrank(w)$, and $subsize(u) \geq 2^{maxrank(w)/2}$ by (a); hence, after the link, $subsize(v) \geq 2^{(rank(v)-1)/2}$. Node v satisfies (c), because before the link it had a normal subroot descendant z of rank $maxrank(v) \geq maxrank(w) + 1$, which it retains after the link.

The last case is $maxrank(v) < maxrank(w)$. In this case we look at the effects of Part 2 and Part 3 separately. If Part 2 does anything, we make v special. Node v satisfies (b), because before the link it had a normal subroot descendant of rank $maxrank(v)$, which satisfied (a); hence, after the link, $subsize(v) \geq 2^{(rank(v)-1)/2}$. Node v satisfies (c) after the link, because before the link w had a normal subroot descendant of rank $maxrank(w) \geq maxrank(v) + 1$ by (a), which becomes a normal subroot descendant of v.

Finally, we must account for the effect of Part 3. Each combination of subtrees done by Part 3 preserves (a), (b), and (c), except possibly for those that combine two subtrees with subroots, say y and z, of equal rank. In this case the rank of the surviving subroot increases by one; and if the ranks of y and z previously equaled $maxrank(v)$, $maxrank(v)$ increases by one. To preserve the invariants in this case, we make the surviving root, say y, normal. Now y satisfies (a), because before the subtrees rooted at y and z were combined, both y and z have subsize at least $2^{(rank(y)-1)/2}$; after the subtrees are combined, $subsize(y) \geq 2 \cdot 2^{(rank(y)-2)/2} = 2^{rank(y)/2}$. Because y satisfies (a), v satisfies (c).

Thus linking preserves the invariants. By induction, they remain true throughout any sequence of links. The lemma follows from (a) and (b). □

COROLLARY 4.4. *The subtrees in any shadow forest built using linking-by-rank are* $\sqrt{2}$*-balanced.*

THEOREM 4.5. *A sequence of operations performed using the sophisticated link-eval structure with either linking-by-size or linking-by-rank takes* $O(n)$ *time for the links and* $O(n + m\alpha(m + n, n))$ *time for the findroot and eval operations.*

Proof. The time for a link is $O(k + 1)$, where k is the decrease in the number of subtrees caused by the link. Thus the total time for all the links is $O(n)$. The total length of compressed paths, and hence the total time for *findroot* and *eval* operations, is $O(n+m\alpha(m+n, n))$ by the Tarjan–van Leeuwen analysis of path compression [61], applying Corollary 4.2 (for linking-by-size) or Corollary 4.4 (for linking-by-rank). □

4.5. Refined analysis of path compression. In order to use path compression on balanced trees as a tool for building linear-time algorithms, we need to show that the total time becomes linear if the compressions are suitably restricted. In order to capture both DSU and link-eval applications, we abstract the situation as follows. An intermixed sequence of the following two kinds of operations is performed on a rooted forest, initially consisting of n single-node trees:

- *assign*(u, v). Given two distinct roots u and v, make u the parent of v.
- *compress*(u). Compress the path to u from the root of the tree containing it by making the root the parent of every other node on the path.

LEMMA 4.6. *Suppose ℓ nodes are* marked *and the remaining $n - \ell$* unmarked. *Suppose the assignments build a balanced forest, and that each node has its parent change at most k times before it is in a tree containing a marked node. If there are m compress operations, then the total number of nodes on compression paths is $O(kn + m\alpha(m + \ell, \ell))$.*

Proof. Let F be the balanced forest built by the entire sequence of assignments, ignoring the compressions; let $c > 1$ be such that F is c-balanced; and let $h(v)$ be the height of a node v in F. Let

$$a = \lceil \log_c (n/\ell) + \log_c (1/(c-1)) + 1 \rceil.$$

Classify each node v into one of three types: *low*, if v has no marked descendant in F; *middle*, if v has a marked descendant in F and $h(v) < a$; and *high* otherwise.

A compression path from a tree root to one of its descendants consists of zero or more high nodes followed by zero or more middle nodes followed by zero or more low nodes. Every node on the path except the first two (totaling at most $2m$ over all compressions) has its parent change to one of greater height as a result of the compression.

Consider a compression path containing only low nodes. Since the root is low, the tree in which the compression takes place contains no marked nodes. All but two nodes on the path change parent but remain in a tree with no marked nodes. The number of times this can happen to a particular node is at most k by the hypothesis of the lemma, totaling at most kn over all compressions.

Consider a compression path containing at least one middle or high node. Every low node on the path except one has its parent change from low to middle or high as a result of the compression. Thus the total number of low nodes on such paths is at most $n + m$. Every middle node on the path whose parent changes obtains a parent of greater height. This can happen to a middle node at most a times before its parent is high. At most one middle node on a compression path has a high parent, totaling at most m over all compression paths. Each middle node has a marked node as a descendant; each marked node has at most $a + 1$ middle nodes as ancestors (at most one per height less than a). The total number of middle nodes is thus at most $\ell(a + 1)$. Combining estimates, we find that the total number of middle nodes on compression paths is at most $\ell \cdot a \cdot (a+1) + m$. Since $\ell \le n$ and a is $O(\log (n/\ell))$, the first term is $O(n)$, implying that the total number of middle nodes on compression paths is $O(n) + m$.

Finally, we need to count the number of high nodes on compression paths. Since F is c-balanced, the total number of high nodes is at most

$$\sum_{i \ge a} \frac{n}{c^i} \le \frac{n}{c^a} \cdot \frac{c}{c-1} = \frac{n}{c^{a-1}(c-1)} \le \ell.$$

Let the *rank* of a node v be $h(v) - a$. Then every high node has nonnegative rank, and the number of high nodes of rank $i \geq 0$ is at most ℓ/c^i. The analysis of Tarjan and van Leeuwen [61, Lem. 6] applied to the high nodes bounds the number of high nodes on compression paths by $O(\ell + m\alpha(m + \ell, \ell))$. Combining all our estimates gives the lemma. □

Lemma 4.6 gives a bound of $O(n+m)$ if, for example, $\ell = O(n/\log\log n)$, by the properties of the inverse-Ackermann function [56]. In our applications $\ell = n/\log^{1/3} n$, which is sufficiently small to give an $O(n + m)$ bound.

We conclude this section by reviewing some previous results on DSU and refined analysis of the DSU structure. The linear-time RAM DSU algorithm of Gabow and Tarjan [29] assumes a priori knowledge of the unordered set of unions. An earlier version of our work [15] contained a result much weaker than Lemma 4.6, restricted to disjoint set union, which required changing the implementation of unite based on the marked nodes. Alstrup et al. [10] also proved a weaker version of Lemma 4.6 in which the $m\alpha(m + \ell, \ell)$ term is replaced by $\ell \log \ell + m$, which sufficed for their purpose. They derived this result for a hybrid algorithm that handles long paths of unary nodes outside the standard DSU structure. Dillencourt, Samet, and Tamminen [20] gave a linear-time result assuming the *stable tree property*: essentially, once a find is performed on any element in a set X, all subsequent finds on elements currently in X must be performed before X can be united with another set. Fiorio and Gustedt [25] exploited the specific order of unions in an image-processing application. Gustedt [36] generalized the previous two works to consider structures imposed on sets of allowable unions by various classes of graphs. This work is orthogonal to that of Gabow and Tarjan [29]. Other improved bounds for path compression [14, 44, 46] restrict the order in which finds are performed, in ways different from our restriction.

5. Topological graph computations. Consider a computation that takes as input a graph G whose vertices and edges (or arcs) have $O(1)$-bit labels and produces some output information (possibly none) associated with the graph itself and with each vertex and edge (or arc). We call such a computation a *topological graph computation*, because it is based only on the graph structure and the $O(1)$-bit labels, in contrast, for example, to a problem in which graph vertices and edges (or arcs) have associated real values. In general the output of a topological graph computation can be arbitrarily complex, even exponential in size, and can contain pointers to elements of the input graph. Our MST verification algorithm will exploit this flexibility; in all our other applications, the size of the output is linear in the size of the input.

Suppose we need to perform a topological graph computation on not just one input graph but on an entire collection of graphs. If the input instances are small and there are many of them, then many of them will be isomorphic. By doing the computation once for each nonisomorphic instance (a *canonical instance*) and copying these solutions to the duplicate instances, we can amortize away the cost of actually doing the computations on the canonical instances; most of the time is spent identifying the isomorphic instances and transferring the solutions from the canonical instances to the duplicate ones. The total time spent is then linear in the total size of all the instances.

Gabow and Tarjan [29] used this idea to solve a special case of DSU in which the unordered set of unions is given in advance; Dixon, Rauch, and Tarjan [21] applied the technique to MST verification and other problems. These applications use table look-up and require a RAM. Here we describe how to accomplish the same thing on a pointer machine. Our approach is as follows. Encode each instance as a list of

pointers. Use a radix sort to sort these lists. Identify the first instance in each group of identically encoded instances as the canonical instance. Solve the problem for each canonical instance. Map the solutions back to the duplicate instances. The details follow.

Let $\mathcal{G}$ be the set of input instances, each of which contains at most g vertices. Let N be the total number of vertices and edges (or arcs) in all the instances. Let k be the maximum number of bits associated with each vertex and edge (or arc) of an instance. Construct a singly linked master list whose nodes, in order, represent the integers from zero through $\max\{g, 2^k + 1\}$ and are so numbered. For each instance G, perform a DFS, numbering the vertices in preorder and adding to each vertex a pointer into the master list corresponding to its preorder number; the preorder numbering allows us to maintain a global pointer into the master list to facilitate this assignment of pointers to vertices. Represent the label of each vertex and edge (or arc) by a pointer into the master list, using a pointer to the zero node to encode the lack of a label. Construct a list L of triples corresponding to the vertices of G, one triple per vertex, consisting of a pointer to the vertex, and its number and label, both represented as pointers into the master list. Construct a list Q of quadruples corresponding to the edges (or arcs) of the graph, one quadruple per edge (or arc), consisting of a pointer to the edge (or arc), and the numbers of its endpoints and its label, represented as pointers into the master list. (For an undirected graph, order the numbers of the edge endpoints in increasing order.) Encode the instance by a list whose first entry is a pair consisting of a pointer to the instance and the number of its vertices, represented as a pointer into the master list, catenated with lists L and Q.

Constructing encodings for all the instances takes $O(N)$ time. Recall that the elements of the encodings are pointers to the master list. Attach a bucket to each element of the master list. Use a radix sort for variable length lists [2], following the encoding pointers to reach the buckets, to arrange the encodings into groups that are identical except for the first components of each list element (pair, triple, or quadruple): instances whose encodings are in the same group are isomorphic. This also takes $O(N)$ time.

Now perform the topological graph computation on any one instance of each group (the canonical instance for that group). Finally, for each duplicate instance, traverse its encoding and the encoding of the corresponding canonical instance concurrently, transferring the solution from the canonical instance to the duplicate instance. The exact form this transfer takes depends upon the form of the output to the topological graph computation. One way to do the transfer is to traverse the encodings of the canonical instance and the duplicate instance in parallel, constructing pointers between corresponding vertices and edges (or arcs) of the two instances. Then visit each vertex and edge (or arc) of the canonical instance, copying the output to the duplicate instance but replacing each pointer to a vertex or edge (or arc) by a pointer to the corresponding vertex or edge (or arc) in the duplicate instance. If the output has size linear in the input, this takes $O(N)$ time. Summarizing, we have the following theorem.

THEOREM 5.1. *If the output of a topological graph computation has size linear in the input size, the computation can be done on a collection of instances of total size N in $O(N)$ time on a pointer machine, plus the time to do the computation on one instance of each group of isomorphic instances.*

This method extends to allow the vertices and edges (or arcs) of the instances to be labeled with integers in the range $[1, g]$ if these labels are represented by pointers to the nodes of a precomputed master list. We shall need this extension in our

applications to finding dominators and computing component trees (sections 9 and 10, respectively). In another of our applications, MST verification, the output of the topological graph computation has exponential size: it is a comparison tree, whose nodes indicate comparisons between the weights of two edges. In this case, we do not construct a new copy of the comparison tree for each duplicate instance. Instead, when we are ready to run the comparison tree for a duplicate instance, we construct pointers from the edges of the canonical instance to the corresponding edges of the duplicate instance and run the comparison tree constructed for the canonical instance, but comparing weights of the corresponding edges in the duplicate instance. The total time is $O(N)$ plus the time to build the comparison trees for the canonical instances plus the time to run the comparison trees for all the instances.

It remains to bound the time required to do the topological graph computation on the canonical instances. The number of canonical instances is $g^{O(g^2)}$. In all but one of our applications, the time to do a topological graph computation on an instance of size g or smaller is $O(g^2)$; for MST verification, it is $g^{O(g^2)}$. Thus the following theorem suffices for us.

THEOREM 5.2. *If a topological graph computation takes $g^{O(g^2)}$ time on a graph with g or fewer vertices, and if $g = \log^{1/3} N$, then the total time on a pointer machine to do the topological graph computation on a collection of graphs of total size N, each having at most g vertices, is $O(N)$.*

Proof. The proof is immediate from Theorem 5.1, since the total time to do the topological graph computation on the canonical instances is $g^{O(g^2)}g^{O(g^2)} = g^{O(g^2)} = O(N)$. □

The ability to recover the answers from the topological graph computations on the instances in $\mathcal{G}$ is subtle but crucial. Alstrup, Secher, and Spork [8] show how to compute connectivity queries on a tree T undergoing edge deletions in linear time. They partition T into bottom-level microtrees (discussed in the next section) and compute, for each vertex v in a microtree, a bit-string that encodes the vertices on the path from v to the root of its microtree. They show how to answer connectivity queries using a constant number of bitwise operations on these bit-strings and applying the Even and Shiloach decremental connectivity algorithm [23] to the upper part of T.

The Alstrup, Secher, and Spork algorithm [8] runs on a pointer machine: since the connectivity queries return yes/no answers, they do not need index tables to recover the answers. In contrast, while their method can be extended to solve the off-line NCAs problem in linear time on a RAM, and even to simplify the Gabow–Tarjan linear-time DSU result [29], both of these extensions require index tables to map the results of the bitwise operations back to vertices in T.

The idea of using pointers to buckets in lieu of indexing an array was described in general by Cai and Paige [17] in the context of multisequence discrimination. Their technique leaves the efficient identification of buckets with specific elements as an application-dependent problem. They solve this problem for several applications, including discriminating trees and DAGs, but their solutions exploit structures specific to their applications and do not extend to general graphs.

6. Nearest common ancestors. We now have the tools to solve our first application, the off-line nearest common ancestors (NCAs) problem: given a rooted n-node tree T and a set P of m queries, each of which is a pair $\{v, w\}$ of nodes in T, compute $nca(v, w)$ for each query $\{v, w\}$. Aho, Hopcroft, and Ullman's algorithm [3] for this problem, as presented by Tarjan [58], solves it using DSU. The algorithm traverses T bottom-up, building a shadow copy as a DSU forest. It maintains, for each subtree

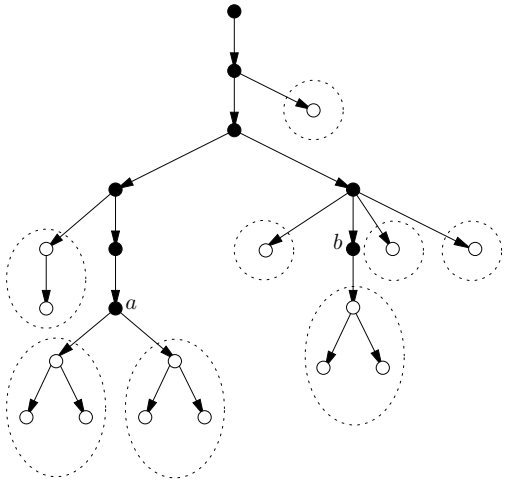

FIG. 6.1. *Partitioning of a tree T with $g = 3$; fringe nodes are open, and core nodes are filled; bottom-level microtrees are encircled. Nodes a and b are the leaves of the core.*

built so far, the set of its nodes, with the root of the subtree as the designated element. Initially, each node is in a singleton set. Each node v also has a set $P(v)$ of queries $\{v, w\}$; each query is in two such lists, one for v and one for w. The algorithm is as follows.

Visit the nodes of T in a postorder [54]. (Any postorder will do.) When visiting a node v, for every pair $\{v, w\}$ in $P(v)$ such that w has already been visited, return *find*(w) as the answer to the query $nca(v, w)$. Finish the visit to v by performing *unite*$(p(v), v)$ if v is not the root of T, where $p(v)$ is the parent of v in T.

The correctness of this algorithm follows from basic properties of postorder. The DSU operations dominate the running time, which is $O(n+m\alpha(m+n, n))$ if the standard DSU structure presented in section 4 is used. In this algorithm, the unordered set of unions is known in advance, since it is given by the input tree T. Thus the use of the Gabow–Tarjan [29] linear-time RAM DSU algorithm results in a linear-time RAM algorithm for NCAs. Knowing the set of unions in advance, however, is not sufficient to solve the DSU problem in linear time on a pointer machine [46]. We exploit a different property of the unions: they occur in a bottom-up order.

We partition T into a set of small bottom-level trees, called *microtrees*, and T', the rest of T. For any node v, let $T(v)$ be the subtree of T induced by the descendants of v, and let $|T(v)|$ be the number of nodes in $T(v)$. Let $g \geq 1$ be a fixed parameter to be chosen later. We define $T(v)$ to be a *microtree* if $|T(v)| \leq g$ but $|T(p(v))| > g$. For a node x in $T(v)$, *micro*$(x) = T(v)$ is the *microtree of* x and *root*(*micro*(x)) is the *root of its microtree*. Let T' be the subtree of T induced by the vertices in T that are not in microtrees. Each leaf in T' has at least g descendants in T, and the descendants of two different leaves of T' form disjoint sets, so T' has at most n/g leaves. We call the microtrees the *fringe* of T and T' the *core* of T. See Figure 6.1. It is straightforward to partition T into its microtrees and core in linear time by visiting the nodes in postorder and computing their numbers of descendants.

We call a query $\{v, w\}$ *small* if v and w are in the same microtree, and *big* otherwise. We can partition the queries into big and small and assign each small query to the microtree containing it in linear time. We answer all the big queries by

using the AHU algorithm. We answer all the small queries by doing a topological graph computation on the set of graphs defined by each microtree and its associated queries. By choosing g appropriately, we get a linear-time bound for both parts of the computation.

Specifically, choose $g = \log^{1/3} n$. Answer all the big queries by running the AHU algorithm, restricted to the big queries. To bound the running time, apply Lemma 4.6 to the tree built by the parent assignments done by the unite operations. Mark every leaf of T'. Each find occurs in a set containing at least one marked node. Therefore, setting $k = 1$, to count the initial parent assignment for each node, satisfies the hypothesis of the lemma. Since the number of marked nodes is at most $n/g = n/\log^{1/3} n$, the lemma implies an $O(n + m)$ bound on the time to answer all the big queries.

Answer all the small queries by constructing, for each microtree, a graph containing the microtree edges and, for each query with both nodes in the microtree, an edge denoted as a query edge by a bit. Then do a topological graph computation on these graphs to answer the small queries, using the method of section 5. With $g = \log^{1/3} n$, this takes $O(n + m)$ time. Thus we obtain the following theorem.

THEOREM 6.1. *The off-line NCAs problem can be solved in $O(n + m)$ time on a pointer machine.*

7. Minimum spanning trees.

7.1. Verification. Our next applications, minimum spanning tree (MST) verification and construction, combine topological graph processing with use of the simple link-eval structure of section 4.2. Let T be a spanning tree of a connected, undirected graph G whose edges have real-valued weights. For any edge $\{v, w\}$, let $c(v, w)$ be the weight of $\{v, w\}$. We denote the set of nontree edges by P. For any pair (v, w) of vertices, we denote by $T(v, w)$ the unique path from v to w in T. The tree T is minimum if and only if, for every edge $\{v, w\}$ in P, $c(v, w) \geq c(x, y)$ for every edge $\{x, y\}$ on $T(v, w)$. Thus to verify that T is minimum it suffices to compute $\max\{c(x, y) : \{x, y\} \text{ on } T(v, w)\}$ for every edge $\{v, w\}$ in P. We assume henceforth that T is rooted at a fixed but arbitrary vertex and that each vertex v has a set $P(v)$ of the pairs $\{v, w\}$ in P.

Tarjan's $O(m\alpha(m, n))$-time MST verification algorithm [58] is like the AHU NCA algorithm, except that it uses a link-eval structure (with max instead of min) in place of a DSU structure to compute the needed path maxima. The algorithm builds the link-eval forest during a bottom-up traversal of T. As part of the process of computing path maxima, the algorithm computes $u = \mathit{nca}(v, w)$ for each pair $\{v, w\}$ in P and stores $\{v, w\}$ in a set $Q(u)$. Initially each node of T is in a single-node tree of the link-eval structure, and $Q(u)$ is empty for each node u. The algorithm follows.

Visit the nodes of T in a postorder. (Any postorder will do.) When visiting a vertex v, for every pair $\{v, w\}$ in $P(v)$ such that w has already been visited, add $\{v, w\}$ to $Q(\mathit{findroot}(w))$. For every pair $\{x, y\}$ in $Q(v)$, return $\max\{\mathit{eval}(x), \mathit{eval}(y)\}$ as the answer to the query $\{x, y\}$. Finish the visit to v by performing $\mathit{link}(p(v), v, c(p(v), v))$ unless v is the root of T.

When the algorithm answers a query $\{x, y\}$ while visiting a vertex v, $v = \mathit{nca}(x, y)$, and $\mathit{eval}(x)$ and $\mathit{eval}(y)$ are the maximum costs of the arcs on $T(v, x)$ and $T(v, y)$, respectively. In Tarjan's original presentation, the NCA calculations are separate from the path evaluations, but combining them gives a more coherent algorithm. Ignoring the arc costs and *eval* operations, the link-eval structure functions exactly like the DSU structure in the AHU NCA algorithm.

If the sophisticated link-eval structure of section 4.3 or section 4.4 is used, this algorithm runs in $O(m\alpha(m,n))$ time. Unfortunately, these structures delay the effect of the links, so parent assignments do not necessarily occur in a bottom-up order, and we cannot immediately apply the approach of section 6 to reduce the running time to linear. This problem was pointed out by Georgiadis and Tarjan [32]. Instead, we use a result of King [40] to transform the original tree into an $O(n)$-node balanced tree on which to compute path maxima. Then we can use the simple link-eval structure of section 4.2 in combination with the approach of section 6 to obtain a linear-time algorithm.

7.2. The Borůvka tree. A *Borůvka step* [13] applied to a weighted, undirected graph G is as follows: Select a least-weight edge incident to each vertex, and contract to a single vertex each connected component formed by the selected edges. Repeating this step until only a single vertex remains produces an MST defined by the original edges corresponding to the edges selected in all the steps if all edge weights are distinct, which we can assume without loss of generality.

This algorithm can be enhanced to produce the *Borůvka tree* B, whose nodes are the connected components that exist during the Borůvka steps, with each node having as children those components from which it is formed during a Borůvka step. If component C is the parent of component D, the weight of arc (C,D) is the weight of the edge selected for the vertex corresponding to D by the Borůvka step in which D is contracted into C. The leaves of B are the vertices of G, each of which is originally a single-vertex component. Each Borůvka step reduces the number of vertices by at least a factor of two; hence, B is 2-balanced. Also, B contains at most $2n-1$ nodes. In general the enhanced Borůvka algorithm runs in $O(m \log n)$ time on a pointer machine. On a tree, however, it runs in $O(n)$ time, because each contracted graph is a tree, and a tree has $O(n)$ edges. We apply the enhanced Borůvka algorithm to the tree T that is to be verified, thereby constructing the Borůvka tree B of T. In addition to being balanced, B has the following key property [40]: for any pair of vertices $\{v,w\}$, $\max\{c(x,y) : (x,y) \text{ on } T(v,w)\} = \max\{c(x,y) : (x,y) \text{ on } B(v,w)\}$. Thus we can compute path maxima on B instead of on T without affecting the answers to the queries.

7.3. Comparison trees for computing path maxima. Now we can apply the approach of section 6. Let $g = \log^{1/3} n$. Partition B into microtrees and a core B' as in section 6. Partition the pairs in P into *big pairs*, those with ends in different microtrees, and *small pairs*, those with ends in the same microtree. Compute path maxima for all the big pairs by running Tarjan's algorithm on B, restricted to the big pairs and using the simple link-eval structure of section 4.2.

To bound the running time of this computation, we apply Lemma 4.6 to B. Mark every leaf of B'. Each *findroot* and *eval* occurs in a subtree of B containing a marked node, so setting $k = 1$ satisfies the hypothesis of the lemma. Since the number of marked nodes is at most $2n/g = 2n/\log^{1/3} n$, the lemma implies an $O(m)$ bound on the time to compute path maxima for all the big pairs.

We would like to compute path maxima for all the small pairs by applying the method of section 5. To this end, construct for each microtree a graph containing the microtree edges and, for each pair with both ends in the microtree, an edge designated as a query edge by a bit. Now a new difficulty arises: since the edge costs are arbitrary real numbers, computing path maxima is not a topological graph computation; we cannot encode the edge costs in $O(1)$ bits, or even in $O(\log g)$ bits.

We overcome this difficulty by following the approach of Dixon, Rauch, and Tar-

jan [22]: Do a topological graph computation that builds, for each distinct marked graph, a comparison tree, whose nodes designate binary comparisons between costs of unmarked edges of the graph (tree edges), such that the output nodes of the comparison tree designate, for each marked edge (query pair), which of the unmarked edges on the path between the ends of the edge has maximum cost. Having built all the comparison trees, run the appropriate comparison tree for each microtree and its associated pairs, using the actual costs of the microtree arcs to determine the outcomes of the comparisons.

With $g = \log^{1/3} n$, the time for this computation is $O(m)$, plus the time to build comparison trees for the topologically distinct instances, plus the time to run the comparison trees for the actual instances. Komlós [41] proved that the path maxima needed for MST verification can be determined in a number of binary comparisons of tree edge costs that is linear in the number of graph edges, which implies for each instance the existence of a comparison tree that has depth linear in the number of edges. Dixon, Rauch, and Tarjan [22] observed that the comparison tree implied by Komlós' result can be built in a time per comparison-tree node that is quadratic in the number of graph vertices. If we use their method to build the comparison trees during the topological graph computation, then $g = \log^{1/3} n$ implies by the results of section 5 that the total time to build the comparison trees is $O(m)$. The total time to run them is linear in the total size of all the actual instances, which is also $O(m)$. Thus we obtain the following theorem.

THEOREM 7.1. *Computing all the path maxima needed for MST verification, and doing the verification itself, takes $O(m)$ time on a pointer machine.*

7.4. Construction of MSTs. The randomized linear-time MST construction algorithm of Karger, Klein, and Tarjan [39] runs on a pointer machine except for the part that computes the path maxima needed for MST verification. Using the algorithm of section 7.3, this part can be done (deterministically) in linear time on a pointer machine, resulting in a randomized linear-time pointer-machine algorithm for constructing an MST.

7.5. Remarks. It is instructive to compare our MST verification algorithm to those of Dixon, Rauch, and Tarjan [22] and of King [40]. Our use of King's Borůvka tree construction as an intermediate step allows us to use only bottom-level microtrees, whereas Dixon et al. partition the original tree entirely into microtrees, with an extra *macrotree* to represent the connections between them. It also allows us to use the simple link-eval structure instead of the sophisticated one. Lemma 4.6 allows us to break big queries into only two parts (having an NCA in common); Dixon et al. break each big query into as many as six parts. King explicitly implements Komlós' comparison algorithm for the Borůvka tree, but her algorithm is heavily table-driven and requires a RAM. She also must compute NCAs separately.

There is an alternative, though more complicated, way to verify an MST in linear time on a pointer machine. This method replaces the use of the Borůvka tree by a partition of the original tree into bottom-level microtrees and a set of maximal paths that partition the core. The method does NCA computations on trees derived from the maximal paths, and it uses a sophisticated link-eval structure instead of the simple one. We discuss this method in more detail in section 9.7. Though the use of the Borůvka tree gives us a simpler algorithm for MST verification, there is no corresponding concept for either of our remaining applications, and we must rely on the alternative of partitioning the core into maximal paths.

8. Interval analysis. We turn now to two problems on flowgraphs. The first is *interval analysis*. Let $G = (V, A, r)$ be a flowgraph, and let D be a given DFS tree rooted at r. Identify vertices by their preorder number with respect to the DFS: $v < w$ means that v was visited before w. *Reverse preorder* of the vertices is decreasing order by (preorder) vertex number. For each vertex v, the *head* of v is

$$h(v) = \max\{u \neq v : \text{there is a path from } v \text{ to } u \text{ containing only descendants of } u\};$$

$h(v) = \mathit{null}$ if this set is empty. The heads define a forest H called the *interval forest*: $h(v)$ is the parent of v in H. Each subtree $H(v)$ of H induces a strongly connected subgraph of G, containing only vertices in $D(v)$ (the descendants of v in D). See Figure 8.1. Tarjan [57] proposed an algorithm that uses an NCA computation, incremental backward search, and a DSU data structure to compute H in $O(m\alpha(m, n))$ time on a pointer machine. We shall add microtrees, a maximal path partition of the core, and a stack to Tarjan's algorithm, thereby improving its running time to $O(m)$ on a pointer machine.

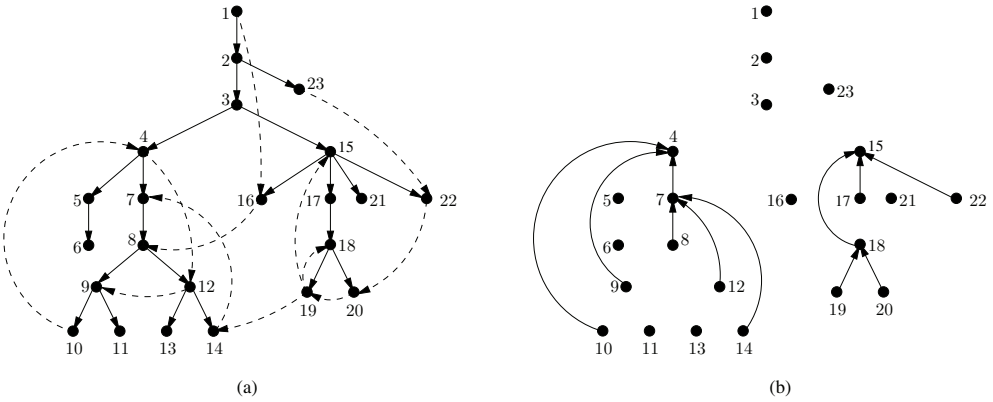

FIG. 8.1. (a) *A DFS tree D of the input flowgraph G; nontree arcs are dashed.* (b) *The interval forest H of G with respect to D; arrows are parent pointers.*

Tarjan's algorithm proceeds as follows: Delete all the arcs from the graph. For each vertex u, form a set of all deleted arcs (x, y) such that $\mathit{nca}(x, y) = u$. Process the vertices in any bottom-up order. (Tarjan uses reverse preorder, but any bottom-up order will do.) To process a vertex u, add back to the graph arcs corresponding to all the deleted arcs (x, y) with $\mathit{nca}(x, y) = u$. Then examine each arc (v, u) entering u. If $v \neq u$, set $h(v) = u$, and contract v into u; for all arcs having v as an end, replace v by u. This may create multiple arcs and loops, which poses no difficulty for the algorithm. Continue until all arcs into u have been examined, including those formed by contraction. When adding arcs back to the graph, the arc corresponding to an original arc is the one formed by doing end replacements corresponding to all the contractions done so far.

To keep track of contractions, Tarjan's algorithm uses a DSU structure whose elements are the graph vertices. The algorithm also uses a reverse adjacency set $R(u)$, initially empty, for each vertex u. A more detailed description of the algorithm is as follows. To process u, for each arc (x, y) such that $\mathit{nca}(x, y) = u$, add x to $R(\mathit{find}(y))$. (The replacement for x is done later.) Then, while $R(u)$ is nonempty, delete a vertex x from $R(u)$; let $v \leftarrow \mathit{find}(x)$; if $v \neq u$, set $h(v) \leftarrow u$, set $R(u) \leftarrow R(u) \cup R(v)$, and do $\mathit{unite}(u, v)$.

With the sets $R(u)$ represented as singly linked circular lists (so that set union takes constant time), the running time of this algorithm on a pointer machine is linear except for the NCA computations and the DSU operations, which take $O(m\alpha(m,n))$ time in Tarjan's original implementation. We shall reduce the running time to linear by using microtrees to eliminate redundant computation and by reordering the unites into a bottom-up order.

As in section 6, partition D into a set of bottom-level microtrees (the fringe), each with fewer than $g = \log^{1/3} n$ vertices, and D', the remainder of D (the core). Use a topological graph computation to compute $h(v)$ for every vertex v such that $h(v)$ is in the fringe. The definition of heads implies that for any such vertex v, $h(v)$ and v are in the same microtree, and furthermore that the only information needed to compute heads in the fringe is, for each microtree, the subgraph induced by its vertices, with nontree edges marked by a bit. With $g = \log^{1/3} n$, this computation takes $O(m)$ time by Theorem 5.2.

It remains to compute heads for vertices whose heads are in the core. Our approach is to run Tarjan's algorithm starting from the state it would have reached after processing the fringe. This amounts to contracting all the strong components in the fringe and then running the algorithm. This approach does not quite work as stated, because the DSU operations are not restricted enough for Lemma 4.6 to apply. To overcome this difficulty, we partition the core into maximal paths. Then we run Tarjan's algorithm path-by-path, keeping track of contractions with a hybrid structure consisting of a DSU structure that maintains contractions outside the path being processed and a stack that maintains contractions inside the path being processed. The latter structure functions in the same way as the one Gabow used in his algorithm [28] for finding strong components. Now we give the complete description of our algorithm.

Partition the vertices in D' into a set of maximal paths by choosing, for each nonleaf vertex v in D', a child $c(v)$ in D'. (Any child will do.) The arcs $(v, c(v))$ form a set of paths that partition the vertices in D'. For such a path P, we denote the smallest and largest vertices on P by $top(P)$ and $bottom(P)$, respectively; $bottom(P)$ is a leaf of D'. Since D' has at most n/g leaves, the number of paths is at most n/g. Partitioning D' into paths takes $O(n)$ time.

After constructing a maximal path partition of the core, initialize a DSU structure containing every vertex (fringe and core) as a singleton set. Visit the fringe vertices in bottom-up order, and, for each fringe vertex v with $h(v)$ also in the fringe, perform $unite(h(v), v)$; for such a vertex, $h(v)$ has already been computed. Initialize $R(u) \leftarrow \emptyset$ for every vertex u. For every arc (x, y) with x and y in the same microtree, add x to $R(find(y))$. For every remaining arc (x, y), compute $u = nca(x, y)$ and add (x, y) to the set of arcs associated with u. These NCA computations take $O(m)$ time using the algorithm of section 6. Indeed, every NCA query is big, so the AHU algorithm answers them in linear time. This completes the initialization.

Now process each path P in the path partition, in bottom-up order with respect to $top(P)$. To process a path P, initialize an empty stack S. Process each vertex u of P in bottom-up order. To process u, for each arc (x, y) such that $nca(x, y) = u$, add x to $R(find(y))$ unless $u = x$ and $p(y) \neq x$. (Heads do not depend on arcs (x, y) such that x is an ancestor of y but not its parent.) Then, while $R(u)$ is nonempty, delete a vertex x from $R(u)$. Let $v \leftarrow find(x)$. If v is not on P, set $h(v) \leftarrow u$, set $R(u) \leftarrow R(u) \cup R(v)$, and do $unite(u, v)$. If, on the other hand, v is on P, $v \neq u$, and v is no less than the top vertex on S, pop from S each vertex w less than or equal to v, set $h(w) \leftarrow u$, and set $R(u) \leftarrow R(u) \cup R(w)$. Once $R(u)$ is empty, push u onto

S. After processing all vertices on P, visit each vertex u on P again, in bottom-up order, and if $h(u)$ is now defined, perform *unite*$(h(u), u)$. See Figure 8.2

This algorithm delays the unites for vertices on a path until the entire path is processed, using the stack to keep track of the corresponding contractions. Specifically, the algorithm maintains the following invariant: if vertex u on path P is currently being processed and x is any original vertex, then the vertex into which x has been contracted is $v =$ *find*(x) if v is not on P, or the largest vertex on S less than or equal to v if v is on P and S is nonempty, or u otherwise. It is straightforward to verify this invariant by induction on time; the correctness of this implementation of Tarjan's algorithm follows.

THEOREM 8.1. *The interval analysis algorithm runs in $O(m)$ time on a pointer machine.*

Proof. The running time is linear except for the find operations: each vertex gets added to S once and has its head set at most once. To bound the time for the find operations, we apply Lemma 4.6 to the tree built by the parent assignments done by the unite operations. Mark the tops of all paths. Since there are at most n/g paths, there are at most $n/g = n/\log^{1/3} n$ marked vertices. We claim that $k = 5$ satisfies the hypothesis of the lemma. We need a property of the interval forest H: if $h(v) = u$, then every vertex $w \neq u$ on the path in D from u to v is a descendant of u in H. This holds because there is a path containing only vertices in $D(u)$ from w to v (via D) to u.

Consider any vertex v. We bound the number of times the parent of v in the DSU structure can change before v is in a set with a marked vertex. One parent change can occur during the initialization. After initialization, the parent of v can change once by a find before v is in a set with a designated vertex on the current path P. The parent of v can change only once more by a find while P is the current path, since its set does not change again until P is no longer the current path. Once P is not the current path, the next parent change of v caused by a find results in v being in a set with a designated vertex on the new current path Q. The parent of v can change only once more while Q is the current path, after which it is in the same set as *top*(P) (by the property above) and thus is in a set with a marked vertex. Therefore, the parent of v can change at most five times before it is in a set with a marked vertex, so the claim is true.

With $k = 5$ and $\ell \leq n/\log^{1/3} n$, Lemma 4.6 gives a bound of $O(m)$ on the time for the *find* operations. □

Interval analysis is an important component of program flow analysis [4]. It also has other applications, including testing flow graph reducibility [60], finding a pair of arc-disjoint spanning trees in a directed graph [57], and verifying a dominator tree [33]. Our interval analysis algorithm gives $O(m)$-time algorithms on a pointer machine for these applications as well.

In the next section we shall need a compressed version of the interval forest H' that is defined with respect to the fringe-core partition: the parent $h'(v)$ of a vertex v is its nearest core ancestor in H if it has one, *null* otherwise. We can easily compute H' from H in linear time, but if we only want H' and not H, we can avoid the topological graph computation on the microtrees: First, find the strong components of the graphs induced by the vertex sets of the microtrees. For each such component, find its smallest vertex u, and perform *unite*(u, v) for every other vertex v in the component. Then run the algorithm above for the core. This computes $h(v) = h'(v)$ for every vertex v with head in the core. Complete the computation by setting $h'(v) = h'(u)$ for each vertex $v \neq u$ in a fringe strong component with smallest vertex u.

9. Dominators. Our second flowgraph problem is finding immediate dominators. Let $G = (V, A, r)$ be a flowgraph. We denote the immediate dominator of any vertex v by $idom(v)$. Let D be an arbitrary but fixed DFS tree rooted at r. As in section 8, we identify vertices by their preorder number with respect to the DFS; reverse preorder is decreasing order by vertex number. We use the notation $v \stackrel{*}{\to} w$ to denote that v is an ancestor of w in D, and $v \stackrel{+}{\to} w$ to denote that v is a proper ancestor of w in D. Sometimes we use the same notation to denote the respective paths in D from v to w. We denote by $p(v)$ the parent of v in D. We shall need the following basic property of DFS.

LEMMA 9.1 (see [54]). *Any path from a vertex v to a vertex $w > v$ contains a common ancestor of v and w.*

We shall describe an algorithm to compute immediate dominators in $O(m)$ time on a pointer machine. This is our most complicated application: it uses all the ideas and algorithms we have developed so far. Our algorithm is a reengineering of the algorithms presented by Buchsbaum et al. [16] and Georgiadis and Tarjan [31, 32]. As we proceed with the description, we shall point out the relationships between concepts we introduce here and the corresponding ideas in those previous works.

9.1. Semidominators, relative dominators, tags, and extended tags. Lengauer and Tarjan (LT) [43] devised a three-pass, $O(m\alpha(m, n))$-time algorithm to compute immediate dominators. We shall improve their algorithm by speeding up the first two steps. Central to the LT algorithm is the concept of *semidominators*. A path $x_0, x_1, \ldots, x_k$ in G is a *high path* if $x_i > x_k$ for $i < k$. As a degenerate case, a single vertex is a high path. A high path avoids all proper ancestors of its last vertex. The *semidominator* of a vertex w is

$$sdom(w) = \min(\{w\} \cup \{u : \text{for some } (u, v) \text{ in } A \text{ there is a high path from } v \text{ to } w\}).$$

The *relative dominator* of a vertex w is

$$rdom(w) = \operatorname{argmin}\{sdom(u) : sdom(w) \stackrel{+}{\to} u \stackrel{*}{\to} w\}.$$

With this definition, relative dominators are not unique, but for any vertex any relative dominator will do.

The LT algorithm operates as follows:

Step 1. Compute semidominators.

Step 2. Compute relative dominators from semidominators.

Step 3. Compute immediate dominators from relative dominators.

Step 3 relies on the following lemma.

LEMMA 9.2 (see [43, Cor. 1]). *For any vertex $v \neq r$, if $sdom(rdom(v)) = sdom(v)$, then $idom(v) = sdom(v)$; otherwise, $idom(v) = idom(rdom(v))$.*

Using Lemma 9.2, the LT algorithm performs Step 3 in a straightforward top-down pass over D that takes $O(n)$ time on a pointer machine.

The LT algorithm performs Steps 1 and 2 in a single pass that visits the vertices of D in reverse preorder and uses a link-eval data structure to compute semidominators and relative dominators. We shall present separate algorithms for Steps 1 and 2, although these steps can be partially combined, as we discuss in section 9.7.

Step 2 is almost identical to MST verification. Indeed, suppose we assign a cost $sdom(v)$ to each tree arc $(p(v), v)$ and apply the MST verification algorithm to the tree D (ignoring arc directions) with query set $Q = \{\{sdom(v), v\} : v \neq r\}$, with the modification that the answer to a query is an arc of minimum cost on the query path

rather than the cost of such an arc. Then for $v \neq r$, $rdom(v)$ is the vertex u such that $(p(u), u)$ is the answer to the query $(sdom(v), v)$. Modifying the link-eval structure to replace maximum by minimum and to return arcs (or, better, vertices) rather than costs is straightforward. The algorithm of section 7 thus performs Step 2 in $O(n)$ time on a pointer machine. (The number of queries is $O(n)$.)

It remains to implement Step 1, the computation of semidominators. Lengauer and Tarjan reduce this computation, also, to a problem of finding minima on tree paths, using the following lemma.

LEMMA 9.3 (see [43, Thm. 4]). *For any vertex w,*

$$sdom(w) = \min\big(\{w\} \cup \{nca(u,w) : (u,w) \in A\} \cup \{sdom(v) : \exists (u,w) \in A, nca(u,w) \stackrel{+}{\rightarrow} v \stackrel{*}{\rightarrow} u\}\big).$$

The lemma gives a recurrence for $sdom(w)$ in terms of $sdom(v)$ for $v > w$. The LT algorithm performs Step 1 by visiting the vertices in reverse preorder and using a link-eval structure to perform the computations needed to evaluate the recurrence.

Even though Step 1 is now reduced to computing minima on tree paths, we cannot use the MST verification algorithm directly for this purpose, because that algorithm answers the queries in an order incompatible with the requirements of the recurrence. Instead we develop an alternative strategy. For convenience we restate the problem, which allows us to simplify slightly the recurrence in Lemma 9.3. Suppose each vertex w has an integer *tag* $t(w)$ in the range $[1, n]$. The *extended tag* of a vertex w is defined to be

$$et(w) = \min\{t(v) : \text{there is a high path from } v \text{ to } w\}.$$

LEMMA 9.4. *If $t(w) = \min(\{w\} \cup \{v : (v,w) \in A\})$ for every vertex, then $sdom(w) = et(w)$ for every vertex.*

Proof. The proof is immediate from the definitions of semidominators and extended tags. □

We can easily compute the tag specified in Lemma 9.4 for every vertex in $O(m)$ time. Thus the problem of computing semidominators becomes that of computing extended tags.

Lemma 9.3 extends to give the following recurrence for extended tags.

LEMMA 9.5. *For any vertex w,*

$$et(w) = \min(\{t(w)\} \cup \{et(v) : \exists (u,w) \in A,\ nca(u,w) \stackrel{+}{\rightarrow} v \stackrel{*}{\rightarrow} u\}).$$

Proof. The proof is analogous to that of Lemma 9.3. Let x be the right side of the equation in the statement of the lemma. First we prove $et(w) \leq x$. If $x = t(w)$, $et(w) \leq x$ is immediate from the definition of $et(w)$. Suppose $x = et(v)$ for v such that $nca(u,w) \stackrel{+}{\rightarrow} v \stackrel{*}{\rightarrow} u$ and (u,w) in A. By the definition of $et(v)$, $et(v) = t(z)$ for some vertex z such that there is a high path from z to v. Extending this path by the tree path from v to u followed by the arc (u,w) gives a high path from z to w. Hence $et(w) \leq et(v) = x$.

Next we prove $x \leq et(w)$. Let z be a vertex such that $et(w) = t(z)$ and there is a high path from z to w (by the definition of the extended tags). If $z = w$, then $x \leq et(w)$ from the definition of x. If not, let (u,w) be the last arc on the high path from z to w. Let v be the first vertex along the high path such that $nca(u,w) \stackrel{+}{\rightarrow} v \stackrel{*}{\rightarrow} u$. Such a v exists since u is a candidate ($nca(u,w) \leq w < u$). We claim that the part of

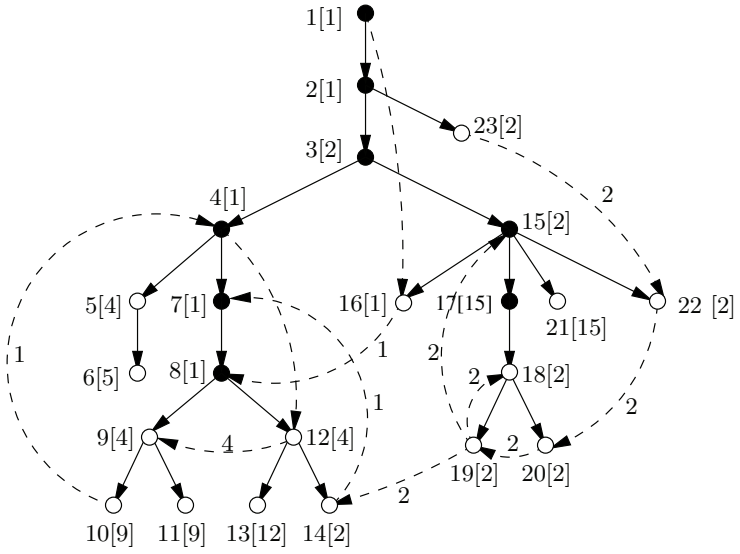

FIG. 9.1. *Extended tags and arc tags. The number inside each bracket is the extended tag of the corresponding vertex. The number on each arc is its tag; the arc tag of a tree or forward arc is infinite and not shown in the figure.*

the high path from z to v is itself a high path. Suppose to the contrary that this part contains a vertex less than v, and let y be the last such vertex. Then y must be an ancestor of v by Lemma 9.1, and since y is on a high path for w, $nca(u,w) \xrightarrow{+} y \xrightarrow{+} v$. This contradicts the choice of v. It follows that $et(v) \le t(z)$; that is, $x \le et(w)$. □

We introduce one more definition that simplifies some of our formulas and discussion. For an arc (u,w), the *arc tag* of (u,w) is

$$at(u,w) = \min\{et(v) : nca(u,w) \xrightarrow{+} v \xrightarrow{*} u\}$$

if this minimum is over a nonempty set, and infinity otherwise (when $nca(u,w) = u$). An example is shown in Figure 9.1. Using arc tags, the recurrence in Lemma 9.5 becomes

$$et(w) = \min(\{t(w)\} \cup \{at(u,w) : (u,w) \in A\}). \tag{9.1}$$

9.2. The interval forest. We could use (9.1) to compute extended tags just as the LT algorithm uses Lemma 9.3 to compute semidominators, but we seek a faster method. Note that there are two kinds of arcs (u,w) that must be handled: those such that u and w are unrelated (*cross arcs*), and those such that $w \xrightarrow{+} u$ (*back arcs*). (Arcs such that $u \xrightarrow{+} w$ do not contribute to the recurrence.) We apply different techniques to the cross arcs and the back arcs, which allows us to tease apart the intertwined computations implied by (9.1) and reorder them to apply our techniques.

To handle the back arcs, we use the interval forest discussed in section 8. Recall the following definitions. For each vertex w, the head $h(w)$ of w is the maximum vertex $u \ne w$ such that there is a path from w to u containing only descendants of u, if this maximum is over a nonempty set, and *null* otherwise. Lemma 9.1 implies that the constraint on u in the definition of $h(w)$ is equivalent to $u \xrightarrow{+} w$ and there is a high path from w to u. The heads define a forest H called the *interval forest*: $h(w)$

is the parent of w in H. The following lemma allows us to compute extended tags by computing arc tags only for the cross arcs and propagating minima up the interval forest.

LEMMA 9.6. *For any vertex w,*

$$et(w) = \min(\{t(v) : v \in H(w)\} \cup \{at(u,v) : (u,v) \in A,\ v \in H(w),\ u \notin D(w)\}).$$

Proof. Let x be the right side of the equation in the statement of the lemma. First we prove $et(w) \le x$. Let v be in $H(w)$. Since there is a high path from v to w, $et(w) \le t(v)$. Let (u,v) be in A such that v is in $H(w)$ but u is not in $D(w)$. Let y be a vertex of minimum $et(y)$ such that $nca(u,v) \xrightarrow{+} y \xrightarrow{*} u$, and let z be a vertex of minimum $t(z)$ such that there is a high path from z to y. Then there is a high path from z to y to u to v to w, which implies $et(w) \le t(z) = et(y) = at(u,v)$. We conclude that $et(w) \le x$.

Next we prove $x \le et(w)$. Let z be a vertex such that $et(w) = t(z)$ and there is a high path from z to w. If z is in $H(w)$, then $x \le t(z) = et(w)$. Suppose z is not in $H(w)$. Let (u,v) be the first arc along the high path from z to w such that v is in $H(w)$. Then u cannot be in $D(w)$, or it would be in $H(w)$, contradicting the choice of (u,v). Thus $nca(u,v) \xrightarrow{+} u$. Let y be the first vertex along the high path such that $nca(u,v) \xrightarrow{+} y \xrightarrow{*} u$. By Lemma 9.1, the part of the high path from z to y is itself a high path. Thus $x \le at(u,v) \le et(y) \le t(z) = et(w)$. □

COROLLARY 9.7. *For any vertex w,*

$$et(w) = \min(\{t(w)\} \cup \{et(v) : h(v) = w\} \cup \{at(v,w) : (v,w) \textit{ is a cross arc}\}).$$

Corollary 9.7 gives an alternative recursion for computing extended tags by processing the vertices in reverse preorder. Lemma 9.6 also allows us to compute extended tags for all the vertices on a tree path, given only arc tags for arcs starting to the right of the path.

9.3. Microtrees and left paths. As in section 6, we partition D into a set of bottom-level microtrees (the fringe), each containing fewer than $g = \log^{1/3} n$ vertices, and D' (the core), the remainder of D. We call a cross arc *small* if both its ends are in the same microtree, and *big* otherwise. We also partition D' into maximal paths as in section 8, but a particular set of maximal paths. Specifically, we partition D' into *left paths*, as follows: An arc $(p(v), v)$ of D' is a *left arc* if v is the smallest child of $p(v)$ in D'. A *left path* is a maximal sequence of left arcs. We can partition D into microtrees and left paths in $O(m)$ time during the DFS that defines D. If P is a left path, as in section 8 we denote by $top(P)$ and $bottom(P)$ the smallest and largest vertices on P, respectively. The importance of left paths is twofold. First, there are at most n/g of them. Second, if $(p(v), v)$ is a left arc, any child of $p(v)$ smaller than v must be in the fringe, not the core. That is, left paths have only microtrees descending on their left. Left paths serve in place of the *lines* of Georgiadis and Tarjan [31, 32]; left paths are catenations of those lines.

Our hypothetical plan for computing extended tags in linear time is to use a topological graph computation to handle the microtrees and a link-eval structure to compute arc tags for the big cross arcs. This plan does not quite work: computing extended tags is unlike the previous problems we have considered in that there is an interaction between the fringe and the core. In particular, we need at least some information about the small cross arcs in order to compute extended tags in the core, and information about the big cross arcs to compute extended tags in the fringe. For

the former computation we do not, however, need to compute arc tags for the small cross arcs: the recurrence in Lemma 9.6 expresses the extended tags of vertices in the core in terms only of tags of vertices and arc tags of big cross arcs. To handle the limited interaction between fringe and core, we use a two-pass strategy. During the first pass, we compute arc tags of big cross arcs and extended tags in the core while computing limited information in the fringe. In the second pass, we use the information computed in the first pass in a topological graph computation to compute extended tags in the fringe.

The information we need in the fringe is a set of values defined as follows. For a vertex w in a microtree $D(s)$, the *microtag* of w is

$$\begin{aligned} mt(w) = \min\big(&\{t(v) : \text{there is a path from } v \text{ to } w \text{ in } D(s)\} \cup \\ &\{at(u,v) : (u,v) \text{ is a cross arc}, v \in D(s), u \notin D(s), \\ &\qquad \text{and there is a path in } D(s) \text{ from } v \text{ to } w\}\big). \end{aligned}$$

Our microtags correspond to the *pushed external dominators* of Buchsbaum et al. [16] (also used by Georgiadis and Tarjan [31, 32]). The next lemma shows that when computing the arc tags of big cross arcs, we can use microtags in place of extended tags for fringe vertices; that is, we shall use microtag values in the link-eval structure when linking fringe vertices.

LEMMA 9.8. *Let w be a vertex in a microtree $D(s)$. Then*

$$\min\{et(v) : s \stackrel{*}{\to} v \stackrel{*}{\to} w\} = \min\{mt(v) : s \stackrel{*}{\to} v \stackrel{*}{\to} w\}.$$

Proof. Let x and y be the values of the left and right sides of the equation in the statement of the lemma, respectively. First we prove that $x \geq y$. Let v be a vertex such that $x = et(v)$ and $s \stackrel{*}{\to} v \stackrel{*}{\to} w$. Let z be a vertex such that $t(z) = et(v)$ and there is a high path from z to v. If z is in $D(s)$, then this high path is in $D(s)$, which implies that $x = t(z) \geq mt(v) \geq y$. Suppose on the other hand that z is not in $D(s)$. Let (p,q) be the last arc along the high path such that p is not in $D(s)$, and let z' be the first vertex along the high path such that $nca(p,q) \stackrel{+}{\to} z' \stackrel{*}{\to} p$. Note that (p,q) must be a cross arc, since p is not in $D(s)$ and is on a high path to v in $D(s)$. See Figure 9.2. As in the proof of Lemma 9.5, the part of the high path from z to z' is itself a high path, which implies $x = t(z) \geq et(z') \geq at(p,q) \geq mt(v) \geq y$.

Next we prove that $x \leq y$. Let v be a vertex such that $y = mt(v)$ and $s \stackrel{*}{\to} v \stackrel{*}{\to} w$. Suppose $mt(v) = t(z)$ for some z in $D(s)$ from which there is a path to v in $D(s)$. Let u be the first vertex on this path that is an ancestor of w. Then the path from z to u is a high path by Lemma 9.1 and the choice of u. Thus $x \leq et(u) \leq t(z) = y$. Suppose on the other hand that $mt(v) = at(p,q)$ for an arc (p,q) such that q but not p is in $D(s)$ and there is a path from q to v. Let u be the first vertex on this path that is an ancestor of w. By Lemma 9.1, the part of the path from q to u is a high path. Let z be a vertex such that $t(z) = at(p,q)$ and there is a high path from z to a vertex z' such that $nca(p,q) \stackrel{+}{\to} z' \stackrel{*}{\to} p$. See Figure 9.2. This path, together with the path $z' \stackrel{*}{\to} p$, the arc (p,q), and the high path from q to u, is a high path. Thus $x \leq et(u) \leq t(z) = at(p,q) = mt(v) = y$. □

To help compute extended tags during the first pass, we use a compressed interval forest H' in place of the interval forest H. Recall that in H', the parent $h'(v)$ of a vertex v is the nearest ancestor of v in H that is a core vertex. Forests H and H' are identical on the core; each subtree of H consisting of fringe vertices with a core root is compressed in H' to the root with all the fringe vertices as children. The use

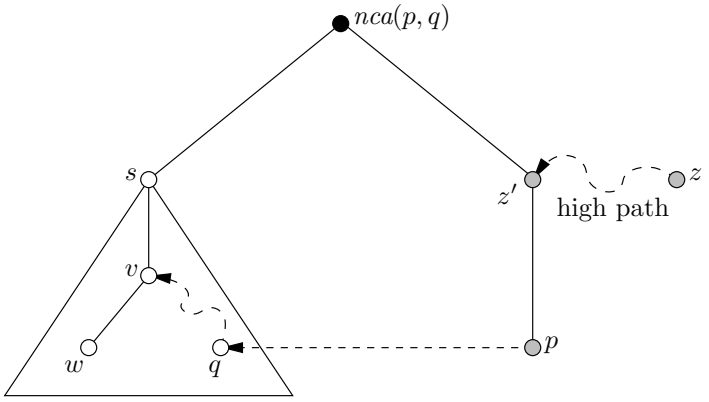

FIG. 9.2. *Proof of Lemma* 9.8. *Dashed curves represent graph paths. Solid edges represent tree paths. Each gray vertex can be in the core or in the fringe.*

of H' in place of H is an optimization only: we can build either H or H' in linear time using the algorithm of section 8, but, as noted in section 8, building H' instead of H avoids the use of topological graph computations on the microtrees and thus is simpler. The algorithm of section 8 builds H' by partitioning D into microtrees and maximal paths. We can use the set of left paths as the maximal paths, avoiding the need for two different partitions.

To compute extended tags in the core, we use the following corollary of Lemma 9.6.

COROLLARY 9.9. *If w is a core vertex*

$$\begin{aligned} et(w) = \min\big(&\{t(v) : v = w \text{ or } v \text{ is fringe with } h'(v) = w\} \cup \\ &\{et(v) : v \text{ is core with } h'(v) = w\} \cup \\ &\{at(u,v) : (u,v) \text{ is a big cross arc such that} \\ &\qquad v = w \text{ or } v \text{ is fringe with } h'(v) = w\}\big). \end{aligned}$$

The algorithm of Georgiadis and Tarjan [32] for computing dominators does not use H' explicitly, but it does do an incremental backward search using a stack to maintain strongly connected parts of lines, in effect doing a just-in-time computation of (part of) H'. Making this computation separate, as we have done, breaks the overall algorithm into smaller, easier-to-understand parts, which could be combined if desired.

9.4. Computation of arc tags. The heart of the algorithm is the computation of arc tags. We split each such computation into two parts, either of which can be void: a *top part*, which computes a minimum of extended tags over part or all of a left path, and a *bottom part*, which computes a minimum of extended tags of core vertices and microtags of fringe vertices using a sophisticated link-eval structure. Specifically, let (u, v) be a big cross arc. Let P be the left path containing $nca(u, v)$, and let Q be the intersection of P and the path $nca(u, v) \xrightarrow{+} u$. We denote the last vertex on Q by $mid(u, v)$. Note that Q can be nonempty (contain arcs) only if v is a fringe vertex. See Figure 9.3.

For a given left path P, we compute minima of extended tags for all such nonempty paths Q at the same time. We do not need to know any of these minima until all

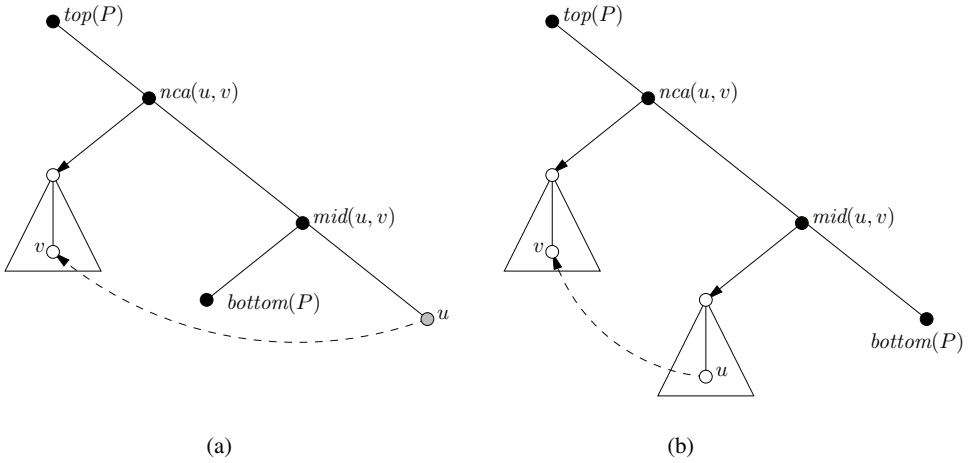

FIG. 9.3. *Examples of nonempty* $nca(u,v) \xrightarrow{+} mid(u,v)$ *paths.* (a) *Case* $u > bottom(P)$. (b) *Case* $u < bottom(P)$.

the extended tags for vertices on P have been computed. This allows us to compute the minima for such paths Q in arbitrary order. One way to compute these minima is to use the MST verification algorithm, as suggested above for doing Step 2 of the LT algorithm. In this application, however, the tree being verified is actually a path, and we can use an algorithm that is at least conceptually simpler, if not asymptotically faster. The problem we need to solve is that of computing minima for given subsequences of a sequence of numbers. This is the *range minimum query* (RMQ) problem [30]. This problem has a linear-time reduction [30] to an NCA problem on a Cartesian tree [65]. We can thus compute minima for paths Q by constructing the Cartesian tree and applying our NCA algorithm. Either method allows us to compute the top parts of arc tags in $O(m)$ time on a pointer machine.

To compute the bottom parts of arc tags, we use a sophisticated link-eval structure. We delay the links for arcs on a left path until the top of the left path is reached, and for arcs in a microtree until its root is reached. This allows us to establish a linear-time bound for all the link-eval operations using Lemma 4.6.

9.5. The first pass. We now have all the pieces necessary to describe the first pass of our algorithm for computing extended tags. Before the first pass, build the compressed interval forest H', compute $nca(u,v)$ for each big cross arc (u,v), and construct, for each core vertex w, the set of big cross arcs (u,v) with $nca(u,v) = w$. This takes $O(m)$ time on a pointer machine using the method of section 8: the NCAs are computed as part of the algorithm that builds H'. Each vertex v has a *computed tag* $ct(v)$ that is initialized to $t(v)$ and that decreases as the first pass proceeds, until $ct(v) = mt(v)$ if v is fringe, or $ct(v) = et(v)$ if v is core. Each fringe vertex v also has an associated set of cross arcs, initially empty. For each fringe vertex v, if v has a parent in H' and $ct(h'(v)) > ct(v)$, replace $ct(h'(v))$ by $ct(v)$. Finally, initialize a sophisticated link-eval data structure with no edges and each vertex of G as a node.

The first pass visits each microtree once and each left path twice. The visits are in reverse preorder with respect to the roots of the microtrees and the top and bottom vertices of the left paths; the first visit to a left path corresponds to its bottom (largest) vertex, and the second visit to its top (smallest) vertex. Conceptually, envision a

reverse preorder traversal of D, with actions taken as described below whenever a microtree root or bottom or top vertex of a left path is visited.

When visiting a microtree $D(s)$, it will be true that, for each vertex v in $D(s)$,

$$et(v) \le ct(v) \le \min(\{t(v)\} \cup \{at(u,v) : (u,v) \in A,\ u \notin D(s)\}). \tag{9.2}$$

Compute microtags for all vertices in $D(s)$ by finding the strong components of the subgraph induced by the vertices in $D(s)$ and processing the strong components in topological order. To process a component, compute a microtag for the component, equal to the minimum of the $ct(\cdot)$ values for all vertices in the component and the microtags for all preceding components (those with an arc leading to the component). Then set $ct(v)$ for every vertex in the component equal to the computed microtag. The assigned value of $ct(v)$ must be $mt(v)$, assuming (9.2) holds. The time required for this computation is linear in the size of the subgraph induced by $D(s)$ [54]. Having computed microtags for $D(s)$, perform $link(p(v), v, ct(v))$ for every vertex in $D(s)$, in bottom-up order. Finally, for each cross arc (u, v) in the set of cross arcs of a vertex u in $D(s)$, set $ct(v) \leftarrow \min\{ct(v), eval(u)\}$, and then set $ct(h'(v)) \leftarrow \min\{ct(h'(v)), ct(v)\}$ if v has a parent in H'. Such computations happen here only for arcs (u, v) such that u is in a microtree hanging on the left of some left path. It will become clear later that, for such an arc, the top part of the evaluation of $at(u, v)$ gets done first, when the left path is processed. The $eval(u)$ operation does the bottom part of the evaluation, finishing the job. We describe below when these arcs are entered in the set associated with u.

When visiting a left path P for the first time, begin by visiting the vertices w of P in bottom-up order and setting $ct(h'(w)) \leftarrow \min\{ct(h'(w)), ct(w)\}$ if w has a parent in H'. Once these updates are completed, $ct(w) = et(w)$ for every vertex w on P. Then collect all the arcs (u, v) in the sets associated with the vertices on P, i.e., the arcs (u, v) such that $nca(u, v) \in P$. For each such arc (u, v), set $mid(u, v) \leftarrow p(root(micro(u)))$ if $u < bottom(P)$, and $mid(u, v) \leftarrow findroot(u)$ otherwise. The *findroot* operation in the latter case is an operation on the link-eval structure. Having computed all the *mid* values for all the cross arcs, evaluate the top parts of their arc tags, using either of the methods discussed in section 9.4. For each such arc (u, v) with computed arc tag top part x, do the following. If $u > bottom(v)$ (see Figure 9.3(a)), set $x \leftarrow \min\{x, eval(u)\}$; otherwise (see Figure 9.3(b)), add (u, v) to the set of cross arcs of u. In the former case, the $eval(u)$ operation computes the bottom part of the arc tag; in the latter case, the computation of the bottom part is done when the microtree containing u (which hangs to the left of P) is visited. In either case, set $ct(v) \leftarrow \min\{ct(v), x\}$, and then set $ct(h'(v)) \leftarrow \min\{ct(h'(v)), ct(v)\}$ if v is a fringe vertex with a parent in H'.

When visiting a left path P for the second time, perform $link(p(w), w, ct(w))$ for each vertex on P in bottom-up order, unless P is the last path, in which case the first pass is done.

Based on the results of the previous sections, it is straightforward (but tedious) to prove that this algorithm correctly computes extended tags. Note that the algorithm eagerly pushes $ct(\cdot)$ values up H', rather than lazily pulling them; the latter would require computing sets of children for H', whereas the former can be done using just parent pointers.

LEMMA 9.10. *The first pass takes $O(m)$ time on a pointer machine.*

Proof. The running time of all parts of the algorithm is linear based on previous results, except for the *findroot* and *eval* operations. To bound the time for these, we

apply Lemma 4.6 to the shadow subtrees built by the link operations. These subtrees are $\sqrt{2}$-balanced by Corollary 4.2 for linking-by-size and Corollary 4.4 for linking-by-rank. Mark the parents (in D) of the tops of all the left paths. This marks at most $n/g = n/\log^{1/3} n$ vertices. We claim that $k = 5$ satisfies the hypothesis of the lemma.

We need to use details of the link implementation, for which we refer the reader to section 4.3 for linking-by-size and section 4.4 for linking-by-rank. The links occur in batches with no intermixed *findroot* or *eval* operations, one batch per microtree and one batch per left path. Let v be any vertex. We count the number of times the subroot of the shadow subtree containing v can change, as the result of a batch of links, before v is in a subtree containing a marked node. Let $v_0 = v, v_1, v_2, \ldots$ be the successive roots of the shadow trees containing v. The subroot of the shadow subtree containing v can change only as the result of a batch of links that include the current v_i as one of the vertices being linked. Suppose v is fringe. The first batch of links to include v_0 is the one for $\mathit{micro}(v)$. This batch of links makes $p(\mathit{root}(\mathit{micro}(v)))$ the root of the tree containing v; that is, $v_1 = p(\mathit{root}(\mathit{micro}(v)))$. The next batches of links that include v_1 are those for other microtrees whose roots are children of v_1 in D. Such a batch does not change the root of the tree containing v but can change the subroot of the subtree containing v, making it equal to v_1. Once such links are done, the only remaining batch of links that includes v_1 is the one for the left path P_1 containing v_1. This batch makes $v_2 = p(\mathit{top}(P_1))$, which means that the shadow tree containing v (but not necessarily the shadow subtree containing v) has a marked vertex. The next batches of links that include v_2 are those for microtrees whose roots are children of v_2 in D. Such a batch cannot change the root of the tree containing v, but it can change the subroot of the subtree containing v, making it equal to v_2, which is marked. Otherwise, the next (and last) batch of links that includes v_2 is the one for the left path P_2 containing v_2. This batch makes $v_3 = p(\mathit{top}(P_2))$.

Now v is either in the subtree rooted at v_3, and hence in a subtree with a marked vertex, or it is a shadow descendant of v_2, which is no longer the root of the shadow tree containing v. No subsequent link can change the root of the subtree containing v without putting v and v_2, which is marked, in the same subtree. Tracing through the analysis above, we see that the subroot of the shadow subtree containing a fringe vertex v can change at most four times before v is in a subtree with a marked vertex. If v is a core vertex, the last part of the same analysis applies: the first batch of links that can change either the root of the tree containing v or the subroot of the subtree containing v is the one for the left path containing v; the subroot of the subtree containing v can change at most twice before v is in a subtree with a marked vertex. The shadow parent of vertex v can change at most once before the root of the shadow subtree containing v changes. Thus the shadow parent of v can change at most five times before v is in a shadow subtree with a marked vertex. This verifies the claim. With $k = 5$ and $\ell \le n/\log^{1/3} n$, Lemma 4.6 gives a bound of $O(m)$ on the time for the *findroot* and *eval* operations. □

9.6. The second pass. Having computed extended tags for all core vertices, we compute extended tags for all fringe vertices by using a topological graph computation on the microtrees. In the first pass, just before a microtree $D(s)$ is processed, each vertex v in $D(s)$ has $ct(v) = \min(\{t(v)\} \cup \{at(u,v) : (u,v) \in A,\ u \notin D(s)\})$. It follows that if we compute extended tags within the subgraph induced by the vertices of $D(s)$, using these $ct(\cdot)$ values as the initial tags, we will obtain the correct extended tags for the vertices in $D(s)$ with respect to the original tags in the entire graph. The $ct(\cdot)$ values are in the range $[1, n]$, but we can map them to the range $[1, g]$ by sorting all the

$ct(\cdot)$ values using a pointer-based radix sort, extracting a sorted list of $ct(\cdot)$ values for each subproblem, and mapping each such sorted list to $[1, g]$. To do this on a pointer machine, we need to maintain a singly linked master list of length n, whose nodes correspond to the integers 1 through n, and store with each integer a pointer to its corresponding position in the master list, and we need to track such pointers through the entire running of the algorithm. We assume that each input tag is given along with a corresponding pointer into the master list. For the special case of computing semidominators, we construct the master list and the corresponding pointers as we perform the DFS and number the vertices. The only manipulations of vertex numbers are comparisons, so it is easy to track these pointers through the entire computation.

Once the tags are mapped to $[1, g]$, the computation of extended tags on the microtrees is a topological graph computation, which we perform using the method described in section 6. With the choice $g = \log^{1/3} n$, the second pass requires $O(m)$ time on a pointer machine.

Combining all the parts of the algorithm, we obtain the following theorem.

THEOREM 9.11. *Finding immediate dominators takes $O(m)$ time on a pointer machine.*

9.7. An alternative method for Step 2. We conclude our discussion of dominators by sketching an alternative method for performing Step 2 (computing relative dominators) that does some of the work in the second pass of Step 1 and then uses a simplification of the algorithm for the first pass of Step 1 to do the rest.

For a microtree $D(s)$, the $ct(\cdot)$ values of its vertices just before $D(s)$ is processed provide enough information not only to compute the semidominators of each of its vertices but also to compute the relative dominator of each vertex v such that $sdom(v)$ is in $D(s)$. This we can do as part of the topological graph computation that forms the second pass of Step 1. The remaining part of Step 2 is to compute $rdom(v) = \text{argmin}\{sdom(u) : sdom(v) \stackrel{+}{\rightarrow} u \stackrel{*}{\rightarrow} v\}$ for each vertex v with $sdom(v)$ in the core. We can do this by running a simplified version of the first pass of Step 1. We modify the link-eval structure so that an *eval* returns a vertex of minimum value, rather than the value itself. We compute the relative dominators in the same way that pass 1 of Step 1 computes the arc tags of big cross arcs, but without using the interval tree H' and without using NCAs. We begin by storing each pair $(sdom(v), v)$ with $sdom(v)$. Then we perform $link(p(v), v, sdom(v))$ for every fringe vertex v, in reverse preorder. Finally, we process each left path P, in reverse preorder with respect to $bottom(P)$. To process a left path P, we collect all the pairs (u, v) stored with its vertices. For each such pair, we set $mid(u, v) \leftarrow findroot(v)$. We evaluate each top part from u to $mid(u, v)$ using an NCA computation on a derived Cartesian tree as discussed in section 9.4, modified to return a candidate relative dominator $rd(u, v)$ for each pair. For each pair we set $rdom(v) \leftarrow \text{argmin}\{sdom(eval(v)), sdom(rd(u, v))\}$. Finally, we perform $link(p(v), v, sdom(v))$ for every vertex on P in reverse preorder, unless P is the last path, in which case we are done. This method for doing Step 2 takes $O(n)$ time.

This approach also leads to an alternative algorithm for MST verification, as mentioned in section 7.5, which avoids the use of the Borůvka tree as an intermediate step, replacing it with NCA computations on Cartesian trees derived from the paths of a partition of the core of the original tree T into maximal paths. We must still do verification within microtrees, but these are microtrees of the original tree rather than of the Borůvka tree.

9.8. Remarks. From the definition of microtags we have that for any w in a microtree $D(s)$, $mt(w) \leq mt(v)$ for any $s \stackrel{*}{\rightarrow} v \stackrel{*}{\rightarrow} w$. This inequality implies that the

eval function need only operate on the core tree. The algorithms of Buchsbaum et al. [16] and Georgiadis and Tarjan [31, 32] rely on this fact but also require a hybrid link-eval structure for the evaluation of path minima on the core. Lemma 4.6 allows us to use a standard (simpler) link-eval structure that can include the fringe, which also yields a more uniform treatment of the core and fringe vertices.

Our dominators algorithm uses the linear-time offline NCA algorithm for two subproblems: interval analysis and range minimum queries. Georgiadis [31] observed that a refined partition of the core tree into unary paths of size $O(g)$ enables us to use trivial algorithms to compute NCAs; topological graph computations are still required, but they are performed on Cartesian trees corresponding to each unary path.

10. Component trees. Our final application is a tree problem, unusual in that it seems to require partitioning all of the given tree, rather than just the bottom part, into microtrees.

10.1. Kruskal trees. The Borůvka tree discussed in section 7 represents the connected components that are formed as Borůvka's MST algorithm is run. We can define the analogous concept for other MST algorithms. For example, the *Kruskal tree* is the tree whose nodes are the connected components formed as Kruskal's MST algorithm [42] is run. Kruskal's algorithm starts with all vertices in singleton components and examines the edges in increasing order by weight, adding an edge to the MST being built, and combining the two corresponding components when the edge has ends in two different components. The Kruskal tree K is binary, with one node per component, whose children are the components combined to form the given component. Each leaf of K is a vertex of the original graph; each nonleaf node is a nonsingleton component. See Figure 10.1.

Even if the given graph is a tree, constructing the Kruskal tree is equivalent to sorting the edges by weight, because the Kruskal tree for a star (a tree of diameter two) contains enough information to sort the edges. If we are given the edges in order by weight, however, the problem of constructing the Kruskal tree becomes more interesting. We shall develop an $O(n)$-time, pointer-machine algorithm to build the Kruskal tree K of a tree T, given a list of the edges of T in order by weight.

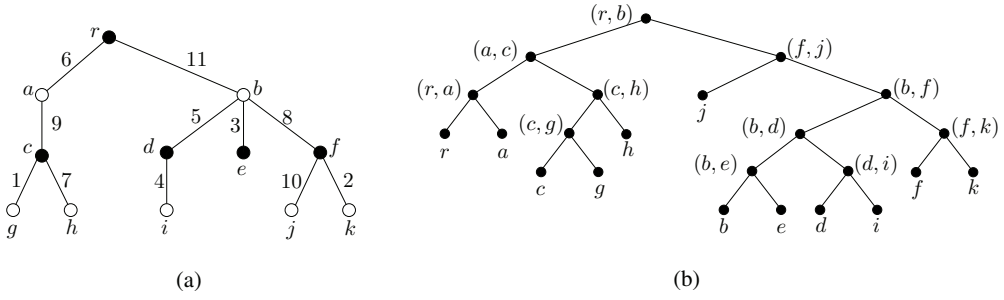

FIG. 10.1. (a) *The input weighted tree T; the filled nodes are subtree roots when T is partitioned with $g = 3$.* (b) *The Kruskal tree K of T. Leaves correspond to the nodes of T; internal nodes correspond to edges of T.*

10.2. Bottom-up construction of a Kruskal tree. It is straightforward to build K bottom-up using a DSU structure whose nodes are the nodes of T and whose sets are the node sets of the current components. As the algorithm proceeds, each designated node of a set stores the node of K corresponding to the set. Root T at an

arbitrary vertex; let $p(v)$ denote the parent of v in the rooted tree. Initialize a DSU structure with each node in a singleton set, storing itself (a leaf of K). Process the edges (now arcs) in the given order. To process an arc $(p(v), v)$, let $u = \mathit{find}(p(v))$. Add a new node x to K, whose two children are the nodes stored at u and v. Store x at u, and perform $\mathit{unite}(u, v)$. (For example, in Figure 10.1, the node corresponding to (f, j) is stored at b.)

This algorithm runs in $O(n\alpha(n, n))$ time on a pointer machine; only the finds take nonlinear time. Although it builds K bottom-up, it does not process T bottom-up but in the given arc order. As in sections 7–9, we thus cannot directly apply the method of section 6 to reduce the running time to linear. On the other hand, if we generalize the DSU structure to allow *unite* operations to have arbitrary nodes, rather than just designated nodes, as parameters, and we replace each $\mathit{unite}(u, v)$ operation in the algorithm by $\mathit{unite}(p(v), v)$, then the (unordered) set of unions is known in advance, because the unions correspond to the arcs of T. As Thorup [62] observed in the context of solving an equivalent problem (see section 10.4), this means that the algorithm runs in linear time on a RAM if the linear-time DSU algorithm of Gabow and Tarjan [29] is used.

Not only are the unions not bottom-up on T, but also there is no obvious way to transform the problem into one on a balanced tree as in section 7. Instead, we partition all of T into microtrees and do a topological graph computation to precompute the answers to finds within the microtrees. Once these answers are known, running the algorithm to build K takes $O(n)$ time. Number the arcs of T from 1 through $n - 1$ in the given order. For any nonroot vertex v, let $\mathit{num}(v)$ be the number of $(p(v), v)$; let $\mathit{num}(v) = \infty$ if v is the root. For any nonroot vertex v, let $f(v)$ be the node returned by $\mathit{find}(p(v))$ in the algorithm that builds K. (For example, in Figure 10.1, $f(j) = b$.) Then $f(v)$ is the nearest ancestor u of v that has $\mathit{num}(u) > \mathit{num}(v)$. We will precompute $f(v)$ if v and $f(v)$ are in the same microtree.

10.3. Linear-time construction. Let $g = n/\log^{1/3} n$. Partition all of T into microtrees, each of size at most g, using the method of Dixon, Rauch, and Tarjan [22], slightly modified. Visit the nodes of T in a bottom-up order, computing, for each node v, a size $s(v)$ and possibly marking v as a subtree root. The value of $s(v)$ is the number of descendants w of v such that no node on the path from v to w is marked. When visiting v, set $s(v) \leftarrow 1 + \sum\{s(w) : w \text{ is a child of } v\}$. If $s(v) > g$, mark every child of v and set $s(v)$ to 1. Every marked node v determines a microtree whose nodes are the descendants w of v such that v is the only marked node on the path from v to w. The construction guarantees that every microtree contains at most g nodes. It also guarantees that there are at most n/g parents of marked nodes, since, for each such parent, the set of microtrees rooted at its children contains at least g nodes. Partitioning T into microtrees takes $O(n)$ time.

To precompute the answers to finds in the microtrees, begin by initializing $f(v) \leftarrow \mathit{null}$ for every nonroot node v. Then use a pointer-based radix sort to renumber the nodes in each microtree consecutively from 1 up to at most g in an order consistent with their original numbers (given by *num*). This does not affect the answers to the finds for any vertex whose answer is in the same microtree. To do the pointer-based radix sort, build a master list of nodes representing the numbers 1 through n, and use pointers to these nodes in lieu of the actual numbers. For each microtree, build a similar master list of nodes representing the numbers 1 through the number of nodes in the microtree, and use pointers to these nodes in lieu of numbers. Now the problem of answering the finds within microtrees is actually a topological graph computation

as defined in section 5, and with $g = n/\log^{1/3} n$ it can be done in $O(n)$ time by Theorem 5.2. This computation gives a nonnull value $f(v)$ for every vertex v such that v and $f(v)$ are in the same microtree.

Having precomputed the answers to some of the finds, we run the algorithm that builds K, but using the precomputed answers. Specifically, to process an arc $(p(v), v)$, let $u = f(v)$ if $f(v) \neq null$, $u = find(p(v))$ otherwise. Then proceed as in section 10.2.

THEOREM 10.1. *Suppose that the edges of a weighted tree T are given in order by weight. Then the Kruskal tree of T can be built in $O(n)$ time on a pointer machine.*

Proof. The algorithm runs on a pointer machine; the running time is $O(n)$ except for the time to do the finds. We bound the time for the finds by applying Lemma 4.6 to the tree built by the parent assignments done by the unite operations. Mark every parent of a microtree root. This marks at most n/g nodes. If an operation $find(p(v))$ is actually done, because its answer is not precomputed, $f(v)$ and v are in different microtrees. The union operations are such that if x and y are in the same set and x is an ancestor of y, every vertex on the tree path from x to y is also in the same set. Thus when $find(p(v))$ is done, $f(v)$, $p(v)$, and $p(root(micro(v)))$ are all in the same set. Since $p(root(micro(v)))$ is marked, this find occurs in a set with a marked node. We conclude that Lemma 4.6 applies with $k = 1$, giving an $O(n)$ time bound for the finds that are not precomputed. □

We do not know whether there is a way to build K in linear time using only bottom-level microtrees. If there is, it is likely to be considerably more complicated than the algorithm we have proposed.

10.4. Compressed Kruskal trees. We can generalize the Kruskal tree to allow equal-weight edges: when adding edges, we add all edges of the same weight at the same time and add a node to the Kruskal tree for every new component so formed, whose children are the components connected together to form it. The resulting component tree is not necessarily binary. Thorup [62] and Pettie and Ramachandran [48] have used such a compressed Kruskal tree in shortest path algorithms. Given a tree and a partition of its edges into equal-weight groups, ordered by weight, we can construct the generalized Kruskal tree in linear time on a pointer machine as follows: Break ties in weight arbitrarily. Build the Kruskal tree, labeling each component node with the group of the edge that formed it. Contract into a single node each connected set of nodes labeled with the same group. The last step is easy to do in $O(n)$ time.

11. Concluding remarks. We have presented linear-time pointer-machine algorithms for six tree and graph problems, all of which have in common the need to evaluate a function defined on paths in a tree. Linear time is optimal and matches the previous bound for RAM algorithms for these problems; our algorithms improve previous pointer-machine algorithms by an inverse-Ackermann-function factor. Our improvements rely mainly on three new ideas: refined analysis of path compression when the compressions favor certain nodes; radix sorting to group isomorphic small subproblems; and careful partitioning of the tree corresponding to the original problem into a collection of microtrees and maximal paths, as appropriate to the particular application.

Our algorithms are simpler than the previous linear-time algorithms. Indeed, our approach provides the first linear-time dominators algorithm that could feasibly be implemented at all: the linear-time algorithm of Alstrup et al. [10] requires Q-heaps [26], implying an impossibly-large constant factor. Buchsbaum et al. implemented their original dominators algorithm [16], of which our algorithm is an improvement,

and presented experimental results demonstrating low constant factors, though the simpler LT algorithm was faster. Georgiadis, Tarjan, and Werneck [34] report more recent experiments with algorithms for finding dominators, with results that vary depending on input size and complexity.

Our methods are sufficiently simple and general that we expect them to have additional applications, which remain to be discovered.

Note Added in Proof. We recently discovered how to avoid the need for NCAs in Tarjan's algorithm for interval analysis described in section 8. The resulting simplified algorithm builds the sets $R(u)$ and finds heads during a single DFS of the flowgraph. It maintains the same DSU structure as in section 8. Initially $R(u)$ is empty for every vertex u. The algorithm is as follows. When the DFS retreats along an arc (x, y), add x to $R(\mathit{find}(y))$. When the DFS visits a vertex u in postorder, while $R(u)$ is nonempty delete a vertex x from $R(u)$, let $v \leftarrow \mathit{find}(x)$, and if $v \neq u$, set $h(v) \leftarrow u$, set $R(u) \leftarrow R(u) \cup R(v)$, and do $\mathit{unite}(u, v)$. This is the computation done by the original algorithm after it does insertions into R-sets for arcs (x, y) such that $\mathit{nca}(x, y) = u$. If the original algorithm processes the vertices in postorder with respect to the DFS, then the R-sets of the descendants of a vertex u just after the insertions for arcs (x, y) such that $\mathit{nca}(x, y) = u$ are exactly the same as they are in the simplified algorithm just before it processes u; the simplified algorithm has done these insertions earlier. It follows that the simplified algorithm is correct.

This idea extends to the linear-time algorithm for interval analysis in section 8, which can be simplified further by making the maximal path partition of the core rightmost instead of arbitrary. Then the computation of heads for vertices whose heads are in the core can be done in a single DFS that also generates the path partition. Here are the details of this computation. Do set unions to combine the vertices in each strong component of the fringe into a single set. Redo the DFS that generated the tree D used to define the fringe and the core, but do the following. Initialize the current path P, the stack S, and all sets $R(u)$ to be empty. When retreating along an arc (x, y), if $\mathit{find}(y)$ is not on P add x to $R(\mathit{find}(y))$; if (x, y) is a tree arc and y is in the core add y to P and push y onto S. (If $\mathit{find}(y)$ is on P when retreating along (x, y), (x, y) is a forward arc; as noted in section 8, heads do not depend on such arcs.) When visiting a core vertex u in postorder, while $R(u)$ is nonempty do the following. Delete a vertex x from $R(u)$. Let $v \leftarrow \mathit{find}(x)$. If v is not on P, set $h(v) \leftarrow u$, set $R(u) \leftarrow R(u) \cup R(v)$, and do $\mathit{unite}(u, v)$. If v is on P and v is no less than the top vertex on S, pop from S each vertex w less than or equal to v, set $h(w) \leftarrow u$, and set $R(u) \leftarrow R(u) \cup R(w)$. When advancing along a tree arc (x, y), do $\mathit{unite}(h(v), v)$ for each vertex on P but not on S, and then empty P and S. It is straightforward to show that this algorithm is correct. An analysis like that in section 8 shows that the algorithm runs in linear time.

Acknowledgment. We thank Stephen Alstrup and Amos Fiat for some pointers to previous work.

THE COMBINED POWER OF CONDITIONS AND INFORMATION ON FAILURES TO SOLVE ASYNCHRONOUS SET AGREEMENT*

ACHOUR MOSTEFAOUI†, SERGIO RAJSBAUM‡, MICHEL RAYNAL†, AND CORENTIN TRAVERS†

Abstract. To cope with the impossibility of solving agreement problems in asynchronous systems made up of n processes and prone to t process crashes, system designers tailor their algorithms to run fast in "normal" circumstances. Two orthogonal notions of "normality" have been studied in the past through *failure detectors* that give processes information about process crashes, and through *conditions* that restrict the inputs to an agreement problem. This paper investigates how the two approaches can benefit from each other to solve the *k-set agreement* problem, where processes must agree on at most k of their input values (when $k = 1$ we have the famous consensus problem). It proposes novel failure detectors for solving k-set agreement and a protocol that combines them with conditions, establishing a new bridge among asynchronous, synchronous, and partially synchronous systems with respect to agreement problems. The paper also proves a lower bound when solving the k-set agreement problem with a condition.

1. Introduction.

Distributed services have to run efficiently and reliably in complex environments with unpredictable processing and communication delays, where components can fail in various ways. It is unavoidable to encounter scenarios where system performance will degrade, or even manual intervention will be required. Therefore, system designers tailor their applications to run fast in "normal" circumstances while having expensive recovery procedures in the rare cases of "abnormal" circumstances. Two complementary notions of "normality" have been considered, mirroring the traditional computer science duality of *control* and *data*. On the control side we have the *failure detector* approach [8], which abstracts away useful failure pattern information, available in common operating scenarios. On the data side, we have the *condition-based* approach [36], which looks at common input data patterns of a certain distributed problem we are interested in. The aim of this paper is to study how the two approaches interact and can benefit from each other, with respect to solving *agreement problems*.

1.1. Context of the paper.

Distributed services often rely on an underlying agreement protocol. The most popular and fundamental of the agreement problems is consensus, which is actually indispensable for a lot of services. This paper investigates the possibilities and limitations of solving consensus, and other weaker agreement problems, in a system with failure detectors and conditions.

Agreement problems. The *consensus* problem can informally be stated as follows. Each process proposes a value, and the processes that are not faulty have to decide the same value such that the value decided is one of the proposed values. As a familiar example, it is easy to see that the *atomic broadcast* problem relies on consensus as it requires that all of the processes deliver the messages they broadcast in the same order: They have, consequently, to agree in one way or another on the same message delivery order. However, it is well known that the consensus problem has no solution in message-passing asynchronous systems made up of n processes that need to tolerate a single process crash failure [16].

The *k-set agreement* problem [9] relaxes the consensus requirement to allow up to k different values, out of the proposed values, to be decided; when $k = 1$, we have the consensus problem. Set agreement is an abstraction of problems that are weaker than consensus. Its discovery was motivated by the search for a problem that is solvable when $k-1$ processes can crash, but not when k can crash, in an asynchronous system. Since then, it has been very valuable in the development of the foundations of distributed computing. The proofs in [6, 29, 50] showing that k-set agreement is not solvable in a system of $k+1$ processes where k can crash uncovered a deep connection between distributed computing and topology and motivated a significant amount of subsequent research.

The situation is totally different in synchronous systems, where both consensus and k-set agreement can be solved for any value of t (the maximum number of process crashes) [10, 49]. However, there are limitations on how fast these problems can be solved in a synchronous system, as a function of the number of failures t to be tolerated. It has been shown that consensus requires $t + 1$ rounds in the worst case [15, 33], and there are protocols that meet this lower bound. These results have been generalized for the set agreement problem in [10, 20, 48].

The following two complementary notions of "normality" have been considered[1] to cope with the consensus and set agreement asynchronous impossibility results and synchronous lower bounds.

Control: Enriching the underlying system. The first approach focuses on the behavior of the underlying system. In this case "normal circumstance" means a period during which the system behaves in a relatively synchronous way. Namely, periods during which upper bounds on process execution speeds and on message transmission delays hold (various such *partially synchronous* models have been considered, e.g., [14]), or periods during which message exchange patterns satisfy some properties (e.g., the notion of winning/losing responses introduced in [35]) that allow solving consensus. A *failure detector* abstracts away such low-level assumptions by providing processes with a primitive they can invoke that returns information on process failures. One of the noteworthy features of failure detectors is the modular approach they favor: One can independently, on one side, solve a problem with the help of a particular class of failure detector, and, on another side, implement the assumed failure detector with the help of the underlying timing or order assumptions. The design, transportability, and proof of protocols then become modular and easier to achieve.

Chandra and Toueg introduced the *failure detector* notion [8] and defined eight classes that can be used to solve asynchronous consensus. Together with Hadzilacos, they later showed that one of these classes is the weakest class of failure detectors to solve consensus when $t < n/2$ [7] (n being the total number of processes, and t an upper bound on the number of faulty processes). The weakest failure detector

[1] There are other approaches, like randomization or stronger shared memory primitives.

for consensus and any value of t was identified in [12]. These results are of great theoretical interest because they identify the minimum knowledge about failures that needs to be abstracted to solve consensus. Failure detectors to solve set agreement have also been proposed [27, 44, 52], but we do not know yet what is the minimum knowledge about failures that needs to be abstracted to solve this problem.

The failure detector approach has favored the design of indulgent protocols [21]. A protocol is *indulgent* with respect to its failure detector if it never violates its safety property. This means that, when the underlying failure detector satisfies its specification (normal circumstances) the protocol terminates correctly; and, when the underlying failure detector does not satisfy its specification (abnormal circumstances), it is possible that the protocol does not terminate, but if it terminates, it does so correctly. Various indulgent failure detector-based consensus protocols have been proposed (e.g., [8, 23, 31, 43, 46, 51]).

Data: Restricting the inputs. The *condition-based* approach [36] consists in looking at certain combinations of input values of a given distributed problem. It is often the case in practice that some combinations of the input values of processes occur more frequently than others. For example, in an election, it is often the case that the difference in the number of votes that candidates receive is significant. More precisely, an *input vector* contains the values proposed by the processes in an execution. A *condition* C is a set of input vectors, each representing a common combination of inputs to the problem. If a protocol solves k-set agreement for C, then whenever the input vector belongs to C, all of the correct processes decide. The solution should be indulgent in the sense that if correct processes decide while the input vector does not belong to the condition, they do not decide more than k values.

It was discovered in [36] that there is a family of conditions, called x*-legal*, that tie together asynchronous and synchronous systems with respect to consensus solvability. Informally, in an x-legal condition any two input vectors $I1, I2$ that force different decisions have $d(I1, I2) > x$ (Hamming distance), assuming $n > x$. Thus, in a sense, x is the "power" of the condition; larger values of x make it easier to solve consensus. Assuming up to t process crashes and $d \leq t$ (d can have a negative value), let $\mathcal{S}_t^{[d]}$ be the set of all x-legal conditions, $x = t-d$ (e.g., $\mathcal{S}_t^{[0]}$ consists of the t-legal conditions). Then

$$\mathcal{S}_t^{[-t]} \subset \cdots \subset \mathcal{S}_t^{[-1]} \subset \mathcal{S}_t^{[0]} \subset \mathcal{S}_t^{[1]} \subset \cdots \subset \mathcal{S}_t^{[t]},$$

where $\mathcal{S}_t^{[t]}$ includes the condition made up of all of the possible input vectors. For a condition $C \in \mathcal{S}_t^{[d]}$, $-t \leq d \leq t$, and a system prone to t process crashes, we have the following:

- For values of $d \leq 0$, for inputs in C, consensus is solvable by more and more efficient protocols in a shared memory asynchronous system as we go from $d = 0$ to $d = -t$ [40].
- For values of $d > 0$, consensus is not solvable in an asynchronous system, but, for inputs in C, it is solvable in a message-passing synchronous system with more and more rounds, as we go from $d = 1$ (two rounds) to $d = t$ ($t + 1$ rounds), and this is tight [37] (namely, when $C \in \mathcal{S}_t^{[d]}$ and $C \notin \mathcal{S}_t^{[d-1]}$, $(d+1)$ rounds are sufficient and necessary in worst case scenarios).
- $d = 0$ is the borderline case. On one hand, asynchronous consensus can be solved (despite up to t faulty processes) for a condition C if and only if C is t-legal [36]. On the other hand, consensus can be solved optimally (2 rounds) in a message-passing synchronous system [37] for any t-legal condition.

The condition-based approach has been considered also for set agreement (and for other problems), but a characterization of the conditions that allow solving set agreement was not known (see section 1.3 for more about this and other related works).

1.2. Motivation and results. As we have seen, failure detectors and conditions are two orthogonal approaches to cope with the impossibility of solving agreement problems in asynchronous systems prone to t process crashes. So, the natural question that comes to mind is,

> *What is the relation between the condition-based approach and the failure detection-based approach when solving asynchronous agreement problems?*

More specifically, we are interested in studying how the two approaches can cooperate to solve set agreement problems. We would like to understand which combinations of failure detectors and conditions can be used to solve k-set agreement for a given value of k.

> *For a given condition C, what is a failure detector that abstracts away the synchrony needed to solve k-set agreement?*

These and similar questions are the topic addressed in the paper.

The paper contains three main contributions. While trying to answer the previous questions, we discovered a new class of failure detectors. We present an asynchronous condition-based set agreement protocol based on this kind of failure detector. We present a lower bound showing that our protocol is optimal. The next three sections describe these results in more detail.

1.2.1. A new class of failure detectors. The first contribution of the paper is the definition of a new class of failure detectors that we denote ϕ_t^y, $0 \leq y \leq t$. A failure detector of ϕ_t^y provides a primitive, denoted $\text{QUERY}_y(S)$, that can be invoked by a process with a set of process identities S to be informed whether they have crashed or not. Roughly speaking, $\text{QUERY}_y(S)$ returns *true* only when all of the processes in S have crashed. If at least one process in S is alive, the output should be *false*. If $|S|$ is outside the range $t - y < |S| \leq t$, the query returns no useful information.

Notice that the nature of our failure detectors is different from the standard failure detectors of [8], that return a set of processes suspected to have crashed, and accept no input parameter. The motivation is that often a process p_i is interested in the failures of only a specific part of the network, namely S, while the standard failure detectors must find out the failure status of all processes in the network, even if p_i cares only about the state of a single process p_j.

For each value of y between 0 and t, there is a class of failure detectors, ϕ_t^y. The class ϕ_t^y provides more information on failures than the class ϕ_t^{y-1}. So, the class ϕ_t^t is the most powerful, while ϕ_t^0 is the weakest (it actually provides no dependable information on failures). Indeed, as shown in the paper, ϕ_t^y can be used to solve k-set agreement for smaller values of k than ϕ_t^{y-1}.

The paper also compares the power of the ϕ_t^y failure detectors and the power of the classic failure detector classes introduced by Chandra and Toueg [8]. It is shown that it is possible to build any class ϕ_t^y, $0 \leq y \leq t$, from a perfect failure detector as defined in [8]. (A perfect failure detector eventually detects all crashed processes and never suspects erroneously a noncrashed process.) In contrast, none of the other classes of classic failure detectors can be used to build a failure detector of a class ϕ_t^y, $1 \leq y \leq t$. When we consider the construction in the other direction, we show that no class ϕ_t^y, $0 \leq y < t$, can be used to build any of the classic failure detector classes. When $y = t$, ϕ_t^t can be used to build a failure detector of the class $\mathcal{P}$.

1.2.2. A condition-based set agreement algorithm using failure detectors. A second contribution of the paper is the design of a condition-based set agreement protocol with access to a failure detector of the class ϕ_t^y, $0 \leq y \leq t$. The considered model is the classical asynchronous read/write shared memory distributed system prone to at most t process crashes. The protocol can be instantiated with any condition $C \in \mathcal{S}_t^{[d]}$, $0 \leq d \leq t$. As we have seen, $x = t - d$ represents the power of the condition. That is, once n and t are fixed, the protocol is parameterized by the power of the failure detector (captured by y) and the power of the condition (captured by $x = t - d$).

We use the following terminology. We say that "a protocol solves the k-set agreement problem" if the correct processes always decide; we say that "*a protocol solves the condition-based k-set agreement* problem" if the correct processes decide at least "in normal circumstances," where "*normal circumstances*" means when (1) the input vector belongs to the condition C; or when (2) a process decides or less than k processes crash; or when (3) at least $t - d$ processes crash initially.

The proposed protocol solves the condition-based k-set agreement for $k = 1 + \max(0, d - y)$. Making more explicit the power y of the failure detector and the power $x = t - d$ of the condition, we have $k = 1 + \max(0, t - (x + y))$. This shows how, by adding the power of the condition and the power of the failure detector, we can counterbalance the power t of the "adversary," in order to reduce the value of k. When we consider the boundary values of y and d, the protocol solves the following problems:

- $d = t$ corresponds to the case where there is no additional power provided by the condition, as then condition C may contain all possible input vectors. But, as any input vector belongs to this trivial condition, all correct processes always decide, and, consequently, the protocol solves the k-set agreement problem. More precisely,
  - If $y = t$ (strongest failure detector), the protocol solves the consensus problem, $k = 1$.
  - If $y = 0$ (no failure detector), the protocol solves the trivial $(t + 1)$-set agreement problem.
  - If $0 < y < t$, the protocol solves k-set agreement, with $k = t+1-y$. When we compare to the previous case, this shows the benefit provided by a failure detector of the class ϕ_t^y. The number of decided values linearly decreases according to the power of the failure detector, as measured by y.
- $d = 0$ means that the condition C is t-legal, which means that condition-based consensus can be solved despite asynchrony and up to t crashes, with no failure detector. So, at most one value is decided, and all of the correct processes terminate in normal circumstances. So, the protocol then solves condition-based consensus. (Let us notice that this is independent of the value of y.)
- if $y = 0$ (no failure detector), the protocol then relies only on the condition and solves the condition-based k-set agreement problem for $k = d + 1$. No more than $(d + 1)$ values are decided, and the termination of the correct processes is guaranteed at least in normal circumstances: The number of decided values decreases linearly according to the parameter d defining the condition.

  This case is particularly interesting as it exhibits a new link relating synchronous and asynchronous systems. More precisely, when the condition C belongs to $\mathcal{S}_t^{[d]}$ and the input vector belongs to C, (1) it is possible to solve

consensus in at most $(d+1)$ rounds in a synchronous system [37]; and (2) it is possible to solve $(d+1)$-set agreement in an asynchronous system, both systems being prone to t crashes. The optimal time bound for synchronous condition-based consensus is equal to the number of decided values in asynchronous condition-based set agreement. This time (in synchronous systems) versus the number of decided values (in asynchronous systems) relation sheds a new light on the global picture concerning the relations between synchronous and asynchronous systems.

When we look at the general case, where the condition-based k-set agreement problem is solved with $k = 1 + \max(0, d-y)$, we see that when $y \geq d$, condition-based consensus is solved. This means that, if d is fixed, we need only to take a failure detector of the class ϕ_t^d to solve condition-based consensus (failure detectors of any class ϕ_t^y, with $y > d$ are stronger than necessary). A similar reasoning can be done when y is fixed, and we have the choice of the condition class.

The proposed protocol is indulgent [21, 23]: It never violates its safety requirement (no more than $k = 1 + \max(0, d-y)$ values are decided), and the correct processes always terminate when the input vector belongs to the condition ("normal circumstances"). Interestingly, a simple modification provides a protocol version in which all of the correct processes always terminate. This is obtained at the price of an increase in the number of values that can be decided when the input vector does not belong to the $(t-d)$-legal condition C, namely, up to $k' = t+1-y$ different values can then be decided. When the system is equipped with a failure detector of the class ϕ_t^t, this protocol variant solves the consensus problem whatever the condition it is instantiated with.

1.2.3. A lower bound. A third contribution of the paper is a lower bound result showing that no protocol with access to a failure detector of the class ϕ_t^y can solve k-set condition-based agreement for $k \leq \max(0, d-y)$, if the condition is in $\mathcal{S}_t^{[d]}$. The proof is by reduction to the standard t-resilient k-set agreement problem, that is known to be impossible if $t \geq k$ [6, 28, 29, 50]. This lower bound result has two nice corollaries. One states that (in the absence of a failure detector) there is no condition-based k-set agreement protocol such that $k \leq d$ for any $(t-d)$-legal condition (a previously open problem). The second one states that, among all of the failure detector classes of the family $(\phi_t^y)_{0 \leq y \leq t}$, the class ϕ_t^y is the weakest that allows solving the k-set agreement problem for $k > t - y$.

1.3. Related work.

The condition-based approach for consensus and set agreement. The condition-based approach has been applied to problems other than consensus like interactive consistency [17] and, more related to our work, set agreement [3, 39]. The paper [3] characterizes the set of input vectors that allow us to solve $(n-1)$-set agreement, wait-free, namely, when $t = n-1$. Their notion of solvability is different from ours, since they assume that a protocol never receives input vectors outside of the condition. In [39], another family of conditions for set agreement is defined, but no general lower bounds were proved. Randomization as a means of circumventing the set agreement asynchronous impossibility result has been considered in [45].

Failure detectors. Most of the research about failure detectors has been directed at solving consensus, but there have also been proposals of failure detectors for solving other problems. Failure detectors for implementing various objects and for solving nonblocking atomic commit have been studied (e.g., [12, 22, 47]). The

weakest class of failure detectors to solve consensus was identified in [7, 12]. For our work, weaker classes of failure detectors are especially relevant, since set agreement is an easier problem than consensus (and if conditions are considered, it becomes even easier). Weaker classes of failure detectors were considered in [18, 44, 47, 52].

Failure detectors for set agreement. Among the failure detectors which are not strong enough to solve consensus, the *limited scope accuracy* failure detectors [25, 44, 52] have been studied with respect to set agreement. To illustrate this notion, let us consider the class denoted $\mathcal{S}_x$. A failure detector of that class satisfies the following two properties. The completeness property states that the processes that crash are eventually suspected in a permanent way. The limited scope accuracy property states that there is a correct process that is not suspected by a set—cluster—of x processes (some of these x processes may be correct, while others may be faulty). An $\mathcal{S}_x$-based k-set agreement protocol is presented in [44]. This protocol assumes that $t < k + x - 1$ (which means that $(t+1) - (x-1)$ is the smallest value of k that it can tolerate). Using topological methods, it has been shown in [27] that this is actually a lower bound for any $\mathcal{S}_x$-based k-set agreement protocol (from which it follows that the previous protocol is optimal with respect to the number of faulty processes that can be tolerated). When the limited scope accuracy property has to hold only after some unknown but finite time, we get the class denoted $\diamond\mathcal{S}_x$. It is shown in [27] that any $\diamond\mathcal{S}_x$-based k-set agreement protocol requires $t < \min(n/2, k + x - 1)$. A $\diamond\mathcal{S}_x$-based protocol meeting this lower bound is also presented in [27]. It is shown in [2] that $t < x$ is a necessary and sufficient requirement to transform any failure detector of the class $\diamond\mathcal{S}_x$ into a failure detector of the class $\diamond\mathcal{S}_y$ for $y > x$.

The class of anonymously perfect failure detectors. A failure detector of our class ϕ_t^y returns a binary output and can be invoked with a parameter S that contains a set of process identities. In contrast, the classic failure detectors of [8] return a set of identities, and are invoked with no parameter. A failure detector class whose output is binary has been introduced by Guerraoui to solve the nonblocking atomic commit problem [22], but, differently from ours, a failure detector of this class does not accept a parameter to invoke it. This class, called *anonymously perfect* failure detectors and denoted $?\mathcal{P}$, is defined as follows. Each process has a flag (initially equal to *false*) that is eventually set to *true* if and only if a process has crashed (the identity of the crashed process is not necessarily known, hence the name "anonymous").

The definition of $?\mathcal{P}$ has been extended in [18] to take into account the fact that ℓ processes have crashed (instead of a single one). This class, denoted $?\mathcal{P}^\ell$, provides each process with a flag that is eventually set to *true* if and only if at least ℓ processes have crashed (observe that $?\mathcal{P}$ is $?\mathcal{P}^1$).

So, a failure detector of the class $?\mathcal{P}^\ell$ answers *true* only if there is a set S of ℓ processes that have crashed. The set S is not known to the processes. Differently, when we consider ϕ_t^y, the set S is user-defined and specific to each invocation.

A variant of Ω. A generalization of the class of leader failure detectors, denoted Ω, has been introduced in [47]. More explicitly, Ω_z is the class of all failure detectors that provide the processes with a primitive LEADER() satisfying the following properties. First, LEADER() always returns a set of at most z process identities. Second, there is a time τ such that, after τ, all of the invocations of LEADER() by the correct processes return the same set of processes, and this set includes at least one correct process. It is easy to see that Ω_1 is Ω, and Ω_n provides no information on failures. That is, in general, Ω_z is weaker than the weakest failure detector for

consensus. However, Neiger introduced them to study questions about augmenting the synchronization power of types in the wait-free hierarchy [26], and their relation to set agreement was not studied.

In a follow-up paper [38], we study the relation of Ω_z to set agreement. Moreover, we study our new failure detectors, with respect to $\diamond\mathcal{S}_x$, Ω_z, and show which reductions among these classes are possible and which are not.

1.4. Organization of the paper. The paper is made up of nine sections. After this introduction and a short section introducing the computation model considered in the paper, section 3 presents the new failure detector classes ϕ_t^y. (Section 8 compares them to classic failure detectors by Chandra and Toueg.) Section 4 provides a quick overview of the most relevant notions (for this paper) of the condition-based approach, including a definition of the condition-based k-set agreement problem. Section 5 presents a generic k-set agreement protocol that is based on the combined power of a failure detector of the class ϕ_t^y and a condition of the class $\mathcal{S}_t^{[d]}$. The protocol is discussed in section 6, where, at the price of an increase of the number of decided values, an always terminating version is presented. Section 7 focuses on the lower bound result. Finally, section 9 summarizes the content of the paper.

2. About the model of computation. This paper considers the usual *asynchronous model* with n processes $p_1, \ldots, p_n$, where at most t can crash $1 \leq t < n$. The processes communicate through a shared memory made up of single-writer, multireaders atomic registers.

We assume that processes have access to an oracle that provides possibly unreliable information on process failures. A *failure detector* provides processes with a primitive they can invoke to get information from the oracle on process failures.

3. The failure detector classes $\{\phi_t^y\}_{0\leq y\leq t}$.

3.1. Definition. This section introduces a new class of failure detectors, parameterized by an integer y, $0 \leq y \leq t$, denoted ϕ_t^y. (A comparison to classic failure detectors is done in section 8.) The power of a such a failure detector depends on the value of y. As we are about to see, a failure detector is more powerful for larger values of y, because it can return information about more specific regions of the network, namely, about smaller sets S of processes, with $|S| > t - y$.

More precisely, a failure detector of the class ϕ_t^y provides a primitive $\text{QUERY}_y(S)$ that returns a boolean answer. A process invokes it with the parameter S, a set of processes specific to each invocation. Intuitively, if p_i invokes $\text{QUERY}_y(S)$, the answer will be *true* only when all processes in S have crashed. In that sense, these failure detectors are different from the standard failure detectors, introduced by Chandra and Toueg [8], that return a set of processes suspected to have crashed, and do not accept an input parameter.[2] The motivation is that often a process p_i is interested in the failures of only a specific sector of the network, namely S, while the Chandra–Toueg failure detectors must find out the failure state of all processes in the network, even if p_i cares only about the state of only one process p_j.

A query $\text{QUERY}_y(S)$ such that $t-y < |S| \leq t$ is *relevant*, otherwise it is *irrelevant*. Intuitively, "relevant" means that it provides dependable information on failures. The class ϕ_t^y is defined by the following properties:

[2]We have shown in [38] that there are transformations between the ϕ failure detectors and a version with no input parameter. It is consequently possible to define them according to the failure pattern only.

- *Triviality property.* If $|S| \leq t - y$, then $\text{QUERY}_y(S)$ returns *true*. If $|S| > t$, then $\text{QUERY}_y(S)$ returns *false*.
- *Safety property.* If $\text{QUERY}_y(S)$ is relevant, then if at least one process in S has not crashed when $\text{QUERY}_y(S)$ is invoked, the invocation returns *false*.
- *Liveness property.* Let $\text{QUERY}_y(S)$ be a relevant query. Let τ be a time such that, at time τ, all of the processes in S have crashed. There is a time $\tau' \geq \tau$ such that all of the invocations of $\text{QUERY}_y(S)$ after τ' return *true*.

The triviality property says that the invoking process gets back a *true* output when the set S is too small, because, in this case, the failure detector is not powerful enough to answer reliably on a region of the network that is too focused. If the set S is too big, the output is *false*, because, by definition, no more than t processes can fail. The safety property states that if the output of a relevant query is *true*, then all of the processes in S have crashed. The liveness property states that $\text{QUERY}_y(S)$ eventually outputs *true* when all of the processes in S have crashed (and the query is relevant).

3.2. Ranking the classes $\{\phi_t^y\}_{0 \leq y \leq t}$. A failure detector of the class ϕ_t^0 provides no information related to failures as the invocation $\text{QUERY}_y(S)$ answers always *true* if $|S| \leq t$, and *false* if $|S| > t$. At the other extreme, with a failure detector of the class ϕ_t^t, a process can query about the failure status of a single specific process, since $\text{QUERY}_y(S)$ may return significant failure information about sets S of any size, $1 \leq |S| \leq t$. That is, ϕ_t^0 and ϕ_t^t are two extreme classes. This section compares the power of distinct classes of failure detectors denoted ϕ_t^{y1} and ϕ_t^{y2}.

DEFINITION 1. *For two classes of failure detectors A and B, we denote $A \leq B$, and say that B is* at least as strong *as A if any failure detector in B can be used to build a failure detector in A. We also say that B is* stronger *than A (denoted $A < B$) if $A \leq B$ and $B \not\leq A$. The classes A and B are* equivalent, *(denoted $A \equiv B$) if $A \leq B$ and $B \leq A$.*

We shall see that ϕ_t^{y1} is stronger than ϕ_t^{y2} if $y1 > y2$, since ϕ_t^{y1} provides more information about failures than ϕ_t^{y2}. Given a run of the processes, let $\text{QUERY}_y(S)$ be a failure detector query invocation that, from some time on, is indefinitely repeated. Let us examine the outputs returned by the infinite sequence of queries when the failure detector belongs to ϕ_t^{y1} and ϕ_t^{y2}, respectively. Notice that $t - y2 > t - y1$ (since $y1 > y2$).

- Case 1: $|S| > t$. Both outputs are systematically equal to *false*.
- Case 2: $|S| \leq t - y1$. Both outputs are systematically equal to *true*.
- Case 3: $t - y2 < |S| \leq t$ (so, we also have $t - y1 < |S| \leq t$) for a relevant query. If at least one process of S never crashes, both outputs are always equal to *false*. If all of the processes of S crash, eventually both outputs are permanently equal to *true*.
- Case 4: $t - y1 < |S| \leq t - y2$. In this case, the output is always *true* if the failure detector belongs to the class Φ_t^{y2}. If it belongs to Φ_t^{y1}, the output is as in Case 3 (it depends on the failures).

The last case, namely, when $t - y1 < |S| \leq t - y2$, exhibits a noteworthy difference between ϕ_t^{y1} and ϕ_t^{y2}: ϕ_t^{y1} provides information on failures while ϕ_t^{y2} does not. Indeed, for $y1 > y2$, it is impossible to build a failure detector in ϕ_t^{y1} from one in ϕ_t^{y2}. On the other hand, any failure detector in ϕ_t^{y1} can be used to build a failure detector in ϕ_t^{y2} by returning *true* if $|S| \leq t - y2$, returning *false* if $|S| > t$, and returning the output of ϕ_t^{y1} if $t - y2 < |S| \leq t$. (Formally, the next theorem is a consequence of Corollary 2 of section 7.)

THEOREM 1. $(y1 > y2) \Rightarrow (\phi_t^{y2} < \phi_t^{y1})$.

4. The condition-based approach. The condition-based approach was introduced in [36] to study conditions restricting the inputs to consensus that make the problem solvable in an asynchronous system where t processes can crash. This line of research has been extended to study conditions for other problems and in other distributed computing models [3, 17, 32, 36, 37, 39, 53]. In this paper, we are interested in conditions for the set agreement problem in an asynchronous system.

4.1. Conditions. Let $\mathcal{V}$ be the set of values that can be proposed by the processes. Moreover, let $\perp \notin \mathcal{V}$ be a default value. An *input vector* is a size n vector over $\mathcal{V} \cup \{\perp\}$. The input vector J *proposed* in an execution has in its ith entry $J[i]$ the value of $\mathcal{V}$ proposed by p_i, or $\perp$ if p_i did not take any step in the execution. We usually denote by I an input vector with all entries in $\mathcal{V}$, and with J an input vector that may have some entries equal to $\perp$; such a vector J is called a *view*. The set $\mathcal{V}_x^n$ consists of all of the input vectors, with at most x entries equal to $\perp$, and $\mathcal{V}^n = \mathcal{V}_0^n$.

DEFINITION 2. *A* condition C *is a subset of* $\mathcal{V}^n$.

Notation. For any pair of vectors $J1, J2 \in \mathcal{V}_x^n$, $J1$ is *contained* in $J2$, denoted $J1 \leq J2$, if for all $k : J1[k] \neq \perp \Rightarrow J1[k] = J2[k]$. Moreover, $J1 < J2$ if $J1 \leq J2$ and $J1 \neq J2$, which means that J_2 has at least one non-$\perp$ value that $J1$ does not have. Also, $\#_a(J)$ denotes the number of occurrences of a value a in the vector J, with $a \in \mathcal{V} \cup \{\perp\}$. For a set of input vectors $C \subseteq \mathcal{V}^n$, $\mathcal{C}_x$ is the set of all vectors J, with at most x entries equal to $\perp$ and such that $J \leq I$ for some $I \in C$. Finally, $dist(J, J')$ is the Hamming distance separating J and J', where J and J' are two vectors of $\mathcal{V}_x^n$.

4.2. Legality of a condition. The main result of the condition-based approach to solve asynchronous consensus is based on the following definition as formulated in [17, 53].

DEFINITION 3. *A condition* C *is* x-legal *if there exists a function* $h : C \mapsto \mathcal{V}$ *with the following properties:*

- *for all* $I \in C$: $h(I) = a \Rightarrow \#_a(I) > x$, *and*
- *for all* $I1, I2 \in C$: $h(I1) \neq h(I2) \Rightarrow dist(I1, I2) > x$.

A fundamental result of the condition-based approach is a characterization of the conditions C for which consensus can be solved (for a precise definition of solving consensus for C, see Definition 5, with $k = 1$).

THEOREM 2 (see [36]). *There is a* t*-fault tolerant protocol solving consensus for* C *if and only if* C *is* t*-legal.*

A general method to define t-legal conditions is described in [40], and two natural t-legal conditions are described in [36].

It is convenient to extend h to vectors J with $\perp$ values. The lemma that follows shows that this is easy, provided $J \in \mathcal{C}_x$.

LEMMA 1. *Let* C *be an* x*-legal condition, and* $I1, I2 \in C$, $J \in \mathcal{C}_x$ *such that* $J \leq I1$ *and* $J \leq I2$. *Then* $h(I1) = h(I2)$.

Proof. Assume for contradiction that $h(I1) \neq h(I2)$. We have $dist(I1, I2) > x$ because C is x-legal. From the fact that J has at most x entries equal to $\perp$ and $J \leq I1$, we have $dist(J, I1) \leq x$ (similarly, we also have $dist(J, I2) \leq x$). From these inequalities, the fact that the entries of J that differ in $I1$ and $I2$ are only its $\perp$ entries, and again the fact that J has at most x entries equal to $\perp$, we conclude that $dist(I1, I2) \leq x$. A contradiction. □

Using this lemma we have a consistent definition.

DEFINITION 4. *Let* C *be an* x*-legal condition and* J *be any vector in* $\mathcal{C}_x$. *The function* h *is extended to* J *by taking any* $I \in C$, *with* $J \leq I$ *and letting* $h(J) = h(I)$.

Assuming up to t process crashes and $-t \leq d \leq t$, let $\mathcal{S}_t^{[d]}$ be the set of all $(t-d)$-legal conditions (thus $\mathcal{S}_t^{[0]}$ consists of the t-legal conditions). It is easy to check that

$$\mathcal{S}_t^{[-t]} \subset \cdots \subset \mathcal{S}_t^{[-1]} \subset \mathcal{S}_t^{[0]} \subset \mathcal{S}_t^{[1]} \subset \cdots \subset \mathcal{S}_t^{[t]},$$

where $\mathcal{S}_t^{[t]}$ includes the condition made up of all of the possible input vectors.

Notation. In the rest of the paper, C_t^d denotes a condition that belongs to $\mathcal{S}_t^{[d]}$.

4.3. The k-set agreement problem.

***k*-set agreement.** Consensus is a fundamental problem in distributed computing that is impossible in an asynchronous system even with a single crash failure. While consensus requires all processes to decide on the same value, *k-set agreement* [9] permits the processes to choose up to k different values. The problem is solvable when $k-1$ processes can crash, but not when k can crash. The proofs [6, 29, 50] of this result uncovered a deep connection between distributed computing and topology and motivated a significant amount of subsequent research.

The set of values $\mathcal{V}$ that can be proposed is assumed to be such that $|\mathcal{V}| > k$. Each process starts an execution with an arbitrary input value from $\mathcal{V}$, the value it *proposes*, and all correct processes have to decide on a value such that (1) any decided value has been proposed, and (2) no more than k different values are decided. The *consensus* problem is k-set agreement for $k = 1$.

Condition-based set agreement. We are interested in conditions C that, when satisfied, make k-set agreement solvable in an asynchronous system where at most t process can crash. As we shall see, k-set agreement is solvable for $C \in \mathcal{S}_t^{[d]}$ if $k \geq d+1$.

Notice that, if an input vector $J \in \mathcal{C}_t$ occurs in an execution of a protocol, then as far as the processes with non-$\perp$ values in J can tell, the input vector could belong to $I \in C$, because they cannot distinguish from another execution where the other processes wake up and propose their values after the former processes have made their decision. Given $C \in \mathcal{S}_t^{[d]}$, we say that C is *d-satisfied* for input vector J if $J \in \mathcal{C}_t$ or $\#_\perp(J) \geq t - d$.

Definition 5. *A t-fault tolerant protocol solves the k-set agreement problem for a condition $C \in \mathcal{S}_t^{[d]}$ if in every execution with input vector J, the protocol satisfies the following properties:*

- Validity. *Every decided value is a proposed value.*[3]
- Agreement. *No more than k different values are decided.*
- Termination. *Every correct process must decide if* (1) *C is d-satisfied for J and no more than t processes crash, or* (2.a) *a process decides, or* (2.b) *fewer than k processes crash.*

The first two are the safety requirements of the standard set agreement problem, and they should hold even if the input pattern does not belong to C. The third item requires termination under "normal" operating scenarios: (1) inputs that could belong to C or at least $t - d$ processes crash, and (2.a) executions where a process decides, or (2.b) fewer than k processes crash (a situation where k-set agreement is solvable without conditions).

[3] It is shown in [13] that the solvability of k-set agreement is highly sensitive to the validity property adopted.

Notice that, if set agreement is solvable for a condition C, then it is solvable for any C' contained in C: the same protocol works. As mentioned above, when $t < k$, k-set agreement is solvable for $\mathcal{V}^n$, hence for any condition C.

5. Combining conditions with ϕ_t^y to solve set agreement. This section presents a set agreement protocol with access to a failure detector of the class ϕ_t^y, $0 \leq y \leq t$, and instantiated with the function h of a $(t-d)$-legal condition $C \in \mathcal{S}_t^{[d]}$, $0 \leq d \leq t$. It is a t-fault tolerant protocol that solves k-set agreement for C_t^d, where $k = 1 + \max(0, d-y)$ (recall Definition 5). Thus, all of the pairs (d, y) such that $d \leq y$ allow solving condition-based consensus.

5.1. Base objects. In order to make the protocol simpler to understand, it is presented in a modular way. More specifically, it relies on the following base objects: Three arrays of atomic registers, a consensus object, an adopt–commit-abort object, and a condition-set agreement object. An adopt–commit-abort object and a condition-set agreement object can always be implemented on top of base read/write registers. As far as the consensus object is concerned, as we will see, it can always be implemented in the particular context in which it is used by the processes.

The shared memory. The shared memory is made up of three arrays (denoted $V[1..n]$, $W[1..n]$, and $DEC[1..n]$) of single-writer multireader atomic registers. All are initialized to $[\perp, \ldots, \perp]$. The jth entry of an array $X[1..n]$ can be read by any process, but only p_i can write to the ith component $X[i]$. To simplify the presentation we assume that, in addition to these atomic read and write operations, a process p_i can also invoke the nonprimitive operation snapshot(X) that allows it to read the content of all of the registers of the array X as if this reading was done instantaneously. (Such an operation can be implemented in shared memory systems made up of single-writer, multireader atomic registers despite any number of process crashes ($1 \leq t < n$) [1, 4].) In accordance with the terminology defined in [30], the read, write, and snapshot() operations are linearizable (i.e., they appear as if they had been executed one after the other, in agreement with their real-time occurrence order).

The underlying consensus object. A consensus object is accessed by a process p_i when p_i invokes the operation alg_cons(v_i), where v_i is the value proposed by p_i. Such an object allows any subset of processes to invoke alg_cons(). Its properties are the following:

- *Termination.* Any correct participating process decides a value.
- *Validity.* A decided value is a proposed value.
- *Agreement.* No two different values are decided.

As we will see, the underlying consensus object is used when more than $t - y$ process crash. It is shown in Theorem 8 that, in this case, a failure detector of the class $\mathcal{P}$ (the class of perfect failure detectors [8]; see section 8) can be built from a failure detector of the class ϕ_t^y (such a construction is described in the proof of Theorem 8), and consensus can be solved in a single-writer multireader atomic register asynchronous system enriched with such a failure detector.[4]

The underlying adopt–commit-abort object. The adopt–commit-abort object we use here is a simple variant of the adopt–commit-abort object introduced in [19, 52] in the context of shared memory systems, and an object introduced in [43]

[4] A $\diamond\mathcal{P}$-based alg_cons() protocol is described in [42]. That protocol uses an underlying adopt–commit-abort object. (Trivially, any failure detector in $\mathcal{P}$ is also in $\diamond\mathcal{P}$.) Other shared memory consensus algorithms based on failure detectors can be found in [5, 24, 34].

in the context of message-passing systems.[5] Such an object has a single operation, denoted adopt_commit(). A process p_i invokes adopt_commit(v_i), where v_i is the value it proposes to the adopt–commit-abort object and obtains a pair (d, v) as a result, where d is control tag and v a value. The object is defined by the following properties.

- *Termination.* Any correct participating process decides a pair (d, v).
- *Validity.* If a process decides (d, v), then $d \in \{commit, adopt, abort\}$, and v is a proposed value.
- *Agreement.* If a process decides $(commit, v)$, then any other process that decides, decides (d, v), with $d \in \{commit, adopt\}$.
- *Obligation.* If all of the participating processes propose the same value v, then only the pair $(commit, v)$ can be decided.

Intuitively, the adopt–commit-abort object is an abortable variant of consensus. Let us observe that a process that decides $(abort, -)$, can conclude that no process decides $(commit, -)$. However, when a process decides $(adopt, -)$, it cannot conclude which control tag has been decided by the other processes.

The underlying condition-set agreement object. A condition-set agreement object has a single operation, denoted cond_algo(). This object is designed to solve a set agreement problem with the help of a $(t - d)$-legal condition C. A process uses this object only in the particular context where the input vector J is such $\#_\perp(J) \leq t - y$.

A process p_i invokes cond_algo(V_i), where V_i is its local view of the input vector J (we have then $V_i \leq J$ and $\#_\perp(V_i) \leq t-y$), and only when the views can be ordered by containment, $V_i \leq V_j$ or $V_j \leq V_i$ for all i, j. If it returns from that invocation, p_i obtains a value v. The object is defined by the following properties.

- *Termination.* Every correct process decides if (1) $J \in \mathcal{C}_t$ or $\#_\perp(J) \geq t - d$ (C is d-satisfied for J), or (2.a) a process decides, or (2.b) more than $(n - k)$ correct processes invoke cond_algo().
- *Validity.* A decided value is a value that has been proposed by a process in its input view.
- *Agreement.* At most, $k = 1 + \max(0, d - y)$ values are decided.

5.2. The set agreement protocol.

Description of the protocol. The k-set agreement protocol based on a condition in $C \in \mathcal{S}_t^{[d]}$ and a failure detector of the class ϕ_t^y is described in Figure 1. The variables subscripted with i are local variables of p_i. A process is made up of two tasks: a main task $T1$ and a background task $T2$. The behavior of the task $T1$ can be decomposed into four parts.

- A process first writes the value v_i it proposes into $V[i]$ (line 1). Then, using the snapshot() operation, it reads the array of proposed values until that array contains "enough" values (line 2). "Enough" means here that there are no more than $(t-y)$ missing values, or there are more than $(t-y)$ processes that have crashed; this is known from the invocation QUERY$_y(S_i)$. (Let us recall that, when $|S_i| \leq t - y$, QUERY$_y(S_i)$ answers always *true*).
- Then, the behavior of p_i depends on the number of values it knows. If there are too many crashes (line 4), p_i sets a local variable $prop_i$ to the value

[5] A wait-free implementation of an adopt–commit-abort object from single-writer multireader atomic registers can be found in [52]. An implementation in message-passing systems, where a majority of processes is correct, is presented in [43]. For completeness, an implementation of an adopt–commit-abort object is described in Appendix A.

```
Function k-set_agreement^{[d,y]}_{n,t} (v_i)

task T1:
(1)  V[i] ← v_i;
(2)  repeat V_i ← snapshot (V); S_i ← {j | V_i[j] = ⊥}
(3)                                  until QUERY_y (S_i) end repeat;
(4)  case (#_⊥(V_i) > t − y) then prop_i ← CONS; w_i ← ⊥
(5)       (#_⊥(V_i) ≤ t − y) then prop_i ← COND; w_i ← cond_algo(V_i)
(6)  end case;
(7)  W[i] ← w_i; (d_i, res_i) ← adopt_commit(prop_i); W_i ← snapshot(W);
(8)  case (res_i = CONS) ∨ (d_i = abort)
(9)                  then DEC[i] ← cond_algo(v_i); return (DEC[i])
(10)      (res_i = COND) ∧ (d_i = commit)
(11)                 then DEC[i] ← W_i[j] such that W_i[j] ≠ ⊥; return(DEC[i])
(12)      (res_i = COND) ∧ (d_i = adopt)
(13)                 then est_i ← W_i[j] such that W_i[j] ≠ ⊥;
(14)                      DEC[i] ← cond_algo(est_i); return(DEC[i])
(15) end case

task T2:
(16) j ← 0;
(17) repeat forever j ← (j mod n) + 1;
(18)                 if (DEC[j] ≠ ⊥) then return(DEC[j]) end if
(19) end repeat
```

FIG. 1. *A k-set agreement protocol with* $k = 1 + \max(0, d - y)$.

CONS to try to decide a value from the underlying consensus algorithm (let us remind that, when there are more than $(t - y)$ crashes, it is possible to solve consensus from ϕ_t^y). In the other case, p_i knows enough proposed values to decide from the condition (line 5); p_i computes, consequently, a value w_i that could be decided from the condition and sets $prop_i$ to *COND*.

- The process then uses the underlying adopt–commit-abort object (line 7) in order to try agreeing on the same tag, namely, *CONS* or *COND*. Moreover, each p_i deposits in the array $W[1..n]$ the value it has computed at line 4 or line 5 and reads that array with the snapshot() operation.
- The last part depends on the result returned by the adopt–commit-abort object.
  - If p_i obtains $d_i = abort$ or $res_i = CONS$, it concludes that no value can be decided from the condition. It consequently uses the consensus object to decide a value (lines 8–9).
  - If p_i obtains $res_i = COND$, at least one entry of W_i is not equal to $\perp$. Then, if, additionally, $d_i = commit$, p_i concludes that any value deposited in W can be decided from the condition, and it decides it (lines 10–11).
  - If p_i obtains $res_i = COND$ together with $d_i = adopt$, it does not know if the other processes p_j have obtained $d_j = commit$ or $d_j = abort$. So, to be consistent, p_i participates in the underlying consensus to which it proposes a value that could be decided from the condition (lines 12–14). It then decides the value returned by the consensus object.

The aim of task $T2$ is to guarantee that a correct process always decides as soon as a process decides. To that end, when a process p_j is about to decide in task

$T1$ (execution of the return(v) statement), it first writes v in $DEC[j]$.[6] Task $T2$ of a process p_i is then a simple loop statement that terminates when the predicate $(\exists j : DEC[j] \neq \perp)$ becomes true. The execution of the return() statement by a process p_i terminates its execution of k-set_agreement$^{[d,y]}_{n,t}$ (v_i).

Proof of correctness.

THEOREM 3. *When instantiated with a failure detector of the class ϕ^y_t and a condition C in $S^{[d]}_t$, the protocol described in Figure* 1 *solves the condition-based k-set agreement problem where $k = 1 + \max(0, d - y)$.*

Proof. Validity property (a decided value has been proposed by a process). Let us observe that a decided value dec_i is either an initial value v_j proposed to the consensus by a process p_j (line 9) or a value w_i obtained by a process p_i from the condition-set agreement object (lines 11 and 14). The validity property follows immediately from the corresponding validity property of the consensus object and the condition-set agreement object, and hence line 18 preserves validity.

Agreement property (at most k different values are decided). Let us observe that, due to the agreement property of the adopt–commit-abort object, it is not possible for two processes p_i and p_j that have invoked adopt_commit() at line 7 to be such that both the predicate $(res_i = CONS) \vee (d_i = abort)$ and the predicate $(res_j = COND) \wedge (d_j = commit)$ are true. It follows from that observation that it is not possible for a process p_i to execute line 9 while another process p_j executes line 11. So, there are only two cases to consider (in addition to the trivial case of line 18).

- No process begins executing line 9 or 14. In that case, these processes decide the value returned by the consensus object. Due to the consensus agreement property, there is a single such value.
- No process begins executing line 11 or 14. In that case, these processes decide a value returned from the condition-set agreement object . Due to the condition agreement property, there are at most $k = 1 + \max(0, d - y)$ such values, which proves the case.

Termination property. Let J be the input vector. We have to show that every correct process decides if (1) the condition C is d-satisfied for J, or (2.a) a process decides, or (2.b) fewer than k processes crash.

Let us notice that, as there are at most t process crashes (model assumption), the repeat loop of lines 2–3 always terminates. Moreover, let us also observe that, due to the termination property of the adopt–commit-abort object, any invocation of adopt_commit() issued by a correct process terminates (observation $O1$).

Let us also observe that the underlying consensus protocol is used only when the number of crashes is greater than $t - y$ (line 4), i.e., when a failure detector of the class $\mathcal{P}$ can be built from a failure detector of the class ϕ^y_t (item (3) of Theorem 8). The termination property of the consensus object ensures that all of the correct processes that invoke cons_alg() terminate their operation (observation $O2$). Let us now proceed by a case analysis.

- Case (1): We have to show that any correct process decides when the condition C is d-satisfied for J, where J is the input vector.
  In that case, it follows from item (1) of the termination property of the condition-set agreement object that any invocation cond_algo() issued by a

[6] This write plays the same role as the reliable broadcast of the decided value in message-passing systems (e.g., see the consensus protocols in [8, 23, 43, 51]). Their aim is to prevent a process from deadlocking.

correct process terminates. This, combined with the observations $O1$ and $O2$, allows us to conclude that any correct process terminates when C is d-satisfied for J.

- Case (2.a): We have to show that any correct process decides, as soon as a process decides.
  This property is trivially guaranteed by the management of the array $DEC[1..n]$ and task $T2$.
- Case (2.b): We have to show that any correct process decides when fewer than k processes crash.
  If no correct process accesses the condition-set agreement object, the fact that any correct process decides follows from the observations $O1$ and $O2$. So, let us consider the case where correct processes access the condition object. As $k = 1 + \max(0, d - y)$ and fewer than k processes crash, this means that at most $\max(0, d-y)$ processes crash. Moreover, as $t \geq d$, we have $t-y \geq d-y$. It follows (from the properties of the failure detector ϕ_t^y) that all of the processes p_i that execute the repeat loop (lines 2–3) and do not crash while executing that loop, eventually exit it, and we have then $\#_\perp(V_i) \leq t - y$. They consequently all of access the condition-set agreement object at line 5. It follows that all of the correct processes (there are more than $(n - k)$ of them) invoke the condition-set agreement object. Due to item (2.b) of the termination property of the condition-set agreement object, it follows that any correct process decides in the k-set agreement protocol. □

5.3. Implementation of a condition-set agreement object.

Description of the protocol. A t-fault tolerant protocol implementing a condition-set agreement object is described in Figure 2. This protocol is instantiated with a function h associated with a $(t - d)$-legal condition C. It uses a deterministic function $F()$ and a predicate $P()$. The function $F()$ takes a view J as a parameter and returns a non-$\perp$ value of the vector J. The value $\top$ is a default value not in $\mathcal{V}$ and different from $\perp$. It is assumed that the function h is extended to all views J of C, with at most $t - d$ entries equal to $\perp$ as in Definition 4. The predicate $P()$ is true on all such views:

$$P(V_i) \equiv \big(\exists I \in C \text{ such that } V_i \leq I\big).$$

Thus, $P()$ is used to test if p_i's current view V_i of the input vector could originate from a vector of the condition.[7]

The protocol can be seen as a case analysis. The first step is for p_i to check whether $\#_\perp(V_i) \leq t - d$ in order to benefit from the condition. If $\#_\perp(V_i) > t - d$, p_i cannot benefit from it and consequently decides a value from its local view V_i at line 18 (the processes executing that line decide at most $\max(0, d - y)$ different values).

Otherwise, we have $\#_\perp(V_i) \leq t - d$, and then p_i has enough non-$\perp$ entries in its view V_i to test if the condition can help it decide. So, p_i enters the lines 2–17. There are three cases. If $P(V_i)$ is satisfied (first case), p_i decides the value from the condition and writes it in the shared array D to help other processes decide (line 4).

If $P(V_i)$ is not satisfied (second case), p_i first checks if $\#_\perp(V_i) = t-d$. If so (second case), it knows that no other process will evaluate P to true in the previous line, and

[7] It is shown in [36] that, for some conditions, there are very efficient ways to compute the predicate $P()$. As an example, for the $(t - d)$-legal condition $C1$ (defined in section 4.2), we have $P(V_i) \equiv \#_{\max(J)}(V_i) > (t - d) - \#_\perp(V_i)$.

(10)                    repeat D_i ←snapshot (D) until ( (∃j : D_i[j] ≠ ⊥, ⊤) ∨ (#_⊥(D_i) < k) );
(11)                    if (∃j :  D_i[j] ≠ ⊥, ⊤) then return (D_i[j] such that D_i[j] ≠ ⊥, ⊤)
(12)                                          else  ∀j : if (D_i[j] = ⊤) then Y_i[j] ← V[j]
(13)                                                                     else  Y_i[j] ← ⊥ end_if;
(14)                                                 w_i ← F(Y_i); D[i] ← w_i; return (w_i)
(15)                    end_if
(16)                end_if
(17)         end_if
(18)   else w_i ← F(V_i); D[i] ← w_i; return (w_i) % Here (t − d) < (#_⊥(V_i) ≤ t − y) %
(19)        % The processes executing that line decide at most max(0, d − y)) values %
     end_if
```

FIG. 2. *A condition protocol.*

that any other process p_j, with $\#_\perp(V_j) = t - d$ has $V_i = V_j$, so it deterministically decides $F(V_i)$ (line 7).

In the third case, $\#_\perp(V_i) < t - d$, and p_i writes $\top$ in $D[i]$ to indicate it cannot decide from its local view V_i (so, $D[j] = \perp$ means that p_j has not yet finished executing its protocol or has crashed). Then, as it cannot decide by itself, p_i starts the "best effort termination" part of the protocol (lines 9–15). It enters a loop (line 10), during which it looks for a decided value ($\exists j : D_i[j] \neq \perp, \top$) and decides if there is one (line 11) or a configuration where $\#_\perp(D_i) < k$ (this is the only place where k is used in the protocol). If the condition $(\nexists j : D_i[j] \neq \perp, \top) \wedge (\#_\perp(D_i) < k)$ is satisfied, p_i builds a local view of the input vector corresponding to the processes that have executed at least until line 9. As we will see in the proof, if several such views (Y_i, Y_j, etc.) are computed, due to the invocations of snapshot(D) at line 10 that precede their construction, the associated containment property implies that these views (Y_i, Y_j, etc.) are also ordered by containment. The process p_i then decides the value $F(Y_i)$. Let us notice that, as $\#_\perp(D_i) < k$, the vector Y_i has at most $k - 1$ entries equal to $\perp$. It follows that at most k different values can be decided at line 14. Let α be the number of values decided at line 4, 7, 11, and 18, and let β be the number of values decided at lines 14. The proof will show that $\alpha + \beta \leq k$.

Correctness proof.

THEOREM 4. *When instantiated with a $(t - d)$-legal condition C, the protocol described in Figure* 2 *implements a condition-set agreement object with $k = 1 + \max(0, d - y)$.*

Proof. Validity property (a decided value is a value proposed in the input view of a process). This property follows directly from the fact that both the function $h()$ and the function $F()$ extract a non-$\perp$ value from the vector they are applied to.

Agreement property (at most $k = 1 + \max(0, d - y)$ different values are decided). The processes that decide, do it at line 4, 7, 11, 14, or 18. We determine the maxi-

mum number of values that are decided by the processes at each of these lines of the protocol.

- Consider the processes that decide at line 4.
  These processes p_i are such that $(\#_\perp(V_i) \leq t-d)$ and $P(V_i)$ is satisfied. We show that a single value can be decided at line 4.
  Let p_i and p_j be two processes that decide at line 4. Due to the use of a snapshot operation, we have either $V_i \leq V_j$ or $V_j \leq V_i$. Let us consider that $V_i \leq V_j$.
  We then have (1) $\#_\perp(V_i) \leq t-d$ and $\#_\perp(V_j) \leq t-d$, (2) both $P(V_i)$ and $P(V_j)$ are satisfied, i.e., $\exists I1 \in C$ such that $V_i \leq I1$ and $\exists I2 \in C$ such that $V_i \leq V_j \leq I2$, (3) and the condition is $(t-d)$-legal. It follows from these three items and Lemma 1 that $h(V_i) = h(V_j) = h(I_1) = h(I_2)$. Consequently, no more than one value can be decided by the processes executing line 4.
- Consider the processes that decide at line 7.
  These processes p_i are such that $(\#_\perp(V_i) = t-d)$ and $P(V_i)$ is not satisfied. In this case, at most one value is decided at line 7, because, due to the snapshot containment property, all processes that execute this line have exactly the same view V_i. Moreover, if a process executes this line, no process executes line 4. This is because any process p_j that executes line 4 has a view V_j such that $(\#_\perp(V_j) \leq t-d = \#_\perp(V_i))$, and as we have either $V_i < V_j$ or $V_j < V_i$, we conclude that $V_i < V_j$. Consequently, if p_i executes line 7, $P(V_i)$ is false, and hence $P(V_j)$ is also false as $V_i \leq V_j$, by definition of the predicate $P()$.
- Consider the processes that decide at line 18.
  These processes p_i are such that $(t-y \geq \#_\perp(V_i) > t-d)$. We show that these processes decide at most $\max(0, d-y)$ different values.
  Due to the containment property on the vectors provided by the snapshot operation, any pair of processes p_i and p_j that execute line 18 are such that $V_i \leq V_j$ (or $V_j \leq V_i$). We conclude from that observation that the processes that execute line 18 have at most $\max(0,(t-y)-(t-d))$=$\max(0,d-y)$ different vectors. As F is deterministic, at most $\max(0,d-y)$ different values can be decided by the processes that decide at line 18.
  It follows that, when we consider the processes that decide at line 4, 7, or 18, at most $k = 1+\max(0,t-d)$ different values can be decided.
- Consider the processes that decide at line 11.
  A process p_i that decides at line 11 decides a value (that it retrieves in $D[j]$) that has been decided by another process p_j (p_j has deposited that value in $D[j]$ at line 4, 7, 14, or 18). Consequently, no additional value can be decided at line 11.
- Finally, consider the processes that decide at line 14.
  Let β be the number of different values decided by the processes that execute line 14. Let α be the number of values decided by the processes that execute line 4, 7, or 18. We claim that $\alpha + \beta \leq k = 1+\max(0,t-d)$.

It follows from this case analysis that at most $k = 1+\max(0,t-d)$ different values can be decided, which proves the theorem.

Proof of the claim. Let us consider two time instants t_0 and t_1 defined as follows:
- t_0 = first time instant where $\#_\perp(D) = k-1$ (or $+\infty$ if it never happens),
- t_1 = first time instant where $\exists\ D[j] \notin \{\top, \perp\}$ (or $+\infty$ if it never happens).[8]

[8]If both t_0 and t_1 are equal to $+\infty$, no process decides, and the claim is trivially true.

Let us first consider $t_1 \leq t_0$. Let us notice that a process p_i stops the repeat loop of line 10 as soon as $(\exists\, D_i[j] \notin \{\top, \bot\} \ \vee\ \#_\bot(D_i) < k)$. As the test that (at line 11) immediately follows the exit of the repeat loop privileges the case $(\exists\, D_i[j] \notin \{\top, \bot\})$ with respect to the case $(\#_\bot(D_i) < k)$ when both are satisfied, it follows that p_i immediately executes the return () statement at line 11. Consequently, when $t_1 \leq t_0$, any process p_i that enters the loop of line 10 and then decides, decides at line 11. We then have $\beta = 0$ (no process decides at line 14).

Let us now consider the case $t_0 < t_1$. Let us first observe that, since the function $F()$ is deterministic and each Y_i computed at lines 12–13 contains at most $(k-1)$ entries equal to $\bot$, it follows that the β values decided at line 14 correspond to (at least) β different Y_i vectors, which means (due to line 12) at least β different D_i vectors.

Due to the containment property of the invocations of the snapshot (D) invocations at line 10, the previous β D_i vectors are totally ordered (see the definition of "$<$" in section 4.1), e.g., $D_{i1} < D_{i2} < \cdots < D_{i\beta} < \cdots$ and contain only $\bot$ and $\top$ entries. Moreover, for any pair of such vectors, there is at least one entry which is equal to $\bot$ in one vector and to $\top$ in the other. As D is initialized to $[\bot, \ldots, \bot]$ and there are at least β different D_{ix}, we conclude that at least $(\beta - 1)$ values $\top$ have been written into D after t_0 (because, due to the snapshot (D) operations, we have $\#_\bot(D_{i1}) \leq k-1$ at time t_0, $\#_\bot(D_{i2}) \leq k-2$ at time t'_0, $t'_0 > t_0$, etc.).

Before being decided, the α different values decided at lines 4, 7, and 18 have been written into the array D (they are decided after t_1). Due to the definition of t_1, they have been written into D at or after t_1, i.e. (from the case assumption), after t_0.

Hence, after t_0, α entries of D have been set to proposed values by lines 4, 7, and 18, and $(\beta - 1)$ entries have been set to $\top$. As, at t_0, the number of entries of D that were equal to $\bot$ was equal to $(k-1)$, it follows that $\alpha + (\beta - 1) \leq (k-1)$, i.e., $\alpha + \beta \leq k$, which proves the claim when $t_0 < t_1$. *End of the proof of the claim.*

Termination property (let J be the actual input vector). Every correct process decides if (1) $J \in \mathcal{C}_t$ or $\#_\bot(J) \geq t - d$ -C is d-satisfied for J-, or (2.a) a process decides, or (2.b) more than $(n-k)$ correct processes invoke cond_algo().

If the input vector V_i, $V_i \leq J$, is such that $\#_\bot(V_i) > t - d$, the process p_i trivially decides at line 18. When $\#_\bot(V_i) = t - d$, the test on line 5 leads to termination. On another side, if $\#_\bot(V_i) \leq t - d$ and $J \in \mathcal{C}_t$, then $P(V_i)$ is satisfied, and p_i decides at line 4. So, the case (1) is done.

Let us consider case (2.a). Before deciding a value at line 4, 7, 14, or 18, a process deposits that value in the array D. It follows that, after a process has decided, the repeat loop of line 10 always terminates, and any process that executes line 11 decides, which proves the case.

Let us finally consider case (2.b). Let us assume that more than $(n-k)$ correct processes invoke the object and no one decides. This means that none of them executes line 4, 7, or 18. They all, consequently, enter the repeat loop at line 10, from which we conclude that eventually the predicate $\#_\bot(D_i) < k$ becomes true. It follows that the correct processes exit the repeat loop and decide. □

6. Discussion.

6.1. Initial crashes: No condition is needed. The theorem that follows considers a particular case, namely, the case where the faulty processes crash before the protocol starts its execution.

THEOREM 5. *Consider an execution of the protocol described in Figure* 1 *instantiated with a failure detector of the class* ϕ_t^y. *Let us assume that more than* $(t - y)$

processes have crashed before the protocol starts. The protocol then solves the consensus problem (whatever the $(t-d)$-legal condition it is instantiated with).

Proof. If more than $(t-y)$ processes have initially crashed, due to the property of the QUERY$_y$ () invocations at line 3, we have $(\#_\perp(V_i) > t-y)$ for any process p_i. It follows that, for any process p_i, we have $prop_i = CONS$ (line 4). Due to the obligation property of the adopt–commit-abort object, every process p_i obtains $(commit, CONS)$. Consequently, all of the processes invoke the underlying consensus object, which proves the theorem. □

Remark 1. The previous theorem considers the case where the faulty processes have crashed before the protocol starts. It is interesting to observe that a similar result appears in [16], where a consensus protocol is presented for asynchronous systems where a majority of processes are correct, and the faulty processes crash before the protocol starts its execution.

6.2. An always terminating version of the protocol. It is possible to trade safety for liveness by providing a version of the protocol where every correct process always decides. This can be obtained at the price of an enlarged set of possibly decided values. More precisely, let I be an input vector, and let C be the $(t-d)$-legal condition the protocol is instantiated with. When $I \in C$, at most $k = 1 + \max(0, d-y)$ values are decided; when $I \notin C$, up to $k' = t+1-y$ values can be decided. Interestingly, this always terminating version of the protocol provides a new insight into the way the parameters t, y (power of the failure detection) and d (power of the condition) are related.

In the protocol described in Figure 2, the statement that can prevent a correct process p_i from terminating is the repeat loop at line 10. This occurs when p_i enters lines 9–15, V_i being such that $\#_\perp(V_i) \leq \min(t-y, t-d)$ (assumption on the input parameter and line 1), while $P(V_i)$ is equal to *false* (line 2). The modification to get an always terminating cond_algo() protocol is very simple: It consists in replacing the lines 9–15 in Figure 2 by a weakened statement that always terminates, namely,

```
[9-15]'   if (∃j : D[j] ≠ ⊥) then return (D[j] such that D[j] ≠ ⊥)
                              else w_i ← F(V_i); D[i] ← w_i; return (w_i)
          end if
```

THEOREM 6. *Let us consider the protocol depicted in Figure* 2 *instantiated with a $(t-d)$-legal condition C, where lines* 9–15 *are replaced by the statement* [9–15]'. *Every correct process decides. Let I be an input vector. If $I \in C$, at most $k = 1+\max(0, d-y)$ values are decided. If $I \notin C$, at most $k' = t+1-y$ values can be decided.*

Proof. Every correct process trivially terminates, and a decided value comes from a proposed vector (same proof as in Theorem 4).

As far as the number of values that are decided is concerned, let us first consider the case where the input vector belongs to the condition. In that case, when a process p_i executes line 2, $P(V_i)$ is trivially satisfied. It follows that the new line [9-15]' is never executed. Consequently, Theorem 4 remains valid when $I \in C$, and at most $k = 1 + \max(0, d-y)$ values are then decided.

Considering now the case where the input vector does not belong to the condition, let us first observe that if a process p_i decides at line [9-15]' a value $D[j]$ such that $D[j] \neq \perp$, it does not decide a new value as $D[j]$ is counted as a decided value at line 4, 7, 18 or in the **else** part of the new **if** statement. So, let us count the number of values that can be decided by the processes executing line 4 or the **else** part of the new line [9-15]'. For each such process p_i, we have $\#_\perp(V_i) \leq t - \max(y, d+1)$. Moreover (due to the containment property on the vectors V_i provided by the cond_algo() invocations), we have $V_i \leq V_j$ (or $V_j \leq V_i$) for two processes executing line 4 or the **else** part of

line [9-15]'. It then follows that there are at most $k1 = t - \max(y, d+1) + 1$ different vectors V_i for the processes that execute line 4 or the **else** part of line [9-15]'. Let us observe that if a process p_j decides at line 4, the same vector V_j will not be used to decide another value at line [9-15]'. Finally, due to that observation and the fact that $F()$ is deterministic, at most $k1$ different values can be decided by the processes executing line 4 or the **else** part of line [9-15]'. On the other side, the processes that execute line 18 decide at most $k2 = \max(0, d-y)$ different values (the proof is the same as the corresponding proof in Theorem 4). Recall that all of the processes that execute line 7 decide the same value. Finally, summing up, we get $k' = k1 + k2 + 1$, i.e., $k' = (t - \max(y, d+1) + 1) + (\max(0, d-y) + 1)$, which can be simplified to provide $k' = t + 1 - y$. □

Let us notice that when the input vector does not belong to the condition, the maximal number of values that can be decided, namely, $k' = t + 1 - y$, does not depend on d. If the information on failure is maximal ($y = t$), the protocol solves consensus. At the other extreme, if there is no information on failures ($y = 0$) and there is no power provided by the condition, the protocol solves the trivial version of the set agreement problem, namely, $k' = t + 1$.

7. A lower bound. This section presents a lower bound matching Theorem 3.

THEOREM 7. *When instantiated with a failure detector of the class ϕ_t^y and a $(t-d)$-legal condition, no protocol solves the condition-based k-set agreement problem for $k \leq \max(0, d-y)$.*

Proof. Assume for contradiction that a protocol solves the k-set agreement problem for $k \leq \max(0, d-y)$. Hence, $d > y$ and $\max(0, d-y) = d - y$. Partition the processes in two groups: the *main* processes $p_1, \ldots, p_{n-t+d}$ and the *secondary* processes, $p_{n-t+d+1}, \ldots, p_n$. Consider the executions where the secondary processes crash before taking any steps. These are executions with at least $t - d$ failures. By Definition 5, all correct process must decide whatever the input vector. Now, consider the subset of these executions with at most $d-y$ additional failures. The total number of failures is at most $t - y$ failures. Recall that any relevant query is invoked with a set the size of which is greater than $(t - y)$. So, all relevant invocations QUERY$_y()$ issued by the main processes will include at least one correct process and thus will return *false*, and all other invocations return the trivial output. Thus, in these executions, the failure detector gives no information, and therefore the main processes have to solve the standard set agreement problem (i.e., terminate for every input vector), tolerating $d-y$ failures. The results of [6, 28, 29, 50] (more specifically, Corollary 5.5 in [28]) imply that, in one of these executions, at least $d - y + 1$ different values are decided, a contradiction. □

The following corollaries are direct consequences of the previous theorem. They consider the extreme cases where there is either no failure detector (i.e., $y = 0$) or no condition (i.e., $d = t$). The first corollary answers an open problem stated in [3, 39]. The second corollary shows the optimality[9] of ϕ_t^y.

COROLLARY 1. *Let C be a $(t-d)$-legal condition. There is no condition-based k-set agreement protocol for C when $k \leq d$.*

COROLLARY 2. *When considering the family $(\phi_t^y)_{0 \leq y \leq t}$ of failure detector classes, ϕ_t^y, with $y = t-k+1$, is the weakest that allows solving the k-set agreement problem.*

[9] This result complements another k-set agreement minimality result [27], which shows that, among the family $(\mathcal{S}_x)_{1 \leq x \leq t+1}$ of perpetual failure detectors (introduced in [44, 52]), $\mathcal{S}_x$ is the weakest to solve the k-set agreement problem for $k > t - x + 1$.

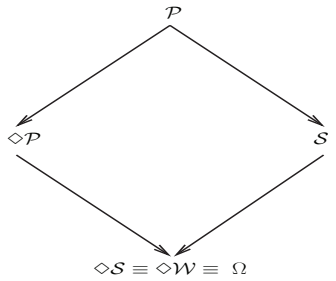

FIG. 3. *Relations among Chandra–Toueg's failure detector classes.*

8. Comparing ϕ_t^y with Chandra and Toueg's failure detector classes.

8.1. Chandra and Toueg's failure detector classes. This section presents the failure detectors introduced by Chandra and Toueg, used in this paper. These classes are defined from the following completeness and accuracy properties [8]:
- *Strong (Weak) completeness.* Eventually, every process that crashes is permanently suspected by every (some) correct process.
- *Perpetual strong accuracy.* No process is suspected before it crashes.
- *Eventual strong accuracy.* There is a time after which no correct process is suspected.
- *Perpetual weak accuracy.* Some correct process is never suspected.
- *Eventual weak accuracy.* There is a time after which some correct process is never suspected.

The classes we are interested in are the following [8]. They are collectively called "Chandra and Toueg's failure detector classes" in the rest of the paper.

- $\mathcal{P}$: The class of *perfect* failure detectors. It includes all of the failure detectors satisfying strong completeness and perpetual strong accuracy.
- $\mathcal{S}$: The class of *strong* failure detectors. It includes all of the failure detectors satisfying strong completeness and perpetual weak accuracy. We have $\mathcal{P} \subseteq \mathcal{S}$.
- $\diamond\mathcal{P}$: The class of *eventually perfect* failure detectors. It includes all of the failure detectors satisfying strong completeness and eventual strong accuracy. We have $\mathcal{P} \subseteq \diamond\mathcal{P}$.
- $\diamond\mathcal{S}$: The class of *eventually strong* failure detectors. It includes all of the failure detectors satisfying strong completeness and eventual weak accuracy. We have $\diamond\mathcal{P} \subseteq \diamond\mathcal{S}$, and $\mathcal{S} \subseteq \diamond\mathcal{S}$.

The class $\diamond\mathcal{S}$ is the weakest that allows solving the consensus problem and is equivalent to the class $\diamond\mathcal{W}$ in shared memory systems and in message-passing systems with reliable channels [8, 7]. It has also been shown that $\diamond\mathcal{S}$ and the class of *leader* failure detectors, denoted Ω, are equivalent in systems where each process initially knows all of the process identities [7, 11, 41].

Figure 3 summarizes Chandra and Toueg's failure detector classes. Following Definition 1, an arrow from A to B means that $A \geq B$ (any failure detector of the class A can be used to build a failure detector of the class B). The absence of a path from A to B means that it is not the case $A \geq B$ (given any failure detector of the class A, it is not possible to build a failure detector of the class B). Finally, $A \equiv B$ if $A \leq B$ and $B \leq A$. The figure follows from [7, 8].

8.2. ϕ_t^y with respect to Chandra and Toueg's failure detector classes. This section studies the relation between ϕ_t^y and the classic failure detectors introduced by Chandra and Toueg. We show that ϕ_t^t allows building a perfect failure

init: $suspected_i \leftarrow \emptyset$

repeat forever for all j **such that** $p_j \in (\{p_1, \ldots, p_n\} \setminus suspected_i)$ **do**
  if QUERY$_t(\{p_j\})$ **then** $suspected_i \leftarrow suspected_i \cup \{p_j\}$ **end if**
end repeat

FIG. 4. *From ϕ_t^t to $\mathcal{P}$ (algorithm for p_i).*

detector, namely, $\mathcal{P} \leq \phi_t^t$ (Theorem 8). Therefore, $\mathcal{P}$ is equivalent to ϕ_t^t as $\phi_t^t \leq \mathcal{P}$ (from their definitions).

THEOREM 8. (1) $\mathcal{P} \equiv \phi_t^t$. *Let f denote the actual number of process crashes in a run.* (2) *If $f \leq t-y$, ϕ_t^y, $0 \leq y \leq t-1$ does not allow building a failure detector of any of Chandra and Toueg's failure detector classes (e.g., $\diamond\mathcal{S}, \diamond\mathcal{P}, \Omega$).* (3) *If $f > t-y$, ϕ_t^y, $0 \leq y \leq t-1$ allows building a failure detector of the class $\mathcal{P}$.*

Proof. Let us first consider item (1). The construction described in Figure 4 constructs a perfect failure detector from a failure detector of the class ϕ_t^t. This construction works as follows. A process that queries the perfect failure detector obtains the current value of the set $suspected_i$. As $y = t$, QUERY$_t(S)$—where S is made up of a single process p—eventually returns *true* if and only if p has crashed. The strong completeness and strong accuracy properties defining the class $\mathcal{P}$ follow. Moreover, $\phi_t^t \leq \mathcal{P}$ follows directly from their definitions. Therefore, $\mathcal{P}$ is equivalent to ϕ_t^t.

For proving item (2), let us first observe that, an implementation that systematically suspects all of the processes trivially satisfies the completeness property of any of Chandra and Toueg's failure detector classes but prevents its accuracy property from being satisfied. So, assuming that ϕ_t^y $(0 \leq y \leq t-1)$ allows implementing the accuracy property of any of Chandra and Toueg's failure detector classes, we show that it does not allow implementing the associated (weak or strong) completeness property.

Let us consider any run during which no more than $x = t-y$ $(1 \leq x \leq t)$ processes crash. Due to the definition of ϕ_t^y, we have the following:

- Any QUERY$_t(S)$, where $|S| \leq t-y = x$ always returns *true* whatever the x (≥ 1) processes composing S. This follows from the triviality property of ϕ_t^y, $|S| \leq t-y = x$.
- Any QUERY$_t(S)$, where $|S| > x$ always returns *false* whatever the processes composing S. This follows from the safety property of ϕ_t^y, as at least one process among these processes has not crashed.

These observations show that, when no more than $x = t-y$ $(1 \leq x \leq t)$ processes crash, the boolean value returned by a query depends only on the number of processes defining S (it depends neither on which processes are in S, nor on the failure pattern). It follows that, when no more than $x = t-y$ $(1 \leq x \leq t)$ processes crash, there is no way for a process to know if a given process has crashed or not, thereby making impossible to implement the (weak or strong) completeness property of any of Chandra and Toueg's failure detector classes.

The proof of item (3) consists in designing an algorithm that, in runs where $f > t-y$, builds a failure detector of the class $\mathcal{P}$ from a failure detector of the class ϕ_t^y. Let us first observe that, as $f > t-y$, there is a set S such as $|S| = t-y+1$, and, after some finite time, QUERY$_y(S)$ returns *true* forever. The algorithm is the following.

- Each set $suspected_i$ is initialized to $\emptyset$. Initially, each process p_i issues QUERY$_y$ (X) for all of the possible sets X of size $|X| = t-y+1$ until such a query

```
when QUERY_y (S) is invoked by p_i:
    case (|S| ≤ t − y)        then return (true)
         (|S| > t)            then return (false)
         (t − y < |S| ≤ t)    then return (S ⊆ suspected_i)
    end case
```

FIG. 5. *From $\mathcal{P}$ to ϕ_t^y (algorithm for p_i).*

returns *true*. Due to the fact that all of the queries are relevant ($t-y < |X| \leq t$), and the previous observation, this eventually happens. When it occurs, p_i considers the corresponding set (say S) and executes $suspected_i \leftarrow S$.

- Then, for each $p_j \notin suspected_i$, p_i regularly executes $\text{QUERY}_y(S \cup \{p_j\})$. If the query returns *true*, p_i can conclude from the property of ϕ_t^y that p_j has crashed. It consequently adds p_j to $suspected_i$. Otherwise, p_i keeps on issuing $\text{QUERY}_y(S \cup \{p_j\})$.

It follows from the definition of S and the safety and liveness properties of ϕ_t^y that the sets $suspected_i$ of the correct processes eventually include all of the crashed processes and never includes a "not yet" crashed process, i.e., they satisfy the properties that define the class $\mathcal{P}$ of perfect failure detectors [8]. □

8.3. From Chandra and Toueg's failure detectors to ϕ_t^y. Figure 5 presents a simple protocol transforming any failure detector of the class $\mathcal{P}$ into a failure detector of the class ϕ_t^y. The underlying set $suspected_i$ satisfies (by assumption) the properties defining the class $\mathcal{P}$. In contrast, we show that there is no protocol transforming any failure detector of the class ϕ_t^y, for $y < t$, into a failure detector of the class $\mathcal{P}$.

THEOREM 9. *The protocol of Figure* 5 *transforms any failure detector of the class $\mathcal{P}$ into a failure detector of the class ϕ_t^y for $0 \leq y \leq t$.*

Proof. The triviality property of ϕ_t^y is ensured by the first two case statements. The safety property follows from the fact that, due to the perpetual strong accuracy of the underlying failure detector, $suspected_i$ contains only crashed processes. Finally, the liveness property of ϕ_t^y follows from the fact that, due to the completeness of the underlying failure detector, the set $suspected_i$ eventually contains all crashed processes. □

The next theorem states that there is no protocol transforming a failure detector of the class $\mathcal{S}$, $\diamond\mathcal{P}$, $\diamond\mathcal{S}$, or $\diamond\mathcal{W}$ into a failure detector of the class ϕ_t^y for $0 < y$. It is surprising that these failure detectors are not strong enough to implement ϕ_t^y, even when $y < t$, as in this case ϕ_t^y cannot solve consensus (Corollary 2), while these failure detectors can solve consensus. (In the case of $y = t$, both ϕ_t^t and those failure detectors can solve consensus.)

THEOREM 10. *For $1 \leq y \leq t$, $\phi_t^y \not\leq \mathcal{S}$, $\phi_t^y \not\leq \diamond\mathcal{P}$, $\phi_t^y \not\leq \diamond\mathcal{S}$, and $\phi_t^y \not\leq \diamond\mathcal{W}$.*

Proof. The impossibility comes from the fact that nothing prevents the sets $suspected_i$ from containing correct processes for an unbounded amount of time. As $\diamond\mathcal{S} < \diamond\mathcal{P}$ and $\diamond\mathcal{W} < \diamond\mathcal{P}$, it is sufficient to prove it for $\diamond\mathcal{P}$, as far as $\diamond\mathcal{S}$, $\diamond\mathcal{W}$, and $\diamond\mathcal{P}$ are concerned. The proof for $\mathcal{S}$ is verbatim the same as the one for $\diamond\mathcal{P}$ (replacing only $\diamond\mathcal{P}$ by $\mathcal{S}$).

The proof consists in assuming (for contradiction) that there is a protocol transforming a failure detector of the class $\diamond\mathcal{P}$ into a failure detector of the class ϕ_t^y. Let us consider a run where an infinite sequence of relevant queries is issued, all of the form $\text{QUERY}_y(S)$, for the same S, $t - y < |S| \leq t$, and suppose that all processes in S are initially crashed. The answers returned by the protocol define then a sequence consisting of a finite prefix of *false* answers followed by an infinite suffix of *true* an-

swers (by the safety and liveness property of ϕ_t^y). Let τ be a time instant after which all of the invocations of QUERY$_y(S)$ return *true*.

However, it could be that no process ever crashes, and no process in S takes a step until after $\tau + \delta$ (where $\delta > 0$ is an arbitrary finite period), with $\diamond\mathcal{P}$ suspecting each process exactly as in the previous fault-prone run from the very beginning until $\tau + \delta$.

As $\diamond\mathcal{P}$ provides each process with the same outputs in both runs until time $\tau + \delta$, it follows that the queries QUERY$_y(S)$ issued between τ and $\tau + \delta$ returns *true* in both runs. This contradicts the safety property of ϕ_t^y in the failure-free run. □

9. Conclusion. This paper focused on the combination of two approaches to solve the *k-set agreement* problem, namely, failure detectors and conditions. It has proposed novel failure detectors for solving the k-set agreement problem, that, when combined with a condition, establish a new bridge among asynchronous, synchronous, and partially synchronous systems with respect to agreement problems.

The paper has presented three main contributions. The first is the new class of failure detectors denoted ϕ_t^y, $0 \leq y \leq t$. The processes can invoke a primitive QUERY$_y(S)$ with any set S of process identities. Roughly speaking, QUERY$_y(S)$ returns *true* only when all processes in S have crashed, provided $t - y < |S| \leq t$. These failure detectors seem interesting in their own right. They have been thoroughly investigated and compared to the classical failure detectors introduced by Chandra and Toueg.

The second contribution of the paper is a condition-based protocol that solves the k-set agreement problem, with $k = 1 + \max(0, t - (x + y))$, for a condition C of power x and a failure detector of power y, with termination guaranteed for inputs in C. By "power" we mean the following: C is *x-legal* if and only if it can be used to solve x-fault tolerant asynchronous consensus and the failure detector is in the class ϕ_t^y, $0 \leq y \leq t$. Several noteworthy properties and variants of this protocol (that provides a new way to solve asynchronous set agreement and, in particular, consensus) have been studied.

The third contribution is a corresponding lower bound, showing that there is no ϕ_t^y-based k-set agreement protocol for $(t - d)$-legal conditions with $k \leq \max(0, d - y)$. It follows from this lower bound that there is no condition-based k-set agreement protocol such that $k \leq d$ for any $(t - d)$-legal condition.

Appendix A. An adopt–commit-abort object implementation.

As announced in the paper, this appendix describes an implementation of an adopt–commit-abort protocol. The implementation described in Figure 6 is a merge of the one described in [52] (designed for an asynchronous shared memory system) and the one described in [43] designed for an asynchronous message-passing system). It uses two arrays of one-writer multireader atomic registers denoted $PHASE1[1..n]$ and $PHASE2[1..n]$, both initialized to $[\perp, \ldots, \perp]$. Then, an entry of such an array contains a pair or remains equal to $\perp$.

The behavior of a process p_i can be decomposed into three phases.

- Phase 1 (lines 1–2). A process p_i first deposits its input value v_i in $PHASE1[i]$ to make public the fact that v_i has been proposed to the adopt–commit-abort object. Then, it reads (asynchronously) the whole array $PHASE1[1..n]$ to know if other values have been proposed. The local set $set1_i$ is used to keep these values.
- Phase 2 (lines 3–6). During the second phase, if (from its point of view) no value different from its value v_i has been proposed, p_i sets $PHASE2[i]$ to the pair $(single, v_i)$, otherwise it sets $PHASE2[i]$ to the pair $(several, v_i)$. Then, p_i determines how many pairs (x, v) have been deposited in $PHASE2[1..n]$.

Function adopt_commit (v_i)

(1) $PHASE1[i] \leftarrow v_i$;
(2) $set1_i \leftarrow \{v \mid PHASE1[j] = v \ \wedge \ v \neq \perp \ \wedge \ 1 \leq j \leq n\}$;
(3) **if** $(set1_i = \{v_i\})$ **then** $PHASE2[i] \leftarrow (single, \ v_i)$
(4) **else** $PHASE2[i] \leftarrow (several, v_i)$
(5) **end if**;
(6) $set2_i \leftarrow \{(x, v) \mid PHASE2[j] \neq \perp \ \wedge \ PHASE2[j] = (x, v) \ \wedge \ 1 \leq j \leq n\}$;
(7) **case** $set2_i = \{(single, v)\}$ **then return** $(commit, v)$
(8) $set2_i = \{(single, v), (several, v'), \dots\}$ **then return** $(adopt, \ v)$
(9) $(single, v) \notin set2_i$ **then return** $(abort, \ v_i)$
(10) **end case**.

FIG. 6. *A shared memory adopt-commit protocol.*

(Let us recall that we have $PHASE2[k] = \perp$ until p_k deposits a pair in $PHASE2[k]$.) These non-$\perp$ values (pairs) are collected in the set $set2_i$.

- Phase 3 (lines 7–10). Finally, p_i computes the final value it will return as the result of its invocation.
  - If $set2_i$ contains only the pair $(single, v)$, p_i returns $(commit, v)$: it "commits" the value v.
  - If $set2_i$ contains several pairs and one of them is $(single, v)$, then p_i "adopts" that value v by returning $(adopt, v)$.
  - Finally, when $set2_i$ does not contain $(single, v)$, p_i has seen no value to be adopted or committed. It consequently "aborts," returning the value v_i it has initially proposed.

The proof of the termination, validity, and obligation properties of the adopt–commit-abort object are trivial. A proof of the agreement property for the shared memory model can be found in [52]. A proof for a message-passing model can be found in [43] (that proof assumes a majority of correct processes). That proof consists in showing that, for any pair of processes p_i and p_j that execute line 6, we have $set2_i = \{(single, v)\} \Rightarrow (single, v) \in set2_j$ (i.e., line 7 and line 9 are "mutually exclusive").

Acknowledgments, We would like to thank Rachid Guerraoui for interesting questions during PODC 2005 that helped us refine our approach, and Matthieu Roy and Xavier Defago for discussions on the set agreement problem and the implementation of failure detectors. Finally, we want to thank the anonymous referees for their very careful reading and valuable comments.

THE PRICE OF STABILITY FOR NETWORK DESIGN WITH FAIR COST ALLOCATION*

ELLIOT ANSHELEVICH†, ANIRBAN DASGUPTA‡, JON KLEINBERG‡, ÉVA TARDOS‡, TOM WEXLER‡, AND TIM ROUGHGARDEN§

Abstract. Network design is a fundamental problem for which it is important to understand the effects of strategic behavior. Given a collection of self-interested agents who want to form a network connecting certain endpoints, the set of *stable* solutions—the Nash equilibria—may look quite different from the centrally enforced optimum. We study the quality of the *best* Nash equilibrium, and refer to the ratio of its cost to the optimum network cost as the *price of stability*. The best Nash equilibrium solution has a natural meaning of stability in this context—it is the optimal solution that can be proposed from which no user will defect. We consider the price of stability for network design with respect to one of the most widely studied protocols for network cost allocation, in which the cost of each edge is divided equally between users whose connections make use of it; this fair-division scheme can be derived from the Shapley value and has a number of basic economic motivations. We show that the price of stability for network design with respect to this fair cost allocation is $O(\log k)$, where k is the number of users, and that a good Nash equilibrium can be achieved via *best-response dynamics* in which users iteratively defect from a starting solution. This establishes that the fair cost allocation protocol is in fact a useful mechanism for inducing strategic behavior to form near-optimal equilibria. We discuss connections to the class of *potential games* defined by Monderer and Shapley, and extend our results to cases in which users are seeking to balance network design costs with latencies in the constructed network, with stronger results when the network has only delays and no construction costs. We also present bounds on the convergence time of best-response dynamics, and discuss extensions to a weighted game.

Key words. network design, price of stability, Shapley cost-sharing

1. Introduction.

In many network settings, the system behavior arises from the actions of a large number of independent agents, each motivated by self-interest and optimizing an individual objective function. As a result, the global performance of the system may not be as good as in a case where a central authority can simply dictate a solution; rather, we need to understand the quality of solutions that are consistent with self-interested behavior. Recent theoretical work has framed this type of question in the following general form: How much worse is the solution quality of a Nash

equilibrium,[1] compared to the quality of a centrally enforced optimum? Questions of this genre have received considerable attention in recent years, for problems including routing [37, 39, 13], load balancing [14, 15, 27, 38], and facility location [41]; see [34, Chapters 17–21] for an overview of this literature.

An important issue to explore in this area is the middle ground between centrally enforced solutions and completely unregulated anarchy. In most networking applications, it is not the case that agents are completely unrestricted; rather, they interact with an underlying protocol that essentially proposes a collective solution to all participants, each of which can either accept it or defect from it. As a result, it is in the interest of the protocol designer to seek the *best* Nash equilibrium; this can naturally be viewed as the optimum subject to the constraint that the solution is *stable*, with no agent having an incentive to unilaterally defect from it once it is offered. Hence, one can view the ratio of the solution quality at the best Nash equilibrium relative to the global optimum as a *price of stability*, since it captures the problem of optimization subject to this constraint. Some recent work [3, 13] has considered this definition (termed the "optimistic price of anarchy" in [3]); it stands in contrast to the larger line of work in algorithmic game theory on the *price of anarchy* [35]—the ratio of the *worst* Nash equilibrium to the optimum—which is more suited to worst-case analysis of situations with essentially no protocol mediating interactions among the agents. Indeed, one can view the activity of a protocol designer seeking a good Nash equilibrium as being aligned with the general goals of mechanism design [33]—producing a game that yields good outcomes when players act in their own self-interest.

Network design games. Network design is a natural area in which to explore the price of stability, given the large body of work in the networking literature on methods for sharing the cost of a designed network—often a virtual overlay, multicast tree, or other subnetwork of the Internet—among a collection of participants. (See, e.g. [19, 22] for overviews of work in this area.)

A cost-sharing mechanism can be viewed as the underlying protocol that determines how much a network serving several participants will cost to each of them. Specifically, say that each user i has a pair of nodes (s_i, t_i) that it wishes to connect; it chooses an s_i-t_i path S_i, and the cost-sharing mechanism then charges user i a cost of $C_i(S_1, \ldots, S_k)$. (Note that this cost can depend on the choices of the other users as well.) Although there are in principle many possible cost-sharing mechanisms, research in this area has converged on a few mechanisms with good theoretical and empirical behavior; here we focus on the following particularly natural one: the cost of each edge is shared equally by the set of all users whose paths contain it, so that

$$C_i(S_1, S_2, \ldots, S_k) = \sum_{e \in S_i} \frac{c_e}{|\{j : e \in S_j\}|}.$$

This equal-division mechanism has a number of basic economic motivations; it can be derived from the Shapley value [32], and it can be shown to be the unique cost-sharing scheme satisfying a number of different sets of axioms [19, 22, 32]. For the former reason, we will refer to it as the *Shapley cost-sharing mechanism*. Note that the total edge cost of the designed network is equal to the sum of the costs in the union of all S_i, and the costs allocated to users in the Shapley mechanism completely pay for this total edge cost: $\sum_{i=1}^{k} C_i(S_1, S_2, \ldots, S_k) = \sum_{e \in \cup_i S_i} c_e$.

[1] Recall that a Nash equilibrium is a state of the system in which no agent has an interest in unilaterally changing its own behavior.

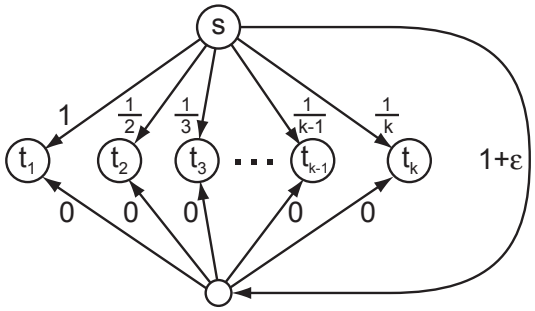

FIG. 1.1. *An instance in which the price of stability converges to* $H(k) = \Theta(\log k)$ *as* $\varepsilon \to 0$.

Now, the general question is to determine how this basic cost-sharing mechanism serves to influence the strategic behavior of the users, and what effect this has on the structure and overall cost of the network one obtains. Given a solution to the network design problem consisting of a vector of paths $(S_1, \ldots, S_k)$ for the k users, user i would be interested in deviating from this solution if there were an alternate s_i-t_i path S_i' such that changing to S_i' would lower its cost under the resulting allocation: $C_i(S_1, \ldots, S_{i-1}, S_i', S_{i+1}, \ldots, S_k) < C_i(S_1, \ldots, S_{i-1}, S_i, S_{i+1}, \ldots, S_k)$. We say that a set of paths is a *Nash equilibrium* if no user has an interest in deviating. As we will see below, there exists a set of paths in Nash equilibrium for every instance of this network design game. (In this paper, we will be concerned only with *pure* Nash equilibria, i.e., with equilibria where each user deterministically chooses a single path.)

The goal of a network design protocol is to suggest for each user i a path S_i so that the resulting set of paths is in Nash equilibrium and its total cost exceeds that of an optimal set of paths by as small a factor as possible; this factor is the *price of stability* of the instance. It is useful at this point to consider a simple example that illustrates how the price of stability can grow to a super-constant value (with k). Suppose k players wish to connect from the common source s to their respective terminals t_i, and assume player i has its own path of cost $1/i$, and all players can share a common path of cost $1 + \varepsilon$ for some small $\varepsilon > 0$ (see Figure 1.1). The optimal solution would connect all agents through the common path for a total cost of $1 + \varepsilon$. However, if this solution were offered to the users, they would defect from it one by one to their alternative paths. The unique Nash equilibrium has a cost of $\sum_{i=1}^{k} 1/i = H(k)$.

While the price of stability in this instance grows with k, it only does so logarithmically. It is thus natural to ask how large the price of stability can be for this network design problem. If we think about the example in Figure 1.1 further, it is also interesting to note that a Nash equilibrium is reached by players taking turns updating their paths (in other words, best-response dynamics) starting from an optimal solution; it is natural to ask to what extent this holds in general.

Our results. Our first main result is that in every instance of the network design problem with Shapley cost-sharing, there always exists a Nash equilibrium of total cost at most $H(k)$ times optimal. In other words, the simple example in Figure 1.1 is in fact the worst possible case.

We prove this result using a *potential function* method due to Rosenthal [36] (based on [6]) and later generalized by Monderer and Shapley [30]: One defines a potential function Φ on possible solutions and shows that every improving move of one of the users (to lower its own cost) reduces the value of Φ. Since the set of possible solutions is finite, it follows that every sequence of improving moves leads to a Nash

equilibrium. The goal of Monderer's and Shapley's and Rosenthal's work was to prove existence statements of this sort; for our purposes, we make further use of the potential function to prove a bound on the price of stability. Specifically, we give bounds relating the value of the potential for a given solution to the overall cost of that solution; if we then iterate using best-response dynamics starting from an optimal solution, the potential does not increase, and hence we can bound the cost of any solution that we reach. Thus, for this network design game, best-response dynamics starting from the optimum do in fact always lead to a good Nash equilibrium.

We can extend our basic result to a number of more general settings. To begin with, the $H(k)$ bound on the price of stability extends directly to the case in which users are selecting arbitrary subsets of a ground set (with elements' costs shared according to the Shapley value), rather than paths in a graph; it also extends to the case in which the cost of each edge is a nondecreasing concave function of the number of users on it. In addition, our results also hold if we introduce capacities into our model; each edge e may be used by at most u_e players, where u_e is the capacity of e.

We arrive at a more technically involved set of extensions if we wish to add latencies to the network design problem. Here each edge has a concave *construction cost* $c_e(x)$ when there are x users on the edge, and a *latency cost* $d_e(x)$; the cost experienced by a user is the full latency plus a fair share of the construction cost, $d_e(x) + c_e(x)/x$. We give general conditions on the latency functions that allow us to bound the price of stability in this case by $d \cdot H(k)$, where d depends on the delay functions used. Moreover, we obtain stronger bounds in the case where users experience only delays, not construction costs; this includes a result that relates the cost of a best Nash equilibrium to that of an optimum with twice as many players, and a result that improves the potential-based bound on the price of stability for the single-source, delay-only case.

Since a number of our proofs are obtained by following the results of best-response dynamics via a potential function, it is natural to investigate the speed of convergence of best-response dynamics for this game. We show that with k players, it can run for a time exponential in k. Whether there is a way to schedule players' moves to make best-response dynamics converge in a polynomial number of steps for this game in general is an interesting open question.

Finally, we consider a natural generalization of the cost-sharing model that carries us beyond the potential-function framework. Specifically, suppose each user has a *weight* (perhaps corresponding to the amount of traffic it plans to send), and we change the cost-allocation so that user i's payment for edge e is equal to the ratio of its weight to the total weight of all users on e. In addition to being intuitively natural, this definition is analogous to certain natural generalizations of the Shapley value [29]. The weighted model, however, is significantly more complicated: There is no longer a potential function whose value tracks improvements in users' costs when they greedily update their solutions. We also show, using a construction involving user weights that grow exponentially in k, that the price of stability can be as high as $\Omega(k)$. We have obtained some initial positive results here, including the convergence of best-response dynamics when all users seek to construct a path from a node s to a node t (the price of stability here is 1), and in the general model of users selecting sets from a ground set, where each element appears in the sets of at most two users.

Related work. Network design games under a different model were considered by a subset of the authors in [3]; there the setting was much more "unregulated" in that users could offer to pay for an arbitrary fraction of any edge in the network. This model resulted in instances where no pure Nash equilibrium existed, and in many cases in

[3] when pure Nash equilibria did exist, certain users were able to act as "free riders," paying very little or nothing at all. The present model, on the other hand, ensures that there is always a pure Nash equilibrium within a logarithmic factor of optimal, in which users pay for a fair portion of the resources they use. Network creation games of a fairly different flavor—in which users correspond to nodes, and can build subsets of the edges incident to them—have been considered in [2, 12, 5, 16, 21, 31]. The model in this paper associates users instead with connection requests, and allows them to contribute to the cost of any edge that helps them to form a path that they need.

The bulk of the work on cost-sharing (see, e.g., [19, 22] and the references there) tends to assume a fixed underlying set of edges. Jain and Vazirani [23] and Kent and Skorin-Kapov [26] consider cost-sharing for a single source network design game. Cost-sharing games assume that there is a central authority that designs and maintains the network, and decides appropriate cost-shares for each agent, depending on the graph and all other agents, via a complex algorithm. The agents' only role is to report their utility for being included in the network.

Here, on the other hand, we consider a simple cost-sharing mechanism, the Shapley value, and ask what the strategic implications of a given cost-sharing mechanism are for the way in which a network will be designed. This question explores the feedback between the protocol that governs network construction and the behavior of self-interested agents that interact with this protocol. An approach of a similar style, though in a different setting, was pursued by Johari and Tsitsiklis [24]; there, they assumed a network protocol that priced traffic according to a scheme due to Kelly [25], and asked how this protocol would affect the strategic decisions of self-interested agents routing connections in the network.

The special case of our game with only delays is closely related to the congestion games of [39, 37]. They consider a game where the amount of flow carried by an individual user is infinitesimally small (a *nonatomic game*), while in this paper we assume that each user has a unit of flow, which it needs to route on a single path. In the nonatomic game of [39, 37] the Nash equilibrium is essentially unique (hence there is no distinction between the price of anarchy and stability), while in our atomic game there can be many equilibria. Fabrikant, Papadimitriou, and Talwar [17] consider our atomic game with delays only. They give a polynomial time algorithm to minimize the potential function Φ in the case that all users share a common source, and show that finding any equilibrium solution is PLS-complete for multiple source-sink pairs. Our results extend the price of anarchy results of [39, 37] about nonatomic games to results on the price of stability for the case of single source atomic games. Subsequent to our work, further results on the price of anarchy and stability in atomic games with delays were obtained in [4, 7, 11, 10, 40]. For games without delays, Agarwal and Charikar [1] give improved bounds on the price of stability in single-source undirected networks, and Fiat et al. [20] give bounds with the additional assumption that each vertex is the destination of some player. Other aspects of these and closely related games were recently explored in [9, 18].

A weighted game similar to ours is presented by Libman and Orda [28], with a different mechanism for distributing costs among users. They do not consider the price of stability and instead focus on convergence in parallel networks. Recently, Chen and Roughgarden [8] proved general results on the price of stability and the existence of approximate Nash equilibria in the weighted version of our game.

2. Nash equilibria of network design with Shapley cost-sharing. In this section we consider the *Fair Connection Game* for k players as defined in the Introduc-

tion. Let a directed graph $G = (V, E)$ be given, with each edge having a nonnegative cost c_e. Each player i has a set of terminal nodes T_i that he wants to connect. A strategy of player i is a set of edges $S_i \subset E$ such that S_i connects all nodes in T_i. We assume that we use the Shapley value to share the cost of the edges; i.e., all players using an edge split up the cost of the edge equally. Given a vector of players' strategies $S = (S_1, \ldots, S_k)$, let x_e be the number of agents whose strategy contains edge e. Then the cost to agent i is $C_i(S) = \sum_{e \in S_i}(c_e/x_e)$, and the goal of each agent is to connect its terminals with minimum total cost.

In the worst case, Nash equilibria can be very expensive in this game, so that the price of anarchy becomes as large as k. To see this, consider k players with common source s and sink t, and two parallel edges of cost 1 and k. The worst equilibrium has all players selecting the more expensive edge, thereby paying k times the cost of the optimal network. However, we can bound the price of stability by $H(k)$, which is the harmonic sum $1 + \frac{1}{2} + \frac{1}{3} + \ldots + \frac{1}{k}$, as follows.

THEOREM 2.1. *The price of stability of the fair connection game is at most* $H(k)$.

Proof. The fair connection game that we have defined falls into the class of congestion games as defined by Rosenthal [36], as the cost of edge e to a user i is $f_e(x) = c_e/x$, which depends only on edge e and the number of users x whose strategy contains e. Rosenthal [36] shows that all congestion games have deterministic Nash equilibria. He proves this using a potential function Φ, defined as follows.

$$\Phi(S) = \sum_{e \in E} \sum_{x=1}^{x_e} f_e(x) \tag{2.1}$$

Rosenthal [36] shows that for any strategy $S = (S_1, \ldots, S_k)$ if a single player i deviates to strategy S_i', then the change in the potential value $\Phi(S) - \Phi(S')$ of the new strategy set $S' = (S_1, \ldots, S_i', \ldots, S_k)$ is exactly the change in the cost to player i. Note that the change of player i's strategy affects the cost of many other players $j \neq i$, but the value of Φ is not affected by the change in the cost of these players, it simply tracks the cost of the player who changes its strategy. Monderer and Shapley [30] call a game in which such a function Φ exists a *potential game*. To show that such a potential game has a Nash equilibrium, start from any state $S = (S_1, \ldots, S_k)$ and consider a sequence of selfish moves (allowing players to change strategies to improve their costs). In a congestion game any sequence of such improving moves leads to a Nash equilibrium as each move decreases the potential function Φ, and hence must lead to a stable state.

Neither Rosenthal nor Monderer and Shapley say anything about the quality of Nash equilibria with respect to the centralized optimum, but we can use their potential function to establish our bound. Let x_e be defined as above with respect to S. Now the potential function of (2.1) in our case is $\Phi(S) = \sum_{e \in E} c_e H(x_e)$. Consider the strategy $S^* = (S_1^*, \ldots, S_k^*)$ defining the optimal centralized solution. Let $OPT = \sum_{e \in S^*} c_e$ be the cost of this solution. Then, $\Phi(S^*) \leq \sum_{e \in S^*}(c_e \cdot H(k))$, which is exactly $H(k) \cdot OPT$. Now we start from strategy S^* and follow a sequence of improving self-interested moves. We know that this will result in a Nash equilibrium S with $\Phi(S) \leq \Phi(S^*)$.

Note that the potential value of any solution S is at least the total cost: $\Phi(S) \geq \sum_{e \in S} c_e = cost(S)$. Therefore, there exists a Nash equilibrium with cost at most $H(k) \cdot OPT$, as desired. ∎

Recall from the example in Figure 1.1 that the upper bound of Theorem 2.1 is tight.

Unfortunately, even though Theorem 2.1 says that cheap Nash equilibria exist, finding them is NP-complete.

THEOREM 2.2. *Given an instance of a fair connection game and a value C, it is NP-hard to determine if the game has a Nash equilibrium of cost at most C.*

Proof. The reduction is from 3D matching. Given an instance of 3D matching with node sets X, Y, Z, form a graph $G = (V, E)$ as follows. Form a node for each node in X, Y, and Z, and also a node $v_{i,j,k}$ for each 3D edge (x_i, y_j, z_k). Also add an additional node t. Form a directed edge from each node $v_{i,j,k}$ to t with cost function $c_e = 3$. Form a directed edge from each node v in X, Y, Z to all nodes representing 3D edges that contain v. Make these edges have a cost $c_e = 0$. Let $C = |X| + |Y| + |Z|$, and form a player for each node v in $X \cup Y \cup Z$. This player has two terminals: v and t.

If there exists a 3D matching in the 3D-matching instance, then there exists a Nash equilibrium in the above fair connection game of cost C: Take the 3D matching M, and let S_i for the player whose terminals are v and t be the edge from v to the unique node $v_{i,j,k}$ corresponding to the 3D edge in M, and the edge from this node to t. Since M is a matching, the cost of S is exactly $3C/3 = C$. S is a Nash equilibrium, since any deviation for a player involves paying for some edge of cost 3 by himself, while the current amount he is paying is 1.

If no 3D matching exists, then any solution to the fair connection game must cost more than C. Therefore, no Nash equilibrium can exist of cost at most C. This finishes the proof. □

Notice that the same proof shows that determining if there exists a Nash equilibrium that costs as little as OPT is NP-complete.

We can extend the results of Theorem 2.1 to concave cost functions. Consider the extended fair connection game where instead of a constant cost c_e, each edge has a cost which depends on the number of players using that edge, $c_e(x)$. We assume that $c_e(x)$ is a nondecreasing, concave function, modeling the buy-at-bulk economies of scale of buying edges that can be used by more players. Notice that the cost of an edge $c_e(x)$ might increase with the number of players using it, but the cost per player $f_e(x) = c_e(x)/x$ decreases if $c_e(x)$ is concave.

THEOREM 2.3. *Take a fair connection game with each edge having a nondecreasing concave cost function $c_e(x)$, where x is the number of players using edge e. Then the price of stability is at most $H(k)$.*

Proof. The proof is analogous to the proof of Theorem 2.1. We use the potential function $\Phi(S)$ defined by (2.1). As before, the change in potential if a player i deviates equals exactly the change of that player's payments. We start with the strategy S^* with minimum total cost, and perform a series of improving deviations until we reach a Nash equilibrium S with $\Phi(S) \leq \Phi(S^*)$. To finish the proof all we need to show is that $cost(S) \leq \Phi(S) \leq H(k) \cdot cost(S)$ for all strategies S. The second inequality follows since $c_e(x)$ is nondecreasing, and therefore $\sum_{x=1}^{x_e}(c_e(x)/x) \leq H(x_e) \cdot c_e(x_e)$. To see that $cost(S) \leq \Phi(S)$ notice that since $c_e(x)$ is concave, the cost per player must decrease with x; i.e., $c_e(x)/x$ is a nonincreasing function. Therefore, $cost(S) = \sum_{e \in S} c_e(x_e) = \sum_{e \in S} x_e \cdot (c_e(x_e)/x_e) \leq \Phi(S)$, which finishes the proof. □

Notice that the requirement of cost functions being concave is general enough to encompass the utility function of a player being a combination of the cost he has to pay for his edges and the distance between his terminals in the network of bought edges. If c_e is the cost function of an edge, we simply set $c'_e(x) = c_e(x) + x$. The

payment of each player i now becomes $|S_i| + \sum_{e \in S_i}(c_e(x_e)/x_e)$, and c'_e is still concave if c_e is concave.

Extensions. The proof of Theorem 2.3 extends to a general congestion game, where players attempt to share a set of resources R that they need. Instead of having an underlying graph structure, we now think of each $s \in R$ as a resource with a concave cost function $c_s(x)$ of the number of users selecting sets containing s. The possible strategies of each player i is a set $\mathcal{S}_i$ of subsets of R. Each player seeks to select a set $S_i \in \mathcal{S}_i$ so as to minimize his cost. Since the proofs above did not rely on the graph structure, they translate directly to this extension.

We can further extend the results to the case where the cost of a player is a combination of the cost $c_e(x)/x$, and a function of the selected set, such as the distance between terminals in the network design case. More precisely, the price of stability is still at most $H(k)$ if each player is trying to minimize the cost $\sum_{e \in S_i}(c_e(x_e)/x_e) + d_i(S_i)$, where c_e is monotone increasing and concave, and d_i is an arbitrary function specific to player i (e.g., a distance function, or diameter of S_i, etc.). The proof is analogous to Theorem 2.3, except with a new potential $\Phi(S) = \sum_i d_i(S_i) + \sum_{e \in S} \sum_{x=1}^{x=x_e}(c_e(x)/x)$. Notice that this is technically not a congestion game on the given graph G. Finally we note that all these results (as well as those subsequent) hold in the presence of capacities. Adding capacities u_e to each edge e and disallowing more than u_e players to use e at any time does not substantially alter any of our proofs.

The case of undirected graphs. While the bound of $H(k)$ is tight for general directed graphs, it is not tight for undirected graphs. Finding the correct bound is an interesting open problem; see [20] for some recent progress. In the case of two players, our bound on the price of stability is $H(2) = 3/2$. In section 4 we show that this bound can be improved to $4/3$ in the case of two players and a single source. We also give an example to show that this bound is tight.

3. Dealing with delays. In most of the previous section, we assumed that the utility of a player depends only on the cost of the edges he uses. What changes if we introduce latency into the picture? We have extended this to the case when the players' cost is a combination of "design" cost and the length of the path selected. More generally, delay on an edge does not have to be simply the "hop-count," but can also depend on congestion, i.e., on the number of players using the edge. In this section we will consider such a model.

Assume that each edge has both a cost function $c_e(x)$ and a latency function $d_e(x)$, where $c_e(x)$ is the cost of building the edge e for x users and the users will share this cost equally, while $d_e(x)$ is the delay suffered by users on edge e if x users are sharing the edge. The goal of each user will be to minimize the sum of his cost and his latency. If we assume that both the cost and latency for each edge depend only on the number of players using that edge, then this fits directly into our model of a congestion game above: the total cost felt by each user on the edge is $f_e(x) = c_e(x)/x + d_e(x)$. If the function $xf_e(x)$ is concave, then Theorem 2.3 applies. But while concave functions are natural for modeling cost, latency tends to be convex.

3.1. Combining costs and delays. First, we extend the argument in the proof of Theorem 2.3 to general functions f_e. The most general version of this argument is expressed in the following theorem.

THEOREM 3.1. *Consider a fair connection game with arbitrary edge-cost functions f_e. Suppose that $\Phi(S)$ is as in (2.1), with $cost(S) \leq A \cdot \Phi(S)$, and $\Phi(S) \leq B \cdot cost(S)$ for all S. Then, the price of stability is at most $A \cdot B$.*

Proof. Let S^* be a strategy such that S_i^* is the set of edges i used in the centralized optimal solution. We know from above that if we perform a series of improving deviations on it, we must converge to a Nash equilibrium S' with potential value at most $\Phi(S^*)$. By our assumptions, $cost(S') \leq A \cdot \Phi(S') \leq A \cdot \Phi(S^*) \leq AB \cdot cost(S^*) = AB \cdot OPT$. □

Our main interest in this section are functions $f_e(x)$ that are the sums of the fair share of a cost and a delay, i.e., $f_e(x) = c_e(x)/x + d_e(x)$. We will assume that $d_e(x)$ is monotone increasing, while $c_e(x)$ is monotone increasing and concave.

COROLLARY 3.2. *If $c_e(x)$ is concave and nondecreasing, $d_e(x)$ is nondecreasing for all e, and $x_e d_e(x_e) \leq A \sum_{x=1}^{x_e} d_e(x)$ for all e and x_e, then the price of stability is at most $A \cdot H(k)$. In particular, if $d_e(x)$ is a polynomial with degree at most l and nonnegative coefficients, then the price of stability is at most $(l+1) \cdot H(k)$.*

Proof. For functions $f_e(x) = c_e(x)/x + d_e(x)$, both the cost and potential of a solution come in two parts corresponding to cost c and delay d.

For the part corresponding to the cost, the potential overestimates the cost by at most a factor of $H(k)$ as proved in Theorem 2.3. If on the delay, the potential underestimates the cost by at most a factor of A, then we get the bound of $A \cdot H(k)$ for the price of stability by Theorem 3.1. □

Therefore, for reasonable delay functions, the price of stability cannot be too large. In particular, if the utility function of each player depends on a concave cost and delay that is independent of the number of users on the edge, then we get that the price of stability is at most $H(k)$ as we have shown at the end of the previous section. If the delay grows linearly with the number of users, then the price of stability is at most $2H(k)$.

3.2. Games with only delays. In this subsection we consider games with only delay. We assume that the cost of a player for using an edge e used by x players is $f_e(x) = d_e(x)$, and d_e is a monotone increasing function of x. This cost function models delays that are increasing with congestion.

We will mostly consider the special case when there is a common source s. Each player i has one additional terminal t_i, and the player wants to connect s to t_i via a directed path. Fabrikant, Papadimitriou, and Talwar [17] showed that in this case, one can compute the Nash equilibrium minimizing the potential function Φ via a minimum cost flow computation. For each edge e they introduce many parallel copies, each with capacity 1, and cost $d_e(x)$ for integers $x > 0$. We will use properties of a minimum cost flow for establishing our results.

3.2.1. A bicriteria result. First we show a bicriteria bound, and compare the cost of the cheapest Nash equilibrium to that of the optimum solution with twice as many players.

THEOREM 3.3. *Consider the single source case of a congestion game with only delays. Let S be the minimum cost Nash equilibrium and S^* be the minimum cost solution for the problem where each player i is replaced by two players. Then $cost(S) \leq cost(S^*)$.*

Proof. Consider the Nash equilibrium obtained by Fabrikant [17] via a minimum cost flow computation. Assume that x_e is the number of users using edge e at this equilibrium. By assumption, all users share a common source s. Let $D(v)$ denote the cost of the minimum cost path in the residual graph from s to v. The length of the path of user i is at most $D(t_i)$ (as otherwise the residual graph would have a negative cycle), and hence we get that $cost(S) \leq \sum_i D(t_i)$.

Now consider modified delay function $\hat{d}_e$ for each edge $e = (u, v)$. Define $\hat{d}_e(x) = d_e(x)$ if $x > x_e$, and $\hat{d}_e(x) = D(v) - D(u)$ if $x \leq x_e$. Note that for any edge e we have $D(v) - D(u) \leq d_e(x_e + 1)$ as edge $e = (u, v)$ is in the residual graph with cost $d_e(x_e + 1)$. This implies that the modified delay $\hat{d}$ is monotone. For edges with $x_e \neq 0$ we also have that $d_e(x_e) \leq D(v) - D(u)$ as the reverse edge (v, u) is in the residual graph with cost $-d_e(x_e)$, so the delay of an edge is not decreased.

Now observe that, subject to new delay $\hat{d}$, the shortest path from s to t_i has length $D(t_i)$. The minimum possible cost of two paths from s to t_i for the two users corresponding to user i is then at least $2D(t_i)$ for each player i. Therefore the minimum cost of a solution with delays $\hat{d}$ is at least $2\sum_i D(t_i)$.

To bound $cost(S^*)$ we need to bound the difference in cost of a solution when measured with delays $\hat{d}$ and d. Note that for any edge $e = (u, v)$ and any number x we have that $x\hat{d}_e(x) - xd_e(x) \leq x_e(D(v) - D(u))$, and hence the difference in total cost is at most $\sum_{e=(u,v)} x_e(D(v) - D(u)) = \sum_i D(t_i)$. Using this, we get that $cost(S^*) \geq \sum_i D(t_i) \geq cost(S)$. □

Note that a similar bound is not possible for a model with both costs and delays, when additional users compensate to some extent for the price of stability. Consider a problem with two parallel links e and e' and k users. Assume on link e the cost function is $c_e(x) = 1 + \varepsilon$ for a small $\varepsilon > 0$, and the latency function is $d_e(x) = 0$. On the other link e' the cost is $c_{e'}(x) = 0$, and the delay with x users is $d_{e'}(x) = 1/(k - x + 1)$. The optimum solution is to use the first edge e, and it costs $1 + \varepsilon$. Note that the optimum with any number of extra users costs the same. On the other hand, the only Nash equilibrium is to have all users on e', incurring delay 1, for a total cost of k.

3.2.2. Bounding the price of stability with only delays. Note that the $H(k)$ term in Corollary 3.2 comes from the concave cost c, and so the bound obtained there improves by an $H(k)$ factor when the cost consists only of the delay. The results from Corollary 3.2 already tell us that if the delay functions are such that $x_e d_e(x_e) \leq A\sum_{x=1}^{x_e} d_e(x)$, the the price of stability is at most A. Specifically, we know that if the delays are polynomial of degree l, then the price of stability is at most $l + 1$, and therefore with linear delays the price of stability is at most 2.

Roughgarden [37] showed a tighter bound for nonatomic games. He assumed that the delay is monotone increasing, and the total cost of an edge $xd_e(x)$ is a convex function of traffic x. He showed that for any class of such functions $\mathcal{D}$ containing all constant functions, the price of anarchy is always obtained on a two-node, two-link network. Let us call $\alpha(\mathcal{D})$ the price of anarchy for nonatomic games with delays from the class $\mathcal{D}$ (which is also the price of stability, since the Nash equilibrium is unique in that context). For example, Roughgarden [37] showed that for polynomials of degree at most l this bound is $O(l/\log l)$, and for linear delays it is 4/3. Here we extend this result to a single source atomic game, and thereby show tighter bounds than in Corollary 3.2 for the single source case.

THEOREM 3.4. *If in a single source fair connection game all costs are delays, and all delays are from a set $\mathcal{D}$ satisfying the above condition, then the price of stability is at most $\alpha(D)$.*

Proof. As in the proof of Theorem 3.3 consider the Nash equilibrium obtained via a minimum cost flow computation, and let $D(v)$ be the length of the shortest path from s to v in the residual graph. As before we have that $cost(S) \leq \sum_i D(t_i)$. Further, for each edge $e = (u, v)$ we have that $D(v) - D(u) \leq d_e(x_e + 1)$, and for edges with $x_e \neq 0$, we also have that $d_e(x_e) \leq D(v) - D(u)$.

Give each edge $e = (u, v)$ a capacity of x_e, and augment our network by adding a parallel edge e' with constant delay $D(v) - D(u)$. Let $\hat{G}$ denote the resulting network flow problem. Note that the new capacity and the added links do not affect the equilibrium, as $d_e(x_e) \leq D(v) - D(u)$. For each edge e, the two parallel copies: Edge e with new capacity x_e and edge e' can carry any number of paths at least as cheaply as the original edge e could since $D(v) - D(u) \leq d_e(x_e + 1)$; hence this change in the network can only improve the minimum possible cost. We will prove the bound in this new network by comparing the cost of the Nash equilibrium with the minimum possible cost of a (possibly fractional) flow carrying one unit of flow from s to each of the terminals t_i.

The nice property of $\hat{G}$ is that the optimum fractional flow $\hat{x}$ in $\hat{G}$ is easy to determine. Consider an edge $e = (u, v)$ that is used by $x_e \neq 0$ paths in the equilibrium. We will obtain a fractional flow $\hat{x}_e$ by splitting the corresponding x_e amount of flow between the two edges e and e'. For an edge e let $\ell_e(x) = d_e(x) + xd'_e(x)$. By assumption, $d_e(x) \leq \ell_e(x)$ for all x. For an edge e such that $\ell_e(x_e) \leq D(v) - D(u)$, we set $\hat{x}_e = x_e$, and $\hat{x}_{e'} = 0$. Otherwise, let $\hat{x}_e$ be such that $\ell_e(\hat{x}_e) = D(v) - D(u)$, and let $\hat{x}_{e'} = x_e - \hat{x}_e$.

First, we claim that $\hat{x}$ is the minimum cost fractional solution in $\hat{G}$. For all edges $e = (u, v)$ such that $\hat{x}_e \neq x_e$, we have that $\ell_e(\hat{x}_e) = D(v) - D(u)$. When $\hat{x}_e = x_e$, then we have that flow $\hat{x}_e$ is equal to the capacity of the edge, and $\ell_e(\hat{x}_e) \leq D(v) - D(u)$. Therefore, if there is a negative cycle in the residual graph of $\hat{x}_e$ with constant edge costs $\ell_e(x_e)$ for e and costs $D(v) - D(u)$ for e', then this is also a negative cost cycle in G with constant edge costs $D(v) - D(u)$. This is impossible, however, since x_e is a min-cost flow with those costs. We can now use Lemma 3.5 to see that $\hat{x}_e$ is also a min-cost flow for edge costs $xd_e(x)$.

The theorem then follows, as on each original edge $e \in E$ the cost $x_e d_e(x_e)$ is at most $\alpha(\mathcal{D})$ times the cost of the corresponding two edges e and e' in $\hat{G}$ by Lemma 3.6. □

To finish the proof of the theorem, we require the following lemmas.

LEMMA 3.5. *Let G be a network, and x_e be a fractional flow sending one unit of flow from the source s to each sink t_i. Let ℓ denote the gradient of the total cost $xd_e(x)$, that is, let $\ell_e(x) = d_e(x) + xd'_e(x)$ for each edge e. The flow x_e is minimum cost subject to the cost $\sum_e xd_e(x)$ if and only if it is a minimum cost flow subject to the constant cost function $c_e = \ell_e(x_e)$.*

Proof. If the flow x_e is not of minimum cost subject to costs c_e, then the residual graph has a negative cycle, and moving a small amount of flow along the cycle decreases the cost $\sum_e xd_e(x)$, as the cost c_e is exactly the gradient of this objective function. To see the other direction, we use the fact that the cost function is convex by assumption, and hence all local optima are also global optima. □

Next, it is useful to recall from [37] what is $\alpha(\mathcal{D})$. Consider edge e, with delay $d(x)$ from class $\mathcal{D}$. Now consider a graph with two parallel links: Edge e, which has delay $d(x)$, that will carry some r units of flow, and a parallel link e' with constant delay $d(r)$ independent of the traffic. Now the unique Nash equilibrium is to route all r units of flow on e, while we get the optimum by setting x such that the gradient $c(x) = d(x) + xd'(x)$ is equal to $d(r)$, and sending x units of flow along e, and the remainder $r - x$ along edge e'. This is because of the following lemma from [37].

LEMMA 3.6 ([37]). *If a set $\mathcal{D}$ of delay functions satisfies the above condition, then the price of stability is at most $\alpha(D) = \max_{r,x,d\in\mathcal{D}} rd(r)/(xd(x) + (r - x)d(r))$, and the maximum is achieved by setting x such that $d(x) + xd'(x) = d(r)$.*

4. The undirected case. While the bound of $H(k)$ on the price of stability is tight for general directed graphs with costs, it is not tight for undirected graphs. Finding the correct bound is an interesting open problem. In the case of two players, our bound on the price of stability is $H(2) = 3/2$. We now show that that this bound can be improved to 4/3 in the case of two players and a single source.

Here is an example of an undirected two-player game with the price of stability approaching 4/3. Let G have 3 nodes: s, t_1, and t_2. Player 1 wants to connect t_1 with s, and player 2 wants to connect t_2 with s. There are edges (s, t_1) and (s, t_2) with cost 2. There is an edge (t_1, t_2) with cost $1 + \varepsilon$. The optimal centralized solution has cost $3 + \varepsilon$. However, the cheapest Nash has cost 4. This example implies that the following claim is tight.

CLAIM 4.1. *The price of stability is at most* 4/3 *in a fair connection game with two players in an undirected graph, each having two terminals with one terminal in common.*

Proof. Let s be the common terminal, and let t_1 and t_2 be the personal terminals. Consider the optimal centralized solution (S_1, S_2). Let $X_1 = S_1 \backslash S_2$ be the edges only being used by player 1, $X_2 = S_2 \backslash S_1$ be the edges only used by player 2, and $X_3 = S_1 \cap S_2$ be the edges shared by the two players. Let (S_1', S_2') be a Nash equilibrium that a series of improving responses converges to starting with (S_1, S_2). Similarly, let $Y_1 = S_1' \backslash S_2'$, $Y_2 = S_2' \backslash S_1'$, and $Y_3 = S_1' \cap S_2'$. Finally, set $x_i = cost(X_i)$ and $y_i = cost(Y_i)$ for $1 \le i \le 3$. By the properties of $\Phi(S_1, S_2)$ from the proof of Theorem 2.1, we know that $\Phi(S_1', S_2') \le \Phi(S_1, S_2)$. Substituting in the definition of Φ, we obtain that

$$y_1 + y_2 + \frac{3}{2} y_3 \le x_1 + x_2 + \frac{3}{2} x_3. \tag{4.1}$$

Look at S_1' and S_2' as paths instead of sets of edges (there will be no cycles since then this would not be a Nash). We now show that in (S_1', S_2'), as in any Nash equilibrium, once the paths of the two players merge, they do not separate again. Suppose to the contrary that this happens. Let v be the first node that S_1' and S_2' have in common, and set P_1 and P_2 be the subpaths of S_1' and S_2' after v, respectively. We know that $cost(P_1 \backslash P_2) = cost(P_2 \backslash P_1)$, since if they were not equal, say $cost(P_1 \backslash P_2) > cost(P_2 \backslash P_1)$, then player 1 could deviate to P_2 instead and pay strictly less. However, even if they are equal, player 1 could deviate to use P_2 instead of P_1, and pay strictly less, since he will pay the same as before on edges in $P_1 \cap P_2$, and pay only $cost(P_1 \backslash P_2)/2$ in total on the other edges. Therefore, the only way this could be a Nash equilibrium is if $P_1 \cap P_2 = P_1 = P_2$, as desired.

Consider a deviation from (S_1', S_2') that player 1 could make. He could decide to use $X_1 \cup X_2 \cup Y_2 \cup Y_3$ instead of $S_1' = Y_1 \cup Y_3$. This is a valid deviation because player 1 still connects his terminals by following X_1 until X_1 meets with X_2, then following X_2 back to t_2, and then following S_2' to s. Since (S_1', S_2') is a Nash equilibrium, this deviation must cost more to player 1 than his current payments, and so $x_1 + x_2 + y_2/2 + y_3/2 \ge y_1 + y_3/2$. By symmetric reasoning, $x_1 + x_2 + y_1/2 + y_3/2 \ge y_2 + y_3/2$. If we add these inequalities together, we obtain that

$$y_1/2 + y_2/2 \le 2x_1 + 2x_2. \tag{4.2}$$

To show that the price of stability is at most 4/3, it is enough to show that $cost(S_1', S_2') \le \frac{4}{3} cost(S_1, S_2)$. Using the above notation, this is the same as showing $3y_1 + 3y_2 + 3y_3 \le 4x_1 + 4x_2 + 4x_3$. We do this by using Inequalities 4.1 and 4.2 as

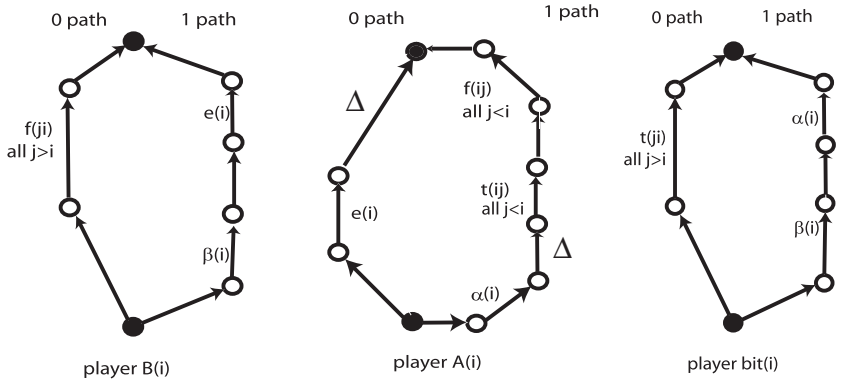

FIG. 5.1. *The construction of an exponential best-response run. The filled-in nodes are the sources and sinks of the players.*

follows:

$$\begin{aligned} 3y_1 + 3y_2 + 3y_3 &\leq 3y_1 + 3y_2 + 4y_3 \\ &= \frac{1}{3}(y_1 + y_2) + \frac{8}{3}\left(y_1 + y_2 + \frac{3}{2}y_3\right) \\ &\leq \frac{4}{3}(x_1 + x_2) + \frac{8}{3}\left(x_1 + x_2 + \frac{3}{2}x_3\right) \\ &= 4x_1 + 4x_2 + 4x_3. \qquad \square \end{aligned}$$

5. Convergence of best response. In this section, we show that, in general, best response dynamics in our game can take a long time to converge to an equilibrium. Specifically, we construct a sequence of best responses that takes exponential time to converge to a Nash equilibrium.

THEOREM 5.1. *Best response dynamics for k players may run in time exponential in k.*

To prove this, we now construct an example (shown in Figure 5.1) in which by appropriate ordering of the best response of players, we can simulate a $\Omega(k)$-bit binary counter. The idea is that we have a set of players corresponding to each bit of the counter. Then we describe a sequence of best response moves that lead to the counter incrementing from the "all zeros" state onwards. Since with n bits, we can implement a counter that counts up to 2^n, and then as long as we can show that each increment of the counter corresponds to a sequence of best response moves from the current configuration, we would have shown an exponentially long best response sequence. In what follows, we first describe the set of gadgets to construct the counter, and then show the set of inequalities that result from the increments of the counter.

The graph has $3n$ players: n "bit" players, each denoted by bit(i), and for each bit player we also have two "auxiliary" players. The auxiliary players of the bit(i) player are denoted by $A(i)$ and $B(i)$. We construct the graph as follows. For each player we form a gadget as shown in Figure 5.1. The gadget for each bit player and each auxiliary player has only two path options, we call these the 0 path and the 1 path. Figure 5.1 shows the set of edges that belong to each gadget. The gadget for the ith bit player, for instance, consists of edges $\alpha(i)$, $\beta(i)$, a set of edges $t(j,i)$, one for each $j > i$, and a few unnamed edges as shown in the figure. To construct the graph, we simply take the union of these gadgets. The labeled edges are shared with the other gadgets, whereas the unlabeled edges are not. Furthermore, the label Δ

actually denotes the cost of the corresponding edges; these edges too are individual to each gadget.

Thus, each of the $\alpha(i)$ edges are in the gadgets of players $A(i)$ and $\text{bit}(i)$, and so appear in the 1 path of both $A(i)$ and $\text{bit}(i)$. Each edge $\beta(i)$ is in the 1 path of two players $B(i)$ and $\text{bit}(i)$, and each edge $e(i)$ is in the 0 path of $A(i)$ and the 1 path of $B(i)$. Each edge $f(i,j)$ and $t(i,j)$ is actually shared by two gadgets. For a specific i and j with $i > j$, the same edge $f(i,j)$, for instance, is present in the 0-path of $B(j)$, and also in the 1 path of $A(i)$. In addition to the unnamed edges drawn in the gadget, assume there are unnamed edges before and after every edge type of $f(i,j)$ or $t(i,j)$ and these unnamed edges are directed and specific to a particular gadget. In the above figure, we have not specified the order in which the edges of, for example, $f(j,i)$ for all $j > i$ in the gadget of $bit(i)$ proceed. In all of these cases, there is one index that is fixed, and one that is variable, so we assume that these edges appear in increasing order of the variable index.

We will later prove that *no player will ever choose a path in this graph other than the* 0 *or the* 1 *path corresponding to its gadget.* This significantly simplifies the strategy sets of the players, so now we can simply think of each player as choosing either strategy 0 or 1. Below we describe an exponential-length best-response run that simulates a binary counter. A sample run of this type is shown in Table 5.1. The first, fifth, and eleventh steps shown correspond to the values 00, 01, and 10 of the counter, and indeed these are the values of the strategies of the $\text{bit}(i)$ players. The rest of the steps pictured are intermediate steps, and only exist to get the $\text{bit}(i)$ players into the correct configuration.

In what follows, we abuse notation and represent the cost of an edge by the label itself, e.g., $\alpha(i)$, $f(i,j)$, and $t(i,j)$ will also be used to denote the cost of the corresponding edges. All the unnamed edges are zero cost, except for the two sets of edges, one in each path of $A(i)$ that each have cost Δ, which is large, say $3n$ times bigger than the sum of the cost of all the named edges. Thus player $A(i)$ always pays at least Δ in order to get to the sink, but never should agree to pay more than $\Delta + \Delta/3n$.

We also refer to the player going on the "one" path as the *player being set* and going on the "zero" path as the *player being reset*. Each player has one source and one sink and the paths of each player are as shown in the gadgets above. The costs of the paths of the ith bit player are referred to as $x_i^{(0)}$ and $x_i^{(1)}$, and those of the player $A(i)$ and $B(i)$ as $a_i^{(0)}$, $a_i^{(1)}$ and $b_i^{(0)}$, $b_i^{(1)}$, respectively. Note that these denote the actual costs of these paths, not the cost shares in any configuration. Now we describe the sequence of best-response moves that lead to the counter incrementing. For the moves that we will describe to actually be best-response moves, particular inequalities will have to hold on the edge costs. Below we give a sequence of best-response moves that is exponential length, together with the inequalities that must hold for these to be valid best-response moves. We will later show that all of these inequalities can be satisfied.

Start Step: All the players are reset.

General Step: The bits from 1 to $\ell - 1$ are all set. The bits from $\ell + 1$ to n may be at 0 or 1. The ℓth bit is currently at 0 and has to be set at 1. Also, all the $A(j)$ players are reset. The $B(j)$ players are set if and only if the jth players are set.

Notice that the first, fifth, and last step in Table 5.1 are of this form. We now show a sequence of best responses which will set the ℓ'th bit, set all the bits 1 to $\ell - 1$ to 0 (which is what should happen in a counter when the ℓ'th bit is set), and return all the auxiliary players to the form described in the "General Step" above.

- First, the ℓth bit sets. At this point, there are no other players using either of bit ℓth player's paths, so for this to happen, we need only the following to be true.

$$x_\ell^{(1)} < x_\ell^{(0)}$$
$$\text{implying, } \alpha(\ell) + \beta(\ell) < \sum_{j>\ell} t(j,\ell)$$

The setting of the bit(ℓ) player will now first trigger $A(\ell)$ and then $B(\ell)$, as follows.

- The cost of the 1 path of $A(\ell)$ has now decreased by $\alpha(\ell)/2$ because of the player bit(ℓ) using it. $A(\ell)$ is thus triggered and is allowed to set. Since both the 0 and 1 path have the Δ cost edges that are to be paid by $A(i)$ alone, they do not matter in the best response calculations. Thus, for this to be a valid best response move, it is enough that

$$a_\ell^{(1)} - \alpha(\ell)/2 < a_\ell^{(0)}$$
$$\text{implying that, } \alpha(\ell)/2 + \sum_{j<\ell} f(\ell,j) + \sum_{j<\ell} t(\ell,j) < e(\ell)$$

- The setting of $A(\ell)$ triggers all the $B(i)$ for $i < \ell$ to be reset. Recall that the corresponding $A(i)$ are already reset. We allow these $B(i)$ to reset. Due to $A(\ell)$ being on its 1 path, the cost of 0 path has changed by $f(\ell,i)/2$. Since only the player bit(i) is using the edge $\beta(i)$, then for $B(i)$ to want to reset, we need that

$$b_i^{(0)} - f(\ell,i)/2 < b_i^{(1)} - e(i)/2 - \beta(i)/2$$
$$\text{that is, } \sum_{j>i} f(j,i) - f(\ell,i)/2 < e(i)/2 + \beta(i)/2$$

- $A(\ell)$ now also triggers all the bit players bit(i) for all $i < l$ to reset by reducing the cost of the 0 path of bit(i) by $t(\ell, i)/2$. For each such $i < \ell$, the bit $B(i)$ has also just been reset. Thus for this to be a best response move, it should be the case that

$$x_i^{(0)} - t(\ell, i)/2 < x_i^{(1)}$$
$$\sum_{j>i} t(j, i) - t(\ell, i)/2 < \alpha(i) + \beta(i)$$

- Now because of the setting of the bit(ℓ), the 1 path of $B(\ell)$ became cheaper by $\beta(\ell)/2$. $B(\ell)$ wants to set and is allowed to do so. For this, we need that

$$b_\ell^{(1)} - \beta(\ell)/2 < b_\ell^{(0)}$$
$$e(\ell) + \beta(\ell)/2 < \sum_{j>\ell} f(j, \ell)$$

- Lastly, we now want $A(\ell)$ to reset. As a result of the setting of $B(\ell)$, the 0 path of $A(\ell)$ became cheaper by $e(\ell)/2$. Edges on the 1-path of $A(\ell)$ are shared by players bit(x) and $B(x)$ for $x < i$, and by the player bit(ℓ). So we need that the 0-path of $A(\ell)$ be less expensive to it even if all these players pay off their corresponding shares on the 1-path. Again since the Δ-cost edges are present on both sides, they do not matter in the computation of the best response. That is, we need that

$$a_\ell^{(0)} - e(\ell)/2 < a_\ell^{(1)} - \sum_{j<\ell} (f(\ell, j)/2 + t(\ell, j)/2) - \alpha(\ell)/2$$
$$e(\ell)/2 < \alpha(\ell)/2 + \sum_{j<\ell} (f(\ell, j)/2 + t(\ell, j)/2)$$

- Now we have the subgame of bit and auxiliary players from 1 to $\ell - 1$ being completely reset, and no other player corresponding to the higher-numbered bits influencing any of their paths. This corresponds to the first $\ell - 1$ bits of the counter becoming 0 because the ℓ'th bit just became 1. We can now use the best response run corresponding to incrementing the first $\ell - 1$ bits of the counter from all 0's to all 1's again, without any interference from the players corresponding to the higher-numbered bits. This gets us back to the configuration in the start of the recursion (the "General Step" above), except now we need to deal with the $(\ell + 1)^{st}$ bit.

Proof of Theorem 5.1. We now prove that the above game has an exponential best response run under the above best response scheduling.

All we need to show is that the moves described in the scheduling are best responses. We first argue that each player has only two cheap paths available to him, which we have described as the zero path and the one path. To complete the construction we next need to come up with a set of values for the links that satisfy the set of best response inequalities above. Taken together, it follows that the moves are all best responses and simulate a $\Omega(k)$-size counter.

First note that the 0 path and 1 path of any one particular player are vertex disjoint. Recall that the unnamed edges, both in the figure and the ones in between the $f(i, j)$ edges and the $t(i, j)$ edges are all exclusive to each gadget. By our construction, the unnamed edges also impose the following property on the 0/1-paths of all players: The 0/1-path of any one player must either have at least one edge in common or must

be vertex disjoint from the 0/1-path of any other player. We do not have to worry about the case of just having vertices in common.

We need to argue that each player has only two cheap paths available to him. Intuitively the argument is as follows. If one player deviates out of his gadget (i.e., takes a path other than its 0 or 1 path), it will never be able to come back to his own sink, or would have to pay an exorbitant amount (Δ) in order to reach its sink. Thus, the only available cheap strategies to a player are the 0 and 1 paths.

Before going into the details, we first define a function to make the notation simpler. For any edge e, define the function $sink(e)$ to be the set of all possible sinks (terminal nodes of players) to which paths from this edge can lead. Note that the graph only has edges $f(x, y)$ and $t(x, y)$ where $x > y$; there are no corresponding edges for $x \leq y$. For notational simplicity, for a general tuple (x, y), we define $sink(f(x, y))$ as follows. Note that $f(x, y)$ can lead to the sink of $A(x)$ and $B(y)$ if $x > y$, as well as to $sink(f(x + 1, y))$ and $sink(f(x, y + 1))$. Thus, inductively, if $x > y$

$$sink(f(x, y)) = \{A(x), \ldots, A(n), B(y), \ldots, B(n)\}$$

and $\emptyset$ otherwise (since the corresponding $f(x, y)$ edges do not appear in the gadget at all).

Similarly, since for $x \leq y$, the edges $t(x, y)$ are not present in the construction, define $sink(t(x, y)) = \emptyset$ for $x \leq y$. In order to compute $sink(t(x, y))$ for $x > y$, note that $t(x, y)$ can lead to $A(x)$, $bit(y)$, as well as $sink(t(x+1, y))$, $sink(t(x, y+1))$, and $sink(f(x, 1))$ (since in the 1 path of $A(x)$, edge $t(x, y)$ can be followed by $f(x, 1)$). Thus, if $x > y$

$$sink(t(x, y)) = \{bit(y), \ldots, bit(n), A(x), \ldots, A(n), B(1), \ldots, B(n)\}$$

and $\emptyset$ else.

We now flesh out the argument for each player for each of the two cases, the set-case and the reset-case. Consider player $B(i)$. If a strategy follows the first unnamed edge of 1-path, then it reaches $\beta(i)$. From the end vertex of $\beta(i)$ it has the option of choosing the next unnamed edge in 1-path of gadget $B(i)$, or in the 1-path of $bit(i)$. In the first case the strategy has to go through $e(i)$. But after it crosses $e(i)$ there is only a zero-cost edge left to be covered to the sink of $B(i)$, and so other deviations are useless. If the path instead had chosen to enter the gadget of $bit(i)$ after the edges $\beta(i)$, then it would have to travel through $\alpha(i)$ and then either get stuck at the sink of $bit(i)$ or travel through one or more edges of the form $\{t(i, y), y < i\}$. But in order to enter an edge of the form $t(i, y)$ this strategy would have to pay at least $\Delta/3n$ to share the edge priced Δ, which is more than the total cost of $B(i)$. So any strategy starting on the 1-path of $B(i)$ does not enter the $A(i)$ gadget.

Next consider a strategy starting out on the 0-path of $B(i)$ through the first unnamed edge. The edges then appearing on this path are of the form $\{f(x, i), x > i\}$. These edges also appear in the gadgets $A(x)$. If this strategy chooses to deviate to exit the $B(i)$ gadget after the edge $f(x, i)$ and enter the $A(x)$ one, the labeled edge that it meets next is $f(x, i + 1)$. But no path from $f(x, i + 1)$ leads to the sink of $B(i)$, as is verified from the sink-function above. So this deviation cannot happen. We have now shown that the best strategies of $B(i)$ must be the 0 and 1 paths only.

Now, take the $A(i)$ player and a strategy which starts out on the first unnamed edge of the 1-path. This strategy then has to go through $\alpha(i)$. From the endpoint of $\alpha(i)$ the only edges are to the sink of $bit(i)$, or continue along the $A(i)$ gadget. The edges that appear next are of the form $\{t(i, x), x < i\}$. If the path does not continue

along the gadget of $A(i)$, and instead switches to the 0-path of $bit(x)$, then the next edge it encounters is $t(i+1,x)$. But according to the sink function, there is no way to reach the sink of $A(i)$ from $t(i+1,x)$, so this is not a valid deviation. Next, the path cannot deviate out of any the $\{f(i,x), x < i\}$ edges since $A(i)$ does not lie in any $sink(f(i+1,x))$. Thus strategies of $A(i)$ starting out on the 1-path of $A(i)$ stay on this path.

Next consider the strategy of $A(i)$ that starts out through the unnamed edge in the 0-path of $A(i)$. This path cannot deviate after $e(i)$ because it would just get stuck in the sink of $B(i)$. Thus, we have shown that the best strategies of $A(i)$ must be the 0 and 1 paths only.

Lastly consider the ith bit player. Along 0-path of bit-i, the only shared nodes and edges of this player are the $t(x,i)$ edges that are each shared with $A(x)$ for all $x > i$. Suppose this bit player follows the $t(x,i)$ edge to the gadget of $A(x)$ with $x > i$. The next edge is then $t(x,i+1)$ which does not lead to $bit(i)$-sink. Thus the 0-path strategies do not allow any deviations. A path starting with the first edge of the 1-path of this bit-player can deviate after $\beta(i)$ and enter edge $e(i)$ of the $B(i)$ gadget. But from there all paths get stuck at sinks. Thus the 1-path deviations cannot happen after $\beta(i)$. But the deviations cannot happen after $\alpha(i)$ either, as the remaining edge is zero cost.

This concludes the proof that the best strategies of the players always correspond to the 0 and 1 paths in the gadgets.

For the last part of the construction, we show that it is possible to come up with a set of values for the links such that the best response inequalities are satisfied. Let the edge costs be as follows. In all the remaining formulae let c be any constant greater than 10. Let $\alpha(i) = 1$, and $\beta(i) = 2c^i(n-i) - c^i/2 - 3e(i)/2$. Also, $e(i) = \sum_{j<i} f(i,j) + \sum_{j<i} t(i,j) + 3/4$ for all i. Finally, for all pairs i, j, $f(i,j) = c^j$ and $t(i,j) = 2c^j$. Given these values, we can check that the inequalities above are satisfied for all $i < n$, and thereby we can have a run of best responses of length exponential in the number of players. □

6. Weighted players. So far we have assumed that players sharing an edge e pay equal fractions of e's cost. We now consider a game with fixed edge costs where players have weights $w_i \geq 1$, and players' payments are proportional to their weight. More precisely, given a strategy $S = (S_1, \ldots, S_k)$, define W to be the total weight of all players, and let W_e be the sum of the weights of players using e. Then player i's payment for edge e will be $\frac{w_i}{W_e} c_e$.

Note that the potential function $\Phi(S)$ used for the unweighted version of the game is not a potential function once weights are added. In particular, in a weighted game, improving moves can increase the value of $\Phi(S)$, as this is no longer a congestion game. The following theorem uses a new potential function for a special class of weighted games.

THEOREM 6.1. *In a weighted game where each edge e is in the strategy spaces of at most two players, there exists a potential function for this game, and hence a Nash equilibrium exists.*

Proof. Consider the following potential function. For each edge e used by players i and j, define

$$\Phi_e(S) = \begin{cases} c_e w_i & \text{if player } i \text{ uses } e \text{ in } S \\ c_e w_j & \text{if player } j \text{ uses } e \text{ in } S \\ c_e \theta_{ij} & \text{if both players } i \text{ and } j \text{ use } e \text{ in } S \\ 0 & \text{otherwise,} \end{cases}$$

where $\theta_{ij} = (w_i + w_j - \frac{w_i w_j}{w_i + w_j})$. For any edge e with only one player i, simply set $\Phi_e(S) = w_i c_e$ if i uses e and 0 otherwise. Define $\Phi(S) = \sum_e \Phi_e(S)$. We now simply need to argue that if a player makes an improving move, then $\Phi(S)$ decreases. Consider a player i and an edge e that player i joins. If the edge already supported another player j, then i's cost for using e is $c_e \frac{w_i}{w_i + w_j}$, while the change in $\Phi_e(S)$ is

$$c_e(w_i - \frac{w_i w_j}{w_i + w_j}) = c_e \frac{{w_i}^2}{w_i + w_j}.$$

Thus the change in potential when i joins e equals the cost i incurs, scaled up by a factor of w_i. In fact, it is easy to show the more general fact that when player i moves, the change in $\Phi(S)$ is equal to the change in player i's payments scaled up by w_i. This means that improving moves always decrease $\Phi(S)$, thus proving the theorem. □

Note that this applies not only to paths, but also to the generalized model in which players select subsets from some ground set. The analogous condition is that no ground element appears in the strategy spaces of more than two players.

COROLLARY 6.2. *Any two-player weighted game has a Nash equilibrium.*

While the above potential function also implies a bound on the price of stability, even with only two players this bound is very weak. However, if there are only two players with weights 1 and $w \geq 1$, then we can show that the price of stability is at most $1 + \frac{1}{1+w}$, and this is tight for all w.

The following result shows the existence of Nash equilibria in weighted single commodity games.

THEOREM 6.3. *For any weighted game in which all players have the same source s and sink t, best response dynamics converge to a Nash equilibrium, and hence Nash equilibria exist.*

Proof. Start with any initial set of strategies S. For every $s - t$ path P define the marginal cost of P to be $c(P) = \sum_{e \in P} \frac{c_e}{W_e}$, where W_e is the sum of the weights of players using e in the state S. Observe that if player i currently uses path P, then i's payment is $w_i c(P)$. Define $P(S)$ to be a tuple of the values $c(P)$ over all paths P, sorted in increasing order. We want to show that the cheapest improving deviation of any player causes $P(S)$ to strictly decrease lexicographically.

Suppose that one of the best moves for player i is to switch paths from P_1 to P_2. Let $\mathcal{P}$ denote the set of paths that intersect $P_1 \cup P_2$. For any pair of paths P and Q, let $c_P(Q)$ denote the new value of $c(Q)$ after player i has switched to path P. To show that $P(S)$ strictly decreases lexicographically, it suffices to show that

$$\min_{P \in \mathcal{P}} c_{P_2}(P) < \min_{P \in \mathcal{P}} c(P). \tag{6.1}$$

Define $P' = \arg\min_{P \in \mathcal{P}} c(P)$. Since P_2 was i's best response, $c_{P_2}(P_2) \leq c_P(P)$ for all paths P. In particular, $c_{P_2}(P_2) \leq c_{P'}(P')$. We also know that $c_{P'}(P') \leq c(P')$, since in deviating to P', player i adds itself to some edges of P'. In fact, $c_{P'}(P') < c(P')$ unless $P' = P_1$. Assuming $P' \neq P_1$, we now have that $c_{P_2}(P_2) < c(P')$, which proves inequality (6.1). If $P' = P_1$, then since player i decided to deviate, $c_{P_2}(P_2) < c(P_1)$. Therefore, we once again have that $c_{P_2}(P_2) < c(P')$, as desired. □

In the case where the graph consists of only 2 nodes s and t joined by parallel links, we can similarly show that any sequence of improving responses converge to a Nash equilibrium.

Weighted games with three or more players need not have a pure Nash equilibrium [8]. The following claim shows that, even when Nash equilibria do exist, the prices of stability bounds from the unweighted case do not carry over.

THEOREM 6.4. *There are weighted games for which the price of stability is* $\Theta(\log W)$ *and* $\Theta(k)$.

An example exhibiting this is a modified version of the graph in Figure 1.1. Change the edge with cost $1+\varepsilon$ to cost 1, and for all other edges with positive cost, set the new cost to be $\frac{1}{2}$. For $1 \le i \le k$ let player i have weight $w_i = 2^{i-1}$. Since each player has a greater weight than all smaller weight players combined, the only Nash equilibrium has cost $\frac{k}{2} = \Theta(\log W)$, while the optimal solution has cost 1.

7. Conclusions and open questions. For the Fair Connection Game, we showed that the price of stability is always at most $H(k)$, and that this is tight for directed graphs. However, the case for undirected graphs remains largely unresolved. The results of section 4 show that, at least for two players, the price of stability for undirected graphs can be strictly better than that for directed. The largest lower bound that we know of for the price of stability in undirected networks is 12/7. The worst-case price of stability in undirected games could be constant, showing that fair sharing works very well in such games. See [1] for improved price of stability bounds in the undirected case, as well as Fiat et al. [20] for recent progress on a special case of this question.

Another open question is whether or not a good Nash equilibrium can be computed in polynomial time for a large number of players. One approach to solving this problem is to first compute an approximation to the centralized optimum, and then simulate best-response dynamics to reach a Nash equilibrium with cost at most $O(\log k)$ times that of the initial state. Unfortunately, Theorem 5.1 shows that arbitrary best-response dynamics can require exponential time to converge. On the other hand, it is possible that best responses can always be scheduled in a way that guarantees convergence in polynomial time. A weaker goal is to show how to compute a $(1+\varepsilon)$-approximate Nash equilibrium, where no player can decrease its cost by more than a $1+\varepsilon$ factor, in polynomial time.

For the version of the Fair Connection Game with latencies instead of edge costs, the main challenge is to provide price of stability results for the general scenario, rather that just the single-source special case. See [7, 10] for recent results for the special case of linear latency functions.

Finally, for weighted games (section 6) we have given only preliminary results. Recently, Chen and Roughgarden [8] proved that pure Nash equilibria need not exist in such games. They also showed that every weighted game has an $O(\log w_{\max})$-approximate Nash equilibrium that costs at most $O(\log W)$ times the centralized optimum (where $w_{\max}$ is the maximum weight and W is the sum of the weights, assuming that the minimum weight is 1). These bounds are nearly tight. But the following natural question is still open: What is the price of stability of approximate Nash equilibria in Weighted Fair Connection Games if all players share a common terminal?

A LOWER BOUND FOR THE SIZE OF SYNTACTICALLY MULTILINEAR ARITHMETIC CIRCUITS*

RAN RAZ†, AMIR SHPILKA‡, AND AMIR YEHUDAYOFF§

Abstract. We construct an explicit polynomial $f(x_1, \ldots, x_n)$, with coefficients in $\{0, 1\}$, such that the size of any syntactically multilinear arithmetic circuit computing f is at least $\Omega(n^{4/3}/\log^2 n)$. The lower bound holds over any field.

Key words. lower bounds, arithmetic circuits, explicit constructions

AMS subject classification. 68Q17

DOI. 10.1137/070707932

1. Introduction. Arithmetic circuits are the standard model for computing polynomials (see section 1.1 for a definition). Roughly speaking, given a set of variables $X = \{x_1, \ldots, x_n\}$, an arithmetic circuit uses additions and multiplications to compute a polynomial f in the set of variables X. Given a polynomial f, we are interested in the number of operations needed to compute f.

The best lower bound known for the size of arithmetic circuits is the classical $\Omega(n \log n)$ of Strassen [8] and of Baur and Strassen [1]. Proving better lower bounds is an outstanding open problem. In this paper, we focus on a restricted class of arithmetic circuits, the class of syntactically multilinear arithmetic circuits. We prove an $\Omega(n^{4/3}/\log^2 n)$ lower bound for the size of syntactically multilinear arithmetic circuits computing an explicit polynomial.

1.1. Syntactically multilinear arithmetic circuits. An *arithmetic circuit* Φ over the field $\mathbb{F}$ and the set of variables $X = \{x_1, \ldots, x_n\}$ is a directed acyclic graph as follows: Every vertex v in Φ is either of in-degree 0 or of in-degree 2. Every vertex v in Φ of in-degree 0 is labeled by either a variable in X or a field element in $\mathbb{F}$. Every vertex v in Φ of in-degree 2 is labeled by either $\times$ or $+$. An arithmetic circuit Φ is called an *arithmetic formula* if Φ is a directed binary tree (the edges of an arithmetic formula are directed from the leaves to the root).

Let Φ be an arithmetic circuit over the field $\mathbb{F}$ and the set of variables X. The vertices of Φ are also called *gates*. Every gate of in-degree 0 is called an *input gate*. Every gate of in-degree 2 labeled by $\times$ is called a *product gate*. Every gate of in-degree 2 labeled by $+$ is called an *addition gate*. Every gate of out-degree 0 is called an *output gate*. For two gates u and v in Φ, if (u, v) is an edge in Φ, then u is called a *son* of v, and v is called a *father* of u. The *size* of Φ, denoted $|\Phi|$, is the number of edges in

Φ. Since the in-degree of Φ is at most 2, the size of Φ is at most twice the number of gates in Φ.

For a gate v in Φ, define Φ_v to be the subcircuit of Φ rooted at v as follows: The gates of Φ_v are all the gates u in Φ such that there exists a directed path from u to v in Φ. The edges and labels of Φ_v are the same edges and labels of Φ (restricted to the set of gates of Φ_v).

An arithmetic circuit computes a polynomial in a natural way. For a gate v in Φ, define $\widehat{\Phi}_v \in \mathbb{F}[X]$ to be the polynomial computed by Φ_v as follows: If v is an input gate labeled by $\alpha \in \mathbb{F} \cup X$, then $\widehat{\Phi}_v = \alpha$. If v is a product gate with sons v_1 and v_2, then $\widehat{\Phi}_v = \widehat{\Phi}_{v_1} \cdot \widehat{\Phi}_{v_2}$. If v is an addition gate with sons v_1 and v_2, then $\widehat{\Phi}_v = \widehat{\Phi}_{v_1} + \widehat{\Phi}_{v_2}$. For a polynomial $f \in \mathbb{F}[X]$, and a gate v in Φ, we say that v *computes* f if $f = \widehat{\Phi}_v$. For a polynomial $f \in \mathbb{F}[X]$, we say that Φ *computes* f if there exists a gate u in Φ that computes f.

A polynomial $f \in \mathbb{F}[X]$ is called *multilinear* if the degree of each variable in f is at most one. An arithmetic circuit Φ is called *(semantically) multilinear* if every gate in Φ computes a multilinear polynomial. An arithmetic circuit Φ is called *syntactically multilinear* if for every product gate v in Φ with sons v_1 and v_2, the set of variables that occur in Φ_{v_1} and the set of variables that occur in Φ_{v_2} are disjoint.

1.2. Background and motivation. There are two ways to define multilinear arithmetic circuits—a syntactic definition and a semantic definition—as described above. The semantic definition is a natural one, but the syntactic definition is more convenient to work with. Note, for example, that given an arithmetic circuit Φ, deciding whether Φ is syntactically multilinear is straightforward, whereas it is not clear if one can decide whether Φ is semantically multilinear in deterministic polynomial time. We note also that similar distinctions between semantic and syntactic definitions occur in other places in computer science (e.g., read k-times branching programs).

Multilinear arithmetic circuits were defined by Nisan and Wigderson in [4]. The model of syntactically multilinear arithmetic formulas was defined in [5]. In [5], it is shown that any multilinear arithmetic *formula* computing the determinant (or the permanent) of an $n \times n$ matrix must be of size $n^{\Omega(\log n)}$. Prior to our work, no lower bounds (better than the $\Omega(n \log n)$ lower bound of Strassen and of Baur and Strassen) for the size of syntactically multilinear arithmetic *circuits* were known.

The techniques of [5] for proving superpolynomial lower bounds for the size of multilinear arithmetic formulas fail for circuits. In fact, [6] used these techniques to prove that syntactically multilinear arithmetic circuits are superpolynomially more powerful than multilinear arithmetic formulas. More specifically, there exists a polynomial f such that every multilinear arithmetic formula computing f is of size $n^{\Omega(\log n)}$, and, on the other hand, there exists a polynomial-size syntactically multilinear arithmetic circuit computing f.

Every multilinear polynomial f can be computed by a syntactically multilinear arithmetic circuit Φ, but Φ might not be the smallest arithmetic circuit computing f. However, computing a multilinear polynomial by an arithmetic circuit that is *not* syntactically multilinear is usually less intuitive, as cancellations of monomials are needed.

A syntactically multilinear arithmetic circuit is semantically multilinear as well. However, it is still not known whether there is an efficient way to transform a semantically multilinear arithmetic circuit into a syntactically multilinear circuit. We note that a semantically multilinear arithmetic *formula* can be transformed *without changing its size* into a syntactically multilinear arithmetic formula that computes

the same polynomial (see section 2 in [5]). We do not know of any significant example of a semantically multilinear arithmetic circuit that is *not* syntactically multilinear.

Finally, we note that two known classes of arithmetic circuits are contained in the class of syntactically multilinear arithmetic circuits: Pure arithmetic circuits (as defined by Nisan and Wigderson in [4]; see also [7]) are a restricted type of syntactically multilinear arithmetic circuits. Monotone arithmetic circuits computing a multilinear polynomial are also syntactically multilinear (see [4]).

1.3. Results and methods. Our main result is a construction of an explicit polynomial f such that any syntactically multilinear arithmetic circuit computing f is of size $\Omega(n^{4/3}/\log^2 n)$. Formally, we have the following theorem.

THEOREM 1.1. *Let $f \in \mathbb{F}[X, \Omega]$ be the polynomial defined in section 6, where $\mathbb{F}$ is any field, and X and Ω are two sets of variables of size n each. Let Φ be a syntactically multilinear arithmetic circuit over the field $\mathbb{F}$ and the sets of variables X and Ω computing f. Then,*

$$|\Phi| = \Omega\left(\frac{n^{4/3}}{\log^2 n}\right).$$

The paper has three main parts: section 3 investigates the method of Baur and Strassen for computing all partial derivatives of a polynomial. Section 5, which is the heart of our proof, gives a simple characterization of a polynomial for which our lower bound applies. Section 6 constructs a polynomial for which the lower bound applies.

In [1], Baur and Strassen showed that given an arithmetic circuit Ψ computing a polynomial $f \in \mathbb{F}[X]$, there exists an arithmetic circuit Ψ' computing all the partial derivatives of f, such that $|\Psi'| = O(|\Psi|)$. In section 3, we apply the method of Baur and Strassen for syntactically multilinear arithmetic circuits. We show that if Ψ is syntactically multilinear, then Ψ' is syntactically multilinear as well. Furthermore, every variable $x \in X$ does not occur in the computation of $\frac{\partial f}{\partial x}$ in Ψ'.

In section 5, we use the results of section 3 to show that the rank of the partial derivative matrix of a polynomial computed by a "small" syntactically multilinear arithmetic circuit is not full (see Theorem 5.1). We use techniques that were previously used in [5] and [6] together with some new ideas. In particular, we use the partial derivative method of Nisan and Wigderson and the partial derivative matrix of Nisan. We mainly study the rank of the partial derivative matrix. We also use the notion of unbalanced gates and the notion of partitions of the variables.

In section 6, we construct a multilinear polynomial f such that the rank of the partial derivative matrix of f is full. As in [6], to show that the partial derivative matrix of f has full rank, we think of f as a polynomial over some extension field. We also show that f is explicit in the sense that f is in the class VNP, which is Valiant's algebraic analogue of NP (see section 6.3 for more details).

Our lower bound follows from sections 5 and 6 since the rank of the partial derivative matrix of a polynomial computed by a "small" syntactically multilinear arithmetic circuit is not full, and since the rank of the partial derivative matrix of f, the polynomial defined in section 6, is full, it follows that any syntactically multilinear arithmetic circuit computing f is "large."

2. Preliminaries.

2.1. Notation. For an integer $n \in \mathbb{N}$, denote $[n] = \{1, \ldots, n\}$. For a set $B \subseteq [n]$, denote $\overline{B} = [n] \setminus B$, the complement set of B. Similarly, for a set of variables X, and a set $X' \subseteq X$, denote $\overline{X'} = X \setminus X'$, the complement set of X'. For a polynomial f in

the set of variables X, and a variable $x \in X$, denote by $d_x(f)$ the degree of x in f. We say that x *occurs* in f if $d_x(f) > 0$.

2.2. Arithmetic circuits—some more definitions. Let Φ be an arithmetic circuit over a field $\mathbb{F}$ and a set of variables X. For a variable $x \in X$, we say that x *occurs* in Φ if x labels one of the input gates of Φ. Recall that, for a gate v in Φ, we defined Φ_v to be the subcircuit of Φ rooted at v. For a gate v in Φ, define X_v to be the set of variables that occur in Φ_v. That is,

$$X_v = \begin{cases} \emptyset, & v \text{ is an input gate labeled by a field element,} \\ \{x\}, & v \text{ is an input gate labeled by a variable } x \in X, \\ X_{v_1} \cup X_{v_2}, & v \text{ has sons } v_1 \text{ and } v_2 \end{cases}$$

(if u is a son of v, then $X_u \subseteq X_v$). For a variable $x \in X$ and a gate v in Φ, define $d_x(v)$, the *algebraic degree* of x in v, to be the degree of x in the polynomial $\widehat{\Phi}_v$. For a variable $x \in X$ and a gate v in Φ, define $sd_x(v)$, the *syntactic degree* of x in v, to be the degree of x in v when one ignores cancellations of monomials (in other words, if all the constants in Φ are replaced by 1's, and the field $\mathbb{F}$ is replaced by $\mathbb{R}$, then the syntactic degree of x in v is the algebraic degree of x in v). More precisely, define $sd_x(v)$ inductively as follows: If v is an input gate labeled by $\alpha \in \mathbb{F} \cup X$, then

$$sd_x(v) = \begin{cases} 1, & \alpha = x, \\ 0, & \alpha \neq x. \end{cases}$$

If v is a product gate with sons v_1 and v_2, then $sd_x(v) = sd_x(v_1) + sd_x(v_2)$. If v is an addition gate with sons v_1 and v_2, then $sd_x(v) = \max(sd_x(v_1), sd_x(v_2))$. The syntactic degree is a nondecreasing function, while the algebraic degree can decrease (in addition gates). That is, for every variable $x \in X$ and gates u and v in Φ, if there exists a directed path from u to v in Φ, then $sd_x(u) \leq sd_x(v)$. On the other hand, if v is an addition gate, and u is a son of v, it might be the case that $d_x(u) > d_x(v)$.

An arithmetic circuit Φ is called a *multilinear* arithmetic circuit if the polynomial computed at each gate in Φ is multilinear; that is, if for all $x \in X$ and v in Φ, it holds that $d_x(v) \leq 1$. An arithmetic circuit Φ is called a *syntactically multilinear* arithmetic circuit if, for all $x \in X$ and v in Φ, it holds that $sd_x(v) \leq 1$. By induction, for all $x \in X$ and v in Φ, it holds that $d_x(v) \leq sd_x(v)$. Hence, indeed, every syntactically multilinear arithmetic circuit is a multilinear arithmetic circuit as well.

2.3. Partial derivatives. Let f be a polynomial over the field $\mathbb{F}$ and the set of variables $X = \{x_1, \ldots, x_n\}$. For $i \in [n]$, define $\frac{\partial f}{\partial x_i}$, the *partial derivative of f with respect to x_i*, as follows: If f is a monomial in the variables $X \setminus \{x_i\}$, then $\frac{\partial f}{\partial x_i} = 0$. If f is a monomial of the form $f = x_i^d g$, where d is a positive integer, and g is a monomial in the variables $X \setminus \{x_i\}$, then

$$\frac{\partial f}{\partial x_i} = \frac{\partial (x_i^d g)}{\partial x_i} = \underbrace{(1 + 1 + \cdots + 1)}_{d \text{ times}} x_i^{d-1} g.$$

If f is a sum of monomials $f = \sum_j m_j$, where m_j is a monomial in $\mathbb{F}[X]$, then $\frac{\partial f}{\partial x_i} = \sum_j \frac{\partial m_j}{\partial x_i}$.

The following lemma is known as the *chain rule of partial derivatives* (we state the lemma without giving a proof).

LEMMA 2.1. *Let g be a polynomial over the field $\mathbb{F}$ and the set of variables $X = \{x_1, \ldots, x_n\}$. Let h be a polynomial over the field $\mathbb{F}$ and the set of variables $X \cup \{x_0\}$. Let $f \in \mathbb{F}[X]$ be the polynomial h after substituting x_0 by g; that is, $f = h|_{x_0=g}$. Then, for all $i \in [n]$,*

$$\frac{\partial f}{\partial x_i} = \left.\frac{\partial h}{\partial x_i}\right|_{x_0=g} + \left.\frac{\partial h}{\partial x_0}\right|_{x_0=g} \frac{\partial g}{\partial x_i}.$$

2.4. Multiplication of variables in an arithmetic circuit. Let Ψ be an arithmetic circuit over the field $\mathbb{G}$ and the set of variables $X = \{x_1, \ldots, x_n\}$. For a variable $x_i \in X$ and a product gate v in Ψ with sons v_1 and v_2, define $\mathcal{M}_v(x_i)$, the *set of variables multiplying x_i in v*, by

$$\mathcal{M}_v(x_i) = \begin{cases} \emptyset, & x_i \notin X_{v_1},\ x_i \notin X_{v_2}, \\ X_{v_2}, & x_i \in X_{v_1},\ x_i \notin X_{v_2}, \\ X_{v_1}, & x_i \notin X_{v_1},\ x_i \in X_{v_2}, \\ X_{v_1} \cup X_{v_2}, & x_i \in X_{v_1},\ x_i \in X_{v_2}. \end{cases}$$

For a variable $x_i \in X$, define $\mathcal{M}_\Psi(x_i)$, the *set of variables multiplying x_i in Ψ*, by

$$\mathcal{M}_\Psi(x_i) = \bigcup_v \mathcal{M}_v(x_i),$$

where the union is over all product gates v in Ψ. For two variables $x_i, x_j \in X$, if x_i multiplies x_j in Ψ, then x_j multiplies x_i in Ψ, and vice versa; that is,

$$x_i \in \mathcal{M}_\Psi(x_j) \Leftrightarrow x_j \in \mathcal{M}_\Psi(x_i).$$

Thus, for two variables $x_i, x_j \in X$, we say that x_i and x_j are multiplied in Ψ if $x_i \in \mathcal{M}_\Psi(x_j)$. Note that the following are equivalent:

- Ψ is a syntactically multilinear arithmetic circuit over the set of variables X.
- Ψ is an arithmetic circuit over the set of variables X such that every $x_i \in X$ admits $x_i \notin \mathcal{M}_\Psi(x_i)$.

2.5. The partial derivative matrix. Let $Y = \{y_1, \ldots, y_m\}$ and $Z = \{z_1, \ldots, z_m\}$ be two sets of variables. Let $f \in \mathbb{G}[Y, Z]$ be a multilinear polynomial over the field $\mathbb{G}$ and the variables Y and Z. Define L_f to be the $2^m \times 2^m$ *partial derivative matrix* of f as follows: for $p \in \mathbb{G}(Y)$, a monic[1] multilinear monomial in Y, and $q \in \mathbb{G}(Z)$, a monic multilinear monomial in Z, define $L_f(p, q)$ to be the coefficient of the monomial $p \cdot q$ in f. Thus, the rows of L_f correspond to monic multilinear monomials in Y, and the columns of L_f correspond to monic multilinear monomials in Z. We are mainly interested in the rank of the partial derivative matrix.

The following propositions bound the rank of the partial derivative matrix in different cases.

PROPOSITION 2.2. *Let $f \in \mathbb{G}[Y, Z]$ be a multilinear polynomial over the field $\mathbb{G}$ and the sets of variables $Y' \subseteq Y$ and $Z' \subseteq Z$. Let $a = \min(|Y'|, |Z'|)$. Then,*

$$\mathrm{Rank}(L_f) \leq 2^a.$$

Proof. There are two cases:

[1] A monic monomial is a monomial whose coefficient is 1.

1. If $|Y'| \leq |Z'|$, then $a = |Y'|$. Thus, L_f has at most 2^a nonzero rows.
2. If $|Y'| > |Z'|$, then $a = |Z'|$. Thus, L_f has at most 2^a nonzero columns. ∎

PROPOSITION 2.3. *Let $f_1, f_2 \in \mathbb{G}[Y, Z]$ be two multilinear polynomials over the field $\mathbb{G}$ and the sets of variables Y and Z. Then,*

$$\mathrm{Rank}(L_{f_1+f_2}) \leq \mathrm{Rank}(L_{f_1}) + \mathrm{Rank}(L_{f_2}).$$

Proof. Note that $L_{f_1+f_2} = L_{f_1} + L_{f_2}$. For any two matrices A and B, it holds that $\mathrm{Rank}(A + B) \leq \mathrm{Rank}(A) + \mathrm{Rank}(B)$. Thus,

$$\mathrm{Rank}(L_{f_1+f_2}) \leq \mathrm{Rank}(L_{f_1}) + \mathrm{Rank}(L_{f_2}). \quad ∎$$

PROPOSITION 2.4. *Let $f_1 \in \mathbb{G}[Y, Z]$ be a multilinear polynomial over the field $\mathbb{G}$ and the sets of variables $Y_1 \subseteq Y$ and $Z_1 \subseteq Z$. Let $f_2 \in \mathbb{G}[Y, Z]$ be a multilinear polynomial over the field $\mathbb{G}$ and the sets of variables $Y_2 \subseteq Y$ and $Z_2 \subseteq Z$. Assume that $Y_1 \cap Y_2 = \emptyset$ and $Z_1 \cap Z_2 = \emptyset$. Then,*

$$\mathrm{Rank}(L_{f_1 \cdot f_2}) = \mathrm{Rank}(L_{f_1}) \cdot \mathrm{Rank}(L_{f_2}).$$

Proof. We think of L_{f_1} as a matrix of size $2^{|Y_1|} \times 2^{|Z_1|}$ and not of size $2^{|Y|} \times 2^{|Z|}$ (an entry in L_{f_1} that corresponds to a monomial that is not in the variables Y_1 and Z_1 is zero). Similarly, we think of L_{f_2} as a matrix of size $2^{|Y_2|} \times 2^{|Z_2|}$, and we think of $L_{f_1 \cdot f_2}$ as a matrix of size $2^{|Y_1 \cup Y_2|} \times 2^{|Z_1 \cup Z_2|}$. Since $Y_1 \cap Y_2 = \emptyset$ and $Z_1 \cap Z_2 = \emptyset$,

$$L_{f_1 \cdot f_2} = L_{f_1} \otimes L_{f_2},$$

where $\otimes$ denotes a tensor product of matrices. For any two matrices A and B, it holds that $\mathrm{Rank}(A \otimes B) = \mathrm{Rank}(A) \cdot \mathrm{Rank}(B)$. Thus,

$$\mathrm{Rank}(L_{f_1 \cdot f_2}) = \mathrm{Rank}(L_{f_1}) \cdot \mathrm{Rank}(L_{f_2}). \quad ∎$$

PROPOSITION 2.5. *Let $f \in \mathbb{G}[Y, Z]$ be a multilinear polynomial over the field $\mathbb{G}$ and the sets of variables Y and Z, where $|Y| = |Z| = m$. Let $t \in Y \cup Z$ be a variable, and let $g = \frac{\partial f}{\partial t}$. Assume that $\mathrm{Rank}(L_f) = 2^m$. Then,*

$$\mathrm{Rank}(L_g) = 2^{m-1}.$$

Proof. Assume without loss of generality that $t \in Z$. Assume without loss of generality that the columns of L_f are ordered such that $L_f = (A\ B)$, where A is a $2^m \times 2^{m-1}$ matrix whose columns correspond to all monomials q in which t does not occur, and B is a $2^m \times 2^{m-1}$ matrix whose columns correspond to all monomials q in which t occurs. Since $g = \frac{\partial f}{\partial t}$, we have $L_g = (B\ 0)$ (where 0 is a $2^m \times 2^{m-1}$ matrix of zeros). Since L_f is of full rank, the rank of B is 2^{m-1}. Hence, $\mathrm{Rank}(L_g) = 2^{m-1}$. ∎

PROPOSITION 2.6. *Let $f \in \mathbb{G}[Y, Z]$ be a multilinear polynomial over the field $\mathbb{G}$ and the sets of variables Y and Z, where $|Y| = |Z| = m$. Assume that the total degree of f is at most $T \in \mathbb{N}$. Then,*

$$\mathrm{Rank}(L_f) \leq 2^{(T+1)\log m}.$$

Proof. Since the total degree of f is at most T, there are at most $\sum_{i=0}^{T} \binom{m}{i} \leq 2^{(T+1)\log m}$ nonzero rows in L_f. ∎

2.6. Unbalanced gates. Let Ψ be an arithmetic circuit over the field $\mathbb{G}$ and the variables $Y = \{y_1, \ldots, y_m\}$ and $Z = \{z_1, \ldots, z_m\}$. Let v be a gate in Ψ. Define Y_v to be the set of Y variables that occur in Ψ_v and Z_v to be the set of Z variables that occur in Ψ_v. Define $b(v)$ to be the *average* of $|Y_v|$ and $|Z_v|$; that is, $b(v) = (|Y_v| + |Z_v|)/2$. Define $a(v)$ to be the *minimum* of $|Y_v|$ and $|Z_v|$; that is, $a(v) = \min(|Y_v|, |Z_v|)$. Define $d(v)$, the *balance gauge* of v, by $d(v) = b(v) - a(v)$. For an integer $k \in \mathbb{N}$, the gate v is called *k-unbalanced* if $d(v) \geq k$. Note that if Ψ is a syntactically multilinear arithmetic circuit, and u is a product gate in Ψ with sons u_1 and u_2, then $b(u) = b(u_1) + b(u_2)$.

3. Computing partial derivatives of syntactically multilinear arithmetic circuits. Let f be a polynomial over the field $\mathbb{G}$ and the variables $X = \{x_1, \ldots, x_n\}$. In [1], Baur and Strassen showed that the complexity of computing all n partial derivatives of f is (up to a constant factor) not more than computing f. More precisely, given an arithmetic circuit Ψ computing f, one can construct an arithmetic circuit Ψ' computing $\frac{\partial f}{\partial x_1}, \ldots, \frac{\partial f}{\partial x_n}$ such that $|\Psi'| = O(|\Psi|)$ (moreover, the depth[2] of Ψ' is up to a constant factor the same as the depth of Ψ). Later, Morgenstern [3] simplified the construction of such a Ψ'.

Let Ψ be a *syntactically multilinear* arithmetic circuit over the field $\mathbb{G}$ and the set of variables X computing f. Let Ψ' be the arithmetic circuit computing $\frac{\partial f}{\partial x_1}, \ldots, \frac{\partial f}{\partial x_n}$ (as constructed by Baur and Strassen and Morgenstern). For every $i \in [n]$, denote by v_i the gate computing $\frac{\partial f}{\partial x_i}$ in Ψ'. Since Ψ is a syntactically multilinear arithmetic circuit, f is a multilinear polynomial. Hence, for all $i \in [n]$ the degree of x_i in $\frac{\partial f}{\partial x_i}$ is 0; that is, $d_{x_i}(v_i) = 0$. The next theorem shows the following (in addition to what Baur and Strassen showed):

- Ψ' is a *syntactically* multilinear arithmetic circuit.
- For all $i \in [n]$, the *syntactic* degree of x_i in v_i is 0; that is, $sd_{x_i}(v_i) = 0$. In other words, for all $i \in [n]$ the variable x_i does not occur in Ψ'_{v_i} (recall that Ψ'_{v_i} is the subcircuit of Ψ' rooted at v_i); that is, $x_i \notin X_{v_i}$.

THEOREM 3.1. *Let Ψ be a syntactically multilinear arithmetic circuit over the field $\mathbb{G}$ and the set of variables $X = \{x_1, \ldots, x_n\}$ computing f. Then, there exists an arithmetic circuit Ψ' over the field $\mathbb{G}$ and the set of variables X such that the following hold:*

1. *Ψ' computes all n partial derivatives $\frac{\partial f}{\partial x_1}, \ldots, \frac{\partial f}{\partial x_n}$.*
2. *$|\Psi'| \leq 5\,|\Psi|$.*
3. *Ψ' is a syntactically multilinear arithmetic circuit.*
4. *For every $i \in [n]$, it holds that $x_i \notin X_{v_i}$, where v_i is the gate computing $\frac{\partial f}{\partial x_i}$ in Ψ'.*

We defer the proof of Theorem 3.1 to section 3.1. We do not know if Theorem 3.1 holds for multilinear arithmetic circuits (that are not *syntactically* multilinear).

For the proof of our lower bound (Theorem 1.1) we need the following corollary of Theorem 3.1. The corollary shows that a gate v in Ψ' such that X_v is large (that is, many variables occur in Ψ'_v) is connected by directed paths to few output gates in Ψ' (the output gates of Ψ' are the gates computing $\frac{\partial f}{\partial x_1}, \ldots, \frac{\partial f}{\partial x_n}$).

COROLLARY 3.2. *Let Ψ be a syntactically multilinear arithmetic circuit over the field $\mathbb{G}$ and the set of variables $X = \{x_1, \ldots, x_n\}$ computing f. Let Ψ' be the arithmetic circuit computing $\frac{\partial f}{\partial x_1}, \ldots, \frac{\partial f}{\partial x_n}$, as described in Theorem* 3.1. *For $i \in [n]$,*

[2]The depth of an arithmetic circuit Ψ is the length of the longest directed path in Ψ.

denote by v_i the gate computing $\frac{\partial f}{\partial x_i}$ in Ψ'. Then, for every gate v in Ψ',

$$|X_v| \leq n - \left|\left\{i \in [n] \ : \ v \text{ is a gate in } \Psi'_{v_i}\right\}\right|.$$

Note that $|\{i \in [n] : v \text{ is a gate in } \Psi'_{v_i}\}|$ is the number of output gates that v is connected to by directed paths in Ψ'.

Proof. Let v be a gate in Ψ'. Let $i \in [n]$ be such that there exists a directed path from v to v_i in Ψ'; that is, v is a gate in Ψ'_{v_i}. Thus, $X_v \subseteq X_{v_i}$. By property 4 of Theorem 3.1, $x_i \notin X_{v_i}$. Hence, $x_i \notin X_v$.

Therefore, $X_v \cap \{x_i \in Xv \text{ is a gate in } \Psi'_{v_i}\} = \emptyset$. Thus,

$$\begin{aligned} |X_v| &\leq |X| - \left|\left\{x_i \in X \ : \ v \text{ is a gate in } \Psi'_{v_i}\right\}\right| \\ &= n - \left|\left\{i \in [n] \ : \ v \text{ is a gate in } \Psi'_{v_i}\right\}\right|. \end{aligned}$$ □

3.1. Proof of Theorem 3.1. The following lemma is a generalization of Theorem 3.1.

LEMMA 3.3. *Let Ψ be an arithmetic circuit over the field $\mathbb{G}$ and the set of variables X computing f. Then, there exists an arithmetic circuit Ψ' over the field $\mathbb{G}$ and the set of variables X such that the following hold:*

1. *Ψ' computes all n partial derivatives $\frac{\partial f}{\partial x_1}, \ldots, \frac{\partial f}{\partial x_n}$.*
2. *$|\Psi'| \leq 5\,|\Psi|$.*
3. *For every $i \in [n]$, it holds that $\mathcal{M}_{\Psi'}(x_i) \subseteq \mathcal{M}_{\Psi}(x_i)$.*
4. *For every $i \in [n]$, it holds that $X_{v_i} \subseteq \mathcal{M}_{\Psi}(x_i)$, where v_i is the gate computing $\frac{\partial f}{\partial x_i}$ in Ψ'.*

We defer the proof of Lemma 3.3 to section 3.2. First we give some intuition for Lemma 3.3. Let Ψ be an arithmetic circuit computing f. Let Ψ' be the arithmetic circuit computing all n partial derivatives of f (as constructed by Baur and Strassen, and Morgenstern).

- Properties 1 and 2 of Lemma 3.3 were shown by Baur and Strassen.
- Property 3 of Lemma 3.3 states that if two variables x_i and x_j in X are not multiplied in Ψ, then x_i and x_j are not multiplied in Ψ' either.
- Let $i \in [n]$. Denote by v_i the gate computing $\frac{\partial f}{\partial x_i}$ in Ψ'. Property 4 of Lemma 3.3 states that Ψ'_{v_i} depends only on variables that multiply x_i in Ψ.

Theorem 3.1 follows from Lemma 3.3.

3.2. Proof of Lemma 3.3.

Proof. Let Ψ be an arithmetic circuit over the field $\mathbb{G}$ and the set of variables X computing f. The proof of the lemma is by induction on the size of Ψ. The proof has four parts:

1. Induction base.
2. Using Ψ to define a *smaller* arithmetic circuit Φ. Using induction to conclude the existence of an arithmetic circuit Φ' that has properties 1, 2, 3, and 4.
3. Using Φ' to construct Ψ'.
4. Proving that Ψ' has all the needed properties.

Induction base. Assume that Ψ has no edges; that is, $|\Psi| = 0$. Thus, $f = \alpha$ for some $\alpha \in \mathbb{G} \cup X$. Hence, for all $i \in [n]$, it holds that $\frac{\partial f}{\partial x_i} \in \{0, 1\}$. Define Ψ' to be an arithmetic circuit with two input gates: an input gate labeled 1 and an input gate labeled 0. Then, Ψ' has properties 1, 2, 3, and 4.

Defining a smaller arithmetic circuit Φ. Let r be the gate computing f in Ψ. Assume that r is the unique output gate in Ψ (otherwise, consider Ψ_r). Assume

that Ψ has at least two edges. Let v^* in Ψ be a gate with sons v_1^* and v_2^* such that v_1^* and v_2^* are input gates. Let $\alpha_1 \in \mathbb{G} \cup X$ be the label of v_1^* in Ψ. Let $\alpha_2 \in \mathbb{G} \cup X$ be the label of v_2^* in Ψ. Let x_0 be a new variable associated with the gate v^*, and denote $X^0 = X \cup \{x_0\}$. Let X^* be the set of X variables labeling v_1^* and v_2^* in Ψ; that is, $X^* = \{\alpha_1, \alpha_2\} \cap X = X_{v^*}$. Denote by g the polynomial computed by v^* in Ψ; that is, if v^* is an addition gate in Ψ, then $g = \alpha_1 + \alpha_2$, and if v^* is a product gate in Ψ, then $g = \alpha_1 \cdot \alpha_2$.

If $X^* = \emptyset$, then define a *smaller* arithmetic circuit Φ *computing* f as follows: Φ is obtained from Ψ by deleting the edges (v_1^*, v^*) and (v_2^*, v^*), and labeling v^* (which is an input gate) by $g(\alpha_1, \alpha_2) \in \mathbb{G}$. Thus, Φ computes f, and $|\Phi| < |\Psi|$. By induction, there exists an arithmetic circuit Φ' with properties $1, 2, 3$, and 4. Set Ψ' to be Φ'. Then, Ψ' has properties $1, 2, 3$, and 4, and the proof is complete.

Hence, we can assume that $X^* \neq \emptyset$.

Let Φ be the arithmetic circuit over the field $\mathbb{G}$ and the set of variables X^0 obtained from Ψ by deleting the edges (v_1^*, v^*) and (v_2^*, v^*) and labeling v^* (which is an input gate) by x_0. For every gate v in Ψ there is a corresponding gate $u = u(v)$ in Φ, and vice versa. For a gate v in Ψ, we think of the gate $u = u(v)$ in Φ as the same gate as v.

Let $u(r)$ be the gate corresponding to r in Φ. Set h to be the polynomial computed by $u(r)$ in Φ. Thus, h is a polynomial in the variables X^0. By the construction of Φ, it follows that upon substituting x_0 by g in h we obtain f; that is, $f(X) = h(X^0)|_{x_0=g}$.

Since $|\Phi| = |\Psi| - 2$, it follows by induction that there exists an arithmetic circuit Φ' over the field $\mathbb{G}$ and the set of variables X^0 such that

1. Φ' computes all $n+1$ partial derivatives $\frac{\partial h}{\partial x_0}, \frac{\partial h}{\partial x_1}, \ldots, \frac{\partial h}{\partial x_n}$,
2. $|\Phi'| \leq 5|\Phi|$,
3. for every $j \in \{0, \ldots, n\}$, it holds that $\mathcal{M}_{\Phi'}(x_j) \subseteq \mathcal{M}_{\Phi}(x_j)$, and
4. for every $j \in \{0, \ldots, n\}$, it holds that $X^0_{u_j} \subseteq \mathcal{M}_{\Phi}(x_j)$, where u_j is the gate computing $\frac{\partial h}{\partial x_j}$ in Φ'.

Using Φ' to construct Ψ'. We construct Ψ' by adding a *few* gates and edges to Φ'.

Step 1*: Gates and edges added to* Φ' *to substitute* x_0 *by* g*, constructing* Ψ_1. Assume without loss of generality that in Φ' there is a unique input gate v' labeled x_0 (otherwise, join all input gates labeled x_0 to a single input gate labeled x_0). Denote by Ψ_1 the arithmetic circuit obtained by the following changes to Φ':

- Add two input gates to Φ': an input gate v_1' labeled α_1 and an input gate v_2' labeled α_2.
- Add two edges to Φ': the edge (v_1', v') and the edge (v_2', v').
- Label v' by the same label of v^*.

Thus, Ψ_1 is an arithmetic circuit over the field $\mathbb{G}$ and the set of variables X. Moreover, Ψ_1 is Φ' after substituting x_0 by g. We note that every gate in Φ' can also be thought of as a gate in Ψ_1.

Step 2*: Gates and edges added to* Ψ_1 *to compute* $\frac{\partial f}{\partial x_1}, \ldots, \frac{\partial f}{\partial x_n}$. Fix $i \in [n]$. We describe what gates and edges are added to Ψ_1 in order for Ψ' to compute $\frac{\partial f}{\partial x_i}$. By Lemma 2.1 (the chain rule of partial derivatives), since $f = h|_{x_0=g}$,

$$\frac{\partial f}{\partial x_i} = \left.\frac{\partial h}{\partial x_i}\right|_{x_0=g} + \left.\frac{\partial h}{\partial x_0}\right|_{x_0=g} \frac{\partial g}{\partial x_i}. \tag{3.1}$$

As Ψ_1 is Φ' after substituting x_0 by g, it follows that $\frac{\partial h}{\partial x_i}|_{x_0=g}$ is computed by u_i (as a gate in Ψ_1), and $\frac{\partial h}{\partial x_0}|_{x_0=g}$ is computed by u_0 (as a gate in Ψ_1). Consider the following four cases.

Case 1: $\alpha_1 = x_i$ *and* $\alpha_2 \neq x_i$. Consider the following two cases:

1. If v^* is an addition gate, then $\frac{\partial g}{\partial x_i} = 1$. Hence, by (3.1),

$$\frac{\partial f}{\partial x_i} = \left.\frac{\partial h}{\partial x_i}\right|_{x_0=g} + \left.\frac{\partial h}{\partial x_0}\right|_{x_0=g}.$$

   To construct Ψ' add one gate and two edges as follows: Add an addition gate v_i, and add the edges (u_0, v_i) and (u_i, v_i). Thus, v_i computes $\frac{\partial f}{\partial x_i}$.

2. If v^* is a product gate, then $\frac{\partial g}{\partial x_i} = \alpha_2$. Hence, by (3.1),

$$\frac{\partial f}{\partial x_i} = \left.\frac{\partial h}{\partial x_i}\right|_{x_0=g} + \left.\frac{\partial h}{\partial x_0}\right|_{x_0=g} \alpha_2.$$

   Recall that, v_2' is an input gate labeled α_2 in Ψ_1. To construct Ψ' add two gates and four edges as follows:
   - A product gate w_1 and the edges (u_0, w_1) and (v_2', w_1). Thus, w_1 computes $\frac{\partial h}{\partial x_0}|_{x_0=g}\alpha_2$.
   - An addition gate v_i and the edges (u_i, v_i) and (w_1, v_i).

   Thus, v_i computes $\frac{\partial f}{\partial x_i}$.

Case 2: $\alpha_1 \neq x_i$ *and* $\alpha_2 = x_i$. We do the same as in case 1 (replacing 1 and 2). Note that in this case, when v^* is a product gate, we add a product gate w_2 to Ψ_1.

Case 3: $\alpha_1 = \alpha_2 = x_i$. Consider the following two cases:

1. If v^* is an addition gate, then $\frac{\partial g}{\partial x_i} = 1 + 1$. Hence, by (3.1),

$$\frac{\partial f}{\partial x_i} = \left.\frac{\partial h}{\partial x_i}\right|_{x_0=g} + \left.\frac{\partial h}{\partial x_0}\right|_{x_0=g} (1+1).$$

   To construct Ψ' add three gates and four edges as follows:
   - An input gate w_3 labeled by $1 + 1$.
   - A product gate w_4 and the edges (w_3, w_4) and (u_0, w_4). Thus, w_4 computes $\frac{\partial h}{\partial x_0}|_{x_0=g}(1+1)$.
   - An addition gate v_i and the edges (u_i, v_i) and (w_4, v_i).

   Thus, v_i computes $\frac{\partial f}{\partial x_i}$.

2. If v^* is a product gate, then $\frac{\partial g}{\partial x_i} = (1+1)x_i$. Hence, by (3.1),

$$\frac{\partial f}{\partial x_i} = \left.\frac{\partial h}{\partial x_i}\right|_{x_0=g} + \left.\frac{\partial h}{\partial x_0}\right|_{x_0=g} (1+1)x_i.$$

   Recall that v_2' is an input gate labeled $x_i = \alpha_2$ in Ψ_1. To construct Ψ' add four gates and six edges as follows:
   - An input gate w_3 labeled by $1 + 1$.
   - A product gate w_4 and the edges (w_3, w_4) and (v_2', w_4). Thus, w_4 computes $(1+1)x_i$.
   - A product gate w_5 and the edges (u_0, w_5) and (w_4, w_5). Thus, w_5 computes $\frac{\partial h}{\partial x_0}|_{x_0=g}(1+1)x_i$.
   - An addition gate v_i and the edges (u_i, v_i) and (w_5, v_i).

Thus, v_i computes $\frac{\partial f}{\partial x_i}$.

Case 4: $\alpha_1 \neq x_i$ *and* $\alpha_2 \neq x_i$. In this case no gates or edges are added. As g is a function of α_1 and α_2, it follows that $\frac{\partial g}{\partial x_i} = 0$. Hence, by (3.1), $\frac{\partial f}{\partial x_i} = \frac{\partial h}{\partial x_i}|_{x_0=g}$. Denote by v_i the gate u_i in Ψ'. Thus, v_i computes $\frac{\partial f}{\partial x_i}$.

Ψ' has the needed properties. Let Ψ' be the arithmetic circuit over the field $\mathbb{G}$ and the set of variables X as constructed above. The following claims show that Ψ' has the needed properties. To prove the claims we make use of the following:

- The construction of Φ from Ψ.
- The properties of Φ' (which we know by induction).
- The construction of Ψ' from Φ'.

In some of the proofs there are several cases to consider. Some of the cases are similar, but we consider all the cases for completeness.

The following claim shows that Ψ' satisfies property 1 of Theorem 3.1.

CLAIM 3.4. Ψ' *computes all* n *partial derivatives* $\frac{\partial f}{\partial x_1}, \ldots, \frac{\partial f}{\partial x_n}$.

Proof. Let $i \in [n]$. By the construction of Ψ' there exists a gate v_i in Ψ' computing $\frac{\partial f}{\partial x_i}$. □

The following claim shows that Ψ' satisfies property 2 of Theorem 3.1.

CLAIM 3.5. $|\Psi'| \leq 5|\Psi|$.

Proof. By the construction of Φ from Ψ, it follows that $|\Phi| = |\Psi| - 2$. By induction, $|\Phi'| \leq 5|\Phi|$. By the construction of Ψ' from Φ', there are at most ten more edges in Ψ' than in Φ'; that is, $|\Psi'| \leq |\Phi'| + 10$. Hence,

$$|\Psi'| \leq 5(|\Psi| - 2) + 10 = 5|\Psi|. \qquad \square$$

Let $j \in \{0, \ldots, n\}$. Think of u_j both as the gate computing $\frac{\partial h}{\partial x_j}|_{x_0=g}$ in Ψ' and as the gate computing $\frac{\partial h}{\partial x_j}$ in Φ'. Thus, X_{u_j} is the set of X variables that occur in Ψ'_{u_j}, and $X^0_{u_j}$ is the set of X^0 variables that occur in Φ'_{u_j}. We use the following claim.

CLAIM 3.6.

1. *For every* $i \in [n]$,

$$X_{u_i} \subseteq \mathcal{M}_\Psi(x_i).$$

2. *For every variable* α *in* X^*,

$$X_{u_0} \subseteq \mathcal{M}_\Psi(\alpha).$$

Proof. For every $j \in \{0, \ldots, n\}$, by property 4 of Theorem 3.1 of Φ', $X^0_{u_j} \subseteq \mathcal{M}_\Phi(x_j)$, and by the construction of Ψ',

$$X_{u_j} = \begin{cases} X^0_{u_j}, & x_0 \notin X^0_{u_j}, \\ (X^0_{u_j} \setminus \{x_0\}) \cup X^*, & x_0 \in X^0_{u_j}. \end{cases}$$

Proof of 1: Fix $i \in [n]$. Since every variable that multiplies x_i in Φ except (possibly) x_0 also multiplies x_i in Ψ, it follows that $\mathcal{M}_\Phi(x_i) \setminus \{x_0\} \subseteq \mathcal{M}_\Psi(x_i)$. Thus, since $X^0_{u_i} \subseteq \mathcal{M}_\Phi(x_i)$, it follows that $X^0_{u_i} \setminus \{x_0\} \subseteq \mathcal{M}_\Psi(x_i)$. Consider the following two cases:

1. $x_0 \notin X^0_{u_i}$. Then, $X_{u_i} = X^0_{u_i} = X^0_{u_i} \setminus \{x_0\} \subseteq \mathcal{M}_\Psi(x_i)$.
2. $x_0 \in X^0_{u_i}$. Since $X^0_{u_i} \subseteq \mathcal{M}_\Phi(x_i)$, it follows that x_0 multiplies x_i in Φ; that is, $x_0 \in \mathcal{M}_\Phi(x_i)$. Thus, $X^* \subseteq \mathcal{M}_\Psi(x_i)$. Hence, $X_{u_i} = (X^0_{u_i} \setminus \{x_0\}) \cup X^* \subseteq \mathcal{M}_\Psi(x_i)$.

Proof of 2: Fix $\alpha \in X^*$. Since every variable that multiplies x_0 in Φ except (possibly) x_0 also multiplies α in Ψ, it follows that $\mathcal{M}_\Phi(x_0) \setminus \{x_0\} \subseteq \mathcal{M}_\Psi(\alpha)$. Thus, as $X^0_{u_0} \subseteq \mathcal{M}_\Phi(x_0)$, we have $X^0_{u_0} \setminus \{x_0\} \subseteq \mathcal{M}_\Psi(\alpha)$. Consider the following two cases:

1. $x_0 \notin X^0_{u_0}$. Then, $X_{u_0} = X^0_{u_0} = X^0_{u_0} \setminus \{x_0\} \subseteq \mathcal{M}_\Psi(\alpha)$.
2. $x_0 \in X^0_{u_0}$. Since $X^0_{u_0} \subseteq \mathcal{M}_\Phi(x_0)$, it follows that x_0 multiplies x_0 in Φ; that is, $x_0 \in \mathcal{M}_\Phi(x_0)$. Thus, as $\alpha \in X^*$, we have $X^* \subseteq \mathcal{M}_\Psi(\alpha)$. Hence, $X_{u_0} = (X^0_{u_0} \setminus \{x_0\}) \cup X^* \subseteq \mathcal{M}_\Psi(\alpha)$. □

The following claim shows that Ψ' satisfies property 3 of Theorem 3.1.

CLAIM 3.7. *For all $i \in [n]$, it holds that $\mathcal{M}_{\Psi'}(x_i) \subseteq \mathcal{M}_\Psi(x_i)$.*

Proof. Let $i, j \in [n]$ be such that x_i and x_j are multiplied in Ψ'; that is, $x_i \in \mathcal{M}_{\Psi'}(x_j)$. To prove the claim it is enough to show that $x_i \in \mathcal{M}_\Psi(x_j)$. By property 3 of Theorem 3.1 of Φ', for all $\ell \in \{0, \ldots, n\}$,

$$\mathcal{M}_{\Phi'}(x_\ell) \subseteq \mathcal{M}_\Phi(x_\ell).$$

Recall that X^* is the set of X variables that occur in Ψ_{v^*}. Consider two cases.

x_i and x_j are not in X^*. Assume that $x_i \notin X^*$ and $x_j \notin X^*$. Thus, as $x_i \in \mathcal{M}_{\Psi'}(x_j)$ and by the construction of Ψ', it follows that x_i and x_j are multiplied in Φ'; that is, $x_i \in \mathcal{M}_{\Phi'}(x_j)$. Thus, since $\mathcal{M}_{\Phi'}(x_j) \subseteq \mathcal{M}_\Phi(x_j)$, it follows that x_i and x_j are multiplied in Φ; that is, $x_i \in \mathcal{M}_\Phi(x_j)$. Hence, by the construction of Φ (as $x_i \neq x_0$ and $x_j \neq x_0$), it follows that x_i and x_j are multiplied in Ψ; that is, $x_i \in \mathcal{M}_\Psi(x_j)$.

At least one of x_i and x_j is in X^*. Assume without loss of generality that $x_j = \alpha_1$ (recall that $x_i \in \mathcal{M}_\Psi(x_j) \Leftrightarrow x_j \in \mathcal{M}_\Psi(x_i)$. Similar arguments hold for $x_j = \alpha_2$). Let v be a gate in Ψ' in which x_i and $x_j = \alpha_1$ are multiplied; that is, $x_i \in \mathcal{M}_v(\alpha_1)$. In the following we think of u_0 as the gate computing $\frac{\partial h}{\partial x_0}|_{x_0=g}$ in Ψ'. Consider the following cases.

Case 1. v is v'. Since $v = v'$ is a product gate in Ψ', we have that v^* is a product gate in Ψ. Since v' and v^* are the "same" gate, $\mathcal{M}_{v'}(\alpha_1) = \mathcal{M}_{v^*}(\alpha_1)$. Thus, $x_i \in \mathcal{M}_{v'}(\alpha_1) = \mathcal{M}_{v^*}(\alpha_1) \subseteq \mathcal{M}_\Psi(\alpha_1)$.

Case 2. v is w_1. Recall that w_1 is the product gate added to Ψ_1 in order for Ψ' to compute $\frac{\partial f}{\partial \alpha_1}$. The two sons of v in Ψ' are u_0 and v'_2. Since w_1 is added only if $\alpha_1 \neq \alpha_2$, it follows that $\mathcal{M}_v(\alpha_1) \subseteq X_{v'_2} \subseteq \{\alpha_2\}$. Thus, $x_i = \alpha_2$. Hence, since w_1 is added only if v^* is a product gate (that multiplies α_1 and α_2) in Ψ, $x_i = \alpha_2 \in \mathcal{M}_{v^*}(\alpha_1) \subseteq \mathcal{M}_\Psi(\alpha_1)$.

Case 3. v is w_2. Recall that w_2 is the product gate added to Ψ_1 in order for Ψ' to compute $\frac{\partial f}{\partial \alpha_2}$. The two sons of v in Ψ' are u_0 and v'_1, and v computes $\frac{\partial h}{\partial x_0}|_{x_0=g}\alpha_1$. By definition of $\mathcal{M}_v(\alpha_1)$,

$$\mathcal{M}_v(\alpha_1) = \begin{cases} X_{u_0}, & \alpha_1 \notin X_{u_0}, \\ \{\alpha_1\} \cup X_{u_0}, & \alpha_1 \in X_{u_0}. \end{cases}$$

Thus, $\mathcal{M}_v(\alpha_1) = X_{u_0}$. Hence, by Claim 3.6,

$$x_i \in X_{u_0} \subseteq \mathcal{M}_\Psi(\alpha_1).$$

Case 4. v is w_4. Recall that w_4 is added to Ψ_1 in the case that $\alpha_1 = \alpha_2$. Since one of v's sons is an input gate labeled by a field element, $\mathcal{M}_v(\alpha_1) = \emptyset$. Hence, this case cannot happen.

Case 5. v is w_5. Recall that w_5 is the product gate added to Ψ_1 in order for Ψ' to compute $\frac{\partial f}{\partial \alpha_1}$ (when $\alpha_1 = \alpha_2$). Thus, v computes $\frac{\partial h}{\partial x_0}|_{x_0=g}(1+1)\alpha_1$. By definition

of $\mathcal{M}_v(\alpha_1)$,

$$\mathcal{M}_v(\alpha_1) = \begin{cases} X_{u_0}, & \alpha_1 \notin X_{u_0}, \\ \{\alpha_1\} \cup X_{u_0}, & \alpha_1 \in X_{u_0}. \end{cases}$$

Thus, $\mathcal{M}_v(\alpha_1) = X_{u_0}$. Hence, by Claim 3.6,

$$x_i \in X_{u_0} \subseteq \mathcal{M}_\Psi(\alpha_1).$$

Case 6. v is also a product gate in Φ'. There are two cases to consider:

1. If $x_i \notin \mathcal{M}_{\Phi'}(\alpha_1)$, then as $x_i \in \mathcal{M}_{\Psi'}(\alpha_1)$, it holds that $x_i \in \mathcal{M}_{\Phi'}(x_0)$. Hence, as $\mathcal{M}_{\Phi'}(x_0) \subseteq \mathcal{M}_\Phi(x_0)$, it follows that $x_i \in \mathcal{M}_\Phi(x_0)$. Since every variable that multiplies x_0 except (possibly) x_0 in Φ also multiplies α_1 in Ψ, we have $\mathcal{M}_\Phi(x_0) \setminus \{x_0\} \subseteq \mathcal{M}_\Psi(\alpha_1)$. Hence, as $x_i \neq x_0$,
$$x_i \in \mathcal{M}_\Psi(\alpha_1).$$
2. If $x_i \in \mathcal{M}_{\Phi'}(\alpha_1)$, then $x_i \in \mathcal{M}_{\Phi'}(\alpha_1) \subseteq \mathcal{M}_\Phi(\alpha_1)$. Since every variable that multiplies α_1 in Φ except (possibly) x_0 also multiplies α_1 in Ψ, it follows that $\mathcal{M}_\Phi(\alpha_1) \setminus \{x_0\} \subseteq \mathcal{M}_\Psi(\alpha_1)$. Thus, as $x_i \neq x_0$,
$$x_i \in \mathcal{M}_\Psi(\alpha_1). \qquad \square$$

The following claim shows that Ψ' satisfies property 4 of Theorem 3.1.

CLAIM 3.8. *For all $i \in [n]$, it holds that $X_{v_i} \subseteq \mathcal{M}_\Psi(x_i)$.*

Proof. Fix $i \in [n]$. For simplicity of notation, denote $v = v_i, u = u_i$, and $u' = u_0$. We think of u and u' both as gates in Φ' and as gates in Ψ'. By the construction of Ψ', we have to consider the following cases.

Case 1: $\alpha_1 = x_i$ *or* $\alpha_2 = x_i$. Note that this case applies both for $\alpha_1 = \alpha_2$ and $\alpha_1 \neq \alpha_2$. Assume without loss of generality that $\alpha_1 = x_i$. Consider the following two cases.

v^* is an addition gate in Ψ. Since u and u' are the sons of v in Ψ', it follows that $X_v = X_u \cup X_{u'}$. By Claim 3.6, it follows that $X_u \subseteq \mathcal{M}_\Psi(x_i)$ and $X_{u'} \subseteq \mathcal{M}_\Psi(\alpha_1) = \mathcal{M}_\Psi(x_i)$. Hence,

$$X_v \subseteq \mathcal{M}_\Psi(x_i).$$

v^* is a product gate. By the construction of Ψ' (loosely speaking, the sons of v in Ψ' are u, u', and v'_2), it follows that $X_v = X_u \cup X_{u'} \cup X_{v'_2}$. As v^* is a product gate in Ψ (v^* multiplies $x_i = \alpha_1$ and α_2), it follows that $X_{v'_2} \subseteq \mathcal{M}_\Psi(x_i)$. By Claim 3.6, it follows that $X_u \subseteq \mathcal{M}_\Psi(x_i)$ and $X_{u'} \subseteq \mathcal{M}_\Psi(\alpha_1) = \mathcal{M}_\Psi(x_i)$. Hence,

$$X_v \subseteq \mathcal{M}_\Psi(x_i).$$

Case 2: $\alpha_1 \neq x_i$ *and* $\alpha_2 \neq x_i$. By the construction of Ψ', it follows that $X_v = X_u$. By Claim 3.6, it follows that $X_u \subseteq \mathcal{M}_\Psi(x_i)$. Hence,

$$X_v \subseteq \mathcal{M}_\Psi(x_i). \qquad \square$$

Thus, Ψ' is an arithmetic circuit over the field $\mathbb{G}$ and the set of variables X such that the following hold:

1. By Claim 3.4, Ψ' computes all n partial derivatives $\frac{\partial f}{\partial x_1}, \ldots, \frac{\partial f}{\partial x_n}$.
2. By Claim 3.5, $|\Psi'| \leq 5 \cdot |\Psi|$.
3. By Claim 3.7, for every $i \in [n]$, it holds that $\mathcal{M}_{\Psi'}(x_i) \subseteq \mathcal{M}_\Psi(x_i)$.
4. By Claim 3.8, for every $i \in [n]$, it holds that $X_{v_i} \subseteq \mathcal{M}_\Psi(x_i)$. $\square$

4. Partitions of the variables of an arithmetic circuit. In this section we define a distribution $\mathcal{D}$ on partitions of the variables of an arithmetic circuit. We show that by the distribution $\mathcal{D}$, a specific gate is unbalanced with high probability.

4.1. Definitions. Let $X = \{x_1, \ldots, x_n\}$, $Y = \{y_1, \ldots, y_m\}$, and $Z = \{z_1, \ldots, z_m\}$ be three sets of variables (where $n = 2m$). A one-to-one function $A : X \to Y \cup Z$ is called a *partition* of X to Y and Z. For a partition A of X to Y and Z and $X' \subseteq X$ a subset of X, denote $A(X') = \{A(x) \ : \ x \in X'\}$.

Let $X_1 \subset X$ be a subset of X of size $n/4$. The distribution $\mathcal{D}(X_1)$ on partitions A of X to Y and Z is the uniform distribution on all partitions A such that $A(X_1) \subset Y$. We write $A \sim \mathcal{D}(X_1)$ if A is a partition of X to Y and Z chosen by the distribution $\mathcal{D}(X_1)$.

Let Ψ be an arithmetic circuit over the field $\mathbb{G}$ and the set of variables X computing a polynomial f. Let A be a partition of X to Y and Z. Denote by Ψ_A the arithmetic circuit Ψ after substituting every $x \in X$ by $A(x) \in Y \cup Z$. Denote by f^A the polynomial f after substituting every $x \in X$ by $A(x) \in Y \cup Z$. Note that Ψ_A is an arithmetic circuit over the field $\mathbb{G}$ and the sets of variables Y and Z computing f^A. For every gate in Ψ there is a corresponding gate in Ψ_A, and vice versa. We think of a gate v in Ψ and v's corresponding gate in Ψ_A as the same gate, and we denote both of them by v.

4.2. The probability that a gate is unbalanced. The following proposition bounds the probability that a gate (with a certain number of variables) is unbalanced.

PROPOSITION 4.1. *Let Ψ be an arithmetic circuit over the field $\mathbb{G}$ and the set of variables $X = \{x_1, \ldots, x_n\}$. Let $Y = \{y_1, \ldots, y_m\}$ and $Z = \{z_1, \ldots, z_m\}$ be two sets of variables (where $n = 2m$ and m is even). Let $X_1 \subset X$ be a subset of X of size $n/4$. Let $A \sim \mathcal{D}(X_1)$ be a random partition of X to Y and Z such that $A(X_1) \subset Y$. Let β be such that $0 < \beta < 1$, and let v be a gate in Ψ such that $n^\beta < |X_v| < n - n^\beta$. Then, for any integer $k \in \mathbb{N}$,*

$$\Pr_{A \sim \mathcal{D}(X_1)}[v \text{ is not } k\text{-unbalanced in } \Psi_A] = O\left(kn^{-\beta/2}\right).$$

To prove Proposition 4.1 we need some property of the hypergeometric distribution. We defer the proof of Proposition 4.1 to section 4.4.

4.3. The hypergeometric distribution. Let $N, M_1, M_2 \in \mathbb{N}$ be three integers such that $M_1 \leq N$ and $M_2 \leq N$. Denote by $\mathcal{H}(N, M_1, M_2)$ the hypergeometric distribution with parameters M_1, M_2, and N; that is, $\mathcal{H}(N, M_1, M_2)$ is the distribution of $|S_1 \cap S_2|$, where S_1 is a random subset of $[N]$ of size M_1 (chosen uniformly at random from all subsets of $[N]$ of size M_1), and S_2 is a fixed subset of $[N]$ of size M_2.

The following proposition shows that a hypergeometric random variable does not take any specific value with high probability (for a certain range of the parameters).

PROPOSITION 4.2. *Let $n \in \mathbb{N}$ be an integer such that $n/4$ is an integer as well. Let β be such that $0 < \beta < 1$, and let χ be a random variable that has the hypergeometric distribution $\mathcal{H}(3n/4, n/4, M)$, where*

$$n^\beta/4 < M < 3n/4 - n^\beta/4. \tag{4.1}$$

Then, every $j \in \mathbb{N}$ admits $\Pr[\chi = j] = O(n^{-\beta/2})$.

Proof. Denote $j_{\max} = \min(M, n/4)$ the maximal value that χ takes. For every

$j \in \mathbb{N}$, denote $P(j) = \Pr[\chi = j]$. Thus, for every $j \in \{0, \ldots, j_{\max}\}$, we have

$$P(j) = \frac{\binom{M}{j}\binom{3n/4-M}{n/4-j}}{\binom{3n/4}{n/4}}, \tag{4.2}$$

and for every $j \notin \{0, \ldots, j_{\max}\}$, we have $P(j) = 0$. Set $j^* \in \{0, \ldots, j_{\max}\}$ to be the integer that maximizes $P(j)$; that is, every $j \in \mathbb{N}$ admits $P(j) \leq P(j^*)$. To find j^* consider $P(j+1)/P(j)$. By (4.2), for all $j \in \{0, \ldots, j_{\max} - 1\}$,

$$\frac{P(j+1)}{P(j)} = \frac{(M-j)(n/4-j)}{(j+1)(n/2-M+j+1)},$$

which implies that

$$P(j) \leq P(j+1) \Leftrightarrow j \leq \frac{Mn/4 + M - n/2 - 1}{3n/4+2} = \frac{M}{3} + \frac{M - 3n/2 - 3}{3(3n/4+2)}.$$

Since $0 < M < 3n/4$, we have $-1 < (M - 3n/2 - 3)/(3(3n/4+2)) < 0$. Thus, $j^* \in \{\lfloor M/3 \rfloor, \lceil M/3 \rceil\}$.

Using Stirling's formula, we have

$$\binom{N}{\lfloor N/3 \rfloor} = \Theta\left(\frac{1}{\sqrt{N}} 2^{N \cdot H(1/3)}\right) \text{ and } \binom{N}{\lceil N/3 \rceil} = \Theta\left(\frac{1}{\sqrt{N}} 2^{N \cdot H(1/3)}\right), \tag{4.3}$$

where $H(1/3) = -(1/3)\log_2(1/3) - (2/3)\log_2(2/3)$. Hence, by (4.2), using (4.3) for N equals $M, 3n/4 - M$, and $3n/4$,

$$\begin{aligned} P(j^*) &= \frac{\Theta\left(\frac{1}{\sqrt{M}} 2^{M \cdot H(1/3)}\right) \Theta\left(\frac{1}{\sqrt{3n/4-M}} 2^{(3n/4-M) \cdot H(1/3)}\right)}{\Theta\left(\frac{1}{\sqrt{3n/4}} 2^{(3n/4) \cdot H(1/3)}\right)} \\ &= \Theta\left(\frac{\sqrt{3n/4}}{\sqrt{M}\sqrt{3n/4-M}}\right) = \Theta\left(n^{-\beta/2}\right), \end{aligned}$$

where the last equality follows from (4.1). Hence, every $j \in \mathbb{N}$ admits $P(j) \leq P(j^*) = O(n^{-\beta/2})$. ∎

4.4. Proof of Proposition 4.1.

Proof. If $k > n^\beta/4$, then the proposition holds (as $kn^{-\beta/2} > 1$). Thus, assume that $k \leq n^\beta/4$. Let $A \sim \mathcal{D}(X_1)$ be a random partition of X to Y and Z such that $A(X_1) \subset Y$. By the definition of $\mathcal{D}(X_1)$, we think of A as obtained by the following randomized process: let X_2 be a random subset of $\overline{X_1} = X \setminus X_1$ of size $n/4$; then let A be a random partition such that $A(X_1 \cup X_2) = Y$. Recall that Y_v is the set of Y variables that occur in the subcircuit of Ψ_A rooted at v. Thus, $|Y_v| = |X_v \cap X_1| + |X_v \cap X_2|$. Hence,

$$|X_v \cap X_1| \leq |Y_v| \leq |X_v \cap X_1| + n/4.$$

There are three cases to consider. In the first two cases X_v either has small intersection with $\overline{X_1}$ or has large intersection with $\overline{X_1}$, and then v is always unbalanced. In the third case we use Proposition 4.2 to show that v is unbalanced with high probability.

Case 1. Assume $\left|X_v \cap \overline{X_1}\right| \leq n^\beta/4$. Then, $|X_v| = \left|X_v \cap \overline{X_1}\right| + |X_v \cap X_1| \leq n^\beta/4 + |X_v \cap X_1|$. Thus, since $|X_v| \geq n^\beta$, it follows that $|Y_v| \geq |X_v \cap X_1| \geq |X_v| - n^\beta/4 \geq |X_v|/2 + n^\beta/4$. Hence, $a(v) \leq |Z_v| = |X_v| - |Y_v| \leq |X_v|/2 - n^\beta/4$. Thus, $d(v) = |X_v|/2 - a(v) \geq n^\beta/4$. Therefore, since $k \leq n^\beta/4$, it follows that v is not k-unbalanced in Ψ_A with probability 0.

Case 2. Assume $\left|X_v \cap \overline{X_1}\right| \geq 3n/4 - n^\beta/4$. Then, $|X_v| = \left|X_v \cap \overline{X_1}\right| + |X_v \cap X_1| \geq 3n/4 - n^\beta/4 + |X_v \cap X_1|$. Hence, $a(v) \leq |Y_v| \leq |X_v \cap X_1| + n/4 \leq |X_v| - n/2 + n^\beta/4$. Thus, since $|X_v| \leq n - n^\beta$, it follows that $d(v) = |X_v|/2 - a(v) \geq -|X_v|/2 + n/2 - n^\beta/4 \geq n^\beta/4$. Thus, since $k \leq n^\beta/4$, it follows that v is not k-unbalanced in Ψ_A with probability 0.

Case 3. Assume

$$n^\beta/4 < \left|X_v \cap \overline{X_1}\right| < 3n/4 - n^\beta/4. \tag{4.4}$$

Denote $Y_1 = X_v \cap X_1$ and $Y_2 = X_v \cap X_2$. Thus, $|Y_v| = |Y_1| + |Y_2|$. Note that Y_1 is a fixed subset of X, and $|Y_2|$ has the hypergeometric distribution $\mathcal{H}(|\overline{X_1}|, n/4, |X_v \cap \overline{X_1}|)$. Thus, by (4.4) and Proposition 4.2, $|Y_2|$ takes any specific value with probability $O(n^{-\beta/2})$. Denote $\mu = |X_v|/2$. Hence,

$$\begin{aligned}
\Pr_{A \sim \mathcal{D}(X_1)}[v \text{ is not } k\text{-unbalanced in } \Psi_A] &\leq \Pr_{A \sim \mathcal{D}(X_1)}[\mu - k \leq |Y_v| \leq \mu + k] \\
&\leq \sum_{j=\lfloor \mu - k \rfloor}^{\lceil \mu + k \rceil} \Pr_{A \sim \mathcal{D}(X_1)}[|Y_v| = j] \\
&= O\left(k n^{-\beta/2}\right). \qquad \square
\end{aligned}$$

5. Small syntactically multilinear arithmetic circuits compute polynomials of low rank. In this section we prove that a small syntactically multilinear arithmetic circuit computes a polynomial whose partial derivative matrix is not of full rank (for some partition of the variables). Formally, we have the following theorem.

THEOREM 5.1. *Let Ψ be a syntactically multilinear arithmetic circuit over the field $\mathbb{G}$ and the set of variables $X = \{x_1, \ldots, x_n\}$ computing f. Let $Y = \{y_1, \ldots, y_m\}$ and $Z = \{z_1, \ldots, z_m\}$ be two sets of variables (where $n = 2m$ and m is even). If for all partitions A of X to Y and Z*

$$\operatorname{Rank}\left(L_{f^A}\right) = 2^m,$$

then

$$|\Psi| = \Omega\left(\frac{n^{4/3}}{\log^2 n}\right).$$

The rest of this section is devoted for the proof of Theorem 5.1. In section 5.1 we introduce the notion of leveled gates and state a lemma. In section 5.2 we use the lemma to prove Theorem 5.1.

5.1. Few leveled gates means low rank. Let Φ be a syntactically multilinear arithmetic circuit over the field $\mathbb{G}$ and the variables $X = \{x_1, \ldots, x_n\}$. Fix $\tau = 3 \log n$. Define $\mathcal{L}(\Phi, \tau)$, the set of *lower leveled* gates in Φ, as $\mathcal{L}(\Phi, \tau)$, the set of all gates u in Φ, such that $2\tau < |X_u| < n - 2\tau$, and u has a father u' such that $|X_{u'}| \geq n - 2\tau$.

The following lemma shows that, if the set of lower leveled gates in a circuit is small, then the partial derivative matrix of a polynomial computed by the circuit is not of full rank (for some partition of the variables).

LEMMA 5.2. *Let Φ be a syntactically multilinear arithmetic circuit over the field $\mathbb{G}$ and the set of variables $X = \{x_1, \ldots, x_n\}$ computing f. Let $Y = \{y_1, \ldots, y_m\}$ and $Z = \{z_1, \ldots, z_m\}$ be two sets of variables (where $n = 2m$ and m is even). Let $\tau = 3 \log n$, and let $\mathcal{L} = \mathcal{L}(\Phi, \tau)$ be the set of lower leveled gates in Φ (as defined above). Let $c > 0$ be a small enough constant ($c = 1/1000$ suffices). Assume $|\mathcal{L}| < \frac{c}{\tau} n^{1/3}$. Then, there exists a partition A of X to Y and Z such that*

$$\operatorname{rank}(L_{f^A}) < 2^{m-1}.$$

We defer the proof of Lemma 5.2 to section 5.4. We use Lemma 5.2 to prove Theorem 5.1.

5.2. Proof of Theorem 5.1.

Proof. Let Ψ' be the arithmetic circuit computing all n partial derivatives of f given by Theorem 3.1. Let $\tau = 3 \log n$, and let $\mathcal{L} = \mathcal{L}(\Psi', \tau)$ be the set of lower leveled gates in Ψ' (as defined in section 5.1). Define $\mathcal{U} = \mathcal{U}(\Psi', \tau)$, the set of *upper leveled* gates in Ψ', by

$$\mathcal{U} = \{u' \text{ is a gate in } \Psi' \ : \ n - 2\tau \leq |X_{u'}| \text{ and } u' \text{ has a son } u \text{ such that } u \in \mathcal{L}\}.$$

To prove the theorem, we will bound from below the size of $\mathcal{U}$.

Let $i \in [n]$. Set $g_i = \frac{\partial f}{\partial x_i}$. Let v_i be the gate computing g_i in Ψ'. Denote by Ψ'_i the arithmetic circuit Ψ'_{v_i}. Define $\mathcal{L}_i = \mathcal{L}(\Psi'_i, \tau)$ to be the set of lower leveled gates in Ψ'_i. The following claim gives two properties of $\mathcal{L}_i$.

CLAIM 5.3. *For every $i \in [n]$,*

1. $\mathcal{L}_i \subseteq \mathcal{L}$.
2. $|\mathcal{L}_i| \geq \frac{c}{\tau} n^{1/3}$, *where c is the constant from Lemma* 5.2.

Proof. Proof of 1: Note that for every gate u in Ψ'_i, the set X_u in Ψ' and in Ψ'_i is the same set. Let $u \in \mathcal{L}_i$. Thus, $2\tau < |X_u| < n - 2\tau$ and u has a father u' in Ψ'_i such that $|X_{u'}| \geq n - 2\tau$. Since u' is a father of u in Ψ', we have $u \in \mathcal{L}$. Hence, $\mathcal{L}_i \subseteq \mathcal{L}$.

Proof of 2: For every partition A of X to Y and Z, we have $g_i^A = (\frac{\partial f}{\partial x_i})^A = \frac{\partial f^A}{\partial A(x_i)}$, which implies using Proposition 2.5 (since L_{f^A} is of full rank) that $\operatorname{Rank}(L_{g_i^A}) = 2^{m-1}$. Hence, by Lemma 5.2, since Ψ'_i computes g_i, $|\mathcal{L}_i| \geq \frac{c}{\tau} n^{1/3}$, where c is the constant from Lemma 5.2. ∎

For a gate v in Ψ', define

$$C_v = |\{i \in [n] \ : \ v \text{ is a gate in } \Psi'_i\}|.$$

For $i \in [n]$, define

$$\mathcal{U}_i = \{u' \in \mathcal{U} \ : \ u' \text{ is a gate in } \Psi'_i\}.$$

Thus, for all $i \in [n]$, we have $\mathcal{U}_i \subseteq \mathcal{U}$. Hence,

$$\sum_{i \in [n]} |\mathcal{U}_i| = |\{(u', i) \ : \ u' \in \mathcal{U} \text{ and } i \in [n] \text{ are such that } u' \text{ is a gate in } \Psi'_i\}|$$

$$= \sum_{u' \in \mathcal{U}} C_{u'}. \tag{5.1}$$

Let $i \in [n]$. By property 1 of Claim 5.3, $\mathcal{L}_i \subseteq \mathcal{L}$. Hence, for every gate $u \in \mathcal{L}_i$, there is a corresponding gate $u' \in \mathcal{U}_i$, which is a father of u. Thus, since the in-degree of the gates in $\mathcal{U}_i$ is 2, we have

$$|\mathcal{L}_i| \leq 2|\mathcal{U}_i|. \tag{5.2}$$

Recall that, for all $u' \in \mathcal{U}$, it holds that $|X_{u'}| \geq n - 2\tau$. Thus, by Corollary 3.2, every $u' \in \mathcal{U}$ admits $C_{u'} \leq n - |X_{u'}| \leq n - (n - 2\tau) = 2\tau$. Thus, by (5.2), (5.1), and property 2 of Claim 5.3,

$$\frac{c}{\tau} n^{4/3} \leq \sum_{i \in [n]} |\mathcal{L}_i| \leq 2 \sum_{i \in [n]} |\mathcal{U}_i| = 2 \sum_{u' \in \mathcal{U}} C_{u'} \leq 2|\mathcal{U}| \cdot 2\tau.$$

Hence, by property 2 of Theorem 3.1, since $\tau = 3 \log n$,

$$|\Psi| = \Omega\left(|\Psi'|\right) = \Omega\left(|\mathcal{U}|\right) = \Omega\left(\frac{n^{4/3}}{\log^2 n}\right). \qquad \square$$

5.3. Unbalancing the lower leveled gates of a small arithmetic circuit. In the rest of this section we prove Lemma 5.2. First we prove that the set of lower leveled gates in a small arithmetic circuit can be made simultaneously unbalanced.

PROPOSITION 5.4. *Under the same assumptions as in Lemma* 5.2*, there exists a partition A of X to Y and Z such that every $u \in \mathcal{L}$ is τ-unbalanced in Φ_A.*

Proof. For a gate v in Φ define $\tilde{X}_v$ by

$$\tilde{X}_v = \begin{cases} X_v, & |X_v| \leq n/2, \\ X \setminus X_v, & |X_v| > n/2. \end{cases}$$

Every partition A of X to Y and Z defines a partition of $\tilde{X}_v$ to $\tilde{Y}_v$ and $\tilde{Z}_v$:

$$\tilde{Y}_v = \left\{ y \in Y \ : \ A^{-1}(y) \in \tilde{X}_v \right\} \text{ and } \tilde{Z}_v = \left\{ z \in Z \ : \ A^{-1}(z) \in \tilde{X}_v \right\}.$$

For every partition A of X to Y and Z and for every gate v in Φ_A,

$$d(v) = \frac{|Y_v| + |Z_v|}{2} - \min(|Y_v|, |Z_v|) = \frac{|\tilde{Y}_v| + |\tilde{Z}_v|}{2} - \min(|\tilde{Y}_v|, |\tilde{Z}_v|),$$

which implies that

$$v \text{ is } \tau\text{-unbalanced in } \Phi_A \Leftrightarrow \frac{|\tilde{Y}_v| + |\tilde{Z}_v|}{2} - \min(|\tilde{Y}_v|, |\tilde{Z}_v|) \geq \tau. \tag{5.3}$$

Partition $\mathcal{L}$ into two sets:

$$\mathcal{L}_{small} = \left\{ v \in \mathcal{L} \ : \ |\tilde{X}_v| \leq n^{2/3} \right\}, \quad \mathcal{L}_{big} = \mathcal{L} \setminus \mathcal{L}_{small} = \left\{ v \in \mathcal{L} \ : \ |\tilde{X}_v| > n^{2/3} \right\}.$$

For all $u \in \mathcal{L}_{small}$, it holds that $|\tilde{X}_u| \leq n^{2/3}$. Define $X'_1 = \bigcup_{u \in \mathcal{L}_{small}} \tilde{X}_u$. Since $|\mathcal{L}| < \frac{c}{\tau} n^{1/3}$, it follows that $|X'_1| \leq \frac{c}{\tau} n^{1/3} n^{2/3} < n/4$. Hence, there exists a set $X_1 \subseteq X$ of size $n/4$ such that, for all $u \in \mathcal{L}_{small}$, we have $\tilde{X}_u \subseteq X_1$ (X_1 is some superset of X'_1 of size $n/4$). Let $A \sim \mathcal{D}(X_1)$ be a random partition of X to Y and Z such that $A(X_1) \subset Y$ (see section 4 for the definition of $\mathcal{D}(X_1)$).

For all $u \in \mathcal{L}_{small}$, it holds that $|\tilde{Y}_u| + |\tilde{Z}_u| = |\tilde{X}_u| \geq 2\tau$ and $\tilde{Z}_u = \emptyset$ (as $A(\tilde{X}_u) \subseteq A(X_1) \subset Y$). Thus, by (5.3), every $u \in \mathcal{L}_{small}$ is τ-unbalanced in Φ_A (with probability 1). Note that every $u \in \mathcal{L}_{big}$ admits $n^{2/3} < |X_u| < n - n^{2/3}$. Thus, by Proposition 4.1 for $\beta = 2/3$, and since $|\mathcal{L}| < \frac{c}{\tau} n^{1/3}$,

$$\mathop{\mathbb{E}}_{A \sim \mathcal{D}(X_1)} \left[|\{ u \in \mathcal{L} \ : \ u \text{ is not } \tau\text{-unbalanced in } \Phi_A \}| \right] \leq O\left(|\mathcal{L}_{big}| \tau n^{-1/3} \right) < 1$$

(for c small enough). Hence, there exists a partition A such that every $u \in \mathcal{L}$ is τ-unbalanced in Φ_A. $\square$

5.4. Proof of Lemma 5.2.

Proof. Let r be a gate computing f in Φ. Assume $|X_r| < n-2$. Let A be a partition of X to Y and Z. Thus, in Φ_A we have $a(r) \leq b(r) < m-1$. Hence, by Proposition 2.2, $\mathrm{Rank}(L_{f^A}) < 2^{m-1}$, which proves the lemma. Thus, assume $|X_r| \geq n-2$.

Since $|\mathcal{L}| < \frac{c}{\tau} n^{1/3}$, by Proposition 5.4 there exists a partition A of X to Y and Z such that every $u \in \mathcal{L}$ is τ-unbalanced in Φ_A. Denote by Ψ the arithmetic circuit Φ_A. In the rest of the proof we focus on Ψ. Recall that, for a gate u in Ψ, Y_u is the set of Y variables that occur in Ψ_u, and Z_u is the set of Z variables that occur in Ψ_u.

Define an order on $\mathcal{L}$ that respects the order of Ψ; that is, $\mathcal{L} = \{u_1, \ldots, u_\ell\}$, where $\ell = |\mathcal{L}|$, and for every $i, j \in [\ell]$ such that $i < j$, there is no directed path from u_i to u_j in Ψ. For $i \in [\ell]$, denote $h_i = \widehat{\Psi}_{u_i}$, the polynomial computed by u_i in Ψ, denote $Y_i = Y_{u_i}$, and denote $Z_i = Z_{u_i}$. For a gate v in Ψ, we say that v is *substituted* by α (which is a field element or a variable) in Ψ if the edges going into v are deleted, and v is relabeled by α.

The following proposition shows how to write the polynomial $f^A \in \mathbb{G}[Y, Z]$ (i.e., the polynomial computed by r in Ψ) as a function of the polynomials $h_1, \ldots, h_\ell \in \mathbb{G}[Y, Z]$ (i.e., the polynomials computed by $u_1, \ldots, u_\ell$ in Ψ).

PROPOSITION 5.5.

$$f^A = \sum_{i \in [\ell]} g_i h_i + g,$$

where $g, g_1, \ldots, g_\ell \in \mathbb{G}[Y, Z]$ are multilinear polynomials such that

1. *for all $i \in [\ell]$, the set of variables that occur in g_i and the set $Y_i \cup Z_i$ are disjoint; and*
2. *g is the polynomial computed by r in Ψ after substituting (in Ψ) each $u \in \mathcal{L}$ by 0.*

Proof. To prove the proposition we follow an inductive process that is based on the following claim.

CLAIM 5.6. *Let Υ be a syntactically multilinear arithmetic circuit over the field $\mathbb{G}$ and the sets of variables Y and Z. Let $\tilde{r}$ be a gate in Υ computing a polynomial $\tilde{f}$. Let v be a gate in Υ such that $Y_v \cup Z_v \neq \emptyset$. Denote by $\tilde{h} = \widehat{\Upsilon}_v$ the polynomial computed by v in Υ. Then, there exist two multilinear polynomials $\tilde{g}_1, \tilde{g}_2 \in \mathbb{G}[Y, Z]$ such that $\tilde{f} = \tilde{g}_1 \tilde{h} + \tilde{g}_2$, where*

1. *the set of variables that occur in $\tilde{g}_1$ and the set $Y_v \cup Z_v$ are disjoint; and*
2. *$\tilde{g}_2$ is the polynomial computed by $\tilde{r}$ in Υ after substituting (in Υ) v by 0.*

Proof. Let t be a new variable. Let Υ_1 be the arithmetic circuit Υ after substituting (in Υ) v by t. Let $G \in \mathbb{G}[Y, Z, t]$ be the polynomial computed by $\tilde{r}$ in Υ_1. Since Υ is syntactically multilinear and since $Y_v \cup Z_v \neq \emptyset$, it follows that G is linear in t; that is, G is of the form $G = \tilde{g}_1 t + \tilde{g}_2$, where $\tilde{g}_1$ and $\tilde{g}_2$ are two multilinear polynomials in $\mathbb{G}[Y, Z]$. Since $\tilde{f}$ is G after substituting (in G) t by $\tilde{h}$, we have $\tilde{f} = \tilde{g}_1 \tilde{h} + \tilde{g}_2$. Recall that $\mathcal{M}_{\Upsilon_1}(t)$ is the set of variables that multiply t in Υ_1 (see section 2.4). The set of variables that occur in $\tilde{g}_1$ is a subset of $\mathcal{M}_{\Upsilon_1}(t)$. Since Υ is syntactically multilinear, the sets $\mathcal{M}_{\Upsilon_1}(t)$ and $Y_v \cup Z_v$ are disjoint. Hence, the set of variables that occur in $\tilde{g}_1$ and the set $Y_v \cup Z_v$ are disjoint. Since $\tilde{g}_2 = G\big|_{t=0}$, we have that $\tilde{g}_2$ is the polynomial computed by $\tilde{r}$ in Υ after substituting (in Υ) v by 0. ∎

For $i \in [\ell]$, define Ψ^i to be the arithmetic circuit Ψ after substituting (in Ψ) $u_1, \ldots, u_i$ by 0. We now describe the inductive process.

First step. Recall that r computes f^A in Ψ, and u_1 computes h_1 in Ψ. Hence, by Claim 5.6 (for $\Upsilon = \Psi$, $\tilde{r} = r$, and $v = u_1$), since $Y_1 \cup Z_1 \neq \emptyset$, there exist two multilinear polynomials $g_1, g_1' \in \mathbb{G}[Y, Z]$ such that

$$f^A = g_1 h_1 + g_1',$$

where the set of variables that occur in g_1 and the set $Y_1 \cup Z_1$ are disjoint, and g_1' is the polynomial computed by r in Ψ^1. We continue in a similar manner.

Inductive step. Assume $g_1, \ldots, g_i$ are already defined (where $i \in [\ell - 1]$), and r computes g_i' in Ψ^i. Since there are no directed paths from the gates $u_1, \ldots, u_i$ to u_{i+1} in Ψ, the polynomial computed by u_{i+1} in Ψ^i is h_{i+1}, and the set of variables that occur in $\Psi^i_{u_{i+1}}$ is the same as the set of variables that occur in $\Psi_{u_{i+1}}$. Hence, by Claim 5.6 (for $\Upsilon = \Psi^i$, $\tilde{r} = r$, and $v = u_{i+1}$), since $Y_{i+1} \cup Z_{i+1} \neq \emptyset$, there exist two multilinear polynomials $g_{i+1}, g_{i+1}' \in \mathbb{G}[Y, Z]$ such that

$$g_i' = g_{i+1} h_{i+1} + g_{i+1}',$$

where the set of variables that occur in g_{i+1} and the set $Y_{i+1} \cup Z_{i+1}$ are disjoint, and g_{i+1}' is the polynomial computed by r in Ψ^{i+1}.

Thus,

$$f^A = g_1 h_1 + g_1' = g_1 h_1 + g_2 h_2 + g_2' = \cdots = \sum_{i \in [\ell]} g_i h_i + g,$$

where, for all $i \in [\ell]$, the set of variables that occur in g_i and the set $Y_i \cup Z_i$ are disjoint, and $g = g_\ell'$ is the polynomial computed by r in Ψ after substituting (in Ψ) $u_1, \ldots, u_\ell$ by 0. □

The following claim shows that the partial derivative matrices of $g_1 h_1, \ldots, g_\ell h_\ell$ are of low rank.

CLAIM 5.7. *For every $i \in [\ell]$,* $\mathrm{Rank}(L_{g_i h_i}) \leq 2^{m-\tau}$.

Proof. Fix $i \in [\ell]$. Denote by Y' the set of Y variables that occur in g_i and by Z' the set of Z variables that occur in g_i, and denote $a' = \min(|Y'|, |Z'|)$. By property 1 of Proposition 5.5, $(Y' \cup Z') \cap (Y_i \cup Z_i) = \emptyset$. Thus, $|Y'| + |Z'| \leq n - 2b(u_i)$, which implies $a' \leq m - b(u_i)$. Hence, by Proposition 2.2,

$$\mathrm{Rank}(L_{g_i}) \leq 2^{a'} \leq 2^{m - b(u_i)}.$$

Since $u_i \in \mathcal{L}$, u_i is τ-unbalanced. Thus, $d(u_i) = b(u_i) - a(u_i) \geq \tau$. Hence, by Proposition 2.2,

$$\mathrm{Rank}(L_{h_i}) \leq 2^{a(u_i)} \leq 2^{b(u_i) - \tau}.$$

Thus, since $(Y' \cup Z') \cap (Y_i \cup Z_i) = \emptyset$, by Proposition 2.4,

$$\mathrm{Rank}(L_{g_i h_i}) \leq 2^{m - b(u_i) + b(u_i) - \tau} = 2^{m - \tau}.$$ □

The following proposition shows that the total degree of g is small.

PROPOSITION 5.8. *The total degree of g is at most 4τ.*

Proof. Denote by Ψ^ℓ the arithmetic circuit Ψ after substituting (in Ψ) each gate $u \in \mathcal{L}$ by 0. For a gate v in Ψ^ℓ, denote by $td(v)$ the total degree of the polynomial computed by v in Ψ^ℓ. Every gate in Ψ^ℓ is also a gate in Φ. For a gate v in Ψ^ℓ, define

X_v to be the set of X variables that occur in Φ_v. Note that every gate v in Ψ^ℓ admits $td(v) \leq |X_v|$.

The following claim shows that, if X_v is large, then $td(v)$ is small (where v is a gate in Ψ^ℓ).

CLAIM 5.9. *Let v be a gate in Ψ^ℓ, and let $k = n - |X_v|$. Assume that $k \leq 2\tau$. Then, $td(v) \leq 4\tau - k$.*

Proof. The proof is by induction on the structure of Ψ^ℓ (that is, we consider a gate v only after considering v's two sons). Since $|X_v| = n - k \geq n - 2\tau$, it follows that v is not an input gate in Ψ^ℓ. Let v_1 and v_2 be the two sons of v in Ψ^ℓ. Let $k_1 = n - |X_{v_1}|$ and $k_2 = n - |X_{v_2}|$. Since $X_v = X_{v_1} \cup X_{v_2}$, it follows that $k \leq k_1$ and $k \leq k_2$. Consider the following two cases.

Case 1: v is an addition gate. First, we claim that $td(v_1) \leq 4\tau - k$ and $td(v_2) \leq 4\tau - k$. Consider v_1 without loss of generality. There are three cases.

(a) Assume $n - 2\tau \leq |X_{v_1}|$. Thus, $k_1 \leq 2\tau$. Hence, by induction, $td(v_1) \leq 4\tau - k_1 \leq 4\tau - k$.

(b) Assume $2\tau < |X_{v_1}| < n - 2\tau$. Since $|X_v| \geq n - 2\tau$, it follows that $v_1 \in \mathcal{L}$. Hence, v_1 is an input gate labeled by 0 in Ψ^ℓ, which implies $td(v_1) = 0 \leq 4\tau - k$.

(c) Assume $|X_{v_1}| \leq 2\tau$. Since $k \leq 2\tau$, we have $td(v_1) \leq |X_{v_1}| \leq 2\tau \leq 4\tau - k$.

Hence, since v is an addition gate, $td(v) \leq \max(td(v_1), td(v_2)) \leq 4\tau - k$.

Case 2: v is a product gate. Assume without loss of generality that $|X_{v_1}| \geq |X_{v_2}|$. Since $X_v = X_{v_1} \cup X_{v_2}$, it follows that $|X_{v_1}| \geq |X_v|/2 > 2\tau$ (for large enough n). Hence, there are two cases.

(a) Assume $n - 2\tau \leq |X_{v_1}|$. Thus, $k_1 \leq 2\tau$. Hence, by induction, $td(v_1) \leq 4\tau - k_1$. Since Φ is syntactically multilinear, $|X_v| = |X_{v_1}| + |X_{v_2}|$, which implies $|X_{v_2}| = k_1 - k$. Thus, $td(v_2) \leq |X_{v_2}| \leq k_1 - k$. Hence, $td(v) = td(v_1) + td(v_2) \leq 4\tau - k_1 + k_1 - k = 4\tau - k$.

(b) Assume $2\tau < |X_{v_1}| < n - 2\tau$. Since $|X_v| \geq n - 2\tau$, it follows that $v_1 \in \mathcal{L}$. Hence, v_1 is an input gate labeled by 0 in Ψ^ℓ, which implies $td(v) = 0 \leq 4\tau - k$. ∎

Since $|X_r| \geq n - 2$, by Claim 5.9, it follows that $td(r) \leq 4\tau$. Since r computes g in Ψ^ℓ, the proposition follows. ∎

By Propositions 5.8 and 2.6, since $\tau = 3 \log n$, we have

$$\mathrm{Rank}(L_g) \leq 2^{(4\tau+1)\log m} \leq 2^{\tau^3}.$$

By Proposition 5.5, $f^A = \sum_{i \in [\ell]} g_i h_i + g$. Thus, by Claim 5.7 and Proposition 2.3,

$$\mathrm{Rank}(L_{f^A}) \leq \sum_{i \in [\ell]} 2^{m-\tau} + 2^{\tau^3} < 2^{m-1},$$

where the last inequality holds for large enough n, as $\ell = |\mathcal{L}| < \frac{c}{\tau} n^{1/3}$ and $\tau = 3 \log n$. ∎

6. The construction. For a field $\mathbb{F}$ and a set of variables T, we denote by $\mathbb{F}[T]$ the *ring of polynomials* over the field $\mathbb{F}$ and the set of variables T, and we denote by $\mathbb{F}(T)$ the *field of rational functions* over $\mathbb{F}$ in the set of variables T. Let $X = \{x_1, \ldots, x_n\}$, $\Omega = \{\omega_1, \ldots, \omega_n\}$, $Y = \{y_1, \ldots, y_m\}$, and $Z = \{z_1, \ldots, z_m\}$ be four sets of variables (where $n = 2m$). Let $\mathbb{F}$ be a field, and let $\mathbb{G} = \mathbb{F}(\Omega)$ be the field of rational functions over $\mathbb{F}$ in the set of variables Ω. Note that a polynomial in $\mathbb{F}[X, \Omega]$ can also be thought of as a polynomial in $\mathbb{G}[X]$.

In this section, we construct a polynomial $f \in \mathbb{F}[X, \Omega]$ such that the following hold:

- Thinking of f as a polynomial in $\mathbb{G}[X]$, for every partition A of X to Y and Z, the partial derivative matrix of f^A has full rank over $\mathbb{G}$ (recall that $f^A \in \mathbb{G}[Y,Z]$ is the polynomial f after substituting every $x \in X$ by $A(x) \in Y \cup Z$).
- f is explicit in the sense that f is in the class VNP, which is Valiant's algebraic analogue of NP. Moreover, the coefficient of every monomial in f, as a polynomial in $\mathbb{F}[X,\Omega]$, is either 0 or 1.

6.1. Definition of f. For a set $B \subset [n]$ of size m, denote by $i_1,\ldots,i_m$ the elements of B in an increasing order (that is, $B=\{i_1,\ldots,i_m\}$ and $i_1<\cdots<i_m$), and denote by $j_1,\ldots,j_m$ the elements of $[n]\setminus B$ in an increasing order (that is, $[n]\setminus B=\{j_1,\ldots,j_m\}$ and $j_1<\cdots<j_m$). Define r_B, a multilinear monomial in $\mathbb{F}[\Omega]$, by $r_B=\prod_{\ell\in B}\omega_\ell$, and define g_B, a multilinear polynomial in $\mathbb{F}[X]$, by $g_B=\prod_{\ell\in[m]}(x_{i_\ell}+x_{j_\ell})$. Define

$$f=\sum_B r_B g_B, \tag{6.1}$$

where the sum is over all sets $B\subset[n]$ of size m. Thus, $f\in\mathbb{F}[X,\Omega]$ is a multilinear polynomial over the field $\mathbb{F}$ and the sets of variables X and Ω. We think of f also as a polynomial in $\mathbb{G}[X]$.

6.2. The partial derivative matrix of f^A has full rank. The following theorem states that, thinking of f as a polynomial in $\mathbb{G}[X]$, for any partition A of X to Y and Z, the partial derivative matrix of f^A has full rank. Formally, we have the following theorem.

THEOREM 6.1. *Let $f\in\mathbb{G}[X]$ be the polynomial defined in* (6.1)*. Then, for any partition A of X to Y and Z, the partial derivative matrix of f^A has full rank (over $\mathbb{G}$).*

We defer the proof of Theorem 6.1 to section 6.4. We remark that, the larger the set Ω is, the simpler it is to construct a polynomial f that satisfies Theorem 6.1. For the purpose of our lower bound, we need Ω to be as small as possible (and Ω such that $|\Omega|=|X|$ suffices).

6.3. f is explicit. In [9], Valiant defined an algebraic theory, analogous to the theory of NP-completeness. The analogue of NP, according to Valiant's theory, is called VNP. In this section, we show that f is in the class VNP.

For simplicity, instead of using the formal definition of VNP, we use a criterion (given by Valiant) for a polynomial to be in VNP. Valiant's criterion states that a polynomial f is in VNP if the coefficient of a monomial in f can be computed efficiently; that is, there exists a polynomial-time Turing machine M such that, given as input the degrees of the variables in a monomial p, M outputs the coefficient of p in f. (In fact, Valiant's criterion is stronger. For more details see Proposition 2.20 in [2].)

We use Valiant's criterion to show that f is in VNP. Let $r\in\mathbb{F}[\Omega]$ and $g\in\mathbb{F}[X]$ be two monic multilinear monomials. To prove that f is in VNP, we describe an efficient algorithm that outputs the coefficient of rg in f. The algorithm is as follows.

If the total degree of r is not m, then the coefficient of rg in f is 0. Therefore, assume that the total degree of r is m. Thus, r is of the form $r=\prod_{\ell\in B}\omega_\ell$ for a set $B\subset[n]$ of size m. Let $i_1,\ldots,i_m$ be the elements of B in an increasing order, and let $j_1,\ldots,j_m$ be the elements of $[n]\setminus B$ in an increasing order. Since

$$g_B=\prod_{\ell\in[m]}(x_{i_\ell}+x_{j_\ell})=\sum_{D\subseteq[m]}\prod_{\ell\in D}x_{i_\ell}\prod_{\ell\in[m]\setminus D}x_{j_\ell},$$

it follows that the coefficient of rg in f is 1 iff g is of the form $g = \prod_{\ell \in D} x_{i_\ell} \prod_{\ell \in [m] \setminus D} x_{j_\ell}$ for some $D \subseteq [m]$ (otherwise, the coefficient is 0). Checking whether g is of the form $g = \prod_{\ell \in D} x_{i_\ell} \prod_{\ell \in [m] \setminus D} x_{j_\ell}$ is straightforward. Hence, f is in VNP.

6.4. Proof of Theorem 6.1.

Proof. We first prove the following lemma, which is a generalization of Theorem 6.1.

LEMMA 6.2. *Let T be a set of variables, and let $\mathbb{F}(T)$ be the field of rational functions over $\mathbb{F}$ in the set of variables T. Let $k \in \mathbb{N}$. Let $s_1, \ldots, s_k \in \mathbb{F}[T]$ be different monic multilinear monomials. Let $h_1, \ldots, h_k \in \mathbb{F}[Y, Z]$ be multilinear polynomials. Denote $h = \sum_{i \in [k]} s_i h_i$ a polynomial in $\mathbb{F}[Y, Z, T]$. Thus, h can be viewed also as a polynomial in $\mathbb{F}(T)[Y, Z]$. Assume that there exists $\ell \in [k]$ such that the partial derivative matrix of h_ℓ has full rank over $\mathbb{F}$. Then, the partial derivative matrix of h has full rank over $\mathbb{F}(T)$.*

Proof. The proof is by induction on the size of T.

Induction base. Assume $|T| = 0$. Since $s_1, \ldots, s_k$ are *different monic* monomials in $\mathbb{F}[T] = \mathbb{F}$, it follows that $k = 1$ and $s_1 = 1$. Hence, $h = h_1$, and the partial derivative matrix of h_1 has full rank over $\mathbb{F} = \mathbb{F}(T)$, which proves the lemma.

The induction step is based on the following claim (the claim is well known, and we omit its proof).

CLAIM 6.3. *Let P and Q be two $M \times M$ matrices with entries in a field $\mathbb{H}$. Let t be a variable. Then,*

$$\exists\ a_1, \ldots, a_{M-1} \in \mathbb{H}\ :\ \det(tQ + P) = t^M \det(Q) + \det(P) + \sum_{d=1}^{M-1} a_d t^d,$$

where $\det(\cdot)$ is the determinant.

Induction step. Assume $|T| > 0$. Let $t \in T$ be a variable. Denote $T' = T \setminus \{t\}$, and denote by $\mathbb{F}(T')$ the field of rational functions over $\mathbb{F}$ in the set of variables T'. Since $s_1, \ldots, s_k$ are multilinear monomials, assume without loss of generality that $h = t \sum_{i=1}^{k'} s'_i h_i + \sum_{i=k'+1}^{k} s_i h_i$, where $k' \in [k]$, $s'_1, \ldots, s'_{k'} \in \mathbb{F}[T']$ are different monic multilinear monomials, and $s_{k'+1}, \ldots, s_k \in \mathbb{F}[T']$ are different monic multilinear monomials. Recall that the partial derivative matrix of h_ℓ has full rank over $\mathbb{F}$. Assume without loss of generality that $\ell \leq k'$ (similar arguments hold for $\ell > k'$). Denote $h' = \sum_{i=1}^{k'} s'_i h_i$ and $h'' = \sum_{i=k'+1}^{k} s_i h_i$. By induction, it follows that $L_{h'}$ has full rank over $\mathbb{F}(T')$, which implies that $\det(L_{h'}) \neq 0$. Hence, since $L_h = t L_{h'} + L_{h''}$, using Claim 6.3 (for $M = 2^m$, $Q = L_{h'}$, $P = L_{h''}$, and $\mathbb{H} = \mathbb{F}(T')$), we have that $\det(L_h) \neq 0$, which implies that L_h has full rank over $\mathbb{F}(T)$. ∎

Fix a partition A of X to Y and Z, and let $B_0 = \{i \in [n]\ :\ A(x_i) \in Y\}$. Recall that g_{B_0} is the polynomial defined in section 6.1. The following claim shows that the partial derivative matrix of $g^A_{B_0}$ is a permutation matrix (a permutation matrix is a matrix obtained by permuting the rows of the identity matrix).

CLAIM 6.4. *The partial derivative matrix of $g^A_{B_0}$ is a permutation matrix.*

Proof. Denote by $i_1, \ldots, i_m$ the elements of B_0 in an increasing order, and denote by $j_1, \ldots, j_m$ the elements of $[n] \setminus B_0$ in an increasing order. By definition of g_{B_0},

$$g^A_{B_0} = \Big(\prod_{\ell \in [m]} \big(x_{i_\ell} + x_{j_\ell}\big) \Big)^A = \prod_{\ell \in [m]} \big(A(x_{i_\ell}) + A(x_{j_\ell})\big).$$

Note that, for every $\ell \in [m]$, we have $A(x_{i_\ell}) \in Y$ and $A(x_{j_\ell}) \in Z$. Thus, there exists a permutation $\pi : [m] \to [m]$ such that $g^A_{B_0} = \prod_{\ell \in [m]} \left(y_\ell + z_{\pi(\ell)}\right)$. Hence, the partial derivative matrix of $g^A_{B_0}$ is a permutation matrix. □

By Claim 6.4, the set B_0 is such that the partial derivative matrix of $g^A_{B_0}$ has full rank over $\mathbb{F}$. Hence, using Lemma 6.2 (for $T = \Omega$), since $\{r_B\}_{B \subset [n] : |B| = m}$ is a set of different monic multilinear monomials in $\mathbb{F}[\Omega]$, it follows that the partial derivative matrix of f^A has full rank over the field $\mathbb{G}$. Since A is an arbitrary partition of X to Y and Z, the theorem follows. □

7. The lower bound: Proof of Theorem 1.1.

Proof. Denote $\mathbb{G} = \mathbb{F}(\Omega)$ the field of rational functions over $\mathbb{F}$ in the set of variables Ω. We can think of Φ as a syntactically multilinear arithmetic circuit over the field $\mathbb{G}$ and the set of variables X: every input gate in Φ labeled by $\omega \in \Omega$ is thought of as labeled by a field element in $\mathbb{G}$, and every other input gate in Φ is labeled by either a field element in $\mathbb{F} \subseteq \mathbb{G}$ or a variable in X. The number of variables in Φ is n (instead of $2n$). The polynomial computed by Φ is f, but we think of f as a polynomial in $\mathbb{G}[X]$. By Theorem 6.1, for all partitions A of X to Y and Z,

$$\mathrm{Rank}(L_{f^A}) = 2^m,$$

where the rank is over $\mathbb{G}$. Hence, by Theorem 5.1,

$$|\Phi| = \Omega\left(\frac{n^{4/3}}{\log^2 n}\right). \qquad \square$$

COST-DISTANCE: TWO METRIC NETWORK DESIGN*

ADAM MEYERSON†, KAMESH MUNAGALA‡, AND SERGE PLOTKIN§

Abstract. We present the COST-DISTANCE problem: finding a Steiner tree which optimizes the sum of edge *costs* along one metric and the sum of source-sink *distances* along an unrelated second metric. We give the first known $O(\log k)$ randomized approximation scheme for COST-DISTANCE, where k is the number of sources. We reduce several common network design problems to COST-DISTANCE, obtaining (in some cases) the first known logarithmic approximation for them. These problems include single-sink buy-at-bulk with variable pipe types between different sets of nodes, facility location with buy-at-bulk–type costs on edges (integrated logistics), constructing single-source multicast trees with good cost and delay properties, priority Steiner trees, and multilevel facility location. Our algorithm is also easier to implement and significantly faster than previously known algorithms for buy-at-bulk design problems.

Key words. approximation algorithms, network design, Steiner trees, facility location

DOI. 10.1137/050629665

1. Introduction.

Consider designing a network from the ground up. We are given a set of customers and need to place various servers and network links in order to cheaply provide sufficient service. If we only need to place the servers, this becomes the facility location problem [36], and constant-factor approximations are known (please refer to [28] for a complete list of citations). If a single server handles all customers, and we impose the additional constraint that the set of available network link types is the same for every pair of nodes (subject to constant scaling factors on cost), then this is the single-sink buy-at-bulk problem [35, 4]. We give the first known approximation for the general version of this problem to optimize both placement of servers and network topology.

We reduce the network design problem to the following theoretical framework, which we call the COST-DISTANCE problem: We are given a graph with a single distinguished sink node (server). Every edge in this graph can be measured along two metrics; the first will be called *cost*, and the second will be *length*. Note that the two metrics are entirely unrelated and that there may be any number of parallel edges in the graph. We are given a set of sources (customers). The objective is to construct a Steiner tree connecting the sources to the sink while minimizing the combined sum of the *cost* of the edges in the tree and sum over sources of the weighted *distance* (i.e., total *length*) from source to sink. Note that this definition is a direct generalization of both the shortest path tree and the minimum cost Steiner tree. If *costs* and *lengths*

are proportional, then constant-factor approximations [24, 5] are known.

We obtain the first general approximation algorithm for this problem with unrelated metrics. We prove an expected competitive ratio of $O(\log |S|)$ (where S is the set of sources) for our randomized algorithm. The algorithm is fairly simple to implement and runs in a relatively fast $O(|S|^2(m + n \log n))$ time bound.

Theoretical significance. In section 5, we show that many standard problems in network design can be reduced to COST-DISTANCE, showing that this problem forms a general theoretical framework for network design. In particular, we describe simple reductions from single-sink buy-at-bulk and the metric facility location problem. We demonstrate that a natural combination of facility location and buy-at-bulk can be solved by reduction to COST-DISTANCE. In fact, we can generalize single-sink buy-at-bulk to account for a scenario where not all network link types are available between every pair of nodes, or where costs do not scale linearly. This better models real-life situations where certain types of hardware may not be available (or may not be practical to install) in certain locations. This problem was subsequently called "integrated logistics" by Ravi and Sinha [34]. Our algorithm provides the first known approximation for this more general problem. We also obtain among the first known combinatorial approximations for the metric multilevel uncapacitated facility location problem [23], the priority Steiner tree problem [11], and for constructing single-source multicast trees with good cost and average per receiver delay [33].

From a more theoretical standpoint, consider routing single-source traffic through a graph where each edge has some function relating the total traffic along the edge to the cost of routing that traffic. If all functions are convex increasing (nondecreasing derivative), then exact solutions are known using min-cost flow techniques. We present the first approximations for the case where all functions are *concave increasing* (nonincreasing derivative). Previous work on buy-at-bulk [4, 3, 35] required that the concave functions between each pair of nodes be identical up to a constant scaling factor; we eliminate this requirement. We present all these connections in more detail in section 5.

Technical contributions. The chief technical contribution is to show that the COST-DISTANCE problem can be solved by layered aggregation of demands. We perform aggregation in pairs by constructing matchings iteratively on a suitably defined complete graph. Our algorithm and analysis exploit the connection of COST-DISTANCE to the budgeted version of the problem [29, 26], where the goal is to find a tree with low cost in the c metric such that the diameter is no more than L in the l metric. This problem has an $O(\log |S|, \log |S|)$ bicriteria approximation on the cost and diameter via layered aggregation by Marathe et al. [29]. We need to make one nontrivial modification when the objective becomes aggregate distance instead of diameter—this is discussed in section 3.1 and makes our algorithm randomized.

The technical framework of layered aggregation pervades all subsequent combinatorial algorithms for single-sink aggregation problems, such as access network design [19], single-sink buy-at-bulk [20], and the rent-or-buy problem [21].

In addition to generalizing previous results, our algorithm is easy to implement and has a small running time. This makes it the algorithm of choice for many of the problems we have previously described. For example, previous algorithms for single-sink buy-at-bulk depended on methods of randomly selecting trees which approximate stretch [6, 7, 9, 10, 16]. The algorithm for access network design [3] depended on a linear programming relaxation.

Previous results. If the cost and distance metrics are proportional, the offline version of COST-DISTANCE has a constant factor approximation [5, 24], and there is

an online algorithm performing a small number of reroutings of existing paths [17]. If the cost and distance metrics are unrelated, this problem has no previously known approximation algorithm. Previous results for many related network design problems are discussed in detail in section 5.

2. The Cost-Distance problem. We are given a graph $G = (E, V)$ along with a set of source vertices $S \subset V$ which need to be connected to a single-sink vertex $t \in V$. We have two metrics along this graph. We will call the first metric cost $c : E \mapsto \Re^+$ and the second metric length $l : E \mapsto \Re^+$. We are also given a weighting function $w : S \mapsto \Re^+$ on the sources. We denote the two metrics on an edge e as $(c(e), l(e))$.

We are asked to find a connected subgraph $G' = (E', V') \subset G$ which contains all sources ($S \subset V'$) and the sink ($t \in V'$) such that the following sum is minimized:

$$\sum_{e \in E'} c(e) + \sum_{s \in S} w(s) L'(s, t).$$

Here $L'(s, t)$ is the total length of the min-length path from s to t along the edges of G'.

Our algorithm will give an $O(\log |S|)$ approximation to this sum. It is important to notice that our approximation ratio does not depend on the number of edges, since there may potentially be a large number of edges connecting the same pair of nodes ($m \gg n^2$).

3. The algorithm. The algorithm works by pairing up sources (or pairing sources with sink) until only the sink remains. At each stage we find a matching on the nodes and then choose one node from each matched pair to be "center." We transport the weight from the noncenter node to the center, paying the appropriate edge costs and weight times distance costs. We then repeat this process on the centers until the sink is the only remaining node. Details of the algorithm are as follows:

1. Define $S_0 = S \cup \{t\}$ and $w_0 = w$. Create empty set E'.
2. Set $i = 0$.
3. For every pair of nonsink nodes $(u, v) \in S_i$:
   - Find the shortest $u - v$ path in G according to the distance function on the edges: $M_{uv}(e) = c(e) + \frac{2w_i(u)w_i(v)}{w_i(u)+w_i(v)} l(e)$.
   - Let $K_i(u, v)$ be the length of this path under the distance function $M_{uv}(e)$.
4. For every nonsink node $u \in S_i$:
   - Find the shortest $u - t$ path in G according to the metric $M_{ut}(e) = c(e) + w_i(u)l(e)$.
   - Let $K_i(u, t)$ be the length of this path under metric $M_{ut}(e)$.
5. Find a matching between nodes in S_i such that the number of unmatched nodes plus half the number of matched nodes is at most S_i/α and the value of $\sum_{(u,v)matched} K_i(u, v)$ is at most β times the value of the minimum K_i-cost perfect matching. We assume α and β are known constants.
6. For each matched pair (u, v) add the edges on the path defining $K_i(u, v)$ to the set E'.
7. Create an empty set S_{i+1}.
8. For each pair of nonsink matched nodes (u, v):
   - Choose u to be the center with probability $w_i(u)/(w_i(u) + w_i(v))$. Otherwise v will be the center.

- Add the chosen center to S_{i+1} and assign the center a weight $w_{i+1}(\mathit{center}) = w_i(u) + w_i(v)$.

9. Add all unmatched nodes $u \in S_i$ to S_{i+1} and define $w_{i+1}(u) = w_i(u)$.
10. Add the sink to S_{i+1}.
11. If S_{i+1} contains only the sink, we are done. Otherwise increment i and return to step 3.
12. We return $G' = (E', V')$, where E' is the set of edges we constructed and V' is the set of adjacent nodes.

Each time through the steps, the size of our set S_i is reduced by α. Thus the process terminates after $\log_\alpha |S|$ iterations.

3.1. Discussion. The overall algorithm is very similar to that in [29], where the bicriteria (cost, diameter) version is solved. There is however one very important and nontrivial difference. Every time there is an aggregation, a choice has to be made about the "center" for the aggregate demand. In the case of [29], any center works since they are approximating the diameter of the tree. In our case, such a choice would be disastrous, and we instead resort to choosing the center at random with probability proportional to the demand aggregated there (step 8). This method has been subsequently derandomized by Chekuri, Khanna, and Naor [13] using the dual of a natural linear programming formulation.

The metric used for constructing the matching is $M_{uv}(e) = c(e) + \frac{2w_i(u)w_i(v)}{w_i(u)+w_i(v)} l(e)$. This is the expected cost of transporting one demand of the pair (u, v) to the other location, when the choice of which location to transport to is made at random in proportion to its demand value.

A little more detail is needed in step 5. We could find the min-cost perfect matching on the set in polynomial time, obtaining $\alpha = 2$ and $\beta = 1$. Polynomial-time algorithms are known for min-cost perfect matching on nonbipartite graphs [32]. However, these algorithms tend to be impractical.[1] The following simpler procedure will work for us, causing only a small constant loss in our approximation ratio. We will find the cheapest pair of nodes to connect (minimum $K_i(u, v)$) and match them. We then remove these two nodes from consideration and repeat. We continue this process until half the nodes have been matched. The jth pair which we choose to match must have had matching cost at most equal to the $(2j-1)$st cheapest edge in the perfect matching, according to the K_i metric. It follows that our total K_i-cost is at most half the K_i-cost of the perfect matching, guaranteeing $\alpha = 4/3$ and $\beta = 1/2$.

Each iteration of this algorithm finds shortest paths between all pairs in S_i. Since the metric is different for each pair, we cannot use all-pairs shortest-path computations. Instead we perform $|S_i|^2$ single-pair shortest paths. We first take $O(m)$ time to compute the metric on every edge. Using Dijkstra's algorithm, we can compute the shortest path between a single pair of nodes in $O(m + n \log n)$ time. The matching step (step 5) can be performed in $O(|S_i|^2 \log |S_i|)$ time. It follows that iteration i takes at most $O(|S_i|^2(m + n \log n))$ time. Since the size of S_i reduces by constant α at each iteration, when we sum over iterations the total running time looks like $O(|S|^2(m + n \log n))$.

4. Analysis. The optimal solution will be a tree, which we will call T^*. To see this, notice that we can take any graph and produce the shortest-path (according to the length metric) tree connecting the sink to all sources. This shortest-path tree

[1] We could use the $O(n^2 \log n)$ approximation algorithm in [18] to get $\beta = 2$ and $\alpha = 2$. Here, n is the total number of nodes in the graph.

will have total cost at most the total cost of the graph and a distance-to-sink from every source node equal to the distance-to-sink from the graph. It follows that the optimal solution must be a tree, since a nontree solution immediately gives rise to a tree solution with equal or superior total value.

We define the following quantities:

$C^* = \sum_{e \in T^*} c(e)$.

$L^*(v) =$ total length of edges along the path from v to the sink in T^*.

$D^* = \sum_{v \in S} w(v) L^*(v)$.

The total "value" of the optimal solution which we will need to approximate is $C^* + D^*$. At each stage in our algorithm, we have some set of nodes S_i which we are trying to connect. We define the following potential function:

$$D_i^* = \sum_{v \in S_i} w_i(v) L^*(v).$$

Notice that $D_0^* = D^*$.

Since our algorithm is randomized, we need to analyze the expected performance. Each stage of the algorithm transports some weight from matched nodes to chosen centers. We can define the value of stage i to be the total cost of the edges used in stage i matching plus the cost to transport the weight across the appropriate edges to the center. The total value of our solution will then be the sum of the values of the stages.

We first prove a lemma bounding the expected potential function at each stage.

LEMMA 4.1. *For every stage i, $\mathbf{E}[D_i^*] \leq D^*$.*

Proof. We will prove this by induction. For $i = 0$ we know $D_0^* = D^*$. Consider stage $i > 0$. Suppose we matched u and v in our previous matching. The contribution of u and v to D_{i-1}^* was $w_{i-1}(u)L^*(u) + w_{i-1}(v)L^*(v)$. We choose a random center. The expected distance from center to sink is now

$$\frac{w_{i-1}(u)L^*(u) + w_{i-1}(v)L^*(v)}{w_{i-1}(u) + w_{i-1}(v)}.$$

The weight of the new center is $w_{i-1}(u) + w_{i-1}(v)$. It follows that the new center's expected contribution to D_i^* is also $w_{i-1}(u)L^*(u) + w_{i-1}(v)L^*(v)$. Of course, unmatched nodes contribute equally to both potentials, and nodes matched with the source contribute less to D_i^* since their weight will disappear. Thus the expected value of D_i^* is at most D_{i-1}^*. It follows that $\mathbf{E}[D_i^*] \leq \mathbf{E}[D_{i-1}^*]$, and the inductive hypothesis implies that $\mathbf{E}[D_i^*] \leq D^*$. ∎

We will now relate the value of a stage to the metric K_i on which we approximated a min-cost perfect matching. This will allow us to bound the expected value of each stage. This lemma previously appeared in [29].

LEMMA 4.2. *Given a tree $T = (E, V)$ and a set of nodes $S \subseteq V$, there exists a perfect matching of the nodes in S which uses each edge of the tree at most once.*

Proof. We prove this by induction on the number of edges in the tree. If the tree includes zero weight edges, then $|V| = 1$ and the result is trivially true. Consider a larger tree. Suppose $v \in V$ is a leaf of this tree. If v is not included in S, then we can remove v and the edge connecting it to its parent from the tree to produce a smaller tree, T'. We inductively produce a perfect matching of the nodes in S on T' and use the same matching for T. If v is included in S, then we consider v's parent node. If the parent node is also in S, then we match v with its parent. We then remove v and its edge from the tree to produce T' and inductively match the rest of S on T'. If the

parent node is not in S, we produce S' by removing v from S and adding v's parent. We again produce T' and match the nodes. Some node u is matched to v's parent. We will use the identical matching to the one on T' except that we will match v with u by adding the edge from v to its parent to the relevant path. This produces the desired matching. ∎

LEMMA 4.3. *The expected value of stage i is at most $\beta(2D^* + C^*)$.*

Proof. Consider the tree T^*. Using Lemma 4.2, there exists a matching of the nodes in S_i using only edges in T^*, such that no edge is used more than once. This matching has edges with total cost at most C^*. The fraction $2w_i(u)w_i(v)/(w_i(u) + w_i(v))$ is at most twice the minimum of the two weights. Each edge in our matching would have to be along the path-to-source in the optimal tree for one of the two matched nodes. It follows that

$$\sum_{(u,v)matched} K_i(u,v) \leq C^* + 2D_i^*.$$

The min-cost perfect matching along metric K_i must do at least this well. Since the matching we actually use has cost at most β times the min-cost perfect matching, we guarantee a matching of K_i-cost at most $\beta(C^* + 2D_i^*)$. We need to relate this cost to the value of the stage.

The value of the stage is the total cost to transfer weight from matched nodes to their centers. Suppose we match u and v. If we choose v as the center, then we need to transport u's weight over to v. This induces a value of $w_i(u)l(u,v)$ in addition to the value induced by the cost of edges used. On the other hand, if we choose u as center, then we pay $w_i(v)l(u,v)$ plus edge costs. The expected value is thus

$$\frac{w_i(v)w_i(u)l(u,v) + w_i(u)w_i(v)l(u,v)}{w_i(u) + w_i(v)} + c(u,v).$$

Notice that this expected value is exactly $K_i(u,v)$. It follows that the expected value of the stage is equal to the total K_i-cost of the matching found—at most $\beta(C^* + 2D_i^*)$. This of course depends on D_i^*, a random variable with expected value at most D^* (as per Lemma 4.1). It follows that the expected value of stage i is at most $\beta(2D^* + C^*)$, as desired. ∎

THEOREM 4.1. *We obtain approximation ratio $2\beta \log_\alpha |S| = O(\log |S|)$ to the optimal.*

Proof. The expected value of our solution is equal to the sum of the expected value of the stages. This gives us a total value $\mathbf{E}[V] \leq \sum_i \mathbf{E}[V_i]$. Using Lemma 4.3 and our bound on the total number of stages, we can bound this by $\mathbf{E}[V] \leq \beta(\log_\alpha |S|)(2D^* + C^*)$. Since the optimal solution has value $D^* + C^*$, this proves the desired approximation ratio. ∎

Using the described greedy algorithm to find a matching, we will attain expected approximation ratio $\log_{4/3} |S|$; exact perfect matchings would improve this to $2 \log_2 |S|$. There will be a small additional loss in the last stages, where an uneven number of nodes could cause a few additional steps; however, our total approximation will remain bounded by an expected $O(\log |S|)$.

5. Relation to network design problems. We will demonstrate approximation-preserving reductions from many commonly encountered network design probems to special cases of COST-DISTANCE. We emphasize that for all these problems, our algorithm produces a logarithmic approximation ratio, while being (in general) simpler to implement and faster to run than previously known algorithms.

5.1. Multicast tree design. In this problem, we are given a network $G(V, E)$ with costs and delays on the edges. We have a source node $s \in V$ and receivers $R \subseteq V$ for multicast data. The goal is to construct a tree T connecting the source to R so that the sum of the cost of the tree and the delays seen by the receivers is minimized. This problem is equivalent to Cost-Distance if the distance metric is the delays. This problem has been extensively studied in the networks community [8, 15, 22, 25, 27, 33, 39], and many heuristics have been proposed. We present the first approximation for this problem. Our approximation ratio is $O(\log |R|)$.

5.2. Facility location. We are given a weighted undirected graph $G(V, E)$ with a cost per unit demand $c : E \to \Re$ on the edges, which forms a metric. We have a set of demand points $D \subseteq V$ with demands d_i and a set of facility locations $F \subseteq V$ with facility costs f_i. The goal is to open a subset of the facilities and assign demands to the open facilities so that the sum of the cost of opening the facilities and the cost of routing the demand to the facilities is minimized.

For edge e in the graph, the bicriteria cost function is $(0, c(e))$. We add a dummy sink and connect it to all the facilities. For facility i, the cost of the edge is $(f_i, 0)$. The demand points will be our source vertices ($S = D$) and their weights will be equal to the demands ($w(v) = d_v$). The cost of a Cost-Distance solution on this modified graph is identical to the cost of its corresponding facility-location solution, so it follows that the reduction is approximation-preserving.

We can also consider the capacitated version of this problem, where facility i has capacity u_i. We can open multiple copies of a facility, but each copy opened at location i costs f_i. Again, we modify the graph exactly as before but assign cost $(f_i, \frac{f_i}{u_i})$ on the edge connecting the sink to facility i. This causes the loss of an additional factor of two (at most) in the approximation ratio, which is seen as follows. Suppose $d > 0$ amount of demand is routed to a facility. Then, the cost paid by the Cost-Distance version is $f_i(1 + \frac{d}{u_i})$, whereas the cost paid by the actual facility location version is $f_i\lceil \frac{d}{u_i} \rceil$. Clearly $(1 + \frac{d}{u_i}) \leq 2\lceil \frac{d}{u_i} \rceil$.

We have therefore obtained an $O(\log(|D|))$ approximation to these problems. Note that several constant-factor approximations are known for this problem. The best known approximation ratio is 1.52 and is due to Mahdian, Ye, and Zhang [28], which builds on a long line of previous work. Please refer to this paper for previous work on this problem.

5.3. Extended single-sink buy-at-bulk. In this problem [35], we are given a weighted graph $G(V, E)$ with length function $l : E \to \Re$. A subset $S \subseteq V$ of nodes has demands d_i. We have a special sink node t to which all this demand must be routed. The demand must be routed by choosing a tree and buying pipes along this tree. There are K types of pipes. The type i pipe has cost c_i per unit length and capacity u_i. We assume that K is $O(\text{poly}(|V|))$. The goal is to minimize the total cost of pipe bought.

We modify the graph as follows. Replace every edge e in the graph with K parallel edges $e_1, e_2, \ldots, e_K$. The edge e_i has bicriteria cost $(l(e)c_i, l(e)\frac{c_i}{u_i})$. The weight of a node is its demand. This new graph is the instance of Cost-Distance that we solve. Intuitively, $l(e)c_i$ is the fixed cost of using pipe i, and $l(e)\frac{c_i}{u_i}$ is the incremental cost of routing demand.

It is implicit in the work of [4, 35] that the optimum tree with the modified cost function is no more than a factor 2 away from the optimum tree for the original problem. This is seen as follows. Suppose that in the original problem, $d > 0$

amount of demand was routed on edge e using cables of type i so that the cost paid is $l(e)c_i\lceil\frac{d}{u_i}\rceil$. In the COST-DISTANCE version, the cost paid for routing the same demand is $l(e)c_i + l(e)\frac{c_i}{u_i}d = l(e)c_i\left(1+\frac{d}{u_i}\right)$. This is clearly at most a factor of 2 away from $l(e)c_i\lceil\frac{d}{u_i}\rceil$ provided $d > 0$.

The best previously known approximation for this problem was $O(\log|S|\log\log|S|)$, which follows by applying the techniques in [10] to the algorithm in [4]. These algorithms are based on the work in [6, 7, 9, 10], which show how to approximate any finite metric by a tree metric so that the distance between any two nodes in the graph is approximated well. For the special case of $K = 1$, Salman et al. [35] showed a constant-factor approximation by using previous results [5, 24] on balancing Steiner trees with shortest-path trees.

Subsequent to our work, several constant-factor approximations have been obtained for this problem; the first one is due to Guha, Meyerson, and Munagala [20], and the most recent (and best) is due to Gupta, Kumar, and Roughgarden [21].

All previous approximations assumed that all the K pipes are available between all pairs of nodes; it is straightforward to see that we can do away with this restriction. This problem arises naturally in network design. There may be a fixed cost of laying cables which depends on the location but is independent of the type of cable being laid (perhaps the cost of installing the cable outweighs the cost of the cable itself). Alternatively, certain types of services might not be available in certain locations. Our algorithm is the first to handle these generalizations.

5.4. Combining facility location with buy-at-bulk. We can define a combination of the previous problems as follows. We are given the same graph as in the (capacitated) facility location problem and also a set of K pipe types just as in the buy-at-bulk problem. We wish to open facilities and construct a forest routing the demands to the facilities. The demands must be routed by buying pipes along the edges of the forest. We wish to optimize the sum of the cost of laying out the pipes and the cost of opening the facilities.

This problem arises, for example, in placing caches over the web and connecting the demand points to the caches by laying out links of some fixed types (like T1, OC10, etc.). We wish to optimize the total cost of placing the caches and buying the links to route the demands.

It should be clear that the combination of the modifications we made in the previous problems gives an instance of COST-DISTANCE. The approximation ratio is therefore $O(\log|D|)$. This holds even if the set of available pipes differs for different pairs of nodes. As far as we are aware, this is the first approximation algorithm for this problem. Ravi and Sinha [34] subsequently gave improved approximations for this problem and called it "integrated logistics."

5.5. Priority Steiner trees. This problem [11] generalizes the Steiner tree problem in the following way. Each edge e has a priority p_e in addition to cost $c(e)$. Each terminal t also has a priority p_t. The goal is to connect these terminals to a sink using a Steiner tree such that all edges on the path from a terminal t to the sink have priority at most p_t. The goal is to minimize the total cost of the edges used. Charikar, Naor, and Schieber [11] present an $O(\log|R|)$ approximation, where R is the set of terminals.

This problem is a special case of COST-DISTANCE, as shown by a reduction due to Chuzhoy et al. [14] that we outline below. The algorithm presented in section 3 then yields an $O(\log|R|)$ approximation, matching the best known guarantee.

Specifically, a priority Steiner tree instance can be converted in an approximation-preserving fashion to an instance of the extended single-sink buy-at-bulk problem defined in section 5.3. Let $C = \max_e c(e)$, and assume $\min_e c_e \geq 1$ by scaling. Suppose there are k priority levels. For each node v with priority i, we set its demand $d_v = (nC)^{5(k-i)}$, and for each edge e with priority i, the capacity of the corresponding cable type is $u_e = (nC)^{5(k-i)+2}$, and its cost per unit cable is $c(e)$. The length of the edge $l(e) = 1$. Given a solution to the priority Steiner tree, suppose edge e is used. Then, purchase one cable along this edge. Suppose this edge has priority i; then the total demand with priority at least i is at most $n \sum_{l \geq i} (nC)^{5(k-l)} \leq (nC)^{5(k-i)+2} = u_e$. This shows that the purchases yield a feasible solution. This yields a solution to the buy-at-bulk problem with the same cost as the priority Steiner tree. Conversely, given a solution to the buy-at-bulk problem, a demand with priority i will be routed only along edges of priority at most i; otherwise, at least $(nC)^3$ cables of higher priority need to be purchased along the violated edge, which costs at least $(nC)^3$. However, the total cost over all demands of purchasing cables along paths that satisfy the priorities is at most n^2C, which is only cheaper. Therefore, in the optimal buy-at-bulk solution, all demands with priority i are routed on paths such that each edge in the path has priority at most i; furthermore, only one copy of any edge is purchased. These sets of edges are feasible for the priority Steiner tree. A solution to the buy-at-bulk instance can be transformed to obtain a solution for the priority Steiner tree instance, thus completing the reduction.

5.6. Multilevel facility location. In the k-level facility location problem, we are given a graph $G(V, E)$ with a cost function c on the edges and a set of demand nodes D. We have to route each demand through k levels of facilities. The cost of placing a facility of level i at location v is f_{iv}. The demand first goes to a facility of level 1, from there to a facility of level 2, and so on until it reaches a facility of level k. As in the classical facility location problem, the goal is to optimize the total cost of facility placement and the cost of routing the demands through the levels of facilities.

This problem has been extensively studied in operations research literature [23, 37, 38, 2, 36]. We note that Shmoys, Tardos, and Aardal [36] present a 4 approximation for the case when the number of levels k is 2, and Aardal, Chudak, and Shmoys [1] subsequently present a 3 approximation for general k. Both these algorithms are based on solving linear program relaxations and rounding the resulting solutions.

We present the first known combinatorial approximation for general values of k. Our approximation ratio is $O(\log |D|)$. We reduce the multilevel facility location problem to Cost-Distance. We first make k copies of G which we denote $G_1, G_2, \ldots, G_k$. We construct a new graph G' from these copies as follows. For an edge $e \in E$, its bicriteria cost in each of the copies is $(0, c(e))$. For $v \in G$, we add an edge between its corresponding vertices in G_i and G_{i+1} with cost $(f_{iv}, 0)$. We call these facility edges. We add a dummy sink node s and connect it to all vertices in G_k with edges of cost $(f_{kv}, 0)$ for vertex v. The demand nodes D map to the corresponding nodes in G_1.

Note that the only way to move from G_i to G_{i+1} is to take one of the level i facility edges. This means that the multilevel facility location problem is equivalent to Cost-Distance on the graph G' with sink s and the demands in G_1. We therefore have the following theorem.

Theorem 5.1. *The* Cost-Distance *algorithm yields an* $O(\log |D|)$ *approximation for the* k*-level uncapacitated metric facility location problem running in* $O(k|D|^2(|E| + |V| \log k|V|))$ *time.*

5.7. Concave functions. Suppose we are given a graph and a set of sources and demands, and we wish to route all the demand to a single-sink node. For every pair of nodes in the graph, we are given a *concave function* which determines the cost of routing between those nodes given the amount of demand to be transported. Suppose further that this concave function for an edge e is of the form $f_e(d) = \min_{i=1}^{r_e}(a_{ie} + b_{ie}d)$. We can convert this problem to an instance of COST-DISTANCE as follows: For edge e, replace it by r_e parallel edges $e_1, e_2, \ldots, e_{r_e}$, where $c(e_i) = a_{ie}$ and $l(e_i) = b_{ie}$. Given d amount of demand, it is clear that in the new instance, the edge with index $\operatorname{argmin}_i(a_{ie} + b_{ie}d)$ will be used, so that the cost of transportation is precisely $\min_i(a_{ie} + b_{ie}d)$. This is precisely the cost of transporting the demand along edge e in the original instance. Therefore, if the cost of each edge is a piecewise linear monotonically nondecreasing concave function with polynomially many segments, this can be converted in polynomial time to an instance of COST-DISTANCE, hence leading to an $O(\log |S|)$ approximation.

6. Conclusion. We presented a general framework, COST-DISTANCE, for studying several network design problems which are unified by the themes of *economies of scale* and *single-sink*. We presented a simple to implement and intuitive randomized algorithm that achieves an $O(\log |S|)$ approximation, where S is the set of terminals. Since the preliminary version [31] appeared, this algorithm has been derandomized [13] using a linear programming formulation. Meyerson [30] presented a randomized online algorithm with a polylogarithmic competitive ratio. It was shown recently by Chuzhoy et al. [14] that this problem is $\Omega(\log \log |S|)$ hard to approximate, ruling out the possibility of a constant-factor approximation. For the multiterminal version of the problem, Chekuri et al. [12] present a polylogarithmic approximation based on rounding a natural linear programming relaxation. We note that despite all this subsequent work, our algorithm still achieves the best known approximation ratio for the single-terminal COST-DISTANCE problem.

UNIVERSAL ARGUMENTS AND THEIR APPLICATIONS*

BOAZ BARAK† AND ODED GOLDREICH‡

Abstract. We put forward a new type of computationally sound proof system called universal arguments. Universal arguments are related but different from both CS proofs (as defined by Micali [*SIAM J. Comput.*, 37 (2000), pp. 1253–1298]) and arguments (as defined by Brassard, Chaum, and Crépeau [*J. Comput. System Sci.*, 37 (1988), pp. 156–189]. In particular, we adopt the *instance-based* prover-efficiency paradigm of CS proofs but follow the computational-soundness condition of argument systems (i.e., we consider only cheating strategies that are implementable by *polynomial-size circuits*). We show that universal arguments can be constructed based on standard intractability assumptions that refer to polynomial-size circuits (rather than based on assumptions that refer to subexponential-size circuits as used in the construction of CS proofs). Furthermore, these protocols have a constant number of rounds and are of the public-coin type. As an application of these universal arguments, we weaken the intractability assumptions used in the non–black-box zero-knowledge arguments of Barak [in *Proceedings of the* 42*nd IEEE Symposiun on Foundations of Computer Science*, 2001]. Specifically, we only utilize intractability assumptions that refer to polynomial-size circuits (rather than assumptions that refer to circuits of some "nice" superpolynomial size).

1. Introduction.

Various types of *probabilistic* proof systems have played a central role in the development of computer science in the last two decades. The best known ones are interactive proofs [20], zero-knowledge proofs [20], and probabilistic checkable proofs (PCP) [15, 5, 14, 2], but other notions such as various types of computationally sound proofs (e.g., arguments [12] and CS proofs [23]) and multiprover interactive proofs [11] have made a prominent appearance as well. *Do we really need yet another type of probabilistic proof system?*

We believe that the answer is positive: the number of different (related) notions that "we need" is exactly the number of different notions that are natural, interesting, and/or useful. Confining ourselves to usefulness, we note that the new type of computationally sound proof system introduced in this paper has emerged in the context of trying to improve the constructions of non–black-box zero-knowledge arguments of Barak [6]. Furthermore, this proof system seems inherent to certain diagonalization techniques used in [6] and (in a different context) in [13].

1.1. Motivation: Applying diagonalization in cryptography.

A naive idea, which was discarded for decades in cryptography, is constructing a cryptographic scheme by "diagonalization," for example, enumerating all probabilistic polynomial-

time adversaries and making sure that each of them fails. The main reason that this idea was discarded is that the resulting scheme will (necessarily) be more complex than the class of adversaries it defeats, while in cryptography a scheme should withstand adversaries that are (at least slightly) more complex than the scheme.

Still, as observed by Canetti, Goldreich, and Halevi [13] and Barak [6], a small twist on diagonalization may be useful in cryptography. The twist is using diagonalization in order to build a "trapdoor" so that the trapdoor can be used in some "imaginary setting" (e.g., by the simulator [6]) but not in the "real" setting (e.g., an actual execution of the proof system [6]).[1] Thus, the complexity of the imaginary setting is affected by the diagonalization, whereas the complexity of the real setting is independent of the diagonalization. Specifically, in the context of Barak's zero-knowledge arguments [6], the trapdoor is knowledge of the (adversarial) verifier's strategy, where this strategy (which is the locus of diagonalization) may be any polynomial-size circuit (where the polynomial is determined only after the proof system is specified). In the actual execution, the (zero-knowledge) prover does not use this trapdoor (but rather uses an NP witness to the real input), and so its complexity is independent of the complexity of the trapdoor (i.e., the cheating verifier's strategy). However, the simulator uses the trapdoor, and so its complexity depends on the latter (and so every polynomial-size adversary yields a related polynomial-time simulation).

For the foregoing idea to make sense, the verifier should not be able to distinguish the case in which the (real) prover uses an NP witness to the real input from the case in which the (simulated) prover uses the trapdoor (i.e., the cheating verifier's strategy). Indeed, Barak's protocol utilizes a witness indistinguishable (WI) proof for which both the NP witness (to the real input) and the trapdoor (i.e., the verifier's strategy) are valid witnesses. Thus, the honest verifier strategy in the WI proof must be independent of the length of the witness used by the prover. This is because, in one of the cases, the length of the witness is determined only after the proof system is specified (i.e., in the simulation, the length of the trapdoor is a polynomial, but this polynomial is determined and fixed only after the proof system is specified).

We conclude that in order to use diagonalization as described above, we should have a (WI) proof system that is capable of handling any "NP statement" (and not merely statements in any a priori fixed NP set). Put in other words, we need a *single* proof system that can be used to provide proofs for *any* set S in $\mathcal{NP}$ such that the running time and communication needed for verifying that $x \in S$ is bounded by a fixed (i.e., *single*) polynomial in $|x|$, which does *not* depend on the set S. In particular, it may be the case that $S \in \mathrm{Ntime}(p)$, where $p(\cdot)$ is a polynomial that is *larger* than the fixed polynomial bounding the verifier's complexity. We stress that, in contrast, typically when the phrase "proof systems for $\mathcal{NP}$" is used, the intended meaning is that every set $S \in \mathcal{NP}$ has a different proof system (and the complexity of verifying that $x \in S$ is bounded by an *S-dependent polynomial* in $|x|$).

1.2. The notion of universal arguments. For the sake of simplicity, we define and present proof systems for only the *universal set* $S_{\mathcal{U}}$ defined such that the tuple (M, x, t) is in $S_{\mathcal{U}}$ if M is a nondeterministic machine that accepts x within

[1] In [13], the "imaginary setting" is an implementation of the random oracle by a function ensemble (shown not to exist), whereas the "real setting" is the ideal (random oracle model) setting in which the scheme uses a random oracle. (Indeed, our perspective here is opposite to the one in [13], where the random oracle is considered "imaginary" and its implementations by function ensembles are considered "real.")

t steps.[2] This suffices for handling any NP set via a single protocol, because every $\mathcal{NP}$ set S is linear-time reducible to $S_{\mathcal{U}}$ (e.g., via the mapping $x \mapsto (M_S, x, 2^{|x|})$, where M_S is any fixed nondeterministic polynomial-time machine that decides S). Thus, a proof system for $S_{\mathcal{U}}$ allows us to handle all "NP statements" (in a uniform manner): for any $S \in \mathcal{NP}$, when wishing to verify the assertion "x in S," the verifier should just use the proof system of $S_{\mathcal{U}}$ on input $(M_S, x, 2^{|x|})$, where M_S is as described above. (In fact, $S_{\mathcal{U}}$ is $\mathcal{NE}$-complete by an analogous linear-time reduction.)[3]

We also consider the natural witness relation for $S_{\mathcal{U}}$, denoted $R_{\mathcal{U}}$: the pair $((M, x, t), w)$ is in $R_{\mathcal{U}}$ if M (viewed here as a two-input deterministic machine) accepts (x, w) within t steps. Loosely speaking, a *universal argument* system (or a *universal argument system for* $S_{\mathcal{U}}$) is a two-party protocol (P, V), for common inputs of the form (M, x, t), that satisfies the following:

Efficient verification. The *total* time spent by the (probabilistic) verifier V is polynomial in length of the common input (i.e., polynomial in $|(M, x, t)| = O(|M| + |x| + \log t)$). In particular, all messages exchanged in the protocol have a length that is so bounded.

Completeness by a relatively efficient prover. For every $((M, x, t), w)$ in $R_{\mathcal{U}}$, on common input (M, x, t), when P is given auxiliary input w, it always convinces V. Furthermore, the total time spent by P in this case is bounded by a fixed polynomial in ($|M|$ and) $T_M(x, w)$, where $T_M(x, w) \leq t$ is the number of steps taken by M on the input (x, w).

Computational soundness. For every polynomial-size circuit family $\{C_n\}_{n \in \mathbf{N}}$ and every $(M, x, t) \in \{0,1\}^n \setminus S_{\mathcal{U}}$, the probability that, on common input (M, x, t), the ("cheating") circuit C_n succeeds in fooling V (into accepting (M, x, t)) is negligible (as a function of n).

(The actual definition appears in section 2.)

Relation to prior notions. Universal arguments are related but different from both CS proofs (as defined by Micali [23]) and arguments (as defined by Brassard, Chaum, and Crepeau [12]). Specifically

1. the efficient-verification condition is identical in all definitions (except that arguments are typically defined only for individual sets in $\mathcal{NP}$);
2. the "completeness by a relatively efficient prover" condition follows the instance-based paradigm of CS proofs (but provides the prover with an auxiliary input);
3. the computational-soundness condition is exactly as it is in argument systems (and is typically weaker than the one in CS proofs).

Thus, in a sense, universal arguments are a hybrid of arguments and CS proofs. Indeed, universal arguments are weaker than CS proofs, but the point is that we will be able to construct a universal argument based on a weaker assumption than the ones that seem necessary for constructing CS proofs (cf. [23, 6]).

We comment that computational soundness seems unavoidable in any proof system for $S_{\mathcal{U}}$ that satisfies the efficient-verification condition (even just "uniformly for

[2] One nice feature of $S_{\mathcal{U}}$ is that it comes with a natural measure of the complexity of instances: the complexity of (M, x, t) is the actual time it takes M to accept x (when using the best sequence of nondeterministic choices). (Similarly, the complexity of (M, x, t) coupled with the witness w is the actual time it takes M to accept x when using w as the sequence of nondeterministic choices.) Such a complexity measure is pivotal to the refined formulation of the prover complexity condition.

[3] That is, for $S \in \mathrm{Ntime}(e)$, where $e(n) = 2^{cn}$ for some constant c, we use the reduction $x \mapsto (M_S, x, 2^{c|x|})$. Furthermore, every set in $\mathcal{NEXP}$ is polynomial-time (but not linear-time) reducible to $S_{\mathcal{U}}$.

all $\mathcal{NP}$"). In contrast, statistical soundness (coupled with the standard notion of efficient verification) would have implied that $S_{\mathcal{U}}$ (or "just" all $\mathcal{NP}$) is in DSPACE(p), for some fixed polynomial p. (The reason is that the total communication in such a protocol must be upper bounded by a fixed polynomial p and that an optimal prover strategy can be implemented in space p.)

On natural applications of universal arguments. A strange-looking aspect of universal arguments is that, on some YES-instances, the designated prover may run in more time than allowed to cheating provers (i.e., a fixed polynomial in $T_M(.,.)$ may be larger than an arbitrary polynomial in the length of the common input).[4] However, in typical applications (such as ours), the designated prover will never be invoked on such inputs (i.e., on inputs requiring the prover to run for a time that is superpolynomial in their length). Actually, we shall use only the fact that a universal-argument system guarantees the following behavior with respect to *any* polynomial p (which may be selected after the system is specified):

1. For every $(y,w) \in R_{\mathcal{U}}$ such that $y = (M,x,t)$ and $t \leq p(|x|)$, it holds that (given y and w) the designated prover convinces the verifier to accept y, and the total time used by the prover is $\text{poly}(|M|+t) = \text{poly}(|y|)$. Specifically, there exists a fixed polynomial q_0 that is associated with the universal-argument system such that the running time of the designated prover on input (M,x,t) (and w) is $q_0(|M|+t) \leq q_0(|M|+p(|x|)) < (q_0 \circ p)(|y|)$.
2. For every polynomial q and every sufficiently long $y = (M,x,t) \notin S_{\mathcal{U}}$, it holds that no $q(|y|)$-size circuit can convince the verifier to accept y.

Thus, in this restricted case, the complexity bound considered in the soundness condition (of item 2) may exceed the complexity of the designated prover when handling YES-inputs of the type mentioned in item 1 (i.e., $(M,x,t) \in S_{\mathcal{U}}$ such that $t \leq p(|x|)$). Needless to say, the foregoing items cover all NP sets (where a set $S \in \mathcal{NP}$ is handled by selecting the polynomial p such that $S \in \text{Ntime}(p)$ holds).

1.3. The construction of universal arguments. By adapting the construction of Kilian [21], one can show that the existence of *strong* collision-resistant hashing functions implies the existence of universal arguments (and even CS proofs for $S_{\mathcal{U}}$; cf. Micali [23]). By *strong* collision-resistant hashing we mean families of functions for which collisions are hard to find even by using *subexponential-size* circuits. The goal, achieved in this paper, is to construct universal arguments based only on *standard* collision-resistant hashing, that is, families of functions for which collisions are hard to find by *polynomial-size* circuits. That is, we obtain the following theorem.

THEOREM 1.1 (our main result). *The existence of* (standard) *collision-resistant hashing functions implies the existence of universal arguments. Furthermore, these proof systems are of the public-coin*[5] *type and use a constant number of rounds.*

Our construction of universal arguments adapts Kilian's construction [21] in a quite straightforward manner. Our contribution is in the analysis of this construction. Unlike in previous analyses (as in [21, 23]), when establishing computational soundness

[4] This phenomena does not occur in arguments [12] and in CS proofs [23]: arguments were defined only for individual sets in $\mathcal{NP}$, and so the issue never arises. In the case of CS proofs, the definition of computational soundness relates to cheating provers of size exponential in the security parameter, which is typically set to be linear in the length of the common input [23]. Thus, the cheating provers are always allowed more running time than the designated prover (since its running time is always at most exponential in the length of the common input). However, it seems that allowing the adversaries time that is exponential in the security parameter requires using intractability assumptions that refer to exponential (or subexponential) circuits.

[5] Also known as (a.k.a.) Arthur–Merlin systems (cf. [3]).

via contradiction, we cannot afford to derive a collision-forming circuit of size that is polynomial in the worst-case time complexity of the designated prover (because the designated prover may have (worst-case) complexity that is superpolynomial (in the input length)).[6] We need to derive a collision-forming circuit of size that is polynomial in the input length. Indeed, doing so allows us to use standard collision-resistant hashing (rather than strong ones).

The analysis is further complicated by our desire to establish a "proof-of-knowledge" property, which is needed for our main application. This is discussed next.
